Tables 1 and 2 represent convergence factors measured after 20 MG V(ν_1, ν_2) cycles for the direct MG and the iterative SMA, respectively. Uniform convergence theory of the direct MG (see the discussion in section 4.2) requires the condition that h_0 is sufficiently small. Clearly, the numerical results reported here show that convergence of the direct MG is not subject to such a constraint since we used $h_0 = 1/4$. The observed convergence factors in Tables 1 and 2 for the direct MG and the iterative SMA are almost same, but the latter costs about twice as many arithmetic operations as the former for one re-entrant corner and much more for several re-entrant corners. This indicates that the direct MG is the method of choice. One V$(2,0)$ or one V$(1,1)$ cycle costs about twice as much as one V$(1,0)$ cycle. Table 1 shows that the reduction rate by two V$(1,0)$ cycles is better than the reduction rate of one V$(2,0)$ or V$(1,1)$ cycle. This suggests that the MG V$(1,0)$ is the most effective solver, which is confirmed by the subsequent tables.

5.2. Discretization errors and FMG performance. To measure the discretization error, we consider the Poisson equation in (2.1) with a known nonzero

TABLE 3

solution by choosing the right-hand side function to be

$$f = \begin{cases} \sin(2\pi x)\big[2\pi^2(y^2+2y)(y^2-1) - (6y^2+6y-1)\big] - \Delta(\eta_\rho s) & \text{if } \ -1 \le y < 0, \\ \sin(2\pi x)\big[2\pi^2(-y^2+2y)(y^2-1) - (-6y^2+6y+1)\big] - \Delta(\eta_\rho s) & \text{if } \ 0 < y \le 1, \end{cases}$$

where $s = r^{\frac{2}{3}} \sin(\frac{2\theta}{3})$ is the singular function. The exact solution of the underlying problem is then

$$u = w + \eta_\rho s,$$

where w is the regular part of the solution, which is the exact solution of (2.7) given by

$$w = \begin{cases} \sin(2\pi x)(\frac{1}{2}y^2 + y)(y^2-1) & \text{if } \ -1 \le y \le 0, \\ \sin(2\pi x)(-\frac{1}{2}y^2 + y)(y^2-1) & \text{if } \ 0 \le y \le 1. \end{cases}$$

Note that the function w is in $H^2(\Omega)$ but not in $H^3(\Omega)$. Let W_h be the exact solution of (4.2), the coefficient vector of the finite element approximation. We first depict the number of iterations required in order to reduce the initial error $|W_h - W_h^0|_{1,h} = |W_h|_{1,h}$ within the given tolerance $\varepsilon = 10^{-4}$ in Tables 3 and 4.

Next, we compute the approximate solution $\hat{W}_h$ of (4.2) on each of the various levels of discretization by using 30 direct MG $V(1,0)$ cycles. This is to ensure that the errors reported in Tables 5 and 6 properly reflect discretization accuracy without contamination from algebraic iteration errors. Let w_h^I be the interpolant of w in $\mathcal{V}_h = \text{span}\{\phi_i(x)\}_{i=1}^N$; i.e.,

$$w_h^I = \sum_{i=1}^N w_j^I \phi_i(x),$$

where w_i^I is the nodal value of w. Let W_I be the coefficient vector of w_h^I, i.e., the vector with components w_i^I. Define the error vector by

$$E(h) = W_I - \hat{W}_h.$$

The rates of convergence for discretization errors in the discrete L^2 norm, the discrete H^1 seminorm, and the absolute value are measured by

$$\log_2 \frac{\|E(h)\|_h}{\|E(\frac{h}{2})\|_{\frac{h}{2}}}, \quad \log_2 \frac{\|E(h)\|_{1,h}}{\|E(\frac{h}{2})\|_{1,\frac{h}{2}}}, \quad \text{and} \quad \log_2 \frac{|\lambda - \lambda_h|}{|\lambda - \lambda_{\frac{h}{2}}|},$$

respectively.

Numerical results given in Tables 5 and 6 show that the discretization accuracy of the finite element approximation to w is $O(h^2)$ with respect to both the discrete L^2 norm and the discrete H^1 seminorm for $\rho = 1.0$ and 0.5. The theoretically predicted error bounds are only $O(h^{\frac{5}{3}})$ in the L^2 norm and $O(h)$ in the H^1 norm. We therefore appear to have obtained optimal convergence in the L^2 and superconvergence in the discrete H^1 seminorm for this particular case. Our finite element theory in [5] requires that the mesh size h is sufficiently small since we used Gårding's inequality in its analysis. It is clear from Tables 5 and 6 that our finite element approximation is not subject to this constraint.

To test overall accuracy for the FMG, we studied the FMG based on $5\,V(1,0)$, $4\,V(2,0)$, and $4\,V(1,1)$ cycles. Tables 7 and 8 show that the total errors produced by the FMG are comparable to those discretization errors estimated in the respective Tables 5 and 6. This indicates that the underlying problem on level h can be solved to within the level of discretization error at a cost of about $\frac{4}{3} \cdot 5V(1,0) \approx 7\,V(1,0)$ or

$5\,V(2,0)$ or $5\,V(1,1)$ cycles on level h. Finally, results for the stress intensity factor are contained in Tables 9 and 10.

6. Conclusion and remarks. We study the MG V-cycle applied directly to the discrete problem in (4.2) and used in the SMA. Our numerical study shows that the direct MG is much more efficient than the iterative SMA. Our numerical study confirms theories on finite element accuracy established in [5] and MG convergence discussed in section 4.2. It especially shows that our finite element method seems to be optimally accurate in the L^2 norm. The theory for MG convergence is subject to the constraint that the coarsest mesh size is sufficiently small. But this condition is not essential numerically since we used $h_0 = 1/4$ in our experiments.

Acknowledgment. We would like to thank the referee for several helpful suggestions.

A VECTOR FINITE ELEMENT TIME-DOMAIN METHOD FOR SOLVING MAXWELL'S EQUATIONS ON UNSTRUCTURED HEXAHEDRAL GRIDS[*]

GARRY RODRIGUE[†] AND DANIEL WHITE[‡]

Abstract. In this paper the vector finite element time-domain (VFETD) method is derived, analyzed, and validated. The VFETD method uses edge vector finite elements as a basis for the electric field and face vector finite elements as a basis for the magnetic flux density. The Galerkin method is used to convert Maxwell's equations to a coupled system of ordinary differential equations. The leapfrog method is used to advance the fields in time. The method is shown to be stable and to conserve energy and charge for arbitrary hexahedral grids. A numerical dispersion analysis shows the method to be second order accurate on distorted hexahedral grids. Several computational experiments are performed to determine the accuracy and efficiency of the method.

Key words. Maxwell's equations, vector finite element, unstructured grids, edge elements

1. Introduction.

This paper is concerned with the numerical solution of the time dependent Maxwell equations in charge-free regions,

$$\begin{aligned} \frac{\partial \mathbf{B}}{\partial t} &= -\nabla \times \mathbf{E} - \sigma_M \mu^{-1}\mathbf{B}, \\ \varepsilon\frac{\partial \mathbf{E}}{\partial t} &= \nabla \times \mu^{-1}\mathbf{B} - \sigma_E \mathbf{E} - \mathbf{J}, \\ \nabla \bullet \varepsilon\mathbf{E} &= 0, \\ \nabla \bullet \mathbf{B} &= 0, \end{aligned} \tag{1}$$

with initial-boundary values

$$\hat{\mathbf{n}} \times \mathbf{E} = \mathbf{E}_{bc} \quad \text{on} \quad \Gamma = \text{boundary } (\Omega), \tag{2}$$

$$\mathbf{E}(t=0) = \mathbf{E}_{ic}, \mathbf{B}(t=0) = \mathbf{B}_{ic}. \tag{3}$$

Here, $\mathbf{E} = \mathbf{E}(x,t)$ is the electric field, $\mathbf{B} = \mathbf{B}(x,t)$ is the magnetic flux density, $\mathbf{J} = \mathbf{J}(x,t)$ is the electric current, and $\hat{\mathbf{n}}$ is the outward normal vector to Γ. The volume $\Omega \subset R^3$ is a domain, not necessarily bounded, whose boundary Γ is sufficiently regular (Lipschitz-continuous). Ω may be inhomogeneous, consisting of several dielectric, magnetic, and metallic regions of arbitrary geometry. The material properties are assumed to be linear and nondispersive. The volume may also contain several independent voltage and current sources. The electric and magnetic conductivities, σ_E

and σ_M, the dielectric permittivity ε, and the magnetic permeability μ are assumed to be time independent symmetric positive definite tensors. Example electromagnetic problems within this class include the design of waveguides and antennas, scattering of electromagnetic waves from automobiles and aircraft, and the penetration and absorption of electromagnetic waves by dielectric objects. Throughout this presentation, unless the physical meaning of quantities suggests otherwise, boldface letters will stand for vector fields whereas plain faced letters will stand for scalar fields.

The most popular numerical scheme for solving the time dependent Maxwell equations on an orthogonal Cartesian grid is the finite difference time-domain (FDTD) method [1, 2, 3, 4]. The method utilizes a centered difference approximation in space and a leapfrog approximation in time to yield a conditionally stable, consistent, and second order accurate scheme. However, when one attempts to use the FDTD method on complicated geometries by approximating curved boundaries with "stair steps," poor results are obtained [4, 5]. Nevertheless the FDTD method is extremely efficient and is the benchmark to which new methods are compared.

There have been several attempts to generalize the FDTD method to unstructured hexahedral grids, most notably the modified finite volume (MFV) and discrete surface integral (DSI) methods [6, 7, 8, 9]. In these methods Maxwell's equations are cast in integral form, then the subsequent volume and/or surface integrals are approximated by standard integration rules. A leap frog time integration is used so that these methods reduce to the FDTD method when orthogonal grids are used. However, the finite volume methods are not provably stable, and weak instabilities leading to nonphysical solution growth have been observed for nonorthogonal grids [10]. The instability is caused by the nonsymmetric discretization of the curl-curl operator. Dissipative time integration schemes may be employed to counteract this nonphysical solution growth, but this results in a violation of conservation of energy [11].

There is another class of finite volume methods where Maxwell's curl equations are cast in conservative form, resulting in a PDE that resembles the Euler equation of fluid dynamics [12, 13, 14]. The classical methods of computational fluid dynamics such as Lax–Wendroff or Godunov can then be used to solve the equations. These methods can be implemented on a structured, but nonorthogonal, hexahedral grid but do not reduce to the FDTD method when implemented on orthogonal Cartesian grids. However, these methods are stable and consistent, and very good accuracy can be achieved as the grid is refined. The methods rely upon dissipative time integration for stability and consequently do not conserve energy. In addition they neglect the divergence properties of the fields so that there is no guarantee that these methods will conserve charge.

Vector finite elements, also known as edge elements, Whitney 1-forms, or $H(curl)$ elements [15, 16, 17, 18, 19], have been used to formulate finite element solutions to the weak form of Maxwell's equations. These elements enforce tangential continuity of the fields but allow for jump discontinuity in the normal component of the fields. Use of these elements also eliminates spurious, divergent solutions of Maxwell's equations that were common with nodal element formulations [20, 21, 22, 23, 24, 25]. Vector finite element methods have been successfully used in the frequency domain to analyze resonant cavities, compute waveguide modes, and perform scattering calculations [26, 27, 28]. Vector finite elements have also been proposed to solve Maxwell's equations directly in the time domain [29, 30, 31, 32, 33]. Theoretical convergence results and error estimates for time dependent vector finite element solutions of Maxwell's equations were developed in [34, 35].

1.1. Vector finite element time-domain (VFETD) method. In this paper, a Galerkin procedure is used to convert the weak form of Maxwell's equations to a semidiscrete coupled system of ordinary differential equations using vector finite elements. A leapfrog time integration scheme similar to that found in the FDTD method is then used to discretize time and update the field variables.

The VFETD method uses vector "edge" finite elements as a basis for the electric field and vector "face" finite elements as a basis for the magnetic flux density. These elements are complementary in the sense that the edge elements have tangential continuity across interfaces whereas the face elements have normal continuity across interfaces. Consequently, the Galerkin approximations preserve field continuities/discontinuities across material interfaces. The properties of these vector finite elements is discussed in detail in [15].

The VFETD method is shown to be conditionally stable. Moreover, if a stable time step is used, the method conserves energy and charge, independent of how distorted the grid is. A numerical dispersion analysis of the method is performed on several different distorted hexahedral grids, with the result that the method is second order accurate. The analysis also shows how the anisotropic part of the numerical dispersion relation depends upon the grid distortion [40, 41, 42, 43].

The VFETD method requires a sparse linear system to be solved at every time step. The computational effort required to solve the system depends upon how distorted the grid is. For Cartesian grids mass lumping can be used, in which case the VFETD method reduces to the classic FDTD method. For non-Cartesian grids conjugate gradient iterative methods are used to solve the system where it is shown, via computational experiments on unstructured hexahedral grids, that the number of iterations required to achieve a given accuracy is a constant independent of the grid cell size (grid refinement) used to discretize the problem. Hence the method is scalable. The accuracy of the method, as well as the required CPU time, are tabulated for resonant cavity, waveguide, and antenna problems.

2. Weak formulation of Maxwell's equations. In this section we convert Maxwell's equations into variational equations posed over suitable function spaces. We first consider the space

$$H(curl;\ \Omega) = \{\mathbf{u} \in \mathbf{L}_2(\Omega);\ \nabla \times \mathbf{u} \in \mathbf{L}_2(\Omega)\}.$$

A function $\mathbf{u}$ in the vector space $\mathbf{H}^1(K_1) \cup \mathbf{H}^1(K_2)$ is in $H(curl;\, \Omega = K_1 \cup K_2)$ if and only if the trace $\mathbf{u} \times \mathbf{n}$ is the same on each side of the face Γ [15, 16]. Consequently, $H(curl;\ \Omega)$ is an appropriate space for the electric field $\mathbf{E}$. Similarly, we define the function space

$$H(\mathrm{div}; \Omega) = \{\mathbf{u} \in \mathbf{L}_2(\Omega); \nabla \bullet \mathbf{u} \in L_2(\Omega)\}.$$

Then, a function $\mathbf{u}$ in the vector space $\mathbf{H}^1(K_1) \cup \mathbf{H}^1(K_2)$ is in $H(\mathrm{div};\, \Omega = K_1 \cup K_2)$ if and only if $\mathbf{u} \bullet \mathbf{n}$ is the same on each side of the face Γ [15, 16]. Hence, $H(\mathrm{div};\ \Omega)$ is an appropriate space to which the magnetic flux density $\mathbf{B}$ should belong. Both spaces, equipped with the canonical inner products, are Hilbert spaces with norms

$$\|\mathbf{u}\|_{H(curl\,:\,\Omega)} = (\|\mathbf{u}\|_2^2 + \|\nabla \times \mathbf{u}\|_2^2)^{1/2},$$
$$\|\mathbf{u}\|_{H(\mathrm{div}\,:\,\Omega)} = (\|\mathbf{u}\|_2^2 + \|\nabla \bullet \mathbf{u}\|_2^2)^{1/2}.$$

We write $\|\mathbf{u}\|_2^2 = \int_\Omega \mathbf{u}^t\mathbf{u}\, d\Omega \equiv (\mathbf{u}, \mathbf{u}) < \infty$ for the $\mathbf{L}_2(\Omega)$-norm and $(\mathbf{u}, \mathbf{v}) = \int_\Omega \mathbf{u}^t\mathbf{v}\, d\Omega$ for the $\mathbf{L}_2(\Omega)$ inner product. The subspace of $H(curl; \Omega)$ containing the vector fields

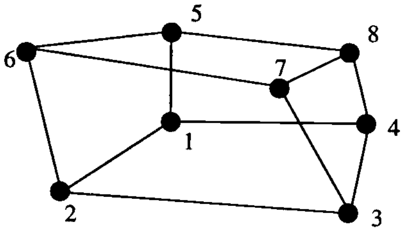

FIG. 1. *Illustration of an arbitrary hexahedron.*

$\mathbf{u}$ with vanishing tangential trace $\mathbf{n} \times \mathbf{u}$ on Γ is denoted by $H_0(curl;\Omega)$. As usual, $\mathbf{n}$ designates the exterior unit normal vector on Γ. Similarly, $H_0(\text{div};\Omega)$ denotes the subspace of $H(\text{div};\Omega)$ containing vectors $\mathbf{u}$ such that $\mathbf{u} \bullet \mathbf{n} = 0$ on Γ.

Given the above definitions, a natural way of defining the weak form of Maxwell's equations (1)–(3) is to determine functions $\mathbf{B} \in H(\text{div};\Omega)$, $\mathbf{E} \in H(curl;\Omega)$ such that

$$\frac{\partial}{\partial t}(\mu^{-1}\mathbf{B},\mathbf{B}^*) = -(\mu^{-1}\nabla \times \mathbf{E},\mathbf{B}^*) = (\mu^{-1}\sigma_M\mu^{-1}\mathbf{B},\mathbf{B}^*), \tag{4}$$

$$\frac{\partial}{\partial t}(\varepsilon\mathbf{E},\mathbf{E}^*) = (\nabla \times \mathbf{E}^*,\mu^{-1}\mathbf{B}) - (\sigma_E\mathbf{E},\mathbf{E}^*) - (J,\mathbf{E}^*) \tag{5}$$

for all $\mathbf{B}^* \in H_0(\text{div};\Omega)$, $\mathbf{E}^* \in H_0(curl;\Omega)$. The multiplication of the first equation by μ^{-1} is done to aid in the analysis of the Galerkin method. Clearly, if $\mathbf{B}$, $\mathbf{E}$ are classical solutions of Maxwell's equations (1)–(3), then they are solutions of the weak equations (4)–(5).

3. Finite element basis functions.

A general definition of finite elements on arbitrary polyhedra is given by the following.

DEFINITION. *A finite element* (K, P, A), *consists of*

1. K, *a polyhedral domain*;
2. P, *a vector space of polynomials defined on* K *having a basis* $\{\psi_1, \psi_2, \dots, \psi_N\}$ *(called shape functions)*;
3. A, *a set of linear functionals defined on* P *having a basis* $\alpha_1, \alpha_2, \dots, \alpha_N$ *(called the degrees of freedom).*

In this section we define K, P, A for the linear edge and face elements. For the elements developed in this paper, we shall approximate the domain Ω with a hexahedral mesh κ consisting of $K_i, i = 1, \dots, N$, hexahedra. Each of the hexahedra can be mapped using the standard trilinear mapping $(x, y, z) = B(\zeta, \eta, \nu)$ to a reference element, $K_0 = \{0 \leq \zeta, \eta, \nu \leq 1\}$. We require that the mapping B be one-to-one and invertible, implying a nonsingular Jacobian matrix J. Consequently, K will be a hexahedron consisting of 8 nodes labeled as in Figure 1. The 12 edges, a_i, and 6 faces, f_i, are numbered according to Table 1. The Dirichlet part of the boundary Γ_D is assumed to be the union of complete faces of elements.

3.1. Finite elements in *H(curl)*: Edge elements.

We consider finite elements (K, P, A), called "edge elements," where K is an arbitrary hexahedron and the degrees of freedom of A are defined by

$$\alpha_i(v) = \int_{a_i} (v \bullet \mathbf{t}_i)\, ds, v \in P \tag{6}$$

Table 1
Node, edge, and face numbering scheme for hexahedrons.

i	edge, a_i	face, f_i
1	1-2	1-4-8-5
2	4-3	2-3-7-6
3	5-6	1-5-6-2
4	8-7	4-8-7-3
5	1-4	1-2-3-4
6	5-8	5-6-7-8
7	2-3	
8	6-7	
9	1-5	
10	2-6	
11	4-8	
12	3-7	

with $\mathbf{t}_i$ being the unit tangent vector along edge a_i of K. The space P is defined by considering the reference element (K_0, P_0, A_0). Here

$$P_0 = \{\mathbf{u} = [u_1, u_2, u_3]^t : u_1 \in Q_{0,1,1}; u_2 \in Q_{1,0,1}; u_3 \in Q_{1,1,0}\},$$

where $Q_{l,m,n}$ denotes the vector space of polynomials in three variables (x, y, z), the maximum degree of which are, respectively, l in x, m in y, n in z. Note that *dimension* $[P_0] = 12$. The basis for P_0, as constructed by (6), is

$$\begin{aligned} &\mathbf{W}_1^{(0)} = (1 - y - z + yz, 0, 0), && \mathbf{W}_2^{(0)} = (y - yz, 0, 0), \\ &\mathbf{W}_3^{(0)} = (z - yz, 0, 0), && \mathbf{W}_4^{(0)} = (yz, 0, 0), \\ &\mathbf{W}_5^{(0)} = (0, 1 - x - z - xz, 0), && \mathbf{W}_6^{(0)} = (0, x - xz, 0), \\ &\mathbf{W}_7^{(0)} = (0, z - xz, 0), && \mathbf{W}_8^{(0)} = (0, xz, 0), \\ &\mathbf{W}_9^{(0)} = (0, 0, 1 - x - y - xy), && \mathbf{W}_{10}^{(0)} = (0, 0, x - xy), \\ &\mathbf{W}_{11}^{(0)} = (0, 0, y - xy), && \mathbf{W}_{12}^{(0)} = (0, 0, xy). \end{aligned} \tag{7}$$

The above polynomial basis defined on the reference element must be transformed to the arbitrary hexahedron K such that the degrees of freedom are preserved. It is well known that the covariant transformation preserves line integrals under a change of coordinates; hence we define P in (K, P, A) by $\mathbf{W}_i = J^{-t}\mathbf{W}_i^{(0)}$.

3.2. Finite elements in *H*(div): Face elements. We now consider a finite element (K, P, A), called "face elements," where K is an arbitrary hexahedron and the degrees of freedom of a face element are

$$\alpha_i(v) = \int_{f_i} (v \bullet \mathbf{n}_i)\, ds, \tag{8}$$

where $\mathbf{n}_i$ is the unit normal vector to the face f_i of K. The space P is defined by again considering the reference element (K_0, P_0, A_0). Here, $P_0 = \{\mathbf{u} = [u_1, u_2, u_3]^t :$

$u_1 \in Q_{1,0,0}$; $u_2 \in Q_{0,1,0}$; $u_3 \in Q_{0,0,1}\}$. The basis functions of P_0 are constructed from (8) to get

$$\begin{aligned} &\mathbf{F}_1^{(0)} = (-1+x,0,0), \quad &\mathbf{F}_2^{(0)} = (x,0,0), \quad &\mathbf{F}_3^{(0)} = (0,-1+y,0), \\ &\mathbf{F}_4^{(0)} = (0,y,0), \quad &\mathbf{F}_5^{(0)} = (0,0,-1+z), \quad &\mathbf{F}_6^{(0)} = (0,0,z). \end{aligned} \tag{9}$$

The above polynomial basis defined on the reference element must be transformed to the arbitrary hexahedron K such that the degrees of freedom are preserved. It is well known that a contravariant transformation preserves surface integrals; hence we define P in (K,P,A) by $\mathbf{F}_i = J\mathbf{F}_i^{(0)}$.

4. Galerkin approximation of Maxwell's equations. The Galerkin method constructs approximations

$$\begin{aligned} \tilde{\mathbf{E}} &= \sum_{j=1}^{N_E} e_j \mathbf{W}_j \in W = \text{span }[\mathbf{W}_1, \mathbf{W}_2, \ldots, \mathbf{W}_{N_B}] \subset H_0(curl;\Omega), \\ \tilde{\mathbf{B}} &= \sum_{j=1}^{N_B} b_j \mathbf{F}_j \in F = \text{span }[\mathbf{F}_1, \mathbf{F}_2, \ldots, \mathbf{F}_{N_E}] \subset H_0(\text{div};\Omega), \end{aligned} \tag{10}$$

such that

$$\begin{aligned} \frac{\partial}{\partial t}(\mu^{-1}\tilde{\mathbf{B}}, \mathbf{F}_i) &= -(\mu^{-1}\nabla \times \tilde{\mathbf{E}}, \mathbf{F}_i) + -(\mu^{-1}\sigma_M \mu^{-1}\tilde{\mathbf{E}}, \mathbf{F}_i), \qquad i = 1,2,\ldots,N_F, \\ \frac{\partial}{\partial t}(\varepsilon\tilde{\mathbf{E}}, \mathbf{W}_i) &= (\nabla \times \mathbf{W}_i, \mu^{-1}\tilde{\mathbf{E}}) - (\sigma_E \tilde{\mathbf{B}}, \mathbf{W}_i) - (\tilde{\mathbf{j}}, \mathbf{W}_i), \qquad i = 1,2,\ldots,N_E, \end{aligned} \tag{11}$$

where N_E and N_F are the number of internal edges and faces, respectively. This leads to systems of ordinary differential equations

$$\begin{aligned} G\frac{\partial \mathbf{b}}{\partial t} &= -K\mathbf{e} - P\mathbf{b}, \\ C\frac{\partial \mathbf{e}}{\partial t} &= K^T\mathbf{b} - S\mathbf{e} - Q\mathbf{j}, \end{aligned} \tag{12}$$

where $\mathbf{b} = [b_1, b_2, \ldots, b_{N_F}]^t$, $\mathbf{e} = [e_1, e_2, \ldots, e_{N_E}]^t$, and the matrices are given by

$$\begin{aligned} G_{ij} &= (\mu^{-1}\mathbf{F}_i, \mathbf{F}_j), \qquad K_{ij} = (\mu^{-1}\nabla \times \mathbf{W}_i, \mathbf{F}_j), \\ P_{ij} &= (\mu^{-1}\sigma_M \mu^{-1}\mathbf{F}_i, \mathbf{F}_j), \qquad C_{ij} = (\varepsilon\mathbf{W}_i, \mathbf{W}_j), \\ K_{ij}^t &= (\mu^{-1}\nabla \times \mathbf{W}_j, \mathbf{F}_i), \qquad S_{ij} = (\sigma_E \mathbf{W}_i, \mathbf{W}_j), \qquad Q_{ij} = (\mathbf{F}_i, \mathbf{W}_j). \end{aligned} \tag{13}$$

5. Leapfrog time differencing. The ordinary differential equations (12) are differenced so that the electric fields are calculated at whole time steps and the magnetic fields are calculated at the half time steps. Specifically,

$$(G + \Delta tP/2)\mathbf{b}^{n+1/2} = -\Delta tK\mathbf{e}^n + (G - \Delta tP/2)\mathbf{b}^{n-1/2}, \tag{14}$$

$$(C + \Delta tS/2)\mathbf{e}^{n+1} = \Delta tK^T\mathbf{b}^{n+1/2} + (C - \Delta tS/2)\mathbf{e}^n - \Delta tQ\mathbf{j}^{n+1/2}. \tag{15}$$

5.1. Stability and conservation. Properties of (14) will be derived by assuming no electric or magnetic conductivity, i.e., $\sigma_E = \sigma_M = \mathbf{J} = 0$. In this case the discrete equations (14) become

$$\begin{bmatrix} \mathbf{e}^{n+1} \\ \mathbf{b}^{n+1/2} \end{bmatrix} = \begin{bmatrix} (I - \Delta t^2 C^{-1}K^t G^{-1}K) & \Delta t C^{-1}K^t \\ -\Delta t G^{-1}K & I \end{bmatrix} \begin{bmatrix} \mathbf{e}^{n} \\ \mathbf{b}^{n-1/2} \end{bmatrix}. \tag{16}$$

The following theorem establishes eigenproperties of the method.

Theorem 1. *Let $T(\Delta t)$ be the amplification matrix in* (16). *Then*

(a) *the eigenvalues of $T(\Delta t)$ either have unit magnitude or are negative*

(b) *the eigenvalues of $T(\Delta t)$ have unit magnitude if and only if*

$$\Delta t \leq \frac{2}{\sqrt{\max(\psi)}}, \tag{17}$$

where ψ is an eigenvalue of $C^{-1}K^tG^{-1}K$.

Proof. (a) Suppose $T(\Delta t)$ has a complex eigenvalue $\lambda = a + ib$. Then there is a complex eigenvector $\left[\begin{smallmatrix} x \\ y \end{smallmatrix} \right]$ that solves the eigenvalue problem

$$\begin{bmatrix} (I - \Delta t^2 C^{-1}K^t G^{-1}K) & \Delta t C^{-1}K^t \\ -\Delta t G^{-1}K & I \end{bmatrix} \begin{bmatrix} \mathbf{x} \\ \mathbf{y} \end{bmatrix} = \lambda \begin{bmatrix} \mathbf{x} \\ \mathbf{y} \end{bmatrix}.$$

Since the matrices C and G are symmetric and positive definite, they admit Cholesky decompositions $C = \tilde{C}^t\tilde{C}$ and $G = \tilde{G}^t\tilde{G}$, respectively. If we let $\tilde{\mathbf{x}} = \tilde{C}\mathbf{x}$ and $\tilde{\mathbf{y}} = \tilde{G}\mathbf{y}$, then the above eigenproblem is equivalent to

$$\begin{bmatrix} (I - \Delta t^2 QQ^t) & \Delta t Q \\ -\Delta t Q^t & I \end{bmatrix} \begin{bmatrix} \tilde{\mathbf{x}} \\ \tilde{\mathbf{y}} \end{bmatrix} = \lambda \begin{bmatrix} \tilde{\mathbf{x}} \\ \tilde{\mathbf{y}} \end{bmatrix}, \tag{18}$$

where the matrix Q is given by $Q = \tilde{C}^{-t}K^t\tilde{G}^{-1}$. Note that $QQ^t = C^{-1}K^tG^{-1}K$. Since

$$\begin{bmatrix} (I - \Delta t^2 QQ^t) & \Delta t Q \\ -\Delta t Q^t & I \end{bmatrix} = \begin{bmatrix} I & \Delta t Q \\ O & I \end{bmatrix} \begin{bmatrix} I & O \\ -\Delta t Q^t & i \end{bmatrix},$$

its determinant is 1 and consequently $\lambda \neq 0$. We can now write (18) as a general eigenproblem:

$$\begin{bmatrix} I & O \\ -\Delta t Q^t & I \end{bmatrix} \begin{bmatrix} \tilde{\mathbf{x}} \\ \tilde{\mathbf{y}} \end{bmatrix} = \lambda \begin{bmatrix} I & \Delta t Q \\ O & I \end{bmatrix}^{-1} \begin{bmatrix} \tilde{\mathbf{x}} \\ \tilde{\mathbf{y}} \end{bmatrix} = \lambda \begin{bmatrix} I & -\Delta t Q \\ O & I \end{bmatrix} \begin{bmatrix} \tilde{\mathbf{x}} \\ \tilde{\mathbf{y}} \end{bmatrix}.$$

We get that

$$(1 - \lambda)\tilde{\mathbf{y}} = \Delta t Q^t \tilde{\mathbf{x}}$$

and

$$-\lambda \Delta t^2 QQ^t \tilde{\mathbf{x}} = (1 - \lambda)^2 \tilde{\mathbf{x}}.$$

Hence, $\tilde{\mathbf{x}}$ is an eigenvector of QQ^t with eigenvalue $-(\lambda - 1)^2/\lambda\Delta t^2$. Since QQ^t is symmetric, it has only real eigenvalues. Thus,

$$\operatorname{Im}\left(\frac{-(\lambda - 1)^2}{\lambda} \right) = \operatorname{Im}\left(2 - \frac{(\lambda^2 + 1)}{\lambda} \right) = \operatorname{Im}(\lambda + \lambda^{-1}) = b(1 - (a^2 + b^2)^{-1}) = 0.$$

It follows that either $b = 0$, in which case λ is real, or $|\lambda| = 1$. If λ is real, then using the fact that QQ^t is positive semidefinite we see its eigenvalues are nonnegative so that $\lambda = 1$ or $\lambda < 0$.

(b) Now suppose that condition (17) holds. In view of (a), we need only consider the case $\lambda < 0$. Then

$$\Delta t^2 \leq \frac{4}{\psi} \leq \frac{-4\lambda\Delta t^2}{(\lambda-1)^2} \Rightarrow (\lambda+1)^2 \leq 0 \Rightarrow \lambda = -1.$$

Now suppose all eigenvalues of $T(\Delta t)$ have unit magnitude. Let $\psi = (2+\alpha)/\Delta t^2$ be the eigenvalue of QQ^t that is largest in magnitude. Let λ be such that $\alpha = -(\lambda^2+1)/\lambda$. Specifically, λ is given by

$$\lambda = \frac{-\alpha \pm \sqrt{\alpha^2-4}}{2}.$$

Moreover, using the same arguments as in (a) to show the connection between the eigenvalues of QQ^t and $T(\Delta t)$, we see that λ is an eigenvalue of $T(\Delta t)$ and by hypothesis has unit magnitude. Then

$$\frac{\Delta t^2}{4}|\psi| = \frac{|\lambda-1|^2}{4|\lambda|} \leq 1$$

and the theorem is proved. □

Theorem 2 (conservation of magnetic charge). *If* $\tilde{\mathbf{B}}^{n+1/2} = \sum_{i=1}^{N_f} b_i^{n+1/2}\mathbf{F}_i$ *is the Galerkin approximation computed from* (16), *then*

$$\int_\Omega \nabla \bullet \tilde{\mathbf{B}}^{n+1/2} d\Omega = \int_\Omega \nabla \bullet \tilde{\mathbf{B}}^{n-1/2} d\Omega, \qquad n = 1, 2, \ldots.$$

Proof. Let $\delta\mathbf{b}^n = (\mathbf{b}^{n+1/2} - \mathbf{b}^{n-1/2})/\Delta t$. Then by (16)

$$G\delta\mathbf{b}^n = -K\mathbf{e}^n.$$

Note that the edge basis functions and the face basis functions are related by the so-called inclusion (or compatibility) condition $\nabla \times \mathbf{W}_i \in F$. In particular, the edge and face basis functions are normalized such that $\nabla \times W_i = \sum_{j=1}^{2} a_{ij}\mathbf{F}_{ij}$, where $\mathbf{F}_{ij}$ are the two face functions associated with the edge function W_i and $a_{ij} = \pm 1$ with the sign depending upon the right-hand rule. Thus,

$$\sum_{i=1}^{N_e} e_i \nabla \times \mathbf{W}_i = \sum_{i=1}^{N_e} e_i \sum_{j=1}^{2} a_{ij}\mathbf{F}_{ij}$$

and by (16) we have

$$\sum_{i=1}^{N_f} \delta b_i^n(\mathbf{F}_i, \mathbf{F}_k) = \sum_{i=1}^{N_e} e_i^n(\nabla \times \mathbf{W}_i, \mathbf{F}_k) = \sum_{i=1}^{N_e} e_i^n \sum_{j=1}^{2} a_{ij}(\mathbf{F}_{ij}, \mathbf{F}_k)$$

for $k = 1, \ldots, N_f$. The two summations in the right-hand term can be combined so that the summation is performed over all N_f face, with four electric field degrees of freedom e_j contributing to each b_i:

$$\sum_{i=1}^{N_f} \delta b_i^n(\mathbf{F}_i, \mathbf{F}_k) = \sum_{i=1}^{N_f} \left(\sum_{j=1}^{4} e_j^n a_{ij} \right) (\mathbf{F}_i, \mathbf{F}_k).$$

It follows that

$$\delta b_i^n = \sum_{j=1}^{4} e_j^n a_{ij}$$

Using Gauss' law, the divergence of the magnetic flux density in a given cell Ω_e is

$$\int_\Omega (\nabla \bullet \delta\tilde{\mathbf{B}}^n) = \oint \delta\tilde{\mathbf{B}}^n \bullet n d\Gamma = \sum_{i=1}^{6} \delta b_i^n = \sum_{i=1}^{6}\sum_{j=1}^{4} e_j^n a_{ij} = 0,$$

and the theorem follows by summing over the cells. □

THEOREM 3 (conservation of electric charge). *Let S_0 be the space of trilinear continuous Lagrangian finite elements vanishing on γ_D. If $\tilde{\mathbf{E}}^n = \sum_{i=1}^{N_e} e_i^n \mathbf{W}_i$ is the Galerkin approximation computed from* (16), *then*

$$\int_\Omega (\nabla \bullet \varepsilon\tilde{\mathbf{E}}^n)\psi \, d\Omega = \int_\Omega (\nabla \bullet \varepsilon\tilde{\mathbf{E}}^{n-1})\psi \, d\Omega, \qquad n = 1, 2, \ldots, \tag{19}$$

for all continuous piecewise linear functions $\phi \in S_0$.

Proof. First note that integration by parts yields

$$\int_\Omega (\nabla \bullet \varepsilon\overline{\mathbf{E}})\phi = -\int_\Omega \varepsilon\tilde{\mathbf{E}} \bullet \nabla\phi d\Omega + \oint_\Gamma \phi\varepsilon\tilde{\mathbf{E}} \bullet \mathbf{n} \, d\Gamma = -\int_\Omega \varepsilon\tilde{\mathbf{E}} \bullet \nabla\phi \, d\Omega.$$

Let $\delta\overline{\mathbf{E}}^n = \Delta t^{-1}(\overline{\mathbf{E}}^n - \overline{\mathbf{E}}^{n-1})$. Then by (16),

$$(\varepsilon\delta\overline{\mathbf{E}}^n, \mathbf{W}_j) = (\nabla \times \mathbf{W}_j, \mu^{-1}\tilde{\mathbf{B}}^{n-1/2}), \qquad j = 1, 2, \ldots, N_E.$$

Now, $\nabla\phi \in W$; cf. [15, 25]. Therefore

$$\int_\Omega (\nabla \bullet \varepsilon\delta\overline{\mathbf{E}}^n)\phi = \int_\Omega \varepsilon\delta\tilde{\mathbf{E}}^n \bullet \nabla\phi \, d\Omega = \int_\Omega (\nabla \times \nabla\phi) \bullet \mu^{-1}\tilde{\mathbf{B}}^{n-1/2} d\Omega = 0,$$

and the theorem is proved. □

5.2. Numerical dispersion. Equation (1) in an infinite, source free, zero conductivity region becomes the vector wave equation

$$\varepsilon\frac{\partial^2 \mathbf{E}}{\partial t^2} = -\nabla \times \mu^{-1}\nabla \times \mathbf{E}. \tag{20}$$

If μ and ε are constant scalars, then

$$\mathbf{E} = \mathbf{E}_0 e^{I(k \bullet x - \omega t)} \tag{21}$$

is a solution to (20) only if the dispersion relation $\omega^2 = c^2k^2$ holds where $k = \|\mathbf{k}\|_2$ and $c = 1/(\sqrt{\mu\varepsilon})$ is the speed of light. Now, consider the solution

$$\mathbf{e}(t) = \sum_i e_i(t)\mathbf{W}_i(\mathbf{x}), \qquad e_i(t) = \int_{a_i} \mathbf{E}(x, t) \bullet \mathbf{t} \, dl$$

of the Galerkin form of (20)

$$C\frac{\partial^2 \mathbf{e}}{\partial t^2} = -A\mathbf{e}, \qquad e_i(0) - \int_{a_i} \mathbf{E}(\mathbf{x}, 0) \bullet \mathbf{t} \, dl \tag{22}$$

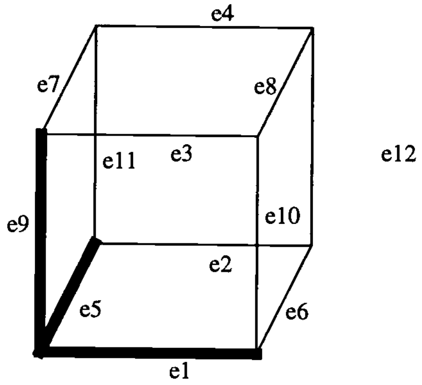

FIG. 2. *Edge numbering for numerical dispersion analysis.*

with $\mathbf{t}$ the unit tangent vector to edge a_i. The matrices C and A are defined by (13) and $A_{ij} = (\mu^{-1}\nabla \times \mathbf{W}_i, \nabla \times \mathbf{W}_j)$, respectively. We now assume the grid to be composed of identical hexahedral cells, which may be distorted. For this analysis the distortion is such that edges $\tilde{e}_1 - \tilde{e}_4$, $\tilde{e}_5 - \tilde{e}_8$, $\tilde{e}_9 - \tilde{e}_{12}$ are parallel; see Figure 2.

If we let

$$X(t) = \int_{\tilde{e}_1} \mathbf{E}(x,t) \bullet \mathbf{t}\, dl, \qquad Y(t) = \int_{\tilde{e}_5} \mathbf{E}(x,t) \bullet \mathbf{t}\, dl, \qquad Z(t) = \int_{\tilde{e}_9} \mathbf{E}(x,t) \bullet \mathbf{t}\, dl,$$

then

$$\begin{array}{lll}
\tilde{e}_1(t) = X(t), & \tilde{e}_2(t) = Xe^{I(\mathbf{k}\bullet\vec{\Delta}_{1,2}-\omega\Delta t)}, & \tilde{e}_3(t) = Xe^{I(\mathbf{k}\bullet\vec{\Delta}_{1,3}-\omega\Delta t)}, \\
\tilde{e}_4(t) = Xe^{I(\mathbf{k}\bullet\vec{\Delta}_{1,4}-\omega\Delta t)}, & \tilde{e}_5(t) = Y(t), & \tilde{e}_6(t) = Ye^{I(\vec{\mathbf{k}}\bullet\vec{\Delta}_{5,6}-\omega\Delta t)}, \\
\tilde{e}_7(t) = Xe^{I(\mathbf{k}\bullet\vec{\Delta}_{5,7}-\omega\Delta t)}, & \tilde{e}_8(t) = Xe^{I(\mathbf{k}\bullet\vec{\Delta}_{5,8}-\omega\Delta t)}, & \tilde{e}_9(t) = Z(t), \\
\tilde{e}_{10}(t) = Ze^{I(\mathbf{k}\bullet\vec{\Delta}_{9,10}-\omega\Delta t)} & \tilde{e}_{11}(t) = Ze^{I(\mathbf{k}\bullet\vec{\Delta}_{9,11}-\omega\Delta t)} & \tilde{e}_{12}(t) = Ze^{I(\mathbf{k}\bullet\vec{\Delta}_{9,12}-\omega\Delta t)},
\end{array}$$
(23)

where $\vec{\Delta}_{i,j}$ is the vector from the midpoint of edge $\tilde{e}_i$ to the midpoint of edge $\tilde{e}_j$.

Clearly,

$$(24) \qquad \left(\frac{\partial^2 \tilde{e}_i}{\partial t^2}\right)^n \approx \frac{\tilde{e}_i^{n+1} - 2\tilde{e}_i^n + \tilde{e}_i^{n-1}}{\Delta t^2} = \frac{\psi \tilde{e}_i}{\Delta t^2}, \qquad \psi = 2\cos(\omega\Delta t - 1).$$

If we assume $\|\vec{\Delta}_{i,j}\|_2 = \Delta x$ for all (i,j), then (22)–(24) yields a homogeneous system of equations:

$$(25) \qquad (\psi F + \eta G)\begin{pmatrix} \mathrm{X} \\ \mathrm{Y} \\ \mathrm{Z} \end{pmatrix} = 0, \qquad \eta = c^2 \frac{\Delta t^2}{\Delta x^2}.$$

The numerical dispersion relation is given by

$$(26) \qquad \det(\psi F + \eta G) = 0,$$

where the 3×3 matrices F, G are complicated nonlinear relationship between the wave vector $\mathbf{k}$ and the radian frequency ω. There are three roots; one is zero, which does not represent anything physical, and the other two correspond to the two distinct polarizations.

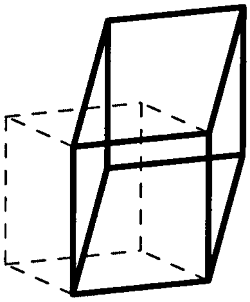

FIG. 3. *Illustration of a cube distorted in the x and z directions by an amount $\theta = 45°$.*

Example: Numerical dispersion for three-dimensional shear distortion. Let

$$\mathbf{k} = k[\cos(\phi)\sin(\Phi), \sin(\phi)\sin(\Phi), \cos(\Phi)]^t \tag{27}$$

be a wave vector as a function of the spherical angles ϕ and Φ. The exact phase velocity for (20)–(21) is given by $\omega/k = c$ and the numerical phase velocity $v = \tilde{\omega}/k$ is computed by specifying a value of $\mathbf{k}$ as a function of ϕ Φ and solving numerically for the value of $\tilde{\omega}$ that satisfies (26).

In this example, a unit cube is sheared by an amount 0 in both the x direction and the z direction; see Figure 3.

In the computational experiments we take $c = 1$ and $\Delta t = 1/3$. Figure 4 shows surfaces of the phase velocity error for shear angles of $\theta = 0°, 15°, 30°, 45°$. Each figure shows the velocity error for $k = 1\pi/5$, where the velocity error is defined as $v - c$. The shape of the velocity error surface remains the same as k is decreased, thus it is not necessary to display different surfaces. Note that the scale is different for each plot.

The maximum velocity, minimum velocity, and anisotropy ratio are tabulated in Table 2 as a function of k for each of the four grid distortions. The results demonstrate that, as the grid becomes more distorted, the numerical dispersion relation becomes more anisotropic.

It is possible to determine the rate of convergence of the numerical dispersion relation for distorted hexahedral grids by applying a least-squares fit to the above data. The logarithm of the error versus the logarithm of k is shown in Figure 5 for each of the four grids, along with a least-squares linear fit. The least-squares fit is applied to the maximum velocity error. For each grid the slope of the linear fit is approximately 2 (from 2.02 to 2.09), indicating second order convergence of the numerical dispersion relation.

6. Linear system solution methods. The VFETD method requires the solution of a large, sparse, symmetric, positive-definite mass matrix equation $Cx = y$ at every time step. In this paper, the incomplete Cholesky conjugate gradient (ICCG) method will be used to solve the mass matrix. Basically, the ICCG method is a preconditioned conjugate gradient method where the preconditioner is constructed by applying the Cholesky factorization algorithm to the mass matrix C and ignoring the nonzero fill-in [39]. This generates an incomplete Cholesky factorization $\tilde{L}\tilde{L}^t$, where $\tilde{L}$ has the same sparsity pattern as the matrix C. For the special case of a Cartesian grid, the following result holds.

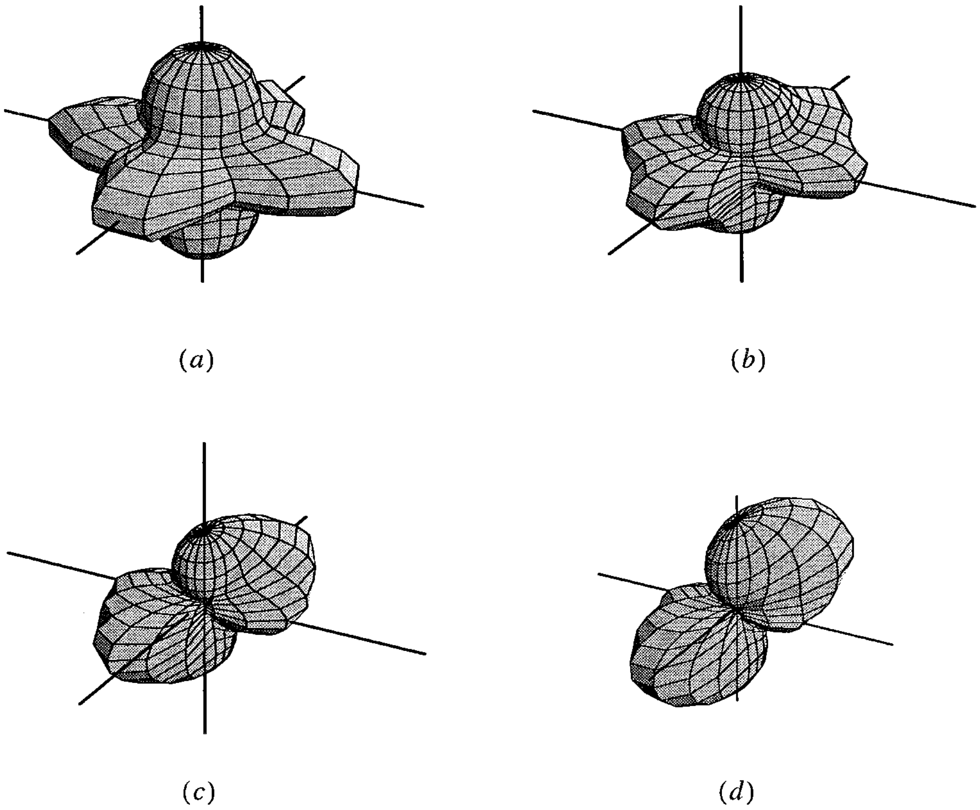

FIG. 4. *Phase velocity error for* $\theta =$ (a) 0°, (b) 15°, (c) 30°, (d) 45°. *The surface corresponds to* $k = 2\pi/5$. *The length of the axes are* (a) 0.15, (b) 0.25, (c) 0.35, (d) 0.35.

TABLE 2
Phase velocity and anisotropy ratio versus k.

	$\theta = 0°$			$\theta = 15°$		
k	$\max v$	$\min v$	ratio	$\max v$	$\min v$	ratio
$2\pi/5$	1.07538	1.03002	1.04404	1.08797	1.01709	1.06969

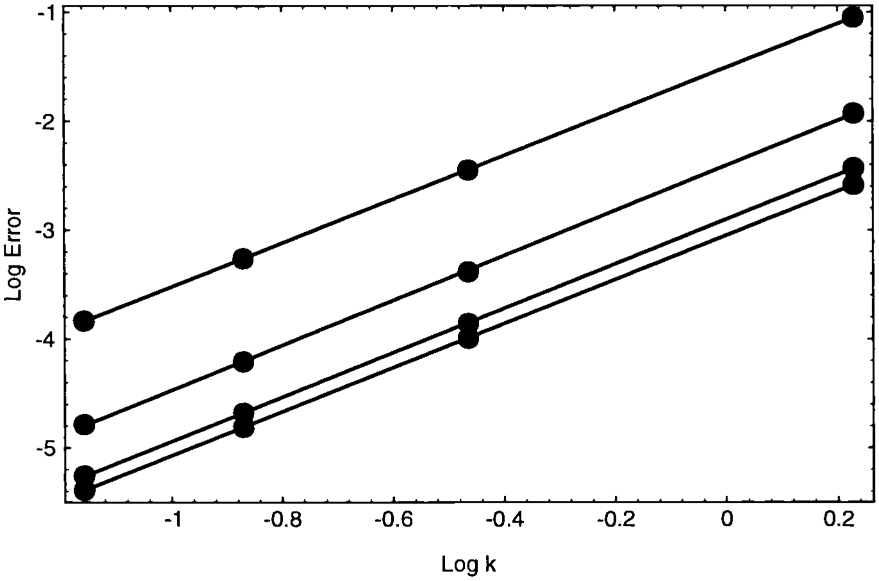

FIG. 5. *Least-squares fit of phase velocity error indicating second order accuracy for distorted hexahedral grids with shear $\theta = 0°, 15°, 30°, 45°$, respectively. The larger error corresponds to the larger shear angle.*

THEOREM 4. *Consider the mass matrix $C = [(\varepsilon \mathbf{W}_i, \mathbf{W}_j)]$ for an orthogonal hexahedral grid. Let $C = LL^t$ be the Cholesky factorization and $\tilde{L}\tilde{L}^t$ the incomplete factorization of C. Then $L = \tilde{L}$, i.e., there is no nonzero fill in the course of the Cholesky decomposition.*

Proof. The proof follows by carefully examining the inner most loop of the decomposition (see Algorithm 4.2.2 in [39])

$$C_{ij} = C_{ij} - C_{ik}C_{jk},$$

where $k < j \le i$. If $C_{ij} = 0$, i.e., there is no interaction between edges i and j, then there will be zero fill only if there is another edge k that interacts with both edges i and j. Numbering the edges sequentially precludes this possibility. This is illustrated on a two-dimensional grid in Figure 6.

It follows from the previous theorem that for the orthogonal case, the ICCG algorithm converges in one iteration. The above result does not hold for arbitrary hexahedral grids. However, as will be seen in the numerical results of the next section, the number of iterations for the ICCG algorithm to converge is quite small, indicating incomplete factorization is a very good preconditioner for the conjugate gradient algorithm.

The classical approach to dealing with the mass matrix is to "lump" it, whereby the matrix C is approximated by a diagonal matrix $\tilde{C}$ given by

$$\tilde{C}_{ii} = \sum_j \alpha_j C_{ij}, \qquad i = 1, \dots, N_e, \tag{28}$$

and the coefficients α_j are such that

$$\sum_j \alpha_j \mathbf{W}_j \bullet \mathbf{W}_i = \int_\Omega \mathbf{E} \bullet \mathbf{W}_i \, d\Omega. \tag{29}$$

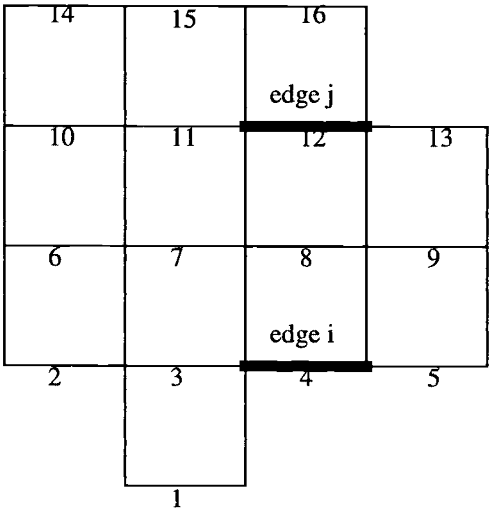

FIG. 6. *Grid numbering scheme for Cartesian grid.*

For a uniform orthogonal Cartesian grid and $\alpha_j = 1$, each diagonal term of the lumped mass matrix $\tilde{C}$ is equal to the row-sum of C and the mass lumping approximation generates the classic FDTD method. Thus, we see that the VFETD method is a generalization of the FDTD method.

7. Numerical experiments. In this section the VFETD method is used to solve several electromagnetics problems for which analytic solutions are known. In all cases the CPU time is for a Silicon Graphics 8000 workstation (64 bit, 300 MFLOPS, SPECfp92 310).

7.1. Spherical cavity. In this section a perfectly conducting spherical cavity of radius $a = 0.05855m$ is analyzed using VFETD and the computed solutions are compared to the exact analytical solution. The electric field within the cavity satisfies (20) where $\sigma_E = \sigma_M = 0$ and $\mu = \varepsilon = 1$ within the cavity. The exact solution is of the form

$$E = \sum_{np} A_{np} \mathbf{E}_{np}^{TE} \cos(\omega_{np} \mathbf{t} + \phi_{np}) + \sum_{np} B_{np} \mathbf{E}_{np}^{TM} \cos(\omega_{np} \mathbf{t} + \theta_{np}), \tag{30}$$

where the sum is over all the modes, and A, B, ϕ, and θ depend upon the initial conditions [37]. Here, ω_{np} are the resonant frequencies given by

$$\omega_{np}^{(j)} = \frac{\zeta_{np}^{(j)}}{a}, \qquad n, p = 1, 2, 3, \ldots, j = 0.1, \tag{31}$$

where $\zeta_{np}^{(j)}$ are the pth zeros of the jth derivative of the spherical Bessel function of order n. The exact resonant frequencies below 20Hz are shown in Table 3.

The spherical cavity was modeled using a sequence of hexahedral grids ranging from a coarse grid with 4 cells per radius to a fine grid with 12 cells per radius. Figure 7(a), (b) are cut-away views of the 256 hexahedral and 2048 hexahedral grids, respectively. The electromagnetic fields in the cavity were excited by a pulsed current source, the pulse having the shape of the second derivative of a Gaussian. The initial

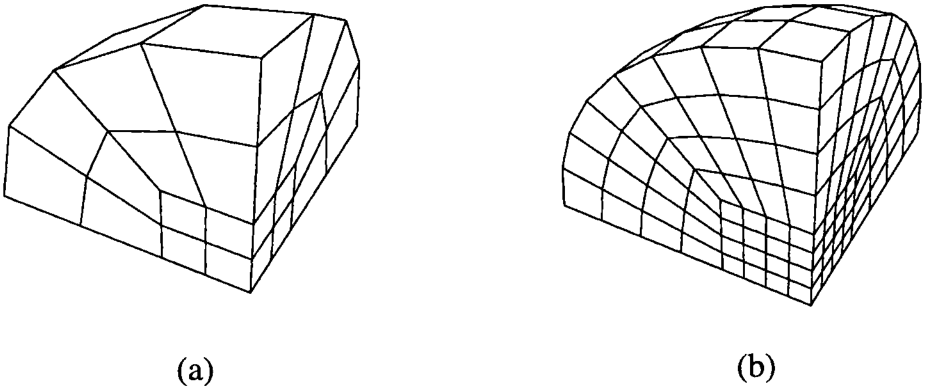

FIG. 7. *Internal view of* (a) 256, (b) 2048 *hexahedral grid of sphere.*

electric and magnetic fields within the cavity were zero. The simulation was run for $t = 6.71315s$, which corresponds to 50 periods of the lowest mode. An edge within the cavity was selected at random and the electric field along this edge was written to disk at every time step. This signal was weighted by a Hamming window and the signal was zero-extended to 32768 samples and then Fourier transformed. The magnitude of the Fourier transform is the *power spectrum* of the signal. The time step and the number of steps was different for each grid due to different stability requirements. The power spectrums for the 256 hexahedral case and the 2048 hexahedral case are shown in Figure 8(a), (b), respectively.

Naturally the power spectrum corresponding to the higher resolution grid is more accurate than the power spectrum corresponding to the lower resolution grid. The order of accuracy of the method is determined by performing a least-squares fit to the data where the error is defined to be the difference between the exact and computed values of $\omega_{31}^{(1)}$. In other words we assume that $|(\omega_{31}^{(1)})_{exact} - (\omega_{31}^{(1)})_{computed}| \propto h^m$ and we solve for the value of m that best models the results. Table 4 records the error as a function of grid size, where h is the average cell size. The logarithm of the error versus the logarithm of h/a is shown in Figure 9, along with a linear least-squares fit. The slope of the line is 2.028, so that the method is second order accurate, thus agreeing with the numerical dispersion analysis.

The CPU time for the calculations is shown in Table 5. The CPU time is for the time stepping part of the calculation only. For the above experiments the matrix fill time is approximately 1/50 of the total CPU time. The stopping criteria for the ICCG algorithm was $\|\boldsymbol{residual}\|_2/\|\boldsymbol{rhs}\|_2 \le 10^{-9}$, where $\boldsymbol{rhs}$ is the right-hand side. Note that the number of ICCG iterations does not increase as the grid is refined, indicating that the condition number of the mass matrix remains constant [38]. Therefore the computational cost per time step is proportional to the number of degrees of freedom.

7.2. Rectangular waveguide. In this section, the VFETD method is used to compute the electromagnetic fields in a rectangular waveguide. Let the rectangular waveguide have width $a = 0.9m$ in the x direction, height $b = 4.5m$ in the y direction, and infinite in the z direction. The fields are modeled by (1)–(3).

A wave is launched by forcing the time dependent boundary condition

$$\begin{aligned} \mathbf{E}_x &= 0, \\ \mathbf{E}_y &= \left(1 - \exp\left(-\left(\frac{t}{2T}\right)^2\right)\right) \sin(\pi x/a)\sin(\omega t) \end{aligned} \tag{32}$$

at the left end ($z = 0$) of the waveguide. Here $\omega = 5.523599$ and $T = 0.5$. The initial electric and magnetic fields in the guide are zero. The exact steady state solution is given by

$$\begin{aligned} \mathbf{E}_x &= 0, \\ \mathbf{E}_y &= A\sin(\pi x/a)\sin(\omega t - \beta_z z), \\ \mathbf{E}_z &= 0, \end{aligned} \tag{33}$$

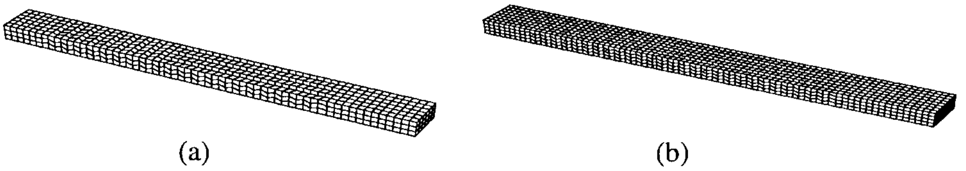

FIG. 10. *Rectangular waveguide model using* (a) 1080, (b) 2560 *chevron cells.*

$$\mathbf{B}_x = \frac{\beta_z}{\omega} A \sin(\pi x/a) \sin(\omega t - \beta_z z),$$
$$H_y = 0, \tag{34}$$
$$\mathbf{B}_z = A \frac{(\pi/a)^2}{\omega} \cos(\pi x/a) \cos(\omega t - \beta_z z),$$

where the wave number is $\beta_z = \sqrt{\omega^2 \mu\varepsilon - (\pi/a)^2}$; see [36].

The waveguide is modeled using a sequence of chevron grids with the coarsest grid having $h = a/6$ and the finest having $h = a/14$, where h is the average cell size. Several finite volume methods have been shown to be unconditionally unstable for these particular chevron grids [10]. Two of the grids are illustrated in Figure 10(a) and Figure 10(b).

The simulation was run for 20 seconds, which was enough time for the wavefront to propagate approximately 20 meters, i.e., twice the length of the finite guide.

The infinite waveguide is approximated by a finite length waveguide of length $10m$ with a radiation (or absorbing) boundary condition. The method used here to eliminate nonphysical reflections from the artificial truncation of the domain is a variant of the perfectly matched layer (PML) method. The original PML method derived in [44] is applicable only for the classic Cartesian grid FDTD method, but many variants have been proposed for unstructured grids [45, 46, 47]. The general idea is to attach to the truncated domain several layers of anisotropic conductive media, using both electric and magnetic conductivity. Grading the layers from low conductivity to high conductivity creates a broadband impedance match, thus eliminating (or nearly eliminating) front face reflections. As the outgoing wave propagates through the PML it is absorbed by the medium. The PML is not really perfect; a small amount of energy will be reflected from the boundary. But the reflection is an exponential function of layer thickness and can be made arbitrarily small. Since the VFETD method allows for arbitrary tensor material properties, the PML technique was used without modification. In this example, the wave will be attenuated by the PML at the right end of the waveguide; thus the simulation will reach a dynamic steady state condition that resembles the exact solution of an infinite waveguide.

In this simulation, a five-layer PML was used to absorb the outgoing wave. Each layer is defined by the tensor material properties μ, ε, σ_E, σ_M. In every layer μ and ε are identity matrices. The conductivity matrices are given by $\sigma_E = \sigma_M = \sigma$, where σ is a diagonal matrix with $\sigma_{xx} = \sigma_{yy} = \sigma_\perp$ and $\sigma_{zz} = 1$. The values of $\sigma_\perp$ used are tabulated in Table 6. The time step, number of steps, and ICCG iterations are shown in Table 7.

Note again that the number of ICCG iterations is constant. The same stopping criteria was the same as for the spherical cavity.

The computed electric and magnetic fields in the waveguide are compared to the

Table 6

exact solution. The error measure is the standard L_2 relative error shown below, where the sum is over all the hexahedral cells (excluding PML cells) in the grid.

$$L_2\,error = \frac{\|(\mathbf{E}_{exact} - \mathbf{E}_{computed})\|_2}{\|\mathbf{E}_{exact}\|_2} \tag{35}$$

The logarithm of the error versus the logarithm of (h/a) is shown in Figure 11. In this figure the initial error is somewhat erratic until the grid spacing h/a is approximately 1/20, and after that the error decreases with second order convergence. This agrees with the analysis in [48] where it is shown that the Galerkin solution of the Helmholtz equation exhibits pollution due to numerical dispersion. In our example, the waveguide is ten wavelengths long and, for large values of h/a, the phase error builds up significantly along the length of the waveguide, degrading the L_2-norm of the error. As discussed in section 5, for a grid spacing of $(h/a) = 10$ and a grid distortion of $\theta = 30°$ the worst-case phase velocity error is approximately 3%; therefore at the termination end of the waveguide the fields are up to 100 degrees out of phase, resulting in a local error of up to 50%. The L_2 error for the $(h/a) = 10$ case is 17.38%, which is relatively poor. The convergence result in Figure 11 shows that for electrically large problems a very fine mesh is required in order to achieve a small L_2 error.

There are several other measures of error that are applicable for this specific waveguide problem. The global error as well as errors in impedance, wavelength, voltage standing wave ratio (VSWR), and reflection coefficient are shown in Table 8. In this case, the impedance in the guide is defined as $Z = E_z/H_y = \omega\mu/\beta_z =$ constant. Since the computed fields are "noisy," the computed impedance is defined to be the average impedance over the entire guide. The wavelength is computed by fitting a sine wave to the magnitude of the electric field, the period of best fit sine wave defining the wavelength of the electric field. The exact wavelength for this problem is simply $\lambda_z = 2\pi/\beta_z$. It is interesting to note that while the L_2 error is relatively large, accurate quantities such as impedance and wavelength can be derived from the computed field. Hence the L_2 error estimate may be overly pessimistic for some applications. The VSWR is defined as $VSWR = |E_{max}|/|E_{min}|$, where $|E_{max}|$ is the maximum of the time average electric field in the waveguide and $|E_{min}|$ is the minimum of the time

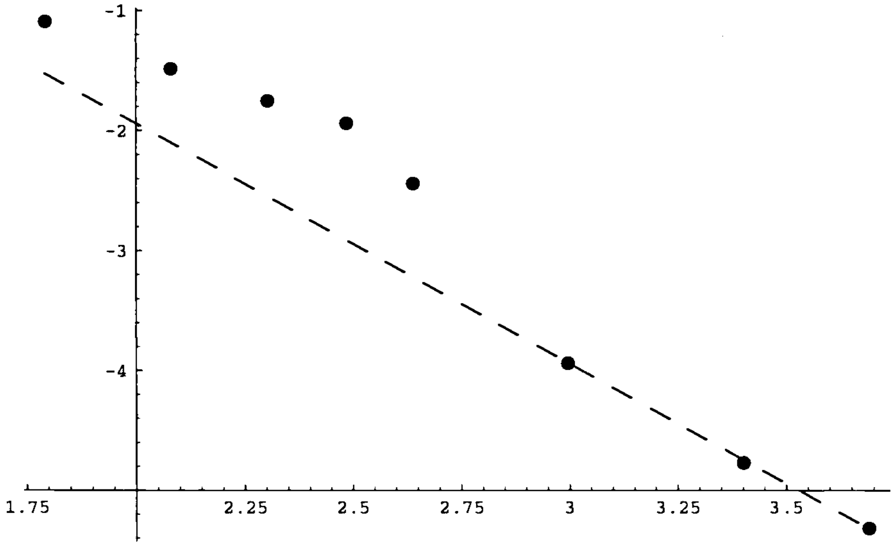

FIG. 11. *Log error versus* Log *h.*

TABLE 8
Quality of computed fields for PML terminated waveguide.

h/a	L_2	impedance	wavelength	VSWR	reflection coefficient
1/10	17.38%	2.713%	0.453%	1.057	−31dB

average electric field in the waveguide. For an infinite waveguide, or a perfectly terminated finite length waveguide, the VSWR is 1.0. For a terminated waveguide, the VSWR can be expressed as a function of the reflection coefficient of the termination, $VSWR = (1 - |\rho|)/(1 + |\rho|)$, where ρ is the reflection coefficient. The VSWR was computed by determining the maximum and minimum fields over one period, and the reflection coefficient is then computed from $|\rho| = (1 - VSWR)/(1 + VSWR)$. The reflection coefficient is a measure of the effectiveness of the PML. If the PML is perfect, the reflection coefficient would be zero. The reported reflection coefficient of −31dB is comparable to that obtained when using finite difference methods on uniform grids [44]. The reflection coefficient can in theory be reduced arbitrarily by adding more layers and/or tuning the material properties. The computed electric and magnetic fields are shown in Figure 12 for the 5000 cell waveguide, with excellent qualitative agreement with theory. Note that the chevron pattern of the underlying computational grid is not imprinted on the computed fields.

7.3. Dipole antenna. In this section, we compute the radiated electromagnetic fields due to a small current source using the VFETD method. Starting at the origin, a current oscillating at frequency ω is aligned in the z direction as illustrated in Figure 13.

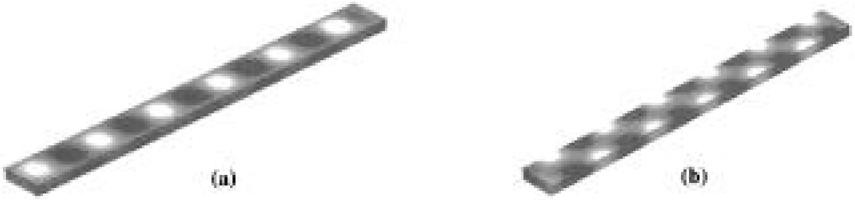

FIG. 12. *z-component of* (a) *electric field* (b) *magnetic field in PML terminated waveguide.*

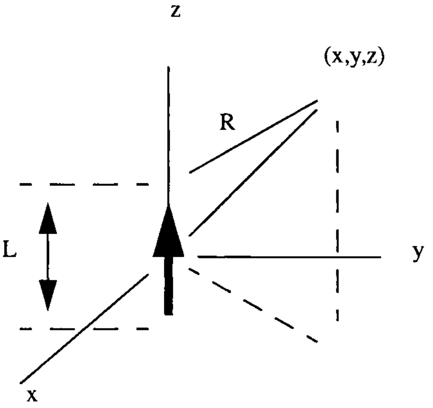

FIG. 13. *Coordinate system for dipole radiation calculation.*

The exact solution is given by

$$\mathbf{B} = \left(\mathbf{x}\frac{\partial A_z}{\partial y} - \mathbf{y}\frac{\partial A_z}{\partial x}\right)\cos(\omega t + \theta),$$
$$\mathbf{E} = \frac{1}{\omega\mu\varepsilon}\left(\mathbf{x}\frac{\partial\partial A_z}{\partial x\partial z} + \mathbf{y}\frac{\partial\partial A_z}{\partial y\partial z} - \mathbf{z}\left(\frac{\partial\partial A_z}{\partial x\partial x} + \frac{\partial\partial A_z}{\partial y\partial x}\right)\right)\sin(\omega t + \theta), \tag{36}$$

where

$$A_z = \frac{\mu I}{4\pi}\int_{-L/2}^{L/2}\frac{\exp(-j\beta R)}{R}dz, \tag{37}$$

and $\theta = \arg(A)$. The parameters for this computational experiment were $\omega = 107.3132$ and $L = \lambda/12 = 0.00487916$. The problem was modeled using a hemispherical grid consisting of 12032 hexahedral cells and 38005 edges. The grid had a spacing of $h = \lambda/24 = 0.00243972$ at the origin with the grid spacing increasing away from the origin. The current source is exactly two edge lengths long and given by

$$I(t) = \left(1 - \exp\left(-\left(\frac{t}{2T}\right)^2\right)\right)\sin(\omega t), \tag{38}$$

where $T = 0.0147$. The simulation was executed for 0.05855 seconds using a time step of $\Delta t = 10^{-4}$ seconds, which corresponds to 585 time steps.

In order to simulate free space, the same 5-layer PML used for the waveguide in the previous section was used with the exception that the conductivity tensor

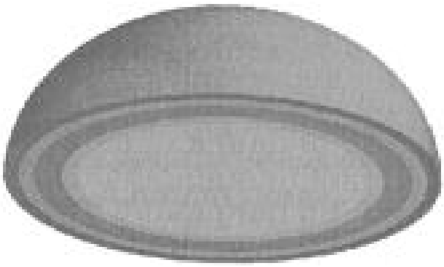

FIG. 14. *Illustration of hexahedral grid with* 5*-layer PML used for dipole calculation.*

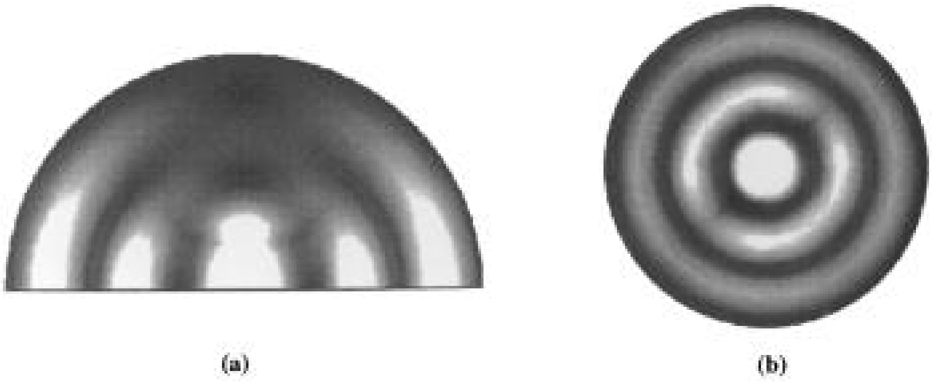

FIG. 15. *Computed* (a) *electric* (b) *magnetic field magnitude in the vicinity of* $\lambda/12$ *dipole.*

is rotated such that the axial direction corresponds to the radial direction so that the PML will absorb outgoing waves. The PML begins at radius $a = \lambda = 0.05855$ and the grid was terminated at $b = 1.5\lambda = 0.087825$; see Figure 14. The global L_2 error was computed in the same manner as for the waveguide, i.e., according to (35) where the sum is over all cells excluding PML cells. The computed electric field matched the exact electric field to within 1.6%, which is an excellent result since the electromagnetic field structure is quite complicated in the near field of the antenna. Snapshots of the computed electric and magnetic field are shown in Figure 15.

8. Conclusion. In this paper the VFETD method is derived, analyzed, and validated. It is demonstrated that the method is weakly stable, charge is conserved, and the continuity/discontinuity of the electromagnetic fields across a material interface are modeled properly. A numerical dispersion analysis indicates that the method is second order accurate, even on distorted, but regular, three-dimensional hexahedral grids.

However, like most finite element methods, the VFETD method requires that a sparse linear system be solved at every time step. The incomplete Cholesky conjugate gradient method was investigated where it is shown that the computational effort required to solve the system depends upon how distorted the grid is. However, for a uniformly refined mesh the number of iterations becomes independent of the number of mesh points; hence the method is scalable.

The VFETD method is validated by comparing computed solutions to analytical solutions for a simple resonant cavity, waveguide, and antenna. The accuracy and computer CPU time is tabulated for a variety of different grids. The computational experiments performed on these distorted hexahedral grids have rates of convergence that agree with previously published analytical approximations. It is also shown that the recently developed PML concept can be used to approximate an infinite space using a finite grid. Since the VFETD method allows for arbitrary tensor material properties, the PML concept is trivial to implement.

Acknowledgment. The authors would like to thank the Institute for Scientific Computing Research (ISCR) at the Lawrence Livermore National Laboratory (LLNL) for their support in this research.

SEMIDISCRETE CENTRAL-UPWIND SCHEMES FOR HYPERBOLIC CONSERVATION LAWS AND HAMILTON–JACOBI EQUATIONS[*]

ALEXANDER KURGANOV[†], SEBASTIAN NOELLE[‡], AND GUERGANA PETROVA[†]

Abstract. We introduce new Godunov-type semidiscrete central schemes for hyperbolic systems of conservation laws and Hamilton–Jacobi equations. The schemes are based on the use of more precise information about the local speeds of propagation and can be viewed as a generalization of the schemes from [A. Kurganov and E. Tadmor, *J. Comput. Phys.*, 160 (2000), pp. 241–282; A. Kurganov and D. Levy, *SIAM J. Sci. Comput.*, 22 (2000), pp. 1461–1488; A. Kurganov and G. Petrova, *A third-order semidiscrete genuinely multidimensional central scheme for hyperbolic conservation laws and related problems*, Numer. Math., to appear] and [A. Kurganov and E. Tadmor, *J. Comput. Phys.*, 160 (2000), pp. 720–742].

The main advantages of the proposed central schemes are the high resolution, due to the smaller amount of the numerical dissipation, and the simplicity. There are no Riemann solvers and characteristic decomposition involved, and this makes them a universal tool for a wide variety of applications.

At the same time, the developed schemes have an upwind nature, since they respect the directions of wave propagation by measuring the *one-sided* local speeds. This is why we call them *central-upwind* schemes.

The constructed schemes are applied to various problems, such as the Euler equations of gas dynamics, the Hamilton–Jacobi equations with convex and nonconvex Hamiltonians, and the incompressible Euler and Navier–Stokes equations. The incompressibility condition in the latter equations allows us to treat them both in their conservative and transport form. We apply to these problems the central-upwind schemes, developed separately for each of them, and compute the corresponding numerical solutions.

Key words. multidimensional conservation laws and Hamilton–Jacobi equations, high-resolution semidiscrete central schemes, compressible and incompressible Euler equations

1. Introduction.

We consider Godunov-type schemes for the multidimensional (multi-D) systems of conservation laws

$$u_t + \nabla_{\mathbf{x}} \cdot f(u) = 0, \quad \mathbf{x} \in \mathbb{R}^d, \tag{1.1}$$

and the multi-D Hamilton–Jacobi equations

$$\varphi_t + H(\nabla_{\mathbf{x}}\varphi) = 0, \quad \mathbf{x} \in \mathbb{R}^d. \tag{1.2}$$

Godunov-type schemes for the system (1.1) are projection-evolution methods. Starting with cell averages at time level t^n, one reconstructs a piecewise polynomial interpolant of degree $r-1$ (where r is the formal order of the scheme), which is

evolved to the next time level t^{n+1}, and then it is projected onto a space of piecewise constants. Depending on the projection step, we distinguish two kinds of Godunov-type schemes: central and upwind. The Godunov-type central schemes are based on exact evolution and averaging over Riemann fans. In contrast to the upwind schemes, they do not employ Riemann solvers and characteristic decomposition, which makes them *simple, efficient,* and *universal*.

In the one-dimensional (1-D) case, examples of such schemes are the first-order (staggered) Lax–Friedrichs scheme [28, 14], the second-order Nessyahu–Tadmor scheme [40], and the higher-order schemes in [39, 8, 30]. Second-order multi-D central schemes were introduced in [3, 4, 5, 6, 19, 34], and their higher-order extensions were developed in [31, 32]. We would also like to mention the central schemes for incompressible flows in [33, 22, 20, 21], and their applications to various systems, for example, [2, 13, 44, 49].

Unfortunately, these staggered central schemes may not provide a satisfactory resolution when small time steps are enforced by stability restrictions, which may occur, for example, in the application of these schemes to convection-diffusion problems. Also, they cannot be used for steady-state computations. These disadvantages are caused by the accumulation of numerical dissipation, which is of order $\mathcal{O}(\frac{(\Delta x)^{2r}}{\Delta t})$, where r is the formal order of the scheme.

The aforementioned problems have been recently resolved in [26], where new high-order Godunov-type central schemes are introduced. The proposed construction is based on the use of the CFL related *local speeds of propagation* and on integration over Riemann fans of variable sizes. In this way, a *nonstaggered* fully discrete central scheme is derived and is naturally reduced to a particularly simple semidiscrete form (for details see [26]). The same idea was used in [24] to develop a third-order semidiscrete central scheme, and in [25], where its genuinely multi-D extension was introduced.

The purpose of the first part of this paper is to present new semidiscrete central schemes for the conservation law (1.1), which we call *central-upwind* schemes. They are based on the *one-sided local speeds of propagation.* For example, in the 1-D case, these one-sided local speeds are the largest and smallest eigenvalues of the Jacobian $\frac{\partial f}{\partial u}$ (in contrast to the less precise local information, used in [26, 24, 25]—the spectral radius $\rho(\frac{\partial f}{\partial u})$).

The new schemes are Godunov-type *central* schemes, because the evolution step employs integration over Riemann fans and does not require a Riemann solver and a characteristic decomposition. They also have an *upwind* nature, since one-sided information is used to estimate the width of the Riemann fans. This more precise estimate makes our schemes less dissipative generalizations of the semidiscrete central schemes in [26, 24, 25].

The second part of this paper is devoted to the Hamilton–Jacobi equations, (1.2), which are closely related to (scalar) conservation laws. For example, in the 1-D case, the unique viscosity solution of the Hamilton–Jacobi equation, $\varphi_t + H(\varphi_x) = 0$, is the primitive of the unique entropy solution of the corresponding conservation law, $u_t + H(u)_x = 0$, where $u = \varphi_x$. However, in the multi-D case, this one-to-one correspondence no longer exists, but the gradient $\nabla_{\mathbf{x}}\varphi$ satisfies (at least formally) a system of (weakly) hyperbolic conservation laws.

This relation allows one to apply techniques, developed for conservation laws, to the derivation of the numerical methods for Hamilton–Jacobi equations. Examples of such methods can be found in [1, 10, 11, 35, 36, 42, 48]. One of the approaches [35, 36] is Godunov-type schemes. As in the case of conservation laws, they are projection-evolution methods. The differences are that here one starts with point values (not cell averages) at time t^n, builds a *continuous* piecewise polynomial reconstruction of degree r, and evolves it to the next time level t^{n+1}. The pointwise projection (not the cell averages) of this evolved solution is used as initial data for the next time step.

Godunov-type central schemes for Hamilton–Jacobi equations were first introduced in [35, 36]. Semidiscrete Godunov-type central schemes for the multi-D equations (1.2) were developed in [27], where the same idea of *local speeds of propagation* was used to separate between smooth and nonsmooth parts of the evolved solution.

In the second part of this work, we present a new second-order semidiscrete central-upwind scheme for the Hamilton–Jacobi equations (1.2). It is a less dissipative generalization of the scheme in [27], which uses more precise one-sided information of the local propagation speeds.

The paper is organized as follows. In section 2, we give a brief overview of the Godunov-type central schemes for conservation laws and Hamilton–Jacobi equations in one space dimension. We also describe the nonoscillatory piecewise quadratic reconstruction from [25], which is later used in the numerical examples. Next, in section 3, we introduce our new Godunov-type *central-upwind* schemes for the conservation laws and Hamilton–Jacobi equations, both in one and in two spatial dimensions. The results of our numerical experiments are presented in section 4. We apply the proposed scheme to a variety of test problems: the one- and two-dimensional compressible Euler equations, a 1-D Hamilton–Jacobi equation with a nonconvex Hamiltonian, the two-dimensional (2-D) eikonal equation of geometric optics. Finally, the incompressible Euler and Navier–Stokes equations are solved using two different approaches, based on either their conservative or transport form. The performed numerical experiments, especially in the case of incompressible flow simulations (see section 4.3), demonstrate the advantage of our new central-upwind approach.

2. Godunov-type central schemes—brief description. In this section, we review Godunov-type central schemes in one spatial dimension. We will consider only uniform grids and use the following notation: let $x_j := j\Delta x$, $x_{j\pm\frac{1}{2}} := (j \pm 1/2)\Delta x$, $t^n := n\Delta t$, $u_j^n := u(x_j, t^n)$, $\varphi_j^n := \varphi(x_j, t^n)$, where Δx and Δt are small spatial and time scales, respectively.

2.1. Central schemes for conservation laws. The starting point for the construction of Godunov-type schemes for conservation laws is the equivalent integral formulation of the system (1.1),

$$\begin{aligned}&\bar{u}(x, t+\Delta t)\\ &= \bar{u}(x,t) - \frac{1}{\Delta x}\left[\int_{\tau=t}^{t+\Delta t} f\left(u\left(x+\frac{\Delta x}{2},\tau\right)\right)d\tau - \int_{\tau=t}^{t+\Delta t} f\left(u\left(x-\frac{\Delta x}{2},\tau\right)\right)d\tau\right],\end{aligned} \tag{2.1}$$

where by

$$\bar{u}(x,t) := \frac{1}{\Delta x}\int_{I(x)} u(\xi,t)\,d\xi, \qquad I(x) = \left\{\xi : |\xi - x| < \frac{\Delta x}{2}\right\} \tag{2.2}$$

we denote the sliding averages of $u(\cdot,t)$ over the interval $(x - \frac{\Delta x}{2}, x + \frac{\Delta x}{2})$. At time level $t = t^n$ we consider problem (2.1) with the piecewise polynomial initial condition

$$\widetilde{u}(x,t^n) = p_j^n(x), \qquad x_{j-\frac{1}{2}} < x < x_{j+\frac{1}{2}} \quad \forall j, \tag{2.3}$$

obtained from the cell averages $\bar{u}_j^n := \bar{u}(x_j, t^n)$, computed at the previous time step. This piecewise polynomial reconstruction should be conservative, accurate of order r, and nonoscillatory.

Second-order schemes require a piecewise linear reconstruction (see the examples in [15, 16, 23, 29, 40, 43]). Third-order schemes employ a piecewise quadratic approximation, and one of the possibilities is to use the essentially nonoscillatory (ENO) reconstruction. In the 1-D case, we refer the reader to [16, 46]. The weighted ENO interpolants are proposed in [38, 18, 30, 32], and the multi-D ENO-type reconstructions can be found in [31, 32]. The ENO-type approach employs smoothness indicators. They require certain a priori information about the solution, which may be unavailable and then spurious oscillations or extra smearing of discontinuities may appear.

1-D nonoscillatory piecewise quadratic reconstructions, which do not require the use of smoothness indicators, were proposed in [37, 39, 25]. 2-D generalizations of these reconstructions were presented in [25, 41].

The reconstructed piecewise polynomial $\widetilde{u}(x, t^n)$ is then evolved exactly according to (2.1), and the solution at time $t = t^{n+1}$ is obtained in terms of its sliding averages, $\bar{u}(x, t^{n+1})$. An evaluation of these sliding averages at particular grid points provides the approximate cell averages of the solution at the next time level.

The choice of $x = x_j$ in (2.1) results in an upwind scheme. The solution then may be nonsmooth in the neighborhood of the points $\{x_{j+\frac{1}{2}}\}$, and the evaluation of the flux integrals in (2.1) requires the use of a computationally expensive (approximate) Riemann solver and characteristic decomposition.

If $x = x_{j+\frac{1}{2}}$ in (2.1), we obtain Godunov-type central schemes, namely,

$$\begin{aligned}\bar{u}_{j+\frac{1}{2}}^{n+1} = \frac{1}{\Delta x}\left[\int_{x_j}^{x_{j+\frac{1}{2}}} p_j^n(x)\,dx + \int_{x_{j+\frac{1}{2}}}^{x_{j+1}} p_{j+1}^n(x)\,dx\right] \\ -\frac{\lambda}{\Delta t}\left[\int_{t^n}^{t^{n+1}} f(u(x_{j+1},t))\,dt - \int_{t^n}^{t^{n+1}} f(u(x_j,t))\,dt\right], \quad \lambda := \frac{\Delta t}{\Delta x}.\end{aligned} \tag{2.4}$$

In contrast to the upwind framework, the solution is smooth in the neighborhood of the points $\{x_j\}$. Therefore, a discretization of the flux integrals in (2.4) can be done, using an appropriate quadrature formula. The corresponding function values can be computed either by Taylor expansion or by a Runge–Kutta method [39, 8].

2.2. Central schemes for Hamilton–Jacobi equations. In this section, we describe second-order Godunov-type central schemes for Hamilton–Jacobi equations. We follow the approach from [36] and construct a 1-D second-order staggered central scheme.

Assume that we have computed the point values of φ at time $t = t^n$. We then start with a continuous piecewise quadratic interpolant,

$$\begin{aligned}\widetilde{\varphi}(x, t^n) := \varphi_j^n + \frac{(\Delta\varphi)_{j+\frac{1}{2}}^n}{\Delta x}(x - x_j) + \frac{(\Delta\varphi)'_{j+\frac{1}{2}}}{2(\Delta x)^2}(x - x_j)(x - x_{j+1}), \\ x \in [x_j, x_{j+1}],\end{aligned} \tag{2.5}$$

where

$$(\Delta\varphi)_{j+\frac{1}{2}}^n := \varphi_{j+1}^n - \varphi_j^n. \tag{2.6}$$

Here, $(\Delta\varphi)'_{j+\frac{1}{2}}/(\Delta x)^2$ is an approximation to the second derivative $\varphi_{xx}(x_{j+\frac{1}{2}}, t^n)$. An appropriate *nonlinear limiter* employed in this approximation guarantees the nonoscillatory nature of $\widetilde{\varphi}(x, t^n)$. Examples of such limiters, developed in the context of hyperbolic conservation laws, may be found in [15, 16, 23, 40, 43]. In this paper we use a one-parameter family of the *minmod* limiters [29, 15, 43]

$$\begin{aligned}(\Delta\varphi)'_{j+\frac{1}{2}} = \text{minmod}\Bigg(&\theta\left[(\Delta\varphi)^n_{j+\frac{3}{2}} - (\Delta\varphi)^n_{j+\frac{1}{2}}\right], \frac{1}{2}\left[(\Delta\varphi)^n_{j+\frac{3}{2}} - (\Delta\varphi)^n_{j-\frac{1}{2}}\right],\\ &\theta\left[(\Delta\varphi)^n_{j+\frac{1}{2}} - (\Delta\varphi)^n_{j-\frac{1}{2}}\right]\Bigg),\end{aligned} \tag{2.7}$$

where $\theta \in [1, 2]$, and the multivariable minmod function is defined by

$$\text{minmod}(x_1, x_2, \ldots) := \begin{cases} \min_j\{x_j\} & \text{if } x_j > 0 \ \ \forall j, \\ \max_j\{x_j\} & \text{if } x_j < 0 \ \ \forall j, \\ 0 & \text{otherwise.} \end{cases} \tag{2.8}$$

Notice that larger θ's in (2.7) correspond to less dissipative, but still *nonoscillatory* limiters [29, 15, 43].

Given a reconstruction (2.5), we consider the Hamilton–Jacobi equation (1.2), subject to the initial data $\varphi(x, 0) = \widetilde{\varphi}(x, t^n)$. Under an appropriate CFL condition, due to the finite speed of propagation, the solution of this initial value problem is smooth in the neighborhood of the line segment $\{(x, t) : \ x = x_{j+\frac{1}{2}},\ t^n \leq t \leq t^{n+1}\}$. Therefore, from the Taylor expansion of the solution about the point $(x_{j+\frac{1}{2}}, t^n)$, we obtain

$$\varphi^{n+1}_{j+\frac{1}{2}} = \frac{\varphi^n_j + \varphi^n_{j+1}}{2} - \frac{(\Delta\varphi)'_{j+\frac{1}{2}}}{8} - \Delta t H\left(\frac{(\Delta\varphi)^n_{j+\frac{1}{2}}}{\Delta x}\right) + \frac{(\Delta t)^2}{2}\left[H'\left(\frac{(\Delta\varphi)^n_{j+\frac{1}{2}}}{\Delta x}\right)\right]^2 \cdot \frac{(\Delta\varphi)'_{j+\frac{1}{2}}}{(\Delta x)^2}. \tag{2.9}$$

Remarks.

1. The derived scheme (2.9) is different from the one in [36]. There, the evolution step is executed by integration of (1.2) over $[t^n, t^{n+1}]$, followed by the application of the midpoint rule to the resulting integrals. For details, see [36, 27].
2. A 2-D staggered central scheme for (1.2) can be found in [36].

3. Central-upwind semidiscrete schemes.

In this section, we develop new semidiscrete central-upwind schemes for conservation laws and Hamilton–Jacobi equations, following the approach presented in [26, 24, 25] and [27], respectively.

3.1. Semidiscrete central-upwind schemes for 1-D conservation laws.

We consider the 1-D system (1.1) of N strictly hyperbolic conservation laws. We start with a piecewise polynomial reconstruction (2.3) with possible discontinuities at the interface points $\{x_{j+\frac{1}{2}}\}$. These discontinuities propagate with right- and left-sided local speeds, which can be estimated by

$$a^+_{j+\frac{1}{2}} := \max_{\omega \in C\left(u^-_{j+\frac{1}{2}}, u^+_{j+\frac{1}{2}}\right)} \left\{\lambda_N\Big(\frac{\partial f}{\partial u}(\omega)\Big), 0\right\}$$

and

$$a^-_{j+\frac{1}{2}} := \min_{\omega \in C\left(u^-_{j+\frac{1}{2}}, u^+_{j+\frac{1}{2}}\right)} \left\{\lambda_1\Big(\frac{\partial f}{\partial u}(\omega)\Big), 0\right\},$$

respectively. Here, $\lambda_1 < \cdots < \lambda_N$ are the N eigenvalues of the Jacobian $\frac{\partial f}{\partial u}$, and $C(u^-_{j+\frac{1}{2}}, u^+_{j+\frac{1}{2}})$ is the curve in the phase space that connects

$$u^+_{j+\frac{1}{2}} := p_{j+1}(x_{j+\frac{1}{2}}) \quad \text{and} \quad u^-_{j+\frac{1}{2}} := p_j(x_{j+\frac{1}{2}}). \tag{3.1}$$

For example, in the genuinely nonlinear or linearly degenerate case, we have

$$\begin{aligned} a^+_{j+\frac{1}{2}} &= \max\left\{\lambda_N\Big(\frac{\partial f}{\partial u}\Big(u^-_{j+\frac{1}{2}}\Big)\Big), \lambda_N\Big(\frac{\partial f}{\partial u}\Big(u^+_{j+\frac{1}{2}}\Big)\Big), 0\right\}, \\ a^-_{j+\frac{1}{2}} &= \min\left\{\lambda_1\Big(\frac{\partial f}{\partial u}\Big(u^-_{j+\frac{1}{2}}\Big)\Big), \lambda_1\Big(\frac{\partial f}{\partial u}\Big(u^+_{j+\frac{1}{2}}\Big)\Big), 0\right\}. \end{aligned} \tag{3.2}$$

In fact, these one-sided local speeds are related to the CFL number. Note that in the schemes from [26, 24] only the spectral radius of $\frac{\partial f}{\partial u}$ is used, and for its computation one actually needs to know both λ_1 and λ_N.

Further, we utilize these one-sided local speeds of propagation in the following way. We consider the nonequal rectangular domains

$$[x^n_{j-\frac{1}{2},r}, x^n_{j+\frac{1}{2},l}] \times [t^n, t^{n+1}] \quad \text{and} \quad [x^n_{j+\frac{1}{2},l}, x^n_{j+\frac{1}{2},r}] \times [t^n, t^{n+1}], \tag{3.3}$$

with $x^n_{j+\frac{1}{2},l} := x_{j+\frac{1}{2}} + \Delta t a^-_{j+\frac{1}{2}}$ and $x^n_{j+\frac{1}{2},r} := x_{j+\frac{1}{2}} + \Delta t a^+_{j+\frac{1}{2}}$, where the solution of (1.1) with the initial data $\widetilde{u}(x, t^n)$ is smooth and nonsmooth, respectively.

The cell averages

$$\bar{w}^{n+1}_j = \frac{1}{x^n_{j+\frac{1}{2},l} - x^n_{j-\frac{1}{2},r}}\left[\int_{x^n_{j-\frac{1}{2},r}}^{x^n_{j+\frac{1}{2},l}} p^n_j(x)\,dx - \int_{t^n}^{t^{n+1}} \Big(f(u(x^n_{j+\frac{1}{2},l}, t)) - f(u(x^n_{j-\frac{1}{2},r}, t))\Big)\,dt\right], \tag{3.4}$$

and

$$\begin{aligned} \bar{w}^{n+1}_{j+\frac{1}{2}} = \frac{1}{x^n_{j+\frac{1}{2},r} - x^n_{j+\frac{1}{2},l}}\Bigg[&\int_{x^n_{j+\frac{1}{2},l}}^{x_{j+\frac{1}{2}}} p^n_j(x)\,dx + \int_{x_{j+\frac{1}{2}}}^{x^n_{j+\frac{1}{2},r}} p^n_{j+1}(x)\,dx \\ &- \int_{t^n}^{t^{n+1}} \Big(f(u(x^n_{j+\frac{1}{2},r}, t)) - f(u(x^n_{j+\frac{1}{2},l}, t))\Big)\,dt\Bigg] \end{aligned} \tag{3.5}$$

are obtained by integrating (1.1) over the corresponding domains in (3.3); see Figure 3.1.

Given the polynomials $\{p^n_j\}$, the spatial integrals in (3.4) and (3.5) can be computed explicitly. To discretize the flux integrals there, one may use an appropriate quadrature formula, since the solution is smooth along the line segments $(x^n_{j+\frac{1}{2},l}, t)$, $t^n \le t < t^{n+1}$ and $(x^n_{j+\frac{1}{2},r}, t)$, $t^n \le t < t^{n+1}$.

Next, from the cell averages, $\bar{w}^{n+1}_{j+\frac{1}{2}}$, $\bar{w}^{n+1}_j$, given by (3.4)–(3.5), we reconstruct a nonoscillatory, conservative, third-order, piecewise polynomial interpolant, denoted by

$$\widetilde{w}^{n+1}(x) = \sum_j \Big(\widetilde{w}^{n+1}_j(x)\chi_{\left[x^n_{j-\frac{1}{2},r},\, x^n_{j+\frac{1}{2},l}\right]} + \widetilde{w}^{n+1}_{j+\frac{1}{2}}(x)\chi_{\left[x^n_{j+\frac{1}{2},l},\, x^n_{j+\frac{1}{2},r}\right]}\Big). \tag{3.6}$$

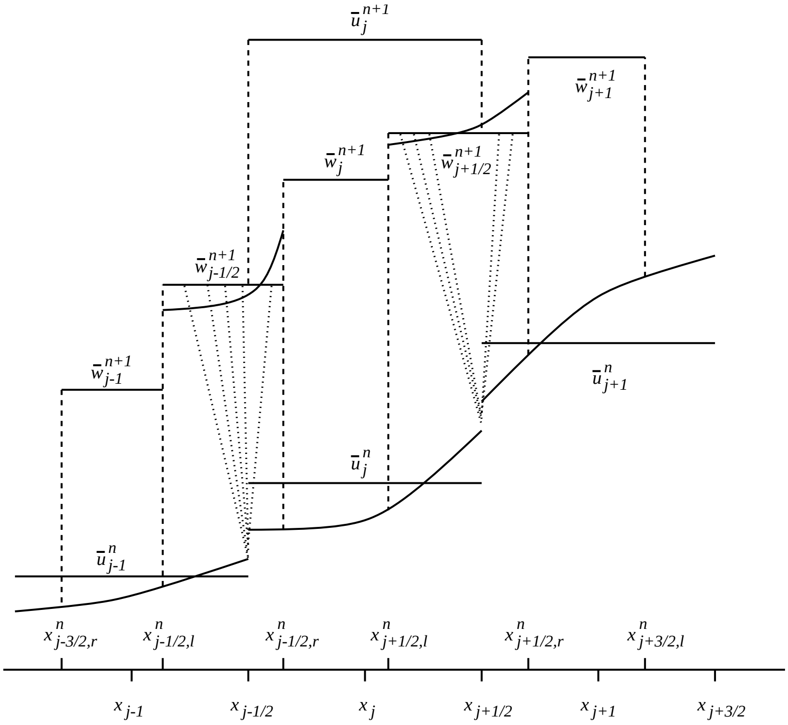

FIG. 3.1. *Central-upwind differencing.*

Here, the χ's are the characteristic functions, and $\{\widetilde{w}_{j+\frac{1}{2}}^{n+1}(x), \widetilde{w}_j^{n+1}(x)\}$ are the quadratic pieces, associated with the corresponding intervals. In fact, we do not need any high-order reconstruction $\widetilde{w}_j^{n+1}(x)$ since it will be averaged out (consult Figure 3.1).

Remark. Notice that even for a nonuniform grid, a particular piecewise quadratic reconstruction can be written explicitly. Since these formulae are rather messy and irrelevant for the semidiscrete scheme, we omit them.

The construction of our scheme is then completed by projecting $\widetilde{w}^{n+1}$ back onto the original grid, namely, we compute the cell averages

$$\bar{u}_j^{n+1} = \frac{1}{\Delta x}\int_{x_{j-\frac{1}{2}}}^{x_{j+\frac{1}{2}}} \widetilde{w}^{n+1}(x)\,dx \tag{3.7}$$

at the next time level. This leads to a fully discrete Godunov-type central-upwind scheme, which can be derived explicitly. Its derivation is similar to the derivation of the central schemes from [26, 24]. We omit here the details of these rather messy computations and continue within a much simpler semidiscrete framework.

The time derivative of $\bar{u}_j(t)$ is expressed with the help of (3.7) as

$$\frac{d}{dt}\bar{u}_j(t) = \lim_{\Delta t\to 0}\frac{\bar{u}_j^{n+1}-\bar{u}_j^n}{\Delta t} = \lim_{\Delta t\to 0}\frac{1}{\Delta t}\left[\frac{1}{\Delta x}\int_{x_{j-\frac{1}{2}}}^{x_{j+\frac{1}{2}}} \widetilde{w}^{n+1}(x)\,dx - \bar{u}_j^n\right]. \tag{3.8}$$

Now, let us suppose that the slopes of $\widetilde{w}_{j\pm\frac{1}{2}}^{n+1}$ are uniformly bounded, independently of

Δt. Since the width of the Riemann fans is bounded by $(a^+_{j+\frac{1}{2}} - a^-_{j+\frac{1}{2}})\Delta t$, we obtain

$$\widetilde{w}^{n+1}_{j\pm\frac{1}{2}}(x) = \bar{w}^{n+1}_{j\pm\frac{1}{2}} + \mathcal{O}(\Delta t) \qquad \forall x \in [x^n_{j\pm\frac{1}{2},l},\ x^n_{j\pm\frac{1}{2},r}]. \tag{3.9}$$

The conservation property of the reconstruction gives

$$\frac{1}{(x^n_{j+\frac{1}{2},l} - x^n_{j-\frac{1}{2},r})} \int_{x^n_{j-\frac{1}{2},r}}^{x^n_{j+\frac{1}{2},l}} \widetilde{w}^{n+1}_j(x)\,dx = \bar{w}^{n+1}_j. \tag{3.10}$$

From (3.8)–(3.10) and the definition of $x^n_{j-\frac{1}{2},r}$ and $x^n_{j+\frac{1}{2},l}$, we derive

$$\frac{d}{dt}\bar{u}_j(t) = \frac{a^+_{j-\frac{1}{2}}}{\Delta x} \lim_{\Delta t\to 0} \bar{w}^{n+1}_{j-\frac{1}{2}} + \lim_{\Delta t\to 0} \frac{1}{\Delta t}\left(\frac{x^n_{j+\frac{1}{2},l} - x^n_{j-\frac{1}{2},r}}{\Delta x}\bar{w}^{n+1}_j - \bar{u}^n_j \right) - \frac{a^-_{j+\frac{1}{2}}}{\Delta x} \lim_{\Delta t\to 0} \bar{w}^{n+1}_{j+\frac{1}{2}}. \tag{3.11}$$

The three limits in (3.11) are computed separately. Using (3.4) and (3.5), we obtain

$$\lim_{\Delta t\to 0} \frac{1}{\Delta t}\left(\frac{x^n_{j+\frac{1}{2},l} - x^n_{j-\frac{1}{2},r}}{\Delta x}\bar{w}^{n+1}_j - \bar{u}^n_j \right) = \frac{a^-_{j+\frac{1}{2}}u^-_{j+\frac{1}{2}} - a^+_{j-\frac{1}{2}}u^+_{j-\frac{1}{2}}}{\Delta x} - \frac{f(u^-_{j+\frac{1}{2}}) - f(u^+_{j-\frac{1}{2}})}{\Delta x}, \tag{3.12}$$

and

$$\lim_{\Delta t\to 0} \bar{w}^{n+1}_{j+\frac{1}{2}} = \frac{a^+_{j+\frac{1}{2}}u^+_{j+\frac{1}{2}} - a^-_{j+\frac{1}{2}}u^-_{j+\frac{1}{2}}}{a^+_{j+\frac{1}{2}} - a^-_{j+\frac{1}{2}}} - \frac{f(u^+_{j+\frac{1}{2}}) - f(u^-_{j+\frac{1}{2}})}{a^+_{j+\frac{1}{2}} - a^-_{j+\frac{1}{2}}}, \tag{3.13}$$

where, similarly to (3.1), $u^\pm_{j+\frac{1}{2}}$ stand for the corresponding right and left values of the piecewise polynomial interpolant $\{p_j\}$, reconstructed at time t.

Finally, a substitution of (3.12) and (3.13) in (3.11) results in our new semidiscrete central-upwind scheme, which can be written in the following conservative form:

$$\frac{d}{dt}\bar{u}_j(t) = -\frac{H_{j+\frac{1}{2}}(t) - H_{j-\frac{1}{2}}(t)}{\Delta x}. \tag{3.14}$$

Here, the numerical fluxes $H_{j+\frac{1}{2}}$ are given by

$$H_{j+\frac{1}{2}}(t) := \frac{a^+_{j+\frac{1}{2}}f(u^-_{j+\frac{1}{2}}) - a^-_{j+\frac{1}{2}}f(u^+_{j+\frac{1}{2}})}{a^+_{j+\frac{1}{2}} - a^-_{j+\frac{1}{2}}} + \frac{a^+_{j+\frac{1}{2}}a^-_{j+\frac{1}{2}}}{a^+_{j+\frac{1}{2}} - a^-_{j+\frac{1}{2}}}\left[u^+_{j+\frac{1}{2}} - u^-_{j+\frac{1}{2}}\right]. \tag{3.15}$$

Remarks.

1. The new semidiscrete scheme (3.14)–(3.15) is a Godunov-type central scheme, since it is based on integration over Riemann fans. It does not require characteristic decompositions and Riemann solvers, and therefore it preserves the main advantage of the central schemes—simplicity.
2. As with the semidiscrete schemes, proposed in [26], the numerical viscosity of (3.14)–(3.15) is independent of $\mathcal{O}(1/\Delta t)$, and thus it can be used for steady-state computations. Moreover, due to a more accurate estimate of the widths of the Riemann fans, the numerical dissipation in (3.14)–(3.15) is even smaller than the numerical viscosity of the schemes from [26, 24]. Notice that if

one takes $a^+_{j+\frac{1}{2}} = -a^-_{j+\frac{1}{2}} = a_{j+\frac{1}{2}} := \max_{\omega\in C(u^{n-}_{j+\frac{1}{2}}, u^{n+}_{j+\frac{1}{2}})} \rho(\frac{\partial f}{\partial u}(\omega))$, then the numerical flux (3.15) reduces to

$$H_{j+\frac{1}{2}}(t) := \frac{f(u^+_{j+\frac{1}{2}}) + f(u^-_{j+\frac{1}{2}})}{2} - \frac{a_{j+\frac{1}{2}}}{2}\left[u^+_{j+\frac{1}{2}} - u^-_{j+\frac{1}{2}}\right],$$

which is the numerical flux of the schemes from [26, 24].

3. We would like to point out that the first-order version of our scheme is exactly the semidiscrete version of the scheme in [17, 12]. Moreover, if the flux f is monotone, it reduces to the standard upwind scheme. That is why we call our new schemes *central-upwind*. For example, if $f'(u) \geq 0$, then $a^-_{j+\frac{1}{2}} = 0$ $\forall j$, and the first-order scheme simplifies to

$$\dot{u}_j(t) = -\frac{f(u^n_j) - f(u^n_{j-1})}{\Delta x}.$$

4. A fully discrete, 2-D, third-order accurate scheme using the Harten–Lax–van Leer approximate Riemann solver [17, 12] was implemented and tested in [41].
5. It can be proved that a scalar second-order version of (3.14)–(3.15), together with the minmod reconstruction,

$$\widetilde{u}^n_j(x) = \bar{u}^n_j + s^n_j(x - x_j),$$
$$s^n_j = \text{minmod}\left(\theta\frac{\bar{u}^n_j - \bar{u}^n_{j-1}}{\Delta x}, \frac{\bar{u}^n_{j+1} - \bar{u}^n_{j-1}}{2\Delta x}, \theta\frac{\bar{u}^n_{j+1} - \bar{u}^n_j}{\Delta x}\right), \tag{3.16}$$

is a TVD scheme (for $1 \leq \theta \leq 2$), that is, $\|u(\cdot,t)\|_{BV} \leq \|u(\cdot,0)\|_{BV}$. The proof is analogous to the proof of Theorem 4.1 in [26], and we leave the details to the reader.
6. The semidiscrete scheme (3.14)–(3.15) is a system of time-dependent ODEs, which can be solved by any stable ODE solver which retains the spatial accuracy of the semidiscrete scheme. In the numerical examples below, we have used the TVD Runge–Kutta method, proposed in [47, 45].
7. The scheme (3.14)–(3.15) can be easily generalized and applied to convection-diffusion equations in a straightforward manner. For details, we refer the reader to [26, 24].

3.2. Semidiscrete central-upwind schemes for multi-D conservation laws. The semidiscrete central-upwind schemes, presented in section 3.1, can be generalized to the multi-D case. Without loss of generality, we consider the 2-D system

$$u_t + f(u)_x + g(u)_y = 0. \tag{3.17}$$

Given the grid points $x_j := j\Delta x$, $y_k := k\Delta y$ and the intermediate points $x_{j\pm\frac{1}{2}} := x_j \pm \frac{\Delta x}{2}$, $y_{k\pm\frac{1}{2}} := y_k \pm \frac{\Delta y}{2}$, we start at time $t = t^n$ with a conservative piecewise polynomial reconstruction of an appropriate order:

$$\widetilde{u}^n(x,y) := \sum_{j,k} p^n_{j,k}(x,y)\chi_{j,k},$$

where $\chi_{j,k}$ is the characteristic function of the cell $[x_{j-\frac{1}{2}}, x_{j+\frac{1}{2}}] \times [y_{k-\frac{1}{2}}, y_{k+\frac{1}{2}}]$. In the numerical examples in this paper, we have used the third-order piecewise quadratic reconstruction, described in [25].

We use the notation

$$u_{j,k} := p^n_{j,k}(x_j, y_k), \quad u^{\mathrm{N}}_{j,k} := p^n_{j,k}(x_j, y_{k+\frac{1}{2}}), \quad u^{\mathrm{S}}_{j,k} := p^n_{j,k}(x_j, y_{k-\frac{1}{2}}),$$

$$u^{\mathrm{E}}_{j,k} := p^n_{j,k}(x_{j+\frac{1}{2}}, y_k), \quad u^{\mathrm{W}}_{j,k} := p^n_{j,k}(x_{j-\frac{1}{2}}, y_k), \quad u^{\mathrm{NE}}_{j,k} := p^n_{j,k}(x_{j+\frac{1}{2}}, y_{k+\frac{1}{2}}), \tag{3.18}$$

$$u^{\mathrm{NW}}_{j,k} := p^n_{j,k}(x_{j-\frac{1}{2}}, y_{k+\frac{1}{2}}), \quad u^{\mathrm{SE}}_{j,k} := p^n_{j,k}(x_{j+\frac{1}{2}}, y_{k-\frac{1}{2}}), \quad u^{\mathrm{SW}}_{j,k} := p^n_{j,k}(x_{j-\frac{1}{2}}, y_{k-\frac{1}{2}})$$

for the corresponding point values and

$$\bar{u}_{j,k} := \frac{1}{\Delta x \Delta y} \int_{x_{j-\frac{1}{2}}}^{x_{j+\frac{1}{2}}} \int_{y_{k-\frac{1}{2}}}^{y_{k+\frac{1}{2}}} p^n_{j,k}(x,y)\, dx\, dy$$

for the cell averages.

The piecewise polynomial interpolant $\widetilde{u}^n$ may have discontinuities along the lines $x = x_{j\pm\frac{1}{2}}$ and $y = y_{k\pm\frac{1}{2}}$, which propagate with different right- and left-sided local speeds. To estimate them is a nontrivial problem, but in practice one may use

$$\begin{aligned}
a^+_{j+\frac{1}{2},k} &:= \max\left\{\lambda_N\Big(\frac{\partial f}{\partial u}(u^{\mathrm{W}}_{j+1,k})\Big), \lambda_N\Big(\frac{\partial f}{\partial u}(u^{\mathrm{E}}_{j,k})\Big), 0\right\}, \\
b^+_{j,k+\frac{1}{2}} &:= \max\left\{\lambda_N\Big(\frac{\partial g}{\partial u}(u^{\mathrm{S}}_{j,k+1})\Big), \lambda_N\Big(\frac{\partial g}{\partial u}(u^{\mathrm{N}}_{j,k})\Big), 0\right\}, \\
a^-_{j+\frac{1}{2},k} &:= \min\left\{\lambda_1\Big(\frac{\partial f}{\partial u}(u^{\mathrm{W}}_{j+1,k})\Big), \lambda_1\Big(\frac{\partial f}{\partial u}(u^{\mathrm{E}}_{j,k})\Big), 0\right\}, \\
b^-_{j,k+\frac{1}{2}} &:= \min\left\{\lambda_1\Big(\frac{\partial g}{\partial u}(u^{\mathrm{S}}_{j,k+1})\Big), \lambda_1\Big(\frac{\partial g}{\partial u}(u^{\mathrm{N}}_{j,k})\Big), 0\right\},
\end{aligned} \tag{3.19}$$

respectively. As in [25], we consider the nonuniform domains, outlined in Figure 3.2 and defined by

$$D_{j,k+\frac{1}{2}} := [x_{j-\frac{1}{2}} + A^+_{j-\frac{1}{2},k+\frac{1}{2}}\Delta t,\ x_{j+\frac{1}{2}} + A^-_{j+\frac{1}{2},k+\frac{1}{2}}\Delta t] \times [y_{k+\frac{1}{2}} + b^-_{j,k+\frac{1}{2}}\Delta t,\ y_{k+\frac{1}{2}} + b^+_{j,k+\frac{1}{2}}\Delta t],$$

$$D_{j+\frac{1}{2},k} := [x_{j+\frac{1}{2}} + a^-_{j+\frac{1}{2},k}\Delta t,\ x_{j+\frac{1}{2}} + a^+_{j+\frac{1}{2},k}\Delta t] \times [y_{k-\frac{1}{2}} + B^+_{j+\frac{1}{2},k-\frac{1}{2}}\Delta t,\ y_{k+\frac{1}{2}} + B^-_{j+\frac{1}{2},k+\frac{1}{2}}\Delta t],$$

$$\begin{aligned}
D_{j+\frac{1}{2},k+\frac{1}{2}} := {}& [x_{j+\frac{1}{2}} + A^-_{j+\frac{1}{2},k+\frac{1}{2}}\Delta t,\ x_{j+\frac{1}{2}} + A^+_{j+\frac{1}{2},k+\frac{1}{2}}\Delta t] \\
& \times [y_{k+\frac{1}{2}} + B^-_{j+\frac{1}{2},k+\frac{1}{2}}\Delta t,\ y_{k+\frac{1}{2}} + B^+_{j+\frac{1}{2},k+\frac{1}{2}}\Delta t],
\end{aligned}$$

$$D_{j,k} := [x_{j-\frac{1}{2}},\ x_{j+\frac{1}{2}}] \times [y_{k-\frac{1}{2}},\ y_{k+\frac{1}{2}}] \ \Big\backslash \ \bigcup_{\pm} [D_{j,k\pm\frac{1}{2}} \cup D_{j\pm\frac{1}{2},k} \cup D_{j\pm\frac{1}{2},k\pm\frac{1}{2}}],$$

where

$$A^+_{j+\frac{1}{2},k+\frac{1}{2}} := \max\left\{a^+_{j+\frac{1}{2},k}, a^+_{j+\frac{1}{2},k+1}\right\}, \qquad B^+_{j+\frac{1}{2},k+\frac{1}{2}} := \max\left\{b^+_{j,k+\frac{1}{2}}, b^+_{j+1,k+\frac{1}{2}}\right\},$$

$$A^-_{j+\frac{1}{2},k+\frac{1}{2}} := \min\left\{a^-_{j+\frac{1}{2},k}, a^-_{j+\frac{1}{2},k+1}\right\}, \qquad B^-_{j+\frac{1}{2},k+\frac{1}{2}} := \min\left\{b^-_{j,k+\frac{1}{2}}, b^-_{j+1,k+\frac{1}{2}}\right\}.$$

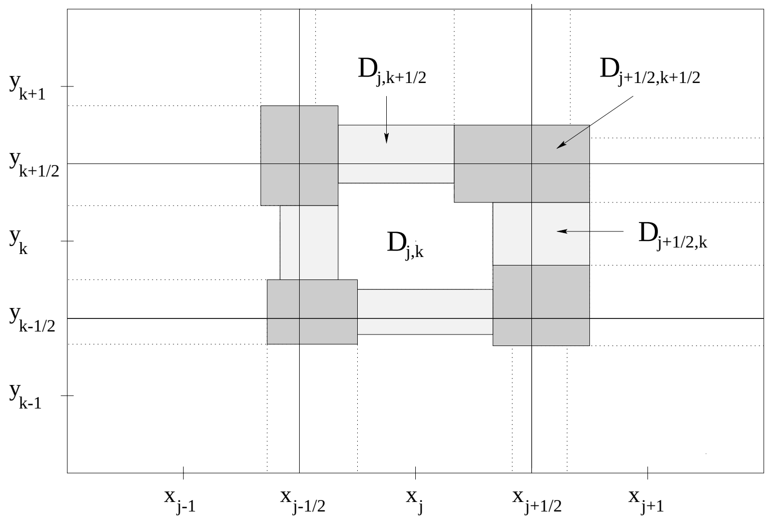

FIG. 3.2. *2-D central-upwind differencing.*

Similarly to the 1-D case, under an appropriate CFL condition, the solution of system (3.17) with initial data $\widetilde{u}(x,y)$ is smooth in the domain $D_{j,k}$ and may be nonsmooth in the other domains. Notice that, in general, $D_{j,k}$ is a nonrectangular domain inside the (j,k)-cell; see Figure 3.2.

An integration of the system (3.17) over the domains

$$D_{j,k} \times [t^n, t^{n+1}], \quad D_{j\pm\frac{1}{2},k} \times [t^n, t^{n+1}], \quad D_{j,k\pm\frac{1}{2}} \times [t^n, t^{n+1}], \quad D_{j\pm\frac{1}{2},k\pm\frac{1}{2}} \times [t^n, t^{n+1}]$$

results in new cell averages $\{\bar{w}^{n+1}_{j,k+\frac{1}{2}}\}$, $\{\bar{w}^{n+1}_{j+\frac{1}{2},k}\}$, $\{\bar{w}^{n+1}_{j+\frac{1}{2},k+\frac{1}{2}}\}$, and $\{\bar{w}^{n+1}_{j,k}\}$. They are used for an intermediate piecewise polynomial reconstruction,

$$\widetilde{w}^{n+1}(x,y) := \sum_{j,k} \left[\widetilde{w}^{n+1}_{j,k}\widetilde{\chi}_{j,k} + \widetilde{w}^{n+1}_{j+\frac{1}{2},k}\widetilde{\chi}_{j+\frac{1}{2},k} + \widetilde{w}^{n+1}_{j,k+\frac{1}{2}}\widetilde{\chi}_{j,k+\frac{1}{2}} + \widetilde{w}^{n+1}_{j+\frac{1}{2},k+\frac{1}{2}}\widetilde{\chi}_{j+\frac{1}{2},k+\frac{1}{2}} \right]. \tag{3.20}$$

Here, similarly to (3.6), $\{\widetilde{w}^{n+1}_{j,k}(x,y), \widetilde{w}^{n+1}_{j+\frac{1}{2},k}(x,y), \widetilde{w}^{n+1}_{j,k+\frac{1}{2}}(x,y), \widetilde{w}^{n+1}_{j+\frac{1}{2},k+\frac{1}{2}}(x,y)\}$ are the quadratic pieces, and the $\widetilde{\chi}$'s stand for the characteristic functions of the corresponding domains D.

The construction of our 2-D fully discrete central-upwind scheme is then completed by projecting the interpolant (3.20) back onto the original cells,

$$\bar{u}^{n+1}_{j,k} = \frac{1}{\Delta x \Delta y} \int_{x_{j-\frac{1}{2}}}^{x_{j+\frac{1}{2}}} \int_{y_{k-\frac{1}{2}}}^{y_{k+\frac{1}{2}}} \widetilde{w}^{n+1}(x,y)\,dxdy. \tag{3.21}$$

The derivation of the explicit form of the fully discrete higher-order scheme is omitted, since it is rather complicated and is of no practical use. Note, however, that Wendroff [50] has recently proposed a 2-D version of the Harten–Lax–van Leer Riemann solver, which is closely related to the first-order fully discrete version of our scheme.

As in [25, section 3.3], we continue within the semidiscrete framework (as $\Delta t \to 0$), where all the computations are much simpler.

We use the following notation for the intersections of the cell $[x_{j-\frac{1}{2}}, x_{j+\frac{1}{2}}] \times [y_{k-\frac{1}{2}}, y_{k+\frac{1}{2}}]$ with the domains D – $C_{j\pm\frac{1}{2},k\pm\frac{1}{2}}$ for the four corners, $S_{j\pm\frac{1}{2},k}$, $S_{j,k\pm\frac{1}{2}}$ for the four side domains, and $D_{j,k}$ for the center. The sizes of these domains are $|C| \sim (\Delta t)^2$ and $|S| \sim \Delta t$. Since we assume that the spatial derivatives of $\widetilde{w}^{n+1}$ are bounded independently of Δt, the relation between $\widetilde{w}^{n+1}$ and $\bar{w}^{n+1}$ is given by

$$\int\!\!\int_{C_{j\pm\frac{1}{2},k\pm\frac{1}{2}}} \widetilde{w}^{n+1}_{j\pm\frac{1}{2},k\pm\frac{1}{2}}\, dxdy = \mathcal{O}((\Delta t)^2), \tag{3.22}$$

$$\int\!\!\int_{S_{j\pm\frac{1}{2},k}} \widetilde{w}^{n+1}_{j\pm\frac{1}{2},k}\, dxdy = |S_{j\pm\frac{1}{2},k}|\, \bar{w}^{n+1}_{j\pm\frac{1}{2},k} + \mathcal{O}(\Delta t^2), \tag{3.23}$$

$$\int\!\!\int_{S_{j,k\pm\frac{1}{2}}} \widetilde{w}^{n+1}_{j,k\pm\frac{1}{2}}\, dxdy = |S_{j,k\pm\frac{1}{2}}|\, \bar{w}^{n+1}_{j,k\pm\frac{1}{2}} + \mathcal{O}(\Delta t^2). \tag{3.24}$$

Also, the conservation property of the reconstruction $\widetilde{w}^{n+1}$ yields

$$\int\!\!\int_{D_{j,k}} \widetilde{w}^{n+1}_{j,k}(x,y)\, dxdy = |D_{j,k}|\bar{w}^{n+1}_{j,k}. \tag{3.25}$$

We now use (3.21) together with (3.22)–(3.25) and obtain

$$\begin{aligned}
\frac{d}{dt}\bar{u}_{j,k}(t) &= \lim_{\Delta t\to 0} \frac{\bar{u}^{n+1}_{j,k} - \bar{u}^{n}_{j,k}}{\Delta t} \\
&= \lim_{\Delta t\to 0} \left(\sum_{\pm} \frac{|S_{j,k\pm\frac{1}{2}}|}{\Delta t\Delta x\Delta y} \bar{w}^{n+1}_{j,k\pm\frac{1}{2}} + \sum_{\pm} \frac{|S_{j\pm\frac{1}{2},k}|}{\Delta t\Delta x\Delta y} \bar{w}^{n+1}_{j\pm\frac{1}{2},k} \right) \\
&\quad + \lim_{\Delta t\to 0} \frac{1}{\Delta t} \left[\frac{|D_{j,k}|}{\Delta x\Delta y} \bar{w}^{n+1}_{j,k} - \bar{u}^{n}_{j,k} \right].
\end{aligned} \tag{3.26}$$

For the first sum on the right-hand side (RHS), we apply Simpson's quadrature formula to the integrals over $D_{j,k\pm\frac{1}{2}}$ in the computation of $\bar{w}^{n+1}_{j,k\pm\frac{1}{2}}$. Since $|S_{j,k\pm\frac{1}{2}}| = \mp b^{\mp}_{j,k\pm\frac{1}{2}}\Delta t\Delta x + \mathcal{O}((\Delta t)^2)$, we arrive at (consult [25] for details)

$$\begin{aligned}
\lim_{\Delta t\to 0} \frac{|S_{j,k\pm\frac{1}{2}}|}{\Delta t\Delta x\Delta y} \bar{w}^{n+1}_{j,k\pm\frac{1}{2}} \approx &-\frac{b^{+}_{j,k\pm\frac{1}{2}} b^{-}_{j,k\pm\frac{1}{2}}}{6\Big(b^{+}_{j,k\pm\frac{1}{2}} - b^{-}_{j,k\pm\frac{1}{2}}\Big)\Delta y} \left[u^{\mathrm{SW(NW)}}_{j,k\pm 1} + 4u^{\mathrm{S(N)}}_{j,k\pm 1} + u^{\mathrm{SE(NE)}}_{j,k\pm 1} \right] \\
&+ \frac{\Big(b^{\mp}_{j,k\pm\frac{1}{2}}\Big)^2}{6\Big(b^{+}_{j,k\pm\frac{1}{2}} - b^{-}_{j,k\pm\frac{1}{2}}\Big)\Delta y} \left[u^{\mathrm{NW(SW)}}_{j,k} + 4u^{\mathrm{N(S)}}_{j,k} + u^{\mathrm{NE(SE)}}_{j,k} \right] \\
&+ \frac{b^{\mp}_{j,k\pm\frac{1}{2}}}{6\Big(b^{+}_{j,k\pm\frac{1}{2}} - b^{-}_{j,k\pm\frac{1}{2}}\Big)\Delta y} \Bigg[g(u^{\mathrm{SW(NW)}}_{j,k\pm 1}) - g(u^{\mathrm{NW(SW)}}_{j,k}) \\
&+ 4\Big(g(u^{\mathrm{S(N)}}_{j,k\pm 1}) - g(u^{\mathrm{N(S)}}_{j,k}) \Big) + g(u^{\mathrm{SE(NE)}}_{j,k\pm 1}) - g(u^{\mathrm{NE(SE)}}_{j,k}) \Bigg].
\end{aligned} \tag{3.27}$$

The second sum on the RHS of (3.26) is treated similarly, and we obtain

$$\begin{aligned}\lim_{\Delta t\to 0}\frac{|S_{j\pm\frac{1}{2},k}|}{\Delta t\Delta x\Delta y}\bar{w}^{n+1}_{j\pm\frac{1}{2},k} \approx & -\frac{a^+_{j\pm\frac{1}{2},k}a^-_{j\pm\frac{1}{2},k}}{6\Big(a^+_{j\pm\frac{1}{2},k}-a^-_{j\pm\frac{1}{2},k}\Big)\Delta x}\left[u^{\mathrm{NW(NE)}}_{j\pm1,k}+4u^{\mathrm{W(E)}}_{j\pm1,k}+u^{\mathrm{SW(SE)}}_{j\pm1,k}\right]\\ & +\frac{\Big(a^{\mp}_{j\pm\frac{1}{2},k}\Big)^2}{6\Big(a^+_{j\pm\frac{1}{2},k}-a^-_{j\pm\frac{1}{2},k}\Big)\Delta x}\left[u^{\mathrm{NE(NW)}}_{j,k}+4u^{\mathrm{E(W)}}_{j,k}+u^{\mathrm{SE(SW)}}_{j,k}\right]\\ & +\frac{a^{\mp}_{j\pm\frac{1}{2},k}}{6\Big(a^+_{j\pm\frac{1}{2},k}-a^-_{j\pm\frac{1}{2},k}\Big)\Delta x}\Bigg[f(u^{\mathrm{NW(NE)}}_{j\pm1,k})-f(u^{\mathrm{NE(NW)}}_{j,k})\\ & +4\Big(f(u^{\mathrm{W(E)}}_{j\pm1,k})-f(u^{\mathrm{E(W)}}_{j,k})\Big)f(u^{\mathrm{SW(SE)}}_{j\pm1,k})-f(u^{\mathrm{SE(SW)}}_{j,k})\Bigg].\end{aligned} \tag{3.28}$$

Finally, we consider the last term on the RHS of (3.26). Since the domain $D_{j,k}$ becomes *rectangular* as $\Delta t\to 0$, up to small corners of a negligible size $\mathcal{O}((\Delta t)^2)$, the integration of (3.17) over $D_{j,k}\times[t^n,t^n+\Delta t]$ and the application of Simpson's rule result in

$$\begin{aligned}&\lim_{\Delta t\to 0}\frac{1}{\Delta t}\left[\frac{|D_{j,k}|}{\Delta x\Delta y}\bar{w}^{n+1}_{j,k}-\bar{u}^n_{j,k}\right]\\ &\approx\frac{a^-_{j+\frac{1}{2},k}}{6\Delta x}\left[u^{\mathrm{NE}}_{j,k}+4u^{\mathrm{E}}_{j,k}+u^{\mathrm{SE}}_{j,k}\right]-\frac{a^+_{j-\frac{1}{2},k}}{6\Delta x}\left[u^{\mathrm{NW}}_{j,k}+4u^{\mathrm{W}}_{j,k}+u^{\mathrm{SW}}_{j,k}\right]\\ &+\frac{b^-_{j,k+\frac{1}{2}}}{6\Delta y}\left[u^{\mathrm{NW}}_{j,k}+4u^{\mathrm{N}}_{j,k}+u^{\mathrm{NE}}_{j,k}\right]-\frac{b^+_{j,k-\frac{1}{2}}}{6\Delta y}\left[u^{\mathrm{SW}}_{j,k}+4u^{\mathrm{S}}_{j,k}+u^{\mathrm{SE}}_{j,k}\right]\\ &-\frac{1}{6\Delta x}\left[f(u^{\mathrm{NE}}_{j,k})-f(u^{\mathrm{NW}}_{j,k})+4\Big(f(u^{\mathrm{E}}_{j,k})-f(u^{\mathrm{W}}_{j,k})\Big)+f(u^{\mathrm{SE}}_{j,k})-f(u^{\mathrm{SW}}_{j,k})\right]\\ &-\frac{1}{6\Delta y}\left[g(u^{\mathrm{NW}}_{j,k})-g(u^{\mathrm{SW}}_{j,k})+4\Big(g(u^{\mathrm{N}}_{j,k})-g(u^{\mathrm{S}}_{j,k})\Big)+g(u^{\mathrm{NE}}_{j,k})-g(u^{\mathrm{SE}}_{j,k})\right].\end{aligned} \tag{3.29}$$

Our 2-D semidiscrete central-upwind scheme is obtained by plugging (3.27)–(3.29) into (3.26). It can be written in the following conservative form:

$$\frac{d}{dt}\bar{u}_{j,k}(t)=-\frac{H^x_{j+\frac{1}{2},k}(t)-H^x_{j-\frac{1}{2},k}(t)}{\Delta x}-\frac{H^y_{j,k+\frac{1}{2}}(t)-H^y_{j,k-\frac{1}{2}}(t)}{\Delta y}, \tag{3.30}$$

where the numerical fluxes are

$$\begin{aligned}H^x_{j+\frac{1}{2},k}:=&\frac{a^+_{j+\frac{1}{2},k}}{6\Big(a^+_{j+\frac{1}{2},k}-a^-_{j+\frac{1}{2},k}\Big)}\left[f(u^{\mathrm{NE}}_{j,k})+4f(u^{\mathrm{E}}_{j,k})+f(u^{\mathrm{SE}}_{j,k})\right]\\ &-\frac{a^-_{j+\frac{1}{2},k}}{6\Big(a^+_{j+\frac{1}{2},k}-a^-_{j+\frac{1}{2},k}\Big)}\left[f(u^{\mathrm{NW}}_{j+1,k})+4f(u^{\mathrm{W}}_{j+1,k})+f(u^{\mathrm{SW}}_{j+1,k})\right]\\ &+\frac{a^+_{j+\frac{1}{2},k}a^-_{j+\frac{1}{2},k}}{6\Big(a^+_{j+\frac{1}{2},k}-a^-_{j+\frac{1}{2},k}\Big)}\left[u^{\mathrm{NW}}_{j+1,k}-u^{\mathrm{NE}}_{j,k}+4(u^{\mathrm{W}}_{j+1,k}-u^{\mathrm{E}}_{j,k})+u^{\mathrm{SW}}_{j+1,k}-u^{\mathrm{SE}}_{j,k}\right]\end{aligned} \tag{3.31}$$

and

$$\begin{aligned}H^y_{j,k+\frac{1}{2}} &:= \frac{b^+_{j,k+\frac{1}{2}}}{6\Big(b^+_{j,k+\frac{1}{2}}-b^-_{j,k+\frac{1}{2}}\Big)}\Big[g(u^{\rm NW}_{j,k})+4g(u^{\rm N}_{j,k})+g(u^{\rm NE}_{j,k})\Big]\\ &\quad-\frac{b^-_{j,k+\frac{1}{2}}}{6\Big(b^+_{j,k+\frac{1}{2}}-b^-_{j,k+\frac{1}{2}}\Big)}\Big[g(u^{\rm SW}_{j,k+1})+4g(u^{\rm S}_{j,k+1})+g(u^{\rm SE}_{j,k+1})\Big]\\ &\quad+\frac{b^+_{j,k+\frac{1}{2}}b^-_{j,k+\frac{1}{2}}}{6\Big(b^+_{j,k+\frac{1}{2}}-b^-_{j,k+\frac{1}{2}}\Big)}\Big[u^{\rm SW}_{j,k+1}-u^{\rm NW}_{j,k}+4(u^{\rm S}_{j,k+1}-u^{\rm N}_{j,k})+u^{\rm SE}_{j,k+1}-u^{\rm NE}_{j,k}\Big].\end{aligned} \tag{3.32}$$

Here, the one-sided local speeds $a^\pm_{j+\frac{1}{2},k}, b^\pm_{j,k+\frac{1}{2}}$ are defined in (3.19), and the values of the u's are computed in (3.18), using the piecewise quadratic reconstruction $\{p_{j,k}\}$ at time t. In our numerical examples, we have implemented the reconstruction introduced in [25].

Remarks.

1. Our 2-D semidiscrete central-upwind scheme (3.30)–(3.32) is a Godunov-type *central* scheme; therefore it can be applied *componentwise* and does not require Riemann solvers. As in [25], this scheme is constructed as a genuinely multi-D scheme. Moreover, if one sets

$$\begin{aligned}a^+_{j+\frac{1}{2},k} &:= -a^-_{j+\frac{1}{2},k} := \max\Big\{a^+_{j+\frac{1}{2},k}, -a^-_{j+\frac{1}{2},k}\Big\},\\ b^+_{j,k+\frac{1}{2}} &:= -b^-_{j,k+\frac{1}{2}} := \max\Big\{b^+_{j,k+\frac{1}{2}}, -b^-_{j,k+\frac{1}{2}}\Big\},\end{aligned}$$

the scheme (3.30)–(3.32) reduces to the one in [25].

2. As in the 1-D case, our 2-D scheme (3.30)–(3.32) has an upwind nature. To illustrate this, let us consider the simplest linear scalar advection equation, $u_t + au_x + bu_y = 0$, with positive a and b. In this setting, the first-order version of the scheme (3.30)–(3.32) becomes a standard first-order upwind scheme

$$\frac{d}{dt}u_{j,k}(t) = -a\frac{u_{j,k}-u_{j-1,k}}{\Delta x} - b\frac{u_{j,k}-u_{j,k-1}}{\Delta y}.$$

3. A second-order version of the 2-D scheme (3.30)–(3.32) can be obtained if one uses a second-order piecewise polynomial reconstruction (say, the minmod reconstruction) and a lower-order midpoint quadrature instead of the fourth-order Simpson's rule. This results in the scheme

$$\frac{d}{dt}u_{j,k}(t) = -\frac{H^x_{j+\frac{1}{2},k}(t)-H^x_{j-\frac{1}{2},k}(t)}{\Delta x} - \frac{H^y_{j,k+\frac{1}{2}}(t)-H^y_{j,k-\frac{1}{2}}(t)}{\Delta y}, \tag{3.33}$$

with the corresponding numerical fluxes

$$H^x_{j+\frac{1}{2},k} := \frac{a^+_{j+\frac{1}{2},k}f(u^{\rm E}_{j,k})-a^-_{j+\frac{1}{2},k}f(u^{\rm W}_{j+1,k})}{a^+_{j+\frac{1}{2},k}-a^-_{j+\frac{1}{2},k}} + \frac{a^+_{j+\frac{1}{2},k}a^-_{j+\frac{1}{2},k}}{a^+_{j+\frac{1}{2},k}-a^-_{j+\frac{1}{2},k}}\Big[u^{\rm W}_{j+1,k}-u^{\rm E}_{j,k}\Big] \tag{3.34}$$

and

$$H^y_{j,k+\frac{1}{2}} := \frac{b^+_{j,k+\frac{1}{2}} g(u^{\rm N}_{j,k}) - b^-_{j,k+\frac{1}{2}} g(u^{\rm S}_{j,k+1})}{b^+_{j,k+\frac{1}{2}} - b^-_{j,k+\frac{1}{2}}} + \frac{b^+_{j,k+\frac{1}{2}} b^-_{j,k+\frac{1}{2}}}{b^+_{j,k+\frac{1}{2}} - b^-_{j,k+\frac{1}{2}}} \Big[u^{\rm S}_{j,k+1} - u^{\rm N}_{j,k}\Big]. \tag{3.35}$$

The same scheme can also be derived by applying the 1-D numerical flux (3.15) in both x- and y-directions (this is the so-called dimension-by-dimension approach, used in [26]).

4. The scheme (3.30)–(3.32) can be generalized and applied to convection-diffusion equations (for details see [26, 25, 24]). Also, it can be rather easily extended to the multi-D case, $d \geq 3$.

3.2.1. Maximum principle for the second-order central-upwind scheme. We consider the 2-D second-order central-upwind scheme (3.33)–(3.35), together with the minmod reconstruction (3.16). We solve the time-dependent ODE system (3.33), using a TVD Runge–Kutta method. Under an appropriate CFL condition, the resulting fully discrete scheme, applied to a scalar conservation law, satisfies the maximum principle; see the following theorem.

THEOREM 3.1 (maximum principle). *Consider the scalar conservation laws* (3.17)*. Then the second-order scheme* (3.33)*–*(3.35)*, with the minmod reconstruction* (3.16)*, coupled with a TVD Runge–Kutta method* [47, 45] *satisfies the maximum principle*

$$\min_{j,k}\{u^n_{j,k}\} \leq \min_{j,k}\{u^{n+1}_{j,k}\} \leq \max_{j,k}\{u^{n+1}_{j,k}\} \leq \max_{j,k}\{u^n_{j,k}\} \tag{3.36}$$

under the CFL condition

$$\max\left(\frac{\Delta t^n}{\Delta x} \max_u |f'(u)|, \frac{\Delta t^n}{\Delta y} \max_u |g'(u)|\right) \leq \frac{1}{8}, \tag{3.37}$$

where Δt^n is the variable time step of the Runge–Kutta method.

We omit the proof since it is similar to the proof of Theorem 5.1 in [26].

3.3. Semidiscrete central-upwind scheme for Hamilton–Jacobi equations. In this section, we propose a new Godunov-type central-upwind scheme for the 1-D and 2-D Hamilton–Jacobi equations (1.2). We follow the approach in [27], but this time we utilize more precise information about the *one-sided* local speeds of propagation.

We begin with the 1-D case and start at time level $t = t^n$ with the continuous piecewise polynomial interpolant $\widetilde{\varphi}(x, t^n)$ and estimate the maximal one-sided local speeds, a^+_j and a^-_j. For example, in the convex case, they are equal to

$$a^+_j := \max\{H'(\varphi^+_x), H'(\varphi^-_x), 0\}, \qquad a^-_j := \min\{H'(\varphi^+_x), H'(\varphi^-_x), 0\}, \tag{3.38}$$

where we use the notation $\varphi^\pm_x := \widetilde{\varphi}_x(x_j \pm 0, t^n)$. To construct the second-order scheme one should use the continuous piecewise quadratic polynomial (2.5), and in this case,

$$\varphi^\pm_x = \frac{(\Delta\varphi)^n_{j\pm\frac{1}{2}}}{\Delta x} \mp \frac{(\Delta\varphi)'_{j\pm\frac{1}{2}}}{2\Delta x}. \tag{3.39}$$

Note that under an appropriate CFL-condition, the solution of the Hamilton–Jacobi equation (1.2) with the piecewise polynomial initial data $\widetilde{\varphi}(x, t^n)$ is smooth

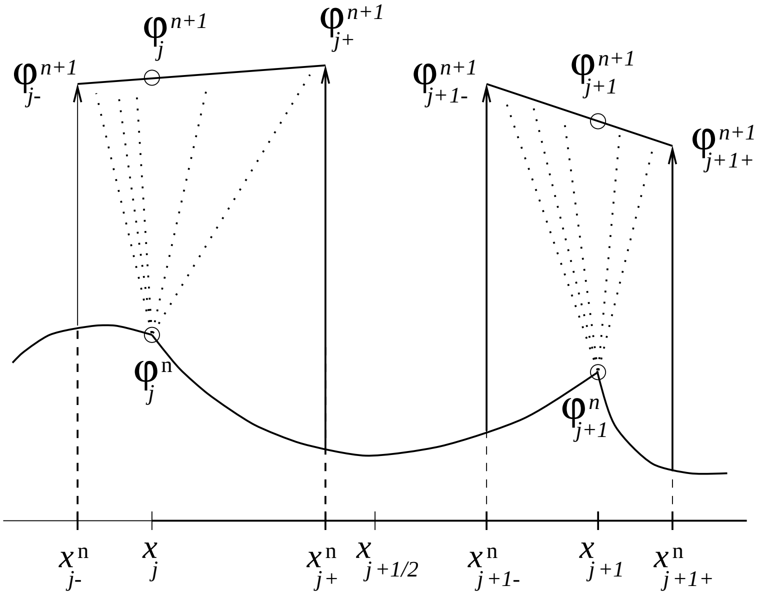

FIG. 3.3. *Central-upwind differencing*—1-D.

along the line segments $(x^n_{j\pm}, t)$, $t^n \le t < t^{n+1}$, $x^n_{j\pm} := x_j + a^{\pm}_j \Delta t$; see Figure 3.3. Therefore, one can use the Taylor expansion to compute the intermediate point values at the next time level:

$$\varphi^{n+1}_{j\pm} = \widetilde{\varphi}(x_{j\pm}, t^n) - \Delta t \cdot H(\widetilde{\varphi}_x(x^n_{j\pm}, t^n)) + \mathcal{O}(\Delta t)^2. \tag{3.40}$$

We complete the construction of our fully discrete central-upwind scheme by projecting the intermediate point values back onto the original grid. Since the distance between x^n_{j+} and x^n_{j-} is proportional to Δt, it suffices to compute the weighted averages of φ^{n+1}_{j+} and φ^{n+1}_{j-}, that is,

$$\varphi^{n+1}_j = \frac{a^+_j}{a^+_j - a^-_j} \varphi^{n+1}_{j-} - \frac{a^-_j}{a^+_j - a^-_j} \varphi^{n+1}_{j+} + \mathcal{O}(\Delta t)^2. \tag{3.41}$$

Finally, we substitute (3.40) in (3.41), and arrive at the fully discrete scheme

$$\begin{aligned} \varphi^{n+1}_j = {} & \frac{a^+_j}{a^+_j - a^-_j} \Big(\widetilde{\varphi}(x_{j-}, t^n) - \Delta t H(\widetilde{\varphi}_x(x^n_{j-}, t^n)) \Big) \\ & - \frac{a^-_j}{a^+_j - a^-_j} \Big(\widetilde{\varphi}(x_{j+}, t^n) - \Delta t H(\widetilde{\varphi}_x(x^n_{j+}, t^n)) \Big), \end{aligned} \tag{3.42}$$

which is high-order in space (depending on the order of the piecewise polynomial reconstruction) and only first-order in time.

A semidiscrete version of the scheme (3.42), coupled with a high-order ODE solver, will allow us to achieve high accuracy both in space and time. To derive such a scheme, we first use the Taylor expansions, $\widetilde{\varphi}(x_{j\pm}, t^n) = \widetilde{\varphi}(x_j, t^n) + \Delta t a_j^{\pm}\widetilde{\varphi}_x(x_j \pm 0, t^n) + \mathcal{O}(\Delta t)^2$, and rewrite the fully discrete scheme (3.42) as

$$\varphi_j^{n+1} = \varphi_j^n - \Delta t \frac{a_j^+ a_j^-}{a_j^+ - a_j^-}\Big[\widetilde{\varphi}_x(x_j + 0, t^n) - \widetilde{\varphi}_x(x_j - 0, t^n)\Big] + \frac{\Delta t}{a_j^+ - a_j^-}\Big[a_j^- H(\widetilde{\varphi}_x(x_{j+}^n, t^n)) - a_j^+ H(\widetilde{\varphi}_x(x_{j-}^n, t^n))\Big] + \mathcal{O}(\Delta t)^2. \tag{3.43}$$

We now let $\Delta t \to 0$, and end up with the following semidiscrete central-upwind scheme:

$$\frac{d}{dt}\varphi_j(t) = \frac{1}{a_j^+ - a_j^-}\Big[a_j^- H(\varphi_x^+) - a_j^+ H(\varphi_x^-)\Big] - \frac{a_j^+ a_j^-}{a_j^+ - a_j^-}\Big(\varphi_x^+ - \varphi_x^-\Big). \tag{3.44}$$

Here, $a_j^{\pm}$ are given by (3.38), and $\varphi_x^{\pm}$ are the right and the left derivatives at the point $x = x_j$ of the reconstruction $\widetilde{\varphi}(\cdot, t)$ at time t.

We continue with the construction of a multi-D extension of the scheme (3.44). Without loss of generality, we consider the 2-D Hamilton–Jacobi equation,

$$\varphi_t + H(\varphi_x, \varphi_y) = 0. \tag{3.45}$$

Assume that at time $t = t^n$ the discrete approximation to the point values of its solution, $\{\varphi_{j,k}^n \approx \varphi(x_j, y_k, t^n)\}$, has already been computed. We then construct the 2-D continuous piecewise polynomial interpolant $\widetilde{\varphi}(x, y, t^n)$. Such a reconstruction is defined over the four triangles (NW, NE, SW, and SE) around each grid-point (x_j, y_k) (see Figure 3.4). We refer the reader to [27] for an example of a nonoscillatory second-order piecewise quadratic interpolant.

We now continue with the construction of our semidiscrete central-upwind scheme. As in the 1-D case, we use the maximal values of the one-sided local speeds of propagation in the x- and y-directions. These values at the grid-point (x_j, y_k) are given by

$$\begin{aligned} a_{j,k}^+ &:= \max_{C_{j,k}}\Big\{H_u(\widetilde{\varphi}_x(x,y), \widetilde{\varphi}_y(x,y))\Big\}_+, \quad & a_{j,k}^- &:= \min_{C_{j,k}}\Big\{H_u(\widetilde{\varphi}_x(x,y), \widetilde{\varphi}_y(x,y))\Big\}_-, \\ b_{j,k}^+ &:= \max_{C_{j,k}}\Big\{H_v(\widetilde{\varphi}_x(x,y), \widetilde{\varphi}_y(x,y))\Big\}_+, \quad & b_{j,k}^- &:= \min_{C_{j,k}}\Big\{H_v(\widetilde{\varphi}_x(x,y), \widetilde{\varphi}_y(x,y))\Big\}_-, \end{aligned} \tag{3.46}$$

where $C_{j,k} := [x_{j-\frac{1}{2}}, x_{j+\frac{1}{2}}] \times [y_{k-\frac{1}{2}}, y_{k+\frac{1}{2}}]$ and $(\,\cdot\,)_+ := \max(\cdot, 0)$, $(\,\cdot\,)_- := \min(\cdot, 0)$.

To compute the solution at the next time level $t = t^{n+1}$, we use the intermediate values $\{\varphi_{j\pm,k\pm}^{n+1}\}$, obtained by the Taylor expansion about the points $(x_{j\pm}^n := x_j + a_{j,k}^{\pm}\Delta t,\ y_{k\pm}^n := y_k + b_{j,k}^{\pm}\Delta t)$,

$$\varphi_{j\pm,k\pm}^{n+1} = \widetilde{\varphi}(x_{j\pm}^n, y_{k\pm}^n, t^n) - \Delta t \cdot H(\widetilde{\varphi}_x(x_{j\pm}^n, y_{k\pm}^n, t^n), \widetilde{\varphi}_y(x_{j\pm}^n, y_{k\pm}^n, t^n)) + \mathcal{O}(\Delta t)^2. \tag{3.47}$$

Expansion (3.47) is valid, since due to the finite speed of propagation, the solution of (3.45) with the initial data $\widetilde{\varphi}(x, y, t^n)$ is smooth around $(x_{j\pm}^n, y_{k\pm}^n)$; see Figure 3.4.

Next, the computed intermediate values (3.47) are projected back onto the original grid. This can be done using the weighted average of the values $\varphi_{j\pm,k\pm}^{n+1}$, since the

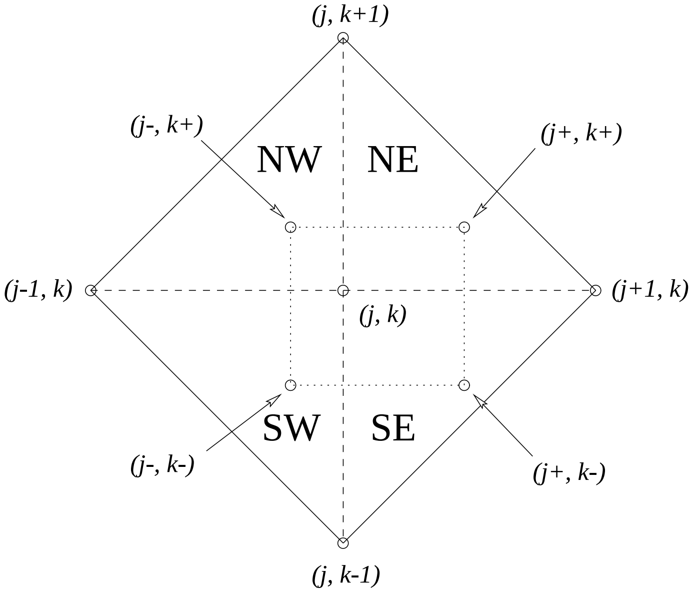

FIG. 3.4. *Central-upwind differencing*—2-D.

distance between the points $(x_{j\pm}, y_{k\pm})$ is proportional to $\mathcal{O}(\Delta t)$. The resulting fully discrete central-upwind scheme is

$$\begin{aligned}
&\varphi_{j,k}^{n+1}\\
&= \frac{a_{j,k}^- b_{j,k}^-}{(a_{j,k}^+ - a_{j,k}^-)(b_{j,k}^+ - b_{j,k}^-)}\Big(\widetilde{\varphi}(x_{j+}^n, y_{k+}^n, t^n) - \Delta t \cdot H(\widetilde{\varphi}_x(x_{j+}^n, y_{k+}^n, t^n), \widetilde{\varphi}_y(x_{j+}^n, y_{k+}^n, t^n))\Big)\\
&- \frac{a_{j,k}^- b_{j,k}^+}{(a_{j,k}^+ - a_{j,k}^-)(b_{j,k}^+ - b_{j,k}^-)}\Big(\widetilde{\varphi}(x_{j+}^n, y_{k-}^n, t^n) - \Delta t \cdot H(\widetilde{\varphi}_x(x_{j+}^n, y_{k-}^n, t^n), \widetilde{\varphi}_y(x_{j+}^n, y_{k-}^n, t^n))\Big)\\
&- \frac{a_{j,k}^+ b_{j,k}^-}{(a_{j,k}^+ - a_{j,k}^-)(b_{j,k}^+ - b_{j,k}^-)}\Big(\widetilde{\varphi}(x_{j-}^n, y_{k+}^n, t^n) - \Delta t \cdot H(\widetilde{\varphi}_x(x_{j-}^n, y_{k+}^n, t^n), \widetilde{\varphi}_y(x_{j-}^n, y_{k+}^n, t^n))\Big)\\
&+ \frac{a_{j,k}^+ b_{j,k}^+}{(a_{j,k}^+ - a_{j,k}^-)(b_{j,k}^+ - b_{j,k}^-)}\Big(\widetilde{\varphi}(x_{j-}^n, y_{k-}^n, t^n) - \Delta t \cdot H(\widetilde{\varphi}_x(x_{j-}^n, y_{k-}^n, t^n), \widetilde{\varphi}_y(x_{j-}^n, y_{k-}^n, t^n))\Big).
\end{aligned}$$

(3.48)

As in the 1-D case, the scheme (3.48) is only first-order in time. This disadvantage can be eliminated by passing to the semidiscrete limit in (3.48) as $\Delta t \to 0$. To this end, we first compute the values of $\widetilde{\varphi}(x_\pm^n, y_\pm^n, t^n)$ by the Taylor expansions,

$$\begin{aligned}
\widetilde{\varphi}(x_{j\pm}, y_{k+}, t^n) &= \widetilde{\varphi}(x_j, y_k, t^n) + \Delta t a_{j,k}^\pm \widetilde{\varphi}_x(x_j \pm 0, y_k, t^n)\\
&\quad + \Delta t b_{j,k}^+ \widetilde{\varphi}_y(x_j, y_k + 0, t^n) + \mathcal{O}(\Delta t)^2,\\
\widetilde{\varphi}(x_{j\pm}, y_{k-}, t^n) &= \widetilde{\varphi}(x_j, y_k, t^n) + \Delta t a_{j,k}^\pm \widetilde{\varphi}_x(x_j \pm 0, y_k, t^n)\\
&\quad + \Delta t b_{j,k}^- \widetilde{\varphi}_y(x_j, y_k - 0, t^n) + \mathcal{O}(\Delta t)^2.
\end{aligned}$$

We then plug these values in (3.48), and after passing to the limit as $\Delta t \to 0$, we obtain the 2-*D semidiscrete central-upwind scheme*,

$$
\begin{aligned}
&\frac{d}{dt}\varphi_{j,k}(t)\\
&= -\ \frac{a^-_{j,k}b^-_{j,k}H(\varphi^+_x,\varphi^+_y) - a^-_{j,k}b^+_{j,k}H(\varphi^+_x,\varphi^-_y) - a^+_{j,k}b^-_{j,k}H(\varphi^-_x,\varphi^+_y) + a^+_{j,k}b^+_{j,k}H(\varphi^-_x,\varphi^-_y)}{(a^+_{j,k}-a^-_{j,k})(b^+_{j,k}-b^-_{j,k})}\\
&\quad - \frac{a^+_{j,k}a^-_{j,k}}{a^+_{j,k}-a^-_{j,k}}\Big(\varphi^+_x-\varphi^-_x\Big) - \frac{b^+_{j,k}b^-_{j,k}}{b^+_{j,k}-b^-_{j,k}}\Big(\varphi^+_y-\varphi^-_y\Big).
\end{aligned}
\tag{3.49}
$$

Here, $\varphi^\pm_x := \widetilde{\varphi}_x(x_j \pm 0, y_k, t)$ and $\varphi^\pm_y := \widetilde{\varphi}_y(x_j, y_k \pm 0, t)$ are the right and the left derivatives in the x- and y-direction, respectively. The one-sided local speeds in (3.49) are given by (3.46). In practice, these speeds can be estimated in a simpler way. For instance, in the numerical examples, we have used

$$
\begin{aligned}
a^+_{j,k} &:= \max_{\pm}\Big\{H_u(\varphi^\pm_x,\varphi^\pm_y)\Big\}_+, \quad a^-_{j,k} := \min_{\pm}\Big\{H_u(\varphi^\pm_x,\varphi^\pm_y)\Big\}_-,\\
b^+_{j,k} &:= \max_{\pm}\Big\{H_v(\varphi^\pm_x,\varphi^\pm_y)\Big\}_+, \quad b^-_{j,k} := \min_{\pm}\Big\{H_v(\varphi^\pm_x,\varphi^\pm_y)\Big\}_-.
\end{aligned}
\tag{3.50}
$$

Finally, to obtain the same second-order accuracy in time, our semidiscrete central-upwind scheme (3.49)–(3.50) should be complemented with at least a second-order ODE solver for time discretization.

4. Numerical examples.

In this section, we implement our scheme for conservation laws and Hamilton–Jacobi equations and perform several numerical experiments. We test the accuracy of the scheme on problems with smooth solutions and solve various equations which admit nonsmooth solutions. Among them are the Euler equations of gas dynamics, the incompressible Euler equations, and others. The numerical results show that our scheme gives sharper resolution and reduces some of the side effects of the schemes from [27, 25].

The high-order semidiscrete methods, presented in this paper, require a time discretization of the corresponding order. In the numerical examples, shown below, we have used the third-order TVD Runge–Kutta method, proposed in [45, 47], and the second-order modified Euler method. Our choice is based on the stability properties of these methods, each time step of which can be viewed as a convex combination of small forward Euler steps.

In all the numerical experiments below, the CFL number is equal to 0.475, and the value of θ in the generalized minmod limiter is 2.

4.1. 1-D problems.

Example 1. Burgers' equation. We consider the initial boundary value problem (IBVP) for the inviscid Burgers' equation

$$
u_t + \left(\frac{u^2}{2}\right)_x = 0, \qquad u(x,0) = 0.5 + \sin x, \quad x \in [0, 2\pi], \tag{4.1}
$$

with periodic boundary conditions. It is known that the unique entropy solution of (4.1) develops a shock discontinuity at time $t = 1$. The solution at the preshock time $T = 0.5$ is smooth, and this allows us to test the accuracy of the 1-D third-order central-upwind scheme (3.14)–(3.15). We couple it with the basic piecewise quadratic reconstruction (for details, see [37, 39, 25]), and compute the solution using N grid points, $N = 40, 80, \dots, 1280$.

The L^∞- and L^1-errors are shown in Table 4.1, and they clearly demonstrate a third-order experimental convergence rate.

Table 4.1
Accuracy test for the Burgers' equation (4.1), $T = 0.5$.

N	L^∞-error	rate	L^1-error	rate
40	1.456e-03	–	1.241e-03	–
80	2.177e-04	2.74	1.683e-04	2.88
160	2.893e-05	2.91	2.187e-05	2.94
320	3.689e-06	2.97	2.794e-06	2.97
640	4.559e-07	3.02	3.484e-07	3.00
1280	5.720e-08	2.99	4.376e-08	2.99

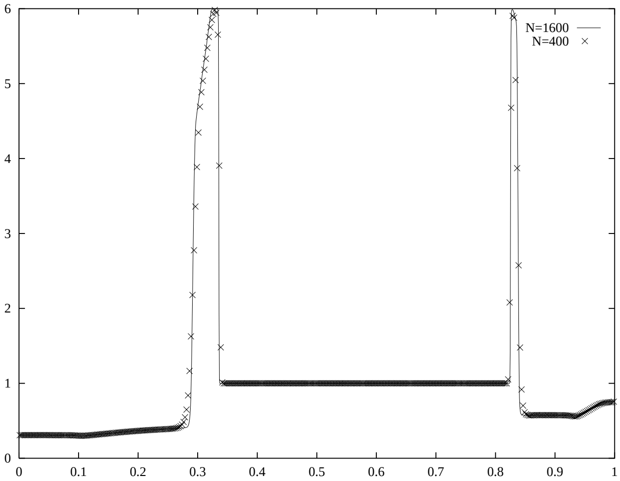

Fig. 4.1. *Problem* (4.2)–(4.3), *density at* $T = 0.01$.

Example 2. 1-D Euler equations of gas dynamics. We solve the 1-D Euler system

$$\frac{\partial}{\partial t}\begin{bmatrix}\rho\\ m\\ E\end{bmatrix}+\frac{\partial}{\partial x}\begin{bmatrix}m\\ \rho u^2+p\\ u(E+p)\end{bmatrix}=0, \qquad p=(\gamma-1)\cdot\Big(E-\frac{\rho}{2}u^2\Big), \tag{4.2}$$

with the initial data

$$\vec{u}(x,0)=\begin{cases}\vec{u}_L=(1,0,2500)^T, & 0\le x<0.1,\\ \vec{u}_M=(1,0,0.025)^T, & 0.1\le x<0.9,\\ \vec{u}_R=(1,0,250)^T, & 0.9\le x<1,\end{cases} \tag{4.3}$$

and solid wall boundary conditions, applied to both ends. This problem, proposed in [51], models the interaction of blast waves. Here, ρ, u, $m = \rho u$, p, and E are the density, velocity, momentum, pressure, and the total energy, respectively; $\gamma = 1.4$.

The solution is computed with our scheme (3.14)–(3.15) and the 1-D reconstruction in [25]. We use $N = 400$ grid points and plot the density, the velocity, and the pressure together with a reference solution, obtained by the same method with $N = 1600$.

Figures 4.1, 4.2, and 4.3 show the density, the velocity, and the pressure at time $T = .01$. Note, that for $N = 400$, the second density spike has a height of ~ 5.9, which is closer to the actual value of the solution. This result is better than the heights of

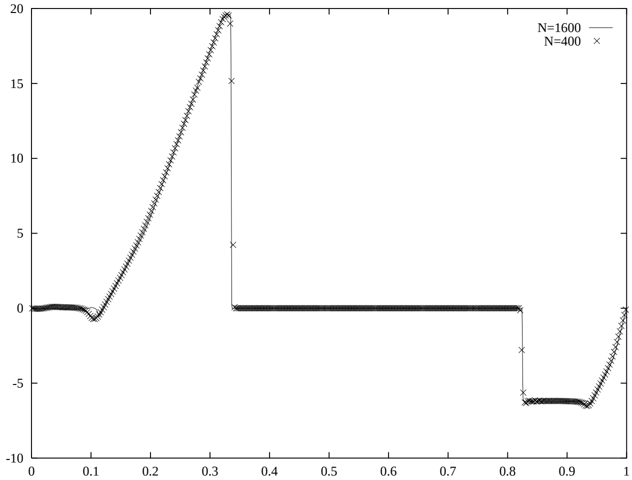

FIG. 4.2. *Problem* (4.2)–(4.3)*, velocity at* $T = 0.01$.

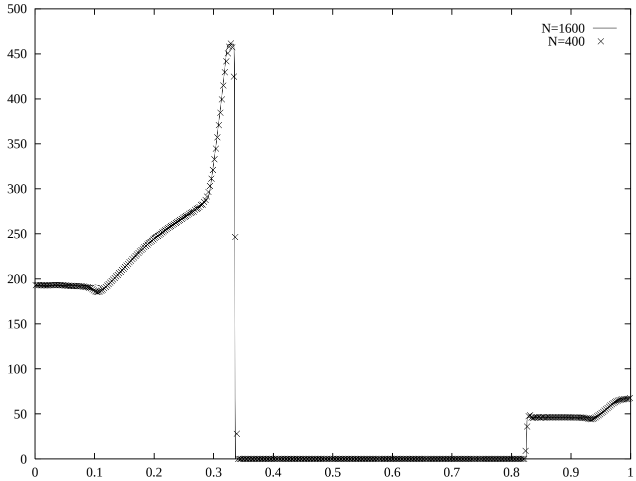

FIG. 4.3. *Problem* (4.2)–(4.3)*, pressure at* $T = 0.01$.

~ 5.75, ~ 5.2, and ~ 3.7, obtained by the third-order central schemes in [25, 39], and the second-order Nessyahu–Tadmor scheme in [40], respectively. This illustrates the higher resolution and smaller numerical dissipation of the central-upwind scheme.

The computations at times $T = 0.03$ and $T = 0.038$ are comparable to the results from [25], and are shown in Figures 4.4–4.9.

Example 3. 1-D Hamilton–Jacobi equation. In this example, we apply the second-order central-upwind scheme (2.7), (3.38)–(3.39), (3.44) to the Riemann problem for a 1-D Hamilton–Jacobi equation with a nonconvex Hamiltonian,

$$\varphi_t + \frac{1}{4}(\varphi_x^2 - 1)(\varphi_x^2 - 4) = 0, \qquad \varphi(x,0) = -2|x|. \tag{4.4}$$

The numerical solution, computed for different numbers of grid points is plotted in Figure 4.10. One can observe a very fast convergence of the approximate solutions

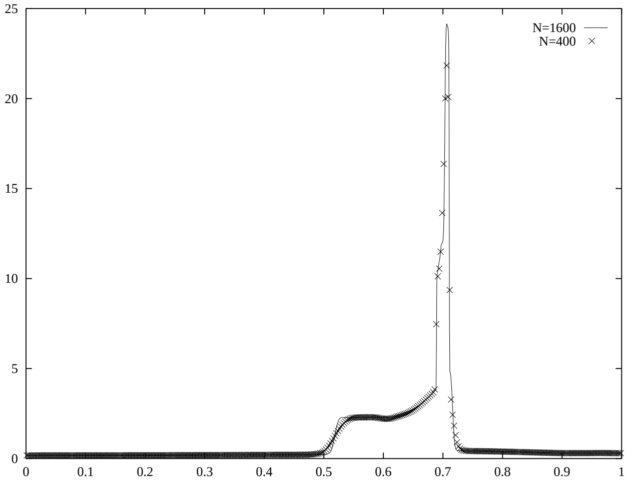

FIG. 4.4. *Problem* (4.2)–(4.3), *density at* $T = 0.03$.

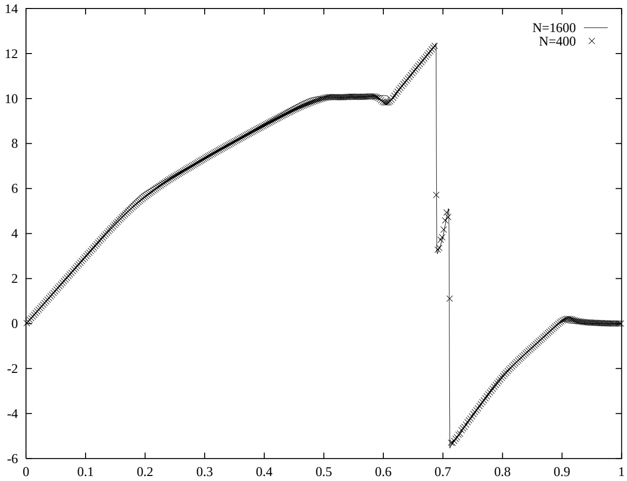

FIG. 4.5. *Problem* (4.2)–(4.3), *velocity at* $T = 0.03$.

toward the exact (viscosity) solution of (4.4) as the mesh is refined. The exact solution is obtained by solving the Riemann problem for the corresponding conservation law.

4.2. 2-D problems.

Example 4. 2-D Euler equations of gas dynamics. We solve the 2-D compressible Euler equations

$$\frac{\partial}{\partial t}\begin{bmatrix}\rho\\ \rho u\\ \rho v\\ E\end{bmatrix}+\frac{\partial}{\partial x}\begin{bmatrix}\rho u\\ \rho u^2+p\\ \rho uv\\ u(E+p)\end{bmatrix}+\frac{\partial}{\partial y}\begin{bmatrix}\rho v\\ \rho uv\\ \rho v^2+p\\ v(E+p)\end{bmatrix}=0,\ \ p=(\gamma-1)\cdot\Big[E-\frac{\rho}{2}(u^2+v^2)\Big]$$
(4.5)

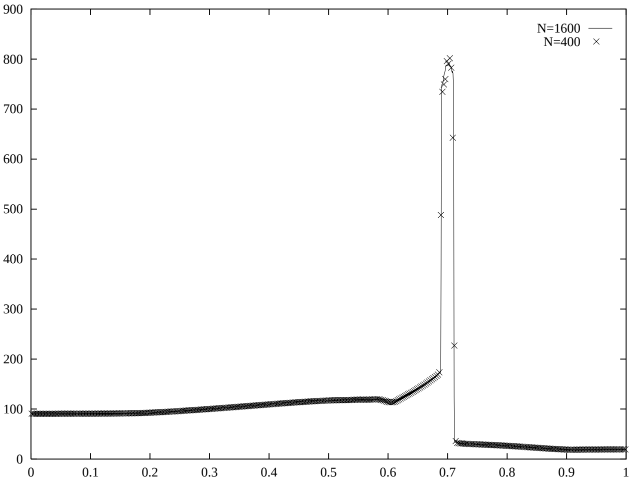

FIG. 4.6. *Problem* (4.2)–(4.3)*, pressure at* $T = 0.03$.

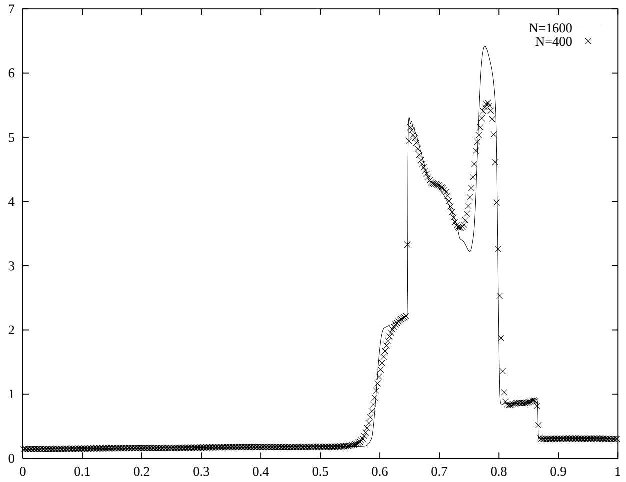

FIG. 4.7. *Problem* (4.2)–(4.3)*, density at* $T = 0.038$.

for an ideal gas, $\gamma = 1.4$, in the domain $[0, 2] \times [0, 0.5] \cup [0, 1] \times [0.5, 1]$, with the initial data corresponding to a vertical left-moving Mach 1.65 shock, positioned at $x = 1.375$. The initial shock propagates and then diffracts around a solid corner. Here ρ, u, v, p , and E are the density, the x- and y-velocities, the pressure, and the total energy, respectively.

We compute the solution at time $T = 0.5$, using the scheme (3.30)–(3.32), coupled with the reconstruction in [25]. The contour plots of the density for 128×64, 256×128, and 512×256 grid points are given in Figures 4.11, 4.12, and 4.13, respectively.

Note that as in [25], the results are obtained without using characteristic decomposition, dimensional splitting, or evolution of nonconservative quantities.

Example 5. 2-D Hamilton–Jacobi equation. We consider the initial value problem for the 2-D eikonal equation of geometric optics, which is a Hamilton–Jacobi

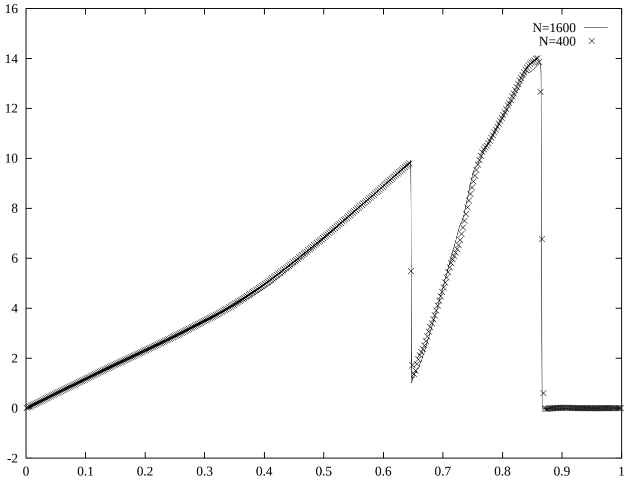

FIG. 4.8. *Problem* (4.2)–(4.3)*, velocity at* $T = 0.038$*.*

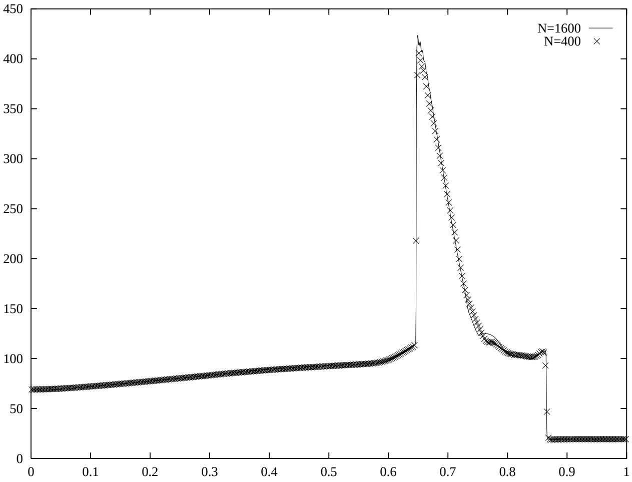

FIG. 4.9. *Problem* (4.2)–(4.3)*, pressure at* $T = 0.038$*.*

equation with a convex Hamiltonian,

$$\varphi_t+\sqrt{\varphi_x^2+\varphi_y^2+1}=0, \quad \varphi(x,y,0)=\frac{1}{4}(\cos(2\pi x)-1)(\cos(2\pi y)-1)-1, \ (x,y)\in[0,1]^2. \tag{4.6}$$

The numerical solution of (4.6) at time $T = 0.6$ (after formation of the singularity) has been computed by the 2-D second-order central-upwind scheme (3.49)–(3.50). The nonoscillatory nature of the computed solution and nearly perfect resolution of the singularity can be clearly seen in Figures 4.14–4.15.

4.3. 2-D incompressible Euler and Navier–Stokes equations. Here, we consider the incompressible Euler ($\nu = 0$) and Navier–Stokes ($\nu > 0$) equations

$$\vec{u}_t + (\vec{u}\cdot\nabla)\vec{u} + \nabla p = \nu\Delta\vec{u}, \tag{4.7}$$

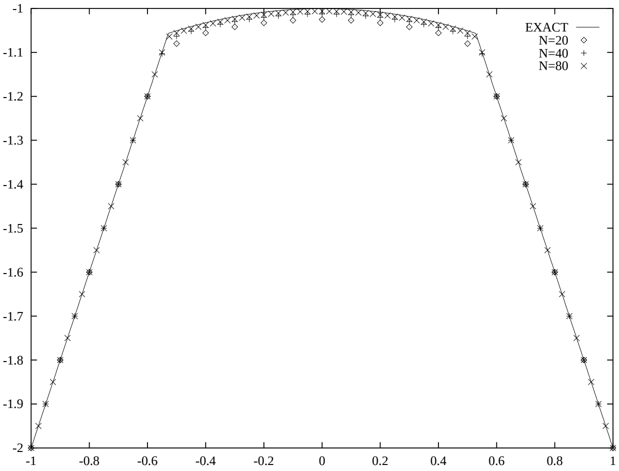

FIG. 4.10. *Problem* (4.4), *solution at* $T = 1$.

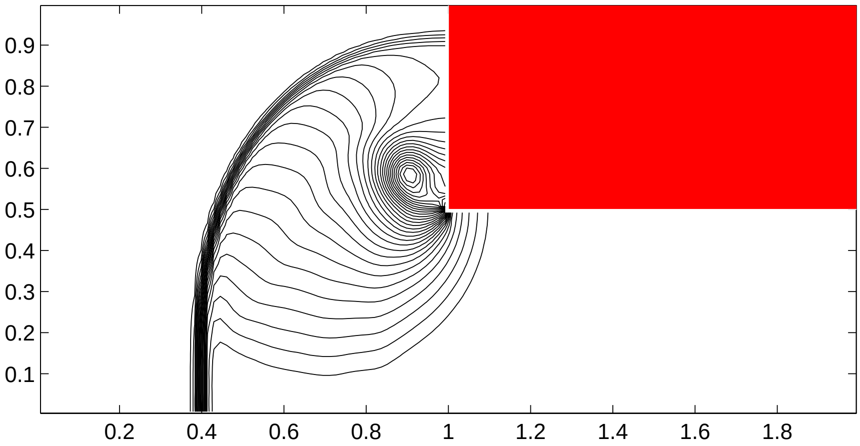

FIG. 4.11. *Equation* (4.5), *density;* $T = 0.5$, 128×64 *grid,* 30 *contours.*

where p denotes the pressure and $\vec{u} = (u, v)$ is the divergence-free velocity field, satisfying $u_x + v_y = 0$. In the 2-D case, equation (4.7) admits an equivalent vorticity formulation, which can be written either in the conservative form,

$$\omega_t + (u\omega)_x + (v\omega)_y = \nu\Delta\omega, \tag{4.8}$$

or in the transport form,

$$\omega_t + u\omega_x + v\omega_y = \nu\Delta\omega, \tag{4.9}$$

where ω is the vorticity, $\omega := v_x - u_y$. Equation (4.8) can be viewed as a 2-D conservation law

$$\omega_t + f(\omega)_x + g(\omega)_y = \nu\Delta\omega, \tag{4.10}$$

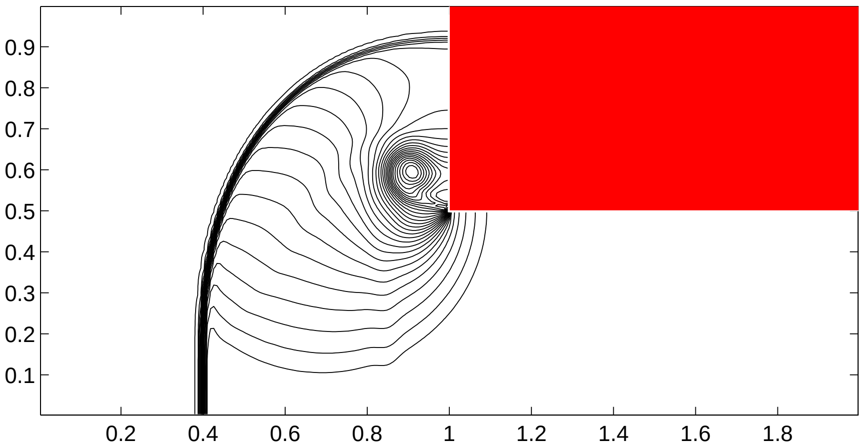

FIG. 4.12. *Equation* (4.5)*, density;* $T = 0.5$, 256×128 *grid,* 30 *contours.*

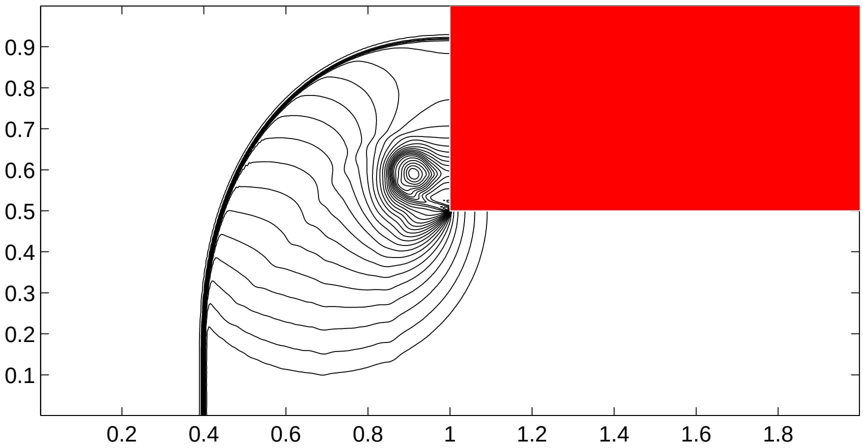

FIG. 4.13. *Equation* (4.5)*, density;* $T = 0.5$, 512×256 *grid,* 30 *contours.*

with a global flux $(f, g) := (u\omega, v\omega)$, while the transport equation (4.9) can be considered as a 2-D (viscous) Hamilton–Jacobi equation

$$\omega_t + H(\omega_x, \omega_y) = \nu\Delta\omega, \tag{4.11}$$

with a global Hamiltonian $H(\omega_x, \omega_y) = u\omega_x + v\omega_y$.

We propose two alternative Godunov-type semidiscrete central-upwind schemes for these two different formulations of the vorticity equation, (4.8) and (4.9). First, we consider (4.8) as a conservation law (4.10) and apply our 2-D third-order central-upwind scheme (3.30)–(3.32) to it. The resulting scheme has the conservative form

$$\frac{d}{dt}\bar{\omega}_{j,k}(t) = -\frac{H^x_{j+\frac{1}{2},k}(t) - H^x_{j-\frac{1}{2},k}(t)}{\Delta x} - \frac{H^y_{j,k+\frac{1}{2}}(t) - H^y_{j,k-\frac{1}{2}}(t)}{\Delta y} + \nu Q_{j,k}(t). \tag{4.12}$$

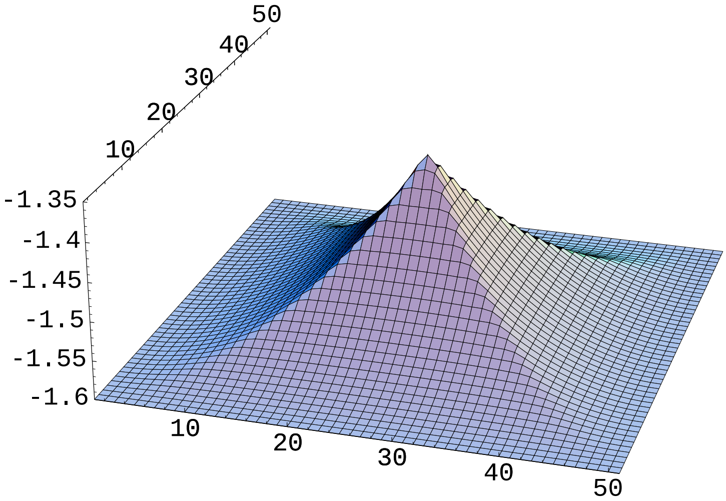

FIG. 4.14. *Problem* (4.6)*;* $T = 0.6$*,* 50×50 *grid.*

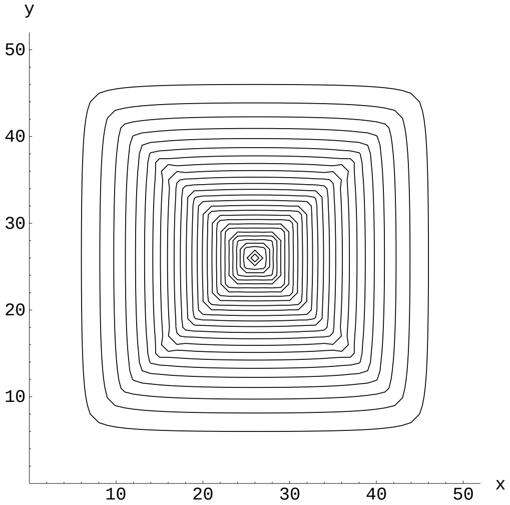

FIG. 4.15. *Contour plot.*

The following choice of the one-sided local speeds,

$$a^{\pm}_{j+\frac{1}{2},k} := \left(u_{j+\frac{1}{2},k}\right)_{\pm}, \qquad b^{\pm}_{j,k+\frac{1}{2}} := \left(v_{j,k+\frac{1}{2}}\right)_{\pm}, \tag{4.13}$$

yields the simplified numerical convection fluxes

$$\begin{aligned} H^x_{j+\frac{1}{2},k} := {} & \frac{a^+_{j+\frac{1}{2},k}}{6\left(a^+_{j+\frac{1}{2},k} - a^-_{j+\frac{1}{2},k}\right)} \left[u_{j+\frac{1}{2},k+\frac{1}{2}}\omega^{\mathrm{NE}}_{j,k} + 4u_{j+\frac{1}{2},k}\omega^{\mathrm{E}}_{j,k} + u_{j+\frac{1}{2},k-\frac{1}{2}}\omega^{\mathrm{SE}}_{j,k}\right] \\ & - \frac{a^-_{j+\frac{1}{2},k}}{6\left(a^+_{j+\frac{1}{2},k} - a^-_{j+\frac{1}{2},k}\right)} \left[u_{j+\frac{1}{2},k+\frac{1}{2}}\omega^{\mathrm{NW}}_{j+1,k} + 4u_{j+\frac{1}{2},k}\omega^{\mathrm{W}}_{j+1,k} + u_{j+\frac{1}{2},k-\frac{1}{2}}\omega^{\mathrm{SW}}_{j+1,k}\right], \end{aligned} \tag{4.14}$$

and

$$H^y_{j,k+\frac{1}{2}} := \frac{b^+_{j,k+\frac{1}{2}}}{6\Big(b^+_{j,k+\frac{1}{2}} - b^-_{j,k+\frac{1}{2}}\Big)}\Big[v_{j-\frac{1}{2},k+\frac{1}{2}}\omega^{\mathrm{NW}}_{j,k} + 4v_{j,k+\frac{1}{2}}\omega^{\mathrm{N}}_{j,k} + v_{j+\frac{1}{2},k+\frac{1}{2}}\omega^{\mathrm{NE}}_{j,k}\Big]$$

$$- \frac{b^-_{j,k+\frac{1}{2}}}{6\Big(b^+_{j,k+\frac{1}{2}} - b^-_{j,k+\frac{1}{2}}\Big)}\Big[v_{j-\frac{1}{2},k+\frac{1}{2}}\omega^{\mathrm{SW}}_{j,k+1} + 4v_{j,k+\frac{1}{2}}\omega^{\mathrm{S}}_{j,k+1} + v_{j+\frac{1}{2},k+\frac{1}{2}}\omega^{\mathrm{SE}}_{j,k+1}\Big]. \tag{4.15}$$

The diffusion term in (4.12) is obtained by the fourth-order central differencing,

$$Q_{j,k} = \frac{-\bar\omega_{j+2,k} + 16\bar\omega_{j+1,k} - 30\bar\omega_{j,k} + 16\bar\omega_{j-1,k} - \bar\omega_{j-2,k}}{12(\Delta x)^2}$$

$$+ \frac{-\bar\omega_{j,k+2} + 16\bar\omega_{j,k+1} - 30\bar\omega_{j,k} + 16\bar\omega_{j,k-1} - \bar\omega_{j,k-2}}{12(\Delta y)^2}. \tag{4.16}$$

The intermediate values of the velocities, required to compute the convection fluxes (4.14) and (4.15), are approximated by the fourth-order averaging, namely,

$$u_{j+\frac{1}{2},k} = \frac{-u_{j+2,k} + 9u_{j+1,k} + 9u_{j,k} - u_{j-1,k}}{16},$$

$$v_{j,k+\frac{1}{2}} = \frac{-v_{j,k+2} + 9v_{j,k+1} + 9v_{j,k} - v_{j,k-1}}{16}. \tag{4.17}$$

The velocities at the grid points, $\{u_{j,k}, v_{j,k}\}$, are recovered from the computed vorticities $\{\omega_{j,k}\}$ at every time step. This is done with the help of the streamfunction ψ, such that $u = \psi_y$, $v = -\psi_x$, and $\Delta\psi = -\omega$. We solve this Poisson equation by the nine-point Laplacian approximation. Then, having the values of $\{\psi_{j,k}\}$, we compute the velocities

$$u_{j,k} = \frac{-\psi_{j,k+2} + 8\psi_{j,k+1} - 8\psi_{j,k-1} + \psi_{j,k-2}}{12\Delta y},$$

$$v_{j,k} = \frac{\psi_{j+2,k} - 8\psi_{j+1,k} + 8\psi_{j-1,k} - \psi_{j-2,k}}{12\Delta x}. \tag{4.18}$$

This completes the construction of the "conservative" central-upwind scheme for the incompressible Euler and Navier–Stokes equations.

We now apply this scheme, coupled with the reconstruction in [25], to the Navier–Stokes equation (4.8) with $\nu = 0.05$, augmented with the smooth periodic initial data

$$u(x,y,0) = -\cos x \sin y, \qquad v(x,y,0) = \sin x \cos y. \tag{4.19}$$

This test problem, proposed in [9], admits the exact classical solution, given by

$$u(x,y,t) = -e^{-2\nu t}\cos x \sin y, \qquad v(x,y,t) = e^{-2\nu t}\sin x \cos y.$$

In this numerical experiment, we check the accuracy of our scheme. The numerical solution is computed at time $T = 2$, and the errors for the vorticity, measured in the L^∞-, L^1-, and L^2-norms, are presented in Table 4.2. These results indicate the expected third-order accuracy of the proposed scheme (4.12)–(4.18).

Next, we apply the scheme (4.12)–(4.18) together with the reconstruction in [25] to the Euler equation, (4.8) with $\nu = 0$, subject to the $(2\pi, 2\pi)$-periodic initial data

$$u(x,y,0) = \begin{cases} \tanh(\frac{1}{\rho}(y - \pi/2)), & y \le \pi, \\ \tanh(\frac{1}{\rho}(3\pi/2 - y)), & y > \pi, \end{cases} \qquad v(x,y,0) = \delta \cdot \sin x. \tag{4.20}$$

Table 4.2

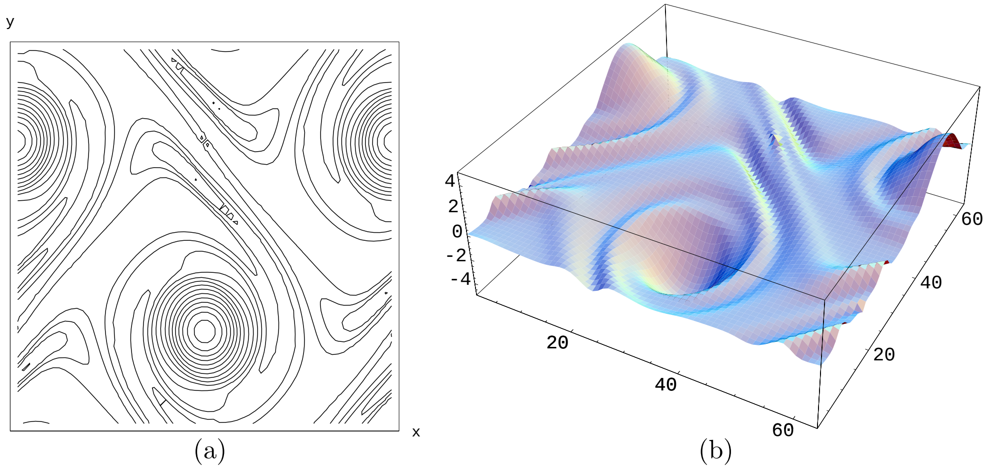

Fig. 4.16. *Vorticity—"conservative" scheme,* 64×64.

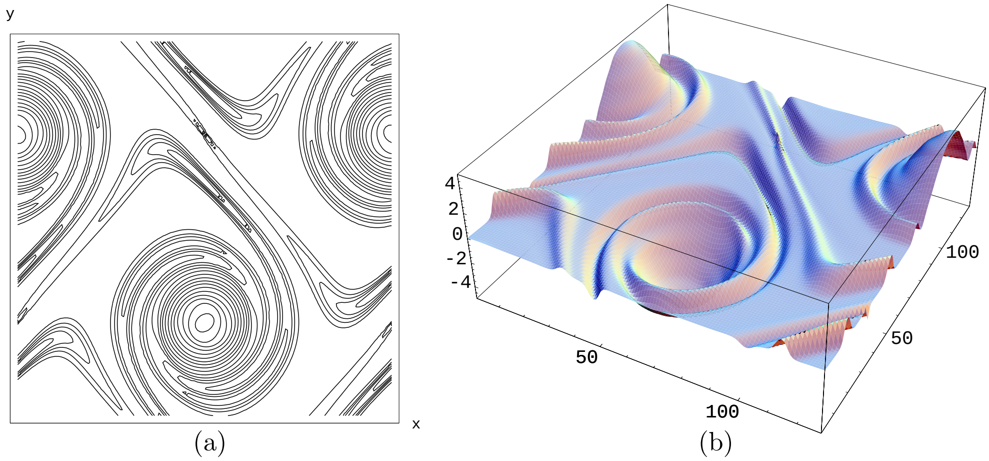

Fig. 4.17. *Vorticity—"conservative" scheme,* 128×128.

This is the double shear-layer model problem, proposed in [7]. We take $\rho = \pi/15$ and $\delta = 0.05$. Figures 4.16(a) and 4.17(a) are the contour plots (30 contours) of the vorticity at time $T = 10$ with 64×64 and 128×128 grid points, respectively. The three-dimensional plots of the same results are shown in Figures 4.16(b) and 4.17(b). The performed numerical experiments demonstrate that our scheme provides a very high resolution. These results are comparable with the results obtained by the third-

TABLE 4.3
Accuracy test for the second-order "transport" scheme for the Navier–Stokes equation (4.9), (4.19), $\nu = 0.05$; *errors at* $T = 2$.

$Nx \times Ny$	L^∞-error	rate	L^1-error	rate	L^2-error	rate

order semidiscrete central scheme in [25].

The second alternative is to solve the vorticity equation in its transport form, (4.9), which can be viewed as a Hamilton–Jacobi equation (4.11).

We choose the one-sided local speeds to be

$$a^{\pm}_{j,k} := (u_{j,k})_{\pm}, \qquad b^{\pm}_{j,k} := (v_{j,k})_{\pm}, \tag{4.21}$$

and in this setting, our 2-D second-order central-upwind scheme (3.49)–(3.50) has the following simple form:

$$\begin{aligned} \frac{d}{dt}\omega_{j,k}(t) = &-\frac{a^-_{j,k}b^-_{j,k}(u_{j,k}\omega_x^+ + v_{j,k}\omega_y^+) - a^-_{j,k}b^+_{j,k}(u_{j,k}\omega_x^+ + v_{j,k}\omega_y^-)}{(a^+_{j,k} - a^-_{j,k})(b^+_{j,k} - b^-_{j,k})} \\ &+\frac{a^+_{j,k}b^-_{j,k}(u_{j,k}\omega_x^- + v_{j,k}\omega_y^+) - a^+_{j,k}b^+_{j,k}(u_{j,k}\omega_x^- + v_{j,k}\omega_y^-)}{(a^+_{j,k} - a^-_{j,k})(b^+_{j,k} - b^-_{j,k})} + \nu L_{j,k}. \end{aligned} \tag{4.22}$$

Here, $w_x^{\pm}$, $w_y^{\pm}$ are the right and the left derivatives in the x- and y-directions of the continuous piecewise polynomial reconstruction of $\{\omega_{j,k}\}$. The term $L_{j,k}$ stands for the standard central difference approximation of the linear viscous term, that is,

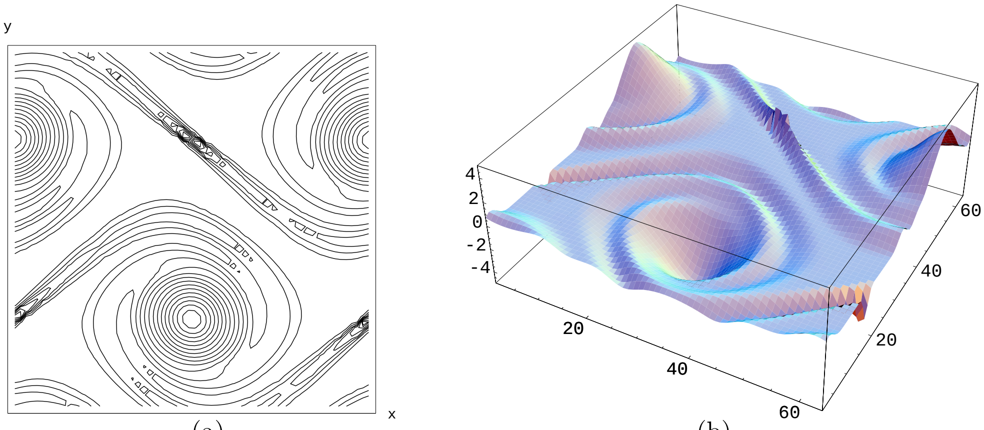
$$L_{j,k} = \frac{\omega_{j+1,k} - 2\omega_{j,k} + \omega_{j-1,k}}{(\Delta x)^2} + \frac{\omega_{j,k+1} - 2\omega_{j,k} + \omega_{j,k-1}}{(\Delta y)^2}. \tag{4.23}$$

As in the "conservative" scheme, we recover the velocities $\{u_{j,k}, v_{j,k}\}$ from the known values of the vorticity $\{\omega_{j,k}\}$, using the streamfunction approach. At each time step we solve the five-points Laplacian $\Delta\psi_{j,k} = -\omega_{j,k}$ and compute the velocities as follows:

$$u_{j,k} = \frac{\psi_{j,k+1} - \psi_{j,k-1}}{2\Delta y}, \qquad v_{j,k} = -\frac{\psi_{j+1,k} - \psi_{j-1,k}}{2\Delta x}. \tag{4.24}$$

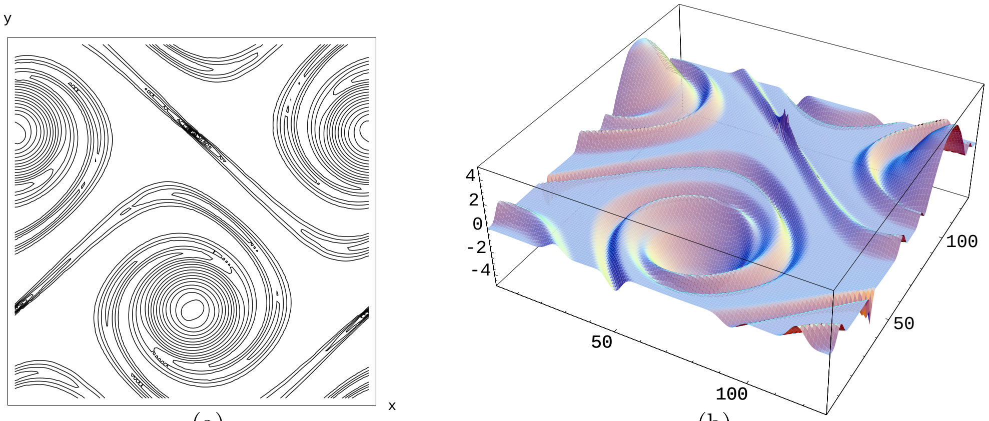
We now apply this second-order "transport" scheme to the IBVP for the Navier–Stokes equation (4.9), (4.19) with $\nu = 0.05$. The numerical solution of this test problem is computed at time $T = 2$, and the L^∞-, L^1-, and L^2-errors for the vorticity are presented in Table 4.3. These results indicate the second-order convergence rate measured in all these norms. We would also like to point out that the absolute values of the errors here are about 10 times smaller than the corresponding errors obtained by the semidiscrete central scheme in [27, Table 6.1].

Finally, we test our scheme (4.21)–(4.24) on the double shear-layer problem (4.9), (4.20). The contour plots (30 contours) of the vorticity are shown in Figures 4.18(a), 4.19(a), and 4.20(a), where the computations are performed at time $T = 10$ with 64×64, 128×128, and 256×256 grid points. The corresponding three-dimensional plots are presented in Figures 4.18(b), 4.19(b), and 4.20(b).



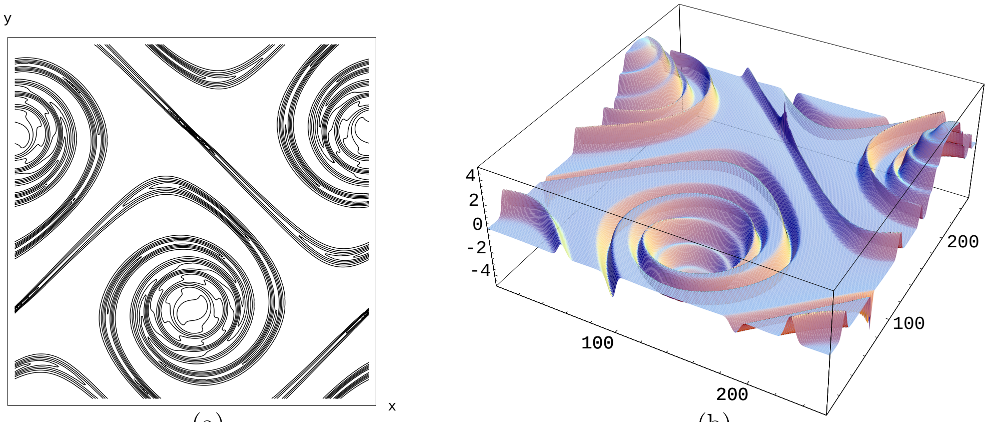
(a) (b)

FIG. 4.18. *Vorticity—"transport" scheme,* 64 × 64.



(a) (b)

FIG. 4.19. *Vorticity—"transport" scheme,* 128 × 128.



(a) (b)

FIG. 4.20. *Vorticity—"transport" scheme,* 256 × 256.

We would like to point out that our second-order "transport" scheme (4.21)–(4.24) has a very high resolution. The numerical experiments show that it is far superior to the second-order semidiscrete central scheme in [27, Figures 6.7–6.10]. This improvement is attributed to the smaller numerical viscosity present in the central-upwind scheme. Moreover, the resolution of (4.21)–(4.24) is almost as good as the resolution of our third-order "conservative" scheme (Figures 4.16 and 4.17).

As in [27, Figures 6.9–6.10], our numerical solution has spurious spikes, but of smaller heights. Also, the consequent mesh refinements (Figures 4.18–4.20) clearly demonstrate that the supports of these spikes diminish as the mesh size decreases.

Concluding remark. We have already mentioned the benefits of using the new central-upwind schemes in comparison to the central schemes in [26, 27, 24, 25]. Namely, they are *less dissipative*, and at the same time they retain the major advantages of central schemes—*simplicity* and *efficiency*.

In particular, the effect of the reduced numerical dissipation can be clearly seen when solving the incompressible Euler equation in its transport form. Moreover, in all of the numerical examples presented above, the achieved resolution is slightly better than the resolution obtained in [27, 24, 25].

The only drawback is the fact that the new schemes require the computation of both left and right local speeds, which increases the computational costs. However, the increase is not substantial, because as in any central scheme, our central-upwind schemes are Riemann-solver-free and do not require any computationally expensive characteristic decomposition.

A NEW FAST-MULTIPOLE ACCELERATED POISSON SOLVER IN TWO DIMENSIONS*

FRANK ETHRIDGE† AND LESLIE GREENGARD‡

Abstract. We present an adaptive fast multipole method for solving the Poisson equation in two dimensions. The algorithm is direct, assumes that the source distribution is discretized using an adaptive quad-tree, and allows for Dirichlet, Neumann, periodic, and free-space conditions to be imposed on the boundary of a square. The amount of work *per grid point* is comparable to that of classical fast solvers, even for highly nonuniform grids.

Key words. fast multipole method, Poisson equation, adaptive refinement, fast Poisson solver

1. Introduction.

A variety of problems in scientific computing involve the solution of the Poisson equation

$$\Delta\psi = f, \tag{1}$$

subject to appropriate radiation or boundary conditions. In simple geometries (circular or rectangular domains) with regular grids, there are well-known fast direct solvers [6, 7] which typically rely on the fast Fourier transform (FFT) and are well suited to the task. When either restriction is relaxed, however, these methods no longer apply. Since practical problems tend to involve complex geometries, highly inhomogeneous source distributions f, or both, there has been a lot of effort directed at developing alternative approaches. Most currently available solvers rely on iterative techniques using multigrid, domain decomposition, or some other preconditioning strategy [5, 9, 21]. Unfortunately, while such multilevel strategies can achieve nearly optimal efficiency in theory, they require an appropriate hierarchy of coarse grids which is not provided in practice. Although there has been significant progress in this direction [1, 2, 10, 11, 20, 23], the available solvers compare unfavorably with the fast direct solvers in terms of work per grid point.

In this paper, we describe an integral equation method for solving the Poisson equation in two dimensions which is direct, high order accurate, insensitive to the degree of adaptive mesh refinement, and accelerated by the fast multipole method (FMM) [16, 17, 26]. It is competitive with standard fast solvers in terms of *work per grid point.* This is a rather stringent test, since we compare the time for a classical, FFT-based solver using N mesh points with our adaptive, FMM-based solver using the same number of points, ignoring the fact that the latter solver uses grids which are highly inhomogeneous. We allow for the imposition of various combinations of free-space, periodic, Dirichlet, and Neumann conditions on the boundary of a square.

Earlier work on FMM-based integral equation schemes in two dimensions includes [15, 22, 29]. The paper [22] describes a fast Poisson solver for complex geometries,

where the boundary can be arbitrarily shaped and multiply-connected, but where the right-hand side is specified on a uniform underlying mesh. The other two papers discuss the inversion of (1) in free space by evaluation of the analytic solution

$$\psi(\mathbf{x}) = \frac{1}{2\pi} \int_D f(\mathbf{y}) \log(|\mathbf{x} - \mathbf{y}|) \, d\mathbf{y}. \tag{2}$$

The algorithms of both [15] and [29] are highly adaptive, with the former relying on a quad-tree and the latter relying on an unstructured triangulation. Neither, however, goes beyond the free-space problem.

The present approach is similar to that outlined in [15] but differs in several respects.

1. In the method of [15], one solves local Poisson problems with spectral methods on each leaf node of a quad-tree data structure and then patches the solutions together using the FMM in a domain decomposition approach. Here, we apply the FMM directly to the volume integral, using high order quadratures.
2. We incorporate a new version of the FMM described in [19], which is based on diagonal forms for translation operators (see section 3.8).
3. We incorporate the method of images to solve a variety of boundary value problems on a square (with adaptive refinement).
4. For fourth and sixth order accurate discretizations, we use locally uniform meshes, compatible with adaptive mesh refinement (AMR) data structures [3]. For eighth order accuracy, we follow [13, 15, 24] and rely on local spectral meshes.

The paper is organized as follows. In section 2, we outline the relevant potential theory, with particular emphasis on the method of images. In section 3, we describe the fast multipole algorithm itself, and in section 4, we present several numerical examples. Finally, it should be noted that our algorithm shares a number of features with the recently developed scheme of [12] for solving the pseudodifferential equation

$$(-\Delta)^{1/2} \psi = \omega \tag{3}$$

in the plane via the integral representation

$$\psi(\mathbf{x}) = \int_{\mathbf{R}^2} \frac{\omega(\mathbf{y})}{|\mathbf{x} - \mathbf{y}|} \, d\mathbf{y}.$$

2. Potential theory.

2. Potential theory. To complete a description of a well-posed problem, we must obviously add to the Poisson equation (1) a specification of boundary conditions on the unit square D. We allow the free-space conditions defined by (2), periodic boundary conditions, Dirichlet conditions, and Neumann conditions. We can also handle mixed conditions, but assume that the transition from one type to another (Dirichlet–Neumann, etc.) occurs only at corners. The solution to all these problems can be constructed analytically using the method of images.

For periodic boundary conditions, one simply imagines the entire plane to be tiled with copies of the source distribution contained in the unit cell D. (How to compute the influence of each of these images efficiently is discussed in the next section.) For other boundary conditions, the construction is a bit more subtle. Let us consider, for example, the boundary value problem

$$\begin{aligned} \Delta\psi &= f && \text{in } D,\\ \psi &= g_L && \text{on } \Gamma_L,\\ \psi &= g_R && \text{on } \Gamma_R,\\ \partial\psi/\partial n &= g_T && \text{on } \Gamma_T,\\ \partial\psi/\partial n &= g_B && \text{on } \Gamma_B, \end{aligned} \tag{4}$$

where Γ_L denotes the "left" boundary ($x = -0.5, -0.5 \leq y \leq 0.5$), Γ_R denotes the "right" boundary ($x = 0.5, -0.5 \leq y \leq 0.5$), Γ_T denotes the "top" boundary ($-0.5 \leq x \leq 0.5, y = 0.5$), and Γ_B denotes the "bottom" boundary ($-0.5 \leq x \leq 0.5, y = -0.5$).

This problem can be conveniently broken up into two parts. First, we can solve the Poisson equation:

$$\begin{aligned} \Delta\psi_1 &= f && \text{in } D,\\ \psi_1 &= 0 && \text{on } \Gamma_L,\\ \psi_1 &= 0 && \text{on } \Gamma_R,\\ \partial\psi_1/\partial n &= 0 && \text{on } \Gamma_T,\\ \partial\psi_1/\partial n &= 0 && \text{on } \Gamma_B. \end{aligned} \tag{5}$$

Then we can solve the Laplace equation with inhomogeneous boundary conditions:

$$\begin{aligned} \Delta\psi_2 &= 0 && \text{in } D,\\ \psi_2 &= g_L && \text{on } \Gamma_L,\\ \psi_2 &= g_R && \text{on } \Gamma_R,\\ \partial\psi_2/\partial n &= g_T && \text{on } \Gamma_T,\\ \partial\psi_2/\partial n &= g_B && \text{on } \Gamma_B. \end{aligned} \tag{6}$$

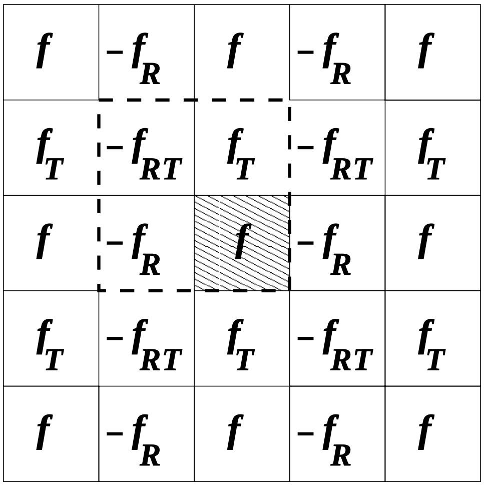
Clearly, $\psi = \psi_1 + \psi_2$.

To solve (5), suppose that we tile the plane with the pattern of images depicted in Figure 1. The shaded box is the computational domain containing the source distribution f. f_T denotes the even reflection of the function f across the top boundary Γ_T, $-f_R$ denotes the odd reflection of the function f across the right boundary Γ_R, and $-f_{RT}$ denotes the even reflection of the function $-f_R$ across the line $y = +\frac{1}{2}$. It is easy to verify that the vertical lines $x = \pm\frac{1}{2}$ are lines of odd symmetry and that the horizontal lines $y = \pm\frac{1}{2}$ are lines of even symmetry. Thus, the desired homogeneous boundary conditions are enforced if we account for the field due to all images. This task is simplified by the observation that the 2×2 supercell outlined with dashes in Figure 1 tiles the plane periodically.

To handle the inhomogeneous boundary conditions in (6), we recall the following classical results from potential theory [18, 30].

LEMMA 2.1. *Let $u(x, y)$ satisfy the Laplace equation $\Delta u = 0$ in the half-space $y > 0$ with Dirichlet boundary conditions $u(x, 0) = f(x)$. Then $u(x, y)$ is given by the double layer potential*

$$u(x, y) = 2\int_{-\infty}^{\infty} \frac{\partial G}{\partial y}(x - \xi, y)\, f(\xi)\, d\xi = \frac{1}{\pi}\int_{-\infty}^{\infty} \frac{y}{(x - \xi)^2 + y^2}\, f(\xi)\, d\xi.$$



f	$-f_R$	f	$-f_R$	f
f_T	$-f_{RT}$	f_T	$-f_{RT}$	f_T
f	$-f_R$	f	$-f_R$	f
f_T	$-f_{RT}$	f_T	$-f_{RT}$	f_T
f	$-f_R$	f	$-f_R$	f

FIG. 1. *A source distribution tiling the plane which solves the Poisson equation with the homogeneous boundary conditions described by the system* (5)*. The shaded box represents the computational domain itself.* f_T *denotes the even reflection of the function* f *across the top boundary* Γ_T*,* $-f_R$ *denotes the odd reflection of the function* f *across the right boundary* Γ_R*, and* $-f_{RT}$ *denotes the even reflection of the function* $-f_R$ *across the line* $y = +\frac{1}{2}$*. The* 2×2 *"supercell" with the dashed outline can be seen to tile the plane periodically.*

The solution satisfying Neumann boundary conditions $\frac{\partial u}{\partial n}(x, 0) = g(x)$ *is given by the single layer potential*

$$u(x, y) = 2\int_{-\infty}^{\infty} G(x - \xi, y)\, g(\xi)\, d\xi = \frac{1}{\pi}\int_{-\infty}^{\infty} \ln\sqrt{(x - \xi)^2 + y^2}\, g(\xi)\, d\xi.$$

Consider now the system of layer potentials depicted in Figure 2. We leave it to the reader to verify that, from the preceding lemma and symmetry considerations, the boundary conditions of (6) are satisfied. As with the tiling of source distributions, the task of accounting for the field due to all images is simplified by the observation that the layer potentials on boundary segments outlined with dots in Figure 2 tile the plane periodically. The evaluation of layer potentials is discussed in section 3.7.

3. Data structures and the FMM. We assume that the source distribution f in (2) is supported inside the unit square D, centered at the origin, on which is superimposed a hierarchy of refinements (a quad-tree). Grid level 0 is defined to be D itself, and grid level $l+1$ is obtained recursively by subdividing each square at level l into four equal parts. Using standard terminology, if d is a fixed square at level l, the four squares at level $l+1$ obtained by its subdivision will be referred to as its children. In order to allow for adaptivity, we do not use the same number of levels in all regions of D. We do, however, assume that the quad-tree satisfies one fairly standard restriction, namely, that two leaf nodes which share a boundary point must be no more than one refinement level apart (Figure 3).

3.1. The volume integral. We restrict our attention, for the moment, to the free-space problem. Extended volume integrals such as the ones depicted in Figure 1 will be discussed in section 3.6.

The leaf nodes on which the source distribution is given will be denoted by D_i.

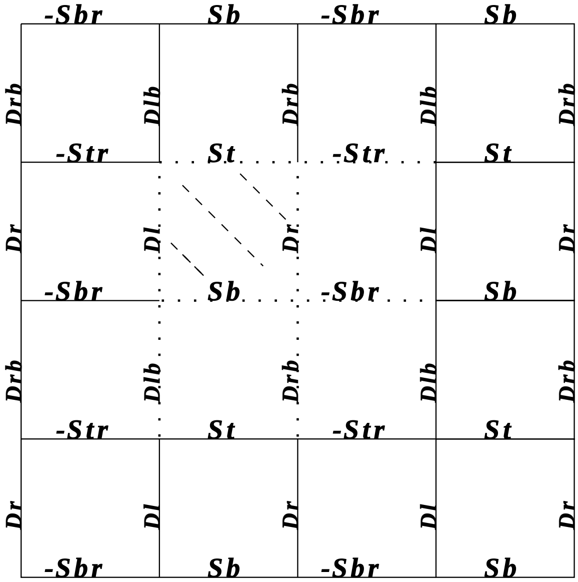


FIG. 2. *A tiling of the plane with layer potentials to solve* (6)*. The computational domain is indicated with diagonal dashes. Dl denotes a double layer potential with density g_L, and Dr denotes a double layer potential with density g_R. Their even reflections across the bottom boundary Γ_B are Dlb and Drb, respectively. St denotes a single layer potential with density g_T, and Sb denotes a single layer potential with density g_B. Their odd reflections across the right boundary Γ_R are $-Str$ and $-Sbr$, respectively. Symmetry considerations show that all four boundary conditions are satisfied. Note that the layer potentials on boundary segments outlined with dots tile the plane periodically.*

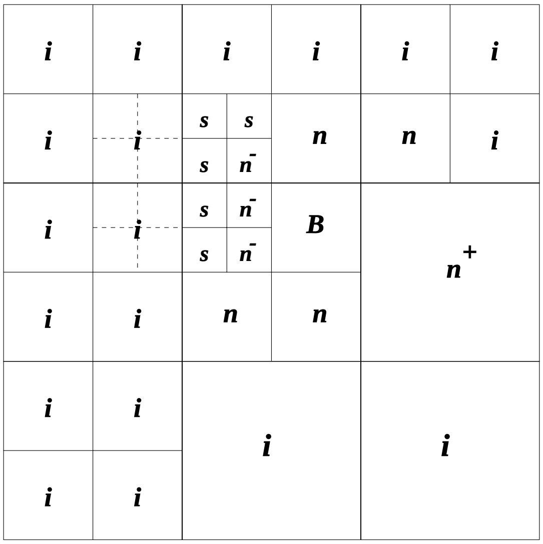

FIG. 3. *For the childless node B, colleagues are labeled n, coarse neighbors are labeled n^+, and fine neighbors are labeled n^-. The interaction list for B consists of the boxes marked i. The boxes marked by s are children of B's colleagues which are separated from B, so they are not fine neighbors. They constitute the* s-list *for B (see Definition* 3.1*).*

Thus, $D = \cup_{i=1}^{M} D_i$ and we rewrite (2) in the form

$$\psi(\mathbf{x}) = \sum_{i=1}^{M} \frac{1}{2\pi} \int_{D_i} f(\mathbf{y}) \log(|\mathbf{x} - \mathbf{y}|)\, d\mathbf{y}. \tag{7}$$

Definition 3.1. *The* colleagues *of a square B are squares at the same refinement level which share a boundary point with B. (B is considered to be a colleague of itself.) The* coarse neighbors *of B are leaf nodes at the level of B's parent which share a boundary point with B. The* fine neighbors *of B are leaf nodes one level finer than B which share a boundary point with B. Together, the union of the colleagues, coarse neighbors, and fine neighbors of B will be referred to as B's* neighbors. *The* s-list *of a box B consists of those children of B's colleagues which are not fine neighbors of B.*

The interaction region *for B consists of the area covered by the neighbors of B's parent, excluding the area covered by B's colleagues and coarse neighbors. The* interaction list *for B consists of those squares in the interaction region which are at the same refinement level, as well as leaf nodes in the interaction region which are at coarser levels. When the distinction is important, the squares at the same refinement level will be referred to as the* standard interaction list*, while the squares at coarser levels will be referred to as the* coarse interaction list.

In our FMM, following [8, 16, 17], terms in the convolution integral (7) from neighbor leaf nodes are computed directly. More distant interactions are accounted for on coarser levels, through the use of a hierarchy of far-field and local multipole expansions. We consider the local interactions first.

3.2. Local interactions. For fourth and sixth order accuracy, we assume that we are given f on a cell-centered $k \times k$ grid for each leaf node B, with $k = 4$ or 6, respectively. We can, therefore, take these k^2 data points and construct a kth order polynomial approximation to f of the form

$$f_B(x, y) \approx \sum_{j=1}^{N_k} c_B(j)\, b_j(x - x_B, y - y_B),$$

where $N_k = \frac{k(k+1)}{2}$ is the number of basis functions needed for kth order accuracy and where (x_B, y_B) denotes the center of B. The basis functions $b_1(x, y), \ldots, b_{N_k}(x, y)$ are given by

$$\{x^i y^j |\; i, j \geq 0, i + j \leq k - 1\}.$$

If we let $\vec{f_B} \in \mathbf{R}^{k^2}$ denote the given function values (in standard ordering), then the calculation of the coefficient vector $\vec{c}_B$ is clearly overdetermined. We obtain it through a least squares fit based on the singular value decomposition. The pseudoinverse matrix $\mathcal{P} \in \mathbf{R}^{N_k \times k^2}$, such that

$$\vec{c}_B = \mathcal{P}\, \vec{f_B},$$

can be precomputed and stored.

Remark 3.1. For eighth order accuracy, we assume that f is given on a scaled 8×8 classical tensor product Chebyshev grid [7] and use as basis functions

$$\{T_i(x) T_j(y) |\; i, j \geq 0, i + j \leq k - 1\},$$

where $T_i(x)$ denotes the Chebyshev polynomial of degree i. The coefficients of the Chebyshev expansion can be computed efficiently using the fast cosine transform.

Consider now a target point Q, which lies in a neighbor of B. The field induced at Q by f_B is approximated by

$$\psi_B(Q) = \sum_{n=1}^{N_k} c_B(n) f(Q,n), \tag{8}$$

where

$$f(Q,n) = \frac{1}{2\pi} \int_B b_n(x - x_B, y - y_B) \log |Q - (x,y)| \, dxdy. \tag{9}$$

Since the target points Q are regularly spaced in each neighboring square, we can precompute the weights (9) for each of the k^2 possible locations at each of 9 possible colleagues, 12 possible fine neighbors, and 12 possible coarse neighbors. To be more precise, we can precompute the weights assuming that B is the unit square $[-0.5, 0.5]^2$ because of the following straightforward lemma.

LEMMA 3.2. *Let B be a leaf node at level l and let Q denote a target point in one of B's neighbors. Let Q^* denote the scaled target point for the unit cell centered at the origin*

$$Q^* = 2^{l-1} \cdot (Q - (x_B, y_B)),$$

let

$$f^*(Q^*, n) = \frac{1}{2\pi} \int_{-1/2}^{1/2} \int_{-1/2}^{1/2} b_n(x,y) \log |Q^* - (x,y)| \, dxdy, \tag{10}$$

and let

$$\bar{f}(n,l) = \frac{1}{2\pi} \left(\frac{1}{2^{l-1}} \right)^{d+2} \int_{-1/2}^{1/2} \int_{-1/2}^{1/2} b_n(x,y) \log \left(\frac{1}{2^{l-1}} \right) dxdy. \tag{11}$$

Then the integral $f(Q,n)$ defined in (9) *is given by*

$$f(Q,n) = \left(\frac{1}{2^{l-1}} \right)^{d+2} f^*(Q^*, n) + \bar{f}(n,l),$$

where d is the degree of the polynomial basis function b_n.

Thus, we need only obtain weights for a box of unit area. Elementary counting arguments show that the storage required for this precomputation is

$$\begin{array}{rl} k \times k \cdot N_k \cdot 9 \text{ real numbers} & \text{for colleagues,} \\ k \times k \cdot N_k \cdot 12 \text{ real numbers} & \text{for fine neighbors,} \\ k \times k \cdot N_k \cdot 12 \text{ real numbers} & \text{for coarse neighbors,} \end{array}$$

for a total of approximately $17 \times k^4$ real numbers.

3.3. Far-field interactions. We turn now to the calculation of far-field interactions, which are computed by means of multipole expansions. We refer the reader to [14, 16] for more detailed discussions of potential theory. Our starting point is the usual multipole expansion for a charge distribution, which we state formally as a theorem.

THEOREM 3.3 (multipole expansion). *Let $\rho(\mathbf{y})$ be a charge distribution contained within a square D_i with center C and let $\Phi(\mathbf{x})$ denote the induced field at a point $\mathbf{x}$ in the interaction list of D_i:*

$$\Phi(\mathbf{x}) = \frac{1}{2\pi}\int_{D_i} \log|\mathbf{x}-\mathbf{y}|\rho(\mathbf{y})\, d\mathbf{y}.$$

Then $\Phi(\mathbf{x})$ can be described by the multipole expansion

$$\Phi(\mathbf{x}) = \alpha_0 \log|\mathbf{x}-C| + \Re\left(\sum_{k=1}^{\infty} \frac{\alpha_k}{(x_1+ix_2-C)^k}\right), \tag{12}$$

where C is viewed as a point in the complex plane, $\mathbf{x}=(x_1,x_2)$, and $\Re(w)$ denotes the real part of the complex quantity w. The coefficients α_k are given by

$$\begin{aligned}\alpha_0 &= \frac{1}{2\pi}\int_{D_i} \rho(y_1,y_2) dy_1\, dy_2,\\ \alpha_k &= -\frac{1}{2\pi}\int_{D_i} \frac{(y_1+iy_2-C)^k\rho(y_1,y_2)}{k} dy_1\, dy_2.\end{aligned} \tag{13}$$

In the hierarchical framework of the FMM, an upper bound for the error in truncating the expansion after n terms is given by

$$\left(\frac{1}{2}\right)^n \frac{1}{2\pi}\int_{D_i} |\rho(y_1,y_2)|\, dy_1\, dy_2. \tag{14}$$

THEOREM 3.4 (local expansion). *Let $\rho(\mathbf{y})$ be a charge distribution contained outside the neighbors of a square D_i with center C and let $\Psi(\mathbf{x})$ denote the induced field at $\mathbf{x}\in D_i$. Then $\Psi(\mathbf{x})$ can be described by a local expansion*

$$\Psi(\mathbf{x}) = \Re\left(\sum_{l=0}^{\infty} \beta_l (x_1+ix_2-C)^l\right), \tag{15}$$

where C is viewed as a point in the complex plane and $\mathbf{x}=(x_1,x_2)$.

The FMM relies on the ability to manipulate multipole and local expansions for every box in the tree hierarchy. We omit the technical details and refer the reader to the original papers [8, 14, 16, 17].

DEFINITION 3.5. *We denote by $S_{l,k}$ the kth square at refinement level l.*

We denote by $\Phi_{l,k}$ the multipole expansion describing the far field due to the source distribution supported inside $S_{l,k}$.

We denote by $\Psi_{l,k}$ the local expansion describing the field due to the source distribution outside the neighbors of $S_{l,k}$.

We denote by $\tilde{\Psi}_{l,k}$ the local expansion describing the field due to the source distribution outside the neighbors of the parent *of $S_{l,k}$.*

Remark 3.2. Let $S_{l,k}$ be a square in the quad-tree hierarchy and let $S_{l',k'}$ be a square in its interaction list. Then there is a linear operator $\mathcal{T}_{MM}$ for which

$$\Phi_{l,k} = \mathcal{T}_{MM}[\Phi(C_1), \Phi(C_2), \Phi(C_3), \Phi(C_4)], \tag{16}$$

where $\Phi(C_j)$ denotes the multipole expansion for the jth child of $S_{l,k}$. In other words, we can merge the expansions for four children into a single expansion for the parent. Similarly, there is a linear operator $\mathcal{T}_{LL}$ for which

$$[\tilde{\Psi}(C_1), \tilde{\Psi}(C_2), \tilde{\Psi}(C_3), \tilde{\Psi}(C_4)] = \mathcal{T}_{LL}\, \Psi_{l,k}, \tag{17}$$

where C_j denotes the jth child of $S_{l,k}$. In other words, we can shift the local expansion Ψ for a box to the corresponding expansion $\tilde{\Psi}$ for each of its children. Finally, there is a linear operator $\mathcal{T}_{ML}$ for which the field in $S_{l,k}$ due to the source distribution in $S_{l',k'}$ is described by $\Psi = T_{ML}\Phi_{l',k'}$. It is easy to verify that

$$\Psi_{l,k} = \tilde{\Psi}_{l,k} + \sum_{i \in \mathcal{IL}} T_{ML}\Phi_i, \tag{18}$$

where $\mathcal{IL}$ denotes the interaction list for square $S_{l,k}$.

Remark 3.3. One slight complication in the adaptive algorithm concerns the interaction between boxes of different sizes. Referring to Figure 3, we need to account for the influence of a childless square B on each box marked s and vice versa. (This interaction doesn't arise if B undergoes further refinement.) For the box marked s, its multipole expansion is rapidly convergent at each of the k^2 target points in B. Thus, its influence can be computed by direct evaluation of the truncated series. For the reverse, however, note that B's multipole expansion is not so rapidly convergent. In this case, we can map directly from the polynomial coefficients $\vec{c}_B$ of B to the local expansion in s. A more precise statement than (18) is

$$\Psi_{l,k} = \tilde{\Psi}_{l,k} + \sum_{i \in SIL} T_{ML}\Phi_i, + \sum_{i \in CIL} L_{direct}(\vec{c}_i), \tag{19}$$

where SIL denotes the standard interaction list and CIL denotes the coarse interaction list. The operator L_{direct}, which maps the coefficients of the polynomial approximation of the density in the coarse box onto the p coefficients of the local expansion can be precomputed and stored.

The bulk of the work in the FMM consists of applying the operators $\mathcal{T}_{MM}, \mathcal{T}_{LL}$, and especially $\mathcal{T}_{ML}$ in a systematic fashion. Unfortunately, these operators are dense. Using multipole and local expansions truncated after p terms, the naive cost of application is proportional to p^2. Recent improvements in the FMM have reduced this cost in both two and three space dimensions [17, 19]. A brief discussion of the technical ideas is presented in section 3.8.

3.4. The FMM algorithm.

Initialization

Comment [We assume we are given a square domain $D = S_{0,0}$, on which is superimposed an adaptive hierarchical quad-tree structure. We let M be the number of leaf nodes and denote them by D_i, $i = 1, \ldots, M$. The number of grid points is, therefore, $N = 16M$. We let p denote the order of the multipole expansion ($p \approx \log_2 \epsilon$, where ϵ is the desired accuracy). We let l_{max} denote the maximum refinement level.]

            form the multipole expansion $\Phi_{l,j}$ by merging the expansions of
            its children using the operator $\mathcal{T}_{MM}$ (see (16))
    end
end
```

Downward pass

```
Initialize the local expansion $\Psi_{0,0} = 0$.
for $l = 1, \ldots, l_{max}$
    for all squares $j$ on level $l$
        Compute $\tilde{\Psi}_{l,j}$ by shifting its parent's $\Psi$ expansion using the operator $\mathcal{T}_{LL}$
        Compute $\Psi_{l,j}$ by adding in the contributions from all squares in $j$'s
          interaction list according to (19).
        if $j$ is childless then
            for all boxes $k$ in the s-list of $j$:
                evaluate the multipole expansion $\Phi_k$ at each
                target in square $j$.
            end
            Evaluate the local expansion $\Psi_{l,j}$ at each
            target in square $j$.
        endif
    end
end
```

Cost [The upward pass requires approximately Mp^2 work, where M is the number of leaf nodes. The downward pass requires approximately $3Mp^2$ work using plane-wave expansions (see section 3.8 below).]

Step II: Local interactions

Comment [At this point, for each leaf node D_i, we have computed the influence of the source distribution f over all leaf nodes D_j outside the neighbors of D_i.]

```
do $i = 1, \ldots, M$
    For each target point in $D_i$, evaluate the influence of each
        neighbor according to (8) using the precomputed
        tables of coefficients (10).
end
```

Cost [The maximum number of neighbors a square can have is thirteen (twelve fine neighbors and itself). Thus the local work is bounded by is $13 \cdot \frac{k(k+1)}{2} \cdot N$ operations.]

3.5. Periodic boundary conditions. The inversion formula (2) and the fast algorithm described above assume that the right-hand side f is supported within a unit square. When imposing periodic boundary conditions, as mentioned in section 2, one can simply assume that the entire plane is tiled with copies of f centered at the lattice points $\{(i,j)|i,j \in \mathbf{Z}\}$. In order to account for the influence of these images, we follow the approach introduced in [16], the essence of which can already be found in

Lord Rayleigh's classic paper [25]. The main thing to notice is that, after the upward pass in the FMM, we have a net multipole expansion describing the far field due to the entire source distribution f contained in the unit cell centered at the origin:

$$\phi(\mathbf{x}) = \Re\left(\sum_{n=1}^{p} \frac{\alpha_n}{z^n}\right). \tag{20}$$

(There is no logarithmic term since we assume that the source distribution has no net charge.) This is then the expansion for each of the periodic images of the box with respect to its own center. All of these images, except for the nearest neighbors centered at {(-1,-1), (-1,0), (-1,1), (0,-1), (0,1), (1,-1), (1,0), (1,1)}, are well separated from the computational domain itself. Thus, the fields they induce inside the computational domain are accurately representable by a p-term local expansion where, as before, p is the number of terms needed to achieve a relative precision ϵ. This local representation can be written as

$$\Psi_{0,0}(w) = \Re\left(\sum_{n=0}^{p} \beta_n w^n\right). \tag{21}$$

It remains only to obtain the operator mapping the coefficients $\{\alpha_n\}$ to the coefficients $\{\beta_n\}$. We refer the reader to [4, 16, 25] for a discussion of this operator, which is based on the precomputation of certain lattice sums. The reason we denote the local expansion in (21) by $\Psi_{0,0}$ is for consistency of notation with the FMM described above; the *downward pass* is modified in the initialization step. In the remainder of the downward pass and in Step II, only two changes are required; the interaction list and the local computations must be adjusted for boxes near the boundary to account for periodic images. This involves no significant increase in the amount of work.

3.6. Other homogeneous boundary conditions. As noted in section 2, problems with homogeneous Dirichlet and Neumann conditions can be solved using the method of images. Since there is a 2 × 2 "supercell" which tiles the plane periodically, it is straightforward to embed such problems in a periodic version of the FMM. Done naively, this would entail a fourfold increase in CPU time and storage. Careful implementation considerations allow one to recover this overhead, but the details are tedious and will be omitted.

3.7. Inhomogeneous boundary conditions. In order to impose inhomogeneous boundary conditions using potential theory, we need to consider arrangements of single and double layer potentials such as the one depicted in Figure 2. These can be viewed as singular charge distributions and can be handled by the same FMM as above, with three modifications. First, the far field due to a box B with a single layer density σ and a double layer density μ along its boundary Γ is given by

$$\phi(\mathbf{x}) = \Re\left(\alpha_0 \log|x_1 + ix_2 - C| + \sum_{k=1}^{\infty} \frac{\alpha_k}{(x_1 + ix_2 - C)^k}\right), \tag{22}$$

where

$$\alpha_0 = -\frac{1}{2\pi}\int_\Gamma \sigma(s)ds \tag{23}$$

and

$$\alpha_k = -\frac{1}{2\pi}\int_\Gamma \frac{(y_1(s) + iy_2(s) - C)^k \sigma(s)}{k} + (y_1(s) + iy_2(s) - C)^{k-1}\mu(s)\, ds. \tag{24}$$

Here, $(y_1(s), y_2(s))$ is an arclength parametrization of Γ. Second, contributions to the local field from a leaf node containing layer potentials are precomputed as in section 3.2. Finally, the interaction list and the local computations must be adjusted for boxes near the boundary.

3.8. Fast translation operators. Consider a box B centered at X_B, containing sources $\{z_1, \ldots, z_M\}$ with source strengths $\{q_1, \ldots, q_M\}$ and a target box D centered at X_D in its interaction list. We assume for the moment that $\Re(X_D) > \Re(X_B)$. In the original FMM, the field outside B is represented as

$$\phi(\mathbf{x}) = \Re\left(\alpha_0 \log(x_1 + ix_2 - X_B) + \sum_{k=1}^{p} \frac{\alpha_k}{(x_1 + ix_2 - X_B)^k}\right). \tag{25}$$

The field inside D is represented as

$$\phi(\mathbf{x}) = \Re\left(\sum_{l=0}^{p} \beta_l \,(x_1 + ix_2 - X_D)^l\right) \tag{26}$$

with

$$\beta_0 = \alpha_0 \log(X_D - X_B) \;+\; \sum_{k=1}^{\infty} \frac{\alpha_k}{(X_D - X_B)^k}(-1)^k,$$

$$\beta_l = -\frac{\alpha_0}{l \cdot (X_D - X_B)^l} \;+\; \frac{1}{(X_D - X_B)^l} \sum_{k=1}^{\infty} \frac{\alpha_k}{(X_D - X_B)^k} \binom{l+k-1}{k-1} (-1)^k \quad \text{for } l \geq 1.$$

This describes the translation operator denoted by $\mathcal{T}_{ML}$ in section 3.3 and requires $O(p^2)$ work to apply. In [19], Hrycak and Rokhlin suggest an alternative representation of ϕ, based on the formula

$$\frac{1}{z - w} = \int_0^{\infty} e^{-\lambda(z-w)}\, d\lambda. \tag{27}$$

This integral can be discretized using generalized Gaussian quadratures [31] which take into account the nature of the integrand as well as the precise geometry of the interaction list. The number of quadrature nodes needed to achieve a precision ϵ is less than or equal to the number of multipole coefficients. Tables of weights and nodes for various values of ϵ are provided in [31]. For numerical purposes, we begin with an approximation of the form

$$\frac{1}{z_i - w} \approx \sum_{k=1}^{p} w_k e^{-\lambda_k (z_i - w)}.$$

Integrating both sides, we have

$$\log(z_i - w) \approx \sum_{k=1}^{p} \frac{-w_k}{\lambda_k} e^{-\lambda_k (z_i - w)} + C,$$

where C is a constant of integration. Choosing

$$C = \sum_{k=1}^{p} \frac{w_k}{\lambda_k} e^{-\lambda_k}$$

enforces the condition that $\log(1) = 0$.

Instead of the classical multipole expansion (25), we instead work with the *exponential representation*

$$\phi(\mathbf{x}) = \Re\left(\sum_{k=1}^{p} a_k e^{-\lambda_k\,(x_1+ix_2-X_B)} + C'\right), \tag{28}$$

where the coefficients a_k are exponential moments of the charge distribution:

$$a_k = \sum_{j=1}^{M} q_j e^{+\lambda_k\,(z_j-X_B)}$$

and

$$C' = \left(\sum_{j=1}^{M} q_j\right) \cdot C.$$

The advantage of this approach is that translation has been diagonalized. Transmitting the expansion from box B to D is carried out by computing

$$\psi(\mathbf{x}) = \Re\left(\sum_{k=1}^{p} b_k e^{-\lambda_k\,(x_1+ix_2-X_D)} + C'\right), \tag{29}$$

where the new coefficients b_k are obtained from the a_k through the translation formula

$$b_k = a_k\, e^{-\lambda_k(X_D-X_B)}.$$

The details of how to incorporate such expansions into an adaptive two-dimensional FMM code can be found in [19]. For the three-dimensional analogue, see [17].

4. Numerical results. Fast Poisson solvers using the algorithms described above have been implemented in Fortran 77. Here, we demonstrate their performance on four problems involving varying degrees of adaptivity. All of the timings listed below correspond to calculations performed on a 440MHz SUN Ultra-10 with 256 MB RAM using the compiler option (-fast).

There are few efficient adaptive solvers which are widely available. Therefore, we have chosen a simple and stringent standard for comparison: the time taken by a classical FFT-based code for the same number of degrees of freedom (grid points). Using the second order accurate FORTRAN code HWSCRT by Swartztrauber [27] and Swartztrauber and Sweet [28] (available from www.netlib.org), with the same machine and compiler option as above, we obtain the data shown in Table 1.

We have, as yet, said little about our adaptive refinement strategy. It is straightforward. Let B be a leaf node with $k \times k$ grid points, as discussed in section 3.2 and let $f_B(\mathbf{x})$ denote the kth order polynomial used to approximate the right-hand side on B. We then evaluate $f_B(x, y)$ on a $2k \times 2k$ grid covering B and compute the discrete L_2 error $E_2 = \|f(x, y) - f_B(x, y)\|_2$ over these target points. If $E_2 > tol$, the leaf node B is subdivided. Of course, the tree obtained by this procedure may not satisfy the level restriction that neighboring leaf nodes be at most one level apart. It is a straightforward matter to "fix" the tree in a subsequent sweep. We omit the details.

Table 1

Timing results for the FFT-based second order accurate code HWSCRT. N denotes the number of grid points, T_{hwscrt} denotes the required solution time in seconds, and rate denote the number of grid points "processed" per second (N/T_{hwscrt}).

N	T_{hwscrt}	Rate
256×256	0.17	$3.8\ 10^5$
512×512	0.78	$3.4\ 10^5$
1024×1024	4.0	$2.6\ 10^5$
2048×2048	19.4	$2.2\ 10^5$

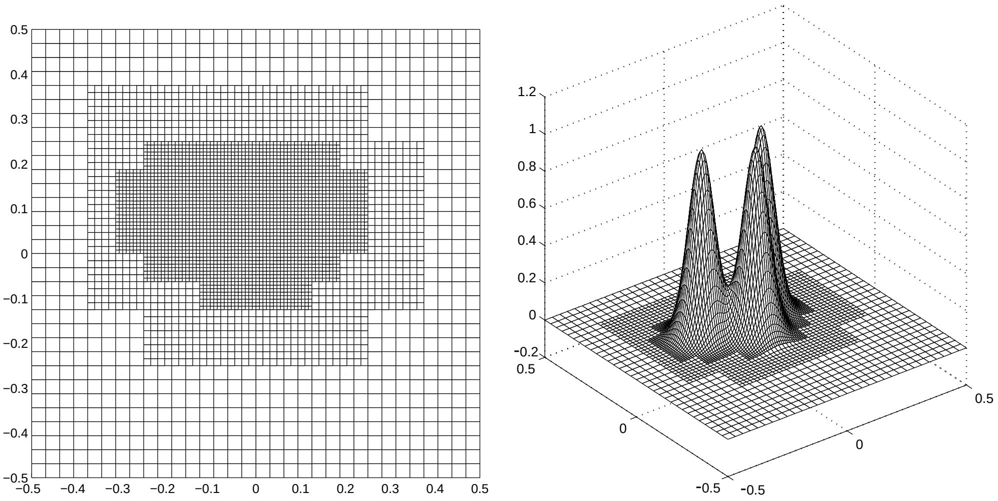

Fig. 4. *The left-hand figure shows an adaptive mesh resolving the source distribution in* (30). *The right-hand figure shows a surface plot of the solution.*

Example 4.1. In our first experiment, we consider the equation

$$\Delta\psi(\mathbf{x}) = \sum_{i=1}^{3} (4\alpha^2\ \|\mathbf{x} - \mathbf{x_i}\|^2 - 4\alpha) e^{-\alpha\|\mathbf{x}-\mathbf{x_i}\|^2} \tag{30}$$

in free space, for which the exact solution (Figure 4) is the sum of three Gaussians

$$\psi(\mathbf{x}) = \sum_{i=1}^{3} e^{-\alpha\|\mathbf{x}-\mathbf{x_i}\|^2}. \tag{31}$$

We consider the case where $\alpha = 250$, $\mathbf{x_1} = (.1, .1)$, $\mathbf{x_2} = (0, 0)$, and $\mathbf{x_3} = (-.15, .1)$. The right-hand side in (30) is supported, with an exponentially small error, in the box $[-0.5, 0.5]^2$, which we use as the computational domain. Our adaptive mesh is depicted in Figure 4. Note that fine grids are created only near the centers of the Gaussians. The performance of the fourth, sixth, and eighth order codes are summarized in Table 2.

Table 2

Timing results for the fourth, sixth, and eighth order accurate codes in Example 4.1. ϵ_{FMM} *denotes the requested precision from far-field interactions within the FMM,* ϵ_{RHS} *denotes the requested precision in discretizing the right-hand side, and* N_{lev} *denotes the number of levels used in the FMM hierarchy.* E_2 *and* E_∞ *denote the relative* L_2 *and* L_∞ *errors of the computed solution,* N *denotes the number of grid points used,* T_{FMM} *denotes the required solution time in seconds, and rate denote the number of grid points "processed" per second* (N/T_{FMM})*.*

10^{-9}	10^{-9}	8	$4.4\ 10^{-10}$	$2.7\ 10^{-9}$	273280	3.62	$7.5\ 10^{4}$
10^{-9}	10^{-12}	9	$4.2\ 10^{-10}$	$2.8\ 10^{-9}$	1281472	16.02	$8.4\ 10^{4}$
10^{-12}	10^{-12}	9	$9.2\ 10^{-13}$	$6.1\ 10^{-13}$	1281472	21.68	$5.9\ 10^{4}$

Example 4.2. For our second experiment, we consider the singular equation

$$\begin{aligned} \Delta\psi &= 0 \quad \text{in } D, \\ \psi &= 0 \quad \text{on } \Gamma_L, \\ \psi &= 0 \quad \text{on } \Gamma_R, \\ \psi &= 1 \quad \text{on } \Gamma_T, \\ \psi &= 0 \quad \text{on } \Gamma_B, \end{aligned} \tag{32}$$

In Figure 5, we plot the solution obtained with our solver on an adaptive grid, the solution obtained by HWSCRT on a uniform 64 × 64 mesh, and the error in the HWSCRT solution. Note that we resolve the corner singularities adaptively and that our solution is exact (up to the requested FMM tolerance), since the data is piecewise polynomial (here, constant).

Remark 4.1. There is an enormous difference in the meaning of "order of accuracy" in our solver and in standard finite difference or finite element codes. Our solver is *exact* for a certain order of approximation of the data. A kth order accurate PDE-based solver on an $N \times N$ mesh has a global error which decays like $(1/N)^k$ with a constant of proportionality which depends on the kth derivative of the solution. In the present example, our solver is exact. The finite difference code is only first order

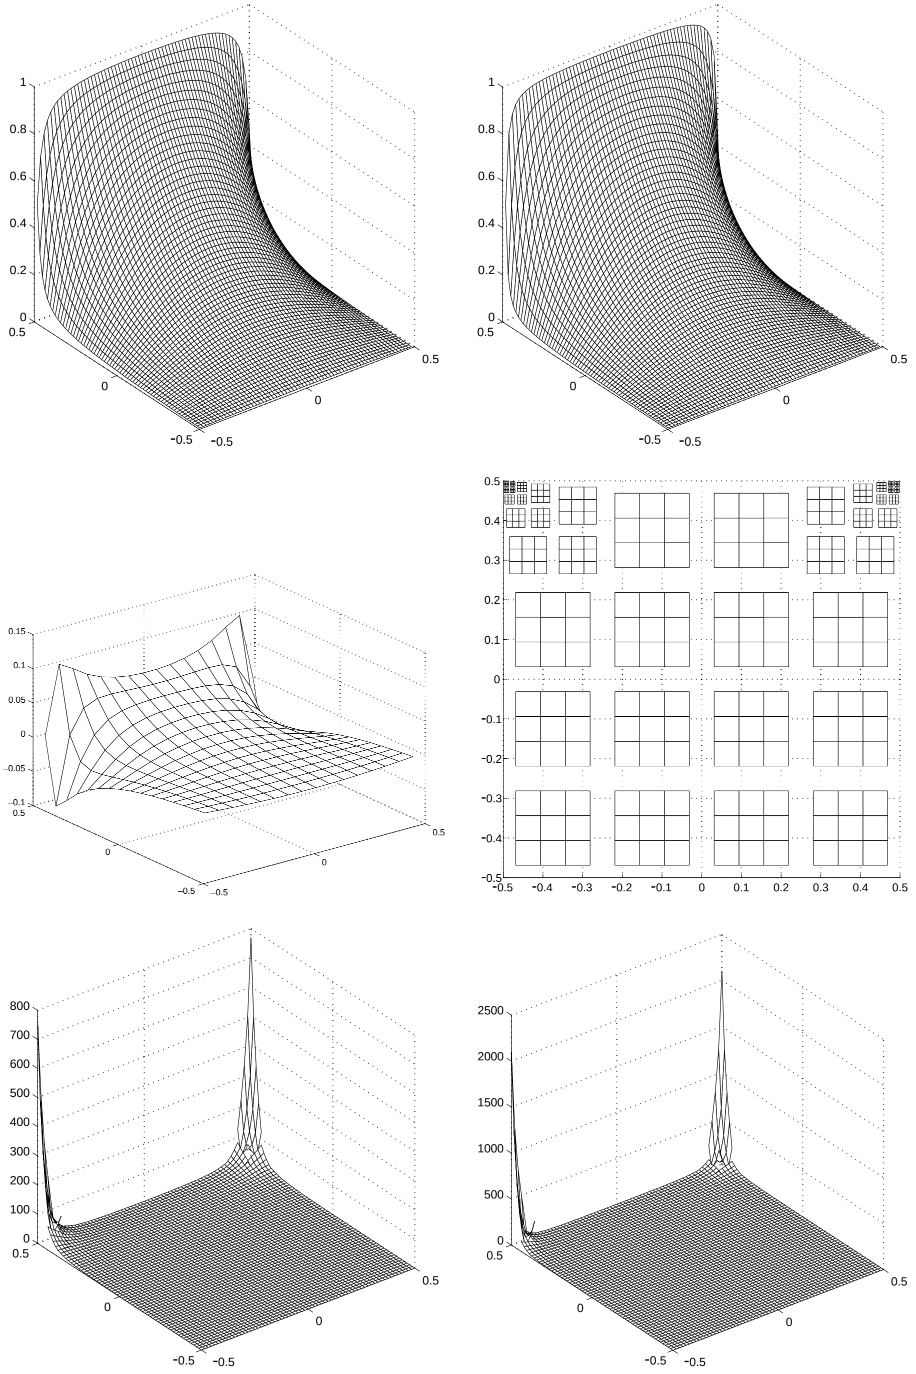

FIG. 5. *The upper left-hand figure shows the solution obtained by HWSCRT to Example* 4.2 *and the upper right-hand figure shows the solution obtained using our solver. The middle figures show the error in the solution obtained by HWSCRT and the adaptive grid use by our solver, respectively. The lower figures show the electrostatic energy* $\|\nabla\psi\|^2$ *obtained from HWSCRT and our solver, respectively.*

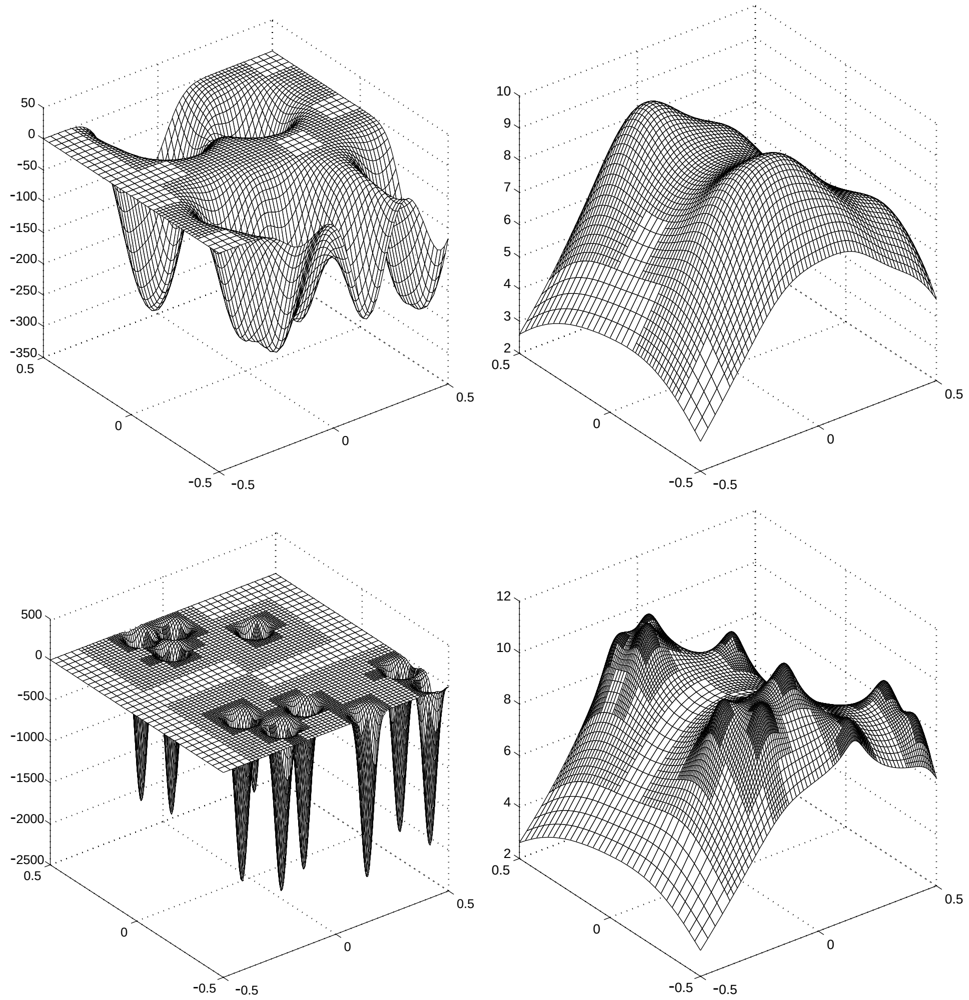

FIG. 6. *The left-most figure shows a surface plot of the right-hand side for* 10 *randomly placed Gaussians as described in* (33) *with* $\alpha = 100$ *and the figure to the right of it shows the corresponding solution. The two lower figures show both the right-hand side and corresponding solution for* $\alpha =$ 1000*.*

accurate because of the corner singularities.

Example 4.3. In order to evaluate the performance of our code with widely varying degrees of adaptivity, we consider the source distribution

$$\Delta\psi(\mathbf{x}) = \sum_{i=1}^{10} -2\alpha e^{-\alpha\|\mathbf{x}-\mathbf{x_i}\|^2} \tag{33}$$

in free space. With $\alpha = 100$, the distribution is fairly smooth, while with $\alpha = 1000$, the Gaussians fall off sharply and require many levels of refinement near the centers (see Figure 6). The experiment was run using the fourth order code and $\epsilon_{FMM} = \epsilon_{RHS} = 10^{-6}$. Table 3 lists our timing data for various values of α.

In addition to comparing various levels of adaptivity, it is also worth noting that

Table 3
Timings for the FMM-based solver in Example 4.3.

M	N	T_{FMM}	Rate	N	T_{FMM}	Rate
	$\alpha = 100$			$\alpha = 250$		
5	43969	0.44	9.9 10^4	73840	0.76	9.7 10^4
10	70864	0.68	1.0 10^5	138640	1.43	9.7 10^4
25	119296	1.33	8.9 10^4	212800	2.06	1.0 10^5
100	233296	2.43	9.6 10^4	262144	2.60	1.0 10^5
	$\alpha = 500$			$\alpha = 1000$		
5	97648	1.08	9.0 10^4	108544	1.17	9.3 10^4
10	196336	2.09	9.4 10^4	225616	2.40	9.4 10^4
25	377248	4.03	9.4 10^4	460912	4.96	9.3 10^4
100	785632	8.39	9.4 10^4	916336	9.44	9.7 10^4

Table 4
Timings for the FMM-based solver in Example 4.3 *using free-space and periodic boundary conditions.*

M	N	T_{FMM}	Rate	N	T_{FMM}	Rate
	Free space			Periodic		
10	138640	1.43	9.7 10^4	139696	1.63	8.6 10^4
30	241168	2.38	1.0 10^5	241552	2.63	9.2 10^4
50	253696	2.41	1.0 10^5	253840	2.62	9.7 10^4
100	262144	2.60	1.0 10^5	262192	2.94	8.9 10^4

the periodic and free-space solvers execute in nearly the same time. To show this, we consider a right-hand side given by

$$\Delta\psi(\mathbf{x}) = \sum_{i=1}^{M} (-1)^i 2\alpha e^{-\alpha\|\mathbf{x}-\mathbf{x_i}\|^2}. \tag{34}$$

This ensures that the net charge in the periodic cell is zero. Table 4 compares the performance of the fourth order accurate code with either free-space or periodic boundary conditions with $\alpha = 250$ and $\epsilon_{FMM} = \epsilon_{RHS} = 10^{-6}$.

Example 4.4. Most of the preceding examples involve adaptive refinement around a "point-like" singularity. Here we consider the case of a singularity along a curve. We simply define a source distribution which takes the value 1 inside a circle of radius .25 and 0 outside. The right-hand side is shown in Figure 7 along with the computed solution. Using the fourth order solver with 7 levels or refinement and 7936 grid points, the L_2 and L_∞ errors are less than 10^{-3} and the solver executes at the rate 1.3 10^5 points per second. Using the sixth order solver with 12 levels or refinement and 681,408 grid points, the L_2 and L_∞ errors are less than 10^{-6} and the solver executes at the rate 8.5 10^4 points per second. Both of these timings are comparable to those in Example 4.1.

The following observations can be made from the preceding data.

1. The timings for the FMM-based solver grow linearly with the number of unknowns. For fourth order accuracy with a three-digit FMM tolerance, the present implementation achieves a processing speed between 5.9 10^4 and 1.5 10^5 points per second. The classical second order FFT-based solver processes 2.6 10^5 points per second on a 1024 × 1024 grid.
2. For three-digit accuracy, the fourth order accurate code is fastest ($\approx$ 1.4 10^5 points per second), while for six-digit accuracy, the sixth order accurate code

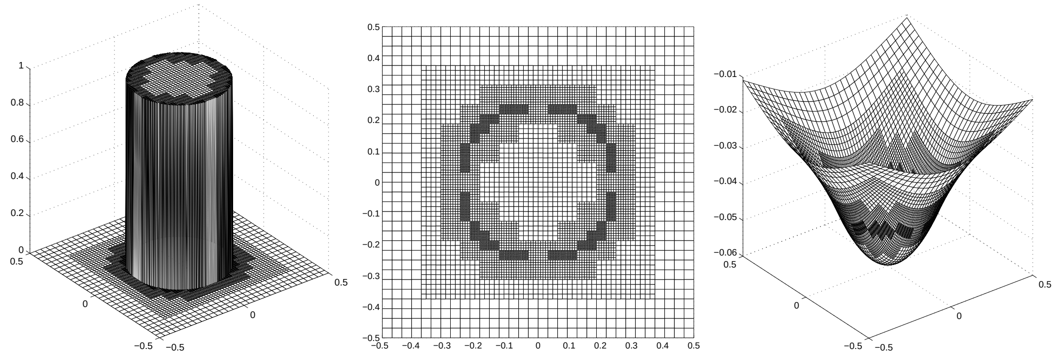

Fig. 7. *The left-hand figure shows the right-hand side. The middle figure shows the grid and the right figure shows the solution.*

is fastest ($\approx 1.1\ 10^5$ points per second). For twelve-digit accuracy, the sixth and eighth order codes are only about twice as slow ($\approx 6.3\ 10^4$ points per second).

5. Conclusions. We have developed a new adaptive, high order accurate solver for the Poisson equation in two dimensions. The method is direct, fast-multipole-based, and allows for the specification of a variety of boundary conditions on a unit square. These include free-space conditions, periodic boundary conditions, Dirichlet, Neumann, and a variety of mixed conditions. The amount of work scales linearly with the number of degrees of freedom in the computational domain and is competitive with classical FFT-based solvers in terms of *work per grid point*, despite the flexibility of adaptive mesh refinement.

In order to develop a black box Poisson solver of broad interest, of course, we need to allow for complex geometry. It would also be of value to be able to solve the Helmholtz and linearized Poisson–Boltzmann equations,

$$\Delta u + \lambda^2 u = f \qquad \text{and} \qquad \Delta u - \lambda^2 u = f,$$

with a similar approach. These extensions are underway and will be reported at a later date.

QMR-BASED PROJECTION TECHNIQUES FOR THE SOLUTION OF NON-HERMITIAN SYSTEMS WITH MULTIPLE RIGHT-HAND SIDES[*]

MISHA KILMER[†], ERIC MILLER[‡], AND CAREY RAPPAPORT[‡]

Abstract. In this work we consider the simultaneous solution of large linear systems of the form $Ax^{(j)} = b^{(j)}, j = 1, \ldots, K$, where A is sparse and non-Hermitian. We describe single-seed and block-seed projection approaches to these multiple right-hand side problems that are based on the QMR and block QMR algorithms, respectively. We use (block) QMR to solve the (block) seed system and generate the relevant biorthogonal subspaces. Approximate solutions to the nonseed systems are simultaneously generated by minimizing their appropriately projected (block) residuals. After the initial (block) seed has converged, the process is repeated by choosing a new (block) seed from among the remaining nonconverged systems and using the previously generated approximate solutions as initial guesses for the new seed and nonseed systems. We give theory for the single-seed case that helps explain the convergence behavior under certain conditions. Implementation details for both the single-seed and block-seed algorithms are discussed and advantages of the block-seed algorithm in cache-based serial and parallel environments are noted. The computational savings of our methods over using QMR to solve each system individually are illustrated in two examples.

Key words. QMR, projection, Krylov subspace, iterative methods, block Krylov

1. Introduction.

In many applications one desires the solution of multiple linear systems of the form

$$Ax^{(j)} = b^{(j)}, \quad j = 1, \ldots, K, \tag{1.1}$$

involving the same $N \times N$ coefficient matrix A but K different right-hand sides $b^{(j)}$, all of which are available simultaneously. Such problems arise, for instance, in the numerical solution of frequency-domain electromagnetic wave scattering; here, the right-hand sides might correspond to incident fields over the scatterer induced either by plane waves at various angles of incidence or by excitation sources at different locations.

Systems involving large, sparse matrices make good candidates for solution by iterative Krylov subspace methods since storage is kept to a minimum and matrix-vector products can be done efficiently. However, the naive approach of solving each of the K linear systems independently using a Krylov subspace method does not take advantage of the fact that the $b^{(j)}$'s, and hence the $x^{(j)}$'s, may be *closely related* due to the underlying physical nature of the problem. By closely related, we mean that the solution to the jth system has large components in the initial directions of the k-dimensional ($k \ll N$) Krylov subspace generated from one of the other systems. Projection-type techniques for both the Hermitian and non-Hermitian cases,

discussed in more detail below, that specifically exploit such shared information have been proposed (e.g., see [5, 26, 24] and the references therein).

Another alternative is to use a block Krylov subspace algorithm to solve the systems simultaneously [16, 23, 4, 8, 15]. Essentially these methods seek solutions in block Krylov subspaces, or some deflated version thereof, generated by the matrix A and the $N \times K$ matrix $R = B - AX_0$; here the columns of B are the $b^{(j)}$ and the columns of X_0 are the initial estimates for each of the systems. However, this approach can be more expensive in terms of storage than projection techniques because the length of the recurrences to update the iterates depends on the number of right-hand sides, or, in the case of deflation [8], the number of right-hand sides corresponding to the deflated Krylov sequences. Also, if a deflation technique is used, a deflation tolerance must be specified in advance, and we have found in experiments that the performance and convergence of the systems depend in a somewhat unpredictable manner on this value. On the other hand, block Krylov subspace algorithms have the advantage that they are better suited to parallelism [17, 14, 15] and make use of higher level BLAS [2]. Therefore, in this paper we develop new single and block-seed projection approaches based on the QMR and block QMR algorithms, respectively; our block-seed method exploits the best properties of the block QMR algorithm while preserving the basic properties of our sequential projection technique. To our knowledge, ours is the first block-seed projection algorithm for non-Hermitian linear systems with multiple right-hand sides; in particular, as our algorithm is built around the BL-QMR algorithm of [8], it incorporates a deflation strategy.

Specifically, the idea of a projection technique is to first select one of the systems as “seed” and solve it by an iterative Krylov subspace method. As the relevant subspaces are generated, the approximations to the other systems are simultaneously updated by projecting the residual onto a particular subspace and by either enforcing a Galerkin-type condition [11, 25] or minimizing the projected residual [24]. Such methods are sometimes referred to as Lanczos–Galerkin approaches [21].

Smith [25] and Joly [11] both consider a projection approach based on BiCG for nonsymmetric A. In [11] a similar approach for CGS is also given. However, the BiCG-projection approach can exhibit the potentially erratic convergence behavior observed when applying BiCG to a single linear system (see the results in [24]). Simoncini and Gallopoulos [24] also present an approach to solving (1.1) when A is nonsymmetric.

Our single-seed projection algorithm is most similar in concept to the project-minimize approach in [24]. However, as a result of the underlying unsymmetric Lanczos process, we do not need to store the basis vectors, we do not need to predetermine a subspace dimension, and we show that the approximate solutions and residuals to the nonseed systems are cheaply computed and available at every stage of the algorithm because they are updated with short-term recurrences. Since we are minimizing quantities rather than enforcing Galerkin conditions, the convergence behavior should be less erratic than methods based on the latter. As noted and as we illustrate in Theorem 3.4, the success of our single-seed method depends on the closeness, in the sense described above, among the right-hand sides. The block-seed approach we introduce here is more efficient when the right-hand sides are not all close.

This paper is organized as follows. In section 2, we give the necessary background on the QMR approach. We give an outline of our single-seed projection approach and discuss its convergence in section 3. Background on the block QMR algorithm is presented in section 4. The block variant of our QMR-projection algorithm is reported in section 5, and related computational issues are discussed in section 6. Section 7 gives numerical results, and section 8 reports conclusions and future work.

2. Background: The QMR algorithm.

The quasi-minimal residual (QMR) algorithm was introduced by Freund and Nachtigal in [9]. The original algorithm was based on three-term recurrences. In [10], the authors proposed a mathematically equivalent algorithm which employed coupled two-term recurrences. Since the latter variant has been found to be more numerically stable for solving linear systems, in numerical experiments we use this implementation. However, to simplify the notation in this section and in section 3, and to be consistent with the notation in section 5, we will follow the notation in [9]. Further, for simplicity, we consider only the version without look-ahead but note that our algorithm could be adapted to account for look-ahead.

In the remainder of the paper, the notation $\|\cdot\|$ always refers to the Euclidean norm $\|\cdot\|_2$. The superscript T is used to denote the transpose operation, and superscript $*$ is used to denote the conjugate transpose operation.

A Krylov subspace of dimension k generated by a matrix G and a vector q is defined according to

$$K_k(G, q) = \text{span}\{q, Gq, G^2q, \ldots, G^{k-1}q\}.$$

The QMR algorithm is a Krylov-subspace-based iterative method that can be used to solve non-Hermitian linear systems of the form $Ax = b, \;\; A \in \mathcal{C}^{N \times N}$. At the kth iteration, the current solution estimate has the form

$$x_k = x_0 + V_k z_k, \tag{2.1}$$

where x_0 denotes the initial guess and $V_k = [v_1, v_2, \ldots, v_k]$ is an $N \times k$ matrix whose columns are basis vectors for $K_k(A, v_1)$ with $v_1 = r_0/\|r_0\|$ and $r_0 = b - Ax_0$. The length k vector z_k is chosen as the solution to a particular minimization problem, as discussed below. Those basis vectors are generated via the nonsymmetric Lanczos process (see [22]) and are constructed to be biorthogonal to vectors $w_i, i = 1, \ldots, k$, which form a basis for $K_k(A^T, w_1)$.[1] The columns of the $N \times k$ matrix W_k are the w_i.

From biorthogonality it follows that

$$W_{k+1}^T V_{k+1} = D_{k+1}, \;\; D_{k+1} = \text{diag}(\delta_1, \ldots, \delta_{k+1}), \qquad \delta_i \neq 0. \tag{2.2}$$

Also as a result of the Lanczos algorithm we obtain the relation

$$AV_k = V_{k+1}\bar{T}_k, \tag{2.3}$$

where $\bar{T}_k$ is a $(k+1) \times k$ tridiagonal matrix. Using (2.1), (2.2), and (2.3), and setting $\beta = \|r_0\|$, at the kth iteration the residual, $r_k = b - Ax_k$, is given by [22]

$$r_k = V_{k+1}(\beta e_1 - \bar{T}_k z_k), \tag{2.4}$$

where e_1 denotes the first Cartesian unit vector. Since the columns of V_{k+1} are not orthonormal,

$$\|r_k\| \leq \|V_{k+1}\| \|\beta e_1 - \bar{T}_k z_k\|.$$

[1] Here we always take $w_1 \equiv v_1$, but note that other choices are possible. A version of the algorithm is also possible using $K_k(A^*, w_1)$ for the second Krylov subspace.

The QMR algorithm determines z_k by minimizing the norm of the quasi-residual term [9]; that is,

$$z_k = \arg \min_{z \in \mathcal{C}^{k \times 1}} \|\beta e_1 - \bar{T}_k z\|.$$

We make the following alternate observation. From (2.4) and using biorthogonality,

$$\|D_{k+1}^{-1} W_{k+1}^T r_k\| = \|\beta e_1 - \bar{T}_k z_k\|.$$

Thus, the z_k which defines the kth QMR iterate can also be thought of as the one that minimizes the norm of the residual projected onto a smaller dimensional subspace. We will make use of this alternate definition of the QMR iterates in subsequent sections.

3. The single-seed QMR-projection algorithm. In this section we describe a single-seed QMR-projection algorithm for solving linear systems of the form (1.1). Our algorithm proceeds as follows. First, we select one system, say, system j, to serve as "seed" and apply QMR (without look-ahead) to the seed system. In the following, we use $r_0^{j,l}$ to denote the initial residual to system l, where l denotes the index of any of the nonconverged systems given the starting guess $x_0^{j,l}$. We use $r_k^{j,l}$ to denote the residual of system l after k iterations. Since different choices of seed lead to different Krylov subspaces and hence different iterates, the superscript j is used to denote that this is the residual at the kth iteration for system l when system j was used as seed. By the beginning of the kth iterate, QMR has generated biorthogonal bases for two k-dimensional Krylov subspaces, $K_k(A, r_0^{j,j})$ and $K_k(A^T, r_0^{j,j})$. We denote the respective bases by the vectors $v_{j,i}$ and $w_{j,i}$, $i = 1, \ldots, k$: the subscript j is used to indicate that this particular set was generated using system j as seed. These vectors are the columns of the $N \times k$ matrices $V_{j,k}$ and $W_{j,k}$, respectively. The corresponding $(k+1) \times k$ tridiagonal matrix is denoted as $\bar{T}_{j,k}$ (compare to (2.3)). By the end of the kth iterate, QMR has also generated the unnormalized versions of the vectors $v_{j,k+1}$ and $w_{j,k+1}$ for use in the $(k+1)$st iteration.

Let us comment on the values of $x_0^{j,l}$. If we suppose that j was the seed system and converged after m steps and that the index of the next seed system is j^*, then we set $x_0^{j^*,l} = x_m^{j,l}$ for all indices l such that system l has not already converged.

In the previous section, we have seen that the kth iterate corresponding to the seed system is given by

$$x_k^{j,j} = x_0^{j,j} + V_{j,k} z_k^{j,j} \quad \text{with } z_k^{j,j} = \arg \min_{z \in \mathcal{C}^{k \times 1}} \|\beta e_1 - \bar{T}_{j,k} z\|.$$

Now we also want the kth iterate of the (nonconverged) nonseed system, say, system l, to lie in $x_0^{j,l} + K_k(A, r_0^{j,l})$, in other words,

$$x_k^{j,l} = x_0^{j,l} + V_{j,k} z_k^{j,l}, \quad l \neq j. \tag{3.1}$$

Next we must decide how to define $z_k^{j,l}$. From (2.3) (with $V_{j,k}$ in place of V_k) and (3.1),

$$\begin{aligned} r_k^{j,l} &= b^{(l)} - A x_k^{j,l} \\ &= r_0^{j,l} - V_{j,k+1} \bar{T}_{j,k} z_k^{j,l}. \end{aligned} \tag{3.2}$$

Therefore, using biorthogonality,

$$\|D_{j,k+1}^{-1} W_{j,k+1}^T r_k^{j,l}\| = \|D_{j,k+1}^{-1} W_{j,k+1}^T r_0^{j,l} - \bar{T}_{j,k} z_k^{j,l}\|.$$

Finally, we use the above equality to determine $z_k^{j,l}$:

$$z_k^{j,l} = \arg \min_{z \in \mathcal{C}^{k \times 1}} \|D_{j,k+1}^{-1} W_{j,k+1}^T r_0^{j,l} - \bar{T}_{j,k} z\|. \tag{3.3}$$

3.1. Computational issues. Let us sketch how to efficiently compute the iterates and residuals of the nonseed systems. More details can be found in [13]. As above, we will use the index l to denote an arbitrary nonseed system and j to denote the seed system.

Let the QR decomposition of $\bar{T}_{j,k}$ be

$$\bar{T}_{j,k} = Q_{j,k}^* \begin{bmatrix} R_{j,k} \\ 0 \end{bmatrix},$$

where $Q_{j,k}$ is a product of Givens rotations and $R_{j,k}$ is $k \times k$ upper triangular with upper bandwidth 2. It can be shown [13] that using the QR factorization to solve (3.3) results in the easily solved system

$$z_k^{j,l} = R_{j,k}^{-1} t_k^{j,l}, \tag{3.4}$$

where $t_k^{j,l}$ differs from $t_{k-1}^{j,l}$ only in its last entry, which we shall denote by $y_k^{j,l}$. The norm of the projected residual in (3.3) is given by the scalar $|\tau_{k+1}^{j,l}|$. Further, $\tau_{k+1}^{j,l}$ and $y_k^{j,l}$ can be updated from $\gamma_{k+1}^{j,l}$ and $\tau_k^{j,l}$ with $\delta_{j,k} \equiv w_{j,k}^T v_{j,k}$:

$$\begin{bmatrix} y_k^{j,l} \\ \tau_{k+1}^{j,l} \end{bmatrix} = \begin{bmatrix} c_{j,k} & s_{j,k} \\ -\bar{s}_{j,k} & c_{j,k} \end{bmatrix} \begin{bmatrix} \tau_k^{j,l} \\ \gamma_{k+1}^{j,l} \end{bmatrix} \quad \text{with } \gamma_{k+1}^{j,l} \equiv \frac{1}{\delta_{j,k+1}} w_{j,k+1}^T r_0^{j,l}, \tag{3.5}$$

where $c_{j,i} \in \mathcal{R},\ s_{j,i} \in \mathcal{C},\ c_{j,i}^2 + |s_{j,i}|^2 = 1$.

As in equation (4.8) of [9], we define $P_{j,k} = [p_{j,1}, p_{j,2}, \ldots, p_{j,k}] \equiv V_{j,k} R_{j,k}^{-1}$. Since $R_{j,k}$ is upper triangular with bandwidth 2, there is a short-term recurrence relation for the $p_{j,k}$ [9]. Using (3.1) and (3.4), the kth iterate of the lth system is given by

$$x_k^{j,l} = x_{k-1}^{j,l} + y_k^{j,l} p_{j,k}. \tag{3.6}$$

From this, we derive an iterative update for $r_k^{j,l}$ that does not require any additional matrix-vector products per iteration as follows.

LEMMA 3.1. *The residual at the kth iteration corresponding to the lth system is given by*

$$r_k^{j,l} = r_{k-1}^{j,l} - y_k^{j,l} f_{j,k}, \quad \textit{where} \quad f_{j,k} \equiv A p_{j,k},$$

and can be computed in $O(N)$ flops.

Proof. The proof follows from (3.6), the bandedness of $R_{j,k}$, and the definition of $p_{j,k}$ above. (A detailed proof can be found in [13].) □

3.2. Seed selection. Clearly, the success of our QMR-projection approach at reducing the total number of matrix-vector products needed to solve all the systems to the desired tolerance depends on which and in what order systems are selected as seed. We use the approach in [24]; namely, we choose the seed index j such that the norm of the residual of the corresponding system is larger than all the remaining nonconverged systems. Developing more informed selection heuristics remains a subject for future research.

3.3. Theory. Suppose that QMR has been run once and that the initial seed system has converged after m steps. Our algorithm proceeds by choosing another seed and using as its initial guess that solution obtained via projection as the first system was solved. One of the results of this section is that in exact arithmetic, assuming A is diagonalizable, if some of the right eigenvectors are well approximated by Ritz vectors corresponding to the first Krylov subspace generated, the rate of convergence of the second seed system behaves as if the corresponding part of the spectrum of A is cut off. The proof technique follows along the lines of the proof of Lemma 3.2 in [5]. $\kappa_2(\cdot)$ denotes the 2-norm condition number of the argument.

We assume A is diagonalizable with eigendecomposition $A = \hat{Z}\Lambda\hat{S}$, where $\hat{S} = \hat{Z}^{-1}$. Here $\Lambda = \text{diag}(\lambda_1, \ldots, \lambda_N)$. We use $\hat{z}_j$ to denote the jth column of $\hat{Z}$ and $\hat{s}_j^*$ to denote the jth row of $\hat{S}$. Without loss of generality, we may assume that $\|\hat{z}_j\| = 1$. After step m of QMR applied to the seed system, let $T_{1,m}U_{1,m} = U_{1,m}\Sigma_{1,m}$ be the eigendecomposition of $T_{1,m}$, where $T_{1,m}$ denotes the tridiagonal $m \times m$ leading submatrix of $\bar{T}_{1,m}$. Since QMR is built on top of the unsymmetric Lanczos process, in exact arithmetic if m is large enough, we expect some of the Ritz vectors given by the columns of $V_{1,m}U_{1,m}$ to be good approximations to, say, $n \leq m$ of the right eigenvectors[2] [1, 6, 7, 2] (assuming these eigenvectors are present in the starting vector for the first seed system). Under these definitions and assumptions, we have the following.

THEOREM 3.2. *Consider two systems $Ax^{(1)} = b^{(1)}$ and $Ax^{(2)} = b^{(2)}$ with A an $N \times N$ matrix. Let $x_0^{2,2}$ be the starting vector for the second system obtained via our projection approach after m steps of QMR have been run using the first system as seed; that is, $x_0^{2,2} = x_m^{1,2}$.*

Define $\mathcal{I}$ as the set of indices of the n right eigenvectors that are well approximated by $n \leq N$ of the m Ritz vectors $V_{1,m}U_{1,m}$. Define $\bar{x}_0^{2,2}$ such that $x^{(2)} - \bar{x}_0^{2,2}$ is the projection of $x^{(2)} - x_0^{2,2}$ on $\text{span}\{\hat{z}_j, j \notin \mathcal{I}\}$. Let $\bar{x}_i^{2,2}$ be the ith iterate of GMRES applied to system 2 with initial guess $\bar{x}_0^{2,2}$. Then for any i

$$\|b^{(2)} - Ax_i^{2,2}\| \leq \kappa_2(V_{2,i+1})(\|b^{(2)} - A\bar{x}_i^{2,2}\| + \delta),$$

where

$$\delta = \sum_{k \in \mathcal{I}} |\lambda_k \tilde{p}(\lambda_k)||\hat{s}_j^* P_m e_0^{1,2}|,$$

$\tilde{p}$ is a particular i-degree polynomial with constant term 1, $e_0^{1,2} \equiv x^{(2)} - x_0^{1,2}$, and $P_m \equiv I - V_{1,m}(\bar{T}_{1,m}^* \bar{T}_{1,m})^{-1}\bar{T}_{1,m} D_{1,m+1}^{-1} W_{1,m+1}^T A$ is a projector.

Proof. Since A is diagonalizable, $e_0^{2,2} \equiv x^{(2)} - x_0^{2,2} = \sum_{k=1}^{N} \phi_k \hat{z}_k$ for some expansion coefficients ϕ_k. Hence, by definition

$$b^{(2)} - Ax_0^{2,2} = \sum_{k=1}^{N} \phi_k \lambda_k \hat{z}_k, \tag{3.7}$$

$$b^{(2)} - A\bar{x}_0^{2,2} = \sum_{k \notin \mathcal{I}} \phi_k \lambda_k \hat{z}_k. \tag{3.8}$$

[2] We caution the reader that our notation is somewhat unconventional, as we use n simply to denote an index $n \leq N$ and N to denote the dimension of the matrix.

Now if $\bar{x}_i^{2,2}$ is the ith GMRES iterate with $\bar{x}_0^{2,2}$ as the initial guess, there exists a polynomial $\tilde{p}_i$ of degree less than or equal to i with $\tilde{p}_i(0) = 1$ such that

$$b^{(2)} - A\bar{x}_i^{2,2} = \sum_{k \notin \mathcal{I}} \phi_k \lambda_k \tilde{p}_i(\lambda_k) \hat{z}_k, \tag{3.9}$$

where $\tilde{p}_i$ satisfies

$$\tilde{p}_i = \arg\min_{p \in \bar{\Pi}^i} \|p(A)(b^{(2)} - A\bar{x}_0^{2,2})\|. \tag{3.10}$$

Here, $\bar{\Pi}^i$ denotes the set of all polynomials with degree less than or equal to i with constant term 1. From Theorem 7.1 in [22], we have a bound on the ith QMR residual in terms of the ith GMRES residual:

$$\|b^{(2)} - Ax_i^{2,2}\| \le \kappa_2(V_{2,i+1}) \min_{p \in \bar{\Pi}^i} \|p(A)(b^{(2)} - Ax_0^{2,2})\|. \tag{3.11}$$

Also,

$$\min_{p \in \bar{\Pi}^i} \|p(A)(b^{(2)} - Ax_0^{2,2})\| \le \|\tilde{p}_i(A)(b^{(2)} - Ax_0^{2,2})\| = \|\sum_{k=1}^{N} \phi_k \lambda_k \tilde{p}_i(\lambda_k) \hat{z}_k\|. \tag{3.12}$$

Substituting this into (3.11) and using (3.9) and the triangle inequality gives

$$\|b^{(2)} - Ax_i^{2,2}\| \le \kappa_2(V_{2,i+1}) \left(\|b^{(2)} - A\bar{x}_i^{2,2}\| + \sum_{k \in \mathcal{I}} |\lambda_k \tilde{p}_i(\lambda_k)||\phi_k| \right). \tag{3.13}$$

Using the definition of $x_0^{2,2}$ as $x_m^{1,2}$, it is straightforward to show

$$e_0^{2,2} = (I - V_{1,m}(\bar{T}_{1,m}^* \bar{T}_{1,m})^{-1} \bar{T}_{1,m}^* D_{1,m+1}^{-1} W_{1,m+1}^T A) e_0^{1,2} = P_m e_0^{1,2}.$$

It is easy to see that P_m is a projector since $(P_m)^2 = P_m$. By the definition of $e_0^{2,2}$ it follows that $P_m e_0^{1,2} = \sum_{k=1}^N \phi_k \hat{z}_k$. Using $\hat{s}_j^* \hat{z}_k = 1$ if $j = k$ and 0 otherwise leads to

$$|\hat{s}_j^* P_m e_0^{1,2}| = |\phi_j| \quad j \in \mathcal{I}. \tag{3.14}$$

Substituting (3.14) into (3.13), we obtain the desired result. □

Now let us discuss why we expect δ to be small. First, it is clear that in exact arithmetic the Ritz vectors lie in $\mathcal{N}(P_m)$. For any vector $q \in \mathcal{C}^N$, since Z is full rank we may write $q = \hat{Z}c$ for the vector of expansion coefficients $c = \hat{Z}^{-1}q = \hat{S}q$ with components $c_j = \hat{s}_j^* q$. Now suppose $q \in \mathcal{R}(P_m)$. Since the columns of Z with indices in $\mathcal{I}$ are approximated by n of the m Ritz vectors, by assumption, and since the Ritz vectors are in $\mathcal{N}(P_m)$, this implies $c_j \approx 0, j \in \mathcal{I}$, which by definition means $\hat{s}_j^* q \approx 0, j \in \mathcal{I}$. Therefore, with $q \equiv P_m e_0^{1,2}$, $|\phi_j| \approx 0, j \in \mathcal{I}$, so δ should be small in exact arithmetic. It is clear that the quality of the Ritz vector approximation and loss of biorthogonality (e.g., the actual $\mathcal{N}(P_m)$) will affect the size of δ in practice.

Using the definition of $\tilde{p}_i$ in (3.10), we obtain in analogy with the standard GMRES upper bound for diagonalizable matrices [22] the following corollary.

Corollary 3.3. *Let $\hat{Z}_n$ denote the $N \times (N-n)$ matrix with columns $\hat{z}_j$ for $j \notin \mathcal{I}$. Then with δ defined as in Theorem* 3.2 *and P being the $(N-n) \times N$ matrix whose rows are the transposed unit vectors $e_k^T, k \notin \mathcal{I}$,*

$$\|b^{(2)} - Ax_i^{2,2}\|_2 \le \kappa_2(V_{2,i+1}) \left(\min_{p \in \Pi^i} \max_{\substack{\lambda_k \\ k \notin \mathcal{I}}} |p(\lambda_k)| \, \|\hat{Z}_n\| \, \|P\hat{S}\bar{r}_0^{2,2}\| + \delta \right).$$

Proof. The proof follows from the result of the theorem by first writing (3.9) as $\hat{Z}_n\tilde{p}(\hat{\Lambda})\sum_{k\notin\mathcal{I}}\phi_k\lambda_k e_k$, where $\hat{\Lambda}$ is $\mathrm{diag}(\lambda_k)_{k\notin\mathcal{I}}$, using the identity $e_k = P\hat{S}\hat{z}_k$, and taking norms. □

Thus, under the assumptions we stated at the beginning of this section so that n right eigenvectors with indices in $\mathcal{I}$ of A have been captured when the first seed system is solved, the second seed system converges in exact arithmetic as if the corresponding part of the spectrum of A has been cut off. The strength of this statement in practice is based on the size of δ, which is affected in finite precision arithmetic as noted above.

In the next theorem, we bound the residual norms of the nonseed systems. A proof and detailed discussion of the size of the upper bound are given in [13]. In short, when the right-hand sides are close and the quasi-residual of the seed system is being efficiently reduced, so are the residuals of the nonseed system.

THEOREM 3.4. *Let j denote the index of the seed system and l denote the index of a (nonconverged) nonseed system. Then*

$$\begin{aligned}(3.15)\quad \|r_k^{j,l}\| \le \sqrt{k+1}&\left(|\gamma_1^{j,l}|\left|\prod_{i=0}^{k-1}s_{j,k-i}\right| + \sum_{i=0}^{k-1}|\gamma_{k-i+1}^{j,l}||c_{j,k-i}|\left|\prod_{m=0}^{i-1}s_{j,k-m}\right|\right)\\ &+\sqrt{N-k-1}\|h_k^{j,l}\|,\end{aligned}$$

where $h_k^{j,l} = [\gamma_{k+2}^{j,l},\ldots,\gamma_N^{j,l}]^T$ and $s_{j,k}, c_{j,k}$ are as defined in section 3.1.

4. BL-QMR background.

The BL-QMR algorithm of Freund and Malhotra attempts to solve (1.1) in the following way. First, given K vectors r_i and p vectors l_i, they define

$$R = [r_1,\ldots,r_K], \quad L = [l_1,\ldots,l_p].$$

The block Krylov sequences generated by R, A and L, A^T are

$$(4.1)\qquad \left\{R, AR, A^2R,\ldots,A^{j-1}R,\ldots\right\} \text{ and } \left\{L, A^TL,\ldots,(A^T)^{j-1}L,\ldots\right\}.$$

However, if $A^{j-1}r_i$ (likewise $(A^T)^{j-1}l_i$) is linearly or nearly linearly dependent on the previous vectors, so are all A^kr_i (likewise $(A^T)^kl_i$) for $k \ge j$. Thus, Freund and Malhotra propose scanning the vectors in the two sequences in (4.1) from left to right and deleting those which are linearly or nearly linearly dependent on previous ones. In the process they obtain deflated Krylov sequences whose vectors are linearly independent. We refer to the n-dimensional subspaces generated by these deflated sequences as $K_n^{\mathrm{dl}}(A,R)$ and $K_n^{\mathrm{dl}}(A^T,L)$. Note that in the presence of no deflation, $K_n^{\mathrm{dl}}(A,R)$ and $K_n^{\mathrm{dl}}(A^T,L)$ are spanned by the first n columns of (4.1) with $n \le jK$ or $n \le jp$, respectively.

Within BL-QMR is a Lanczos-type algorithm which incorporates the deflation as mentioned above in order to generate biorthogonal bases for $K_n^{\mathrm{dl}}(A,R)$ and $K_n^{\mathrm{dl}}(A^T,L)$: that is, two sequences of right and left Lanczos vectors

$$v_1,\ldots,v_n \text{ and } w_1,\ldots,w_n, \quad n = 1,2,\ldots,$$

such that

$$(4.2)\qquad \mathrm{span}\{v_1,\ldots,v_n\} = K_n^{\mathrm{dl}}(A,R), \quad \mathrm{span}\{w_1,\ldots,w_n\} = K_n^{\mathrm{dl}}(A^T,L),$$

$$w_j^Tv_k = \left\{\begin{array}{cl} 0 & \mathrm{if} j \ne k, \\ \delta_j \ne 0 & \mathrm{if} j = k. \end{array}\right.$$

Defining the $N \times n$ matrices $V_n = [v_1, \ldots, v_n]$ and $W_n = [w_1, \ldots, w_n]$, it follows that

$$W_n^T V_n = D_n \equiv \operatorname{diag}(\delta_1, \ldots, \delta_n), \quad n = 1, 2, \ldots.$$

Also, the matrix equation relating the v's is

$$AV_\mu = V_n T_\mu + \hat{V}_\mu^{\mathrm{dl}}, \quad \mu \geq 1,$$

where $\mu = n - m_{\mathrm{cr}}$ and m_{cr} is defined by the fact that $K - m_{\mathrm{cr}}$ is the total number of deflations performed in the v sequence up to iteration n in the Lanczos algorithm. Further, T_μ is $n \times \mu$ with lower bandwidth $K+1$ and upper bandwidth $p+1$. Also, $\hat{V}_\mu^{\mathrm{dl}} = V_\mu^{\mathrm{dl}} + E_\mu$, where V_μ^{dl} is $N \times \mu$ but has only $K - m_{\mathrm{cr}}$ nonzero columns corresponding to vectors that are deflated and E_μ has nonzero entries in row i column $p+j, j = 1, \ldots,$ only if a deflation of the ith w occurs for $i > K$. We note that if *deftol* is the deflation tolerance, then $\|V_\mu^{\mathrm{dl}}\| \leq$ *deftol* $\sqrt{K - m_{\mathrm{cr}}}$. For further details, the reader is referred to [8].

Now let us assume $R = [r_0^{(1)}, r_0^{(2)}, \ldots, r_0^{(K)}]$; that is, the matrix R contains the initial residuals of each of the K systems we would like to solve. Thus, the v's correspond to the initial residuals. The way the deflation strategy in [8] works is that if a v is deflated, one linear system is also set aside; then upon convergence of the remaining systems, the solution to the deflated system is updated using the solutions of the other systems. Thus, in what follows we consider only the updates to the nondeflated linear systems, and we denote with a subscript "cr" submatrices of the originals with m_{cr} columns that correspond to these systems.

Recall that when QMR is applied to a single linear system, the μth iterate is an appropriate linear combination of the Lanczos vectors, plus the initial guess. Similarly, the block QMR iterate is defined as

$$X_{\mu,\mathrm{cr}} = X_{0,\mathrm{cr}} + V_\mu Z, \;\; Z \in \mathcal{C}^{\mu \times m_{\mathrm{cr}}}.$$

As with QMR, then, we need to find the matrix Z which determines the appropriate linear combination. Following [8], the residual block $R_{\mu,\mathrm{cr}}$ related to $X_{\mu,\mathrm{cr}}$ satisfies

$$\begin{aligned} R_{\mu,\mathrm{cr}} &= B_{\mathrm{cr}} - AX_{\mu,\mathrm{cr}} \\ &= R_{0,\mathrm{cr}} - AV_\mu Z \\ &= R_{0,\mathrm{cr}} - V_n T_\mu Z - \hat{V}_\mu^{\mathrm{dl}} Z \\ &= V_n \left(\begin{bmatrix} \beta_{\mathrm{cr}} \\ 0 \end{bmatrix} - T_\mu Z \right) - \hat{V}_\mu^{\mathrm{dl}} Z, \end{aligned}$$

where β_{cr} is $m_1 \times m_{\mathrm{cr}}$ defined by taking the appropriate columns of β, with

$$V_{m_1} \beta + V_0^{\mathrm{dl}} = R,$$

and m_1 is the number of columns of R (recall R has K columns) that are not deflated as the first K Lanczos vectors are created ($m_1 \leq K$). Here B contains the $b^{(j)}$'s as its columns, and B_{cr} is the submatrix of B with the appropriate m_{cr} columns.

Because the columns of V_n are not unitary and $\hat{V}_\mu^{\mathrm{dl}}$ has nonzero columns, one cannot find Z such that $\|R_{\mu,\mathrm{cr}}\|$ is minimal. Rather, we seek $Z = Z_\mu$ such that

$$Z_\mu = \arg \min_{Z \in \mathcal{C}^{\mu \times m_{\mathrm{cr}}}} \left\| \begin{bmatrix} \beta_{\mathrm{cr}} \\ 0 \end{bmatrix} - T_\mu Z \right\|.$$

Since T_μ is banded, the standard approach based on the QR factorization of T_μ is used to implicitly determine Z_μ and ultimately determine short-term recurrences for $X_{\mu,\mathrm{cr}}$. Following [8] we have

$$T_\mu = (Q^{(\mu)})^* \begin{bmatrix} R^{(\mu)} \\ 0 \end{bmatrix}$$

for a unitary $n \times n$ matrix $Q^{(\mu)}$ and a nonsingular, $\mu \times \mu$, upper triangular matrix $R^{(\mu)}$. Thus,

$$Z_{(\mu)} = (R^{(\mu)})^{-1} t_\mu, \quad \text{where} \quad \begin{bmatrix} t_\mu \\ \tau_\mu \end{bmatrix} = Q^{(\mu)} \begin{bmatrix} \beta_{\mathrm{cr}} \\ 0 \end{bmatrix}.$$

Finally,

$$\begin{aligned} X_{\mu,\mathrm{cr}} &= X_{0,\mathrm{cr}} + V_{(\mu)}(R^{(\mu)})^{-1} t_\mu \\ &= X_{\mu-1,\mathrm{cr}} + p_\mu y_\mu^T, \end{aligned} \tag{4.3}$$

where p_μ and y_μ^T are given by (refer to [8, equations (5.10), (5.8)])

$$p_\mu = \left(v_\mu - \sum_{i=j^*}^{\mu-1} p_i \theta_i \right) / \theta_\mu, \qquad \begin{bmatrix} y_\mu^T \\ \tau_\mu \end{bmatrix} = Q_\mu \begin{bmatrix} \tau_{\mu-1} \\ 0 \end{bmatrix}. \tag{4.4}$$

The θ_i are scalars corresponding to the last column of $R^{(\mu)}$, Q_μ (not to be confused with $Q^{(\mu)}$) is a particular matrix of Givens rotations described in (5.2) of [8], and j^* is an index described in [8] satisfying $(\mu - j^*) \le 2m$.

5. The block QMR-projection method. In a manner similar to section 3, we describe a block QMR-projection approach to solving (1.1) that combines the advantageous properties of the block QMR algorithm and our single-seed projection algorithm.

Suppose that we select a subset of size $m < K$ linear systems to serve as "seed" from among the original K. Let $\mathcal{I}_{m_1}$ be the index set $i_1, \ldots, i_m$ of the chosen systems. We use $\mathcal{I}_{m_1}^c$ to denote the indices from 1 to K which are not in $\mathcal{I}_{m_1}$. Let $b^{(j)}$ with $j \in \mathcal{I}_{m_1}$ be the m columns of the matrix $B^{(1)}$ and let the remaining $J = K - m$ right-hand sides (corresponding to nonseed systems indexed by $\mathcal{I}_{m_1}^c$) be the columns of the matrix $B^{(2)}$. We define $X_0^{(1)}$ as the matrix $[x_0^{(i_1)}, \ldots, x_0^{(i_m)}]$ of initial guesses for the m seed systems, and $X_0^{(2)}$ as the matrix of initial guesses for the nonseed systems. The corresponding initial block residuals are $R_0^{(1)} = B^{(1)} - AX_0^{(1)}$ and $R_0^{(2)} = B^{(2)} - AX_0^{(2)}$.

The idea is to set R (and L) defined in the previous section to $R_0^{(1)}$ and run BL-QMR to solve the seed systems while using a projection idea to update the nonseed systems. Once BL-QMR converges on the seed system, the process is repeated by choosing a new subset, indexed by $\mathcal{I}_{m_2} \subset \mathcal{I}_{m_1}^c$, of the nonconverged, nonseed systems. The systems indexed by $\mathcal{I}_{m_2}$ now serve as seed, where the columns of $X_0^{(1)}$ are understood to be the estimated solutions, generated in the first round of projected BL-QMR, to the systems with indices in $\mathcal{I}_{m_2}$. The remaining systems, indexed by $\mathcal{I}_{m_2}^c = \mathcal{I}_{m_1}^c \backslash \mathcal{I}_{m_2}$, are updated by projection. In the following, $X_\mu^{(1)}$ ($R_\mu^{(1)}$) denotes the μth block iterate (residual) of the current block seed while $X_\mu^{(2)}$ ($R_\mu^{(2)}$) denotes the μth block iterate (residual) of the current nonseed block. We shall further assume that m

is the number of *current* seed systems and J is the number of *current* nonconverged, nonseed systems. The numbers m and J can change at each round.

At iteration μ, we want our nonseed systems to also lie in the current Krylov subspace. That is, we desire

$$X_\mu^{(2)} \in X_0^{(2)} + K_\mu^{\text{dl}}(A, R_0^{(1)}).$$

Since the columns of V_μ span this subspace, this means

$$X_\mu^{(2)} = X_0^{(2)} + V_\mu Z_\mu^{(2)}$$

for some $\mu \times J$ matrix $Z_\mu^{(2)}$. Now we must decide how to define $Z_\mu^{(2)}$. We observe

$$\begin{aligned} R_\mu^{(2)} &= B^{(2)} - A(X_0^{(2)} + V_\mu Z_\mu^{(2)}) \\ &= R_0^{(2)} - V_n T_\mu Z_\mu^{(2)} - \hat{V}_\mu^{\text{dl}} Z_\mu^{(2)}. \end{aligned}$$

Using biorthogonality

$$D_n^{-1} W_n^T R_\mu^{(2)} = D_n^{-1} W_n^T R_0^{(2)} - T_\mu Z_\mu^{(2)} - D_n^{-1} W_n^T \hat{V}_\mu^{\text{dl}} Z_\mu^{(2)}.$$

Then

$$\|D_n^{-1} W_n^T R_\mu^{(2)}\| \leq \|D_n^{-1} W_n^T R_0^{(2)} - T_\mu Z_\mu^{(2)}\| + \|D_n^{-1} W_n^T \hat{V}_\mu^{\text{dl}} Z_\mu^{(2)}\|.$$

Note that if no deflations have occurred, $\hat{V}_\mu^{\text{dl}}$ is zero, so we have equality rather than inequality. Therefore, in analogy with the single-seed algorithm of section 3, we define

$$Z_\mu^{(2)} \equiv \arg \min_{Z \in \mathcal{C}^{\mu \times J}} \|D_n^{-1} W_n^T R_0^{(2)} - T_\mu Z\|.$$

Using the QR factorization of T_μ described in the previous section, we obtain

$$Z_\mu^{(2)} = \arg \min_{Z \in \mathcal{C}^{\mu \times J}} \left\| Q^{(\mu)} G_n - \begin{bmatrix} R^{(\mu)} \\ 0 \end{bmatrix} Z \right\|,$$

where G_n is the $n \times J$ matrix $G_n = D_n^{-1} W_n^T R_0^{(2)}$. If

$$\begin{bmatrix} t_\mu^{(2)} \\ \tau_\mu^{(2)} \end{bmatrix} = Q^{(\mu)} G_n, \tag{5.1}$$

we obtain

$$Z_\mu^{(2)} = (R^{(\mu)})^{-1} t_\mu^{(2)}, \tag{5.2}$$

so that

$$\|D_n^{-1} W_n^T R_0^{(2)} - T_\mu Z_\mu^{(2)}\| = \|\tau_\mu^{(2)}\|. \tag{5.3}$$

Using $G_n^T = \left[G_{n-1}^T, g_n\right]$, together with (5.1) and the definition of $Q^{(\mu)}$ in (5.1) of [8], it is easy to show that

$$\begin{bmatrix} t_\mu^{(2)} \\ \tau_\mu^{(2)} \end{bmatrix} = \begin{bmatrix} I_{\mu-1} & 0 \\ 0 & Q_\mu \end{bmatrix} \begin{bmatrix} t_{\mu-1}^{(2)} \\ \tau_{\mu-1}^{(2)} \\ g_n^T \end{bmatrix} = \begin{bmatrix} t_{\mu-1}^{(2)} \\ Q_\mu \begin{bmatrix} \tau_{\mu-1}^{(2)} \\ g_n^T \end{bmatrix} \end{bmatrix}. \tag{5.4}$$

Thus, $t_\mu^{(2)}$ differs from $t_{\mu-1}^{(2)}$ only in its last row, which we call $(y_\mu^{(2)})^T$:

$$t_\mu^{(2)} = \left[\begin{array}{c} t_{\mu-1}^{(2)} \\ (y_\mu^{(2)})^T \end{array} \right], \text{ where } (y_\mu^{(2)})^T \in \mathcal{C}^{1\times J}.$$

From the above relation and (5.4) it follows that to obtain $(y_\mu^{(2)})^T$ one need only perform a product with Q_μ:

$$\left[\begin{array}{c} (y_\mu^{(2)})^T \\ \tau_\mu^{(2)} \end{array} \right] = Q_\mu \left[\begin{array}{c} \tau_{\mu-1}^{(2)} \\ g_n^T \end{array} \right],$$

which, since Q_μ by definition is a product of m_{cr} Givens rotations, is an easy task.

With p_i defined as in (4.4), it is now easy to show that the μth nonseed block iterate is

$$X_\mu^{(2)} = X_{\mu-1}^{(2)} + p_\mu (y_\mu^{(2)})^T. \tag{5.5}$$

Thus, we may readily show

$$R_\mu^{(2)} = R_{\mu-1}^{(2)} - Ap_\mu (y_\mu^{(2)})^T. \tag{5.6}$$

However, using the definition of p_μ, we find an update formula for the block residual which does not actually require any additional matrix-vector products.

Lemma 5.1. *$R_\mu^{(2)}$ can be updated from $R_{\mu-1}^{(2)}$ in at most $O(N(J+2m))$ additional floating point operations.*

Proof. By substituting (4.4) into (5.6), we obtain a formula for updating $R_\mu^{(2)}$:

$$R_\mu^{(2)} = R_{\mu-1}^{(2)} - f_\mu (y_\mu^{(2)})^T \quad \text{with} \quad f_i \equiv Ap_i = \frac{1}{\theta_i}\left(Av_i - \sum_{k=j^*}^{i-1} \theta_k f_k \right). \tag{5.7}$$

Consider forming f_μ. Now the matrix-vector product Av_μ is computed in the course of the Lanczos process at iteration μ and need not be recomputed. Therefore, it is clear that to compute the length N vector f_μ requires at most $O(2mN)$ flops since $(\mu - j^*) \leq 2m$ by definition (see section 5 of [8]). We note that the computation of the outer product $f_\mu (y_\mu^{(2)})^T$ requires $O(JN)$ operations, and the proof is complete. □

We note that a similar update is valid for $R_\mu^{(1)}$:

$$R_\mu^{(1)} = R_{\mu-1}^{(1)} - f_\mu (y_\mu^{(1)})^T. \tag{5.8}$$

6. Issues in practical computation for the block algorithm.

6.1. Block-seed selection heuristic. Clearly, the performance of our multiple-seed algorithm in terms of savings of matrix-vector products depends on which, and how many, systems are chosen to be seed. Deflation in BL-QMR solves the problem of removing redundancy if systems with starting residuals which are nearly linearly dependent are chosen as seed. Ideally, however, we would like to choose as seed systems some subset of the nonconverged systems which are in some sense optimally independent in order to increase the chance that the solutions to the nonseed systems will lie nearly in the Krylov subspaces generated by the seed systems, thereby ensuring the effectiveness of the projection process.

In our examples, we used the following heuristics to determine which and how many seed systems to use. First, we let $B = [b^{(1)}, \ldots, b^{(K)}]$. Since $K \ll N$ was not too large in these examples, we computed a compact pivoted QR factorization of B,

$$\tilde{B} \equiv B\Pi = QR, \quad Q \in \mathcal{C}^{N \times K}, \ R \in \mathcal{C}^{K \times K},$$

to determine which of the remaining were most independent. Here, Π is just a permutation matrix which serves to permute the columns of B such that the first few columns of $B\Pi$ are the most independent. In particular, if ρ denotes the diagonal entries of R and if $|\rho(1)|/|\rho(i)| > \alpha$ for any $1 \leq i \leq K$, then we discard the corresponding column of $\tilde{B}$. The remaining m columns of $\tilde{B}$ serve as the seed systems. We set the maximum value of α to 10^5 to ensure the columns were not too linearly dependent, but adjusted it lower if necessary so that the size of the seed block was no bigger than about $K/2$. On the next round of projected BL-QMR, however, we simply decided on a new number of seeds to use ($m \leftarrow \lceil m/2 \rceil$) and took those with the largest m relative residuals to serve as seed. More efficient means of selecting m for each round and for determining the m seeds need to be examined in the future.[3]

6.2. Loss of biorthogonality. One additional problem that we encountered in practice in using either our single-seed or our multiple-seed algorithm was that loss of biorthogonality could affect the accuracy of the $\gamma_n^{jl} = (1/\delta_{j,n}) w_{j,n}^T r_0^{jl}$, or $g_n^T = (1/\delta_n) w_n^T R_0^{(2)}$. This loss of accuracy would thereby adversely affect the convergence of the computed solution. To avoid this difficulty for the block projection algorithm, we used the following fact. If no deflations were performed up to the μth iteration when solving the single-seed system,

$$R_{\mu-1}^{(2)} = R_0^{(2)} - V_{n-1} T_{\mu-1} Z_{\mu-1}^{(2)} \quad \Rightarrow \quad g_n^T = \frac{1}{\delta_n} w_n^T R_{\mu-1}^{(2)} = \frac{1}{\delta_n} w_n^T R_0^{(2)},$$

where it is understood that $R_j^{(2)} = R_0^{(2)}, j < 0$. Thus, at the beginning of iteration $\mu \geq 1$, we computed g_n^T based on the current residual estimate, then updated the residual estimate using Lemma 5.1. If deflations do occur, observe

$$g_n^T = \frac{1}{\delta_n} w_n^T R_{\mu-1}^{(2)} - \frac{1}{\delta_n} w_n^T \hat{V}_{\mu-1}^{\mathrm{dl}} Z_{\mu-1}^{(2)}.$$

In our examples, the second term was on the order of the deflation tolerance. This was because $\hat{V}_\mu^{\mathrm{dl}} = V_\mu^{\mathrm{dl}}$ since no w deflations occurred for indices larger than J. Hence nonzero columns of V_{dl} were nearly linear combinations of the first m_1 v's for which $\frac{1}{\delta_n} w_n^T v = 0$. In this work we choose to ignore the second term rather than go to the extra expense of computing inner products with the nonzero columns of $\hat{V}_{\mathrm{dl}}$.

Likewise, for the single-seed algorithm we use

$$\gamma_n^{jl} = \frac{1}{\delta_{j,n}} w_{j,n}^T r_0^{jl} = \frac{1}{\delta_{j,n}} w_{j,n}^T r_{n-2}^{jl}, \quad n \geq 2.$$

An investigation into the reason behind the success of these approaches in finite precision arithmetic will be the subject of future work. We note that a similar phenomenon was observed in [20] with respect to practical implementation of GMRES variants, and an explanation for such behavior in finite precision arithmetic was given.

[3] In the worst case, if the seed block is too small, then it could require many rounds and much computation for all the systems to converge, and performance could be worse than BL-QMR without projection. If the seed block is too large, gains in execution time over BL-QMR would probably also be reduced, and our algorithm's behavior would become more dependent on the deflation tolerance.

6.3. Computational aspects of the block-seed algorithm. It may be relatively expensive in terms of execution time to move data between the smaller, faster cache and the larger, slower main memory. When data is available in cache, it is desirable to use it as much as possible. The level-2 and level-3 BLAS are better for achieving this than level-1 BLAS operations. Thus, one advantage that the block Krylov subspace algorithms enjoy over standard Krylov subspace algorithms (and our single-seed algorithm) is that the former can be implemented to be rich in higher level BLAS operations, whereas the latter class of algorithms requires a large number of level-1 BLAS operations [14, 2].

Further, Krylov subspace algorithms require a large number of vector inner products relative to the remaining number of computations. These inner products, when implemented on a distributed memory parallel machine, correspond to synchronization points (that is, computation cannot proceed until all processors receive the result of the inner product) and require numerous smaller messages among processors [17]. Our single-seed method inherits these problems, although updates to the seed and nonseed systems can be done independently. Block Krylov subspace algorithms, however, can be implemented to provide more computation between communications and larger but fewer messages among processors [14, 17]. Below, we provide one implementation of the block-seed projection algorithm from the proceeding section. We do not claim that this implementation is optimal in terms of cache utilization or parallelism; our goal is to illustrate the potential efficiencies of the block-seed algorithm and show that it retains the same advantages that the block QMR algorithm enjoys.

Suppose that m is the number of right-hand sides in a given seed block and that J is the number of systems in the nonseed block. Let $m_1 \leq m$ be the number of linearly independent right Lanczos vectors that are formed, using deflation, from the initial residuals to the seed block. In the following, $V_{(k)} = [v_{m_1 k+1}, \ldots, v_{m_1(k+1)}]$ and $W_{(k)} = [w_{m_1 k+1}, \ldots, w_{m_1(k+1)}], 0 \leq k$.

Algorithm 1. $\mu = 1 = \phi$. Given $X_0^{(1)}, R_0^{(1)} \in C^{N \times m_1}$ and $X_0^{(2)}, R_0^{(2)} \in C^{N \times J}$; Given the m_1 columns of $V_{(1)}$ and $W_{(1)}$ and $D_{(1)} = \text{diag}(\delta_1, \ldots, \delta_{m_1})$.

