A CENTRAL-DIFFERENCE SCHEME FOR A PURE STREAM FUNCTION FORMULATION OF INCOMPRESSIBLE VISCOUS FLOW*

RAZ KUPFERMAN†

Abstract. We present a numerical scheme for incompressible viscous flow, formulated as an equation for the stream function. The pure stream function formulation obviates the difficulty associated with vorticity boundary conditions. The resulting biharmonic equation is discretized with a compact scheme and solved with an algebraic multigrid solver. The advection of vorticity is implemented with a high-resolution central scheme that remains stable and accurate in the presence of large gradients. The accuracy and robustness of the method are demonstrated for high Reynolds number flows in a lid-driven cavity.

Key words. incompressible Navier–Stokes equations, vorticity, stream function, biharmonic equation, algebraic multigrid, high-resolution schemes

1. Introduction.

The vorticity formulation of the Navier–Stokes equations is a classical starting point for approximation methods, due to the distinguished role of vorticity in high Reynolds number flows. The difficulty with a vorticity formulation is the lack of natural boundary conditions; the no-slip boundary conditions do not have a simple counterpart in terms of vorticity. In the context of computational methods, the problem of vorticity boundary conditions has a long history, dating back to the 30's [22]; it has received much attention within the context of vortex methods [6], and there exists a substantial amount of recent work (see, e.g., Goodrich and Soh [11], Auteri and Quartapelle [3], Anderson and Reider [2], and E and Liu [8, 7]).

Recently, Ben-Artzi, Fishelov, and Trachtenberg have developed a method of vorticity/stream function dynamics [4]. This method uses explicitly the space of functions in which the dynamics take place. Specifically, the stream function dynamics take place in the Sobolev space H_0^2, whereas the vorticity field resides in the image of H_0^2 under the action of the Laplace operator. At the end of every time step a provisional solution is projected back onto the right functional space, in analogy with the projection onto the space of divergence-free velocity fields in the primitive-variable formalism [5]. As a result, no reference to vorticity boundary conditions is needed, and instead, natural boundary conditions are imposed (as an integral part of the dynamics space) on the stream function. The scheme we present in this paper belongs to this category. Like the scheme in [4], it evolves the stream function within the above-mentioned functional space, but rather than using a "predictor-corrector" approach, it does it via implicit time stepping. In both cases, the computational complexity is dominated by the solution of a linear system of biharmonic type.

The advection of vorticity has been implemented using the Kurganov–Tadmor (KT) scheme [16], which was developed in the context of hyperbolic conservation laws; this scheme has been shown to remain accurate and robust in the presence of large

†Institute of Mathematics, The Hebrew University, Jerusalem 91904 Israel (raz@math.huji.ac.il).

gradients; at the same time, it shares the relative simplicity of the central differencing framework. In addition, the KT scheme has a well-behaved semidiscrete limit, and as a result, time stepping is not tied to the spatial discretization (except for the standard stability requirements). The independence of the spatial and temporal discretizations adds a degree of modularity that may greatly simplify subsequent adaptations and improvements.

The biharmonic viscous term is discretized by means of a compact stencil (see [1]), which simplifies the treatment of boundary conditions. The fourth-order elliptic equation is then solved with an algebraic multigrid (AMG) solver [13]. This technique can be adapted with little modification to more complicated systems and geometries.

In section 2 we present the flow equations in vorticity-stream function formulation and describe the difficulty associated with boundary conditions. In section 3 we investigate a linear model equation, $u_{xxt} - u_{xxxx} = 0$, inspired by the stream function formulation of the Navier–Stokes equations. This system is simple enough to be completely tractable but is still rich enough to capture the issue of boundary conditions. We prove the convergence of an implicit scheme that uses a compact stencil. The convergence is with respect to the H^2 norm, which is the appropriate norm for a variable analogous to the stream function. In section 4 we extend the scheme of section 3 to the Navier–Stokes equations in a two-dimensional bounded domain. In section 5 we present numerical results for a classical benchmark problem: flow in a two-dimensional lid-driven cavity. The method is found to be accurate and robust up to a regime of high Reynolds numbers, in which the flow becomes highly unstable and generates convoluted vorticity patterns. The scheme seems to be able to resolve vorticity patterns almost down to the scale of a single mesh size.

2. The vorticity-stream function formulation.

We consider incompressible viscous flow in a two-dimensional domain. The motion of the fluid is governed by the Navier–Stokes equations,

$$\begin{aligned} \frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u}\cdot\boldsymbol{\nabla})\mathbf{u} &= -\boldsymbol{\nabla} p + \nu\Delta\mathbf{u}, \\ \boldsymbol{\nabla}\cdot\mathbf{u} &= 0, \end{aligned} \tag{2.1}$$

where $\mathbf{u} = \mathbf{u}(\mathbf{x},t) = (u(\mathbf{x},t), v(\mathbf{x},t))$ is the Eulerian velocity field, $p = p(\mathbf{x},t)$ is the pressure, and ν is the kinematic viscosity. In a bounded domain Ω enclosed by rigid walls, the impermeability of the walls and the no-slip condition imply

$$\mathbf{u}(\mathbf{x},t) = \mathbf{U}(\mathbf{x},t), \qquad \mathbf{x}\in\partial\Omega, \quad t>0, \tag{2.2}$$

where $\mathbf{U}$ is the velocity of the wall.

In terms of the vorticity field $\omega = (\boldsymbol{\nabla}\times\mathbf{u})_z = \partial_x v - \partial_y u$, the flow equations read

$$\frac{\partial\omega}{\partial t} + (\mathbf{u}\cdot\boldsymbol{\nabla})\omega = \nu\Delta\omega, \tag{2.3}$$

where $\mathbf{u}$ is obtained from ω through the div-curl relations

$$\begin{aligned} \boldsymbol{\nabla}\cdot\mathbf{u} &= 0, \\ (\boldsymbol{\nabla}\times\mathbf{u})\cdot\hat{z} &= \omega. \end{aligned} \tag{2.4}$$

The divergence condition implies that the flow field is derivable from a scalar stream function, $\psi(\mathbf{x},t)$,

$$\mathbf{u} = \boldsymbol{\nabla}^{\perp}\psi = \left(-\frac{\partial\psi}{\partial y}, \frac{\partial\psi}{\partial x}\right), \tag{2.5}$$

which, substituted into the curl condition, yields the Poisson equation

$$(\boldsymbol{\nabla} \times \mathbf{u}) \cdot \hat{z} = \Delta\psi = \omega. \tag{2.6}$$

Finally, the boundary conditions (2.2) translate into boundary conditions for the stream function

$$\boldsymbol{\nabla}^{\perp}\psi = \mathbf{U}, \qquad \mathbf{x} \in \partial\Omega. \tag{2.7}$$

The set of equations (2.3), (2.5), and (2.6), together with the boundary conditions, (2.7), is known as the vorticity-stream function formulation of the Navier–Stokes equations.

The classical difficulty with the vorticity-stream function formulation is the improper partition of boundary conditions. The presence of a dissipative term in (2.3) requires the specification of boundary conditions for the vorticity, but these are not prescribed explicitly. Vorticity boundary conditions are extremely important from a physical point of view as they represent the mechanism of vorticity generation at the boundary. On the other hand, the Poisson equation (2.6) is overdetermined by both Neumann *and* Dirichlet boundary conditions (2.7).

This difficulty is immediately removed if the vorticity equation (2.3) is interpreted instead as an equation for the stream function

$$\frac{\partial}{\partial t}\Delta\psi + \Big[(\boldsymbol{\nabla}^{\perp}\psi) \cdot \boldsymbol{\nabla}\Big]\,\Delta\psi = \nu\Delta^2\psi. \tag{2.8}$$

This equation contains a biharmonic operator so that the boundary conditions (2.7) are the natural ones with no over- or underdetermination.

3. A linear model equation. The issue of vorticity boundary conditions can be illustrated by considering a simple model equation inspired by (2.8): a fourth-order linear equation for a one-dimensional scalar field $u(x,t)$,

$$\begin{cases} u_{xxt} = u_{xxxx}, & x \in (0,1), \\ u(0,t) = u(1,t) = 0, \\ u_x(0,t) = u_x(1,t) = 0, \\ u(x,0) = u_0(x), \end{cases} \tag{3.1}$$

where subscripts denote differentiation. Here u plays a role analogous to the stream function, and u_{xx} is the analogue of vorticity. We consider homogeneous boundary conditions; inhomogeneous ones are readily reduced to the homogeneous case by a standard change of variables [12].

Equation (3.1) is solvable by standard techniques, and its solution can be represented as a Fourier sine-series

$$\begin{aligned} u(x,t) = \sum_{q=1}^{\infty} a_q \sin(\pi q x)\, e^{-\pi^2 q^2 t} + \int_0^t b_1(s) \sum_{q=1}^{\infty} \sin(\pi q x)\, e^{-\pi^2 q^2 (t-s)}\, ds \\ + \int_0^t b_2(s) \sum_{q=1}^{\infty} (-1)^q \sin(\pi q x)\, e^{-\pi^2 q^2 (t-s)}\, ds, \end{aligned} \tag{3.2}$$

where

$$a_q = \int_0^1 u_0(x)\, \sin(\pi q x)\, dx$$

and $b_1(t)$,$b_2(t)$ are functions to be determined. The sine-series (3.2) automatically satisfies the Dirichlet boundary conditions $u(0,t) = u(1,t) = 0$. The role of the functions $b_1(t)$,$b_2(t)$ is to enforce the Neumann boundary conditions; they are determined implicitly by the conditions $u_x(0,t) = u_x(1,t) = 0$. Note that

$$\lim_{s\to t} \quad \sum_{q=1}^{\infty} \sin(\pi q x)\, e^{-\pi^2 q^2 (t-s)} = \delta(x),$$
$$\lim_{s\to t} \quad \sum_{q=1}^{\infty} (-1)^q \sin(\pi q x)\, e^{-\pi^2 q^2 (t-s)} = \delta(1-x),$$

which means that $b_1(t)$,$b_2(t)$ can be regarded as the strength of point sources that are concentrated on the left and right boundary, respectively; they play a role analogous to vortex sheets in fluid mechanics.

The solution (3.2) can also be expanded in eigenfunctions,

$$u(x,t) = \sum_q \alpha_q \varphi_q(x) e^{\Omega_q t},$$

where the index q runs over a discrete set of wavenumbers, and $\Omega_q = -\pi^2 q^2$ is the corresponding amplification rate. The eigenfunctions, φ_q, divide into two families:

$$\varphi_q^{(1)}(x) = \left[1 - \cos(\pi q x)\right], \tag{3.3}$$

where $q = 2, 4, \dots$, and

$$\varphi_q^{(2)}(x) = (2/\pi q)\sin(\pi q x) - \cos(\pi q x) - 2x + 1, \tag{3.4}$$

where the wavenumbers q are solutions of the transcendental equation

$$\tan\frac{\pi q}{2} = \frac{\pi q}{2}.$$

Such wavenumbers are typical to a system with mixed boundary conditions [12]. The eigensolutions $\varphi_q^{(1)}$ correspond to the case where the boundary terms are identically zero: $b_1(t) = b_2(t) \equiv 0$ (no generation of "vortex sheets").

A natural approach in approximating (3.1) is to view it as an implicit equation for $u_t(x,t)$; this is analogous to the choice of stream function variables in fluid mechanics. For simplicity, it is sufficient to consider schemes that are first-order in time; the generalization to higher-order is straightforward. For example, a backward-Euler scheme reads

$$\frac{u_{xx}^{n+1} - u_{xx}^{n}}{k} = u_{xxxx}^{n+1},$$

where $k = t^{n+1} - t^n$ is the time step interval.

We discretize the unit segment using a regular mesh of $N+1$ points, with the first and last points coinciding with the left and right boundaries, $x_0 = 0$, $x_N = 1$; the mesh spacing is $h = 1/N$. The standard discretizations of second and fourth derivatives involve stencils of three and five points, respectively, which implies that boundary conditions need to be prescribed at two points near each boundary. Alternatively, it is possible to use a compact 3-point stencil by introducing an auxiliary field v that approximates u_x. Following [1], we propose the following scheme:

$$\begin{aligned} D^0\left(v_j^{n+1}-v_j^n\right) &= 12\lambda\left(D^0 v_j^{n+1} - D^+D^-u_j^{n+1}\right), \\ D^0 u_j^{n+1} &= \left(I+\frac{1}{6}h^2D^+D^-\right)v_j^{n+1}, \end{aligned} \qquad j=1,\dots,N-1, \tag{3.5}$$

where D^0,$D^{\pm}$ are the standard central-, forward-, and backward-difference operators, $\lambda = k/h^2$, and $u_0 = u_N = v_0 = v_N = 0$ at the boundary points. Equation (3.5) is a discrete *differential-algebraic* system; the first equation is an evolution equation, whereas the second is a constraint.

To prove that the numerical scheme (3.5) is convergent we first analyze its consistency and stability properties. Convergence follows from a generalization of Lax's theorem.

LEMMA 3.1. *The numerical scheme* (3.5) *is consistent with truncation error* $\tau = O(h^2,k)$.

Proof. Let $u(x,t)$ be a smooth solution of $u_{xxt} = u_{xxxx}$, and let the discrete auxiliary field $v_j(t)$ be defined implicitly by

$$D^0u(x_j,t) = \left(I+\frac{1}{6}h^2D^+D^-\right)v_j(t)$$

with $v_0(t) = v_N(t) = 0$. A Taylor expansion gives

$$\left(I+\frac{1}{6}h^2D^+D^-\right)[u_x(x_j,t)-v_j(t)] = O(h^4),$$

from which we conclude that

$$v_j(t) = u_x(x_j,t) + O(h^4). \tag{3.6}$$

Substituting (3.6) into the first equation in (3.5) and performing another Taylor expansion, we finally obtain

$$D^0\left[v_j(t+k)-v_j(t)\right] = 12\lambda\left[D^0v_j(t+k) - D^+D^-u(x_j,t+k)\right] + k\,\tau_j^n$$

with $\tau_j^n = O(h^2,k)$. □

LEMMA 3.2. *The numerical scheme* (3.5) *is unconditionally stable.*

Proof. It is possible to construct two families of eigenvectors analogous to (3.3), (3.4) that span the space of solutions of (3.5). Specifically,

$$u_j^n = \sum_q \alpha_q \tilde{\varphi}_q(x_j)\,\tilde{\Omega}_q^n,$$

where the eigenvectors that correspond to (3.3) are

$$\tilde{\varphi}_q^{(1)}(x_j) = 1-\cos(\pi q x_j) \tag{3.7}$$

for $q = 2,4,\dots,N-1$, and the eigenvectors that correspond to (3.4) are

$$\tilde{\varphi}_q^{(2)}(x_j) = (2/A_q)\,\sin(\pi q x_j) - \cos(\pi q x_j) - 2x_j + 1 \tag{3.8}$$

with

$$\tan\frac{\pi q}{2} = \frac{A_q}{2}, \qquad A_q = \frac{3\,\sin(\pi q h)}{h\,[2+\cos(\pi q h)]}.$$

The amplification factor $\tilde{\Omega}_q$ is given in both cases by

$$\Omega_q = \left(1 + \frac{4k}{h^2}\tan^2\frac{\pi q h}{2}\right)^{-1}.$$

It is readily verified that (3.7) and (3.8) form a total of $n-1$ eigenvectors and thus span the space of solutions. For all values of q the amplification factor $|\Omega_q|$ is strictly less than one, from which follows that all eigenmodes decay and the scheme is stable. □

THEOREM 3.3. *The numerical scheme* (3.5) *is convergent.*

Proof. The proof is essentially a generalization of Lax's theorem. It relies on the facts that the truncation errors are small (consistency), and that there is no mechanism that amplifies errors (stability).

Let $u(x,t)$ be a smooth solution of (3.1), let u_j^n be a numerical solution of (3.5), and let $e_j^n = u(jh,nk) - u_j^n$ be the global error. By virtue of Lemma 3.1 and the linearity of (3.5), we obtain the equation for the error

$$\begin{aligned} D^0\left(w_j^{n+1} - w_j^n\right) &= 12\lambda\left(D^0 w_j^{n+1} - D^+D^- e_j^{n+1}\right) + k\,\tau_j^n, \\ D^0 e_j^{n+1} &= \left(I + \frac{1}{6}h^2 D^+D^-\right) w_j^{n+1}, \end{aligned} \tag{3.9}$$

where w_j^n is the auxiliary field associated with e_j^n.

We next expand the error in the discrete eigenmodes (3.7), (3.8),

$$e_j^n = \sum_q \alpha_q^n \tilde{\varphi}_q(x_j). \tag{3.10}$$

Substitution of (3.10) into the auxiliary equation in (3.9) gives

$$w_j^n = \sum_q \alpha_q^n \tilde{\psi}_q(x_j), \tag{3.11}$$

where

$$\begin{aligned} \tilde{\psi}_q^{(1)}(x_j) &= A_q\,\sin(\pi q x_j), \\ \tilde{\psi}_q^{(2)}(x_j) &= 2\,\cos(\pi q x_j) + A_q\,\sin(\pi q x_j) - 2 \end{aligned}$$

are the two families of functions that correspond to $\tilde{\varphi}_q^{(1)}$ and $\tilde{\varphi}_q^{(2)}$. Noting that

$$D^0\tilde{\psi}_q(x_j) = \frac{hA_q}{4}\,\frac{\sin(\pi q h)}{\sin^2(\frac{1}{2}\pi q h)}\,D^+D^-\tilde{\varphi}_q(x_j) = \frac{3\,\cos^2(\frac{1}{2}\pi q h)}{1 + 2\,\cos^2(\frac{1}{2}\pi q h)}\,D^+D^-\tilde{\varphi}_q(x_j),$$

we substitute (3.11) into the first equation in (3.9) and obtain after some basic manipulations

$$\sum_q \left(\tilde{\Omega}_q^{-1}\alpha_q^{n+1} - \alpha_q^n\right) D^0\tilde{\psi}_q(x_j) = k\,\tau_j^n, \qquad j = 1,2,\ldots,N-1. \tag{3.12}$$

Now let $\chi_q(x_j) = D^0\tilde{\psi}_q(x_j)$; these functions span the space of grid functions defined over the $N-1$ inner points x_j, $j = 1, 2, \ldots, N-1$. Let $(f, g) = \sum_{j+1}^{N-1} h f_j g_j$ denote the discrete inner product, and let B be the $(N-1) \times (N-1)$ matrix whose entries are $B_{q,q'} = (\chi_q, \chi_{q'})$.

To obtain an explicit recursion relation for the α_q^n, we take the scalar product of (3.12) with $\chi_{q'}$ and invert by multiplying on the left by B^{-1}; thus

$$\alpha_q^{n+1} = \tilde{\Omega}_q \alpha_q^n + k\, \tilde{\Omega}_q \sum_{q'} B^{-1}_{q,q'} (\chi_{q'}, \tau^n),$$

which by the discrete Duhammel principle gives

$$\alpha_q^n = \tilde{\Omega}_q^n \alpha_q^0 + k \sum_{r=0}^{n-1} \tilde{\Omega}_q^{n-r} \sum_{q'} B^{-1}_{q,q'} (\chi_{q'}, \tau^r). \tag{3.13}$$

The first term of the right-hand side represents the amplification of the initial error, whereas the second represents the accumulation of the local truncation errors.

The vector which we are going to estimate is $D^0 w^n = \sum_q \alpha_q^n \chi_q$, which is equivalent to the second derivative of the error e^n. If $\left\| D^0 w^n \right\|_2 \to 0$ as $h, k \to 0$, then the scheme converges in the H^2 norm, which is indeed the relevant norm for u [4]. Using (3.13), the Cauchy–Schwarz inequality, and the fact that $0 < \Omega_q < 1$, we find

$$\begin{aligned} \left\| D^0 w^n \right\|_2^2 &= \sum_{q,q'} \alpha_q^n B_{q,q'} \alpha_{q'}^n \\ &\le \left\| D^0 w^0 \right\|_2^2 + 2\,kn \left\| D^0 w^0 \right\|_2 \|\tau\|_2 + (kn)^2 \|\tau\|_2^2, \end{aligned}$$

where $\|\tau\|_2 = \max_n \|\tau^n\|_2$. We need only the initial conditions to converge at least as $O(h^2)$ to conclude with the aid of Lemma 3.2 that the scheme converges in H^2, and that the order of convergence is $O(h^2, k)$. □

4. The numerical scheme. Inspired by the model equation presented in the previous section, we construct an approximation scheme for (2.8). The temporal and the spatial discretizations are considered separately; this is legitimate when the scheme has a well-behaved semidiscrete limit [16].

4.1. Temporal discretization. Let ψ^n denote the stream function at time t^n. We approximate (2.8) by a discretization that is second-order in time:

$$\begin{aligned} \left(\Delta - \frac{1}{4}\nu k\, \Delta^2\right) \psi^{n+\frac{1}{2}} &= \left(\Delta + \frac{1}{4}\nu k\, \Delta^2\right) \psi^n - \frac{1}{2} k\, \left[(\mathbf{u}\cdot\boldsymbol{\nabla})\omega\right]^n, \\ \left(\Delta - \frac{1}{2}\nu k\, \Delta^2\right) \psi^{n+1} &= \left(\Delta + \frac{1}{2}\nu k\, \Delta^2\right) \psi^n - k\, \left[(\mathbf{u}\cdot\boldsymbol{\nabla})\omega\right]^{n+\frac{1}{2}}; \end{aligned} \tag{4.1}$$

that is, we use Crank–Nicholson for the viscous term and a midpoint rule for the advection term.

4.2. Spatial discretization. We discretize the system on a rectangular grid with fixed mesh spacing, $\Delta x = \Delta y = h$; a generalization to more complicated metrics will be presented elsewhere. The examples below are for a square domain, where the outermost grid points coincide with the boundaries of the system. We assume that at the beginning of each time step we possess second-order approximations for ψ and its first derivatives—the two velocity components—at the grid points (x_i, y_j), which we denote by $\psi_{i,j}$, $u_{i,j}$, and $v_{i,j}$, respectively.

4.2.1. The advection term. We start with the advection term, which describes the conservative transport of vorticity along streamlines. Due to the incompressibility of the flow, it can be written in an equivalent conservative form,

$$(\mathbf{u} \cdot \boldsymbol{\nabla})\omega = \boldsymbol{\nabla} \cdot (\omega \mathbf{u}),$$

where the vector field $\omega\mathbf{u}$ is the vorticity flux.

The numerical analysis of nonlinear advection has been studied extensively in the context of hyperbolic systems of conservation laws (see, e.g., [10, 17]). Considerable effort has been devoted to the construction of so-called high-resolution schemes, which are designed to capture the structure of singularities, such as shocks and rarefaction waves. Although incompressible flows do not form shocks, experience shows that a careful treatment of the advection is still of primary importance in the presence of sharp gradients. Indeed, sharp gradients seem as discontinuities on the scale of a mesh spacing.

Our discretization of the advection term is based on the central-difference scheme introduced by Kurganov and Tadmor (KT) [16]. Central schemes tend to be simpler than their upwind counterpart and can more easily be used and adapted as "black box" solvers. The KT scheme was found to introduce less numerical viscosity than earlier central schemes [19, 14]; its other advantage is that it can be brought to a simple semidiscrete formulation by letting the time step k tend to zero; thus it is possible to consider the spatial discretization independently from the temporal discretization, which can then be implemented by any standard ODE solver.

Conservative schemes are based on an integral representation of the conservation law; the discrete variables represent averages of the conserved quantities—here vorticity—over control cells. Due to conservation, the rate of change of the mean vorticity equals to the integral of the vorticity flux over the cell's boundaries. We take for control cells squares centered at the grid points. Every time step consists of the following steps. (i) Reconstruction of point values from the given cell averages; for a second-order scheme the reconstructed field is piecewise-linear. (ii) Evaluation of the fluxes at the cell's boundaries; because the reconstructed solution might be discontinuous, a careful treatment is necessary. The KT scheme introduces at the cells' interfaces local control volumes of adaptive size over which the discontinuous behavior is integrated; thus, Riemann solvers are avoided. (iii) Update of cell averages by integrating the fluxes using an appropriate quadrature rule.

Specifically, the spatial discretization of $\boldsymbol{\nabla} \cdot (\omega\mathbf{u})$ proceeds as follows.

- Using the standard 5-point Laplacian, we obtain a second-order approximation for the cell-average vorticity,

$$\omega_{i,j} = \Delta_h \psi_{i,j} = \frac{1}{h^2} \left(\psi_{i+1,j} + \psi_{i-1,j} + \psi_{i,j+1} + \psi_{i,j-1} - 4\,\psi_{i,j} \right), \tag{4.2}$$

  valid in all interior cells, $i,j = 1, \ldots, N-1$; our scheme does not require the evaluation of vorticity at boundary cells.
- We proceed with a piecewise-linear reconstruction of the vorticity,

$$\omega(x,y) = \sum_{i,j} \left[\omega_{i,j} + (\omega_x)_{i,j}(x - x_i) + (\omega_y)_{i,j}(y - y_j) \right] \chi_{i,j}(x,y),$$

  where $\chi_{i,j}$ is the indicator function of the (i,j) cell. The numerical slopes, $(\omega_x)_{i,j}$ and $(\omega_y)_{i,j}$, can be evaluated by simple central differencing when the solution is smooth (on the scale of a mesh spacing). Otherwise, nonlinear slope limiters should be used—for example, the min-mod limiters

$$(\omega_x)_{i,j} = \frac{1}{h}\,\text{minmod}\left[\theta\left(\omega_{i+1,j} - \omega_{i,j}\right), \frac{1}{2}\left(\omega_{i+1,j} - \omega_{i-1,j}\right), \theta\left(\omega_{i,j} - \omega_{i-1,j}\right)\right]$$

with $1 < \theta < 2$. In particular, we evaluate the vorticity at the centers of the cells' edges:

$$\begin{aligned}\omega_{i,j}^{E,W} &= \omega_{i,j} \pm \frac{1}{2}h(\omega_x)_{i,j},\\ \omega_{i,j}^{N,S} &= \omega_{i,j} \pm \frac{1}{2}h(\omega_y)_{i,j}\end{aligned}$$

with the superscripts W="west," E="east," S="south," and N="north" referring to the orientations of the four edges.

- We then evaluate the normal velocities on the cells' edges by simple second-order averaging [18]:

$$\begin{aligned}u_{i-\frac{1}{2},j} &= \frac{1}{2}\left(u_{i,j} + u_{i-1,j}\right),\\ v_{i,j-\frac{1}{2}} &= \frac{1}{2}\left(v_{i,j} + v_{i,j-1}\right).\end{aligned}$$

- At each edge we define a numerical flux

$$\begin{aligned}H_{i-\frac{1}{2},j} &= \frac{1}{2}\left(\omega_{i,j}^{W} + \omega_{i-1,j}^{E}\right)u_{i-\frac{1}{2},j} - \frac{1}{2}|a_{i-\frac{1}{2},j}|\left(\omega_{i,j}^{W} - \omega_{i-1,j}^{E}\right),\\ H_{i,j-\frac{1}{2}} &= \frac{1}{2}\left(\omega_{i,j}^{S} + \omega_{i,j-1}^{N}\right)v_{i,j-\frac{1}{2}} - \frac{1}{2}|a_{i,j-\frac{1}{2}}|\left(\omega_{i,j}^{S} - \omega_{i,j-1}^{N}\right),\end{aligned}$$

where the first term on the right-hand side is the average of the one-sided flux evaluations, whereas the second term is a correction that arises from the more precise treatment at the discontinuous boundaries; the prefactors $a_{i-\frac{1}{2},j}$ and $a_{i,j-\frac{1}{2}}$ correspond to the local characteristic speeds at the cells' interfaces, which in our case are simply the normal velocities, u and v, respectively.

- Finally, the divergence of the flux is approximated by

$$[\boldsymbol{\nabla}\cdot(\omega\mathbf{u})]_{i,j} = \frac{H_{i+\frac{1}{2},j} - H_{i-\frac{1}{2},j}}{h} + \frac{H_{i,j+\frac{1}{2}} - H_{i,j-\frac{1}{2}}}{h}.$$

4.2.2. The viscous term. We next address the spatial discretization, Δ_h^2, of the biharmonic operator. The standard second-order discretization uses a 13-point stencil. Noncompact stencils are problematic from the point of view of linear solvers. An alternative representation of the discrete biharmonic operator that uses a compact 9-point stencil was developed by Altas et al. [1], and its one-dimensional version was presented in section 3. The idea is to express $\Delta_h^2\psi_{i,j}$ in terms of the grid values of ψ and its first derivatives, $\psi_x = v$ and $\psi_y = -u$. A second-order approximation of the biharmonic operator can then be written as

$$\Delta_h^2\psi_{i,j} = \frac{12}{h^2}\left(-\frac{4}{3}\Delta_h\psi_{i,j} + \frac{1}{3}\tilde{\Delta}_h\psi_{i,j} + D_x^0 v_{i,j} - D_y^0 u_{i,j}\right), \tag{4.3}$$

where $D^{0;\pm}_{x,y}$ are the standard differencing operators and $\tilde{\Delta}_h$ is the star-Laplacian

$$\tilde{\Delta}_h \psi_{i,j} = \frac{1}{2\,h^2}\left(\psi_{i+1,j+1} + \psi_{i-1,j+1} + \psi_{i+1,j-1} + \psi_{i-1,j-1} - 4\,\psi_{i,j}\right).$$

In addition, we need fourth-order expressions for $u_{i,j}$ and $v_{i,j}$:

$$\begin{aligned} \left(I + \frac{1}{6}h^2 D_x^+ D_x^-\right) v_{i,j} &= +D_x^0 \psi_{i,j}, \\ \left(I + \frac{1}{6}h^2 D_y^+ D_y^-\right) u_{i,j} &= -D_y^0 \psi_{i,j}. \end{aligned} \tag{4.4}$$

These approximations are valid for all interior points; at boundary points ψ, u, and v are prescribed by the boundary conditions.

4.3. The linear solver. From a computational point of view, the most time-consuming part of the computation is the solution of a linear system of the form

$$(\Delta_h - \alpha\,\Delta_h^2)\psi_{i,j} = \text{rhs}_{i,j},$$

which results from the spatial discretization of (4.1); two such linear systems need to be solved at every time step. Standard iterative methods are known to converge very slowly, if at all, for biharmonic operators.

Biharmonic systems that use the compact stencil representation (4.3), (4.4) can be solved very efficiently with AMG solvers. AMG methods are powerful techniques for the solution of sparse linear systems. They are "black box" solvers, in the sense that they treat the problem to be solved as a pure algebraic system, without reference to the geometrical interpretation of the transition between coarse and fine grids. The advantage of such an approach is that it is readily portable to more complicated systems of coordinates and geometries.

The principle of AMG methods can be summarized as follows. Given an n-dimensional linear system $Ax = b$, an $m \times n$ restriction matrix R is generated by an algorithm that inspects the graph of the matrix A. The m-dimensional vector Rx is the projection of x on the restricted ("coarse") subspace. The transpose of the restriction matrix, $I = R^T$, is used as an interpolation matrix to revert back to the original ("fine") space. AMG methods are based on the presumption that if the right-hand side vector, b, is sufficiently "smooth" (in a sense that needs to be specified), then the solution x is close to the range of the interpolation matrix I, i.e., there exists an m-dimensional vector y such that $x \approx Iy$. Multiplying the system $Ax = b$ by R on the left and approximating x by Iy, we obtain the restricted system

$$(RAI)y = Rb.$$

This two-level approach can be applied recursively to form a multilevel method. It then remains to introduce an appropriate "smoother" to operate on the solution before and after being projected to the lower-dimensional subspace.

AMG solvers vary in the way they generate the restriction matrix, in the choice of smoothers, and in the choice of multigrid cycles. Our coarsening method is based on a red-black coloring algorithm developed by Kickinger [13]. Gauss–Seidel iterations have been used for smoothing. Each multigrid cycle starts from the finest level down to the coarsest level and back up (V-cycle). For a 128 × 128 grid (that is, a linear system of dimension 3 × 128 × 128), about ten multigrid cycles with two pre- and postsmoothing steps were needed to reduce the error norm to 10^{-8}.

There are a number of implementational issues. As long as the time step is not modified, the linear operator is unchanged. In such a case, it is efficient to compute the set of restriction matrices, R, with the corresponding linear operators, RAI, once, and store them. Most of the computational time is then spent on sparse matrix-vector multiplications, which can be parallelized easily.

5. Numerical results. We have tested our numerical scheme on a classical benchmark problem: flow in a lid-driven cavity. The fluid is confined in a square domain, $\Omega = [0,1]^2$, and is driven by the transversal motion of its boundaries. This setup is a challenging test problem, in particular, because the velocity field is discontinuous at the corners adjacent to the moving boundaries, and the viscous stresses diverge logarithmically. (In a method that uses the primitive variables $(\mathbf{u}, p)$, one faces the logarithmic divergence of the pressure.)

We first conducted convergence tests to obtain error estimates and assess the order of accuracy. In Table 1 we show the discrete L_2 norm $\|\psi_{N+1} - \psi_{2N+1}\|_2$, where ψ_M denotes the computational solution on an $M \times M$ grid. The initial conditions are

$$\psi(x,y,0) = \frac{1}{\pi} \sin^2(\pi x) \sin^2(\pi y), \tag{5.1}$$

and the boundaries are stationary; the Reynolds number here is 10^3. For short times the convergence rate seems to be less than expected; this is because the errors are very small and therefore dominated by the tolerance specified for the linear solver. For times longer than $t = 0.4$ we get an estimated second-order convergence, as expected. Similar results were found for a range of Reynolds numbers between 10^2 and 10^4.

Table 1

Error estimate and convergence test for the initial conditions (5.1) *and Reynolds number* 10^3.

Time	$\|\psi_{33} - \psi_{65}\|_2$	$\|\psi_{65} - \psi_{129}\|_2$	Rate
0.1	4.1×10^{-5}	1.3×10^{-5}	1.64
0.2	7.2×10^{-5}	2.1×10^{-5}	1.81
0.3	9.5×10^{-5}	2.5×10^{-5}	1.90
0.4	1.2×10^{-4}	2.9×10^{-5}	1.99
0.5	1.4×10^{-4}	3.3×10^{-5}	2.08

We next display results for lid-driven flows. For low enough Reynolds numbers the flow approaches a steady state; the lower the Reynolds number is, the shorter the transient is. In Figure 1(a) we display stream function contour lines in the steady state for Re = 400. The fluid is initially at rest, and it is driven impulsively by the rightward motion of the top boundary. For comparison we display the same level sets as in [9, Figure 3 and Table III]. In Figure 1(b), (c) we plot the steady-state profile of the $u(v)$ component of the velocity as a function of $y(x)$ at $x = 0.5$ ($y = 0.5$). The solid line represents our results, whereas the symbols are data reported in [9]). The agreement is excellent. In Table 2 we list the minimum value of the stream function, which takes place in the core of the primary vortex, at different times and for three different grid sizes. For a grid size of 128 × 128 the results seem to have fully converged. It takes about 35 time units to reach a steady flow; the minimum value of the stream function is then −0.1140; in [9] the reported value is −0.1139; the same value has also been reported by Pan and Glowinski for a slightly regularized flow [20]. We also compare extremal values of the stream function for the secondary

The top boundary moves to the right with velocity $u = 1$.* (b) *Steady-state profile of the u velocity component as a function of y at $x = 0.5$.* (c) *Steady-state profile of the v velocity component as a function of x at $y = 0.5$.*

TABLE 2

Minimum value of the stream function at different times and for different mesh sizes. The Reynolds number is $Re = 400$.

Time	64×64	96×96	128×128
$t = 5.0$	-0.09062	-0.09074	-0.09076
$t = 15.0$	-0.11164	-0.11173	-0.11174
$t = 25.0$	-0.11378	-0.11385	-0.11385
$t = 35.0$	-0.11393	-0.11400	-0.11401

vortices. For the bottom-right secondary vortex the maximum value of the stream function is 6.579×10^{-4}, and it is 1.404×10^{-5} for the bottom-left vortex; the numbers reported in [9] are 6.423×10^{-4} and 1.419×10^{-5}, respectively. In [11] the time to reach a steady state was estimated to be about 46 time units. A precise quantitative comparison is hard to perform due to the arbitrary nature of the stopping criterion.

Similar calculations were carried out for Re = 5000. In Figure 2(a) we plot the minimum value of the stream function versus time. Steady-state velocity profiles are shown in Figure 2(b), (c). Snapshots of stream function contour lines are presented in Figure 3. Note the much longer transient; its takes about 340 time units to reach

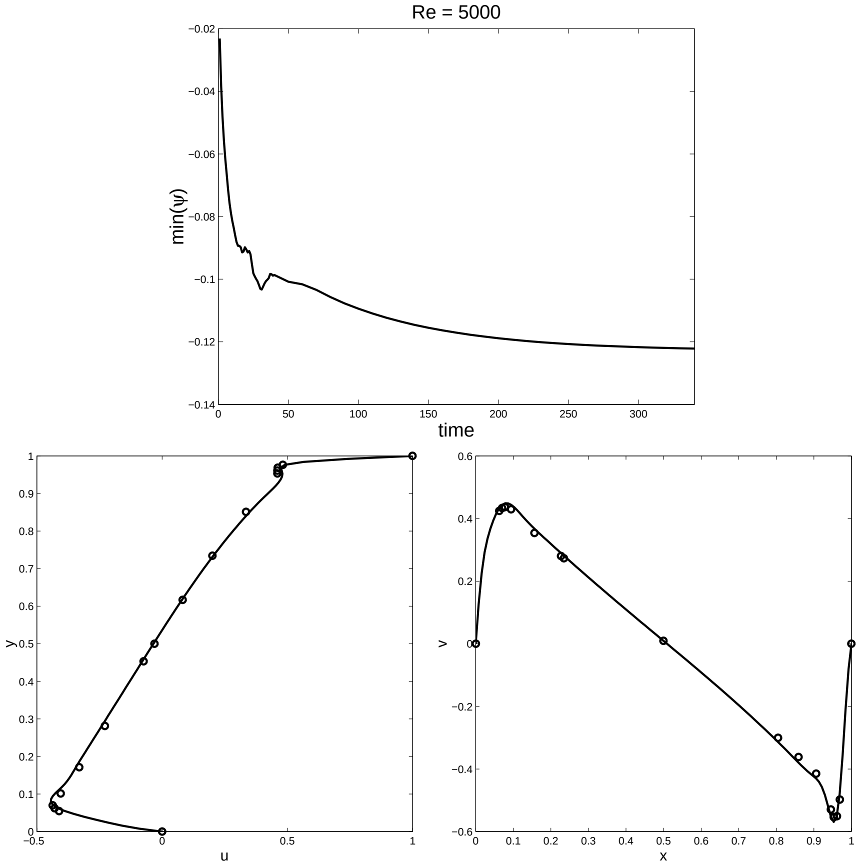

FIG. 2. (a) *Minimum value of the stream function versus time for Re* = 5000. (b) *Steady-state profile of the u velocity component as a function of y at* $x = 0.5$. (c) *Steady-state profile of the v velocity component as a function of x at* $y = 0.5$.

a steady flow. Note also the nonmonotonic behavior of the minimum value of the stream function, which reflects the fact that recirculation zones are created and annihilated along the side and bottom walls until the final vorticity pattern emerges. Such dynamics were also reported in [11] and are consistent with subcritical behavior prior to an oscillatory instability, whose occurrence has been predicted in [21, 20]. Eventually, the stream function reaches the value of -0.122160; in [9] the predicted value is -0.118966, whereas in [20] it is -0.121218. The velocity profiles are again in excellent agreement with the data reported in [9].

In a recent paper, Pan and Glowinski [20] obtained limit cycle solutions for Re = 8500. The occurrence of a Hopf bifurcation has been speculated before [21] but was believed to take place at a significantly higher Reynolds number. Our results for Re = 8500 support the findings of [20]. In Figure 4 we plot the time evolution of the kinetic energy over a time interval of $t = 3$; the function is oscillatory with a period of about 2.5; the period reported in [20] is 2.27. In Figure 5 we show a complete cycle of stream function contours during a time interval of 2.5. The primary vortex remains practically unchanged, variations being noticeable only within the secondary vortices. It takes about 200 time units to reach this state starting from a fluid at rest.

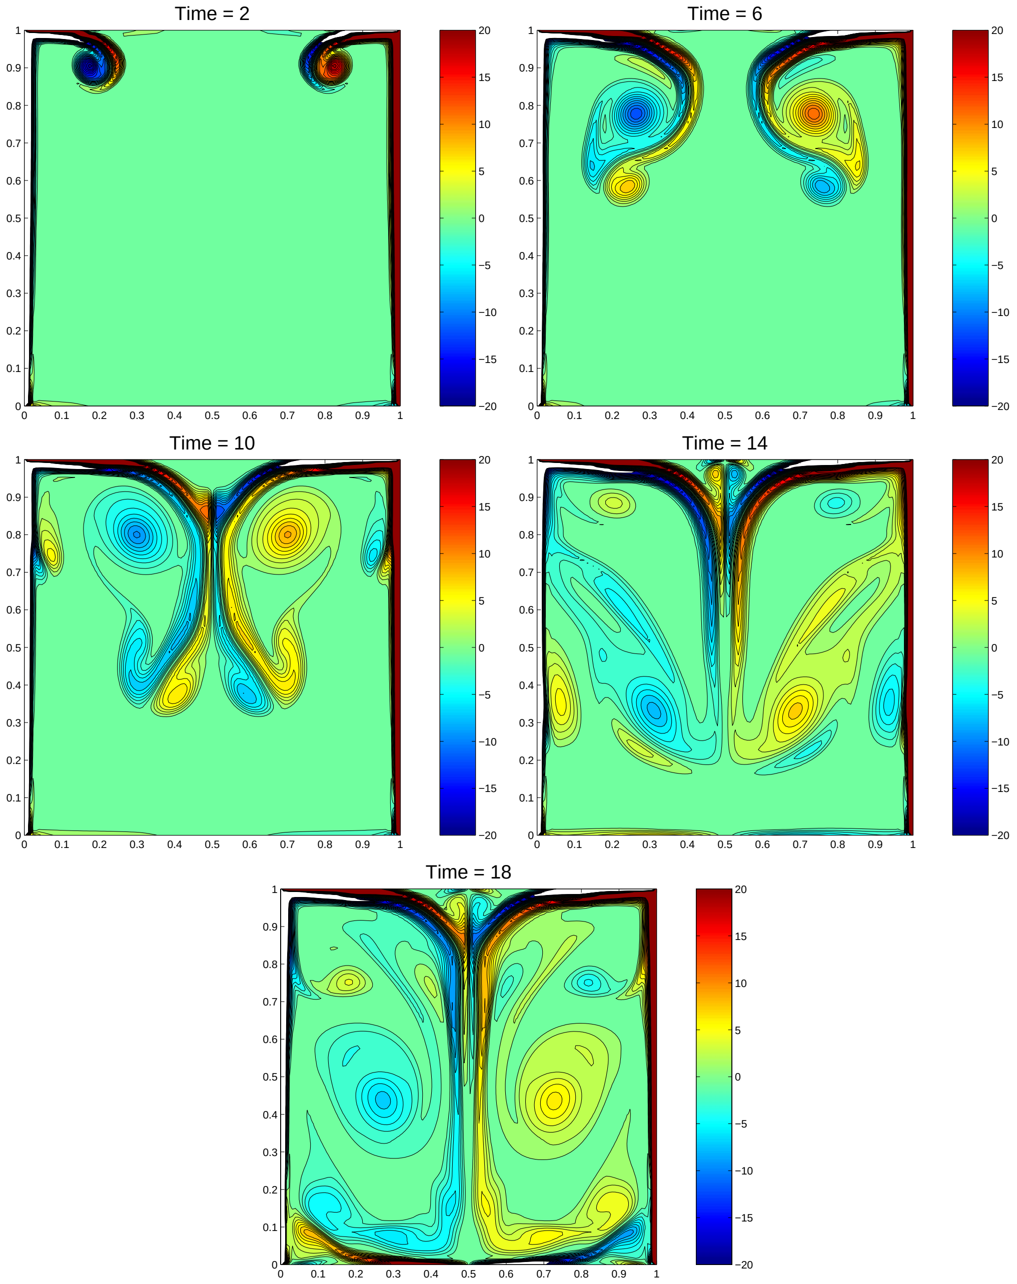
For even higher Reynolds numbers the flows are much more complex. An Re = 20000 flow is shown in Figure 6, where we display snapshots of vorticity contour lines for a fluid that is driven by the upward motion of its left and right boundaries. Narrow and concentrated shear layers are generated along the moving boundaries and



Time = 2

FIG. 6. *Contour plots of vorticity. The left and right walls move upward with velocity* $v = 1$. *The Reynolds number is* $Re = 20000$. *The contours are shown for time* $t = 2$, $t = 6$, $t = 10$, $t = 14$, *and* $t = 18$. *The grid size is* 128×128.

transported with the flow. The shear layers are unstable and rapidly intermingle to form a convoluted vorticity pattern. This sequence of vorticity contours demonstrates the robustness of the scheme. The vorticity gradients are large with sharp variations over single cells.

6. Concluding remarks. The present scheme is based on the paradigm that has been established in [4], whereby vorticity dynamics should be viewed as a projection of stream function dynamics; thus vorticity boundary conditions are totally avoided, and natural boundary conditions are imposed on the stream function. Numerical methods based on stream function variables are by themselves not a novel idea. What have been missing for many years are accurate and efficient ways of implementation. We make no claim, however, that methods based on vorticity boundary conditions are invalid. Such methods have been proven to work within the frameworks of both difference schemes and vortex methods.

An important property of the proposed scheme is its modularity. It is not restricted to a specific type of hyperbolic or biharmonic solver, and each of its elements can be implemented in various ways. In particular, higher-order spatio-temporal discretizations are relatively easy to implement (see, e.g., [1] for a fourth-order discretization of the biharmonic equation and [15] for a third-order version of the KT scheme). Finally, an extension to three dimensions seems realizable.

Acknowledgments. I am grateful to Professors M. Ben-Artzi, D. Fishelov, and S. Trachtenberg for introducing me to stream function dynamics and for making their work and data accessible. This paper has been motivated and influenced by their work. I have benefited from useful discussions with Professor A. Chorin, Mr. Y. Farjoun, Professor R. Glowinski, Professor O. Hald, Professor E. Tadmor, and Dr. D. von Terzi. Special thanks to Mr. Y. Farjoun, who implemented the multigrid solver.

TWO-DIMENSIONAL SIMULATIONS OF VALVELESS PUMPING USING THE IMMERSED BOUNDARY METHOD*

EUNOK JUNG† AND CHARLES S. PESKIN‡

Abstract. Flow driven by pumping without valves is examined, motivated by biomedical applications: cardiopulmonary resuscitation (CPR) and the human fetus before the development of the heart valves. The direction of flow inside a loop of tubing which consists of (almost) rigid and flexible parts is investigated when the boundary of one end of the flexible segment is forced periodically in time. Despite the absence of valves, net flow around the loop may appear in these simulations. The magnitude and even the direction of this flow depend on the driving frequency of the periodic forcing.

Key words. valveless pumping, immersed boundary method, frequency, CPR

1. Introduction.

Pumping blood in one direction is the main function of the heart, which is equipped with valves that ensure unidirectional flow. Is it possible, though, to pump blood without valves? This paper is intended to show by numerical simulation the possibility of a net flow which is generated by a valveless mechanism in a circulatory system. Simulations of valveless pumping are motivated by physical experiments of Kilner [12], which had been developed from experiments by Liebau [13, 14, 15]. Kilner observed net flow in one direction which depends on the location of periodic forcing in his experiments. We have examined flows driven by pumping without valves in Liebau's model, a loop of tubing of which part is almost rigid and the other part is flexible. In agreement with Kilner, we find that net flow can indeed be driven around such a loop by periodic forcing at one location, but we also find something new: the direction of the flow depends on the driving frequency of the periodic forcing.

As reviewed by Moser et al. [18], there have been several earlier investigations of valveless pumping. Harvey (1628), Weber (1834), Donders (1856), and Thomann [26] suggest theories of valveless pumping, and Ozanam (1881) and Liebau [13, 14, 15] make the various types of physical experiments to explain the mechanism of valveless pumping. Moser et al. [18] try to identify the responsible mechanism and conditions under which this mechanism operates. Their proposed mechanism involves a difference in impedance of two pathways between compliant reservoirs.

One of the applications of valveless pumping may turn out to be cardiopulmonary resuscitation (CPR). The blood flow during CPR has been explained by two theories:

*Received by the editors February 1, 2000; accepted for publication (in revised form) June 8, 2000; published electronically May 10, 2001. Preliminary accounts of this work have appeared in the conference paper of the International Conference on Mechanics in Medicine and Biology, Maui, Hawaii, 2000, pp. 41–44. This work was supported by the National Science Foundation under research grant DMS-9626104. Computation was performed at the Applied Mathematics Laboratory, New York University, and also in part on the Cray T90 computer at the San Diego Supercomputer Center under a grant of resources MCA93S004 from the National Resource Allocations Committee (NRAC).

the thoracic pump and cardiac compression mechanisms. In support of the thoracic pump model, it has been reported that the heart is "a passive conduit for blood flow" during chest compression [1, 3, 10], with an open mitral valve throughout the cardiac cycle and anterograde (forward) transmitral blood flow even during chest compression. Werner et al. [27] also report that the mitral valve remains open throughout the entire compression-release cycle of CPR while the aortic valve opens during the compression phase of CPR and closes during the release phase. Thus, the left side of the heart appears to act as a conduit for passage of blood, and mitral valve closure is not necessary for forward blood flow during CPR. Despite the observed lack of valve function, some patients with cardiac arrest are successfully resuscitated by external chest-compression CPR [25]. These findings are controversial, however. Other researchers such as Feneley et al. [4] report results that are inconsistent with the thoracic pump theory and support direct cardiac compression as the primary mechanism of blood flow with the high-impulse manual CPR technique. These investigators favor the cardiac compression theory, in which the heart acts as a pump and its valves function normally. It is possible, of course, that both theories are correct, each in a different set of circumstances. Our computational model of valveless pumping might be applicable to the thoracic pump model and help to understand the thoracic pump mechanism. If the magnitude and even the direction of flow in valveless pumping are indeed frequency dependent, as our results seem to indicate, it is of obvious importance to know what frequency of chest compression will produce the most effective CPR.

Another biological example of valveless pumping may occur in the human embryo at the end of the third week of gestation. At this stage of development, the valves of the heart have not yet formed. Nevertheless, there is a net flow in the circulatory system that is somehow generated by the beating of the heart.

An industrial application of valveless pumping is in microelectromechanical system (MEMS) devices [17], where there is a need to produce fluid motion without moving anything inside the fluid. MEMS devices could be built that incorporate flexible flow channels. In that case, our findings might be applicable to the design of valveless pumps for MEMS devices.

We do not attempt to construct a theory of valveless pumping in this report. Instead, we use numerical simulation as an "experimental" tool to study this mysterious phenomenon.

The rest of the paper is organized as follows. In section 2 the immersed boundary method will be introduced. Section 3 is devoted to the description of the two-dimensional valveless pumping model. The results will be discussed in section 4. In section 5 several special cases will be observed. Finally, some conclusions will be drawn in section 6.

2. The immersed boundary method.

2.1. Mathematical formulation. The immersed boundary method is applicable to problems involving an elastic structure interacting with a viscous incompressible fluid. It has been applied to a variety of problems, particularly in biophysics, including two-dimensional and three-dimensional simulations of blood flow in the heart [19, 20, 9, 21, 22], the design of prosthetic cardiac valves [16], platelet aggregation during blood clotting [7], wave propagation in the cochlea [2], the flow of suspensions [8], peristaltic pumping of solid particles [6], and aquatic animal locomotion [5]. The version of the immersed boundary method used in this work is that of [23], except that here we are in two space dimensions.

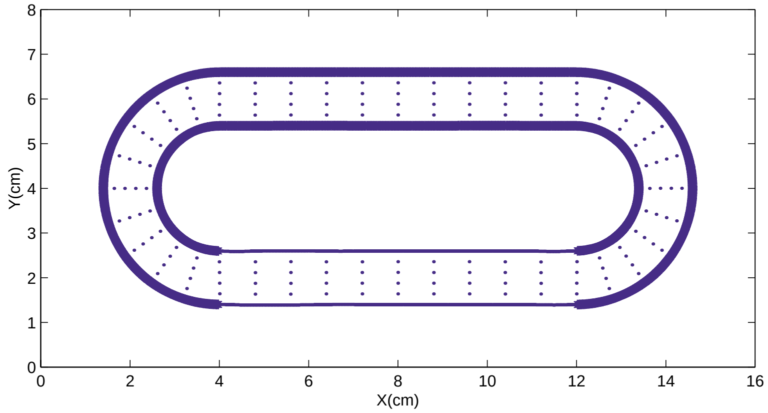

FIG. 1. *Initial position of two-dimensional valveless pumping: flexible boundary (thin lines), almost rigid (thick lines), and fluid markers (dots).*

The philosophy of the immersed boundary method is that the elastic material is treated as a part of the fluid in which singular forces are applied. The fluid and the elastic immersed boundary constitute a coupled mechanical system: The motion of the fluid is influenced by the force generated by the immersed boundary on the fluid, but at the same time the immersed boundary moves at the local fluid velocity and exerts singular forces locally on the fluid. The strength of this method is that it can handle the complicated and time dependent geometry of the elastic immersed boundary which interacts with the fluid, and that it does so while using a fixed regular lattice for the fluid computation.

Consider a viscous incompressible fluid which fills a periodic rectangular box Ω and an immersed boundary S_b in the shape of a racetrack which is contained in the box, where $b = 1$ (inner immersed boundary) or $b = 2$ (outer immersed boundary). Figure 1 displays the two-dimensional model in which we shall simulate valveless pumping.

We shall now consider the mathematical formulation of the equations of motion for the fluid-immersed boundary system. Let ρ be the constant fluid density and μ be the constant viscosity. The equations of motion are then as follows:

$$\rho\left(\frac{\partial \boldsymbol{u}(\boldsymbol{x},t)}{\partial t} + (\boldsymbol{u}(\boldsymbol{x},t)\cdot\nabla)\boldsymbol{u}(\boldsymbol{x},t)\right) + \nabla p(\boldsymbol{x},t) = \mu\nabla^2\boldsymbol{u}(\boldsymbol{x},t) + \boldsymbol{F}(\boldsymbol{x},t), \tag{2.1}$$

$$\nabla\cdot\boldsymbol{u}(\boldsymbol{x},t) = 0, \tag{2.2}$$

$$\boldsymbol{F}(\boldsymbol{x},t) = \int_{S_b} \boldsymbol{f}_b(s,t)\,\delta^2(\boldsymbol{x} - \boldsymbol{X}_b(s,t))\,ds, \tag{2.3}$$

$$\boldsymbol{U}_b(s,t) = \int_{\Omega} \boldsymbol{u}(\boldsymbol{x},t)\,\delta^2(\boldsymbol{x} - \boldsymbol{X}_b(s,t))\,d\boldsymbol{x}, \tag{2.4}$$

$$\frac{\partial \boldsymbol{X}_b(s,t)}{\partial t}(s,t) = \boldsymbol{U}_b(s,t), \tag{2.5}$$

$$\boldsymbol{f}_b(s,t) = -(\kappa_t)_b(\boldsymbol{X}_b(s,t) - \boldsymbol{Z}_b(s,t)) + \kappa_c\left(\frac{\partial^2 \boldsymbol{X}_b(s,t)}{\partial s^2}\right). \tag{2.6}$$

Equations (2.1) and (2.2) are the fluid (Navier–Stokes) equations in Eulerian form. The fluid velocity $\boldsymbol{u}(\boldsymbol{x},t)$, fluid pressure $p(\boldsymbol{x},t)$, and singular force density $\boldsymbol{F}(\boldsymbol{x},t)$ are unknown functions of $(\boldsymbol{x},t)$, where $\boldsymbol{x} = (x,y)$ are fixed Cartesian coordinates and t is the time. Equations (2.5) and (2.6) are the immersed boundary equations in Lagrangian form. The configurations of the immersed boundaries are described by the unknown functions $\boldsymbol{X}_b(s,t)$, where $b = 1$ (inner immersed boundary) or 2 (outer immersed boundary), and $0 \leq s \leq L_1$ for the inner immersed boundary and $0 \leq s \leq L_2$ for the outer immersed boundary. L_1 and L_2 are the unstressed lengths of the inner and outer boundaries, respectively. The boundary force densities $\boldsymbol{f}_b(s,t)$ and the boundary velocities $\boldsymbol{U}_b(s,t)$, for the inner and outer boundaries $b = 1$ and $b = 2$, are also unknown functions of s and t. A fixed value of the Lagrangian parameter s marks a material point of the immersed boundary.

In (2.6) the boundary force is computed as a sum of two terms. In the first term, the given function $\boldsymbol{Z}_b(s,t)$ is called the *target position* of the immersed boundary. This first term provides a restoring force that keeps the boundary points near their target positions. Target positions are used for two purposes in this work: first to maintain the shape of the flow loop, and second, by allowing $\boldsymbol{Z}_b(s,t)$ to change with time, to apply periodic forcing to the immersed boundaries. The curvature term in (2.6) models an elastic membrane under tension. Together, the two terms model the boundaries as tethered elastic membranes.

Note that the curvature term actually is the response to stretching of the membrane; it is not a response to curvature per se. It can be derived from an energy function which is just the sum of the squares of the lengths of the individual segments. Also, the curvature term has little effect on the parts of the racetrack that are stiffly pinned to target points, since those forces dominate there. It is important only on the straight flexible segment.

Equations (2.4) and (2.5) are, in effect, the no-slip condition, since they state that the immersed boundary moves at the local fluid velocity. Equations (2.3) and (2.4) are the interaction equations in mixed Eulerian and Lagrangian form. The core of the immersed boundary method is the delta function, which describes the interaction between the fluid and the immersed boundary. Both of the interaction equations are in integral form with kernel $\delta^2(\boldsymbol{x} - \boldsymbol{X}_b(s,t))$. The integral in (2.4) is taken over the two-dimensional space occupied by the fluid. However, in (2.3), the integral is taken over a one-dimensional space, the immersed boundary, but the delta function is a product of two one-dimensional delta functions: $\delta^2(\boldsymbol{x}) = \delta(x)\delta(y)$. Therefore, $\boldsymbol{F}(\boldsymbol{x},t)$ is a singular force density. The total force is finite despite the singularity in the force density $\boldsymbol{F}(\boldsymbol{x},t)$.

2.2. Numerical method. In this section, we present the summary of the immersed boundary method to find a numerical solution to the system of equations (2.1)–(2.6). For details of this numerical method, see [11, 23]. Let superscripts and subscripts denote the time step index and the spatial discretization, respectively. Let the time proceed in steps of duration Δt, let Δx and Δy be the fluid-lattice spacing, and let Δs_b be the unstressed distance between material points of the immersed boundary. The fluid equations (2.1) and (2.2) in Eulerian form are discretized on a fixed rectangular lattice at time $t = n\Delta t$: $\boldsymbol{x}^n_{jk} = \boldsymbol{x}(j\Delta x, k\Delta y, n\Delta t)$, where $j = 0,\dots,N_x - 1$, $k = 0,\dots,N_y - 1$, and $n = 0,1,\dots$. The immersed boundary equations (2.5) and (2.6) in Lagrangian form are discretized on a collection of moving points in the immersed boundary at time $t = n\Delta t$: $\boldsymbol{X}_{bl}^n = \boldsymbol{X}_b(l\Delta s_b, n\Delta t)$ which do not coincide with the fluid lattice, where $l = 1, \dots,\ M_1$ and $L_1 = M_1\Delta s_1$ for $b = 1$ (inner boundary) or $l = 1, \dots,\ M_2$ and $L_2 = M_2\Delta s_2$ for $b = 2$ (outer boundary).

Our goal is to compute the update $\boldsymbol{u}^{n+1}$, $\boldsymbol{X}_b^{n+1}$ from given $\boldsymbol{u}^n$, $\boldsymbol{X}_b^n$. This is done as follows:

For simplicity, let $N_x = N_y = N$ and choose $\Delta x = \Delta y = h$.

Step 1. Find the force $\boldsymbol{f}_b^n$ on the immersed boundary from the given boundary configuration $\boldsymbol{X}_b^n$.

For $l = 1,\ \dots,\ M_b$, and $b = 1$ (inner boundary) or 2 (outer boundary),

$$\boldsymbol{f}_{bl}^n = -(\kappa_t)_l(\boldsymbol{X}_{bl}^n - \boldsymbol{Z}_{bl}^n) + \kappa_c \left(\frac{\boldsymbol{X}_{b(l+1)}^n - 2\boldsymbol{X}_{bl}^n + \boldsymbol{X}_{b(l-1)}^n}{\Delta s_b^2} \right), \tag{2.7}$$

where $\boldsymbol{Z}_b^n$ is a target position at $t = n\Delta t$, Δs_b is an arc length, κ_t is a stiffness constant, and κ_c is another stiffness constant for the curvature force term.

Note that the subscript arithmetic on l in (2.7) has to be interpreted in a periodic sense, since the boundary is closed: when $l = M_b$, $l + 1 = 1$; when $l = 1$, $l - 1 = M_b$. The target positions $\boldsymbol{Z}_b^n$ are calculated by the given boundary configuration $\boldsymbol{X}_b^n$. The formulations of the target positions will be given in the following section.

Step 2. Spread the boundary force into the nearby lattice points of the fluid using the δ function.

$$\boldsymbol{F}_{jk}^n = \sum_{b=1}^{2}\sum_{l=1}^{M_b} \boldsymbol{f}_{bl}^n \delta_h^2(\boldsymbol{x}_{jk} - \boldsymbol{X}_{bl}^n)\Delta s_b \qquad \text{for} \quad j, k = 0, 1, \dots, N-1, \tag{2.8}$$

where $\boldsymbol{x}_{jk} = (jh, kh)$ and δ_h^2 is a smoothed approximation to the two-dimensional Dirac delta function:

$$\delta_h^2(\boldsymbol{x}) = \frac{1}{h^2}\phi(x/h)\phi(y/h),$$

where

$$\phi(r) = \begin{cases} \frac{3-2|r|+\sqrt{1+4|r|-4r^2}}{8} & \text{if } |r| \le 1, \\ \frac{5-2|r|-\sqrt{-7+12|r|-4r^2}}{8} & \text{if } 1 \le |r| \le 2, \\ 0 & \text{if } 2 \le |r|. \end{cases}$$

The motivation for this particular choice of $\phi(r)$ is given in [22].

Step 3. Solve the Navier–Stokes equations on the rectangular lattice to get the update $\boldsymbol{u}^{n+1}$ and p^{n+1} from $\boldsymbol{u}^n$ and $\boldsymbol{F}^n$. The periodic boundary conditions for the computational domain are imposed. These equations are solved by the following implicit first order scheme in time and space:

$$\rho \left(\frac{\boldsymbol{u}^{n+1} - \boldsymbol{u}^n}{\Delta t} + \boldsymbol{u}^n \cdot \nabla_h^{\pm} \boldsymbol{u}^n \right) + \boldsymbol{D}^0 p^{n+1} = \mu \Delta_h \boldsymbol{u}^{n+1} + \boldsymbol{F}^n, \tag{2.9}$$

$$\boldsymbol{D}^0 \cdot \boldsymbol{u}^{n+1} = 0. \tag{2.10}$$

The difference operators in these equations are constructed as follows. First, the forward (D^+), backward (D^-), and centered (D^0) difference operators are defined in the standard way. Then $\boldsymbol{D}^0$ is defined by $\boldsymbol{D}^0 = (D_x^0, D_y^0)$. This is used in the discrete divergence and gradient. Next, the discrete Laplacian for the viscous term is defined by $\Delta_h \boldsymbol{u} = \sum_{\alpha=1}^{2} D_\alpha^+ D_\alpha^- \boldsymbol{u}$. Finally, the upwind difference operator $\boldsymbol{u} \cdot \nabla_h^\pm = \sum_{\alpha=1}^{2} \boldsymbol{u}_\alpha D_\alpha^\pm$, where

$$u_\alpha D_\alpha^\pm = \begin{cases} u_\alpha D_\alpha^+ & \text{if } u_\alpha < 0, \\ u_\alpha D_\alpha^- & \text{if } u_\alpha > 0. \end{cases}$$

This difference scheme is stable (provided that $\sum_{\alpha=1}^{2} |u_\alpha| \Delta t < h$) because of the choice of the upwind scheme for the convection terms and the backward Euler differencing used for the Stokes system.

Because of the periodic boundary conditions of the computational domain, it is natural to use the fast fourier transform (FFT) algorithm to solve (2.9) and (2.10) for the unknowns $(\boldsymbol{u}^{n+1}, p^{n+1})$. To get the update $\boldsymbol{u}^{n+1}$ and p^{n+1}, first take the discrete Fourier transformation of (2.9) and (2.10). Then, the system can be solved for $\widehat{u}_{lm}$, $\widehat{v}_{lm}$, and $\widehat{p}_{lm}$ for each l and m, $0 \le l, m \le N-1$. Finally, evaluate $\boldsymbol{u}^{n+1}$ and p^{n+1} by applying the inverse FFT algorithm to $\widehat{p}^{n+1}$ and $\widehat{\boldsymbol{u}}^{n+1}$.

Step 4. Once the updated fluid velocity, $\boldsymbol{u}^{n+1}$, has been determined, we can find the velocity, $\boldsymbol{U}_b^{n+1}$, and then the new position, $\boldsymbol{X}_b^{n+1}$, of the immersed boundary points. This is done using a discretization of (2.4) and (2.5).

The difference approximations to the interpolation equation and no-slip condition are expressed as follows:

For $l = 1, \ldots, M_b$, and $b = 1$ (inner boundary) or 2 (outer boundary),

$$\boldsymbol{U}_{bl}^{n+1} = \sum_{j,k=0}^{N-1} \boldsymbol{u}_{jk}^{n+1} \delta_h^2 (\boldsymbol{x}_{jk} - \boldsymbol{X}_{bl}^n) h^2, \tag{2.11}$$

$$\boldsymbol{X}_{bl}^{n+1} = \boldsymbol{X}_{bl}^n + \Delta t \boldsymbol{U}_{bl}^{n+1}. \tag{2.12}$$

Note that we use the same delta function in (2.11) as the one in the interaction equation for the force term, (2.8).

This completes the description of the process (Steps 1–4, above) by which the quantities $\boldsymbol{u}$ and $\boldsymbol{X}$ are updated.

3. Two-dimensional model of valveless pumping.

In this section, we shall introduce a two-dimensional computational model of valveless pumping. The initial configuration of our model is presented first. Then we present the motions of target positions to investigate fluid motions around the flow loop. In particular, we explain how the time dependent target positions are used to provide the periodic forcing which is applied on the one end of the immersed boundary. Finally, we display the physical and computational parameters which are used in our numerical experiments.

3.1. Initial position.

Consider an incompressible viscous fluid with a constant density ρ and viscosity μ in a periodic rectangular box which contains an immersed elastic boundary. Figure 1 shows the initial configuration of the immersed boundary of two-dimensional valveless pumping in our numerical experiments. In this two-dimensional model, the immersed boundary consists of two closed curves, each in the form of a racetrack. The part of each curve shown with thick lines in Figure 1 is almost rigid and the other part with thin lines is flexible. The fluid fills the entire box. Fluid markers, however, are only shown inside the flow loop, since that is the region of interest.

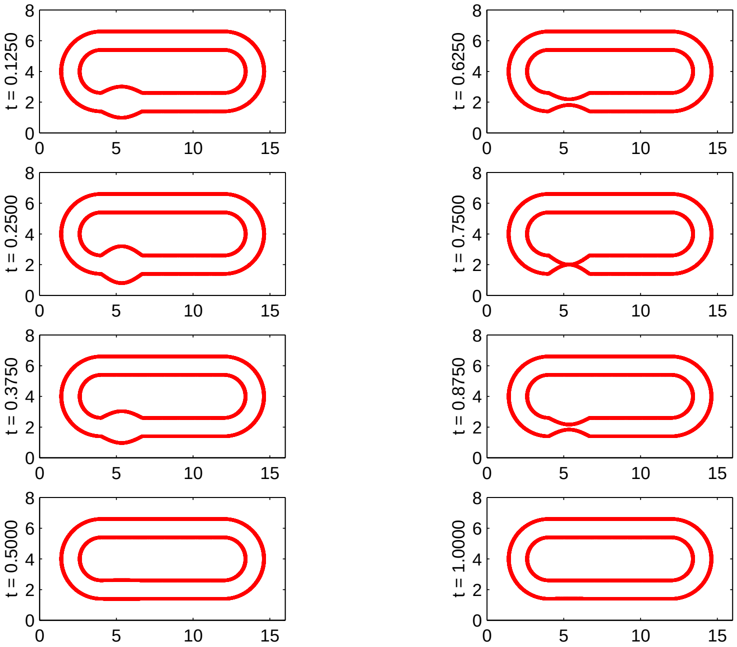

FIG. 2. *The target positions during one cycle: The motion of fluid inside the loop is driven by the periodic vertical expansion and contraction of the target configuration of the tube. This motion is confined to the left* 1/3 *of the flexible segment of tubing.*

Throughout this paper, we assume that the motions are driven by periodic vertical oscillations of the left 1/3 of the flexible tube boundary. Details of how these oscillations are applied will be described next.

3.2. Target positions and parameters. Recall that the equation for the force on the immersed boundary (2.6) involves target positions $\boldsymbol{Z}_b(s,t)$. After discretization, these become $\boldsymbol{Z}_{bl}^n$. For most of the flow loop, these are independent of time and serve the purpose of maintaining the racetrack shape of the flow loop. Time dependent target positions are used in the left 1/3 of the flexible segment of the flow loop (as shown in Figure 2) in order to provide periodic forcing to the flow. Figure 2 displays the target positions at eight equally spaced times over one cycle.

Now we describe the mathematical formulations of the time dependent target positions in the left 1/3 of the flexible segment of tubing.

Let $\boldsymbol{Z}_b(s,t) = (Z_{xb}(s), Z_{yb}(s,t))$, where s is restricted to the range of values that defines the left 1/3 of the flexible segment of tubing. This may be a different range of s values in the case $b = 1$ (inner boundary) than in the case $b = 2$ (outer boundary). Note that the x component of the target position $\boldsymbol{Z}_b(s,t)$ is independent of t, whereas the y component varies with time in the manner that we prescribe.

Define

$$A(s,t) = A_0 \sin\left(\frac{2\pi t}{T}\right) \sin\left(\pi \frac{Z_{xb}(s) - 0.25X_{scale}}{\frac{1}{3}0.5X_{scale}}\right),$$

where A_0 is the amplitude of the target position motion, T is its period, and X_{scale} is the length of the computational domain (i.e., its size in the x direction).

TABLE 1
Physical parameters.

Physical parameters	Symbol	
Density	ρ	1 g/cm^3
Viscosity	μ	0.01 g/cm $\cdot s$
Circumference of a loop	D	28.57 cm
Diameter of tube	d	0.6 cm
Computational domain	$X_{scale} \times Y_{scale}$	16 cm × 8 cm
Period	T	0.05 s $\sim$ 4 s
Amplitude(target)	A_0	0.4 cm and 0.6 cm
Duration of experiment	t_{max}	150 s
Stiffness constant(almost rigid)	κ_t	26000 g/s$^2 \cdot$ cm
Stiffness constant(flexible)	κ_t	900 g/s$^2 \cdot$ cm
Stiffness constant(curvature)	κ_c	120 $g\cdot$ cm/s^2

TABLE 2
Computational parameters.

Computational parameters	Symbol	
Fluid lattice	$N_x \times N_y$	256 × 128
Number of immersed boundary points	$M_1 + M_2$	3654
Meshwidth	$h = \Delta x = \Delta y$	0.0625 cm
Initial distance between boundary points	$\Delta s_1 = \Delta s_2$	$h/4 = 0.0156$ cm
Time step duration	Δt	0.5 h^2 = 0.00195 s

The flexible segment begins at $x = 0.25X_{scale}$ and ends at $x = 0.75X_{scale}$. Thus, the whole flexible segment has length $0.5X_{scale}$, and the part of it in which we allow the target position to move has length $\frac{1}{3}0.5X_{scale}$.

With $A(s,t)$ defined as above, let $Z_{by}(s,t)$ be defined as follows:

$$Z_{by}(s,t) = \begin{cases} 0.25Y_{scale} + 0.5d + A(s,t) & \text{if } b = 1 \text{ (inner boundary)}, \\ 0.25Y_{scale} - 0.5d - A(s,t) & \text{if } b = 2 \text{ (outer boundary)}, \end{cases}$$

where d is the resting diameter of the tube, Y_{scale} is the width of the computational domain (i.e., its size in the y direction), and s is again restricted to the range of values that defines the left 1/3 of the flexible segment of tubing.

The flows that we have investigated are all driven by these periodic motions of the time dependent target positions in the left 1/3 of the flexible segment of tubing.

Note that the target tube, taken as a whole, has nonconstant volume. This is reasonable, since the physical tube is only connected to the target tube by springs and does not follow the target motion in detail; see Figures 10, 11, and 12. In fact, the volume conservation of the physical tube is valid (see Figures 4 and 5) and does not reflect the periodic volume changes imposed on the target tube.

In this work, we use CGS units, but to give a sense of the dimensionless character of the flow, we sometimes report results in terms of a Reynolds number, which is defined by $Re = \frac{\rho U d}{\mu} = \frac{\rho \Phi}{\mu}$, where U is a time-averaged velocity, d is a diameter of the tube, ρ is a constant density, μ is viscosity, and Φ is a time-averaged flux. Note that this Reynolds number refers to the time-averaged velocity and flux, so any nonzero value indicates that valveless pumping has occurred. The Reynolds number, so defined, has varied in our computations between 0 and about 160.

Tables 1 and 2 display the physical and computational parameters, respectively. As indicated in Table 1, the two physical parameters that we systematically vary

Table 3
The ratios of the L_2 difference of velocities.

L_2 difference ratio	
$\|u_{64}\text{-}u_{128}\|_2/\|u_{128}\text{-}u_{256}\|_2$	1.910726
$\|u_{128}\text{-}u_{256}\|_2/\|u_{256}\text{-}u_{512}\|_2$	1.995359
$\|v_{64}\text{-}v_{128}\|_2/\|v_{128}\text{-}v_{256}\|_2$	1.662576
$\|v_{128}\text{-}v_{256}\|_2/\|v_{256}\text{-}v_{512}\|_2$	1.869106

in this work are the period and amplitude of the prescribed motion of the target positions. The resulting flows are definitely dependent on these two parameters. In particular, they determine not only the amount of net flow that develops but even the direction of the net flow around the loop.

4. Results and discussion. The two main results of this paper are as follows: First, a net flow around the loop is produced by the periodic forcing on one end of the flexible boundary, despite the absence of valves. Previous investigators have observed this phenomenon in physical experiments [12], and a theoretical explanation based on a lumped parameter (ODE) model has been proposed [18], but this is the first time, to our knowledge, that valveless pumping has been demonstrated by a computer simulation based on the Navier–Stokes equations. Second, we find that the direction of flow around the loop is determined not only by the position of the periodic compression (as in [12]) but also by the amplitude and frequency of the driving force. This is a new, unexpected phenomenon, not previously reported, and the most important prediction of our model.

Preliminary physical experiments performed in the Courant Institute WetLab confirm that the flow can be driven in either direction from the same location depending on the details of the forcing. Experiments will be described in a future publication with Jun Zhang.

In this section, we first justify our numerical method and then show that the amplitude and the frequency are the crucial parameters to determine the direction of a net flow around the loop. Some special cases of valveless pumping are then discussed.

4.1. Checks on the numerical method. We report two checks on the validity of the numerical method. One check on the computation is to show that our numerical scheme has first order accuracy in time and space. Another check is to see whether the volume of the closed flow loop is conserved.

Numerical convergence. To test accuracy of our numerical scheme, we perform the same computation on the successive lattice refinements and compare the results in the L_2 norm. The physical parameters of this computation are as follows: period = 1.55 s, amplitude of the target position = 0.6 cm, and number of cycles = 96. The other physical parameters are the same as ones in Table 1. We consider the three successive mesh sizes within a fixed size physical domain: $N_x \times N_y = 128\times64$, 256×128, and 512×256. The ratio of the time step duration to the meshwidth is kept fixed throughout this study: $\Delta t/\Delta x = 0.0312$ s/cm. As N_x and N_y vary, the number of points on the immersed boundary changes in proportion to N_x or N_y, which, of course, are changing in proportion to each other. Specifically, we choose an initial distance between immersed boundary points which is equal to $\Delta x/4$.

Table 3 shows the results of the numerical convergence. The ratio of the L_2 norms on the difference of velocities, $\boldsymbol{u} = (u, v)$, at the successive lattice refinements

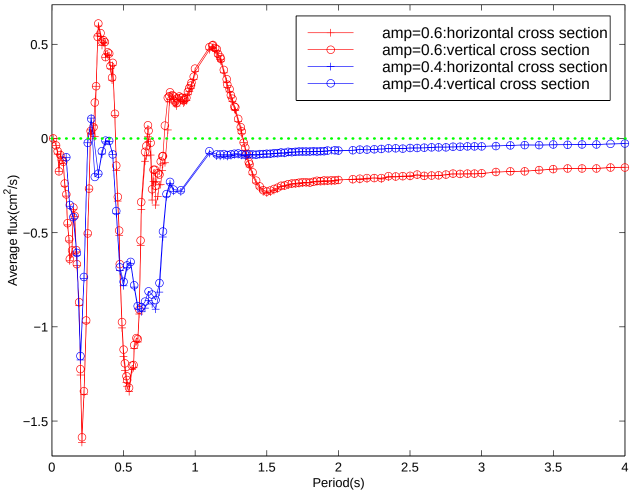

FIG. 3. *Average flow versus period (1/frequency): Flows with two different amplitudes of target positions, $A_0 = 0.6$ cm and $A_0 = 0.4$ cm, are compared. The plus data points denote fluxes computed on a horizontal cross section through the middle of the curved segment of tubing on the right side of the racetrack, and the circle data points denote fluxes computed on a vertical cross section through the middle of the straight segment of tubing at the top of the racetrack. In both cases, the time-averaged flux is plotted as a function of the period of the imposed oscillation in target position that drives the flow. Each pair of data points summarizes a separate numerical experiment, the duration of which is* 150 *s. Positive flux denotes clockwise net flow around the loop of tubing; negative flux denotes counterclockwise net flow. The existence of net flow in these numerical experiments is evidence of valveless pumping. This figure shows that the frequency is a crucial factor to determine the direction and magnitude of flow, and also shows the conservation of volume (area) by the comparison of time-averaged fluxes at two locations.*

are compared in Table 3. Since the asymptotic ratio is almost 2, our numerical method has almost first order accuracy. Presumably, the numbers in the table are converging to 2, but it would take computations on finer grids to show this.

Conservation of volume (area). The volume (area) should be conserved in time, since the fluid is incompressible. The conservation of volume (area) is checked in the following two ways: First, the time-averaged flux on two different cross sections of flow loop are compared. Second, the area inside the flow loop is computed as a function of time to see how much it varies. The time-averaged flux is defined by the mean flux computed on a cross section through the middle of the curved (or straight) segment of tubing on the racetrack over the simulated time.

Figure 3 displays the time-averaged flux, which is the main output of our numerical experiments concerning valveless pumping, plotted as a function of the period of the imposed oscillation in target position that drives the flow. To check volume conservation, these fluxes have been computed on two different cross sections of the tube: a vertical cross section in the middle of the straight segment that forms the top of the tube and a horizontal cross section in the middle of the curved segment of tubing on the right. Two different amplitudes of the target positions, $A_0 = 0.6$ cm and $A_0 = 0.4$ cm, are chosen. The time-averaged fluxes at each of these two cross sections practically coincide, over a wide range of periods. (Figure 3 contains four plots but appears to contain only two because the agreement of flows measured at different cross sections is so good.) Other physical and numerical parameters are as

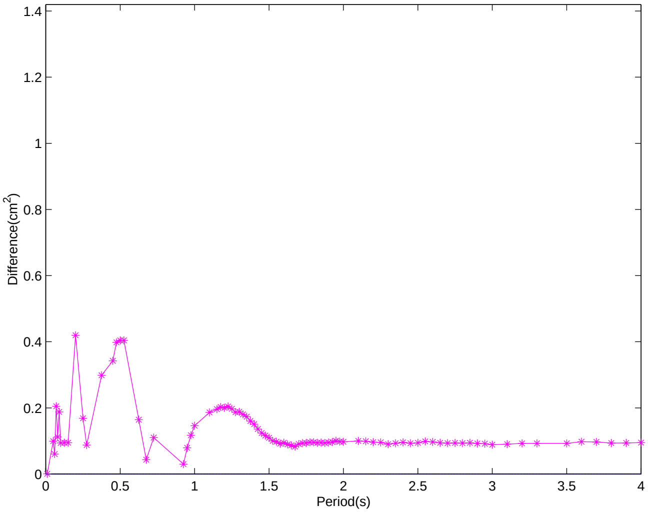

FIG. 4. *Conservation of volume (area): The difference between the time-averaged area and the initial area inside the loop versus the period of the driving oscillation. Each data point summarizes a different numerical experiment of* 150 *s duration (simulated time). The area of the loop is* 34.2796 *cm*^{2} *initially. The maximum error occurs at a driving period of* 0.2 *s, and is equal to* 0.4196 *cm*^{2}*, which is* 1.22% *of the initial area.*

shown in Tables 1 and 2.

Figure 4 shows the difference between the time-averaged area inside the flow loop and the initial area inside the flow loop plotted as a function of the period of the driving oscillation. Each data point summarizes a different numerical experiment of 150 s duration (simulated time). The parameters are also given in Tables 1 and 2 except the amplitude of the driving oscillation, which is 0.6 cm. The initial area of the flow loop is 34.2796 cm^2. The maximum difference between the time-averaged area and the initial area occurs at period 0.2 s, and it is only 0.4196 cm^2, which is 1.22% of the initial area inside the flow loop.

As a further check on the volume (area) conservation, we plot the area within the flow loop as a function of time. This is done for only one case, the driving period of 0.2 s, at which the maximum difference between the time-averaged area and the initial area occurs. Even in this worst case, the area as a function of time is nearly constant; see Figure 5, and note the expanded scale of the plot.

The volume errors we observed in this subsection are judged to be acceptable, but it could be further reduced if desired by using the method of Peskin and Printz [24].

4.2. The time-averaged flow around the loop as a function of the amplitude of the driving oscillation. In this section, we investigate the influence of the amplitude of the driving oscillation (i.e., the amplitude of the prescribed target position motion) on the magnitude and direction of the net flow around the loop of simulated tubing. Four different periods of the driving oscillation are considered: $T = 0.3$ s, 0.375 s, 0.525 s, and 1.7 s. Figure 6 displays the time-averaged flux as a function of the amplitude of the driving oscillation at these four chosen periods. Other parameters besides amplitude and period are given in Tables 1 and 2. Positive flow values denote clockwise net flow, and negative values denote counterclockwise net flow.

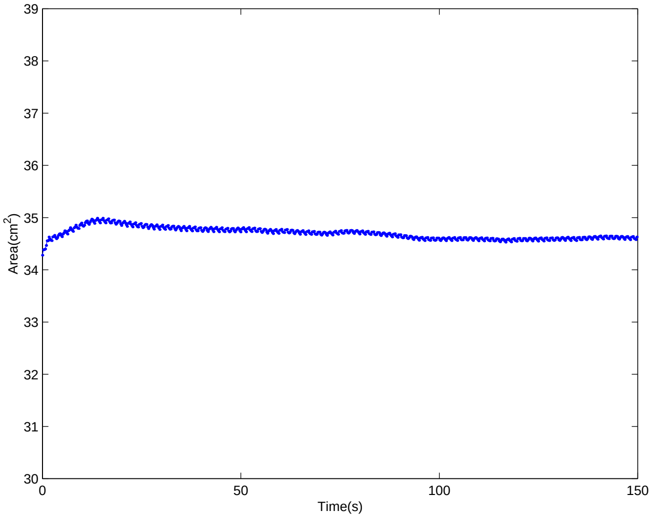

FIG. 5. *Conservation of volume (area): Area versus time at a driving period of* 0.2 *s. The area inside the flow loop is almost constant in time (note the expanded scale of the plot:* 0 *is way offscale) even though the chosen period of* 0.2 *s is the one at which the maximum difference between the time-averaged area and the initial area occurs.*

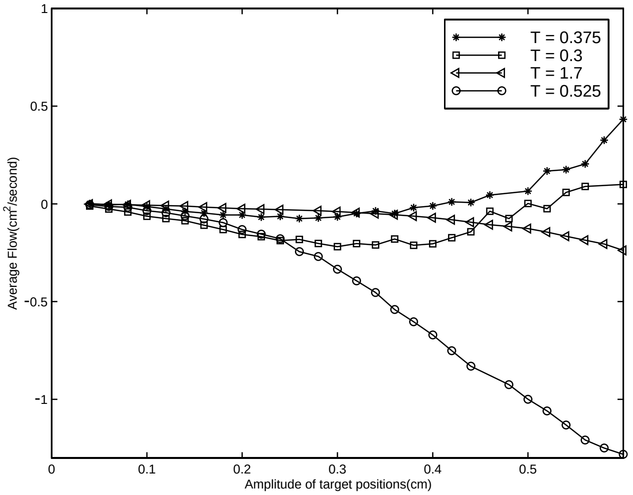

FIG. 6. *Average flux versus amplitude: The flows at four different periods, $T = 0.3$ s, 0.375 s, 0.525 s, and 1.7 s, are compared. Each data point summarizes a separate numerical experiment of 150 s duration (simulated time). For all periods shown, the flow is negative (counterclockwise) at low amplitude, but for some periods ($T = 0.3$ s and $T = 0.375$ s) it reverses and becomes positive (clockwise) at high amplitude.*

The results plotted in Figure 6 show the following features:

- At low amplitude of the driving oscillation, net flow is always in the counterclockwise direction. Its magnitude at any given amplitude depends on the period of the driving oscillation. Of the four examples given in the figure, the periods $T = 0.375$ s and $T = 1.7$ s result in only weak counterclockwise flow, whereas $T = 0.3$ s and $T = 0.525$ s result in much stronger counterclockwise flow.

- As the amplitude increases a qualitative distinction between the different cases appears. For $T = 0.525$ s and $T = 1.7$ s, the counterclockwise flow simply gets stronger monotonically as the amplitude of the driving oscillation increases. But for $T = 0.3$ s and for $T = 0.375$ s, the flow changes direction at some critical amplitude and becomes clockwise at high amplitude. Note that one cannot predict from the strength of the counterclockwise flow at low amplitude which of the cases will have clockwise flow at high amplitude: Of the two cases that have clockwise flow at high amplitude, one had a strong counterclockwise flow and the other had a weak counterclockwise flow at low amplitude.

Overall, there seems to be a preference for counterclockwise flow in these results. All periods generate counterclockwise flow at low amplitude, and only some periods generate flows that reverse and become clockwise at high amplitude. We can speculate on the reason for this, as follows. Recall that the driving oscillation is imposed at the left end of the flexible segment of tubing, which forms the lower straight segment of the racetrack; see Figure 2. If waves propagate from this source to the right along the flexible segment, these would tend to generate counterclockwise flow by a peristaltic mechanism. This argument leaves open the question of why the flows reverse and become clockwise, for some periods of the driving oscillation, when the amplitude of the driving oscillation becomes sufficiently large.

4.3. The time-averaged flow around a loop as a function of frequency. In this subsection, we present a new, unexpected phenomenon which is the most important prediction of our model: the driving frequency (1/period) is a crucial parameter to determine the magnitude and even the direction of a net flow generated by valveless pumping.

The time-averaged flow around a loop as a function of the period of the driving oscillation is investigated for two different amplitudes of the driving oscillation, $A_0 = 0.4$ cm and $A_0 = 0.6$ cm. In Figure 3, we plot the time-averaged flux versus period for these two cases. Each data point is the result of a separate numerical experiment, and the parameters are the same as in Tables 1 and 2. As before, positive flow is clockwise, and negative flow is counterclockwise.

The result that is obvious from a glance at Figure 3 is that valveless pumping has a strong dependence on the frequency of the driving oscillation. Indeed, there appear to be resonances at rather specific frequencies, which are most effective in driving the flow in one direction or the other. At the lower amplitude, the net flow is almost always counterclockwise, so these peaks are in the negative direction. As we shift to the higher amplitude, the negative peaks seem to be preserved, but now positive peaks emerge as well. Another indication of the dynamic character of valveless pumping is that it seems to disappear at the extremes of frequency. In the high-frequency (low-period) limit, it is clear from Figure 3 that the net flow approaches zero. This also seems to be true in the low-frequency (high-period) limit, although for the higher amplitude data one cannot be sure whether the net flux is approaching zero or some negative value. In any case, strong valveless pumping happens at specific frequencies that are neither too large nor too small.

Since the driving frequency is an important parameter of valveless pumping, it may be of interest to interpret our results in terms of the Womersley number $Wo = d\sqrt{\omega/\nu}$, where d is the tube diameter (0.6 cm), ν is the kinematic viscosity ($\nu = \mu/\rho =$

0.01 cm^2/s), and ω is the driving frequency in radians/s ($\omega = 2\pi/T$). For example, the maximum average clockwise flow occurs at a period of $T = 0.325$ s, which is a Womersley number of $Wo = 26$, and the maximum average counterclockwise flow occurs at a period of $T = 0.21$ s, corresponding to a Womersley number of $Wo = 33$. In both cases, the Womersley number is substantially larger than 1, which means that the velocity profile is far from parabolic.

5. Case studies. In this section, several special cases of valveless pumping are studied. Recall Figure 3 in the previous section. We chose the special cases based on the results from that figure. The amplitude of the driving oscillation, $A_0 = 0.6$ cm, is chosen, since a qualitative distinction between the different cases appears as the amplitude increases, and $A_0 = 0.6$ cm is large enough to show that distinction. The following three cases are considered:

- Maximum average clockwise flow ($T = 0.325$ s).
- Almost zero flow ($T = 1.34$ s).
- Maximum average counterclockwise flow ($T = 0.21$ s).

As before, the fluid motions are driven by the oscillations in target positions which are imposed along the 1/3 left end of the flexible segment of tubing, which forms the lower straight segment of the racetrack. The parameters are as given in Table 1 and 2.

These three cases have been investigated and compared qualitatively in the following ways.

- The angles from the center of the computational domain, $(x, y) =$ (8 cm, 4 cm), to the current positions of the fluid markers inside the flow loop are measured in order to determine the direction of the flow.
- Flowmeter fluxes computed on the vertical cross section through the middle of the straight segment of tubing at the top of the racetrack as functions of time are measured to test whether the fluid motion is in a periodic steady-state through the final duration, $t_{max} = 150$ s, and to show the nature of the oscillation and the net progress of the fluid motions.
- The wave motions along the top of the flexible boundaries over one cycle of the periodic steady-state are investigated in order to determine whether the motion looks like a traveling wave or a standing wave (or some other more complicated kind of wave motion).
- The target positions and the real physical positions of the immersed boundary, in particular the flexible segment, are compared in order to see how the time dependent target positions affect the motions of the real physical boundary.
- The velocity vector fields and pressure contours of the maximum clockwise and the maximum counterclockwise cases at 4 different phases over one period after the periodic steady-state are presented.
- Changing the direction of the flow by changing the period *during* a computer experiment.
- Zero net flux for the symmetric driving force.

5.1. Three cases. Angle. Here we examine the net progress of the flow by following the angular position of selected fluid markers. The angles are measured from the center of the computational domain, $(x, y) =$ (8 cm, 4 cm), to the positions of the fluid markers as functions of time. The angle is increased as the position of the fluid marker is changed in the clockwise direction. We choose arbitrarily 6 fluid markers around the flow loop for each case. These 6 fluid markers are located at the same position initially in all three cases.

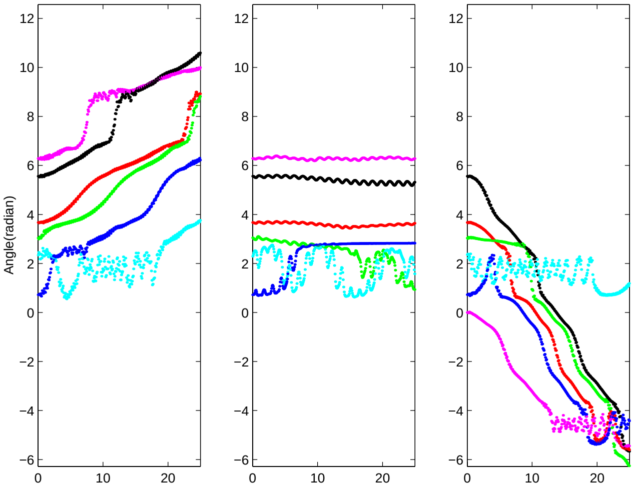

FIG. 7. *The angles of fluid markers are plotted as functions of time. The leftmost and rightmost figures show the case of maximum average flow in the clockwise direction (positive slope) and the case of maximum average flow in the counterclockwise direction (negative slope), respectively. The middle figure shows the case of almost zero flow (almost zero slope).*

Figure 7 displays the change of the positions of 6 fluid markers by measuring the angle as a function of time for the three cases. The angles are plotted at every 10 time steps up to $t_{max} = 25$ s. Since there are some vortices inside the flexible segment, some fluid markers get trapped and take time to escape the segment. Once fluid markers do escape, however, they move much faster along the rigid part of the racetrack. Examples are the sixth fluid marker in the leftmost frame, the second one in the middle frame, and the third one at the rightmost frame. Some other fluid markers stick to the immersed boundary. Ignoring these details and looking at the general trend, we can see that there is net clockwise motion of the markers in the leftmost frame, no net motion in the middle frame, and net counterclockwise motion in the rightmost frame of Figure 7.

Flowmeter. Figure 8 displays flowmeter results, which are the fluxes computed on the vertical cross section through the middle of the straight segment of tubing at the top of the racetrack. These results are plotted as functions of time over the last 5 cycles in each case. The positive values denote clockwise flow and the negative denote counterclockwise flow. In all three cases the flow is oscillatory, and the oscillation has settled down to a periodic steady state. The flow changes direction with a positive phase and a negative phase during each cycle. In two of the three cases (top and bottom in Figure 8) there is a nonzero mean flow superimposed upon the oscillatory motion. This nonzero mean flow is the phenomenon of valveless pumping.

The motions of wave along the flexible segment. We observe another interesting phenomenon of valveless pumping by investigating the wave motions along the flexible boundary. Figure 9 displays the motions of wave along the top of the flexible segment. Sixteen equal-time snapshots of the wave motions along the top of flexible segment over one cycle of the periodic steady-state are plotted for the three cases. In the top frame, there is a standing wave pattern with two nodes (at about 6.3 cm and 9.8 cm). For reasons that we do not understand, this standing wave

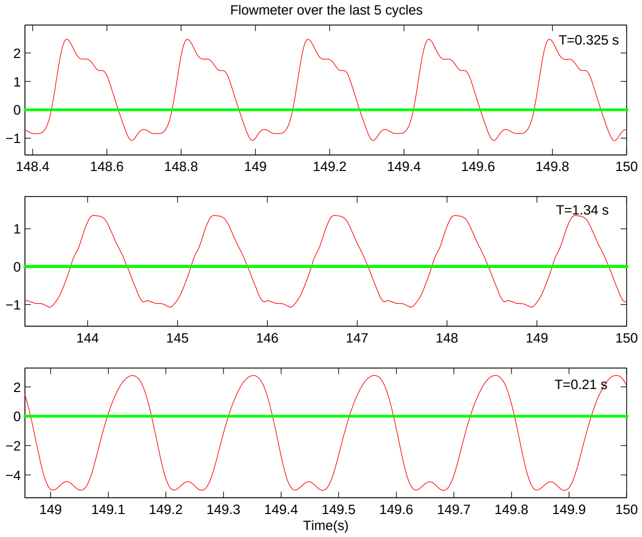

Fig. 8. *Flowmeter. The fluxes are computed on the vertical cross section through the middle of the straight segment of tubing at the top of the racetrack. They are plotted as functions of time are plotted over the last five cycles in each case (note the different time scales). The case of maximum average flow in the clockwise direction, almost zero flow, and maximum flow in the counterclockwise direction are considered from top and bottom. Note that the mean flow is positive (clockwise) in the top frame and negative (counterclockwise) in the bottom frame.*

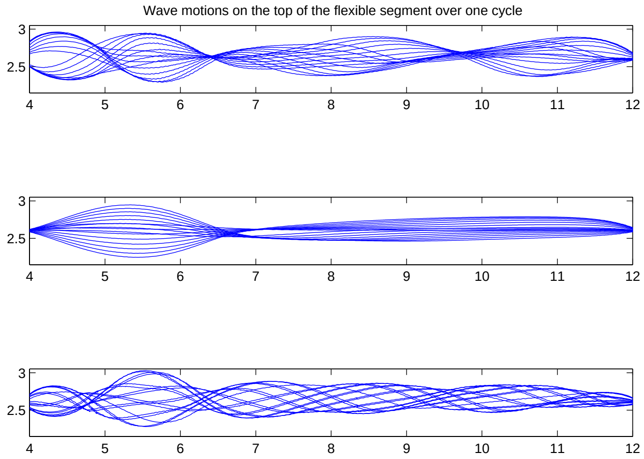

Fig. 9. *Sixteen equal-time snapshots over one cycle of the periodic steady-state wave motions along the top of the flexible segment are plotted. The top frame shows the case of maximum average flow in the clockwise direction. The middle frame shows the case of almost zero net flow. The bottom frame shows the case of maximum average flow in the counterclockwise direction. In all these cases, the source of vibration is confined to the left* 1/3 *of the flexible segment, i.e., to the interval from* 4 *cm to* 6.7 *cm.*

pattern is associated with maximum clockwise flow. In the middle frame, there again seems to be a standing wave pattern with just one node (at about 6.7 cm). Note,

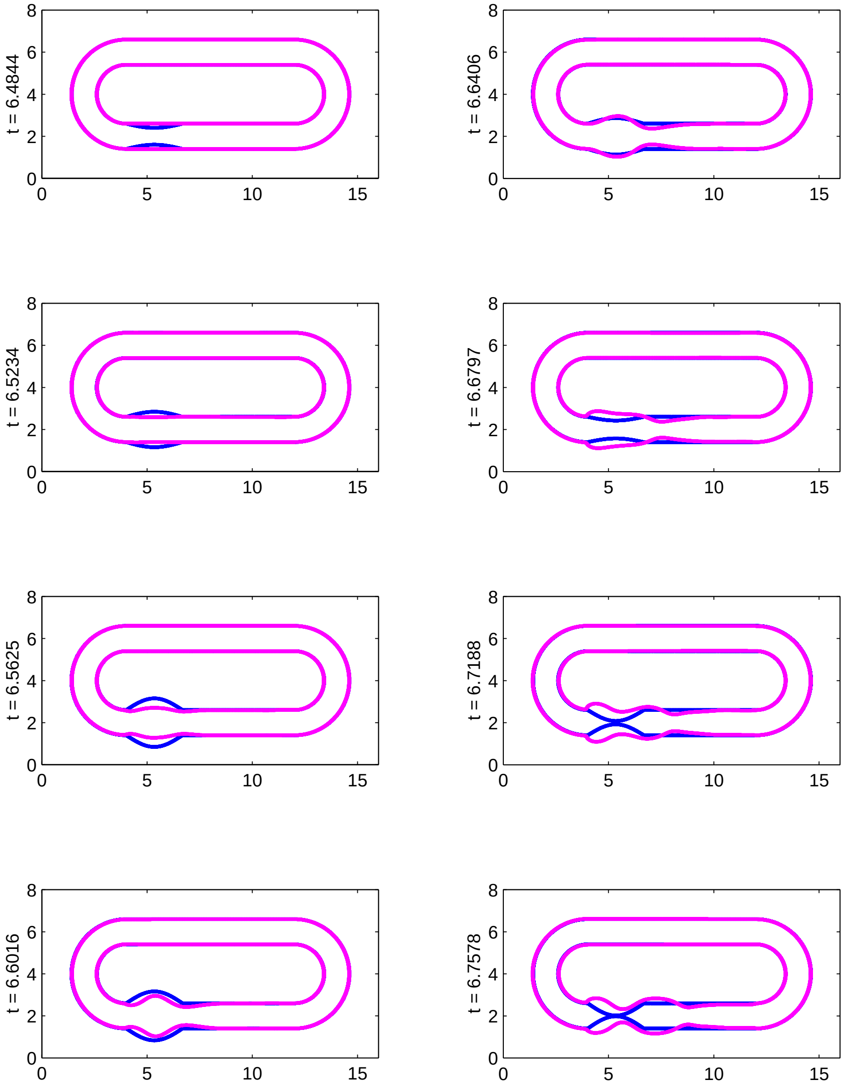

FIG. 10. *Comparison of the motions of the target positions (dark) and the physical boundary (light) for the case of maximum average clockwise flow.*

however, that the location of this node coincides with the edge of the driven part of the flexible boundary, i.e., the part where an oscillation of the target positions is imposed. Thus, it seems that the driven part of the flexible boundary is oscillating in one phase, and that the rest of the flexible boundary is oscillating in antiphase with flexible part. This wave pattern seems to be associated with the absence of valveless pumping, i.e., with zero net flow. In the bottom frame we see traveling waves (note the absence of nodes) propagating to the right, away from the driven part of the flexible boundary. Such traveling waves might be expected to pump fluid in the direction of propagation by a peristaltic mechanism, and indeed what we see in this case is maximum counterclockwise flow.

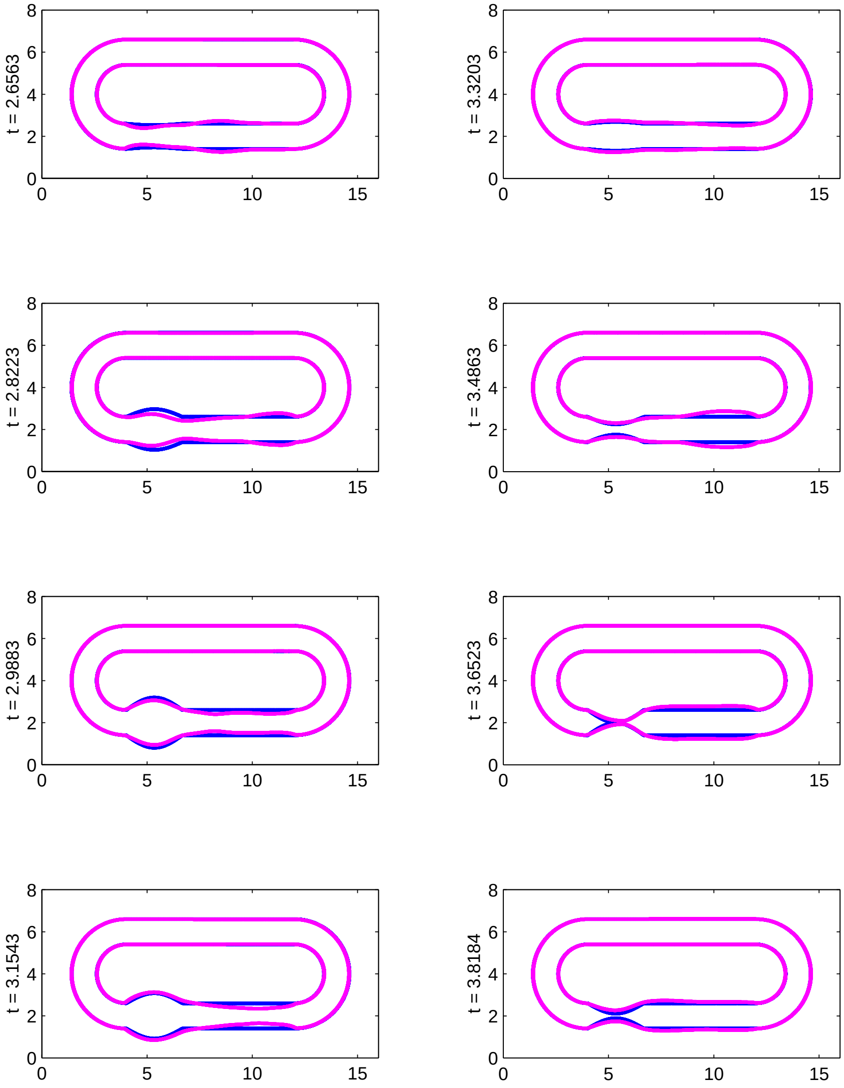

FIG. 11. *Comparison of the motions of the target positions (dark) and the physical boundary (light) for the case of almost zero flow.*

Comparison of the motions of the target positions and the real physical boundary. Here we compare the motions of the target positions and the physical boundary for the three cases. This is done in Figure 10 for the case of maximum average clockwise flow, in Figure 11 for the case of almost zero net flow, and in Figure 12 for the case of maximum average counterclockwise flow. The target positions (dark) are the same in all three figures, since the target motion is specified in advance and differs in three cases only with respect to time scale. Note also that the target positions are time dependent only in the left 1/3 of the flexible segment, which form the bottom of the racetrack.

Only in the case of zero net flow (Figure 11) does the physical boundary motion

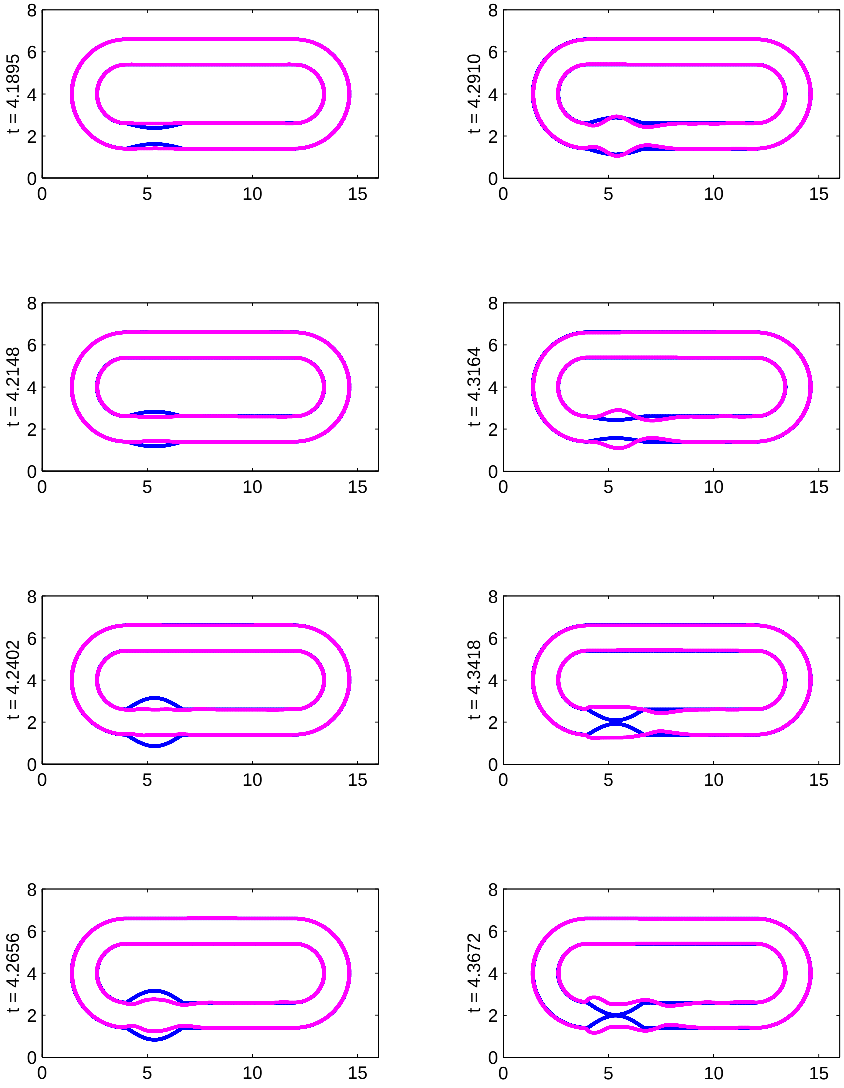

FIG. 12. *Comparison of the motions of the target positions (dark) and the physical boundary (light) for the case of maximum average counterclockwise flow.*

track the target position motion. This is probably because the frequency is too low for inertia to introduce any phase lags. In the other two cases, there are substantial phase differences (presumably consequences of fluid inertia) between the target position and the physical boundary position.

The velocity vector fields and pressure contours. Figures 13 and 14 display the velocity vector fields of the maximum clockwise flow (period = 0.325 s). Four equal-time snapshots over one cycle of the periodic steady-state are plotted. Figures 15 and 16 display the velocity vector fields of the maximum counterclockwise flow (period = 0.21 s). Four equal-time snapshots over one cycle of the periodic steady-state are also plotted.

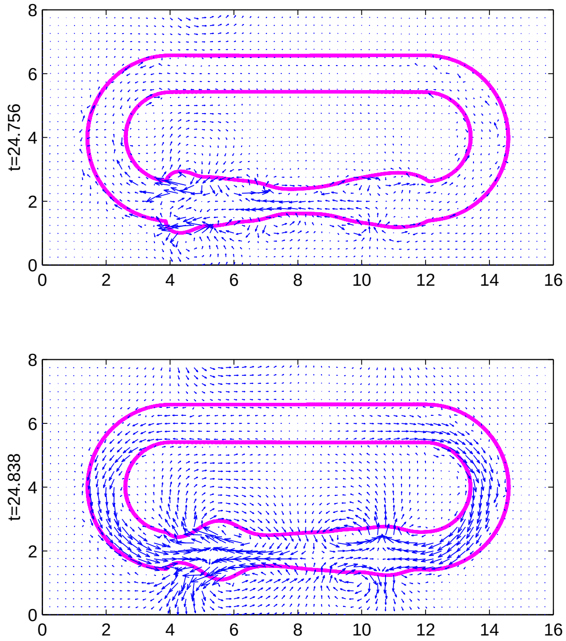

Fig. 13. *Velocity vector fields of the maximum clockwise flow. Four equal-time snapshots over one cycle of the periodic steady-state are plotted here and in Figure* 14.

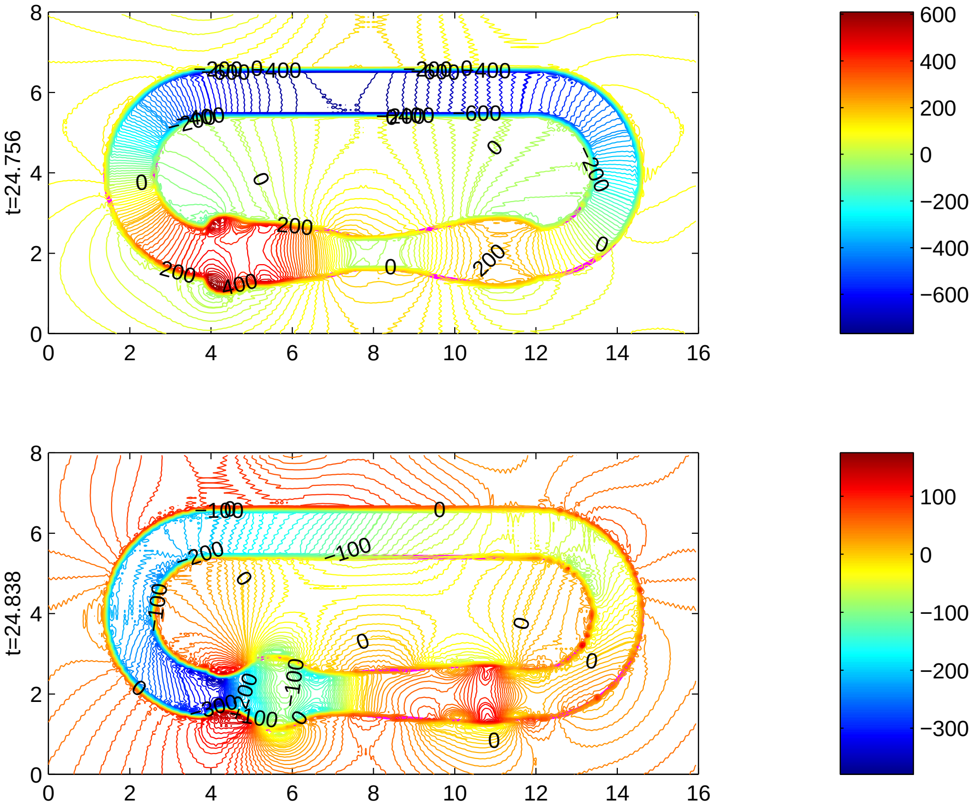

Fig. 17. *Pressure contours of the maximum clockwise flow. Four equal-time snapshots over one cycle after the periodic steady-state, plotted here and in Figure* 18. *The units of pressure are dynes/cm*^{2}.

Figures 17 and 18 display the pressure contours of the maximum clockwise flow. Four equal-time snapshots over one cycle of the periodic steady-state are plotted. Figures 19 and 20 display the pressure contours of the maximum counterclockwise flow. Four equal-time snapshots over one cycle of the periodic steady-state are also plotted.

Note that it is true that the positions of the immersed boundary are influenced not only by the fluid inside of the loop but also by the fluid outside of the loop. However, motions of the fluid inside the loop seem to be dominant, since that is where the larger velocities and pressure gradients are typically seen in Figures 13–20.

5.2. Further case studies. Flow which is changing the direction by changing the period *during* a computer experiment (periods, $T = 0.325$ s and $T = 0.21$ s). In this section, we present two more interesting cases. In Figure 21, we show that the result does not depend on initial conditions. One might worry that once the flow starts going one way it will keep going that way, but this case shows this is *not* true. In order to show that the crucial parameter to decide the direction of a net flow is frequency, we have examined the situation in which the period of the driving oscillation is 0.325 s for the first half of the simulated experiment, and then

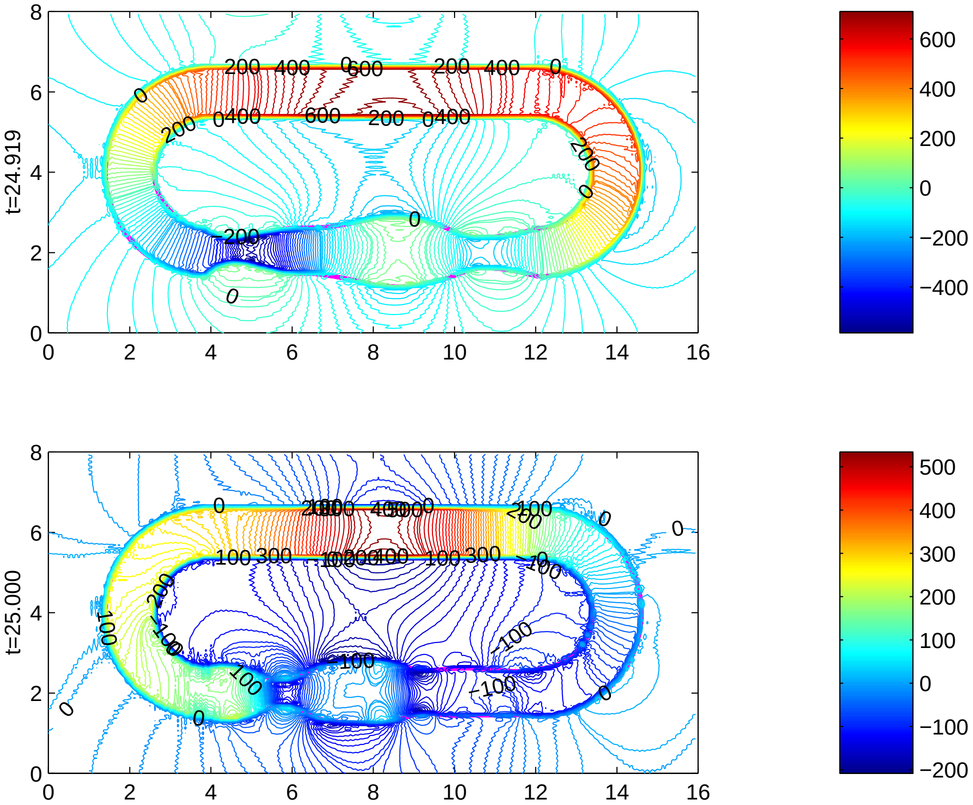

FIG. 18. *Continuation of Figure* 17.

changes to 0.21 s for the balance of the simulated experiment. Note that these are the periods which generated maximum net flow in the clockwise and counterclockwise direction, respectively. All other parameters except the period are fixed during the simulation.

Figure 21 displays the changing of the positions of two arbitrary fluid markers inside the flow loop by measuring the angles from the center, (x, y) = (8 cm, 4 cm), to the current positions of the markers. We plot angles as functions of time at every 10 time steps up to t = 20 s for each fluid marker. The curves in Figure 21 are changing from increasing (clockwise direction) to decreasing (counterclockwise direction) around 10 s.

Zero net flux for the symmetric driving force. Is there still a net flow if the system of valveless pumping would be symmetric? We consider the following special case to show that there is almost zero net flow when the periodic driving forcing is imposed on the center of the flexible segments. All other parameters are chosen for the case of the maximum counterclockwise flow, $T = 0.21$ s. This experiment is run until the periodic steady-state $t = 150$ s. The time-averaged flux for this case is -0.023625 cm^2/s. This shows that there is almost zero net flow when the system is symmetric.

From this case and the previous one, we see that valveless pumping does *not* represent an instability of a symmetric situation. On the contrary, the direction of

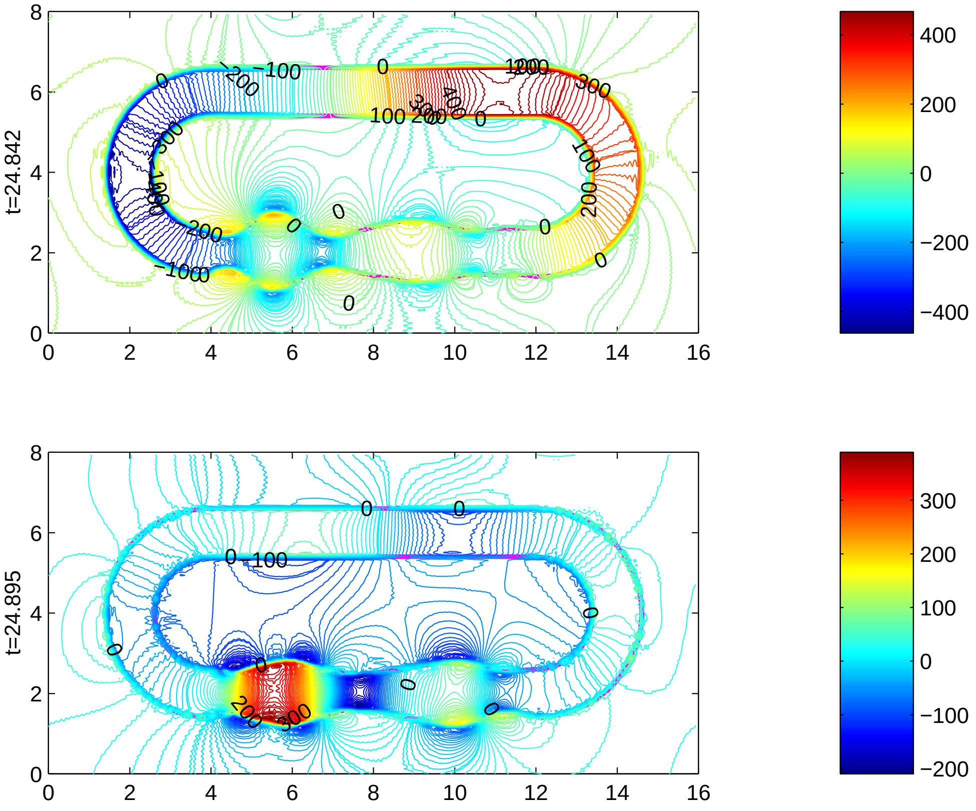

FIG. 19. *Pressure contours of the maximum counterclockwise flow. Four equal-time snapshots over one cycle after the periodic steady-state, plotted here and in Figure* 20. *The units of pressure are dynes/cm*^{2}*.*

the mean flow is determined by the asymmetry of the problem but in a frequency and amplitude dependent manner.