```
For $k = 2$ until seed block converges do
  1. $V_{(k)} = AV_{(k-1)}; W_{(k)} = A^T W_{(k-1)}.$
  2. If deflations occurred in the $W$ (or $V$) sequence, update $V_{(k)}$ (or $W_{(k)}$).
  3. Biorthogonalize the columns of $V_{(k)}$ against the columns of $V_{(k-2)}$, $V_{(k-1)}$;
     biorthogonalize the columns of $W_{(k)}$ against the columns of $W_{(k-2)}, W_{(k-1)}$.
  4. Set $i = 0, j = 0, s = 1, \hat{s} = 1$. Set $\mu = \mu + 1$; $\phi = \phi + 1$.
  5. For $n = (k-1)m_1+1, \ldots, km_1$, set $i = i + 1$ and do
     (a) If $V_{(k)}(:, i)$ does not exist, put $V_{(k)}(:, i) = AV_{(k)}(:, s)$ and biorthogonalize
         against $\phi_\mu$ previous Lanczos pairs; $s = s + 1$.
     (b) If $\|V_{(k)}(:, i)\| < deftol$, then $j = j + 1$ and deflate:
           i. Compute $(y_\mu^{(1)})^T, (y_\mu^{(2)})^T, \tau_\mu^{(1)}, \tau_\mu^{(1)}$; compute $f_\mu, p_\mu$ (via gaxpy's).
          ii. "Delete" $i$th column of $V_{(k)}$, "shift" remaining columns left 1.
         iii. Compute which system gets dropped from the seed block (that row
              of $y_\mu^{(1)}$ will have a zero entry).
          iv. Let $y_\mu^{(i_v)}, f_\mu, p_\mu$ be the $j$th columns of $Y^{(i_v)}, i_v = 1, 2; F; P$.
           v. Update deflation index sets. Set $\mu = \mu + 1$, goto step 5(a).
     (c) Normalize $V_{(k)}(:, i)$ and set $\mu_n = \mu$; $j = j + 1$:
     (d) If $W_{(k)}(:, i)$ does not exist, put $W_{(k)}(:, i) = A^T W_{(k)}(:, \hat{s})$ and biorthogo-
         nalize against $\mu_\phi$ previous Lanczos pairs; $\hat{s} = \hat{s} + 1$.
     (e) If $\|W_{(k)}(:, i)\| < deftol$, then deflate:
            i. "Delete" $i$th column of $W_{(k)}$, "shift" remaining columns left 1.
            ii. Update deflation index sets. Set $\phi = \phi + 1$, goto step 5(d).
        (f) Normalize $W_{(k)}(:,i)$. Set $\phi_n = \phi$ and $\delta_n = W_{(k)}(:,i)^T V_{(k)}(:,i)$.
        (g) Continue the MGS[4] process on columns $\geq i$ of $V_{(k)}, W_{(k)}$.
        (h) Set $g_n^T = (1/\delta_n) W_{(k)}(:,i)^T R_{\mu-j}^{(2)}$.
        (i) Compute $(y_\mu^{(1)})^T, (y_\mu^{(2)})^T, \tau_\mu^{(1)}, \tau_\mu^{(2)}$; compute $f_\mu, p_\mu$ (via gaxpy's).
        (j) Let $y_\mu^{(i_v)}, f_\mu p_\mu$ be the $j$th columns of $Y^{(i_v)}, i_v = 1,2; F; P$.
    6. $X_\mu^{(1)} = X_{\mu-j}^{(1)} + P(Y^{(1)})^T$;   $R_\mu^{(1)} = R_{\mu-j}^{(1)} - F(Y^{(1)})^T$.
    7. $X_\mu^{(2)} = X_{\mu-j}^{(2)} + P(Y^{(2)})^T$;   $R_\mu^{(2)} = R_{\mu-j}^{(2)} - F(Y^{(2)})^T$.
    8. "Remove" deflated systems from $X_\mu^{(1)}$.
```

One benefit of this implementation is that A, A^T are accessed only once each block iteration, if no deflation occurs, and computing products of A and A^T with dense, rectangular matrices of Lanczos vectors makes better use of cache than products of A with a single vector. In step 2 (also 5(a), 5(d)) some columns of either or both of the current blocks may have to be biorthogonalized against some previous Lanczos vectors if certain previous deflations occurred in the V and/or W sequence. In step 3, the current blocks of Lanczos vectors are biorthogonalized against the appropriate columns[5] of the previous two blocks. Considering the matrix $V_{(k)}$ (or $W_{(k)}$) rather than its columns separately, we can do this using level-2 BLAS with a two-sided modified Gram–Schmidt approach or, at the expense of some stability, we could accomplish this with level-3 BLAS via a block modified Gram–Schmidt approach [14]. For each deflation step, however, we incur the price of one matrix-vector product and several vector-wise inner products. It is possible to reorganize the algorithm so that a Lanczos block effectively decreases in size after deflation (possibly leaving left and right blocks of different sizes) and thereby put off this extra work until it can be done with higher-level BLAS, but as the notation is more tedious, we use the current implementation to illustrate our points.

Notice we are using modified Gram–Schmidt to biorthogonalize within the current block, but that computation toward updating the solution and residual blocks is done between each step of the process. Notice also that the block iterates and residuals are only updated after a new block of Lanczos vectors has been generated; this was done in order to minimize the number of accesses to the block iterates and residuals and to incorporate level-3 BLAS operations. The updating could be done (via level-2 BLAS operations) inside the innermost loop according to (4.3), (5.5), (5.7), (5.8), or one might opt to track the size of $\tau_\mu^{(1)}$ and update only when necessary.

One way to implement the algorithm on a distributed memory parallel machine is to row partition [17, 14] the matrices $F, P, V_{(k)}, W_{(k)}, X_\mu^{(i_v)}, R_\mu^{(i_v)}, i_v = 1, 2$. Thus, the matrix-multiplications with A, A^T, the biorthogonalization steps, and steps 5(b), (c), (e), (f), (h) require communication among processors; most of the other steps require only local updates of portions of the rectangular matrices. As in [17, section 3.1], it may be possible in a parallel implementation to exploit any computations that are mostly decoupled: for example, the updates to solution and residual blocks are somewhat independent of the generation of the Lanczos vectors and of each other.

[4] Modified Gram–Schmidt.

[5] If deflations have occurred in the W sequence, then one need only biorthogonalize $V_{(k)}$ against some of the columns of $W_{(k-2)}$ (or $W_{(k-1)}$), rather than against the whole block, and similarly for computing $W_{(k)}$ if deflations occurred in the V sequence.

Techniques for performing matrix-vector products with A, A^T in parallel should also be employed.

Before executing Algorithm 1, using our heuristic in section 6.1, we do a compact pivoted QR factorization of B to determine the seed block and therefore should not incur much overhead beyond what the BL-QMR algorithm in [8] would need to generate its initial block using deflation. Every other time that a seed must be chosen, we select those $\lceil m/2 \rceil$ systems with largest residual norm, so a small amount of additional computations/communication are needed at the seed selection steps.

Clearly, if the first time Algorithm 1 is called $J = 0$, it is just the block QMR algorithm with deflation. If $J \neq 0$, then the first time Algorithm 1 is executed, for a given k, the same number of solution vectors and residual vectors must be updated (at most) as if J had been 0: the difference is that updates are separated into updates on two different solution and residual blocks, and these updates are independent of one another. Thus, if Algorithm 1 is implemented in parallel, the independent updates may help compensate for the execution time that is due to processor communication. The computation of g_n^T and $(y_\mu^{(2)})^T$ are the most notable differences between the unprojected and projected algorithms. Overall, the block-seed projection approach may yield the following advantages over block QMR:

- fewer accesses to A and less communication among processors;
- smaller seed block sizes with the block-projection approach mean fewer flops are needed to compute products with A, A^T and fewer flops are needed to construct Lanczos pairs and to factor T_μ;
- less storage per processor during a given run of Algorithm 1 (as fewer vectors are needed in the recurrences for p_μ, f_μ and the number of columns of $V_{(k)}, W_{(k)}$, etc., are reduced);
- updating the seed and nonseed blocks can be done independently.

7. Numerical results. In this section we give numerical results which indicate the potential effectiveness of our approach on electromagnetic scattering problems. All experiments were conducted in Matlab using IEEE double precision floating point arithmetic on a 600 MHz Pentium II processor. We compare our results with results from the Matlab implementation of block QMR with deflation, algorithm BL-QMR in [8]. For comparison purposes, the implementation of our block-seed algorithm mirrors the implementation of BL-QMR in [8] with modifications where necessary, rather than the one in the preceding section.

Mathematically, we would like to solve a two-dimensional Helmholtz-type equation for the scattered electric field $E(x, y)$:

$$(\Delta + k^2(x,y))E(x,y) = \chi_m(x,y)E_0(x,y) \quad \text{in } \Omega \tag{7.1}$$

with perfectly matched layer (PML) boundary conditions [3, 18]: the specific mathematical formulation we use is described in [12]. Here $k^2(x, y) = \omega^2\mu_0\epsilon(x, y)$ is the square of the wave number, with ω representing angular frequency and μ_0 a constant denoting the magnetic permeability. The function $\epsilon(x, y)$, called the electrical permittivity, is defined as $\epsilon = \epsilon_0\epsilon_{rel} + i\frac{\sigma}{\omega}$ for some real $\sigma \geq 0, \epsilon_{rel} \geq 1$ with $i = \sqrt{-1}$ and ϵ_0 a constant (the permittivity of free-space). The value σ is the conductivity of the material. The function χ_m describes the properties of the buried object and has support only over the object location. $E_0(x, y)$ is the known incident electric field.

We discretize using finite differences, which leads to a matrix equation involving the matrix A which is $N \times N$, sparse, complex, and structured but neither symmetric nor Hermitian due to the boundary conditions. Because the matrix is highly indefinite,

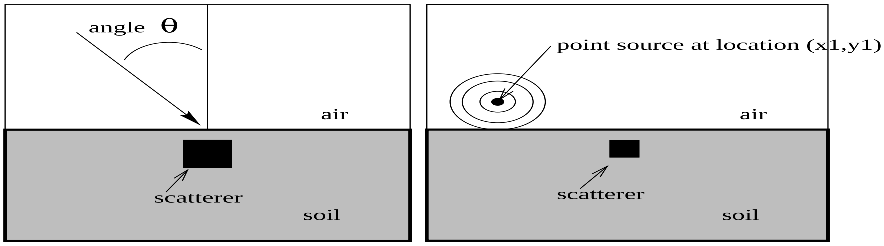

FIG. 7.1. *Physical configurations for Example* 1 *(left) and Example* 2 *(right).*

we need to use a preconditioner to speed convergence. The preconditioner we use is the one described in [12], and we perform all preconditioning from the right.

For all algorithms, we take the initial starting guesses $x_0^{(j)}$ to be zero. We stop running our algorithms when the relative residual norms of all of the systems are less than $tol = 10^{-7}$. For the two block-based algorithms, ours and BL-QMR, we update (seed) block residuals via (5.8) ((5.7) is used for the nonseed block[6]). We monitor convergence of the current seed block by checking norms of the columns of $R_\mu^{(1)}$. However, the true norms of the residuals in the seed block were computed and checked to satisfy the convergence tolerance before the block was deemed to have converged. Since for these examples the major computational expense per iteration is the two matrix-vector products with applications of the preconditioner, we consider the total number of matrix-vector products required for all the systems to converge as our primary measure of success and discuss some timing results.

7.1. Example 1. In this experiment we would like to find the scattered electric fields caused when plane waves at various angles impinge on a horizontal air-soil interface and scatter from a 7cm × 6cm object buried 5cm below the surface. Each angle corresponds to a different E_0 in (7.1), which in turn corresponds to a different right-hand side $b^{(j)}$ in (1.1). Figure 7.1 gives a physical illustration of the problem.

In this example, we use a soil type (referred to as "Seabee" in the literature [19]) and conduct experiments at two different frequencies, $\omega/(2\pi) = 45$ MHz and 475 MHz. At 45 MHz, Seabee has $\epsilon_{rel} = 35.65$ and $\sigma = .13$, while at 475 MHz $\epsilon_{rel} = 21.31$ and $\sigma = .23$. We assumed that the buried object has $\epsilon_{rel} = 2.9$ and $\sigma = .001$ at both frequencies. For air, $\epsilon_{rel} = 1$, $\sigma = 0$. We have discretized at a rate of 50 points per wavelength of soil at 45 MHz and 20 points per wavelength at 475 MHz. In both cases, the total number of unknowns (N) is $(2^7 + 15)^2$.

We centered the buried object (refer to Figure 7.1) and considered the scattered field due to plane waves impinging on the surface at evenly spaced angles from −60 to 60 degrees from the normal. The second columns in Tables 7.1 and 7.2 give the total number of matrix-vector products needed if preconditioned QMR is applied to each system separately.[7] The third column gives the total number of matrix-vector products needed if our preconditioned QMR with projection algorithm is used. The next several columns give the total number of matrix-vector products computed when solving the problem using BL-QMR with various deflation tolerances. The final

[6] Note that the latter needs to be computed each iteration to determine the update for the nonseed block, whereas one could use the bound in [8] to monitor convergence of the seed block at the possible expense of computing many extra matrix-vector products.

[7] Note that we define the matrix-vector product count as the number of multiplies by AM^{-1} or its transpose where M is the preconditioner.

25	2378	492	–	321	319	–	245

column shows results when our block-seed approach is used ($deftol = 10^{-9}$), where the seed blocks are chosen using the heuristic outlined in section 6.1 with $\alpha = 10^5$. Dashes indicate that the convergence tolerance was not met within $maxit = 300$ iterations.

As Table 7.1 shows, for the 45 MHz case, BL-QMR failed to converge after 300 iterations in all cases when the deflation tolerance was set to 10^{-8}, but it outperformed our single-seed projection method if the deflation tolerance was small enough. Our block-seed projection approach performs better than all the other methods in terms of the number of matrix-vector products; however, we note that for these nonoptimized implementations, the execution times for the best BL-QMR runs and our block algorithm are about the same. Solving sequentially took 4.5 times longer than our single-seed method and over 6 times longer than block-based algorithms.

At 475 MHz, we expected our $x^{(j)}$'s not to be as close as in the previous case due to the underlying physics of the problem, and therefore we did not expect as much savings with our single-seed projection approach. Indeed, Table 7.2 shows that the difference between the second and third columns is not as dramatic as in Table 7.1. Table 7.2 also shows that BL-QMR, with the deflation tolerance set at either 10^{-8} or 10^{-9}, outperforms our single-seed projection approach. However, comparing the last column with the others, we find that our block-seed projection approach can provide substantial savings over the other methods. There is also a difference in execution times: for example, for 25 systems our block-seed projection method takes about 6.2 minutes while BL-QMR with deflation tolerance of 10^{-9} takes about 7.1 minutes.

7.2. Example 2. For our second example, each of our K systems corresponds to solving for the scattered electric field from a buried object when the source of the incident field is a point source, located at position x_i, y_i above the earth (see Figure 7.1). We consider the case when the frequency is 480 MHz, and the soil has $\epsilon_{rel} = 6.5$ and $\sigma = .019$. As before, the buried object has $\epsilon_{rel} = 2.9$ and $\sigma = .001$. The buried object is 7cm × 4cm buried 5cm deep and centered left to right. The width of each cell in the discrete grid is 1cm, and the total number of unknowns (N) is $(2^6 + 15)^2$. Our point sources are each located 3cm above the earth and either

vary in the horizontal direction, with 0 being in the middle, from −12cm to 12cm in 1cm increments or −17cm to 17cm in 1cm increments. The numbers of matrix-vector products required by each of the different methods to solve these systems are given in Table 7.3. However, as illustrated by the timing results in Table 7.4, both the single- and block-seed projection give dramatic improvements over BL-QMR without projection.[8]

8. Conclusions and future work. We have introduced two new projection approaches, based on QMR and block QMR, respectively, for solving multiple linear systems with the same coefficient matrix but different right-hand sides. Compared to solving each system separately by QMR, both approaches can significantly reduce the work and execution time needed to solve all the systems to within a specified tolerance provided there is sufficient shared information among the right-hand sides; the block-seed algorithm requires less shared information to perform well. We provided theory for the single-seed approach which suggests that under certain conditions in exact arithmetic, QMR on subsequent seed systems converges as if part of the spectrum has been cut off; we also gave an upper bound for the rate of convergence of the nonseed systems. More work needs to be done to determine convergence behavior of the block-seed algorithm in both exact and finite precision arithmetic.

As our numerical results showed, with appropriate deflation tolerance, the BL-QMR algorithm [8] could outperform our single-seed QMR-projection method in terms of matrix-vector product savings (although not always reflected in the execution times) particularly when the right-hand sides are not as close; however, our block-seed projection method consistently exhibited the greatest savings in such cases. The performance of our block-seed approach depends on our choices of successive seed blocks, and overall execution time depends on the actual implementation. We gave one block-seed selection heuristic and discussed possible efficiencies of block-seed algorithm. Determining good seed selection strategies, efficient serial and parallel implementations, and formal time comparisons with other methods remain subjects for future research.

[8] Part of the improvement can be attributed to the difference in size of the BL-QMR block iterate with the size of the seed for our methods.

ON AN ADAPTIVE MULTIGRID SOLVER FOR CONVECTION-DOMINATED PROBLEMS*

WOLFGANG DAHMEN†, SIEGFRIED MÜLLER†, AND THOMAS SCHLINKMANN†

Abstract. The objective of this paper is to develop and describe an adaptive multigrid scheme for the numerical solution of convection-diffusion-reaction equations with dominating convection or reaction term. Specifically, we propose a systematic construction of problem and *scale-dependent* restriction, prolongation and smoothing operators in combination with an *adaptive mesh refinement* strategy. In particular, adaptivity is not only to reduce computational complexity but also to *stabilize* standard Galerkin discretizations so that adding artificial viscosity can be avoided. The approach is suited for any choice of underlying multiresolution sequences, in particular for standard finite element discretizations on nested but possibly nonuniform meshes. Moreover, all concepts are in principle independent of the spatial dimension and avoid any special flow-dependent enumeration of unknowns. The performance of the scheme is illustrated by various examples in one and two spatial dimensions. They are chosen so as to exhibit possibly many types of adverse or singular behavior in connection with constant and varying convection or the interplay between convective and reactive terms. In the light of these tests those issues are identified that require further research.

Key words. convection dominated problems, stable completions, scale-dependent transfer operators and smoothers, full multigrid, adaptive refinements

1. Introduction.

This paper is concerned with the numerical solution of *convection-diffusion equations* which appear as core ingredients of more complex models such as the Navier–Stokes equations or models for two-phase flow problems. To be specific, we consider scalar boundary value problems

$$-\nabla \cdot (\boldsymbol{\nu}\, \nabla\, u) + \boldsymbol{\beta} \cdot \nabla\, u + \gamma\, u = f \quad \text{in } \Omega \subset \mathbb{R}^d, \quad u = 0 \ \text{ on } \partial\Omega, \tag{1}$$

where the principal part of the differential operator is assumed to be self-adjoint and positive definite, i.e., $\boldsymbol{\nu} = \boldsymbol{\nu}^{\mathrm{T}}$ and there exists some $\lambda > 0$ such that $\boldsymbol{\xi}^T\, \boldsymbol{\nu}(\mathbf{x})\, \boldsymbol{\xi} \geq \lambda\, \boldsymbol{\xi}^T\, \boldsymbol{\xi}$ for all $\mathbf{x} \in \overline{\Omega}$, $\boldsymbol{\xi} \in \mathbb{R}^d$. The flow direction $\boldsymbol{\beta}$ as well as $\gamma \geq 0$ may vary in $\mathbf{x}$.

The corresponding variational formulation of (1) then reads as follows: Find $u \in H_0^1(\Omega)$ such that

$$a_{\boldsymbol{\nu}}(v, u) = b(v) \quad \forall\, v \in H_0^1(\Omega), \tag{2}$$

where the bilinear form $a_{\boldsymbol{\nu}} : H_0^1(\Omega) \times H_0^1(\Omega) \to \mathbb{R}$ and the linear form $b : H_0^1(\Omega) \to \mathbb{R}$ are defined by the integrals

$$a_{\boldsymbol{\nu}}(v, u) := \int_\Omega (\nabla\, v)^T\, (\boldsymbol{\nu}\, \nabla\, u) + (\boldsymbol{\beta} \cdot \nabla\, u)\, v + \gamma\, u\, v\, d\Omega, \quad b(v) := \int_\Omega f\, v\, d\Omega. \tag{3}$$

The work of the first author was supported in part by the European Commission within the TMR project (Training and Mobility for Researchers) "Wavelets and Multiscale Methods in Numerical Analysis and Simulation," ERB FMRX CT98 018TA. The work of the second author was supported in part by the SFB 401 of the Deutsche Forschungsgemeinschaft.

Our notation indicates the dependence on $\boldsymbol{\nu}$ because we will be particularly interested in those cases where $\boldsymbol{\nu}$ is small compared with $\boldsymbol{\beta}$ and γ.

Under the assumptions $\nu_{ik} = \nu_{ki} \in C(\overline{\Omega})$, $\beta_i \in C^1(\overline{\Omega})$, $\gamma \in C(\overline{\Omega})$, $\gamma \geq 0$, $f \in L_2(\Omega)$, and $\gamma(\mathbf{x}) - \frac{1}{2}(\operatorname{div} \boldsymbol{\beta})(\mathbf{x}) > -\lambda \min(1, \alpha)$ for all $\mathbf{x} \in \overline{\Omega}$, where the constant $\alpha > 0$ results from Friedrich's first inequality, the existence of a unique solution can be inferred immediately from the Lax–Milgram lemma. The verification of the coercivity condition, i.e., the existence of finite positive constants c, C such that

$$c\|v\|^2_{H^1(\Omega)} \leq a(v,v) \leq C\|v\|^2_{H^1(\Omega)} \quad \forall\, v \in H^1_0(\Omega),$$

can be found, e.g., in [1].

When $\|\boldsymbol{\nu}\|$ is large compared with $\|\boldsymbol{\beta}\|$ and $\|\gamma\|$ the behavior of the solution to (1) is essentially governed by the dominating second order elliptic operator. Correspondingly standard Galerkin discretizations are appropriate and fast multilevel solvers are available that facilitate an efficient numerical treatment. However, when the convective part dominates, i.e., when $\|\boldsymbol{\beta}\| \gg \|\boldsymbol{\nu}\|$, at least the following two serious obstructions arise.

Robustness. Multilevel or multigrid schemes which are asymptotically optimal in the elliptic case $\boldsymbol{\beta} = \mathbf{0}$ lose their efficiency or even fail to converge. Therefore considerable effort has been spent in attempts to increase the *robustness* of the schemes. Strategies for restoring robustness concern algebraic multigrid concepts [29], the development of scale- and problem-dependent multigrid ingredients [32, 16, 24], local Fourier analysis [25, 26], or special enumeration schemes combined with incomplete LU factorizations as smoothers [18, 33, 19, 8] when the flow is by and large acyclic.

Stability. Standard Galerkin discretizations become *unstable*, i.e., if the *grid-Péclet number* $P_h := \|\boldsymbol{\beta}\|h/(2\|\nu\|)$ is of the order 1 (where h denotes the meshsize of the underlying trial space), the solution of the discrete problem may exhibit oscillations that have nothing to do with the true solution. However, a-priorily fixed *stabilization techniques* such as *Petrov–Galerkin* discretizations or *streamline diffusion* [21, 10, 20, 22] add in one way or the other some *artificial viscosity* which, at least in certain regions (often of primary interest), diminish accuracy.

Thus overall, it is fair to say that the problem has by far not been solved to complete satisfaction with regard to both adequate discretization as well as efficiency of the solution process.

Our objectives. Our point of view here is different in that we aim at *jointly* addressing *both stability and robustness* together with the issue of *accuracy*. Our primary goal is to retain accuracy also in critical regions through *dynamically adapting* discretizations. Our main point is that thereby we restore stability of the discretization, as well as efficiency and also to some extent robustness of the solver without a priori stabilization. This is similar in spirit to the approach in [3, 2] where adaptivity is based on a defect correction scheme for finite difference discretizations. The stabilizing effect is also reminiscent of *Shishkin-grids* for which stability of Galerkin discretizations can be shown in special situations [27].

Our starting point is the familiar hierarchical two-by-two blocking of the linear discrete system as in the hierarchical basis multigrid (HBMG) scheme from [5]. The level-dependent multigrid ingredients will be automatically generated through approximately *decoupling* such block systems quite similar in spirit to the approach in [7].

An essential *distinction* from previous work lies in stabilization solely through adaptation and in the way adaptation is realized. Here this becomes possible through an *adaptive full multigrid* scheme combined with a *problem homotopy.* This means that on coarse levels viscosity is being added which will then be successively removed when progressing to higher (possibly local) refinement levels. Unless one decides to still use some weak a priori stabilization the refinement process only stops when all artificial viscosity has been removed everywhere. The adaptation criterion is based on wavelet thresholding combined with the concept of *stable completions* from [9]. This requires no a priori knowledge of the solution and, in particular, avoids regularity assumptions as in [3, 2]. Finally, our decoupling mechanism *automatically* modifies the test spaces resulting in a *Petrov–Galerkin* discretization with increasing upwind effect when descending to coarser scales.

Although the scheme will be tested only for one- and two-dimensional examples we emphasize that all ingredients work in higher dimensions in the same way. In particular, flow-dependent numberings are avoided.

The contents. The paper is organized as follows. In section 2 we briefly describe the general discretization setting. Section 3 is devoted to the development of the basic multigrid ingredients such as scale-dependent intergrid transfer operators and smoothers. An "ideal" two-grid scheme will serve as a guideline for the multigrid scheme. In section 4 an adaptive full multigrid scheme is developed.

In section 5 the performance of this concept is tested for problems which exhibit different types of obstructions or singular behavior. This concerns the formation of boundary layers due to a strong constant convection and reaction terms or their interplay or the effect of variable convection, especially for mass accumulation.

2. Discretization. We will base the numerical treatment of (1) on a hierarchy $\mathcal{S}$ of *nested* trial spaces $S_0 \subset S_1 \subset \cdots \subset H_0^1(\Omega)$ whose union is dense in $H_0^1(\Omega)$. Each space S_j is spanned by a finite set $\Phi_j = \{\phi_{j,k} : k \in \mathcal{I}_j\}$ of basis functions, i.e., each $u_j \in S_j$ has a unique expansion

$$u_j = \sum_{k \in \mathcal{I}_j} u_{j,k} \phi_{j,k} =: \Phi_j^{\mathrm{T}} \mathbf{u}_j.$$

Moreover, we will always assume that the bases Φ_j are uniformly stable in the sense that for some finite positive constants c, C

$$c\|\boldsymbol{u}_j\|_{\ell_2(\mathcal{I}_j)} \leq \|\Phi_j^T \boldsymbol{u}_j\|_{L_2(\Omega)} \leq C\|\boldsymbol{u}_j\|_{\ell_2(\mathcal{I}_j)}, \tag{4}$$

where $\|\cdot\|_{\ell_2(\mathcal{I}_j)}, \|\cdot\|_{L_2(\Omega)}$ denote the respective Euclidean and L_2-norms. Canonical choices of S_j are spaces of globally continuous piecewise linear functions with respect to a nested sequence of successively refined mesh partitions of Ω. The stability of the corresponding bases of *hat functions* is known to hold as long as the triangles are shape regular. It will be helpful to always think in terms of this example although any standard finite element spaces are covered.

Although we are ultimately interested in *standard Galerkin* discretizations of (1) it will be adequate to consider the more general setting of *Petrov–Galerkin* schemes, i.e., fixing some highest level J we look for $u_J \in S_J$ such that

$$a_{\boldsymbol{\nu}}(v, u_J) = b(v) \quad \forall\, v \in \tilde{S}_J, \tag{5}$$

where the $\tilde{S}_j = \operatorname{span}\{\tilde{\phi}_{j,k} : k \in \mathcal{I}_j\}$ are suitable nested *test spaces.* Clearly this amounts to solving the linear system

$$\mathbf{A}_J \, \mathbf{u}_J = \mathbf{b}_J, \tag{6}$$

where the stiffness matrix $\mathbf{A}_J$ and the right-hand side $\mathbf{b}_J$ are defined by

$$\mathbf{A}_J := \Big(a_{\boldsymbol{\nu}}(\tilde{\phi}_{J,i}, \phi_{J,j})\Big)_{i,j\in\mathcal{I}_J}, \quad \mathbf{b}_J := \Big(b(\tilde{\phi}_{J,i})\Big)_{i\in\mathcal{I}_J}. \tag{7}$$

It will often be convenient to use the abbreviation $\mathbf{A}_J = a_{\boldsymbol{\nu}}(\tilde{\Phi}_J, \Phi_J)$, i.e., for any two finite collections Θ, Ξ we set $a_{\boldsymbol{\nu}}(\Theta, \Xi) := (a_{\boldsymbol{\nu}}(\theta, \xi))_{\theta\in\Theta,\xi\in\Xi}$.

3. Space splittings and multigrid ingredients. Our goal is to solve (6) efficiently by exploiting lower scale discretizations. We proceed with briefly recalling the mechanisms for problem-dependent space splittings.

3.1. Stable completions. A key idea is to split a given trial space S_{j+1} in the above hierarchy into a *coarse* subspace S_j and a *complement space* W_{j+1} that represents the *high frequencies.* Since it suffices to consider two successive spaces we simplify the notation and write $S_j =: S_H$, $S_{j+1} =: S_h$, $W_{j+1} =: W$ and accordingly Φ_H, Φ_h for the corresponding bases. The analogous quantities on the test side are denoted by $\tilde{S}_H$, $\tilde{S}_h$, $\tilde{W}$, $\tilde{\Phi}_H$, $\tilde{\Phi}_h$.

If we view the bases as vectors, the fact that test and trial spaces are nested implies that there are $\#\mathcal{I}_h \times \#\mathcal{I}_H$ matrices $\boldsymbol{P}_0, \tilde{\boldsymbol{P}}_0$ such that

$$\Phi_H^T = \Phi_h^T \boldsymbol{P}_0, \quad \tilde{\Phi}_H^T = \tilde{\Phi}_h^T \tilde{\boldsymbol{P}}_0. \tag{8}$$

Denoting by $\Psi = \{\psi_k : k \in \mathcal{J}\}$, and by $\tilde{\Psi} = \{\tilde{\psi}_k : k \in \mathcal{J}\}$ bases for the complement spaces $W, \tilde{W}$, respectively, the fact that $\Psi \subset S_h$ and $\tilde{\Psi} \subset \tilde{S}_h$ implies that there must be $\#\mathcal{I}_h \times \#\mathcal{J}$ matrices $\boldsymbol{P}_1, \tilde{\boldsymbol{P}}_1$, respectively, such that

$$\Psi^T = \Phi_h^T \boldsymbol{P}_1, \quad \tilde{\Psi}^T = \tilde{\Phi}_h^T \tilde{\boldsymbol{P}}_1. \tag{9}$$

The relations

$$S_h = S_H \oplus W, \quad \tilde{S}_h = \tilde{S}_H \oplus \tilde{W} \tag{10}$$

are equivalent to the fact that the composed matrices $\boldsymbol{P} := (\boldsymbol{P}_0, \boldsymbol{P}_1)$, $\tilde{\boldsymbol{P}} := (\tilde{\boldsymbol{P}}_0, \tilde{\boldsymbol{P}}_1)$ are invertible. Their inverses will be denoted by $\boldsymbol{R} = \binom{\boldsymbol{R}_0}{\boldsymbol{R}_1}$ and $\tilde{\boldsymbol{R}} = \binom{\tilde{\boldsymbol{R}}_0}{\tilde{\boldsymbol{R}}_1}$, respectively. For the complement bases to also be stable in the sense of (4) it is necessary and sufficient that

$$\|\boldsymbol{P}\|, \ \|\boldsymbol{R}\| \leq c \tag{11}$$

holds for some constant c independent of the current level; see [9]. Here $\|\cdot\|$ denotes the spectral norm. The matrices $\boldsymbol{P}_1$, $\tilde{\boldsymbol{P}}_1$ are called *completions* of $\boldsymbol{P}_0$, $\tilde{\boldsymbol{P}}_0$. The point is that choosing a complement space W is equivalent to finding a *completion* $\boldsymbol{P}_1$ of $\boldsymbol{P}_0$ to an invertible matrix. When (11) holds (uniformly with respect to the refinement level) then the completions are called (uniformly) *stable.*

Note that since $\Phi_H^T \boldsymbol{u}_H = \Phi_h^T(\boldsymbol{P}_0 \boldsymbol{u}_H) =: \Phi_h^T \boldsymbol{u}_h$ the matrix $\boldsymbol{P}_0$ (and likewise $\tilde{\boldsymbol{P}}_0$) represents a *prolongation operator.* Conversely, in view of $\Phi_h^T \boldsymbol{u}_h = \Phi_H^T(\boldsymbol{R}_0 \boldsymbol{u}_h) + \Psi^T(\boldsymbol{R}_1 \boldsymbol{u}_h)$, the matrix $\boldsymbol{R}_0$ acts as a *restriction operator.* The matrices $\boldsymbol{P}_1, \boldsymbol{R}_1$ (and likewise $\tilde{\boldsymbol{P}}_1, \tilde{\boldsymbol{R}}_1$) play analogous roles with respect to the complement spaces.

Hierarchical complements. As in [5] it will be of crucial importance that in the present context of Lagrange finite elements *hierarchical complement* spaces and corresponding completions are easily realized. In this case it is particularly convenient to adopt the convention to identify the *indices* in $\mathcal{I}_H$ with the *nodes* in the underlying mesh, i.e., one simply has to take $\mathcal{J} := \mathcal{I}_h \backslash \mathcal{I}_H$ and $\psi_k := \phi_{h,k}, k \in \mathcal{J}$ where $k \in \mathcal{I}_H$ or $k \in \mathcal{J}$ also denote points in Ω. In this case the matrices $\boldsymbol{P}_e$, $\boldsymbol{R}_e, e \in \{0,1\}$, are easily identified. In particular, they are very sparse, i.e., both prolongation and restriction operators are *local.*

Since this will frequently be referred to, we recall for the convenience of the reader some (well-known) details when the underlying trial spaces are standard continuous piecewise linear functions on a sequence of uniformly refined triangulations [35]. Denoting by $\mathcal{N}_k \subset \mathcal{J}$ the set of neighbors of $k \in \mathcal{I}_H$ in $\mathcal{I}_h$, one obviously has $\phi_{H,k} = \sum_{m\in\{k\}\cup\mathcal{N}_k} \frac{\phi_{H,k}(m)}{\|\phi_{h,m}\|_{L_\infty}}\phi_{h,m}$. One easily checks that

$$(12)\quad (\boldsymbol{P}_0)_{m,k} = \frac{\phi_{H,k}(m)}{\|\phi_{h,m}\|_{L_\infty}},\quad m\in\mathcal{I}_h,\ k\in\mathcal{I}_H,\qquad (\boldsymbol{P}_1)_{m,k} = \delta_{m,k},\quad m\in\mathcal{I}_h,\ k\in\mathcal{J}.$$

Moreover, the relation $\phi_{h,m} = 2\phi_{H,m} - \sum_{k\in\mathcal{N}_m}\frac{1}{2}\psi_{H,k}$ implies that

$$(13)\ (\boldsymbol{R}_0)_{k,m} = 2\delta_{k,m},\ m\in\mathcal{I}_h,\ k\in\mathcal{I}_H,\quad (\boldsymbol{R}_1)_{k,m} = \begin{cases} -\frac{1}{2}, & m\in\mathcal{I}_H, k\in\mathcal{N}_m,\\ \delta_{k,m}, & k,m\in\mathcal{J},\\ 0 & \text{else.}\end{cases}$$

One readily checks that (11) is satisfied in this case so that the hierarchical completions are stable in the above sense.

The importance of the above hierarchical completions is that they provide easily accessible *initial* completions from which other *problem adapted* completions will be derived. In this context the following remarks should be kept in mind. When S_H, S_h are both given then $\boldsymbol{P}_0$ is *determined.* It will sometimes be useful to change the point of view. Given S_h and *prescribing* $\boldsymbol{P}_0$ determines a *subspace* S_H of S_h spanned by the collection $\boldsymbol{P}_0^T\Phi_h$ regardless of whether S_h was originally obtained through a refinement process or not.

A key idea of the following development is to *adapt* the complements W (and hence restriction and prolongation operators) to the problem at hand. We will therefore make systematic use of the following *modification of stable completions* through coarse grid corrections [9, 13] of the initial hierarchical stable completion. For any $(\#\mathcal{I}_H)\times(\#\mathcal{J})$ matrix $\check{\boldsymbol{L}}$ we infer from $\boldsymbol{PR}=\boldsymbol{I}$ that

$$(14)\qquad \boldsymbol{I} = \boldsymbol{P}\begin{pmatrix}\boldsymbol{I} & \check{\boldsymbol{L}}\\ \boldsymbol{0} & \boldsymbol{I}\end{pmatrix}\begin{pmatrix}\boldsymbol{I} & -\check{\boldsymbol{L}}\\ \boldsymbol{0} & \boldsymbol{I}\end{pmatrix}\boldsymbol{R} =: \check{\boldsymbol{P}}\check{\boldsymbol{R}},$$

so that

$$(15)\qquad \check{\boldsymbol{P}}_0 = \boldsymbol{P}_0,\quad \check{\boldsymbol{P}}_1 = \boldsymbol{P}_0\check{\boldsymbol{L}} + \boldsymbol{P}_1,\quad \check{\boldsymbol{R}}_0 = \boldsymbol{R}_0 - \check{\boldsymbol{L}}\boldsymbol{R}_1,\quad \check{\boldsymbol{R}}_1 = \boldsymbol{R}_1.$$

Thus, one obtains a new complement space

$$(16)\qquad \check{W} := \operatorname{span}\check{\Psi},\quad \check{\Psi}^T := \Phi_h^T\check{\boldsymbol{P}}_1.$$

Retaining the prolongation $\boldsymbol{P}_0$ to S_h means that the original coarse space remains unchanged. Modifications of this sort will be referred to as *type* (I) modification and will be applied to the splitting of trial spaces.

In contrast to [7] we apply a *type* (II) modification to the test spaces. This time we observe that

$$\boldsymbol{I} = \tilde{\boldsymbol{R}}^T \tilde{\boldsymbol{P}}^T = \tilde{\boldsymbol{R}}^T \begin{pmatrix} \boldsymbol{I} & \hat{\boldsymbol{L}} \\ \boldsymbol{0} & \boldsymbol{I} \end{pmatrix} \begin{pmatrix} \boldsymbol{I} & -\hat{\boldsymbol{L}} \\ \boldsymbol{0} & \boldsymbol{I} \end{pmatrix} \tilde{\boldsymbol{P}}^T =: \hat{\boldsymbol{R}}^T \hat{\boldsymbol{P}}^T, \tag{17}$$

which yields

$$\hat{\boldsymbol{R}}_0 = \tilde{\boldsymbol{R}}_0, \quad \hat{\boldsymbol{R}}_1 = \hat{\boldsymbol{L}}^T \tilde{\boldsymbol{R}}_0 + \tilde{\boldsymbol{R}}_1, \quad \hat{\boldsymbol{P}}_0 = \tilde{\boldsymbol{P}}_0 - \tilde{\boldsymbol{P}}_1 \hat{\boldsymbol{L}}^T, \quad \hat{\boldsymbol{P}}_1 = \tilde{\boldsymbol{P}}_1. \tag{18}$$

This time the restriction stays the same while the *prolongation changes*, i.e., the coarse space is now given by span $\hat{\boldsymbol{P}}_0^T \tilde{\Phi}_h$.

Later these modifications may be different for each level j. As long as the corresponding matrices $\hat{\boldsymbol{L}}$, $\check{\boldsymbol{L}}$ have uniformly bounded spectral norms, the corresponding modified bases stay stable [9].

3.2. Stable multiscale bases. The successive splitting of a fine scale trial space into coarser versions and complement spaces gives rise to *hierarchical representations* of the trial functions. The coefficients in such an expansion reflect the detail information needed to upgrade the coarse scale approximations. We will exploit this fact later for adaptive mesh refinement. However, this will require a tight interrelation between the norms of the whole coefficient arrays over all levels and the relevant function norm of the corresponding function. Unfortunately, the hierarchical basis representations based on the stable completions (12) and (13), although being uniformly stable on each individual level, do not give rise to such norm equivalences across levels for either the L_2-norm or the H^1-norm. However, suitable type (I) modifications of stable completions according to (15) allow one to efficiently generate new complement bases $\check{\Psi}_j = \{\check{\psi}_{j,k} : k \in \mathcal{J}_j\}$ with better stability properties. For instance, the coarse grid stabilization proposed in [31] offers one way of determining matrices $\check{\boldsymbol{L}}$ (see also [13] and [12]) to generate stable wavelets from hierarchical basis functions as initial stable completions through the type (I) modifications from (15). An alternative is offered in [9]; see also [23]. The corresponding matrices $\check{\boldsymbol{P}}_j, \check{\boldsymbol{R}}_j$ from (15) remain sparse in all cases.

We will therefore employ later for a posteriori local error control multiscale basis functions $\check{\psi}_{j,k}$ that are H^s-stable for some regularity range of $s \in [0, \alpha)$, $\alpha > 1$, in the sense that

$$c\|\boldsymbol{D}^s \check{\boldsymbol{d}}\|_{\ell_2} \le \left\| \sum_{k \in \mathcal{I}_{j_0}} u_{j_0,k} \phi_{j_0,k} + \sum_{j=j_0+1}^{\infty} \sum_{k \in \mathcal{J}_j} \check{d}_{j,k} \check{\psi}_{j,k} \right\|_{H^s(\Omega)} \le C \|\boldsymbol{D}^s \check{\boldsymbol{d}}\|_{\ell_2}, \tag{19}$$

where $\check{\boldsymbol{d}} = \{u_{j_0,k} : k \in \mathcal{I}_{j_0}\} \cup \{\check{d}_{j,k} : k \in \mathcal{J}_j, j \ge j_0\}$ and $\boldsymbol{D}$ is the diagonal matrix $(\boldsymbol{D})_{(j,k),(j',k')} = 2^j \delta_{(j,k),(j',k')}$. Specifically, in connection with multilinear shape functions $\phi_{j,k}$ on regular quadrilateral meshes, one can employ tensor product wavelets, which will be the choice in our numerical examples below. Their univariate versions are determined as follows: The columns of (the univariate) $\check{\boldsymbol{P}}_0$ are given by $\sqrt{2}/4, \sqrt{2}/2, \sqrt{2}/4$, those of $\check{\boldsymbol{P}}_1$ by $-\sqrt{2}/6, -\sqrt{2}/3, \sqrt{2}, -\sqrt{2}/3, -\sqrt{2}/6$ for interior wavelets, by $-7/12, 1/6, 1/12$ for the left boundary wavelet, and by $1/12, 1/6, -7/12$ for the right boundary wavelet. A typical row of $\check{\boldsymbol{R}}_0$ is given by $-\sqrt{2}/8, \sqrt{2}/4, 3\sqrt{2}/4, \sqrt{2}/4, -\sqrt{2}/8$, of $\check{\boldsymbol{R}}_1$ by $-3\sqrt{2}/16, 3\sqrt{2}/8, -3\sqrt{2}/16$ with the left and right boundary versions $-3/2, 3/4$, respectively, $3/4, -3/2$. In this case (19) holds for $\alpha = 3/2$.

3.3. Two-by-two block systems. Recall that the analogue to (6) for a current discretization level h reads

$$a_{\boldsymbol{\nu}}(\tilde{\Phi}_h, \Phi_h)\boldsymbol{u}_h = \boldsymbol{f}_h := (\tilde{\Phi}_h, f), \tag{20}$$

where $(u, v) := \int_\Omega u(x)v(x)dx$ is the standard inner product on Ω. This system is obviously equivalent to

$$\hat{\boldsymbol{P}}^T a_{\boldsymbol{\nu}}(\tilde{\Phi}_h, \Phi_h)\boldsymbol{P}\boldsymbol{R}\boldsymbol{u}_h = \hat{\boldsymbol{P}}^T \boldsymbol{f}_h, \tag{21}$$

where the matrices $\hat{\boldsymbol{P}}, \hat{\boldsymbol{R}}$ are defined by (18). We will think of the new system matrix $\hat{\boldsymbol{P}}^T a_{\boldsymbol{\nu}}(\tilde{\Phi}_h, \Phi_h)\boldsymbol{P}$ to be obtained in two steps. Starting with easily computable *initial* stable completions $\boldsymbol{P}_1$, $\tilde{\boldsymbol{P}}_1$ and the corresponding complement bases $\Psi, \tilde{\Psi}$ we have as in [5] the *initial blocking*

$$\tilde{\boldsymbol{P}}^T a_{\boldsymbol{\nu}}(\tilde{\Phi}_h, \Phi_h)\boldsymbol{P} := \begin{pmatrix} \mathbf{A}_{0,0} & \mathbf{A}_{0,1} \\ \mathbf{A}_{1,0} & \mathbf{A}_{1,1} \end{pmatrix}. \tag{22}$$

The two-by-two block matrix $\mathbf{A} = (\mathbf{A}_{i,l})_{i,l=0}^1$ is the stiffness matrix relative to the *initial* two-level bases $\Phi_H \cup \Psi$ and $\tilde{\Phi}_H \cup \tilde{\Psi}$ for the trial and test spaces according to the splitting (10). Setting briefly $\Psi^0 := \Phi_H$, $\Psi^1 := \Psi$ and $\tilde{\Psi}^0 := \tilde{\Phi}_H$, $\tilde{\Psi}^1 := \tilde{\Psi}$, one clearly has $\mathbf{A}_{i,l} := a_{\boldsymbol{\nu}}(\tilde{\Psi}^i, \Psi^l)$, $i, l = 0, 1$. Recalling from (14) and (17) how the modified completions are related to the initial stable completions, we may rewrite (21), in turn, in the form

$$\begin{pmatrix} \boldsymbol{I} & -\hat{\boldsymbol{L}} \\ \boldsymbol{0} & \boldsymbol{I} \end{pmatrix} \begin{pmatrix} \mathbf{A}_{0,0} & \mathbf{A}_{0,1} \\ \mathbf{A}_{1,0} & \mathbf{A}_{1,1} \end{pmatrix} \begin{pmatrix} \boldsymbol{u}_H \\ \boldsymbol{d} \end{pmatrix} = \begin{pmatrix} \hat{\boldsymbol{f}}_0 \\ \hat{\boldsymbol{f}}_1 \end{pmatrix}, \tag{23}$$

where $\boldsymbol{u}_H = \boldsymbol{R}_0\boldsymbol{u}_h$, $\boldsymbol{d} = \boldsymbol{R}_1\boldsymbol{u}_h$, $\hat{\boldsymbol{f}}_0 = \hat{\boldsymbol{P}}_0^T \boldsymbol{f}_h$, $\hat{\boldsymbol{f}}_1 = \hat{\boldsymbol{P}}_1^T \boldsymbol{f}_h$.

The choice of the stable completions for the trial spaces will always be the above hierarchical ones. In principle the test spaces may (and will) be different from the trial spaces. Let us postpone for the moment the discussion of the stable completions for the test spaces. Straightforward calculations show that the matrix on the left-hand side of (23) is given by

$$\hat{\boldsymbol{A}} = \begin{pmatrix} \mathbf{A}_{0,0} - \hat{\boldsymbol{L}}\mathbf{A}_{1,0} & \mathbf{A}_{0,1} - \hat{\boldsymbol{L}}\mathbf{A}_{1,1} \\ \mathbf{A}_{1,0} & \mathbf{A}_{1,1} \end{pmatrix} =: \begin{pmatrix} \hat{\boldsymbol{A}}_{0,0} & \hat{\boldsymbol{A}}_{0,1} \\ \hat{\boldsymbol{A}}_{1,0} & \hat{\boldsymbol{A}}_{1,1} \end{pmatrix}. \tag{24}$$

The upper left block in (24) represents the *coarse grid problem.*

As mentioned earlier, methods based on similar blockings have been studied extensively in the literature; see, e.g., [5, 4]. Specifically, the approach in [7, 6] is closely related. In the present terminology, a type (II) modification (17) is applied also to the trial spaces in order to annihilate both off diagonal blocks in (24); see also the discussion in [13] for the merits of these options.

3.4. The choice of $\hat{\boldsymbol{L}}$. Our main objective in exploiting the degrees of freedom offered by the matrices $\hat{\boldsymbol{L}}$ is to decouple the system (23) by (approximately) annihilating the upper right block $\hat{\boldsymbol{A}}_{0,1}$, i.e., choosing $\hat{\boldsymbol{L}}$ so that $\mathbf{A}_{0,1} = \hat{\boldsymbol{L}}\mathbf{A}_{1,1}$, thereby rendering $\hat{\boldsymbol{A}}$ block lower triangular. Thus, our first *ideal* choice would therefore be

$$\hat{\boldsymbol{L}} = \mathbf{A}_{0,1}\mathbf{A}_{1,1}^{-1}. \tag{25}$$

Except in the one-dimensional case where $\mathbf{A}_{1,1}$ is diagonal, the exact solution of the matrix equation (25) (which guarantees $\hat{\boldsymbol{A}}_{0,1} = \mathbf{0}$ with $\check{\boldsymbol{L}} = \mathbf{0}$) would be by far too expensive. In fact, except when $\mathbf{A}_{1,1}$ is diagonal, the matrix $\hat{\boldsymbol{L}}$ would be densely populated. Nevertheless, solving (25) *approximately* will later be seen to lead to a natural multigrid preconditioner.

Given an initial blocking $\mathbf{A}$ we wish to determine a *nearly decoupling* $\hat{\boldsymbol{L}}$ which satisfies (25) approximately, i.e.,

$$\hat{\boldsymbol{L}}\mathbf{A}_{1,1} \approx \mathbf{A}_{0,1}. \tag{26}$$

Note that the rows of $\hat{\boldsymbol{L}}$ can be determined independently of each other, which strongly supports parallelization. Of course, in this context it will be essential to quantify the meaning of $\approx$ in (26). The issue is to find a good compromise between efficiency and accuracy. As long as $\mathbf{A}_{1,1}$ is diagonally dominant (as in the univariate case and in general for moderate convection) the rows of $\hat{\boldsymbol{L}}$ can be determined efficiently with the aid of simple Jacobi iterations.

However, for more demanding problems, e.g., when $\nu \leq 2^{-8}$ while $\|\boldsymbol{\beta}\|$ is at least of the order 1, Jacobi iterations are no longer appropriate. A suitable approximate decoupling then gradually becomes the most demanding part of the whole concept. In this regime of very small diffusion any a-priorily chosen pattern for nonzero entries in $\hat{\boldsymbol{L}}$ turns out to fail. Therefore we have developed a suitable modification of the *sparse approximate inverse* (SPAI) *technique* from [17] where the nonzero pattern for $\hat{\boldsymbol{L}}$ is determined *adaptively.* The objective is to generate for each relevant index $k \in \mathcal{I}_H$, for which the kth row in $\mathbf{A}_{0,1}$ is not identically zero, an index set $\mathcal{P} = \mathcal{P}(k) \subset \mathcal{J}$, the index set of the current complement basis, and a vector $\boldsymbol{x} = \boldsymbol{x}(k)$ supported in $\mathcal{P}$ representing the kth row of $\hat{\boldsymbol{L}}$. $\mathcal{P}$ and $\boldsymbol{x}$ will be successively updated starting with some initialization. We refer to this scheme as $\mathbf{DEC}\,(\mathbf{A}) = \mathbf{DEC}\,(\mathbf{A}, \mathrm{Tol}) \to \hat{\boldsymbol{L}}$, where Tol measures the accuracy of the approximate decoupling; see [30] for a detailed description of this scheme. In fact, when $\boldsymbol{x}^T$ and $\boldsymbol{b}^T$ denote corresponding rows in $\hat{\boldsymbol{L}}$ and $\mathbf{A}_{0,1}$ the scheme continues until $\|\boldsymbol{x}^T\mathbf{A}_{1,1} - \boldsymbol{b}^T\|_{\ell_2}/\|\boldsymbol{b}\|_{\ell_2} \leq \mathrm{Tol}$. A detailed description with all distinctions from the original version in [17] can be found in [14]. The main distinctions result from our primary objective to minimize the size of $\mathcal{P}$ relative to the desired accuracy and to keep the number of least squares solutions as small as possible.

3.5. The basic multigrid iteration. Consider the transformed system $\hat{\boldsymbol{A}}\boldsymbol{u} = \hat{\boldsymbol{f}}$, where $\boldsymbol{u} = (\boldsymbol{u}_0^T, \boldsymbol{u}_1^T)^T = (\boldsymbol{u}_H^T, \boldsymbol{d}^T)^T$ (see (23)), $\hat{\boldsymbol{f}} = (\hat{\boldsymbol{f}}_0^T, \hat{\boldsymbol{f}}_1^T)^T$, and set $\boldsymbol{r}^\mu := \hat{\boldsymbol{f}} - \hat{\boldsymbol{A}}\boldsymbol{u}^\mu = (\boldsymbol{r}_0^\mu, \boldsymbol{r}_1^\mu)^T$. For the above *ideal* choice $\hat{\boldsymbol{A}}_{0,1} = \mathbf{0}$ implied by (25) block elimination applied to the block lower triangular matrix $\hat{\boldsymbol{A}}$ is equivalent to one iteration of the scheme

$$\boldsymbol{u}^{\mu+1} = \boldsymbol{u}^\mu + \left\{ \begin{pmatrix} \hat{\boldsymbol{A}}_{0,0}^{-1} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{pmatrix} + \begin{pmatrix} \mathbf{0} & \mathbf{0} \\ -\mathbf{A}_{1,1}^{-1}\mathbf{A}_{1,0}\hat{\boldsymbol{A}}_{0,0}^{-1} & \mathbf{A}_{1,1}^{-1} \end{pmatrix} \right\} \boldsymbol{r}^\mu \tag{27}$$

for any initial guess $\boldsymbol{u}^\mu$. The application of the first matrix on the right-hand side of (27) corresponds to a *coarse grid correction* and amounts to solving

$$\hat{\boldsymbol{A}}_{0,0}\boldsymbol{e}_0 = \boldsymbol{r}_0^\mu = \hat{\boldsymbol{f}}_0 - \hat{\boldsymbol{A}}_{0,0}\boldsymbol{u}_0^\mu, \tag{28}$$

which gives $\boldsymbol{u}_0^{\mu+1} = \boldsymbol{u}_0^\mu + \boldsymbol{e}_0$. The second matrix affects only the *high frequency part* of the iterates. Substituting (28), we see that its application is equivalent to

$$\boldsymbol{u}_1^{\mu+1} = \boldsymbol{u}_1^\mu + \mathbf{A}_{1,1}^{-1}\left(\boldsymbol{r}_1^\mu - \mathbf{A}_{1,0}\boldsymbol{e}_0\right), \tag{29}$$

which, in turn, amounts to solving

$$\mathbf{A}_{1,1}\boldsymbol{e}_1 = \boldsymbol{r}_1^{\mu} - \mathbf{A}_{1,0}\boldsymbol{e}_0, \tag{30}$$

to obtain $\boldsymbol{u}_1^{\mu+1} = \boldsymbol{u}_1^{\mu} + \boldsymbol{e}_1$.

Of course, the above scheme is idealized because it involves the *exact* inversion of matrices. However, an iterative two-grid scheme is obtained when viewing the first matrix on the right-hand side of (27) as a coarse grid correction and *approximating* the second matrix to define a *smoother* which can be written as a *basic iteration* of the form

$$\boldsymbol{u}^{\mu+1} = (\boldsymbol{I} - \boldsymbol{G}\hat{\boldsymbol{A}})\boldsymbol{u}^{\mu} + \boldsymbol{G}\boldsymbol{f} = \boldsymbol{u}^{\mu} + \boldsymbol{G}\boldsymbol{r}^{\mu},$$

where

$$\boldsymbol{G} = \begin{pmatrix} \mathbf{0} & \mathbf{0} \\ \boldsymbol{M} & \boldsymbol{Q} \end{pmatrix}, \quad \left(\boldsymbol{I} - \boldsymbol{G}\hat{\boldsymbol{A}}\right) = \begin{pmatrix} \boldsymbol{I} & \mathbf{0} \\ -\left(\boldsymbol{M}\hat{\boldsymbol{A}}_{0,0} + \boldsymbol{Q}\mathbf{A}_{1,0}\right) & \boldsymbol{I} - \boldsymbol{Q}\mathbf{A}_{1,1} \end{pmatrix}, \tag{31}$$

and

$$\boldsymbol{Q} \approx \mathbf{A}_{1,1}^{-1}, \quad \boldsymbol{M} \approx -\boldsymbol{Q}\mathbf{A}_{1,0}\hat{\boldsymbol{A}}_{0,0}^{-1}. \tag{32}$$

Thus the *high frequency part* of the error is reduced when

$$\left\| - \left(\boldsymbol{M}\hat{\boldsymbol{A}}_{0,0} + \boldsymbol{Q}\mathbf{A}_{1,0}\right)\boldsymbol{e}_0 + (\boldsymbol{I} - \boldsymbol{Q}\mathbf{A}_{1,1})\,\boldsymbol{e}_1 \right\| < \eta\|\boldsymbol{e}_1\| \tag{33}$$

holds for some $\eta < 1$ and a suitable norm $\|\cdot\|$.

Note that one application of the smoother (31) takes the form

$$\boldsymbol{u}^{\mu+1} = \begin{pmatrix} \boldsymbol{u}_0^{\mu} \\ \boldsymbol{u}_1^{\mu} + \boldsymbol{e}_1 \end{pmatrix}, \quad \boldsymbol{e}_1 = \boldsymbol{M}\boldsymbol{r}_0^{\mu} + \boldsymbol{Q}\boldsymbol{r}_1^{\mu}.$$

The coarse grid correction (28) as well as the smoothing step require solving a system with matrix $\hat{\boldsymbol{A}}_{0,0}$. Note that $\hat{\boldsymbol{A}}_{0,0}$ can be viewed as an *approximate Schur complement* of $\mathbf{A}$ with respect to the complement block $\mathbf{A}_{1,1}$; see [13]. One immediately obtains now a multigrid scheme by applying the same procedure to $\hat{\boldsymbol{A}}_{0,0}$ and so on. To do this we need to specify the initial blocking also for subsequent coarser levels. In the subsequent numerical experiments we have employed the following choice: The initial complement functions $\Psi = \Psi_j$ on the trial side are always the hierarchical ones, that is, when H stands for the jth level, $\boldsymbol{P}_1 = \boldsymbol{P}_{j,1}$ is given by (12). Likewise when h corresponds to the currently highest level we let $\tilde{\Phi}_h = \Phi_h = \Phi_{j+1}$ and $\tilde{\Psi}_{j+1} = \Psi_{j+1}$, i.e., $\tilde{\boldsymbol{P}}_j = \boldsymbol{P}_j = (\boldsymbol{P}_{j,0}, \boldsymbol{P}_{j,1})$. Although on lower levels j, due to the dual modification (18) applied to the test side, the coarse test spaces are no longer spanned by standard hat functions, we can always use the *same* stable completions for the initial blocking of the coarse system $\hat{\boldsymbol{A}}_{0,0}^{j}$ defined by $\boldsymbol{P}_{j-1}^{T}\hat{\boldsymbol{A}}_{0,0}^{j}\boldsymbol{P}_{j-1}$, where $\boldsymbol{P}_{j-1}$ is given by (12). By (11) the corresponding initial complement functions always form uniformly stable bases in the sense of (4).

Recall from [13] that in the univariate case the complement block $\mathbf{A}_{1,1}$ is diagonal and hence easily invertible so that $\hat{\boldsymbol{L}}$ according to (25) can be computed exactly. The following figures illustrate that this choice of $\hat{\boldsymbol{L}}$ produces more and more deformed basis functions for the test spaces when descending to lower levels. In case of dominating convection this has a clear *upwind* effect which in the limit appears to reduce to an upwind finite difference scheme; see Figure 1. In fact, it is known that in the univariate case (with $\check{\boldsymbol{L}} = \mathbf{0}$) decoupling is equivalent to employing L-splines. Figure 2 illustrates the analogous effect for zero convection and large reaction. It would be interesting to relate this to L-splines and so-called exact discretizations [34, 28].

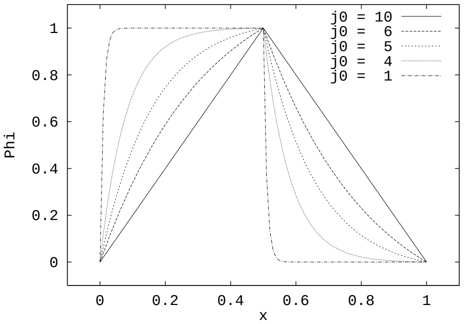

FIG. 1. $\nu = 1$, $\beta = 100$, $\gamma = 0$.

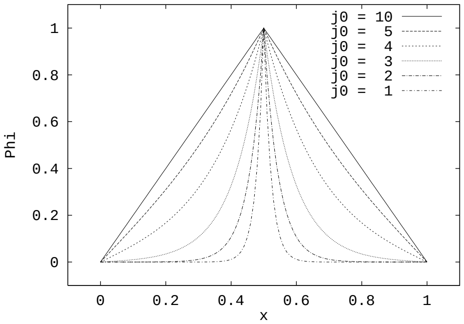

FIG. 2. $\nu = 1$, $\beta = 0$, $\gamma = 2000$.

We can now describe the resulting basic multigrid iteration. It refers to a hierarchy $\mathcal{S}$ of nested trial spaces (which will later not necessarily arise from *uniform* refinements). As before j denotes the current discretization level.

$\mathbf{MG}\,(j, \mathcal{S}, \mathbf{A}_j, \boldsymbol{f}_j, \boldsymbol{u}_j^{\mu}) \rightarrow \boldsymbol{u}_j^{\mu+1}$.

- **Input:** $\mathbf{A}_j := a_{\boldsymbol{\nu}}(\tilde{\Phi}_j, \Phi_j)$ and a current approximation $\boldsymbol{u}_j^{\mu}$ to the solution of the system $\mathbf{A}_j \boldsymbol{u}_j = \boldsymbol{f}_j$.
- **Initial blocking:** Compute $(\mathbf{A}_{i,l})_{i,l=0}^{1} := \boldsymbol{P}^T \mathbf{A}_j \boldsymbol{P}$ where $\boldsymbol{P} := \boldsymbol{P}_{j-1}$ is induced by the initial hierarchical decomposition (10). (In the case of uniform refinements one can, for instance, take $\boldsymbol{P}$ defined by (12).)
- **Decoupling:** Determine $\check{\boldsymbol{L}}$, apply $\mathbf{DEC}\,(\mathbf{A}) \rightarrow \hat{\boldsymbol{L}}$. Compute the matrix $\hat{\boldsymbol{A}}$ according to (24) as well as

$$\begin{pmatrix} \boldsymbol{f}_0 \\ \boldsymbol{f}_1 \end{pmatrix} = \hat{\boldsymbol{P}}_j^T \boldsymbol{f}_j, \quad \begin{pmatrix} \boldsymbol{u}_0 \\ \boldsymbol{u}_1 \end{pmatrix} = \boldsymbol{R}_j \boldsymbol{u}_j^{\mu}.$$

- **Smoothing and coarse grid correction:**
  (1) Compute $\boldsymbol{r}_0 := \boldsymbol{f}_0 - \hat{\boldsymbol{A}}_{0,0}\boldsymbol{u}_0 - \hat{\boldsymbol{A}}_{0,1}\boldsymbol{u}_1$, $\boldsymbol{r}_1 := \boldsymbol{f}_1 - \hat{\boldsymbol{A}}_{1,0}\boldsymbol{u}_0 - \hat{\boldsymbol{A}}_{1,1}\boldsymbol{u}_1$; and if $j > j_0 + 1$ for a coarsest level j_0 apply $\mathbf{MG}\,(j-1, \mathcal{S}, \hat{\boldsymbol{A}}_{0,0}, \boldsymbol{r}_0, \mathbf{0}) \rightarrow \boldsymbol{e}_0'$ to obtain an approximate solution of the coarse grid problem

$$\hat{\boldsymbol{A}}_{0,0}\boldsymbol{e}_0 = \boldsymbol{r}_0; \tag{34}$$

  else apply a direct solver to (34).
  (2) Determine an approximate solution $\boldsymbol{e}_1'$ of the complement system

$$\mathbf{A}_{1,1}\boldsymbol{e}_1 = \boldsymbol{r}_1 - \mathbf{A}_{1,0}\boldsymbol{e}_0' \tag{35}$$

  and compute $\boldsymbol{u}_0' := \boldsymbol{u}_0 + \boldsymbol{e}_0'$, $\boldsymbol{u}_1' = \boldsymbol{u}_1 + \boldsymbol{e}_1'$.
  (3) Set

$$\boldsymbol{u}_j^{\mu+1} := (\boldsymbol{P}_{j,0}, \boldsymbol{P}_{j,1}) \begin{pmatrix} \boldsymbol{u}_0' \\ \boldsymbol{u}_1' \end{pmatrix}. \tag{36}$$

A few comments on the above scheme are in order. Of course, the rationale behind the above scheme is that it is essentially a perturbation of the ideal scheme from section 3.5. In fact, since the matrix $\hat{\boldsymbol{L}}$ produced by **DEC** does not satisfy (25) exactly the upper right block $\hat{\boldsymbol{A}}_{0,1}$ does not vanish. Moreover, (34) and (35) mean that the operators $\boldsymbol{M}, \boldsymbol{Q}$ in the smoother (31) are only approximations to the ideal choices in (32). Since these ideal choices would, according to (33), annihilate the high frequency part of the error completely the damping of this high frequency part and hence the convergence properties of the iterative scheme will depend on the accuracy of the approximations to $\hat{\boldsymbol{L}}$, $\boldsymbol{M}$, and $\boldsymbol{Q}$. By recursion this affects also the solution in (34) and will produce a better reduction in (33). Thus the number of multigrid cycles can be kept small at the expense of investing more computational effort, e.g., in the computation of $\hat{\boldsymbol{L}}$ or the execution of $\boldsymbol{M}$ and $\boldsymbol{Q}$. In this context note that the above multigrid iteration has V-cycle structure. It would be straightforward to formulate smoothing and coarse grid correction in terms of W-cycles. However, our numerical tests have shown that the number of cycles in either mode depends essentially on the quality of the approximate decoupling and the smoother. So far this is done by adapting the accuracy of **DEC** (**A**). Of course, it would be highly desirable to have a robust automatic procedure for adapting the involved tuning parameters, which is still subject to further research; see the discussion in section 5.

4. Adaptive full multigrid.

The objective is to design an adaptive refinement strategy which, as long as layers are to be *resolved*, in combination with the above multigrid scheme not only reduces computational cost and storage but also *stabilizes* the numerical solution without the need of an a priori stabilization technique. We proceed now describing the main ingredients.

4.1. Locally refined trial spaces.

Instead of working with an a priori fixed sequence of *uniformly refined* trial spaces we will seek for approximate solutions of (1) in a suitably adapted hierarchy of *subspaces* $S_j^\circ \subset S_j$. To describe the underlying setting let j_0 denote the coarsest level, i.e., S_{j_0} is the usual finite element space with respect to a (quasi-) uniform triangulation of Ω. As before each of the (full) spaces S_j is spanned by a basis $\Phi_j = \{\phi_{j,k} : k \in \mathcal{I}_j\}$ of Lagrange type, i.e., identifying $\mathcal{I}_j$ with the nodes, we have

$$\phi_{j,k}(k')/\|\phi_{j,k}\|_{L_\infty(\Omega)} = \delta_{k,k'}, \quad k,k' \in \mathcal{I}_j. \tag{37}$$

We will describe now how to generate larger spaces that are not necessarily spanned by *all* basis functions of a given level. Instead we make use of the refinement equation (8) which for each individual coarse basis function reads

$$\phi_{j,k} = \sum_{l\in\mathcal{I}_{j+1,k}} (\boldsymbol{P}_{j,0})_{l,k}\phi_{j+1,l}, \tag{38}$$

where $\mathcal{I}_{j+1,k}$ is the support of the kth column of $\boldsymbol{P}_{j,0}$, i.e., $\mathcal{I}_{j+1,k} = \{l \in \mathcal{I}_{j+1} : (\boldsymbol{P}_{j,0})_{l,k} \neq 0\}$.

It will be convenient to characterize the locally refined trial spaces by *grids* or better yet by collections of nodes that will eventually be nonuniformly spaced. These collection of nodes are generated as follows.

- **Initialization:** Let $\mathcal{G} := \{(j_0,k) : k \in \mathcal{I}_{j_0}\}$.
- For a given $\mathcal{G}$ a refinement step consists of selecting some set $\mathcal{R} \subseteq \mathcal{G}$ and setting

  $$(\mathcal{G}\setminus\mathcal{R}) \cup \mathcal{G}_\mathcal{R} \to \mathcal{G} \quad \text{where} \quad \mathcal{G}_\mathcal{R} := \{(l+1,m) : (l,k) \in \mathcal{R},\ m \in \mathcal{I}_{l+1,k}\}. \tag{39}$$

> Thus one marks a set of nodes in the current set and replaces them by those nodes on the next finer level which correspond to the fine grid basis functions needed to represent the marked coarse grid basis functions through (38).

Note that at a given stage the set $\mathcal{R}$ could contain pairs (l,k) from *different* levels l. Of course, associating with each $(l,k)\in\mathcal{G}$ the basis function $\phi_{l,k}$ the corresponding piecewise polynomial structure induces a *mesh* which is generally nonuniform and contains *hanging nodes.* This is illustrated in Figures 3 and 4. The solid circles (●) in Figure 3 form a typical set $\mathcal{R}$ of coarse grid nodes that are to be refined. The coarse grid basis functions marked by (○) remain unchanged. Figure 4 displays the refined nodes (•) replacing the elements of $\mathcal{R}$.

Defining $S_{\mathcal{G}} := \operatorname{span}\{\phi_{j,k} : (j,k)\in\mathcal{G}\}$, and given any refinement $\mathcal{G}'$ of $\mathcal{G}$ in the above sense, it is clear then that $S_{\mathcal{G}}\subset S_{\mathcal{G}'}$ and $\Phi_{\mathcal{G}} := \{\phi_{j,k} : (j,k)\in\mathcal{G}\}$ is a basis of $S_{\mathcal{G}}$.

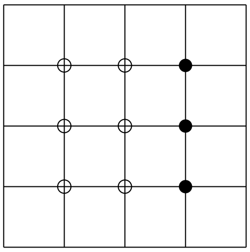

FIG. 3. *Nodes to be refined.*

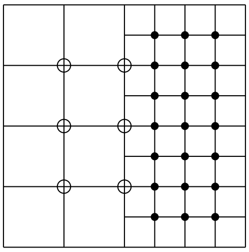

FIG. 4. *Refined grid.*

It will be useful to decompose $\mathcal{G}$ in its contributions to different levels. Let $J := \max\{j : (j,k)\in\mathcal{G}\}$ and define

$$\mathcal{I}_j^- := \{k : (j,k)\in\mathcal{G}\} \quad \text{for } j = J,\dots,j_0.$$

Obviously one has $\mathcal{G} = \bigcup_{j=j_0}^J\{(j,k) : k\in\mathcal{I}_j^-\}$ and $\mathcal{I}_j^-\cap\mathcal{I}_l^- = \emptyset$ for $j\neq l$. Every element $u_J\in S_{\mathcal{G}}$ has a unique representation

$$u_J = \sum_{j=j_0}^{J}\sum_{k\in\mathcal{I}_j^-} u_{j,k}^{\circ}\phi_{j,k}. \tag{40}$$

This representation involves the standard shape functions on the *locally* highest level of current resolution. The coarse grid matrix will be represented with respect to this basis because it allows us best to exploit sparseness.

4.2. Local multiscale transformations. In addition to the nodal basis representation of trial functions we will have to make use of two-level or even multilevel representations in terms of complement basis functions of the form (9). They are determined by stable completions represented by matrix pairs $\boldsymbol{P}^\circ, \boldsymbol{R}^\circ$. Here $\boldsymbol{P}^\circ$ will stand for either hierarchical complements $\boldsymbol{P}^\circ = \boldsymbol{P}$ or for stable bases in the sense of (19) $\boldsymbol{P}^\circ = \check{\boldsymbol{P}}$. Recall that in all cases both $\boldsymbol{P}^\circ$ and $\boldsymbol{R}^\circ$ are sparse.

In principle, the structure of transformations between representations in terms of nodal functions and complement functions is well known for uniform refinements. The only issue here is to realize such transformations for the locally refined case without unnecessarily increasing the complexity. To explain the essence of the matter, recall from section 3.1 that $\Phi_h^T\boldsymbol{u}_h = \Phi_H^T(\boldsymbol{R}_0^\circ\boldsymbol{u}_h) + \Psi^T(\boldsymbol{R}_1^\circ\boldsymbol{u}_h)$, which splits a fine scale representation into a coarse scale representation and a complement part determined by the given stable completion. Now suppose that J is the highest level occurring in a locally refined space as described above. Thus the support $\mathcal{I}_J^-$ could be much smaller than the full set of nodes on level J. By the above splitting, the coarse coefficients and complement coefficients are given by

$$\boldsymbol{u}_J^\circ \rightarrow \left\{ \begin{array}{lcl} \boldsymbol{R}_0^\circ \boldsymbol{u}_J^\circ & =: & \hat{\boldsymbol{u}}_{J-1}, \\ \boldsymbol{R}_1^\circ \boldsymbol{u}_J^\circ & =: & \boldsymbol{d}_J^\circ, \end{array} \right. \tag{41}$$

where these matrix/vector multiplications are carried out in a sparse format. That is, only the active coefficients in $\boldsymbol{u}_J^\circ$ select the corresponding active columns of $\boldsymbol{R}^\circ$ so that, due to the sparseness of $\boldsymbol{R}^\circ$, the computational work stays proportional to $\#\mathcal{I}_J^-$. The array $\boldsymbol{d}_J^\circ$ with support $\mathcal{J}_J^\circ$ are the *wavelet coefficients* on the highest level and will remain untouched in subsequent steps. The coarse scale coefficients $\hat{\boldsymbol{u}}_{J-1}$ will be added (if applicable) to the coefficients $\boldsymbol{u}_{J-1}^\circ$ to form the resulting contribution $\bar{\boldsymbol{u}}_{J-1} := \hat{\boldsymbol{u}}_{J-1} + \boldsymbol{u}_{J-1}^\circ$ with support $\bar{\mathcal{I}}_{J-1}$ on level $J-1$.

In the above multigrid scheme this two-level splitting already suffices. Below we will also need a full transformation involving all lower levels. This means the above procedure will be successively applied to the arrays $\bar{\boldsymbol{u}}_j$ for $j < J$, each time splitting off the wavelet coefficients $\boldsymbol{d}_j^\circ$ with supports $\mathcal{J}_j^\circ$. This results in the alternative representation

$$u_J = \sum_{k \in \bar{\mathcal{I}}_{j_0}} \bar{u}_{j_0,k} \phi_{j_0,k} + \sum_{j=j_0+1}^{J} \sum_{k \in \mathcal{J}_j^\circ} d_{j,k}^\circ \psi_{j,k}^\circ \tag{42}$$

of the function u_J in (40). Hence, denoting by

$$\boldsymbol{u}_{\mathcal{G}}^J := ((\boldsymbol{u}_{j_0}^\circ)^T, (\boldsymbol{u}_{j_0+1}^\circ)^T, \ldots, (\boldsymbol{u}_J^\circ)^T)^T, \quad \boldsymbol{u}_{ms}^J := ((\bar{\boldsymbol{u}}_{j_0})^T, (\boldsymbol{d}_{j_0+1}^\circ)^T, \ldots, (\boldsymbol{d}_J^\circ)^T)^T$$

the coefficient arrays in (40) and (42), respectively, the transformation $\boldsymbol{T}_{\mathcal{G}}^\circ : \boldsymbol{u}^J \rightarrow \boldsymbol{u}_{ms}^J$ can be carried out by successively applying (41). It is clear that the number of operations required by this transformation remains proportional to $\#\mathcal{G}$.

Likewise, an analogous local successive application of the steps

$$\boldsymbol{P}_{j-1,0}^\circ \bar{\boldsymbol{u}}_{j-1} + \boldsymbol{P}_{j-1,1}^\circ \boldsymbol{d}_j^\circ = \bar{\boldsymbol{u}}_j \tag{43}$$

realizes the transformation $(\boldsymbol{T}_{\mathcal{G}}^\circ)^{-1} : \boldsymbol{u}_{ms}^J \rightarrow \boldsymbol{u}_{\mathcal{G}}^J$ also at an expense of $\mathcal{O}(\#\mathcal{G})$ flops. The reader is referred to [15] for the details of these transformations.

The full multiscale transformation will be needed only for the adaptive mesh refinement and thus involves $\boldsymbol{P}^\circ = \check{\boldsymbol{P}}$. However, the corresponding transformations $\check{\boldsymbol{T}}_{\mathcal{G}}, \check{\boldsymbol{T}}_{\mathcal{G}}^{-1}$ can be efficiently generated through the hierarchical basis transformations and (15). Therefore we briefly indicate the simple interrelation between the sets $\mathcal{G}$ and $\{\bar{\mathcal{I}}_{j_0}, \mathcal{J}_{j_0+1}^\circ, \ldots, \mathcal{J}_J^\circ\}$ in the special case $\boldsymbol{P}^\circ = \boldsymbol{P}$. To describe this let $\mathcal{I}_J^+ := \mathcal{I}_J^-$ and for $j_0 < j \leq J$

$$\mathcal{J}_j^\circ := \mathcal{I}_j^+ \setminus \mathcal{I}_{j-1}, \quad \mathcal{I}_{j-1}^+ := \mathcal{I}_{j-1}^- \cup \left(\mathcal{I}_j^+ \cap \mathcal{I}_{j-1}\right). \tag{44}$$

Thus there is a simple one-to-one correspondence between the set $\mathcal{G}$ and the set $\mathcal{J} := \{(j_0, k) : k \in \mathcal{I}_{j_0}\} \cup \bigcup_{j=j_0+1}^{J} \{(j,k) : k \in \mathcal{J}_j^\circ\}$. It is important to bear in mind that both sets $\mathcal{G}$ and $\mathcal{J}$ contain index *pairs* (j,k) where only the second index k refers to a spatial location as a node. The same node k may have different level indices j,l depending on the data structure context $(l,k)\in\mathcal{G}$ or $(j,k)\in\mathcal{J}$.

4.3. Refinement strategy. The norm equivalence (19) offers new ways of estimating errors. To see this suppose $u_J = \sum_{k\in\mathcal{I}_{j_0}} u_{j_0,k}\phi_{j_0,k} + \sum_{j=j_0+1}^{J}\sum_{k\in\mathcal{J}_j}\check{d}_{j,k}\check{\psi}_{j,k}$ is a current approximation to u. Among the many possible examples, consider the following thresholding scheme for coarsening a given approximation:

(i) Fix a tolerance $\eta > 0$.

(ii) For $j = j_0+1,\dots,J$, find the largest $\tilde{\mathcal{J}}_j \subset \mathcal{J}_j$ such that for some fixed $\alpha > 0$ one has $\sum_{k\in\tilde{\mathcal{J}}_j} |\check{d}_{j,k}|^2 \le 2^{\alpha(j-J)}\eta^2$ and set

$$\tilde{d}_{j,k} := \begin{cases} \check{d}_{j,k} & \text{if} \quad k\in\mathcal{J}_j\setminus\tilde{\mathcal{J}}_j; \\ 0 & \text{if} \quad k\in\tilde{\mathcal{J}}_j. \end{cases}$$

Clearly, by (19), $\tilde{u}_J := \sum_{(j,k)\in\mathcal{J}\setminus\tilde{\mathcal{J}}}\check{d}_{j,k}\check{\psi}_{j,k}$ then satisfies $\|u_J - \tilde{u}_J\|_{L_2(\Omega)} \le c\eta$, where c depends only on the constants in (19) for $s=0$. Applying an analogous procedure to $2^j\check{d}_{j,k}$ yields estimates in H^1. This strategy imposes higher accuracy for low-level coefficients. Alternatively one could determine the largest $\tilde{\mathcal{J}} \subset \mathcal{J}$ such that $\sum_{(j,k)\in\tilde{cJ}} |\check{d}_{j,k}|^2 \le \eta^2$ to arrive at the same conclusion. A detailed account of related strategies for elliptic problems is given in [11].

Conversely, denoting by $\partial\mathcal{J}$ those indices reflecting a locally highest level, elements in $\partial\mathcal{J}\cap(\mathcal{J}\setminus\tilde{\mathcal{J}})$ may be taken to determine the next refinement (again variants are possible). The corresponding modifications of the meshes $\mathcal{G}$ will be described in the routines below.

We will now describe how the collections $\mathcal{G}$ and corresponding trial spaces $S_{\mathcal{G}}$ emerge through a refinement strategy by monitoring the multiscale coefficients $\boldsymbol{u}^J_{ms}$ based on the above considerations. Since the coefficients of the complement functions $\check{\psi}_{j,k}$ represent high scale fluctuations, whenever for some $(j,k)\in\partial\mathcal{G}$ the coefficient $|d_{j,k}|$ is large, this indicates that u^J exhibits strong oscillations of locally high frequency. Such oscillations may be caused by (locally) large grid-Péclet numbers or by the fact that the current approximation is locally not yet accurate enough. In *both* cases a refinement is needed. In particular, the approximate solutions of the complement problem (35) can be used to control local refinements. Hence a natural refinement strategy is to refine the trial spaces at locations where even *after smoothing* such high oscillations are still exhibited by the current approximate solution. It will be seen later that due to the nature of the full multigrid scheme below, it will be necessary to coarsen a space. Moreover, it will simplify data management significantly when working only with *graded* sets $\mathcal{G}$. This means that each edge in the mesh contains at most one hanging node, i.e., the levels of neighboring mesh points differ at most by one. It turns out that this is a very mild restriction which is satisfied in most cases automatically. We describe next a scheme that combines all three tasks: coarsening, refining, and grading. Its input are the current grid $\mathcal{G}$, the set $\mathcal{R}$ marking the last refinement in a prior step (which is needed to organize the coarsening), the array $\boldsymbol{u}^J_{ms}$ of wavelet coefficients with highest level J of the current solution, a vector $\boldsymbol{\tau} = (\tau_{j_0+1},\dots,\tau_J)$ of tolerances for refinement, and a corresponding vector $\boldsymbol{\tau}'$ for coarsening. The latter ones should be somewhat smaller. A typical choice is $\tau'_j = \tau_j/2$. The choice of the τ_j will be discussed later in connection with applications; see section 4.4.

REF-COARSE ($\mathcal{G}$, $\mathcal{R}$, $\boldsymbol{u}^J_{ms}$ $\boldsymbol{\tau}$, $\boldsymbol{\tau}'$) → ($\mathcal{R}$, $\mathcal{G}$).

```
• $\mathcal{R}' := \mathcal{R}$
• for $j = J, J-1, \ldots, j_0+1$
      $\mathcal{K}_{j+1} := \{k \in \mathcal{J}_{j+1} \ : \ \check{d}_{j+1,k} \neq 0\}$
      for $(j,k) \in \mathcal{R}'$
          if $(j+1,l) \notin \mathcal{R}' \ \forall\, l \in \mathcal{I}_{j+1,k}$
             $\mathcal{K}^G_l := \{l' \in \mathcal{J}_{j+1} \ : \ g^{j,1}_{l',l} \neq 0\}$
             if $|\check{d}_{j+1,l'}| < \tau'_{j+1} \ \forall\, l' \in \mathcal{K}_{j+1} \cap \bigcup_{l \in \mathcal{I}_{j+1,k}} \mathcal{K}^G_l$
                $\mathcal{R} := \mathcal{R} \setminus \{(j,k)\}$

                $\mathcal{I}^+_{j+1} := \mathcal{I}^+_{j+1} \cup \mathcal{I}_{j+1,k}$
          else $\mathcal{G} := \mathcal{G} \cup \{(j,k)\}$
• $\mathcal{G} := \mathcal{G} \cup \{(j+1,k) : k \in \mathcal{I}^+_{j+1}\}$
```

4.4. The main algorithm. We have by now collected the main ingredients that will enter the adaptive full multigrid scheme. The basic idea may be sketched as follows. We begin on a coarse mesh and raise the viscosity so that the grid-Péclet number is approximately one. This means that the solution to the modified problem starts to exhibit oscillations while the above multigrid scheme is still efficient. A (possibly local) refinement based on the multiscale representation of the current solution is then made according to the above refinement strategy. The viscosity is reduced by a factor two and the (prolonged) current solution is used as an initial guess for the problem with lowered viscosity on the refined space. Note that the viscosity is halved *globally* even when the refinement is only *local.* This procedure is repeated until one either arrives at a prescribed highest level J_{max} of highest local resolution or until the original viscosity is restored. The multigrid iteration on this final mesh proceeds then until a stopping criterion is met. Thus in the course of nested iteration the original problem is approached through a sequence of auxiliary problems.

Before describing the algorithmic details a few preparatory remarks are necessary. By $\|\cdot\|_X$ we denote the norm in which the accuracy is to be measured. We will consider here only $X = L_2(\Omega)$ and $X = H^1_0(\Omega)$, but other choices are conceivable. The threshold parameters $\boldsymbol{\tau}, \boldsymbol{\tau}'$ appearing in **REF-COARSE** have the form

$$\tau_j = \kappa \, \|u_J\|_\infty \, 2^{(j-J)d/2}, \quad \tau'_j \leq \tau_j, \tag{45}$$

where κ is a constant controlling the overall accuracy of the approximate solutions. Note that the tolerances τ_j require higher relative accuracy on lower levels. In fact, in our experiments level-independent thresholds always produced worse results. We use a fixed choice for the matrices $\check{\boldsymbol{L}}$ controlling the splittings of the trial spaces according either to (Ia) or to (Ib) described in section 3.4. The multiscale transformation $\boldsymbol{T}_{\mathcal{G}}$ appearing below corresponds to the wavelet basis used in **REF-COARSE**; see sections 3.2 and 4.3. Finally, tol represents the target accuracy for the discrete systems and μ is the number of iterations in **MG**.

```
FMG $(f, \mu, \mathrm{tol}) \to \boldsymbol{u}$.
(1) Choose a coarsest level $j_0$, set $J = j_0 + 1$, choose the smallest $L$ such that
    $P_J(2^L\nu) < 1$, and set $\nu_J := 2^L\nu$. Let $\mathcal{G} = \mathcal{I}_{j_0+1}$, $\mathcal{R} = \emptyset$. Fix $J_{max} > L$ and
    compute
    $\mathbf{A}_J := a_{\nu_J}(\Phi_J, \Phi_J), \quad \boldsymbol{f}_J := (\Phi_J, f), \quad \mathcal{S} = \{\mathrm{span}\,\Phi_{j_0}, \mathrm{span}\,\Phi_{j_0+1}\}, \; \boldsymbol{u}_J = \mathbf{0}.$
(2) Set $\boldsymbol{u}_J^{(0)} = \boldsymbol{u}_J$.
    For $i = 1, \dots, \mu$ apply MG $(J, \mathcal{S}, \mathbf{A}_J, \boldsymbol{f}_J, \boldsymbol{u}_J^{(i-1)}) \to \boldsymbol{u}_J^{(i)}$.
    Set $\boldsymbol{u}'_J = \boldsymbol{u}_J^{(\mu)}$, $\boldsymbol{u}_J = \boldsymbol{u}_J^{(\mu-1)}$.
(3) If $J = J_{max}$
        compute $e_J := \|\boldsymbol{u}_J - \boldsymbol{u}'_J\|_X$.
        If $e_J \le$ tol accept $\boldsymbol{u}'_J$ as solution, set $\boldsymbol{u} := \boldsymbol{u}'_J$ and STOP. Else
        Set $\mu = 1$.
        Replace $\boldsymbol{u}_J$ by $\boldsymbol{u}'_J$ and go to (2).
(4) Compute $\boldsymbol{u}'_{ms} := \boldsymbol{T}_{\mathcal{G}}\boldsymbol{u}'_J$ and $\boldsymbol{\tau}, \boldsymbol{\tau}'$ based on $\boldsymbol{u}'_J$ according to (45).
(5) Apply REF-COARSE $(\mathcal{G}, \mathcal{R}, \boldsymbol{u}'_{ms}, \boldsymbol{\tau}, \boldsymbol{\tau}',) \to (\mathcal{R}, \mathcal{G}')$;
    If $\mathcal{G}' = \mathcal{G}$, $\nu_J = \nu$ and $J < J_{max} - 1$, set $J = J + 1$ and go to (5).
    Else
      • Set $\nu_{J+1} := \max\{\nu, \nu_J/2\}$;
      • Replace $J$ by $J + 1$;
      • Compute initial guess for next iteration:
            if $(j,k) \in \mathcal{G} \cap \mathcal{G}'$ then $u_{j,k} = u'_{j,k}$
            else if $(j,k) \in \mathcal{G}' \backslash \mathcal{G}$ then $u_{j,k} = \sum_{l \in \mathcal{I}^-_{j-1}} m^{j-1,0}_{k,l} u'_{j-1,l}$
            else if $(j,k) \in \mathcal{G} \backslash \mathcal{G}'$ then $u_{j,k} = \sum_{l \in \mathcal{I}^-_{j+1}} g^{j,0}_{k,l} u'_{j+1,l}$.
      • Replace $\mathcal{G}$ by $\mathcal{G}'$;
      • Determine the sets $\mathcal{I}^-_j$, $\mathcal{I}^+_j$, $j = j_0, \dots, J$ and set $\Phi^\circ_j := \{\phi_{l,k} : k \in$
        $\mathcal{I}^+_j, k \in \mathcal{I}^-_l, l = j_0, \dots, j-1\}$;
      • Set $\mathcal{S} = \{\mathrm{span}\,\Phi_{j_0}, \mathrm{span}\,\Phi^\circ_{j_0+1}, \dots, \mathrm{span}\,\Phi^\circ_J\}$;
      • Compute the new stiffness matrix $\mathbf{A}_J := a_{\nu_J}(\Phi_J, \Phi_J)$ and right-hand
        side $\boldsymbol{f}_J = (\Phi_J, f)$;
      • Go to (2).
```

One should note that the approximate solutions u_J are given in the form (40). Hence the stiffness matrices are always computed in the sparsest format. A multiscale stiffness matrix is never assembled. Only one step of the multiscale transformation is used to produce the block matrices. Otherwise it is used to produce the representation (42) for analysis purposes.

We close this section with some comments on the coarsening step in step (5). This step is necessary because the variation of the viscosity ν_j during the refinement process may cause layers to *migrate*. This is illustrated by the following simple univariate example where $\nu = 2^{-11}$, $f = 1$, $\gamma = 0$, and $\beta = \beta(x)$ is the ninth-degree truncated Taylor expansion of $-1-\sin(4\pi x)$. With the above parameters the algorithm produces 25 refinement steps while $J = 17$ is the highest level of local refinements. As shown by

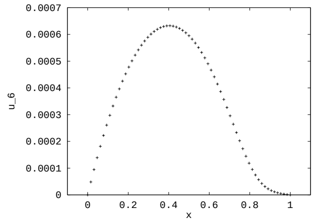

FIG. 5. $\nu_J = 2^{18}\nu,\ J = 6$.

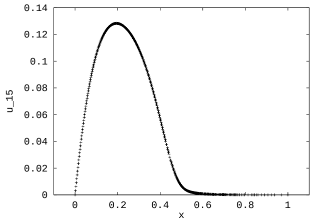

FIG. 6. $\nu_J = 2^{9}\nu,\ J = 15$.

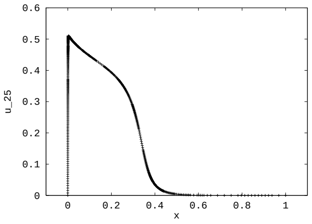

FIG. 7. $\nu_J = \nu,\ J = 25$.

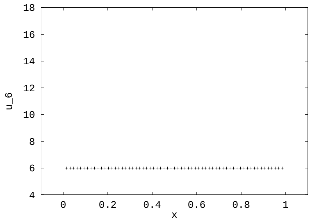

FIG. 8. $\nu_J = 2^{18}\nu,\ J = 6$.

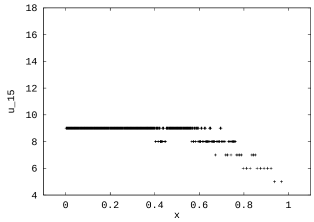

FIG. 9. $\nu_J = 2^{9}\nu,\ J = 15$.

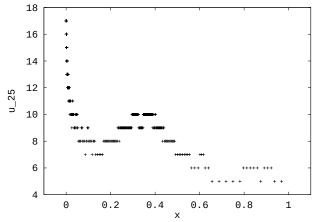

FIG. 10. $\nu_J = \nu,\ J = 25$.

Figures 5–10 the peak of intermediate approximate solutions migrates to the left when proceeding to higher levels and lowering viscosity. Without coarsening one would end up with unnecessary refinements throughout most of the domain.

Figures 5, 6, and 7 display approximate solutions for various current highest levels J and corresponding viscosity ν_J. The corresponding distributions of nodes are depicted in Figures 8, 9, and 10 to demonstrate how they evolve in the course of nested iteration.

5. Numerical results.

Algorithm **FMG** will be tested now on several examples posing different potential obstructions. Our main interest concerns (i) the reliability of the algorithm, i.e., all physical relevant effects should be appropriately resolved, (ii) the performance of the computation, e.g., in comparison with quasi-uniform discretizations, and (iii) the accuracy of the solution in terms of the involved degrees of freedom.

The test cases. We consider the following examples: (A) a constant direction of convection which results in a typical boundary layer, (B) variable convection causing a "near singularity" at a point in the interior, and (C) the interaction of convection and reaction. The corresponding convection and reaction coefficients are given by

(A) constant convection:
$\beta_1(x,y) = 1,\ \beta_2(x,y) = 1,\ \gamma = 0;$
(B) variable convection:
$\beta_1(x,y) = \frac{1}{2} - x,\ \beta_2(x,y) = \frac{1}{2} - y,\ \gamma = 0;$
(C) interaction of convection and reaction:
$\beta_1(x,y) = 1 + x^2,\ \beta_2(x,y) = x\,y,\ \gamma(x,y) = 10\,(\frac{1}{2} - x);$

In all cases we have employed finite element spaces spanned by standard bilinear shape functions on the domain $\Omega = (0,1)^2$. The coarsest level is always $j_0 = 2$, and $f = 1$ is always chosen as the right-hand side. We have deliberately dispensed with employing predetermined solutions because we wanted the singular behavior of the solution to truly reflect the particular choice of parameters in the variational problem.

The highest level of (local) refinement is always bounded by some integer J_{max}. Depending on the accuracy requirements and the coefficients in (1) this will sometimes be attained and sometimes a lower level $J = J_c$ turns out to suffice. All remaining parameters that have to be specified for the different computations are listed in Table 1. In particular, the threshold parameters $\tau_j = \kappa \, \|u_J\|_\infty \, 2^{j-J}$ and $\tau_j' = \kappa' \, \|u_J\|_\infty \, 2^{j-J}$ are characterized by the parameters κ and κ', respectively.

Table 1
Parameters for the computations.

Case	ν	κ	κ'	μ	J
A1	2^{-13}	2×10^{-6}	1×10^{-6}	5	14
A2	2^{-7}	1×10^{-5}	1×10^{-6}	3	9
B1	2^{-15}	5×10^{-5}	2.5×10^{-5}	5	14
B2	2^{-8}	2×10^{-4}	2×10^{-5}	3	9
C	2^{-7}	5×10^{-5}	5×10^{-5}	2	8

All computations have been carried out on a PC with a Pentium III processor (600 MHz).

Reliability. Some figures illustrating the numerical results for Cases A1, B1, and C follow. In Figures 11–16, we display the graph of the approximate solution and the corresponding adaptive mesh in order to see whether the automatic refinement actually captures the essential features of the solution and avoids unnecessary refinements.

Case A1. The refinement pattern in Figure 12 looks very appropriate—medium refinement around the diagonal ridge, strong local refinements at the corners and along the boundary layers. Of course, anisotropic refinements would be even better, but the present scheme does not require any a priori knowledge of the structure of the solution, and whenever alignment with meshlines is violated, isotropic refinements would evolve anyway.

Case B1. In Figure 14 we see a perfect symmetry and the refinement pattern accurately reflects the structure of the solution; see Figure 13.

Case C. Overall the test confirms that the algorithm deals with convection and reaction in essentially the same way. Although the reduction of unknowns is not as strong as before, one obtains a stable meaningful solution; see Figures 15 and 16.

In all cases we notice that the adaptation process works reliable in the sense that higher resolution levels occur only near steep gradients, whereas for moderate variation of the solution a much coarser resolution is recognized to suffice.

In particular, we emphasize that in Cases A1 and B1 we have chosen a fairly small diffusion without any a priori stabilization in the Galerkin discretization in order to see how this affects the various algorithmic ingredients. Progressing to extremely fine local resolutions turns out to put more and more burden on the approximate decoupling routine **DEC** (**A**), and a proper choice of the involved control parameters becomes essential when ν is of the order of 2^{-13}. So far these parameters are still set based on experience. A robust automatic adaptation is still subject to further research.

Performance. In order to demonstrate the benefits of the adaptive algorithm we compare the results with those for uniform meshes. Here we consider only the Cases A2 and B2, since the number of refinement levels has to be moderate due to the high memory requirements of the full grid.

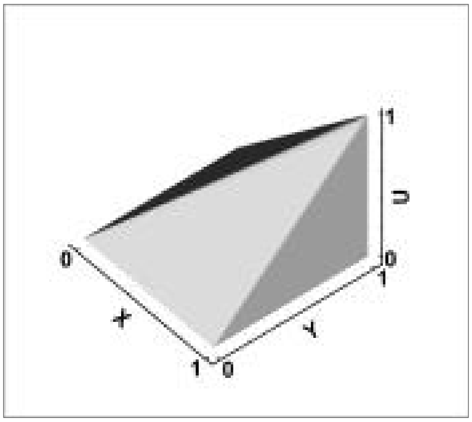

Fig. 11. *Case* A1.

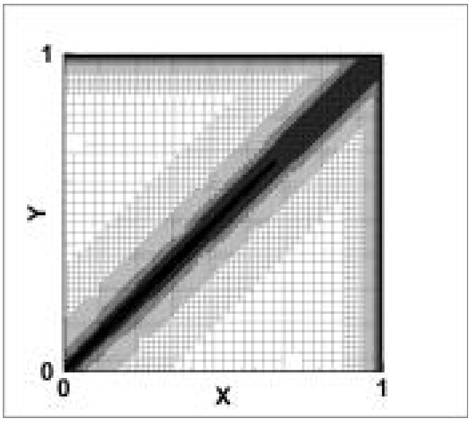

Fig. 12. *Case* A1.

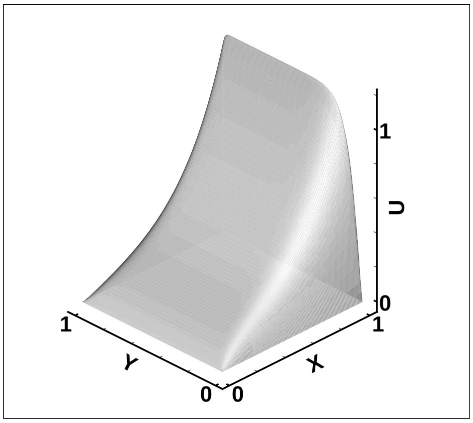

Fig. 15. *Case* C.

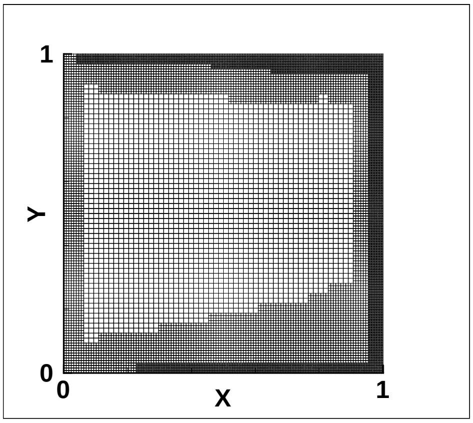

Fig. 16. *Case* C.

The results of these computations are collected in the Tables 2 and 3. The parameter j counts the number of refinements during nested iteration while j_c and j_f represent the *coarsest*, respectively, *finest* resolution that occurs locally at that stage. $\#\Phi_j^{adapt}$ stands for the actual number of degrees of freedom at the jth stage compared with the dimension $\#\Phi_j$ of the corresponding fully refined trial space. ν_j is the current viscosity. Employing highly nonuniform grids, we find that the meaning of grid-Péclet numbers is less clear. Of course, one can define them locally. P_f will stand for the local grid-Péclet number at the currently highest discretization level, while P_c refers to the locally coarsest level at stage j. The numerical results will show that their interpretation is no longer straightforward, particularly since variable convection will be considered. For instance, it will be seen that the spaces are *not* always refined at locations where the local grid-Péclet numbers are large.

Table 2
Case A2.

j	j_f	j_c	$\#\Phi_j^{adapt}$	$\#\Phi_j$	ν_j	P_f	P_c
3	3	3	49	49	2^{-3}	0.50	0.5
4	4	4	225	225	2^{-4}	0.50	0.5
5	5	5	961	961	2^{-5}	0.50	0.5
6	6	5	3829	3969	2^{-6}	0.50	1.0
7	7	5	7585	16129	2^{-7}	0.50	2.0
8	8	5	15059	65025	2^{-7}	0.25	2.0
9	9	5	29448	261121	2^{-7}	0.125	2.0

Table 3
Case B2.

j	j_f	j_c	$\#\Phi_j^{adapt}$	$\#\Phi_j$	ν_j	P_f	P_c
3	3	3	49	49	2^{-5}	0.708	0.708
4	4	4	225	225	2^{-5}	0.427	0.427
5	5	5	961	961	2^{-6}	0.464	0.464
6	6	5	2717	3969	2^{-7}	0.482	0.964
7	6	6	3969	16129	2^{-8}	0.482	0.482
8	7	6	4705	65025	2^{-8}	0.245	0.490
9	7	6	5045	261121	2^{-8}	0.245	0.490

According to Table 2 the number of unknowns is reduced by almost a factor 1/9. The Galerkin discretization is stable although $P_c = 2$ is encountered. While the number of degrees of freedom has been reduced by a factor of 8.9, the total CPU time has reduced by a factor of 4.6 in the comparison to the uniform grid.

Table 3 confirms that the savings in terms of grid compression are better than in Case A2 (a factor 1/52). Note that in this case also P_c remains moderate. The reduction rates of degrees of freedom and CPU time are 51.8, respectively, 27.4.

We like to emphasize that in Cases A1 and B1 the compression rates are even much higher. In Case A1 we have $\#\Phi_{14}^{adapt} = 461943$ and $\#\Phi_{14} = 268,402,689$ and for Case B1 $\#\Phi_{14}^{adapt} = 65173$ and $\#\Phi_{14} = 268,402,689$, respectively.

Accuracy. To assess the accuracy of an approximate solution $u_{\mathcal{G}}$ with coefficient array $\boldsymbol{u} =: \boldsymbol{u}_{\mathcal{G}}$ on an adaptive mesh $\mathcal{G}$, we will compare it with a highly accurate fixed reference solution u_L that will play the role of the exact solution. The difference $\|u_{\mathcal{G}} - u_L\|_X$ for $X \in \{L_2, H^1\}$ can be evaluated with the aid of the norm equivalences

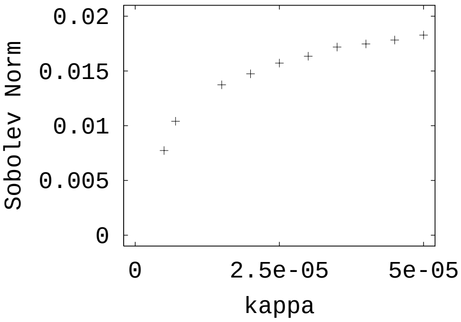

FIG. 17. *Case* A2: H^1*-norm.*

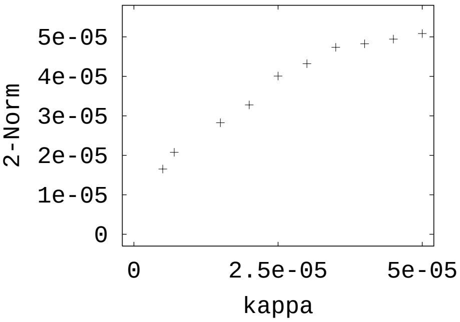

FIG. 18. *Case* A2: L_2*-norm.*

(19), which requires only expanding $u_{\mathcal{G}}$ and u_L in the stable multiscale basis described earlier.

To interpret the results correctly recall that on uniform grids with meshsize h piecewise linear approximands can produce at best errors in $\|\cdot\|_{H^s(\Omega)}$ of order h^{2-s}, provided that the approximated function belongs at least to $H^2(\Omega)$. In terms of degrees of freedom N the error can therefore decay at best with order $N^{-(2-s)/d}$ in d spatial dimensions. This remains the best possible order also when using adaptive approximations. The gain of adaptive schemes is that this best possible order can be realized under weaker regularity assumptions. The relevant (weaker) regularity measure is known to be based on a certain scale of Besov spaces; see, e.g., [11].

Therefore we wish to determine how $\|u_{\mathcal{G}} - u_L\|_X$ relates to the number N of adaptively generated unknowns. Since for small viscosity H^1 is not the right energy space we are primarily interested in the L_2-error, i.e., $X = L_2$. Nevertheless, we monitor also the H^1-error, which is expected to be much larger due to the large gradients in layer regions.

Recall that the threshold parameter κ is to control the accuracy of the approximate solutions. It is therefore also of interest to study the dependence of $\|u_{\mathcal{G}} - u_L\|_X$ on κ, again mainly for $X = L_2$.

Figures 17 and 18 display the dependence of the H^1-error, respectively, the L_2-error on the parameter κ. We see that in Case A2 the L_2-error stays essentially proportional to κ (in the range between $\kappa = 5 \cdot 10^{-6}$ and $5 \cdot 10^{-5}$) up to a factor of 2 so that κ is a good accuracy measure. As expected the H^1-error is much larger.

Figures 19 and 20 show the dependence of the H^1- and L_2-errors on the number N of degrees of freedom. In agreement with the dependence on κ the optimal rates $N^{-1/2}$, respectively, N^{-1} seem to be matched. Figures 21 and 22 confirm the same behavior for the L_2-norm in Case B2.

5.1. Concluding remarks. The above examples show that the algorithm **FMG** exhibits essentially the same performance in a variety of test cases with different characteristic features. The adaptive refinements reduce the computational complexity significantly in all cases and seem to stabilize the Galerkin approximations in a reliable way. In none of the examples have we used an a priori stabilization technique. The adaptive meshes appear to reflect the structure of the solutions in all cases very well. Nevertheless, our tests also show that a proper choice of the threshold parameters is important. The selection of these parameters is at this point still partly based on heuristics and experience. Likewise the role of appropriate approximate decoupling becomes more and more crucial when the convection term grows. The above variant

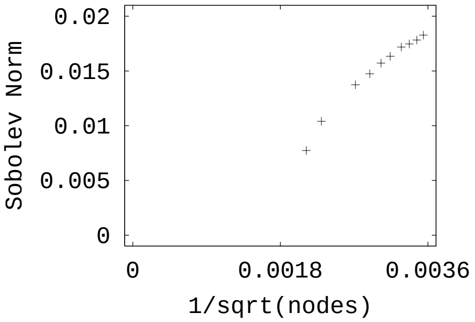

FIG. 19. *Case* A2: H^1*-norm.*

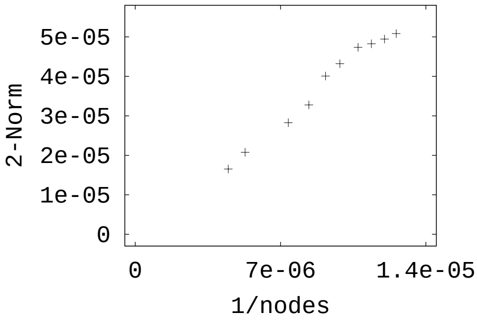

FIG. 20. *Case* A2: L_2*-norm.*

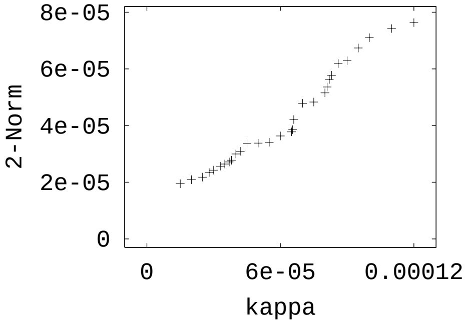

FIG. 21. *Case* B2: L_2*-norm.*

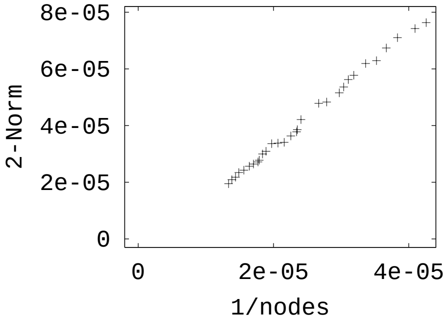

FIG. 22. *Case* B2: L_2*-norm.*

of SPAI techniques has so far been the only successful scheme that works in the viscosity range under consideration. However, further efforts are needed to increase its robustness.

So far we have used for simplicity a very crude way of modifying the original problem in **FMG** for a proper low-level treatment. Alternatively one could use more sophisticated schemes like *streamline diffusion* or any other stabilization scheme. Since the stabilization will gradually be removed when moving up to higher levels the precise tuning of parameters is irrelevant. Likewise, one could employ a weak a priori stabilization corresponding to the prescribed highest level J_{max} if it is not important to resolve all features of the solution with high accuracy. In fact, it should be clear that without *any* a priori stabilization it would be much harder to progress to significantly higher Reynolds numbers than with conventional stabilized versions. In this sense the present investigation is to explore the potential of such aspects.

POINT VALUE MULTISCALE ALGORITHMS FOR 2D COMPRESSIBLE FLOWS*

GUILLAUME CHIAVASSA† AND ROSA DONAT†

Abstract. The numerical simulation of physical problems modeled by systems of conservation laws is difficult due to the presence of discontinuities in the solution. High-order shock capturing schemes combine sharp numerical profiles at discontinuities with a highly accurate approximation in smooth regions, but usually their computational cost is quite large.

Following the idea of A. Harten [*Comm. Pure Appl. Math.*, 48 (1995), pp. 1305–1342] and Bihari and Harten [*SIAM J. Sci. Comput.*, 18 (1997), pp. 315–354], we present in this paper a method to reduce the execution time of such simulations. It is based on a point value multiresolution transform that is used to detect regions with singularities. In these regions, an expensive high-resolution shock capturing scheme is applied to compute the numerical flux at cell interfaces. In smooth regions a cheap polynomial interpolation is used to deduce the value of the numerical divergence from values previously obtained on lower resolution scales.

This method is applied to solve the two-dimensional compressible Euler equations for two classical configurations. The results are analyzed in terms of quality and efficiency.

Key words. conservation laws, multiresolution, shock capturing schemes

1. Introduction.

The computation of solutions to hyperbolic systems of conservation laws has been a very active field of research for the last 20 to 30 years and, as a result, there are now a variety of methods that are able to compute accurate numerical approximations to the physically relevant solution. The latest addition to the pool of numerical methods for hyperbolic conservation laws are the modern high-resolution shock capturing (HRSC) schemes. These schemes succeed in computing highly accurate numerical solutions, typically second- or third-order in smooth regions, while maintaining sharp, oscillation-free numerical profiles at discontinuities.

State-of-the-art shock capturing schemes usually perform a "delicate art-craft" on the computation of the numerical flux functions. A typical computation involves at least one eigenvalue-eigenvector decomposition of the Jacobian matrix of the system, as well as the approximation of the values of the numerical solution at both sides of each cell interface, obtained via some appropriately chosen approximating functions. The numerical result is very often spectacular in terms of resolution power, but the computational effort also tends to be quite spectacular.

Without doubt, the computational speed of the latest personal computers and workstations has made it possible for an increasing number of researchers to become interested in HRSC methods and, as a result, HRSC methods are now being tested in a variety of physical scenarios that involve hyperbolic systems of conservation laws (see, e.g., [7, 10, 19] and references therein).

When the underlying grid is uniform, the implementation of most of these shock capturing schemes is quite straightforward and numerical simulations on uniform grids

are routinely used to investigate the behavior of the different HRSC schemes in use, and also their limitations. It is known that some HRSC schemes can produce an anomalous behavior in certain situations; a catalog of numerical pathologies encountered in gas dynamics simulations can be found in [20], where it is observed that some of these pathologies appear only when very fine meshes are used.

When using very fine uniform grids, in which the basic code structure of an HRSC scheme is relatively simple, we find that the computational time becomes the main drawback in the numerical simulation. For some HRSC schemes, fine mesh simulations in two dimensions are out of reach simply because they cost too much. The numerical flux evaluations are too expensive, and the computational time is measured by days or months on a personal computer. As an example we notice that a typical computation of a two-dimensional (2D) jet configuration in [19] is 10 to 50 days on an HP710 or 1 to 5 days on an Origin 2000 with 64 processors.

It is well known, however, that the heavy-duty flux computations are needed only because nonsmooth structures may develop spontaneously in the solution of a hyperbolic system of conservation laws and evolve in time, and this basic observation has lead researchers to the development of a number of techniques that aim at reducing the computational effort associated to these simulations. Among these, shock tracking and adaptive mesh refinement (AMR) techniques (often combined with one another) are very effective at obtaining high-resolution numerical approximations, but the computational effort is transferred to the programming and the data structure of the code.

Starting with the pioneering work of Harten [14], a different multilevel strategy aiming to reduce the computational effort associated to high-cost HRSC methods entered the scene. The key observation is that the information contained in a multiscale decomposition of the numerical approximation can be used to determine its local regularity (smoothness). At discontinuities or steep gradients, it is imperative to use a numerical flux function that models correctly the physics of the problem, but in smoothness regions the costly exact value of an HRSC numerical flux can be replaced by an equally accurate approximation obtained by much less expensive means. The multiscale decomposition of the numerical solution can then be used as a tool to decide *in which regions* a sophisticated evaluation of the numerical flux function is truly needed. In smoothness regions, Harten proposes [14] to evaluate the numerical flux function of the HRSC scheme only on a coarse grid and then use these values to compute the fluxes on the finest grid using an inexpensive polynomial interpolation process in a multilevel fashion.

Harten's approach can be viewed, in a way, as an AMR procedure, in which grids of different resolutions are considered in the numerical simulation, but in reality it is far from being an AMR technique. The different grids are used *only* to analyze the smoothness of the numerical solution. The numerical values on the highest-resolution grid need to be *always* available, because the computation of the numerical fluxes with the HRSC scheme, when needed, use directly the finest-grid values. This is clearly a disadvantage with respect to the memory savings that an AMR technique can offer in certain situations. On the other hand, using the values of the numerical solution in the direct computation has some nice features. First, it avoids the use of complicated data structures, which is very useful when one is trying to incorporate the algorithm into an existing code. Second, the availability of the numerical solution on the finest grid guarantees that the "delicate art-craft" involved in the direct evaluation of the numerical fluxes (via a sophisticated HRSC scheme) is performed adequately.

When memory requirements do not impose a severe restriction (as it often happens in many 2D, as well as in some three-dimensional (3D), computations), the techniques proposed in [14, 5, 22, 1] and in this paper can help to reduce the large running times associated to numerical simulations with HRSC schemes. We view Harten's approach as an acceleration tool, which can be incorporated in a straightforward manner into an existing code.

The novelty of our approach with respect to the multilevel strategies described in [14, 5, 22, 1] lies in the multiresolution transform used to analyze the smoothness of the numerical solution. We use the interpolatory framework, while in the references mentioned above the cell-average framework is used. In addition, our implementation incorporates several features that improve the efficiency of the algorithm (see section 3.3), while maintaining the quality of the numerical approximation.

The rest of the paper is organized as follows: In section 2, we briefly describe the essential features of the HRSC schemes we shall employ in our simulations. In section 3 we describe the interpolatory framework for multiresolution and its role in our multilevel strategy, as well as some implementation details. Section 4 examines the accumulation of error in the multilevel simulation. In section 5 we perform a series of numerical experiments and analyze the results in terms of *quality*, i.e., closeness to the reference simulation, and *efficiency*, i.e., time savings of the multilevel simulations with respect to the reference simulation. Finally, some conclusions are drawn in section 6.

2. Shock capturing schemes for 2D systems of conservation laws. Let us consider a 2D system of hyperbolic conservation laws:

$$\partial_t \vec{U} + \vec{f}(\vec{U})_x + \vec{g}(\vec{U})_y = \vec{0}, \tag{2.1}$$

where $\vec{U}$ is the vector of conserved quantities. We shall consider discretizations of this system on a Cartesian grid $\mathcal{G}^0 = \{(x_i = i\delta x, y_j = j\delta y), \quad i = 0, \dots, Nx \ j = 0, \dots, Ny\}$ that follow a semidiscrete formulation,

$$\frac{d\vec{U}_{ij}}{dt} + \mathcal{D}(\vec{U})_{ij} = 0, \tag{2.2}$$

with the numerical divergence $\mathcal{D}(\vec{U})_{ij}$ in *conservation form*, i.e.,

$$\mathcal{D}(\vec{U})_{ij} = \frac{\vec{F}_{i+1/2,j} - \vec{F}_{i-1/2,j}}{\delta x} + \frac{\vec{G}_{i,j+1/2} - \vec{G}_{i,j-1/2}}{\delta y}. \tag{2.3}$$

One typically has $\vec{F}_{i+1/2,j} = \vec{F}(\vec{U}_{i-k,j}, \dots, \vec{U}_{i+m,j})$, $\vec{G}_{i,j+1/2} = \vec{G}(\vec{U}_{i,j-k}, \dots, \vec{U}_{i,j+m})$, where $\vec{F}(\vec{w}_1, \dots, \vec{w}_{k+m})$ and $\vec{G}(\vec{w}_1, \dots, \vec{w}_{k+m})$ are consistent numerical flux functions, which are the trademark of the scheme.

In this paper we shall use two numerical flux formulae, which are significantly different in terms of computational effort:

- The essentially nonoscillatory (ENO) method of order 3 (ENO-3 henceforth) from [21], which uses the nonlinear piecewise parabolic ENO reconstruction procedure to achieve high accuracy in space.
- Marquina's scheme from [8] together with the piecewise hyperbolic method (PHM) [18] to obtain high accuracy in space (M-PHM henceforth).

In both cases, the reconstruction procedure (piecewise parabolic ENO or piecewise hyperbolic) is applied directly on the fluxes, as specified by Shu and Osher in [21].

The ENO-3 scheme uses Roe's linearization and involves one Jacobian evaluation per cell interface, while M-PHM uses a flux-splitting technique in the flux computation that requires two Jacobian evaluations per cell interface. Although M-PHM is more expensive than ENO-3, it has been shown in [8, 12, 9] that it is a pretty robust scheme that, in addition, avoids (or reduces) certain numerical pathologies associated to the Roe solver.

In both cases, a third-order fully discrete scheme is obtained by applying a TVD Runge–Kutta method for the time evolution as proposed in [21].

3. The multilevel algorithm. As explained in the introduction, the goal of the multilevel method is to *decrease the cpu time* associated to the underlying scheme by reducing the number of expensive flux evaluations. To understand the basic mechanism by which this goal is achieved, let us consider, for the sake of simplicity, Euler's method applied to (2.2), i.e.,

$$\vec{U}_{ij}^{n+1} = \vec{U}_{ij}^{n} - \delta t\, \mathcal{D}(\vec{U})_{ij}^{n}. \tag{3.1}$$

If *both* U^n and U^{n+1} are smooth around (x_i, y_j) at time t^n, then (3.1) implies that the numerical divergence is also smooth at that location; thus we can, in principle, avoid using the numerical flux functions of the HRSC scheme in its computation. On the other hand, if a discontinuity appears during the time evolution (or when a steep gradient makes it imminent), the Riemann solver of the HRSC scheme has to be called necessarily to compute the numerical divergence if the high-resolution properties of the underlying scheme are to be maintained.

Consequently, the most important steps in the multilevel algorithm concern the smoothness analysis of U^n *and* U^{n+1} (observe that the latter is unknown at time n) and how this information is used in the computation of $\mathcal{D}(\vec{U})$.

3.1. Interpolatory multiresolution. Finite volume schemes for (2.1) produce numerical values that can be naturally interpreted as approximations to the mean values of the solution in each computational cell (the *cell averages*). Because of this, all applications of Harten's idea known to us [14, 5, 22, 6, 1, 2, 17] have invariably used the cell-average multiresolution framework (see [14] for definitions and details) to analyze the smoothness of the numerical approximation.

In Shu and Osher's framework, the numerical values can be interpreted as approximations to the point values of the solution. In a point value framework for multiresolution, the numerical data to be analyzed are interpreted as the values of a function on an underlying grid; consequently, in our multilevel strategy the *point value multiresolution framework* is used to analyze the smoothness properties of the numerical approximation.

Multiscale decompositions within the point value framework were initially introduced by Harten [13] (and also independently developed by Sweldens [23]) and have been extensively analyzed in a series of papers [15, 3]. Here we present only a brief summary to clarify the notation in the remainder of the paper.

One first defines a set of nested grids $\{\mathcal{G}^l,\ l = 1, \dots, L\}$ by

$$(x_i, y_j) \ \in\ \mathcal{G}^l \Longleftrightarrow (x_{2^l i}, y_{2^l j}) \ \in\ \mathcal{G}^0. \tag{3.2}$$

The values of a function v on $\mathcal{G}^0$ (which is considered the finest resolution level), $(v_{ij}^0)_{i,j}$, are the input data. Due to the embedding of the grids, the representation of the function on the coarser grid $\mathcal{G}^l$, its point values on $\mathcal{G}^l$, is

$$v_{ij}^l = v_{2^l i\ 2^l j}^0, \quad i = 0, \dots, Nx/2^l, \quad j = 0, \dots, Ny/2^l. \tag{3.3}$$

To recover the representation of v on $\mathcal{G}^{l-1}$ from the representation on $\mathcal{G}^l$ (the next coarser grid), the following procedure is used:

- A set of predicted values is first computed:

$$\begin{aligned} &\tilde{v}_{ij}^{l-1} = v_{i/2\ j/2}^l \quad \text{if } (x_i, y_j) \in\ \mathcal{G}^l, \\ &\tilde{v}_{ij}^{l-1} = I[(x_i, y_j); v^l] \quad \text{if } (x_i, y_j) \in \mathcal{G}^{l-1} \backslash\ \mathcal{G}^l, \end{aligned} \tag{3.4}$$

  where $I(.;.)$ denotes an rth-order polynomial interpolation.
- The difference between the exact values (3.3), v_{ij}^{l-1}, and $\tilde{v}_{ij}^{l-1}$ is then represented by the details, or wavelet coefficients:

$$d_{ij}^l = v_{ij}^{l-1} - \tilde{v}_{ij}^{l-1}, \quad (x_i, y_j) \in \mathcal{G}^{l-1}. \tag{3.5}$$

  Observe that $d_{2p,2q}^l = 0$ because of the interpolation property. Thus even-even detail coefficients are never computed (or stored).
- Relations (3.4) and (3.5) lead immediately to

$$\begin{aligned} &v_{ij}^{l-1} = v_{i/2\ j/2}^l \quad \text{if } (x_i, y_j) \in \mathcal{G}^l, \\ &v_{ij}^{l-1} = I[(x_i, y_j); v^l] + d_{ij}^l \quad \text{if } (x_i, y_j) \in \mathcal{G}^{l-1} \backslash\ \mathcal{G}^l. \end{aligned} \tag{3.6}$$

Applying this procedure from $l = 1$ to L gives an equivalence between the discrete set v^0 and its multiresolution representation: $Mv^0 = (v^L, d^L, \ldots, d^1)$.

Remark 3.1. In our numerical experiments we use a tensor-product interpolation procedure of order 4 ($r = 4$). The corresponding formulae come from standard 2D polynomial interpolation; explicit details can be found, for example, in [5, section 3].

The point value framework for multiresolution is probably the simplest one, because the detail coefficients are simply interpolation errors. When the grid is uniform and the interpolation technique is constructed using a tensor product approach, it is very simple to analyze the smoothness information contained in the interpolation errors, which can then be used directly as "regularity sensors" to localize the nonsmooth structures of the solution (compare with the derivation of the regularity sensors in [5] in the 2D cell-average framework for multiresolution).

3.2. The basic strategy. As observed in [5], the original idea of a multilevel computation of the numerical flux function (in one dimension) described by Harten in [14] cannot be used in a robust and general manner in two dimensions. The key point is then to observe that it is the *numerical divergence* the quantity that should be adapted to the multilevel computations. For the sake of simplicity, let us consider again the simplest ODE solver: Euler's method. When applying it to the semidiscrete formulation (2.2), we get

$$\vec{U}_{ij}^{n+1} - \vec{U}_{ij}^n = -\delta t\ \mathcal{D}(\vec{U})_{ij}^n, \tag{3.7}$$

and this relation shows that a multilevel computation of the numerical divergence must be carried out within the same framework as the sets $\vec{U}_{ij}^{n,n+1}$. The idea to use the numerical divergence instead of the flux for the multilevel computation was a key step in the development of multilevel strategies in multidimensions in [5, 1]. Once this fact is recognized, the choice of the particular framework used to analyze the smoothness information contained in the numerical approximation is not crucial. We propose to use the point value framework because of its simplicity.

As in [5], the computation of the numerical divergence $\mathcal{D}(\vec{U}^n)$ on the finest grid is carried out in a sequence of steps. First the numerical divergence is evaluated at all points on the coarsest grid $\mathcal{G}^L$ using the numerical flux function of the prescribed HRSC scheme. Then, for the finer grids, $\mathcal{D}$ is evaluated recursively, either by the same procedure *or* with a cheap interpolation procedure using the values obtained on the coarser grids. The choice depends on the regularity analysis of the approximate solution, made with the help of its multiresolution representation.

Thus, the main ingredients of the algorithm are the following:

- The *multiresolution transform* described in section 3.1 to obtain the wavelet coefficients of $\vec{U}^n$.
- A *thresholding algorithm* which associates to each wavelet coefficient a boolean flag, b^l_{ij}, whose value (0 or 1) will determine the choice of the procedure to evaluate $\mathcal{D}(U)$. The goal is to use this flag to mark out the nonsmooth regions of *both* $\vec{U}^n$ and $\vec{U}^{n+1}$. This is done as follows:

  For a given tolerance parameter ϵ, the tolerance at level l is defined as $\epsilon_l = \epsilon/2^l$. Starting from a zero value for all b^l_{ij}, one applies for each detail coefficient the following two tests:

  $$\begin{aligned}&\text{if } |d^l_{ij}| \geq \epsilon_l \implies b^l_{i-k\ j-m} = 1, \quad k,m = -2,\dots,2,\\ &\text{if } |d^l_{ij}| \geq 2^{r+1}\epsilon_l \quad \text{and} \quad l > 1 \implies b^{l-1}_{2i-k\ 2j-m} = 1, \quad k,m = -1,0,1.\end{aligned}$$

  The first test takes into account the propagation of information (recall that the propagation of "real" information is limited by the CFL condition). The second one aims at detecting shock formation. In a smooth region the local rate of decay of the detail coefficients is determined by the accuracy of the interpolation and the local regularity of the function. The second test measures whether the decay rate is that of a smooth function; if this is not the case, compression leading to shock formation might be taking place and the location is also flagged (see [5] for specific details on both tests).
- The *multilevel evaluation* of the numerical divergence.

  For all points $(x_i, y_j) \in \mathcal{G}^L$, $\mathcal{D}^L(\vec{U})_{ij}$ is computed with the prescribed HRSC scheme. Once the divergence is known on $\mathcal{G}^l$, its value on $\mathcal{G}^{l-1}$, $\mathcal{D}^{l-1}(\vec{U})$ is evaluated using the boolean flag:

  $$\text{If } b^l_{ij} = 1, \quad \text{compute } \mathcal{D}^{l-1}(\vec{U})_{ij} \text{ directly (with the HRSC method).}$$

  $$\text{If } b^l_{ij} = 0, \quad \mathcal{D}^{l-1}(\vec{U})_{ij} = I[(x_i, y_j); \mathcal{D}^l(\vec{U})].$$

Letting l go from L to 1 gives us the values of $\mathcal{D}(\vec{U}^n)$ on the finest grid $\mathcal{G}^0$.

Remark 3.2. Recall that $\mathcal{D}^{l-1}(\vec{U})_{ij} = \mathcal{D}^0(\vec{U})_{2^{l-1}i,2^{l-1}j}$, and thus the direct evaluation of $\mathcal{D}^{l-1}(\vec{U})_{ij}$ is performed by computing the numerical flux functions using the values of $\vec{U}$ on $\mathcal{G}^0$: $\vec{F}(\vec{U}_{2^{l-1}i-k,j}, \dots, \vec{U}_{2^{l-1}i+m,j})$ and $\vec{G}(\vec{U}_{i,2^{l-1}j-k}, \dots, \vec{U}_{i,2^{l-1}j+m})$. As a consequence, the finest grid, $\mathcal{G}^0$, is always needed and no memory savings is obtained in comparison to the direct method (without multiresolution).

3.3. Some implementation details. In the original work of Harten [14], the flag coefficients are obtained using a multiresolution transform for each component of the vector $\vec{U}$. The thresholding algorithm is then applied to the largest resulting wavelet coefficient, i.e., $\tilde{d}^l_{ij} = \max(|d_{ij}(\rho)|, |d_{ij}(m_x)|, |d_{ij}(m_y)|, |d_{ij}(E)|)$.

For the Euler equations of gas dynamics, the density retains all the possible nonsmooth structures of the flow (shocks, contact discontinuities, and corners of rarefaction waves); thus it seems appropriate to derive the flag only from the multiresolution representation of the density, a modification that has also been implemented by

Table 3.1

Cpu time in seconds for the overhead steps of the multilevel algorithm. First column for all the components of $\vec{U}$, second one only for the density.

	$\vec{U}$ multiresolution	ρ multiresolution
MR transform	0.09	0.024
Maximum	0.014	–
Thresholding	0.026	0.027
Total	0.13	0.051

Sjögreen [22]. In our experiments, no significant differences are noted in the quality of the numerical results obtained by computing the flag from the density only; thus in the numerical tests we report, the boolean flag is computed using only the multiscale information of the density. This option saves time in the overhead associated to the multiscale algorithm. In Table 3.1, we present the cpu time measured for both methods for an initial grid $\mathcal{G}^0$ of 512×128 points and 5 levels for the multiresolution transform.

We observe a reduction of the computational time by a factor of 2 in that case.

In [22], Sjögreen presents numerical simulations for 2D systems of conservation laws using a "dimension-by-dimension" cell-average multilevel algorithm and uniform meshes. This means that for the fluxes in the x-direction, $\vec{F}_{i+1/2,j}$, a one-dimensional (1D) multilevel algorithm is applied to each grid line $j = j_0$. Then, the same procedure is applied to each line $i = i_0$ to compute the y-fluxes. The major advantage of Sjögreen's implementation lies in its simplicity: only 1D procedures are used for the multiresolution transform, the thresholding algorithm, and the interpolation process.

We have also implemented Sjögreen's version in the point value context and have compared it with our algorithm, in which a fully bidimensional multiresolution transform is used. Qualitatively speaking, the results are very similar and the percentage of fluxes computed by the solver is the same in both cases. Nevertheless, Sjögreen's version turns out to be less efficient than the 2D one and, in our implementation, a factor of 1.6 is observed between the corresponding cpu times. The difference could be explained by the fact that each point of the domain is visited two times by the multiresolution transform and thresholding algorithm (for the x- and y-flux computations) and that this algorithm requires more memory access.

A Runge–Kutta ODE solver is applied to the semidiscrete scheme (2.2)–(2.3) to obtain a fully discrete scheme. In [5, 1, 22], a flag vector is computed at the beginning of each Runge–Kutta step between t^n and t^{n+1}, but it is possible to avoid this computation for the last step. The third-order TVD Runge–Kutta method of [21] is defined as follows:

$$\begin{aligned} \vec{U}^* &= \vec{U}^n - \delta t\ \mathcal{D}(\vec{U}^n), \\ \vec{U}^{**} &= (3\vec{U}^n + \vec{U}^* - \delta t\ \mathcal{D}(\vec{U}^*))/4, \\ \vec{U}^{n+1} &= (\vec{U}^n + 2\vec{U}^{**} - 2\delta t\ \mathcal{D}(\vec{U}^{**}))/3, \end{aligned} \tag{3.8}$$

and the intermediate steps can be represented on the time axis as in Figure 3.1. Clearly, $\vec{U}^*$ is an order-1 approximation of $\vec{U}^{n+1}$; thus it contains similar nonsmooth structures at the same places, and the flag coefficients obtained from its multiresolution transform could be used to compute $\vec{U}^{n+1}$ from $\vec{U}^{**}$, instead of deriving them from the $\vec{U}^{**}$ multiresolution transform. This modification reduces the computational cost of the multilevel algorithm while keeping the same quality in the numerical results.

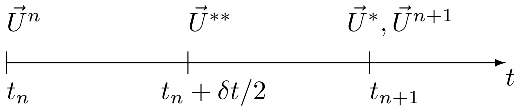

FIG. 3.1. *Representation on the time axis of the intermediate steps of the third-order Runge–Kutta method.*

Remark 3.3. The implementation of the multilevel strategy into an existing code would then amount to the following:

– Define two additional matrices, one to store the scale coefficients of the multiresolution representation of the density, the other to store the flag coefficients.
– Include the multiresolution transform routine. Apply it to the density values according to the guidelines in this section.
– Use the flag to modify the computation of the numerical divergence. Use the numerical flux function of the scheme only when the flag value is 1.

4. Error analysis. In [14] Harten performs a study of the accumulation of the error in the multilevel strategy. When the underlying shock capturing scheme is monotone, Harten shows that the global accumulation error, i.e., the difference between the true solution and the numerical approximation obtained with the multilevel algorithm, can be bounded in terms of the thresholding parameters and the local truncation error of the underlying shock capturing scheme. In addition, if the tolerance for thresholding is of the order of the local truncation error of the scheme, then the multilevel scheme is of the same order as the underlying shock capturing scheme (see [14] for details). The main ingredients in his proof are the stability of the multiresolution transform and the monotonicity of the shock capturing scheme.

The schemes we consider in this paper are not monotone, and an estimate on the global error cannot be obtained. Keeping in mind that we view the multilevel scheme as an acceleration tool, and that our target is to lower the cost that is needed to obtain the numerical solution on the finest grid, we seek only to control the global error between the multilevel and the reference solution. The nonlinearity of the schemes we are considering prevents us from carrying out a rigorous analysis similar to that of [14]; we conjecture that this error can be controlled due to the stability of the multiresolution transform. In section 5.2, we perform several numerical experiments that seem to indicate that

$$||v^{ref} - v^{mult}||_1 \leq C\epsilon^{\alpha} \tag{4.1}$$

for some real number $\alpha > 1$.

5. Numerical experiments. This section is devoted to the presentation and analysis of the results obtained with our multilevel algorithm. We focus on two classical configurations for numerical simulations involving the Euler equations in two dimensions. A detailed description of the flow structure, for both test cases, can be found in [24].

Test A: Double mach reflection of a strong shock. The problem involves a Mach 10 shock in air ($\gamma = 1.4$) which makes a 60^o angle with a reflecting wall. The computational domain is a tunnel 4 units long and 1 unit high, starting at $x = 0$, $y = 0$.

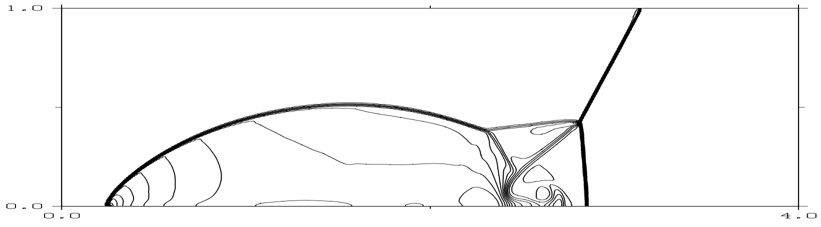

FIG. 5.1. *Density reference solution for Test A at time* $t = 0.2$*, obtained with* 512×128 *points and M-PHM scheme without multiresolution.*

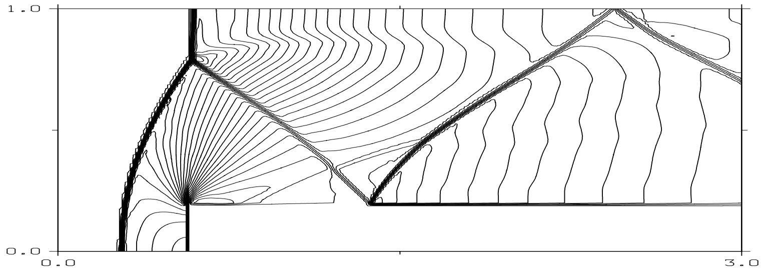

FIG. 5.2. *Density reference solution for Test B at time* $t = 4$*, obtained with* 256×80 *points and M-PHM scheme without multiresolution.*

Initially the shock extends from the point $x = \frac{1}{4}$ at the bottom of the computational domain to the top boundary. The reflecting wall begins at $x = \frac{1}{4}$ on this bottom wall. Postshock conditions, $\vec{U}_{left} = (8., 57.1597, -33.0012, 563.544)$, are assigned at the boundaries located to the left of the shock; the air ahead of the shock is left undisturbed and has density 1.4 and pressure 1. Outflow conditions are applied at the right end of the domain, and the values on the top boundary to the right of the shock are those of undisturbed air.

The finest resolution grid, $\mathcal{G}^0$, that we shall consider for this test problem has 512×128 points. The density obtained at time $t = 0.2$ using M-PHM on $\mathcal{G}^0$ is displayed in Figure 5.1. We see that all the features of the flow are appropriately represented, including the jet-like structure near the reflecting wall. This is our *reference* simulation. We shall apply the multilevel algorithm to this test case with $L = 5$ and $\epsilon = 5 \times 10^{-3}$.

Test B: Mach 3 *wind tunnel with a step.* The problem begins with a uniform Mach 3 flow in a tunnel containing a step. The tunnel is 3 units long and 1 unit wide, and the step is located 0.6 units from the left-hand end of the tunnel and is 0.2 units high. Inflow boundary conditions are applied at the left of the domain and outflow conditions occur at the right end. Along all the walls of the tunnel, reflecting boundary conditions are applied. Initially the tunnel is filled with a gamma-law gas with $\gamma = 1.4$, which has density 1.4, pressure 1.0, and velocity 3.

At time $t = 4$, the flow has a rich and interesting structure that can be accurately described using M-PHM on a grid with 256×80 points, which is then considered as our finest grid, $\mathcal{G}^0$, for this test case. In Figure 5.2, we display the density distribution at time $t = 4$ obtained with M-PHM on $\mathcal{G}^0$. This is our *reference* simulation. We shall apply the multilevel algorithm to this test case with $L = 4$ and $\epsilon = 5 \times 10^{-3}$.

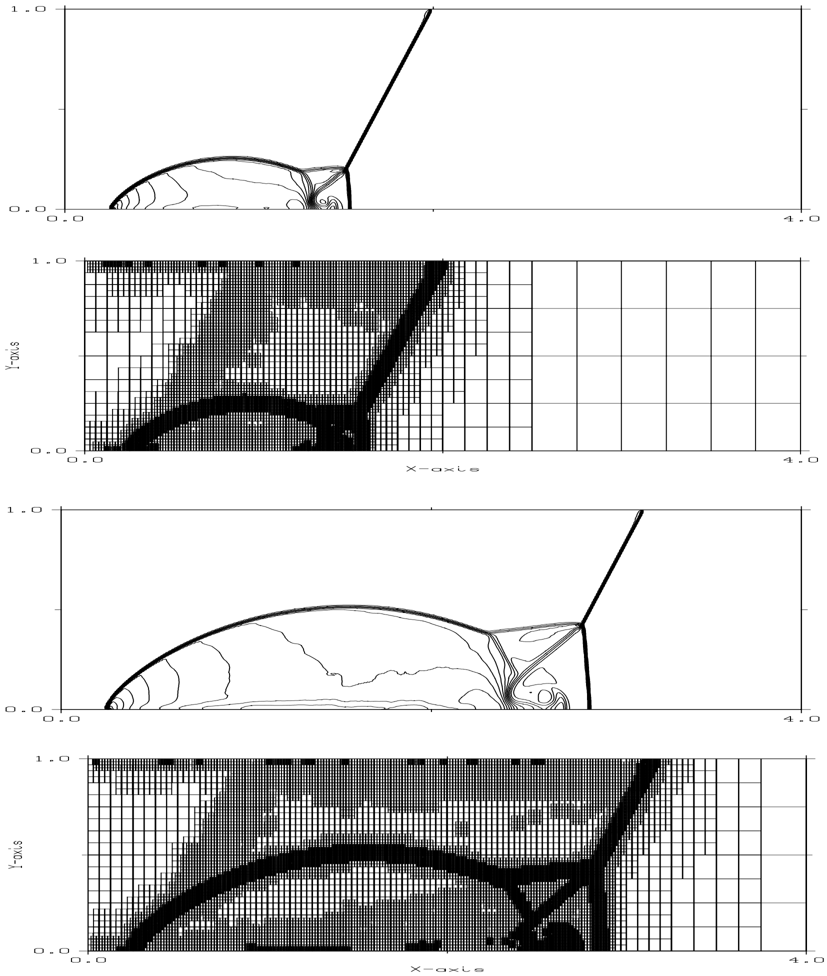

FIG. 5.3. *Density field of the multilevel solution and adaptive grids for Test A at time* $t = 0.1$ *(top) and* $t = 0.2$ *(bottom). Initial grid* $\mathcal{G}^0$ *contains* 512×128 *points,* $L = 5$ *levels, and* $\epsilon = 5 \times 10^{-3}$.

5.1. Test results: Marquina's scheme. In this first set of experiments we apply the multilevel algorithm to the M-PHM scheme in order to compute the solution to the previous test problems.

In Figures 5.3 (Test A), 5.4, and 5.5 (Test B) we display the level curves of the numerical solution obtained with the multilevel algorithm at different times of the flow evolution. For each simulation, we also present a second plot displaying only the points of $\mathcal{G}^0$ where the numerical divergence is computed directly with the HRSC scheme. The graphical display is arranged so that it looks like a structure of *adaptive grids*, similar to those used in numerical simulations involving AMR techniques. The plots of the *adaptive grids* give a very good indication of the amount of work saved by the strategy. It must be pointed out that these plots do not represent, as in AMR, the various grids involved in the computation. We must remember that the multilevel strategy uses the data on the finest grid for the direct flux evaluations. There is only one CFL number, dictated by the finest grid, and the memory requirements correspond to those of the finest grid (in fact they are slightly larger, since we need

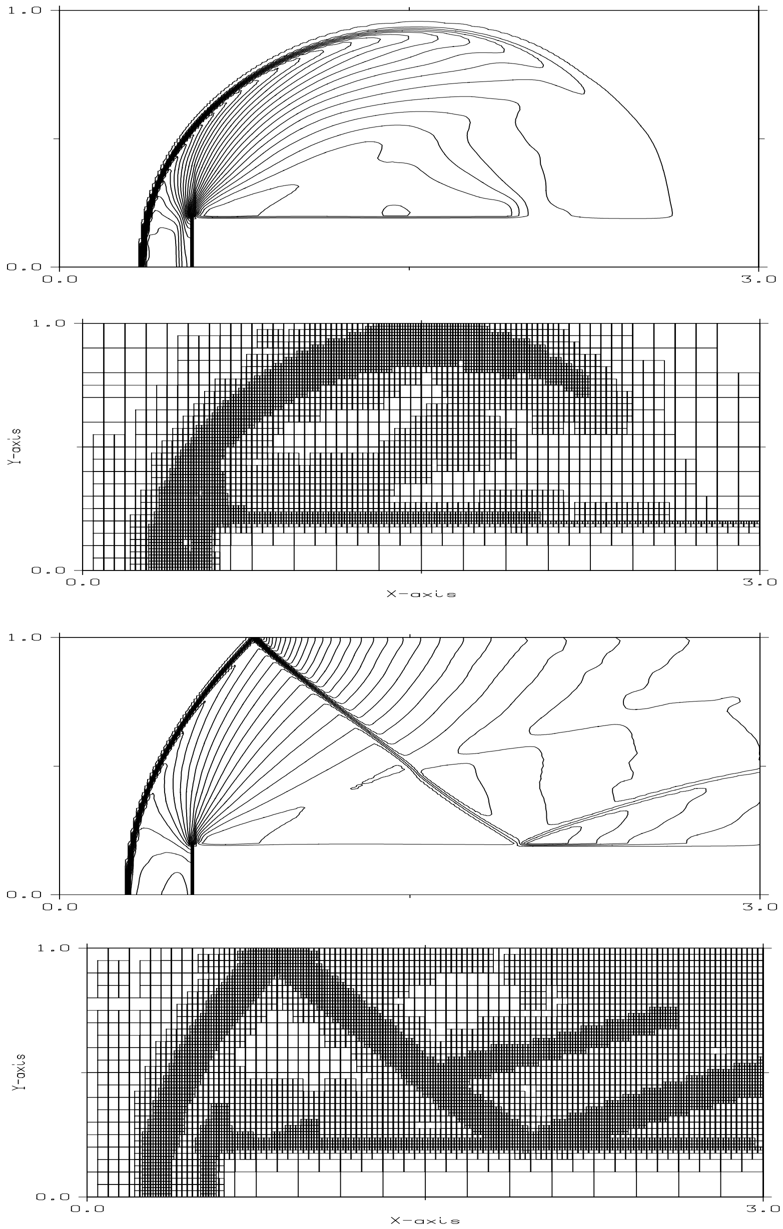

Fig. 5.4. *Density field of multilevel solution and adaptive grids for Test B at time* $t = 0.5$ *(top) and* $t = 1.5$ *(bottom). Initial grid* $\mathcal{G}^0$ *contains* 256×80 *points,* $L = 4$ *levels, and* $\epsilon = 5 \times 10^{-3}$.

two more matrices).

In looking at the plots of level curves, we readily observe that the numerical simulation is of the same "quality" as the reference simulation. The plots of the adaptive grids show that the smoothness analysis performed on the wavelet coefficients is able to localize correctly the nonsmooth structures of the flow. A direct evaluation of the numerical fluxes is being performed in the neighborhood of all singularities, as well as in the shock formation process, and, as a result, the numerical solution presents

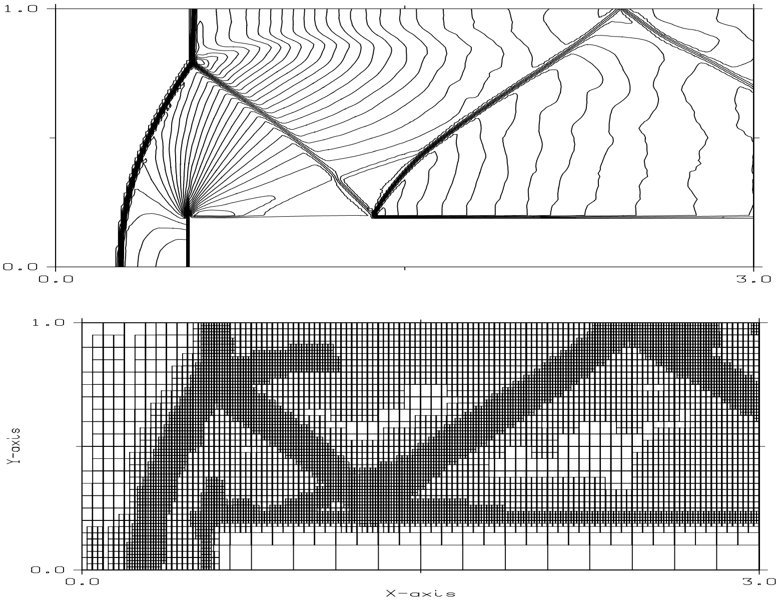

FIG. 5.5. *Same as Figure* 5.4 *for the time* $t = 4$.

the sharp shock profiles that are typical of a third-order scheme such as M-PHM.

The plots of the adaptive grids give additional information also. As observed in [24], the numerical results for Test A are marred by small errors that are due to the description of the initial data and to the fact that the boundary conditions on the top boundary are set to describe the exact motion of the initial Mach 10 shock. These errors are identified as nonsmooth behavior by the multiresolution-based smoothness analysis and, as a consequence, there is some unnecessary refinement in smooth regions, since no shock formation or evolution is taking place there. It is important to notice that this phenomenon occurs for both the reference and multilevel simulations. Through the plots of the *adaptive grid* structure, the occurrence and relative importance of these errors can be clearly appreciated.

Notice also the refinement appearing at reflecting walls in both tests. The problem of dealing with reflecting boundary conditions in high-resolution simulations has been addressed by various authors in recent papers (see, e.g., [11] and references therein), and here the multilevel algorithm can also help to detect which areas of the computational domain are displaying a numerical behavior susceptible to improvement. In addition, it is clear that any improvement with respect to lowering the level of numerical noise close to boundaries will produce in turn an increase in the efficiency of the multilevel algorithm, since the unnecessary refinement will be eliminated.

5.2. Quality and efficiency. As discussed in section 4, the question of quality will be analyzed by measuring the difference between the multilevel solution $\vec{U}^n$ and the reference one, $\vec{U}^n_{ref}$. Our objective is to examine the relation between the tolerance parameter ϵ and the difference $||\vec{U}^n - U^n_{ref}||$, measured in some appropriate norm, which in our case we choose to be the (discrete) l_1-norm. To examine the relation between the tolerance ϵ and the difference $||\vec{U}^n - U^n_{ref}||_1$, we consider the density, for

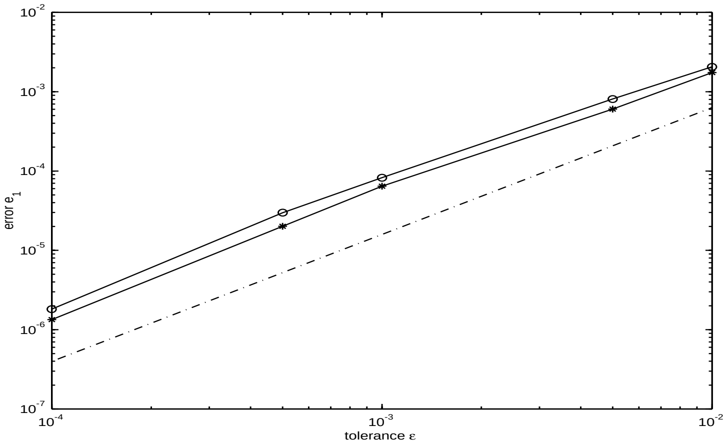

FIG. 5.6. *Error* e_1*, for the density* (∗) *and the pressure* (o)*, between the multilevel algorithm and the reference one versus the tolerance* ϵ*. The dotted line represents the curve of equation:* $\epsilon^{1.6}$.

example, as a representative variable and compute

$$e_1^\rho = \frac{1}{N_p}\sum_{i=0}^{N_x}\sum_{j=0}^{N_y} |\rho_{ij}^n - \rho_{ref_{ij}}^n| / \|\rho_{ref}^n\|_{l_1}, \tag{5.1}$$

where $N_p = (N_x + 1) \times (N_y + 1)$ is the total number of points on the finest grid $\mathcal{G}^0$.

We apply the multilevel algorithm to Test A with $N_p = 128 \times 32$ and $L = 3$ for different values of the tolerance ϵ. The error is measured, for the density ρ and pressure p, at time $t = 0.2$; results are presented on Figure 5.6. It is readily observed that both e_1^ρ and e_1^P decrease with ϵ according to (4.1), with $\alpha = 1.6$. Numerical experimentation indicates that this exponent is solution-dependent, but the behavior is similar in all test cases we have considered (i.e., $\alpha > 1$).

The results of Figure 5.6 imply that the *quality* of the numerical solution obtained with the multilevel scheme, i.e., the closeness to the reference simulation, can be controlled by adjusting the tolerance suitably.

The goal of the multilevel algorithm is to save time in the evaluation of costly numerical flux functions; thus an important quantity is the percentage of numerical divergences computed directly per time step, $\%f$. Table 5.1 (for Test A) and Table 5.2 (for Test B) show the maximum and minimum values for $\%f$ in the simulation. Observe that, for a given test, the finer the grid, the smaller the percentage of direct flux evaluations, since the direct evaluation of the numerical divergence is carried out in a neighborhood of the nonsmooth structures of the flow, and the percentage of computational grid cells involved in these regions decreases when increasing the grid resolution.

A more concrete measure of the efficiency of the multilevel algorithm with respect to the reference simulation is given by θ_{iter}, the cpu gain for a given iteration, and θ, the gain for the global simulation. Introducing t_{ref}^{iter} and t_{mr}^{iter} as the cpu times at iteration $iter$ for the reference and the multilevel algorithm, respectively, θ_{iter} and θ are defined as

$$\theta_{iter} = \frac{t_{ref}^{iter}}{t_{mr}^{iter}} \quad \text{and} \quad \theta = \frac{\sum t_{ref}^{iter}}{\sum t_{mr}^{iter}}. \tag{5.2}$$

Table 5.1
Percentage of resolved flux and cpu gain for Test A at time $t = 0.2$.

Grid size $\mathcal{G}^0$	$\%f_{\min}$ – $\%f_{\max}$	cpu gain θ
128×32	17.6 – 52.7	1.7
256×64	8.9 – 33.2	2.45
512×128	4.5 – 23.2	3.8

Table 5.2
Same as Table 5.1 *for Test B at time $t = 4$.*

Grid size $\mathcal{G}^0$	$\%f_{\min}$ – $\%f_{\max}$	cpu gain θ
128×40	7 – 69.5	0.9
256×80	2.8 – 45	1.4

Table 5.1 (for Test A) and Table 5.2 (for Test B) show the global gain for each simulation. It is obvious that the global gain, θ, is problem dependent. In Figure 5.7, we represent $\theta(t)$. In the early stages of the computation, when there are very few nonsmooth structures in the flow, the gain is quite large; as expected, $\theta(t)$ is a decreasing function, and the gain is larger when we compute on finer grids. The bottom part of Figure 5.7 displays $\%f(t)$ for these simulations. It can be observed that the behavior of θ is roughly inversely proportional to that of $\%f$.

There is an overhead associated to the multilevel computation. In Table 5.3 we show the cpu time for one step of the multilevel algorithm and one stage of the Runge–Kutta method. These results have been obtained with Test A and 512×128 points in $\mathcal{G}^0$ when $\%f$ has its maximum value, 23%. It is worth noting that the overhead caused by the multiresolution transform and the threshold represents only a small part of the total cpu time, $\approx 2\%$, and that most of the time is spent in the numerical divergence evaluation, $\approx 96\%$.

To end this section, we apply the multilevel method, with the same underlying HRSC scheme, to Test A with a very fine grid of 2560×640 points. We set $L = 7$ and $\epsilon = 3.10^{-4}$. In Figure 5.8 we show a zoom of the double-Mach reflection region displaying the level curves of the computed density. The small mesh-size of the underlying grid $\mathcal{G}_0$ used for the simulation reduces the numerical viscosity of the shock capturing scheme and, as a result, we can observe the development of Kelvin–Helmholtz-type instabilities at the contact discontinuities. Such phenomena are not observable for lower-resolution grids, but in fact they correspond to physical effects that have been reported in numerical tests in [16], where a fifth-order shock capturing scheme is being used, and also observed in real experiments [4].

In this case, the percentage of numerical divergences computed directly with M-PHM grows from $\%f = 1\%$ to $\%f = 10\%$, which leads to an estimated global gain $\theta = 7.5$. From the practical point of view, it is important to notice that the estimated computing time for the reference simulation, i.e., full M-PHM, on this fine grid is approximately one month, while the actual time for the multilevel computation was 3–4 days.[1]

5.3. Test results: ENO schemes. As observed by Sjögreen in [22], a multilevel strategy like the one described in this paper should lead to a considerable gain in efficiency with respect to the reference simulation under the following conditions:

1. Large number of grid points.
2. Computationally expensive underlying shock capturing scheme.

[1] All simulations were done with a 350-MHz PC.

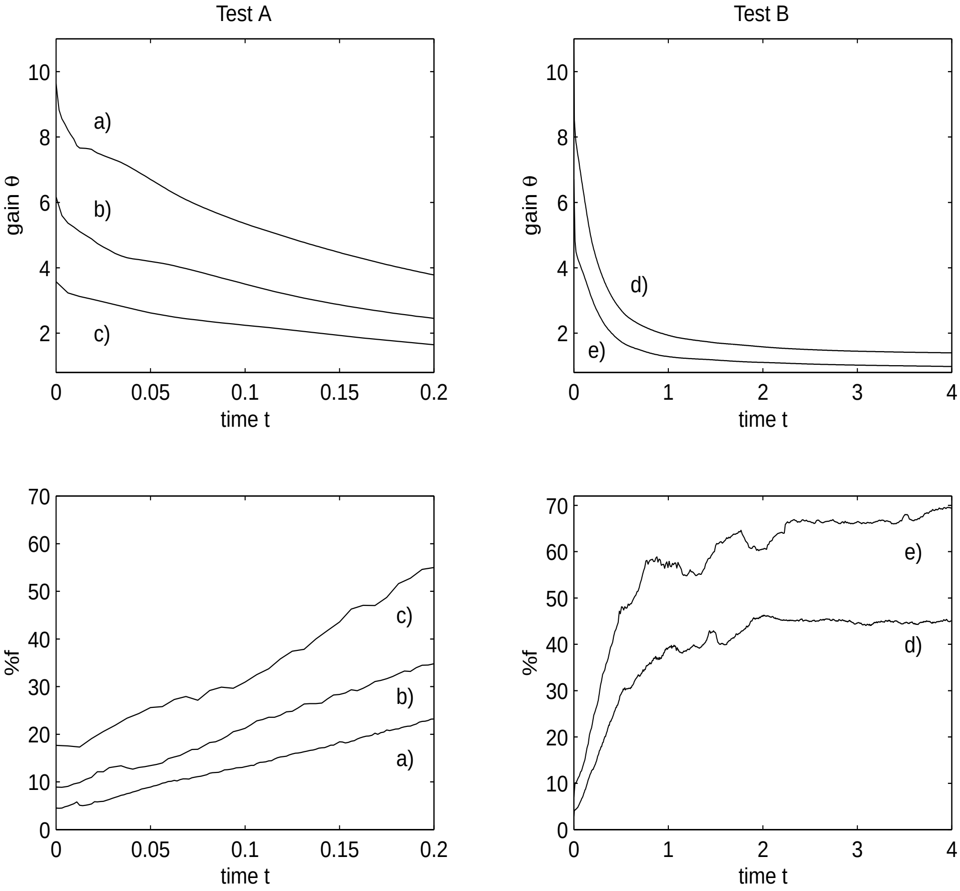

FIG. 5.7. *Time evolution of θ (top) and $\%f$ (bottom) for Test A (left) and Test B (right) and for different initial grid $\mathcal{G}^0$.* (a) 512×128, (b) 256×64, (c) 128×32, (d) 256×80, (e) 128×40.

TABLE 5.3
Cpu time in seconds for the different steps of the multilevel and reference algorithms for one Runge–Kutta stage. These values are obtained with Test A and the largest grid 512×128 *and with* $\%f = 23$.

	Multilevel algorithm	Reference algorithm
Transform	0.06	–
Thresholding	0.08	–
Divergence Evaluation	6.9	13.8
Other	0.15	0.15
Total	7.2	13.95

We have seen this to be the case in the previous section. In this section we would like to compare the computational gain of the multilevel strategy when applied to the M-PHM scheme and to the ENO-3 scheme.

Remark 5.1. It should be mentioned that some entropy corrections, as proposed in [11], are needed near the reflecting wall when using the ENO-3 scheme to avoid the occurrence of a carbuncle phenomenon in the case of the finest grid for Test A; these

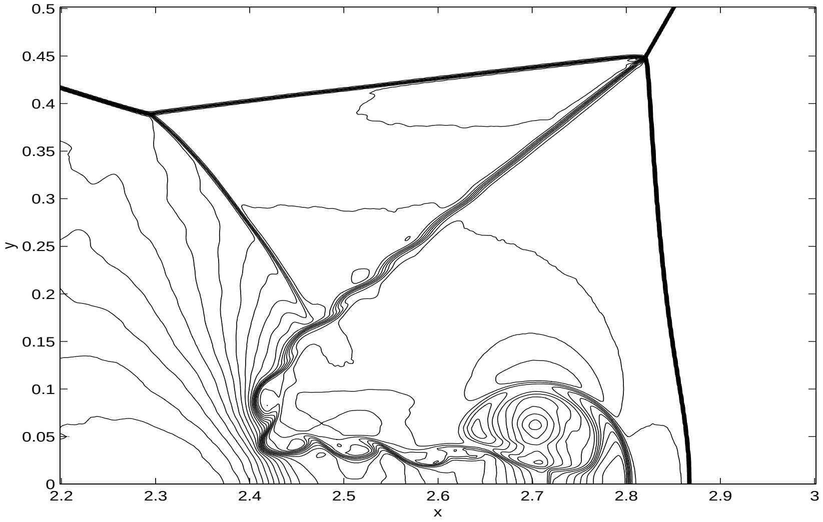

FIG. 5.8. *Zoom of the double Mach reflection region for Test A at* $t = 0.2$ *obtained with* 2560×640 *grid points.*

TABLE 5.4
*Percentage of resolved fluxes and cpu gain for Test A with ENO-*3 *fluxes at time* $t = 0.2$.

Grid size $\mathcal{G}^0$	$\%f_{\min}$ – $\%f_{\max}$	cpu gain θ
128×32	17.6 – 54.2	1.54
256×64	8.9 – 38.4	2.2
512×128	4.5 – 25.7	2.9

corrections are unnecessary for Marquina's scheme. For Test B, a Roe-matrix-related numerical instability develops for grids of size 256×64 or larger, which leads to a crash of the code [9]. These instabilities can be avoided by using appropriate entropy corrections on the bottom wall of the wind tunnel as specified in [11], but we will not pursue this here.

Table 5.4 reports the minimum and maximum percentage of ENO-computed numerical divergences and the global gain θ for the simulation with Test A. Comparing with the results of Table 5.1, we observe that the gain is not as large as in the case of the M-PHM-based multilevel scheme but remains significant. This fact is consistent with Sjögreen's observations, since the cost of a direct evaluation of the numerical divergence by the M-PHM scheme is higher than that of the ENO-3 scheme (by a factor of 2 in our implementation).

It is interesting to display also the gain per iteration θ_{iter} as a function of $\%f$. In Figure 5.9 we represent $\theta_{iter}(\%f)$ for the M-PHM-based and ENO-3-based multilevel strategies. Notice that this representation is more or less independent of the considered test case since the time evolution is not taken into account.

We observe that the gain is much more important for the M-PHM multilevel scheme and small values of $\%f$. Observe also that the difference is reduced when this percentage increases, a fact that could be easily understood considering the following (crude) estimate of θ_{iter}:

$$\theta_{iter} = \frac{N_p t_f}{t_{mr} + t_{thres} + N_f t_f + (N_p - N_f) t_I}$$

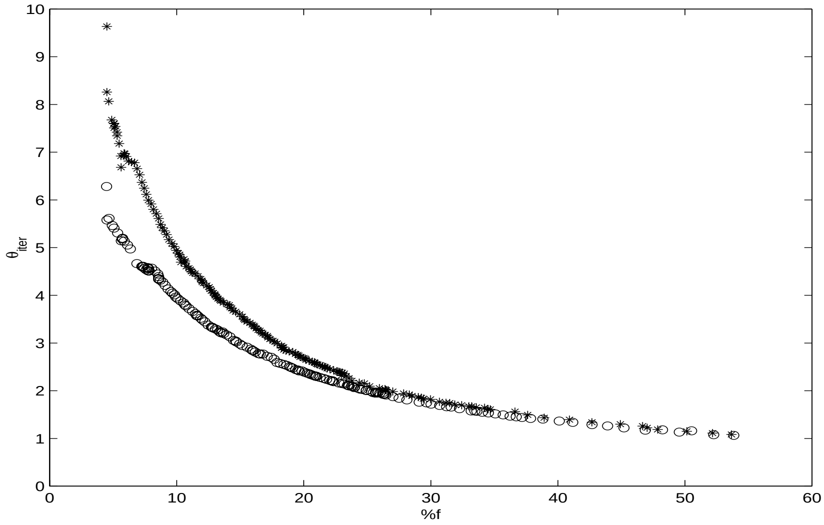

FIG. 5.9. *Gain per iteration θ_{iter} versus the percentage of resolved fluxes $\%f$ for Marquina $(*)$ and ENO (o) schemes.*

$$= \frac{t_f}{\frac{1}{N_p}(t_{mr} + t_{thres}) + \lambda t_f + (1-\lambda)t_I}, \tag{5.3}$$

where t_f is the cpu time to compute one value of the numerical divergence with the HRSC scheme, t_I is the cpu time for one interpolation, and t_{mr} and t_{thres} denote, respectively, the multiresolution transform and thresholding cpu times (which are essentially negligible, as shown in Table 5.3). N_p is the total number of grid points, N_f represents the number of points where the numerical divergence is evaluated directly, and $\lambda = N_f/N_p$.

Considering the same percentage of resolved fluxes for both schemes, i.e., $\%f^M = \%f^E (= 100 * \lambda)$, we can write

$$\frac{\theta^M_{iter}}{\theta^E_{iter}} = \frac{t^M_f}{t^E_f}\,\frac{\frac{1}{N_p}(t_{trans} + t_{thres}) + \lambda t^E_f + (1-\lambda)t_I}{\frac{1}{N_p}(t_{trans} + t_{thres}) + \lambda t^M_f + (1-\lambda)t_I} \sim 2\frac{\lambda + (1-\lambda)\frac{t_I}{t^E_f}}{2\lambda + (1-\lambda)\frac{t_I}{t^E_f}}, \tag{5.4}$$

since in our implementation $t^M_f / t^E_f \sim 2$.

The function

$$g(\lambda) = 2\frac{\lambda + (1-\lambda)\beta}{2\lambda + (1-\lambda)\beta} \tag{5.5}$$

is monotonically decreasing and approaches 1 when λ tends to 1. Moreover, the smaller the ratio β, the faster the convergence to the limit value. In our computations, the ratio $\beta := t_I/t_f$ is approximately 1/56, which leads to $g(.4) = 1.01$ and explains the behavior observed on Figure 5.9. When $\%f \geq 60\%$ the multilevel algorithm is no longer computationally competitive with respect to the reference simulation (see also the first entry in Table 5.2).

6. Conclusions. We have presented a multilevel algorithm designed to reduce the high computational cost associated to HRSC schemes for hyperbolic systems of conservation laws, and we have investigated the application of this multilevel strategy to state-of-the-art HRSC schemes using standard tests for the 2D Euler equations.

The numerical results presented in this paper point out that there is a significant reduction of the computational time when using the multilevel algorithm and confirm Sjögreen's observations in [22]: the more expensive the flux computation, the better the efficiency of the multilevel computation with respect to the reference simulation.

Our multilevel strategy follows the basic design principle of Bihari and Harten in [5], but it is built upon the interpolatory multiresolution framework, instead of the cell-average framework, as in [1, 2, 5, 6, 22, 17]. Through a series of numerical experiments, we show that the strategy we propose offers the possibility of obtaining a high-resolution numerical solution on a very fine grid at the cost of the user's own numerical technique on a much coarser mesh. Its potential users might be researchers performing computational tests with state-of-the-art HRSC methods and using uniform grids.

As in [1, 2, 5, 22], our technique works on the discrete values at the highest resolution level, which need to be always available. There are no memory savings with respect to the reference simulation. In [6, 17], the authors concentrate on solving the evolution equations associated to the (cell-average) scale coefficients. While this option opens the door to what might be an alternative to AMR, a fully adaptive algorithm with selective refinement and real memory savings, it also suffers, in our opinion, from some of the drawbacks of AMR: the need of a special data structure which invariably leads to a very complicated coding structure.

On the other hand, our approach (due in part to the use of the interpolatory framework) is pretty transparent, even to the nonexpert in multiscale analysis, and its incorporation into an existing hydrodynamical code is, in principle, much easier.

A MODEL FOR THE UNSTABLE MANIFOLD OF THE BURSTING BEHAVIOR IN THE 2D NAVIER–STOKES FLOW[*]

NEJIB SMAOUI[†]

Abstract. Quasi-periodic and bursting behaviors of the two-dimensional (2D) Navier–Stokes flow are analyzed. The tools used are the proper orthogonal decomposition (POD) method and the artificial neural network (ANN) method. The POD is used to extract coherent structures and prominent features from PDE simulations of a quasi-periodic regime and a bursting regime. Eigenfunctions of the two regimes were related by the symmetries of the 2D Navier–Stokes equations. Three eigenfunctions that represent the dynamics of the quasi-periodic regime and two eigenfunctions associated with the unstable manifold of the bursting regime were derived. Calculations of the POD eigenfunctions are performed on the Fourier amplitudes in a comoving frame. Inverse Fourier transform is applied to represent the POD eigenfunctions in both streamfunction and vorticity formulations so that the number of relevant eigenfunctions for streamfunction and vorticity data is the same. Projection onto the two eigenfunctions associated with the unstable manifold reduces the data to two time series. Processing these time series through an ANN results in a low-dimensional model describing the unstable manifold of the bursting regime that can be used to predict the onset of a burst.

1. Introduction.

The use of the artificial neural network (ANN) in modelling various real-world problems has shown a remarkable success in diverse areas such as speech recognition [1], combinatorial optimization [2], image processing, artificial intelligence, control systems [3], and pattern recognition [4]. Recently, ANN has been applied to process nonlinear time series particularly for the prediction of temporally complicated dynamics [5, 6, 7] and the identification of long-term dynamic behavior [8] and bifurcation [9]. A neural network is a logical structure in which multiple nodes, or neurons, operating in parallel, communicate with each other through connecting synapses. The greatest advantage of a neural network is its ability to model complex nonlinear relationships without any a priori assumptions about the nature of the relationships. ANN was also combined with proper orthogonal decomposition to estimate rock permeability [10], to model fluid flow in porous media [11], and to model cellular flames [12].

The proper orthogonal decomposition (POD), also known as Karhunen–Loève decomposition, principal component analysis, and singular value decomposition, has wide applications in scientific problems for both data compression and feature identification [13, 14, 15, 16]. Recently, most applications of the POD method have concentrated on modelling PDE simulations with optimal POD eigenfunctions to generate Galerkin systems that behave like the large-scale numerical simulations of the PDE

[17, 18, 19, 20]. The system of ordinary differential equations (ODEs), thus obtained, is valid most of the time for a finite range of the bifurcation parameter. However, if the POD method is used to analyze experimental data when there is no known mathematical model for the data, then there is no straight way of reducing the data via a Galerkin projection. Therefore, the use of ANN combined with POD has been shown to be a feasible approach [12].

The objective of this research is to develop a model for the unstable manifold of the bursting behavior in the two-dimensional (2D) Navier–Stokes flow known as Kolmogorov flow. The model will then be used to predict the onset of a burst during the bursting regime; thus, controlling the chaotic regime or delaying its instability. To achieve the above objectives, POD in conjunction with ANN is used. The POD eigenfunctions are obtained from numerical Kolmogorov simulations for a regime characterized by a quasi-periodic behavior at a Reynolds number, $Re = 25.7$. Those eigenfunctions are related to the POD eigenfunctions of the laminar part of the bursting regime at $Re = 25.77$ by the symmetries of the 2D Navier–Stokes equations. The idea of symmetry was first introduced by Sirovich [21]. He suggested the use of symmetry operations to enlarge the available dataset in order to get better averaging behavior. Later on, Aubry, Lian, and Titi [22] have shown that by using a symmetrized dataset, the resulting POD Galerkin system is equivariant with respect to the symmetry which is a necessary condition to achieve a representation of the global phase space. Berkooz and Titi [23] showed that there is no need to apply a symmetry group on an actual realization since all information gained is contained in the eigenfunctions and eigenvalues of the original experiment. Therefore, the symmetry group should be applied on the eigenfunctions. They suggested possible computational savings. Smaoui and Armbruster [17] demonstrated that the computational savings promised in [23] can only be realized if the eigenfunctions are obtained using the snapshot method.

Using the snapshot method, the difference between the data field at $Re = 25.77$ and the symmetrized data at $Re = 25.7$ describes the unstable manifold that leads toward bursting. A POD analysis of this data reveals that 97% of the energy in the unstable manifold is contained in two eigenfunctions. Instead of projecting the 2D Navier–Stokes equations onto these two eigenfunctions, and getting a nonautonomous 2D system of ODEs, we project the unstable data onto those two eigenfunctions to reduce the data to a small number of time series. Finally, the time series is processed through an ANN which results in a low-dimensional, nonlinear dynamical model describing the unstable manifold of the bursting regime.

The remainder of this paper is organized as follows: Section 2 discusses the bursting behavior of the Kolmogorov flow. Section 3 describes the POD analysis and how it is adapted to Kolmogorov flow. Section 4 presents the ANN model for the unstable manifold, and we conclude in section 5.

2. The bursting regime of the Kolmogorov flow. The 2D Kolmogorov flow is the solution of the 2D Navier–Stokes equation with force $\vec{f} = (\frac{1}{R_e}k^3 \cos ky, 0)$ assumed stationary and spatially biperiodic. It was introduced by Kolmogorov in the late 1950s as an example with which to study transition to turbulence. This 2D Kolmogorov flow is studied because of the rich symmetries and the lack of boundary layer associated with it as compared to the Navier–Stokes equations. This will help us gain insight in the understanding of the behaviors of the three-dimensional Navier–Stokes equations. For very low macroscopic Reynolds number R_e, the only stable flow is the plane parallel periodic shear flow $\vec{u}_0 = (k \cos ky, 0)$, usually called the "basic Kolmogorov flow." In a 2 π-periodic square box the equations are

$$\tag{1} \begin{gathered} \frac{\partial \vec{u}}{\partial t} + \vec{u}.\nabla\vec{u} + \nabla p = \frac{1}{R_e}\nabla^2\vec{u} + \vec{f}, \qquad \nabla.\vec{u} = 0, \\ \vec{f} = \left(\tfrac{1}{R_e}k^3\cos ky, 0\right), \qquad 0 \le x, y \le 2\pi. \end{gathered}$$

In the usual stream function representation of the flow, (1) becomes

$$\tag{2} \frac{\partial \Delta\phi'}{\partial t} + \frac{\partial}{\partial x}\left(\Delta\phi'\frac{\partial\phi'}{\partial y}\right) - \frac{\partial}{\partial y}\left(\Delta\phi'\frac{\partial\phi'}{\partial x}\right) = \frac{1}{R_e}\Delta^2\phi' + \frac{\partial f_1}{\partial y} - \frac{\partial f_2}{\partial x}.$$

The stability of the basic Kolmogorov flow, $\sin ky$, is analyzed by perturbing it as $\phi' = \phi + \sin ky$. Thus, the equations for a perturbation of the Kolmogorov flow reduce to

$$\tag{3} \frac{\partial\Delta\phi}{\partial t} = \Delta^2\phi - kR_e\frac{\partial}{\partial x}[\Delta\phi + k^2\phi]\cos ky - R_e\left[\frac{\partial}{\partial x}\left(\Delta\phi\frac{\partial\phi}{\partial y}\right) - \frac{\partial}{\partial y}\left(\Delta\phi\frac{\partial\phi}{\partial x}\right)\right].$$

The symmetries of (3) follow from the Euclidean invariance of the Navier–Stokes equations restricted by the form of the force. All the symmetries are generated by the following transformations:

$$\tag{4} \begin{array}{cccc} T_\xi & : & x & \rightarrow & x+\xi, \\ r & : & (x,y) & \rightarrow & (-x, -y+\frac{\pi}{k}), \\ s & : & (y,\phi) & \rightarrow & (-y,-\phi), \\ t & : & y & \rightarrow & y + \frac{2\pi}{k}. \end{array}$$

Since $(rs)^2 = t$ and $(rs)^{2k} = id$, the two symmetry operations s and rs generate the symmetry group of the regular $2k$-gon D_{2k}. The complete symmetry group of (3) can be written as the semidirect product $D_{2k}\dot{+}SO(2)$.

In the simplest case, $k = 1$, the Kolmogorov flow with 2π-periodic boundary conditions is not unstable for any value of R_e [24, 25, 26], and one is forced to consider $k > 1$. Bifurcations of the 2D Navier–Stokes equation have been investigated in [27, 28, 29, 30, 31, 32] and transitions that occur at higher Reynolds number when $k = 8$ have been studied in [33, 34, 35]. Recently, symmetries and dynamical information for all attractors at low Reynolds number when $k = 2$ have been investigated in [30, 36]. In [30] most bifurcations that occur at low Reynolds number were analyzed and it has been shown that the low-dimensional attractor for the 2D Navier–Stokes flow has a crucial component that lies in the stable eigenspace of the trivial solution. In this study, we focus on a weakly chaotic regime that occurs at $Re = 25.77$ for $k = 2$ (the laminar states are still stable at $Re = 25.70$). The most striking feature of this regime is that the dynamics follows a long laminar regime, then undergoes a burst and settles down to a laminar regime at the same level as before; then other explosions follow. Intervals between bursts are not constant and fluctuate randomly. A study of the Fourier modes [30, 36] shows that

- the laminar regime can be described by a modulated travelling wave with well-defined symmetries;
- successive laminar intervals may not correspond to identical dynamical states but rather to a sequence of states mapped onto each other under some group action.

This kind of behavior was discussed in terms of heteroclinic and homoclinic connections in phase space involving an analysis of the symmetry group of the system [30, 36]. Information is obtained on the unstable manifold of the hyperbolic tori where

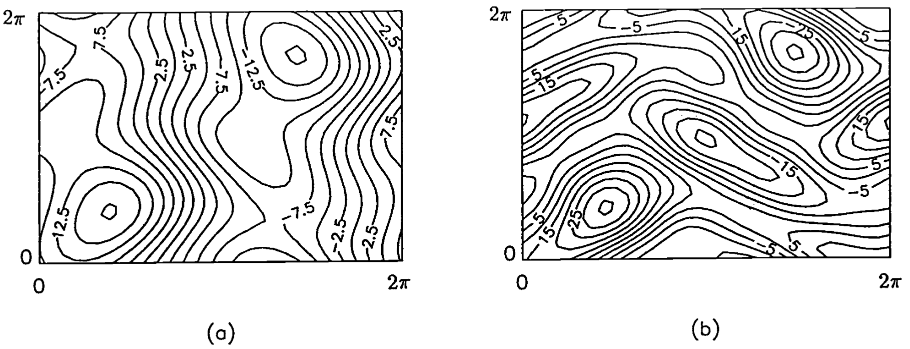

FIG. 1. (a) *Level set for the streamfunction for* $R_e = 25.7$. (b) *Level set for the vorticity for* $R_e = 25.7$.

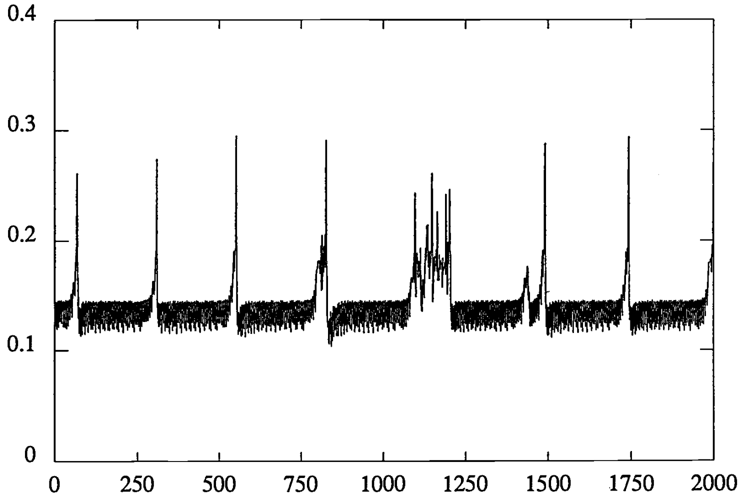

FIG. 2. *Time evolution of the maximum vorticity at* $R_e = 25.77$.

the dynamics is still weakly chaotic and remains for a very long time in a neighborhood of the tori. Figure 1 shows a typical plot of the streamfunction, ϕ, and the vorticity, $w = -\Delta\phi$ at $R_e = 25.7$. Figure 2 depicts the maximal vorticity against time in typical time series at $Re = 25.77$. Figure 2 reveals a long laminar sequence with “microbursts” spaced far apart. We will use POD analysis on these “microbursts” to be able to reveal the trigger mechanism for the bursting behavior.

3. POD. POD is a well-known procedure. It has been used in various fields of applications with different names [13, 14, 15, 16]. We summarize the main idea only briefly. One begins with a given inhomogeneous, chaotic and/or random realization of some state variable $u(x)$, which could be laboratory experimental data or data created by a large-scale simulation as in [21]. We assume that the average of $u(x, t)$, defined as

$$\langle u(x,t) \rangle = \frac{1}{M} \sum_{i=1}^{M} u_i, \tag{5}$$

is equal to zero. The data set $u\left(x,t\right)$ is defined over a finite spatial domain R and finite interval M. A scalar product is given as

$$(u,u')=\int_{R}u\left(x,t\right)u^{'}\left(x,t\right)dx. \tag{6}$$

We choose a function $\psi_1(x)$ such that the projection of the dataset onto all possible functions $\psi(x)$, given by

$$\lambda_1=\frac{1}{M}\sum_{i=1}^{M}\left(\psi_1(x),u_i(x)\right)^2, \tag{7}$$

is maximal, where we can normalize $(\psi_1,\psi_1)=1$. Proceeding inductively, we can find ψ_2 with $(\psi_2,\psi_1)=0$, $(\psi_2,\psi_2)=1$ such that

$$\lambda_2=\frac{1}{M}\sum_{i=1}^{M}\left(\psi_2(x),u_i(x)\right)^2 \tag{8}$$

is maximal. In this way, we can find a unique orthonormal set of functions ψ_n which are the eigenfunctions of the Fredholm-type integral equation

$$\int_{R}K\left(x,y\right)\psi\left(y\right)dy=\lambda\psi\left(x\right), \tag{9}$$

where $K\left(x,y\right)$ is the time-averaged correlation function

$$K\left(x,y\right)=\left\langle u\left(x,t\right)u\left(y,t\right)\right\rangle=\lim_{M\to\infty}\frac{1}{M}\sum_{i=1}^{M}u_i(x)u_i(y), \tag{10}$$

approximated by

$$K\left(x,y\right)=\frac{1}{M}\sum_{i=1}^{M}u_i(x)u_i(y). \tag{11}$$

The ψ_n's are called the empirical eigenfunctions, the coherent structures, etc. It can be shown that any projection of the data $u\left(x,t\right)$ onto a finite set of ψ_k, given by

$$u_N=P_Nu=\sum_{k=1}^{N}a_k\left(t\right)\psi_k\left(x\right), \tag{12}$$

yields amplitudes a_k that are uncorrelated with respect to the averaging process; that is,

$$\left\langle a_j\left(t\right)a_k\left(t\right)\right\rangle=\lambda_j\delta_{jk}, \tag{13}$$

where λ_j is the variance of the data in the direction of the kth eigenfunction. Furthermore, the error given by

$$\epsilon_N=\|u-u_N\|^2 \tag{14}$$

is a minimum over all possible sets of orthonormal functions for any given N, where $\|.\|$ is the L^2-norm. The "energy" of the data is defined as the sum of eigenvalues of the correlation function, $E = \sum_i \lambda_i$. We assign an energy percentage to each eigenfunction based on its associated eigenvalues, i.e., $E_k = \frac{\lambda_k}{E}$.

Since we hope to identify the building blocks of low-dimensional attractors in spatio-temporally complex data, we assume that we have a high resolution in space and a comparatively low-dimensional attractor. That is, we assume $N \gg M$, since we can sample the attractor with only a few snapshots. Two approaches were known in the literature [21] for calculating the correlation function. The first is the direct method in which the covariance matrix is approximated by

$$C = \frac{1}{M} \sum_{i=1}^{M} u_i(x) u_i(x)^T. \tag{15}$$

This covariance matrix is an $N \times N$ matrix. For large N, this matrix can become too large for practical computation. The second method, known as the snapshot method, makes the computation more tractable [17]. In this case, the practical approach for calculating the correlation matrix is not to determine the $N \times N$ correlation matrix but to use the dual approach on the M snapshots, also known as the sample space setting [21]. We take the snapshot vector $u_k(x)$, $k = 1, \ldots, M$, and determine the empirical eigenfunctions $\psi_k(x)$ as an admixture of the given snapshots, i.e.,

$$\psi_k\left(x\right) = \sum_{j=1}^{M} \phi_j^{(k)} u_j\left(x\right), \tag{16}$$

where $\phi_j^{(k)}$ is the jth component of the kth eigenvector and such that the projection of the data is maximal on the $\psi_k\left(x\right)$, as in the previous process. The corresponding eigenvalue problem is then to find the eigenvalues and eigenfunctions of the symmetric $M \times M$ matrix C with

$$C_{ij} = \frac{1}{M}\left(u_i\left(x\right), u_j\left(x\right)\right) = \frac{1}{M} \sum_{k=1}^{N} u_i\left(x_k\right) u_j\left(x_k\right). \tag{17}$$

First, we concentrate on a laminar regime characterized by travelling waves that consist of a travelling structure plus additional time-dependent behavior at $R_e = 25.70$. We perform POD analysis on the Fourier amplitudes in a comoving frame of the travelling wave and find three eigenfunctions that capture 99.8% of the energy of the datafield. The inverse Fourier transformation of those three eigenfunctions is represented in terms of the streamfunction and vorticity formulations in Figures 3 and 4, respectively. The first eigenfunction captures 96.6% of the energy and lies in the invariant subspace Fix(sT_π). This is shown in Figure 5 by first operating with the T_π symmetry on the first streamfunction eigenfunction and by the s symmetry on the resulting eigenfunction. Figure 6 is the same as Figure 5 except for the first vorticity eigenfunction. The difference between the original eigenfunction and the symmetrized one in both streamfunction and vorticity formulations is shown in Figure 5(d) and Figure 6(d), respectively. The second and third eigenfunctions capture 2.6% and 0.62% of the energy, respectively. Inspection shows that those two eigenfunctions span a plane in phase space orthogonal to Fix(sT_π). These findings confirm that the laminar flow can be described as a modulated travelling wave which in phase space is represented by a torus. If we act with the whole symmetry group on the torus, we determine the group orbit of the torus. In particular, we can act with t and r on the solution to obtain different solutions; two solutions in Fix(sT_π) and two in Fix(tsT_π).

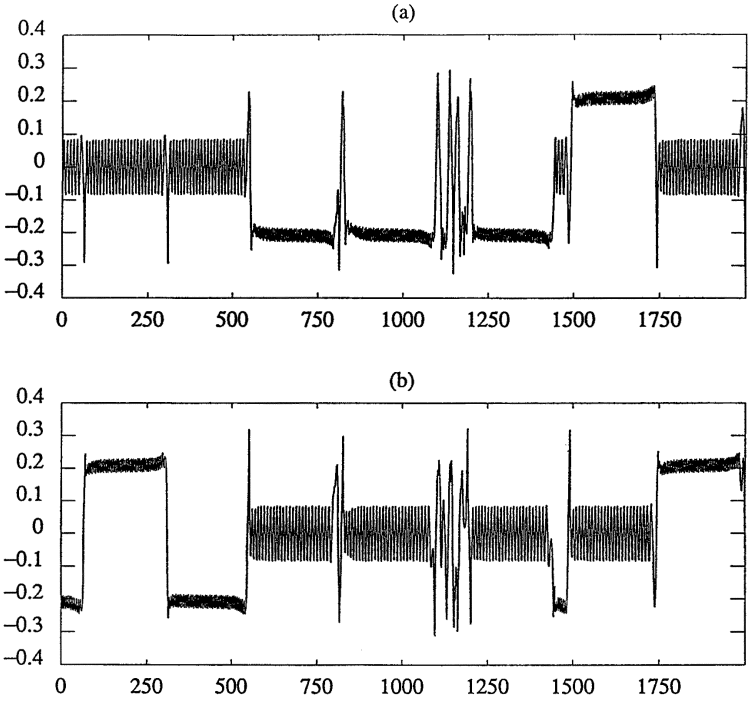

FIG. 7. *Real and imaginary part of the Fourier amplitude e^{iy} for $R_e = 25.77$.*

Next, we consider a slightly higher Reynolds number, namely, $R_e = 25.77$, that leads to a bursting behavior (see Figure 2). This Reynolds number varies very little as compared to the Reynolds number of the laminar regime. If we look closely enough at the Fourier amplitudes of the mode e^{iy} (see Figure 7), we notice that the laminar phases in between bursts look very much like the laminar phase at $Re = 25.7$. In particular, if we plot the imaginary part versus the real part of the Fourier amplitudes of the mode e^{iy}, we observe the four modulated travelling waves discussed earlier (see Figure 8). Therefore, it is reasonable to assume that there exists a close connection between the stable laminar flow at $R_e = 25.7$ and the laminar phase in between bursts at $R_e = 25.77$. Figure 8 also shows that the bursting behavior is not associated with structurally stable heteroclinic cycles. To extract the unstable manifold of the modulated travelling wave that leads toward bursting, we consider a particular laminar window of the dataset in Figure 7. This is obtained by considering the data that look perfectly laminar. These data are contaminated with the dataset associated with the unstable manifold of the bursting regime, and therefore the eigenfunctions extracted from it will not correspond to the pure laminar state. As a result, we use the dataset of the modulated travelling wave at $R_e = 25.7$ to extract the eigenfunctions responsible for the laminar regime. We then relate these eigenfunctions by the symmetry of the Navier–Stokes equations in order to obtain the eigenfunctions responsible for the laminar state between two bursts. This is done by showing that the most energetic eigenfunction of the data in between two bursts is almost identical up to a phase shift to one of the four possible laminar phases that appears at $R_e = 25.70$ (see Figure 9). This phase shift is determined by matching the amplitudes and phase of e^{ix} mode.

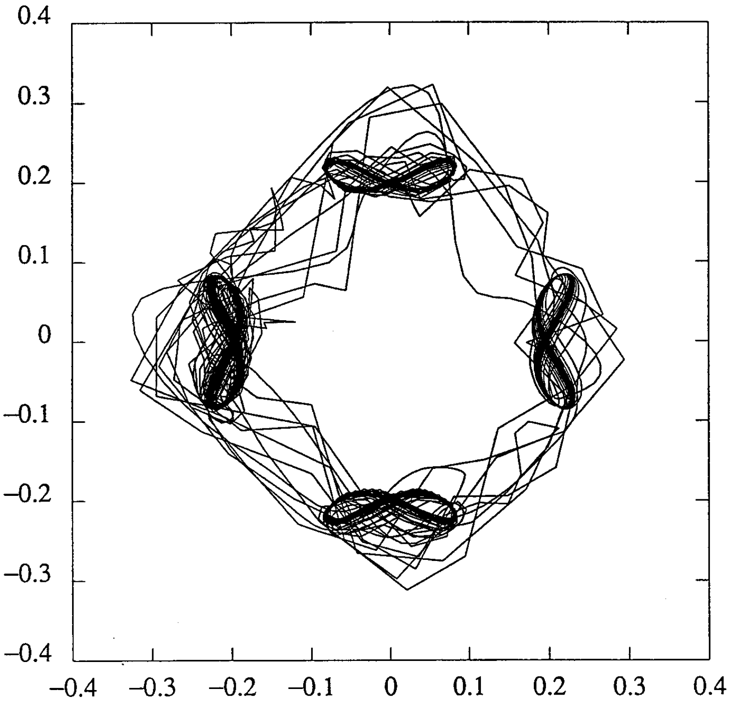

FIG. 8. *Phase plot of the simulation at $R_e = 25.77$. The (x, y) coordinates are the real and imaginary parts of the Fourier amplitude e^{iy}.*

We then shift the first three eigenfunctions of the laminar case by the phase shift thus determined and project the data in between two bursts onto these modes. The difference between this projection and the datafield describes the unstable manifold that leads toward bursting. A POD analysis of this data reveals that 97% of the energy in the unstable manifold is contained in two eigenfunctions (see Figure 10). The time series of the amplitudes of those eigenfunctions can be displayed by projecting the unstable manifold data onto those two POD eigenfunctions (see Figure 11). To model the unstable manifold for this particular datafield, we will use ANN on the time series.

4. ANN. ANN can be considered as a nonlinear dynamic system consisting of a large number of highly interconnected processing nodes. These nodes were inspired by studies of biological nervous systems and the internal operation of the human brain. They operate in parallel, communicating with each other through connecting synapses. Each node receives input, computes an activation, and transmits that activation to other processing nodes. The connection between two nodes is characterized by a weight. Learning occurs while modification of a weight matrix is undertaken. Therefore, what the network computes is highly dependent on how the nodes are interconnected and on the strengths of the connections or weights between them. The architecture of a neural network depends on the node characteristics, network topology, and learning algorithm. A sensitivity study on different neural network architectures led to the choice of an optimal network topology that consists of a six-node input layer, two ten-node hidden layers, both with a nonlinear sigmoid

function $\sigma(x) = \tanh x$, and a two-node output layer with linear transfer function is used (see Figure 12). The input layer consists of the time series $a_1(t)$, a suitable number of delays $[a_1(t-\Delta), a_1(t-2\Delta)]$, and the time series $a_2(t)$ with two delays $[a_2(t-\Delta), a_2(t-2\Delta)]$. The output is the predicted values $a_1(t+P)$ and $a_2(t+P)$ of the time series at time $t+P$, that is, we have the following mapping:

$$a_i(t+P) = f(a_j(t), a_j(t-\Delta), a_j(t-2\Delta)); \quad i,j = 1,2, \tag{18}$$

where f is a set of nonlinear functions representing the neural network model, Δ is a time delay, and P is the prediction time into the future.

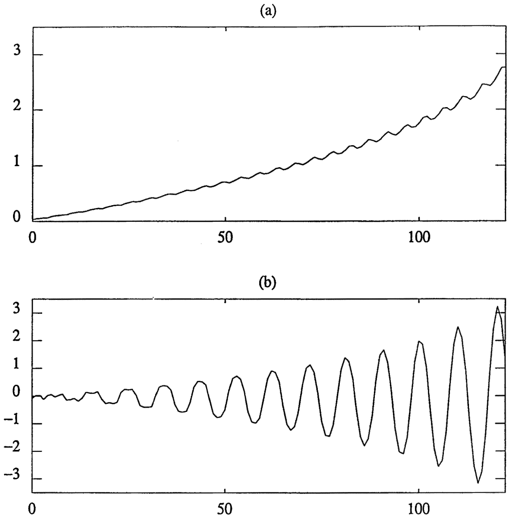

FIG. 11. *The data coefficients of the first two eigenfunctions associated with the unstable manifold.*

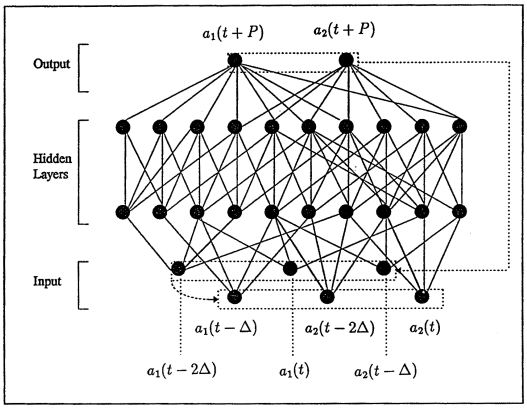

FIG. 12. *ANN paradigm used for the time series of the data coefficients of the unstable manifold.*

Once an architecture has been chosen, it remains to select a learning algorithm. The standard backpropagation learning algorithm has been the most widely used. The backpropagation algorithm is a gradient descent or steepest descent that uses the mean square error of the system over a given set of input-output pairs [37]. The overall error is usually defined as

$$e = \frac{1}{2} \sum_p \sum_k (z_k - y_k)_p^2 \tag{19}$$

over all output nodes k and input vector patterns p. In this notation, z_k is the target vector of the kth output node and y_k is the actual output vector of the kth output node. During the training phase, the weights are successively modified in order to reduce e. The backpropagation algorithm has been demonstrated to be effective in learning but is known to have a slow learning convergence rate because the generalized delta rule is basically a gradient descent scheme with constant step length. Gradient descent is simply the technique where parameters, such as weights, are moved in the opposite direction to the error gradient. Each step down the gradient results in a smaller error until an error minima is reached.

Recently, many learning algorithms and procedures were proposed to improve the modelling capability and learning convergence rate of the backpropagation algorithm [38, 39, 40]. Among the procedures proposed is the momentum procedure. It is basically used to avoid the search process getting stuck in a local minimum rather than a global one, a detailed description of which can be found in [10]. In this study, the training algorithm uses the Levenberg–Marquardt variation of Newton's method to modify the neural network weights. Newton's method can be written as

$$\Delta w = (J^T J)^{-1} J^T e, \tag{20}$$

where J is the Jacobian matrix of derivatives of each error to each weight, and e is an error vector. The problem with the above equation is that $J^T J$ may not be invertible. Thus, the Levenberg–Marquardt algorithm guarantees invertibility when

$$\Delta w = (J^T J + \mu I)^{-1} J^T e, \tag{21}$$

where μ is a scalar. When μ is small the above expression approximates the Gauss–Newton method, and when it is very large it approximates gradient descent. The Gauss–Newton method is used because it is faster and more accurate near an error minimum. Thus, μ is decreased after each successful step and increased only when a step increases the error.

The optimal network architecture discussed earlier with $\Delta = 4$, and $P = 4$, has been trained using data coefficients obtained from the time series of the unstable manifold of one of the four possible modulated travelling waves (i.e., data from vectors corresponding to $420 \leq t \leq 530$; see Figure 7). The choice of Δ implies that a prediction made P time steps into the future past the last actual data coefficients $a_1(t)$, $a_2(t)$ will be made using actual dataset at times: $a_1(t)$, $a_1(t-4)$, $a_1(t-8)$, $a_2(t)$, $a_2(t-4)$, and $a_2(t-8)$. The training was considered successful when the mean square error $e \leq 10^{-4}$. Figure 13 shows both original and predicted time series during the training procedure for the first and second data coefficient $a_1(t)$ and $a_2(t)$. The neural network model is then tested on a different time series associated with another unstable manifold (i.e., data from vectors corresponding to $1640 \leq t \leq 1720$; see Figure 7). Figure 14 shows the excellent agreement between the original time series and the one estimated using the neural network model. Different tests were done on other generated unstable manifolds and excellent prediction has been achieved in each case.

5. Conclusions. We have shown that the use of ANN in conjunction with POD for predicting the data coefficients associated with the unstable manifold of the bursting behavior is very successful. The POD analysis was used to analyze and extract coherent structures from a bursting behavior and a quasi-periodic behavior. Two types of dynamics were observed during the bursting regime: a large-scale, low-dimensional one similar to the one observed in the quasi-periodic regime which can be represented by three coherent structures. Riding on top of that dynamics is a small-scale dynamics characterized by two coherent structures. Those two coherent structures play a role in triggering the burst event and hence in the randomness of the time between

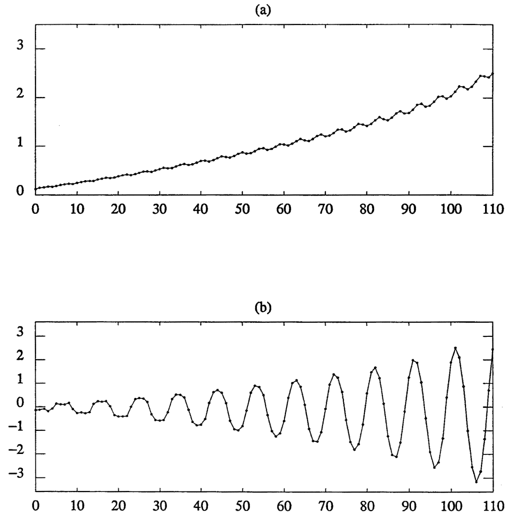

FIG. 13. *Time series plot for the training data set of the two data coefficients $a_1(t)$ and $a_2(t)$. Original (solid line) and predicted (circle) data set values.*

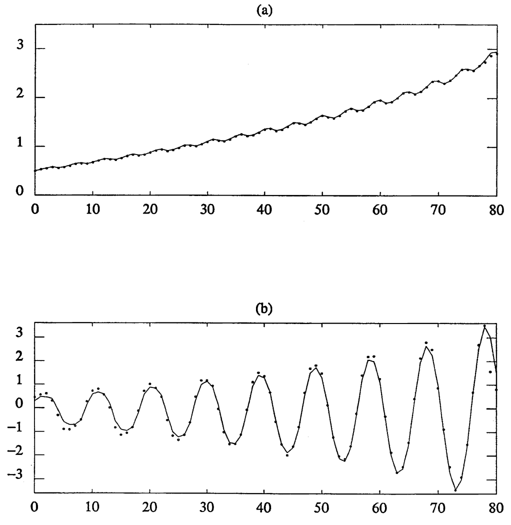

FIG. 14. *Time series plot for the testing data set of the two data coefficients $a_1(t)$ and $a_2(t)$. Original (solid line) and predicted (circle) data set values.*

bursts. Modelling the small-scale dynamics using ANN helps predict the time needed for the occurrence of a burst. The combination of the two approaches has shown to be a powerful method capable of accurately producing a model that can be used to predict the onset of a burst, thus delaying the bursting regime.

This work establishes a foundation for using neural network to predict the small-scale dynamics of more complicated regimes (e.g., $k = 4$ and $k = 8$) which will be the subject of future studies.

A MINIMAX METHOD FOR FINDING MULTIPLE CRITICAL POINTS AND ITS APPLICATIONS TO SEMILINEAR PDES[*]

YONGXIN LI[†] AND JIANXIN ZHOU[‡]

Abstract. Most minimax theorems in critical point theory require one to solve a two-level *global* optimization problem and therefore are not for algorithm implementation. The objective of this research is to develop numerical algorithms and corresponding mathematical theory for finding multiple saddle points in a stable way. In this paper, inspired by the numerical works of Choi–McKenna and Ding–Costa–Chen, and the idea to define a solution submanifold, some local minimax theorems are established which require us to solve only a two-level *local* optimization problem. Based on the local theory, a new local numerical minimax method for finding multiple saddle points is developed. The local theory is applied, and the numerical method is implemented successfully to solve a class of semilinear elliptic boundary value problems for multiple solutions on some nonconvex, non star-shaped and multiconnected domains. Numerical solutions are illustrated by their graphics for visualization. In a subsequent paper [Y. Li and J. Zhou, *Convergence results of a minimax method for finding critical points*, in review], we establish some convergence results for the algorithm.

1. Introduction.

Multiple solutions with different performance and instability indices exist in many nonlinear problems in natural and social sciences [33, 30, 24, 36, 23]. When cases are variational, the problems can be reduced to solving the Euler–Lagrange equation

$$J'(u) = 0, \tag{1.1}$$

where J, called *a generic energy functional*, is a C^1-functional on a Banach space H, and J' or ∇J is its Frechet derivative. A solution to the Euler–Lagrange equation (1.1) is called *a critical point* of J. The first candidates for critical points are the local maxima and minima to which the classical critical point theory was devoted in calculus of variation. Traditional numerical methods focus on finding such stable solutions. Critical points that are not local extrema are called *saddle points*, that is, critical points u^* of J for which any neighborhood of u^* in H contains points v, w such that (s.t.) $J(v) < J(u^*) < J(w)$. In physical systems, saddle points appear as *unstable* equilibria or transient excited states. Note that this definition is different from and much more general than the saddle point in optimization and game theory in which a splitting structure for the space H is required to be known in advance and which is therefore not used in critical point theory.

A number $c \in \mathbb{R}$ is a *critical value* of J if $J(\hat{u}) = c$ for some critical point $\hat{u}$. For a critical value c, the set $J^{-1}(c)$ is called a *critical level*. When the second Frechet derivative J'' exists at a critical point $\hat{u}$, then $\hat{u}$ is said to be *nondegenerate* if $J''(\hat{u})$ is invertible. Otherwise, $\hat{u}$ is said to be *degenerate*.

Stability is one of the main concerns in control and system design. On the other hand, in many applications, higher maneuverability and performance are desirable, in particular, in system design for emergency or combat machineries. Unstable solutions may have much higher maneuverability and performance indices.

Can one find a way to provide a choice or balance between instability and maneuverability or performance indices? Thus one needs to solve for multiple solutions and then study their individual properties.

Numerically finding such unstable solutions in a stable way is very challenging. So far, there is virtually no theory existing in the literature to devise such a feasible numerical algorithm. The objective of this research project is to systematically develop effective numerical algorithms and corresponding mathematical theory for finding multiple saddle points in a stable way. To do so, we need to know the local mathematical structure of a critical point and its connection to a critical point at the next critical level. We do not intend to establish *new* existence theorems.

Structure and behavior of critical points have attracted the attention of many researchers. In 1925, Morse proved that if $\hat{u}$ is a nondegenerate critical point of a real function J of n variables, then there exists a neighborhood $\mathcal{N}(\hat{u})$ of $\hat{u}$ and a local homeomorphism h from $\mathcal{N}(\hat{u})$ into H s.t.

$$J(h(u)) = J(\hat{u}) + \frac{1}{2}\langle J''(\hat{u})u, u\rangle \quad \forall u \in \mathcal{N}(\hat{u}).$$

That is, J behaves locally like a quadratic function around a nondegenerate critical point. This result, called the Morse lemma, has been extended to a real-valued infinite-dimensional functional [10]. Therefore, critical levels with a local minimum, if it exists, at the bottom can be imagined.

The *Morse index* (MI) of a critical point $\hat{u}$ of a real-valued functional J is the maximal dimension of a subspace of H on which the operator $J''(\hat{u})$ is negative definite; the *nullity* of a critical point $\hat{u}$ is the dimension of the null-space of $J''(\hat{u})$. Thus, for a nondegenerate critical point, if its MI $= 0$, then it is a local minimizer and a stable solution, and if its MI > 0, then it is a saddle point, an unstable solution.

DEFINITION 1.1. *A point $v \in H$ is called a* descent (*ascent*) *direction of J at a critical point $\hat{u}$ if there exists $\delta > 0$ s.t.*

$$J(\hat{u} + tv) < \ (>)\, J(\hat{u}) \quad \forall 0 < |t| < \delta.$$

Thus J has at least k linearly independent descent directions at a critical point with MI $= k$.

Many boundary value problems (BVPs) are equivalent to solving [33]

$$A(u) = 0 \tag{1.2}$$

for a solution $u \in H$ and an operator $A : H \to H^*$. When the problem is variational, there exists $J : H \to \mathbb{R}$ s.t.

$$\langle A(u), v\rangle = \langle J'(u), v\rangle = \lim_{t\to 0} \frac{J(u+tv) - J(u)}{t} \quad \forall v \in H, \tag{1.3}$$

or $A(u) = J'(u)$. Thus $\hat{u}$ is a (weak) solution to (1.2) if and only if $\hat{u}$ is a critical point of J.

The following semilinear BVP is our model problem in this paper; it is known that this model has originated from many applications in physics, engineering, biology, ecology, geometry, etc. Consider

$$\Delta u(x) - \ell u(x) + f(x, u(x)) = 0, \quad x \in \Omega, \tag{1.4}$$

for $u \in H$ with either the zero Dirichlet boundary condition (BC) or the zero Neumann BC, where Ω is a bounded open domain in $\mathbb{R}^N$, and f is a nonlinear function of $(x, u(x))$ with $u \in H$. For the zero Dirichlet BC, we let $H = H_0^1(\Omega)$ and $\ell \geq 0$; for the zero Neumann BC, we let $H = H^1(\Omega)$ and $\ell > 0$, where $H^1(\Omega)$ is the Sobolev space $W^{1,2}(\Omega)$ and $H_0^1(\Omega) = \{v \in H^1 : v(x) = 0, x \in \partial\Omega\}$ [1]. The associated variational functional is the energy

$$J(u) = \int_\Omega \left\{ \frac{1}{2}|\nabla u(x)|^2 + \frac{1}{2}\ell u^2(x) - F(x, u(x)) \right\} dx, \tag{1.5}$$

where $F(x, t) = \int_0^t f(x, \tau) d\tau$ satisfies the assumptions (h1)–(h5) as stated in section 4 and $u \in H$. Then a direct computation shows that a point $\hat{u} \in H$ is a critical point of J in H if and only if $\hat{u}$ is a weak solution to the BVP (1.4) and, therefore, a classical solution to (1.4) by a standard elliptic regularity argument.

Since Ljusternik–Shnirelman (1934), under a deformation assumption, proved the existence of a saddle point as a minimax solution, i.e., a solution to a two-level optimization problem

$$\min_{A \in \mathcal{A}} \max_{v \in A} J(v) \tag{1.6}$$

for some collection $\mathcal{A}$ of subsets A in H, the minimax principle has become the most popular approach in critical point theory. Note that there is another minimax approach in multilevel optimization and game theory, which is a two-level optimization of the form

$$\min_{x \in X} \max_{y \in Y} J(x, y),$$

where $H = X \times Y$ for some subspaces X and Y. Due to its splitting structure, this minimax approach prevents us from turning around in a search for a critical point. Although, it is known that if $J''(\hat{u})$ is self-adjoint and Fredholm, H has such a splitting structure around a nondegenerate critical point $\hat{u}$ according to the Morse theory. But such a splitting structure depends on $\hat{u}$ and is not known until one finds $\hat{u}$. Thus this minimax approach does not help in searching for a critical point and is not used in critical point theory.

It is the mountain pass lemma, proved in 1973 by Ambrosetti–Rabinowitz [3] by constructing a deformation, that sets a milestone in nonlinear analysis. Since then, minimax theorems have gained great popularity in the study of nonlinear PDEs and dynamic systems. Various minimax theorems, such as linking and saddle point theorems, have been successfully established to prove the existence of multiple solutions to various nonlinear PDEs and dynamic systems [5, 8, 10, 13, 14, 16, 22, 23, 24, 26, 27, 30, 31, 32, 33, 34, 36]. For example, for a semilinear elliptic equation $\Delta u + f(u) = 0$ with the zero Dirichlet BC, when $f(u)$ is superlinear, it is known that if f is odd, then infinitely many solutions exist; otherwise, a third sign-changing solution (MI = 2) exists [34, 5, 9] in addition to a positive and a negative solution.

When multiple solutions exist in a nonlinear system, some are stable and others are unstable. A stable solution (MI = 0) can be found through local minimization techniques or a monotone iterative scheme (see, e.g., [2, 7, 11, 15, 18, 19, 28, 29]). However, relatively little is known in the literature on constructing algorithms to compute such unstable saddle points in a numerically stable way. One might mention Newton's method. Note that zeros and critical points are different concepts. Without knowing or using the local structure of a (degenerate) critical point, the usual Newton method will not be effective or stable. When a local minimization is involved in a quasi-Newton method, it will lead to a local minimum, in the case of (1.4), the zero.

Most minimax theorems in the literature mainly focus on the existence issue. They require one to solve a two-level *global* optimization problem, i.e., (constrained) global maximizations at the first level and a global minimization at the second level, and therefore are not for algorithm implementation.

By studying the mountain pass lemma and using an idea from Aubin–Ekeland [4], in 1993 Choi–McKenna [12] proposed a numerical minimax algorithm, called a mountain pass method, to solve the model problem basically for a solution with MI = 1. The algorithm opens a brand new door to numerically compute unstable solutions. The algorithm has been modified in [17] and further revised in [11]. Since the function J in [12] has only one maximum along each direction, whether or not it is a local or global maximum at the first level is not a concern there. The merit of this algorithm is that (a) at the first level, a maximization is taken over an affine line starting from 0, and (b) a steepest descent direction is used to search for a local minimum at the second level. In contrast, the mountain pass lemma requires a maximization on every continuous path connecting 0 and a given point v at the first level and then a global minimization at the second level. Thus the method in [12] cannot be justified by the mountain pass lemma. An earlier result of Ding–Ni [27], which proved for the model problem the existence of a saddle point as a minimax solution that requires a unique maximization on each affine line starting from 0 at the first level and a global minimization at the second level, can only be viewed as a partial justification.

In [11], for a class of functionals, a very simple scheme called a scaling iterative method is designed to find a solution with MI = 1. That approach is not based on functional analysis. A partial justification of that algorithm is also given there.

A high linking theorem for the existence of a third solution (MI = 2) is proved in [34] by constructing a "local link" at a mountain pass solution. Motivated by this idea, a numerical high linking method is proposed in [17] by Ding–Costa–Chen to solve the model problem for a sign-changing solution (MI = 2). The basic idea is to assume a mountain pass solution w_1 has been found, and by using an ascent direction and a descent direction at w_1, one can form a triangle as a "local linking." Then one can proceed to find a maximum on this triangle. If the maximum is inside the triangle, go to the next step; otherwise, deform the triangle so as to contain this point as an interior point, and continue to search for an interior maximum. This method uses constrained maximizations at the first level and a local minimization at the second level. Since in the original version of the high linking theorem, the argument never left a mountain pass solution, and a global minimization is required at the second level, the theorem itself cannot serve as a justification of that algorithm. Accordingly, the theoretical justification of that algorithm will be very difficult. The problem is that once an iterate has departed a mountain pass solution, the triangle is no longer a "local linking"; the triangle may degenerate. However, this is the first time in the literature that the idea of a "local linking" is used to find solutions basically with MI = 2.

Inspired by the above numerical works, we developed a new minimax method for finding multiple saddle points. Many numerical results including those presented in section 5 were obtained in the summer of 1997 and appeared to be very promising. Then we decided to try to establish some mathematical justification for the algorithm and to find out why and under what conditions the algorithm works. This may eventually help us improve the algorithm. This has been soon proved to be a much more challenging task. Since we try to set a general framework and at the same time always keep some model problems in mind, every time a new model problem is solved numerically, new interesting mathematical questions can be asked. We try to answer the question in a more general way.

For the purpose of mathematical justification, let us adopt another approach. In studying a dynamic system, Nehari [25] introduced the concept of a solution submanifold $\mathcal{M}$, and proved that a global minimizer of the energy functional on $\mathcal{M}$ is a solution to the dynamic system with MI = 1. Ding–Ni used Nehari's idea to study the model problem with the zero Dirichlet BC and $\ell = 0$. They defined a solution submanifold

$$\mathcal{M} = \left\{ v \in H_0^1(\Omega) | v \neq 0, \int_\Omega \left[|\nabla v|^2 - v f(v) \right] \, dx = 0 \right\}. \tag{1.7}$$

Under the condition that $f'(t) > \frac{f(t)}{t}, t \neq 0$, Ding–Ni [27] proved that a global minimizer of the energy function J on $\mathcal{M}$ is a solution with MI = 1 to the model problem.

Our basic idea to design an algorithm for finding multiple saddle points consists of three main elements.

(1) First define a solution (stable) submanifold $\mathcal{M}$ s.t. a local minimum point of $J(u)$ on $\mathcal{M}$ yields a critical point. Thus the problem becomes a minimization of J on the submanifold $\mathcal{M}$, and a saddle point becomes stable on the submanifold $\mathcal{M}$. If a monotone decreasing search is used in the minimization process, the algorithm will be stable. At a point on $\mathcal{M}$, we can apply, e.g., a steepest descent search to approximate a local minimizer of J on $\mathcal{M}$.

(2) There must be a *return rule.* As a steepest descent search usually leaves the submanifold $\mathcal{M}$, for the algorithm to continue to iterate we need to design a return rule for the search to return to $\mathcal{M}$.

(3) There must be a strategy to *avoid degeneracy.* Since we are searching for a saddle point at a higher critical level, at least, for a new solution, a simple minimization may cause degeneracy to an (old) saddle point at a lower critical level. Thus a strategy to avoid degeneracy is crucial to guarantee that the new critical point found is different from the old ones. This strategy may also be incorporated in the definition of the solution submanifold. It can be seen as follows.

(a) Choi–McKenna's algorithm has a return rule and a strategy to avoid a degeneracy to the zero with MI = 0. We will provide a mathematical justification for their algorithm in section 2; see Theorem 2.1 with $L = \{0\}$ or Theorem 4.2.

(b) Ding–Costa–Chen's algorithm has a return rule and a strategy to avoid a degeneracy to a solution with MI = 1. We will modify their algorithm and then provide a mathematical justification; see Theorem 2.1 with $L = \{w_1\}$.

The organization of this paper is as follows. In section 2, we first prove an important technical lemma. Then we establish a local minimax characterization of a saddle point, which can be used to design a numerical minimax algorithm for finding multiple saddle points. An existence theorem is also proved in this section. Section 3 presents our numerical minimax algorithm in detail and gives some convergence related properties. In section 4, we apply our minimax method to solve a class of semilinear elliptic equations and present some related analysis. Finally, in section 5, we exhibit some numerical examples for multiple solutions and their graphics to illustrate the algorithm and theory.

We do not intend to prove any new existence theorem. Our objective is to develop numerical algorithms and corresponding mathematical theory for finding multiple critical points. It is understood that many critical points cannot be approximated. Only those with "nice properties" can be numerically approximated. We try to classify those "nice" saddle points through mathematical analysis. It is reasonable that the hypotheses in our local minimax characterization of saddle points in this paper are stronger than those in the existence theorems. Our hypotheses will be gradually localized and generalized as research advances. Methods to check these hypotheses will also be developed in subsequent papers.

2. Local min-max theorems. Let H be a Hilbert space with inner product $\langle , \rangle$ and norm $\| \ \|$, and let J be a real C^1-generic energy functional on H. For any subspace $H' \subset H$, denote $S_{H'} = \{v | v \in H', \|v\| = 1\}$ the unit sphere in H'. Let L be a closed subspace in H, called a base subspace, and let $H = L \oplus L^{\perp}$ be the orthogonal decomposition, where $L^{\perp}$ is the orthogonal complement of L in H. For each $v \in S_{L^{\perp}}$ let $[L, v] = \{tv + w | w \in L,\ t \geq 0\}$ be the closed half subspace. L can be either finite or infinite dimensional.

DEFINITION 2.1. *A set-valued mapping $P: S_{L^{\perp}} \to 2^H$ is called the* peak mapping *of J with respect to $H = L \oplus L^{\perp}$ if for any $v \in S_{L^{\perp}}$, $P(v)$ is the set of all local maximum points of J in $[L, v]$. A single-valued mapping $p: S_{L^{\perp}} \to H$ is a* peak selection *of J with respect to L if*

$$p(v) \in P(v) \quad \forall v \in S_{L^{\perp}}.$$

For a given $v \in S_{L^{\perp}}$, we say that J has a local peak selection with respect to L at v if there is a neighborhood $\mathcal{N}(v)$ of v and a function $p: \mathcal{N}(v) \cap S_{L^{\perp}} \to H$ s.t.

$$p(u) \in P(u) \quad \forall u \in \mathcal{N}(v) \cap S_{L^{\perp}}.$$

In a special case when $L = \{0\}$, the peak mapping $P(v)$ is the set of all local maximum points of J along the direction v, for any point $v \in S$.

Most minimax theorems in critical point theory used a (constrained) global maximization (on a compact set) at the first level. Thus a solution at the first level always exists. For algorithm implementation, existence is not enough; we want an approximation scheme to a solution. Therefore, we use unconstrained local maximization at the first level. Numerically this is great. However, it then raises three major problems in analysis. (a) For some $v \in S_{L^{\perp}}$, $P(v)$ may contain multiple local maxima in $[L, v]$. In particular, P may contain multiple branches, even U-turn or bifurcation points. (b) p may not be defined at some points in $S_{L^{\perp}}$. (c) The limit of a sequence of local maximum points may not be a local maximum point. Thus the analysis involved becomes much more complicated. Although, it is well known that the energy function (1.5) of our model problem goes to negative infinity uniformly in any finitely dimensional subspace (see [30]). Thus, in any finite-dimensional subspace, there must be at least one maximum point, i.e., $P(v) \neq \emptyset$. That is, problem (b) will not happen. Problem (a) is not concerned in the numerical works of Choi–McKenna and Ding–Costa–Chen. However, for more general settings, all three problems have to be resolved. As for (a), we use a selection p to choose one branch from the others. Numerically it is done by following a certain negative gradient flow and developing some consistent strategies to avoid jumps between different branches. For (b), we need only p to exist locally around a point v along a negative gradient flow. We are currently working on a min-orthogonal algorithm where $p(v)$ need only be a local suborthogonal point. This will further resolve problem (b). When P contains some U-turn or bifurcation points, if a saddle point happens to be a U-turn or bifurcation point of P, a local minimax search at either one of the branches connecting to the point will follow the negative gradient flow to the saddle point. If a saddle point is not a U-turn or bifurcation point of P, when a local minimax search is at the same branch of P as the saddle point, according to our local characterization results, it is not a problem. In the case when a local minimax search is at a different branch of P connecting to the U-turn or bifurcation point, we will develop a technique to allow the search to pass through a U-turn or bifurcation point. We will address this technique in a future article. As for problem (c), more analysis is required. One of the reasons for problem (c) to take place is that under the definition of a peak selection $p(v)$, the solution submanifold $\mathcal{M} = \{p(v) : v \in S_{L^\perp}\}$ is not closed. In a future paper, we will define a more general local (orthogonal) selection $p(v)$ with which the new solution submanifold is closed and contains the current solution submanifold as a subset. Then we prove that a local minimum point of J on the new solution submanifold also yields a saddle point, and the implicit function theorem can be used to check if p is continuous (differentiable) at a given point v, a condition required by all the results we proved in this paper. This study leads to a completely different approach and will be addressed in a future paper.

The following technical lemma plays a crucial role in this paper. It describes the relation between the gradient of J and the variation of a peak selection.

LEMMA 2.1. *For $v_\delta \in S_{L^\perp}$, if there is a local peak selection p of J with respect to L at v_δ s.t.* (i) *p is continuous at v_δ,* (ii) *$d(p(v_\delta), L) > \alpha > 0$, and* (iii) *$\|\nabla J(p(v_\delta))\| > \delta > 0$, then there exists $\varepsilon > 0$ s.t.*

$$J(p(v(s))) - J(p(v_\delta)) < -\alpha\delta\|v(s) - v_\delta\| \quad \forall 0 < s < \varepsilon$$

and

$$v(s) = \frac{v_\delta + sw}{\|v_\delta + sw\|}, \quad w = -\frac{\nabla J(p(v_\delta))}{\|\nabla J(p(v_\delta))\|}.$$

Proof. Let $\mathcal{N}(v_\delta)$ be a neighborhood of v_δ for the local peak selection p. By (iii),

$$\langle \nabla J(p(v_\delta)), w\rangle < -\delta.$$

Since $p(v_\delta) \in [L, v_\delta]$, $p(v_\delta) = x_\delta + t_\delta v_\delta$, where $x_\delta \in L$ and $t_\delta \in \mathbb{R}$, we have $t_\delta > \alpha$. $p(v_\delta)$ is a local maximum point of $J(p(x))$ on $[L, v_\delta]$. So it is clear that $w \in L^\perp$ and $w \perp v_\delta$. Due to the continuity, there exist positive numbers ε_1, ε_2, t_1, and t_2 with $0 < t_1 < t_\delta < t_2$ and open balls $B_{\varepsilon_1,L} = \{x | x \in L,\ \|x - x_\delta\| < \varepsilon_1\}$ and $B_{\varepsilon_2,L^\perp} = \{x | x \in L^\perp,\ \|x - t_\delta v_\delta\| < \varepsilon_2\}$ s.t.

(a) $p(v_\delta)$ is a maximum point of J on $[t_1, t_2] \times v_\delta + B_{\varepsilon_1,L}$,

(b) $\langle \nabla J(x_1 + x_2), w\rangle < -\delta$ for all $x_1 \in B_{\varepsilon_1,L}, x_2 \in B_{\varepsilon_2,L^\perp}$,

(c) $tv_\delta + sw \in B_{\varepsilon_2,L^\perp}$ for any $t \in [t_1, t_2]$ and s, $0 < s < \frac{\varepsilon_2}{2}$.

For any $x_1 \in B_{\varepsilon_1,L}$, and $t \in [t_1, t_2]$, by the mean value theorem,

$$J(tv_\delta + x_1 + sw) - J(tv_\delta + x_1) = \langle \nabla J(tv_\delta + x_1 + \xi w), sw\rangle < -s\delta. \tag{2.1}$$

By (a), $J(tv_\delta + x_1) \le J(p(v_\delta))$, so we have $J(tv_\delta + x_1 + sw) - J(p(v_\delta)) < -s\delta$. Since $w \perp v_\delta$,

$$\lim_{s\to 0^+} \left\| \frac{1}{s}\left(\frac{t_\delta v_\delta + sw}{\|t_\delta v_\delta + sw\|} - v_\delta\right)\right\| = \frac{1}{t_\delta} < \frac{1}{\alpha}. \tag{2.2}$$

Thus, without loss of generality, we can assume that for $s > 0$ small

$$\left\| \frac{t_\delta v_\delta + sw}{\|t_\delta v_\delta + sw\|} - v_\delta \right\| < \frac{s}{\alpha}. \tag{2.3}$$

By our notation

$$v\left(\frac{s}{t_\delta}\right) = \frac{t_\delta v_\delta + sw}{\|t_\delta v_\delta + sw\|},$$

so we have, for sufficient small s,

$$\alpha \| v\left(\frac{s}{t_\delta}\right) - v_\delta \| < s. \tag{2.4}$$

Combine (2.1) and (2.4), and we can find $\varepsilon_3 > 0$ s.t.

$$J(tv_\delta + x_1 + sw) - J(p(v_\delta)) < -\alpha\delta \| v\left(\frac{s}{t_\delta}\right) - v_\delta \| \quad \forall t \in [t_1, t_2],\ x_1 \in B_{\varepsilon_1, L},\ 0 < s < \varepsilon_3.$$

Denote $D = \{tv_\delta + x_1 + sw | s < \varepsilon_3,\ t \in (t_1, t_2),\ x_1 \in B_{\varepsilon_1, L}\}$. Then D is an open neighborhood of $p(v_\delta) = t_\delta v_\delta + x_\delta$ in the subspace spanned by L, v_δ, and w. By the continuity of p at v_δ, there exists positive ε s.t. $v(\frac{s}{t_\delta}) \in S_{L^\perp} \cap \mathcal{N}(v_\delta)$ and $p(v(\frac{s}{t_\delta})) \in D$ for all $\frac{s}{t_\delta} < \varepsilon$. Besides, since $p(v(\frac{s}{t_\delta})) \in [L, v(\frac{s}{t_\delta})]$, $p(v(\frac{s}{t_\delta})) = ct_\delta v_\delta + x_1 + csw$ uniquely for some constant number c and $x_1 \in B_{\varepsilon_1, L}$ with $t_1 < ct_\delta < t_2$ and $cs < \varepsilon_3$. Thus

$$\begin{aligned} J\left(p\left(v\left(\frac{s}{t_\delta}\right)\right)\right) - J(p(v_\delta)) &= J(ct_\delta v_\delta + x_1 + csw) - J(p(v_\delta)) \\ &< -\alpha\delta \| v\left(\frac{cs}{ct_\delta}\right) - v_\delta \| = -\alpha\delta \| v\left(\frac{s}{t_\delta}\right) - v_\delta \|. \qquad \square \end{aligned}$$

The following theorem characterizes a saddle point as a local minimax solution and serves as a mathematical justification for our algorithm to be proposed.

THEOREM 2.1. *Let $v_0 \in S_{L^\perp}$. If J has a local peak selection p with respect to L at v_0 s.t.* (i) *p is continuous at v_0,* (ii) $d(p(v_0), L) > 0$, *and* (iii) *v_0 is a local minimum point of $J(p(v))$ on $S_{L^\perp}$, then $p(v_0)$ is a critical point of J.*

Proof. Suppose that $p(v_0)$ is not a critical point of J. By Lemma 2.1, for a sufficient small positive s, set

$$w = -\frac{\nabla J(p(v_0))}{\|\nabla J(p(v_0))\|}, \quad v(s) = \frac{v_\delta + sw}{\|v_\delta + sw\|}, \tag{2.5}$$

and we have

$$J(p(v(s))) - J(p(v_0)) \leq -\frac{1}{2} \|\nabla J(p(v_0))\| \|v(s) - v_0\| d(p(v_0), L) < 0,$$

which contradicts the fact that v_0 is a local minimum point of $J(p(v))$ on $S_{L^\perp}$. Thus $p(v_0)$ must be a critical point of J. $\square$

Remark 2.1. Condition (i) is required for a numerical algorithm to be stable and convergent. Condition (ii) is a separation condition posed by almost all minimax theorems to have a new critical point. Condition (iii) replaces a global minimization, used in most minimax theorems in the literature, by a local minimization. Due to the local nature of the above characterization and (2.5), it is clear that $S_{L^\perp}$ in condition (iii) can be localized to be any subset containing $v(s)$ for small $s \geq 0$.

To establish an existence result, the following Palais–Smale (PS) condition is used to replace the usual compactness condition.

Definition 2.2. *A function $J \in C^1(H)$ is said to satisfy the PS condition if any sequence $\{u_n\} \in H$ with $J(u_n)$ bounded and $J'(u_n) \to 0$ has a convergent subsequence.*

Theorem 2.2. *Let J be C^1 and satisfy the PS condition. If there is a peak selection p of J with respect to L s.t.* (i) *p is continuous,* (ii) *$d(p(v), L) \geq \alpha$ for some positive α, and for any $v \in S_{L^\perp}$,* (iii) $\inf_{v \in S_{L^\perp}} J(p(v)) > -\infty$, *then there exists $v_0 \in S_{L^\perp}$ s.t. $p(v_0)$ is a critical point of J, and*

$$J(p(v_0)) = \min_{v \in S_{L^\perp}} J(p(v)).$$

Proof. Since $S_{L^\perp}$ is a closed metrical subspace and $J(p(v))$ is a continuous function on $S_{L^\perp}$, bounded from below, by Ekeland's variational principle, for any integer n, there exists $v_n \in S_{L^\perp}$ s.t.

$$J(p(v_n)) \leq \inf_{v \in S_{L^\perp}} J(p(v)) + \frac{1}{n}, \tag{2.6}$$

and for any $v \in S_{L^\perp}, v \neq v_n$,

$$J(p(v)) - J(p(v_n)) \geq -\frac{1}{n}\|v - v_n\|.$$

From Lemma 2.1, for some v in $S_{L^\perp}$ and close to v_n,

$$J(p(v)) - J(p(v_n)) \leq -\frac{1}{2}\|v - v_n\| \|\nabla J(p(v_n))\| d(p(v_n), L).$$

Thus

$$\|\nabla J(p(v_n))\| \leq \frac{2}{n d(p(v_n), L)} < \frac{2}{n\alpha}. \tag{2.7}$$

By the PS condition, $\{p(v_n)\}$ has a subsequence, denoted again by $\{p(v_n)\}$, converging to some point $u_0 \in H$. Note that $p(v_n) = t_n v_n + x_n$ for some scalar $t_n > 0$, $v_n \in S_{L^\perp}$, and $x_n \in L$. It follows from $\|p(v_n) - p(v_m)\|^2 = \|t_n v_n - t_m v_m\|^2 + \|x_n - x_m\|^2$ that $\{t_n v_n\}$ is a Cauchy sequence as well. Since $\|v_n\| = 1$, $\|t_n v_n\| = t_n \to t_0$. By our assumption (ii), $t_0 \geq \alpha > 0$. Thus $v_n \to v_0 \in S_{L^\perp}$. By the continuity, we have $u_0 = p(v_0)$. Then by (2.7), $p(v_0)$ is a critical point of J, and, moreover, (2.6) leads to

$$J(p(v_0)) = \min_{v \in S_{L^\perp}} J(p(v)). \qquad \square$$

The following corollary is a special case of Theorem 2.2 with $L = \{0\}$, which can be viewed as a mathematical justification of the modified Choi–McKenna algorithm to find a solution with MI = 1.

Corollary 2.1. *Let $J \in C^1(H)$ and satisfy the PS condition. Let S be the unit sphere of H and $p(v)$ be a local maximum point of J on $\{tv | t \in (0, +\infty)\}$ for each $v \in S$ s.t.* (i) *p is continuous,* (ii) *$\|p(v)\| \geq \alpha$ for some $\alpha > 0$, and for any $v \in S$,* (iii) $\inf_{v \in S} J(p(v)) > -\infty$; *then there exists $v_0 \in S$ s.t. $p(v_0)$ is a critical point of J, and, moreover,*

$$J(p(v_0)) = \min_{v \in S} J(p(v)).$$

Proof. We can simply apply Theorem 2.2 with $L = \{0\}$ to draw the conclusion. □

Remark 2.2. To apply Ekeland's variational principle, a function must be bounded from below. In general, J is not bounded from below. However, $J(p(v))$ has a much better chance to be bounded from below. Therefore, we use condition (iii) in Theorem 2.2. This condition is satisfied automatically by our model problem; see section 4.

3. A minimax algorithm for finding critical points. If we define a solution submanifold by

$$\mathcal{M} = \{p(v) : v \in S_{L^\perp}\},$$

then by Theorem 2.1 a local minimum point $p(v_0)$ of J on $\mathcal{M}$ is a critical point of J. Numerically, a local minimum point can be approximated by the steepest descent search. When the steepest descent search leaves $\mathcal{M}$ to a point v, a local maximization on $[L, v]$ yields $p(v)$, a point returned to $\mathcal{M}$. Thus our algorithm can continue to iterate. Since $J'(p(v(s))) \perp L$, the search will not degenerate to L, which contains previously found solutions.

```
The Flow Chart of a Minimax Algorithm
Step 1. Let $n-1$ critical points $w_1, w_2, \ldots, w_{n-1}$ of $J$ be previously found
        and $w_{n-1}$ have the highest critical value. Set the base space
        $L = \text{span}\{w_1, w_2, \ldots, w_{n-1}\}$. Let $v^0 \in L^\perp$ be an ascent direction at $w_{n-1}$ and
        $\bar{\alpha}_k > 0$ be given;
Step 2. For $k = 0$, solve
            $w^k \equiv p(v^0) \equiv t_0^* v^0 + v_L^* = \arg \max_{u \in [L, v^0]} J(u);$
Step 3. Compute the steepest descent direction $d^k$ of $J$ at $w^k$;
Step 4. if $\|d^k\| \leq \varepsilon$, then output $w_n \equiv w^k$ and stop, else goto Step 5;
Step 5. For each $0 < \alpha \leq \bar{\alpha}_k$, denote $v^k(\alpha) = \frac{v^k - \alpha * d^k}{\|v^k - \alpha * d^k\|}$ and with the initial guess
        $u = t_0^* v^k(\alpha) + v_L^*$, solve
            $p(v^k(\alpha)) = \arg \max_{u \in [L, v^k(\alpha)]} J(u);$
        then solve
            $w^{k+1} \equiv p(v^{k+1}) \equiv t_0^* v^k(\alpha^*) + v_L^* = \arg \min_{0 < \alpha \leq \bar{\alpha}_k} J(p(v^k(\alpha)));$
Step 6. Update $k = k + 1$ and goto step 3.
```

Remark 3.1. Let us make some remarks on each step in the above algorithm.

In step 1, when we start from some known critical points, if the critical point w_0 with $\text{MI} = 0$ is not zero, we should add w_0 to the base space L. We first start from w_0 to find w_1 and so on. As for our model problem, $w_0 = 0$, so $L = \{0\}$, and according to the Morse theory, to find w_1, we may use any direction $v^0 \in H$ as an ascent direction of J at w_0.

Now assume $w_1, w_2, \ldots, w_{n-1}$ have been found this way and w_{n-1} is the one with the highest critical value. The base space L is spanned by $w_1, w_2, \ldots, w_{n-1}$. We start the algorithm with an ascent direction v^0 of J at w_{n-1}.

It is clear that the separation condition is quite reasonable to ensure that the critical point found is not in the base space L spanned by the old critical points and therefore will be a new one at a higher critical level.

The idea to choose a direction $v^0 \in L^\perp$ as an ascent direction is quite useful in practice. It makes the separation condition easier to satisfy. For example, in section 4, to choose an ascent direction, we always use a functional in $H_0^1(\Omega)$ whose peak is away from the peaks of the known critical points $w_1, w_2, \ldots, w_{n-1}$. This idea works very well.

In step 2, we have a simple unconstrained local maximization problem.

In step 3, to find the steepest descent direction d^k of J at a point w^k is usually equivalent to solving a linear system. As for the model problem, a direct calculation shows that the steepest descent direction d^k of J at w^k can be obtained by solving the linear elliptic BVP

$$(3.1) \qquad \begin{cases} \Delta d^k(x) - \ell d^k(x) = \Delta w^k(x) - \ell w^k(x) + f(x, w^k(x)), \quad x \in \Omega, \\ d^k(x) = 0, \quad x \in \partial\Omega \qquad\qquad \text{for the zero Dirichlet BC}, \\ \dfrac{\partial d^k(x)}{\partial n} = \dfrac{\partial w^k(x)}{\partial n}, \quad x \in \partial\Omega \qquad \text{for the zero Neumann BC}, \end{cases}$$

which can be solved numerically by various finite element, finite difference, or boundary element solvers. Since one important topic in nonlinear analysis is to study how a variation of the domain affects the profile of a solution [14] and the boundary element method can easily handle a complex domain or trace a variation of the domain, we use a boundary element method. Note that for the zero Neumann BC problem, if we choose an initial ascent direction v^0 with $\frac{\partial v^0}{\partial n}(x)|_{\partial\Omega} = 0$, then in every iterate we have $\frac{\partial d^k}{\partial n}(x)|_{\partial\Omega} = 0$ in (3.1).

In step 4, for our model problem, we can use a norm $\|\Delta d^k - l \cdot d^k\|_{L^2} < \varepsilon$ to control the error. Note that this is an absolute error indicator for our model problem, since

$$\Delta d^k(x) - l \cdot d^k(x) = \Delta w^k(x) - \ell w^k(x) + f(x, w^k(x)).$$

In step 5, for each point $v^k(\alpha) = v^k - \alpha \cdot d^k$ in the steepest descent direction, we can find a local maximum $p(v^k(\alpha))$ of J in $[L, v^k(\alpha)]$. We then try to find the point in the steepest descent direction with the smallest such maximum. We must follow a consistent way to find a local maximum point of J so that $p(v)$ depends on v continuously and is kept away from L. Thus we specify the initial guess $u = t_0^* v^k(\alpha) + v_L^*$ in searching for a local maximum in $[L, v^k(\alpha)]$. This initial guess closely and consistently traces the position of the previous point $w^k = t_0^* v^k + v_L^*$. This strategy is also to avoid the algorithm from possible oscillating between different branches of the peak mapping P.

The number $\bar{\alpha}$ is to enhance the stability of the algorithm. It controls the stepsize of the search along the steepest descent direction to avoid the search going too far, i.e., to leave the solution (stable) submanifold $\mathcal{M}$ too far to lose stability of the algorithm.

The following theorem implies that the local minimax algorithm is strictly descending and therefore a stable algorithm.

THEOREM 3.1. *If $d^k = \nabla J(w^k) \neq 0$, $w^k \notin L$, and p is continuous at v^k, then*

$$J(w^{k+1}) < J(w^k).$$

If p is continuous and $d(p(v), L) > \alpha > 0$ for all $v \in S_{L^\perp}$, then there exist $\bar{\alpha}_k > 0$ and $d > 0$ s.t.

$$J(w^{k+1}) - J(w^k) < -d\|\nabla J(w^k)\|\|v^{k+1} - v^k\| \quad \forall k = 1, 2, \ldots, \tag{3.2}$$

where $w^k = p(v^k)$ and $w^{k+1} = p(v^{k+1})$ are determined in step 5 of the algorithm.

Proof. We have only to prove (3.2). Using the notation in the algorithm scheme, write

$$v^{k+1} = v^k(\alpha_k^*) = \frac{v^k - \alpha_k^* d^k}{\|v^k - \alpha_k^* d^k\|}.$$

Take $\delta = \|d^k\|/2$; by Lemma 2.1, we can find $\bar{\alpha}_k > 0$, s.t. if $\bar{\alpha}_k > s > 0$, then

$$J(p(v^k(s))) - J(p(v^k)) < -\alpha\delta\|v^k(s) - v^k\|.$$

In particular, we choose such $\bar{\alpha}_k$ in the algorithm, and $0 < \alpha_k^* \leq \alpha_k$ is satisfied; with $d = 2\alpha$, we have

$$J(p(v^k(\alpha_k^*))) - J(p(v^k)) < -d\|d^k\|\|v^k(\alpha) - v^k\|,$$

i.e., (3.2). □

Convergence is always a paramount issue for any numerical algorithm. Due to multiplicity, degeneracy, and instability of saddle points, general convergence analysis will be very difficult. More profound analysis is required. We will establish some convergence results of the algorithm in a subsequent paper [20]. Instead, in section 4, we present some applications of our minimax theorem and method to a class of semilinear elliptic PDEs.

4. Application to semilinear elliptic PDEs.

In this section, we apply our local minimax method to study the model problem. We use the notations as in [30] with a slight change. Ω is a smooth bounded domain in $\mathbb{R}^n$. Consider a semilinear elliptic Dirichlet BVP

$$\begin{cases} \Delta u(x) + f(x, u(x)) &= 0, \qquad x \in \Omega, \\ u(x) &= 0, \qquad x \in \partial\Omega, \end{cases} \tag{4.1}$$

where the function $f(x, \xi)$ satisfies the following standard hypotheses.

(h1) $f(x, \xi)$ is locally Lipschitz on $\bar{\Omega} \times \mathbb{R}$.

(h2) There are positive constants a_1 and a_2 s.t.

$$|f(x, \xi)| \leq a_1 + a_2|\xi|^s, \tag{4.2}$$

where $0 \leq s < \frac{n+2}{n-2}$ for $n > 2$. If $n = 2$,

$$|f(x, \xi)| \leq a_1 \exp\phi(\xi), \tag{4.3}$$

where $\phi(\xi)\xi^{-2} \to 0$ as $|\xi| \to \infty$.

(h3) $f(x, \xi) = o(|\xi|)$ as $\xi \to 0$.

(h4) There are constants $\mu > 2$ and $r \geq 0$ s.t. for $|\xi| \geq r$,

$$0 < \mu F(x, \xi) \leq \xi f(x, \xi), \tag{4.4}$$

where $F(x, \xi) = \int_0^\xi f(x, t)dt$.

In our later numerical computation, we solve problems in $\mathbb{R}^2$, where (h2) is not a substantial restriction. (h4) says that f is superlinear, which implies that there exist positive numbers a_3 and a_4 s.t. for all $x \in \bar{\Omega}$ and $\xi \in \mathbb{R}$

$$F(x, \xi) \geq a_3|\xi|^\mu - a_4. \tag{4.5}$$

The variational functional associated to the Dirichlet problem (4.1) is

$$J(u) = \frac{1}{2}\int_\Omega |\nabla u(x)|^2 dx - \int_\Omega F(x, u(x))dx, \quad u \in H \equiv H_0^1(\Omega), \tag{4.6}$$

where we use an equivalent norm $\|u\| = \int_\Omega |\nabla u(x)|^2 dx$ for the Sobolev space $H = H_0^1(\Omega)$.

It is well known [30] that under conditions (h1)–(h4), J is C^1 and satisfies the PS condition. A critical point of J is a weak solution and also a classical solution of (4.1). 0 is a local minimum point (MI = 0) of J. Moreover, in any finitely dimensional subspace of H, J goes to negative infinity uniformly. Therefore, for any finite dimensional subspace L, the peak mapping P of J with respect to L is nonempty. We need one more hypothesis:

(h5) $\frac{f(x,\xi)}{|\xi|}$ is increasing with respect to ξ, or

(h5′) $f(x,\xi)$ is C^1 with respect to ξ and $f_\xi(x,\xi) - \frac{f(x,\xi)}{\xi} > 0$.

It is clear that (h5′) implies (h5). If $f(x,\xi)$ is C^1 in ξ, then (h5) and (h5′) are equivalent. All the power functions of the form $f(x,\xi) = |\xi|^k\xi$ with $k > 0$ satisfy (h1) through (h5′), and so do all the positive linear combinations of such functions. Under (h5) or (h5′), J has only one local maximum point in any direction, or, the peak mapping P of J with respect to $L = \{0\}$ has only one selection. In other words, $P = p$. The proof can be found in [27] and [14].

Lemma 4.1. *Under* (h5) *or* (h5′)*, for any* $u \in H$*, the function* $g(t) = J(tu)$*,* $t \geq 0$*, has a unique local and so a global maximum point.*

Let $L = \{0\}$ and $\mathcal{M} = \{p(v) | v \in S_{L^\perp} = S_H\}$, where $p(v)$ is the unique peak selection of J with respect to L. By the above lemma, it can be easily checked that $\mathcal{M}$ is exactly the solution submanifold (1.7) defined by Ding and Ni. Our definition displays the essence of why such a solution submanifold works. Our definition is also given in a more general way. It also works for finding a critical point as a local minimax solution with a higher MI. Actually, under (h5), the peak selection is not only unique but also continuous. In other words, $\mathcal{M}$ is a topological manifold. The following theorem is given in a more general form, which mainly states that uniqueness implies continuity.

Theorem 4.1. *Under the hypotheses* (h1)–(h5)*, if the peak mapping* P *of* J *with respect to a finitely dimensional subspace* L *is singleton at* $v_0 \in S_{L^\perp}$ *and for any* $v \in S_{L^\perp}$ *around* v_0*, a peak selection* $p(v)$ *is a global maximum point of* J *in* $[L, v]$*, then* p *is continuous at* v_0*.*

Proof. (h4) implies (4.5); namely, $F(x,\xi) \geq a_3|\xi|^\mu - a_4$, where a_3 and a_4 are positive constants depending on F and Ω. It is known that $\int_\Omega |u(x)|^\mu dx$ is a positive continuous functional in H and $S_H \cap [L, v_0]$ is compact; thus we can write

$$\alpha_0 \equiv \min_{v \in S_H \cap [L, v_0]} \int_\Omega |v(x)|^\mu dx > 0.$$

Let $\alpha = \frac{\alpha_0}{2}$. For each $v \in S_H \cap [L, v_0]$ there is a neighborhood $\mathcal{N}(v)$ of v s.t.

$$\int_\Omega |u(x)|^\mu dx > \alpha \quad \forall u \in \mathcal{N}(v).$$

Since

$$\Big(S_H \cap [L, v_0]\Big) \subset \bigcup_{v \in S_H \cap [L, v_0]} \mathcal{N}(v)$$

and $S_H \cap [L, v_0]$ is compact, there exist $v_1, \ldots, v_n \in S_H \cap [L, v_0]$ s.t.

$$\Big(S_H \cap [L, v_0]\Big) \subset \bigcup_{i=1}^{n} \mathcal{N}(v_i) \quad \text{and} \quad \int_\Omega |u(x)|^\mu dx > \alpha \quad \forall u \in \bigcup_{i=1}^{n} \mathcal{N}(v_i).$$

Note that for each $v \in S_{L^\perp}$ and $w \in S_H \cap [L, v]$, we can write $w = w_l + t_w v$ with $w_L \in L$ and $|t_w| \leq 1$. Then $w_0 = w_l + t_w v_0 \in S_H \cap [L, v_0]$ and $\|w - w_0\|^2 = t_w^2 \|v - v_0\|^2 \leq \|v - v_0\|^2$. Thus we can find a neighborhood D of v_0 s.t.

$$\Big(S_H \cap [L, v]\Big) \subset \bigcup_{i=1}^{n} \mathcal{N}(v_i) \quad \forall v \in D \cap S_{L^\perp}.$$

Therefore, we have

$$\int_\Omega |w|^\mu dx \geq \alpha \quad \forall v \in D \cap S_{L^\perp},\ w \in S_H \cap [L, v]. \tag{4.7}$$

For any $v \in D \cap S_{L^\perp}$, $p(v)$ is a maximum point of J in $[L, v]$. In particular, $p(v)$ is a maximum point of J on the half line $\{tp(v)|\, t \in \mathbb{R}^+\}$. Set $w = \frac{p(v)}{\|p(v)\|}$ and define

$$g(t) = J(tw) = \frac{1}{2} t^2 \int_\Omega |\nabla w(x)|^2 \, dx - \int_\Omega F(x, tw(x)) \, dx.$$

Then g is positive and increasing near 0 and goes to $-\infty$ as $t \to \infty$. A local maximum is solved from

$$0 = \frac{dg}{dt}|_{t=t_1} = t_1 \int_\Omega |\nabla w(x)|^2 \, dx, - \int_\Omega w(x) f(x, t_1 w(x)) \, dx$$

or

$$0 = \|p(v)\| \int_\Omega |\nabla w|^2 dx - \int_\Omega w f(x, \|p(v)\| w) dx. \tag{4.8}$$

Since $\|w\| = 1$, by using (4.4) and (4.7), we have

$$\begin{aligned} 1 &= \frac{1}{\|p(v)\|^2} \int_\Omega \|p(v)\| w f(x, \|p(v)\| w) dx \geq \frac{1}{\|p(v)\|^2} \int_\Omega \mu F(x, \|p(v)\| w) dx \\ &\geq \frac{1}{\|p(v)\|^2} \int_\Omega \mu (a_3 \|p(v)\|^\mu |w|^\mu - a_4) dx \\ &= a_3 \mu \|p(v)\|^{\mu - 2} \int_\Omega |w|^\mu dx - \frac{1}{\|p(v)\|^2} \int_\Omega \mu a_4 dx \\ &\geq \mu a_3 \|p(v)\|^{\mu - 2} \alpha - \frac{1}{\|p(v)\|^2} \int_\Omega \mu a_4 dx. \end{aligned}$$

Note that $\mu > 2$, the right-hand side of the last inequality goes to ∞ if $\|p(v)\| \to \infty$, and this violates the above inequalities. Therefore, there must exist $\beta > 0$ s.t. $\|p(v)\| \leq \beta$.

Now let $\{v_n\} \subset D \cap S_{L^\perp}$ be any sequence s.t. $v_n \to v_0$. Denote $p(v_n) = t_n v_n + x_n$, where $x_n \in L$. Since $\|p(v_n)\| \leq \beta$ and $v_n \perp x_n$, we have $t_n \leq \beta$ and $\|x_n\| \leq \beta$. Therefore, we can find a subsequence $\{v_{n_k}\}$ s.t. t_{n_k} and x_{n_k} converge, respectively, to t_0 and x_0. In other words, $p(v_{n_k})$ goes to $t_0 v_0 + x_0$, which lies in $[L, v_0]$. Since we assume that $p(v_{n_k})$ is a global maximum point of J in $[L, v_{n_k}]$ for each n_k, the limit point $t_0v_0 + x_0$ must be a maximum point of J in $[L, v_0]$ as well. But by the assumption, the peak mapping P of J is singleton at v_0, so $t_0v_0 + x_0 = p(v_0)$. Since $\{v_n\}$ is arbitrary, by the above argument, p is continuous at v_0. □

As an immediate conclusion of Theorem 4.1, we have the following continuous result (see [36, Lemma 4.1]).

COROLLARY 4.1. *Under the hypotheses* (h1)–(h5)*, the only peak selection p of J with respect to $L = \{0\}$ is continuous.*

Proof. By Lemma 4.1, there is only one peak selection p of J with respect to $L = \{0\}$. In any direction v, the function $g(t) = J(tu)$ possesses only one local maximum point and therefore a global maximum point of J over the subset $\{tv|t \in \mathbb{R}^+\}$. Thus from Theorem 4.1, it is continuous at any point. □

Moreover, the unique selection p of peak mapping with respect to $L = \{0\}$ satisfies all the requirements of Theorems 2.1 and 2.2. Thus we can apply Theorems 2.1 and 2.2 to establish the following existence result.

THEOREM 4.2. *Under the hypotheses of* (h1)–(h5)*, there exists at least one solution to*

$$\text{local} \min_{x \in \mathcal{M}} J(x), \tag{4.9}$$

and any such solution is a critical point of J and therefore a solution to problem (4.1)*.*

Proof. $\mathcal{M}$ is the image of the unique peak selection p of J with respect to $L = \{0\}$. By Corollary 4.1, p is continuous. Under the conditions of (h2)–(h4), we know that (see [30])

$$J(u) = \frac{1}{2}\|u\|^2 + o(\|u\|^2)$$

as $u \to 0$. Thus we can find $\delta > 0$ s.t.$\|p(v)\| > \delta$ for any direction $v \in H$. This is exactly the separation condition in Theorems 2.1 and 2.2. Obviously, $J(p(v)) > 0$ for each direction $v \in H$, and thus is bounded from below. Therefore, all the conditions in Theorems 2.1 and 2.2 are satisfied. Theorem 2.2 states that there is at least one critical point as a minimax solution, and Theorem 2.1 confirms that any local minimax solution is a critical point. □

By a similar argument as in the proof of the above theorem and taking Lemma 4.1 into account, we can show that for BVP (4.1), for any closed subspace L and any peak selection p of J with respect to L, we have $\inf_{v \in S_{L^\perp}} J(p(v)) > \delta > 0$.

It is known that for BVP (4.1), solution prefers open space. When the domain has multiple compartments connected by narrow corridors, such as a dumbbell-shaped domain in section 5 for our computational examples, multiple solutions do exist as local minimax solutions. The one with the smallest energy is the global minimax solution, i.e., the ground state.

The following results indicate that under conditions (h1)–(h5′), for $L = \{0\}$, the minimax algorithm is actually a minimization on a differentiable submanifold $\mathcal{M}$.

THEOREM 4.3. *Assume that conditions* (h1)–(h5′) *are satisfied and that there exist $a_5 > 0$ and $a_6 > 0$ s.t. for s as specified in* (h2)*,*

$$|f_\xi(x, \xi)| \le a_5 + a_6|\xi|^{s-1}. \tag{4.10}$$

Then the only peak selection p of J with respect to $L = \{0\}$ is C^1.

Proof. Set $G: S_H \times \mathbb{R}^+ \to \mathbb{R}$, $G(v,t) = t - \int_\Omega v(x)f(x,tv(x))dx$. Thus under (4.10), G is C^1. Denote $\mathcal{M} = \{p(v)|v \in S_H\}$, where $p(v)$ is the only peak selection of J with respect to $L = \{0\}$, i.e., $p(v)$ is the maximum point of J on $\{tv|t > 0\}$. As in the proof of Theorem 4.1, for any v, if $p(v) = tv$, then we have

$$0 = t - \int_\Omega v(x)f(x,tv(x))dx.$$

Thus $\mathcal{M}$ is essentially the inverse image of G at 0, i.e., $\mathcal{M} = G^{-1}(0)$, and $\|p(v)\|$, as a positive number, is the solution of $t(v)$ to the equation $G(v,t(v)) = 0$. On the other hand,

$$\frac{\partial G}{\partial t} = 1 - \int_\Omega v^2(x) f_\xi(x,tv(x))\,dx. \tag{4.11}$$

For each v_0, at each pair (v_0,t_0) with $G(v_0,t_0) = 0$,

$$0 = 1 - \int_\Omega v_0^2(x)\frac{f(x,t_0v_0(x))}{t_0v_0(x)}\,dx > 1 - \int_\Omega v_0^2 f_\xi(x,t_0v_0(x))\,dx \quad \text{(by (h5}'\text{))},$$

i.e., $\frac{\partial G}{\partial t} < 0$ at (v_0,t_0), provided $G(v_0,t_0) = 0$. By the implicit function theorem, the solution $t(v)$ to the equation $G(v,t(v)) = 0$ exists uniquely in a neighborhood of each v_0 and is C^1 in v. Therefore, $\|p(v)\|$ is a C^1 function in v, and so is $p(v)$. □

Actually, in the proof, we can see that the solution submanifold, $\mathcal{M}$, is a differentiable manifold because Lemma 2.1 implies

$$\|\nabla J|_{\mathcal{M}}\| \geq \delta\|\nabla J\| \quad \text{for some } \delta > 0.$$

Example 4.1. Let us consider the BVP on a smooth bounded domain $\Omega \subset \mathbb{R}^n$ for $p > 2$:

$$\begin{cases} \Delta u(x) + |u(x)|^{p-2}u(x) = 0, & x \in \Omega, \\ u(x) = 0, & x \in \partial\Omega. \end{cases} \tag{4.12}$$

The associated variational functional is

$$J(u) = \frac{1}{2}\int_\Omega |\nabla u|^2\,dx - \frac{1}{p}\int_\Omega |u(x)|^p\,dx, \quad u \in H = H_0^1(\Omega).$$

For each $v \in S$, let $u = tv, t > 0$; then

$$J(tv) = \frac{t^2}{2}\int_\Omega |\nabla v|^2\,dx - \frac{t^p}{p}\int_\Omega |v(x)|^p\,dx = \frac{t^2}{2} - \frac{t^p}{p}\int_\Omega |v(x)|^p\,dx.$$

Thus

$$0 = \frac{\partial}{\partial t}J(tv) = t - t^{p-1}\int_\Omega |v(x)|^p\,dx$$

leads to

$$t_v = \left[\frac{1}{\int_\Omega |v(x)|^p\,dx}\right]^{\frac{1}{p-2}} > 0.$$

The peak selection p of J with respect to $L = \{0\}$ is

$$p(v) = t_v v = \left[\frac{1}{\int_\Omega |v(x)|^p \, dx} \right]^{\frac{1}{p-2}} v \quad \forall v \in S,$$

a continuously differentiable function, and the solution manifold

$$\mathcal{M} = \left\{ \left[\frac{1}{\int_\Omega |v(x)|^p \, dx} \right]^{\frac{1}{p-2}} v : v \in S \right\}$$

is a differentiable manifold.

5. Computational examples. We have applied our numerical algorithm to solve many semilinear BVPs with zero Dirichlet BC on various domains, such as the Lane–Emden equation, the Henon equation, and the Chandrasekhar equation on a disk, a rectangle, a concentric annulus, a nonconcentric annulus, dumbbell-shaped domains, and dumbbell-shaped domains with cavities. Here we present the computational results for the Lane–Emden equation

$$\begin{cases} \Delta u(x) + u^3(x) = 0, & x \in \Omega, \\ u(x) = 0, & x \in \partial\Omega, \end{cases} \tag{5.1}$$

where the domain Ω is, respectively, a dumbbell-shaped domain, a dumbbell-shaped domain with cavities (nonsymmetric), and a concentric annulus (highly degenerate). Here the solution $u(x)$ represents the density, so we are interested only in positive solutions. In all examples, we use a *cos* function to create a "mound-shaped" function as an initial ascent direction v_0 and a norm $\|\Delta \hat{u}\|_{L^2} = \|\Delta u + u^3\|_{L^2} < \varepsilon$ to control the error and terminate the iterate. Some solutions with MI = 1 have been computed elsewhere; see, e.g., [12, 17, 11] and references therein. It is to the best of our knowledge that those solutions with higher MI are to be computed for the first time.

Case 1. We have a dumbbell-shaped domain, as shown in Figure 1.

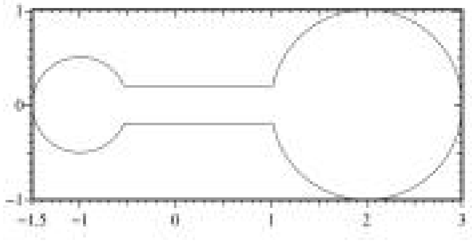

Fig. 1. *A dumbbell-shaped domain.*

We use, respectively, the following three "mound" functions as initial ascent directions.

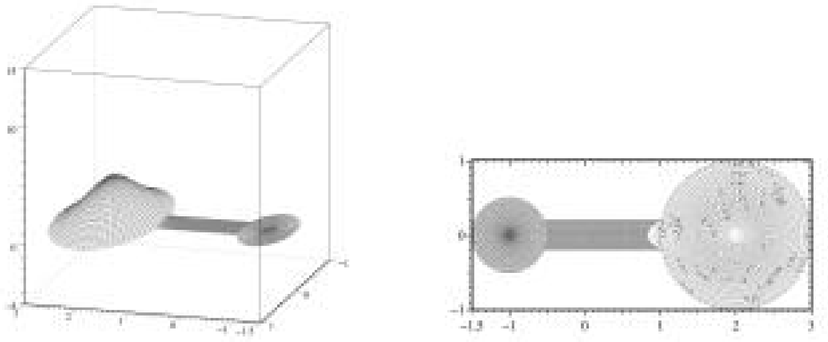

FIG. 2. *The ground state solution* w_1^1 *with MI* $= 1$ *and its contours.* $v_0 = v_0^1$, $\varepsilon = 10^{-4}, J = 10.90, u_{\max} = 3.652$.

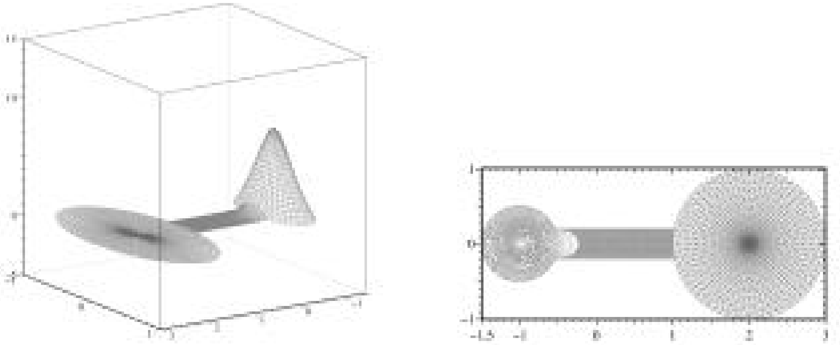

FIG. 3. *The second solution* w_1^2 *with MI* $= 1$ *and its contours.* $v_0 = v_0^2$, $\varepsilon = 10^{-4}$, $J = 42.22, u_{\max} = 7.037$.

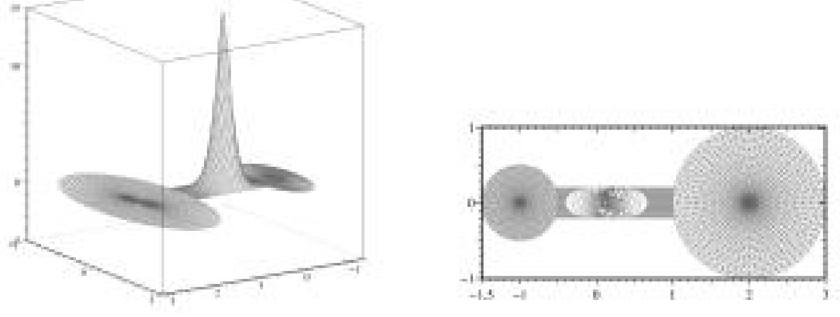

FIG. 4. *The third solution* w_1^3 *with MI* $= 1$ *and its contours.* $v_0 = v_0^3$, $\varepsilon = 10^{-4}$, $J = 159.0, u_{\max} = 13.63$. *So far, the existence of such a positive solution is still an open problem.*

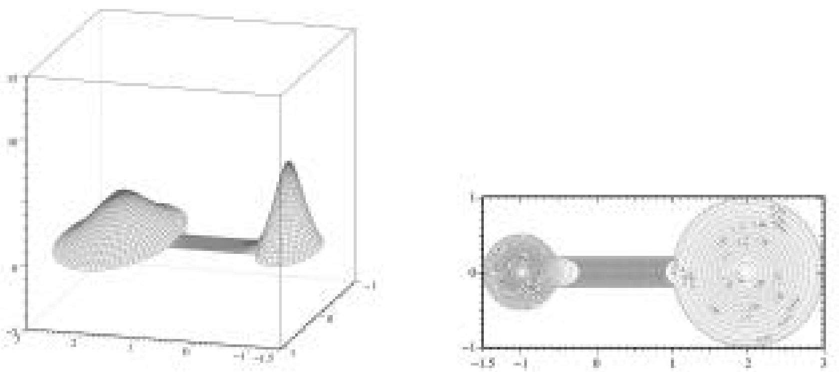

FIG. 5. *A solution w_2 with MI $= 2$ and its contours.* $L = [w_1^1], v_0 = v_0^2$, $\varepsilon = 10^{-4} \times 6, J = 53.12, u_{\max} = 7.037$.

$$v_0^i(x) = \begin{cases} \cos\left(\dfrac{|x - x_i|}{d_i}\dfrac{\pi}{2}\right) & \text{if } |x - x_i| \le d_i, \\ 0 & \text{otherwise,} \end{cases}$$

where $x_1 = (2, 0), d_1 = 1, x_2 = (-1, 0), d_2 = 0.5, x_3 = (0.25, 0)$, and $d_3 = 0.2$.

If we use $L = [w_1^1, w_2]$ and $v_0 = v_0^3$ to search for a solution with MI $= 3$, the algorithm yields a solution with positive and negative peaks. This can be explained as follows. A function with a larger energy value becomes less stable, and a solution with a larger MI is also less stable. Note that

$$J(w_1^1) < J(w_1^2) < J(w_1^3).$$

When we use $L = [w_1^1, w_2]$ and $v_0 = v_0^3$ to search for a solution with MI $= 3$, we start the process at searching for a peak with lower energy for a solution with a lower MI and then go to search for a peak with larger energy for a solution with a higher MI. The process becomes very unstable. Now if we switch the order, we start the process at searching for a peak with higher energy for a solution with a lower MI and then go to next stage to search for a peak with lower energy for a solution with a higher MI. The stability of the process is balanced. Thus we use $L = [w_1^3]$ and $v_0 = v_0^2$ to find a solution w_2^2 with MI $= 2$ and two positive peaks in the left compartment and the central corridor. Then we use $L = [w_1^3, w_2^2]$ and $v_0 = v_0^1$ to search for a positive solution with MI $= 3$, and we obtain the following solution as shown in Figure 6.

Case 2. We have a dumbbell-shaped domain with two cavities.

We use, respectively, the following four “mound” functions as initial ascent directions.

$$v_0^i(x) = \begin{cases} \cos\left(\dfrac{|x - x_i|}{d_i}\dfrac{\pi}{2}\right) & \text{if } |x - x_i| \le d_i, \\ 0 & \text{otherwise,} \end{cases}$$

with

$$x_1 = (2, -0.6), \quad d_1 = 0.4, x_2 = (-0.5, 0), \quad d_2 = 0.2,$$
$$x_3 = (0.25, 0), \quad d_3 = 0.2, \, x_4 = (-1.35, 0), \quad d_4 = 0.15.$$

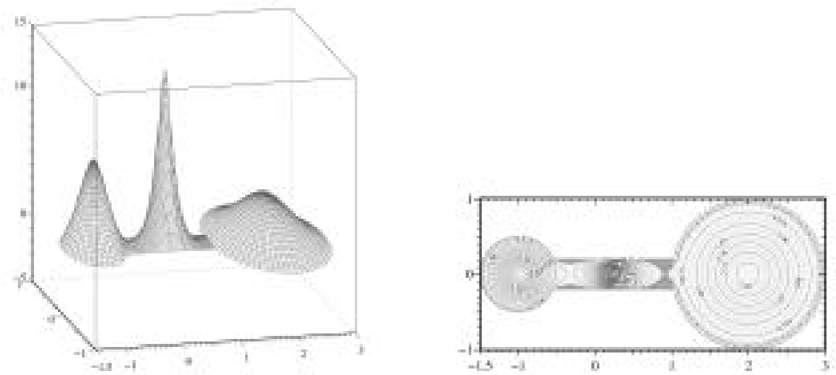

FIG. 6. *A solution w_3 with MI $= 3$ and its contours.* $\varepsilon = 10^{-3}, J = 212.5$*,* $u_{\max} = 13.78$*. This is the only positive solution with MI $= 3$ we can find.*

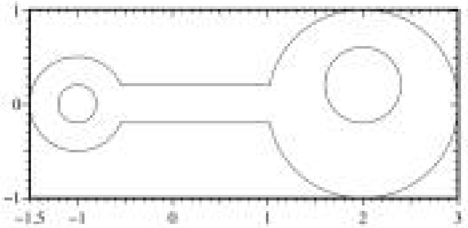

FIG. 7. *A dumbbell-shaped domain with two cavities.*

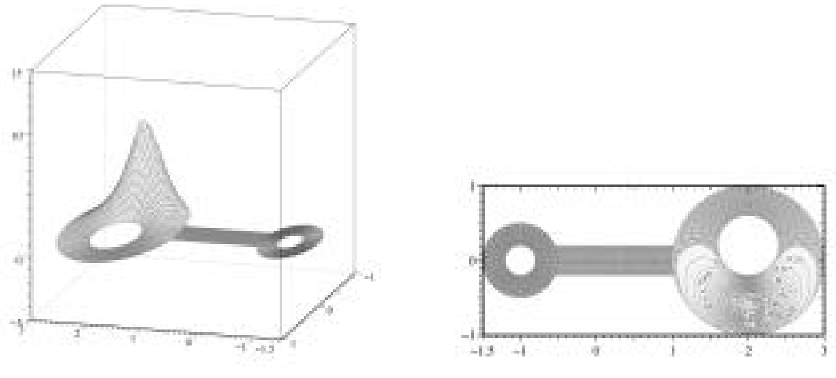

FIG. 8. *The ground state solution w_1^1 with MI $= 1$ and its contours.* $v_0 = v_0^1$*,* $\varepsilon = 10^{-4}, J = 44.18, u_{\max} = 6.664$*.*

Case 3. We have a concentric annulus with inner radius $= 0.7$ and outer radius $= 1$.

The domain is a nice geometric figure. However, due to the symmetry, any solution being rotated for any angle is still a solution. Thus each solution belongs to a one parameter family of solutions. For this case, the existence of nonradially symmetric positive solutions has been established by Coffman [13] and Li [22]. The number of positive peaks that a solution may have depends on the width of the annulus.

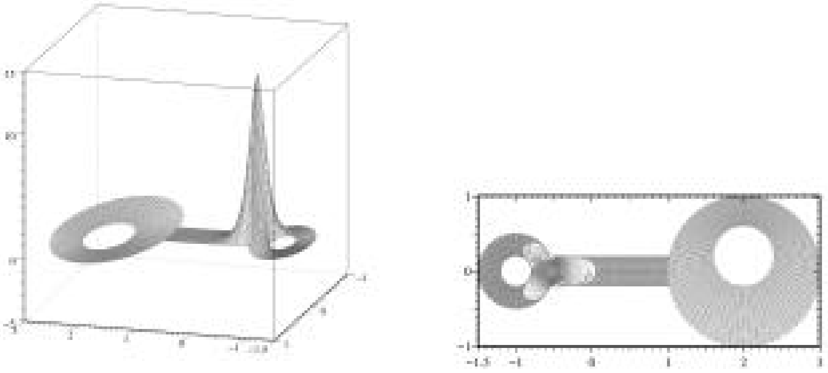

Fig. 9. *The second solution* w_1^2 *with MI* $= 1$ *and its contours.* $v_0 = v_0^3$, $\varepsilon = 10^{-4}, J = 153.5$, $u_{\max} = 12.94$.

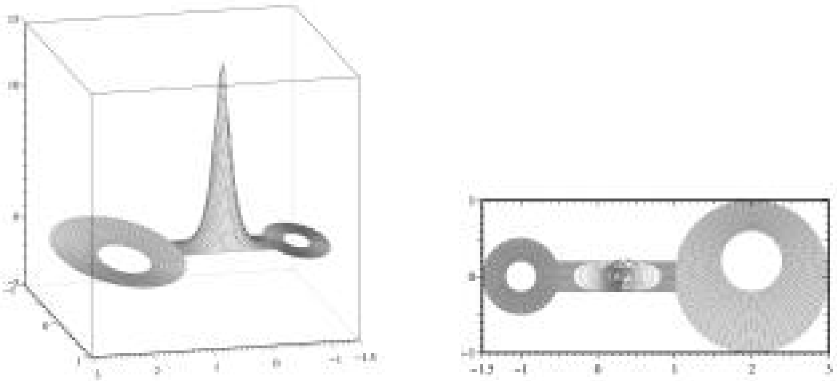

Fig. 10. *The third solution* w_1^3 *with MI* $= 1$ *and its contours.* $v_0 = v_0^2$, $\varepsilon = 10^{-4}, J = 165.6, u_{\max} = 13.64$. *Its profile is similar to* w_1^3 *in Figure* 4*. So far, the existence of such a positive solution is still an open problem.*

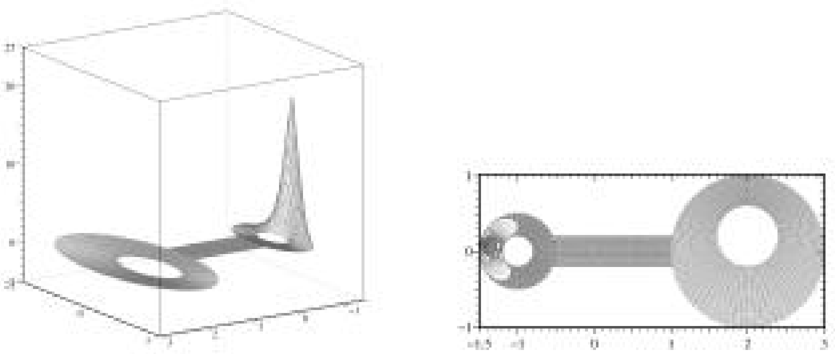

Fig. 11. *The fourth solution* w_1^4 *with MI* $= 1$ *and its contours.* $v_0 = v_0^4$, $\varepsilon = 10^{-4}, J = 286.1, u_{\max} = 17.85$.

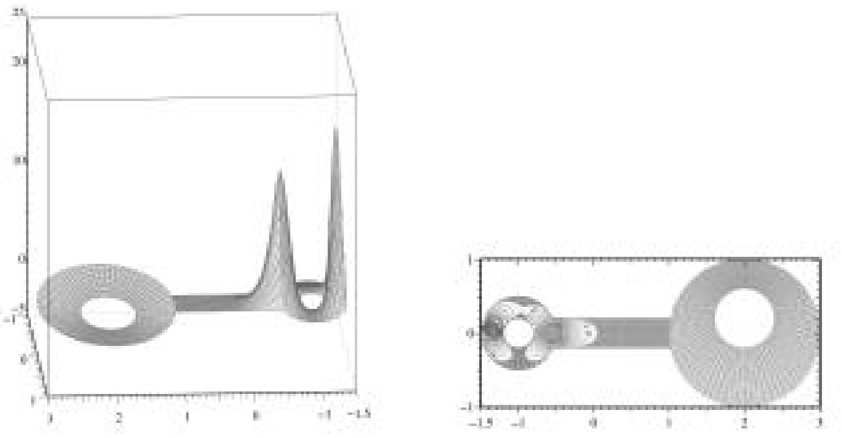

FIG. 12. *A solution* w_2 *with MI* $= 2$ *and its contours.* $L = [w_1^4], v_0 = v_0^2$*,* $\varepsilon = 10^{-4} \times 6, J = 439.5, u_{\max} = 17.85$*. There are other positive solutions with MI* $= 2$*.*

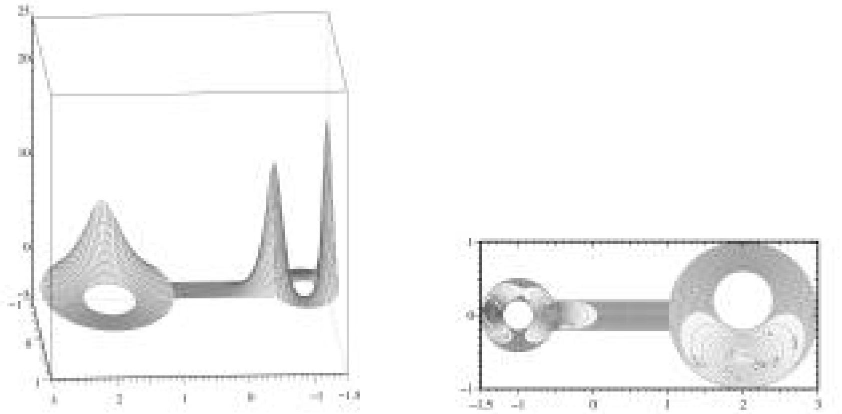

FIG. 13. *A solution* w_3 *with MI* $= 3$ *and its contours.* $L = [w_1^4, w_2], v_0 = v_0^1$*,* $\varepsilon = 10^{-3}, J = 483.6, u_{\max} = 17.86$*. There are other positive solutions with MI* $= 3$*.*

If we utilize the symmetry, we can find a radially symmetric solution that turns out to be a local (global) maximum. Otherwise, this case is highly degenerate. When the boundary is discretized into a polygon, theoretically the case becomes nondegenerate. However, when the discretization is fine, each solution has other solutions nearby. The computation becomes even tougher. After several iterations, there are multiple solutions inside a small neighborhood of the numerical solution. The algorithm may start to wander around. We have used 384 elements on the outer circle, 192 elements on the inner circle, and the following "mound" function as an initial ascent direction for $\theta_i = \frac{(i-1)\pi}{4}$,

$$v_0^i(x) = \begin{cases} \cos\left(\dfrac{|x - 0.85(\cos\theta_i, \sin\theta_i)|}{0.15}\dfrac{\pi}{2}\right) & \text{if } |x - 0.85(\cos\theta_i, \sin\theta_i)| \le 0.15, \\ 0 & \text{otherwise.} \end{cases}$$

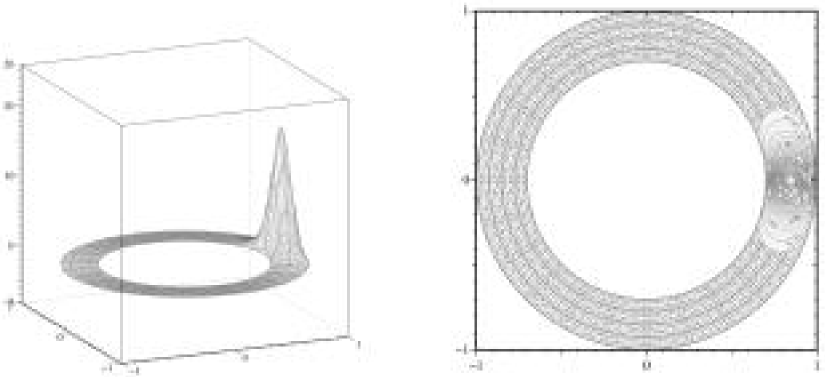

FIG. 14. *A ground state solution w_1 with MI = 1 and its contours.* $v_0 = v_0^1$*,* $\varepsilon = 10^{-4}, J = 289.1, u_{\max} = 18.12$*.*

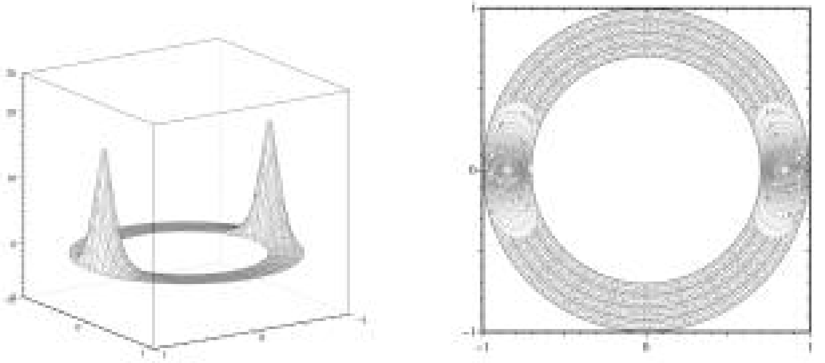

FIG. 15. *A solution w_2 with MI = 2 and its contours.* $L = [w_1], v_0 = v_0^3$*,* $\varepsilon = 10^{-4}, J = 579.0, u_{\max} = 18.12$*.*

Finding multiple saddle points is important for both theory and applications. However, it is very challenging. Little is known in the literature. We try to develop some numerical algorithms and corresponding mathematical theory for finding such saddle points in a stable way. It is known that many saddle points cannot be approximated. One can only numerically approximate those multiple saddle points with some "nice" properties, e.g., minimax solutions. We classify those saddle points through mathematical analysis. The results presented in this paper are under some "reasonably nice" conditions. They provide a mathematical foundation for our further research. Meanwhile, those conditions will be further generalized. Methods to check those conditions (e.g., the continuity or differentiability condition of p) will be developed as research as this direction progresses.[1] So far, the algorithm is still better than mathematical analysis. It produced many interesting numerical results that go beyond theoretical results. For example, when the profiles of the solutions in Figures 4 and 10 were presented to nonlinear PDE analysts in 1997 and 1998, they generated

[1] Results in this project have been obtained and will be presented in a future paper.

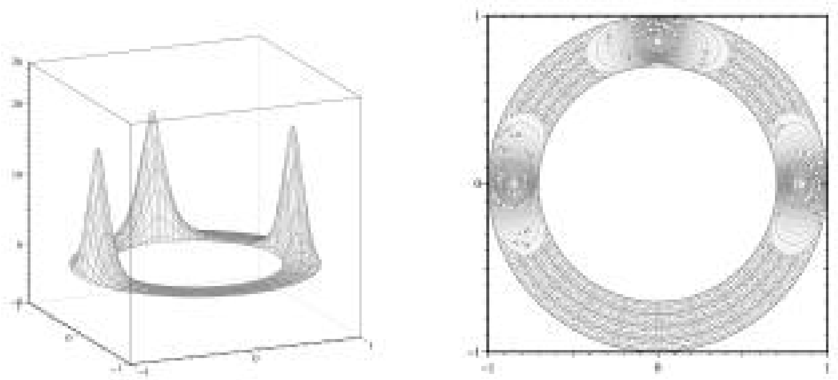

FIG. 16. *A solution w_3 with MI $= 3$ and its contours.* $L = [w_1, w_2], v_0 = v_0^2$*,* $\varepsilon = 10^{-4} \times 6, J = 868.8, u_{\max} = 18.12$.

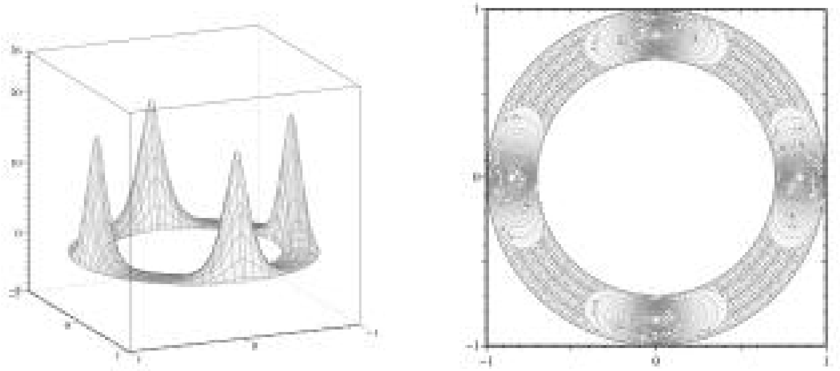

FIG. 17. *A solution w_4 with MI $= 4$ and its contours.* $L = [w_1, w_2, w_3]$*,* $v_0 = v_0^4$*,* $\varepsilon = 10^{-3} \times 3, J = 1159, u_{\max} = 18.12$.

warm debates about the existence and the MIs of such solutions. We are pleased to know that some results on the existence of such solutions have been recently proved (see [35]). Our algorithm can be used to solve for a critical point which is not a minimax solution, e.g., a Monkey saddle point. However, the analysis is beyond the scope of any minimax principle; a more profound approach is required. As mathematical analysis in this research progresses, the algorithm will be accordingly modified. Convergence is a paramount issue of any numerical algorithm. The MI of a solution is an important notion that provides understanding of the local structure of a saddle point and can be used to measure instability of a saddle point. Although, in the above numerical examples, we have printed the MI for each numerical solution, it is based on the way we compute the solution in the algorithm; its mathematical verification has not been established. Due to the length limitations of this paper, results on those issues will be addressed in a subsequent paper [20] and future papers [21, 37].

A LIE ALGEBRAIC APPROACH TO NUMERICAL INTEGRATION OF STOCHASTIC DIFFERENTIAL EQUATIONS[*]

TETSUYA MISAWA[†]

Abstract. In this article, "composition methods (or operator splitting methods)" for autonomous stochastic differential equations (SDEs) are formulated to produce numerical approximation schemes for the equations. In the proposed methods, the exponential map, which is given by the solution of an SDE, is approximated by composition of the stochastic flows derived from simpler and exactly integrable vector field operators having stochastic coefficients. The local and global errors of the numerical schemes derived from the stochastic composition methods are investigated. The new schemes are advantageous to preserve the special character of SDEs numerically and are useful for approximations of the solutions to stochastic nonlinear equations. To examine their superiority, several numerical simulations on the basis of the proposed schemes are carried out for SDEs which arise in mathematical finance and stochastic Hamiltonian dynamical systems.

Key words. stochastic differential equations, Lie algebra, composition methods (operator splitting method), mathematical finance, stochastic Hamiltonian dynamical systems, stochastic nonlinear system

1. Introduction. The theory of stochastic differential equations (SDEs) is understood as a fundamental tool for the description of random phenomena treated in physics, engineering, economics, and so on. Particularly, as the famous Black–Scholes option pricing model, the stochastic equations are used to describe the price process of underlying asset in mathematical finance. However, it is often difficult to obtain the solutions of SDEs explicitly, and hence there has been increasing interest in numerical analysis of SDEs. Indeed, many numerical schemes for SDEs have been proposed (e.g., [8], [15], [23]).

The purpose of the present article is to propose some new numerical schemes for autonomous SDEs on the basis of "composition methods." The reasons why we address this topic are as follows.

In numerical analysis for deterministic ordinary differential equations, whether or not some special character or structure of the equations is preserved precisely is an important point in performing reliable numerical calculations. From this point of view, various numerical methods to realize the characters of differential equations have been proposed. Indeed, we can find such examples as energy conservative methods [10], [13], symplectic integrators for Hamiltonian dynamical systems [24], [7], [26], and composition methods [19], [22]. In particular, the composition methods are useful to produce numerical schemes which leave some structure or character of general differential equations numerically invariant. Hence, it seems to be quite natural that we investigate the methods for SDEs to produce numerical schemes having the conservation properties; this is the first reason for setting up the numerical schemes proposed here.

Moreover, in the theory of differential equations, composition methods are known as operator splitting methods, and they are often utilized for approximation of nonlinear equations to which solutions are not obtained explicitly [25], [12]. From this viewpoint, we may expect that the methods bring us a convenient and powerful way of approximations for "stochastic nonlinear" differential equations, and this is the second reason for our investigation.

We will first outline the original composition methods for ordinary differential equations. Let X denote vector fields on some space with coordinates x with flows $\exp(tX)$; that is, the solutions of differential equations of the form $\dot{x}(t) = X(x)$ are given in the form $x(t) = \exp(tX)(x(0))$. Then, the vector field X is to be integrated numerically with fixed time step t. In this framework, we can apply composition methods to the differential equation if we can write $X = A + B$ in such a way that $\exp(tA)$ and $\exp(tB)$ can both be calculated *explicitly.* More generally, this can be relaxed by approximations of the exponential maps. In the most elementary case, the method gives the approximation for $x(t)$ through

$$\tilde{x}(t) = \exp(tA)\exp(tB)(x) = x(t) + O(t^2);$$

the last equality is obtained by using Baker–Campbell–Hausdorff (BCH) formula, which is well known in Lie algebraic theory.

Thus, in composition methods, we use the exponential representation of solutions to differential equations as an important tool. To formulate the methods for SDEs, therefore, one needs a stochastic version of the notion of exponential representation of solutions. In [16], this topic has been investigated in detail. Hence, in section 2, we first review Kunita's work on an explicit expression of solutions of SDEs as a functional of multiple Wiener integrals. We next give a formal extension of Kunita's explicit expression of solutions of SDEs, and on the basis of the formal result, we will propose new schemes for SDEs. Moreover, to estimate the error for the new schemes, we touch upon some lemmas and a proposition concerning mean-square order of multiple Wiener integrals.

In section 3, on the basis of the results in section 2, composition methods are formulated for autonomous SDEs with a one-dimensional Wiener process. Through these methods, we will obtain some numerical schemes for the stochastic equations. Then, the approximation error of numerical solutions derived from the schemes must be estimated. In this paper, we first apply the local error estimation in mean-square sense to the obtainable numerical solutions. The BCH formula will be useful for calculating the approximation error in a way analogous to that in the deterministic case. Using the result on local error estimation, we next address global error estimation for our new schemes. At the present stage, we obtain only local and global error orders through indirect estimation, and hence such orders will be said to be "in a weak sense."

In section 4, in order to examine the superiority of the new schemes, we investigate some illustrative examples of the numerical simulations using the proposed schemes. In the first example, the following nonlinear scalar SDE is treated, which is often adopted as a model of an asset price process in mathematical finance [9]:

$$dS(t) = S(t)dt + 2\sqrt{S(t)} \circ dW(t), \quad S(0) = s(> 0). \tag{1.1}$$

It is known that the value of the solution to this equation is "nonnegative" for any $t \in [0, T]$. Through the standard stochastic numerical schemes, however, such a character of this equation is not always preserved numerically. In contrast with this, we will see that our new numerical schemes by composition methods in section 3 leave the structure invariant numerically, and thereby the first advantage of composition methods is revealed. In the second and third examples, we examine the second advantage of composition methods as a tool of approximation for stochastic nonlinear systems. Particularly, such a superiority is often found in Hamiltonian dynamical systems through the dimensional splitting methods. Therefore, in the third example, we treat the composition methods for "stochastic" Hamiltonian systems. At the end of that section, to show the advantage of composition methods, we further touch upon a way to produce numerical schemes which realize the numerical preservation of conserved quantities for stochastic systems [20], [21].

Some concluding remarks and a discussion of future problems are given in section 5.

Finally, we note the recent remarkable work by K. Burrage and P.M. Burrage [4] as another numerical approach to SDEs through Lie algebra.

2. Representation of solutions of SDEs. In this section, we first review Kunita's work mentioned in section 1 [16]. Next we will give a formal extension of Kunita's explicit expression of solutions of SDEs. On the basis of this formal expression, our new schemes for SDEs are formulated in the next section. At the end of this section, as a preparation for the error estimation of the new schemes, we will discuss mean-square order of multiple Wiener integrals dealt with in the representation of solutions of SDEs.

2.1. Review of Kunita's explicit expression of solutions of SDEs. In order to explain Kunita's main result, we first address Campbell–Hausdorff formula for n vector fields. Let $Y_1, \dots, Y_n$ be n C^∞ vector fields on a connected C^∞-manifold M of dimension d. Suppose that $Y^{i_1 \cdots i_m} = [[\dots[Y_{i_1}, Y_{i_2}]\dots]Y_{i_m}], \quad m = 1, 2, \dots$, and their sums are all complete vector fields, where $[X, Y]$ is the Lie bracket defined by $XY - YX$. Moreover, we assume that the power series

$$Z = \sum_{m=1}^{\infty} \sum_{(i_1 \cdots i_m)} c_{i_1 \cdots i_m} Y^{i_1 \cdots i_m} \tag{2.1}$$

is absolutely convergent and defines a complete vector field. Here, for a given multi-index $I = (i_1, \dots, i_m)$, each coefficient $c_{i_1 \cdots i_m}$ is determined through (2.3) given below. Then (2.2) holds

$$\exp Y_n \cdots \exp Y_1 = \exp Z. \tag{2.2}$$

This is the Campbell–Hausdorff formula for n vector fields [16].

We will touch upon the explicit form of the coefficients $c_{i_1 \cdots i_m}$. Let us divide the multi-index $I = (i_1, \dots, i_m)$ into a sequence of shorter ones $I_j, j = 1, \dots, \ell$, and denote it by $\hat{I}$;

$$\hat{I} = (I_1, \dots, I_{k_1})(I_{k_1+1}, \dots, I_{k_2}) \cdots (I_{k_{\ell-1}+1}, \dots, I_{k_\ell}),$$

where each I_k consists of the same number $\hat{i}_k$ and the numbers $\hat{i}_k, k = 1, \dots, k_\ell$, satisfy

$$\hat{i}_1 > \hat{i}_2 > \cdots > \hat{i}_{k_1} < \hat{i}_{k_1+1} > \cdots > \hat{i}_{k_2} \cdots < \hat{i}_{k_{\ell-1}+1} > \cdots > \hat{i}_{k_\ell}.$$

We call $\hat{I}$ a natural division. Moreover, we denote the number of elements in I_k by n_k, where $\sum_{k=1}^{k_\ell} n_k = m$. Divide again each index I_k into j_k indices, each of which consists of $n_k^{(i)} (i = 1, \dots, j_k)$ elements (hence $\sum_{i=1}^{j_k} n_k^{(i)} = n_k$). Then according to [16], the coefficients $c_{i_1 \cdots i_m}$ are given by (2.3):

$$\begin{aligned} c_{i_1,\cdots i_m} &= \frac{1}{m} \sum_{s=0}^{\ell-1} \sum_{*} {}_{\ell-1}C_s (-1)^{j_1+\cdots+j_{k_\ell}-s-1} (j_1 + \cdots + j_{k_\ell} - s)^{-1} \\ &\quad \times \frac{1}{n_1^{(1)}! \cdots n_1^{(j_1)}! \cdots n_{k_\ell}^{(1)}! \cdots n_{k_\ell}^{(j_\ell)}!}, \end{aligned} \tag{2.3}$$

where the sum $\sum_*$ is taken for all subdivisions of $I_k (k = 1, \dots, k_\ell)$, that is, for positive integers $n_k^{(i)} (i = 1, \dots, j_k; k = 1, \dots, k_\ell)$ under $\sum_{i=1}^{j_k} n_k^{(i)} = n_k$.

Let I' be another multi-index of length m such that the natural division is given by $\hat{I}' = (I'_1, \dots, I'_{k'_1}) \cdots (I'_{k'_{\ell-1}+1}, \dots, I'_{k'_\ell})$. We say I and I' are equivalent if for each k, I_k and I'_k contain the same number of elements and $k'_j = k_j (j = 1, \dots, \ell)$ hold. Then we note that $c_I = c_{I'}$ holds.

Now, we proceed to our stochastic systems governed by SDEs. Let us consider an autonomous SDE of Stratonovich type (e.g., [11], [1]) under the probability space $(\Omega, \mathcal{F}, \mathcal{P})$:

$$dS(t) = b(S(t))dt + \sum_{j=1}^{r} g_j(S(t)) \circ dW^j(t) \tag{2.4}$$

defined on a connected C^∞-manifold M of dimension d, where $b = (b^i)_{i=1}^d$ and $g_j = (g_j^i)_{i=1}^d$ $(j = 1, \dots, r)$ are d-dimensional C^∞ functions on M, respectively, and $W(t) = (W^1(t), \dots, W^r(t))$ is a standard Wiener process. Here $S(t)$ is assumed to be adapted with a nondecreasing family of sigma-algebra $(\mathcal{F}_t)_{t \geq 0} \subset \mathcal{F}$. Note that (2.4) is rewritten in the form of SDE of Itô type as follows:

$$dS_t = \{b(S(t)) + \frac{1}{2} \sum_{k=1}^{r} \sum_{i=1}^{d} g_k^i \partial_i g_k(S(t))\}dt + \sum_{j=1}^{r} g_j(S(t)) dW^j(t), \tag{2.5}$$

where $\partial_i = \partial / \partial S^i$. Using the coefficient-functions in (2.4), we define C^∞ vector fields $X_0, X_1, \dots, X_r$ as follows:

$$X_0 = \sum_{i=1}^{d} b^i \partial_i, \quad X_j = \sum_{i=1}^{d} g_j^i \partial_i \quad (j = 1, \dots, r). \tag{2.6}$$

We will now review Kunita's result (Lemma 2.1 in [16]). For this purpose, we begin with notations on multi-index. Let us divide a multi-index $I = (i_1, \dots, i_m)$ $(i_1, \dots, i_m \in 0, 1, \dots, r)$ into shorter ones $I_1 \cdots I_q (q \leq m)$, where each I_k consists of the same element $\hat{i}_j$. For given positive integers $k_1 < k_2 < \cdots < k_\ell = q$, we define a division of I as

$$\Delta I = (I_1, \dots, I_{k_1})(I_{k_1+1}, \dots, I_{k_2}) \cdots (I_{k_{\ell-1}+1}, \dots, I_{k_\ell}). \tag{2.7}$$

We call ΔI single or double when each I_k contains a single element or at most two. Here we remark that ΔI may not be equal to a natural division of I; but if there is an index $\tilde{I}$ such that its natural division is equivalent to ΔI, we set $c_{\Delta I} = c_{\tilde{I}}$ in (2.3) for convention.

Now suppose that we are given an index I and a divided index ΔI. Moreover, we set $W^0(t) = t$. For a single divided index ΔI, we define the multiple Wiener–Stratonovich integral $W^{\Delta I}(t)$ as

$$W^{\Delta I}(t) = \int \cdots \int_A \circ dW^{i_1}(t_1) \cdots \circ dW^{i_m}(t_m), \tag{2.8}$$

where $A = \{t_{k_1} < \cdots < t_1 < t, \dots, t_{k_\ell} < \cdots < t_{k_{\ell-1}+1} < t, t_{k_i} < t_{k_i+1}\,(i = 1, \dots, \ell)\}$. On the other hand, if ΔI is a double index, we define

$$W^{\Delta I}(t) = \int \cdots \int_A \circ dW^{I_1}(t_1) \cdots \circ dW^{I_{k_\ell}}(t_\ell), \tag{2.9}$$

where

$$\begin{aligned} W^{I_k}(t) &= W^{i_k}(t) \quad (I_k : \text{single}; \quad I_k = \{i_k\}) \\ &= t \quad (I_k : \text{double}; \quad I_k = \{i_k, i_k\} \quad \text{and} \quad i_k \neq 0) \\ &= 0 \quad (I_k = \{0, 0\}). \end{aligned} \tag{2.10}$$

Under the notations defined above, Kunita proved the following lemma.

Kunita's lemma. Suppose that the Lie algebra $L = L(X_0, \dots, X_r)$ generated by $X_0, \dots, X_r$ is nilpotent of step p. Then the solution $S(t)$ of (2.4) with $S(0) = s$ is represented as

$$S(t) = \exp(Y_t)(s), \tag{2.11}$$

where $Y_t(\omega)$ is the vector field for each t and almost surely (a.s.) $\omega \in \Omega$ given by

$$Y_t = \sum_{i=0}^{r} W^i(t) X_i + \sum_{J;2 \le |J| \le p} \left\{ {\sum_{\Delta J}}^{*} c_{\Delta J} W^{\Delta J}(t) \right\} X^J, \tag{2.12}$$

and $X^J = [[\cdots[X_{j_1}, X_{j_2}]\cdots]X_{j_m}] \quad (J = (j_1, \dots, j_m))$. Here, $\sum_{\Delta J}^{*}$ is the sum for all single and double divided indices of J, and $c_{\Delta J}$ are the coefficients determined through (2.3) for the divided indices of J. Moreover, $|J|$ denotes the length of a multi-index J.

We remark that (2.11) with (2.12) means that the solution $S(t, \omega)$ equals $\phi(1, s, \omega)$ a.s., where $\phi(\tau, s, \omega)$ is the solution of the *ordinary* differential equation

$$\frac{d\phi(\tau)}{d\tau} = Y_t(\omega)(\phi(\tau)), \quad \phi(0) = s, \tag{2.13}$$

regarding t and ω as parameters.

The proof of Kunita's lemma is outlined as follows. For a fixed positive integer n and positive time t, we define $\delta W_k^i = W^i(\frac{k}{n}t) - W^i(\frac{(k-1)}{n}t) \quad (i = 1, \dots, r)$ and define $Z_j = \frac{t}{n} X_0 + \sum_{i=1}^{r} \delta W_j^i(t) X_i \quad (j = 1, \dots, n)$. We further set

$$S^n(t) = (\exp Z_n \cdots \exp Z_1)(s). \tag{2.14}$$

Then, there is a subsequence of $S^n(t)$ converging to $S(t)$ a.s.. On the other hand, applying the Campbell–Hausdorff formula to the right-hand side of (2.14), we obtain

$$\sum_J \left\{ \sum_{\Delta J} c_{\Delta J} \sum_{I:\hat{I} \sim \Delta J} \delta W_{i_1}^{j_1} \cdots \delta W_{i_m}^{j_m} \right\} X^J,$$

where $\sum_{I:\hat{I}\sim\Delta J} \delta W_{i_1}^{j_1} \cdots \delta W_{i_m}^{j_m}$ means the sum for all indices I such that the natural division $\hat{I}$ is equivalent to ΔJ. Then the sum converges to $W^{\Delta J}(t)$ if ΔJ is a single or double index, and it converges to 0 if ΔJ is more than double. Note that the last assertion corresponds to the following result from formal calculus with respect to stochastic differentials dt and $dW^i \quad (i = 1, \ldots, r)$ [11]; $dW^i dW^j = \delta_{ij} dt$, $dtdW^i = 0$, $dtdt = 0$, and $dW^i dW^j dW^k = 0$. Finally, we can also prove that the sum converges to the right-hand side of (2.11) with (2.12) a.s..

Remark 2.1. According to Lemma 2.2 in Kunita's paper [16], we can calculate the coefficients of X^J in the case of $|J| = 2, 3$. On account of these results, the vector field (2.12) is rewritten as

$$
\begin{aligned}
(2.15)\quad Y_t = &\sum_{i=0}^{r} W^i(t) X_i + \frac{1}{2}\sum_{i<j}^{r} [W^i, W^j](t)[X_i, X_j] \\
&+\frac{1}{36}\sum_{i=0}^{r}\sum_{j=1}^{r} tW^i(t)[[X_i, X_j], X_j] \\
&+\frac{1}{18}\sum_{i<j,k}^{r} [[W^i, W^j], W^k](t)[[X_i, X_j], X_k] \\
&+\sum_{J;4\le|J|\le p}\left\{\sum_{\Delta J}{}^{*} c_{\Delta J} W^{\Delta J}(t)\right\} X^J \ (i = 0, 1, \ldots, r; j, k = 1, \ldots, r).
\end{aligned}
$$

In (2.15), we define $[W^i, W^j](t)$ and $[[W^i, W^j], W^k](t)$ as multiple Wiener–Stratonovich integrals of degrees equal to 2 and 3 given by

$$[W^i, W^j](t) = \int_0^t W^i(\tau) \circ dW^j(\tau) - \int_0^t W^j(\tau) \circ dW^i(\tau)$$

and

$$[[W^i, W^j], W^k](t) = \int_0^t [W^i, W^j](\tau) \circ dW^k(\tau) - \int_0^t W^k(\tau) \circ d[W^i, W^j](\tau),$$

respectively.

Note that the condition that Lie algebra L is nilpotent of step p is required only in order to make the sum in (2.12) finite. This suggests that if L is general, we may *formally* represent the solution $S(t)$ of (2.4) as

$$(2.16) \qquad S(t) = (\exp Y_t)(s),$$

where

$$(2.17) \qquad Y_t = \sum_{i=0}^{r} W^i(t) X_i + \sum_{J;2\le|J|}\left\{\sum_{\Delta J}{}^{*} c_{\Delta J} W^{\Delta J}(t)\right\} X^J,$$

and this is just the formal expression we want. In what follows, we suppose that one may obtain the explicit representation of solution (2.16) with (2.17).

Remark 2.2. If the Lie algebra generated by $X_0, X_1, \ldots, X_r$ is of finite dimension, Ben Arous has proved that the stochastic infinite series in (2.17) actually converges before a stopping time. Therefore, in such a case, the representation of solution (2.16) with (2.17) is well-defined (Theorem 20 in [2]). We will see such examples in subsections 4.1 and 4.2 of section 4.

Moreover, we restrict ourselves to the SDEs (2.4) with a one-dimensional Wiener process; that is, we consider

$$dS(t) = b(S(t))dt + g(S(t)) \circ dW(t), \tag{2.18}$$

where b and g are d-dimensional vector-valued C^∞ functions. Then, we may rewrite (2.17) in a simpler form in terms of Kloeden–Platen's representation for multiple Wiener–Stratonovich integrals and multiple Wiener–Itô ones [14]; they are defined by

$$J_{(\alpha)}(t,s) = \int_s^{s+t}\int_s^{\tau_k}\cdots\int_s^{\tau_2} \circ dY^{(j_1)}(\tau_1)\cdots \circ dY^{(j_{k-1})}(\tau_{k-1}) \circ dY^{(j_k)}(\tau_k), \tag{2.19}$$

$$I_{(\alpha)}(t,s) = \int_s^{s+t}\int_s^{\tau_k}\cdots\int_s^{\tau_2} dY^{(j_1)}(\tau_1)\cdots dY^{(j_{k-1})}(\tau_{k-1}) dY^{(j_k)}(\tau_k), \tag{2.20}$$

respectively, where $\alpha = (j_1, \dots, j_k)$ $(j_i = 0, 1; i = 1, \dots, k)$ and

$$dY^{(j)}(u) = \begin{cases} du & \text{for } j = 0, \\ dW(u) & \text{for } j = 1. \end{cases}$$

In what follows, we denote $J_{(\alpha)}(t,s)$ and $I_{(\alpha)}(t,s)$ by $J_{(\alpha)}(t)$ and $I_{(\alpha)}(t)$, respectively, if $s = 0$.

Remark 2.3. Note that $J_{(\alpha)}(t,s)$ can be rewritten in terms of $I_{(\alpha)}(t,s)$ (see pp. 174–175 in [15]). For example, we have

$$J_{(j_1)} = I_{(j_1)} \quad (j_1 = 0, 1), \tag{2.21}$$

$$J_{(j_1,j_2)} = I_{(j_1,j_2)} + \frac{1}{2}1_{\{j_1=j_2=1\}}I_{(0)} \quad (j_1, j_2 = 0, 1), \tag{2.22}$$

$$J_{(j_1,j_2,j_3)} = I_{(j_1,j_2,j_3)} + \frac{1}{2}(1_{\{j_1=j_2=1\}}I_{(0,j_3)} + 1_{\{j_2=j_3=1\}}I_{(j_1,0)}) \quad (j_1, j_2, j_3 = 0, 1), \tag{2.23}$$

where $1_{\{\cdot\}}$ denotes the defining function. In general, any multiple Stratonovich integral $J_{(\alpha)}$ can be written as a multiple Itô integral $I_{(\alpha)}$ or a finite sum of $I_{(\alpha)}$ and multiple Itô integrals $I_{(\beta)}$ satisfying

$$\ell(\alpha) + n(\alpha) \le \ell(\beta) + n(\beta), \tag{2.24}$$

where $\ell(\alpha)$ ={the number of elements of α} and $n(\alpha)$ ={the number of 0's in the elements of α} (Remark 5.2.8 in [15]).

In terms of (2.19) and stochastic Stratonovich integration by parts formula for $W^i(t)$ $(i = 0, 1)$ and $[W^0, W^1](t)$, we can rewrite (2.17) in the following form:

$$\begin{aligned} Y_t = {} & J_{(0)}(t)X_0 + J_{(1)}(t)X_1 + \frac{1}{2}(J_{(0,1)}(t) - J_{(1,0)}(t))[X_0, X_1] \\ & + \frac{1}{18}\{2J_{(0,1,0)}(t) - 2J_{(1,0,0)}(t) + J_{(0)}(t)J_{(1,0)}(t) - J_{(0)}(t)J_{(0,1)}(t)\}[[X_0, X_1], X_0] \\ & + \frac{1}{18}\{2J_{(0,1,1)}(t) - 2J_{(1,0,1)}(t) + J_{(1)}(t)J_{(1,0)}(t) - J_{(1)}(t)J_{(0,1)}(t)\}[[X_0, X_1], X_1] \\ & + \frac{1}{36}\{J_{(0)}(t)\}^2[[X_0, X_1], X_1] + \sum_{J;4\le|J|} K^J(t)X^J. \end{aligned} \tag{2.25}$$

Here, in the last term on the right-hand side of the above equation, $K^J(t) = \{\sum_{\Delta J}{}^{*} c_{\Delta J} W^{\Delta J}(t)\}$, and $J = (j_1, \dots, j_\ell)$ $(j_i = 0, 1; i = 1, \dots, \ell;\ \ell \geq 4)$. In terms of Remark 2.3, this can be described by multiple Wiener–Itô integrals as follows:

$$\begin{aligned}
(2.26)\qquad Y_t &= I_{(0)}(t)X_0 + I_{(1)}(t)X_1 + \frac{1}{2}(I_{(0,1)}(t) - I_{(1,0)}(t))[X_0, X_1] \\
&+\frac{1}{18}\{2I_{(0,1,0)}(t) - 2I_{(1,0,0)}(t) + I_{(0)}(t)I_{(1,0)}(t) - I_{(0)}(t)I_{(0,1)}(t)\}[[X_0, X_1], X_0] \\
&+\frac{1}{18}\{2I_{(0,1,1)}(t) - 2I_{(1,0,1)}(t) + I_{(1)}(t)I_{(1,0)}(t) - I_{(1)}(t)I_{(0,1)}(t)\}[[X_0, X_1], X_1] \\
&+\frac{1}{36}\{I_{(0,0)}(t) + \{I_{(0)}(t)\}^2\}[[X_0, X_1], X_1] + \sum_{J;4\leq|J|} H^J(t)X^J,
\end{aligned}$$

where $H^J(t)$ is another version of $K^J(t)$ under each multi-index J, which is derived by transforming multiple Stratonovich integrals in $K^J(t)$ into Itô ones through Remark 2.3. Therefore, for each multi-index J, $H^J(t)$ is described as a polynomial function of multiple Itô integrals. In the next section, we will formulate the numerical schemes for the solution of SDE (2.18) on the basis of (2.16) with (2.26).

2.2. Mean-square order of multiple Wiener integrals. Now, in the remainder of this section, as a preparation for the error estimation for the new schemes in the next section, we will prove a proposition concerning the coefficients $H^J(t)$ of X^J for multiple indices J in (2.26). For this purpose, we first touch upon a lemma for multiple Itô integrals (2.20) proved by Kloeden and Platen (Lemma 5.7.5 in [15]). Let $E[\cdot|\mathcal{F}_s]$ be the conditional expectation with respect to a nondecreasing family of σ-subalgebra $\mathcal{F}_s$.

LEMMA 2.1. *For any* $\alpha = (j_1, \dots, j_k)$, $(j_i = 0, 1;\ i = 1, \dots, k)$, *and* $q = 1, 2, \dots,$

$$(2.27)\qquad E[|I_{(\alpha)}(\Delta t, s)|^{2q}|\mathcal{F}_s] = O((\Delta t)^{q(\ell(\alpha)+n(\alpha))}) \quad (\Delta t \downarrow 0),$$

where $\ell(\alpha)$ *and* $n(\alpha)$ *are the indices defined in Remark* 2.3*; that is,* $\ell(\alpha) =\{$*the number of elements of* $\alpha\}$ *and* $n(\alpha) = \{$*the number of* 0*'s in the elements of* $\alpha\}$.

Let $F(t, s)$ be a function of multiple stochastic integrals $I_{(\alpha)}(t, s)$. Suppose that

$$(2.28)\qquad E[\{F(\Delta t, s)\}^2|\mathcal{F}_s] = O((\Delta t)^m) \quad (\Delta t \downarrow 0)$$

holds. Then, in what follows, we call the real number m "*mean-square order (MSO)*" of $F(t, s)$.

From Lemma 2.1 we see that MSO of a multiple Itô integral $I_{(\alpha)}(t, s)$ is equal to $\ell(\alpha) + n(\alpha)$. Moreover, the following lemma shows that MSO of $I_{(\alpha)}(t, s)I_{(\beta)}(t, s)$ is given by $\ell(\alpha) + n(\alpha) + \ell(\beta) + n(\beta)$; that is, MSO of a product of multiple Itô integrals equals the sum of MSO of each of the stochastic integrals.

LEMMA 2.2. *For any multi-indices* α *and* β,

$$(2.29)\quad E[|I_{(\alpha)}(\Delta t, s)I_{(\beta)}(\Delta t, s)|^2|\mathcal{F}_s] = O((\Delta t)^{(\ell(\alpha)+n(\alpha)+\ell(\beta)+n(\beta))}) \quad (\Delta t \downarrow 0)$$

holds.

Proof. Through the Schwartz inequality, we obtain

$$E[|I_{(\alpha)}(\Delta t, s)I_{(\beta)}(\Delta t, s)|^2|\mathcal{F}_s] \leq \sqrt{E[\{I_{(\alpha)}(\Delta t, s)\}^4|\mathcal{F}_s]E[\{I_{(\beta)}(\Delta t, s)\}^4|\mathcal{F}_s]}.$$

The lemma is straightforwardly proved using this inequality and Lemma 2.1.

Remark 2.4. By Lemmas 2.1 and 2.2 together with Remark 2.3, we may verify that multiple Stratonovich integrals $J_{(\alpha)}(t,s)$ also satisfy the results in Lemmas 2.1 and 2.2. Hence, for a given α, we find that MSO of a multiple Stratonovich integral $J_{(\alpha)}(t,s)$ is also equal to $\ell(\alpha)+n(\alpha)$; that is, MSO of $J_{(\alpha)}(t,s)$ agrees with that of $I_{(\alpha)}(t,s)$ for the same multi-index α.

We now proceed to our goal. Using Lemmas 2.1 and 2.2, we can estimate MSO of each coefficient of X^J in (2.26) which is given by a polynomial function of multiple Itô integrals on $[0,t]$. For example, in the case of $|J|=1$, MSOs of the coefficients of X_0 and X_1, that is, MSOs of $I_0(t)$ and $I_1(t)$ are equal to 2 and 1, respectively. In the case of $|J|=2$, MSO of $I_{(0,1)}(t)$ or $I_{(1,0)}(t)$ in the coefficient of $[X_0,X_1]$ is given by 3, and thereby we can easily prove that MSO of the coefficient $(I_{(0,1)}(t)-I_{(1,0)}(t))/2$ itself is also equal to 3. In the same manner, we find MSOs of the coefficients of X^J when $|J|=3$; that is, MSOs of the coefficients of $[X_0,X_1],X_0]$ and $[X_0,X_1],X_1]$ are given by 5 and 4, respectively. Hence, in this case, *the least value* of MSOs of the coefficients of X^J equals 4. These facts suggest that we may verify the following proposition which we wish to establish.

PROPOSITION 2.1. *Suppose that k is a given integer greater than or equal to* 2, *and that the multi-indices J satisfy $|J|=k$; that is, $J=(j_1,\dots,j_k)$ ($j_i=0$ or 1; $i=1,\dots,k$). Then the least value of MSOs of the coefficients $H^J(t)$ of X^J in* (2.26) *is equal to $k+1$.*

Proof. We may prove this by induction. From the above examples, this proposition is obvious in the case of $|J|=2,3$. We assume that the assertion of this proposition holds for the case of $|J|=\ell(\geq 3)$. That is, the least value of MSOs of the coefficients $H^J(t)$ of X^J under $J=(j_1,\dots,j_\ell)$ in (2.26) equals $\ell+1$. Then, note that under the same J, the least value of MSOs of $K^J(t)$ in (2.25) agrees with that of $H^J(t)$, since $H^J(t)$ is only another version of $K^J(t)$ in terms of multiple Itô integrals. Now, let us consider the coefficients $K^{\tilde{J}}(t)$ of $X^{\tilde{J}}$ under $|\tilde{J}|=\ell+1$. On account of the definition of multiple integrals $W^{\Delta J}(t)$ (2.8) or (2.9) with (2.10) in the coefficients, one may obtain $K^{\tilde{J}}(t)$ by adding a stochastic integral with respect to dW or dt to each multiple integral in $K^J(t)$. Moreover, the following equations show that the MSOs for the integrals with increments dW and dt correspond to 1 and 2, respectively:

$$E\left[|\int_s^{s+\Delta t} dW(\tau)|^2|\mathcal{F}_s\right]=O(\Delta t),\quad E\left[|\int_s^{s+\Delta t} dt|^2|\mathcal{F}_s\right]=O((\Delta t)^2)\ (\Delta t\downarrow 0).$$

Hence, the least value of MSOs of $K^{\tilde{J}}(t)$ is equal to $\ell+2$, and thereby, the least value of MSOs of $H^{\tilde{J}}(t)$ is also so. Thus, the assertion in our proposition is proved. □

3. Composition methods for numerical integration of SDEs.

In this section, we will formulate some new stochastic numerical schemes for SDEs on the basis of composition methods and estimate the approximation errors for the schemes in the local and global senses.

3.1. Procedures of composition methods for SDEs.

We start with a numerical integration of the stochastic equation (2.18) on the discretized time series in the framework of the previous results on representation of solutions to SDEs. It adopts a uniform discretization of the time interval $[0,T]$ with stepsize

$$\Delta t=\frac{T}{N}$$

for fixed natural number N. Let $t_n = n\Delta t(n = 0, 1, 2, \dots, N)$ be the nth step-point. Then, for all $n \in \{0, \dots, N\}$, we abbreviate $S_n = S(t_n)$. Moreover, we use ΔW_n for $n = 0, 1, \dots, N$ to denote the increments $W(t_{n+1}) - W(t_n)$; they are independent Gaussian random variables with mean 0 and variance Δt, that is, $N(0, \Delta t)$-distributed random variables.

On account of (2.16), we may find the numerical solutions $S_n(n = 0, 1, \dots, N)$ to SDE (2.18) by using

$$S_{n+1} = \exp{(Y_{n\Delta t})}(S_n) \ (n = 0, 1, 2, \dots, N - 1), \tag{3.1}$$

formally, where $Y_{n\Delta t}$ is a vector field derived by replacing all the multiple Wiener integrals $I_{(\alpha)}(t) = I_{(\alpha)}(t, 0)$ in (2.26) by $I_{(\alpha)}(\Delta t, n\Delta t)$. In the following, $I_{(\alpha)}(\Delta t, n\Delta t)$ is denoted by $I_{(\alpha),n}(\Delta t)$. Moreover, we set $S_0 = S(0) = s_0$. According to the theory of ordinary differential equations, $\exp{(Y_{n\Delta t})}(\cdot)$ is often called the time-Δt map or exponential map. However, it is usually difficult to find the explicit form of the exponential map, and hence we need to build an approximation for (3.1).

To do this, we formulate a new stochastic numerical scheme as the following two procedures, which are composed of the truncation of the vector field (2.26) and a composition method (or operator splitting method) applied to the exponential map derived from the truncated vector field.

Procedure 1. For the vector field Y_t described by (2.26), we define a "truncated" vector field $\hat{Y}_t$ which is given by a truncation of the higher-order terms with respect to MSO of the coefficients of X^J in (2.26). Then, we define a numerical sequence $(\hat{S}_n)_{n=0}^N$ through

$$\hat{S}_{n+1} = \exp(\hat{Y}_{n\Delta t})(\hat{S}_n) \ (n = 0, 1, \dots, N - 1), \tag{3.2}$$

where $\hat{S}_0 = S(0) = s_0$.

Procedure 2. For $\hat{S}_{n+1} = \exp(\hat{Y}_{n\Delta t})(\hat{S}_n)$, we apply a composition method in a way analogous to that in the theory of ordinary differential equations. Suppose that the vector field $\hat{Y}_{n\Delta t}$ is of the form

$$\hat{Y}_{n\Delta t} = A_{n\Delta t} + B_{n\Delta t}, \tag{3.3}$$

where $\exp(A_{n\Delta t})$ and $\exp(B_{n\Delta t})$ can both be explicitly calculated through (2.13). Then an approximation to the exponential map of $\hat{Y}_{n\Delta t}$ is given by $\exp(A_{n\Delta t})\exp(B_{n\Delta t})$. Hence, the sequence of $(\hat{S}_n)_{n=0}^N$ in Procedure 1 is approximated by

$$\tilde{S}_{n+1} = \exp(A_{n\Delta t})\exp(B_{n\Delta t})(\tilde{S}_n) \ (n = 0, 1, \dots, N - 1), \tag{3.4}$$

where $\tilde{S}_0 = S(0) = s_0$.

We regard $(\tilde{S}_n)_{n=0}^N$ as a numerical approximation to the exact discretized solutions $(S_n)_{n=0}^N$.

3.2. Local error estimation for the new numerical scheme. We will estimate the approximation error of the numerical scheme described above. For this purpose, we first examine "local errors in the mean-square sense" for the scheme. Using this result, we will finally address the "global" error estimation in the next subsection.

We start with the definition of "local error order" in a manner analogous to that in [15].

Definition 3.1. *Suppose that $S(t)$ and $(\bar{S}_n)_{n=0}^N$ are an exact solution and the numerical approximation solutions to SDE* (2.18), *respectively. Let $E_{\tau,\xi}$ be the expectation conditioned on starting at ξ at time τ. Then the local error order α is defined by*

$$E_{t_n,s}[|\bar{S}_{n+1} - S_{n+1}|^2] = O((\Delta t)^{2\alpha}) \ (\Delta t \downarrow 0), \tag{3.5}$$

where $t_n = n\Delta t$ $(n = 0, \ldots, N-1)$, $S_n = S(n\Delta t)$, and $|\cdot|$ denotes the Euclidean norm on the space R^d. Note that the condition in the expectation (3.5) *means $S_n = \bar{S}_n = s$.*

We note that the accuracy of a numerical scheme improves with increasing local order.

Remark 3.1. In the framework of local error order defined by [23], the local order of $\bar{S}_n$ satisfying (3.5) is given by $2\alpha - 1$.

On the basis of this definition of local error estimation, we will investigate the error estimation of our approximation procedures. In what follows, we set $S_n = s$, where s is a given value.

Local error estimation for the truncation error in Procedure 1. First, we investigate the truncation error in Procedure 1. Let ${H_n}^J(\Delta t)$ be the coefficient of X^J in $Y_{n\Delta t}$ which is represented by a polynomial function of multiple Itô integrals for a given multi-index J as in (2.26).

Proposition 3.1. *Suppose that a truncation vector field $\hat{Y}_{n\Delta t}$ is given in the following form:*

$$\hat{Y}_{n\Delta t} = \sum_{J;1\le|J|\le\gamma} {H_n}^J(\Delta t)X^J. \tag{3.6}$$

That is, we assume the terms in $Y_{n\Delta t}$ satisfying $|J| \ge \gamma + 1$ are neglected. Then,

$$E_{t_n,s}[|\hat{S}_{n+1} - S_{n+1}|^2] = O((\Delta t)^{\gamma+2}) \ (\Delta t \downarrow 0). \tag{3.7}$$

Proof. In terms of Proposition 2.1, we can easily show that the least value of MSOs of ${H_n}^J(\Delta t)$ in the neglected terms equals $\gamma + 2$, since $|J| \ge \gamma + 1$. This fact, together with the definition of exponential map (see 2.11 with 2.13 [16], [3]), straightforwardly shows (3.7). Thus, we obtain the local order $(\gamma/2)+1$ for numerical approximation solutions $(\hat{S}_n)_{n=0}^N$ in the sense of Definition 3.1.

Remark 3.2. If the Lie algebra generated by X_0 and X_1 is of finite dimension, our error estimation derived above agrees with that of truncation of stochastic exponential maps by [2], since the convergence of (2.17), and hence (2.26), are actually guaranteed (cf. Remark 2.2). That is, under the assumption that such a convergence holds, the local error estimation derived above holds exactly. In general, however, our result may give only a formal error estimation. Indeed, according to [6], when the convergence is not guaranteed, the asymptotic expansion of stochastic exponential maps is estimated only in a "probability" sense.

Local error estimation for the composition scheme in Procedure 2. Next, we will proceed to the local error estimation for Procedure 2. We can carry this out using the BCH formula [3] together with Lemma 2.2; the formula is given by the following form:

$$\begin{aligned} \exp(\epsilon(\Delta t)X)\exp(\delta(\Delta t)Y) &= \exp(\epsilon(\Delta t)X + \delta(\Delta t)Y + \frac{1}{2}\epsilon(\Delta t)\delta(\Delta t)[X,Y] \\ &+ \frac{1}{12}(\epsilon(\Delta t)^2\delta(\Delta t)[X,[X,Y]] + \epsilon(\Delta t)\delta(\Delta t)^2[Y,[Y,X]]) + \cdots), \end{aligned} \tag{3.8}$$

where X and Y are C^∞ vector fields, and $\epsilon(\Delta t)$ and $\delta(\Delta t)$ are any functions of Δt; in our case, they correspond to polynomial functions of multiple Itô stochastic integrals $I_{(\alpha),n}(\Delta t)$.

PROPOSITION 3.2. *Let $\hat{Y}_{n\Delta t}$ be a truncated vector field given by* (3.6). *Suppose that the vector fields $A_{n\Delta t}$ and $B_{n\Delta t}$ in a decomposition* (3.3) *for $\hat{Y}_{n\Delta t}$ are described by*

$$A_{n\Delta t} = \sum_{J;1\le |J| \le \gamma} {F_n}^J(\Delta t) X^J, \quad B_{n\Delta t} = \sum_{J;1\le |J| \le \gamma} {G_n}^J(\Delta t) X^J, \tag{3.9}$$

respectively, and that the least values of MSOs of ${F_n}^J(\Delta t)$ and ${G_n}^J(\Delta t)$ in (3.9) *are given by α and β, respectively. If $X_A^{J_\alpha}$ and $X_B^{J_\beta}$, which are vector fields corresponding to the coefficients with α and β as MSO, respectively, satisfy $[X_A^{J_\alpha}, X_B^{J_\beta}] \neq 0$, then*

$$E_{t_n,s}[|\tilde{S}_{n+1} - \hat{S}_{n+1}|^2] = O((\Delta t)^{\alpha+\beta})) \ (\Delta t \downarrow 0). \tag{3.10}$$

Proof. Let ${F_n}^{J_\alpha}(\Delta t)$ and ${G_n}^{J_\beta}(\Delta t)$ be the coefficients in (3.9) whose MSOs are equal to α and β, respectively. Then, in an analogous way to that in Lemma 2.2, we can prove that

$$E_{t_n,s}[|{F_n}^{J_\alpha}(\Delta t){G_n}^{J_\beta}(\Delta t)|^2] = O((\Delta t)^{\alpha+\beta}) \ (\Delta t \downarrow 0). \tag{3.11}$$

Therefore, on account of the BCH formula (3.8), (3.11), and the definition of α and β given above, one may find that

$$\begin{aligned} E_{t_n,s}[|\tilde{S}_{n+1} - \hat{S}_{n+1}|^2] &= E_{t_n,s}[|\exp(A_{n\Delta t} + B_{n\Delta t})(s) - \exp(A_{n\Delta t})\exp(B_{n\Delta t})(s)|^2] \\ &= E_{t_n,s}\Bigg[\Bigg| \quad \exp(A_{n\Delta t} + B_{n\Delta t})(s) \\ &\qquad - \exp\left(A_{n\Delta t} + B_{n\Delta t} + \frac{1}{2}[A_{n\Delta t}, B_{n\Delta t}] + \cdots\right)(s)\Bigg|^2\Bigg] \\ &= O((\Delta t)^{\alpha+\beta}). \end{aligned} \tag{3.12}$$

Thus, the local order between $(\tilde{S}_n)_{n=0}^N$ and $(\hat{S}_n)_{n=0}^N$ is given by $(\alpha+\beta)/2$.

Remark 3.3. By further manipulating the BCH formula to eliminate higher-order terms, we can obtain various schemes which give higher-order approximations to the exponential map. For example, the scheme corresponding to "leapfrog," which is well known in deterministic numerical analysis, is given by

$$\exp((\Delta t)(X+Y)) = \exp\left(\frac{\Delta t Y}{2}\right)\exp(\Delta t X)\exp\left(\frac{\Delta t Y}{2}\right) + O((\Delta t)^3). \tag{3.13}$$

In a way analogous to that in (3.4), we define a stochastic leapfrog scheme as follows:

$$\tilde{S}_{n+1} = \exp\left(\frac{B_{n\Delta t}}{2}\right)\exp(A_{n\Delta t})\exp\left(\frac{B_{n\Delta t}}{2}\right)(\tilde{S}_n) \ (n = 0, 1, \ldots, N-1). \tag{3.14}$$

Then, using the BCH formula (3.8) and (3.11) repeatedly, we can find that the local error for this scheme is given by $(\alpha + 2\beta)/2$ as follows:

$$E_{t_n,s}[|\tilde{S}_{n+1} - \hat{S}_{n+1}|^2] = O((\Delta t)^{\alpha+2\beta}). \tag{3.15}$$

Thus, we can produce another numerical scheme having a better local order than that of the scheme (3.4). Moreover, using this scheme as a basis element for further leapfrog schemes, we may also produce an approximation to exponential map up to any order in a similar way to that in ordinary numerical analysis.

Total local error estimation for the numerical scheme of Procedures 1 and 2. Finally, we estimate the local error order between the exact discretized solutions $(S_n)_{n=0}^N$ and the numerical approximation solutions $(\tilde{S}_n)_{n=0}^N$. This is easily carried out by using Propositions 3.1 and 3.2 (or Remark 3.3) for the local orders in the above two procedures together with

$$E_{t_n,s}[|S_{n+1} - \tilde{S}_{n+1}|^2] \leq E_{t_n,s}[|S_{n+1} - \hat{S}_{n+1}|^2] + E_{t_n,s}[|\hat{S}_{n+1} - \tilde{S}_{n+1}|^2], \tag{3.16}$$

and thereby we obtain the following theorem.

THEOREM 3.1. *Under the conditions of Propositions* 3.1 *and* 3.2*,*

$$E_{t_n,s}[|S_{n+1} - \tilde{S}_{n+1}|^2] \leq O((\Delta t)^\delta) \ (\Delta t \downarrow 0) \tag{3.17}$$

holds, where $\delta = \min(\alpha + \beta, \gamma + 2)$ *in the case of* (3.4) *and* $\delta = \min(\alpha + 2\beta, \gamma + 2)$ *in the case of* (3.14)*.*

On account of Definition 3.1, if (3.17) holds, we may regard $(\delta/2)$ as a local order for the scheme giving the numerical approximation solutions $(\tilde{S}_n)_{n=0}^N$. In this article, however, we call the value a local order in a "weak sense" for the scheme, since the estimation of error order is "indirectly" derived from the inequality (3.16).

3.3. Global error estimation and some examples for the new schemes. Now, we proceed to global error estimation for our schemes. We start with the definition of "global error order" in a manner analogous to that in [15] mentioned in Definition 3.1.

DEFINITION 3.2. *Suppose that* $S(t)$ *and* $(\bar{S}_n)_{n=0}^N$ *are an exact solution and the numerical approximation solutions to SDE* (2.18)*, respectively. Moreover, let* $E_{0,\xi}$ *be the expectation conditioned on starting at* ξ *at "initial time"* τ*. Then the global error order* λ *is defined by*

$$E_{0,s}[|\bar{S}_N - S_N|^2] = O((\Delta t)^{2\lambda}) \ (\Delta t \downarrow 0), \tag{3.18}$$

where $S_N = S(N\Delta t)$*,* $N\Delta t = T$ *and* $|\cdot|$ *denotes the Euclidean norm on the space* R^d*.*

Note that the condition in the expectation (3.18) means $S_0 = \bar{S}_0 = s$. It is obvious that the accuracy of a numerical scheme improves with increasing global order.

Remark 3.4. In the framework of global error order defined by [23], the global order for the numerical solutions $\bar{S}_n$ satisfying (3.18) is given by 2λ.

Using Theorem 3.1, we can prove the following lemma and thereby find the global order of our schemes in a weak sense.

LEMMA 3.1. *Suppose that the numerical approximation solutions* $(\tilde{S}_n)_{n=0}^N$ *to SDE* (2.18) *given by* (3.4) *or* (3.14) *satisfy* (3.17)*; that is, the local order in a weak sense for the solutions is equal to* $(\delta/2)$*. Then*

$$E_{0,s}[|S_{n+1} - \tilde{S}_{n+1}|^2] \leq (n+1) \times O((\Delta t)^\delta) \ (\Delta t \downarrow 0). \tag{3.19}$$

Proof. Here, we treat only the case of $(\tilde{S}_n)_{n=0}^N$ given by (3.4) because we can prove (3.19) for the case of numerical solutions by (3.14) in a way analogous to that shown below.

We prove this lemma by induction. First, if $n = 0$, the inequality (3.19) is obvious, since it reduces to (3.17). We assume that (3.19) holds in the case of $n = k-1$. Then, for $n = k$, we rewrite the left-hand side of (3.19) as follows:

$$\begin{aligned}(3.20)\qquad & E_{0,s}[|S_{k+1} - \tilde{S}_{k+1}|^2] \\ &= E_{0,s}[|S_{k+1} - \exp(A_{(k+1)\Delta t})\exp(B_{(k+1)\Delta t})(S_k) \\ &\qquad + \exp(A_{(k+1)\Delta t})\exp(B_{(k+1)\Delta t})(S_k) - \tilde{S}_{k+1}|^2] \\ &\leq E_{0,s}[|S_{k+1} - \exp(A_{(k+1)\Delta t})\exp(B_{(k+1)\Delta t})(S_k)|^2] \\ &+ E_{0,s}[|\exp(A_{(k+1)\Delta t})\exp(B_{(k+1)\Delta t})(S_k) - \tilde{S}_{k+1}|^2],\end{aligned}$$

where $\exp(A_{(k+1)\Delta t})\exp(B_{(k+1)\Delta t})$ is the composition exponential map given by (3.4). Using (3.4) for $n = k$, that is, $\tilde{S}_{k+1} = \exp(A_{(k+1)\Delta t})\exp(B_{(k+1)\Delta t})(\tilde{S}_k)$, we may rewrite the first term on the right-hand side in (3.20) in the following form:

$$E_{0,s}[|S_{k+1} - \exp(A_{(k+1)\Delta t})\exp(B_{(k+1)\Delta t})(S_k)|^2] = E[|S_{k+1} - \tilde{S}_{k+1}|^2 | S_k = \tilde{S}_k].$$

This fact, together with the assumption about the local order for $(\tilde{S}_n)_{n=0}^N$, gives

$$E_{0,s}[|S_{k+1} - \exp(A_{(k+1)\Delta t})\exp(B_{(k+1)\Delta t})(S_k)|^2] \leq O((\Delta t)^\delta).$$

In a similar manner, using (3.4), we can put the second term on the right-hand side in (3.20) into the following form:

$$\begin{aligned}& E_{0,s}[|\exp(A_{(k+1)\Delta t})\exp(B_{(k+1)\Delta t})(S_k) - \tilde{S}_{k+1}|^2] \\ &= E_{0,s}[|\exp(A_{(k+1)\Delta t})\exp(B_{(k+1)\Delta t})(S_k - \tilde{S}_k)|^2].\end{aligned}$$

Then, the definition of exponential map [16], [3], together with (3.8) and the assumption of the induction, proves

$$E_{0,s}[|\exp(A_{(k+1)\Delta t})\exp(B_{(k+1)\Delta t})(S_k - \tilde{S}_k)|^2] \leq k \times O((\Delta t)^\delta).$$

Therefore, we find

$$(3.21)\qquad E_{0,s}[|S_{k+1} - \tilde{S}_{k+1}|^2] \leq (k+1) \times O((\Delta t)^\delta) \quad (\Delta t \downarrow 0),$$

and hence (3.19) holds for $n = k$, thus completing the proof. □

We note that $N\Delta t = T = constant$. Therefore, Lemma 3.1, together with this fact, straightforwardly proves the following theorem.

THEOREM 3.2. *Suppose that the local order in a weak sense for numerical approximation solutions* $(\tilde{S}_n)_{n=0}^N$ *given by* (3.4) *or* (3.14) *is equal to* $(\delta/2)$. *Then*

$$(3.22)\qquad E_{0,s}[|S_N - \tilde{S}_N|^2] \leq O((\Delta t)^{\delta-1}) \ (\Delta t \downarrow 0).$$

Thus, we can estimate the global error order for our schemes, although the estimation is indirectly derived through the inequality (3.22). Hence, on account of Definition 3.2, if (3.22) holds, we call the value $(\delta - 1)/2$ a global order in a weak sense for the schemes of (3.4) or (3.14).

Now, in the following, we will investigate some examples of new numerical schemes for (2.18), which are derived from the procedures given above, and estimate the local and global errors on the basis of Theorems 3.1 and 3.2.

Example 3.1. Suppose that a truncated vector field $\hat{Y}_{n\Delta t}$ in Procedure 1 is given by

$$\begin{aligned}\hat{Y}_{n\Delta t} &= I_{(0),n}(\Delta t)X_0 + I_{(1),n}(\Delta t)X_1,\\ &= \Delta t X_0 + \Delta W_n X_1.\end{aligned} \tag{3.23}$$

On account of (2.26), we see that γ in Proposition 3.1 for this truncated vector field equals 1. We further set $A_{n\Delta t} = \Delta t X_0$ and $B_{n\Delta t} = \Delta W_n X_1$ in the decomposition (3.3) and assume that the explicit forms of both exponential maps for them are obtained through (2.13). In this case, α and β in Proposition 3.2 become 2 and 1, respectively, because of Lemma 2.1. Then, the scheme (3.4) can be put into the following form.

Scheme 3.1.

$$\tilde{S}_{n+1} = \exp(\Delta t X_0)\exp(\Delta W_n X_1)(\tilde{S}_n). \tag{3.24}$$

Assume that $[X_0, X_1] \neq 0$. Then, through Theorems 3.1 and 3.2, we obtain

$$E_{t_n,s}[|S_{n+1} - \tilde{S}_{n+1}|^2] \leq O((\Delta t)^3) \tag{3.25}$$

and

$$E_{0,s}[|S_N - \tilde{S}_N|^2] \leq O((\Delta t)^2). \tag{3.26}$$

Thus, we find that the local order and the global order in a weak sense for Scheme 3.1 equals 1.5 and 1, respectively.

Example 3.2. For $\hat{Y}_n(\Delta t)$ in Example 3.1, we set $A_{n\Delta t} = \Delta t X^A{}_0 + \Delta W_n X^A{}_1$ and $B_{n\Delta t} = \Delta t X^B{}_0 + \Delta W_n X^B{}_1$ in (3.3), where $X_0 = X^A{}_0 + X^B{}_0$ and $X_1 = X^A{}_1 + X^B{}_1$. We assume that $[X^A{}_1, X^B{}_1] \neq 0$ and that the explicit forms of both exponential maps for them are obtained. In this case, α and β in Proposition 3.2 are both equal to 1; hence the local order of the scheme (3.4) for the above $A_{n\Delta t}$ and $B_{n\Delta t}$ becomes 1. In order to produce a scheme having better accuracy than that of this scheme, we use (3.14) instead of (3.4).

Scheme 3.2.

$$\tilde{S}_{n+1} = \exp\left(\frac{B_{n\Delta t}}{2}\right)\exp(A_{n\Delta t})\exp\left(\frac{B_{n\Delta t}}{2}\right), \tag{3.27}$$

where $A_{n\Delta t} = \Delta t X^A{}_0 + \Delta W_n X^A{}_1$ and $B_{n\Delta t} = \Delta t X^B{}_0 + \Delta W_n X^B{}_1$ under $X_0 = X^A{}_0 + X^B{}_0$ and $X_1 = X^A{}_1 + X^B{}_1$.

Then, Theorems 3.1 and 3.2 indicate that (3.25) and (3.26) also hold in this case. That is, the local error order and the global order of this scheme are equal to 1.5 and 1, respectively.

Example 3.3. We will formulate a scheme with better accuracy than that of the schemes described above. For this purpose, we choose the following vector field as $\hat{Y}_{n\Delta t}$ in (3.6):

$$\hat{Y}_{n\Delta t} = \Delta t X_0 + \Delta W_n X_1 + \frac{1}{2}(I_{(0,1),n}(\Delta t) - I_{(1,0),n}(\Delta t))[X_0, X_1]. \tag{3.28}$$

Then, from (2.26), we see that γ in Proposition 3.1 for this truncated vector field becomes 2. Moreover, we set

$$\exp(A_{n\Delta t}) = \exp(\Delta t X_0) \tag{3.29}$$

and

$$\exp(B_{n\Delta t}) = \exp\left(\Delta W_n X_1 + \frac{1}{2}(I_{(0,1),n}(\Delta t) - I_{(1,0),n}(\Delta t))[X_0, X_1]\right). \tag{3.30}$$

Assume that the explicit forms of both exponential maps for these are obtained through (2.13). In this case, Lemmas 2.1 and 2.2 show that α and β in Proposition 3.2 are equal to 2 and 1, respectively. Moreover, we adopt (3.14) for these vector fields which leads to the following scheme.

Scheme 3.3.

$$\tilde{S}_{n+1} = \exp\left(\frac{B_{n\Delta t}}{2}\right)\exp(A_{n\Delta t})\exp\left(\frac{B_{n\Delta t}}{2}\right)(\tilde{S}_n), \tag{3.31}$$

where $\exp(A_{n\Delta t})$ is given by (3.29) and $\exp(B_{n\Delta t}/2)$ is derived by replacing $B_{n\Delta t}$ by $B_{n\Delta t}/2$ in (3.30).

Then, because of Theorems 3.1 and 3.2, we find that

$$E_{t_n,s}[|S_{n+1} - \tilde{S}_{n+1}|^2] \le O((\Delta t)^4) \tag{3.32}$$

and

$$E_{0,s}[|S_N - \tilde{S}_N|^2] \le O((\Delta t)^3), \tag{3.33}$$

and hence conclude that the local order and the global order in a weak sense for Scheme 3.3 equals 2 and 1.5, respectively.

4. Examples.

In this section, we will give several illustrative examples of applying our new stochastic numerical schemes to SDEs.

4.1. Numerical simulation of a nonlinear asset price process in mathematical finance.

As was mentioned in section 1, we first work with the following nonlinear scalar SDE which is often treated as a model of an asset price process of Bessel type in mathematical finance [9] (cf. Remark 4.1):

$$dS(t) = S(t)dt + 2\sqrt{S(t)} \circ dW(t), \quad S(0) = s(> 0). \tag{4.1}$$

This system has a structure such that the value of solution remains nonnegative for any $t \in [0, T]$. In standard stochastic numerical schemes, however, this property is not always preserved numerically; in particular, if an initial value s is close to zero, the numerical solutions often go into the domain of negative values in the midst of numerical simulations. Such troublesome behavior will be observed in the numerical results given later. In contrast with this, through the results in previous section, we may obtain a scheme which leaves the structure of the stochastic system (4.1) invariant numerically. We will examine it now.

First, from (2.6) and (4.1), we see that the vector fields X_0 and X_1 become

$$X_0 = S\frac{d}{dS}, \; X_1 = 2\sqrt{S}\frac{d}{dS}, \tag{4.2}$$

respectively. Here, we note that $[X_0, X_1] = -X_1/2$, and the Lie algebra generated by X_0 and X_1 is of finite dimension. Hence, Remark 2.2 indicates that (2.26) actually converges in this case.

We proceed to investigate the application of Scheme 3.1 to SDE (4.1). On account of (3.24), we suppose that $A_{n\Delta t}$ and $B_{n\Delta t}$ in (3.3) are given by

$$A_{n\Delta t} = \Delta t X_0 = \Delta t S\frac{d}{dS}, \quad B_{n\Delta t} = \Delta W_n X_1 = \Delta W_n 2\sqrt{S}\frac{d}{dS}. \tag{4.3}$$

Then, in view of (2.13), we obtain the exponential maps for $A_{n\Delta t}$ and $B_{n\Delta t}$ explicitly as follows:

$$\exp(A_{n\Delta t})(s) = s\exp(\Delta t), \quad \exp(B_{n\Delta t})(s) = \{\Delta W_n + \sqrt{s}\}^2. \tag{4.4}$$

Inserting these into (3.24), we find that Scheme 3.1 applied to SDE (4.1) leads to

$$\tilde{S}_{n+1} = \left\{\Delta W_n + \sqrt{\tilde{S}_n}\right\}^2 \exp(\Delta t), \tag{4.5}$$

where $\tilde{S}_0 = S(0) = s$. Clearly, the numerical solutions derived from our scheme *never* take negative values, and this is just the result we want. Moreover, as mentioned in section 3.3, the local and global orders in a weak sense for this scheme are given by 1.5 and 1, respectively.

Next we will apply Scheme 3.3 to SDE (4.1). On account of (3.29), in this case, we also obtain $s\exp(\Delta t)$ as $\exp(A_{n\Delta t})(s)$. In contrast with this, (3.30) takes the form

$$\exp(B_{n\Delta t}) = \exp\left\{\left(\Delta W_n - \frac{1}{4}(I_{(0,1),n}(\Delta t) - I_{(1,0),n}(\Delta t))\right) X_1\right\}, \tag{4.6}$$

since $[X_0, X_1] = -X_1/2$. In a way similar to that of Scheme 3.1, this is also calculated explicitly as follows:

$$\exp(B_{n\Delta t})(s) = \left\{\Delta W_n - \frac{1}{4}(I_{(0,1),n}(\Delta t) - I_{(1,0),n}(\Delta t)) + \sqrt{s}\right\}^2, \tag{4.7}$$

and thereby we obtain the result of Scheme 3.3 applied to SDE (4.1) as

$$\tilde{S}_{n+1} = \left\{\frac{\Delta W_n}{2} - \frac{1}{8}(I_{(0,1),n}(\Delta t) - I_{(1,0),n}(\Delta t)) + \sqrt{\hat{s}}\right\}^2, \tag{4.8}$$

together with

$$\hat{s} = \left\{\frac{\Delta W_n}{2} - \frac{1}{8}(I_{(0,1),n}(\Delta t) - I_{(1,0),n}(\Delta t)) + \sqrt{\tilde{S}_n}\right\}^2 \exp(\Delta t), \tag{4.9}$$

where $\tilde{S}_0 = S(0) = s$. This also indicates that the numerical solutions derived from this scheme take only nonnegative values. Then, as mentioned in section 3.3, the local and global orders for this scheme are equal to 2 and 1.5, respectively.

Here, we will examine the numerical solutions of SDE (4.1) given by these schemes. Then, we will compare these numerical results with those of several standard numerical schemes. For this purpose, we adopt the Euler–Maruyama scheme (Taylor scheme of

global order 0.5) and Kloeden's Taylor scheme of global order 1.5 [15], [23]; they are given in the following forms for the SDE (4.1):

Euler–Maruyama scheme.

$$S_{n+1} = S_n + (S_n + 1)\Delta t + 2\sqrt{S_n}\Delta W_n. \tag{4.10}$$

Kloeden's Taylor scheme of global order 1.5.

$$\begin{aligned} S_{n+1} = S\ _n &+ (S_n + 1)\Delta t + 2\sqrt{S_n}\Delta W_n \\ &+ \{(\Delta W_n)^2 - \Delta t\} \\ &+ 2\sqrt{S_n} I_{(1,0),n}(\Delta t) + \sqrt{S_n} I_{(0,1),n}(\Delta t) \\ &+ \frac{1}{2}(S_n + 1)(\Delta t)^2. \end{aligned} \tag{4.11}$$

In the schemes (4.5), (4.8) with (4.9), (4.10), and (4.11), ΔW_n, $I_{(1,0),n}(\Delta t)$, and $I_{(0,1),n}(\Delta t)$ are numerically realized by the independent $N(0,1)$ random numbers γ_n and $\hat{\gamma}_n$ $(n = 0, 1, \ldots)$ as follows [15]:

$$\begin{aligned} \Delta W_n &= \gamma_n \sqrt{\Delta t}, \\ I_{(1,0),n}(\Delta t) &= \frac{1}{2}\left(\gamma_n + \frac{1}{\sqrt{3}}\hat{\gamma}_n\right)(\Delta t)^{3/2}, \\ I_{(0,1),n}(\Delta t) &= \frac{1}{2}\left(\gamma_n - \frac{1}{\sqrt{3}}\hat{\gamma}_n\right)(\Delta t)^{3/2}. \end{aligned} \tag{4.12}$$

Moreover, we choose $T = 1$ and $N = 1000$ here, and hence the stepsize $\Delta t = 10^{-3}$.

Tables 1 and 2 display the results of the numerical solutions from these schemes listed above for the initial value $s = 0.01$ and $s = 0.001$, respectively. (Note: in the case of Table 2, the scheme (4.10) is excluded.) Here we have used the same sequences of random numbers for each scheme together with (4.12). As was mentioned in the introductory part of this section, from these results we observe that the values of numerical solutions derived from the standard schemes become negative during their computation if their initial values are close to zero. In contrast with these results, all of our schemes are free from such problems. Thus, our scheme (4.5) and (4.8) with (4.9) are superior with respect to numerical realization of the character of SDE (4.1); that is, nonnegativity of solutions is preserved in contrast to the results of the standard schemes.

Table 3 displays the results for the initial value $s = 1$. In Table 3, it is observed that numerical results of the schemes (4.5) and (4.8) are closer to those of Kloeden's scheme (4.11) than to the results of Euler's scheme (4.10). In particular, the numerical solutions from (4.8) are very similar to those of (4.11); from theoretical consideration of local and global orders in section 3.3, these observations are as expected.

Remark 4.1. Let us consider the following SDE:

$$dS(t) = S(t)dt + \frac{1}{1-\gamma}\{S(t)\}^{\gamma} \circ dW(t), \quad S(0) = s(> 0),$$

where $0 < \gamma < 1$. This is also often treated as a model of an asset price process in mathematical finance, and it is a generalization of (4.1). For this process, we can also construct numerical schemes like those described above in a similar way. Indeed, Scheme 3.1 for this SDE, of which local and global orders equal 1.5 and 1, respectively, is given by

$$\tilde{S}_{n+1} = [\{\Delta W_n + \tilde{S}_n^{1-\gamma}\}^2]^{1/\{2(1-\gamma)\}} \exp(\Delta t),$$

where $\tilde{S}_0 = S(0) = s$. Note that the numerical solutions derived from this scheme also satisfy nonnegativity.

4.2. Example of Scheme 3.2 for a nonlinear SDE. We study an example for Scheme 3.2 given by (3.27). Let us consider the following nonlinear scalar SDE:

$$dS(t) = S(t)dt + \{S(t) + 2\sqrt{S(t)}\} \circ dW(t), \quad S(0) = s(> 0). \tag{4.13}$$

In this case, the vector fields X_0 and X_1 are set as

$$X_0 = S\frac{d}{dS}, \qquad X_1 = (S + 2\sqrt{S})\frac{d}{dS}, \tag{4.14}$$

respectively. Then, we remark that $[X_0, X_1] = -\sqrt{S}(d/dS)$, $[X_0, [X_0, X_1]] = -[X_0, X_1]/2$, and $[X_1, [X_0, X_1]] = -[X_0, X_1]/2$ hold; hence the Lie algebra generated by X_0 and X_1 is of finite dimension. Therefore, as in section 4.1, (2.26) also actually converges in this case.

We may regard the SDE (4.13) as a linear SDE with the additional random perturbation $2\sqrt{S(t)} \circ dW(t)$. On account of this, as $A_{n\Delta t}$ and $B_{n\Delta t}$ in (3.27), we adopt

$$A_{n\Delta t} = \Delta t S\frac{d}{dS} + \Delta W_n S\frac{d}{dS}, \quad B_{n\Delta t} = \Delta W_n 2\sqrt{S}\frac{d}{dS}; \tag{4.15}$$

that is, we set $X_0^A = S(d/dS)$, $X_1^A = S(d/dS)$, $X_0^B = 0$, and $X_1^B = 2\sqrt{S}(d/dS)$. Then, in view of (2.13), we obtain the exponential maps for them explicitly as follows:

$$\exp(A_{n\Delta t})(s) = s\exp(\Delta t + \Delta W_n), \quad \exp(B_{n\Delta t})(s) = \{\Delta W_n + \sqrt{s}\}^2. \tag{4.16}$$

Inserting these equations into (3.27), we find Scheme 3.2 for the SDE (4.13); it is given by

$$\tilde{S}_{n+1} = \left\{\Delta W_n/2 + \sqrt{\{\Delta W_n/2 + \sqrt{\tilde{S}_n}\}^2 \exp(\Delta t + \Delta W_n)}\right\}^2, \tag{4.17}$$

where $\tilde{S}_0 = S(0) = s$. Then, the theoretical consideration of error stimation in section 3.3 proves that the local and global orders for this scheme equal 1.5 and 1, respectively.

Here, in a way similar to that in section 4.1, we will observe the results of numerical solutions through this scheme and compare them with the results of the following Euler–Maruyama scheme and Kloeden's Taylor scheme for (4.13):

Euler–Maruyama scheme.

$$S_{n+1} = S_n + \left\{\frac{3}{2}(S_n + \sqrt{S_n}) + 1\right\}\Delta t + (S_n + 2\sqrt{S_n})\Delta W_n. \tag{4.18}$$

Kloeden's Taylor scheme of global order 1.5.

$$\begin{aligned} S_{n+1} = S_n &+ \left\{\frac{3}{2}(S_n + \sqrt{S_n}) + 1\right\}\Delta t + (S_n + 2\sqrt{S_n})\Delta W_n \\ &+ \frac{1}{2}\left(S_n + 3\sqrt{S_n} + 2\right)\{(\Delta W_n)^2 - \Delta t\} \\ &+ \frac{3}{2}\left(S_n + \frac{5}{2}\sqrt{S_n} + 1\right) I_{(1,0),n}(\Delta t) + \frac{3}{2}\left(S_n + \frac{11}{6}\sqrt{S_n} + 1\right) I_{(0,1),n}(\Delta t) \\ &+ \frac{1}{6}\left(S_n + \frac{7}{2}\sqrt{S_n} + 3\right)\{(\Delta W_n)^3 - 3\Delta t\Delta W_n\} \\ &+ \frac{9}{8}\left(S_n + \frac{17}{12}\sqrt{S_n} + \frac{5}{6}\right)(\Delta t)^2. \end{aligned} \tag{4.19}$$

Finally, inserting (4.12) into the schemes (4.17)–(4.19), we obtain numerical solutions which are shown in Table 4 for the initial value $s = 1$, $T = 1$, $N = 1000$, and $\Delta t = 10^{-3}$.

TABLE 4

An example of numerical solutions to SDE (4.13) *from the Euler–Maruyama scheme* (4.18)*, Kloeden's Taylor scheme* (4.19) *and Scheme* (4.17) *for an initial value* $s = 1$.

n	Euler–Maruyama	Kloeden's Taylor	Scheme (4.17)
991	9.07412	9.83114	9.83382
992	9.77413	10.5897	10.5926
993	9.35542	10.1398	10.1426
994	9.79685	10.6085	10.6114
995	9.86074	10.6656	10.6686
996	9.91146	10.7086	10.7115
997	9.57355	10.3428	10.3456
998	9.27501	10.0183	10.021
999	9.64218	10.4042	10.407
1000	9.47959	10.2216	10.2244

From Table 4 it is also observed that the numerical results of the scheme (4.17) are closer to those of Kloeden's scheme than to the results of Euler's scheme. On account of local and global orders for each scheme, this is also to be expected.

4.3. Composition method applied to stochastic Hamiltonian dynamical systems. As mentioned in section 1, composition methods (or operator splitting methods) are not only a superior integration method for differential equations in preserving the special character or structure of the equations but also often useful for approximations of nonlinear equations whose solutions are not obtained explicitly. The results in sections 4.1 and 4.2 given above show that this is also true in the case of stochastic systems. As also mentioned, such an advantage is remarkable in the case of dynamical systems with multiple space dimensions or Hamiltonian dynamical systems using dimensional splitting methods (e.g., [25], [12]). To illustrate this, we will investigate numerical schemes by composition methods for stochastic dynamical systems with "Hamiltonian structure" [20], [21].

First we review stochastic Hamiltonian dynamical systems [20]. Let us consider the following 2ℓ-dimensional stochastic dynamical system:

$$(4.20)\qquad d\begin{pmatrix} x^i(t) \\ x^{\ell+i}(t) \end{pmatrix} = \begin{pmatrix} \partial_{\ell+i}H_0(x(t)) \\ -\partial_i H_0(x(t)) \end{pmatrix} dt + \begin{pmatrix} \partial_{\ell+i}H_1(x(t)) \\ -\partial_i H_1(x(t)) \end{pmatrix} \circ dW(t) \qquad (i = 1, \cdots \ell),$$

where $x = (x^k)_{k=1}^{2\ell}$ and $\partial_j = \partial/\partial x^j$ $(j = 1, 2, \ldots, 2\ell)$, respectively. In (4.20), $H_\alpha(x)$ $(\alpha = 0, 1)$ are smooth scalar functions on $R^{2\ell}$. Formally, one may regard this as a Hamiltonian dynamical system

$$\frac{d}{dt}\begin{pmatrix} x^i \\ x^{\ell+i} \end{pmatrix} = \begin{pmatrix} \partial_{\ell+i}\hat{H}(x) \\ -\partial_i \hat{H}(x), \end{pmatrix} \qquad (i = 1, \ldots, \ell)$$

with a "randomized" Hamiltonian $\hat{H}$ given by

$$\hat{H} = H_0 + H_1\gamma_t,$$

where γ_t is a one-dimensional Gaussian white noise. With these definitions, we call (4.20) and H_α $(\alpha = 0, 1)$ an (ℓ-dimensional) *stochastic Hamiltonian dynamical system* and the *Hamiltonian*, respectively.

Now, we proceed to an illustration of our new scheme for stochastic Hamiltonian systems. For simplicity, we set $\ell = 1$ and denote $x^1(t)$ and $x^2(t)$ by $q(t)$ and $p(t)$, respectively. Let us consider the class of Hamiltonian systems with the typical Hamiltonian $H_0 = p^2/2 + V_0(q)$ and $H_1 = p^2/2 + V_1(q)$, where $V_0(q)$ and $V_1(q)$ are any potential functions. With this notation, (4.20) becomes

$$d\begin{pmatrix} q(t) \\ p(t) \end{pmatrix} = \begin{pmatrix} p(t) \\ -V_0'(q(t)) \end{pmatrix} dt + \begin{pmatrix} p(t) \\ -V_1'(q(t)) \end{pmatrix} \circ dW(t). \tag{4.21}$$

In general, this is a stochastic nonlinear system. For this system, the vector fields X_0 and X_1 become

$$X_0 = p\partial_q - V_0'(q)\partial_p, \quad X_1 = p\partial_q - V_1'(q)\partial_p, \tag{4.22}$$

respectively.

We will apply our scheme to this system. As an important example of the decomposition of (3.3) for the above system, we choose the following splitting:

$$A_{n\Delta t} = p(\Delta t + \Delta W_n)\partial_q, \quad B_{n\Delta t} = -(V_0'(q)\Delta t + V_1'(q)\Delta W_n)\partial_p. \tag{4.23}$$

This corresponds to the decomposition mentioned in Scheme 3.2; that is, X_0^A, X_1^A, X_0^B, and X_1^B in Scheme 3.2 are given by $p\partial_q$, $p\partial_q$, $-V_0'(q)\partial_p$, and $-V_1'(q)\partial_p$, respectively. Then we note that $\exp(A_{n\Delta t})$ and $\exp(B_{n\Delta t})$ are exponential maps which correspond to the flows of solutions to the following SDEs, respectively:

$$d\begin{pmatrix} q(t) \\ p(t) \end{pmatrix} = \begin{pmatrix} p(t) \\ 0 \end{pmatrix} dt + \begin{pmatrix} p(t) \\ 0 \end{pmatrix} \circ dW(t),$$

$$d\begin{pmatrix} q(t) \\ p(t) \end{pmatrix} = \begin{pmatrix} 0 \\ -V_0'(q(t)) \end{pmatrix} dt + \begin{pmatrix} 0 \\ -V_1'(q(t)) \end{pmatrix} \circ dW(t).$$

Therefore, we can obtain the explicit forms of them; this may be regarded as an example of dimensional splitting. The results are given by

$$\exp(A_{n\Delta t})\begin{pmatrix} q_n \\ p_n \end{pmatrix} = \begin{pmatrix} p_n(\Delta t + \Delta W_n) + q_n \\ p_n \end{pmatrix},$$

$$\exp(B_{n\Delta t})\begin{pmatrix} q_n \\ p_n \end{pmatrix} = \begin{pmatrix} q_n \\ -(\Delta t V_0'(q_n) + \Delta W_n V_1'(q_n)) + p_n \end{pmatrix}.$$

Inserting these equations into (3.27), we finally find Scheme 3.2 for this system as follows:

$$\begin{pmatrix} \tilde{q}_{n+1} \\ \tilde{p}_{n+1} \end{pmatrix} = \begin{pmatrix} \hat{q}_n \\ -\frac{1}{2}(\Delta t V_0'(\hat{q}_n) + \Delta W_n V_1'(\hat{q}_n)) + \hat{p}_n \end{pmatrix}, \tag{4.24}$$

where

$$\begin{pmatrix} \hat{q}_n \\ \hat{p}_n \end{pmatrix} = \begin{pmatrix} \hat{p}_n(\Delta t + \Delta W_n) + \tilde{q}_n \\ -\frac{1}{2}(\Delta t V_0'(\tilde{q}_n) + \Delta W_n V_1'(\tilde{q}_n)) + \tilde{p}_n \end{pmatrix}. \tag{4.25}$$

As in the example in section 4.2, the local and global orders in a weak sense for this scheme are equal to 1.5 and 1, respectively. Thus, for the class of stochastic Hamiltonian dynamical systems with typical Hamiltonians mentioned above, we can numerically approximate them through our scheme (4.24) with (4.25) and achieve an accuracy corresponding to Taylor scheme of global order 1.

4.4. Remark on composition methods and conserved quantities in stochastic dynamical systems. Finally, we remark on numerical schemes for stochastic dynamical systems which preserve "conserved quantities" of the systems. It is well known that conserved quantities play an essential role to determine the structure of dynamical systems; hence, it is important to find a numerical scheme which has the conservation properties for the quantities related to stochastic systems. On the other hand, composition methods often give such schemes for deterministic systems. Therefore, we may expect that one may obtain such schemes through our results, which have the advantage of numerically preserving the conserved quantities for stochastic systems; and in the remainder of this section, we will briefly examine this feature of our schemes.

Let us consider d-dimensional stochastic dynamical systems (2.18). Suppose that a smooth function $I = I(S)$ satisfies

$$X_0 I = 0, \quad X_1 I = 0, \tag{4.26}$$

where X_0 and X_1 are the vector fields given by (2.6). According to [20], $I(S)$ becomes a constant quantity; that is, $I(S(t)) = \textit{constant}$ holds for the diffusion process $S(t)$ governed by SDE (2.18).

Under some conditions, we may straightforwardly formulate a stochastic scheme satisfying numerical preservation of conserved quantities. Assume that the exponential maps of $A_{n\Delta t} = \Delta t X_0$ and $B_{n\Delta t} = \Delta W_n X_1$ are explicitly calculated. Then, it is obvious that Scheme 3.1 preserves the conserved quantity I numerically because of the definition of exponential map and (4.26).

Now, we investigate a trivial example of a stochastic dynamical system with a conserved quantity and the numerical scheme through composition methods. Let us consider

$$d\begin{pmatrix} S^1(t) \\ S^2(t) \end{pmatrix} = \begin{pmatrix} S^2(t) \\ -S^1(t) \end{pmatrix} dt + \begin{pmatrix} S^2(t) \\ -S^1(t) \end{pmatrix} \circ dW(t); \tag{4.27}$$

this is a stochastic system with the conserved quantity $I(S) = \frac{1}{2}((S^1)^2 + (S^2)^2)$, since (4.26) holds. However, as mentioned in [21], ordinary schemes do not conserve $I(S)$ numerically. On the other hand, for this system, we adopt Scheme 3.1 with $A_{n\Delta t} = \Delta t X_0 = \Delta t(S^2\partial_1 - S^1\partial_2)$ and $B_{n\Delta t} = \Delta W_n X_1 = \Delta W_n(S^2\partial_1 - S^1\partial_2)$; then through (2.13), the numerical scheme is explicitly given by

$$\begin{pmatrix} \tilde{S}^1_{n+1} \\ \tilde{S}^2_{n+1} \end{pmatrix} = \begin{pmatrix} \cos(\Delta t) & \sin(\Delta t) \\ -\sin(\Delta t) & \cos(\Delta t) \end{pmatrix} \begin{pmatrix} \cos(\Delta W_n) & \sin(\Delta W_n) \\ -\sin(\Delta W_n) & \cos(\Delta W_n) \end{pmatrix} \begin{pmatrix} \tilde{S}^1_n \\ \tilde{S}^2_n \end{pmatrix}. \tag{4.28}$$

Therefore, for any n, the numerical solutions (4.28) for (4.27) satisfy $I(\tilde{S}^1_n, \tilde{S}^2_n) = \textit{constant}$. Thus, our scheme numerically preserves a conserved quantity I of the stochastic system (4.27), and this fact also shows the superiority of the scheme derived through composition methods.

5. Concluding remarks.

In this article, we have formulated composition methods for SDEs, and through these we have proposed some stochastic numerical schemes. Several illustrative examples show that the new schemes are superior in their conservation properties related to the character of SDEs, and they are useful for approximating the solutions to SDEs. Moreover, we have investigated local and global error orders for our schemes. Finally, we offer some remarks and note some future research problems related to this work.

(i) As mentioned in Remark 3.2, we plan to carry out a more detailed analytical error estimation for our schemes using the result on time asymptotics of exponential maps for SDEs by [6], since the stochastic series (2.26) is only a formal representation.

(ii) In our error estimation, we have addressed local and global error orders "in a weak sense" for our new schemes, since we have *indirectly* estimated the error orders for numerical solutions using these schemes. To obtain a precise local or global error order, it would be necessary to carry out a direct error estimation for such numerical solutions.

(iii) In this article, we have treated the SDEs with a one-dimensional Wiener process. However, it often happens that the error order of a numerical method collapses if there is more than one Wiener process. Hence, it would be important to investigate the error orders of our schemes in the case of SDEs with a multidimensional Wiener process. Moreover, in any approach to this problem, account should be taken of the remarkable work by K. Burrage and P.M. Burrage [4], [5]. In their papers, they have developed stochastic Runge–Kutta schemes of higher order for such SDEs through the Magnus formula related to Lie algebra. Therefore, based on their work, we should be able to improve our composition methods and offer new schemes with high order for SDEs with a multidimensional Wiener process.

(iv) It is to be noted that Li and Liu [18] and Kunita [17] have studied stochastic exponential maps for a more general class of stochastic processes (e.g., Lévy processes). Hence, using their results, it would be interesting to formulate stochastic composition methods for such general stochastic processes.

The research on these topics will be reported in future papers.

Acknowledgments. The author would like to thank Professor N. Nakamura, Professor M. Maejima, Professor Y. Miyahara, Professor S. Ogawa, and Professor A. Shimizu for useful discussions about the numerical approach to SDE (4.1). He also sincerely thanks Professor H. Kunita, Professor P. E. Kloeden, Professor K. Burrage, Professor T. Mitsui, Professor Y. Saito, and Professor M. Suzuki for their valuable suggestions and for making available their recent research.

MODIFICATION OF A FINITE VOLUME SCHEME FOR LAPLACE'S EQUATION[*]

N. B. PETROVSKAYA[†]

Abstract. For Laplace's equation, we discuss whether it is possible to construct a linear positive finite volume (FV) scheme on arbitrary unstructured grids. Dealing with the arbitrary grids, we state a control volume which guarantees a positive FV scheme with linear reconstruction of the solution. The control volume is defined by a property of the analytical solution to the equation and does not depend on the grid geometry. For those problems where the choice of the control volume is prescribed a priori, we demonstrate how to improve positivity of the linear FV scheme by using corrected reconstruction stencils. The difficulties arising when grids with no geometric restrictions are used for the discretization are discussed. Numerical examples illustrating the developed approach to the stencil correction are given.

Key words. Laplace's equation, finite volume scheme, positivity, stencil correction

1. Introduction.

A discrete Laplace operator is often considered to be a good model for investigating a discretization of partial differential equations which contain diffusion operator $\nabla\cdot(D\nabla)$. Two important examples are given by convection-diffusion equations and Navier–Stokes equations with possible applications that include the problems of fluid dynamics, chemical engineering, and environmental pollution. For the numerical solution of these equations, what is desirable are discretization schemes which satisfy a discrete maximum principle (monotone schemes); otherwise one can expect strong oscillations or even divergency of the solution.

There are two possible approaches for development of monotone schemes on unstructured grids. The first approach is to use the grids with some geometric constraints on the triangulation. It is well known that triangulations with no obtuse triangles allow us to construct monotone schemes. The relevant examples are given in [6, 11]. However, nonobtuse triangulations can be used on very few practical problems. In the process of the grid generation it is often required to resolve some complicated features of the problem geometry that makes strict angle control to be difficult.

Looking for a wider class of triangulations, in the two-dimensional case a Delaunay triangulation [10] is very attractive. For Laplace's equation, in the two-dimensional case the Delaunay triangulation provides positivity (that guarantees the discrete maximum principle) of the linear finite element/finite volume scheme (Barth [3]). This important property may be applied for the solution of a wide range of problems, even more general than discretization of the Laplace equation. For instance, Xu and Zikatanov [17] developed a linear monotone finite element scheme for convection-diffusion equations in any spatial dimension. To obtain a positive discretization of the diffusion operator they assumed the restrictive geometrical conditions which in the two-dimensional case mean that the triangulation is a Delaunay triangulation.

Sakovich [16] used a Delaunay triangulation to control the grid quality for the construction of the monotone scheme for the system of two-dimensional conservation laws. In [16] the Laplace equation has been discretized first on the Delaunay grid. The coefficients of this discretization have then been exploited to obtain grid quality functional for the unstructured grids considered in the work.

Although giving us all advantages of using monotone schemes, for many complex geometries (e.g., multicomponent airfoil configuration) the Delaunay triangulation does not provide grids optimal in the sense of the accuracy of the solution. In particular, the Delaunay triangulation does not control the maximum angle, so that nearly collapsed triangles may appear as the result of grid generation (Barth [4]). On the other hand, for the equations mentioned above, grid adaptation to the solution usually results in non-Delaunay meshes, while fully automatic generation of adapted Delaunay grids is a technically difficult task for many practical applications. That is why another approach appears, where the grids with no geometric restrictions are allowed for the discretization. In the present work, an effort has been made to investigate whether it is possible to construct a linear positive finite volume (FV) scheme for the Laplace equation on arbitrary unstructured grids. We demonstrate the impact of grid geometry on the quality of the FV scheme and discuss to what extent arbitrary grids are good for the positive discretization.

When dealing with the arbitrary grid cells, it has been shown many times that for linear FV schemes a proper choice of the control volume allows us to improve the results of the discretization both on the structured and unstructured grids. Barth and Linton [5] successfully used the containment dual volume instead of the median dual on stretched triangulated quadrilateral grids to compute viscous flows. Having applied the viscous term discretization to the Laplace operator, Delanaye et al. [8] showed that a correction of the diamond-shaped control volume on Cartesian grids leads to the more positive scheme and obtained a robust discretization of the viscous terms in Navier–Stokes equations. Putti and Cordes [13] have proposed a modification of the control volume that allowed them to obtain the positive discretization of the Laplace equation on three-dimensional Delaunay meshes. In all these cases the choice of the control volume has been dictated by the geometry of grid cells.

In the present paper we show that it is possible to derive a convex control volume which guarantees a positive FV scheme for the Laplace equation and does not depend on the grid geometry. A property of the analytical solution to the equation is taken into account for the construction of the control volume. Since a maximum principle is exploited to obtain the solution on the central node of a cell, the produced FV scheme is entirely positive on any two-dimensional unstructured mesh.

For those practical applications where the geometry of the control volume is prescribed by some a priori conditions, we discuss how to improve the measures of positivity of the linear FV scheme on non-Delaunay meshes. Based on the analysis of the grid cell geometry, the stencils used for the linear reconstruction are corrected to obtain a more positive scheme. For some triangles, additional nodes of the triangulation are included into the stencils, while "far" stencil nodes generating negative scheme coefficients are eliminated from the discretization. This correction technique gives good results, producing a linear "quasipositive" FV scheme on the arbitrary meshes.

The results obtained in the work lead us to a better understanding of the difficulties one may expect discretizing the Laplace equation on arbitrary meshes. The limits of using grids with no geometric restrictions for the positive discretization are

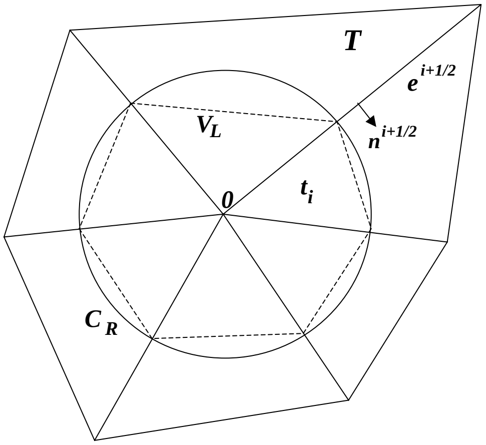

FIG. 1. *The geometry of an FV scheme for Laplace's equation.*

discussed in the conclusions.

2. Control volume for the discrete Laplace operator.

We consider Laplace's equation with Dirichlet boundary conditions in the unit square $\bar{\Omega}$:

$$\Delta u(x,y) \equiv \frac{\partial^2 u(x,y)}{\partial x^2} + \frac{\partial^2 u(x,y)}{\partial y^2} = 0, \quad (x,y) \in \Omega = (0,1) \times (0,1), \qquad (1)$$
$$u(x,y) = g(x,y), \quad (x,y) \in \partial\Omega.$$

Let a triangulation T be the union of all triangles t_i, $i = 1, \ldots, N$, incident to a central node 0 (see Figure 1). To obtain an FV discretization of (1) on node 0, the contour integral

$$\oint_{\partial V_{dual}} \frac{\partial u(x,y)}{\partial \mathbf{n}} dl = 0 \qquad (2)$$

is calculated over the edges of a control volume V_{dual} according to Green–Gauss theorem. For calculating $\frac{\partial u(x,y)}{\partial \mathbf{n}}$ =$(\nabla u, \mathbf{n})$ in (2) a linear reconstruction of the solution $u(x,y)$ in each triangle t_i is used:

$$u^i(x,y) = a_0^i + a_1^i x + a_2^i y. \qquad (3)$$

A standard stencil for the linear reconstruction in triangle t_i includes three nodes of the triangle. Expansion coefficients a_k^i, $k = 0,1,2$, in triangle t_i are calculated by the condition

$$u^i(x_k, y_k) = u(x_k, y_k) \equiv u_k.$$

After calculation $\frac{\partial u(x,y)}{\partial \mathbf{n}}$ and summation over all dual edges, the discrete Laplace operator on central node 0 is written as a weighted sum of nodal values u_n of the solution $u(x,y)$:

$$L(u) \equiv \sum_{n=0}^{N_T} \omega_n u_n = 0, \qquad (4)$$

where N_T is the number of the nodes of the triangulation. The requirement of non-negativity

$$\omega_0 < 0, \quad \omega_n \geq 0, \quad n = 1, \dots, N_T, \qquad \sum_{n=0}^{N_T} \omega_n = 0 \tag{5}$$

guarantees a maximum principle, which must hold for the discrete Laplacean (4) to provide stability and uniform convergence.

For the standard FV scheme (4) coefficients ω_n depend on what control volume V_{dual} is used for the discretization. A possible choice is a median dual or a centroid dual. The discretizations obtained over these control volumes are consistent and conservative, but they are not positive on arbitrary triangulations. Below we consider the following problem: *For arbitrary triangulation T, find a control volume V_L which provides conditions* (5) *for the scheme* (4).

Let $\mathbf{r}_0 = (x_0, y_0)$ be a radius-vector of central node 0: $u(\mathbf{r}_0) = u_0$. An analytical expression for the solution to the Laplace equation in point $\mathbf{r}_0$ is

$$u(\mathbf{r}_0) = \frac{1}{2\pi R} \int_{C_R} u(x,y)dl, \tag{6}$$

where C_R is the circumference of radius R, the circle center being point $\mathbf{r}_0$. Since triangulation T may contain boundary edges, the value R is restricted by the requirement $C_R \subset T$ to provide $u(x,y)$ being a harmonic function inside the circle C_R. Note that formula (6) expresses a maximum principle for Laplace's equation.

We calculate integral (6) assuming the linear reconstruction (3) of the solution. Substituting (3) into (6) and integrating over a circle arc A_i, we obtain the integral term for triangle t_i:

$$\begin{aligned}
\frac{1}{2\pi R} \int_{A_i} u(x,y)dl &= \frac{1}{2\pi R} \int_{A_i} (a_0^i + a_1^i x + a_2^i y)dl \\
= \frac{1}{2\pi R} &\int_{\phi_1^i}^{\phi_2^i} (a_0^i + a_1^i x_0 + a_2^i y_0 + a_1^i R\cos\phi + a_2^i R \sin\phi) R d\phi \\
= u_0 \frac{\delta\phi^i}{2\pi} &+ \frac{R}{2\pi}[a_1^i(\sin\phi_2^i - \sin\phi_1^i) - a_2^i(\cos\phi_2^i - \cos\phi_1^i)],
\end{aligned}$$

where ϕ_1^i and ϕ_2^i are the arc angles and $\delta\phi^i = \phi_2^i - \phi_1^i$. The summation over all triangles yields

$$u_0 = \frac{u_0}{2\pi} \sum_{i=1}^{N} \delta\phi_i + \frac{R}{2\pi} \sum_{i=1}^{N} [a_1^i(\sin\phi_2^i - \sin\phi_1^i) - a_2^i(\cos\phi_2^i - \cos\phi_1^i)].$$

Noting that $\sum_{i=1}^{N} \delta\phi_i = 2\pi$, the following condition for a discrete Laplace operator with the linear reconstruction appears:

$$\sum_{i=1}^{N} [a_1^i(\sin\phi_2^i - \sin\phi_1^i) - a_2^i(\cos\phi_2^i - \cos\phi_1^i)] = 0. \tag{7}$$

Since $\nabla u^i = (a_1^i, a_2^i)$ and $\mathbf{n}^{i+1/2} = (\sin\phi_2^i, -\cos\phi_2^i)$, where $\mathbf{n}^{i+1/2}$ is the unit normal vector for an interior edge $\mathbf{e}^{i+1/2}$, condition (7) takes the following form:

$$\sum_{i=1}^{N} (\nabla u^i, \mathbf{n}^{i+1/2} - \mathbf{n}^{i-1/2}) = 0. \tag{8}$$

Now let us consider a control volume V_L defined as a convex polygon created by connecting in every triangle t_i the endpoints of arc A_i (see Figure 1). For control volume V_L, the difference $\mathbf{n}^{i+1/2} - \mathbf{n}^{i-1/2}$ gives a vector, normal to dual edge $\mathbf{e}_L^i$. The unit outward normal vector $\mathbf{n}^i$ to edge $\mathbf{e}_L^i$ is calculated as

$$\mathbf{n}^i = \frac{R}{|\mathbf{e}_L^i|}(\mathbf{n}^{i+1/2} - \mathbf{n}^{i-1/2});$$

therefore, a flux Φ^i across edge $\mathbf{e}_L^i$ is

$$\Phi^i = |\mathbf{e}_L^i|(\nabla u^i, \mathbf{n}^i) = R(\nabla u^i, \mathbf{n}^{i+1/2} - \mathbf{n}^{i-1/2}).$$

Multiplying by R and taking into account that in the case of linear reconstruction (3) the sum (8) is the result of the exact integration, formula (8) transforms into the following:

$$\oint_{\partial V_L} \frac{\partial u(x,y)}{\partial \mathbf{n}} dl = 0. \tag{9}$$

The above results show us that the calculation of the solution on the central node of the triangulation by using formula (6) with condition (3) is equivalent to the linear FV discretization over control volume V_L. For the discretization over V_L, maximum principle (6) holds; therefore, scheme (4) is entirely positive on any two-dimensional unstructured mesh.

3. Correction of the stencils used for linear reconstruction. The construction of control volume V_L provides us with the positive discretization. However, on arbitrary grids the convex dual V_L is not consistent with the grid cell geometry, since gaps (or overlappings) appear in a convex dual mesh when stretched grid cells are considered. Concerning the issue of positivity, our next purpose is to discuss how far the geometry of the grid cells impacts on the discretization and whether it is possible to obtain the positive discretization (4) over the given control volume which completely covers domain Ω.

For the prescribed geometry of dual cell V_{dual} , the only way to render the fluxes in (2) closer to those in (9) is to change the approximation of the gradients. The following example illustrates the situation. Suppose a flux Φ_1 obtained as a result of the discretization on control volume V_L in triangle t_i is given as follows (index i is omitted):

$$\Phi_1 = (a_1 n_1 + a_2 n_2)|\mathbf{e}_L|.$$

Now consider a control volume V_{dual} different from V_L. Provided the same reconstruction (a_1, a_2) of the gradient is used, the discretization on control volume V_{dual} results in a flux Φ_2:

$$\Phi_2 = (a_1 n_1^{dual} + a_2 n_2^{dual})|\mathbf{e}_{dual}|,$$

where $\mathbf{n}^{dual} = (n_1^{dual}, n_2^{dual})$ is the unit vector, normal to control volume edge $\mathbf{e}_{dual}$ in triangle t_i. Evidently, if it is possible to find in every triangle t_i the new approximation of the gradient

$$\bar{a}_k = a_k \frac{n_k |\mathbf{e}_L|}{n_k^{dual}|\mathbf{e}_{dual}|} \quad k = 1, 2,$$

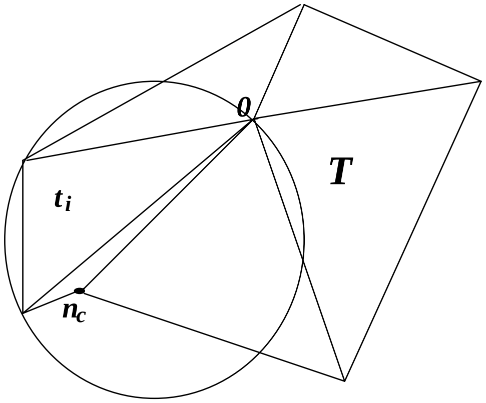

FIG. 2. *The Delaunay correction: implementation of a circumcircle test to include close nodes into the reconstruction stencil.*

then the positive scheme is guaranteed.

Below we consider modifications of a standard FV scheme obtained by including other nodes of the triangulation into the reconstruction stencils. In this case the following least squares problem is solved to calculate expansion coefficients a^i in triangle t_i:

$$\sum_{l=0}^{N_s}(u^i(x_l,y_l)-u(x_l,y_l))^2=\min, \tag{10}$$

where N_s is the number of stencil nodes, $N_s > 3$. Using extended stencils, it is possible to change the values of a^i in (2) and improve the discretization as a result. The crucial question for such a correction of the reconstruction stencils is how to select additional nodes.

Since a Delaunay triangulation provides a positive discretization on a dual cell different from V_L, the choice of convex polygon V_L as a control volume is not a necessary condition for the positive discretization. On the other hand, a simple linear search of the triangulation nodes shows that for many triangulations there is a variety of extended stencils providing a positive scheme. These facts allow us to suggest an existence of a more than one way for the stencil correction.

Unlike the linear reconstruction on a 3-point stencil, where it is possible to state exact conditions of positivity (cf. [3]), a strict geometric analysis of the scheme coefficients in the case of using the least squares method is very laborious and can hardly lead to production a fast and cheap algorithm for getting a positive scheme. That is why our present intention is not to obtain a rigorous mathematical formulation but to develop a reliable empirical approach to the selection of stencils.

The first possible way of stencil correction is based on the following hypothesis. Consider triangulation T shown in Figure 2. Since it is intuitively clear that it would be reasonable to include the closest to triangle t_i node n_c into the reconstruction stencil in the triangle, the following question arises:

Given triangulation T, differential operator $\mathcal{L}[u]$, and polynomial basis set $\{\Psi\}$ for a linear reconstruction, what is measure $M(T,\mathcal{L}[u],\{\Psi\})$ of proximity of stencil nodes? In other words, what nodes can be considered as being close to reconstruction stencil t_i?

Based on the theorem (Barth [3]), which states positivity of an FV scheme with a linear reconstruction on Delaunay triangulations, we suggest that for the Laplace operator the right answer to the above question is given by a circumcircle criterion which is the unique characterization of the Delaunay triangulation (Joe [10]). Namely, if node n_c belonging to T lies inside the circumcircle of given triangle t_i , it is considered as being close to the given triangle and should be included into reconstruction stencil t_i. In the general case, if the number k of triangulation nodes lie inside the circumcircle, they are included into the stencil for the reconstruction in triangle t_i by using the least squares method. This way of the stencil selection we call the Delaunay correction (DC).

For each grid node where the standard FV scheme is nonpositive, the algorithm for the Delaunay correction may be written as follows:

```
1. Define triangulation $T$ as a the union of all triangles $t_i$, $i = 1, \dots, N$, incident
   to the central node, and put all nodes of the triangulation (except of the central
   one) into array $T\_nodes$.
2. $For$ each triangle $t_i \subset T$, $Do$:
   2.1. Define the reconstruction stencil $S_i$ as a set of triangle's vertices.
   2.2. Define circumcircle $C_i$.
   2.3. Form array $marked\_nodes$ as a subset of the set $T\_nodes$:
      – $For$ each node $n_k$, $1 \leq k \leq N_T$, from the array $T\_nodes$ $Do$:
      – $If$ the circumcircle $C_i$ contains the node $n_k$ $And$ the node $n_k \notin S_i$ $Then$:
      – Add $n_k$ to the array $marked\_nodes$.
      – $EndDo$
   2.4. Include all nodes from the array $marked\_nodes$ into the reconstruction
        stencil $S_i$ by using the least squares method.
3. $EndDo$
```

Now let us discuss another type of the grid cell geometry. For triangulation T shown in Figure 3, there are no nodes obviously close to triangle t_i. On the contrary, node n_f is so far from others that if we were allowed to reconnect the nodes of the triangulation, it would be natural to connect node n_i with node n_l and remove n_f from T. Thus, another important for a proper correction of stencils question may be formulated as follows:

Given triangulation T, differential operator $\mathcal{L}[u]$, and basis set $\{\Psi\}$ for a linear reconstruction , what nodes have no effect on a discretization of $\mathcal{L}[u]$? In other words, what nodes in t_i can be considered as being far from any other reconstruction stencil?

To answer this question ("inverse" to the previous one), again consider formula (6) for solution u_0 on central node 0. We define the value R_{max} as the maximum radius which holds the requirement $C_R \subset T$ stated in the previous section (see Figure 3). Evidently, only those R which satisfy

$$R \leq R_{max} \tag{11}$$

should be considered in (6). Due to inequality (11) we conclude that for the discretization of the Laplace operator a characteristic size of the triangulation is not the maximum edge length but radius R_{max}. To make certain that far node n_f with the edge length $|\mathbf{e}_f| \gg R_{max}$ is odd for the scheme on node 0, let us consider standard FV scheme (4) on a median dual. According to [3], the coefficient ω_{n_f} corresponding to node n_f is calculated as

$$\omega_{n_f} = \frac{1}{2}\left(\frac{\sin(\alpha_i + \alpha_l)}{\sin(\alpha_i)\sin(\alpha_l)}\right), \tag{12}$$

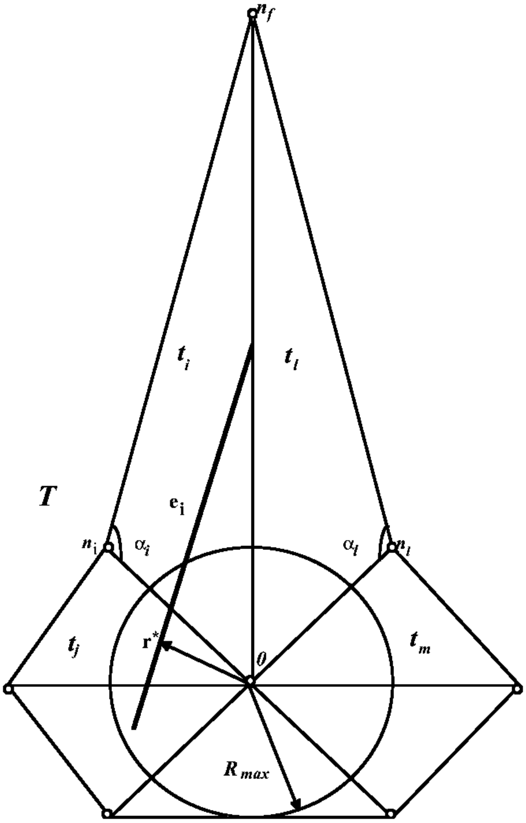

FIG. 3. *The gradient correction: elimination of a "far" node from the reconstruction stencil.*

where angles α_i and α_l are depicted in Figure 3. It can be seen from the figure that the more distant node n_f is from the central node of the triangulation, the more obtuse are the angles α_i and α_l. Obviously, the condition $\alpha_i + \alpha_l \leq \pi$, necessary for positive ω_{n_f}, fails for far node n_f.

To develop a correction technique for the stencils which contain node n_f, consider linear reconstruction (3) on a median control volume in triangle t_i. Since the gradient is constant in triangle t_i, the value of $\frac{\partial u}{\partial \mathbf{n}}$ in (2) is also constant at any point inside the given control volume in t_i

$$\frac{\partial u}{\partial \mathbf{n}} \approx a_1^i n_1^i + a_2^i n_2^i = \text{const} = C^i, \tag{13}$$

where $\mathbf{n}^i = (n_1^i, n_2^i)$ is the unit vector, normal to a control volume edge e_i. On the other hand, by definition,

$$\frac{\partial u}{\partial \mathbf{n}} = \lim_{\Delta t \to 0} \frac{u(\mathbf{r}_0 + \Delta t \mathbf{n}) - u(\mathbf{r}_0)}{\Delta t},$$

and we approximately calculate $\frac{\partial u}{\partial \mathbf{n}}$ at point $\mathbf{r}_0 \in t_i$ as

$$\frac{\partial u}{\partial \mathbf{n}} \approx \frac{u(\mathbf{r}^*) - u(\mathbf{r}_0)}{|\mathbf{r}^* - \mathbf{r}_0|}, \tag{14}$$

where $\mathbf{r}^* = (x^*, y^*)$ is an interior point of triangulation T, point $\mathbf{r}^*$ belongs to the line, normal to edge e_i, and $u(\mathbf{r}_0) = u_0$. The linear reconstruction at point $\mathbf{r}^*$ yields

$$u(\mathbf{r}^*) - u(\mathbf{r}_0) = a_0^* + a_1^* x^* + a_2^* y^* - u_0 = a_1^*(x^* - x_0) + a_2^*(y^* - y_0). \tag{15}$$

Since the components of the normal vector may be calculated as

$$n_1^i = \frac{x^* - x_0}{|\mathbf{r}^* - \mathbf{r}_0|}, \qquad n_2^i = \frac{y^* - y_0}{|\mathbf{r}^* - \mathbf{r}_0|},$$

we obtain from (14) and (15)

$$\frac{\partial u}{\partial \mathbf{n}} \approx a_1^* n_1^i + a_2^* n_2^i = \text{const} = C^*. \tag{16}$$

In "nice" triangle t_i point $\mathbf{r}^* \in t_i$; therefore,

$$a_1^* = a_1^*(u_0, u_1^i, u_2^i) = a_1^i, \qquad a_2^* = a_2^*(u_0, u_1^i, u_2^i) = a_2^i,$$

and the values C^i and C^* are the same. In "bad" triangle t_i point $\mathbf{r}^*$ belongs to another triangle t_j (see Figure 3), where the gradient depends on the values u_1^j and u_2^j: $\boldsymbol{a}^* = (a_1^*, a_2^*) = \boldsymbol{a}^*(u_0, u_1^j, u_2^j) = \boldsymbol{a}^j \neq \boldsymbol{a}^i$. In this case, when formula (13) is used for calculating $\frac{\partial u}{\partial \mathbf{n}}$, a nonphysical flux across edge e_i appears:

$$\begin{aligned}\left(\frac{\partial u}{\partial \mathbf{n}}\right)_{false} = C^* - C^i &= (a_1^* n_1^i + a_2^* n_2^i) - (a_1^i n_1^i + a_2^i n_2^i) = (a_1^j - a_1^i) n_1^i + (a_2^j - a_2^i) n_2^i \\ &= (\boldsymbol{\nabla} u_{false}, \mathbf{n}^i),\end{aligned}$$

where the false gradient $(\boldsymbol{\nabla} u)_{false}$ is defined as the difference between the gradients in triangles t_j and t_i, respectively. To improve the situation when false gradients appear, we suggest in "bad" triangle t_i to include stencil t_j into the reconstruction in t_i by using the least squares method. Another even more radical way is to change the stencil t_i by stencil t_j. These corrections change the value of the gradient in triangle t_i that may decrease the nonphysical flux. We refer to such a correction technique as the gradient correction (GC). Numerical experiments show that for geometry T from Figure 3 the gradient correction results in the positive scheme when the stencil points from triangles t_j and t_m are captured to form extended stencils for triangles t_i and t_l, respectively.

The idea of GC correction leads us to the following algorithm.

```
1. Define triangulation $T$ and all control volume edges $e_i$, $i = 1, \dots, N$.[1]
2. *For* each triangle $t_i \subset T$, *Do*:
    2.1 Define the reconstruction stencil $S_i$ as a set of triangle's vertices.
    2.2 Define point $\mathbf{r}^*$ as a point of intersection between the line $e_i$ and the perpendicular dropped to the line $e_i$ from the central node of the triangulation.
    2.3 Find a triangle $t_j$ point $\mathbf{r}^*$ belongs to.
    2.4 If $j \neq i$, include nodes of the triangle $t_j$ into the reconstruction stencil $S_i$ by using the least squares method.
3. *EndDo*
```

[1] According to Green–Gauss theorem, it is possible to consider a segment e_i created by connection of the edge midpoints (see Figure 3) instead of treating two median segments in each triangle.

Concerning practical realization of the suggested correction technique, there are still some open questions. Thus for the Delaunay correction, it is unclear whether or not the nodes which lie on a circumcircle boundary should be included into the reconstruction. Similar questions arise in the implementation of the GC. For instance, in the case when point $\mathbf{r}^*$ comes to an edge of the triangulation it is possible to include either one of the adjacent triangles or both of them into the stencil. Also, point $\mathbf{r}^*$ may coincide with a grid node n_g or lay outside domain $\bar{\Omega}$.

Since there is no strict mathematical foundation of the suggested algorithms, only practical recommendations can be given for correct treatment of these cases. One may find extended discussion based on our numerical experience with the correction algorithms in [12].

To conclude this section, let us make some remarks on the possible implementation of the suggested algorithms. Considering the discretization of a given differential operator on unstructured grids where stretched cells can appear, a most important problem is how to indicate cells which are "bad" for the discretization. Although the strict mathematical conditions based on error estimation are obtained for some important cases (Babuška and Aziz [1]), and stretched triangular cells proved to not always be bad (Rippa [14]), the general concept of "bad" or "nice" triangles requires further analysis, its formulation depending upon what differential operator is considered and what discretization method is used. For the FV discretization of the Laplace equation, the developed technique provides us with a kind of an empirical indicator of the "bad"/"nice" triangle, as those triangles where the stencil correction is needed may be considered as the "bad" ones.

4. Numerical results. The aim of this section is to present numerical validation of the suggested ways of the stencil correction. Unfortunately, by now we are not able to formulate precisely under what conditions each correction algorithm should be implemented. That is why a combined approach is used to correct scheme stencils. For those nodes where the standard FV scheme (4) is nonpositive, both DC and GC scheme stencils are constructed. Then the stencil providing the least nonpositive scheme is selected. This procedure may appear rather costly, but keeping in mind our present purpose we do not discuss here a computational efficiency of the developed algorithm.

To assess nonpositivity of the scheme coefficients we use a simple criterion taken from the work (Coirier [7]). Let us rewrite (4) as

$$u_0 = \sum_{n=1}^{N_T} \alpha_n u_n,$$

where $\alpha_n = -\omega_n/\omega_0$. Then the value α_{min}

$$\alpha_{min} = \frac{\min_{1\leq n\leq N_T}(\alpha_n, 0)}{\sqrt{\sum_{n=0}^{N_T} \frac{\alpha_n^2}{N_T}}} \tag{17}$$

is a measure of positivity[2] of the scheme coefficients for the given node u_0. For the nonpositive function α_{min} defined on the grid nodes we introduce the following

[2] The definition of α_{min} formally misses the case when $\omega_n < 0 \ \forall n \neq 0$, $\omega_0 > 0$. In practice, this case should be treated separately as it indicates strong degeneration of an FV volume cell. The consideration of this situation is beyond the scope of the paper.

Table 1

Positivity measures for standard (FVS) and corrected (CS) FV schemes with linear reconstruction.

Grid	$\alpha^{L_1}_{min}$		α^{C}_{min}	
	FVS	CS	FVS	CS
$G1$	-0.191	$-9.6 \cdot 10^{-3}$	-1.355	-0.354
$G2$	-0.126	$-6.9 \cdot 10^{-3}$	-3.593	-0.411
$G3$	-0.437	$-2.42 \cdot 10^{-2}$	-1.696	-0.377
$G4$	-0.188	$-4.2 \cdot 10^{-3}$	-1.587	-0.241
$G5$	-0.416	$-3.45 \cdot 10^{-2}$	-1.438	-0.412
$G6$	-0.485	$-7.2 \cdot 10^{-3}$	-1.602	-0.286

quantity:

$$\alpha^{L_1}_{min} = \frac{\sum_{m=0}^{N_g} \alpha^{m}_{min}}{N_g},$$

where N_g is the number of mesh nodes. The value $\alpha^{L_1}_{min}$, as well as α^{C}_{min}, where

$$\alpha^{C}_{min} = \min_{m}\{\alpha^{m}_{min}\},$$

are used to estimate nonpositivity of the discretization over the whole mesh. Evidently, $\alpha^{L_1}_{min} = 0$ for an entirely positive scheme.

What are reasonable values for the parameter α_{min}? Coirier [7] has investigated a number of different stencils for an FV discretization of the Laplace equation on adaptive Cartesian grids for further implementing to the Navier–Stokes equations. It was found that schemes with $\alpha^{L_1}_{min} \sim -10^{-1} \div -10^{-2}$ are acceptable for calculating a low Reynolds number laminar flow. At the same time the discretization with $\alpha^{L_1}_{min} \sim -1.0$ proved to be divergent. Delanaye et al. [8] have also considered a discrete Laplacean on Cartesian meshes. They discovered that the value $\alpha^{L_1}_{min} = -1.62$ leads to the loss of the scheme stability. After stencil correction a new value $\alpha^{L_1}_{min} = -0.366$ provided convergence to the solution. Based on these results, in our work we consider stencils with $\alpha^{L_1}_{min} \sim -1.0$ to be strongly nonpositive.

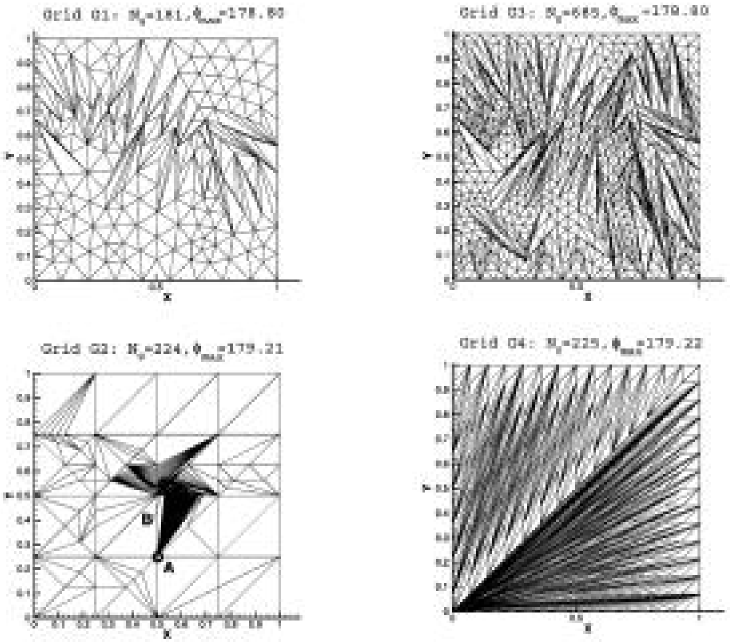
Our first numerical experiment is to verify that the corrected scheme exhibits better measures of positivity. A number of grids with various geometries of grid cells have been generated to test suggested correction algorithms. Generating these "bad" grids, the main requirement was to produce the most possible number of non-Delaunay cells, where a standard FV scheme is nonpositive. The grids are shown in Figures 4 and 5.

To calculate the positivity measures, the Laplace equation is discretized in the unit square with the following boundary conditions:

$$u(x,0) = x^2, \quad u(0,y) = y^2, \quad u(x,1) = x^2 - 1, \quad u(1,y) = 1 - y^2. \tag{18}$$

The values of $\alpha^{L_1}_{min}$ and α^{C}_{min} for the standard FV scheme and the corrected scheme calculated on the generated grids are shown in Table 1. It can be seen from the table that the corrected scheme is much more positive than the standard one. Examples of function $\alpha_{min}(x_i, y_i)$ for the standard and the corrected schemes on some of generated grids are shown in Figure 5.

Grid G2 (see Figure 4) gives us a nice example of how the GC algorithm treats stretched cells. Fans on the grid are generated using the "torture test" idea (GGNS



Grid G1: N_g=181, φ_max=178.80
Grid G3: N_g=685, φ_max=179.80
Grid G2: N_g=224, φ_max=179.21
Grid G4: N_g=225, φ_max=179.22

FIG. 4. *Examples of "bad" grids used to estimate positivity measures of the corrected FV scheme; N_g is the number of the grid nodes, ϕ_{max} is the maximum grid angle (in degrees).*

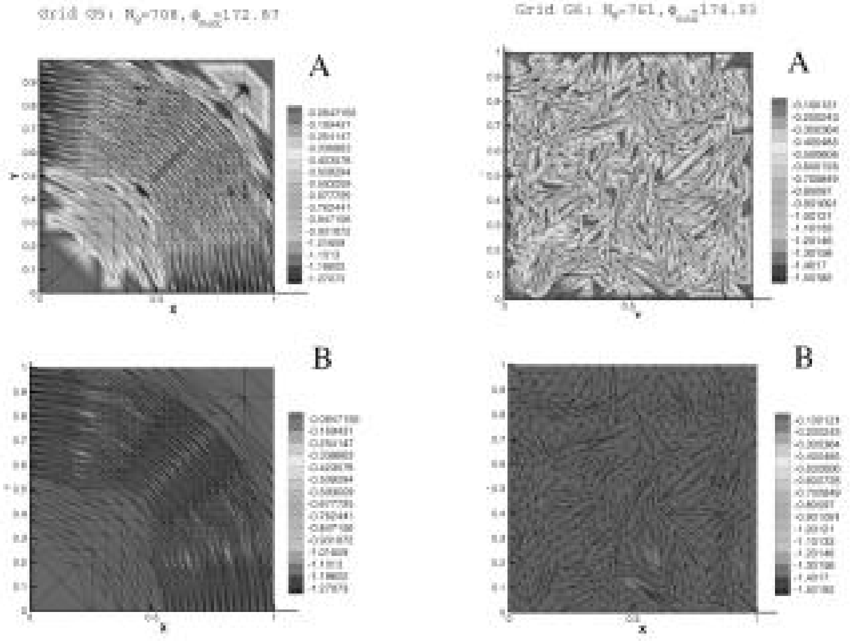

FIG. 5. *Function $\alpha_{min}(x, y)$ for (*A*) the standard and (*B*) the corrected FV scheme with the linear reconstruction.*

team [9]). In this test the following procedure has been implemented to generate a grid with large angles. At each step of the grid generation, the boundary problem (e.g., the convection-diffusion equation with Dirichlet boundary conditions in the considered example) is solved numerically. Given the numerical solution, a new grid node is always placed in the cell with the maximum solution error and the old triangle is subdivided into three triangles to increase the maximum angle in the new triangles. Then the boundary problem is solved again over the new grid, and the above procedure is repeated until the required value of the maximum angle is reached.

As a result of the grid generation, each of the triangulations with central nodes A and B shown in Figure 4 comprises 85 nodes. The standard FV discretization of the boundary problem (18) on median control volume produces the extremely nonpositive scheme on nodes A and B : $\alpha_{min}(A) = -3.498$, $\alpha_{min}(B) = -3.593$. For triangulations A and B, the gradient correction not only renders the scheme positive ($\alpha_{min}(A) = \alpha_{min}(B) = 0.0$) but also crucially transforms the scheme stencils N_s^A and N_s^B. New stencil N_s^A for the scheme in node A includes seven nodes while new stencil N_s^B includes only five nodes.

Our next test is to compare convergence to the exact solution for the standard and the corrected schemes. Due to the strong distortion of the finite volume cells the "bad" grids generated in the previous test exhibit poor approximation properties that makes it difficult to assess the convergence rate. That is why for the convergence test we generate a sequence of model meshes as follows. First, cells of a uniform Cartesian grid are cut by two diagonals. Then, the central node in each Cartesian cell is moved down vertically to increase the angle ϕ_{max} corresponding to the central node. Thus a parametric family of meshes with different geometry of stencils can be obtained, the maximum grid angle ϕ_{max} ($\pi/2 \leq \phi_{max} < \pi$) being a controlling parameter. The angle $\phi_{max} = \pi/2$ determines the standard grid considered in the previous test and provides positive standard FV discretization. For any angle $\phi_{max} > \pi/2$ the standard FV scheme is nonpositive.

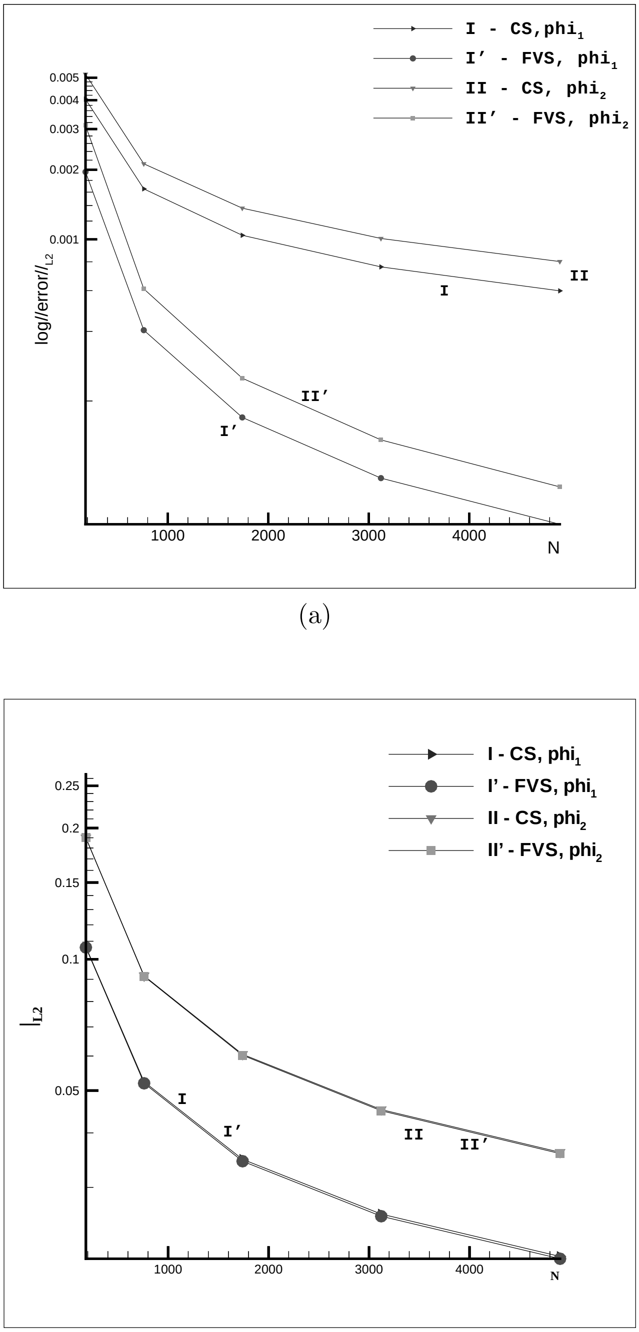
For the convergence test we solve the following boundary problem in the unit square:

$$u(x,0) = \cos(\omega x), u(0,y) = \exp(\omega y), u(x,1) = \cos(\omega x)\exp(\omega), u(1,y) = \cos(\omega)\exp(\omega y). \tag{19}$$

The analytical solution to the problem is

$$u(x,y) = \cos(\omega x)\exp(\omega y). \tag{20}$$

The numerical solution is calculated for the value $\omega = -5.0$. The convergence results for both the standard FV scheme (FVS) and the corrected scheme (CS) are plotted in Figure 6. The error measured in the L^2-norm is shown in the semilogarithmic scale. The value of ϕ_{max} has been varied to study how the convergence rate depends on the maximum grid angle. Figure 6(a) shows the convergence history for the solution on grids with $\phi_{max} \equiv \phi_1 = \frac{2}{3}\pi$ (curves I and I' in the figure for the CS and FVS, respectively). Curves II and II' in the figure present the convergence results for the value $\phi_{max} \equiv \phi_2 = \frac{5}{6}\pi$. In both cases the corrected scheme converges, although the rate of the convergence is slower in comparison with that for the standard scheme. Let us note that for the corrected scheme the approximation over nonsymmetric stencils may impact on the convergence rate as well as geometric degeneration of the finite volume cells. These two factors may slow down the convergence rate on the grids with large values of angle ϕ_{max}.



(a)

(b)

FIG. 6. *Convergence test problem* (19), (20). *The convergence history of* (a) *the solution and* (b) *the gradient for the corrected (curves* I, II*) and the standard (curves* I', II'*) schemes.*

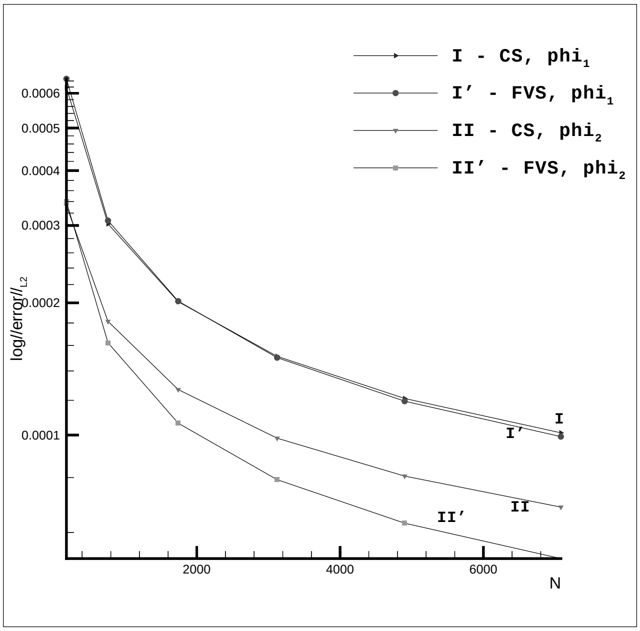


FIG. 7. *Convergence test problem with discontinous boundary conditions* (21), (22). *The convergence history of the solution for the corrected (curves* I, II*) and standard (curves* I', II'*) schemes.*

The convergence history for the gradient obtained on grids with the same values of ϕ_{max} is shown in Figure 6(b). As can be seen from the figure, the gradient convergence results are almost the same for both schemes.

For the function $u(x, y)$ considered in the test, the effect of the triangle geometry on approximation is that increasing the angle ϕ_{max} leads to the slower convergence rate for both standard and corrected schemes. In our numerical experiments we have obtained the slowest convergence rate for the extreme case of $\phi_{max} = 0.99\pi$.

Now we consider the problem with discontinuous boundary conditions

$$(21)\ u(x,0) = 0, \quad u(0,y) = 0, \quad u(x,1) = u_0, \quad u(1,y) = \frac{2u_0}{\pi} arctg\left(th\frac{\pi}{2} tg\frac{\pi y}{2}\right).$$

The analytical solution to the problem is given by function

$$(22) \qquad u(x,y) = \frac{2u_0}{\pi} arctg\left(th\frac{\pi x}{2} tg\frac{\pi y}{2}\right).$$

Convergence to the exact solution for the FVS and the CS is shown in Figure 7. The plots are obtained for the same values of angle ϕ_1 (curves I and I' in the figure for the CS and FVS, respectively) and ϕ_2 (curves II and II'), the parameter $u_0 = 0.1$. As one can see from the figure, the convergence rate is slightly different for stencils with $\phi_{max} = \phi_1$, while for $\phi_{max} = \phi_2$ the standard scheme converges noticeably better. The dependence of the convergence rate on the maximum grid angle is not so trivial as in the previous example; for a wide range of ϕ_{max} the greater value of the maximum grid angle provides the better convergence for both schemes. However, for angles ϕ_{max} close to π the degeneration of FV cells becomes as strong as to make the convergence rate slower.

Table 2
GMRES convergence test for standard (FVS) and corrected (CS) FV schemes.

N	FVS	CS	N_{st}	FVS_{st}
181	29	14	181	10
685	95	28	761	20
2665	251	69	3121	43

In our code we use GMRES algorithm (Saad [15]) to solve the algebraic system of equations obtained as a result of the discretization. The convergence of GMRES depends on the condition number of the system matrix A. A low rate of the convergence corresponds to a poorly conditioned matrix, while positive definite matrix A provides the best rate of convergence [15]. That is why the study of the convergence rate of GMRES may be considered as stability test for the corrected scheme.

To assess the GMRES convergence rate, the convergence test has been taken from the PETSc library (Balay et al. [2]). In this test the number of iterations necessary to meet the convergence is counted, the other GMRES parameters being fixed.

The sequence of “bad” grids with the number N of grid nodes, where the standard scheme produces a poorly conditioned matrix A, is generated by isotropic refinement of grid G3 shown in Figure 4. For each “bad” grid, the standard grid with the similar number N_{st} of nodes, where the standard FV scheme produces the positive definite matrix A, is generated by cutting cells of a uniform Cartesian grid by two diagonals. The convergence rate of GMRES for both the standard (FVS) and the corrected (CS) schemes on “bad” grids is then compared with the results obtained for the FV scheme on the corresponding standard grid (FVS_{st}). Table 2 reports the number of GMRES iterations needed for the convergence. The test matrix A is generated for the boundary problem (18).

As one may expect, the “quasi-positive” corrected scheme produces a well-conditioned system matrix even on “bad” grids and, therefore, requires essentially fewer number of GMRES iterations than the standard scheme. The GMRES convergence rate for the corrected scheme is close to that obtained for the positive defined matrix A.

5. The three-dimensional case. In this section, we briefly discuss whether it is possible to extend the obtained results to the three-dimensional case. Let T be the volume formed by the union of all tetrahedra t_i, $i = 1, \dots, N$, which have the central node 0 as a common vertex. Consider a sphere S_R of radius R with the center at the point $\mathbf{r}_0$. As in the two-dimensional case, it is possible to introduce a control volume V_L as a convex polyhedron with faces created by setting in each tetrahedron t_i the plane passing through the points of intersection between the sphere S_R and the edges of the tetrahedron. Let us calculate the solution on the central node of the triangulation by using the formula

$$u(\mathbf{r}_0) = \frac{1}{4\pi R^2} \int_{S_R}\!\!\int u(x, y, z) ds. \tag{23}$$

We assume the linear reconstruction of the solution in each tetrahedron t_i:

$$u^i(x, y, z) = a_0^i + a_1^i x + a_2^i y + a_3^i z = a_0^i + (\boldsymbol{\nabla} u^i, \mathbf{r}). \tag{24}$$

For integration over the sphere the vector $\mathbf{r}$ in (24) is

$$\mathbf{r}(x, y, z) = \mathbf{r}_0 + R\mathbf{n}_s, \tag{25}$$

where $\mathbf{n}_s$ is the unit vector normal to the sphere surface. Substitution of (24), (25) into (23) and summation over all tetrahedra yields

$$u(\mathbf{r}_0) = \frac{1}{4\pi R^2}\sum_{i=1}^{N}\int_{S_R^i}\!\!\int \left[a_0^i + (\boldsymbol{\nabla} u^i, \mathbf{r}_0 + R\mathbf{n}_s)\right] ds = u(\mathbf{r}_0) + \frac{1}{4\pi R}\sum_{i=1}^{N}\int_{S_R^i}\!\!\int (\boldsymbol{\nabla} u^i, \mathbf{n}_s) ds. \tag{26}$$

The equality (26) gives us the following condition which may be considered as a finite volume discretization of the Laplace equation over the sphere S_R:

$$\sum_{i=1}^{N}\int_{S_R^i}\!\!\int (\boldsymbol{\nabla} u^i, \mathbf{n}_s) ds = 0. \tag{27}$$

It can be seen from (23), (27) that the discretization over the sphere provides us with the positive scheme. The sufficient condition, which allows us to consider in (27) the polyhedron V_L instead of the sphere S_R as a control volume providing the positive scheme, is that

$$\int_{S_R^i}\!\!\int (\boldsymbol{\nabla} u^i, \mathbf{n}_s) ds \equiv \int_{V_L^i}\!\!\int (\boldsymbol{\nabla} u^i, \mathbf{n}_s) ds \quad \forall i = 1, \ldots, N, \tag{28}$$

where the face V_L^i of V_L belongs to the tetrahedron t_i. However, unlike the two-dimensional case, this condition does not hold for the inscribed polyhedron V_L. Let S_{side}^i be the union of the three plane segments of the tetrahedron faces in the tetrahedron t_i, each segment being bounded by the edge of V_L^i, the circle arc of S_R^i, and the edges of t_i. To estimate the integral over S_R^i in (28), we consider for each tetrahedron t_i the auxiliary closed surface S_{aux}^i which comprises S_{side}^i, the face V_L^i, and the part S_R^i of the sphere. Since the gradient is a constant vector in each tetrahedron, the integral (28) may be transformed as

$$\int_{S_R^i}\!\!\int (\boldsymbol{\nabla} u^i, \mathbf{n}_s) ds = \left(\boldsymbol{\nabla} u^i, \int_{S_R^i}\!\!\int d\mathbf{s}\right),$$

where a vector elemental area $d\mathbf{s} = \mathbf{n}_s ds$. According to the gradient theorem,

$$\oiint_{S_{aux}^i} d\mathbf{s} \equiv \int_{S_R^i}\!\!\int d\mathbf{s} + \int_{V_L^i}\!\!\int d\mathbf{s} + \int_{S_{side}^i}\!\!\int d\mathbf{s} = 0.$$

It is not difficult to see that $\int_{S_{side}^i}\!\int d\mathbf{s} \neq 0$; therefore, the weight coefficients of the discretization over the control volume V_L are different from those in (27). Thus, in the three-dimensional case the condition (28) sufficient for the positive discretization does not hold.

Now we consider a discretization over the prescribed control volume V_{dual} defined as a polyhedron with faces e_i constructed under some geometric conditions (i.e., median or centroid dual). As in the two-dimensional case, we suggest that including close nodes into the reconstruction stencil provides us with a more positive scheme. Since the results of [13] demonstrate that it is possible to obtain the positive scheme for the Laplace equation on three-dimensional Delaunay meshes, we believe that a circumsphere criterion may be used to find the nodes close to the given tetrahedron t_i. If node n_c belonging to T lies inside the circumsphere S_i , it may be considered as being close to t_i and included into the reconstruction stencil for the given tetrahedron.

To analyze the behavior of the fluxes in the three-dimensional case we calculate the directional derivative $\frac{\partial u}{\partial \mathbf{n}}$ across the face e_i in the given tetrahedron t_i as

$$\frac{\partial u}{\partial \mathbf{n}} \approx \frac{u(\mathbf{r}^*) - u(\mathbf{r}_0)}{|\mathbf{r}^* - \mathbf{r}_0|}, \tag{29}$$

where $\mathbf{r}^* = (x^*, y^*, z^*)$ is defined as the point of intersection between the plane e_i and the perpendicular dropped to this plane from the central node of the triangulation. Since the components of the unit vector normal to the plane e_i may be calculated as

$$n_1^i = \frac{x^* - x_0}{|\mathbf{r}^* - \mathbf{r}_0|}, \quad n_2^i = \frac{y^* - y_0}{|\mathbf{r}^* - \mathbf{r}_0|}, \quad n_3^i = \frac{z^* - z_0}{|\mathbf{r}^* - \mathbf{r}_0|},$$

the expression (29) is transformed as

$$\frac{\partial u}{\partial \mathbf{n}} \approx a_1^* n_1^i + a_2^* n_2^i + a_3^* n_3^i = \text{const} = C^*,$$

provided the linear reconstruction of the solution $u(\mathbf{r}^*) - u(\mathbf{r}_0) = a_1^*(x^* - x_0) + a_2^*(y^* - y_0) + a_3^*(z^* - z_0)$ is used. The result of calculation is then compared with the formula

$$\frac{\partial u}{\partial \mathbf{n}} \approx a_1^i n_1^i + a_2^i n_2^i + a_3^i n_3^i = \text{const} = C^i.$$

If the value C^i is different from C^*, then we consider t_i as the tetrahedron where the false gradient appears. In this case it is possible to include nodes of the tetrahedron t_j which contains point r^* into the reconstruction stencil for the given tetrahedron t_i by using the least squares method. This correction may decrease the false gradient.

6. Conclusions. In the present work the analysis of how a discretization of Laplace's equation depends on grid geometry has been made. We have demonstrated the way to construct a control volume for a positive FV scheme with a linear reconstruction on any two-dimensional unstructured grid. The important result obtained here is that on arbitrary grids the Laplace operator requires a convex control volume to provide a positive discretization. This result indicates that grids with highly stretched cells are not appropriate for constructing the positive scheme, since gaps (or overlappings) may appear in the convex dual mesh.

For the prescribed geometry of the control volume, we have investigated whether it is possible to improve the positivity measures of the linear FV scheme on arbitrary grids by using extended stencils. Although having the empirical nature, the suggested approach to the stencil correction allows us to treat stretched cells effectively. Numerical experiments show that the developed technique produces a "quasi-positive" scheme. However, in spite of giving us all advantages of the positive discretization, the practical applicability of the corrected scheme is restricted. The produced stencils are nonsymmetric which may lead to the loss of conservativity of the scheme.

The property of positivity is very important and can be considered as a criterion of a proper discretization of Laplace's equation as it expresses a maximum principle which is an inherent feature of the Laplacean. On the other hand, being a natural property of FV schemes conservativity makes them attractive for many practical applications. The results obtained in this paper seem to indicate that the properties of positivity and conservativity are incompatible with each other on arbitrary grids. This fact demonstrates how far grid quality is crucial for the discretization.

In our opinion, in order to overcome the incompatibility between these two basic requirements, one should admit that due to space isotropy of the Laplace equation its discretization needs the grid to be isotropic, in a certain sense. A mesh with all edges of the same length gives us the simplest example, while a Delaunay triangulation can be considered as a more general kind of grid with space isotropy.

Grids with stretched cells are "alien" for the Laplace equation. For those problems, where stretched grids arise as a result of grid adaptation, it may be better to make a discretization of the full problem operator rather than discretize diffusion terms separately. Meanwhile, the further development of algorithms of fully automatic Delaunay grid generation is strongly needed to provide us with a positive discretization which holds the property of conservativity.

Acknowledgments. The author is grateful to two anonymous referees for their valuable comments which helped to improve the paper. The author appreciates the help of colleagues from the BOIM CFD research team, especially A.A. Martynov, S. Yu. Medvedev, and A.M. Sorokin, who provided the grids used in the work.

ADAPTIVE WAVELET SCHEMES FOR ELLIPTIC PROBLEMS—IMPLEMENTATION AND NUMERICAL EXPERIMENTS*

ARNE BARINKA†, TITUS BARSCH†, PHILIPPE CHARTON‡, ALBERT COHEN§, STEPHAN DAHLKE¶, WOLFGANG DAHMEN†, AND KARSTEN URBAN†

Abstract. Recently an adaptive wavelet scheme could be proved to be asymptotically optimal for a wide class of elliptic operator equations in the sense that the error achieved by an adaptive approximate solution behaves asymptotically like the smallest possible error that can be realized by *any* linear combination of the corresponding number of wavelets. On one hand, the results are purely asymptotic. On the other hand, the analysis suggests new algorithmic ingredients for which no prototypes seem to exist yet. It is therefore the objective of this paper to develop suitable data structures for the new algorithmic components and to obtain a quantitative validation of the theoretical results. We briefly review first the main theoretical facts, describe the main ingredients of the algorithm, highlight the essential data structures, and illustrate the results by one- and two-dimensional numerical examples including comparisons with an adaptive finite element scheme.

Key words. elliptic operator equations, multiscale methods, adaptive methods, wavelets, quasi-sparse matrices and vectors, adaptive operator application, fast matrix–vector multiplication, best N-term approximation, thresholding, Besov spaces, C++, STL

1. Introduction.

The development of adaptive numerical methods is of enormous current interest. Although such concepts have not yet entered industrial applications at large, current research developments, for instance, in a finite element context, indicate their very promising potential [1, 3, 10, 12, 49]. Such hopes and numerical experiences are, however, contrasted by negative statements proved in the context of complexity theory. In fact, on a rigorous level not much has been proved about adaptive finite element schemes in comparison with a priori fixed meshes. To our knowledge, the only result in this direction is [38], where an adaptive finite element scheme for the bivariate Poisson's equation using piecewise linear elements was proven to converge without a priori assumptions on the unknown solution such as the *saturation property*. On the other hand, in the context of wavelet discretizations,

nowadays much more is known. In [22] an adaptive wavelet scheme was proved to converge for a wide class of elliptic operator equations including, in particular, differential operators as well as singular integral operators. This result was extended to saddle point problems in [24].

Moreover, quite recently substantial progress could also be accomplished in the analysis of the *speed* of convergence [17]. In [17], an adaptive wavelet scheme has been developed which is shown to be *asymptotically optimal* for the same class of elliptic operator equations referred to above in the following sense: its rate of convergence to the exact solution with respect to the number N of degrees of freedom—i.e., of wavelets which are used to describe the solution—is the same as the rate of convergence of the *best N-term approximation* which would typically be obtained by retaining the N largest wavelet coefficients of the exact solution. Moreover, the number of floating point operations required to compute the approximate solution stays proportional to the number N of wavelets needed to approximate the solution at any desired level of accuracy. In addition, sorting requires at most the order of $N \log(N)$ operations. The proof of the latter fact is constructive in the sense that the algorithm is described to the level of detail that the number of arithmetic operations can be rigorously estimated. To our knowledge, these are the first rigorously proven convergence rates accompanied with a corresponding operations count.

The result is interesting from two points of view. First, it is known that the rate of best approximation either by N-term wavelet combinations or by optimal adaptive refinement of finite element spaces can be characterized by a certain type of Besov regularity [36], in contrast to the rate of approximation by uniform refinements which is determined by Sobolev regularity. Therefore, the above adaptive wavelet scheme provides an asymptotically better accuracy/work balance than schemes based on uniform discretizations, e.g., when the solution has isolated singularities or, more systematically, when the solution lacks Sobolev regularity relative to Besov regularity. However, since the results are asymptotic a more quantitative assessment of the performance is of equal interest in practical applications. Second, the analysis of the scheme suggests new algorithmic ingredients centering on an adaptive matrix–vector multiplication combined with sorting entries of sequences. Therefore the efficient realization of these ingredients and the development of suitable data structures that best support the conceptual strength of the scheme in practical realizations is a challenging task. In fact, the realization of that task seems to be essential for a quantitative validation of the theoretical results which after all are phrased in a necessarily simplified computational model.

This paper describes the developments of such algorithmic ingredients and corresponding data structures and reports numerical results in one and two dimensions. The paper is organized as follows. In section 2, we briefly review the main theoretical facts needed for the understanding of the algorithm and extract from theory the essential requirements on implementation. Moreover, these considerations will guide the selection of test examples. Section 3 is devoted to a brief outline of the new data structures. These structures follow the code design principle of *separating data from the algorithm*, i.e., here the adaptive algorithm is realized independently of the input parameters such as the underlying domain and the choice of the wavelet basis. In section 4, we present our numerical experiments. The examples are designed to highlight the effects of different sources of singularities whose occurrence, according to the theoretical part, makes adaptive schemes more efficient than nonadaptive ones. This covers singularities induced by the right-hand side date, by the shape of the domain, or by both, as well as the effect of large Sobolev norms versus Besov norms. To exploit theoretical knowledge for our validation we choose as a test example the classical Poisson problem on an L-shaped domain as well as a Helmholtz problem with small viscosity. In the latter case the energy space differs more and more from the Sobolev space H^1 when the viscosity decreases. This allows us to test the robustness of the scheme. Moreover, we confirm the quantitative advantage of the stronger compressibility of higher order wavelets in spite of their larger supports. Finally, we compare the wavelet scheme with an adaptive finite element scheme. Several other examples, figures, and also some movies can be obtained from the web page http://www.igpm.rwth-aachen.de/adaptive.

2. Theoretical background.

2.1. The abstract problem. The algorithms discussed in this paper apply to the following scope of problems. Suppose that H is a Hilbert space with norm $\|\cdot\|_H$ induced by the inner product $\langle\cdot,\cdot\rangle$ and that the self-adjoint operator $A : H \to H'$, where H' is the normed dual of H, is *H-elliptic*, i.e.,

$$a(v,w) := \langle Av, w\rangle \lesssim \|v\|_H\|w\|_H \quad \text{and} \quad a(v,v) \sim \|v\|_H^2. \tag{2.1}$$

Here $a \lesssim b$ means that a can be uniformly bounded by a constant multiple of b independent of any parameters on which a and b may depend. $a \gtrsim b$ is to be understood analogously and $a \sim b$ states that $a \lesssim b$ and $a \gtrsim b$. Clearly (2.1) implies that A is an isomorphism from H to H', i.e.,

$$\|Av\|_{H'} \sim \|v\|_H, \quad v \in H. \tag{2.2}$$

Thus the equation

$$Au = f \tag{2.3}$$

has for any $f \in H'$ a unique solution which will always be denoted by u. Typical examples are second order elliptic boundary value problems with homogeneous Dirichlet boundary conditions on some open domain $\Omega \subset \mathbb{R}^d$. In this case $H = H_0^1(\Omega)$ and $H' = H^{-1}(\Omega)$. Other examples are obtained by turning an exterior boundary value problem into a singular integral equation on the boundary Γ of the domain. For a formulation in terms of the single layer potential operator one obtains, for instance, $H = H^{-1/2}(\Gamma)$ and $H' = H^{1/2}(\Gamma)$; see [19, 45] for details. In the above examples H is a Sobolev space and one has either $H \subset L_2 \subset H'$ or $H' \subset L_2 \subset H$. We sometimes write $H = H^t$ to indicate the Sobolev regularity although often a closed subspace of the full Sobolev space determined by boundary conditions is meant. H^{-t} is always the dual of this particular subspace.

We hasten to add though that A need not be a scalar equation but could as well represent a system in which case H is typically a product of Sobolev spaces as long as the above assumptions are fulfilled.

We finally emphasize that H should be viewed as representing the *energy* space associated with (2.1) and therefore need not be a Sobolev space. As a typical example consider $Au = -\varepsilon\Delta u + u$ on $\Omega \subset \mathbb{R}^d$ with homogeneous Dirichlet boundary conditions. In this case H-ellipticity holds *uniformly* in $\varepsilon > 0$ for the norm $\|\cdot\|_H^2 := \|\cdot\|_{L_2(\Omega)}^2 + \varepsilon|\cdot|_{H^1(\Omega)}^2$.

We are interested in solving (2.3) approximately with the aid of a Galerkin method, i.e., we pick some finite-dimensional space $S \subset H$ and search for $u_S \in S$

such that

$$\langle Au_S, v\rangle = \langle f, v\rangle, \qquad v \in S, \tag{2.4}$$

where $\langle\cdot,\cdot\rangle$ denotes the standard L_2-inner product.

We have paused above to describe a wide class of examples for the following reason. The *separation of algorithm and data* can be realized for the scheme discussed below to a significantly higher extent than for more conventional discretizations. The algorithm remains essentially the same in all the mentioned examples. It is therefore no principal limitation to consider only numerical tests for second order elliptic boundary value problems including, however, the above example of parameter dependent energy spaces. The main point will be that for this class of examples we can resort to important analytical information that will help to validate and interpret the numerical results in a more quantitative fashion.

2.2. An equivalent ℓ_2-problem. In our context the trial spaces S in (2.4) will be spanned by elements of a *wavelet* basis $\Psi = \{\psi_\lambda : \lambda \in \mathcal{J}\}$ for H. We will postpone at this point any technical description of the basis Ψ (which necessarily depends on the particular setting at hand) but will only list those properties that will be relevant in the following. The indices $\lambda \in \mathcal{J}$ typically encode several types of information, namely, the *scale*, often denoted by $|\lambda|$, the spatial location, and also the type of the wavelet. Recall that in a classical setting a tensor product construction yields $2^d - 1$ types of wavelets [34, 46]. For instance, for wavelets on the real line, λ can be identified with (j,k), where $j = |\lambda|$ denotes the dyadic refinement level and $2^{-j}k$ signifies the location of the wavelet. In fact, we will require the wavelets to be local in the sense that $\operatorname{diam}(\operatorname{supp}\psi_\lambda) \sim 2^{-|\lambda|}$, $\lambda \in \mathcal{J}$.

These wavelets are usually normalized in L_2. What matters in the present case is that a properly scaled version of Ψ is a *Riesz basis* for the energy space H. This means that there exists a *diagonal matrix* $\mathbf{D} = \operatorname{diag}(\omega_\lambda : \lambda \in \mathcal{J}\}$ such that each $v \in H$ has a unique expansion $v = \sum_{\lambda\in\mathcal{J}} v_\lambda \omega_\lambda^{-1}\psi_\lambda =: \mathbf{v}^T\mathbf{D}^{-1}\Psi$ such that

$$\|\mathbf{v}\|_{\ell_2(\mathcal{J})} \sim \|\mathbf{v}^T\mathbf{D}^{-1}\Psi\|_H. \tag{2.5}$$

For instance, when $H = H^t$ a canonical choice is $\omega_\lambda = 2^{t|\lambda|}$. When $\|\cdot\|_H^2 := \|\cdot\|_{L_2(\Omega)}^2 + \varepsilon|\cdot|_{H^1(\Omega)}^2$ the choice $\omega_\lambda := 1 + \sqrt{\varepsilon}2^{|\lambda|} \sim a(\psi_\lambda,\psi_\lambda)^{1/2}$ ensures that (2.5) holds with constants *independently* of ε provided that $\{\psi_\lambda\}_{\lambda\in\mathcal{J}}$ and $\{2^{-|\lambda|}\psi_\lambda\}_{\lambda\in\mathcal{J}}$ are Riesz bases for L_2 and H^1, respectively. This will be seen to entail asymptotically optimal performance of the adaptive wavelet scheme uniformly in ε.

Relations similar to (2.5) are also known to hold for Sobolev spaces in L_p for $p \neq 2$. Moreover, interpolation between such spaces provides norm equivalences for a whole range of *Besov spaces* $B_q^\alpha(L_p)$ [25, 37, 39, 46]. In the present context we will have to make use of the following special case:

$$\|\boldsymbol{d}\|_{\ell_\tau(\mathcal{J})} \sim \|\boldsymbol{d}^T\Psi\|_{B_\tau^\alpha(L_\tau)}, \tag{2.6}$$

where the smoothness index α and the integrability index τ are related by $\tau^{-1} = \alpha/d + 1/2$.

Once a basis with the above properties is given, the operator equation (2.3) over a function space H can be transformed into an *equivalent matrix* equation over the corresponding *sequence space*. In fact, the representation of

$$\boldsymbol{A} := \mathbf{D}^{-1}\langle\Psi, A\Psi\rangle\mathbf{D}^{-1} := \left(\omega_\lambda^{-1}\omega_\nu^{-1}\langle\psi_\lambda, A\psi_\nu\rangle\right)_{\lambda,\nu\in\mathcal{J}} \tag{2.7}$$

of A with respect to the Riesz basis $\mathbf{D}^{-1}\Psi$ of H is, because of the norm equivalence (2.5) in conjunction with ellipticity (2.2), an automorphism on ℓ_2 [26, 28].

THEOREM 2.1. *The function $u = \boldsymbol{d}^T\Psi \in H$ solves the original operator equation* (2.3) *if and only if the sequence $\mathbf{u} := \mathbf{D}\boldsymbol{d}$ solves the matrix equation*

$$\boldsymbol{A}\mathbf{u} = \mathbf{f}, \tag{2.8}$$

where $\mathbf{f} := \mathbf{D}^{-1}\langle\Psi, f\rangle = \{\omega_\lambda^{-1}\langle\psi_\lambda, v\rangle\}_{\lambda\in\mathcal{J}}$.

Moreover, denoting by $\|\cdot\|$ the spectral norm on ℓ_2, the matrix $\boldsymbol{A}$ defined by (2.7) *satisfies*

$$\|\boldsymbol{A}\|,\ \|\boldsymbol{A}^{-1}\| < \infty. \tag{2.9}$$

As an immediate consequence there exists a finite number κ such that all finite sections $\boldsymbol{A}_\Lambda := \left(\omega_\lambda^{-1}\omega_\nu^{-1}\langle\psi_\lambda, A\psi_\nu\rangle\right)_{\lambda,\nu\in\Lambda}$, $\Lambda \subset \mathcal{J}$, have uniformly bounded condition numbers

$$\operatorname{cond}_2(\boldsymbol{A}_\Lambda) \le \kappa, \qquad \Lambda \subset \mathcal{J}. \tag{2.10}$$

Hence the original problem has been reduced to an equivalent well-posed problem in ℓ_2. This fact will be crucial in the following.

2.3. Quasi-sparse matrices. A specific advantage of wavelet discretizations is that for a large class of elliptic operators (including singular integral operators), the resulting matrix $\boldsymbol{A}$ exhibits fast decay off the diagonal. More precisely, when $H = H^t$ and $\omega_\lambda = 2^{t|\lambda|}$, this takes the form of the following estimate:

$$2^{-(|\lambda'|+|\lambda|)t}|\langle A\psi_{\lambda'}, \psi_\lambda\rangle| \ \lesssim\ \frac{2^{-||\lambda|-|\lambda'||\sigma}}{(1+d(\lambda,\lambda'))^{d+2\tilde{m}+2t}},\quad d(\lambda,\lambda') := 2^{\min(|\lambda|,|\lambda'|)}\operatorname{dist}(\Omega_\lambda,\Omega_{\lambda'}), \tag{2.11}$$

where $\Omega_\lambda := \operatorname{supp}\psi_\lambda$ and $\sigma > d/2$ is a constant depending on the regularity of the wavelets ψ_λ. The validity of (2.11) has been established for a wide range of cases, including classical pseudodifferential operators and Calderon–Zygmund operators (see, e.g., [28]).

It is important to note, however, that (2.11) is only a *sufficient* condition for the following *compression property* of $\boldsymbol{A}$ that will be needed later. $\boldsymbol{A}$ is said to belong to the class $\mathcal{A}_s$ if there exists a positive summable sequence $(\alpha_j)_{j\ge0}$ and for every $j \ge 0$ there exists a matrix $\boldsymbol{A}_j$ with at most $2^j\alpha_j$ nonzero entries per row and column such that

$$\|\boldsymbol{A}_j - \boldsymbol{A}\| \ \lesssim\ \alpha_j 2^{-sj}. \tag{2.12}$$

The following fact has been proved in [17].

PROPOSITION 1. *Let*

$$s^* := \min\left\{\frac{\sigma}{d} - \frac{1}{2}, \frac{2t+2\tilde{m}}{d}\right\}. \tag{2.13}$$

Then $\boldsymbol{A}$ belongs to $\mathcal{A}_s$ for every $s < s^*$.

For matrices with the particular decay properties (2.11) concrete truncation rules can be given [17]. Given j, set

$$\tilde{a}_{\lambda,\nu} := \begin{cases} a_{\lambda,\nu}, & ||\lambda| - |\nu|| \le j/d \text{ and } d(\lambda,\nu) \le 2^{j/d-||\lambda|-|\nu||}\,\gamma(||\lambda|-|\nu||), \\ 0, & \text{else.} \end{cases} \tag{2.14}$$

Here $\gamma(n)$ is any summable sequence, e.g., $\gamma(n) := (1+n)^{-2/d}$.

One should note that because of the locality of the wavelets the first condition in (2.14) already suffices for local operators A (such as differential operators) which will be used later in the examples.

2.4. The adaptive strategy. The practical realization of adaptive approximations to (2.3) in a finite element context is to refine and derefine step by step a given mesh according to a posteriori local error indicators. The point of view taken by wavelet schemes is somewhat different. Trial spaces are refined directly by incorporating additional basis functions whose selection depends on the previous step. Specifically, setting for any finite subset $\Lambda \subset \mathcal{J}$ our trial spaces will always be of the form $S_\Lambda := \operatorname{span}\{\psi_\lambda : \lambda \in \Lambda\}$, where the index set Λ is to be adapted to the solution. In fact, denoting by $u_\Lambda \in S_\Lambda$ always the Galerkin solution determined by (2.4), we start with some small index set Λ_0 (possibly the empty set) and proceed as follows:

> *Given* Λ_j *and* u_{Λ_j} *and some* fixed $\theta \in (0,1)$*, find* $\Lambda_{j+1} \supset \Lambda_j$ *as* small as possible *such that the new error* $u - u_{\Lambda_{j+1}}$ *in the energy norm is at most* θ *times the previous error. Obviously, iteration of this step entails convergence of the resulting sequence of approximations in the energy norm.*

Successively enlarging index sets in this way, one hopes to track the *most significant* coefficients in the true wavelet expansion $\boldsymbol{d}^T\Psi = \mathbf{u}^T\mathbf{D}^{-1}\Psi$ of the unknown solution u. It is easy to see that the function $u_\Lambda = \sum_{\lambda\in\Lambda} \omega_\lambda^{-1} (\mathbf{u}_\Lambda)_\lambda \psi_\lambda$ with coefficient vector $\mathbf{u}_\Lambda = ((\mathbf{u}_\Lambda)_\lambda)_{\lambda\in\Lambda}$ (with respect to the scaled wavelet basis) solves the Galerkin system (2.4) for $S = S_\Lambda$ if and only if $\mathbf{u}_\Lambda$ solves

$$\boldsymbol{A}_\Lambda \mathbf{u}_\Lambda = \mathbf{f}_\Lambda := \mathbf{f}|_\Lambda. \tag{2.15}$$

Moreover, Theorem 2.1 suggests working completely on the *discrete* side for both the finite- and infinite-dimensional problems. Therefore, although $\mathbf{u}_\Lambda \in \mathbb{R}^{\#\Lambda}$ is a finite vector, it will sometimes be convenient to view $\mathbf{u}_\Lambda$ as a sequence in ℓ_2, i.e., all components of $\mathbf{u}_\Lambda$ outside Λ are understood to be zero. Since it will always be clear from the context which interpretation is meant we will not introduce any notational distinction between the finite vector $\mathbf{u}_\Lambda$ and its canonical injection in ℓ_2. Likewise for $\mathbf{v} \in \ell_2$ its restriction to Λ is denoted by $\mathbf{v}|_\Lambda$.

Defining now the *discrete energy norm*

$$\|\mathbf{v}\|^2 := \mathbf{v}^T\boldsymbol{A}\mathbf{v} =: \mathbf{a}(\mathbf{v},\mathbf{v}), \tag{2.16}$$

(2.5) and equation (2.9) in Theorem 2.1 say that

$$\|\mathbf{v}^T\mathbf{D}^{-1}\Psi\|_H \sim \|\mathbf{v}\| \sim \|\mathbf{v}\|_{\ell_2} \sim \|\boldsymbol{A}\mathbf{v}\| \sim \|\boldsymbol{A}\mathbf{v}\|_{\ell_2}, \tag{2.17}$$

so that measuring errors in $\|\cdot\|$ or $\|\cdot\|_{\ell_2}$ and for the corresponding functions in the energy norm $\|\cdot\|_H$ is the same up to uniform constants.

Next note that if we can find for a given $\Lambda \subset \mathcal{J}$ an index set $\hat\Lambda \supset \Lambda$ such that for some $\beta \in (0,1)$

$$\|\mathbf{u}_{\hat\Lambda} - \mathbf{u}_\Lambda\| \geq \beta\|\mathbf{u} - \mathbf{u}_\Lambda\|, \tag{2.18}$$

Galerkin orthogonality and the Pythagoras theorem ensure the error reduction

$$\|\mathbf{u} - \mathbf{u}_{\hat\Lambda}\| \leq \theta\|\mathbf{u} - \mathbf{u}_\Lambda\| \tag{2.19}$$

with $\theta := \sqrt{1-\beta^2}$. This strategy is also the starting point in [22] and has been used even earlier in the finite element context; see, e.g., [12, 38]. There, it was usually *assumed* to hold for some *fixed* refinement of the old trial space and therefore referred to as *saturation assumption.* However, as in [22] and before for a much more specialized situation in [38] the scheme described below will *guarantee* (2.18) without an a priori assumption like the saturation property. In addition, in contrast to previous cases, concrete and in some sense asymptotically optimal *convergence rates*, relating the error $\|\mathbf{u}-\mathbf{u}_{\Lambda_j}\|$ to the number of degrees of freedom $N_j = \#\Lambda_j$, will be realized.

To this end, for any $\hat\Lambda \supset \Lambda$ one has by Galerkin orthogonality

$$\|\mathbf{u}_{\hat\Lambda}-\mathbf{u}_\Lambda\| \gtrsim \|\boldsymbol{A}(\mathbf{u}_{\hat\Lambda}-\mathbf{u}_\Lambda)\|_{\ell_2} \geq \|\boldsymbol{A}(\mathbf{u}_{\hat\Lambda}-\mathbf{u}_\Lambda)|_{\hat\Lambda}\|_{\ell_2} = \|\boldsymbol{A}(\mathbf{u}-\mathbf{u}_\Lambda)|_{\hat\Lambda}\|_{\ell_2}.$$

Thus defining the residual

$$\mathbf{r}_\Lambda := \boldsymbol{A}(\mathbf{u}-\mathbf{u}_\Lambda) = \mathbf{f} - \boldsymbol{A}\mathbf{u}_\Lambda,$$

the above estimate states that for some constant $c_1 \in (0,1)$ depending only on the constants in (2.17)

$$\|\mathbf{u}_{\hat\Lambda}-\mathbf{u}_\Lambda\| \geq c_1\|\mathbf{r}_\Lambda|_{\hat\Lambda}\|_{\ell_2}. \tag{2.20}$$

Key idea. If $\hat\Lambda$ can be chosen such that

$$\|\mathbf{r}_\Lambda|_{\hat\Lambda}\|_{\ell_2} \geq a\|\mathbf{r}_\Lambda\|_{\ell_2} \tag{2.21}$$

holds for some fixed $a \in (0,1)$, then, since (2.17) implies $\|\mathbf{r}_\Lambda\|_{\ell_2} \gtrsim \|\mathbf{u}_\Lambda - \mathbf{u}\|$, one infers from (2.20) that there exists a constant $\beta \in (0,1)$ such that (2.18) and hence also (2.19) $\|\mathbf{u}_{\hat\Lambda}-\mathbf{u}\| \leq \theta\|\mathbf{u}_\Lambda-\mathbf{u}\|$ holds.

Thus the reduction (2.19) of the error has been reduced to catching the *bulk* of the *residual* $\mathbf{r}_\Lambda$ by finding its most significant coefficients in the sense of (2.21). However, $\mathbf{r}_\Lambda$ is in general still an *infinite* array. So in practice, $\mathbf{r}_\Lambda$ has to be approximated first sufficiently well. This will be realized by exploiting the structure of $\boldsymbol{A}$ and the knowledge about the right-hand-side data $\mathbf{f}$; see [17] and the appendix below for details. Nevertheless, to make the basic mechanisms more transparent we suppress these issues for a moment and formulate a core ingredient of the refinement strategy as the following (idealized) routine:

GROW $(\Lambda, \mathbf{u}_\Lambda) \to (\hat\Lambda, \mathbf{u}_{\hat\Lambda})$. *Given* $(\Lambda, \mathbf{u}_\Lambda)$ *find the* **smallest** $\hat\Lambda \supset \Lambda$ *such that* $\|\mathbf{r}_\Lambda|_{\hat\Lambda}\|_{\ell_2} \geq a\|\mathbf{r}_\Lambda\|_{\ell_2}$.

Note, however, that even if one were able to perform **GROW** it is by no means clear whether merely iterating the procedure **GROW** leads to (in some sense) an optimal algorithm.

2.5. Best N-term approximation.

To obtain a conceptual *benchmark* it is important to clarify first what the *optimal* outcome of an adaptive scheme might be. If N is the number of degrees of freedom produced by the algorithm and if we wish to measure the error $\|u-u_\Lambda\|_H$, the optimal outcome is clearly given by a function u_N which minimizes $\|v-u\|_H$ over all v which are N-term linear combinations of wavelets. Again Theorem 2.1 and (2.17) imply that, up to a multiplicative uniform constant, this amounts to defining the corresponding vector $\mathbf{u}_N$ as the *best approximation* of $\mathbf{u}$ in ℓ_2 by a vector with N nonzero coordinates, i.e., $\mathbf{u}_N$ is obtained by retaining the N largest components of $\mathbf{u}$. Of course, since $\mathbf{u}$ is not known, $\mathbf{u}_N$ is not directly available. In summary, the best that can be achieved by an adaptive scheme is to produce approximate solutions $\mathbf{u}_\Lambda$ such that $\|\mathbf{u}-\mathbf{u}_\Lambda\|$ has the same asymptotic decay rate as $\|\mathbf{u}-\mathbf{u}_{\#\Lambda}\|_{\ell_2}$.

It has been shown in [17] that optimality in the above sense can indeed be ensured when the iteration of **GROW** is every so often interrupted by a *clean-up* step. This simply means that after several applications of **GROW** one has to discard all coefficients in the current approximation $\mathbf{u}_\Lambda$ whose modulus is below a certain threshold. This threshold is chosen so that the current error is at most multiplied by a fixed uniform constant. While thereby the error gets only worse by a little this will turn out to have an essential effect on the behavior of the residual with respect to certain norms that are somewhat stronger than the ℓ_2-norm. We summarize this clean-up or *thresholding step* as follows.

THRESH $(\Lambda,\mathbf{u}_\Lambda)\rightarrow(\tilde\Lambda,\mathbf{u}_{\tilde\Lambda})$. *If* $\|\mathbf{u}-\mathbf{u}_\Lambda\|_{\ell_2}\le\varepsilon$, *find* **smallest** $\tilde\Lambda\subset\Lambda$ *such that* $\|\mathbf{u}_\Lambda-\mathbf{u}_\Lambda|_{\tilde\Lambda}\|_{\ell_2}\le 4\varepsilon$.

Note that both routines require us to *sort* the coefficients with respect to their modulus.

2.6. An optimal (idealized) algorithm. We next give a rough idealized version of an adaptive wavelet scheme whose practical counterpart will turn out to be optimal with respect to convergence rates as well as work count.

ALGORITHM.

```
(i) $\Lambda_0=\emptyset$, $\mathbf{r}_{\Lambda_0}=\mathbf{f}$, $\varepsilon_0:=\|\mathbf{f}\|_{\ell_2}$, $j=0$, $\varepsilon$ given target accuracy.
(ii) Determine $(\Lambda_{j+1},\mathbf{u}_{\Lambda_{j+1}})$ from $(\Lambda_j,\mathbf{u}_{\Lambda_j})$ such that $\|\mathbf{u}-\mathbf{u}_{\Lambda_{j+1}}\|_{\ell_2}\le\varepsilon_j/2:=\varepsilon_{j+1}$ as follows.
        Set $\Lambda_{j,0}:=\Lambda_j$, $\mathbf{u}_{j,0}:=\mathbf{u}_j$;
            For $k=1,2,\dots,K$ apply GROW $(\Lambda_{j,k-1},\mathbf{u}_{\Lambda_{j,k-1}})\rightarrow(\Lambda_{j,k},\mathbf{u}_{\Lambda_{j,k}})$
            $(\|\mathbf{r}_{\Lambda_{j,k-1}}|_{\Lambda_{j,k}}\|_{\ell_2}\ge\frac{1}{2}\|\mathbf{r}_{\Lambda_{j,k-1}}\|_{\ell_2})$;
        Apply THRESH $(\Lambda_{j,K},\mathbf{u}_{\Lambda_{j,K}})\rightarrow(\Lambda_{j+1},\mathbf{u}_{\Lambda_{j+1}})$;
        If $\varepsilon_{j+1}\le\varepsilon$ stop; else $j+1\rightarrow j$, go to (ii).
```

The maximal (and total) number K of applications of **GROW** can be shown to be uniformly bounded, depending only on the constants in (2.17). Moreover, a detailed description of the fully computable version **ALGORITHM**^{c} of the above algorithm is given in the appendix to which the following result refers. In what follows it will always be assumed that the right-hand-side data $\langle f,\psi_\lambda\rangle$ are entirely given and that the computation of the entries of $\boldsymbol{A}$ can be computed on average at unit cost.

THEOREM 2.2 (see [17]). *The computable version* **ALGORITHM**^{c} *always produces a solution with the desired accuracy after a finite number of steps.*

Moreover, assume that $\boldsymbol{A}\in\mathcal{A}_s$ *for* $0\le s<s^*$ *(recall Proposition* 1*). If the solution* u *to the operator equation* (2.3) *has the property that for some* $s<s^*$

$$\sigma_N(u):=\inf_{d_\lambda,\lambda\in\Lambda,\#\Lambda\le N}\|u-\sum_{\lambda\in\Lambda}d_\lambda\psi_\lambda\|\ \lesssim\ N^{-s},\tag{2.22}$$

then **ALGORITHM**^{c} *generates a sequence* $u_{\Lambda_j}=\sum_{\lambda\in\Lambda_j}(\mathbf{u}_{\Lambda_j})_\lambda\omega_\lambda^{-1}\psi_\lambda$ *of Galerkin solutions to* (2.4) *satisfying*

$$\|u-u_{\Lambda_j}\|\ \lesssim\ (\#\Lambda_j)^{-s}.\tag{2.23}$$

Moreover, the number of arithmetic operations *needed to compute* u_{Λ_j} *stays* proportional *to* $\#\Lambda_j$. *The number of operations needed for* sorting *stays bounded by* $(\#\Lambda_j)\log(\#\Lambda_j)$.

It is important to note that the above algorithm does *not* require any a priori knowledge about the rate of N-term approximability of the solution. It is shown to automatically match the rate of best N-term approximation for a certain asymptotic range depending on the operator and the chosen basis.

2.7. Computational tasks. We add a few comments on the concrete computational tasks required by the computable version of **ALGORITHM**. A detailed account of these routines can be found in the appendix; see also [17], where, in particular, various parameters are identified that steer the refinement process. Of course, the central issue is to determine the bulk of $\mathbf{r}_\Lambda$ or, equivalently, to find a *good approximation* $\bar{\mathbf{r}}_\Lambda$ of finite length to $\mathbf{r}_\Lambda$ in ℓ_2. In this context one faces the following obvious obstructions. In order to stay within the promised bounds of computational complexity, one has to employ iterative solvers to determine an approximation $\bar{\mathbf{u}}_\Lambda$ to $\mathbf{u}_\Lambda$. One then still faces the problem of approximating the application of the *infinite* matrix $\boldsymbol{A}$ to the finitely supported sequence $\bar{\mathbf{u}}_\Lambda$ by some finite vector $\mathbf{w}_\eta$ within a suitable tolerance η. Approximating also $\mathbf{f}$ within that tolerance by a finite vector $\mathbf{f}_\eta$, one has to deal with the following perturbations of the true residual:

$$\mathbf{r}_\Lambda - \underbrace{(\mathbf{f}_\eta - \mathbf{w}_\eta)}_{\bar{\mathbf{r}}_\Lambda} = \underbrace{\mathbf{f} - \mathbf{f}_\eta + \boldsymbol{A}(\bar{\mathbf{u}}_\Lambda - \mathbf{u}_\Lambda) + \mathbf{w}_\eta - \boldsymbol{A}\bar{\mathbf{u}}_\Lambda}_{\text{error}}. \tag{2.24}$$

In the computable version **ALGORITHM**^{c} the routine **GROW** works with approximate residuals $\bar{\mathbf{r}}_\Lambda$ corresponding to suitable dynamic tolerances η, specified in [17]; see also the appendix below. This amounts to the following tasks:

(1) Determine a sufficiently good approximation $\mathbf{f}_\eta$.
(2) Determine $\bar{\mathbf{u}}_\Lambda$ by an iterative scheme. This requires repeated matrix–vector multiplications.
(3) Compute an approximation $\mathbf{w}_\eta$ to $\boldsymbol{A}\bar{\mathbf{u}}_\Lambda$. This requires an (approximate) application of the (infinite) matrix $\boldsymbol{A}$.
(4) Find a best N-term approximation to the resulting approximation (2.24) (or keep it).
(5) Threshold the current approximate Galerkin solution.

2.8. Adaptive matrix–vector multiplication. Clearly (3) reveals that a core requirement is the application of the *infinite*-dimensional operator $\boldsymbol{A}$ to a *finite* vector (formally extended by zero entries). Since $\boldsymbol{A}$ is an infinite matrix we also call such an application of $\boldsymbol{A}$ *matrix–vector multiplication.* An essential ingredient of the scheme is therefore the following *approximate* adaptive matrix–vector multiplication from [17] (see the appendix).

Proposition 2. *Let* $\mathbf{v}$ *be any finitely supported vector and suppose that* $\boldsymbol{A} \in \mathcal{A}_s$*; recall* (2.12)*. Defining* $\mathbf{v}_{[j]} := \mathbf{v}_{2^j}$ *(best N-term approximation in ℓ_2 for $N = 2^j$) and*

$$\mathbf{w}_j := \boldsymbol{A}_j \mathbf{v}_{[0]} + \boldsymbol{A}_{j-1}(\mathbf{v}_{[1]} - \mathbf{v}_{[0]}) + \cdots + \boldsymbol{A}_0(\mathbf{v}_{[j]} - \mathbf{v}_{[j-1]}), \tag{2.25}$$

then

$$\|\boldsymbol{A}\mathbf{v} - \mathbf{w}_j\|_{\ell_2} \lesssim 2^{-sj}, \tag{2.26}$$

uniformly in $\mathbf{v}$ *provided that* $\|\mathbf{v} - \mathbf{v}_{[j]}\|_{\ell_2} \lesssim 2^{-sj}$ *holds uniformly in* $\mathbf{v}$.

As a consequence, under the above assumptions on $\mathbf{v}$, the computational work $\mathbf{CW}(\eta)$ needed to realize an approximation $\mathbf{w}_\eta$ to $\boldsymbol{A}\mathbf{v}$ such that $\|\boldsymbol{A}\mathbf{v} - \mathbf{w}_\eta\|_{\ell_2} \le \eta$ is of the order

$$\mathbf{CW}(\eta) \sim \#\mathrm{supp}\, \mathbf{w}_\eta \lesssim \eta^{-1/s}. \tag{2.27}$$

It can be shown that only a finite uniformly bounded number of such approximate matrix–vector multiplications of the form (2.25) will be needed at each stage to fulfill the accuracy requirements for the next step. In particular, (2.27) will guarantee that the computational work stays in the desired bounds.

Note next that (1), (4), and (5) involve *thresholding* of a known array. The way this is performed here is to discard the largest possible number of small entries so that a desired accuracy is preserved by this perturbation. The core task there is to first *sort* the arrays and then sum successively entries in increasing order. This is also used in the error control of the fast matrix–vector multiplication (2.25) because the algorithm should at no stage use any a priori assumption about $\mathbf{u}$.

The above remarks explain the pivoting role of *sorting* and of the *fast approximate matrix–vector multiplication.* We will discuss later some consequences of these facts for the implementation. In particular, it will be seen that most of the data structures needed here can be designed *independently* of the particular application and even of the particular wavelet basis. The special application (e.g., whether $\boldsymbol{A}$ represents a differential or integral operator) enters primarily through calling the significant entries in the columns of $\boldsymbol{A}$ when performing (2.25).

2.9. When does adaptivity pay? Before discussing the implementation of the above scheme, we have to address some issues that will later explain the selection of test examples and subsequent numerical experiments. The guiding questions can be formulated as follows: (a) Theorem 2.2 asserts *asymptotic optimality.* It will be important to *quantify* how much the Galerkin solutions differ from the true best N-term approximations. (b) The range of decay rates N^{-s} for which the scheme is optimal depends, in particular, on the range of compressibility of $\boldsymbol{A}$. Proposition 1 indicates that this range, in turn, depends on the *regularity* of the wavelets. However, higher regularity entails wavelets with larger support. What is the interplay of these opposing effects? (c) What is the nature of functions $u = \mathbf{u}^T\mathbf{D}^{-1}\Psi$ whose best wavelet N-term approximation in the energy norm $\|\cdot\|_{H^t}$, say, or equivalently for which $\|\mathbf{u} - \mathbf{u}_N\|_{\ell_2}$ decays like N^{-s}? (d) In which case is the performance of the adaptive scheme asymptotically better compared with discretizations based on *uniform* mesh refinements?

Questions (c) and (d) are closely interrelated and can be answered theoretically. These answers will help us in properly interpreting subsequent numerical tests. As for (c), the functions u in question are nearly characterized by a certain *Besov regularity.* More precisely, their best wavelet N-term approximation in $\|\cdot\|_{H^t}$ decays like $N^{-(\alpha-t)/d}$ if u belongs to $B^{\alpha}_{\tau^*}(L_{\tau^*}(\Omega))$ with $\frac{1}{\tau^*} := \frac{\alpha-t}{d} + \frac{1}{2}$, $\alpha > t$. In contrast, to obtain the same rate by uniformly refined discretizations, u would have to belong to the much smaller Sobolev space H^{α}. In fact, $B^{\alpha}_{\tau^*}(L_{\tau^*}(\Omega))$ is the largest space of smoothness α in L_{τ^*} that is still continuously embedded in the energy space H^t. Thus adaptivity retains best possible decay rates under weaker regularity requirements on the approximant. The above Besov spaces admit singularities that may not occur in corresponding Sobolev spaces. In particular, when (within the compressibility range of $\boldsymbol{A}$) the solution u has higher Besov regularity than Sobolev regularity the adaptive scheme outperforms uniform mesh schemes asymptotically.

Such results have recently motivated a general effort to revisit the regularity of elliptic boundary value problems in terms of the above scale of Besov spaces and to identify the instances where this level of smoothness is substantially higher than when measured in the classical Sobolev scale; see [23] (and also [42]) for Lipschitz domains and [21] for polygonal domains. These facts will be used to validate our numerical test and to select relevant examples. However, our algorithm provides optimal approximations *without any a priori knowledge on the nature of the singularities.*

Finally, it should be kept in mind that, aside from such asymptotic considerations, the quantitative improvement over a uniform mesh scheme, even if the solution u has arbitrarily high pointwise smoothness, is stronger the more the relevant Sobolev norm exceeds the corresponding Besov norm, a fact that will be confirmed by the numerical examples.

3. Data structures and implementation. One key ingredient for the realization of the adaptive algorithm presented above is the organization of the data, i.e., how to handle the adaptively chosen wavelets so as to best suit the requirements of the adaptive algorithm. Clearly, since for uniform discretizations the number of unknowns is a priori known and can therefore be organized in static vectors containing all coefficients while this is no longer true for adaptive schemes, a certain overhead of data management is necessary but should be minimized.

In this section, we highlight the main features of our data structures for two reasons. First, the requirements of the presented adaptive wavelet algorithm differ essentially from the demands for more conventional methods such as adaptive finite element methods. Second, to our knowledge, this is the first consistent design of appropriate data structures for adaptive wavelet methods.

The description of the method in section 2 reveals the following key requirements so as

(a) to efficiently insert a new index $\lambda \notin \Lambda$ (**GROW**),

(b) to efficiently erase an index $\lambda \in \Lambda$ (**THRESH**),

(c) for a given index λ to have fast access to the corresponding wavelet coefficient $\mathbf{u}_\lambda$,

(d) to sort the indices both with respect to the size of the wavelet coefficients and some “natural” ordering of the indices (which will be discussed in detail later),

(e) to efficiently perform a loop over all indices $\lambda \in \Lambda$ for iteratively solving the linear system $\boldsymbol{A}_\Lambda \mathbf{u}_\Lambda = \boldsymbol{f}_\Lambda$ in order to determine the Galerkin solution $\mathbf{u}_\Lambda$.

At this stage it is already clear that we cannot use any kind of (classical) matrix–vector structures since due to (a), (b), and (d) allocation and deallocation would destroy the efficiency of the method. Note that due to (d) and (e) it is not sufficient to use only a clever way of storing the coefficients as, e.g., provided by *hash tables.* We also need some kind of ordering for the indices. Hence, sophisticated sorted lists seem to suggest themselves.

Moreover, in order to keep the implementation feasible and reusable we are also interested in

(f) separating the adaptive algorithm from the particular choice of the wavelet basis Ψ on Ω. In particular, all geometric information on Ω will be stored in Ψ, whereas the adaptive algorithm uses Ψ only as a parameter (the adaptive method should work for all instances of Ψ);

(g) making the use of our data structures as easy as possible.

The issues (a)–(e) can be realized by using certain data structures that are already provided by the C++-*Standard Template Library* (STL) [47, 48]. Let us describe these structures first before we detail the application to our adaptive wavelet scheme.

3.1. Generic programming. The STL provides, among other things, a huge collection of *generic* classes. This means that these data structures may have various parameters in the form of other classes. In C++ such *container classes*, i.e., classes containing some elements of (almost) arbitrary type, are realized by *templates.* Particular examples of container classes are *key-based* data structures that seem to us best suited to our demands. Moreover, the STL provides certain algorithms that operate on the containers. These algorithms turn out to be important for task (e).

The STL classes `map` and `multimap` depend on three parameters, namely, a `key`, a `value`, and a binary relation `compare`. Both classes provide a sophisticated kind of ordered list of objects indexed by a class `key` and having a certain `value`. The sorting is done with respect to `compare`. The difference of the two classes is that the `compare` relation for `map` has to be total whereas this is not required for `multimap`.

Let us review the efficiency properties of these STL classes. Let N be the number of keys in the list and n the number of elements with the same key ($n = 1$ for `map` and $n \geq 1$ for `multimap`). Then, the average complexity to insert, find, and erase an element is at most $\mathcal{O}(\log(N))$, whereas sorting the whole map is at most $\mathcal{O}(N\ \log(N))$. This means that requirements (a)–(d) are already fulfilled as long as we are able to create appropriate instances for `key`, `value`, and `compare` for our adaptive wavelet method.

The requirement (e), namely, the efficient performance of a loop over all indices $\lambda \in \Lambda$ is guaranteed by the separation of data and algorithms, which is the second main concept of generic programming. So if we have the data structure modeling a wavelet index, a generic algorithm operating on this structure can be used.

3.2. Realization of the wavelet bases. It now remains to find an appropriate realization for the wavelet bases Ψ on Ω. The realization of the adaptive method urges us to realize wavelet bases with sophisticated properties as detailed in section 2.2. It is meanwhile understood how to construct such bases with the desired properties for essentially all cases of interest [13, 14, 18, 29, 30, 32].

We will be dealing with domains that can be written as the disjoint union of smooth parametric images $\Omega_i = \kappa_i(\Box)$ of the unit cube $\Box := (0,1)^d$, i.e., $\bar{\Omega} = \bigcup_{i=1}^M \bar{\Omega}_i$. Then, each ψ_λ, $\lambda \in \nabla$, restricted to Ω_i is the image through κ_i of a linear combination of tensor product wavelets $\hat{\psi}_\mu$ on $\Box$, i.e.,

$$\psi_\lambda|_{\Omega_i}(x) = \sum_{\mu \in S(i,\lambda)} \gamma_{\mu,i}\, \hat{\psi}_\mu((\kappa_i)^{-1}(x)),$$

where $S(i,\lambda)$ is a suitable set of indices of the form $\mu = (j, \boldsymbol{k})$, $j := |\lambda|$, and $\gamma_{\mu,i}$ are suitable (matching) coefficients independent of j (in order to ensure global continuity). To be specific, each wavelet on $\Box$ has the following representation:

$$\hat{\psi}_\mu(\hat{x}) = \prod_{\nu=1}^{d} \vartheta_{\mu_\nu}(\hat{x}_\nu),$$

where each index μ_ν is of the form $\mu_\nu = (j, e_\nu, k_\nu)$ and

$$\vartheta_{(j,e_\nu,k_\nu)} := \begin{cases} \xi_{j,k_\nu} & \text{if } e_\nu = 0, \\ \eta_{j,k_\nu} & \text{if } e_\nu = 1. \end{cases}$$

Here ξ_{j,k_ν} and η_{j,k_ν} are scaling functions and wavelets on $[0,1]$, respectively.

Data structure: `index`. From what has been said so far, it is clear that λ can be viewed as a quadruple $(j, p, \boldsymbol{e}, \boldsymbol{k})$, where p denotes the number of the patch, $j \geq j_0$ the level. The vectors $\boldsymbol{k} = (k_1, \ldots, k_d)$ and $\boldsymbol{e} = (e_1, \ldots, e_d)$ contain the indices k_ν and the types e_ν of the univariate scaling or wavelet functions, respectively, as explained above. Of course, the valid ranges for these parameters are determined by the choice of the wavelet bases on $[0, 1]$.

Next, we define the above-mentioned "natural" ordering of the indices that is adequate for handling the geometry and the multiresolution spaces. For two indices $\lambda = (j, p, \boldsymbol{e}, \boldsymbol{k})$, $\lambda' = (j', p', \boldsymbol{e}', \boldsymbol{k}')$ we define $\lambda < \lambda'$ if $(j, p, \boldsymbol{e}, \boldsymbol{k}) < (j', p', \boldsymbol{e}', \boldsymbol{k}')$ in the usual lexicographic ordering of these vectors.

Finally, the particular construction of Ψ depends on two parameters, namely, the choice of the wavelet bases on the interval and the geometry of Ω which—besides the choice of the construction method—determines the coefficients $\gamma_{\mu,i}$. Following the philosophy of separating algorithm and data, we kept these two data as parameters.

Hence, the construction of an `index` amounts to the computation of the chosen wavelet bases on the interval and then to the setup of the whole basis Ψ in the above form. It is important to stress the fact that this construction has to be done only *once and for all* in a preprocessing step and only for the minimum level, say, j_0. All information for higher levels $j > j_0$ can be deduced from that on j_0.

Particular choices and used software. As wavelet bases on Ω (which in our tests will be an interval for $d = 1$ or an L-shaped domain for $d = 2$) we choose the construction from [29], but the other variants would work in the same way. First numerical results of wavelet methods on the L-shaped domain can be found in [15]. The routines for constructing the wavelets we have used in this paper have been implemented by Vorloeper and are described in detail in [50].

For the wavelet systems on $[0, 1]$ we choose biorthogonal B-spline wavelets on the interval as constructed in [27, 31]. A detailed description of C++-software for constructing wavelets on the interval can be found in [9]. It is based on the *Multilevel Library* presented in [7] and [8].

3.3. Computation of matrix and right-hand-side entries. Based upon the above-described data structures, the adaptive algorithm in section 2 has been realized. In particular, all routines described in the appendix have been implemented.

For the fast matrix–vector multiplication, we have to identify the set

$$\Lambda(\lambda, J) := \Big\{\nu = (j', k') \in \nabla : \operatorname{supp} \psi_\lambda \cap \operatorname{supp} \psi_\nu \neq \emptyset,\ |j - j'| \leq J\Big\}, \tag{3.1}$$

which is determined by (2.14). For our example of a second order differential operator this set contains for a given wavelet ψ_λ the indices of those wavelet functions, whose support intersects the support of ψ_λ along with a cut-off criterion of level differences. These are exactly the nonvanishing entries of the stiffness matrix in the corresponding range of level differences.

In one dimension, this is a technical but straightforward task since explicit formulas for the supports of the wavelets are available. The technicalities are due to the modifications of functions near the end points of the interval. Since the supports of these functions are not given by the same formula as for the interior functions, several cases have to be considered.

In two dimensions, the situation is much more involved. This is mainly due to the fact that also wavelet functions on different patches interact. The corresponding information can be deduced from member functions of `index` so that the realization of the corresponding routine can still be done independently of these parameters.

It remains to address the following two issues:

(i) the computation of the right-hand-side data, i.e., L_2-inner products of the given function f and wavelets as in (2.4), and

(ii) the computation of the entries of the stiffness matrix. This means the evaluation of the bilinear form $a(\psi_\lambda, \psi_\nu)$ for any active indices λ, ν.

As for (i), the capability of computing all relevant wavelet coefficients with respect to the dual basis with sufficient accuracy depends on what kind of information on f is available. In fact, f as part of the model set up by the user involves in many cases simple data. Recently significant progress has been made in rendering the computation of $\mathbf{f}_\eta$ very efficient under reasonably general assumptions on f [4, 5, 11].

The second issue (ii) is practically much more delicate. When dealing with piecewise polynomial wavelets and constant coefficient differential operators as in the example below the requirement of computing the entries at unit cost can certainly be met. When nonconstant coefficients or nontrivial parametric mappings are involved this is by far less obvious. In order to be able to validate the convergence behavior of the scheme at a possibly early stage we employ here a provisional strategy of precomputing the relevant matrix entries via a high level scaling function representation. Of course this module is to be exchanged by more advanced strategies along the following possible lines. Schemes for the adaptive computation of products (of derivatives) of scaling and wavelet functions (also possibly multiplied by a given function) have recently been developed in [11].

A different strategy aiming at optimal computational complexity in the present context is proposed in [6]. There a suitable approximation process provides approximations to the whole summands in (2.25) simultaneously following the lines of [33].

3.4. Conclusions. Let us conclude by comparing the properties of our data structures with the tasks that have been identified at the beginning of this section. The use of STL data structures already ensures that the requirements (a)–(e), and also (f), are in fact met. Moreover, since we made heavy use of existing STL classes, the implementation could be done in a reasonable amount of time. Finally, since our data structures are actually special cases of STL classes, their handling coincides with the corresponding STL classes. These, however, are well documented [48] (also online [47]) so that an easy application is guaranteed. This means, in particular, that also other types of wavelet bases can easily be included only by providing the appropriate interfaces. This holds for other wavelet bases both on the interval and on Ω.

It is clear from the above discussions that a full exploitation of the conceptual power requires new algorithmic ingredients that largely had to be designed from scratch. Specifically, for the problem-dependent part, little can be borrowed from existing software. Consequently, not all parts could be brought to a mature state yet. Nevertheless, we think that the current summary of affairs will provide valuable guidelines for further developments.

4. Numerical tests. In spite of the much wider principal scope of applicability, we confine the numerical tests to second order elliptic boundary value problems in one and two spatial dimensions. In particular, this allows us to exploit special Besov regularity results for the validation of the schemes especially in situations where adaptivity is expected to pay off most. Moreover, we consider only a simple L-shaped domain and refer to [43] for further tests and examples on general two-dimensional domains with piecewise smooth boundary. However, to study the dependence on parameters we include Helmholtz-type problems for which the energy space differs more and more from H^1 when the viscosity parameter decreases.

Bearing in mind that adaptivity is expected to pay off in the presence of singularities, in section 4.1 we consider first a one-dimensional model problem where a nearly singular behavior of the solution is caused only by a strong gradient of the right-hand side. Unlike earlier studies of wavelet schemes we do not confine the discussion to periodic problems.

The second class of examples in section 4.2 is concerned with more sophisticated problems on nonsmooth domains in $\mathbb{R}^2$. In these cases, there also occur singularities which are not generated by the right-hand sides but by the shape of the domain. To our knowledge, such examples have not been studied before in the wavelet context. Therefore, the quantitative performance of the scheme should be very instructive.

4.1. One-dimensional examples. As a first simple example we consider the second order boundary value problem

$$-\frac{d^2u}{dx^2} = f \quad \text{on } \Omega = (0,1), \qquad u(0) = u(1) = 0. \tag{4.1}$$

The choice of the right-hand side will be discussed later. The variational formulation of (4.1) reads

$$\langle u', v' \rangle = \langle f, v \rangle \quad \text{for all } v \in H_0^1(0,1). \tag{4.2}$$

For the treatment of (4.2) the wavelet basis has to satisfy (2.5) at least for $H = H^1(0,1)$. Therefore we choose cardinal B-spline wavelets on the interval that are induced by the generators

$$\varphi := N_m(x), \quad \tilde{\varphi} := \tilde{N}_{m,\tilde{m}}(x), \qquad m, \tilde{m} \geq 2, \tag{4.3}$$

on the real line [16].

Due to (4.2), the trial functions have to satisfy homogeneous Dirichlet boundary conditions. To facilitate a possibly sparse representation of the right-hand side with respect to the dual basis, we employ so-called *complementary boundary conditions* (cf. [31]), i.e., the primal functions fulfill homogeneous Dirichlet boundary conditions whereas the dual functions remain unconstrained.

Since here $H = H_0^1(0,1)$, the diagonal matrix in (2.5) can be chosen as $\omega_\lambda := 2^{|\lambda|}$. For the validity of norm equivalences of the form (2.5) in the presence of boundary conditions, see [31].

4.1.1. Compressibility of the stiffness matrix. To be able to interpret the results, we have to identify first the *range of asymptotic optimality* permitted by the above choice of bases. Theorem 2.2 implies that the asymptotic behavior depends on the compressibility of the matrix $\mathbf{A}$. In particular, the parameter s^* defined in (2.13) provides a range where optimality is guaranteed. However, in the present situation this criterion is too weak. In fact, we know from [22] that the parameter σ in (2.11) must satisfy $t + \sigma < \gamma$ where γ bounds the Sobolev regularity of the wavelets. In this case we have $t = 1$ and $\gamma = m - 1/2$, which gives $\sigma = m - 3/2$, i.e., $s^* = m - 2$. Therefore, in the case $\varphi = N_2$, we end up with $s^* = 0$, which is clearly useless. Of course, the condition (2.13) is only sufficient, and in this case a more detailed analysis of the compression properties is necessary. In fact, for our special case, we have the following sharper result.

Lemma 4.1. *Let* $\mathbf{A}$ *denote the stiffness matrix to* (4.1) *obtained by B-spline wavelets of order* m *as basis functions. Then for any* $\epsilon > 0$ *the following compression estimate holds:*

$$\|\mathbf{A} - \mathbf{A}_J\| \lesssim 2^{-J(m-3/2-\epsilon)}, \quad \textit{i.e.,} \quad \mathbf{A} \in \mathcal{A}_s \textit{ for all } s < m - 3/2. \tag{4.4}$$

Proof. Equation (4.4) can be established directly by using a version of the *Schur lemma*: If for the matrix $\mathbf{B} = (b_{\lambda,\lambda'})_{\lambda,\lambda'\in\mathcal{J}}$ there is a sequence $\omega_\lambda, \lambda \in \mathcal{J}$ and a positive constant c such that

$$\sum_{\lambda'\in\mathcal{J}} |b_{\lambda,\lambda'}|\omega_{\lambda'} \leq c\omega_\lambda \quad \text{and} \quad \sum_{\lambda\in\mathcal{J}} |b_{\lambda,\lambda'}|\omega_\lambda \leq c\omega_{\lambda'}, \quad \lambda, \lambda' \in \mathcal{J}, \tag{4.5}$$

then $\|\mathbf{B}\| \leq c$. We want to use (4.5) for the sequence $\omega_\lambda = 1$ for all $\lambda \in \mathcal{J}$. Let us briefly sketch the arguments. The first step is to estimate the entries in the stiffness matrix corresponding to (4.2). Ignoring for the moment the boundary effects, recalling that derivatives of wavelets are again wavelets (see, e.g., [26]), and using the vanishing moment property of wavelets, we obtain for any polynomial $P_{\lambda'}$ on $\Omega_{\lambda'}$ of degree $< m - 1$ and $j' \geq j$

$$\begin{aligned}\left\langle \frac{d\psi_\lambda}{dx}, \frac{d\psi_{\lambda'}}{dx} \right\rangle &= \left\langle \frac{d\psi_\lambda}{dx} - P_{\lambda'}, \frac{d\psi_{\lambda'}}{dx} \right\rangle \leq \left\| \frac{d\psi_\lambda}{dx} - P_{\lambda'} \right\|_{L_2(\Omega_{\lambda'})} \left\| \frac{d\psi_{\lambda'}}{dx} \right\|_{L_2} \\ &\lesssim \left\| \frac{d\psi_\lambda}{dx} - P_{\lambda'} \right\|_{L_2(\Omega_{\lambda'})} 2^{j'}.\end{aligned}$$

Since $\frac{d}{dx}\psi_\lambda \in H^s,\ s < m - 3/2$, a classical Whitney-type estimate therefore yields

$$\begin{aligned}\left\langle \frac{d\psi_\lambda}{dx}, \frac{d\psi_{\lambda'}}{dx} \right\rangle &\lesssim 2^{j'}2^{-j'(m-3/2-\epsilon)} \left| \frac{d\psi_\lambda}{dx} \right|_{H^{m-3/2-\epsilon}} \lesssim 2^{j'}2^{-j'(m-3/2-\epsilon)}|\psi_\lambda|_{H^{m-1/2-\epsilon}} \\ &\lesssim 2^{j'}2^{-j'(m-3/2-\epsilon)}2^{j(m-1/2-\epsilon)} \lesssim 2^{(j-j')(m-3/2-\epsilon)}2^{j+j'},\end{aligned}$$

so that, taking the preconditioning matrix $\mathbf{D}$ into account, we get

$$|a_{\lambda,\lambda'}| \lesssim 2^{(j-j')(m-3/2-\epsilon)}, \qquad j' \geq j. \tag{4.6}$$

The case $j' < j$ can be treated analogously,

$$|a_{\lambda,\lambda'}| \lesssim 2^{(j'-j)(m-3/2-\epsilon)}, \qquad j' < j. \tag{4.7}$$

Moreover, the vanishing moment property of wavelets implies that the only nonvanishing entries $a_{\lambda,\lambda'}$ correspond to the wavelets $\psi_{\lambda'}$ whose supports intersect the singular support of ψ_λ. It can be shown that the number of these entries does not depend on the refinement level. Consequently, we obtain

$$\sum_{|\lambda'|=j'} |a_{\lambda,\lambda'}| \lesssim 2^{-|j-j'|(m-3/2-\epsilon)}. \tag{4.8}$$

According to (2.14) and (4.5), we have to show that

$$\sum_{|j-j'|>J} \sum_{|\lambda'|=j'} |a_{\lambda,\lambda'}| \lesssim 2^{-J(m-3/2-\epsilon)}. \tag{4.9}$$

Let us again first consider the case $j' > j$. By using (4.8), we obtain

$$\begin{aligned}\sum_{j'-j>J} \sum_{|\lambda'|=j'} |a_{\lambda,\lambda'}| &\lesssim \sum_{j'=j+J}^{\infty} 2^{(j-j')(m-3/2-\epsilon)} \lesssim 2^{j(m-3/2-\epsilon)}2^{-(J+j)(m-3/2-\epsilon)} \\ &\lesssim 2^{-J(m-3/2-\epsilon)}.\end{aligned} \tag{4.10}$$

The case $j' \leq j$ can be treated analogously. The second condition in (4.5) can be checked in a similar fashion, and hence (4.4) is established. □

4.1.2. Fast matrix–vector multiplication. In view of the pivotal role of the approximate fast matrix–vector multiplication, we present first some tests of this ingredient. The error estimate (2.26) indicates that the approximation power of the fast matrix–vector multiplication is determined by the parameter s^* which, according to (4.4), is given by $s^* = m - 3/2$. In Figure 4.1, the error $\|\mathbf{Av} - \mathbf{w}_j\|_{\ell_2}$ is plotted in a logarithmic scale for different choices of m and $\tilde{m}$ in (4.3). Since the slopes do not change when keeping m fixed and varying $\tilde{m}$, we display only one particular choice of $\tilde{m}$ for each m. In Table 4.1, the values of s^*, the observed values s of the numerical tests, and the ratio s^*/s are shown. We deduce that the estimate (4.4) derived above is in fact sharp.

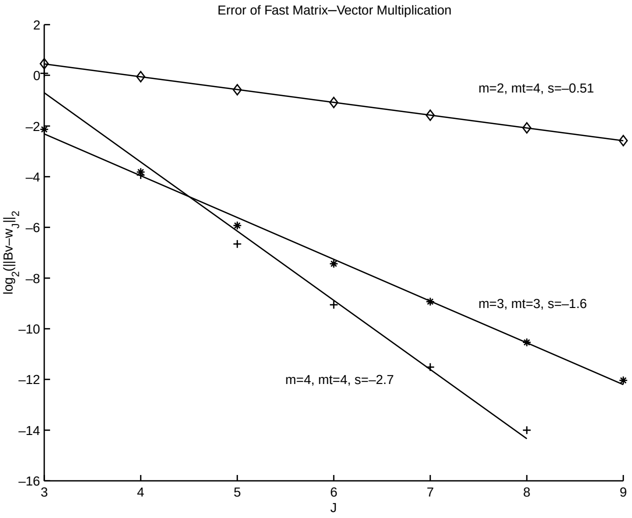

FIG. 4.1. *The slope of error reduction in the fast matrix–vector multiplication.*

TABLE 4.1
Expected and observed slopes for the error of the fast matrix–vector multiplication.

d	s^*	s	Ratio
2	0.5	0.51	0.98
3	1.5	1.60	0.94
4	2.5	2.70	0.93

4.1.3. Example 1. In our first test case, we choose f corresponding to the solution

$$u(x) = 4\frac{e^{ax}-1}{e^a-1}\left(1-\frac{e^{ax}-1}{e^a-1}\right), \tag{4.11}$$

which satisfies the boundary conditions. For our tests, we choose $a = 5.0$. The exact solution and the right-hand side are shown in Figure 4.2.

We first compare the computed Galerkin solution with the best N-term approximation. Recall that the convergence rate realized by the adaptive scheme is limited by the compressibility range of the matrix $\boldsymbol{A}$ which by Lemma 4.1 is $s^* = m - 3/2$. Note that this parameter is related to the *regularity* of the wavelets. This effect has

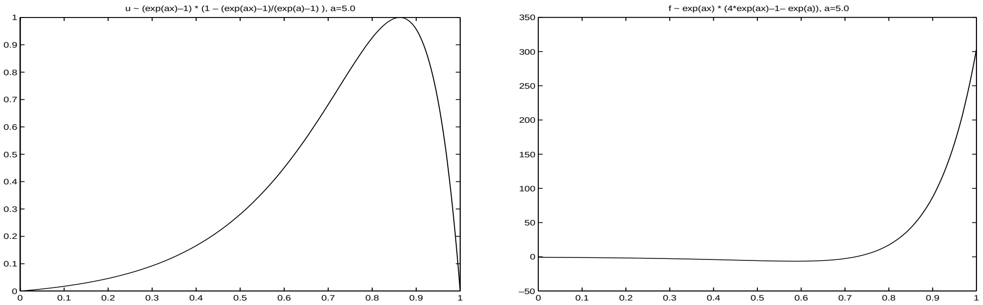

FIG. 4.2. *The exact solution and the right-hand side for the one-dimensional example.*

no counterpart in uniform discretizations. We expect that the performance of the adaptive scheme can be improved by increasing the smoothness of the wavelet basis. At this point, we want to emphasize that in contrast to linear schemes the maximal approximation order of the adaptive scheme is *not* limited by the polynomial exactness of the multiresolution analysis but apparently by its regularity. Of course, using B-spline wavelets both quantities are not far apart from each other. In Figure 4.3 we have displayed in a logarithmic scale the error for both the best N-term approximation (lines) and the adaptive algorithm (dots) as N increases. We see that both errors show almost the same behavior. We also see that the performance of the algorithm improves as the smoothness of the wavelet bases increases.

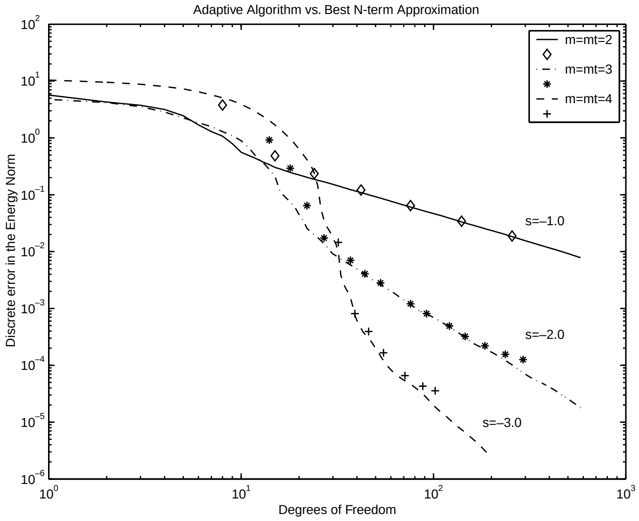

FIG. 4.3. *Comparison between best N-term approximation and adaptive algorithm for the one-dimensional example.*

Note that the solution to our test problem has pointwise smoothness of arbitrary order and therefore belongs to every Sobolev space. Thus, by the discussion in section 2.9, in principle, a uniform refinement scheme provides the same asymptotic order of approximation for functions in $H^{m-1/2}(0,1)$, i.e., in $\mathcal{O}(N^{-(m-3/2)})$. However, as pointed out at the end of section 2.9, a quantitative gain of efficiency is still possible if the $H^{m-1/2}$-norm of the solution u is large when compared with the corresponding norm in the Besov space $B^{m-1/2}_{\tau^*}(L_{\tau^*}(\Omega))$, $1/\tau^* = m - 3/2 + 1/2 = m - 1$. In our example, these norms indeed differ significantly as can be seen in Table 4.2. We have estimated the Besov norms by employing the norm equivalences (2.6), i.e., by computing weighted sequence norms of wavelet expansions. Figure 4.2 explains the difference between Sobolev and Besov norms. The boundary layer of the solution u increases the Sobolev norm but has less influence on the (weaker) Besov norm.

TABLE 4.2
Sobolev and Besov norms of the exact solution (4.11) *to the one-dimensional example.*

m	$H^{m-1/2}$	$B^{(m-1/2)}_{(m-1)^{-1}}(L_{(m-1)^{-1}})$
1.5	6.73	6.73
2	39.4	14.5
2.5	240	47.8
3	1617	275

We have compared the adaptive scheme with uniform refinement in order to get an impression of the effect of the different sizes of the above-mentioned norms. The results of these numerical tests are shown in Figure 4.4. They confirm indeed the gain of efficiency for adaptive schemes for this example as indicated by the comparison of Sobolev and Besov norms in Table 4.2. In spite of the significant quantitative gain, the slopes of the curves are indeed the same reflecting equal asymptotic behavior, as predicted by the above comments.

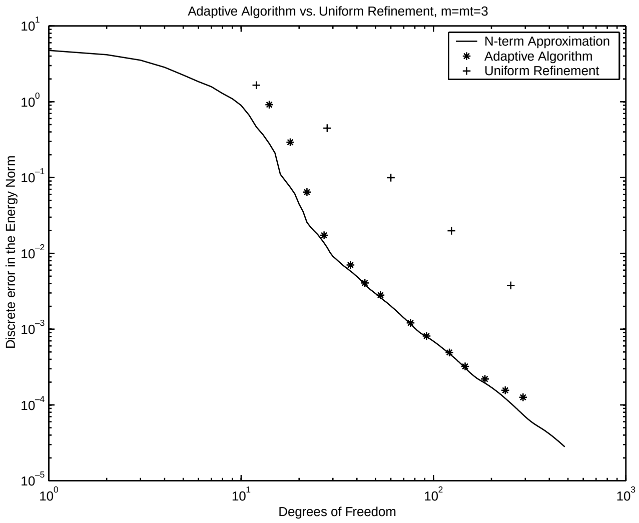

FIG. 4.4. *Error of the adaptive algorithm and of a uniform refinement for the one-dimensional example.*

In Figure 4.5, we have plotted the sets of wavelet indices that correspond to the adaptively chosen wavelets. These wavelets are sometimes called *active*. One observes that the adaptive algorithm in fact recognizes the strong gradient of the solution u according to the boundary layer and adds wavelet coefficients locally in these regions.

4.2. Two-dimensional examples. We have tested our algorithm for the Poisson and the Helmholtz equations on an L-shaped domain Ω in $\mathbb{R}^2$,

$$-\triangle u = f \quad \text{on} \quad \Omega, \quad u|_{\partial\Omega} = 0, \quad \text{and} \quad -\varepsilon\triangle u + u = f \quad \text{on} \quad \Omega, \quad u|_{\partial\Omega} = 0. \tag{4.12}$$

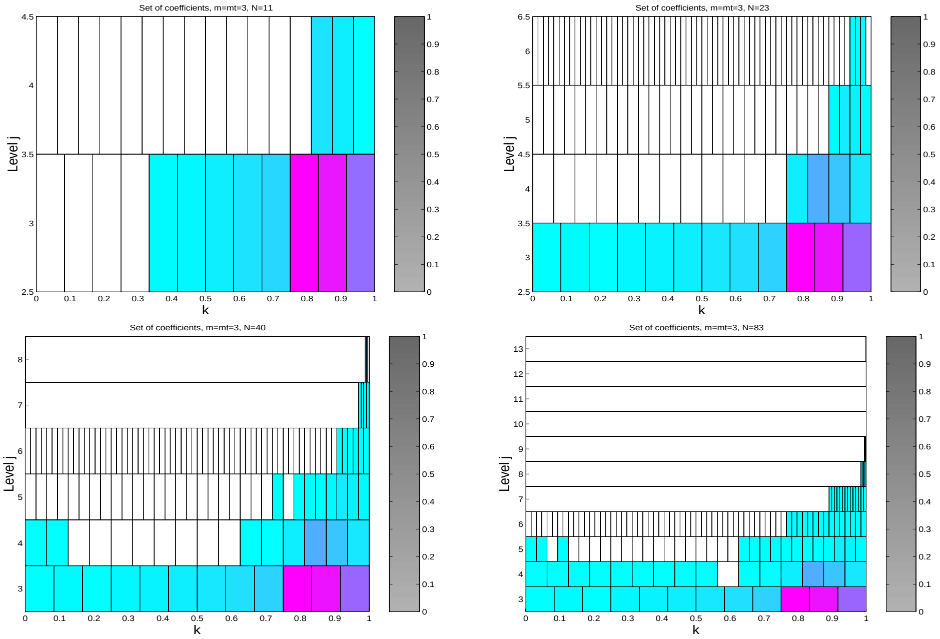

FIG. 4.5. *The sets of active indices* Λ_1*,* Λ_3*,* Λ_4*, and* Λ_6 *for the one-dimensional example.*

As already said, these problems are interesting because the solution may exhibit singularities solely caused by the shape of the domain even for smooth right-hand sides. Moreover, we can test the robustness of the scheme with respect to decreasing viscosity. We refer to [35, 44, 40] for the classical theory of singularities on polygonal domains, and to [20, 21] for an analysis of these singularities in terms of Besov smoothness.

4.2.1. Example 1: The Poisson equation, singular solution with smooth right-hand side. Introducing polar coordinates (r, θ), we define the right-hand side f in (4.12) corresponding to the solution

$$u(r,\theta) := \zeta(r) r^{2/3} \sin(\tfrac{2}{3}\theta), \tag{4.13}$$

where $\zeta \in C^\infty(\Omega)$ is a truncation function defined by

$$\zeta(r) := \frac{w(\frac{3}{4}-r)}{w(r-\frac{1}{2})+w(\frac{3}{4}-r)} \quad \text{with} \quad w(r) := \begin{cases} e^{-1/r^2} & \text{if} \quad r>0, \\ 0 & \text{else.} \end{cases}$$

The function u is shown in Figure 4.6. Observe that u is harmonic in the vicinity of the reentrant corner. Therefore the right-hand side f is C^∞ everywhere in Ω which confirms that the singularity of u is generated by the shape of the domain; see Figure 4.6. To our knowledge so far adaptive wavelet schemes have not been applied yet to situations of this type.

Due to its singularity at the reentrant corner, the solution u is contained in $H^\alpha(\Omega)$ only for $\alpha < 5/3$. Consequently, uniform grids yield at best an H^1-convergence rate $N^{-1/3}$. On the other hand, it is well known that an optimal mesh refinement allows us to restore the rate $N^{-1/2}$ in the case of affine finite elements (which would be

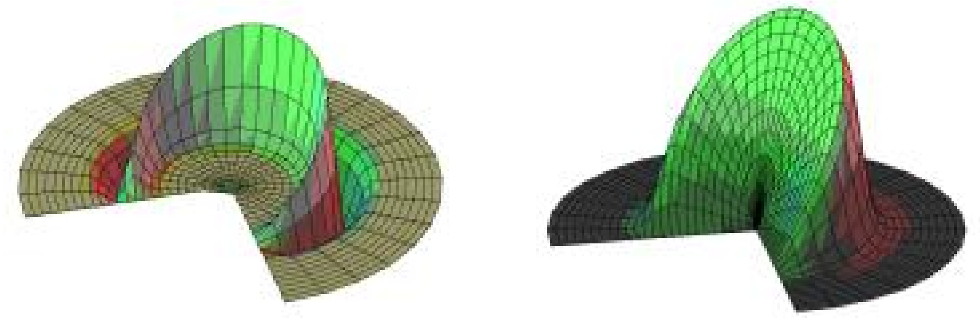

FIG. 4.6. *The right-hand side (left) and exact solution (right) to our model problem.*

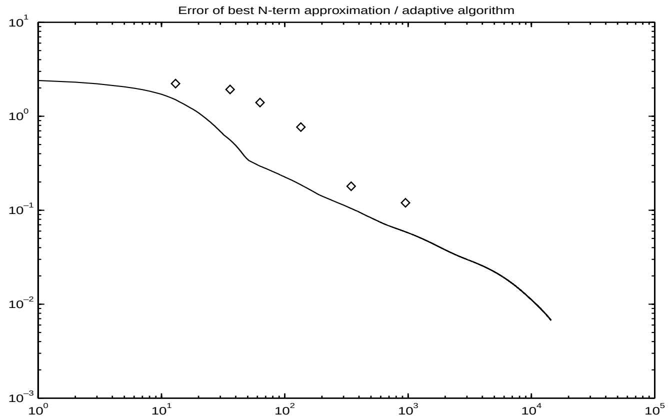

FIG. 4.7. *Comparison of best N-term approximation and adaptive algorithm for the first two-dimensional example.*

obtained by a uniform method if there were no singularity) and one can easily check that the same holds for the best N-term approximation with piecewise affine wavelets.

Again, we have tested the performance of the adaptive algorithm in this regard. In Figure 4.7, the errors are shown for increasing N. The continuous line corresponds to the best N-term approximation. Aside from the quantitatively very good matching, we observe the optimal rate $N^{-1/2}$. Similar to the one-dimensional examples it turns out that the approximation rate of the adaptive scheme can be significantly increased by using smoother and higher order wavelet bases; see section 4.2.4.

As for the quantitative refinement history, starting with the empty set, the residual in the first step is influenced only by the wavelet coefficients of the right-hand side. These wavelet coefficients are small near the vertex due to the fact that u is harmonic there. Now in the next steps the adaptive scheme has to track down the singularity at the reentrant corner and add wavelet coefficients there.

Figure 4.8 displays both the approximate solution and the error to the exact solution. At first, coefficients are added to reduce the error where strong gradients are induced by the right-hand side, whereas in the subsequent iterations the error is reduced in the vicinity of the reentrant corner, so that after five iterations the error is equally distributed. Figure 4.9 shows the sets of active wavelet coefficients

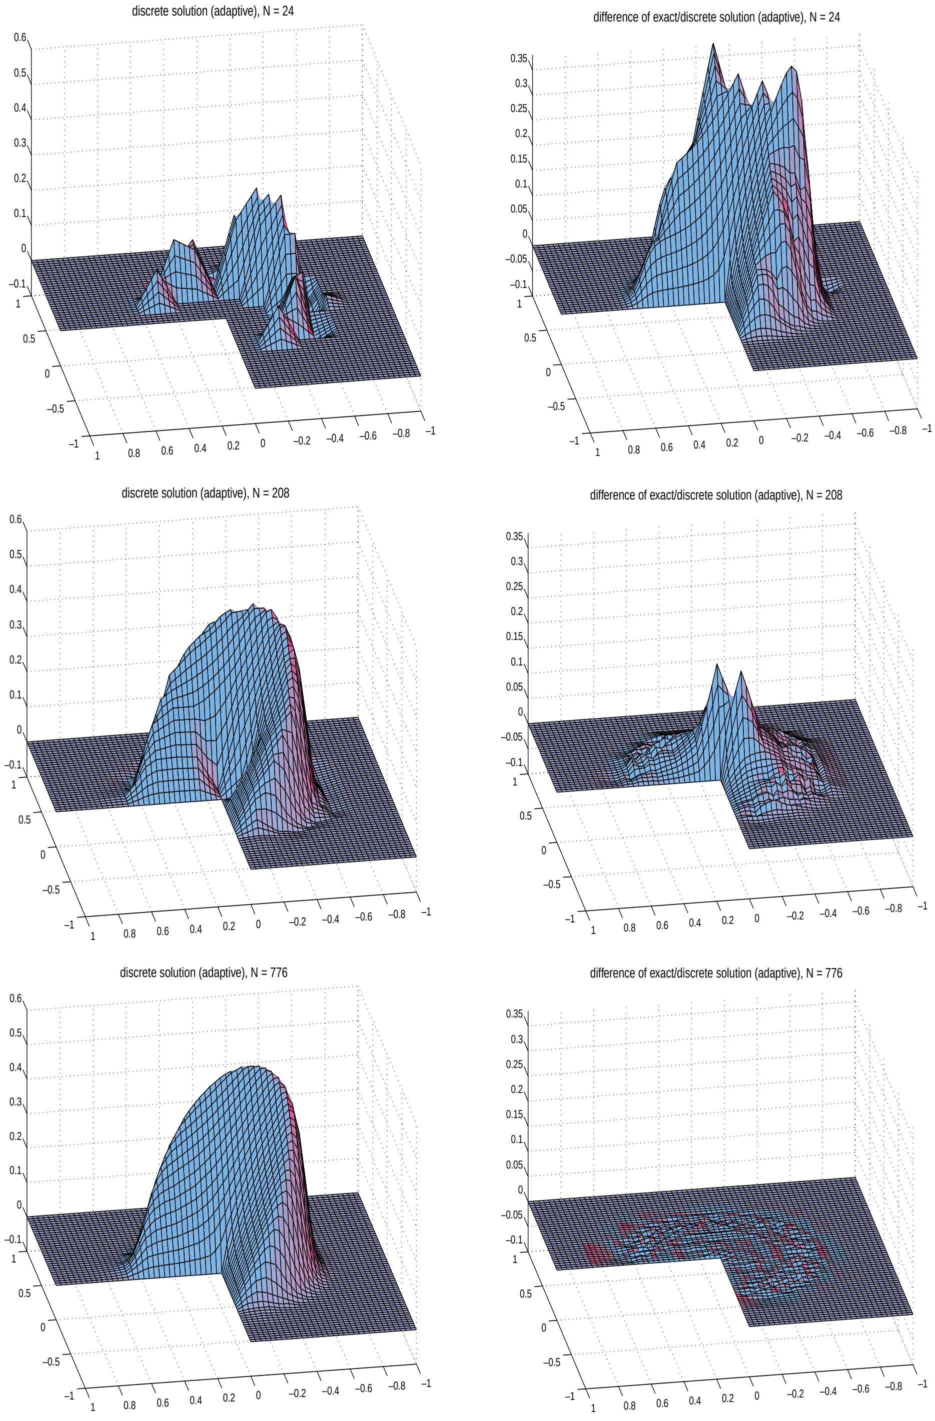

FIG. 4.8. *The first, third, and fifth approximate solutions and the differences to the exact solution for the first two-dimensional example.*

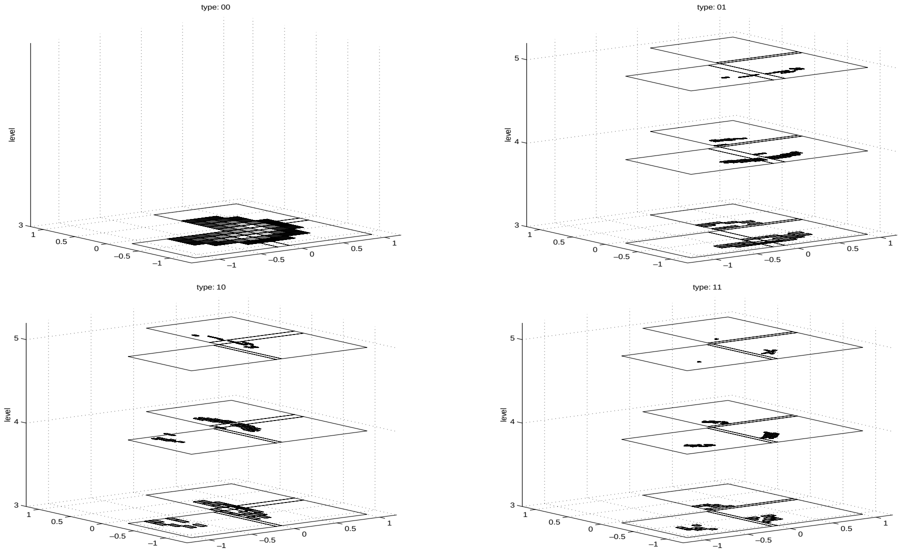

FIG. 4.9. *Index sets for the fifth iteration, first two-dimensional example.*

corresponding to the fifth iteration of the adaptive algorithm. The first picture shows the set of coefficients corresponding to the scaling functions, whereas in the remaining three pictures we have plotted the three different types of wavelets (corresponding to $\boldsymbol{e}$ in section 3.2) separately. It is shown in detail which coefficients are added on each refinement level. We see that the symmetry of the exact solution is reflected by the similarity of the pictures in the upper right and lower left corner. These two pictures correspond to tensor product functions of wavelet/generator and generator/wavelet type, respectively.

4.2.2. Example 2: The Poisson equation, singular right-hand side. In order to test the quantitative performance of the scheme in the presence of singularities that are induced by the right-hand side, we have constructed, with the aid of a dual relation of the norm equivalences (2.5), a special right-hand side with an isolated singularity "far away" from the reentrant corner. This is obtained by setting all wavelet coefficients of f equal to zero except the ones in the vicinity of one chosen point. At this specific point, we choose the coefficients as $\langle f, \psi_\lambda \rangle = 2^{(|\lambda|/2)}$. Consequently, the resulting functional f is not contained in L_2 but only in $H^s,\ s < -1/2$. An approximation of a typical example consisting of the wavelets on the first six levels is plotted in Figure 4.10.

We expect that the singularity of the right-hand side is reflected by the corresponding solution. In Figure 4.11, we have depicted the Galerkin approximations with respect to two different iterations of the adaptive algorithm. We see that the solution indeed behaves as expected, i.e., the singularity of the right-hand side shows up in a somewhat smeared shape. In this case, the right-hand side dominates the influence of the domain. Nevertheless, for the last iterations, the singularity caused by the domain (as in our first example) can again be seen, but its impact is almost negligible.

4.2.3. Example 3: The Helmholtz equation. We include a test for the Helmholtz equation (4.12) to see how the scheme copes with different small values of ε.

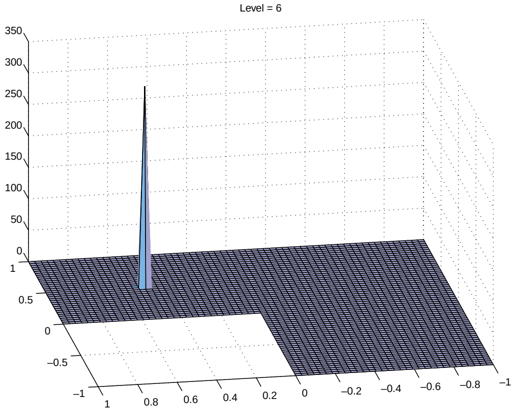

FIG. 4.10. *A right-hand side with a sharp singularity, second two-dimensional example.*

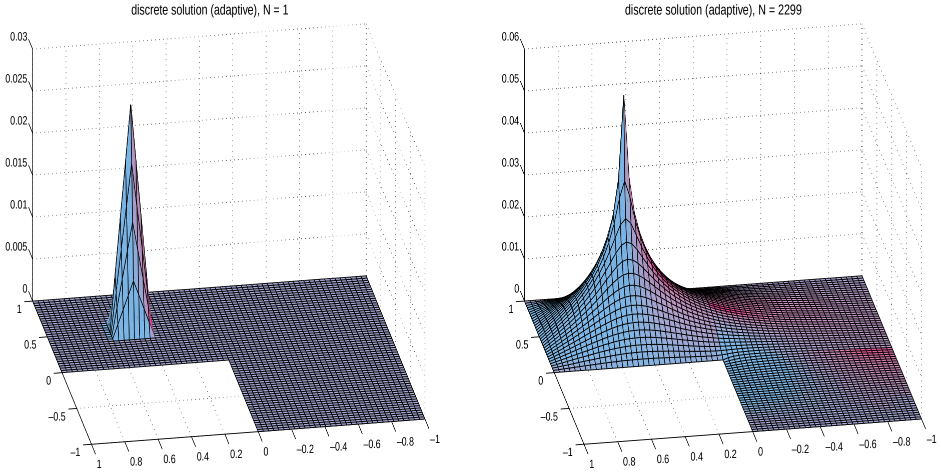

FIG. 4.11. *The first and the last computed Galerkin approximation for a right-hand side with a singularity, second two-dimensional example.*

In this case, if the right-hand side does not vanish at the boundary, the solution has a boundary layer. For $\varepsilon = 10^{-5}$ we used the sum of the singular solution and a constant as the right-hand side. The solution to this problem is displayed in Figure 4.12. The main observations can be summarized as follows: The proper ε-dependent diagonal scaling explained in section 2.2 leads to uniformly bounded condition numbers of about the same size as for the Poisson equation uniformly in ε. Note that for decreasing ε the energy space changes from H^1 toward L_2. Since we are employing Riesz bases for both spaces this has no adverse effect on the adaptive scheme, not even in quantitative terms. Again, the adaptive algorithm produces approximate solutions with an error of the same order as the best N-term approximation and very good quantitative matching.

4.2.4. Comparison with finite element schemes. We have also compared our method with a well-established finite element scheme, i.e., with the software package Differential Equation Analysis Library (`deal.II`) which was developed at the IWR in Heidelberg [2]. This package seemed to be suitable for a meaningful comparison

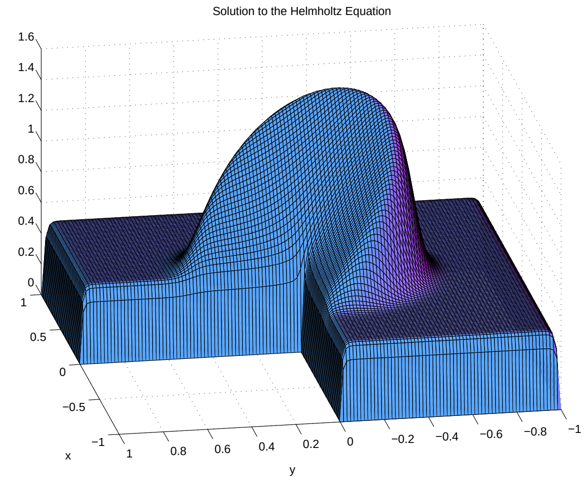

Fig. 4.12. *Solution for the third two-dimensional example.*

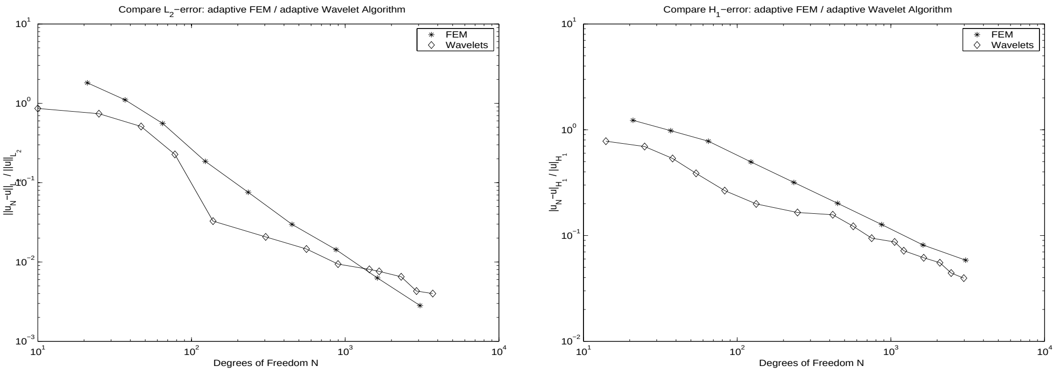

Fig. 4.13. *Rel. L_2- and H_1-error for piecewise affine functions.*

for the following reasons:

- it is written as an open source code;
- it realizes a fully adaptive finite element scheme, using a refinement strategy based on a posteriori error estimators developed by Kelly et al. [41];
- it is based on rectangular partitions.

In Figure 4.13 the results are displayed for the Poisson equation with right-hand side as in Example 1 and piecewise affine finite elements and wavelets. The wavelet scheme seems to produce a somewhat better accuracy for the same number of degrees of freedom, but the asymptotic behavior appears to be the same. In Figure 4.14, a similar comparison is shown for piecewise quadratic functions. Now the wavelet scheme exhibits a better performance in a much more pronounced way. The predicted asymptotically better compressibility of the wavelet representation starts to show up quantitatively. This difference seems to be even more enhanced for the Helmholtz problem; see Figure 4.15. Because of the different nature of the energy space, we show here both the L_2- as well as the H^1-error. This seems to confirm that finite element preconditioners are usually better suited for H^1 problems than for L_2-like problems, while the wavelet scheme shows the same robust behavior in both cases.

Appendix. The adaptive algorithm ALGORITHM^c. In this appendix, we detail all steps that are needed for the fully computable version **ALGORITHM^c** described in section 2. Let us first recall some constants that will be needed here. Let c_1, c_2 be the constants appearing in the first equivalence of (2.17), i.e.,

$$c_1\|\mathbf{v}\|^2_{\ell_2(\nabla)} \le \|\mathbf{v}\|^2 \le c_2\|\mathbf{v}\|^2_{\ell_2(\nabla)}, \tag{A.1}$$

and let $\kappa \ge \|\boldsymbol{A}\|\,\|\boldsymbol{A}^{-1}\|$ be an estimate for the condition number of $\boldsymbol{A}$, e.g., $\kappa := c_2c_1^{-1}$.

We start with an initialization step that also sets global constants and parameters:

INIT.

(i) *Fix some γ in $(0,1]$.*

(ii) *Determine F according to $\|\mathbf{f}\|_{\ell_2} \le F$.*

(iii) *Determine q_1, q_2, q_3, and q_4 such that*

$$\left(\frac{q_3}{c_2} + \frac{2(1+\gamma)(q_1+q_2+q_3)}{\gamma c_1}\right) \le q_4, \quad \left(q_4\sqrt{\kappa} + \frac{q_3}{c_2}\right) \le \frac{1}{10},$$

$$(q_1+q_2+q_3+\kappa^{-1}q_3) \le \frac{c_1}{20}.$$

- *Set $q_0 := \kappa^{1/2} + q_3/c_2$, $\theta := \sqrt{1-\frac{c_1}{4c_2}}$, and $\bar{\theta} := 1 - \frac{1}{6\kappa}$.*

(iv) *Define*

$$K := K(\kappa, \theta) := \left\lceil \frac{\log 20\kappa}{|\log \theta|} \right\rceil + 1. \tag{A.2}$$

We first describe the main algorithm **ALGORITHM**^{c}. The subroutines will be detailed below.

ALGORITHM^c.

(i) **Initialization.** *Let $\varepsilon > 0$ be the target accuracy. Perform* **INIT**. *Set $\Lambda := \emptyset$, $\mathbf{v} = \mathbf{0}$, and $\delta := F$.*
(ii) *If $\delta \le c_1^{1/2}\varepsilon$, accept $\mathbf{u}(\varepsilon) := \mathbf{v}$, $\Lambda(\varepsilon) := \Lambda$ as the final solution and STOP. Otherwise,* **NPROG** $[\Lambda, \mathbf{v}, \delta, \mathbf{f}] \to (\hat\Lambda, \hat{\mathbf{v}}, \hat{\mathbf{r}})$.
(iii) *If $\|\hat{\mathbf{r}}\|_{\ell_2} + (q_1 + q_2 + (1 + \kappa^{-1})q_3)\delta \le c_1\varepsilon$ accept $\bar{\mathbf{u}}(\varepsilon) := \bar{\mathbf{u}}_{\Lambda^k}$, $\Lambda(\varepsilon) = \Lambda^k$ as the solution, where $\bar{\mathbf{u}}_{\Lambda^k}$, $\Lambda(\varepsilon) = \Lambda^k$ are the last outputs of* **NGROW** *in* **NPROG** *before thresholding.*
Otherwise, replace δ by $\delta/2$, $\mathbf{v}$ by $\hat{\mathbf{v}}$, and Λ by $\hat\Lambda$ and go to (ii).

We now list the routines called above in recursive order of their call.

NPROG $[\Lambda, \mathbf{v}, \delta, \mathbf{f}] \to (\hat\Lambda, \hat{\mathbf{v}}, \hat{\mathbf{r}})$. *Given a set Λ, an approximation $\mathbf{v}$ to the exact solution $\mathbf{u}$ of $\boldsymbol{A}\mathbf{u} = \mathbf{f}$ whose support is contained in Λ and such that $\|\mathbf{v} - \mathbf{u}\|_{\ell_2} \le \delta$.*

(i) *Apply* **GALERKIN** $[\Lambda, \mathbf{v}, \delta, q_3\delta/c_2] \to \bar{\mathbf{u}}_\Lambda$. *Set $\Lambda^0 := \Lambda$, $\bar{\mathbf{u}}_{\Lambda^0} := \bar{\mathbf{u}}_\Lambda$, $k := 0$.*
(ii) *Apply* **NGROW** $[\Lambda^k, \bar{\mathbf{u}}_{\Lambda^k}, q_1\delta, q_2\delta, \mathbf{f}, \gamma] \to (\Lambda^{k+1}, \mathbf{r}^k)$.
(iii) *If $\|\mathbf{r}^k\|_{\ell_2} \le c_1\delta/20$ or $k = K$ defined in* (A.2) *go to* (iv).
Otherwise, apply **GALERKIN** $[\Lambda^{k+1}, \bar{\mathbf{u}}_{\Lambda^k}, q_0\delta, q_3\delta/c_2] \to \bar{\mathbf{u}}_{\Lambda^{k+1}}$. *Replace k by $k+1$, Λ^k by Λ^{k+1}, $\bar{\mathbf{u}}_{\Lambda^k}$ by $\bar{\mathbf{u}}_{\Lambda^{k+1}}$, and go to* (ii).
(iv) *Apply* **NCOARSE** $[\bar{\mathbf{u}}_{\Lambda^k}, 2\delta/5] \to (\hat\Lambda, \hat{\mathbf{v}})$, *set $\hat{\mathbf{r}} := \mathbf{r}^k$ and STOP.*

GALERKIN $[\Lambda, \mathbf{v}, \delta, \eta] \to \bar{\mathbf{u}}_\Lambda$.

(i) *Apply* **INRESIDUAL** $[\mathbf{v}, \Lambda, \mathbf{f}, \frac{c_1\eta}{6}, \frac{c_1\eta}{6}] \to \mathbf{r}$. *If* $\min\left\{\bar\theta\delta, c_1^{-1}\|\mathbf{r}\|_{\ell_2} + \eta/3\right\} \le \eta$, *define the output $\bar{\mathbf{u}}_\Lambda$ to be $\mathbf{v}$ and STOP, else go to* (ii).
(ii) *Set $\bar{\mathbf{v}}' := \mathbf{v} - \frac{1}{c-2}\mathbf{r}$. Replace $\mathbf{v}$ by $\bar{\mathbf{v}}'$, δ by $\bar\theta\delta$, and go to* (i).

INRESIDUAL $[\mathbf{v}, \Lambda, \mathbf{f}, \eta_1, \eta_2] \to \mathbf{r}$.

(i) *Apply* **APPLY** $\boldsymbol{A}_\Lambda\,[\mathbf{v}, \eta_1] \to \mathbf{w}$;
(ii) *Apply* **NCOARSE** $[\boldsymbol{P}_\Lambda\mathbf{f}, \eta_2] \to \mathbf{g}$.
(iii) *Set $\mathbf{r} := \mathbf{g} - \mathbf{w}$.*

APPLY A $[\eta, \mathbf{v}] \to (\mathbf{w}, \Lambda)$.

(i) *Sort the nonzero entries of the vector $\mathbf{v}$ and form the vectors $\mathbf{v}_{[0]}$, $\mathbf{v}_{[j]} - \mathbf{v}_{[j-1]}$, $j = 1, \dots, \lfloor \log N \rfloor$ with $N := \#\mathrm{supp}\,\mathbf{v}$. Define $\mathbf{v}_{[j]} := \mathbf{v}$ for $j > \log N$.*
(ii) *Compute $\|\mathbf{v}\|^2_{\ell_2(\nabla)}$, $\|\mathbf{v}_{[0]}\|^2_{\ell_2}$, $\|\mathbf{v}_{[j]} - \mathbf{v}_{[j-1]}\|^2_{\ell_2(\nabla)}$, $j = 1, \dots, \lfloor \log N \rfloor + 1$.*
(iii) *Set $k = 0$.*
  (a) *Compute $R_k := c_2\|\mathbf{v} - \mathbf{v}_{[k]}\|_{\ell_2(\nabla)} + a_k\|\mathbf{v}_{[0]}\|_{\ell_2(\nabla)} + \sum_{j=0}^{k-1} a_j\|\mathbf{v}_{[k-j]} - \mathbf{v}_{[k-j-1]}\|_{\ell_2(\nabla)}$.*
  (b) *If $R_k \le \eta$ stop and output k; otherwise replace k by $k+1$ and return to* (a).
(iv) *For the output k of* (iii) *and for $j = 0, 1, \dots, k$, compute the nonzero entries in the matrices $\boldsymbol{A}_{k-j}$ (see Proposition* 1*) which have a column index in common with one of the nonzero entries of $\mathbf{v}_{[j]} - \mathbf{v}_{[j-1]}$.*
(v) *For the output k of* (iii), *compute $\mathbf{w}_k$ as in* (2.25) *and take $\mathbf{w}(\mathbf{v}, \eta) := \mathbf{w}_k$ and $\Lambda = \mathrm{supp}\,\mathbf{w}$.* □

NCOARSE $[\mathbf{w}, \eta] \to (\Lambda, \bar{\mathbf{w}})$.

(i) *Define $N := \#(\mathrm{supp}\,\mathbf{w})$ and sort the nonzero entries of $\mathbf{w}$ into decreasing order. Thereby one obtains the vector $\lambda^* := \lambda^*(\mathbf{w}) = (\lambda_1, \lambda_2, \dots, \lambda_N)$ of indices* *which gives the decreasing rearrangement* $\mathbf{w}^* = (|\mathbf{w}_{\lambda_1}|, |\mathbf{w}_{\lambda_2}|, \ldots, |\mathbf{w}_{\lambda_N}|)$ *of the nonzero entries of* $\mathbf{w}$*; then compute* $\|\mathbf{w}\|_{\ell_2}^2 = \sum_{i=1}^N |\mathbf{w}_{\lambda_i}|^2$.

(ii) *For* $k = 1, 2, \ldots$, *form the sum* $\sum_{j=1}^k |\mathbf{w}_{\lambda_j}|^2$ *in order to find the smallest value* k *such that this sum exceeds* $\|\mathbf{w}\|_{\ell_2}^2 - \eta^2$. *For this* k, *define* $\bar{K} := k$ *and set* $\Lambda := \{\lambda_j\ ;\ j = 1, \ldots, \bar{K}\}$*; define* $\bar{\mathbf{w}}$ *by* $\bar{w}_\lambda := w_\lambda$ *for* $\lambda \in \Lambda$ *and* $\bar{w}_\lambda := 0$ *for* $\lambda \notin \Lambda$.

NGROW $[\Lambda, \bar{\mathbf{u}}_\Lambda, \xi_1, \xi_2, \mathbf{f}, \gamma] \to (\tilde{\Lambda}, \mathbf{r})$. *Given an initial approximation* $\bar{\mathbf{u}}_\Lambda$ *to the Galerkin solution* $\mathbf{u}_\Lambda$ *supported on* Λ.

(i) *Apply* **NRESIDUAL** $[\bar{\mathbf{u}}_\Lambda, \Lambda, \mathbf{f}, \xi_1, \xi_2] \to (\Lambda^r, \mathbf{r})$.

(ii) *Apply* **NCOARSE** $[\mathbf{r}, \sqrt{1-\gamma^2}\|\mathbf{r}\|_{\ell_2}] \to (\Lambda^c, \boldsymbol{P}_{\Lambda^c}\mathbf{r})$ *and define* $\tilde{\Lambda} := \Lambda \cup \Lambda^c$.

NRESIDUAL$[\mathbf{v}, \Lambda, \mathbf{f}, \eta_1, \eta_2] \to (\mathbf{r}, \tilde{\Lambda})$.

(i) *Apply* **APPLY A** $[\mathbf{v}, \eta_1] \to (\mathbf{w}, \Lambda_1)$.

(ii) *Apply* **NCOARSE** $[\mathbf{f}, \eta_2] \to (\mathbf{g}, \Lambda_2)$.

(iii) *Set* $\mathbf{r} := \mathbf{w} - \mathbf{g}$ *and* $\tilde{\Lambda} := \operatorname{supp} \mathbf{r} \subseteq \Lambda_1 \cup \Lambda_2$.

Acknowledgments. The authors feel grateful to Yvon Maday for giving them the opportunity to participate in the European Summer School. They also want to thank Jürgen Vorloeper for putting his software concerning the composite wavelet basis at their disposal. Furthermore, they want to thank Nicole Mulders, who helped them produce some of the pictures. This paper was partially written when the last author was in residence at the Istituto di Analisi Numerica del C.N.R. in Pavia, Italy.

A GLOBALLY CONVERGENT NEWTON-GMRES SUBSPACE METHOD FOR SYSTEMS OF NONLINEAR EQUATIONS[*]

STEFANIA BELLAVIA[†] AND BENEDETTA MORINI[†]

Abstract. Newton–Krylov methods are variants of inexact Newton methods where the approximate Newton direction is taken from a subspace of small dimension. Here we introduce a new hybrid Newton-GMRES method where a global strategy restricted to a low-dimensional subspace generated by GMRES is performed. The obtained process is consistent with preconditioning and with matrix-free implementation. Computational results indicate that our proposal enhances the classical backtracking inexact method.

Key words. nonlinear systems, Krylov subspace methods, generalized minimal residual, inexact Newton, backtracking

1. Introduction.

We consider the numerical solution of systems of nonlinear equations

$$F(x) = 0, \tag{1.1}$$

where $F : \mathbb{R}^n \mapsto \mathbb{R}^n$ is continuously differentiable. Inexact Newton methods [6] are iterative processes for solving (1.1) that result in the following scheme:

Let x_0 be given.
For $k = 0$ until "convergence" do:
    Find some $\bar{\eta}_k \in [0, 1)$ and $\bar{s}_k$ that satisfy

$$\|F(x_k) + F'(x_k)\bar{s}_k\| \le \bar{\eta}_k \|F(x_k)\|, \tag{1.2}$$

    Set $x_{k+1} = x_k + \bar{s}_k$,

where $F'(x)$ is the Jacobian matrix and the *forcing term* $\bar{\eta}_k$ is used to control the level of accuracy. Clearly, these methods are variants of Newton's method in which at each iteration the Newton equation

$$F'(x_k)s = -F(x_k), \qquad k \ge 0, \tag{1.3}$$

is solved only approximately. Local convergence analysis for inexact Newton methods [6] shows that if x_0 is sufficiently close to a solution x^* of (1.1) and the η_k's are uniformly bounded away from one, then the sequence $\{x_k\}$ converges to x^*.

When the dimension n of the problem is large, a relevant class of inexact Newton methods is constituted by Newton–Krylov methods [1], [2], [3], [4], [6], [13]: a Krylov subspace projection method is used to compute $\bar{s}_k$ satisfying (1.2). An attractive

feature of Krylov methods is that they require only the action of the Jacobian F' on a vector v. Moreover, for an appropriately chosen scalar ϵ, this action can be approximated by finite differences [1], [4], [13]

$$F'(x)v \sim \frac{F(x+\epsilon v) - F(x)}{\epsilon}, \tag{1.4}$$

giving rise to a process that is referred to as "matrix-free."

In order to enhance convergence from arbitrary starting points, hybrid globally convergent modifications of Newton–Krylov methods have been considered by several authors (see, e.g., [3], [4], [8], [9], [13], [20]): to a Newton–Krylov method one adds either a linesearch procedure or a trust-region technique. Among the inexact Newton methods where a linesearch procedure is used, an inexact Newton backtracking (INB) method was proposed in [8]. It performs backtracking along the inexact Newton step $\bar{s}_k$, and computational results on a large set of test problems have shown its robustness and efficiency [9], [20]. It is worth noting that inexact Newton methods that incorporate a linesearch procedure based on the Armijo condition [14, p. 40] are a special case of INB (see [8]).

Also, in the numerical solution of large-scale nonlinear systems and bound constrained minimization problems by Newton–Krylov methods there has been much research in using the information concerning the low-dimensional subspaces that are built into the process of solving the linear system (see, e.g., [3], [5], [10], [11], [15]).

Here we are concerned with a *Newton-GMRES* method: a Newton–Krylov method where GMRES [21] is used to solve (1.3) approximately. We propose a new hybrid method where a global strategy restricted to a suitable Krylov subspace is performed. Our globalization strategy consists of two parts. The first is the backtracking procedure of the INB method. The second is a backtracking technique along a piecewise linear curve that involves the current search direction $\bar{s}_k$ and an additional direction selected in a properly chosen subspace, which is itself obtained using the information provided by GMRES. Our method is an extension of Newton-GMRES backtracking techniques designed to improve performance when $\bar{s}_k$ is a poor descent direction. We give extensive numerical tests in support of this claim. Further, we point out that our method is consistent with efficient matrix-free implementation and with preconditioning.

The paper is organized as follows. In section 2 the Newton-GMRES algorithm and the INB method are reviewed. In section 3 a hybrid Newton-GMRES paradigm with globally convergent strategy restricted to a subspace is introduced. Further, the new hybrid method is proposed and the convergence analysis is given. Its consistency with restarting and preconditioning procedures is also investigated. Finally, in section 4 we make some comments on the implementation of the new method and give some numerical results.

2. Preliminaries. Throughout this paper, given a smooth real function $f : \mathbb{R}^n \mapsto \mathbb{R}$, its gradient is denoted by ∇f; the vector $\bar{x} = \text{argmin}_{x \in S} f(x)$ represents a minimizer of f in the set $S \subset \mathbb{R}^n$, and the vector (matrix) norm is always the 2-norm. Further, e_j denotes the jth unit vector, with its dimension inferred from the context; $(x)_i$ represents the ith component of the vector x, and the closed ball with center y and radius δ is indicated by $N_\delta(y)$. Finally, concerning iterative methods for solving nonlinear systems (1.1), the term *breakdown* refers to the case in which an iterate can not be determined, and the term *nonlinear iteration* denotes the sequence of steps that are performed to update the current iterate.

2.1. Newton-GMRES method.

GMRES (generalized minimal residual) is an iterative method for solving indefinite systems of linear equations [21]. When used to solve the Newton equation (1.3) approximately, the resulting method is called Newton-GMRES. The application of GMRES to the Newton equation (1.3) is outlined in the following algorithm.

ALGORITHM 1. GNE (GMRES for the kth Newton equation).