6. Conclusions.

We have presented numerical experiments concerning "valveless pumping" in the two-dimensional case using the immersed boundary method. As in the earlier papers and physical experiments of valveless pumping, we have also observed the existence of a net flow. Furthermore, we have presented the new, unexpected result that the direction of the flow around the loop of tubing is decided not only by the position of the driving oscillations but also by the *frequency* and the *amplitude* of the driving oscillations. Since CPR may involve valveless pumping, it is of obvious importance to know what frequency and amplitude of chest compression will produce the most effective CPR. Of course we cannot hope to answer this question quantitatively with such an idealized model, but perhaps we have shown qualitatively what phenomena may be expected as the frequency and amplitude of the driving oscillation are varied. We have put special emphasis on the conditions that generate maximum net flow, since that is the goal of CPR.

In studying these cases, we have found an interesting phenomenon: the clockwise net flow seems to be associated with a standing wave in the flexible segment of tubing,

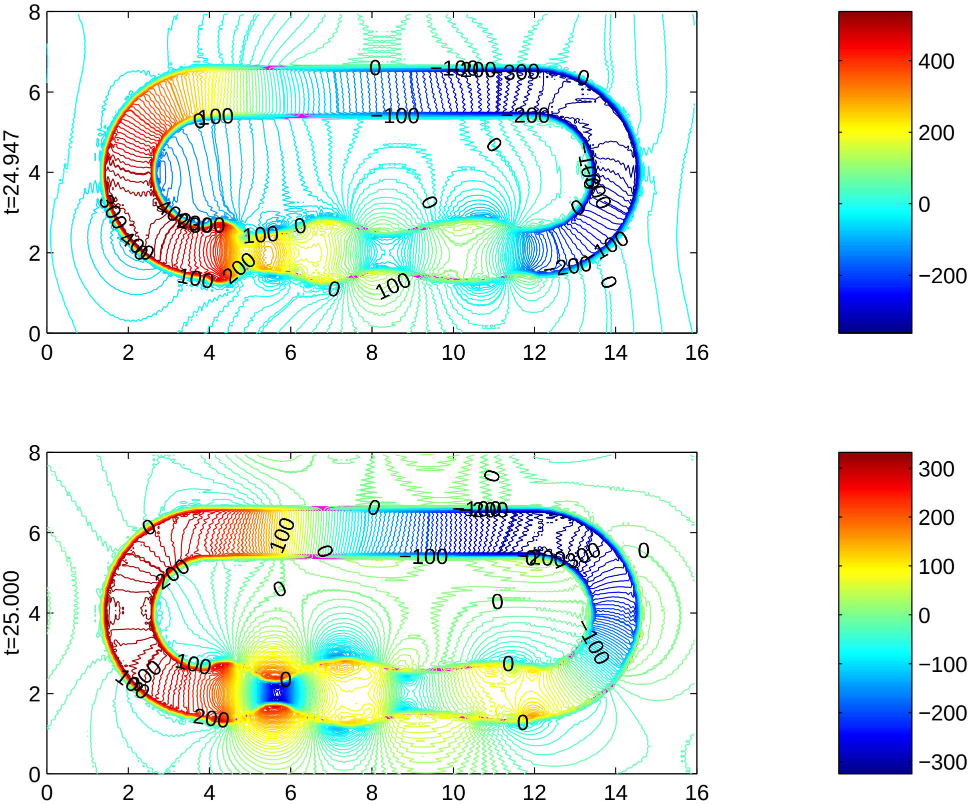

FIG. 20. *Continuation of Figure* 19.

whereas the counterclockwise net flow seems to be associated with a traveling wave. In the clockwise case (standing wave) the flow in the flexible segment of tubing is going toward the site at which the periodic forcing is applied, but in the counterclockwise case (traveling wave) it is going away from that site and in the same direction as the traveling wave. Therefore, we believe that the counterclockwise flow is driven by the traveling wave via a peristaltic mechanism, but we have no explanation for the clockwise flow in the standing-wave case.

The immersed boundary methodology used here may also be applicable to other biological instances of valveless pumping, such as the blood circulation within the human embryo at the end of the third week of gestation, and to engineering applications such as the design of MEMS.

We are confident that numerical experiments such as those begun in this paper will help answer many questions about the mechanism of valveless pumping. Even though the results demonstrate success in modeling valveless pumping, there is still much future work that remains to be done, such as giving a theoretical explanation for this mysterious phenomenon, and extending this model to the three-dimensional case in order to make it more realistic and more applicable to real-world biomedical problems, like CPR.

A physical experiment of valveless pumping is being constructed at the Courant

TIME MARCHING MULTILEVEL TECHNIQUES FOR EVOLUTIONARY DISSIPATIVE PROBLEMS[*]

B. COSTA[†], L. DETTORI[‡], D. GOTTLIEB[§], AND R. TEMAM[¶]

Abstract. In this article we use a pseudospectral Fourier discretization in conjunction with a multilevel splitting of high and low modes to solve dissipative partial differential equations. We develop unconditionally stable explicit techniques for the temporal integration of the linear terms and apply them to the high modes equation, improving the overall temporal stability of the multilevel method and resulting in a competitive fully explicit numerical scheme for nonlinear problems. In the cases where the linear term determines the time step restriction, numerical experiments with the Burgers equation in one and two dimensions showed substantial CPU cost reduction when comparing the resulting method with the standard spectral collocation associated with regular temporal integration schemes.

Key words. Runge–Kutta methods, nonlinear Galerkin, Fourier collocation, Burgers equation

1. Introduction. For partial differential equations modeling dissipative problems, the large scale and the small scale components of the unknown play different roles in the dynamics of their solutions. When solving such problems with a multilevel scheme of the nonlinear Galerkin type (NLG) or with a more general collocation splitting, the unknown u is decomposed in the physical space into its low modes component y and high modes component z, and the governing equation is split into two equations, one containing only the low modes and the other containing only the high modes. This separation of modes allows the use of distinct time integration techniques for each equation.

Certain problems require a minimum number of modes to be contained in the numerical approximation of their solutions. However, increasing the number of modes in dissipative problems decreases the size of the time step when using explicit temporal integration. In this article, we show that by using the splitting of modes we are able to relax the stability constraint of the high modes equation, allowing the use of time steps larger than the ones permitted by the standard time integration of the original variable u.

In the original NLG method, the high frequency component z of the solution was computed as a function of the low frequency component y through the utilization of an approximate inertial manifold (see [21]). This has proven to yield very unstable

schemes (see [19]). In the schemes that were subsequently considered (see [9]) the temporal variation term z_t was maintained, leading to much more stable discretizations than the original NLG with the same computational cost. Nevertheless, the essential idea of computing the low and high modes differently was retained, since their physical significances are different.

The collocation version of NLG was introduced in [6] and [7] for the Fourier and Chebyshev bases, respectively. There, the original approach of earlier papers in NLG (see [8] and [20]) was maintained. This approach, which consists in disregarding the nonlinear interactions of high and low modes and, sometimes, even the temporal evolution of the high modes, although leading to better accuracy with respect to the standard collocation method (SCM), would do so at a higher computational cost (see [13] and [14]). In [2] it was shown that by keeping all terms in both equations, the resulting splitting scheme would generate the same numerical solution as the SCM with equivalent computational effort. In this article we propose temporal evolution methods which integrate the low and high modes equations of the splitting scheme of [2] in different ways.

The general idea stems from the fact that high modes carry very little energy and, when computing steady state solutions, they evolve much faster than the low modes to an equilibrium state. This fast convergence at the transient stage of the temporal evolution requires small time intervals in the numerical integration process in order to capture the fast changes of the high modes. Therefore, artificially slowing this convergence to the same pace as the low modes enables the use of time intervals as large as the ones determined by the low modes only. Note that although we aim to approximate time dependent solutions, we believe that a proper approximation of the stationary solution is a necessary requirement for such a numerical scheme.

From the numerical point of view, the speed of convergence of the high modes is determined by the size of the corresponding eigenvalues of the dissipative operator. As hinted in [6], the size of these eigenvalues can be decreased by shifting the upper part of the spectrum through an exponential transformation in the z variable, hereafter referred to as the eigenvalues shifting technique. This involves the computation of a parameter, which determines the intensity of the shifting and can be chosen in a way of turning the high modes equation unconditionally stable. However, this technique has the drawback of altering the steady state solution of the high modes. A similar alternative way of shifting the spectrum that fixes this problem is proposed, and we call it the implicit correction technique. This technique, which is similar to previous ones developed in the study of stiff ODEs (see [10], [11], [17], [18], [22], and [24]), is applied through a modification of the temporal scheme, in our case, a Runge–Kutta scheme, allowing the use of a much larger time step. This method is consistent at steady state with the original method and has time accuracy at the transient stage.

A necessary observation is that we propose in this work a multilevel method for nonlinear problems, but since the stability analysis for these is mathematically too involved to be presented in this article, we will only apply the above techniques to the linear terms of the corresponding equations, relaxing only the time step restriction imposed by the dissipative linear operator. Nevertheless, the numerical results show computational advantages even in the cases of a weak dissipation.

This article is organized as follows. In section 2 we present the Runge–Kutta method modified by the eigenvalues shifting and analyze its stability and generation of steady state solutions. Section 3 presents the implicit correction technique and its application to some temporal integration schemes. Stability and error analysis for the modified schemes are also presented. Numerical experiments are shown in section 4.

2. The eigenvalues shifting technique. We start by considering the Burgers equation in one dimension, with periodic boundary conditions as below:

$$\begin{cases} u_t - \nu u_{xx} + \frac{1}{2}(u^2)_x = f, \quad x \in (0, 2\pi), \quad t > 0, \\ u(0,t) = u(2\pi, t), \quad t > 0. \end{cases} \tag{1}$$

The multilevel splitting procedure applied to this equation yields the following system for the low and high modes components y and z:

$$\begin{cases} y_t - \nu y_{xx} + \frac{1}{2} J_N((y+z)^2)_x = J_N f, \\ z_t - \nu z_{xx} + \frac{1}{2} G_M((y+z)^2)_x = G_M f, \end{cases} \tag{2}$$

where J_N and G_M are the projectors onto the low and high modes spaces, respectively (see [2] and [6]).

In the next two sections, we will introduce three modified time integration schemes to be applied in conjunction with the above decomposition. If the numerical solution contains $M = 2N$ modes, the y component corresponds to the first N modes and the z component to the last N modes. The stability condition imposed by the linear term of the low modes equation yields a time step proportional to $\frac{1}{N^2}$, while the time step for the high modes should be proportional to $\frac{1}{M^2} \ll \frac{1}{N^2}$. The idea of the methods presented below is to modify the time integration of the high modes equation in a way that reduces its stability constraint to that of the low modes equation allowing the choice of a much larger Δt. Thus, for the sake of simplicity, and since we are only interested in changing the time step restriction coming from the linear terms, we will consider for the numerical analysis that follows the linear equation

$$u_t = u_{xx} + f \tag{3}$$

with periodic boundary conditions and its corresponding multilevel splitting

$$\begin{cases} y_t = \nu y_{xx} + J_N f, \\ z_t = \nu z_{xx} + G_M f. \end{cases} \tag{4}$$

Nevertheless, the analysis that follows remains valid for nonlinear problems where the linear stability restriction is dominant. In these cases, the methods proposed in this section lead to fully explicit schemes with time steps much larger than the ones allowed by the standard explicit integration methods, as we shall see in the numerical experiments of section 4.

Consider a high modes function z in the form

$$z(x) = e^{iNx} \sum_{k=1}^{N} \hat{z}_k^M e^{ikx} \tag{5}$$

and the homogeneous linear equation

$$z_t = z_{xx}. \tag{6}$$

Multiplying (6) by $e^{\beta N^2 t}$, $\beta > 0$, and defining the new variable $w = e^{\beta N^2 t} z$, we have

$$w_t = w_{xx} + \beta N^2 w. \tag{7}$$

Substituting $\hat{w}_k = e^{\beta N^2 t}\hat{z}_k$ into (7), we obtain the following system of equations in the phase space:

$$\frac{d}{dt}\hat{w}_k = \lambda_k^\beta \hat{w}_k, \quad k = 1, \dots, N, \tag{8}$$

where

$$\lambda_k^\beta = -((N+k)^2 - \beta N^2), \quad k = 1, \dots, N. \tag{9}$$

To improve stability we need to choose a β that decreases the absolute values of the eigenvalues (9). As shown in [6], $\beta = \frac{5}{2}$ minimizes $\max_k \ |\lambda_k^\beta|$, yielding

$$\max_k \ |\lambda_k^{5/2}| = \frac{3}{2}N^2, \quad k = 1, \dots, N,$$

allowing the use of a time step proportional to $\frac{2}{3N^2}$. Hereafter, we denote this transformation of variables as the eigenvalues shifting (ES) technique.

A straightforward application of this idea to a temporal integration method consists in integrating the variable $\hat{w}_k$ for one iteration and recovering $\hat{z}_k$ at the end by setting

$$\hat{z}_k = e^{-\beta N^2 \Delta t}\hat{w}_k. \tag{10}$$

The choice of the parameter β will depend on the specific temporal discretization. In what follows, we apply the modification above to the fourth order Runge–Kutta (RK4) scheme and give an estimate for the parameter β.

Let us consider (6) in the phase space:

$$\frac{d}{dt}\hat{z}_k = \lambda_k^0 \hat{z}_k. \tag{11}$$

The standard RK4 scheme is given by

$$\begin{aligned}
&L\hat{z}_k^n = \lambda_k^0 \hat{z}_k^n, && K_1 = L\hat{z}_k^n,\\
&\hat{z}_k^{n+1/4} = \left(\hat{z}_k^n + \frac{\Delta t}{2}K_1\right), && K_2 = L\hat{z}_k^{n+1/4},\\
&\hat{z}_k^{n+2/4} = \left(\hat{z}_k^n + \frac{\Delta t}{2}K_2\right), && K_3 = L\hat{z}_k^{n+2/4},\\
&\hat{z}_k^{n+3/4} = \left(\hat{z}_k^n + \Delta t K_3\right), && K_4 = L\hat{z}_k^{n+3/4},\\
&\hat{z}_k^{n+1} = \left[\hat{z}_k^n + \frac{\Delta t}{6}(K_1 + 2(K_2+K_3) + K_4)\right]
\end{aligned} \tag{12}$$

and may be written in the form

$$\hat{z}_k^{n+1} = G(\lambda_k^0 \Delta t)\hat{z}_k^n, \tag{13}$$

where the amplification factor $G(\lambda_k^0 \Delta t)$ is given by

$$G(\lambda_k^0 \Delta t) = 1 + \lambda_k^0 \Delta t + \frac{(\lambda_k^0 \Delta t)^2}{2} + \frac{(\lambda_k^0 \Delta t)^3}{6} + \frac{(\lambda_k^0 \Delta t)^4}{24}. \tag{14}$$

If we apply the eigenvalues shifting to RK4 (ES–RK), we obtain

$$\tilde{z}_k^{n+1} = \tilde{G}(\lambda_k^\beta \Delta t)\tilde{z}_k^n, \tag{15}$$

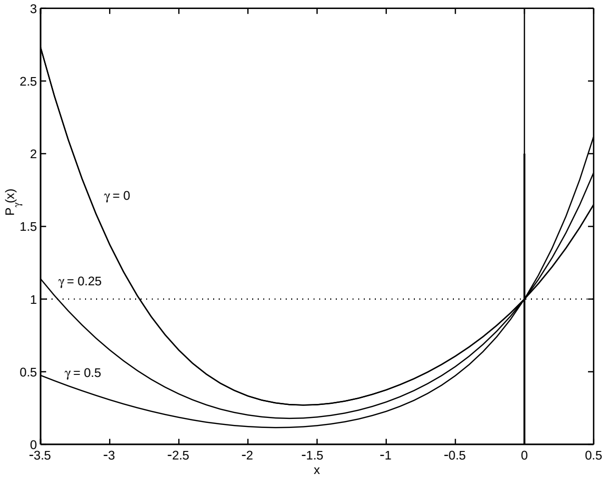

FIG. 1. *Graph of $P_\gamma(x)$.*

where the amplification factor $\tilde{G}(\lambda_k^\beta \Delta t)$ is given by

$$\tilde{G}(\lambda_k^\beta \Delta t) = \left[1 + \lambda_k^\beta \Delta t + \frac{(\lambda_k^\beta \Delta t)^2}{2} + \frac{(\lambda_k^\beta \Delta t)^3}{6} + \frac{(\lambda_k^\beta \Delta t)^4}{24}\right] e^{-\beta N^2 \Delta t}. \tag{16}$$

2.1. Stability analysis of ES–RK. In order to incorporate both methods in a common framework, we define the following family of functions:

$$\begin{cases} P(x) & = 1 + x + \frac{x^2}{2} + \frac{x^3}{6} + \frac{x^4}{24}, \\ P_\gamma(x) & = P(x)e^{\gamma x}. \end{cases} \tag{17}$$

Let us define the parameter

$$\gamma_k^\beta = \frac{-\beta N^2}{\lambda_k^\beta}. \tag{18}$$

Note that $\gamma_k^0 = 0$ and that γ_k^β increases when β increases.

Setting $x_k^\beta = \lambda_k^\beta \Delta t$, we can write the amplification factor of both methods as

$$G(\lambda_k^0 \Delta t) = P_0(x_k^0) = P_{\gamma_k^0}(x_k^0), \qquad \tilde{G}(\lambda_k^\beta \Delta t) = P_{\gamma_k^\beta}(x_k^\beta). \tag{19}$$

Figure 1 depicts the graphs of $P_\gamma(x)$ for increasing values of γ. The stability condition is determined by the first negative value of x such that $P_\gamma(x) = 1$. Note that increasing the value of β and therefore of γ increases the maximum absolute value of x_k^β that yields stability and therefore increases Δt. In the following we show that there is a value of β that makes the scheme unconditionally stable.

LEMMA 2.1. *Let the function $P_\gamma(x)$ be defined as in* (17). *There exist two real numbers $\gamma_b > 0$ and $\gamma_a < 0$ such that if $\gamma > \gamma_b$, then $P_\gamma(x) < 1$ for $x < 0$, and if $\gamma < \gamma_a$, then $P_\gamma(x) < 1$ for $x > 0$.*

Proof. The proof follows from the fact that $P(x) \leq e^{|x|}$. Therefore,

$$P_\gamma(x) = P(x)e^{\gamma x} \leq e^{\gamma x} e^{|x|},$$

yielding

$$\gamma \geq 1 = \gamma_b, \quad x \leq 0, \qquad \gamma \leq -1 = \gamma_a, \quad x \geq 0. \qquad \square$$

In light of the previous results, if we can find a value of β for which $\gamma_k^\beta \notin (\gamma_a, \gamma_b)$ for all k, the method (15) becomes unconditionally stable.

THEOREM 2.2. *For $\beta = \frac{3}{2}$, $\gamma_k^\beta \notin (\gamma_a, \gamma_b)$ for all $k = 1, \ldots, N$, and therefore the modified method is unconditionally stable for the high modes equation.*

Proof. Let us rewrite γ_k^β as

$$\gamma_k^\beta = \frac{\beta N^2}{(1-\beta)N^2 + 2kN + k^2}. \tag{20}$$

For a fixed positive β there exists $1 \leq k_0 \leq N$ such that

$$\begin{aligned} k < k_0 \quad &\Rightarrow \quad \gamma_k^\beta < 0, \\ k > k_0 \quad &\Rightarrow \quad \gamma_k^\beta > 0. \end{aligned}$$

Moreover, γ_k^β is increasing and decreasing in modulus for $k < k_0$ and $k > k_0$, respectively. Therefore, we just need to check that γ_1^β and γ_N^β are not in (γ_a, γ_b). The value $\beta = \frac{3}{2}$ is the one corresponding to $\gamma_N^\beta = \gamma_b$, and for this value of β, $\gamma_1^\beta \approx -2 < \gamma_a$. $\square$

REMARK 2.1. *The proposed modification shifts the upper part of the spectrum and causes the stability condition to be determined by the low modes. However, when considering the high mode solution $\hat{z}_k^n$ after n iterations*

$$\hat{z}_k^n = \left[\left(1 + \lambda_k^\beta \Delta t + \frac{(\lambda_k^\beta \Delta t)^2}{2} + \frac{(\lambda_k^\beta \Delta t)^3}{6} + \frac{(\lambda_k^\beta \Delta t)^4}{24}\right) e^{-\beta N^2 \Delta t}\right]^n \hat{z}_k^0, \tag{21}$$

one can easily see that the mode $\hat{z}_k^n$ converges exponentially to 0. *The scheme will therefore be inconsistent whenever the high modes of the exact solution do not go to* 0 *exponentially. This suggests that the exponential correction to retrieve the original variable z at the end of each iteration may be too strong. In the following section we propose a different correction that will eliminate this inconvenience.*

Further evidence of the inconsistency of this scheme is the fact that the steady state solution generated by ES–RK does not converge to the steady state solution of the original problem (3)

$$\hat{z}_k^{st} = -\frac{\hat{f}_k}{\lambda_k^0}. \tag{22}$$

For the sake of simplicity, consider the eigenvalues shifting for the forward Euler method:

$$\hat{z}_k^{n+1} = ((1 + \lambda_k^0 \Delta t + \beta N^2 \Delta t)\hat{z}_k^n + \Delta t \hat{f}_k) e^{-\beta N^2 \Delta t}. \tag{23}$$

The steady state solution for this method is

$$\hat{z}_k^{st} = \frac{\Delta t \hat{f}_k}{e^{\beta N^2 \Delta t} - (1 + \beta N^2 \Delta t) - \lambda_k^0 \Delta t}. \tag{24}$$

Note that, due to the desired stability condition, $\beta N^2 \Delta t = O(1)$; therefore, (24) is not a good approximation to (22).

3. The implicit correction technique. As pointed out in the previous section, the exponential correction to the Runge–Kutta scheme for the modified (8) is too strong and yields a different steady state solution from the original problem. This is due to the fact that applying an RK4 corresponds to applying a fourth order polynomial approximation of the exponential which we then counterbalance using a negative exponential at the end of each iteration.

The idea is to use a milder polynomial correction instead of an exponential one. In this section we illustrate the details of this idea first on the forward Euler scheme and later we extend it to higher order Runge–Kutta schemes.

3.1. Nonconsistent implicit correction. Let us consider the first iteration of the standard forward Euler scheme for the modified (8):

$$\hat{w}_k^1 = (1 + \lambda_k \Delta t + \beta N^2 \Delta t)\tilde{z}_k^0. \tag{25}$$

Note that the forward Euler scheme for the original equation can be retrieved by setting

$$\hat{z}^1 = \hat{w}_k^1 - \beta N^2 \Delta t \tilde{z}_k^0. \tag{26}$$

Instead, we propose the implicit correction

$$\tilde{z}_k^1 = \hat{w}_k^1 - \beta N^2 \Delta t \tilde{z}_k^1, \tag{27}$$

which leads to the modified forward Euler scheme for the nonhomogeneous equation:

$$\tilde{z}_k^{n+1} = \frac{1 + \lambda_k \Delta t + \beta N^2 \Delta t}{1 + \beta N^2 \Delta t} \tilde{z}_k^n + \frac{\Delta t}{1 + \beta N^2 \Delta t} \hat{f}_k. \tag{28}$$

Remark 3.1. *The scheme above, although obtained from the ES idea presented in the last section, can be classified in the more general class of rational Runge–Kutta schemes, which have been previously considered by ODE analysts in the study of stiff systems (see* [17], [18], *and* [24]*). Nevertheless, here we conjugate scheme* (28) *with the multilevel splitting method by applying it only to the high modes equation.*

The implicit correction technique differs from the ES in the substitution of the exponential term $e^{-\beta N^2 \Delta t}$ for the polynomial correction $(1 + \beta N^2 \Delta t)^{-1}$, which can be seen as a formal truncation in the Taylor series approximation to $e^{-\beta N^2 \Delta t}$. It is easy to check that the steady state solution of the modified Euler scheme coincides with the steady state solution of the original nonhomogeneous problem.

The following theorem shows that for certain values of the parameter β this polynomial correction is enough to improve the stability of the method or even make it unconditionally stable.

Theorem 3.1. *The modified forward Euler scheme* (28) *applied to the high modes equation in* (4) *with $\beta = 3/2$ is stable for*

$$\Delta t \leq \frac{2}{N^2}, \tag{29}$$

which is the same stability condition of the original forward Euler scheme applied to the low modes. Moreover, if $\beta = 2$, the scheme is unconditionally stable.

Proof. The scheme (28) is stable if

$$\frac{|1 + \lambda_k \Delta t + \beta N^2 \Delta t|}{|1 + \beta N^2 \Delta t|} \leq 1.$$

Knowing that $\lambda_k = -k^2$ and $\beta \geq 0$, we obtain the condition

$$\Delta t \leq \frac{2}{k^2 - 2\beta N^2}.$$

Considering the largest eigenvalue λ_{2N}, we have

$$\Delta t \leq \frac{2}{4N^2 - 2\beta N^2} = \frac{2}{(4-2\beta)N^2}.$$

Therefore, the choice of $\beta = 3/2$ yields (29), and if $\beta = 2$, the denominator vanishes, yielding unconditional stability. $\square$

REMARK 3.2. *When choosing $\Delta t = \frac{1}{N^2}$, as required by the stability condition for the low modes equation, it can be shown that the homogeneous version of the scheme is a discretization of the modified equation*

$$\frac{d}{dt}\tilde{z}_k = \frac{\lambda_k}{1+\beta}\tilde{z}_k, \tag{30}$$

which, in the physical space, corresponds to solving

$$(1+\beta)z_t = z_{xx}. \tag{31}$$

It is necessary to point out that adding the term βz_t in (31) *is the correct way of decreasing the viscosity without changing the steady state solution of* (6)*. However, this modification introduces an inconsistency and affects the order of the truncation error of the temporal scheme. In the next section we will consider a consistent implicit correction.*

In the following we compare the error committed by the standard forward Euler scheme,

$$\hat{u}_k^n = (1+\lambda_k\Delta t)^n \hat{u}_k^0 - \frac{1-(1+\lambda_k\Delta t)^n}{\lambda_k}\hat{f}_k, \tag{32}$$

with that committed by the modified forward Euler (28):

$$\tilde{u}_k^n = \left(1 + \frac{\lambda_k \Delta t}{1+\beta N^2\Delta t}\right)^n \hat{u}_k^0 - \frac{1-(1+\frac{\lambda_k\Delta t}{1+\beta N^2\Delta t})^n}{\lambda_k}\hat{f}_k. \tag{33}$$

Defining $\hat{\epsilon}_k^n = \tilde{u}_k^n - \hat{u}_k^n$ and considering that $\lambda_k = -k^2$, we obtain

$$\begin{aligned} |\hat{\epsilon}_k^n| &= \left| \left[\left(1 - \frac{k^2\Delta t}{1+\beta N^2 \Delta t}\right)^n - (1-k^2\Delta t)^n\right]\left(\hat{u}_k^0 - \frac{\hat{f}_k}{k^2}\right)\right| \\ &\leq \left|\left[k^2 n\Delta t\left(1 - \frac{1}{1+\beta N^2\Delta t}\right) + \cdots\right]\right| \left(|\hat{u}_k^0| + \frac{|\hat{f}_k|}{k^2}\right). \end{aligned} \tag{34}$$

Since $N^2\Delta t = O(1) = n\Delta t$, the term $(1 - \frac{1}{1+\beta N^2\Delta t}) = O(1)$, and we obtain

$$|\hat{\epsilon}_k^n| = O(k^2)|\hat{u}_k^0| + |\hat{f}_k|. \tag{35}$$

Let us consider, for example, f to be a continuous differentiable function, whose Fourier modes $\hat{f}_k$ decay as $O(\frac{1}{k^2})$, and an initial data u_0, whose Fourier modes decay as $\hat{u}_k^0 = O(\frac{1}{k^4})$. The contribution to the error in the low and high modes, respectively, is

$$(36)\left\{\begin{array}{l} O(\hat{u}_k^0) = O(f_k) = O(k^2) = O(1) \qquad \text{for } k \leq N, \\ O(\hat{u}_k^0) = O(\Delta t^2), O(\hat{f}_k) = O(\Delta t), \text{ and } O(k^2) = O(\Delta t^{-1}) \qquad \text{for } k > N. \end{array}\right.$$

Substituting this into (35), we get

$$|\epsilon_k^n| = \left\{\begin{array}{ll} O(1) & \text{for } k \leq N, \\ O(\Delta t) & \text{for } k > N. \end{array}\right. \tag{37}$$

This shows that for f with the required regularity, we will have an error of the first order in time if we apply the modification to the high modes equation and no convergence if we apply it to the low modes equation.

Scheme (28) is unconditionally stable even when applied to the nonsplit equation (3). However, (37) shows that no time accuracy is obtained when including the low modes in the modified scheme.

3.2. The nonconsistent implicit correction of RK2 and RK4. The extension of the method to a multistage scheme like a higher order Runge–Kutta is done following the guidelines of Remark 3.2, where the addition of the term βz_t is enforced at each stage. Thus, the nonconsistent implicit correction of the second order Runge–Kutta (NCIC2) for the nonhomogeneous version of (11) is the following:

$$\begin{array}{ll} \tilde{L}\tilde{z}_k^n = (\lambda_k^0 + \beta N^2)\tilde{z}_k^n, & \tilde{K}_1 = \tilde{L}\tilde{z}_k^n + \hat{f}_k, \\ \tilde{z}_k^{n+\frac{1}{2}} = \left(\tilde{z}_k^n + \dfrac{\Delta t}{2}\tilde{K}_1\right) / \left(1 + \beta N^2 \dfrac{\Delta t}{2}\right), & \tilde{K}_2 = \tilde{L}\tilde{z}_k^{n+\frac{1}{2}} + \hat{f}_k, \\ \tilde{z}_k^{n+1} = \left(\tilde{z}_k^n + \Delta t \tilde{K}_2\right) / (1 + \beta N^2 \Delta t). & \end{array} \tag{38}$$

As before, the steady state solution of scheme (38) converges to the original steady state solution, and the value $\beta = 1/2$ allows the use of the same time step of the low modes equation.

Finally, we introduce the nonconsistent implicit correction of the fourth order Runge–Kutta scheme (NCIC4):

$$\begin{array}{ll} \tilde{L}\tilde{z}_k^n = (\lambda_k^0 + \beta N^2)\tilde{z}_k^n, & \tilde{K}_1 = \tilde{L}\tilde{z}_k^n + \hat{f}_k, \\ \tilde{z}_k^{n+\frac{1}{4}} = \left(\tilde{z}_k^n + \dfrac{\Delta t}{2}\tilde{K}_1\right) / \left(1 + \beta N^2 \dfrac{\Delta t}{2}\right), & \tilde{K}_2 = \tilde{L}\tilde{z}_k^{n+\frac{1}{4}} + \hat{f}_k, \\ \tilde{z}_k^{n+\frac{2}{4}} = \left(\tilde{z}_k^n + \dfrac{\Delta t}{2}\tilde{K}_2\right) / \left(1 + \beta N^2 \dfrac{\Delta t}{2}\right), & \tilde{K}_3 = \tilde{L}\tilde{z}_k^{n+\frac{2}{4}} + \hat{f}_k, \\ \tilde{z}_k^{n+\frac{3}{4}} = \left(\tilde{z}_k^n + \Delta t \tilde{K}_3 +\right) / (1 + \beta N^2 \Delta t), & \tilde{K}_4 = \tilde{L}\tilde{z}_k^{n+\frac{3}{4}} + \hat{f}_k, \\ \tilde{z}_k^{n+1} = \left[\tilde{z}_k^n + \dfrac{\Delta t}{6}(\tilde{K}_1 + 2(\tilde{K}_2 + \tilde{K}_3) + \tilde{K}_4)\right] / (1 + \beta N^2 \Delta t). & \end{array} \tag{39}$$

The computation of the corresponding parameter β is more involved in this case; however, the discussion in section 2 hints at the correct range for β, since both methods apply the same idea. Numerical experiments indicate that for $\beta = 2$, unconditional stability is achieved for (39).

3.3. A consistent implicit correction. The idea that led to the NCIC can be improved to yield a consistent method. In this method we replace $\tilde{z}_k^0$ in (26) by $\frac{(\tilde{z}_k^1+\tilde{z}_k^{-1})}{2}$ and obtain

$$\tilde{z}_k^1 = \hat{w}_k^1 - \beta N^2 \Delta t \frac{(\tilde{z}_k^1 + \tilde{z}_k^{-1})}{2}. \tag{40}$$

This leads to the modified forward Euler scheme (CIC1)

$$\tilde{z}_k^{n+1} = (1+\lambda_k \Delta t)\tilde{z}_k^n - \frac{\beta N^2 \Delta t}{2}(\tilde{z}_k^{n+1} - 2\tilde{z}_k^n + \tilde{z}_k^{n-1}), \tag{41}$$

or, alternatively,

$$\tilde{z}_k^{n+1} = \frac{1+\lambda_k \Delta t}{1+\beta N^2 \frac{\Delta t}{2}}\tilde{z}_k^n + \frac{\beta N^2 \frac{\Delta t}{2}}{1+\beta N^2 \frac{\Delta t}{2}}(2\tilde{z}_k^n - \tilde{z}_k^{n-1}). \tag{42}$$

The stability analysis of the scheme above follows by defining a new variable $v^{n+1} = z^n$, transforming (42) into a system of equations whose amplification matrix G is given by

$$G(\lambda, \beta, \Delta t) = \begin{pmatrix} \frac{1+\lambda_k \Delta t + \beta N^2 \Delta t}{1+\beta N^2 \frac{\Delta t}{2}} & -\beta N^2 \frac{\Delta t}{2} \\ 1 & 0 \end{pmatrix}.$$

We will show that the eigenvalues of G are strictly less than 1 in magnitude for the high modes, and stability will follow. In order to simplify the calculations, we set $\lambda = \gamma N^2$, where $\gamma \in [1,2]$ and $\Delta t = \frac{2}{N^2}$, since we are only interested in stability for the set of high modes when using the low modes time step. Additionally, if, as before, we put $\beta = 2$, the matrix G above becomes

$$G = \begin{pmatrix} \frac{5-2\gamma^2}{3} & -\frac{2}{3} \\ 1 & 0 \end{pmatrix}$$

with its eigenvalues given by

$$\alpha_\gamma = \frac{a \pm \sqrt{a^2+4b}}{2},$$

where $a = \frac{5-2\gamma^2}{3}$ and $b = -\frac{2}{3}$. When $\gamma \in [1,2]$, it is easily proven that $a^2 + 4b < 0$; therefore,

$$|\alpha_\gamma|^2 < 1.$$

It is easily shown that the steady state solution of the CIC1 scheme (42) converges to the original steady state solution.

The truncation error of scheme (42) is given by

$$O(\Delta t) + O((\Delta t N)^2 z_{tt}). \tag{43}$$

The first term comes from the forward Euler scheme, and the second is the one associated with the implicit correction (40). Differently from scheme (28), scheme (42) possesses time accuracy independently of the particular set of modes being solved. If $\Delta t N^2$ is fixed (O(1)), then the second term in (43) is $O(\Delta t z_{tt})$.

REMARK 3.3. *Observe for* (43) *that z_{tt} is not small in the sup norm, but it is small in average. Hence there is here a new issue in numerical analysis on how to understand and define truncation error accuracy for high modes.*

REMARK 3.4. *The CIC scheme is similar to the Du Fort–Frankel scheme (see* [4], [15]*, and* [16]*)*

$$u^{n+1} = u^{n-1} + 2\Delta t \delta^2 u^n - \gamma N^2 \Delta t (u_j^{n+1} - 2u_j^n + u_j^{n-1}), \tag{44}$$

*where δ^2 represents the discrete second derivative operator and γ is a coefficient playing the same role as β for the previous schemes. The fundamental difference is in the way the first derivative in time is discretized. The Du Fort–Frankel scheme uses a central approximation resulting in a nondissipative scheme, not well suited for the parabolic equations under consideration, while in the CIC*1 *a forward approximation is used.*

By applying the consistent implicit correction at each stage of the fourth order Runge–Kutta we obtain the CIC scheme of order 4 (CIC4):

$$\begin{aligned}
\tilde{L}\tilde{z}_k^n &= (\lambda_k^0 + \beta N^2)\tilde{z}_k^n, & \tilde{K}_1 &= \tilde{L}\tilde{z}_k^n - \tfrac{\beta N^2}{2}\tilde{z}_k^{(n-1)+\frac{2}{4}} + \hat{f}_k,\\
\tilde{z}_k^{n+\frac{1}{4}} &= \left(\tilde{z}_k^n + \frac{\Delta t}{2}\tilde{K}_1\right) \Big/ \left(1 + \beta N^2 \frac{\Delta t}{2}\right), & \tilde{K}_2 &= \tilde{L}\tilde{z}_k^{n+\frac{1}{4}} - \frac{\beta N^2}{2}\tilde{z}_k^n + \hat{f}_k,\\
\tilde{z}_k^{n+\frac{2}{4}} &= \left(\tilde{z}_k^n + \frac{\Delta t}{2}\tilde{K}_2\right) \Big/ \left(1 + \beta N^2 \frac{\Delta t}{2}\right), & \tilde{K}_3 &= \tilde{L}\tilde{z}_k^{n+\frac{2}{4}} - \frac{\beta N^2}{2}\tilde{z}_k^n + \hat{f}_k,\\
\tilde{z}_k^{n+\frac{3}{4}} &= \left(\tilde{z}_k^n + \Delta t\tilde{K}_3\right) / \left(1 + \beta N^2 \Delta t\right), & \tilde{K}_4 &= \tilde{L}\tilde{z}_k^{n+\frac{3}{4}} - \frac{\beta N^2}{2}\tilde{z}_k^n + \hat{f}_k,\\
\tilde{z}_k^{n+1} &= \left[\tilde{z}_k^n + \frac{\Delta t}{6}(\tilde{K}_1 + 2(\tilde{K}_2 + \tilde{K}_3) + \tilde{K}_4)\right] / (1 + \beta N^2 \Delta t).
\end{aligned} \tag{45}$$

3.4. The nonlinear case. The analysis presented above is still valid for nonlinear problems where the stiffness of the linear dissipative operator determines the stability restriction on the time step, in particular, problems with a high value for the viscosity parameter ν. For those where the choice of the Δt is also influenced by the Courant, Friedrichs, and Lewy (CFL) condition, an extra modification in the implicit correction is necessary in order to control the numerical instability coming from the nonlinear advective terms. This is the subject of a forthcoming work. Here we limit ourselves to see the numerical advantages obtained when the above schemes relax the stability restrictions of the linear operator without recurring to implicit integration.

Thus, in the next section, when applying the implicit correction schemes to nonlinear problems, the nonlinear terms will be treated explicitly as in the standard Runge–Kutta schemes. All the gain in the size of the time step will come from the weaker stability restriction of the linear term obtained with the new schemes. The resulting scheme when applying the modified forward Euler scheme (28) to the nonlinear system (2) is given by

$$\left\{\begin{array}{l}
y^{n+1} = y^n + \Delta t(\nu y_{xx}^n + \frac{1}{2}J_N((y^n + z^n)^2) + J_N f^n),\\
z^{n+1} = \frac{\Delta t}{1+\beta N^2 \Delta t}(z^n + \nu z_{xx}^n + \beta N^2 \Delta t z^n) + \frac{\Delta t}{1+\beta N^2 \Delta t}(\frac{1}{2}G_M(y^n + z^n)_x^2 + G_M f^n).
\end{array}\right. \tag{46}$$

The second equation of the nonlinear system above is obtained from the linear scheme (28) by adjoining the nonlinear term to the forcing term. For the sake of completeness we include below the fourth order scheme corresponding to (39) when applied to the high modes equation of the nonlinear system (2):

$$
\begin{aligned}
&\tilde{L}\tilde{z}_k^n = (\lambda_k^0 + \beta N^2)\tilde{z}_k^n, && \tilde{K}_1 = \tilde{L}\tilde{z}_k^n + \hat{\mathrm{NL}}_k^{\,n} + \hat{f}_k,\\
&\tilde{z}_k^{n+\frac{1}{4}} = \left(\tilde{z}_k^n + \frac{\Delta t}{2}\tilde{K}_1\right) / \left(1 + \beta N^2 \frac{\Delta t}{2}\right), && \tilde{K}_2 = \tilde{L}\tilde{z}_k^{n+\frac{1}{4}} + \hat{\mathrm{NL}}_k^{\,n+\frac{1}{4}} + \hat{f}_k,\\
&\tilde{z}_k^{n+\frac{2}{4}} = \left(\tilde{z}_k^n + \frac{\Delta t}{2}\tilde{K}_2\right) / \left(1 + \beta N^2 \frac{\Delta t}{2}\right), && \tilde{K}_3 = \tilde{L}\tilde{z}_k^{n+\frac{2}{4}} + \hat{\mathrm{NL}}_k^{\,n+\frac{2}{4}} + \hat{f}_k,\\
&\tilde{z}_k^{n+\frac{3}{4}} = \left(\tilde{z}_k^n + \Delta t\tilde{K}_3 +\right) /(1 + \beta N^2 \Delta t), && \tilde{K}_4 = \tilde{L}\tilde{z}_k^{n+\frac{3}{4}} + \hat{\mathrm{NL}}_k^{\,n+\frac{3}{4}} + \hat{f}_k,\\
&\tilde{z}_k^{n+1} = \left[\tilde{z}_k^n + \frac{\Delta t}{6}(\tilde{K}_1 + 2(\tilde{K}_2 + \tilde{K}_3) + \tilde{K}_4)\right] /(1 + \beta N^2 \Delta t), &&
\end{aligned}
\tag{47}
$$

where

$$NL^n = \left(\frac{1}{2}G_M(y^n + z^n)_x^2\right).$$

One obtains the higher order schemes for the nonlinear case corresponding to (38) and (45) in an analogous way.

4. Numerical experiments.

In what follows we will refer to the SCM with the standard fourth order Runge–Kutta as SCM4. The collocation splitting coupled with the nonconsistent and consistent implicit corrections of the fourth order Runge–Kutta schemes ((39) and (45)) will be denoted by NCIC4 and CIC4, respectively.

The parameter β is set to 2 in order to yield unconditional stability for the high modes. The time step is written in the form

$$\Delta t = \frac{C}{\nu M^2}, \tag{48}$$

where the constant C is the parameter determining the size of Δt.

It is shown in [2] that the computational cost per iteration is the same when solving (3) with the SCM or the collocation splitting. Since the modification in the Runge–Kutta methods does not cause any relevant increase in the number of flops with respect to the original Runge–Kutta method, the constant C, and therefore the number of iterations to achieve a final time T, can also be used as a measure of the computational effort for comparison purposes. In this paper, we are interested only in measuring the gain in computational time by the use of a bigger Δt. It is shown in [2] that by just applying the splitting, CPU effort reduction can be achieved; however, this might also depend on the particular equation being solved.

Remark 4.1. *As was mentioned in the previous section, the following numerical experiments deal only with problems where the linear stability restriction on the time step is stronger than the CFL condition arising from the nonlinear advective terms. More precisely, since the nonlinear terms in scheme* (46) *are treated explicitly, the quantity*

$$\frac{\Delta x_{\min}}{||u||_\infty} \tag{49}$$

must be larger than (48) *at all times. For the dissipative problems below, it is sufficient that the initial data satisfies the above condition. However, depending on the strength of the nonlinearity, the time step bound* (49) *must also be checked during temporal integration to avoid blow-up of solutions.*

4.1. The one dimensional case. We start by solving the linear equation

$$\left\{ \begin{array}{l} u_t - \nu u_{xx} = f, \quad x \in (0, 2\pi), \quad t > 0, \\ u(0,t) = u(2\pi, t), \quad t > 0, \end{array} \right. \tag{50}$$

with a right-hand side of the form

$$f(x,t) = \cos(\nu\alpha t) \sum_{k=1}^{M} \frac{\cos(kx)}{k^2}. \tag{51}$$

The exact solution is

$$u(x,t) = \sum_{k=1}^{M} \left[c_k e^{-k^2 t} + \frac{\nu \cos(\alpha t)}{\nu(\alpha^2 + k^4)} + \frac{\alpha \sin(\nu \alpha t)}{\nu k^2 (\alpha^2 + k^4)} \right] \cos(kx), \tag{52}$$

where $c_k = O(\frac{1}{k^4})$. We set $\alpha = 0.01$ (providing a small variation in time) and $M = 33$.

Figures 2 and 3 show the L^2 error generated by SCM4, NCIC4, and CIC4 for $\nu = 0.1$ and $\nu = 0.001$, respectively. We took $C = 2$ in (48) when using SCM4. (The maximum value of C for SCM4 is 2.8; see section 2.) However, when using the modified methods NCIC4 and CIC4, C was taken equal to 8, a time step four times larger. Since we are considering 33 modes in (52), a minimum of 66 points is necessary to completely represent low, $k \leq 16$, and high modes, $k > 17$. Note that the multilevel methods generate intermediate solutions between SCM4 with 34 and 66 points, but at a lower computational cost than this last one since they use a bigger Δt.

Another interesting aspect of Figures 2 and 3 is the different behavior of NCIC4 and CIC4 with regard to the temporal stage of the solution. We see that NCIC4 presents a smaller error during the transient phase. This can be understood by analyzing the special form of the solution (52). At the beginning of the temporal evolution, the dominating term in (52) is the negative exponential, which represents the transient part of $u(x,t)$. Therefore, for small t we can write that

$$z_{tt} = O(N^2 z_t).$$

This makes both NCIC4 and CIC4 of the same order whenever a strong dissipation is dominating the evolution of z (see Remark 3.2 and (43)). Figure 4 shows the graph of the numerical values of z_t and $\Delta t z_{tt}$ for $\nu = 0.001$ and confirms the preceding analysis.

In the next example we solve the full Burgers equation

$$\left\{ \begin{array}{l} u_t - \nu u_{xx} + \frac{1}{2}(u^2)_x = f, \quad x \in (0, 2\pi), \quad t > 0, \\ u(0,t) = u(2\pi, t), \quad t > 0, \end{array} \right. \tag{53}$$

with an exact solution of the form

$$u(x,t) = \sum_{k=1}^{16} (1 - e^{-\nu k^2 t}) \frac{\cos(kx)}{k^4}. \tag{54}$$

We applied SCM4 with two grids containing 34 and 66 points. Due to the nonlinearity, only this last one solves the problem without aliasing. The solution was computed up to $t = 25$ with $\nu = 0.1$ and $C = 2$. For the modified methods, NCIC4 and CIC4, we used the 66 points grid with $C = 8$.

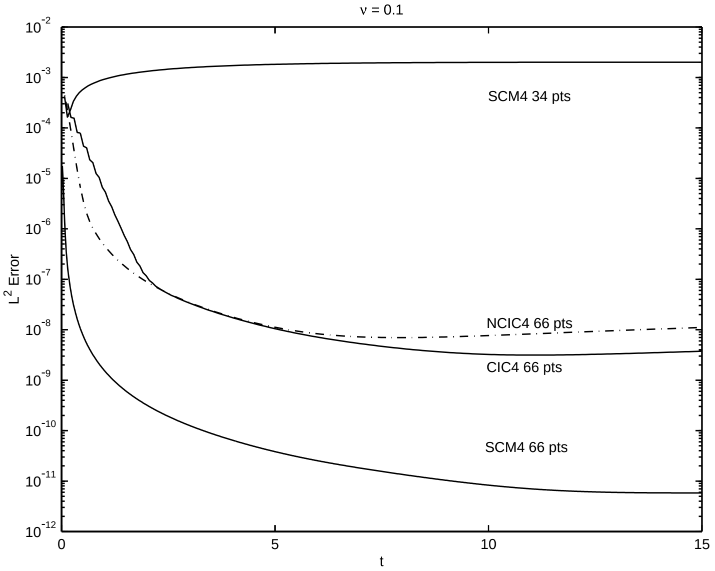

FIG. 2. *Comparison between* SCM4, NCIC4, *and* CIC4 *for* $\nu = 0.1$.

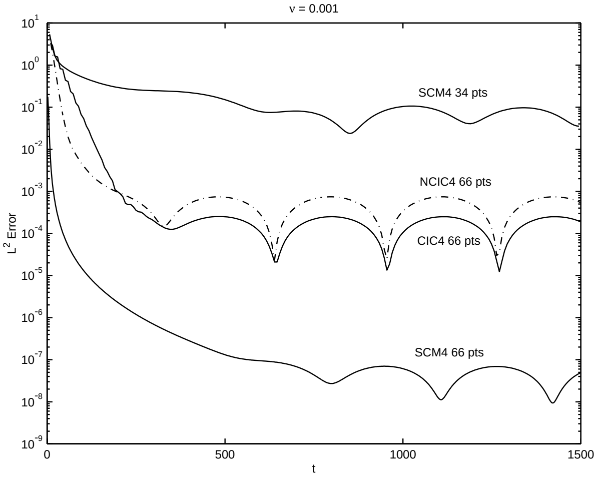

FIG. 3. *Comparison between* SCM4, NCIC4, *and* CIC4 *for* $\nu = 0.001$.

Figure 5 shows the L^2 error results for these experiments. Note that the high modes interactions, which are not captured by the 34 points grid, are relevant for the correct solution at the steady state. NCIC4 and CIC4 achieved the same steady state with the bigger time step. Now, CIC4 presents a better result than NCIC4 at the transient stage due to its consistency.

Finally, Figure 6 shows that although the modified schemes achieved the steady state at a later value of t, they did so at a smaller computational cost than SCM4 due to the utilization of the bigger Δt. The little discrepancy observed at the steady state of the 66 points grid is due to the better roundoff error presented by the modified methods (see [2, section 4]).

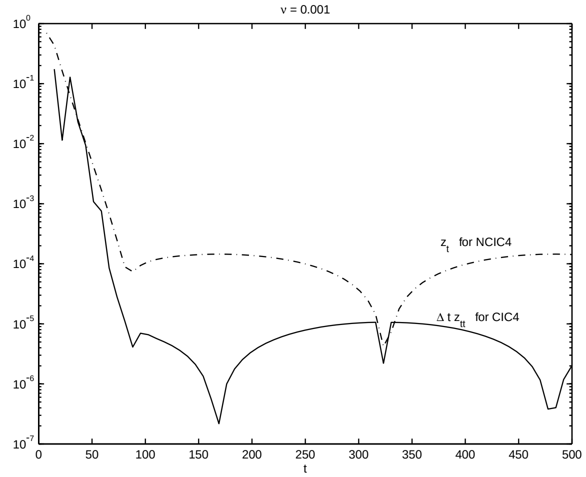

FIG. 4. *Comparison between the numerical values of z_t when using* NCIC4 *and $\Delta t z_{tt}$ when using* CIC4: *(z_t) dashed line; ($\Delta t z_{tt}$) continuous line.*

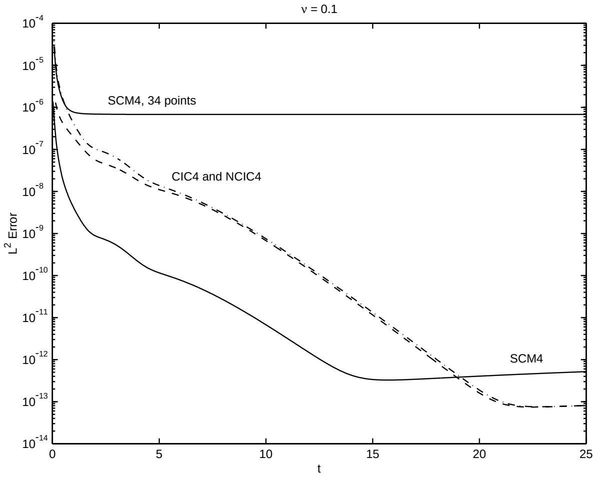

FIG. 5. *L^2 error for the Burgers equation.* (SCM4) *continuous line;* (CIC4) *dashed line;* (NCIC4) *dash–dotted line.*

4.2. The two dimensional case. In the next example we solve the periodic Burgers equation in two dimensions:

$$\begin{cases} U_t - \nu \Delta U + (U \cdot \nabla) U = 0, & x \in [0, 2\pi]^2, \\ U(0,t) = U(2\pi, t), \quad t > 0, \end{cases} \tag{55}$$

where $U = (u, v)$ with the initial conditions

$$\begin{cases} u(0,x,y) = \sin(x)\cos(3y), \\ v(0,x,y) = \cos(3x)\cos(y). \end{cases} \tag{56}$$

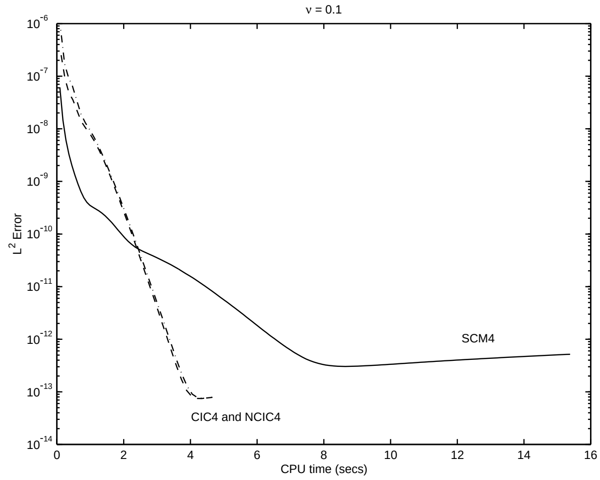

FIG. 6. *CPU time for the Burgers equation.* (SCM4) *continuous line;* (CIC4) *dashed line;* (NCIC4) *dash–dotted line.*

As shown in [2], in the two dimensional case each component of the unknown U is split in four quantities w, z_1, z_2, and z_3, depending on the mode $\vec{k} = (k_1, k_2)$:

$$\begin{array}{lll}
\text{low modes } w, & |k_1| \le N, & |k_2| \le N, \\
\text{mixed modes } z_1, & N < |k_1| \le M, & |k_2| \le N, \\
\text{mixed modes } z_2, & |k_1| \le N, & N < |k_2| \le M, \\
\text{pure high modes } z_3, & N < |k_1| \le M, & N < |k_2| \le M.
\end{array}$$

In this case, we apply the modified methods above to the three resulting equations involving the z variables. The determination of the parameter β_i for each set of modes follows along the same lines as in the one dimensional case.

In the first example we consider a high viscosity problem, $\nu = 0.5$, and compare the SCM coupled with a forward Euler scheme for the time integration (SCM1) with the multilevel method coupled with the nonconsistent (NCIC1) and the consistent (CIC1) implicit corrections. Figure 7 shows the SCM1 solution at $t = 1$ when using ten Fourier modes in each direction for the solution representation. The time step in (48) was taken with $C = 1$. Figure 8 shows the NCIC1 and CIC1 solutions at the same time and same number of modes, but now using $C = 4$, i.e., we use a time step four times bigger than the SCM. At $t = 1$ the problem is still in its transient stage, and we notice the difference between the solutions in Figure 8. The parameters β_i were taken to be $\beta_i = 4$, $i = 1, 2, 3$, for both NCIC1 and CIC1.

Figure 9 shows the solutions at $t = 4$ for all methods above. Here NCIC1 and CIC1 display the same graphic solutions. On the other hand, since these last two schemes used a bigger time step than SCM1, their computational costs are much lower. Figure 10 presents the CPU time results for the three methods when integrating in time up to $t = 10$.

In the case of a lower viscosity, the stability constraint is influenced by the advective term of (55). Therefore, increasing the time step requires a modification also in the nonlinear part of the equation. Since this is out of the scope of this article, we want to show instead that the splitting of modes can also reduce computational costs by generating solutions with fewer modes than the minimum resolution required by

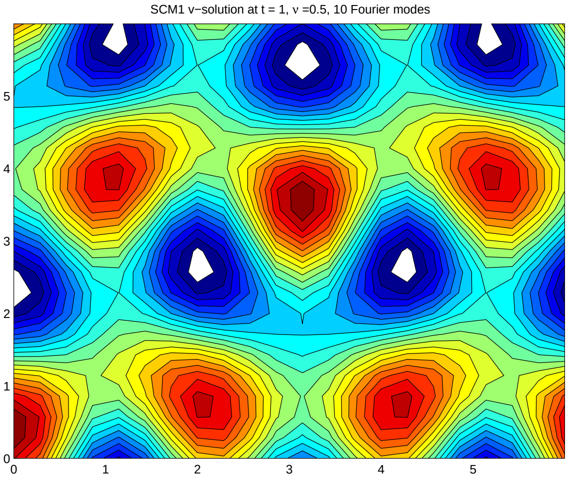

FIG. 7. SCM1 *v-solution for* (55) *at* $t = 1$ *and* $\nu = 0.5$.

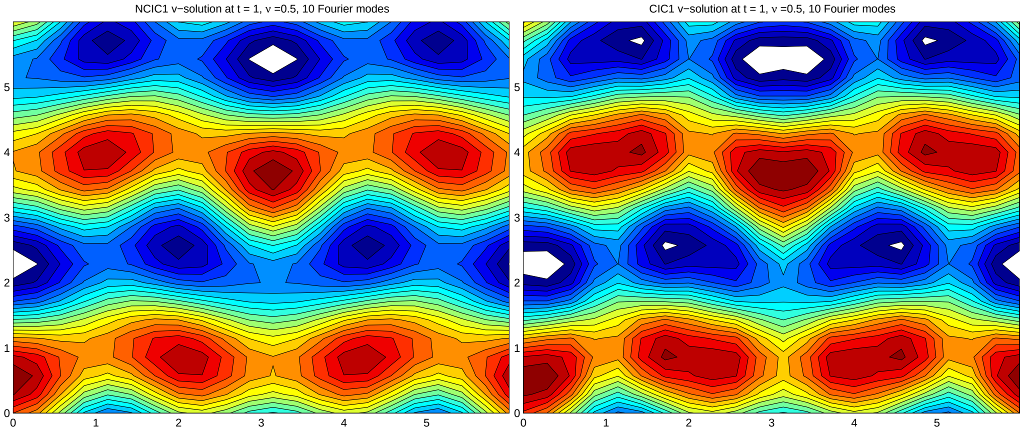

FIG. 8. NCIC1 *and* CIC1 *v-solutions for* (55) *at* $t = 1$ *and* $\nu = 0.5$.

the standard collocation in order to avoid blow-up due to the accumulation of energy in the high modes.

Thus, in this second example, we compare the solutions obtained by SCM1 and NCIC1 when solving problem (55), (56) with a value of $\nu = 0.01$. Due to the low viscosity, the solution goes through a critical high gradient phase before being smoothed out by the dissipative term. When using SCM1, a minimum of 80 Fourier modes in each direction is necessary to pass the high gradient stage, which occurs at $t = 1$, without the blow-up of the solutions. The results are shown in Figure 11 for $t = 1$ and $t = 6$. On the other hand, when using NCIC1, only 40 modes are necessary to overcome the high gradients and continue the temporal integration achieving the results shown in Figure 12 for $t = 1$ and $t = 6$.

5. Conclusions. In this article we introduced new time marching techniques that make use of distinguished treatments of low and high modes to improve the stability condition of explicit time integration schemes, allowing the use of larger time

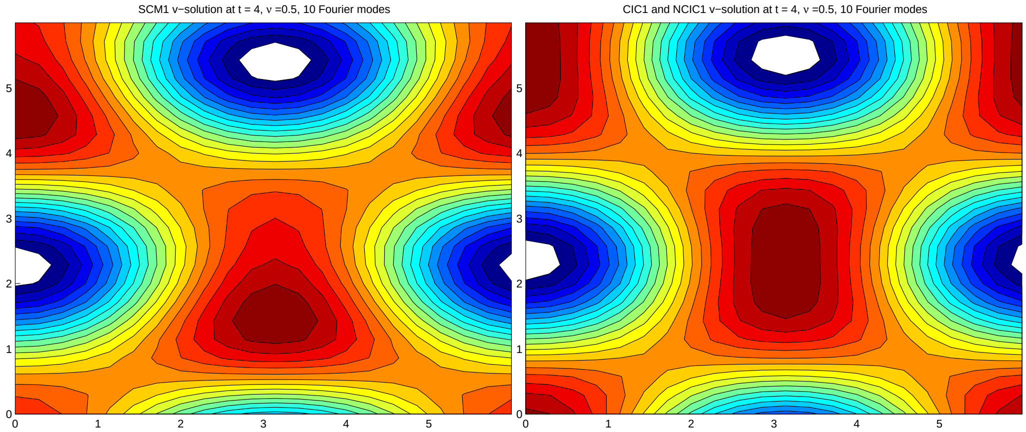

FIG. 9. SCM1, NCIC1, *and* CIC1 *solutions for* (55) *at $t = 4$ and $\nu = 0.5$.*

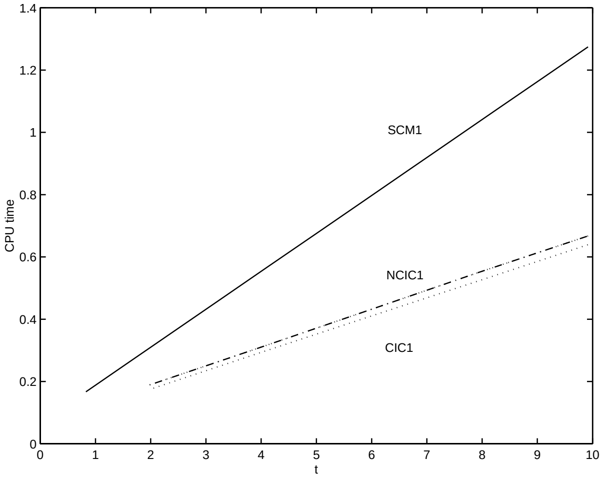

FIG. 10. *CPU time for* (55).

steps. These techniques consist of applying an unconditionally stable explicit scheme to the high modes equation in order to use the larger time step determined by the low modes equation. They are based on a shifting of the upper part of the spectrum of the dissipative operator and they bear similarities with well-known explicit numerical schemes like the Du Fort–Frankel and rational Runge–Kutta methods.

The numerical experiments showed that association of the new techniques with spatial discretizations of the collocation type can substantially reduce the computational effort in numerically approximating the solution of partial differential equations due to the utilization of a larger step to march in time. In this article, we altered only the stability condition related to the linear dissipative operator. In a forthcoming work we intend to treat the nonlinear hyperbolic case where the numerical stability is strongly influenced by the CFL condition when dealing with low viscosity problems.

A NEW TRIANGULAR FINITE-ELEMENT WITH OPTIMUM CONSTRAINT RATIO FOR COMPRESSIBLE FLUIDS[*]

DANIEL Y. LE ROUX[†]

Abstract. The discretization of the shallow-water equations using the finite-element method is a delicate problem. Apart from the possible occurrence of pressure and/or velocity modes, other spurious modes may appear that are essentially a consequence of having more momentum than continuity discretized equations, contrary to the continuum case. In this paper a new triangular finite-element pair is proposed which overcomes this imbalance problem. The new pair is shown to improve on results obtained with existing pairs in representing the propagation of fast gravity and slow Rossby waves by discretizing the linear shallow-water equations.

Key words. finite elements, compressible fluids, gravity waves, Rossby waves

1. Introduction.

In the case of the compressible Navier–Stokes and shallow-water equations, the contribution of the time derivative in the continuity equations leads, at least theoretically, to a problem that is always stable without an inf-sup (or LBB) [2] condition. An important result obtained in [11, 12], in the context of the incompressible Navier–Stokes equations, is, however, generalized in [14] to include the shallow-water and the compressible Navier–Stokes equations by examining their numerical dispersion relations. It is found that spurious solutions may arise from the coupling of the momentum and continuity equations, and that their existence and behavior depend upon the placement of the variables on a mesh and upon the choice of appropriate basis functions for finite-element formulations. These spurious modes are small-scale artifacts introduced by the spatial discretization scheme which do not propagate but are trapped within the model grid. In [14] two basic sets of such spurious modes are described. For the first set the velocity field is zero and nonconstant pressure functions lie in the null space of the discrete gradient operator. Solution uniqueness is then lost since any multiple of a spurious mode can be added to any solution of the discrete equations and still satisfy them. The second set of possible modes are those for which the pressure is zero and the velocity field is in the null space of the discrete divergence operator. Having noted their possible existence, little else is said about them in [14]; attention is focused almost exclusively on the spurious pressure modes of zero velocity, since these are argued to be the most troublesome. The occurrence of such spurious pressure and/or velocity modes has been observed in a variety of finite-difference [15] and finite-element [14] approximations to the shallow-water equations.

Another difficulty comes from the so-called constraint ratio (CR), defined to be the ratio of the number of continuity equations to the number of vector momentum equations. In the continuum, at each point in the fluid, one vector momentum equation is balanced with one continuity equation; hence CR = 1. A desirable goal of the

discrete approximation would be to achieve the same balance. For most of the finite-difference schemes the balance is obtained and CR $\simeq 1$. A valuable example, however, is the C-D finite-difference grid [1] leading to CR $\simeq 1/2$. The dispersion relation obtained in [1] by discretizing the shallow-water equations on the C-D grid reveals the presence of spurious frequencies; they are essentially a consequence of having twice as many momentum equations as pressure equations. The use of the finite-element method in discretizing the shallow-water equations is even more problematic because for many popular finite-element pairs, e.g., the $P_2 - P_1$, $P_1 \,\mathrm{iso}\, P_2 - P_1$, and $Q_2 - Q_1$ pairs, CR $\simeq 1/4$ [9]; hence spurious frequencies are highly expected.

The purpose of this paper is to find new triangular finite-element pairs which are able to improve upon the discretization of the shallow-water equations; such pairs need to have no pressure modes and preferably satisfy CR $\simeq 1$. All the aforementioned problems occur in the context of linear formulations; hence solving *inviscid linear* equations is sufficient for our purpose. The shallow-water equations are of considerable importance for a variety of problems of coastal and environmental engineering, including oceanic, atmospheric, and groundwater flows. For many of these flows the boundary conditions require the calculation of the normal at the boundary. The latter is generally not unique at boundary vertices, and hence velocity nodes should be located elsewhere in order to exactly satisfy the boundary conditions.

Element pairs satisfying CR $\simeq 1$ and avoiding the placement of velocity nodes at vertices are found in section 2. The ability of these pairs to generate pressure modes and to solve two basic equations embedded in the shallow-water equations is examined in sections 3 and 4, respectively. This leads to the choice of a new pair. In section 5 the linear inviscid shallow-water equations are discretized using this pair. The results of environmental flow experiments, namely, propagation of fast gravity modes and slow Rossby modes, are presented and discussed in section 6. Conclusions are summarized in section 7.

2. Finite elements candidates.

In the two-dimensional case, for one connected component, let V be the total number of vertices of a given domain, C the number of cells or triangles, TF the total number of faces of the triangulation, and IF the number of interior faces. Euler's relations may then be expressed as

$$TF + IF = 3\,C\,, \tag{2.1}$$

$$V + IF = 2\,C + 1\,. \tag{2.2}$$

Assuming $TF \simeq IF$ we deduce from (2.1) and (2.2) that the number of triangles and midpoint nodes is approximately $2\,V$ and $3\,V$, respectively. This estimate provides an easy tool for finding velocity and pressure node locations leading to CR $\simeq 1$. An obvious choice—and the subject of this section—is to locate one variable at midpoints and the other at both vertices and barycenters. A second possibility offers three possible locations for the variables: at vertices, barycenters, and midpoints (P_2^+ [2]) or twice at midpoints (P_2^{NC} [3]) or at three internal nodes (P_{0-3} [9]). However, because the P_2^{NC} element is not directly usable [5] and the P_2^+ has nodes at the vertices, this second possibility is not investigated here. Further, it seems difficult to obtain other tractable combinations.

In the following let the subscripts $_A$, $_B$, and $_C$ distinguish new elements from existing ones, and let $N^{\mathbf{u}}$ and N^p be, respectively, the number of velocity and pressure nodes of the domain. In all figures the symbol • indicates the location of nodes.

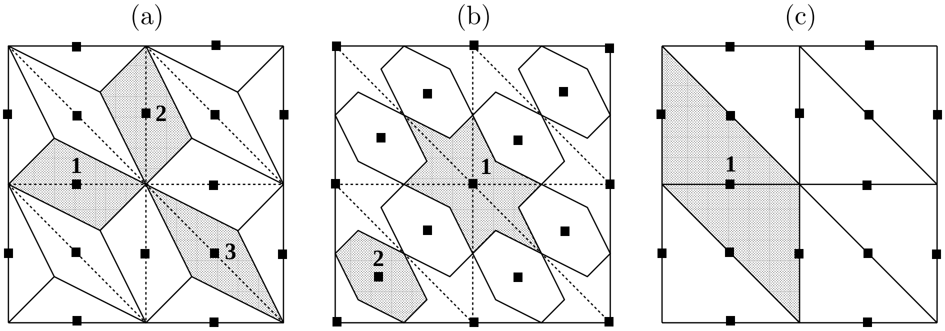

FIG. 2.1. *The elements* (a) P_{0-A}*,* (b) P_{0-B}*,* (c) P_1^{NC}*. The compact support of the basis function at selected nodes is shaded.*

2.1. Constant and linear elements. Examples of P_{0-A} and P_{0-B} elements are shown in Figures 2.1(a) and (b), respectively, on a square domain made up of eight biased dotted triangles (except for the boundaries). The element P_{0-A} is obtained in Figure 2.1(a) by joining the barycenters of biased triangles (dotted lines) with their vertices. The nodes are defined at midpoints and the basis functions are constant over the resulting quadrangles (solid lines), or triangles for boundary nodes. The element P_{0-B} shown in Figure 2.1(b) has nodes at both vertices and barycenters, and the basis functions are constant over the hexagonal and "star" areas defined by solid lines. The P_1^{NC} element [3, 7], shown in Figure 2.1(c), has nodes at triangle midpoints. The nonconforming linear basis functions are continuous only across triangle boundaries at midpoint nodes and are discontinuous everywhere else around a triangle boundary. Four pairs are considered: the $P_{0-A} - P_{0-B}$, the $P_{0-A} - P_1^{NC}$, the $P_1^{NC} - P_{0-A}$, and the $P_1^{NC} - P_{0-B}$ pairs. The first of these pairs is treated as a finite volume.

2.2. Linear–linear element pairs.

2.2.1. The P_1^{NC}–cross-grid P_1 element pair. The cross-grid P_1 element shown in Figure 2.2(a) has nodes at the triangle vertices and barycenters. The basis functions are linear upon each one of the three subtriangles sharing the center of gravity of the element as a common vertex and vanishing on the element boundary. We have $N^p = V + C$ and $N^{\mathbf{u}} = TF$, and thus $N^p - N^{\mathbf{u}} = V + C - TF$. From (2.1) and (2.2) we have $TF - V = C - 1$, and thus $N^p - N^{\mathbf{u}} = 1$ and CR $\simeq 1$.

$\omega_1 = -\dfrac{1}{6}$	$\omega_3 = \dfrac{109}{450}$	$\omega_5 = \dfrac{2}{225}$	$\omega_7 = \dfrac{1}{3}$	$\omega_9 = \dfrac{3}{25}$	$\varpi_1 = \dfrac{1}{18}$	$\varpi_3 = \dfrac{1}{9}$
$\omega_2 = \dfrac{16}{45}$	$\omega_4 = \dfrac{23}{225}$	$\omega_6 = -\dfrac{13}{225}$	$\omega_8 = -\dfrac{3}{25}$	$\omega_{10} = \dfrac{11}{50}$	$\varpi_2 = \dfrac{7}{18}$	$\varpi_4 = -\dfrac{1}{18}$

2.2.2. The P_1^{NC} iso $P_2 - P_{1-A}$ and P_1^{NC} iso $P_2 - P_{1-B}$ element pairs. The P_1^{NC} iso P_2 element is obtained by dividing each biased triangle of Figure 2.2(b) (solid lines) into four subtriangles (dotted lines) using the midpoints of the triangle sides. On each subtriangle, the nodes are defined at triangle midpoints and nonconforming linear basis functions (P_1^{NC}) are used over the refined triangulation. The P_1^{NC} iso P_2 element is chosen to approximate the velocity variable, and so there are 9 velocity nodes per unrefined triangle or $12\,V$ over the domain. To obtain CR $= 1$ we need to find $12\,V$ pressure nodes. If we suppose that the pressure variables are at least located at the V vertices, we search for two positive integers n_1 and n_2, respectively, the number of nodes per face and per cell of the unrefined triangulation, such that

$$(3\,V)\,n_1 + (2\,V)\,n_2 = 12\,V - V \qquad \text{or} \qquad 3\,n_1 + 2\,n_2 = 11\,. \tag{2.3}$$

Equation (2.3) has only two solutions, $(n_1, n_2) = (3, 1)$ and $(n_1, n_2) = (1, 4)$, which define the nodal positions for the P_{1-A} and P_{1-B} pairs, as shown in Figure 2.3 for two biased triangles. In both cases 12 subtriangles are defined per unrefined triangle and conforming linear basis functions are used over the refined triangulation. We have $N_A^p = V + 3\,TF + C$, $N_B^p = V + TF + 4\,C$, and $N_{A,B}^{\mathbf{u}}(u) = 2\,TF + 3\,C$. Let BF to be the number of boundary faces, with $TF = IF + BF$. From (2.1)–(2.2) we deduce $N_A^p - N_{A,B}^{\mathbf{u}} = BF + 1$ and $N_B^p - N_{A,B}^{\mathbf{u}} = 1$; thus CR $\simeq 1$ for both elements.

The weights ω_i $(i = 1, 10)$ and ϖ_i $(i = 1, 4)$ given in Table 2.1 are used to calculate the discrete gradient matrix of a scalar field (e.g., pressure) for any original triangulation, even an unstructured one. For example, in Figure 2.3(a) let I (denoted by the symbol ○) be a velocity node and (x_B, y_B) and (x_C, y_C) denote the coordinates of the nodes B and C. The entries of the gradient matrix at line I and column A (for the contribution of triangle (A, B, C) only) are $\omega_4\,(y_B - y_C)$ and $\omega_4\,(x_C - x_B)$ for the

x- and y-derivatives, respectively. The other entries are obtained in the same manner by cyclic permutations. For the element P_{1-A} only, two different sets of weights are defined depending on whether I is an interior or a boundary element node.

2.2.3. The P_1^{NC}–P_{1-C} element pair. The cross-grid P_1 element is shown in Figure 2.4(a) over a biased triangulation intentionally represented with dotted faces, except for the bottom and right boundaries. The P_{1-C} element is derived from the cross-grid P_1 in the following manner. Each dotted face (Figure 2.4(a)) is suppressed and replaced by a new face (Figure 2.4(b)) joining the barycenters of the two adjacent triangles (except for the boundary faces). For example, faces 1-2, 2-3, and 3-1 are suppressed in Figure 2.4(a) and faces 4-5, 4-6, and 4-7 are created in Figure 2.4(b). Except for the boundary triangles, such a transformation preserves equilateral triangles. As for the P_1^{NC}–cross-grid P_1 pair, $N^p - N^{\mathbf{u}} = 1$; thus CR $\simeq 1$.

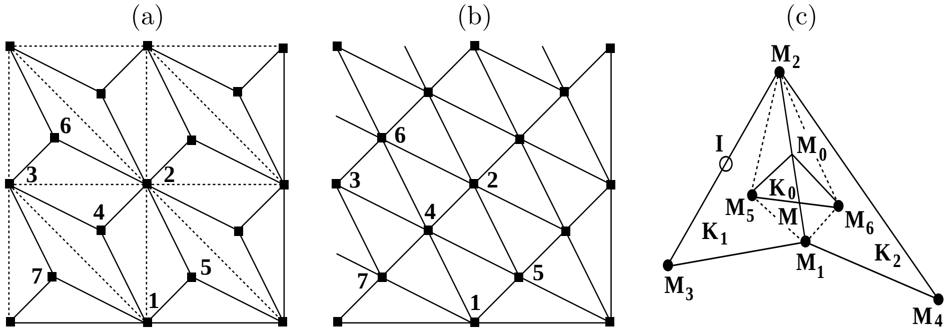

FIG. 2.4. *The elements* (a) *cross-grid P_1,* (b) *P_{1-C},* (c) *reconnection of faces for nonregular geometries.*

The determination of the weights used to calculate the discrete gradient matrix of a scalar field in the case of the P_1^{NC}–P_{1-C} pair now follows. The computation is more difficult than in section 2.2.2 because the P_{1-C} element results from a redefinition of the triangulation by swapping the faces. Except for regular geometries (e.g., biased triangles of Figure 2.4(b)), it is no longer guaranteed that the midpoints of old and new faces coincide. The problem is illustrated in Figure 2.4(c). Let M_0 and M be the middle points of (M_1, M_2) and (M_5, M_6), respectively, where M_5 and M_6 are the respective barycenters of the triangles K_1 (M_1, M_2, M_3) and K_2 (M_1, M_4, M_2). Let (x_i, y_i) and (x, y) be the coordinates of M_i $(i = 0, 6)$ and M, respectively, and let K_0 be the triangle (M_0, M_5, M_6) with

$$\text{Area}(K_0) = \frac{\varepsilon}{2}\,[\,(x_5 - x_0)\,(y_6 - y_0) - (y_5 - y_0)\,(x_6 - x_0)\,]\,, \tag{2.4}$$

where $\varepsilon = +1$ if M_0, M_5, M_6 are numbered counterclockwise (as in Figure 2.4 (c)) and $\varepsilon = -1$ otherwise.

PROPOSITION 2.1. *We have*

$$\overrightarrow{MM_0} = \frac{3\,\varepsilon\,Area(K_0)}{Area(K_1) + Area(K_2)}\;\overrightarrow{M_1M_2}\;. \tag{2.5}$$

Proof. Since $\overrightarrow{MM_0}$ and $\overrightarrow{M_1M_2}$ are parallel,

$$(x_0 - x)\,(y_2 - y_1) + (y_0 - y)\,(x_1 - x_2) = 0\,. \tag{2.6}$$

Then, noting that M belongs to (M_5, M_6), we obtain

$$x\,(y_6 - y_5) + y\,(x_5 - x_6) = x_5\,y_6 - x_6\,y_5\,. \tag{2.7}$$

By using the property $\overrightarrow{M_3M_4} = 3\ \overrightarrow{M_5M_6}$ and (2.4), equation (2.7) reduces to

$$(x_0 - x)\,(y_3 - y_4) + (y_0 - y)\,(x_4 - x_3) = 6\,\varepsilon\,\text{Area}(K_0)\,. \tag{2.8}$$

Some elementary calculations show that

$$\begin{vmatrix} y_2 - y_1 & x_1 - x_2 \\ y_3 - y_4 & x_4 - x_3 \end{vmatrix} = 2\,[\,\text{Area}(K_1) + \text{Area}(K_2)\,]\,, \tag{2.9}$$

and the solution of (2.6) and (2.8) then gives

$$x_0 - x = \frac{3\,\varepsilon\,\text{Area}(K_0)}{\text{Area}(K_1) + \text{Area}(K_2)}\,(x_2 - x_1)\,, \tag{2.10}$$

$$y_0 - y = \frac{3\,\varepsilon\,\text{Area}(K_0)}{\text{Area}(K_1) + \text{Area}(K_2)}\,(y_2 - y_1)\,. \tag{2.11}$$

Thus, we obtain (2.5), and the proof is completed. □

Let I be a velocity node located at the middle point of (M_2, M_3) as shown in Figure 2.4(c). Typical weights associated with I over the triangles (M_1, M_6, M_5), (M_2, M_5, M_6), and (M_2, M_3, M_5) of the P_{1-C} triangulation are

$$\omega_{(M_1,M_6,M_5)} = \left(-\frac{1}{9} + \frac{\varepsilon}{3}\,\frac{\|\overrightarrow{MM_0}\|}{\|\overrightarrow{M_1M_2}\|}\right)\,\frac{\text{Area}(K_1)}{\text{Area}(K_1) + \text{Area}(K_2)}\,, \tag{2.12}$$

$$\omega_{(M_2,M_5,M_6)} = \left(\frac{2}{9} + \frac{\varepsilon}{3}\,\frac{\|\overrightarrow{MM_0}\|}{\|\overrightarrow{M_1M_2}\|}\right)\,\frac{\text{Area}(K_1)}{\text{Area}(K_1) + \text{Area}(K_2)}\,, \tag{2.13}$$

$$\omega_{(M_2,M_3,M_5)} = \frac{7}{18} \quad \text{whether } (M_2, M_3) \text{ is a boundary face or not}\,, \tag{2.14}$$

where $\|\overrightarrow{MM_0}\|$ is obtained from (2.5). If (M_1, M_2) is a boundary face, we have $\omega_{(M_1,M_2,M_5)} = 1/18$. All the weights are derived by analogy with (2.12)–(2.14) and they are used in the same manner as in section 2.2.2 to calculate the entries of the gradient matrix of a scalar field at line I.

3. Examination of the pressure modes. To determine if the element pairs considered in section 2 have pressure modes, their corresponding discrete gradient matrices are computed on Grid 1, as shown in Figure 3.1(a), and then decomposed in singular values (SV). For all pairs at least 3 SV are zero, implying that the kernel of the discrete gradient operator is more than one-dimensional and hence that pressure modes exist. On Grid 1 two sides of a triangle may coincide with the boundary. By requiring triangulation into corners, as shown on Grid 2 in Figure 3.1(b) at the upper right and lower left corners, better results are obtained as shown in Table 3.1 for different types of boundary conditions.

For the $P_{0-A} - P_1^{NC}$ and the $P_1^{NC} - P_{1-C}$ pairs only 1 SV is zero; the null space of their discrete gradient operator is one-dimensional and these pairs have no pressure modes. This result reflects the fact that pressure is only determined to within an

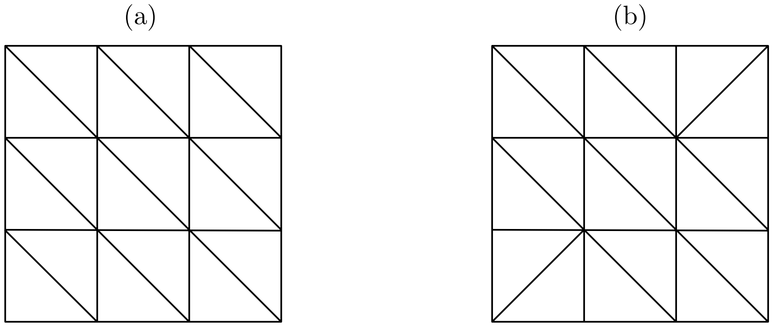

FIG. 3.1. (a) *Grid* 1*, a* 4×4 *mesh;* (b) *Grid* 2*, as for* (a) *with triangulation into corners.*

TABLE 3.1
Number of zero SV of the discrete gradient matrix computed on Grid 2 *for several element pairs.*

Element pair	Dirichlet boundary conditions	Normal velocity specified	Tangential velocity specified
P_{0-A}–P_{0-B}	2	2	1
P_{0-A}–P_1^{NC}	1	1	1
P_1^{NC}–cross-grid P_1	2	2	1
P_1^{NC} iso P_2–P_{1-A}	2	2	1
P_1^{NC} iso P_2–P_{1-B}	2	2	1
P_1^{NC}–P_{1-C}	1	1	1

arbitrary additive constant by fixing the pressure reference level. The requirement to triangulate into corners is a minor constraint, even sometimes desirable to impose boundary conditions. The other pairs in Table 3.1 have 2 zero SV and thus have pressure modes. Finally, the $P_1^{NC} - P_{0-A}$ and the $P_1^{NC} - P_{0-B}$ pairs (not included in Table 3.1) have many pressure modes whatever the grid.

The results shown in Table 3.1 have been found to be identical on meshes $n \times n$ with $n \geq 5$ and do not depend on whether the number of nodes in each direction is even or odd. It has been also verified that when only 1 SV is zero no other SV converges to zero as the mesh parameter becomes small.

At this stage of the argument, the P_{0-A}–P_1^{NC} and P_1^{NC}–P_{1-C} pairs are favorable candidates for solving the coupled momentum-continuity equations.

4. Representing basic equations. Two basic equations embedded in the shallow-water formulation are now considered:

$$\mathbf{u} = \alpha \nabla p \,, \tag{4.1}$$

$$p = \gamma \nabla \cdot \mathbf{u} \,, \tag{4.2}$$

where $\mathbf{u} = (u, v)$ and p are, respectively, the velocity field and the pressure, and α and γ are constant scaling factors.

In [9] it is shown that pairs having a low CR perform poorly in solving (4.1), while smooth results are obtained for pairs with a CR larger than 1. A similar situation is expected to arise, in the opposite sense, when computing p from $\mathbf{u}$ in (4.2); this has been verified for several pairs (results not shown). As a preliminary before solving

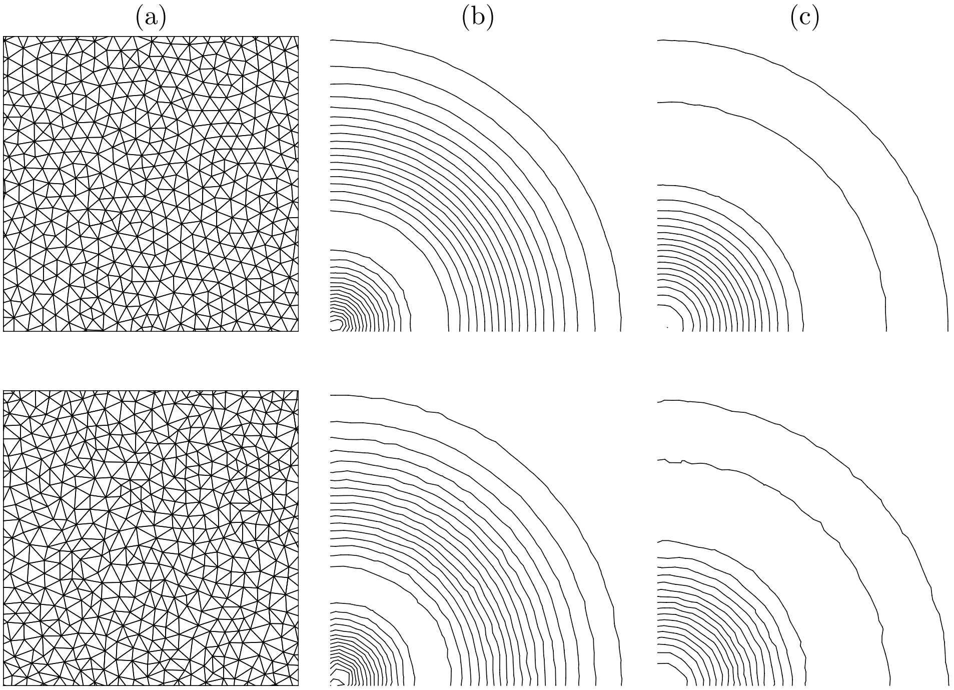

FIG. 4.1. (a) *A window of Mesh* 1 *made up of unstructured triangles with smoothing (row* 1*), a window of Mesh* 2 *made up of unstructured triangles without smoothing (row* 2*);* (b) *isolines (upper right quarter) of the simulated flow speed field corresponding to* (4.1) *on Mesh* 1 *(row* 1*) and Mesh* 2 *(row* 2*) for the* P_1^{NC}*–*P_{1-C} *pair;* (c) *isolines (upper right quarter) of the simulated pressure corresponding to* (4.2) *on Mesh* 1 *(row* 1*) and Mesh* 2 *(row* 2*) for the* P_1^{NC}*–*P_{1-C} *pair.*

the shallow-water equations, smooth results should be obtained for $\mathbf{u}$ and p in (4.1) and (4.2). These two basic equations are now solved for the pairs in Table 3.1.

The pressure in (4.1) is a specified Gaussian distribution with an e-folding radius that is resolved by about 15 velocity nodes on Meshes 1 and 2, shown in Figure 4.1(a), and $\mathbf{u}$ is to be determined from the finite-element discretization of (4.1). The velocity field in (4.2) is the exact gradient of the specified Gaussian distribution used for p in (4.1) and p is to be determined from the finite-element discretization of (4.2). The exact solutions for the flow-speed field $(u^2+v^2)^{1/2}$ and p are shown in Figure 4.2. The numerical solutions shown here are all obtained using the visualization environment VU [10].

For the P_1^{NC}–P_{1-C} pair smooth solutions, shown in Figures 4.1(b) and (c), are obtained on Mesh 1. Good results are also found on Mesh 2 considering the unusually high level of mesh distortion. The other pairs of Table 3.1 also give smooth results for both solutions, due to the fact that CR $\simeq 1$. There is, however, an exception for the P_{0-A}–P_1^{NC} pair, which gives a very noisy representation of p in (4.2). The problem arises from a lack of contribution of u and v to the discretization of the divergence term at horizontal and vertical nodes, respectively. This is consistent with the lack of equations for u and v on horizontal and vertical faces, respectively, in solving (4.1) with the P_1^{NC}–P_{0-A} pair (and also the P_1^{NC}–P_0 pair [9, Figure 3(a)]).

By a process of elimination, the P_1^{NC}–P_{1-C} pair has been identified as a promising choice. The discretization of the linear inviscid shallow-water equations using this pair now follows.

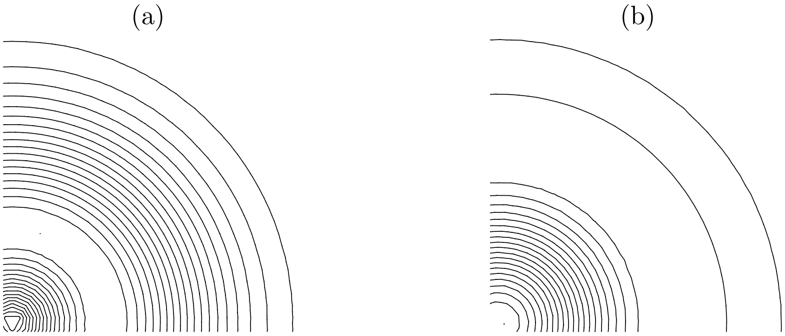

FIG. 4.2. (a) *Isolines (upper right quarter) of the exact solution for the flow-speed field corresponding to* (4.1)*, where the pressure is a specified Gaussian;* (b) *isolines (upper right quarter) of the exact solution for pressure corresponding to* (4.2)*, where the velocity field is the exact gradient of a specified Gaussian.*

5. Discretization of the inviscid linear shallow-water equations. Let Ω be the model domain with boundary Γ. The inviscid linear shallow-water equations are expressed in Cartesian coordinates [8] as

$$\mathbf{u}_t + f\,\mathbf{k}\times\mathbf{u} + g\,\nabla\eta = 0\,, \tag{5.1}$$

$$\eta_t + H\,\nabla\cdot\mathbf{u} = 0\,, \tag{5.2}$$

where η is the surface elevation with respect to the reference level $z = 0$, f and g are the Coriolis parameter and the gravitational acceleration, respectively, $\mathbf{k}$ is a unit vector in the vertical, and the mean depth H is constant. Note that η plays the role that pressure plays in the Navier–Stokes equations. For a contained flow, (5.1) and (5.2) are solved subject to the no-normal flow boundary condition

$$\mathbf{u}\cdot\mathbf{n} = 0 \quad \text{on } \Gamma\,, \tag{5.3}$$

where $\mathbf{n}$ is the outward pointing normal at the boundary.

An implicit Crank–Nicolson time discretization of (5.1) and (5.2) gives

$$\mathbf{u} + \frac{f\,\Delta t}{2}\,\mathbf{k}\times\mathbf{u} + \frac{g\,\Delta t}{2}\,\nabla\eta = \left[\mathbf{u} - \frac{f\,\Delta t}{2}\,\mathbf{k}\times\mathbf{u} - \frac{g\,\Delta t}{2}\,\nabla\eta\right]_{t-\Delta t} \equiv \mathbf{R}^{\mathbf{u}}\,, \tag{5.4}$$

$$\eta + \frac{H\,\Delta t}{2}\,\nabla\cdot\mathbf{u} = \left[\eta - \frac{H\,\Delta t}{2}\,\nabla\cdot\mathbf{u}\right]_{t-\Delta t} \equiv R^{\eta}\,, \tag{5.5}$$

where $[\,.\,]_{t-\Delta t}$ denotes evaluation at the previous timestep.

The Sobolev space $H^1(\Omega)$ is the space of functions in the square-integrable space $L^2(\Omega)$, whose first derivatives belong to $L^2(\Omega)$. Let η be in a subspace V of $H^1(\Omega)$ and let each component of $\mathbf{u}$ be a sufficiently regular scalar function such that $\mathbf{u}\cdot\mathbf{n} = 0$ on Γ. The weak formulation of (5.4) and (5.5) requires the test functions $\boldsymbol{\varphi}$ (whose x- or y-component is formally denoted by φ) and ψ to belong, respectively, to the same function space as $\mathbf{u}$ and η, such that

$$\int_\Omega \mathbf{u}\cdot\boldsymbol{\varphi}\,d\Omega + \frac{\Delta t}{2}\int_\Omega f\,(\mathbf{k}\times\mathbf{u})\cdot\boldsymbol{\varphi}\,d\Omega + \frac{g\,\Delta t}{2}\int_\Omega \nabla\eta\cdot\boldsymbol{\varphi}\,d\Omega = \int_\Omega \mathbf{R}^{\mathbf{u}}\cdot\boldsymbol{\varphi}\,d\Omega\,, \tag{5.6}$$

$$\int_\Omega \eta\,\psi\,d\Omega + \frac{H\,\Delta t}{2}\int_\Omega \nabla\cdot\mathbf{u}\,\psi\,d\Omega = \int_\Omega R^{\eta}\,\psi\,d\Omega\,, \tag{5.7}$$

where $d\Omega$ is the areal element.

On both sides of (5.7) the term $\nabla\cdot\mathbf{u}$ is integrated by parts using Green's theorem. The boundary integrals vanish by applying (5.3); thus (5.7) can be rewritten as

$$\int_\Omega \eta\,\psi\,d\Omega - \frac{H\,\Delta t}{2}\int_\Omega \mathbf{u}\cdot\nabla\,\psi\,d\Omega = \int_\Omega R^\eta\,\psi\,d\Omega\,, \tag{5.8}$$

where

$$\int_\Omega R^\eta\,\psi\,d\Omega = \int_\Omega [\,\eta\,]_{t-\Delta\,t}\,\psi\,d\Omega + \frac{H\,\Delta t}{2}\int_\Omega [\,\mathbf{u}\,]_{t-\Delta\,t}\cdot\nabla\,\psi\,d\Omega\,. \tag{5.9}$$

The Galerkin finite-element method then approximates the solution of (5.6) and (5.8) in finite-dimensional subspaces. Consider two triangulations $\mathcal{T}_h^{\mathbf{u}}$ and $\mathcal{T}_h^{\eta}$ of the polygonal domain Ω, defined in Figures 2.1(c) and 2.4(b), respectively, where h is a discretization parameter tending to zero. For triangles $K^{\mathbf{u}}\in\mathcal{T}_h^{\mathbf{u}}$ and $K^\eta\in\mathcal{T}_h^\eta$, let $P_1(K^{\mathbf{u}})$ and $P_1(K^\eta)$ denote the space of linear polynomials on $K^{\mathbf{u}}$ and K^η, respectively.

The discrete solution $\mathbf{u}_h$ sought belongs to a finite-dimensional space $\mathbf{W}_h$ defined to be the set of functions $\mathbf{u}_h$ whose restriction on $K^{\mathbf{u}}$ belongs to $P_1(K^{\mathbf{u}})\times P_1(K^{\mathbf{u}})$, with $\mathbf{u}_h$ being continuous only at the midpoints of each face of $\mathcal{T}_h^{\mathbf{u}}$, and $\mathbf{u}_h\cdot\mathbf{n}=0$ on Γ. The discrete solution η_h is sought in a finite-dimensional subspace V_h of V, where V_h is defined to be the set of functions η_h whose restriction on K^η belongs to $P_1(K^\eta)$, with η_h being continuous at each vertex of $\mathcal{T}_h^\eta$.

By applying the Galerkin procedure the problem can be summarized as seeking solutions $\mathbf{u}_h$ and η_h, respectively, in $\mathbf{W}_h$ and V_h such that

$$\begin{aligned}\sum_{K^{\mathbf{u}}\in\mathcal{T}_h^{\mathbf{u}}}\int_{K^{\mathbf{u}}}\mathbf{u}_h\cdot\boldsymbol{\varphi}_i\,d\Omega &+ \frac{\Delta\,t}{2}\sum_{K^{\mathbf{u}}\in\mathcal{T}_h^{\mathbf{u}}}\int_{K^{\mathbf{u}}} f\,(\mathbf{k}\times\mathbf{u}_h)\cdot\boldsymbol{\varphi}_i\,d\Omega\\ &+\frac{g\,\Delta\,t}{2}\sum_{K^{\mathbf{u}}\in\mathcal{T}_h^{\mathbf{u}}}\int_{K^{\mathbf{u}}}\nabla\eta_h\cdot\boldsymbol{\varphi}_i\,d\Omega = \sum_{K^{\mathbf{u}}\in\mathcal{T}_h^{\mathbf{u}}}\int_{K^{\mathbf{u}}}\mathbf{R}^{\mathbf{u}}\cdot\boldsymbol{\varphi}_i\,d\Omega\,,\end{aligned} \tag{5.10}$$

$$\sum_{K^\eta\in\mathcal{T}_h^\eta}\int_{K^\eta}\eta_h\,\psi_j\,d\Omega - \frac{H\,\Delta\,t}{2}\sum_{K^\eta\in\mathcal{T}_h^\eta}\int_{K^\eta}\mathbf{u}_h\cdot\nabla\psi_j\,d\Omega = \sum_{K^\eta\in\mathcal{T}_h^\eta}\int_{K^\eta}R^\eta\,\psi_j\,d\Omega \tag{5.11}$$

for all basis functions $\boldsymbol{\varphi}_i$ and ψ_j (defined in [3]) belonging to $\mathbf{W}_h$ and V_h, respectively, where i and j are typical nodes of $\mathcal{T}_h^{\mathbf{u}}$ and $\mathcal{T}_h^\eta$, respectively.

After insertion of the expansions $\mathbf{u}_h=\sum_{k=1}^3\mathbf{u}_k\,\varphi_k$ over $K^{\mathbf{u}}$ and $\eta_h=\sum_{l=1}^3\eta_l\,\psi_l$ over K^η into (5.10) and (5.11), where $\mathbf{u}_k$ and η_l are the values of $\mathbf{u}_h$ and η_h at nodes k and l of $\mathcal{T}_h^{\mathbf{u}}$ and $\mathcal{T}_h^\eta$, respectively, we obtain a set of linear equations of the form

$$\mathsf{M}^{\mathbf{u}}\,\mathbf{u} + \frac{g\,\Delta\,t}{2}\,\mathsf{G}\,\eta = \mathsf{R}^{\mathbf{u}}\,, \tag{5.12}$$

$$\mathsf{M}^\eta\,\eta - \frac{H\,\Delta\,t}{2}\,\mathsf{G}^t\,\mathbf{u} = \mathsf{R}^\eta\,, \tag{5.13}$$

where $\mathsf{M}^{\mathbf{u}}$ and M^η denote the velocity and surface-elevation mass matrices, respectively, G is the gradient matrix, and $\mathsf{R}^{\mathbf{u}}$ and R^η are the right-hand sides.

Since the velocity nodes are located at triangle midpoints, the normal direction along the boundary is defined uniquely, a property which is not true in general for boundary vertices. Following [4], the x-y momentum equations corresponding to a boundary node in (5.12) are transformed into tangential and normal equations, the local x-y coordinate system at this node is rotated to coincide with the tangential and normal directions, and the boundary condition (5.3) is then applied.

Due to the orthogonality property of the velocity basis functions [13], $\mathsf{M}^{\mathbf{u}}$ is a diagonal matrix with 2×2 blocks along the diagonal. Equation (5.12) is rewritten as

$$\mathbf{u} = -\frac{g\,\Delta t}{2}\,(\mathsf{M}^{\mathbf{u}})^{-1}\,\mathsf{G}\,\eta + (\mathsf{M}^{\mathbf{u}})^{-1}\,\mathsf{R}^{\mathbf{u}}\,, \tag{5.14}$$

and (5.14) is then used to eliminate $\mathbf{u}$ from (5.13). The substitution results in

$$\left(\mathsf{M}^{\eta} + g\,H\,\frac{(\Delta\,t)^2}{4}\,\mathsf{G}^t\,(\mathsf{M}^{\mathbf{u}})^{-1}\,\mathsf{G}\right)\,\eta = \mathsf{R}^{\eta} + H\,\frac{\Delta\,t}{2}\,\mathsf{G}^t\,(\mathsf{M}^{\mathbf{u}})^{-1}\,\mathsf{R}^{\mathbf{u}}\,. \tag{5.15}$$

The elimination of $\mathbf{u}$ thus leads to a linear system for the η only, which greatly enhances computational efficiency. The matrix on the left-hand side of (5.15) is a very sparse matrix, with an average of 31 nonzero elements per row. Finally, once η is obtained from (5.15), $\mathbf{u}$ is computed explicitly from (5.14).

6. Numerical results. A linear stability analysis of (5.1) and (5.2) reveals that there are two basic kinds of associated motion: small-amplitude fast-moving gravitational oscillations and slow-moving Rossby modes [6]. To determine how the P_1^{NC}–P_{1-C} pair approximates these two types of modes, two tests are proposed. The first test examines the propagation and dispersion of fast surface gravity waves in a circular basin and their reflection at the lateral boundary. In the second test, the slowly propagating Rossby modes are simulated in the case of the evolution of a typical anticyclonic vortex at midlatitudes.

For both tests, the linear inviscid shallow-water equations are solved with a Gaussian distribution of the surface elevation prescribed at initial time, i.e.,

$$\eta\,(r,0) = a\,e^{-b\,r^2}\,, \tag{6.1}$$

where r is the distance from the Gaussian's center, and a and b are prescribed.

The second, more stringent test was applied in [9] and the $P_1\,\mathrm{iso}\,P_2$–P_{0-3} pair (CR = 3/2) was shown to give much better results than already existing pairs. Hence, this pair is chosen for comparison with the P_1^{NC}–P_{1-C} pair.

6.1. Gravity wave propagation and dispersion. For many applications very little energy is carried by the small-amplitude fast-moving surface gravity waves, and this justifies slowing them down via a semi-implicit time discretization. Nevertheless, the numerical solution of (5.1)–(5.3) at small values of the gravitational Courant number $C_g \equiv c\,\Delta\,t\,/\,h_0$, where $c \equiv \sqrt{g\,H}$ is the phase speed of the surface gravity waves and h_0 is the smallest distance between two nodes of $\mathcal{T}_h^{\mathbf{u}}$ or $\mathcal{T}_h^{\eta}$, should be expected to reasonably well approximate the analytical one when using the semi-implicit scheme.

The analytical solution of the problem is obtained from (5.1) and (5.2) by exploiting the circular symmetry. In order to do so, the Coriolis term is set to zero, leading to a second-order wave equation in polar coordinates for η, viz.

$$\eta_{tt} - c^2\,\frac{1}{r}\,(\,r\,\eta_r\,)_r = 0 \tag{6.2}$$

subject to the boundary conditions $\eta_r|_{r=R} = 0$, and no singularity at the origin. The initial conditions are $\eta\,(r,0) = a\,e^{-b\,r^2}$ and $\eta_t\,(r,0) = 0$; the latter condition follows from setting the initial velocity to zero. The exact solution of (6.2) is the Bessel-function expansion

$$\eta\,(r,t) = \sum_{n=1}^{\infty} \mu_n\, J_0\,(\,\sqrt{\lambda_n}\, r\,)\,\cos c\,\sqrt{\lambda_n}\, t\,,$$

where $\mu_n = \frac{\int_0^R \eta\,(r,0)\, J_0\,(\,\sqrt{\lambda_n}\, r\,)\, r\, dr}{\int_0^R J_0^2\,(\,\sqrt{\lambda_n}\, r\,)\, r\, dr}$ and λ_n are the roots of $J_1\,(\,\sqrt{\lambda_n}\, R\,) = 0$.

The circular domain has a radius of $R = 1000\,\mathrm{km}$ and is discretized using a 40 km vertex node spacing unstructured triangulation $\mathcal{T}_h^{\mathbf{u}}$ with smoothing ($h_0 = 20\,\mathrm{km}$). A flat bottom with mean depth $H = 2000\,\mathrm{m}$ is assumed, leading to $c \approx 140\,\mathrm{m\,s^{-1}}$. By taking a timestep of 20 s, C_g is approximately 0.15. The Gaussian distribution parameters that define η at initial time are set to $a = 100\,\mathrm{m}$ and $b = 6.4 \times 10^{-11}\,\mathrm{m}^{-2}$.

Time sequences for η are shown in Figure 6.1. The surface elevation is first shown at stage 1, after a single timestep. At stage 3 it is being reflected by the basin wall, and by stages 5, 6, 7, and 8 it has returned one, two, three, and four times, respectively, to its starting point. Comparing panels 1 and 5 of Figure 6.1 we can see that very little dispersion has occurred after a single cycle, but after two and three cycles the dispersion effect is quite obvious. The dispersion is due to the individual Bessel modes of the exact solution propagating with different phase speeds.

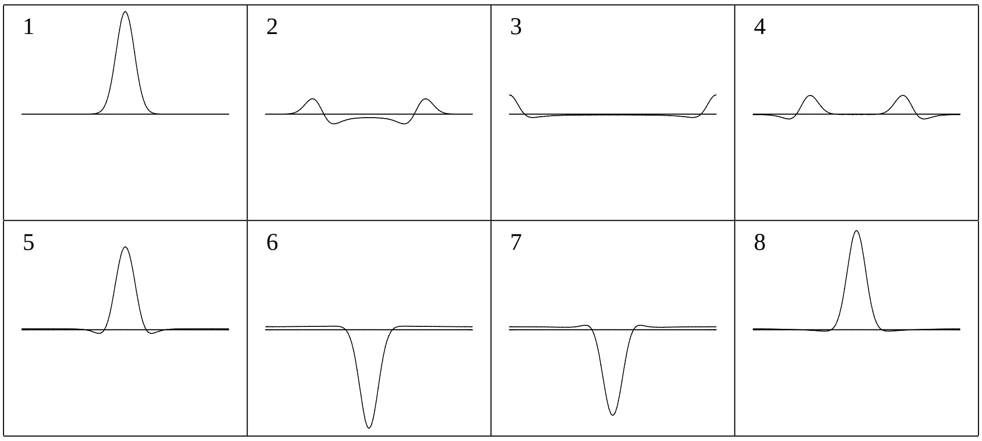

FIG. 6.1. *Vertical cross sections in the x, z plane of the surface elevation η at different stages of gravity wave propagation and dispersion. The initial Gaussian distribution is shown in panel* 1. *Reflection occurs at the boundary in panel* 3, *and in panels* 5, 6, 7, *and* 8 *the disturbance has returned to its starting point one, two, three, and four times, respectively.*

Good agreement is obtained between the analytical and the computed solutions for the P_1^{NC}–P_{1-C} pair as shown in Table 6.1. Further, it has been observed that the radial symmetry of the exact solution is very well reproduced by the numerical one. For the $P_1\,\mathrm{iso}\,P_2 - P_{0-3}$ pair the discrepancy with the analytical solution after stage 4 may arise from the constant approximation for η and/or from an inaccurate calculation of the normal at the boundary vertices. The test has been done on a Power Challenge XL machine with MIPS R8000 processor chips. Note that for the P_1^{NC}–P_{1-C} pair the computational cost and the memory requirement are reduced by a factor of $\delta_1 = 3.74$ and $\delta_2 = 1.84$, respectively, compared to the $P_1\,\mathrm{iso}\,P_2$–P_{0-3} pair. A conjugate gradient method is used to solve for (5.15) and residuals are found

TABLE 6.1

to decrease by a factor of 10^{-6} within 10 iterations for both pairs using a diagonal preconditioner.

6.2. Eddy propagation. In the second experiment the domain is an idealized 1200 km × 1200 km square basin discretized using a 10 km vertex node spacing unstructured triangulation $\mathcal{T}_h^{\mathbf{u}}$ with smoothing ($h_0 = 5\,\mathrm{km}$). The constant depth $H = 1.63\,\mathrm{m}$ results in a phase speed for gravity waves of approximately $4\,\mathrm{m\,s^{-1}}$. Such a small equivalent depth is pertinent for the adjustment under gravity of a density-stratified fluid [6]. The initial Gaussian surface-elevation distribution is centered on a point 600 km from both the south and west walls. By setting $b = 5.92 \times 10^{-11}\,\mathrm{m^{-2}}$ the e-folding radius is 130 km. The β-plane approximation, $f = f_0 + \beta\, y$, is used, where f_0 and β are evaluated at 25^o N ($f_0 = 6.16 \times 10^{-5}\,\mathrm{s^{-1}}$ and $\beta = 2.07 \times 10^{-11}\,\mathrm{m^{-1}\,s^{-1}}$). The radius of deformation at midbasin is thus $R_d \equiv \sqrt{g\,H}/f_0 \approx 65\,\mathrm{km}$.

The initial symmetric anticyclonic velocity field is taken to be in exact geostrophic balance $f\,\mathbf{k} \times \mathbf{u} = -g\,\nabla\,\eta$, and thus

$$u\,(x, y, 0) = 2\,\frac{g}{f}\,a\,b\,y\,e^{-b\,(x^2 + y^2)}\,, \tag{6.3}$$

$$v\,(x, y, 0) = -2\,\frac{g}{f}\,a\,b\,x\,e^{-b\,(x^2 + y^2)}\,. \tag{6.4}$$

By setting $a = 0.95\,\mathrm{m}$, the initial maximum surface azimuthal velocity is $1\,\mathrm{m\,s^{-1}}$. The timestep is 30 minutes and thus C_g is approximately 1.5; the results are relatively insensitive to the precise choice of the timestep.

During the first inertial period ($2\,\pi/f_0 \simeq 28\,\mathrm{h}\,22\,\mathrm{mn}$) the initial condition adjusts to the β-plane balance of the model. After this initial adjustment, the anticyclonic vortex evolves purely westward at an average translation speed of $\beta\,{R_d}^2 \simeq 7.5\,\mathrm{km\,day^{-1}}$. The evolution of the flow-speed field and surface elevation is shown in Figure 6.2

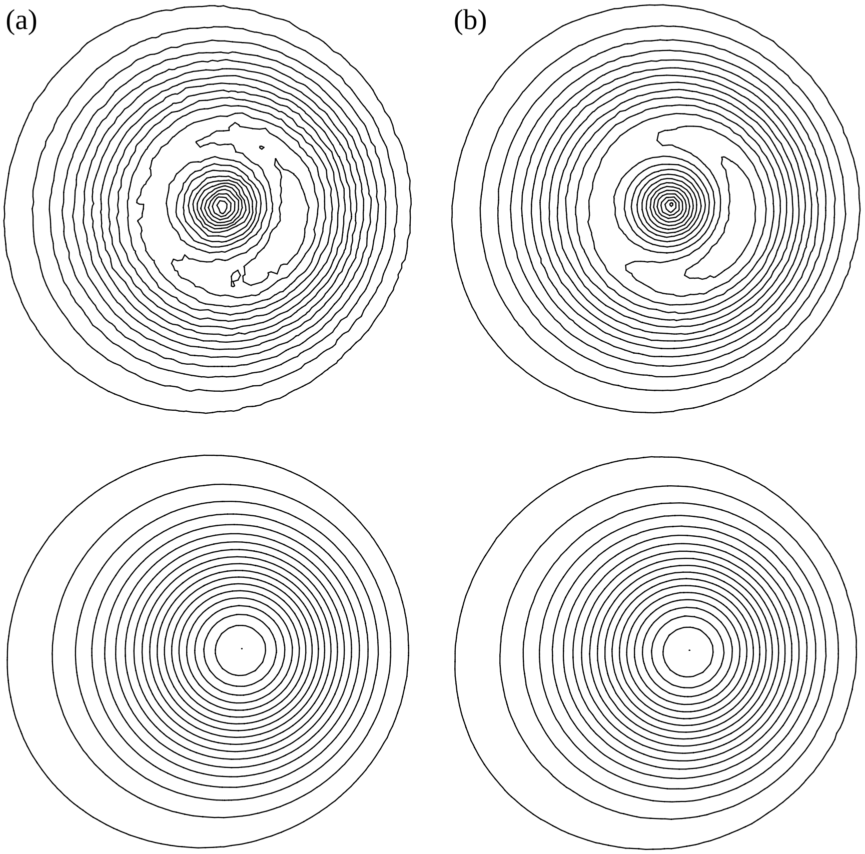

FIG. 6.2. *Isolines of the flow-speed field (row* 1*) and surface elevation (row* 2*) after one week of simulation for the* (a) P_1 *iso* P_2–P_{0-3}*,* (b) P_1^{NC}–P_{1-C} *pairs. The contour interval is* $0.05\,m\,s^{-1}$ *for the flow-speed field and* 0.05 *m for the surface elevation.*

for the P_1^{NC}–P_{1-C} and P_1 iso P_2–P_{0-3} element pairs after one week of simulation. Smooth surface elevations are obtained for both pairs. For the P_1 iso P_2–P_{0-3} pair, noise gradually develops in the flow-speed field during the week of simulation while results obtained with the P_1^{NC}–P_{1-C} pair are much smoother.

For this experiment δ_1 and δ_2 are similar to the first test. A GMRES iterative method is used to solve for (5.15) and residuals are found to decrease by a factor of 10^{-6} within 21 and 32 iterations for the P_1^{NC}–P_{1-C} and P_1 iso P_2–P_{0-3} pairs, respectively, using a diagonal preconditioner.

The P_1^{NC}–P_{1-C} element pair is shown to give favorable results not only for the propagation and dispersion of gravity waves, but also for the simulation of the slowly propagating Rossby modes.

7. Conclusions. Most popular finite-element pairs result in having more vector momentum than continuity discretized equations. Consequently, relevant problems such as wave propagation may be poorly approximated. In this paper several new pairs are proposed which lead to a good balance. Of these, one pair is shown to be preferable; it has no pressure modes (assuming a triangulation into corners) and gives smooth results for two basic equations embedded in the inviscid linear shallow-water equations. The latter set of equations is then solved using this new pair. Two tests are performed: simulation of propagation of gravity waves in a circular basin and simulation of evolution of an anticyclonic velocity field. In both experiments the new pair gives better results than those obtained previously, and at much lower computational and memory requirement costs. It is concluded that this pair is a very promising choice for the discretization of the nonlinear shallow-water equations with forcing and varying depth.

Acknowledgments. The author gratefully acknowledges Dr. Andrew Staniforth for his continued interest and support of this work, and both Dr. Andrew Staniforth and Professor Roger Pierre for reviewing a draft of the manuscript. Special thanks are due to Dr. Léonard Rivier and Dr. Isla Gilmour for critical proofreading and comments. EVALUATION OF SINGLE LAYER POTENTIALS OVER CURVED SURFACES[*]

LEANDRO FARINA[†]

Abstract. The evaluation of nearly singular single layer potentials encountered in boundary element methods is treated by a new approach. The potential is expressed as a sum of a one-dimensional integral and a correction term that vanishes for planar surfaces. The small variance of the second term's integrand allows the use of a quasi-Monte Carlo quadrature. Numerical results show that a significant reduction in computational time is obtained over algorithms employing domain subdivisions.

1. Introduction.

In boundary element methods, the solution of a boundary value problem is expressed in terms of an integral over the boundary S of the original domain. For potential problems, a solution ϕ is obtained by solving the Fredholm integral equation

$$\lambda(p)\phi(p) + \int_S \phi(q)G(p,q)\ d\sigma = f(p), \quad p \in S, \tag{1.1}$$

where $G = \frac{1}{4\pi}\frac{1}{|p-q|}$. $p = (\xi, \eta, \zeta) \in \mathbb{R}^3$ is called the field point.

Discretization of (1.1) poses the task of evaluating

$$U = \int_S g(q)\ G(p,q)\ d\sigma_q, \tag{1.2}$$

called the single layer potential with density g. A number of methods has been described [4], [10] to deal with integrals where the integrand behaves like the fundamental solution of Laplace's equation. However, usually the assumption that S is of a particular form or has a certain parametrization is made, and/or the case where the integral is nearly singular is ill treated. In this paper, we will relax the usual conditions over the parametrization on S, and we also treat the case where U assumes a moderate to a highly near singular character, as explained below. This is a topic of interest in the boundary element method, in particular, in higher-order methods.

Let S be defined by a mapping $T : \mathcal{P} = [a,b] \times [c,d] \longrightarrow S$ with the property

$$T(\partial\mathcal{P}) = \partial S. \tag{1.3}$$

It is useful to classify U according with the order of magnitude of the distance dist(p,S) between the field point p and the surface S. Thus we say

$$\text{if } \operatorname{dist}(p,S) = O(1), \quad U \text{ is regular,} \tag{1.4}$$

$$\text{if } 0 < \operatorname{dist}(p,S) \le o(1), \quad U \text{ is nearly singular, and} \tag{1.5}$$

$$\text{if } \operatorname{dist}(p,S) = 0, \quad U \text{ is singular.} \tag{1.6}$$

We are mainly interested in the case in (1.5). In this case, the integral U above is regular. However, as the integrand is near a singularity, standard quadrature formulae are not appropriate. This case appears in the boundary element method, typically in applications involving bodies with thin components where one part of S is close to another part of this surface. Moreover, the occurrence of nearly singular integrals is also associated with more general types of domains, depending on how the surface is discretized or panelized. A large difference in size between two panels may create the condition described in (1.5). Recently, it was shown by Luo, Liu, and Berger [7] that conventional boundary integral methods will not degenerate even when applied to thin structures with the thickness to length ratio in the micro (10^{-6}) or nano (10^{-9}) scales. This is true as long as numerical difficulties, such as the calculation of the nearly singular integrals, are addressed.