```
Let $x_k$, $\bar{\eta}_k$ be given.
1. Choose $s_k^0$. Set $m = 0$.
   Compute $r_k^0 = -F'(x_k)s_k^0 - F(x_k)$, $\beta_k = \|r_k^0\|$, $v_1 = r_k^0/\beta_k$.
2. While $\|r_k^m\| > \bar{\eta}_k\|F(x_k)\|$ do
   GMRES iteration:
      2.1. Set $m = m + 1$.
      2.2. Compute $F'(x_k)v_m$ and
              $h_{i,m} = (F'(x_k)v_m)^T v_i, \quad i = 1, 2, \ldots, m,$
              $v_{m+1} = F'(x_k)v_m - \sum_{i=1}^m h_{i,m}v_i,$
              $h_{m+1,m} = \|v_{m+1}\|,$
              $v_{m+1} = v_{m+1}/h_{m+1,m}.$
           Let $\bar{H}_m \in \mathbb{R}^{(m+1)\times m}$ be the upper Hessenberg matrix whose nonzero
           entries are the coefficients $h_{i,j}$, $i = 1, \ldots, j+1$, for $j = 1, \ldots, m$.
      2.3. Find the vector $y_m \in \mathbb{R}^m$ that solves the least-squares problem
              $\min_{y\in\mathbb{R}^m} \|\beta_k e_1 - \bar{H}_m y\|.$
      2.4. Set $\|r_k^m\| = \|\beta_k e_1 - \bar{H}_m y_m\|$.
3. Define $V_m \equiv [v_1, v_2, \ldots, v_m] \in \mathbb{R}^{n\times m}$ and form
      $s_k^m = s_k^0 + V_m y_m .$
4. Let $\bar{s}_k = s_k^m$.
```

Note that a GMRES iteration corresponds to a single value of m in step 2 of the above algorithm. At each GMRES iteration, s_k^m solves the least-squares problem

$$\min_{s\in s_k^0+K_m} \|F'(x_k)s + F(x_k)\|, \tag{2.1}$$

where K_m is the Krylov subspace:

$$K_m = span\{r_k^0, F'(x_k)r_k^0, (F'(x_k))^2 r_k^0, \ldots, (F'(x_k))^{m-1} r_k^0\}. \tag{2.2}$$

Step 2.2 is the Arnoldi process [13] for the construction of an orthonormal basis $v_1, \ldots, v_m$ of K_m. From this process it follows that [21]

$$F'(x_k)V_m = V_{m+1}\bar{H}_m, \tag{2.3}$$

and so the least-squares problem (2.1) reduces to

$$\min_{y\in\mathbb{R}^m} \|\beta_k e_1 - \bar{H}_m y\|. \tag{2.4}$$

One iterates until the residual vector

$$r_k^m = -F'(x_k)s_k^m - F(x_k)$$

satisfies $\|r_k^m\| \leq \bar{\eta}_k \|F(x_k)\|$, i.e., until $\bar{s}_k = s_k^m$ satisfies the stopping criterion (1.2). Then, the vector $\bar{s}_k$ is used to form the Newton iterate $x_{k+1} = x_k + \bar{s}_k$.

Although from (2.1) the residual norm $\|r_k^m\|$ is nonincreasing with m, GMRES may stagnate, i.e., the residual norm may remain constant for a number of iterations. However, in theory GMRES finds the solution of the linear system in at most n iterations [21]. In practice, because of rounding errors, GMRES is best thought of as an iterative method. In fact, the vectors v_j computed by the Arnoldi process in step 2.2 may become nonorthogonal as a result of accumulated roundoff errors. Consequently, if a large number of GMRES iterations must be performed, more complex implementations of step 2.2 are necessary (see [13] and the references cited therein). A further aspect of the above algorithm we have not yet considered is that the basis of the Krylov subspace K_m must be stored. Namely, in order to perform m iterations one must store m vectors of length n. This may become prohibitive when n is large. Typically a maximum value m_{max} of GMRES iterations is fixed. If after m_{max} GMRES iterations the norm of the residual is still greater than $\bar{\eta}_k \|F(x_k)\|$, GMRES is *restarted* with initial guess s_k^0 equal to $s_k^{m_{max}}$. The convergence of such a procedure is not always guaranteed, but the idea works well in practice [21].

2.2. Backtracking strategies. To enlarge the convergence basin of a locally convergent method, linesearch techniques are often used [7, section 6.5], [18, section 11.2]. They are based upon a globally convergent method for a problem of the form $\min_{x \in \mathbb{R}^n} M(x)$, where M is an appropriately chosen merit function whose global minimum is a zero of F. In these cases, for p a given direction in $\mathbb{R}^n$, the iterate x_{k+1} has the form $x_{k+1} = x_k + \lambda p$, where $0 < \lambda \leq 1$ is such that $M(x_k + \lambda p) < M(x_k)$. The existence of such a λ is ensured if p is a descent direction for M at x_k, i.e., if there exists a $\lambda_0 > 0$ such that $M(x_k + \lambda p) < M(x_k)$ for all $\lambda < \lambda_0$. When M is differentiable this is equivalent to the following condition [7]:

$$\nabla M(x_k)^T p < 0.$$

Proposition 3.3 of [4] shows that if $M = \|F\|^2/2$ or $M = \|F\|$, a vector p is a descent direction for M at x_k if $\|F'(x_k)p + F(x_k)\| < \|F(x_k)\|$. Thus, from (1.2) $\bar{s}_k$ is a descent direction for these choices of M. Also, note that each GMRES iterate s_k^m, $m \geq 0$, satisfying $\|F'(x_k)s_k^m + F(x_k)\| < \|F(x_k)\|$, is a descent direction for M at x_k even if the residual violates $\|r_k^m\| \leq \bar{\eta}_k \|F(x_k)\|$.

To make the linesearch method succeed, the simple decrease $M(x_k + \lambda p) < M(x_k)$ is not sufficient. In fact, to ensure the convergence of $\{x_k\}$ to a minimum of M, at each iteration a "sufficient decrease" of M must be required (see, e.g., [7, pp. 116–120], [8], [19, pp. 36–43]).

In typical linesearch strategies, the step length λ is chosen by using a so-called backtracking approach. The usual convention is to start with $\lambda = 1$ and then to backtrack, i.e., to reduce λ, until M is sufficiently decreased.

Among the backtracking methods, INB [8] is a globally convergent process where the kth iteration of an inexact Newton method is embedded in a backtracking strategy. In what follows, we will restrict our attention to the INB method where GMRES is used to solve the Newton equations approximately. The kth nonlinear iteration of this method can be sketched as follows.

Algorithm 2. NGB (Newton-GMRES with backtracking).

```
Let $x_k$, $\eta_{max} \in (0,1)$, $t \in (0,1)$, $0 < \theta_l < \theta_u < 1$ be given.
1. Choose $\bar{\eta}_k \in [0, \eta_{max}]$.
```

```
2. Apply Algorithm GNE to compute $\bar{s}_k = s_k^m$ such that
        $\|F(x_k) + F'(x_k)\bar{s}_k\| \leq \bar{\eta}_k \|F(x_k)\|$.
3. Perform the **Backtracking Loop (BL)**, i.e.,
   3.1. Set $s_k = \bar{s}_k$, $\eta_k = \bar{\eta}_k$.
   3.2. While $\|F(x_k + s_k)\| > (1 - t(1 - \eta_k))\|F(x_k)\|$ do:
            Choose $\theta \in [\theta_l, \theta_u]$.
            Update $s_k = \theta s_k$ and $\eta_k = 1 - \theta(1 - \eta_k)$.
4. Set $x_{k+1} = x_k + s_k$.
```

In step 3, the following sufficient decrease in the merit function $\|F(x)\|$ is provided:

$$\|F(x_k + s_k)\| \leq (1 - t(1 - \eta_k))\|F(x_k)\|. \tag{2.5}$$

In particular, moving along the direction of the inexact Newton step $\bar{s}_k$, successively shorter steps $s_k = s_k(\eta)$ of the form $s_k = (1 - \eta)\bar{s}_k/(1 - \bar{\eta}_k)$ are selected.

3. NGECB: A hybrid Newton-GMRES method.

Here we present a hybrid inexact method based on NGB. To provide a thorough description of it, we first introduce a new general algorithm that serves as paradigm. In this, the backtracking strategy is augmented with a second global strategy. In particular, we know from [8] that the backtracking loop BL in step 3 of Algorithm NGB terminates after a finite number of steps. However, if for reasonable values of the constants t, θ_l, θ_u, relatively few steps do not suffice to decrease $\|F\|$, instead of insisting on the direction $\bar{s}_k$ we select different directions and try to decrease the value of an appropriate merit function M moving from x_k along these directions. To be more specific, in our proposed method, the number of backtracking steps is limited to a number, N_b, that is fixed in advance. If the linesearch terminates successfully within N_b steps, the method proceeds as usual. Otherwise, a new procedure is invoked to find a different search direction; the intention is to avoid repeated backtracking steps along a poor direction. The relevant aspect of our proposal is that such direction is chosen in a low-dimensional subspace S which involves information already generated during the GMRES iterations. We shall deliberately not specify the form of this set S. In fact, the subspace S depends on whether or not restarting and/or preconditioning are employed in GMRES. Our intention here is to provide a general paradigm; in the following subsections we will specify our choices for the set S.

The kth nonlinear iteration of the hybrid method we propose belongs to the following framework.

General paradigm.

```
Let $x_k$, $\eta_{max} \in (0,1)$, $t \in (0,1)$, $0 < \theta_l < \theta_u < 1$, $N_b \geq 0$ be given.
1. Choose $\bar{\eta}_k \in [0, \eta_{max}]$.
2. Apply Algorithm GNE to compute $\bar{s}_k = s_k^m$ such that
        $\|F(x_k) + F'(x_k)\bar{s}_k\| \leq \bar{\eta}_k \|F(x_k)\|$.
3. Apply the backtracking loop BL and perform at most $N_b$ iterations.
4. If
        $\|F(x_k + s_k)\| \leq (1 - t(1 - \eta_k))\|F(x_k)\|$,
   set $\Delta_k = s_k$. Go to step 6.
5. Form the set $S$ by using information provided by Algorithm GNE and
```

compute $\Delta_k \in S$ such that

$$\nabla M(x_k)^T \Delta_k < 0 \qquad \text{and} \qquad M(x_k + \Delta_k) < M(x_k).$$

6. Set $x_{k+1} = x_k + \Delta_k$.

The above scheme can be viewed as a paradigm for hybrid Newton-GMRES processes since step 5 does not specify the form of the subspace S, the choice of the vector Δ_k, or the merit function M. Note that the simple condition $M(x_{k+1}) < M(x_k)$ is imposed for each k. However, a "sufficient decrease" of M has to be required in order to ensure the convergence of $\{x_k\}$ to a minimum of M. Specific implementations of step 5 in the given paradigm lead to different procedures.

Here we present a Newton-GMRES method where step 5 is performed by using $M = \|F\|$ and a new globalization strategy that will be called ECB (equality curve backtracking) strategy. The resulting method will be denoted the NGECB (Newton-GMRES with ECB) method.

In the presentation of the NGECB method, first we take $s_k^0 = 0$ in GNE and select Δ_k in the Krylov subspace K_m defined by (2.2). Namely, we set $S = K_m$ in step 5 of the general paradigm. The convergence analysis of the new process is given and the modifications needed in the case $s_k^0 \neq 0$ are discussed. Then, the consistency with preconditioning will be analyzed.

3.1. A globalization strategy restricted to $\boldsymbol{K_m}$. We assume that at most m_{max} GMRES iterations are performed in step 2 of Algorithm GNE and that restarting is not employed. Further, we assume that the initial guess $s_k^0 = 0$ is used. If within $m = m_{max}$ GMRES iterations, Algorithm GNE fails to provide a vector $\bar{s}_k = s_k^m$ satisfying (1.2), we continue using the last GMRES iterate. This is done letting $\bar{s}_k = s_k^m$ and $\bar{\eta}_k = \|F(x_k) + F'(x_k)\bar{s}_k\| / \|F(x_k)\|$ after step 2 of the general paradigm. It is worth noting that when $s_k^0 = 0$ is chosen, in Algorithm GNE we have

$$\beta_k = \|F(x_k)\| \qquad \text{and} \qquad F(x_k) = -\beta_k v_1.$$

To devise a reliable global strategy restricted to a subspace S, first we need to identify in S descent directions for $M = \|F\|$ at x_k. In our approach, the choice $S = K_m$ plays a central role since descent directions can be identified in K_m at no additional cost, as follows. Step 3 of Algorithm GNE provides the orthonormal basis V_m for K_m and clearly each vector $\delta \in K_m$ has the form $\delta = V_m y$ for some $y \in \mathbb{R}^m$. As a consequence, the problem of decreasing $M : \mathbb{R}^n \to \mathbb{R}$ is replaced by the problem of decreasing the function $g : \mathbb{R}^m \to \mathbb{R}$ defined by

$$g(y) = M(x_k + V_m y). \tag{3.1}$$

It is easy to determine if $g(y)|_{y=0} = M(x_k)$ can be reduced. In fact, using (2.3) we have

$$F(x_k)^T F'(x_k) V_m = -\beta_k v_1^T V_{m+1} \bar{H}_m = -\beta_k e_1^T \bar{H}_m, \tag{3.2}$$

and

$$\nabla g(y)|_{y=0} = (F'(x_k) V_m)^T F(x_k) / \beta_k = -\bar{H}_m^T e_1.$$

Further, the inexact Newton step $\bar{s}_k = V_m y_m$ is the solution of the least-squares problem (2.4), so that

$$y_m = -\beta_k (\bar{H}_m^T \bar{H}_m)^{-1} \nabla g(y)|_{y=0}. \tag{3.3}$$

Hence, $\nabla g(y)|_{y=0} = 0$ if and only if $y_m = 0$. Since we need a nonzero inexact Newton step, it is crucial to require m_{max} large enough so that $y_m \neq 0$. This way, the existence of descent directions for M at x_k within the subspace K_m is guaranteed. Therefore, we will assume $\bar{s}_k \neq 0$ in the following description of the ECB-strategy.

Finally, it is worth noting that the first row of the Hessenberg matrix $\bar{H}_m$ gives the directional derivatives of M at x_k along the directions v_j. Thus, we determine if v_j is a descent direction at no additional cost. In fact, for any $\delta \in K_m$ the directional derivative $\nabla M(x_k)^T\delta$ is such that

$$\nabla M(x_k)^T\delta = \nabla M(x_k)^T V_m y = -e_1^T \bar{H}_m y, \qquad y \in \mathbb{R}^m.$$

Consequently, recalling that $v_j = V_m e_j$, we get

$$\nabla M(x_k)^T v_j = \nabla g(y)|_{y=0}^T e_j = -e_1^T \bar{H}_m e_j = -h_{1,j}, \quad j = 1, \ldots, m. \tag{3.4}$$

Clearly, v_j is a descent direction if and only if $h_{1,j} > 0$.

We are now ready to specify the strategy we use to form the vector Δ_k in step 5 of the general paradigm. In fact, the merit function $M = \|F\|$ will be used and a sufficient decrease in M will be ensured applying a backtracking strategy along a curve $\sigma_k(\eta)$. The curve $\sigma_k(\eta)$ is such that $\sigma_k(1) = 0$ and each trial step satisfies (1.2) with equality, i.e.,

$$\|F(x_k) + F'(x_k)\sigma_k(\eta)\| = \eta\|F(x_k)\|. \tag{3.5}$$

In order to construct $\sigma_k(\eta)$, we model $g(y) = M(x_k + V_m y)$ at $y = 0$ by the following function:

$$\hat{g}(y) = \|F'(x_k)V_m y + F(x_k)\|,$$

whose steepest descent direction d_m at $y = 0$ is given by

$$d_m = -\nabla\hat{g}(y)|_{y=0} = -\nabla g(y)|_{y=0} = \bar{H}_m^T e_1. \tag{3.6}$$

It is important to note that, by definition of GMRES, $\bar{s}_k = s_k^m$ solves (2.1). Namely, letting $s_k^m = V_m y_m$, the vector $y_m \in \mathbb{R}^m$ minimizes the quadratic model $\hat{g}$ in K_m.

Algorithm 3. ECB-strategy.

```
Let $x_k$, $t \in (0, 1)$ be given. Let $\bar{s}_k$ be the inexact Newton step and $\bar{H}_m$ and $V_m$ be
the matrices defined, respectively, in steps 2.2 and 3 of Algorithm GNE.
1. Choose $\epsilon > 0$, $h_{min} > 0$ and set $\beta_k = \|F(x_k)\|$.
2. Compute $d_m$ using (3.6).
3. Compute $\alpha_d = \text{argmin}_{\alpha\in\mathbb{R}}\ \hat{g}(\alpha d_m)$:   $\alpha_d = \beta_k\,\|d_m\|^2/\|\bar{H}_m d_m\|^2$.
4. Set $z = \alpha_d V_m d_m$.
5. Form $J = \{1 \le j \le m \text{ s.t. } h_{1,j} \ge h_{min}\}$,  $D = \{e_j \text{ s.t. } j \in J\}$.
6. If $D \neq \emptyset$
      Let $e_{j^*}$ be such that $\|F(x_k + \epsilon V_m e_{j^*})\| = \min_{e_j\in D} \|F(x_k + \epsilon V_m e_j)\|$.
      Set $v_{j^*} = V_m e_{j^*}$.
      Compute $\alpha_e = \text{argmin}_{\alpha\in\mathbb{R}}\ \hat{g}(\alpha e_{j^*})$:   $\alpha_e = -F^T(x_k)F'(x_k)v_{j^*}/\|F'(x_k)v_{j^*}\|^2$.
      If $\|F(x_k + \alpha_e v_{j^*})\| \le \|F(x_k + z)\|$,  set $z = \alpha_e v_{j^*}$.
7. Compute
```

$$\begin{aligned} \eta_1 = {} & \|F'(x_k)z + F(x_k)\|/\|F(x_k)\|, \\ \eta_2 = {} & \|F'(x_k)\bar{s}_k + F(x_k)\|/\|F(x_k)\|. \end{aligned}$$

```
   Set $\eta = \eta_2$.
8. Repeat
      Choose $\theta \in [\theta_l, \theta_u]$. Set $\eta = 1 - \theta(1 - \eta)$.
      If $\eta < \eta_1$
            Let $\tau = (\frac{\eta^2-\eta_2^2}{\eta_1^2-\eta_2^2})^{1/2}$, $\hat{z} = \tau z + (1 - \tau)\bar{s}_k$.
      Else
            Let $\tau = (\frac{\eta^2-\eta_1^2}{1-\eta_1^2})^{1/2}$, $\hat{z} = (1 - \tau)z$.
   Until $\|F(x_k + \hat{z})\| \leq (1 - t(1 - \eta))\|F(x_k)\|$.
9. Set $\Delta_k = \hat{z}$, $\eta_k = \eta$.
```

In step 8 of the above algorithm, the following decrease condition in $\|F\|$ is imposed:

$$\|F(x_k + \sigma_k(\eta))\| \leq (1 - t(1 - \eta))\|F(x_k)\|, \tag{3.7}$$

where $t \in (0, 1)$ is a given constant. The backtracking is performed along the piecewise linear curve $\sigma_k(\eta)$ connecting the point zero, the point $z = \sigma_k(\eta_1) \in K_m$, and the inexact Newton step $\bar{s}_k = \sigma_k(\eta_2) \in K_m$. This curve has the form

$$\sigma_k(\eta) = \begin{cases} \tau(\eta)z + (1 - \tau(\eta))\bar{s}_k, & \tau(\eta) = (\frac{\eta^2-\eta_2^2}{\eta_1^2-\eta_2^2})^{1/2} \quad \text{if } \eta_2 \leq \eta < \eta_1, \\ (1 - \tau(\eta))z, & \tau(\eta) = (\frac{\eta^2-\eta_1^2}{1-\eta_1^2})^{1/2} \quad \text{if } \eta_1 \leq \eta \leq 1. \end{cases} \tag{3.8}$$

Some relevant features characterize z and $\bar{s}_k$. First, $\bar{s}_k$ minimizes $\|F'(x_k)s + F(x_k)\|$ in K_m due to the properties of GMRES and z minimizes $\|F'(x_k)s + F(x_k)\|$ along an appropriately chosen direction $V_m\bar{u} \in K_m$, i.e.,

$$z = \bar{\alpha}V_m\bar{u}, \qquad \bar{\alpha} = \text{argmin } \hat{g}(\alpha\bar{u}). \tag{3.9}$$

Second, the vector $\bar{u}$ is selected from d_m and the coordinate vectors e_j in $\mathbb{R}^m$ as the most promising descent direction for $\hat{g}$ at $y = 0$. This is done taking into account the value of $\|F\|$ according to the following strategy. From (3.4), the set D defined in step 5 of the ECB-strategy contains the coordinate vectors $e_j \in \mathbb{R}^m$ that are descent directions for $\hat{g}$ at $y = 0$. If $D = \emptyset$, we set $\bar{u} = d_m$. Otherwise, we consider the values $\|F(x_k + \epsilon V_m e_j)\|$, $e_j \in D$, and choose the vector e_{j^*} that gives the minimum value. Then, we form $\alpha_d V_m d_m$ and $\alpha_e V_m e_{j^*}$, i.e., the minimizers of $\hat{g}$ along d_m and e_{j^*}, respectively. Finally, $\bar{u}$ is chosen as either d_m or e_{j^*} depending on whether $\|F(x_k + \alpha_d V_m d_m)\|$ or $\|F(x_k + \alpha_e V_m e_{j^*})\|$ is smaller. Namely, $\bar{u} = d_m$ if $\|F(x_k + \alpha_d V_m d_m)\| < \|F(x_k + \alpha_e V_m e_{j^*})\|$, and $\bar{u} = e_{j^*}$ otherwise.

We remark that the path $\sigma_k(\eta)$ is not well defined if $\eta_1 = 1$. This occurrence means that there exist no descent directions for $\hat{g}$ at $y = 0$ in K_m and this case was previously excluded in the presentation of the ECB-strategy. Moreover, the path $\sigma_k(\eta)$ is not well defined if $\eta_1 = \eta_2$. This means that $\bar{s}_k$ is parallel to z. In this case, $\sigma_k(\eta)$ becomes a straight line and the ECB-strategy reduces to a backtracking technique along $\bar{s}_k$. However, in order to avoid the situation where $\sigma_k(\eta)$ becomes a straight line, a modification of the ECB-strategy can be considered. If $z = \alpha_e V_m e_{j^*}$, z can be set equal to $\alpha_d V_m d_m$; on the contrary, if $z = \alpha_d V_m d_m$ and $D \neq \emptyset$, one can take $z = \alpha_e V_m e_{j^*}$. Summarizing, the ECB-strategy cannot be used as an alternative strategy to the backtracking along $\bar{s}_k$ only either if $\bar{s}_k$ is parallel to both $V_m d_m$ and $V_m e_{j^*}$ or if $\bar{s}_k$ is parallel to $V_m d_m$ and the set D is empty. Also, it should be mentioned that in the context of globally convergent Newton-GMRES methods, a relevant trust-region model restricted to K_m was proposed in [3]. It employs a dogleg path based on

$\bar{s}_k$ and $\alpha_d V_m d_m$. We note that when $\bar{s}_k$ is parallel to $V_m d_m$, this dogleg path reduces to a straight line, while the outlined modification of the ECB-strategy prevents this degeneration of $\sigma_k(\eta)$ if $D \neq 0$ and $\bar{s}_k$ is not parallel to $V_m e_{j^*}$. In view of all above considerations, we will exclude the case $\eta_1 = \eta_2$ for the remainder of the paper.

The theorem below shows that along the curve $\sigma_k(\eta)$ we satisfy (3.5). Consequently, moving from $x_k + \bar{s}_k$ to x_k along $\sigma_k(\eta)$, the relative residual norm $\eta = \|F(x_k) + F'(x_k)\sigma_k(\eta)\|/\|F(x_k)\|$ is monotone increasing.

THEOREM 3.1. *If $m > 1$ and $\bar{s}_k$ provided by Algorithm GNE is such that $\bar{s}_k \neq 0$, along the piecewise curve $\sigma_k(\eta)$, the equality condition* (3.5) *is satisfied.*

Proof. By construction, the vectors $\bar{s}_k$ and z satisfy

$$\bar{s}_k = \underset{s \in K_m}{\operatorname{argmin}} \|F'(x_k)s + F(x_k)\|, \qquad z = \underset{s \in \bar{K}}{\operatorname{argmin}} \|F'(x_k)s + F(x_k)\|,$$

where $\bar{K} = span\{V_m d_m\}$ or $\bar{K} = span\{v_{j^*}\}$. Hence, if $m > 1$ and $\bar{s}_k \neq 0$, $\bar{K} \subset K_m$ and $\eta_1 > \eta_2$. Using [8, Lemma 8.1] the result follows. □

Remark 3.1. The proposed NGECB method is consistent with a matrix-free implementation. To see why, we turn our attention to the given general paradigm and consider the implementation of Algorithm GNE in step 2 and the implementation of the ECB-strategy in step 5. Step 2 can be implemented by using (1.4) to approximate the products $F'(x_k)v_i$, $i = 1, \dots, m$. Moreover, considering steps 6 and 7 of the ECB-strategy, α_e and η_1 can be computed without explicitly forming the Jacobian $F'(x_k)$. In particular, if $z = \alpha_e v_{j^*}$, the vector $F'(x_k)v_{j^*}$ has already been computed in Algorithm GNE. If $z = \alpha_d V_m d_m$, from (2.3) we have

$$\alpha_d F'(x_k) V_m d_m + F(x_k) = \alpha_d V_{m+1} \bar{H}_m d_m + F(x_k),$$

and then we have to perform only two matrix-vector products to compute η_1. Further, the scalar ϵ used in the ECB-strategy can be chosen equal to the constant ϵ previously used to form the products $F'(x_k)v_i$, $i = 1, 2, \dots, m$, by means of (1.4). This way, vectors of the form $F(x_k + \epsilon v_j)$ are available and the NGECB method can be advantageously implemented at a low computational cost.

3.2. Convergence analysis. To analyze the NGECB method, we observe that it belongs to the following framework:

```
Given $x_0$ and $t \in (0, 1)$.
For $k = 0$ until "convergence" do:
    Find a scalar $\eta_k \in [0, 1)$ and a vector $\Delta_k = \Delta_k(\eta_k)$ that satisfy
    (3.10)    $\|F(x_k) + F'(x_k)\Delta_k(\eta_k)\| \leq \eta_k \|F(x_k)\|$
    and
    (3.11)    $\|F(x_k + \Delta_k(\eta_k))\| \leq (1 - t(1 - \eta_k))\|F(x_k)\|$.
    Set $x_{k+1} = x_k + \Delta_k(\eta_k)$.
```

The value of Δ_k may be $\bar{s}_k$ or, alternatively, computed either in the backtracking loop BL, $\Delta_k(\eta) = s_k$ with $s_k = (1 - \eta)\bar{s}_k/(1 - \bar{\eta}_k)$, $\bar{\eta}_k \leq \eta \leq 1$, or by the ECB-strategy, $\Delta_k(\eta) = \sigma(\eta)$, $\eta_2 \leq \eta \leq 1$.

Next, we show that if the NGECB method does not break down, and if there exists a limit point x^* of $\{x_k\}$ such that $F'(x^*)$ is invertible, then the iterates are guaranteed to remain near x^* and

- $F(x^*) = 0$ and $x_k \to x^*$;
- for k sufficiently large, x_{k+1} has the form $x_{k+1} = x_k + \bar{s}_k$. Hence, the ultimate rate of convergence depends on the choices of the $\bar{\eta}_k$'s as shown in the local convergence theory of [6].

On the other hand, the NGECB method can fail in one of the following cases:

- $\|x_k\| \to \infty$, i.e., $\{x_k\}$ has no limit points;
- $\{x_k\}$ has one or more limit points, and F' is singular at each of them;

and it breaks down if

- $F'(x_k)$ is singular for some k;
- the vector $\bar{s}_k$ computed by Algorithm GNE is such that $\bar{s}_k = s_k^0 = 0$.

In our analysis we will refer to the theoretical results of [8] for processes that fit into the above framework, i.e., that generate a sequence $\{x_k\}$ where $\{\Delta_k\}$ and $\{\eta_k\}$ satisfy (3.10) and (3.11) for all k. For the sake of completeness, we recall these facts.

THEOREM 3.2 (see [8, Theorem 3.4]). *If* $\sum_{k=0}^{\infty}(1-\eta_k)$ *is divergent, then* $F(x_k) \to 0$.

THEOREM 3.3 (see [8, Theorem 3.5]). *Let* x^* *be a limit point of* $\{x_k\}$ *for which there exists a* Γ *independent of* k *such that*

$$\|\Delta_k(\eta_k)\| \leq \Gamma(1-\eta_k)\|F(x_k)\|, \tag{3.12}$$

whenever x_k *is sufficiently near* x^* *and* k *is sufficiently large. Then,* $x_k \to x^*$.

Next, we give sufficient conditions for the NGECB method to not break down in the backtracking loop in step 8 of the ECB-strategy. Then, we give a global convergence result.

LEMMA 3.1. *Assume that* $\Delta_k(\eta) = \sigma_k(\eta)$, $F(x_k) \neq 0$, *and there exist* $\eta_\sigma \geq \eta_2$ *and a constant* Γ *such that*

$$\|\Delta_k(\eta)\| \leq \Gamma(1-\eta)\|F(x_k)\|, \quad \eta_\sigma \leq \eta \leq 1. \tag{3.13}$$

Let $\delta > 0$ *be sufficiently small so that*

$$\|F(x) - F(x_k) - F'(x_k)(x-x_k)\| \leq \frac{1-t}{\Gamma}\|x-x_k\| \tag{3.14}$$

holds whenever $x \in N_\delta(x_k)$. *Then, in step* 8 *of the ECB-strategy, the backtracking loop terminates with*

$$1-\eta_k \geq \min\left\{1-\eta_\sigma, \frac{\theta_l \delta}{\Gamma\|F(x_k)\|}\right\}.$$

Proof. The proof is a straightforward application of [8, Lemma 5.1]. □

Remark 3.2. Note that [19, Lemma 3.2.10] ensures the existence of δ such that (3.14) holds whenever $x \in N_\delta(x_k)$.

The next lemma gives conditions under which (3.13) is satisfied.

LEMMA 3.2. *Assume that* $\Delta_k(\eta) = \sigma_k(\eta)$, $\bar{s}_k \neq 0$, $F(x_k) \neq 0$, *and* $F'(x_k)$ *is invertible. Then, there exist* η_σ *and* Γ *such that* (3.13) *holds.*

Proof. If

$$\gamma_k = \inf_{\eta_2 \leq \eta < 1} \frac{|F(x_k)^T(F'(x_k)\sigma_k(\eta))|}{\|F(x_k)\|\|F'(x_k)\sigma_k(\eta)\|}$$

is positive, [8, Lemma 7.2] gives (3.13) with

$$\Gamma = \frac{2\|F'(x_k)^{-1}\|}{\gamma_k} \quad \text{and} \quad \eta_\sigma = \max\{\eta_2, (1-\gamma_k^2)^{1/2}\}.$$

We now show that $\gamma_k > 0$. If $\eta_1 \le \eta < 1$, from (3.8) we have $\sigma_k(\eta) = (1-\tau(\eta))z$, where $z = \alpha_e v_{j^*}$ or $z = \alpha_d V_m d_m$. If $z = \alpha_e v_{j^*}$, the assumption $h_{1,j^*} \ge h_{min} > 0$ in the ECB-strategy and (3.2), give

$$\begin{aligned}\gamma_k &= \frac{|F(x_k)^T(F'(x_k)V_m e_{j^*})|}{\beta_k\|F'(x_k)V_m e_{j^*}\|}\\ &= \frac{\beta_k h_{1,j^*}}{\beta_k\|F'(x_k)V_m e_{j^*}\|} \ge \frac{h_{min}}{\|F'(x_k)V_m e_{j^*}\|} > 0. \end{aligned} \tag{3.15}$$

If $z = \alpha_d V_m d_m$, from (3.2) and (3.6), it follows $F(x_k)^T F'(x_k)V_m = -\beta_k d_m^T$, and thus

$$\begin{aligned}\gamma_k &= \frac{|F(x_k)^T(F'(x_k)V_m d_m)|}{\beta_k\|F'(x_k)V_m d_m\|}\\ &= \frac{\|d_m\|^2}{\|F'(x_k)V_m d_m\|} > 0,\end{aligned} \tag{3.16}$$

where the last inequality holds since $\bar{s}_k \ne 0$ (see (3.3)).

Finally, if $\eta_2 \le \eta < \eta_1$, the equality condition (3.5) gives

$$\begin{aligned}\gamma_k &= \inf_{\eta_2\le\eta<\eta_1} \frac{|-F(x_k)^T F(x_k) + F(x_k)^T(F'(x_k)\sigma_k(\eta) + F(x_k))|}{\beta_k\|F'(x_k)\sigma_k(\eta)\|}\\ &\ge \inf_{\eta_2\le\eta<\eta_1} \frac{\beta_k^2(1-\eta)}{\beta_k(\beta_k + \|F'(x_k)\sigma_k(\eta) + F(x_k)\|)}\\ &= \inf_{\eta_2\le\eta<\eta_1} \frac{1-\eta}{1+\eta} \ge \frac{1-\eta_1}{1+\eta_1} > 0. \qquad \square\end{aligned} \tag{3.17}$$

Lemmas 3.1 and 3.2 yield the result below.

COROLLARY 3.1. *Assume that* $\Delta_k(\eta) = \sigma_k(\eta)$, $\bar{s}_k \ne 0$, $F(x_k) \ne 0$, *and* $F'(x_k)$ *is invertible. Then, the backtracking loop in step* 8 *of the ECB-strategy terminates with*

$$1 - \eta_k \ge \min\left\{1-\eta_2, 1-(1-\gamma_k^2)^{1/2}, \frac{\theta_l\delta}{\Gamma\|F(x_k)\|}\right\} \tag{3.18}$$

for any $\delta > 0$ *sufficiently small so that* (3.14) *holds whenever* $x \in N_\delta(x_k)$.

To prove the global convergence result we need an intermediate result.

THEOREM 3.4. *Assume that* $\bar{s}_k$ *satisfies*

$$\|F'(x_k)\bar{s}_k + F(x_k)\| \le \bar{\eta}_k\|F(x_k)\|, \qquad \bar{\eta}_k \le \eta_{max}, \tag{3.19}$$

for k *sufficiently large, and* $\Delta_k(\eta) = \sigma_k(\eta)$. *If* x^* *is a limit point of* $\{x_k\}$ *such that* $F'(x^*)$ *is invertible, then there exists* Γ_1 *independent of* k *for which*

$$\|\Delta_k(\eta_k)\| \le \Gamma_1(1-\eta_k)\|F(x_k)\| \tag{3.20}$$

whenever x_k *is sufficiently close to* x^* *and* k *is sufficiently large.*

Proof. Let $\delta > 0$ be sufficiently small so that $F'(x)^{-1}$ exists and $\|F'(x)^{-1}\| \le 2\|F'(x^*)^{-1}\|$ whenever $x \in N_\delta(x^*)$. Set $K = \|F'(x^*)^{-1}\|$, $K_1 = \sup_{x\in N_\delta(x^*)}\|F'(x)\|$, and suppose that $x_k \in N_\delta(x^*)$ and k is sufficiently large that (3.19) holds.

Lemma 3.2 gives (3.13) with $\Gamma = 2\|F'(x_k)^{-1}\|/\gamma_k$, dependent of k. To prove the theorem we now show that there exists $\gamma > 0$ such that $\gamma_k > \gamma$ whenever $x_k \in N_\delta(x^*)$.

First, consider the case $\eta_1 \le \eta \le 1$, i.e., $\sigma_k(\eta) = (1-\tau(\eta))z$. If $z = \alpha_e v_{j^*}$, from (3.15) we have $\gamma_k > h_{min}/K_1$. If $z = \alpha_d V_m d_m$, (3.16) yields

$$\gamma_k \ge \frac{\|d_m\|^2}{\|F'(x_k)\|\|d_m\|} = \frac{\|V_m^T F'(x_k)^T F(x_k)\|}{\beta_k \|F'(x_k)\|} \ge \frac{1}{k_2(F'(x_k))} \frac{\|V_m^T F'(x_k)^T F(x_k)\|}{\|F'(x_k)^T F(x_k)\|},$$

where $k_2(F'(x_k)) = \|F'(x_k)\|\|F'(x_k)^{-1}\|$. Recalling that in K_m there is $\bar{s}_k$ satisfying (3.19), we also have

$$\frac{\|V_m^T F'(x_k)^T F(x_k)\|}{\|F'(x_k)^T F(x_k)\|} \ge \frac{1}{k_2(F'(x_k))} \frac{1-\bar{\eta}_k}{1+\bar{\eta}_k}$$

(see [4, Corollary 3.5]), and we get

$$\gamma_k > \frac{1}{4K^2K_1^2} \frac{1-\eta_{max}}{1+\eta_{max}}.$$

In what follows, we let γ_1 be the constant

$$\gamma_1 = \min\left\{ \frac{h_{min}}{K_1}, \frac{1-\eta_{max}}{4K^2K_1^2(1+\eta_{max})} \right\}. \tag{3.21}$$

Next, we turn our attention to the case $\eta_2 \le \eta < \eta_1$. Due to (3.17), we need an upper bound, independent of k, on η_1. Using the definition of η_1 and the definition (3.9) of z we have

$$\eta_1 = \frac{\|F'(x_k)z + F(x_k)\|}{\|F(x_k)\|} = \frac{\min_\alpha \|F'(x_k)\alpha V_m \bar{u} + F(x_k)\|}{\|F(x_k)\|} = \left(1 - \frac{(F(x_k)^T F'(x_k) V_m \bar{u})^2}{\beta_k^2 \|F'(x_k) V_m \bar{u}\|^2}\right)^{1/2} = \left(1 - \inf_{\eta_1 \le \eta < 1} \frac{(F(x_k)^T F'(x_k)\sigma_k(\eta))^2}{\beta_k^2 \|F'(x_k)\sigma_k(\eta)\|^2}\right)^{1/2},$$

and from (3.17) and (3.21) we get

$$\gamma_k \ge \frac{1-\eta_1}{1+\eta_1} \ge \frac{1-\sqrt{1-\gamma_1^2}}{1+\sqrt{1-\gamma_1^2}}.$$

Hence, by setting $\gamma = \min\{\gamma_1, \frac{1-\sqrt{1-\gamma_1^2}}{1+\sqrt{1-\gamma_1^2}}\}$ and $\Gamma_1 = 4K/\gamma$, we obtain

$$\|\sigma_k(\eta)\| \le \Gamma_1(1-\eta)\|F(x_k)\|, \quad \min\{\eta_2, 1-(1-\gamma^2)^{1/2}\} \le \eta \le 1,$$

and the proof is completed. □

We are ready to state the global convergence result.

Theorem 3.5. *Assume that the NGECB method does not break down, and* (3.19) *holds for k sufficiently large. If x^* is a limit point such that $F'(x^*)$ is invertible, then $x_k \to x^*$, and $F(x^*) = 0$. Furthermore, for sufficiently large k, we have $\eta_k = \bar{\eta}_k$.*

Proof. Let $\delta > 0$ be sufficiently small so that (3.20) holds whenever $x \in N_\delta(x^*)$. Set $K_2 = \sup_{x \in N_\delta(x^*)} \|F(x)\|$. Assume that $x_k \in N_\delta(x^*)$ and k is sufficiently large that (3.19) holds.

If $\Delta_k(\eta) = s_k$, from [8, Theorem 6.1] we know that there exists a constant, say, Γ_2, independent of k such that (3.12) holds. Then, we conclude that whenever x_k is sufficiently close to x^*, the NGECB method generates a Δ_k that satisfies (3.12) with $\Gamma = \min\{\Gamma_1, \Gamma_2\}$ independent of k. Hence $x_k \to x^*$ because of Theorem 3.3.

If s_k is computed in the backtracking loop BL, the backtracking terminates with η_k such that

$$1 - \eta_k \geq \min\left\{1 - \bar{\eta}_k, \frac{\delta\theta_l}{\Gamma\|F(x_k)\|}\right\} \tag{3.22}$$

(see [8, Lemma 5.1]). Hence, in this case we have

$$1 - \eta_k \geq \min\left\{1 - \eta_{max}, \frac{\delta\theta_l}{\Gamma K_2}\right\}.$$

Further, if the ECB-strategy is used, (3.18) yields

$$1 - \eta_k \geq \min\left\{1 - \eta_{max}, 1 - (1 - \gamma^2)^{1/2}, \frac{\theta_l\delta}{\Gamma K_2}\right\}.$$

But, since $x_k \to x^*$, we have $x_k \in N_\delta(x^*)$ for k sufficiently large. Therefore, the series $\sum_{k=0}^{\infty}(1 - \eta_k)$ is divergent and Theorem 3.2 yields $F(x^*) = 0$. Finally, since $\|F(x_k)\| \to 0$, from (3.22) it follows $\eta_k = \bar{\eta}_k$ for k sufficiently large. □

3.3. Restarting and enlarged subspace ECB-strategy. In typical implementations of GMRES, a maximum value m_{max} of m is dictated by storage requirements. If a restarted GMRES is applied, GMRES is used iteratively and restarted every m_{max} iterations. At each restart the initial guess is set equal to the last computed GMRES iterate. The NGECB method studied in section 3.1 does not cover this situation, because, in general, after a restart the new initial guess s_k^0 is nonzero. We now show how to define the NGECB method in this case.

When $s_k^0 \neq 0$, the major impact on our hybrid method is that the vector $\bar{s}_k$ provided by Algorithm GNE belongs to $s_k^0 + K_m$ and $s_k^0 + K_m \neq K_m$. Then, the step in $s_k^0 + K_m$ from x_k has the form $s_k^0 + V_m y$, $y \in \mathbb{R}^m$, and $g(y)$ in (3.1) is now given by $g(y) = M(x_k + s_k^0 + V_m y)$. In general, $g(0) \neq M(x_k)$, and we cannot search for a decrease of M moving from x_k in K_m. Hence, following the approach of [3] we let the contribution of the step s_k^0 be variable, and we search for a descent direction in the subspace $S = span\{v_1, v_2, \ldots, v_m, s_k^0\}$.

Letting $W = [w_1, w_2, \ldots, w_{m+1}] \in \mathbb{R}^{n\times(m+1)}$ be the orthonormal basis of S such that $w_i = v_i$ for $i = 1, 2, \ldots, m$, we replace the function g given in (3.1) with the following function:

$$g(\tilde{y}) = M(x_k + W\tilde{y}),$$

where $g : \mathbb{R}^{m+1} \to \mathbb{R}$.

The model $\hat{g}(\tilde{y})$ for $M(x_k + W\tilde{y})$ becomes

$$\hat{g}(\tilde{y}) = \|F'(x_k)W\tilde{y} + F(x_k)\|, \tag{3.23}$$

where $F'(x_k)W = [V_{m+1}\bar{H}_m, F'(x_k)w_{m+1}]$, and the steepest descent direction for $\hat{g}$ at $\tilde{y} = 0$ is given by

$$\tilde{d}_m = -\frac{(F'(x_k)W)^T F(x_k)}{\|F(x_k)\|} = \frac{1}{\|F(x_k)\|}\begin{pmatrix} -\bar{H}_m^T V_{m+1}^T F(x_k) \\ -w_{m+1}^T F'(x_k)^T F(x_k) \end{pmatrix}. \tag{3.24}$$

Clearly, there will be descent directions for $\hat{g}$ at $\tilde{y} = 0$ in S if $F'(x_k)W$ is not singular. This is ensured if $s_k^0 \notin K_m$.

In order to define the equality curve σ_k, we need the minimizer $\hat{s}_k$ of $\|F'(x_k)s + F(x_k)\|$ in S. This vector can be easily computed in a matrix-free manner using the information provided by GMRES, as shown in [3]. Hence, we let σ_k be of the form (3.8), where $\bar{s}_k$ is replaced by $\hat{s}_k$ and z is such that

$$z = \bar{\alpha} W \tilde{u}, \qquad \bar{\alpha} = \text{argmin } \hat{g}(\alpha\tilde{u}). \tag{3.25}$$

The definition of $\tilde{u}$ can be restated along the same lines as in the ECB-strategy. In particular, $\tilde{u}$ is selected among $\tilde{d}_m$ and the vectors $e_j \in \mathbb{R}^{m+1}$ that are descent directions for $\hat{g}$ at $\tilde{y} = 0$. To establish whether the vectors e_j are descent directions, we use the relation

$$\nabla\hat{g}(y)|_{y=0}^T e_j = -(\tilde{d}_m)_j, \quad j = 1, \ldots, m+1.$$

Going on as in the proof of Theorem 3.1, it follows that the curve σ_k constructed by using $\hat{s}_k$ and the vector z defined in (3.25) satisfies (3.5). Therefore, the theoretical results of section 3.2 hold.

Based upon the preceding discussion, the ECB-strategy can be applied by replacing $\bar{s}_k$ with $\hat{s}_k$ and rephrasing steps 2–6 as follows.

```
2. Compute $\tilde{d}_m$ using (3.24).
3. Compute $\alpha_d = \text{argmin}_{\alpha\in\mathbb{R}}\ \hat{g}(\alpha\tilde{d}_m)$: $\alpha_d = \|F(x_k)\|\ \|\tilde{d}_m\|^2/\|F'(x_k)W\tilde{d}_m\|^2$.
4. Set $z = \alpha_d W\tilde{d}_m$.
5. Form $J = \{1 \le j \le m+1 \text{ s.t. } (\tilde{d}_m)_j \ge h_{min}\}$,  $D = \{e_j \text{ s.t. } j \in J\}$.
6. If $D \ne \emptyset$
     Let $e_{j^*}$ be such that $\|F(x_k + \epsilon W e_{j^*})\| = \min_{e_j\in D} \|F(x_k + \epsilon W e_j)\|$.
     Set $w_{j^*} = We_{j^*}$.
     Compute $\alpha_e = \text{argmin}_{\alpha\in\mathbb{R}}\ \hat{g}(\alpha e_{j^*})$: $\alpha_e = -F^T(x_k)F'(x_k)w_{j^*}/\|F'(x_k)w_{j^*}\|^2$.
     If $\|F(x_k + \alpha_e w_{j^*})\| \le \|F(x_k + z)\|$  set $z = \alpha_e w_{j^*}$.
```

We point out that the above computations are implementable using only matrix-vector products. In particular, the evaluation of $\tilde{d}_m$ does not need the Jacobian explicitly since the product $F'(x_k)w_{m+1}$ can be approximated by finite differences. Moreover, if $z = \alpha_e w_{j^*}$, $1 \le j^* \le m$, the matrix-vector product $F'(x_k)w_{j^*}$ has already been computed by Algorithm GNE. Similarly, the evaluation of α_d does not need the Jacobian explicitly.

Regarding the function evaluations, if in step 1 of the ECB-strategy we take the scalar ϵ equal to the one used in (1.4), the vectors $F(x_k + \epsilon We_j)$ are available.

3.4. Preconditioning.

In order to increase the convergence rate of Krylov methods, preconditioning techniques are commonly used. Given the Newton equation (1.3), preconditioning leads to the equivalent system

$$P_l F'(x_k) P_r P_r^{-1} s = -P_l F(x_k), \qquad k \ge 0.$$

The matrices P_l and P_r are chosen so that the preconditioned system is easier to solve than the original one. The system is preconditioned on the right if P_l is equal to the identity matrix I, on the left if $P_r = I$.

In our case, we need to restrict ourselves to right preconditioning in order to use the NGECB method. This is because if $P_l \neq I$, the residual of the linear system is $\|P_l F'(x_k)s + P_l F(x_k)\|$. Hence, $\hat{g}$ should be $\|P_l F'(x_k)V_m y + P_l F(x_k)\|$. In other words, $\hat{g}$ would be a model for $\|P_l F(x_k + V_m y)\|$ instead of $\|F(x_k + V_m y)\|$. On the contrary, right preconditioning does not affect the residual associated to the linear system. Thus, we consider the linear system

$$F'(x_k)P_r p = -F(x_k), \qquad p = P_r^{-1}s.$$

Without loss of generality, we concentrate on the case where a null initial guess for GMRES, $p_k^0 = 0$, is chosen and restart is not used. In this case, the Krylov space generated by GMRES has the form

$$K_m^p = \{r_k^0, (F'(x_k)P_r)r_k^0, (F'(x_k)P_r)^2 r_k^0, \ldots, (F'(x_k)P_r)^{m-1} r_k^0\},$$

where $r_k^0 = -F(x_k)$ and (2.3) becomes $F'(x_k)P_r V_m = V_{m+1}\bar{H}_m$. Clearly, the vector $\bar{p}_k$ in K_m^p such that $\|F'(x_k)P_r\bar{p}_k + F(x_k)\| \leq \bar{\eta}_k\|F(x_k)\|$ gives rise to the approximate solution $\bar{s}_k = P_r\bar{p}_k$ of (1.3). Consequently, $\bar{s}_k \in P_r K_m^p$ and this leads to the low-dimensional globalization strategy in the subspace $S = P_r K_m^p$.

Following the lines of the unpreconditioned case, since each vector $s \in P_r K_m^p$ is such that $s = P_r V_m y$, $y \in \mathbb{R}^m$, the function $g(y)$ in (3.1) becomes

$$g(y) = M(x_k + P_r V_m y).$$

Noting that for each $s \in P_r K_m^p$, the relation

$$\nabla M(x_k)^T s = \nabla g(y)|_{y=0}^T y = -e_1^T \bar{H}_m y$$

holds, then the directional derivatives have the same form of the unpreconditioned case. Finally, if we let

$$\hat{g}(y) = \|F'(x_k)P_r V_m y + F(x_k)\|,$$

the application of the ECB-strategy is straightforward.

4. Numerical tests. Our numerical experiments show that the combination of two backtracking strategies yields a significant benefit in the likelihood of convergence of an inexact method. To support this claim, we compared performance of NGB and NGECB methods on several problems.

The tests were conducted on an IBM Risc 3CT workstation using MATLAB 5.2. The machine precision is $\epsilon_m \simeq 2.10^{-16}$. In our implementation, products of the form $F'(x_k)v$ that are required by Algorithm GNE were approximated by (1.4) with $\epsilon = \sqrt{\epsilon_m}\|x_k\|/\|v\|$. Note that for $v = v_j$, $j = 1, \ldots, m$, ϵ reduces to $\sqrt{\epsilon_m}\|x_k\|$, i.e., it is independent of j. Also, in order to implement an efficient matrix-free procedure, this value of ϵ was used to construct the piecewise linear curve σ_k in step 6 of the ECB-strategy. Further, in the ECB-strategy, h_{min} was set equal to $10\epsilon_m$.

Concerning the forcing terms $\{\bar{\eta}_k\}$, we adopted one of the proposals of [9, p. 305]: we used "*Choice* 2 *safeguard*" with $\gamma = 0.9$, $\alpha = 2$, $\eta_{max} = 0.9$, $\eta_0 = \eta_{max}$.

Algorithm GNE was started with $s_k^0 = 0$. At most $m_{max} = 40$ GMRES-iterations were allowed, and restarting was not employed. If after $m = m_{max}$ steps

$\|r_k^m\| > \bar{\eta}_k \|F(x_k)\|$, NGB and NGECB algorithms continued with the vector provided in the final GMRES iteration. Namely, the inexact Newton step $\bar{s}_k$ was set equal to s_k^m and $\bar{\eta}_k = \|F'(x_k)\bar{s}_k + F(x_k)\|/\|F(x_k)\|$ was used. Right diagonal and ILU(1) preconditioners were allowed.

In the backtracking loop BL defined in step 3 of NGB and in the backtracking loop performed in step 8 of the ECB-strategy, the typical values $t = 10^{-4}$, $\theta_l = 0.1$, $\theta_u = 0.5$ were used.

In both algorithms, the iterations were halted when $\|F(x_k)\|/\sqrt{n} \leq 10^{-6}$. A failure was declared if one of the following situations occurred: the maximum of 300 nonlinear iterations was reached, or $\|F(x_{k-1})\| - \|F(x_k)\| \leq 10^{-6}\|F(x_k)\|$ was detected. This last occurrence is commonly indicated as a "stagnation" of the nonlinear iterates [10], [15], and it may indicate that the method did not manage to escape from a local minimizer of the merit function. Also, a failure of NGB was declared if 50 iterations of the backtracking loop BL failed to produce the sufficient decrease (2.5) in $\|F\|$. Analogously, if in step 8 of the ECB-strategy (3.7) was not verified within 50 backtracking steps, a failure of NGECB was declared.

In order to analyze the computational performance of NGECB, we conducted experiments with different choices of the parameter N_b. We recall that N_b is the maximum number of times the backtracking loop BL can be repeated in the NGECB algorithm, i.e., is the maximum number of backtracks allowed along $\bar{s}_k$ before switching to the ECB-strategy. For the sake of brevity, we will shorten NGECB with $N_b = p$ to NGECB(p). We emphasize that NGECB(p) reduces to NGB for all the problems that, at each iteration, require a number of backtracks less than or equal to p. Further, the choice $N_b = 0$ means that we turn off backtracking along the inexact Newton step. In other words, NGECB(0) uses a globalization strategy where only backtracking along the piecewise linear curve is performed.

In reporting the results of NGB and NGECB, the following values are given in the tables:

- `NI`, number of nonlinear iterations;
- `FE`, number of function evaluations;
- `BT`, number of backtracks;
- `SW`, number of switches to the ECB-strategy. The symbol "*" indicates a failure. We remark that, due to the backtracking strategies and the matrix-free implementation, the most significant part of the computational cost is revealed by `FE`.

To realistically assess performance of NGECB, numerical experiments were carried out on a large set of problems; see Table 4.1. For each problem, several starting guesses x_0 were used. In particular, letting x_s be the standard initial guess used in literature, *ones* be the vector in $\mathbb{R}^n$ with all components equal to 1, and *null* be the zero vector in $\mathbb{R}^n$, we used $x_0 = \pm x_s, \pm 2x_s, \pm 5x_s, ones, 2\,ones, 5\,ones, null$. However, for several problems we neglected those initial guesses x_0 for which we had $F(x_0) = 0$ or singular $F'(x_0)$. Further, the dimension n of each test was varied. Below we will discuss the results obtained with n given in Table 4.1.

We notice that our test problems display different features: problems with ill-conditioned Jacobian (P2, P14), problems with singular Jacobian at the solution (P4, P10, P11), and one parameter-dependent problem (P17).

Our experiments showed a wide array of convergence behaviors: often NGB needed few or no backtracks to enforce convergence, but at times it was unsuccessful. On a total of 143 tests, NGB failed 51 times. The most recurrent failure was stag-

nation, which occurred for 42 tests; for 10 of them, no backtracks were performed. We point out that none of these failures can be ascribed to the absence of restarts in GMRES. In fact, the stopping criterion (1.2) is satisfied within m_{max} GMRES iterations in most of the tests. For the remaining tests we verified that stagnation occurred even if a restarted version of GMRES is used to satisfy (1.2).

First, we fixed $N_b = 5$ for NGECB. We remark that there is nothing critical about this choice. However, on the basis of our numerical tests it seems to work well and serves to prove the effectiveness of our method.

For 98 tests, NGECB(5) reduced to NGB. So we now focus on the remaining 45 tests (problems P2, P4, P5, P6, P7, P8, P9, P11, P14, P15, P16): NGB and NGECB(5) solved 9 and 24 tests, respectively. Then, the number of failures dropped from 80% to 47%. In Table 4.2 we summarize results for problems P2 and P14. These are the only two problems on which NGB failed to converge for all initial guesses; the most recurrent failure was due to stagnation.

For the 21 tests that were not solved by NGECB(5), we reran NGECB varying N_b from 0 to 4. This yielded a significant benefit since we managed to solve 6 tests; see Table 4.3 for results with $N_b = 0,\ 3$. Note that, except for P14, all the tests were solved at a low computational cost.

TABLE 4.3
Tests solved by NGECB, $p < 5$, that were unsuccessful for NGB and NGECB(5).

Pb#	x_0	NGECB(3)				NGECB(0)			
		NI	FE	BT	SW	NI	FE	BT	SW
P6	$5\,x_s$	20	128	20	3	17	76	3	2

P16	x_s	19	159	5	1	19	169	3	3
P16	$5\,x_s$	*	*	*	*	23	227	13	6

The computational experiments presented above illustrate that on a total of 143 tests NGB converged 64% of the time, NGECB 85% of the time. Since for 10 failures no backtracks were performed, and hence cannot be recovered by NGECB, our results indicate that our hybrid strategy enhances the robustness of NGB. Further, it is worth noting that only for problems P7 and P16 with $x_0 = 5\,x_s$, the use of $N_b = 0$ was crucial to obtain convergence in cases where NGB failed. This underscores that the improvement in the global convergence properties of NGB is due to the combination of the linesearch strategies.

We stress the apparent similarity of the ECB-strategy and the dogleg strategy proposed by Brown and Saad in [3] and already mentioned in section 3.1. They introduce the quadratic model $\|F'(x_k)V_m y + F(x_k)\|^2$ and minimize it along a dogleg path based on the inexact Newton step $\bar{s}_k$ and the steepest descent direction $V_m d_m$. To be more precise, this dogleg path has 3 nodes, $\bar{s}_k$, $\alpha_d V_m d_m$, and zero. On the contrary, as was seen in the detailed description of the ECB-strategy, the piecewise linear curve $\sigma_k(\eta)$ connects $\bar{s}_k$, the vector z chosen between $\alpha_d V_m d_m$ and $\alpha_e V_m e_{j^*}$, and zero. Therefore, $\sigma_k(\eta)$ differs from the dogleg curve of [3] when $z \neq \alpha_d V_m d_m$ is selected in step 6 of the ECB-strategy. Let us consider the frequency of taking $z \neq \alpha_d V_m d_m$ in NGECB. Restricting our attention to the 30 tests for which NGECB(5) differs from NGB and succeeded, we observed that NGECB selected $z \neq \alpha_d V_m d_m$ 47% of the time. To show a conclusive proof that backtracking along the curve $\sigma_k(\eta)$ of the ECB-strategy can be more robust than backtracking along the dogleg curve, we considered a modified version of NGECB(p) where only $z = \alpha_d V_m d_m$ can be selected. We will refer to this modified version as NGDOG(p) (Newton-GMRES dogleg).

Thus, we verified that for some tests, the choice $z \neq \alpha_d V_m d_m$ was crucial to obtaining convergence. For example, among the tests contained in Table 4.3, NGDOG(p), $0 \leq p \leq 5$, did not solve problems P6 and P7 with $x_0 = 5\,x_s$. Also, Table 4.4 shows NGECB(p) and NGDOG(p) applied to problem P8. For the reported initial guesses, NGB failed to converge. The symbols ND and NV denote the number of times where $z = \alpha_d V_m d_m$ and $z = \alpha_e V_m e_{j^*}$ were selected, respectively. One sees that the ECB-strategy outperformed the dogleg strategy when the standard initial guess is used, while NGECB reduced to NGDOG when $x_0 = ones$ and $x_0 = 2\,ones$.

Finally, more insight into the behavior of NGECB may be gleaned by comparing the overall computational effort of NGB and NGECB. Therefore, we extensively examined successful runs. At this regard, the results in Table 4.5 are typical: there, we summarize the results on problem P5 for the full set of starting guesses. Note that starting with $x_0 = 2\,x_s$ NGB failed, but NGECB succeeded. Otherwise, except for $x_0 = 5\,x_s$, all the methods were successful. Notice that they perform very similarly on tests requiring a few backtracks ($x_0 = -x_s$, $-5\,x_s$, *null*) as well as on tests requiring several backtracks ($x_0 = x_s$, $5\,ones$).

One final aspect that should be noted is the comparison of NGECB with an "exact" version of NGB. Therefore, we ran NGB with a tight stopping criterion for GMRES, i.e.,

$$\|F'(x_k)\bar{s}_k + F(x_k)\| \le \max\{100\epsilon_m\|F(x_k)\|, 100\epsilon_m\}. \tag{4.1}$$

In our experience, NGECB proved to be more efficient than the "exact" NGB. This is due to the choice of forcing terms that gives desirable fast local convergence and also tends to minimize "oversolving." In fact, as noted in [9], these forcing terms avoid wasting effort in the initial stages of the nonlinear iterative method. Obviously, we obtained a less significant benefit when GMRES converged quickly. Figure 4.1 shows NGECB and "exact" NGB applied to problems P7 and P8. There the graphs plot the value of $\|F\|$ as a function of the number of F-evaluations required to reach that value of $\|F\|$. One sees that for problem P7, NGECB showed a significant improvement in the number of function evaluations over the "exact" NGB counterpart. On the contrary, NGECB performed slightly better on problem P8, where only a few number of GMRES iterations were necessary to satisfy (4.1).

Summarizing the overall computational experiments, we have tackled 143 commonly used tests. We have shown that the introduction of the ECB-strategy enhances global convergence for cases where NGB fails. Further, although the ECB-strategy may coincide with a backtracking strategy along the dogleg curve given in [3], we have shown that in practice NGECB benefits from the possibility of selecting a backtracking curve different from the dogleg one. Finally, regarding the computational effort, the numerical tests suggest that our approach and the classical backtracking Newton-GMRES method have very similar cost.

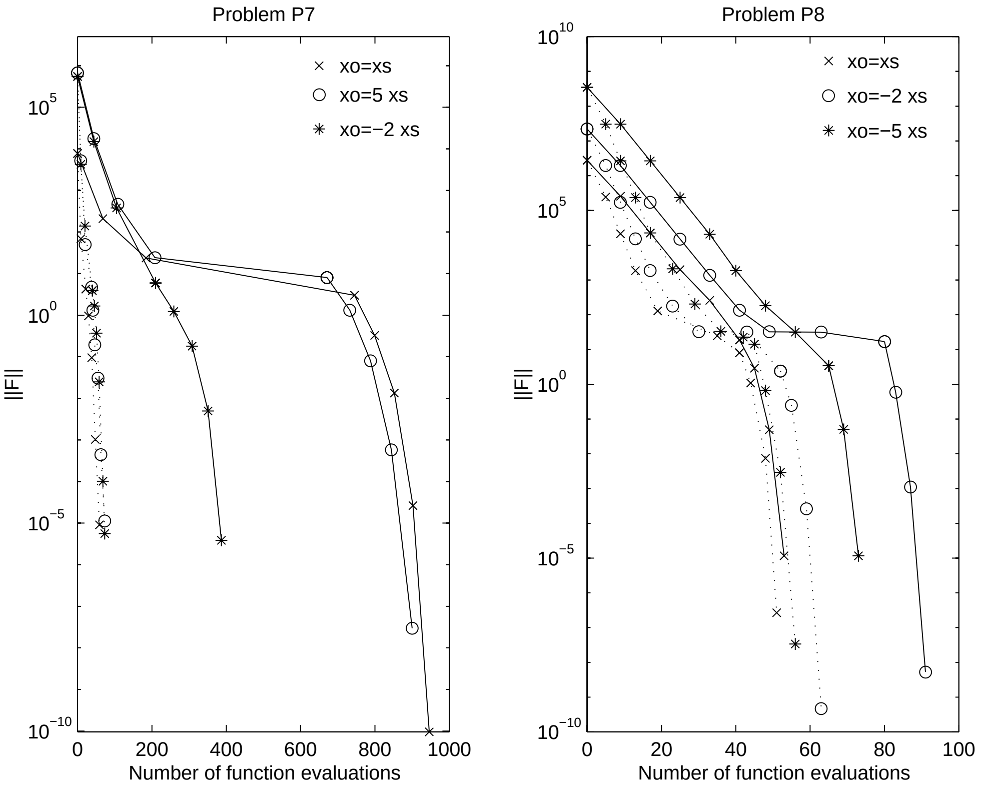

FIG. 4.1. *Comparison between NGECB(p), $p \leq 5$, and "exact" NGB. Dotted line: NGECB; solid line: "exact" NGB.*

Acknowledgments. The authors are indebted to Prof. Luca Dieci and Prof. Maria Macconi for many helpful discussions and suggestions related to this paper. Also, thanks are due to Prof. Margaret Wright for her careful reading of the manuscript and for several suggestions that improved the presentation of this work.

THE LINEAR RATIONAL PSEUDOSPECTRAL METHOD WITH ITERATIVELY OPTIMIZED POLES FOR TWO-POINT BOUNDARY VALUE PROBLEMS*

JEAN-PAUL BERRUT† AND HANS D. MITTELMANN‡

Abstract. An algorithm is proposed which improves upon the polynomial pseudospectral method for solving linear two-point boundary value problems. In the latter, the collocation points are the vertical projection onto the interval of points equidistant or nearly equidistant on the circle, and they therefore accumulate in the vicinity of the extremities of the interval. Thus the method is well-suited for solving problems whose solutions have boundary layers but not as good at approximating solutions with large gradients (shocks) away from the extremities of their domain of definition. Our idea is to modify the polynomial ansatz by attaching a denominator so as to make it a *rational* interpolant. The denominator is then successively optimized in an iterative procedure with each step consisting of the solution of two problems: an optimization of the denominator for *given* values of the approximation to the solution u at the interpolation points and a collocation in the linear space of the rational interpolants with the just obtained *fixed* denominator to obtain new approximate values of u. We show the efficiency of a Galerkin version of the method and discuss the power of the collocation version with several numerical examples.

Key words. two-point boundary value problems, linear rational collocation, pole optimization

1. Introduction.

The problem. Our aim in the present work is to improve upon the polynomial pseudospectral method for solving linear two-point boundary value problems (BVPs)

$$u''(x) + p(x)u'(x) + q(x)u(x) = f(x), \qquad x \in (-1,1), \tag{1.1a}$$

$$u(-1) = u_\ell, \quad u(1) = u_r, \tag{1.1b}$$

where all arising functions belong to $C^\infty[-1,1]$ and u_ℓ and u_r are given real numbers. We assume that p, q, and f are such that the problem is well-posed. (For conditions guaranteeing the latter, see, e.g., [Kel, p. 12], [As-Ma-Ru, p. 88], or [Sto-Bul].) The generalization of the method to be presented below to nonlinear problems is straightforward but does not bring more insight.

The version of the pseudospectral method we have in mind is that consisting of replacing the solution in (1.1a) by an interpolating polynomial in Lagrangian form between well-chosen points and collocating at those same points. Since such points are vertical projections on the interval of points (nodes) equidistant or nearly equidistant on the circle, they accumulate in the vicinity of the extremities of the interval. As a consequence, the method is well-suited for solving problems whose solutions have boundary layers. (This property can even be accentuated by conformally shifting the points to make them more tilted toward the extremities, e.g., by a sine-map

[Tan-Tru].) Correspondingly, however, the center nodes are about equidistant and further from each other than the same number of nodes equidistant on the whole interval. As a consequence, the pseudospectral method has a hard time approximating solutions with large gradients (shocks) away from the extremities of their domain of definition.

Several methods can be used to cope with this difficulty. The most efficient ones, as measured by the size of the error, are probably methods where the solution is not approximated by a global but by a piecewise interpolant (see, e.g., [As-Ch-Ru, Bad-Asc, Lee-Gre]). Here we are interested only in methods which preserve the infinite differentiability of the solution. One of them consists of constructing and switching in an analytic function that displaces the interpolation points so as to have them concentrate close to the abscissae where the shocks arise [Mu-Hu-Sl]. To obtain this function, the method solves a sequence of problems for values of a parameter corresponding to stiffer and stiffer problems.

We will instead develop a method that improves on the pseudospectral (polynomial) method without any change in the problem nor in the interpolation/collocation points. The idea is to modify the ansatz by attaching a denominator to the polynomial so as to make it a *rational* interpolant, as in [Ber-Mit2] and [Ba-Be-Du]. The denominator is then successively optimized in an iterative procedure with each step consisting of the solution of two problems: an optimization of the denominator for *given* values of the approximation to u at the interpolation points and a collocation in the linear space of the rational interpolants with the just obtained *fixed* denominator to obtain new approximate values of u.

We will describe the methods for solving these two problems in section 2. Section 3 introduces the then very simple full algorithm, whose viability is motivated in section 4 by a theorem proving that a corresponding Galerkin algorithm yields a sequence of approximations with a certainly nonincreasing, and in most cases decreasing, error in the energy norm. Finally, in section 5, we report on numerical experiments that demonstrate the efficiency of the algorithm.

2. The ingredients of the solution.

As just mentioned in the introduction, the method presented here consists of the iterative application of two algorithms which we describe in this section.

2.1. The linear rational collocation method for boundary value problems.

This generalization, suggested in [Ber-Bal] and [Ba-Be-Du], of the now classical polynomial pseudospectral method is the application to BVPs of the corresponding method for time evolution problems [Bal-Ber2]. It is based on the fact [Ber2, Ber-Mit1] that every rational function $r \in \mathcal{R}_{N,N}$ interpolating a continuous function f between interpolation points $x_0, \dots, x_N$ can be written in its *barycentric form*

$$r(x) = \sum_{j=0}^{N} \frac{\beta_j}{x - x_j} f(x_j) \Bigg/ \sum_{j=0}^{N} \frac{\beta_j}{x - x_j} \tag{2.1}$$

for some (nonunique) numbers β_j, one per node, called *weights* of the interpolant. Here $\mathcal{R}_{m,n}$ denotes the set of all rational functions with numerator degree $\leq m$ and denominator degree $\leq n$. The polynomial interpolant is the special case of (2.1) in which the β_j's are proportional to the barycentric weights

$$w_j := 1 \Big/ \prod_{k \neq j} (x_j - x_i)$$

of polynomial interpolation [Hen]. For instance, for equidistant points the w_j's are proportional to $(-1)^j\binom{N}{j}$, for Čebyšev points $\cos\phi_j$ of the first kind they are proportional to $(-1)^j\sin\phi_j$ and for Čebyšev points of the second kind they are proportional to $(-1)^j\eta_j$, with $\eta_j = 1$ for all j but at the boundary points, where $\eta_0 = \eta_N = 1/2$. In view of the presence in the problem of the boundary values (1.1b) we will restrict ourselves here to sets of nodes containing the extremities -1 and 1, i.e., Lobatto points (and in particular to Čebyšev points of the second kind in numerical computations).

For fixed $\beta := [\beta_0, \ldots, \beta_N]^T$ the set of all interpolants (2.1) is a linear space, which we denote by $\mathcal{R}_N^{(\beta)}$. The functions

$$L_j^{(\beta)}(x) := \frac{\beta_j}{x - x_j}\Bigg/\sum_{k=0}^{N}\frac{\beta_k}{x - x_k}, \quad j = 0, 1, \ldots, N,$$

make up a basis for this space and they satisfy the Lagrange property

$$L_j^{(\beta)}(x_i) = \delta_{ij}. \tag{2.2}$$

In the *linear rational collocation method* (in barycentric form) for the nodes x_j, one tries to find u as an interpolant

$$\widetilde{u}(x) = \sum_{j=0}^{N}\widetilde{u}_j L_j^{(\beta)}(x) \in \mathcal{R}_N^{(\beta)}$$

for some *given* weights β and some unknown values $\widetilde{u}_j$ at the x_j's, one inserts $\widetilde{u}$ into (1.1a), and one collocates at the same interior x_j's for simplicity. (Collocation points different from the interpolation points, as in [Fun], are equally possible.) This yields the following linear system of equations for the $\widetilde{u}_j$:

$$\sum_{j=0}^{N}\widetilde{u}_j L_j^{(\beta)''}(x_i) + p(x_i)\sum_{j=0}^{N}\widetilde{u}_j L_j^{(\beta)'}(x_i) + q(x_i)\sum_{j=0}^{N}\widetilde{u}_j L_j^{(\beta)}(x_i) = f(x_i), \tag{2.3}$$
$$i = 1, \ldots, N-1, \qquad \widetilde{u}_0 = u_r, \widetilde{u}_N = u_\ell.$$

In order to write this expression in a more concise way, we introduce the following vectors and matrices in $\mathbb{R}^{N-1}$ (resp., $\mathbb{R}^{(N-1)\times(N-1)}$):

$$\begin{aligned}
&\widetilde{\mathbf{u}} := [\widetilde{u}_1, \widetilde{u}_2, \ldots, \widetilde{u}_{N-1}]^T,\\
&\mathbf{D}^{(1)} = \big(D_{ij}^{(1)}\big), \quad D_{ij}^{(1)} := L_j^{(\beta)'}(x_i),\\
&\mathbf{D}^{(2)} = \big(D_{ij}^{(2)}\big), \quad D_{ij}^{(2)} := L_j^{(\beta)''}(x_i),\\
&\mathbf{P} := \operatorname{diag}\big(p(x_i)\big), \quad \mathbf{Q} := \operatorname{diag}\big(q(x_i)\big),\\
&\mathbf{f} := [f(x_i) - u_r\big(L_0^{(\beta)''}(x_i) + p(x_i)L_0^{(\beta)'}(x_i)\big) - u_\ell\big(L_N^{(\beta)''}(x_i) + p(x_i)L_N^{(\beta)'}(x_i)\big)]^T,\\
&\qquad\quad i,\ j = 1, \ldots, N-1.
\end{aligned}$$

In view of (2.2), the system (2.3) for the unknown values $\widetilde{\mathbf{u}}$ of the approximant then reads $\mathbf{A}\widetilde{\mathbf{u}} = \mathbf{f}$ with

$$\mathbf{A} := \mathbf{D}^{(2)} + \mathbf{P}\mathbf{D}^{(1)} + \mathbf{Q}.$$

Despite its large condition number for N large, it can be solved very precisely by Gaussian elimination [Ber1, Tan-Tru], for only the differentiation operator $\mathbf{A}$ is ill-conditioned, not the integration operator $\mathbf{A}^{-1}$. The system can often also be solved efficiently via iterative methods [Ber1], although the ill-conditioned $\mathbf{A}$ then slows down the convergence. (A conformal shift of the points can improve on this; see [Ber-Bal].) In our calculations we have alleviated the instability by using the modified Schneider–Werner formulae [Bal-Ber1, Bal]

$$D_{ij}^{(1)} = \begin{cases} \dfrac{\beta_j/\beta_i}{x_i - x_j}, & i \neq j, \\ -\displaystyle\sum_{k \neq i} D_{ik}^{(1)}, & i = j, \end{cases}$$

and

$$D_{ij}^{(2)} = \begin{cases} 2D_{ij}^{(1)}\Big(D_{ii}^{(1)} - \dfrac{1}{x_i - x_j}\Big), & i \neq j, \\ -\displaystyle\sum_{k \neq i} D_{ik}^{(2)}, & i = j \end{cases}$$

for the differentiation matrices.

In the polynomial case ($\beta_j = w_j$, all j) and with the interpolation points used here, the convergence of $\widetilde{u}$ toward the exact solution u is *exponential* if p, q, and f are analytic in an ellipse containing $[-1, 1]$. This can be seen through subtraction (and use of the exponential convergence of the interpolant of f) if p and q are constant, by more elaborate theorems [Can-Qua] in general cases. However, this fast convergence may show up only after too large an N for practical purposes if u has huge gradients (see the introduction in [Ber-Mit2]). For error bounds through estimates of the norm of the inverse operator, see the work by Wright and collaborators, from [Cru-Wri] to [Ahm-Wri].

2.2. Optimal attachment of poles to the interpolating polynomial. It is intuitively clear, and well known in practice, that rational interpolation can better accommodate large gradients. (For literature on rational interpolation, see the catalogue [Gro].) However, at least for small numbers of nodes, the classical rational interpolation problem (interpolate a given function, here $\widetilde{u}$, between N points by a $r \in \mathcal{R}_{m,n}$ with $m + n = N$) is hampered by two drawbacks: the nonexistence of the solution in certain cases, which shows itself in the occurrence of "unattainable points" [Sto, p. 56], and the possible presence of poles in the interval of interpolation, a common phenomenon for N small.

To overcome these difficulties, we have suggested in [Ber-Mit2] to complement the interpolating polynomial $\widetilde{u}$ with a denominator with, say, P poles z_ℓ, $\ell = 1, \ldots, P$ (and corresponding modification of the numerator so as to maintain interpolation). In practice, if the real part is to lie in the interval of interpolation, the poles will be chosen as pairs of conjugate complex numbers, so as to stay with real interpolants.

It has been noted in [Ber3] ([Ber-Mit2] contains a more obvious derivation) that introducing preassigned poles is easily achieved in the barycentric setting by multiplying the weights w_j of polynomial interpolation by a multiple of

$$d_j := \prod_{\ell=1}^{P} (x_j - z_\ell), \quad j = 0, \ldots, N. \tag{2.4}$$

By writing r as

$$r(x) := \sum_{j=0}^{N} \frac{w_j \prod_{\ell=1}^{P}\Bigl(1 - \frac{x_j}{z_\ell}\Bigr)}{x - x_j} \widetilde{u}_j \Bigg/ \sum_{j=0}^{N} \frac{w_j \prod_{\ell=1}^{P}\Bigl(1 - \frac{x_j}{z_\ell}\Bigr)}{x - x_j},$$

one sees that the polynomial is the case where all z_ℓ are at infinity. The suggestion in [Ber-Mit2] is to move them from there to an optimal position where they minimize some error functional, which we take here as the norm

$$J(\mathbf{z}) := \|r'' + pr' + qr - f\|_\infty, \quad \mathbf{z} := [z_1, \ldots, z_P]^T, \tag{2.5}$$

of the *residual* of the differential equation for the approximation r with given values $\widetilde{\mathbf{u}}$ of the solution u at the x_j's. *The optimization can only decrease the value of J*, since the interpolation polynomial belongs to the feasible set.

Note that the interpolated values $\widetilde{u}_j$ at the nodes are not modified as one displaces the poles: interpolation is warranted by the barycentric formula [Wer, Ber2, Ber-Mit1]—r' and r'' do change, however, so that r no longer satisfies (2.3).

Optimizing the poles z_ℓ is a nonlinear problem to be solved by iteration. There is always an optimal $\mathbf{z}$, but, at least in special cases, there can be several of them. (Think of the case in which all functions arising in (1.1a) are constant.) Whether the optimal r is unique is an open question [Ber-Mit2]. Nevertheless, in every undetermined case among our many tests (there were very few such cases, and none for N large enough), the optimal set was a continuum and the multiplicity could easily be detected from the divergence of the optimization procedure.

3. The linear rational pseudospectral method with iteratively optimized poles. The algorithm we suggest here for solving (1.1a) improves iteratively upon the polynomial pseudospectral method. It consists of recursively performing the two methods described in section 2.

Let the $N+1$ interpolation points $x_0, \ldots, x_N$ be given, as well as the number P of poles to be optimized, which are first supposed at infinity (if no information on their final location is known at the onset). For $k = 1, 2, \ldots$, repeat the following steps.

Step 1. Compute the approximate solution $\widetilde{\mathbf{u}}^{(k)} = [\widetilde{u}_1^{(k)}, \ldots, \widetilde{u}_{N-1}^{(k)}]^T$ of (1.1a) by the linear rational collocation method with $\beta_j = w_j d_j$, d_j from (2.4) ($d_j \equiv 1$ for $k = 1$). This modifies $\widetilde{\mathbf{u}}$ (for $k > 1$) but not the poles $\mathbf{z}$ nor the weights β.

Step 2. For the $\widetilde{\mathbf{u}}^{(k)}$ inherited from Step 1, optimize the location of the poles $\mathbf{z}$ by minimizing $J(\mathbf{z})$. This changes β, but not $\widetilde{\mathbf{u}}^{(k)}$, and yields a new interpolant $\widehat{u}^{(k)}$ of the latter values.

When do we stop? Roughly speaking, we stop when the decrease in J becomes too small in comparison with the cost of one more step of the algorithm.

The recurrence of Step 2 makes the algorithm costly. However, for a given problem and a given N, the cost of the optimized solution is a constant multiple of the cost of the polynomial method without memory increase, whereas reaching a better precision by increasing N requires at least a quadratic increase in computing time (when using iteration methods for solving the systems of equations) and memory. Moreover, at the outcome, when β and $\widetilde{\mathbf{u}}$ have been computed, evaluating $\widetilde{u}$ by the formula (2.1) is exactly as expensive as evaluating the polynomial solution. The algorithm presented here may therefore be especially interesting in cases in which the time for finding the solution is not very relevant, but the latter must be evaluated a great many times, as in animated graphics or in the use of $\widetilde{u}$ as the reference solution in optimal control problems.

Also notice that in certain cases the location of the poles of u may be directly read from the equations (equations belonging to the Fuchsian class) or approximated with the WKB theory [Wei]. In which cases the β_j are known, there is no need for optimization and Step 1 yields $\widetilde{u}$: this is precisely the method introduced in [Ba-Be-Du].

4. Motivation: A corresponding Galerkin method. Why should the method work, i.e., bring improvement as compared to the classical pseudospectral solution? A corresponding Galerkin method, more complicated and computationally more expensive, gives some indication.

Denote by L the operator which to every function u in some appropriate space V associates the function on the left-hand side of (1.1a). Then a weak form of the latter consists of finding $u \in V$ for which

$$a(u,v) := (Lu, Lv) = (f, Lv) \qquad \forall\; v \in V,$$

where (,) is the L_2-scalar product in V. (Notice that, in contrast with the classical Galerkin method, we also apply L to the test functions v.) In an appropriate space, $a(u,v)$ is a symmetric positive definite form which induces the *energy norm*

$$\|v\|_a^2 := a(v,v) = \|Lv\|_2^2.$$

We may now introduce the linear rational Galerkin solution of (1.1a) as the function $\widetilde{u} \in \mathcal{R}_N^{(\beta)}$ such that

$$a(\widetilde{u}, \widetilde{v}) = (f, L\widetilde{v}) \qquad \forall\; \widetilde{v} \in \mathcal{R}_N^{(\beta)}.$$

$\widetilde{u}$ exists and it is unique because of the symmetry and V-ellipticity of a, and it notoriously possesses the important property of minimizing the norm $\| \quad \|_a$ of the error in $\mathcal{R}_N^{(\beta)}$, i.e.,

$$\|\widetilde{u} - u\|_a = \min_{v \in \mathcal{R}_N^{(\beta)}} \|v - u\|_a. \tag{4.1}$$

This Galerkin method would replace Step 1 of the algorithm to yield another $\widetilde{u}^{(k)}$. In Step 2 we would simply change the norm in (2.5) from $\| \quad \|_\infty$ to $\| \quad \|_2$ when computing $\widehat{u}^{(k)}$. Indeed, since $Lu = f$, $\|Lr - f\|_2^2 = \|L(r-u)\|_2^2 = \|r - u\|_a^2$. And, again, the optimal attachment of the poles can only decrease J, not increase it.

Because of (4.1), the next Step 1 (with the new β) can in its turn lead only to a $\widetilde{u}^{(k+1)}$ with

$$\|\widetilde{u}^{(k+1)} - u\|_a \le \|\widehat{u}^{(k)} - u\|_a \le \|\widetilde{u}^{(k)} - u\|_a,$$

and so on. We therefore have the following result.

THEOREM. *The linear rational Galerkin method with successive optimization of the poles, as described above, yields, in the energy norm* $\| \quad \|_a$*, a distance decreasing sequence of approximations to the solution of* (1.1a).

Since the minimum property (4.1) does not hold for the collocation method, the above result is merely an indication for the success of our algorithm. Still, in all problems we have solved, the successive optimal attachment of the poles has resulted in a decrease of J.

It should be noted, however, that a smaller residual does not necessarily imply an approximation $\widetilde{u}$ that is everywhere closer to the exact solution u: on rare occasions, the error becomes larger at particular points when one takes too small an N (see Example 1 with $N = 12$ in Table 1).

5. Numerical examples. We now report on computations performed on four examples, taken from the literature for the sake of comparison: three are borrowed from [Gre], the last one from [As-Ch-Ru]. Graphs of the solutions can be found in those articles.

As mentioned in section 2.1, our interpolation/collocation points have been in all examples Čebyšev points of the second kind $x_j := \cos \frac{j\pi}{N}$, $j = 0, \dots, N$. We have solved the systems arising in the linear rational collocation method by means of Gaussian elimination, since for some difficult examples the simple iterative procedure of [Ber1] did not converge. The optimization of the poles in Step 2 of the algorithm has been performed as in [Ber-Mit2] by a discrete differential correction algorithm according to [Ka-Le-Ta] for small N, by the simulated annealing method of [C-M-M-R] for larger numbers of nodes. The L_∞-norm in (2.5) has been approximated by considering the values at the 100 equally spaced points

$$\widehat{x}_k = -\frac{5}{4} + \frac{k-1}{K-1}\frac{5}{2}, \qquad k = 1(1)K, \quad K = 100,$$

on the interval $[-5/4, 5/4]$ and computing the maximal absolute value at those $\widehat{x}_k$ lying in $[-1, 1]$. (Tests with 1000 points instead of 100 have shown that the results do not depend much on this number of points.)

The computations were performed in Fortran77 on HP-workstations.

Example 1. The first example is from the classical book [Sto-Bul]. Modified by the change of variable $x = (t+1)/2$ to take place on the interval $[-1, 1]$, it reads

$$2y''(t) - 200y(t) = 200\cos^2(\pi x) + \pi^2\cos(2\pi x),$$
$$y(-1) = y(1) = 0,$$

and its exact solution is

$$y(t) = \frac{e^{-20}}{1+e^{-20}}e^{20x} + \frac{1}{1+e^{-20}}e^{-20x} - \cos^2(\pi x).$$

When applying the algorithm with an increasing number of poles P, one notices that as soon as $P \geq 4$, four of the poles have the tendency to arrange themselves symmetrically about the origin. This is not surprising, in view of the symmetry of the problem with respect to the imaginary axis. Since the difficulty of the optimization (the delicate part of the whole algorithm) grows sharply with the number of variables, it is natural to set the poles in groups of four and to diminish that way the number of variables from 8 to 2. The results we have obtained are summarized in Table 1. The first column gives N, the number of nodes minus 1, the second the number P of optimized poles, the third the residual norm (2.5) achieved by the optimized rational, the fourth the maximum error of the latter as above but with $K = 1000$ and the last the location of one of the four poles—the others being the same with the three other combinations of signs.

As in all our tests, the residual norm is significantly larger than the maximal error at the nodes. The results with $P = 0$ for increasing N document the exponential convergence of the polynomial pseudospectral method. For every fixed N the first

set of four poles improves the residual by three to five orders of magnitude and the maximal error by two to three, a very significant improvement especially spectacular for small N if one thinks in relative terms. The next four poles diminish the error by another power of 10. Also note that the poles come to lie to the left and to the right of the interpolation interval, and quite far from it, in order to best help the large gradients at the extremities.

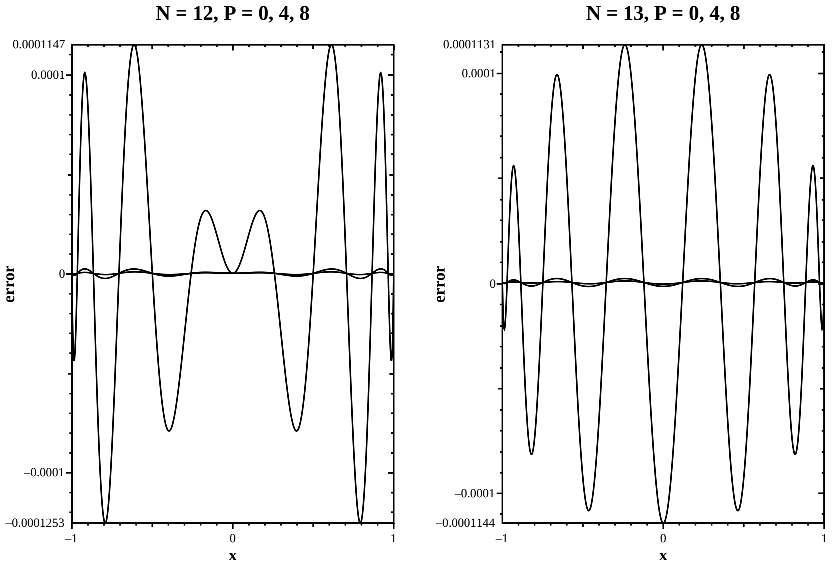

Fig. 1. *Error curves in Example* 1.

Figure 1 displays the improvement in the error curves for $N = 12$ and $N = 13$ with $P = 0$, 4, and 8 poles. The error pattern is very regular; the attached poles decrease the amplitude of the oscillations, whereas the abscissae of minimal absolute error do not move much.

Example 2. The classical problem

$$u'' - \epsilon u = 0, \qquad y(-1) = 1, \quad y(1) = 2$$

displays boundary layers at the extremities of the interval. Written in such a way as to avoid overflow for large ϵ, the solution reads

$$u(x) = \frac{3}{2}\frac{e^{\delta(x-1)} + e^{-\delta(x+1)}}{1 + e^{-2\delta}} + \frac{1}{2}\frac{e^{\delta(x-1)} - e^{-\delta(x+1)}}{1 - e^{-2\delta}}, \qquad \delta := \sqrt{\epsilon}.$$

The results, as displayed in Table 2, again show that the first four poles improve the residual by three to almost five orders of magnitude and that the next four add one to two more orders. Also note that as ϵ increases and the layers become more pronounced, the poles move closer to the extremities of the interval, as could be expected.

Example 3. The third example in [Gre] is chosen in such a way that the solution is very oscillatory. Written in a more general way, the problem is

$$u''(x) + \frac{a}{2}u'(x) + \frac{b^2}{4}u(x) = -\frac{ab}{2}\cos(bx)e^{-ax},$$
$$y(0) = 0, \qquad y(1) = \sin be^{-a}$$

and its solution is given by

$$u(x) = \sin(bx)e^{-ax},$$

where a and b are two positive real parameters. b controls the frequency of the oscillations: the bigger b, the larger the number of oscillations and the steeper the function in each of the latter. As a consequence, the number of optimized poles should be increased in step with b. This, however, is not possible, in view of the difficulty of solving optimization problems with large numbers of variables.

The same change of variable as in Example 1 must be made. In Table 3 we give the numbers obtained with $a = 5$, $N = 16$, and increasing b's. They show that up to about $b = 25$ the optimal attachment of few poles yields a very significant improvement of the solution, a surprising and heartening result. With $b = 100$, the case considered by Greengard, the improvement is no longer as pronounced.

Example 4. Finally we comment on results with a problem containing a parameter which can make for a large slope in the interior of the interval [Hem]:

$$u''(x) + \epsilon x u'(x) = -\pi^2\cos(\pi x) - \epsilon\pi x\sin(\pi x),$$
$$y(-1) = -2, \qquad y(1) = 0.$$

The solution

$$u(x) = \cos \pi x + \frac{\operatorname{erf}(\delta x)}{\operatorname{erf}(\delta)}, \qquad \delta = \sqrt{\epsilon/2},$$

becomes steeper and steeper at zero as ϵ grows larger. We have solved the problem for $\epsilon = 100$, 500, 1'000, 5'000, and 10'000.

Some of our results with the larger ϵ are summarized in Table 4. Since for too small an N the optimization procedure may fail to converge [Ber-Mit2], we give numbers only for $N \geq 128$. They share some common features. For instance, for given ϵ and N, the imaginary parts of the optimal poles are quite close to one another. Moreover, if four poles are optimized, they have the tendency to gather as the vertices of a rectangle about the origin, where the maximum gradient arises.

As for the errors, the optimization improves the residual by 4–6 digits, much more than it does with the maximum error (less than 3 digits)—see the comment on the condition in the conclusion. Nevertheless, with $\epsilon = 5'000$ and $N = 64$ or $\epsilon = 10'000$ and $N = 128$, attaching poles decreases the maximum error more than doubling N!

Our results are not quite as good as those obtained in [As-Ch-Ru] with the same example. We recall, however, that they are not comparable, for our method yields

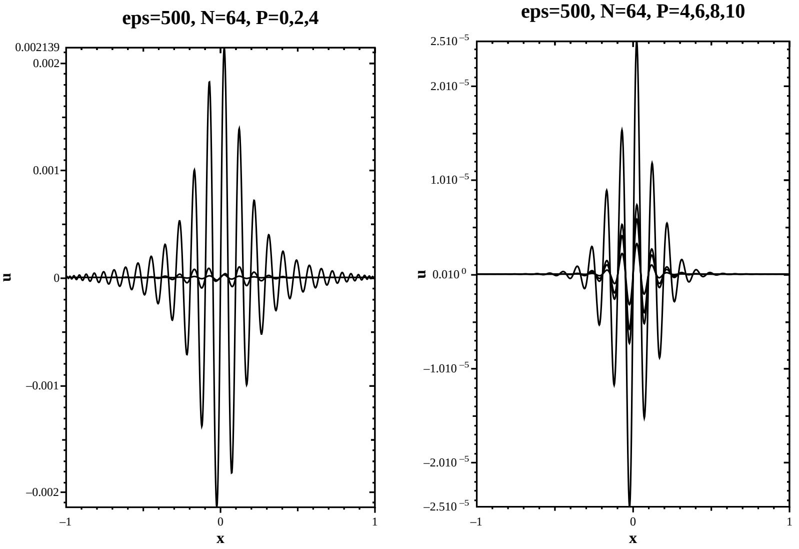

FIG. 2. *Error curves in Example* 4.

C^∞-approximations of the C^∞-solutions of the problems considered in the present work.

Finally, in Figure 2 we give error curves for a fixed ϵ-N pair and an increasing number of attached poles: even with the large gradient the error behaves nicely as P increases.

6. Conclusion.

In the present article we have applied to the solution of two-point boundary value problems the fact that rational interpolation is often more efficient than its polynomial counterpart. (We may mention in passing that this fact has been applied to the solution of Cauchy-type integral equations; see [Dri-Sri] and [Kai-Nod].) Our approach consists of an iterative improvement of the polynomial pseudospectral method, which is known to converge exponentially for good interpolation points and infinitely differentiable problems. After having obtained the solution at some (collocation) points by the polynomial method, we compute (one of the) rational interpolant(s) of these same values, with a denominator of given degree, by minimizing the residual of the differential equation. This defines the new linear space of all rationals interpolating between these same points and sharing that same denominator. We then just have to start again with the solution of the original equation in the new space, and so on. Although we can prove the effectiveness of a Galerkin version of the method, in practice we solve the problem with the much simpler collocation method.

The computed examples show the somewhat surprising result that one can usually gain between three and five digits of accuracy in comparison with classical polynomial collocation, and this almost independently of N. This is especially significant in cases where the precision obtained with the latter method is low and one does not want to increase the number of points so as to keep consequent evaluation of the solution as cheap as possible.

The placement of the poles is a very well-conditioned problem in the sense that many of their locations around the optimal one yield merely slightly larger residuals.

The tables show, however, that the gain in the residual error is usually much larger than the improvement in the precision of $\widetilde{u}$. This is probably due in part to the fact that the computation of the residual is smeared by the ill condition of the differentiation matrices, despite the improvement by the methods in [Bal-Ber1]. We hope to improve on this in the not too distant future.

Although not our purpose here, the method also seems applicable to problems whose solution u is not infinitely smooth, in fact, even when u displays discontinuities: it could then be compared with, e.g., methods which use especially constructed jump functions such as those advocated by Geer [Gee-Ban] or methods that call upon the help of several grids and fictious points, as suggested in [Dri-For].

The generalization of the method to elliptic problems in parallelpipeds seems straightforward. In the two-dimensional case, on a tensor grid in a rectangle, the ansatz would become

$$\widetilde{u}(x,y) = \sum_{j,k=0}^{N} \widetilde{u}_{jk} L_j^{(\beta)}(x) L_k^{(\gamma)}(y) \in \mathcal{R}_N^{(\beta)} \otimes \mathcal{R}_N^{(\gamma)},$$

and the new approximation of u would be obtained in Step 2 of the algorithm by minimizing $J(\mathbf{z}, \mathbf{t})$ with respect to the poles $\mathbf{z}$ and $\mathbf{t} = [t_1, \ldots, t_Q]$ in

$$r(x,y) := \frac{\displaystyle\sum_{j=0}^{N}\sum_{k=0}^{M} \frac{w_j \displaystyle\prod_{\ell=1}^{P}(x_j - z_\ell)}{x - x_j} \frac{s_k \displaystyle\prod_{m=1}^{Q}(y_k - t_m)}{y - y_k} \widetilde{u}_{jk}}{\displaystyle\sum_{j=0}^{N}\sum_{k=0}^{M} \frac{w_j \displaystyle\prod_{\ell=1}^{P}(x_j - z_\ell)}{x - x_j} \frac{s_k \displaystyle\prod_{m=1}^{Q}(y_k - t_m)}{y - y_k}}$$

(i.e., by optimizing the weights $\beta_j = w_j \prod_{\ell=1}^{P}(x_j - z_\ell)$ and $\gamma_k = s_k \prod_{m=1}^{Q}(y_k - t_m)$), where the s_k's denote the polynomial weights in the y-direction.

Another natural extension of the method is its application to time evolution partial differential equations: we intend to address the question in future work [Be-Mi-Tr].

A POSTERIORI ERROR CONTROL OF FINITE ELEMENT APPROXIMATIONS FOR COULOMB'S FRICTIONAL CONTACT*

PATRICE COOREVITS†, PATRICK HILD‡, AND MOHAMMED HJIAJ§

Abstract. This paper is concerned with the frictional unilateral contact problem governed by Coulomb's law. We define an a posteriori error estimator based on the concept of error in the constitutive relation to quantify the accuracy of a finite element approximation of the problem. We propose and study different mixed finite element approaches and discuss their properties in order to compute the estimator. The information given by the error estimates is then coupled with a mesh adaptivity technique which provides the user with the desired quality and minimizes the computation costs. The numerical implementation of the error estimator as well as optimized computations are performed.

Key words. Coulomb's friction law, a posteriori error estimates, finite elements, error in the constitutive relation, optimized computations

1. Introduction and problem setup.

The finite element method is currently used in the numerical realization of frictional contact problems occurring in many engineering applications (see [13]). An important task consists of evaluating numerically the quality of the finite element computations by using a posteriori error estimators. In elasticity, several different approaches leading to various error estimators have been developed: in particular, the error estimators introduced in [2] based on the residual of the equilibrium equations, the estimators linked to the smoothing of finite element stresses (see [22]), and the estimators based on the errors in the constitutive relation (see [14, 17]). A review of different a posteriori error estimators can be found in [21].

For frictionless unilateral contact problems, the residual based method was considered and studied in [3] (see also the references quoted therein) using a penalized approach, and the study of error in the constitutive relation was performed in [5].

In the present paper, we are interested in the more general and currently used Coulomb's frictional contact model, and we choose the estimators in the constitutive relation to quantify the accuracy of the finite element approximations. As far as we know, there is no literature concerning a posteriori error estimators for Coulomb's frictional unilateral contact model. The latter is recalled hereafter.

Let us be given an elastic body occupying a bounded domain Ω in $\mathbb{R}^2$ whose generic point is denoted $\boldsymbol{x} = (x_1, x_2)$. The boundary Γ of Ω is Lipschitz and divided as follows: $\Gamma = \overline{\Gamma_D} \cup \overline{\Gamma_N} \cup \overline{\Gamma_C}$, where Γ_D, Γ_N, and Γ_C are three open disjoint parts. We suppose that the displacement field is given on Γ_D. (To simplify, we assume afterwards that the body is clamped on Γ_D.) On the boundary part Γ_N, a density of forces denoted $\boldsymbol{F} \in (L^2(\Gamma_N))^2$ is applied. The third part is the segment Γ_C, in

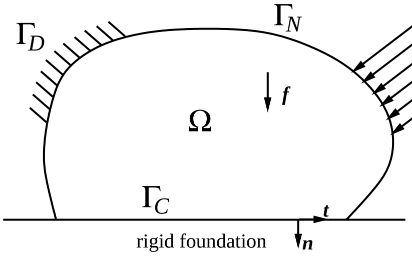

FIG. 1. *Setting of the problem.*

frictional contact with a rigid foundation (see Figure 1). The body Ω is submitted to a given density of volume forces $\boldsymbol{f} \in (L^2(\Omega))^2$. Let the notation $\boldsymbol{n} = (n_1, n_2)$ represent the unit outward normal vector on Γ and define the unit tangent vector $\boldsymbol{t} = (-n_2, n_1)$. Let us denote by $\mu > 0$ the friction coefficient on Γ_C.

The problem consists of finding the displacement field $\boldsymbol{u} : \Omega \longrightarrow \mathbb{R}^2$ and the stress tensor field $\boldsymbol{\sigma} : \Omega \longrightarrow \mathcal{S}_2$ satisfying (1.1)–(1.10):

$$\boldsymbol{\sigma}(\boldsymbol{u}) = \mathcal{C}\,\boldsymbol{\varepsilon}(\boldsymbol{u}) \quad \text{in } \Omega, \tag{1.1}$$

$$\mathbf{div}\,\boldsymbol{\sigma}(\boldsymbol{u}) + \boldsymbol{f} = 0 \quad \text{in } \Omega, \tag{1.2}$$

$$\boldsymbol{\sigma}(\boldsymbol{u})\boldsymbol{n} = \boldsymbol{F} \quad \text{on } \Gamma_N, \tag{1.3}$$

$$\boldsymbol{u} = 0 \quad \text{on } \Gamma_D, \tag{1.4}$$

where $\mathcal{S}_2$ stands for the space of second order symmetric tensors on $\mathbb{R}^2$, $\boldsymbol{\varepsilon}(\boldsymbol{u}) = \frac{1}{2}(\nabla\boldsymbol{u} + \nabla^T\boldsymbol{u})$ denotes the linearized strain tensor field, $\mathcal{C}$ is a fourth order symmetric and elliptic tensor of linear elasticity, and **div** represents the divergence operator of tensor valued functions.

In order to introduce the equations on Γ_C, let us adopt the following notation: $\boldsymbol{u} = u_n\boldsymbol{n} + u_t\boldsymbol{t}$ and $\boldsymbol{\sigma}(\boldsymbol{u})\boldsymbol{n} = \sigma_n(\boldsymbol{u})\boldsymbol{n} + \sigma_t(\boldsymbol{u})\boldsymbol{t}$. The equations modelling unilateral contact with Coulomb friction are as follows on Γ_C:

$$u_n \le 0, \tag{1.5}$$

$$\sigma_n(\boldsymbol{u}) \le 0, \tag{1.6}$$

$$\sigma_n(\boldsymbol{u})\, u_n = 0, \tag{1.7}$$

$$|\sigma_t(\boldsymbol{u})| \le \mu|\sigma_n(\boldsymbol{u})|, \tag{1.8}$$

$$|\sigma_t(\boldsymbol{u})| < \mu|\sigma_n(\boldsymbol{u})| \Longrightarrow u_t = 0, \tag{1.9}$$

$$|\sigma_t(\boldsymbol{u})| = \mu|\sigma_n(\boldsymbol{u})| \Longrightarrow \exists\lambda \ge 0 \ \text{ such that } \ u_t = -\lambda\sigma_t(\boldsymbol{u}). \tag{1.10}$$

The variational formulation of problem (1.1)–(1.10) has been obtained by Duvaut and Lions in [8]. It consists of finding $\boldsymbol{u}$ such that

$$\boldsymbol{u} \in \boldsymbol{K}_{ad}, \qquad a(\boldsymbol{u}, \boldsymbol{v} - \boldsymbol{u}) + j(\boldsymbol{u}, \boldsymbol{v}) - j(\boldsymbol{u}, \boldsymbol{u}) \ge L(\boldsymbol{v} - \boldsymbol{u}) \quad \forall \boldsymbol{v} \in \boldsymbol{K}_{ad}, \tag{1.11}$$

where

$$a(\boldsymbol{u}, \boldsymbol{v}) = \int_\Omega (\mathcal{C}\boldsymbol{\varepsilon}(\boldsymbol{u})) : \boldsymbol{\varepsilon}(\boldsymbol{v})\, d\Omega,$$

$$j(\boldsymbol{u}, \boldsymbol{v}) = \int_{\Gamma_C} \mu|\sigma_n(\boldsymbol{u})||v_t|\, d\Gamma,$$

$$L(\boldsymbol{v}) = \int_\Omega \boldsymbol{f}.\boldsymbol{v}\, d\Omega + \int_{\Gamma_N} \boldsymbol{F}.\boldsymbol{v}\, d\Gamma,$$

are defined for any $\boldsymbol{u}$ and $\boldsymbol{v}$ in

$$\boldsymbol{V} = \Big\{\boldsymbol{v} \in (H^1(\Omega))^2;\ \boldsymbol{v} = 0 \text{ on } \Gamma_D\Big\}.$$

The notation $H^1(\Omega)$ represents the standard Sobolev space; $\cdot$ and : stand for the inner product in $\mathbb{R}^2$ and $\mathcal{S}_2$, respectively. In (1.11), $\boldsymbol{K}_{ad}$ denotes the closed convex cone of admissible displacement fields satisfying the nonpenetration condition

$$\boldsymbol{K}_{ad} = \Big\{\boldsymbol{v} \in \boldsymbol{V};\ v_n \leq 0 \text{ on } \Gamma_C\Big\}.$$

The first existence result for problem (1.11) has been obtained in [20] when Ω is an infinitely long strip and if the friction coefficient of compact support in Γ_C is sufficiently small. The extension of these results to domains with smooth boundaries can be found in [12]. A recent improvement in [9] states existence when the friction coefficient μ is lower than $\frac{\sqrt{3-4\nu}}{2-2\nu}$, ν denoting Poisson's ratio in Ω $(0 < \nu < \frac{1}{2})$. When the loads $\boldsymbol{f}$ and $\boldsymbol{F}$ are not equal to zero, there is to our knowledge neither uniqueness result nor nonuniqueness example for problem (1.11). Let us mention that there exists several laws "mollifying" Coulomb's frictional contact model (see, e.g., [13, 19] and the references quoted therein) and that such regularizations lead to more existence and uniqueness properties.

Our paper is outlined as follows. In section 2, we first recall the convenient setting which consists of separating the kinematic conditions, the equilibrium equations, and the constitutive relations in order to define the error estimator and to study its properties. In section 3, we propose two mixed finite element methods for Coulomb's frictional unilateral contact problem. We prove the existence of solutions and we study the discrete frictional contact properties satisfied by such solutions. Section 4 is concerned with the practical construction of such an estimator. In section 5, several numerical studies in which we compute and couple the estimator with a mesh adaptivity procedure are performed.

2. The error estimator for Coulomb's frictional contact problem.

The aim of this section is to introduce the concept of error in the constitutive relation for the frictional unilateral contact problem. Before defining the estimator, let us begin with some useful setting and notation.

2.1. The appropriate setting for error in the constitutive relation.

To define the error in the constitutive relation, the contact part Γ_C is considered as in [15, 5] as an interface on which two unknowns $\boldsymbol{w}$ (displacement field) and $\boldsymbol{r}$ (density of surface forces due to the frictional contact with the rigid foundation) are to be found. If $\boldsymbol{n} = (n_1, n_2)$ and $\boldsymbol{t} = (-n_2, n_1)$ stand for the unit outward normal and tangent on Γ, we adopt afterwards the notation $\boldsymbol{z} = z_n\boldsymbol{n} + z_t\boldsymbol{t}$ for any vector $\boldsymbol{z}$.

The unilateral contact problem with Coulomb's friction law (1.1)–(1.10) is reformulated by using these quantities, and it consists of finding the displacement field $\boldsymbol{u}$ on Ω, the stress tensor field $\boldsymbol{\sigma}$ on Ω, and $\boldsymbol{w}$, $\boldsymbol{r}$ on Γ_C satisfying the following equations (2.1)–(2.9).

- The displacement fields $\boldsymbol{u}$ and $\boldsymbol{w}$ verify the kinematic conditions

$$\boldsymbol{u} = 0 \text{ on } \Gamma_D \quad \text{and} \quad \boldsymbol{w} = \boldsymbol{u} \text{ on } \Gamma_C. \tag{2.1}$$

- The fields $\boldsymbol{\sigma}$ and $\boldsymbol{r}$ satisfy the equilibrium equation

$$-\int_\Omega \boldsymbol{\sigma} : \boldsymbol{\varepsilon}(\boldsymbol{v})\, d\Omega + \int_\Omega \boldsymbol{f}.\boldsymbol{v}\, d\Omega + \int_{\Gamma_N} \boldsymbol{F}.\boldsymbol{v}\, d\Gamma + \int_{\Gamma_C} \boldsymbol{r}.\boldsymbol{v}\, d\Gamma = 0 \quad \forall \boldsymbol{v} \in \boldsymbol{V}. \tag{2.2}$$

- The fields $\boldsymbol{\sigma}$ and $\boldsymbol{u}$ are linked by the constitutive law of linear elasticity:

$$\boldsymbol{\sigma} = \mathcal{C}\boldsymbol{\varepsilon}(\boldsymbol{u}). \tag{2.3}$$

- The displacement field $\boldsymbol{w} = w_n\boldsymbol{n} + w_t\boldsymbol{t}$ and the density of forces $\boldsymbol{r} = r_n\boldsymbol{n} + r_t\boldsymbol{t}$ satisfy the unilateral contact conditions with Coulomb's friction law along Γ_C:

$$w_n \leq 0, \tag{2.4}$$
$$r_n \leq 0, \tag{2.5}$$
$$r_n w_n = 0, \tag{2.6}$$
$$|r_t| \leq \mu|r_n|, \tag{2.7}$$
$$|r_t| < \mu|r_n| \quad \Longrightarrow \quad w_t = 0, \tag{2.8}$$
$$|r_t| = \mu|r_n| \quad \Longrightarrow \quad \exists\lambda \geq 0 \text{ such that } w_t = -\lambda r_t. \tag{2.9}$$

Let us define the convex cones

$$K = \Big\{\boldsymbol{z}; \boldsymbol{z} = z_n\boldsymbol{n} + z_t\boldsymbol{t} \text{ such that } z_n \leq 0\Big\},$$
$$C_\mu = \Big\{\boldsymbol{s}; \boldsymbol{s} = s_n\boldsymbol{n} + s_t\boldsymbol{t} \text{ such that } s_n \leq 0 \text{ and } |s_t| \leq \mu|s_n|\Big\}.$$

Denoting by I_A the indicator function of the set A (i.e., $I_A(\boldsymbol{z}) = 0$ if $\boldsymbol{z} \in A$ and $I_A(\boldsymbol{z}) = +\infty$ if $\boldsymbol{z} \notin A$), it can easily be checked that the frictional contact conditions (2.4)–(2.9) can be also written in a more compact form:

$$I_K(\boldsymbol{w}) + I_{C_\mu}(\boldsymbol{r}) + \mu|r_n||w_t| + r_t w_t + r_n w_n = 0 \quad \text{on } \Gamma_C. \tag{2.10}$$

We begin with recalling the definition of an admissible pair.

Definition 2.1. *A pair* $\hat{s} = ((\hat{\boldsymbol{u}}, \hat{\boldsymbol{w}}), (\hat{\boldsymbol{\sigma}}, \hat{\boldsymbol{r}}))$ *is admissible if the kinematic conditions* (2.1) *and the equilibrium equations* (2.2) *are fulfilled.*

We are now in a position to define the estimator based on the error in the constitutive relation.

Definition 2.2. *Let* $\hat{s} = ((\hat{\boldsymbol{u}}, \hat{\boldsymbol{w}}), (\hat{\boldsymbol{\sigma}}, \hat{\boldsymbol{r}}))$ *be admissible. The error estimator* $e(\hat{s})$ *is as follows:*

$$e(\hat{s}) = \left(\|\hat{\boldsymbol{\sigma}} - \mathcal{C}\boldsymbol{\varepsilon}(\hat{\boldsymbol{u}})\|^2_{\sigma,\Omega} + 2\int_{\Gamma_C}\Big(I_K(\hat{\boldsymbol{w}}) + I_{C_\mu}(\hat{\boldsymbol{r}}) + \mu|\hat{r}_n||\hat{w}_t| + \hat{r}_t\hat{w}_t + \hat{r}_n\hat{w}_n\Big)\,d\Gamma\right)^{\frac{1}{2}}, \tag{2.11}$$

where the norm $\|.\|_{\sigma,\Omega}$ *on the stress tensor fields is defined by*

$$\|\boldsymbol{\sigma}\|_{\sigma,\Omega} = \left(\int_\Omega (\mathcal{C}^{-1}\boldsymbol{\sigma}) : \boldsymbol{\sigma}\, d\Omega\right)^{\frac{1}{2}}.$$

Let us notice that the function in the integral term of (2.11) is always nonnegative at $\boldsymbol{x} \in \Gamma_C$: it is equal to $+\infty$ if $\hat{\boldsymbol{w}}(\boldsymbol{x}) \notin K$ or $\hat{\boldsymbol{r}}(\boldsymbol{x}) \notin C_\mu$; otherwise it is nonnegative owing to $(\mu|\hat{r}_n||\hat{w}_t|+\hat{r}_t\hat{w}_t)(\boldsymbol{x}) \geq 0$ and $(\hat{r}_n\hat{w}_n)(\boldsymbol{x}) \geq 0$. To avoid more notation, we will skip over the regularity aspects of the functions defined on Γ_C which are beyond the scope of this paper and we write afterwards integral terms instead of duality pairings. The first natural property arising directly from the definition of $e(\hat{s})$ becomes the following property.

Property 2.3. *Let* $\hat{s}$ *be admissible. Then* $e(\hat{s}) = 0$ *if and only if* $\hat{s} = ((\hat{\boldsymbol{u}}, \hat{\boldsymbol{w}}), (\hat{\boldsymbol{\sigma}}, \hat{\boldsymbol{r}}))$ *is a solution to the reference problem* (2.1)–(2.9).

Let us define some quantities useful for the forthcoming study.

Definition 2.4. *Let $\hat{s}$ be admissible. The relative error $\epsilon(\hat{s})$ is as follows:*

$$\epsilon(\hat{s}) = \frac{e(\hat{s})}{\|\hat{\boldsymbol{\sigma}} + \mathcal{C}\boldsymbol{\varepsilon}(\hat{\boldsymbol{u}})\|_{\sigma,\Omega}}. \tag{2.12}$$

Given a part E of Ω, the local error contribution $\epsilon_E(\hat{s})$ is defined as

$$\epsilon_E(\hat{s}) = \frac{\left(\|\hat{\boldsymbol{\sigma}} - \mathcal{C}\boldsymbol{\varepsilon}(\hat{\boldsymbol{u}})\|^2_{\sigma,E} + 2\displaystyle\int_{\Gamma_C\cap E}\Big(I_K(\hat{\boldsymbol{w}}) + I_{C_\mu}(\hat{\boldsymbol{r}}) + \mu|\hat{r}_n||\hat{w}_t| + \hat{r}_t\hat{w}_t + \hat{r}_n\hat{w}_n\Big)\, d\Gamma\right)^{\frac{1}{2}}}{\|\hat{\boldsymbol{\sigma}} + \mathcal{C}\boldsymbol{\varepsilon}(\hat{\boldsymbol{u}})\|_{\sigma,\Omega}}, \tag{2.13}$$

where $\|\boldsymbol{\sigma}\|_{\sigma,E} = (\int_E(\mathcal{C}^{-1}\boldsymbol{\sigma}) : \boldsymbol{\sigma}\ d\Omega)^{\frac{1}{2}}$.

For the sake of simplicity of notations, we will write ϵ and ϵ_E instead of $\epsilon(\hat{s})$ and $\epsilon_E(\hat{s})$ in the following studies. It is straightforward that

$$\bigcup_{E_i\cap E_j=\emptyset,\ i\neq j} E_i = \Omega \quad\Longrightarrow\quad \epsilon^2 = \sum_i \epsilon^2_{E_i}.$$

2.2. Link between the estimator and the other errors. This part is concerned with the relation between the error in the constitutive law and the other errors. We suppose that a solution to the exact problem (2.1)–(2.9) exists which is satisfied when μ is small enough (see [9]). The next proposition generalizes former results (see [5]) obtained in the frictionless case (corresponding to $\mu = 0$).

Proposition 2.5. *Let $(\boldsymbol{u}, \boldsymbol{w}, \boldsymbol{\sigma}, \boldsymbol{r})$ be a solution to Coulomb's frictional contact problem* (2.1)–(2.9). *Let $\hat{s} = ((\hat{\boldsymbol{u}}, \hat{\boldsymbol{w}}), (\hat{\boldsymbol{\sigma}}, \hat{\boldsymbol{r}}))$ be admissible. Then*

$$\|\boldsymbol{\sigma} - \hat{\boldsymbol{\sigma}}\|^2_{\sigma,\Omega} + \|\boldsymbol{u} - \hat{\boldsymbol{u}}\|^2_{u,\Omega} + 2\mu\int_{\Gamma_C}(r_n - \hat{r}_n)(|\hat{w}_t| - |w_t|)\, d\Gamma \leq e^2(\hat{s}), \tag{2.14}$$

where the norm $\|.\|_{u,\Omega}$ on the displacement fields is defined by

$$\|\boldsymbol{u}\|_{u,\Omega} = \left(\int_\Omega(\mathcal{C}\boldsymbol{\varepsilon}(\boldsymbol{u})) : \boldsymbol{\varepsilon}(\boldsymbol{u})\ d\Omega\right)^{\frac{1}{2}} = \big(a(\boldsymbol{u}, \boldsymbol{u})\big)^{\frac{1}{2}}.$$

Consequently,

$$\|\boldsymbol{\sigma} - \hat{\boldsymbol{\sigma}}\|^2_{\sigma,\Omega} + 2\mu\int_{\Gamma_C}(r_n - \hat{r}_n)(|\hat{w}_t| - |w_t|)\, d\Gamma \leq e^2(\hat{s}), \tag{2.15}$$

$$\|\boldsymbol{u} - \hat{\boldsymbol{u}}\|^2_{u,\Omega} + 2\mu\int_{\Gamma_C}(r_n - \hat{r}_n)(|\hat{w}_t| - |w_t|)\, d\Gamma \leq e^2(\hat{s}). \tag{2.16}$$

Proof. We begin with noticing that the property obviously holds when $\hat{\boldsymbol{w}} \notin K$ or $\hat{\boldsymbol{r}} \notin C_\mu$ on a set of positive measure. In such a case, the error estimator is equal to infinity. Next, we then suppose that $\hat{\boldsymbol{w}} \in K$ and $\hat{\boldsymbol{r}} \in C_\mu$ almost everywhere. One immediately gets

$$\begin{aligned}\|\hat{\boldsymbol{\sigma}} - \mathcal{C}\boldsymbol{\varepsilon}(\hat{\boldsymbol{u}})\|^2_{\sigma,\Omega} &= \|\hat{\boldsymbol{\sigma}} - \boldsymbol{\sigma} + \mathcal{C}\boldsymbol{\varepsilon}(\boldsymbol{u} - \hat{\boldsymbol{u}})\|^2_{\sigma,\Omega}\\ &= \|\hat{\boldsymbol{\sigma}} - \boldsymbol{\sigma}\|^2_{\sigma,\Omega} + \|\boldsymbol{u} - \hat{\boldsymbol{u}}\|^2_{u,\Omega} + 2\int_\Omega(\hat{\boldsymbol{\sigma}} - \boldsymbol{\sigma}) : \boldsymbol{\varepsilon}(\boldsymbol{u} - \hat{\boldsymbol{u}})\ d\Omega.\end{aligned}$$

The stress fields $\boldsymbol{\sigma}$ and $\hat{\boldsymbol{\sigma}}$ satisfy the equilibrium equation (2.2) and the displacement fields $\boldsymbol{u}$ and $\hat{\boldsymbol{u}}$ verify the kinematic conditions (2.1). Hence

$$\|\hat{\boldsymbol{\sigma}} - \mathcal{C}\boldsymbol{\varepsilon}(\hat{\boldsymbol{u}})\|^2_{\sigma,\Omega} = \|\hat{\boldsymbol{\sigma}} - \boldsymbol{\sigma}\|^2_{\sigma,\Omega} + \|\boldsymbol{u} - \hat{\boldsymbol{u}}\|^2_{u,\Omega} + 2\int_{\Gamma_C} (\hat{\boldsymbol{r}} - \boldsymbol{r}).(\boldsymbol{w} - \hat{\boldsymbol{w}})\, d\Gamma. \tag{2.17}$$

Developing the integral term yields

$$\begin{aligned} &\int_{\Gamma_C} (\hat{\boldsymbol{r}} - \boldsymbol{r}).(\boldsymbol{w} - \hat{\boldsymbol{w}})\, d\Gamma \\ &\quad = \int_{\Gamma_C} \hat{r}_n w_n \, d\Gamma + \int_{\Gamma_C} \hat{r}_t w_t \, d\Gamma + \int_{\Gamma_C} r_n \hat{w}_n \, d\Gamma + \int_{\Gamma_C} r_t \hat{w}_t \, d\Gamma \\ &\quad\quad - \int_{\Gamma_C} r_n w_n \, d\Gamma - \int_{\Gamma_C} r_t w_t \, d\Gamma - \int_{\Gamma_C} \hat{r}_n \hat{w}_n \, d\Gamma - \int_{\Gamma_C} \hat{r}_t \hat{w}_t \, d\Gamma. \end{aligned} \tag{2.18}$$

Putting together (2.17) and (2.18) in the definition (2.11) of the estimator leads to

$$\begin{aligned} e^2(\hat{s}) = {} & \|\boldsymbol{\sigma} - \hat{\boldsymbol{\sigma}}\|^2_{\sigma,\Omega} + \|\boldsymbol{u} - \hat{\boldsymbol{u}}\|^2_{u,\Omega} \\ & + 2\int_{\Gamma_C} \hat{r}_n w_n \, d\Gamma + 2\int_{\Gamma_C} \hat{r}_t w_t \, d\Gamma + 2\int_{\Gamma_C} r_n \hat{w}_n \, d\Gamma + 2\int_{\Gamma_C} r_t \hat{w}_t \, d\Gamma \\ & - 2\int_{\Gamma_C} r_n w_n \, d\Gamma - 2\int_{\Gamma_C} r_t w_t \, d\Gamma + 2\int_{\Gamma_C} \mu |\hat{r}_n||\hat{w}_t| \, d\Gamma. \end{aligned}$$

Noting that $r_n \hat{w}_n \geq 0$, $\hat{r}_n w_n \geq 0$, and $r_n w_n = 0$ on Γ_C, we get

$$\begin{aligned} e^2(\hat{s}) \geq {} & \|\boldsymbol{\sigma} - \hat{\boldsymbol{\sigma}}\|^2_{\sigma,\Omega} + \|\boldsymbol{u} - \hat{\boldsymbol{u}}\|^2_{u,\Omega} \\ & + 2\int_{\Gamma_C} \hat{r}_t w_t \, d\Gamma + 2\int_{\Gamma_C} r_t \hat{w}_t \, d\Gamma - 2\int_{\Gamma_C} r_t w_t \, d\Gamma + 2\int_{\Gamma_C} \mu |\hat{r}_n||\hat{w}_t| \, d\Gamma. \end{aligned}$$

According to (2.7)–(2.9), the equality $-r_t w_t = \mu |r_n||w_t|$ holds on Γ_C. Moreover, $\boldsymbol{r} \in C_\mu$ and $\hat{\boldsymbol{r}} \in C_\mu$ lead to the bounds $r_t \hat{w}_t \geq -\mu |r_n||\hat{w}_t|$ and $\hat{r}_t w_t \geq -\mu |\hat{r}_n||w_t|$. Consequently,

$$e^2(\hat{s}) \geq \|\boldsymbol{\sigma} - \hat{\boldsymbol{\sigma}}\|^2_{\sigma,\Omega} + \|\boldsymbol{u} - \hat{\boldsymbol{u}}\|^2_{u,\Omega} + 2\mu \int_{\Gamma_C} (|r_n| - |\hat{r}_n|)(|w_t| - |\hat{w}_t|)\, d\Gamma.$$

The bound (2.14) is obtained thanks to $r_n \leq 0$ and $\hat{r}_n \leq 0$. Both bounds (2.15) and (2.16) are an obvious consequence. □

It is easy to check that no information on the sign of the integral term in (2.14) is available. This is not at all surprising because the evaluation of such a term corresponds also to the study of the uniqueness for the (quasi-)variational inequality (1.11) with classical arguments (i.e., by choosing and subtracting two solutions) which does not lead to a successful conclusion. Nevertheless, the following remark shows that the integral term can be bounded at least in a particular case.

Remark 2.6. If the exact solution and the admissible solution satisfy $w_t \geq 0$ and $\hat{w}_t \geq 0$ on Γ_C (or $w_t \leq 0$ and $\hat{w}_t \leq 0$ on Γ_C), and if the measure of Γ_D is positive, then inequality (2.14) becomes more relevant since the integral term in (2.14) can be estimated as follows:

$$\begin{aligned}\left|\int_{\Gamma_C}(r_n-\hat{r}_n)(|\hat{w}_t|-|w_t|)\,d\Gamma\right| &= \left|\int_{\Gamma_C}(r_n-\hat{r}_n)(\hat{w}_t-w_t)\,d\Gamma\right| \\ &\le \|r_n-\hat{r}_n\|_{H^{-\frac{1}{2}}(\Gamma_C)}\|w_t-\hat{w}_t\|_{H^{\frac{1}{2}}(\Gamma_C)} \\ &\le C\|\boldsymbol{\sigma}-\hat{\boldsymbol{\sigma}}\|_{(L^2(\Omega))^4}\|\boldsymbol{u}-\hat{\boldsymbol{u}}\|_{(H^1(\Omega))^2} \\ &\le C'\|\boldsymbol{\sigma}-\hat{\boldsymbol{\sigma}}\|_{\sigma,\Omega}\|\boldsymbol{u}-\hat{\boldsymbol{u}}\|_{u,\Omega} \\ &\le C''\Big(\|\boldsymbol{\sigma}-\hat{\boldsymbol{\sigma}}\|^2_{\sigma,\Omega}+\|\boldsymbol{u}-\hat{\boldsymbol{u}}\|^2_{u,\Omega}\Big),\end{aligned}$$

where $H^{\frac{1}{2}}(\Gamma_C)$ stands for a fractionally Sobolev space (see [1]) and $H^{-\frac{1}{2}}(\Gamma_C)$ is its dual space. The bounds of $\|r_n-\hat{r}_n\|_{H^{-\frac{1}{2}}(\Gamma_C)}$ and $\|w_t-\hat{w}_t\|_{H^{\frac{1}{2}}(\Gamma_C)}$ are obtained using Green's formula and the trace theorem, respectively. Moreover, the norms $\|.\|_{(H^1(\Omega))^2}$ and $\|.\|_{u,\Omega}$ are equivalent since meas$(\Gamma_D)>0$. In such a case, the integral term can be removed from (2.14), (2.15), and (2.16), and we come to the conclusion that there exists a positive constant C such that for small friction coefficients, $\|\boldsymbol{\sigma}-\hat{\boldsymbol{\sigma}}\|_{\sigma,\Omega}$ and $\|\boldsymbol{u}-\hat{\boldsymbol{u}}\|_{u,\Omega}$ can be bounded by $(1/\sqrt{1-\mu C})e(\hat{s})$. Concerning the general case, we think that one could reasonably expect that if the exact and admissible solutions are smooth enough and if the friction coefficient is small, then the integral term multiplied by 2μ is small in comparison with $\|\boldsymbol{u}-\hat{\boldsymbol{u}}\|^2_{u,\Omega}$ and $\|\boldsymbol{\sigma}-\hat{\boldsymbol{\sigma}}\|^2_{\sigma,\Omega}$.

Remark 2.7. If instead of Coulomb's law (2.10), one considers a Tresca's type friction law,

$$I_K(\boldsymbol{w})+I_C(\boldsymbol{r})+k|w_t|+r_tw_t+r_nw_n=0 \quad \text{on } \Gamma_C, \tag{2.19}$$

where $k\ge 0$ and where $C=\{\boldsymbol{s};\boldsymbol{s}=s_n\boldsymbol{n}+s_t\boldsymbol{t}$ such that $s_n\le 0$ and $|s_t|\le k\}$, then the problem (2.1)–(2.3), (2.19) admits a unique solution $(\boldsymbol{u}_k,\boldsymbol{w}_k,\boldsymbol{\sigma}_k,\boldsymbol{r}_k)$ and the bound

$$\|\boldsymbol{\sigma}_k-\hat{\boldsymbol{\sigma}}\|^2_{\sigma,\Omega}+\|\boldsymbol{u}_k-\hat{\boldsymbol{u}}\|^2_{u,\Omega}\le e^2(\hat{s}) \tag{2.20}$$

holds for any admissible $\hat{s}=((\hat{\boldsymbol{u}},\hat{\boldsymbol{w}}),(\hat{\boldsymbol{\sigma}},\hat{\boldsymbol{r}}))$.

Estimate (2.20) is obtained by following the same points as in the proof of estimate (2.14). In particular, if $k=0$ in (2.19) or equivalently $\mu=0$ in (2.10), we recover the frictionless unilateral contact model.

3. The discrete Coulomb's frictional contact problem.

In this section, we propose and study the properties of two mixed discrete finite element formulations for Coulomb's frictional contact in order to implement the error estimator. Let us mention that a detailed study of several (different) mixed finite element methods for frictionless and frictional contact problems can be found in [10, 11].

3.1. The mixed finite element formulations.

The body Ω is discretized by using a family of triangulations $(\mathcal{T}_h)_h$ made of finite elements of degree one. For technical purposes, we assume (in section 3.1 only) that $\overline{\Gamma_D}\cap\overline{\Gamma_C}=\emptyset$ which is generally not restrictive in engineering applications and that the bilinear form $a(.,.)$ is $\boldsymbol{V}$-elliptic. Let us denote by $h>0$ the discretization parameter representing the greatest diameter of a triangle in $\mathcal{T}_h$. The space approximating $\boldsymbol{V}$ becomes

$$\boldsymbol{V}_h=\Big\{\boldsymbol{v}_h;\ \boldsymbol{v}_h\in(\mathcal{C}(\overline{\Omega}))^2,\ \boldsymbol{v}_h|_T\in(P_1(T))^2\ \ \forall T\in\mathcal{T}_h,\ \boldsymbol{v}_h=0 \text{ on } \Gamma_D\Big\},$$

where $\mathcal{C}(\overline{\Omega})$ stands for the space of continuous functions on $\overline{\Omega}$, and $P_1(T)$ represents the space of polynomial functions of degree one on T. On the boundary of Ω, we still keep the notation $\boldsymbol{v}_h = v_{hn}\boldsymbol{n} + v_{ht}\boldsymbol{t}$ for every $\boldsymbol{v}_h \in \boldsymbol{V}_h$ and we denote by $(T_h)_h$ the family of monodimensional meshes on Γ_C inherited by $(\mathcal{T}_h)_h$.

We next introduce two convex sets of Lagrange multipliers denoted $\boldsymbol{M}'_h(g)$ and $\boldsymbol{M}''_h(g)$. The convex $\boldsymbol{M}'_h(g)$ is defined by $\boldsymbol{M}'_h(g) = M'_{hn} \times M'_{ht}(g)$, where

$$M'_{hn} = \Big\{\nu; \nu \in \mathcal{C}(\overline{\Gamma_C}),\ \nu|_S \in P_1(S)\ \ \forall S \in T_h,\ \nu \leq 0 \text{ on } \Gamma_C\Big\},$$

and for $g \in -M'_{hn}$, we define $M'_{ht}(g)$ as follows:

$$M'_{ht}(g) = \Big\{\nu; \nu \in \mathcal{C}(\overline{\Gamma_C}),\ \nu|_S \in P_1(S)\ \ \forall S \in T_h,\ |\nu| \leq g \text{ on } \Gamma_C\Big\}.$$

We denote by p the number of nodes of the triangulation on Γ_C and by $\psi_i, 1 \leq i \leq p$ the monodimensional basis functions on Γ_C. (The function ψ_i is continuous on Γ_C, linear on each segment of T_h, and equal to 1 at node i and to 0 at the other nodes.) The second convex $\boldsymbol{M}''_h(g)$ is given by $\boldsymbol{M}''_h(g) = M''_{hn} \times M''_{ht}(g)$ with

$$M''_{hn} = \left\{\nu; \nu \in \mathcal{C}(\overline{\Gamma_C}),\ \nu|_S \in P_1(S)\ \ \forall S \in T_h,\ \int_{\Gamma_C} \nu\psi_i \, d\Gamma \leq 0\ \ \forall 1 \leq i \leq p\right\}.$$

If $g \in -M''_{hn}$, $M''_{ht}(g)$ is given by

$$M''_{ht}(g) \\ = \left\{\nu; \nu \in \mathcal{C}(\overline{\Gamma_C}),\ \nu|_S \in P_1(S)\ \ \forall S \in T_h, \left|\int_{\Gamma_C} \nu\psi_i \, d\Gamma\right| \leq \int_{\Gamma_C} g\psi_i \, d\Gamma\ \ \forall 1 \leq i \leq p\right\}.$$

Next, the notation $\boldsymbol{M}_h(g) = M_{hn} \times M_{ht}(g)$ denotes either $\boldsymbol{M}'_h(g) = M'_{hn} \times M'_{ht}(g)$ or $\boldsymbol{M}''_h(g) = M''_{hn} \times M''_{ht}(g)$.

We then introduce an intermediary problem with a given slip limit $-\mu g_{hn}$, where $g_{hn} \in M_{hn}$. This problem is denoted by $P(g_{hn})$ and consists of finding $\boldsymbol{u}_h \in \boldsymbol{V}_h$ and $(\lambda_{hn}, \lambda_{ht}) \in M_{hn} \times M_{ht}(-\mu g_{hn}) = \boldsymbol{M}_h(-\mu g_{hn})$ such that

$$(P(g_{hn})) \quad \left\{\begin{array}{l} a(\boldsymbol{u}_h, \boldsymbol{v}_h) - \displaystyle\int_{\Gamma_C} \lambda_{hn} v_{hn} \, d\Gamma - \int_{\Gamma_C} \lambda_{ht} v_{ht} \, d\Gamma = L(\boldsymbol{v}_h)\ \ \forall \boldsymbol{v}_h \in \boldsymbol{V}_h, \\ \displaystyle\int_{\Gamma_C} (\nu_{hn} - \lambda_{hn}) u_{hn} \, d\Gamma + \int_{\Gamma_C} (\nu_{ht} - \lambda_{ht}) u_{ht} \, d\Gamma \geq 0 \\ \hfill \forall (\nu_{hn}, \nu_{ht}) \in \boldsymbol{M}_h(-\mu g_{hn}). \end{array}\right. \tag{3.1}$$

Problem $P(g_{hn})$ is the equivalent of finding a saddle-point $(\boldsymbol{u}_h, \lambda_{hn}, \lambda_{ht}) = (\boldsymbol{u}_h, \boldsymbol{\lambda}_h)$ in $\boldsymbol{V}_h \times \boldsymbol{M}_h(-\mu g_{hn})$ verifying

$$\mathcal{L}(\boldsymbol{u}_h, \boldsymbol{\nu}_h) \leq \mathcal{L}(\boldsymbol{u}_h, \boldsymbol{\lambda}_h) \leq \mathcal{L}(\boldsymbol{v}_h, \boldsymbol{\lambda}_h) \qquad \forall \boldsymbol{v}_h \in \boldsymbol{V}_h,\ \forall \boldsymbol{\nu}_h \in \boldsymbol{M}_h(-\mu g_{hn}),$$

where

$$\mathcal{L}(\boldsymbol{v}_h, \boldsymbol{\nu}_h) = \frac{1}{2} a(\boldsymbol{v}_h, \boldsymbol{v}_h) - \int_{\Gamma_C} \nu_{hn} v_{hn} \, d\Gamma - \int_{\Gamma_C} \nu_{ht} v_{ht} \, d\Gamma - L(\boldsymbol{v}_h).$$

By using classical arguments on saddle-point problems as Haslinger, Hlaváček, and Nečas [11, p. 338], we deduce that there exists such a saddle-point. The strict convexity of $a(.,.)$ implies that the first argument $\boldsymbol{u}_h$ is unique. Besides, the assumption $\overline{\Gamma_D} \cap \overline{\Gamma_C} = \emptyset$ allows us to write

$$\int_{\Gamma_C} \nu_{hn} v_{hn} \, d\Gamma - \int_{\Gamma_C} \nu_{ht} v_{ht} \, d\Gamma = 0\ \ \forall \boldsymbol{v}_h \in \boldsymbol{V}_h, \qquad \Longrightarrow \qquad \nu_{hn} = 0, \nu_{ht} = 0.$$

Consequently, the second argument $\boldsymbol{\lambda}_h$ is unique and $P(g_{hn})$ admits a unique solution.

It then becomes possible to define a map Φ_h as follows:

$$\begin{array}{rll} \Phi_h : & M_{hn} & \longrightarrow M_{hn}, \\ & g_{hn} & \longmapsto \lambda_{hn}, \end{array}$$

where $(\boldsymbol{u}_h, \lambda_{hn}, \lambda_{ht})$ is the solution of $P(g_{hn})$. The introduction of this map allows the definition of a discrete solution of Coulomb's frictional contact problem.

Definition 3.1. *Let $\boldsymbol{M}_h(g) = \boldsymbol{M}'_h(g)$ or $\boldsymbol{M}_h(g) = \boldsymbol{M}''_h(g)$. A solution of Coulomb's discrete frictional contact problem is the solution of $P(\lambda_{hn})$, where $\lambda_{hn} \in M_{hn}$ is a fixed point of Φ_h.*

Proposition 3.2. *Let $\boldsymbol{M}_h(g) = \boldsymbol{M}'_h(g)$ or $\boldsymbol{M}_h(g) = \boldsymbol{M}''_h(g)$. Then for any μ, there exists a solution to Coulomb's discrete frictional contact problem.*

Proof. To establish existence, we use Brouwer's fixed point theorem.

Step 1. We prove that the mapping Φ_h is continuous. Set

$$\tilde{\boldsymbol{V}}_h = \Big\{ \boldsymbol{v}_h \in \boldsymbol{V}_h;\ v_{ht} = 0 \text{ on } \Gamma_C \Big\}, \quad W_h = \Big\{ \nu; \nu \in \mathcal{C}(\overline{\Gamma_C}),\ \nu|_S \in P_1(S)\ \ \forall S \in T_h \Big\}.$$

Since $\overline{\Gamma_D} \cap \overline{\Gamma_C} = \emptyset$, it is easy to check that the definition of $\|.\|_{-\frac{1}{2},h}$ given by

$$\|\nu\|_{-\frac{1}{2},h} = \sup_{\boldsymbol{v}_h \in \tilde{\boldsymbol{V}}_h} \frac{\displaystyle\int_{\Gamma_C} \nu v_{hn}\, d\Gamma}{\|\boldsymbol{v}_h\|_1},$$

is a norm on W_h. The notation $\|.\|_1$ represents the $(H^1(\Omega))^2$-norm.

Let $(\boldsymbol{u}_h, \lambda_{hn}, \lambda_{ht})$ and $(\overline{\boldsymbol{u}_h}, \overline{\lambda_{hn}}, \overline{\lambda_{ht}})$ be the solutions of $(P(g_{hn}))$ and $(P(\overline{g_{hn}}))$, respectively. On the one hand, we get

$$a(\boldsymbol{u}_h, \boldsymbol{v}_h) - \int_{\Gamma_C} \lambda_{hn} v_{hn}\, d\Gamma = L(\boldsymbol{v}_h) \qquad \forall \boldsymbol{v}_h \in \tilde{\boldsymbol{V}}_h,$$
$$a(\overline{\boldsymbol{u}_h}, \boldsymbol{v}_h) - \int_{\Gamma_C} \overline{\lambda_{hn}} v_{hn}\, d\Gamma = L(\boldsymbol{v}_h) \qquad \forall \boldsymbol{v}_h \in \tilde{\boldsymbol{V}}_h.$$

Subtracting the previous equalities and using the continuity of the bilinear form $a(.,.)$ gives

$$\int_{\Gamma_C} (\lambda_{hn} - \overline{\lambda_{hn}}) v_{hn}\, d\Gamma = a(\boldsymbol{u}_h - \overline{\boldsymbol{u}_h}, \boldsymbol{v}_h) \le M \|\boldsymbol{u}_h - \overline{\boldsymbol{u}_h}\|_1 \|\boldsymbol{v}_h\|_1 \qquad \forall \boldsymbol{v}_h \in \tilde{\boldsymbol{V}}_h.$$

Hence, we get a first estimate

$$\|\lambda_{hn} - \overline{\lambda_{hn}}\|_{-\frac{1}{2},h} \le M \|\boldsymbol{u}_h - \overline{\boldsymbol{u}_h}\|_1. \tag{3.2}$$

On the other hand, we have from (3.1)

$$a(\boldsymbol{u}_h, \boldsymbol{v}_h) - \int_{\Gamma_C} \lambda_{hn} v_{hn}\, d\Gamma - \int_{\Gamma_C} \lambda_{ht} v_{ht}\, d\Gamma = L(\boldsymbol{v}_h) \qquad \forall \boldsymbol{v}_h \in \boldsymbol{V}_h, \tag{3.3}$$

$$a(\overline{\boldsymbol{u}_h}, \boldsymbol{v}_h) - \int_{\Gamma_C} \overline{\lambda_{hn}} v_{hn}\, d\Gamma - \int_{\Gamma_C} \overline{\lambda_{ht}} v_{ht}\, d\Gamma = L(\boldsymbol{v}_h) \qquad \forall \boldsymbol{v}_h \in \boldsymbol{V}_h. \tag{3.4}$$

Choosing $\boldsymbol{v}_h = \overline{\boldsymbol{u}_h} - \boldsymbol{u}_h$ in (3.3) and $\boldsymbol{v}_h = \boldsymbol{u}_h - \overline{\boldsymbol{u}_h}$ in (3.4) implies by addition that

$$\begin{aligned} & a(\boldsymbol{u}_h - \overline{\boldsymbol{u}_h}, \boldsymbol{u}_h - \overline{\boldsymbol{u}_h}) \\ & = \int_{\Gamma_C} (\lambda_{hn} - \overline{\lambda_{hn}})(u_{hn} - \overline{u_{hn}})\, d\Gamma + \int_{\Gamma_C} (\lambda_{ht} - \overline{\lambda_{ht}})(u_{ht} - \overline{u_{ht}})\, d\Gamma. \end{aligned} \tag{3.5}$$

Let us notice that the inequality in (3.1) is obviously equivalent to the two following conditions:

$$\int_{\Gamma_C} (\nu_{hn} - \lambda_{hn}) u_{hn}\, d\Gamma \geq 0 \qquad \forall \nu_{hn} \in M_{hn}, \tag{3.6}$$

$$\int_{\Gamma_C} (\nu_{ht} - \lambda_{ht}) u_{ht}\, d\Gamma \geq 0 \qquad \forall \nu_{ht} \in M_{ht}(-\mu g_{hn}). \tag{3.7}$$

According to the definitions of M'_{hn} and M''_{hn}, we can choose $\nu_{hn} = 0$ and $\nu_{hn} = 2\lambda_{hn}$ in (3.6), which gives

$$\int_{\Gamma_C} \lambda_{hn} u_{hn}\, d\Gamma = 0 \quad \text{ and } \quad \int_{\Gamma_C} \nu_{hn} u_{hn}\, d\Gamma \geq 0 \qquad \forall \nu_{hn} \in M_{hn},$$

from which we deduce that

$$\int_{\Gamma_C} (\lambda_{hn} - \overline{\lambda_{hn}})(u_{hn} - \overline{u_{hn}})\, d\Gamma \leq 0.$$

Denoting by α the ellipticity constant of the bilinear form $a(.,.)$, (3.5) becomes

$$\alpha \|\boldsymbol{u}_h - \overline{\boldsymbol{u}_h}\|_1^2 \leq \int_{\Gamma_C} (\lambda_{ht} - \overline{\lambda_{ht}})(u_{ht} - \overline{u_{ht}})\, d\Gamma. \tag{3.8}$$

To evaluate the latter integral term, let us first introduce the p-by-p mass matrix $\mathcal{M} = (m_{ij})_{1 \leq i,j \leq p}$ on Γ_C as

$$m_{ij} = \int_{\Gamma_C} \psi_i \psi_j\, d\Gamma, \qquad 1 \leq i,j \leq p, \tag{3.9}$$

and let U_T, $\overline{U_T}$, G_N, $\overline{G_N}$, denote the vectors of components the nodal values of u_{ht}, $\overline{u_{ht}}$, g_{hn}, and $\overline{g_{hn}}$, respectively.

• We begin with considering the mixed method, where $\boldsymbol{M}_h(g) = \boldsymbol{M}'_h(g)$. From (3.7), we get

$$\int_{\Gamma_C} \lambda_{ht} u_{ht}\, d\Gamma \leq \int_{\Gamma_C} \nu_{ht} u_{ht}\, d\Gamma \quad \forall \nu_{ht} \in M_{ht}(-\mu g_{hn}),$$

or, equivalently,

$$\int_{\Gamma_C} \lambda_{ht} u_{ht}\, d\Gamma \leq \sum_{i=1}^{p} M_i (\mathcal{M} U_T)_i \quad \forall M \in \mathbb{R}^p \text{ such that } |M_i| \leq -\mu (G_N)_i,\ 1 \leq i \leq p.$$

It is easy to construct a vector M minimizing the sum and yielding the following bound:

$$\int_{\Gamma_C} \lambda_{ht} u_{ht}\, d\Gamma \leq \mu \sum_{i=1}^{p} (G_N)_i |(\mathcal{M} U_T)_i|.$$

A similar expression can be obtained when integrating the term $\overline{\lambda_{ht}u_{ht}}$. The two remaining terms of the integral in (3.8) are roughly bounded as follows:

$$-\int_{\Gamma_C} \lambda_{ht}\overline{u_{ht}}\, d\Gamma \le -\mu\sum_{i=1}^{p}(G_N)_i|(\mathcal{M}\overline{U_T})_i|;\ -\int_{\Gamma_C} \overline{\lambda_{ht}}u_{ht}\, d\Gamma \le -\mu\sum_{i=1}^{p}(\overline{G_N})_i|(\mathcal{M}U_T)_i|.$$

Finally, (3.8) becomes

$$\begin{aligned}\alpha\|\boldsymbol{u}_h - \overline{\boldsymbol{u}_h}\|_1^2 &\le \mu\sum_{i=1}^{p}(G_N - \overline{G_N})_i\left(|(\mathcal{M}U_T)_i| - |(\mathcal{M}\overline{U_T})_i|\right)\\ &\le \mu\left(\sum_{i=1}^{p}(G_N - \overline{G_N})_i^2\right)^{\frac{1}{2}}\left(\sum_{i=1}^{p}(\mathcal{M}(U_T - \overline{U_T}))_i^2\right)^{\frac{1}{2}}\\ &= \mu\|G_N - \overline{G_N}\|_{\mathbb{R}^p}\ \|U_T - \overline{U_T}\|_{\mathbb{R}^p,\mathcal{M}}, \end{aligned} \tag{3.10}$$

where $\big||x| - |y|\big| \le |x - y|$ and the Hölder inequality have been used. The notations $\|.\|_{\mathbb{R}^p}$ and $\|.\|_{\mathbb{R}^p,\mathcal{M}}$ whose definitions are straightforward represent norms on $\mathbb{R}^p$. (The mass matrix $\mathcal{M}$ is nonsingular.) As a consequence, there exist constants $C_1(h)$ and $C_2(h)$ depending on h (or equivalently on p) such that

$$\|G_N - \overline{G_N}\|_{\mathbb{R}^p} \le C_1(h)\|g_{hn} - \overline{g_{hn}}\|_{-\frac{1}{2},h} \tag{3.11}$$

and

$$\|U_T - \overline{U_T}\|_{\mathbb{R}^p,\mathcal{M}} \le C_2(h)\|u_{ht} - \overline{u_{ht}}\|_{L^2(\Gamma_C)} \le C_3(h)\|\boldsymbol{u}_h - \overline{\boldsymbol{u}_h}\|_1, \tag{3.12}$$

where the trace theorem has been used. Combining (3.10), (3.11), (3.12), and (3.2) implies that there exists a constant $C(h)$ such that

$$\|\lambda_{hn} - \overline{\lambda_{hn}}\|_{-\frac{1}{2},h} \le \mu C(h)\|g_{hn} - \overline{g_{hn}}\|_{-\frac{1}{2},h}. \tag{3.13}$$

Hence Φ_h is continuous.

- In the case where $\boldsymbol{M}_h(g) = \boldsymbol{M}''_h(g)$, the proof is analogous: first (3.7) implies

$$\int_{\Gamma_C} \lambda_{ht}u_{ht}\, d\Gamma \le \sum_{i=1}^{p}(\mathcal{M}M)_i(U_T)_i \ \ \forall M \in \mathbb{R}^p \text{ such that}$$
$$|(\mathcal{M}M)_i| \le -\mu(\mathcal{M}G_N)_i, \quad 1 \le i \le p.$$

Therefore,

$$\int_{\Gamma_C} \lambda_{ht}u_{ht}\, d\Gamma \le \mu\sum_{i=1}^{p}(\mathcal{M}G_N)_i|(U_T)_i|.$$

Expression (3.8) then leads to

$$\begin{aligned}\alpha\|\boldsymbol{u}_h - \overline{\boldsymbol{u}_h}\|_1^2 &\le \mu\sum_{i=1}^{p}(\mathcal{M}(G_N - \overline{G_N}))_i\left(|(U_T)_i| - |(\overline{U_T})_i|\right)\\ &\le \mu\left(\sum_{i=1}^{p}(\mathcal{M}(G_N - \overline{G_N}))_i^2\right)^{\frac{1}{2}}\left(\sum_{i=1}^{p}(U_T - \overline{U_T})_i^2\right)^{\frac{1}{2}}\\ &= \mu\|G_N - \overline{G_N}\|_{\mathbb{R}^p,\mathcal{M}}\ \|U_T - \overline{U_T}\|_{\mathbb{R}^p},\end{aligned}$$

and the continuity of Φ_h is proved following the same arguments as in the first case.

Step 2. Let $(\boldsymbol{u}_h, \lambda_{hn}, \lambda_{ht})$ be the solution of $(P(g_{hn}))$. Taking $\boldsymbol{v}_h = \boldsymbol{u}_h$ in (3.1) gives

$$a(\boldsymbol{u}_h, \boldsymbol{u}_h) - \int_{\Gamma_C} \lambda_{hn} u_{hn} \, d\Gamma - \int_{\Gamma_C} \lambda_{ht} u_{ht} \, d\Gamma = L(\boldsymbol{u}_h). \tag{3.14}$$

According to

$$\int_{\Gamma_C} \lambda_{hn} u_{hn} \, d\Gamma = 0 \quad \text{and} \quad \int_{\Gamma_C} \lambda_{ht} u_{ht} \, d\Gamma \leq 0,$$

we deduce from (3.14), the $\boldsymbol{V}$-ellipticity of $a(.,.)$, and the continuity of $L(.)$ that

$$\alpha \|\boldsymbol{u}_h\|_1^2 \leq a(\boldsymbol{u}_h, \boldsymbol{u}_h) \leq L(\boldsymbol{u}_h) \leq C \|\boldsymbol{u}_h\|_1,$$

where the constant C depends on the loads $\boldsymbol{f}$ and $\boldsymbol{F}$. Therefore, we get

$$\|\boldsymbol{u}_h\|_1 \leq \frac{C}{\alpha}.$$

In other respects

$$a(\boldsymbol{u}_h, \boldsymbol{v}_h) - \int_{\Gamma_C} \lambda_{hn} v_{hn} \, d\Gamma = L(\boldsymbol{v}_h) \qquad \forall \boldsymbol{v}_h \in \tilde{\boldsymbol{V}}_h,$$

leads to

$$\int_{\Gamma_C} \lambda_{hn} v_{hn} \, d\Gamma \leq M \|\boldsymbol{u}_h\|_1 \|\boldsymbol{v}_h\|_1 + C \|\boldsymbol{v}_h\|_1 \qquad \forall \boldsymbol{v}_h \in \tilde{\boldsymbol{V}}_h.$$

That implies

$$\|\lambda_{hn}\|_{-\frac{1}{2},h} \leq M \|\boldsymbol{u}_h\|_1 + C \leq \left(\frac{M}{\alpha} + 1\right) C.$$

Finally,

$$\|\Phi_h(g_{hn})\|_{-\frac{1}{2},h} \leq C' \qquad \forall g_{hn} \in M_{hn},$$

where C' depends only on the applied loads $\boldsymbol{f}, \boldsymbol{F}$ and on the continuity and ellipticity constant of $a(.,.)$. This together with the continuity of Φ_h proves that there exists at least a solution of Coulomb's discrete frictional contact problem according to Brouwer's fixed point theorem. □

Remark 3.3. From (3.13) when $\boldsymbol{M}_h(g) = \boldsymbol{M}'_h(g)$ or from the equivalent bound which is obtained when $\boldsymbol{M}_h(g) = \boldsymbol{M}''_h(g)$, we get a (quite weak) uniqueness result when $\mu \, C(h) \leq 1$. That means that uniqueness holds when μ is small enough, where the denomination "small" depends on the discretization parameter. A more detailed study would show that we are not able to prove that $C(h)$ remains bounded as h tends towards 0. Using another mixed finite element formulation (with a single multiplier instead of two which is not adapted to our a posteriori error estimator) leads to similar existence and uniqueness results (see [10, 11]).

3.2. The matrix formulation of the frictional contact conditions. Let us consider a solution $(\boldsymbol{u}_h, \lambda_{hn}, \lambda_{ht}) \in \boldsymbol{V}_h \times M_{hn} \times M_{ht}(-\mu\lambda_{hn})$ of Coulomb's discrete frictional contact problem. We are interested in the matrix translation of the frictional contact conditions

$$\int_{\Gamma_C} (\nu_{hn} - \lambda_{hn}) u_{hn} \, d\Gamma \geq 0 \qquad \forall \nu_{hn} \in M_{hn}, \tag{3.15}$$

$$\int_{\Gamma_C} (\nu_{ht} - \lambda_{ht}) u_{ht} \, d\Gamma \geq 0 \qquad \forall \nu_{ht} \in M_{ht}(-\mu\lambda_{hn}). \tag{3.16}$$

As before, Γ_C contains p nodes of the triangulation and ψ_i, $1 \leq i \leq p$, denote the scalar monodimensional basis functions on Γ_C. The p-by-p mass matrix $\mathcal{M} = (m_{ij})_{1\leq i,j\leq p}$ on Γ_C is given by (3.9).

Let U_N and U_T denote the vectors of components the nodal values of u_{hn} and u_{ht}, respectively, and let L_N and L_T denote the vectors of components the nodal values of λ_{hn} and λ_{ht}, respectively. We begin with considering the mixed method, where $\boldsymbol{M}_h(g) = \boldsymbol{M}'_h(g)$.

PROPOSITION 3.4. *Let $\boldsymbol{M}_h(g) = \boldsymbol{M}'_h(g)$. The vectors U_N, U_T, L_N, L_T associated with a solution of Coulomb's discrete frictional contact problem satisfy, for any $1 \leq i \leq p$,*

$$(L_N)_i \leq 0, \tag{3.17}$$

$$(\mathcal{M}U_N)_i \leq 0, \tag{3.18}$$

$$(L_N)_i(\mathcal{M}U_N)_i = 0, \tag{3.19}$$

$$|(L_T)_i| \leq -\mu(L_N)_i, \tag{3.20}$$

$$|(L_T)_i| < -\mu(L_N)_i \implies (\mathcal{M}U_T)_i = 0, \tag{3.21}$$

$$(L_T)_i(\mathcal{M}U_T)_i \leq 0. \tag{3.22}$$

Proof. From $\lambda_{hn} \in M'_{hn}$, we immediately get (3.17). Condition (3.15) is equivalent to

$$\int_{\Gamma_C} \nu_{hn} u_{hn} \, d\Gamma \geq 0 \quad \forall \nu_{hn} \in M'_{hn} \qquad \text{and} \qquad \int_{\Gamma_C} \lambda_{hn} u_{hn} \, d\Gamma = 0. \tag{3.23}$$

Choosing in the inequality of (3.23), $\nu_{hn} = -\psi_i$, $1 \leq i \leq p$, and writing $u_{hn} = \sum_{j=1}^{p} (U_N)_j \, \psi_j$ gives (3.18). Putting $\lambda_{hn} = \sum_{i=1}^{p} (L_N)_i \, \psi_i$ and $u_{hn} = \sum_{j=1}^{p} (U_N)_j \, \psi_j$ in the equality of (3.23) yields

$$\sum_{i=1}^{p} (L_N)_i (\mathcal{M}U_N)_i = 0.$$

The latter estimate together with (3.17) and (3.18) implies (3.19).

Inequality (3.20) follows directly from $\lambda_{ht} \in M'_{ht}(-\mu\lambda_{hn})$. For any $1 \leq i \leq p$, choose ν_{ht} in (3.16) as follows: $\nu_{ht} = \mu\lambda_{hn}$ at node i and $\nu_{ht} = \lambda_{ht}$ at the $p-1$ other nodes. We obtain

$$\begin{aligned} \int_{\Gamma_C} (\nu_{ht} - \lambda_{ht}) u_{ht} \, d\Gamma &= (\mu L_N - L_T)_i \int_{\Gamma_C} \psi_i u_{ht} \, d\Gamma \\ &= (\mu L_N - L_T)_i (\mathcal{M}U_T)_i \geq 0. \end{aligned} \tag{3.24}$$

Similarly, take $\nu_{ht} = -\mu\lambda_{hn}$ at node i and $\nu_{ht} = \lambda_{ht}$ at the $p-1$ other nodes. We get

$$\int_{\Gamma_C} (\nu_{ht} - \lambda_{ht})u_{ht}\, d\Gamma = (-\mu L_N - L_T)_i(\mathcal{M}U_T)_i \geq 0. \tag{3.25}$$

Putting together estimates (3.24) and (3.25) implies (3.21).

It remains to prove (3.22). Define ν_{ht} in (3.16) as follows: $\nu_{ht} = \frac{1}{2}\lambda_{ht}$ at node i and $\nu_{ht} = \lambda_{ht}$ at the $p-1$ other nodes. Therefore

$$\int_{\Gamma_C} (\nu_{ht} - \lambda_{ht})u_{ht}\, d\Gamma = -\frac{1}{2}(L_T)_i \int_{\Gamma_C} \psi_i u_{ht}\, d\Gamma = -\frac{1}{2}(L_T)_i(\mathcal{M}U_T)_i \geq 0.$$

Hence inequality (3.22) is proved. □

Proceeding in a similar way when $\boldsymbol{M}_h(g) = \boldsymbol{M}''_h(g)$, we obtain the following proposition.

PROPOSITION 3.5. *Let $\boldsymbol{M}_h(g) = \boldsymbol{M}''_h(g)$. The vectors U_N, U_T, L_N, L_T associated with a solution of Coulomb's discrete frictional contact problem satisfy, for any $1 \leq i \leq p$,*

$$\begin{aligned}
(\mathcal{M}L_N)_i &\leq 0,\\
(U_N)_i &\leq 0,\\
(\mathcal{M}L_N)_i(U_N)_i &= 0,\\
|(\mathcal{M}L_T)_i| &\leq -\mu(\mathcal{M}L_N)_i,\\
|(\mathcal{M}L_T)_i| &< -\mu(\mathcal{M}L_N)_i \implies (U_T)_i = 0,\\
(\mathcal{M}L_T)_i(U_T)_i &\leq 0.
\end{aligned}$$

Remark 3.6. We show in the next section that the choice of the method using $\boldsymbol{M}'_h(g)$ is quite appropriate and easier than $\boldsymbol{M}''_h(g)$ to compute the estimator. However, most of the finite element codes solving contact problems (with or without friction) make use of nodal displacements U_N, U_T and of nodal forces F_N, F_T as dual unknowns (and not pressures like L_N, L_T) on the contact part Γ_C. This means that the frictional contact conditions are generally $(F_N)_i \leq 0$, $(U_N)_i \leq 0$, $(F_N)_i(U_N)_i = 0$, $|(F_T)_i| \leq -\mu(F_N)_i$, and so on. This is precisely the choice of $\boldsymbol{M}''_h(g)$ when supposing that pressures and forces are linked by $F_N = \mathcal{M}L_N$ and $F_T = \mathcal{M}L_T$. As a consequence, we must also be able to propose a practical computation of the estimator for this widespread case.

4. Construction of admissible fields.

4. Construction of admissible fields. The purpose of this section is to describe the building of admissible fields $\hat{\boldsymbol{u}}, \hat{\boldsymbol{w}}, \hat{\boldsymbol{\sigma}}, \hat{\boldsymbol{r}}$ satisfying the kinematic conditions (2.1) and the equilibrium equations (2.2) to compute the error estimator (2.11). Moreover, in order to obtain a finite value of the error estimator, the displacement fields $\hat{\boldsymbol{w}}$ on the contact part Γ_C must satisfy the nonpenetration conditions, and the densities of forces $\hat{\boldsymbol{r}}$ should belong to Coulomb's friction cone C_μ on Γ_C.

To perform such a construction, we will obviously make use of the finite element solution of Coulomb's frictional contact problem $(\boldsymbol{u}_h, \lambda_{hn}, \lambda_{ht}) \in \boldsymbol{V}_h \times M_{hn} \times M_{ht}(-\mu\lambda_{hn}) = \boldsymbol{V}_h \times \boldsymbol{M}_h(-\mu\lambda_{hn})$ which satisfies

$$\begin{cases}
a(\boldsymbol{u}_h, \boldsymbol{v}_h) - \displaystyle\int_{\Gamma_C} \lambda_{hn} v_{hn}\, d\Gamma - \int_{\Gamma_C} \lambda_{ht} v_{ht}\, d\Gamma = L(\boldsymbol{v}_h) \quad \forall \boldsymbol{v}_h \in \boldsymbol{V}_h,\\
\displaystyle\int_{\Gamma_C} (\nu_{hn} - \lambda_{hn})u_{hn}\, d\Gamma + \int_{\Gamma_C} (\nu_{ht} - \lambda_{ht})u_{ht}\, d\Gamma \geq 0 \quad \forall (\nu_{hn}, \nu_{ht}) \in \boldsymbol{M}_h(-\mu\lambda_{hn}),
\end{cases}$$

where $\boldsymbol{M}_h(-\mu\lambda_{hn}) = M_{hn} \times M_{ht}(-\mu\lambda_{hn})$ denotes either $\boldsymbol{M}'_h(-\mu\lambda_{hn}) = M'_{hn} \times M'_{ht}(-\mu\lambda_{hn})$ or $\boldsymbol{M}''_h(-\mu\lambda_{hn}) = M''_{hn} \times M''_{ht}(-\mu\lambda_{hn})$.

We begin with building the displacement fields $\hat{\boldsymbol{u}}$ and $\hat{\boldsymbol{w}}$ satisfying the kinematic conditions (2.1) and the nonpenetration conditions.

4.1. Construction of the displacement fields. For both finite element approaches (i.e., $\boldsymbol{M}_h(g) = \boldsymbol{M}'_h(g)$ or $\boldsymbol{M}_h(g) = \boldsymbol{M}''_h(g)$) the finite element displacement field $\boldsymbol{u}_h$ verifies the embedding conditions in (2.1).

When $\boldsymbol{M}_h(g) = \boldsymbol{M}'_h(g)$, the finite element displacement field may not fulfill the nonpenetration conditions according to Proposition 3.4. At the nodes $\boldsymbol{x}_j$ which are not located on Γ_C, we set $\hat{\boldsymbol{u}}(\boldsymbol{x}_j) = \boldsymbol{u}_h(\boldsymbol{x}_j)$. At the nodes $\boldsymbol{x}_i$ lying on Γ_C, we set $\hat{u}_t(\boldsymbol{x}_j) = u_{ht}(\boldsymbol{x}_j)$ and $\hat{u}_n(\boldsymbol{x}_j) = \min(u_{hn}(\boldsymbol{x}_j), 0)$. Using these nodal values, the displacement field $\hat{\boldsymbol{u}}$ is then built in $\boldsymbol{V}_h$ (and $\hat{\boldsymbol{w}} = \hat{\boldsymbol{u}}$ on Γ_C).

When $\boldsymbol{M}_h(g) = \boldsymbol{M}''_h(g)$, the finite element displacement field also satisfies the nonpenetration conditions according to Proposition 3.5. In that case, we simply take $\hat{\boldsymbol{u}} = \boldsymbol{u}_h$ in Ω (and $\hat{\boldsymbol{w}} = \hat{\boldsymbol{u}}$ on Γ_C).

4.2. Construction of the stress fields. Let us describe the building of the stress fields $\hat{\boldsymbol{\sigma}}$ and $\hat{\boldsymbol{r}}$ verifying the equilibrium equations and $\hat{\boldsymbol{r}} \in C_\mu$ on Γ_C.

4.2.1. Building of $\hat{\boldsymbol{r}} \in \boldsymbol{C_\mu}$ on $\boldsymbol{\Gamma_C}$. When $\boldsymbol{M}_h(g) = \boldsymbol{M}'_h(g)$, the building is straightforward. According to Proposition 3.4, we can directly choose $\hat{\boldsymbol{r}} = \boldsymbol{\lambda}_h$ (i.e., $\hat{r}_n = \lambda_{hn}$ and $\hat{r}_t = \lambda_{ht}$).

When $\boldsymbol{M}_h(g) = \boldsymbol{M}''_h(g)$, the situation is more complicated. However, from Proposition 3.5, we are not ensured that the multipliers $\boldsymbol{\lambda}_h = (\lambda_{hn}, \lambda_{ht})$ always belong to C_μ on Γ_C (i.e., satisfy $\lambda_{hn} \leq 0$ and $|\lambda_{ht}| \leq -\mu\lambda_{hn}$) as in the previous case. Nevertheless, there is in the construction a freedom on the choice of the tangential components $\hat{r}_t$. Indeed, they can be modified edge by edge by adding a density with null resultant and moment. More precisely, when the computed multipliers satisfy $|\lambda_{ht}| > -\mu\lambda_{hn}$ at the node i, it is possible to compute a new density $\tilde{\lambda}_{ht}$ on the edge $[i, j]$ (j is one of the neighboring nodes) as follows:

$$\begin{aligned} \tilde{\lambda}_{ht} &= \lambda_{ht} - d \text{ at node } i, \\ \tilde{\lambda}_{ht} &= \lambda_{ht} + d \text{ at node } j. \end{aligned} \tag{4.1}$$

If $d \in \mathbb{R}$ is chosen such that $|\tilde{\lambda}_{ht}| \leq -\mu\lambda_{hn}$ at nodes i and j, then the modification is satisfying. In such a case, the modified tangential pressure $\tilde{\lambda}_{ht}$ is piecewise linear on each mesh and possibly discontinuous on Γ_C. We finally choose $\hat{r}_n = \lambda_{hn}$ and $\hat{r}_t = \tilde{\lambda}_{ht}$.

4.2.2. Building of $\hat{\boldsymbol{\sigma}}$ verifying the equilibrium equations. Next, having at our disposal $\hat{\boldsymbol{r}}$, the stress fields $\hat{\boldsymbol{\sigma}}$ satisfying (2.2) are to be constructed. It is straightforward that the stress field obtained from the finite element displacement field $\boldsymbol{u}_h$ with the constitutive relation $\boldsymbol{\sigma}_h = \mathcal{C}\,\boldsymbol{\varepsilon}(\boldsymbol{u}_h)$ does not satisfy the equilibrium equation (2.2). If we want to compute the error estimator, a stress field $\hat{\boldsymbol{\sigma}}$ that strictly satisfies the equilibrium equations must be obtained. The construction of $\hat{\boldsymbol{\sigma}}$ is performed in two steps which can be summarized as follows:

- The first step consists of building densities of forces $\hat{\boldsymbol{F}}$ on each edge of the mesh satisfying equilibrium with the body forces $\boldsymbol{f}$:

$$\int_E \boldsymbol{f}.\boldsymbol{v}\, d\Omega + \int_{\partial E} \eta_E \hat{\boldsymbol{F}}.\boldsymbol{v}\, d\Gamma = 0 \qquad \forall \boldsymbol{v} \text{ such that } \boldsymbol{\varepsilon}(\boldsymbol{v}) = 0,$$

where η_E is a function defined on the boundary of the triangular element E, constant on each edge of E, equal to 1 or equal to -1 and satisfying $\eta_E+\eta_{E'}=0$ on the common edge to adjacent elements E and E'. Note that the construction of $\hat{\boldsymbol{F}}$ is always possible and it is generally not unique. In the numerical experiments, the nonuniqueness of $\hat{\boldsymbol{F}}$ is handled in minimizing (locally, on each patch of elements connected to a node) the difference (least squares) with the finite element solution. The choice of such a technique very often leads to satisfactory effectivity indexes (between 1 and 1.5; see 5.3.1 hereafter). The details of these techniques can be found in [18].

• The second step is devoted to the construction of $\hat{\boldsymbol{\sigma}}$ locally on each element E by solving

$$\left\{\begin{array}{lll} \mathbf{div}\,\hat{\boldsymbol{\sigma}}+\boldsymbol{f} & =0 & \text{in } E,\\ \hat{\boldsymbol{\sigma}}\boldsymbol{n} & =\eta_E\hat{\boldsymbol{F}} & \text{on } \partial E,\end{array}\right.$$

where $\boldsymbol{n}$ stands for the unit outward normal on ∂E.

There are two techniques to compute locally the stress admissible field from the densities:

1. analytical construction; it is easy to check that there does not exist an $\hat{\boldsymbol{\sigma}}$ linear on E due to the stress symmetry requirement. The chosen technique for determining $\hat{\boldsymbol{\sigma}}$ on each triangle E is then to divide E into three subtriangles and to search $\hat{\boldsymbol{\sigma}}$ which is linear on each subtriangle. The details of this construction can be found in [18];
2. numerical construction by using higher-degree polynomials (see [4]).

5. Numerical studies.

5.1. Mesh adaption. The aim of adaptive procedures is to offer the user a level of accuracy denoted ϵ_0 with a minimal computational cost. We use the h-version which is the most widespread procedure of adaptivity currently in use: the size and the topology of the elements are modified but the same kind of basis functions for the different meshes are retained. A mesh T^* is said to be optimal with respect to a measure of the error ϵ^* if (see [16])

$$\left\{\begin{array}{l}\epsilon^*=\epsilon_0,\\ N^*\text{minimal } (N^*\text{: number of elements of } T^*).\end{array}\right. \tag{5.1}$$

To solve problem (5.1), the following procedure is applied:

1. An initial analysis is performed on a relatively uniform and coarse mesh T.
2. The corresponding global error ϵ in (2.12) and the local contributions ϵ_E in (2.13) are computed.
3. The characteristics of the optimal mesh T^* are determined in order to minimize the computational costs in respect of the global error.
4. A second finite element analysis is performed on the mesh T^*.

The optimal mesh T^* is determined by the computation of a size modification coefficient r_E on each element E of the mesh T:

$$r_E=\frac{h_E^*}{h_E},$$

where h_E denotes the size of E and h_E^* represents the size that must be imposed to the elements of T^* in the region of E in order to ensure optimality. The computation of the coefficients r_E uses the rate of convergence of the error which depends on the used element but also on the regularity of the solution [6]. Therefore, to compute the coefficients r_E, we use a technique detailed in [7] that automatically takes into account the steep gradient regions. The mesh T^* is generated by an automatic mesher able to accurately respect a map of sizes. Practically, the previous procedure allows us to divide in two or three the error ϵ. If the user wishes more accuracy, then the procedure is repeated as far as a precision close to ϵ_0 is reached (see [6]).

5.2. Examples. We consider two-dimensional plane strain problems where no body forces are applied. As a constitutive relation in Ω, we choose Hooke's law of homogeneous isotropic elastic materials:

$$\boldsymbol{\sigma}_{ij} = \frac{E\nu}{(1-2\nu)(1+\nu)}\delta_{ij}\boldsymbol{\varepsilon}_{kk}(\boldsymbol{u}) + \frac{E}{1+\nu}\boldsymbol{\varepsilon}_{ij}(\boldsymbol{u}),$$

where E and ν denote Young's modulus and Poisson's ratio, respectively, and the notation δ_{ij} stands for Kronecker's symbol. The implementation is achieved using CASTEM 2000 developed at the CEA, and an HP-C3000 computer has been used.

Three examples are studied with various friction coefficients. The computations have been carried out by using the mixed finite element method with $\boldsymbol{M}_h(g) = \boldsymbol{M}''_h(g)$. (See Remark 3.6 for comments.)

5.3. First example. We consider the problem depicted in Figure 2. The dimensions of the rectangular body are 40mm × 160mm, and computations are performed on the left half of the structure due to symmetry. The material characteristics are $E = 13$Gpa, $\nu = 0.2$, and $\mu = 0.5$ is the friction coefficient. The load on the left side is 10N.mm^{-2} and the upper side is clamped.

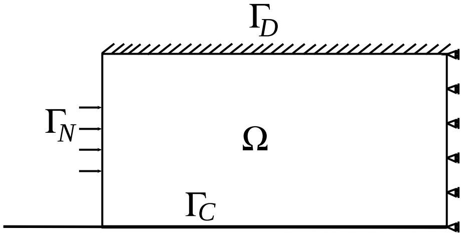

FIG. 2. *Setting of the problem.*

The initial mesh comprises 1088 three-node elements and 627 nodes for an accuracy ϵ of 9.74% (Figure 3). We show the deformed body in which separation occurs in Figure 4 and the contributions to the error ϵ_E in Figure 5. The contact pressures are reported in Figure 6. We show the normal pressure $-\lambda_{hn}$, the friction cone (between $-|\lambda_{hn}|$ and $|\lambda_{hn}|$), the tangential pressure $-\lambda_{ht}$, and the modified tangential pressure $-\tilde{\lambda}_{ht}$.

Due to the separation on the left part of Γ_C and the choice of the finite element method $\boldsymbol{M}_h(g) = \boldsymbol{M}''_h(g)$, we see that the normal pressure does not always satisfy the convenient sign property. Moreover, at the last mesh on the right part, the tangential pressure is outside the friction cone. By using the modification of the densities (4.1), we are able to compute a modified tangential pressure inside the cone which allows the computing of the statically admissible field. Concerning the normal pressure, the difficulty cannot be solved by the densities modification. The proposed mixed finite element method $\boldsymbol{M}_h(g) = \boldsymbol{M}'_h(g)$ will allow us to solve this difficulty.

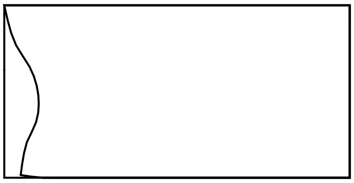

FIG. 4. *Deformed configuration.*

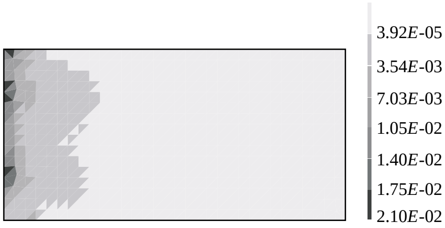

FIG. 5. *Local contributions* ϵ_E.

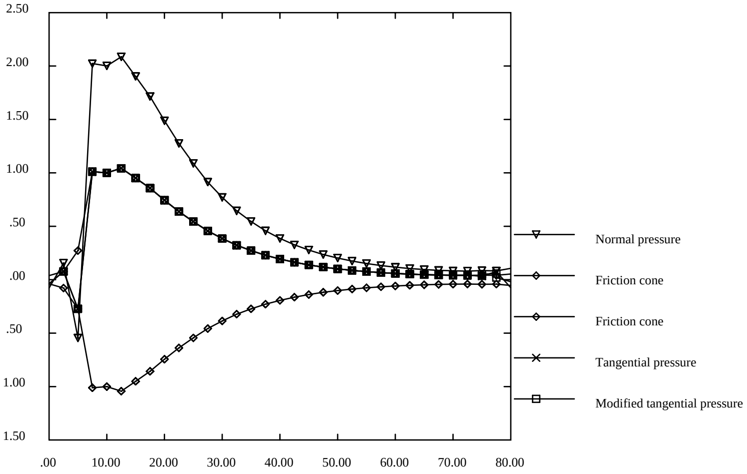

FIG. 6. *Contact pressures.*

The prescribed accuracy ϵ_0 is 5%. The optimized mesh is obtained in one step and comprises 1148 three-node elements and 647 nodes for an accuracy ϵ of 4.28% (Figure 7).

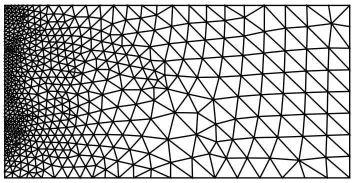

FIG. 7. *Optimized mesh:* 1148 *three-node elements,* 647 *nodes,* $\epsilon = 4.28\%$.

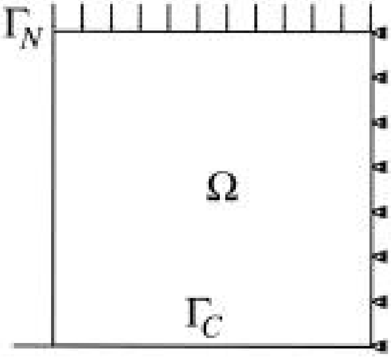

FIG. 8. *Setting of the problem.*

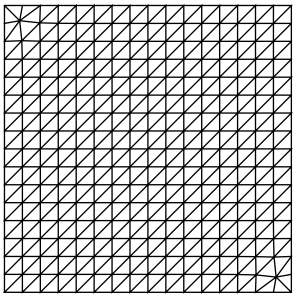

FIG. 9. *Initial mesh:* 544 *three-node elements,* 323 *nodes,* $\epsilon = 1.46\%$.

5.3.1. Second example. Next, we consider the structure depicted in Figure 8. The dimensions of the rectangle are 40mm × 80mm, and symmetry conditions are adopted. We choose $E = 13$Gpa, $\nu = 0.2$, and a friction coefficient of 0.3. The load on the upper side is 5N.mm^{-2}, and no embedding conditions are applied. In such a case, the bilinear form $a(.,.)$ is no longer $\boldsymbol{V}$-elliptic but satisfies some semicoercivity property (see [11, Theorem 6.3]).

The initial mesh is made of 544 three-node elements and 323 nodes corresponding to an accuracy ϵ of 1.46% (Figure 9). The deformed configuration and the map of local contributions ϵ_E are shown in Figures 10 and 11, respectively. In Figure 12, the normal contact pressure, the friction cone, and the tangential pressure are reported. We can notice that on the left node, the tangential pressure is outside the cone. By using the modification of the densities (4.1), we compute a modified tangential pressure which gives a new pressure inside the cone. Notice that in this example, we have stick on the contact zone, whereas the body was slipping in the previous

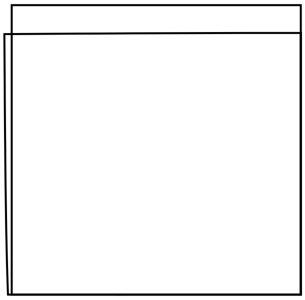

Fig. 10. *Deformed configuration.*

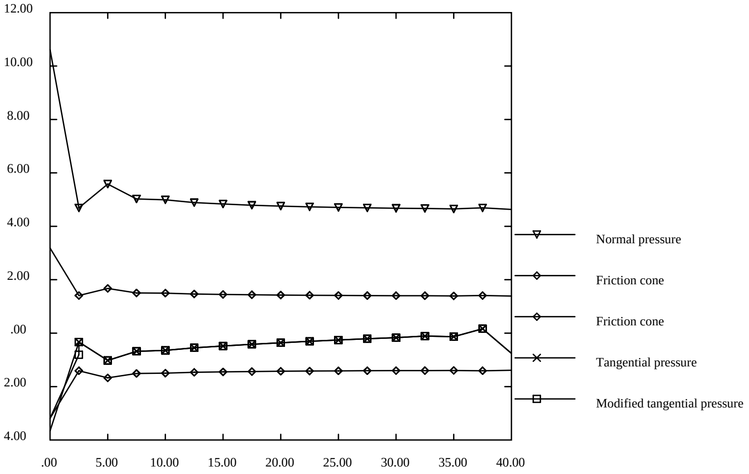

Fig. 12. *Contact pressures.*

example. (See also Proposition 3.5 for some corroboration.)

The prescribed accuracy ϵ_0 is 0.5%. The optimized mesh (obtained in one step) comprising 1178 three-node elements and 666 nodes for an accuracy ϵ of 0.57% is represented in Figure 13.

Next, we again consider the initial mesh in Figure 9, and we compute the effec-

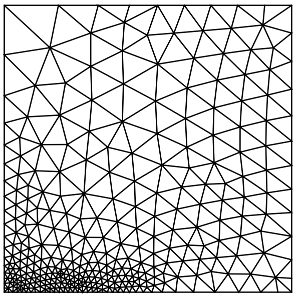

FIG. 13. *Optimized mesh:* 1178 *three-node elements,* 666 *nodes,* $\epsilon = 0.57\%$.

TABLE 1
Effectivity indexes.

μ	ϵ (in %)	ϵ_{ex} (in %)	effectivity γ
0.2	1.26	0.93	1.36
0.4	1.50	1.02	1.48
0.6	1.50	1.02	1.48
0.8	1.50	1.02	1.48

tivity indexes as a function of the friction coefficient μ. Since no analytical solution is available, we use a reference solution denoted $\boldsymbol{u}_{ref}$ corresponding to a very refined mesh. The exact error denoted ϵ_{ex} and the effectivity index γ can be defined as follows:

$$\epsilon_{ex} = \frac{\|\boldsymbol{u}_{ref} - \boldsymbol{u}_h\|_{u,\Omega}}{\|\boldsymbol{u}_{ref} + \boldsymbol{u}_h\|_{u,\Omega}}, \qquad \gamma = \frac{e}{\|\boldsymbol{u}_{ref} - \boldsymbol{u}_h\|_{u,\Omega}},$$

where e is the error estimator defined in (2.11). The results are reported in Table 1. Note that the frictionless case is not interesting because it corresponds to a pure compression case, and the error is negligible. The effectivity indexes close to 1 show the accuracy of the error estimator.

5.3.2. Third example: Numerical extension to two bodies in frictional contact. We consider the problem of two elastic bodies initially in contact (Figure 14). The upper body is submitted to a uniform load of 10N.mm^{-2}. We have adopted symmetry conditions on the lower side of Ω^2 in order to avoid a greater

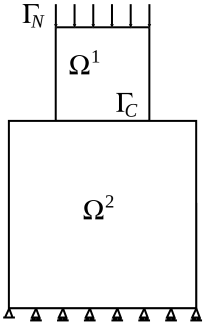

FIG. 14. *Setting of the problem.*

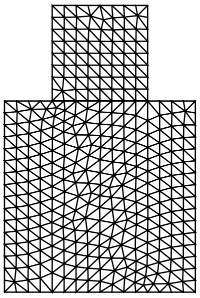

Fig. 15. *Initial mesh:* 640 *three-node elements,* 370 *nodes,* $\epsilon = 8.51\%$.

number of singularities, and the lower body is fixed on the left node of its lower side. The two materials are identical (E = 200GPa, $\nu = 0.25$), the dimensions are 100mm × 100mm and 200mm × 200mm, and the friction coefficient μ is 0.3.

The initial mesh with 640 three-node elements, 370 nodes, and an accuracy ϵ of 8.51% is shown in Figure 15. We show the deformed bodies (Figure 16) and the contributions to the error ϵ_E (Figure 17). The contact pressures are drawn in Figure 18. As in the previous example, the computed tangential pressure is outside the friction cone (on both extreme meshes), and as before, it can be successfully modified to compute the estimator.

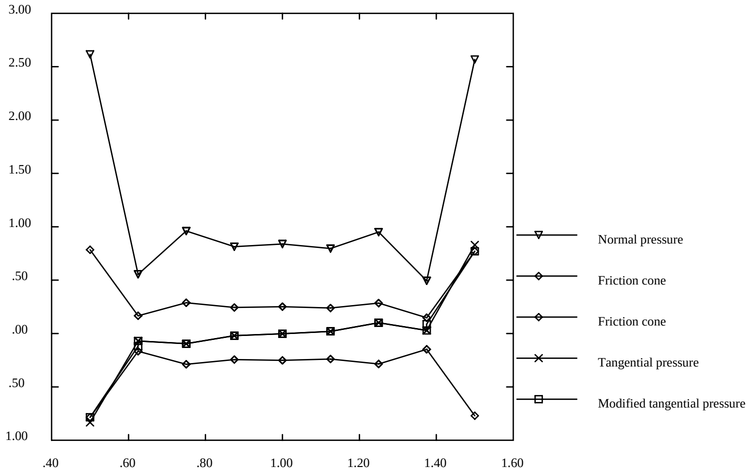

FIG. 18. *Contact pressures.*

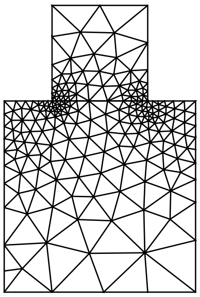

FIG. 19. *Optimized mesh:* 381 *three-node elements,* 230 *nodes,* $\epsilon = 5.46\%$.

An accuracy ϵ_0 of 5% is prescribed. The optimized mesh, obtained in one step, made of 381 three-node elements and 230 nodes for an accuracy ϵ of 5.46% is shown in Figure 19.

THE RANDOM PROJECTION METHOD FOR STIFF DETONATION CAPTURING*

WEIZHU BAO† AND SHI JIN‡

Abstract. In this paper we present a simple and robust random projection method for under-resolved numerical simulation of stiff detonation waves in chemically reacting flows. This method is based on the random projection method proposed by the authors for general hyperbolic systems with stiff reaction terms [W. Bao and S. Jin, *J. Comput. Phys.*, 163 (2000), pp. 216–248], where the ignition temperature is randomized in a suitable domain. It is simplified using the equations of instantaneous reaction and then extended to handle the interactions of detonations. Extensive numerical experiments, including interaction of detonation waves, and in two dimensions, demonstrate the reliability and robustness of this novel method.

Key words. detonation, random projection method, reacting flow, shock capturing

1. Introduction.

An inviscid, compressible, reacting flow is described by the reactive Euler equations

$$U_t + F(U)_x + G(U)_y = \frac{1}{\varepsilon}\Psi(U), \tag{1.1}$$

$$U = \begin{pmatrix} \rho \\ m \\ n \\ e \\ \rho z \end{pmatrix}, \quad F(U) = \begin{pmatrix} m \\ m^2/\rho + p \\ mn/\rho \\ m(e+p)/\rho \\ mz \end{pmatrix}, \quad G(U) = \begin{pmatrix} n \\ mn/\rho \\ n^2/\rho + p \\ n(e+p)/\rho \\ nz \end{pmatrix}, \tag{1.2}$$

$$\Psi(U) = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \\ -\rho z e^{-T_c/T} \end{pmatrix} \equiv \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \\ \psi(U) \end{pmatrix}. \tag{1.3}$$

The dependent variables $\rho(x,y,t)$, $m(x,y,t)$, $n(x,y,t)$, $e(x,y,t)$, and $z(x,y,t)$ are the density, x- and y-momentum, total energy, and the fraction of unburnt fluid, respectively. The pressure for ideal gas is given by

$$p = (\gamma - 1)\left(e - \frac{1}{2}\left(m^2 + n^2\right)/\rho - q_0\rho z\right),$$

and the temperature is defined as $T = p/\rho$. Let $(u,v) = (m/\rho, n/\rho)$ be the velocity. The parameters q_0, T_c, γ, and ε correspond to chemical heat release, ignition temperature, c_p to c_v ratio, and reaction time, respectively. The equations have been

nondimensionalized, leaving the choice of these four parameters to completely determine the problem.

The focus of this paper is on the computations of stiff detonation waves. For these waves the viscosity is not as important as for the slower deflagration wave solutions.

Equations (1.1)–(1.3) are usually referred to as the reactive Euler equations with Arrhenius kinetics. When the source term is replaced by

$$-\frac{1}{\varepsilon}\rho z H(T - T_c),$$

where $H(x) = 1$ for $x > 0$ and $H(x) = 0$ for $x < 0$, the kinetics is referred to as the *Heaviside kinetics* [21]. The difference in the kinetics affect the details of the detonation layers, which are of width $O(\varepsilon)$ with pressure and temperature spikes that decay exponentially into the postdetonation equilibria.

One of the main numerical challenges for reacting flows is that the kinetics equations (1.1) often include reactions with widely varying time scales. The chemical time scales, as characterized by ε, may be orders of magnitude faster than the fluid dynamical time scale. This leads to problems of severe numerical stiffness. Actually, the stiffness issue with the Heaviside kinetics is the more severe one [11]. Even a stable numerical scheme may lead to spurious unphysical solutions unless the small chemical time scale is fully resolved numerically.

Numerical methods for such problems have attracted a great deal of attention in the last decade. In particular, many works have contributed to the analysis and development of underresolved numerical methods which are capable of capturing the physically relevant macroscopic solutions without resolving the details of the denotation layers . Of course, when one does not resolve the chemical scale numerically (using grid size larger than the reaction zone $O(\varepsilon)$), it is impossible to capture the pressure and temperature spikes in the reaction zone. Thus the best one can hope for is to capture the speed of detonation, as well as other wave features associated with the fluid dynamics. It was first observed by Colella, Majda and Roytburd [9] that an underresolved numerical method, where ε is not resolved by suitably small time steps and grid sizes, leads to a spurious weak detonation wave that travels one grid per time step. Since then, lots of attention has been paid to study this peculiar numerical phenomenon (see [4], [6], [13], [18], [19]). It is known that numerical shock profile, an essential ingredient in all shock capturing methods, leads to premature chemical reactions once the smeared value of the temperature in the numerical detonation layer is above the ignition temperature. Various approaches have been suggested to fix this numerical problem. For example, in [11], a temperature extrapolation technique was proposed. In [5] the ignition temperature was artificially raised. In [20] the reaction time ε was replaced by a larger one, and thus the reaction zone was made much wider than the physical one. Recently, a modified fractional step method was introduced [15], where the structure of the Riemann solution of the homogeneous part was used to determine where burning should occur in each time step. This recipe works within the framework of the Godunov-type methods.

Recently, we proposed the random projection method as a general and systematic method to solve hyperbolic systems with stiff reaction term, applicable to reacting flow problems [1]. Unlike the random choice method of Chorin for reacting flow [7], which was originated from Glimm's scheme [12], and requires solving a generalized Riemann problem for hyperbolic systems with source terms [4], our method is a fractional step method, which combines a standard—no Riemann solver is needed—shock capturing method for the homogeneous convection with a strikingly simple random projection step for the reaction terms. In the random projection step, the ignition temperature is chosen to be a uniformly distributed random variable between the two stable equilibria. At each time step, this random projection will move the shock by at most one grid point. The statistical average, however, yields the correct speed, even though the small time scale ε is not numerically resolved. In particular, when the random number is chosen to be the equidistributed van der Corput sampling sequence [14], [8] we have proven, for a model scalar problem, a first order accuracy on the shock speed if a monotonicity-preserving method, which includes all TVD schemes, is used in the convection step [1], [2]. A large amount of numerical experiments for one- and two-dimensional detonation waves demonstrate the robustness of this novel approach.

The generality of the random projection method lies in the fact that it applies to *any* shock capturing method for the homogeneous part, while other approaches, such as the ideas of [7], [15], are restricted to Godunov-type methods that require Riemann or generalized Riemann solvers.

In this paper, we conduct extensive numerical experiments to examine the applicability of the random projection method for reacting flows. We focus on stiff detonation waves and their interactions with other waves, including the interaction of detonation waves. Since the aim is to test the validity of an underresolved numerical method, which completely ignores the details of the reaction zone but captures all the main features of the solution outside the reaction zone, it is adequate to formulate this method using the reacting flow model of instantaneous reaction (with zone-width reaction zone, the so-called Chapman–Jouguet (C-J) model [10]), as given by [7], in which the chemical heat is released instantaneously:

$$U_t + F(U)_x + G(U)_y = 0, \tag{1.4}$$

$$U = \begin{pmatrix} \rho \\ m \\ n \\ e \end{pmatrix}, \quad F(U) = \begin{pmatrix} m \\ m^2/\rho + p \\ mn/\rho \\ m(e+p)/\rho \end{pmatrix}, \quad G(U) = \begin{pmatrix} n \\ mn/\rho \\ n^2/\rho + p \\ n(e+p)/\rho \end{pmatrix}, \tag{1.5}$$

with equation of state

$$p = (\gamma - 1)\left(e - \frac{1}{2}\left(m^2 + n^2\right)/\rho - q_0\rho z\right), \tag{1.6}$$

and the fraction of unburnt gas

$$z = \begin{cases} 0 & \text{if } T > T_c, \\ 1 & \text{if } T < T_c. \end{cases} \tag{1.7}$$

Formally, when the reaction time goes to zero, (1.1)–(1.3) with Arrhenius or Heaviside kinetics reduce effectively to this model. Although this "zero reaction limit" is not rigorously justified mathematically, the numerical comparisons between the random projection method based on this model with the resolved calculations based on the original kinetics of Arrhenius or Heaviside, as carried out later in this paper, do support the validity of this reduction unless one wants the full details of the reaction layer.

There certainly are restrictions with the instantaneous reaction model, or more generally, with any underresolved numerical method. First, if one needs the details of the reaction layer, then one does need to numerically resolve the layer by solving the full equations (1.1)–(1.3) using fine meshes. Second, these methods cannot predict the instability in overdrive detonation waves, since, by ignoring the reaction layer, the peak value of pressure, which oscillates due to the instability, cannot be accurately computed. In order to obtain such fine structures, one has no choice but to use fine meshes, at least around the reaction zone by using techniques such as the adaptive mesh refinements.

The random projection method consists of two steps, the first being any standard shock capturing method for (1.4), followed by a random projection for the fraction variable z in (1.7), in which the ignition temperature T_c is replaced by a uniformly distributed random sequence. Here, the convection step is slightly simpler than the original one proposed in [1], where the full convection equation, including the homogeneous part of the species equation in (1.1)–(1.3), is solved. Algorithms for the collision of detonation waves are also introduced. Many numerical examples, including the C-J detonation, strong detonation, collisions of detonation with shocks, rarefaction wave, or another detonation, as well as two dimensional examples, will be used to justify the robustness of this novel approach.

The paper is organized as follows. In section 2 we provide a random projection method for the problem (1.4)–(1.7) in one space dimension with general initial data. Algorithms for multidetonations are also introduced. In section 3 this method is extended to two space dimension. In section 4 many numerical examples will be presented. In section 5 some conclusions are drawn.

2. One-dimensional detonations.

In this section, we shall describe the random projection method for (1.4)–(1.7) in one space dimension. Moreover, we will describe its implementation for the case of interaction of detonation waves. The problem to be solved is given by

$$U_t + F(U)_x = 0, \tag{2.1}$$

$$U = \begin{pmatrix} \rho \\ m \\ e \end{pmatrix}, \qquad F(U) = \begin{pmatrix} m \\ m^2/\rho + p \\ m(e+p)/\rho \end{pmatrix}, \tag{2.2}$$

with equation of state

$$p = (\gamma - 1)\left(e - \frac{1}{2}m^2/\rho - q_0\rho z\right), \tag{2.3}$$

and the fraction of unburnt gas

$$z = \begin{cases} 0 & \text{if } T > T_c, \\ 1 & \text{if } T < T_c. \end{cases} \tag{2.4}$$

Let the grid points be x_i, $i = \cdots, -1, 0, 1, \ldots$, with equal mesh spacing $h = x_{i+1} - x_i$. The time level $t_0 = 0$, t_1, t_2, $\ldots$ are also uniformly spaced with time step $k = t_{n+1} - t_n$. We use $U_i^n = (\rho_i^n, m_i^n, e_i^n, (\rho z)_i^n)$ to denote the approximate solution of $U = (\rho, m, e, \rho z)$ at the point $(x_i, t_n) = (ih, nk)$. Our main interest is an underresolved numerical method which allows $k = O(h) \gg \varepsilon$ and still obtains physically relevant numerical solutions.

The random projection method is a fractional step method that consists of a standard shock capturing method for (2.1), denoted by $S_F(k)$ for one time step, followed by a random projection step for the fraction variable z defined by (2.4) where T_c, the ignition temperature, is randomized in a suitable domain. Let $U^{n+1} = S_F(k)U^n$. To obtain z^{n+1}, we replace (2.4) by

$$z_j^{n+1} = \begin{cases} 0 & \text{if } T_j^{n+1} > \theta_n, \\ 1 & \text{if } T_j^{n+1} < \theta_n, \end{cases} \tag{2.5}$$

where $T_j^{n+1} = p_j^{n+1}/\rho_j^{n+1}$ and θ_n is a random number, chosen one per time step, between two equilibrium temperatures on both sides of the detonation. To be more precise, consider the initial data

$$(\rho(x,0), u(x,0), p(x,0), z(x,0)) = \begin{cases} (\rho_l(x), u_l(x), p_l(x), 0) & \text{if } x \le x_0, \\ (\rho_r(x), u_r(x), p_r(x), 1) & \text{if } x > x_0, \end{cases} \tag{2.6}$$

where x_0 is a given point. Without loss of generality these data are chosen such that the detonation, initially at $x = x_0$, moves to the right. The case when the detonation moved to the left can be treated similarly. Since our projection always makes z either 1 or 0, therefore, at any time step t_n, there is an $l(n) = j_0$, j_0 an integer, such that

$$z_j^n = \begin{cases} 0 & \text{if } j \le l(n), \\ 1 & \text{if } j > l(n). \end{cases} \tag{2.7}$$

Here $l(n)$ is the location of the jump for z in the approximate solution at time t_n and we assume $x_0 = l(0)h$ to be a grid point. Let

$$\theta_n = (T_l - T_r)\vartheta_n + T_r, \qquad T_l = \min_{x<x_0} \frac{p_l(x,0)}{\rho_l(x,0)}, \qquad T_r = \max_{x>x_0} \frac{p_r(x,0)}{\rho_r(x,0)} \tag{2.8}$$

with ϑ_n being the van der Corput sampling sequence on the interval $[0,1]$.

The van der Corput sequence is an equidistributed sequence with the minimal deviation among all random sequences [14]. It is obtained as follows: let $1 \le n = \sum_{k=0}^m i_k 2^k$, $i_k = 0, 1$, be the binary expansion of the integer n. One gets ϑ_n on $[0,1]$ as

$$\vartheta_n = \sum_{k=0}^m i_k 2^{-(k+1)}, \qquad n = 1, 2, \ldots . \tag{2.9}$$

Since there are other waves in the domain, one cannot project z according to (2.5) in the whole domain. Instead, we do it around the denotation, a procedure called the *local random projection* in [1]. Specifically, we move the jump of z according to the following algorithm:

```
(2.10)  $S_{sp}(k)$ :  set $l(n+1) := l(n) - 1$;
                For $l = l(n)-1, l(n), \ldots, l(n)+d$, do
                  $l(n+1) := l$   if $T_l^{n+1} > \theta_n$;
                $z_j^{n+1} = \begin{cases} 0 & \text{if } j \le l(n+1) \\ 1 & \text{if } j > l(n+1) \end{cases}$   for all $j$,
```

where d is the number of smeared points in the shock layer. In the above algorithm, only $d + 2$ points will be scanned.

The stability condition for this algorithm, as well as the algorithms for multidetonations (2.15) and (2.20), is the usual CFL condition determined by the operator $S_F(k)$ for the convection terms.

In our numerical comparison, we will compare the random projection method with the *deterministic* projection method which projects the fraction of unburnt gas, z, after the convection step according to the *fixed* ignition temperature T_c in (2.4).

We now extend the random projection method to handle the problems involving more than one detonation wave. For clarity of presentation we present only the case of two detonations. It is straightforward to extend to the case where there are more than two detonations.

Consider (2.1)–(2.4) with initial data

$$(\rho(x,0),u(x,0),p(x,0),z(x,0)) = \begin{cases} (\rho_l(x),u_l(x),p_l(x),0) & \text{if } x \le x_1, \\ (\rho_m(x),u_m(x),p_m(x),1) & \text{if } x_1 < x < x_2, \\ (\rho_r(x),u_r(x),p_r(x),0) & \text{if } x_2 \le x. \end{cases} \tag{2.11}$$

These data are chosen such that the two detonations move toward each other; i.e., the detonation initially at $x = x_1$ moves to the right and the one initially at $x = x_2$ moves to the left. Thus after some time, the two detonations will collide.

Let

$$T_l = \min_{x<x_1} \frac{p_l(x)}{\rho_l(x)}, \qquad T_m = \max_{x_1<x<x_2} \frac{p_m(x)}{\rho_m(x)}, \qquad T_r = \min_{x>x_2} \frac{p_r(x)}{\rho_r(x)} \tag{2.12}$$

and

$$\theta_n^{(1)} = (T_l - T_m)\vartheta_n + T_m, \qquad \theta_n^{(2)} = (T_r - T_m)\vartheta_n + T_m. \tag{2.13}$$

Since the projection always makes z either 1 or 0, the profile of z at any time step is a piecewise constant function. Therefore, at any time step t_n, there are $l_1(n) = j_1$ and $l_2(n) = j_2$ with $j_1 \le j_2$ integers such that

$$z_j^n = \begin{cases} 0 & \text{if } j \le l_1(n), \\ 1 & \text{if } l_1(n) < j < l_2(n), \\ 0 & \text{if } l_2(n) \le j. \end{cases} \tag{2.14}$$

Here we assume that $x_1 = l_1(0)h$ and $x_2 = l_2(0)h$ are grid points. Since $x_1 \le x_2$, then $l_1(0) \le l_2(0)$. One can use the following algorithm to obtain z^{n+1} if the positions of the two detonations at time t_n, i.e., $l_1(n)$ and $l_2(n)$, are known. The detailed algorithm to find z^{n+1} is as follows:

```
$S_{cp}(k)$ :  $l_{\text{mid}} = (l_1(n) + l_2(n))/2$;
               set $l_1(n+1) := l_1(n) - 1$;
               For $l = l_1(n) - 1, l_1(n), \ldots, \min\{l_1(n) + d,\ l_{\text{mid}} + 1\}$ do
                   $l_1(n+1) := l$  if $T_l^{n+1} > \theta_n^{(1)}$;
               set $l_2(n+1) := l_2(n) + 1$;
               For $l = l_2(n) + 1, l_2(n), \ldots, \max\{l_2(n) - d,\ l_{\text{mid}} - 1\}$ do
                   $l_2(n+1) := l$  if $T_l^{n+1} > \theta_n^{(2)}$;
```

$$z_j^{n+1} = \begin{cases} 0 & \text{if } j \le l_1(n+1) \\ 1 & \text{if } l_1(n+1) < j < l_2(n+1) \\ 0 & \text{if } l_2(n+1) \le j \end{cases} \qquad \text{for all } j. \tag{2.15}$$

This algorithm still works even after the detonations have collided and then become extinct. After the detonations have collided, the fraction of unburnt gas $z \equiv 0$. From this algorithm, once $l_1(n) \geq l_2(n)$ at some time step $t = t_n$, then $l_1(n+1) \geq l_2(n+1)$ for the next step. Thus the profile of z^{n+1} determined from (2.15) is the zero function.

Another case is when two detonations move away from each other. Consider the initial data

$$(\rho(x,0), u(x,0), p(x,0), z(x,0)) = \begin{cases} (\rho_l(x), u_l(x), p_l(x), 1) & \text{if } x < x_1, \\ (\rho_m(x), u_m(x), p_m(x), 0) & \text{if } x_1 \leq x \leq x_2, \\ (\rho_r(x), u_r(x), p_r(x), 1) & \text{if } x_2 < x. \end{cases} \tag{2.16}$$

These data are chosen such that the two detonations move away from each other; i.e., the detonation initially at $x = x_1$ moves to the left and the one initially at $x = x_2$ moves to the right. In this case, there is no collision of detonations at all.

Let

$$T_l = \max_{x<x_1} \frac{p_l(x)}{\rho_l(x)}, \qquad T_m = \min_{x_1<x<x_2} \frac{p_m(x)}{\rho_m(x)}, \qquad T_r = \max_{x>x_2} \frac{p_r(x)}{\rho_r(x)} \tag{2.17}$$

and

$$\theta_n^{(1)} = (T_m - T_l)\vartheta_n + T_l, \qquad \theta_n^{(2)} = (T_m - T_r)\vartheta_n + T_r. \tag{2.18}$$

At any time step t_n, there are $l_1(n) = j_1$ and $l_2(n) = j_2$ with $j_1 \leq j_2$ integers such that

$$z_j^n = \begin{cases} 1 & \text{if } j < l_1(n), \\ 0 & \text{if } l_1(n) \leq j \leq l_2(n), \\ 1 & \text{if } l_2(n) < j. \end{cases} \tag{2.19}$$

The detailed algorithm to find z^{n+1} is as follows:

```
$S_{bp}(k)$ :  set $l_1(n+1) := l_1(n) + 1$;
               For $l = l_1(n)+1, l_1(n), \ldots, l_1(n) - d$, do
                 $l_1(n+1) := l$  if $T_l^{n+1} > \theta_n^{(1)}$;
               set $l_2(n+1) := l_2(n) - 1$;
               For $l = l_2(n)-1, l_2(n), \ldots, l_2(n) + d$, do
                 $l_2(n+1) := l$  if $T_l^{n+1} > \theta_n^{(2)}$;
```

$$z_j^{n+1} = \begin{cases} 1 & \text{if } j < l_1(n+1) \\ 0 & \text{if } l_1(n+1) \leq j \leq l_2(n+1) \\ 1 & \text{if } l_2(n+1) < j \end{cases} \qquad \text{for all } j. \tag{2.20}$$

Remark 2.1. The algorithms presented in this section reply on the assumption that initially the detonation front is already formed. Thus it cannot be used to predict the creation of a detonation from a completely unburned gas (when the initial value of z is identically zero in the entire domain). Since the detonation will be formed beyond the initial layer, one can use a refined calculation within the initial layer and then use the random projection method beyond the initial layer. While one can afford to resolve the initial layer with a refined computation, it is certainly more advantageous to use an underresolved numerical method for all later time beyond the initial layer.

3. The two-dimensional method. In this section, the random projection method is extended to the two space dimensional problem (1.4)–(1.7). For simplicity, we consider the detonation waves in a two-dimensional channel. Let the initial data be

$$(\rho(x,y,0),u(x,y,0),v(x,y,0),p(x,y,0),z(x,y,0)) = \begin{cases} (\rho_l,u_l,0,p_l,0) & \text{if } x \le \xi(y), \\ (\rho_r,u_r,0,p_r,1) & \text{if } x > \xi(y), \end{cases} \tag{3.1}$$

where $\xi(y)$ is a given function of y and these data are chosen such that the detonation moves to the right. Let

$$\theta_n = (T_l - T_r)\vartheta_n + T_r, \qquad T_l = \frac{p_l}{\rho_l}, \qquad T_r = \frac{p_r}{\rho_r} \tag{3.2}$$

with ϑ_n (see (2.9) for detail) being the van der Corput sampling sequence on the interval $[0,1]$.

Let the grid points $(x_i,y_j) = (ih,jh)$, $i,j = \cdots,-1,0,1,\ldots$, with equal mesh spacing h. The time level $t_n = nk$, $k = 0,1,2,\ldots$, are also uniformly spaced with time step k. Let $U^n_{i,j} = \left(\rho^n_{i,j}, m^n_{i,j}, n^n_{i,j}, e^n_{i,j}, (\rho z)^n_{i,j}\right)$ be the approximate solution of $U = (\rho,m,n,e,(\rho z))$ at $(x_i,y_j,t_n) = (ih,jh,nk)$. Let $S_{FG}(k)$ be a standard shock capturing method for (1.4). Notice that, at any time step, for each j, there is an $l_j(n) = j_n$, j_n an integer such that

$$z^n_{i,j} = \begin{cases} 0 & \text{if } j \le l_j(n), \\ 1 & \text{if } i > l_j(n). \end{cases} \tag{3.3}$$

Here, $l_j(n)$ is the location of the jump for z at the grid line $y = y_j$ in the approximate solution at time $t_n = nk$. Then the random project algorithm to find z^{n+1} is as follows:

```
$S_{2p}(k)$ :  For $j$ do
                   Set $l_j(n+1) := l_j(n) - 1$,
                   For $l = l_j(n)-1, l_j(n), \ldots, l_j(n)+d$, do
                       $l_j(n+1) := l$   if $T^{n+1}_{l,j} > \theta_n$;
```

$$z^{n+1}_{i,j} = \begin{cases} 0 & \text{if } i \le l_j(n+1) \\ 1 & \text{if } i > l_j(n+1) \end{cases} \qquad \text{for all } i. \tag{3.4}$$

The stability condition for this algorithm is still the usual CFL condition determined from the convection step $S_{FG}(k)$.

Although the above algorithm is written for a detonation traveling in the direction of the x-axis, little additional effort is needed to extend it to more general cases where the detonation front moves toward all possible directions. One such example is given in the next section (Example 4.8) where the detonation is advancing in circular direction.

4. Numerical examples. In order to verify the performance of the random projection method proposed in this paper, we conduct extensive numerical experiments, including the C-J detonation, strong detonation, collision of a detonation with a shock, a rarefaction wave, and another detonation. We also give two-dimensional examples. In our computation, the operators $S_F(k)$ and $S_{FG}(k)$ are chosen as the second order relaxed scheme [17], which is a TVD scheme without the usage of Riemann solvers or local characteristic decompositions. We choose $d = 5$ in (2.10), (2.15), (2.20), and (3.4) in our computations in this section.

In this section, we compare our numerical results with the resolved solutions. The resolved ones are obtained by solving (1.1)–(1.3) with Heaviside kinetics with a fractional step approach that consists of a second order relaxed scheme for the homogeneous part in (1.1) for one time step, followed by an implicit backward Euler scheme for the chemical reaction. One can see the details in [1] and [11]. Resolved computations based on the Arrhenius kinetics vary only the detailed structure of the reaction zones, so it will not be reported here since the goal of the paper is not to get the accurate reaction zone but all the macroscopic structures outside the reaction zone.

Example 4.1 (C-J detonation). This is Example 4.1 in [1] revisited. We choose here the case of ozone decomposition C-J detonation discussed and computed in [9] and [4]. We use CGS units and the following parameter values:

$$\gamma = 1.4, \qquad q_0 = 0.5196 \times 10^{10}, \qquad \frac{1}{\varepsilon} = K = 0.5825 \times 10^{10}, \qquad T_c = 0.1155 \times 10^{10}.$$

The initial data are taken as the piecewise constant data defining a C-J detonation as a single wave. (Recall that in the C-J model a C-J detonation corresponds to a sonic detonation, or, in other words, a sharp reaction wave that moves at minimal speed relative to the unburnt gas.) The reaction rate K in all the examples is irrelevant for the projection method but is needed for the resolved calculations. The initial state was given by

$$(\rho, u, p, z)(x, 0) = \begin{cases} (\rho_l, u_l, p_l, 0) & \text{if } x \le 0.005, \\ (\rho_r, u_r, p_r, 1) & \text{if } x > 0.005, \end{cases}$$

where $p_l = p_{CJ} = 6.270 \times 10^6$, $\rho_l = \rho_{CJ} = 1.945 \times 10^{-3}$, $u_l = u_{CJ} = 4.162 \times 10^4$; and $p_r = 8.321 \times 10^5$, $\rho_r = 1.201 \times 10^{-3}$, $u_r = 0$. The speed of the sharp front in this example is $D = D_{CJ} = 1.088 \times 10^5$. In this example, the width of the reaction zone is approximately 5×10^{-5} [4], [9]. This width is irrelevant for the underresolved calculation but is used for the resolved calculation and for a comparison with the mesh size to check whether the calculation is resolved or underresolved.

This problem is solved on the interval $[0, 0.05]$. The "exact" solution is obtained by using a resolved calculation with $h = 5 \times 10^{-6}$ (i.e., 10001 grid points on the interval $[0, 0.05]$) and $k = 5 \times 10^{-12}$. The mesh size and time step resolve the chemical scale. Now we compare the results obtained by the random projection method and the deterministic method when the reaction scale is underresolved. We use $h = 5 \times 10^{-4}$ (i.e., 101 grid points for the interval $[0, 0.05]$) and $k = 5 \times 10^{-10}$ and output the numerical solution at $t = 2 \times 10^{-7}$.

Figure 4.1(a) shows the numerical solution by using the random projection method (2.10), while Figure 4.1(b) shows the numerical solution obtained by the deterministic method. It can be seen that the random projection method can capture the correct speed of the discontinuity of the C-J detonation wave even when the chemical reaction scale is not numerically resolved. As mentioned earlier, with an underresolved method it is impossible to capture the pressure spike which has a width in the order of reaction scale ε. There are small postshock statistical fluctuations due to the random nature of the method, but they are at an acceptable level. The deterministic method produces spurious waves, as was observed in earlier literatures.

In all of the following examples, the deterministic method always produces spurious waves when the chemical scale is not resolved. We will not report those results and will present only the solutions obtained by the random projection method.

Example 4.2 (a strong detonation). This is Example 4.3 in [1] revisited. The setup of this example is similar to those in Example 4.1 (i.e., γ, q_0, $K = \frac{1}{\varepsilon}$, and T_c are the same), except that the initial data are changed to

$$(\rho, u, p, z)(x, 0) = \begin{cases} (\rho_l, u_l, p_l, 0) & \text{if } x \le 0.005, \\ (\rho_r, u_r, p_r, 1) & \text{if } x > 0.005, \end{cases}$$

where $u_l = 9.162 \times 10^4 > u_{CJ}$, $\rho_l = \rho_{CJ}$, $p_l = 8.27 \times 10^6 > p_{CJ}$, and p_r, u_r, ρ_r, p_{CJ}, u_{CJ}, and ρ_{CJ} are the same as those in Example 4.1. In this case there is a strong detonation, a contact discontinuity, and a shock, all moving to the right.

The "exact" solution is obtained similarly as that in Example 4.1. Figure 4.2

FIG. 4.1 (*cont.*). (b) *The deterministic method.*

shows the numerical solutions by the random projection method (2.10) with $h = 5 \times 10^{-4}$ (i.e., 101 grid points for the interval $[0, 0.05]$) and $k = 5 \times 10^{-10}$ at time $t = 2 \times 10^{-7}$.

Example 4.3 (collision of a detonation with a rarefaction wave). We choose $\gamma = 1.2$, $q_0 = 50$, $T_c = 3.0$, and $\frac{1}{\varepsilon} = K = 230.75$. The data are taken from [16]. The initial state was given by

$$(\rho, u, p, z)(x, 0) = \begin{cases} (\rho_l, u_l, p_l, 0) & \text{if } x \leq 10, \\ (\rho_m, u_m, p_m, 0) & \text{if } 10 < x \leq 20, \\ (\rho_r, u_r, p_r, 1) & \text{if } 20 < x, \end{cases}$$

where $p_l = 40.0$, $\rho_l = 2.0$, $u_l = 4.0$; $p_m = 54.8244$, $\rho_m = 3.64282$; $u_m = 6.2489$; and

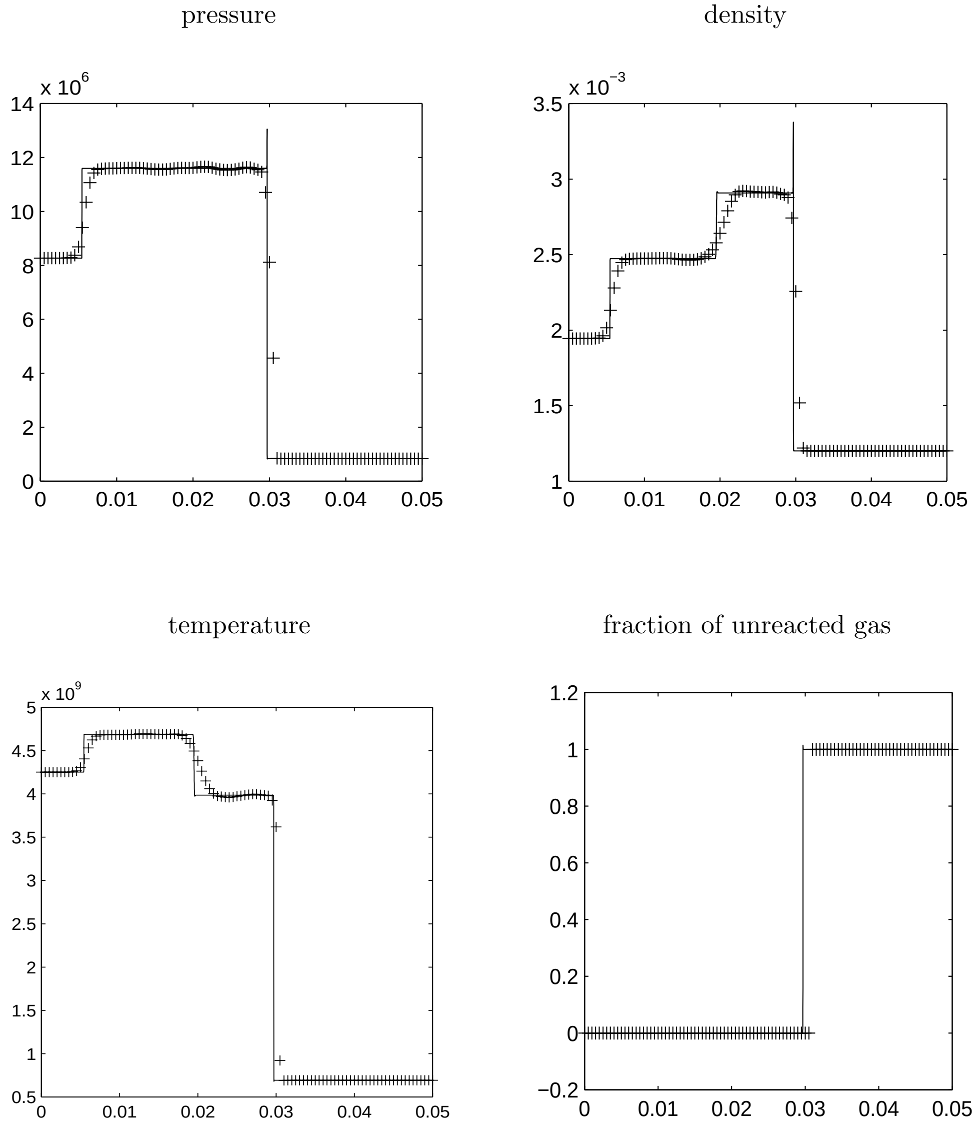

FIG. 4.2. *Numerical results at $t = 2 \times 10^{-7}$ for a strong detonation in Example* 4.2 *calculated by the random projection method* (2.10). $h = 5 \times 10^{-4}$*,* $k = 5 \times 10^{-10}$*. −: "exact" solutions; ++: computed solutions.*

$p_r = 1.0$, $\rho_r = 1.0$, $u_r = 0$. By selecting these data, the "half reaction length" $L_{\frac{1}{2}}$ is the spatial unit 1 [16]. This number is used to compare the mesh sizes in resolved and underresolved numerical experiments.

In this example, there is a right moving detonation, a right moving rarefaction wave, a right moving contact discontinuity, and a left moving rarefaction wave before the right moving rarefaction catches the detonation wave.

This problem is solved on the interval $[0, 100]$. The "exact" solution is obtained by using a resolved calculation $h = 0.005$ (i.e., 20001 grid points on the interval $[0, 100]$) and $k = 0.00025$.

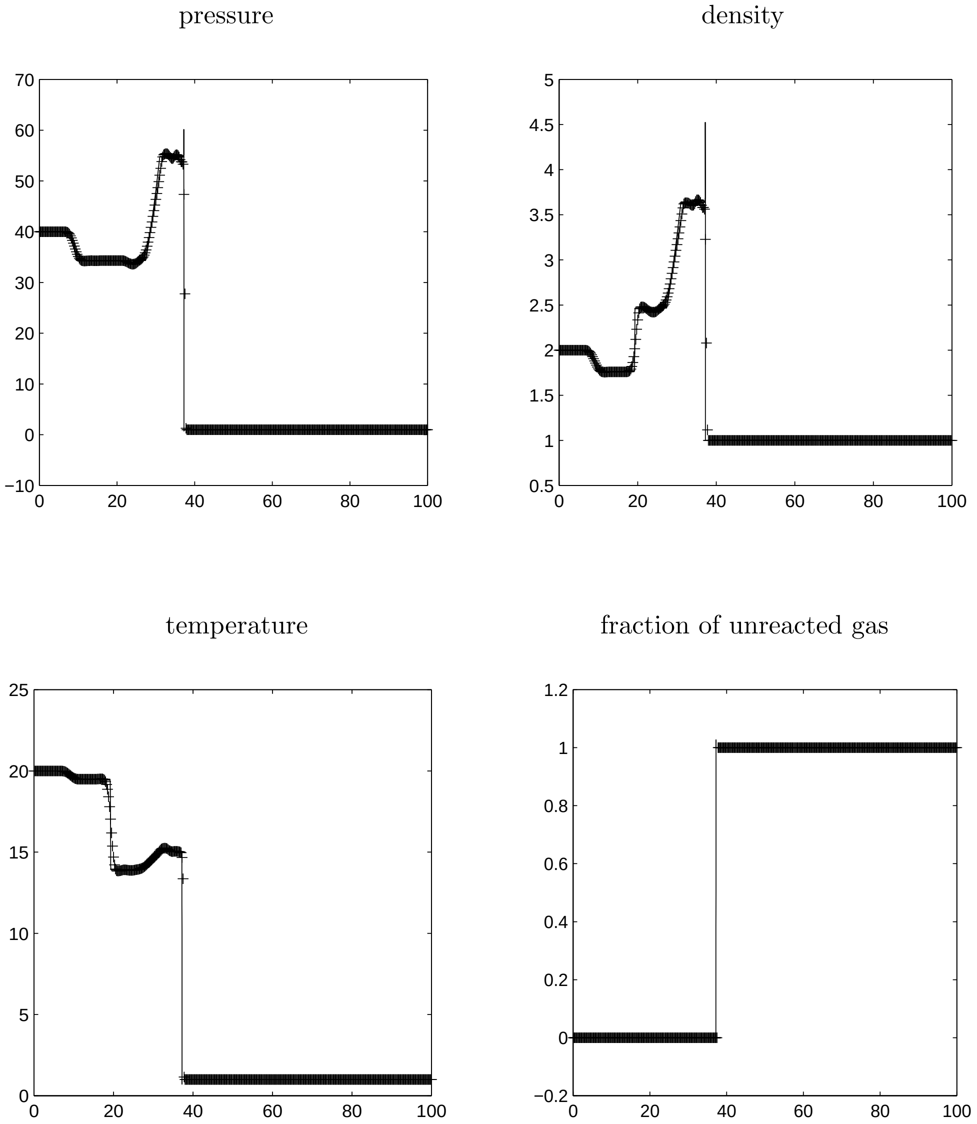

FIG. 4.3. *Numerical results of Example* 4.3 *involving the collision of a detonation with a rarefaction wave using the random projection method* (2.10). $h = 0.25$, $k = 0.01$. $-$: *"exact" solutions;* $++$: *computed solutions.* (a) $t = 2$ *(before collision).*

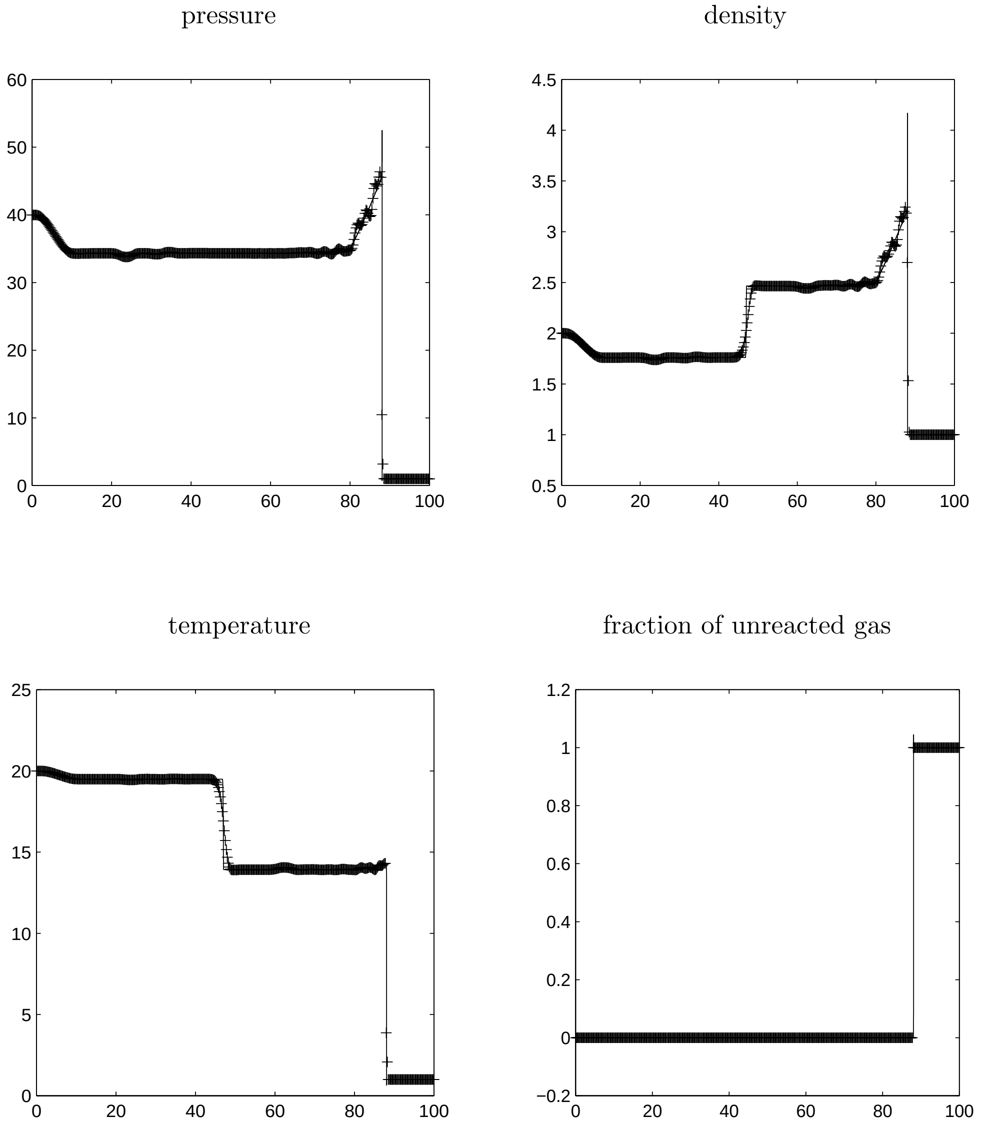
Figure 4.3 shows the numerical solution by using the random projection method (2.10) with $h = 0.25$ (i.e., 401 grid points for the interval $[0, 100]$) and $k = 0.01$ at time $t = 2$ (before collision) and $t = 8.0$ (after collision), respectively. After the collision, there are some small downstream wiggles which are numerical artifacts and do not appear in the resolved calculation.

Example 4.4 (a detonation interacting with an oscillatory profile). The setup of this problem is similar to those in Example 4.3 (i.e., γ, q_0, and T_c are the same),



pressure

density

temperature

fraction of unreacted gas

FIG. 4.3 (*cont.*). (b) $t = 8$ *(after collision).*

except that we change $K = 1000.0$ and the initial data to

$$(\rho, u, p, z)(x, 0) = \begin{cases} (\rho_l, u_l, p_l, 0) & \text{if } x \le \frac{\pi}{2}, \\ (\rho_r(x), u_r, p_r, 1) & \text{if } \frac{\pi}{2} < x, \end{cases}$$

where $p_l = 21.53134$, $\rho_l = 1.79463$, $u_l = 3.0151$; and $p_r = 1.0$, $\rho_r(x) = 1.0 + 0.5 \sin 2x$, $u_r = 0$.

This problem is solved on the interval $[0, 2\pi]$. The "exact" solutions are obtained by using $h = \frac{\pi}{10000}$ (i.e., 20001 grid points on the interval $[0, 2\pi]$) and $k = \frac{h}{20}$. This is a resolved calculation.

Figure 4.4 shows the numerical solutions by using the random projection method (2.10) with $h = \frac{\pi}{400}$ (i.e., 801 grid points for the interval $[0, 2\pi]$) and $k = \frac{h}{20}$ at time

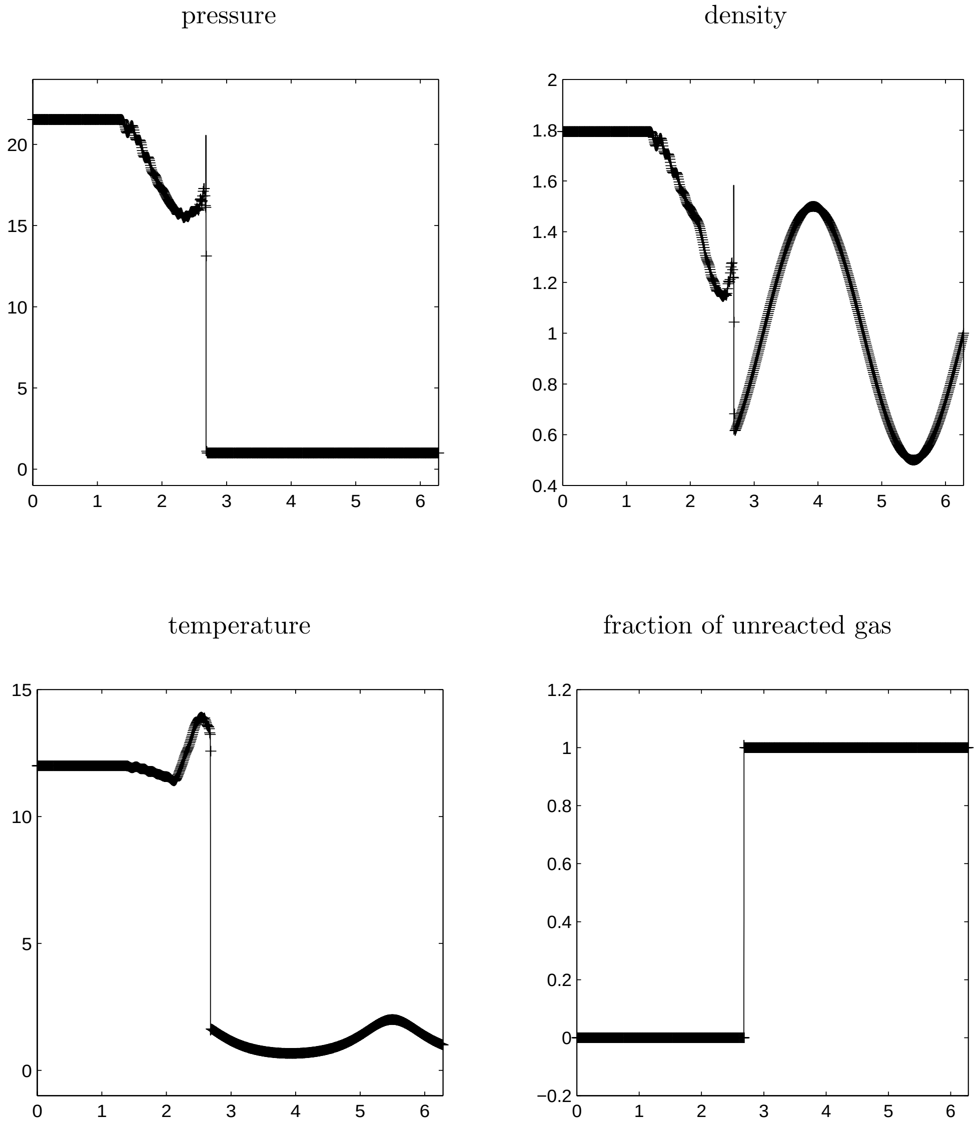


FIG. 4.4. *Numerical results of Example* 4.4 *by the random projection method* (2.10). $h = \frac{\pi}{400}$, $k = \frac{h}{20}$. $-$: *"exact" solutions;* $++$: *computed solutions.* (a) $t = \frac{\pi}{20}$.

$t = \frac{\pi}{20}$ and $t = \frac{\pi}{5}$, respectively.

Example 4.5 (collision of a detonation with a shock, a contact discontinuity, and a rarefaction). The setup of this problem is similar to those in Example 4.3 (i.e., γ, q_0, $K = \frac{1}{\varepsilon}$, and T_c are the same), except that we change the initial data to

$$(\rho, u, p, z)(x, 0) = \begin{cases} (\rho_l, u_l, p_l, 0) & \text{if } x \le 10, \\ (\rho_m, u_m, p_m, 1) & \text{if } 10 < x \le 40, \\ (\rho_r, u_r, p_r, 1) & \text{if } 40 < x, \end{cases}$$

where $p_l = 54.8244$, $\rho_l = 3.64282$, $u_l = 6.2489$; $p_m = 1.0$, $\rho_m = 1.0$, $u_m = 0.0$; and $p_r = 10.0$, $\rho_r = 4.0$, $u_r = 0$.

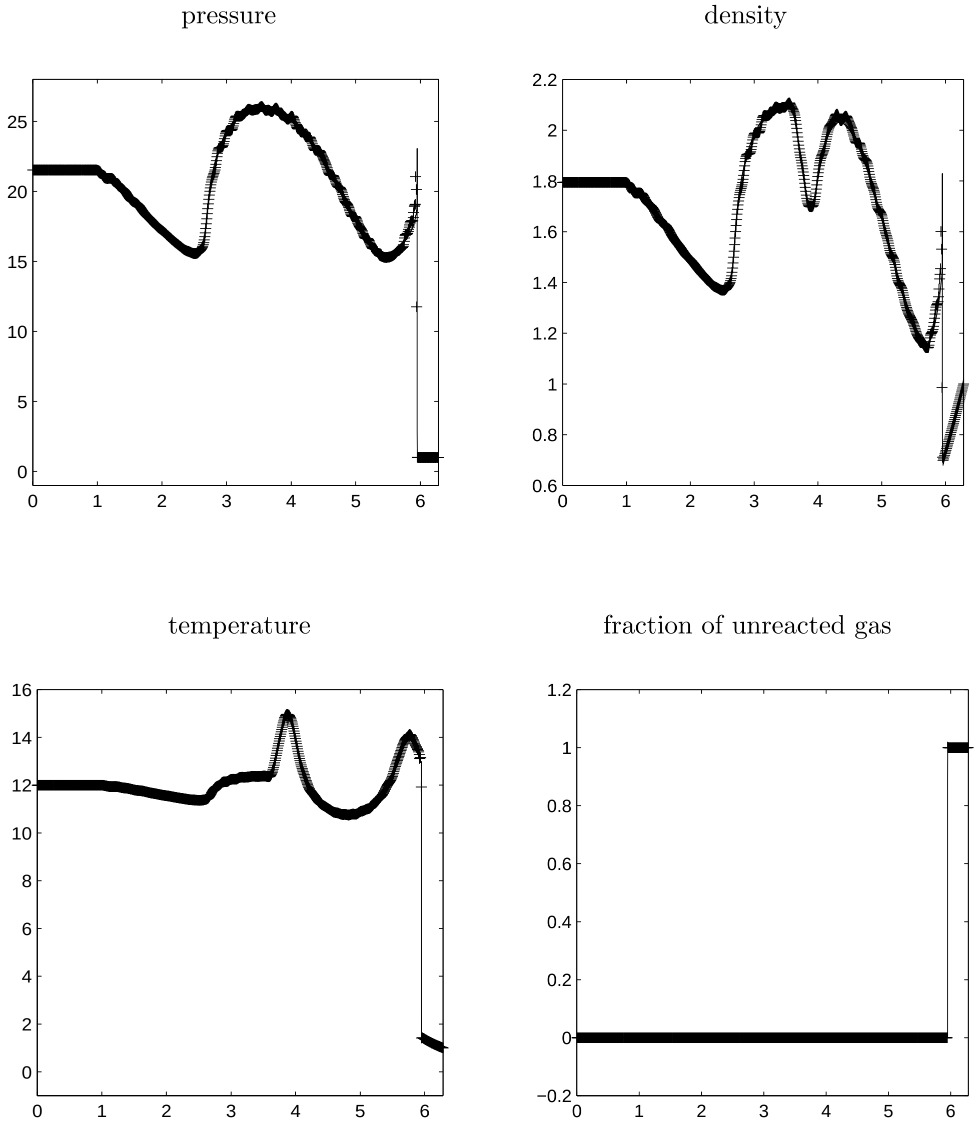

FIG. 4.4 (*cont.*). (b) $t = \frac{\pi}{5}$.

In this example, there is a right moving detonation, a right moving rarefaction, a stationary contact discontinuity, and a left moving shock before a series of collisions occur after the detonation catches up with the other waves.

The "exact" solution is obtained similarly as that in Example 4.3. Figures 4.5(a)–(c) show the numerical solution by using the random projection method (2.10) with $h = 0.125$ (i.e., 801 grid points for the interval $[0, 100]$) and $k = 0.005$ at time $t = 2$ (before collision) $t = 4$ (between the collisions with the shock and with the rarefaction), and $t = 8.0$ (after all collisions), respectively.

This example shows that the random projection method is able to handle the interactions between the detonation and all other waves of a compressible gas.

Example 4.6 (collision of two detonations). The setup in this example is similar

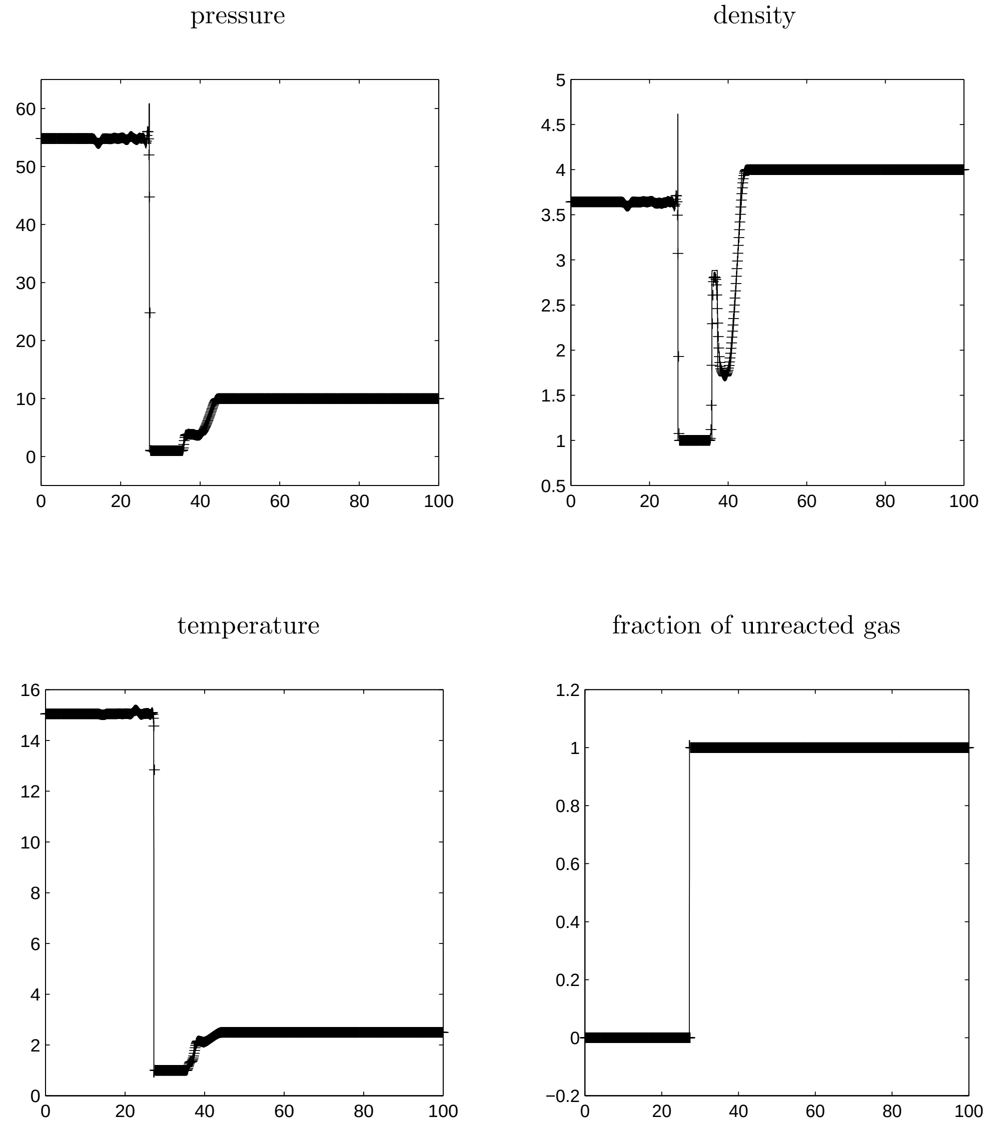

FIG. 4.5. *Numerical results of Example* 4.5 *involving the collisions of a detonation with a shock and then a rarefaction wave by the random projection method* (2.10). $h = 0.125$*,* $k = 0.005$. $-$: *"exact" solutions;* $++$: *computed solutions.* (a) $t = 2$ *(before collision).*

to those in Example 4.3 (i.e., γ, q_0, $K = \frac{1}{\varepsilon}$, and T_c are the same), except that we change the initial data to

$$(\rho, u, p, z)(x, 0) = \begin{cases} (\rho_l, u_l, p_l, 0) & \text{if } x \le 10, \\ (\rho_m, u_m, p_m, 1) & \text{if } 10 < x < 90, \\ (\rho_r, u_r, p_r, 0) & \text{if } 90 \le x, \end{cases}$$

where $p_l = 30.0$, $\rho_l = 1.79463$, $u_l = 3.0151$; $p_m = 1.0$, $\rho_m = 1.0$, $u_m = 0.0$; and $p_r = 21.53134$, $\rho_r = 1.79463$, $u_r = -8.0$.

In this example, there is a right moving detonation, a left moving strong det-

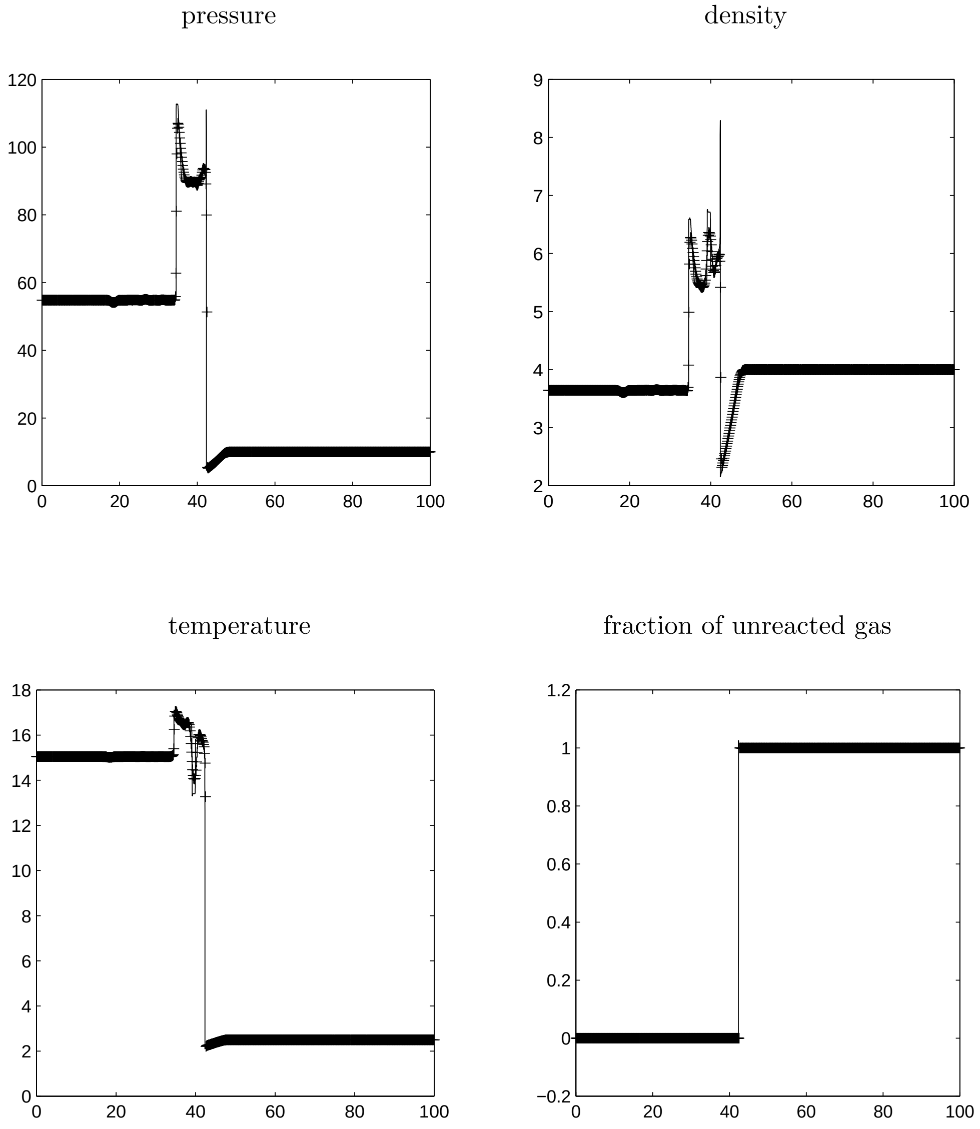

FIG. 4.5 (*cont.*). (b) $t = 4$ *(between the collisions with the shock and the rarefaction).*

onation, and other waves. After some time, there is a collision between the two detonations.

The "exact" solution is obtained similarly as that in Example 4.3. Figure 4.6 shows the numerical solution by using the random projection method (2.15) with $h = 0.25$ (i.e., 401 grid points for the interval $[0, 100]$) and $k = 0.01$ at time $t = 4$ (before collision) and $t = 6.0$ (after collision), respectively. After the collisions, the detonation becomes extinct and two shocks are formed. This example shows that the random projection is valid even after the detonation disappears.

From the above examples, we can see that the random projection method works very well for one-dimensional detonation wave problems even if the reaction scale is not numerically resolved. It not only captures the correct speeds of detonations but

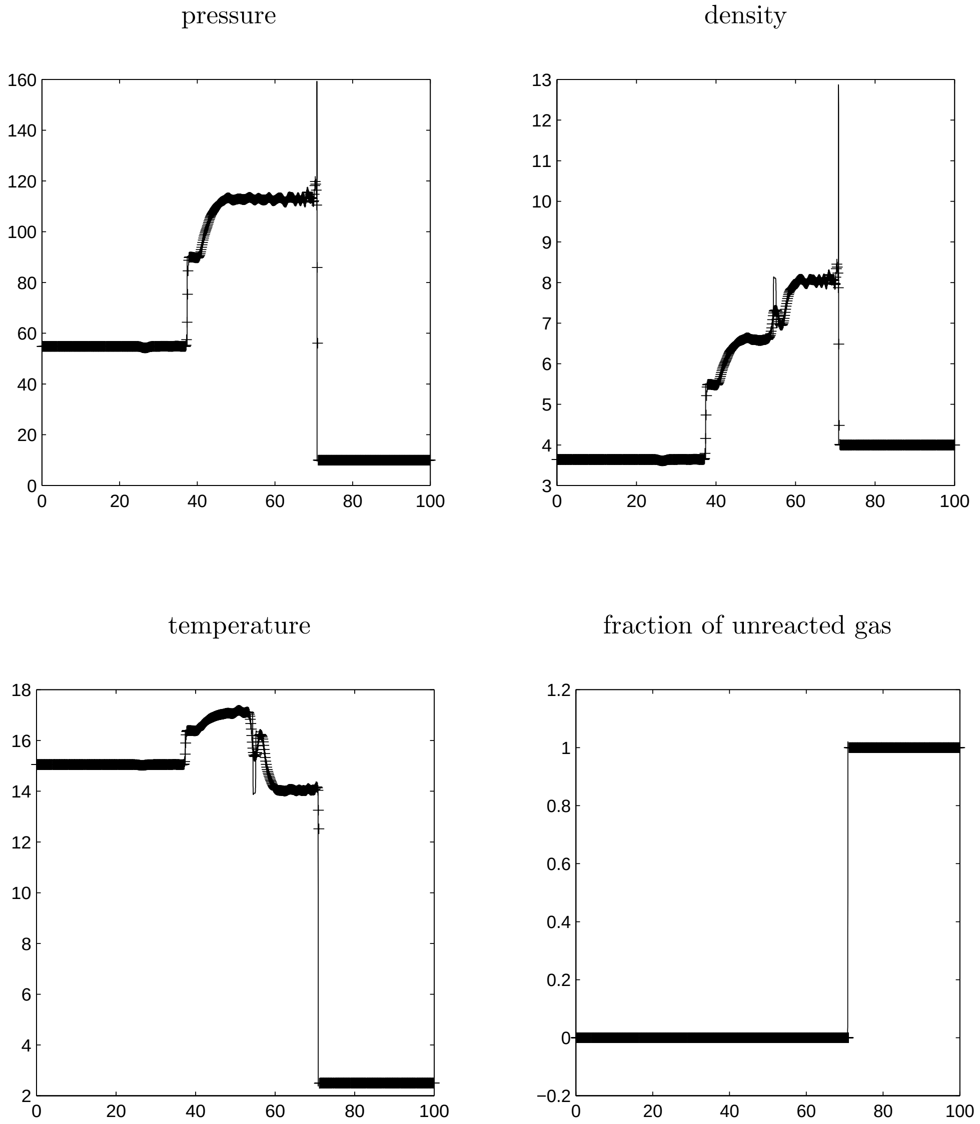

FIG. 4.5 (*cont.*). (c) $t = 8$ *(after all collisions).*

also is able to handle the interactions between detonations and between a detonation with other waves of a compressible gas. Its applicability remains after the extinction of the detonation.

Example 4.7 (a two-dimensional circular detonation front). We consider the problem (1.4)–(1.7) in a two-dimensional channel; the upper and lower boundaries are solid walls. We choose γ, q_0, $K = \frac{1}{\varepsilon}$, and T_c the same as those in Example 4.3. The initial data (3.1) are chosen as $p_l = 54.8244$, $\rho_l = 3.64282$, $u_l = 6.2489$, $v_l = 0.0$; and $p_r = 1.0$, $\rho_r = 1.0$, $u_r = 0.0$, $v_r = 0.0$. The corresponding initial setup in one dimension is a strong detonation. This problem is solved on $[0, 300] \times [0, 50]$ with a

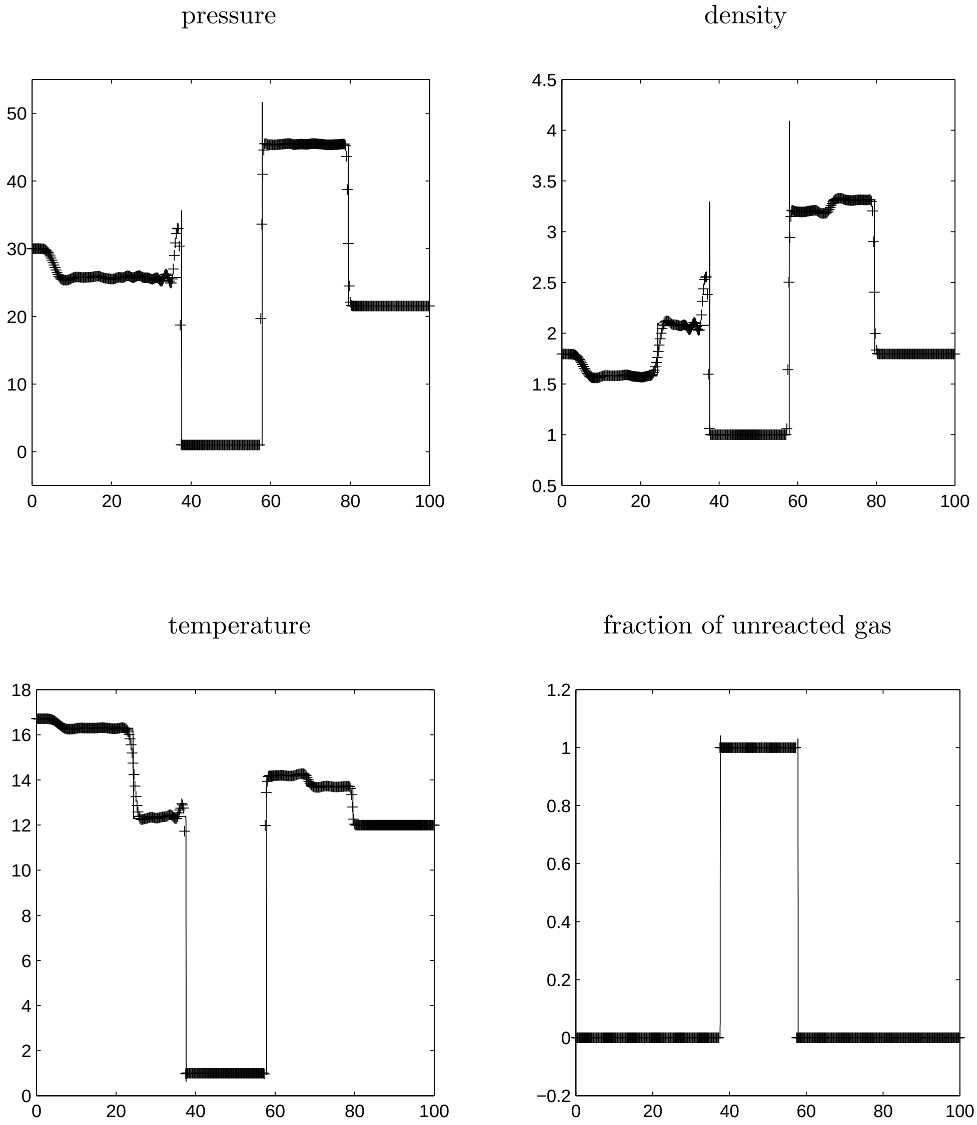

FIG. 4.6. *Numerical results of Example* 4.6 *involving the collision of two detonations by the random projection method* (2.15)*.* $h = 0.25$*,* $k = 0.01$*.* $-$: *"exact" solutions;* $++$: *computed solutions.* (a) *at* $t = 4$ *(before collision).*

301×51 mesh, and

$$\xi(y) = \begin{cases} 10, & |y-25| \geq 15, \\ 25 - |y-25|, & |y-25| < 15. \end{cases}$$

Thus the mesh size $h = 1$. The time step is chosen as $k = 0.01$.

Figure 4.7 shows density contours at several different times. One can see that the triple points, which are the important features of the solution, travel in the transverse direction and bounce back and forth against the upper and lower walls. On the con-

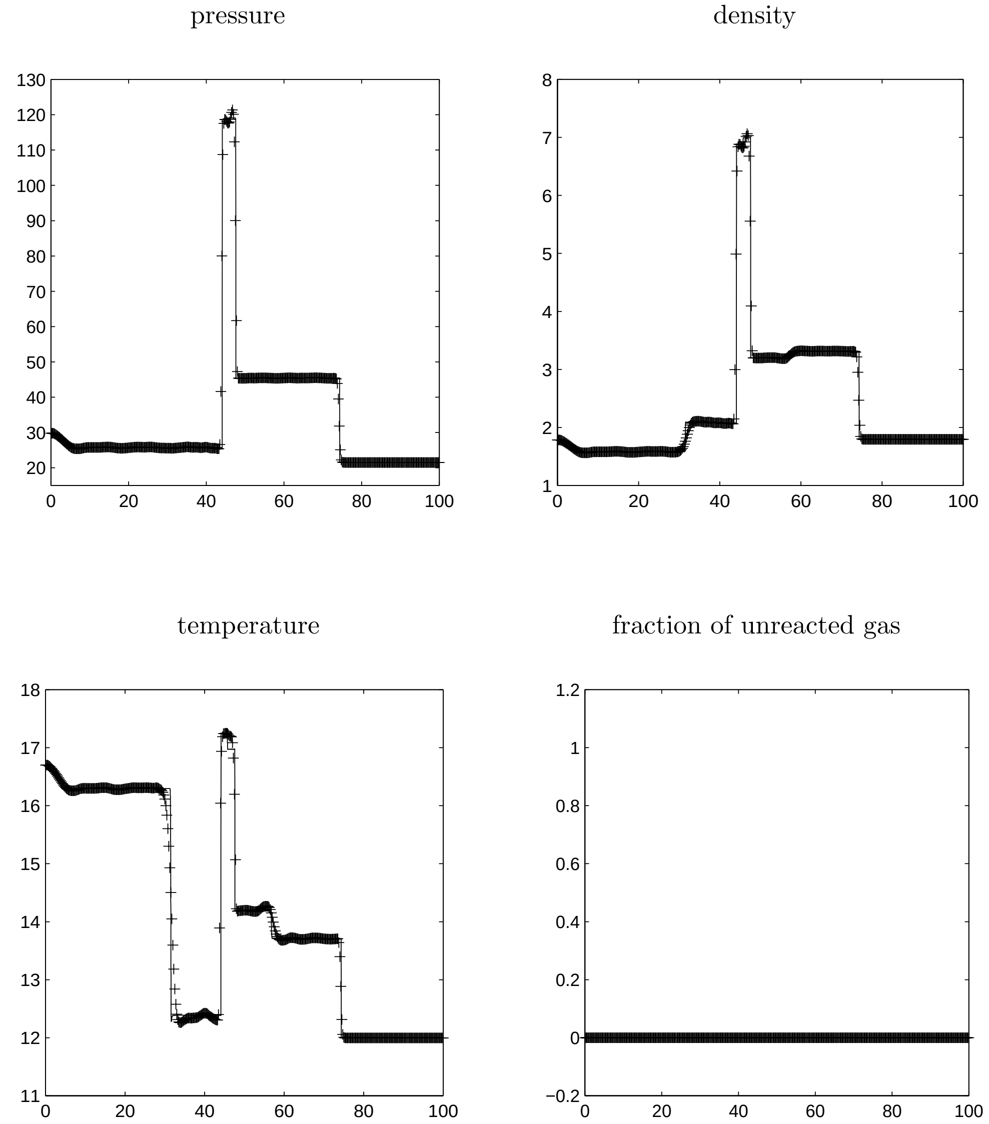

FIG. 4.6 (*cont.*). (b) *at $t = 6$. After collision the detonation becomes extinct and the gas is completely burned.*

trary, the triple points cease to move after some time by using the usual deterministic method [11].

Example 4.8 (another two-dimensional detonation wave). This is a two-dimensional example with radial symmetry. The parameters are chosen as

$$\gamma = 1.2, \qquad q_0 = 50, \qquad K = \frac{1}{\varepsilon} = 1000, \qquad \text{and} \qquad T_c = 2.0.$$

A similar example was used in [15].

The initial values consist of totally burnt gas inside of a circle with radius 10 and totally unburnt gas everywhere outside of the circle. Furthermore, the unburnt and burnt states are chosen in a way analogous to the one-dimensional case, i.e.,

$$(\rho, u, v, p, z)(x, y, 0) = \begin{cases} (\rho_l, u_l(x, y), v_l(x, y), p_l, 0) & \text{if } r \leq 10, \\ (\rho_r, u_r, v_r, p_r, 1) & \text{if } r > 10, \end{cases}$$

where $r = \sqrt{x^2 + y^2}$; $p_l = 21.53134$, $\rho_l = 1.79463$, $u_l(x, y) = 10x/r$, $v_l(x, y) = 10y/r$; and $p_r = 1.0$, $\rho_r = 1.0$, $u_r = 0.0$, $v_r = 0.0$.

This is a radially symmetric problem, and the important feature is that the detonation front is circular. This problem is solved on the domain $[-50, 50] \times [0, 50]$ with mesh size $h = 0.5$ and time step $k = 0.01$. Solid wall boundary conditions are used along $x = 0$. Inflow boundary condition is used along $x = -50$. Outflow boundary conditions are used along $x = 50$ and $y = 50$.

The random projection algorithm for this example is as follows. Notice that at any time step $t = t_n$, for each j, there are two integers, $l_j(n) = l_n$ and $r_j(n) = r_n$, such that $l_n \leq r_n$ and

$$z_{i,j}^n = \begin{cases} 1 & \text{if } j \leq l_j(n), \\ 0 & \text{if } l_j(n) < j < r_j(n), \\ 1 & \text{if } i \geq r_j(n). \end{cases} \tag{4.1}$$

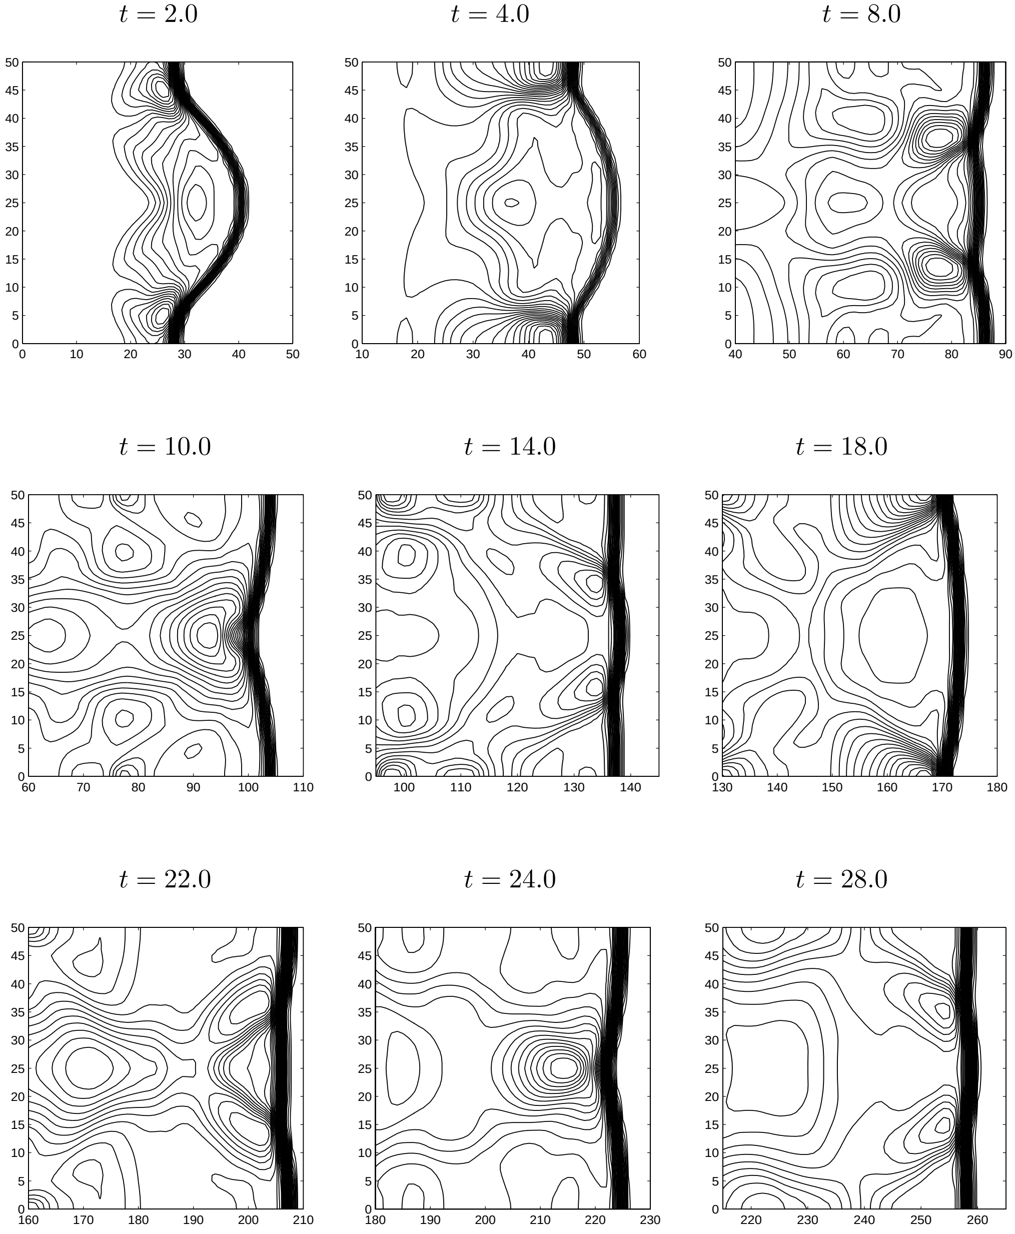
Here $l_j(n)$ and $r_j(n)$ are the left and right locations of the jump for z at the grid line $y = y_j$ in the approximate solution at time $t_n = nk$. Then the random project algorithm to find z^{n+1} is as follows:

```
$\tilde{S}_{2p}(k)$ :  For $j$ do
        Set $l_j(n+1) := l_j(n) + 1$,
        For $l = l_j(n) + 1, l_j(n), \ldots, l_j(n) - d$, do
            $l_j(n+1) := l$   if $T_{l,j}^{n+1} > \theta_n$,
        Set $r_j(n+1) := r_j(n) - 1$,
        For $r = r_j(n) + 1, r_j(n), \ldots, r_j(n) + d$, do
            $r_j(n+1) := r$   if $T_{r,j}^{n+1} > \theta_n$,
        If $l_j(n+1) > r_j(n+1)$ then
            $l_j(n+1) := r_j(n+1) := (l_j(n+1) + r_j(n+1))/2$,
```

$$z_{i,j}^{n+1} = \begin{cases} 1 & \text{if } i \leq l_j(n+1) \\ 0 & \text{if } l_j(n+1) < i < r_j(n+1) \\ 1 & \text{if } i \geq r_j(n+1) \end{cases} \quad \text{for all } i. \tag{4.2}$$

The stability condition for this algorithm is still the usual CFL condition determined from the convection step.

Figure 4.8(a) shows the velocity fields and Figure 4.8(b) shows profiles of the pressure p, temperature T, and 30 times the mass fraction of unburnt gas, $30z$ (here we show $30z$, not z itself, for better visualization), on the line $y = x$ ($0.0 \leq x \leq 50$) by the random projection method (4.2) at time $t = 1$, $t = 2$, $t = 4$, and $t = 5$, respectively.



$t = 2.0$ $t = 4.0$ $t = 8.0$

$t = 10.0$ $t = 14.0$ $t = 18.0$

$t = 22.0$ $t = 24.0$ $t = 28.0$

FIG. 4.7. *Numerical density contours for Example* 4.7 *by the two-dimensional random projection method* (3.4). $h = 1.0$, $k = 0.01$.

It can be seen that the detonation front remains circular, and no spurious nonphysical wave is generated when using the random projection method (4.2). On the other hand, if one uses the deterministic method, the detonation front does not remain circular, and spurious nonphysical wave is generated if the same grid size and time step are used.

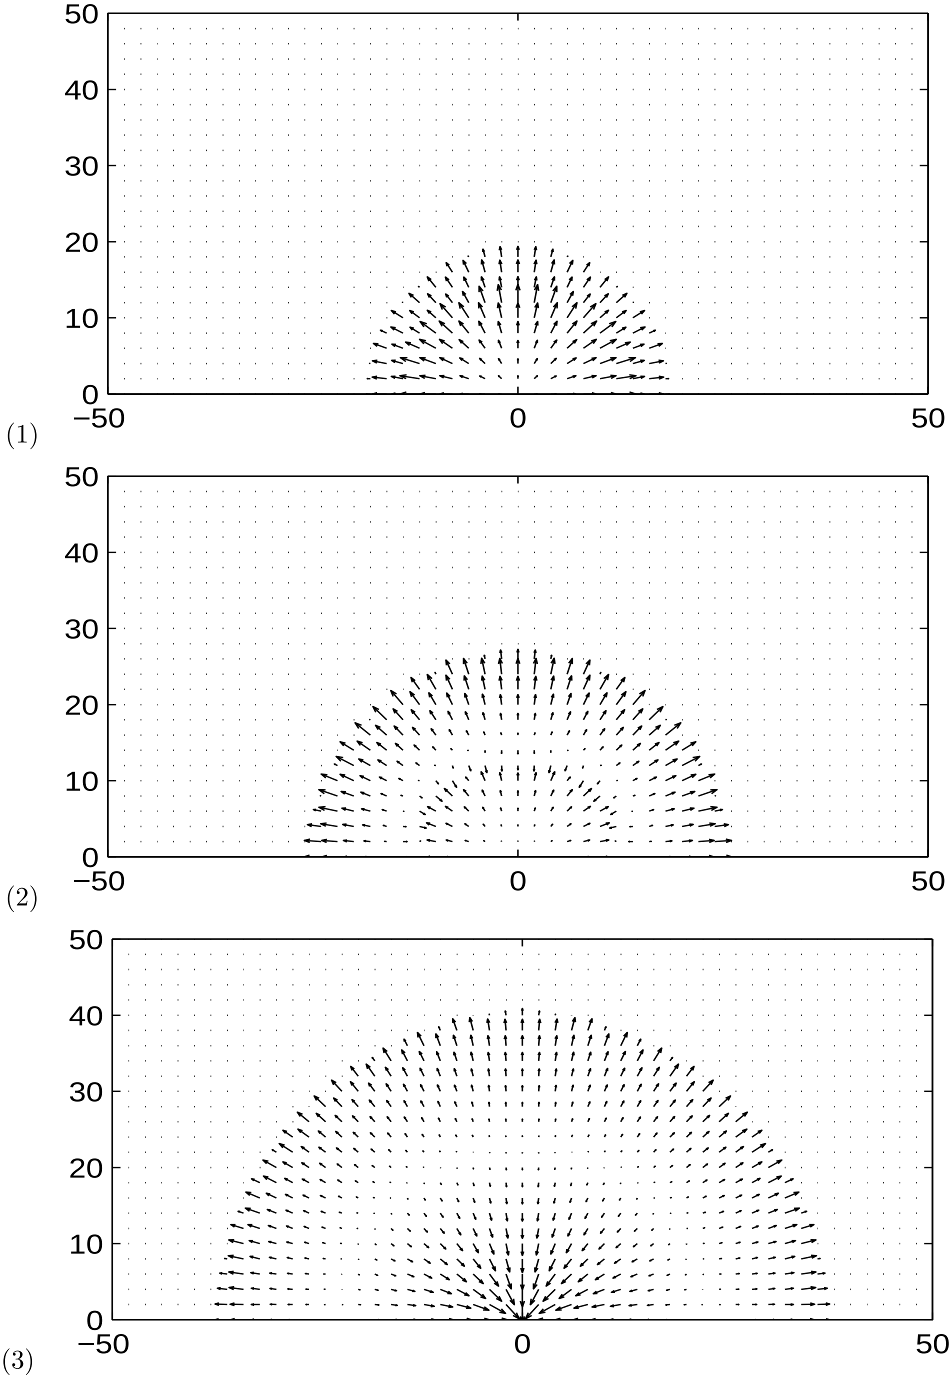


FIG. 4.8. *Numerical solutions of Example* 4.8 *calculated by the two-dimensional random projection method* (4.2) *with* $h = 0.5$, $k = 0.01$. (1): $t = 1.0$, (2): $t = 2.0$, (3): $t = 4.0$. (a) *Velocity fields at different times.*

5. Conclusions.

In this paper we presented a simple and robust random projection method for underresolved numerical simulation of stiff detonation waves in chemically reacting flows. This method is based on the random projection method proposed by the authors for general hyperbolic systems with stiff reaction terms [1], where the ignition temperature is randomized in a suitable domain. The method is simplified using the equations of instantaneous reaction and then extended to handle the interactions of detonations. Extensive numerical experiments, including interaction of detonation waves, and in two dimensions, demonstrate that this method, although very simple and efficient, is very reliable and robust in calculating a wide range of problems in reacting flows.

In [3] this method is generalized to multispecies reactions.

AN INTERPOLATING POLYNOMIAL METHOD FOR NUMERICAL CONFORMAL MAPPING[*]

R. MICHAEL PORTER[†]

Abstract. A simple algorithm is presented for numerical approximation of conformal mappings for simply connected planar regions. The desired mapping is represented by a normalized polynomial of degree N, determined by the boundary values which it is presumed to take at the Nth roots of unity; then its values at the N intermediate $2N$th roots of unity are used to correct the initial guess. Each iteration, which consists essentially of matrix multiplication and boundary projection, costs $O(N \log N)$ arithmetic operations. Numerical results are provided to confirm linear convergence of the algorithm.

1. Introduction.

We present here a method for calculating boundary values of conformal mappings from the unit disk D_0 to simply connected planar domains D. Following the notation of [4], suppose that the boundary ∂D is parametrized by the simple closed curve $\gamma : [0, L] \to \mathbb{C}$ and that the Riemann mapping $f : D_0 \to D$, normalized by $f(0) = 0$ (and perhaps $f'(0) > 0$ or $f(1) = w_0$), sends the Nth roots of unity $(\zeta_N)^j$ to $w_j \in \partial D$. We wish to compute the w_j, or, equivalently, the values $\sigma_0, \dots, \sigma_{N-1}$ such that $\gamma(\sigma_j) = w_j$. As is well known, f is determined in the interior of the domain D by its boundary values (see [1], [10]).

The method derived here resembles in some ways that given by Fornberg in [6]. In Fornberg's method, the starting boundary data, given by an N-tuple of purported image points $\vec{w}^* = (w_j^*)$, determine the set of Fourier coefficients of a boundary function $\zeta_N^j \mapsto w_j^*$, and equations are derived for replacing w_j^* with the true values w_j, characterized by the property that the Fourier coefficients with negative indices all vanish. When this is accomplished, the corresponding Laurent series is a polynomial and gives an approximation to f.

In our method, in contrast, we start with the interpolating polynomial $P = P_{\vec{w}^*}$ of degree N defined by $P(0) = 0$, $P(\zeta_N^j) = w_j^*$. The criterion we use to adjust the values of w_j^* is that P *should send the remaining* $2N$*th roots of unity,* $\zeta_N^{j+(1/2)}$ *onto the curve* γ *as well.*

Interpolating polynomials were studied by Wegmann [13]. There it is shown that for ∂D sufficiently smooth and for N sufficiently large, there is a unique (suitably normalized) polynomial of degree $N+1$ close to f which takes the $2N$th roots of unity to points cyclicly ordered along ∂D. These polynomials approach f as $N \to \infty$. Two algorithms were derived there for approximating these polynomials. The method we give here (together with several variants) is much simpler than the aforementioned one: each iteration consists of two multiplications by fixed matrices (alternatively,

four discrete Fourier transforms) and two projections to ∂D of the N-tuples thus obtained.

Although faster methods than that of [6] have been developed, we use an example given there for the purpose of numerical comparison, since that example is well known and there exist in the literature comparisons of that method with others. (See, for example, [11], [12] for calculations with methods by Fornberg, Theodorsen, and Wegmann, each of which proves superior in certain instances.) Further, this example is an excellent illustration of the problems caused by the well-known "crowding" phenomenon [4], [9], that is, the tendency for $|f'|$ to be much larger at certain parts of ∂D_0 than others, especially, in loose terms, at points which are sent farther from the origin. This causes the images of the grid points to be sparse at some parts of ∂D and heavily concentrated at others, so a large number of grid points is intrinsically required for a good approximation over the whole boundary.

One must bear in mind that the error in approximating f stems from two contributions: the error of our method in approximating P and the degree to which P serves as an approximation to f (as studied in [13]). For an analysis of the inherent error in using a truncated power series in place of f, see [4]. For methods which calculate the inverse mapping $D \to D_0$, see the references in [9], [10]. In many such cases the most appropiate algorithm would be a Schwarz–Christoffel method, such as the excellent algorithm given in [5], which completely eliminates the problem of crowding for polygons.

The method given here is a "boundary method" in the sense that we are not concerned explicitly with the values of $f(z)$ for $0 < |z| < 1$. Some features of our method are the following. For a fixed value of N, linear convergence is observed for most domains. No extra work (e.g., interpolation) is required for doubling the number of grid points. The method produces the image values w_j directly, rather than giving, say, Taylor coefficients (which would then require an additional calculation to find the w_j). Once these image points are found, the values at general boundary points $P(e^{i\beta}\zeta_N^j)$ can be obtained easily via a discrete Fourier transform. The simplicity of the method lends itself to easy programming.

2. Notation and preliminaries. Let the domain D be bounded by the curve $\gamma(\sigma) \in \mathbb{C}$, $0 \le \sigma \le L$, as described in the introduction. For each $\theta \in [0, 2\pi]$ there is $\sigma(\theta) \in [0, L]$ such that $f(e^{i\theta}) = \gamma(\sigma(\theta))$. We can assume that the real-valued function $\sigma(\theta) - \theta$ is continuous and L-periodic. We do not require γ to be parametrized according to arc length. We will need to be able to calculate the projection $\rho_\gamma(w)$ to the boundary ∂D for points w near ∂D. For this it may be helpful to have the complex derivative $\gamma' \neq 0$ available computationally. This would be the case, for instance, if points along the boundary are given numerically and γ is obtained by cubic spline interpolation [3]. As an alternative, one may work with ∂D defined implicitly by an equation $F(x, y) = 0$ and then will need to make only minor adjustments in the following, eliminating explicit mention of γ and σ.

Let the number $N > 1$ of grid points be fixed (normally a power of 2 for efficiency of calulation) and write $\zeta = \zeta_N = \exp(2\pi i/N)$. Given $0 = \sigma_0 < \sigma_1 < \cdots < \sigma_{N-1} < L$, set $w_j = \gamma(\sigma_j)$ and abbreviate $\vec{\zeta} = (\zeta^j) = (1, \zeta, \ldots, \zeta^{N-1})$, $\vec{w} = (w_j) = (w_0, w_1, \ldots, w_{N-1}) \in \mathbb{C}^N$. The interpolating polynomial taking the Nth root of unity $\zeta^j \in \partial D_0$ to w_j and fixing the origin can be expressed as

$$P_{\vec{w}}(z) = \sum_{j=0}^{N-1} Q(\zeta^{-j} z) w_j, \tag{2.1}$$

where

$$Q(z) = \frac{z}{N}\frac{1-z^N}{1-z} \;=\; \frac{1}{N}(z+z^2+\cdots+z^N)$$

is the unique polynomial of degree N satisfying $Q(0)=0$, $Q(1)=1$, $Q(\zeta^j)=0$ for $1 \le j \le N-1$. (Observe that P is not identical to the trigonometric interpolation polynomial as in [8], [9], often given in barycentric form, and which does not fix the origin.)

We will follow the convention in [13] of writing scalar functions applied elementwise to N-tuples when there is no cause for confusion. Thus $P_{\vec{w}}$ is characterized among polynomials of degree $\le N$ fixing the origin by the property $P_{\vec{w}}(\vec{\zeta}) = \vec{w}$.

2.1. Rotation of an *N*-tuple. Fix $\beta \in \mathbb{R}$ and define the "rotated" N-tuple $\vec{w}^{[\beta]} \in \mathbb{C}^N$ by

$$(\vec{w}^{[\beta]})_j = P_{\vec{w}}(\zeta^{j+\beta}) = \sum_k Q(\zeta^{j-k+\beta})w_k = \sum_k R^{[\beta]}_{jk} w_k,$$

where $R^{[\beta]}_{jk} = r^{[\beta]}_{j-k}$ and

$$r^{[\beta]}_j = Q(\zeta^{j+\beta}) = \frac{1}{N}e^{\pi i\beta}(\sin\pi\beta)\left(\cot\left(\frac{\pi}{N}(j+\beta)\right)+i\right) \; . \tag{2.2}$$

(We will always understand subindices of elements of $\mathbb{C}^N$ to be taken modulo N.) Thus $R^{[\beta]} = (R^{[\beta]}_{jk})$ is a *circulant matrix* [2]; that is, its columns are $\vec{r}^{[\beta]}$, $E\vec{r}^{[\beta]}$, $E^2\vec{r}^{[\beta]}, \ldots$, where the shift operator $E : \mathbb{C}^N \to \mathbb{C}^N$ moves the elements cyclically one space forward. The point of these definitions is that we can express

$$\vec{w}^{[\beta]} = R^{[\beta]}\vec{w} \; . \tag{2.3}$$

Since $\vec{w}^{[\beta]}$ can also be interpreted as the convolution $\vec{r}^{[\beta]} * \vec{w}$, we know that it can be evaluated by a fast fourier transform (FFT) (see [8], [9]) implying a computational cost of $O(N\log N)$ multiplications.

The matrix $R^{[\beta]}$ is a smooth function of β of period N. Since the function $z \mapsto P_{\vec{w}}(\zeta^\beta z)$ sends $\vec{\zeta}$ to $\vec{w}^{[\beta]}$, by the characterization of our interpolating polynomials we have $P_{R^{[\beta]}\vec{w}}(z) = P_{\vec{w}}(\zeta^\beta z)$ for all β, $\vec{w}$, and z. Applying this in particular with $\beta+\beta'$ in place of β yields the matrix relation

$$R^{[\beta]}R^{[\beta']} = R^{[\beta+\beta']} \; .$$

2.2. Half-click matrix *C*. We shall mainly be interested in the special value $\beta = 1/2$ and make use of the constants

$$c_j = r^{[1/2]}_j = \frac{1}{N}\left(-1 + i\cot\frac{\pi}{N}\left(j+\frac{1}{2}\right)\right) \tag{2.4}$$

and $\vec{c} = (c_j)$, $C = R^{[1/2]}$. From the symmetry $\bar{c}_j = c_{-(j+1)}$, in other words, $\bar{C} = EC^T$, and the fact that $C^2 = R^{[1]} = E$, it follows that C is unitary:

$$C^{-1} = \bar{C}^T \; . \tag{2.5}$$

In summary, we see that given the values $\vec{w}$ of a normalized interpolating polynomial at the points of $\vec{\zeta}$ via a single matrix multiplication (or FFT) we obtain the values $C\vec{w}$ of the same polynomial at the intermediate points $\zeta^{1/2}\vec{\zeta} = (\zeta^{1/2}, \zeta^{3/2}, \ldots, \zeta^{N-1/2})$.

2.3. Boundary projection. For the present method, the specific algorithm for approximating the projection $\rho_\gamma(w)$ of the point w onto the curve $\gamma = \partial D$ is of little importance. For most examples in which ∂D is parametrized as $\gamma(\sigma)$, we have proceeded as follows. Note that $\rho_\gamma(w)$ is defined if γ is sufficiently smooth and if w is sufficiently close to ∂D, i.e., if $\vec{w}$ lies in a neighborhood of the N-torus $(\partial D)^N \subseteq \mathbb{C}^N$. The boundary curve is covered by a fixed number of small disks, and any point lying outside of all of these disks is simply mapped to the closest of the centers. For a point w inside one of these disks, centered at, say, $\gamma(s_0)$, first w is projected orthogonally to a point $\hat{w}$ lying on the tangent line to γ at $\gamma(s_0)$. This determines the approximate amount $\Delta s = |\gamma(s_0) - \hat{w}|/\gamma'(s_0)$ by which s_0 should be incremented. One uses $s_0 + \Delta s$ as the new s_0 and $\hat{w}$ as the new w. This process, when repeated, converges quadratically to a point $\rho_\gamma(w)$ on ∂D.

3. Description of the iterative method. With the preliminary material in hand, the algorithm is quite simple to describe. Consider "guess" values σ_j^* and write $w_j^* = \gamma(\sigma_j^*)$. If these values were correct, i.e., if $w_j^* = w_j$, then by the result of [13] cited above, we may expect (if N is large) that all values of $P_{\vec{w}^*}(e^{i\theta})$ lie on or close to ∂D. This will be true in particular of the values $u_j^* = P_{\vec{w}^*}(\zeta^{j+1/2})$, i.e., for

$$\vec{u}^* = P_{\vec{w}^*}(\zeta^{1/2}\vec{\zeta}) = C\vec{w}^* \ . \tag{3.1}$$

On the other hand, if $\vec{w}^*$ is badly placed, then $P_{\vec{w}^*}(\partial D_0)$ may stray quite far from ∂D, as illustrated in Figure 1. Consider the set Σ_N of N-tuples $\vec{w} \in (\partial D)^N$ such that $\vec{u} = C\vec{w} \in (\partial D)^N$ and such that the interleaved points $w_0, u_0, w_1, u_1 \ldots, w_{N-1}, u_{N-1}$ lie in cyclic order, positively oriented, along ∂D. This is a topological circle lying as "diagonal" in $(\partial D)^N$, and we consider it to be the set of solutions to the (nonnormalized) mapping problem. The composition

$$\Phi_\gamma = \rho_\gamma \circ C^{-1} \circ \rho_\gamma \circ C \tag{3.2}$$

is defined on a neighborhood of $(\partial D)^N$ and fixes all elements of Σ_N. Conversely, as long as the interleaved values of $\vec{w}$ and $\vec{u}$ lie in cyclic order, and if D is such that the reasoning in section 5 applies, then any fixed point $\vec{w} \in (\partial D)^N$ of Φ in fact lies on Σ_N and thus is a solution.

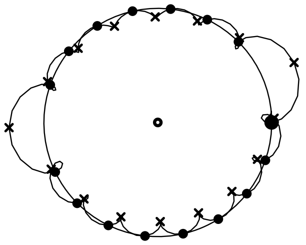

FIG. 1. *$P_{\vec{w}}(\partial D_0)$, where D is the unit disk, $N = 16$, and the values σ_j are displaced from the grid values $2\pi j/N$ by reducing $\sigma_{j+1} - \sigma_j$ by 10% for $j \neq 0, 7$ and increasing the remaining two intervals accordingly. The target points $w_j = e^{2\pi i\sigma_j}$ are marked with a spot (w_0 slightly larger), the origin with a hollow dot, and the intermediate values $u_j = P_{\vec{w}}(\zeta_N^{j+(1/2)})$ with an "x." Note how the increased space between the w_j tends to push u_j outwards, whereas decreasing the space moves it inwards.*

These considerations suggest the following algorithm: *beginning with $\vec{\sigma}^*$, define $\vec{w}^* = \gamma(\vec{\sigma}^*)$ and calculate the successive approximations*

$$(\Phi_\gamma)^n(\vec{w}^*)\ . \tag{3.3}$$

As mentioned in the introduction, the approximation of the mapping f via (3.3) invoves two types of truncation error: first, the discrepancy remaining between the nth iterate and its limiting value $\vec{w}$ (assuming convergence exists), and, second, the discrepancy between the best possible degree N polynomial approximation $P_{\vec{w}} \in \Sigma_N$ and f itself (i.e., our notion of "solution" Σ_N may not be adequate for a given problem).

3.1. Doubling. For many irregular domains, the mapping may be difficult to calculate because if one begins with an initial guess w_j^* too far from the correct values, the u_j^* may project to the boundary in the wrong order and the iteration will not approach the true mapping function. Often the difficulty can be avoided by beginning with a smaller value of N, applying Φ_γ one or more times, and then working with $2N$ points. Happily, we obtain the doubling at no cost, since the most recently calculated values of $\rho_\gamma(u_j)$, arrived at after half of the calculations involved in (3.2), can simply be interleaved in between those of w_j; that is, $\vec{w}$ is replaced by the "doubled" vector $(w_0, \rho_\gamma(u_0), w_1, \rho_\gamma(u_1), \ldots) \in \mathbb{C}^N$.

4. Normalization.

Repeated application of the operator Φ_γ of (3.2) does not need to conserve any reasonable normalization of the polynomials as mapping functions. We describe here two ways of obtaining normalized solutions to the mapping problem.

4.1. Boundary point normalization. Here we consider the normalization $f(1) = b \in \partial D$ (equivalently, $\sigma_0 = 0$ where $b = \gamma(0)$). Rather than complicate the iterative procedure by trying to make it produce $\Delta\vec{w} = 0$ automatically, we may rotate the vector $\vec{w}$ back to a normalized position via the operator $R^{[\beta]}$ of (2.3). The equation determining the appropriate value of β is nonlinear, hence it is convenient to use the following approximation procedure.

Consider the quadratic polynomial $q(t)$ determined by

$$q(-1) = w_{-1}, \quad q(0) = w_0, \quad q(1) = w_1.$$

There are in general two values t^+, t^- for which $q(t^\pm) = b$. They need not be real numbers; however, if all four points w_{-1}, w_0, w_1, b are close together on ∂D and if this boundary is reasonably smooth, there will be a unique root close to the real interval $[-1, 1]$. This leads us to define

$$\beta^* = \operatorname{Re} \frac{4(b - w_0)}{(w_1 - w_{-1}) \pm \sqrt{(w_1 - w_{-1})^2 + 8(b - w_0)(w_1 - 2w_0 + w_{-1})}}$$

(choosing the smaller of the two values) and then to replace $\vec{w}$ by $\rho_\gamma R^{[-\beta^*]}\vec{w}$. We repeat this until w_0 is sufficiently close to b. The limit is $\Psi_{\gamma,b}\vec{w}$, where we define

$$\Psi_{\gamma,b} = \rho_\gamma R^{[-\beta]} \tag{4.1}$$

for an appropriately chosen β, so that by construction $(\Psi_{\gamma,b}\vec{w})_0 = b$. There is no difficulty in implementing it computationally; the convergence of this operaton is quadratic.

This "correction by rotation" may be applied after each iteration, after every few iterations, or at the end. If the value w_0 has been allowed to wander very far, a preliminary applicaton of a power E^n of the shift operator, i.e., a cyclic rearrangement of the w_j, may be necessary as a preliminary step so that w_0 is as close to a as possible.

4.2. Normalized first derivative. The other normalization frequently considered, of interest especially for theoretical considerations, is $f'(0) > 0$. Writing $P'_{\vec{w}}(0) = \sum_j w_j Q'(0) = \sum w_j = a$, we see that $f(z) = P_{\vec{w}}((|a|/a)z)$ satisfies this normalization. The new grid values $f(\vec{\zeta})$ are thus obtained from $\vec{w} = P_{\vec{w}}(\vec{\zeta})$ as $\rho_\gamma R^{[-\beta]}\vec{w}$, where $\beta = (N/2\pi)\arg a$. It may be necessary to repeat the process until the desired accuracy is obtained.

5. Justification of convergence. Here we give an analysis, partly heuristic, of the effect on $\Phi_\gamma(\vec{w})$ caused by a small change $\Delta\vec{w}$ in $\vec{w}$. This will enable us to conclude that under reasonable conditions the iterative procedure defined in section 3 converges.

Suppose $\vec{w}^*$ is near the solution set Σ_N, and let $\vec{w} \in \Sigma_N$ be the closest element to $\vec{w}^*$ in the sense of minimizing the L_2 norm $\|\vec{w} - \vec{w}^*\|_2 = (\sum |w_j - w_j^*|^2)^{1/2}$. Write $\vec{w}^* = \vec{w} + \Delta\vec{w}$, $\vec{u} = C\vec{w}$, $\vec{u}^* = C\vec{w}^* = \vec{u} + \Delta\vec{u}$. By linearity, $\Delta\vec{u} = C\Delta\vec{w}$, and since C is unitary,

$$\|\Delta\vec{u}\|_2 = \|\Delta\vec{w}\|_2 \ . \tag{5.1}$$

Recall that $\rho_\gamma(u_j) = u_j$ by the definition of Σ_N. Write

$$\rho_\gamma\vec{u}^* = \vec{u} + \vec{d} \ ; \tag{5.2}$$

that is, d_j is the projection of the complex quantity Δu_j parallel to the tangent direction of ∂D at w_j.

We will suppose that N is so large that ∂D is approximated by a straight segment from $w_{j-\sqrt{N}}$ to $w_{j+\sqrt{N}}$. Recall that c_j is given by (2.4). It will be convenient to subdivide the indices from $-N/2$ to $N/2$ into the following sets:

$$\begin{aligned} &I_1 : 0 \le |j| < \sqrt{N} \ , \\ &I_2 : \sqrt{N} \le |j| < N/4 \ , \\ &I_3 : N/4 \le |j| \le N/2 \ . \end{aligned}$$

We may use as approximations the values

$$\begin{aligned} c_0 &= \frac{-1}{N} + \frac{2}{\pi}i + O(N^{-2}) \ , \\ c_{\sqrt{N}} &= \frac{-1}{N} + \frac{1}{\pi}\left(\frac{1}{\sqrt{N}} - \frac{1}{2N}\right)i + O(N^{-3/2}) \ , \\ c_{N/4} &= \frac{-1}{N} + \frac{i}{N} + O(N^{-2}) \ , \\ c_{N/2} &= \frac{-1}{N} + O(N^{-2}) \ . \end{aligned}$$

For our purposes it will be sufficient to obtain the remaining c_j from these values by linear interpolation over the corresponding j-intervals. With this approximation one finds that

$$\sum_{I_1} c_j = \frac{-2}{\sqrt{N}} + \frac{1}{\pi}\left(2\sqrt{N} + 1 - \frac{1}{2\sqrt{N}}\right) i + O(N^{-1}) \ ,$$

$$\sum_{I_2} c_j = \frac{-1}{2} + \frac{1}{8\pi}(2\sqrt{N} + 2\pi - 9)i + O(N^{-1/2}) \ ,$$

$$\sum_{I_3} c_j = \frac{-1}{2} + \frac{1}{4}i + O(N^{-1}) \ .$$

We will fix $j = 0$ for the moment for clarity. Thus $\Delta u_0 = \sum_{k=-N/2}^{N/2} c_{-k}\Delta w_k$. For $|k|$ near 0 modulo N, Δw_k is approximately parallel to Δw_0; there is no loss in generality in supposing that this direction is horizontal. We make the simplifying assumption that all the Δw_k are approximately the same size, say, $|\Delta w_k| = \delta$. Under this assumption we have

$$\frac{1}{\delta}\,|\Delta u_0| \geq \left|\sum_{I_1} c_{-k}\right| - \frac{1}{\delta}\left|\sum_{I_2 \cup I_3} c_{-k}\Delta w_k\right| \geq \frac{7}{4\pi}\sqrt{N} + O(1) \ .$$

Now we estimate $d_0 = \text{Re } \Delta u_0 = \sum_{k=-N/2}^{N/2} \text{Re } (c_{-k}\Delta w_k)$. For $k \in I_1$ we have

$$\frac{1}{\delta}\text{Re } \sum_{I_1} c_{-k}\Delta w_k = \frac{-2}{\sqrt{N}} + O(N^{-2})$$

from the assumption $\Delta w_k \in \mathbb{R}$. However, over I_2 and I_3 the directions of Δw_k may upset the cancellation in the sum $\sum c_j$ estimated earlier. We can at least say

$$\frac{1}{\delta}|d_0| \leq \frac{2}{\sqrt{N}} + \frac{1}{\delta}\left|\sum_{I_2 \cup I_3} c_{-k}\Delta w_k\right| \leq \frac{1}{4\pi}\sqrt{N} + O(1) \ .$$

(The dominant contribution of order $\sqrt{N}$ in these estimates comes from I_2, where there is likely to be a large amount of cancellation which has not been taken into account. This cancellation would be favorable to our estimates. On the other hand, cancellation in I_1, caused by Δw_k in opposing directions, would be unfavorable.)

Since the reasoning applies equally well for all j, we conclude from these upper and lower bounds (equating $|w_j|$ again with δ) that

$$|d_j| \leq A|\Delta u_j| \tag{5.3}$$

for any $A > 1/7$ if N is sufficiently large. In particular, $\|\vec{d}\|_2 \leq A\|\Delta\vec{u}\|_2$. Using (5.1), we may express this as

$$\|\rho_\gamma C\vec{w}^* - \vec{u}\|_2 \leq A\|\vec{w}^* - \vec{w}\|_2 \ ; \tag{5.4}$$

i.e., the operator $\rho_\gamma C$ reduces the L_2-distance from vectors to Σ_N by a factor less than 1. The same is evidently true of the operator $\rho_\gamma C^{-1}$, and hence by (3.2) of Φ_γ as well.

The above reasoning depends on several assumptions regarding the distribution of the w_j, their relative sizes, the value of N, etc. To the extent that these assumptions are valid, we infer that the distance of the sequence $\{\Phi_\gamma^n(\vec{w}^*)\}$ to the set Σ_N tends to zero. We can say more. Note that in fact

$$\Phi_\gamma(\vec{w}^*) = \rho_\gamma(\vec{w} + C^{-1}\vec{d}) .$$

Since projection onto ∂D does not increase distance,

$$\begin{aligned} &(5.5) \qquad & |\Phi_\gamma(\vec{w}^*)_j - w_j| &< |(C^{-1}d)_j| \le \|C^{-1}d\|_2 \\ &(5.6) \qquad & &\le A\|\Delta\vec{w}\|_2. \end{aligned}$$

We have argued that $\|\Delta\vec{w}\|_2$ decreases geometrically over successive iterations. Therefore the w_j form a Cauchy sequence as $n \to \infty$, and it follows that $\Phi_\gamma^n(w^*)$ tends in fact to an element of Σ_N.

6. Computational results. The numerical experiments reported here were carried out on a SPARC 10 workstation, programmed in C and in Mathematica. In order to take advantage of the FFT algorithm, N is always taken to be a power of 2. From the experiments made, the convergence is linear. For convenience we report the changes of values in the max norm $\|\vec{v}\|_\infty = \max|v_j|$; observations with the L_2 norm produced no significant differences. Where an explicit formula for the mapping function is available, we have used this data in the comparisons. Since this does not hold in most practical problems, we comment first on ways to ensure that the results obtained are reasonable. Mere convergence of $\vec{w}^{(n)} = \Phi^n(\vec{w}^*)$ to $\vec{w}$ is of course insufficient.

Observe that in the context we are working, the values w_j represent most naturally not the polygon with these points as vertices but rather the image of the unit circle under the polynomial $P_{\vec{w}}$. This image curve can be calculated exactly using the rotation operator $R^{[\beta]}$ of (2.3). We have done this for all of the figures presented in this article, choosing a number M $(= 10)$ of subdivisions for each of the N subarcs and applying the rotation matrices $R^{[m/M]}$ to $\vec{w}$ for $m = 1, \dots, M-1$. The elements of the resulting M N-tuples were then interleaved and then graphed.

Suppose $\vec{w}^{(n)} \to \vec{w} \in (\partial D)^N$. Whenever there is evidence that the image curves $P_{\vec{w}^{(n)}}(\partial D_0)$ tend to ∂D (and wrap only once around the domain), it follows from standard reasoning using the argument principle that the holomorphic functions $P_{\vec{w}^{(n)}}$ in fact converge to a normalized univalent polynomial P. Since clearly $P(\vec{\zeta}) = \vec{w}$, we have $P = P_{\vec{w}}$. As an alternative to checking graphically, one can examine the norm $\|(\vec{w}^{(n)})^{[\beta]} - \vec{w}^{[\beta]}\|_\infty$ of the discrepancies of the rotated points. At any rate, it is sufficent to check convergence of the half-click points $\vec{u}^{(n)}$ to verify that the iterations are approximating a point of Σ_N; we have marked these points in the figures with an "x".

Example 1. The disk $D = |w - \alpha| < 1$ admits as conformal mapping the normalized Möbius transformation $f(z) = \alpha - (\alpha - z)/(1 - \alpha z)$. Let $\alpha = 0.8$. We have applied successive doubling of points from $N = 4$ up to $N = 32$ after a single application of Φ_γ for each N and then continued to iterate from that point with N fixed. Table 1 shows the changes observed in $\vec{w}$ in the norm $\|\ \|_\infty$ (these are roughly proportional to the changes in σ) to each iteration from the previous one. For comparison, the differences between the approximations and the true values $w^\infty = f(z)$ are given in the rightmost column. These are also seen to decrease geometrically.

TABLE 1

Changes in $\vec{w}$ and discrepancy from true value for mapping to shifted disk, $\alpha = .8$, $N = 32$.

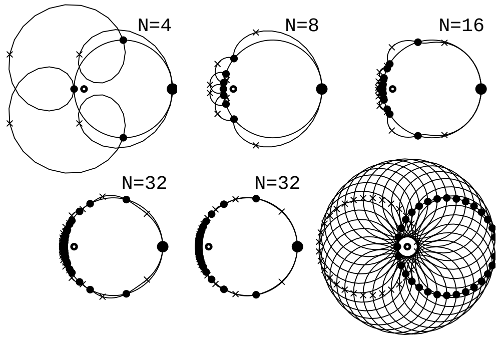

FIG. 2. *Successive doubling of grid points for mapping to a shifted disk. We begin with the* 4*th roots of unity as the initial guess. For $N = 4, 8, 16$ (top row) and* 32 *(bottom row, left) the image of the unit circle is shown after a single application of Φ_γ. The half-click points are interleaved into the N-tuple obtained, thus effectively doubling N for the next step. For $N = 32$ we also show the image after the second iteration. Convergence would not be obtained if the initial guess were the* 32*nd roots of unity; the last image depicts the corresponding image boundary.*

The images of ∂D_0 under the interpolating polynomials are drawn for the first five iterations in Figure 2. Note that for $N = 32$ the interpolating polynomial gives quite a good approximation even near the right-hand side of the domain, where extremely few grid points are mapped due to the crowding phenomenon.

Example 2. We consider the inverted ellipse with mapping function $f(z) = 2\alpha z/((1+\alpha) - (1-\alpha)z^2)$; the image domain is bounded by the curve $\gamma(\sigma) = (e^{i\sigma}(1 - (1-\alpha^2)\sin^2\sigma))^{1/2}$, $0 \le \sigma \le 2\pi$. We will use $\alpha = .25$.

Starting with the Nth roots of unity, $N = 32$, iteration of (3.2) yields the results given in Table 2. The images of ∂D_0 under some of the corresponding interpolating polynomials are shown in Figure 3. After 14 iterations we found the value of the first coordinate σ_0 to be less than 10^{-11}, which indicates that there has essentially been no wandering of the base point w_0, even though no normalization was applied. This was to be expected due to the symmetry of the domain. Upon further iteration, we found that while the successive differences $\|\Delta\vec{w}\|_\infty$ continued to manifest linear convergence, around the 20th iterate the true discrepancy $\|\vec{w} - \vec{w}^\infty\|_\infty$ stabilized at around 10^{-4}. This clearly reflects the fact that a polynomial of degree $N = 32$ cannot

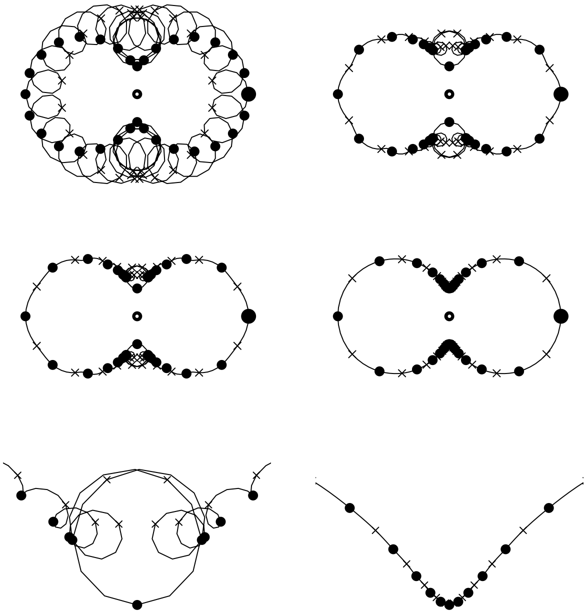

FIG. 3. *Image curves for inverted ellipse of Example* 2*: iterations* 1*,* 2*,* 3*, and* 14 *(top two rows). Magnifications of the middle row near the point $w = f(i)$ (bottom row) shows how the algorithm has straightened out "knotting" of the boundary.*

approximate this domain any better. When we doubled the grid size (using the $\vec{w}$ just obtained), the discrepancy was reduced to about 10^{-8} (see Figure 4). We have observed this type of improvement of the absolute accuracy with increased N in all examples tested.

Example 3. We give a nondifferentiable example, the square with vertices at $\pm 1 \pm i$. Here N is taken to be 32, and the original points are equally spaced along the perimeter. For the projection ρ_γ we have preferred to use an obvious ad-hoc function taking advantage of the easy geometry. The true mapping is given by an elliptic integral, $f(z) = az\int_0^1 (1 + r^4 z^4)^{-1/2} dr$, where $a > 0$ is chosen so that $f(1) = 1$. It can be seen from Figure 5 that a good approximation at the corners requires, apart from reducing $\|\Delta\vec{w}\|_\infty$, a large number of grid points. As Table 3 confirms, the approximation of f is not improved by iterating closer to Σ_N for fixed N.

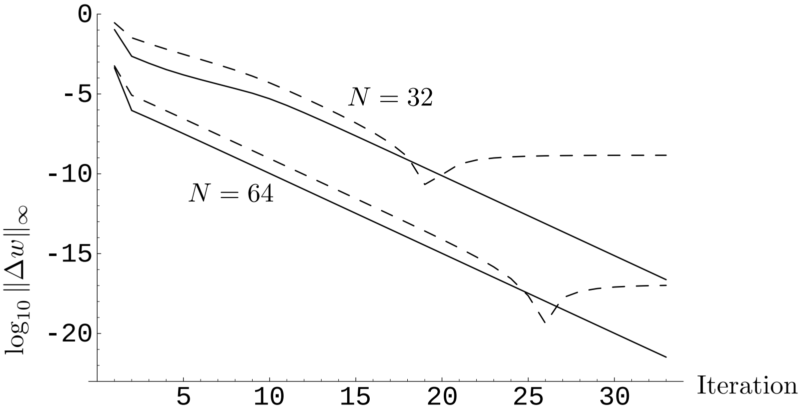

FIG. 4. *Comparison between successive differences (solid lines) and discrepancy from true value (dotted lines) for the inverted ellipse of Example* 2. *With $N = 32$ grid points, after $n = 20$ the mappings corresponding to $\Phi_\gamma^n(\vec{w}^*)$ no longer approach the true f but rather continue to tend towards the best possible approximation by a degree-N polynomial. For $N = 64$ the polynomials approximate f several orders of magnitude more closely.*

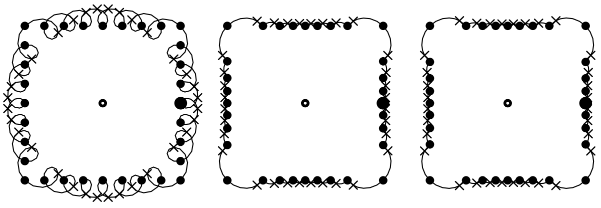

FIG. 5. *Polynomial approximation of conformal mapping to square domain. The rounding of the image of ∂D at the corners is not improved even as the iterates converge to a limiting value, as the number $N = 32$ of grid points is insufficient.*

Example 4. The last example we study is taken from Fornberg [6]. The boundary of D is defined to be the set of points w such that $F_\alpha(w) = 0$, where

$$(6.1)\ F_\alpha(w) = ((\mathrm{Re}\, w - .5)^2 + (\mathrm{Im}\, w - \alpha)^2)(1 - (\mathrm{Re}\, w - .5)^2 - (\mathrm{Im}\, w)^2) - 0.1\ .$$

In this example no parametrization of the boundary curve is explicitly needed; the projection to the boundary was carried out by Newton's method, that is, replacing w by $w - F(w)|\nabla F(w)|^{-2}$ where $\nabla F(w) \in \mathbb{C}$ is the gradient of F.

For α large, D approximates the disk $|w - .5| = 1$; see Figure 6. A more detailed depiction may be found in [6]. For $\alpha = .5$ the crowding phenomenon has reached the stage where the distance between consecutive grid points at the upper right edge of the domain is more than 500 times as large as at the upper left. One consequence of this is that an initial guess must be rather close to the sought-after values in order for the algorithm to converge.

To explain the comparative chart given in Table 4, it is necessary to summarize a few basic features of Fornberg's method. The initial guess is used to calculate a matrix and a vector; this step is referred to as an "outer iteration." Given this data, a series of "inner iterations" is carried out to arrive at essentially what we have called

here $\Delta\vec{w}$. According to [6], the cost of one outer iteration with K inner iterations is $7 + 4K$ FFTs, whereas the cost of our Φ_γ is 4 FFTs.

The strategy in Fornberg's calculation, which we have applied here as well, is to let the values of α decrease gradually. We have also replicated the strategy of applying two Newton iterations to bring the points closer to the curve for each new α and have used a single Newton iteration as an approximation of ρ_γ in calculating Φ_γ. To compensate for the increased crowding with decreasing α, at certain moments the number of grid points is doubled (recall section 3). In [6] the doubling was done by a fourth-order polynomial approximation, requiring an additional type of calculation as compared to the present method.

We have found that under the above conditions, our method does not jump well from $\alpha = \infty$ to $\alpha = 2.0$ with $N = 128$ grid points. In [6] this was accomplished, starting from 128 equidistant points, in 11 outer iterations, corresponding to 225 FFTs. Instead we have doubled repeatedly from $N = 4$ to $N = 128$, utilizing 44 FFTs, and afterwards copied the decrements and doublings in [6]. The results are gathered in Table 4. To facilitate the comparison, we show the number of FFTs (each Φ_γ is 4 FFTs) used at each step.

Table 4

Comparative results for domain given by (6.1)*. Increments of the domain parameter α are paralleled by doubling of grid size N as in* [6]*; the cost in FFTs for the changes $\|\Delta\vec{w}\|_\infty$ and "Accuracy of Taylor coefficients" is shown for the two methods. The change $\|\Delta\vec{a}\|_\infty$ of the Taylor coefficients recalculated from the output of our method is also reported.*

Several observations are in order regarding the accuracy obtained. As in the previous examples, we have measured the error given for $\vec{w}$ as the largest change in w_j in the last iteration of Φ_γ calculated. The error reported in [6] is in terms of the Taylor coefficients, which is what that method produces directly; these range from 10^{-7} to 10^{-11} approximately for the values of α considered here. In each row of Table 4 from $\alpha = 1.5$ on, to provide an additional comparison we calculated at the beginning of the last iteration of Φ_γ the (Taylor) coefficients $\vec{a}^* = (a_1^*, \ldots, a_N^*)$ of $P_{\vec{w}^*}$ from the values obtained for $\vec{w}^*$. This was accomplished by applying the inverse Fourier transform and shifting to the left (not included in the FFT count in the table). After the iteration we similarly calculated the corresponding Taylor coefficients $\vec{a}$ and have included in Table 4 the maximal difference of $a_j - a_j^*$. However, it must be noted that comparison of this data with that of [6] is complicated by the fact that the results given there correspond only to the change caused by the "outer iterations." It may also be noted that an error of 10^{-7} in each of $N = 16{,}384$ coefficients of a polynomial evaluated for $|z| = 1$ may induce an error of as much as 10^{-3} in w^j, regardless of the algorithm used to evaluate the polynomial. Since in these calculations we have not

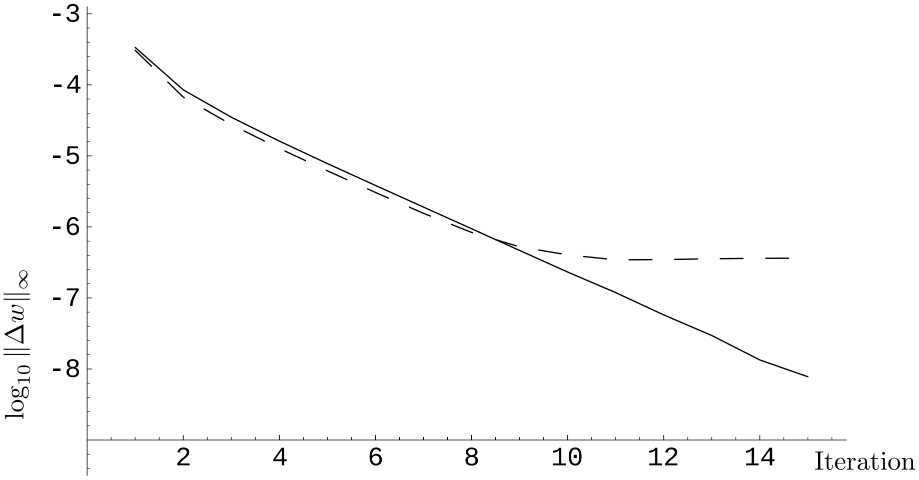

FIG. 7. *Comparison of decreasing of Δw for methods based on Φ_γ (solid line) and $\Psi_{\gamma,b}\Phi_\gamma$ (dotted line). Note that the renormalization by the rotation $\Psi_{\gamma,b}$ has not increased the accuracy of convergence for the first* 8 *rotations, but after that point it has impeded loss of convergence coming from floating of the base point.*

applied any normalization as described in section 4, w_0 is allowed to "float" along the boundary; its position is marked by spots near the right-hand side of Figure 6.

One may ask to what extent the changes observed in $\vec{w}$ may be due to this floating of the base point, which could thus mask how fast $\vec{w}$ is really approaching the set of solutions Σ_N. In another experiment, we took the 2048-point vector $\vec{w}$ corresponding to $\alpha = 0.75$ in Table 4 and constructed a new initial guess $\vec{w}^*$ by sampling from it $N = 256$ points defined by $w_j^* = w_{(8j)}$. When Φ_γ was applied, the differences $\Delta\vec{w}$ ceased to decrease at about 10^{-6}. Then we applied to the initial $\vec{w}^*$ the algorithm defined by $\Psi_{\gamma,b}\Phi_\gamma$. (After each Φ_γ, a single b was calculated as described in 4.1 to rotate the initial boundary point approximately to where it had been.) Now differences as small as 10^{-9} were obtained in the same number of iterations, as shown in Figure 7. Thus we see that in the Φ_γ algorithm, the floating base point phenomenon has destroyed convergence, which is recovered by renormalizing in each iteration. To discount the possibility that the sequence obtained with $\Psi_{\gamma,b}$ had better convergence merely due to a contribution of the additional projection involved in this operation, in another test several extra iterations of Newton's method were added to Φ_γ; these made no significant difference.

In contrast, in several other tests, in particular with the examples given in this paper, the $\Psi_{\gamma,b}\Phi_\gamma$ method produced little or no acceleration of convergence with indeed a higher cost in terms of FFTs.

7. Closing remarks. While we have studied exclusively the algorithm obtained by iterating the operator Φ_γ (with possible renormalization), we wish to suggest that the interpolating polynomial $P_{\vec{w}}$ is an object of intrinsic interest. Possibly more sophisticated algorithms could be developed, based on the ideas presented here, to obtain better convergence. This could involve using $R^{[\beta]}$ with values other than $\beta = 1/2$, or perhaps using the fact that the derivatives of the $P_{\vec{w}}$ at the points of $\vec{\zeta}$ are also readily available computationally.

The conjugate operator, also known as the Hilbert transform (see [7], [9], [10]), which transforms a real-valued function on ∂D_0 into its conjugate function, involves integration of the kernel $\cot(s-t)$. This looks suspiciously like the multipliers in the matrix C. It would be interesting to know if our iterative process is the discretization of an integral operator or some similar concept as $N \to \infty$. Unfortunately, letting $N \to \infty$ in the four operators composing ϕ_γ in (3.2) causes each of them to tend to the identity operator, which thus gives no information.

We close with the following question. Consider in general N points w_j on ∂D equally spaced according to arc length. These generate N intermediate points u_j as we have seen, not generally lying on ∂D. If the w_j are shifted by a fixed amount of arc length in the same direction, we obtain from them a new set of u_j. Since the linear operators C and E commute, the $\vec{u}$ thus obtained evidently trace out a curve, in some sense dual to ∂D. What curve is this in general, how does it depend on N, and what information can it give us regarding conformal mapping?

Acknowledgment. I am grateful to the referees who pointed out some serious errors in the first version of this article and supplied several valuable suggestions.

APPLICATION OF AN INVERSE PROBLEM FOR SYMMETRIC PERIODIC POTENTIALS*

G. B. XIAO†, K. YASHIRO‡, N. GUAN‡, AND S. OHKAWA‡

Abstract. This paper gives an algorithm for constructing symmetric periodic potential $q(x)$ of Hill's equation from given roots of $\Delta(\lambda) - 2 = 0$. The problem arises from synthesizing dual-mode ring electrical circuits. In the presented method, the discriminant $\Delta(\lambda)$ of Hill's equation is determined from the roots of $\Delta(\lambda) - 2 = 0$ at first, and then $q(x)$ is constructed from the roots of $\Delta(\lambda) \pm 2 = 0$ and $\Delta(\lambda) = 0$. Examples are provided to verify the algorithm.

Key words. inverse problem, Hill's equation, dual-mode ring circuit

AMS subject classifications. 94C99, 78A46

PII. S1064827500376211

1. Introduction.

In analyzing lossless dual-mode ring circuits with distributed parameters, it is often required to solve the following Hill's equation [1]:

$$-y''(x) + q(x)y(x) = \lambda y(x), \tag{1.1}$$

where the real periodic potential function $q(x)$ is related to the characteristic impedance of the ring circuit and satisfies

$$q(1+x) = q(x), \qquad q(1-x) = q(x), \qquad x \in (0,1). \tag{1.2}$$

Let $y_1(x,\lambda)$ and $y_2(x,\lambda)$ denote the two linearly independent solutions of (1.1), where $y_1(0,\lambda) = 1, y_1'(0,\lambda) = 0$ and $y_2(0,\lambda) = 0, y_2'(0,\lambda) = 1$. Their Wronskian is given by $W(y_1,y_2) = y_1y_2' - y_1'y_2 = 1$, and the Hill's discriminant is defined by $\Delta(\lambda) = y_1(1,\lambda) + y_2'(1,\lambda)$. The roots of $\Delta(\lambda) - 2 = 0$, $\Delta(\lambda) + 2 = 0$, and $\Delta(\lambda) = 0$ are denoted by $\lambda_i (i = 0,1,2,\ldots)$, $\mu_i (i = 1,2,\ldots)$, and $\gamma_i (i = 1,2,\ldots)$, respectively. In intervals of $(-\infty, \lambda_0)$, $(\lambda_{2i-1}, \lambda_{2i})$, and (μ_{2i-1}, μ_{2i}), there exists $\mid \Delta(\lambda) \mid> 2$. These intervals are instability intervals known as forbidden bands because the solutions of (1.1) are unbounded on the line [2].

Especially in ring electrical circuits, $\sqrt{\lambda_i}$ stand for resonating frequencies. The synthesis of such ring circuits is equivalent to solving the potential function $q(x)$ from given resonating frequencies $\sqrt{\lambda_i}$. Generally, periodic potentials can be uniquely recovered from norming constants and the zeros of $y_2(1,\lambda)$ [2], [3], but in this practical case, the norming constants are not known in advance. This paper will show that although $q(x)$ cannot be uniquely constructed in this case, but under the condition of (1.2), $q(x)$ can belong only to a function set $\{q_n(x)\}$, which can be wholly determined. A practical algorithm is provided and is verified by examples.

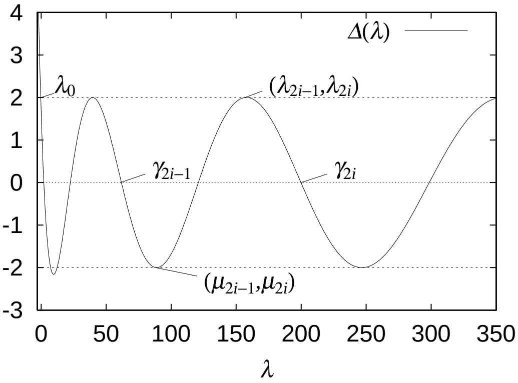

FIG. 1. *A general shape of* $\Delta(\lambda)$.

2. Recover $q(x)$ from λ_i's. Without loss of generality, we assume that $\int_0^1 q(s)ds = 0$ in the following discussions. A general shape of $\Delta(\lambda)$ is depicted in Figure 1. The roots are arranged as

$$\lambda_0 < \cdots < \gamma_{2i-1} < \mu_{2i-1} \leq \mu_{2i} < \gamma_{2i} < \lambda_{2i-1} \leq \lambda_{2i} < \cdots . \tag{2.1}$$

Let α_i, β_i denote the zeros of $y_1'(1,\lambda)$ and $y_2(1,\lambda)$, respectively. We recall some necessary results at first.

LEMMA 2.1. *When $q(x) \in L_2(0,1)$ and $\int_0^1 q(s)ds = 0$, we have the following asymptotic formulae for eigenvalues:*

$$\alpha_i = (i\pi)^2 + \nu_{1i}, \tag{2.2}$$

$$\beta_i = (i\pi)^2 + \nu_{2i}, \tag{2.3}$$

$$\lambda_{2i-1} = (2i\pi)^2 + \nu_{3i}, \tag{2.4}$$

$$\lambda_{2i} = (2i\pi)^2 + \nu_{4i}, \tag{2.5}$$

$$\mu_{2i-1} = [(2i-1)\pi]^2 + \nu_{5i}, \tag{2.6}$$

$$\mu_{2i} = [(2i-1)\pi]^2 + \nu_{6i}, \tag{2.7}$$

$$\gamma_i = [(i-0.5)\pi)]^2 + \nu_{7i}, \tag{2.8}$$

as $\lambda \uparrow \infty$, and $\sum_{i=1}^{\infty} \nu_{1i}^2, \ldots, \sum_{i=1}^{\infty} \nu_{7i}^2$ all converge. [4], [5].

LEMMA 2.2. *All entire functions of order $1/2$, type 1 can be expressed as a constant multiple of the canonical product formed from its roots* [6].

$\Delta(\lambda)$, $\Delta(\lambda) \pm 2$ are all entire functions of order 1/2 and type 1 [2], [6]. Thus, we can write

$$\Delta(\lambda) = C_1 \prod_{i=1}^{\infty} \left(1 - \frac{\lambda}{\gamma_i}\right), \tag{2.9}$$

$$\Delta(\lambda) - 2 = C_2 \prod_{i=0}^{\infty} \left(1 - \frac{\lambda}{\lambda_i}\right), \tag{2.10}$$

$$\Delta(\lambda) + 2 = C_3 \prod_{i=1}^{\infty} \left(1 - \frac{\lambda}{\mu_i}\right). \tag{2.11}$$

The estimates of $y_1(1,\lambda)$ and $y_2'(1,\lambda)$ are $y_1(\lambda) = \cos(\sqrt{\lambda})[1 + o(1)]$ and $y_2'(\lambda) = \cos(\sqrt{\lambda})[1 + o(1)]$ for $\lambda \downarrow -\infty$ [2]. It follows that $\Delta(\lambda) = 2\cos(\sqrt{\lambda})[1 + o(1)]$ for $\lambda \downarrow -\infty$. Therefore, we have

$$\lim_{\lambda \to -\infty} \frac{\Delta(\lambda)}{2\cos(\sqrt{\lambda})} = 1. \tag{2.12}$$

Using $\cos(\sqrt{\lambda}) = \prod_{i=1}^{\infty}(1 - \frac{\lambda}{\Gamma_i})$, $\Gamma_i = [(i - 0.5)\pi]^2$, the left-hand side of (2.12) can be spelled out as

$$\begin{aligned} \lim_{\lambda \to -\infty} \frac{\Delta(\lambda)}{2\cos(\sqrt{\lambda})} &= \lim_{\lambda \to -\infty} \frac{C_1 \prod_{i=1}^{\infty}(1 - \frac{\lambda}{\gamma_i})}{2\prod_{i=0}^{\infty}(1 - \frac{\lambda}{\Gamma_i})} = \lim_{\lambda \to -\infty} \frac{C_1}{2} \prod_{i=1}^{\infty} \frac{1 - \frac{\lambda}{\gamma_i}}{1 - \frac{\lambda}{\Gamma_i}} \\ &= \lim_{\lambda \to -\infty} \frac{C_1}{2} \prod_{i=1}^{\infty} \Big(1 + \frac{\lambda(\gamma_i - \Gamma_i)}{\gamma_i(\Gamma_i - \lambda)}\Big). \end{aligned} \tag{2.13}$$

From (2.8), $\gamma_i - \Gamma_i = o(1)$; therefore $\sum_{i=1}^{\infty} \frac{\lambda(\gamma_i - \Gamma_i)}{\gamma_i(\Gamma_i - \lambda)}$ is uniformly convergent at least in $(-\infty, 0)$, as is (2.13). This enables us to pass the limit $\lambda \to -\infty$ into the product in (2.13),

$$\lim_{\lambda \to -\infty} \frac{C_1}{2} \prod_{i=1}^{\infty} \Big(1 + \frac{\lambda(\gamma_i - (i - 0.5)^2)}{\gamma_i(\Gamma_i - \lambda)}\Big) = \frac{C_1}{2} \prod_{i=1}^{\infty} \frac{\Gamma_i}{\gamma_i} = 1; \tag{2.14}$$

hence,

$$C_1 = 2\prod_{i=1}^{\infty} \frac{\gamma_i}{\Gamma_i}. \tag{2.15}$$

In the same way,

$$C_2 = \lambda_0 \prod_{i=1}^{\infty} \frac{\lambda_{2i-1}\lambda_{2i}}{P_i^2}, \tag{2.16}$$

$$C_3 = 4\prod_{i=1}^{\infty} \frac{\mu_{2i-1}\mu_{2i}}{Q_i^2}, \tag{2.17}$$

where $P_i = (2\pi i)^2$, $Q_i = [(2i-1)\pi]^2$. As a result, (2.9), (2.10), (2.11) become

$$\Delta(\lambda) = 2\prod_{i=1}^{\infty} \frac{\gamma_i - \lambda}{\Gamma_i}, \tag{2.18}$$

$$\Delta(\lambda) - 2 = (\lambda_0 - \lambda)\prod_{i=1}^{\infty} \frac{(\lambda_{2i-1} - \lambda)(\lambda_{2i} - \lambda)}{P_i^2}, \tag{2.19}$$

$$\Delta(\lambda) + 2 = 4\prod_{i=1}^{\infty} \frac{(\gamma_{2i-1} - \lambda)(\gamma_{2i} - \lambda)}{Q_i^2}. \tag{2.20}$$

These equations show that λ_i, μ_i, γ_i, and $\Delta(\lambda)$ are actually equivalent pieces of information. If λ_i are provided, $\Delta(\lambda)$, μ_i, and γ_i are all obtainable.

We now prove the following theorem.

THEOREM 2.3. *$y_2'(1,\lambda) = y_1(1,\lambda) = \frac{1}{2}\Delta(\lambda)$ if $q(1-x) = q(x)$.*

Proof. When $q(1-x) = q(x)$, it is obvious that the eigenvalues corresponding to the boundary conditions of $y'(0,\lambda) = 0, y(1,\lambda) = 0$ and $y(0,\lambda) = 0, y'(1,\lambda) = 0$ are the same. This means that $y_1(1,\lambda)$ and $y_2'(1,\lambda)$ have the same zeros. Because $y_1(1,\lambda)$ and $y_2'(1,\lambda)$ are also entire functions of type 1, order 1/2, from Lemma 2.1, it is reasonable to write $y_1(1,\lambda) = Cy_2'(1,\lambda)$, where C is a constant, and from their estimates

$$C = \lim_{\lambda\to-\infty} \frac{y_1(1,\lambda)}{y_2'(1,\lambda)} = 1, \tag{2.21}$$

it leads to

$$y_2'(1,\lambda) = y_1(1,\lambda) = \frac{1}{2}\Delta(\lambda). \tag{2.22}$$

This proves the theorem. □

With it the following relation can be drawn from the Wronskian of y_1 and y_2:

$$y_1'(1,\lambda)y_2(1,\lambda) = y_2'(1,\lambda)y_1(1,\lambda) - 1 = \frac{1}{4}[\Delta(\lambda)+2][\Delta(\lambda)-2]. \tag{2.23}$$

Equation (2.23) illustrates that the zeros of $y_1'(1,\lambda)$ and $y_2(1,\lambda)$, i.e., α_i, β_i, can be only those values of the zeros of $\Delta(\lambda)-2$ or $\Delta(\lambda)+2$, i.e., λ_i or μ_i. In order to divide these zeros, more preparatory results are needed as follows.

LEMMA 2.4. *If $\int_0^1 q(s)ds = 0$, then $\lambda_0 < 0$ and $\alpha_0 < 0$, unless $q(x) = 0$ for all x[7].*

Proof. Let $y_0(x)$ denote the eigenfunction corresponding to λ_0 or α_0; then $y_0(x) \neq 0$ for all x because $y_0(x)$ has the least oscillation in all the eigenfunctions in both cases. Write (1.1) as

$$\frac{y_0''(x)}{y_0(x)} + \lambda_c - q(x) = 0, \tag{2.24}$$

where $\lambda_c = \lambda_0$, or α_0. Integrating it over (0,1), we get

$$\int_0^1 \frac{y_0''(x)}{y_0(x)}dx + \lambda_c = 0. \tag{2.25}$$

Forwarding the integration by part leads to

$$\frac{y_0'(x)}{y_0(x)}\bigg|_0^1 + \int_0^1 \left(\frac{y_0'(x)}{y_0(x)}\right)^2 dx + \lambda_c = 0. \tag{2.26}$$

Recall the boundary conditions of $y_0(1) = y_0(0), y_0'(1) = y_0'(0)$ for $\lambda_c = \lambda_0$, and $y_0'(1) = y_0'(0) = 0$ for $\lambda_c = \alpha_0$. In both cases, $\frac{y_0'(x)}{y_0(x)}\Big|_0^1 = 0$. Therefore $\lambda_c < 0$ unless $y_0'(x) = 0$ almost everywhere. In the latter instance, $y_0(x)$ must be a constant. From (1.1) and $\int_0^1 q(x)dx = 0$, we can see that $q(x) = 0$ must hold for all x.

This lemma shows that in (2.23) λ_0 ought to be assigned to α_0.

LEMMA 2.5. *The zeros of $y_1(1,\lambda)$ and those of $y_1'(1,\lambda)$ interlace; the zeros of $y_2(1,\lambda)$ and those of $y_2'(1,\lambda)$ interlace* [4].

It follows from Lemma 2.5 that μ_{2i-1} and μ_{2i} can be assigned only to one zero of $y_2(1,\lambda)$ and one zero of $y_1'(1,\lambda)$, as well as for λ_{2i-1} and λ_{2i}.

We conclude these points in Theorem 2.6.

THEOREM 2.6. *When $q(1-x) = q(x)$, the zeros of $y_1(1,\lambda)$ and $y_2'(1,\lambda)$ coincide with those of $\Delta(\lambda)$, while α_i and β_i satisfy*

$$\begin{aligned} &\alpha_0 = \lambda_0, \\ &(\alpha_{2i-1}, \beta_{2i-1}) \leftrightarrow (\mu_{2i-1}, \mu_{2i}), \\ &(\alpha_{2i}, \beta_{2i}) \leftrightarrow (\lambda_{2i-1}, \lambda_{2i}). \end{aligned} \tag{2.27}$$

Here we have used a symbolical expression $(\alpha_{2i-1}, \beta_{2i-1}) \leftrightarrow (\mu_{2i-1}, \mu_{2i})$, which means that we can choose either α_{2i-1} to be μ_{2i-1} and β_{2i-1} to be μ_{2i} or choose α_{2i-1} to be μ_{2i} and β_{2i-1} to be μ_{2i-1}.

By now, we have shown a method to generate the zeros of $y_1(1,\lambda)$, $y_1'(1,\lambda)$ and $y_2(1,\lambda)$, $y_2'(1,\lambda)$ from λ_i provided. It is known that to construct $q(x)$ from the zeros of $y_1(1,\lambda)$ and $y_1'(1,\lambda)$ or $y_2(1,\lambda)$ and $y_2'(1,\lambda)$ are both overdetermined inverse classical Sturm–Liouville problems that are uniquely solvable [6], [8]. Theoretically, the division according to (2.27) is infinite, so there exists an infinite function sequence $q_n(x)$ comprising a same $\Delta(\lambda)$. However, as the width of forbidden band decreases exponentially fast [3], only a limited number of forbidden bands (say, M) will cause significant influence on $q_n(x)$, or we need to consider only approximately 2^M $q_n(x)$ for given λ_i. Practically, if we just want to obtain a $q(x)$ which comprises the provided λ_i , not minding whether $q(x)$ is unique or not, we may simply choose a kind of combination from (2.27). Also, we can construct several $q_n(x)$ and from them select the most proper one for the practical problem at hand.

3. Algorithm and examples.

We detail our algorithm as follows.

(1) Generate $\Delta(\lambda)$ from given λ_i by (2.19).

It is inconvenient to use (2.19) directly in calculation because the canonical product contains infinite terms. From (2.4) we assume that $\lambda_{2i-1} \approx \lambda_{2i} \approx P_i$ when $i > N$. Then (2.19) becomes

$$\begin{aligned} \tilde{\Delta}(\lambda) - 2 &= (\lambda_0 - \lambda) \prod_{i=1}^{N} \frac{(\lambda_{2i-1} - \lambda)(\lambda_{2i} - \lambda)}{P_i^2} \prod_{i=N+1}^{\infty} \frac{(P_i - \lambda)(P_i - \lambda)}{P_i^2} \\ &= 4 \sin^2 \frac{\sqrt{\lambda}}{2} \frac{\lambda_0 - \lambda}{\lambda} \prod_{i=1}^{N} \frac{(\lambda_{2i-1} - \lambda)(\lambda_{2i} - \lambda)}{(P_i - \lambda)^2}, \end{aligned} \tag{3.1}$$

where $\sin\frac{\sqrt{\lambda}}{2} = \frac{\sqrt{\lambda}}{2}\prod_1^{\infty}(\frac{P_i-\lambda}{P_i})$ is used. Though (3.1) is an approximate formula for $\Delta(\lambda)-2$, it guaranteed that the first $2N$ zeros are actually those provided. This is enough in practical applications, where we often care only about a limited frequency range.

(2) Compute μ_i, γ_i ($i \le 2N$) from $\tilde{\Delta}(\lambda)$.

(3) Obtain α_i and β_i from (2.27), while the zeros of $y_1(1,\lambda)$ and $y_2'(1,\lambda)$ are the same as γ_i.

(4) Construct $q(x)$ from either the zeros of $y_1(1,\lambda)$ and $y_1'(1,\lambda)$ or from the zeros of $y_2(1,\lambda)$ and $y_2'(1,\lambda)$. Readers are suggested to [8] for the detailed procedure of solving these kinds of inverse problems.

We will verify this algorithm by two examples.

Example 3.1. The provided λ_i are those of $q^0(x) = cos(2\pi x)$. In this case, only the first forbidden band has significant width, so $q_n(x)$ contains two typical potential functions. The second forbidden band may slightly affect the reconstructed potentials. The four reconstructed potentials from the combination of the first two pairs of zeros in (2.27) are shown in Figure 2, while the effect of other forbidden bands are too small to yield a potential function that can be distinguished from these four potentials.

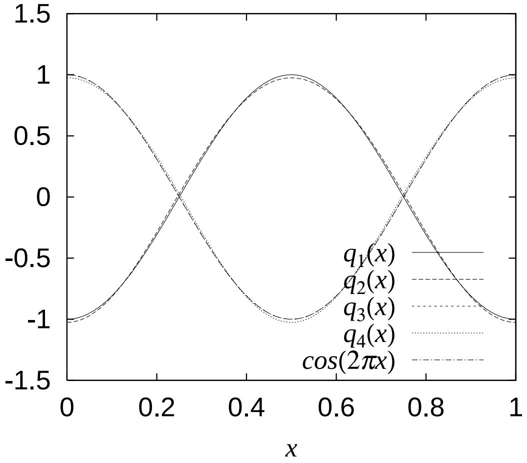

FIG. 2. *Example of continuous potential $q^0(x) = cos(2\pi x)$. $q_1(x) \sim q_4(x)$ are corresponding to different choices of the first two pairs of zeros in* (2.27).

Example 3.2. The provided λ_i are those of a rectangular pulse $q^0(x)$. In this case, about 15 forbidden bands have significant width, so we may have about 2^{15} different potentials that comprise the same λ_i's as $q^0(x)$ and can also be recovered. In Figure 3, we present only eight of them, which are corresponding to different choices for $i \le 3$ in (2.27), and probably the typical shapes in the set of $\{q_n(x)\}$. $q^a(x)$ in the figures are constructed from the zeros of $y_1(1,\lambda)$ and $y_1'(1,\lambda)$, while $q^b(x)$ are from the zeros of $y_2(1,\lambda)$ and $y_2'(1,\lambda)$. $q^a(x)$ and $q^b(x)$ agree very well in all these cases.

We have adopted a parameter $E_r(\lambda_i)$ to examine the errors of the presented algorithm. $E_r(\lambda_i)$ is defined as

$$E_r(\lambda_i) = \Big|\frac{\lambda_i - \tilde{\lambda_i}}{\lambda_i}\Big|, \tag{3.2}$$

where λ_i are those provided values, and $\tilde{\lambda_i}$ are calculated from (1.1) by applying

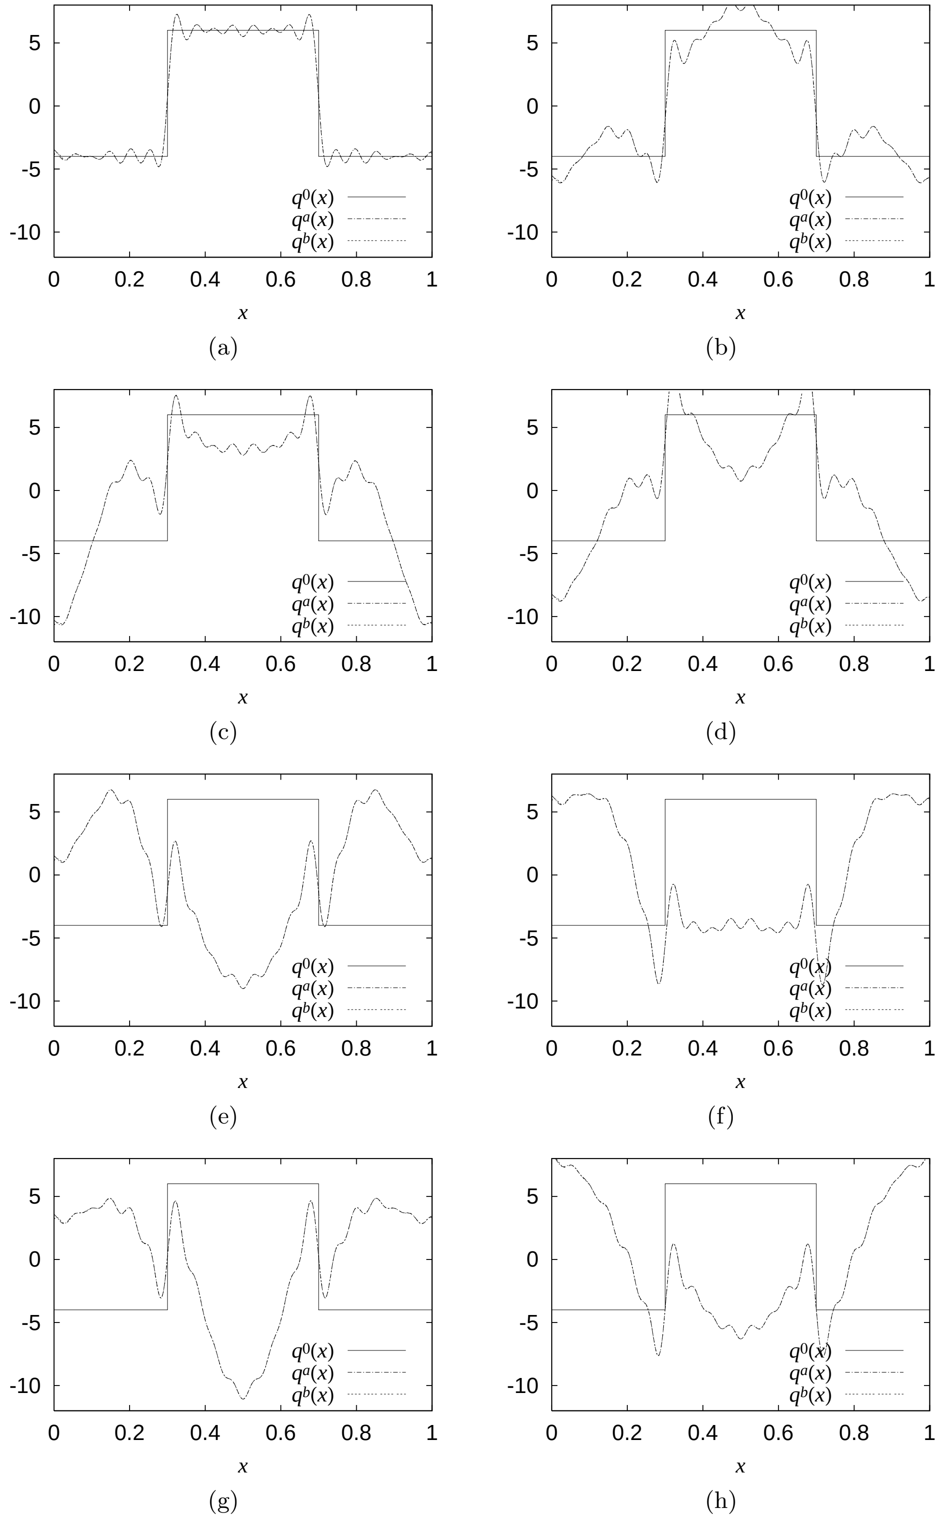

FIG. 3. *$q^0(x)$ is a rectangular pulse. Only 2^3 $q_n(x)$ are constructed here.*

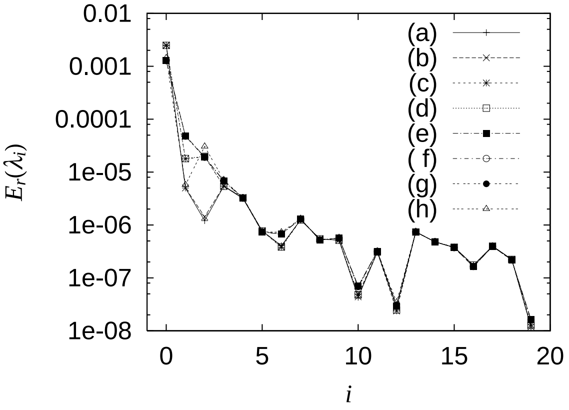

FIG. 4. $E_r(\lambda_i)$ *for* $0 \le i \le 20$.

constructed $q_n(x)$. Figure 4 shows the $E_r(\lambda_i)$ of all the $(a) \sim (h)$ cases in Example 3.2.

4. Conclusion. The inverse problem of constructing $q(x)$ of Hill's equation from given roots of $\Delta(\lambda) - 2 = 0$ has been changed to an inverse classical Sturm–Liouville problem of constructing $q(x)$ from two eigenvalue sequences, which can be solved by several established procedures. With the presented algorithm, it is possible to synthesize a ring electrical circuit that resonates at given frequencies.

A NOTE ON PRECONDITIONING NONSYMMETRIC MATRICES[*]

ILSE C. F. IPSEN[†]

Abstract. The preconditioners for indefinite matrices of KKT form in [M. F. Murphy, G. H. Golub, and A. J. Wathen, *SIAM J. Sci. Comput.*, 21 (2000), pp. 1969–1972] are extended to general nonsymmetric matrices.

Key words. preconditioner, minimal polynomial

AMS subject classifications. 65F10, 15A23

PII. S1064827500377435

In [2] preconditioners for real indefinite matrices of KKT form

$$\mathcal{A} \equiv \begin{pmatrix} A & B^* \\ C & 0 \end{pmatrix}$$

are presented.[1] The preconditioners $\mathcal{P}$ are of the following form:

$$\begin{pmatrix} A & B^* \\ 0 & \pm CA^{-1}B^* \end{pmatrix}, \quad \begin{pmatrix} A & B^* \\ C & 2CA^{-1}B^* \end{pmatrix}, \quad \begin{pmatrix} A & 0 \\ 0 & CA^{-1}B^* \end{pmatrix}.$$

The preconditioned matrices $\mathcal{P}^{-1}\mathcal{A}$ have minimal polynomials of degree at most 4. Hence a Krylov subspace method like GMRES applied to a preconditioned linear system with coefficient matrix $\mathcal{P}^{-1}\mathcal{A}$ converges in 4 iterations or less, in exact arithmetic.

We extend the preconditioners $\mathcal{P}$ in [2] to general matrices $\mathcal{A}$ by deriving them from LU decompositions of $\mathcal{A}$. As before, the preconditioned matrices $\mathcal{P}^{-1}\mathcal{A}$ and $\mathcal{A}\mathcal{P}^{-1}$ have minimal polynomials of degree at most 4.

Let

$$\mathcal{A} \equiv \begin{pmatrix} A & B^* \\ C & D \end{pmatrix}$$

be a complex, nonsingular matrix where the leading principal submatrix A is nonsingular. Let $S \equiv D - CA^{-1}B^*$ be the Schur complement with respect to A. Since $\mathcal{A}$ is nonsingular, so is S. The idea is to factor $\mathcal{A} = \mathcal{L}\mathcal{D}\mathcal{U}$ such that the preconditioned matrix $\mathcal{L}^{-1}\mathcal{A}\mathcal{U}^{-1} = \mathcal{D}$ has a minimal polynomial of small degree.

PROPOSITION 1 (extension of Remark 2 in [2]). *If*

$$\mathcal{P} \equiv \begin{pmatrix} A & B^* \\ 0 & S \end{pmatrix},$$

then

$$\mathcal{A}\mathcal{P}^{-1} = \begin{pmatrix} I & 0 \\ CA^{-1} & I \end{pmatrix},$$

and $\mathcal{P}^{-1}\mathcal{A}$ and $\mathcal{A}\mathcal{P}^{-1}$ have the minimal polynomial $(\lambda - 1)^2$.

[1] The superscript * denotes the conjugate transpose.

PROPOSITION 2 (extension of (5) in [2]). *If*

$$\mathcal{P} \equiv \begin{pmatrix} A & B^* \\ 0 & -S \end{pmatrix},$$

then

$$\mathcal{A}\mathcal{P}^{-1} = \begin{pmatrix} I & 0 \\ CA^{-1} & -I \end{pmatrix},$$

and $\mathcal{P}^{-1}\mathcal{A}$ *and* $\mathcal{A}\mathcal{P}^{-1}$ *have the minimal polynomial* $(\lambda - 1)(\lambda + 1)$.

The preconditioned matrix below is the same, up to permutations, as the one in [1, section 2.1].

PROPOSITION 3. *If*

$$\mathcal{P}_1 \equiv \begin{pmatrix} I & 0 \\ CA^{-1} & -I \end{pmatrix}, \qquad \mathcal{P}_2 \equiv \begin{pmatrix} A & B^* \\ 0 & S \end{pmatrix},$$

then

$$\mathcal{P}_1^{-1}\mathcal{A}\mathcal{P}_2^{-1} = \begin{pmatrix} I & 0 \\ 0 & -I \end{pmatrix}.$$

The preconditioned matrix is also similar to $\mathcal{P}^{-1}\mathcal{A}$ and $\mathcal{A}\mathcal{P}^{-1}$, where

$$\mathcal{P} \equiv \begin{pmatrix} A & B^* \\ C & D - 2S \end{pmatrix},$$

which is an extension of the preconditioner in [2, p. 7].

REMARK 1. *Extending the preconditioner in* [2, Proposition 1] *to general matrices gives*

$$\mathcal{P} \equiv \begin{pmatrix} A & \\ & -S \end{pmatrix}.$$

It can be derived from the scaled LU decomposition $\mathcal{A} = \mathcal{L}\mathcal{U}\mathcal{D}$, *where*

$$\mathcal{L} \equiv \begin{pmatrix} I & \\ CA^{-1} & I \end{pmatrix}, \qquad \mathcal{U} \equiv \begin{pmatrix} I & -B^*S^{-1} \\ & -I \end{pmatrix}, \qquad \mathcal{D} \equiv \begin{pmatrix} A & \\ & -S \end{pmatrix}.$$

The preconditioned matrix is

$$\mathcal{T} \equiv \mathcal{A}\mathcal{P}^{-1} = \mathcal{L}\mathcal{U} = \begin{pmatrix} I & -B^*S^{-1} \\ CA^{-1} & -DS^{-1} \end{pmatrix}.$$

If $\mathcal{A}$ *is of KKT form with* $D = 0$, *then*

$$\mathcal{T}^2 - \mathcal{T} = \begin{pmatrix} -B^*S^{-1}CA^{-1} & 0 \\ 0 & I \end{pmatrix}.$$

Since $(\mathcal{T}^2 - \mathcal{T})^2 = \mathcal{T}^2 - \mathcal{T}$, *the preconditioned matrix* $\mathcal{T}$ *has a minimal polynomial of degree* 4.

CONSTRUCTION OF NEARLY ORTHOGONAL NEDELEC BASES FOR RAPID CONVERGENCE WITH MULTILEVEL PRECONDITIONED SOLVERS[*]

DIN-KOW SUN[†], JIN-FA LEE[‡], AND ZOLTAN CENDES[†]

Abstract. This paper presents a systematic approach to constructing high-order tangential vector basis functions for the multilevel finite element solution of electromagnetic wave problems. The new bases allow easy computation of a preconditioner to eliminate or at least weaken the indefiniteness of the system matrix and thus reduce the condition number of the system matrix. When these bases are used in multilevel solutions, where the multilevels correspond to the order of the basis functions, the resulting p-multilevel-ILU preconditioned conjugate gradient method (MPCG) provides an optimal rate of convergence. We first derive an admissible set of vectors of order p, and decompose this set into two subspaces—rotational and irrotational (gradient). We then reduce the number of vectors by making them orthogonal to all previously constructed lower-order bases. The remaining vectors are made mutually orthogonal in both the vector space and in the range space of the curl operator. The resulting vector basis functions provide maximum orthogonality while maintaining tangential continuity of the field. The zeroth-order space is further decomposed using a scalar-vector formulation to eliminate convergence problems at extremely low frequencies. Numerical experiments show that number of iterations needed for the solution by MPCG is basically constant, regardless of the order of the basis or of the matrix size. Computational speed is improved by several orders of magnitude due to the fast matrix solution of MPCG and to the high accuracy of the higher-order bases.

1. Introduction.

In 1980, Nedelec defined a set of vector finite element basis functions having the properties that they are complete to order p in the range space of the curl operator, that they impose tangential but not normal continuity of the vector, and that they are unisolvent [1].

In this paper, we will call finite elements based on these functions Nedelec elements and denote the function space spanned by these elements as $E^p(curl)$. Nedelec elements have been shown to be important in the solution of electromagnetic field problems [2], [3]. In particular, [4], [5], [6], [7] showed that these elements eliminate the problem of spurious modes that plague conventional node based approximations of the vector wave equation derived from Maxwell's equations. Numerous authors have derived alternative forms of the Nedelec bases, both for low-order "edge elements" [3], [7], [8], [9], [10], [11], [12] and for high-order tangential vector elements [5], [6], [13], [14], [15], [16], [17], [18], [19], [20], [21]. The goal of these constructions has often been to make the Nedelec bases interpolatory or hierarchical. Hiptmair [22] recently provided a general abstract framework for the systematic construction of these vector bases. With such an abundance of methods, the best choice of bases is often debated. All of the high-order bases are complete to order p-1 in the range space of the curl

operator, so their numerical solutions have the same order of accuracy. This means that they are all optimal in the sense of requiring the minimum number of unknowns to obtain a pth-order convergence rate. Nevertheless, the question arises: Does any particular basis set have advantages over the others?

To answer this question, we need to examine more closely the meaning of the word "optimal" in the tangential vector finite element framework. In terms of accuracy, an infinite number of optimal, nonunique bases may be constructed in this space. However, the overall performance of these elements varies greatly when one considers matrix solution speed. Researchers have found that the convergence of iterative matrix solution algorithms such as the conjugate gradient algorithm varies considerably when the system of equations is created using different tangential vector finite elements [23], [24]. These papers study the condition number of various basis sets and compare the convergence behavior of the conjugate gradient algorithm with preconditioning and without preconditioning. Contrary to common belief, some badly conditioned matrices converge more rapidly than other better conditioned matrices. Some preconditioned matrices converge slower than others without preconditioning, while others converge faster with preconditioning; still others take too many iterations to converge at all. What is going on?

Let us first note that many positive definite systems of equations do not converge rapidly without preconditioning. Also, note that although it may take considerable work, even a matrix with a large condition number can be preconditioned to form a nearly identity matrix. The convergence rate of the conjugate gradient algorithm is determined by the matrix after preconditioning and is inversely proportional to the condition number of the preconditioned matrix, not that of the original matrix. This explains why the performance of some vector sets is dramatically improved after preconditioning, while the others are not. Further, in the case of the vector wave equation, the matrix equation is not positive definite and the conjugate gradient method is not applicable. However, as shown in [25], [26], [27], if the indefinite nature of the matrix can be eliminated or at least greatly reduced, then the conjugate gradient method can be applied. The varying convergence results indicate the sensitivity of the condition number of the preconditioned matrix to both the preconditioner and the choice of basis functions. Therefore, the question of which basis to use is intimately tied to the need to find, with reasonable computational cost, a good preconditioner for the matrix generated by that basis.

This leads us to answer the "optimal by what criteria" question. We propose that some high-order tangential vector basis sets are better than others because they are more amenable to preconditioning. Hence we adopt the following criteria for choosing the optimum tangential vector basis. *The optimum tangential vector finite element basis set is the one that results in the fastest convergence when the resulting system of equations is solved by the conjugate gradient algorithm.*

A matrix perfectly preconditioned into the identity matrix allows the conjugate gradient algorithm to converge in one iteration. A mutually orthogonal set of vectors, with the additional property of mutually orthogonal curls of the vectors, generates a diagonal system matrix for the vector wave equation. Such vectors are, of course, the eigenvectors of the associated generalized matrix eigenvalue problem and are too expensive to compute in general. Even if expense were not a factor, the resulting system eigenvectors span the entire problem domain, unlike finite element basis functions that are local in nature. However, we may readily compute the eigenvectors of the element matrices. This leads to the question: Is it possible to have high degrees of local orthogonality without violating the property of tangential continuity?

The current work extends Babuska, Griebel, and Pitkaranta [28], where orthogonal scalar bases are constructed with nodal elements. Further, the construction of preconditioners for the p-version of scalar finite elements is given in [29], [30], [31]. Here we construct orthogonal vector bases based on the reduction of the number of negative eigenvalues and the condition number of the system matrix. Unlike previous work, we optimize the performance of the iterative solver by explicitly exploiting the connection between the basis vectors, the system matrix, and the preconditioner.

In the following analysis, we focus on the vector wave equation defined in terms of the curl-curl operator and requiring tangential continuity. Different differential equations have different requirements of orthogonality and continuity; an optimal basis set for one differential equation may not be optimal for another. We begin in section 2 by deriving the system equation from Maxwell equations. In section 3, we enumerate our strategy for achieving maximum orthogonality, and in section 4 we describe how to accomplish each strategy. In section 5, we count the numbers of bases in various spaces. Section 6 provides details of the multilevel-ILU preconditioned conjugate gradient method (MPCG) algorithm used to solve the system equation. Numerical results that demonstrate the effectiveness of the newly constructed set are presented in section 7, and conclusions are drawn in section 8.

2. System equation. From Maxwell's equations, the field in a three-dimensional discontinuity region Ω satisfies the vector wave equation

$$\nabla \times \frac{1}{\mu_r} \nabla \times \vec{E} - k^2 \varepsilon_r \vec{E} = 0 \quad \text{in } \Omega \tag{1}$$

with the boundary conditions

$$\begin{aligned} \vec{H} \times \vec{n} &= \vec{H}_t \quad \text{on } \Gamma_H, \\ \vec{E} \times \vec{n} &= 0 \qquad \text{on } \Gamma_E. \end{aligned}$$

Here $\vec{E}$ and $\vec{H}$ are the electric and magnetic fields, $\vec{H}_t$ is the excitation magnetic field on the boundary, $\vec{n}$ is the outward unit normal to the boundary, ε_r and μ_r are the relative permittivity and permeability of the material, respectively, and k is the free space wave-number.

Applying Galerkin's method to (1) gives the system equation

$$Ae = b, \tag{2}$$

where

$$\begin{aligned} A &= S - k^2 T, \\ S_{ij} &= \int \frac{1}{\mu_r} \nabla \times \vec{\alpha}_i \cdot \nabla \times \vec{\alpha}_j \, d\Omega, \\ T_{ij} &= \int \varepsilon_r \vec{\alpha}_i \cdot \vec{\alpha}_j \, d\Omega, \end{aligned} \tag{3}$$

and $\{\vec{\alpha}_i\}$ is a set of vector basis functions.

3. Strategy. Two vectors $\vec{\alpha}_i$ and $\vec{\alpha}_j$ are orthogonal in a tetrahedra if they satisfy

$$\vec{\alpha}_i \perp \vec{\alpha}_j \;\; \equiv \;\; \int_{tet} \vec{\alpha}_i \cdot \vec{\alpha}_j \, d\Omega = 0 \quad \text{when } i \neq j.$$

To derive orthogonal bases, we employ the following strategy.

3.1. Admissible space. We first define the maximum space of admissible functions that satisfies tangential continuity across the faces of the tetrahedron and then search the functions in this space to obtain maximum orthogonality.

3.2. Subspace decomposition. The primary reason for nonconvergence of the conjugate gradient algorithm is that the coefficient matrix A is either nearly singular or has many negative eigenvalues [25]. As defined in (3), a number of the eigenvalues of S are zero, generating many negative eigenvalues in A. The combination of zero and nonzero eigenmodes from S makes it hard to compute a good approximate inverse matrix. However, if we decompose the basis vectors into two orthogonal subspaces, rotational and irrotational (gradient), the contribution of S from the gradient space vanishes [26], [27]. Thus that part of A becomes negative definite and can be roughly inverted by an incomplete Cholesky factorization.

To avoid confusion, we note that the rotational subspace we construct is only approximately rotational because one cannot construct a normally continuous basis in the tangential vector space. However, for the sake of convenience, we use the term “rotational” throughout this paper to describe the component remaining after removing the gradient space.

3.3. Model tetrahedron. An orthogonal vector set over one tetrahedron shape is not necessarily orthogonal in other shapes. However, we cannot have different orthogonal basis functions over different elements because the continuity requirement across the common face of two adjacent tetrahedra would be violated. Therefore, we use the regular tetrahedron as the canonical shape by which to construct the orthogonal bases, and we use the same bases in all elements. Most tetrahedra in a well-made mesh are close to being regular so that we achieve near orthogonality in these elements. Numerical experiments indicate that using the regular tetrahedron as the canonical tetrahedron shape works well in practice.

3.4. Symmetrization. Symmetrized basis vectors are independent of tetrahedron orientation and avoid mixing degenerate modes. Symmetrized or antisymmetrized basis vectors provide unique sets of basis functions.

3.5. ST-orthogonal. The construction we present is hierarchical in the geometry of the element: edge-associated vectors are made orthogonal to edge-associated vectors first, and then to face-associated vectors if there are extra degrees of freedom. A face-associated vector is made orthogonal to face-associated vectors first, and then to volume-associated vectors if there are extra degrees of freedom. However, volume-associated vectors are made orthogonal only to themselves. Taking vector products between admissible vectors and the orthogonalized vectors generates an underdetermined matrix equation. This equation is solved using singular value decomposition to find the basis vectors.

To avoid mixing gradient vectors with rotational vectors, it is possible only to make the gradient vectors orthogonal to the other gradient vectors. On the other hand, rotational vectors can be made orthogonal to both rotational and gradient vectors. It is crucial to preserve the complete separation of the gradient space as discussed in section 3.2. The remaining edge-associated, face-associated, and volume-associated vectors are made mutually orthogonal not only in the vector space itself, but also in the range space of the curl operator. This is done by forming S and T matrices for the vector set and then computing the eigenvectors of the (S, T) pair. We call the newly formed eigenvector set ST-orthogonal, because the local S and T matrices computed from this basis set are diagonal. This leads to diagonal matrices for the local individual blocks within the global matrix.

3.6. $\boldsymbol{E^0(curl)}$ decomposition. We further decompose $E^0(curl)$, the lowest-order tangential vector space, into rotational and gradient spaces by the scalar-vector formulation of [32]. Without this decomposition, A becomes singular in the low frequency limit [32], [33], [34]. With this decomposition, A can be scaled by frequency into a well-conditioned matrix even at low frequencies. This completes the separation of rotational and gradient spaces.

4. Orthogonal tangential vectors.

Let us define the following terms to be used in the remainder of the paper.

- G_e^i, G_f^i, G_v^i are additional edge-associated, face-associated, and volume-associated gradient spaces when the order increases from $i-1$ to i, respectively.
- R_e^i, R_f^i, R_v^i are similar to G_e^i, G_f^i, G_v^i for rotational spaces.
- E_e^i, E_f^i, E_v^i : $E_e^i = G_e^i \cup R_e^i$. E_f^i, E_v^i are similar to E_e^i.
- G_e^I, G_f^I, G_v^I are gradient spaces of order i, i.e., $G_e^I = G_e^i \cup G_e^{i-1} \ldots \cup G_e^1$. G_f^I, G_v^I are similar to G_e^I.
- R_e^I, R_f^I, R_v^I are similar to G_e^I, G_f^I, G_v^I.
- E_e^I, E_f^I, E_v^I are similar to G_e^I, G_f^I, G_v^I.
- E^i is the tangential vector space for a single tetrahedron with function space complete to order i.
- $E^i(curl)$ is the tangential vector space of a single tetrahedron with range space complete to order i.
- F^i is the tangential finite element space of a contiguous set of tetrahedra with function space complete to order i.
- $F^i(curl)$ is the tangential finite element space of a contiguous set of tetrahedra with range space complete to order i.
- P^i is a polynomial of degree i.
- $\overline{P}^i$ is a homogeneous polynomial of degree i.

$$P_e^i, P_f^i, P_v^i : P_e^i = P^i(\lambda_0, \lambda_1), P_f^i = P^i(\lambda_0, \lambda_1, \lambda_2), P_v^i = P^i(\lambda_0, \lambda_1, \lambda_2, \lambda_3).$$

- $\#(A)$ is the number of vectors in A.
- $\#(e)$, $\#(f)$, $\#(v)$ are the numbers of edges, faces, and tetrahedra for a mesh, respectively.
- $A \perp B$ basis vectors in A are orthogonal to those in B.

4.1. Admissible tangential vectors of order p.

4.1.1. Edge-associated vectors. A vector along edge $\vec{l}_{01}$ of a triangle can be written as

$$\vec{v} = f(\lambda_0, \lambda_1)\nabla\lambda_0 + g(\lambda_0, \lambda_1)\nabla\lambda_1,$$

where the λ_i's are simplex coordinates in the triangle, and f and g are polynomials of degree p. To preserve tangential continuity, $\vec{v}$ must vanish on the other two edges of the triangle, i.e., on $\vec{l}_{02}$ and $\vec{l}_{12}$. On edge $\vec{l}_{02}$

$$\vec{l}_{02} \cdot \vec{v}\Big|_{\lambda_1=0} = 0.$$

Since

$$\vec{l}_{ij} \cdot \nabla\lambda_k = \begin{cases} 0, & i \neq j \neq k, \\ 1, & j = k, \\ -1, & i = k, \end{cases}$$

f must include a factor of λ_1. By the same reasoning, along $\vec{l}_{12}$, g must include a factor of λ_0. Consequently, the admissible edge-associated vector has the form

$$\vec{v} = s(\lambda_0, \lambda_1)\lambda_1 \nabla\lambda_0 + t(\lambda_0, \lambda_1)\lambda_0 \nabla\lambda_1, \tag{4}$$

where s and t are polynomials of degree $p-1$. The tangential components of (4) are seen to vanish on the faces of the tetrahedron except for the faces sharing edge $\vec{l}_{01}$. As long as the coefficients of (4) are common on the edge shared by adjacent tetrahedra, (4) can be added to a tangential vector without altering its tangential continuity. The number of independent variables in (4) is $\#(P_e^{p-1}) \times 2 = 2\binom{p+1}{2}$.

4.1.2. Face-associated vectors. A vector on face Δ_{012} of a tetrahedron can be written as

$$\vec{v} = f(\lambda_0, \lambda_1, \lambda_2)\nabla\lambda_0 + g(\lambda_0, \lambda_1, \lambda_2)\nabla\lambda_1 + h(\lambda_0, \lambda_1, \lambda_2)\nabla\lambda_2.$$

To preserve tangential continuity, $\vec{v}$ must vanish on the other three faces of the tetrahedron. On face Δ_{123}

$$\vec{v} \times \nabla\lambda_0 \Big|_{\lambda_0=0} = 0.$$

Since

$$\nabla\lambda_i \times \nabla\lambda_j = \begin{cases} 0, & i = j, \\ \vec{l}_{kl}/V, & i \neq j, \end{cases}$$

where V is the volume of the tetrahedron, this gives

$$\frac{1}{V}(g\vec{l}_{32} + h\vec{l}_{13})|_{\lambda_0=0} = 0.$$

Therefore, g and h must include a factor of λ_0. By the same reasoning, on face Δ_{023}, f and h must include a factor of λ_1, and on Δ_{013} f and g must have a factor of λ_2. Consequently, the admissible face-associated vector has the form

$$\vec{v} = s(\lambda_0, \lambda_1, \lambda_2)\lambda_1\lambda_2\nabla\lambda_0 + t(\lambda_0, \lambda_1, \lambda_2)\lambda_0\lambda_2\nabla\lambda_1 + u(\lambda_0, \lambda_1, \lambda_2)\lambda_0\lambda_1\nabla\lambda_2, \tag{5}$$

where s, t,and u are polynomials of degree $p-2$. The tangential components of (5) vanish at all points on all of the faces of the tetrahedron except for the interior region of face Δ_{012}. As long as the coefficients of (5) are common on the face shared by the two adjacent tetrahedra, (5) can be added to a tangential vector without altering its tangential continuity. The number of independent variables in (5) is $\#(P_f^{p-2}) \times 3 = 3\binom{p+1}{2}$.

4.1.3. Volume-associated vectors. Along the lines of the above derivation, the admissible volume-associated vector in the tetrahedron has the form

$$\begin{aligned} \vec{v} &= s(\lambda_0, \lambda_1, \lambda_2, \lambda_3)\lambda_1\lambda_2\lambda_3\nabla\lambda_0 + t(\lambda_0, \lambda_1, \lambda_2, \lambda_3)\lambda_0\lambda_2\lambda_3\nabla\lambda_1 \\ &\quad + u(\lambda_0, \lambda_1, \lambda_2, \lambda_3)\lambda_0\lambda_1\lambda_3\nabla\lambda_2 + w(\lambda_0, \lambda_1, \lambda_2, \lambda_3)\lambda_0\lambda_1\lambda_2\nabla\lambda_3, \end{aligned} \tag{6}$$

where s, t, u, and w are polynomials of degree $p-3$. Since the tangential components of (6) vanish on all points on all of the faces of the tetrahedron, (6) can be added to a tangential vector without altering its tangential continuity. Vector (6) has no direct interaction with the adjacent tetrahedra and hence can be eliminated to reduce the total number of unknowns [37].

For reasons to be discussed later, in three dimensions we will use only the following subspace of the vectors in (6):

$$\begin{aligned}\vec{v} &= \bar{s}(\lambda_1,\lambda_2,\lambda_3)\lambda_1\lambda_2\lambda_3\nabla\lambda_0 + \bar{t}(\lambda_0,\lambda_2,\lambda_3)\lambda_0\lambda_2\lambda_3\nabla\lambda_1 \\ &\quad + \bar{u}(\lambda_0,\lambda_1,\lambda_3)\lambda_0\lambda_1\lambda_3\nabla\lambda_2 + \bar{w}(\lambda_0,\lambda_1,\lambda_2)\lambda_0\lambda_1\lambda_2\nabla\lambda_3 \\ &\quad + \lambda_0\lambda_1\lambda_2\lambda_3 \begin{bmatrix} \bar{f}(\lambda_0,\lambda_1,\lambda_2,\lambda_3)(\nabla\lambda_0 - \nabla\lambda_1) \\ + \bar{g}(\lambda_0,\lambda_1,\lambda_2,\lambda_3)(\nabla\lambda_2 - \nabla\lambda_3) \\ + \bar{h}(\lambda_0,\lambda_1,\lambda_2,\lambda_3)(\nabla\lambda_2 + \nabla\lambda_3) \end{bmatrix},\end{aligned} \tag{6'}$$

where $\bar{s}$, $\bar{t}$, $\bar{u}$, and $\bar{w}$ are homogeneous polynomials of degree $p-3$, and $\bar{f}$, $\bar{g}$, and $\bar{h}$ are homogeneous polynomials of degree $p-4$. The number of independent variables in (6′) is

$$\#(\bar{P}_f^{p-3}) \times 4 + \#(\bar{P}_v^{p-4}) \times 3 = 4\binom{p-1}{2} + 3\binom{p-1}{3}.$$

4.2. Admissible gradient vectors of order p.

4.2.1. Edge-associated vectors. Edge-associated gradient vectors can be written as $\nabla P(\lambda_0,\lambda_1)$, where P is a polynomial of degree $p+1$. Comparing $\nabla P(\lambda_0,\lambda_1) = \frac{\partial P}{\partial\lambda_0}\nabla\lambda_0 + \frac{\partial P}{\partial\lambda_1}\nabla\lambda_1$ with (4), we must have $\frac{\partial P}{\partial\lambda_0} = s\lambda_1$ and $\frac{\partial P}{\partial\lambda_1} = t\lambda_0$. Therefore, P must include factors of λ_0 and λ_1. Thus admissible edge-associated gradient vectors have the form

$$\nabla P(\lambda_0,\lambda_1) = \nabla(\lambda_0\lambda_1 h(\lambda_0,\lambda_1)), \tag{7}$$

where h is a polynomial of degree $p-1$. The number of independent variables in (7) is $\#(P_e^{p-1}) = \binom{p+1}{2}$.

4.2.2. Face-associated vectors. By the same reasoning, admissible face-associated gradient vectors have the form

$$\nabla P(\lambda_0,\lambda_1,\lambda_2) = \nabla(\lambda_0\lambda_1\lambda_2 h(\lambda_0,\lambda_1,\lambda_2)), \tag{8}$$

where h is a polynomial of degree $p-2$. The number of independent variables in (8) is $\#(P_f^{p-2}) = \binom{p+1}{2}$.

4.2.3. Volume-associated vectors. In the same way, admissible volume-associated gradient vectors have the form

$$\nabla P(\lambda_0,\lambda_1,\lambda_2,\lambda_3) = \nabla(\lambda_0\lambda_1\lambda_2\lambda_3 h(\lambda_0,\lambda_1,\lambda_2,\lambda_3)), \tag{9}$$

where h is a polynomial of degree $p-3$. As was the case with volume-associated admissible vectors, instead of (9) we use the subspace vectors

$$\nabla P(\lambda_0,\lambda_1,\lambda_2,\lambda_3) = \nabla(\lambda_0\lambda_1\lambda_2\lambda_3)\bar{h}(\lambda_0,\lambda_1,\lambda_2,\lambda_3), \tag{9'}$$

where $\bar{h}$ is a homogeneous polynomial of degree $p-3$. The number of independent variables in (9′) is $\#(\bar{P}_v^{p-3}) = \binom{p}{3}$.

4.3. Symmetrization. Let us define two operators, $O_s(i,j)$ and $O_a(i,j)$. $O_s(i,j)$ symmetrizes a token by adding its symmetric complement as follows:

$$O_s(i,j)f(\dots\lambda_i,\dots\lambda_j,\dots) = f(\dots\lambda_i,\dots\lambda_j,\dots) + f(\dots\lambda_j,\dots\lambda_i,\dots);$$

$O_a(i,j)$ antisymmetrizes a token by subtracting its symmetric complement as follows:

$$O_a(i,j)f(\dots\lambda_i,\dots\lambda_j,\dots) = f(\dots\lambda_i,\dots\lambda_j,\dots) - f(\dots\lambda_j,\dots\lambda_i,\dots).$$

4.3.1. Edge-associated vectors. Given (4) or (7), we compute $O_s(0,1)\ \vec{v}\ (\lambda_0,\lambda_1)$ and $O_a(0,1)\ \vec{v}\ (\lambda_0,\lambda_1)$.

4.3.2. Face-associated vectors. Given (5) or (8), we compute $O_s(0,1)\ \vec{v}\ (\lambda_0,\lambda_1,\lambda_2)$ and $O_a(0,1)\ \vec{v}\ (\lambda_0,\lambda_1,\lambda_2)$. The face-associated vectors are not symmetrized or antisymmetrized with respect to λ_2.

4.3.3. Volume-associated vectors. Given (6) or (9), we have the following four possibilities:

$$\begin{gathered}
O_s(0,1)O_s(2,3)\ \vec{v}\ (\lambda_0,\lambda_1,\lambda_2,\lambda_3),\\
O_s(0,1)O_a(2,3)\ \vec{v}\ (\lambda_0,\lambda_1,\lambda_2,\lambda_3),\\
O_a(0,1)O_s(2,3)\ \vec{v}\ (\lambda_0,\lambda_1,\lambda_2,\lambda_3),\\
O_a(0,1)O_a(2,3)\ \vec{v}\ (\lambda_0,\lambda_1,\lambda_2,\lambda_3).
\end{gathered}$$

4.4. Procedure for constructing hierarchical vector bases of order p.

4.4.1. The procedure. The following algorithm may be used to generate the correct vector basis:

For $i = 1$ to p do {

1(a) If $i >= 3$, start with $(9')$ and construct G_v^i such that

$$G_v^i \perp G_v^{I-1}. \tag{10}$$

1(b) If $i >= 3$, start with $(6')$ and construct R_v^i such that

$$R_v^i \perp (G_v^i \cup E_v^{I-1}). \tag{11}$$

2(a) If $i >= 2$, start with (8) and construct G_f^i such that

$$G_f^i \perp (G_f^{I-1} \cup G_v^I). \tag{12}$$

2(b) If $i >= 2$, start with (5) and construct R_f^i such that

$$R_f^i \perp (G_f^i \cup E_f^{I-1} \cup E_v^I). \tag{13}$$

3(a) Start with (7) and construct G_e^i such that

$$G_e^i \perp (G_e^{I-1} \cup G_f^I). \tag{14}$$

3(b) Start with (4) and construct R_e^i such that

$$R_e^i \perp (G_e^i \cup E_e^{I-1} \cup E_f^I). \tag{15}$$

}

Note the following points about this procedure.

1. One needs to construct the volume-associated basis first, because the face-associated basis is constructed by making it orthogonal to the volume-associated one. Similarly, the face-associated basis is constructed before the edge-associated one.

2. As mentioned before, to maximize orthogonality, the constructed G_e^i, R_e^i, G_f^i, R_f^i, G_v^i, and R_v^i are all made ST-orthogonal in each step. This is done by computing all of the eigenvectors of the local generalized (S, T) eigenvalue problem and using the full set of eigenvectors in the local element as the new basis. This new basis makes both the local S and T matrices diagonal. By the definition of S and T, this means that we generate a double orthogonality: not only is the new basis orthogonal over the tetrahedron, the curls of the new basis functions are also orthogonal. For a gradient space, the S matrix vanishes, and orthogonality is required only between the vectors themselves. However, in the case of two dimensional waveguide problems where the field consists of transverse and longitudinal components, one employs vector bases to approximate the transverse components and scalar bases to approximate the longitudinal components. In this case, one may want to derive gradient vector bases from a set of mutually orthogonal scalar bases.

3. The volume-associated vector basis is constructed differently from the edge-associated and the face-associated ones. It starts with a homogeneous polynomial instead of a polynomial of complete degree. This restricts its orthogonality with higher-dimensional spaces, i.e., four-dimensional space, but does not affect its orthogonality with lower-dimensional ones. If desired for some reason, one could construct the four-dimensional components of the basis first and then construct the volume-associated components using (6) and (9).

The computed bases up to third order are given in Tables 1–6. Notice in Table 1 that the coefficients of G_e^3 are not homogeneous. If one starts with a homogeneous polynomial, it is not possible to simultaneously make it orthogonal to the gradient space of lower order and to the higher dimensional gradient space.

4.4.2. Finite element vector spaces. Since a tetrahedron has six edges, four faces, and one volume, E^i can be expressed as

$$E^i = 6E_e^I \cup 4E_f^I \cup E_v^I. \tag{16}$$

The accuracy of S is two orders lower than that of T; thus S dominates the accuracy of A. Since missing gradient bases does not affect the accuracy of S, one may without

penalty decrease the accuracy of T by removing a gradient space of order i. This results in an associated space, $E^{i-1}(curl)$:

$$E^{i-1}(curl) = E^i - (6G_e^i \cup 4G_f^i \cup G_v^i). \tag{17}$$

Similarly, for a finite element mesh, we have

$$\begin{aligned} F^i &= \#(e)E_e^I \cup \#(f)E_f^I \cup \#(v)E_v^I, \\ F^{i-1}(curl) &= F^i - (\#(e)G_e^i \cup \#(f)G_f^i \cup \#(v)G_v^i). \end{aligned} \tag{18}$$

4.5. Further decomposition of $\boldsymbol{E^0(curl)}$. $E^0(curl)$ is equal to R_e^1. Strictly speaking, R_e^1 is only locally rotational, and it can have a global gradient subspace. By using the scalar-vector formulation in [32], this space may be split into two subspaces R_{ce}^1 and $\nabla\phi^1$, where R_{ce}^1 is a cotree subspace of R_e^1, and ϕ^1 is the first-order nodal basis

$$R_e^1 = R_{ce}^1 \cup \nabla\phi^1. \tag{19}$$

The definition of the cotree space and the reason that it resolves convergence problems at low frequency is provided in [34]. We emphasize that separating the gradient space from the rotational space for additional orders empowers us to deal with only R_e^1. In addition, $\nabla\phi^1$ is not orthogonal to R_{ce}^1 in (19), and R_{ce}^1 still contains significant low frequency components. Incomplete Cholesky decomposition is not a good preconditioner because of this.

5. Basis count. Since the higher dimensional space is constructed before the lower dimensional space, we count the number of basis vectors in three dimensions first.

h/8	1.0	5.8	17.4	38.8
Eq. (20)	1.16	6.32	18.48	40.64

5.1. Volume-associated vectors.

5.1.1. G_v^i. Since the volume-associated gradient space is constructed from (9′) and satisfies (10), it follows that

$$\begin{aligned}\#(G_v^i) &= \#(\bar{P}_v^{i-3}) - \#(\bar{P}_v^{i-4}) \\ &= \binom{i}{3} - \binom{i-1}{3} \\ &= \frac{1}{2}(i-1)(i-2)\end{aligned}$$

and

$$\#(G_v^I) = \binom{i}{3}.$$

5.1.2. $\boldsymbol{R_v^i}$. Since the volume-associated rotational space is constructed from (6′) and satisfies (11), it follows that

$$\begin{aligned}\#(R_v^i) &= \#(\bar{P}_f^{i-3}) \times 4 + \#(\bar{P}_v^{i-4}) \times 3 - [\#(G_v^i) + \#(\bar{P}_f^{i-4}) \times 4 + \#(\bar{P}_v^{i-5}) \times 3] \\ &= i(i-2)\end{aligned}$$

and

$$\#(E_v^I) = \frac{1}{2}(i-2)(i-1)(i+1).$$

5.2. Face-associated vectors.

5.2.1. $\boldsymbol{G_f^i}$. Since the face-associated gradient space is constructed from (8) and satisfies (12), it follows that

$$\begin{aligned}&\#(G_f^i) = \#(P_f^{i-2}) - [\#(G_f^{I-1}) + \#(G_v^I)] \\ &\Rightarrow \#(G_f^I) = \frac{1}{2}i(i-1) \\ &\Rightarrow \#(G_f^i) = i-1.\end{aligned}$$

5.2.2. $\boldsymbol{R_f^i}$. Since the face-associated rotational space is constructed from (5) and satisfies (13), it follows that

$$\begin{aligned}&\#(R_f^i) = \#(P_f^{i-2}) \times 3 - [\#(G_f^I) + \#(E_f^{I-1}) + \#(E_v^I)] \\ &= \ 3\binom{i+1}{3} - [\#(G_f^I) + \#(R_f^{I-1}) + \#(E_v^I)] \\ &\quad \Rightarrow \ \#(R_f^I) = \frac{1}{2}(i-1)(i+2) \\ &\quad \Rightarrow \ \#(R_f^i) = i\end{aligned}$$

and

$$\#(E_f^I) = (i-1)(i+1).$$

5.3. Edge-associated vectors.

5.3.1. $\boldsymbol{G_e^i}$. Since the edge-associated gradient space is constructed from (7) and satisfies (14), it follows that

$$\begin{aligned}&\#(G_e^i) = \#(P_e^{i-1}) - [\#(G_e^{I-1}) + \#(G_f^I)] \\ &\Rightarrow \#(G_e^I) = i \\ &\Rightarrow \#(G_e^i) = 1.\end{aligned}$$

5.3.2. $\boldsymbol{R_e^i}$. Since the edge-associated rotational space is constructed from (4) and satisfies (15), it follows that

$$\begin{aligned}&\#(R_e^i) = \#(P_e^{i-1}) \times 2 - [\#(G_e^i) + \#(E_e^{I-1}) + \#(E_f^I)] \\ &= \ 2\binom{i+1}{2} - [\#(G_e^I) + \#(R_e^{I-1}) + \#(E_f^I)] \\ &\Rightarrow \#(R_e^I) = 1 \\ &\Rightarrow \#(R_e^i) = \begin{cases} 1, & i = 1, \\ 0, & i \geq 2, \end{cases}\end{aligned}$$

and

$$\#(E_e^I) = i + 1.$$

5.4. E^i and $E^{i-1}(curl)$. From (16), we see that

$$\begin{aligned}\#(E^i) &= 6 \times \#(E_e^I) + 4 \times \#(E_f^I) + \#(E_v^I)\\ &= \frac{1}{2}(i+1)(i+2)(i+3),\end{aligned}$$

and also from (17) we observe

$$\begin{aligned}\#(E^{i-1}(curl)) &= \#(E^i) - [6 \times \#(G_e^i) + 4 \times \#(G_f^i) + \#(G_v^i)]\\ &= \frac{1}{2}i(i+2)(i+3).\end{aligned}$$

The numbers of basis functions thus computed are identical to those of Nedelec [1].

5.5. F^i and $F^{i-1}(curl)$. From (18), we find that

$$\begin{aligned}&\#(F^i) = \#(e) \times \#(E_e^I) + \#(f) \times \#(E_f^I) + \#(v) \times \#(E_v^I),\\ &\#(F^{i-1}(curl)) = \#(F^i) - [\#(e) \times \#(G_e^i) + \#(f) \times \#(G_f^i) + \#(v) \times \#(G_v^i)].\end{aligned}$$

According to [7], ignoring Dirichlet boundaries, an ideal Delaunay tessellation in three dimensions obeys the following approximate relationships:

$$\begin{aligned}\#(e) &\approx \#(v) \times 1.16,\\ \#(f) &\approx \#(v) \times 2.\end{aligned}$$

Consequently, the total number of degrees of freedom is linearly proportional to $\#(v)$ and can be estimated from the following equations:

$$\begin{aligned}\#(F^i) &\approx \#(v) \times \frac{1}{2}(i+1)(i^2+i+0.32),\\ \#(F^{i-1}(curl)) &\approx \#(v) \times \frac{1}{2}i(i^2+i+0.32).\end{aligned} \tag{20}$$

As discussed earlier, using F^i does not result in a more accurate solution. $F^{i-1}(curl)$ is favored because it contains fewer unknowns. Notice, however, that the ratio $(i+1)/i$ is not significant with higher orders.

When the volume unknowns are eliminated, $\#(F^i)$ and $\#(F^{i-1}(curl))$ are greatly reduced to

$$\begin{aligned}\#(F^i) &\approx \#(v) \times (i+1)(2i-0.84),\\ \#(F^{i-1}(curl)) &\approx \#(v) \times i(2i-0.84).\end{aligned} \tag{21}$$

One can also estimate the number of nonzero entries by assuming an ideal Delaunay tessellation, where an edge is shared by 5 connecting tetrahedra forming a saucer. This edge interacts with the surrounding 26 edges (including itself), 15 faces, and 5 tetrahedra. Because a face is shared by 2 tetrahedra, it interacts with 9 edges, 7 faces (including itself), and 2 tetrahedra. A volume unknown interacts with 6 edges, 4 faces, and itself. Therefore, we have the following formula for the number of nonzero entries for $\#(F^{i-1}(curl))$:

$$NZ \approx \left(1.16i \times NZ_e + 2(i-1)i \times NZ_f + \frac{1}{6}(i-1)(i-2)(2i+3) \times NZ_v\right) \#(v). \tag{22}$$

NZ_e, NZ_f, and NZ_v and are calculated as

$$\begin{aligned} NZ_e &= 26i + 15(i-1)i + \frac{5}{6}(i-1)(i-2)(2i+3), \\ NZ_f &= 9i + 7(i-1)i + \frac{2}{6}(i-1)(i-2)(2i+3), \\ NZ_v &= 6i + 4(i-1)i + \frac{1}{6}(i-1)(i-2)(2i+3). \end{aligned}$$

6. Multilevel preconditioned conjugate gradient method.

In this work, we employ Schwarz methods, often used in the domain decomposition area, and apply them to form an efficient preconditioner for the conjugate gradient algorithm with p-type finite elements. In particular, we use a multiplicative Schwarz preconditioner. This structure can be viewed as an overlapping block Gauss–Seidel preconditioner. Even without conjugate gradient acceleration, the multiplicative method can take far fewer iterations than the additive version. This theory is provided in [35]. Conventionally, multilevel methods are associated with a nested grid that employs a multilevel of grids [36]. In this paper, the multilevel algorithm employs a single grid but a multilevel of basis functions. We may think of the approach presented here as a p-refinement multilevel method [37], [38] instead of as the more traditional h-refinement multilevel method, where p refers to the order of the element and h refers to the element size. We employ Schur factorization to obtain an approximate inverse of the system matrix and treat it as a preconditioner in the conjugate gradient method. It can be proved that the current approach is equivalent to a V-cycle multigrid method. An advantage of the current approach is that it provides a better understanding of the approximation made in computing the preconditioner. We will call the resulting procedure the MPCG method.

Numbering unknowns from the lowest level to the highest, i.e., from 1 to p, the system matrix A_P has the following block structure:

$$A_P = \begin{bmatrix} A_{1,1} & A_{1,2} & \dots & A_{1,p} \\ A_{2,1} & A_{2,2} & & \vdots \\ \vdots & \ddots & & \vdots \\ \vdots & & \ddots & \\ A_{p,1} & \dots & \dots & A_{p,p} \end{bmatrix}.$$

As in section 4, capital index letters denote the entire hierarchy, and lower case letters denote the additional unknowns. To utilize the multilevel concept, we write the above in two-level recursive form:

$$A_P = \begin{bmatrix} A_{P-1} & A_{P-1,p} \\ A_{p,P-1} & A_{p,p} \end{bmatrix}.$$

The above matrix is factorized by Schur factorization:

$$A_P = \begin{bmatrix} A'_{P-1} & A_{P-1,p} \\ 0 & A_{p,p} \end{bmatrix} \begin{bmatrix} I & 0 \\ A_{p,p}^{-1} A_{p,P-1} & I \end{bmatrix}, \tag{23}$$

$$A'_{P-1} = A_{P-1} - A_{P-1,p} A_{p,p}^{-1} A_{p,P-1}.$$

When A'_{P-1} is approximated by $B_{P-1} = A_{P-1}$ and the $A_{p,p}$'s are approximated by an incomplete Cholesky decomposition with thresholding ILU, i.e., $A_{p,p} \approx B_{p,p} = LDL^T$, we obtain a multiplicative preconditioner

$$B_P = \begin{bmatrix} B_{P-1} & A_{P-1,p} \\ 0 & B_{p,p} \end{bmatrix} \begin{bmatrix} I & 0 \\ B_{p,p}^{-1} A_{p,P-1} & I \end{bmatrix}.$$

We use ILU preconditioners to take advantage of the orthogonality of the basis functions. When $A_{P-1,p}$ and $B_{p,p}^{-1} A_{p,P-1}$ are further removed, we obtain a less effective additive preconditioner. Although the multiplicative preconditioner requires approximately one additional matrix multiplication in each conjugate gradient iteration (three matrix vector multiplications versus two for the additive preconditioner), the saving on the number of conjugate gradient iterations well compensates this cost. Numerical experiments show that for $A_{p,p}$, a thresholding constant of 0.01 is a good choice.

Matrix A_p has two sets of negative eigenvalues: physical and nonphysical [25], [26], [27]. Nonphysical ones correspond to the gradient space. Physical ones are the resonance modes of the system with resonance frequency less than the prescribed frequency. As discussed in section 3.2, nonphysical ones from p greater or equal to 1 can be easily preconditioned to positive eigenvalues. However, for $E^0(curl)$, the complete separation of gradient and rotational spaces is not done. In order for MPCG to converge for indefinite problems, $A_{1,1}$ has to be decomposed exactly. Otherwise, the preconditioned matrix will remain highly indefinite such that MPCG will not converge. Also, the mesh has to be fine enough such that $A_{1,1}$ accurately contains the low frequency spectrum below the prescribed frequency.

7. Numerical results.

Since $E^p(curl)$ is computationally advantageous, we will focus on studying it numerically. All computations are performed with a Pentium II, 550 MHz processor PC. First, we demonstrate the accuracy of the elements by computing the lowest eigenvalue of a rectangular cavity of dimensions $8\times10\times16$ mm^3. We choose this problem because the fields in the cavity are smooth. The eigenvalues are computed using the Lanczos algorithm implemented with MPCG. The cavity is first split into two boxes along the longest dimension, and each box is then broken into six tetrahedra. This gives the coarse mesh. Splitting the boxes into eight boxes of equal size gives the next finer mesh, and so on. Therefore, the tetrahedra in the mesh are not perfectly regular, but they are well shaped. To speed computation of the system matrix, we precomputed the set of constant matrices [21]. For MPCG, we start with a zero initial guess and allow the residual norm to go down to less than 1e-4 of the norm of the right-hand side vector. If the discretization error of solution is less than 1e-4, we let the residuals go two orders of magnitude less than the discretization error. The results in Figures 1–5 show the normalized error in the computed eigenvalues varying the basis order and the element size. P-refinement is clearly superior to h-refinement and is therefore preferred wherever the solution is

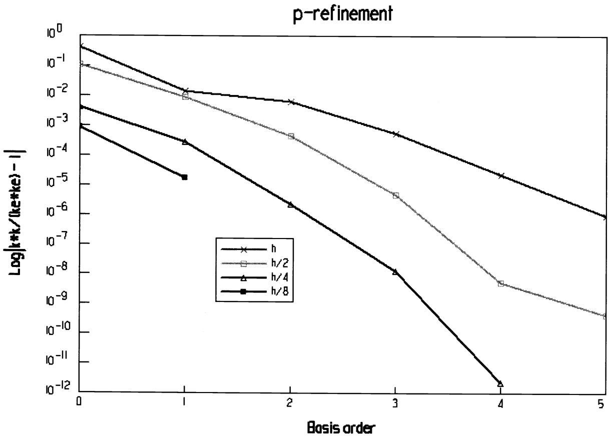

FIG. 1. *Convergence with respect to p-refinement, k_e is the exact eigenvalue.*

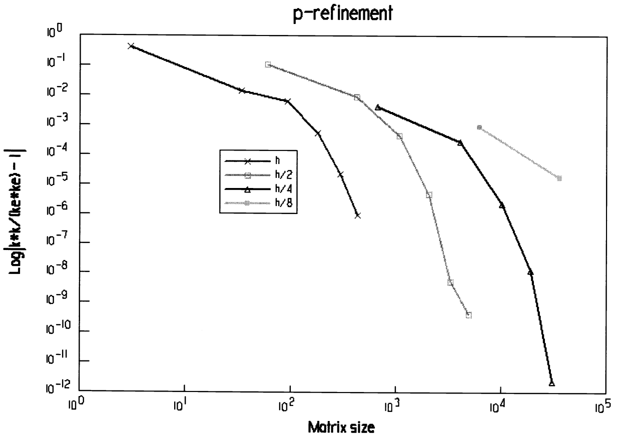

FIG. 2. *Convergence of p-refinement plotted versus matrix size.*

smooth. As shown in Figure 5 and also expressed in (21), the cost of going to higher order is small, especially at already high orders. The convergence rates of each basis order can be computed from the slopes of Figure 3. These agree with the optimal theoretical rates of $2 \times p + 2$.

Next, we demonstrate the effectiveness of MPCG. The rectangular box of the previous example is now treated as a waveguide by sending the TE_{01} mode through the faces with dimensions 8×16 mm^2. As shown in Figure 6, although the residual curve is bumpy, it reaches machine precision without stagnation. Table 7 exhibits an almost constant number of iterations, regardless of the mesh fineness or of the basis order. In Figure 7, we demonstrate the effect of increasing frequency by several or-

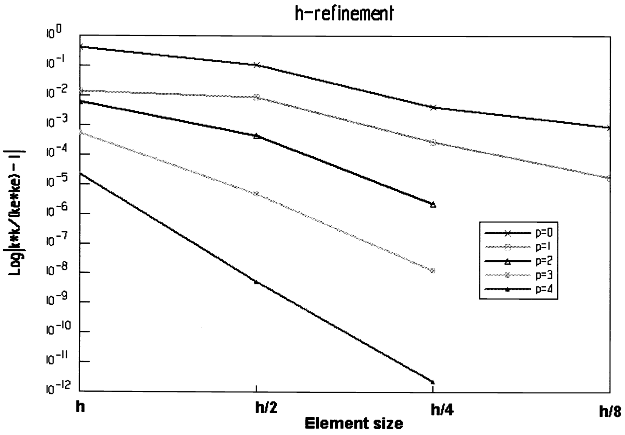

FIG. 3. *Convergence versus h-refinement.*

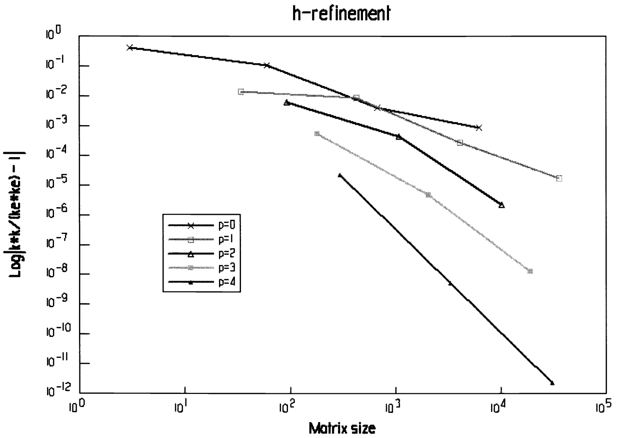

FIG. 4. *Convergence of h-refinement plotted versus matrix size.*

ders of magnitude. As expected, at low frequencies, the number of iterations is almost constant. However, at higher frequencies, when the element size exceeds a quarter wavelength, MPCG starts to oscillate irregularly. At extremely high frequencies, the finite element solutions are, of course, meaningless since the elements are relatively large compared to the wavelength of the field. Nevertheless, the matrix A approaches the positive definite matrix T, and MPCG again converges quickly. Figure 8 compares h- and p-refinement in terms of CPU time. Again, p-refinement is clearly superior. In Figure 9, we separate the portions of time spent on CG iterations and on the decomposition of $A_{1,1}$. This figure shows that another advantage of p-refinement is that the time spent on the full decomposition of $A_{1,1}$ stays constant as p increases. With

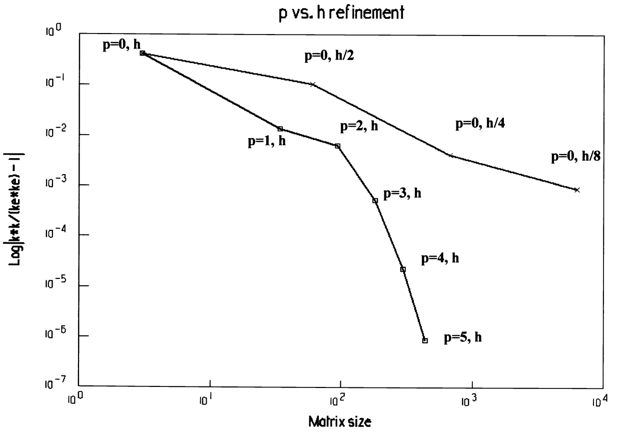

FIG. 5. *Comparison of p- and h-refinement for the cavity problem.*

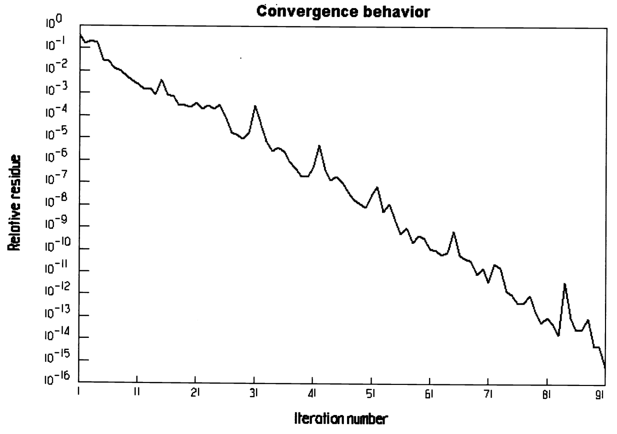

FIG. 6. *The convergence behavior of MPCG for E^1(curl) at* 10 *GHz.*

the problem sizes reported here, CG dominates the computational time. However, the decomposition of $A_{1,1}$ will become the bottleneck with much larger problems. Research on eliminating full decomposition of $A_{1,1}$ is underway.

Going to higher orders is not without cost. The matrices are denser as seen from Table 5. Despite this, the higher rates of convergence are worthwhile. We compare the estimated number of nonzeros per row from (22) with real ones. Real ones approach the estimated ones for a larger mesh, where the unknowns on Dirichlet boundaries are only a small portion of the entire domain. The number of unknowns per tetrahedron is also compared to the estimate from (20) in Tables 3–6.

To examine the reasons why MPCG works so well for indefinite systems, we re-

TABLE 7

distorted	1.4e4	1	3.3e4	4.5e1	1.0e9	1.4e2

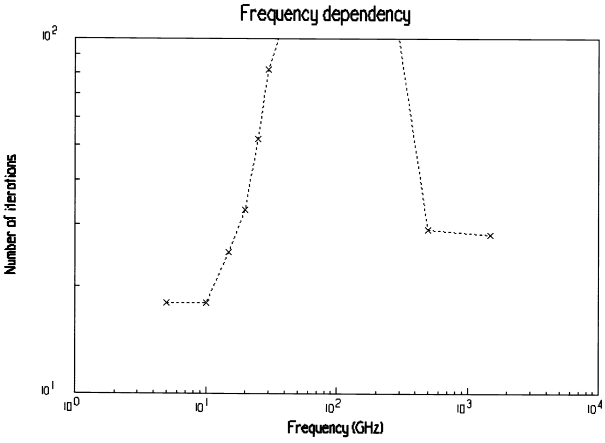

FIG. 7. *The effect of varying frequency on the number of MPCG iterations for $E^1(curl)$.*

visit the last problem and study the spectrum of original and preconditioned matrices. The results are presented in Table 7 and in Figures 10 and 11. Although the original matrix is highly indefinite due to the presence of the gradient space, at 10 GHz it is preconditioned into a positive-definite matrix. The condition number of preconditioned matrix grows at a much slower rate than those of the original matrix, as shown in Table 7. The eigenvalues of the original matrix are real because it is a real symmetric matrix. On the other hand, the preconditioned matrix is not symmetric, and therefore its eigenvalues are either real or in complex conjugate pairs. The three clusters in Figure 10(b) help to explain why MPCG converges better than what would be expected from the computed condition numbers. At higher frequencies, i.e., at 35 GHz in Figure 11, the preconditioned matrix is no longer positive definite, and therefore MPCG starts to oscillate irregularly.

Our derivation is based on a regular tetrahedron, so that the basis vectors derived above are in general not orthogonal in tetrahedra of arbitrary shape. In complex problems, the tetrahedra are rarely regular. Thus, the matrix generated by using the derived basis functions is not less sparse than that obtained by using nonorthogonal bases. However, we have found empirically that the fill-in generated by the incomplete Cholesky decomposition is greatly reduced by using the orthogonal bases. Thus, while

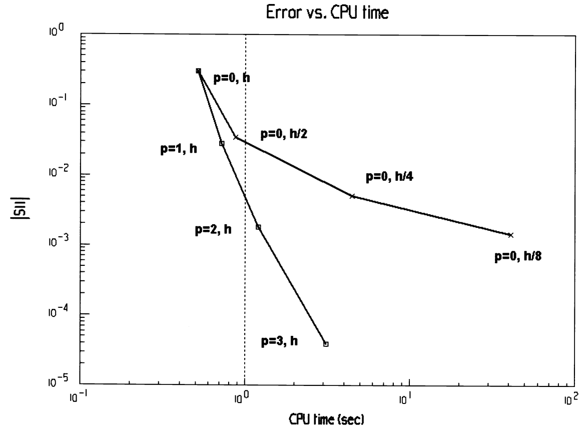

FIG. 8. *Comparison of h- and p-refinement for a waveguide problem.*

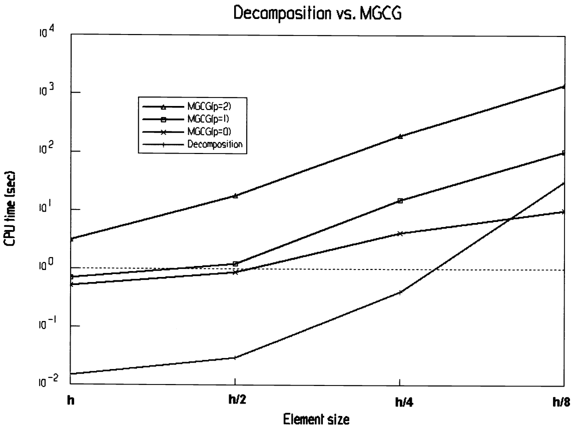

FIG. 9. *Computational complexity.*

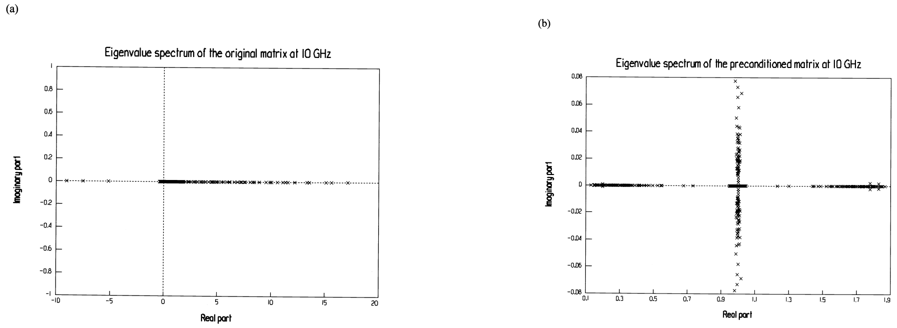
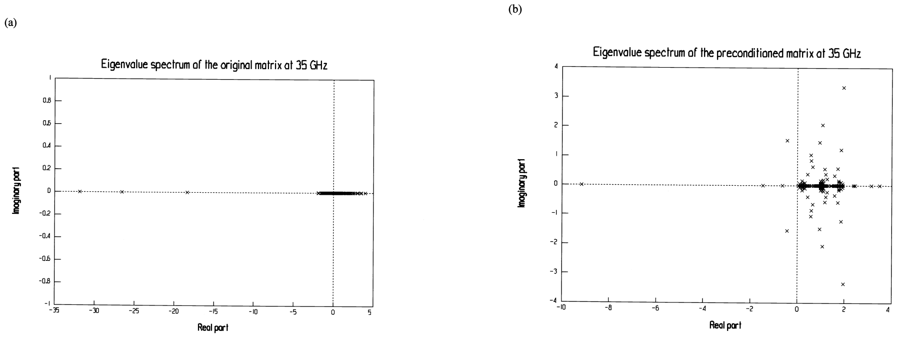
we have not obtained diagonal matrices, we have obtained matrices that are much more diagonally dominant. Even with an arbitrary mesh, the number of iterations increases only slightly from low to high order, suggesting that the basis vectors are quite orthogonal although not perfectly so. In addition, refining the mesh does not increase the number of iterations. On the contrary, the number of iterations is reduced with mesh refinement in most cases. The reason for this is that the $E^0(curl)$ solution improves with mesh refinement and so fewer conjugate gradient iterations are required for convergence with the higher-order solutions. However, if one overrefines the mesh, the increase in the condition number can make MPCG nonconverging.



(a) (b)

FIG. 10. *Spectrum of the original and preconditioned matrices for the h/2 mesh and* $p = 1$ *at* 10 *GHz.*

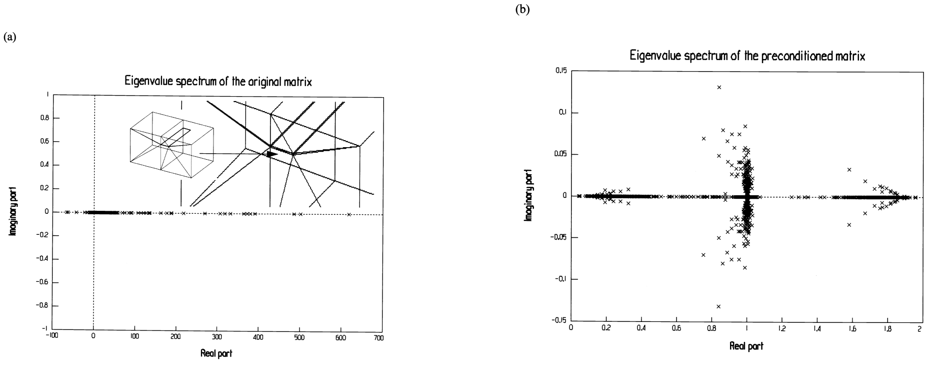


(a) (b)

FIG. 11. *Spectrum of the original and preconditioned matrices for a h/2 mesh and* $p = 1$ *at* 35 *GHz.*

Finally, we study the effect of severely distorted tetrahedra. We distort the mesh by inserting an artificial, rectangular strip of 0.1 mm thickness into the previous waveguide. As shown in the inserts in Figure 12(a), the surface mesh on the port is very badly distorted. Although we are able to precondition the problem into a positive definite matrix, its spectrum, shown in Figure 12(b), spreads out greatly. The condition numbers of the original matrices increase two orders of magnitude, but those of the preconditioned matrices do not, as shown in Table 7. This explains why the number of iterations only increases slightly, from 10 for the $h/2$ mesh, to 14 for $p = 1$, and up to 17 for $p = 2$. We compare the distorted mesh with the $h/2$ mesh because numbers of unknowns are closest in these cases.

If the mesh is not fine enough, the resulting preconditioned matrix is indefinite, and in this case, MPCG fails. There are two remedies for this problem: one is to refine the mesh, and the other is to include the $E^1(curl)$ bases in $A_{1,1}$. With mesh refinement or with enlargement of the lowest level matrix, the nonconverging problem is overcome. We monitor the diagonal entries in the Cholesky matrix to see if they have the opposite sign to the corresponding entries in the original matrix. If they do, this indicates that the Cholesky matrix has different spectral characteristics from the original matrix. Therefore, the decomposition is unstable, and a refinement or



(a) (b)

FIG. 12. *Spectrum of the original and preconditioned matrices for a distorted mesh and $p = 1$ at* 10 *GHz.*

enlargement is performed.

8. Conclusions. Tangential vector finite element basis functions are not unique and can be defined in many ways. This paper suggests that the best choice—indeed the optimal choice—is that basis set which results in the fastest convergence when the resulting system of equations is solved by using the conjugate gradient algorithm. The goal of constructing tangential vector finite element basis functions should therefore be to allow efficient preconditioning, and thus reduce the condition number of the system matrix. Computational efficiency results by using basis sets and associated preconditioners that speed up the conjugate gradient process.

We have shown that the optimal rate of convergence is obtained by using bases computed using a multistep process in which the admissible basis set is decomposed into gradient and rotational subspaces, and each vector is made orthogonal to the others by computing the eigenvectors of the element submatrix. This orthogonalization is performed on a regular tetrahedron and is therefore not strictly valid on tetrahedra of arbitrary shape. Empirical results, however, demonstrate that the orthogonality is largely preserved with meshes of arbitrary shape, and the resulting global finite element matrix is therefore well suited for solution with the conjugate gradient method. Numerical experiments show that the number of iterations needed for solution by MPCG is basically a constant, regardless of the order of the basis or of the matrix size. Computational speed is improved by several orders of magnitude due to the fast matrix solution of MPCG and to the high accuracy of the higher-order bases.

ITERATIVE MULTIGRID REGULARIZATION TECHNIQUES FOR IMAGE MATCHING[*]

STEFAN HENN[†] AND KRISTIAN WITSCH[‡]

Abstract. In this paper, we consider the problem of matching images, i.e., to find a deformation u, which transforms a digital image into another such that the images have nearly equal gray values in every image element. The difference of the two images is measured by their L_2-difference, which should be minimized. This yields a nonlinear ill conditioned inverse problem for u, so the numerical solution is quite difficult. A Tikhonov regularization method is considered to rule out discontinuous and irregular solutions to the minimization problem. An important problem is a proper choice of the regularization parameter α. For the practical choice of α, we use iterative regularization methods based on multigrid techniques. To obtain a suitable initial guess, we use an approach similar to the full multigrid (FMG) developed by Brandt [*Math. Comp.,* 31 (1977), pp. 333–390]. The algorithms have optimal complexity: the amount of work is proportional to the number of picture elements. Finally, we present some experimental results for synthetic and real images.

1. Introduction.

An important problem in two- and three-dimensional medical image analysis is to match two similar images resulting from different imaging modalities. In brain research, which was our starting point, it is necessary for the analysis of the organization and variation in the structure of human brains. A good survey of a part of the practical applications is given in [6]. In this paper, we consider a gray-level based mapping method of two similar images. The description of the problem and the numerical algorithms for its solution will be given for the two-dimensional problem. The extension to three dimensions is obvious and has been done.

In two dimensions, the matching leads to the following problem: find a displacement vector $u = (u_1, u_2)^t$ (whose components are functions of the variables $x = (x_1, x_2)^t$) that transforms one image T, called the template, into another image R, called the reference, so that

$$R(x) = T(x - u(x)). \tag{1.1}$$

In continuous two-dimensional variables, the reference R and the template T can be represented by functions $T, R : \Omega \subset \mathbb{R}^2 \longrightarrow \mathbb{R}^{\geq 0}$ which associate with the pixel (picture element) $(x_1, x_2) \in \mathbb{R}^2$ its intensity (gray level), $T(x_1, x_2)$, and $R(x_1, x_2)$, respectively. In our example, Ω will simply be the unit square $[0,1]^2 \subset \mathbb{R}^2$. A digital image B^h is a finite-dimensional approximation of a continuous image B with $B^h : \Omega_h \to [0, g_{max}] \subset \mathbb{N}^{\geq 0}$ and maximal gray-level g_{max}.

We define a map $F = T \circ \phi$, with $\phi(x) = x - u(x)$, from the space of displacements

$\mathcal{X}$ into the set $\mathcal{Y}$ of images

$$F : \mathcal{D}(F) \subset \mathcal{X} \longrightarrow \mathcal{Y}, \qquad F : u \longmapsto T(x - u(x)). \tag{1.2}$$

We consider the subset

$$\mathcal{D}(F) = \left\{ u \in \mathcal{X} \;\middle|\; x - u(x) \in \Omega \quad \forall x \in \Omega \right\}$$

of $\mathcal{X}$. This means that T, and therefore F, are defined. (This restriction can be avoided by extending T to a larger domain.) Thus, the gray-value matching problem (1.1) can be identified with an inverse problem

find u in (1.2), so that (1.1) holds approximately.

In general, this problem is ill-posed in the sense of Hadamard. The information provided from R and the model (1.1) are not sufficient to ensure existence, uniqueness, and stability of a solution u.

In practical applications, only a noisy version R^δ of the exact data R is given with

$$||R - R^\delta|| \leq \delta.$$

In our application, δ is unknown, and we make no assumptions about statistics of the noise. In the case of perturbed data R^δ, the computation of a proper approximation u^δ of (1.1) requires regularization methods.

In section 2, we will present more precisely the minimization problem studied here, as well as the assumptions to impose on the model. We use a Tikhonov regularization for the so-called output least squares functional. It uses a regularization term which favors smooth transformations. This leads to a nonlinear variational problem similar to many other approaches in digital image processing or pattern recognition; cf. [1], [3], [7], [11], [12], [13], and [15].

The first attempts to deal with the issue of medical image matching can be traced back to Bajcsy and Kovacic [5]. These ideas were further developed in [8] using successive overrelaxation for a linearized model and in [1] using Fourier and wavelet representations of a nonlinear functional. In [11] a Landweber iteration scheme was developed, including the multigrid correction scheme (CS) and a trust region method for one-dimensional minimization.

The minima of the Tikhonov functional depend significantly on the choice of the regularization parameter α. Theoretically, decreasing α should give a better agreement of the images, but in practice a too small α leads to strong artifacts because of the influence of high-frequency structures in the image data. Increasing α removes these artifacts and allows only smoother transformations. For further increasing α, the matching of the images becomes worse.

Our aim is to develop methods for the efficient and robust solution of the matching problem and to find a good value of the regularization problem without a priori information.

These methods are described in section 4. In a first approach, a standard multigrid method and the choice of a suitable regularization parameter are combined. The second method follows the solution curve for decreasing α. One starts with a relative large α, which is helpful for the solution method. Then one computes for decreasing α minimal solutions of the functional consisting of the output least squares part and a regularizing part applied to the difference from the previous solution. This process is stopped at the point where the output least squares functional increases.

Another important idea is to use a nested iteration or full multigrid (FMG) approach as introduced by Brandt [4]. The solution process starts with the same problem but a coarser resolution. It is easier to solve the nonlinear problem there and to find global minima. This solution is the starting point for the next finer resolution and usually needs only relatively small corrections.

The Euler–Lagrange equations of the Tikhonov functional are a coupled system of nonlinear PDEs which depend on the regularization parameter. Its discretization and approximation is described in section 3. Finally, we present some experimental results for synthetic and real images in section 6.

2. Tikhonov regularization of the nonlinear inverse problem.

To find an approximate solution of (1.1), we measure the $L_2(\Omega)$ difference of the two images $h(u) = T(x - u) - R(x) = F(u) - R(x)$ by

$$D(u) = \langle h(u), h(u)\rangle_{L_2(\Omega)} = ||h(u)||^2_{L_2(\Omega)} = \int_\Omega (F(u(x)) - R(x))^2 d\Omega.$$

Here, $D(u)$ is the so-called output least squares functional with given data $R(x)$. The inverse problem will be solved by approximatively minimizing $D(u)$, which is a standard method for inverse problems. We can add further terms related, for example, to edges without essential changes in the algorithm presented here.

2.1. Tikhonov regularization.

To rule out discontinuous and irregular solutions to the minimization problem, it is necessary to introduce a smoothing or regularizing term $\alpha||u||^2_{\mathcal{X}}$ with a parameter $\alpha > 0$ for the deformation u. This means that one minimizes the Tikhonov functional

$$J_\alpha(u) = ||h(u)||^2_{L_2(\Omega)} + \alpha||u||^2_{\mathcal{X}} \quad \text{for} \quad u \in \mathcal{D}(F) \tag{2.1}$$

with an appropriate norm $||\cdot||_{\mathcal{X}}$ for the space $\mathcal{X}$.

The statistical model proposed by Amit, Grenander, and Piccioni [2] for image restoration leads us to choose $||u||^2_{\mathcal{X}} = a(u, u)$ with a bilinear form a and to search for a solution among the minima of the energy

$$J_\alpha(u) = ||h(u)||^2_{L_2(\Omega)} + \alpha a(u, u) \quad \text{over} \quad \mathcal{D}(F). \tag{2.2}$$

The parameter $\alpha \in \mathbb{R}^+$ allows us to balance the influence of both terms in the Tikhonov functional $J_\alpha(u)$. For the brain data set, we use a regularizing term of the form

$$a(u, v) = \int_\Omega \left[\sum_{i,j=1}^{2} \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) \left(\frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i} \right) \right] d\Omega \tag{2.3}$$

defined on $\mathcal{X} \subset H^1(\Omega) \times H^1(\Omega)$. This model assumes that the difference between the images comes from an elastic deformation of the brain. The elastic constants are chosen so that the changes in volume are maximal, which corresponds to longitudinal stretch without lateral shrink. The bilinear form measures the energy of the elastic deformation, is isotropic in the directions, and is neutral with respect to translations and rotations but penalizes these transformations by the boundary conditions introduced in section 2.2.

This is an appropriate model for the case that the template image T is obtained by slicing and scanning the brain as described in [5]. Other bilinear forms on $H^1(\Omega) \times H^1(\Omega)$ as the Laplacian would give similar results but have no coupling between the directions as (2.3). Regularization in $H^2(\Omega) \times H^2(\Omega)$ as by the biharmonic operator enforces too much smoothness of the displacements.

Total variation based regularization as in [7], [13] is not appropriate in this case, but useful for other applications, and will be investigated in the future.

2.2. Minimization by a variational equation. With the described form of regularization in the functional J_α and $f(u) = -\frac{1}{\alpha} h'(u) \cdot h(u)$, the Euler–Lagrange equation for the minimizer u is given by the nonlinear variational equation

$$a(u, \phi) = \langle f(u), \phi \rangle_{L_2(\Omega)} \quad \forall \phi \in (H^1(\Omega))^2 = H^1(\Omega) \times H^1(\Omega). \tag{2.4}$$

For α very small, this is a singular perturbed problem which is difficult to solve.

Equation (2.4) is the weak form of a nonlinear coupled PDE. For $\mathcal{X} = (H^1(\Omega))^2$, one obtains Neuman boundary conditions. In our application, it is appropriate to use $\mathcal{X} = (H_0^1(\Omega))^2$ which yields Dirichlet boundary conditions

$$u(x) = 0 \quad \text{for} \quad x \in \partial\Omega.$$

(In principle, one has to enforce $u \in \mathcal{D}(F)$, but this was no problem in our application.) The minimization of the Tikhonov functional is therefore equivalent to finding a solution of the boundary value problem

$$E(u(x)) = \begin{cases} -\alpha(\Delta u(x) + \operatorname{grad}(\operatorname{div} u(x))) - f(u(x)) & = & 0 & \text{for } x \in \Omega, \\ u(x) & = & 0 & \text{for } x \in \partial\Omega. \end{cases} \tag{2.5}$$

3. Discretization, approximation, and solution methods of the nonlinear PDE. For the purpose of the numerical solution of (2.5), we approximate the infinite-dimensional space $\mathcal{X}$ by a finite-dimensional space $\mathcal{X}_n$.

3.1. Discretization. The image T^h obtained from the continuous image T can be considered as a function which is piecewise constant on each pixel of a regular square grid G_h. For the discretization of the PDE (2.5), we use G_h with the pixel-centered gridpoints as in Figure 1:

$$G_h = \{x \in \mathbb{R}^2 : x = (x_i, x_j) = (h/2 + ih, h/2 + jh),\ i, j = 0, 1, \ldots, n-1\}.$$

The displacement vector is a grid function $u_h(x_h) = (u_{1,h}, u_{2,h})^t \in (\mathcal{F}(G_h))^2 = \mathcal{F}(G_h) \times \mathcal{F}(G_h)$ on G_h. (In three-dimensional magnetic resonance (MR), there is a sampling difference between the $x-y$-plane and the z-direction. In practice, it is not necessary to take this into account for the adaptation process. It could be done, but then the multigrid (MG) components would have to be modified.)

3.2. Computation of the nonlinear functional $f(u(x))$. The nonlinear functional $f(u(x))$ in (2.5) has to be evaluated by discretization. With $\phi(u) = \phi(x, u) = x - u(x)$, one gets

$$f(u) = h'(u) \cdot h(u) = J_{T^h}(\phi(u)) \cdot J_\phi(u) \cdot h(u) = -\nabla T^h(\phi(u)) \cdot h(u),$$

since $J_\phi(u) = -I_2$, the 2×2 identity, and $J_{T^h}(x) = T^{h\prime}(x) = \nabla T^h(x)^t$. For determining a second order approximation of ∇T^h, the right-hand side $f_h(u_h) = (f_{1,h}, f_{2,h})^t \in$

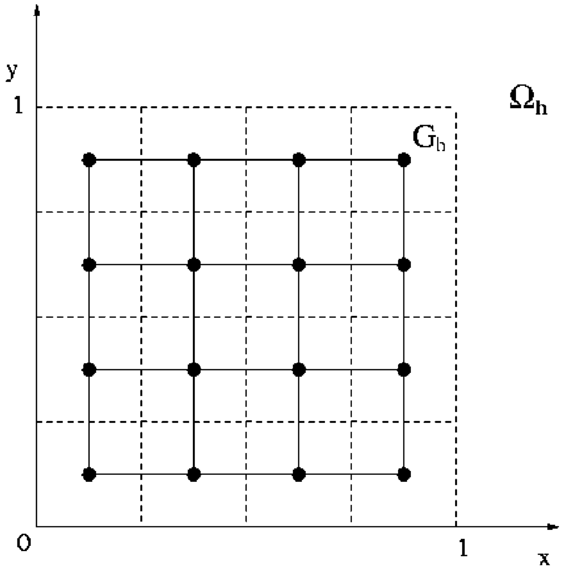

FIG. 1. *The pixel-centered grid G_h in two-dimensions for* 4×4 *pixels.*

$\mathcal{F}(G_h) \times \mathcal{F}(G_h)$ for an inner point (x_i, x_j) of G_h is computed with central differences by

$$f_h(u_h(x_i, x_j)) = \frac{1}{2} \left(\frac{T^h_{i+1,j} - T^h_{i-1,j}}{h}, \frac{T^h_{i,j+1} - T^h_{i,j-1}}{h} \right)^t (T^h_{i,j} - R^h_{i,j}), \tag{3.1}$$

where t denotes the transpose, $T^h_{i,j} = T^h(x_i - u_{1,h}(x_i, x_j), x_j - u_{2,h}(x_i, x_j))$ the deformed template image, and $R^h_{i,j} = R^h(x_i, x_j)$ the reference image.

3.3. Approximation of the PDE. The PDE (2.5) is discretized by the finite difference method using second order approximations. This is done by replacing the partial derivatives by corresponding difference quotients. This yields the following second order stencils:

$$-\Delta u = -u_{xx} - u_{yy} = \frac{1}{h^2} \begin{bmatrix} 0 & -1 & 0 \\ -1 & +4 & -1 \\ 0 & -1 & 0 \end{bmatrix} u_h + \mathcal{O}(h^2)$$

and

$$-u_{xy} = \frac{1}{4h^2} \begin{bmatrix} 1 & 0 & -1 \\ 0 & 0 & 0 \\ -1 & 0 & 1 \end{bmatrix} u_h + \mathcal{O}(h^2).$$

Therefore, the discrete operator $L_h = -\Delta_h - \text{grad}_h(\text{div}_h)$ is represented by

$$L_h(u_h) = \begin{cases} \frac{1}{h^2} \begin{bmatrix} 0 & -1 & 0 \\ -2 & 6 & -2 \\ 0 & -1 & 0 \end{bmatrix} u_{1,h} + \frac{1}{4h^2} \begin{bmatrix} 1 & 0 & -1 \\ 0 & 0 & 0 \\ -1 & 0 & 1 \end{bmatrix} u_{2,h}, \\ \\ \frac{1}{h^2} \begin{bmatrix} 0 & -2 & 0 \\ -1 & 6 & -1 \\ 0 & -2 & 0 \end{bmatrix} u_{2,h} + \frac{1}{4h^2} \begin{bmatrix} 1 & 0 & -1 \\ 0 & 0 & 0 \\ -1 & 0 & 1 \end{bmatrix} u_{1,h} \end{cases} \tag{3.2}$$

for $u_h = (u_{1,h}, u_{2,h})^t \in (\mathcal{F}(G_h))^2$. By using (3.2) for all inner gridpoints $x_h \in G_h$ and $u_h = 0$ for all boundary gridpoints, together with the discretized form of the nonlinear functional $f(u)$ as described in (3.1), one obtains a nonlinear system for the unknown values of the translation vector

$$E_h(u_h(x)) = \alpha L_h(u_h(x)) - f_h(u_h(x)) = 0. \tag{3.3}$$

This is the discretized form of the boundary value problem (2.5). The nonlinear system in two dimensions for typical images with 256 × 256 pixels has 2^{17} equations and unknowns. The corresponding system in three dimensions with 256 × 256 × 128 voxel has 3×2^{23} equations and unknowns. This makes clear that it is extremely important to use very efficient solvers. Otherwise, in particular the three-dimensional problem cannot be solved.

3.4. Coarse grid problems and intergrid transfers. In the discretized PDE (3.3), the nonlinear functional $f_h(u_h)$ is naturally defined on the fine grid G_h by the pixel size of the digital images T^h and R^h (section 3.2). To use efficient solution methods like the multigrid full approximation scheme (FAS) [4], [14], for the nonlinear PDE we have to define the functional $f_h(u_h)$ also on coarse grids.

The basic idea of the FAS is to smooth the errors of the solution such that they can be approximated on a coarser grid. On the coarse grid, a defect equation is solved, and then the coarse grid corrections are interpolated back to the fine grid, where the errors are smoothed again. The components of the FAS for this problem are described in the following.

By coarsening the digital images, a corresponding nonlinear functional $f_H(u_H)$ can be defined on coarse grids $G_{2^l h}$ with $l > 0$. This means that we approximate the infinite-dimensional spaces $\mathcal{X}$ and $\mathcal{Y}$ by a sequence of finite-dimensional subspaces $\{\mathcal{Y}_l\}_{l=0,1,2,...}$ with $\mathcal{Y}_l = \mathcal{Y}_{2^l h}$ for the images and $\{\mathcal{X}_l\}_{l=0,1,2,...}$ with $\mathcal{X}_l = \mathcal{X}_{2^l h}$ for the displacements. The sequences have the properties

$$\mathcal{X}_L \subset \mathcal{X}_{L-1} \subset \cdots \subset \mathcal{X}_0 \subset \cdots \subset \mathcal{X} \quad \text{and} \quad \mathcal{Y}_L \subset \mathcal{Y}_{L-1} \subset \cdots \subset \mathcal{Y}_0 \subset \cdots \subset \mathcal{Y}.$$

The images are coarsened by collecting several picture elements into one coarse picture element. This can be described by the operator $R^l_{l-1} : \mathcal{Y}_{l-1} \to \mathcal{Y}_l$. This corresponds to a lowpass filter in digital imaging. This procedure yields a sequence of coarser and coarser images with containing only information about corresponding coarse structure. On all grids, the discretization of the PDE is done in the same way as on the finest grid as described in section 3.1; cf. Figure 2.

Standard components for the intergrid transfers (injection, half weighting, and full weighting for restriction and linear and bilinear interpolation) in the FAS were implemented.

4. Approximate solution methods.

We now introduce two different methods for obtaining approximate solutions to the nonlinear problem. We consider the finite-dimensional Tikhonov functional $J_{\alpha,h} : G_h \times G_h \to \mathbb{R}^{\geq 0}$. The functional is positive and continuous. Therefore the Tikhonov functional has at least one global minimum on $\mathcal{X}$ because $J_{\alpha,h} \to \infty$ for $||u||_{\mathcal{X}} \to \infty$.

In general, the minimum is not unique. Moreover, a solution of $J_{\alpha,h}$ depends crucially on the regularization parameter α. The aim of our methods is to find a suitable solution of the minimization problem, hopefully a global one, without any a priori information about the image data and about a suitable choice of α in (2.2).

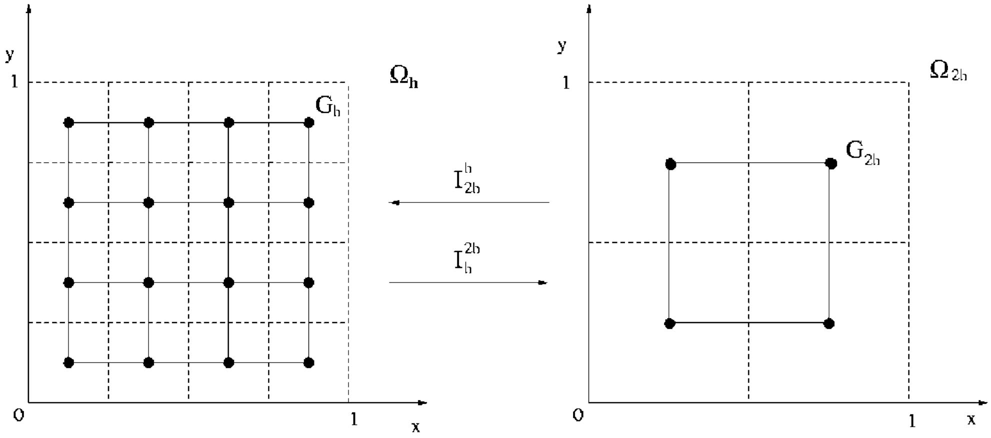

FIG. 2. *Intergrid transfers.*

The regularization parameter α determines the ratio between the influence of the image least squares differences $D(u)$ and the smoothness $a(u, u)$ of the displacements. For α too large, the influence of $D(u)$ is damped, and the matching is quite bad since the images behave as stiff materials. For α too small, the displacements are not smooth and are useless. Then, the numerical solution is difficult or even impossible. In particular, for $\alpha = 0$, each pixel could be mapped onto any other pixel with the same gray level.

In the first algorithm, we try to choose a deformation which is relatively independent of α. In the second algorithm, we solve a sequence of subproblems with decreasing parameter α. For each subproblem, we determine the parameter α within the iteration.

4.1. Algorithm 1: Modified FAS for minimizing output least squares functional. In this section, we will describe a method which incorporates the solution process and the choice of a suitable regularization in a modified FAS algorithm. We combine the multigrid idea and the minimization of the functional as follows.

The main components of every multigrid process are the relaxation and the coarse grid correction. As in standard multigrid methods, the coarse grid correction is determined by restricting the defect and the current approximation to the coarse grid. The coarse grid problem is solved approximately, the solution is interpolated to the fine grid and the solution is added to the fine grid approximation. However, in our case a proper scaling of the coarse grid correction and of the result of the relaxation yields significantly faster convergence, in particular for smaller α. Therefore, we proceed as follows.

On the fine grid an intermediate approximation $\overline{u}_h^{(k+1)}$ is computed by a nonlinear relaxation method for (2.5). We use a nonlinear Jacobi relaxation. With respect to the discretization and approximation of (2.5), we get

$$\frac{6}{h^2} u_{1,h}^{(n+1)} + f_{1,h}(u^{(n+1)}) = \frac{1}{h^2} \begin{bmatrix} & 1 & \\ 2 & & 2 \\ & 1 & \end{bmatrix} u_{1,h}^{(n)} + \frac{1}{4h^2} \begin{bmatrix} -1 & & 1 \\ & & \\ 1 & & -1 \end{bmatrix} u_{2,h}^{(n)}$$

$$\frac{6}{h^2} u_{2,h}^{(n+1)} + f_{2,h}(u^{(n+1)}) = \frac{1}{h^2} \begin{bmatrix} & 2 & \\ 1 & & 1 \\ & 2 & \end{bmatrix} u_{2,h}^{(n)} + \frac{1}{4h^2} \begin{bmatrix} -1 & & 1 \\ & & \\ 1 & & -1 \end{bmatrix} u_{1,h}^{(n)}$$

with initial guess $u_h^{(0)} \in \mathcal{D}(F)$. (On the coarse grids, the restricted defect of the next finer grid has to be added to the right-hand side.)

Due to the dependence on α, this approximation may result in a bad matching, as described above. To correct this, the approximation is modified by

$$u_h^{(k+1)} = u_h^{(k)} + \omega \cdot \left(\overline{u}_h^{(k+1)} - u_h^{(k)} \right).$$

The parameter ω is the solution of the one-dimensional minimization problem

$$\text{find } \omega \in \mathbb{R} \quad \text{so that} \quad \omega = \arg \min_{\overline{\omega} \in \mathbb{R}^{>0}} D \left(u_h^{(k)} + \overline{\omega} \cdot \left(\overline{u}_h^{(k+1)} - u_h^{(k)} \right) \right).$$

This approximation and its defect

$$d_h = rhs_h - E_h \left(\overline{u}_h^{(k+1)} \right)$$

are transferred to the coarse grid as in standard multigrid. On the fine grid, the right-hand side is given by $rhs_h = 0$ and as described in (4.2) on the coarse grid. On the coarse grid, we first choose a nonlinear relaxation scheme

$$\overline{u}_H = u_H + v_H = \mathcal{R}_H(u_H, v_H, d_H) \tag{4.1}$$

for the resulting nonlinear discrete system

$$E_H(u_H + v_H) = d_H + E_H(u_H) \tag{4.2}$$

with

$$u_H = \left(u_1^{(1,1)}, \ldots, u_1^{(n-1,n-1)}, u_2^{(1,1)}, \ldots, u_2^{(n-1,n-1)} \right) \in \mathcal{F}(G_H) \times \mathcal{F}(G_H)$$

and defect $d_H \in \mathcal{F}(G_H) \times \mathcal{F}(G_H)$ on the coarse grid to compute the coarse grid correction v_H in the full approximation scheme.

Again, we choose a parameter ω as the solution of the one-dimensional minimization-problem

$$\text{find } \omega \in \mathbb{R} \quad \text{so that} \quad \omega = \arg \min_{\overline{\omega} \in \mathbb{R}^{>0}} D(u_H + \overline{\omega} \cdot v_H). \tag{4.3}$$

Then the coarse grid correction is

$$\overline{v}_H = \omega \cdot v_H$$

and

$$u_h^{new} = u_h + I(\overline{v}_H).$$

In standard multigrid, a similar scaling is known, but $J_{\alpha,h}$ would be minimized. Here, the regularization term is used in determining the direction v_H but omitted in choosing ω. This reduces the influence of α on the final solution.

This two-level algorithm can be converted into a multigrid algorithm in the same way as in a standard FAS by recursive solution of the coarse grid problem by the two grid method.

4.2. Algorithm 2: Iterative Tikhonov regularization. In the previous section, we have described an algorithm which computes an approximation for a given parameter α but which reduces the influence of α on the solution by a one-dimensional minimization problem within a FAS.

In this section, we present an algorithm which is more complicated than algorithm 1 and is in some respect similar to the solution with the L-curve criterion investigated by Hansen [9] and Hansen and O'Leary [10]. The L-curve criterion is a practical method for choosing the regularization parameter α for linear inverse problems. It was observed that the log-log-graphic presentation of the curve $L = \{x(\alpha), y(\alpha)\}$ with the norm $x(\alpha)$ of the regularized solution $u_\alpha(x)$ of (2.2) and the corresponding residual norm $y(\alpha)$ can be useful in studying the problem.

The so-called L-curve method derives its name from the plot of the graph $\{x(\alpha), y(\alpha)\}$, which resembles the shape of the letter "L." Here, the basic idea is that a point on the graph near the "corner" of the "L" represents a reasonable compromise between data fit and smallness of the regularizing term. In our situation, the use of the L-curve criterion is dissatisfying due to the following reasons:

- The description of the L-curve criterion is for linear problems. (This means that F in (1.2) is a linear operator.) The idea can be generalized to nonlinear problems, but in general we saw no useful "L."
- For the iterative solution and the singular perturbation problems, we cannot compute solutions for small α.
- An important role for minimizing an nonlinear functional is the choice of an initial guess. This is not taken into account within the L-curve criterion. In contrast to linear problems, there is no optimal regularization parameter for an optimal solution.
- The L-curve criterion seems to prefer too smooth solutions in our case with nonoptimal matching of the images; see Figure 3.

In the following, we introduce a method which may be viewed as an iterated Tikhonov regularization. The method consists of a sequence of minimization subproblems

$$\left\{ \min_{u\in\mathcal{D}(F)} \{||h(u)||^2_{L_2(\Omega)} + \alpha_k||u - u^{(k)}||^2_{\mathcal{X}}\} \right\}_{k\in\mathbb{N}} \tag{4.4}$$

whose solutions $u = u_\alpha^{(k+1)}$ depend on the parameter $\alpha_k > 0$ and on the initial guess $u^{(k)}$. Each subproblem is well posed for α sufficiently large and can be solved efficiently by a FAS.

There are two ideas: The first is, not to use a very small α in order to simplify the solution process. The second is the use of $u - u^{(k)}$ in the regularization term diminishes the influence of the regularization since $u^{(k)} \approx u$ but allows only reasonable solutions. An important issue herein is the determination of the first iterate.

For the numerical implementation of the iterative Tikhonov regularization, we compute the solution $u_\alpha^{(1)}$ with relative large α and an initial guess $u^{(0)} \in \mathcal{D}(F)$; cf. section 5. This is done by solving the nonlinear Euler–Lagrange equation (2.5) with a FAS and initial guess $u^{(0)}$. For the next iteration, we reduce α by a factor $0 < \kappa < 1$ (e.g., $\kappa = 1/2$) and take the solution $u_\alpha^{(1)}$ as the initial guess.

We get a sequence of displacement fields $\{u^{(k)}\}_{k\in\mathbb{N}}$ which successively reduces the value of the nonlinear functional $D(u)$. We stop the iteration if $D(u^{(k+1)}) > D(u^{(k)})$ and get the following algorithm.

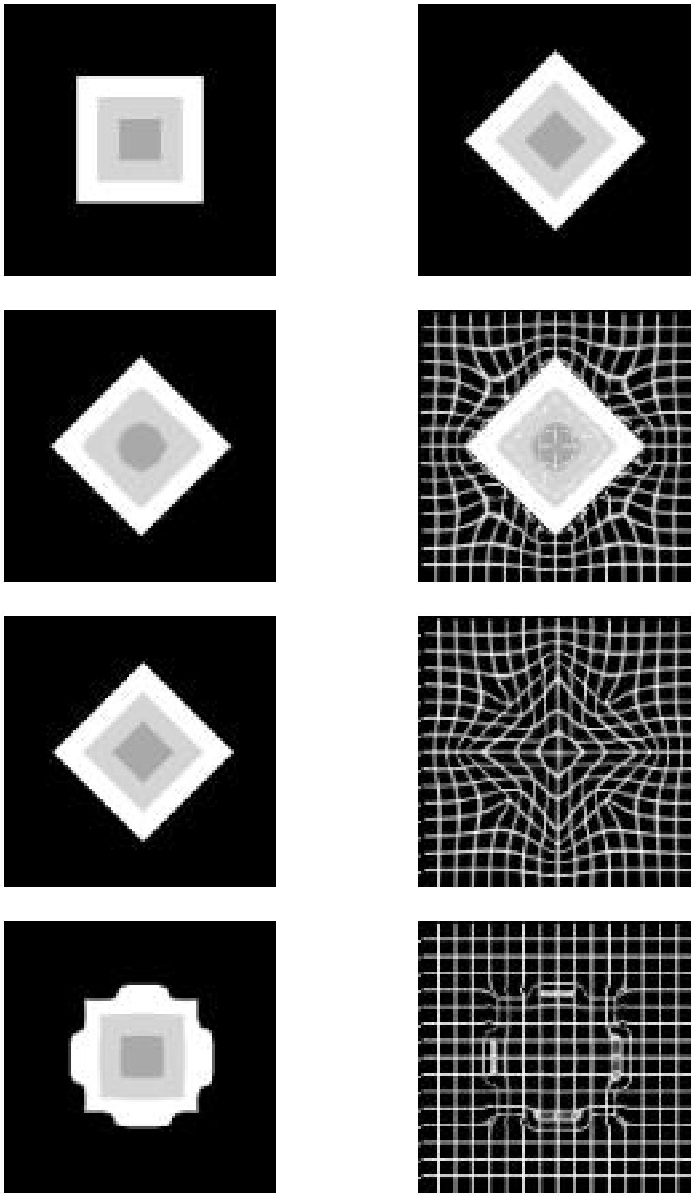

FIG. 3. *From left to right:* 1. *Template image* T. 2. *Reference image* R. 3. *Template deformed by the solution of algorithm* 1 *introduced in section* 4.1. 4. *Deformed template and superimposed deformed uniform grid for showing the deformation applied to the template.* 5. *Template deformed by the solution of algorithm* 2 *introduced in section* 4.2. 6. *Uniform grid deformed by the solution.* 7. *Template deformed by the solution of the L-curve criterion.* 8. *Uniform grid deformed by the solution of the L-curve criterion.*

  compute $u^{(k+1)} = \arg\min_{u \in \mathcal{D}(F)} ||h(u)||_2^2 + \alpha_k ||u^{(k)} - u^*||_{\mathcal{X}}^2$
  reduce $\alpha = \kappa \cdot \alpha$;
until $\big(D(u^{(k+1)}) > D(u^{(k)})\big)$.
```

5. Multiresolution minimization and multilevel image matching. Within the minimization of the Tikhonov functional (2.1) in sections 4.1 and 4.2, the subsets $\mathcal{X}_h \subset \mathcal{X}$ and $\mathcal{Y}_h \subset \mathcal{Y}$ are given by the number of pixels. This pixel size h is also the step size of the discretization of the PDE in section 3.

The use of a small discretization parameter h causes two difficulties:

- The adaption process mainly adapts structures with size h and neglects coarser structures. Therefore the minimization process finds local minima far from the global one.
- The minimization process requires many iterations with a fine resolution h.

Both difficulties can be avoided to a large extent by considering the Tikhonov functional also on coarser resolutions. The basic principle of this approach is that the image structures will be matched on that resolution on which they can be represented. This means that we approximate the infinite-dimensional spaces $\mathcal{X}$ and $\mathcal{Y}$ by a sequence of finite-dimensional subspaces, as in section 3.4. We get a sequence of minimization problems

$$(M_l) \qquad \min_{u_l \in \mathcal{X}_l} \left\{ ||h(u)||_2^2 + \alpha a(u, u) \right\}$$

defined on the spaces $\mathcal{X}_l$. With an interpolation operator $I_l^{l-1} : \mathcal{X}_{2^l h} \to \mathcal{X}_{2^{(l-1)}h}$, we transform the solution $u_l \in \mathcal{X}_l$ onto the next finer resolution. Then $I_l^{l-1}(u_l) \in \mathcal{X}_{l-1}$ is a suitable initial guess for the minimization of M_{l-1}.

Multilevel image matching.

```
$u_L = 0; l = L$;
repeat
  if $(l = L)$
    compute $u_L^*$ with initial approximation $u_L$;
    $l = l - 1$;
  else
    $u_{l-1} = I_l^{l-1}(u_l^*)$;
    compute $u_{l-1}^*$ with initial approximation $u_{l-1}$;

6. Results. In order to conclude this paper, we present experimental results for synthetic as well as MR images. To demonstrate the principle and reliability of the iterative Tikhonov iteration scheme and the modified FAS described in sections 4.1 and 4.2, we consider the synthetic images shown in Figure 3. These images are quite different but can be adapted quite well, depending on the required smoothness.

Comparing the synthetic template image (leftmost in Figure 3) with the synthetic reference image (second left in Figure 3) shows a difference of $\frac{1}{N}||T(x) - R(x)||_{L_2} \approx 71$ with $N = 128^2$ pixels. After the iteration described in sections 4.1 and 4.2 on a

sequence of the three subspaces $X_{1/32} \subset X_{1/64} \subset X_{1/128}$, we get a sequence of deformation fields $u^{(k)}$ on every subspace which reduces the difference $\frac{1}{N}||T(x - u^{(k)}(x)) - R(x)||_{L_2}$ within the iteration. Figures 4 and 5 show for the algorithms the decreasing least squares difference on the three different resolutions applied to the example in

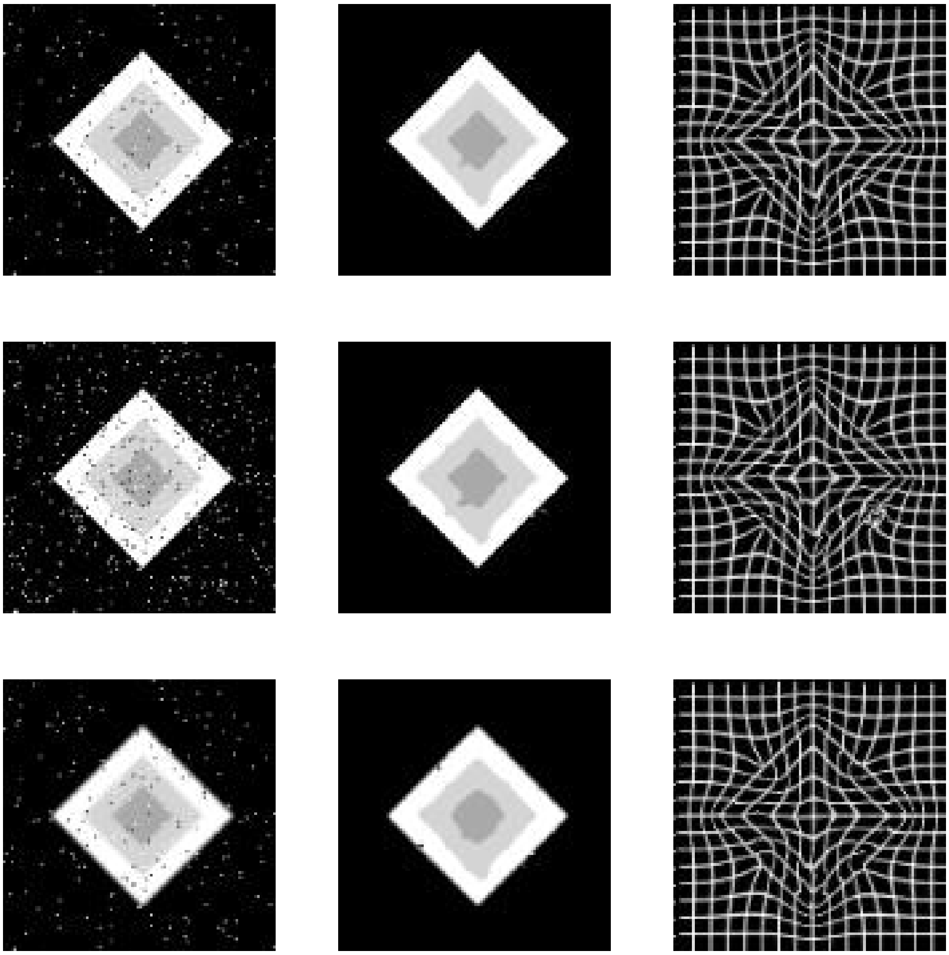

Fig. 6. *Images of the three experiments with different noise levels. Left: The reference with added noise R^δ (added noise from top to bottom:* 1. 2% *salt and pepper noise* 2. 5% *salt and pepper noise* 3. *blurred with* 2% *salt and pepper noise). Middle: Template image deformed by the solution of algorithm* 2. *Right: Uniform grid deformed by the solution of algorithm* 2.

Figure 3. The graphs are scaled by work units (WUs) on the finest grid, corresponding to the effort of a multigrid cycle.

In the examples, a WU of the first algorithm corresponds to approximately a $\frac{1}{3}$ WU of the second one. In all examples, we used a FAS with one relaxation before and one after the coarse grid correction for smoothing the error on three levels: full weighting restriction, bilinear interpolation, and the injection operator for the restriction of the image data and the approximate solutions.

In the next experiment, we analyze the dependence of the solution on the noise level $||R^\delta - R|| \leq \delta$ of the reference image R. For this, we added different types of noise to the synthetic reference images which appear in Figure 3. These images are shown in Figure 6. We observe that the results (in the middle of Figure 6) obtained by algorithm 2 are similar to the reference shown in Figure 3, except for artifacts caused by the added noise. The graphs of the decreasing defect functional $D(u)$ for these experiments scaled by WUs on the finest grid are shown in Figure 7. As expected, the

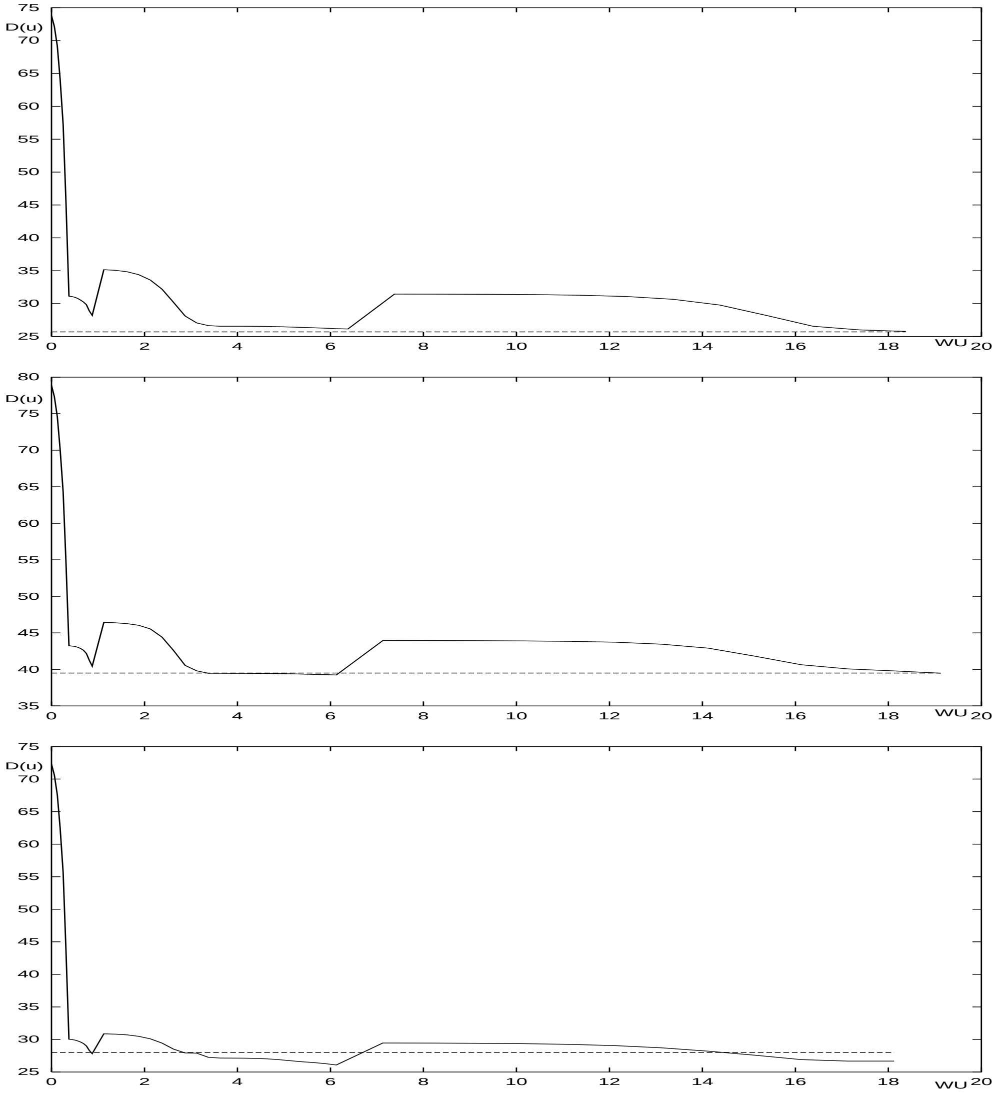

FIG. 7. *Least squares difference* $D(u^{(k)})$ *after each iteration step of algorithm* 2 *for the three experiments shown in Figure* 6 *and the noise level* δ *parallel to the abscissa.*

decreasing least squares functional on the three different resolutions can be reduced down to the noise level δ.

For estimation of the registration quality on MR slices, the iterative minimization algorithms for image matching are applied to a deformed MR template image $T(x)$ and a MR reference image $R(x)$, shown in Figures 8 and 9. Figure 10 shows the calculated result $T(x - u^*(x))$ deformed by the solution u^* of the minimization problem. The minimization problem is also solved on three subsets $X_{1/64} \subset X_{1/128} \subset X_{1/256}$. One can easily see in Figure 10 how the deformation field produces an image similar to the reference image. This can be stressed by the graphs in Figures 11 and 12. They show the decreasing least squares difference $D(u)$ between the images after each iteration step of the algorithms on different resolutions. The graphs are scaled by WUs on the finest grid.

7. Conclusion. In this paper, we have introduced a nonlinear model for digital image matching. This inverse problem is ill-posed and its treatment requires careful use of regularizing techniques. For Tikhonov regularization, which aims at smooth solutions, a bilinear form is added. In section 4 we have presented two efficient methods for solving the problem.

The main advantages of these methods, compared to other known methods, are the self-controlled choices of the regularization parameter. In other papers [5], [1], this problem is not discussed, and therefore in practical applications "trial an error" methods for the parameter choice are inevitable. On the other hand, the use of a FAS for solving the nonlinear Euler–Lagrange equations is an essential benefit of the presented methods. This results in computing time which is linear in the number of the picture elements. This optimal scaling is important for the treatment of large, in particular three-dimensional, problems which are in practice unsolvable only with relaxation methods. In order to compare our methods with other methods in literature, Bajcsy and Kovacic [5] use the Jacobi method to determine deformations of a template and Christensen et al. [8] use successive overrelaxation (SOR) with checkerboard update to compute viscous fluid deformations of a template. In practice, due to the h-dependence convergence rates of the Jacobi method and the SOR, these methods are rather slow. For instance, the method in [8] has an execution time of 7 days with a MIPS R440 processor and 10 hours using a massively parallel DECmpp 128×64 MasPar computer with a resolution of $128 \times 128 \times 100$ voxel. With this resolution, our algorithm takes (with a nonoptimized implementation in C++) approximately one hour on an Ultra-Sparc Workstation.

Acknowledgment. We would like to thank the referees for useful remarks on the first version of the manuscript.

A LAGRANGE SCHEME FOR A MATHEMATICAL MODEL OF POWDER COMPRESSION*

G. GODINAUD[†], M. N. LE ROUX[†], AND A. Y. LE ROUX[†]

Abstract. A mathematical model to simulate the compression of pharmaceutical powder under fixed deformation is proposed. This model is an hydrodynamic one, completed with the description of the porosity in the medium. This study leads to the elaboration of a general monodimensional model, made of three nonlinear partial derivative equations and a state law for the pressure. The mathematical resolution of this system is made using a splitting technique and an efficient numerical method.

Key words. nonconservative hyperbolic systems, conservative hyperbolic systems, splitting techniques, Lagrange method, pressure terms, diffusion terms

1. Introduction.

Studies on powder compression lead to descriptions of the compaction processes and also to predictions of the compactibility of powders. The consolidation mechanisms of a product subject to compression are many:

- elastic deformation,
- fragmentation or plastic deformation,
- mechanical binding,
- thermal effect.

In practice, the products undergo time-dependent deformation imposed by the punch of a press. At first contact with a powder bed, punch speed varies between 100 and 120 mm/s and decreases to 0 at the point of maximal penetration.

In this work, we propose a mathematical model to simulate the change from pulverulent state to compact state. With this aim in view, we have studied the dynamic behavior of powder undergoing deformation.

The experimental device is modelized in one dimension. The die containing the powder is described in space by [0,1], and the time by $[0, T]$ (T between 20 and 100 ms). We have decided to modelize the transitional part of the phenomenon and to follow the vanishing of the vacuum in the powder (evolution of the porosity) during the compression. This model is based on experimental results in pharmaceutical science, together with the specialists (see [7], [8], [9], [10]) for physical background.

To implement this model, we have considered that the evolution of the porosity was bound with the deformation speed tensor, and we have coupled this equation with the mass and momemtum conservations. Thus, the state law for the pressure is a function of the relative porosity and the density. Using the quantities

- σ : porosity parameter in [0,1],
- m : mass of powder,
- ρ : real density (without air),
- q : apparent density (with air), $q = (1 - \sigma)\rho$,
- v : volume,

- u : particle speed,
- p : pressure,

we get the following nonconservative system (S):

$$\left\{\begin{array}{l} q_t + (qu)_x = 0, \\ \sigma_t + (\sigma u)_x = k(\sigma)\sigma u_x, \\ (qu)_t + (qu^2 + p)_x = \dfrac{\partial}{\partial x}(\varepsilon(q,\sigma)u_x), \\ + \ \text{state law} \quad : \quad p = a(\sigma)b(q), \end{array}\right. \tag{1}$$

where the function $k(\sigma)$ describes the features of the products and has the properties [1]

$$\left\{\begin{array}{l} 0 \leq k(\sigma) \leq 1, \\ k(1) = 1, \end{array}\right.$$

and the diffusion term $\frac{\partial}{\partial x}(\varepsilon(q,\sigma)u_x)$ allows a display of the phenomenon.

We are going to present the method of resolution for the system. It is a splitting technique which allows us to treat separately the different physical terms. We will group the terms in order to reproduce physical phenomena for which one can adapt a specific numerical method. In, particular, we will perform a Lagrangian treatment of the convection terms, well adapted to the following of the powder during the compression. This treatment must be conservative. The system (1) is nonconservative, and we have found a solution to obtain a conservative system equivalent to (1).

This splitting technique leads to degenerated problems, whose solutions are obtained by perturbation methods involving well-posed problems [1], [2], [3].

2. The conservative form. We consider system (1):

$$\left\{\begin{array}{l} q_t + (qu)_x = 0, \\ \sigma_t + (\sigma u)_x = k(\sigma)\sigma u_x, \\ (qu)_t + (qu^2 + p)_x = \dfrac{\partial}{\partial x}(\varepsilon(q,\sigma)u_x), \\ + \ \text{state law} \quad : \quad p = a(\sigma)b(q). \end{array}\right.$$

We denote the vector

$$W = \begin{pmatrix} q \\ \sigma \\ u \end{pmatrix},$$

and system (1) is equivalent to the system

$$W_t \ + \ A(W)\, W_x \ = \ V, \tag{2}$$

where the matrix A and the right-hand-side member V are given by

$$A(W) = \begin{pmatrix} u & 0 & q \\ 0 & u & \sigma(1 - k(\sigma)) \\ \dfrac{a(\sigma)b'(q)}{q} & \dfrac{a'(\sigma)b(q)}{q} & u \end{pmatrix},$$

$$V \ = \ \text{diffusion term}.$$

Under the condition

$$a(\sigma)b'(q) \; + \; \sigma(1-k(\sigma))\frac{a'(\sigma)b(q)}{q} \; > \; 0 \tag{3}$$

the matrix $A(W)$ has three real eigenvalues:

$$\begin{cases} \lambda_1 \; = \; u \; + \; \sqrt{a(\sigma)b'(q) \; + \; \sigma(1-k(\sigma))\dfrac{a'(\sigma)b(q)}{q}}, \\ \lambda_2 \; = \; u, \\ \lambda_3 \; = \; u \; - \; \sqrt{a(\sigma)b'(q) \; + \; \sigma(1-k(\sigma))\dfrac{a'(\sigma)b(q)}{q}}. \end{cases}$$

W is the solution of

$$\begin{cases} W_t \; + \; A(W)W_x \; = \; V, \\ W(0,x) \; = \; \begin{cases} W^l \text{ if } x < 0, \\ W^r \text{ if } x > 0. \end{cases} \end{cases} \tag{4}$$

We denote by (H_q, H_σ, H_u) the microscopic profile of shock associated with a solution of (1):

$$q \; = \; q_l \; + \; \Delta q H_q(x-ct), \tag{5}$$

$$\sigma \; = \; \sigma_l \; + \; \Delta\sigma H_\sigma(x-ct), \tag{6}$$

$$u \; = \; u_l \; + \; \Delta u H_u(x-ct), \tag{7}$$

where c is constant; H_q, H_σ, and H_u are Heaviside generalized functions [5], [6]; and $\Delta q = q_r - q_l$, $\Delta\sigma = \sigma_r - \sigma_l$, and $\Delta u = u_r - u_l$.

Replacing q and u with (5) and (7) in the first equation of (1), we get

$$(c - u_l - \Delta u H_u)\Delta q H_q' \; = \; (q_l + \Delta q H_q)\Delta u H_u', \tag{8}$$

so, by integration in $G_s(\mathbb{R})$,

$$q_l \; + \; \Delta q H_q \; = \; \frac{A}{(c - u_l - \Delta u H_u)}. \tag{9}$$

We get c, the sound speed, knowing that

$$\begin{cases} H_u = H_q = 0 \;\; \text{if} \;\; x < 0, \\ H_u = H_q = 1 \;\; \text{if} \;\; x > 0, \end{cases}$$

and so

$$c \; = \; \frac{\Delta(qu)}{\Delta q}. \tag{10}$$

Now we replace σ and u with (6) and (7) in the second equation of (1):

$$(c - u_l - \Delta u H_u)\Delta q H_\sigma' \; = \; (\sigma_l + \Delta\sigma H_\sigma)(1 - k(\sigma_l + \Delta\sigma H_\sigma))\Delta u H_u'. \tag{11}$$

Using the same method, we take the function ϕ defined by

$$\phi(\sigma) \; = \; \int \frac{d\sigma}{\sigma(1-k(\sigma))},$$

and we get

$$\phi(\sigma_l + \Delta\sigma H_\sigma) \;=\; -\ln(c - u_l - \Delta u H_u) + A, \tag{12}$$

where A is constant. The speed c is given by

$$c \;=\; \overline{u} \;+\; \frac{\Delta u}{2}\coth\frac{\Delta\phi}{2}, \tag{13}$$

where $\overline{u} \;=\; \frac{1}{2}(u_l+u_r)$. Thus, the Rankine–Hugoniot relations for the nonconservative system (1) are given by

$$c \;=\; \overline{u} \;+\; \Delta u\frac{\overline{q}}{\Delta q}, \tag{14}$$

$$c \;=\; \overline{u} \;+\; \Delta u\frac{1}{2}\coth\frac{\Delta\phi}{2}. \tag{15}$$

To get a conservative form for system (1), we must find with the jump conditions (13), (14) a variable w satisfying

$$\frac{\overline{w}}{\Delta w} \;=\; \frac{1}{2th\frac{\Delta\phi}{2}}. \tag{16}$$

Let us consider $w \;=\; \exp\phi(\sigma)$. We obtain

$$\begin{cases} \dfrac{\partial w}{\partial t} \;=\; w\;\dfrac{1}{\sigma(1-k(\sigma))}\sigma_t, \\ \dfrac{\partial w}{\partial x} \;=\; w\;\dfrac{1}{\sigma(1-k(\sigma))}\sigma_x. \end{cases}$$

This gives

$$\frac{\partial w}{\partial t} \;+\; \frac{\partial(wu)}{\partial x} \;=\; \frac{w}{\sigma(1-k(\sigma))}(\sigma_t + u\sigma_x + \sigma(1-k(\sigma))u_x), \tag{17}$$

but $\sigma_t + u\sigma_x + \sigma(1-k(\sigma))u_x \;=\; 0$, so we get the next theorem.

THEOREM 1. *Using the variables* $q, w \;=\; \exp\phi(\sigma)$ *and* u, *system* (1) *is equivalent to the following conservative system:*

$$\begin{cases} q_t + (qu)_x = 0, \\ w_t + (wu)_x = 0, \\ (qu)_t + (qu^2+p)_x = \frac{\partial}{\partial x}(\varepsilon(q,\sigma)u_x), \\ +\;\; state\;\; law\;\; :\;\; p = g(w)b(q). \end{cases} \tag{18}$$

System (18) is equivalent to the system

$$W_t \;+\; B(W)\,W_x \;=\; V, \tag{19}$$

where

$$B(W) = \begin{pmatrix} u & 0 & q \\ 0 & u & w \\ \dfrac{g(w)b'(q)}{q} & \dfrac{g'(w)b(q)}{q} & u \end{pmatrix}.$$

The matrix $B(W)$ has three real distinct eigenvalues, under the condition

$$g(w)b'(q) \;+\; w\,\frac{g'(w)b(q)}{q} \;>\; 0. \tag{20}$$

This condition is always true, because $g(w), b(q), g'(w), b'(q)$, and w are always positive.

3. Resolution. Let us consider the conservative system (18). We try to build a strong numerical method to resolve it. This leads us to use a splitting method, dividing (18) into three subsystems which will be solved separately. The usual numerical technique consists of taking an approximation of the initial problem [4]. Here, system (18) will be solved in three steps:

- convection terms,
- pressure terms,
- diffusion terms,

and the global scheme is made of the combination of the schemes adapted to each step.

3.1. The convection terms. We consider the system of convection terms (C):

$$\begin{cases} q_t + (qu)_x = 0, \\ w_t + (wu)_x = 0, \\ (qu)_t + (qu^2)_x = 0, \\ + \;\text{ state law } \;:\; p = g(w)b(q). \end{cases}$$

This system is degenerated: the speed u is a triple eigenvalue and Riemann solvers are very difficult to realize. The solution of this problem is obtained through perturbation method involving a well-posed problem. Let us consider the perturbed Riemann problem (C$_\varepsilon$):

$$\begin{cases} q_t + (qu)_x = 0, \\ w_t + (wu)_x = 0, \\ (qu)_t + (qu^2)_x + \varepsilon^2 p_x = 0 \end{cases} \tag{21}$$

with the piecewise constant initial data

$$(q, w, u) \;=\; \begin{cases} q_l, w_l, u_l & \text{for } \; x < 0, \\ q_r, w_r, u_r & \text{for } \; x > 0. \end{cases} \tag{22}$$

For a fixed $\varepsilon > 0$, system (21) is hyperbolic and has three distinct real eigenvalues:

$$u \;-\; c_\varepsilon, \quad u, \quad u \;+\; c_\varepsilon,$$

where

$$c_\varepsilon \;=\; \varepsilon\,\sqrt{g(w)b'(q) \;+\; w\frac{g'(w)b(q)}{q}}.$$

For $\varepsilon > 0$, the solution of the Riemann problem (21), (22) is made up of three waves: shock wave, rarefaction wave, or contact discontinuity (see Figure 1).

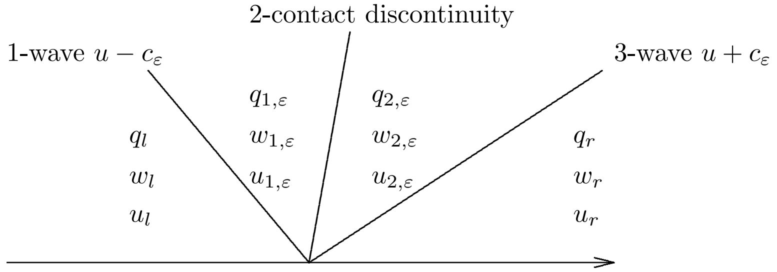

Fig. 1.

3.1.1. Eventuality of shock waves. We consider the case where the solutions of (C_ε) are discontinuous. These discontinuities correspond to shock waves propagating along the trajectories of shock. The velocity of propagation of the shock wave is given by the Rankine–Hugoniot relations:

$$\dot{x} \;=\; \frac{\Delta(qu)}{\Delta q} \;=\; \frac{\Delta(wu)}{\Delta w} \;=\; \frac{\Delta(qu^2+p)}{\Delta(qu)}.$$

Thus we get two equations of compatibility:

$$\Delta u(\overline{q}\Delta w - \overline{w}\Delta q) = 0, \tag{23}$$

$$q_+ q_- \Delta u^2 = \varepsilon^2 \Delta p \Delta q, \tag{24}$$

where q_+, q_- are the values of q here and of one of the three states 1-shock, 2-contact discontinuity, and 3-shock. Using (23) and (24), we deduce the following:

1. On the contact discontinuity,

$$\Delta u = 0 \quad \text{and} \quad \Delta p = 0. \tag{25}$$

2. On the 1-shock or the 3-shock,

$$\Delta u^2 = \frac{\varepsilon^2}{q_+ q_-} \Delta p \Delta q \quad \text{and} \quad \Delta\left(\frac{w}{q}\right) = 0. \tag{26}$$

Knowing that $p = g(w)b(q)$ and that g' and p' are positive, applying the finite increments theorem, we obtain

$$\frac{\Delta p}{\Delta q} \;\geq\; 0.$$

With (26), we deduce

$$\left\{\begin{array}{rcl} \Delta u & = & s\varepsilon \dfrac{\Delta q}{\sqrt{q_+ q_-}} \sqrt{\dfrac{\Delta p}{\Delta q}}, \\ s & = & +1 \;:\; \text{shock with the velocity } u + c_\varepsilon,\ q \text{ increasing } (q_2 > q_r), \\ s & = & -1 \;:\; \text{shock with the velocity } u - c_\varepsilon,\ q \text{ decreasing } (q_1 > q_l). \end{array}\right.$$

3.1.2. Eventuality of rarefaction waves. The rarefaction waves are the smooth solutions of the Riemann problem (21), (22). We express w, u, and p as functions of q:

$$\begin{cases} w = w(q), \\ u = u(q), \\ p = p(q). \end{cases}$$

Replacing the expressions of w, u, and p in (21), we get

$$w(q) = w'(q)q, \tag{27}$$

$$u'^2(q)q^2 = \varepsilon^2 p'(q). \tag{28}$$

Integrating (28) we obtain

$$\begin{cases} u = u_0 + s\varepsilon(\psi(q) - \psi(q_0)), \\ \text{where} \quad \psi(q) = \int_0^q \frac{\sqrt{p'}}{q} dq. \end{cases} \tag{29}$$

Taking $u_0 = u_r$ and $u_0 = u_l$,

$$u = u_r + \varepsilon(\psi(q_{2,\varepsilon}) - \psi(q_r)), \tag{30}$$

$$u = u_l - \varepsilon(\psi(q_{1,\varepsilon}) - \psi(q_l)). \tag{31}$$

3.1.3. Limit on the perturbed problem ($\mathbf{C}_\varepsilon$). We have the following situations.

- Wave $u + c$:
  1. shock if q decreases: $q_2 > q_r$,
  2. rarefaction if q increases: $0 < q_2 < q_r$.
- Wave $u - c$:
  1. shock if q increases: $q_1 > q_l$,
  2. rarefaction if q decreases: $0 < q_1 < q_l$.

In order to characterize the physically allowable solutions, we have the following theorem.

THEOREM 2. *When we study the limit for $\varepsilon \longrightarrow 0$ of the Riemann problem*

$$\begin{cases} q_t + (qu)_x = 0, \\ w_t + (wu)_x = 0, \\ (qu)_t + (qu^2)_x + \varepsilon^2 p_x = 0, \\ (q, w, u) = \begin{cases} q_l, w_l, u_l & for \quad x < 0, \\ q_r, w_r, u_r & for \quad x > 0, \end{cases} \end{cases} \tag{32}$$

supposing that q_l and q_r are not equal to zero, we get the following:

1. *For $u_l > u_r$: The solution of* (39) *converges almost everywhere to the limit:*

$$(q, w, u) = \begin{cases} q_l, w_l, u_l & for \quad x < u^*t, \\ q_r, w_r, u_r & for \quad x > u^*t, \end{cases}$$

where $u^* = \frac{\sqrt{q_l}u_l + \sqrt{q_r}u_r}{\sqrt{q_l} + \sqrt{q_r}}$.

2. *For $u_l < u_r$: We obtain*

$$(q, w, u) = \begin{cases} q_l, w_l, u_l & for \quad x < u_l t, \\ q_r, w_r, u_r & for \quad x > u_r t. \end{cases}$$

The proof is detailed in [1], [2].

The study of this convection step permits us to implement the Lagrange method for the resolution, using the shock velocity u^*.

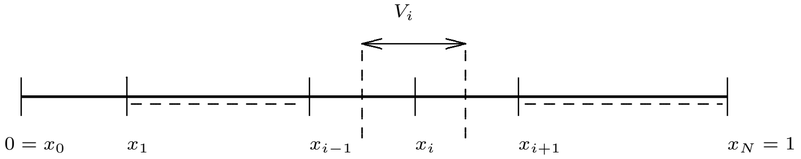

FIG. 2.

3.1.4. Numerical resolution: Finite volume Lagrange method. We denote by Ω the space $\Omega = [0,1]\times[0,T]$. We take a regular initial mesh of [0,1]:

$$0 = x_0 < x_1 < \cdots < x_i < \cdots < x_N = 1, \qquad \text{where } \forall\ i \in [0,N]\ ,\ x_i \ = \ ih.$$

We take a time increment Δt and we define

$$0 = t_0,\ t_1 = \Delta t\ ,\ldots,\ t_n = t_{n-1} + \Delta t\ ,\ldots,\ t_N = T.$$

We have the following definitions:

- $\forall\ i \in [0,N]$, $]x_i,x_{i+1}[$ is *a mesh.*
- $\forall\ i \in [0,N]$, x_i is *a node* of the mesh.
- $\forall\ i \in [0,N]$, V_i is *the volume* corresponding to the space taken by the material assigned to the node x_i.

For $t = 0$, we have the representation, where the V_i are centered on the x_i.

- In each V_i, we define

$$m_i \ = \ \int_{V_i} q\ dx,$$

$$Q_i \ = \ \int_{V_i} qu\ dx,$$

$$W_i \ = \ \int_{V_i} w\ dx.$$

We denote by x_i^n the position of the node x_i at the time t_n. For a quantity α, we shall denote by α_i^n the corresponding value of α. Now that we have the data necessary for the computation, let us describe a cycle of the method. Suppose that we know the solution of the problem

$$\left\{\begin{array}{l} U_t(x,t) + AU(x,t) = 0, \\ U(x,0) = U_0(x). \end{array}\right. \tag{33}$$

With $U_h(.,t_{n-1})$ at t_{n-1}, we want to build the solution at $t_n \ = \ t_{n-1} + \Delta t$. We get the following.

1. *Construction of the mesh at t_n (see Figure* 2*).* For $i \in [0,N]$ we define a new series of nodes x_i^n from the x_i^{n-1}:

$$x_i^n \ = \ x_i^{n-1} \ + \ \Delta t u_i^{n-1}. \tag{34}$$

The moving of the mesh must stay compatible with the computation, which means that the series of $(x_i^n)_{i=0,N}$ must be increasing:

$$x_{i-1}^n < x_i^n. \tag{35}$$

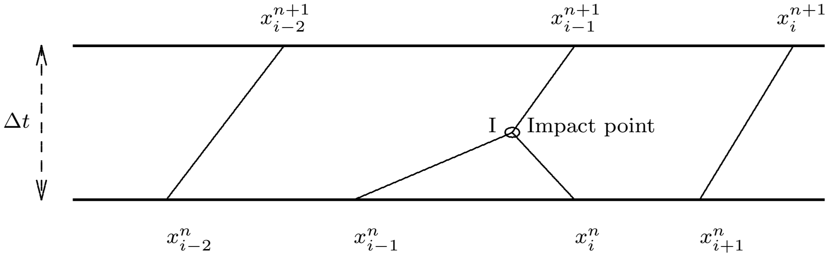

FIG. 3.

That means

$$(x_i^{n-1} - x_{i-1}^{n-1}) \;+\; \Delta t(u_i^{n-1} - u_{i-1}^{n-1}) > 0, \tag{36}$$

which is the condition of stability warranting $x_{i-1}^n < x_i^n$. We must also treat the case where a cell becomes too long and avoid that its length goes beyond a fixed value L:

$$x_i^n \;-\; x_{i-1}^n < L. \tag{37}$$

These conditions (36)–(37) involve a restriction on the time step Δt, so to treat these problems of stability without restriction of time step, we are going to present a method of creation/suppression of cells.

- (a) Suppression of cell (see Figure 3): when $x_i^n \;<\; x_{i-1}^n$.
  - (α) Position of impact point I: I=(x_I,$dt1$) is the point of intersection of the straight lines stem from x_i^{n-1} and x_{i-1}^{n-1}.
  - (β) Determination of the new quantities assigned to I:
    - * $m_I \;=\; m_{i-1}^{n-1} + m_i^{n-1}$.
    - * $Q_I \;=\; Q_{i-1}^{n-1} + Q_i^{n-1}$.
    - * $W_I \;=\; W_{i-1}^{n-1} + W_i^{n-1}$.
    - * $u_I \;=\; \dfrac{\sqrt{q_{i-1}^{n-1}}u_{i-1}^{n-1} \;+\; \sqrt{q_i^{n-1}}u_i^{n-1}}{\sqrt{q_{i-1}^{n-1}} \;+\; \sqrt{q_i^{n-1}}}$ using Theorem 2.
  - (γ) Determination of x_i^n: The new node x_i^n is given by

$$x_i^n \;=\; x_I + (\Delta t - dt1)u_I.$$

- (b) Creation of cell (see Figure 4): When $x_i^n \;-\; x_{i-1}^n > L$, we cut the cell into two parts and we assign new quantities to the new node.
  - (α) Position of the additional point S: $S =$ middle ofx_i^n and x_{i-1}^n.
  - (β) Determination of the new quantities assigned to S:
    - * $V_S \;=\; \frac{x_i^n - x_{i-1}^n}{2}$.
    - * $m_S \;=\; Am_{i-1}^n + Bm_i^n$.
    - * $W_S \;=\; AW_{i-1}^n + BW_i^n$.
    - * $u_S \;=\; \frac{u_{i-1}^n + u_i^n}{2}$.
    - * $q_S \;=\; \frac{m_S}{V_S}$.
    - * $Q_S \;=\; m_S u_S$.
  - (γ) Determination of A and B: In case of a regular mesh it is logical to take A and B constant. In our case two successive cells can

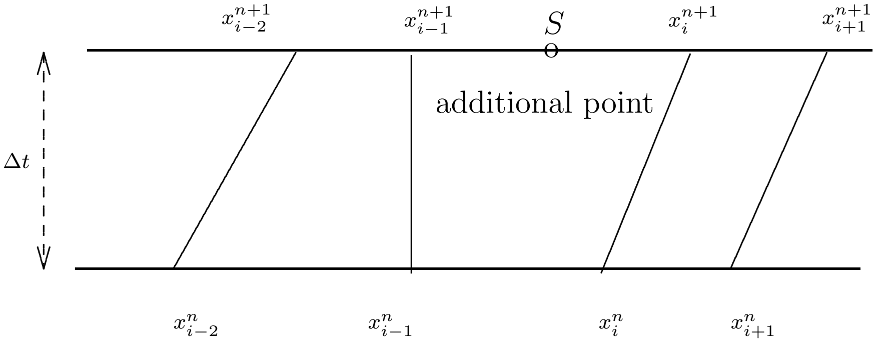

FIG. 4.

have very different volume. Therefore, it seems more advisable to consider A and B as functions of the volume of each cell.

- (δ) Computation of the new quantities assigned to the new mesh:
  * A and B are constant: We compute the three new mass in function of the two old, using the conservation of mass. Thus, we have

$$\begin{cases} m_i^n = \frac{2}{3} m_i^{n-1}, \\ m_{i-1}^n = \frac{2}{3} m_{i-1}^{n-1}, \\ m_S^n = \frac{1}{2} m_{i-1}^n + \frac{1}{2} m_i^n. \end{cases}$$

  * A and B are functions of the volume: We use the point S_{n-1} which is the middle of $[x_{i-1}n-1, x_in-1]$ and we get

$$\begin{cases} m_i^n = \frac{v_i^{n-1}}{V_i^{n-1}} m_i^{n-1}, \\ m_{i-1}^n = \frac{v_{i-1}^{n-1}}{V_{i-1}^{n-1}} m_{i-1}^{n-1}, \\ m_S^n = \frac{v_S^{n-1}}{2V_i^{n-1}} m_i^n + \frac{v_S^{n-1}}{2V_{i-1}^{n-1}} m_{i-1}^n, \end{cases}$$

where

$$\begin{cases} v_S^{n-1} = \frac{x_i^{n-1} - x_{i-1}^{n-1}}{2}, \\ v_{i-1}^{n-1} = V_{i-1}^{n-1} - \frac{v_S^{n-1}}{2}, \\ v_i^{n-1} = V_i^{n-1} - \frac{v_S^{n-1}}{2}. \end{cases}$$

We will compare the results of the two methods in section 4, and we will see that the good one is the second one, where A and B are functions of the volume of the cells.

2. Computation of the new V_i^n.
3. Computation of m_i^n, Q_i^n, W_i^n.
4. Distribution of the density and the speed.

Thus, we obtain the solution at t_n and we close the treatment for the convection.

3.2. The pressure terms. We recall the system (P):

$$\begin{cases} q_t = 0, \\ w_t = 0, \\ (qu)_t + p_x = 0. \end{cases} \tag{38}$$

Just like the system (C), (P) is degenerate: 0 is a triple eigenvalue. Let us consider the perturbed system (P$_\varepsilon$):

$$\left\{\begin{array}{l} q_t + \varepsilon^2 (qu)_x = 0, \\ w_t + \varepsilon^2 (wu)_x = 0, \\ (qu)_t + \varepsilon^2 (qu^2)_x + p_x = 0 \end{array}\right. \tag{39}$$

with the piecewise constant initial data:

$$(q, w, u) \;=\; \left\{\begin{array}{ll} q_l, w_l, u_l & \text{for } \; x < 0, \\ q_r, w_r, u_r & \text{for } \; x > 0. \end{array}\right. \tag{40}$$

For a fixed $\varepsilon > 0$, the system (46) is hyperbolic and has three distinct real eigenvalues:

$$\varepsilon^2 u \;-\; \varepsilon c_\varepsilon, \;\; \varepsilon^2 u, \;\; \varepsilon^2 u \;+\; \varepsilon c_\varepsilon,$$

where

$$c_\varepsilon \;=\; \sqrt{g(w) b'(q) \;+\; w \frac{g'(w) b(q)}{q}}.$$

We proceed as for the system (C$_\varepsilon$) and we consider the discontinuous and the regular solutions of the Riemann problem (39), (40).

3.2.1. Eventuality of shock waves. We have the next three Rankine–Hugoniot relations:

$$\dot{x} \;=\; \frac{\varepsilon^2 \Delta(qu)}{\Delta q} \;=\; \frac{\varepsilon^2 \Delta(wu)}{\Delta w} \;=\; \frac{\varepsilon^2 \Delta(Qu)}{\Delta(Q)} \;+\; \frac{\Delta(p)}{\Delta(Q)},$$

where

$$Q = qu.$$

This gives two equations of compatibility:

$$\Delta u (\overline{q} \Delta w - \overline{w} \Delta q) = 0, \tag{41}$$

$$q_+ q_- \varepsilon^2 \Delta u^2 = \Delta p \Delta q. \tag{42}$$

From (41) and (42), we deduce the following.

1. On the contact discontinuity:

$$\Delta u = 0 \;\text{ and }\; \Delta p = 0. \tag{43}$$

2. On the 1-shock or the 3-shock:

$$\varepsilon^2 \Delta u^2 = \frac{1}{q_+ q_-} \Delta p \Delta q \;\text{ and }\; \Delta\left(\frac{w}{q}\right) = 0. \tag{44}$$

With (44), we get

$$\left\{\begin{array}{rcl} \Delta u & = & s \dfrac{\Delta q}{\varepsilon \sqrt{q_+ q_-}} \sqrt{\dfrac{\Delta p}{\Delta q}}, \\ s & = & +1 \; : \text{ shock with the velocity } u + c_\varepsilon, q \text{ decreasing}, \\ s & = & -1 \; : \text{ shock with the velocity } u - c_\varepsilon, \; q \text{ increasing}. \end{array}\right.$$

Now we are going to study the regular solutions of the Riemann problem (39), (40).

3.2.2. Eventuality of rarefaction waves. We express w, u, and p as functions of q. Replacing w, u, and p in (P_ε), we get

$$w(q) = w'(q)q, \tag{45}$$

$$\varepsilon^2 u'^2(q)q^2 = p'(q). \tag{46}$$

Integrating (46) we obtain

$$\left\{\begin{array}{l} u = u_0 + \frac{s}{\varepsilon}(\psi(q) - \psi(q_0)), \\ \text{where} \quad \psi(q) = \int_0^q \frac{\sqrt{p'}}{q} dq. \end{array}\right. \tag{47}$$

Taking $u_0 = u_r$ and $u_0 = u_l$,

$$u = u_r + \frac{1}{\varepsilon}(\psi(q_{2,\varepsilon}) - \psi(q_r)), \tag{48}$$

$$u = u_l - \frac{1}{\varepsilon}(\psi(q_{1,\varepsilon}) - \psi(q_l)). \tag{49}$$

3.2.3. Limit on the perturbed problem $(\mathbf{P}_\varepsilon)$. We have the following possibilities.

- Wave $u + c$:
  1. shock if q decreases: $q_2 > q_r$,
  2. rarefaction if q increases: $0 < q_2 < q_r$.
- Wave $u - c$:
  1. shock if q increases: $q_1 > q_l$,
  2. rarefaction if q decreases: $0 < q_1 < q_l$.

Therefore, to characterize the solutions, we have the following theorem.

THEOREM 3. *When we study the limit for $\varepsilon \longrightarrow 0$ of the Riemann problem*

$$\left\{\begin{array}{l} q_t + \varepsilon^2(qu)_x = 0, \\ w_t + \varepsilon^2(wu)_x = 0, \\ (qu)_t + \varepsilon^2(qu^2)_x + p_x = 0, \\ (q, w, u) = \left\{\begin{array}{ll} q_l, w_l, u_l & if \quad x < 0, \\ q_r, w_r, u_r & if \quad x > 0, \end{array}\right. \end{array}\right. \tag{50}$$

1. *For $q_l < q_r$: The solution of* (57) *is made up of three waves: shock wave (velocity $u - c$), contact discontinuity, rarefaction wave (velocity $u + c$), and the density is given by*

$$\psi(q_2) - \psi(q_r) + \frac{1}{\sqrt{q_1 q_l}}(q_1 - q_l)\sqrt{\frac{(p - p_l)}{(q_1 - q_l)}};$$

2. *For $q_l > q_r$: The solution of* (57) *is made of three waves: rarefaction wave (velocity $u - c$), contact discontinuity, shock wave (velocity $u + c$), and the density is given by*

$$\psi(q_l) - \psi(q_1) - \frac{1}{\sqrt{q_2 q_r}}(q_2 - q_r)\sqrt{\frac{(p - p_r)}{(q_2 - q_r)}}.$$

The proof is detailed in [1].

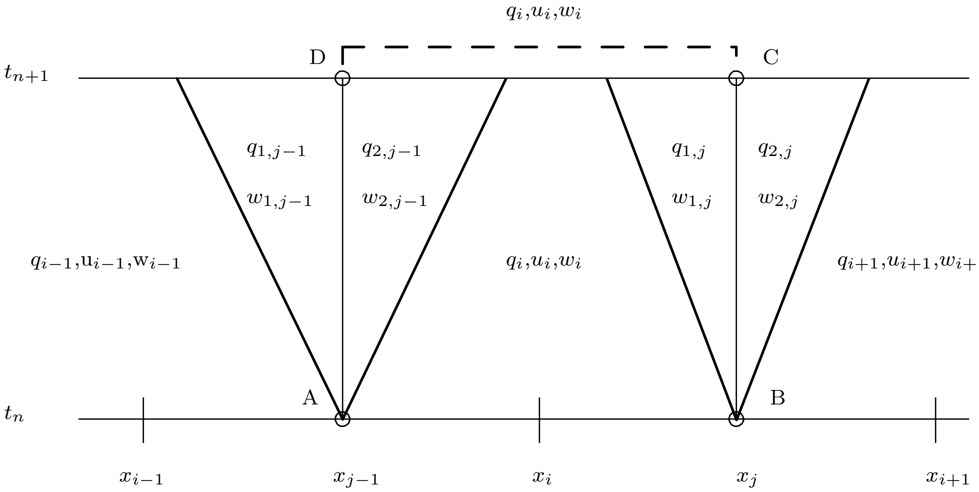

FIG. 5.

3.2.4. Numerical resolution. We denote by Δt and Δx the time and space increments. The resolution of the Riemann problem will give us the values of q and w through the interfaces of the volumes V_i^n, building an approximate Riemann solver. To compute q_i^{n+1}, w_i^{n+1}, and u_i^{n+1}, we integrate on the rectangle (ABCD) the three equations of the system

$$\begin{cases} q_t = 0, \\ w_t = 0, \\ (qu)_t + p_x = 0, \end{cases} \tag{51}$$

and so we get

$$q_i^{n+1} = q_i^n, \tag{52}$$

$$w_i^{n+1} = w_i^n, \tag{53}$$

$$u_i^{n+1} = u_i^n - \frac{\Delta t}{\Delta x}\frac{1}{q_i^n}(p_{j+1}^n - p_j^n). \tag{54}$$

(52), (53), and (54) give the new values of q, w, and u after the treatment of the pressure terms. See Figure 5 for a cycle in time.

3.3. The diffusion term. It remains to solve the following problem:

$$\begin{cases} qu_t = \frac{\partial}{\partial x}(\varepsilon(q,\sigma)u_x), \\ u(x,0) = u_0(x) \quad \text{for } x \text{ in } [0,1], \\ u(0,t) = \alpha \quad \text{and} \quad u(1,t) = 0 \quad \text{for } t \text{ in } [0,T]. \end{cases} \tag{55}$$

3.3.1. The approximate problem. For the space discretization, we use a finite element method P_1. Let us introduce the variational form of the problem.

For any functions ϕ and $\psi \in \mathrm{H}_0^1(\Omega)$ we define the bilinear form $a(.,.)$ by

$$a(\phi,\psi) \;=\; \int_\Omega \varepsilon \phi_x \psi_x \, dx,$$

and the problem to solve is as follows: Determine $u \in \mathrm{H}^1(\Omega)$ with $u(0) = \alpha$ and $u(1) = 0$, such that $\forall v \in \mathrm{H}_0^1(\Omega)$

$$(qu_t, v) \;+\; a(u,v) \;=\; 0. \tag{56}$$

We set

$$\begin{cases} x_i \;=\; ih \text{ for } 0 \le i \le N, \\ K_i \;=\; [x_i, x_{i+1}] \text{ for } 0 \le i \le N, \\ \Delta t \text{ time increment.} \end{cases}$$

We consider the following set:

$$V_h \;=\; \{\; v_h \;\in\; C^0(\Omega)/v_h|_{K_i} \in\; P_1(K_i),\; v_h(0) = 0 \;\; v_h(1) = 0 \;\}.$$

On V_h we have the approximate scalar product:

$$(\phi_h, \psi_h)_h \;=\; h \sum_{i=0}^{N} \phi_i \psi_i \quad \text{for} \;\; \phi_h,\; \psi_h \;\in\; V_h.$$

For ϕ_h, ψ_h $\in \mathrm{V}_h$ we define $\pi_h v$ $\in \mathrm{V}_h$ by

$$\pi_h v(x_i) \;=\; v(x_i), \quad 0 \le i \le N,$$

and we define

$$a_h(\phi_h, \psi_h) \;=\; \frac{1}{h} \sum_{i=0}^{N} \frac{\varepsilon_i + \varepsilon_{i+1}}{2} (\phi_{i+1} - \phi_i)(\psi_{i+1} - \psi_i) \;\; \text{for} \;\; \phi_h,\; \psi_h \;\in\; V_h.$$

For the time discretization we use an implicit Euler's method and we obtain the next approximate problem:

$$\begin{cases} \pi_h(q(u_h^{n+1} - u_h^n), v_h)_h \;+\; \Delta t a_h(u_h^{n+1}, v_h) = 0 \;\; \forall v_h \in V_h, \\ u_h^0 \;=\; \pi_h u_0, \\ u_h^n(0) = \alpha \;\; \text{and} \;\; u_h^n(1) = 0. \end{cases} \tag{57}$$

Thus, we get a linear system with a tridiagonal matrix, which is very easy to solve.

4. Applications and results. This section is divided into two parts. In the first subsection, we apply our splitting method to the hydrodynamic model, especially the Lagrangian treatment of the convection part, with the method of creation/suppression of cells. The second subsection is devoted to the application of the method to the whole system described in section 2.

4.1. Application to the hydrodynamic model. Here, we test the Lagrangian treatment on the convection terms of the hydrodynamic model. There are two tests, one for the suppression of cells, the other one for the creation of cells. In each case, we have the representation of the mesh and the density.

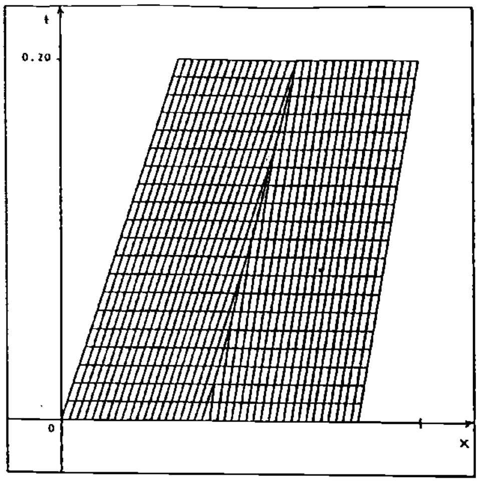

FIG. 6. *Suppression of cells: evolution of the mesh.*

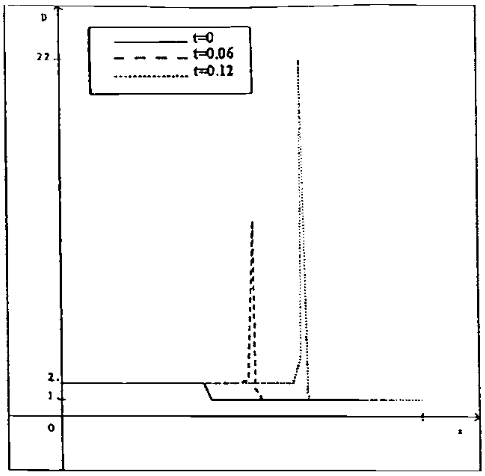

FIG. 7. *Representation of the density.*

4.1.1. Suppression of cells. The test (Figures 6 and 7) is achieved with the data

$$\text{for } x < 0.5 \begin{cases} U_l = 2, \\ \rho_l = 2 \end{cases}$$

and

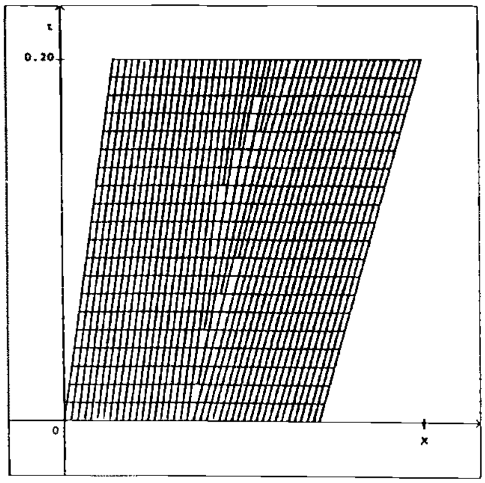

FIG. 8. *Creation of cells: evolution of the mesh.*

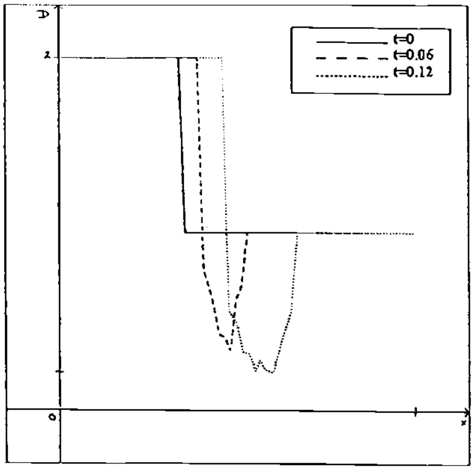

FIG. 9. *Representation of the density with A and B constant.*

$$\text{for } x > 0.5 \begin{cases} U_r = 1, \\ \rho_r = 1. \end{cases}$$

4.1.2. Creation of cells. The test (Figures 8 and 9) is realized with the data

$$\text{for } x < 0.5 \begin{cases} U_l = 1, \\ \rho_l = 2 \end{cases} \quad \text{and for } x > 0.5 \begin{cases} U_l = 2, \\ \rho_l = 1. \end{cases}$$

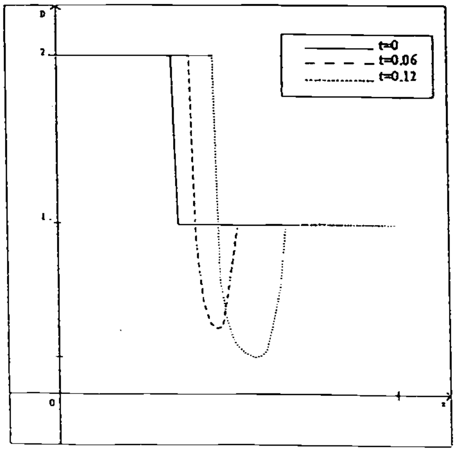

FIG. 10. *Representation of the density with A and B function of volume.*

We can see with these tests that is better to take into account the volume of the cells to compute the quantities assigned to the additional point.

4.2. Application to the compression of pharmaceutical powders. The tests we present here are computed with the whole system (see section 2). The different functions $k(\sigma)$, $p = a(\sigma)b(q)$, and $\varepsilon(\sigma, q)$ for the behavior of powder, the state law, and the diffusion term can be chosen according to the powder. Here we have used the functions

- $k(\sigma) = \sigma$,
- $p = a(\sigma)b(q) = \sigma.q$,
- $\varepsilon(\sigma, q) = \sigma^2.q$.

Figures 11 and 12 show, respectively, the evolution of the porosity in the powder during the compression and the computed pressure in the powder.

We can see that when the porosity approaches to zero (compact powder), it stays with this value, so when the powder is compact, it stays compact, and our goal is achieved.

5. Conclusion. This study leads to implementation of a mathematical model to simulate the compression of pharmaceutical powders. We have obtained a very general model which can adapt to a lot of products. The simulations allow one to infer the behavior of various materials; in particular it permits one to adjust the different parameters used by the model:

- the function $k(\sigma)$ which describes the behavior of powder,
- the state law $p = a(\sigma)b(q)$.

These simulations also permit an analysis of the behavior of the powder during the compression phase [8], especially the equilibrium between the compaction term (pressure term) and the diffusion term, which represents some phenomena occurring during the compression. Further, with these simulation of real experiences, it is possible to

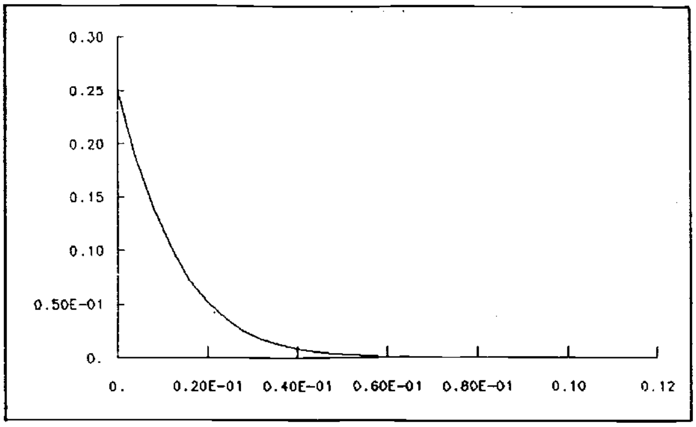

FIG. 11. *Evolution of the porosity.*

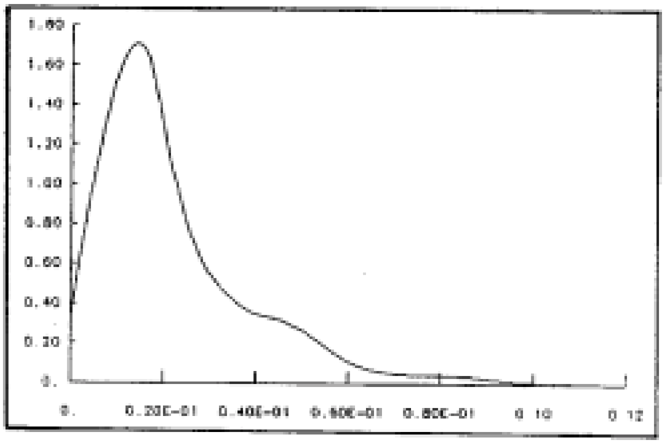

FIG. 12. *Evolution of the pressure (computed).*

characterize the properties of some new products in order to predict their tableting behavior.

COMPUTATION OF LYAPUNOV-TYPE NUMBERS FOR INVARIANT CURVES OF PLANAR MAPS[*]

K. D. EDOH[†] AND J. LORENZ[‡]

Abstract. Invariant manifolds play an important role in the study of dynamical systems, and it is often crucial to know when they persist under small perturbations of the system. Sufficient conditions for persistence have been formulated in the literature in terms of so-called Lyapunov-type numbers, which measure and compare attractivity rates. The numerical evaluations of these numbers in a simple setting is the subject of this paper. We consider planar diffeomorphisms depending on a parameter; the diffeomorphisms have invariant curves which deform as the parameter changes. The Lyapunov-type numbers are then monitored as functions of parameter and are related to the dynamics on the invariant curves. As an example, we consider the delayed logistic map. We also describe how the invariant curves have been computed.

Key words. invariant curves, invariant manifolds under perturbations, Lyapunov exponents, Lyapunov-type numbers

1. Introduction.

Assume that M is an invariant manifold of a diffeomorphism f. If f is perturbed to f_ε, will M persist, i.e., will f_ε have a nearby invariant manifold M_ε diffeomorphic to M? This fundamental question has been studied in various works. Particularly strong results have been obtained by Fenichel [8]. His main assumption is formulated in terms of two Lyapunov-type numbers, $\nu(p)$ and $\sigma(p)$, which are defined for every point $p \in M$ by using the linearized dynamics of f. Roughly speaking, if $\nu(p) < 1$ and $\sigma(p) < 1$ for all $p \in M$ and f_ε is C^1 close to f, then M will persist. This result makes it important to obtain insight into the Lyapunov-type numbers $\nu(p)$ and $\sigma(p)$.

If p is a fixed point or a periodic point of f, then $\nu(p)$ and $\sigma(p)$ can be expressed by the eigenvalues of a suitable matrix. In other cases the determination of $\nu(p)$ and $\sigma(p)$ involves a limit process, which makes the evaluation nontrivial. If p is a periodic point of high period, the numerical evaluation of $\nu(p)$ and $\sigma(p)$ is also far from trivial.

In this paper we consider the simple case where $f : \mathbb{R}^2 \to \mathbb{R}^2$ is a diffeomorphism (or f is a diffeomorphism defined on an open subset of $\mathbb{R}^2$) and $M = \Gamma$ is a smooth, simply closed curve invariant under f. For this case we will define the numbers $\nu(p)$ and $\sigma(p)$, describe some of their properties, and study their numerical approximation; see section 2.

As an interesting example, in section 3 we will consider the delayed logistic map $f_\lambda(x,y) = (y, \lambda y(1-x))$, where λ is a parameter. As λ increases from $\lambda < 2$ to $\lambda > 2$, the fixed point

$$\left(\frac{\lambda-1}{\lambda}, \frac{\lambda-1}{\lambda}\right)$$

of f_λ loses stability, and an invariant curve Γ_λ is born in a Neimark–Sacker bifurcation; see, for example, [9, 12]. The breakdown of Γ_λ, with f_λ embedded in a two-parameter family of maps, has been studied extensively in [2]. In our paper, the main emphasis is the behavior of the Lyapunov-type numbers for Γ_λ when λ crosses an interval of phase locking. In this λ-interval, the map f_λ has two seven-periodic orbits on the curve Γ_λ. This allows us to compare the numerical approximations that we obtain for the Lyapunov-type numbers with values that can be computed more directly from linearizing about the seven-periodic orbits.

The phase-locking λ-interval has a subinterval where the attracting seven-periodic orbit consists of spiral points. For the corresponding λ-values, the invariant curve Γ_λ is not C^1 but merely continuous, as it winds infinitely often about each point of the orbit. In agreement with the general perturbation theory of invariant manifolds, this breakdown of smoothness of Γ_λ is related to a Lyapunov-type number approaching the value 1. As we will show, our numerical computations are in agreement with this observation. We will also show how the Lyapunov-type numbers may be used to distinguish phase-locked dynamics on Γ_λ from ergodic dynamics with irrational rotation number.

In section 4 we describe, for completeness, the algorithm that we used for approximating the invariant curves. The algorithm may be viewed as a discrete version of the Hadamard graph transform [10]. An application, confirming earlier results of [2], is given. For related work on computing invariant curves and more general invariant manifolds we refer to [3, 5, 7, 11, 14, 16, 17, 20, 21], for example.

In principle, the approach described in our paper can be applied to compute Lyapunov-type numbers for Poincaré maps of continuous-time dynamical systems such as the periodically forced oscillator of van der Pol. This work, which is in progress, will extend the results of [6].

The case of an invariant curve of a planar diffeomorphism is clearly a comparatively simple case of an invariant manifold. Nevertheless, as our study for the delayed logistic map shows, the behavior of the Lyapunov-type numbers for a parameter-dependent problem may be quite rich. They can be related to the geometry of the curves (e.g., to the appearance of spiral points) as well as to the dynamics on the curves, which may be phase locked or ergodic. We believe that the numerical approximation of the numbers, $\nu(p)$ and $\sigma(p)$, which we describe here only in a special situation, deserves further attention by researchers working on the numerical analysis of dynamical systems. The numbers are central in the perturbation theory of invariant manifolds and may give considerable insight into the dynamics.

2. Lyapunov-type numbers.

Let $f : \mathbb{R}^2 \longrightarrow \mathbb{R}^2$ denote an orientation preserving diffeomorphism and let $\Gamma \subset \mathbb{R}^2$ denote a simply closed C^1 curve which is invariant under f, i.e., $f(\Gamma) = \Gamma$. In this section we will define four Lyapunov-type numbers, $\nu(p), \bar{\nu}(p), \sigma(p)$, and $\bar{\sigma}(p)$, for every $p \in \Gamma$ and prove some useful properties. Most of the results are not new and could be inferred from more general theorems in the literature. However, since our setting is very special, the proofs given here are simple and, we believe, instructive.

We refer to [6] for similar discussions of fixed points and periodic orbits in continuous-time systems. Constancy of the numbers along orbits is well known [8]. As our setting is very special, our results on limits (see Theorems 2.3 and 2.4) are sharper than more general results on semicontinuous behavior at limit sets [8].

We summarize the results at the end of the section and obtain a rather complete description of the theoretical behavior of the functions $\nu(\cdot), \bar{\nu}(\cdot), \sigma(\cdot)$, and $\bar{\sigma}(\cdot)$.

Notation. For every $p \in \Gamma$, let T_p and N_p denote a unit tangent and a unit normal to Γ at p, respectively (see Figure 2.1). We will assume that T_p and N_p change continuously with p. If we have a smooth parameterization $z(s) = (x(s), y(s)), 0 \leq s \leq L$, of Γ with $\dot{z}(s) \neq 0$ for all s, then T_p and N_p can be obtained as follows: For $p \in \Gamma$ determine the parameter s with $p = z(s)$ and then compute

$$\vec{T}_p = \begin{pmatrix} \dot{x}(s) \\ \dot{y}(s) \end{pmatrix}, \quad T_p = \frac{1}{|\vec{T}_p|}\vec{T}_p, \quad N_p = \frac{1}{|\vec{T}_p|}\begin{pmatrix} \dot{y}(s) \\ -\dot{x}(s) \end{pmatrix}.$$

Here $|\vec{T}_p|^2 = (\dot{x}(s))^2 + (\dot{y}(s))^2$. As a further notation, let A_p denote the Jacobian of f at p. Since f is an orientation-preserving diffeomorphism, we have $\det(A_p) > 0$.

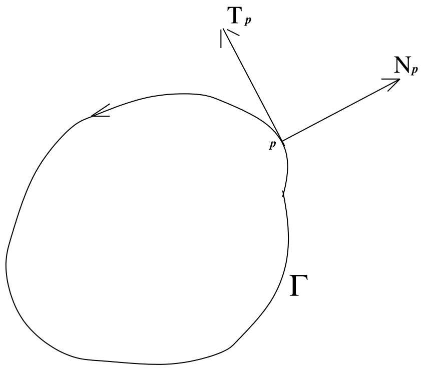

FIG. 2.1. *An invariant circle with the normal N_p and the tangent T_p at the point p.*

Definition of a_p and b_p. Invariance of Γ under f implies that A_pT_p is a multiple of T_{fp},

$$A_pT_p = a_pT_{fp}. \tag{2.1}$$

(Here $fp := f(p)$.) Since f preserves orientation we have[1] $a_p > 0$. The number a_p measures locally contraction (for $0 < a_p < 1$) or stretching (for $a_p > 1$) of the dynamics *within* Γ. One can compute a_p by taking a scalar product, $a_p = \langle T_{fp}, A_pT_p\rangle$. Here $\langle u, v\rangle = u_1v_1 + u_2v_2$.

To measure local contraction or stretching of the dynamics *toward* Γ, we compute A_pN_p and decompose

$$A_pN_p = c_pT_{fp} + b_pN_{fp}. \tag{2.2}$$

[1] Since f is a diffeomorphism, we have $a_p \neq 0$ for all $p \in \Gamma$. Then, by continuity, either $a_p > 0$ for all $p \in \Gamma$ or $a_p < 0$ for all $p \in \Gamma$. Suppose that $a_p < 0$ for all $p \in \Gamma$; then, if p moves around Γ clockwise, the image point fp would move counterclockwise, contradicting our assumption that f preserves orientation.

Then $b_p = \langle N_{fp}, A_p N_p \rangle$ measures this contraction (for $0 < b_p < 1$) or expansion (for $b_p > 1$).

Remark 2.1. Equations (2.1) and (2.2) can be written in matrix form as

$$A_p \Big(T_p \; N_p \Big) = \Big(T_{fp} \; N_{fp} \Big) \begin{pmatrix} a_p & c_p \\ 0 & b_p \end{pmatrix}, \tag{2.3}$$

where T_p, etc., denote column vectors with two components. Here

$$\det \Big(T_p \; N_p \Big) = \det \Big(T_{fp} \; N_{fp} \Big) = \pm 1,$$

and, therefore, $\det(A_p) = a_p b_p$. Since $\det(A_p) > 0$ and $a_p > 0$ we also have $b_p > 0$.

Definition of $\boldsymbol{\nu(p), \bar{\nu}(p), \sigma(p)}$, and $\boldsymbol{\bar{\sigma}(p)}$. Let $p \in \Gamma$. Invariance of Γ under f implies that the complete orbit

$$f^n p, \quad n \in \mathbb{Z}, \tag{2.4}$$

lies on Γ; therefore, the numbers $a_{f^n p}$ and $b_{f^n p}$ are well-defined for all integers n. We will define $\nu(p)$ as a measure of attractivity of the dynamics toward Γ along the orbit (2.4); correspondingly, $\sigma(p)$ will measure the rate of the ratio[2] of attractivity within and toward Γ along the orbit (2.4).

To define $\nu(p)$, one has two possibilities; (1) go forward along the orbit (2.4); or (2) first go backward from p to $f^{-n}p$, then go forward by n steps, and let $n \to \infty$. Both processes lead to useful numbers that are generally not equal. In [8], Fenichel considered *overflowing* invariant manifolds for which forward orbits are not always meaningful; therefore, he used the process (2) to define $\nu(p)$ and $\sigma(p)$. We use similar notation and set

$$\nu(p,n) = \Big(b_{f^{-1}p} \, b_{f^{-2}p} \cdots b_{f^{-n}p} \Big)^{1/n} \tag{2.5}$$

and $\nu(p) = \limsup_{n\to\infty} \nu(p,n)$. If $\nu(p) < 1$, we also define

$$\sigma(p,n) = \frac{\log \Big(a_{f^{-1}p} \cdots a_{f^{-n}p} \Big)}{\log \Big(b_{f^{-1}p} \cdots b_{f^{-n}p} \Big)} \tag{2.6}$$

and $\sigma(p) = \limsup_{n\to\infty} \sigma(p,n)$. Going forward along the orbit (2.4) leads to the following definitions:

$$\bar{\nu}(p,n) = \Big(b_{fp} \cdots b_{f^n p} \Big)^{1/n} \tag{2.7}$$

and $\bar{\nu}(p) = \limsup_{n\to\infty} \bar{\nu}(p,n)$. Furthermore, if $\bar{\nu}(p) < 1$, we set

$$\bar{\sigma}(p,n) = \frac{\log \Big(a_{fp} \cdots a_{f^n p} \Big)}{\log \Big(b_{fp} \cdots b_{f^n p} \Big)} \tag{2.8}$$

and $\bar{\sigma}(p) = \limsup_{n\to\infty} \bar{\sigma}(p,n)$.

[2] In general, this is finer than measuring the ratio of the rates.

Bounds for the Lyapunov-type numbers. Let us show that $\nu(p), p \in \Gamma$, is always a well-defined number and, if $\nu(p) < 1$, then $\sigma(p)$ is also a well-defined number, i.e., the lim sup's are finite. Completely similar arguments apply to $\bar{\nu}(p)$ and $\bar{\sigma}(p)$.

First, by continuity, there are constants $C_j > 1$ with

$$\frac{1}{C_1} \le a_r \le C_1 \quad \text{and} \quad \frac{1}{C_2} \le b_r \le C_2 \qquad \text{for all} \quad r \in \Gamma.$$

This implies $1/C_2 \le \nu(p,n) \le C_2$ for all n and, therefore, $\nu(p)$ is well-defined with $1/C_2 \le \nu(p) \le C_2$. Now assume $\nu(p) < 1$ and choose $\varepsilon > 0$ with $\nu(p) + \varepsilon < 1$. Then we have, for all large n,

$$0 < b_{f^{-1}p} \cdots b_{f^{-n}p} \le \Big(\nu(p) + \varepsilon\Big)^n < 1;$$

thus

$$\log(b_{f^{-1}p} \cdots b_{f^{-n}p}) \le n \log\Big(\nu(p) + \varepsilon\Big) < 0,$$

and thus

$$\frac{1}{|\log(b_{f^{-1}p} \cdots b_{f^{-n}p})|} \le \frac{1}{n \log\Big(\frac{1}{\nu(p)+\varepsilon}\Big)}.$$

Also, from $1/C_1 \le a_r \le C_1$ for all $r \in \Gamma$, it follows that $|\log(a_{f^{-1}p} \cdots a_{f^{-n}p})| \le n \log C_1$. Since $\varepsilon > 0$ was arbitrary, the previous bounds yield $|\sigma(p,n)| \le \log C_1 / \log(1/\nu(p))$. Therefore, $\sigma(p)$ is a well-defined number satisfying the same bound. The number $\sigma(p)$ may be positive, negative, or zero. For an illustration, assume

$$1 > a_p = \exp(-\alpha) > 0 \quad \text{and} \quad 1 > b_p = \exp(-\beta) > 0$$

with $\alpha > 0, \beta > 0$ independently of p. Then we have

$$0 < \nu(p,n) = \exp(-\beta) < 1 \quad \text{and} \quad 0 < \sigma(p,n) = \frac{\alpha}{\beta}.$$

One obtains that $\sigma(p) < 1$ iff $0 < \alpha < \beta$, i.e., if the attraction in the normal direction is stronger than in the tangential direction.

Fixed points. A simple case occurs if $p \in \Gamma$ is a fixed point of f, i.e., $fp = p$. Since $f^{-j}p = p$ for $j = 1, \dots, n$ we have (see (2.5) and (2.6))

$$\nu(p,n) = b_p, \quad \sigma(p,n) = \frac{\log a_p}{\log b_p};$$

thus $\nu(p) = b_p$ and $\sigma(p) = \frac{\log a_p}{\log b_p}$. Clearly, the same expressions are obtained for $\bar{\nu}(p)$ and $\bar{\sigma}(p)$. Furthermore, by (2.3), the numbers a_p and b_p are the eigenvalues of A_p. Here a_p is the eigenvalue to the eigenvector T_p, and b_p is the other eigenvalue. We summarize the result.

Theorem 2.1. *Let $p = fp$ and let $A_p = f'(p)$ denote the Jacobian of f. Furthermore, let a_p and b_p denote the eigenvalues of A_p, where $A_pT_p = a_pT_p$ with T_p the tangent vector to Γ at p. Then we have*

$$\nu(p) = \bar{\nu}(p) = b_p \quad \textit{and} \quad \sigma(p) = \bar{\sigma}(p) = \frac{\log a_p}{\log b_p}.$$

Periodic points. Let $p \in \Gamma$ denote a point of period q of f, i.e.,

$$fp \neq p, \quad f^2p \neq p, \ldots, f^{q-1}p \neq p, \quad f^qp = p.$$

Introduce the orthogonal matrix $Q_p = (T_p \ N_p)$ and the upper triangular matrix

$$\mathcal{T}_p = \begin{pmatrix} a_p & c_p \\ 0 & b_p \end{pmatrix}.$$

According to (2.3) we have $A_pQ_p = Q_{fp}\mathcal{T}_p$. Replacing p by fp we also have $A_{fp}Q_{fp} = Q_{f^2p}\mathcal{T}_{fp}$. Therefore,

$$A_{fp}A_pQ_p = Q_{f^2p}\mathcal{T}_{fp}\mathcal{T}_p.$$

The argument can be repeated. If Π_p denotes the product matrix

$$\Pi_p = A_{f^{q-1}p} \cdots A_{fp}A_p, \tag{2.9}$$

then

$$\Pi_p\mathcal{O}_p = \mathcal{O}_{f^qp}\mathcal{T}_{f^{q-1}p} \cdots \mathcal{T}_{fp}\mathcal{T}_p. \tag{2.10}$$

By assumption, $f^qp = p$. Therefore, (2.10) says that the matrix product (2.9) is similar to the upper triangular matrix $\mathcal{T}_{f^{q-1}p} \cdots \mathcal{T}_{fp}\mathcal{T}_p$. Consequently, the eigenvalues of Π_p are

$$\alpha_p = a_p\, a_{fp} \, \cdots \, a_{f^{q-1}p} \quad \text{and} \quad \beta_p = b_p\, b_{fp} \, \cdots \, b_{f^{q-1}p}.$$

(Here $\Pi_pT_p = \alpha_pT_p$.) It follows that $\bar{\nu}(p,q) = \beta_p^{1/q}$ and $\bar{\sigma}(p,q) = \frac{\log \alpha_p}{\log \beta_p}$.

Using the q-periodicity of f^np, it is not difficult to show that we also have

$$\nu(p) = \bar{\nu}(p) = \beta_p^{1/q} \tag{2.11}$$

and

$$\sigma(p) = \bar{\sigma}(p) = \frac{\log \alpha_p}{\log \beta_p}. \tag{2.12}$$

Therefore, we have obtained the following result.

THEOREM 2.2. *Let*

$$\mathcal{O}(p) = \Big\{p, fp, f^2p, \ldots, f^{q-1}p\Big\}$$

denote an orbit of period q of f. Form the matrix product Π_p in (2.9)*, where $A_{f^jp} = f'(f^jp)$. Let α_p, β_p denote the eigenvalues of Π_p with α_p corresponding to the eigenvector T_p which is tangent to Γ at p. Then we have the formulas* (2.11) *and* (2.12) *for the Lyapunov-type numbers.*

Constancy along orbits. Each of the functions $\nu(\cdot), \bar{\nu}(\cdot), \sigma(\cdot)$, and $\bar{\sigma}(\cdot)$ is constant along each orbit $f^np, \ p \in \Gamma$. To show this for $\bar{\nu}$, for example, note that

$$\Big(\bar{\nu}(p,n)\Big)^n = b_{fp} \ldots b_{f^np} \quad \text{and} \quad \Big(\bar{\nu}(fp,n)\Big)^n = b_{f^2p} \ldots b_{f^{n+1}p}.$$

Therefore,

$$\left(\frac{\bar{\nu}(p,n)}{\bar{\nu}(fp,n)}\right)^n = \frac{b_{fp}}{b_{f^{n+1}p}},$$

and the bound $C_2^{-1} \leq b_r \leq C_2$ for all r implies

$$C_2^{-2/n} \leq \frac{\bar{\nu}(p,n)}{\bar{\nu}(fp,n)} \leq C_2^{2/n}.$$

For $n \to \infty$ it follows that $\bar{\nu}(p) = \bar{\nu}(fp)$, which yields constancy of $\bar{\nu}(\cdot)$ along the orbit through p. The arguments for the functions ν, σ, and $\bar{\sigma}$ are similar.

Behavior at limits. Assume that an orbit $f^n p$, $p \in \Gamma$, approaches a fixed point p_+ of f as $n \to \infty$. We claim that, in this case, $\bar{\nu}(p) = \bar{\nu}(p_+)$ and $\bar{\sigma}(p) = \bar{\sigma}(p_+)$. A similar result holds for ν and σ if $f^n p \to p_-$ as $n \to -\infty$.

THEOREM 2.3. *If $f^n p \to p_+$ as $n \to \infty$, then*

$$\bar{\nu}(p) = \bar{\nu}(p_+) = \nu(p_+) \quad \textit{and} \quad \bar{\sigma}(p) = \bar{\sigma}(p_+) = \sigma(p_+).$$

Similarly, if $f^n p \to p_-$ as $n \to -\infty$, then

$$\nu(p) = \bar{\nu}(p_-) = \nu(p_-) \quad \textit{and} \quad \sigma(p) = \bar{\sigma}(p_-) = \sigma(p_-).$$

Proof. Note that the equations $\bar{\nu}(p_+) = \nu(p_+)$, etc., at the fixed points have already been shown in Theorem 2.1. We will prove only that $\bar{\nu}(p) = \bar{\nu}(p_+)$ if $f^n p \to p_+$ as $n \to \infty$. The other claims follow similarly. To show the theorem, we first note that, for any $N \in \mathbf{N}$,

$$\log \bar{\nu}(f^N p, n) = \frac{1}{n} \sum_{j=1}^{n} \log b_{f^{N+j}p}. \tag{2.13}$$

Let $\varepsilon > 0$ be given. Continuity of the function $r \to \log b_r$ implies that $|\log b_{f^{N+j}p} - \log b_{p_+}| \leq \varepsilon$ for all $j \geq 1$ if $N = N(\varepsilon)$ is sufficiently large. Therefore, (2.13) yields $|\log \bar{\nu}(f^N p, n) - \log \bar{\nu}(p_+)| \leq \varepsilon$ for all $n \geq 1$. As $n \to \infty$ one obtains $|\log \bar{\nu}(f^N p) - \log \bar{\nu}(p_+)| \leq \varepsilon$. However, since $\bar{\nu}(\cdot)$ is constant along orbits, $\bar{\nu}(f^N p) = \bar{\nu}(p)$, thus $|\log \bar{\nu}(p) - \log \bar{\nu}(p_+)| \leq \varepsilon$. Since $\varepsilon > 0$ was arbitrary, the equality $\bar{\nu}(p) = \bar{\nu}(p_+)$ follows. □

Orbits that approach periodic orbits. Assume that f has an orbit of period q,

$$\mathcal{O}(p_+) = \left\{p_+, fp_+, f^2 p_+, \ldots, f^{q-1} p_+\right\}, \tag{2.14}$$

which is approached by $f^n p$ as $n \to \infty$,

$$dist\left(f^n p, \mathcal{O}(p_+)\right) \to 0 \quad \text{as} \quad n \to \infty.$$

(Here $dist(f^n p, \mathcal{O}(p_+)) = \min_j |f^n p - f^j p_+|$.) We claim that $\bar{\nu}(p) = \bar{\nu}(p_+)$ and $\bar{\sigma}(p) = \bar{\sigma}(p_+)$, and that a similar result holds for ν and σ if $f^n p$ approaches a periodic orbit $\mathcal{O}(p_-)$ as $n \to -\infty$. To prove this, we first note that the q points of the orbit (2.14) are all fixed points of f^q,

$$f^q(f^j p_+) = f^j p_+, \quad j = 0, \ldots, q-1. \tag{2.15}$$

As $n \to \infty$, the sequence

$$f^{qn}p, \quad n = 1, 2, \ldots, \tag{2.16}$$

approaches precisely *one* of the fixed points (2.15). To conclude this, we use that the dynamics of f restricted to Γ is one-dimensional. This implies that the iteration (2.16) always progresses *monotonically* between any two fixed points of f^q. An approach of the sequence (2.16) to the orbit (2.14) which oscillates between two or more fixed points of f^q is, therefore, impossible.

Without loss of generality (by renaming p_+, if necessary) we may assume that $f^{qn}p \to p_+$ as $n \to \infty$. This yields

$$f^{qn+j}p \to f^j p_+ \quad \text{as} \quad n \to \infty \quad \text{for} \quad j = 0, \ldots, q-1.$$

We have $\bar{\nu}(p_+) = \bar{\nu}(fp_+) = \cdots = \bar{\nu}(f^{q-1}p_+)$, and a limit argument as in the proof of Theorem 2.3 then yields the equality $\bar{\nu}(p) = \bar{\nu}(p_+)$.

THEOREM 2.4. *Let $p \in \Gamma$. Assume that $f^n p$ approaches a periodic orbit*

$$\{p_+, fp_+, \ldots, f^{q-1}p_+\}$$

of f as $n \to \infty$. Then we have

$$\bar{\nu}(p) = \bar{\nu}(p_+) = \nu(p_+) \quad \textit{and} \quad \bar{\sigma}(p) = \bar{\sigma}(p_+) = \sigma(p+).$$

Similarly, if $f^n p$ approaches a periodic orbit $\{p_-, fp_-, \ldots, f^{q-1}p_-\}$ as $n \to -\infty$, then

$$\nu(p) = \bar{\nu}(p_-) = \nu(p_-) \quad \textit{and} \quad \sigma(p) = \bar{\sigma}(p_-) = \sigma(p_-).$$

Dense orbits. The restriction of f to the invariant curve Γ can be identified with an orientation-preserving circle diffeomorphism, which we denote by F. To be precise, assume that $z(s) = (x(s), y(s))$, $0 \le s \le L$, parameterizes Γ by arclength s. Then, for any $0 \le s \le L$, we can write $f(z(s)) = z(\tilde{s})$ with $\tilde{s} = \tilde{s}(s)$. The normalization $F(s/L) = \tilde{s}(s)/L, 0 \le s/L \le 1$, determines the circle diffeomorphism F, where the circle is identified with $\mathbb{R} \bmod \mathbb{Z}$.

Let $\rho(F)$ denote the rotation number of F (see, e.g., [1, 13]). A well-known result of Poincaré states that $\rho(F)$ is irrational iff the orbits of F are dense on the circle. (See, for example, [1, 13].) Consequently, if $\rho(F)$ is irrational, the orbits $f^n p$ with $p \in \Gamma$ are dense on Γ. We will then show, under a mild smoothness assumption, that the Lyapunov-type numbers $\nu(p)$, etc., are constant functions on Γ.

The result is closely related to Birkhoff's ergodic theorem; see, for example, [18]. In general, however, one obtains only an *almost-everywhere* result under the assumptions of Birkhoff's theorem. Since one computes only on a set of (Lebesgue) measure zero, it is of some interest to know that the *almost-everywhere* restriction may be dropped under our special assumptions.

THEOREM 2.5. *Assume that $\mu := \rho(F)$ is irrational and that $F \in C^2$. Then the functions $\nu(p) \equiv \bar{\nu}(p)$ and $\sigma(p) \equiv \bar{\sigma}(p)$ are constant on Γ.*

Remark 2.2. The assumption $F \in C^2$ can be weakened. It suffices to assume that $dF/d\xi$ is of bounded variation. The assumption $F \in C^1$, however, is not sufficient for the application of Denjoy's theorem below.

Our proof of Theorem 2.5 is based on the following lemma.

LEMMA 2.6. *Let $\mu \in \mathbb{R}$ be irrational and let $\phi : \mathbb{R} \to \mathbf{C}$ denote a continuous, 1-periodic function. Then we have, for all $x \in \mathbb{R}$,*

$$\frac{1}{n}\sum_{j=1}^{n} \phi(x+\mu j) \to \int_0^1 \phi(\xi)\,d\xi \quad as \quad n \to \infty. \tag{2.17}$$

The convergence in (2.17) *is uniform in x.*

Proof. (a) First let $\phi(x) = e^{2\pi ikx}$ with integer k. For $k \neq 0$ we have

$$\sum_{j=1}^{n} \phi(x+\mu j) = e^{2\pi ikx}\,\frac{q^{n+1}-q}{q-1} \quad \text{with} \quad q = e^{2\pi ik\mu}.$$

(The irrationality of μ ensures $q \neq 1$, of course.) It follows that

$$\Big|\sum_{j=1}^{n} \phi(x+\mu j)\Big| \le \frac{2}{|q-1|}$$

is bounded uniformly in n and x. Therefore, convergence in (2.17) to $0 = \int_0^1 \phi\,d\xi$ is uniform in x.

If $k = 0$, then $\phi \equiv 1$, and uniform convergence in (2.17) is immediate.

(b) Consider any finite sum

$$\phi_K(x) = \sum_{k=-K}^{K} c_k\, e^{2\pi ikx}. \tag{2.18}$$

Applying (a), we obtain uniform convergence in (2.17) for $\phi = \phi_K$.

(c) Let ϕ be continuous and 1-periodic. Given any $\varepsilon > 0$, there is a function ϕ_K of the form (2.18) with[3]

$$|\phi - \phi_K|_\infty \le \varepsilon. \tag{2.19}$$

Then, by (b), there is an integer N with

$$\Big|\ \frac{1}{n}\sum_{j=1}^{n} \phi_K(x+\mu j)\ -\ \int_0^1 \phi_K\,d\xi\ \Big| \le \varepsilon$$

for all $n \ge N$ and all x. Together with (2.19) we obtain

$$\Big|\ \frac{1}{n}\sum_{j=1}^{n} \phi(x+\mu j)\ -\ \int_0^1 \phi\,d\xi\ \Big|\ \le\ 3\varepsilon,$$

and the lemma is proved. □

To prove Theorem 2.5, let $\phi : \mathbb{R} \to \mathbb{R}$ denote any continuous, 1-periodic function and consider the averages

$$\frac{1}{n}\sum_{j=1}^{n} \phi(F^j y). \tag{2.20}$$

[3] Here $|\psi|_\infty = \max_\xi |\psi(\xi)|$ denotes the maximum norm.

Let $R_\mu = R_\mu(x)$ denote the rigid rotation of the circle by angle $2\pi\mu$, i.e., $R_\mu(x) = (x + \mu) \bmod 1$ since the circle is identified with $\mathbb{R} \bmod \mathbb{Z}$. By Denjoy's theorem (see [4] or, for example, [1, 13]) the circle map F is topologically conjugate to R_μ, i.e., there is a circle homeomorphism H with $F = H^{-1} \circ R_\mu \circ H$. We then obtain $F^j = H^{-1} \circ R_\mu^j \circ H$, thus $F^j y = H^{-1}(Hy + \mu j)$. Substitution into (2.20) yields

$$\frac{1}{n} \sum_{j=1}^{n} \phi(F^j y) = \frac{1}{n} \sum_{j=1}^{n} \phi \circ H^{-1}(Hy + \mu j),$$

and, therefore, by Lemma 2.6 the averages (2.20) converge,

$$\frac{1}{n} \sum_{j=1}^{n} \phi(F^j y) \to \int_0^1 \phi(H^{-1}(\xi))\, d\xi. \tag{2.21}$$

The convergence is uniform in y.

Now recall that $r \to b_r$ is a continuous, positive function on Γ and

$$\bar{\nu}(p,n) = \Big(b_{fp} \dots b_{f^n p}\Big)^{1/n}.$$

Therefore,

$$\log \bar{\nu}(p,n) = \frac{1}{n} \sum_{j=1}^{n} \log b_{f^j p}.$$

When we identify the invariant curve Γ with the circle $\mathbb{R} \bmod \mathbb{Z}$, the function $r \to b_r$ corresponds to a positive, continuous, 1-periodic function $\beta(\xi)$, and $\log b_{f^j p}$ corresponds to $\log \beta(F^j y)$. With these identifications we have

$$\log \bar{\nu}(p,n) = \frac{1}{n} \sum_{j=1}^{n} \log \beta(F^j y).$$

Therefore, by (2.21), the sequence $\log \bar{\nu}(p,n)$ converges to the integral

$$\text{Int} := \int_0^1 \phi(H^{-1}(\xi))\, d\xi \quad \text{with} \quad \phi(y) = \log \beta(y).$$

In particular,

$$\bar{\nu}(p) = \limsup_{n \to \infty} \bar{\nu}(p,n) = e^{Int}$$

is independent of p. We claim that we also have $\nu(p) = e^{Int}$ for all $p \in \Gamma$. To prove this, first note that

$$\frac{1}{n} \sum_{j=1}^{n} \phi(x - \mu j) \to \int_0^1 \phi(\xi)\, d\xi \quad \text{as} \quad n \to \infty$$

under the assumptions of Lemma 2.6. The arguments, then, are the same as before,

$$\begin{aligned} \log \nu(p,n) &= \frac{1}{n} \sum_{j=1}^{n} \log b_{f^{-j} p} \\ &= \frac{1}{n} \sum_{j=1}^{n} \phi(F^{-j} y) \to \int_0^1 \phi(H^{-1}(\xi))\, d\xi \quad \text{as} \quad n \to \infty. \end{aligned}$$

Here the functions ϕ, F, and H are exactly the same as above.

To prove $\sigma(p) = \bar{\sigma}(p) = \text{const}$ for $p \in \Gamma$ we note that

$$\bar{\sigma}(p,n) \;=\; \frac{\frac{1}{n}\sum_{j=1}^{n} \log a_{f^j p}}{\frac{1}{n}\sum_{j=1}^{n} \log b_{f^j p}}.$$

The denominator and the numerator can be treated separately by the same arguments as above. This completes the proof of Theorem 2.5. □

Summary and discussion. As above, let F denote the circle map corresponding to the restriction f_Γ of f to Γ, and let $\rho(F)$ denote the rotation number of F.

If $\rho(F)$ is irrational, then all orbits $f^n p, p \in \Gamma$, are dense on Γ, and we have

$$\nu(p) = \bar{\nu}(p) = C_1, \quad \sigma(p) = \bar{\sigma}(p) = C_2$$

with constants C_1, C_2 independent of p.

For the further discussion assume that $\rho(F) = \frac{m}{q}$ is rational, where the integers m and q have no common divisor. Then f_Γ has at least one orbit of period q. (A fixed point is considered as an orbit of period 1.) Furthermore, *every* periodic orbit of f_Γ has period q. On such an orbit, $\mathcal{O}(p) = \{p, fp, \dots, f^{q-1}p\}$, the Lyapunov-type numbers are constant, and the two numbers $\nu(p) = \bar{\nu}(p)$ and $\sigma(p) = \bar{\sigma}(p)$ can be computed in terms of the eigenvalues of a 2×2 matrix. This matrix is obtained by linearizing f about $\mathcal{O}(p)$.

If the orbit $f^n p, p \in \Gamma$, is not periodic, then it approaches a q-periodic orbit $\mathcal{O}(p_+)$ as $n \to \infty$ and a q-periodic orbit $\mathcal{O}(p_-)$ as $n \to -\infty$. Typically, the two limit orbits, $\mathcal{O}(p_+)$ and $\mathcal{O}(p_-)$, are not the same. Then one can expect that

$$\nu(p_+) = \bar{\nu}(p_+) \neq \bar{\nu}(p_-) = \nu(p_-)$$

and

$$\sigma(p_+) = \bar{\sigma}(p_+) \neq \bar{\sigma}(p_-) = \sigma(p_-)$$

since the linearizations of f about $\mathcal{O}(p_+)$ and $\mathcal{O}(p_-)$ are not directly related.

The Lyapunov-type numbers are constant along the orbit $\{f^n p\}_{n\in\mathbb{Z}}$, and we have shown that

$$\begin{aligned} \nu(f^n p) &= \nu(p_-), \quad & \bar{\nu}(f^n p) &= \bar{\nu}(p_+), \\ \sigma(f^n p) &= \sigma(p_-), \quad & \bar{\sigma}(f^n p) &= \bar{\sigma}(p_+). \end{aligned}$$

For an illustration, assume that $\nu(p_+) > \nu(p_-)$. (In the next section we will give a simple example where this occurs for two seven-periodic orbits $\mathcal{O}(p_+)$ and $\mathcal{O}(p_-)$.) Since $f^n p$ approaches $\mathcal{O}(p_+)$ for $n \to \infty$, but

$$\nu(f^n p) = \nu(p_-) < \nu(p_+) \quad \text{for all} \quad n,$$

the function $\nu(\cdot)$ cannot be continuous at the points of the periodic orbit $\mathcal{O}(p_+)$. (For the example, the resulting jump discontinuities of $\nu(\cdot)$ at the seven points of $\mathcal{O}(p_+)$ are shown in Figure 2.3.) See Figures 2.2–2.5.

This piecewise constant and discontinuous behavior is typical for the functions

$$\nu(\cdot), \quad \bar{\nu}(\cdot), \quad \sigma(\cdot), \quad \bar{\sigma}(\cdot) \tag{2.22}$$

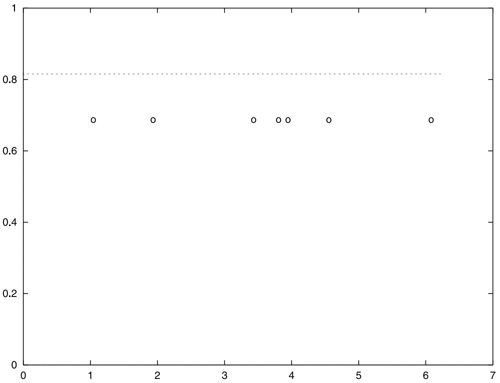

FIG. 2.2. *The values of* $\bar{\nu}(\theta)$ *for* $\lambda =$ 2.18 *and* $0 \leq \theta \leq 2\pi$.

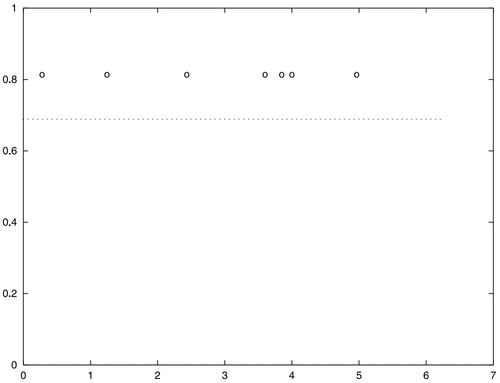

FIG. 2.3. *The values of* $\nu(\theta)$ *for* $\lambda =$ 2.18 *and* $0 \leq \theta \leq 2\pi$.

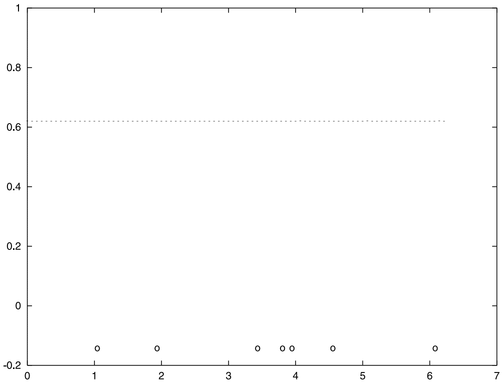

FIG. 2.4. *The values of* $\bar{\sigma}(\theta)$ *for* $\lambda =$ 2.18 *and* $0 \leq \theta \leq 2\pi$.

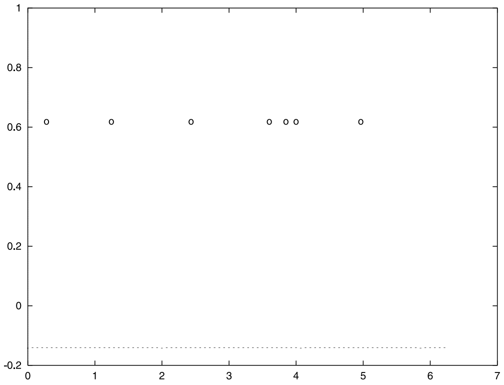

FIG. 2.5. *The values of* $\sigma(\theta)$ *for* $\lambda =$ 2.18 *and* $0 \leq \theta \leq 2\pi$.

in the phase-locked situation under consideration. To see this, assume that p_1 and p_2 are two fixed points of f^q, i.e., $p_{1,2}$ belong to q-periodic orbits of f on Γ. Denote by $\mathcal{C} = \mathcal{C}(p_1, p_2)$ the segment of Γ which lies strictly between p_1 and p_2 if one moves from p_1 to p_2 along Γ counterclockwise, say. Assume that $\mathcal{C}$ does not contain any fixed point of f^q. Then we have the following alternative: either (a) for all $p \in \mathcal{C}$,

$$\lim_{n\to\infty} f^{nq} p = p_2 \quad \text{and} \quad \lim_{n\to-\infty} f^{nq} p = p_1$$

or (b) for all $p \in \mathcal{C}$,

$$\lim_{n\to\infty} f^{nq} p = p_1 \quad \text{and} \quad \lim_{n\to-\infty} f^{nq} p = p_2.$$

In case (a) we have, for all $p \in \mathcal{C}$,

$$\begin{aligned} \nu(p) &= \nu(p_1), \quad \bar{\nu}(p) = \bar{\nu}(p_2), \\ \sigma(p) &= \sigma(p_1), \quad \bar{\sigma}(p) = \bar{\sigma}(p_2). \end{aligned}$$

Similarly, in case (b),

$$\begin{aligned} \nu(p) &= \nu(p_2), \quad \bar{\nu}(p) = \bar{\nu}(p_1), \\ \sigma(p) &= \sigma(p_2), \quad \bar{\sigma}(p) = \bar{\sigma}(p_1). \end{aligned}$$

This shows that the functions (2.22) are constant between consecutive fixed points of f^q on Γ.

Let us summarize the results: If $\rho(F)$ is irrational, then $\nu(p) = \bar{\nu}(p)$ and $\sigma(p) = \bar{\sigma}(p)$ are constant on Γ. If $\rho(F) = m/q$ is rational, then the functions (2.22) are piecewise constant, and jumps may occur only at fixed points of f^q. If $\rho(F)$ is rational, then, in general,

$$\nu(p) - \bar{\nu}(p) \quad \text{and} \quad \sigma(p) - \bar{\sigma}(p) \tag{2.23}$$

differ from zero. This last observation is numerically important, because we can compute good approximations of the numbers (2.23). If the differences (2.23) are significantly different from zero, we may conclude that we have phase-locking of f on Γ. Conversely, if the differences (2.23) are close to zero with high accuracy, then either $\rho(F)$ is irrational or we may expect that $\rho(F) = m/q$ with large q. (This last conclusion is not rigorous and needs further investigation.) In the latter case, where $\rho(F) = m/q$ with large q, the dynamics of f on Γ is close to the ergodic case where $\rho(F)$ is irrational. In any case, the numbers (2.23), and the amount by which they differ from zero, are numerically computable indicators of the degree of phase-locking of f on Γ. We will demonstrate this by an example in the next section.

3. Numerical results for the delayed logistic map. A simple model for the discrete-time evolution of the size of a population is given by $N_{n+1} = \lambda N_n(1 - N_{n-1})$. Here N_n is the scaled size of the population in the nth generation and $\lambda > 0$ is a parameter. Define $f_\lambda : \mathbb{R}^2 \to \mathbb{R}^2$ by $f_\lambda(x, y) = (y, \lambda y(1 - x))$. If one sets $(x_n, y_n) = (N_{n-1}, N_n)$, then the evolution for N_n corresponds to the planar map

$$(x_n, y_n) \to f_\lambda(x_n, y_n) = (x_{n+1}, y_{n+1}).$$

The map $f_\lambda, \lambda > 0$, has the fixed points, $P_1 = (0, 0)$ and $P_2 = (1 - \frac{1}{\lambda})(1, 1)$. Of interest is the fixed point $P_2 = P_2(\lambda)$, which is asymptotically stable for $0 < \lambda < 2$ and unstable for $\lambda > 2$. At $\lambda = 2$, where $P_2(\lambda)$ loses its stability, a Neimark–Sacker bifurcation (see, e.g., [12]) occurs, leading to an invariant curve $\Gamma = \Gamma_\lambda$ of f_λ. A detailed computer-assisted study of the curves Γ_λ and their breakdown has been made in [2].

In this paper we are mostly interested in the Lyapunov-type numbers, but we also briefly describe in the next section how we computed the approximations to Γ_λ. Figure 3.1 shows these curves for some λ-values between $\lambda = 2.001$ (near the Neimark–Sacker bifurcation) and $\lambda = 2.27$ (near breakdown). Our algorithm yields a cubic periodic C^2 spline through a discrete set of points representing Γ_λ. The spline is then used to obtain approximations to tangents and normals of Γ_λ. These are needed in (2.1) and (2.2) to obtain a_p and b_p. Approximations for the Lyapunov-type numbers, $\nu(p), \sigma(p), \bar{\nu}(p)$, and $\bar{\sigma}(p)$, can then be obtained from (2.5), (2.6), (2.7), and (2.8). See Figures 3.1–3.3.

Study of $\nu(p,n)$, etc., for $\lambda = 2.18$. We first fix $\lambda = 2.18$ and evaluate $\nu(p, n)$ and $\bar{\nu}(p, n)$ using (2.5) and (2.7) for increasing n. The point p is chosen as the point corresponding to $\theta = 0$ in our parameterization of Γ_λ, but any other point $p \in \Gamma_\lambda$ would serve the same purpose. The results for $\nu(p, n)$ and $\bar{\nu}(p, n)$ are shown in Figure 3.4. For $n \geq 300$ (about) the results are practically independent of n, giving approximations to $\nu(p)$ and $\bar{\nu}(p)$. It is clearly seen that $\nu(p) \neq \bar{\nu}(p)$, which implies phase-locking of the dynamics on Γ_λ.

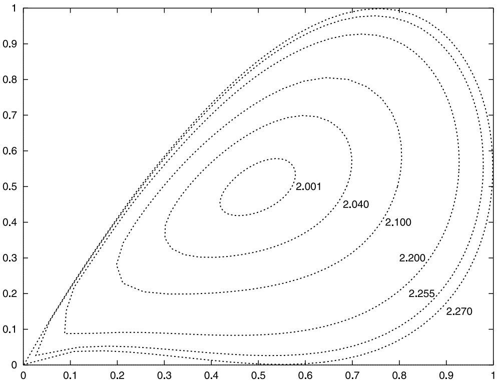

Fig. 3.1. *Invariant circles for the delayed logistic map for various values of* λ.

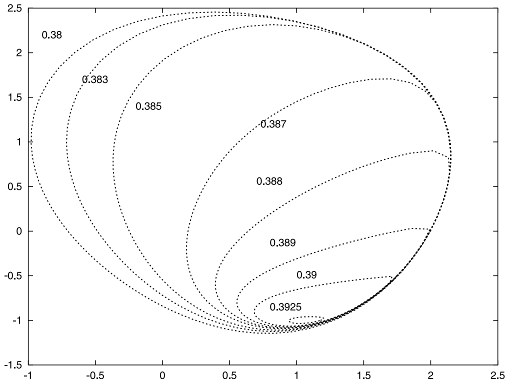

Fig. 3.2. *Invariant circles for the forced oscillator of van der Pol for various values of* λ.

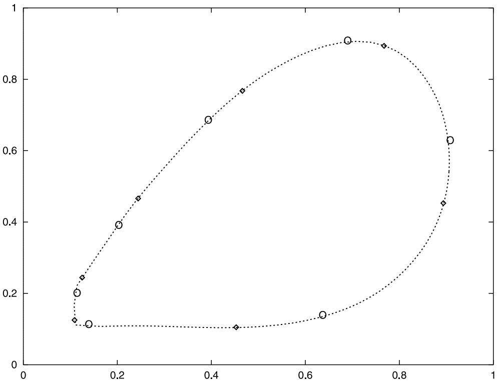

Fig. 3.3. *The invariant circle for* $\lambda = 2.18$ *with seven saddles denoted by* ($\diamond$) *and seven sinks denoted by* (o).

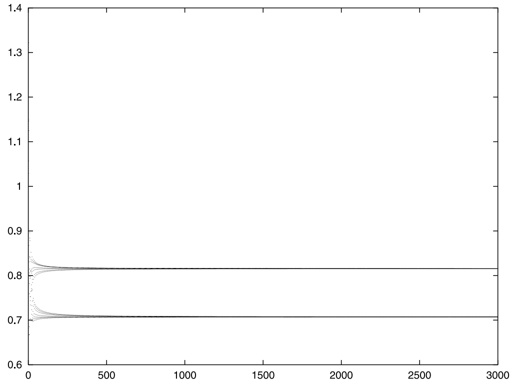

Fig. 3.4. *The values of* $\bar{\nu}(p,n)$ *and* $\nu(p,n)$ *for* $\lambda = 2.18$ *and* $0 \le n \le 3000$.

Study of $\boldsymbol{\nu(p,n)}$, etc., for $\boldsymbol{\lambda = 2.10}$. If $\lambda = 2.10$ then, according to Figure 3.4 of [2], the rotation number ρ of f_λ on Γ_λ is not a rational number with small denominator; i.e., either ρ is irrational or $\rho = m_1/m_2$ is rational with large denominator m_2. We have again computed $\nu(p,n)$ and $\bar{\nu}(p,n)$ for increasing n.

Here we see that there is no significant difference between the two numbers $\nu(p,n)$ and $\bar{\nu}(p,n)$ for large n.

The results for $\nu(p,n)$ and $\bar{\nu}(p,n)$ for $\lambda = 2.10$ are shown in Figures 3.5 and 3.6, respectively.

Study of the $\boldsymbol{\lambda}$-dependence of the Lyapunov-type numbers. If n is large enough, the numbers $\nu(p,n)$, etc., practically agree with their limits $\nu(p)$, etc. We found that the choice $n = 1{,}000$ was always sufficient for the map f_λ under consideration. Furthermore, the numbers $\nu(p)$, etc., are independent of p if we ignore the discontinuities at the sink orbit (for $\nu(p)$ and $\sigma(p)$) and the saddle orbit (for $\bar{\nu}(p)$ and $\bar{\sigma}(p)$) in a phase-locked situation. Thus, for every parameter value λ, we can compute

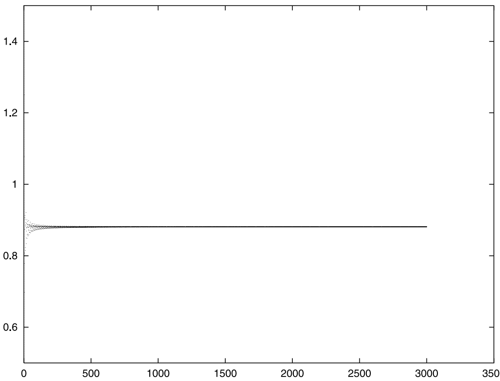

FIG. 3.5. *The values of $\nu(p,n)$ for $\lambda =$ 2.10 and $0 \leq n \leq 3000$.*

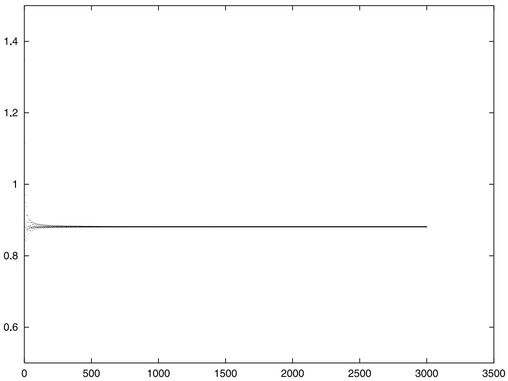

FIG. 3.6. *The values of $\bar{\nu}(p,n)$ for $\lambda =$ 2.10 and $0 \leq n \leq 3000$.*

four numbers,

$$\nu_\lambda, \quad \sigma_\lambda, \quad \bar{\nu}_\lambda, \quad \bar{\sigma}_\lambda. \tag{3.1}$$

Numerically, we have obtained these numbers by choosing $n = 1{,}000$ in the formulae for $\nu(p,n)$, etc., and by choosing p as the point corresponding to $\theta = 0$ in our parameterization of Γ_λ. (Any other point p on Γ_λ would serve the same purpose.)

Our numerical approximations of the functions (3.1) for $2 \leq \lambda \leq 2.27$ are shown in Figures 3.7, 3.9, 3.11, and 3.13.

If the dynamics of f_λ on Γ_λ is phase-locked, then we can compute the numbers (3.1) also by linearizing f_λ about the corresponding periodic orbits and using the results of section 2. This gives us a possibility of checking the accuracy of the computations. We have carried this out for the λ-interval with rotation number $\rho = 1/7$, i.e., for $\lambda_1 \leq \lambda \leq \lambda_4$, where

$$\lambda_1 \approx 2.1763, \quad \lambda_4 \approx 2.2006.$$

The results of the comparison are shown in Figures 3.8, 3.10, 3.12, and 3.14. Note that the solid lines correspond to the computations of the Lyapunov-type numbers based on eigenvalues; the dotted lines are based on the approximations $\nu(p,n)$, etc., for large n. The chosen λ-interval in the figures is somewhat larger than $[\lambda_1, \lambda_4]$, but the solid curves exist only for $\lambda_1 \leq \lambda \leq \lambda_4$. We will explain below that the numbers $\bar{\nu}_\lambda$ and $\bar{\sigma}_\lambda$ are, strictly speaking, not defined for λ in a certain subinterval of $[\lambda_1, \lambda_4]$.

The Lyapunov-type numbers in the phase-locked interval with $\rho = 1/7$. As shown in Figures 3.8, 3.10, 3.12, and 3.14, the behavior of the Lyapunov-type numbers as functions of λ is rather complicated. This is in agreement with the rather complex behavior of the eigenvalues of the linearizations about the periodic orbits, which we want to discuss in some detail.

For $\lambda_1 < \lambda < \lambda_4$ there are two seven-periodic orbits of f_λ on Γ_λ, which we denote by

$$\mathcal{O}^{(sa)} = \left\{q, f_\lambda q, f_\lambda^2 q, \ldots, f_\lambda^6 q\right\} \quad \text{and} \quad \mathcal{O}^{(si)} = \left\{r, f_\lambda r, f_\lambda^2 r, \ldots, f_\lambda^6 r\right\}$$

with $q = q_\lambda$ and $r = r_\lambda$. For $\lambda \to \lambda_1+$ and $\lambda \to \lambda_4-$ the two orbits collide, leading to a single nonhyperbolic orbit. The orbit $\mathcal{O}^{(sa)}$ consists of saddle fixed points of f_λ^7 and

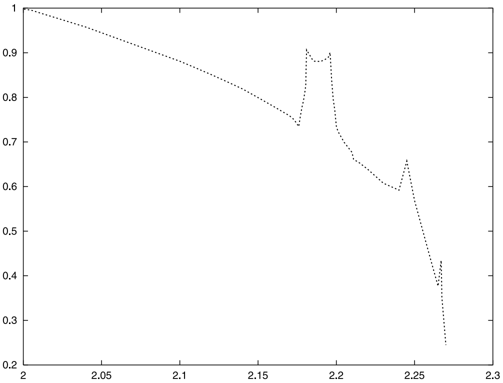

Fig. 3.7. *The values of $\bar{\nu}_\lambda$ for $2 \le \lambda \le 2.27$.*

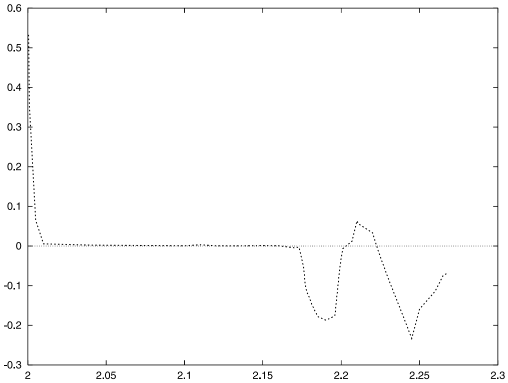

FIG. 3.13. *The values of σ_λ for $2 \leq \lambda \leq 2.27$.*

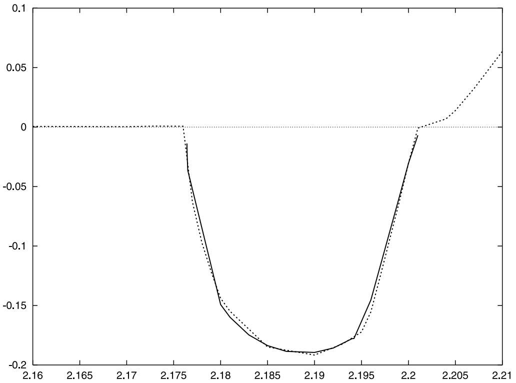

FIG. 3.14. *The values of σ_λ obtained from eigenvalues for $\lambda_1 \leq \lambda \leq \lambda_4$ (solid line).*

$\mathcal{O}^{(si)}$ consists of sinks. All points can be computed accurately by Newton's method applied to $f_\lambda^7(p) - p = 0$, together with continuation in λ. For $\lambda = 2.18$ the orbits are shown in Figure 3.3. Let

$$\Pi_\lambda^{(sa)} = \left(f_\lambda^7\right)'(q_\lambda) \quad \text{and} \quad \Pi_\lambda^{(si)} = \left(f_\lambda^7\right)'(r_\lambda)$$

denote the linearizations of f_λ about the orbits, and let $\mu_{1,2}^{(sa)}(\lambda)$ and $\mu_{1,2}^{(si)}(\lambda)$ denote the eigenvalues of these two matrices.

Behavior of $\bar{\nu}_\lambda$ and $\bar{\sigma}_\lambda$ for $\lambda_1 \leq \lambda \leq \lambda_4$. As stated in Theorems 2.2 and 2.4, the behavior of $\bar{\nu}_\lambda$ and $\bar{\sigma}_\lambda$ is determined by the eigenvalues at the sinks, $\mu_{1,2}^{(si)} = \mu_{1,2}^{(si)}(\lambda)$. However, this is only true as long as the sinks are *not* of spiral type. In the present example, the phase-locking interval $\lambda_1 \leq \lambda \leq \lambda_4$ contains a subinterval, $\lambda_2 < \lambda < \lambda_3$,

$$\lambda_2 \approx 2.181, \quad \lambda_3 \approx 2.196,$$

where the points of $\mathcal{O}^{(si)}$ are spiral points of f_λ^7, however. For the eigenvalues $\mu_{1,2}^{(si)}$ the following hold:

(1) For $\lambda_1 < \lambda < \lambda_2$ and for $\lambda_3 < \lambda < \lambda_4$ we have

$$0 < \mu_1^{(si)} < \mu_2^{(si)} < 1. \tag{3.2}$$

(2) At $\lambda = \lambda_2$ and at $\lambda = \lambda_3$ we have

$$0 < \mu_1^{(si)} = \mu_2^{(si)} < 1. \tag{3.3}$$

(3) For $\lambda_2 < \lambda < \lambda_3$ the eigenvalues $\mu_{1,2}^{(si)}$ form a complex conjugate pair with

$$0 < |\mu_1^{(si)}| = |\mu_2^{(si)}| < 1. \tag{3.4}$$

The inequalities (3.2) imply that

$$0 < \bar{\sigma}_\lambda < 1 \quad \text{and} \quad 0 < \bar{\nu}_\lambda < 1 \tag{3.5}$$

for $\lambda_1 < \lambda < \lambda_2$ and for $\lambda_3 < \lambda < \lambda_4$. Furthermore, we obtain from (3.3) that

$$\bar{\sigma}_\lambda \to 1 \quad \text{as} \quad \lambda \to \lambda_2 - \quad \text{or} \quad \lambda \to \lambda_3 + . \tag{3.6}$$

As $\lambda \to \lambda_1+$ or $\lambda \to \lambda_4-$, the orbits $\mathcal{O}^{(sa)}$ and $\mathcal{O}^{(si)}$ collide. At the saddle orbit $\mathcal{O}^{(sa)}$ we have

$$0 < \mu_1^{(sa)} < 1 < \mu_2^{(sa)} \quad \text{for} \quad \lambda_1 < \lambda < \lambda_4.$$

Together with (3.2) this implies that we have at collision

$$\mu_2^{(si)} = \mu_2^{(sa)} = 1 \quad \text{for} \quad \lambda = \lambda_1 \quad \text{and} \quad \lambda = \lambda_4. \tag{3.7}$$

Then $0 < \mu_1^{(si)} < 1 = \mu_2^{(si)}$ yields

$$\bar{\sigma}_\lambda = 0 \quad \text{for} \quad \lambda = \lambda_1 \quad \text{and} \quad \lambda = \lambda_4. \tag{3.8}$$

The behavior (3.6) and (3.8) for $\bar{\sigma}_\lambda$, as well as $0 < \bar{\sigma}_\lambda < 1$ for $\lambda_1 < \lambda < \lambda_2$ and for $\lambda_3 < \lambda < \lambda_4$, is clearly seen in Figure 3.10.

For $\lambda_2 < \lambda < \lambda_3$ the seven points of the sink orbit $\mathcal{O}^{(si)}$ are spiral fixed points of f_λ^7, which implies that Γ_λ winds infinitely often about each of the seven sinks. In particular, Γ_λ is not smooth at the sinks, but merely continuous. This breakdown of smoothness of Γ_λ is consistent with the general perturbation theory of invariant manifolds (see, e.g., [8]) in view of the limit behavior

$$\bar{\sigma}_\lambda \to 1 \quad \text{as} \quad \lambda \to \lambda_2 - \quad \text{or} \quad \lambda \to \lambda_3 + .$$

Since Γ_λ is not smooth for $\lambda_2 < \lambda < \lambda_3$, the Lyapunov-type numbers are, strictly speaking, not defined in this λ-interval. For $\nu_\lambda(p)$ and $\sigma_\lambda(p)$ the breakdown of smoothness at the *sinks* is irrelevant, however, because $\nu_\lambda(p)$ and $\sigma_\lambda(p)$ are determined by going along *backward* orbits. (This holds true unless $p \in \mathcal{O}^{(si)}$.) For $\bar{\nu}_\lambda$ and $\bar{\sigma}_\lambda$ it is natural to use the following definitions, in terms of eigenvalues,

$$\bar{\sigma}_\lambda = 1 \quad \text{and} \quad \bar{\nu}_\lambda = |\mu_{1,2}^{(si)}|. \tag{3.9}$$

(In case of an attracting spiral, the rates of attractivity toward and within Γ_λ are the same; thus $\bar{\sigma}_\lambda = 1$. The attractivity toward Γ_λ is governed by the absolute values of the eigenvalues; thus $\bar{\nu}_\lambda = |\mu_{1,2}^{(si)}|$.) The numerical curves (dotted lines) in Figures 3.8 and 3.10, which are based on (2.7) and (2.8), agree reasonably well with the solid curves, which are based on the eigenvalues.

Remark 3.1. The algorithm that we used to approximate Γ_λ is robust enough to ignore the difficulties caused by the presence of the small spirals. They are simply ignored. According to the computations in [19], the spiral diameters are less than 10^{-4}.

Behavior of $\boldsymbol{\nu_\lambda}$ and $\boldsymbol{\sigma_\lambda}$ for $\boldsymbol{\lambda_1 \le \lambda \le \lambda_4}$. According to Theorems 2.2 and 2.4, the numbers ν_λ and σ_λ are determined by the eigenvalues at the saddles, $\mu_{1,2}^{(sa)} = \mu_{1,2}^{(sa)}(\lambda)$. From the inequalities $0 < \mu_1^{(sa)} < 1 < \mu_2^{(sa)}$ it follows that

$$0 < \nu_\lambda = \left(\mu_1^{(sa)}\right)^{1/7} < 1 \quad \text{and} \quad \sigma_\lambda = \frac{\log\left(\mu_2^{(sa)}\right)}{\log\left(\mu_1^{(sa)}\right)} < 0.$$

As remarked above, we have

$$\mu_2^{(sa)} = 1 \quad \text{for} \quad \lambda = \lambda_1 \quad \text{and} \quad \lambda = \lambda_4,$$

which yields

$$\sigma_\lambda = 0 \quad \text{for} \quad \lambda = \lambda_1 \quad \text{and} \quad \lambda = \lambda_4.$$

This predicted behavior of ν_λ and σ_λ is clearly seen in Figures 3.12 and 3.14. We also see reasonable agreement between the results based on (2.5) and (2.6) (for large n) and the results based on the eigenvalues $\mu_{1,2}^{(sa)}(\lambda)$.

Remark on the accuracy of the computations. In Figures 3.8, 3.10, 3.12, and 3.14 we show two approximations to the functions $\bar{\nu}_\lambda, \bar{\sigma}_\lambda, \nu_\lambda$, and σ_λ. One approximation is obtained from eigenvalues, the other by evaluating the formulas for $\bar{\nu}(p,n)$, etc., for $n = 1{,}000$. The results of the two computations are in reasonable agreement, making it rather certain that we do not have major bugs in our codes. However, the agreement is far from perfect. We are rather sure that the discrepancies can be traced to inaccurate approximations of the invariant curves Γ_λ. (See the algorithm in the next section.) One can obtain better approximations of Γ_λ than we have used here by increasing the number of mesh points. However, the following difficulty arises: For $\lambda_2 < \lambda < \lambda_3$ the true invariant curves Γ_λ contain seven (infinite) spirals of small diameter ($< 10^{-4}$). If one chooses too many mesh points, these spirals are no longer ignored by the algorithm and the computations become extremely slow.

4. Invariant curves of planar maps. Our method of computing an invariant curve of a planar map is a discrete form of the Hadamard graph transformation. As an analytical tool, the Hadamard graph transform has been used in many works to establish perturbation results for invariant manifolds. We refer to Fenichel [8], for example. The constructive nature of the transformation suggests to apply it also in a numerical context.

For the convenience of the reader, we will describe the transformation—and a discrete version—here for the simple case of an invariant curve of a planar map. It should be noted, however, that the approach has much wider applicability.

We first describe the transformation in its analytical form. To this end, let $(\theta, r), 0 \le \theta < 2\pi, r \ge 0$, denote polar coordinates in the plane. Let g denote a map from the plane into itself whose representation in polar coordinates is given by

$$(\theta, r) \to \Big(g_{an}(\theta, r), g_{ra}(\theta, r)\Big),$$

that is, g_{an} and g_{ra} denote the angular and the radial part of the image under g. We assume that g has an invariant closed curve $\Gamma = g(\Gamma)$, which surrounds the origin and can be represented in the form

$$\Gamma : \quad (\theta, R^*(\theta)), \quad 0 \le \theta \le 2\pi.$$

Here R^* is a positive, 2π-periodic C^1 function.

We assume that we know an approximation $R^{old}(\theta)$ to the unknown function $R^*(\theta)$. Then, starting with the graph

$$\Gamma^{old} : \quad (\theta, R^{old}(\theta)), \quad 0 \le \theta \le 2\pi, \tag{4.1}$$

the Hadamard graph transform determines a new graph

$$\Gamma^{new}: \quad (\theta, R^{new}(\theta)), \quad 0 \le \theta \le 2\pi, \tag{4.2}$$

as follows.

Graph transform: For any $0 \le \theta < 2\pi$ *determine* $0 \le \alpha < 2\pi$ *with*

$$g_{an}(\alpha, R^{old}(\alpha)) = \theta \tag{4.3}$$

and then set

$$g_{ra}(\alpha, R^{old}(\alpha)) = R^{new}(\theta). \tag{4.4}$$

Remark. If one assumes that the Lyapunov-type numbers $\nu(p)$ and $\sigma(p)$ of the invariant curve Γ satisfy

$$\max_p \nu(p) < 1 \quad \text{and} \quad \max_p \sigma(p) < 1 \tag{4.5}$$

and if Γ^{old} is sufficiently close to Γ (in C^1), then the above equation (4.3) for α is uniquely solvable.

The transformation which transforms the graph (4.1) into (4.2) via (4.3) and (4.4) is known as Hadamard's graph transform. In our context, where the graphs are simply determined by functions $R(\theta)$, we may think of the transform as a map between functions,

$$R^{old} \to R^{new} = \mathcal{H}(R^{old}).$$

In an iterative fashion, the process can be repeated, leading to a sequence of functions,

$$\mathcal{H}^k(R^{old}), \quad k = 1, 2, 3 \dots .$$

Then, assuming (4.5) and closeness of Γ^{old} to Γ, a contraction argument can be applied to prove convergence,

$$\lim_{k\to\infty} \left| \mathcal{H}^k(R^{old}) - R^* \right|_\infty .$$

Here $|\cdot|_\infty$ denotes the maximum norm.

Numerical aspects. Let $0 = \theta_1 < \theta_2 < \cdots < \theta_N < 2\pi$ denote a finite grid,[4] and let

$$R_i^{old} = R_i^{old}(\theta_i), \quad i = 1, \dots, N,$$

denote a known grid function. We use these grid values to determine a 2π-periodic interpolant, denoted again by $R^{old}(\theta)$. In our code we have used periodic cubic splines for interpolation.

Discrete graph transform: For $i = 1, \dots, N$, *determine* $0 \le \alpha < 2\pi$ *with*

$$g_{an}(\alpha, R^{old}(\alpha)) = \theta_i \tag{4.6}$$

[4] In our applications to the delayed logistic map it was always sufficient to work with a uniform grid.

and then set

$$g_{ra}(\alpha, R^{old}(\alpha)) = R^{new}(\theta_i). \tag{4.7}$$

In our code, the scalar equation (4.6) for α is solved by bisection (to obtain a starting value) and Newton's method. Assuming convergence of the solutions for (4.6), the above process defines a transformation between grid functions,

$$(R_i^{old})_{1\leq i\leq N} \to (R_i^{new})_{1\leq i\leq N} = \mathcal{H}^{dis}((R_i^{old})).$$

Repeated application of the discrete transform $\mathcal{H}^{dis}$ leads to a (finite) sequence of grid functions,

$$\left(\mathcal{H}^{dis}\right)^k((R_i^{old})), \quad k = 1, 2, 3, \ldots .$$

We terminate the iteration when the estimate

$$\left|\left(\mathcal{H}^{dis}\right)^{k+1}((R_i^{old})) - \left(\mathcal{H}^{dis}\right)^k((R_i^{old}))\right|_2 < \text{tolerance}$$

is satisfied for a given tolerance. Here $|\cdot|_2$ is the discrete L_2-norm, which approximates $(\int_0^{2\pi}\psi^2(\theta)d\theta)^{1/2}$.

Application near a Neimark–Sacker bifurcation. Assume that $(x, y) \to f_\lambda(x, y)$ is a family of smooth maps of the plane, depending smoothly on the real parameter λ. An example is given by the maps $f_\lambda(x, y) = (y, \lambda y(1 - x))$ of section 3. Let $P_\lambda = (x_\lambda, y_\lambda)$ denote a branch of fixed points, $f_\lambda(P_\lambda) = P_\lambda$ and let $\mu_{1,2}(\lambda)$ denote the eigenvalues of the Jacobian $f'_\lambda(P_\lambda)$. It is well known that P_λ is an asymptotically stable fixed point if $\max_j |\mu_j(\lambda)| < 1$, whereas P_λ is unstable if $\max_j |\mu_j(\lambda)| > 1$.

Thus, a loss of stability of P_λ occurs at $\lambda = \lambda_0$ if the eigenvalues $\mu_{1,2}(\lambda)$ form a complex conjugate pair which leaves the unit circle when λ increases from $\lambda < \lambda_0$ to $\lambda > \lambda_0$. Then, under some additional assumptions, the map f_λ will have an attractive invariant curve Γ_λ for λ in some interval $\lambda_0 < \lambda < \lambda_1$. For details of this so-called Neimark–Sacker (or second Hopf or Poincaré–Andronov–Hopf) bifurcation we refer to [12], for example.

To apply our algorithm for approximating Γ_λ, we introduce polar coordinates in the (x, y)-plane which are centered at the bifurcation point $P_{\lambda_0} = (x_{\lambda_0}, y_{\lambda_0})$. In other words, we let

$$x = x_{\lambda_0} + r\cos\theta, \quad y = y_{\lambda_0} + r\sin\theta,$$

and then rewrite the map f_λ in terms of (θ, r)-coordinates obtaining $g_\lambda(\theta, r)$,

$$f_\lambda(x, y) \Longleftrightarrow g_\lambda(\theta, r).$$

The algorithm can then be applied to g_λ with λ as a continuation parameter. A computed invariant curve $\Gamma_{\lambda_{old}}$ provides starting values for approximating $\Gamma_\lambda, \lambda = \lambda_{old} + \Delta\lambda$. A first approximation to Γ_λ for λ near the bifurcation value λ_0 is provided by the Neimark–Sacker bifurcation theorem. Results for the delayed logistic map $f_\lambda(x, y) = (y, \lambda y(1 - x))$ are shown in Figure 3.1.

Acknowledgment. The authors wish to thank the referees for their careful reading of the first manuscript. Their comments led to an improved presentation of the paper.

A NUMERICAL STUDY OF FETI ALGORITHMS FOR MORTAR FINITE ELEMENT METHODS*

DAN STEFANICA†

Abstract. The finite element tearing and interconnecting (FETI) method is an iterative substructuring method using Lagrange multipliers to enforce the continuity of the finite element solution across the subdomain interface. Mortar finite elements are nonconforming finite elements that allow for a geometrically nonconforming decomposition of the computational domain into subregions and, at the same time, for the optimal coupling of different variational approximations in different subregions.

We present a numerical study of FETI algorithms for elliptic self-adjoint equations discretized by mortar finite elements. Several preconditioners which have been successful for the case of conforming finite elements are considered. We compare the performance of our algorithms when applied to classical mortar elements and to a new family of biorthogonal mortar elements, and we discuss the differences between enforcing mortar conditions instead of continuity conditions for the case of matching nodes across the interface. Our experiments are carried out for both two and three dimensional problems, and include a study of the relative costs of applying different preconditioners for mortar elements.

Key words. FETI algorithms, mortar finite elements, Lagrange multipliers, domain decomposition

1. Introduction.

The finite element tearing and interconnecting (FETI) method is an iterative substructuring method using Lagrange multipliers which is actively used in industrial-size parallel codes for solving difficult computational mechanics problems. This method was introduced by Farhat and Roux [26]; a detailed presentation is given in [27], a monograph by the same authors. Originally used to solve second order, self-adjoint elliptic equations, it has later been extended to many other problems, e.g., time-dependent problems [18], plate bending problems [19, 24, 41], heterogeneous elasticity problems with composite materials [43, 44], acoustic scattering and Helmholtz problems [22, 23, 28, 29], linear elasticity with inexact solvers [32], and Maxwell's equations [42, 50]. Another Lagrange multiplier based method, the dual-primal FETI method, has recently been introduced by Farhat et al. [20] and Farhat, Lesoinne, and Pierson [21] for two dimensional problems, and a coordinate–free formulation of the FETI method has been analyzed by Brenner [11].

The FETI method is a nonoverlapping domain decomposition method and requires the partitioning of the computational domain Ω into nonoverlapping subdomains. It has been designed for conforming finite elements and makes use of Lagrange multipliers to enforce pointwise continuity across the interface of the partition. After eliminating the subdomain variables, the dual problem, given in terms of Lagrange

multipliers, is solved by a projected conjugate gradient (PCG) method. Once an accurate approximation for the Lagrange multipliers has been obtained, the values of the primal variables are obtained by solving a local problem for each subdomain.

It was shown experimentally in [25] that a certain projection operator used in the PCG solver plays a similar role to that of a coarse problem for other domain decomposition algorithms and that certain variants of the FETI algorithm are numerically scalable with respect to both the subproblem size and the number of subdomains. Mandel and Tezaur later showed that for a FETI method which employs a Dirichlet preconditioner, the condition number grows at most in proportion to $(1+\log(H/h))^2$ if the decomposition of Ω does not have crosspoints, i.e., the points that belong to the closure of more than two subdomains, and as $C(1+\log(H/h))^3$ in the general case; cf [40, 49]. Here, H is the subdomain diameter and h is the mesh size. Using a different preconditioner, Klawonn and Widlund obtained a FETI method which converges in fewer iterations than the classical FETI method. In [33], they proved an upper bound for the condition number of their method for elliptic problems with heterogeneous coefficients which is on the order of $(1+\log(H/h))^2$; see section 4.3 for more details.

Rixen and Farhat [43, 44] considered a Dirichlet preconditioner with a maximal number of pointwise continuity conditions at crosspoints, which results in a FETI algorithm with redundant Lagrange multipliers. It was shown in [33] that this algorithm is equivalent to using the preconditioner of Klawonn and Widlund and nonredundant multipliers for the FETI method.

In this paper, we study the numerical convergence properties of a family of FETI algorithms applied to mortar finite elements. Mortar finite elements are nonconforming finite element methods that allow for a geometrically nonconforming decomposition of the computational domain into subregions and, at the same time, for the optimal coupling of different variational approximations in different subregions. Here, optimality means that the global error is bounded by the sum of the local approximation errors on each subregion.

The importance of our study is related to the inherent advantages of mortar methods over the conforming finite elements. For example, the mesh generation is more flexible and can be made quite simple on individual subregions. This also makes it possible to move different parts of the mesh relative to each other, e.g., in a study of time-dependent problems. The same feature is most valuable in optimal design studies, where the relative position of parts of the model is not fixed a priori. The mortar methods also allow for local refinement of finite element models in only certain subregions of the computational domain, and they are also well suited for parallel computing; cf. [30].

We have used geometrically nonconforming mortar finite elements. Three FETI algorithms with different preconditioners for the dual problem have been considered: the Dirichlet preconditioner of Farhat and Roux [26], the block-diagonal preconditioner of Lacour [34], and the new preconditioner of Klawonn and Widlund [33]. These algorithms have been implemented for both the classical mortar finite elements of Bernardi, Maday, and Patera [8], and for the new biorthogonal mortar elements of Wohlmuth [52, 53], in two and three dimensions. Based on the results presented in this paper, we proposed and analyzed a new FETI algorithm with inexact solvers applied to three dimensional mortar finite elements in [47]. We note that a study of a FETI preconditioner for Maxwell's equations on nonmatching grids has been completed by Rapetti and Toselli [42].

Our results show that the Dirichlet preconditioner does not perform well in the mortar case, since convergence is achieved only after hundreds or thousands of iterations. However, the new preconditioner performs satisfactory; i.e., the number of iterations required to achieve convergence and the condition number of the algorithms depend only weakly on the number of nodes in each subregion and is independent of the number of subregions. For each of the three preconditioners, using the biorthogonal mortars results in algorithms which require less computational effort and fewer iterations than those using the classical mortar finite elements.

We have also studied the extra computational effort, due to the complexity of the mortar conditions, required for the implementation of the FETI algorithm with the new preconditioner. These costs might have been significant, in particular, in the three dimensional case. We conclude that the improvement of the iteration count was enough to offset this extra cost.

In the conforming finite element case, the meshes across the interface match. Therefore, continuity conditions, as well as mortar conditions, may be enforced across the interface. We have studied the differences between the FETI algorithms using both types of constraints in terms of iteration counts and computational costs. We conclude that the new preconditioner for either continuity conditions or for biorthogonal mortars results in the best algorithms.

The rest of the paper is structured as follows. In the next section, we describe the mortar finite element method. In section 3, we present the classical FETI method and the Dirichlet preconditioner, and in section 4, we discuss the FETI algorithm for mortars with two different preconditioners. In sections 5 and 6, we present numerical comparisons of the performances of three different FETI algorithms for mortar finite elements, and for two and three dimensional problems, respectively. In the last section, we discuss the differences between enforcing mortar conditions instead of continuity conditions for the case of matching nodes across the interface.

2. Mortar finite elements.

The mortar finite element methods were first introduced by Bernardi, Maday, and Patera in [8] for low order and spectral finite elements. A three dimensional version was developed by Ben Belgacem and Maday in [7] and was further analyzed for three dimensional spectral elements in [6]. Another family of biorthogonal mortar elements has recently been introduced by Wohlmuth [52, 53]. See also [45] for mortar *hp* finite elements and [4, 12, 31] for mortar $H(\mathrm{curl})$ elements. Cai, Dryja, and Sarkis [13] have extended the mortar methods to overlapping decompositions.

Several domain decomposition methods for mortar finite elements have been shown to perform similarly to the case of conforming finite elements; cf. [3, 15] for iterative substructuring methods, [16, 37, 38] for Neumann–Neumann algorithms, and [36, 48] for the FETI method. For other studies of preconditioners for the mortar method, see [14] for a hierarchical basis preconditioner and [1, 2] for iterative substructuring preconditioners. Multigrid methods have also been used to solve mortar problems; cf. [9, 10, 51].

2.1. Two dimensional low order mortar finite elements.

For simplicity, we restrict our presentation to mortar elements used in our numerical experiments, i.e., first order mortar finite elements on polygonal domains. The computational domain Ω is decomposed using a nonoverlapping polygonal partition $\{\Omega_i\}_{i=1:N}$. Let $\partial\Omega_D$ be the part of $\partial\Omega$ where Dirichlet conditions are imposed. If an edge of a polygon intersects $\partial\Omega_D$, we require that the entire edge belongs to $\partial\Omega_D$. The partition is said to be geometrically conforming if the intersection between the closure of any two subregions is either empty, a vertex, or an entire edge, and it is geometrically

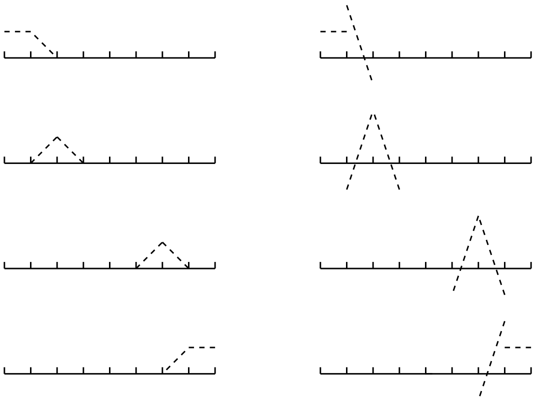

FIG. 1. *Test functions. Left: classical mortars; right: new mortars.*

nonconforming otherwise.

The interface between the subregions $\{\Omega_i\}_{i=1:N}$, denoted by Γ, is defined as the set of points that belong to the boundaries of at least two subregions.

The mortar finite element space V^h is defined as follows: Any mortar function $v \in V^h$ vanishes at all the nodes on $\partial\Omega_D$. The restriction of v to any Ω_i is a P_1 or a Q_1 finite element function. We do not require pointwise continuity across Γ. Instead, we choose a set of open edges of the subregions $\{\Omega_i\}_{i=1:N}$, called nonmortars, which form a disjoint partition of the interface. The edges of $\{\Omega_i\}_{i=1:N}$, which are part of Γ and were not chosen to be nonmortars, are called mortars. Across each nonmortar side γ, we impose weak continuity conditions for v. Let $\Gamma(\gamma)$ be the union of the parts of the mortars that coincides geometrically with $\overline{\gamma}$. Let v_γ and $v_{\Gamma(\gamma)}$ be the restriction of v to γ and $\Gamma(\gamma)$, respectively. The values of v on the nonmortar γ are then given by the mortar conditions

$$(1) \qquad \int_\gamma \left(v_\gamma - v_{\Gamma(\gamma)}\right) \ \psi \ ds \ = \ 0 \quad \forall \ \psi \in \Psi^h(\gamma),$$

where $\Psi^h(\gamma)$ is the space of test functions. Here, $\Psi^h(\gamma)$ is a subspace of codimension two of $V^h(\gamma)$, the restriction of V^h to γ. It consists of continuous, piecewise linear functions on γ that are constant in the first and last mesh intervals of $\overline{\gamma}$; cf. Figure 1.

We note that a nonmortar partition of the interface is always possible; cf. Stefanica [46]. The partition is not unique, but any choice can be treated the same from a theoretical point of view.

From (1), it results that the interior nodes of the nonmortar sides are not associated with genuine degrees of freedom in the finite element space V^h, while the values of v at the end points of $\overline{\gamma}$ are genuine degrees of freedom. To emphasize this aspect, we present here the matrix formulation of the mortar conditions, which will be further used in section 4.

Let $\bar{v}_\gamma$ be the vector of the interior nodal values of v on γ. For simplicity, we assume that the mesh is uniform on γ of mesh size h. Let $\bar{v}_{\Gamma(\gamma)}$ be the vector of the values of v at the end points of γ and at all the nodes on the edges opposite γ such that the intersection of γ and the supports of the corresponding nodal basis functions are not empty. Then $\bar{v}_\gamma$ is uniquely determined by $\bar{v}_{\Gamma(\gamma)}$; the matrix formulation of the mortar conditions (1) is

$$M_\gamma \bar{v}_\gamma - N_\gamma \bar{v}_{\Gamma(\gamma)} \;=\; 0, \tag{2}$$

or, solving for $\bar{v}_\gamma$, $\bar{v}_\gamma \;=\; P_\gamma \bar{v}_{\Gamma(\gamma)}$, with $P_\gamma = M_\gamma^{-1} N_\gamma$.

We note that N_γ is a banded matrix with a bandwidth of similar size for both the classical and the new mortars. For the classical mortar method, M_γ is a tridiagonal matrix and the mortar projection matrix P_γ is a full matrix. The projection of a nodal basis function from the mortar side results in a function with support equal to γ. The nodal values of this function decay exponentially to 0 at the end points of γ, away from the nodes on γ opposite the support of the nodal basis function from the mortar side.

Since $V^h(\Omega_i) \subset H^1(\Omega_i)$, we know that $v_\gamma \in H^{1/2}(\gamma)$. Thus, the test functions space $\Psi^h(\gamma)$ may be embedded in the dual space of $H^{1/2}(\gamma)$ with respect to the L^2 inner product, and therefore $\Psi^h(\gamma) \subset H^{-1/2}(\gamma)$. Based on this observation, a space of discontinuous piecewise linear test functions $\Psi^h_{new}(\gamma)$ for low order mortars has been developed by Wohlmuth [52]. The test function associated with the first interior node on γ is the constant 1 on the first mesh interval, decreases linearly from 2 to -1 on the second mesh interval, and vanishes everywhere else. A similar test function is introduced for the last interior node on γ. The test function for any other node on γ has the support on the two mesh intervals having the node as an end point; it increases linearly from -1 to 2 on the first interval and decreases from 2 to -1 on the second; cf. Figure 1.

The new mortar space has similar approximation properties to the classical mortar space; cf. [52]. A major advantage of the new mortar finite element space is that the mortar projection can be represented by a banded matrix, as opposed to the classical mortar finite element method, where the mortar projection matrix is, in general, a full matrix. More precisely, for the new mortar method, $M_\gamma = hI$ is a diagonal matrix and $P_\gamma = N_\gamma/h$ is banded. Therefore, the mortar projection of a nodal basis function on the mortar side vanishes outside the mesh intervals on the nonmortar which intersect its support.

2.2. The three dimensional case. For three dimensional problems, the mortars and nonmortars are open faces of the subregions which form the nonconforming decomposition of the computational domain Ω.

To introduce the mortar finite element space, we follow the outline from the previous section. Let $\{\Omega_i\}_{i=1:N}$ be a nonoverlapping polyhedral partition of Ω. If a face or an edge of a polyhedron intersects $\partial\Omega_D$ at an interior point, then the entire face or edge is assumed to belong to $\partial\Omega_D$. The partition is said to be geometrically conforming if the intersection between the closures of any two subregions is either empty, a vertex, an entire edge, or an entire face, and it is nonconforming otherwise.

The nonmortars $\{\mathcal{F}_l\}_{l=1}^{L}$ are faces of the subregions which form a disjoint partition of the interface Γ. The faces of $\{\Omega_i\}_{i=1:N}$ that are part of Γ and were not chosen to be nonmortars are called mortars.

We now describe the test functions associated with an arbitrary nonmortar face $\mathcal{F}$. Let $\Gamma(\mathcal{F})$ be the union of parts of mortar faces opposite $\mathcal{F}$. The test function space $\Psi^h(\mathcal{F})$ is a subset of $V^h(\mathcal{F})$, the restriction of V^h to $\mathcal{F}$, such that the value of a test function at a node on $\partial\mathcal{F}_l$ is a convex combination of its values at the neighboring interior nodes of $\mathcal{F}_l$. If $V^h(\mathcal{F})$ is a P_1 or a Q_1 space, then the dimension of $\Psi^h(\mathcal{F})$ is equal to the number of interior nodes of $\mathcal{F}$.

The mortar finite element space V^h consists of functions v which vanish at all the nodal points of $\partial\Omega_D$. Its restriction to any Ω_i is a P_1 or a Q_1 finite element function. The values of a mortar function $v \in V^h$ on any nonmortar face $\mathcal{F}$ are given by the mortar conditions

$$\int_{\mathcal{F}} \left(v_{\mathcal{F}} - v_{\Gamma(\mathcal{F})}\right) \ \psi \ ds \ = \ 0 \quad \forall \ \psi \in \Psi^h(\mathcal{F}).$$

A version of the new mortars for the three dimensional case, based on biorthogonal test functions such as those described in section 2.1, has been developed by Wohlmuth. For details, we refer the reader to [53].

3. The classical FETI algorithm.

In this section, we review the original FETI method of Farhat and Roux [27] for elliptic problems discretized by *conforming finite elements*. To simplify our presentation, we discuss only the Poisson equation with mixed Neumann–Dirichlet boundary conditions. The extension of the algorithm to the case of other self-adjoint elliptic equations is straightforward.

Let $f \in L^2(\Omega)$. We look for a solution $u \in H^1(\Omega)$ of the mixed boundary value problem

$$\left\{ \begin{array}{rcll} -\Delta u & = & f & \text{on} \quad \Omega, \\ u & = & 0 & \text{on} \quad \partial\Omega_D, \\ \frac{\partial u}{\partial n} & = & 0 & \text{on} \quad \partial\Omega_N, \end{array} \right. \tag{3}$$

where $\partial\Omega = \partial\Omega_N \cup \partial\Omega_D$. For unique solvability, we require that $\partial\Omega_D$ has positive Lebesgue measure.

On Ω, we consider P_1 or Q_1 finite elements with mesh size h. The finite element mesh is partitioned along mesh lines into N nonoverlapping subdomains $\Omega_i \subset \Omega$, $i = 1 : N$. Since the finite element mesh is conforming, the boundary nodes of the subdomains match across the interface. A subdomain Ω_i is said to be floating if $\partial\Omega_i \cap \partial\Omega_D = \emptyset$, and nonfloating otherwise.

As in other substructuring methods, the first step of the FETI method consists of eliminating the interior subdomain variables, which results in a Schur complement formulation of our problem. Let $S^{(i)}$ be the Schur complement matrix of Ω_i, and let f_i be the contribution of Ω_i to the load vectors. Let $S = \text{diag}_{i=1}^{N} S^{(i)}$ be a block-diagonal matrix, and let f be the vector $[f_1, \ldots, f_N]$. We denote by u_i the vector of nodal values on $\partial\Omega_i$ and by u the vector $[u_1, \ldots, u_N]$.

If Ω_i is a floating subdomain, then $S^{(i)}$ is a singular matrix, and its kernel is generated by a vector Z_i with entries corresponding to the nodes of $\partial\Omega_i$ equal to 1 and entries corresponding to all the other nodes equal to 0. Let Z consist of all the column vectors Z_i. Then $\text{Ker}S = \text{Range}Z$.

Let B be the matrix of constraints which measures the jump of a given vector u across the interface; B will also be referred to as the Lagrange multiplier matrix. Each row of the matrix B is associated with two matching nodes across the interface, and has values 1 and -1, respectively, at the two nodes, and zero entries everywhere else. A finite element function with corresponding vector values u is continuous if and only if $Bu = 0$.

For a method without redundant constraints and multipliers, the number of pointwise continuity conditions required at crosspoints, i.e., the points that belong to the closure of more than two subdomains, and, therefore, the number of corresponding rows in the matrix B, is one less then the number of the subdomains meeting at the crosspoint. There exist several different ways of choosing which conditions to enforce at a crosspoint, all of them resulting in algorithms with similar properties.

An alternative suggested in [43, 44] is to connect all the degrees of freedom at the crosspoints by Lagrange multipliers and use a special scaling, resulting in a method with redundant multipliers; see section 4.3 for further details.

Let W_i be the space of the degrees of freedom associated with $\partial\Omega_i \setminus \partial\Omega_D$, and let W be the direct sum of all spaces W_i. If $U = \text{Range}B$ is the space of the Lagrange multipliers, then $S : W \to W$ and $B : W \to U$. Let B^t be the transpose of B. By introducing Lagrange multipliers λ for the constraint $Bu = 0$, we obtain a saddle point Schur formulation of (3),

$$\left\{ \begin{array}{lclcl} Su & + & B^t\lambda & = & f, \\ Bu & & & = & 0. \end{array} \right. \tag{4}$$

3.1. Algebraic formulation. In the FETI method, the primal variable u is eliminated from (4), and the resulting equation for the dual variable λ is solved by a PCG method.

We note that S is singular if there exist at least one floating subdomain among the subdomains Ω_i, $i = 1 : N$. Let $S^\dagger$ be the pseudoinverse of S; i.e., for any $b \perp \text{Ker}S$, $S^\dagger b$ is the unique solution of $Sx = b$ such that $S^\dagger b \in \text{Range}S$. The first equation in (4) is solvable if and only if

$$f - B^t\lambda \ \perp \ \text{Ker}S. \tag{5}$$

If (5) is satisfied, then

$$u \ = \ S^\dagger(f - B^t\lambda) + Z\alpha, \tag{6}$$

where $Z\alpha$ is an element of $\text{Ker}S = \text{Range}Z$ to be determined.

Let $G = BZ$. Substituting (6) into the second equation in (4), it follows that

$$BS^\dagger B^t\lambda \ = \ BS^\dagger f + G\alpha. \tag{7}$$

An important role in the FETI algorithm is played by V, a subset of U defined by $V = \text{Ker}G^t$. In other words, $V \ = \ \text{Ker}G^t \ \perp \ \text{Range}G \ = \ B\text{Range}Z \ = \ B\text{Ker}S$. Let $P = I - G(G^tG)^{-1}G^t$ be the orthogonal projection onto V. It is easy to see that G^tG is nonsingular, by using the fact that $\text{Ker}B \cap \text{Range}Z = \text{Ker}B \cap \text{Ker}S = \emptyset$. Since $P(G\alpha) = 0$, if P is applied to (7), it results that

$$PBS^\dagger B^t\lambda \ = \ PBS^\dagger f. \tag{8}$$

We now return to the necessary condition (5). Since $\text{Ker}S \ = \ \text{Range}Z$, we obtain that (5) is equivalent to $f - B^t\lambda \perp \text{Range}Z$, which leads to $Z^t(f - B^t\lambda) \ = \ 0$ and therefore to

$$G^t\lambda \ = \ Z^tf. \tag{9}$$

Let $F = BS^\dagger B^t$, $d = BS^\dagger f$, and $e = Z^tf$. We concluded that we have to solve the dual problem (8) for λ subject to the constraint (9); with the new notations,

$$PF\lambda = Pd, \tag{10}$$

$$G^t\lambda = e. \tag{11}$$

We note that, from (7), it follows that $\alpha = (G^tG)^{-1}G^t(F\lambda - d)$. Therefore, after an approximate solution for λ is found, the primal variable u is obtained from (6) by solving a Neumann or a mixed boundary problem on each floating and nonfloating subdomain, respectively, corresponding to a vector multiplication by $S^{\dagger}$.

The main part of the FETI algorithm consists of solving (10) for the dual variable λ, which is done by a PCG method. Since λ must also satisfy the constraint (11), let $\lambda_0 = G(G^tG)^{-1}e$ be the initial approximation. Then $G^t\lambda_0 = e$ and $\lambda - \lambda_0 \in \mathrm{Ker}G^t = V$. If all the increments $\lambda_k - \lambda_{k-1}$, i.e., the search directions, are in V, then (11) will be satisfied.

One possible preconditioner for (10) is of the form PM, where $M = BSB^t$. When a vector multiplication by M is performed, N independent Dirichlet problems have to be solved in each iteration step. Therefore, M is known as the Dirichlet preconditioner. We note that the Schur complement matrix S is never computed explicitly, since only the action of S on a vector is needed.

Mandel and Tezaur [40] have shown that the condition number of this FETI method is bounded from above by $C(1 + \log(H/h))^3$, where C is a positive constant independent of h, H. If there are no crosspoints in the partition of Ω, then this polylogarithmic bound improves to $C(1 + \log(H/h))^2$.

We conclude this section with a few comments on the PCG algorithm:

Projected Preconditioned Conjugate Gradient Iteration (PCG)