2. Semianalytical approach. Integrals of type (1.2), where g is a polynomial, can be evaluated in closed form when the surface S is a flat polygon (see Newman [8]). However, for an arbitrary surface S, numerical integration becomes mandatory in the evaluation of U. Our approach here is to use analytical evaluation to a maximum degree in this ultimately numerical task. This will sustain the accuracy and efficiency of an analytical evaluation into the method.

Thus we decompose the surface integral U as

$$U = U_o + U_c, \tag{2.1}$$

where U_o is a planar approximation to U in the sense that it is given as an integral over a flat domain in $\mathbb{R}^3$ and it coincides with U when S is flat. U_c is the correction due to this approximation. As we will see, the inner integral in U_o will be evaluated analytically.

A precise expression for U_o and U_c will be given later. Let us first describe the change of variables defining the auxiliary flat domain.

3. New coordinate systems. The function G presents a weak singularity at $q = (x, y, z) = p$, where it is unbounded. The fact that this function's integral is finite can be easily proved by using polar coordinates, since the jacobian will cancel the singularity. This also suggests a way of evaluating U numerically as a regular integral. Consider a new coordinate system given by

$$(\tilde{x}, \tilde{y}, \tilde{z}) = M^{-1} \begin{pmatrix} x \\ y \\ z \end{pmatrix},$$

where the field point p is the origin lying on the $\tilde{x}\tilde{y}$-plane, denoted by D. M^{-1} is a 3×3 matrix. Using the polar coordinates $\rho = \sqrt{\tilde{x}^2 + \tilde{y}^2}, \theta = \arctan(\tilde{y}/\tilde{x})$ gives

$$U = \frac{1}{4\pi} \int_0^{2\pi} \int_0^{\mathcal{R}(\theta)} g(\rho,\theta) \frac{\rho}{\sqrt{\rho^2 + h^2}} \, \tilde{J} \; d\rho d\theta, \tag{3.1}$$

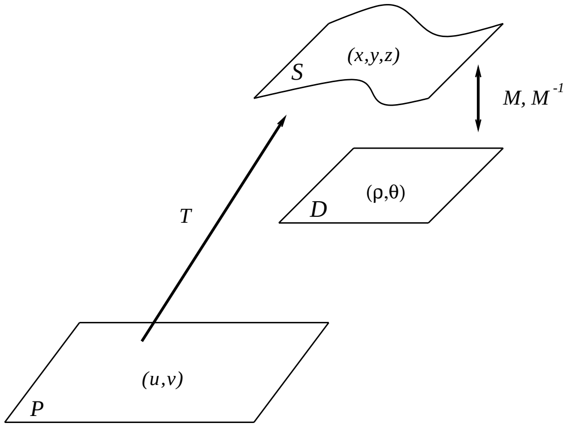

FIG. 1. *The domains $\mathcal{P}, S, D$ and the transformations $T, M,$ and M^{-1}.*

where $h = \tilde{z}(\rho, \theta)$ and $\mathcal{R}(\theta)$ is the value of ρ, as a function of θ, at the boundary of S. $\tilde{J}$ is the jacobian of the transformation M^{-1}, and it is given by $\tilde{J} = \frac{1}{n_D \cdot n_S}$, where n_D and n_S are the respective normal vectors to D and S at q. Because D is flat, $\tilde{J} = n3$, where $n3$ is the third component of n_S.

With this new setting, we see that as q approaches p, the integrand remains bounded and approaches the value of $g\tilde{J}$ at that point. Thus, in our approach, the integral defining U is represented in the physical three-dimensional space.

There are three domains of interest in our problem: the parameter domain

$$\mathcal{P} = [a, b] \times [c, d],$$

the three-dimensional space $\mathbb{R}^3$ (where S is embedded), spanned by the canonical basis

$$\mathcal{C} = \{x, y, z\},$$

or by the alternative basis

$$\mathcal{B} = \{\tilde{x}, \tilde{y}, \tilde{z}\},$$

and the flat domain

$$D = \operatorname{span}\{\tilde{x}, \tilde{y}\} = \operatorname{span}\{\rho, \theta\}$$

where the integrand is regularized.

The main difficulty associated with evaluating (3.1) is that it is not possible, in general, to evaluate $\mathcal{R}, h,$ and $\tilde{J}$ as functions of (ρ, θ). This is a result of the lack of restriction on S. Indeed, we assume S can be *any* parametrized surface with the property (1.3). Then, the fact that the transformation $T : \mathcal{P} = [a, b] \times [c, d] \longrightarrow S$ is not, in general, invertible prevents us from evaluating $\mathcal{R}, h,$ and $\tilde{J}$ directly as functions of variables in S or D (see Figure 1) and therefore from using a quadrature formula where the location of the integration points are predefined. In other words, the control over the integration points is lost; the relative locations of these points in $\mathcal{P}$ will be altered by the transformation T. Thus our approach is to use a interpolation quadrature [2] based on linear functions or on splines for computing U_o and a Monte Carlo method for U_c. We will describe and give details about this approach in the following sections.

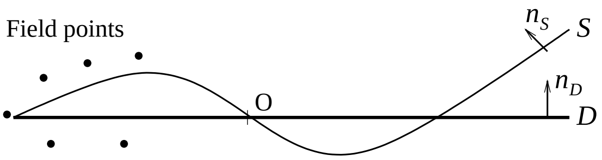

FIG. 2. *The domain D and the surface S.*

4. Independence on the field point. We saw that the change of variables described in the last section, above formula (3.1), provides a regular and simple integrand. However, the new variables are dependent on the field point p. This feature is inconvenient from the computational point of view if the objective is to evaluate U for several, say, L field points, as is usual in boundary element methods for numerical solution of integral equations. Therefore, we will use a similar change of variables, but independent on the field point. In this way, the matrix of the linear transformation between $\mathcal{C}$ and $\mathcal{B}$ is determined once for all computations associated with the surface S. Moreover, the integration points and certain parts of the integrands are computed only once. Then consider $\mathcal{B} = \{\tilde{x}, \tilde{y}, \tilde{z}\}$, as defined in section 3, but with a fixed origin $O = (O_1, O_2, O_3) \in S$, which will be a free parameter specified as one finds appropriate (see Figure 2). The optimum location of O is found by minimizing

$$\max\{|\tilde{z}| : ((\tilde{x}, \tilde{y}, \tilde{z}) - O) \in S\}.$$

Let us assume g may be expanded in powers of $x-\xi$, $y-\eta$, and $z-\zeta$. In view of this, for the evaluation of U, it is sufficient to consider $U^{\mu\nu\upsilon} := \int_S P_{\mu\nu\upsilon}(p-q)\; G(p,q)\; d\sigma_q$, where $P_{\mu\nu\upsilon}(p-q) = (x-\xi)^{\mu}(y-\eta)^{n}u(z-\zeta)^{\upsilon}$.

Now define $U_o^{\mu\nu\upsilon}$ as

$$U_o^{\mu\nu\upsilon} = \frac{1}{4\pi}\int_0^{2\pi}\int_0^{\mathcal{R}(\theta)} P_{\mu\nu\upsilon}(p-q)\frac{\rho}{\sqrt{\rho^2 + b\rho + a}}\; d\rho d\theta, \tag{4.1}$$

where $a = \xi^2 + \eta^2 + (\overline{z} - \zeta)^2$ and $b(\theta) = -2(\xi\cos\theta + \eta\sin\theta)$. The value $\overline{z}$ represents an average value of $\tilde{z}$ and can be taken as $\overline{z} = O_3$.

We now have

$$U^{\mu\nu\upsilon} = U_o^{\mu\nu\upsilon} + U_c^{\mu\nu\upsilon},$$

where

$$U_c^{\mu\nu\upsilon} = \frac{1}{4\pi}\int_0^{2\pi}\int_0^{\mathcal{R}(\theta)} P_{\mu\nu\upsilon}(p-q)\left\{\frac{\rho}{r}\frac{1}{n3} - \frac{\rho}{\overline{r}}\right\}\; d\rho d\theta, \tag{4.2}$$

with $r = |p-q|$ and $\overline{r} = \sqrt{(\tilde{x}-\xi)^2 + (\tilde{y}-\eta)^2 + (\overline{z}-\zeta)^2} = \sqrt{\rho^2 + b\rho + a}$.

5. Quadrature of $\boldsymbol{U_o}$. The objective in this section is to express (4.1) in the form

$$U_o^{nm} = \frac{1}{4\pi}\int_0^{2\pi} F(\mathcal{R}(\theta), \theta)\; d\theta, \tag{5.1}$$

where F is an exact closed form expression for the inner integral in (4.1), and to subsequently apply a one-dimensional quadrature to (5.1). This quadrature will be based on nodes (θ_i, F_i) obtained from a sample of points (u_i, v_i) selected in $\partial\mathcal{P} := \mathcal{P}_1 \cup \mathcal{P}_2 \cup \mathcal{P}_3 \cup \mathcal{P}_4$, where

$$\begin{aligned} \mathcal{P}_1 &= \{(u,v) : v = c\}, \quad \mathcal{P}_2 = \{(u,v) : u = b\}, \\ \mathcal{P}_3 &= \{(u,v) : v = d\}, \quad \mathcal{P}_4 = \{(u,v) : u = a\}. \end{aligned}$$

Condition (1.3) assures that $\mathcal{R}$ is in fact evaluated at the boundary of S. This is the only place where (1.3) is used. Thus the quadrature nodes (θ_i, F_i) are obtained without the knowledge of their exact location. For smooth integrands F, a quadrature based on interpolating cubic splines or Hermite functions [5] can be used. Alternatively, noninterpolating methods could be used, such as the locally corrected quadrature proposed by Strain [9], where singularities are allowed in the integrand F.

In order to make $F(\mathcal{R}(\theta), \theta)$ explicit, note that

$$(x, y, z) = M \begin{pmatrix} \tilde{x} \\ \tilde{y} \\ \tilde{z} \end{pmatrix} - O,$$

where $M = \{M_{ij}\}$ is a 3×3 matrix. It follows that on D we have

$$\begin{cases} x = M_{11}\ \rho\cos\theta + M_{12}\ \rho\sin\theta - O_1, \\ y = M_{21}\ \rho\cos\theta + M_{22}\ \rho\sin\theta - O_2, \\ z = M_{31}\ \rho\cos\theta + M_{32}\ \rho\sin\theta - O_3. \end{cases}$$

Therefore,

$$F(\mathcal{R}(\theta), \theta) = \int_0^{\mathcal{R}(\theta)} (c\rho + d)^\mu (e\rho + f)^\nu (h\rho + l)^\upsilon \frac{\rho}{\sqrt{\rho^2 + b\rho + a}}\, d\rho, \tag{5.2}$$

where $d = -\xi - O_1$, $f = -\eta - O_2$, $l = -\zeta - O_3$, $c(\theta) = M_{11}\cos\theta + M_{12}\sin\theta$, $e(\theta) = M_{21}\cos\theta + M_{22}\sin\theta$, and $h(\theta) = M_{31}\cos\theta + M_{32}\sin\theta$. Expanding the binomials in (5.2), we get

$$\begin{aligned} F(\mathcal{R}(\theta), \theta) = &\sum_{i=0}^{\mu}\sum_{j=0}^{\nu}\sum_{k=0}^{\upsilon} \binom{\mu\nu\upsilon}{ijk} d^i f^j l^k c^{\mu-i}(\theta) e^{\nu-j}(\theta) h^{\upsilon-k}(\theta) \\ &\times H_{\mu+\nu+\upsilon-i-j-k+1}(\theta), \end{aligned}$$

where $\binom{\mu\nu\upsilon}{ijk} := \binom{\mu}{i}\binom{\nu}{j}\binom{\upsilon}{k}$ and

$$H_t(\theta) = \int_0^{\mathcal{R}(\theta)} \frac{\rho^t}{\sqrt{\rho^2 + b\rho + a}}\, d\rho. \tag{5.3}$$

The integral (5.3) can be recursively evaluated using [3]

$$H_t(\theta) = \frac{\rho^{t-1}}{t}\sqrt{\rho^2 + b\rho + a} - \frac{(2t-1)b}{2t} H_{t-1}(\theta) - \frac{(t-1)a}{t} H_{t-2}(\theta),$$

with the starting functions

$$H_0(\theta) = \begin{cases} \log|2\rho + b + 2\sqrt{\rho^2 + b\rho + a}|\Big|_{\rho=0}^{\rho=\mathcal{R}(\theta)}, & 4a \neq b^2, \\ \log|b + 2\rho|\Big|_{\rho=0}^{\rho=\mathcal{R}(\theta)}, & 4a = b^2, \end{cases} \tag{5.4}$$

$$H_1(\theta) = \sqrt{\rho^2 + b\rho + a}\Big|_{\rho=0}^{\rho=\mathcal{R}(\theta)} - \frac{b}{2}H_0(\theta). \tag{5.5}$$

6. Quadrature of U_c by quasi-Monte Carlo. The evaluation of expression (4.2) is more complex than the numerical integration of (4.1). In the case of U_o, it was possible to separate the variables ρ and θ in order to evaluate the inner integral analytically. Because $n3$ is an arbitrary function associated with the given surface S, the correction component U_c does not permit a similar variable separation. Thus U_c has to be integrated numerically as a two-dimensional integral. Since U_c presents the same discretization condition as U_o, namely, the location of the nodes in the (ρ, θ) variables is arbitrary, this makes the problem more delicate. The apparent solution[1] seems to use interpolation in two variables, imitating the procedure for evaluating (5.1). However, we believe that interpolation provides neither more efficiency nor more accuracy than a Monte Carlo quadrature. Traditionally, since its convergence rate is independent of the problem dimension, Monte Carlo quadrature has been used in high-dimensional integrals as an efficient and robust alternative to grid-based methods. In what follows we will outline the reasons for using a Monte Carlo type of quadrature in a low-dimensional (i.e., two-dimensional) integral and describe the specific approach employed.

Let $(\rho_i, \theta_i)_{i=\{1,\ldots,N\}}$ be a sequence of points in D. To evaluate (4.2) we use an integration formula Q_N of the form

$$Q_N(U_c) = A(D)\mu_N(K), \tag{6.1}$$

where

$$A(D) = \frac{1}{4\pi}\int_0^{2\pi} \mathcal{R}(\theta)\, d\theta,$$

$$K = P_{\mu\nu v}(p - q)\left\{\frac{\rho}{r}\frac{1}{n3} - \frac{\rho}{r}\right\},$$

and μ_N denotes the sample mean of K on D, given as

$$\mu_N(K) = \frac{1}{N}\sum_{i=1}^{N} K(\rho_i, \theta_i).$$

Note that the evaluation of $A(D)$ is intimately related with the numerical integration of U_o. From (5.1), we see that $A(D)$ is a special case, where $F(\mathcal{R}(\theta), \theta) \equiv \mathcal{R}(\theta)$.

[1] Strain's approach [9] does not seem applicable here because of its restriction that the domain of integration must be a hypercube.

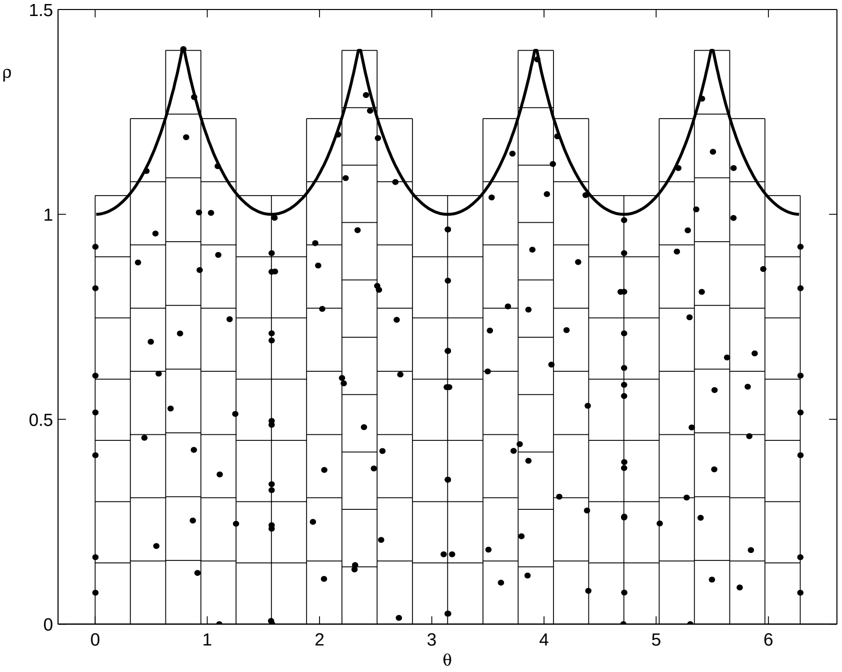

FIG. 3. *The effect of the partitioning algorithm represented by the location of the integration nodes in the $\theta - \rho$ plane bounded by $\mathcal{R}(\theta)$. Here $N_c = 1$, and S is a curved quadrilateral.*

As is well known in the theory of Monte Carlo methods, there are basically two resources for improving the convergence rate of our approximation (6.1) to U_c. One is to force the nodes to be as uniform as possible, and the other is to reduce somehow the variance

$$\sigma^2(K) := \int_D (K - \overline{K})^2 \; d\rho d\theta,$$

where $\overline{K}$ is the mean of the integrand K.

We will use both means to obtain a suitable algorithm for the computation of U_c. The particular procedure to achieve this goal in the correction integral will be described next.

The control variates [1], [6, Chapter 6] form of variance reduction is in fact used from the beginning in our approach to evaluate the single layer potential as in the decomposition (2.1). The term

$$\left\{ \frac{\rho}{r} \frac{1}{n3} - \frac{\rho}{\overline{r}} \right\}$$

in K vanishes where the S is flat and, for moderate curvatures in S, presents small variances.

The other resource that we will use to improve convergence rates is the *uniformization* of the nodes distribution over the domain of integration.

The sequence of the nodes will fill the integration domain more uniformly and less uncorrelatedly than random nodes characterizing a quasi-Monte Carlo formula. For

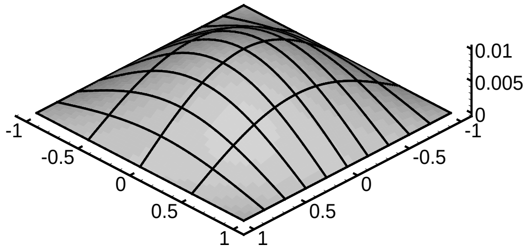

FIG. 4. *The surface S_c.*

our case, the transformations T and M would void any deterministic choice of points in $\mathcal{P}$. In order to obtain low-discrepancy nodes, we combine the *stratification* and the *acceptance-rejection* methods [6] into a partitioning algorithm. Thus we divide the $\rho-\theta$ domain in approximately equal sized *cells*, or subregions, and we accept or reject the pseudorandom generated points for the formula (6.1) until an equal number of subnodes N_c are present in each cell. A typical example of the effect of this algorithm can be seen in Figure 3, where the distribution of the integration nodes in the $\theta-\rho$ plane is represented. In this figure, the bounding curve is $\mathcal{R}(\theta)$, given for a curved quadrilateral with equal, straight sides, and the cells are rectangles with one subnode.

7. Numerical results. In this section we present numerical results obtained from the Monte Carlo-based method described above and compare them with a standard quadrature employing the Gauss–Legendre formula combined with subdivision of the integration domain. This subdivision takes place whenever $\operatorname{dist}(p, S)$ becomes small compared with the area of S. All results in this section are believed to have relative error less than 0.3%.

Let S_c be a curved quadrilateral given by

$$S_c : (x(u,v), y(u,v), z(u,v)) = T(u,v) = (u, v, 0.01\sin u \sin v + 0.01)$$

and represented in Figure 4. In Figure 5, the dotted line represents a subdivision method, and the solid line indicates quasi-Monte Carlo. The computing time (on a UNIX workstation) is plotted as a function of the number L of single layer potentials computed, each layer potential corresponding to a field point. Thus up to 1000 field points p_i were chosen satisfying the condition $\operatorname{dist}(p_i, S) \geq 10^{-2}$. For $L \approx 28$, quasi-Monte Carlo requires less computational time than a standard subdivision method. The graph shows monotonically increasing linear functions, and for a large number of evaluations (1000 field points), we see a factor of 3 difference between the two methods. This difference is due to the fact that in our field point independent approach, information such as the location of the integration nodes and parts of the integrands are reused in all the integrals evaluated. In particular, calls to a subroutine or function defining the transformation T are made only for the first integral. Furthermore, the value of $A(D)$ in (6.1) is fixed. Hence the effort to evaluate successive integrals becomes minimal with the increase of L.

Let us now comment on another example. Suppose now that the surfaces over which the integration is done are a family of planar quadrilaterals given as

$$S_\epsilon : (x(u,v), y(u,v), z(u,v)) = T(u,v) = (u, v, \epsilon),$$

where $10^{-7} \leq \epsilon \leq 0.1$. In this case, $U_c = 0$, and the Monte Carlo method is not

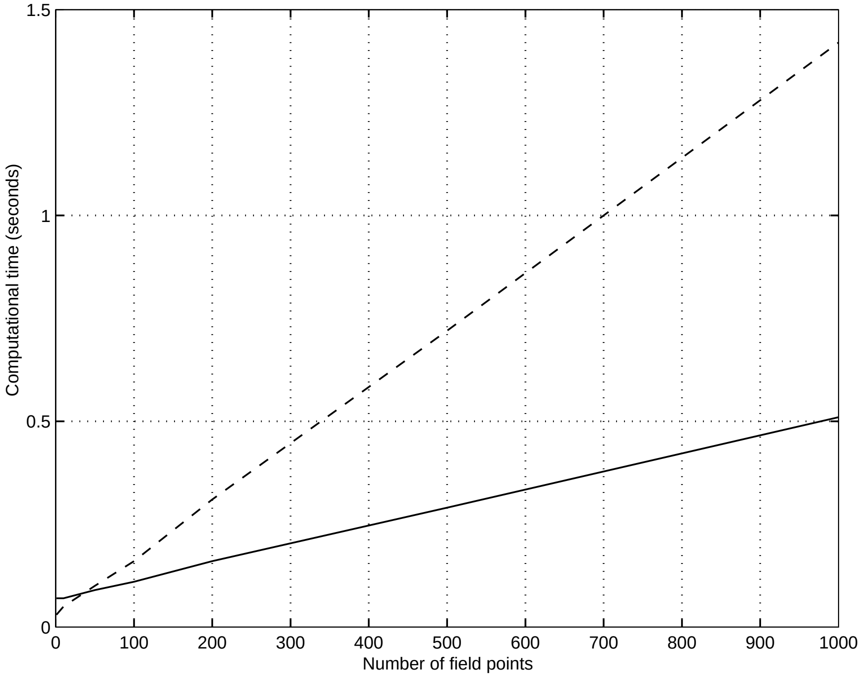

FIG. 5. *The results for the surface S_c and for dist$(p_i, S) \geq 10^{-2}$. The dotted line represents the subdivision method, and the solid line indicates the quasi-Monte Carlo method.*

necessary to use. The integrals are evaluated by one-dimensional quadrature since

$$U = U_o.$$

In Figure 6, with the same representations for the dotted and solid line, we see the computational time as a function of $\mathrm{dist}(p_i, s) = \epsilon$, in the range of ϵ specified above. Here $L = 500$, and the field points are distributed uniformly over the x-axis. As can be seen, the computation of U_o is not affected by the degree of the near singularity, represented by ϵ. On the other hand, the use of standard quadratures, even with domain subdivision, suffers from the necessity of an excessive number of nodes and/or domain subdivisions.

It should be noted that under certain conditions the algorithm presented here will not be appropriate in its present form. Although it will provide good results for the case (1.4) because the integrand will be smooth and well approximated by polynomials, its efficiency will not be superior to a regular quadrature with a small number of nodes. Also, for surfaces with large curvature, the contribution from U_c will be large compared with U_o, and a large number of nodes may be required to sustain accuracy.

8. Conclusion. A method for computing nearly singular single layer potentials has been introduced. Restrictions on the parametrization of the integration domain are relaxed, and the original integral is decomposed in a sum two terms, U_o and U_c, where the first is an approximation which coincides with the single layer potential when the surface is planar. The term U_c provides the correction when the surface loses its planar character. This decomposition not only allows U_o to be evaluated in terms

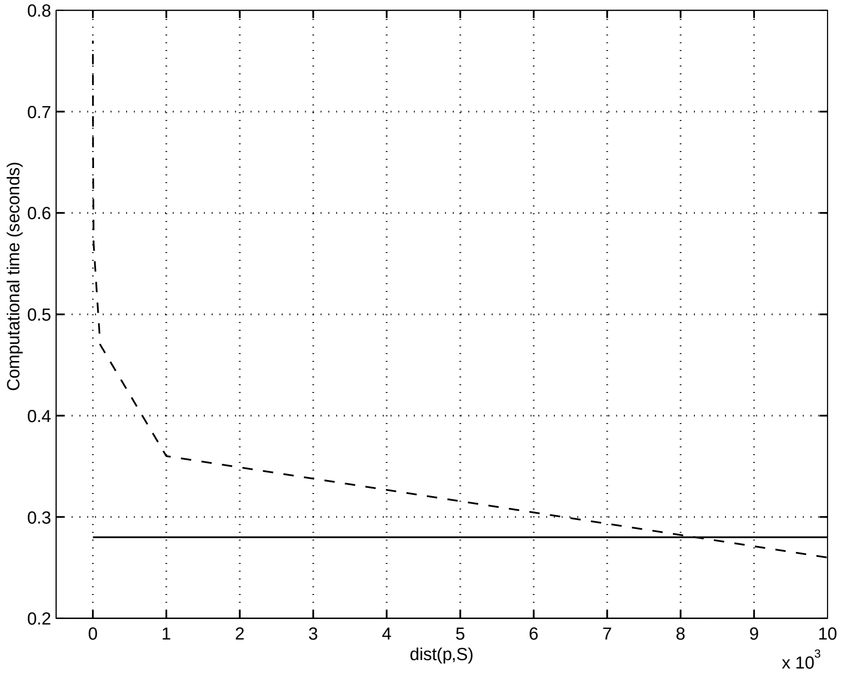

FIG. 6. *The results for S_ϵ and for $L = 500$. The dotted line represents the subdivision method, and the solid line indicates the quasi-Monte Carlo method.*

of a one-dimensional regular quadrature but also reduces the integrand variance in U_c, making it viable to apply a two-dimensional quadrature based on pseudorandom nodes. This latter quadrature also employs a uniformization algorithm to the nodes distribution in order to improve the formula convergence rate. Also, because the quadrature of U_c is not grid-based, adaptiveness can be easily incorporated.

Usually, in boundary element methods, integrals like U have to be computed several times according with different field points. The method described above explores this fact by reusing information from previous computations. Numerical results clearly show an economy in computational costs for this approach when compared with standard quadrature employing domain subdivisions. For surfaces with moderate curvature, previously prohibitive nearly singular integrals where the ratio distance from the field point to the surface average length reaches 10^{-7} or less can be dealt with using the present algorithm without significant increase in the computational cost.

It may be possible to extend this approach to other types of integrands, such as the double layer potential. In order to achieve this successfully, one needs to efficiently integrate the strong near singularity that will be present in U.

Acknowledgments. The author thanks the people at the Computational Hydrodynamics Facility at MIT for helpful discussions about this work.

A FETI PRECONDITIONER FOR TWO DIMENSIONAL EDGE ELEMENT APPROXIMATIONS OF MAXWELL'S EQUATIONS ON NONMATCHING GRIDS[*]

FRANCESCA RAPETTI[†] AND ANDREA TOSELLI[‡]

Abstract. A class of FETI methods for the mortar approximation of a vector field problem in two dimensions is proposed. Edge element discretizations of lowest degree are considered. The method proposed can be employed with geometrically conforming and nonconforming partitions. Our numerical results show that its condition number increases only with the number of unknowns in each subdomain and is independent of the number of subdomains and the size of the problem.

Key words. edge elements, Maxwell's equations, domain decomposition, FETI, preconditioners, nonmatching grids

1. Introduction.

In this paper, we consider the boundary value problem

$$\begin{aligned} L\mathbf{u} := \mathbf{curl}\,(a\,\mathrm{curl}\,\mathbf{u}) + A\,\mathbf{u} &= \mathbf{f} \quad \text{in } \Omega, \\ \mathbf{u}\cdot\mathbf{t} &= 0 \quad \text{on } \partial\Omega, \end{aligned} \tag{1}$$

with Ω a bounded polygonal domain in $\mathbb{R}^2$. Here

$$\mathbf{curl}\,v := \begin{bmatrix} \dfrac{\partial v}{\partial x_2} \\ -\dfrac{\partial v}{\partial x_1} \end{bmatrix}, \quad \mathrm{curl}\,\mathbf{u} := \frac{\partial u_2}{\partial x_1} - \frac{\partial u_1}{\partial x_2};$$

see, e.g., [17]. The coefficient matrix A is a symmetric, uniformly positive definite matrix-valued function with entries $A_{ij} \in L^\infty(\Omega)$, $1 \le i,j \le 2$, and $a \in L^\infty(\Omega)$ is a positive function bounded away from zero. The domain Ω has unit diameter, and $\mathbf{t}$ is the unit tangent to its boundary.

The weak formulation of problem (1) requires the introduction of the Hilbert space $H(\mathrm{curl}\,;\Omega)$, defined by

$$H(\mathrm{curl}\,;\Omega) := \left\{\mathbf{v} \in (L^2(\Omega))^2 | \quad \mathrm{curl}\,\mathbf{v} \in L^2(\Omega)\right\}.$$

The space $H(\mathrm{curl}\,;\Omega)$ is equipped with the following inner product and graph norm:

$$(\mathbf{u},\mathbf{v})_{\mathrm{curl}} := \int_\Omega \mathbf{u}\cdot\mathbf{v}\,d\mathbf{x} + \int_\Omega \mathrm{curl}\,\mathbf{u}\,\mathrm{curl}\,\mathbf{v}\,d\mathbf{x}, \qquad \|\mathbf{u}\|^2_{\mathrm{curl}} := (\mathbf{u},\mathbf{u})_{\mathrm{curl}}.$$

The tangential component $\mathbf{u} \cdot \mathbf{t}$, of a vector $\mathbf{u} \in H(\mathrm{curl}\,;\Omega)$ on the boundary $\partial\Omega$, belongs to the space $H^{-\frac{1}{2}}(\partial\Omega)$; see [17, 8]. The subspace of vectors in $H(\mathrm{curl}\,;\Omega)$ with a vanishing tangential component on $\partial\Omega$ is denoted by $H_0(\mathrm{curl}\,;\Omega)$.

For any $\mathcal{D} \subset \Omega$, we define the bilinear form

$$a_{\mathcal{D}}(\mathbf{u}, \mathbf{v}) := \int_{\mathcal{D}} (a \,\mathrm{curl}\,\mathbf{u}\,\mathrm{curl}\,\mathbf{v} + A\,\mathbf{u} \cdot \mathbf{v})\, d\mathbf{x}, \quad \mathbf{u}, \mathbf{v} \in H(\mathrm{curl}\,;\Omega). \tag{2}$$

The variational formulation of (1) is as follows.

Find $\mathbf{u} \in H_0(\mathrm{curl}\,;\Omega)$ such that

$$a_{\Omega}(\mathbf{u}, \mathbf{v}) = \int_{\Omega} \mathbf{f} \cdot \mathbf{v}\, d\mathbf{x}, \quad \mathbf{v} \in H_0(\mathrm{curl}\,;\Omega). \tag{3}$$

We discretize this problem using edge elements, also known as Nédélec elements; see [24]. These are vector-valued finite elements that ensure only the continuity of the tangential component across the common side of adjacent mesh triangles, as is physically required for the electric and magnetic fields, which are solutions of Maxwell's equations.

In this paper, we consider a mortar approximation of this problem. The computational domain is partitioned into a family of nonoverlapping subdomains, and independent triangulations are introduced in each subdomain. The weak continuity of the tangential component of the solution is then enforced by using suitable integral conditions that require that the jumps across the subdomain inner boundaries are perpendicular to suitable finite element spaces defined on the edges of the partition. The mortar method was originally introduced in [9] for finite element approximations in H^1. Mortar approximations for edge element approximations in two and three dimensions have been studied in [3] and [4], respectively. There has also been additional recent work for the case of sliding meshes for the study of electromagnetic fields in electrical engines; see, e.g., [25, 26].

The applications that we have in mind are mainly problems arising from static and quasi-static Maxwell equations (eddy current problems); see, e.g., [6, 5]. In this paper, we consider only the model problem (3), where the dependency on the time variable or on the frequency has been eliminated, and we generically refer to it as Maxwell's equations. A good preconditioner for this model problem is the first step for the efficient solution of linear systems arising from the edge element approximation of static problems, and of time- or frequency-dependent problems arising from the quasi-static approximation of Maxwell's equations.

The aim of this paper is to build an iterative method of finite element tearing and interconnecting (FETI) type for a mortar edge element approximation of problem (1). FETI methods were first introduced for the solution of conforming approximations of elasticity problems in [15]. In this approach, the original domain Ω is decomposed into nonoverlapping subdomains Ω_i, $i = 1, \ldots, N$. On each subdomain Ω_i a local stiffness matrix is obtained from the finite element discretization of $a_{\Omega_i}(\cdot, \cdot)$. Analogously, a set of right-hand sides is built. The continuity of the solution corresponding to the primal variables is then enforced by using Lagrange multipliers across the interface defined by the subdomain inner boundaries. In the original FETI algorithm, the primal variables are then eliminated by solving local Neumann problems, and an equation in the Lagrange multipliers is obtained. Several preconditioners have been proposed and studied for its solution; see, e.g., [14, 16, 23, 13, 30, 27, 19, 33].

Many iterative methods for the solution of linear systems arising from mortar approximations have been proposed. We cite, in particular, [22, 1, 20, 2, 10, 11, 7, 12, 21, 34] and refer to the references therein for a more detailed discussion.

To our knowledge, the application of FETI-type preconditioners to mortar approximations was first explored in [21, 18] and then tested more systematically in [29]. The idea is fairly simple and relies on the observation that mortar approximations with Lagrange multipliers and FETI formulations, where the pointwise continuity across the substructures is enforced by using Lagrange multipliers, give rise to indefinite linear systems that have the same form. FETI preconditioners can then be devised for mortar approximations in a straightforward way; see [29]. In this paper, we apply the FETI preconditioner introduced in [19] for the case of nonredundant Lagrange multipliers to the mortar approximation originally studied in [3]. Our work generalizes our previous study of FETI preconditioners for two dimensional conforming edge element approximations in [33]. As opposed to the H^1 case, the generalization of FETI preconditioners to mortar approximations requires some modifications in $H(\mathrm{curl}\,)$. More precisely, the coarse components of the preconditioners need to be modified here in order to obtain a scalable method, and a suitable scaling matrix Q has to be introduced; see section 5. As shown in [29], no modification appears to be necessary for nodal finite elements in H^1. Finally, we note that in this paper we consider only problems without jumps of the coefficients. For conforming approximations, FETI methods that are robust with respect to large variations of jumps of the coefficients have been developed and studied (see [27, 19]), but the case of nodal or edge element approximations on nonmatching grids still needs to be explored and is left for a future work.

The outline of the remainder of this paper is as follows. In section 2, we introduce a partition of the domain Ω and local finite element spaces. In section 3, we consider the mortar condition, and in section 4, we present our FETI method, in terms of a projection onto a low dimensional subspace and a local preconditioner. The expressions for the projection and the preconditioner are then given in section 5, and some numerical results for geometrically conforming and nonconforming partitions are presented in section 6.

2. Finite element spaces. We first consider a nonoverlapping partition of the domain Ω,

$$\mathcal{F}_H = \left\{ \Omega_i,\ i=1,\dots,N \;\middle|\; \bigcup_{i=1}^{N} \overline{\Omega_i} = \overline{\Omega} \quad ; \quad \Omega_k \cap \Omega_l = \emptyset \quad , \quad 1 \le k < l \le N \right\},$$

such that each subdomain Ω_i is a connected polygonal open set in $\mathbb{R}^2$. We remark that $\mathcal{F}_H$ does not need to be geometrically conforming. We denote the diameter of Ω_i by H_i and the maximum of the diameters of the subdomains by H:

$$H := \max_{1 \le i \le N} \{H_i\}.$$

The elements of $\mathcal{F}_H$ are also called *substructures.* Let $\mathbf{t}_i$ be the unit tangent to $\partial\Omega_i$, chosen so that, following the direction of $\mathbf{t}_i$, Ω_i is on the left.

For every subdomain Ω_i, we define the set of its open edges that do not lie on $\partial\Omega$ by $\{\Gamma^{i,j} |\, j \in \mathcal{I}_i\}$. We then define the interface Γ, also called the “skeleton” of the decomposition, as the union of the edges of $\mathcal{F}_H$ that do not lie on $\partial\Omega$:

$$\Gamma := \bigcup_{i=1}^{N} \partial\Omega_i \setminus \partial\Omega = \bigcup_{i=1}^{N} \bigcup_{j\in\mathcal{I}_i} \Gamma^{i,j}.$$

We also define the local spaces of restrictions of vectors in $H_0(\mathrm{curl}\,;\Omega)$ to Ω_i:

$$H_\star(\mathrm{curl}\,;\Omega_i) := \{\mathbf{u}_i \in H(\mathrm{curl}\,;\Omega_i)|\ \mathbf{u}_i \cdot \mathbf{t} = 0 \text{ on } \partial\Omega \cap \partial\Omega_i\}.$$

For every substructure Ω_i, we consider a triangulation $\mathcal{T}_{i,h}$ made of triangles or rectangles. Let $\mathcal{E}_{i,h}$ be the set of edges of $\mathcal{T}_{i,h}$. For every edge $e \in \mathcal{E}_{i,h}$, we fix a direction, given by a unit vector $\mathbf{t}_e$. The length of the edge e is denoted by $|e|$. The local triangulations are assumed to be shape-regular and quasi-uniform, and they do not need to match across the inner boundaries of the subdomains. We define h as the maximum of the mesh-sizes of the triangulations.

We next consider the lowest-order Nédélec finite element spaces, originally introduced in [24], defined on each subdomain Ω_i as

$$X_h(\Omega_i) = X_i := \{\mathbf{u}_i \in H_\star(\mathrm{curl}\,;\Omega_i)|\ \mathbf{u}_{i|_t} \in \mathcal{R}(t),\ t \in \mathcal{T}_{i,h}\},$$

where, in the case of triangular meshes, we have

$$\mathcal{R}(t) := \left\{ \left[\begin{array}{c} \alpha_1 + \alpha_3 x_2 \\ \alpha_2 - \alpha_3 x_1 \end{array} \right] \mid \alpha_k \in \mathbb{R} \right\}.$$

We recall that the tangential component of a vector $\mathbf{u}_i \in X_i$ is constant on the edges of the triangulation $\mathcal{T}_{i,h}$ and that the degrees of freedom can be chosen as the values of the tangential component on the edges

$$\lambda_{e_k}(\mathbf{u}_i) = u_k^{(i)} := \mathbf{u}_i \cdot \mathbf{t}_{e_k|_{e_k}}, \quad e_k \in \mathcal{E}_{i,h}. \tag{4}$$

We next introduce the product space

$$X_h(\Omega) = X := \prod_{i=1}^{N} X_i \subset \prod_{i=1}^{N} H_\star(\mathrm{curl}\,;\Omega_i),$$

the spaces of tangential vectors

$$W_h(\partial\Omega_i) = W_i := \{(\mathbf{u}_i \cdot \mathbf{t}_i)\,\mathbf{t}_i \text{ restricted to } \partial\Omega_i \setminus \partial\Omega\ \mid \mathbf{u}_i \in X_i\},$$

and the product space

$$W_h(\Gamma) = W := \prod_{i=1}^{N} W_i.$$

We note that we have chosen a different definition of the trace spaces than that employed in [33]. Here, the spaces W_i consist of piecewise constant tangential *vectors* on $\partial\Omega_i \setminus \partial\Omega$.

Throughout this paper, we will use the following conventions. We will use the same notation for the vectors in X_i and tangential vectors in W_i. We denote a generic vector function in X_i using a bold letter with the subscript i, e.g., $\mathbf{u}_i$, and

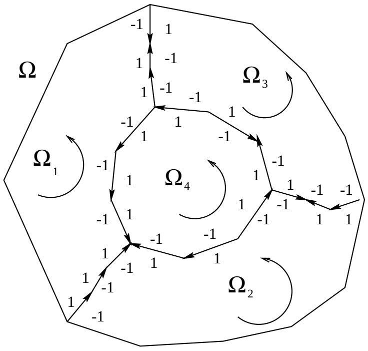

FIG. 1. *Example of a partition of the domain Ω. We show the directions of the subdomain boundaries, given by the unit vectors $\{\mathbf{t}_i\}$, those of the fine edges on the interface Γ, and the corresponding values of the degrees of freedom $t^{(i)}$.*

the column vector of its degrees of freedom, defined in (4), using the same letter with the superscript (i), e.g., $u^{(i)}$. Its kth degree of freedom corresponding to the edge e_k, defined in (4), is $u_k^{(i)}$. A generic vector in the product space X (or W) is also denoted by a bold letter, e.g., $\mathbf{u}$, and the corresponding vector of degrees of freedom by the same letter, e.g., u. We will use the same notation for the spaces of functions X_i and W_i and the corresponding spaces of degrees of freedom.

Given the unit vectors $\mathbf{t}_i$, the column vectors $t^{(i)}$ are defined by

$$t_k^{(i)} := \mathbf{t}_i \cdot \mathbf{t}_{e_k}, \quad e_k \subset \partial\Omega_i \setminus \partial\Omega, \quad e_k \in \mathcal{E}_{i,h}.$$

We will need these tangential vectors in the definition of our FETI method; see section 5. We remark that in case all the edges e_k on $\partial\Omega_i$ have the same direction of the boundary $\partial\Omega_i$, the entries of the vector $t^{(i)}$ are equal to one. Figure 1 shows an example of a partition, with the directions of the subdomain boundaries and of the fine edges on the interface Γ, and the corresponding degrees of freedom $t^{(i)}$.

Finally, for $i = 1, \dots, N$, we define the discrete harmonic extensions with respect to the bilinear forms $a_{\Omega_i}(\cdot,\cdot)$ into the interior of Ω_i:

$$\mathcal{H}_i : W_i \longrightarrow X_i.$$

We recall that $\mathcal{H}_i\mathbf{u}_i$ minimizes the energy $a_{\Omega_i}(\mathcal{H}_i\mathbf{u}_i, \mathcal{H}_i\mathbf{u}_i)$ among all the vectors of X_i with tangential component equal to $\mathbf{u}_i$ on $\partial\Omega_i \setminus \partial\Omega$.

3. A mortar condition. The mortar method presented in this section was originally developed and studied in [3]. We consider the skeleton Γ and choose a splitting of Γ as the disjoint union of some edges $\{\overline{\Gamma}^{k,j}\}$, which we call *mortars*. We note that this partition is not in general unique; see Figure 2 (left) for an example of decomposition.

A unique set of indices corresponds to this choice, and we denote it by

$$\mathcal{I}_M := \{m = (k,j) \text{ such that } \Gamma^{k,j} \text{ is a mortar }\}.$$

To simplify the notation, we denote the mortars by $\{\Gamma^m |\ m \in \mathcal{I}_M\}$. We have

$$\overline{\Gamma} := \bigcup_{i=1}^{M} \overline{\Gamma}^m, \quad \Gamma^m \cap \Gamma^n = \emptyset, \qquad \text{if } m \neq n \text{ and } n, m \in \mathcal{I}_M.$$

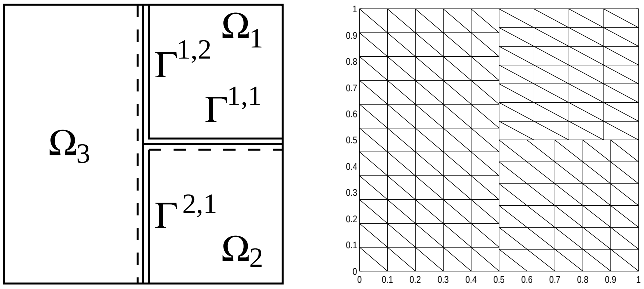

Fig. 2. *An example where the domain is decomposed into three (rectangular) nonoverlapping subdomains. The skeleton has two partitions (figure on the left): one in terms of mortars (solid dark line) and the other in terms of nonmortars (long dashed lines). On the right is an example of discretization of the subdomains by means of triangular grids that do not match at the interfaces between adjacent subdomains.*

For any m in $\mathcal{I}_M$, we denote by W^m the space $W^{k,j}$ $(m = (k, j) \in \mathcal{I}_M)$ given by

$$W^{k,j} := \{(\mathbf{u}_k \cdot \mathbf{t}_k)\, \mathbf{t}_k \text{ restricted to } \Gamma^{k,j} \ \mid \mathbf{u}_k \in X_k\}.$$

We note that the vectors in $W^{k,j}$ are also the restrictions of vectors in W_k to $\Gamma^{k,j}$. Before introducing the mortar space, we need to fix a last point. Let Γ^m be a mortar edge with $m = (k, j)$ and $\mathbf{u} \in X_h$: for almost every $\mathbf{x} \in \Gamma^m$, there exists an index l $(1 \leq l \leq N)$, $l \neq k$ such that $\mathbf{x} \in \Gamma^m \cap \partial\Omega_l$. At this point $\mathbf{x}$ we have two fields, namely, $\mathbf{u}_k$ and $\mathbf{u}_l$. Since the domain decomposition is in general nonconforming, the value of l depends on $\mathbf{x}$, and we denote by $\mathcal{J}_m$ the set of indices l $(1 \leq l \leq N)$ such that $\Gamma^m \cap \partial\Omega_l \neq \emptyset$. We then define

$$\mathbf{u}_{-k}(\mathbf{x}) := \mathbf{u}_l(\mathbf{x}), \quad \mathbf{x} \in \Gamma^m \cap \partial\Omega_l, \quad l \in \mathcal{J}_m.$$

The function $\mathbf{u}_{-k}$ is defined for almost all $\mathbf{x} \in \Gamma^m$. In general, it is not the tangential component at Γ^m of a field $\mathbf{u} \in H_\star(\mathrm{curl}\,; \Omega_i)$: it can indeed correspond to tangential components from different subdomains which share a subset of Γ^m and live on different grids.

The equality between $\mathbf{u}_{-k} \cdot \mathbf{t}_k$ and $\mathbf{u}_k \cdot \mathbf{t}_k$ at Γ^m becomes too stringent a condition since the two fields are in general defined on different and nonmatching grids. As is usually done in nonconforming mortar domain decomposition methods, we impose these constraints in a weak form by means of suitable Lagrange multipliers. Here, the Lagrange multiplier space consists of the tangential components of the shape functions at the mortar edges; see [3].

Remark 3.1. The definition of the mortar space for the edge elements is simpler than for nodal finite elements. In the nodal case, the space of Lagrange multipliers cannot be chosen as a space of traces on the mortar edges but only as a suitable subspace of it. In the edge case, it is not necessary to decrease the dimension of the multiplier space since the information is associated to edges and not to nodes; see [9] for more details.

The Lagrange multiplier (mortar) space is now defined by

$$\{\mathbf{v} \in L^2(\Gamma) \mid \mathbf{v}_{|\Gamma^m} \in W^m, \quad m \in \mathcal{I}_M\}.$$

We remark that this is a space of tangential vectors on Γ. The transmission conditions at the interface between adjacent subdomains are then weakly imposed by means of these Lagrange multipliers. A solution $\mathbf{u} \in W$ is required to satisfy the constraints

$$(5) \qquad \int_{\Gamma^m} (\mathbf{u}_k \cdot \mathbf{t}_k - \mathbf{u}_{-k} \cdot \mathbf{t}_k\,)\, \mathbf{v} \cdot \mathbf{t}_k \, ds = 0, \quad \mathbf{v} \in W^m, \quad m = (k,j) \in \mathcal{I}_M.$$

The set of transmission conditions can be expressed in matrix form in the following way.

Let $\mathbf{w}_i^k$ be the basis function associated to the kth mesh edge of $\partial\Omega_i \setminus \partial\Omega$. We introduce two matrices C and D by

$$C_{kl} := \int_{\Gamma^m} (\mathbf{w}_i^k \cdot \mathbf{t}_i)(\mathbf{w}_i^l \cdot \mathbf{t}_i)\, ds = \delta_{kl}\, |e_k|, \quad e_k, e_l \subset \Gamma^m,$$

$$D_{kn} := \int_{\Gamma^m} (\mathbf{w}_i^k \cdot \mathbf{t}_i)(\mathbf{w}_r^n \cdot \mathbf{t}_i)\, ds, \quad e_k \subset \Gamma^m, \quad e_n \subset \partial\Omega_r, \quad r \in \mathcal{J}_m,$$

where $\Gamma^m = \Gamma^{i,j}$. Then the matching conditions (5) have the form

$$Bu = 0, \qquad \text{where} \qquad B = C - D.$$

We remark that the entries of C and D depend on the particular choice of degrees of freedom defined in (4).

The matrix B can also be written as

$$B = \left[B^{(1)} \; B^{(2)} \; \cdots \; B^{(N)} \right],$$

where the local matrices $B^{(i)}$ act on vectors in W_i. The entries of B do not belong in general to $\{0, 1, -1\}$ as in the conforming case described in [33], and, since we are working with nonmatching grids, they take into account the edge intersections at the interfaces.

We conclude this section by recalling an a priori estimate of the approximation error for the mortar edge element method in two dimensions (see [3] for a proof).

Theorem 3.1. *Assume that the exact solution* $\mathbf{u}$ *of* (1) *is such that* $\mathbf{u}_i \in H^1(\Omega_i)^2$ *and* $\operatorname{curl} \mathbf{u}_i \in H^1(\Omega_i)$*, and that the data* $\mathbf{f}$ *is such that* $\mathbf{f}_i \in H^1(\Omega_i)^2$*. Then the following estimate holds:*

$$||\mathbf{u} - \mathbf{u}_h||_{*,\Omega} \le C \sum_{i=1}^{N} h_i (||\mathbf{u}_i||_{H^1(\Omega_i)^2} + ||\operatorname{curl} \mathbf{u}_i||_{H^1(\Omega_i)^2} + ||\mathbf{f}_i||_{H^1(\Omega_i)^2}),$$

where

$$||\mathbf{u} - \mathbf{u}_h||_{*,\Omega} = \left(\sum_{i=1}^{N} ||\mathbf{u} - \mathbf{u}_h||^2_{L^2(\Omega_i)^2} + ||\operatorname{curl}(\mathbf{u} - \mathbf{u}_h)||^2_{L^2(\Omega_i)} \right)^{\frac{1}{2}}.$$

4. A FETI method. In this section, we introduce a FETI method for the solution of the linear system arising from the mortar edge element approximation of problem (3).

We first assemble the local stiffness matrices, relative to the bilinear forms $a_{\Omega_i}(\cdot,\cdot)$, and the local load vectors. The degrees of freedom that are not on the interface Γ belong only to one substructure and can be eliminated in parallel by block Gaussian elimination. Let $f^{(i)}$ be the resulting right-hand sides, and let $S^{(i)}$ be the Schur complement matrices

$$S^{(i)}:\ W_i \longrightarrow W_i,$$

relative to the degrees of freedom on $\partial\Omega_i \setminus \partial\Omega$.

We recall that the local Schur complements satisfy the following property:

$$u^{(i)^t} S^{(i)} u^{(i)} = a_{\Omega_i}(\mathcal{H}_i \mathbf{u}_i, \mathcal{H}_i \mathbf{u}_i); \tag{6}$$

see, e.g., [28, 32].

Following [19, 33], we can then write our mortar problem as

$$\begin{aligned} &Su + B^t\lambda = f,\\ &Bu = 0, \end{aligned} \tag{7}$$

where

$$u := \begin{bmatrix} u^{(1)} \\ \vdots \\ u^{(N)} \end{bmatrix} \in W, \quad S := \mathrm{diag}\{\mathrm{S}^{(1)}, \dots, \mathrm{S}^{(\mathrm{N})}\}, \quad \mathrm{f} := \begin{bmatrix} f^{(1)} \\ \vdots \\ f^{(N)} \end{bmatrix}.$$

The vector λ is a Lagrange multiplier relative to the weak continuity constraint $Bu = 0$.

We remark that the $S^{(i)}$ are always invertible, and, consequently, there is no natural coarse space associated to the substructures; we are in a similar case as the one considered in [13]. We first find u from the first equation in (7) and substitute its value in the second equation. We obtain the system

$$F\lambda = d, \tag{8}$$

where

$$F := B\,S^{-1}\,B^t, \quad d := B\,S^{-1}\,f.$$

Following [19, 33, 29], we now define a preconditioner. Since we assume that the coefficients do not have any jump, we do not need to introduce a set of scaling matrices as is required for problems with coefficient jumps; see, e.g., [31, 32, 19, 33]. We introduce the matrices

$$R := \left[R^{(1)}\ R^{(2)}\ \cdots\ R^{(M)}\right], \quad G := Q\,B\,R, \tag{9}$$

where $R^{(i)}$ are vectors in W, related to the substructures $\{\Omega_i\}$, and Q is a suitable invertible matrix that we will specify in the next section. More precisely, we suppose that $R^{(i)}$ is obtained from a local vector $\mathbf{r}_i \in W_i$ on $\partial\Omega_i \setminus \partial\Omega$ by extending it by zero on the boundaries of the other substructures. We will make a particular choice of R for problem (3) in section 5 and specify the dimension M.

Following [13, 33], we define the projection

$$P := I - G(G^tFG)^{-1}G^tF$$

onto the complement of Range(G). This projection is orthogonal with respect to the scalar product induced by F. Following [19, 33], we next define the preconditioner

$$\widehat{M}^{-1} := (BB^t)^{-1}\,BSB^t\,(BB^t)^{-1}.$$

It can be easily seen that BB^t is invertible and is block-diagonal only if the partition $\mathcal{F}_H$ is geometrically conforming.

Now we consider a projected conjugate gradient method as in [13, 33].

```
1. Initialize
       $\lambda^0 = G(G^t F G)^{-1} G^t d$
       $q^0 = d - F\lambda^0$

2. Iterate $k = 1, 2, \cdots$ until convergence
       Project: $w^{k-1} = P^t q^{k-1}$
       Precondition: $z^{k-1} = \widehat{M}^{-1} w^{k-1}$
       Project: $y^{k-1} = P z^{k-1}$
       $\beta^k = \langle y^{k-1}, w^{k-1} \rangle / \langle y^{k-2}, w^{k-2} \rangle \quad [\beta^1 = 0]$
       $p^k = y^{k-1} + \beta^k p^{k-1} \quad [p^1 = y^0]$
       $\alpha^k = \langle y^{k-1}, w^{k-1} \rangle / \langle p^k, F p^k \rangle$
       $\lambda^k = \lambda^{k-1} + \alpha^k p^k$
       $q^k = q^{k-1} - \alpha^k F p^k$
```

The first projection can be omitted; because of the choice of the initial vector λ^0, we have $w^{k-1} = q^{k-1}$ after the first projection step. Here we have denoted the residual at the kth step by q^k. In practice, partial or full reorthogonalization may be required; cf. [16].

The method presented here is equivalent to using the conjugate gradient method for solving the preconditioned system

$$P\widehat{M}^{-1}P^t F\lambda = P\widehat{M}^{-1}P^t d, \quad \lambda \in \lambda_0 + V, \tag{10}$$

with

$$V := \text{Range}(P). \tag{11}$$

We remark that the matrices S and S^{-1} do not need to be calculated in practice. The action of S on a vector requires the solution of a Dirichlet problem on each substructure, while the action of S^{-1} requires the solution of a Neumann problem on each substructure; see [28, Ch. 4].

Remark 4.1. The extension of FETI-type preconditioners to the case of problems with jump coefficients on nonmatching grids appears to be hard, both for nodal and Nédélec finite elements. In the conforming case, suitable scaling diagonal matrices are employed. For each degree of freedom on the subdomain interface (a node for nodal elements or an edge for Nédélec elements), the corresponding entry is constructed with the values of the coefficients on the subdomains that share this degree of freedom; see, e.g., [19, 33]. This can certainly be generalized to the corresponding mortar methods built on *geometrically conforming partitions*. However, in the general case, an edge on the interface may belong only *partially* to a subdomain, and it is reasonable to assume that the scaling matrices should also take into account the relative size of the intersection of an edge with a subdomain boundary. Presently, it is not clear to the authors how exactly this can be accomplished, and this generalization is left for a future work.

5. A particular choice of the matrices R and Q. In this section, we consider a particular choice of the matrices R and Q in the definition of the FETI algorithm for problem (3).

We proceed in a similar way as in [33, sect. 5], but we will need to introduce a suitable matrix Q, different from the identity.

The definition of R is the same as in the conforming case (see [33, sect. 5]) and is given in terms of local vectors.

DEFINITION 5.1. *The local vectors $\{\mathbf{r}_i,\ i = 1, \dots, N\}$ with the corresponding vectors of degrees of freedom $\{r^{(i)}\}$ are the unique vectors that satisfy*

$$r^{(i)^t} v^{(i)} = \sum_{\substack{e_k \subset \partial\Omega_i \setminus \partial\Omega \\ e_k \in \mathcal{E}_{i,h}}} r_k^{(i)} v_k^{(i)} = \int_{\partial\Omega_i \setminus \partial\Omega} \mathbf{v}_i \cdot \mathbf{t}_i \, ds, \quad \mathbf{v}_i \in W_i.$$

The global vectors $R^{(i)}$ are obtained by extending the local vectors $r^{(i)}$ by zero outside $\partial\Omega_i$.

We can easily find that

$$r_k^{(i)} = |e_k| \, t_k^{(i)}, \quad e_k \subset \partial\Omega_i \setminus \partial\Omega.$$

The vectors $\mathbf{r}_i$ have then the same direction as the $\mathbf{t}_i$ and are scaled using the lengths of the edges of the triangulations $\mathcal{T}_{i,h}$.

We then define the matrix Q as

$$Q := (BB^t)^{-1}. \tag{12}$$

Remark 5.1. In the case of a conforming triangulation the matrix Q is a multiple of the identity; see [33]. For matching grids, we then obtain the same preconditioner as introduced in [33] for conforming approximations. Here our choice of Q does not require any additional calculation since $(BB^t)^{-1}$ is also needed for the application of the preconditioner $\widehat{M}^{-1}$. When Q is applied to a vector, this requires the solution of a linear system involving BB^t. The matrix BB^t is block-diagonal only in the case of conforming partitions. However, it can be shown that if the two meshes across the interface are not too different, it is strongly diagonally dominant. It is thus well conditioned, and few iterations of the conjugate gradient method are enough to obtain the solution.

The idea behind the choice of the matrix Q can be explained in the following way. In the conforming case, a proof of an upper bound for the condition number of the operator $P\widehat{M}^{-1}P^tF$ that is independent of the number of substructures is possible if certain tangential vectors have a mean value of zero on the boundary of each substructure. In particular, for the case with no jumps, it is necessary that

$$u = B^t(BB^t)^{-1}Bw$$

has mean value zero if $w \in W$ satisfies

$$\mu^t Bw = 0, \quad \mu \in \mathrm{Range}(G);$$

see [33, sect. 5]. One can show that this is not satisfied in our more general case but that this condition holds if a modified matrix G is employed,

$$\tilde{G} := QBR,$$

and our numerical results in section 6 confirm our choice of modified coarse space.

It remains to decide how many of the local vectors $R^{(i)}$ need to be considered in the definition of the matrix R. We introduce $\mathcal{G}_H$ as the dual graph of the partition $\mathcal{F}_H$. Thus $\mathcal{G}_H$ has a vertex for each substructure of $\mathcal{F}_H$, and there is an edge in $\mathcal{G}_H$ between two vertices if the intersection of the boundaries of the corresponding substructures has positive measure. As in [33], we define the matrix R by

$$R := \begin{cases} \left[R^{(1)}\; R^{(2)}\; \cdots\; R^{(N-1)}\right] & \text{if } \mathcal{G}_H \text{ is two-colorable,} \\ \left[R^{(1)}\; R^{(2)}\; \cdots\; R^{(N)}\right] & \text{otherwise .} \end{cases} \tag{13}$$

The following result can be proven using [33, Lem. 5.2 and Thm. 5.1].

LEMMA 5.1. *Let R be defined in* (13)*. Then the matrix G has full rank.*

Remark 5.2. An analogous FETI method can also be devised for problems involving the bilinear form

$$\int_\Omega (a \operatorname{div} \mathbf{u} \operatorname{div} \mathbf{v} + A\, \mathbf{u} \cdot \mathbf{v})\, d\mathbf{x}, \quad \mathbf{u}, \mathbf{v} \in H(\operatorname{div}; \Omega),$$

discretized with the lowest-order Raviart–Thomas spaces. Here, $H(\operatorname{div}; \Omega)$ is the space of vectors in $(L^2)^2$ with divergence in L^2. Since, in two dimensions, vectors in the Raviart–Thomas spaces can be obtained from those in the Nédélec spaces by a rotation of 90 degrees, the unit outward normal vectors $\mathbf{n}_i$ to the boundaries $\partial\Omega_i$, instead of the unit tangent vectors $\mathbf{t}_i$, have to be employed in the construction of the local functions $\mathbf{r}_i$. All the definitions in this paper remain valid in this case. For Raviart–Thomas discretizations in three dimensions, an analogous method can also be defined, and all our definitions remain valid.

6. Numerical results.

The purpose of this section is to show that, for problems without jumps, the FETI method proposed here performs similarly to the corresponding method for conforming approximations; see [33, sect. 6]. In particular, our method appears to be scalable, its condition number depends only on the number of degrees of freedom per subdomain, and it is quite insensitive to variations of the ratios of the coefficients.

In many iterative substructuring methods, an important role is played by the ratio H/h that measures the number of degrees of freedom per subdomain. In particular, the condition number of these methods grows only quadratically with the logarithm of H/h; see, e.g., [28]. This ratio is regarded as a local quantity and can vary greatly from one subdomain to another. In our numerical results, we always report the maximum value of this ratio taken over the subdomains.

We consider the domain $\Omega = (0, 1)^2$ and assume that the coefficient matrix A is diagonal and equal to

$$A = \begin{bmatrix} b & 0 \\ 0 & b \end{bmatrix}.$$

In our first set of results, we consider a family of geometrically conforming partitions of Ω, into $2^d \times 2^d$ substructures of equal size, with $d = 1, 2, 3, 4$. For a fixed

partition, we consider two kinds of uniform triangulations for the substructures in such a way that on the interface between two adjacent substructures the meshes do not match. The ratio between the mesh-sizes of the two triangulations is $h_1/h_2 = 4/3$. Figure 3 shows an example of this checkerboard-type discretization for $d = 2$.

We first consider the case $a = 1$ and $b = 1$. In Table 1, we show the estimated condition number and the number of iterations to obtain a relative residual $\|q_k\|/\|f\|$ less than 10^{-6} as a function of the diameter of the finer mesh and the partition. Here q_k is the kth residual as defined in the algorithmic description given in section 4. For a fixed ratio H/h, the condition number and the number of iterations are quite insensitive to the dimension of the fine meshes. In addition, even for nonmatching

Table 2

The FETI method for conforming partitions with $h_1/h_2 = 4/3$. Estimated condition number and number of CG iterations necessary to obtain relative preconditioned residual ($\|q_k\|/\|f\|$) less than 10^{-6} (in parentheses), versus H/h and b. Case of $1/h = 128$ and $a = 1$.

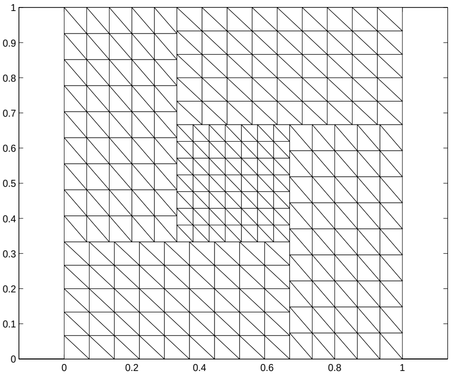

Fig. 5. *A block consisting of five subdomains, employed for building a nonconforming partition.*

grids, the ratio H/h appears to play an important role; see also Figure 4.

In Table 2, we show some results when the ratio of the coefficients b and a changes. For a fixed value of $1/h = 128$ and $a = 1$, and for the partitions into 2^d by 2^d substructures with $d = 2, 3, 4$, the estimated condition number and the number of iterations are shown as a function of H/h and b. The number of iterations and the condition number appear to be bounded independently of the ratio of the coefficients.

We then consider some test cases relative to geometrically nonconforming partitions of the domain $(0, 1)^2$. We consider partitions consisting of $2^d \times 2^d$ equal blocks, $d = 0, 1, 2, 3$. A block is made of five nonconforming subdomains and is shown in Figure 5 together with a possible triangulation. Figure 6 shows a partition for the case $d = 1$ (four blocks and twenty subdomains). The number of subdomains is five times the number of blocks. We then consider uniform triangulations for the subdomains in each block. The rectangular subdomains have the same mesh.

We first consider a case where the ratio between the mesh sizes of the rectangular and square subdomains is $h_1/h_2 = 7/5$; see Figures 5 and 6 for two examples. In Table 3, we show the estimated condition number and the number of iterations to obtain a relative residual $\|q_k\|/\|f\|$ less than 10^{-6} as a function of the diameter of the finer mesh and the ratio H/h. The condition number appears to increase slowly with H/h and to be quite insensitive to the size of the fine meshes.

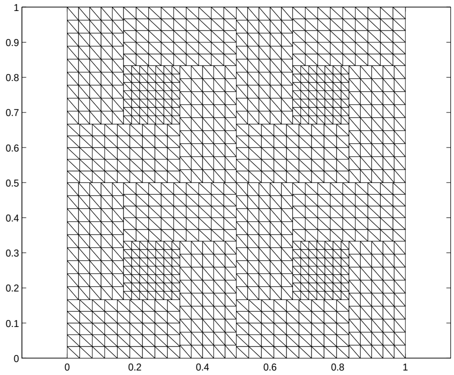

FIG. 6. *A nonconforming partition consisting of four blocks.*

TABLE 3

The FETI method for nonconforming partitions with $h_1/h_2 = 7/5$. Estimated condition number and number of CG iterations necessary to obtain a relative residual $\|q_k\|/\|f\|$ less than 10^{-6} (in parentheses), versus H/h and h. Case of $a = 1$, $b = 1$.

H/h	20	10	5
$1/h = 21$ (1832 el.)	-	2.728 (8)	2.63 (10)
$1/h = 42$ (7328 el.)	3.459 (8)	3.23 (11)	2.876 (10)
$1/h = 84$ (29312 el.)	4.034 (13)	3.619 (12)	2.901 (10)
$1/h = 168$ (117248 el.)	4.552 (14)	3.619 (12)	*

In Table 4, we show some results when the ratio of the coefficients b and a changes. For a fixed value of $1/h = 84$ (29312 elements) and $a = 1$, and for the partitions into 2^d by 2^d blocks with $d = 1, 2, 3$, the estimated condition number and the number of iterations are shown as a function of H/h and b.

For the same nonconforming partitions, we finally consider a case where the ratio between the diameters of the meshes of the rectangular and square subdomains is larger. We choose $h_1/h_2 = 2.8$. In Table 5, we show some results when the ratio of the coefficients b and a changes. For a fixed value of $1/h = 168$ (48128 elements) and $a = 1$, and for the partitions into 2^d by 2^d blocks with $d = 1, 2, 3$, the estimated condition number and the number of iterations are shown as a function of H/h and b. In this case, the meshes of adjacent substructures are fairly different, but the condition numbers and the number of iterations are still quite satisfactory.

To end this section, we give an upper bound for the condition number of the proposed method, both in the cases of conforming and nonconforming partitions. Figure 4 shows the estimated condition numbers (asterisk) from Tables 1 (left) and 3 (right) for $a = b = 1$ as a function of $\rho = H/h$ for different values of n. We have also plotted the best second-order logarithmic polynomial least-square fits. Our results for both conforming and nonconforming partitions are consistent with the bound for the condition number

$$\kappa(P\widehat{M}^{-1}P^tF) \leq C\left(1 + \log\frac{H}{h}\right)^2,$$

which was proven in [33, Thm. 5.2] for conforming approximations, and suggest that this bound is sharp.

AMGe BASED ON ELEMENT AGGLOMERATION*

JIM E. JONES† AND PANAYOT S. VASSILEVSKI†

Abstract. This paper contains the main ideas for an AMGe (algebraic multigrid for finite elements) method based on element agglomeration. In the method, coarse grid elements are formed by agglomerating fine grid elements. Compatible interpolation operators are constructed which yield coarse grid basis functions with a minimal energy property. Heuristics based on interpolation quality measures are used to guide the agglomeration procedure. The performance of the resulting method is demonstrated in two-level numerical experiments.

Key words. algebraic multigrid, element agglomeration, algebraic coarsening, implementation

1. Introduction.

The algebraic multigrid (AMG) [5], [6], [13], [14], was developed as a generalization of the standard geometric multigrid to problems that either had no grid or were posed on unstructured grids where standard geometric multigrid methods are difficult to apply. The standard AMG method works well for many problems; however, its performance on some finite element problems is unsatisfactory. The heuristics used in the standard AMG method are based on properties of M-matrices, and finite element discretizations can produce non-M-matrices. This deficiency in the standard AMG method led Brezina et al. [7] to develop the algebraic multigrid for finite elements (AMGe). This previous paper showed how to use multigrid convergence theory and the local stiffness matrices for the individual finite elements to produce interpolation operators superior to those produced by standard AMG. This current paper uses AMGe ideas to produce not only interpolation operators but coarse grids (and elements) as well. The coarse elements are based on agglomeration of fine elements. A key point is the construction of a local, compatible interpolation operator. The interpolation is local in the sense that degrees of freedom (dofs) in an agglomerate interpolate only from other dofs in the same agglomerate. The interpolation is compatible in that the interpolation to dofs shared by two or more agglomerates is uniquely defined. In this way, the coarse element matrices are variationally related to the assembled matrices in a given agglomerated element, and (due to the compatibility) the global coarse matrix is variationally obtained from the global fine grid matrix.

In the remainder of this introductory section, we outline the proposed agglomeration AMGe method. The goal is to solve a system

$$A\mathbf{u} = \mathbf{f},$$

where A is the positive definite matrix arising from a finite element discretization. In the agglomeration AMGe method, we assume that we have access to the individual

element matrices. Our goal is to produce the components needed for a two-level solver: a coarse grid, grid transfer operators, and the coarse grid operator. In order to apply the method recursively (i.e., multigrid as opposed to two-level), individual element matrices on the coarse level must be produced. These goals are outlined below.

- *Given information.*
  1. A list $\mathcal{D}_f = \{d\}$ of the fine grid dofs.
  2. A list $\mathcal{E}_f$ of fine grid elements $\{e\}$, where each element e, by definition, is a list of dofs, i.e., $e = \{d_1,\ d_2, \dots,\ d_{n_e}\}$. Typically, $\mathcal{E}_f$ provides an overlapping partition of the set $\mathcal{D}_f$.
  3. The element matrices A_e, i.e., a list of $n_e \times n_e$ real numbers associated with the dofs of $e = \{d_1,\ d_2, \dots,\ d_{n_e}\}$. Equivalently, one may say that a quadratic form $a_e(\mathbf{v},\ \mathbf{v}) = \mathbf{v}_e^T A_e \mathbf{v}_e$ is given, where $\mathbf{v}$ is a vector (or discrete function) defined on $\mathcal{D}_f$ restricted to e; i.e.,

$$\mathbf{v}_e = \mathbf{v}\big|_e = \begin{bmatrix} v(d_1) \\ v(d_2) \\ \vdots \\ v(d_{n_e}) \end{bmatrix}.$$

     Note that this will be the notation consistently used throughout this paper, namely, for any subset $\Omega \subset \mathcal{D}$ and a vector $\mathbf{v}$ defined on $\mathcal{D}$ we will denote by $\mathbf{v}_\Omega = \mathbf{v}|_\Omega$ the restriction of $\mathbf{v}$ to Ω. When it simplifies the notation, we will sometimes use superscripts instead of subscripts with the same meaning (restriction to subset).
- *Output coarse information.*
  1. A coarse set of dofs, $\mathcal{D}_c \subset \mathcal{D}_f$.
  2. A set of coarse elements $\mathcal{E}_c = \{E_c\}$, i.e., an overlapping partition of $\mathcal{D}_c$.
  3. The coarse element matrices A_{E_c} for each $E_c \in \mathcal{E}_c$.
  4. An interpolation mapping $P:\ \mathcal{D}_c \mapsto \mathcal{D}_f$ such that

$$P = \begin{bmatrix} P_c^f \\ I \end{bmatrix} \begin{matrix} \}\mathcal{D}_f \setminus \mathcal{D}_c \\ \}\mathcal{D}_c \end{matrix}.$$

To be specific, assume that our "algebraic" elements (i.e., a list of collections $\{e\}$ of dofs) come from a finite element triangulation of a three-dimensional (3D) domain and respective conforming finite element spaces with nodal dofs. To create the coarse information we propose the following steps.

- Create a set of agglomerated elements $\mathcal{E} = \{E\}$, where each $E = e_1 \cup e_2 \cup \cdots \cup e_{n_E}$, $e_i \in \mathcal{E}_f$, and E is a connected set. By connected we mean that for any two elements, $e_i, e_j \in E$, there exists a connecting path of elements also in E beginning with e_i and ending with e_j such that consecutive elements in the path have nonempty intersection. This is a result of the "topological" algorithm used in the agglomeration procedure (Algorithm 4.1). Note that each fine grid element e should belong to a unique agglomerated element.
- Define faces and vertices of the agglomerated elements as follows.
  1. Consider all intersections $E_i \cap E_j$ for all pairs of different agglomerated elements E_i and E_j. An intersection of this type is called a face if it is a maximal one, i.e., if it is not contained in any other intersection. This defines the set of faces $\mathcal{F} = \{F\}$. We will also assume that a list of boundary faces $\partial\mathcal{D}$ will be given, and we will append them to $\mathcal{E}_f$. A

formal definition of a boundary face is then simply a maximal set of the type $E \cap \partial\mathcal{D}$, i.e., it is not a proper subset of any other intersection set (either of type $E_i \cap E_j$ or of type $E_i \cap \partial\mathcal{D}$).

2. Finally, consider all faces $F \in \mathcal{F}$ as lists of dofs. For each dof d compute the intersection $\cap\{F :\ d \in F\}$. The minimal (nonempty) intersections define the set of vertices $\mathcal{V} = \{V\}$.

For true finite element applications the last set of vertices will be disjoint sets; each vertex may contain more than one dof. This is the case if the underlying problem is a finite element discretization of a system of PDEs, such as elasticity, for example. For 3D problems, one may refine the above algorithm to create edges of the agglomerated elements; edges are defined to be maximal intersections of faces. In order to keep the presentation simple, we will focus mostly on two-dimensional (2D) problems.

At any rate, the above "topological" information (faces and vertices of elements) is readily provided by most of the finite element grid generators. So one may assume that this information is given on the fine grid. If not, one can create it as explained above based on computing, for faces, the maximal intersection sets of the type $e_i \cap e_j$, $e_i \neq e_j$ or of the type $e_i \cap$ boundary surface.

In order to generate the same information on a coarse level, it can be advantageous to carry out the intersection sets algorithm by preserving the dimensionality (or topology) in the following sense. If E is an agglomerated element, one has the option to represent E either in terms of the dofs of the original elements or in terms of the faces of the original elements. If the agglomerated elements and the boundary surfaces $\partial\mathcal{D}$ are represented in terms of the faces of the original elements, then all nonempty intersections of the type $E_i \cap E_j$ or $E_i \cap \partial\mathcal{D}$ are maximal. This is the storage (agglomerated elements in terms of faces of elements) that we use in practice.

Definition 1.1 (coarse dofs). *Having computed the set of vertices, we define our (minimal) coarse set of dofs to be those dofs which are contained in a vertex of an agglomerated element:*

$$\mathcal{D}_c = \{d \in \mathcal{D}_f :\ \exists V \in \mathcal{V} \text{ with } d \in V\}.$$

Note that in practice, one may have to enrich the minimal (vertex) set of coarse dofs for better performance.

Figure 1 shows the coarse dofs for a 2D scalar problem. Note that for a scalar problem, vertex and degree of freedom are synonymous.

Definition 1.2 (coarse elements). *For each agglomerated element E, we define a coarse element E_c consisting of dofs contained in a vertex of E, i.e.,*

$$E_c = \mathcal{D}_c \cap E.$$

For each agglomerated element E (or, equivalently, for each coarse element E_c), we construct a local interpolation operator P_E. This operator maps a vector defined at coarse dofs in E_c to a vector defined at the fine dofs in E. We require the set of local interpolation operators be compatible in that if $d \in E_1 \cap E_2$, then $P_{E_1}\mathbf{v}_{E_1^c}(d) = P_{E_2}\mathbf{v}_{E_2^c}(d)$ for all vectors $\mathbf{v}$. In other words, compatibility means that at shared dofs, the interpolation rules for the agglomerates must agree. Compatibility implies the following restriction.

Requirement 1.1. For $d \in \mathcal{D}_f$, let $N(d) = \cap\{$all agglomerated elements $E(d)$ that contain $d\}$. Then the value $v(d)$ must be interpolated from the dofs at the vertices of $N(d)$. Note that we assume interpolation is the identity at the vertices.

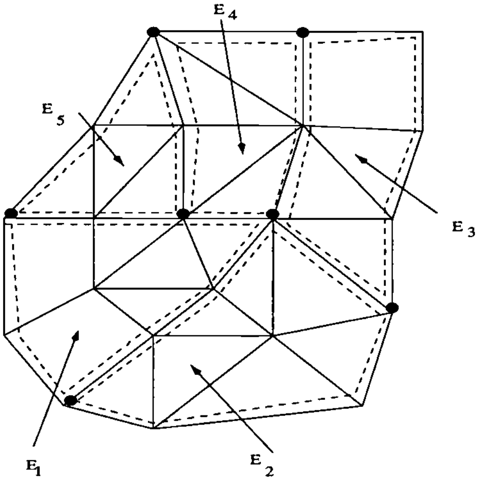

FIG. 1. *Triangulation of domain Ω into triangular and quadrilateral fine grid elements. Agglomerated elements $E_1, E_2, \dots, E_5$ and coarse dofs.*

DEFINITION 1.3 (interpolation mapping). *Having constructed a compatible set of local interpolation mappings $\{P_E\}$, define a global mapping $P : \mathcal{D}_c \mapsto \mathcal{D}$ by $P\mathbf{v}_c|_E \equiv P_E \mathbf{v}_{E_c}$. Compatibility implies that this uniquely defines P.*

DEFINITION 1.4 (coarse element matrices). *Assume that a compatible set of interpolation operators $\{P_E\}$ has been computed. Let A_E be the assembled matrix corresponding to the agglomerated element $E = e_1 \cup e_2 \cup \cdots \cup e_{n_E}$ defined by*

$$\mathbf{v}_E^T A_E \mathbf{w}_E \equiv \sum_{i=1}^{n_E} \mathbf{v}_{e_i}^T A_{e_i} \mathbf{w}_{e_i} \quad \text{for any } \mathbf{v}_E,\ \mathbf{w}_E. \tag{1.1}$$

Then, the coarse element matrix for the coarse element E_c is defined by

$$A_E^c \equiv P_E^T A_E P_E. \tag{1.2}$$

Note that the global coarse (stiffness) matrix A^c defined as

$$A^c = P^T A P$$

can be assembled from the coarse element matrices, i.e., that

$$\mathbf{v}_c^T A^c \mathbf{w}_c = \sum_{i=1}^{n_c} \mathbf{v}_{E_i^c}^T A_{E_i}^c \mathbf{w}_{E_i^c}.$$

Indeed, for $E_i = \bigcup_{j=1}^{n_{E_i}} e_i^j$,

$$\begin{aligned}
\sum_{i=1}^{n_c} \mathbf{v}_{E_i^c}^T A_{E_i}^c \mathbf{w}_{E_i^c} &= \sum_{i=1}^{n_c} (P_{E_i} \mathbf{v}_{E_i^c})^T A_{E_i} (P_{E_i} \mathbf{w}_{E_i^c}) \\
&= \sum_{i=1}^{n_c} (P\mathbf{v}_c|_{E_i})^T A_{E_i} (P\mathbf{w}_c|_{E_i}) \\
&= \sum_{i=1}^{n_c} \sum_{j=1}^{n_{E_i}} (P\mathbf{v}_c|_{e_i^j})^T A_{e_i^j} (P\mathbf{w}_c|_{e_i^j}) \\
&= \sum_{i=1}^{n_f} (P\mathbf{v}_c|_{e_i})^T A_{e_i} (P\mathbf{w}_c|_{e_i}) \\
&= \mathbf{v}_c^T P^T A P \mathbf{w}_c.
\end{aligned}$$

We should mention at this point that there are other approaches of constructing AMG methods that target non-M-matrices. One example is the aggregation based AMG of Vanek, Mandel, and Brezina [15]. In this method, one constructs aggregates (nonoverlapping partitions of the dofs) and forms a generally unstable (but simple) tentative prolongator. Finally, a smoothing step is applied in order to get a better quality interpolation. In Wan, Chan, and Smith [17], a direct approach of constructing coarse bases is proposed. The bases are selected by minimizing a quadratic energy functional while enforcing locality and a partition of unity property. In Mandel, Brezina, and Vanek [12], this approach was further developed by proposing fast algorithms for minimizing the quadratic functional. In Chan, Xu, and Zikatanov [9], the construction of the agglomerated elements is used a posteriori in the sense that one first selects a coarse grid (as a maximal independent set) and then agglomerated elements are constructed (based on the dual matrix graph). The agglomerates are subsequently divided into triangles, and the procedure can be recursively applied. The interpolation weights are computed based on averaging. In that sense, the present paper substantially differs from [9]. Our agglomeration algorithm is different (the coarse dofs are selected after the agglomeration is performed), and we assume more information. Namely, similar to the original AMGe paper [7], we require access to the individual elements and the respective element matrices on the fine grid. Note that this information is readily provided by most finite element grid generators. In contrast to [7] we are able to more systematically generate the input information (elements and their respective element matrices) on the coarse levels. This allows straightforward recursive use of the same two-level algorithm.

The remainder of the present paper is organized as follows. In section 2 we consider the construction of the local interpolation mappings based on a minimal energy principle. Section 3 deals with the energy minimization property of the coarse basis. In section 4, we specify an algorithm for agglomerating elements, which provides nicely matched agglomerated elements for structured triangular or quadrilateral meshes. We also discuss using measures of interpolation quality to guide the agglomeration procedure yielding semicoarsening for problems with anisotropy. In the final section, the performance of the resulting method is demonstrated in two-level numerical experiments.

2. The local interpolation mappings.

In this section we present an algorithm for generating the local interpolation mappings in a way that produces coarse grid basis functions with a quasi-minimal energy property. Most of the proofs in this section rely on basic properties of Schur complements of symmetric positive semidefinite matrices. A summary of these properties can be found, for example, in [1, section 3.2]. The problems that we target are second-order scalar elliptic problems without the low-order term as well as elasticity in two and three dimensions.

We begin by defining, for each fine grid dof d, the following sets:

- a neighborhood $\Omega(d) = \cup\{$all agglomerated elements $E(d)$ that contain $d\}$;
- a minimal set $N(d) = \cap\{$all agglomerated elements $E(d)$ that contain $d\}$.

Note that $N(d)$ can be a vertex, a face, or even an agglomerated element. From the definition of vertices, each $N(d)$ contains at least one vertex. Note also that there might be multiple copies of $N(d)$, i.e., $N(d_i) = N(d_j)$ for a $d_i \neq d_j$. We next introduce the following definition for the boundary of the sets $N(d)$.

Definition 2.1. *For any set $N(d)$ different than a face or an agglomerated element, define the boundary of $N(d)$, denoted $\partial N(d)$, to be the vertices contained in $N(d)$ (which is a nonempty set). If $N(d)$ is a face of an agglomerated element, define*

$\partial N(d)$ as the dofs in $N(d)$ that belong to more than one face. Finally, if $N(d)$ is an agglomerated element E, define the boundary, ∂E, as the union of all faces of E.

We now describe the construction of the local and compatible interpolation mappings. The set of interpolatory coarse dofs $d_1^c, \ldots, d_p^c$ that will be used to interpolate to d is constructed according to Requirement 1.1. That is, $d_1^c = d$ if d belongs to a vertex; otherwise, the interpolatory coarse dofs are the vertices of the set $N(d)$.

To define the interpolation weights for a dof d we use the following recursive procedure. The interpolation is the identity at the vertices. Then, for the set $N(d)$ assume that the interpolation at the dofs on $\partial N(d)$ has already been defined, i.e., $(P\mathbf{v}_c)|_{\partial N(d)}$ is well defined for $\mathbf{v}_c$ specified at the vertices of $N(d)$. Now extend the definition of $P\mathbf{v}_c$ on $N(d) \setminus (\partial N(d))$ by considering the neighborhood $\Omega(d)$ of all agglomerated elements that contain d. Let $A_{\Omega(d)}$ be the assembled matrix corresponding to all elements contained in that neighborhood. Consider the following two-by-two block structure of $A_{\Omega(d)}$, corresponding to the partitioning $(\Omega(d) \setminus \partial N(d)) \cup \partial N(d)$,

$$A_{\Omega(d)} = \begin{bmatrix} A_{ii} & A_{ib} \\ A_{bi} & A_{bb} \end{bmatrix} \begin{matrix} \}\Omega(d) \setminus \partial N(d), \\ \}\partial N(d). \end{matrix}$$

Here "i" stands for interior, and "b" stands for boundary dofs. Note that $\{d_1^c, \ldots, d_p^c\} \subset \partial N(d)$. The interpolation coefficients $w_{d,\, d_i^c}$, $i = 1, 2, \ldots, p$ are obtained by solving the following equation ($\mathbf{x}^c$ given):

$$A_{ii}\mathbf{x}^i + A_{ib}(P\mathbf{x}^c)_{\partial N(d)} = 0.$$

Then the equation corresponding to a dof d_f in $N(d) \setminus \partial N(d)$ gives

$$(\mathbf{x}^i)_{d_f} = \left(-A_{ii}^{-1}A_{ib}(P\mathbf{x}^c)_{\partial N(d)}\right)\big|_{d_f}.$$

That is, in particular for $d_f = d$, and $\mathbf{x}^c = \left[\begin{smallmatrix} 0 \\ 1 \end{smallmatrix}\right] \begin{smallmatrix} \}\text{vertices of } N(d)\setminus\{d_i^c\}, \\ \}d_i^c \end{smallmatrix}$, one gets the interpolatory coefficient

$$w_{d,\, d_i^c} = \left(-\, A_{ii}^{-1}A_{ib} \left(P \begin{bmatrix} 0 \\ 1 \end{bmatrix} \begin{matrix} \}\text{vertices of } N(d) \setminus \{d_i^c\} \\ \}d_i^c \end{matrix} \right)_{\partial N(d)} \right) \Bigg|_d .$$

This approach assumes that A_{ii} is invertible. As the following lemma shows, this is always the case for symmetric positive semidefinite matrices $A_{\Omega(d)}$ if the set of boundary dofs $\partial N(d)$ is sufficiently rich.

Lemma 2.2. *Given a set E, a union of fine elements, partition it into two groups: "f"-dofs denoted by $\mathcal{D}_{E,\, f}$ and "c"-dofs denoted $\mathcal{D}_{E,\, c}$. Let A_E be the assembled matrix corresponding to E partitioned as follows:*

$$A_E = \begin{bmatrix} A_{E,\, ff} & A_{E,\, fc} \\ A_{E,\, cf} & A_{E,\, cc} \end{bmatrix}.$$

If there exists a basis $\{\mathbf{d}_i\}$ for the null-space of the assembled, symmetric positive semidefinite matrix A_E, such that $\{\mathbf{d}_i\}$ restricted to $\mathcal{D}_{E,\, c}$ remain linearly independent, then $A_{E,\, ff}$ is invertible.

Proof. Assume that $A_{E,\, ff}\mathbf{x}^f = 0$. This implies that

$$\begin{bmatrix} \mathbf{x}^f \\ 0 \end{bmatrix}^T A_E \begin{bmatrix} \mathbf{x}^f \\ 0 \end{bmatrix} = 0,$$

and since A_E is positive semidefinite, this implies

$$A_E \begin{bmatrix} \mathbf{x}^f \\ 0 \end{bmatrix} = 0.$$

That is, $\left[\begin{smallmatrix} \mathbf{x}^f \\ 0 \end{smallmatrix}\right]$ is in the null-space of A_E. Therefore, we can expand it in terms of the basis of the null-space, i.e.,

$$\begin{bmatrix} \mathbf{x}^f \\ 0 \end{bmatrix} = \sum_i c_i \mathbf{d}_i.$$

The second block equation implies

$$0 = \sum_i c_i \mathbf{d}_i^c.$$

The assumption that $\{\mathbf{d}_i\}$ remains linearly independent when restricted to $\mathcal{D}_{E,\,c}$ means that $\{\mathbf{d}_i^c\}$ are linearly independent. Thus all $c_i = 0$ and $\mathbf{x}^f = 0$. That is, $A_{E,\,ff}\mathbf{x}^f = 0$ implies $\mathbf{x}^f = 0$; hence $A_{E,\,ff}$ is invertible. □

Remark 2.1. For the model case of second-order scalar elliptic equations, $\mathcal{L}u \equiv -\operatorname{div}(a\nabla u) = F$, a basis of the null-space of A_E is $\begin{bmatrix} 1 \\ \vdots \\ 1 \end{bmatrix}$, and its restriction onto the set of coarse dofs is again the constant vector; hence it is linearly independent. The above lemma shows that the corresponding $A_{E,\,ff}$ will be invertible.

Remark 2.2. If $\mathbf{x}$ is in the null-space of A_E, i.e.,

$$\mathbf{x} = \begin{bmatrix} \mathbf{x}^f \\ \mathbf{x}^c \end{bmatrix} \text{ and } A_E\mathbf{x} = 0,$$

then

$$A_{E,\,ff}\mathbf{x}^f + A_{E,\,fc}\mathbf{x}^c = 0.$$

Thus the previously defined interpolation procedure is exact for vectors in the null-space of A_E.

In showing that the interpolation mappings produce coarse basis functions enjoying a certain energy minimization property, we rely on the following relationships between energy minimization and Schur complements.

Remark 2.3. Consider a matrix A with any two-by-two blocking

$$A = \begin{bmatrix} A_{ff} & A_{fc} \\ A_{cf} & A_{cc} \end{bmatrix}.$$

Assume A_{ff} is invertible, and define the Schur complement of A on c as $S_c \equiv A_{cc} - A_{cf}A_{ff}^{-1}A_{fc}$. If A is symmetric positive semidefinite, then

$$\mathbf{v}_c^T S_c \mathbf{v}_c = \inf_{\mathbf{v}|_c = \mathbf{v}_c} \mathbf{v}^T A \mathbf{v}. \tag{2.1}$$

In cases where A_{ff} is not invertible, (2.1) can be used to define the Schur complement. Note that if A is symmetric positive semidefinite, then so is S_c. Finally, one has the identity

$$A\mathbf{v} = \begin{bmatrix} 0 \\ S_c\mathbf{v}_c \end{bmatrix} \tag{2.2}$$

for any minimizer $\mathbf{v}$, i.e., for any vector $\mathbf{v}$ for which $\mathbf{v}_c^T S_c \mathbf{v}_c = \mathbf{v}^T A \mathbf{v}$ and $\mathbf{v}|_c = \mathbf{v}_c$. The following lemma is a straightforward consequence of Remark 2.3.

LEMMA 2.3. *Using the notation of the previous remark, assume A_{ff} is invertible, and let $\mathbf{v}_c$ be a null-vector of S_c; then $\mathbf{v}_c$ can be uniquely extended to the null-space of A.*

We are now ready to show several energy minimization properties of the local interpolation mappings P_E formulated for simplicity for 2D elements.

We first demonstrate an energy minimization property for dofs interior to an agglomerated element. Let d belong to a unique agglomerated element E. Thus the neighborhood $\Omega(d)$, used to define interpolation, consists of the fine-grid elements that are contained in E. Then, $P = P_E$ is constructed based on the following block-ordering of A_E:

$$A_E = \begin{bmatrix} A_{ii} & A_{ib} \\ A_{bi} & A_{bb} \end{bmatrix} \begin{matrix} \} & E \setminus \partial E, \\ \} & \partial E. \end{matrix}$$

The coefficients of P_E are obtained by solving the equation ($\mathbf{x}^c$ given)

$$A_{E,\, ii}\mathbf{x}^i + A_{E,\, ib}(P_E \mathbf{x}^c)_{\partial E} = 0.$$

It is equivalent then to say that $\mathbf{x}^i = -A_{ii}^{-1} A_{ib}(P_E \mathbf{x}^c)$ solves the minimization problem

$$\min_{\mathbf{x}:\ \mathbf{x}|_{\partial E} = (P_E \mathbf{x}^c)_{\partial E}} \mathbf{x}^T A_E \mathbf{x}. \tag{2.3}$$

By definition, $P_E \mathbf{x}_c|_d = -\left. A_{ii}^{-1} A_{ib}(P_E \mathbf{x}^c)_{\partial E}\right|_d$ for all $d \in E$ that do not belong to a face of E.

We next show an energy minimization property for dofs on faces; this is used later to show a global energy minimization property of the coarse grid basis functions. For every face F, the neighborhood used to define interpolation is $E_F^+ \cup E_F^-$, where E_F^+ and E_F^- are the two neighboring agglomerated elements that form the face F (one of them can be $\emptyset$ if F is a boundary face).

LEMMA 2.4. *For every face $F = E_F^+ \cap E_F^-$, the interpolation P minimizes the quadratic form $(\mathbf{w}_F)^T(S_{E_F^+,\, F} + S_{E_F^-,\, F})\mathbf{w}_F$ for $\mathbf{w}_F$ fixed at the vertices of F, where $S_{E,\, F}$ denotes the Schur complement of A_E on F.*

Proof. Denote $E_1 = E_F^-$ and $E_2 = E_F^+$. Each dof on F which is not a vertex is interpolated from the vertices of F based on the assembled matrix $A_{E_1 \cup E_2}$ corresponding to the domain $E_1 \cup E_2$. To define P on F, one looks at the matrix

$$A_{E_1 \cup E_2} = \begin{bmatrix} A_{ff} & A_{fc} \\ A_{cf} & A_{cc} \end{bmatrix} \begin{matrix} \}E_1 \cup E_2 \setminus (\text{ vertices of } F), \\ \}(\text{ vertices of } F). \end{matrix}$$

Then $(P\mathbf{v}^c)(d_f) = (-A_{ff}^{-1} A_{fc}\mathbf{v}^c)(d_f)$ for any $d_f \in F \setminus (\text{ vertices of } F)$. Equivalently, from the equations that define P on F,

$$A_{ff}\mathbf{w}^f + A_{fc}\mathbf{w}^c = 0,$$

one can eliminate the dofs that are on $E_1 \cup E_2 \setminus F$, thus ending up with the Schur complement problem

$$S_{E_1 \cup E_2,\, F}\mathbf{w}^F|_{F \setminus (\text{ vertices of } F)} = 0, \quad \mathbf{w}^F = \begin{bmatrix} \mathbf{w}^f \\ \mathbf{w}^c \end{bmatrix} \begin{matrix} \}F \setminus (\text{ vertices of } F), \\ \}\text{ vertices of } F. \end{matrix} \tag{2.4}$$

Since F is a separator for $E_1 \cup E_2$, one has that $S_{E_1 \cup E_2,\, F} = S_{E_1,\, F} + S_{E_2,\, F}$. Since $S_{E_1 \cup E_2,\, F}$ is symmetric semidefinite, (2.4) is equivalent to the following minimization problem:

$$\inf_{\mathbf{w}^F|_{\text{vertices of } F} = \mathbf{w}^c} (\mathbf{w}^F)^T S_{E_1 \cup E_2,\, F} \mathbf{w}^F.$$

By definition $\mathbf{w}^F = P\mathbf{w}^c$ solves (2.4) and thus has this equivalent minimization property. □

Throughout the remainder of the paper we will assume the following relations between the null-spaces of the assembled matrices A_{E_-} and A_{E_+} for any two neighboring agglomerated elements E_- and E_+ that share a common face F.

Assumption 2.1. For any $\mathbf{x}_{E_-}$ such that $A_{E_-}\mathbf{x}_{E_-} = 0$ there is an extension $\mathbf{x}$ of $\mathbf{x}_{E_-}$ defined on $E_- \cup E_+$ such that $A_{E_- \cup E_+}\mathbf{x} = 0$ and $\mathbf{x}|_{E_-} = \mathbf{x}_{E_-}$. Equivalently, $A_{E_+}\mathbf{x}_{E_+} = 0$ and $\mathbf{x}|_F = \mathbf{x}_{E_-}|_F$.

As a corollary of the above assumption, the respective Schur complements $S_{E_-;\, F}$ and $S_{E_+;\, F}$ of A_{E_-} and A_{E_+} on the face F are spectrally equivalent or, equivalently, have the same null-space.

Actually, the following local estimates hold.

Lemma 2.5. *Assume, in addition to Assumption* 2.1*, that every null-vector* $\mathbf{v}$ *of* A_E *restricted to a face* F *of* E *is uniquely determined from its vertex values* $\mathbf{v}_c$ *on* F*. Note that this is always the case if the set of coarse dofs on any* F *is sufficiently rich (see Lemma* 2.2*). If we have determined* $\mathbf{x} = P_E\mathbf{x}_c$ *first on* ∂E *and then in the interior of* E *as specified above, the local quadratic forms*

$$(P_E\mathbf{x}_c)^T A_E P_E \mathbf{x}_c, \quad \inf_{\mathbf{x}:\ \mathbf{x}|_{\mathcal{D}_c} = \mathbf{x}_c} \mathbf{x}^T A_E \mathbf{x}$$

are spectrally equivalent. That is, there exists a constant η_E *such that*

$$\inf_{\mathbf{x}:\ \mathbf{x}|_{\mathcal{D}_c} = \mathbf{x}_c} \mathbf{x}^T A_E \mathbf{x} \le (P_E\mathbf{x}_c)^T A_E P_E \mathbf{x}_c \le \eta_E \inf_{\mathbf{x}:\ \mathbf{x}|_{\mathcal{D}_c} = \mathbf{x}_c} \mathbf{x}^T A_E \mathbf{x}.$$

In other words, the coarse element matrix $A^c_{E_c}$ *and the Schur complement* S_c *of* A_E *on* $\mathcal{D}_c \cap E$ *are spectrally equivalent.*

Proof. To prove the result it is sufficient to show that both matrices have the same null-space. Assume now that $S_c\mathbf{x}_c = 0$. For any face F of E one can compute the Schur complement of S_c on F denoted by $S_{c,\, F}$. It is clear then (see (2.2)) that

$$S_{c,\, F}\mathbf{x}_{c,\, F} = 0. \tag{2.5}$$

Our goal is to show that $(P_E)^T A_E P_E \mathbf{x}_c = 0$, which is equivalent to $A_E(P_E\mathbf{x}_c) = 0$. By construction, one has $A_E(P_E\mathbf{x}_c) = 0$ in the interior of E. Also, from the definition of P_E for dofs on faces F (see (2.4)) one has

$$\left(S_{E,F} + S_{E_+,F}\right)(P_E\mathbf{x}_c)_F|_{F \setminus \text{vertices of } F} = 0.$$

Here, E_+ is the neighboring element to E which shares a common face F with E. From Assumption 2.1 it follows that $S_{E,F} + S_{E_+,F}$ and $S_{E,F}$ have the same null-space. Therefore, their respective Schur complements on the vertices of F ($F \cap \mathcal{D}_c$), $\sigma_{c,\, F}$ and $S_{c,\, F}$ will have the same null-space. Then (2.5) implies that $\sigma_{c,\, F}\mathbf{x}_{c,\, F} = 0$. Applying identity (2.2) (based on Lemma 2.4) yields

$$\left(S_{E,F} + S_{E_+,F}\right)(P_E\mathbf{x}_c)_F = \begin{bmatrix} 0 \\ \sigma_{c,\, F}\mathbf{x}_{c,\, F} \end{bmatrix} \begin{matrix} \} & F \setminus \text{vertices of } F, \\ \} & \text{vertices of } F, \end{matrix}$$

from which it follows that

$$\left(S_{E,F} + S_{E_+,F}\right)\left(P_E \mathbf{x}_c\right)_F = 0 \text{ on } F.$$

Again, the fact that $S_{E,F} + S_{E_+,F}$ and $S_{E,F}$ have the same null-space implies that

$$S_{E,F}\left(P_E \mathbf{x}_c\right)_F = 0 \ \text{ on } F.$$

This shows that $\left(P_E \mathbf{x}_c\right)_F$ is a restriction of a null-vector of A_E on F. Assumption 2.1 and the additional assumption we have made that every vector in the null-space of A_E restricted to a face is uniquely determined by its vertex values on that face then imply that $\left(P_E \mathbf{x}_c\right)_{\partial E}$ is the restriction of a null-vector of A_E on ∂E. This together with the fact that $A_E\left(P_E \mathbf{x}_c\right) = 0$ in the interior of E finally show that

$$A_E\left(P_E \mathbf{x}_c\right) = 0 \ \text{ on } E.$$

This completes the proof that $P_E \mathbf{x}_c$ is in the null-space of A_E, i.e., that $\mathbf{x}_c$ is in the null-space of $A^c_{E_c}$. The converse is also true. Namely, $A^c_{E_c}\mathbf{x}_c = 0$ implies that $(P_E \mathbf{x}_c)^T A_E P_E \mathbf{x}_c = 0$, and since A_E is symmetric positive semidefinite, one gets that $A_E P_E \mathbf{x}_c = 0$ or that $P_E \mathbf{x}_c$ belongs to the null-space of A_E. Therefore, $\mathbf{x}_c = P_E \mathbf{x}_c|_{\text{vertices of } E}$ belongs to the null-space of the Schur complement S_c of A_E. □

We then have the following global estimate by summing up the local estimates over the individual agglomerated elements.

THEOREM 2.6. *The compatible local interpolation mapping $P = P_E$ is approximately harmonic in the sense that its norm in the energy inner product is bounded, i.e.,*

$$\begin{aligned}\mathbf{v}_c^T A_c \mathbf{v}_c &= (P\mathbf{v}_c)^T A (P\mathbf{v}_c)\\ &\leq \sum_E \eta_E \inf_{\mathbf{v}_E|_{\mathcal{D}_c \cap E} = \mathbf{v}_c} \mathbf{v}_E^T A_E \mathbf{v}_E\\ &\leq \eta \inf_{\mathbf{v}|_{\mathcal{D}_c} = \mathbf{v}_c} \mathbf{v}^T A \mathbf{v}.\end{aligned}$$

The exact harmonic mapping corresponds to the best constant $\eta = 1$. As shown in Lemma 2.5, *$\eta = \max_{E\in\mathcal{E}} \eta_E$, and thus the individual η_E can be estimated locally. With this result, a classical two-level Gauss–Seidel iteration (see, e.g., Bank and Dupont* [3] *or Bank* [2]*) will have a convergence factor bounded by $\gamma^2 = 1 - \frac{1}{\eta}$.*

Remark 2.4. Note that the proof of Theorem 2.6 does not require uniqueness of the minimizers (hence of P). Note, however, that we assumed uniqueness on the faces (see Lemma 2.5). Hence it applies to element matrices coming from 2D and 3D elasticity. If one assumes a little more (see Assumption 2.2) the uniqueness of P (or of the minimizers) is guaranteed. Namely, one may assume the following.

Assumption 2.2. If d_c is a dof at a vertex and E is an agglomerated element containing that vertex, the only vector in the null-space of A_E and vanishing at d_c is the zero vector.

For the model case of 2D and 3D second-order scalar elliptic equations (of the form $\mathcal{L}u \equiv -\operatorname{div} a\nabla u = f$), this assumption holds. However, it may not hold for systems of PDEs. (It is not true for elasticity problems, for example.) If Assumption 2.2 holds, P_E is defined uniquely at the interior of $N(d)$ (edge, face, or agglomerated element E) based on a Schur complement of $A_{\Omega(d)}$ (to $N(d)$) by harmonically extending the values from the boundary of $N(d)$ into its interior. In particular, one has (see (2.3)) that for each E (2.6) holds, $\mathbf{w}_F = P_E \mathbf{w}_c|_F$, for any face (or edge) $F \subset E$:

$$\mathbf{w}_c^T A_E^c \mathbf{w}_c = \inf_{\mathbf{v}_E|_F = \mathbf{w}_F,\text{ for all } F\subset E} \mathbf{v}_E^T A_E \mathbf{v}_E. \tag{2.6}$$

Remark 2.5. The constants η_E in Lemma 2.5 are computable and can be used as local measures for interpolation quality in the sense that smaller η_E implies better interpolation. Theorem 2.6 shows that the local measures imply the approximate harmonic property of P. More details on how to compute measures of interpolation quality and their relation with other local constants are found in section 4.

3. Energy minimization properties of coarse basis functions. With the local interpolation operators defined, one can construct a coarse grid basis function v_d for each $d \in \mathcal{D}_c$ as follows. Define the coarse grid vector $\mathbf{v}_d^c$ that is one at d and zero elsewhere, and define $\mathbf{v}_d$ as this vector interpolated to the fine grid (i.e., $\mathbf{v}_d = P\mathbf{v}_d^c$). It is clear then that it will be zero outside the neighborhood $\Omega(d) = \cup_{i=1}^{p} E_i$ of the given dof d. In this way, $\mathbf{v}_d$ can be viewed as a basis vector (function) of the interpolated coarse space. Using finite element terminology, one may also say that $\mathbf{v}_d$ is a fine grid vector representation of a coarse-grid basis function.

Lemma 3.1. *For the model problem of finite element matrices (before imposing Dirichlet boundary conditions) coming from second-order scalar elliptic problems (*2D *or* 3D*), the* $\{\mathbf{v}_d\}$ *provide the partition of unity, i.e.,*

$$\sum_{d \in \mathcal{D}_c} \mathbf{v}_d = \begin{bmatrix} 1 \\ \vdots \\ 1 \end{bmatrix}. \tag{3.1}$$

Proof. In the case of finite element matrices coming from 2D (or 3D) second-order scalar elliptic problems, constant vectors are in the null-space of the element matrices. By Remark 2.2, if $\mathbf{v}_c = \begin{bmatrix} 1 \\ \vdots \\ 1 \end{bmatrix} \in \mathcal{R}^{n_c}$, then $\mathbf{v} = P\mathbf{v}_c = \begin{bmatrix} 1 \\ \vdots \\ 1 \end{bmatrix} \in \mathcal{R}^n$. This holds since $\mathbf{v}_E = P_E \mathbf{v}_{c,\, E_c}$ for each coarse element E_c (or agglomerated element E). This, in particular, implies that $\sum_{d \in \mathcal{D}_c} \mathbf{v}_d = \begin{bmatrix} 1 \\ \vdots \\ 1 \end{bmatrix} \in \mathcal{R}^n$. □

Corollary 3.2. *Consider the model case of finite element matrices (before imposing Dirichlet boundary conditions) coming from second-order scalar elliptic problems (*2D *or* 3D*) on quasi-uniform triangulation. Let* $\{\mathbf{v}_d\}$ *be the set of basis functions generated by the local interpolation operators. Let* $\{\mathbf{w}_d\}$ *be any other potential set of local basis functions, i.e., a basis function exists for each* $d \in \mathcal{D}_c$ *with* $\mathbf{w}_d(d) = 1$ *and* $\mathbf{w}_d = 0$ *outside of the neighborhood* $\Omega(d)$*. Then the following energy minimization property of* $\{\mathbf{v}_d\}$ *holds:*

$$\sum_{d \in \mathcal{D}_c} \mathbf{v}_d^T A \mathbf{v}_d \le C \sum_{d \in \mathcal{D}_c} \inf_{\mathbf{w}_d} \mathbf{w}_d^T A \mathbf{w}_d. \tag{3.2}$$

Proof. Applying the approximate harmonic property of P_E for each agglomerated element E (Lemma 2.5), one ends up with the estimate

$$(\mathbf{v}_d|_E)^T A_E (\mathbf{v}_d|_E) \le \eta_E \inf_{\mathbf{w}_E:\ \mathbf{w}|_{\text{vertices of } E} = \mathbf{v}_d|_{\text{vertices of } E}} \mathbf{w}_E^T A_E \mathbf{w}_E.$$

Summing up over the agglomerated elements $E : \ E \subset \Omega(d)$, where $\Omega(d)$ is the union of all agglomerated elements that contain the vertex d (note that $\mathbf{v}_d$ is zero outside $\Omega(d)$), one ends up with the global estimate

$$\mathbf{v}_d^T A \mathbf{v}_d \le \eta \inf_{\mathbf{w}_d:\ \mathbf{w}_d|_{\mathcal{D}_c} = \mathbf{v}_d|_{\mathcal{D}_c}} \mathbf{w}_d^T A_{\Omega(d)} \mathbf{w}_d, \quad \eta = \max_E \eta_E.$$

Note that $\mathbf{w}_d = 1$ at the vertex d and is zero at the remaining vertices, and it is also zero outside $\Omega(d)$, i.e., it is locally supported.

Finally, summing over all $d \in \mathcal{D}_c$, one ends up with the desired estimate

$$\begin{aligned}\sum_{d\in\mathcal{D}_c} \mathbf{v}_d^T A \mathbf{v}_d &\leq C \sum_{d\in\mathcal{D}_c} \inf_{\mathbf{w}_d:\ \mathbf{w}_d|_{\mathcal{D}_c} = \mathbf{v}_d|_{\mathcal{D}_c}} \mathbf{w}_d^T A_{\Omega(d)} \mathbf{w}_d \\ &= C \sum_{d\in\mathcal{D}_c} \inf_{\mathbf{w}_d:\ \mathbf{w}_d|_{\mathcal{D}_c} = \mathbf{v}_d|_{\mathcal{D}_c}} \mathbf{w}_d^T A \mathbf{w}_d. \qquad \square\end{aligned}$$

Remark 3.1. Theorem 3.2 shows, for the model case of finite element matrices coming from second-order scalar elliptic equations as well as in the elasticity, that the coarse basis functions corresponding to the coefficient vectors $\mathbf{v}_d$ solve the energy minimization functional as defined in Wan, Chan, and Smith [17] up to a multiplicative constant. Fast algorithms to solve the problem of the energy minimization functional are proposed and analyzed in Mandel, Brezina, and Vanek [12].

Remark 3.2. For finite element matrices coming from 2D and 3D second-order scalar elliptic problems on quasi-uniform triangulation, the coarse space produced by the above algorithm also admits a weak approximation property (or, equivalently, provides partition of unity—see Lemma 3.1 and also estimate (4.2)) since the element matrices contain the constants in their null-space. Therefore, the constant is exactly interpolated from the vertices of the agglomerated elements as the same constant on the rest of the agglomerated element. That is, with the above minimization property, the AMGe method can actually become an optimal- (or almost optimal) order MG method if one can control the local constants η_E from Lemma 2.5 which depend on the way we agglomerate the elements at every coarsening step. If η gets large, a potential remedy might be the algebraic multilevel iteration (AMLI) stabilization procedure (cf. Vassilevski [16]) which is like the W-cycle or even more cycles. Approaches to rigorously study the convergence of the underlined AMG method can draw on the existing analytical tools for geometric MG convergence theory for finite element problems (see, e.g., the book by Bramble [4]). In the present paper we do not deal with multilevel convergence results.

Remark 3.3. One can actually apply the same interpolation procedure on agglomerated elements using it recursively to fine-grid element matrices coming from a nonsymmetric elliptic operator like convection-diffusion, e.g., $\mathcal{L}u \equiv -\operatorname{div}(\epsilon\nabla u) + \underline{b}\cdot\nabla u$. In Figures 2 and 3 a coarse basis function is shown (face and rotated) using four levels of coarsening procedure for a constant convection field $b_1 = 1$, $b_2 = -0.5$, and $\epsilon = 0.1$. Note also that in this case of the convection-diffusion operator the basis functions computed on the coarse levels by the proposed AMGe method will provide a partition of unity (as in the symmetric operator case), and hence the coarse spaces will admit a certain weak approximation property. The same applies for the so-called streamline diffusion operator $\mathcal{L}_\delta u \equiv -\operatorname{div}((\epsilon + \delta\underline{b}\,\underline{b}^T)\nabla u) + \underline{b}\cdot\nabla u$, where δ is a mesh-dependent parameter.

Remark 3.4. We finally remark that the presented AMGe method can be used in the so-called “homogenization” procedures to generate averaged coarse problems from problems on computationally unfeasible highly refined meshes and possibly with oscillatory coefficients (cf., e.g., [11] and references therein; see also [10]). The difference that we see here is that our coarsening procedure is local. We require the solution of small local problems (involving a few elements) rather than large subdomain solves in order to compute the effective coarse grid basis functions (or coarse-grid element matrices).

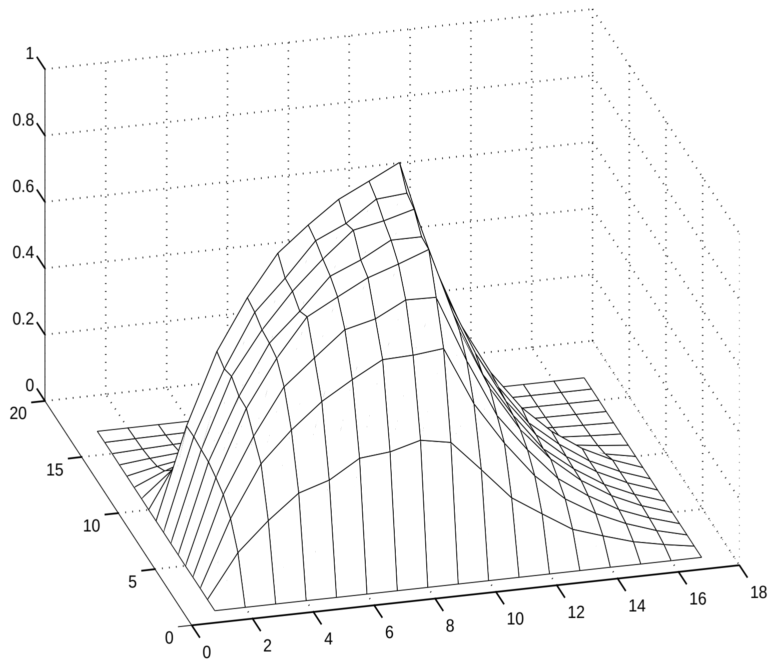

FIG. 2. *AMGe constructed "minimum energy" coarse basis function for convection-diffusion operator.*

4. Algorithms for element agglomeration. This section introduces the algorithm we have used in selecting the coarse grid agglomerates. The algorithm relies of the faces and edges of the original elements $\{e\}$; to simplify the discussion, we will focus mainly on 2D elements (i.e., having faces and vertices only). The method is based on the face-face graph of the fine grid elements (i.e., face f_1 and f_2 are neighbors if they share a common vertex) and uses an integer weight $w(f)$ for each face f. The eliminated faces f will have a weight $w(f) = -1$.

ALGORITHM 4.1 (element agglomeration based on the face-face graph).

- **initiate**. *Set* $w(f) = 0$ *for all faces* f*;*
- **global search**. *Find a face* f *with maximal* $w(f)$*; set* $E = \emptyset$*;*
  1. *Set* $E = E \cup e_1 \cup e_2$*, where* $e_1 \cap e_2 = f$*, and set* $w_{\max} = w(f)$*,* $w(f) = -1$*;*
  2. *Increment* $w(f_1) = w(f_1) + 1$ *for all faces* f_1 *such that* $w(f_1) \neq -1$ *and* f_1 *is a neighbor of* f*;*
  3. *Increment* $w(f_2) = w(f_2) + 1$ *for all faces* f_2 *such that* $w(f_2) \neq -1$*,* f_2 *is a neighbor of* f*, and* f_2 *and* f *are faces of a common element;*
  4. *From the neighbors of* f*, choose a face* g *with a maximal* $w(g)$*; if* $w(g) \geq w_{\max}$*, set* $f = g$*, and go to step* (1)*;*
  5. *If all neighbors of* f *have smaller weight than* $w_{\max}$*, the agglomerated element* E *is complete; set* $w(g) = -1$ *for all faces of the elements* e *contained in* E*; go to step* **global search***;*

This algorithm tends to produce nicely matched agglomerated elements and produces standard multigrid coarsening (up to boundary effects) for structured grid problems using linear or bilinear elements. See Figures 4 and 5 for the results of this procedure applied to a uniform triangular mesh after one and two agglomeration

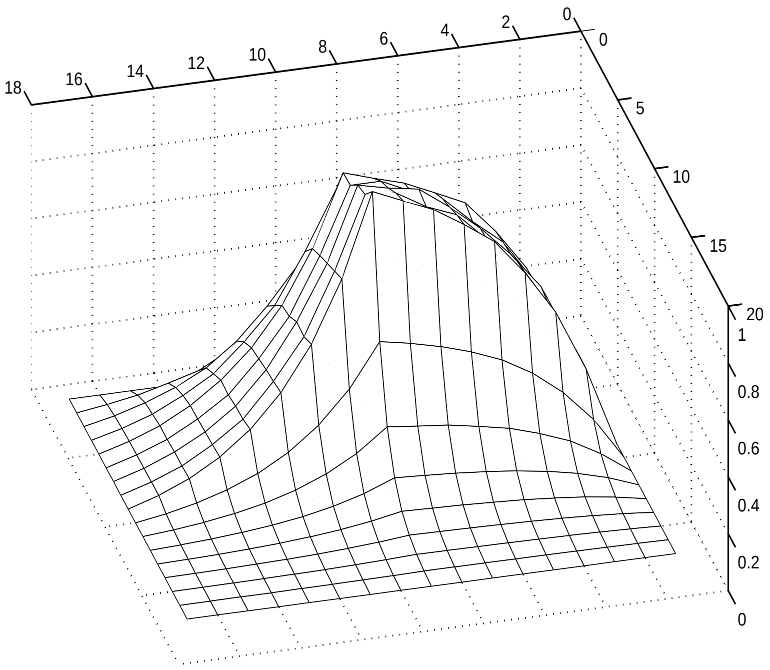

FIG. 3. *AMGe constructed "minimum energy" coarse basis function for convection-diffusion operator, rotated.*

steps, respectively. The setup cost of the algorithm is linear, i.e., proportional to the total number of dofs. The algorithm is easily implemented using, for example, double linked lists.