```
$\lambda_0 = G(G^tG)^{-1}e$, $r_0 = Pd - PF\lambda_0$, $n = 1$
while $(Mr_{n-1}, r_{n-1}) \geq tol$
  $w_{n-1} = Pr_{n-1}$
  $z_{n-1} = Mw_{n-1}$
  $y_{n-1} = Pz_{n-1}$
  $\beta_n = (y_{n-1}, r_{n-1})/(y_{n-2}, r_{n-2})$        $(\beta_1 = 0)$
  $p_n = y_{n-1} + \beta_n p_{n-1}$                        $(p_1 = y_0)$
  $\alpha_n = (y_{n-1}, r_{n-1})/(Fp_n, p_n)$
  $\lambda_n = \lambda_{n-1} + \alpha_n p_n$
  $r_n = r_{n-1} - \alpha_n PFp_n$
  $n = n + 1$
end
```

In each iteration step of the PCG algorithm, the residual and the search directions are projected onto the space V, i.e., $w_{n-1} = Pr_{n-1}$ and $y_{n-1} = Pz_{n-1}$. This projection step plays the role of a coarse problem which is solved in each iteration and is the reason why the FETI method is numerically scalable, even though it lacks an explicit coarse space construction. We note that $r_{n-1} \in V$ at every step. Therefore, it follows that $w_{n-1} = r_{n-1}$, and thus only one projection onto V is required per iteration step. This observation is particularly important for some of the algorithms suggested in [33].

4. The FETI algorithm for mortars. As we have seen in section 3, in the classical FETI algorithm the computational domain Ω is partitioned into nonoverlapping subregions, multiple degrees of freedom are introduced for the matching nodes across the interface, and pointwise continuity across the interface is enforced by a Lagrange multiplier matrix B. This methodology is very similar to that used in [5], where a saddle point formulation for the mortar finite element method has been introduced.

In fact, the FETI method can be applied without any algorithmic changes for a mortar finite element discretization of Ω, using the nonoverlapping partition $\{\Omega_i\}_{i=1:N}$ considered in section 2. We recall that this partition may be geometrically nonconforming and the nodes across the interface do not necessarily match. To keep the presentation clear, we assume that each subregion Ω_i has a diameter of order H and that its triangulation has a mesh size of order h. The matrix S is again a block-diagonal matrix $\mathrm{diag}_{i=1}^{N} S^{(i)}$, where the local Schur complement matrices $S^{(i)}$ are obtained from the finite element discretizations on individual subregions. We have to solve the problem

$$\left\{ \begin{array}{lclcl} Su & + & B^t\lambda & = & f, \\ Bu & & & = & 0, \end{array} \right.$$

where the matrix B enforces mortar conditions across the interface. The dual problem is obtained as in section 3.1. It results in solving

$$PF\lambda \;=\; Pd, \tag{12}$$

with a PCG method, with initial approximation $\lambda_0 = G(G^tG)^{-1}e$, and with all the search directions in V.

The price we pay for the inherent flexibility of the mortar finite elements is due to the fact that the matrix B is more complicated in the mortar case, compared to that of the classical FETI method with conforming finite elements. The matrix B has one block, B_γ, for each nonmortar side γ. We adopt the matrix formulation of the mortar conditions from section 2.1. Let M_γ and N_γ be the matrices which multiply the nonmortar and mortar nodal values in the mortar conditions across γ, respectively. Then B_γ consists of the columns of M_γ and $-N_\gamma$ for the nodes of γ and those on the mortars opposite γ, and has zero columns corresponding to all the other nodes.

We note that the mortar conditions are all associated with the interior nodes on the nonmortar sides. Therefore, the problem of choosing the crosspoints constraints does not arise in the mortar case.

In our numerical experiments, we have implemented three different preconditioners suggested in the FETI literature for the dual problem (12). In sections 4.1–4.3, we present each of them briefly.

4.1. The Dirichlet preconditioner. In [26], Farhat and Roux introduced the Dirichlet preconditioner for the FETI method

$$PM = PBSB^t. \tag{13}$$

This preconditioner was shown to perform well for conforming finite elements; see, e.g., [26] for numerical results and [40] for condition number estimates.

4.2. A block-diagonal preconditioner. In [34, 35], Lacour suggested another preconditioner designed specifically for a mortar version of the FETI algorithm and without a counterpart in the conforming case. Let $\mathrm{diag} B_\gamma B_\gamma^t$ be the block-diagonal matrix which has a block $B_\gamma B_\gamma^t$ of size equal the number of interior nodes on γ for each nonmortar γ. We note that $\mathrm{diag} B_\gamma B_\gamma^t$ is the block-diagonal part of the matrix BB^t. In the three dimensional case, each block corresponds to a nonmortar face $\mathcal{F}$, and the block-diagonal matrix is $\mathrm{diag} B_\mathcal{F} B_\mathcal{F}^t$. To simplify our presentation, we will use the same notation, $\mathrm{diag} B_\gamma B_\gamma^t$, for the three dimensional block-diagonal matrix.

The preconditioner $P\overline{M}$ is defined as follows:

$$P\overline{M} \;=\; P(\mathrm{diag} B_\gamma B_\gamma^t)^{-1} BSB^t (\mathrm{diag} B_\gamma B_\gamma^t)^{-1}. \tag{14}$$

4.3. A new preconditioner. In [33], Klawonn and Widlund studied a FETI method for elliptic problems with heterogeneous coefficients, discretized by conforming finite elements, and designed a new preconditioner for these types of problems. They used this preconditioner to show the connection between FETI methods and Neumann–Neumann methods, in particular the balancing method [39].

In the case of no coefficient jump, as in our Poisson problem, the new preconditioner has the form

$$P\widehat{M} \;=\; P(BB^t)^{-1}BSB^t(BB^t)^{-1}. \tag{15}$$

Klawonn and Widlund established the following upper bound for the condition number of their FETI algorithms, which is valid for all cases, including when the partition contains crosspoints

$$\kappa(P\widehat{M}PF) \;\leq\; C\left(1+\log(H/h)\right)^2.$$

In the same paper, it is proven that the preconditioner $\widehat{M}$ with a minimal number of pointwise continuity conditions at the crosspoints, and therefore of Lagrange multipliers, results in a similar algorithm as the FETI method with redundant Lagrange multipliers of Rixen and Farhat [43, 44]. Since the Lagrange multipliers in the mortar case are not associated with the vertices of the subregions, a FETI algorithm with redundant multipliers cannot be implemented for mortars.

To use the new preconditioner of Klawonn and Widlund for the FETI method with mortars, we must show that the matrix BB^t is nonsingular in the mortar case. The number of columns of B is equal to the number of nodes from W, while the number of rows of B is equal to the number of Lagrange multipliers. Since each Lagrange multiplier is associated with an interior node on a nonmortar side, it results that B has fewer rows than columns. Therefore, if we show that the rank of B is equal to its number of rows, we may conclude that BB^t is nonsingular. We consider the minor of B consisting of the columns corresponding to the interior nodes of the nonmortars. The resulting block-diagonal square matrix diagM_γ is nonsingular, since each block M_γ is a diagonally dominant matrix for the classical mortar elements, and the identity matrix for the new mortar elements.

We conclude this section with comments on the difficulties of extending the convergence analysis of the FETI method from conforming finite elements to mortar elements.

The numerical evidence presented in sections 5.1 and 6.1 strongly suggested that, in the mortar case, the new preconditioner performed as well as it did in the conforming finite element case. Extending the analysis of Klawonn and Widlund to the mortar case would require establishing the bound

$$|B^t(BB^t)^{-1}Bw|_S^2 \;\leq\; C\left(1+\log(H/h)\right)^2|w|_S^2 \quad \forall\, w\in W, \quad Bw\in V. \tag{16}$$

In the conforming finite element case, the matrix BB^t is equal to twice the identity matrix, except for the entries corresponding to crosspoint conditions, where it has a block-diagonal structure. The inverse matrix $(BB^t)^{-1}$ has the same block-diagonal structure, and (16) can be obtained by using Sobolev-type inequalities for finite element functions (also known as cutoff estimates).

In the mortar finite element case, the matrix BB^t is not close to a multiple of the identity and is no longer block diagonal. There are two types of entries outside the diagonal blocks. Some correspond to Lagrange multipliers associated with the first and last interior points of the nonmortars. Others occur because there exist nodal basis functions associated with points on the mortar sides, the support of which intersects more than one nonmortar; see Figure 4 for the sparsity pattern of BB^t.

An important consequence of such structure of BB^t is that the matrix $(BB^t)^{-1}$ is a full matrix in the mortar case. Therefore, cutoff estimates can no longer be used to prove (16). An alternative solution would require new tools in order to reduce the inequality (16) to the two subdomain case. This case would then be solved by deriving some specific stability estimates for the mortar projection.

5. Numerical results for two dimensional problems.

In this section, we present numerical results for the FETI method for a mortar finite element discretization of a two dimensional problem. We have tested each of the three preconditioners of sections 4.1–4.3 on nonconforming discretizations of the computational domain.

Our interests were three fold:

- to compare the convergence performances of the different FETI preconditioners for mortar methods, based on iteration counts and estimates for the condition numbers;
- to apply the FETI algorithms for the new mortar finite elements and compare the iteration counts and the flop counts to those obtained for the classical mortar finite elements;
- to analyze the extra computational effort, due to the complexity of the mortar conditions, required for the implementation of the FETI algorithm with the new preconditioner.

As the model problem in two dimensions, we chose the Poisson equation on the unit square $\Omega = [0,1]^2$ with zero Dirichlet boundary conditions. The right-hand side function f in (3) was selected such that the exact solution of the problem is known.

The computational domain Ω was partitioned into 16, 32, 64, and 128 geometrically nonconforming rectangular subregions, respectively; see Figure 2. On each subregion, we considered Q_1 elements of mesh size h, and, to make the comparisons easier, all the subregions had diameters of the same order, H. For each partition, the number of nodes on each edge, H/h, was taken to be, *on average*, 4, 8, 16, and 32, respectively, for different sets of experiments. Across the partition interface Γ the meshes did not necessarily match. A saddle point formulation of the problem was used, and mortar conditions were enforced across Γ.

We report the iteration counts and the flop counts of the algorithms. We also report condition number estimates for the algorithms, obtained directly from the conjugate gradient iteration. The PCG iteration was stopped when the residual norm had decreased by a factor of 10^{-6}. All the experiments were carried out in MATLAB.

We now present some implementation details. We did not compute the Schur complements explicitly, nor their pseudoinverses, but only the stiffness matrices for each subdomain. To multiply a vector by a Schur complement matrix, we solved, in each subregion, a Poisson problem with Dirichlet boundary conditions. To multiply a vector by $S^\dagger$, we solved a Poisson problem with mixed boundary conditions in each nonfloating subregion and with Neumann boundary conditions in each floating subregion; see, e.g., [17]. We stored only the interior-boundary and boundary-boundary blocks of the local stiffness matrix and the Cholesky factor of the interior-interior block, which is symmetric and positive definite. To have a uniquely solvable problem on the floating subregions, we required that the solution of the local Neumann problem be orthogonal to Ker$S$, i.e., to the constant functions on the subregion. A simple way of enforcing this orthogonality condition was by adding a Lagrange multiplier

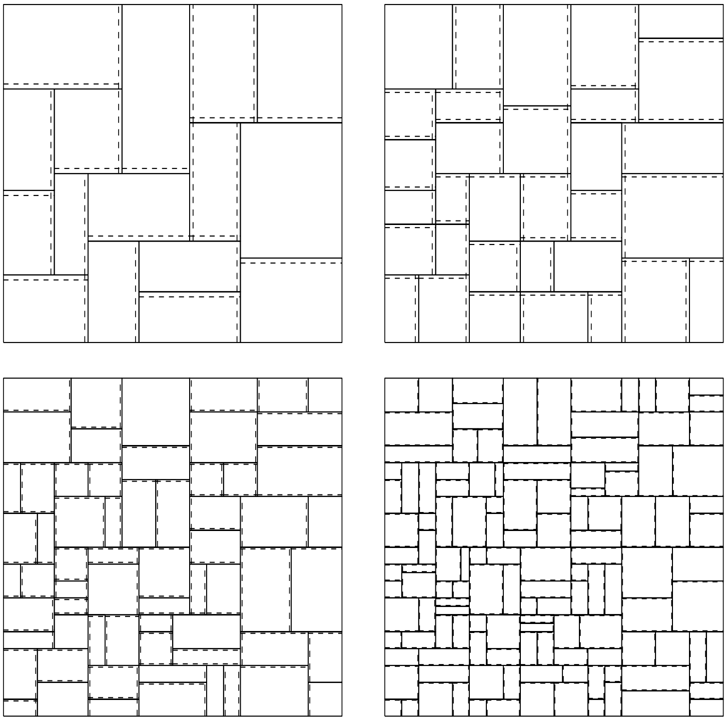

FIG. 2. *Geometrically nonconforming partitions of* Ω. *Upper left:* 16 *subdomains; upper right:* 32 *subdomains; lower left:* 64 *subdomains; lower right:* 128 *subdomains.*

and storing the LU components of the extended stiffness matrix.

5.1. Convergence properties of the FETI algorithms. We now turn to the main part of this section, a discussion of the performance of the FETI algorithms for mortar finite elements with the new preconditioner $\widehat{M}$, (15), the preconditioner $\overline{M}$, (14), and the Dirichlet preconditioner M, (13). In Table 1 we report the iteration count, the condition number approximation, and the flop count for the aforementioned preconditioners.

The FETI algorithm with the Dirichlet preconditioner M required hundreds of iterations to converge, and the computational costs were one to two orders of magnitude bigger than for the other preconditioners. The iteration count grew faster than polylogarithmically as a function of the number of nodes on each subdomain edge, H/h, and appeared to grow linearly with the number of subdomains. The Dirichlet preconditioner is therefore noncompetitive, since many domain decomposition methods have convergence rates independent of the number of subdomains. The condition numbers estimates were on the order of 10^4–10^6, unusually large for these types of algorithms. Moreover, our estimates are likely to be smaller than the actual condition numbers, since there was no convincing convergence pattern for the condition number approximation obtained in the iteration; see section 6.1 and Figure 3 therein for more details. Thus, unlike in the case of FETI algorithms with conforming finite elements, the Dirichlet preconditioner M did not yield a numerically scalable method for mortar finite element methods.

The new preconditioner $\widehat{M}$ scaled similarly to M in the conforming case. When

the number of nodes on each subdomain edge, H/h, was fixed and the number of subdomains, N, was increased, the iteration count showed only a slight growth. When H/h was increased, while the partition was kept unchanged, the increase in the number of iterations was quite satisfactory and very similar to that of the conforming case. The condition number estimates exhibited a similar dependence on the number of subdomains and on the number of nodes on each subdomain edge.

The block-diagonal preconditioner $\overline{M}$ had good convergence properties as well. The iteration counts showed just a small increase when the number of nodes on each subdomain edge was increased, while the partition was kept unchanged. There seemed to be a stronger than desired dependence of the iteration counts on the number of subdomains, which was less than optimal. The condition number estimates followed a similar pattern but were significantly larger than the condition number estimates for the new preconditioner $\widehat{M}$.

Overall, the block-diagonal preconditioner $\overline{M}$ required about twice as many iterations to convergence and twice as much computational effort as $\widehat{M}$; cf. Table 1. Therefore, even though multiplying $\overline{M}$ by a vector required less computational effort than when $\widehat{M}$ was used, the increase in the iteration count resulted in flop counts which were twice as large. This suggests that dropping the nonzero diagonal terms of BB^t relaxed the weak continuity conditions for mortar finite elements more than is optimal.

We conclude that, among the three preconditioners for FETI algorithms for mortar finite element methods analyzed here, the new preconditioner $\widehat{M}$ is the best.

5.2. New mortars vs. classical mortars. Another objective of our study was to compare the performance of the FETI algorithms for new mortar element methods with the performance of the FETI algorithms for classical mortar element methods.

We used the same nonconforming partitions of our computational domain (see Figure 2) and considered new mortar finite elements on the subdomains. As explained in section 2.1, the only difference between the two mortars methods is due to different mortar conditions across the interface Γ. This results in different Lagrange multiplier

matrices B.

We ran the same set of experiments for the new mortars discretization, for preconditioners $\widehat{M}$, $\overline{M}$, and M. The PCG iteration was stopped when the residual norm had decreased by a factor of 10^{-6}. We report the iteration count, the condition number approximation, and the flop counts in Table 2.

Due to the inherent simplification of the Lagrange multiplier matrix B for the new mortar constraints, we expected the results for the new mortar method to be similar but somewhat better than those for the classical mortar method. Indeed, this was confirmed by our numerical results.

The iteration counts for the new preconditioner $\widehat{M}$ were identical to those for $\widehat{M}$ for classical mortars. The condition number estimates and the flop counts were slightly smaller than in the classical mortar case but essentially the same. Therefore, $\widehat{M}$ scaled just as well as in the classical mortar case.

For the new mortar conditions, the matrix BB^t had fewer nonzero entries outside its block-diagonal structure and fewer terms to be dropped in order to obtain diag$B_\gamma B_\gamma^t$. Therefore, the block-diagonal preconditioner $\overline{M}$ was closer to $\widehat{M}$ than in the classical mortar case. This resulted in lower iteration counts and condition numbers for $\overline{M}$ than in the classical mortar case, and, consequently, in lower flop counts.

Once again, the iteration counts increased moderately with H/h and seemed to have a stronger than desired dependence on the number of subdomains. Overall, the block-diagonal preconditioner still performed worse than $\widehat{M}$ for the new mortars with iteration counts one and a half times higher and with significantly bigger condition numbers.

An even greater improvement over the classical mortar case was obtained for the Dirichlet preconditioner M. The number of iterations required for M in the new mortar case was less than half the number of iterations required in the classical mortar case, and a similar improvement can be observed for the flop counts. The condition number estimates were about an order of magnitude less than for the classical mortar case.

Despite these improvements, the FETI algorithm with the Dirichlet preconditioner still required hundreds of iterations to converge and the iteration count appeared to grow linearly with the number of subdomains. The condition number estimates were on the order of 10^3–10^5, much higher than desired. Therefore, as in the classical mortar case, applying the preconditioner M for the FETI method did not result in a scalable algorithm.

Once again, among the three preconditioners for FETI algorithms methods, the new preconditioner $\widehat{M}$ was the best. There was no significant improvement when using the new mortar elements instead of the classical mortar elements for the FETI algorithm with optimal preconditioner $\widehat{M}$.

5.3. Complexity study of the preconditioners. The last topic of this section is an analysis of how expensive it is to apply the preconditioners $\widehat{M}$ and $\overline{M}$, compared to applying the Dirichlet preconditioner M.

In each iteration step, we compute one vector multiplication by the preconditioner, which requires solving two systems with the matrix BB^t, and $\text{diag}B_\gamma B_\gamma^t$, respectively. In section 4.2, we mentioned that $\text{diag}B_\gamma B_\gamma^t$ is obtained from BB^t by eliminating the nonzero entries outside the diagonal blocks. There are two such types of entries; see section 4.3 for more details. While in the three dimensional case the sparsity pattern of BB^t is complex, in the two dimensional case there are relatively few nonzero entries; see Figure 4.

It is easy to see that $\text{diag}B_\gamma B_\gamma^t$ has a bandwidth of order H/h, the number of interior nodes on an arbitrary nonmortar. The matrix BB^t is also banded, but in this case the band depends on the ordering of the nodes on the interface, and it is possible to have bandwidth of order $1/h$. Therefore, multiplying a vector by $(BB^t)^{-1}$ is potentially an expensive operation. To minimize the effect of these vector multiplications, we computed the Cholesky factorizations of BB^t and $\text{diag}B_\gamma B_\gamma^t$ just once and stored the factors. Then, solving systems with BB^t or $\text{diag}\, B_\gamma B_\gamma^t$ amounted only to one back and one forward solve.

Our results showed that the costs of a vector multiplication by $(BB^t)^{-1}$ were between two and ten times larger than those associated with $(\text{diag}B_\gamma B_\gamma^t)^{-1}$. However, due to the sparsity pattern of BB^t, even the costs associated with $(BB^t)^{-1}$ were relatively small compared to those for other operations performed during one iteration, e.g., multipling a vector by the Schur complement or by its pseudoinverse; cf. Table 3. These low relative costs result in very similar flop counts per iteration step for the two preconditioners, almost identical for the case of many nodes per subdomain edge, i.e., $H/h = 16$ and $H/h = 32$.

As expected, the costs associated with $(BB^t)^{-1}$ in each iteration step decreased significantly, from six percent to less than .05 percent, when the partition was fixed and H/h increased, since the costs of multiplying S and $S^\dagger$ by a vector rose much faster than those corresponding to $(BB^t)^{-1}$.

From the flop counts reported in Table 1, it is clear that the improvement of the iteration count easily offsets the small extra costs due to the complexity of $\widehat{M}$ and $\overline{M}$.

6. Numerical results for three dimensional problems. In this section, we report numerical results for the FETI method for mortar finite element discretizations of a three dimensional problem. As before, we compare the performance of different FETI preconditioners and discuss the effects of using the new mortar finite elements instead of the classical ones. We include a study of the costs of applying the new preconditioner for the for classical mortar elements and more details on the convergence rate of the condition number approximation for some of our algorithms.

As the model problem in three dimensions, we chose the Poisson equation on the unit cube $\Omega = [0,1]^3$ with zero Dirichlet boundary conditions. The right-hand side was selected such that the exact solution is known. The computational domain Ω was partitioned into 8, 16, and 32 nonconforming parallelepipeds, respectively. We chose these partitions such that in each case there exist floating subdomains, i.e., interior subdomains.

The subdomains of the partition had diameter of order H, and Q_1 elements of mesh size h were used in each subdomain. The number of nodes on each edge was, *on average*, 4, 8, and 16. Across the partition interface Γ the meshes did not match, and mortar conditions for three dimensional elements were enforced; cf. section 2.2. This results in a Lagrange multipliers matrix B, which, as explained for the two dimensional case, plays a very important role in all FETI algorithms.

We report the iteration counts, the condition number approximations, and the flop counts of the algorithms. The PCG iteration was stopped when the residual norm had decreased by a factor of 10^{-6}. All the experiments were carried out in MATLAB.

6.1. Convergence properties of the FETI algorithms. We did not compute the Schur complements explicitly but only stored those components of the stiffness matrices which were relevant for the multiplication of a vector by the Schur complement matrix and by the pseudoinverse of the Schur complement. We tested the performance of the same preconditioners as in the two dimensional case, i.e., the new preconditioner $\widehat{M}$, cf. (15); the preconditioner $\overline{M}$, cf. (14); and the Dirichlet preconditioner M, cf. (13). We report the iteration count, the condition number estimate, and the flop count of the algorithms in Table 4.

As in the two dimensional case, the FETI algorithm with the Dirichlet preconditioner M did not scale well and required thousands of iterations to converge. Since it soon became clear that M was not an optimal preconditioner, and due to significant computational costs, we performed only tests for every partition of Ω in the case of 4 nodes on each edge, and for the 8 and the 16 subdomains partitions for the case of 8

nodes on each edge of the subdomains.

The iteration count seemed to be a linear function of the number of subdomains, and it grew by an order of magnitude when H/h was doubled while keeping the 8 and the 16 subdomain partitions fixed. The computational costs were also at least two orders of magnitude bigger than those for the other preconditioners and deteriorated as the number of nodes per subdomain edge increased.

The condition number estimates followed a similar dependence pattern on H/h and the number of subdomains. They were on the order of 10^6–10^8, much worse than even in the two dimensional case. In Figure 3, we present the convergence pattern of the condition number estimates for the eight subdomains partition with $H/h = 4$. For M, the PCG iteration was stopped when the residual norm had decreased by a tolerance factor of 10^{-6}, while for $\widehat{M}$ and $\overline{M}$ the tolerance was set at 10^{-10}.

For the Dirichlet preconditioner, there was no clear convergence pattern for the condition number estimates. This suggests that the (extremely large) condition number approximations reported in Table 4 are just lower bounds for the actual condition number. For the other two preconditioners, convergence was achieved early in the iteration count. The estimates reported in Table 4 are within one percent of the condition number corresponding to a tolerance of 10^{-10}.

The new preconditioner $\widehat{M}$ scaled similarly to the two dimensional case and to the Dirichlet preconditioner in the conforming case. The number of iterations grew very slowly when the number of nodes on each subdomain edge (i.e., H/h) was fixed and the number of subdomains was increased. When the partition was kept unchanged and H/h was increased, the iteration count increased slightly, and it seemed to have a polylogarithmic dependence on H/h.

The convergence analysis for the block-diagonal preconditioner $\overline{M}$ is particularly interesting in the three dimensional case; $\overline{M}$ was a possible alternative to $\widehat{M}$ since it required significantly less computational effort per iteration step. However, our results showed a much stronger than desired dependence of the iteration count for $\overline{M}$ on the number of nodes on each subdomain edge. This dependence grew stronger as the number of subdomains in the partition increased. The number of iterations increased with the number of subdomains, another undesirable property. The condition number estimates followed a similar pattern and were significantly larger than those corresponding to $\widehat{M}$. Their relatively large values, on the order of 10^2, and their dependence on the number of subdomains were unsatisfactory.

6.2. New mortars vs. classical mortars. In this section, we compare the performance of the FETI algorithms for new mortar element methods with that of the FETI algorithms for classical mortar element methods.

Using the same nonconforming partitions of Ω as before, we introduced new mortar finite elements on the subdomains and run the same set of experiments as before. We report the results in Table 5.

The iteration counts for the new preconditioner were identical to those for classical mortars. The condition number estimates were slightly smaller than in the classical mortar case but essentially the same. The flop counts were between one percent and five percent smaller than in the classical mortar case. In other words, $\widehat{M}$ scaled as well as in the classical mortar case.

As explained in the two dimensional case, the new mortar conditions resulted in simpler mortar conditions. An important consequence was that the off-diagonal entries of BB^t were fewer and smaller in absolute value than in the classical mortar case. Therefore, the block-diagonal preconditioner $\overline{M}$ was closer to $\widehat{M}$ than in the classical mortar case.

This generated a clear improvement for the iteration count and for the condition number estimate of the block-diagonal preconditioner $\overline{M}$. The number of iterations decreased from the classical mortar case, in particular when the iteration count for $\overline{M}$ was higher than desired, e.g., for the partition of Ω into 32 subdomains. It also resulted in a decrease in the flop counts. However, the iteration count appeared to depend on the number of subdomains when the number of nodes on each edges was fixed. The dependence of the iteration count on H/h seemed to be stronger than polylogarithmic.

The improvement generated by the new mortar method was even more significant for the Dirichlet preconditioner. The iteration count decreased to hundreds of iterations, instead of thousands, as was the case for the classical mortar method. The condition number estimates were lower by two orders of magnitude, in a range of order 10^4–10^5, and the flop counts were one order of magnitude bigger than for the other preconditioners. However, the FETI algorithm with the Dirichlet preconditioner did not scale as a good domain decomposition method.

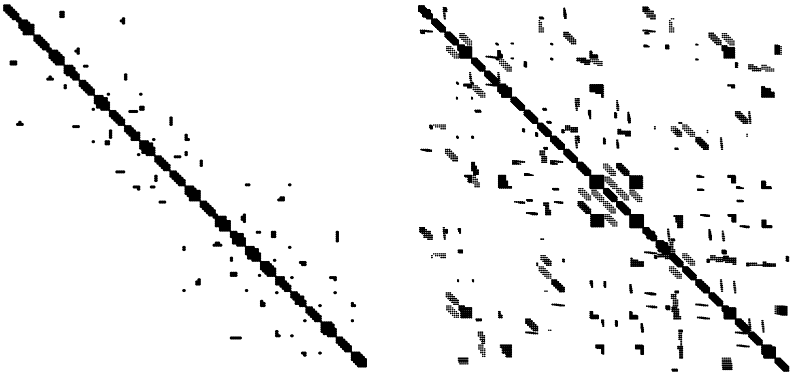

FIG. 4. *Sparsity pattern of BB^t. Left: two dimensional partition, $N = 16$, $H/h = 8$; right: three dimensional partition, $N = 16$, $H/h = 8$.*

6.3. Complexity study of the preconditioners. A comparison between the block-diagonal and the new preconditioner showed that using the preconditioner $\overline{M}$ resulted in a method which converged in about three times as many iterations than when $\widehat{M}$ was used. We recall that, in the two dimensional case, the number of iterations for the method with $\overline{M}$ was only about twice as large as that for $\widehat{M}$. This appears to be due to the fact that, in the three dimensional case, there are many nodes, e.g., the nodes on the wire baskets of the subdomains, which influence several nonmortar conditions. Therefore, the block-diagonal structure of BB^t is no longer as dominant, and many nonzero entries of BB^t need to be dropped; see Figure 4 for the differences in the sparsity pattern of BB^t for the two dimensional and three dimensional cases.

The flop counts for $\overline{M}$ were less than twice as large as those required for the convergence of the new preconditioner, even if the FETI method with $\overline{M}$ required about three times as many iterations as that with $\widehat{M}$. Moreover, for partitions with many subdomains and a small number of nodes on each edge, e.g., for $N = 32$ and $H/h = 4$ or $H/h = 8$, the complexities of the mortar conditions and of the Lagrange multiplier matrix B are higher relative to those of the Schur complement and its pseudoinverse. In these cases, the flop count for the block-diagonal preconditioner was less than that for the new preconditioner, despite the difference in iteration count.

This suggested that the costs of applying $(BB^t)^{-1}$ were significant in the three dimensional case, and this was confirmed by our results. In Table 6, we present the costs of applying $(BB^t)^{-1}$ and $\mathrm{diag}B_\gamma B_\gamma^t$ twice during an iteration step, relative to the total flop count for one iteration step.

Table 6

Complexity study of one iteration step for the new preconditioner and the block-diagonal preconditioner; three dimensional geometrically nonconforming partition.

		New preconditioner			Block-diagonal preconditioner		
N	H/h	Mflops for $(BB^t)^{-1}$	Mflops per iteration	Ratio	Mflops for $(diagB_\gamma B_\gamma^t)^{-1}$	Mflops per iteration	Ratio
8	4	3.2e–2	1.5e–1	.22	4.8e–3	1.2e–1	.04
8	8	5.8e–1	2.7e+0	.21	9.2e–2	2.2e+0	.04
8	16	6.8e+0	6.9e+1	.10	1.2e+0	6.4e+1	.02
16	4	1.3e–1	3.9e–1	.34	1.1e–2	2.7e–1	.04
16	8	2.1e+0	6.6e+0	.32	1.8e–1	4.6e+0	.04
16	16	2.2e+1	1.5e+2	.15	1.9e+0	1.3e+2	.02
32	4	6.9e–1	1.3e+0	.55	3.0e–2	6.0e–1	.05
32	8	1.1e+1	2.1e+1	.54	5.0e–1	9.9e+0	.05
32	16	1.2e+2	3.8e+2	.32	5.4e+0	2.7e+2	.02

The costs associated with $(BB^t)^{-1}$ were between 10 and 55 percent of those for one iteration step. This was much higher than for the two dimensional case, when the relative costs were at most 13 percent, and as low as .02 percent; cf. Table 3. The costs associated with $(\mathrm{diagB}_\gamma B_\gamma^t)^{-1}$ were much smaller, at most 5 percent of those for one iteration step. This was the reason why the flop counts per iteration were significantly lower for the block-diagonal preconditioner than for the new preconditioner.

The dependence of the relative cost of applying $(BB^t)^{-1}$ on the number of subdomains N and the number of nodes on each edge H/h was similar to that for the two dimensional case. It increased when H/h was kept fixed while the partition became more complex, and decreased when the partition was kept unchanged and H/h was increased. These results are consistent with the increased costs of multiplying a vector by the Schur complement and the pseudoinverse of the Schur complement when H/h increases, and the increased complexity of the Lagrange multiplier matrix B when the partition had more subdomains.

7. Continuity and mortar conditions for matching meshes. In the classical FETI algorithm, the underlying partition of Ω is geometrically conforming, the meshes across the interface match, and continuity conditions are enforced across the interface; cf. section 3. However, it is also possible to require mortar matching across the interface. It is important to note that using either mortar elements or conforming finite elements results in approximation errors of the exact solution that are of the

same order. In particular, for our example, the difference in the discretization errors corresponding to the two types of elements is negligible.

In this section, we compare the performance of the resulting FETI algorithms for the two different types of matchings. We considered both two and three dimensional problems. For mortar finite elements, we tested FETI algorithms with all three preconditioners, while for conforming finite elements we used only the new preconditioner and the Dirichlet preconditioner. The block-diagonal preconditioner is identical to the new preconditioner for continuity matchings, since BB^t is a block-diagonal matrix.

The convergence results for the classical mortar methods and the new mortar methods were once again very similar, except for the case of the Dirichlet preconditioner, where the new mortars provided a significant improvement. However, our main goal was to compare the performance of continuity matchings versus mortar matchings. Therefore, we present only here the results for the new mortar methods, which always resulted in better algorithms than the classical mortar methods.

7.1. The two dimensional case. For the two dimensional experiments, the computational domain Ω, the unit square, was partitioned into 4×4, 6×6, 8×8, and 11×11 congruent squares, and Q_1 elements were used in each square. The meshes match across Γ, and nonredundant pointwise continuity conditions, or mortar conditions, were used across Γ for comparison purposes. Except for the different partitions, the experiments have the same parameters as in section 5. We report the iteration count, the condition number estimate, and the flop count for the FETI algorithms with new mortar finite elements in Table 7.

When new mortar conditions were used across the interface, computing the Lagrange multiplier matrix B was very simple for matching nodes. In particular, no computations of integrals resulting from the mortar conditions (1) were necessary. The new mortar conditions are equivalent to continuity conditions for all matchings except for those corresponding to the first and last interior nodes on the nonmortar sides, where the end point nodes are involved as well. Therefore, B was very similar for the two types of matchings, and BB^t was very close to twice the identity matrix.

Almost no extra work was required when a system with the matrix BB^t had to be solved.

Another consequence of matching meshes was that BB^t had very few nodes outside its block-diagonal structure diag$B_\gamma B_\gamma^t$. Therefore, we expected the convergence results for the new preconditioner and for the block-diagonal preconditioner to be similar. Indeed, the results from Table 7 show that $\widehat{M}$ and $\overline{M}$ behaved similarly in terms of iteration counts and condition number estimates, which were just slightly higher for the block-diagonal preconditioner $\overline{M}$. Both preconditioners scaled very well with the number of subdomains and the number of nodes on each edge. The computational costs for one iteration step were almost identical, which resulted in better flop counts for $\widehat{M}$, even when the iteration counts differed by only one iteration.

In contrast with the other algorithms, the Dirichlet preconditioner M performed very well for two dimensional problems with matching nodes. The iteration counts were very small, comparable to those corresponding to $\widehat{M}$ and $\overline{M}$. However, since BB^t is close to twice the identity matrix, the computational costs per iteration do not show a relevant improvement for M. The Dirichlet preconditioner yielded higher flop counts than the other two preconditioners.

We now turn our attention to the case when pointwise continuity was enforced across the interface; cf. Table 8. As expected, both the Dirichlet preconditioner and the new preconditioner had very good scaling properties. In particular, the condition number estimates were almost constant when H/h was kept fixed and the number of subdomains was changed. However, $\widehat{M}$ converged in less than half the number of iterations necessary for M, and the same was true for the computational costs.

For continuity matchings, the vector matrix multiplication by $B^t(BB^t)^{-1}B$ is very easy to compute, since it is close to an operator from the balancing algorithm; see [33]. It is possible to write the PCG algorithm with the new preconditioner such that only the product of a vector by $B^t(BB^t)^{-1}B$, and not by $(BB^t)^{-1}$, needs to be computed.

Using the data from Table 7 and Table 8, we can address the main topic of this section, finding the best FETI algorithm for conforming partitions of Ω. We compared

Table 9

Convergence results; three dimensional geometrically conforming partition; matching grids; and new mortar constraints.

32	16	12	10.31	2.2e+3	15	18.62	2.8e+3	–	–	–

the new preconditioner for new mortar matchings and for continuity conditions. The iteration counts and the condition number estimates were slightly lower for the new mortar case. The flop counts were also better for mortar matchings, since the Lagrange multiplier matrices had similar structure for the two types of matchings and the costs per iteration step were almost identical.

We conclude that the new mortar matchings represent an improvement over the continuity matchings. This might be due in part to the fact that the mortar matching conditions corresponding to the first and last interior points on the nonmortars replace the continuity constraints at the crosspoints and their neighboring nodes.

7.2. The three dimensional case. For the three dimensional experiments, the unit cube was partitioned into $2 \times 2 \times 2$, $2 \times 2 \times 4$, and $2 \times 4 \times 4$ geometrically conforming, noncongruent parallelepipeds; Q_1 meshes were considered in each subdomain such that the meshes across the interface matched. Across Γ, nonredundant pointwise continuity conditions, or biorthogonal mortar conditions, were enforced by using Lagrange multipliers.

For the mortar matchings, we present convergence results only for the new mortar method. We run the same set of experiments as in section 6 for all three preconditioners and for 4, 8, and 16 nodes on each subdomain edge. We report the results in Table 9.

For the three dimensional case, the Lagrange multiplier matrix B was no longer very close to a multiple of the identity. The mortar matching conditions were different than the continuity matchings for all the interior nodes on the nonmortar faces with neighbors on the boundary of the face.

Once again, the new preconditioner $\widehat{M}$ scaled well. The iteration count and the condition number estimate depended only weakly on H/h and on N, the number of subdomains in the partition of Ω. A similar behavior was observed for the block-diagonal preconditioner, at somewhat higher iteration counts. However, due to the relative complexity of BB^t, which was no longer very close to its block-diagonal structure $\text{diag}B_\gamma B_\gamma^t$, the preconditioner $\overline{M}$ required less computational effort per iteration than $\widehat{M}$. The difference in the iteration counts has thus been compensated, the two preconditioners resulting in algorithms with very close flop counts.

Unlike in the two dimensional case with matching nodes, the Dirichlet preconditioner M required hundreds of iterations to converge and did not have good scalability properties. The condition number estimates were on the order of 10^4–10^5, and the flop counts were at least one order of magnitude greater than for the other preconditioners.

Table 10

Convergence results; three dimensional geometrically conforming partition; matching grids; and continuity constraints.

		New precond.			Dirichlet precond.		
N	H/h	Iter	Cond	Mflops	Iter	Cond	Mflops
8	4	6	1.77	4.6e–1	21	75.54	1.5e+0
8	8	8	2.50	1.4e+1	25	80.30	4.4e+1
8	16	9	3.17	5.3e+2	27	84.25	1.6e+3
16	4	8	3.34	1.4e+0	31	84.12	5.4e+0
16	8	9	4.91	3.4e+1	35	90.73	1.3e+2
16	16	11	6.30	1.3e+3	36	94.35	4.3e+3
32	4	8	4.13	2.6e+0	38	95.51	1.2e+1
32	8	10	6.76	6.0e+1	41	98.12	2.4e+2
32	16	12	8.73	2.2e+3	43	99.82	7.9e+3

The convergence results for pointwise continuity matchings across the interface are reported in Table 10. The new preconditioner yielded a scalable algorithm with very low iteration counts and condition numbers. The Dirichlet preconditioner also resulted in a scalable algorithm but required at least three times as many iterations as $\widehat{M}$ for convergence. The condition number estimates were much larger as well but depended weakly on changes of parameters H/h and N. The complexity of the matrix B was compensated by the improvement in the iteration counts. The flop counts for $\widehat{M}$ were at least half of those for M.

We conclude this section by discussing the differences between the two types of matchings for three dimensional problems. The new preconditioner resulted in the best algorithms for both new mortar and continuity matchings. The iteration counts and the condition number estimates were slightly lower for the continuity case. The computational effort per iteration required in the mortar case is greater than in the continuity case, since BB^t is no longer very close to a multiple of the identity. Coupled with lower iteration counts, this results in better flop counts for the continuity matching algorithms.

NEAR-OPTIMAL PARAMETERS FOR TIKHONOV AND OTHER REGULARIZATION METHODS*

DIANNE P. O'LEARY†

Abstract. Choosing the regularization parameter for an ill-posed problem is an art based on good heuristics and prior knowledge of the noise in the observations. In this work, we propose choosing the parameter, without a priori information, by approximately minimizing the distance between the true solution to the discrete problem and the family of regularized solutions. We demonstrate the usefulness of this approach for Tikhonov regularization and for an alternate family of solutions. Further, we prove convergence of the regularization parameter to zero as the standard deviation of the noise goes to zero.

Key words. ill-posed problems, regularization, Tikhonov

1. Introduction.

Linear, discrete ill-posed problems of the form

$$\min_x \|Ax-b\|_2, \quad \text{or, equivalently,} \quad A^*Ax = A^*b \tag{1.1}$$

arise, for example, from the discretization of first-kind Fredholm integral equations and occur in a variety of applications. We shall assume the following:

1. The full-rank matrix A is $m \times n$ with $m \geq n$.
2. A is ill-conditioned with no significant gap in the singular value spectrum. (A gap would make the problem somewhat easier.) The problem is normalized so that the largest singular value is 1.
3. The right-hand side b consists of true data plus random noise: $b = b_t + e$, where the components of e are an independent sample from a probability distribution with mean 0 and standard deviation s.
4. The discretization error caused by making a finite dimensional approximation to the continuous operator is much smaller than the noise.
5. The system satisfies the *discrete Picard condition*, which we will define in section 2 after introducing some notation.

The noise in the measurements, in combination with the ill conditioning of A, means that the exact solution of (1.1) has little relationship to the noise-free solution and is worthless. Instead, we use a *regularization* method to determine a solution that approximates the noise-free solution. Regularization methods replace the original operator by a better-conditioned, but related, one in order to diminish the effects of noise in the data and produce a *regularized solution* to the original problem. In this work, we first consider Tikhonov regularization, in which the problem (1.1) is replaced by

$$\min_x \left(\|Ax-b\|_2^2 + \lambda\|Lx\|_2^2\right), \quad \text{or, equivalently,} \quad (A^*A + \lambda L^*L)x = A^*b, \tag{1.2}$$

where L is a regularization operator chosen to obtain a solution with desirable properties, such as a small norm ($L = I$) or good smoothness (L a discrete approximation to a derivative operator), and $\lambda > 0$ is a scalar parameter. Throughout this paper we will use the 2-norm and denote it by $\| * \|$.

The central question in Tikhonov regularization is how to choose the parameter λ in order to produce a solution x close to the true noise-free solution x_{true}. Hoerl and Kennard [11] showed that on average a smaller error is produced using a nonzero λ, and numerous heuristics have been proposed for the choice of this parameter. Some of these (e.g., the discrepancy principle [14]) assume that the standard deviation of the noise is known. Others (e.g., generalized cross-validation [6] and the L-curve [8]) work with less knowledge of the noise properties. An interesting recent approach of Rust [17] uses visualization of residual and singular component plots to choose reasonable parameters. Pierce and Rust [15] minimize the lengths of confidence intervals using appropriate parameter choices, and Kilmer and O'Leary [13] discuss the choice of parameters when iterative solution methods are used.

In this work, we propose another rule for parameter choice. We go back to first principles: among all solutions in a given family such as Tikhonov, we want the solution that is a minimal distance from the true solution. Kay [12] has developed asymptotic expressions for this distance as the size of the problem grows large. Others have determined a Tikhonov parameter by minimizing a bound on this distance; Raus [16], Gfrerer [5], and Engl and Gfrerer [3] propose minimizing one such bound, while Hanke and Raus [7] propose an alternative. Rather than using asymptotic results or minimizing a bound, we compute in section 2 a parameter that approximately minimizes the distance to the true solution to the discretized problem and accomplishes this goal without a priori knowledge of the standard deviation or distribution of the noise in the observations. We discuss convergence of this choice in section 3. Section 4 contains a similar development for an alternative to Tikhonov regularization. Section 5 discusses some algorithmic issues, and in section 6 we show the effectiveness of these methods on numerical examples.

2. Choosing the Tikhonov regularization parameter. In order to analyze the problem, we convert to the coordinate system of the singular value decomposition (SVD) of A. For simplicity of exposition, we assume that the regularization operator L is the identity matrix. A similar development, using the generalized SVD, could be done for general L (see, for example, [10, sect. 2.1.2]), but the resulting function is considerably more complicated to compute and minimize.

Suppose $A = U\Sigma V^*$, where U and V have orthonormal columns and Σ is a matrix of zeros except for diagonal entries $\sigma_1 \geq \cdots \geq \sigma_n > 0$. Exploiting the property that $\|Uz\| = \|z\|$ and $\|V^* z\| = \|z\|$, the problem (1.2) takes the form

$$\min_z \|\Sigma z - \beta\|^2 + \lambda \|z\|^2 ,$$

where $\beta_i \equiv u_i^* b$ and $z = V^* x$. Setting the derivative equal to zero, we find that for a fixed value of λ, we need to solve the equation

$$(\Sigma^T \Sigma + \lambda I) z = \Sigma^T \beta.$$

Thus, the Tikhonov solution is

$$x_{tik} = \sum_{i=1}^{n} \frac{\beta_i \sigma_i}{\sigma_i^2 + \lambda} v_i, \tag{2.1}$$

where v_i is the ith column of V.

The true solution to the discrete (noise-free) problem is

$$x_{true} = \sum_{i=1}^{n} \frac{\beta_i - \epsilon_i}{\sigma_i} v_i ,$$

where $\epsilon_i \equiv u_i^* e$ represents the unknown noise component.

The goal in regularization is to produce a solution as close as possible to the true solution, so let us (rather naively) try to minimize this distance:

$$\min_{\lambda} \|x_{tik} - x_{true}\|^2 \equiv \min_{\lambda} f(\lambda) \, .$$

Using the singular value representation, we see that

$$f(\lambda) = \sum_{i=1}^{n} \left[\frac{\beta_i \sigma_i}{\sigma_i^2 + \lambda} - \frac{\beta_i - \epsilon_i}{\sigma_i} \right]^2 \, .$$

Setting the derivative equal to zero yields

$$\begin{aligned} 0 = g(\lambda) \equiv \frac{1}{2} f'(\lambda) &= - \sum_{i=1}^{n} \left[\frac{\beta_i \sigma_i}{\sigma_i^2 + \lambda} - \frac{\beta_i - \epsilon_i}{\sigma_i} \right] \left[\frac{\beta_i \sigma_i}{(\sigma_i^2 + \lambda)^2} \right] \\ &= \sum_{i=1}^{n} \frac{\beta_i^2 \lambda}{(\sigma_i^2 + \lambda)^3} - \sum_{i=1}^{n} \frac{\beta_i \epsilon_i}{(\sigma_i^2 + \lambda)^2} \, . \end{aligned}$$

Now the first summation in this last expression is computable, but the second is not because the noise values ϵ_i are unknown. However, there are two interesting properties of the second summation.

- First, the terms for $i \approx n$ tend to be the largest because the denominators are the smallest.
- Second, the system satisfies the discrete Picard condition, meaning that for large enough values of the discretization parameter n, the sequence of true data values $\{\beta_i - \epsilon_i\}$ goes to zero faster than the sequence of singular values $\{\sigma_i\}$. Thus, for terms with i greater than or equal to some parameter k, $\epsilon_i \approx \beta_i$.

Therefore, although we cannot compute the function $g(\lambda)$, we can compute the following approximation to it:

$$\hat{g}(\lambda) \equiv \sum_{i=1}^{n} \frac{\beta_i^2 \lambda}{(\sigma_i^2 + \lambda)^3} - \sum_{i=k}^{n} \frac{\beta_i^2}{(\sigma_i^2 + \lambda)^2} - \mathcal{E} \left(\sum_{i=1}^{k-1} \frac{\beta_i \epsilon_i}{(\sigma_i^2 + \lambda)^2} \right)$$

for a suitable index k, depending on the standard deviation s. Finding the zero of this function yields an approximation to the optimal value of λ. The last term denotes the expected value of the quantity. Under assumption 3 of section 1, β_i is some true value plus noise ϵ_i, so $\mathcal{E}(\beta_i \epsilon_i) = \mathcal{E}(\epsilon_i^2) = s^2$, and

$$\hat{g}(\lambda) = \sum_{i=1}^{n} \frac{\beta_i^2 \lambda}{(\sigma_i^2 + \lambda)^3} - \sum_{i=k}^{n} \frac{\beta_i^2}{(\sigma_i^2 + \lambda)^2} - s^2 \sum_{i=1}^{k-1} \frac{1}{(\sigma_i^2 + \lambda)^2} \, . \tag{2.2}$$

As λ increases from zero, this function is monotonically increasing, and we denote the first zero by λ_{hat} and the corresponding solution vector x_{hat}.

3. Convergence for the Tikhonov parameter choice. We know that we cannot, in general, compute the optimal Tikhonov parameter. How far do we stray from the optimal vector when we use a nonoptimal parameter? The following theorem bounds the relative distance between the optimal solution and the computed one.

THEOREM 3.1. *Let λ_{opt} be the optimal parameter for the Tikhonov family (i.e., the (generally uncomputable) one that produces the solution closest to x_{true}). Then for any value of λ,*

$$\frac{\|x_{tik}(\lambda_{opt}) - x_{tik}(\lambda)\|}{\|x_{tik}(\lambda_{opt})\|} \le \frac{|\lambda_{opt} - \lambda|}{\sigma_n^2 + \lambda}\,.$$

Proof. The result follows from the computation

$$\begin{aligned}\|x_{tik}(\lambda_{opt}) - x_{tik}(\lambda)\|^2 &= \sum_{i=1}^{n} \left(\frac{\beta_i \sigma_i}{\sigma_i^2 + \lambda_{opt}} - \frac{\beta_i \sigma_i}{\sigma_i^2 + \lambda} \right)^2 \\ &= \sum_{i=1}^{n} \beta_i^2 \sigma_i^2 \left(\frac{\lambda - \lambda_{opt}}{(\sigma_i^2 + \lambda_{opt})(\sigma_i^2 + \lambda)} \right)^2 \\ &\le \frac{(\lambda - \lambda_{opt})^2}{(\sigma_n^2 + \lambda)^2} \sum_{i=1}^{n} \left(\frac{\beta_i \sigma_i}{\sigma_i^2 + \lambda_{opt}} \right)^2 \\ &= \frac{(\lambda - \lambda_{opt})^2}{(\sigma_n^2 + \lambda)^2} \|x_{tik}(\lambda_{opt})\|^2\,. \qquad \square\end{aligned}$$

Our algorithm for choosing the regularization parameter also behaves well as the size of the observation noise is decreased.

THEOREM 3.2. *If we choose the parameter k so that $\epsilon_i \approx \beta_i$ for $i \ge k$, then in the limit as the standard deviation s of the noise converges to zero, the solution x_{hat} produced by our algorithm converges to the correct discrete solution x_{true}.*

Proof. As the standard deviation of the noise goes to zero, the value k increases to $n+1$, and the solution to $\hat{g}(\lambda) = 0$ becomes $\lambda = 0$, as desired. Thus, as the noise goes to zero, our solution converges to the noise-free solution. □

4. An alternate family of solutions. We have studied how the regularization parameter might be chosen for one family of solutions, the Tikhonov solutions, which take the form

$$x_{tik} = \sum_{i=1}^{n} \frac{\beta_i \sigma_i}{\sigma_i^2 + \lambda} v_i\,.$$

A similar algorithm can be found for other solution families, and in this section we consider the family

$$x_{alt} = \sum_{i=1}^{n} \frac{\beta_i}{\sigma_i + \lambda} v_i\,.$$

This family was proposed by Franklin [4] for Hermitian positive definite A and is also associated with Lavrentiev [10, p.107]. Ekstrom and Rhoads [2] discussed the use of the algorithm for convolution problems symmetrized by reordering, and this method was also considered by Cullum [1].

In his Regularization Tool Package for Matlab [9], Hansen includes a function `dsvd` that can be used to apply the method to general problems. In this more general context, there is more than one interpretation. The solution x_{alt} satisfies the regularized equation

$$(A + \lambda U V^*)x = b\,.$$

However, it may be more intuitive to interpret the family as a set of filter factors [10, sect. 4.2]

$$\frac{\sigma_i}{\sigma_i + \lambda},$$

multiplying the corresponding terms in the least squares solution

$$\sum_{i=1}^{n} \frac{\beta_i}{\sigma_i} v_i\,.$$

To choose the parameter λ, we mimic the procedure in section 2: we naively try to minimize the distance between our solution and the true one:

$$\min_{\lambda} \|x_{alt} - x_{true}\|^2 \equiv \min_{\lambda} f(\lambda)\,.$$

Using the singular value representation, we see that

$$f(\lambda) = \sum_{i=1}^{n} \left[\frac{\beta_i}{\sigma_i + \lambda} - \frac{\beta_i - \epsilon_i}{\sigma_i} \right]^2 .$$

Setting the derivative equal to zero yields

$$\begin{aligned} 0 = g(\lambda) \equiv \frac{1}{2} f'(\lambda) &= -\sum_{i=1}^{n} \left[\frac{\beta_i}{\sigma_i + \lambda} - \frac{\beta_i - \epsilon_i}{\sigma_i} \right] \left[\frac{\beta_i}{(\sigma_i + \lambda)^2} \right] \\ &= \sum_{i=1}^{n} \frac{\beta_i^2 \lambda}{\sigma_i(\sigma_i + \lambda)^3} - \sum_{i=1}^{n} \frac{\beta_i \epsilon_i}{\sigma_i(\sigma_i + \lambda)^2}\,. \end{aligned}$$

Again, the first summation in this last expression is computable. The second is not, because the observation noise values ϵ_i are unknown, but the terms for $i \approx n$ dominate, and for these $\epsilon_i \approx \beta_i$, so our approximate function becomes

$$\hat{g}(\lambda) \equiv \sum_{i=1}^{n} \frac{\beta_i^2 \lambda}{\sigma_i(\sigma_i + \lambda)^3} - \sum_{i=k}^{n} \frac{\beta_i^2}{\sigma_i(\sigma_i + \lambda)^2} - \mathcal{E} \left(\sum_{i=1}^{k-1} \frac{\beta_i \epsilon_i}{\sigma_i(\sigma_i + \lambda)^2} \right)$$

for a suitable index k that depends on the standard deviation of the noise. Finding the zero of the function

$$\hat{g}(\lambda) \equiv \sum_{i=1}^{n} \frac{\beta_i^2 \lambda}{\sigma_i(\sigma_i + \lambda)^3} - \sum_{i=k}^{n} \frac{\beta_i^2}{\sigma_i(\sigma_i + \lambda)^2} - s^2 \sum_{i=1}^{k-1} \frac{1}{\sigma_i(\sigma_i + \lambda)^2} \tag{4.1}$$

yields an approximation to the optimal value of λ.

We have a bound for the relative distance between the optimal solution and the computed one similar to the Tikhonov case.

THEOREM 4.1. *Let λ_{alt} be the optimal parameter for the alternate family (i.e., the one that produces the solution closest to x_{true}). Then for any value of λ,*

$$\frac{\|x_{alt}(\lambda_{alt}) - x_{alt}(\lambda)\|}{\|x_{alt}(\lambda_{alt})\|} \leq \frac{|\lambda_{alt} - \lambda|}{\sigma_n^2 + \lambda}.$$

Proof. The result follows from a computation similar to that in the proof of Theorem 3.1. □

Again, we can show that the solution converges to the true solution as the observation noise goes to zero.

THEOREM 4.2. *If we choose the parameter k so that $\epsilon_i \approx \beta_i$ for $i \geq k$, then in the limit as the standard deviation s of the noise converges to zero, the solution x_{hat} produced by our algorithm converges to x_{true}.*

Proof. The proof is the same as above. □

5. Algorithmic notes. The standard deviation s of the noise is not assumed to be known, so we estimate it using the last $\max(m-n, 10)$ components of the right-hand side. If $|b_n| > 3.5s$, then we choose $k = n$. Otherwise we use a T-test to determine the index k. We choose k as the smallest index, among the values $n-9, n-14, \ldots$, for which a T-test with 0.05 significance level indicates that the sequence $\beta_k, \ldots, \beta_n$ has zero mean. If the mean of the noise-free sequence is likely to be near zero, then this test would not be appropriate, but many alternatives are available. One would be to use the Mann–Whitney Test, a nonparametric test to determine whether two independent groups of sampled data are taken from the same underlying distribution without making assumptions on the distribution.

A root of either function (2.2) or (4.1) can be found using standard algorithms (e.g., `fzero` in Matlab). Since $\hat{g}(0) < 0$ for both functions, we can find a lower bound on the root by searching $s, s/10, s/100, \ldots$ for a negative function value. The simple strategy of searching $100s, 1000s, \ldots$ has proved effective in finding a value for which $\hat{g}$ is positive, thus providing the root finder with an initial interval containing the root.

6. Performance of the algorithms. The ideas of the previous sections were tested using two sets of test problems. In the first, the 200×200 matrix was diagonal, with entries ranging between 1 and 10^{-5}, evenly spaced on a log scale. The true solution was assumed to be the vector with elements evenly spaced between 1.0 and 0.9, and 100 sets of random noise were generated for the right-hand side. The value of the standard deviation of the noise was not made available to the algorithms; instead, we estimated it as in section 5. We generated solutions using the Tikhonov and the alternate method and calculated the distance between these computed solutions and the exact noise-free solution, tabulating the relative x-error $\|x - x_{true}\|/\|x_{true}\|$. Then we calculated the *optimal* Tikhonov and alternate solutions, the ones corresponding to the parameter values that minimize the distance to the noise-free solution. These optimal solutions, of course, cannot be computed in practical situations since the noise-free solution is unknown, but the results tell us how far we are from optimal. We also compared our results with three other methods:

1. We computed the the Tikhonov parameter by minimizing the generalized cross-validation (GCV) function using Matlab's `fmin` with tolerance 1.0e-07. In some sense this is an unfair comparison, since GCV aims to minimize the residual norm, not the x-error.

2. We also compared our results with those of the Tikhonov algorithm of Hanke and Raus [7], which chooses the parameter by minimizing

$$f(\lambda) = \sqrt{1 + 1/\lambda}\sqrt{r_1^T(\lambda) r_0(\lambda)}\,,$$

where

$$\begin{aligned} x_0 &= (A^*A + \lambda I)^{-1} A^* b\,, \\ r_0(\lambda) &= b - A x_0\,, \\ x_1 &= (A^*A + \lambda I)^{-1} A^* r_0 + x_0\,, \\ r_1(\lambda) &= b - A x_1\,. \end{aligned}$$

3. We used our estimate of the standard deviation of the noise to apply the discrepancy principle [14].

The results are summarized in Table 6.1. Several trends are apparent. First, the average relative x-errors in the solutions computed by our algorithm are within a factor of 2 of the average relative x-errors for the optimal parameter values. Second, for large noise in the observations, the Tikhonov solution is on average closer to the true solution, but for small noise the alternate algorithm does somewhat better than Tikhonov. Third, the Tikhonov solutions computed by our algorithm are on average better than the GCV Tikhonov solutions and the Hanke–Raus solutions over the full range of noise values, and for small noise, the alternate solutions are better too. Our Tikhonov solutions are better than the discrepancy principle solutions except for a noise level of 10^{-3}.

The trends in the medians are similar to those of the averages, except that our values are always better than the discrepancy principle. The maximum relative errors show that only in the small number of cases in which the standard deviation of the error fails to be computed accurately are the GCV and Hanke–Raus solutions much better than our solutions.

Our algorithm for choosing the parameter k tested values in increments of 5. (See section 5.) Results are relatively insensitive to this increment: for experiments with noise level 1.0e-03 and increments of 1, 5, or 10, for example, the mean for

the computed Tikhonov values was between 7.01e-01 and 7.56e-01, while the median changed by at most 3 in the third significant digit. Similarly, the mean for the computed alternate values was between 1.06 and 1.34, while the median changed by at most 1 in the third significant digit.

Histograms of the relative errors are presented in Figures 6.1 and 6.2.

The second experiment used the inverse helioseismatic data of Hansen (`helio.mat`, taken from the Regularization Tool Package homepage [9]). The problem is an integral equation of the first kind modeling internal rotation of the sun as a function of radius. The matrix A of size 212×100 and the true solution x were obtained from there, and random observation noise was added as before. The right-hand side values had a mean close to zero, so a rather primitive scheme was used to determine k; it was determined so that the values b_j for $j > k$ were not larger than 3.5 times the estimated standard deviation. The results (Table 6.2) show that the median relative x-errors

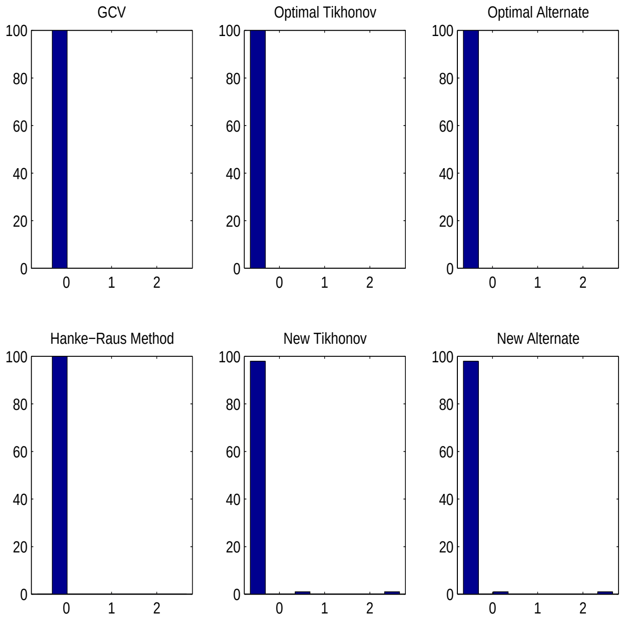

Fig. 6.4. *Histograms of the relative errors in the solutions computed for the helioseismatic matrix problem with standard deviation of the observation noise equal to* 1.0e-06*. The horizontal axis indicates the log of the relative error. The bars have height equal to the number of test problems yielding errors in that range.*

are at most 1.1 times as large as the optimal and at most 0.8 times the GCV values or the Hanke–Raus values. The trends are similar to the diagonal matrix problem: when the value of k is estimated well, the new algorithms perform much better than GCV and Hanke–Raus. However, since the k estimation problem is more difficult with this right-hand side, the mean and maximum values of the relative errors are not well behaved.

Still, the histograms of the relative errors presented in Figures 6.3 and 6.4 show that the new algorithms can be expected to produce much better results than GCV or Hanke–Raus when the errors are small enough that k is easily estimated.

7. Conclusions.

We have proposed a method for choosing a regularization parameter that approximately minimizes the Euclidean distance between the computed solution and the noise-free solution, and we have demonstrated by numerical experiments that it produces solutions quite close to optimal.

We have demonstrated the use of these methods of parameter choice when the SVD of the matrix A can be explicitly computed. If the problem is too large for this to be practical, the ideas could be used in conjunction with iterative methods by applying them in the subspace generated by the iteration. For example, the SVD of the reduced matrix produced by a GMRES iteration could be substituted for the SVD of the full matrix. The effectiveness of this general methodology is discussed in [13].

Acknowledgments. I am grateful for the hospitality provided by Professor Walter Gander and the Departement Informatik, ETH Zürich, Switzerland, which enabled this work to be completed. The manuscript benefited greatly from helpful comments by Misha E. Kilmer, Per Christian Hansen, Bert W. Rust, and the referees.

PRACTICAL CONSTRUCTION OF MODIFIED HAMILTONIANS*

ROBERT D. SKEEL† AND DAVID J. HARDY†

Abstract. One of the most fruitful ways to analyze the effects of discretization error in the numerical solution of a system of differential equations is to examine the "modified equations," which are equations that are exactly satisfied by the (approximate) discrete solution. These do not actually exist in general but rather are defined by an asymptotic expansion in powers of the discretization parameter. Nonetheless, if the expansion is suitably truncated, the resulting modified equations have a solution which is remarkably close to the discrete solution. In the case of a Hamiltonian system of ordinary differential equations, the modified equations are also Hamiltonian if and only if the integrator is symplectic. Evidence for the existence of a Hamiltonian for a particular calculation is obtained by calculating modified Hamiltonians and monitoring how well they are conserved. Also, energy drifts caused by numerical instability are better revealed by evaluating modified Hamiltonians. Doing this calculation would normally be complicated and highly dependent on the details of the method, even if differences are used to approximate derivatives. A relatively simple procedure is presented here, nearly independent of the internal structure of the integrator, for obtaining highly accurate estimates for modified Hamiltonians. As a bonus of the method of construction, the modified Hamiltonians are exactly conserved by a numerical solution in the case of a quadratic Hamiltonian.

Key words. symplectic, Hamiltonian, modified equation, integrator, backward error, numerical

1. Introduction.

One of the most fruitful ways to analyze the effects of discretization error in the numerical solution of differential equations is to examine the "modified equations," which are equations that are exactly satisfied by the (approximate) discrete solution. These do not actually exist (in general) but rather are defined by an asymptotic expansion in powers of the discretization parameter. Nonetheless, if the expansion is suitably truncated, the resulting modified equations have a solution which is remarkably close to the discrete solution [9] (over relatively short time intervals). In the case of a Hamiltonian system of ordinary differential equations, the modified equations are also Hamiltonian if and only if the integrator is symplectic. The existence of a modified (or "shadow" [4]) Hamiltonian is an indicator of the validity of statistical estimates calculated from long time integration of chaotic Hamiltonian systems [20]. In addition, the modified Hamiltonian is a more sensitive indicator than the original Hamiltonian of drift in the energy (caused by instability). Evidence for the existence of a Hamiltonian for a particular calculation can be obtained by calculating modified Hamiltonians and monitoring how well they are conserved. Doing this calculation would normally be complicated and highly dependent on the details of the method, even if differences are used to approximate higher derivatives. Presented here is a relatively simple procedure, nearly independent of the internal structure of the integrator, for obtaining highly accurate estimates for modified Hamiltonians.

Consider a step by step numerical integrator $x^{n+1} = \Phi_h(x^n)$ which evolves an

approximate solution $x^n \approx x(nh)$ for a system of ordinary differential equations $\dot{x} = f(x)$. For such discrete solutions, there exists modified equations $\dot{x}_h = f_h(x_h)$ defined by an asymptotic expansion such that *formally* the numerical solution $x^n = x_h(nh)$. The modified right-hand-side function f_h is defined uniquely by postulating an asymptotic expansion $f_0 + hf_1 + h^2 f_2 + \cdots$ in powers of h, substituting this into the equations for the numerical solution, expanding in powers of h, and equating coefficients [17, 27, 6, 24]. The asymptotic expansion does not generally converge except for (reasonable integrators applied to) linear differential equations.

A Hamiltonian system is of the form

$$\dot{x}(t) = JH_x(x(t)), \qquad J = \begin{bmatrix} 0 & I \\ -I & 0 \end{bmatrix},$$

for some Hamiltonian $H(x)$, $x = [q^{\mathrm{T}}, p^{\mathrm{T}}]^{\mathrm{T}}$. The modified equation for an integrator Φ_h applied to this system is Hamiltonian; i.e., $f_h = JH_{h,x}(x)$ for some modified Hamiltonian $H_h(x)$ if and only if the integrator is symplectic [25, 22]. The integrator is symplectic if $\Phi_{h,x}(x)J^{\mathrm{T}}\Phi_{h,x}(x) \equiv J$. There is theoretical [18, 2, 8, 20] and empirical evidence that

$$x_n = x_h(nh) + \text{ very small error}$$

for a very long time, where x_h is the solution for a suitably truncated Hamiltonian H_h. In what follows we assume that H_h is such a Hamiltonian and *we neglect the very small error.*

If we plot total energy as a function of time for a numerical integrator such as leapfrog/Störmer/Verlet applied to a molecular dynamics simulation, we get a graph like Figure 3. What we observe are large fluctuations in the original Hamiltonian, as the trajectory moves on a hypersurface of a constant modified Hamiltonian. A small drift or jump in the energy would be obscured by the fluctuations. A plot of a modified Hamiltonian might be more revealing. As an example, the plots of modified Hamiltonians in Figure 4 already show a clear rise in energy in a 400-step simulation. This indicates that plots of suitable modified Hamiltonians can make it easier to test integration algorithms for instability and programming bugs. Details of this and other numerical tests are given in section 2. Before continuing, it is worth emphasizing that the concern of this paper is stability monitoring—not the monitoring and enhancement of accuracy, as in [4] and [16].

The goal is to construct an approximate modified Hamiltonian

$$H_{[2k]}(q,p) = H_h(q,p) + O(h^{2k})$$

that can be conveniently assembled from quantities, such as forces and energies, already available from the numerical integration. These requirements do *not* uniquely determine $H_{[2k]}$. We consider the special separable Hamiltonian $H(q,p) = \frac{1}{2}p^{\mathrm{T}}M^{-1}p + U(q)$ for which the system is of the form

$$\dot{q} = M^{-1}p, \qquad \dot{p} = F(q) \overset{\text{def}}{=} -U_q(q).$$

A "brute force" approach would be to determine an asymptotic expansion for H_h and of the quantities available for making an approximation and then to form a suitable linear combination of the latter. By such a matching of asymptotic expansions one could derive the following modified Hamiltonians for the leapfrog method:

$$H_{[2]}(q^n,p^n) = H(q^n,p^n) - \underbrace{\frac{1}{8}h^2(F^n)^{\mathrm{T}}M^{-1}F^n}_{\text{why?}}, \tag{1.1}$$

$$H_{[4]}(q^n,p^n) = H(q^n,p^n) + \frac{1}{4}\delta^2 U^n + \frac{1}{6}h(p^n)^{\mathrm{T}}M^{-1}\mu\delta F^n + \frac{5}{24}h^2(F^n)^{\mathrm{T}}M^{-1}F^n + \frac{1}{12}h^2(F^n)^{\mathrm{T}}M^{-1}\delta^2F^n, \tag{1.2}$$

$$H_{[6]}(q^n,p^n) = H(q^n,p^n) + \frac{11}{60}\delta^2 U^n + \frac{1}{10}h(p^n)^{\mathrm{T}}M^{-1}\mu\delta F^n + \frac{17}{120}h^2(F^n)^{\mathrm{T}}M^{-1}F^n + \frac{1}{10}h^2(F^n)^{\mathrm{T}}M^{-1}\delta^2F^n + \frac{1}{60}h^2(\mu\delta F^n)^{\mathrm{T}}M^{-1}\mu\delta F^n - \frac{1}{240}h^2(\delta^2F^n)^{\mathrm{T}}M^{-1}\delta^2F^n. \tag{1.3}$$

Here a superscript n denotes evaluation at q^n, the centered difference operator is defined by $\delta w^n = w^{n+1/2} - w^{n-1/2}$, the averaging operator is defined by $\mu w^n = \frac{1}{2}w^{n+1/2} + \frac{1}{2}w^{n-1/2}$, and values $q^{n\pm1}$, $p^{n\pm1}$ are defined in terms of q^n, p^n by the leapfrog method:

$$p^{n\pm1/2} = p^n \pm \frac{h}{2}F^n, \quad q^{n\pm1} = q^n \pm hM^{-1}p^{n\pm1/2}, \quad p^{n\pm1} = p^{n\pm1/2} \pm \frac{h}{2}F^{n\pm1}.$$

Thus, in principle, analytical expressions for the $H_{[2k]}(q,p)$ could be produced.

Note. The terms of order h^2 in $H_{[4]}$ and $H_{[6]}$ are different; but if expanded in powers of h, they agree up to $O(h^4)$.

An easier and more elegant construction is presented in sections 3–5. The technique is developed only for splitting methods. It is likely that a similar construction is also possible for symplectic implicit Runge–Kutta methods. The idea is to add a new position variable and a conjugate momentum variable to get an extended Hamiltonian $\bar{H}_h(y)$ which is homogeneous of order 2. For such a Hamiltonian $\bar{H}_h(y_h(t)) \equiv \frac{1}{2}\dot{y}_h(t)^{\mathrm{T}}\bar{J}y_h(t)$. Thus the problem is reduced to that of forming an approximation for $y_h(t)$ using the numerical solution of an extended Hamiltonian system. It is plausible that such a construction might be useful theoretically due to the availability of robust approximation techniques.

Equation (1.1) for $H_{[2]}$ contains an h^2 term which is not needed for achieving second order accuracy. Similarly, the last terms of $H_{[4]}$ and $H_{[6]}$ are not needed for fourth and sixth order, respectively. They are present because the given "truncations" $H_{[2k]}$ are designed to exactly conserve energy for the numerical solution when H is quadratic. (See sections 4.1 and 5.1.) This is a very useful property because typical applications, including molecular dynamics, are dominated by harmonic motion. The existence of a modified Hamiltonian that is exactly conserved for a quadratic Hamiltonian is noted in [19, Eq. (4.7b)], and the search for similar methods having this property was central to the results of this paper. For a quadratic Hamiltonian the modified Hamiltonian H_h actually exists (if h is not too large), but $H_{[2k]} \neq H_h$. (A simple derivation of H_h for the one-dimensional case is given in [24].) It should also be noted that the Hamiltonians $H_{[2k]}$ will not detect numerical instability in the case of quadratic Hamiltonians H.

2. Numerical experiments. The approximate modified Hamiltonians $H_{[2k]}(x)$, $k = 1, 2, 3, 4$, defined by (5.3), (4.4), (5.2), and (4.3) are computed and plotted as

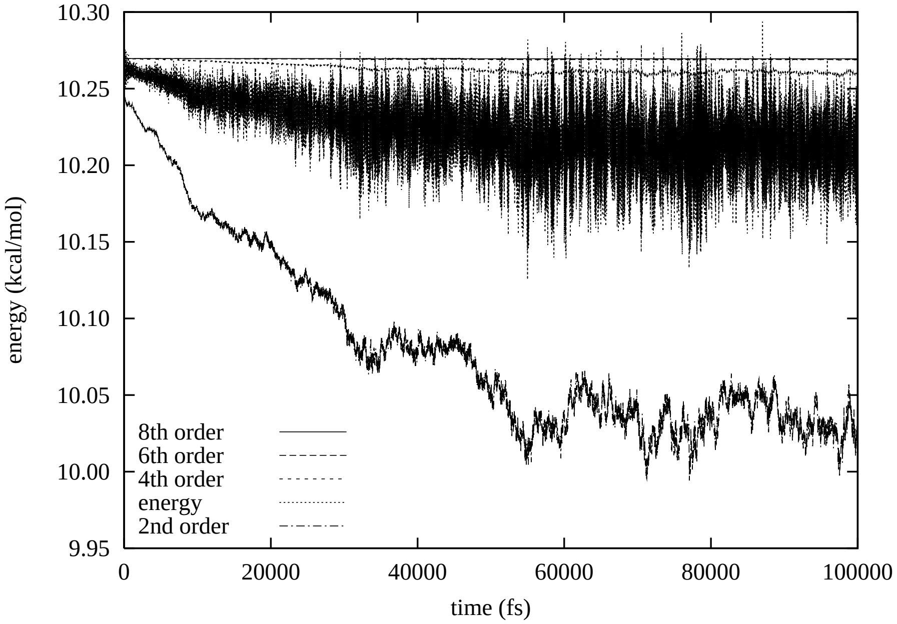

FIG. 1. *Energy and various truncations of the modified Hamiltonian for decalanine.*

functions of time for numerical solutions generated by the leapfrog method. The unmodified Hamiltonians are those of classical molecular dynamics. The testing was done with a molecular dynamics program written by the second author, which is compatible with NAMD [12] but limited in features to facilitate algorithm testing.

The first couple of experiments demonstrate the quality of the modified Hamiltonians. The test problem is a 66-atom peptide, decalanine, in a vacuum [1]. The force field parameters are those of CHARMM 22 for proteins [15, 14] without cutoffs for nonbonded forces.

Figure 1 shows a plot of the Hamiltonian and second, fourth, sixth, and eighth order modified Hamiltonian approximations vs. time for 100,000 fs (femtoseconds) for a step size $h = 1\,\mathrm{fs}$ with the energy sampled every eighth step. The level graph at the top is the eighth order truncation, the one just barely beneath it is sixth order, and the one under that is fourth order. The greatly fluctuating graph is the energy itself, and the undulating one well below it is the second order truncation. Note how well the asymptotic theory holds for the higher order truncations—one could not obtain such flat plots by simply smoothing the original Hamiltonian.

Figure 2 expands the vertical scale to show fluctuations in the eighth, sixth, and fourth order truncations of modified Hamiltonians.

An explanation is in order concerning the initial drop in energy. The initial velocities are zero, so integrating backward in time is the same as integrating forward. Hence the first part of the trajectory is simply the second half of a very unusual fluctuation. In other words, the initial conditions are atypical, i.e., not properly equilibrated (with respect to the original Hamiltonian). This is particularly well revealed by the plot of the second order truncation.

The remaining experiments demonstrate the ability of modified Hamiltonians to detect instability. The test problem is a set of 125 water molecules harmonically

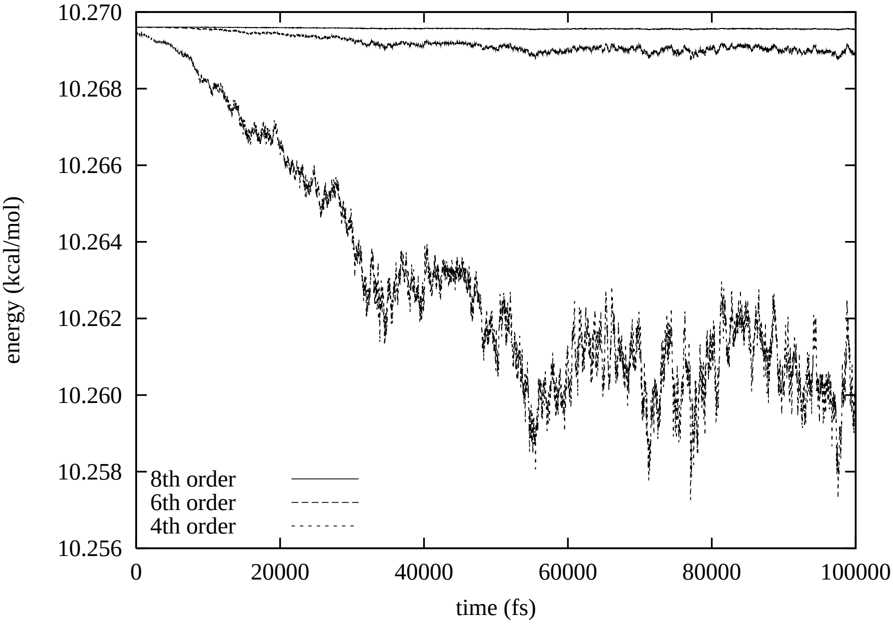

FIG. 2. *A closer look at higher order truncations for decalanine.*

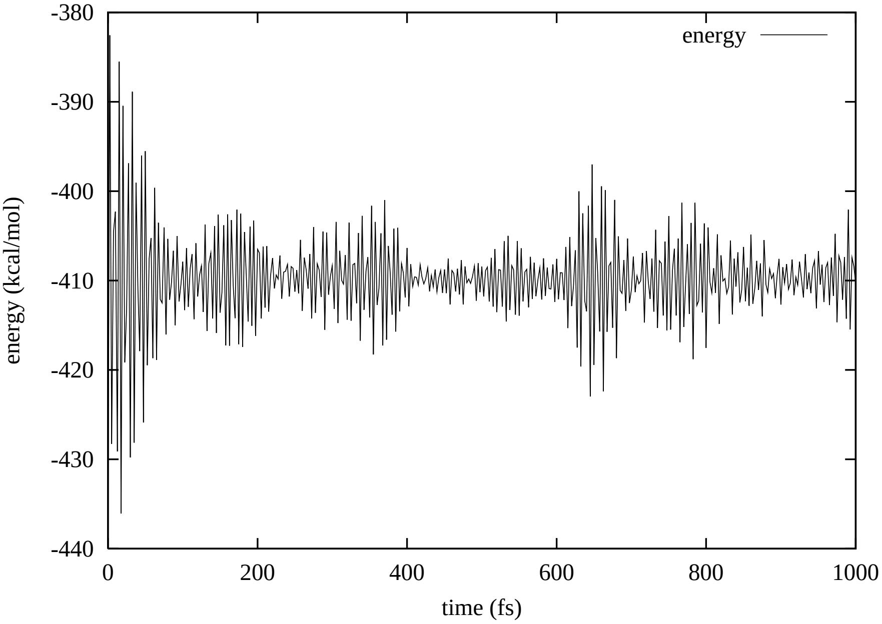

FIG. 3. *Energy for flexible water with step size* 2.5 *fs.*

restrained to a 10 Å-radius sphere. The water is based on the TIP3P model [11] without cutoffs and with flexibility incorporated by adding bond stretching and angle bending harmonic terms (cf. [13]).

Figure 3 shows a plot of the energy vs. time for 1,000 fs for a step size $h = 2.5\,\mathrm{fs}$ with the energy sampled every step. Note that the large fluctuations make it difficult

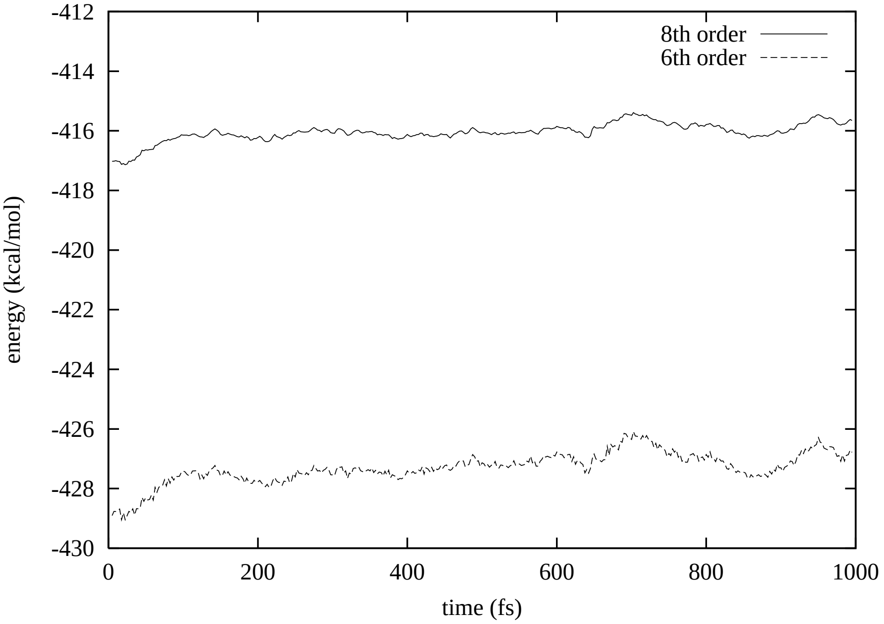

FIG. 4. *Sixth and eighth order truncations with step size* 2.5 *fs.*

to determine whether or not there is energy drift.

Figure 4 shows a plot of the sixth and eighth order modified Hamiltonians for the same step size $h = 2.5\,\mathrm{fs}$. An upward energy drift is now obvious. The second and fourth order approximations are not shown because neither of them was as flat. Normal mode analysis for this system [10] shows that the 250 fastest frequencies have periods in the range 9.8–10.2 fs and use of the formula in [24, p. 131] shows that a 2.5 fs step size is 30% of the effective period for discrete leapfrog dynamics. It is remarkable that the eighth order approximation is the flattest, even for such a large step size.

Figure 5 shows a plot of the sixth and eighth order modified Hamiltonians for step size $h = 2.15\,\mathrm{fs}$. There is no apparent upward drift of the energy. Theoretically, instability due to 4:1 resonance [23] should occur for the leapfrog method at $h \cdot \text{angular\_frequency} = \sqrt{2}$, which is in the range 2.2–2.3 fs for flexible water.

3. Augmenting the integrator. The integrator is augmented to make it homogeneous of order 1. This is motivated by the desire to extend results obtained for homogeneous linear mappings to affine mappings. Affine mappings can be reduced to homogeneous linear mappings through the use of homogeneous coordinates, in which the given set of coordinates is augmented by a scale factor, denoted here by α.

We assume that one step of size h for the given method applied to a system with Hamiltonian H is the composition of exact h-flows for Hamiltonian systems with Hamiltonians $H_1, H_2, \ldots, H_L$. Each $H_l(x)$ is assumed to be sufficiently smooth on some domain containing the infinite time trajectory. For example,

1. the leapfrog method for separable Hamiltonian systems $H(q,p) = K(p)+U(q)$ uses $L = 3$, $H_1(x) = \frac{1}{2}U(q)$, $H_2(x) = K(p)$, and $H_3(x) = \frac{1}{2}U(q)$;
2. the Rowlands method [21] for *special* separable Hamiltonian systems uses $H_1(x) = H_3(x) = \frac{1}{2}U(q) - \frac{1}{48}h^2U_q(q)^{\mathrm{T}}M^{-1}U_q(q)$ and $H_2(x) = \frac{1}{2}p^{\mathrm{T}}M^{-1}p$;

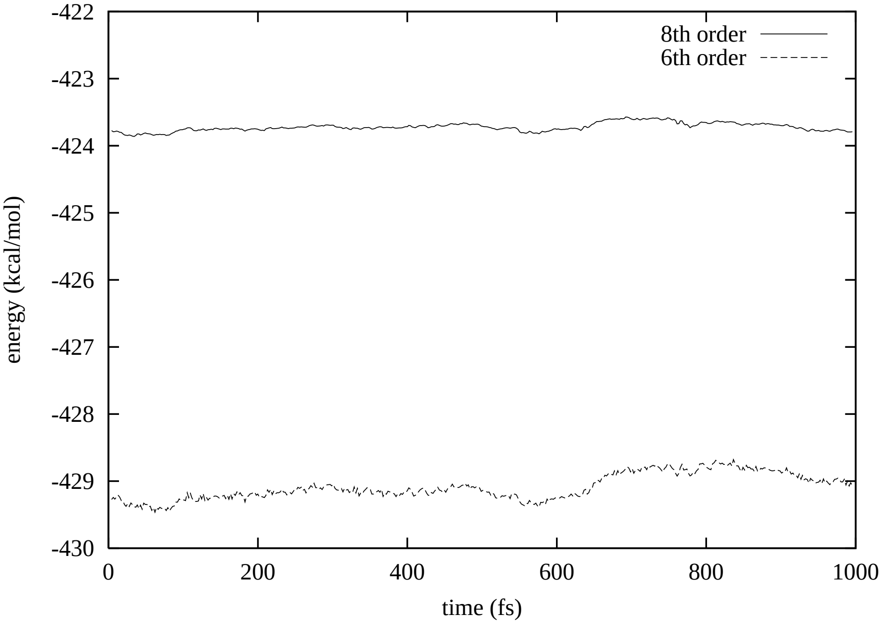

FIG. 5. *Sixth and eighth order truncations with step size* 2.15 *fs.*

3. double time-stepping [7, 26] uses $L = 5$, $H_1(x) = H_5(x) = \frac{1}{2}U^{\mathrm{slow}}(q) + \frac{1}{4}U^{\mathrm{fast}}(q)$, $H_2(x) = H_4(x) = \frac{1}{2}K(p)$, and $H_3(x) = \frac{1}{2}U^{\mathrm{fast}}(q)$,
4. *Molly* [5] does the same as double time-stepping except for the substitution of $U^{\mathrm{slow}}(\mathcal{A}(q))$ for $U^{\mathrm{slow}}(q)$, where $\mathcal{A}(q)$ is a local temporal averaging of q over vibrational motion.

We define the *homogeneous extension* of a Hamiltonian by

$$\bar{H}(q, \alpha, p, \beta) \stackrel{\mathrm{def}}{=} \alpha^2 H(\alpha^{-1}q, \alpha^{-1}p).$$

Then $\bar{H}$ is homogeneous of order 2:

$$\bar{H}(\sigma y) = \sigma^2 \bar{H}(y), \tag{3.1}$$

where $y \stackrel{\mathrm{def}}{=} [q^{\mathrm{T}}, \alpha, p^{\mathrm{T}}, \beta]^{\mathrm{T}}$. The extended Hamiltonian yields the augmented system

$$\dot{q} = \alpha H_p(\alpha^{-1}q, \alpha^{-1}p), \qquad \dot{p} = -\alpha H_q(\alpha^{-1}q, \alpha^{-1}p),$$

$$\dot{\alpha} = 0, \qquad \dot{\beta} = q^{\mathrm{T}} H_q(\alpha^{-1}q, \alpha^{-1}p) + p^{\mathrm{T}} H_p(\alpha^{-1}q, \alpha^{-1}p) - 2\alpha H(\alpha^{-1}q, \alpha^{-1}p).$$

With initial condition $\alpha(0) = 1$, we have $\alpha \equiv 1$ and the system simplifies to

$$\dot{q} = H_p(q, p), \qquad \dot{p} = -H_q(q, p), \qquad \dot{\beta} = q^{\mathrm{T}} H_q(q, p) + p^{\mathrm{T}} H_p(q, p) - 2H(q, p).$$

For $H(q, p) = \frac{1}{2}p^{\mathrm{T}}M^{-1}p + U(q)$, the extended Hamiltonian is $\bar{H}(q, \alpha, p, \beta) = \frac{1}{2}p^{\mathrm{T}}M^{-1}p + \alpha^2 U(\alpha^{-1}q)$ and the simplified augmented system is

$$\dot{q} = M^{-1}p, \qquad \dot{p} = -U_q(q), \qquad \dot{\beta} = q^{\mathrm{T}} U_q(q) - 2U(q).$$

Remark. The association of α with q rather than with p is of practical importance in that it enables one to get values of $\dot\beta$ for free whenever $\dot p$ is calculated.

The following proposition shows that the value of the extended Hamiltonian can be calculated knowing only the solution.

PROPOSITION 1. *Let $\bar H(y)$ be the homogeneous extension of a given Hamiltonian $H(x)$, and let $y(t)$ be a solution of the extended Hamiltonian system with α initially* 1. *Then*

$$H(x(t)) \equiv \frac{1}{2}\dot y(t)^{\mathrm T}\bar J y(t),$$

where $\bar J$ is the matrix $\begin{bmatrix} 0 & I \\ -I & 0 \end{bmatrix}$ of augmented dimension.

Proof. Differentiating (3.1) with respect to σ gives $\bar H_y(y)^{\mathrm T} y = 2\bar H(y)$, so

$$\frac{1}{2}\dot y(t)^{\mathrm T}\bar J y(t) = \frac{1}{2}(\bar J \bar H_y(y(t)))^{\mathrm T}\bar J y(t) = \frac{1}{2}\bar H_y(y(t))^{\mathrm T} y(t) = \bar H(y(t)).$$

Because $\bar H$ is a homogeneous extension of H, the solution of $\bar H$ "includes" that of H and we have $\bar H(y(t)) \equiv H(x(t))$. □

Of course, the goal is not to calculate the original Hamiltonian for which we know a formula but not the solution; rather, it is to calculate a modified Hamiltonian for which we know the solution (at grid points) but not a formula. Therefore, we must augment the integrator so that its solution at grid points is that of the homogeneous extension of the modified Hamiltonian. For an integrator that is a composition of Hamiltonian flows, this is accomplished by using the homogeneous extension of each of the constituent Hamiltonians. More specifically, we define the augmented method $y^{n+1} = \Psi_h(y^n)$ for $\bar H$ to be the composition of exact flows for systems with Hamiltonians $\bar H_1$, $\bar H_2$, ..., $\bar H_L$, where

$$\bar H_l(q, \alpha, p, \beta) \overset{\mathrm{def}}{=} \alpha^2 H_l(\alpha^{-1}q, \alpha^{-1}p).$$

LEMMA 1 (commutativity). *The method Ψ_h defined above has a modified Hamiltonian*

$$\bar H_h(q, \alpha, p, \beta) = \alpha^2 H_h(\alpha^{-1}q, \alpha^{-1}p),$$

where $H_h(q,p)$ is the modified Hamiltonian of the original method Φ_h, i.e., the following diagram commutes:

$$\begin{tikzcd} H \arrow[r, "\textit{homogeneous extension}"] \arrow[d, "\textit{discretization}"'] & \bar H \arrow[d, "\textit{discretization}"] \\ H_h \arrow[r, "\textit{homogeneous extension}"'] & \bar H_h \end{tikzcd}$$

Proof. The modified Hamiltonian $\bar H_h$ for method Ψ_h can be expressed as an asymptotic expansion using the Baker–Campbell–Hausdorf formula [22]. This formula combines Hamiltonians using the operations of scalar multiplication, addition, and the Poisson bracket $\{H, N\} = H_x^{\mathrm T}\, J N_x$. It is thus sufficient to show that each of these three commute with the operation of forming the homogeneous extension. We show this only for the last of these. The homogeneous extension of the Poisson bracket is

$$\alpha^2 H_x(\alpha^{-1}x)^{\mathrm T} J N_x(\alpha^{-1}x).$$

This is exactly the same as the (extended) Poisson bracket of $\alpha^2 H(\alpha^{-1}x)$ and $\alpha^2 N(\alpha^{-1}x)$. □

Remark. The aim is to discretize the extended Hamiltonian so that this commutativity property holds. Extension of this technique to implicit Runge–Kutta methods would require an augmentation of the method so that commutativity holds.

The following proposition allows the value of the Hamiltonian to be approximated from known values of $y_h(t)$ at grid points.

PROPOSITION 2. *Let $x_h(t)$ and $y_h(t)$ be the solutions for modified Hamiltonians H_h and $\bar{H}_h$, respectively. Then*

$$H_h(x_h(t)) \equiv \frac{1}{2}\dot{y}_h(t)^{\mathrm{T}}\bar{J}y_h(t). \tag{3.2}$$

Proof. The proof is similar to that of Proposition 1. □

4. Using full step values. This section presents the construction of $H_{[2k]}$ for *even values of* k. The idea is to use (3.2) in a judiciously chosen weighted average.

Let $y_h(t)$ be the solution of the modified extended Hamiltonian system with initial condition $y(0) = y$. It has values $y_h(jh) = \Psi_h^j(y)$, $j = 0, \pm 1, \dots, \pm k/2$. Let $\pi_k(t)$ be the degree k polynomial interpolant of these values. (For large k it may be preferable, instead, to use trigonometric interpolation suitably modified [3].)

From Proposition 2, $\frac{1}{2}\dot{\pi}_k(t)J\pi_k(t) \approx \bar{H}_h(y)$. Let

$$H_{k,j} \overset{\text{def}}{=} \frac{1}{jh}\int_{-jh/2}^{jh/2}\frac{1}{2}\dot{\pi}_k(t)^{\mathrm{T}}J\pi_k(t)\mathrm{d}t, \qquad j = 2, 4, \dots, k.$$

The interpolant $\pi_k(t) = y_h(t) + e(t)$, where the error $e(t) = (t^2 - \frac{1}{4}k^2h^2)\cdots(t^2 - h^2)ty_h^{[k+1]}(t)$ and $y_h^{[k+1]}(t) \overset{\text{def}}{=} y_h[-\frac{1}{2}kh, \dots, \frac{1}{2}kh, t]$ with the brackets denoting a $(k+1)$th divided difference. Noting that $\dot{e}(t)^{\mathrm{T}}\bar{J}e(t) = O(h^{2k+2})$, we get

$$\begin{aligned}
H_{k,j} &= \bar{H}_h + \frac{1}{jh}\int_{-jh/2}^{jh/2}\frac{1}{2}\dot{y}_h(t)^{\mathrm{T}}\bar{J}e(t)\mathrm{d}t - \frac{1}{jh}\int_{-jh/2}^{jh/2}\frac{1}{2}y_h(t)^{\mathrm{T}}\bar{J}\dot{e}(t)\mathrm{d}t + O(h^{2k+2}) \\
&= \bar{H}_h + \frac{1}{jh/2}\int_{-jh/2}^{jh/2}\frac{1}{2}\dot{y}_h(t)^{\mathrm{T}}\bar{J}e(t)\mathrm{d}t + O(h^{2k+2}) \\
&= \bar{H}_h + \frac{1}{jh/2}\int_{-jh/2}^{jh/2}\left(t^2 - \frac{1}{4}k^2h^2\right)\cdots(t^2 - h^2)t\gamma(t)\mathrm{d}t + O(h^{2k+2}),
\end{aligned}$$

where the second equation is obtained by integration by parts and where $\gamma(t) \overset{\text{def}}{=} \frac{1}{2}\dot{y}_h(t)^{\mathrm{T}}\bar{J}y_h^{[k+1]}(t)$. This can be expressed as an expansion

$$H_{k,j} = \bar{H}_h + c_{j1}h^{k+2}\gamma'(0) + c_{j3}h^{k+4}\gamma'''(0) + \cdots + O(h^{2k+2}).$$

By forming a suitable linear combination of the values $H_{k,j}$, $j = 1, 2, \dots, k/2$, it is expected that one can get $\bar{H}_h$ with the first $k/2 - 1$ leading error terms eliminated:

$$\text{linear combination of the } H_{k,j} = \bar{H}_h + O(h^{2k}).$$

Note. The value $\dot{\pi}_k(0)^{\mathrm{T}}\bar{J}\pi_k(0)$ contains a leading term that is only $O(h^k)$, so it is not useful for eliminating error terms.

The case $k = 2$ is the fourth order accurate formula

$$H_{[4]}(x) \overset{\text{def}}{=} H_{2,2} = \bar{H}_h(y) + O(h^4).$$

For the case $k = 4$, we have

$$\begin{aligned} H_{4,2} &= \bar{H}_h + \frac{1}{h}\int_{-h}^{h}(t^2 - 4h^2)(t^2 - h^2)t\gamma(t)\mathrm{d}t + O(h^{10}) \\ &= \bar{H}_h + \frac{20}{21}h^6\gamma'(0) + O(h^8) \end{aligned}$$

and

$$\begin{aligned} H_{4,4} &= \bar{H}_h + \frac{1}{2h}\int_{-2h}^{2h}(t^2 - 4h^2)(t^2 - h^2)t\gamma(t)\mathrm{d}t + O(h^{10}) \\ &= \bar{H}_h - \frac{64}{21}h^6\gamma'(0) + O(h^8), \end{aligned}$$

and hence

$$H_{[8]}(x) \overset{\text{def}}{=} \frac{16}{21}H_{4,2} + \frac{5}{21}H_{4,4} = \bar{H}_h(y) + O(h^8).$$

Below are given formulas for $H_{[8]}$ and for $H_{[4]}$ in terms of values of $y_h(t)$ at grid points. Let a_j be the jth centered difference of $y_h(t)$ at $t = 0$:

$$a_j = \begin{cases} \delta^j y_h(0), & j = 0, 2, 4, \ldots, \\ \mu\delta^j y_h(0), & j = 1, 3, \ldots, \end{cases}$$

where the centered difference operator is defined by $\delta w(t) = w(t + h/2) - w(t - h/2)$ and the averaging operator is defined by $\mu w(t) = \frac{1}{2}w(t + h/2) + \frac{1}{2}w(t - h/2)$.

The fourth degree interpolant in divided difference form is

$$\pi_4(t) = y_h(0) + t\frac{\mu\delta y_h(0)}{h} + t^2\frac{\delta^2 y_h(0)}{2h^2} + t(t^2 - h^2)\frac{\mu\delta^3 y_h(0)}{6h^3} + t^2(t^2 - h^2)\frac{\delta^4 y_h(0)}{24h^4}.$$

Hence,

$$\pi_4(sh) = a_0 + a_1 s + \frac{1}{2}a_2 s^2 + \frac{1}{6}a_3 s(s^2 - 1) + \frac{1}{24}a_4 s^2(s^2 - 1)$$

and

$$h\dot{\pi}_4(sh) = a_1 + a_2 s + \frac{1}{2}a_3\left(s^2 - \frac{1}{3}\right) + \frac{1}{6}a_4 s\left(s^2 - \frac{1}{2}\right).$$

Define

$$A_{ij} = a_i^{\mathrm{T}}\bar{J}a_j/(2h),$$

and we have

$$\begin{aligned} \frac{1}{2}\dot{\pi}_4(sh)^{\mathrm{T}}\bar{J}\pi_4(sh) = A_{10} &- \frac{1}{2}A_{12}s^2 + \frac{1}{2}A_{30}\left(s^2 - \frac{1}{3}\right) + \frac{1}{12}A_{32}s^2(s^2 + 1) \\ &- \frac{1}{8}A_{14}s^2\left(s^2 - \frac{1}{3}\right) \\ &- \frac{1}{144}A_{34}s^2(s^2 - 1)^2 + \text{ odd powers of } s. \end{aligned}$$

Averaging over $-1 \le s \le 1$ yields

$$H_{4,2} = A_{10} - \frac{1}{6}A_{12} + \frac{2}{45}A_{32} - \frac{1}{90}A_{14} - \frac{1}{1890}A_{34}, \tag{4.1}$$

and averaging over $-2 \le s \le 2$ yields

$$H_{4,4} = A_{10} - \frac{2}{3}A_{12} + \frac{1}{2}A_{30} + \frac{17}{45}A_{32} - \frac{31}{90}A_{14} - \frac{107}{3780}A_{34}.$$

Therefore,

$$H_{[8]}(x) = \frac{16}{21}H_{4,2} + \frac{5}{21}H_{4,4} \tag{4.2}$$

$$= A_{10} - \frac{2}{7}A_{12} + \frac{5}{42}A_{30} + \frac{13}{105}A_{32} - \frac{19}{210}A_{14} - \frac{1}{140}A_{34}. \tag{4.3}$$

For a second degree interpolant, it follows from (4.1) that

$$H_{[4]}(x) = H_{2,2} = A_{10} - \frac{1}{6}A_{12}. \tag{4.4}$$

An implementation of these formulas might calculate $H_{[2k]}(x^n)$ for consecutive values of n in terms of quantities $A^n_{ij} = (a^n_i)^{\mathrm{T}}\bar{J}a^n_j/(2h)$ defined in terms of centered differences of y^n which can be obtained from the x^n. (Only first and higher differences of β^n are needed.)

Example 1. To make this concrete, we calculate $H_{[4]}(x)$ for the leapfrog method, as given by (1.2). The leapfrog method advances one step by

$$\begin{aligned}
p^{n+1/2} &= p^n + \frac{h}{2}F^n,\\
\beta^{n+1/2} &= \beta^n + \frac{h}{2}(-(q^n)^{\mathrm{T}}F^n - 2U^n),\\
q^{n+1} &= q^n + hM^{-1}p^{n+1/2},\\
p^{n+1} &= p^{n+1/2} + \frac{h}{2}F^{n+1},\\
\beta^{n+1} &= \beta^{n+1/2} + \frac{h}{2}(-(q^{n+1})^{\mathrm{T}}F^{n+1} - 2U^{n+1}).
\end{aligned}$$

We have

$$H_{[4]}(q^n, p^n) = \frac{1}{2h}(\mu\delta y^n)^{\mathrm{T}}\bar{J}\left(y^n - \frac{1}{6}\delta^2 y^n\right).$$

Suppressing the n in the superscript,

$$y^{\pm 1} = \begin{bmatrix} q \pm hM^{-1}p + \frac{1}{2}h^2M^{-1}F \\ 1 \\ p \pm \frac{1}{2}hF \pm \frac{1}{2}hF^{\pm 1} \\ \beta \pm \frac{1}{2}h(-2U - q^{\mathrm{T}}F) \pm \frac{1}{2}h(-2U^{\pm 1} - (q^{\pm 1})^{\mathrm{T}}F^{\pm 1}) \end{bmatrix},$$

whence

$$\mu\delta y = \begin{bmatrix} hM^{-1}p \\ 0 \\ hF + \frac{1}{4}h\delta^2 F \\ -2hU - hq^{\mathrm{T}}F - \frac{1}{2}h\delta^2 U - \frac{1}{4}h\delta^2(q^{\mathrm{T}}F) \end{bmatrix}, \quad \delta^2 y = \begin{bmatrix} h^2M^{-1}F \\ 0 \\ h\mu\delta F \\ \text{not needed} \end{bmatrix}. \tag{4.5}$$

From $\delta(ab) = \delta a \cdot \mu b + \mu a \cdot \delta b$ and $\mu^2 = 1 + \frac{1}{4}\delta^2$, we get

$$\delta^2(ab) = \delta^2 a \cdot b + 2\mu\delta a \cdot \mu\delta b + a \cdot \delta^2 b + \frac{1}{2}\delta^2 a \cdot \delta^2 b,$$

so

$$\delta^2(q^{\mathrm{T}}F) = h^2 F^{\mathrm{T}} M^{-1} F + 2hp^{\mathrm{T}} M^{-1}\mu\delta F + q^{\mathrm{T}}\delta^2 F + \frac{1}{2}h^2 F^{\mathrm{T}} M^{-1}\delta^2 F. \tag{4.6}$$

Therefore,

$$\begin{aligned} H_{[4]}(q^n, p^n) = H(q^n, p^n) &+ \frac{1}{4}\delta^2 U^n + \frac{1}{6}h(p^n)^{\mathrm{T}} M^{-1}\mu\delta F^n + \frac{5}{24}h^2(F^n)^{\mathrm{T}} M^{-1} F^n \\ &+ \frac{1}{12}h^2(F^n)^{\mathrm{T}} M^{-1}\delta^2 F^n. \end{aligned}$$

4.1. The case of a quadratic Hamiltonian. The following result implies that, in the case where $H(x)$ is quadratic, the numerical solution exactly conserves an approximate modified Hamiltonian which is a linear functional of $\frac{1}{2}\dot\pi(t)^{\mathrm{T}}\bar J\pi(t)$, where $\pi(t)$ is a linear combination of numerical solution values.

Proposition 3. *Assume that Φ_h is the composition of flows for systems with quadratic Hamiltonians and that Ψ_h is constructed as in Lemma* 1. *Then the quantity*

$$\bar H_*(y) \overset{\text{def}}{=} \sum_{i,j} a_{i,j}\Psi_h^i(y)^{\mathrm{T}}\bar J\Psi_h^j(y),$$

where the sum is taken over a finite set of pairs of integers, is exactly conserved by method Ψ_h.

Proof. The mapping $\Psi_h(y) = Sy$ for some symplectic matrix S because Ψ_h is the composition of flows for systems with homogeneous quadratic Hamiltonians. Then

$$\begin{aligned} \bar H_*(\Psi_h(y)) &= \sum_{i,j} a_{i,j}(S^i S y)^{\mathrm{T}}\bar J(S^j S y) \\ &= \sum_{i,j} a_{i,j}(S^i y)^{\mathrm{T}} S^{\mathrm{T}}\bar J S(S^j y) \\ &= \sum_{i,j} a_{i,j}\Psi_h^i(y)^{\mathrm{T}}\bar J\Psi_h^j(y). \qquad \square \end{aligned}$$

5. Using intermediate values. This section presents the construction of $H_{[2k]}$ for *odd values of k.*

For most numerical integrators one can define "sensible" midstep values

$$y^{n\pm1/2}, y^{n\pm3/2}, \ldots, y^{n\pm k/2},$$

and these can be used instead of full step values to get an estimate accurate up to $O(h^{2k})$. We assume that $\Psi_h = \hat\Psi_{-h/2}^{-1} \circ \hat\Psi_{h/2}$, where $\hat\Psi_{h/2}$ is a composition of exact flows of homogeneously extended Hamiltonians.

Remark. It is not necessary that the midstep values be approximations to $y(t)$ at midpoints nor that Ψ_h be time symmetric ($\Psi_h^{-1} = \Psi_{-h}$). All we need is that $\Psi_h = \Psi_{2,h} \circ \Psi_{1,h}$ where each of $\Psi_{1,h}$, $\Psi_{2,h}$ is a composition of exact flows of homogeneously extended Hamiltonians.

For example, the leapfrog method separates into half steps $\hat{\Psi}_{-h/2}^{-1} \circ \hat{\Psi}_{h/2}$ with $\hat{\Psi}_{h/2}$ as follows:

$$\begin{aligned} p^{n+1/2} &= p^n + \frac{h}{2}F^n, \\ \beta^{n+1/2} &= \beta^n + \frac{h}{2}(-(q^n)^{\mathrm{T}}F^n - 2U^n), \\ q^{n+1/2} &= q^n + \frac{h}{2}M^{-1}p^{n+1/2}. \end{aligned}$$

Remark. For the leapfrog method, the estimate over an interval from $(n - \frac{1}{2}k)h$ to $(n + \frac{1}{2}k)h$, where k is odd, actually uses only values of energy and forces from the shorter interval from $(n - \frac{1}{2}k + \frac{1}{2})h$ to $(n + \frac{1}{2}k - \frac{1}{2})h$.

The midstep values are values at midpoints of some function $z_h(t)$ which can be used to construct the Hamiltonian.

PROPOSITION 4. *Let $z_h(t) = \Phi_{h/2}(y_h(t - h/2))$. Then*

$$H_h(x_h(t)) \equiv \frac{1}{2}\dot{z}_h(t)^{\mathrm{T}}\bar{J}z_h(t).$$

Proof. For any real s, we define $\Psi_h^s = sh$-flow for $\dot{y} = \bar{J}\bar{H}_{h,y}(y)$. Then $z_h(t) = \chi_h(y_h(t))$, where $\chi_h = \Phi_{h/2} \circ \Psi_h^{-1/2}$. Because χ_h is symplectic, $z_h(t) = \chi_h(y_h(t))$ satisfies a Hamiltonian system with Hamiltonian $\bar{H}_h \circ \chi_h^{-1}$. Also, $\chi_h(\sigma z) = \sigma\chi_h(z)$ because χ_h is the composition of flows of Hamiltonians that are second order homogeneous, and hence $\bar{H}_h \circ \chi_h^{-1}$ is homogeneous of order 2. Therefore,

$$\frac{1}{2}\dot{z}_h(t)^{\mathrm{T}}\bar{J}z_h(t) \equiv \bar{H}_h \circ \chi_h^{-1}(z_h(t)) = \bar{H}_h(y_h(t)). \qquad \square$$

Let $\pi_k(t)$ be the degree k polynomial interpolant of the values $z_h(jh) = \hat{\Psi}_{h/2} \circ \Psi_h^{j-1/2}(y)$, $j = \pm\frac{1}{2}, \pm\frac{3}{2}, \dots, \pm k/2$.

As before, let

$$H_{k,j} = \frac{1}{jh}\int_{-jh/2}^{jh/2} \frac{1}{2}\dot{\pi}_k(t)^{\mathrm{T}}\bar{J}\pi_k(t)\mathrm{d}t, \qquad j = 1, 3, \dots, k.$$

The interpolant $\pi_k(t) = z_h(t) + e(t)$, where the error $e(t) = (t^2 - \frac{1}{4}k^2h^2)\cdots(t^2 - \frac{1}{4}h^2)z_h^{[k+1]}(t)$ and $z_h^{[k+1]}(t) \stackrel{\text{def}}{=} z_h[-\frac{1}{2}kh, \dots, \frac{1}{2}kh, t]$. Similar to before, we get

$$H_{k,j} = \bar{H}_h + \frac{1}{jh/2}\int_{-jh/2}^{jh/2}\left(t^2 - \frac{1}{4}k^2h^2\right)\cdots\left(t^2 - \frac{1}{4}h^2\right)\gamma(t)\mathrm{d}t + O(h^{2k+2}),$$

where $\gamma(t) \stackrel{\text{def}}{=} \frac{1}{2}\dot{z}_h(t)^{\mathrm{T}}\bar{J}z_h^{[k+1]}(t)$. This can be expressed as an expansion

$$H_{k,j} = \bar{H}_h + c_{j0}h^{k+1}\gamma(0) + c_{j2}h^{k+3}\gamma''(0) + \cdots + O(h^{2k+2}).$$

Again, it is expected that a suitable linear combination of the $(k+1)/2$ different values of $H_{k,j}$ yields $\bar{H}_h$ with the first $(k+1)/2 - 1$ leading error terms eliminated:

$$\text{linear combination of the } H_{k,j} = \bar{H}_h + O(h^{2k}).$$

Note. It does not seem possible to combine values obtained from full steps with those from half steps to further increase the order of accuracy because the error expansions for the two kinds of averages do not have terms in common that can cancel.

For $k = 1$, we have the second order formula

$$H_{[2]}(x) \overset{\text{def}}{=} H_{1,1} = \bar{H}_h(y) + O(h^2).$$

For $k = 3$, we have

$$\begin{aligned} H_{3,1} &= \bar{H}_h + \frac{1}{h/2}\int_{-h/2}^{h/2}\left(t^2 - \frac{9}{4}h^2\right)\left(t^2 - \frac{1}{4}h^2\right)\gamma(t)\mathrm{d}t + O(h^8) \\ &= \bar{H}_h + \frac{11}{15}h^4\gamma(0) + O(h^6) \end{aligned}$$

and

$$\begin{aligned} H_{3,3} &= \bar{H}_h + \frac{1}{3h/2}\int_{-3h/2}^{3h/2}\left(t^2 - \frac{9}{4}h^2\right)\left(t^2 - \frac{1}{4}h^2\right)\gamma(t)\mathrm{d}t + O(h^8) \\ &= \bar{H}_h - \frac{3}{5}h^4\gamma(0) + O(h^6), \end{aligned}$$

whence

$$H_{[6]}(x) \overset{\text{def}}{=} \frac{9}{20}H_{3,1} + \frac{11}{20}H_{3,3} = \bar{H}_h(y) + O(h^6).$$

Let b_j be the jth centered difference of $z_h(t)$ at $t = 0$ using midstep values

$$b_j = \begin{cases} \mu\delta^j z_h(0), & j = 0, 2, 4, \ldots, \\ \delta^j z_h(0), & j = 1, 3, \ldots. \end{cases}$$

The third degree interpolant is

$$\pi_3(t) = \mu z_h(0) + t\frac{\delta z_h(0)}{h} + \left(t^2 - \frac{1}{4}h^2\right)\frac{\mu\delta^2 z_h(0)}{2h^2} + \left(t^2 - \frac{1}{4}h^2\right)t\frac{\delta^3 z_h(0)}{6h^3}.$$

Hence,

$$\pi_3(sh) = b_0 + b_1 s + \frac{1}{2}b_2\left(s^2 - \frac{1}{4}\right) + \frac{1}{6}b_3 s\left(s^2 - \frac{1}{4}\right)$$

and

$$h\dot{\pi}_3(sh) = b_1 + b_2 s + \frac{1}{2}b_3\left(s^2 - \frac{1}{12}\right).$$

Define

$$B_{ij} = b_i^{\mathrm{T}}\bar{J}b_j/(2h),$$

and we have

$$\begin{aligned} \frac{1}{2}\dot{\pi}_3(sh)^{\mathrm{T}}\bar{J}\pi_3(sh) = B_{10} - \frac{1}{2}B_{12}\left(s^2 + \frac{1}{4}\right) + \frac{1}{2}B_{30}\left(s^2 - \frac{1}{12}\right) \\ + \frac{1}{12}B_{32}\left(s^2 - \frac{1}{4}\right)^2 + \text{ odd powers of } s. \end{aligned}$$

Averaging over $-\frac{1}{2} \le s \le \frac{1}{2}$ yields

$$H_{3,1} = B_{10} - \frac{1}{6}B_{12} + \frac{1}{360}B_{32}, \tag{5.1}$$

and averaging over $-\frac{3}{2} \le s \le \frac{3}{2}$ yields

$$H_{3,3} = B_{10} - \frac{1}{2}B_{12} + \frac{1}{3}B_{30} + \frac{7}{120}B_{32}.$$

Therefore,

$$H_{[6]}(x) = B_{10} - \frac{7}{20}B_{12} + \frac{11}{60}B_{30} + \frac{1}{30}B_{32}. \tag{5.2}$$

For a first degree interpolant, it follows from (5.1) that

$$H_{[2]}(x) = B_{10}. \tag{5.3}$$

Example 2. We calculate $H_{[2]}(x)$ for the leapfrog method, as given by (1.1). We have

$$H_{[2]}(q^n, p^n) = \frac{1}{2h}(\delta y^n)^{\mathrm{T}} \bar{J}(\mu y^n).$$

Suppressing the n in the superscript,

$$y^{\pm 1/2} = \begin{bmatrix} q \pm \frac{1}{2}hM^{-1}p + \frac{1}{4}h^2M^{-1}F \\ 1 \\ p \pm \frac{1}{2}hF \\ \pm\frac{1}{2}h(-2U - q^{\mathrm{T}}F) \end{bmatrix},$$

whence

$$\delta y = \begin{bmatrix} hM^{-1}p \\ 0 \\ hF \\ -2hU - hq^{\mathrm{T}}F \end{bmatrix}, \qquad \mu y = \begin{bmatrix} q + \frac{1}{4}h^2M^{-1}F \\ 1 \\ p \\ 0 \end{bmatrix}. \tag{5.4}$$

Therefore,

$$H_{[2]}(q^n, p^n) = H(q^n, p^n) - \frac{1}{8}h^2(F^n)^{\mathrm{T}}M^{-1}F^n.$$

Example 3. We calculate $H_{[6]}(x)$ for the leapfrog method, as given by (1.3). From (5.4) we have

$$\delta^3 y = \begin{bmatrix} hM^{-1}\delta^2 p \\ 0 \\ h\delta^2 F \\ -2h\delta^2 U - h\delta^2(q^{\mathrm{T}}F) \end{bmatrix}, \qquad \mu\delta^2 y = \begin{bmatrix} \delta^2 q + \frac{1}{4}h^2M^{-1}\delta^2 F \\ 0 \\ \delta^2 p \\ 0 \end{bmatrix}.$$

We have $\delta^2 q = h^2M^{-1}F$ and $\delta^2 p = h\mu\delta F$ from the second part of (4.5), and $\delta^2(q^{\mathrm{T}}F)$ is given by (4.6). Then

$$
\begin{aligned}
b_1^{\mathrm{T}}\bar{J}b_0 &= 2hU + hp^{\mathrm{T}}M^{-1}p - \frac{1}{4}h^3F^{\mathrm{T}}M^{-1}F,\\
b_1^{\mathrm{T}}\bar{J}b_2 &= h^2p^{\mathrm{T}}M^{-1}\mu\delta F - h^3F^{\mathrm{T}}M^{-1}F - \frac{1}{4}h^3F^{\mathrm{T}}M^{-1}\delta^2F,\\
b_3^{\mathrm{T}}\bar{J}b_0 &= 2h\delta^2U + 3h^2p^{\mathrm{T}}M^{-1}\mu\delta F + h^3F^{\mathrm{T}}M^{-1}F + \frac{1}{4}h^3F^{\mathrm{T}}M^{-1}\delta^2F,\\
b_3^{\mathrm{T}}\bar{J}b_2 &= -h^3F^{\mathrm{T}}M^{-1}\delta^2F + h^3(\mu\delta F)^{\mathrm{T}}M^{-1}\mu\delta F - \frac{1}{4}h^3(\delta^2F)^{\mathrm{T}}M^{-1}\delta^2F,
\end{aligned}
$$

and, therefore,

$$
\begin{aligned}
H_{[6]}(q^n,p^n) = H(q^n,p^n) &+ \frac{11}{60}\delta^2U^n + \frac{1}{10}h(p^n)^{\mathrm{T}}M^{-1}\mu\delta F^n + \frac{17}{120}h^2(F^n)^{\mathrm{T}}M^{-1}F^n\\
&+ \frac{1}{10}h^2(F^n)^{\mathrm{T}}M^{-1}\delta^2F^n + \frac{1}{60}h^2(\mu\delta F^n)^{\mathrm{T}}M^{-1}\mu\delta F^n\\
&- \frac{1}{240}h^2(\delta^2F^n)^{\mathrm{T}}M^{-1}\delta^2F^n.
\end{aligned}
$$

5.1. The case of a quadratic Hamiltonian.

PROPOSITION 5. *Assume that Φ_h is the composition of flows for systems with quadratic Hamiltonians, that Ψ_h is constructed as in Lemma* 1, *and that $\hat{\Psi}_{h/2}$ is as assumed at the beginning of this section. Then the quantity*

$$
\bar{H}_*(y) \overset{\mathrm{def}}{=} \sum_{i,j} a_{i,j}\hat{\Psi}_{h/2}\circ\Psi_h^i(y)^{\mathrm{T}}\bar{J}\hat{\Psi}_{h/2}\circ\Psi_h^j(y),
$$

where the sum is taken over a finite set of pairs of integers, is exactly conserved by method Ψ_h.

Proof. Because $\hat{\Psi}_{h/2}$, Ψ_h are the compositions of flows for systems with homogeneous quadratic Hamiltonians, the mappings $\hat{\Psi}_{h/2}(y) = S_1y$ and $\Psi_h(y) = S_2S_1y$ for some symplectic matrices S_1, S_2. Then

$$
\begin{aligned}
\bar{H}_*(\Psi_h(y)) &= \sum_{i,j} a_{i,j}(S_1S^iSy)^{\mathrm{T}}\bar{J}(S_1S^jSy)\\
&= \sum_{i,j} a_{i,j}(S_1S^iy)^{\mathrm{T}}(S_1S_2)^{\mathrm{T}}\bar{J}S_1S_2(S_1S^jy)\\
&= \sum_{i,j} a_{i,j}\hat{\Psi}_{h/2}\circ\Psi_h^i(y)^{\mathrm{T}}\bar{J}\hat{\Psi}_{h/2}\circ\Psi_h^j(y). \qquad \square
\end{aligned}
$$

A CHANGING-CHART SYMPLECTIC ALGORITHM FOR RIGID BODIES AND OTHER HAMILTONIAN SYSTEMS ON MANIFOLDS*

GIANCARLO BENETTIN[†], ANNA MARIA CHERUBINI[‡], AND FRANCESCO FASSÒ[†]

Abstract. We revive the elementary idea of constructing symplectic integrators for Hamiltonian flows on manifolds by covering the manifold with the charts of an atlas, implementing the algorithm in each chart (thus using coordinates) and switching among the charts whenever a coordinate singularity is approached. We show that this program can be implemented successfully by using a splitting algorithm if the Hamiltonian is the sum $H_1 + H_2$ of two (or more) integrable Hamiltonians. Profiting from integrability, we compute exactly the flows of H_1 and H_2 in each chart and thus compute the splitting algorithm on the manifold by means of its representative in any chart. This produces a symplectic algorithm on the manifold which possesses an interpolating Hamiltonian, and hence it has excellent properties of conservation of energy. We exemplify the method for a point constrained to the sphere and for a symmetric rigid body under the influence of positional potential forces.

Key words. symplectic integrators, constrained Hamiltonian systems, rigid body

1. Introduction and description of the method.

Symplectic integrators are currently very popular for Hamiltonian systems, particularly in view of their stability and excellent energy conservation. Since the phase space of a number of Hamiltonian systems of relevant interest (e.g., rigid bodies) is not the Euclidean space $\mathbb{R}^{2n}$, but a symplectic manifold M, symplectic integrators on manifolds are of special importance.

If a manifold does not possess a global system of coordinates, integrations performed using coordinates must necessarily deal with the presence of coordinate singularities. Probably the simplest idea for overcoming this situation is to consider a number of different systems of coordinates which have the singularities in different positions, and hence they form an atlas for M. One then implements an algorithm within each coordinate system and switches from one to the other during the integration whenever a coordinate singularity is approached. A changing-chart method of this kind has indeed been used in early molecular dynamics integrations of diatomic molecules [1] (in which case the manifold M is the cotangent bundle of the two-dimensional sphere), but the adopted algorithm was not symplectic. In fact, as noticed, e.g., in [13], even using a symplectic algorithm in each chart (e.g., a leapfrog) does not necessarily produce an algorithm on the manifold which has the stability and energy conservation of symplectic algorithms.[1]

To our knowledge, no symplectic changing-chart method has ever been developed.

[1] More precisely, of symplectic integrators which possess a global interpolating Hamiltonian; see section 2.

From the (vast) literature on the subject, one receives the impression that the presence of singularities has generally been felt as a serious difficulty for any approach based on the use of local coordinates (e.g., Euler angles in the rigid body case). A variety of alternative "geometric" approaches have thus been developed. A number of them share the common idea of embedding the manifold M in a higher-dimensional space $\mathbb{R}^{2N}$ for some $N > n$, where $2n$ is the dimension of M (see, e.g., [6], [7], [10], [13], [14], [15], [16], [17]); this achieves the goal of obtaining a global parametrization but at the price of introducing more variables. In addition, the confinement to M has to be enforced in some way: for instance, the so called RATTLE algorithm, successfully applied, in particular, to the rigid body, resorts to the use of $2(N-n)$ Lagrange multipliers, so the number of variables to be managed further increases.[2] Moreover, these geometric algorithms are often implicit; i.e., numeric inversions are necessary at each time-step. Nevertheless, in the literature these geometric schemes are generally considered superior to changing-charts methods.

In this article we propose a different point of view; namely, we suggest the following.

(i) It is possible to implement changing-chart symplectic algorithms simply by *choosing the algorithms in the individual charts in such a way that they are the local representatives of a symplectic map on the manifold.* This is indeed enough to ensure, as is crucial, that the trajectories computed in the local charts are the local representatives of trajectories of a symplectic map on the manifold (the "geometric integrator"); all properties of the map are then automatically preserved, up to the round-off errors, by the local algorithms.

(ii) A natural way of implementing this program is by means of the so-called "splitting methods"; moreover, such an implementation ensures the existence on the manifold of the so-called "interpolating Hamiltonian"—a rather crucial fact for symplectic integrators.

(iii) In various situations, this leads to computationally efficient explicit algorithms, which are competitive with other geometric algorithms.

We will discuss the method theoretically in section 2. In addition, in section 3 we will illustrate the method by means of two examples, which are of interest, for instance, in molecular dynamics and in celestial mechanics. The first example is the point constrained to a sphere and subject to conservative forces, for which $M = T^*S^2$. The second is the symmetric rigid body in a positional conservative force field; assuming for the purpose of the discussion that the body has a fixed point, then $M = T^*\mathrm{SO}(3)$. We will use an atlas for the sphere made of two systems of spherical coordinates and an atlas for SO(3) made of two systems of Euler angles.

We now shortly describe the method. We use the following notations: if (M, σ) is a symplectic manifold and $F : M \to \mathbb{R}$ is a smooth function, then we denote by Φ^F_ϵ the map at time ϵ of the flow of the Hamiltonian vector field X_F of F; as is well known, for each ϵ, Φ^F_ϵ is a symplectic diffeomorphism from M to itself. (The vector field X_F is assumed to be complete.)

The splitting methods (see, e.g., [18], [19], [17]) are based on the idea of decomposing the Hamiltonian as the sum of two or more terms, the flows of which are easily computable. If

$$H = H_1 + H_2,$$

[2] For the rigid body, schemes using quaternions [6], [7] require only a normalization of the quaternion, but this seems to destroy symplecticity.

then the map

$$\Psi_\epsilon = \Phi^{H_2}_{\epsilon/2} \circ \Phi^{H_1}_{\epsilon} \circ \Phi^{H_2}_{\epsilon/2} \tag{1.1}$$

is easily seen to be a symplectic map from M to M, which differs from the flow Φ^H_ϵ of H by terms of order ϵ^3. Therefore, Ψ_ϵ is a symplectic algorithm of second order on the manifold. (Higher order splitting methods can be constructed; see [18], [19].) In our application to the two problems mentioned above, we shall take as H_1 and H_2 the kinetic energy and, respectively, the potential energy. Both H_1 and H_2 are then individually integrable, and even more, exact explicit expressions of $\Phi^{H_1}_\epsilon$ and $\Phi^{H_2}_{\epsilon/2}$ in coordinates, actually very manageable ones, are easily written. (H_1 corresponds in one case to the geodesic motion on the sphere, in the other case to the Euler–Poinsot motion of the free rigid body, while in both cases H_2 is independent of momenta and thus trivially integrable.) The fact that $\Phi^{H_1}_\epsilon$ and $\Phi^{H_2}_{\epsilon/2}$ are computed exactly (up to the round-off errors) in each coordinate system automatically fulfills the above requirement (i). In other cases, like the triaxial rigid body, the kinetic energy H_1 is still integrable, but computing $\Phi^{H_1}_\epsilon$ requires handling elliptic functions. In such cases, a further convenient splitting of H_1, leading to more manageable expressions, could be preferable; we shall come back to this point in section 5.

As a final remark, we mention that the use of the splitting algorithm (1.1) to integrate the motion of a (triaxial) rigid body has already been proposed in [17], [16], [15]; the first of these references also contains numerical integrations of rigid body motions. The two approaches, however, though similar for the use of (1.1), differ in the main point; namely, we implement Ψ_ϵ in coordinates (two systems of Euler angles), while the point of view of the mentioned references is that, in order to avoid the coordinate singularities, one should implement the algorithm in a geometric way, specifically, using a Lie–Poisson integrator (coupled with the consideration of either rotational matrices or quaternions for the body orientation).

2. Theoretical description of the method.

The good energy conservation of a class of symplectic algorithms is explained in terms of the existence of an "interpolating Hamiltonian flow." We begin by showing that this is the case for the splitting method on a manifold. In this context, it is important to distinguish between Hamiltonian and locally Hamiltonian flows. (See the remark below for some comments.) Recall that a vector field X on a symplectic manifold (M, σ) is called *Hamiltonian* if the one-form $\sigma(X, \cdot)$ is exact and *locally Hamiltonian* if this one-form is only closed. In the former case, there exists a Hamiltonian function, namely, a function $H : M \to \mathbb{R}$ such that $\sigma(X, \cdot) = -dH$; in the latter case, such functions exist only locally.

By a *one-parameter family of analytic symplectic diffeomorphisms* on an analytic symplectic manifold (M, σ) we mean an analytic map

$$\Psi : I \times M \to M, \qquad (\epsilon, m) \mapsto \Psi_\epsilon(m),$$

where $I \subset \mathbb{R}$ is an interval containing zero, such that $\Psi_0 =$ identity and, for any $\epsilon \in I$, Ψ_ϵ is an analytic symplectic diffeomorphism. An elementary generalization of known results for the Euclidean case $M = \mathbb{R}^{2n}$, $\sigma = \sum_i dp_i \wedge dq_i$, gives the following proposition.

PROPOSITION 1. *Let Ψ_ϵ be a one-parameter family of analytic symplectic diffeomorphisms on a symplectic manifold (M, σ). Then, for any ϵ sufficiently near zero,*

(i) *there exists a locally Hamiltonian ("interpolating") vector field X_ϵ such that*

$$\Psi_\epsilon = \Phi_\epsilon^{X_\epsilon} + \mathcal{O}\big(e^{-1/\epsilon}\big). \tag{2.1}$$

Assume, moreover, that Ψ_ϵ is a composition of a finite number of flows of analytic Hamiltonian vector fields, each acting for a time which depends analytically on ϵ:

$$\Psi_\epsilon = \Phi_{\epsilon_1(\epsilon)}^{F_1} \circ \Phi_{\epsilon_2(\epsilon)}^{F_2} \circ \cdots \circ \Phi_{\epsilon_s(\epsilon)}^{F_s}$$

for analytic functions $\epsilon_j(\epsilon)$, which vanish at $\epsilon = 0$, and analytic functions $F_j : M \to \mathbb{R}$. Then

(ii) *the vector field X_ϵ is Hamiltonian.*

(iii) *If Ψ_ϵ is an algorithm of order $r \geq 1$ for a given Hamiltonian H, that is,*

$$\Psi_\epsilon = \Phi_\epsilon^H + \mathcal{O}(\epsilon^{r+1}),$$

then the Hamiltonian K_ϵ of X_ϵ satisfies

$$K_\epsilon = H + \mathcal{O}(\epsilon^r). \tag{2.2}$$

Proof. First note that all statements are true in the Euclidean case: statements (i) and (iii) are proven, e.g., in [5], while statement (ii) is obvious since $\mathbb{R}^{2n}$ is simply connected. The fact that statements (i) and (iii) remain true on a manifold is seen by observing that, within the quoted proof, X_ϵ and K_ϵ are constructed as formal series, the coefficients of which are commutators of vector fields and Poisson brackets of functions, respectively. Since these objects are intrinsically defined on the manifold (i.e., their local representatives commute with the change of charts), the argument of [5] applies as is to the case of a manifold. Estimates, which allow one going beyond the formal level and obtaining (2.1), are performed locally within each chart. (Analyticity is required for this.)

Now let us prove statement (ii). Consider, for simplicity, the case of the composition of two flows. Then, formally

$$\Phi_{\epsilon_1}^{X_1} \circ \Phi_{\epsilon_2}^{X_2} = \Phi_1^{\epsilon_1 X_1} \circ \Phi_1^{\epsilon_2 X_2} = \Phi_1^X$$

for a vector field X which is given, as a formal series, by the BCH formula. The fact that if X_1 and X_2 are Hamiltonian, then X is also Hamiltonian, not only locally Hamiltonian, is seen by observing that the terms of the BCH series are built up of commutators of X_1 and X_2 and recalling that the commutator of two Hamiltonian vector fields is Hamiltonian. (The Hamiltonian is the Poisson bracket of the Hamiltonians of X_1 and X_2.) The extension to any number of flows is obvious. □

The Hamiltonian K_ϵ is called the *interpolating Hamiltonian* of the algorithm Ψ_ϵ (*Modified Hamiltonian* is also used.) The existence of the interpolating Hamiltonian explains the very good energy conservation of symplectic algorithms. Up to quantities $\mathcal{O}(e^{-1/\epsilon})$, which can easily be made smaller than the round-off even in multiple precision [2] by taking the step-size ϵ small enough, the iteration of the symplectic integrator follows exactly the flow of the nearby vector field X_ϵ. If this vector field is Hamiltonian (not just locally Hamiltonian), then its Hamiltonian K_ϵ is preserved by the algorithm up to an exponentially small error. Accumulation of these extremely small errors produces acceptable overall effects on significantly long integration times.[3]

[3] In *special* situations, the errors on the energy do not accumulate; see [5] and, for numerical results, [2].

$$\begin{tikzcd}
 & M \arrow[dl, "z"'] \arrow[dr, "z'"] & \\
\mathbb{R}^{2n} \arrow[rr, "\mathcal{C}"] \arrow[d, "\psi_\epsilon"] & & \mathbb{R}^{2n} \arrow[d, "\psi'_\epsilon"] \\
\mathbb{R}^{2n} \arrow[rr, "\mathcal{C}"] & & \mathbb{R}^{2n}
\end{tikzcd}$$

FIG. 1. *The local representatives of the algorithm commute with the change of charts.*

Remark. The distinction between the existence of a Hamiltonian interpolating vector field and a locally Hamiltonian one is important, even though so far it has not drawn much attention. (For some results, see [5] and [8].) A locally Hamiltonian interpolating vector field does not ensure energy conservation: any local interpolating Hamiltonian is conserved by the algorithm, but this conservation law might be broken by orbits winding around the manifold. Of course, the problem does not exist in the Euclidean case because of the simple connectedness of $\mathbb{R}^{2n}$. However, simple examples demonstrate that, on a manifold, some condition is necessary to ensure the Hamiltonian character of the interpolating vector field (e.g., $M = \mathbb{R} \times S^1 \ni (I, \varphi)$, $\sigma = dI \wedge d\varphi$, $\Psi_\epsilon(I, \varphi) = (I + \epsilon, \varphi)$).

By Proposition 1, the algorithm Ψ_ϵ on M defined by (1.1) has a global interpolating Hamiltonian $K_\epsilon = H_1 + H_2 + \mathcal{O}(\epsilon^2)$. This fact alone makes clear that, however implemented in local coordinates, this algorithm will exhibit good energy conservation.

For the sake of the discussion, assume that M has a symplectic atlas which consists of just two charts with coordinates $z = (q, p)$ and $z' = (q', p')$. Let $\mathcal{C}$ be the change of chart, so that $z' = \mathcal{C} \circ z$. If $h = h_1 + h_2$ and $h' = h'_1 + h'_2$ are the local representatives of the Hamiltonian $H = H_1 + H_2$ in the two charts,[4] then the local representatives ψ_ϵ and ψ'_ϵ of the map Ψ_ϵ are

$$\psi_\epsilon = \Phi^{h_2}_{\epsilon/2} \circ \Phi^{h_1}_{\epsilon} \circ \Phi^{h_2}_{\epsilon/2}, \qquad \psi'_\epsilon = \Phi^{h'_2}_{\epsilon/2} \circ \Phi^{h'_1}_{\epsilon} \circ \Phi^{h'_2}_{\epsilon/2}.$$

By construction, these two maps commute with the change of chart, i.e.,

$$\mathcal{C} \circ \psi_\epsilon = \psi'_\epsilon \circ \mathcal{C} \tag{2.3}$$

(see Figure 1). It follows that *we can freely switch from one chart to the other and keep following the iteration of the map Ψ_ϵ on the manifold.* In other words, this changing-chart method is an actual implementation of the algorithm (1.1) on the manifold. Note that the coordinate systems used, and the adopted criterion for when to switch

[4] This means that the restriction of H to the first chart equals $h \circ z$, etc. Note that $h = h' \circ \mathcal{C}$ in the intersection of the chart domains.

charts, are completely immaterial: different choices may produce more or less simple and efficient implementations but do not affect the algorithm.[5] The implementations of the changing-chart methods mentioned in the introduction did not satisfy (2.3), and this makes the difference.

In the next section, we illustrate this procedure on the two cases mentioned in the introduction, in which H_1 is the kinetic energy of an integrable system and H_2 is a positional potential. The flow of H_2 is trivially integrated: if $h_2(q)$ is the local representative of H_2 in a chart with coordinates (p,q), then

$$(p,q) \;\mapsto\; \left(p + t\,\frac{\partial h_2}{\partial q}(q), q\right).$$

The local representatives of H_1 depend on both coordinates and momenta, but since H_1 is integrable, in principle one knows the solution in each chart. The crucial step, on which the efficiency of the algorithm relies, is to have an analytical representation of the flow $\Phi_\epsilon^{H_1}$ of the kinetic energy which is suitable for numerical computations.

3. Two examples.

3.1. The point constrained to the sphere.

As a first elementary example, we consider a point constrained to the unit sphere in $\mathbb{R}^3$ subject to positional potential forces. The flow $\Phi_\epsilon^{H_1}$ of the kinetic energy is the geodesic flow on the sphere and is easily written in any system of coordinates. We used two systems of spherical coordinates and the corresponding momenta, that we denote $(\varphi, \theta, p_\varphi, p_\theta)$ and $(\varphi', \theta', p'_\varphi, p'_\theta)$, relative to two orthogonal frames $\{e_x, e_y, e_z\}$ and, respectively, $\{e'_x, e'_y, e'_z\} = \{e_x, -e_z, e_y\}$. The change of charts are given by

$$\begin{cases} \cos\theta = -\sin\theta'\,\sin\varphi', \\ \sin\theta = \sqrt{1-\cos^2\theta}, \\ \cos\varphi = \frac{\sin\theta'\,\cos\varphi'}{\sin\theta}, \\ \sin\varphi = \frac{\cos\theta'}{\sin\theta}, \\ p_\theta = \frac{\cos\theta'\,\sin\varphi'}{\sin\theta}\,p'_\theta + \frac{\cos\varphi'}{\sin\theta\,\sin\theta'}\,p'_\varphi, \\ p_\varphi = -\cos\varphi'\,p'_\theta + \frac{\sin\varphi'\,\cos\theta'}{\sin\theta'}\,p'_\varphi, \end{cases} \qquad \begin{cases} \cos\theta' = \sin\theta\,\sin\varphi, \\ \sin\theta' = \sqrt{1-\cos^2\theta'}, \\ \cos\varphi' = \frac{\sin\theta\,\cos\varphi}{\sin\theta'}, \\ \sin\varphi' = -\frac{\cos\theta}{\sin\theta'}, \\ p'_\theta = -\frac{\cos\theta\,\sin\varphi}{\sin\theta'}\,p_\theta - \frac{\cos\varphi}{\sin\theta\,\sin\theta'}\,p_\varphi, \\ p'_\varphi = \cos\varphi\,p_\theta - \frac{\sin\varphi\,\cos\theta}{\sin\theta}\,p_\varphi. \end{cases}$$

Due to rotational invariance, both the kinetic energy and the geodesic flow have the same expression in the two charts, so we write them down only in the first chart. The kinetic energy is

$$h_1(\varphi, \theta, p_\varphi, p_\theta) = \frac{p_\theta^2}{2} + \frac{p_\varphi^2}{2\sin^2\theta}.$$

The geodesic flow is determined either by integrating Hamilton's equations or just by observing that it consists of a uniform translation along a great circle. Consider the initial datum $(\varphi(0), \theta(0), p_\varphi(0), p_\theta(0)) = (\varphi_0, \theta_0, J, P_0)$ and denote

$$G = \sqrt{P_0^2 + \Big(\frac{J}{\sin\theta_0}\Big)^2}, \qquad \hat{P}_0 = \frac{P_0}{G}, \qquad \hat{J} = \frac{J}{G}\,;$$

[5] In fact, it is not even necessary that the coordinates z and z' be symplectic, even though this is likely to be the simplest choice. If the coordinates are not symplectic, one should repeat the previous argument by considering not the Hamiltonians and their local representatives but the corresponding Hamiltonian vector fields.

G is the norm of the angular momentum and, as p_φ, is an integral of motion. (This is the reason why we do not append the subscript 0 to G and J.) Then the solution $(\varphi(t), \theta(t), p_\varphi(t), p_\theta(t))$ of the system with Hamiltonian h_1 can be written as

$$\begin{pmatrix} \cos\theta(t) \\ \frac{p_\theta(t)}{G}\sin\theta(t) \end{pmatrix} = \begin{pmatrix} \cos Gt & -\sin Gt \\ \sin Gt & \cos Gt \end{pmatrix} \begin{pmatrix} \cos\theta_0 \\ \hat{P}_0 \sin\theta_0 \end{pmatrix},$$

$$\begin{pmatrix} \cos\varphi(t) \\ \sin\varphi(t) \end{pmatrix} = \frac{1}{\sin\theta(t)} \begin{pmatrix} C & -S \\ S & C \end{pmatrix} \begin{pmatrix} \cos\varphi_0 \\ \sin\varphi_0 \end{pmatrix}$$

for

$$\begin{aligned} C &= \sin\theta_0 \, \cos Gt + \hat{P}_0 \, \cos\theta_0 \, \sin Gt, \\ S &= \frac{\hat{J}}{\sin\theta_0} \, \sin Gt. \end{aligned}$$

3.2. The symmetric rigid body. We now consider the symmetric rigid body with a fixed point. (Here symmetric just means that two of the three moments of inertia relative to the fixed point are equal.) Let $\{e_1, e_2, e_3\}$ be an orthogonal frame centered on the body's fixed point with axes oriented like the principal axes of inertia, and let $I_1 = I_2$ and I_3 be the corresponding principal moments of inertia. In order to obtain an atlas for $T^*\mathrm{SO}(3)$, we consider two systems of standard Euler angles (see Figure 2), say, $q = (\varphi, \psi, \theta)$ and $q' = (\varphi', \psi', \theta')$, relative to different spatial frames $\{e_x, e_y, e_z\}$ and, respectively, $\{e'_x, e'_y, e'_z\} = \{e_z, e_x, e_y\}$. These coordinates and their conjugate momenta $p = (p_\varphi, p_\psi, p_\theta)$ and $p' = (p'_\varphi, p'_\psi, p'_\theta)$ are related by the equations

$$\begin{cases} \cos\theta = \sin\theta' \, \sin\varphi', \\ \sin\theta = \sqrt{1 - \cos^2\theta}, \\ \cos\varphi = -\cos\theta' / \sin\theta, \\ \sin\varphi = -\sin\theta' \, \cos\varphi' / \sin\theta, \\ \cos\psi = -(\cos\varphi' \, \sin\psi', \\ \qquad + \cos\theta' \, \sin\varphi' \, \cos\psi') / \sin\theta, \\ \sin\psi = (\cos\varphi' \, \cos\psi' \\ \qquad - \cos\theta' \, \sin\varphi' \, \sin\psi') / \sin\theta, \\ p_\theta = -\frac{\sin\varphi' \cos\theta'}{\sin\theta} p'_\theta, \\ \qquad - \frac{\cos\varphi'}{\sin\theta \sin\theta'} (p'_\varphi + \cos\theta' p'_\psi), \\ p_\varphi = \cos\varphi \, p'_\theta - \frac{\sin\varphi'}{\sin\theta'} (\cos\theta' p'_\varphi + p'_\psi), \\ p_\psi = p'_\psi, \end{cases} \qquad \begin{cases} \cos\theta' = - \sin\theta \, \cos\varphi, \\ \sin\theta' = \sqrt{1 - \cos^2\theta'}, \\ \cos\varphi' = -\sin\theta \sin\varphi / \sin\theta', \\ \sin\varphi' = \cos\theta / \sin\theta', \\ \cos\psi' = -(\sin\varphi \, \sin\psi \\ \qquad - \cos\theta \, \cos\varphi \, \cos\psi) / \sin\theta', \\ \sin\psi' = (\sin\varphi \, \cos\psi \\ \qquad + \cos\theta \, \cos\varphi \, \sin\psi) / \sin\theta', \\ p'_\theta = \frac{\cos\varphi \, \cos\theta}{\sin\theta'} p_\theta \\ \qquad - \frac{\sin\varphi}{\sin\theta \, \sin\theta'} (p_\varphi - \cos\theta \, p_\psi), \\ p'_\varphi = \sin\varphi \, p_\theta \\ \qquad + \frac{\cos\varphi}{\sin\theta} (\cos\theta p_\varphi + p_\psi), \\ p'_\psi = p_\psi. \end{cases}$$

Here too the kinetic energy has the same form in both coordinate systems, precisely

$$h_1(q, p) = \frac{p_\theta^2}{2I_1} + \frac{(p_\varphi - p_\psi \cos\theta)^2}{2I_1 \sin^2\theta} + \frac{p_\psi^2}{2I_3}.$$

The components of the angular momentum along the axes e_z and e_3, namely, p_φ and p_ψ, are constants of motion of the free system; their values will hereafter be denoted J and L, respectively. Also the norm G of the angular momentum vector is constant; one has

$$G = \sqrt{p_\theta^2 + p_\psi^2 + \Big(\frac{p_\varphi - p_\psi \cos\theta}{\sin\theta}\Big)^2}. \tag{3.1}$$

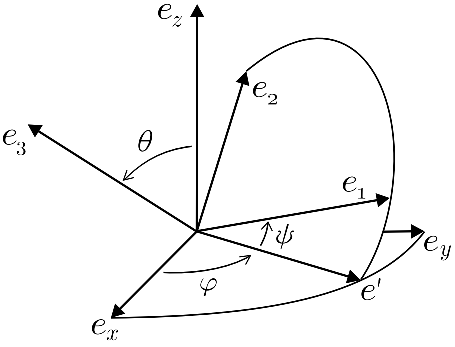

FIG. 2. *The Euler angles φ, ψ, θ. (e' is the unit vector in the direction of $e_z \times e_3$.)*

In the classical textbooks and manuals we consulted, we found the expression of the solution of the Euler–Poinsot system only in special systems of Euler angles with the spatial axis e_z parallel to the angular momentum. Since this is not sufficient for our purposes, we computed the solution in a generic system of Euler angles. (This is elementary in the symmetric case.)

PROPOSITION 2. *Consider an initial datum $(\varphi(0), \psi(0), \theta(0), p_\varphi(0), p_\psi(0), p_\theta(0)) = (\varphi_0, \psi_0, \theta_0, J, L, P_0)$, and let G be the corresponding norm of the angular momentum. Denote*

$$\hat{J} = \frac{J}{G}, \qquad \hat{L} = \frac{L}{G}, \qquad \hat{P}_0 = \frac{\hat{P}_0}{G}, \qquad \Omega = \frac{G}{I_1}, \qquad \Lambda = \frac{I_1 - I_3}{I_1 I_3} L.$$

Then, for all t such that $\sin\theta(t) \neq 0$, the solution of the system of Hamiltonian h_1 is given by

$$\begin{pmatrix} \cos\theta(t) - \hat{J}\hat{L} \\ \frac{p_\theta(t)}{G}\sin\theta(t) \end{pmatrix} = \begin{pmatrix} \cos\Omega t & -\sin\Omega t \\ \sin\Omega t & \cos\Omega t \end{pmatrix} \begin{pmatrix} \cos\theta_0 - \hat{J}\hat{L} \\ \hat{P}_0 \sin\theta_0 \end{pmatrix}, \tag{3.2}$$

$$\begin{pmatrix} \cos\varphi(t) \\ \sin\varphi(t) \end{pmatrix} = \frac{1}{\sin\theta_0 \, \sin\theta} \begin{pmatrix} C(\hat{J},\hat{L}) & S(\hat{J},\hat{L}) \\ -S(\hat{J},\hat{L}) & C(\hat{J},\hat{L}) \end{pmatrix} \begin{pmatrix} \cos\varphi_0 \\ \sin\varphi_0 \end{pmatrix}, \tag{3.3}$$

$$\begin{aligned} \begin{pmatrix} \cos\psi(t) \\ \sin\psi(t) \end{pmatrix} = \frac{1}{\sin\theta_0 \, \sin\theta} & \begin{pmatrix} C(\hat{L},\hat{J}) & S(\hat{L},\hat{J}) \\ -S(\hat{L},\hat{J}) & C(\hat{L},\hat{J}) \end{pmatrix} \\ & \times \begin{pmatrix} \cos\Lambda t & -\sin\Lambda t \\ \sin\Lambda t & \cos\Lambda t \end{pmatrix} \begin{pmatrix} \cos\psi_0 \\ \sin\psi_0 \end{pmatrix}, \end{aligned} \tag{3.4}$$

where

$$\begin{aligned} C(x,y) = {} & y(y - x\cos\theta_0) \\ & + \left[\sin^2\theta_0 - y(y - x\cos\theta_0)\right]\cos\Omega t + \hat{P}_0 \sin\theta_0 \cos\theta_0 \sin\Omega t, \end{aligned} \tag{3.5}$$

$$S(x,y) = (1 - \cos\Omega t)\hat{P}_0 \sin\theta_0 y + (x - y\cos\theta_0)\sin\Omega t. \tag{3.6}$$

A proof of this proposition is given in the appendix.

Remark. If the algorithm is regarded as mapping sine and cosine of the angles at time zero to sine and cosine of the angles at time t, then only four trigonometric functions must be computed, namely, sine and cosine of Ωt and of Λt; all other operations are algebraic (elementary operations and a few square roots). Developing an efficient, accurate algorithm for the symmetric rigid body was the original motivation of this work. We were interested in performing long-time integrations of rigid bodies under generic potential force fields, so as to investigate the presence of the chaotic behavior predicted in the works [3] and [4]. We will publish the results of these integrations somewhere else. We just mention here that the algorithm appeared to be simple, efficient, and stable. Overall, it seemed to perform exceptionally well.

4. Numerical tests and comparisons. Our algorithm exhibits the typical very good conservation of energy of the symplectic algorithms which possess an interpolating Hamiltonian.

The best way of illustrating this fact and of enlightening the mechanism underneath is probably by means of the comparison with a slightly (but crucially) different algorithm. Specifically, we consider within each chart a (generalized) leapfrog, namely, the map $\tilde{\psi}^h_\epsilon = \tilde{\psi}^h_{II} \circ \tilde{\psi}^h_I$, where $\tilde{\psi}^h_I : (q,p) \mapsto (q^I, p^I)$ and $\tilde{\psi}^h_{II} : (q^I, p^I) \mapsto (q^{II}, p^{II})$ are (implicitly) defined by

$$\tilde{\psi}^h_I : \begin{cases} p^I = p - \frac{\epsilon}{2}\frac{\partial h}{\partial q}(p^I, q), \\ q^I = q + \frac{\epsilon}{2}\frac{\partial h}{\partial p}(p^I, q), \end{cases} \qquad \tilde{\psi}^h_{II} : \begin{cases} q^{II} = q^I + \frac{\epsilon}{2}\frac{\partial h}{\partial p}(p^I, q^{II}), \\ p^{II} = p^I - \frac{\epsilon}{2}\frac{\partial h}{\partial q}(p^I, q^{II}). \end{cases} \tag{4.1}$$

The standard leapfrog (or Verlet) algorithm is obtained when $h(q,p)$ is separated, namely, $h(q,p) = h_1(p) + h_2(q)$; in such a case, as we have already mentioned, this algorithm also coincides with the splitting algorithm (1.1). In the two cases considered above, the point on the sphere in polar coordinates and the symmetric rigid body in Euler angles, the Hamiltonians are not separated but the generalized leapfrogs $\tilde{\psi}^h_\epsilon$ and $\tilde{\psi}^{h'}_\epsilon$ in the two charts are explicit anyway.

As is well known, the generalized leapfrog $\tilde{\psi}^h_\epsilon$ in each chart is symplectic, possesses an interpolating Hamiltonian, and differs from Φ^h_ϵ by $\mathcal{O}(\epsilon^3)$. *However, the two generalized leapfrogs do not commute with the change of chart, namely,* $\mathcal{C} \circ \tilde{\psi}^h_\epsilon \neq \tilde{\psi}^{h'}_\epsilon \circ \mathcal{C}$. This means that the two algorithms are not the local representatives of a single algorithm on the manifold. In particular, *the interpolating Hamiltonians of the individual algorithms in the two charts are not the local representatives of a single function on the manifold.* The consequence is that each change of chart introduces a change of order ϵ^2 in the conserved quantity (i.e., the interpolating Hamiltonian of the local algorithm), and this results typically in a progressive drift of the energy proportional to ϵ^2 and to the number of chart changes.[6]

This is illustrated in Figure 3, which refers to the simple case of the spherical pendulum, namely, a heavy point on the sphere; the potential energy in the two charts are $h_2 = \cos\theta$ and $h'_2 = -\sin\theta' \sin\varphi'$. All figures report the relative error in the energy along the same orbit, which has been computed with the splitting algorithm (solid line) and switching between the two generalized leapfrogs (dotted line). The two methods are implemented using the same coordinate systems, the same criterion for switching charts, and the same integration step. The superimposed dots identify the instants at which the chart is switched. In all figures, the initial datum is $(\varphi, \theta, p_\varphi, p_\theta) = (\pi/3, \pi/3, 1.1, 0.35)$ (in the first chart) and the integration step is $\epsilon = 0.05$. Figures 3(a), 3(b), and 3(c) differ only for the total integration time, which equals 50, 400, and 1000 time-steps, respectively. The difference between the two methods is evident: switching charts has no consequence for the splitting algorithm, while it produces accumulation of errors for the pair of generalized leapfrogs.

[6] This mechanism was already observed in [13].

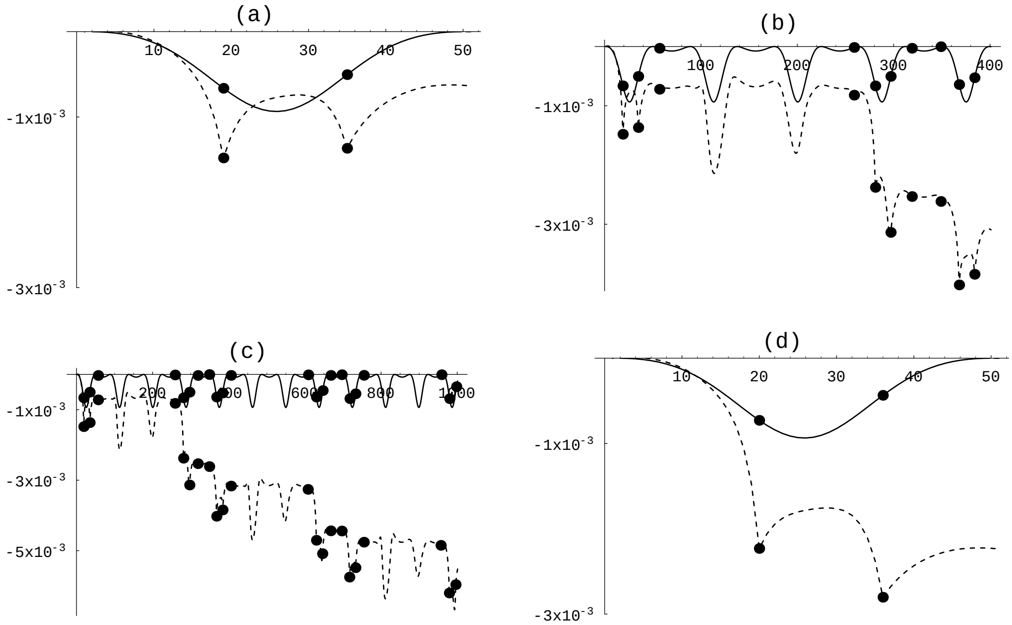

FIG. 3. *Error in the energy along an orbit of the spherical pendulum for our algorithm (solid line) and for a pair of leapfrogs (dotted line). Charts are switched when* $\arcsin\theta$ *reaches* 0.7 *in* (a), (b)*, and* (c)*, and* 0.5 *in* (d).

In Figures 3(a), 3(b), and 3(c), the chart was changed whenever the colatitude θ (or θ') reached the value arcsin(0.7). In Figure 3(d) we used a different criterion for changing charts, so as to force the change of charts at different instants. Specifically, we changed chart when the colatitude reached arcsin(0.5). Comparison with Figure 3(a) indicates that this has a consequence for the pair of generalized leapfrogs, but not for our algorithm, which is completely transparent to the change of charts.

The same behavior is found in the symmetric rigid body. Figure 4 refers to a rigid body with moments of inertia $I_1 = I_2 = 1$ and $I_3 = 2/3$. The potential energy in the two Euler angles charts introduced in the previous section is

$$\begin{aligned} h_2(q,p) &= \sin\theta\cos\varphi + (\sin\theta\cos\psi)^2, \\ h_2'(q',p') &= -\sin\theta'\sin\varphi' + (\sin\varphi\sin\psi - \cos\varphi\cos\psi\cos\theta)^2. \end{aligned}$$

Figures 4(a)–(c) show the energy error on 120 time-steps for the orbit with initial datum $(\varphi,\psi,\theta,p_\varphi,p_\psi,p_\theta) = (0.5,-0.45,\pi/3,2.2,0.8,1.3)$; the integration step is 0.05 in all cases, while the chart is switched when $\sin\varphi$ reaches the values 0.7, 0.5, 0.2, respectively. Figure 4(d) is the same as Figure 4(a) but for a longer integration time.

Remark. Figure 3 indicates that, even within a given chart, the error on the energy is smaller for the splitting algorithm than for the generalized leapfrog. This is largely due to the fact that, within our algorithm, the flow of the kinetic energy is computed exactly, which produces a more stable algorithm. In fact, the leapfrog has a factor $(\sin\theta)^{-3}$ which degrades the precision already at moderate distances from the singularities. The same situation is met with the symmetric rigid body: Figures 4(a)–

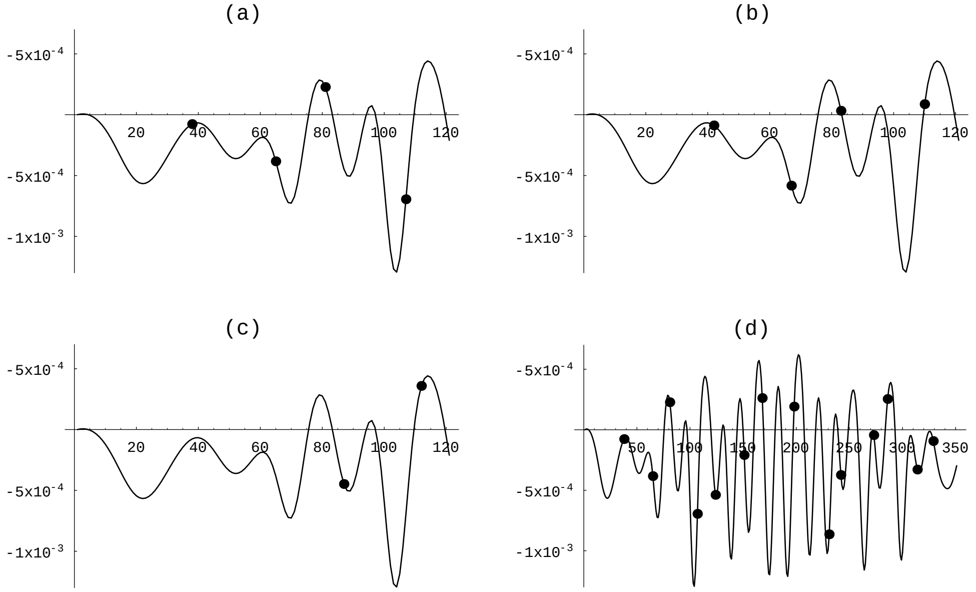

FIG. 4. *Error in the energy along an orbit of the symmetric rigid body in an external potential computed with our algorithm. The chart is switched when* $\arcsin\theta$ *reaches* 0.7 *in* (a) *and* (d)*,* 0.5 *in* (b)*, and* 0.2 *in* (c).

(c) indicate that the energy conservation does not get worse when the singularities are approached (up to arcsin(0.2) in the case of Figure 4(c)). In this case, too, the energy error with a pair of leapfrogs is much bigger.

As a further evidence that the algorithm, though written in coordinates, is nevertheless coordinate independent, let us propose another elementary test. Consider a Lagrange top that is a heavy symmetric rigid body, and let e_g be the unit vector in the direction of gravity. The component of the angular momentum along e_g, that we shall denote m, is then a constant of motion. Quite clearly, if we use a chart of Euler angles, relative to a spatial frame $\{e_x, e_y, e_z\}$ with $e_g = e_z$, then $m = p_\varphi$, and since the Hamiltonian is independent of φ, m is exactly conserved. Now, *since the algorithm commutes with the change of charts, the same must be true,* up to the round-off errors, *in any other chart,* for example, a chart of Euler angles relative to a spatial frame $\{e_x, e_y, e_z\}$ such that e_g has no special direction. This is precisely what we found numerically: working in double precision, for several choices of e_g and of the initial data, the error we found in m, after many thousands of time-steps and hundreds of chart changes, was at most of order 10^{-13}, independently of the step-size, and reduced to 10^{-30} in quadruple precision. Such an especially good conservation law is not obvious, for a second order algorithm, and reflects in an essential way its geometrical nature, while the implementation in coordinates is irrelevant.

5. Conclusions. In our opinion, the method described here has potentially many advantages and is worthy of further consideration.

A crucial fact which is missing in the present analysis is a comparison with other methods. We made some comparisons with RATTLE in the case of the point on the sphere and found that the two algorithms perform in a comparable way. For the same step-size, RATTLE was somewhat faster (by about a factor 1.5 to 2, depending on the potential), but our algorithm was more stable. (The same energy conservation was obtained, typically, with a step-size bigger by a factor 1.5.)

As is clear, this comparison is not conclusive. In the case of the rigid body, a thorough comparison with other methods (RATTLE [14], [10], Lie–Poisson integrators [17], [15], [16], and the methods of [11], [12]) is necessary and is in our programs. As already remarked, in the case of the rigid body, RATTLE is not explicit and the codimension $2(N-n)$ is 12; hence, the algorithm must handle 18 variables and in addition to a total of 12 Lagrange multipliers.[7] Our algorithm instead uses only six variables, and for a symmetric rigid body it is explicit and fully manageable, requiring only the evaluation of four trigonometric functions at each time-step. We expect in this case for our algorithm to be faster. (We guess significantly faster.)

The situation is more delicate for the triaxial rigid body. Since the representation of the Euler–Poinsot flow in Euler angles uses elliptic functions, the exact integration of the flow of the kinetic energy might significantly lengthen the integration time. Alternatives are based on the further splitting of the Euler–Poinsot Hamiltonian as the sum of two or more integrable Hamiltonians, each of which is (more) easily integrated. This approach was already proposed and used in [17], [15], [16], though, as already remarked, not using coordinates. Convenient splittings of the Euler–Poinsot system are expected to produce quite manageable algorithms with good (perhaps slightly worse) stability. A careful analysis in our opinion is necessary to evaluate the different possibilities.

We prefer to leave these tests and comparisons to a dedicated work. In addition to such tests, of course, it is also important to experiment with the performance of the algorithm in concrete problems, especially when accuracy is important. As we have already remarked in section 3, we are presently working on the symmetric rigid body in order to evaluate the degree of optimality of some previous perturbative studies; such an investigation is numerically delicate, but the preliminary results are rather satisfying. Other studies, for example in molecular dynamics, would be of great interest.

In this regard, we should mention a further positive feature of the splitting method. The estimate (2.2) on the interpolating Hamiltonian given in Proposition 1 can be further detailed: $H-K_\epsilon$ is in fact of the order of ϵ^r times the biggest of (some norm of) the Poisson brackets $\{F_i,F_j\}$, $i,j=1,\dots,s$. Now consider the case in which one has a nearly integrable Hamiltonian H, say,

$$H = H_1 + \mu H_2, \qquad \mu \ll 1.$$

If one can integrate exactly the flow of H_1 and H_2, then it is possible to use the second order splitting algorithm $\Phi^{H_2}_{\epsilon/2}\circ\Phi^{H_1}_{\epsilon}\circ\Phi^{H_2}_{\epsilon/2}$. In this case, the interpolating Hamiltonian gets the form

$$K_\epsilon = H_1 + \mu\big[H_2 + \mathcal{O}(\epsilon^2)\big];$$

i.e., the correction due to the algorithm remains small with respect to the perturbation (as is obviously necessary in a perturbation problem) for small ϵ, with no need to

[7] There are formulations of RATTLE which use fewer coordinates (e.g., the four Euler parameters; see [9]), so that these numbers can be drastically reduced, but to our knowledge they are not symplectic.

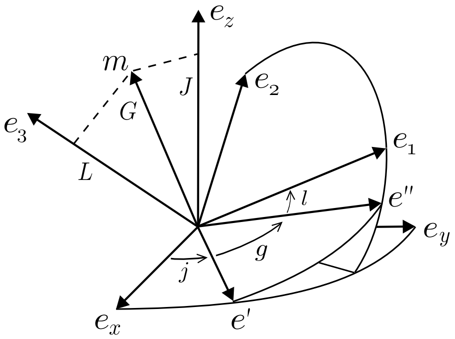

FIG. 5. *The action-angle coordinates of the symmetric Euler–Poinsot system; m is the angular momentum, and e' and e'' are unit vectors in the directions of $e_z \times m$ and, respectively, of $m \times e_3$.*

reduce ϵ dependently on μ. This fact is especially useful if one is interested in exploring numerically the case $\mu \to 0$. Unfortunately, in the case of a triaxial body, this positive feature is destroyed by a splitting of the Euler–Poinsot Hamiltonian, so for very small μ the exact integration of H_1 via elliptic functions could become competitive.

Anyhow, beyond these special applications, it seems to us that the possibility described here of constructing changing-chart symplectic algorithms on manifolds, just by implementing splitting algorithms in coordinates, has a character of simplicity which makes it of interest by itself, even independently of its performance in specific situations.

Appendix. Proof of Proposition 2. Probably the simplest way of obtaining the expressions for the flow of the symmetric Euler–Poinsot system given in Proposition 2 is by referring to the action-angle coordinates (G, L, J, g, l, j) of the system in which the flow is trivial. These coordinates, which are also known as Andoyer or Deprit coordinates, are defined as follows: G, L, and J are, respectively, the length, the component along the symmetry axis, and the component along the z-axis of the angular momentum vector; their three conjugate angles g, l, and j are defined as shown in Figure 5, where e_1, e_2, e_3 is an orthonormal frame fixed in the body, with e_3 along the symmetry axis. Clearly, these coordinates are singular when the angular momentum is aligned with either e_3 or e_z, namely, for either $G = \pm L$ or $G = \pm J$.

The advantage of the action-angle coordinates is that the flow of the symmetric Euler–Poinsot system is linear in these coordinates. In fact, the Hamiltonian is

$$H(G, L) = \frac{1}{2I_1}\, G^2 + \frac{I_1 - I_3}{2I_1 I_3}\, L^2,$$

and hence the flow is given by G, L, J, j constant and

$$g(t) = g_0 + \Omega\, t, \qquad l(t) = l_0 + \Lambda\, t, \tag{A.1}$$

where $\Omega = G/I_1$ and $\Lambda = \frac{I_1 - I_3}{2I_1 I_3} L$. Obviously, this solution is valid as long as the system stays away from the singularities of the action-angle coordinates; this limitation will be eliminated below.

In order to prove the proposition, we convert the flow written in action-angle coordinates to Euler angles. The formulas relating the Euler angles to the action-angle coordinates which are needed here are as follows:

$$G = \sqrt{p_\theta^2 + p_\psi^2 + \Big(\frac{p_\varphi - p_\psi \cos\theta}{\sin\theta}\Big)^2}, \qquad L = p_\psi, \qquad J = p_\varphi, \tag{A.2}$$

$$\cos g = \frac{\hat J\,\hat L - \cos\theta}{\sqrt{1-\hat J^2}\sqrt{1-\hat L^2}}, \qquad \sin g = -\,\frac{p_\theta \sin\theta}{G\sqrt{1-\hat J^2}\sqrt{1-\hat L^2}}, \tag{A.3}$$

$$j = \varphi + \alpha, \qquad l = \psi + \beta, \tag{A.4}$$

where $\hat J = J/G$, $\hat L = L/G$, the angle α satisfies

$$\cos\alpha = \frac{\hat L - \hat J\cos\theta}{\sin\theta\sqrt{1-\hat J^2}}, \qquad \sin\alpha = \frac{p_\theta\,\sin\theta}{G\sqrt{G^2-J^2}},$$

and the angle β satisfies these same expressions with $\hat J$ and $\hat L$ interchanged. These equalities are easily proven. (See, e.g., [3], where a few of them are proven.) In what follows, we use the notation

$$R_\delta = \begin{pmatrix} \cos\delta & -\sin\delta \\ \sin\delta & \cos\delta \end{pmatrix}.$$

Equations (A.3) and (A.1) together imply

$$\begin{pmatrix} \hat J\hat L - \cos\theta(t) \\ \frac{p_\theta(t)}{G}\sin\theta(t) \end{pmatrix} = R_{\Omega t}\begin{pmatrix} \hat J\hat L - \cos\theta(t) \\ \frac{p_\theta(0)}{G}\sin\theta(0) \end{pmatrix},$$

namely, (3.2). Next, since $j = \varphi + \alpha$, one has

$$\begin{pmatrix} \cos\varphi(t) \\ \sin\varphi(t) \end{pmatrix} = R_{\alpha(t)}\begin{pmatrix} \cos j_0 \\ \sin j_0 \end{pmatrix} = R_{\alpha(t)}\,R_{-\alpha(0)}\begin{pmatrix} \cos\varphi_0 \\ \sin\varphi_0 \end{pmatrix};$$

a trivial although somewhat lengthy, computation shows that the product of the two matrices can be written in the form given in (3.3). Finally,

$$\begin{pmatrix} \cos\psi(t) \\ \sin\psi(t) \end{pmatrix} = R_{\beta(t)}\begin{pmatrix} \cos l(t) \\ \sin l(t) \end{pmatrix} = R_{\beta(t)}\,R_{-\beta(0)}\,R_{\Lambda t}\begin{pmatrix} \cos\psi_0 \\ \sin\psi_0 \end{pmatrix},$$

where we have used the fact that planar rotations commute; (3.4) is now obtained by observing that $R_{\beta(t)}R_{-\beta(0)}$ equals $R_{\alpha(t)}R_{-\alpha(0)}$ after switching $\hat J$ and $\hat L$.

In this way, we have proven the expressions (3.3)–(3.4) for times t such that the solution remains within the domain of the action-angle coordinates for all times $0 < t' < t$. However, analyticity in t of the solution ensures that these expressions are in fact valid for all t such that $\sin\theta(t) \neq 0$. This remains true (continuity is sufficient for this) even if $\sin\theta$ had vanished at some earlier time $t' < t$.

Acknowledgments. We wish to thank Ben Leimkuhler and Massimiliano Guzzo for useful discussions.

THE METHOD OF REGULARIZED STOKESLETS[*]

RICARDO CORTEZ[†]

Abstract. A numerical method for computing Stokes flows in the presence of immersed boundaries and obstacles is presented. The method is based on the smoothing of the forces, leading to regularized Stokeslets. The resulting expressions provide the pressure and velocity field as functions of the forcing. The latter expression can also be inverted to find the forces that impose a given velocity boundary condition. The numerical examples presented demonstrate the wide applicability of the method and its properties. Solutions converge with second-order accuracy when forces are exerted along smooth boundaries. Examples of segmented boundaries and forcing at random points are also presented.

Key words. Stokes flow, immersed boundaries

1. Introduction.

The numerical method presented here is for the computation of two- and three-dimensional Stokes flows driven by external forcing. The forces are applied on volumes or along boundaries, which may be curves, segments, or sets of disconnected points. In this way, the method applies to moving interfaces, elastic membranes interacting with a fluid, or flows through an array of fixed obstacles.

Stokes flows are of interest in many physical applications, particularly those in which the relevant length scales are extremely small or the fluid is extremely viscous. Many such applications emerge from biology, including the locomotion of bacteria and other cells, flagellated microorganisms, and flows in small capillaries. Other applications are the study of free surfaces, such as bubble motion, and flows around impurities or through a porous medium, which may be modeled as a collection of point obstacles for dilute cases.

The steady Stokes equations in two or three dimensions are

$$\mu\Delta\mathbf{u} = \nabla p - \mathbf{F}, \tag{1}$$

$$\nabla\cdot\mathbf{u} = 0, \tag{2}$$

where μ is the fluid viscosity, p is the pressure, $\mathbf{u}$ is the velocity, and $\mathbf{F}$ is force. A fundamental solution of these equations is called a *Stokeslet*, and it represents the velocity due to a concentrated external force acting on the fluid at a single point [32, 34, 1, 25]. Other, more singular solutions can also be derived from the Stokeslet by differentiation. Many important models have been created from the superposition of these fundamental solutions. Examples are analyses of flagellar motions [17, 16, 24]; the beating motion of cilia [4]; flows between plates, inside cylinders, or in periodic geometries [26, 27, 15, 33]; and slender body theories [6, 20, 23, 13]. Many of these analyses make use of images to enforce boundary conditions on the surface of spheres or planes.

The singularity in the Stokeslet is proportional to $1/r$ in three dimensions and $\log(r)$ in two dimensions. Consequently, when forces are concentrated on surfaces embedded in $\mathbb{R}^3$ (curves in $\mathbb{R}^2$), the expression for velocity is integrable and the flow is bounded in the vicinity of the surfaces. Most of the works cited above rely on this fact and the smoothness of the surfaces to get final expressions for the fluid velocity.

When the forces are concentrated along curves in $\mathbb{R}^3$ (points in $\mathbb{R}^2$) or when surfaces are not smooth, the situation is more difficult because the velocity formula is singular. One technique for dealing with this problem is to desingularize the expressions by introducing a small cutoff parameter in the kernels in order to regularize them. This approach has been extremely useful for the modeling of vortex motion [7, 3, 21, 14], interface motion in inviscid fluids [5, 35, 10, 8, 36], and other processes [11, 9, 12]. In all of these applications, the errors involved have been analyzed extensively and are well understood.

Our approach here is to consider the forces to be applied over a small ball, where they vary smoothly from a maximum value at the center to zero on its surface, rather than being concentrated at points (as Dirac measures). The radius of the support of the forces is a numerical parameter that can be controlled independently from any boundary discretization. Sometimes the radius of the ball is infinite, but the forces decay fast away from the center. From this starting point, expressions for the pressure and velocity due to this regularized force are derived. These expressions are bounded in any bounded set and differ only from the standard Stokeslet near the points where the forces are exerted. The resulting method is applicable to any situation in which forces drive the motion, whether they are concentrated along interfaces or points. This gives the method wide applicability. The derivation of the expressions is presented in section 2 for radially symmetric regularizations and a specific example is presented in detail. Section 3 contains several numerical examples with particular focus on the performance of the method. The case of a smooth closed boundary in $\mathbb{R}^2$ is further developed in section 4, where the velocity expressions can be written in terms of single and double layer potentials. Recent work by Beale and Lai [2] is used to achieve second-order accuracy everywhere. The final section contains concluding remarks and future directions.

2. Equations.

We first consider the generic situation in which the forces are spread over a small ball centered at the points $\mathbf{x}_0$. The force is given by

$$\mathbf{F}(\mathbf{x}) = \mathbf{f}_0\ \phi_\epsilon(\mathbf{x} - \mathbf{x}_0), \tag{3}$$

where ϕ_ϵ is a radially symmetric smooth function with the property that $\int \phi_\epsilon(\mathbf{x})d\mathbf{x} = 1$. Examples of these functions, called *blobs* or *cutoffs*, are

$$\text{in } \mathbb{R}^2: \qquad \phi_\epsilon(\mathbf{x}) = \frac{1}{\pi\epsilon^2}e^{-|\mathbf{x}|^2/\epsilon^2} \quad \text{and} \quad \phi_\epsilon(\mathbf{x}) = \frac{3\epsilon^3}{2\pi(|\mathbf{x}|^2+\epsilon^2)^{5/2}},$$

$$\text{in } \mathbb{R}^3: \qquad \phi_\epsilon(\mathbf{x}) = \frac{3}{4\pi\epsilon^3}e^{-|\mathbf{x}|^3/\epsilon^3} \quad \text{and} \quad \phi_\epsilon(\mathbf{x}) = \frac{15\epsilon^4}{8\pi(r^2+\epsilon^2)^{7/2}}.$$

A typical blob is displayed in Figure 1. The graph shows the same blob with two different values of the parameter ϵ, which controls the width, or spreading. A tighter function (smaller ϵ) must necessarily be taller for the total integral to be 1. In the limit $\epsilon \to 0$, the blob approaches a Dirac delta.

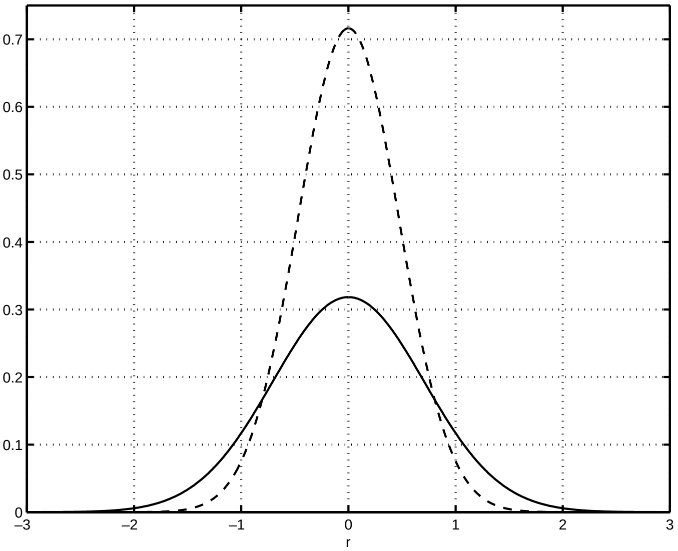

FIG. 1. *Typical blob for two different values of ϵ.*

To derive the solution of the problem in (1)–(2) in the case when the force is given by (3), we will use the following definitions. Let

$$G_\epsilon(\mathbf{x}) \text{ be the solution of } \Delta G_\epsilon = \phi_\epsilon(\mathbf{x}) \text{ in infinite space,}$$
$$B_\epsilon(\mathbf{x}) \text{ be the solution of } \Delta B_\epsilon = G_\epsilon(\mathbf{x}) \text{ in infinite space.}$$

The function $G_\epsilon(\mathbf{x})$ is a smooth approximation of the Green's function

$$\text{in } \mathbb{R}^2\text{: } G(\mathbf{x}) = \frac{1}{2\pi}\ln(|\mathbf{x}|), \qquad \text{in } \mathbb{R}^3\text{: } G(\mathbf{x}) = \frac{-1}{4\pi|\mathbf{x}|} \tag{4}$$

for $|\mathbf{x}| > \epsilon$. However, for small values of $|\mathbf{x}|$, the function G_ϵ is bounded. Similarly, $B_\epsilon(\mathbf{x})$ is smooth and approximates

$$\text{in } \mathbb{R}^2\text{: } B(\mathbf{x}) = \frac{|\mathbf{x}|^2}{8\pi}[\log(|\mathbf{x}|) - 1], \qquad \text{in } \mathbb{R}^3\text{: } B(\mathbf{x}) = \frac{-|\mathbf{x}|}{8\pi}, \tag{5}$$

which is the solution of the biharmonic equation $\Delta^2 B(\mathbf{x}) = \delta(\mathbf{x})$.

Taking the divergence of (1) and using (2) we find that the pressure satisfies

$$\Delta p = \nabla \cdot \mathbf{F},$$

which gives the particular solution

$$p = \mathbf{f}_0 \cdot \nabla G_\epsilon.$$

Now we use this expression to rewrite the equation for $\mathbf{u}$ as $\mu\Delta\mathbf{u} = (\mathbf{f}_0 \cdot \nabla)\nabla G_\epsilon - \mathbf{f}_0\, \phi_\epsilon$, whose particular solution is

$$\mu\mathbf{u}(\mathbf{x}) = (\mathbf{f}_0 \cdot \nabla)\nabla B_\epsilon(\mathbf{x} - \mathbf{x}_0) - \mathbf{f}_0 G_\epsilon(\mathbf{x} - \mathbf{x}_0).$$

This might be referred to as a *regularized Stokeslet* velocity.

If there are N forces, $\mathbf{f}_k$, centered at points $\mathbf{x}_k$, the pressure and velocity are given by

$$p(\mathbf{x}) = \sum_{k=1}^{N} \mathbf{f}_k \cdot \nabla G_\epsilon(\mathbf{x}-\mathbf{x}_k), \tag{6}$$

$$\mathbf{u}(\mathbf{x}) = \mathbf{U}_o + \frac{1}{\mu}\sum_{k=1}^{N} \{(\mathbf{f}_k\cdot\nabla)\nabla B_\epsilon(\mathbf{x}-\mathbf{x}_k) - \mathbf{f}_k G_\epsilon(\mathbf{x}-\mathbf{x}_k)\}, \tag{7}$$

where we have added a constant flow $\mathbf{U}_o$ to be determined shortly. The functions G_ϵ and B_ϵ are completely determined by the blob used. They are radially symmetric just like their singular counterparts. Consequently, the velocity expression can be modified using the formulas (for $r = |\mathbf{x}|$)

$$\nabla B_\epsilon = B_\epsilon{}'(r)\frac{\mathbf{x}}{r} \quad \text{and} \quad (\mathbf{f}\cdot\nabla)\nabla B_\epsilon = \mathbf{f}\,\frac{B_\epsilon{}'(r)}{r} + (\mathbf{f}\cdot\mathbf{x})\mathbf{x}\left[\frac{rB_\epsilon{}''(r) - B_\epsilon{}'(r)}{r^3}\right],$$

which yield for $r_k = |\mathbf{x}-\mathbf{x}_k|$

$$p(\mathbf{x}) = \sum_{k=1}^{N} [\mathbf{f}_k\cdot(\mathbf{x}-\mathbf{x}_k)]\left[\frac{G_\epsilon{}'(r_k)}{r_k}\right], \tag{8}$$

$$\begin{aligned}\mathbf{u}(\mathbf{x}) = \mathbf{U}_o + \frac{1}{\mu}\sum_{k=1}^{N}\Bigg\{&\mathbf{f}_k\left[\frac{B_\epsilon{}'(r_k)}{r_k} - G_\epsilon(r_k)\right] \\ &+ [\mathbf{f}_k\cdot(\mathbf{x}-\mathbf{x}_k)](\mathbf{x}-\mathbf{x}_k)\left[\frac{r_kB_\epsilon{}''(r_k) - B_\epsilon{}'(r_k)}{r_k^3}\right]\Bigg\}.\end{aligned} \tag{9}$$

In two dimensions, one can use (4)–(5) to check that $B'(r)/r - G(r) = -G(r)/2 - 1/8\pi$, so one can choose $\mathbf{U}_o = \sum_k \mathbf{f}_k/8\pi\mu$ in order to eliminate this remaining constant flow. In three dimensions, one can simply let $\mathbf{U}_o = \mathbf{0}$.

The method of regularized Stokeslets uses (8)–(9) to find the velocity induced by given forces. One important property of this formulation is that the flow given by (7) satisfies the incompressibility constraint $\nabla\cdot\mathbf{u} = 0$ analytically everywhere. This important property is key in the conservation of fluid volumes bounded by elastic membranes.

2.1. Deriving G_ϵ and B_ϵ. Since ϕ_ϵ is radially symmetric and $\Delta G_\epsilon = \phi_\epsilon$, we have that

$$\Delta G_\epsilon = \frac{1}{r}[rG_\epsilon{}'(r)]' = \phi_\epsilon(r)$$

and

$$G_\epsilon{}'(r) = \frac{1}{r}\int_0^r s\ \phi_\epsilon(s)ds.$$

After integrating once more, we obtain $G_\epsilon(r)$. Similarly,

$$\frac{1}{r}[rB_\epsilon{}'(r)]' = G_\epsilon(r)$$

so that $B_\epsilon(r)$ can be found in the same way.

2.1.1. A specific choice of blob in two dimensions. We present a concrete example of the regularized Stokeslet method by deriving the two-dimensional pressure and velocity formulas for the specific blob

$$\phi_\epsilon(\mathbf{x}) = \frac{3\epsilon^3}{2\pi(|\mathbf{x}|^2+\epsilon^2)^{5/2}}.$$

The corresponding regularized Green's function is

$$G_\epsilon(r) = \frac{1}{2\pi}\left[\ln\left(\sqrt{r^2+\epsilon^2}+\epsilon\right) - \frac{\epsilon}{\sqrt{r^2+\epsilon^2}}\right]$$

and

$$B_\epsilon{}'(r) = \frac{1}{8\pi}\left[2r\ln\left(\sqrt{r^2+\epsilon^2}+\epsilon\right) - r - \frac{2r\epsilon}{\sqrt{r^2+\epsilon^2}+\epsilon}\right].$$

With these functions we can write the final expressions to be used in the numerical method

$$p(\mathbf{x}) = \sum_{k=1}^{N}\frac{1}{2\pi}[\mathbf{f}_k\cdot(\mathbf{x}-\mathbf{x}_k)]\left[\frac{r_k^2+2\epsilon^2+\epsilon\sqrt{r_k^2+\epsilon^2}}{\left(\sqrt{r_k^2+\epsilon^2}+\epsilon\right)(r_k^2+\epsilon^2)^{3/2}}\right], \tag{10}$$

$$\begin{aligned}\mathbf{u}(\mathbf{x}) = \sum_{k=1}^{N}\frac{-\mathbf{f}_k}{4\pi\mu}&\left[\ln\left(\sqrt{r_k^2+\epsilon^2}+\epsilon\right) - \frac{\epsilon\left(\sqrt{r_k^2+\epsilon^2}+2\epsilon\right)}{\left(\sqrt{r_k^2+\epsilon^2}+\epsilon\right)\sqrt{r_k^2+\epsilon^2}}\right]\\ &+\frac{1}{4\pi\mu}[\mathbf{f}_k\cdot(\mathbf{x}-\mathbf{x}_k)](\mathbf{x}-\mathbf{x}_k)\left[\frac{\sqrt{r_k^2+\epsilon^2}+2\epsilon}{\left(\sqrt{r_k^2+\epsilon^2}+\epsilon\right)^2\sqrt{r_k^2+\epsilon^2}}\right],\end{aligned} \tag{11}$$

where $r_k = |\mathbf{x}-\mathbf{x}_k|$.

One can verify that these formulas are consistent with the standard Stokeslet expressions for the case of a Dirac delta distribution of forces. Taking the limit $\epsilon \to 0$ in (10)–(11), we obtain the well-known formulas (in $\mathbb{R}^2$)

$$p(\mathbf{x}) = \sum_{k=1}^{N}\frac{[\mathbf{f}_k\cdot(\mathbf{x}-\mathbf{x}_k)]}{2\pi r_k^2}, \tag{12}$$

$$\mathbf{u}(\mathbf{x}) = \sum_{k=1}^{N}\frac{-\mathbf{f}_k}{4\pi\mu}\ln(r_k) + [\mathbf{f}_k\cdot(\mathbf{x}-\mathbf{x}_k)]\,\frac{(\mathbf{x}-\mathbf{x}_k)}{4\pi\mu r_k^2}. \tag{13}$$

Notice that (13) is singular at the point where the force is centered. When the sum is replaced by an integral, the velocity expression is generally not problematic when the forces are defined along smooth closed curves, since the kernel is integrable. The same is not true for the pressure which typically displays discontinuities across boundaries. A much different scenario is when the forces are defined at disconnected points, not closed curves. In this case, (12)–(13) cannot be interpreted as discretizations of integrals but simply as the superposition of singular solutions. The singularities in these formulas make the Stokeslet expression somewhat impractical for computation, since

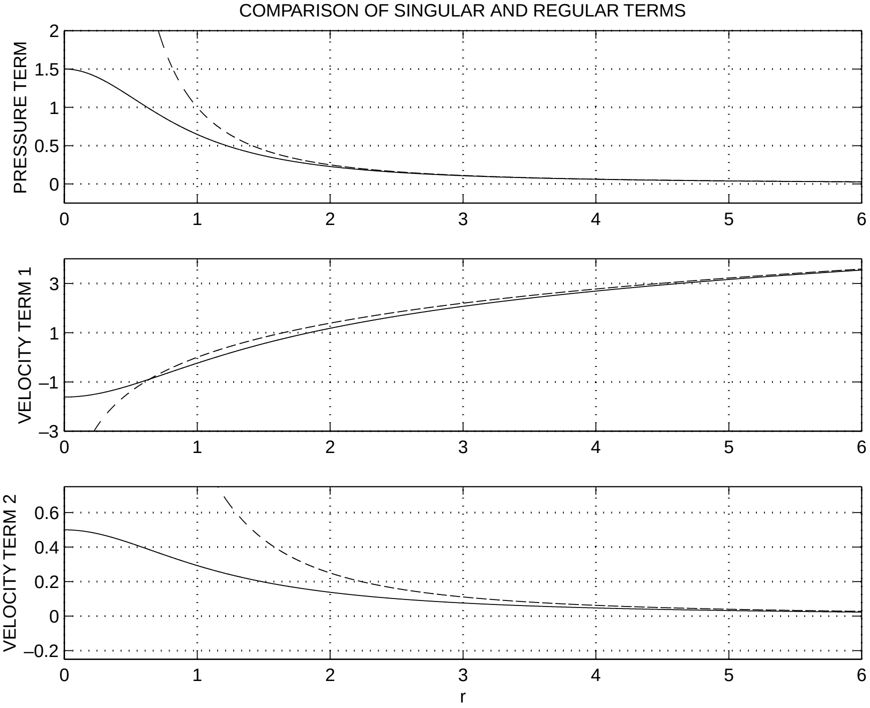

Fig. 2. *Comparison of the radial factors (in brackets) in* (10)–(11) *shown by solid lines. The regularization parameter was set to* $\epsilon = 1$. *The dashed lines are the corresponding singular terms in the Stokeslet formulas* (12)–(13).

the evaluation of the expression at a point very close to an $\mathbf{x}_k$ would lead to extremely large velocities. The regularization in (10)–(11) provides the necessary stability.

A comparison of the terms in brackets in (10)–(11) for $\epsilon = 1$ is shown in Figure 2. The smooth functions eliminate the singularity but approach asymptotically the Stokeslet expressions for $r \gg \epsilon$. In practice, the value of ϵ would be of the same order of magnitude as the particle separation in the spatial discretizations.

2.2. Finding the forces from the velocities. The numerical method derived so far can be used directly to compute the flow due to given forces. For example, elastic membranes interacting with a fluid exert forces given in terms of their configuration, which can be computed from the current position of the membrane. There are situations when the velocity of a given body is known and one is interested in finding the forces that yield that flow. Equation (9) can be used to impose velocity boundary conditions on the surface of a body. One can write, for $i = 1, \ldots, N$, the system of equations

$$\mathbf{u}(\mathbf{x}_i) = \sum_{j=1}^{N} M_{ij}(\mathbf{x}_1, \ldots, \mathbf{x}_N)\ \mathbf{f}_j$$

or, as a matrix equation,

$$\mathcal{U} = \mathcal{M}\mathcal{F}, \tag{14}$$

where, in two dimensions, $\mathcal{U}$ and $\mathcal{F}$ are $2N \times 1$ vectors and $\mathcal{M}$ is $2N \times 2N$. Generally, the matrix $\mathcal{M}$ is not invertible. This is most easily seen for the case of a closed membrane surrounding the fluid. An arbitrary constant can be added to the normal component of the forces, causing a change in the pressure but not in the velocities because of the incompressibility of the fluid. Fortunately, any solution of the system is acceptable in the present context so that one can add the constraint that the normal component of the forces sum to zero or simply find any solution of the system via an iterative process. In this paper, we use GMRES with zero initial guess.

In steady flow problems or in situations where the geometry of the body is fixed, the matrix and any required factorization need be computed only once. In problems of moving interfaces, the matrix must be rebuilt at every time step.

3. Numerical examples.

3.1. Example 1: Flow past a cylinder. As a simple numerical experiment, consider the classical example of a circular cylinder of radius a moving at a constant speed $(1,0)$. The exact solution is given by a combination of a Stokeslet and a dipole at the origin (see [1, p. 245]):

$$\mathbf{u}(\mathbf{x}) = \frac{-\mathbf{f}_o}{8\pi}\left(2\ln|\mathbf{x}| - a^2/|\mathbf{x}|^2\right) + \frac{(\mathbf{f}_o\cdot\mathbf{x})\mathbf{x}}{4\pi|\mathbf{x}|^2}\left(1 - a^2/|\mathbf{x}|^2\right)$$

with

$$\mathbf{f}_o = \frac{8\pi}{1-2\ln(a)}\begin{pmatrix}1\\0\end{pmatrix}.$$

Note that the velocity is unbounded as $|\mathbf{x}| \to \infty$, consistent with two-dimensional flow due to a nonzero net force (Stokes's paradox). However, the solution is valid in a region containing the cylinder.

To compute the solution with the numerical method, we discretize the circle with N particles, set the velocity at each point to $(1,0)$, and find a vector of forces that solves the system in (14). Once the forces are known, we use (11) to find the velocity on a grid, where the exact solution is also computed for comparison. The parameters used in this example are $a = 0.25$, $N = 160$ (with $\Delta s = 2\pi a/N$), and $\epsilon = 0.25\Delta s$. Figure 3 shows the contours of the two components of velocity. Each plot shows the analytic solution (solid) and the computed solution (dashed). The velocities at the boundary points are computed with the accuracy of the iteration solver for the forces; in this case, the velocities are within 10^{-15} of their intended value.

The solutions satisfy $\|\mathbf{u}-\mathbf{u}_{exact}\|_\infty \leq 2.6\times10^{-3}$ for the parameters used, although the error in the velocities is largest near the cylinder and decays nearly as $\sim |\mathbf{x}|^{-2}$ away from the boundary. In section 4, we explain how to improve on this solution. The regularization parameter ϵ is taken to be proportional to the discretization size Δs, where the proportionality constant depends on the blob ϕ_ϵ and on the particular application. In our experience, this constant is typically less than 1.

3.2. Example 2: Flow past fixed obstacles. As a second example, we consider the problem of a uniform background flow around fixed line obstacles. In this problem, the boundaries that exert forces on the fluid are not closed curves; they are disconnected line segments as shown in Figure 4. The background flow is $(1,0)$ and two fixed line obstacles of different lengths are placed at different angles relative to the flow. The boundaries were discretized with 45 particles $\mathbf{x}_k$ (26 on the top segment and 19 on the bottom one) separated by a distance $\Delta s = 0.00447$, and the regularization parameter was set to $\epsilon = \Delta s/2$, although the solution is not very sensitive to this choice.

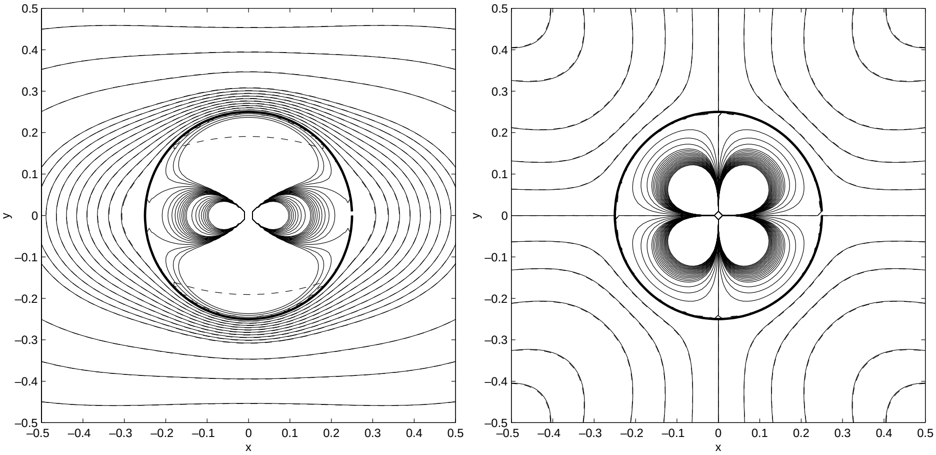

FIG. 3. *Velocity contours of the flow due to a circular cylinder of radius* $a = 0.25$ *moving with velocity* $(1, 0)$*. The left graph compares* u *in* (11) *(dashed) and the exact solution (solid). The right graph compares* v *in the same way.*

In this case, the forces on the boundaries must cancel the background flow at the $\mathbf{x}_k$'s, so the left-hand side of (14) was set to velocities corresponding to $(-1, 0)$. Once the forces are found, the flow at any point $\mathbf{x}$ is the flow induced by the forces plus the background flow. The velocity at the boundaries was no larger than 10^{-14} in magnitude. Using this steady flow computed on a regular grid, a cloud of "smoke" was advected through the obstacles for visualization purposes. This was done by solving an advection equation with the precomputed steady flow using an upwind method. The grid covered the region $[0, 1] \times [0, 0.5]$ and Neumann boundary conditions were used at the edge of the computational domain. Three snapshots are shown in Figure 4, where the fixed segments obstruct the flow and force it to go around and between them.

The same method can be used to compute the flow due to a collection of forces located at random points or the flow around a collection of point obstacles which may represent, for example, a porous medium. As an example, we consider a group of fixed particles placed randomly in a domain blocking a uniform background flow $(1, 0)$. Figure 5 shows a smaller subdomain containing 53 of the point obstacles and the flow around them. The forces at the particles are computed so that they remain stationary. The computational parameter ϵ was set to 0.03 so as to provide a resolution length scale.

3.3. Example 3: Quasi-steady flow. In this example, we consider the unsteady motion of an interface initially given in polar coordinates by $r(\theta) = \sqrt{r_o^2 - a^2/2} + a\cos(2\theta)$, where a is a perturbation amplitude. The area enclosed by this interface equals πr_o^2. The parameters used were $r_o = 0.25$ and $a = 0.05$ (see Figure 6). Since we are interested in the interface motion as it relaxes from its initial shape to a circle, we need to compute the velocity only along the interface using (11). Although the steady Stokes equations are used to compute the velocity, the time-dependent forces impose a time scale. The interface was tracked by computing the velocity as a steady flow at every time step. A similar problem was discussed in [38, 22].

Suppose $\mathbf{x}(s, t)$ defines the interface at time t in terms of the arclength parameter

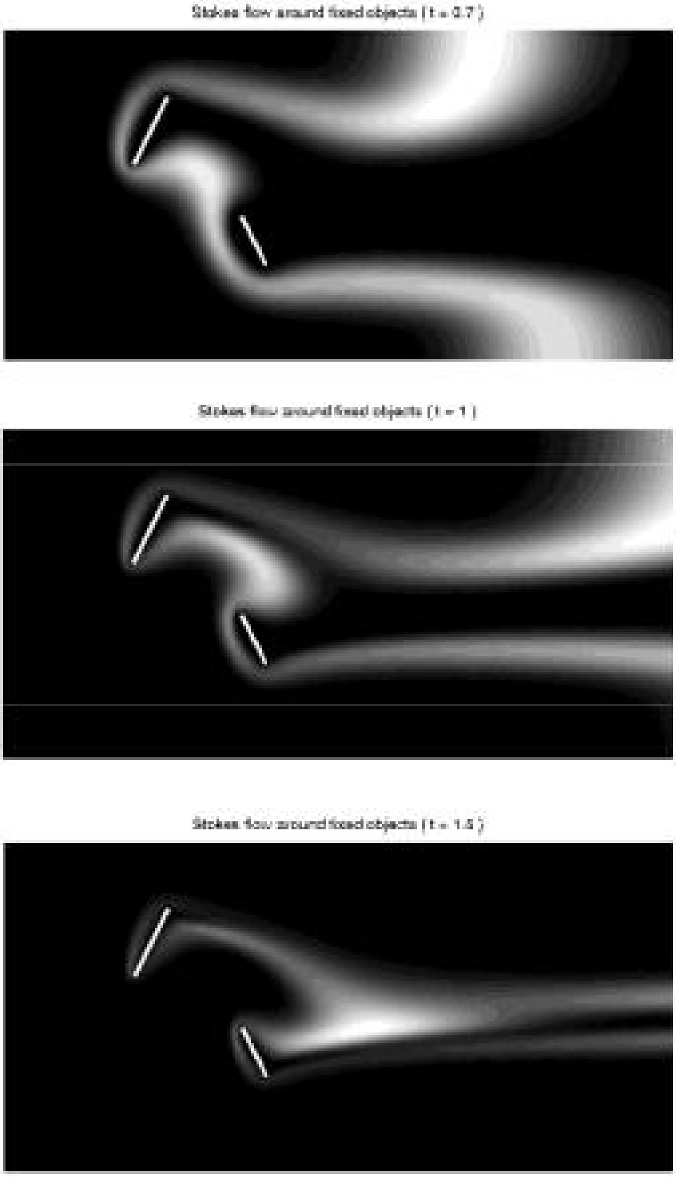

FIG. 4. *Stokes flow around two fixed line obstacles at three different times. The white cloud (initially a wide vertical stripe at the inflow) represents a quantity advected by the precomputed flow for visualization.*

s. A force

$$\mathbf{f}(s) = \frac{\partial^2 \mathbf{x}(s)}{\partial s^2} + \frac{1}{r_o}\hat{n}(s)$$

representing the curvature of the interface minus that of the final state is applied so that the shape will converge to a circle of radius r_o. This restoring force vanishes as the equilibrium state is reached. Following the suggestion in [22], one way to verify

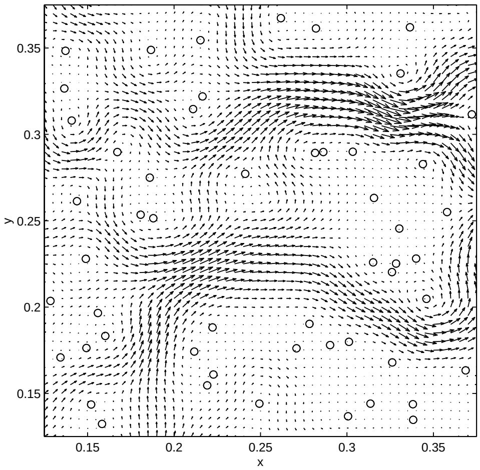

FIG. 5. *Flow around* 53 *fixed point obstacles.*

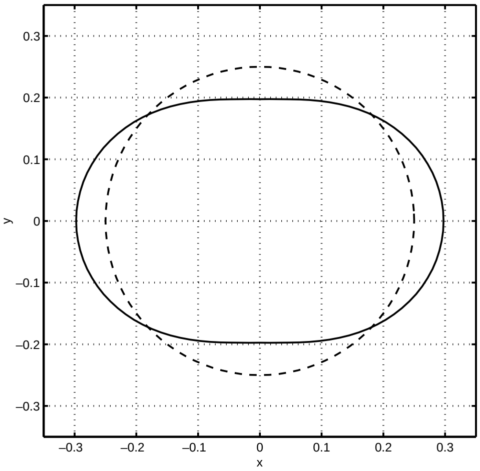

FIG. 6. *Initial shape (solid) and circle of radius* $r_o = 0.25$ *enclosing the same area.*

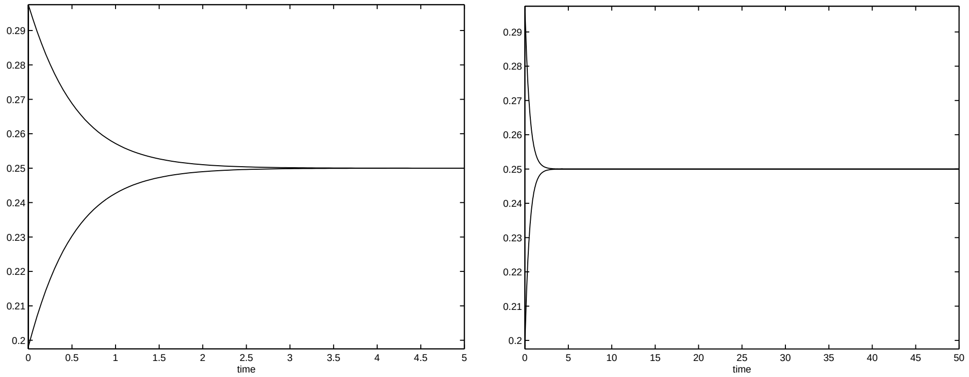
the shape of the final solution is to compute

$$r_{min}(t) = \min_{1 \le k \le N} \|\mathbf{x}_k(t)\| \quad \text{and} \quad r_{max}(t) = \max_{1 \le k \le N} \|\mathbf{x}_k(t)\|$$

and to check their convergence as $t \to \infty$. Figure 7 shows these results for a discretization corresponding to $N = 50$ points along the interface (equally spaced at $t = 0$). Figure 7(a) is for early times and Figure 7(b) shows the longtime behavior. The figure shows that both $r_{max}(t)$ and $r_{min}(t)$ converge to r_o. In addition, the membrane retains its circular shape indefinitely, indicating that the computation remains stable for very long times.

The interface will stop moving once the discretization errors dominate the force giving and indication of the accuracy of the method. Table 1 summarizes the results for discretizations corresponding to $N = 50$, 100, and 200. The second column of the table shows the discretization size for each run. In every case, the regularization parameter was set to $\epsilon = 1.2\Delta s$. We found this to give good results, although the



(a) (b)

TABLE 1
Results showing r_{min}, r_{max}, area conservation A, and the magnitude of the forces for long times and various discretizations.

N	Δs	$r_{max} - r_{min}$	$\lvert A(t = 50) - \pi r_o^2\rvert$	$\lVert\mathbf{f}(t \geq 10)\rVert_\infty$
50	0.0323193	1.156836×10^{-6}	1.758022×10^{-6}	5.700275×10^{-5}
100	0.0161693	0.048211×10^{-6}	0.078004×10^{-6}	0.323780×10^{-5}
200	0.0080858	0.012735×10^{-6}	0.016602×10^{-6}	0.001307×10^{-5}

differences from other choices were not significant. The third column shows the convergence of the shape to a circle at $t = 50$; however, these numbers are essentially constant for $t \geq 10$. Note that the numbers indicate quadratic convergence in terms of Δs. The fourth column of Table 1 shows the error in the computed area inside the interface relative to the expected value πr_o^2. These numbers remained nearly constant throughout the runs. The areas were computed by discretizing a boundary integral using fourth-order finite differences. The errors in the table are within this discretization error. Finally, the last column of the table shows the maximum magnitude of the forces for $t \geq 10$ as a function of the discretization. They give an indication of the errors involved in the numerical method.

4. Modifications for closed, smooth boundaries. The case of a closed, smooth boundary is the most widely studied and one for which several numerical methods exist. This is because the situation is simplified by the absence of endpoints or by the presence of a boundary consisting of disconnected points. Techniques discussed in [34, 22, 28, 29, 30, 31, 37] are often used to compute accurate solutions of elliptic problems in general regions. In the context of fluid flow, the computation of the velocities and pressure far from the boundary or on the boundary are not typically problematic. The challenge is the computation of the solution at points very close to but off the boundary. This situation arises, for example, when the velocity is required in the entire computational domain for the advection of chemicals or solvents.

We present a modified regularization approach that leads to pointwise second-order accuracy in ϵ.

We consider a closed boundary parametrized by arclength $\mathbf{x}(s)$ for $0 \leq s \leq L$.

Our strategy will be to write the solution as a combination of integrals of the form

$$I_1(\mathbf{x}, f) = \int_0^L f(s)\ \mathbf{x}'(s) \times \nabla G(\mathbf{x} - \mathbf{x}(s))\ ds$$

and

$$I_2(\mathbf{x}, g) = \int_0^L g(s)\ \mathbf{x}'(s) \cdot \nabla G(\mathbf{x} - \mathbf{x}(s))\ ds$$

for some functions $f(s)$ and $g(s)$ and Green's function G. The reason is that Beale and Lai [2] have developed correction terms that can be added to the trapezoid rule applied to these integrals that guarantee second-order accuracy. To approximate these integrals, first we use the identities

$$\int_0^L \mathbf{x}'(s) \cdot \nabla G(\mathbf{x} - \mathbf{x}(s))\ ds = 0 \quad \text{for all } \mathbf{x} \text{ off the curve,}$$

$$\int_0^L \mathbf{x}'(s) \times \nabla G(\mathbf{x} - \mathbf{x}(s))\ ds = \begin{cases} 1 & \text{for } \mathbf{x} \text{ inside the boundary,} \\ 0 & \text{for } \mathbf{x} \text{ outside the boundary} \end{cases}$$

to rewrite them, for any value of s^*, as

$$I_2(\mathbf{x}, g) = \int_0^L [\mathbf{x}'(s) \cdot \nabla G(\mathbf{x} - \mathbf{x}(s))]\,[g(s) - g(s^*)]\ ds$$

and

$$I_1(\mathbf{x}, f) = \int_0^L [\mathbf{x}'(s) \times \nabla G(\mathbf{x} - \mathbf{x}(s))]\,[f(s) - f(s^*)]\ ds + \chi(\mathbf{x}) f(s^*),$$

where $\chi(\mathbf{x}) = 1$ if $\mathbf{x}$ is enclosed by the boundary and $\chi(\mathbf{x}) = 0$ otherwise. This formulation gives additional regularity to the integrands. The idea is to discretize the integrals with the trapezoid rule and to realize that when the evaluation point $\mathbf{x}$ is very near the boundary, i.e., $\|\mathbf{x} - \mathbf{x}(s)\| \le O(\Delta s)$ for some s, the accuracy of the quadrature is compromised. However, the leading-order error terms can be identified and subtracted from the quadrature in order to achieve second-order accuracy pointwise. Therefore,

$$\begin{aligned} I_1(\mathbf{x}, f) = \sum_{k=0}^{N} \mathbf{x}'(s_k) \times \nabla G_\epsilon(\mathbf{x} - \mathbf{x}(s_k))[f_k - f(s^*)]\Delta s \\ + \chi(\mathbf{x}) f(s^*) + T_1^{(n)}(\mathbf{x}) + T_2^{(n)}(\mathbf{x}) + O(\Delta s^2), \end{aligned}$$

where the $T^{(n)}$ terms are corrections associated with the use of G_ϵ in place of G and the discretization of the integral. Similarly,

$$I_2(\mathbf{x}, g) = \sum_{k=0}^{N} \mathbf{x}'(s_k) \cdot \nabla G_\epsilon(\mathbf{x} - \mathbf{x}(s_k))[g_k - g(s^*)]\Delta s + T_1^{(t)}(\mathbf{x}) + T_2^{(t)}(\mathbf{x}) + O(\Delta s^2).$$

For each point $\mathbf{x}$ where the sum is evaluated we require s^*, which is the value of the curve parameter that identifies the boundary point closest to $\mathbf{x}$. These formulas have been derived for the specific cutoff function

$$\phi_\epsilon(r) = \frac{1}{\pi \epsilon^2} e^{-r^2/\epsilon^2}.$$

Refer to [2] for more details.

In order to write formulas for p and $\mathbf{u}$ in terms of this type of integrals, it will be convenient to use the decomposition of the forces

$$\mathbf{f}(s) = f^{(n)}\hat{n}(s) + f^{(t)}\mathbf{x}'(s),$$

where the outward normal vector is $\hat{n}(s) = (y'(s), -x'(s))$. Based on (12) we have that

$$\begin{aligned} p(\mathbf{x}) &= \int_0^L \frac{\mathbf{f}(s)\cdot(\mathbf{x}-\mathbf{x}(s))}{2\pi|\mathbf{x}-\mathbf{x}(s)|^2}\,ds = \int_0^L \mathbf{f}(s)\cdot\nabla G(\mathbf{x}-\mathbf{x}(s))\,ds \\ &= \int_0^L -f^{(n)}(s)\ \mathbf{x}'(s)\times\nabla G(\mathbf{x}-\mathbf{x}(s))\,ds + \int_0^L f^{(t)}(s)\ \mathbf{x}'(s)\cdot\nabla G(\mathbf{x}-\mathbf{x}(s))\,ds \\ &= -I_1(\mathbf{x}, f^{(n)}) + I_2(\mathbf{x}, f^{(t)}). \end{aligned} \tag{15}$$

From (13) we have

$$\begin{aligned} \mathbf{u}(\mathbf{x}) &= \int_0^L \frac{-\mathbf{f}(s)}{4\pi\mu}\ \ln|\mathbf{x}-\mathbf{x}(s)| + [\mathbf{f}(s)\cdot(\mathbf{x}-\mathbf{x}(s))]\frac{(\mathbf{x}-\mathbf{x}(s))}{4\pi\mu|\mathbf{x}-\mathbf{x}(s)|^2}\,ds \\ &= \int_0^L \left(\frac{-\mathbf{f}(s)}{2\mu}\right) G(\mathbf{x}-\mathbf{x}(s))\,ds + \int_0^L (\mathbf{x}-\mathbf{x}(s))\frac{[\mathbf{f}(s)\cdot\nabla G(\mathbf{x}-\mathbf{x}(s))]}{2\mu}\,ds. \end{aligned}$$

By defining the vector

$$\mathbf{F}(s) = \int_0^s \frac{-\mathbf{f}(\alpha)}{2\mu}\,d\alpha,$$

we can write the first integral as

$$\int_0^L \mathbf{F}(s)\ \mathbf{x}'(s)\cdot\nabla G(\mathbf{x}-\mathbf{x}(s))\,ds = I_2(\mathbf{x}, \mathbf{F}). \tag{16}$$

The second integral becomes

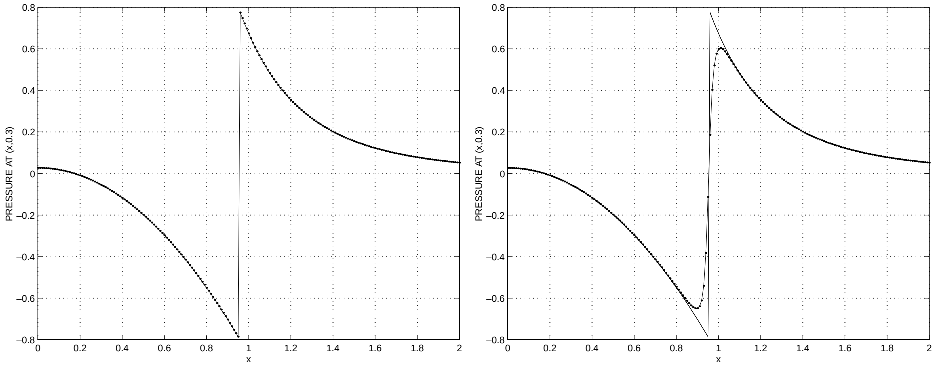
$$\begin{aligned} &\int_0^L (\mathbf{x}-\mathbf{x}(s))\frac{[\mathbf{f}(s)\cdot\nabla G(\mathbf{x}-\mathbf{x}(s))]}{2\mu}\,ds \\ &= \int_0^L \frac{(\mathbf{x}-\mathbf{x}(s))}{2\mu}[-f^{(n)}(s)\mathbf{x}'(s)\times\nabla G(\mathbf{x}-\mathbf{x}(s)) + f^{(t)}(s)\mathbf{x}'(s)\cdot\nabla G(\mathbf{x}-\mathbf{x}(s))]\,ds \\ &= I_1(\mathbf{x}, \mathbf{Q^a}) + I_2(\mathbf{x}, \mathbf{Q^b}), \end{aligned}$$

where

$$\mathbf{Q^a}(s) = -\frac{(\mathbf{x}-\mathbf{x}(s))f^{(n)}(s)}{2\mu}, \quad \mathbf{Q^b}(s) = \frac{(\mathbf{x}-\mathbf{x}(s))f^{(t)}(s)}{2\mu}.$$

Then,

$$\mathbf{u}(\mathbf{x}) = I_2(\mathbf{x}, \mathbf{F}) + I_1(\mathbf{x}, \mathbf{Q^a}) + I_2(\mathbf{x}, \mathbf{Q^b}). \tag{17}$$



(a) (b)

FIG. 8. (a) *Computed pressure p along the line $(x, 3/10)$ for $N = 100$ (dots) using the method of section* 4. *Also plotted is the exact (discontinuous) solution.* (b) *Pressure computed using* (10).

4.1. Example 4a: Normal forces on a circle. Consider a circular boundary of radius 1 parametrized by $\mathbf{x}(\theta) = (\cos(\theta), \sin(\theta))$ and define the forces on the boundary by

$$\mathbf{f}(\theta) = 2\sin(3\theta)\mathbf{x}(\theta)$$

so that the forces are *normal* to the boundary. The exact solution is given by

$$p(r,\theta) = \begin{cases} -r^3\sin(3\theta), & r < 1, \\ r^{-3}\ \sin(3\theta), & r > 1, \end{cases}$$

$$u(r,\theta) = \begin{cases} \frac{3}{8}r^2\sin(2\theta) + \frac{1}{16}r^4\sin(4\theta) - \frac{1}{4}r^4\sin(2\theta), & r < 1, \\ \\ \frac{1}{8}r^{-2}\sin(2\theta) - \frac{3}{16}r^{-4}\sin(4\theta) + \frac{1}{4}r^{-2}\sin(4\theta), & r \geq 1, \end{cases}$$

$$v(r,\theta) = \begin{cases} \frac{3}{8}r^2\cos(2\theta) - \frac{1}{16}r^4\cos(4\theta) - \frac{1}{4}r^4\cos(2\theta), & r < 1, \\ \\ \frac{1}{8}r^{-2}\cos(2\theta) + \frac{3}{16}r^{-4}\cos(4\theta) - \frac{1}{4}r^{-2}\cos(4\theta), & r \geq 1. \end{cases}$$

We note that p is discontinuous across the boundary, but $\partial p/\partial r$, u, ∇u, v, and ∇v are continuous.

In order to show representative results, we choose to compare the solution along the line $(x, 3/10)$ for $0 < x < 2$. The boundary was discretized with N equally spaced points, and the regularization parameter was set equal to $\epsilon = 2\pi/16N$. Figures 8 and 9 show results for $N = 100$.

Figure 8(a) displays the computed pressure using the method in section 4. For larger values of N, the solutions are nearly indistinguishable from one another. The formula based on (15) is able to capture the jump in the pressure in spite of the use of regularization. This is because the jump was explicitly included in the formula for $I_1(\mathbf{x}, f)$. If instead one used (10) to compute the pressure, the effect of the regularization would be to replace the discontinuity with a rapid but smooth transition over a region of size $O(\epsilon)$, as shown in Figure 8(b). This, of course, leads to $O(1)$ errors near the interface.

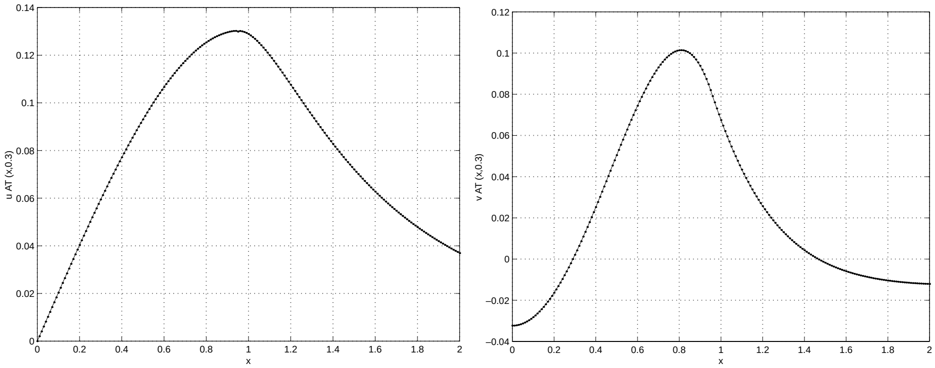


FIG. 9. *Velocity components u (left) and v (right) along the line* $(x, 3/10)$ *for* $N = 100$ *(dots). Also plotted is the exact solution (solid).*

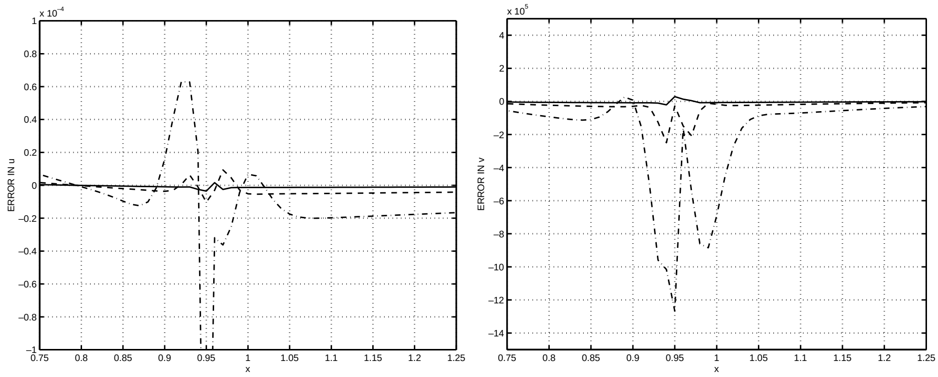

FIG. 10. *Error in the velocity components along the line* $(x, 3/10)$ *for* $N = 100$*,* 200*, and* 400.

The velocities are $C^1(\mathbb{R}^2)$ and this additional smoothness allows the numerical method to approximate the velocities very well everywhere, as seen in Figure 9. The largest discrepancy, however, is still near the boundary. To be more precise, we compute the error in the solution for the various discretizations. We recall that, in this example, ϵ is inversely proportional to N. Figure 10 shows the error in the velocities and Figure 11 the error in the pressure.

The largest velocity errors are $O(10^{-4})$, corresponding to the smallest value of N. More importantly, the L_2 norm of these errors, shown in Table 2, decreases by a factor of about 4 as the number of boundary points N is doubled, indicating that the pressure and velocity errors are $O(\epsilon^2)$ as $\epsilon \to 0$.

4.2. Example 4b: Tangential forces on a circle. Now consider the same circular boundary of radius 1 parametrized by $\mathbf{x}(\theta) = (\cos(\theta), \sin(\theta))$ but define the forces on the boundary by

$$\mathbf{f}(\theta) = 2\sin(3\theta)\mathbf{x}'(\theta)$$

so that the forces are now *tangential* to the boundary. The difference between this and the previous example is significant because of the character of the solution. Here, p and $\mathbf{u}$ are continuous everywhere, but their gradients are discontinuous across the

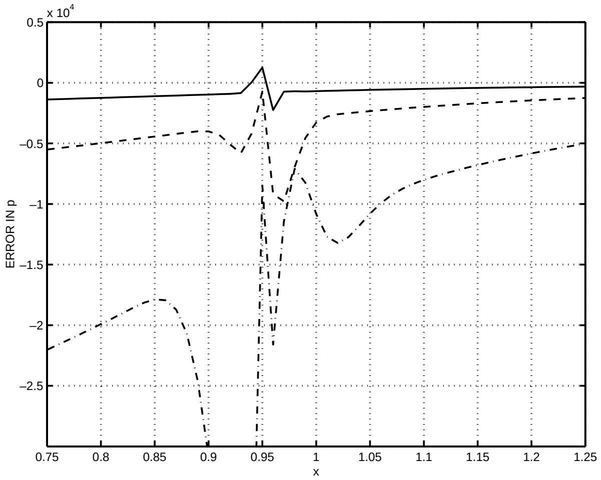

FIG. 11. *Error in the pressure along the line* $(x, 3/10)$ *for* $N = 100$, 200, *and* 400.

TABLE 2

L_2 *norm of errors shown in Figures* 10–11. *When the number of particles is doubled, the errors decrease by a factor of about* 4, *showing second order convergence.*

N	Error in p	Error in u	Error in v
100	25.35×10^{-4}	4.603×10^{-4}	4.656×10^{-4}
200	6.023×10^{-4}	0.781×10^{-4}	1.052×10^{-4}
400	1.468×10^{-4}	0.200×10^{-4}	0.248×10^{-4}

boundary. The exact solution is

$$p(r,\theta) = \begin{cases} -r^3\cos(3\theta), & r < 1, \\ -r^{-3}\ \cos(3\theta), & r > 1, \end{cases}$$

$$u(r,\theta) = \begin{cases} \frac{1}{8}r^2\cos(2\theta) + \frac{1}{16}r^4\cos(4\theta) - \frac{1}{4}r^4\cos(2\theta), & r < 1, \\ -\frac{1}{8}r^{-2}\cos(2\theta) + \frac{5}{16}r^{-4}\cos(4\theta) - \frac{1}{4}r^{-2}\cos(4\theta), & r \geq 1, \end{cases}$$

$$v(r,\theta) = \begin{cases} -\frac{1}{8}r^2\sin(2\theta) + \frac{1}{16}r^4\sin(4\theta) + \frac{1}{4}r^4\sin(2\theta), & r < 1, \\ \frac{1}{8}r^{-2}\sin(2\theta) + \frac{5}{16}r^{-4}\sin(4\theta) - \frac{1}{4}r^{-2}\sin(4\theta), & r \geq 1. \end{cases}$$

Again we compare the solution along the line $(x, 3/10)$ for $0 < x < 2$, which crosses the boundary at around $x = 0.954$. The boundary was discretized with N particles (initially equally spaced), and this time the regularization parameter was set to $\epsilon = \Delta s/4$. For other values of ϵ, the results were similar. Figures 12 and 13 show the results. We note that the corners in the solution (gradient discontinuities) are captured well with the method.

The errors using $N = 100$, 200, and 400 are shown in Figure 14. The magnitude of the errors is comparable to those in the previous example, and the convergence appears to be second order as well.

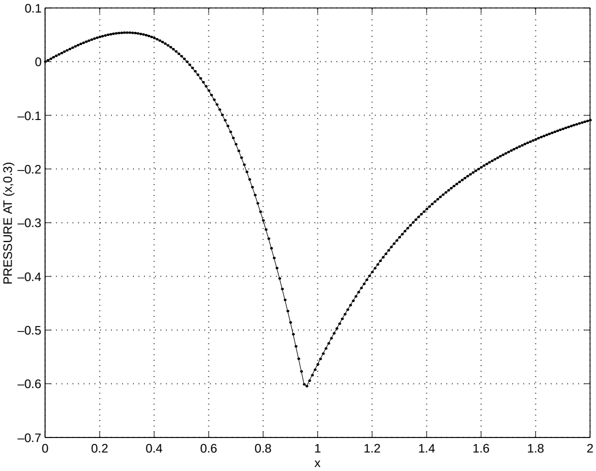

FIG. 12. *Computed pressure p along the line $(x, 3/10)$ for $N = 100$ (dots). Also plotted is the exact solution (solid).*

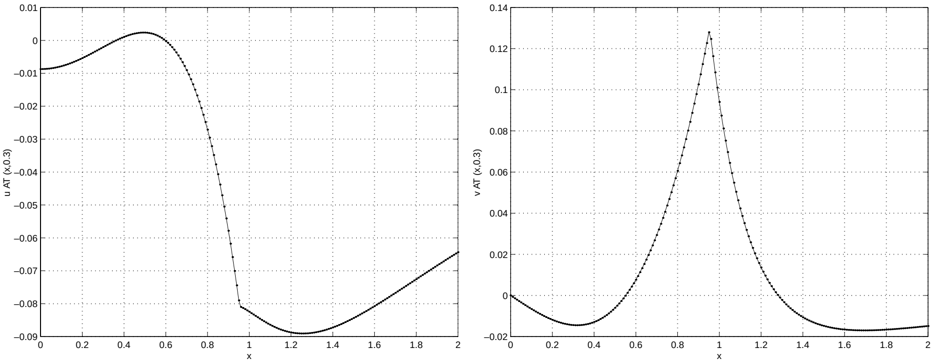

FIG. 13. *Computed velocity components u (left) and v (right) along the line $(x, 3/10)$ for $N = 100$ (dots). Also plotted is the exact solution (solid).*

We make one more comment about the choice of the regularization parameter ϵ in the present context. While it is usually taken as $\epsilon = O(\Delta s)$, the errors in computing integrals of the form

$$\int_0^L \hat{n}(s) \cdot \nabla G(\mathbf{x} - \mathbf{x}(s))[f(s) - f(s^*)]ds$$

or

$$\int_0^L \mathbf{x}'(s) \cdot \nabla G(\mathbf{x} - \mathbf{x}(s))[g(s) - g(s^*)]ds$$

are slightly different when the evaluation point $\mathbf{x}$ is near, but off, the curve. This is because

$$\nabla G(\mathbf{x} - \mathbf{x}(s^*)) = \frac{\mathbf{x} - \mathbf{x}(s^*)}{2\pi|\mathbf{x} - \mathbf{x}(s^*)|^2} = \frac{\hat{n}(s^*)}{2\pi|\mathbf{x} - \mathbf{x}(s^*)|},$$

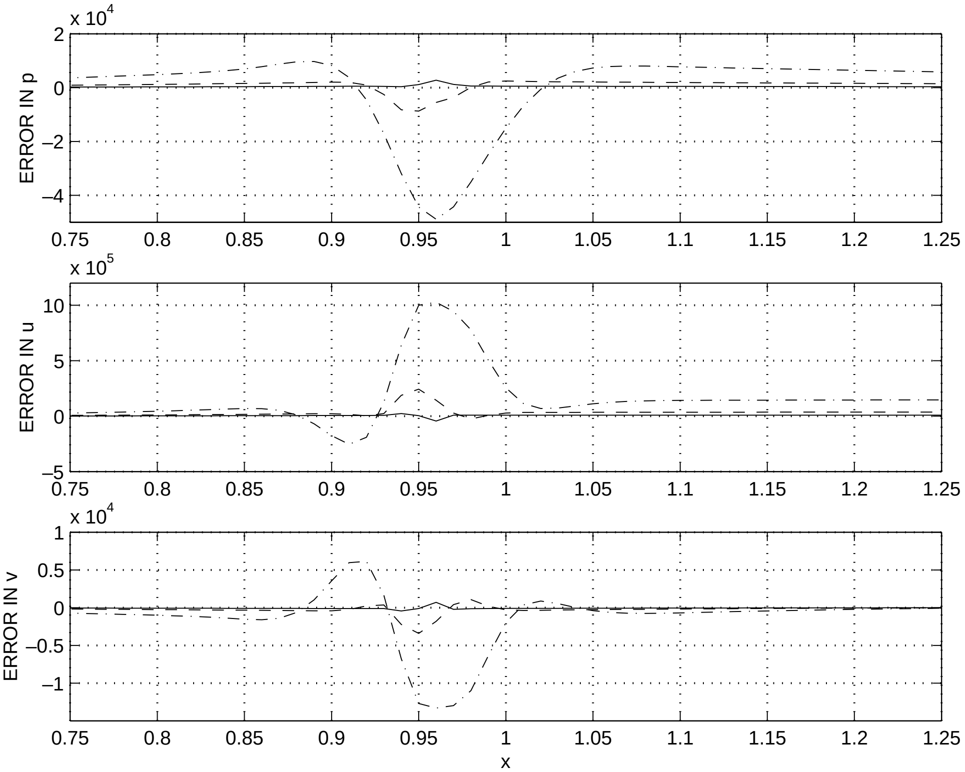

FIG. 14. *Error in the pressure and velocity components for Example* 4*b. The errors are measured along the line* $(x, 3/10)$ *for* $N = 100$, 200, *and* 400.

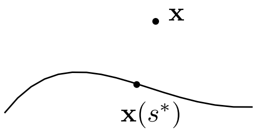

FIG. 15. *Schematic diagram.*

which implies that for $s \approx s^*$ (see Figure 15)

$$\hat{n}(s) \cdot \nabla G(\mathbf{x} - \mathbf{x}(s)) \sim \frac{O(1)}{|\mathbf{x} - \mathbf{x}(s^*)|},$$

while

$$\mathbf{x}'(s) \cdot \nabla G(\mathbf{x} - \mathbf{x}(s)) \sim \frac{O(s - s^*)}{2\pi|\mathbf{x} - \mathbf{x}(s^*)|},$$

so that the first integrand above is “more nearly singular” than the second. This somewhat affects the optimal size of ϵ relative to Δs.

4.3. Numerical example 5: Computing stresses. We consider a final example of flow in a channel obstructed by a semicircular protrusion (see Figure 16). This problem has been studied in [19] as a model for the adhesion of a cell to the wall of a channel and the stresses exerted on these cells by fluid flowing within the channel. Additional numerical studies of this problem are found in [39] and a variant of it

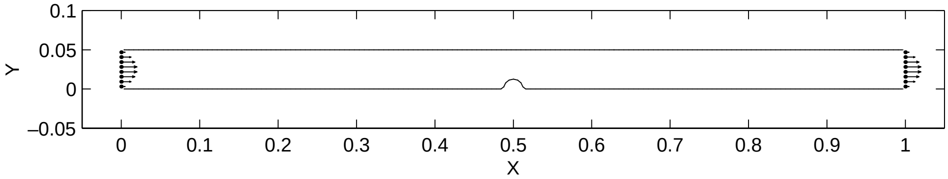

FIG. 16. *Geometry of the problem and velocity boundary conditions.*

in [18]. The objective is to determine the stresses along the channel walls, including the obstruction. It is assumed that the flow is driven by a constant pressure gradient and has reached a steady state. In our case, the corners where the semicircle meets the channel wall have not been smoothed with fillets. The velocity inflow and outflow conditions were assumed to be the parabolic Poiseuille flow, while the fluid velocity at the channel walls was set to zero.

Using the nondimensionalization in [19], the parameters used were $\Delta p = 1$, $\mu = H^2/8L^2$, $L = 1$, and $H = 0.05$, where L and H are the length and height of the channel. The radius of the obstruction was set to $R = H/4$. A particle separation of $\Delta s = 0.0025$ was used along the straight horizontal boundaries and approximately the same on the semicircle and the inflow/outflow ends. The regularization parameter was set to $\epsilon = \Delta s/4$. To simulate the flow induced by the constant pressure gradient, a constant force $(\Delta p, 0)$ was imposed on a grid covering the interior of the channel. The velocity due to this force was computed on the channel walls using (11). As a second step, the forces along the channel walls are computed with (14) so that the desired boundary conditions, including the parabolic inflow/outflow, are obtained. The resulting boundary forces were then used to compute the normal and shear stresses on the bottom part of the channel. This was done by decomposing the forces into the normal and tangential components along the channel walls. The results are shown in Figure 17.

The shear stress has been normalized by the shear stress on a channel without the obstruction. This allows one to see that away from the obstruction, the shear stress approaches that of the free channel. Also apparent from the graph is that the maximum shear stress is nearly three times that of the flat wall. On the other hand, the normal stress is nearly equal to the pressure which decreases linearly from $p(0) = 1$ to $p(L) = 0$. The obstruction merely slightly perturbs this profile. These results are nearly identical to those shown in Figure 5 of [19] with the exception of the values at the points where the semicircle meets the wall. In [19], this corner was smoothed with small fillets to minimize the oscillation observed here, where no smoothing was used.

5. Concluding remarks. We have introduced a numerical technique for the computation of force-driven Stokes flows. At the core of the method is the regularized Stokeslet, which gives the solution due to the regular force field in (3). The standard Stokeslet is recovered in the limit as the regularization parameter vanishes. Several examples were presented that demonstrate the use of the method when the forces are applied at random points, flexible or solid boundaries. The results show that the motion of the immersed boundaries is captured very well. The volume conservation is excellent due to the exact satisfaction of the incompressibility condition in the formula (7). The solution off the boundaries is also computed accurately with a slightly modified formulation in terms of single and double layer potentials. These

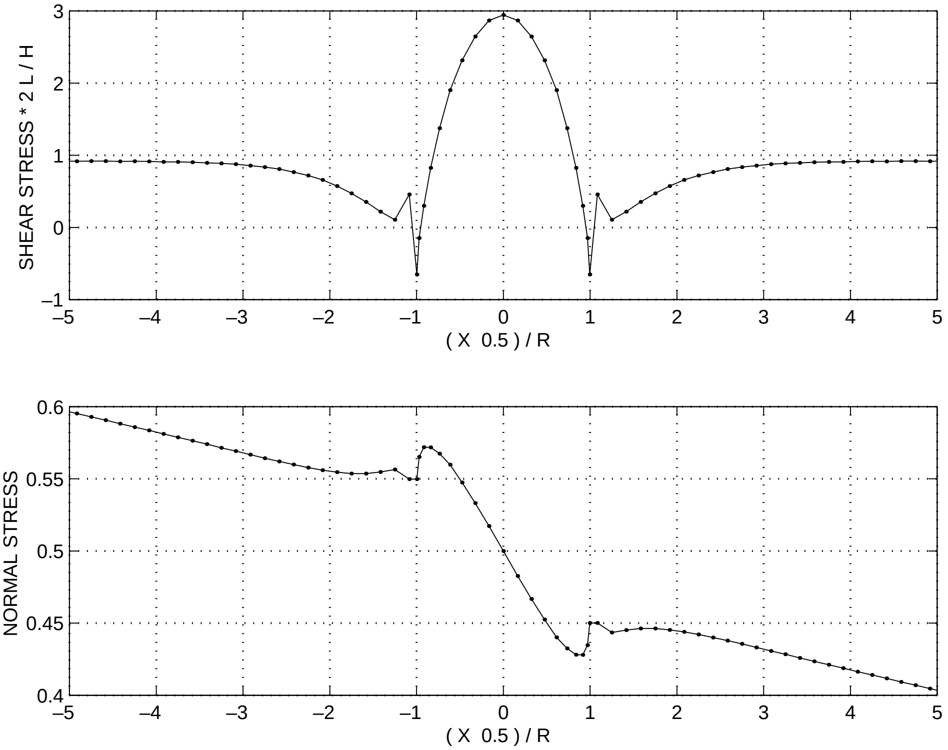

Fig. 17. *Shear and normal stresses along the bottom wall of the channel.*

results can be combined when the velocity in the entire domain is required in order to track other quantities advected by the flow.

Velocity boundary conditions can be satisfied to great precision by inverting the velocity equation and solving for the forces on the boundaries. Thus far, this has been done by the iterative procedure GMRES, although other techniques and associated preconditioners are being considered for future implementations. The resulting forces can also be used to determine stresses along walls, producing profiles without excess noise.

There are other singular solutions of Stokes equations that are also important for many applications. Elements such as dipoles, rotlets, and stresslets can be derived by applying certain differential operators to the Stokeslet. One can derive the regularized versions of these elements from the regularized Stokeslet. Regularized dipoles are already used in other fluid flow applications [5, 10, 35].

Another future direction of research is the extension of this work to three dimensions. In principle, this is already done here, since the derivation of the formulas is identical. For the simulation of bubbles or waving surfaces, these can be combined with existing triangulation or other discretization techniques. We expect to report on this case in a future article.

hp-ADAPTIVE DISCONTINUOUS GALERKIN FINITE ELEMENT METHODS FOR FIRST-ORDER HYPERBOLIC PROBLEMS*

PAUL HOUSTON† AND ENDRE SÜLI‡

Abstract. We consider the a posteriori error analysis of *hp*-discontinuous Galerkin finite element approximations to first-order hyperbolic problems. In particular, we discuss the question of error estimation for linear functionals, such as the outflow flux and the local average of the solution. Based on our a posteriori error bound we design and implement the corresponding adaptive algorithm to ensure reliable and efficient control of the error in the prescribed functional to within a given tolerance. This involves exploiting both local polynomial-degree variation and local mesh subdivision. The theoretical results are illustrated by a series of numerical experiments.

Key words. *hp*-finite element methods, a posteriori error analysis, hyperbolic problems

1. Introduction.

Adaptive finite element methods that are capable of exploiting both local polynomial-degree variation (p-refinement) and local mesh subdivision (h-refinement) offer greater flexibility and improved efficiency than mesh refinement methods which incorporate only h-refinement or p-refinement in isolation. The aim of this paper is to develop the a posteriori error analysis of the *hp*-version of the discontinuous Galerkin finite element method; see [9], and the references cited therein, and [6] for earlier work in this area. In particular, we shall be concerned with the derivation of computable error bounds for linear functionals of the solution to scalar first-order hyperbolic problems. Relevant examples of linear functionals of the solution include the mean value of the field over the computational domain and the normal flux through the outflow boundary.

The paper is structured as follows. In section 2 we introduce the model problem and formulate its discontinuous Galerkin finite element approximation. Then, in section 3, we derive both a posteriori and a priori error bounds for linear functionals of the solution. Our a posteriori error bounds stem from a hyperbolic duality argument and include computable residual terms multiplied by local weights involving the dual solution; cf. [14, 19]. Guided by our a posteriori error analysis, in section 4 we design an *hp*-adaptive finite element algorithm to guarantee both reliable and efficient control of the error in the computed functional with respect to a fixed user-defined tolerance. A key question in *hp*-adaptive algorithms is how to automatically decide when to h-refine/derefine and when to p-refine/derefine. Here, stimulated by the work of Ainsworth and Senior [2], we develop a decision mechanism based on the estimation of local Sobolev regularities of the primal and dual solutions by means of the a priori error bounds from section 3 (see also [23]). The performance of the resulting *hp*-refinement strategy is then studied in section 5 through a series of numerical ex-

periments. In particular, we demonstrate the superiority of using *hp*-adaptive mesh refinement over the traditional *h*-refinement method, where the degree of the approximating polynomial is kept fixed at some low value. Finally, in section 6 we summarize the work presented in this paper and draw some conclusions.

2. Model problem and discretization.

Let Ω be a bounded open polyhedral domain in $\mathbb{R}^d$, $d \geq 2$, and let Γ denote the union of open faces of Ω. Suppose that $\mathbf{b} = (b_1, \ldots, b_d)$ is a d-component vector function defined on $\bar{\Omega}$ with $b_i \in W^1_\infty(\Omega)$, $i = 1, \ldots, d$, and consider the following subsets of Γ:

$$\Gamma_- = \{x \in \Gamma : \mathbf{b}(x) \cdot \mathbf{n}(x) < 0\}, \qquad \Gamma_+ = \{x \in \Gamma : \mathbf{b}(x) \cdot \mathbf{n}(x) > 0\};$$

here, $\mathbf{n}(x)$ denotes the unit outward normal vector to Γ at $x \in \Gamma$. The sets Γ_- and Γ_+ are referred to as the inflow and outflow boundary, respectively. We shall suppose that Γ is a.e. noncharacteristic in the sense that the set $\Gamma \setminus (\Gamma_- \cup \Gamma_+)$ has $(d-1)$-dimensional measure zero. Given $c \in L_\infty(\Omega)$, $f \in L_2(\Omega)$, and $g \in L_2(\Gamma_-)$, we consider the following boundary value problem: find $u \in H(\mathcal{L}, \Omega)$ such that

$$\begin{aligned} \mathcal{L}u \equiv \mathbf{b} \cdot \nabla u + cu = f, &\quad x \in \Omega\ , \\ u = g, &\quad x \in \Gamma_-\ , \end{aligned} \tag{2.1}$$

where $H(\mathcal{L}, \Omega) = \{v \in L_2(\Omega) : \mathcal{L}v \in L_2(\Omega)\}$ denotes the *graph space* of the partial differential operator $\mathcal{L}$ in $L_2(\Omega)$. In addition, we adopt the following (standard) hypothesis: there exists a vector $\xi \in \mathbb{R}^d$ and a positive real number δ such that

$$c - \frac{1}{2}\nabla \cdot \mathbf{b} + \mathbf{b} \cdot \xi \geq \delta^2 \ \text{ for a.e. } x \in \Omega\ . \tag{2.2}$$

We note that assumption (2.2) ensures the uniqueness of a solution $u \in H(\mathcal{L}, \Omega)$ to (2.1); cf., for example, [15]. General results concerning the existence and uniqueness of solutions to boundary value problems for first-order hyperbolic equations are given in [4], and [10, pp. 215–262]. For the sake of simplicity of presentation, we assume that (2.2) is satisfied with $\xi = 0$, and we define $c_0 \in L_\infty(\Omega)$ by

$$c_0^2(x) = c(x) - \frac{1}{2}\nabla \cdot \mathbf{b}(x), \qquad x \in \Omega\ . \tag{2.3}$$

Clearly, $c_0(x) \geq \delta > 0$ for almost every $x \in \Omega$.

2.1. Finite element spaces.

Suppose that $\mathcal{T}$ is a regular or 1-irregular subdivision of Ω into disjoint open element domains κ such that $\bar{\Omega} = \cup_{\kappa \in \mathcal{T}} \bar{\kappa}$. Thus a $(d-1)$-dimensional face of each element κ in $\mathcal{T}$ is allowed to contain at most one hanging (irregular) node—typically the barycenter of the face. It will be assumed that $\mathcal{T}$ respects the decomposition of Γ into Γ_- and Γ_+ in the following sense: if a $(d-1)$-dimensional open face e of an element κ lies on Γ, then e is a subset of either Γ_- or Γ_+. We shall suppose that the family of subdivisions $\mathcal{T}$ is shape-regular (cf. pp. 61 and 113 and Remark 2.2 on p. 114 in [8], for example) and that each $\kappa \in \mathcal{T}$ is a smooth bijective image of a fixed master element $\hat{\kappa}$; that is, $\kappa = F_\kappa(\hat{\kappa})$ for all $\kappa \in \mathcal{T}$, where $\hat{\kappa}$ is either the open unit simplex or the open unit hypercube in $\mathbb{R}^d$. On the reference element $\hat{\kappa}$ we define spaces of polynomials of degree $p \geq 1$ as follows:

$$\mathcal{Q}_p = \operatorname{span}\{\hat{x}^\alpha : 0 \leq \alpha_i \leq p,\ 1 \leq i \leq d\}, \qquad \mathcal{P}_p = \operatorname{span}\{\hat{x}^\alpha : 0 \leq |\alpha| \leq p\}.$$

To each $\kappa \in \mathcal{T}$ we assign an integer $p_\kappa \geq 1$; collecting the p_κ and F_κ in the vectors $\mathbf{p} = \{p_\kappa : \kappa \in \mathcal{T}\}$ and $\mathbf{F} = \{F_\kappa : \kappa \in \mathcal{T}\}$, respectively, we introduce the finite element space

$$\begin{aligned} S^{\mathbf{p}}(\Omega, \mathcal{T}, \mathbf{F}) = \{u \in L_2(\Omega) \,:\, & u|_\kappa \circ F_\kappa \in \mathcal{Q}_{p_\kappa} \text{ if } F_\kappa^{-1}(\kappa) \text{ is the open unit hypercube,} \\ \text{and} \quad & u|_\kappa \circ F_\kappa \in \mathcal{P}_{p_\kappa} \text{ if } F_\kappa^{-1}(\kappa) \text{ is the open unit simplex; } \kappa \in \mathcal{T}\} \,. \end{aligned}$$

Assuming that $\mathcal{T}$ is a subdivision of Ω, we consider the broken Sobolev space $H^{\mathbf{s}}(\Omega, \mathcal{T})$ of composite index $\mathbf{s}$ with nonnegative components s_κ, $\kappa \in \mathcal{T}$, defined by

$$H^{\mathbf{s}}(\Omega, \mathcal{T}) = \{u \in L_2(\Omega) : \; u|_\kappa \in H^{s_\kappa}(\kappa) \quad \forall \kappa \in \mathcal{T}\} \,.$$

If $s_\kappa = s \geq 0$ for all $\kappa \in \mathcal{T}$, we shall simply write $H^s(\Omega, \mathcal{T})$.

In the next section, we formulate the *hp*-version of the discontinuous Galerkin finite element method (*hp*-DGFEM, for short) for the numerical solution of (2.1).

2.2. The *hp*-discontinuous Galerkin method. Given that κ is an element in the subdivision $\mathcal{T}$, we denote by $\partial\kappa$ the union of $(d-1)$-dimensional open faces of κ. This is nonstandard notation in that $\partial\kappa$ is a subset of the boundary of κ. Let $x \in \partial\kappa$ and suppose that $\mathbf{n}_\kappa(x)$ denotes the unit outward normal vector to $\partial\kappa$ at x. With these conventions, we define the inflow and outflow parts of $\partial\kappa$, respectively, by

$$\partial_-\kappa = \{x \in \partial\kappa : \; \mathbf{b}(x) \cdot \mathbf{n}_\kappa(x) < 0\} \,, \quad \partial_+\kappa = \{x \in \partial\kappa : \; \mathbf{b}(x) \cdot \mathbf{n}_\kappa(x) \geq 0\} \,. \tag{2.4}$$

For each $\kappa \in \mathcal{T}$ and any $v \in H^1(\kappa)$ we denote by v_κ^+ the interior trace of v on $\partial\kappa$ (the trace taken from within κ). Now consider an element κ such that the set $\partial_-\kappa\backslash\Gamma_-$ is nonempty; then, for each $x \in \partial_-\kappa\backslash\Gamma_-$ (with the exception of a set of $(d-1)$-dimensional measure zero), there exists a unique element κ', depending on the choice of x, such that $x \in \partial_+\kappa'$. Suppose that $v \in H^1(\Omega, \mathcal{T})$. If $\partial_-\kappa\backslash\Gamma_-$ is nonempty for some $\kappa \in \mathcal{T}$, then we define the outer trace v_κ^- of v on $\partial_-\kappa\backslash\Gamma_-$ relative to κ as the inner trace $v_{\kappa'}^+$ relative to those elements κ' for which $\partial_+\kappa'$ has intersection with $\partial_-\kappa\backslash\Gamma_-$ of positive $(d-1)$-dimensional measure. We also introduce the jump of v across $\partial_-\kappa\backslash\Gamma_-$: $[\,v\,]_\kappa = v_\kappa^+ - v_\kappa^-$. Since below it will always be clear from the context which element κ in the subdivision $\mathcal{T}$ the quantities $\mathbf{n}_\kappa$, v_κ^+, v_κ^- and $[v]_\kappa$ correspond to, for the sake of notational simplicity we shall suppress the letter κ in the subscript and instead write $\mathbf{n}$, v^+, v^-, and $[v]$, respectively.

For $v, w \in H^1(\Omega, \mathcal{T})$, we define the bilinear form

$$\begin{aligned} B_{\mathrm{DG}}(w, v) = \sum_{\kappa \in \mathcal{T}} \int_\kappa \mathcal{L}w\, v \;\mathrm{d}x - \sum_{\kappa \in \mathcal{T}} \int_{\partial_-\kappa\backslash\Gamma_-} (\mathbf{b} \cdot \mathbf{n})[w]\, v^+ \;\mathrm{d}s \\ - \sum_{\kappa \in \mathcal{T}} \int_{\partial_-\kappa\cap\Gamma_-} (\mathbf{b} \cdot \mathbf{n}) w^+\, v^+ \;\mathrm{d}s, \end{aligned}$$

and, for $v \in H^1(\Omega, \mathcal{T})$, we consider the linear functional

$$\ell_{\mathrm{DG}}(v) = \sum_{\kappa \in \mathcal{T}} \int_\kappa f v \;\mathrm{d}x - \sum_{\kappa \in \mathcal{T}} \int_{\partial_-\kappa\cap\Gamma_-} (\mathbf{b} \cdot \mathbf{n})\, g v^+ \;\mathrm{d}s \,.$$

The *hp*-DGFEM for (2.1) is defined as follows: find $u_{\mathrm{DG}} \in S^{\mathbf{p}}(\Omega, \mathcal{T}, \mathbf{F})$ such that

$$B_{\mathrm{DG}}(u_{\mathrm{DG}}, v) = \ell_{\mathrm{DG}}(v) \quad \forall v \in S^{\mathbf{p}}(\Omega, \mathcal{T}, \mathbf{F}) \,. \tag{2.5}$$

We note that

$$\begin{aligned}B_{\mathrm{DG}}(v,v) &= \sum_\kappa \int_\kappa c_0^2(x)|v|^2\,\mathrm{d}x + \frac{1}{2}\sum_\kappa \int_{\partial_-\kappa\cap\Gamma_-} |\mathbf{b}\cdot\mathbf{n}|\,|v^+|^2\,\mathrm{d}s \\ &+\frac{1}{2}\sum_\kappa \int_{\partial_-\kappa\setminus\Gamma_-} |\mathbf{b}\cdot\mathbf{n}|\,|[v]|^2\,\mathrm{d}s + \frac{1}{2}\sum_\kappa \int_{\partial_+\kappa\cap\Gamma_+} |\mathbf{b}\cdot\mathbf{n}|\,|v^+|^2\,\mathrm{d}s\end{aligned}$$

for all $v \in H^1(\Omega,\mathcal{T})$ (see, for example, (2.31) in [16]), and therefore $B_{\mathrm{DG}}(v,v) > 0$ for all $v \in H^1(\Omega,\mathcal{T}) \setminus \{0\}$; thus, recalling that (2.5) is a linear problem on the finite-dimensional linear space $S^{\mathbf{p}}(\Omega,\mathcal{T},\mathbf{F})$, we deduce the existence of a unique solution u_{DG} in $S^{\mathbf{p}}(\Omega,\mathcal{T},\mathbf{F})$ to (2.5). Further, for each $v \in H^1(\Omega,\mathcal{T})$,

$$\begin{aligned}|\ell_{\mathrm{DG}}(v)| &\le \left(\sum_{\kappa\in\mathcal{T}} \int_\kappa c_0^{-2}(x)|f|^2\,\mathrm{d}x + 2\sum_{\kappa\in\mathcal{T}} \int_{\partial_-\kappa\cap\Gamma_-} |\mathbf{b}\cdot\mathbf{n}|\,|g|^2\,\mathrm{d}s\right)^{1/2} \\ &\times \left(\sum_{\kappa\in\mathcal{T}} \int_\kappa c_0^2(x)|v|^2\,\mathrm{d}x + \frac{1}{2}\sum_{\kappa\in\mathcal{T}} \int_{\partial_-\kappa\cap\Gamma_-} |\mathbf{b}\cdot\mathbf{n}|\,|v^+|^2\,\mathrm{d}s\right)^{1/2}.\end{aligned}$$

Hence, letting $|||v|||_{\mathrm{DG}} = [B_{\mathrm{DG}}(v,v)]^{1/2}$, we deduce the stability of the method in the sense that

$$|||u_{\mathrm{DG}}|||_{\mathrm{DG}} \le \left(\sum_{\kappa\in\mathcal{T}} \int_\kappa c_0^{-2}(x)|f(x)|^2\,\mathrm{d}x + 2\sum_{\kappa\in\mathcal{T}} \int_{\partial_-\kappa\cap\Gamma_-} |\mathbf{b}(x)\cdot\mathbf{n}(x)|\,|g(s)|^2\,\mathrm{d}s\right)^{1/2}.$$

For the a priori error analysis of (2.5) in the DG-norm $|||\cdot|||_{\mathrm{DG}}$ we refer to the paper [15]; cf. Lemma 3.9 below. The analysis of the scheme (2.5) with the addition of streamline-diffusion stabilization has been considered in [16]; see also Bey and Oden [6]. Here we shall concentrate on the situation when there is no streamline-diffusion stabilization in the method.

3. A posteriori and a priori error analysis.

In many problems of physical importance the quantity of interest is a linear functional $J(\cdot)$ of the solution. Relevant examples include the lift and drag coefficients for a body immersed into an inviscid fluid, the local mean value of the field, or its flux through the outflow boundary of the computational domain.

Suppose that we wish to control the discretization error in some linear functional $J(\cdot)$ defined on a linear space which contains $H(\mathcal{L},\Omega) + S^{\mathbf{p}}(\Omega,\mathcal{T},\mathbf{F})$. Following the argument presented in [14] for stabilized continuous finite element approximations, we do so by deriving an a posteriori bound on the error between $J(u)$ and $J(u_{\mathrm{DG}})$. We begin our analysis by considering the following *dual* or *adjoint* problem: find z in $H(\mathcal{L}^*,\Omega)$ such that

$$B_{\mathrm{DG}}(w,z) = J(w) \quad \forall w \in H(\mathcal{L},\Omega)\,, \tag{3.1}$$

where $H(\mathcal{L}^*,\Omega)$ denotes the graph space of the adjoint operator $\mathcal{L}^*$ in $L_2(\Omega)$. Let us assume that (3.1) possesses a unique solution. Clearly, the validity of this assumption depends on the choice of the linear functional under consideration. Below, we present some important examples which are covered by our hypotheses.

Example 1: *Mean flow.* Consider approximating the (weighted) mean value $J(\cdot) \equiv M_\psi(\cdot)$ defined by

$$J(w) \equiv M_\psi(w) = \int_\Omega w\psi\,\mathrm{d}x\,, \tag{3.2}$$

where $\psi \in L_2(\Omega)$ is a given weight function. In this case the dual problem takes the following form: find z in $H(\mathcal{L}^*, \Omega)$ such that

$$\begin{aligned} \mathcal{L}^* z \equiv -\nabla \cdot (\mathbf{b} z) + cz = \psi, \quad & x \in \Omega\,, \\ z = 0, \quad & x \in \Gamma_+\,. \end{aligned} \tag{3.3}$$

Example 2: *Point value.* Under the assumption that the analytical solution u is a continuous function in the neighborhood of a given point x_c in Ω, the point value $u(x_c)$ may also be approximated. However, now $J(w) = w(x_c)$, and when this is inserted as the right-hand side into the dual problem (3.1), the resulting weak solution z is a measure rather than a regular distribution; in particular, z does not belong to $L_2(\Omega)$. Thus, to avoid technical complications, we mollify the functional J by considering a nonnegative function φ in $L_{1,\mathrm{loc}}(\mathbb{R}^d)$ whose support is contained in the unit ball $B(0,1)$ centered at $x = 0$ and such that the integral of φ over $B(0,1)$ is equal to 1. Writing $\psi(x) = \varphi_\varepsilon(x) \equiv \varepsilon^{-d}\varphi((x - x_c)/\varepsilon)$, $M_\psi(u)$ converges to $u(x_c)$ as $\varepsilon \to 0$. Further, setting $J(w) = M_\psi(w)$ into (3.1) as the right-hand side, for $0 \ll \varepsilon < 1$ fixed, now results in a unique solution z in $H(\mathcal{L}^*, \Omega)$.

Example 3: *Outflow normal flux.* As a final example, consider the (weighted) normal flux $J(\cdot) \equiv N_\psi(\cdot)$ through the outflow boundary Γ_+, defined, for $w \in H(\mathcal{L}, \Omega)$, by

$$J(w) \equiv N_\psi(w) = \int_{\Gamma_+} (\mathbf{b} \cdot \mathbf{n})\, w\psi \,\mathrm{d}s\,, \tag{3.4}$$

where ψ is a given "weight" function in $L_2(\Gamma_+)$. A simple calculation based on the divergence theorem shows that z is the (unique) solution to the following boundary value problem: find z in $H(\mathcal{L}^*, \Omega)$ such that

$$\begin{aligned} \mathcal{L}^* z \equiv -\nabla \cdot (\mathbf{b} z) + cz = 0, \quad & x \in \Omega\,, \\ z = \psi, \quad & x \in \Gamma_+\,. \end{aligned}$$

For a given linear functional $J(\cdot)$ the proceeding a posteriori error bound will be expressed in terms of the finite element residual $r_{h,p}$ defined on $\kappa \in \mathcal{T}$ by

$$r_{h,p}|_\kappa = (f - \mathcal{L} u_{\mathrm{DG}})|_\kappa,$$

which measures the extent to which u_{DG} fails to satisfy the differential equation on the union of the elements κ in the mesh $\mathcal{T}$; thus we refer to $r_{h,p}$ as the *internal residual.* Also, since u_{DG} satisfies only the boundary conditions approximately, the difference $g - u_{\mathrm{DG}}$ is not necessarily zero on Γ_-; thus, for each element κ with $\partial_-\kappa \cap \Gamma_-$ of positive $(d-1)$-dimensional measure, we define the *boundary residual* $r_{h,p-}$ by

$$r_{h,p-}|_{\partial_-\kappa\cap\Gamma_-} = (g - u_{\mathrm{DG}}^+)|_{\partial_-\kappa\cap\Gamma_-}\,.$$

With these definitions we observe from (2.5) the following relationship between the internal and boundary residual:

$$\begin{aligned} B_{\mathrm{DG}}(u - u_{\mathrm{DG}}, v) \equiv & \sum_{\kappa\in\mathcal{T}} (r_{h,p}, v)_\kappa + \sum_{\kappa\in\mathcal{T}} ((\mathbf{b}\cdot\mathbf{n})[u_{\mathrm{DG}}], v^+)_{\partial_-\kappa\setminus\Gamma_-} \\ & - \sum_{\kappa\in\mathcal{T}} ((\mathbf{b}\cdot\mathbf{n}) r_{h,p-}, v^+)_{\partial_-\kappa\cap\Gamma_-} = 0 \end{aligned} \tag{3.5}$$

for all v in $S^{\mathbf{p}}(\Omega, \mathcal{T}, \mathbf{F})$. The identity (3.5) is referred to as the *Galerkin orthogonality* property of the *hp*-DGFEM. We remark that the second term on the right-hand side of (3.5) reflects the fact that while the normal flux $(\mathbf{b}u) \cdot \mathbf{n} = (\mathbf{b} \cdot \mathbf{n})u$ of the analytical solution u is continuous across element interfaces (even if the analytical solution u is only piecewise continuous on Ω), the normal flux of the numerical solution u_{DG} is *not*, due to the choice of the finite element space $S^{\mathbf{p}}(\Omega, \mathcal{T}, \mathbf{F})$; for finite element approximations to (2.1) based on continuous piecewise polynomials, this term is, of course, equal to zero.

3.1. Type I a posteriori error bound. The starting point of the a posteriori error analysis is the following general result.

THEOREM 3.1. *Let u and u_{DG} denote the solutions of* (2.1) *and* (2.5)*, respectively, and suppose that the dual solution z is defined by* (3.1)*. Then, the following error representation formula holds:*

$$\begin{aligned} J(u) - J(u_{\mathrm{DG}}) = {} & \sum_{\kappa \in \mathcal{T}} (r_{h,p}, z - z_{h,p})_\kappa + \sum_{\kappa \in \mathcal{T}} ((\mathbf{b} \cdot \mathbf{n})[u_{\mathrm{DG}}], (z - z_{h,p})^+)_{\partial_-\kappa \setminus \Gamma_-} \\ & - \sum_{\kappa \in \mathcal{T}} ((\mathbf{b} \cdot \mathbf{n}) r_{h,p-}, (z - z_{h,p})^+)_{\partial_-\kappa \cap \Gamma_-} \\ \equiv {} & \mathcal{E}_\Omega(u_{\mathrm{DG}}, h, p, z - z_{h,p}) \end{aligned} \tag{3.6}$$

for all $z_{h,p}$ in $S^{\mathbf{p}}(\Omega, \mathcal{T}, \mathbf{F})$.

Proof. On choosing $w = u - u_{\mathrm{DG}}$ in (3.1) and recalling the linearity of $J(\cdot)$ and the Galerkin orthogonality property (3.5), we deduce that

$$\begin{aligned} J(u) - J(u_{\mathrm{DG}}) &= J(u - u_{\mathrm{DG}}) = B_{\mathrm{DG}}(u - u_{\mathrm{DG}}, z) = B_{\mathrm{DG}}(u - u_{\mathrm{DG}}, z - z_{h,p}) \\ &= \sum_{\kappa \in \mathcal{T}} (r_{h,p}, z - z_{h,p})_\kappa + \sum_{\kappa \in \mathcal{T}} ((\mathbf{b} \cdot \mathbf{n})[u_{\mathrm{DG}}], (z - z_{h,p})^+)_{\partial_-\kappa \setminus \Gamma_-} \\ &\quad - \sum_{\kappa \in \mathcal{T}} ((\mathbf{b} \cdot \mathbf{n}) r_{h,p-}, (z - z_{h,p})^+)_{\partial_-\kappa \cap \Gamma_-} \, , \end{aligned}$$

and hence (3.6). □

Given a linear functional $J(\cdot)$ and a positive tolerance TOL, the aim of the computation is to calculate u_{DG} such that

$$|J(u) - J(u_{\mathrm{DG}})| \leq \mathtt{TOL} \, . \tag{3.7}$$

According to (3.6), a necessary and sufficient condition for this to hold is that the *stopping criterion*

$$|\mathcal{E}_\Omega(u_{\mathrm{DG}}, h, p, z - z_{h,p})| \leq \mathtt{TOL} \tag{3.8}$$

is satisfied. If (3.8) holds, then $J(u_{\mathrm{DG}})$ is accepted as an accurate representation of $J(u)$; otherwise, u_{DG} is discarded and a new, improved approximation is computed on a refined subdivision. In order to ensure that the subdivision is refined only where necessary, a decision has to be made on each element κ as to whether the local mesh size h_κ and the local polynomial degree p_κ are acceptable in relation to TOL. A convenient approach to obtaining a local refinement criterion which relates the local discretization parameters h_κ and p_κ to TOL is to *localize* $\mathcal{E}_\Omega(u_{\mathrm{DG}}, h, p, z - z_{h,p})$. More precisely, $|\mathcal{E}_\Omega(u_{\mathrm{DG}}, h, p, z - z_{h,p})|$ is further bounded above by noting that

$\mathcal{E}_\Omega(u_{\rm DG}, h, p, z - z_{h,p})$ can be decomposed as $\sum_\kappa \chi_\kappa$, with

$$\chi_\kappa = (r_{h,p}, z - z_{h,p})_\kappa + ((\mathbf{b}\cdot\mathbf{n})[u_{\rm DG}], (z - z_{h,p})^+)_{\partial_-\kappa\backslash\Gamma_-} \\ +((\mathbf{b}\cdot\mathbf{n})r_{h,p-}, (z - z_{h,p})^+)_{\partial_-\kappa\cap\Gamma_-} \,,$$

and applying the inequality $|\sum_\kappa \chi_\kappa| \leq \sum_\kappa |\chi_\kappa|$. Thus we arrive at the following result.

COROLLARY 3.2. *Under the assumptions of Theorem* 3.1, *the following a posteriori error bound holds:*

$$|J(u) - J(u_{\rm DG})| \leq \mathcal{E}(u_{\rm DG}, h, p, z - z_{h,p}) \,, \tag{3.9}$$

where

$$\mathcal{E}(u_{\rm DG}, h, p, z - z_{h,p}) \equiv \sum_{\kappa\in\mathcal{T}} \eta_\kappa \,, \tag{3.10}$$

and

$$\eta_\kappa = |(r_{h,p}, z - z_{h,p})_\kappa + ((\mathbf{b}\cdot\mathbf{n})[u_{\rm DG}], (z - z_{h,p})^+)_{\partial_-\kappa\backslash\Gamma_-} \\ -((\mathbf{b}\cdot\mathbf{n})r_{h,p-}, (z - z_{h,p})^+)_{\partial_-\kappa\cap\Gamma_-}| \,. \tag{3.11}$$

Now, a possible local refinement criterion might, for example, consist of checking whether, on each element κ in the subdivision $\mathcal{T}$, the inequality

$$\eta_\kappa \leq \frac{\texttt{TOL}}{N} \tag{3.12}$$

holds, where N is the number of elements in $\mathcal{T}$. If (3.12) is valid on each element κ in $\mathcal{T}$, then, according to (3.9), the stopping criterion (3.8) has been reached and the required error control (3.7) has been achieved. The a posteriori error bound (3.9)–(3.11), where the difference between the dual solution z and its discrete representation (e.g. interpolant, quasi-interpolant, or projection) $z_{h,p}$ defined on the primal subdivision $\mathcal{T}$ enters into the error estimate as local weight function, will be referred to as an a posteriori error bound of Type I.

It may seem natural to further bound η_κ in (3.11) by writing

$$\eta_\kappa \leq |(r_{h,p}, z - z_{h,p})_\kappa| + |((\mathbf{b}\cdot\mathbf{n})[u_{\rm DG}], (z - z_{h,p})^+)_{\partial_-\kappa\backslash\Gamma_-}| \\ +|((\mathbf{b}\cdot\mathbf{n})r_{h,p-}, (z - z_{h,p})^+)_{\partial_-\kappa\cap\Gamma_-}| \equiv \zeta_\kappa \,.$$

We may then consider the a posteriori error bound

$$|J(u) - J(u_{\rm DG})| \leq \sum_{\kappa\in\mathcal{T}} \zeta_\kappa \,. \tag{3.13}$$

Indeed, we could proceed even further, to eliminate $z_{h,p}$ from the a posteriori error estimate, by bounding each term in ζ_κ via the Cauchy–Schwarz inequality and standard results from approximation theory to estimate the expressions $\|z - z_{h,p}\|_{L_2(\kappa)}$ and $\|(z - z_{h,p})^+\|_{L_2(\partial_-\kappa)}$ in terms of the discretization parameters h_κ and p_κ and Sobolev seminorms of z. For then, finally, the dual solution z may also be eliminated from the a posteriori error estimate by bounding norms of z by suitable norms of the data for the dual problem via hyperbolic well-posedness results. The resulting a posteriori error bound will then, in the spirit of Erikson et al. [11], involve only the residual terms

r_{hp}, $(\mathbf{b}\cdot\mathbf{n})[u_{\mathrm{DG}}]$ and $r_{h,p-}$, the discretization parameters, the interpolation constants, and the stability factor of the dual problem; such an estimate will be referred to here as a Type II a posteriori error bound. We note that the residual-based weighted a posteriori error bounds of Becker and Rannacher [5] are intermediate between Type I and Type II bounds, although, due to the locality of the weight, closer in spirit to those of Type I. For earlier work on Type I and Type II error bounds for finite element and finite volume approximations to linear hyperbolic problems, we refer to [14, 22].

The seemingly harmless transition from the Type I error bound (3.9)–(3.13) and the subsequent elimination of the dual solution z *en route* to a Type II bound can be detrimental: due to loss of global cancellations the resulting Type II bound may, under mesh refinement, exhibit a rate of convergence inferior to that of $|J(u)-J(u_{\mathrm{DG}})|$, resulting in uneconomical meshes and an inefficient adaptive algorithm (see, for example, [14]). For this reason we refrain from bounding the terms η_κ further; in particular, we shall not attempt to eliminate the dual solution z from our a posteriori error bound by exploiting standard approximation results and the strong stability of the dual problem. Instead, in the practical implementation of (3.9) we replace z in the bound (3.9) by an approximation $\tilde{z}_{\mathrm{DG}}$, computed by an *hp*-adaptive discontinuous Galerkin finite element method on a sequence of auxiliary (dual) subdivisions $\tilde{\mathcal{T}}$ of the computational domain Ω; see section 4.1 below. We then define $z_{h,p}$ as the $L_2(\Omega)$ projection of $\tilde{z}_{\mathrm{DG}}$ onto the "primal" finite element space $S^{\mathbf{p}}(\Omega,\mathcal{T},\mathbf{F})$ over the "primal" subdivision $\mathcal{T}$. Thus, after decomposing the error representation formula derived in Theorem 3.1 into terms which are computable, i.e., those involving the numerical approximation $\tilde{z}_{\mathrm{DG}}$ to the dual problem, and those that involve the analytical dual solution z, we arrive at the following result.

COROLLARY 3.3. *Under the assumptions of Theorem* 3.1*, the following a posteriori error bound holds:*

$$\begin{aligned}|J(u)-J(u_{\mathrm{DG}})| &\leq \mathcal{E}(u_{\mathrm{DG}},h,p,\tilde{z}_{\mathrm{DG}}-z_{h,p}) + |\mathcal{E}_\Omega(u_{\mathrm{DG}},h,p,z-\tilde{z}_{\mathrm{DG}})| \\ &\equiv \mathcal{E}_{\mathrm{P}}+\mathcal{E}_{\mathrm{D}}\,,\end{aligned} \tag{3.14}$$

where $\mathcal{E}$ and $\mathcal{E}_\Omega$ are defined in (3.10) *and* (3.6)*, respectively.*

We emphasize here that the key difference between the terms $\mathcal{E}(u_{\mathrm{DG}},h,p,\cdot)$ and $|\mathcal{E}_\Omega(u_{\mathrm{DG}},h,p,\cdot)|$ is that in the former the absolute value signs appear under the summation over the elements $\kappa\in\mathcal{T}$, while in the latter the absolute value sign is outside the sum. It will be shown through numerical experiments that the true weighting function $z-z_{h,p}$ appearing in the a posteriori error bound (3.9) may be accurately approximated by $\tilde{z}_{\mathrm{DG}}-z_{h,p}$; indeed, we shall show that $\mathcal{E}_{\mathrm{D}}$ is typically an order of magnitude smaller than $\mathcal{E}_{\mathrm{P}}$; cf. Table 5.1 and Figures 5.4 and 5.8, below, and [13, 24] in the case of nonlinear hyperbolic conservation laws. Therefore, $\mathcal{E}_{\mathrm{D}}$ can be safely absorbed into $\mathcal{E}_{\mathrm{P}}$ without compromising the reliability of the adaptive algorithm when the stopping criterion (3.8) is replaced by

$$\mathcal{E}_{\mathrm{P}} \leq \mathtt{TOL}\,.$$

By this we mean that the right-hand side of (3.14) remains an upper bound on the true error in the linear functional $J(\cdot)$, even when the term $\mathcal{E}_{\mathrm{D}}$ is neglected in the process of error control for the primal problem.

The *hp*-DGFEM approximation $\tilde{z}_{\mathrm{DG}}$ to the dual solution z appearing in $\mathcal{E}_{\mathrm{P}}$ will be computed by an *hp*-adaptive finite element algorithm, on a sequence of "dual meshes" $\tilde{\mathcal{T}}$, which, in general, differ from the "primal meshes" $\mathcal{T}$. The sequence of dual meshes will be generated by means of an a posteriori error bound on

$$\mathcal{E}_{\mathrm{D}} = \left|\mathcal{E}_\Omega(u_{\mathrm{DG}}, h, p, z) - \mathcal{E}_\Omega(u_{\mathrm{DG}}, h, p, \tilde{z}_{\mathrm{DG}})\right| .$$

Since $\mathcal{E}_\Omega(u_{\mathrm{DG}}, h, p, \cdot)$ is a linear functional, we can derive an a posteriori bound on $\mathcal{E}_{\mathrm{D}}$ by mimicking the process of error estimation for the primal problem described above with the primal problem replaced by the dual and the functional $J(\cdot)$ substituted by $\mathcal{E}_\Omega(u_{\mathrm{DG}}, h, p, \cdot)$. As the use of a Type I a posteriori error bound on $\mathcal{E}_{\mathrm{D}}$ would involve the solution of the dual to the dual problem, which would then in turn have to be solved numerically, we shall instead use a crude Type II a posteriori error bound on $\mathcal{E}_{\mathrm{D}}$ so as to terminate the potentially infinite succession of mutually dual problems that would otherwise arise. The crudeness of the Type II bound on $\mathcal{E}_{\mathrm{D}}$ will be of no concern: as noted above, numerical experiments indicate that $\mathcal{E}_{\mathrm{D}} \ll \mathcal{E}_{\mathrm{P}}$, so from the practical point of view there appears to be little advantage in performing reliable error control for $\mathcal{E}_{\mathrm{D}}$; our aim, when using the Type II bound on $\mathcal{E}_{\mathrm{D}}$, is merely to generate an adequate sequence of finite element approximations $\tilde{z}_{\mathrm{DG}}$ to the dual solution z which we can then use to compute $\mathcal{E}_{\mathrm{P}}$. The next section is, therefore, devoted to Type II a posteriori error bounds for the hp-DGFEM.

3.2. Type II a posteriori error bounds. For convenience, in the rest of this section we shall restrict ourselves to meshes consisting of affine equivalent d-parallelepiped elements. Generalizations to nonaffine elements may be treated by constructing meshes consisting of local patches as in [16].

Assuming that m is a positive integer, we define the negative Sobolev norm $\|\cdot\|_{H^{-m}(\Omega)}$ in the usual way:

$$\|w\|_{H^{-m}(\Omega)} = \sup_{v \in C_0^\infty(\Omega)} \frac{|(w, v)|}{\|v\|_{H^m(\Omega)}} .$$

Further, we write $\|v\|_\tau$, $\tau \subset \partial\kappa$, $\kappa \in \mathcal{T}$, to denote the (semi-) norm induced by the (semi-) inner product

$$\langle v, w\rangle_\tau = \int_\tau |\mathbf{b}\cdot\mathbf{n}|\, vw \,\mathrm{d}s,$$

for $v, w \in L_2(\tau)$. Finally, we recall from [16] and [21] the following approximation results for the finite element space $S^{\mathbf{p}}(\Omega, \mathcal{T}, \mathbf{F})$.

Lemma 3.4. *Suppose that $u|_\kappa \in H^{k_\kappa}(\kappa)$, $k_\kappa \geq 1$, for some κ in $\mathcal{T}$. Then, there exists $\Pi_{hp}u$ in the finite element space $S^{\mathbf{p}}(\Omega, \mathcal{T}, \mathbf{F})$, a constant C_{int} dependent only on d and the shape-regularity of $\mathcal{T}$, but independent of u, $h_\kappa = diam(\kappa)$, p_κ and k_κ, such that*

$$\|u - \Pi_{hp}u\|^2_{L_2(\kappa)} \leq C^2_{\mathrm{int}} h_\kappa^{2s_\kappa} \frac{1}{p_\kappa(p_\kappa+1)}\, \Phi_1(p_\kappa, s_\kappa)\, |u|^2_{H^{s_\kappa}(\kappa)} ,$$

and

$$\|\nabla(u - \Pi_{hp}u)\|^2_{L_2(\kappa)} \leq C^2_{\mathrm{int}} h_\kappa^{2s_\kappa-2}\, \Phi_1(p_\kappa, s_\kappa)\, |u|^2_{H^{s_\kappa}(\kappa)} ,$$

for $1 \leq s_\kappa \leq \min(k_\kappa, p_\kappa+1)$. Here,

$$\Phi_1(p, s) := \frac{\Gamma(p-s+2)}{\Gamma(p+s)} + \frac{1}{p(p+1)}\frac{\Gamma(p-s+3)}{\Gamma(p+s-1)}, \qquad 1 \leq s \leq p+1 .$$

THEOREM 3.5. *Let u and u_{DG} denote the solutions of* (2.1) *and* (2.5)*, respectively. Suppose further that the dual problem* (3.1) *has a unique solution $z \in H(\mathcal{L}^*, \Omega)$ such that $z|_\kappa \in H^{t_\kappa}(\kappa)$ for each $\kappa \in \mathcal{T}$ with $1 \le t_\kappa \le p_\kappa + 1$. Then,*

$$|J(u) - J(u_{\mathrm{DG}})| \le C_0 C_{\mathrm{int}} |z|_{H^{\mathbf{t}}(\Omega,\mathcal{T})} \left[\left(\sum_{\kappa \in \mathcal{T}} \frac{h_\kappa^{2t_\kappa}}{p_\kappa(p_\kappa+1)} \, \Phi_1(p_\kappa, t_\kappa) \, \|r_{h,p}\|^2_{L_2(\kappa)} \right)^{1/2} \right.$$
$$+ \left(\sum_{\kappa \in \mathcal{T}} \frac{h_\kappa^{2t_\kappa - 1}}{p_\kappa} \, \Phi_1(p_\kappa, t_\kappa) \, \|[u_{\mathrm{DG}}]\|^2_{\partial_-\kappa \setminus \Gamma_-} \right)^{1/2}$$
$$\left. + \left(\sum_{\kappa \in \mathcal{T}} \frac{h_\kappa^{2t_\kappa - 1}}{p_\kappa} \, \Phi_1(p_\kappa, t_\kappa) \, \|r_{h,p-}\|^2_{\partial_-\kappa \cap \Gamma_-} \right)^{1/2} \right],$$

where C_0 depends only on $\|\mathbf{b}\|_{L_\infty(\Omega)}$, the dimension d, and the shape-regularity of $\mathcal{T}$.

Proof. Applying the Cauchy–Schwarz inequality to the right-hand side of (3.9) in Corollary 3.2 gives

$$\begin{aligned} |J(u) - J(u_{\mathrm{DG}})| &\le \sum_{\kappa \in \mathcal{T}} \|r_{h,p}\|_{L_2(\kappa)} \|z - z_{h,p}\|_{L_2(\kappa)} \\ &\quad + \sum_{\kappa \in \mathcal{T}} \|[u_{\mathrm{DG}}]\|_{\partial_-\kappa \setminus \Gamma_-} \|(z - z_{h,p})^+\|_{\partial_-\kappa \setminus \Gamma_-} \\ &\quad + \sum_{\kappa \in \mathcal{T}} \|r_{h,p-}\|_{\partial_-\kappa \cap \Gamma_-} \|(z - z_{h,p})^+\|_{\partial_-\kappa \cap \Gamma_-} \\ &\equiv \mathrm{I} + \mathrm{II} + \mathrm{III}\,. \end{aligned} \tag{3.15}$$

Exploiting the approximation result stated in Lemma 3.4, together with the Cauchy–Schwarz inequality, we get

$$\mathrm{I} \le C_{\mathrm{int}} \left(\sum_{\kappa \in \mathcal{T}} \frac{h_\kappa^{2t_\kappa}}{p_\kappa(p_\kappa+1)} \, \Phi_1(p_\kappa, t_\kappa) \, \|r_{h,p}\|^2_{L_2(\kappa)} \right)^{1/2} \left(\sum_{\kappa \in \mathcal{T}} |z|^2_{H^{t_\kappa}(\kappa)} \right)^{1/2}$$

for $1 \le t_\kappa \le p_\kappa + 1$ and κ in $\mathcal{T}$. To bound the approximation error $z - z_{h,p}$ on a subset τ of the boundary of a given element κ in $\mathcal{T}$, we use the following trace inequality:

$$\|v\|^2_\tau \le \frac{1}{2} C_0^2 (\|\nabla v\|_{L_2(\kappa)} \|v\|_{L_2(\kappa)} + h_\kappa^{-1} \|v\|^2_{L_2(\kappa)}); \tag{3.16}$$

here, C_0 depends only on $\|\mathbf{b}\|_{L_\infty(\Omega)}$, d, and the shape-regularity of $\mathcal{T}$.

Exploiting (3.16), together with Lemma 3.4, gives the following bounds on terms II and III:

$$\mathrm{II} \le C_0 C_{\mathrm{int}} \left(\sum_{\kappa \in \mathcal{T}} \frac{h_\kappa^{2t_\kappa - 1}}{p_\kappa} \, \Phi_1(p_\kappa, t_\kappa) \, \|[u_{\mathrm{DG}}]\|^2_{\partial_-\kappa \setminus \Gamma_-} \right)^{1/2} \left(\sum_{\kappa \in \mathcal{T}} |z|^2_{H^{t_\kappa}(\kappa)} \right)^{1/2},$$
$$\mathrm{III} \le C_0 C_{\mathrm{int}} \left(\sum_{\kappa \in \mathcal{T}} \frac{h_\kappa^{2t_\kappa - 1}}{p_\kappa} \, \Phi_1(p_\kappa, t_\kappa) \, \|r_{h,p-}\|^2_{\partial_-\kappa \cap \Gamma_-} \right)^{1/2} \left(\sum_{\kappa \in \mathcal{T}} |z|^2_{H^{t_\kappa}(\kappa)} \right)^{1/2}$$

for $1 \le t_\kappa \le p_\kappa + 1$ and κ in $\mathcal{T}$. Upon inserting the estimates on I, II, and III into (3.15) the result follows. □

REMARK 3.6. *As an application of Theorem* 3.5*, let us consider the problem of a posteriori error estimation for the hp-DGFEM approximation of the weighted mean value of the solution u to the model problem* (2.1)*. Choosing $J(u) = M_\psi(u)$ in Theorem* 3.5 *with the weight function $\psi \in C_0^\infty(\Omega)$ gives*

$$\begin{aligned} |M_\psi(u) - M_\psi(u_{\mathrm{DG}})| &\equiv |(u - u_{\mathrm{DG}}, \psi)| \\ &\le C_0 C_{\mathrm{int}} \left[\left(\sum_{\kappa\in\mathcal{T}} \frac{h_\kappa^{2t_\kappa}}{p_\kappa(p_\kappa+1)} \, \Phi_1(p_\kappa, t_\kappa) \, \|r_{h,p}\|^2_{L_2(\kappa)} \right)^{1/2} \right. \\ &\quad + \left(\sum_{\kappa\in\mathcal{T}} \frac{h_\kappa^{2t_\kappa-1}}{p_\kappa} \, \Phi_1(p_\kappa, t_\kappa) \, \|[u_{\mathrm{DG}}]\|^2_{\partial_-\kappa\setminus\Gamma_-} \right)^{1/2} \\ &\quad \left. + \left(\sum_{\kappa\in\mathcal{T}} \frac{h_\kappa^{2t_\kappa-1}}{p_\kappa} \, \Phi_1(p_\kappa, t_\kappa) \, \|r_{h,p-}\|^2_{\partial_-\kappa\cap\Gamma_-} \right)^{1/2} \right] |z|_{H^{\mathbf{t}}(\Omega)} . \end{aligned} \tag{3.17}$$

Letting $m = \max_{\kappa\in\mathcal{T}} t_\kappa$, it follows by the differentiability theorem of Rauch [20] *applied to* (3.3) *that*

$$\|z\|_{H^m(\Omega)} \le C_{\mathrm{stab}} \|\psi\|_{H^m(\Omega)} , \tag{3.18}$$

where C_{stab} is a positive constant, independent of ψ, called the stability factor of the dual problem. Denoting by $\mathcal{B}(h, p, u_{\mathrm{DG}})$ the expression in the square bracket in (3.17)*, we deduce the following Type* II *a posteriori error bound:*

$$|M_\psi(u) - M_\psi(u_{\mathrm{DG}})| \le C_0 C_{\mathrm{int}} C_{\mathrm{stab}} \|\psi\|_{H^m(\Omega)} \mathcal{B}(h, p, u_{\mathrm{DG}}) .$$

In fact, upon dividing both sides of the last inequality by $\|\psi\|_{H^m(\Omega)}$ and taking the supremum over all $\psi \in C_0^\infty(\Omega)$) yields the following Type II *a posteriori error bound in a negative Sobolev norm:*

$$\|u - u_{\mathrm{DG}}\|_{H^{-m}(\Omega)} \le C_0 C_{\mathrm{int}} C_{\mathrm{stab}} \mathcal{B}(h, p, u_{\mathrm{DG}}) .$$

We note that a bound identical to (3.17) *holds for the weighted normal flux $N_\psi(u)$ of u through the outflow boundary Γ_+ with ψ a sufficiently smooth weight function defined on Γ_+.*

3.3. A priori error bounds. As indicated in the introduction, the *hp*-adaptive algorithms for the primal and dual problems will be driven by a posteriori error bounds: a Type I bound for the primal problem and a Type II bound for the dual problem. The decision about whether a local h-refinement/derefinement or a local p-refinement/derefinement is to be performed in the course of mesh adaptation will be based on assessing the local regularity of the primal and the dual solution. The estimation of local Sobolev indices which measure local regularity will, in turn, rely on an a priori bound on the error in the computed functional in terms of Sobolev norms of the analytical primal and dual solutions u and z, respectively; this will indicate the expected rate of convergence for $|J(u) - J(u_{\mathrm{DG}})|$ as the finite element space is enriched, i.e., as h tends to 0 and p tends to infinity, assuming that the primal and dual solutions have certain Sobolev regularities. The present section is devoted to the derivation of this a priori error bound.

We assume for the moment that the data for the problem (2.1) satisfy the following assumptions:

$$\begin{aligned} \mathbf{b}\cdot\nabla_{\mathcal{T}} v_h \in S^{\mathbf{p}}(\Omega,\mathcal{T},\mathbf{F}) \quad &\forall v_h \in S^{\mathbf{p}}(\Omega,\mathcal{T},\mathbf{F})\,, \\ c \in S^{\mathbf{0}}(\Omega,\mathcal{T},\mathbf{F})\,, \qquad &f \in S^{\mathbf{p}}(\Omega,\mathcal{T},\mathbf{F})\,. \end{aligned} \tag{3.19}$$

Here, $\nabla_{\mathcal{T}} v$, $v \in H^1(\Omega,\mathcal{T})$, denotes the broken gradient of v defined by $(\nabla_{\mathcal{T}} v)|_\kappa = \nabla(v|_\kappa)$, $\kappa \in \mathcal{T}$. To ensure that (2.1) is then meaningful (i.e., that the characteristic curves of the differential operator $\mathcal{L}$ are correctly defined), we still assume that $\mathbf{b} \in \left[W^1_\infty(\Omega)\right]^d$.

REMARK 3.7. *The condition placed on* $\mathbf{b}$ *is required in the proof of the a priori error bound stated below (Lemma* 3.9*), cf.* [15]*; the conditions on the reaction/absorption term* c *and the forcing function* f *are required to ensure that the internal residual* $r_{h,p}$ *belongs to the finite element space* $S^{\mathbf{p}}(\Omega,\mathcal{T},\mathbf{F})$*, cf. Lemma* 3.10*. However, we shall see in section* 5 *that the restrictions* (3.19) *are not essential in practice for our a priori error bounds to hold.*

Before embarking on the a priori error analysis, we quote from Schwab [21, Theorem 4.76, p. 208] the following inverse inequality for the finite element space $S^{\mathbf{p}}(\Omega,\mathcal{T},\mathbf{F})$.

LEMMA 3.8. *Given* v *in* $S^{\mathbf{p}}(\Omega,\mathcal{T},\mathbf{F})$*, there exists a positive constant* C*, dependent only on* d *and the shape-regularity of* $\mathcal{T}$*, such that*

$$|v|_{H^1(\kappa)} \le C\,\frac{p_\kappa^2}{h_\kappa}\,\|v\|_{L_2(\kappa)}$$

for all κ *in* $\mathcal{T}$*.*

In the following lemma (cf. [15]) we formulate an a priori bound on the error $u - u_{\mathrm{DG}}$ in terms of the DG–norm $|||\cdot|||_{\mathrm{DG}}$ defined in section 2.2. We recall that

$$\begin{aligned} |||v|||^2_{\mathrm{DG}} := \sum_{\kappa\in\mathcal{T}} \Big\{ &\|c_0 v\|^2_{L_2(\kappa)} + \frac{1}{2}\|v^+\|_{\partial_-\kappa\cap\Gamma_-} + \frac{1}{2}\|v^+\|^2_{\partial_+\kappa\cap\Gamma_+} \\ &+ \frac{1}{2}\|v^+ - v^-\|^2_{\partial_-\kappa\setminus\Gamma_-} \Big\}\,, \end{aligned} \tag{3.20}$$

where c_0 is the (positive) function defined in (2.3).

LEMMA 3.9. *Let* u *and* u_{DG} *denote the solutions of* (2.1) *and* (2.5)*, respectively. Assuming that* (3.19) *holds and* $u|_\kappa \in H^{k_\kappa}(\kappa)$*,* $k_\kappa \ge 1$*, for all* κ *in* $\mathcal{T}$*, we have*

$$|||u - u_{\mathrm{DG}}|||^2_{\mathrm{DG}} \le C \sum_{\kappa\in\mathcal{T}} h_\kappa^{2s_\kappa - 1}\,\Phi_2(p_\kappa, s_\kappa)\,|u|^2_{H^{s_\kappa}(\kappa)}$$

for any integers $1 \le s_\kappa \le \min(p_\kappa + 1, k_\kappa)$*,* $\kappa \in \mathcal{T}$*. Here,*

$$\begin{aligned} \Phi_2(s,p) = \frac{1}{2p+1}\,&\left(\frac{\Gamma(p+2-s)}{\Gamma(p+s)} + \frac{\Gamma(p+3-s)}{\Gamma(p+1+s)}\right) \\ &+ \left(\frac{\Gamma(p+2-s)}{\Gamma(p+2+s)}\right)^{\frac{1}{2}} \left(\frac{\Gamma(p+3-s)}{\Gamma(p+1+s)}\right)^{\frac{1}{2}} + \frac{\Gamma(p+2-s)}{\Gamma(p+2+s)}\,, \end{aligned}$$

and C is a positive constant depending only on d, $\|\mathbf{b}\|_{L_\infty(\Omega)}$, $\|c\|_{L_\infty(\Omega)}$, and the shape-regularity of $\mathcal{T}$.

Furthermore, we need the following bound on the internal residual $r_{h,p}$.

LEMMA 3.10. *Assuming that the conditions on the data* (3.19) *hold, there exists a positive constant C, dependent only on d and the shape-regularity of $\mathcal{T}$, such that*

$$\sum_{\kappa\in\mathcal{T}} \frac{h_\kappa}{p_\kappa^2+1}\|r_{h,p}\|^2_{L_2(\kappa)} \leq C|||u-u_{\mathrm{DG}}|||^2_{\mathrm{DG}}\,.$$

Proof. From the Galerkin orthogonality property (3.5) we have

$$\sum_{\kappa\in\mathcal{T}}(r_{h,p},v)_\kappa = -\sum_{\kappa\in\mathcal{T}}((\mathbf{b}\cdot\mathbf{n})[u_{\mathrm{DG}}],v^+)_{\partial_-\kappa\backslash\Gamma_-} + \sum_{\kappa\in\mathcal{T}}((\mathbf{b}\cdot\mathbf{n})r_{h,p-},v^+)_{\partial_-\kappa\cap\Gamma_-} \tag{3.21}$$

for any v in $S^{\mathbf{p}}(\Omega,\mathcal{T},\mathbf{F})$. Under the conditions (3.19), the internal residual $r_{h,p}$ belongs to the finite element space $S^{\mathbf{p}}(\Omega,\mathcal{T},\mathbf{F})$; thereby, choosing $v=\theta r_{h,p}$ in (3.21), where θ is in $S^{\mathbf{0}}(\Omega,\mathcal{T},\mathbf{F})$ such that $\theta|_\kappa=\theta_\kappa>0$, and applying the Cauchy–Schwarz inequality gives

$$\begin{aligned}\sum_{\kappa\in\mathcal{T}}\theta_\kappa\|r_{h,p}\|^2_{L_2(\kappa)} \leq{}& \sum_{\kappa\in\mathcal{T}}\theta_\kappa\|[u_{\mathrm{DG}}]\|_{\partial_-\kappa\backslash\Gamma_-}\|r^+_{h,p}\|_{\partial_-\kappa\backslash\Gamma_-}\\ &+\sum_{\kappa\in\mathcal{T}}\theta_\kappa\|r_{h,p-}\|_{\partial_-\kappa\cap\Gamma_-}\|r^+_{h,p}\|_{\partial_-\kappa\cap\Gamma_-}\,.\end{aligned}$$

Exploiting the trace inequality (3.16), together with the inverse inequality stated in Lemma 3.8, we deduce that

$$\sum_{\kappa\in\mathcal{T}}\theta_\kappa\|r_{h,p}\|^2_{L_2(\kappa)} \leq C\sum_{\kappa\in\mathcal{T}}\theta_\kappa\frac{p_\kappa^2+1}{h_\kappa}\left(\|[u_{\mathrm{DG}}]\|^2_{\partial_-\kappa\backslash\Gamma_-}+\frac{1}{2}\|r_{h,p-}\|^2_{\partial_-\kappa\cap\Gamma_-}\right).$$

Choosing $\theta_\kappa = h_\kappa/(p_\kappa^2+1)$ together with the definition of the DG-norm (3.20) gives the desired result. □

Equipped with Lemmas 3.9 and 3.10, together with the approximation results stated in Lemma 3.4, we are now in a position to prove the following hp-bound on the error in the computed functional $J(\cdot)$.

THEOREM 3.11. *Let u and u_{DG} denote the solutions of* (2.1) *and* (2.5), *respectively. Given that $u|_\kappa\in H^{k_\kappa}(\kappa)$, $k_\kappa\geq 1$, and $z|_\kappa\in H^{l_\kappa}(\kappa)$, $l_\kappa\geq 1$, for all κ in $\mathcal{T}$, we have*

$$\begin{aligned}|J(u)-J(u_{\mathrm{DG}})|^2 \leq C&\sum_{\kappa\in\mathcal{T}}h_\kappa^{2s_\kappa-1}\,\Phi_2(p_\kappa,s_\kappa)\,|u|^2_{H^{s_\kappa}(\kappa)}\\ &\times\sum_{\kappa\in\mathcal{T}}h_\kappa^{2t_\kappa-1}\,\Phi_1(p_\kappa,t_\kappa)\,|z|^2_{H^{t_\kappa}(\kappa)}\end{aligned} \tag{3.22}$$

for any $1\leq s_\kappa\leq\min(p_\kappa+1,k_\kappa)$, $1\leq t_\kappa\leq\min(p_\kappa+1,l_\kappa)$, $\kappa\in\mathcal{T}$. Here, C is a positive constant depending only on d, $\|\mathbf{b}\|_{L_\infty(\Omega)}$, $\|c\|_{L_\infty(\Omega)}$, and the shape-regularity of $\mathcal{T}$.

Proof. With terms I, II, and III defined as in the proof of Theorem 3.5 (cf. (3.15)), we deduce from Lemma 3.4 and (3.16) the following bounds:

$$\mathrm{I} \le C \left(\sum_{\kappa \in \mathcal{T}} \frac{h_\kappa}{p_\kappa^2 + 1} \, \|r_{h,p}\|^2_{L_2(\kappa)} \right)^{1/2}$$

$$\times \left(\sum_{\kappa \in \mathcal{T}} h_\kappa^{2t_\kappa - 1} \, \frac{p_\kappa^2 + 1}{p_\kappa(p_\kappa + 1)} \, \Phi_1(p_\kappa, t_\kappa) \, |z|^2_{H^{t_\kappa}(\kappa)} \right)^{1/2} , \tag{3.23}$$

$$\mathrm{II} \le C \left(\sum_{\kappa \in \mathcal{T}} \|[u_{\mathrm{DG}}]\|^2_{\partial_-\kappa \setminus \Gamma_-} \right)^{1/2} \left(\sum_{\kappa \in \mathcal{T}} \frac{h_\kappa^{2t_\kappa - 1}}{p_\kappa} \Phi_1(p_\kappa, t_\kappa) |z|^2_{H^{t_\kappa}(\kappa)} \right)^{1/2} , \tag{3.24}$$

$$\mathrm{III} \le C \left(\sum_{\kappa \in \mathcal{T}} \|r_{h,p-}\|^2_{\partial_-\kappa \cap \Gamma_-} \right)^{1/2} \left(\sum_{\kappa \in \mathcal{T}} \frac{h_\kappa^{2t_\kappa - 1}}{p_\kappa} \Phi_1(p_\kappa, t_\kappa) |z|^2_{H^{t_\kappa}(\kappa)} \right)^{1/2} , \tag{3.25}$$

respectively. Collecting the bounds (3.23), (3.24), and (3.25), and exploiting Lemma 3.10, we get

$$|J(u) - J(u_{\mathrm{DG}})|^2 \le C |\!|\!| u - u_{\mathrm{DG}} |\!|\!|^2_{\mathrm{DG}} \sum_{\kappa \in \mathcal{T}} h_\kappa^{2t_\kappa - 1} \Phi_1(p_\kappa, t_\kappa) |z|^2_{H^{t_\kappa}(\kappa)} .$$

Finally, employing Lemma 3.9 gives the desired result. □

Let us now discuss some special cases of the general error bound derived in Theorem 3.11. We first note that, for fixed s, Stirling's formula implies

$$\Phi_1(p, s) \le C(s) p^{-2s+2} , \qquad \Phi_2(p, s) \le C(s) p^{-2s+1} , \tag{3.26}$$

as $p \to \infty$. Thereby, for uniform orders $p_\kappa = p$, $s_\kappa = s$, $t_\kappa = t$, $k_\kappa = k$, $l_\kappa = l$, s, t, k and l integers, and $h_\kappa = h$ for all κ in $\mathcal{T}$, we get the bound

$$|J(u) - J(u_{\mathrm{DG}})| \le C \left(\frac{h}{p} \right)^{s+t-1} p^{1/2} \, |u|_{H^s(\Omega)} |z|_{H^t(\Omega)} , \tag{3.27}$$

where $1 \le s \le \min(p+1, k)$ and $1 \le t \le \min(p+1, l)$. Hence, we deduce that

$$|J(u) - J(u_{\mathrm{DG}})| \le C \frac{h^{s+t-1}}{p^{k+l-1}} p^{1/2} \, \|u\|_{H^k(\Omega)} \|z\|_{H^l(\Omega)} , \tag{3.28}$$

where $1 \le s \le \min(p+1, k)$ and $1 \le t \le \min(p+1, l)$; cf. [23]. We note that in the transition from (3.27) to (3.28) the generic constant C is increased by the factor $(k-1)^{k-1}(l-1)^{l-1}$. Here, the bounds (3.27) and (3.28) are optimal in h and suboptimal in p by $p^{1/2}$; in the case of fixed p, (3.27), (3.28) reduce to the optimal h-convergence error bound proved in [14] for a stabilized continuous approximation to u. From (3.28) we may deduce the following a priori error bound:

$$\|u - u_{\mathrm{DG}}\|_{H^{-m}(\Omega)} \le C \frac{h^{s+\theta-1}}{p^{k+m-1}} p^{1/2} \, \|u\|_{H^k(\Omega)}, \tag{3.29}$$

where $1 \le s \le \min(p+1, k)$ and $1 \le \theta \le \min(p+1, m)$. In the presence of streamline-diffusion stabilization, with stabilization of size $\delta = h/p$, the bounds (3.27), (3.28), and (3.29) can be sharpened to ones that are simultaneously optimal in both h and p.

The explicit dependence of the error bound stated in Theorem 3.11 on the local regularity of the primal and dual solutions u and z, respectively, allows us to deduce that the error in the functional $J(\cdot)$ is exponentially convergent as $p_\kappa \to \infty$ for each κ in $\mathcal{T}$. To this end, let us assume that z is elementwise analytic in the sense that, for each $\kappa \in \mathcal{T}$, $z|_\kappa$ has analytic extension to an open set, independent of h_κ, containing $\bar{\kappa}$. Then,

$$\forall \kappa \in \mathcal{T} \quad \exists d_\kappa > 1 \quad \exists C(z) > 0 \quad \forall s > 0 : \ |z|_{H^s(\kappa)} \le C(z)(d_\kappa)^s s!\, [\mathrm{meas}(\kappa)]^{1/2} .$$

In order to emphasize the dependence of d_κ on the particular function z under consideration, we write $d_\kappa(z)$ in lieu of d_κ. Thereby, assuming that z is elementwise analytic and $h_\kappa > 0$ is fixed for all κ in $\mathcal{T}$, on setting $t_\kappa = \alpha_\kappa p_\kappa + 1$, where $0 < \alpha_\kappa = (1 + (d_\kappa(z))^2)^{-1/2} < 1$ for all $\kappa \in \mathcal{T}$, it can be shown that

$$\sum_{\kappa \in \mathcal{T}} h_\kappa^{2t_\kappa - 1}\, \Phi_1(p_\kappa, t_\kappa)\, |z|^2_{H^{t_\kappa}(\kappa)} \le C(z) \sum_{\kappa \in \mathcal{T}} h_\kappa^{2t_\kappa - 1} p_\kappa^3\, \mathrm{e}^{-2\lambda_\kappa p_\kappa} \mathrm{meas}(\kappa) , \tag{3.30}$$

where λ_κ is a positive constant on each element κ in the mesh $\mathcal{T}$; namely,

$$\lambda_\kappa = \frac{1}{2} |\log F(\alpha_\kappa, d_\kappa(z))| , \qquad \text{where} \qquad F(\alpha, d) = \frac{(1-\alpha)^{1-\alpha}}{(1+\alpha)^{1+\alpha}}\, (\alpha d)^{2\alpha};$$

see [16] for details. Similarly, assuming that u is elementwise analytic, setting $s_\kappa = \beta_\kappa p_\kappa + 1$, where $0 < \beta_\kappa = (1 + (d_\kappa(u))^2)^{-1/2} < 1$ for all $\kappa \in \mathcal{T}$, we have that

$$\sum_{\kappa \in \mathcal{T}} h_\kappa^{2s_\kappa - 1}\, \Phi_2(p_\kappa, s_\kappa)\, |u|^2_{H^{s_\kappa}(\kappa)} \le C(u) \sum_{\kappa \in \mathcal{T}} h_\kappa^{2s_\kappa - 1} p_\kappa^2\, \mathrm{e}^{-2\mu_\kappa p_\kappa} \mathrm{meas}(\kappa) , \tag{3.31}$$

where $\mu_\kappa = (1/2)|\log F(\beta_\kappa, d_\kappa(u))|$. Thereby, combining (3.30) and (3.31), we deduce the exponential convergence estimate

$$\begin{aligned} |J(u) - J(u_{\mathrm{DG}})|^2 \le K &\sum_{\kappa \in \mathcal{T}} h_\kappa^{2s_\kappa - 1} p_\kappa^2\, \mathrm{e}^{-2\mu_\kappa p_\kappa} \mathrm{meas}(\kappa) \\ &\times \sum_{\kappa \in \mathcal{T}} h_\kappa^{2t_\kappa - 1} p_\kappa^3\, \mathrm{e}^{-2\lambda_\kappa p_\kappa} \mathrm{meas}(\kappa) , \end{aligned} \tag{3.32}$$

where $K = C(u)C(z)$.

REMARK 3.12. *The bound* (3.32) *indicates that in order to ensure that the error in the functional $J(\cdot)$ decays exponentially as the degree of the approximating polynomial is increased, it is only necessary to assume that either u or z is elementwise analytic; this will be demonstrated numerically in section* 5.

4. Implementational issues.

4.1. Numerical approximation of the dual solution. In this section we formulate the discontinuous Galerkin finite element approximation of the dual problem (3.1). As stated in section 3, the particular form of the dual problem is dependent on the functional under consideration. For generality, let us suppose that z is the (unique) solution to the following problem: find $z \in H(\mathcal{L}^*, \Omega)$ such that

$$\begin{aligned} \mathcal{L}^* z \equiv -\nabla \cdot (\mathbf{b} z) + cz = \varphi, &\quad x \in \Omega , \\ z = \chi, &\quad x \in \Gamma_+ . \end{aligned} \tag{4.1}$$

Clearly, (4.1) covers both the case when the functional $J(\cdot)$ under consideration represents the local mean value of the solution u and when $J(\cdot)$ is the outflow normal flux of u; cf. section 3.

As in section 2.1, we define $\tilde{S}^{\tilde{\mathbf{p}}}(\Omega, \tilde{\mathcal{T}}, \tilde{\mathbf{F}})$ to be the finite element space consisting of piecewise polynomials of degree $\tilde{\mathbf{p}}|_{\tilde{\kappa}} = \tilde{p}_{\tilde{\kappa}}$ on a mesh $\tilde{\mathcal{T}}$ consisting of shape-regular elements $\tilde{\kappa}$ of size $\tilde{h}_{\tilde{\kappa}}$. With $\partial_+ \tilde{\kappa}$ defined as in (2.4), we introduce the bilinear form

$$\begin{aligned}\tilde{B}_{\mathrm{DG}}(w, v) = \sum_{\tilde{\kappa} \in \tilde{\mathcal{T}}} \int_{\tilde{\kappa}} \mathcal{L}^* w \, v \, \mathrm{d}x + \sum_{\tilde{\kappa} \in \tilde{\mathcal{T}}} \int_{\partial_+ \tilde{\kappa} \setminus \Gamma_+} (\mathbf{b} \cdot \mathbf{n}) [w] \, v^+ \, \mathrm{d}s \\ + \sum_{\tilde{\kappa} \in \tilde{\mathcal{T}}} \int_{\partial_+ \tilde{\kappa} \cap \Gamma_+} (\mathbf{b} \cdot \mathbf{n}) w^+ \, v^+ \, \mathrm{d}s\end{aligned}$$

and linear functional

$$\tilde{\ell}_{\mathrm{DG}}(v) = \sum_{\tilde{\kappa} \in \tilde{\mathcal{T}}} \int_{\tilde{\kappa}} \varphi v \, \mathrm{d}x + \sum_{\tilde{\kappa} \in \tilde{\mathcal{T}}} \int_{\partial_+ \tilde{\kappa} \cap \Gamma_+} (\mathbf{b} \cdot \mathbf{n}) \, \chi v^+ \, \mathrm{d}s$$

associated with the *hp*-DGFEM approximation of the dual problem (4.1). Now the *hp*-DGFEM for (4.1) is defined as follows: find $\tilde{z}_{\mathrm{DG}} \in \tilde{S}^{\tilde{\mathbf{p}}}(\Omega, \tilde{\mathcal{T}}, \tilde{\mathbf{F}})$ such that

$$\tilde{B}_{\mathrm{DG}}(\tilde{z}_{\mathrm{DG}}, v) = \tilde{\ell}_{\mathrm{DG}}(v) \quad \forall v \in \tilde{S}^{\tilde{\mathbf{p}}}(\Omega, \tilde{\mathcal{T}}, \tilde{\mathbf{F}}) \, . \tag{4.2}$$

4.2. Adaptive algorithm. For a user-defined tolerance TOL, we now consider the problem of designing the *hp*-finite element space $S^{\mathbf{p}}(\Omega, \mathcal{T}, \mathbf{F})$ such that

$$|J(u) - J(u_{\mathrm{DG}})| \le \mathtt{TOL} \, , \tag{4.3}$$

subject to the constraint that the total number of degrees of freedom in $S^{\mathbf{p}}(\Omega, \mathcal{T}, \mathbf{F})$ is minimized. Following the discussion presented in section 3, we exploit the a posteriori error bound (3.14) to construct $S^{\mathbf{p}}(\Omega, \mathcal{T}, \mathbf{F})$ such that

$$\mathcal{E}_{\mathrm{P}} \le \mathtt{TOL} \, . \tag{4.4}$$

The stopping criterion (4.4) is enforced by equidistributing $\mathcal{E}_{\mathrm{P}}|_{\kappa} \equiv \tilde{\eta}_{\kappa}$ over the elements κ in the primal mesh $\mathcal{T}$, where $\tilde{\eta}_{\kappa}$ is defined in a similar manner to η_{κ} with z replaced by $\tilde{z}_{\mathrm{DG}}$ in (3.11). Thus, we insist that

$$\tilde{\eta}_{\kappa} \approx \frac{\mathtt{TOL}}{N} \tag{4.5}$$

holds for each κ in $\mathcal{T}$; here, N denotes the number of elements in the mesh $\mathcal{T}$.

Thereby, each of the elements in the primal mesh is flagged for either refinement or derefinement to ensure that the equidistribution principle (4.5) holds. Once an element κ has been flagged a decision must be made whether the local mesh size h_{κ} or the local degree p_{κ} of the approximating polynomial should be adjusted accordingly. Let us first deal with refinement, i.e., when the local error estimator $\tilde{\eta}_{\kappa}$ is larger than the "localized-tolerance" $\mathtt{TOL}/N$. Clearly, if the primal or dual solutions u and z, respectively, are locally "smooth," then p-enrichment will be more effective than h-refinement, since the error will be expected to decay quickly within the current element κ as p_{κ} is increased. However, if u and z have low regularity within the element κ, then h-refinement will be performed. Thus, regions in the computational domain where the primal and dual solution are locally nonsmooth are isolated from smooth regions, thereby reducing the influence of singularities/discontinuities as well as making p-enrichment more effective.

To ensure that the desired level of accuracy is achieved efficiently, an automatic procedure for deciding when to h- or p-refine must be implemented. To this end, we first compute the local error indicator $\tilde{\eta}_\kappa$ on each element κ in the mesh $\mathcal{T}$ using both a p_κ and a $p_\kappa - 1$ representation for u_{DG}; we denote the corresponding values of $\tilde{\eta}_\kappa$ by $\tilde{\eta}_\kappa(p_\kappa)$ and $\tilde{\eta}_\kappa(p_\kappa - 1)$, respectively. Assuming that $\tilde{\eta}_\kappa(p_\kappa - 1) \neq 0$, the perceived smoothness of the primal and dual solutions may be estimated using the ratio

$$\rho_\kappa = \tilde{\eta}_\kappa(p_\kappa)/\tilde{\eta}_\kappa(p_\kappa - 1); \tag{4.6}$$

cf. Adjerid, Aiffa, and Flaherty [1] and Gui and Babuška [12], for example. If $\rho_\kappa \leq \gamma$, $0 < \gamma < 1$, the error is decreasing as the polynomial degree is increased, indicating that p-enrichment should be performed. On the other hand, $\rho_\kappa > \gamma$ means that the element κ should be locally subdivided. The number γ is referred to as the *type-parameter* [12]. Clearly, the choice of γ is critical to the success of this algorithm and will depend on the asymptotic behavior of the quantity of interest. Instead of assigning an *ad hoc* value to the type parameter γ, we use ρ_κ, together with the a priori error bound (3.22), to directly estimate the local regularities k_κ and l_κ of the primal and dual solutions, respectively, on each element κ in $\mathcal{T}$. More precisely, motivated by (3.28), we assume that on a given element κ in $\mathcal{T}$

$$\tilde{\eta}_\kappa = \mathcal{E}_{\mathrm{P}}|_\kappa \approx C_\kappa\, p_\kappa^{-k_\kappa - l_\kappa + 1}.$$

Thus, we have that

$$k_\kappa + l_\kappa = \log(\rho_\kappa)/\log((p_\kappa - 1)/p_\kappa) + 1.$$

Ideally, we would like to know k_κ and l_κ individually. To do so, we compute an estimate of l_κ. The dual regularity l_κ may be estimated by calculating the $L^2(\kappa)$ norm of the error between the projection of $\tilde{z}_{\mathrm{DG}}$ in $\tilde{S}^{\tilde{\mathbf{p}}}(\Omega, \tilde{\mathcal{T}}, \tilde{\mathbf{F}})$ onto the finite element spaces $S^{\mathbf{p}}(\Omega, \mathcal{T}, \mathbf{F})$ and $S^{\mathbf{p-1}}(\Omega, \mathcal{T}, \mathbf{F})$, together with the approximation results derived in [3]. Once both k_κ and l_κ have been determined on element κ, then κ is p-enriched if either k_κ or l_κ is larger than $p_\kappa + 1$; otherwise, the element is subdivided. For computational simplicity, only one hanging node is allowed on each side of a given element κ; additionally, we restrict the variation in the polynomial degree vector $\mathbf{p}$ to be at most one between neighboring elements. We note that this approach has been developed by Ainsworth and Senior [2] in the context of norm control for second-order elliptic problems.

On the other hand, if an element has been flagged for derefinement, then the strategy implemented here is to coarsen the mesh in low-error regions where either the primal or dual solutions u and z, respectively, are smooth and decrease the degree of the approximating polynomial in low-error regions when both u and z are not sufficiently regular; cf. [1]. To this end, we again compute the local regularities k_κ and l_κ of the primal and dual solutions, respectively, on each element κ in $\mathcal{T}$ as described above. The element κ is then coarsened if either k_κ or l_κ is larger than $p_\kappa + 1$; otherwise, the degree p_κ is reduced by one.

The finite element space $\tilde{S}^{\tilde{\mathbf{p}}}(\Omega, \tilde{\mathcal{T}}, \tilde{\mathbf{F}})$ and the finite element approximation $\tilde{z}_{\mathrm{DG}} \in \tilde{S}^{\tilde{\mathbf{p}}}(\Omega, \tilde{\mathcal{T}}, \tilde{\mathbf{F}})$ of the dual solution z will be constructed adaptively at the same time as $S^{\mathbf{p}}(\Omega, \mathcal{T}, \mathbf{F})$. To this end, we note that $\mathcal{E}_\Omega(u_{\mathrm{DG}}, h, p, \cdot)$ is a linear functional on

$H(\mathcal{L}^*, \Omega)$, and we define the error indicator

$$\eta_{\tilde\kappa} = \frac{\tilde h_{\tilde\kappa}}{\tilde p_{\tilde\kappa}} \|\varphi - \mathcal{L}^* \tilde z_{\mathrm{DG}}\|_{L_2(\tilde\kappa)} + \left(\frac{\tilde h_{\tilde\kappa}}{\tilde p_{\tilde\kappa}}\right)^{1/2} \left(\|[\tilde z_{\mathrm{DG}}]\|_{\partial_+\tilde\kappa\backslash\Gamma_+} + \|\chi - \tilde z_{\mathrm{DG}}\|_{\partial_+\tilde\kappa\cap\Gamma_+}\right) \tag{4.7}$$

for

$$\mathcal{E}_{\mathrm{D}} \equiv |\mathcal{E}_\Omega(u_{\mathrm{DG}}, h, p, z) - \mathcal{E}_\Omega(u_{\mathrm{DG}}, h, p, \tilde z_{\mathrm{DG}})|.$$

The error indicator (4.7) arises from a Type II a posteriori error bound on $\mathcal{E}_{\mathrm{D}}$ upon setting all constants in the bound (such as the stability factor C_{stab} of the dual-dual problem and the interpolation constant C_{int}) to unity; cf. Theorem 3.5 and the subsequent Remark 3.6 with $m = 1$, and note that $\Phi_1(p_{\tilde\kappa}, 1)$ is $\mathcal{O}(1)$ by (3.26). The *hp*-adaptive algorithm for the dual problem will be based on the *fixed fraction strategy* outlined in [19]. Consequently, the absolute size of $\eta_{\tilde\kappa}(\tilde p_{\tilde\kappa})$ is insignificant: only the relative sizes of these quantities matter; in particular, this justifies setting all constants to unity in the dual error indicator (4.7). Once the elements have been flagged for refinement/derefinement, $\tilde h_{\tilde\kappa}$ and $\tilde p_{\tilde\kappa}$ are altered accordingly by estimating the local regularity $\tilde l_{\tilde\kappa}$ of the dual solution on the mesh $\tilde{\mathcal{T}}$ as above by calculating $\eta_{\tilde\kappa}$ using a $\tilde p_{\tilde\kappa}$ and $\tilde p_{\tilde\kappa} - 1$ representation of $\tilde z_{\mathrm{DG}}$, together with the a priori bound (3.29).

For related work concerning the design of automatic *hp*-adaptive mesh refinement algorithms, we refer, for example, to the articles by Bey, Oden, and Patra [7], Mavripilis [17], and Rachowicz, Oden, and Demkowicz [18].

5. Numerical experiments. In this section we present a number of experiments to numerically verify the a priori error bounds derived in section 3, as well as to demonstrate the performance of the *hp*-adaptive algorithm outlined in section 4.2.

5.1. Example 1. In this example we let $\Omega = (-1, 1)^2$, $\mathbf{b} = (2 - y^2, 2 - x)$, $c = 1 + (1 + x)(1 + y)^2$, and f is chosen so that the analytical solution to (2.1) is

$$u(x, y) = 1 + \sin(\pi(1 + x)(1 + y)^2/8); \tag{5.1}$$

cf. [15]. Furthermore, we choose the functional of interest $J(\cdot)$ to represent the mean flow of u over Ω, i.e., $J(\cdot) \equiv M_\psi(\cdot)$, where $M_\psi(\cdot)$ is given by (3.2); here, we define the weight function ψ so that the solution of the corresponding dual problem (3.3) is

$$z = 4\sin(\pi(1 + x)/2)\sin(\pi(1 + y)/2)\,\mathrm{e}^{-(2+x+y)^2/2}.$$

Thus, the true value of the mean flow of u over Ω is $M_\psi(u) = 3.9381$.

Here, we investigate the asymptotic behavior of the *hp*-DGFEM on a sequence of successively finer square and quadrilateral meshes for different p. In each case the quadrilateral mesh is constructed from a uniform $N \times N$ square mesh by randomly perturbing each of the *interior* nodes by up to 10% of the local mesh size; cf. [16].

In Figure 5.1 we present a comparison of the error in the functional $|J(u) - J(u_{\mathrm{DG}})|$ with the mesh size h for $p = 1, 2, 3$. Here, we observe that $|J(u) - J(u_{\mathrm{DG}})|$ converges to zero at the rate $\mathcal{O}(h^{2p+1})$ as the mesh is refined for each fixed p, thereby confirming Theorem 3.11 in the case when the assumptions on the data (3.19) are violated; cf. Remark 3.7. Finally, we investigate the convergence of the *hp*-DGFEM with p-enrichment for fixed h. Since the true solution (5.1) is a (real) analytic function, we expect to observe exponential rates of convergence; cf. section 3. Indeed, Figure 5.2 clearly illustrates this behavior: on the linear-log scale, the convergence plots for each

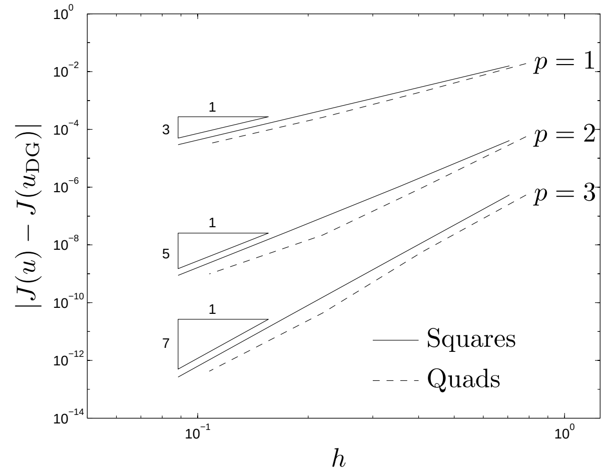

FIG. 5.1. *Example* 1. *Convergence of the hp-DGFEM with h-refinement.*

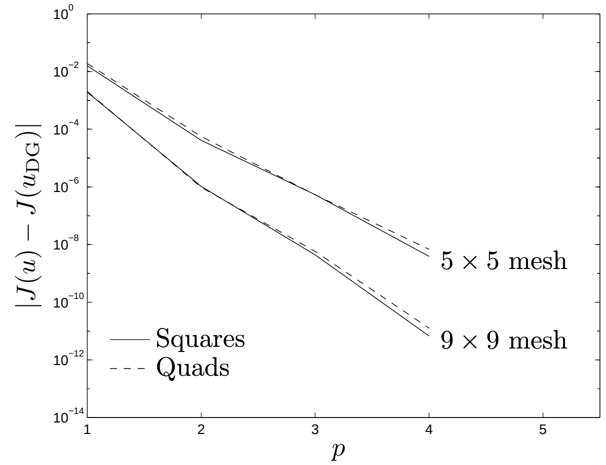

FIG. 5.2. *Example* 1. *Convergence of the hp-DGFEM with p-refinement.*

p become straight lines as the degree of the approximating polynomial is increased. Furthermore, we observe from Figures 5.1 and 5.2 that the h- and p-convergence, respectively, of the hp-DGFEM is robust with respect to mesh distortion.

5.2. Example 2. Here we consider a compressible hyperbolic problem subject to discontinuous inflow boundary condition with $\mathbf{b} = (2y^2 - 4x + 1, 1 + y)$, $c = 0$, and $f = 0$. The characteristics enter the computational domain Ω from three sides of Γ, namely, from $x = 0$, $y = 0$, and $x = 1$, and exit Ω through $y = 1$. Thus, we may prescribe

$$u(x,y) = \begin{cases} 0 & \text{for } x = 0,\ 0.5 < y \leq 1, \\ 1 & \text{for } x = 0,\ 0 \leq y \leq 0.5, \\ 1 & \text{for } 0 \leq x \leq 0.75,\ y = 0, \\ 0 & \text{for } 0.75 < x \leq 1,\ y = 0, \\ \sin^2(\pi y) & \text{for } x = 1,\ 0 \leq y \leq 1. \end{cases}$$

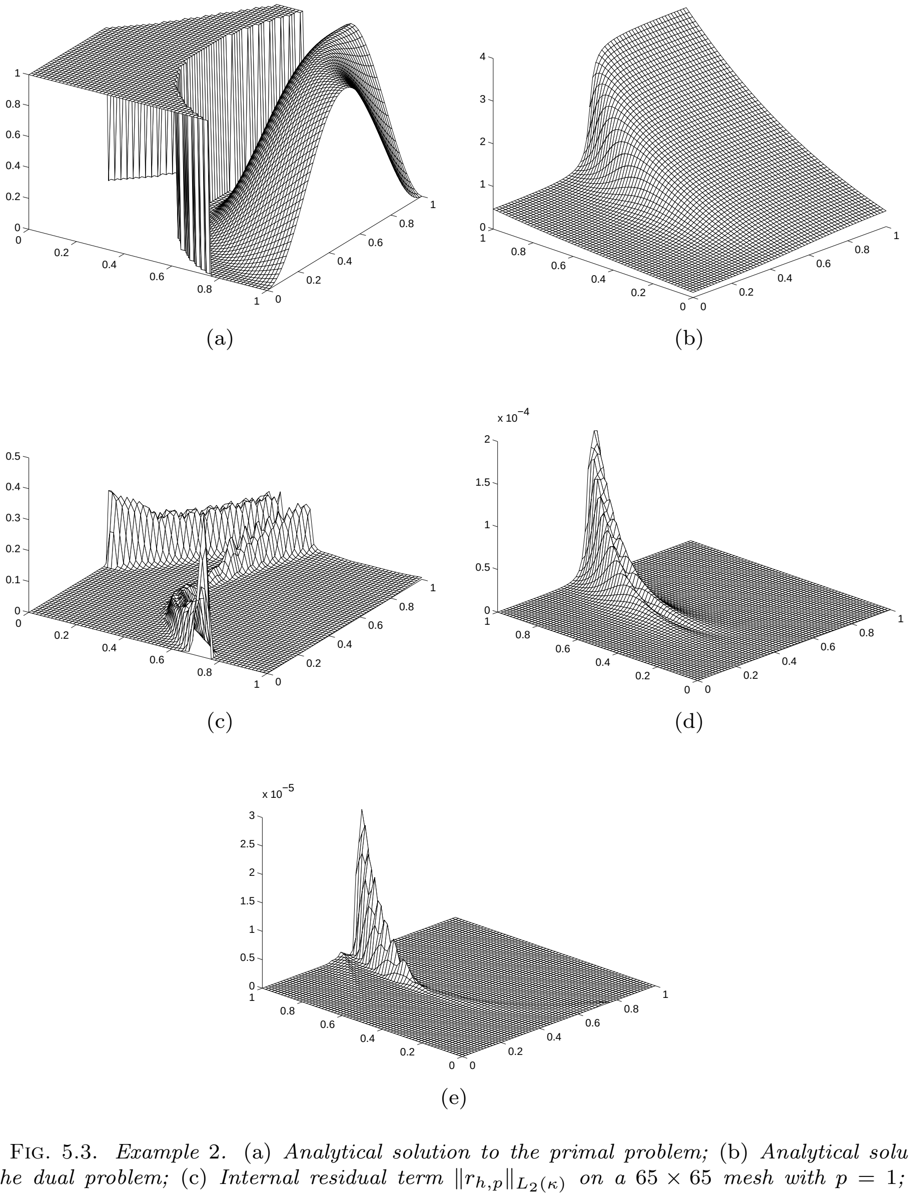

FIG. 5.3. *Example* 2. (a) *Analytical solution to the primal problem;* (b) *Analytical solution to the dual problem;* (c) *Internal residual term* $\|r_{h,p}\|_{L_2(\kappa)}$ *on a* 65×65 *mesh with* $p = 1$*;* (d) *Weighting term* $\|z - z_{h,p}\|_{L_2(\kappa)}$ *on a* 65×65 *mesh with* $p = 1$*;* (e) *Product of* (c) *and* (d)*, i.e.,* $\|r_{h,p}\|_{L_2(\kappa)}\,\|z - z_{h,p}\|_{L_2(\kappa)}$ *on a* 65×65 *mesh with* $p = 1$.

In this example we choose the functional of interest $J(\cdot)$ to represent the normal flux through the outflow boundary Γ_+, i.e., $J(\cdot) \equiv N_\psi(\cdot)$, where $N_\psi(\cdot)$ is given by (3.4); here, we define the weight function ψ by

$$\psi = 2 + \arctan((x - 1/2)/\varepsilon) \quad \text{for } 0 \le x \le 1,\ y = 1,$$

where $\varepsilon = 0.02$. Thereby, the true value of the outward normal flux is $N_\psi(u) = 2.0203$. The analytical solutions to both the primal and dual problems are shown in Figures 5.3(a) and 5.3(b), respectively. Furthermore, to understand how the terms

in the a posteriori error bound (3.14) interact with each other, in Figures 5.3(c) and 5.3(d), we have plotted the $L_2(\kappa)$ norm of the internal residual $r_{h,p}$ and the exact weight function $z - z_{h,p}$ on a 65×65 mesh with $p = 1$. Here, we observe that $\|r_{h,p}\|_{L_2(\kappa)}$ is large in the vicinity of the discontinuities as we would expect, while the weight function $\|z - z_{h,p}\|_{L_2(\kappa)}$ is large in the region where the layer in ψ enters the computational domain through Γ_+. The product of these two quantities is shown in Figure 5.3(e); here, we observe that the discontinuity emanating from $(x, y) = (0, 0.5)$ will have very little effect on the error in the linear function $N_\psi(\cdot)$ (see below).

In Table 5.1 we show the performance of the adaptive algorithm presented in section 4.2 for $\mathtt{TOL} = \mathtt{10}^{-7}$; we note that this level of accuracy may be far beyond what is of practical importance but is chosen to illustrate that the true error and the bound $\mathcal{E}_{\mathrm{P}}$ exhibit the same asymptotic behavior as the finite element space $S^{\mathbf{p}}(\Omega, \mathcal{T}, \mathbf{F})$ is enriched. In Table 5.1 we show the mesh number, the number of degrees of freedom (DOF) in $S^{\mathbf{p}}(\Omega, \mathcal{T}, \mathbf{F})$, the true error in the functional $|N_\psi(u - u_{\mathrm{DG}})|$, the error bound $\mathcal{E}_{\mathrm{P}}$, the remaining error $\mathcal{E}_{\mathrm{D}}$ (which in general will be noncomputable), the effectivity index $\theta = \mathcal{E}_{\mathrm{P}}/|N_\psi(u - u_{\mathrm{DG}})|$, and the ratio of $\mathcal{E}_{\mathrm{P}}$ and $\mathcal{E}_{\mathrm{D}}$. Here, we see that initially on very coarse meshes $\mathcal{E}_{\mathrm{P}}$ slightly underestimates the true error in the functional; however, as the finite element space is enriched the error bound overestimates $|N_\psi(u) - N_\psi(u_{\mathrm{DG}})|$ by a consistent factor in the range 1–6. Furthermore, we see that the remaining error term $\mathcal{E}_{\mathrm{D}}$ is about an order of magnitude smaller than the computable part of the a posteriori error bound $\mathcal{E}_{\mathrm{P}}$; this numerically justifies neglecting this term in the construction of the stopping criterion (4.4) for the design of our adaptive algorithm for the primal problem.

In Figure 5.4 we plot the results shown in Table 5.1; in particular, we plot $|N_\psi(u) - N_\psi(u_{\mathrm{DG}})|$, $\mathcal{E}_{\mathrm{P}}$, and $\mathcal{E}_{\mathrm{D}}$ using *hp*-refinement against the square root of the number of DOF on a linear-log scale. We see that after the initial transient, the error in the computed functional using *hp*-refinement becomes a straight line, thereby indicating exponential convergence; cf. Remark 3.12. Furthermore, in Figure 5.4 we plot the true error in the linear functional using *h*-refinement; here, we clearly observe the superiority of the adaptive *hp*-refinement algorithm. Indeed, on the final mesh the true error in the linear functional using *hp*-refinement is almost three orders of magnitude smaller than the true error in $N_\psi(\cdot)$ when *h*-refinement is employed.

Finally, in Figures 5.5 and 5.6 we show the primal and dual meshes after six and nine adaptive mesh refinements, respectively. For clarity, in each case we show the *h*-mesh alone, as well as the corresponding distribution of the polynomial degree and the percentage of elements with that degree. From Figure 5.5, we see that the elements in the primal mesh have been refined along the first discontinuity emanating

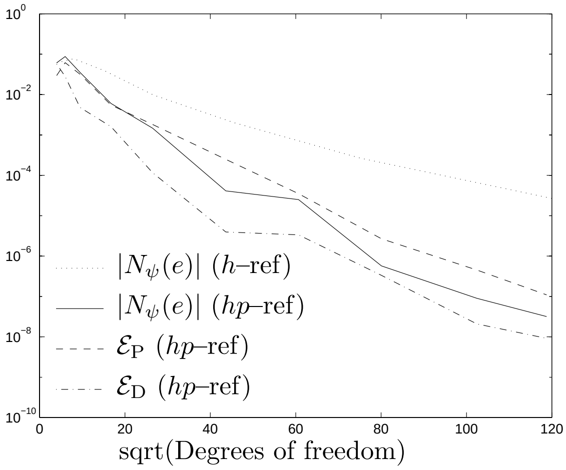

FIG. 5.4. *Example* 2. *Comparison between h- and hp-adaptive mesh refinement.*

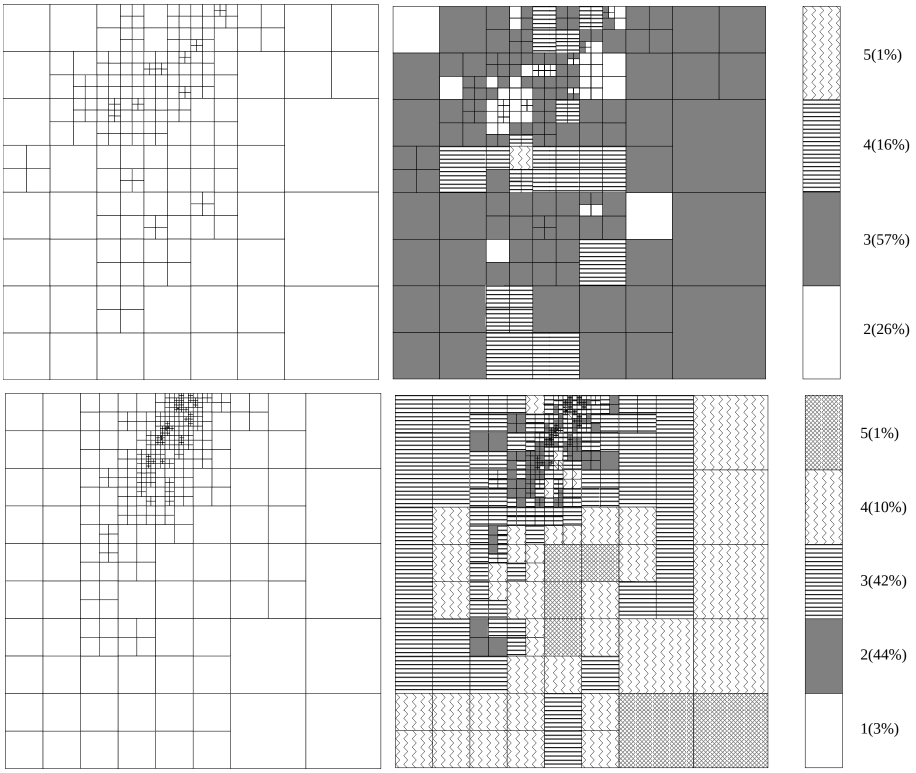

FIG. 5.5. *Example* 2. *Mesh* 7: *Primal (top:* 235 *elements,* 303 *nodes, and* 3679 *DOF) and dual (bottom:* 493 *elements,* 616 *nodes, and* 6781 *DOF) h- and hp-meshes. Here,* $N_\psi(u - u_{\rm DG}) = 2.502 \times 10^{-5}$, $\mathcal{E}_{\rm P} = 3.506 \times 10^{-5}$, *and* $\theta = 1.40$.

from $(x, y) = (0.75, 0)$, since the dual solution has a layer in this region as well. In contrast, elements lying on the second discontinuity in the primal problem, which emanates from $(x, y) = (0, 0.5)$, have been less refined, since the dual solution is smooth here, and hence the corresponding weights involving $\tilde{z}_{\rm DG} - z_{h,p}$ are inactive;

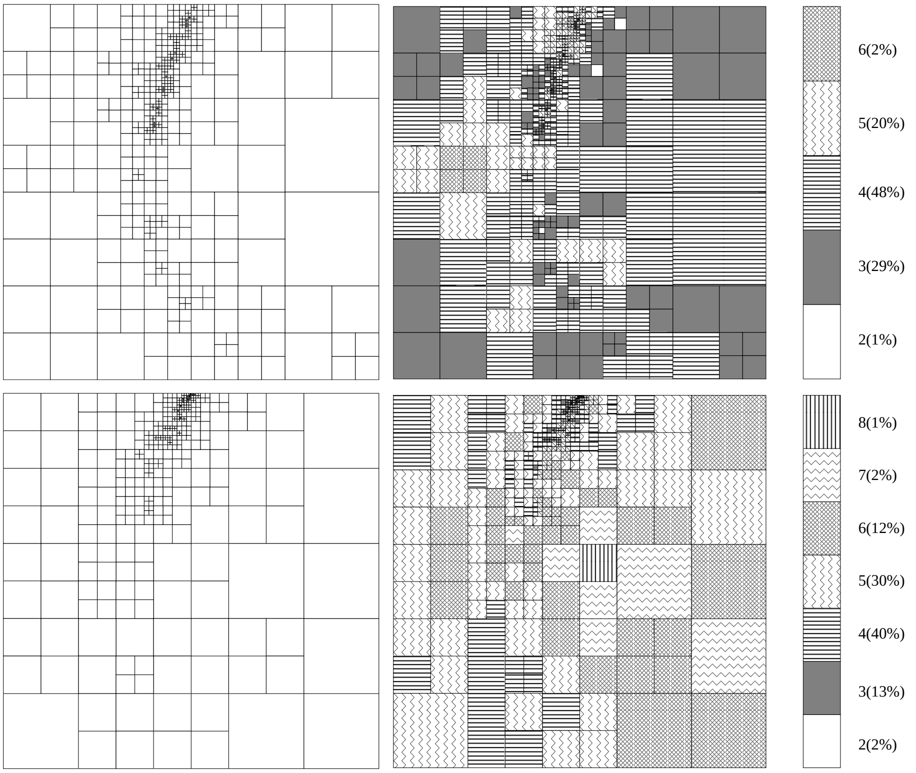

FIG. 5.6. *Example* 2. *Mesh* 10*: Primal (top:* 565 *elements,* 719 *nodes, and* 14107 *DOF) and dual (bottom:* 445 *elements,* 564 *nodes, and* 13629 *DOF) h- and hp-meshes. Here,* $N_\psi(u - u_{\mathrm{DG}}) = 3.175 \times 10^{-8}$, $\mathcal{E}_{\mathrm{P}} = 1.092 \times 10^{-7}$, *and* $\theta = 3.43$.

cf. Figure 5.3(e). Furthermore, the mesh for the dual solution is concentrated within the steep layer in the weight function ψ; the inherent smoothing in the dual problem introduced by the compressible nature of $\mathbf{b}$ leads to p-refinement in this layer as the flow moves away from Γ_+. The same behavior is observed in Figure 5.6 for the primal and dual solutions.

5.3. Example 3. In this final example, we consider the same primal problem presented in section 5.2. Furthermore, we again let $J(\cdot)$ denote the normal flux through the outflow boundary Γ_+, i.e., $J(\cdot) \equiv N_\psi(\cdot)$, where $N_\psi(\cdot)$ is given by (3.4); however, here we define the weight function ψ by

$$\psi = \begin{cases} 1 + \sin(2\pi(4x - 1)) & \text{for } 1/4 \leq x \leq 3/4, \\ 0 & \text{otherwise.} \end{cases}$$

In this case, the true value of the outward normal flux is $N_\psi(u) = 0.9175$. In Figures 5.7(a), 5.7(b), and 5.7(c) we plot the analytical to the dual problem, the weight function $\|z - z_{h,p}\|_{L_2(\kappa)}$, and the product of the weight function $\|z - z_{h,p}\|_{L_2(\kappa)}$ with the $L_2(\kappa)$ norm of the internal residual $r_{h,p}$ (see Figure 5.3(c) for the plot of $\|r_{h,p}\|_{L_2(\kappa)}$), respectively. From Figure 5.7(b), we see that the weighting term $\|z - z_{h,p}\|_{L_2(\kappa)}$ is large in the vicinity of the discontinuities emanating from Γ_+. By multiplying these terms by $\|r_{h,p}\|_{L_2(\kappa)}$ (cf. Figure 5.7(c)), we see that the discontinuity originating from $(0.75, 1)$ will dominate the error in the outward normal flux $N_\psi(\cdot)$; however, there

(b)

(c)

FIG. 5.7. *Example* 3. (a) *Analytical solution to the dual problem;* (b) *Weighting term* $\|z - z_{h,p}\|_{L_2(\kappa)}$ *on a* 65×65 *mesh with* $p = 1$*;* (c) *Product of* (b) *and Figure* 5.3(c)*, i.e.,* $\|r_{h,p}\|_{L_2(\kappa)} \|z - z_{h,p}\|_{L_2(\kappa)}$ *on a* 65×65 *mesh with* $p = 1$.

are visible peaks emanating from the top of the sin function as well as the second discontinuity located at $(0.25, 1)$.

In Figure 5.8 we show the performance of the adaptive algorithm for $\mathtt{TOL} = \mathtt{10}^{-6}$. We note that since both the primal and dual solutions are nonsmooth, we no longer expect to observe exponential convergence of the error in the functional $N_\psi(\cdot)$; thus, here we plot the same quantities as in Figure 5.4 against the number of degrees of freedom in $S^{\mathbf{p}}(\Omega, \mathcal{T}, \mathbf{F})$ on a log-log scale. We clearly observe that the error bound $\mathcal{E}_{\mathrm{P}}$ overestimates the true error by a consistent factor between 1–10. Furthermore, as in the previous example, the remaining error term $\mathcal{E}_{\mathrm{D}}$ is about an order of magnitude smaller than $\mathcal{E}_{\mathrm{P}}$, thereby justifying the absorption of $\mathcal{E}_{\mathrm{D}}$ into $\mathcal{E}_{\mathrm{P}}$. In addition, in Figure 5.8 we plot the true error in the linear functional using h-refinement; here, we observe that the true error in $N_\psi(\cdot)$ is (almost) always smaller if hp-refinement is employed. Indeed, on the final mesh the true error in $N_\psi(\cdot)$ is almost two orders of magnitude smaller if hp-refinement is employed as opposed to h-refinement only.

Finally, in Figures 5.9 and 5.10 we show the primal and dual meshes after six and nine adaptive mesh refinements, respectively. From Figure 5.9, we see that the primal mesh has only been h-refined in a small neighborhood of the two discontinuities in u as they exit the computational domain Ω. Furthermore, from Figure 5.10, we now see that the h-mesh has been refined in the vicinity of the discontinuity emanating from $(x, y) = (0, 0.5)$, while the h-mesh has in fact been coarsened in the region containing the second discontinuity originating from $(x, y) = (0.5, 0)$. In this latter region, the

Here,* $N_\psi(u - u_{\rm DG}) = 3.568 \times 10^{-6}$, $\mathcal{E}_{\rm P} = 6.164 \times 10^{-6}$, *and* $\theta = 1.73$.

local polynomial degree has been enriched as the primal solution u is smooth here. Finally, Figures 5.9 and 5.10 show that the dual mesh has been extensively h-refined in the vicinity of both discontinuities with the degree p of the approximating polynomial increased as we move into the parts of the computational domain where the dual

Here,* $N_\psi(u - u_{\rm DG}) = 1.072 \times 10^{-7}$, $\mathcal{E}_{\rm P} = 5.505 \times 10^{-7}$, *and* $\theta = 5.14$.

solution z is smooth.

6. Concluding remarks. In this article we have developed the a posteriori error analysis of the *hp*-version of the discontinuous Galerkin finite element method. In particular, by using a hyperbolic duality argument, we have derived computable error bounds for linear functionals of the solution, such as the mean flow of the field over the computational domain Ω and the normal flux through the outflow boundary Γ_+. Furthermore, based on our a posteriori error bound, we have designed and implemented a fully automatic adaptive algorithm that is capable of exploiting both local mesh subdivision and local polynomial-degree enrichment. Numerical experiments have been presented which clearly highlight the superiority of such a general adaptive strategy over the traditional *h*-refinement method, where the degree of the approximating polynomial p is kept fixed at some low value.

TIME RELAXED MONTE CARLO METHODS FOR THE BOLTZMANN EQUATION*

LORENZO PARESCHI† AND GIOVANNI RUSSO‡

Abstract. A new family of Monte Carlo schemes is introduced for the numerical solution of the Boltzmann equation of rarefied gas dynamics. The schemes are inspired by the Wild sum expansion of the solution of the Boltzmann equation for Maxwellian molecules and consist of a novel time discretization of the equation. In particular, high order terms in the expansion are replaced by the equilibrium Maxwellian distribution. The two main features of the schemes are high order accuracy in time and asymptotic preservation. The first property allows to recover accurate solutions with time steps larger than those required by direct simulation Monte Carlo (DSMC), while the latter guarantees that for the vanishing Knudsen number, the numerical solution relaxes to the local Maxwellian. Conservation of mass, momentum, and energy are preserved by the scheme. Numerical results on several space homogeneous problems show the improvement of the new schemes over standard DSMC. Applications to a one-dimensional shock wave problem are also presented.

1. Introduction.

When a gas is near thermodynamical equilibrium, a detailed kinetic description is unnecessary, and the evolution of the moments can be described by Euler or Navier–Stokes equations. From a computational point of view, these equations are much less expensive than the full Boltzmann equation.

Far from thermodynamic equilibrium, the equation of gas dynamics do not give a satisfactory description of the physical system, and the full kinetic description is necessary.

The departure from local thermodynamic equilibrium can be measured by the so-called Knudsen number, which is the ratio between the collisional mean free path of the molecules and the characteristic length of variation of macroscopic variables. When the Knudsen number is small, then the distribution function is close to the local Maxwellian. Collisions occur at a fast rate, and a kinetic treatment of the system is very expensive, because of the large ratio of time scales between macroscopic and microscopic effects. One may say that the system is numerically *stiff* [10]. Because of the stiffness, standard explicit schemes for the numerical solution of the Boltzmann equation become extremely expensive in this case.

If the Knudsen number is uniformly small in the region one is interested in, then one should use a gas dynamic description of the system. There are several circumstances, however, where the Knudsen number varies over several orders of magnitude. In such cases, a standard kinetic treatment would be too expensive and a pure gas dynamic approach inappropriate. Domain decomposition methods have been pro-

posed for this problem, in which the computational domain is divided into an *aerodynamic region* in which the system is treated by gas dynamic equations (Euler or Navier–Stokes), and a *Boltzmann region*, where a kinetic treatment is used. Suitable boundary conditions make the two regions coupled together [5]. Such schemes can be very effective in treating large scale problems, but they are quite complicated to implement, and they require a great care by the user.

In some recently developed Monte Carlo methods, a different approach is taken with the goal of constructing simple and efficient numerical methods for the solution of the Boltzmann equation in regions with a large variation in the mean free path [16, 15].

These algorithms are based on a suitable time discretization of the Boltzmann equation, first introduced in [9], which has the following properties: for the large Knudsen number, it is a time discretization of the Boltzmann equation of a given order, and when the Knudsen number vanishes, the numerical solution tends to the local Maxwellian. We will call this last property *asymptotic preservation.* In addition, the time discretization preserves mass, momentum, and energy.

Although the paper deals mainly with the space homogeneous case, the real motivation for the development of these Monte Carlo methods is their use for spatially dependent problems. In that case, standard splitting can be used, and the evolution of the system is obtained by alternating a collision step, which is space homogeneous in each space cell, and a convection step, which describes the free flow of the molecules. In the limit of the very small Knudsen number, the collision step replaces the distribution function by a local Maxwellian with the same moments. A Monte Carlo method based on such time discretization will behave as a sort of stochastic kinetic scheme for the underlying Euler equations of gas dynamics. Such a limit scheme was introduced by Pullin [18].

The plan of the paper is the following. In the next section, we give a short introduction on the Boltzmann equation and some of its relevant properties. In section 3, we introduce the time relaxed (TR) discretizations, starting from the Wild sum expansion, and making use of some of its properties. Section 4 is devoted to the derivation of time relaxed Monte Carlo (TRMC) methods. The section starts with a review of direct simulation Monte Carlo (DSMC), in particular of the Nanbu–Babovsky scheme [1], which is revisited and reinterpreted in a new light. A detailed description is given of TRMC algorithms. In the last section, we show some numerical tests performed with the new schemes. In particular, it is shown that it is possible to obtain the same accuracy of the Nanbu–Babovsky scheme with a lower computational cost. We conclude the paper with a plan of future extensions and improvements.

2. Time discretizations of the Boltzmann equation.

2.1. The Boltzmann equation. We consider the Boltzmann equation [7]

$$\frac{\partial f}{\partial t} + v \cdot \nabla_x f = \frac{1}{\varepsilon} Q(f, f), \tag{2.1}$$

supplemented with the initial condition

$$f(x, v, t = 0) = f_0(x, v), \tag{2.2}$$

where $f = f(x, v, t)$ is a nonnegative function describing the time evolution of the distribution of particles which move with velocity v in the position x at time $t > 0$. The parameter $\varepsilon > 0$ is the Knudsen number and is proportional to the mean free path between collisions. The bilinear collision operator $Q(f,f)$ describes the binary collisions of the particles and is given by

$$Q(f,f)(v) = \int_{\mathbb{R}^3}\int_{S^2} \sigma(|v-v_1|,\omega)[f(v')f(v'_*) - f(v)f(v_*)]\,d\omega\,dv_*. \tag{2.3}$$

In the above expression, ω is a unit vector of the sphere S^2 so that $d\omega$ is an element of area of the surface of the unit sphere S^2 in $\mathbb{R}^3$. Moreover, (v', v'_*) represent the postcollisional velocities associated with the precollisional velocities (v, v_*) and the collision parameter ω; i.e.,

$$v' = \frac{1}{2}(v + v_* + |v-v_*|\omega), \quad v'_* = \frac{1}{2}(v + v_* - |v-v_*|\omega). \tag{2.4}$$

The kernel σ is a nonnegative function which characterizes the details of the binary interactions. In the case of inverse kth power forces between particles, the kernel has the form

$$\sigma(|v-v_*|,\theta) = b_\alpha(\theta)|v-v_*|^\alpha, \tag{2.5}$$

where $\alpha = (k-5)/(k-1)$. For numerical purposes, a widely used model is the variable hard sphere (VHS) model [3], corresponding to take $b_\alpha(\theta) = C_\alpha$ where C_α, is a positive constant. The case $\alpha = 0$ is referred to as the Maxwellian gas, whereas the case $\alpha = 1$ yields the hard sphere gas.

2.2. Fluid-dynamical limit. During the evolution process, the collision operator preserves mass, momentum, and energy; i.e.,

$$\int_{\mathbb{R}^3} Q(f,f)\phi(v)\,dv = 0, \quad \phi(v) = 1, v, v^2, \tag{2.6}$$

and in addition it satisfies Boltzmann's well-known H-theorem

$$\int_{\mathbb{R}^3} Q(f,f)\log(f)dv \le 0. \tag{2.7}$$

From a physical point of view, Boltzmann's H-theorem implies that any equilibrium distribution function, i.e., any function f for which $Q(f,f) = 0$, has the form of a locally Maxwellian distribution

$$M(\rho,u,T)(v) = \frac{\rho}{(2\pi T)^{3/2}} \exp\left(-\frac{|u-v|^2}{2T}\right), \tag{2.8}$$

where ρ, u, and T are the density, mean velocity, and temperature of the gas defined by

$$\rho = \int_{\mathbf{R}^3} f\,dv, \qquad u = \frac{1}{\rho}\int_{\mathbf{R}^3} vf\,dv, \qquad T = \frac{1}{3\rho}\int_{\mathbf{R}^3}[v-u]^2 f\,dv. \tag{2.9}$$

As $\varepsilon \longrightarrow 0$, the distribution function approaches the local Maxwellian (2.8). In this case, the higher order moments of the distribution f can be computed as function of ρ, u, and T, by using (2.8), and we obtain to the leading order the closed system of compressible Euler equations of gas dynamics

$$\begin{aligned}
&\frac{\partial \rho}{\partial t} + \nabla_x \cdot (\rho u) = 0,\\
&\frac{\partial \rho u}{\partial t} + \nabla_x \cdot (\rho u \otimes u) + \nabla_x p = 0, \qquad (2.10)\\
&\frac{\partial E}{\partial t} + \nabla_x \cdot (Eu + pu) = 0,
\end{aligned}$$

$$p = \rho T, \quad E = \frac{3}{2}\rho T + \frac{1}{2}\rho u^2. \qquad (2.11)$$

2.3. Time discretizations. The time integration of the Boltzmann equation represents a challenging problem, since the nonlinear collision operator becomes highly stiff near the fluid regime ($\varepsilon \ll 1$). An additional limitation is given by the high computational cost required for evaluating the fivefold collisional integral. The starting point is the usual first order splitting in time of (2.1), which consists of solving separately a purely convective step (i.e., $Q \equiv 0$ in (2.1)) and a collision step characterized by a space homogeneous Boltzmann equation (i.e., $\nabla_x f \equiv 0$ in (2.1)). Clearly, after this splitting, almost all the main difficulties are contained in the collision step. For this reason, in what follows we will fix our attention on the time discretization of the homogeneous Boltzmann equation

$$\frac{\partial f}{\partial t} = \frac{1}{\varepsilon} Q(f,f). \qquad (2.12)$$

Let us consider the simple forward Euler scheme

$$f^{n+1} = f^n + \frac{\Delta t}{\varepsilon} Q(f^n, f^n), \qquad (2.13)$$

which has been widely used in simulation. It leads to a stability condition which requires the time step Δt to be of order ε. Thus for small values of ε the scheme is unusable for practical purposes.

On the other hand, the use of fully implicit schemes for (2.12), like the backward Euler method

$$f^{n+1} = f^n + \frac{\Delta t}{\varepsilon} Q(f^{n+1}, f^{n+1}), \qquad (2.14)$$

requires the solution of a large nonlinear system of algebraic equations, and this makes the method prohibitively expensive.

Alternatively, semi-implicit discretizations have been proposed [20] based on taking only the function $f(v)$ implicitly in (2.3), whereas $f(v')$, $f(v'_*)$, and $f(v_*)$ are evaluated explicitly. This gives rise to unconditionally stable schemes that have the same cost of an explicit scheme. Unfortunately, these schemes do not possess the correct fluid limit as $\varepsilon \to 0$, and, in addition, except for Maxwell molecules, the numerical solution does not preserve the conserved quantities.

High order extensions of the previous schemes can be developed. At present, however, the practical interest of high order schemes is strongly reduced by the high computational cost required by multiple evaluations of the fivefold integral (2.3).

In the next sections, following the approach presented in [9], we will show how it is possible to construct unconditionally stable schemes for the space homogeneous equation that are accurate for a wide range of Knudsen numbers, while avoiding the solution of nonlinear algebraic equations.

3. The TR schemes.

As proposed in [9], a general idea for deriving robust numerical schemes, that is, schemes that are unconditionally stable and preserve the asymptotic of the fluid-dynamic limit, for a nonlinear equation like (2.12), is to replace high order terms of a suitable well-posed power series expansion by the local equilibrium. We will call this class of schemes TR schemes. Here we will first derive the schemes as presented in [9], and then we will show how it is possible to generalize this approach.

3.1. Derivation.

Let us consider a differential system of the type

$$\frac{\partial f}{\partial t} = \frac{1}{\varepsilon}\left[P(f,f) - \mu f\right], \tag{3.1}$$

with the same initial condition (2.2), and where $\mu \neq 0$ is a constant and P a bilinear operator.

Let us replace the time variable t and the function $f = f(v,t)$ using the equations

$$\tau = (1 - e^{-\mu t/\varepsilon}), \qquad F(v,\tau) = f(v,t)e^{\mu t/\varepsilon}. \tag{3.2}$$

Then F is easily shown to satisfy

$$\frac{\partial F}{\partial \tau} = \frac{1}{\mu}P(F,F) \tag{3.3}$$

with $F(v,\tau = 0) = f_0(v)$.

Now, the solution to the Cauchy problem for (3.3) can be sought in the form of a power series

$$F(v,\tau) = \sum_{k=0}^{\infty} \tau^k f_k(v), \qquad f_{k=0}(v) = f_0(v), \tag{3.4}$$

where the functions f_k are given by the recurrence formula

$$f_{k+1}(v) = \frac{1}{k+1}\sum_{h=0}^{k} \frac{1}{\mu}P(f_h, f_{k-h}), \quad k = 0,1,\dots. \tag{3.5}$$

Making use of the original variables, we obtain the following formal representation of the solution to the Cauchy problem (2.12):

$$f(v,t) = e^{-\mu t/\varepsilon}\sum_{k=0}^{\infty}(1 - e^{-\mu t/\varepsilon})^k f_k(v). \tag{3.6}$$

Remark 3.1. The method was originally developed by Wild [22, 6] to solve the Boltzmann equation for Maxwellian molecules. Here we describe the method under a more general hypothesis on P, as derived in [9]. We emphasize that the representation (3.6) is not unique, and other well-posed power series expansions can be obtained in a similar way [9].

Finally, note that expansion (3.6) continues to hold also if μ is a function of v. Unfortunately, this choice leads to nonconservative schemes.

From this representation, a class of numerical schemes can be naturally derived.

In [9], the following class of numerical schemes, based on a suitable truncation for $m \geq 1$ of (3.6), has been constructed:

$$f^{n+1}(v) = e^{-\mu\Delta t/\varepsilon}\sum_{k=0}^{m}(1 - e^{-\mu\Delta t/\varepsilon})^k f_k^n(v) + (1 - e^{-\mu\Delta t/\varepsilon})^{m+1}M(v), \tag{3.7}$$

where $f^n = f(n\Delta t)$ and Δt is a small time interval. The quantity M (referred to as the local Maxwellian associated with f) is the asymptotic stationary solution of the equation.

It can be shown that the schemes obtained in this way are of order m in time. Furthermore, we have [9] the following proposition.

PROPOSITION 3.1. *The schemes defined by* (3.7) *satisfy the following:*

(i) Conservation.

If $P(f,g)$ is a nonnegative bilinear operator such that there exist some functions $\phi(v)$ with the following property,

$$\int_{R^3} P(f,f)\phi(v)\,dv = \mu \int_{R^3} f\phi(v)\,dv, \tag{3.8}$$

and the initial condition f^0 is a nonnegative function, then f^{n+1} is nonnegative for any $\mu\Delta t/\varepsilon$ and satisfies

$$\int_{R^3} f^{n+1}\phi(v)\,dv = \int_{R^3} f^n\phi(v)\,dv. \tag{3.9}$$

(ii) Asymptotic preservation (AP).

For any $m \geq 1$, we have

$$\lim_{\mu\Delta t/\varepsilon\to\infty} f^{n+1} = M(v). \tag{3.10}$$

3.2. Application to the Boltzmann equation. Now we apply the previous general approach to the Boltzmann equation and related kinetic models. To this aim, we will need a bound on the loss term, which is essential in most numerical methods.

Let us consider the space homogeneous problem

$$\frac{\partial f}{\partial t} = \frac{1}{\varepsilon}Q(f,f). \tag{3.11}$$

Problem (3.11) can be written in the form (3.1), taking

$$P(f,f) = Q^+(f,f) + f(v)\left(\mu - \int_{\mathbb{R}^3}\int_{S^2} \sigma(|v-v_*|,\omega)f(v_*)\,d\omega\,dv_*\right), \tag{3.12}$$

where

$$Q^+(f,f,) = \int_{\mathbb{R}^3}\int_{S^2} \sigma(|v-v_*|,\omega)f(v')f(v'_*)\,d\omega\,dv_*, \tag{3.13}$$

and the constant μ must satisfy

$$\mu \geq \int_{\mathbb{R}^3}\int_{S^2} \sigma(|v-v_*|,\omega)f(v_*)\,d\omega\,dv_*. \tag{3.14}$$

In general, the previous condition cannot be satisfied for all $v \in \mathbb{R}^3$. The usual way to overcome this difficulty is to replace the kernel σ with the following bounded kernel σ_b:

$$\sigma_b(|v-v_*|,\omega) = \min\{\sigma(|v-v_*|,\omega),\bar{\sigma}\}, \quad \bar{\sigma} > 0.$$

In this case, it is enough to choose $\mu = 4\pi\rho\bar{\sigma}$ in order to satisfy (3.14).

Note that, in a particle method, there is a natural bound $\bar{\sigma}$ on the cross section due to the finite number of velocities, and therefore it is always possible to satisfy (3.14).

It is a simple exercise to verify that Proposition 3.1 holds with $\phi(v) = 1, v, v^2$.

Let us consider the first order scheme, in which $f_k, k \geq 2$, is substituted by the local Maxwellian (2.8). With the notations of the previous sections, the scheme reads

$$f^{n+1}(v) = (1-\tau)f^n(v) + \tau(1-\tau)f_1^n(v) + \tau^2 M(v), \tag{3.15}$$

where $\tau = 1 - e^{-\mu\Delta t/\varepsilon}$. The results from the last two subsections show that the approximation defined by (3.15) is well defined independently of the Knudsen number and, by Proposition 3.1, has the correct moments and converges towards the correct fluid-dynamic limit.

Remark 3.2. In the case of Maxwell molecules, the method simplifies considerably. In fact, since the collision kernel does not depend on the relative velocity $\sigma_b = \sigma_b(\omega)$, we simply have $P(f,f) = Q^+_{\bar{\sigma}}(f,f)$ and $\mu = 4\pi\rho\bar{\sigma}$, where

$$\bar{\sigma} = \frac{1}{4\pi}\int_{S^2} \sigma_b(\omega)d\omega. \tag{3.16}$$

3.3. Generalized TR schemes. The approach we have seen in the previous sections can be generalized using different weight functions to combine the influence of the high order coefficients appearing in the Wild sum (3.6). In general, such schemes can be written as

$$f^{n+1} = \sum_{k=0}^{m} A_k f_k + A_{m+1}M, \tag{3.17}$$

where the coefficients f_k are given by (3.5).

The weights $A_k = A_k(\tau)$ are nonnegative functions that satisfy the following proposition.

PROPOSITION 3.2. *Let the weights $A_k = A_k(\tau)$ be nonnegative functions that satisfy the following.*

(i) Consistency.

$$\lim_{\tau\to 0} A_1(\tau)/\tau = 1, \quad \lim_{\tau\to 0} A_k(\tau)/\tau = 0, \quad k = 2,\ldots,m+1. \tag{3.18}$$

(ii) Conservation.

$$\sum_{k=0}^{m+1} A_k = 1, \quad \tau \in [0,1]. \tag{3.19}$$

(iii) Asymptotic preservation (AP).

$$\lim_{\tau\to 1} A_k(\tau) = 0, \quad k = 0,\ldots,m; \tag{3.20}$$

then (3.17) *is a consistent discretization of problem* (3.1) *that satisfies Proposition* 3.1.

The proof is a simple exercise, and we leave it to the reader.

A choice of functions which satisfies the previous requirements is given by

$$A_k = (1-\tau)\tau^k,\ k = 0,\dots,m, \quad A_{m+1} = \tau^{m+1}, \tag{3.21}$$

which correspond to the scheme (3.7). A better choice of parameters is [16]

$$A_k = (1-\tau)\tau^k,\ k = 0,\dots,m-1, \quad A_m = 1-\sum_{k=0}^{m} A_k - A_{m+1}, \quad A_{m+1} = \tau^{m+2}, \tag{3.22}$$

which corresponds to take $f_{m+1} = f_m$, $f_k = M$, $k \geq m+2$ in (3.6).

However, other choices are possible; and it is an open problem, the determination of the *optimal* set of functions A_k, that satisfies the previous requirements and guarantees the most accurate approximation.

3.4. Stability analysis of the TR schemes. In this paragraph, we report some results related to the stability of the TR schemes. In particular, we show that the first and second order TR schemes are L-stable [16].

Let us apply the TR scheme to the test equation

$$y' = \lambda y \tag{3.23}$$

with $y(0) = 1$ and $\lambda \in C^-$.

The equation can be written in the form

$$y' = P(y,y) - \mu y,$$

with $P(f,g) = \frac{1}{2}(\mu+\lambda)(f+g)$, and μ is a positive constant such that $|\lambda| < \mu$. The numerical solution after one time step is given by

$$y^1 = \sum_{k=0}^{m} A_k y_k. \tag{3.24}$$

The $m+1$ term vanishes because the equilibrium solution is zero. The term y_k can be explicitly computed by applying formula (3.5). A simple calculation yields

$$y_k = \frac{1}{k!}\prod_{j=1}^{k}(j+a) = \frac{\Gamma(k+1+a)}{\Gamma(k+1)\,\Gamma(1+a)}, \quad k = 0,\dots,m, \tag{3.25}$$

where $a = \lambda/\mu$ and Γ denotes the usual Γ-function. The numerical solution after one time step, called the *function of absolute stability*, is therefore a function of a real parameter τ and a complex parameter a such that

$$R_m(\tau,a) = \sum_{k=0}^{m} A_k(\tau) y_k(a),$$

where $\tau = 1-\exp(-\mu\Delta t)$ is the relaxed time, and a is a complex number $a \in C^-$, $|a| \leq 1$. Here we give definitions of A- and L-stability which are the natural generalization of the standard definition [10] to the case where the function of absolute stability depends on an additional real parameter.

DEFINITION 3.3.

(i) *We say that the scheme is A-stable if*

$$|R(\tau,a)| \le 1 \quad \forall \tau \in [0,1],\ a \in C^-, |a| \le 1.$$

(ii) *We say that the scheme is L-stable if it is A-stable and*

$$\lim_{\tau\to 1} R(\tau,a) = 0 \quad \forall a \in C^-, |a| \le 1.$$

It is clear that, because of the asymptotic preserving properties, if a TR scheme is A-stable it is also L-stable.

Here we recall the main result about the stability of first and second order TR schemes with weights given by (3.21).

The functions of absolute stability for these schemes are

$$R_1(\tau,a) = (1-\tau)[1+\tau(1+a)], \tag{3.26}$$

$$R_2(\tau,a) = (1-\tau)\left[1+\tau(1+a)+\frac{1}{2}\tau^2(1+a)(2+a)\right]. \tag{3.27}$$

We have the following theorem [16].

THEOREM 3.4. *The schemes defined by* (3.21) *for* $m=1$ *and* $m=2$ *are A-stable, i.e.,*

$$|R_1(\tau,a)| \le 1 \quad \forall \tau \in [0,1],\ a \in C^-, |a| \le 1,$$

$$|R_2(\tau,a)| \le 1 \quad \forall \tau \in [0,1],\ a \in C^-, |a| \le 1.$$

4. TRMC methods.

In this section, we describe the TRMC method for the evolution of the density function f. We shall include the description of the classical DSMC no-time counter algorithm, so that it will be easier to make a comparison between the new formulation and the previous one.

We develop the algorithms first in the simple case of constant cross sections (Maxwellian molecules) and then for the Boltzmann equation for VHS gas.

4.1. DSMC methods.

Here we will describe the classical DSMC method in the general framework we have introduced in the previous sections. More specifically, we consider the Nanbu–Babovsky algorithm [14, 1]. The convergence of this scheme has been proved by Babovsky and Illner [2].

The kinetic equations we are considering can be written in the form

$$\frac{\partial f}{\partial t} = \frac{1}{\epsilon}[P(f,f) - \mu f]. \tag{4.1}$$

In particular, for the Boltzmann equation for Maxwellian molecules, we have $P(f,f) = Q^+(f,f)$ (see *Remark* 3.2), whereas for general kernels with cut-off, $P(f,f)$ is given by (3.12).

We assume that f is a probability density; i.e.,

$$\rho = \int_{\mathbb{R}^3} f(v,t)\,dv = 1.$$

Let us discretize time and denote by $f^n(v)$ an approximation of $f(v,n\Delta t)$. The forward Euler scheme applied to (4.1) writes

$$f^{n+1} = \left(1 - \frac{\mu\Delta t}{\epsilon}\right) f^n + \frac{\mu\Delta t}{\epsilon}\frac{P(f^n,f^n)}{\mu}. \tag{4.2}$$

This equation has the following probabilistic interpretation: a particle with velocity v_i will not collide with probability $(1-\mu\Delta t/\epsilon)$, and it will collide with probability $\mu\Delta t/\epsilon$, according to the collision law described by $P(f^n, f^n)(v)$.

We remark here that the probabilistic interpretation of (4.2) breaks down if $\Delta t/\epsilon$ is too large because the coefficient of f^n on the right-hand side may become negative. This implies that the time step becomes extremely small when approaching the fluid-dynamic limit. Therefore, the classical DSMC method becomes almost unusable near the fluid regime.

For clarity of exposition, let us first consider kinetic equations for which $P(f,f) = Q^+(f,f)$; i.e., the collision kernel does not depend on the relative velocity of the particles.

An algorithm based on this probabilistic interpretation was proposed by Nanbu [14].

In its first version, Nanbu's algorithm was not conservative; i.e., energy and momentum were conserved only in the mean but not at each collision. A conservative version of the algorithm was introduced by Babovsky [1]. Instead of selecting single particles, independent particle pairs are selected, and conservation is maintained at each collision. The expected number of particles that collide in a small time step Δt is $N\mu\Delta t/\epsilon$, and the expected number of collision pairs is $N\mu\Delta t/(2\epsilon)$. The algorithm for evolving the density up to time $t = n_{\mathrm{TOT}}\Delta t$ is the following.

Algorithm 4.1 (DSMC for Maxwell molecules).