Figures 6 and 7 show the results of the algorithm for several unstructured problems. Figures 8, 9, 10, and 11, show fine unstructured grids using triangular elements, the agglomerated elements are shown in Figures 12, 13, 14, and 15 respectively. The latter are the actual grids on which the first set of numerical tests was performed.

In three dimensions one has the opportunity to introduce edges. Then one may construct more refined agglomeration algorithms that exploit this additional topological information, namely, the edge-edge and edge-face graphs. This information, however, has not been utilized in the present paper.

It is important to note that the above algorithm does not take into account any matrix entries while agglomerating the elements. For structured grid problems with anisotropy, it will produce full-coarsening. To produce semicoarsening for such problems, one can introduce barriers. This can be implemented by assigning to each face another (binary) weight $a(f) = \begin{cases} 0, \text{ acceptable,} \\ 1, \text{ unacceptable.} \end{cases}$ To prevent agglomeration through a face f, one can simply set $a(f) = 1$, and then in step 4 of Algorithm 4.1 one searches for a face g, a neighbor to f, which is with a maximal weight $w(g)$, and if $a(g) = 1$ (i.e., unacceptable), one looks for an acceptable face g_a (neighbor to f) such that $w(g_a) = w(g)$. If such a face does not exist, the agglomeration step is terminated and the agglomerated element E is ready.

The way we have put barriers on the faces is based on the element matrices; namely, given a face $f = e_1 \cap e_2$, assemble $A_{e_1 \cup e_2}$ and ask if the dofs on f can be well interpolated from the rest of the dofs in $e_1 \cup e_2$. If the resulting measure of

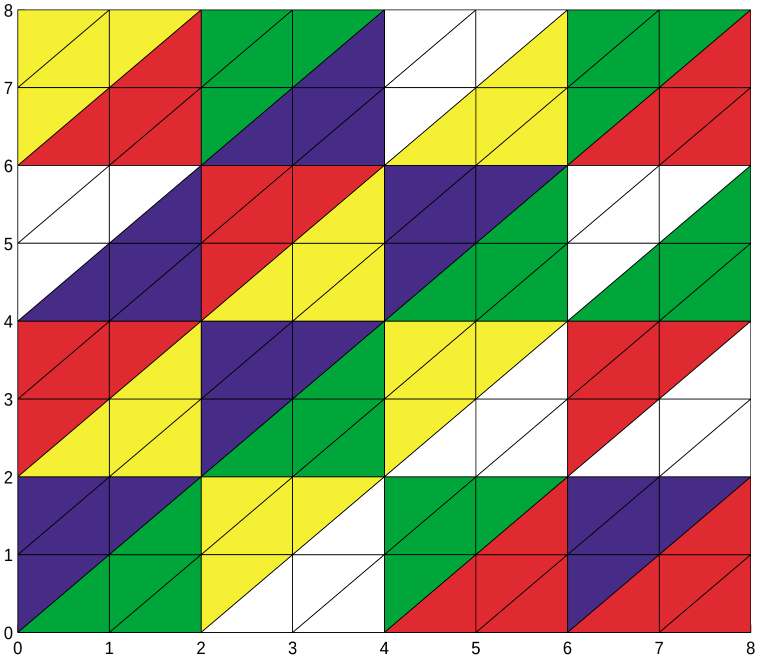

FIG. 4. *Agglomerated elements for structured triangular mesh: One step of agglomeration.*

interpolation quality is reasonable, we say that the face f is acceptable; otherwise, we label f as unacceptable by initializing $a(f) = 1$ to prevent agglomeration of e_1 and e_2. To implement this approach, one must be able to access the quality of the interpolation for the dofs on f. A measure of interpolation quality was proposed in [7]. In our setting, it can be reformulated as follows. Given the interpolation mapping P defined by interpolating dofs on f from the rest of the dofs in $e_1 \cup e_2$, define the quadratic form (or matrix) W_{ff} for vectors on f by

$$\mathbf{v}_f^T W_{ff} \mathbf{v}_f = \inf_{\mathbf{v}_c} (\mathbf{v} + P\mathbf{v}_c)^T A_{e_1 \cup e_2} (\mathbf{v} + P\mathbf{v}_c); \quad \mathbf{v} = \begin{bmatrix} \mathbf{v}_f \\ 0 \end{bmatrix} \begin{matrix} \}\text{dofs on } f, \\ \}e_1 \cup e_2 \setminus f. \end{matrix}$$

Then the measure of interpolation quality (denoted by M_1 in [7]) is

$$m_P = \frac{1}{\lambda_{\min}[D_{ff}^{-1} W_{ff}]}, \tag{4.1}$$

where D_{ff} is, for example, the diagonal of $A_{e_1 \cup e_2}$ restricted to f. Small m_P indicates good quality interpolation; interpolation well approximates functions with low energy. In finite element notation, small m_P means that the functions v_c from the coarse space can approximate well the fine-grid functions v in a weighted L^2-norm $\|.\|_0$. To show this, let m be a bound such that

$$\inf_{v_c} \|v - v_c\|^2_{0,\, e_1 \cup e_2} \le m\, a_{e_1 \cup e_2}(v, v) \quad \text{for all } v: \ v|_{\mathcal{D}_c} = v_c|_{\mathcal{D}_c}. \tag{4.2}$$

This is equivalent (letting $v = v_f + v_c$ above) to

$$\|v_f\|^2_{0,\, e_1 \cup e_2} \le m \inf_{v_c} a_{e_1 \cup e_2}(v_f + v_c,\ v_f + v_c) \quad \text{for all } v_f: \ v_f|_{\mathcal{D}_c} = 0.$$

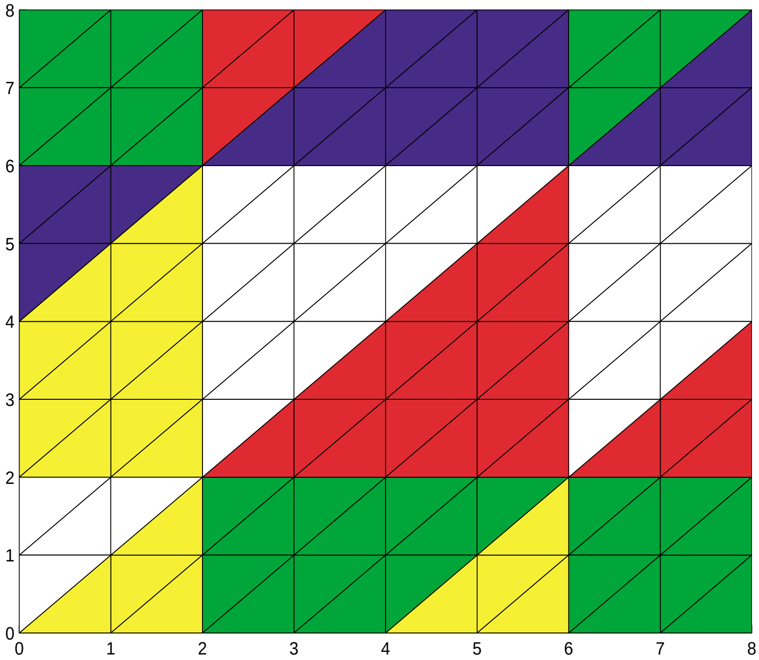

FIG. 5. *Agglomerated elements for structured triangular mesh: Two steps of agglomeration.*

In vector notation, this becomes

$$\begin{aligned}(\mathbf{v}_f)^T D_{ff}\mathbf{v}_f &\le m \inf_{\mathbf{v}_c} (\mathbf{v}+P\mathbf{v}_c)^T A_{e_1\cup e_2}(\mathbf{v}+P\mathbf{v}_c) \text{ for all } \mathbf{v} = \begin{bmatrix} \mathbf{v}_f \\ 0 \end{bmatrix}\\ &= m\ (\mathbf{v}_f)^T W_{ff}\mathbf{v}_f, \text{ for all } \mathbf{v}_f.\end{aligned}$$

This, with the best choice of m, leads to the definition (4.1) of the measure m_P. It is clear, from (4.2), that smaller m_P corresponds to better interpolation quality.

Remark 4.1. One can actually compute the minimum

$$\mathbf{v}_f^T W_{ff}\mathbf{v}_f = \min_{\mathbf{v}_c} (\mathbf{v}+P\mathbf{v}_c)^T A_{e_1\cup e_2}(\mathbf{v}+P\mathbf{v}_c), \quad \mathbf{v} = \begin{bmatrix} \mathbf{v}_f \\ 0 \end{bmatrix} \begin{matrix} \} & \text{dofs on } f, \\ \} & (e_1\cup e_2)\setminus f. \end{matrix}$$

One has, with $A := A_{e_1\cup e_2}$ and $\mathbf{v}_c := t\mathbf{v}_c$ for any $t\in\mathcal{R}$,

$$(\mathbf{v}+tP\mathbf{v}_c)^T A(\mathbf{v}+tP\mathbf{v}_c) = \mathbf{v}^T A\mathbf{v} + 2t\mathbf{v}^T AP\mathbf{v}_c + t^2(P\mathbf{v}_c)^T AP\mathbf{v}_c.$$

The minimum with respect to t is achieved for $t = -\frac{\mathbf{v}^T AP\mathbf{v}_c}{(P\mathbf{v}_c)^T AP\mathbf{v}_c}$ and equals

$$\mathbf{v}^T A\mathbf{v} - \frac{(\mathbf{v}^T AP\mathbf{v}_c)^2}{(P\mathbf{v}_c)^T AP\mathbf{v}_c}.$$

Hence,

$$\mathbf{v}_f^T W_{ff}\mathbf{v}_f = \min_{\mathbf{v}_c}\left(\mathbf{v}_f^T A_{ff}\mathbf{v}_f - \frac{(\mathbf{v}^T AP\mathbf{v}_c)^2}{(P\mathbf{v}_c)^T AP\mathbf{v}_c}\right), \quad \mathbf{v} = \begin{bmatrix} \mathbf{v}_f \\ 0 \end{bmatrix}.$$

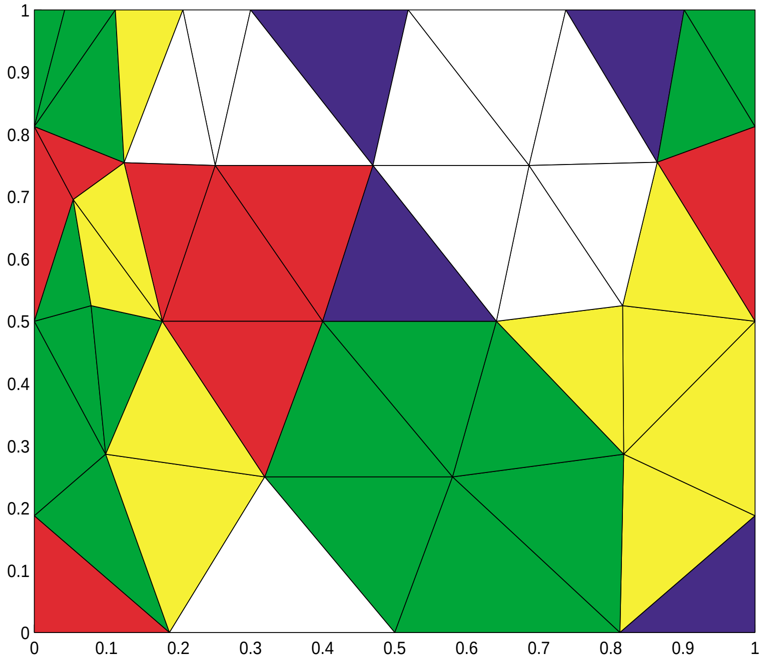

FIG. 6. *Agglomerated elements: Rectangular domain with unstructured triangular elements.*

In particular, $\mathbf{v}_f^T W_{ff} \mathbf{v}_f \le \mathbf{v}_f^T A_{ff} \mathbf{v}_f$. Here, A_{ff} represents the f-f block of $A := A_{e_1 \cup e_2}$ (see (4.3) below). Note that if there is a $\mathbf{v}_c$ such that $(AP\mathbf{v}_c)|_f = 0$, then $\mathbf{v}_f^T W_{ff} \mathbf{v}_f = \mathbf{v}_f^T A_{ff} \mathbf{v}_f$. The latter is true also for the so-called "optimal" P, i.e., such that $P = -A_{ff}^{-1} A_{fc}$, where $A_{e_1 \cup e_2}$ is partitioned as follows:

$$A_{e_1 \cup e_2} = \begin{bmatrix} A_{ff} & A_{fc} \\ A_{cf} & A_{cc} \end{bmatrix} \begin{array}{l} \} \quad \text{dofs on } f, \\ \} \quad (e_1 \cup e_2) \setminus f. \end{array} \tag{4.3}$$

In that case, $m_P = \frac{1}{\lambda_{\min}[D_{ff}^{-1} A_{ff}]}$.

Remark 4.2. Note that if instead of D_{ff} one uses in (4.1) the principal submatrix A_{ff} of A corresponding to the fine dofs that are not coarse, then $m_P = \frac{1}{1-\gamma^2}$, where $\gamma \in [0, 1)$ stands for the cosine of the abstract angle between the coarse space $V_c = \{\mathbf{v}^c = P\mathbf{v}_c\}$ and its hierarchical complement $V_f = \{\mathbf{v}^f = [\begin{smallmatrix} \mathbf{v}_f \\ 0 \end{smallmatrix}]\}$. The angle is measured in the energy inner product, i.e.,

$$(\mathbf{v}^f)^T A_{e_1 \cup e_2} \mathbf{v}^c \le \gamma \sqrt{(\mathbf{v}^f)^T A_{e_1 \cup e_2} \mathbf{v}^f} \sqrt{(\mathbf{v}^c)^T A_{e_1 \cup e_2} \mathbf{v}^c} \;\text{ for all } \mathbf{v}^f \in V_f, \; \mathbf{v}^c \in V_c.$$

For a proof of the relation $m_P = \frac{1}{1-\gamma^2}$, see, e.g., Vassilevski [16].

Instead of m_P one can use γ as a measure of the interpolation quality. Then small γ will correspond to small m_P and hence to good quality interpolation, whereas γ close to one will imply large m_P and hence poor quality interpolation.

In following example, we will use γ to define a measure for strength on connections between neighboring elements and thus label faces as acceptable or unacceptable. Consider two fine elements e_1 and e_2 sharing a face f as shown in Figure 16. Let i_{F_2} be an interpolation rule for dof x_3 from x_1 and x_5, and let i_{F_1} be an interpolation rule for

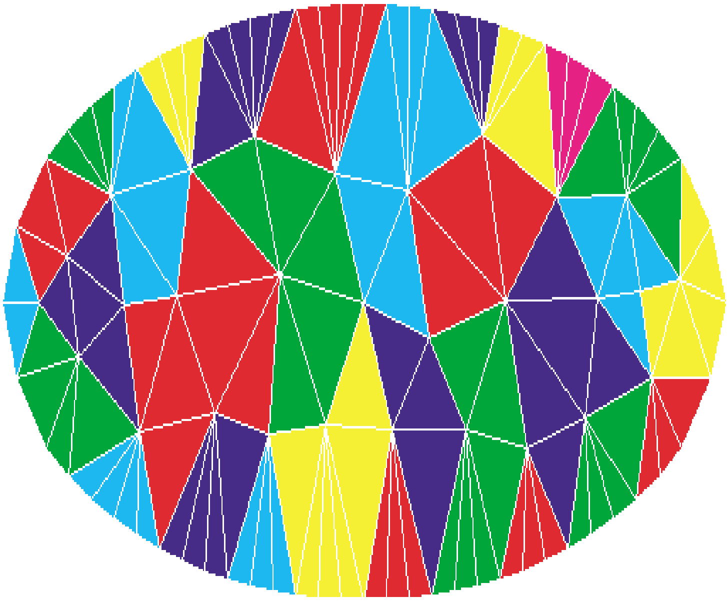

FIG. 7. *Agglomerated elements: Elliptical domain with triangular elements.*

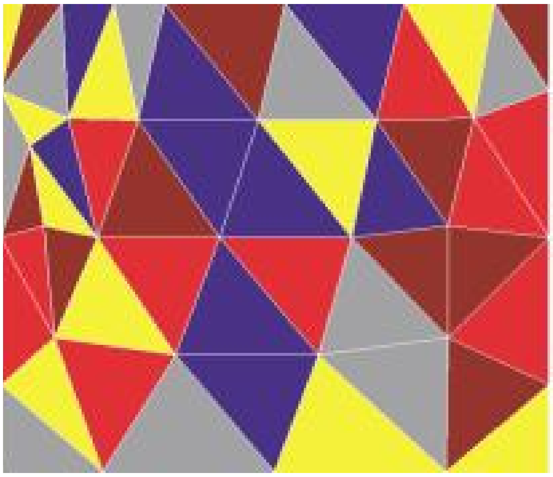

FIG. 8. *Fine elements: Rectangular domain with* 48 *unstructured triangular elements.*

dof x_4 from x_2 and x_6; these could be constructed as proposed in the previous section. For 2D scalar elliptic problems with constant coefficients, these are linear interpolants along the faces F_1 and F_2 treating x_1, x_2, x_5, and x_6 as coarse-grid nodes and x_3 and x_4 as complementary to the coarse-grid, fine-grid nodes. Then, given a coarse function v_c defined at the nodes x_1, x_2, x_5, and x_6, the mapping $P_c^f v_c = \left\{ \begin{smallmatrix} i_{F_1} v_c, & x=x_4, \\ i_{F_2} v_c, & x=x_3 \end{smallmatrix} \right.$ defines a coarse-to-fine prolongation operator.

Let $E = e_1 \cup e_2$, and let A_E be the assembled matrix corresponding to E. Given

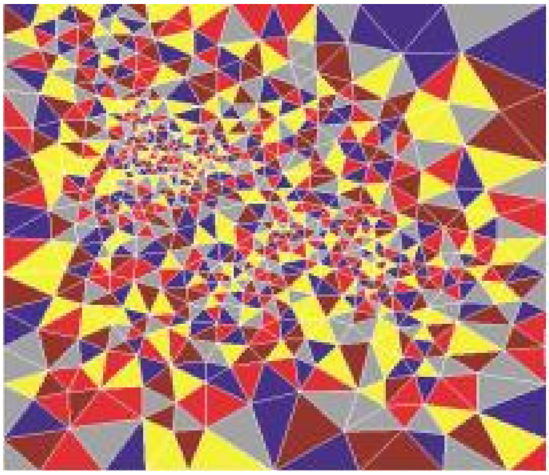

FIG. 9. *Fine elements: Rectangular domain with* 1001 *unstructured triangular elements.*

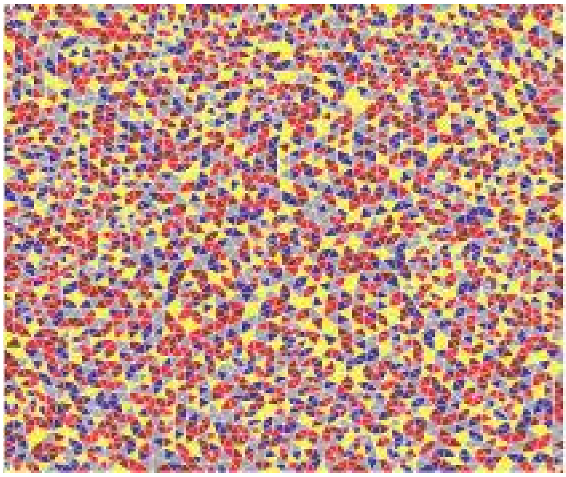

FIG. 10. *Fine elements: Rectangular domain with* 4016 *unstructured triangular elements.*

a coarse-grid vector $\mathbf{v}_c$, let $\widehat{v}_c = P_c^f v_c$ be its representation on the fine-grid. Then the local fine-grid space is decomposed as $P_c^f v_c \oplus v_f^0$, where v_f^0 are the fine-grid functions which vanish on the coarse-grid. As mentioned, the cosine $\gamma \in [0, 1)$ of the angle between these components can be used to measure a strength of connection between e_1 and e_2 with respect to the given matrix A_E (or pair of element matrices A_{e_1} and A_{e_2} that correspond to the pair of elements e_1 and e_2). Recall that the constant γ is defined as the best constant in the strengthened Cauchy inequality

$$a_E(\widehat{v}_c,\ v_f^0) \leq \gamma\ \sqrt{a_E(\widehat{v}_c,\ \widehat{v}_c)}\ \sqrt{a_E(v_f^0,\ v_f^0)} \quad \text{for all } \widehat{v}_c,\ v_f^0. \tag{4.4}$$

To write this inequality in matrix-vector notation, let

$$P = \left[\left[\begin{array}{c} I \\ 0 \end{array} \right], P_c^f \right]$$

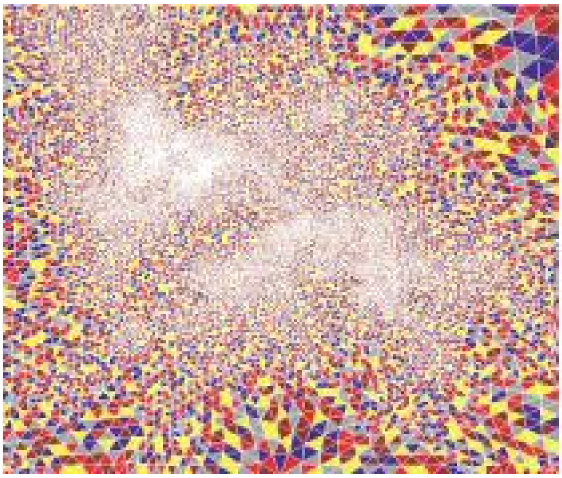

Fig. 11. *Fine elements: Rectangular domain with* 16000 *unstructured triangular elements.*

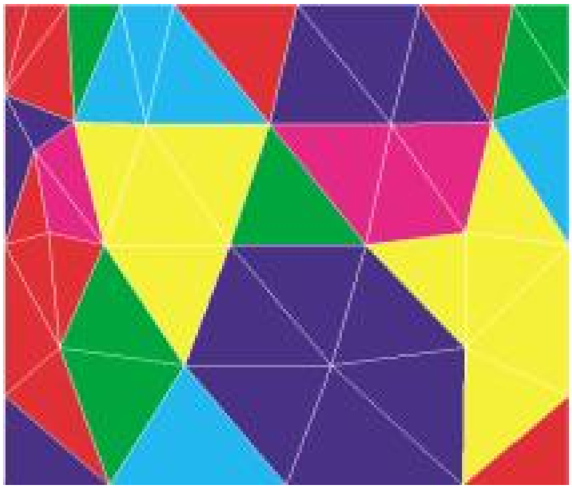

Fig. 12. *Agglomerated elements: Rectangular domain with unstructured triangular elements.*

and $\widehat{A}_E = P^T A_E P$. Consider the following two-by-two blocking of $\widehat{A}_E$:

$$\widehat{A}_E = \begin{bmatrix} A_{E;\,ff} & \widehat{A}_{E;\,fc} \\ \widehat{A}_{E;\,cf} & A_{E;\,cc} \end{bmatrix} \begin{array}{l} \} \quad \text{complementary fine-grid nodes; i.e., } x_3,\ x_4, \\ \} \quad \text{coarse nodes; i.e., } x_1, x_2, x_5,\ x_6. \end{array}$$

Note that $A_{E;\,cc}$ is the resulting coarse matrix corresponding to E. Then the strengthened Cauchy inequality (4.4) reads

$$\mathbf{v}_c^T \widehat{A}_{E;\,cf} \mathbf{v}_f^0 \le \gamma \sqrt{\mathbf{v}_c^T A_{E;\,cc} \mathbf{v}_c} \sqrt{{\mathbf{v}_f^0}^T A_{E;\,ff} \mathbf{v}_f^0} \quad \text{for all } \mathbf{v}_c,\ \mathbf{v}_f^0.$$

A way to compute γ is to find the largest eigenvalue $m = \lambda_{\max} \ge 1$ of the generalized eigenvalue problem

$$A_{E,\,cc}\mathbf{q} = \lambda S_{E,\,f}\mathbf{q},$$

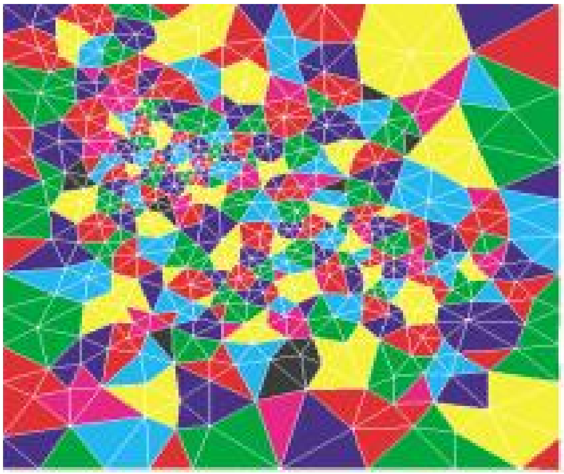

Fig. 13. *Agglomerated elements: Rectangular domain with unstructured triangular elements.*

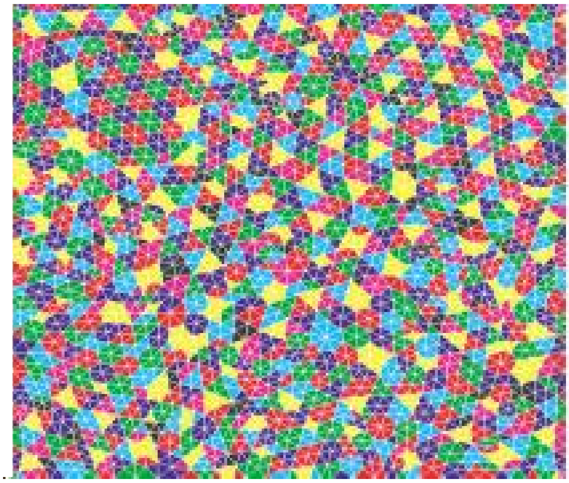

Fig. 14. *Agglomerated elements: Rectangular domain with unstructured triangular elements.*

where $S_{E,\,f}$ is the Schur complement of $\widehat{A}_E$ on f, i.e.,

$$S_{E,\,f} = A_{E,\,cc} - \widehat{A}_{E;\,cf}\,(A_{E;\,ff})^{-1}\,\widehat{A}_{E;\,fc}.$$

Then $\gamma = \sqrt{1 - \frac{1}{m}}$.

Definition 4.1 (strongly connected elements). *We call e_1 and e_2 strongly connected if γ is close to zero, i.e., when the resulting local coarse space is almost orthogonal to its complementary (the so-called two-level hierarchical complementary) space.*

Algorithm 4.1 can be modified to agglomerate only strongly connected elements. One would set a threshold α and label a face f unacceptable if $\gamma > \alpha$ by initializing $a(f) = 1$.

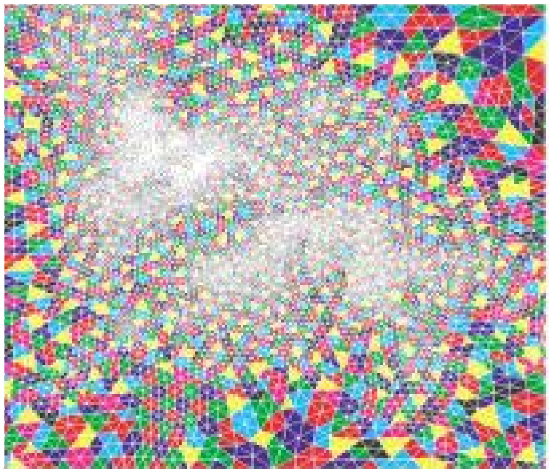

FIG. 15. *Agglomerated elements: Rectangular domain with unstructured triangular elements.*

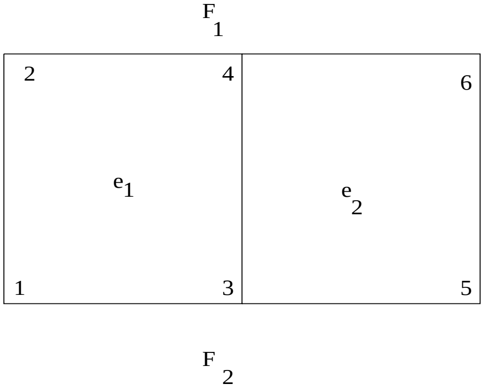

FIG. 16. *Neighboring elements* e_1 *and* e_2 *with a common face* $f = \{x_3, x_4\}$*; the nodes* x_1, x_2, x_5*, and* x_6 *are viewed as coarse-grid nodes.*

4.1. Examples of γ. We conclude this section with examples showing that this definition of strongly connected elements can lead to the correct semicoarsening for anisotropic problems. Consider the model second-order elliptic bilinear form, which, restricted to an element e, reads

$$a_e(\varphi, \psi) = \int_e \left(\frac{\partial \varphi}{\partial x} \frac{\partial \psi}{\partial x} + \frac{\partial \varphi}{\partial y} \frac{\partial \psi}{\partial y} \right) dx\, dy. \tag{4.5}$$

Consider two vertically adjacent rectangular elements (see Figure 17) and bilinear test functions. Consider the following cases.

(a) Anisotropic elements $h_x < h_y$; $h_x = 0.1h_y$, $\gamma = 0.8649$; $h_x = 0.01h_y$, $\gamma = 0.8660$. These values of γ indicate that the elements are weakly connected and one should not agglomerate them.

(b) Anisotropic elements $h_x > h_y$; $h_x = 10h_y$, $\gamma = 0.1698$; $h_x = 100h_y$, $\gamma = 0.0173$. This example shows that since γ is close to zero, the elements are strongly connected, and hence one should agglomerate this pair of elements.

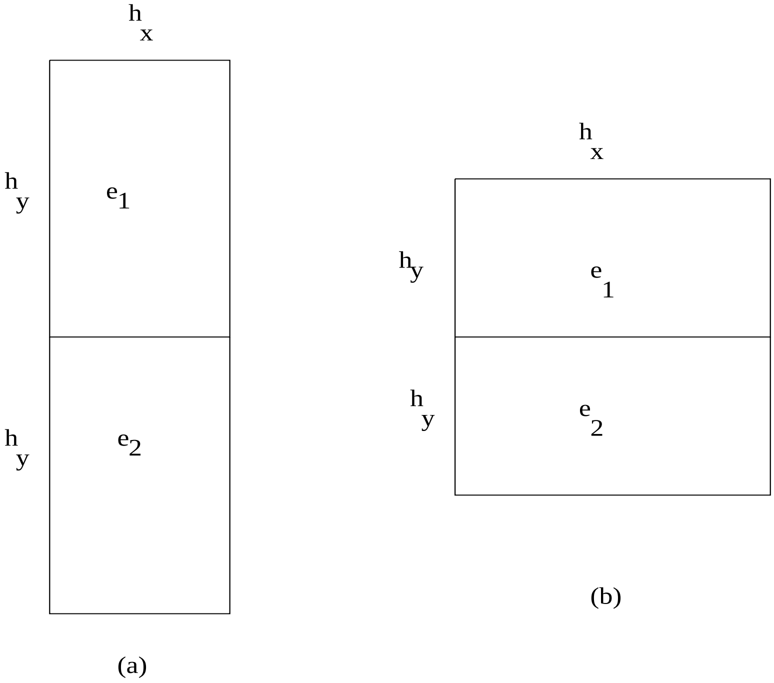

FIG. 17. *Neighboring elements* e_1 *and* e_2*;* (*a*) $h_x < h_y$, (*b*) $h_x > h_y$.

(c) For comparison, if $h_x = h_y$, $\gamma = 0.7746$ (or $\gamma^2 = \frac{3}{5}$).

Thus, this measure correctly leads to coarsening only in the direction of small mesh size.

5. Numerical experiments.

5. Numerical experiments. In this section we present some preliminary numerical results that show the potential of the proposed element agglomeration AMGe method.

We have tested the two-grid method with the coarse-grid obtained using the agglomeration algorithm described in section 4. After the coarse dofs were selected the interpolation mapping was constructed as described in section 2. We used one forward Gauss–Seidel iteration as a presmoother and one backward Gauss–Seidel iteration for a postsmoothing. The stopping criterion was a relative reduction of the residual ℓ^2-norm by a factor of 10^{-6}.

We tested two sets of problems.

- The Poisson equation discretized on a square domain on four “unstructured” rectangular grids are shown in Figures 8, 9, 10, and 11, and the respective grids with agglomerated elements are shown in Figure 12, 13, 14, and 15. Dirichlet boundary conditions were imposed, and the results are collected in Table 1.
- The elasticity equation which comes from minimizing the quadratic functional discretized with square bilinear elements.

(5.1)
$$\int_{\Omega} \left[\frac{1+\nu}{2}(\partial_x u + \partial_y v)^2 + \frac{1-\nu}{2}(\partial_x u - \partial_y v)^2 + \frac{1-\nu}{2}(\partial_y u + \partial_x v)^2 \right] \, dxdy.$$

Table 1

Two-grid convergence results; unstructured triangular grid; Laplace operator; Gauss–Seidel smoother.

Grid #	1	2	3	4
# fine elements	48	1 001	4 016	16 016
# coarse elements	20	242	1 016	3 859
# fine dof	35	523	2 085	8 095
# coarse dof	27	281	1 083	3 515
# iterations	7	9	8	8
ϱ	0.159	0.320	0.256	0.260

Table 2

Two-grid convergence results; structured rectangular grid; elasticity operator; Gauss–Seidel smoother.

Grid #	1	2	3	4
# fine elements	400	900	1600	2500
# coarse elements	118	253	438	673
# fine dof	882	1922	3362	5202
# coarse dof	314	624	1034	1544
# iterations	9	9	9	9
ϱ	0.251	0.245	0.254	0.248

Here $\nu = \frac{1}{3}$. Again, Dirichlet boundary conditions were imposed, and these results are in Table 2.

One notices the similar convergence factors ϱ and the number of iterations for Poisson and elasticity problems.

Acknowledgments. The present authors would like to acknowledge the stimulating discussions with the authors of [7] without which this research direction may not have been pursued. The unstructured triangular grids used in our numerical tests were provided by Dr. Ludmil Zikatanov. Finally, the careful reading of the paper by the referees is gratefully appreciated.

ASYNCHRONOUS PARALLEL PATTERN SEARCH FOR NONLINEAR OPTIMIZATION*

PATRICIA D. HOUGH†, TAMARA G. KOLDA†, AND VIRGINIA J. TORCZON‡

Abstract. We introduce a new asynchronous parallel pattern search (APPS). Parallel pattern search can be quite useful for engineering optimization problems characterized by a small number of variables (say, fifty or less) and by objective functions that are expensive to evaluate, such as those defined by complex simulations that can take anywhere from a few seconds to many hours to run. The target platforms for APPS are the loosely coupled parallel systems now widely available. We exploit the algorithmic characteristics of pattern search to design variants that dynamically initiate actions solely in response to messages, rather than routinely cycling through a fixed set of steps. This gives a versatile concurrent strategy that allows us to effectively balance the computational load across all available processors. Further, it allows us to incorporate a high degree of fault tolerance with almost no additional overhead. We demonstrate the effectiveness of a preliminary implementation of APPS on both standard test problems as well as some engineering optimization problems.

Key words. asynchronous parallel optimization, pattern search, direct search, fault tolerance, distributed computing, cluster computing

1. Introduction.

We consider solving the unconstrained nonlinear optimization problem, minimize $f(x)$, where $x \in \mathbb{R}^n$ and $f : \mathbb{R}^n \to \mathbb{R}$. The problems of particular interest to us are defined by computationally expensive computer simulations of complex physical processes. Such simulations may take anywhere from a few seconds to many hours of computation on a single processor. In addition, we often cannot use derivative-based methods to solve these problems because no procedure exists for the evaluation of the gradient and the function evaluations are not precise enough to produce an accurate finite-difference gradient.

Pattern search is a class of direct search methods that is popular for solving the problems described above because no derivative information is required. Further, pattern search methods admit a wide range of algorithmic possibilities; see, e.g., [15, 16, 26]. The dominant computational cost for pattern search methods lies in the evaluation of the objective function. We can exploit the definition of pattern search to derive variants that perform multiple independent function evaluations simultaneously. We then can take advantage of parallel computing platforms to reduce the overall computational cost of the search.

Both the nature of the problems of interest and the features of current distributed computing environments raise some issues that we address in this work.

The original investigation into parallel direct search methods [7, 25] made two fundamental assumptions about the parallel computing environment: (1) that the processors were both homogeneous and tightly coupled and (2) that the amount of time needed to finish a single evaluation of the objective function was effectively constant. It is time to reexamine these two assumptions. Clearly, given the current variety of parallel computing platforms, including distributed systems comprising loosely coupled, often heterogeneous, off-the-shelf commercial components [24], the first assumption is no longer valid. The second assumption may not hold in our case because we focus on problems defined by the simulations of complex physical processes. Typically, the simulations themselves are based on iterative numerical techniques and so the assumption that evaluations of the objective finish in constant computational time on equivalent processors often does not hold. In fact, the behavior of the simulation for any given input is difficult to assess in advance since it can vary substantially depending on a variety of factors.

Because the original assumptions underlying parallel direct search are not valid for the situations we now face, we can no longer assume that the computation proceeds in lockstep. A single synchronization step at the end of every iteration, as in [25], is neither appropriate nor effective when any of the following factors holds: function evaluations finish in varying amounts of time (even on equivalent processors), the processors employed in the computation possess different performance characteristics, or the processors have varying loads. Our goal is to introduce a class of asynchronous parallel pattern search (APPS) methods that make more effective use of a variety of computing environments, as well as to devise strategies that accommodate the variation in completion time for function evaluations. Our approach is outlined in section 3.

Another consideration we address in this paper is incorporating fault-tolerant strategies into APPS since one intent is to use this software on large-scale systems. As the number of individual computers participating in a computation grows, the chance that one (or more) will fail also grows. If we embark on a lengthy computation, we want reasonable assurance of producing a final result, even if a subset of processors fails. Thus, our goal is to design methods that respond to such failures and protect the solution process. Rather than simply checkpointing intermediate computations to disk and then restarting in the event of a failure, we are instead considering methods with heuristics that adaptively modify the search strategy. We discuss the technical issues in further detail in section 4.

In section 5 we provide numerical results, for both standard and engineering optimization test problems, that compare a preliminary implementation of APPS with an implementation of parallel pattern search (PPS) that incorporates a blocking synchronization point within each iteration. Finally, in section 6 we outline additional questions to pursue.

Although we are not the first to embark on the design of asynchronous parallel optimization algorithms, we are aware of little other work, particularly in the area of nonlinear programming. Approaches to developing asynchronous parallel Newton or quasi-Newton methods are proposed in [4, 10], though the assumptions underlying these approaches differ markedly from those we address. Specifically, both assume that solving the Newton equation at each iteration is the dominant computational cost of the optimization algorithm because the dimensions of the problems of interest are relatively large. A different line of inquiry [23] considers the use of quasi-Newton methods in the context of asynchronous stochastic global optimization algorithms; we consider only the problem of identifying local stationary points.

2. Parallel pattern search.

Before proceeding to a discussion of APPS, let us first review some key features of pattern search.

A primary characteristic of pattern search methods is that they sample the function over a predefined pattern of points, all of which lie on a rational lattice. By enforcing structure on the form of the points in the pattern, as well as simple rules on both the outcome of the search and the subsequent updates, we are guaranteed global convergence to a stationary point [9, 16, 26].

For our purposes, the feature of pattern search that is amenable to parallelism is that once the candidates in the pattern have been defined, the function values at these points can be computed independently and, thus, concurrently.

To make this more concrete, consider the following particularly simple version of a parallel pattern search algorithm. At iteration k, we have an iterate $x_k \in \mathbb{R}^n$ and a steplength control parameter $\Delta_k > 0$. The pattern of p search directions is denoted by $\mathcal{D} = \{d_1, \ldots, d_p\}$. Although other choices for $\mathcal{D}$ are possible, for our simple variant we choose $\mathcal{D} \equiv \{e_1, \ldots, e_n, -e_1, \ldots, -e_n\}$, where e_j represents the jth unit vector. Figure 2.1 illustrates an example of this search pattern when $n = 2$.

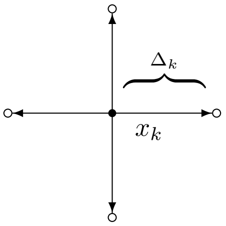

FIG. 2.1. *A simple instance of a pattern for pattern search.*

Now that we have selected $\mathcal{D}$, multiple algorithmic options are open to us. An obvious strategy for concurrent computing is to identify an $x_+ \in \{x_k + \Delta_k d_i,\ i = 1, \ldots, p\}$ such that $f(x_+) = \min\{f(x_k + \Delta_k d_i),\ i = 1, \ldots, p\}$. This strategy requires us to compute $f(x_k + \Delta_k d_i)$ for all p vectors in the set $\mathcal{D}$. To ensure global convergence of some subsequence to a stationary point we can accept any point $x_k + \Delta_k\, d_i$ for which $f(x_k + \Delta_k d_i) < f(x_k)$ [26]. Thus, finding $f(x_+) = \min\{f(x_k + \Delta_k d_i),\ i = 1, \ldots, p\}$ is in some sense more than is really needed. However, concurrency masks the computational expense of the stronger acceptance condition.

If none of the points in the pattern reduces the objective, then we set $x_{k+1} = x_k$ and reduce Δ by setting $\Delta_{k+1} = \frac{1}{2}\Delta_k$; otherwise, we set $\Delta_{k+1} = \Delta_k$ and $x_{k+1} = x_+$. We repeat this process until some reasonable stopping criterion, such as $\Delta_k \leq tol$, is satisfied [8, 9]. This basic strategy leads us to the algorithm we call parallel pattern search (PPS), which is given in Figure 2.2.

There still remains the question of what constitutes an acceptable pattern. Following the examples in [16], we borrow the following definition from [6].

DEFINITION 2.1. *A set of vectors $\{d_1, \ldots, d_p\}$ positively spans $\mathbb{R}^n$ if any vector $v \in \mathbb{R}^n$ can be written as a nonnegative linear combination of the vectors in the set; i.e., for any $v \in \mathbb{R}^n$ there exist $\alpha_1, \alpha_2, \ldots, \alpha_p \geq 0$ such that*

$$v = \alpha_1 d_1 + \cdots + \alpha_p d_p.$$

```
Initialization:
    • Set the iteration counter $k = 0$.
    • Select a set of search directions $\mathcal{D} = \{d_1, \dots, d_p\}$.
    • Select a steplength control parameter $\Delta_0$.
    • Select a stopping tolerance $tol$.
    • Select a starting point $x_0$ and evaluate $f(x_0)$.
Iteration:
    1. Compute $x_k + \Delta_k d_i$ and evaluate $f(x_k + \Delta_k d_i)$, for $i = 1, \dots, p$, concurrently.
    2. Determine $x_+$ and $f(x_+)$ such that $f(x_+) = \min \{ f(x_k + \Delta_k d_i),\ i = 1, \dots, p \}$
       (synchronization point).
    3. If $f(x_+) < f(x_k)$, then $x_k \leftarrow x_+$ and $f(x_k) \leftarrow f(x_+)$. Else $\Delta_k \leftarrow \frac{1}{2}\Delta_k$.
    4. If $\Delta_k > tol$, $k \leftarrow k + 1$, go to step 1. Else, exit.
```

FIG. 2.2. *The PPS algorithm.*

We require $\mathcal{D}$ to be a *positive spanning set* for $\mathbb{R}^n$. (This is a bit of a misnomer; given the definition, it perhaps would be more apt to call it a “nonnegative” spanning set.) We add the condition that $\mathcal{D}$ be composed of rational vectors [16].

3. Asynchronous parallel pattern search.

3. Asynchronous parallel pattern search. The appeal of the PPS strategy outlined in Figure 2.2 is that it is straightforward to implement. Unfortunately, inefficiencies in processor utilization for PPS arise when the objective function evaluations do not finish in approximately the same amount of time. This may happen for several reasons. First, the objective function evaluations may be complex simulations that require different amounts of work depending on the input parameters. Second, the computational loads on the individual processors may vary. Third, the processors participating in the calculation may possess different computational characteristics. When the objective function evaluations take varying amounts of time, those processors that can finish their share of the computation more quickly wait for the remaining processors to contribute their results. Fourth, the number of processes we are interested in executing may not exactly match the number of available processors. Finally, there is the real risk that either processes or processors may fail during the course of the computation. For all these reasons, we pursue a more versatile concurrent strategy, which we call asynchronous parallel pattern search (APPS), that allows us to effectively balance the computational load across the available processors.

Were we simply interested in load-balancing issues, the *master-slave* paradigm for the design of parallel programs would be inviting. Given such a design perspective, we could localize all decision making to a single process (the master) and devote all remaining processes (the slaves) to the evaluation of $f(x_{\text{trial}})$ for various choices of x_{trial} determined by the master process. Since we are assuming that the evaluation of the objective is the dominant computational cost, we would not have to be overly concerned about the communication bottlenecks that can sometimes occur using such a paradigm. However, fault tolerance is our other prominent concern. If we localize the decision making to a single process and the master process fails, we would be unable to finish the computation. (Recovery in the event that one of the slave processes fails is easy; once a failure is detected, the master process can simply restart the failed slave process.)

Such concerns lead us to the *peer-to-peer* paradigm. We want each process to be an independent unit, capable of making its own decisions and equipped to respond intelligently whenever it detects that other processes have failed.

```
Initialization:
    • Determine my search direction $d \in \mathcal{D}$.
    • Receive the initial value of the steplength control parameter $\Delta_{\text{trial}}$.
    • Receive the value of the stopping tolerance $tol$.
    • Receive the starting point $x_{\text{best}}$ and receive (or evaluate) $f_{\text{best}} \equiv f(x_{\text{best}})$.
Iteration:
    1. Compute $x_{\text{trial}} \leftarrow x_{\text{best}} + \Delta_{\text{trial}}\, d$ and evaluate $f_{\text{trial}} \equiv f(x_{\text{trial}})$.
    2. Perform a global reduction to determine $f_+$ (and the associated $x_+$) such that $f_+$ is the minimum of all $f_{\text{trial}}$ values on all $p$ processes.
    3. (a) If $f_+ < f_{\text{best}}$, then
              i. $\Delta_{\text{trial}} \leftarrow \lambda\, \Delta_{\text{trial}}$ with $\lambda \in \{2^{\ell} \mid \ell \in \mathbb{Z}_+\}$ and
              ii. $\{x_{\text{best}}, f_{\text{best}}\} \leftarrow \{x_+, f_+\}$.
       (b) Else $\Delta_{\text{trial}} \leftarrow \frac{1}{2}\Delta_{\text{trial}}$.
    4. If $\Delta_{\text{trial}} > tol$, go to step 1. Else, exit.
```

FIG. 3.1. *Peer-to-peer version of (synchronous) PPS.*

3.1. Peer-to-peer synchronous PPS.

In order to better understand APPS, let us first consider a peer-to-peer version of synchronous PPS.

For PPS, there are p processes, with each process in charge of a single search direction in the set $\mathcal{D}$. In Figure 3.1, we show the peer-to-peer version of synchronous PPS from the perspective of a single process. We drop the subscript $i = \{1, \ldots, p\}$ to emphasize that each process is only concerned with its own unique direction. In the initialization, each process determines its search direction and "receives" the values of Δ_{trial}, tol, and x_{best} either by reading them from an input file or by receiving them in a message from another process.

In the main iteration of PPS, the only communication a process has with its peers is the reduction in step 2, where all the processes participating in the computation contribute their values for x_{trial} and f_{trial}. The reduction operation returns f_+, the minimum value of f_{trial} over all processes, and x_+, the associated point. This reduction operation is the synchronization point for PPS—the minimum value of f_{trial} over all processes cannot be determined until all processes have finished their evaluation of $f(x_{\text{trial}})$.

As indicated in step 3(a)i, we may increase Δ_{trial} when a decrease in f is obtained. We have two possible reasons for doing so. First, we do not want Δ_{trial} to become too small based on the outcome of a search along a single direction. So if we find a step that produces decrease in f, but for which Δ_{trial} is smaller than some $\Delta_{\min} > tol$, then we choose the least nonnegative integer ℓ (i.e., $\ell \in \mathbb{Z}_+$) such that $2^{\ell}\Delta_{\text{trial}} > \Delta_{\min}$ (in our implementation we somewhat arbitrarily choose $\Delta_{\min} \equiv 2^3 \cdot tol$). Assuming, instead, that we ended the search successfully with a choice of Δ_{trial} that satisfies $\Delta_{\text{trial}} > \Delta_{\min}$, we may still choose to expand Δ_{trial}. In our implementation we double Δ_{trial} (i.e., we choose $\ell = 1$) if the same search direction produces at least two successful iterates in a row. Our reason for this condition is straightforward: if we have just completed a sequence of reductions in Δ_{trial} to arrive at a steplength that is sufficiently small to produce descent, it is counterproductive to follow this with an immediate doubling of Δ_{trial}. However, if the same search direction produces at least two successful iterates in a row, then this would indicate that the size of the step we are taking is probably too short, so we double Δ_{trial} in an effort to accelerate the search along that direction. If neither of the above two situations holds, then we do not alter Δ_{trial} (i.e., we choose $\ell = 0$).

On the other hand, if there is no decrease in f, in step 3(b) we reduce Δ_{trial} by a factor of one-half.

In step 4, all processes simultaneously check for convergence, each using its own locally stored, locally updated copy of Δ_{trial}. We note that in a heterogeneous environment, there exists the possibility that the processes may not have identical values for Δ_{trial} because of slight differences in both storage and arithmetic for floating-point numbers; see [2]. We address this issue in further detail in section 3.3.2.

```
Iteration:
    0. For each **new best** message in my queue:
        (a) If $f_+ < f_{\text{best}}$ for an incoming triplet $\{x_+, f_+, \Delta_+\}$, then
            i. $\{x_{\text{best}}, f_{\text{best}}, \Delta_{\text{best}}\} \leftarrow \{x_+, f_+, \Delta_+\}$, and
            ii. $\Delta_{\text{trial}} \leftarrow \Delta_{\text{best}}$.
        (b) Else, discard the triplet $\{x_+, f_+, \Delta_+\}$.
    1. Compute $x_{\text{trial}} \leftarrow x_{\text{best}} + \Delta_{\text{trial}}\, d$ and evaluate $f_{\text{trial}} \equiv f(x_{\text{trial}})$.
    2. Set $\{x_+, f_+, \Delta_+\} \leftarrow \{x_{\text{trial}}, f_{\text{trial}}, \Delta_{\text{trial}}\}$.
    3. (a) If $f_+ < f_{\text{best}}$, then
            i. $\Delta_{\text{trial}} \leftarrow \lambda\, \Delta_{\text{trial}}$ with $\lambda \in \{2^\ell \mid \ell \in \mathbb{Z}_+\}$; $\Delta_+ \leftarrow \Delta_{\text{trial}}$;
            ii. $\{x_{\text{best}}, f_{\text{best}}, \Delta_{\text{best}}\} \leftarrow \{x_+, f_+, \Delta_+\}$; and
            iii. *broadcast* a nonblocking **new best** message with the triplet
                 $\{x_{\text{best}}, f_{\text{best}}, \Delta_{\text{best}}\}$.
        (b) Else $\Delta_{\text{trial}} \leftarrow \frac{1}{2}\Delta_{\text{trial}}$.
    4. If $\Delta_{\text{trial}} > tol$, go to step 0. Else *broadcast* a nonblocking **single direction
       convergence** message with the triplet $\{x_{\text{best}}, f_{\text{best}}, \Delta_{\text{best}}\}$.
    5. Wait and process each incoming message in my queue until either
       (a) enough of the processes report single direction convergence for this same point
       or
       (b) a better point is received.
       In case (a), exit. In case (b), go to step 0.
```

FIG. 3.2. *Peer-to-peer version of APPS.*

3.2. Peer-to-peer APPS. The peer-to-peer version of APPS, from the perspective of a single process, is given in Figure 3.2. Note that the process's local values for x_{best}, x_+, Δ_{trial}, etc., *may not always agree with the local values on other processes.* This is in contrast to PPS, where all values except f_{trial} and x_{trial} are synchronized. While PPS relies on a global reduction operation to synchronize all critical values, APPS relies on nonblocking broadcasts to exchange information between processes. Descriptions of the individual steps of APPS follow. (The initialization for APPS is unchanged from that for PPS.) As we examine these steps, keep in mind that at each step, every process decides what to do next based only on its current *local* information.

Step 0: Checking for candidates from other processes. Before a process undertakes a new evaluation of the objective function, it considers any "new best" messages that may have arrived during the previous function evaluation. The receiving process considers each incoming triplet $\{x_+, f_+, \Delta_+\}$ as a candidate for a new best; hence the test in step 0(a). To make the procedure robust, we handle tie-breaking (i.e., the case where $f_+ = f_{\text{best}}$) in a consistent fashion, the details of which are deferred to section 3.3.2.

Step 1: Evaluating the function. Step 1 is the computational workhorse of PPS and is equivalent to the same step in synchronous PPS. The one substantive difference is that in PPS, x_{best} and Δ_{trial} are identical across all processes. In APPS, these values are no longer synchronized; they depend only on the information that is currently known to the process when it constructs $x_{\rm trial}$.

Step 2: Assigning the local candidate. This step does not actually require any action; it is here to emphasize that, in contrast to PPS, accepting the local trial point as a possible candidate for the new best does not involve the other processes. Instead, input from other processes is assessed in step 0, as it becomes available.

Step 3: Assessing the local candidate. If f_+, the function value at x_+, is better than $f_{\rm best}$, then $\Delta_{\rm trial}$ (and Δ_+) are increased (using the same strategy given in section 3.1 for PPS), the process's triplet $\{x_{\rm best}, f_{\rm best}, \Delta_{\rm best}\}$ is updated, and a message is broadcast to the other processes to inform them of this improvement. Otherwise, the process reduces $\Delta_{\rm trial}$ and continues.

Step 4: Checking for convergence along my search direction. There are two possible outcomes for step 3: either f_+ replaces $f_{\rm best}$ (in which case, $\Delta_{\rm trial}$ may be increased) or $f_{\rm best}$ is unchanged and $\Delta_{\rm trial}$ is reduced. If the second outcome occurs and $\Delta_{\rm trial} \leq tol$, this signals that no improvement can be found from the current $x_{\rm best}$ along the search direction d that this process owns and thus we may have arrived at a stationary point [9]. The process then notifies the other processes, by broadcasting a "single direction convergence" message, that it has converged (within tolerance) along its search direction.

Step 5: Waiting for a more complete picture of the entire search. The last step in APPS is the one step where a process may wait in an idle loop. Step 5 is reached only when a process has converged along its search direction. The idle process waits until either one of two things happens: it receives enough single direction convergence messages to verify global convergence to a stationary point of the objective function, or another process produces a point with a function value that is lower than $f_{\rm best}$. The details regarding what constitutes "enough" single direction convergence messages are deferred to section 3.3.3, where we discuss the precise measure of "enough" and how this can be determined.

3.3. Handling messages and exploiting parallelism. Now that we have discussed the essential logic of APPS, we change it slightly to better handle the message traffic and to better exploit parallelism.

There are technical considerations underlying the implementation of APPS that cause us to modify the algorithm slightly from the version presented in Figure 3.2. In particular, in the discussion above we have referred to a set of p processes, each of which handles computation, communication, and decision making. However, it is convenient to split the computation (i.e., the evaluation of the objective function) from the communication and decision making. One motivation for spawning a separate process to handle each evaluation of the objective function is that as a consequence of receiving a new best point from another process, it may be desirable to terminate an evaluation at some $x_{\rm trial}$ in order to move to the search to the new $x_{\rm best}$. A second motivation is that it should eliminate the accumulation of a large number of unprocessed messages, which can cause the message queue to overflow.

We start with a group of APPS *agent* processes that are in charge of the communication and decision making. Each evaluation of $f(x_{\rm trial})$ is spawned as a separate process that is subservient to a single APPS agent. The result is a set of APPS agents working in peer-to-peer mode, with each APPS agent spawning function evaluation processes as necessary. In contrast with the description of APPS given in Figure 3.2, APPS agents now dynamically initiate actions solely in response to messages, rather than routinely cycling through a fixed set of steps. It should be noted that the APPS agents require very little processing time, relative to the amount of time devoted to evaluating $f(x_{\text{trial}})$. Essentially, each APPS agent lies dormant until the arrival of an incoming message, which then triggers some action.

The types of incoming messages that an APPS agent receives are categorized as follows: a "return" from the process it spawned for the evaluation of $f(x_{\text{trial}})$, a "new best" message from another APPS agent, a "single direction convergence" message from another APPS agent, or a "shutdown" message from another APPS agent. We now investigate in more detail an APPS agent's reaction to each type of incoming message.

3.3.1. Handling "return" messages. An APPS agent receives a "return" message when the process it spawned to evaluate $f(x_{\text{trial}})$ returns the computed value f_{trial}. In Figure 3.3 we show an APPS agent's actions in response. In the discussions that follow, we introduce here an additional item to be associated with each point—a *convergence table* Π. The convergence table is used to detect a stationary point. It lists which of the p search directions from x have converged to within tolerance. We defer a further discussion of how this information is processed to section 3.3.3, where we discuss an APPS agent's action in response to a "single direction convergence" message in more detail.

```
Return from evaluation of the objective. Receive $f_{\text{trial}}$.
    1. Update $x_{\text{best}}$ and/or $\Delta_{\text{trial}}$.
        (a) If $f_{\text{trial}} < f_{\text{best}}$, then
                i. $\Delta_{\text{trial}} \leftarrow \lambda\, \Delta_{\text{trial}}$ with $\lambda \in \{2^\ell \mid \ell \in \mathbb{Z}_+\}$,
               ii. $\{x_{\text{best}}, f_{\text{best}}, \Delta_{\text{best}}, \Pi_{\text{best}}\} \leftarrow \{x_{\text{trial}}, f_{\text{trial}}, \Delta_{\text{trial}}, \Pi_{\text{trial}}\}$, and
              iii. broadcast a nonblocking new best message with the quadruple
                   $\{x_{\text{best}}, f_{\text{best}}, \Delta_{\text{best}}, \Pi_{\text{best}}\}$.
        (b) Else if $x_{\text{best}}$ is not the point used to generate $x_{\text{trial}}$, then $\Delta_{\text{trial}} \leftarrow \Delta_{\text{best}}$.
        (c) Else $\Delta_{\text{trial}} \leftarrow \frac{1}{2}\Delta_{\text{trial}}$.
    2. Check for convergence and spawn next objective function evaluation.
        (a) If $\Delta_{\text{trial}} > tol$, then compute $x_{\text{trial}} \leftarrow x_{\text{best}} + \Delta_{\text{trial}}\, d$, initialize $\Pi_{\text{trial}}$ to
            FALSE, and spawn a new process to evaluate $f(x_{\text{trial}})$.
        (b) Else update $\Pi_{\text{best}}$ (to signal convergence to $x_{\text{best}}$ along my direction $d$) and
            broadcast a nonblocking single direction convergence message with the
            quadruple $\{x_{\text{best}}, f_{\text{best}}, \Delta_{\text{best}}, \Pi_{\text{best}}\}$.
```

Fig. 3.3. *APPS agent's response to a return message.*

After receiving a return message, an APPS agent first must determine if a new best point has been identified, as shown in step 1(a). If so, the steplength Δ_{trial} may be increased (using the same rule as for PPS, given in section 3.1) and $\{x_{\text{trial}}, f_{\text{trial}}, \Delta_{\text{trial}}, \Pi_{\text{trial}}\}$ replaces $\{x_{\text{best}}, f_{\text{best}}, \Delta_{\text{best}}, \Pi_{\text{best}}\}$. The improvement is broadcast to all other APPS agents.