```
• compute the initial velocity of the particles, $\{v_i^0, i = 1, \dots, N\}$,
  by sampling them from the initial density $f_0(v)$
• for $n = 1$ to $n_{\mathrm{TOT}}$
      given $\{v_i^n, i = 1, \dots, N\}$,
          ○ compute $\{v_i^{n+1}\}$ as follows:
          ○ set $N_c = \mathrm{Iround}(\mu N\Delta t/(2\epsilon))$
          ○ select $N_c$ pairs $(i, j)$ uniformly among all possible pairs,
            and for those
              ○ perform the collision between $i$ and $j$, and
                compute $v_i'$ and $v_j'$ according to the collisional law
              ○ set $v_i^{n+1} = v_i'$, $v_j^{n+1} = v_j'$
          ○ set $v_i^{n+1} = v_i^n$ for all particles that have not been selected
  end for
```

During each step, all the other $N - 2N_c$ particle velocities remain unchanged. Here, by $\mathrm{Iround}(x)$, we denote a suitable integer rounding of a positive real number x. In our algorithm, we choose

$$\mathrm{Iround}(x) = \begin{cases} [x] & \text{with probability} \quad [x] + 1 - x, \\ [x] + 1 & \text{with probability} \quad x - [x], \end{cases}$$

where $[x]$ denotes the integer part of x.

The postcollisional velocities are computed through relations

$$v_i' = \frac{v_i + v_j}{2} + \frac{|v_i - v_j|}{2}\omega, \quad v_j' = \frac{v_i + v_j}{2} - \frac{|v_i - v_j|}{2}\omega, \tag{4.3}$$

where ω is chosen uniformly in the unit sphere, according to

$$\omega = \begin{pmatrix} \cos\phi\sin\theta \\ \sin\phi\sin\theta \\ \cos\theta \end{pmatrix}, \quad \theta = \arccos(2\xi_1 - 1), \quad \phi = 2\pi\xi_2, \tag{4.4}$$

and ξ_1, ξ_2 are uniformly distributed random variables in $[0, 1]$.

Note that this approach is equivalent to sampling the postcollisional velocity according to $P(f, f)/\mu$, where $\mu = 4\pi\sigma$ and σ is the constant cross section.

The above algorithm has to be modified when the scattering cross section is not constant. In this case, a simple algorithm is obtained by using an upper bound $\bar{\sigma}$ of the scattering cross section and the acceptance-rejection technique.

Algorithm 4.2 (DSMC for VHS molecules).

```
• compute the initial velocity of the particles, $\{v_i^0, i = 1, \dots, N\}$,
  by sampling them from the initial density $f_0(v)$
• for $n = 1$ to $n_{\mathrm{TOT}}$
      given $\{v_i^n, i = 1, \dots, N\}$,
          ◦ compute an upper bound $\bar{\sigma}$ for the cross section
          ◦ set $\mu = 4\pi\bar{\sigma}$
          ◦ set $N_c = \mathrm{Iround}(\mu N \Delta t/(2\epsilon))$
          ◦ select $N_c$ dummy collision pairs $(i, j)$ uniformly
            among all possible pairs, and for those
              ◦ compute the relative cross section $\sigma_{ij} = \sigma(|v_i - v_j|)$
              ◦ if $\bar{\sigma}\,\mathrm{Rand} < \sigma_{ij}$
                    ◦ perform the collision between $i$ and $j$, and
                      compute $v_i'$ and $v_j'$ according to the collisional law
                    ◦ set $v_i^{n+1} = v_i'$, $v_j^{n+1} = v_j'$
                else
                    ◦ set $v_i^{n+1} = v_i^n$, $v_j^{n+1} = v_j^n$
          ◦ set $v_i^{n+1} = v_i^n$ for the $N - 2N_c$ particles that have not been selected
  end for
```

The new velocities v_i' and v_j' are computed using (4.3) and (4.4).

The upper bound $\bar{\sigma}$ should be chosen as small as possible, to avoid inefficient rejection, and it should be computed fast.

An upper bound can be derived taking $\bar{\sigma}$ as

$$\sigma_{\max} = \max_{v_i, v_j} \sigma(|v_i - v_j|). \tag{4.5}$$

Classically, since this computation would require $O(N^2)$ operations, instead of (4.5) it is preferable to use an upper bound of $\sigma_{\max}$ given by

$$\sigma_{\max} \le \bar{\sigma} = \sigma(2\Delta v), \quad \Delta v = \max_i |v_i - \bar{v}|, \quad \bar{v} = \sum_i v_i/N. \tag{4.6}$$

For the general collisional kernel, the algorithm is slightly modified by introducing the angular dependence. In this case, the collision is always performed, and the new velocities are extracted according to the differential cross section. Then a rejection is used to decide whether the collision is accepted.

Remark 4.1. Note that if the time step is small enough, only a small fraction of particles, let us say N_c, will collide. The computational cost of the collisions is therefore $O(N_c)$. On the other hand, the cost of the computation of the upper bound $\bar{\sigma}$ is $O(N)$, which may be much larger than $O(N_c)$. A possible way to overcome this difficulty is to update at each time step the value of the upper bound $\bar{\sigma}$ only if it increases. This may be done as follows. During the computation of the collision between particles i and j, let $\tilde{v}_i$ and $\tilde{v}_j$ denote the new particle velocities. Then the quantity Δv is updated according to

$$\Delta v = \max(\Delta v, |\tilde{v}_i - \bar{v}|, |\tilde{v}_j - \bar{v}|). \tag{4.7}$$

At the end of the collision loop, the upper bound on the cross section is computed as

$$\bar{\sigma} = \sigma(2\Delta v).$$

In space nonhomogeneous calculations, assuming that there are several collisional time steps during a convection time step, the bound can be computed according to (4.6) the first time step and then updated as described above.

4.2. TRMC methods. The first order TRMC algorithm is based on the TR schemes

$$f^{n+1} = A_0 f^n + A_1 f_1 + A_2 M. \tag{4.8}$$

The probabilistic interpretation of the above equation is the following: a particle extracted from f^n will not collide with probability A_0; it will collide with another particle extracted from f^n with probability A_1; or it will be replaced by a particle sampled from a Maxwellian with probability A_2.

In this formulation, the probabilistic interpretation holds uniformly in $\mu\Delta t/\epsilon$, at variance with standard DSMC, which requires $\mu\Delta t/\epsilon < 1$. Furthermore, as $\mu\Delta t/\epsilon \to \infty$, the distribution at time $n+1$ is sampled from a Maxwellian. In this limit, the density f^{n+1} relaxes immediately to its equilibrium distribution. In a space nonhomogeneous case, this would be equivalent to the particle method for Euler equations proposed by Pullin [18].

The Monte Carlo schemes described above are conservative in the mean. It is possible to make it exactly conservative by selecting collision pairs uniformly, rather than individual particles, and by using a suitable algorithm for sampling a set of particles with prescribed momentum and energy from a Maxwellian [19].

The conservative version of the methods can be formalized in the following algorithm.

Algorithm 4.3 (first order TRMC for VHS molecules).

```
• compute the initial velocity of the particles, $\{v_i^0, i = 1, \dots, N\}$,
  by sampling them from the initial density $f_0(v)$
• for $n = 1$ to $n_{\mathrm{TOT}}$
      given $\{v_i^n, i = 1, \dots, N\}$,
          ○ compute an upper bound $\bar{\sigma}$ of the cross section
          ○ set $\tau = 1 - \exp(-\rho\bar{\sigma}\Delta t/\epsilon)$
          ○ compute $A_1(\tau)$, $A_2(\tau)$
          ○ set $N_c = \mathrm{Iround}(N A_1/2)$
          ○ perform $N_c$ dummy collisions, as in Algorithm 4.2
          ○ set $N_M = \mathrm{Iround}(N A_2)$
          ○ select $N_M$ particles among those that have not collided,
            and compute their mean momentum and energy
          ○ sample $N_M$ particles from the Maxwellian with the above
            momentum and energy, and replace the $N_M$ selected particles
            with the sampled ones
          ○ set $v_i^{n+1} = v_i^n$ for all the $N - 2N_c - N_M$ particles that
            have not been selected
  end for
```

A second order Monte Carlo scheme is obtained by the TR scheme

$$f^{n+1} = A_0 f^n + A_1 f_1 + A_2 f_2 + A_3 M \tag{4.9}$$

with

$$f_1 = \frac{P(f^n, f^n)}{\mu}, \quad f_2 = \frac{P(f^n, f_1)}{\mu}.$$

Given N particles distributed according to f^n, the probabilistic interpretation of scheme (4.9) is the following: NA_0 particles will not collide; NA_1 will be sampled from f_1 (as in the first order scheme); NA_2 will be sampled from f_2; i.e., $NA_2/2$ particles sampled from f^n will undergo dummy collisions with $NA_2/2$ particles sampled from f_1; and NA_3 particles will be sampled from a Maxwellian.

Once again, the methods can be made conservative using the same techniques adopted in the first order scheme. The various steps of the method can be summarized in the following algorithm.

Algorithm 4.4 (second order TRMC for VHS molecules).

```
• compute the initial velocity of the particles, $\{v_i^0, i = 1, \ldots, N\}$,
  by sampling them from the initial density $f_0(v)$
• for $n = 1$ to $n_{\mathrm{TOT}}$
      given $\{v_i^n, i = 1, \ldots, N\}$,
          ◦ compute an upper bound $\bar\sigma$ of the cross section
          ◦ set $\tau = 1 - \exp(-\rho\bar\sigma\Delta t/\epsilon)$
          ◦ compute $A_1(\tau)$, $A_2(\tau)$,$A_3(\tau)$
          ◦ set $N_1 = \mathrm{Iround}(NA_1/2)$ , $N_2 = \mathrm{Iround}(NA_2/4)$
          ◦ select $N_1 + N_2$ dummy collision pairs $(i, j)$ uniformly
            among all possible pairs
          ◦ for $N_1$ pairs
              ◦ compute the relative cross section $\sigma_{ij} = \sigma(|v_i - v_j|)$
              ◦ if $\bar\sigma\,\mathrm{Rand} < \sigma_{ij}$
                    ◦ perform the collision between $i$ and $j$, and
                      compute $v_i'$ and $v_j'$ according to the collisional law
                    ◦ set $v_i^{n+1} = v_i'$, $v_j^{n+1} = v_j'$
          ◦ for $N_2$ pairs
              ◦ compute the relative cross section $\sigma_{ij} = \sigma(|v_i - v_j|)$
              ◦ if $\bar\sigma\,\mathrm{Rand} < \sigma_{ij}$
                    ◦ perform the collision between $i$ and $j$,
                      compute $v_i'$ and $v_j'$ according to the collisional law and
                      store them
          ◦ select $2N_2$ particles from $f^n$
          ◦ perform the collision of these selected particles with the
            second set of $2N_2$ particles that have collided once
          ◦ update the velocity of the $4N_2$ particles with the outcome
            of the $2N_2$ collisions (of particles that have never collided
            before with particles that collided once)
          ◦ set $N_M = \mathrm{Iround}(NA_3)$
          ◦ replace $N_M$ particles with samples from Maxwellian, as in Algorithm 4.3
          ◦ set $v_i^{n+1} = v_i^n$ for all the $N - 2N_1 - 4N_2 - N_M$ particles that
            have not been selected
  end for
```

Similarly, higher order TRMC methods can be constructed. For example, a third order scheme is obtained from

$$f^{n+1} = A_0 f^n + A_1 f_1 + A_2 f_2 + A_3 f_3 + A_4 M \tag{4.10}$$

with

$$f_1 = \frac{P(f^n, f^n)}{\mu}, \quad f_2 = \frac{P(f^n, f_1)}{\mu}, \quad f_3 = \frac{1}{3\mu}[2P(f^n, f_2) + P(f_1, f_1)].$$

We omit for brevity the details of the resulting Monte Carlo algorithm.

We remark here that the TR scheme is a direct consequence of the time discretization of the Boltzmann equation. In this respect, the choice of a particular Monte Carlo scheme used to model the collision is not crucial. Here we considered a commonly used Monte Carlo scheme. If a different technique is used to model the collision, then the same technique could be used in conjunction with the TR discretization.

5. Numerical results.

In this section, we present some numerical results for the new TRMC method and compare them with the standard DSMC method.

5.1. Space homogeneous results.

First we consider homogeneous test problems for the Kac equation [12] and for the Boltzmann equation for Maxwell molecules. Exact solutions are known in these special situations, and so we can compare the accuracy of the different schemes. In our tests, we have performed a single run with a number of particles sufficiently large to control the effects of the fluctuations. We express the results as a function of the scaled time variable t/ϵ, which we denote again by t, in order to simplify the notations.

5.1.1. Test I: Kac equation.

In the first test, we compare the different Monte Carlo methods using an exact solution of the Kac equation [12]. This test is used to check the accuracy of the methods using different time steps.

The Kac equation is a simplified one-dimensional model of the Boltzmann equation for Maxwell molecules characterized by

$$Q(f,f)(v) = \frac{1}{2\pi}\int_0^{2\pi}\int_{\mathbb{R}}[f(v')f(v'_*) - f(v)f(v_*)]\,dv_*\,d\theta, \tag{5.1}$$

where

$$v' = v\cos\theta - v_*\sin\theta, \qquad v'_* = v\sin\theta + v_*\cos\theta. \tag{5.2}$$

An exact solution for this equation is [4, 13]

$$f(v,t) = \frac{1}{2C^{3/2}}\left[\frac{3}{2}(C-1) + (3-C)\frac{v^2}{C^2}\right]\exp\left(-v^2/C\right)$$

with $C(t) = 3 - 2\exp(-\sqrt{\pi}t/16)$.

The previous TR schemes can be applied directly to (5.1), taking

$$P(f,f) = \frac{1}{2\pi}\int_0^{2\pi}\int_{\mathbb{R}^3} f(v')f(v'_*)\,dv_*\,d\theta, \tag{5.3}$$

and $\mu = \rho$.

The density function f has been reconstructed on a regular grid, by convolving the particle distribution by a suitable mollifier [8]

$$f(V_I) = \frac{1}{N}\sum_{j=1}^{N} W_H(V_I - v_j), \tag{5.4}$$

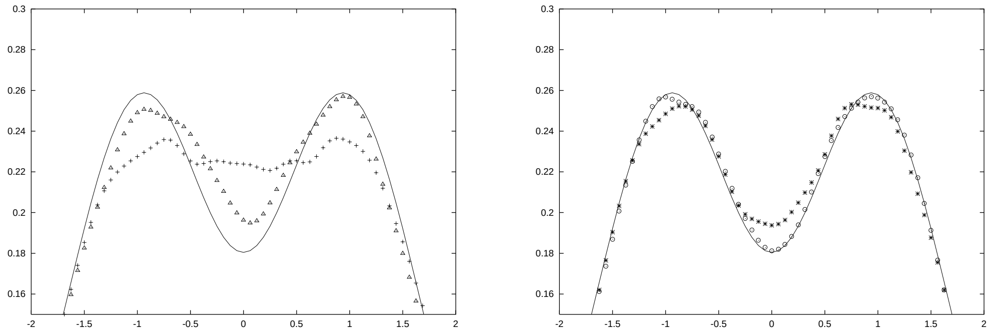

FIG. 1. *Test* I *(Kac equation). Details of the distribution function at time* $t = 2.0$ *for* $\Delta t = 1.0$. *Exact (line), DSMC (+), first order TRMC* ($\triangle$)*, second order TRMC* ($*$)*, third order TRMC* ($\circ$)*.*

where

$$\{V_I = V_{\min} + I\Delta V, I = 1, \dots, N_g\}.$$

The smoothing function W_{H} is given by

$$W_H(x) = \frac{1}{H} W\left(\frac{x}{H}\right), \quad W(x) = \left\{ \begin{array}{cl} 3/4 - x^2 & \text{if } |x| \le 0.5, \\ (x - 3/2)^2/2 & \text{if } 0.5 < |x| \le 1.5, \\ 0 & \text{otherwise.} \end{array} \right.$$

The value $H = 0.2$ has been selected as a good compromise between fluctuations and resolution. The simulations are performed for $t \in [0, 8]$ by starting with $N = 5 \times 10^4$ particles.

In Figure 1 we present the numerical results obtained at time $t = 2$ for the different schemes with the same time step $\Delta t = 1.0$, which represents the upper bound for the stability of DSMC.

It is evident that all TRMC schemes gives a better representation of the solution, especially near the local extrema.

Figure 2 shows the results of the L^2-norm of the error for the same test. At the bottom of the same figure, we show how it is possible to use larger time steps in TRMC schemes with respect to DSMC without any deterioration of the accuracy.

5.1.2. Test II: Maxwell molecules. Next we perform the same kind of accuracy test in the case of the Boltzmann equation for Maxwell molecules in the two-dimensional case. An exact solution to this equation [4, 13] is given by

$$f(v, t) = \frac{1}{2\pi C}\left[1 - \frac{(1 - C)}{C}\left(1 - \frac{v^2}{2C}\right)\right] \exp\left(-\frac{v^2}{2C}\right), \tag{5.5}$$

where $C(t) = 1 - (1/2)\exp(-t/8)$.

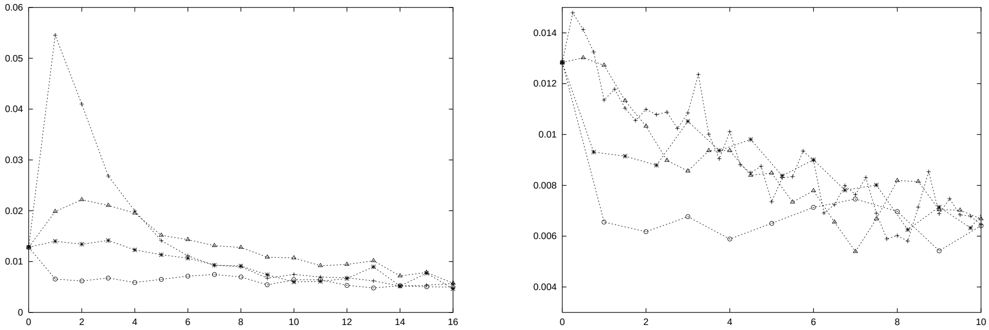

FIG. 2. *Test* I *(Kac equation).* L^2 *norm of the error vs time. DSMC (+), first order TRMC* $(\triangle)$*, second order TRMC* $(*)$*, third order TRMC* $(\circ)$*. Top: Time step* $\Delta t = 1.0$*. Bottom: DSMC with* $\Delta t = 0.25$*, first order TRMC with* $\Delta t = 0.5$*, second order TRMC with* $\Delta t = 0.75$*, third order TRMC*3 *with* $\Delta t = 1.0$*.*

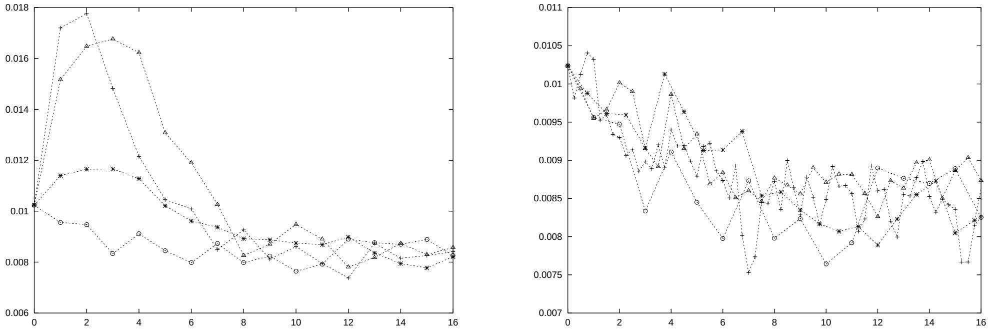

FIG. 3. *Test* II *(Maxwell molecules).* L^2 *norm of the error vs time. DSMC (+), first order TRMC* $(\triangle)$*, second order TRMC* $(*)$*, third order TRMC* $(\circ)$*. Top: Time step* $\Delta t = 1.0$*. Bottom: DSMC with* $\Delta t = 0.25$*, first order TRMC with* $\Delta t = 0.5$*, second order TRMC with* $\Delta t = 0.75$*, third order TRMC*3 *with* $\Delta t = 1.0$*.*

The comparison with the exact solution is obtained by reconstructing the function on a regular grid of spacing $\Delta v = 0.25$ by the "weighted area rule" [11].

All the simulations have been performed for $t \in [0, 16]$ by starting with $N = 10^5$ particles.

In Figure 3 we show the L^2 norm of the error in time for both DSMC and TRMC schemes. In the first picture, we report the results obtained with the same time step $\Delta t = 1.0$. The results confirm the gain of accuracy of the TRMC methods on the transient time scale. Next, the results obtained with different time steps, chosen in such a way that the different errors are roughly the same, are also reported.

5.2. Shock wave profiles. The last test problem deals with the numerical solution of the space nonhomogeneous Boltzmann equation for hard sphere molecules (VHS, for $\alpha = 1$) with $C_\alpha = 1$. We present some numerical results for one-dimensional stationary shock profiles. In particular, we have computed the structure of the shock for different Knudsen numbers, from the rarefied regime up to the fluid limit. In all our numerical tests, the gas is initially at the upstream equilibrium state in the left

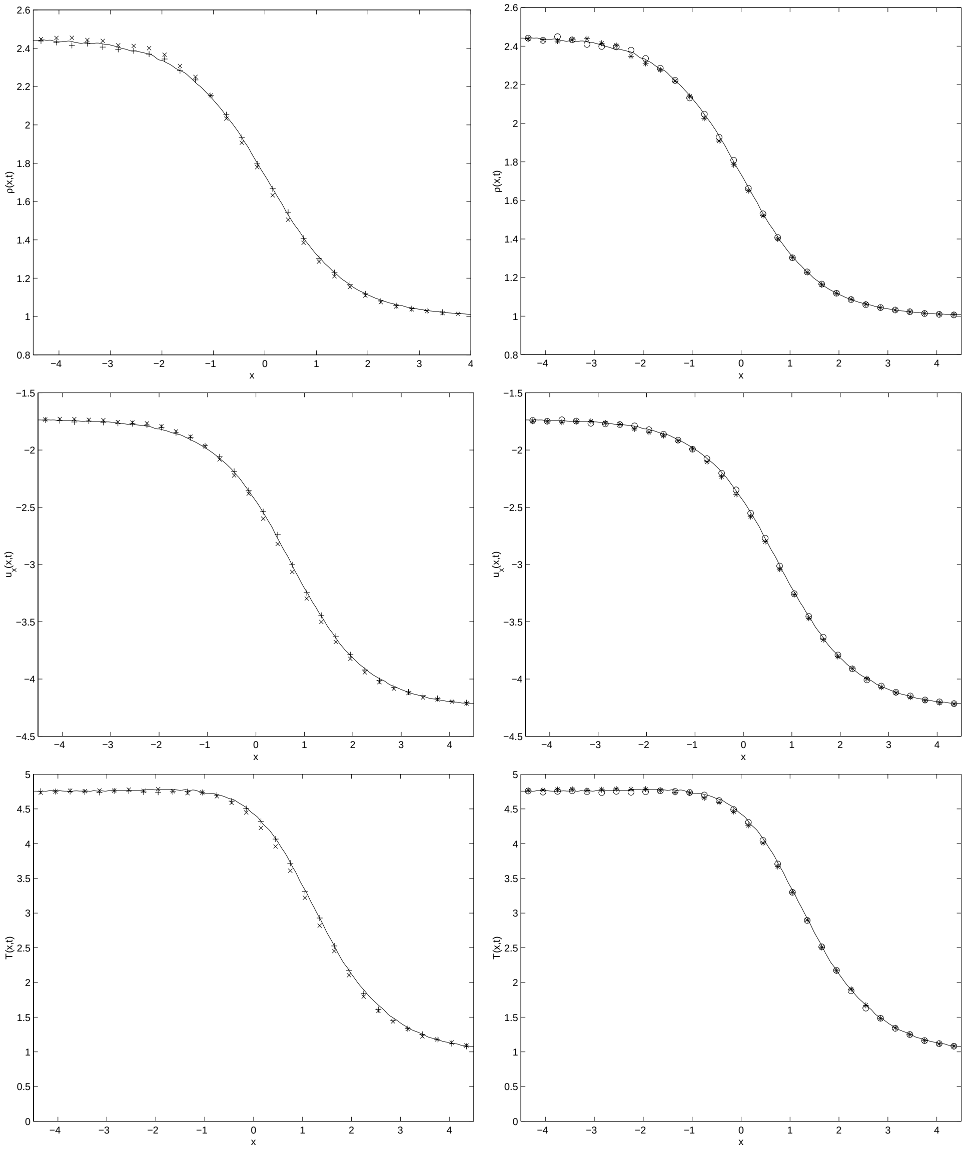

FIG. 4. *Shock wave profiles (rarefied regime): DSMC(+) and first order TRMC (×) (left column), second order (∗) and third order (○) TRMC (right column) for* $\epsilon = 1.0$ *and* $\Delta t = 0.025$. *From top to bottom:* ρ, u, T. *The line is the reference solution.*

half-space and in the downstream equilibrium state in the right half-space. The upstream state is determined from the downstream state using the Rankine–Hugoniot relations [21].

In the present calculations, the downstream state is characterized by

$$\rho = 1.0, \quad T = 1.0, \quad M = 3.0,$$

where M is the Mach number of the shock. The downstream mean velocity is then

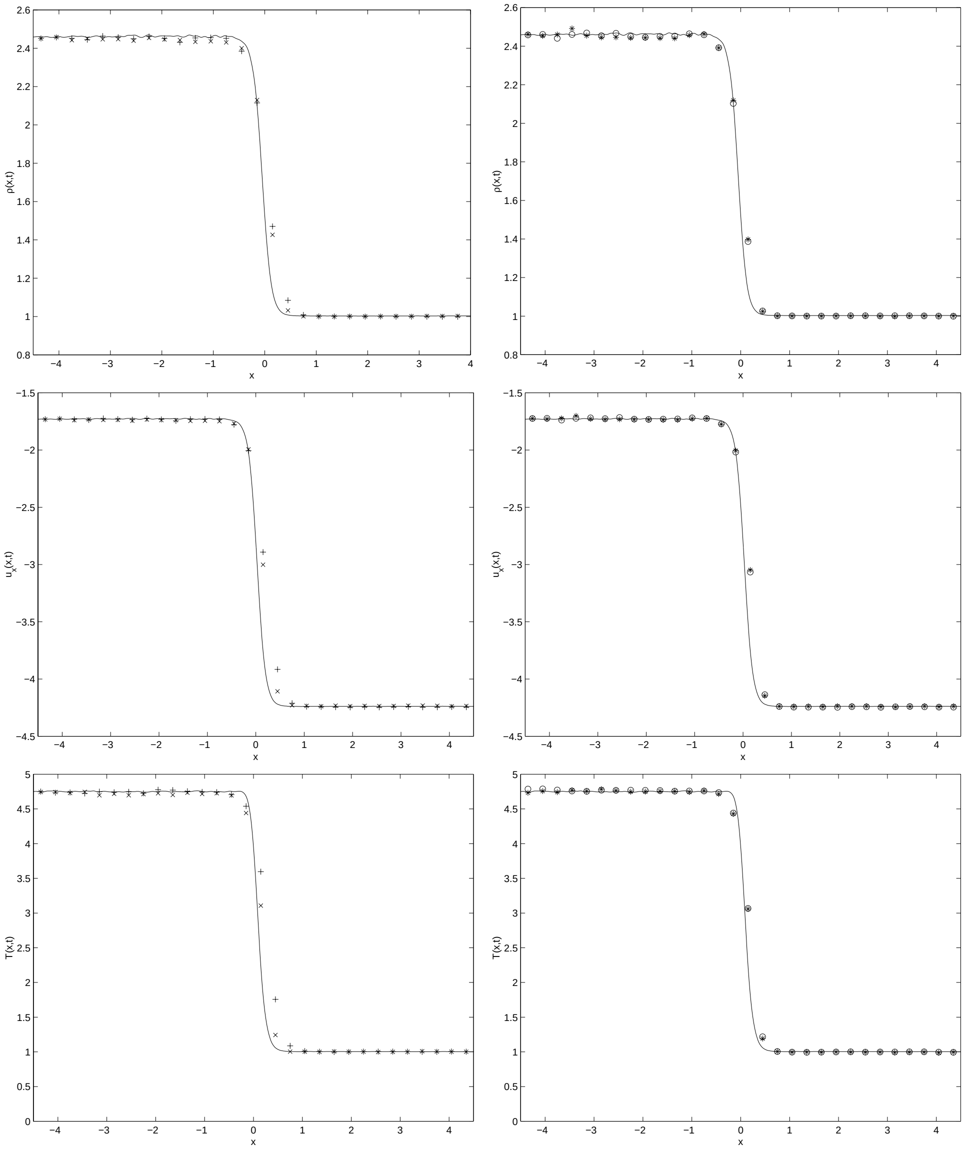

FIG. 5. *Shock wave profiles (intermediate regime): DSMC(+) and first order TRMC (×) (left column), second order (∗) and third order (○) TRMC (right column) for $\epsilon = 1.0$ and $\Delta t = 0.0025$ for DSMC, $\Delta t = 0.025$ for TRMC. From top to bottom: ρ, u, T. The line is the reference solution.*

given by

$$u_x = -M\sqrt{(\gamma T)}, \quad u_y = 0,$$

with $\gamma = 2$ since we have considered a two-dimensional monatomic gas in velocity space.

The infinite physical space is truncated to the finite region $[-7.5, 7.5]$. A suitable stabilizing technique [3] has been used to keep the number of particles constant during the time evolution. We report the result obtained with the different schemes using

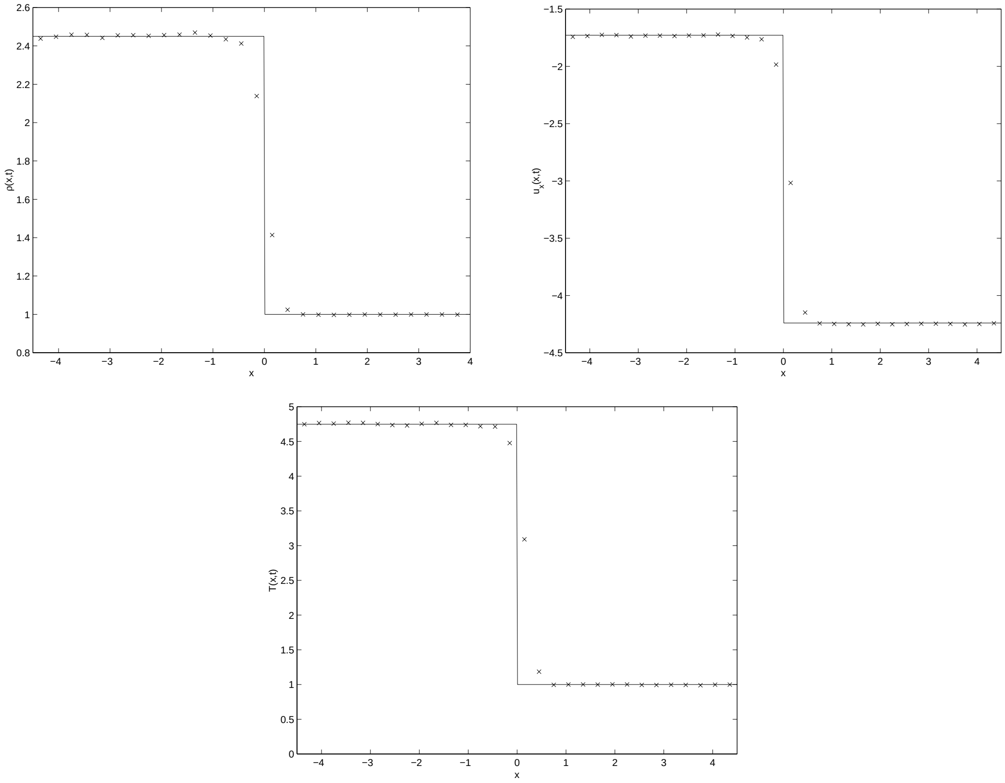

FIG. 6. *Shock wave profiles (fluid regime): First order TRMC* ($\times$) *for* $\epsilon = 10^{-6}$ *and* $\Delta t = 0.025$. *From top to bottom:* ρ, u, T.

50 space cells and 500 particles in each downstream cell. Since we are computing a stationary solution after a fixed initial time, we can strongly improve the accuracy of the Monte Carlo solution by averaging in time the solution itself. To this aim, we started accumulating statistics at time $t = 5$, and we average up to $t = 20$, which corresponds approximatively to 1500 time steps. The reference solution in the rarefied and intermediate regime is obtained using the DSMC method with 200 space cells and 500 particles in each downstream cell and averaging over approximatively 8000 time steps. All the results are reported on the space interval $[-4.5, 4.5]$.

In Figure 4 we plot the result obtained in the rarefied regime ($\epsilon = 1$) using the different Monte Carlo methods. The computational cost of the methods is comparable, since here we are far from the fluid limit. As expected, the results show that, essentially, the TRMC methods and the DSMC method are equivalent and provide a good description of the rarefied shock.

Next we consider the intermediate regime ($\epsilon = 0.1$). Two different time steps have been used for DSMC, a convection time step Δt and a collision time step $\Delta t_{\text{coll}} = \Delta t/10$. The collision time step for TRMC is equal to the convection time step. The results show that, despite the larger time step, the accuracy of the solution obtained with TRMC schemes is essentially the same of DSMC (see Figure 5).

Finally, we give the result of the computations close to the Euler limit ($\epsilon = 10^{-6}$). The profiles obtained with the TRMC methods are reported in Figure 6. Due to the small Knudsen number, the DSMC method is unusable in practice in this test. Note that the TRMC methods are all equivalent to Pullin's method. Thus we have plotted only one approximate solution.

Conclusion and future works. In this paper, a new family of schemes is proposed for the numerical solution of the Boltzmann equation.

The schemes have been tested on several problems for the Boltzmann equation, and they provide good results compared with standard Monte Carlo methods.

There is still a lot to do to improve the accuracy and robustness of the schemes. In particular, the optimal choice of the coefficients A_k, $k = 1, \ldots, m$, is still an open problem. Several possibilities are presently under consideration. The first one corresponds to choosing the coefficients in such a way that some moments of the distribution function for Maxwellian molecules are computed exactly. It is well known, in fact, that exact closure for the moment equations is possible in the case of Maxwellian molecules [23]. The same coefficients could then be used for VHS molecules.

A second alternative is to compute several terms of the Wild sum expansion. If the weights of the expansion decay fast enough, the computation can be done very efficiently by a recursive algorithm, even for large values of k. The recursive tree can eventually be truncated and the corresponding value of f_k substituted by sampling from a Maxwellian. Such an approach is very promising and is considered in [17].

CONDITIONS OF NONDEGENERACY OF THREE-DIMENSIONAL CELLS. A FORMULA OF A VOLUME OF CELLS[*]

OLGA V. USHAKOVA[†]

Abstract. Numerical solutions of partial differential equations in three dimensions often use hexahedral cells composing a computational grid. After the grid is constructed, it is first of all verified whether the grid is unfolded or not. For such a test in this paper, conditions of nondegeneracy are found for hexahedral cells which are given by eight corner points and generated by the trilinear map from a unit cube to a region defined by these points. The conditions include necessary conditions and two sets of sufficient conditions. They are found as conditions of positivity of the Jacobian of the trilinear map. Thus, the conditions which guarantee the invertibility of the trilinear map from a unit cube to a hexahedron are given. How general the nondegeneracy conditions are is shown by a numerical experiment. Formulas of the Jacobian of the trilinear map are obtained, and following from them, as a separate result, a formula of a volume of a cell is obtained.

Key words. grid generation, hexahedral cells, positivity of the Jacobian of the trilinear map, conditions of nondegeneracy of cells, formula of a volume of a cell

Introduction. For grid generation methods, good grid quality tests are needed. In the two-dimensional case [1, 2], the tests are suggested in [3]. Among them, in the first place, there is the criterion of nondegeneracy of cells since this criterion is a common requirement for a computational grid and a major objective of grid generation algorithms. Therefore, both a mathematician developing a grid generation method and a practicing engineer must care about this. Such tests are very important, especially, in three dimensions when a visualization of a grid is complicated. The purpose of the present research was to find this criterion for a grid consisting of hexahedrons generated by a trilinear map of a unit cube. Hexahedral cells are often used [4] by finite difference and finite element methods. As a result, the conditions of nondegeneracy of cells were found. The obtained conditions were briefly presented in [5]. In this paper, conditions of nondegeneracy and their deduction are given in detail.

Earlier, the problem of nondegeneracy of hexahedral cells (the problem of invertibility of the trilinear map) was investigated in a number of works; see, for example, [6, 7, 8].

In section 1, the criterion of nondegeneracy of cells is formulated in terms of positivity of the Jacobian of the transformation used for generation of cells. Formulas of the Jacobian are obtained in section 2. In section 3, both necessary and sufficient conditions of positivity of the Jacobian are found. The conditions are formulated as restrictions on the volumes of tetrahedrons with the vertices located at the corners

of hexahedral cells. (The faces of tetrahedrons are planar.) The formulas of the Jacobian are written in the form of polynomials with the coefficients proportional to the volumes of tetrahedrons. The results of computations for hexahedrons randomly selected by the computer are presented. The results give the success rate of the obtained conditions as well as examples of hexahedral cells, the nondegeneracy of which is verified by means of these conditions.

In section 4, a new formula of a volume of a cell is derived. Formulas of a volume of a cell published in [4, 9] are rather complex and demand a large amount of computations. Efficient volume computation and another formula of a cell volume were suggested in [10]. The formula obtained in this work is similar to [10] but requires computation of volumes of ten tetrahedrons.

1. Generation of ruled hexahedral cells. Let eight points $\mathbf{z}_{i_1i_2i_3} = (z^1_{i_1i_2i_3}, z^2_{i_1\text{“}i_2i_3}, z^3_{i_1i_2i_3})$, $i_1, i_2, i_3 = 0, 1$ be given. The trilinear map

$$\begin{aligned} \mathbf{z}(\mathbf{y}) = {} & \mathbf{a}_{000} + \mathbf{a}_{100}y^1 + \mathbf{a}_{010}y^2 + \mathbf{a}_{001}y^3 \\ & + \mathbf{a}_{110}y^1y^2 + \mathbf{a}_{101}y^1y^3 + \mathbf{a}_{011}y^2y^3 + \mathbf{a}_{111}y^1y^2y^3 \end{aligned} \tag{1.1}$$

of the unit cube $P = \{\mathbf{y} = (y^1, y^2, y^3) : 0 \le y^l \le 1,\ l = 1, 2, 3\}$ defines the ruled cell with the corners $\mathbf{z}_{i_1i_2i_3} = \mathbf{z}(i_1, i_2, i_3)$, $i_1, i_2, i_3 = 0, 1$. The vectors $\mathbf{a}_{i_1i_2i_3}$ are found from the following relations:

$$\begin{aligned} &\mathbf{a}_{000} = \mathbf{z}_{000}, && \mathbf{a}_{111} = \mathbf{z}_{111} - \mathbf{z}_{110} - \mathbf{z}_{101} - \mathbf{z}_{011} + \mathbf{z}_{100} + \mathbf{z}_{010} + \mathbf{z}_{001} - \mathbf{z}_{000}, \\ &\mathbf{a}_{001} = \mathbf{z}_{001} - \mathbf{z}_{000}, && \mathbf{a}_{011} = \mathbf{z}_{011} - \mathbf{z}_{010} - \mathbf{z}_{001} + \mathbf{z}_{000}, \\ &\mathbf{a}_{010} = \mathbf{z}_{010} - \mathbf{z}_{000}, && \mathbf{a}_{101} = \mathbf{z}_{101} - \mathbf{z}_{100} - \mathbf{z}_{001} + \mathbf{z}_{000}, \\ &\mathbf{a}_{100} = \mathbf{z}_{100} - \mathbf{z}_{000}, && \mathbf{a}_{110} = \mathbf{z}_{110} - \mathbf{z}_{100} - \mathbf{z}_{010} + \mathbf{z}_{000}. \end{aligned} \tag{1.2}$$

The concept of the ruled cell and techniques of generation of grids by such cells can be found, for example, in [4, 9]. In two dimensions, the ruled cell is a quadrilateral. If all eight corners of the cell are different, the edges of the cube are transformed by the trilinear map to straight line edges of the hexahedron, and the faces of the cube are transformed to ruled surfaces of the second order or planes (Figures 1.1, 3.1, and 3.2).

Many of the grid properties can be controlled by the Jacobian matrix of the map used for generating a grid or a cell [11]. The criterion of nondegeneracy of a cell is usually formulated in terms of positivity of the Jacobian (the determinant of the Jacobian matrix) of such a map [7, 8, 12, 13]. A grid element or a cell is said to be nondegenerate (noninverted, valid, unfolded, nonsingular) if the Jacobian is positive. In the general case, the nonzero Jacobian does not globally guarantee a one-to-one correspondence of the map ([13, Example 1.3.4, p. 9]). It guarantees only locally. In the case of a trilinear map (smooth map) from a cube (a domain), the nonzero Jacobian in the whole cube (including boundary) globally guarantees a one-to-one correspondence of the map ([8, Theorem 1, p. 8-4]). Positivity of the Jacobian provides the same orientation of edges of a cell that a unit cube has. Nondegeneracy of the joint grid is attained by the nondegeneracy of all its cells [8].

The Jacobian of map (1.1),

$$J(y^1, y^2, y^3) = \frac{\partial(z^1, z^2, z^3)}{\partial(y^1, y^2, y^3)} = \det\left(\frac{\partial z^i}{\partial y^j}\right)_{i=1,2,3,\, j=1,2,3},$$

is equal to the triple scalar product

$$J = \left[\frac{\partial \mathbf{z}}{\partial y^1}, \frac{\partial \mathbf{z}}{\partial y^2}, \frac{\partial \mathbf{z}}{\partial y^3}\right], \tag{1.3}$$

where

$$\begin{aligned}
\frac{\partial \mathbf{z}}{\partial y^1} &= \mathbf{a}_{100} + \mathbf{a}_{110} y^2 + \mathbf{a}_{101} y^3 + \mathbf{a}_{111} y^2 y^3,\\
\frac{\partial \mathbf{z}}{\partial y^2} &= \mathbf{a}_{010} + \mathbf{a}_{110} y^1 + \mathbf{a}_{011} y^3 + \mathbf{a}_{111} y^1 y^3,\\
\frac{\partial \mathbf{z}}{\partial y^3} &= \mathbf{a}_{001} + \mathbf{a}_{101} y^1 + \mathbf{a}_{011} y^2 + \mathbf{a}_{111} y^1 y^2.
\end{aligned} \tag{1.4}$$

The properties of the Jacobian are studied in [6, 7, 8, 12]. In two dimensions, a bilinear map of a unit square is considered. Its Jacobian is a linear function. If the Jacobian is positive at the corners of the square, then due to linearity the Jacobian will be positive everywhere in the square. The converse is also true. In two dimensions, if the Jacobian is positive, then the cell is convex, and the condition of nondegeneracy of cells is equivalent to the condition of convexity of cells [8, 12, 13].

A three-dimensional case is much more complicated. Since the faces of the cell can be nonplanar, the cell can be nonconvex. In [6] it is implied that the Jacobian in three dimensions is positive everywhere if and only if the Jacobian is positive at the corners of a cube. In [7] this statement is shown to be false. It is also demonstrated that for the positivity of the Jacobian in the interior of the cube the positivity of the Jacobian on the edges of the cube is not sufficient. The Jacobian in [7] is written in terms of polynomials, the coefficients of which are the values of the Jacobian on the edges.

2. The Jacobian of the trilinear map.

For each point $\mathbf{z}_{i_1 i_2 i_3}$, $i_1, i_2, i_3 = 0, 1$, consider the vectors (Figure 1.1(a))

$$\begin{aligned}
\mathbf{p}_{i_1 i_2 i_3} &= \mathbf{z}_{\bar{i}_1 i_2 i_3} - \mathbf{z}_{i_1 i_2 i_3}, & \mathbf{q}_{i_1 i_2 i_3} &= \mathbf{z}_{i_1 \bar{i}_2 i_3} - \mathbf{z}_{i_1 i_2 i_3},\\
\mathbf{r}_{i_1 i_2 i_3} &= \mathbf{z}_{i_1 i_2 \bar{i}_3} - \mathbf{z}_{i_1 i_2 i_3}, & \mathbf{u}_{i_1 i_2 i_3} &= \mathbf{z}_{i_1 \bar{i}_2 \bar{i}_3} - \mathbf{z}_{i_1 i_2 i_3},\\
\mathbf{v}_{i_1 i_2 i_3} &= \mathbf{z}_{\bar{i}_1 i_2 \bar{i}_3} - \mathbf{z}_{i_1 i_2 i_3}, & \mathbf{w}_{i_1 i_2 i_3} &= \mathbf{z}_{\bar{i}_1 \bar{i}_2 i_3} - \mathbf{z}_{i_1 i_2 i_3},\\
\mathbf{d}_{i_1 i_2 i_3} &= \mathbf{z}_{\bar{i}_1 \bar{i}_2 \bar{i}_3} - \mathbf{z}_{i_1 i_2 i_3}.
\end{aligned} \tag{2.1}$$

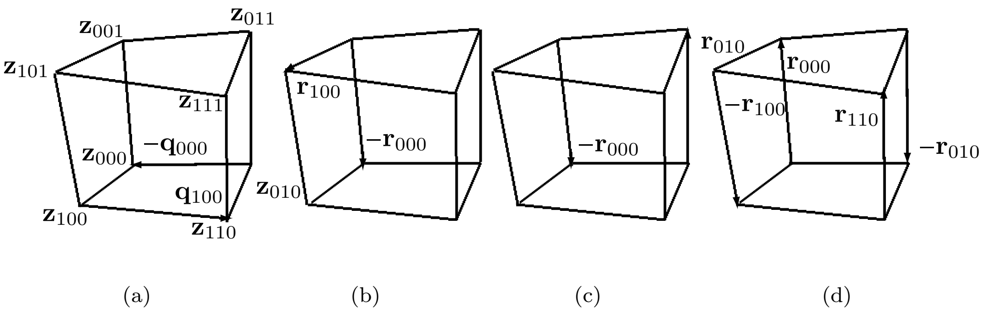

FIG. 2.1. *Vectors* $\mathbf{a}_{i_1 i_2 i_3}$: (a) $\mathbf{a}_{110}$; (b) $\mathbf{a}_{101}$; (c) $\mathbf{a}_{011}$; (d) $\mathbf{a}_{111}$.

Here and hereafter, $\bar{0} = 1$, $\bar{1} = 0$. The vectors $\mathbf{p}$, $\mathbf{q}$, $\mathbf{r}$ are directed along the edges, the vectors $\mathbf{u}$, $\mathbf{v}$, $\mathbf{w}$ play the role of "diagonals" of the faces, and vectors $\mathbf{d}$ are "inner diagonals" of the cell.

The vectors (2.1) have the properties

$$\begin{aligned} \mathbf{p}_{0 i_2 i_3} &= (-1)^{i_1} \mathbf{p}_{i_1 i_2 i_3}, \\ \mathbf{q}_{i_1 0 i_3} &= (-1)^{i_2} \mathbf{q}_{i_1 i_2 i_3}, \\ \mathbf{r}_{i_1 i_2 0} &= (-1)^{i_3} \mathbf{r}_{i_1 i_2 i_3}, \quad i_1, i_2, i_3 = 0, 1, \end{aligned} \tag{2.2}$$

and they can also be represented by vector sums; for example,

$$\begin{aligned} \mathbf{r}_{\bar{i}_1 i_2 0} &= (-1)^{i_3} (\mathbf{v} - \mathbf{p})_{i_1 i_2 i_3}, \\ \mathbf{r}_{i_1 \bar{i}_2 0} &= (-1)^{i_3} (\mathbf{u} - \mathbf{q})_{i_1 i_2 i_3}, \\ \mathbf{q}_{i_1 0 \bar{i}_3} &= (-1)^{i_2} (\mathbf{u} - \mathbf{r})_{i_1 i_2 i_3}. \end{aligned} \tag{2.3}$$

Consider the decompositions of the coefficients (1.2) with respect to vectors (2.1) (see Figure 2.1):

$$\begin{aligned} &\mathbf{a}_{100} = \mathbf{p}_{000}, \quad \mathbf{a}_{010} = \mathbf{q}_{000}, \quad \mathbf{a}_{001} = \mathbf{r}_{000}, \\ &\mathbf{a}_{110} = -\mathbf{q}_{000} + \mathbf{q}_{100} = \mathbf{w}_{010} - \mathbf{p}_{000} - \mathbf{w}_{010} + \mathbf{p}_{010} = -\mathbf{p}_{000} + \mathbf{p}_{010}, \\ &\mathbf{a}_{101} = -\mathbf{r}_{000} + \mathbf{r}_{100} = \mathbf{v}_{000} - \mathbf{p}_{000} - \mathbf{v}_{000} + \mathbf{p}_{001} = -\mathbf{p}_{000} + \mathbf{p}_{001}, \\ &\mathbf{a}_{011} = -\mathbf{r}_{000} + \mathbf{r}_{010} = \mathbf{u}_{000} - \mathbf{q}_{000} - \mathbf{u}_{000} + \mathbf{q}_{001} = -\mathbf{q}_{000} + \mathbf{q}_{001}, \\ &\mathbf{a}_{111} = -\mathbf{a}_{101} + \mathbf{r}_{110} - \mathbf{r}_{010} = -\mathbf{a}_{101} - \mathbf{p}_{010} + \mathbf{v}_{010} - \mathbf{v}_{010} + \mathbf{p}_{011} \\ &\qquad = \mathbf{p}_{000} - \mathbf{p}_{001} - \mathbf{p}_{010} + \mathbf{p}_{011} = -\mathbf{a}_{011} - \mathbf{r}_{100} + \mathbf{r}_{110} \\ &\qquad = \mathbf{r}_{000} - \mathbf{r}_{010} - \mathbf{r}_{100} + \mathbf{r}_{110} = -\mathbf{a}_{011} - \mathbf{q}_{100} + \mathbf{u}_{100} - \mathbf{u}_{100} + \mathbf{q}_{101} \\ &\qquad = \mathbf{q}_{000} - \mathbf{q}_{001} - \mathbf{q}_{100} + \mathbf{q}_{101}. \end{aligned} \tag{2.4}$$

By (2.4), vectors (1.4) can be obtained in the form

$$\begin{aligned} \frac{\partial \mathbf{z}}{\partial y^1} &= \mathbf{p}_{000}(1 - y^2)(1 - y^3) + \mathbf{p}_{010} y^2 (1 - y^3) + \mathbf{p}_{001} y^3 (1 - y^2) + \mathbf{p}_{011} y^2 y^3, \\ \frac{\partial \mathbf{z}}{\partial y^2} &= \mathbf{q}_{000}(1 - y^1)(1 - y^3) + \mathbf{q}_{100} y^1 (1 - y^3) + \mathbf{q}_{001} y^3 (1 - y^1) + \mathbf{q}_{101} y^1 y^3, \\ \frac{\partial \mathbf{z}}{\partial y^3} &= \mathbf{r}_{000}(1 - y^1)(1 - y^2) + \mathbf{r}_{100} y^1 (1 - y^2) + \mathbf{r}_{010} y^2 (1 - y^1) + \mathbf{r}_{110} y^1 y^2. \end{aligned} \tag{2.5}$$

Using properties (2.2) and formulas (2.5), we compute the Jacobians at the corners

$$J_{i_1 i_2 i_3} = J(i_1, i_2, i_3) = \delta_{i_1 i_2 i_3} [\mathbf{p}, \mathbf{q}, \mathbf{r}]_{i_1 i_2 i_3} = 6V^{pqr}_{i_1 i_2 i_3}, \quad i_1, i_2, i_3 = 0, 1.$$

Here and hereafter, $\delta_{i_1 i_2 i_3} = (-1)^{i_1+i_2+i_3}$, and lower indices related to brackets refer to each element inside brackets. The value $J_{i_1 i_2 i_3}$ is six times the volume of a tetrahedron with the corner $\mathbf{z}_{i_1 i_2 i_3}$ and edges $\mathbf{p}_{i_1 i_2 i_3}$, $\mathbf{q}_{i_1 i_2 i_3}$, $\mathbf{r}_{i_1 i_2 i_3}$ (the notation $V^{pqr}_{i_1 i_2 i_3}$). The notations of such type will be used to designate the volumes of tetrahedrons with the corner $\mathbf{z}_{i_1 i_2 i_3}$ and the edges corresponding to superscripts.

Lemma 2.1. *The Jacobian of trilinear map* (1.1) *can be written in the form*

$$\begin{aligned}
J = &\sum_{i_1, i_2, i_3 = 0}^{1} \alpha_{i_1 i_2 i_3} {Y_{i_1}}^2 {Y_{i_2}}^2 {Y_{i_3}}^2 \\
&+ \sum_{k=1}^{3} \sum_{\substack{i_l, i_m = 0, \\ (klm)=(123)}}^{1} \left(\sum_{i_k=0}^{1} \beta^{k i_k}_{i_l i_m} \right) y^k (1 - y^k) {Y_{i_l}}^2 {Y_{i_m}}^2 \\
&+ \sum_{k=1}^{3} \sum_{i_k=0}^{1} \left(\sum_{\substack{i_l, i_m = 0, \\ (klm)=(123)}}^{1} \gamma^{k i_k}_{i_l i_m} \right) {Y_{i_k}}^2 y^l (1 - y^l) y^m (1 - y^m) \\
&+ \sum_{i_1, i_2, i_3 = 0}^{1} \kappa_{i_1 i_2 i_3} y^1 (1 - y^1) y^2 (1 - y^2) y^3 (1 - y^3),
\end{aligned} \tag{2.6}$$

where $Y_{i_l} = i_l + (-1)^{i_l}(1 - y^l)$, $l = 1, 2, 3$, $i_l = 0, 1$ ($Y_{i_l} = 1 - y^l$ *if* $i_l = 0$ *and* $Y_{i_l} = y^l$ *if* $i_l = 1$),

$$\begin{aligned}
&\alpha_{i_1 i_2 i_3} = [\mathbf{p}_{0 i_2 i_3}, \mathbf{q}_{i_1 0 i_3}, \mathbf{r}_{i_1 i_2 0}], \quad &&\kappa_{i_1 i_2 i_3} = [\mathbf{p}_{0 i_2 i_3}, \mathbf{q}_{i_1 0 \bar{i}_3}, \mathbf{r}_{\bar{i}_1 \bar{i}_2 0}], \\
&\beta^{1 i_1}_{i_2 i_3} = \beta^1_{i_1 i_2 i_3} = [\mathbf{p}_{0 i_2 i_3}, \mathbf{q}_{i_1 0 i_3}, \mathbf{r}_{\bar{i}_1 i_2 0}], &&\gamma^{1 i_1}_{i_2 i_3} = \gamma^1_{i_1 i_2 i_3} = [\mathbf{p}_{0 i_2 i_3}, \mathbf{q}_{i_1 0 \bar{i}_3}, \mathbf{r}_{i_1 \bar{i}_2 0}], \\
&\beta^{2 i_2}_{i_3 i_1} = \beta^2_{i_1 i_2 i_3} = [\mathbf{p}_{0 i_2 i_3}, \mathbf{q}_{i_1 0 i_3}, \mathbf{r}_{i_1 \bar{i}_2 0}], &&\gamma^{2 i_2}_{i_3 i_1} = \gamma^2_{i_1 i_2 i_3} = [\mathbf{p}_{0 i_2 i_3}, \mathbf{q}_{i_1 0 \bar{i}_3}, \mathbf{r}_{\bar{i}_1 i_2 0}], \\
&\beta^{3 i_3}_{i_1 i_2} = \beta^3_{i_1 i_2 i_3} = [\mathbf{p}_{0 i_2 i_3}, \mathbf{q}_{i_1 0 \bar{i}_3}, \mathbf{r}_{i_1 i_2 0}], &&\gamma^{3 i_3}_{i_1 i_2} = \gamma^3_{i_1 i_2 i_3} = [\mathbf{p}_{0 i_2 i_3}, \mathbf{q}_{i_1 0 i_3}, \mathbf{r}_{\bar{i}_1 \bar{i}_2 0}],
\end{aligned} \tag{2.7}$$

and indices k, l, m *form the permutation of the cycle* (123)*; i.e.,* k, l, m *are equal to the values* $1, 2, 3,\ 2, 3, 1,\ 3, 1, 2$, *respectively.* (*The last one is denoted by* $(klm) = (123)$.)

Proof. Substituting (2.5) into (1.3) gives

$$J = \left[\sum_{i_2, i_3 = 0}^{1} \mathbf{p}_{0 i_2 i_3} Y_{i_2} Y_{i_3}, \sum_{i_1, i_3 = 0}^{1} \mathbf{q}_{i_1 0 i_3} Y_{i_1} Y_{i_3}, \sum_{i_1, i_2 = 0}^{1} \mathbf{r}_{i_1 i_2 0} Y_{i_1} Y_{i_2} \right].$$

We shall decompose the triple scalar product of sums of vectors into a sum of triple scalar products. First we obtain

$$J = \sum_{i_2, i_3 = 0}^{1} \left[\mathbf{p}_{0 i_2 i_3} Y_{i_2} Y_{i_3}, \sum_{i_1=0}^{1} (\mathbf{q}_{i_1 0 i_3} Y_{i_1} Y_{i_3} + \mathbf{q}_{i_1 0 \bar{i}_3} Y_{i_1} Y_{\bar{i}_3}), \mathbf{R}_{i_2} \right],$$

where

$$\mathbf{R}_{i_2} = \sum_{j_1=0}^{1} \left(\mathbf{r}_{j_1 i_2 0} Y_{j_1} Y_{i_2} + \mathbf{r}_{j_1 \bar{i}_2 0} Y_{j_1} Y_{\bar{i}_2} \right) = \sum_{j_1, j_2 = 0}^{1} \mathbf{r}_{j_1 j_2 0} Y_{j_1} Y_{j_2}, \quad i_2 = 0, 1.$$

Now we decompose with respect to the sum containing vectors $\mathbf{q}_{i_1 0 i_3}$ and take common factors of vectors out of the sign of the triple scalar product. We get

$$\begin{aligned} J = &\sum_{i_1,i_2,i_3=0}^{1} [\mathbf{p}_{0 i_2 i_3}, \mathbf{q}_{i_1 0 i_3}, \mathbf{R}_{i_1 i_2}] Y_{i_1} Y_{i_2} Y_{i_3}^2 \\ &+ \sum_{i_1,i_2,i_3=0}^{1} [\mathbf{p}_{0 i_2 i_3}, \mathbf{q}_{i_1 0 \bar{i}_3}, \mathbf{R}_{i_1 i_2}] Y_{i_1} Y_{i_2} Y_{i_3} Y_{\bar{i}_3}, \end{aligned}$$

where

$$\mathbf{R}_{i_1 i_2} = \mathbf{r}_{i_1 i_2 0} Y_{i_1} Y_{i_2} + \mathbf{r}_{\bar{i}_1 i_2 0} Y_{\bar{i}_1} Y_{i_2} + \mathbf{r}_{i_1 \bar{i}_2 0} Y_{i_1} Y_{\bar{i}_2} + \mathbf{r}_{\bar{i}_1 \bar{i}_2 0} Y_{\bar{i}_1} Y_{\bar{i}_2} = \mathbf{R}_{i_2}, \quad i_1, i_2 = 0, 1.$$

Now decompose the rest of the triple scalar products (with respect to the sum $\mathbf{R}_{i_1 i_2}$). Using the relations $Y_{i_l} Y_{\bar{i}_l} = y^l(1 - y^l)$, $i_l = 0, 1$, $l = 1, 2, 3$, we obtain (2.6) and (2.7). □

Let us introduce the notations $\alpha^{1 i_1}_{i_2 i_3} = \alpha^{2 i_2}_{i_3 i_1} = \alpha^{3 i_3}_{i_1 i_2} = \alpha_{i_1 i_2 i_3}$.

LEMMA 2.2. *The following relations are valid for coefficients* (2.7):

$$\alpha_{i_1 i_2 i_3} = [\mathbf{p}_{0 i_2 i_3}, \mathbf{q}_{i_1 0 i_3}, \mathbf{r}_{i_1 i_2 0}] = \delta_{i_1 i_2 i_3} [\mathbf{p}, \mathbf{q}, \mathbf{r}]_{i_1 i_2 i_3} = J_{i_1 i_2 i_3} = 6 V^{pqr}_{i_1 i_2 i_3} \tag{2.8}$$

$$\begin{aligned} \beta^1_{i_1 i_2 i_3} &= [\mathbf{p}_{0 i_2 i_3}, \mathbf{q}_{i_1 0 i_3}, \mathbf{r}_{\bar{i}_1 i_2 1}] = \delta_{i_1 i_2 i_3} [\mathbf{p}, \mathbf{q}, \mathbf{v}]_{i_1 i_2 i_3} = 6 V^{pqv}_{i_1 i_2 i_3}, \\ \beta^2_{i_1 i_2 i_3} &= [\mathbf{p}_{0 i_2 i_3}, \mathbf{q}_{i_1 0 i_3}, \mathbf{r}_{i_1 \bar{i}_2 0}] = \delta_{i_1 i_2 i_3} [\mathbf{p}, \mathbf{q}, \mathbf{u}]_{i_1 i_2 i_3} = 6 V^{pqu}_{i_1 i_2 i_3}, \\ \beta^3_{i_1 i_2 i_3} &= [\mathbf{p}_{0 i_2 i_3}, \mathbf{q}_{i_1 0 \bar{i}_3}, \mathbf{r}_{i_1 i_2 0}] = \delta_{i_1 i_2 i_3} [\mathbf{p}, \mathbf{u}, \mathbf{r}]_{i_1 i_2 i_3} = 6 V^{pur}_{i_1 i_2 i_3}, \end{aligned} \tag{2.9}$$

$$\begin{aligned} \sum_{\substack{i_l, i_m = 0 \\ (klm)=(123)}}^{1} \gamma^{k i_k}_{i_l i_m} &= \sum_{\substack{i_l, i_m = 0 \\ (klm)=(123)}}^{1} \left(\bar{\gamma}^{k i_k}_{i_l i_m} + \mu^{k i_k}_{i_l i_m}\right) = \sum_{\substack{i_l, i_m = 0 \\ (klm)=(123)}}^{1} \bar{\gamma}^{k i_k}_{i_l i_m} \\ &= \sum_{\substack{i_l, i_m = 0 \\ (klm)=(123)}}^{1} \left(-\alpha^{k i_k}_{i_l i_m} + \beta^{l i_l}_{i_m i_k} + \beta^{m i_m}_{i_k i_l}\right), \end{aligned} \tag{2.10}$$

$$\begin{aligned} \mu^{1 i_1}_{i_2 i_3} &= \mu^1_{i_1 i_2 i_3} = \delta_{i_1 i_2 i_3} [\mathbf{q}, \mathbf{u}, \mathbf{r}]_{i_1 i_2 i_3}, \\ \bar{\gamma}^{1 i_1}_{i_2 i_3} &= \bar{\gamma}^1_{i_1 i_2 i_3} = \delta_{i_1 i_2 i_3} [\mathbf{d}, \mathbf{q}, \mathbf{r}]_{i_1 i_2 i_3} = 6 V^{dqr}_{i_1 i_2 i_3}, \\ \mu^{2 i_2}_{i_3 i_1} &= \mu^2_{i_1 i_2 i_3} = \delta_{i_1 i_2 i_3} [\mathbf{v}, \mathbf{p}, \mathbf{r}]_{i_1 i_2 i_3}, \\ \bar{\gamma}^{2 i_2}_{i_3 i_1} &= \bar{\gamma}^2_{i_1 i_2 i_3} = \delta_{i_1 i_2 i_3} [\mathbf{p}, \mathbf{d}, \mathbf{r}]_{i_1 i_2 i_3} = 6 V^{pdr}_{i_1 i_2 i_3}, \\ \mu^{3 i_3}_{i_1 i_2} &= \mu^3_{i_1 i_2 i_3} = \delta_{i_1 i_2 i_3} [\mathbf{q}, \mathbf{p}, \mathbf{w}]_{i_1 i_2 i_3}, \\ \bar{\gamma}^{3 i_3}_{i_1 i_2} &= \bar{\gamma}^3_{i_1 i_2 i_3} = \delta_{i_1 i_2 i_3} [\mathbf{p}, \mathbf{q}, \mathbf{d}]_{i_1 i_2 i_3} = 6 V^{pqd}_{i_1 i_2 i_3}, \end{aligned} \tag{2.11}$$

$$\sum_{i_1,i_2,i_3=0}^{1} \kappa_{i_1 i_2 i_3} = \sum_{i_1,i_2,i_3=0}^{1} \sum_{k=1}^{3} \beta^k_{i_1 i_2 i_3} - 2 \sum_{i_1,i_2,i_3=0}^{1} \alpha_{i_1 i_2 i_3} = 2\bar{\kappa}_{000} + 2\bar{\kappa}_{111}, \tag{2.12}$$

$$\bar{\kappa}_{lll} = \delta_{lll} [\mathbf{u}, \mathbf{v}, \mathbf{w}]_{lll} = 6 V^{uvw}_{lll}, \quad l = 0, 1, \tag{2.13}$$

$$\sum_{i_1,i_2,i_3=0}^{1} \sum_{k=1}^{3} \gamma^k_{i_1 i_2 i_3} = \sum_{i_1,i_2,i_3=0}^{1} \alpha_{i_1 i_2 i_3} + 4(\bar{\kappa}_{000} + \bar{\kappa}_{111}), \tag{2.14}$$

$$\sum_{i_1,i_2,i_3=0}^{1} \sum_{k=1}^{3} \beta^k_{i_1 i_2 i_3} = 2 \sum_{i_1,i_2,i_3=0}^{1} \alpha_{i_1 i_2 i_3} + 2(\bar{\kappa}_{000} + \bar{\kappa}_{111}). \tag{2.15}$$

Proof. Obviously, (2.8) and (2.9) are valid by (2.2) and (2.3).

Now we prove (2.10) and (2.11). It is seen that

$$\begin{aligned}\gamma^1_{i_1i_2i_3} &= [\mathbf{p}_{0i_2i_3}, \mathbf{q}_{i_10\bar{i}_3}, \mathbf{r}_{i_1\bar{i}_20}] = [(-1)^{i_1}\mathbf{p}, (-1)^{i_2}(\mathbf{u}-\mathbf{r}), (-1)^{i_3}(\mathbf{u}-\mathbf{q})]_{i_1i_2i_3}\\ &= -\delta_{i_1i_2i_3}[\mathbf{p},\mathbf{q},\mathbf{r}]_{i_1i_2i_3} + \delta_{i_1i_2i_3}[\mathbf{p},\mathbf{q},\mathbf{u}]_{i_1i_2i_3} + \delta_{i_1i_2i_3}[\mathbf{p},\mathbf{u},\mathbf{r}]_{i_1i_2i_3}\\ &= -\alpha_{i_1i_2i_3} + \beta^2_{i_1i_2i_3} + \beta^3_{i_1i_2i_3}\end{aligned}$$

and

$$\begin{aligned}\gamma^1_{i_1i_2i_3} &= [\mathbf{p}_{0i_2i_3}, \mathbf{q}_{i_10\bar{i}_3}, \mathbf{r}_{i_1\bar{i}_20}] = \left[(-1)^{i_1}(\mathbf{d}-\mathbf{u}), (-1)^{\bar{i}_2}\mathbf{q}, (-1)^{\bar{i}_3}\mathbf{r}\right]_{i_1\bar{i}_2\bar{i}_3}\\ &= \delta_{i_1\bar{i}_2\bar{i}_3}[\mathbf{d},\mathbf{q},\mathbf{r}]_{i_1\bar{i}_2\bar{i}_3} + \delta_{i_1\bar{i}_2\bar{i}_3}[\mathbf{q},\mathbf{u},\mathbf{r}]_{i_1\bar{i}_2\bar{i}_3} = \bar{\gamma}^1_{i_1\bar{i}_2\bar{i}_3} + \mu^1_{i_1\bar{i}_2\bar{i}_3}.\end{aligned}$$

Because of $\sum_{i_2,i_3=0}^{1}\mu^1_{i_1i_2i_3} = 0$ ($[\mathbf{q},\mathbf{u},\mathbf{r}]_{i_100} = [\mathbf{u}-\mathbf{r},\mathbf{q}-\mathbf{r},-\mathbf{r}]_{i_101} = [\mathbf{q},\mathbf{u},\mathbf{r}]_{i_101} = [\mathbf{q},\mathbf{u},\mathbf{r}]_{i_111} = [\mathbf{q},\mathbf{u},\mathbf{r}]_{i_110}$, $i_1 = 0,1$), the first formula from (2.10) is valid. Similarly, we can prove other relations from (2.10) and (2.11). Also note that if all $\mu^k_{i_1i_2i_3} = 0$, $i_1, i_2, i_3 = 0,1$, $k = 1,2,3$, the faces of the cell are planar.

Let us prove further (2.14). We have

$$\begin{aligned}&\bar{\gamma}^1_{i_1i_2i_3} + \bar{\gamma}^2_{i_1i_2i_3} + \bar{\gamma}^3_{i_1i_2i_3}\\ &\quad= \delta_{i_1i_2i_3}\left([\mathbf{d},\mathbf{q},\mathbf{r}] + [\mathbf{p},\mathbf{d},\mathbf{r}] + [\mathbf{p},\mathbf{q},\mathbf{d}]\right)_{i_1i_2i_3} = \delta_{i_1i_2i_3}\left([\mathbf{p}-\mathbf{r},\mathbf{q},\mathbf{d}] + [\mathbf{p},\mathbf{d},\mathbf{r}]\right)_{i_1i_2i_3}\\ &\quad= \delta_{i_1i_2i_3}\left([\mathbf{v},\mathbf{u}-\mathbf{r},\mathbf{w}-\mathbf{r}]_{i_1i_2\bar{i}_3} + \left[\mathbf{p}_{i_1i_2i_3}, \mathbf{q}_{i_1i_2i_3} + \mathbf{v}_{i_1\bar{i}_2i_3}, \mathbf{r}_{i_1i_2i_3}\right]\right)\\ &\quad= \delta_{i_1i_2i_3}\Big(\left([\mathbf{v},\mathbf{u},\mathbf{w}] - [\mathbf{v},\mathbf{r},\mathbf{w}] - [\mathbf{v},\mathbf{u},\mathbf{r}]\right)_{i_1i_2\bar{i}_3} + [\mathbf{p},\mathbf{q},\mathbf{r}]_{i_1i_2i_3}\\ &\qquad+ \left[\mathbf{p}_{i_1i_2i_3}, \mathbf{v}_{i_1\bar{i}_2i_3}, \mathbf{r}_{i_1i_2i_3}\right]\Big)\\ &\quad= \delta_{i_1i_2i_3}\left([\mathbf{p},\mathbf{q},\mathbf{r}]_{i_1i_2i_3} + \left([\mathbf{v},\mathbf{u},\mathbf{w}] - [\mathbf{v},\mathbf{r},\mathbf{w}] - [\mathbf{v},\mathbf{u},\mathbf{r}] + [\mathbf{v}-\mathbf{r},\mathbf{w}-\mathbf{u},-\mathbf{r}]\right)_{i_1i_2\bar{i}_3}\right)\\ &\quad= \delta_{i_1i_2i_3}\left([\mathbf{p},\mathbf{q},\mathbf{r}]_{i_1i_2i_3} + \left([\mathbf{w},\mathbf{v},\mathbf{u}] - [\mathbf{v},\mathbf{r},\mathbf{w}] - [\mathbf{v},\mathbf{u},\mathbf{r}] + [\mathbf{v},\mathbf{r},\mathbf{w}] + [\mathbf{v},\mathbf{u},\mathbf{r}]\right)_{i_1i_2\bar{i}_3}\right)\\ &\quad= \delta_{i_1i_2i_3}\left[\mathbf{p},\mathbf{q},\mathbf{r}\right]_{i_1i_2i_3} - \delta_{i_1i_2i_3}\left[\mathbf{u},\mathbf{v},\mathbf{w}\right]_{i_1i_2\bar{i}_3}.\end{aligned}$$

Relations (2.13) (since $[\mathbf{u},\mathbf{v},\mathbf{w}]_{lll} = [-\mathbf{u},\mathbf{w}-\mathbf{u},\mathbf{v}-\mathbf{u}]_{l\bar{l}\bar{l}} = [\mathbf{u},\mathbf{v},\mathbf{w}]_{l\bar{l}\bar{l}} = [\mathbf{u},\mathbf{v},\mathbf{w}]_{\bar{l}\bar{l}l} = [\mathbf{u},\mathbf{v},\mathbf{w}]_{\bar{l}l\bar{l}}$, $l = 0,1$) finally leads to

$$\bar{\gamma}^1_{i_1i_2i_3} + \bar{\gamma}^2_{i_1i_2i_3} + \bar{\gamma}^3_{i_1i_2i_3} = \alpha_{i_1i_2i_3} + \bar{\kappa}_{lll},$$

where $l = 0$ if $\delta_{i_1i_2i_3} = -1$, and $l = 1$ if $\delta_{i_1i_2i_3} = 1$. Then (2.10) implies (2.14) and (2.15).

Next we prove (2.12). For each $\kappa_{i_1i_2i_3}$, consider the representation

$$\begin{aligned}\kappa_{i_1i_2i_3} &= \left[\mathbf{p}_{0i_2i_3}, \mathbf{q}_{i_10\bar{i}_3}, \mathbf{r}_{\bar{i}_1\bar{i}_20}\right] = \left[(-1)^{i_1}\mathbf{p}, (-1)^{i_2}(\mathbf{u}-\mathbf{r}), (-1)^{i_3}(\mathbf{d}-\mathbf{w})\right]_{i_1i_2i_3}\\ &= \delta_{i_1i_2i_3}\left([\mathbf{p},\mathbf{u},\mathbf{d}] + [\mathbf{p},\mathbf{d},\mathbf{r}] + [\mathbf{p},\mathbf{w},\mathbf{u}] - [\mathbf{p},\mathbf{w},\mathbf{r}]\right)_{i_1i_2i_3}.\end{aligned}$$

Since

$$\begin{aligned}\delta_{i_1i_2i_3}\left[\mathbf{p},\mathbf{u},\mathbf{d}\right]_{i_1i_2i_3} &= \delta_{i_1i_2i_3}\left[\mathbf{u}-\mathbf{d},\mathbf{p}-\mathbf{d},-\mathbf{d}\right]_{\bar{i}_1\bar{i}_2\bar{i}_3} = -\delta_{\bar{i}_1\bar{i}_2\bar{i}_3}\left[\mathbf{p},\mathbf{u},\mathbf{d}\right]_{\bar{i}_1\bar{i}_2\bar{i}_3}\\ \delta_{i_1i_2i_3}\left[\mathbf{p},\mathbf{w},\mathbf{u}\right]_{i_1i_2i_3} &= -\delta_{i_1i_2i_3}\left[-\mathbf{p},\mathbf{d}-\mathbf{p},\mathbf{q}-\mathbf{p}\right]_{\bar{i}_1i_2i_3} = -\delta_{i_1i_2i_3}\left[\mathbf{p},\mathbf{q},\mathbf{d}\right]_{\bar{i}_1i_2i_3}\\ &= \bar{\gamma}^3_{\bar{i}_1i_2i_3},\\ -\delta_{i_1i_2i_3}\left[\mathbf{p},\mathbf{w},\mathbf{r}\right]_{i_1i_2i_3} &= -\delta_{i_1i_2i_3}\left[-\mathbf{p},\mathbf{q}-\mathbf{p},\mathbf{v}-\mathbf{p}\right]_{\bar{i}_1i_2i_3} = -\beta^1_{i_1i_2i_3},\\ \delta_{i_1i_2i_3}\left[\mathbf{p},\mathbf{d},\mathbf{r}\right]_{i_1i_2i_3} &= \bar{\gamma}^2_{i_1i_2i_3},\end{aligned}$$

we have $\sum_{i_1,i_2,i_3=0}^{1} \delta_{i_1 i_2 i_3}[\mathbf{p}, \mathbf{u}, \mathbf{d}]_{i_1 i_2 i_3} = 0$. Hence, the relation (2.12) is proved by (2.10) and (2.15). □

Therefore, the Jacobian of the map can be represented by the sum of polynomials of the sixth degree (second degree in each of variables). The coefficients of the polynomial are expressed in terms of the volumes of tetrahedrons of four types (2.8), (2.9), (2.11) ($\bar{\gamma}^k_{i_1 i_2 i_3}$), (2.13). Tetrahedrons (2.8) are formed by three edges (with the common corner), tetrahedrons (2.9) by two edges and "diagonal" of one of adjacent faces, tetrahedrons (2.11) ($\bar{\gamma}^k_{i_1 i_2 i_3}$) by two edges and "inner diagonal" of the cell, tetrahedrons (2.13) by "diagonals" of faces. The total number of tetrahedrons is $8 + 24 + 24 + 2 = 58$.

Lemmas 2.1 and 2.2 allow us to prove the theorem.

THEOREM 2.3. *The Jacobian of trilinear map* (1.1) *is a polynomial of the degree not higher than fourth* (*second in each of variables*). *It can be written in the form*

$$\begin{aligned} J = &\sum_{i_1,i_2,i_3=0}^{1} \alpha_{i_1 i_2 i_3} Y_{i_1} Y_{i_2} Y_{i_3} (Y_{i_1} + Y_{i_2} + Y_{i_3} - 2) \\ &+ \sum_{k=1}^{3} \sum_{\substack{i_l, i_m = 0 \\ (klm)=(123)}}^{1} \left(\sum_{i_k=0}^{1} \beta^{k i_k}_{i_l i_m} \right) y^k (1 - y^k) Y_{i_l} Y_{i_m}. \end{aligned} \tag{2.16}$$

Proof. Substitute (2.10) and (2.12) in (2.6). Because of $Y_{i_l} + Y_{\bar{i}_l} = 1$, $i_l = 0, 1$, $l = 1, 2, 3$, the factors of coefficients $\alpha_{i_1 i_2 i_3}$, $\beta^k_{i_1 i_2 i_3}$ are equal to

$$Y_{i_1} Y_{i_2} Y_{i_3} - Y_{i_1} Y_{\bar{i}_2} Y_{\bar{i}_3} - Y_{\bar{i}_1} Y_{i_2} Y_{\bar{i}_3} - Y_{\bar{i}_1} Y_{\bar{i}_2} Y_{i_3} - 2 Y_{\bar{i}_1} Y_{\bar{i}_2} Y_{\bar{i}_3} = Y_{i_1} + Y_{i_2} + Y_{i_3} - 2,$$

$$Y_{i_n} Y_{i_m} + Y_{i_n} Y_{\bar{i}_m} + Y_{\bar{i}_n} Y_{i_m} + Y_{\bar{i}_n} Y_{\bar{i}_m} = 1, \qquad n \neq m \neq k, \quad n, m = 1, 2, 3,$$

respectively. This proves (2.16). □

Since $Y_{i_1} + Y_{i_2} + Y_{i_3} - 2 = 1 - Y_{\bar{i}_1} - Y_{\bar{i}_2} - Y_{\bar{i}_3}$, the formula (2.16) can be reduced to the following one:

$$J = \sum_{i_1,i_2,i_3=0}^{1} \alpha_{i_1 i_2 i_3} Y_{i_1} Y_{i_2} Y_{i_3} + \sum_{k=1}^{3} \sum_{\substack{i_l, i_m = 0 \\ (klm)=(123)}}^{1} \left(\sum_{i_k=0}^{1} \left(\beta^{k i_k}_{i_l i_m} - \alpha^{k i_k}_{i_l i_m} \right) \right) y^k (1 - y^k) Y_{i_l} Y_{i_m}. \tag{2.17}$$

Formula (2.17) requires computations of eight volumes of tetrahedrons (2.8) and 12 triple scalar products

$$\begin{aligned} \delta_{i_1 i_2 i_3} \left[\mathbf{p}_{i_1 i_2 i_3}, \mathbf{p}_{\bar{i}_1 \bar{i}_2 i_3}, \mathbf{p}_{i_1 i_2 \bar{i}_3} \right] &= \sum_{i_1=0}^{1} \left(\beta^1_{i_1 i_2 i_3} - \alpha_{i_1 i_2 i_3} \right), \\ \delta_{i_1 i_2 i_3} \left[\mathbf{q}_{\bar{i}_1 \bar{i}_2 i_3}, \mathbf{q}_{i_1 i_2 i_3}, \mathbf{q}_{i_1 i_2 \bar{i}_3} \right] &= \sum_{i_2=0}^{1} \left(\beta^2_{i_1 i_2 i_3} - \alpha_{i_1 i_2 i_3} \right), \\ \delta_{i_1 i_2 i_3} \left[\mathbf{r}_{\bar{i}_1 i_2 \bar{i}_3}, \mathbf{r}_{i_1 \bar{i}_2 i_3}, \mathbf{r}_{i_1 i_2 i_3} \right] &= \sum_{i_3=0}^{1} \left(\beta^3_{i_1 i_2 i_3} - \alpha_{i_1 i_2 i_3} \right). \end{aligned} \tag{2.18}$$

Expressions for J on the edges have the form

$$J\left(y^1, y^2, y^3\right) \Big|_{\substack{y^l = i_l \\ y^m = i_m}} = \alpha^{k0}_{i_l i_m} \left(1 - y^k\right)^2 + \alpha^{k1}_{i_l i_m} {y^k}^2 + \left(\beta^{k0}_{i_l i_m} + \beta^{k1}_{i_l i_m}\right) y^k \left(1 - y^k\right),$$
$$(klm) = (123), \quad i_l, i_m = 0, 1. \tag{2.19}$$

Using (2.19), the formula (2.17) can be rewritten in the following terms of values of J on the edges as in [7]:

$$\begin{aligned}(2.20)\qquad J = &\sum_{i_1,i_2=0}^{1} J\left(i_1,i_2,y^3\right) Y_{i_1} Y_{i_2} + \sum_{i_1,i_3=0}^{1} J\left(i_1,y^2,i_3\right) Y_{i_1} Y_{i_3} \\ &+ \sum_{i_2,i_3=0}^{1} J\left(y^1,i_2,i_3\right) Y_{i_2} Y_{i_3} - 2 \sum_{i_1,i_2,i_3=0}^{1} J\left(i_1,i_2,i_3\right) Y_{i_1} Y_{i_2} Y_{i_3}.\end{aligned}$$

Apparently, if $\sum_{i_k=0}^{1} \beta^k_{i_1 i_2 i_3}$ can be expressed in terms of the values $J_{i_1 i_2 i_3}$, $J_{\frac{1}{2} i_2 i_3}$, $J_{i_1 \frac{1}{2} i_3}$, $J_{i_1 i_2 \frac{1}{2}}$ (see (3.1)), then J can be represented as a polynomial with coefficients that are the values of J at the corners and midpoints of edges. Such representation is also given in [7].

If a hexahedral cell is a parallelepiped, then

$$(2.21)\qquad \alpha_{i_1 i_2 i_3} = \alpha_{000} = \beta^k_{i_1 i_2 i_3}, \quad k = 1,2,3, \quad i_1,i_2,i_3 = 0,1,$$

and the formula for the Jacobian (2.17) becomes

$$(2.22)\qquad J = \alpha_{000}(1 - y^1 - y^2 - y^3) + \alpha_{100} y^1 + \alpha_{010} y^2 + \alpha_{001} y^3.$$

(In [7] the coefficients α_{000}, α_{100}, α_{010}, α_{001} from (2.22) are the values J_{000}, J_{100}, J_{010}, J_{001}, respectively.) Using (2.21) and (2.22), we have

$$J = \alpha_{000} = \text{const}.$$

3. Positivity of the Jacobian of a trilinear map.

3.1. Necessary conditions. The condition $J > 0$ implies the inequalities

$$\begin{aligned}(3.1)\qquad & J\left(i_1,i_2,i_3\right) = \alpha_{i_1 i_2 i_3} > 0, \quad i_1,i_2,i_3 = 0,1; \\ & J\left(y^1,y^2,y^3\right)\Bigg|_{\substack{y^k=\frac{1}{2} \\ y^l,y^m=i_l,i_m}} = \frac{1}{4}\sum_{i_k=0}^{1}\left(\alpha^{k i_k}_{i_l i_m} + \beta^{k i_k}_{i_l i_m}\right) > 0, \quad (klm) = (123), \quad i_l,i_m = 0,1; \\ & J\left(y^1,y^2,y^3\right)\Bigg|_{\substack{y^k=i_k \\ y^l,y^m=\frac{1}{2}}} = \frac{1}{8}\sum_{i_l,i_m=0}^{1}\left(\beta^{l i_l}_{i_m i_k} + \beta^{m i_m}_{i_k i_l}\right) > 0, \quad (klm) = (123), \quad i_k = 0,1; \\ & J\left(\frac{1}{2},\frac{1}{2},\frac{1}{2}\right) = \frac{1}{16}\left(\sum_{i_1,i_2,i_3=0}^{1}\sum_{k=1}^{3}\beta^k_{i_1 i_2 i_3} - \sum_{i_1,i_2,i_3=0}^{1}\alpha_{i_1 i_2 i_3}\right) > 0,\end{aligned}$$

which compose the necessary conditions of nondegeneracy of a cell.

3.2. Sufficient conditions 1. The polynomials corresponding to the coefficients from (2.6) in the interior of the cube P are positive. Hence, if coefficients $\alpha_{i_1 i_2 i_3}$ are positive, and the rest of the coefficients are greater than or equal to zero, then the Jacobian is positive in the interior. It is easy to see that J is positive on the boundary.

Since the coefficients $\gamma^k_{i_1 i_2 i_3}$, $\sum_{i_1,i_2,i_3=0}^{1} \kappa_{i_1 i_2 i_3}$ can be expressed in terms of $\alpha_{i_1 i_2 i_3}$, $\beta^k_{i_1 i_2 i_3}$, the conditions of the positivity of the Jacobian (sufficient conditions 1) have the form

$$
\begin{aligned}
&(3.2)\qquad \alpha_{i_1 i_2 i_3} > 0, \quad i_1, i_2, i_3 = 0, 1;\\
&\sum_{i_k=0}^{1} \beta^{k i_k}_{i_l i_m} \geq \mathrm{B}^k_{i_l i_m}, \quad (klm) = (123), \quad i_l, i_m = 0, 1;\\
&\sum_{i_l, i_m=0}^{1} \gamma^{k i_k}_{i_l i_m} = \sum_{i_l, i_m=0}^{1} \left(\beta^{l i_l}_{i_m i_k} + \beta^{m i_m}_{i_k i_l} - \alpha^{k i_k}_{i_l i_m}\right) \geq \Gamma^k_{i_k}, \quad (klm) = (123), \quad i_k = 0, 1;\\
&2\bar{\kappa}_{000} + 2\bar{\kappa}_{111} = \sum_{i_1, i_2, i_3=0}^{1} \sum_{k=1}^{3} \beta^k_{i_1 i_2 i_3} - 2 \sum_{i_1, i_2, i_3=0}^{1} \alpha_{i_1 i_2 i_3} \geq \mathrm{K},
\end{aligned}
$$

where $\alpha_{i_1 i_2 i_3}$, $\beta^k_{i_1 i_2 i_3}$ are calculated according to formulas (2.8), (2.9), and

$$\mathrm{B}^k_{i_l i_m} = \Gamma^k_{i_k} = \mathrm{K} = 0. \tag{3.3}$$

The conditions (3.2) and (3.3) are satisfied, in particular, for hexahedral cells with the same orientation of vectors of 58 tetrahedrons (2.8), (2.9), (2.11), (2.13), corresponding to coefficients $\alpha_{i_1 i_2 i_3}$, $\beta^k_{i_1 i_2 i_3}$, $\bar{\gamma}^k_{i_1 i_2 i_3}$, $\bar{\kappa}_{000}$, $\bar{\kappa}_{111}$, that a cube has (right-handed orientation). Also note that necessary conditions coincide with (3.2), where equality signs are excluded (strict inequality form of (3.2)) and the following expressions are used:

$$\mathrm{B}^k_{i_l i_m} = -\sum_{i_k=0}^{1} \alpha^{k i_k}_{i_l i_m}, \quad \Gamma^k_{i_k} = -\sum_{i_l, i_m=0}^{1} \alpha^{k i_k}_{i_l i_m}, \quad \mathrm{K} = -\sum_{i_1, i_2, i_3=0}^{1} \alpha_{i_1 i_2 i_3}.$$

It is clear that necessary conditions assume a wider range of values for $\alpha_{i_1 i_2 i_3}$, $\beta^k_{i_1 i_2 i_3}$ than sufficient conditions 1. Both conditions include 27 inequalities (for 8 corners, 12 edges, 6 faces, and the interior part of a cell).

The expression for J is also positive if (2.18) and (2.8) are positive. However, these conditions restrict (in comparison with (3.2)) the set of values of $\alpha_{i_1 i_2 i_3}$, $\beta^k_{i_1 i_2 i_3}$ for which J is positive. Therefore, sufficient conditions 1 are more general conditions.

Thus, the result of sections 3.1 and 3.2 is the following theorem.

THEOREM 3.1. *In order that the Jacobian of trilinear map* (1.1) *be positive in the whole cube P including boundary,*

1. *it is necessary that conditions* (3.1) *be satisfied;*
2. *it is sufficient that conditions* (3.2) *with parameters* (3.3) *be satisfied.*

3.3. Necessary and sufficient conditions of positivity of the Jacobian on the edges. Consider the quadratic trinomial

$$f(y) = -ay^2 + (a + \alpha_1 - \alpha_0)y + \alpha_0, \tag{3.4}$$

where a, α_0, α_1 are parameters, and $a \neq 0$.

LEMMA 3.2. *Function $f(y)$* (3.4) *is positive on the segment* $[0, 1]$ *if and only if the parameters a, α_0, α_1 satisfy the inequalities*

$$\alpha_0 > 0, \quad \alpha_1 > 0, \tag{3.5}$$

$$a + \alpha_0 + \alpha_1 > -2\sqrt{\alpha_0 \alpha_1}. \tag{3.6}$$

Proof. Since $f'(y) = -2ay + a + \alpha_1 - \alpha_0$, the extremum of function (3.4) $y_* = \frac{1}{2} + \frac{\alpha_1 - \alpha_0}{2a}$ belongs to the segment $[0, 1]$ if

$$\left|\frac{\alpha_1 - \alpha_0}{2a}\right| \leq \frac{1}{2}.$$

Let $f_M = \max_{[0,1]} f(y)$, $f_m = \min_{[0,1]} f(y)$, $\alpha_M = \max(\alpha_0, \alpha_1)$, $\alpha_m = \min(\alpha_0, \alpha_1)$.

The discriminant of quadratic trinomial (3.4) has the form

$$D = (a + \alpha_1 - \alpha_0)^2 + 4a\alpha_0 = (a + \alpha_1 + \alpha_0)^2 - 4\alpha_0\alpha_1. \tag{3.7}$$

Inequalities (3.5) are obvious. Assume that they are satisfied.

Consider the following five cases.

1. If $a > \max[(\alpha_1 - \alpha_0), (\alpha_0 - \alpha_1)]$, then the function $f(y)$ has a maximum at the point $y = y_*$, $y_* \in [0, 1]$, $f_M = f(y_*) > 0$, $f_m = \alpha_m$.
2. In the case $0 \leq a \leq \max[(\alpha_1 - \alpha_0), (\alpha_0 - \alpha_1)]$ the function $f(y)$ has a maximum at the point $y = y_*$, $y_* \notin [0, 1]$, $f_M = \alpha_M$, $f_m = \alpha_m$.
3. If $\min[(\alpha_1 - \alpha_0), (\alpha_0 - \alpha_1)] \leq a < 0$, the function $f(y)$ has a minimum at the point $y = y_*$, $y_* \notin [0, 1]$, $f_M = \alpha_M$, $f_m = \alpha_m$.
4. If $-\alpha_1 - \alpha_0 - 2\sqrt{\alpha_0\alpha_1} < a < \min[(\alpha_1 - \alpha_0), (\alpha_0 - \alpha_1)]$, the function $f(y)$ has a minimum at the point $y = y_*$, $y_* \in [0, 1]$, $f_M = \alpha_M$, $f_m = f(y_*) > 0$.
5. If $a \leq -\alpha_1 - \alpha_0 - 2\sqrt{\alpha_0\alpha_1}$, then the function $f(y)$ has a minimum at the point $y = y_*$, $y_* \in [0, 1]$, $f_M = \alpha_M$, but $f_m = f(y_*) \leq 0$.

Cases 1–5 imply (3.6). □

Note. If $a = 0$, then necessary and sufficient conditions of positivity for f coincide with (3.5).

For quadratic trinomial (3.4), also consider the sufficient conditions of its positivity involving inequalities (3.5) and the conditions

$$a + \alpha_1 + \alpha_0 > -2\alpha_j \quad (a + 3\alpha_{\bar{j}} + \alpha_j > 0), \quad j = 0, 1, \tag{3.8}$$

or their equivalent form with max/min operation

$$a > \max[-3\alpha_0 - \alpha_1, -\alpha_0 - 3\alpha_1] = -\min[3\alpha_0 + \alpha_1, \alpha_0 + 3\alpha_1],$$

arising from cases 1–5 above and the condition $D < 0$ for (3.7). If (3.5) holds, then the value $a = 0$ satisfies inequalities (3.8). Therefore, for any values of parameter a, for the positivity of function f (3.4), sufficient conditions (3.5) and (3.8) will be considered.

Polynomials (2.19) can be reduced to the form (3.4), where

$$\begin{aligned}
a = \phi^3_{i_1 i_2} &= \beta^3_{i_1 i_2 1} + \beta^3_{i_1 i_2 0} - \alpha_{i_1 i_2 1} - \alpha_{i_1 i_2 0}, \quad \alpha_1 = \alpha_{i_1 i_2 1}, \quad \alpha_0 = \alpha_{i_1 i_2 0}, \quad y = y^3;\\
a = \phi^2_{i_1 i_3} &= \beta^2_{i_1 1 i_3} + \beta^2_{i_1 0 i_3} - \alpha_{i_1 1 i_3} - \alpha_{i_1 0 i_3}, \quad \alpha_1 = \alpha_{i_1 1 i_3}, \quad \alpha_0 = \alpha_{i_1 0 i_3}, \quad y = y^2;\\
a = \phi^1_{i_2 i_3} &= \beta^1_{1 i_2 i_3} + \beta^1_{0 i_2 i_3} - \alpha_{1 i_2 i_3} - \alpha_{0 i_2 i_3}, \quad \alpha_1 = \alpha_{1 i_2 i_3}, \quad \alpha_0 = \alpha_{0 i_2 i_3}, \quad y = y^1
\end{aligned} \tag{3.9}$$

for $J(i_1, i_2, y^3)$, $J(i_1, y^2, i_3)$, $J(y^1, i_2, i_3)$, respectively. The following theorem follows from Lemma 3.2 and (3.4) and (3.9).

Theorem 3.3. *Necessary and sufficient conditions of positivity of J on the edges of the cube have the form*

$$\begin{aligned}
&\alpha_{i_1 i_2 i_3} > 0, \quad i_1, i_2, i_3 = 0, 1;\\
&\sum_{i_k=0}^{1} \beta^{k i_k}_{i_l i_m} > -2\sqrt{\alpha^{k0}_{i_l i_m}\alpha^{k1}_{i_l i_m}}, \quad (klm) = (123), \quad i_l, i_m = 0, 1.
\end{aligned} \tag{3.10}$$

Note. If for some edges the value a turned out to be equal to zero, then corresponding restrictions on coefficients $\beta^k_{i_1 i_2 i_3}$ can be excluded from conditions (3.10). (In this case, such restrictions are satisfied.)

Now we reduce the expression for the Jacobian J on the faces $y^l = 0, 1$, $l = 1, 2, 3$, and the general formula (2.17) to the form (3.4).

Using (2.20), the Jacobian for the face $y^3 = 0$ can be written as

$$\begin{aligned} J(y^1, y^2, 0) &= g(y^1, y^2) \\ &= J(0, y^2, 0)(1 - y^1) + J(1, y^2, 0)y^1 + J(y^1, 0, 0)(1 - y^2) \\ &\quad + J(y^1, 1, 0)y^2 - J(0, 0, 0)(1 - y^1)(1 - y^2) - J(0, 1, 0)(1 - y^1)y^2 \\ &\quad - J(1, 0, 0)y^1(1 - y^2) - J(1, 1, 0)y^1y^2 \\ &= -(\phi^2_{00}(1 - y^1) + \phi^2_{10}y^1){y^2}^2 \\ &\quad + (\phi^2_{00}(1 - y^1) + \phi^2_{10}y^1 + J(y^1, 1, 0) - J(y^1, 0, 0))y^2 + J(y^1, 0, 0). \end{aligned} \tag{3.11}$$

Here, $a = a^2_{00}(y_1) = \phi^2_{00}(1-y^1)+\phi^2_{10}y^1$, $\alpha_1 = J(y^1, 1, 0)$, $\alpha_0 = J(y^1, 0, 0)$, $y = y^2$, and $\phi^2_{i_1 0}$, $i_1 = 0, 1$, are defined in (3.9). A similar representation in the form of quadratic trinomial is valid with respect to the variable y^1.

The representations (3.4), where

$$\begin{aligned} &a = a^3_{i_1 0}(y^2) = \phi^3_{i_1 0}(1 - y^2) + \phi^3_{i_1 1}y^2, \quad \alpha_1 = J(i_1, y^2, 1), \quad \alpha_0 = J(i_1, y^2, 0), \quad y = y^3; \\ &a = a^3_{0 i_2}(y^1) = \phi^3_{0 i_2}(1 - y^1) + \phi^3_{1 i_2}y^1, \quad \alpha_1 = J(y^1, i_2, 1), \quad \alpha_0 = J(y^1, i_2, 0), \quad y = y^3; \\ &a = a^2_{0 i_3}(y^1) = \phi^2_{0 i_3}(1 - y^1) + \phi^2_{1 i_3}y^1, \quad \alpha_1 = J(y^1, 1, i_3), \quad \alpha_0 = J(y^1, 0, i_3), \quad y = y^2, \end{aligned} \tag{3.12}$$

will be used for the faces $y^1 = i_1$, $i_1 = 0, 1$ $y^2 = i_2$, $i_2 = 0, 1$, $y^3 = i_3$, $i_3 = 0, 1$, respectively.

The Jacobian in the general case can be represented in the form of a quadratic trinomial in one variable with fixed two other variables. For example,

$$J(y^1, y^2, y^3) = -A^3_{00}{y^3}^2 + (A^3_{00} + J(y^1, y^2, 1) - J(y^1, y^2, 0))y^3 + J(y^1, y^2, 0), \tag{3.13}$$

where $A^3_{00} = A^3_{00}(y^1, y^2) = a^3_{00}(y^1) + (a^3_{01}(y^1) - a^3_{00}(y^1))y^2$, and $a^3_{01}(y^1), a^3_{00}(y^1)$ are defined in (3.12).

An attempt to find necessary and sufficient conditions of positivity of the Jacobian using its representation in the form of a quadratic trinomial fails since even in the case of faces (3.12) the discriminant (3.7) of quadratic trinomial (3.4) is a fourth-degree polynomial in one variable; in the case (3.13), the discriminant will be the polynomial in two variables. Because of the above reasons an analysis of the discriminant on the property of having fixed sign fails. However, using conditions (3.5) and (3.8), it is possible to find sufficient conditions more general than (3.2).

3.4. Sufficient conditions 2. To obtain sufficient conditions 2, we shall write down (3.5) and (3.8) for different representations (3.4).

Sufficient conditions for the edges include relations (3.5), (3.8), and (3.9).

Sufficient conditions of positivity of the Jacobian on the faces of a cell are conditions (3.5), (3.8), and (3.12). Substituting (3.12) into (3.5) and (3.8) gives the conditions of positivity of polynomials (3.4) with the following parameters for the planes:

$$\begin{array}{l}
y^1 = i_1, i_1 = 0,1 : \\
\quad a = 3\phi^2_{i_1 1} + \phi^2_{i_1 0}; \quad \alpha_0 = \phi^3_{i_1 0} + \alpha_{i_1 00} + 3\alpha_{i_1 01}, \quad \alpha_1 = \phi^3_{i_1 1} + \alpha_{i_1 10} + 3\alpha_{i_1 11}, \quad y = y^2; \\
\quad a = \phi^2_{i_1 1} + 3\phi^2_{i_1 0}; \quad \alpha_0 = \phi^3_{i_1 0} + 3\alpha_{i_1 00} + \alpha_{i_1 01}, \quad \alpha_1 = \phi^3_{i_1 1} + 3\alpha_{i_1 10} + \alpha_{i_1 11}, \quad y = y^2; \\
y^2 = i_2, i_2 = 0,1 : \\
\quad a = 3\phi^1_{i_2 1} + \phi^1_{i_2 0}; \quad \alpha_0 = \phi^3_{0 i_2} + \alpha_{0 i_2 0} + 3\alpha_{0 i_2 1}, \quad \alpha_1 = \phi^3_{1 i_2} + \alpha_{1 i_2 0} + 3\alpha_{1 i_2 1}, \quad y = y^1; \\
\quad a = \phi^1_{i_2 1} + 3\phi^1_{i_2 0}; \quad \alpha_0 = \phi^3_{0 i_2} + 3\alpha_{0 i_2 0} + \alpha_{0 i_2 1}, \quad \alpha_1 = \phi^3_{1 i_2} + 3\alpha_{1 i_2 0} + \alpha_{1 i_2 1}, \quad y = y^1; \\
y^3 = i_3, i_3 = 0,1 : \\
\quad a = 3\phi^1_{1 i_3} + \phi^1_{0 i_3}; \quad \alpha_0 = \phi^2_{0 i_3} + \alpha_{00 i_3} + 3\alpha_{01 i_3}, \quad \alpha_1 = \phi^2_{1 i_3} + \alpha_{10 i_3} + 3\alpha_{11 i_3}, \quad y = y^1; \\
\quad a = \phi^1_{1 i_3} + 3\phi^1_{0 i_3}; \quad \alpha_0 = \phi^2_{0 i_3} + 3\alpha_{00 i_3} + \alpha_{01 i_3}, \quad \alpha_1 = \phi^2_{1 i_3} + 3\alpha_{10 i_3} + \alpha_{11 i_3}, \quad y = y^1.
\end{array}$$
(3.14)

In turn, considering conditions (3.5) and (3.8) for polynomials (3.4) and (3.14), together with conditions (3.5) and (3.12), we obtain sufficient conditions of positivity of J on the faces of a cell.

Write down conditions (3.5) and (3.8) for the plane $y^3 = 0$. They have the form

$$\begin{array}{l}
\Phi^2_{i_1 0} + \mathrm{A}_{i_1 00} + 3\mathrm{A}_{i_1 10} > 0, \\
\Phi^2_{i_1 0} + 3\mathrm{A}_{i_1 00} + \mathrm{A}_{i_1 10} > 0, \quad i_1 = 0,1,
\end{array} \tag{3.15}$$

$$\begin{array}{l}
3\Phi^1_{10} + \Phi^1_{00} + 3\Phi^2_{10} + \Phi^2_{00} + \mathrm{A}_{000} + 3\mathrm{A}_{010} + 3\mathrm{A}_{100} + 9\mathrm{A}_{110} > 0, \\
3\Phi^1_{10} + \Phi^1_{00} + \Phi^2_{10} + 3\Phi^2_{00} + \mathrm{A}_{100} + 3\mathrm{A}_{110} + 3\mathrm{A}_{000} + 9\mathrm{A}_{010} > 0, \\
\Phi^1_{10} + 3\Phi^1_{00} + \Phi^2_{10} + 3\Phi^2_{00} + \mathrm{A}_{110} + 3\mathrm{A}_{010} + 3\mathrm{A}_{100} + 9\mathrm{A}_{000} > 0, \\
\Phi^1_{10} + 3\Phi^1_{00} + 3\Phi^2_{10} + \Phi^2_{00} + \mathrm{A}_{010} + 3\mathrm{A}_{000} + 3\mathrm{A}_{110} + 9\mathrm{A}_{100} > 0,
\end{array} \tag{3.16}$$

where

$$\Phi^k_{ij} = \phi^k_{ij}, \quad \mathrm{A}_{ij0} = \alpha_{ij0}, \quad k = 1,2, \quad i,j = 0,1. \tag{3.17}$$

Conditions (3.15) and (3.17) are equivalent to conditions (3.5), and (3.16) and (3.17) are equivalent to conditions (3.8) for the face $y^3 = 0$. Apparently, conditions (3.5) for the face $y^3 = 0$ coincide with conditions (3.8) for the edges $y^1 = 0, 1$, $y^3 = 0$.

Using (3.5) in (3.11),

$$g(y^1, i_2) = \alpha_{i_2} = J(y^1, i_2, 0) > 0, \quad i_2 = 0,1, \tag{3.18}$$

conditions (3.15)–(3.17), and the conditions for $\mathrm{A}_{i_1 i_2 0} = \alpha_{i_1 i_2 0}$,

$$\mathrm{A}_{i_1 i_2 0} > 0, \tag{3.19}$$

we get the conditions of positivity for function g (3.11) in the square $0 \leq y^1, y^2 \leq 1$.

Now consider the Jacobian in the general case. By representation (3.13), $J > 0$ in the cube P, if conditions (3.5) for (3.13),

$$\alpha_{i_3} = J(y^1, y^2, i_3) > 0, \quad 0 \leq y^1, y^2 \leq 1, \quad i_3 = 0,1, \tag{3.20}$$

are satisfied, and if conditions (3.8), also for (3.13),

$$g_0(y^1, y^2) = A^3_{00} + 3J(y^1, y^2, 1) + J(y^1, y^2, 0) > 0, \tag{3.21}$$

$$g_1(y^1, y^2) = A^3_{00} + J(y^1, y^2, 1) + 3J(y^1, y^2, 0) > 0 \tag{3.22}$$

are satisfied. Conditions (3.21) and (3.22) hold if inequalities (3.15)–(3.16) and (3.18)–(3.19) for functions $g = g_l(y^1, y^2)$ from (3.21) and (3.22) are satisfied for the following parameters:

$$\begin{aligned} &(3.23) && \Phi^k_{00} = 3\phi^k_{01} + \phi^k_{00}, \quad \Phi^k_{10} = 3\phi^k_{11} + \phi^k_{10}, \quad k = 1, 2,\\ &&& \mathrm{A}_{i_1 i_2 0} = 3\alpha_{i_1 i_2 1} + \alpha_{i_1 i_2 0} + \phi^3_{i_1 i_2}, \quad i_1, i_2 = 0, 1, \quad l = 0;\\ &(3.24) && \Phi^k_{00} = \phi^k_{01} + 3\phi^k_{00}; \quad \Phi^k_{10} = \phi^k_{11} + 3\phi^k_{10}, \quad k = 1, 2,\\ &&& \mathrm{A}_{i_1 i_2 0} = \alpha_{i_1 i_2 1} + 3\alpha_{i_1 i_2 0} + \phi^3_{i_1 i_2}, \quad i_1, i_2 = 0, 1, \quad l = 1. \end{aligned}$$

The conditions (3.16), (3.23), and (3.24) (8 inequalities) are equivalent to conditions (3.8) for the general form of J. The conditions (3.20), $g_l(y^1, 0) > 0$, and (3.15) and (3.23)–(3.24) give conditions (3.8) for planes $y^3 = 0, 1$, $y^2 = 0, 1$, $y^1 = 0, 1$, respectively ($6 \times 4 = 24$ inequalities); conditions (3.19), (3.23), and (3.24) give conditions (3.8) for the edges $y^1 = 0, 1$, $y^2 = 0, 1$; inequalities (3.20) also give conditions (3.8) for the edges $y^1 = 0, 1$, $y^3 = 0, 1$. Adding to the above conditions the conditions (3.8) for the rest of edges (the conditions of the form (3.18) must be satisfied for (3.20), for the edges there will be $12 \times 2 = 24$ inequalities) and 8 conditions $\alpha_{i_1 i_2 i_3} > 0$ yield sufficient conditions 2 of positivity of J in the cube. There will be 64 inequalities. We shall formulate them in the following theorem using the equivalent form of inequalities (as for (3.8)) with min operation and notations $\alpha_{i_1 i_2 i_3}$, $\beta^k_{i_1 i_2 i_3}$.

Theorem 3.4 (sufficient conditions 2). *In order that the Jacobian of trilinear map* (1.1) *be positive in the whole cube P including boundary, it is sufficient that conditions* (3.2) (*in strict inequality form*), *where*

$$\mathrm{B}^k_{i_l i_m} = -2 \min(\alpha^{k0}_{i_l i_m}, \alpha^{k1}_{i_l i_m}), \quad (klm) = (123), \quad i_l, i_m = 0, 1;$$

$$\Gamma^k_{i_k} = -2 \min_{j_l, j_m = 0,1} \left(2\alpha^{k i_k}_{j_l j_m} + \sum_{i_l=0}^{1} \beta^{l i_l}_{j_m i_k} + \sum_{i_m=0}^{1} \beta^{m i_m}_{i_k j_l} \right), \quad (klm) = (123), \quad i_k = 0, 1;$$

$$\begin{aligned} \mathrm{K} = -2 \min_{j_1, j_2, j_3 = 0,1} & \left(3\alpha_{j_1 j_2 j_3} + 2 \left(\sum_{i_2, i_3 = 0}^{1} \gamma^1_{j_1 i_2 i_3} + \sum_{i_1, i_3 = 0}^{1} \gamma^2_{i_1 j_2 i_3} + \sum_{i_1, i_2 = 0}^{1} \gamma^3_{i_1 i_2 j_3} \right) \right.\\ & \left. + \sum_{i_1=0}^{1} \beta^1_{i_1 j_2 j_3} + \sum_{i_2=0}^{1} \beta^2_{j_1 i_2 j_3} + \sum_{i_3=0}^{1} \beta^3_{j_1 j_2 i_3} \right), \end{aligned}$$

be satisfied.

Note. In sufficient conditions 2 the strict inequality form of (3.2) is considered: from inequalities (3.2) equality signs are excluded.

It is obvious that cells satisfying sufficient conditions 1 satisfy sufficient condition 2. Sufficient conditions 2 are more general than sufficient conditions 1 but demand more computations. It is possible to show that when sufficient conditions 1 are satisfied, necessary conditions (3.1) also hold (but not vice versa). Really, considering the form of sufficient conditions 2 without min operation and summing inequalities corresponding to each min operation, we have system of inequalities (3.1).

3.5. Numerical results. To see how general the obtained conditions are, a numerical experiment was carried out. The corners of a hexahedron were selected randomly. Of 10^7 hexahedrons randomly generated by the computer only 36251 were found to have positive Jacobians at the corners of a cell. From them only 14622 cases satisfied necessary conditions for edges, 14010 cases satisfied necessary conditions for

faces, and 14004 cases satisfied necessary conditions for the whole cell. The Jacobian was positive in 11582 cases. Sufficient conditions 1 were satisfied in 33.63% of the cases (from the number 11582), while sufficient conditions 2 were satisfied in 63.91% of the cases. In 11660 cases the Jacobian was positive on the edges (conditions (3.10)); 99.33% of them had positive Jacobian everywhere in the whole cell.

In Figures 3.1 and 3.2 there are hexahedrons nondegeneracy of which was checked by means of sufficient conditions 1 and 2, respectively. Figures 3.1(a) and 3.2(a) show the edges of cells, while Figures 3.1(b) and 3.2(b) show the faces of cells (hidden lines are removed). The corners of cells for Figures 3.1 and 3.2 are given in Table 3.1.

All computations were performed on a personal computer. A computer code first generated a hexahedron for each case and then checked different types of conditions. For all cases, necessary conditions were checked. For some cases, necessary and sufficient conditions on the edges, sufficient conditions 1, and sufficient conditions 2 were checked. Besides checking all these conditions, in some cases a special algorithm of a search for a minimum of the Jacobian in the whole cube was applied. On the personal computer Pentium 3 (800 MHz), such a test of 10^7 cases demanded about 1 minute of computation (58 seconds). The test of sufficient conditions 2 (as the most expensive) for 10^7 nondegenerate cells required about one and half minute of computation (95 seconds).

Numerical result showed the following.

1. Necessary conditions allowed the exclusion of a great number of cells which were degenerate.
2. In less than one third of cases when the Jacobian was positive at the corners of a cell the Jacobian was positive everywhere in the cell. Therefore, it would be unreliable to draw a conclusion about the invertibility of the Jacobian on the basis of positive Jacobians at the corners of a cell.
3. Necessary and sufficient conditions of positivity of the Jacobian on the edges (provided that necessary conditions (3.1) were satisfied) in a large percentage of cases gave positive Jacobians everywhere in the cell. However, these conditions did not also guarantee the invertibility of the trilinear map.
4. Sufficient conditions 2 permitted recognition of the nondegeneracy of cells in most of the cases.

4. A formula of a volume of a cell.

THEOREM 4.1. *The volume of a ruled hexahedral cell is*

$$V = \frac{1}{12}\left(\sum_{i_1,i_2,i_3=0}^{1} \alpha_{i_1i_2i_3} + \bar{\kappa}_{000} + \bar{\kappa}_{111}\right) = \frac{1}{2}\left(\sum_{i_1,i_2,i_3=0}^{1} V^{pqr}_{i_1i_2i_3} + V^{uvw}_{000} + V^{uvw}_{111}\right).$$

Proof. Integrate the Jacobian J. Using (2.17) gives

$$\begin{aligned} V &= \iiint_{0\le y^l\le 1} J dy^1 dy^2 dy^3 = \frac{1}{24}\sum_{i_1,i_2,i_3=0}^{1}\sum_{k=1}^{3}\beta^k_{i_1i_2i_3} \\ &= \frac{1}{4}\sum_{i_1,i_2,i_3=0}^{1}\left(V^{pqv}_{i_1i_2i_3} + V^{pqu}_{i_1i_2i_3} + V^{pur}_{i_1i_2i_3}\right), \end{aligned} \tag{4.1}$$

and then (2.15) implies the above formula. □

This formula requires computation of only 10 volumes of tetrahedrons.

It is possible to see that (if volumes $V^{pqr}_{i_1i_2i_3}$, V^{uvw}_{000}, and V^{uvw}_{111} are positive) the volume of the ruled cell is equal to one-half of a sum of volumes of two dodecahedrons with planar faces, with the same corners $\mathbf{z}_{i_1i_2i_3}$, edges $\mathbf{p}_{i_1i_2i_3}$, $\mathbf{q}_{i_1i_2i_3}$, $\mathbf{r}_{i_1i_2i_3}$, and with different $\mathbf{u}$, $\mathbf{v}$, $\mathbf{w}$ (or faces) (see Figure 1.1(b)).

5. Conclusions. The conditions obtained allow the establishment of nondegeneracy of a general class of cells. If necessary conditions of positivity of the Jacobian in the whole cell (or necessary and sufficient conditions of positivity of the Jacobian on the edges of the cell) are not satisfied, the cell is degenerate. If sufficient conditions 1 or 2 hold, the cell is nondegenerate. Sufficient conditions 1 demand fewer computations than sufficient conditions 2.

In the case of cells satisfying necessary conditions but not satisfying sufficient conditions 2 there is nothing for it but to find numerically the minimum of the Jacobian in the cube using, for example, one of the obtained representations. If the minimum is positive, the cell is nondegenerate. Otherwise, it is degenerate.

The formula of a volume of a cell is simple and does not demand verification of numerous conditions and computations as in [4, 9].

Acknowledgment. I devote this work to the memory of my teacher, academician of the Russian Academy of Sciences, Anatolii F. Sidorov. I am thankful to him for the discussion of part of the results.

A MULTIGRID METHOD ENHANCED BY KRYLOV SUBSPACE ITERATION FOR DISCRETE HELMHOLTZ EQUATIONS[*]

HOWARD C. ELMAN[†], OLIVER G. ERNST[‡], AND DIANNE P. O'LEARY[§]

Abstract. Standard multigrid algorithms have proven ineffective for the solution of discretizations of Helmholtz equations. In this work we modify the standard algorithm by adding GMRES iterations at coarse levels and as an outer iteration. We demonstrate the algorithm's effectiveness through theoretical analysis of a model problem and experimental results. In particular, we show that the combined use of GMRES as a smoother and outer iteration produces an algorithm whose performance depends relatively mildly on wave number and is robust for normalized wave numbers as large as 200. For fixed wave numbers, it displays grid-independent convergence rates and has costs proportional to the number of unknowns.

Key words. Helmholtz equation, multigrid, Krylov subspace methods

1. Introduction.

Multigrid algorithms are effective for the numerical solution of many partial differential equations, providing a solution in time proportional to the number of unknowns. For some important classes of problems, however, standard multigrid algorithms have not been useful, and in this paper we focus on developing effective multigrid algorithms for one such class, the discrete Helmholtz equation.

Our main interest lies in solving exterior boundary value problems of the form

$$-\Delta u - k^2 u = f \qquad \text{on } \Omega \subset \mathbb{R}^d, \tag{1.1}$$

$$Bu = g \qquad \text{on } \Gamma \subset \partial\Omega, \tag{1.2}$$

$$\frac{\partial u}{\partial n} = Mu \qquad \text{on } \Gamma_\infty \subset \partial\Omega, \tag{1.3}$$

that arise in the modeling of time-harmonic acoustic or plane-polarized electromagnetic scattering by an obstacle. The boundary Γ represents the scattering obstacle, and the boundary operator B can be chosen so that a Dirichlet, Neumann, or Robin boundary condition is imposed. The original unbounded domain is truncated to the finite domain Ω by introducing the artificial boundary Γ_∞ on which the radiation boundary condition (1.3) approximates the outgoing Sommerfeld radiation condition. Depending on what type of radiation condition is chosen, M can be either a (local) differential operator or a global integral operator coupling all points on Γ_∞ (see [16]). The data for the problem are given by the right-hand side f and the boundary data

g. In the most common case, $f \equiv 0$ and $-g$ is the boundary data of an incident plane wave. The critical parameter is the wave number k, which is positive in the case of unattenuated wave propagation. Due to the radiation boundary condition, the solution of (1.1)–(1.3) is a complex-valued function $u : \Omega \to \mathbb{C}$.

Discretization of (1.1)–(1.3) by finite differences or finite elements leads to a linear system of equations

$$\boldsymbol{A}\boldsymbol{u} = \boldsymbol{f} \tag{1.4}$$

in which the coefficient matrix $\boldsymbol{A}$ is complex-symmetric, i.e., not Hermitian. Moreover, for large values of the wave number k, it becomes highly indefinite.

This indefiniteness has prevented multigrid methods from being applied to the discrete Helmholtz equation with the same success as these methods have enjoyed for symmetric positive-definite problems. Some proposed multilevel strategies for the Helmholtz equation impose restrictions on the coarse grid, requiring that these grids be sufficiently fine for the algorithm to be convergent [2, 6, 10, 31, 35]; such restrictions limit the utility of these techniques. It is also possible to precondition the indefinite Helmholtz problem with preconditioners for the leading (second order) term [4, 5, 17, 36], although the effectiveness of this approach is limited for problems with large wave numbers. Our aim in this work is to identify the difficulties arising in a standard multigrid iteration for the Helmholtz equation and to analyze and test techniques designed to address these difficulties. In particular, in section 2, we show there are difficulties with both of the main multigrid components, smoothing and coarse grid correction. Standard smoothers such as Jacobi or Gauß–Seidel relaxation become unstable for indefinite problems since there are always error components—usually the smooth ones—that are amplified by these smoothers. The difficulties with the coarse grid correction are usually attributed to the poor approximation of the Helmholtz operator on very coarse meshes, since such meshes cannot adequately resolve waves with wavelength $\lambda = 2\pi/k$ of which the solution primarily consists. We show, however, that although the coarse grid correction is inaccurate when coarse grid eigenvalues do not agree well with their fine-grid counterparts, coarse meshes can still yield useful information in a multigrid cycle.

Our approach for smoothing is to use standard damped Jacobi relaxation when it works reasonably well (on fine enough grids) and then to replace this with a Krylov subspace iteration when it fails as a smoother. Earlier works by Bank [2] and Brandt and Ta'asan [12] have employed relaxation on the normal equations in this context. Krylov subspace smoothing, principally using the conjugate gradient method, has been considered by a variety of authors [3, 8, 9, 30, 32].

For coarse grid correction, we identify the type and number of eigenvalues that are handled poorly during the correction, and we remedy the difficulty by introducing an acceleration for multigrid; that is, we use multigrid as a preconditioner for an outer Krylov subspace iteration. This approach has been used by many authors; see, e.g., [7, 22, 25, 26, 31, 35]. In some settings, where it is used for positive-definite systems [7, 22], the Krylov subspace method accelerates the multigrid computations, but multigrid alone is also rapidly convergent and improvements in performance are not dramatic. A significant point in the present study is that multigrid does a poor job of eliminating some modes from the error. As a result, it converges slowly and even diverges in some cases, and the outer Krylov subspace iteration is needed for the method to be robust. (This phenomenon is also observed for the convection-diffusion equation in [25, 26].) Any Krylov subspace method is an option for both the smoother and the outer iteration; we use GMRES [28].

A different approach for adapting multigrid to the Helmholtz equation, based on representing oscillatory error components on coarse grids as the product of an oscillatory Fourier mode and a smooth amplitude—or ray—function, has been developed by Brandt and Livshits [11]. The standard V-cycle is augmented by so-called ray cycles, in which the oscillatory error components are eliminated by approximating the associated ray functions in a multigrid fashion. This wave-ray methodology has also been combined by Lee et al. [23] with a first-order system least-squares formulation for the Helmholtz equation. Results in [11, 23] suggest that these techniques may be somewhat more efficient than the methods of this paper, but they are considerably more difficult to implement, and it is unclear whether they can be generalized to handle variable coefficient problems.

An outline of the paper is as follows. In section 2, we perform a model problem analysis, using a one-dimensional problem to identify the difficulties encountered by both smoothers and coarse grid correction, and supplementing these observations with an analysis of how dimensionality of the problem affects the computations. In section 3, we present the refined multigrid algorithms and test their performance on a set of two-dimensional benchmark problems on a square domain. In particular, we demonstrate the effectiveness of an automated stopping criterion for use with GMRES smoothing, and we show that the combined use of GMRES as a smoother and outer iteration produces an algorithm whose performance depends relatively mildly on wave number and is robust for wave numbers as large as 200. In section 4, we show the performance of the multigrid solver on an exterior scattering problem. Finally, in section 5, we draw some conclusions.

2. Model problem analysis.

Most of the deficiencies of standard multigrid methods for solving Helmholtz problems can be seen from a one-dimensional model problem. Therefore, we consider the Helmholtz equation on the unit interval $(0, 1)$ with homogeneous Dirichlet boundary conditions

$$-u'' - k^2 u = f, \quad u(0) = u(1) = 0. \tag{2.1}$$

This problem is guaranteed to be nonsingular only if k^2 is not an eigenvalue of the negative Laplacian, and we will assume here that this requirement holds. The problem is indefinite for $k^2 > \pi^2$, which is the smallest eigenvalue of the negative Laplacian.

Finite difference discretization of (2.1) on a uniform grid containing N interior points leads to a linear system of equations (1.4) with the $N \times N$ coefficient matrix $\boldsymbol{A} = \boldsymbol{A}^h = (1/h^2)\,\mathrm{tridiag}(-1, 2, -1) - k^2\boldsymbol{I}$, where $h = 1/(N + 1)$ denotes the mesh width and $\boldsymbol{I}$ denotes the identity matrix. Under the assumptions on k above, it is well known (see [29]) that for sufficiently fine discretizations, the discrete problems are also nonsingular. We also assume that all coarse grid problems are nonsingular.

The eigenvalues of $\boldsymbol{A}$ are

$$\lambda_j = \frac{2(1 - \cos j\pi h)}{h^2} - k^2 = \frac{4}{h^2}\sin^2\frac{j\pi h}{2} - k^2, \qquad j = 1, \dots, N, \tag{2.2}$$

and the eigenvectors are

$$\boldsymbol{v}_j = \sqrt{2h}\,[\sin ij\pi h]_{i=1}^{N}, \quad j = 1, \dots, N. \tag{2.3}$$

The choice of Dirichlet boundary conditions in (2.1) allows us to perform Fourier analysis using these analytic expressions for eigenvalues and eigenvectors. In experiments described in section 3, we will examine how our observations coincide with performance on problems with radiation conditions, which are nonsingular for all k [20]. Aspects of the algorithm that depend on the dimensionality of the problem will be considered at the end of this section.

2.1. Smoothing. For the smoothing operator, we consider damped Jacobi relaxation, defined by the stationary iteration

$$\boldsymbol{u}_{m+1} = \boldsymbol{u}_m + \omega \boldsymbol{D}^{-1}\boldsymbol{r}_m = \boldsymbol{u}_m + \omega \boldsymbol{D}^{-1}\boldsymbol{A}\boldsymbol{e}_m,$$

where $\boldsymbol{r}_m = \boldsymbol{f} - \boldsymbol{A}\boldsymbol{u}_m$ and $\boldsymbol{e}_m = \boldsymbol{A}^{-1}\boldsymbol{f} - \boldsymbol{u}_m$ denote the residual and error vectors at step m, respectively. $\boldsymbol{D} = (2/h^2 - k^2)\boldsymbol{I}$ denotes the matrix consisting of the diagonal of $\boldsymbol{A}$, and ω is the damping parameter. The associated error propagation matrix is $\boldsymbol{S}_\omega = \boldsymbol{I} - \omega\boldsymbol{D}^{-1}\boldsymbol{A}$, and the eigenstructure of this matrix governs the behavior of the error $\boldsymbol{e}_{m+1} = \boldsymbol{S}_\omega \boldsymbol{e}_m$. Since $\boldsymbol{D}$ is a multiple of the identity matrix, $\boldsymbol{S}_\omega$ is a polynomial in $\boldsymbol{A}$ and hence shares the same system of orthonormal eigenvectors (2.3). The eigenvalues of $\boldsymbol{S}_\omega$ are

$$\mu_j = 1 - \omega\left(1 - \frac{\cos j\pi h}{1 - \frac{1}{2}k^2h^2}\right), \quad j = 1, \dots, N. \tag{2.4}$$

Thus, the eigenvalue μ_j of $\boldsymbol{S}_\omega$ is the damping factor for the error component corresponding to the eigenvalue λ_j of $\boldsymbol{A}$.

We now consider the effects of damped Jacobi smoothing on three levels of grids: fine, coarse, and intermediate.

2.1.1. Fine grids. The fine-grid mesh size is determined by accuracy requirements on the discretization, and this allows us to make certain assumptions on the size of h versus k on the fine grid. Recall that the wavelength λ associated with a time-harmonic wave with wave number $k > 0$ is given by $\lambda = 2\pi/k$. The quantity

$$\frac{\lambda}{h} = \frac{2\pi}{kh} = \frac{2\pi}{k}(N+1)$$

is the number of mesh points per wavelength. We will enforce the condition

$$\lambda/h \geq 10 \quad \text{or, equivalently,} \quad kh \leq \pi/5, \tag{2.5}$$

which is a rule of thumb for approximability of second order discretizations commonly used in engineering computations [19]. We also note that, for reasons of stability, a bound on the quantity h^2k^3 is also required [20]; for high wave numbers this bound is more restrictive than the bound on kh.

As a consequence of (2.5), the quantity multiplying the smoothing parameter ω in (2.4) will vary between about $-1/4$ and $9/4$ for $j = 1, \dots, N$, and plain Jacobi smoothing ($\omega = 1$) results in a slight amplification of the most oscillatory modes as well as of the smoothest modes. One can adjust ω so that the most oscillatory mode is damped, and this is the case as long as $\omega < \omega_1 := (4 - 2k^2h^2)/(4 - k^2h^2)$. For $\boldsymbol{S}_\omega$ to be an effective smoother, ω is usually chosen to maximize damping for the oscillatory half of the spectrum. This leads to the choice

$$\omega_0 = \frac{2 - k^2h^2}{3 - k^2h^2}, \tag{2.6}$$

which is equal to the familiar optimal value of $2/3$ for the Laplacian [24, p. 11] when $k = 0$ and equals 0.61 when $\lambda/h = 10$. However, the smoothest mode is amplified for

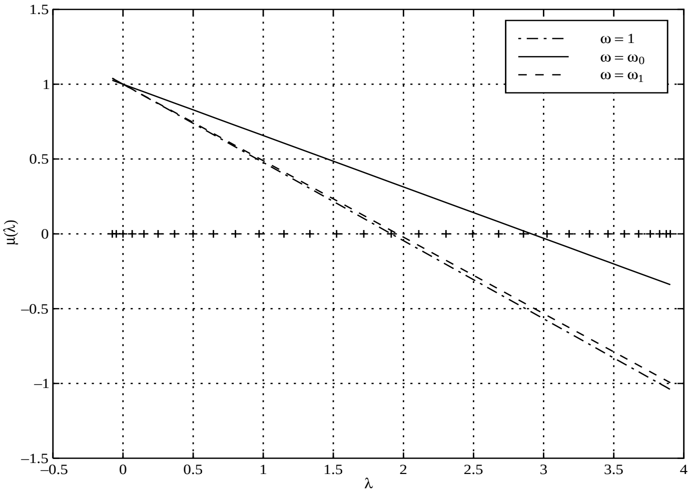

FIG. 2.1. *The damping factors for the damped Jacobi relaxation plotted against the eigenvalues of $\boldsymbol{A}$ (+) for $\omega = 1$, $\omega = \omega_0$, and $\omega = \omega_1$ ($N = 31$, $k = 3\pi$).*

any positive choice of ω when the discrete problem is indefinite, and this is the case for the discrete Helmholtz operator (1.4) when $k^2 > \pi^2$. As can be seen from (2.4), more smooth-mode eigenvalues of $\boldsymbol{S}_\omega$ become larger than one in magnitude as h is increased, thus making damped Jacobi—as well as other standard smoothers—increasingly more unstable as the mesh is coarsened.

Figure 2.1 shows the damping factors μ_j for each of the eigenvalues λ_j of $\boldsymbol{A}$ for wave number $k = 3\pi$ on a grid with $N = 31$. The maximal amplification occurs for the smoothest mode, corresponding to the leftmost eigenvalue of $\boldsymbol{A}$. When $\omega = \omega_0$ this amplification factor is approximately equal to

$$\rho = \rho(kh) = \frac{1}{1 - \frac{1}{3}k^2h^2}. \tag{2.7}$$

Figure 2.2 shows how ρ varies with kh. Limiting this largest amplification factor, say, to $\rho \le 1.1$, would lead to the mesh size restriction $kh \le 0.52$, somewhat stronger than (2.5). One also observes that, for $kh > \sqrt{6}$, this mode is once again damped.

In summary, the situation on the finest grids is similar to the positive-definite case, except for the small number of amplified smooth modes whose number and amplification factors increase as the mesh is coarsened.

2.1.2. Very coarse grids.

As the mesh is coarsened, the eigenvalues of $\boldsymbol{A}$ that correspond to the larger eigenvalues of the underlying differential operator disappear from the discrete problem, while the small ones—those with smooth eigenfunctions—remain. This means that, for a fixed k large enough for the differential problem to be indefinite, there is a coarsening level below which all eigenvalues are negative. For the model problem (2.1), this occurs for $kh > 2\cos(\pi h/2)$ for any fixed $k > \pi$. In this (negative-definite) case, the damped Jacobi iteration is convergent for $\omega \in (0, \omega_2)$, with

$$\omega_2 = \frac{2 - k^2h^2}{2\sin^2(\pi h/2) - \frac{1}{2}k^2h^2},$$

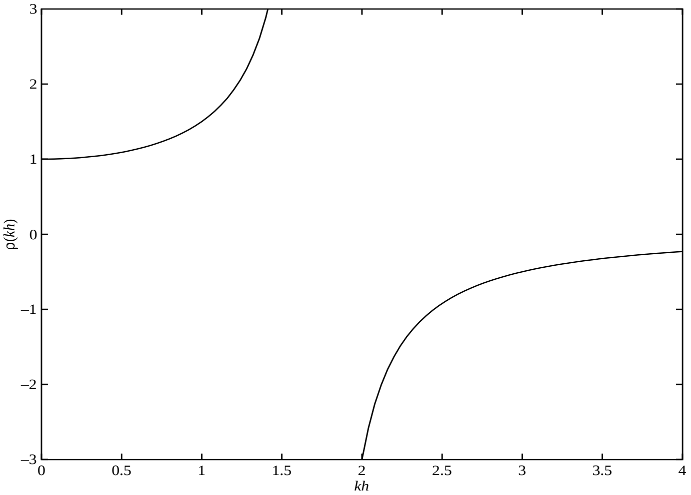

FIG. 2.2. *The variation of the damping/amplification factor of the smoothest mode as a function of kh for $\omega = \omega_0$.*

and the spectral radius of $\boldsymbol{S}_\omega$ is minimized for $\omega = 1$. This would permit the use of (undamped) Jacobi as a smoother on very coarse grids, but we shall not make use of this.

2.1.3. Intermediate grids. What remains is the difficult case: values of kh for which the problem is not yet negative definite but for which a large number of smooth modes are amplified by damped Jacobi relaxation. Jacobi smoothing and other standard smoothers are therefore no longer suitable, and it becomes necessary to use a different smoothing procedure. In [12] and [18] it was proposed to replace classical smoothers with the Kaczmarz iteration, which is Gauß–Seidel relaxation applied to the symmetric positive-definite system $\boldsymbol{A}\boldsymbol{A}^*\boldsymbol{v} = \boldsymbol{f}$ for the auxiliary variable $\boldsymbol{v}$ defined by $\boldsymbol{A}^*\boldsymbol{v} = \boldsymbol{u}$. This method has the advantage of not amplifying any modes, but it suffers from the drawback that the damping of the oscillatory modes is very weak. In the following section we propose using Krylov subspace methods such as GMRES for smoothing. These methods possess the advantage of reducing error components on both sides of the imaginary axis without resorting to the normal equations.

2.2. Coarse grid correction. The rationale behind coarse grid correction is that smooth error components can be well represented on coarser grids, and hence a sufficiently good approximation of the error can be obtained by approximating the fine-grid residual equation using the analogous system on a coarser mesh. This assumes both that the error consists mainly of smooth modes and that the solution of the coarse grid residual equation is close to its counterpart on the fine grid. In this section, we present an analysis of what goes wrong for the Helmholtz problem.

2.2.1. Amplification of certain modes. Assume the number of interior grid points on the fine grid is odd, and consider the next coarser mesh, with $n = (N-1)/2$ interior points. We identify $\mathbb{R}^N$ and $\mathbb{R}^n$, respectively, with the spaces of grid functions on these two meshes that vanish at the endpoints, and we indicate the mesh such vectors are associated with using the superscripts h and H. Let $\boldsymbol{e}^h = \boldsymbol{u} - \boldsymbol{u}^h$ denote the fine-grid error, let $\boldsymbol{r}^h = \boldsymbol{f} - \boldsymbol{A}^h\boldsymbol{u}^h$ denote the residual, and let $H = 2h$ denote the coarse mesh size. Let the coarse-to-fine transformation be given by the interpolation operator $\boldsymbol{I}_H^h : \mathbb{R}^n \to \mathbb{R}^N$,

$$\left[\boldsymbol{I}_H^h \boldsymbol{w}^H\right]_i := \begin{cases} \boldsymbol{w}_{i/2}^H, & i \text{ even}, \\ \frac{1}{2}[\boldsymbol{w}_{(i-1)/2}^H + \boldsymbol{w}_{(i+1)/2}^H], & i \text{ odd}, \end{cases} \qquad i = 1, \dots, N.$$

The following indication of what can go wrong with the (exact) coarse grid correction was given in [12]: consider a fine-grid error $\boldsymbol{e}^h = \boldsymbol{v}^h$ consisting of only the smoothest eigenvector $\boldsymbol{v}^h$ of $\boldsymbol{A}^h$ with associated eigenvalue λ^h. The fine-grid residual is thus given by $\boldsymbol{r}^h = \boldsymbol{A}^h \boldsymbol{e}^h = \lambda^h \boldsymbol{v}^h$, and, since we are assuming that $\boldsymbol{v}^h$ is smooth, its restriction $\hat{\boldsymbol{r}}^H := \boldsymbol{I}_h^H \boldsymbol{r}^h = \lambda^h \boldsymbol{I}_h^H \boldsymbol{v}^h$ to the coarse grid will again be close to an eigenvector of the coarse grid operator $\boldsymbol{A}^H$ but with respect to a slightly different eigenvalue λ^H. The coarse grid version of the correction is

$$\boldsymbol{e}^H = (\boldsymbol{A}^H)^{-1} \hat{\boldsymbol{r}}^H = \lambda^h (\boldsymbol{A}^H)^{-1} \boldsymbol{I}_h^H \boldsymbol{v}^h \approx \frac{\lambda^h}{\lambda^H} \boldsymbol{I}_h^H \boldsymbol{v}^h.$$

Hence the error on the fine grid after the correction is

$$\boldsymbol{e}^h - \boldsymbol{I}_H^h \boldsymbol{e}^H \approx \boldsymbol{v}^h - \frac{\lambda^h}{\lambda^H} \boldsymbol{I}_H^h \boldsymbol{I}_h^H \boldsymbol{v}^h = \left(1 - \frac{\lambda^h}{\lambda^H}\right) \boldsymbol{v}^h, \tag{2.8}$$

where we have assumed that the smooth mode $\boldsymbol{v}^h$ is invariant under restriction followed by interpolation. This tells us that, under the assumption that the restrictions of smooth eigenvectors are again eigenvectors of $\boldsymbol{A}^H$, the quality of the correction depends on the ratio λ^h/λ^H. If the two are equal, then the correction is perfect, but if the relative error is large, the correction can be arbitrarily bad. This occurs whenever one of λ^h, λ^H is close to the origin and the other is not. Moreover, if λ^h and λ^H have opposite signs, then the correction is in the wrong direction.

We now go beyond existing analysis and examine which eigenvalues are problematic in this sense for finite differences; a similar analysis can also be performed for linear finite elements. Consider the coarse grid eigenfunctions $\boldsymbol{v}_j^H = [\sin ij\pi H]_{j=1}^n$. To understand the effects of interpolation of these grid functions to the fine grid, we must examine both the first n fine-grid eigenfunctions $\{\boldsymbol{v}_j^h\}_{j=1}^n$ and their *complementary modes* $\{\boldsymbol{v}_{N+1-j}^h\}_{j=1}^n$; these are related by $\left[\boldsymbol{v}_{N+1-j}^h\right]_i = (-1)^{i+1} \left[\boldsymbol{v}_j^h\right]_i$. As is easily verified, there holds [13]

$$\boldsymbol{I}_H^h \boldsymbol{v}_j^H = c_j^2 \boldsymbol{v}_j^h - s_j^2 \boldsymbol{v}_{N+1-j}^h, \qquad j = 1, \dots, n, \tag{2.9}$$

with $c_j := \cos j\pi h/2$ and $s_j := \sin j\pi h/2$, $j = 1, \dots, N$.

If full weighting is used for the restriction operator $\boldsymbol{I}_h^H : \mathbb{R}^N \to \mathbb{R}^n$, we have componentwise

$$\left[\boldsymbol{I}_h^H \boldsymbol{u}^h\right]_i := \frac{1}{4} \left(\left[\boldsymbol{u}^h\right]_{2i-1} + 2 \left[\boldsymbol{u}^h\right]_{2i} + \left[\boldsymbol{u}^h\right]_{2i+1} \right), \qquad i = 1, \dots, n,$$

and the relation $\boldsymbol{I}_H^h = 2 \left(\boldsymbol{I}_h^H\right)^\top$. The following mapping properties are easily established:

$$\boldsymbol{I}_h^H \boldsymbol{v}_j^h = \begin{cases} c_j^2 \boldsymbol{v}_j^H, & j = 1, \dots, n, \\ 0, & j = n+1, \\ -c_j^2 \boldsymbol{v}_{N+1-j}^H, & j = n+2, \dots, N, \end{cases} \tag{2.10}$$

with c_j and s_j as defined above.

If $\boldsymbol{A}^H$ denotes the coarse grid discretization matrix, then the corrected iterate $\tilde{\boldsymbol{u}}^h := \boldsymbol{u}^h + \boldsymbol{I}_H^h(\boldsymbol{A}^H)^{-1}\boldsymbol{r}^H$ possesses the error propagation operator $\boldsymbol{C} := \boldsymbol{I} - \boldsymbol{I}_H^h(\boldsymbol{A}^H)^{-1}\boldsymbol{I}_h^H\boldsymbol{A}^h$. Denoting the eigenvalues of $\boldsymbol{A}^h$ and $\boldsymbol{A}^H$ by $\{\lambda_j^h\}_{j=1}^N$ and $\{\lambda_j^H\}_{j=1}^n$, respectively, we may summarize the action of $\boldsymbol{C}$ on the eigenvectors using (2.9) and (2.10) as follows.

THEOREM 2.1. *The image of the fine-grid eigenfunctions* $\{\boldsymbol{v}_h^h\}_{j=1}^N$ *under the error propagation operator* $\boldsymbol{C}$ *of the exact coarse grid correction is given by*

$$\boldsymbol{C}\boldsymbol{v}_j^h = \begin{cases} \left(1 - c_j^4\frac{\lambda_j^h}{\lambda_j^H}\right)\boldsymbol{v}_j^h + s_j^2c_j^2\frac{\lambda_j^h}{\lambda_j^H}\boldsymbol{v}_{N+1-j}^h, & j = 1,\dots,n, \\ \boldsymbol{v}_{n+1}^h, & j = n+1, \\ \left(1 - c_j^4\frac{\lambda_j^h}{\lambda_{N+1-j}^H}\right)\boldsymbol{v}_j^h + s_j^2c_j^2\frac{\lambda_j^h}{\lambda_{N+1-j}^H}\boldsymbol{v}_{N+1-j}^h, & j = n+2,\dots,N. \end{cases} \tag{2.11}$$

As a consequence, the two-dimensional spaces spanned by a smooth mode and its complementary mode are invariant under $\boldsymbol{C}$: $\boldsymbol{C}[\boldsymbol{v}_j^h, \boldsymbol{v}_{N+1-j}^h] = [\boldsymbol{v}_j^h, \boldsymbol{v}_{N+1-j}^h]\boldsymbol{C}_j$ with

$$\boldsymbol{C}_j := \begin{bmatrix} 1 - c_j^4\frac{\lambda_j^h}{\lambda_j^H} & c_j^2s_j^2\frac{\lambda_{N+1-j}^h}{\lambda_j^H} \\ s_j^2c_j^2\frac{\lambda_j^h}{\lambda_j^H} & 1 - s_j^4\frac{\lambda_{N+1-j}^h}{\lambda_j^H} \end{bmatrix}, \quad j = 1,\dots,n. \tag{2.12}$$

The following result shows the dependence of the matrices $\boldsymbol{C}_j$ on kh.

THEOREM 2.2. *Using the notation defined above, there holds*

$$\boldsymbol{C}_j = \begin{bmatrix} s_j^2\left(1 - \frac{k^2c_j^2}{\lambda_j^H}\right) & c_j^2\left(1 + \frac{k^2c_j^2}{\lambda_j^H}\right) \\ s_j^2\left(1 + \frac{k^2s_j^2}{\lambda_j^H}\right) & c_j^2\left(1 - \frac{k^2s_j^2}{\lambda_j^H}\right) \end{bmatrix}, \qquad j = 1,\dots,n. \tag{2.13}$$

Moreover,

$$\lim_{kh\to 0}\boldsymbol{C}_j = \begin{bmatrix} s_j^2 & c_j^2 \\ s_j^2 & c_j^2 \end{bmatrix}, \quad \lim_{kh\to\infty}\boldsymbol{C}_j = \begin{bmatrix} s_j^2(1+c_j^2) & s_j^2c_j^2 \\ s_j^2c_j^2 & c_j^2(1+s_j^2) \end{bmatrix}, \qquad j = 1,\dots,n. \tag{2.14}$$

Proof. Both (2.13) and (2.14) are simple consequences of (2.12) and the representation (2.2) of the eigenvalues λ_j^h. □

Application of the error propagation operator to a smooth mode $\boldsymbol{v}_j^h$ gives

$$\boldsymbol{C}\boldsymbol{v}_j^h = \boldsymbol{C}[\boldsymbol{v}_j^h, \boldsymbol{v}_{N+1-j}^h]\begin{pmatrix} 1 \\ 0 \end{pmatrix} = [\boldsymbol{v}_j^h, \boldsymbol{v}_{N+1-j}^h]\boldsymbol{C}_j\begin{pmatrix} 1 \\ 0 \end{pmatrix}.$$

If the entries of the first column of $\boldsymbol{C}_j$ are small, then this mode is damped by the coarse grid correction. However, if the $(1,1)$-entry is large, then this mode is amplified; and if the $(2,1)$-entry is large (somewhat less likely), then the smooth mode is corrupted by its complementary mode. As seen from (2.13), these difficulties occur whenever λ_j^H is small in magnitude. From the limits (2.14), it is evident that no such problems arise in the symmetric positive-definite case (a fact that is well known), but they also do not occur when kh is very large, i.e., when the coarse grid Helmholtz operator is negative definite. These observations can be extended by returning to (2.8) and using (2.2), wherein it holds that

$$\frac{\lambda_j^h}{\lambda_j^H} = \frac{4s_j^2/h^2 - k^2}{4s_j^2c_j^2/h^2 - k^2} = 1 + \frac{s_j^4}{s_j^2c_j^2 - (kh/2)^2}. \tag{2.15}$$

That is, the coarse grid correction strongly damps smooth error modes for either very small or very large values of kh, but it may fail to do so in the intermediate range where $s_j^2c_j^2 \approx (kh/2)^2$ for some index j associated with a smooth mode.

We also note that in the limit $k = 0$ the eigenvalues of $\boldsymbol{C}_j$ are 0 and 1, so that $\boldsymbol{C}_j$ is a projection, and in this case the projection is orthogonal with respect to the inner product induced by the symmetric and positive-definite operator $\boldsymbol{A}^h$. The projection property is lost for $k > 0$, since the coarse grid operator as we have defined it fails to satisfy the Galerkin condition $\boldsymbol{A}^H = \boldsymbol{I}_h^H\boldsymbol{A}^h\boldsymbol{I}_H^h$. (The Galerkin condition is, however, satisfied, e.g., for finite element discretizations with interpolation by inclusion.) Moreover, regardless of the type of discretization, the term $\boldsymbol{A}^h$-orthogonality ceases to makes sense once k is sufficiently large that $\boldsymbol{A}^h$ is indefinite.

2.2.2. Number of sign changes. In this section, we determine the number of eigenvalues that undergo a sign change during the coarsening process. In light of the discussion above, this number gives an indication of the number of smooth modes that are not eliminated from the error by coarse grid correction. Since these modes are not properly handled by the multigrid algorithm, another construction is needed to reduce the error associated with them. In the next section, we will introduce an *outer* Krylov subspace iteration designed for this task.

This is the only aspect of the algorithm that significantly depends on the dimensionality of the problem. Thus, here we are considering the Helmholtz equation (1.1) on the d-dimensional unit cube $(0,1)^d$, $d = 1$, 2 or 3, with homogeneous Dirichlet boundary conditions. We consider standard finite differences (second order three-point, five-point, or seven-point discretizations of the Laplacian in one, two, or three dimensions, respectively), as well as the class of low order finite elements consisting of linear, bilinear, or trilinear elements.

We first state the issue more precisely using finite differences. In d dimensions, the eigenvalues of the discrete operator on a grid with mesh size h and N grid points in each direction are

$$\lambda_{\mathcal{I}}^h = \sum_{i=1}^{d} \frac{4}{h^2}\left(\sin^2\frac{j_i\pi h}{2}\right) - k^2, \quad \mathcal{I} = \{j_1, \dots, j_d\}, \quad j_i = 1, \dots N. \tag{2.16}$$

For any fixed multi-index $\mathcal{I}$, this eigenvalue is a well-defined function of h that converges to the corresponding eigenvalue of the differential operator as $h \to 0$. Our concern is the indices for which this function changes sign, for these are the troublesome eigenvalues that are not treated correctly by some coarse grid correction. As the mesh is coarsened, the oscillatory modes ($j_i > N/2$ for some i) are not represented on the next coarser mesh, but the smooth-mode eigenvalues $\{\lambda_{\mathcal{I}}^H\}$ are slightly shifted to the left with respect to their fine-grid counterparts $\{\lambda_{\mathcal{I}}^h\}$, and some of these eigenvalues change sign at some point during the coarsening process.

The following theorem gives a bound, as a function of k, on the maximal number eigenvalue sign changes occurring on all grids.

Theorem 2.3. *For finite difference discretization of the Helmholtz equation with Dirichlet boundary conditions on the unit cube in d dimensions ($d = 1, 2, 3$), the* *number of eigenvalues that undergo a change in sign during the multigrid coarsening process is bounded above by*

$$\begin{cases} k\left(\frac{1}{2}-\frac{1}{\pi}\right) \approx 0.18\,k, & d=1, \\ k^2\left(\frac{1}{8}-\frac{1}{4\pi}\right) \approx 0.045\,k^2, & d=2, \\ k^3\left(\frac{1}{24\sqrt{3}}-\frac{1}{6\pi^2}\right) \approx 0.0072\,k^3, & d=3. \end{cases} \tag{2.17}$$

For the finite element discretizations, the number of sign changes is bounded above by

$$\begin{cases} k\left(\frac{1}{\pi}-\frac{1}{\sqrt{12}}\right) \approx .030\,k, & d=1, \\ k^2\left(\frac{1}{4\pi}-\frac{1}{24}\right) \approx .038\,k^2, & d=2, \\ k^3\left(\frac{1}{6\pi^2}-\frac{1}{216}\right) \approx .012\,k^3, & d=3. \end{cases} \tag{2.18}$$

Proof. For finite differences, let η^-_{fine} denote the number of negative eigenvalues on some given fine grid, and let η^-_{lim} denote the number of negative eigenvalues of the continuous Helmholtz operator. Because eigenvalues (2.16) with the same index $\mathcal{I}$ shift from right to left with grid coarsening, it follows that

$$\eta^-_{\text{lim}} \le \eta^-_{\text{fine}}\,; \tag{2.19}$$

this is an equality for all fine enough grids, as the discrete eigenvalues tend to the continuous ones. To identify η^-_{lim}, consider the continuous eigenvalues

$$\begin{aligned} \lambda_\ell &= \pi^2\ell^2 - k^2, & \ell &\in \mathbb{N} & (d&=1), \\ \lambda_{\ell,m} &= \pi^2(\ell^2+m^2) - k^2, & \ell,m &\in \mathbb{N} & (d&=2), \\ \lambda_{\ell,m,n} &= \pi^2(\ell^2+m^2+n^2) - k^2, & \ell,m,n &\in \mathbb{N} & (d&=3). \end{aligned}$$

It is convenient to view the indices of these eigenvalues as lying in the positive orthant of a d-dimensional coordinate system. The negative eigenvalues are contained in the intersection of this orthant with a d-dimensional sphere of radius k/π centered at the origin. Let $\mathcal{N}$ denote this intersection, and let $\hat{\mathcal{N}}$ denote the d-dimensional cube enclosing $\mathcal{N}$. The number of indices in $\hat{\mathcal{N}}$ is $\lfloor k/\pi \rfloor^d$, and the number in $\mathcal{N}$ is $\rho\lfloor k/\pi \rfloor^d$, where

$$\rho = \begin{cases} \left(\frac{k}{\pi}\right) / \left(\frac{k}{\pi}\right) = 1, & d=1, \\ \frac{1}{4}\pi\left(\frac{k}{\pi}\right)^2 / \left(\frac{k}{\pi}\right)^2 = \frac{\pi}{4}, & d=2, \\ \frac{1}{8}\cdot\frac{4}{3}\pi\left(\frac{k}{\pi}\right)^3 / \left(\frac{k}{\pi}\right)^3 = \frac{\pi}{6}, & d=3 \end{cases}$$

is the ratio of the volume of $\mathcal{N}$ to that of $\hat{\mathcal{N}}$. It follows that

$$\eta^-_{\text{lim}} = \begin{cases} k\cdot\frac{1}{\pi}, & d=1, \\ k^2\cdot\frac{1}{4\pi}, & d=2, \\ k^3\cdot\frac{1}{6\pi^2}, & d=3. \end{cases} \tag{2.20}$$

Now consider the eigenvalues of discrete problems. Again, since sign changes occur from right to left with coarsening, the mesh size that yields the maximum number of negative eigenvalues is the smallest value h for which the discrete operator is negative semidefinite. With N mesh points in each coordinate direction, this is equivalent to

$$d \sin^2 \frac{N\pi h}{2} = \left(\frac{kh}{2}\right)^2, \qquad d = 1, 2, 3.$$

Thus, $h = 2\sqrt{d}/k$, and

$$\eta^-_{\max} = \left(\frac{k}{2\sqrt{d}}\right)^d = \begin{cases} k \cdot \frac{1}{2}, & d = 1, \\ k^2 \cdot \frac{1}{8}, & d = 2, \\ k^3 \cdot \frac{1}{24\sqrt{3}}, & d = 3. \end{cases}$$

Combining (2.19) with the fact that $\eta^-_{\text{fine}} \le \eta^-_{\max}$, it follows that

$$\eta^-_{\max} - \eta^-_{\text{fine}} \le \eta^-_{\max} - \eta^-_{\lim}.$$

The latter difference, shown in (2.17), is then a bound on number of sign changes.

For finite elements, we are concerned with the eigenvalues of the coefficient matrix $\boldsymbol{A}^h$, but it is also convenient to consider the associated operator $\mathcal{A}^h$ defined on the finite element space V^h. The eigenvalues of $\mathcal{A}^h$ are those of the generalized matrix eigenvalue problem

$$\boldsymbol{A}^h \boldsymbol{u}^h = \sigma^h \boldsymbol{M}^h \boldsymbol{u}^h, \tag{2.21}$$

where $\boldsymbol{M}^h$ is the mass matrix. These eigenvalues tend to those of the continuous operator. Moreover, since V^H is a subspace of V^h, the Courant–Fischer min-max theorem implies that eigenvalues σ^h and σ^H with a common index shift to the right with coarsening (or to the left with refinement). In addition, since $\boldsymbol{M}^h$ is symmetric positive definite, Sylvester's inertia theorem implies that the number of negative eigenvalues of $\boldsymbol{A}^h$ is the same as that of (2.21). It follows from these observations that the maximal number of negative eigenvalues of $\boldsymbol{A}^h$ is bounded above by the fine-grid limit $\eta^-_{\lim}$.

This is also a bound on the number of sign changes. It can be improved by examining the eigenvalues of $\boldsymbol{A}^h$ more closely. Using the tensor product form of the operators, we can express these eigenvalues as

$$\lambda^h_{j_1,j_2,j_3} = \kappa_{j_1}\mu_{j_2}\mu_{j_3} + \mu_{j_1}\kappa_{j_2}\mu_{j_3} + \mu_{j_1}\mu_{j_2}\kappa_{j_3} - k^2\mu_{j_1}\mu_{j_2}\mu_{j_3}, \tag{2.22}$$

where $h = 1/(N+1)$, the indices j_1, j_2, j_3 run from 1 to N, and

$$\kappa_j = \frac{1}{h}(2 - 2\cos j\pi h), \qquad \mu_j = \frac{h}{6}(4 + 2\cos j\pi h). \tag{2.23}$$

Consider the requirement $\lambda^h_{j_1,j_2,j_3} \le 0$ for all indices j_1, j_2, j_3, so that $\boldsymbol{A}^h$ is negative semidefinite. This is equivalent to

$$\frac{\kappa_{j_1}}{\mu_{j_1}} + \frac{\kappa_{j_2}}{\mu_{j_2}} + \frac{\kappa_{j_3}}{\mu_{j_3}} \le k^2.$$

Since the expression κ_j/μ_j is monotonically increasing with j, the largest eigenvalue in d dimensions equals zero if

$$k^2 = d \cdot \frac{\kappa_N}{\mu_N} = d \cdot \frac{6}{h^2}\frac{1 - \cos N\pi h}{2 + \cos N\pi h} \approx d \cdot \frac{12}{h^2},$$

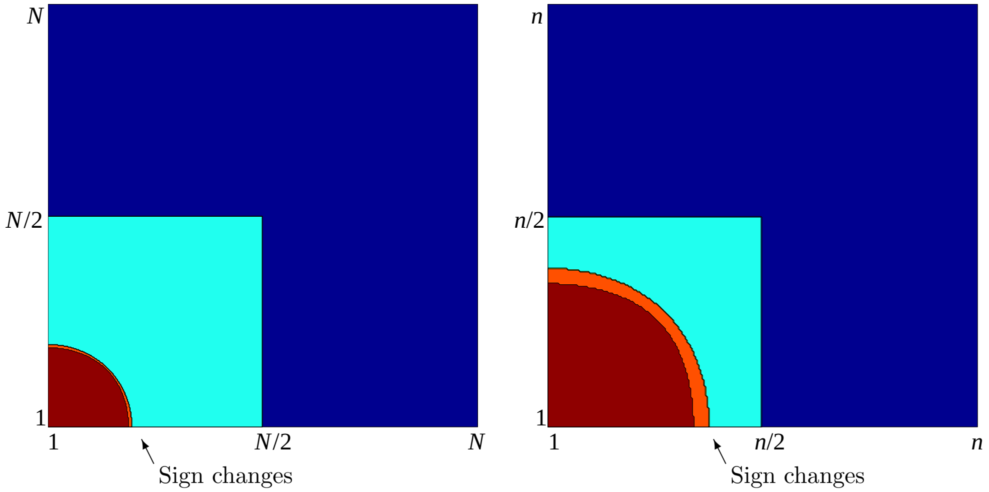

Fig. 2.3. *Indices of eigenvalues undergoing a sign change during coarsening of an $N \times N$ finite element grid with $kh = \pi/5$, $kH = 2\pi/5$ (left) and during further coarsening of the next coarser ($n \times n$) grid with $kh = 2\pi/5$, $kH = 4\pi/5$ (right).*

i.e., $h = \sqrt{12d}/k$. For this value of h, there are $\eta^-_{\max} = (k/\sqrt{12d})^d$ negative eigenvalues, and, on coarser meshes, the problem remains negative definite. Consequently, none of these $\eta^-_{\max}$ quantities undergo a sign change, giving the bound $\eta^-_{\lim} - \eta^-_{\max}$ of (2.18). □

Figure 2.3 gives an idea of how sign changes are distributed for bilinear elements in two dimensions. At levels where the changes take place, the indices of the eigenvalues lie in a curved strip in the two-dimensional plane of indices. Typically, there is one level where the majority of sign changes occur. As k is increased and h decreased correspondingly via (2.5), the shape of these strips remains fixed, but the number of indices contained in them grows like $O(h^{-d}) = O(k^d)$. (Note, however, that (2.5) is not needed for the analysis.) The behavior for finite differences is similar.

The remedy suggested in [12] for these difficulties consists of maintaining an approximation of the eigenspace V^H of the troublesome eigenvalues. A projection scheme is then used to orthogonalize the coarse grid correction against V^H, and the coefficients of the solution for this problematic space are obtained separately. Since it involves an explicit separate treatment of the problematic modes, this approach is restricted to cases where there are only very a small number of these.

Finally, we note that although the closed forms for the eigenvalues studied here are restricted to rectangular domains, we expect the trends displayed to be general. For example, the direction of shifts of eigenvalues, derived from the form of the matrices for finite differences and from the Courant–Fischer theorem for bilinear elements, will be the same for general domains. This assertion is also largely borne out by experiments on a nonsquare domain shown in section 4.

3. Incorporation of Krylov subspace methods. In view of the observations about smoothing in section 2.1 and coarse grid correction in section 2.2, we modify the standard multigrid method in the following way to treat Helmholtz problems:

- To obtain smoothers that are stable and still provide a strong reduction of oscillatory components, we use Krylov subspace iteration such as GMRES as smoothers on intermediate grids.

- To handle modes with eigenvalues that are either close to the origin on all grids—and hence belong to modes not sufficiently damped on any grid—or that cross the imaginary axis and are thus treated incorrectly by some coarse grid corrections, we add an outer iteration; that is, we use multigrid as a preconditioner for a GMRES iteration for (1.4).

We will demonstrate the effectiveness of this approach with a series of numerical experiments. In all tests the outer iteration is run until the stopping criterion

$$\|\boldsymbol{r}_m\|/\|\boldsymbol{r}_0\| < 10^{-6}$$

is satisfied, where $\boldsymbol{r}_m = \boldsymbol{f} - \boldsymbol{A}\boldsymbol{u}_m$ is the residual of the mth GMRES iterate and the norm is the vector Euclidean norm. The multigrid algorithm is a V-cycle in all cases; the smoothing schedules are specified below.

3.1. GMRES accelerated multigrid.

We begin with an experiment for the one-dimensional Helmholtz equation on the unit interval with forcing term $f = 0$ and inhomogeneous Dirichlet boundary condition $u(0) = 1$ on the left and Sommerfeld condition on the right. We discretize using linear finite elements on a uniform grid, where the discrete right-hand side $\boldsymbol{f}$ is determined by the boundary conditions. We apply both a V-cycle multigrid algorithm and a GMRES iteration preconditioned by the same V-cycle multigrid method. The smoother in these tests is one step of damped Jacobi iteration for both presmoothing and postsmoothing, using $\omega = (12 - 4k^2h^2)/(18 - 3k^2h^2)$, the analogue of (2.6) for finite element discretization that provides maximal damping of oscillatory modes. The initial guess was a vector with normally distributed entries of mean zero and variance one, generated by the Matlab function `randn`.

Table 3.1 shows the iteration counts for increasing numbers of levels beginning with fine grids containing $N = 256$, 512, and 1024 elements, for wave numbers $k = 4\pi$ and $k = 8\pi$, which correspond to two and four wavelengths in the unit interval, respectively.

Table 3.1

Iteration counts for multigrid V-cycle as an iteration and as a preconditioner for GMRES applied to the one-dimensional model Helmholtz problem with damped Jacobi smoothing. A dash denotes divergence of the iteration.

	256 elements				512 elements				1024 elements			
	$k = 4\pi$		$k = 8\pi$		$k = 4\pi$		$k = 8\pi$		$k = 4\pi$		$k = 8\pi$	
# levels	MG	GMRS	MG	GMRS	MG	GMRS	MG	GMRS	MG	GMRS	MG	GMRS
2	7	3	7	4	7	3	7	3	7	3	7	3
3	7	5	7	6	7	5	7	5	7	5	7	5
4	7	6	9	7	7	5	7	6	7	5	7	5
5	7	6	76	10	7	6	8	7	7	5	7	6
6	16	8	–	13	7	6	69	10	7	6	7	7
7	–	9	–	16	13	8	–	13	7	6	50	10
8	–	11	–	16	–	9	–	16	9	8	–	12
9	–	11	–	17	–	11	–	16	–	9	–	16
10					–	11	–	17	–	11	–	16

We observe first that both methods display typical h-independent multigrid behavior until the mesh size on the coarsest grid reaches $kh \approx \pi/2$. (With 256 elements, this occurs for $k = 4\pi$ with 6 levels, coarsest mesh $h = 1/8$, and for $k = 8\pi$ with 5 levels, coarsest $h = 1/16$.) At this point both methods require noticeably more iterations, the increase being much more pronounced in the stand-alone multigrid case.

Table 3.2

Iteration counts for the two-dimensional problem for fine grids with $k = 4\pi$ and $k = 8\pi$ on 128×128 and 256×256 meshes. A dash denotes divergence of the iteration.

	128 × 128 elements				256 × 256 elements				512 × 512 elements			
	$k = 4\pi$		$k = 8\pi$		$k = 4\pi$		$k = 8\pi$		$k = 4\pi$		$k = 8\pi$	
# levels	MG	GMRS	MG	GMRS	MG	GMRS	MG	GMRS	MG	GMRS	MG	GMRS
2	12	7	12	7	12	7	12	7	12	6	12	6
3	12	7	12	7	12	7	12	7	12	6	12	6
4	12	7	22	11	12	7	12	8	12	6	12	7
5	13	8	–	33	12	7	21	11	12	7	21	7
6	–	15	–	64	12	8	–	34	12	7	–	11
7	–	19	–	64	–	15	–	64	12	8	–	33
8					–	19	–	63	–	15	–	63

When yet coarser levels are added, multigrid diverges, whereas the multigrid preconditioned GMRES method again settles down to an h-independent iteration count, which does, however, increase with k.

Table 3.2 shows the same iteration counts for the two-dimensional Helmholtz problem on the unit square with a second order absorbing boundary condition (see [1, 14]) imposed on all four sides and discretized using bilinear quadrilateral finite elements on a uniform mesh. Since the problem cannot be forced with a radiation condition on the entire boundary, in this and the remaining examples of section 3, an inhomogeneity was imposed by choosing a discrete right-hand side consisting of a random vector with mean zero and variance one, generated by `randn`. The initial guess was identically zero. (Trends for problems with smooth right-hand sides were the same.) In addition, for all two-dimensional problems, we use two Jacobi pre- and postsmoothing steps whenever Jacobi smoothing is used. The damping parameter ω is chosen to maximize damping of the oscillatory modes. For the grids on which we use damped Jacobi smoothing this optimum value was determined to be $\omega = 8/9$. The results show the same qualitative behavior as for the one-dimensional problem, in that multigrid begins to diverge as coarse levels are added while the GMRES-accelerated iteration converges in an h-independent number of iterations growing with k, although with a larger number of iterations than in the one-dimensional case.

A natural question is whether corrections computed on the very coarse grids, in particular those with meshes containing fewer than ten points per wavelength ($2\pi/k < 10$), make any contribution at all towards reducing the error. We investigate this in a sequence of experiments with GMRES accelerated multigrid with $k = 8\pi$, where we omit all calculations—be they smoothing or direct solves—on an increasing number of coarse levels.

The results, for a one-dimensional example with 512 elements and a two-dimensional example with 256^2 elements are in Table 3.3. The leftmost entries of the table show the iteration counts when no coarse grid information is used, i.e., for GMRES with preconditioning by two steps of Jacobi iteration. Reading from left to right, subsequent entries show the counts when smoothings on a succession of coarser grids are included, but no computations are done at grid levels below that of the coarsest grid. For the rightmost entry, a direct solve was done on the coarsest mesh; this is a full V-cycle computation. The results in two dimensions indicate improved performance for coarse grids with mesh width less than 1/16, which corresponds to four points per wave; performance degrades, but not dramatically so, for coarser meshes. For the one-dimensional test, the coarse grid at level two, which has only two points per wavelength, still accelerates the outer iteration. These results also show that multigrid

Table 3.3

Iteration counts when varying amount of course grid information is used. Table entries further to the right result from using more multigrid levels than those to the left. Test problems are $k = 8\pi$ with 512 elements in the one-dimensional example and 256^2 elements in the two-dimensional example.

		No V-Cycle ↓							Full V-cycle ↓
1D	h^{-1} for coarsest grid	512	256	128	64	32	16	8	4
	GMRES iterations	152	78	42	25	18	17	16	16
2D	h^{-1} for coarsest grid	256	128	64	32	16	8	4	2
	GMRES iterations	387	173	89	57	52	64	63	63

is dramatically superior to simple Jacobi-preconditioned GMRES.

These results show that, although multigrid by itself may diverge, it is nevertheless a powerful enough preconditioner for GMRES to converge in an h-independent number of steps. Two additional questions are whether replacing the unstable Jacobi smoother with a Krylov subspace iteration leads to a convergent multigrid method and how sensitive convergence behavior is as a function of the wave number k. We address the former in the following section.

3.2. GMRES as a smoother.

In this section we replace the unstable Jacobi smoother with GMRES smoothing. We use GMRES on all levels j where $kh_j \geq 1/2$ and continue using damped Jacobi relaxation when $kh_j < 1/2$. This choice is motivated by the discussion at the end of section 2.1.1, and it ensures that the largest amplification factor for the Jacobi smoother does not become too large. The results of section 2.1.2 show that we could switch back to Jacobi smoothing for very coarse meshes, but we have not explored this option.

3.2.1. Nonconstant preconditioners.

This introduces a slight complication with regard to the *outer* GMRES iteration when multigrid is used as a preconditioner. The inner GMRES smoothing steps are not linear iterations, and therefore a different preconditioner is being applied at every step of the outer iteration. A variant of GMRES able to accommodate a changing preconditioner (known as flexible GMRES (FGMRES)) is due to Saad [27]. It requires the following minor modification of the standard (right preconditioned) GMRES algorithm: if the orthonormal basis of the $(m+1)$st Krylov space $\mathcal{K}_{m+1}(\boldsymbol{A}\boldsymbol{M}^{-1}, \boldsymbol{r}_0)$ in the case of a constant preconditioner $\boldsymbol{M}$ is denoted by $\boldsymbol{V}_{m+1} = [\boldsymbol{v}_1, \dots, \boldsymbol{v}_{m+1}]$, then the Arnoldi relation $\boldsymbol{A}\boldsymbol{M}^{-1}\boldsymbol{V}_m = \boldsymbol{V}_{m+1}\tilde{\boldsymbol{H}}_m$ holds with an $(m+1) \times m$ upper Hessenberg matrix $\tilde{\boldsymbol{H}}_m$. If the preconditioning and matrix multiplication step

$$\boldsymbol{z}_m := \boldsymbol{M}^{-1}\boldsymbol{v}_m, \qquad \boldsymbol{w} := \boldsymbol{A}\boldsymbol{z}_m,$$

is performed with a changing preconditioner $\boldsymbol{M} = \boldsymbol{M}_m$, this results in the modified Arnoldi relation

$$\boldsymbol{A}\boldsymbol{Z}_m = \boldsymbol{V}_{m+1}\tilde{\boldsymbol{H}}_m,$$

where $\boldsymbol{Z}_m = [\boldsymbol{z}_1, \dots, \boldsymbol{z}_m]$. The residual vector is now minimized over the space $\operatorname{span}\{\boldsymbol{z}_1, \dots, \boldsymbol{z}_m\}$, which need no longer be a Krylov space. This requires storing the vectors $\{\boldsymbol{z}_j\}$ in addition to the orthonormal vectors $\{\boldsymbol{v}_j\}$, which form a basis of $\operatorname{span}\{\boldsymbol{A}\boldsymbol{z}_j : j = 1, \dots m\}$.

Table 3.4

Manually optimized GMRES smoothing schedule for the two-dimensional model Helmholtz problem: "J" denotes Jacobi smoothing and "D" denotes a direct solve. The FGMRES algorithm uses the multigrid V-cycle as a preconditioner.

3.2.2. Hand-tuned smoothing schedules. Numerical experiments with a fixed number of GMRES smoothing steps at every level did not result in good performance. To get an idea of an appropriate smoothing schedule, we proceed as follows. For given k, we calculate the number $o_{\max}$ of FGMRES iterations needed with j-level multigrid preconditioning, where we use Jacobi smoothing on all grids for which $kh_i < 1/2$ and do a direct solve at the next coarser grid, making j grids in all. We then replace the direct solve on the coarsest grid of the j-level scheme with GMRES smoothing on this grid, coupled with a direct solve on the next coarser grid, and determine the smallest number m_j of GMRES smoothing steps required for the outer iteration to converge in $o_{\max}$ steps. For example, for the first line of Table 3.4, six outer FGMRES steps were needed for a 5-level scheme, and then $m_5 = 13$ GMRES smoothing steps were needed for the outer iteration of the new 6-level preconditioner to converge in six steps. When the number m_j has been determined, we could fix the number of

GMRES smoothing steps to m_j on this grid, add one coarser level, determine the optimal number of GMRES smoothing steps on the coarser grid, and continue in this fashion until the maximal number of levels is reached. This approach is modified slightly by, whenever possible, trying to reduce the number of smoothings on finer levels once coarser levels have been added. This is often possible, since replacing the exact solve on the coarsest grid with several GMRES smoothing steps often has a regularizing effect, avoiding some damage possibly done by an exact coarse grid correction in modes whose eigenvalues are not well represented on the coarse grid. This hand-tuning procedure gives insight into the best possible behavior of this algorithm.

In contrast to classical linear smoothers, whose damping properties for different modes is fixed, the damping properties of GMRES depend on the initial residual. In particular, since GMRES is constructed to minimize the residual, it will most damp those modes that lead to the largest residual norm reduction. For this reason, we will favor postsmoothing over presmoothing to prevent the unnecessary damping of smoother modes that should be handled by the coarse grid correction. We do include two GMRES presmoothing steps to avoid overly large oscillatory components in the residual prior to restricting it to the next lower level, which could otherwise lead to spurious oscillatory error components being introduced by the coarse grid correction.

The results are shown in Table 3.4. The entry "D" denotes a direct solve on the corresponding level, and "J" indicates that damped Jacobi smoothing was used on this level. Looking at the smoothing schedules, we observe a "hump" in the number of GMRES smoothing steps on the first two levels on which GMRES smoothing is used. Below this, the number decreases and is often zero for the coarsest levels. However, GMRES smoothing still helps on levels which are extremely coarse with regard to resolution of the waves: in the case $k = 32\pi$, for instance, performing three GMRES smoothing steps on level 4 (which corresponds to 1/2 point per wavelength) still improves convergence.

We remark that the number of outer iterations in all these tests, for both preconditioned FGMRES and stand-alone MG, is the same as for the corresponding two-grid versions of these methods, so we cannot expect faster convergence with respect to the wave number k. We also note that the number of iterations for multigrid is very close to that for FGMRES with multigrid preconditioning. We believe this is because the relatively large number of GMRES smoothing steps on intermediate levels eliminates lower frequency errors, and this mitigates the effects of axis crossings. We will return to this point in section 3.4.

3.3. A stopping criterion based on L^2-sections.

Hand tuning as in the previous section is clearly not suitable for a practical algorithm. In this section, we develop a heuristic for finite element discretizations that automatically determines a stopping criterion for the GMRES smoother. This technique is based on an idea introduced in [32].

We briefly introduce some standard terminology for multilevel methods applied to second order elliptic boundary value problems on a bounded domain $\Omega \subset \mathbb{R}^2$ (see [34]). We assume a nested hierarchy of finite element spaces

$$V_1 \subset V_2 \subset \cdots \subset V_J \subset V = H^1(\Omega)$$

in which the largest space V_J corresponds to the grid on which the solution is sought. We require the L^2-orthogonal projections $Q_\ell : V \to V_\ell$, defined by

$$(Q_\ell u, v) = (u, v) \qquad \forall v \in V_\ell, \qquad \ell = 1, \dots, J,$$

where $(\cdot,\cdot)$ denotes the L^2-inner product on Ω. Let $\Phi_\ell = \{\phi_1^{(\ell)}, \dots, \phi_{n_\ell}^{(\ell)}\}$ denote the basis of the finite element space V_ℓ of dimension n_ℓ used in defining the stiffness and mass matrices. By the nestedness property $V_\ell \subset V_{\ell+1}$, there exists an $n_{\ell+1} \times n_\ell$ matrix $\mathcal{I}_\ell^{\ell+1}$ whose columns contain the coefficients of the basis Φ_ℓ in terms of the basis $\Phi_{\ell+1}$, so that, writing the bases as row vectors,

$$[\phi_1^{(\ell)}, \dots, \phi_{n_\ell}^{(\ell)}] = [\phi_1^{(\ell+1)}, \dots, \phi_{n_{\ell+1}}^{(\ell+1)}]\mathcal{I}_\ell^{\ell+1}.$$

The stopping criterion we shall use for the GMRES smoothing iterations is based on the representation of the residual r_ℓ of an approximate solution $\tilde{u}_\ell$ of the level-ℓ equation as the sum of differences of L^2-projections,

$$r_\ell = (I - Q_{\ell-1})r_\ell + (Q_{\ell-1} - Q_{\ell-2})r_\ell + \cdots + (Q_2 - Q_1)r_\ell + Q_1 r_\ell,$$

which we refer to as *residual sections.* The following result for coercive problems, which was proven in [32], shows that the error $u_\ell - \tilde{u}_\ell$ is small if each appropriately weighted residual section is small.

THEOREM 3.1. *Assume the underlying elliptic boundary value problem is H^1-elliptic and $H^{1+\alpha}$-regular with $\alpha > 0$. Then there exists a constant c independent of the level ℓ such that the $H^1(\Omega)$-norm of the error on level ℓ is bounded by*

$$\|u_\ell - \tilde{u}_\ell\|_1 \le c \left(\|Q_1 r_\ell\| + \sum_{j=2}^{\ell} h_j^\alpha \|(Q_j - Q_{j-1})r_\ell\| \right). \tag{3.1}$$

The boundary value problem (1.1)–(1.3) under consideration is not H^1-elliptic and therefore does not satisfy the assumptions of this theorem. We have found, however, that the bound (3.1) suggests a useful stopping criterion: terminate the GMRES smoothing iteration on level ℓ as soon as the residual section $(Q_\ell - Q_{\ell-1})r_\ell$ has become sufficiently small. To obtain a formula for the computation of these sections, assume the residual r_ℓ is represented by the coefficient vector $\boldsymbol{r}_\ell$ in terms of the dual basis of Φ_ℓ. The representation of $Q_{\ell-1}r_\ell$ with respect to the dual basis of $\Phi_{\ell-1}$ is then given by the coefficient vector $\mathcal{I}_\ell^{\ell-1}\boldsymbol{r}_\ell \in \mathbb{C}^{n_{\ell-1}}$, where $\mathcal{I}_\ell^{\ell-1} := (\mathcal{I}_{\ell-1}^{\ell})^\top$. Returning to the representation with respect to the basis $\Phi_{\ell-1}$ requires multiplication with $\boldsymbol{M}_{\ell-1}^{-1}$, so that we obtain

$$\|Q_{\ell-1}r_\ell\|^2 = (Q_{\ell-1}r_\ell, Q_{\ell-1}r_\ell) = (\mathcal{I}_\ell^{\ell-1}\boldsymbol{r}_\ell)^\top \boldsymbol{M}_{\ell-1}^{-1}\mathcal{I}_\ell^{\ell-1}\boldsymbol{r}_\ell.$$

If the sequence of triangulations underlying the finite element spaces V_ℓ is quasi-uniform, then the mass matrix of level ℓ is uniformly equivalent to the identity scaled by h^d, where d denotes the dimension of the domain. For the case $d = 2$ under consideration, this means that the Euclidean inner product on the coordinate space $\mathbb{C}^{n_\ell}$, denoted by $(\cdot,\cdot)_E$, when scaled by h_ℓ^2, is uniformly equivalent (with respect to the mesh size) to the L^2-inner product on V_ℓ. Therefore, the associated norms satisfy

$$ch_\ell^2\|\boldsymbol{v}_\ell\|_E^2 \le \|v_\ell\|^2 = \boldsymbol{v}_\ell^\top \boldsymbol{M}_\ell \boldsymbol{v}_\ell \le Ch_\ell^2\|\boldsymbol{v}_\ell\|_E^2 \qquad \forall v_\ell \in V_\ell,$$

where $\boldsymbol{v}_\ell$ is the coordinate vector of v_ℓ with respect to Φ_ℓ. Using this norm equivalence it is easily shown that

$$\begin{aligned} c\|(\mathcal{I} - h_\ell^2/h_{\ell-1}^2\mathcal{I}_{\ell-1}^{\ell}\mathcal{I}_\ell^{\ell-1})\boldsymbol{r}_\ell\|_E &\le h_\ell\|(I - Q_{\ell-1})r_\ell\| \\ &\le C\|(\mathcal{I} - h_\ell^2/h_{\ell-1}^2\mathcal{I}_{\ell-1}^{\ell}\mathcal{I}_\ell^{\ell-1})\boldsymbol{r}_\ell\|_E \end{aligned}$$

for some constants c and C uniformly for all levels ℓ. As a result, the residual sections may be computed sufficiently accurately without the need for inverting mass matrices.

In [32], it was suggested that the GMRES smoothing iteration for a full multigrid cycle be terminated as soon as the residual section on the given level is on the order of the discretization error on that level. For the problem under consideration here, we shall use the relative reduction of L^2-sections as a stopping criterion, so that roughly an equal error reduction for all modes is achieved in one V-cycle. On the first level on which GMRES smoothing is used, we have the additional difficulty that many eigenvalues may be badly approximated on the next-coarser level. For this reason, it is better to also smooth the oscillatory modes belonging to the next lower level and base the stopping criterion on the residual section $(I - Q_{\ell-2})r_\ell$ instead; we will use this "safer" choice on all levels. Numerical experiments with optimal smoothing schedules have shown the relative reduction of this residual section to scale like kh_ℓ, so that we arrive at the stopping criterion

$$\left\| \boldsymbol{r} - \frac{h_\ell^2}{h_{\ell-2}^2} \mathcal{I}_{\ell-1}^{\ell} \mathcal{I}_{\ell-2}^{\ell-1} (\mathcal{I}_{\ell-1}^{\ell} \mathcal{I}_{\ell-2}^{\ell-1})^\top \boldsymbol{r} \right\|_E \leq \gamma k h_\ell. \tag{3.2}$$

A complete description of the multigrid V-cycle algorithm starting on the finest level ℓ is as follows.

Algorithm 3.1. $\tilde{\boldsymbol{u}}_\ell = MG(\boldsymbol{u}_\ell^{(0)}, \boldsymbol{f}_\ell)$. *Multigrid V-cycle with GMRES smoothing on coarse levels*

```
if $\ell = 1$
    $\tilde{\boldsymbol{u}}_\ell := \boldsymbol{A}_\ell^{-1} \boldsymbol{f}_\ell$
else
    if $kh_\ell < 1/2$
        perform $m_1$ steps of damped Jacobi smoothing to obtain $\boldsymbol{u}_\ell^{(1)}$
    else
        perform 2 steps of GMRES smoothing to obtain $\boldsymbol{u}_\ell^{(1)}$
    endif
    $\boldsymbol{u}_\ell^{(2)} := \boldsymbol{u}_\ell^{(1)} + \mathcal{I}_{\ell-1}^{\ell} MG(0, \mathcal{I}_\ell^{\ell-1}(\boldsymbol{f}_\ell - \boldsymbol{A}_\ell \boldsymbol{u}_\ell^1))$
    if $kh_\ell < 1/2$
        perform $m_2$ steps of damped Jacobi smoothing to obtain $\tilde{\boldsymbol{u}}_\ell$
    else
        perform GMRES smoothing until stopping criterion (3.2) is satisfied
        or $m = m_{\max}$ to obtain $\tilde{\boldsymbol{u}}_\ell$
    endif
endif
```

In the multigrid V-cycle, Algorithm 3.1 is used recursively beginning with the finest level and iterated until the desired reduction of the relative residual is achieved on the finest level. In the FGMRES variant, Algorithm 3.1 represents the action of the inverse of a preconditioning operator being applied to the vector $\boldsymbol{f}_\ell$.

3.4. Experiments with automated stopping criterion. We now show how the multigrid solver and preconditioner perform with the automated stopping criterion for GMRES smoothing. Each method is applied to the two-dimensional Helmholtz problem on the unit square with a second order absorbing boundary condition and random right-hand side data. In these tests, we used $\gamma = 0.1$ in (3.2), and we also imposed an upper bound $m_{\max}$ on the number of GMRES smoothing steps, terminating the smoothing if the stopping criterion is not satisfied after $m_{\max}$ steps; we tested two

Table 3.5

Iteration counts for multigrid and multigrid-preconditioned FGMRES for various fine-grid sizes and wave numbers. In all cases, GMRES smoothing is performed on levels for which $kh > 1/2$ and the smoothing is terminated by the L^2-section stopping criterion or when $m_{\max}$ smoothing steps are reached. A dash denotes divergence.

	Multigrid						MG-preconditioned FGMRES					
$N\backslash k$	2π	4π	8π	16π	32π	64π	2π	4π	8π	16π	32π	64π
	$m_{\max} = 40$											
64	12	12	13				7	8	9			
128	12	12	13	16			7	8	9	13		
256	12	12	13	17	27		7	8	9	13	20	
512	12	12	13	16	27	78	7	8	9	13	21	36
	$m_{\max} = 20$											
64	12	12	13				7	8	9			
128	12	12	13	22			7	8	9	16		
256	12	12	13	21	201		7	8	10	16	37	
512	12	12	13	21	331	—	7	8	10	16	36	80

values, $m_{\max} = 40$ and $m_{\max} = 20$. At fine-grid levels, where damped Jacobi smoothing is used, the number of presmoothings and postsmoothings was $m_1 = m_2 = 2$.

We present three sets of results. Table 3.5 shows iteration counts for a variety of wave numbers and mesh sizes. Table 3.6 examines performance in more detail by showing the automatically generated smoothing schedules for two wave numbers, $k = 8\pi$ and $k = 32\pi$. Finally, to give an idea of efficiency, Table 3.7 shows an estimate for the operation counts (multiplications) required for the problems treated in Table 3.6.

Table 3.6

Smoothing schedules with automated stopping criterion for selected parameters.

128×128	24.0	22.1		
256×256	61.2	43.2	1091.2	971.1
512×512	196.6	148.1	1418.1	1377.8

We make the following observations on these results:

- For low wave numbers, the number of iterations of stand-alone multigrid is close to that for FGMRES. The difference increases as the wave number increases, especially for the case $m_{\max} = 20$. For large enough k, multigrid fails to converge, whereas MG-preconditioned FGMRES is robust. This behavior is explained by the results of section 2.2.2. For large wave numbers, the increased number of amplified modes eventually causes multigrid to fail; a larger number of smoothing steps mitigates this difficulty, presumably by eliminating some smooth errors. The (outer) FGMRES iteration handles this situation in a robust manner.
- The automated stopping criterion leads to smoothing schedules close to those obtained by hand tuning (see Table 3.4), and correspondingly similar outer iteration counts.
- The operation counts shown in Table 3.7 suggest that MG-preconditioned FGMRES is more efficient than stand-alone multigrid even when the latter method is effective. Operation counts for MG-preconditioned FGMRES with $m_{\max} = 20$ (not shown) indicate that the costs for this strategy, which uses more outer iterations but fewer smoothing steps than when $m_{\max} = 40$, are essentially the same, although the larger number of outer FGMRES steps requires more memory to store more fine-grid vectors.
- For fixed wave number, outer iteration counts are mesh independent, so that standard "multigrid-like" behavior is observed. The costs per unknown (for fixed k and smoothing schedule) also display textbook multigrid efficiency, i.e., they are constant. However, because Jacobi smoothing is less expensive than GMRES smoothing, during the initial stages of mesh refinement the operation counts grow at less than a linear rate.
- The growth in outer iteration counts with increasing wave number is slower than linear in k. The operation counts increase more rapidly, however, because of the increased number of smoothing steps required for larger wave numbers.

We also note that GMRES has nontrivial storage requirements; we expect other Krylov subspace methods with lower storage requirements (e.g., QMR [15] or Bi-CGSTAB [33]) to perform in a similar manner.

4. Application to an exterior problem. As a final example we apply the algorithm to an exterior scattering problem for the Helmholtz equation as given in (1.1)–(1.3). The domain Ω consists of the exterior of an ellipse bounded externally by a circular artificial boundary Γ_∞ on which we impose the exact nonlocal Dirichlet-to-Neumann (DtN) boundary condition (see [21]). The source function is $f = 0$; forcing is due to the boundary condition on the boundary Γ of the scatterer, given by

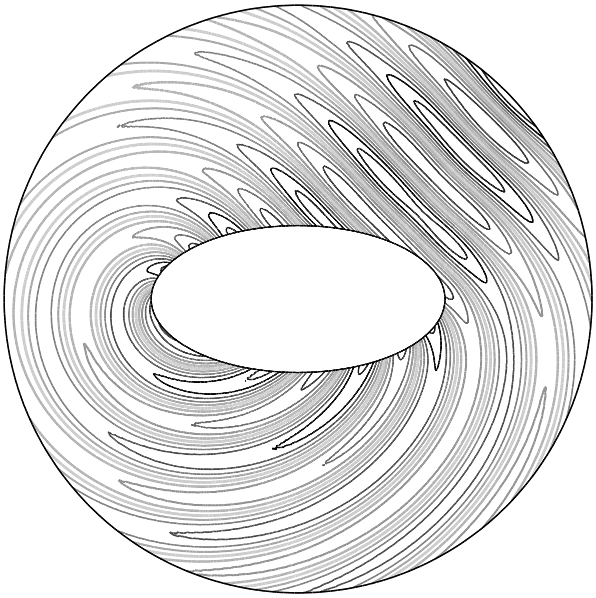

FIG. 4.1. *Contour plot of the solution of the Dirichlet problem with wave number $k = 8\pi$.*

$$u(x,y) = g(x,y) \quad \text{or} \quad \frac{\partial u(x,y)}{\partial n} = \frac{\partial g(x,y)}{\partial n}, \qquad (x,y) \in \Gamma,$$

with data $g(x,y) = -e^{ik(x\cos\alpha + y\sin\alpha)}$ representing a plane wave incident at angle α to the positive x-axis. The solution u represents the scattered field associated with the obstacle and incident field g; the resulting total field $u+g$ then satisfies a homogeneous Dirichlet or Neumann boundary condition on Γ, respectively. An angle of incidence $\alpha = \pi/4$ was chosen to avoid a symmetric solution. The problems were discretized using linear finite elements beginning with a very coarse mesh which is successively refined uniformly to obtain a hierarchy of nested finite element spaces. The finest mesh, obtained after five refinement steps, contains 32768 degrees of freedom. Several combinations of k and h were tested, where in each case $kh < 0.5$ on the finest mesh. Figure 4.1 shows a contour plot of the solution u of the Dirichlet problem for $k = 8\pi$. The computations make use of the PDE Toolbox of the Matlab 5.3 computing environment.

The problems were solved using both the stand-alone and FGMRES-accelerated versions of multigrid, with GMRES smoothing using the residual section stopping criterion with $\gamma = 0.1$, outer stopping criterion requiring residual reduction by a factor of 10^{-6} as in section 3, and zero initial guess. We used the maximal number of levels in all examples with the exception of the Dirichlet problem for $k = 8\pi$, where we also varied the number of levels from six down to two. The results are shown in Table 4.1. The table gives the wave number k and the length of the ellipse E in wavelengths $\lambda = 2\pi/k$. The third column gives the maximum value of kh on the finest mesh and the fourth column indicates the number of levels used in each computation. The last two columns list the iteration counts.

We observe that the preconditioned iteration performs well in all cases with a growth in number of iterations slower than linear in k. The stand-alone multigrid variant performs less well in comparison, requiring more than 100 steps to converge

TABLE 4.1

Iteration counts for the exterior scattering problem with Dirichlet or Neumann plane wave data on the boundary of an ellipse for various wave numbers, grid sizes, and numbers of levels. A dash denotes divergence.

k	Size $E[\lambda]$	$(kh_{\max})_{\text{fine}}$	# Levels	MG	FGMRES
		Dirichlet problem			
2π	1	.10	6	36	13
		.21	5	27	12
		.42	4	26	12
4π	2	.21	6	38	16
		.42	5	27	14
8π	4	.42	6	41	20
			5	—	28
			4	100	26
			3	41	16
			2	41	13
		Neumann problem			
2π	1	.10	6	—	21
		.21	5	37	15
		.42	4	21	12
4π	2	.21	6	—	28
		.42	5	53	21
8π	4	.42	6	—	32

in several cases and even diverging in one case. This is particularly the case for the Neumann problem, where the superiority of the preconditioned variant is even more pronounced. For the Neumann problems we also notice a slight growth in iteration counts for fixed k and decreasing h.

5. Conclusions. The results of this paper show that the addition of Krylov subspace iteration to multigrid, both as a smoother and as an outer accelerating procedure, enables the construction of a robust multigrid algorithm for the Helmholtz equation. GMRES is an effective smoother for grids of intermediate coarseness, in that it appears not to amplify any error modes and in addition tends to have a regularizing effect on the contribution to the coarse grid correction coming from smoothing on a given level. The combination of our multigrid algorithm as a preconditioner with FGMRES is effective in handling the deficiencies of standard multigrid methods for the Helmholtz equation, and the outer FGMRES acceleration is necessary, particularly for high wave numbers. In addition, results in the paper indicate that grids too coarse to result in a meaningful discretization of the Helmholtz equation may still provide some useful information for coarse grid corrections. Using an automated stopping criterion based on L^2-sections of the residual leads to smoothing cycles that are close to hand-tuned optimal smoothing schedules.

An important aspect of our algorithm is that it consists of familiar building blocks and is thus easily implemented. For very large wave numbers for which the discretization must not only keep kh but also k^3h^2 small, the grid hierarchy will contain more grids fine enough to use Jacobi smoothing, thus making the algorithm more efficient. The result is a multigrid method that appears to converge with a rate independent of the mesh size h and with only moderate dependence on the wave number k. Finally, the numerical results show that we are able to effectively solve Helmholtz problems with wave numbers of practical relevance.

OPTIMIZING SCHRÖDINGER FUNCTIONALS USING SOBOLEV GRADIENTS: APPLICATIONS TO QUANTUM MECHANICS AND NONLINEAR OPTICS[*]

JUAN JOSÉ GARCÍA-RIPOLL[†] AND VÍCTOR M. PÉREZ-GARCÍA[†]

Abstract. In this paper we study the application of the Sobolev gradients technique to the problem of minimizing several Schrödinger functionals related to timely and difficult nonlinear problems in quantum mechanics and nonlinear optics. We show that these gradients act as preconditioners over traditional choices of descent directions in minimization methods and show a computationally inexpensive way to obtain them using a discrete Fourier basis and a fast Fourier transform. We show that the Sobolev preconditioning provides a great convergence improvement over traditional techniques for finding solutions with minimal energy as well as stationary states and suggest a generalization of the method using arbitrary linear operators.

1. Introduction.

The observation of nature reveals that many unforced continuous systems tend to accommodate into stationary configurations, in which the distributions of mass, charge, velocity, etc., do not change throughout time. In the language of mathematical modeling all configurations are represented by points of a certain space of functions, $\psi(\mathbf{x}) \in W$, while the tendency of the system to lie into any of these states is given by a functional, $E(\psi) : W \to \mathbb{R}$, *the energy*, whose minima are precisely those stationary "states." For this reason it is possible to see many physical problems written as variational principles of the type "find $\psi \in W$ such that $E(\psi) : W \to \mathbb{R}$ achieves a minimum on W." In most situations the functional to be minimized has a dependence on ψ of the form

$$E(\psi) = \int f\left(\nabla\psi(\mathbf{x}), \psi(\mathbf{x})\right) d^n x. \tag{1.1}$$

However, a complete analytical description of the minima of the functional $E(\psi)$ is usually not possible. In this paper we will introduce several techniques for performing this study numerically, focusing on the minimization of $E(\psi)$ subject to physical constraints.

From a practical point of view, this problem is similar to that of finding the minima of a real function defined over a finite-dimensional space, such as $\mathbb{R}^n$. First, a definition of derivative of the functional, $\nabla E(\psi)$, must be chosen. If the domain of the functional W is equipped with some scalar product, we may use the Fréchet derivative which is given by a first order expansion of the functional around a function ψ,

$$E(\psi + \delta) = E(\psi) + \langle \delta, \nabla E(\psi)\rangle + \langle \nabla E(\psi), \delta\rangle + O\left(\|\delta\|^2\right). \tag{1.2}$$

The *critical points,* ψ_c, are defined as the points where the first order variation of the functional vanishes for any perturbation δ. That is, the derivative vanishes in a weak sense:

$$\langle \delta, \nabla E(\psi_c)\rangle = 0 \quad \forall \delta. \tag{1.3}$$

Just like in the finite-dimensional case it is possible to show that any minimum of the functional must also be a critical point. Thus a common approach is to solve (1.3) and verify a posteriori which solutions are actually minima of the functional. If $W = L^2(\mathbb{R}^n)$, this procedure gives us the well-known Euler–Lagrange equations of the problem, which is a partial derivatives equation (PDE):

$$\frac{\partial f}{\partial \bar{\psi}} - \nabla \cdot \frac{\partial f}{\partial \nabla \bar{\psi}} = 0. \tag{1.4}$$

However, we have no guarantee of reducing the complexity of the problem, as it is by no means trivial to solve (1.4). We are also likely to obtain more solutions than we actually need, since not only minima, but also maxima and saddle node points, will satisfy the Lagrange equations.

To avoid these problems some other methods are used which aim at finding the minima of the functional directly, constructing minimizing sequences, $\{\psi_i\}$, whose limit is a minimum of the functional: $\psi_c = \lim_{i\to\infty} \psi_i$. These methods will be discussed in the following sections.

The outline of this paper is as follows. In section 2 we recall the definition of Sobolev gradients as given in [2, 3]. We derive a formal solution to the problem of finding these gradients which is based on the inversion of a positive Hermitian operator. In section 3 we derive an explicit expression for the Sobolev gradients in the trigonometric Fourier basis and comment on its implementation using fast Fourier transforms.

In sections 4 and 5 we apply the previous tools to two physical problems. Using descent techniques with Sobolev gradients over Fourier spaces we will find the ground states of a Bose–Einstein condensate in a rotating magnetic trap and the excited states for coupled laser beams propagating through a nonlinear medium. Both physical systems are modeled by nonlinear equations of Schrödinger type and present difficulties when traditional minimization techniques are used. We comment on the great improvements that are achieved using Sobolev gradients. Finally in section 6 we summarize our results and offer some conclusions.

2. Sobolev gradients.

2.1. Direct solutions of the variational problem.

There are two traditional approaches to the problem of finding the minima of a functional using a discrete basis. The first one expands the unknown solution using a Fourier basis $\{\phi_k\}$, $\psi = \sum_k c_k \phi_k$, and defines a new functional over the finite-dimensional space

$$E(\{c_k\}) \equiv E\left(\sum c_k \phi_k\right). \tag{2.1}$$

The functional is then minimized using methods which are well known from the domain of finite-dimensional problems, e.g., Newton's method or nonlinear conjugate gradient.

This procedure is quite straightforward and there is a huge amount of literature and tools which can be immediately applied to (2.1). However, for some types of problems one has to deal with highly nonlinear algebraic equations with many terms on each equation, something which is computationally too expensive to work with.

The second approach involves what is known as *descent techniques.* The idea is to manipulate the original functional (1.1) building an analytic equation for a minimizing trajectory in the target space W. This equation is then discretized and solved on a suitable basis. In the *continuous steepest descent* version, the trajectory $\psi(t) : \mathbb{R} \to W$ is continuous and defined by a PDE which involves the gradient of the functional (1.2),

$$\frac{\partial \psi}{\partial t} = -\nabla E. \tag{2.2}$$

The *discrete steepest descent* technique is computationally cheaper since instead of requiring an integrator for the PDE it constructs a sequence of estimates to the minimum, $\{\psi_{k+1} = \psi_k + \lambda_k \nabla E(\psi_k)\}$, by locally minimizing $E(\psi_k + \lambda \nabla E)$ with respect to the real parameter λ.

In this paper we deal only with descent techniques. The first and most important reason is that we will work with the definition of $\nabla E(\psi_k)$ trying to improve its convergence. As was already shown in [3], this work pays off: a good choice of the gradient improves convergence by several orders of magnitude. The second motivation is that by focusing on the gradient, we find that our algorithms will be essentially independent on the descent method, which leaves space for further improvement. For instance, one might apply these techniques to a nonlinear conjugate gradient method—which dynamically adjusts the search direction, $d_k \equiv \nabla E(\psi_k)$, with an estimate that takes into account the history of the evolution. Finally, by working with (2.2) or its discrete version we avoid the complex nonlinearities that arise in other methods, and we will have a more ample choice of Fourier basis to work with.

2.2. Boundary conditions. Before proceeding with the study of Sobolev gradients, we must make more precise the boundary conditions of our functional spaces. In this paper we will compare applications to several problems of physics in which the solutions concentrate on a narrow region of space and decrease exponentially as we move out of this region, that is,

$$|\psi(\mathbf{r})| = \mathcal{O}(e^{-|r|^2}), \quad |r| \to \infty.$$

Naturally, computers allow us to study only a small region of space, which means we have to introduce some reasonable boundary conditions and hope that the solutions of this simplified problem do not deviate much from the original one.

In our case we will perform our study with functions which are defined over a d-dimensional rectangular volume, $\Omega \equiv \{\mathbf{x} \in \Pi_i [a_i, b_i]\}$ (see section 2.13), and we will impose zero boundary conditions on the sides of this box.

2.3. Ordinary gradients. It is customary in the literature to work in spaces which are equipped with an L^2 scalar product and its corresponding norm

$$\langle \psi, \phi \rangle_{L^2} \equiv \int_\Omega \bar{\psi}\phi, \tag{2.3}$$

$$\|\psi\|^2_{L^2} \equiv \int_\Omega |\psi|^2. \tag{2.4}$$

If one does so and works with (1.2) as well as the boundary conditions, then the formal definition of the gradient is one of Lagrange's:

$$\nabla E(\psi) = \frac{\partial E}{\partial \bar{\psi}} - \nabla \frac{\partial E}{\partial \left(\nabla \bar{\psi}\right)}. \tag{2.5}$$

We will refer to this definition as the "ordinary" gradient to distinguish it from the different definitions that we will derive below.

2.4. Sobolev gradients. Following the ideas from [3] we will move our problem to a different space, which is the Sobolev space of functions, such that ψ and its derivatives, $\nabla\psi$, have a well-defined L^2-norm:

$$\mathbb{H}^1 \equiv \{\psi/\psi, \nabla\psi \in L^2\}. \tag{2.6}$$

This Sobolev space will also be equipped with a scalar product and a norm:

$$\langle \psi, \phi \rangle \equiv \int_\Omega \left[\bar{\psi}(\mathbf{x})\phi(\mathbf{x}) + \nabla\bar{\psi}(\mathbf{x}) \cdot \nabla\phi(\mathbf{x})\right] d^n x, \tag{2.7}$$

$$\|\psi\|^2 \equiv \int_\Omega \left[|\psi|^2 + |\nabla\psi|^2\right] d^n x. \tag{2.8}$$

To obtain a new explicit expression for the gradient of the functional in the Sobolev space we will follow a less rigorous derivation than in [2]. Performing a first order expansion of our functional around a trial state ψ we obtain

$$\begin{aligned} E(\psi + \varepsilon\delta) = E(\psi) &+ \varepsilon \int_\Omega \left[\bar{\delta}\frac{\partial E}{\partial \bar{\psi}} + \nabla\bar{\delta}\frac{\partial E}{\partial(\nabla\bar{\psi})}\right] \\ &+ \varepsilon \int_\Omega \left[\frac{\partial E}{\partial \psi}\delta + \frac{\partial E}{\partial(\nabla\psi)}\nabla\delta\right] + O(\varepsilon^2). \end{aligned} \tag{2.9}$$

Here the bars over δ and ψ denote complex conjugation.

We have to turn this expression into something like (1.2). This means that we have to find some function, $\phi \equiv \nabla_S E$, which is the gradient and satisfies

$$\int_\Omega \left[\bar{\delta}\frac{\partial E}{\partial \bar{\psi}} + \nabla\bar{\delta}\frac{\partial E}{\partial(\nabla\bar{\psi})}\right] = \int_\Omega \left[\bar{\delta}\phi + \nabla\bar{\delta}\nabla\phi\right] = \langle \delta, \phi \rangle, \tag{2.10}$$

$$\int_\Omega \left[\frac{\partial E}{\partial \psi}\delta + \frac{\partial E}{\partial(\nabla\psi)}\nabla\delta\right] = \int_\Omega \left[\bar{\phi}\delta + \nabla\bar{\phi}\nabla\delta\right] = \langle \phi, \delta \rangle. \tag{2.11}$$

If we use the boundary conditions to integrate by parts and then impose that any of these equalities be satisfied for all perturbations δ, the problem has a formal solution which is given by a Lagrange equation,

$$(1 - \triangle)\,\phi = \frac{\partial E}{\partial \bar{\psi}} - \nabla\frac{\partial E}{\partial(\nabla\bar{\psi})}. \tag{2.12}$$

In consequence, our formal expression for the Sobolev gradient of $E(\psi)$ finally reads

$$\nabla_S E \equiv (1 - \triangle)^{-1}\,\nabla E. \tag{2.13}$$

Here $\nabla_S E$ stands for the Sobolev gradient, ∇E is the ordinary one, and $(1 - \triangle)^{-1}$ represents the inverse of a linear and strictly positive definite operator.

3. Sobolev gradients on discrete Fourier spaces. As mentioned above, we will work with functions which are defined over a rectangular Ω with side lengths given by $L_i = b_i - a_i$. We customarily define an orthogonal set of basis functions, $\phi_n = e^{ik_n x}$, over Ω, where $\{k_n = 2\pi(\frac{n_1}{L_1}, \dots, \frac{n_d}{L_d}),\ n_i \in Z\}$.

It is well known that it is possible to expand any continuous function $f(x)$ with periodic boundary conditions using this basis:

$$f(x) = \sum_{n=-\infty}^{+\infty} \hat{f}_n \phi_n(x), \tag{3.1}$$

where

$$\hat{f}_n = \frac{1}{V} \int_\Omega \bar{\phi}_n(x) f(x). \tag{3.2}$$

In the previous formula $V = \Pi_i L_i$ is the volume of Ω and arises because of the lack of normalization of the basis functions, a common practice which saves some computation time.

To discretize the problem we will work within the set of functions sampled over a set of evenly spaced points from Ω, $\{x_n = (n_1 h_1, \dots, n_d h_d),\ n_i = 0, \dots, N_i - 1\}$. Here h_i represents the spacing along the ith dimension, n is a vector of nonnegative integers, and we denote a sampled function by an index, as in $f_n \equiv f(x_n)$.

Due to this procedure our previous Fourier basis is now redundant. We can choose finite subset of functions that represent any sampled function. These functions are given by $\{k_n = 2\pi(\frac{n_1}{L_1}, \dots, \frac{n_d}{L_d}),\ n_i = -M_i + 1, \dots, M_i\}$, where $M_i = [N_i/2]$ is the integer quotient of N_i divided by 2. In this basis a sampled function is given by an expansion which reads

$$f_m = \sum_n \hat{f}_n \phi_n(x_m) \tag{3.3}$$

and which makes use of the same coefficients as (3.2).

The advantage of the finite Fourier basis over other approaches is that it provides an approximant of any function whose error is of order $O(L_i/N_i)^p$, where p is the maximum differentiability of the sampled function. Furthermore, there is a numerically efficient method known as the fast Fourier transform (FFT), which allows one to compute the Fourier coefficients up from the sampled function, $f_n \to \hat{f}_m$, and vice versa [1].

Solving (2.13) numerically in a discrete Fourier basis is simple. Let us say that we have computed the ordinary gradient and that its sampled version has some Fourier coefficients

$$\nabla E(\mathbf{x}_n) = \sum \hat{e}_m \phi_m(x_n), \tag{3.4}$$

and let us assume that there exists a certain solution to (2.13) and that it has another discrete Fourier expansion

$$\nabla_s E(\mathbf{x}_n) = \sum \hat{s}_m \phi_m(x_n). \tag{3.5}$$

Then by virtue of (2.13)

$$\hat{s}_m = \frac{\hat{e}_m}{1 + k_m^2}; \tag{3.6}$$

that is, in the sampled space the Sobolev gradient represents a preconditioning of the ordinary gradient such that the most oscillating modes are more attenuated. Furthermore, due to this very simple expression, computing the Sobolev preconditioning is computationally cheap and involves only minor changes to existing computer codes based on Fourier transforms.

4. Applications to quantum mechanics.

4.1. The problem. In this section we apply the Sobolev gradients technique to a timely problem from quantum physics. The system that we will study is a dilute gas of bosonic atoms which are cooled down to ultralow temperatures at which their dynamics become synchronized. When the temperature is low enough, the gas or "condensate" may be described using a single complex wave function, $\psi(\mathbf{x}, t)$, which is ruled by the so-called Gross–Pitaevskii equation, a type of nonlinear Schrödinger equation that for a Bose gas in a rotating trap reads [4]

$$i\partial_t \psi(\mathbf{x}, t) = \left[-\frac{1}{2}\triangle + V(\mathbf{x}) + g|\psi(\mathbf{x}, t)|^2 - \Omega L_z\right]\psi(\mathbf{x}, t). \tag{4.1}$$

Here $g \in \mathbb{R}^+, \Omega \in \mathbb{R}$, $L_z = i\,(x_1\partial_2 - x_2\partial_1)$ is a Hermitian operator whose expected value $\langle L_z\rangle = \int \bar{\psi} L_z \psi$ represents the *angular momentum* of the condensate along an axis of the trap, and the equation has been properly adimensionalized.

There is a conserved quantity associated to (4.1) which is called the *energy functional* of the condensate

$$E(\psi) = \frac{1}{2}\int\left\{|\nabla\psi|^2 + \bar{\psi}\left[V(\mathbf{x}) + \frac{1}{2}g|\psi|^2 - \Omega L_z\right]\psi\right\} d^n x. \tag{4.2}$$

Our objective in this part of the work will be to *find the solutions which are the minima of the energy subject to a restriction of the L^2-norm*

$$\int |\psi|^2 \equiv N. \tag{4.3}$$

The particular value of N is imposed by the experimental conditions and remains constant throughout evolution. Furthermore, without this restriction the absolute minimum of the energy is always reached at the trivial solution $\psi = 0$.

In quantum mechanics the variational formulation of the problem is traditionally converted into a Lagrange equation (1.4), which is nothing but the Gross–Pitaevskii equation for the so-called *stationary states.* In short the word "stationary" refers to solutions of the type

$$\psi(\mathbf{x}, t) = e^{-i\mu t}\phi_\mu(\mathbf{x}). \tag{4.4}$$

The pair $\{\mu, \phi_\mu(\mathbf{x})\}$ satisfies a nonlinear eigenvalue problem

$$\mu\phi_\mu(\mathbf{x}) = \left[-\frac{1}{2}\triangle + V(\mathbf{x}) + g|\phi_\mu(\mathbf{x})|^2 - \Omega L_z\right]\phi_\mu(\mathbf{x}). \tag{4.5}$$

Due to the difficulty of solving problem (4.5) directly we will try to find a direct solution to the variational problem.

4.2. Numerical methods: Imaginary time evolution. We can search the minima of (4.2) using descent techniques modified to account for the restriction on the norm (4.3). The first way to do this is to use a version of the continuous steepest descent which is known as *imaginary time evolution.* We can summarize this method with the following set of equations:

$$\nu(\mathbf{x},\tau) = \sqrt{\frac{N}{\|\sigma\|^2_{L^2}}}\sigma(\mathbf{x},\tau), \tag{4.6}$$

$$\frac{\partial\sigma}{\partial\tau}(\mathbf{x},\tau) = -\nabla E(\nu), \tag{4.7}$$

$$\nabla E(\nu) = \left[-\frac{1}{2}\triangle + V(\mathbf{x}) + g|\nu|^2 - \Omega L_z\right]\nu. \tag{4.8}$$

Here we see that $\nu(\mathbf{x},\tau)$ evolves continuously maintaining a fixed L^2-norm N and following the direction of decreasing energy given by ∇E. Indeed it is easy to show that $\frac{\partial}{\partial\tau}\left[E(\nu(\mathbf{x},\tau))\right] \leq 0$. Hence, the limit given by

$$\phi(\mathbf{x}) = \lim_{\tau\to\infty}\nu(\mathbf{x},\tau) \tag{4.9}$$

is at least a critical point of the energy, if not a minimum.[1]

From a practical point of view, the simplest way to find the minimizer using imaginary time evolution is to repeatedly integrate (4.7) for a very short time, Δt, apply (4.6) for the newly found $\sigma(\mathbf{x}, t+\Delta t)$, and use the new estimate for ν to redefine $\sigma \equiv \nu$ and repeat the procedure until convergence. This way one avoids the problem that according to (4.7) the norm of σ may grow indefinitely. The same consideration applies to the remaining methods that we will present here.

Although the method from (4.7) was derived using an ordinary gradient, nothing prevents us from applying our Sobolev preconditioning and all results should still be valid. If we do so, our new equations are

$$\nu(\mathbf{x},\tau) = \sqrt{\frac{N}{\|\sigma\|^2_{L^2}}}\sigma(\mathbf{x},\tau), \tag{4.10}$$

$$\frac{\partial\sigma}{\partial\tau}(\mathbf{x},\tau) = -\nabla_S E(\nu), \tag{4.11}$$

$$\nabla_S E(\nu) = (1-\triangle)^{-1}\left[-\frac{1}{2}\triangle + V(\mathbf{x}) + g|\nu|^2 - \Omega L_z\right]\nu \tag{4.12}$$

and the critical point is still given by (4.9).

4.3. Numerical methods: Minimization of the free energy. While the imaginary time evolution is easy to understand and to implement, the fact that it performs the descent over a path of functions with a certain norm makes it too restricted and sometimes too slow. A different approach is to define a new functional called *free energy* with a Lagrange multiplier that takes care of the restriction on the norm. In quantum mechanics this free energy is usually defined as

$$F_{QM}(\psi) = E(\psi) - \mu N(\psi), \tag{4.13}$$

[1] As is common with these local minimization procedures, it remains the problem that iterations may be trapped in a critical point which is not a minimum. Linear stability analysis may then be applied to check the validity of the solution.

because it preserves the linear form of the equations. Since our equations are already nonlinear we define a free energy functional more conveniently as

$$F(\psi) = E(\psi) + \frac{1}{2}\left(N(\psi) - \lambda\right)^2. \tag{4.14}$$

First and most important, it is not difficult to show that any absolute or relative minimum of $F(\psi)$ is also a minimum of $E(\psi)$ subject to (4.3) with a nonlinear eigenvalue given by $\mu = N(\psi) - \lambda$.

Second, as we will prove in Appendix A, $F(\psi)$ must have at least one finite norm minimum, something which cannot be easily assured for F_{QM}.

The practical advantage of our new functional consists in that fixing λ and Ω we can perform a continuous descent over the whole domain of $F(\psi)$ without renormalizing the solution on each iteration—i.e., the search space is larger. The new equation that we must integrate is thus

$$\frac{\partial \nu}{\partial \tau}(\mathbf{x}, \tau) = -\nabla F(\nu) = -\left[-\frac{1}{2}\triangle + V(\mathbf{x}) + g|\nu|^2 - \Omega L_z\right]\nu. \tag{4.15}$$

Using Sobolev preconditioning, we derive the following from (4.15):

$$\frac{\partial \nu}{\partial \tau}(\mathbf{x}, \tau) = -\nabla_S F(\nu) = -\left(1 - \triangle\right)^{-1}\left[-\frac{1}{2}\triangle + V(\mathbf{x}) + g|\nu|^2 - \Omega L_z\right]\nu. \tag{4.16}$$

In both cases the actual solution is still given by the limit of (4.9).

4.4. Numerical results. Up to this point we have shown four different numerical methods, two of them incorporating Sobolev preconditioning ((4.11) and (4.16)) and two without it ((4.7) and (4.15)). We have compared the efficiency of these methods for several test situations. The details of our study are as follows.

All methods have been implemented using the discrete Fourier basis mentioned above. This applies both to the calculation of derivatives and to the application of the Sobolev preconditioning. We restricted our simulations to two-dimensional problems with a radially symmetric potential, $V(\mathbf{x}) = \frac{1}{2}|\mathbf{x}|^2$, over a grid of 128×128 points. Practical experience with more complex problems shows that our results generalize to higher dimensionality and denser grids.

Due to the requirements of the method, both variants of imaginary time evolution ((4.7) and (4.11)) are integrated using a Runge–Kutta–Fehlberg method, where the tolerance is adapted as the solution converges to its target. On the other hand, instead of performing a continuous descent for both variants of the free energy descent ((4.15) and (4.16)), we found it more convenient and faster to perform a discrete steepest descent.

All programs have been implemented using the tensor-algebra environment called Yorick [6], an interpreted environment which is capable of fast numerical computations and which can be equipped with the FFTW library [7]. Execution times are given for a Digital Personal workstation 500au, but the programs run equally well on modest personal computers with Pentium-II processors and less than 64 Mb of memory.

As a test case we have considered three situations. Case A is the simplest one, corresponding to a stationary trap $\Omega = 0$, an intense nonlinearity $g = 100$, and starting the minimization with a radially symmetric Gaussian of unit width, that is, $\psi_0 \propto e^{-|\mathbf{x}|^2}$, a shape which is similar to that of the true ground state.

Cases B and C involve a rotating condensate with $\Omega = 0.6$ and $g = 100$. Under these conditions the functional achieves both an absolute minimum, which is the same

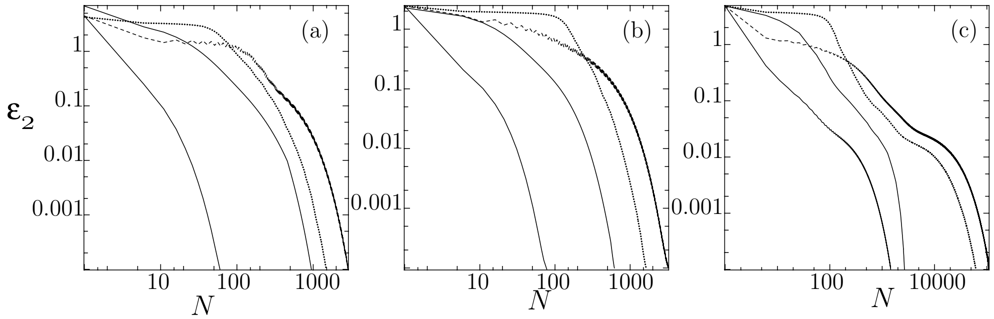

FIG. 4.1. *Evolution of error, $\varepsilon_2 \equiv \|\psi - \psi_{exact}\|_2$, through different minimization processes for continuous steepest descent with Sobolev preconditioning (lower solid line) and without it (dashed line) and for imaginary time evolution with Sobolev preconditioning (upper solid line) and without it (dotted line). Plots* (a) *to* (c) *correspond, respectively, to the cases* A, B, *and* C *described in the text. Both axes, error and number of iterations, are in a logarithmic scale.*

TABLE 4.1

Iterations and computation time for each minimization method: Imaginary time without (IT) and with (ITS) Sobolev preconditioning and free energy without (FE) and with (FES) Sobolev preconditioning. Shown are results for the initial data described in the text (cases A, B, *and* C*).*

Methods		IT	ITS	FE	FES
Case A	Iterations	1320	945	2850	55
	Time (s)	416	371	285	13
Case B	Iterations	1630	615	3210	320
	Time (s)	468	242	75	9
Case C	Iterations	64195	2665	108505	1455
	Time (s)	19863	1165	10861	168

as that found in case A, and a local minimum. The local minimum is a solution of vortex type, a topological defect, whose behavior near zero is $\psi \propto (x_1 + ix_2)/|\mathbf{x}|^2$.

For this reason we designed two test cases with different initial conditions. Case B starts with a Gaussian profile with a centered vortex or $\psi_0 \propto |\mathbf{x}|e^{-|\mathbf{x}|^2}(x_1 + ix_2)/|\mathbf{x}|^2$. In this case all methods are trapped on the local minimum with the centered vortex.

Finally, a third set of simulations, case C, uses the same parameters $\{\Omega = 0.6, g = 100\}$ but starts from a nonsymmetric initial state, $\psi_0 \propto |\mathbf{x}|e^{-|\mathbf{x}|^2}((x_1 - y_1) + i(x_2 - y_1))/|\mathbf{x} - \mathbf{y}|^2$ which is close to the vortex solution but belongs to the basin of attraction of the ground state. Here all minimization methods require more computational work since they must find a path out of the local minimum, and it is precisely in this case where the differences between methods are best shown.

In Figure 4.1 and Table 4.1 we summarize the results of the simulations. In case A it is apparent that the Sobolev preconditioning has a positive influence over convergence, with an astonishing result of 55 steps for the steepest descent with free energy. A similar behavior is found in case B.

In case C, the Sobolev preconditioning enhances convergence speed by two orders of magnitude. An intuitive explanation of why the steepest descent with a Sobolev gradient takes less steps to converge will be discussed in detail in Appendix B.

5. Applications to nonlinear optics.

5.1. The model. In this section we consider a model for a pair of incoherently interacting light beams. To be precise we will study the light field of each beam, $u(\mathbf{x}, t)$

and $w(\mathbf{x},t)$, propagating through a weakly nonlinear saturable optical medium. This system may be modeled by the Cauchy problem

$$i\partial_t u = -\triangle u + \frac{u}{1+\kappa(|u|^2+|w|^2)}, \tag{5.1}$$

$$i\partial_t w = -\triangle w + \frac{w}{1+\kappa(|u|^2+|w|^2)} \tag{5.2}$$

for the complex functions $u, w : \mathbb{R}^2 \times \mathbb{R}^+ \to \mathbb{C}$, which vanish at infinity and satisfy the initial data $u(\mathbf{x},0) = u_0(\mathbf{x})$ and $w(\mathbf{x},0) = w_0(\mathbf{x})$. Here $\kappa \in \mathbb{R}^+$, $-\triangle = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}$ is the Laplacian operator which accounts for the diffraction of light, and the nonlinear term $(1+|u|^2+|w|^2)^{-1}$ models the saturable interaction among the beams.

Let us define the two-component vector

$$\tilde{U}(\mathbf{x},t) = \begin{pmatrix} u(\mathbf{x},t) \\ w(\mathbf{x},t) \end{pmatrix}; \tag{5.3}$$

then the energy functional for the system reads

$$E(\tilde{U}) = \int \left[-\tilde{U}^\dagger \triangle \tilde{U} + G(|\tilde{U}|^2) \right] d^n x, \tag{5.4}$$

where $G(\rho) = \frac{1}{\kappa^2}\left(\ln(1+\kappa\rho) - \kappa\rho\right)$. The analysis of this section may be generalized to more general nonlinearities with only minor changes to $G(\rho)$.

5.2. Stationary solutions. We are interested in stationary solutions, which are of the form

$$\tilde{U}(\mathbf{x},t) = \begin{pmatrix} e^{i\mu_u t} & 0 \\ 0 & e^{i\mu_w t} \end{pmatrix} U(\mathbf{x}) = e^{iMt} U(\mathbf{x}). \tag{5.5}$$

The equations for the stationary solutions now are of elliptic type,

$$MU = -\triangle U + G'(|U|^2)U, \tag{5.6}$$

with zero Dirichlet boundary conditions at infinity. Again this formulation poses a nonlinear eigenvalue problem for the pair $\{M, U\}$.

The stationary solutions are critical points of the energy functional subject to a constraint on the L^2-norm of each component. That is, defining

$$N_u = \int |u|^2 d^n x, \tag{5.7}$$

$$N_w = \int |w|^2 d^n x, \tag{5.8}$$

the first order variation of the energy around U_0 for fixed N_u and N_w must be zero:

$$\left.\frac{\delta E}{\delta U}\right|_{N_u,N_w} = 0. \tag{5.9}$$

The particular fixed values of $\{N_u, N_w\}$ represent the total intensity of each beam of light.

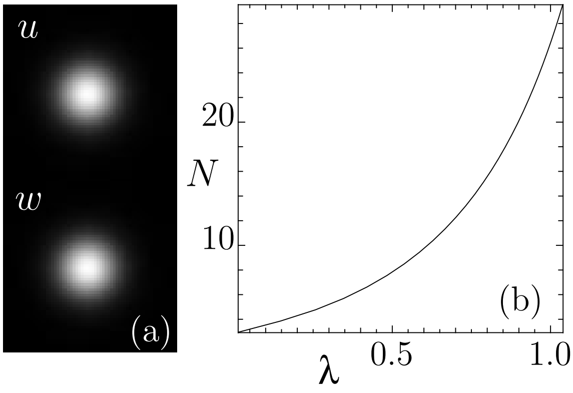

FIG. 5.1. (a) *Density profile of a ground state for* $N_u = N_w = 30$. (b) *Norms* $N_u = N_w = N$ *as a function of the nonlinear Lagrange multipliers* $\lambda_u = \lambda_w = \lambda$.

5.3. Ground states. In principle there are many different stationary solutions of (5.6). However, if we focus on the ground states (stationary solutions of minimal energy) we can apply some of the methods that we mentioned in section 4 with minor modifications to account for the higher dimensionality of the problem. For instance, one may define a free energy functional

$$F(U) = E(U) + \frac{1}{2}(N_u - \lambda_u)^2 + \frac{1}{2}(N_w - \lambda_w)^2 \tag{5.10}$$

and minimize it using a discrete steepest descent with Sobolev preconditioning.

By performing this minimization using different parameters $\{\lambda_u, \lambda_w\}$ one obtains nodeless localized solutions for u and w as shown in Figure 5.1. The precise values of λ_u and λ_w determine the norm of each component.

Let us remark that, up to a global factor, the ground state has the same shape in both envelopes. That is,

$$\begin{aligned} u_0(\mathbf{x}) &= N\sqrt{\xi}\,\rho(|\mathbf{x}|, N), \\ w_0(\mathbf{x}) &= N\sqrt{1-\xi}\,\rho(|\mathbf{x}|, N) \quad \forall \xi \in [0,1]. \end{aligned} \tag{5.11}$$

The common shape ρ depends on the total intensity $N = N_u + N_w$, and it is the one that fixes the values of μ_u and μ_w. For this reason if we had chosen the traditional definition of the free energy $F_{QM}(U) = E(U) + \mu_u N_u + \mu_w N_w$ we would have found an infinite degeneracy which prevents convergence to the desired values of $\{N_u, N_w\}$. This problem is removed by the use of our nonlinear Lagrange multipliers and the $\{\lambda_u, \lambda_w\}$ parameters.

5.4. Excited states. In the field of guided light waves there is a great interest on the properties of solutions of (5.6) which are not ground states, the so-called *excited states*. Minimization methods based on the energy functional (see section 4) cannot be applied to this task since excited states are not necessarily local minima of the energy. Instead, a variational principle somehow equivalent to (5.6) must be defined.

Let us rewrite (5.6) as the application of a nonlinear operator

$$f(U) \equiv \left[-\triangle - M + I(|U|^2)\right] U = 0, \tag{5.12}$$

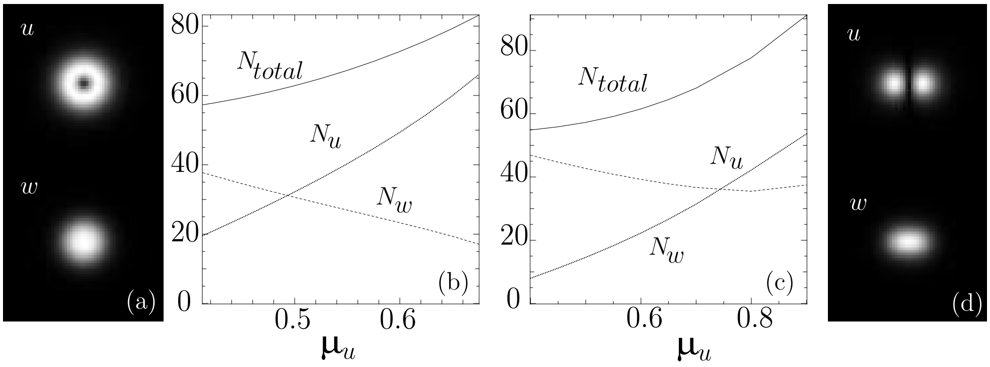

FIG. 5.2. (a) *Vortex-mode vector solitons and* (b) *their norms N_u, N_w, $N_{total} = N_u + N_w$ as a function of μ_u for $\mu_w = 1$.* (d) *Dipole-mode vector solitons and* (c) *their norms N_u, N_w, $N_{total} = N_u + N_w$ as a function of μ_u for $\mu_w = 1$.*

define the error functional

$$F(U) \equiv \int f(U)^\dagger f(U) \geq 0, \tag{5.13}$$

and take our variational principle to be *find U_0 such that F reaches an absolute minimum $F(U_0) = 0$.*

With this principle and Sobolev preconditioning our descent technique becomes

$$\frac{\partial \nu(\mathbf{x},\tau)}{\partial \tau} = -\nabla_S F(\nu) = -\left(1 - \triangle\right)^{-1} \nabla F, \tag{5.14}$$

and it may be proven that $U_0(\mathbf{x}) = \lim_{\tau\to\infty} \nu(\mathbf{x},\tau)$. The ordinary gradient ∇F reads

$$G \equiv (-\triangle + I(|U|^2))U, \tag{5.15}$$

$$\nabla F = (-\triangle + I(|U|^2))G + I'(|U|^2)\left(U^\dagger G + G^\dagger U\right) U. \tag{5.16}$$

Its calculation using a discrete Fourier basis is straightforward.

There are several advantages to this approach. The first one is that $F(U)$ makes no distinction between ground and excited states: any stationary state with the right eigenvalues $\mu_i = M_{ii}$ is a local minimum of this new functional. The second one is that we do not need to add any Lagrange multipliers to $F(U)$ since they are already present in the M operators. Finally we expect the minima of $F(U)$ to be finite, discrete, and separated so as to avoid problems with descent methods being trapped on critical points that are not minima. Indeed, it is very easy for teach the computer to know when this accidental trapping happens since any absolute minimum of F must also be a zero of it, $F(U_0) = 0$.

A remarkable feature of the method that we have outlined above is that to distinguish among the different excited states we have to change both the ad hoc eigenvalues, $\{\mu_u, \mu_w\}$, and the initial data of the minimization method.

We have concentrated on two types of *excited states* of particular interest for applications: the first one is called the *vortex vector soliton* [8], its features being summarized in Figures 5.2(a)–(b). Choosing different initial data for the minimization process, we obtain a second type of excited states which are called *dipole-mode vector solitons* [9]. An example of these asymmetric solutions is depicted in Figure 5.2(d).

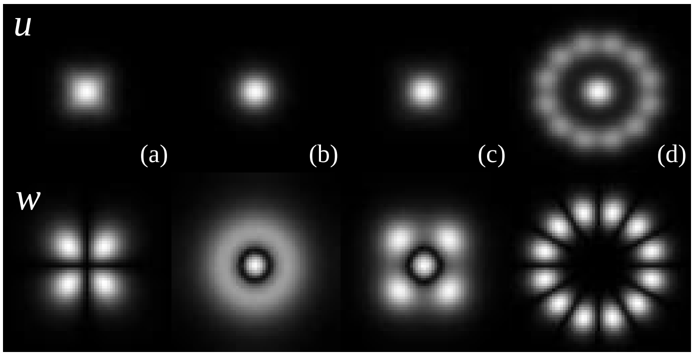

FIG. 5.3. *Different unstable multisolitonic configurations arising from* (5.14) *with a change of the initial conditions for fixed* $\mu_u = -1, \mu_w = -0.3, \kappa = 0.5$.

Depending on the parameters $\mu_{u,w}$ we find different norms of the solution. The fact that our method allows the finding of these nonsymmetric stationary states is very interesting since conventional approaches to the problem have severe difficulties. In fact, the application of the Sobolev preconditioning not only greatly enhances the convergence but is necessary for obtaining convergence.

Nevertheless the method works equally well for more complicated stationary solutions. In Figure 5.3 we show several exotic solutions that are obtained by solving (5.14) with different initial conditions. All of those states are dynamically unstable and could have not been found with traditional minimization methods.

5.5. Performance and grid refinement. In this section we want to analyze the performance of the method from section 5.4 and to introduce a multigrid-like technique to improve convergence rates while looking for more accurate solutions.

The idea of the multigrid technique is to use solutions from coarse-grain grids to calculate better approximations on finer grids [10]. Roughly the algorithm consists of setting a coarse-grain initial data, solving the equation or the variational principle with this initial data until the error is small enough, interpolating the result over a finer grid, and iterating using this new grid until both the error and the spatial discretization of the solution are the ones we desire.

Since we are already working with Fourier modes over discrete grids the logical choice for our algorithm is indeed Fourier interpolation. The idea is to use the expansion from (3.3) *outside of the original grid*, that is,

$$\psi^{(new)}(x) \equiv \sum_n c_n e^{i\mathbf{k}_n \mathbf{x}} \quad \forall \mathbf{x} \in \Omega. \tag{5.17}$$

This approximation is then discretized over a finer grid, resulting in an expansion with a larger number of modes,

$$\psi_m^{(new)} = \sum_n c^{(new)} e^{i\mathbf{k}_\mathbf{n}^{(\mathbf{new})} \mathbf{x}_m}, \tag{5.18}$$

which may be used as the starting point for further iteration.

In our case we have used only two different grids, one with 32×32 points (*coarse grid*) and another with 64×64 points (*fine grid*). We have used two different initial data for our minimization method: either a pair of Hermite modes which resemble

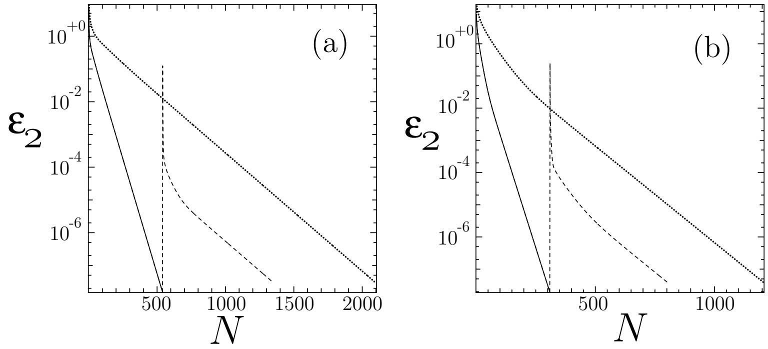

FIG. 5.4. *Dependence of the L^2 error on the number of iterations when looking for* (a) *a* vortex-mode vector soliton *or* (b) *a* dipole-mode vector soliton. *We show results for a grid with* 32 × 32 *points (solid),* 64 × 64 *points (dotted), and* 64 × 64 *points starting from an interpolation of the* 32 × 32 *solution (dashed).*

TABLE 5.1
Results for the search of stationary solutions of (5.1)–(5.2) *with and without grid refinement. Shown are the results for different initial data. The initial data named "interpolated solution" corresponds to taking as initial data the approximated solution on the* 32 × 32 *grid.*

	Initial data type					
	Hermite modes for vortex solitons		Interpolated solution for vortex	Hermite modes for dipole solitons		Interpolated solution for dipole
Grid	32×32	64×64	64×64	32×32	64×64	64×64
Iterations	540	2101	812	496	1206	496
Time (s)	106	2006	757	60	1141	466

the desired shape or the solution of the coarse grid interpolated over the finer grid. As both the evolution of the error in Figure 5.4 and the computation times in Table 5.1 show, interpolation saves a significant amount of time. Indeed, the interpolated solution with only 32×32 Fourier modes is already a good approximation for the fine grid, as it shows the small change of the error in Figure 5.4

6. Conclusions.

In this paper we have shown a numerically efficient way to improve the convergence of several minimization methods using the so-called Sobolev gradients and applied it to different problems which involve nonlinear Schrödinger equations. We have also proven that these gradients represent a preconditioning over the traditional definition of gradients on L^2. In Appendix B we suggest a generalization of this method to different vector spaces and scalar products.

We have presented two different methods for solving our minimization problems: a traditional one, the *imaginary time evolution*, and a new one, *the minimization of a nonlinear free energy*. Both methods have been shown to be suitable for Sobolev preconditioning, giving us two new methods that we call *preconditioned imaginary time evolution* and a *preconditioned free energy*.

We have implemented all four methods using a discrete Fourier basis and an FFT. With these tools we have shown that the Sobolev preconditioning becomes an inexpensive additional step over existing methods. The four resulting solvers have been applied to several realistic problems, and in all tests the nonlinear free energy with the Sobolev preconditioning showed the best convergence rates. Indeed the Sobolev preconditioning has an important effect on convergence, which can be as good as gaining two orders of magnitude over the traditional techniques. Furthermore, in contrast to what happens with finite differences [2], the preconditioning may be applied without significant computational cost.

We have derived a new method for finding excited states of coupled nonlinear Schrödinger equations. This method introduces a new variational principle which is not based on an energy functional but on finding the zeros of a nonlinear operator which corresponds to the equation to be solved. We have also shown how to improve convergence using Fourier interpolation and a two-grid method as a source for better initial approximations of the iterative method. This approach may be extended to more sophisticated multigrid methods.

Appendix A. Existence of minimizers for the nonlinear free energy functional. In this appendix we want to prove the existence of minimizers for the free energy (4.14). Let us write the free energy functional in the following form:

$$F(\psi) = \int \bar{\psi} A_\Omega \psi d^n x + \int \frac{g}{2}|\psi|^4 d^n x + \frac{1}{2}\left(N-\lambda\right)^2, \tag{A.1}$$

where $N = \int |\psi|^2 d^n r$ and

$$A_\Omega = -\frac{1}{2}\triangle + V(\mathbf{x}) - \Omega L_z, \quad \Omega \in [0,1), \tag{A.2}$$

is a positive Hermitian operator $A_\Omega \geq \mu_{min} > 0$.

Let us also define the following spaces of functions defined over $\mathbb{R}^n$. We will work in L^p spaces:

$$L^p = \left\{ \psi : \mathbb{R}^2 \to \mathbb{C} \;/\; \|\psi\|_p := \left(\int |\psi(\mathbf{x})|^p d^n x \right)^{1/p} < +\infty \right\}. \tag{A.3}$$

Also of interest will be the space of functions over which A_Ω is well defined:

$$H_\Omega = \left\{ \psi : \mathbb{R}^2 \to \mathbb{C} \;/\; \|\psi\|_\Omega := \left(\int \bar{\psi}(\mathbf{x}) A_\Omega \psi(\mathbf{x}) \right)^{1/2} < +\infty \right\}. \tag{A.4}$$

Let us remark that the dimensionality of the space, $\mathbb{R}^2$, is important, since for $n \leq 2$ it follows that $H_\Omega \subset L^4$.

With the preceding notation we will state the following relevant theorem.

Theorem A.1. *The free energy functional F given by* (A.1) *has at least one absolute minimum in the set given by the inequalities*

$$0 < \|\psi\|_\Omega^2 \leq \lambda \|\psi\|_2^2 \leq \lambda(\lambda - \mu_{min}).$$

Proof. The first step of the proof will be to show that the domain of F is indeed the whole space H_Ω. Using the positivity of the A_Ω operator we show that

$$\|\psi\|_2 \leq \sqrt{\mu_{min}} \|\psi\|_\Omega, \tag{A.5}$$

which means that $H_\Omega \subset L^2$. We need Sobolev's inequality [11]

$$\|\psi\|_k \leq \|\psi\|_2^{1-d} \|\nabla \psi\|_2^d, \tag{A.6}$$

where $d = n/2 - n/k$, n is the dimensionality of the space, and for us $d = 1/2$. Applying this inequality we obtain the following bound:

$$\|\psi\|_4 \leq \sqrt{\|\psi\|_2 \|\nabla\psi\|_2} \leq \mu_{min}^{\frac{1}{4}} \|\psi\|_\Omega, \tag{A.7}$$

which means that $H_\Omega \subset L^4$. Since $\|\cdot\|_2$, $\|\cdot\|_4$, $\|\cdot\|_\Omega < +\infty$ inside H_Ω we conclude that F as given by (A.1) is well defined over the whole space.

F is also continuous. To prove it let us rewrite the free energy functional as

$$F(\psi) = \|\psi\|_\Omega^2 + \frac{g}{2}\|\psi\|_4^4 + \frac{1}{2}(\|\psi\|_2^2 - \mu)^2, \tag{A.8}$$

and using the bounds (A.5) and (A.7) one shows that

$$|F(\psi) - F(\xi)| \leq \delta(\varepsilon) \quad \forall \xi \ : \ \|\psi - \xi\|_\Omega \leq \epsilon, \tag{A.9}$$

where the constant $\delta(\varepsilon)$ is given by ε and $\|\psi\|_4$.

We will also need to show that F is coercive:

$$\lim_{\|\psi\|\to\infty} \frac{F(\psi)}{\|\psi\|} \geq \alpha > 0. \tag{A.10}$$

Using (A.8) one may show that indeed

$$\frac{F(\psi)}{\|\psi\|_\Omega} \geq \|\psi\|_\Omega, \tag{A.11}$$

and thus the quotient tends to infinity as the norm grows. The continuity and coercitivity of F allow us to use Theorem 1 of [12, section 1.2], which states the existence of at least one minimizer $\{\inf F(u) \ : \ u \in X\}$ of F provided it is a weakly lower semicontinuous and coercive application $F : X \to \mathbb{R}$ in the reflexive Banach space X.

So we know that there is at least one minimum, but we do not know where to look for it. Let us now show how the λ parameter allows us to select different targets for the minimization problem. To do so we define a real one-dimensional function for any given direction $\psi \in H_\Omega$,

$$f(k) \equiv F(k\psi). \tag{A.12}$$

This function is nothing but a polynomial over k,

$$f(k) = kNa_\psi + k^2 N^2 \frac{u_\psi}{2} + \frac{1}{2}(kN - \lambda)^2, \tag{A.13}$$

where $a_\psi = \int \bar{\psi} A \psi / N$ and $u_\psi = \frac{g}{2} \int |\psi|^4 / N^2$ are constants that depend only on the precise direction ψ.

By differentiating the polynomial and imposing $k = 0$ we find that $f'(0) < 0$ at the origin for all possible directions. This means that, as we mentioned above, our Lagrange "multiplier" λ allows us to avoid the useless solution, $\psi = 0$.

Furthermore, we can restrict the location of the minimizer to a surface of a certain norm. By differentiating $f(k)$ we reach

$$(a_\psi - \lambda) + Nk(u_\psi + 1) = 0. \tag{A.14}$$

This equation has a single solution which gives us the norm of minimal energy along the ψ-direction,

$$N_{min}(\psi) = \max\left\{0, \frac{\lambda - a_\psi}{u_\psi + 1}\right\} \leq \lambda - \mu_{min}, \tag{A.15}$$

a value which is bounded above by our Lagrange multiplier λ.

From (A.14) it also follows that for any absolute minimum of the functional ψ_{min}, the expected value of the A_Ω operator must be bounded by the L^2-norm

$$\int \bar{\psi}_{min} A \psi_{min} = \|\psi_{min}\|_\Omega^2 \leq \lambda N(\psi_{min}). \tag{A.16}$$

Otherwise the trivial solution $\psi = 0$ would have less energy than ψ_{min}. We can thus, instead of working with an unknown surface, delimit the location of the minimum to a set which is given by two inequalities, (A.15) and (A.16):

$$W = \{\psi \in H_\Omega \;:\; 0 < N(\psi) \leq \lambda - \mu_{min}, \|\psi\|_\Omega^2 \leq \lambda N(\psi)\}. \qquad \square \tag{A.17}$$

There are several practical consequences of this theorem. First, it states that the problem of finding the minima of $E(\psi)$ subject to fixed norm has one solution, i.e., there exists at least one ground state. Second, but equally important, it proves our Lagrange penalizer $\frac{1}{2}(N - \mu)^2$ to be specially well suited for this problem since it avoids both the useless solution $\psi = 0$ and those with too large norm. And finally it gives us a bounded set in which the minimizer must be. Indeed we can extend this result by proving that we can restrict our search space to a compact superset of W.

THEOREM A.2. *Any absolute minimum, ψ, of the functional F given by* (A.1) *lays inside the compact set of L^2,*

$$\bar{U} = \{\psi \in L^2 \;:\; \|\psi\|_\Omega^2 \leq \lambda \|\psi\|_2^2 \leq \lambda(\lambda - 1)\}.$$

Proof. For the type of spaces that we work with, a set is compact iff it is closed and we can build an ε-net for any positive number ε. The ε-net is a finite set $K_\varepsilon = \{\nu_1, \ldots, \nu_k\}$ such that for each $\psi \in \bar{U}$ there is an element $\nu \in K_\epsilon$ verifying $\|\psi - \nu\|_\Omega < \varepsilon$. Thus compactness is equivalent to the possibility of building an arbitrarily good approximation of our minimizer using a finite but sufficiently large basis of functions.

It is evident that the set $\bar{U}$ is closed in the subspace H_Ω of L^2. Let $\{u_n\} \in \bar{U}$ be a convergent sequence and let u be their limit. Since for each element of the sequence

$$\|u_n\|_\Omega \leq \sqrt{\lambda}\|u_n\|_2 < \lambda(\lambda - 1) \tag{A.18}$$

it is also obvious that

$$\|u\|_\Omega \leq \sqrt{\lambda}\|u\|_2 \leq \lambda(\lambda - 1), \tag{A.19}$$

thus also the limit belongs to $\bar{U}$.

The compactness of the closed set $\bar{U}$ essentially follows from the fact that the eigenstates of A_Ω form a complete basis of H_Ω, and that the eigenvalues of A_Ω form a monotonously growing unbounded set of positive numbers. These eigenstates are of the form

$$\phi_{n,l} = P_n^l(|\mathbf{x}|)\frac{x_1 + ix_2}{|\mathbf{x}|^2} e^{-|\mathbf{x}|^2/2}, \tag{A.20}$$

where P_n^l are Laguerre's generalized polynomials and the corresponding eigenvalues are

$$A_\Omega \phi_{n,l} = \mu_{n,l}\phi_{n,l} = (2n + (1-\Omega)l + 1)\phi_{n,l}, \quad n, l \in \mathbb{N} \cup \{0\}. \tag{A.21}$$

Let us choose any natural number k such that $k+1 > \lambda$. We can split the whole space as a direct sum $H_\Omega = H_0^{k+1} \oplus H_{k+1}^\infty$, where

$$H_j^k = \mathrm{lin}\{\phi_{n,l} \ : \ j \leq 2n + l < k\}. \tag{A.22}$$

The important point is that since H_0^{k+1} is isomorph to $\mathbb{R}^m$ for some natural number m, and $\bar{U}_k = \bar{U} \cap H_0^{k+1}$ lays inside a compact m-dimensional ball of radius $\sqrt{\lambda - 1}$, then we can always find an ε-net for $\bar{U}_k$. Furthermore, by separating

$$\psi = \psi_a + \psi_b, \quad \psi_a \in \bar{U}_k, \psi_b \in H_{k+1}^\infty, \tag{A.23}$$

and using the definition of $\bar{U}_k$ we show that the projection of ψ outside of $\bar{U}_k$ can be made arbitrarily small:

$$\|\psi_b\|_2^2 \leq \frac{\lambda}{k+1} N. \tag{A.24}$$

A direct consequence of this is that for $k > \lambda N/\varepsilon$, an ε-net of $\bar{U}_k$ is also an ε-net of $\bar{U}$, which proves the compactness.

Finally, by inspecting the eigenvalues of A_Ω and using (A.15)–(A.16) it is not difficult to see that the absolute minimum of F must lay in $\bar{U}$. □

Appendix B. Extending the Sobolev gradients. We have shown that redefining the gradient turns out to be a kind of preconditioning over the original choice of the direction of descent. Let us assume that our functional has the following form:

$$E(\psi) = \int \bar{\psi} A \psi + f(|\psi|^2, \mathbf{x}), \tag{B.1}$$

where A is a nonnegative Hermitian operator that may involve some derivatives. Let us also assume that H is a suitable space equipped with the following scalar product:

$$\langle \psi, \phi \rangle = \int \bar{\psi}\,(1 + A)\,\phi, \tag{B.2}$$

which is indeed a scalar product because $A|_H \geq 0$.

Let us rewrite the energy functional in the following way:

$$E(\psi) = \langle \psi, \psi \rangle + \int f(|\psi|^2, \mathbf{x}) - |\psi|^2. \tag{B.3}$$

The Sobolev gradient in H is

$$\nabla_A E = \psi + (1 + A)^{-1}\left[\partial_1 f - \psi\right], \tag{B.4}$$

while the so-called ordinary gradient is $\nabla E = A\psi + \partial_1 f$. Hence the preconditioning nature of the method is recovered:

$$\nabla_A E = (1 + A)^{-1}\,\nabla E. \tag{B.5}$$

We can thus think that the new choice of the scalar product aims at making the linear part of the energy functional close to some quadratic form, $\langle \psi, B\psi \rangle$, such that the new operator B is almost the unity. In our example, indeed, $B\psi = \psi$. We believe that this preconditioning will both enhance the directions of decreasing energy and have a smoothing effect on the nonlinear part. However, the problem is complicated and we know of no proof that these arguments are of general applicability.

A MODIFIED FINITE VOLUME APPROXIMATION OF SECOND-ORDER ELLIPTIC EQUATIONS WITH DISCONTINUOUS COEFFICIENTS[*]

R. EWING[†], O. ILIEV[‡], AND R. LAZAROV[§]

Abstract. A modified finite difference approximation for interface problems in R^n, $n = 1, 2, 3$, is presented. The essence of the modification falls in the simultaneous discretization of any two normal components of the flux at the opposite faces of the finite volume. In this way, the continuous normal component of the flux through an interface is approximated by finite differences with second-order consistency. The derived scheme has a minimal $(2n + 1)$-point stencil for problems in R^n. Second-order convergence with respect to the discrete H^1-norm is proved for a class of interface problems. Second-order pointwise convergence is observed in a series of numerical experiments with one-dimensional (1-D), two-dimensional (2-D), and three-dimensional (3-D) interface problems. The numerical experiments presented demonstrate advantages of the new scheme compared with the known schemes which use arithmetic and harmonic averaging of the discontinuous diffusion coefficient.

Key words. finite volume method, interface problems, finite differences, elliptic problems with variable coefficients

1. Introduction.

Elliptic problems with discontinuous coefficients (often called interface problems) arise naturally in mathematical modeling processes in heat and mass transfer, diffusion in composite media, flows in porous media, etc. These processes are described by the model diffusion equation

$$-\nabla(K\nabla u) = f(x) \quad \text{for } x \in \Omega, \tag{1.1}$$

subject to various boundary conditions. Here $\Omega \subset R^n$ is a bounded polyhedra, and $K(x)$ is a symmetric and uniformly positive definite matrix in Ω which may have a jump discontinuity across a given surface Γ. Due to the nature of the processes, often the fluxes across Γ, defined as $-K\nabla u \cdot \mathbf{n}$, where $\mathbf{n}$ is the normal unit vector to Γ, are smooth, although the coefficients and the derivatives of the solution are discontinuous. Often the surfaces of discontinuity of the coefficient matrix $K(x)$ are called interfaces. The assumption that the solution and the normal component of the flux are continuous through the interface is physical and is often used to close the mathematical problem. In this paper we derive a new class of finite difference schemes for second-order elliptic equations with diagonal coefficient matrix $K(x) = \mathrm{diag}(k_1(x), \ldots, k_n(x))$. The derived schemes are based on finite volume techniques

and use two main assumptions: (1) both the right-hand side $f(x)$ and the normal components of the flux across the interface are smooth enough; (2) the interfaces Γ (i.e., the surfaces where the coefficients $k_i(x)$ have jumps) are parallel to the grid planes (lines).

In the one-dimensional (1-D) case, the first assumption reduces just to the smoothness of the right-hand side $f(x)$. In the multidimensional case, these two assumptions are much more complicated and restrictive. First, the interfaces have to be planes parallel to the coordinate planes. Second, the smoothness properties of the solution will depend on the smoothness of the boundary of the domain, the smoothness of the interface Γ, and the ratio of the coefficient jumps in a pretty complicated manner. Some particular results in this direction can be found in the fundamental work of Kondratiev [11]. In general, when the normal component of the flux is smooth it makes sense to use schemes with better approximation properties away from the corners and the points of intersection of the interface Γ with itself or with the boundary $\partial\Omega$.

Finite difference schemes obtained from discretization of the balance equation over a finite number of control volumes have been widely used in computational practice for differential equations. In the early stages, these were finite difference schemes on rectangular meshes with quite complicated treatment of the coefficients and the right-hand side (see, for example, the classical books [14, 16] and references therein). In [20, 21], Tikhonov and Samarskii derived an $O(h^{2m+1})$-accurate finite difference scheme, where $m \geq 0$ is an arbitrary integer, for two-point boundary value problems. The coefficients of the scheme are, in general, certain nonlinear functionals of the differential equation coefficients, which were assumed to be piecewise smooth.

Further, in [18] Shashkov has extended the balance equation approximation idea to a large class of differential operators (including divergence, gradient, and curl) on quite general quadrilateral grids (see also [7]). This new approach has produced discrete operators which approximate the corresponding differential operators and have the same properties as the continuous ones. For example, the discrete gradient is adjoint in a special inner product to the discrete divergence.

In recent years, the finite volume approach has been combined with finite element method techniques in a new development which is capable of producing accurate approximations on general triangular and quadrilateral grids (see, e.g., [2, 3, 4, 10, 12, 15]). The main advantages of the method are compactness of the discretization stencil, good accuracy, and local discrete conservation. In all of these discretization methods, it is assumed that the possible jumps of the diffusion coefficient are aligned with the finite element partitioning. This means that inside each finite element the diffusion coefficient is sufficiently smooth, and the jumps may occur only at the finite element boundaries.

A straightforward application of the finite volume method to a generic interface problem results in a scheme which uses harmonic averaging of the coefficient. This is particularly important in the case of discontinuous coefficients (see, for example, [16]). Inspecting these schemes, one easily sees that the normal component of the flux at the interface is discretized with a local truncation error $O(h)$. In this paper we present a modification of the classical finite volume method so the normal component of the flux in the new scheme has $O(h^2)$-local truncation for interface problems with smooth normal flux. Note that we do not suppose that the interfaces are aligned with finite volume surfaces. However, we assume that the interfaces are orthogonal to the coordinate axes. Our approach can be viewed as a defect correction of the standard scheme with harmonic averaging of the coefficient, since it takes into account the next term in the Taylor expansion of the flux. This correction does preserve the standard $(2n+1)$-point overall stencil and uses data only from the neighboring 2^n cells. We were able to increase the order of the local truncation error and at the same time preserve the standard stencil by discretizing the normal components of the flux at the opposite sides of the finite volume as a couple.

Recently, Il'in [9] and LeVeque and Li [13] have derived second-order finite difference approximations of the two-dimensional (2-D) interface problem using similar assumptions about the normal flux through the interface. However, in order to get a second-order scheme, Il'in [9] uses a larger stencil than the compact $(2n+1)$-point stencils for problems in R^n, while LeVeque and Li [13] use Taylor expansions for the solution around the interface. The latter paper does not consider the discretization of the fluxes, and this can be viewed as a disadvantage when the problem requires their accurate reconstruction, e.g., with velocities in porous media or the heat fluxes in thermal problems. Below we propose a homogeneous difference scheme for a class of 1-D, 2-D, and three-dimensional (3-D) elliptic problems with variable discontinuous coefficients with arbitrarily located interfaces. The coefficients of the scheme are obtained from the coefficients of the differential equation by a simple formula. The approach of LeVeque and Li from [13] requires solving small systems of linear equations for determining these coefficients at each point near the interface. Moreover, our scheme is easily extendible to fine-scale inhomogeneities of the coefficients (finer than the grid size). However, our approach deals only with interfaces orthogonal to the coordinate axes, while the approach from [13] can treat arbitrarily located interfaces.

Below we summarize advantages and disadvantages of the new scheme in comparison with known ones for grids not aligned with the diffusion coefficient jump. On the positive side are the following features of the new scheme: (1) the scheme has $O(h^2)$-local truncation error for the normal component of the flux; recall that the standard schemes with arithmetic and harmonic averaging of the coefficient at the interface have, in general, local truncation error $O(1)$ and $O(h)$, respectively; (2) the proposed scheme is algebraically equivalent to a scheme which is second-order consistent with the interface differential problem; (3) the numerical experiments for problems with large jumps of the diffusion coefficient demonstrate that the new scheme is orders of magnitude more accurate than the scheme which uses harmonic averaging.

On the negative side are the following two main disadvantages: (1) in general, the scheme is only asymptotically (for $h \to 0$) locally conservative; (2) the corresponding matrix is a nonsymmetric M-matrix; this will add some costs to the solution method for the algebraic problem. However, the numerical experiments on a wide class of problems with discontinuous coefficients show that the scheme is so accurate that these two disadvantages cannot diminish the value of the method.

We have run several numerical experiments in order to validate the new scheme and to compare it with the known schemes. These experiments include solving 1-D, 2-D, and 3-D interface problems with known analytical solutions, as well as solving a 2-D problem with a singular solution. Also, we considered problems where the interfaces are aligned with the finite volume surfaces, as well as problems with arbitrarily located interfaces, orthogonal to the coordinate axes. Pointwise second-order convergence is observed in numerical experiments. Note that the accuracy of the new scheme observed in our experiments is almost uniform with respect to the jump of coefficients, and it is comparable with the accuracy of the solution of the Poisson equation with a constant diffusion coefficient. What is even more interesting is that this conclusion is valid not only for the case of interfaces aligned with the finite volume boundaries but also for the nonaligned case. Meanwhile, for problems with large jumps of the coefficients, the accuracy of the scheme with harmonic averaging is very sensitive to the jump size, and its accuracy is orders of magnitude less than the accuracy of the new scheme. Numerical experiments for the so-called thin lenses problem are especially interesting. In this case our scheme provides very accurate results even on very coarse grids, in considerable contrast with the other known schemes.

The paper is organized as follows. Section 2 is devoted to the derivation and study of modified finite volume schemes for 1-D problems. Section 3 contains the formulation of the new finite volume scheme for multidimensional interface problems. Finally, section 4 summarizes and discusses the results of the numerical experiments of a series on interface problems in R^n, $n = 1, 2, 3$.

2. Modified finite volume discretization for 1-D problems. In order to illustrate our approach, we shall first consider the 1-D case and rewrite (1.1) into its mixed form: find $u(x)$ such that

$$\frac{\partial W}{\partial x} = f(x), \quad W = -k(x)\frac{\partial u}{\partial x}, \quad 0 < x < 1, \quad u(0) = 0, \quad u(1) = 0. \tag{2.1}$$

Here $k = k(x) > k_0$ is a known diffusion coefficient, $W(x)$ is the flux dependent variable, and $f(x)$ is the given source term. Conditions for continuity of the function and of the flux through interface points ξ are added:

$$[u] = [W] = 0 \quad \text{for } x = \xi. \tag{2.2}$$

Here $[u]$ denotes the difference of the right and left limits of u at the point of discontinuity. The main assumptions for this problem are (1) the coefficient $k(x)$ has a finite number of jump discontinuities and in the closed intervals between the jumps $k(x)$ is twice continuously differentiable; (2) the right-hand side $f(x)$ is continuous and has the continuous first derivative on the closed interval $[0, 1]$.

We introduce a standard uniform cell-centered grid $x_0 = 0$, $x_1 = h/2$, $x_i = x_{i-1} + h$, $i = 2, \ldots, N$, $x_{N+1} = 1$, where $h = 1/N$. Note that the endpoints $x = 0$ and $x = 1$ are part of the grid, but they are at $h/2$ distance from their neighboring grid points. This type of shifted grid is slightly inconvenient for Dirichlet boundary conditions, but it is natural and very convenient for computations when the boundary condition involves the flux W. The internal grid points can be considered as centered around the volumes $V_i = (x_{i-\frac{1}{2}}, x_{i+\frac{1}{2}})$, where $x_{i+\frac{1}{2}} = x_i + \frac{1}{2}h$, $x_{i-\frac{1}{2}} = x_i - \frac{1}{2}h$. The values of a function f defined at the grid points x_i are denoted by f_i. Nonuniform grids can be treated in a similar way. A reason to work with cell-centered grids is that they are widely used, say, in the computational fluid dynamics. Considering, for example, nonisothermal fluid-structure interaction problems, one has to solve problems close to the one considered here. However, our approach is defined locally, at a particular finite volume level, and it can work with standard vertex-based grids as well.

The finite volume method exploits the idea of writing the balance equation over the finite volume V_i, i.e., integrating (2.1) over each volume V_i:

$$W_{i+\frac{1}{2}} - W_{i-\frac{1}{2}} = h\ \varphi_i, \quad \varphi_i = \frac{1}{h}\int_{x_{i-\frac{1}{2}}}^{x_{i+\frac{1}{2}}} f(x)dx, \quad i = 1, 2, \ldots, N. \tag{2.3}$$

Next, we rewrite the flux equation in the form

$$-\frac{\partial u}{\partial x} = \frac{W(x)}{k(x)}$$

and integrate this expression over the interval (x_i, x_{i+1}):

$$-(u_{i+1} - u_i) = -\int_{x_i}^{x_{i+1}} \frac{\partial u}{\partial x} dx = \int_{x_i}^{x_{i+1}} \frac{W(x)}{k(x)} dx. \tag{2.4}$$

We assume that flux $W(x)$ is two times continuously differentiable on the interface so it can be expanded around the point $x_{i+\frac{1}{2}}$ in Taylor series

$$W(x) = W_{i+\frac{1}{2}} + (x - x_{i+\frac{1}{2}}) \frac{\partial W_{i+\frac{1}{2}}}{\partial x} + \frac{(x - x_{i+\frac{1}{2}})^2}{2} \frac{\partial^2 W(\eta)}{\partial x^2}, \quad \eta \in (x_i, x_{i+1}). \tag{2.5}$$

After replacing the first derivative of the flux at $x_{i+\frac{1}{2}}$ by a two-point backward difference, we get the following approximation of (2.4):

$$\begin{aligned} -(u_{i+1} - u_i) = W_{i+\frac{1}{2}} &\int_{x_i}^{x_{i+1}} \frac{dx}{k(x)} \\ &+ \frac{W_{i+\frac{1}{2}} - W_{i-\frac{1}{2}}}{h} \int_{x_i}^{x_{i+1}} \frac{(x - x_{i+\frac{1}{2}})}{k(x)} dx + O(h^3). \end{aligned} \tag{2.6}$$

Finally, we rewrite this equation in the following basic form:

$$-k^H_{i+\frac{1}{2}} \frac{u_{i+1} - u_i}{h} = W_{i+\frac{1}{2}} + a_{i+\frac{1}{2}}(W_{i+\frac{1}{2}} - W_{i-\frac{1}{2}}) + \psi_i, \tag{2.7}$$

where

$$k^H_{i+\frac{1}{2}} = \left(\frac{1}{h} \int_{x_i}^{x_{i+1}} \frac{dx}{k(x)} \right)^{-1}, \quad a_{i+\frac{1}{2}} = k^H_{i+\frac{1}{2}} \frac{1}{h^2} \int_{x_i}^{x_{i+1}} \frac{x - x_{i+\frac{1}{2}}}{k(x)} dx, \quad \psi_i = O(h^2). \tag{2.8}$$

Here $k^H_{i+\frac{1}{2}}$ is the well-known harmonic averaging of the coefficient $k(x)$ over the cell (x_i, x_{i+1}), which has played a fundamental role in deriving accurate schemes for discontinuous coefficients (see, e.g., [14, 16]). This presentation of the flux $W(x)$ is a starting point for our discretization. Since we have assumed that the flux is smooth, then the consecutive terms in the right-hand side in (2.7) are $O(1)$, $O(h)$, and $O(h^2)$, respectively. Truncation of this sum after the first term produces the well-known scheme of Samarskii [16] with harmonic averaging of the coefficient. This scheme is $O(h)$-consistent at the interface points and second-order accurate in the discrete H^1-norm. Further, we call this scheme the *harmonic averaging* (HA) scheme. The scheme we shall derive takes the two terms of the presentation (2.7) and disregards the ψ_i-term. Let $F_{i+\frac{1}{2}}$ and $F_{i-\frac{1}{2}}$ denote the approximation to the exact fluxes $W_{i+\frac{1}{2}}$ and $W_{i-\frac{1}{2}}$, respectively, and let y_i denote the approximate values of the exact solution $u(x_i)$. Thus we get the following relations:

$$-k^H_{i+\frac{1}{2}} \frac{y_{i+1} - y_i}{h} = F_{i+\frac{1}{2}} + a_{i+\frac{1}{2}}(F_{i+\frac{1}{2}} - F_{i-\frac{1}{2}}), \tag{2.9}$$

$$-k^H_{i-\frac{1}{2}} \frac{y_i - y_{i-1}}{h} = F_{i-\frac{1}{2}} + a_{i-\frac{1}{2}}(F_{i+\frac{1}{2}} - F_{i-\frac{1}{2}}). \tag{2.10}$$

The two relations above allow us to derive the final expression for $F_{i+\frac{1}{2}} - F_{i-\frac{1}{2}}$, which is needed in the balance equation (2.3): subtract (2.10) from (2.9) to get

$$(1 + a_{i+\frac{1}{2}} - a_{i-\frac{1}{2}})(F_{i+\frac{1}{2}} - F_{i-\frac{1}{2}}) = -k^H_{i+\frac{1}{2}} \frac{y_{i+1} - y_i}{h} + k^H_{i-\frac{1}{2}} \frac{y_i - y_{i-1}}{h}. \tag{2.11}$$

Since the grid points x_0 and x_{N+1} are shifted by $h/2$ from their neighbors, the finite difference equations at x_1 and x_N have to be modified. Combining (2.11) with (2.3), we get the following finite difference approximation of the differential problem (2.1):

$$L_h y_i = \varphi_i \quad \text{for } i = 1, \ldots, N, \tag{2.12}$$

where

$$L_h y_i \equiv \begin{cases} -\frac{4}{3}\frac{1}{h}\left(k^H_{\frac{3}{2}}\frac{y_2 - y_1}{h} - k^H_{\frac{1}{2}}\frac{2y_1}{h}\right) & \text{for } i = 1, \\ -\left(1 + a_{i+\frac{1}{2}} - a_{i-\frac{1}{2}}\right)^{-1}\frac{1}{h}\left(k^H_{i+\frac{1}{2}}\frac{y_{i+1} - y_i}{h} - k^H_{i-\frac{1}{2}}\frac{y_i - y_{i-1}}{h}\right), & i \neq 1, N, \\ -\frac{4}{3}\frac{1}{h}\left(-k^H_{N+\frac{1}{2}}\frac{2y_N}{h} - k^H_{N-\frac{1}{2}}\frac{y_N - y_{N-1}}{h}\right) & \text{for } i = N. \end{cases} \tag{2.13}$$

Here in the first and last difference equations, we have explicitly imposed the homogeneous boundary conditions $y_0 = 0$ and $y_{N+1} = 0$. Further, in the text we refer to this approximation as a scheme using the *improved harmonic averaging* (IHA) scheme.

REMARK 2.1. *For $a_{i+\frac{1}{2}} = a_{i-\frac{1}{2}} = 0$, the operator L_h is the well-known finite difference operator corresponding to harmonic averaging of the diffusion coefficient, which is second-order accurate in the discrete H^1-norm* (*see, e.g.,* [16]).

REMARK 2.2. *Near the boundary the discretization* (2.13) *has a special form due to the use of a cell-centered grid. The well-known discretization for such grids uses the factor* 1 *instead of* $\frac{4}{3}$. *Although the difference scheme with the factor* 1 *is not consistent with the differential problem at the points x_1, x_N, it is proven* (*see, for example,* [23]) *that this does not influence the order of convergence of the scheme. We prefer the factor* $\frac{4}{3}$ *because the fluxes at $x = 0$ and $x = 1$ are $O(h^2)$-accurate in this case. Moreover, the numerical experiments of numerous test problems with continuous and discontinuous coefficients showed that the constant in the convergence was smaller when the discretization* (2.12)–(2.13) *was used.*

REMARK 2.3. *Alternative ways for deriving three-point approximations of* 1*-D problems in the framework of the finite element method are discussed, for example, in* [1, 5, 22]. *In the latter work, the finite element spaces involve the local solutions of the problem* (2.1), *while in the former work the schemes are derived by the dual mixed hybrid formulation.*

In our computations for comparison of the performance of the new scheme, we also use the scheme (2.12) in which $a_{i+\frac{1}{2}} = a_{i-\frac{1}{2}} = 0$ and $k^H_{i+\frac{1}{2}}$ is replaced by $0.5(k_i + k_{i+1})$. This scheme is referred to as the *arithmetic averaging* (*AA*) scheme.

Accurate computations of the fluxes are needed in many applications. The following expression approximates the continuous flux with second-order accuracy (even at the interface):

$$F_{i+\frac{1}{2}} = \frac{-k^H_{i+\frac{1}{2}}\frac{y_{i+1} - y_i}{h}\left(1 - a_{i-\frac{1}{2}}\right) - k^H_{i-\frac{1}{2}}\frac{y_i - y_{i-1}}{h}\left(a_{i+\frac{1}{2}}\right)}{\left(1 + a_{i+\frac{1}{2}}\right)\left(1 - a_{i-\frac{1}{2}}\right) + a_{i+\frac{1}{2}}a_{i-\frac{1}{2}}} = W_{i+\frac{1}{2}} + O(h^2).$$

The new scheme approximates the fluxes to second-order accuracy, *independent* of the positions of the discontinuity of the coefficient $k(x)$. The price we paid is the necessity to evaluate the expressions $k^H_{i+\frac{1}{2}}$ and $a_{i+\frac{1}{2}} - a_{i-\frac{1}{2}}$ with an error no larger than $O(h^2)$. We shall assume that any point ξ where the coefficient $k(x)$ is discontinuous is known and can be presented in the form $\xi = x_i + \theta h$ for some i and $0 \leq \theta \leq 1$.

Obviously, if $\theta = 0$ or $\theta = 1$ (i.e., when the interfaces are aligned with grid nodes), then $a_{i+\frac{1}{2}} - a_{i-\frac{1}{2}} = O(h^2)$. Thus, disregarding this term and taking into account that $k^H_{i+\frac{1}{2}} = k(x_{i+\frac{1}{2}}) + O(h^2)$, we end up with a scheme which is the same as those obtained from finite difference or linear finite element approximations. Further, if the diffusion coefficient $k(x)$ has jump discontinuities and $0 < \theta < 1$, but the flux is still smooth, the second term in the right-hand side in (2.6) will be essential to derive a better approximation. *Note that accounting for this second term is the main difference between our approach and the standard finite volume discretization of interface problems.* In short, this term does not affect the order of convergence, but it allows us to improve the constant of convergence in the case of discontinuous coefficients and to derive more accurate difference schemes.

Now we consider some particular realizations of this scheme. If the point of discontinuity ξ is in the subinterval $[x_i, x_{i+1}]$: $\xi = x_i + \theta h$, where $0 \leq \theta \leq 1$, then the approximation of the integral in $k^H_{i+\frac{1}{2}}$ is done by splitting it into integrals over (x_i, ξ) and (ξ, x_{i+1}) and then applying the trapezoidal or midpoint rule for each integral. This approach will produce accurate enough evaluation of $k^H_{i+\frac{1}{2}}$. The following formula will be only $O(h)$-accurate:

$$k^H_{i+\frac{1}{2}} \approx \left(\frac{\theta}{k_i} + \frac{1-\theta}{k_{i+1}} \right)^{-1}.$$

Note that in the case of piecewise constant coefficients, this formula is exact. However, it is based on the use of left and right rectangular quadrature formulas, and it might not be accurate enough in the general case. Second-order accurate evaluation of the integrals is given by

$$k^H_{i+\frac{1}{2}} \approx \left[\frac{\theta}{2} \left(\frac{1}{k_i} + \frac{1}{k_{\xi-0}} \right) + \frac{1-\theta}{2} \left(\frac{1}{k_{i+1}} + \frac{1}{k_{\xi+0}} \right) \right]^{-1}. \tag{2.14}$$

Note that $k_{\xi-0}, k_{\xi+0}$ are known from the second interface condition (2.2).

Further, we continue with the second integral in (2.8). Our aim is to obtain a second-order approximation for the flux $W(x)$. We again split the integral into two integrals and apply the following trapezoidal rule for each of the two integrals:

$$\begin{aligned} \frac{1}{h^2} \int_{x_i}^{x_{i+1}} \frac{(x - x_{i+1})}{k(x)} dx &= \frac{1}{h^2} \int_{x_i}^{\xi} \frac{(x - x_{i+\frac{1}{2}})}{k(x)} dx + \frac{1}{h^2} \int_{\xi}^{x_{i+1}} \frac{(x - x_{i+\frac{1}{2}})}{k(x)} dx \\ &= \frac{\theta}{2} \left(\frac{\theta - 0.5}{k_{\xi-0}} - \frac{0.5}{k_i} \right) + \frac{1-\theta}{2} \left(\frac{0.5}{k_{i+1}} + \frac{\theta - 0.5}{k_{\xi+0}} \right) + O(h^2). \end{aligned} \tag{2.15}$$

The case of piecewise constant coefficient $k(x)$ is very important for the applications. In this case the formulas presented above are exact and reduce to

$$k^H_{i+\frac{1}{2}} = \left(\frac{\theta}{k_i} + \frac{1-\theta}{k_{i+1}} \right)^{-1} \quad \text{and} \quad a_{i+\frac{1}{2}} = \frac{1}{2} \frac{\theta(1-\theta)(k_i - k_{i+1})}{(1-\theta)k_i + \theta k_{i+1}}. \tag{2.16}$$

Obviously, if the point of discontinuity ξ is a midpoint of the grid, i.e., $\xi = x_{i+\frac{1}{2}}$, then $\theta = 1/2$ and

$$k^H_{i+\frac{1}{2}} = 2 \left(\frac{1}{k_i} + \frac{1}{k_{i+1}} \right)^{-1} \quad \text{and} \quad a_{i+\frac{1}{2}} = \frac{1}{4} \left(\frac{k_i - k_{i+1}}{k_i + k_{i+1}} \right).$$

It is reasonable to assume that the step size h is so small that if there is a jump in the coefficient $k(x)$ in the interval (x_i, x_{i+1}), then $k(x)$ is smooth at the two neighboring intervals (x_{i-1}, x_i) and (x_{i+1}, x_{i+2}). Thus

$$1 + a_{i+\frac{1}{2}} - a_{i-\frac{1}{2}} = 1 + \frac{\theta(1-\theta)}{2}\left(\frac{k_i - k_{i+1}}{(1-\theta)k_i + \theta k_{i+1}}\right) + O(h^2) \geq 1/2.$$

Similarly, we also have an estimate from above: $1 + a_{i+\frac{1}{2}} - a_{i-\frac{1}{2}} \leq 3/2$. These two estimates will guarantee that the finite difference scheme is well conditioned.

The following result is valid.

Proposition 1. *Assume that the coefficient $k(x)$ is a piecewise C^1-function and has a finite number of jump discontinuities, the grid is such that the discontinuities are at the points $x_{i+\frac{1}{2}}$, and the source term $f(x)$ is a C^1-function on* $(0,1)$. *Then the finite difference scheme* (2.12), (2.8), (2.14), (2.15) *is second-order accurate in the discrete H^1-norm; i.e., the error $e_i = u(x_i) - y_i$ satisfies the estimate*

$$||e||_{H^1} \equiv ||y-u||_{H^1} \equiv \left(\sum_{i=1}^{N} k^H_{i-1/2}(e_i - e_{i-1})^2/h\right)^{1/2} \leq M\ h^2.$$

The second-order of accuracy in H^1 follows from the second-order of discretization for the fluxes by using the classical technique for deriving a priori estimates for the solution of the finite difference scheme (see, e.g., [16, 17]).

Remark 2.4. *Note that if $f(x) \equiv 1$, then $W''(x) \equiv 0$ and the local truncation error is identically zero. This means that the IHA scheme is exact (i.e., it reproduces exactly the solution at the grid points) for problems with a piecewise constant diffusion coefficient and a constant right-hand side, while the HA scheme is exact only for homogeneous problems. Thus the HA scheme reproduces exactly piecewise linear solutions, while the IHA scheme reproduces exactly piecewise quadratic solutions.*

3. Modified finite volume discretization for 3-D problems. In this section we shall introduce the finite difference scheme for the equation (1.1) in R^3 with homogeneous Dirichlet boundary conditions on a rectangular domain Ω. Now we introduce the flux $\mathbf{W} = -K(x)\nabla u$. If the diffusion coefficient is discontinuous on a certain surface (so-called interface denoted by Γ), then two conditions for continuity of the solution and the normal component of the flux through the interface are added:

$$[u] = 0, \quad [\mathbf{W}\cdot\mathbf{n}] = 0, \quad x \in \Gamma, \tag{3.1}$$

where $[g]$ denotes the difference of the limit values of the function g from both sides of Γ and $\mathbf{n}$ is the unit vector normal to Γ.

In this paper we consider multidimensional problems that can be discretized in a coordinatewise way. This means that the interfaces are parallel to the faces of the finite volumes, and the diffusion coefficient matrix $K(x)$ is a diagonal. Thus the discretization of a 3-D problem is obtained as a tensor product discretization of three 1-D problems (like the one investigated in the preceding section).

The finite volume approach is used for discretizing the above equation on cell-centered grids which are tensor products of grids in each direction. The grid sizes and the number of the nodes in the x_i-direction is h_i and N_i for $i = 1,2,3$. The grid points are denoted by $(x_{1,i}, x_{2,j}, x_{3,k})$, where $0 \leq i \leq N_1$, $0 \leq j \leq N_2$, $0 \leq k \leq N_3$. The values of the unknown function are related to the volumes' centers. The discretization at the internal points is based on the local flux balance for the finite volume around the point. For the finite volume V_P corresponding to node P this balance is

$$\int_{\partial V_P} \mathbf{W}\cdot\mathbf{n}ds = h_1h_2h_3\varphi_P, \quad \varphi_P = \frac{1}{h_1h_2h_3}\int_{V_P} f(x)dx. \tag{3.2}$$

Here $\mathbf{n}$ is the unit outward normal to the volume boundary ∂V_P. Next, we approximate the integrals over the volume faces by the midpoint rule to get

$$h_2h_3\left(W_e - W_w\right) + h_3h_1\left(W_n - W_s\right) + h_1h_2\left(W_t - W_b\right) = h_1h_2h_3\varphi_P + O(h^2). \tag{3.3}$$

Subscripts with capital letters W, E, S, N, B, T are used to denote the values at the west, east, south, north, bottom, and top neighboring grid points; and the subscript P is used for the center of the stencil, while w, e, s, n, b, t stand for the respective values in the center points of the control volume faces. For example, $W_e = -k_1\frac{\partial u}{\partial x_1}|_{x_e}$ is the flux through a face perpendicular to the axis x_1 at the point $x_e = (x_{1,i+\frac{1}{2}}, x_{2,j}, x_{3,k})$, and the grid point P is denoted by $x_P = (x_{1,i}, x_{2,j}, x_{3,k})$. The grid point east of P is denoted by $x_E = (x_{1,i+1}, x_{2,j}, x_{3,k})$, while that north of P is $x_N = (x_{1,i}, x_{2,j+1}, x_{3,k})$, etc. Further, we approximate the differences $W_e - W_w$, $W_n - W_s$, and $W_t - W_b$ as 1-D fluxes in the directions x_1, x_2, and x_3, correspondingly, using formula (2.11) in each direction.

In the particular case when the diffusion coefficient is a constant within any finite volume and the interfaces are aligned with finite volume surfaces (i.e., $\theta = 0.5$), the finite volume scheme, approximating the 3-D problem and preserving second-order of discretization for the normal components of the fluxes through interfaces, can be written as

$$\begin{aligned} &h_2h_3\mu_1^{-1}\left[k_e^H\,\frac{y_E - y_P}{h_1} - k_w^H\frac{y_P - y_W}{h_1}\right] + h_3h_1\mu_2^{-1}\left[k_n^H\frac{y_N - y_P}{h_2} - k_s^H\frac{y_P - y_S}{h_2}\right] \\ &\quad + h_1h_2\mu_3^{-1}\left[k_u^H\frac{y_T - y_P}{h_3} - k_d^H\frac{y_P - y_B}{h_3}\right] = h_1h_2h_3\varphi_P, \end{aligned} \tag{3.4}$$

where

$$\begin{aligned} \mu_1 &= \left[1 + \frac{1}{4}\left(\frac{k_{1,P} - k_{1,E}}{k_{1,P} + k_{1,E}} + \frac{k_{1,P} - k_{1,W}}{k_{1,P} + k_{1,W}}\right)\right], \\ \mu_2 &= \left[1 + \frac{1}{4}\left(\frac{k_{2,P} - k_{2,N}}{k_{2,P} + k_{2,N}} + \frac{k_{2,P} - k_{2,S}}{k_{2,P} + k_{2,S}}\right)\right], \\ \mu_3 &= \left[1 + \frac{1}{4}\left(\frac{k_{3,P} - k_{3,T}}{k_{3,P} + k_{3,T}} + \frac{k_{3,P} - k_{3,B}}{k_{3,P} + k_{3,B}}\right)\right]. \end{aligned}$$

Here k_e^H stands for harmonic averaging of $k_1(x)$ in the direction east from P, i.e., over the interval $(x_{1,i}, x_{1,i+1})$, $k_{1,P}$ is its value at the point P, etc. These finite difference equations are written for all internal points except those for which the $(2n + 1)$-stencil includes points at the boundary. For these points, essentially one has to add the modification of the approximation at the direction of the neighboring boundary point. Such modification has been introduced for 1-D problems in section 2 (see formulas (2.12)–(2.13)). To close the system to this set of finite difference equations, we add the equations accounting for the Dirichlet boundary conditions.

Note that in the case when the interfaces are not aligned with the finite volume surfaces (but are orthogonal to the axes), the multidimensional θ-HA scheme, as well as the multidimensional θ-IHA scheme, are derived as tensor products of the respective 1-D schemes.

It is obvious that the finite difference scheme can be written as a linear system of algebraic equations with a nonsymmetric M-matrix. If the coefficients $k_i(x)$, $i = 1,\dots,n$, are C^2-functions in the whole domain, then the factors μ_1, μ_2, and μ_3 are all of the order $O(h^2)$ and the nonsymmetry is negligible. On the other hand, $\mu_i > 1/2$, $i = 1,2,3$, for grids with jump discontinuities of the coefficient $k_i(x)$ parallel to the grid faces, regardless of the size of the jump. Therefore, although the condition number of the linear system will depend on the size of the jump, this dependence will be the same as in the case of arithmetic or harmonic averaging. The finite difference scheme (3.4) is the IHA scheme that has been used in our numerical experiments for both 2-D and 3-D problems, in the case when the interfaces are aligned with the finite volume surfaces. The multidimensional θ-HA scheme and θ-IHA scheme are used in the nonaligned case.

4. Numerical experiments.

A series of computational experiments were performed in order to experimentally study the accuracy and the convergence rate of the new scheme and to compare it with known schemes for 1-D, 2-D, and 3-D interface problems. Two kind of problems were solved in 1-D and 2-D cases. The first one is a problem with the known analytical solution with the right-hand side being calculated from the known solution. The second one is a problem with the right-hand side identically equal to 1. Note that in the 1-D case this problem also has an analytical solution. Only problems with known analytical solutions are solved in the 3-D case.

The relative discrete maximum norm (denoted as C-norm) of the solution error is calculated as $\max|u-y|/\max|u|$. Also, the relative discrete L_2-norm of the solution error is computed as $(\sum_V \operatorname{meas}(V)(u-y)^2)^{\frac{1}{2}}/\max|u|$. Here the operations max and the summation are considered over all grid nodes. The relative C- and L_2-norms of the error are reported in the tables below for cases when the analytical solution is known. In all tables we have used the following shorthand notations: B stands for the problem when $k(x) \equiv 1$; i.e., we solve the Poisson equation; AA stands for schemes with arithmetic averaging; HA stands for schemes with harmonic averaging; and, finally, IHA is used for a heading with the results obtained by the new scheme which uses improved harmonic averaging.

4.1. Numerical experiments for 1-D problems.

Results from the problem computation with exact solution $u^{ex} = \frac{1}{k}\sin(\frac{\pi x}{2})(x-\frac{1}{2})(1+x^2)$ and diffusion coefficient equal to 1 for $0 < x < 0.5$ and equal to 10^{-4} for $0.5 < x < 1$ are presented in Tables 4.1 and 4.2.

The results from solving the Dirichlet problem with the right-hand side identically equal to 1 are presented in Tables 4.3 and 4.4. The diffusion coefficient in this case is 1 for $0 < x < 0.4$, 10^{-3} for $0.4 < x < 0.7$, and 10 for $0.7 < x < 1$. Note that this problem has a piecewise quadratic solution.

The results from numerical experiments in the 1-D case demonstrate that the new scheme has a much smaller constant of convergence than the scheme based on harmonic averaging. Both schemes asymptotically converge with second-order, as predicted by the theory. Tables 4.3 and 4.4 confirm the theory that the IHA scheme is exact for interface problems with piecewise quadratic solutions.

4.2. Numerical experiments for 2-D problems.

Here we consider an isotropic case, i.e., $k_i(x) = k(x)$, $i = 1,\dots,n$. First of all, a 2-D interface problem with a different coefficient in four subregions and with a known analytical solution is solved.

exact ≡ the difference scheme is exact for this problem.

We compute the solution using schemes obtained from HA and IHA averaging of the diffusion coefficient. The notations HA and IHA are preserved for the case when $\theta = \frac{1}{2}$, while notations θ-HA and θ-IHA are used for other values of θ. Two sets of values for the diffusion coefficient in the four subregions are used in order to demonstrate the influence of the size of the jump discontinuity on the accuracy of the schemes. The results from these computations are presented in Tables 4.5 and 4.6 for the first set and in Tables 4.7 and 4.8 for the second set.

Let us discuss the results presented in Tables 4.5–4.8. The scheme with harmonic averaging of $k(x)$ is $O(h^2)$-accurate. The new scheme also converges with second-order, but the constant in front of the convergence factor is two orders of magnitude smaller for the example with large jumps of the coefficients. This means that in practical computations the new scheme allows computations on significantly coarser grids in comparison with known schemes. The accuracy of the new scheme is almost uniform with respect to the size of the jump discontinuity, as one can observe from the tables, and it is comparable with the accuracy of computing the Poisson equation with a constant coefficient (denoted as Case B in the tables). An interesting fact is that the IHA scheme preserves this behavior even in the case when interfaces are not aligned with the finite volume boundaries. At the same time, the accuracy of the HA scheme depends on the jump discontinuity. Note that the larger the jump of the coefficient, the better the advantages of the IHA scheme are seen.

The results in the nonaligned case need special discussion. It was observed in the experiments that the θ-schemes converge uniformly (with respect to refinement of the grid) with second-order only if the grid is refined in a such a way that θ remains constant. In our experiments θ varies from one grid to the next, and this is the reason for the nonmonotone values obtained for the ratios of the norms of the error on consecutive grids. A possible explanation of such a behavior is that the reminder term is different for the cases $0 \leq \theta \leq 0.5$ and $0.5 \leq \theta \leq 1$. This phenomenon needs further detailed investigations.

As a second 2-D example, an interface problem with the right-hand side identically equal to 1 is considered. Dirichlet boundary conditions on the east and west sides and zero Neumann boundary conditions on the north and south sides are prescribed. The computed problem is also known as a thin lenses problem: the diffusion coefficient is very small within two thin lenses and is equal to 1 elsewhere. In our computations the lenses are $\{0.4 < x_1 < 0.9;\ 0.2 < x_2 < 0.25\}$ and $\{0.2 < x_1 < 0.8;\ 0.7 < x_2 < 0.75\}$. The diffusion coefficient of the lenses has value 10^{-4}. The analytical solution of the problem is not known. The solution of the problem has singularities around corners of the lenses, and $u \in W_2^{1+\beta}$, where $\beta \sim \frac{1}{3}$ for our examples. (For details see [19].) The computed solutions are presented in Figure 4.1 for the AA scheme, in Figure 4.2 for the HA scheme, and in Figure 4.3 for the IHA scheme. The left plot on any figure presents the solution on a coarse 22×22 grid, while the right plot presents the solution on a fine 162×162 grid. Note that only one layer of grid cells in the x_2 direction is laying inside a lens on the coarse grid.

The maximum values of the computed numerical solutions are presented in Table 4.9. In this case we refine the grid by tripling the number of nodes in any direction so we have nested grids, and we can monitor the value of the numerical solution at a fixed grid point on the plane.

Table 4.9
2-D thin lenses problem; the maximum value of the numerical solution.

Grid	AA	HA	IHA
22 × 22	1.0000	7.1186	3.9940
62 × 62	2.2620	4.3444	3.9952
182 × 182	3.3417	4.0356	3.9961
542 × 542	3.7970	4.0012	3.9965

Solutions computed by the IHA scheme are very close to the exact solution even when coarse grids are used. (The first three digits of the maximum value of the solution are correct even on the coarsest grid.) This fact is confirmed by the plots on Figure 4.3, as well as by the data in Table 4.9. At the same time, the HA scheme produces rough approximation to the solution on the coarse grid. The AA scheme is practically unusable for coarse grids and produces inaccurate solutions even on a very fine grid.

It should be noted that, in addition to the thin lenses problem, we have also computed the above example in the cases when the diffusion coefficient takes value 10^{-4} in larger domains (say, in an internal square which cover several grid nodes in each direction, etc.). In all cases the IHA scheme produces much better results than the HA scheme. However, improved harmonic averaging seems to be especially efficient for the thin lenses problems. A possible explanation for this phenomenon is that in the case of the thin lenses problems, the solution behaves in some subregions as a function of one variable; therefore, the scheme reduces to a scheme for a 1-D problem. As we know, for $f(x) \equiv 1$, this scheme is exact.

4.3. Numerical experiments for 3-D problems. We solved a 3-D problem (suggested in [6]) with nonhomogeneous Dirichlet boundary conditions and the known solution $u^{ex} = \frac{1}{k}(x_1 - 0.5)(x_2 - 0.5)(x_3 - 0.5)\sin(\frac{\pi x_1}{2})(1 + x_1^2 + x_2^2 + x_3^2)$, where k is a constant over each of the eight corners of this cube. More precisely, $k = \{10^2, 10^3, 10^7, 10^8, 10^{-2}, 10^{-1}, 10^3, 10^4\}$ in the eight corners, counting from the left to the right, and from the bottom to the top. Interfaces are aligned with the finite volume surfaces in this case, i.e., $\theta = 0.5$. The results from the numerical experiments are presented in Tables 4.10 and 4.11. In all cases we use the discretization of the boundary conditions reported in [8]. Tables 4.10 and 4.11 show that the numerical solution of the interface problem, obtained with the new scheme (3.4), is at least two orders more accurate than the numerical solutions, computed with the other two schemes. Table 4.10 shows that the AA scheme does not have a satisfactory accuracy, especially in the maximum norm. The HA scheme is much better, and the new IHA scheme produces the best results. We note that the solution computed with the new scheme on the coarsest grid with 18^3 points is more accurate than the solution computed by the HA scheme on the finest grid. The same observation can be made when comparing the arithmetic and harmonic averaging schemes. The HA scheme will need approximately 16^{11} nodes to produce the solution with the accuracy achieved by the new scheme on an 18^3-node grid. It can be also observed from Tables 4.10 and 4.11 that the constant of convergence of the new scheme does not depend on the jump of discontinuity in this example, and it is practically equal to the constant from the convergence rate of the scheme for Poisson's equation.

5. Conclusions. A family of new difference schemes for self-adjoint second-order elliptic equations with discontinuous coefficients is derived via a finite volumes approach. A new scheme, based on improved harmonic averaging of the coefficient, has second-order accuracy under the following assumptions: (1) the diffusion coefficient matrix $K(x)$ is diagonal; (2) the interfaces are planes perpendicular to the coordinate axes; (3) the normal (to the boundaries of a given finite volume) component of the flux is continuously differentiable at the finite volume boundaries. Second-order convergence of the new scheme in the maximum-norm is observed in various numerical experiments for problems in R^n, $n = 1, 2, 3$. The numerical experiments also demonstrate that the new scheme is much more accurate than the known schemes in solving interface problems, especially in the cases of large jumps of the coefficient. The advantages of the new scheme are better seen in solving multidimensional problems with many interfaces and the thin lenses problems.

A MULTILEVEL ALGORITHM FOR WAVEFRONT REDUCTION*

Y. F. HU† AND J. A. SCOTT‡

Abstract. A multilevel algorithm for reordering sparse symmetric matrices to reduce the wavefront and profile is described. The algorithm is a combinatorial algorithm that uses a maximal independent vertex set for coarsening the adjacency graph of the matrix and an enhanced version of the Sloan algorithm on the coarsest graph. On a range of examples arising from practical applications, the multilevel algorithm is shown to produce orderings that are better than those produced by the Sloan algorithm and are of comparable quality to those obtained using the hybrid Sloan algorithm. Advantages over the hybrid Sloan algorithm are that the multilevel approach requires no spectral information and less CPU time.

Key words. sparse matrices, wavefront and profile reduction, multilevel algorithm, row ordering, frontal method

1. Introduction.

We consider a multilevel algorithm for ordering sparse symmetric matrices for the small wavefront and profile. The resulting ordering may be used to construct a row order for use with the row-by-row frontal method applied to a matrix with a symmetric sparsity pattern (see [27]). Since we are primarily concerned with matrices that are positive definite, we work only with the pattern of the matrix and do not take into account permutations needed for stability. In cases where the matrix is nondefinite, or is symmetric only in its sparsity pattern, the actual factorization may be more expensive and require more storage.

Minimizing the profile of a matrix is known to be an NP-complete problem [23]. A number of heuristic algorithms have been proposed, including the Cuthill–McKee [4], reverse Cuthill–McKee [9, 24], Gibbs–King [12], Gibbs–Poole–Stockmeyer [11], and Sloan [31] algorithms (see also [5, 22, 27]). More recently, spectral orderings based on the Fiedler vector of the Laplacian matrix associated with a matrix have been developed [1, 25, 26]. Kumfert and Pothen [22] propose combining an enhanced version of the second phase of the Sloan algorithm with the spectral ordering. The resulting hybrid Sloan algorithm (hereafter referred to as the *Hybrid algorithm*) has been shown to give significantly better orderings for large problems than either the spectral method or the Sloan method alone. This has been confirmed by Reid and Scott [27], who provide efficient implementations of the Sloan and Hybrid algorithms within the HSL 2000 [15] code MC60.

One reason for the success of the Hybrid algorithm is that the spectral algorithm takes a global view of the graph of the matrix. This global view is fed into the Sloan algorithm as a priority vector, and the Sloan algorithm then performs local refinement.

The spectral algorithm has also been used in the area of graph partitioning [14, 30]. More recently, researchers have found that, for large graphs, a multilevel approach

[2, 13, 18, 33] can also provide good partitionings, while being much faster, because the calculation of the Fiedler vector of a large matrix is avoided. A number of efficient and high-quality graph partitioning codes based on the multilevel approach have been developed [14, 18, 33]. The success of the multilevel approach in graph partitioning motivated the work reported in this paper.

In this paper, we describe a multilevel Sloan algorithm for the ordering of sparse symmetric matrices. Numerical tests on a range of problems illustrate that the multilevel algorithm yields orderings that are better than those from the Sloan algorithm and are of comparable quality to the Hybrid algorithm. The main advantage of the multilevel approach over Hybrid is that it does not require any spectral information. Moreover, it is less expensive than the Hybrid algorithm.

The paper is organized as follows. In section 2, definitions and terminology are introduced, and the Sloan and Hybrid algorithms are recalled. In section 3, our multilevel approach is presented. Numerical results comparing our method with the Sloan and the Hybrid algorithms are given in section 4. Section 5 summarizes our findings and considers possible future directions for research.

We remark that while the writing of the present paper was in progress, our attention was brought to a report by Boman and Hendrickson [3]. In this report, Boman and Hendrickson propose using a multilevel method for envelope reduction. Their algorithm combines a multilevel approach with a 1-sum local refinement procedure (see section 3.1). Boman and Hendrickson found that the implementation of the Sloan algorithm developed by Kumfert and Pothen [22] often produced better envelopes and required less CPU time than their multilevel approach. This led Boman and Hendrickson to conclude that "Since the Sloan algorithm has recently been shown to be a fast and good algorithm for envelope reduction, we expect that the multilevel algorithm can be improved by replacing our 1-sum local refinement with a modified version of the Sloan algorithm." Although we were originally unaware of it, this paper takes up their challenge of combining the idea of a multilevel approach with the Sloan algorithm.

2. Background.

2.1. Definitions. We first need to introduce some nomenclature and notation. Let $A = \{a_{ij}\}$ be an $n \times n$ symmetric matrix. At the ith step of the factorization of A, row k is said to be *active* if $k \geq i$ and there exists a column index $l \leq i$ such that $a_{kl} \neq 0$. The ith *wavefront* f_i of A is defined to be the number of rows that are active during the ith step of the factorization. The *maximum* and *root-mean-squared* (RMS) wavefronts are, respectively,

$$F(A) = \max_{1 \leq i \leq n} \{f_i\}$$

and

$$\mathrm{rmsf}(A) = \left(\frac{\sum_{i=1}^{n} f_i^2}{n} \right)^{\frac{1}{2}}.$$

The *profile* of A is the total number of entries in the lower triangle when any zero ahead of the first entry in its row is excluded, that is,

$$P(A) = \sum_{i=1}^{n} \max_{a_{ij} \neq 0} \{i + 1 - j\}. \tag{2.1}$$

It is straightforward to show that

$$P(A) = \sum_{i=1}^{n} f_i.$$

The matrix envelope Env(A) is $P(A) - n$. For a frontal solver these statistics are important because

- the memory needed to store the frontal matrix is F^2;
- P is the total storage needed for the factorized matrix;
- the number of floating-point operations when eliminating a variable is proportional to the square of the current wavefront size.

Our goal therefore is to construct an efficient ordering algorithm that reduces the above quantities.

It is often convenient when developing ordering algorithms to treat the matrix A in terms of its adjacency graph. An undirected graph $\mathcal{G}$ is defined to be a pair (V, E), where V is a finite set of *vertices* (or *nodes*) and E is a finite set of *edges* defined as unordered pairs of distinct vertices. In a *weighted* graph, each vertex and edge has a weight associated with it. The adjacency graph $\mathcal{G}(A)$ of the square symmetric matrix A comprises the vertices $V(A) = \{1, 2, \ldots, n\}$ and the edges

$$E(A) = \{(i,j) \mid a_{ij} \neq 0,\ i > j\}.$$

Two vertices i and j are said to be *neighbors* (or to be *adjacent*) if they are connected by an edge. The notation $i \leftrightarrow j$ will be used to show that i and j are neighbors. The *adjacency* set for i is the set of its neighbors, that is,

$$\mathrm{adj}(i) = \{j \mid j \leftrightarrow i,\ i, j \in V\}.$$

The *degree* of $i \in V$ is $\deg(i) = |\mathrm{adj}(i)|$, the number of neighbors. If X is a subset of V, its adjacency set is defined to be

$$\mathrm{adj}(X) = \bigcup_{j \in X} \mathrm{adj}(j) \backslash X.$$

Observe that, given the graph representation of a symmetric matrix, the ith wavefront can be defined as the vertex i plus the set of vertices adjacent to the vertex set $\{1, 2, \ldots, i\}$, that is,

$$f_i = \mathrm{adj}\left(\{1, 2, \ldots, i\}\right) \cup \{i\}.$$

A *path* of length k in $\mathcal{G}$ is an ordered set of distinct vertices $\{v_1, v_2, \ldots, v_k, v_{k+1}\}$ with $v_i \leftrightarrow v_{i+1}$ $(1 \leq i \leq k)$. Two vertices are *connected* if there exists a path between them. A graph $\mathcal{G}$ is connected if each pair of distinct vertices is connected. The *distance*, $\mathrm{dist}(u, v)$, between two vertices u and v in $\mathcal{G}$ is the length of the shortest path connecting them. The *eccentricity* of a vertex u is defined to be

$$\mathrm{ec}(u) = \max\{\mathrm{dist}(u, v) \mid v \in \mathcal{G}\}.$$

The *diameter* of $\mathcal{G}$ is then

$$\delta(\mathcal{G}) = \max\{\mathrm{ec}(u) \mid u \in \mathcal{G}\}.$$

A vertex u is a *peripheral* vertex if its eccentricity is equal to the diameter of the graph, that is, $\mathrm{ec}(u) = \delta(\mathcal{G})$. A *pseudoperipheral* vertex u is defined by the condition that, if v is any vertex for which $\mathrm{dist}(u, v) = \mathrm{ec}(u)$, then $\mathrm{ec}(v) = \mathrm{ec}(u)$. The pair u, v of pseudoperipheral vertices define a *pseudodiameter*.

Throughout our discussion, it is assumed that the matrix A of interest is irreducible so that its adjacency graph $\mathcal{G}(A)$ is connected. Disconnected graphs can be treated by considering each component separately.

2.2. The Sloan algorithm. The Sloan algorithm [31] is widely used for profile and wavefront reduction. The algorithm, which uses the adjacency graph of the matrix, has the following two distinct phases:

1. selection of a start vertex s and an end vertex e,
2. vertex reordering.

The first phase looks for a pseudodiameter of the graph and chooses s and e to be the endpoints of this pseudodiameter. A pseudodiameter may be computed using a modification of the Gibbs–Poole–Stockmeyer algorithm. (See [27] for details of an efficient approach.) In the second phase, the chosen start vertex is numbered first, and a list of vertices that are eligible to be numbered next is formed. At each stage of the numbering, the list of eligible vertices comprises the neighbors of the vertices that have already been renumbered and their neighbors. The next vertex to be numbered is selected from the list of eligible vertices by means of a priority function. The priority of vertex i is given by $P(i)$, where

$$P(i) = -W_1 \mathrm{inc}(i) + W_2 \mathrm{dist}(i, e) \tag{2.2}$$

and (W_1, W_2) are positive weights. The first term (the "local" term), $\mathrm{inc}(i)$, is the amount by which the wavefront will increase if vertex i is ordered next. The second term (the "global" term), $\mathrm{dist}(i, e)$, is the distance between i and the end vertex e. Thus, a balance is maintained between the aim of keeping the wavefront small and bringing in vertices that have been left behind (far away from e). A vertex has a high priority if it causes either no increase or only a small increase to the current front size and is at a large distance from the end vertex e. The best choice for the weights (W_1, W_2) is problem dependent, but Sloan suggested that weights $(2, 1)$ usually gave satisfactory results for his test problems. Once an ordering for the vertices of the weighted graph has been obtained, an ordering for A can be constructed.

Duff, Reid, and Scott [5] extended Sloan's algorithm to vertex-weighted graphs obtained from finite element meshes and used the resulting orderings to generate element assembly orderings for the frontal method. The vertex-weighted graph is derived from the unweighted graph by "condensing" vertices to form supervertices. Vertices i and j are condensed into a supervertex if

$$i \cup \mathrm{adj}(i) = j \cup \mathrm{adj}(j). \tag{2.3}$$

The weight of a supervertex is the number of unweighted vertices it represents. The use of condensing can sometimes reduce the size of the graph considerably, thus reducing the time required for reordering.

The implementation of Sloan's algorithm was further enhanced by Kumfert and Pothen [22] in a number of ways.

- Sloan [32] used a simple search method to manage the priority queue but noted that, for large problems, using a binary heap would be the method of choice. Kumfert and Pothen implemented the use of a binary heap and were able to achieve a considerable efficiency gain. They also analyzed the time complexity of their efficient implementation.
- They applied the Sloan algorithm to the vertex-weighted graph so that it mimics what the algorithm would do on the corresponding unweighted graph. This resulted in smaller wavefront sizes.
- They divided their test problems into two classes and showed that, by using different weights for each class, for some problems the wavefront sizes obtained

by the Sloan algorithm could be substantially reduced. However, they were not able to predict a priori to which class a given problem belongs.

Most recently, Reid and Scott [27] have provided a Fortran implementation of Sloan's algorithm in HSL 2000 [15] as routine MC60. This code uses and extends the ideas of Kumfert and Pothen. MC60 optionally uses the vertex-weighted graph. For efficiency on problems of all sizes, when managing the priority queue, the code starts by using the simple search used by Sloan and switches to using a binary heap if the number of eligible vertices exceeds a given threshold. By default, MC60 tries both the pairs of weights $(2,1)$ and $(16,1)$. Alternatively, the user can supply the weights. The code also allows the user to provide a global priority vector to be used in place of the distance $\text{dist}(i,e)$ in the priority function. This enables MC60 to be used to implement the Hybrid algorithm of Kumfert and Pothen [22], which we discuss in the next section.

Throughout the rest of this paper, when referring to the Sloan algorithm, we mean the enhanced version of the algorithm as implemented within MC60.

2.3. The Hybrid algorithm. The first term in (2.2) affects the priority function in a local way by giving higher priority to vertices that will result in a small (or negative) increase to the current wavefront. This is done in a greedy fashion without consideration of the long-term effect. The second term acts in a more global manner, ensuring vertices lying far away from the end vertex are not left behind. The second phase of the Sloan algorithm can therefore be viewed as an algorithm that refines the ordering implied by the distance function $\text{dist}(i,e)$.

The distance function in (2.2) can be replaced by other orderings that provide a global view. In particular, Kumfert and Pothen [22] proposed using a spectral ordering. The spectral algorithm associates a Laplacian matrix $L = \{l_{ij}\}$ with the symmetric matrix A as follows:

$$l_{ij} = \begin{cases} -1 & \text{if } i \neq j \text{ and } i \leftrightarrow j, \\ \deg(i) & \text{if } i = j, \\ 0 & \text{otherwise.} \end{cases} \tag{2.4}$$

An eigenvector corresponding to the smallest positive eigenvalue of the Laplacian matrix is called a *Fiedler vector* [7, 8]. The spectral algorithm orders the vertices of $\mathcal{G}(A)$ by sorting the components of the Fiedler vector into monotonic order. The same permutation is applied to the original matrix to obtain the spectral ordering. This approach has been found to produce small profiles and wavefronts [1], although it is much more computationally expensive. (This is illustrated in [22].) An analysis of the spectral method for envelope reduction has been presented by George and Pothen [10].

The spectral algorithm has also been used in the context of graph partitioning [14], where it has been found that results can be improved by incorporating a local refinement step. This refinement performs local optimizations and smoothes out local oscillations that may be present. In the context of wavefront reduction, the Hybrid algorithm of Kumfert and Pothen [22] combines the spectral algorithm with a modified version of the second phase of the Sloan algorithm. It appears that it is this combination of global and local ordering algorithms that accounts for the good performance of the Hybrid algorithm, particularly for very large problems.

The Hybrid algorithm, as presented in [27], chooses as the start vertex s the first vertex in the spectral ordering and replaces (2.2) with the priority function

$$P(i) = -W_1 \text{inc}(i) - W_2\, \nu\, p(i). \tag{2.5}$$

Here ν is a normalizing factor and $p(i)$ is the position of vertex i in the spectral ordering, also referred to as its global priority value. ν is chosen so that the factor for W_2 varies up to $\text{dist}(s, e)$, as in (2.2). On the basis of their numerical experimentation, Reid and Scott [27] propose the pairs of weights $(1, 2)$ and $(16, 1)$. Note that $(1, 2)$ is recommended instead of the pair $(2, 1)$ used by default in their implementation of the Sloan algorithm. Reid and Scott argue that the global priority based on the spectral ordering has been found to be better than that obtained from a pseudodiameter, justifying a larger value for W_2 in this case. Numerical experiments [22, 27] have shown that, for large problems, in terms of the quality of the orderings produced, the Hybrid method can significantly outperform the Sloan algorithm. The Hybrid method does, however, require significantly more CPU time because it is more expensive to compute the Fiedler vector than it is to find a pseudodiameter for A. This is illustrated in section 4.

Through the use of (2.5), the modified second phase of Sloan's algorithm locally refines the spectral ordering. We therefore refer to this phase as Sloan refinement and denote by *SloanRefine*$(\mathcal{G}, p)$ the algorithm that takes the graph $\mathcal{G}$ together with a global priority vector p and uses (2.5) to return a refined ordering for $\mathcal{G}$.

3. The multilevel ordering algorithm.

The matrix ordering algorithm proposed in this paper is based on a multilevel approach. Given the adjacency graph $\mathcal{G}(A)$, a series of graphs is generated, each coarser than the preceding one. The coarsest graph is then ordered. This ordering is recursively prolonged to the next finer graph, local refinement is performed at each level, and the final ordering on the finest graph gives an ordering for A.

3.1. The multilevel approach.

In the context of graph partitioning, the multilevel approach generates a series of coarser and coarser graphs [2, 13, 19, 33]. The aim is for each successive graph to encapsulate the information needed to partition its "parent," while containing fewer vertices and edges. The coarsening continues until a graph with only a small number of vertices is reached. This can be partitioned cheaply. The partitions on the coarse graphs are recursively prolonged (usually by injection) to the finer graphs with further refinement at each level.

One of the first uses of a multilevel approach for the partitioning of undirected graphs was reported by Barnard and Simon [2]. Motivated by the need to reduce the time for computing the Fiedler vector, Barnard and Simon combined a multilevel approach with a spectral bisection algorithm. It was soon realized [13, 20, 33] that the multilevel approach can be used to advantage with a good local optimizer. In graph partitioning, the Kernighan–Lin algorithm [21] is used and, combined with the multilevel approach, has proved very successful at rapidly computing high quality partitions.

Boman and Hendrickson [3] propose adopting a multilevel approach for profile and wavefront reduction. They introduce a *weighted* 1-*sum* metric

$$\sigma_1(A) = \sum_{i=1}^{n} \sum_{j \leftrightarrow i,\ j<i} w_{ij}(i-j),$$

where w_{ij} are edge weights, and aim to minimize $\sigma_1(A)$. The edge weights are all one on the finest graph; on the coarser graphs, edge weights are assigned as edges are collapsed. (See [3] for details.) Although Boman and Hendrickson's objective is to minimize the matrix envelope of A, they report finding it more efficient and effective to work with the 1-sum. Boman and Hendrickson propose combining a multilevel approach with a refinement algorithm that is similar to the Kernighan–Lin algorithm and is based on swapping consecutive vertices. The gain in swapping each such pair of vertices k and $k+1$ is calculated initially and then updated during the refinement. The gain from a swap is measured using the weighted 1-sum. Boman and Hendrickson compare their approach with an implementation of the Sloan algorithm that incorporates the enhancements of Kumfert and Pothen [22] (referred to by Boman and Hendrickson as the fast Sloan). Boman and Hendrickson conclude that "The fast Sloan algorithm operates in the same performance range and often produces better envelopes in less time than the multilevel algorithm, but not always." Since, in turn, the Hybrid algorithm significantly outperforms Sloan for large problems, the multilevel algorithm of Boman and Hendrickson is not competitive with the Hybrid algorithm in terms of ordering quality.

As recognized by Boman and Hendrickson in their concluding remarks, because the reordering phase of the Sloan algorithm provides a good local refinement algorithm, it is of interest to try and use it directly with the multilevel approach. This combining of Sloan with the multilevel approach forms the basis of our multilevel wavefront reduction algorithm. The algorithm has three distinct phases: coarsening, coarsest graph ordering, and, finally, prolongation and refinement. We discuss each of these phases and then, in section 3.5, we outline our multilevel Sloan algorithm.

3.2. The coarsening phase. There are a number of ways to coarsen an undirected graph. The most popular method in graph partitioning is based on edge collapsing [13, 20], in which pairs of adjacent vertices are selected and each pair is coalesced into one new vertex. Because of its success for graph partitioning, coarsening using edge collapsing was the first strategy we employed when developing our multilevel wavefront reduction algorithm. However, we found that, while we were able to improve on the wavefronts obtained using the Sloan algorithm, the results were of a poorer quality than those given by the Hybrid algorithm. Full details and comparisons are given in the report [17]. This led us to consider alternative coarsening strategies.

In [2], a *maximal independent vertex set* of a graph is chosen as the vertices for the coarse graph. An independent set of vertices is a subset of the vertices such that no two vertices in the subset are connected by an edge in the graph. An independent set is maximal if the addition of an extra vertex always destroys the independence. An algorithm for constructing a maximal independent set is discussed below. Edges of the coarse graph are formed through a process based on the Galerkin product (see section 3.5 for details), which effectively links two vertices in the maximal independent vertex set by an edge if their distance apart is no greater than three. Figure 3.1 illustrates a graph $\mathcal{G}$ with 788 vertices, together with two levels of coarsening using this method, giving graphs with 332 and 94 vertices, respectively.

The coarsening process is applied recursively until one of the following is achieved:

- The number of levels exceeds a preset limit.
- The number of vertices in the coarsest graph is less than a preset number (chosen to be 100 in this study, but see section 4.4 for further discussions).
- The ratio of the number of vertices in two successive graphs exceeds a preset constant (0.8 in this study).

The last condition is necessary to avoid a slow reduction between fine and coarse graph sizes that can lead to a high algorithmic complexity for the multilevel algorithm.

3.2.1. Maximal independent vertex set algorithm. When used for the multilevel spectral algorithm, a maximal independent set is chosen in a greedy fashion

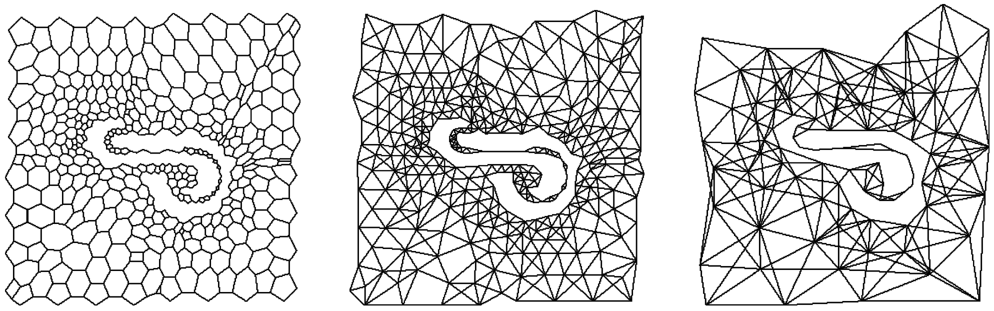

FIG. 3.1. *Graph coarsening based on the maximal independent vertex set: the original graph* $\mathcal{G}$ *with* 788 *vertices (left);* $\mathcal{G}_1$ *with* 332 *vertices (center);* $\mathcal{G}_2$ *with* 94 *vertices (right).*

by picking unmatched vertices at random and, when a vertex is picked, masking its neighboring vertices as matched [1, 2]. Hereafter this method of coarsening is referred to as the simple greedy approach.

We adopt a more sophisticated approach that yields comparable quality of orderings but requires less CPU time. (See section 4.3 for a comparison.) Our algorithm is based on that of Ruge and Stüben [28], which has been used successfully in the field of algebraic multigrid. This algorithm was designed for unsymmetric matrices; we have modified it for symmetric matrices. At each step, each vertex in V lies in one of three sets: it is either uncolored (V_U), it is in the maximal independent set (V_C), or it is not a candidate for the maximal independent set (V_F). Each vertex has a gain value associated with it, indicating the preference for this vertex to belong to V_C. Initially, each vertex i is uncolored (lies in V_U) and is assigned a gain value gain(i) equal to its degree. The gains are held in a priority queue. At each step, an uncolored vertex with the highest gain is removed from the queue and is moved into V_C. Its neighbors are then moved into V_F. They are also removed from the queue. For each such new vertex in V_F, the gain values of its uncolored neighbors are increased by one. The procedure is repeated until the queue is empty (that is, until all the vertices belong to either V_C or V_F).

In this algorithm, the gain of an uncolored vertex is always equal to the number of neighbors in V_U plus twice the number of neighbors in V_F. An uncolored vertex with a large number of neighbors in V_F is therefore more likely to be moved into V_C. This ensures that V_F vertices are well "covered" by V_C vertices, yielding a more uniform distribution of V_C vertices and allowing a more aggressive coarsening compared with the simple greedy approach. Our maximal independent vertex set algorithm is outlined below.

MAXIMAL INDEPENDENT VERTEX SET ALGORITHM.

```
• initialization:

    – $V_U = V$
    – for each vertex $i \in V$
        $\mathrm{gain}(i) = \deg(i)$
• do while $V_U \neq \emptyset$
    – $i_{\max} : \mathrm{gain}(i_{\max}) = \max_{j \in V_U}(\mathrm{gain}(j))$
    – $V_U = V_U \backslash \{i_{\max}\}$
    – $V_C = V_C \cup \{i_{\max}\}$
    – for each vertex $j \in \mathrm{adj}(i_{\max}) \cap V_U$
    $V_U = V_U \backslash \{j\}$
    for each vertex $k \in \text{adj}(j) \cap V_U$
      $\text{gain}(k) = \text{gain}(k) + 1$
```

3.3. The coarsest graph ordering. Because the coarsest graph has a small number of vertices and edges, it can be reordered quickly using any standard profile reduction algorithm. We have used both the Sloan and the Hybrid algorithms and present results for both approaches (using the MC60 implementation of these algorithms) in section 4.

3.4. The prolongation and refinement phase. During the prolongation phase, the vertices of the fine graph are given global priority values by mapping the coarse graph ordering onto the fine graph. This mapping can be represented by a prolongation matrix P. If the coarse and fine graphs have n_c and n_f vertices, respectively, the prolongation matrix is of order $n_f \times n_c$.

When coarsening is based on a maximal independent vertex set, the coarse graph vertices comprise the maximal independent set of the fine graph. The global priority value of a vertex in the fine graph that belongs to the maximal independent set is defined as the position of this vertex in the coarse graph ordering. The global priority value of a fine graph vertex not in the maximal independent set is calculated by averaging the global priority values of its neighbors that belong to the maximal independent set. (By definition there is at least one such neighbor.) For each coarse graph vertex j, let fine(j) be the index of this vertex in the fine graph. For each fine graph vertex i, define mdeg(i) to be the number of neighboring fine graph vertices that belong to the maximal independent set. The prolongation matrix $P = \{p_{ij}\}$ has entries

$$p_{ij} = \begin{cases} 1 & \text{if } i = \text{fine}(j), \\ \frac{1}{\text{mdeg}(i)} & \text{if } i \leftrightarrow \text{fine}(j),\ i \neq \text{fine}(j), \\ 0 & \text{otherwise}. \end{cases} \tag{3.1}$$

The global priority values are refined using the second phase of the enhanced Sloan algorithm (that is, by using the priority function (2.5)) to give the final ordering for the fine graph.

3.5. The multilevel algorithm. We can now formulate our multilevel wavefront reduction algorithm. For this it is convenient to introduce some further notation. The subscripts f and c are used to represent fine and coarse graph quantities, respectively. For example, $\mathcal{G}_f$ denotes the fine graph with n_f vertices and $\mathcal{G}_c$ is the graph with n_c vertices obtained after coarsening ($n_c < n_f$). We will associate with $\mathcal{G}_f$ an $n_f \times n_f$ matrix A_f which has zero diagonal entries and nonzero off-diagonal entries a_{ij} if and only if vertices i and j are adjacent in $\mathcal{G}_f$. A_c is defined analogously.

If P denotes an $n_f \times n_c$ prolongation matrix, the coarse graph may be expressed as the Galerkin product

$$A_c \leftarrow P^T\ A_f\ P.$$

This expression means that the matrix product $P^T A_f P$ is computed and the matrix A_c is obtained by setting the diagonal entries of the resulting matrix to zero.

The *global priority vector* p of a graph is a vector with entries $p(i)$, where $p(i)$ is the global priority value of vertex i. This vector indicates the preferred ordering of the vertices. For the Hybrid algorithm, the global priority vector is obtained by ordering the vertices based on the values of the Fiedler vector. Note that the global priority vector need *not* be a permutation vector. We let $\mathit{CoarsestOrder}(\mathcal{G})$ be an algorithm that returns an ordering for the coarsest graph $\mathcal{G}$ and recall that $\mathit{SloanRefine}(\mathcal{G}, p^0)$ denotes the algorithm that takes the graph $\mathcal{G}$, and a global priority vector p^0, and returns a refined ordering for $\mathcal{G}$ using (2.5) with $p = p^0$.

With this notation, if *MinSize* is the preset number of vertices beyond which there is no further coarsening, our multilevel wavefront reduction algorithm can be formally presented as follows. The starting point is the fine graph $\mathcal{G}_f$ and associated matrix A_f.

```
FUNCTION MultilevelOrder($\mathcal{G}_f$).
  • If $n_f$ < MinSize, then
      – $p_f$ = CoarsestOrder($\mathcal{G}_f$)
      – return $p_f$
  • The coarsening phase:
      – set up the $n_f \times n_c$ prolongation matrix $P$
      – $A_c \leftarrow P^T A_f P$
      – $p_c$ = MultilevelOrder($\mathcal{G}_c$)
  • The prolongation and refinement phase:
      – $p_f^0 = P p_c$
      – $p_f$ = SloanRefine($\mathcal{G}_f, p_f^0$)
      – return $p_f$
```

Figure 3.2 illustrates the multilevel algorithm applied to the test problem bcsstk11 (see the appendix). Notice that on the coarsest level, the lower right-hand part of the matrix after reordering (bottom right) has no nonzero entries. This is because the graph corresponding to the bcsstk11 matrix has nine components, eight of which are small, and coarsening gives eight isolated vertices on the coarsest level. Since diagonal elements are not displayed, after reordering there is an 8 × 8 null matrix in the lower right-hand part of the coarsest matrix.

Figure 3.3 presents a simple example of the two-level ordering algorithm using a maximal independent vertex set. The vertices $v3$, $v6$ are chosen to form the maximal independent set. Vertex $v1$ has one neighbor in the maximal independent set; therefore $\mathrm{mdeg}(v1) = 1$. Similarly, $\mathrm{mdeg}(v4) = 1$, and $\mathrm{mdeg}(v2) = \mathrm{mdeg}(v5) = 2$. Thus from (3.1), the prolongation matrix is

$$P = \begin{pmatrix} 1 & 0 \\ \frac{1}{2} & \frac{1}{2} \\ 1 & 0 \\ 1 & 0 \\ \frac{1}{2} & \frac{1}{2} \\ 0 & 1 \end{pmatrix}.$$

It follows that the Galerkin product is

$$P^T A_f P = \frac{1}{4} \begin{pmatrix} 2 & 0 \\ 1 & 1 \\ 2 & 0 \\ 2 & 0 \\ 1 & 1 \\ 0 & 2 \end{pmatrix}^T \begin{pmatrix} 0 & 1 & 1 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 & 1 & 1 \\ 1 & 1 & 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 0 & 1 & 0 \\ 0 & 1 & 1 & 1 & 0 & 1 \\ 0 & 1 & 0 & 0 & 1 & 0 \end{pmatrix} \begin{pmatrix} 2 & 0 \\ 1 & 1 \\ 2 & 0 \\ 2 & 0 \\ 1 & 1 \\ 0 & 2 \end{pmatrix} = \begin{pmatrix} 8.5 & 3.5 \\ 3.5 & 2.5 \end{pmatrix}.$$

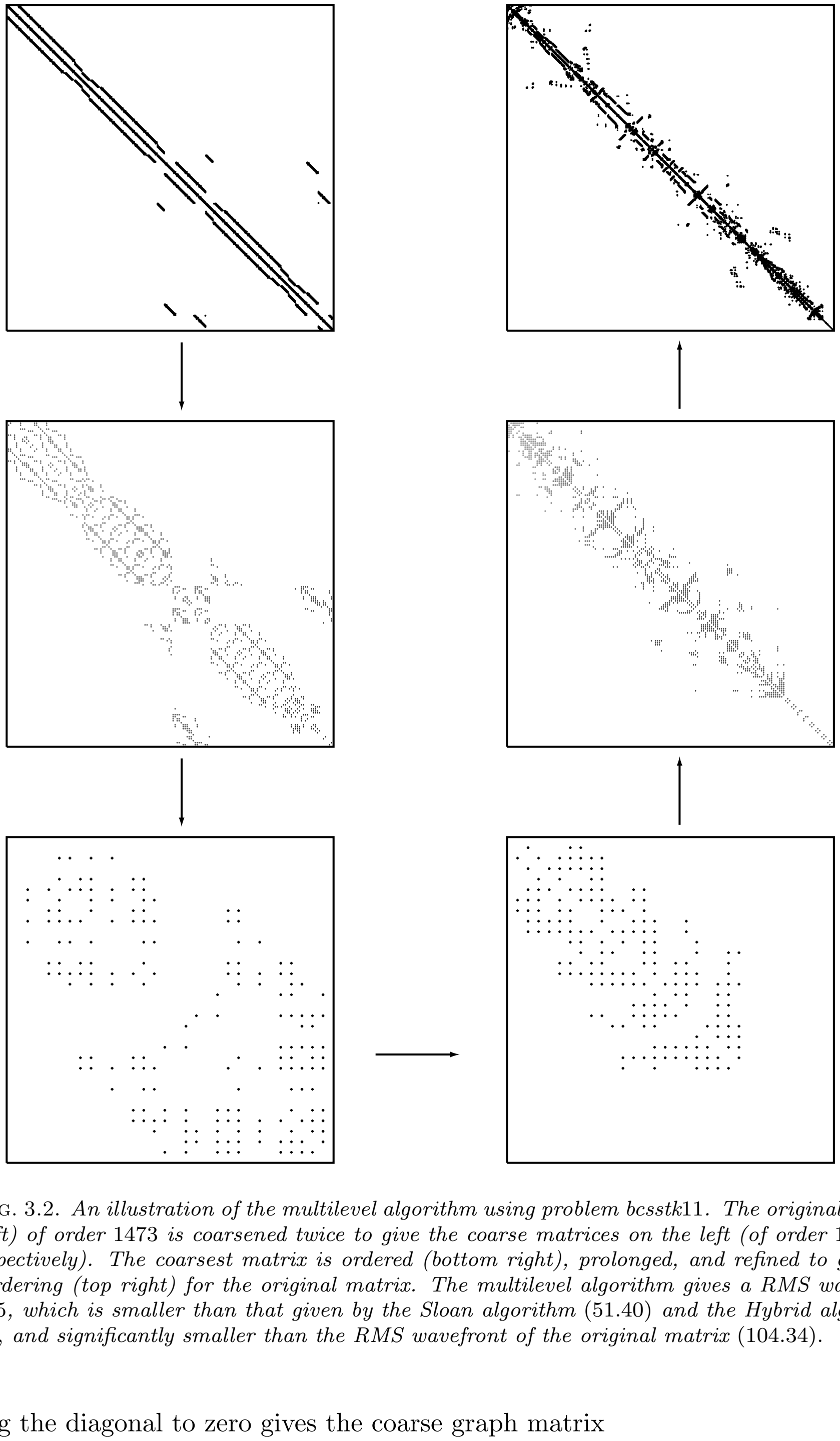

FIG. 3.2. *An illustration of the multilevel algorithm using problem bcsstk*11*. The original matrix (top left) of order* 1473 *is coarsened twice to give the coarse matrices on the left (of order* 162 *and* 30*, respectively). The coarsest matrix is ordered (bottom right), prolonged, and refined to give the final ordering (top right) for the original matrix. The multilevel algorithm gives a RMS wavefront of* 46.55*, which is smaller than that given by the Sloan algorithm* (51.40) *and the Hybrid algorithm* (47.76)*, and significantly smaller than the RMS wavefront of the original matrix* (104.34).

Setting the diagonal to zero gives the coarse graph matrix

$$A_c = \begin{pmatrix} 0 & 3.5 \\ 3.5 & 0 \end{pmatrix},$$

which corresponds to the coarse graph in Figure 3.3 (middle).

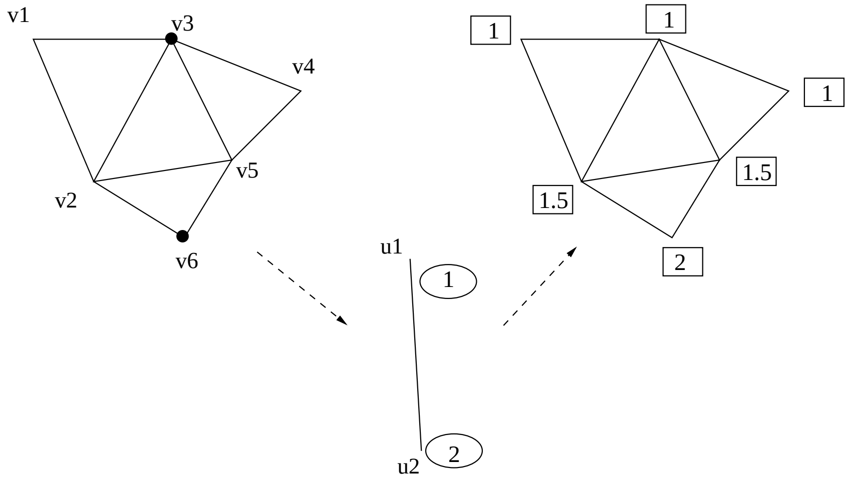

FIG. 3.3. *A graph (top left) is coarsened using the maximal independent vertex set (shaded and circled) to give the coarse graph (middle). The coarse graph is ordered, and this ordering is prolonged to give the priority vector for the fine graph (top right). Numbers in ellipses are the coarse graph ordering, and numbers in squares are global priority values.*

Assuming the coarse graph is ordered as $p_c(u1) = 1$, $p_c(u2) = 2$, the global priority vector for the fine graph is

$$p_f^0 = Pp_c = \frac{1}{2}\begin{pmatrix} 2 & 0 \\ 1 & 1 \\ 2 & 0 \\ 2 & 0 \\ 1 & 1 \\ 0 & 2 \end{pmatrix}\begin{pmatrix} 1 \\ 2 \end{pmatrix} = \begin{pmatrix} 1 \\ 1.5 \\ 1 \\ 1 \\ 1.5 \\ 2 \end{pmatrix}. \tag{3.2}$$

This is shown on the right-hand side of Figure 3.3.

4. Numerical results. In this section, our multilevel approach is compared with the Sloan and Hybrid algorithms on a large set of test problems. All the codes used to obtain the reported results are written in Fortran. The experiments are performed on a COMPAQ computer with a 300 MHz Alpha EV5 processor, using the DIGITAL Fortran 90 V5.2 compiler.

The MC60 code of Reid and Scott [27] is used in the experiments for the Sloan algorithm, for ordering the coarsest graph, and for subsequent refinement. The spectral ordering needed for the Hybrid algorithm is computed using a multilevel Fiedler vector code written by the first author. The algorithm implemented by this Fiedler code is similar to that described in [2]. Coarsening based on heavy edge collapsing is used, and, on the coarsest graph, vertex weights and edge weights are not used in the computation of the Fiedler vector.

The coarsest graph ordering algorithm *CoarsestOrder* is taken to be either the Sloan or the Hybrid algorithm. We denote by *Sloan*(MIV, K) (and *Hybrid*(MIV, K)) the multilevel algorithm that uses the Sloan (respectively, Hybrid) algorithm on the coarsest graph together with the *MIV* (maximal independent vertex set) coarsening scheme on up to K levels. Thus *Sloan*$(MIV, 1)$ is the Sloan algorithm and

Hybrid$(MIV, 1)$ the Hybrid algorithm. Similarly, *Sloan*$(MIV, 3)$ is the multilevel algorithm, with maximal independent vertex set coarsening and a maximum of three levels, with the Sloan algorithm used on the coarsest graph.

Our suite of 101 test problems is listed in alphabetical order in the appendix. The problems are all symmetric and range in order from 66 (dwt66) to 224,617 (Halfb). We have included all the nontrivial symmetric problems of order at least 1000 from MatrixMarket (http://math.nist.gov/MatrixMarket). In addition, we have the Everstine test set [6], which, although small by today's standards, is widely used as a test set for profile and wavefront reduction algorithms. The Everstine problems are available from the Harwell–Boeing Sparse Matrix Collection (http://www.cse.clrc.ac.uk/Activity/SparseMatrices). We also have all the test problems used by Kumfert and Pothen [22], together with some additional finite element problems supplied by Christian Damhaug of Det Norske Veritas, Norway. Included in the appendix are the initial RMS wavefronts (rmsf) for each matrix and the ratio, ρ, between the RMS wavefronts before and after reordering with the Hybrid algorithm. In general, the Hybrid algorithm substantially improves the ordering (although there are a small number of exceptions, notably problems bscctk13, bcsstk17, and bcsstm13).

4.1. Multilevel Sloan algorithm. Figure 4.1 compares the RMS wavefront for the Sloan and the Hybrid algorithms with the multilevel algorithm *Sloan*(MIV, K).

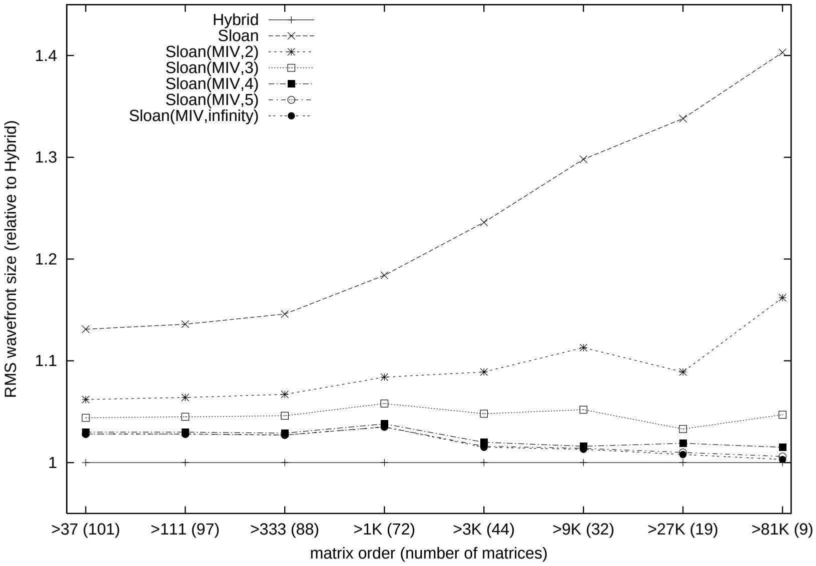

FIG. 4.1. *A comparison of the RMS wavefronts for the Sloan, the Hybrid, and the Sloan*(MIV, K) *algorithms.*

In this and subsequent figures, comparisons are given with respect to the Hybrid algorithm so that the RMS wavefront for each algorithm is divided by the corresponding RMS wavefront for the Hybrid algorithm and geometrically averaged over the test cases to give a relative score for the algorithm. The smaller the score, the better the algorithm. With this metric, the Hybrid algorithm always has a score of one. To show the effect of matrix order, the scores for each algorithm for matrices of order greater than $37 \times 3^k (1 \leq k \leq 8)$ are plotted separately in the figure with the number of matrices over the threshold printed in brackets. A log scale is used for the x-axis (matrix order).

A number of interesting features can be observed. The first observation is that, relative to the Hybrid algorithm, the RMS wavefront given by the Sloan algorithm deteriorates as the order of the matrix increases. Overall, the RMS wavefront for the Sloan algorithm is about 13% greater than for the Hybrid algorithm, while for the largest 10 matrices, it is about 40% more. This deterioration further confirms the earlier findings reported in [22, 27].

The second observation is that, as the number of levels increases, the multilevel orderings improve. The multilevel algorithm without a preset maximum number of levels, *Sloan*(MIV, ∞), produces orderings of comparable quality (within 3.5%) to the Hybrid algorithm and, in terms of CPU time (Figure 4.2), is substantially faster in our experiments, requiring about half the time of the Hybrid algorithm. Since *Sloan*(MIV, ∞) is generally no more expensive in terms of CPU time than *Sloan*(MIV, K) with $K > 2$, and it produces the smallest RMS wavefronts, we recommend not imposing a maximum number of levels on the multilevel algorithm. Thus we have a combinatorial algorithm for wavefront reduction that performs as well as the Hybrid algorithm in less time.

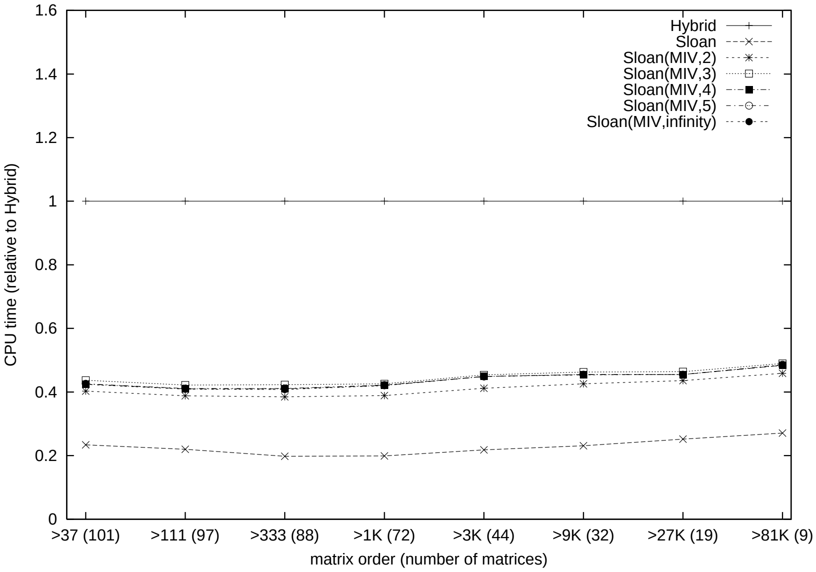

FIG. 4.2. *A comparison of the CPU times for the Sloan, the Hybrid, and the Sloan(MIV, K) algorithms.*

The above results were obtained using the modified version of the Ruge and Stüben [28] algorithm for selecting a maximal independent set. As discussed in section 3.2.1, a simple greedy algorithm can be used instead. The Ruge and Stüben algorithm selects coarse vertices by maximizing the number of neighbors in V_F and V_U. In general, this gives a more aggressive coarsening and fewer dense matrices on the coarse graphs. The result is that a multilevel algorithm based on the Ruge and Stüben approach requires less CPU time than the simple greedy algorithm. This is illustrated in Figure 4.3, where *Sloan*(MIV, ∞) is compared with *Sloan*$(MIVG, \infty)$, with the latter denoting the multilevel algorithm using the simple greedy approach for selecting the maximal independent set. *Sloan*(MIV, ∞) clearly takes less CPU time while yielding orderings of comparable quality.

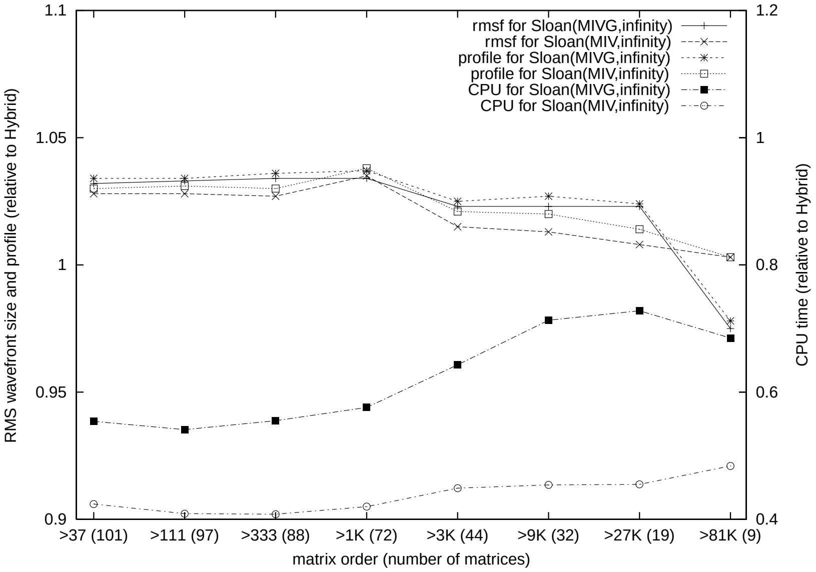

FIG. 4.3. *A comparison of the multilevel algorithms based on two approaches of selecting a maximal independent vertex set. $Sloan(MIV, \infty)$ is based on the Ruge and Stüben algorithm* [28]. *$Sloan(MIVG, \infty)$ is based on the simple greedy algorithm. All results are relative to the Hybrid algorithm. The left y-axis is used for RMS wavefront* (rmsf) *and profile; the right y-axis for CPU time.*

Figure 4.3 also includes the profile for the $Sloan(MIV, \infty)$ and $Sloan(MIVG, \infty)$ orderings relative to the Hybrid orderings. As can be seen, the trend for the profile is very similar to that of the RMS wavefront. In the remainder of this paper, we will present only RMS wavefront results.

4.2. Sloan versus Hybrid on the coarsest graph. The coarsest graph has only a small number of vertices, and so it can be rapidly ordered using any appropriate algorithm. In the results presented in the previous section, the Sloan algorithm was used, but the Hybrid algorithm can be used instead. This gives the multilevel Hybrid algorithm, $Hybrid(MIV, K)$.

Figure 4.4 compares the RMS wavefront for this algorithm with that for the Sloan and the Hybrid algorithms. We see that, for any preset maximum number of levels K, results for the $Hybrid(MIV, K)$ algorithm are comparable to those for the Hybrid algorithm. Even if there are only two levels, the quality of the ordering on the coarsest (level 2) graph is such that the application of a prolongation and refinement step is able to produce a high quality ordering on the fine graph. This is in contrast to $Sloan(MIV, 2)$, where, on the coarsest graph, the Sloan algorithm does not yield such a good ordering. As the number of levels increase, the performance of $Sloan(MIV, K)$ is comparable to $Hybrid(MIV, K)$, indicating that, because the Sloan algorithm performs well on small problems, in terms of quality, the choice between the Sloan and the Hybrid algorithms on the coarsest graph is not important when that graph is small. However, using the Sloan algorithm has the advantage of not requiring the computation of any spectral information.

The fact that the quality of the $Hybrid(MIV, K)$ orderings varies little with the number of levels K indicates that the multilevel process based on the maximal independent vertex set combined with Sloan refinement is of good quality, in the sense

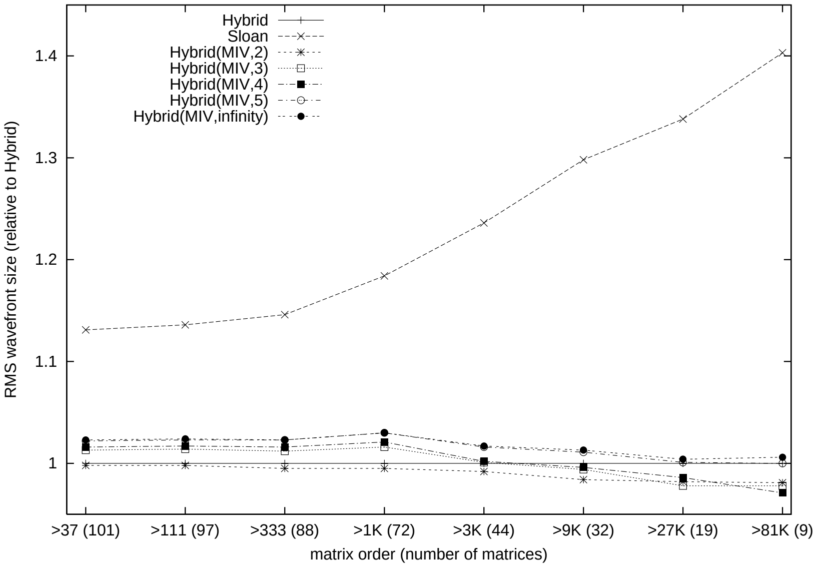

FIG. 4.4. *A comparison of the RMS wavefronts for the Sloan, the Hybrid, and the Hybrid(MIV, K) algorithms.*

that it preserves, if not enhances, the quality of the ordering achieved on the coarsest graph using the Hybrid algorithm.

The CPU time comparisons for the Sloan, the Hybrid, and the *Hybrid*(MIV, K) algorithms are given in Figure 4.5. The *Hybrid*(MIV, K) algorithm needs about half the CPU time of the Hybrid algorithm. For small K, it is slightly more expensive than *Sloan*(MIV, K) because of the extra cost associated with using the Hybrid algo-

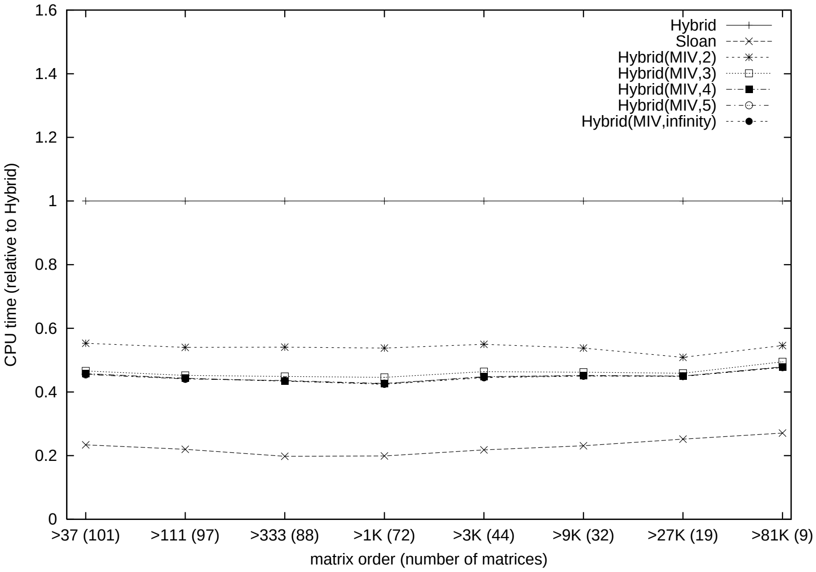

FIG. 4.5. *A comparison of the CPU times for the Sloan, the Hybrid, and the Hybrid(MIV, K) algorithms.*

rithm on the coarsest graph. For large K, the main disadvantage of $\mathit{Hybrid}(MIV, K)$ compared with $\mathit{Sloan}(MIV, K)$ is that $\mathit{Hybrid}(MIV, K)$ requires the computation of a spectral vector on the coarsest graph.

We are primarily interested in how the multilevel approach performs on large problems. Table 4.1 lists the RMS wavefronts for the Hybrid, $\mathit{Sloan}(MIV, \infty)$, and $\mathit{Hybrid}(MIV, \infty)$ algorithms for each of the test problems of order greater than 10000. The smallest wavefront for each problem (and those within 3% of the smallest) are given in bold. It can be seen that, although the three algorithms on average produce orderings with similar RMS wavefronts, their behavior on individual matrices can differ significantly. This is typical of heuristic-based algorithms and, for a given problem, which algorithm will produce the best ordering cannot be predicted a priori. Table 4.2 reports the CPU timings for the three algorithms. The multilevel algorithms $\mathit{Sloan}(MIV, \infty)$ and $\mathit{Hybrid}(MIV, \infty)$ require a similar amount of time, and both are faster than the Hybrid algorithm.

Table 4.1

4.3. Sensitivity of the multilevel algorithm to the priority function weights. So far, we have established that a multilevel Sloan algorithm based on a maximal independent vertex set gives orderings of comparable quality to the Hybrid algorithm and is significantly faster. Since Kumfert and Pothen [22] showed that the choice of weights can have a very important influence of the quality of Sloan's ordering, in this section we look at the sensitivity of the multilevel algorithm to the

choice of weights used in the priority function (2.5), first when ordering the coarsest graph and, second, during the prolongation and refinement stages.

We have seen that, with an unlimited number of levels, the coarsest graph ordering based on both the Sloan algorithm (*Sloan*(MIV,∞)) and the Hybrid algorithm (*Hybrid*(MIV,∞)) yield orderings of similar quality. Following Reid and Scott [27], when the Sloan algorithm is used on the coarsest graph, two orderings are generated from the weight pairs $(2,1)$ and $(16,1)$, and the better of the two is chosen. Figure 4.6 illustrates the effect of using a single pair of weights. If we generate only one ordering based on a single pair of weights (chosen among $(64,1)$, $(16,1)$, $(4,1)$, $(2,1)$, $(1,1)$, $(1,2)$, $(1,4)$, $(1,16)$, and $(1,64)$), the quality of the final ordering obtained using the multilevel algorithm is not as good, although the difference is usually less than 10%. If instead of the pairs $(2,1)$ and $(1,16)$ we use $(1,2)$ and $(1,16)$, the difference in the quality of the final ordering is extremely small, indicating that the precise choice for the weights is not critical. As the coarsest graph can be ordered very quickly because of its small size, if it is important to obtain the smallest possible wavefront, it may be worthwhile to try a number of different weights and choose the best ordering among them.

We have also looked at the sensitivity of the ordering to the choice of weights for the prolongation and refinement stage of the multilevel algorithm. In all the experiments reported so far, we have used the weights $(1,2)$ and $(16,1)$. This choice was recommended in Reid and Scott [27] for the Hybrid algorithm, where it was

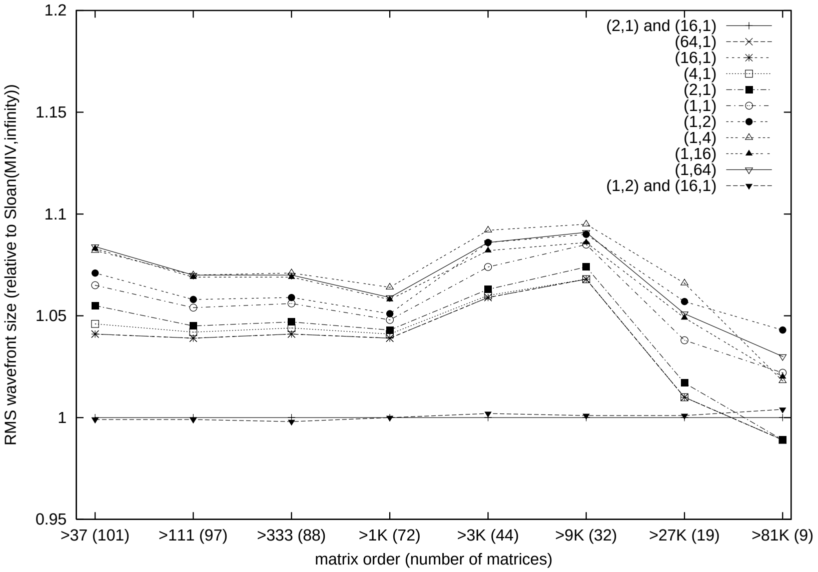

FIG. 4.6. *The effect of the weights used in the coarse graph ordering on the RMS wavefront of the multilevel algorithm. The Sloan(MIV, ∞) algorithm is used with either a single pair of weights (chosen from $(64, 1), \ldots, (1, 64)$) or the two pairs $(1, 2)$ and $(16, 1)$ on the coarsest graph. All results are relative to Sloan(MIV, ∞) with the weights $(2, 1)$ and $(16, 1)$ on the coarsest graph.*

argued that a larger W_2 in (2.5) is preferred when $p(i)$ is of good quality. Figure 4.7 illustrates the effect of varying the first pair of weights on the quality of the ordering given by *Sloan*(MIV, ∞). In this experiment, the second pair is fixed at $(16, 1)$, while the first pair is allowed to vary between $(4, 1)$ and $(1, 16)$. We see using (W_1, W_2)

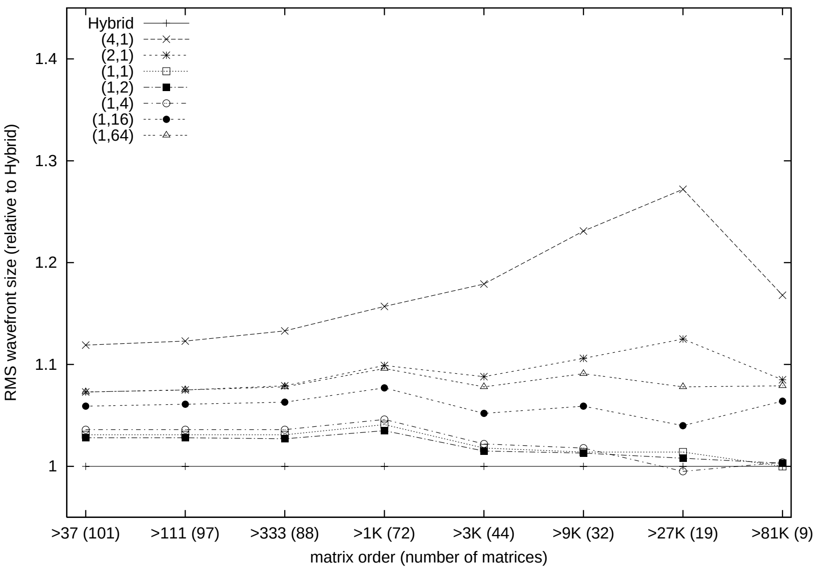

FIG. 4.7. *The effect of the first pair of weights during the refinement process on the RMS wavefront of the multilevel algorithm Sloan(MIV, ∞). The second pair of weights is fixed at $(16, 1)$. All results are relative to the Hybrid algorithm.*

with W_2 slightly larger than or equal to W_1 is beneficial. In general, the pairs $(1,1)$, $(1,2)$, and $(1,4)$ yield similar RMS wavefronts. We performed further experiments that showed the same conclusion can be drawn for the *Hybrid*(MIV,∞) algorithm.

4.4. Effect of the size of the coarsest graph. In the multilevel ordering algorithm, a parameter *MinSize* is used to control the size of the coarsest graph. Further coarsening is not carried out once the size of the current graph is less than *MinSize*. We have chosen *MinSize* $= 100$ in our work.

On small graphs, the Sloan algorithm is competitive with the Hybrid algorithm, but its competitiveness deteriorates as the size of the graph increases. Since we use the Sloan algorithm on the coarsest graph we do not, therefore, want this graph to be too large. Conversely, coarsening down to a very small number of vertices is not recommended either because applying the Sloan algorithm to such a graph does not feed into the refinement process any more information than would be given by a random ordering of the coarsest graph. Figure 4.8 demonstrates the effect of *MinSize* on the quality of the *Sloan*(MIV,∞) ordering. It is seen that *MinSize* $= 50$ or 100 gives the best results, but the precise choice of *MinSize* is not critical. A value that is either too small or too large causes deterioration in the quality of the ordering, although all the values tested yielded orderings that were within 8% of the RMS wavefront given by the Hybrid algorithm.

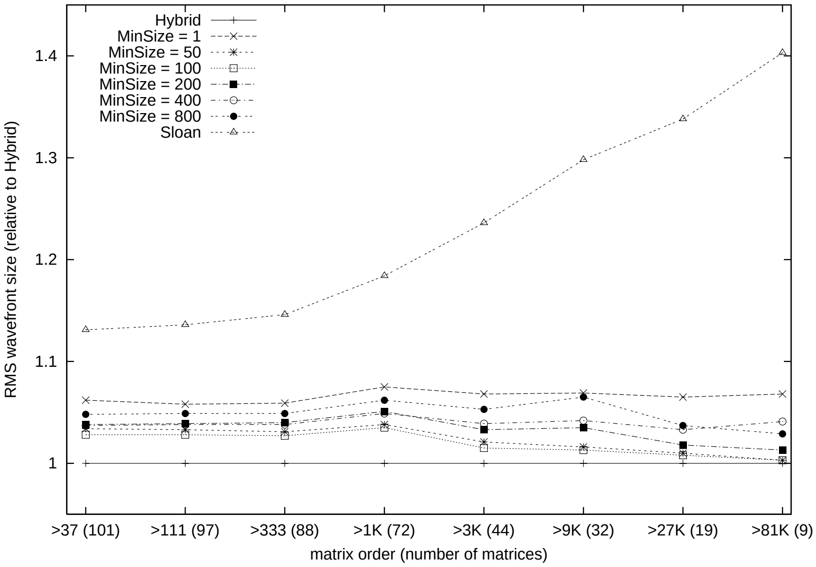

FIG. 4.8. *The effect of the size of the coarsest graph* (*MinSize*) *on the multilevel algorithm Sloan*(MIV,∞). *All results are relative to the Hybrid algorithm.*

5. Conclusions and future work. In this paper, a multilevel reordering algorithm for minimizing the profile and wavefront of sparse symmetric matrices has been developed. This algorithm, which combines a coarsening strategy based on a maximal independent vertex set with the Sloan or Hybrid algorithm on the coarsest graph, has been found to give orderings of similar quality to that of the best existing algorithm (the Hybrid algorithm of Kumfert and Pothen [22]), while being significantly faster. Of particular note is the multilevel Sloan algorithm. In common with the Sloan algorithm, this is a combinatorial algorithm, but it produces much better orderings, particularly for large problems. With no limit imposed on the maximum number of levels, the multilevel Sloan algorithm has been shown to yield orderings of similar quality to that of the Hybrid algorithm with the advantage of not requiring any spectral information.

We are investigating the possibility of further improving the multilevel algorithm so that it consistently outperforms the Hybrid algorithm, not only in terms of CPU time but also in ordering quality. We believe that to achieve this goal it may be necessary to utilize the vertex and edge weights of the coarse graphs. We are looking at whether we can include this information in the reordering and refinement of the coarse graphs. Another possible way of improving the multilevel algorithm is to use a more sophisticated ordering algorithm on the coarsest graph and then to look at translating improvements in the quality of the ordering on the coarsest graph into corresponding improvements on the original fine graph.

It may also be possible to extend our multilevel approach to the ordering of unsymmetric matrices for use with frontal solvers. This will build on the work of Scott [29] on row ordering algorithms and the work of Hu, Maguire, and Blake [16] on applying a multilevel algorithm for reordering unsymmetric matrices into bordered form.

Appendix. The test problems.

ON THE SOLUTION OF EQUALITY CONSTRAINED QUADRATIC PROGRAMMING PROBLEMS ARISING IN OPTIMIZATION*

NICHOLAS I. M. GOULD†, MARY E. HRIBAR‡, AND JORGE NOCEDAL§

Abstract. We consider the application of the conjugate gradient method to the solution of large equality constrained quadratic programs arising in nonlinear optimization. Our approach is based implicitly on a reduced linear system and generates iterates in the null space of the constraints. Instead of computing a basis for this null space, we choose to work directly with the matrix of constraint gradients, computing projections into the null space by either a normal equations or an augmented system approach. Unfortunately, in practice such projections can result in significant rounding errors. We propose iterative refinement techniques, as well as an adaptive reformulation of the quadratic problem, that can greatly reduce these errors without incurring high computational overheads. Numerical results illustrating the efficacy of the proposed approaches are presented.

1. Introduction.

A variety of algorithms for linearly and nonlinearly constrained optimization (e.g., [9, 14, 15, 36, 37]) use the conjugate gradient (CG) method [28] to solve subproblems of the form

$$\underset{x}{\text{minimize}} \quad q(x) = \tfrac{1}{2}x^T Hx + c^T x \tag{1.1}$$

$$\text{subject to} \qquad Ax = b. \tag{1.2}$$

In nonlinear optimization, the n-vector c usually represents the gradient ∇f of the objective function or the gradient of the Lagrangian, the $n \times n$ symmetric matrix H stands for either the Hessian of the Lagrangian or an approximation to it, and the solution x represents a search direction. The equality constraints $Ax = b$ are obtained by linearizing the constraints of the optimization problem at the current iterate. We will assume here that A is an $m \times n$ matrix, with $m < n$, and that A has full row rank so that the constraints $Ax = b$ constitute m linearly independent equations. We also assume for convenience that H is positive definite in the null space of the constraints, as this guarantees that (1.1)–(1.2) has a unique solution.

As we shall see in section 2.1, the solution of (1.1)–(1.2) can be characterized in terms of a nonunique matrix Z whose columns form a basis for the null space of A. Numerous options are available for computing and representing Z, both explicitly and

implicitly [11, 12, 19, 26, 41, 44]. In the context of large-scale optimization, operations with Z and Z^T can be performed using the LU factorization of a nonsingular submatrix of A; see, for example, [20].

In this paper, we consider techniques for solving (1.1)–(1.2) that use a preconditioned CG method and retain feasibility of the iterates by performing projections into the null space of A without a representation of Z. Unfortunately, a straightforward implementation of these techniques may produce computational errors that cause deteriorating feasibility of the CG iterates. We describe iterative refinement techniques that can improve accuracy, when needed. We also propose a mechanism for redefining the vector c adaptively that does not change the solution of the quadratic problem but that has more favorable numerical properties.

Notation. Throughout the paper $\|\cdot\|$ stands for the ℓ_2 matrix or vector norm. We will denote the floating-point *unit roundoff* (or machine precision) by ϵ_m. For double precision IEEE arithmetic, $\epsilon_m \approx 10^{-16}$. We let $\kappa(A)$ denote the condition number of A, i.e., $\kappa(A) = \sigma_1/\sigma_m$, where $\sigma_1 \geq \cdots \geq \sigma_m > 0$ are the nonzero singular values of A.

2. The CG method with linear constraints.

We now look at applying CG to approximate the solution of the quadratic problem (1.1)–(1.2). First, we present CG method for a reduced problem; then we show how to apply CG to the full system with a scaled projection operator. Finally, we consider the problem (1.1)–(1.2) with a trust region constraint and show how the given CG methods apply.

2.1. The CG method for the reduced system.

A common approach for solving linearly constrained problems is to eliminate the constraints and solve a reduced problem (cf. [21, 39]). More specifically, suppose that Z is an $n \times (n-m)$ matrix spanning the null space of A. Then $AZ = 0$, the columns of A^T together with the columns of Z span $\mathbf{R}^n$, and any solution x^* of the linear equations $Ax = b$ can be written as

$$x^* = A^T x_A{}^* + Z x_Z{}^* \tag{2.1}$$

for some vectors $x_A{}^* \in \mathbf{R}^m$ and $x_Z{}^* \in \mathbf{R}^{n-m}$. The constraints $Ax = b$ yield

$$AA^T x_A{}^* = b, \tag{2.2}$$

which determines the vector $x_A{}^*$. Substituting (2.1) into (1.1), and omitting constant terms ($x_A{}^*$ is a constant now), we see that $x_Z{}^*$ solves the reduced problem

$$\underset{x_Z}{\text{minimize}} \quad \tfrac{1}{2} x_Z{}^T H_{ZZ} x_Z + c_Z{}^T x_Z, \tag{2.3}$$

where

$$H_{ZZ} = Z^T H Z, \quad c_Z = Z^T (H A^T x_A{}^* + c).$$

As we have assumed that the reduced Hessian H_{ZZ} is positive definite, the solution of (2.3) is equivalent to that of the linear system

$$H_{ZZ} x_Z = -c_Z. \tag{2.4}$$

We can now apply the conjugate gradient method to compute an approximate solution of the problem (2.3), or, equivalently, the system (2.4), and substitute this into (2.1) to obtain an approximate solution of the quadratic program (1.1)–(1.2).

This strategy of computing the normal component $A^T x_A$ exactly and the tangential component Zx_Z inexactly is followed in many nonlinear optimization algorithms which ensure that, once linear constraints are satisfied, they remain so throughout the remainder of the optimization calculation (cf. [21]).

Let us now consider the practical application of the CG method to the reduced system (2.4). It is well known that *preconditioning* can improve the rate of convergence of the CG iteration (cf. [3]). We therefore assume that a preconditioner W_{ZZ} is given, where W_{ZZ} is a symmetric, positive definite matrix of dimension $n-m$, which might be chosen to reduce the span of, and to cluster, the eigenvalues of $W_{ZZ}^{-1}H_{ZZ}$. Ideally, one would like to choose W_{ZZ} so that $W_{ZZ}^{-1}H_{ZZ} = I$, and thus $W_{ZZ} = Z^T HZ$ is an ideal preconditioner. Based on this ideal, we consider in this paper preconditioners of the form $W_{ZZ} = Z^T GZ$, where G is a symmetric matrix such that $Z^T GZ$ is positive definite. Some choices of G will be discussed in the next section.

For preconditioners of the form $W_{ZZ} = Z^T GZ$, the preconditioned CG method applied to the $(n-m)$-dimensional reduced system $H_{ZZ}x_Z = -c_Z$ is as follows (see, e.g., [22, p. 532]).

Algorithm 2.1 (preconditioned CG for reduced systems). *Choose an initial point x_Z, compute $r_Z = Z^T HZx_Z + c_Z$, $g_Z = (Z^T GZ)^{-1}r_Z$, and $p_Z = -g_Z$. Repeat the following steps, until a termination test is satisfied:*

$$\alpha = {r_Z}^T g_Z / {p_Z}^T Z^T HZp_Z, \tag{2.5}$$

$$x_Z \leftarrow x_Z + \alpha p_Z, \tag{2.6}$$

$${r_Z}^+ = r_Z + \alpha Z^T HZp_Z, \tag{2.7}$$

$${g_Z}^+ = (Z^T GZ)^{-1}{r_Z}^+, \tag{2.8}$$

$$\beta = ({r_Z}^+)^T {g_Z}^+ / {r_Z}^T g_Z, \tag{2.9}$$

$$p_Z \leftarrow -{g_Z}^+ + \beta p_Z, \tag{2.10}$$

$$g_Z \leftarrow {g_Z}^+ \quad \textit{and} \quad r_Z \quad \leftarrow \quad {r_Z}^+. \tag{2.11}$$

This iteration may be terminated, for example, when ${r_Z}^T(Z^T GZ)^{-1}r_Z$ is sufficiently small.

Several algorithms for large-scale optimization are based on combining a suitable representation of Z with CG methods for solving the reduced system [18, 33, 46]. Coleman and Verma [13] and Nash and Sofer [38] have proposed strategies for defining reduced-system preconditioners which approximate $Z^T HZ$ in different ways.

We present Algorithm 2.1 for illustrative purposes only. In the next section, we describe modifications to this algorithm which make it possible to avoid operating with the null space basis Z.

2.2. The CG method for the full system. If we were to compute an approximate solution using Algorithm 2.1, it must be multiplied by Z and substituted in (2.1) to give the approximate solution of the quadratic program (1.1)–(1.2). Alternatively, we may rewrite Algorithm 2.1 so that the multiplication by Z and the addition of the term $A^T {x_A}^*$ is computed within the CG iteration. To do so, we introduce, in the following algorithm, the n-vectors x, r, g, p which satisfy $x = Zx_Z + A^T {x_A}^*$, $Z^T r = r_Z$, $g = Zg_Z$, and $p = Zp_Z$. We also define the scaled projection matrix

$$P = Z(Z^T GZ)^{-1}Z^T. \tag{2.12}$$

We note, for future reference, that P is independent of the choice of null space basis Z.

ALGORITHM 2.2 (preconditioned CG in expanded form). *Choose an initial point x satisfying $Ax = b$, compute $r = Hx + c$, $g = Pr$, and $p = -g$. Repeat the following steps, until a convergence test is satisfied:*

$$\alpha = r^T g / p^T Hp, \tag{2.13}$$

$$x \leftarrow x + \alpha p, \tag{2.14}$$

$$r^+ = r + \alpha Hp, \tag{2.15}$$

$$g^+ = Pr^+, \tag{2.16}$$

$$\beta = (r^+)^T g^+ / r^T g, \tag{2.17}$$

$$p \leftarrow -g^+ + \beta p, \tag{2.18}$$

$$g \leftarrow g^+ \quad \textit{and} \quad r \leftarrow r^+. \tag{2.19}$$

This will be the main algorithm studied and further refined in this paper. It is important to notice that this algorithm, unlike its predecessor, is independent of the choice of Z. In the next section, different choices for P will be presented.

Note that the vector g^+, which we call the *preconditioned residual*, has been defined to be in the null space of A. As a result, in exact arithmetic, all the search directions p generated by Algorithm 2.2 will also lie in the null space of A, and thus the iterates x will all satisfy $Ax = b$. However, computed representations of the scaled projection P can produce rounding errors that may cause p to have a significant component outside the null space of A, leading to convergence difficulties. This will be the subject of later sections of the paper.

Several types of stopping tests can be used, but since their choice depends on the requirements of the optimization method, we shall not discuss them here. In the numerical tests reported in this paper, we terminate the CG iteration based on the quantity $r^T g \equiv r^T Pr \equiv g^T Gg$. An initial point satisfying $Ax = b$ can be computed, for example, by solving the normal equations (2.2).

Two simple choices of G are $G = \operatorname{diag}(H)$, and $G = I$. The first choice may be appropriate when the diagonal elements of H are of widely different magnitudes. This is the case, for example, in barrier methods for constrained optimization that handle bound constraints $l \le x \le u$ by adding terms of the form $-\mu \sum_{i=1}^{n} (\log(x_i - l_i) + \log(u_i - x_i))$ to the objective function for some positive barrier parameter μ. The second choice, $G = I$, arises in trust region methods, as we discuss next.

2.3. The CG method and the trust region problem. In trust region methods, the problem (1.1)–(1.2) also contains a trust region constraint of the form $\|x\| \le \Delta$. Steihaug [43] noted, however, that the trust region constraint can be easily imposed if the initial estimate of the solution of (1.1)–(1.2) is chosen to be the vector zero. In this case the CG iterates are monotonically increasing in norm, and the CG iteration can be terminated as soon as the norm of one of the iterates exceeds the trust region radius. No other changes to the CG iteration are needed.

For the reduced problem (2.3), the added trust region constraint has the form $\|Zx_z\| \le \Delta_z$. In order to transform it into a spherical constraint, we introduce the change of variables $x_z \leftarrow (Z^T Z)^{-1/2} x_z$ whose effect in the CG iteration is identical to that of replacing $(Z^T GZ)^{-1}$ by $(Z^T Z)^{-1}$ in (2.8). Thus, the choice $G = I$ arises in several trust region methods for constrained optimization [9, 15, 16, 27, 36, 40, 47]. Since the role of this matrix is not to produce a clustering of the eigenvalues, we will regard Algorithm 2.2 with the choice $G = I$ as an *unpreconditioned* CG iteration.

3. The CG algorithm without a null space basis. We are interested here in using Algorithm 2.2 in such a way that a representation of Z is not necessary. This will be possible because, as is well known, there are alternative ways of expressing the scaled projection operator (2.12).

3.1. Computing projections. We now discuss how to apply the projection operator $Z(Z^TGZ)^{-1}Z^T$ to a vector without a representation of the null space basis Z.

Let us begin by considering the simple case when $G = I$, so that P is the orthogonal projection operator onto the null space of A. We denote it by P_Z, i.e.,

$$P_Z = Z(Z^TZ)^{-1}Z^T. \tag{3.1}$$

Thus the preconditioned residual g^+ (2.16) is the result of projecting r^+ into the null space of A and can be written as

$$g^+ = P_Z r^+. \tag{3.2}$$

This projection can be performed in two alternative ways.

The first is to replace P_Z by the equivalent formula

$$P_A = I - A^T(AA^T)^{-1}A \tag{3.3}$$

and thus to replace (3.2) with

$$g^+ = P_A r^+. \tag{3.4}$$

We can express this as

$$g^+ = r^+ - A^Tv^+, \tag{3.5}$$

where v^+ is the solution of

$$AA^Tv^+ = Ar^+. \tag{3.6}$$

Noting that (3.6) are the normal equations, it follows that v^+ is the solution of the least squares problem

$$\underset{v}{\text{minimize}} \quad \|r^+ - A^Tv^+\| \tag{3.7}$$

and that the desired projection g^+ is the corresponding residual. The approach (3.5)–(3.6) for computing the projection $g^+ = P_Z r^+$ will be called the *normal equations approach*. In this paper, we assume that (3.6) will be solved using a Cholesky factorization of AA^T.

The second possibility is to express the projection (3.2) as the solution of the augmented system

$$\begin{pmatrix} I & A^T \\ A & 0 \end{pmatrix} \begin{pmatrix} g^+ \\ v^+ \end{pmatrix} = \begin{pmatrix} r^+ \\ 0 \end{pmatrix}. \tag{3.8}$$

In this paper, we assume that this system will be solved by means of a symmetric indefinite factorization that uses 1 × 1 and 2 × 2 pivots [22]. We refer to this as the *augmented system approach*.

Now let us suppose that preconditioning has the more general form

$$g^+ = P_{Z:G} r^+, \quad \text{where} \quad P_{Z:G} = Z(Z^T G Z)^{-1} Z^T. \tag{3.9}$$

This may be expressed as

$$g^+ = P_{A:G} r^+, \quad \text{where} \quad P_{A:G} = G^{-1}\left(I - A^T(AG^{-1}A^T)^{-1}AG^{-1}\right) \tag{3.10}$$

if G is nonsingular, and can be found as the solution of

$$\begin{pmatrix} G & A^T \\ A & 0 \end{pmatrix} \begin{pmatrix} g^+ \\ v^+ \end{pmatrix} = \begin{pmatrix} r^+ \\ 0 \end{pmatrix} \tag{3.11}$$

whenever $z^T G z \neq 0$ for all nonzero z for which $Az = 0$ (see, e.g., [21, section 5.4.1]). While (3.10) is far from appealing when G^{-1} does not have a simple form, (3.11) is a useful generalization of (3.8). Clearly, the system (3.8) may be obtained from (3.11) by setting $G = I$, and the perfect preconditioner results if $G = H$, but other choices for G are also possible; all that is required is that $z^T G z > 0$ for all nonzero z for which $Az = 0$. The idea of using the projection (3.3) in the CG method dates back to at least [42]; the alternative (3.11), and its special case (3.8), are proposed in [10], although [10] unnecessarily requires that G be positive definite. A more recent study on preconditioning the projected CG method is [13], while the eigenstructure of the preconditioned system is examined by [35, 37].

Interestingly, preconditioning in Coleman and Verma's null space approach [13] requires the solution of systems like (3.11), but it allows A to be replaced by a sparser matrix. (The price to pay for this relaxation is that products involving a suitable null space matrix are required.) Such an approach has considerable merit, especially in the case where using the exact A leads to significant fill-in during the factorization of the coefficient matrix of (3.11). It remains to be seen how such an approach compares with those we propose here when used in algorithms for large-scale constrained optimization.

Note that (3.4), (3.8), and (3.11) do not make use of a null space basis Z and require only factorization of matrices involving A. Significantly, all three forms allow us to compute an initial point satisfying $Ax = b$, the first because it relies on a factorization of AA^T, from which we can compute $x = A^T(AA^T)^{-1}b$, while factorizations of the system matrices in (3.8) and (3.11) allow us to find a suitable x by solving

$$\begin{pmatrix} I & A^T \\ A & 0 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} 0 \\ b \end{pmatrix} \quad \text{or} \quad \begin{pmatrix} G & A^T \\ A & 0 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} 0 \\ b \end{pmatrix}.$$

Unfortunately all three of our proposed alternatives, (3.4), (3.8), and (3.11) for computing g^+ can give rise to significant roundoff errors that prevent the iterates from remaining in the null space of A, particularly as the CG iterates approach the solution. The difficulties are caused by the fact that, as the iterations proceed, the projected vector $g^+ = Pr^+$ becomes increasingly small while r^+ does not. Indeed, the optimality conditions of the quadratic program (1.1)–(1.2) state that the solution x^* satisfies

$$Hx^* + c = A^T \lambda \tag{3.12}$$

for some Lagrange multiplier vector λ. The vector $Hx + c$, which is denoted by r in Algorithm 2.2, will generally stay bounded away from zero, but as indicated by

(3.12), it will become increasingly closer to the range of A^T. In other words, r will tend to become orthogonal to Z, and hence, from (3.9), the preconditioned residual g will converge to zero so long as the smallest eigenvalue of Z^TGZ is bounded away from zero.

That this discrepancy in the magnitudes of $g^+ = Pr^+$ and r^+ will cause numerical difficulties is apparent from (3.5), which shows that significant cancellation of digits will usually take place. The generation of harmful roundoff errors is also apparent from (3.8) and (3.11) because g^+ will be small while the remaining components v^+ remain large. Since the magnitude of the errors generated in the solution of (3.8) and (3.11) is governed by the size of the large component v^+, the vector g^+ is likely to contain large relative errors. These arguments will be made more precise in the next section.

Now consider an example problem. Since the goal of this paper is not to evaluate the efficiency of particular choices of preconditioners, in all the examples given in this paper we will choose $G = I$, which, as we have mentioned, arises in trust region optimization methods without preconditioning. To assess the techniques to be proposed, we need to measure the closeness of g to the null space of A. For this purpose, we have chosen

$$\cos\theta = \max_i \left\{ \frac{A_i^T g}{||A_i||\ ||g||} \right\}, \tag{3.13}$$

where A_i is the ith row of A. The value of $\cos\theta$ provides a relative measure of orthogonality with the property that, for nonzero g, it vanishes if and only if g lies in the null space of A.

Example 3.1. We applied Algorithm 2.2 to solve problem CVXQP3 from the CUTE collection [6], with $n = 1000$ and $m = 750$, where the simple bounds were removed to create a problem of the form (1.1)–(1.2). We used both the normal equations (3.5)–(3.6) and augmented system (3.8) approaches to compute the projection and define $G = I$. The results are given in Figure 3.1, which plots $\sqrt{r^Tg} = ||r_z||$ (resid), the norm of the null space component of the residual, as a function of the iteration number. In both cases the CG iteration was terminated when r^Tg became negative, which indicates that severe errors have occurred since r^Tg must be positive. (Continuing the iteration past this point resulted in oscillations in the norm of the gradient without any significant improvement.) At iteration 50 of both runs, r is of order 10^5 whereas its projection g is of order 10^{-1}. Figure 3.1 also plots (3.13), the cosine of the angle between the preconditioned residual g and the rows of A. Note that this cosine, which should be zero in exact arithmetic, increases and indicates that the CG iterates leave the constraint manifold $Ax = b$.

We believe it is reasonable to attribute the failure of the CG algorithm to the deviation of the iterates from the constraint manifold $Ax = b$, since the derivation of Algorithm 2.2 from its predecessor is predicated on the assumption that the search is restricted to this manifold. An analysis by Arioli, Duff, and de Rijk [2] (which improves on [1]) indicates that, with care, it is possible to ensure that the backward error[1]

$$A_i^T g^+ / (|A||g^+|)_i$$

of the computed g^+ is of the order of the machine precision, ϵ_m for the case $G = I$. (Here $|\cdot|$ denotes the componentwise absolute value.)

[1] This definition needs to be modified if $|A||g^+|$ is (close to) zero. See [1] for details.

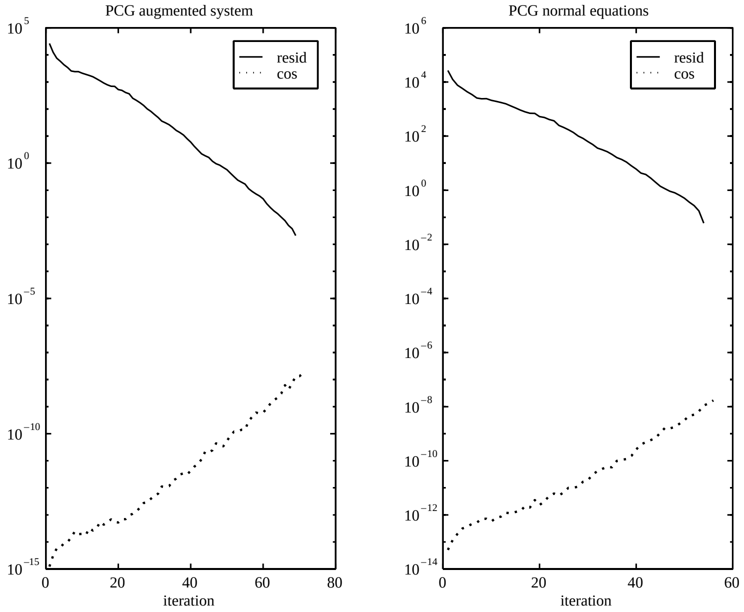

FIG. 3.1. *The CG method with two options for the projection.*

Errors such as those illustrated in Example 3.1 are not uncommon in optimization calculations based on Algorithm 2.2. This is of concern, as it may cause the outer optimization algorithms to fail to achieve feasibility or to require many iterations to do so. A particular example is given by problem ORTHREGA from the CUTE collection, which cannot be solved to a prescribed accuracy using the trust region CG approach of [31]; see [31, pp. 33–34] and section 7.

In sections 5 and 6 we propose several remedies. One of them is based on an adaptive redefinition of r that attempts to minimize the differences in magnitudes between $g^+ = Pr^+$ and r^+. We also describe several forms of iterative refinement for the projection operation. All these techniques are motivated by the roundoff error analysis given next.

4. Sources of errors. We now present error bounds that support the arguments made in the previous section, particularly the claim that the most problematic situation occurs in the latter stages of the CG iteration when g^+ is converging to zero, but r^+ is not. That is, we shall presume that $\|r^+\|$ is much larger than its projection $\|g^+\|$. For simplicity, we shall assume henceforth that A has been scaled so that $\|A\| = \|A^T\| = 1$ and shall only consider the simplest possible choice, $G = I$. Any computed, as opposed to exact, quantity will be denoted by a subscript c.

First consider the *normal equations approach.* Here the projection $g^+ = P_A r^+$ is given by (3.5), where (3.6) is solved by means of the Cholesky factorization of AA^T. In finite precision, it is straightforward to deduce that the relative error in the projection satisfies[2]

$$\frac{\|g^+ - g_c^+\|}{\|g^+\|} \leq \gamma \epsilon_m \kappa^2(A) \frac{\|v^+\|}{\|g^+\|}, \tag{4.1}$$

[2] If $\|g^+\|$ is small, it is preferable to replace the denominators in (4.1) by $\max(\|g^+\|, \epsilon)$, where ϵ is a suitable multiple (e.g., 10) of ϵ_m.

where $\gamma = 2.5n^{3/2}$, using the analysis of [5, p. 49].[3] We can thus conclude that the error in the projection (4.1) can be significant when $\kappa(A)$ or

$$\frac{\|v^+\|}{\|g^+\|} = \frac{\|v^+\|}{\|P_A r^+\|} \approx \frac{\|r^+\|}{\|P_A r^+\|} \tag{4.2}$$

is large, the latter approximation resulting from (3.5) and the assumption that $\|A\| = 1$, since then $\|r^+\| \approx \|A^T v^+\| \leq \|v^+\|$.

When the condition number $\kappa(A)$ is moderate, the contribution of the ratio (4.2) to the relative error (4.1) is normally not large enough to cause failure of the outer optimization calculation. For example, a stopping test in a nonlinear optimization algorithm, which causes termination when projected residual g^+ is (say) 10^{-6} times smaller in norm than the initial residual, has a ratio (4.2) of roughly 10^6. In this case, using double precision arithmetic, one would have sufficient accuracy to make progress toward the solution. However, as the condition number $\kappa(A)$ grows, the loss of significant digits becomes severe, especially since $\kappa(A)$ appears squared in (4.1).

Now consider the *augmented system approach* (3.11). Again we will focus on the choice $G = I$ for which the preconditioned residual $g^+ = Pr^+$ is computed by solving the system (3.8) using a direct method. There are a number of such methods, the strategies of Bunch and Kaufman [7] and Duff and Reid [17] being the best known examples for dense and sparse matrices, respectively. Both form the LDL^T factorization of the augmented matrix (i.e., the matrix appearing on the left-hand side of (3.8)), where L is unit lower triangular and D is block diagonal with 1×1 or 2×2 blocks. This approach is usually (but not always) more stable than the normal equations approach.

In the case which concerns us most, when $\|g^+\|$ converges to zero while $\|v^+\|$ is bounded, an error analysis [4] shows that

$$\frac{\|g^+ - g_c^+\|}{\|g^+\|} \leq \eta\epsilon_m(\sigma_1 + \kappa(A))\frac{\|v^+\|}{\|g^+\|},$$

where η is the product of a low degree polynomial in $n + m$ with the growth factor from the elimination, while σ_1 is the largest singular value of A. It is interesting to compare this bound with (4.1). We see that the ratio (4.2) again plays a crucial role in the analysis and that the augmented system approach is likely to give a more accurate solution g^+ than the method of normal equations in this case. This cannot be stated categorically, however, since the size of the factor η is difficult to predict.

The residual update strategy described in section 6 aims at minimizing the size of the ratio (4.2), and, as we will see, has a highly beneficial effect in Algorithm 2.2. Before presenting it, we discuss various iterative refinement techniques designed to improve the accuracy of the projection operation.

5. Iterative refinement.

Iterative refinement is known as an effective procedure for improving the accuracy of a solution obtained by a method that is not backwards stable. We will now consider how to use it in the context of our normal equations and augmented system approaches.

[3] The bound assumes that there are no errors in the formation of AA^T and Ar^+ or in the backsolves using the Cholesky factors; this is a reasonable assumption in our context [29, section 19.4] provided that $\epsilon_m\kappa^2(A)$ is somewhat smaller than 1. It also ignores less significant errors that arise in the computation of the matrix-vector product A^Tv^+ and in the subtraction $r^+ - A^Tv^+$ given in (3.5).

5.1. Normal equations approach. Let us suppose that we choose $G = I$ and that we compute the projection $P_A r^+$ via the normal equations approach (3.5)–(3.6). An appealing idea for trying to improve the accuracy of this computation is to apply the projection repeatedly. Therefore, rather than computing $g^+ = P_A r^+$ in (2.16), we let $g^+ = P_A \cdots P_A r^+$, where the projection is applied as many times as necessary to keep the errors small. The motivation for this *multiple projections technique* stems from the fact that the computed projection $g_c^+ = (P_A r^+)_c$ is likely to have only a small component, consisting almost entirely of rounding errors, outside of the null space of A. Therefore, applying the projection P_A to the first projection g_c^+ will give an improved estimate because the ratio (4.2) will now be much smaller. By repeating this process we may hope to obtain further improvement of accuracy.

The multiple projection technique may simply be described as setting $g_0^+ = r^+$ and applying the following algorithm.

ALGORITHM 5.1 (multiple projections—normal equations). *Set $i = 0$ and repeat the following steps until a convergence test is satisfied:*

$$\begin{aligned} &\textit{solve} \quad L(L^T v_i^+) = A g_i^+, && (5.1)\\ &\textit{set} \quad g_{i+1}^+ = g_i^+ - A^T v_i^+, && (5.2)\\ &\qquad\ \ i \leftarrow i+1, \end{aligned}$$

where L is the Cholesky factor of AA^T.

We note that this method is only appropriate when $G = I$, although a simple variant is possible when G is diagonal. Also note that the multiple projection technique is equivalent to performing fixed-precision iterative refinement on the normal equations. In the multiple projections approach, the projection g^+ is updated at each iteration. In fixed-precision iterative refinement of the normal equations, the solution of the normal equations v^+ is updated and the projection g^+ is recomputed from this solution.

We resolved the problem given in Example 3.1 using multiple projections and setting $G = I$. At every CG iteration, we measured the cosine (3.13) of the angle between g and the columns of A. If this cosine was greater than 10^{-12}, multiple projections were applied until the cosine was smaller than this value. Using this strategy, we were able to reduce the norm of the null space component of the residual to around 10^{-16} of its initial value.

In the optimization setting we would apply multiple corrections only when needed, e.g., when the angle between the projected residual and the columns of A is not very small; see Algorithm 6.2 in section 6.1.

It is straightforward to analyze the multiple projections strategy (5.1)–(5.2) provided that, as before, we make the simplifying assumptions that A has norm one and that the only rounding errors we make are in forming L and solving (5.1). In this case, we have that

$$\|(g_{i+1}^+)_c - g^+\| \le \|\Delta v_i^+\| \le \left(\gamma \epsilon_m \kappa^2(A)\right)^i \|v^+\|, \tag{5.3}$$

and thus that the error converges R-linearly to zero with constant $\gamma \epsilon_m \kappa^2(A)$, so long as this factor is less than 1. Of course, the reduction in error at this rate cannot be sustained indefinitely, as the other errors we have ignored in (5.1)–(5.2) become important. Nonetheless, one would expect (5.3) to reflect the true behavior until $\|(g_{i+1}^+)_c - g^+\|$ approaches a small multiple of the unit roundoff ϵ_m. It should be stressed, however, that this approach is still limited by the fact that the condition number of A appears squared in (5.3); improvement can be guaranteed only if $\gamma\epsilon_m\kappa^2(A) < 1$.

We should also note that multiple projections are almost identical in their form and numerical properties to *fixed precision iterative refinement to the least squares problem* [5, p. 125]. Since a perturbation analysis of the least squares problem [5, Theorem 1.4.6] gives

$$\|g^+ - g_c^+\| = O\left(\epsilon_m(\|v\| + \kappa(A)\|g^+\|)\right), \tag{5.4}$$

and as the dependence here on the condition number is linear—not quadratic as we have seen for (4.1)—we may deduce that the normal equations approach is not backward stable [5, section 2.2]. Indeed, since $\kappa(A)$ is multiplied by $\|g^+\|$, when g^+ is small the effect of the condition number of A is much smaller in (5.4) than in (4.1). It is precisely under such circumstances that fixed-precision iterative refinement is most appropriate [5, section 2.9.3].

We should mention two other iterative refinement techniques that one might consider which are either not effective or not practical in our context.

The first is to use fixed-precision iterative refinement [5, section 2.9] to attempt to improve the solution v^+ of the normal equations (3.6). This, however, will generally be unsuccessful because fixed-precision iterative refinement improves only a measure of backward stability [22, p. 126], and the Cholesky factorization is already a backward stable method. We have performed numerical tests and found no improvement from this strategy.