Upon first inspection, the need for step 1(b) may not be clear. An APPS agent constructs x_{trial} using its current values of x_{best} and Δ_{trial} (step 2(a) in Figure 3.3). While the process spawned by an APPS agent is busy evaluating $f(x_{\text{trial}})$, there is always the chance that another APPS agent will broadcast a quadruple $\{x_+, f_+, \Delta_+, \Pi_+\}$ whose value of f_+ improves upon the resident value of f_{best}. As we shall see in section 3.3.2, when an APPS agent receives such an incoming message, it replaces $\{x_{\text{best}}, f_{\text{best}}, \Delta_{\text{best}}, \Pi_{\text{best}}\}$ with $\{x_+, f_+, \Delta_+, \Pi_+\}$. Before constructing the next x_{trial}, the APPS agent ascertains if, while $f(x_{\text{trial}})$ was being computed, x_{best} was replaced as the result of an incoming message from another APPS agent. If so, then this new x_{best} will be used to compute the next x_{trial}. In this case, the APPS agent replaces Δ_{trial} with Δ_{best}; using the value of Δ associated with the best point retains some scaling information.

In step 1(c), we halve Δ_{trial} after confirming that f_{best} has not been replaced either by f_{trial} or by some f_+ contained in a message that arrived from another APPS agent while $f(x_{\text{trial}})$ was being computed.

Step 2 in Figure 3.3 checks the value of Δ_{trial}, our measure of progress toward a solution, and reacts appropriately. If Δ_{trial} is greater than *tol*, we continue the search. Otherwise, when $\Delta_{\text{trial}} \leq tol$, the search along the APPS agent's direction d has converged to x_{best}, and this information needs to be broadcast to all APPS agents.

3.3.2. Handling "new best" messages. When an APPS agent receives a "new best" message from another APPS agent, the first thing to check is whether or not the incoming quadruple really does contain the best function value seen thus far.

Here we encounter an important caveat of heterogeneous computing [2]. The comparison of floating-point values (in particular, f's and Δ's) controls the flow of APPS and we depend on these comparisons to give consistent results across all processes. Therefore, we must ensure that values are compared only to a level of precision available on all processors. In other words, a "safe" comparison declares a equivalent to b if

$$\frac{|\,a-b\,|}{\max\{|a|,|b|\}} < \epsilon^*_{\text{mach}}, \tag{3.1}$$

where ϵ^*_{mach} is greater than or equal to the maximum value of machine epsilon across the values for machine epsilon on all processors participating in the computation. If both $|a|$ and $|b|$ are below ϵ^*_{mach}, then they are automatically considered equal and (3.1) is not evaluated.

The second concern raised by the concurrency of the processes is what to do when f_+ and f_{best} are equivalent. Currently, APPS uses the following tie-breaking scheme. If f_+ and f_{best} satisfy (3.1), then compare Δ_+ and Δ_{best} and select the candidate with the larger value of Δ. If Δ_+ and Δ_{best} also satisfy (3.1), check next to see if x_+ and x_{best} are the same. Rather than comparing x_+ and x_{best} directly, by computing some norm of the difference, we use a unique global identifier with which APPS tags each point. Thus, two points are considered equivalent if and only if their f-values, Δ-values, and unique global identifiers are equivalent. This means that two points that actually are equal, but were generated via different paths on different processes, will be considered to be "different" points since their global identifiers do not match. However, since the purpose of the identification is to break ties in a consistent fashion, all we need worry about is what to do when both the f-values and the Δ-values are equivalent but the global identifier is not. In this last case, ties are broken in favor of the point with the lower global identifier. Since the global identifier of each point is a unique integer, the resolution is unambiguous. So, whenever we compare f_+ and f_{best}, the comparison incorporates this tie-breaking strategy.

Now that we can assess "improvement" on f_{best} in a way that both handles the vagaries of floating-point representation and breaks ties in a consistent fashion, we examine in more detail an APPS agent's actions to a "new best" message, shown in Figure 3.4.

```
New best. Receive $\{x_+, f_+, \Delta_+, \Pi_+\}$.
    1. If $f_+ < f_{\text{best}}$, then
        (a) If I had converged to $x_{\text{best}}$ along my search direction $d$, then
            i. $\{x_{\text{best}}, f_{\text{best}}, \Delta_{\text{best}}, \Pi_{\text{best}}\} \leftarrow \{x_+, f_+, \Delta_+, \Pi_+\}$, $\Delta_{\text{trial}} \leftarrow \Delta_{\text{best}}$,
            ii. compute $x_{\text{trial}} \leftarrow x_{\text{best}} + \Delta_{\text{trial}}\, d$, initialize $\Pi_{\text{trial}}$ to all FALSE, and
                spawn a new process to evaluate $f(x_{\text{trial}})$.
        (b) Else if $\Delta_{\text{trial}} < \Delta_+$, then
            i. terminate the process evaluating $f(x_{\text{trial}})$,
            ii. $\{x_{\text{best}}, f_{\text{best}}, \Delta_{\text{best}}, \Pi_{\text{best}}\} \leftarrow \{x_+, f_+, \Delta_+, \Pi_+\}$, $\Delta_{\text{trial}} \leftarrow \Delta_{\text{best}}$,
            iii. compute $x_{\text{trial}} \leftarrow x_{\text{best}} + \Delta_{\text{trial}}\, d$, initialize $\Pi_{\text{trial}}$ to all FALSE, and
                spawn a new process to evaluate $f(x_{\text{trial}})$.
        (c) Else, $\{x_{\text{best}}, f_{\text{best}}, \Delta_{\text{best}}, \Pi_{\text{best}}\} \leftarrow \{x_+, f_+, \Delta_+, \Pi_+\}$.
    2. Else discard $\{x_+, f_+, \Delta_+, \Pi_+\}$.
```

FIG. 3.4. *APPS agent's response to a new best message.*

Assuming improvement on f_{best}, the first action taken by an APPS agent is to determine the status of the search along the direction d. There are three possibilities to consider.

The first possibility, shown in step 1(a), is that at some point the search along d had converged within tolerance and so the APPS agent is now waiting for incoming messages to either confirm overall convergence of the search or, as in this case, produce a new best point (see step 5 in Figure 3.2). When the latter occurs, the incoming quadruple is accepted and the search is resumed from the new x_{best}.

The second possibility, shown in step 1(b), is that the search along d is still in progress, but that the steps along d have become small, i.e., $\Delta_{\text{trial}} < \Delta_{\text{best}}$. If so, then the search along d has reduced Δ_{trial}—perhaps repeatedly—in an effort to find improvement on f_{best}. In this case, it is particularly useful to have an APPS agent acting independently of the function evaluation process. An APPS agent can terminate the current evaluation of $f(x_{\text{trial}})$ before it actually finishes (step 1(b)i) in favor of starting a new evaluation of the objective based on a new value of x_{best} (step 1(b)iii). The question to ask is why we would choose to do so.

In certain cases, the current evaluation of the objective function is terminated in favor of starting one based on a new best point. Imagine the following scenario. Suppose three APPS agents, A, B, and C, start off with the same value for x_{best}, generate their own x_{trial}'s, and spawn their own evaluations of $f(x_{\text{trial}})$. Each evaluation of the objective function takes several hours. The evaluation for Agent A completes first and there is no improvement, so Agent A reduces its steplength, generates a new trial point, and spawns a new evaluation of the objective function. A few minutes later, Agent B's evaluation finishes and it produces improvement. Agent B broadcasts a "new best" message to the other APPS agents. Agent A receives this message and terminates its current evaluation of the objective function in order to move to the better point. This may save several hours of wasted computing time. However, Agent C, which is still working on its first evaluation of the objective function, waits for that to complete before considering a move to the new x_{best} because the inequality on Δ_{trial} does not hold in step 1(b) of Figure 3.4.

The third possibility when the incoming value of f_+ improves upon the local value of f_{best} is to simply accept the incoming quadruple, as shown in step 1(c). This is exactly the strategy for Agent C outlined in the scenario described above.

The final observation to be made is that if f_+ does not improve upon f_{best}, the

```
Single direction convergence. Receive ${x_+, f_+, \Delta_+, \Pi_+}$.
    1. If $f_+ < f_{\text{best}}$, then go through the steps for a new best message.
    2. If $f_+ = f_{\text{best}}$, then
        (a) Update $\Pi_{\text{best}}$ to include any new information contained in $\Pi_+$.
        (b) If I am the temporary master, then check for convergence.
            If enough of the other processes have converged (i.e., their associated
            directions form a positive spanning set), then
              i. report ${x_{\text{best}}, f_{\text{best}}}$,
             ii. broadcast a nonblocking shutdown message to the remaining APPS
                 agents, and
            iii. exit.
    3. Else discard ${x_+, f_+, \Delta_+, \Pi_+}$.
```

FIG. 3.5. *APPS agent's response to a single direction convergence message.*

quadruple $\{x_+, f_+, \Delta_+, \Pi_+\}$ is simply discarded; it already has been superseded by another point and thus is of no interest.

3.3.3. Handling "single direction convergence" messages. Detecting convergence for APPS is a trickier issue than it is for PPS because the APPS agents do not perform a synchronized test for convergence. Instead, each APPS agent stops spawning processes to evaluate $f(x_{\text{trial}})$ when its local value of Δ_{trial} satisfies $\Delta_{\text{trial}} \leq tol$. Any APPS agent that arrives at this conclusion then waits until either enough other APPS agents stop at the same best point (we describe "enough" below) or another APPS agent produces a better point from which to resume the search. Since every quadruple $\{x_{\text{trial}}, f_{\text{trial}}, \Delta_{\text{trial}}, \Pi_{\text{trial}}\}$ which improves upon f_{best} is broadcast to all APPS agents, every APPS agent eventually agrees on the best point.

When an APPS agent receives a "single direction convergence" message (see Figure 3.5), it checks to make sure that this function value and associated point have been seen before. If not (a distinct possibility since messages may arrive out of order), then the APPS agent handles the incoming quadruple as if it were part of a "new best" message.

If the incoming point is the same as the best point we have, i.e., $f_+ = f_{\text{best}}$, then the APPS agent receiving the message must update its convergence table Π_{best} to include any new information regarding the convergence of other search directions to the same point x_{best}. Again, timing issues must be taken into account as either the sending or the receiving APPS agent may have information that has not yet been seen by the other.

Next, in order to check for convergence of a sufficient number of the p independent search directions, it is useful to have a *temporary master* to avoid redundant computation. We define the temporary master to be the APPS agent with the lowest process identification number. While this is usually process 0, it is not necessarily the case if a fault occurs; we discuss this scenario further in section 4. The temporary master checks to see if the set of directions along which the search has converged forms a positive spanning set. If so, it reports to the user the final result of the search, broadcasts a "shutdown" message, and exits.

Checking for a positive spanning set can be done as follows. We know that a positive spanning set for $\mathbb{R}^n$ must contain at least $n + 1$ vectors [6]. So if the convergence table has at least $n + 1$ entries, it is time for the temporary master to check for convergence of the overall process. (Every APPS agent knows $\mathcal{D}$, which is why it is possible for any APPS agent to serve as temporary master.) Let $\mathcal{V} \subseteq \mathcal{D}$ be the candidate for a positive spanning set. We solve $n + 1$ nonnegative least squares problems according to the following theorem.

THEOREM 3.1. *A set $\mathcal{V} = \{v_1, v_2, \ldots, v_m\}$ is a positive spanning set if the set $\mathcal{E} = \{e_1, e_2, \ldots, e_n, -\mathbf{1}\}$ is in its positive span (where $-\mathbf{1}$ is the vector of all -1's).*

Alternatively, we can check the positive basis by first verifying that $\mathcal{V}$ is a spanning set using, say, a QR factorization with pivoting, and then solving a linear program.

THEOREM 3.2 (see Wright [27]). *A spanning set $\mathcal{V} = \{v_1, v_2, \ldots, v_m\}$ is a positive spanning set if the maximum of the following linear program is 1.*

$$\max\ t \quad \text{subject to } Vx = 0,\ x_i \geq t\ \forall\, i,\ 0 \leq t \leq 1,$$

where V is a matrix representing the spanning set $\mathcal{V}$.

We make use of Theorem 3.1 since Netlib provides freely available software, due to Lawson and Hanson [14], for solving nonnegative least squares problems. To make use of Theorem 3.2 requires software both for QR factorizations and for the solution of linear programs; the latter is particularly difficult to come by in a freely available, portable, and easy-to-use format.

3.3.4. Handling "shutdown" messages. The reactions of the other APPS agents to a "shutdown" message from the temporary master should be clear after the discussion in section 3.3.3; they are given in Figure 3.6. Again we note the value of having both an APPS agent and a separate process for evaluating $f(x_{\text{trial}})$; once the shutdown message has been received, an APPS agent can immediately terminate the process evaluating $f(x_{\text{trial}})$ and exit.

Shutdown. Receive the shutdown message from the temporary master.
1. *Terminate* the process evaluating $f(x_{\text{trial}})$ and
2. exit.

FIG. 3.6. *APPS agent's response to a shutdown message.*

4. Fault tolerance in APPS.

The move toward a variety of computing environments, including heterogeneous distributed computing platforms, brings with it increased attention to the fault tolerance of parallel algorithms. The large size, diversity of components, and complex architecture of such systems create numerous opportunities for hardware failures, and our computational experience confirms that these failures do, in fact, occur.

In addition, the size and complexity of current simulation codes call into question the robustness of the function evaluations. For example, our experience has been that it is possible to generate input parameters that are both physically and mathematically feasible but for which the simulation codes fail to finish successfully. Thus, we must contend with software failures as well as hardware failures.

A great deal of work has been done in the computer science community with regard to fault tolerance; however, much of that work has focused on making fault tolerance as transparent to the user as possible. This often entails strategies such as checkpointing the entire state of an application to disk or replicating processes. Fault tolerance has traditionally been used with loosely coupled distributed applications that do not depend on each other to finish, such as business database applications. This lack of interdependence is atypical of most scientific applications. While checkpointing and replication are adequate techniques for scientific applications, they incur a substantial amount of unwanted overhead; however, certain scientific applications have characteristics that can be exploited to derive more efficient and elegant stratagems for fault tolerance. Algorithm-dependent strategies for incorporating fault tolerance have already received attention in the scientific computing community; see, e.g., [21]. These approaches rely primarily on the use of diskless checkpointing, a significant improvement over traditional approaches. The nature of APPS is such that we can even further reduce the overhead for fault tolerance and dispense with checkpointing altogether.

Two important observations should be made regarding fault tolerance in APPS. First, there are no single points of failure in the APPS algorithm itself. Assuming initialization is successful, there is just one scenario that requires a single APPS agent to coordinate efforts among all agents (i.e., the *temporary master* used to check convergence of the entire search, as shown in Figure 3.5). However, the choice of master is not fixed. If the APPS agent serving as temporary master should fail while performing its tasks, another APPS agent steps up to take over. This means the degree of fault tolerance in APPS is constrained only by the underlying communication architecture. The current implementation of APPS uses PVM [11], which provides a rich library of communication and process management procedures needed by the APPS agents. The one limitation we inherit from PVM is that it executes multiple processes on multiple processors under the control of a single master PVM daemon. Thus the PVM daemon introduces a single point of failure within our current implementation of APPS. We expect HARNESS [1], the successor to PVM, to eliminate this disadvantage. The second observation to be made is that no checkpointing or replication of processes is necessary. The APPS agents can be reconfigured dynamically. New APPS agents require only a small packet of information from any active APPS agent in order to take over where a failed APPS agent left off. Therefore, we have been able to take advantage of algorithmic characteristics of pattern search in order to incorporate a high degree of fault tolerance into APPS with almost no additional overhead.

Having made these two observations, we now describe how fault tolerance is addressed in APPS. Every APPS agent keeps a record of active and inactive APPS agents (one per search direction), the available hosts, and a mapping of the active APPS agents to the available hosts. There are three types of faults with which we are concerned: (1) the failure of a process evaluating the objective function, (2) the failure of an APPS agent, and (3) the failure of a host processor. Once again we note the advantage of maintaining pairs of processes: an APPS agent to handle all communication (including information from PVM regarding the failure of processes) that is separate from the processes tasked with the major computations, the evaluations of the objective function. An individual APPS agent uses its record of active and inactive APPS agents to decide whether or not it is the temporary master and to determine the other APPS agents with whom it should interact in response to a failure. The responses to these three scenarios are shown in Figure 4.1.

When a process evaluating $f(x_{\text{trial}})$ fails, the failure is reported to its master (i.e., the APPS agent that originally spawned it), and that APPS agent respawns the evaluation of the objective function at the current trial point. If several (e.g., five) attempts to evaluate the objective function fail at the same trial point, the APPS agent that was spawning those evaluations exits, triggering an APPS agent failure message to be sent to the other APPS agents. The failure of an evaluation could be handled in different ways for different applications; for instance, attempts to evaluate

- **An APPS agent detects failure of its function evaluation process.**
  1. If the number of attempts to evaluate $f(x_{\mathrm{trial}})$ is less than the maximum number allowed, then respawn a new process to evaluate $f(x_{\mathrm{trial}})$.
  2. Else exit.
- **An APPS agent detects failure of another APPS agent.**
  1. Record the failure.
  2. If "my" process number is the lowest among the APPS agents still active, then assume the responsibility of *temporary master*.
  3. If I am the *temporary master*, then
     - (a) Check for convergence. If enough of the other APPS agents report convergence (i.e., their associated directions form a positive spanning set), then
       - i. report $\{x_{\mathrm{best}}, f_{\mathrm{best}}\}$,
       - ii. *broadcast* a nonblocking **shutdown** message to the remaining APPS agents, and
       - iii. exit.
     - (b) If the directions corresponding to the remaining APPS agents do not form a positive spanning set, respawn all failed APPS agents on available host processors.
- **An APPS agent detects failure of a host processor.**
  1. Remove failed host from list of available host processors.
  2. Determine all APPS agents residing on the failed host processor and treat each as a failed APPS agent.

FIG. 4.1. *Fault tolerance messages and actions.*

the objective function at a certain point could be abandoned without necessarily terminating the APPS agent.

When an APPS agent fails, all the remaining APPS agents record this failure. If the APPS agent that failed happened to be serving the role of temporary master, then another APPS agent must assume this responsibility. We maintain the convention that the active APPS agent with the lowest process number serves as temporary master. Once the question of who is temporary master is resolved, the first thing the new temporary master does is check for convergence since the now defunct APPS agent may have been in the midst of that check when it failed. If the search has not yet converged, the temporary master checks whether or not the set of directions owned by the remaining active APPS agents forms a positive spanning set. If so, then it is still possible to reliably determine whether or not the algorithm has converged, so nothing is done. Otherwise, all defunct APPS agents are restarted on the available hosts by the temporary master. Note that multiple APPS agents may be assigned to a single host.

If a host fails, the defunct host processor is removed from the list of viable hosts. The APPS agents that were running on the defunct host are regarded individually as failed APPS agents, which are then handled using the rules stated for APPS agent failures.

Despite the growing attention to fault tolerance in the parallel computing world, we are aware of only one other parallel optimization algorithm that incorporates fault tolerance, FATCOP [3]. FATCOP is a parallel mixed integer program solver that has been implemented using a Condor-PVM hybrid as the communication substrate. FATCOP is implemented in a master-slave fashion, which means that there is a single point of failure at the master process. This is addressed by having the master checkpoint information to disk (via Condor), but recovery requires user intervention to restart the program in the event of a failure. In contrast, once APPS has finished initialization, it can recover from the failure of any process of its own creation, including the failure of the temporary master. It does so on its own, with no checkpointing whatsoever.

5. Numerical results.

We compare APPS and PPS on several test problems as well as two engineering problems: a thermal design problem and a circuit simulation problem.

The tests were performed on the CPlant supercomputer at Sandia National Labs in Livermore, CA. CPlant is a cluster of DEC Alpha Miata 433 MHz processors. For our tests, we used 50 processors dedicated to our sole use.

5.1. Standard test problems.

We compare APPS and PPS with 8, 16, 24, and 32 processors on six four-dimensional test problems [20, 5], shown in Table 5.1.

Table 5.1
Six standard test problems.

1	2	3	4	5	6
`broyden2a`	`broyden2b`	`chebyquad`	`epowell`	`toint_trig`	`vardim`

Since the function evaluations are extremely fast, we added extra "busy work" (in the form of solving a 100×101 nonnegative least squares problem) in order to slow down the processes evaluating f and better simulate the computational behavior of the optimization problems in which we are interested.

The parameters for APPS and PPS were set as follows. Let $n = 4$ be the problem dimension, and let $p \in \{8, 16, 24, 32\}$ be the number of processors. The first $2n$ search directions in $\mathcal{D}$ are $\{e_1, e_2, \ldots, e_n, -e_1, -e_2, \ldots, -e_n\}$. The remaining $p-2n$ directions are generated randomly (with a different seed for every run) and normalized to unit length. This construction ensures that $\mathcal{D}$ is a positive spanning set. We initialize $\Delta = 1.0$ and $tol = 0.001$. We start each of these six problems from the standard starting point [20, 5].

Before considering the summary results, we discuss the details of two sample runs (one each for APPS and PPS) given in Table 5.2. Each process reports its own counts and timings. All times are reported in seconds and are wall clock times. Because APPS is asynchronous, the number of function evaluations spawned by each APPS agent varies considerably. Furthermore, the APPS agents sometimes terminate ("break") processes evaluating $f(x_{\text{trial}})$. On the other hand, because PPS is synchronous, every process executes the same number of function evaluations and there are no breaks. For both APPS and PPS, the initialization time is longer for Process 0 since it is in charge of spawning all remaining tasks. The idle time varies from process to process, but is overall lower for APPS than PPS. An APPS agent is idle only when it has converged along its search direction, but a PPS process may potentially have some idle time every iteration while it waits for the completion of the global reduction. The total wall clock time varies from process to process since each starts and stops at slightly different times. The summary information reports the mean over all eight processes, except in the case of total time, where the *maximum* total time over all eight processes is reported.

Because some of the search directions are generated randomly, every run of APPS and PPS follows a different path to the solution and generates possibly different solutions in the case of multiple minima. (The exception is PPS with $p = 8$. Because there are no "extra" search directions, the path to the solution is the same for every run—only the timings differ. The nondeterministic nature of APPS causes us to see

Table 5.2
Detailed results for `epowell` *on eight processors.*

Method	Process	Function	Function	Init	Idle	Total

Summary statistics		235	N/A	0.22	6.10	30.63

different counts and different timings for every run, even if the search directions for each run are identical.) Therefore, for each problem in Table 5.1 we report the mean of the summary statistics from 25 runs; for each *individual* run we collected the same summary statistics (except the initialization time) reported in Table 5.2.

The test results are summarized in Table 5.3. These tests were executed in what should have been a particularly favorable environment for PPS—a cluster of homogeneous, dedicated processors. The primary difficulty for PPS is the cost of synchronization in the global reduction. In terms of average function evaluations per processor, APPS and PPS typically required about the same number. In general, for both APPS and PPS, the number of function evaluations per processor decreased as the number of processes increased. We expected the idle time for APPS to be less than that for PPS; and, indeed, the idle time is two orders of magnitude less. Furthermore, the idle time for PPS increases as the number of processors goes up. APPS was faster (on average) than PPS in 23 out of 24 cases. The total time (on average) for APPS either stayed more or less steady or actually decreased as the number of processors increased. In contrast, the total time (on average) for PPS almost always increased as the number of processors increased, due to the synchronization penalty incurred with the addition of more processes.

Comparing APPS and PPS on simple problems is not necessarily indicative of results for typical engineering problems. The results in sections 5.2 and 5.3 yield more meaningful comparisons, given the types of problems for which pattern search is best suited.

5.2. TWAFER: A thermal design problem. In this set of tests, the engineering application is an optimal control problem for a thermal deposition furnace for silicon wafers. The furnace contains a vertical stack of wafers and several heater zones. The goal is to choose power settings for the heaters in each of n zones to achieve a prescribed constant temperature across each wafer and throughout the stack. The simulation code, TWAFER [12], yields measurements at a discrete collection of points

Table 5.3

	32	64.09	46.04	15.96	0.03	9.58	6.14	15.51

on the wafers. The objective function f is defined as

$$f(x) = \sum_{j=1}^{N} \left(T_j(x) - T_*\right)^2 , \tag{5.1}$$

where N is the number of discrete temperature measurement points, $T_j(x)$ is the simulated temperature at the jth point for the power settings defined by x, and T_* is the prescribed ideal temperature.

We consider the four- and seven-zone (or variable) problems with $N = 40$ and $N = 400$, respectively. For the four-zone problem, the initial guess produced a function value of 2.26×10^6. The initial guess for the seven-zone problem produced a function value of 7.43×10^4. (The initial guess for the seven-zone problem was much closer to the final solution.)

We used the following settings for APPS and PPS. The first $n+1$ search directions are the points of a regular simplex centered about the origin. The remaining $p-n-1$ points are generated randomly and normalized to unit length. Because the magnitude of the variables was $O(100)$, we set $\Delta = 10.0$. Note that it can be quite useful to choose the initial Δ based on the magnitudes of the components in x_0 as a way to capture some scaling information about the problem [25]. We chose $tol = 0.1$, which corresponds to a level of accuracy that is reasonable in the power settings.

There are some difficulties from the implementation point of view that are quite common when dealing with simulation codes. Because TWAFER is a legacy code, it expects an input file with a specific name and produces an output file with a specific name. The names of these files cannot be changed, and TWAFER cannot be hooked directly to PVM. As a consequence, we must write a "wrapper" program that runs an input filter, executes TWAFER via a system call, and runs an output filter. Because TWAFER is executed via a system call, APPS has no way of terminating its execution prematurely. (APPS can terminate the wrapper program, but TWAFER itself will continue to run, consuming system resources.) Therefore, we allow all function evaluations to run to completion; that is, we do not allow any breaks.

Another feature of TWAFER is that there are nonnegativity constraints on the power settings. The solution is known to be strictly positive, and the constraints play only a minor role in finding the solution. We did not invoke TWAFER at any point that had one or more negative components; to accomplish this, we use a simple barrier function that returns a large value (e.g., 10^{50}). This is a classic trick used by direct search methods for dealing with bound constraints. With the correct choice of $\mathcal{D}$, pattern search methods that use such a strategy can be shown to have at least one subsequence of iterates that converge to a Karush–Kuhn–Tucker point [18, 19].

Table 5.4
Summary statistics (across multiple runs) for the four- and seven-zone TWAFER problems.

Problem	Method	Procs	$f(x*)$	Function evals	Idle time	Total time
4 Zone	APPS	20	0.67	334.6	0.17	395.94
4 Zone	PPS	20	0.66	379.9	44.77	503.88
7 Zone	APPS	35	3.30	240.4	71.48	2260.46
7 Zone	PPS	35	2.85	202.2	213.90	2306.83

Results for the TWAFER problem are given in Table 5.4. The four-zone results report the means across all twenty processors over all ten runs. The seven-zone results report the means across all 35 processors over all nine runs. (We started ten runs for the seven-zone problem. One of the ten PPS runs failed due to a processor fault. One of the ten APPS runs experienced several faults and, although it did get the final solution, the summary data was incomplete.)

Recall that the goal is to choose power settings to achieve a constant temperature across each wafer and throughout the stack. In Figure 5.1 we show the temperatures computed by TWAFER at each wafer along a line of discretization points from the bottom to the top of the furnace. We show results for both the initial settings we were given for the seven-zone problem and the best and worst settings returned by APPS, corresponding to function values of 1.48 and 7.74, respectively. (The plots of the results from the best and worst PPS solutions are indistinguishable from the best and worst plots for APPS.) Table 5.4 shows that for this problem, on average, PPS yields slightly better function values than APPS (less than 1/1000th of a percent relative difference compared to the function value at the starting point) but required more total time. Figure 5.1 demonstrates that, qualitatively, all the solutions produced were comparable, particularly given the modest choice of $tol = 0.1$.

Clearly, the idle time figures prominently in the overall performance of PPS. The average simulation time is 1.3 seconds for the four-zone problems and 10.4 seconds for the seven-zone problem. However, when the nonnegativity constraints are violated, TWAFER is not called, so the execution time is essentially zero since we simply return 10^{50} after checking the coordinates of x_{trial}. The relatively high mean idle time for APPS (for the seven-zone problem) can be traced to a single run for which the idle time was particularly high for some processors (634 seconds on average across all 35 processors); on the remaining runs, the average APPS idle time per processor was

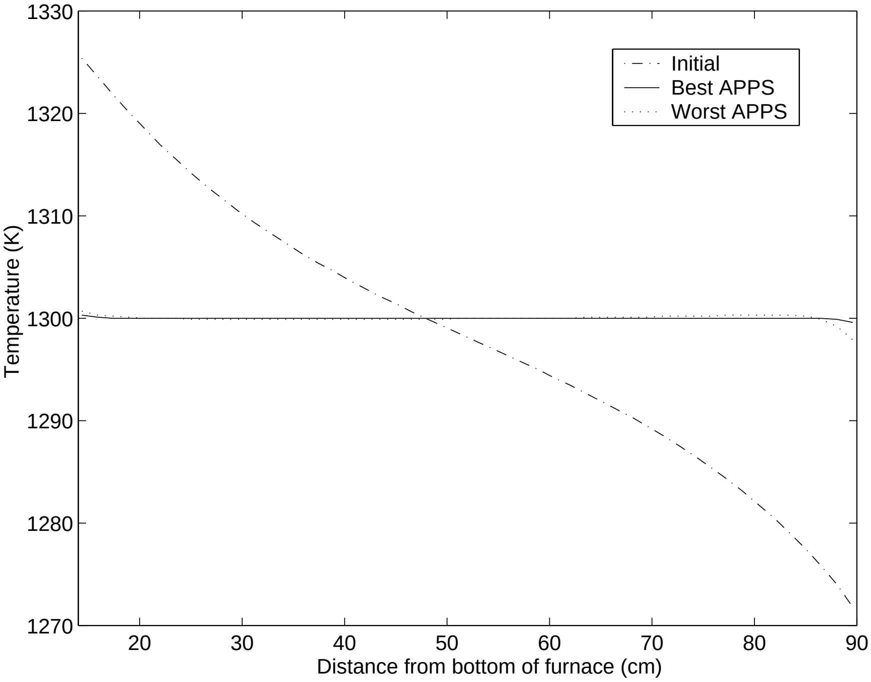

FIG. 5.1. *TWAFER results for the seven-zone problem using APPS with tol* = 0.1. *The solid line represents the simulation output for the best settings found by APPS and the dotted line represents the simulation output for the worst settings found by APPS. The dashed line represents the simulation output for the initial settings. The target is a constant temperature of* 1300.

lower by several orders of magnitude. We were unable to determine the cause of the unusually large idle time.

5.3. SPICE: A circuit simulation problem. The problem is to match simulation data to experimental data for a particular circuit in order to determine its characteristics. In our case, we have 17 variables representing inductances, capacitances, diode saturation currents, transistor gains, leakage inductances, and transformer core parameters. The objective function is defined as

$$f(x) = \sum_{j=1}^{N} \left(V_j^{\mathrm{SIM}}(x) - V_j^{\mathrm{EXP}}\right)^2, \tag{5.2}$$

where N is the number of time steps, $V_j^{\mathrm{SIM}}(x)$ is the simulation voltage at time step j for input x, and V_j^{EXP} is the experimental voltage at time step j.

The SPICE3 [22] package is used for the simulation. Like TWAFER, SPICE3 communicates via file input and output and so we again use a wrapper program.

The input filter for SPICE is more complicated than that for TWAFER because the variables for the problem are on different scales. Since APPS has no mechanism for scaling, we handled this within the input filter by computing an affine transformation of the variables used to formulate the objective function (5.2). Additionally, all the variables have upper and lower bounds. Once again, we use a simple barrier function.

The output filter for SPICE is also more complicated than that for TWAFER. The SPICE output files consist of voltages that are to be matched to the experimental data.

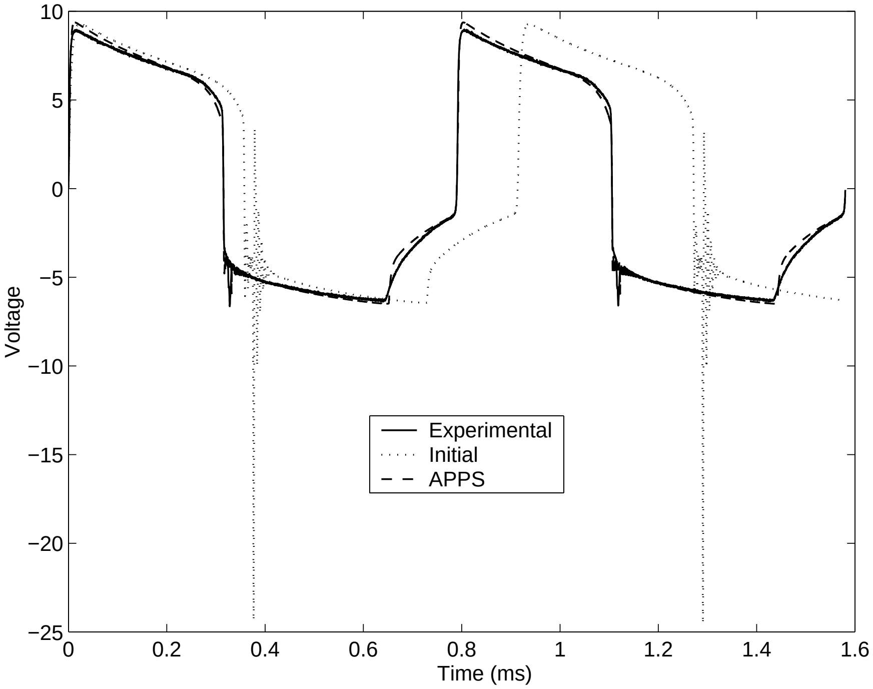

Fig. 5.2. *Spice results using APPS with tol* = 0.1*. The solid line represents the experimental output. The dashed line represents the simulation output after optimization. The dotted line represents the simulation output for the initial point.*

The experimental data is two cycles of output voltage measured at approximately $N = 2700$ discrete time steps (see Figure 5.2). The simulation data contains approximately 10 or more cycles, but only the last few complete cycles are used because the early cycles are not stable. The cycles must be automatically identified so that the data can be aligned with the experimental data. Furthermore, the time steps from the simulation may differ from the time steps in the experiment, and so the simulation data are interpolated (piecewise constant) to match the experimental data. The function value at the initial point is 465.

The APPS parameters were set as follows. The search directions were generated in the same way as those for the test problems in section 5.1. We set $\Delta = 1.0$ (the affine transformation means the variables are well scaled) and *tol* is 0.1 (the tolerance corresponds to a less than 1% change in the circuit parameter). Once again, we do not allow "breaks" since the function evaluation is called from a wrapper program via a system call.

The results from APPS and PPS on the SPICE problem are reported in Table 5.5. In this case, we are reporting the results of single runs; we give results for 34 and 50 processors. The average SPICE run time is approximately 20 seconds; however, once again we do not differentiate between times when the boundary conditions are violated and when the SPICE code is actually executed. Increasing the number of processors by 47% results in a 39% reduction in execution time for APPS but only 4% for PPS. For both 34 and 50 processors, APPS is faster than PPS and even produces a slightly better objective value (compared to the starting value of more than 400). At the solution, two constraints are binding.

TABLE 5.5
Results (one run each) for the 17 *variable SPICE problem.*

Method	Procs	$f(x*)$	Function evals	Idle time	Total time
APPS	34	26.3	57.5	111.92	1330.55

PPS	50	34.9	47.0	905.48	1646.53

TABLE 5.6
APPS results for the 17 *variable SPICE with a failure approximately every* 30 *seconds.*

Initial procs	Final procs	$f(x*)$	Total time
34	34	27.8	1618.46
50	32	54.2	1041.14

Table 5.6 shows the results of running APPS with faults. In this case, we used a program that automatically killed one PVM process every 30 seconds. The PVM processes are the APPS agents and the wrapper programs. The SPICE3 simulation is executed via a system call, and so continues to execute even if its wrapper terminates; regardless, the SPICE3 program can no longer communicate with APPS and is effectively dead.

The results are quite good. In the case of 34 processors, every APPS task that fails must be restarted in order to maintain a positive basis. So, the final number of APPS processes is 34. The total time is only increased by 21% despite approximately 50 failures; furthermore, this time is still faster than PPS. In the case of 50 processors, the final number of processors is 32. (Recall that tasks are only restarted if there are not enough remaining to form a positive basis.) In the case of 50 processors, the solution time is only increased by 29% with faults, and is once again still faster than PPS. In this case, however, the quality of the solution is degraded. This is likely due to the fact that the solution lies on the boundary and some of the search directions that failed were needed to ensure convergence to a KKT point (see [18, 19]).

6. Conclusions. Our preliminary numerical results make clear that because APPS dynamically initiates actions solely in response to messages, it is a more effective method—even in a homogeneous cluster environment—than PPS, where "more effective" means that APPS requires less total time to return results that are comparable to those returned by PPS. We expect the differences to be even more pronounced for larger problems (where by "larger" we mean in terms of both the execution time and the number of variables) and for heterogeneous cluster computing environments. Unlike PPS, which routinely cycles through a fixed set of steps, APPS does not have any required synchronizations and, thus, appears to gain most of its advantage by reducing idle time.

Further, APPS is a fault-tolerant algorithm. We accomplish this by making algorithmic changes to PPS that introduce almost no additional overhead. As we saw in the results for the SPICE problem solved using 34 processors (section 5.3), APPS does not suffer much slow-down when faults do occur.

Finally, in forthcoming work, Kolda and Torczon [13] will show that in the unconstrained case, APPS is globally convergent (even when faults occur) under the standard assumptions for pattern search [16, 26].

These features duly noted, we are investigating further improvements to the implementation of APPS. For instance, in the implementation described here, each APPS agent is responsible for exactly one process to evaluate the objective function. For multiprocessor (MPP) compute nodes, this means there will be multiple agents per node. An alternative implementation of APPS is being developed in which there is exactly one agent per node, with the single agent managing multiple evaluations of the objective function. As part of this alternative implementation, the ability to dynamically add new hosts as they become available (or to re-add previously failed hosts) also will be incorporated.

Another improvement to the implementation will be the addition of a cache to store the values of the function at all the points visited by the search in order to avoid reevaluating the same point more than once. The challenges are to make the recovery of this information fast and to decide when two points are actually equal. The latter is especially difficult when we do not know the sensitivity of the function to changes in each variable.

The importance of positive bases in the pattern also raises several interesting questions. In general, we might consider the best way to generate the starting basis. The analysis of pattern search makes clear that the "conditioning" of the positive basis has an effect on the amount of decrease that may be realized [16]. Our numerical studies have indicated that the quality of the positive basis can, indeed, affect the progress of the search. Thus, explicitly monitoring the conditioning of the positive basis, which changes dynamically, could improve the overall performance of APPS. Further, supposing that enough failures have occurred so that there is no longer a positive basis, we may ask if we can easily determine the smallest number of vectors to add to once again have a positive basis. Our current implementation simply restarts all failed APPS agents (see Figure 4.1). In general, we desire a pattern that maximizes the probability of maintaining a well-conditioned positive basis in the event of failures, without requiring us to keep a large number of processes active when it is neither necessary nor convenient to do so.

Finally, although the engineering examples used in this work have bound constraints, the current version of APPS does not handle constraints in a rigorous fashion. The poor results on the SPICE problem with faults on 50 processors may well be attributed to this fact since several constraints are active at a known solution. The analysis for pattern search suggests several algorithmic options we could pursue [17, 18, 19], but the challenge is to do so in a way that works effectively within the asynchronous framework we have devised. Future work will explore robust extensions for handling constraints.

Acknowledgments. We thank Jim Kohl, Ken Marx, and Juan Meza for helpful comments and advice in the implementation of APPS and the test problems. We also thank the referees for their careful reading of an earlier draft of this manuscript. Their suggestions considerably improved the presentation of this work.

ON BLOCK PRECONDITIONERS FOR NONSYMMETRIC SADDLE POINT PROBLEMS*

PIOTR KRZYŻANOWSKI†

Abstract. We discuss a class of preconditioning methods for an iterative solution of algebraic nonsymmetric saddle point problems arising from a mixed finite element discretization of partial differential equations, in particular the Navier–Stokes equation. We prove that block diagonal and block triangular preconditioners based on *symmetric, positive definite* blocks guarantee that the convergence rate of the method is independent of the mesh parameter h.

Key words. saddle point problems, nonsymmetric, block preconditioners

1. Introduction.

In many applications one needs to solve a discrete system of linear equations with a block matrix

$$\mathcal{M}\begin{pmatrix} u \\ p \end{pmatrix} \equiv \begin{pmatrix} A & B^T \\ B & -C \end{pmatrix}\begin{pmatrix} u \\ p \end{pmatrix} = \begin{pmatrix} f \\ g \end{pmatrix}, \tag{1.1}$$

where the matrix block A is positive definite, yet not necessarily symmetric, and C is nonnegative. Our motivation for considering this kind of problem comes from computational fluid dynamics, precisely, from the linearized discrete mixed finite element Navier–Stokes equations, where, except in some very simple cases, A is nonsymmetric, while usually it is reasonable to assume that it is positive definite [10]. C can be zero or positive semidefinite when a stabilized method is applied. Since (1.1) is ill conditioned with respect to the mesh parameter h, our aim in this paper is to design and/or analyze block preconditioners for this system, for which an iterative method converges independently of h.

Block preconditioners for a symmetric matrix $\mathcal{M}$ have been considered by many authors, for example, Bramble and Pasciak [1], [3], Rusten and Winther [27], Silvester and Wathen [29], and Klawonn [20], [19]. A symmetrized approach has been considered by D'yakonov [7] and Bramble and Pasciak [2]. Block preconditioned Uzawa-type methods have also attracted research interest; see, for example, papers by Elman and Golub [12] or Bramble, Pasciak, and Vassilev [4]. These preconditioners have been verified in computational tests (see the references listed above and also [9]).

Elman and Silvester [10] were probably the first to analyze how block preconditioners do work in the nonsymmetric case. They analyzed discretizations of the Oseen equations

$$\begin{cases} -\nu\Delta u + (k\cdot\nabla)u + \nabla p = f, \\ \operatorname{div} u = 0, \end{cases}$$

which serve as a model of the linearized Navier–Stokes equations and lead to a nonsymmetric system. In papers by Elman, Silvester, and Wathen [13], [14], Elman [11], Silvester et al. [30], and Golub and Wathen [17], a range of block preconditioning methods for this kind of problem has been introduced and analyzed. Some of these methods show very good convergence properties with respect to both h and ν. Of these, [10], [11], and [30] address diagonal/triangular preconditioners using also inexact nonsymmetric solves, while [17] develops a method based on Stokes-like solves with inexact blocks. Recently, Bramble, Pasciak, and Vassilev studied the inexact Uzawa algorithm for nonsymmetric saddle point problems [5], exploiting preconditioners for the symmetric part of A.

Independently, Klawonn and Starke [23] provided a field-of-values analysis of block triangular preconditioners for the Oseen problem. Their analysis is valid for triangular block preconditioner with upper diagonal block that is "sufficiently close" to A.

In this paper, based on [24] and [26], we present a new mathematical analysis of block preconditioning algorithms and propose other approaches as well. Our analysis is valid for inexact *and* symmetric block solvers and shows that for diffusion-dominated Oseen equations, a sufficient preconditioner can be based just on the symmetric part of the diagonal blocks of $\mathcal{M}$. We perform our analysis in a discrete $H^1 \times L^2$-like norm (which is natural for the problem), using a custom inner product derived from the preconditioner being used.

We focus on block preconditioners built up from preconditioners for *symmetric* parts of diagonal blocks of (1.1) and we consider two preconditioning strategies, using block diagonal or block triangular matrices. The first approach is to symmetrize the problem. We prove that the resulting system spectral condition number is independent of the dimension of (1.1), so that the PCG method [16] converges uniformly in h. However, the numerical experiments that we report on show that this method is quite computationally intensive (because it uses two or more solves per iteration). Thus, our second approach relies on applying the GMRES [28] iterative method to system (1.1) preconditioned by a block triangular matrix. We prove that, under minor assumptions, the block triangular preconditioner guarantees the GMRES to converge independently of h.

In the case of the linearized Navier–Stokes equations, block preconditioners discussed in the paper can be based on symmetric and positive definite preconditioners for the discrete Laplacian and mass matrices. That gives an application programmer a great opportunity to reuse, in an efficient way, existing very powerful methods (or software) like domain decomposition [31] or multigrid [18] methods for these simpler problems. Using symmetric solvers can also lead to some computational savings. We believe that in certain cases this may be a robust alternative to custom domain decomposition preconditioners, such as those proposed by Klawonn and Pavarino [21], developed for the whole saddle point problem (for a comparison between a 2-level Schwarz method and block preconditioners based also on 2-level Schwarz methods, see another paper by Klawonn and Pavarino [22]).

A general drawback of the methods being analyzed in the paper is that their convergence rate deteriorates when the ellipticity constant of A decreases. Clearly, in such a case, the symmetric part holds too little information about A. This limits the application of these methods to flows with reasonably small Reynolds number.

The plan of the remaining sections is as follows. In section 2, we introduce the framework in which we shall analyze our algorithms. Some useful estimates are also provided there. Section 3 is devoted to the analysis of preconditioning methods which lead to symmetric positive definite systems. In section 4, we analyze a block triangular preconditioner for the GMRES method. We conclude with section 5, which contains the results of numerical experiments for the Oseen equation.

2. General assumptions.

We consider the saddle point problem (1.1) with matrix $\mathcal{M}$, which arises from a mixed finite element discretization of partial differential equations, so our framework should reflect the dependence of (1.1) on the mesh parameter h. For theoretical convenience, we shall carry our analysis in terms of linear operators rather than in terms of matrices.

Let $\bar{V}, \bar{W}$ be real Hilbert spaces with scalar products denoted by $((\cdot,\cdot))$ and $(\cdot,\cdot)$, respectively. The norms in these spaces, induced by the inner products, will be denoted by $||\cdot||$ and $|\cdot|$. We consider a family of finite-dimensional subspaces indexed by the parameter $h \in (0,1)$: $V_h \subset \bar{V}$, $W_h \subset \bar{W}$. If V_h, W_h come from the finite element approximation, the dimension of these subspaces increases for decreasing h.

Let us introduce three continuous bilinear forms, $a : \bar{V} \times \bar{V} \to R$, $b : \bar{V} \times \bar{W} \to R$, $c : \bar{W} \times \bar{W} \to R$, and assume that $a(\cdot,\,\cdot)$ is $\bar{V}$-elliptic, i.e.,

$$\exists 0 < \nu \le 1 \quad \forall v \in \bar{V}, \qquad a(v,\,v) \ge \nu ||v||^2 \tag{2.1}$$

(by analogy to the Oseen equations, we shall call ν the viscosity parameter), and that $c(\cdot,\,\cdot)$ satisfies

$$\exists \gamma \ge 0 \quad \forall p \in \bar{W}, \qquad c(p,\,p) \ge \gamma |p|^2 \tag{2.2}$$

(we allow $\gamma = 0$). Notice that $a(\cdot,\cdot)$ does not need to be symmetric. We shall also assume that V_h and W_h satisfy the uniform LBB condition (see [15])

$$\exists \beta > 0 \quad \forall h \in (0,1), \quad \forall p \in W_h, \qquad \beta |p| \le \sup_{v \in V_h, v \ne 0} \frac{b(v,\,p)}{||v||}. \tag{2.3}$$

In what follows we consider preconditioners for a family of finite-dimensional problems (we drop the subscript h for simplicity of notation).

Problem 2.1. *Find $(u,p) \in V \times W$ such that*

$$\mathcal{M}\begin{pmatrix} u \\ p \end{pmatrix} \equiv \begin{pmatrix} A & B^* \\ B & -C \end{pmatrix}\begin{pmatrix} u \\ p \end{pmatrix} = \begin{pmatrix} F \\ G \end{pmatrix}. \tag{2.4}$$

The operators in (2.4) are

$$\begin{aligned} &A : V \to V, \quad ((Au,v)) = a(u,\,v) \quad \forall u,v \in V,\\ &B : V \to W, \quad (Bu,p) = b(u,\,p) \quad \forall u \in V,\ p \in W,\\ &C : W \to W, \quad (Cp,q) = c(p,\,q) \quad \forall p,q \in W, \end{aligned}$$

while the right-hand side $F \in V, G \in W$ is defined through $((F,v)) \equiv \langle\langle f,v \rangle\rangle$ and $(G,w) \equiv \langle g,w \rangle$, where f,g are given continuous functionals on $\bar{V}$, $\bar{W}$, and $\langle\langle\cdot,\cdot\rangle\rangle$, $\langle\cdot,\cdot\rangle$ denote the duality pairing in $\bar{V}$, $\bar{W}$, respectively. B^* denotes the formal adjoint operator to B, i.e., $(Bu,p) = ((u,B^*p))\ \forall u \in V,\ p \in W$.

We introduce two more operators, $A_0 : V \to V$ and $J_0 : W \to W$. We assume that they are self-adjoint, their inverses are easy to apply, and there exist positive constants a_0, a_1, b_0, b_1, which are independent of h and ν, such that

$$a_0((u,u)) \le ((A_0u,u)) \le a_1((u,u)) \qquad \forall u \in V, \tag{2.5}$$

$$b_0(p,p) \le (J_0p,p) \le b_1(p,p) \qquad \forall p \in W. \tag{2.6}$$

In other words, we shall always assume that A_0 and J_0 define good preconditioners for the Grammian matrices for the chosen bases in V and W, respectively. For example, in the case of the linearized Navier–Stokes equations, A_0 may be a preconditioner for the discrete Laplace operator, while J_0 may be a pressure mass matrix operator preconditioner. Thus, the A_0 preconditioner may be constructed using very efficient domain decomposition or multigrid techniques; for J_0, instead of domain decomposition, one can also use very cheap diagonal scaling [33].

For $f \in V$, $g \in W$, the energetic norms defined by $|||f|||_{A_0^{-1}} = ((A_0^{-1}f, f))^{1/2}$ and $|||g|||_{J_0^{-1}} = (J_0^{-1}g, g)^{1/2}$ are equivalent, with constants independent of h and ν, to $||f||$ and $|g|$, respectively. This fact follows directly from (2.5) and (2.6). The product space $V \times W$ is equipped with the natural scalar product $\langle \cdot, \cdot \rangle$,

$$\left\langle \begin{pmatrix} u \\ p \end{pmatrix}, \begin{pmatrix} v \\ q \end{pmatrix} \right\rangle = ((u, v)) + (p, q);$$

however, we are going to analyze the preconditioned problem using a custom inner product $[\cdot, \cdot]$, which is dependent on the preconditioners being used:

$$\left[\begin{pmatrix} u \\ p \end{pmatrix}, \begin{pmatrix} v \\ q \end{pmatrix} \right] = ((A_0 u, v)) + (J_0 p, q) = \left\langle \begin{pmatrix} A_0 & 0 \\ 0 & J_0 \end{pmatrix} \begin{pmatrix} u \\ p \end{pmatrix}, \begin{pmatrix} v \\ q \end{pmatrix} \right\rangle . \tag{2.7}$$

Again, the norms generated by both products are equivalent to one another, with constants independent of h and ν.

The generic constant "const," which we shall use later in the paper, is independent of both the mesh parameter h and the viscosity parameter ν. The following estimates hold for the operators involved in Problem 2.1.

LEMMA 2.1. *The norms of A, B, C, A_0, J_0, $\mathcal{M}$ operators and their adjoints in adequate spaces are bounded independently of h and ν:*

$$\begin{aligned} &||A||_{V\to V}, \quad ||B||_{V\to W}, \quad ||C||_{W\to W}, \\ &||A^*||_{V\to V}, \quad ||B^*||_{W\to V}, \quad ||C^*||_{W\to W}, \\ &||A_0||_{V\to V}, \quad ||J_0||_{W\to W}, \quad ||\mathcal{M}||_{V\times W\to V\times W}, \quad ||\mathcal{M}^*||_{V\times W\to V\times W} \le \text{const}\,. \end{aligned}$$

Moreover,

$$\begin{aligned} &||A_0^{-1}||_{V\to V}, \quad ||J_0^{-1}||_{W\to W} \le \text{const}, \\ &||\mathcal{M}^{-1}||_{V\times W\to V\times W} \le \frac{1}{\nu}\,\text{const}\,. \end{aligned}$$

Proof. The norm estimates for $A, B, C, A_0, J_0, A_0^{-1}, J_0^{-1}$ and their adjoints follow from our assumptions on the corresponding bilinear forms and from (2.5), (2.6). Then the estimate for $\mathcal{M}$ and its adjoint follows. The estimate $||\mathcal{M}^{-1}||_{V\times W\to V\times W} \le \frac{1}{\nu}$ const is another statement of the stability result for saddle point problem solutions [6]: there exists const > 0, independent of h and ν, such that any solution $(u, p) \in V \times W$ of Problem 2.1 satisfies $||u|| + |p| \le \frac{1}{\nu}\,\text{const}(||F|| + |G|)$. □

3. Preconditioners leading to symmetric, positive definite problems. In this section we are going to extend the results obtained previously for symmetric saddle point problems, e.g., in [7] and [2]. This approach is of normal equations type, which influences the convergence speed and the computational complexity of the method, though it has certain interesting advantages, too. The transformed system allows for using the conjugate gradients (PCG) method, which is less memory consuming than, e.g., GMRES; for fixed ν, the condition number of transformed system is independent of h. Moreover, the analysis remains valid for A only V^0-elliptic; see Remark 3.1. As the condition number grows like $O(\nu^{-2})$, the use of these preconditioners is practically limited only to diffusion-dominated flows.

3.1. Block diagonal preconditioner. Using the block diagonal preconditioner

$$\mathcal{M}_D = \begin{pmatrix} A_0 & 0 \\ 0 & J_0 \end{pmatrix},$$

we transform system (2.4) into the following one.

PROBLEM 3.1. *Find $(u,p) \in V \times W$ such that*

$$\mathcal{M}_D^{-1}\mathcal{M}^*\mathcal{M}_D^{-1}\mathcal{M}\begin{pmatrix} u \\ p \end{pmatrix} = \mathcal{M}_D^{-1}\mathcal{M}^*\mathcal{M}_D^{-1}\begin{pmatrix} F \\ G \end{pmatrix}. \tag{3.1}$$

Clearly, the operator $\mathcal{P} = \mathcal{M}_D^{-1}\mathcal{M}^*\mathcal{M}_D^{-1}\mathcal{M}$ is self-adjoint with respect to the inner product $[\cdot,\cdot]$. The following theorem guarantees $\mathcal{P}$ is also well conditioned.

THEOREM 3.1. *There exist positive constants m_0, m_1, independent of h, ν, such that*

$$m_0 \cdot \nu^2 \cdot \left[\begin{pmatrix} u \\ p \end{pmatrix}, \begin{pmatrix} u \\ p \end{pmatrix}\right] \le \left[\mathcal{P}\begin{pmatrix} u \\ p \end{pmatrix}, \begin{pmatrix} u \\ p \end{pmatrix}\right] \le m_1 \cdot \left[\begin{pmatrix} u \\ p \end{pmatrix}, \begin{pmatrix} u \\ p \end{pmatrix}\right]. \tag{3.2}$$

Proof. Observe that

(3.3)
$$\begin{aligned}\left[\mathcal{P}\begin{pmatrix} u \\ p \end{pmatrix}, \begin{pmatrix} u \\ p \end{pmatrix}\right] &= ((A_0^{-1}(Au + B^*p), Au + B^*p)) + (J_0^{-1}(Bu - Cp), Bu - Cp) \\ &= |||Au + B^*p|||^2_{A_0^{-1}} + |||Bu - Cp|||^2_{J_0^{-1}}.\end{aligned}$$

In what follows we will use the fact that for $a, b \ge 0$, there holds $a^2 + b^2 \le (a+b)^2 \le 2(a^2 + b^2)$. Defining $\tilde{f} = Au + B^*p$ and $\tilde{g} = Bu - Cp$, we obviously have that (u,p) satisfies

$$\begin{cases} Au + B^*p &= \tilde{f}, \\ Bu - Cp &= \tilde{g}, \end{cases} \tag{3.4}$$

so from Lemma 2.1 we obtain

$$\left[\mathcal{P}\begin{pmatrix} u \\ p \end{pmatrix}, \begin{pmatrix} u \\ p \end{pmatrix}\right] = |||\tilde{f}|||^2_{A_0^{-1}} + |||\tilde{g}|||^2_{J_0^{-1}} \ge \text{const}\, \nu^2 \left(||u||^2 + |p|^2\right),$$

which yields the lower bound in (3.2). In order to prove the upper bound, we return to (3.3) and use Lemma 2.1 again.

$$\begin{aligned}\left[\mathcal{P}\begin{pmatrix} u \\ p \end{pmatrix}, \begin{pmatrix} u \\ p \end{pmatrix}\right] &= \left\langle \mathcal{M}^*\mathcal{M}_D^{-1}\mathcal{M}\begin{pmatrix} u \\ p \end{pmatrix}, \begin{pmatrix} u \\ p \end{pmatrix}\right\rangle \\ &\le ||\mathcal{M}^*|| \cdot ||\mathcal{M}_D^{-1}|| \cdot ||\mathcal{M}|| \cdot \left\langle \begin{pmatrix} u \\ p \end{pmatrix}, \begin{pmatrix} u \\ p \end{pmatrix}\right\rangle \\ &\le \text{const}\left[\begin{pmatrix} u \\ p \end{pmatrix}, \begin{pmatrix} u \\ p \end{pmatrix}\right],\end{aligned}$$

since from Lemma 2.1 it follows that $||\mathcal{M}_D^{-1}||_{V\times W \to V\times W} \le \text{const}$. □

Remark 3.1. *From a theoretical point of view it is worth noticing that the V-ellipticity assumption in Theorem* 3.1 *on A may be weakened. Indeed, all that is needed in the proof is that the saddle point problem* (3.4) *be uniquely solvable and that the stability estimate holds. According to* [15], *a sufficient condition is to assume the LBB condition* (2.3) *and the V^0-ellipticity of A:*

$$a(u,\, u) \geq \nu ||u||^2 \qquad \forall v \in V^0, \tag{3.5}$$

where $V^0 = \{v \in V : b(v,\, p) = 0 \quad \forall p \in W\}$.

The above preconditioning technique has been previously investigated in [25] in the context of micropolar equations.

3.2. Block triangular preconditioner. It is also possible to construct a symmetric preconditioner for the operator $\mathcal{M}$, which is based on a block lower triangular matrix:

$$\mathcal{M}_T = \begin{pmatrix} A_0 & 0 \\ B & J_0 \end{pmatrix}. \tag{3.6}$$

We transform system (2.4) into an equivalent one,

$$\mathcal{P}\begin{pmatrix} u \\ p \end{pmatrix} \equiv \mathcal{M}^*\mathcal{L}_T^*\mathcal{K}_0^{-1}\mathcal{L}_T\mathcal{M}\begin{pmatrix} u \\ p \end{pmatrix} = \mathcal{M}^*\mathcal{L}_T^*\mathcal{K}_0^{-1}\mathcal{L}_T\begin{pmatrix} F \\ G \end{pmatrix},$$

where

$$\mathcal{L}_T^*\mathcal{K}_0^{-1}\mathcal{L}_T \equiv \begin{pmatrix} I & A_0^{-1}B^* \\ 0 & -I \end{pmatrix}\begin{pmatrix} A_0^{-1} & 0 \\ 0 & J_0^{-1} \end{pmatrix}\begin{pmatrix} I & 0 \\ BA_0^{-1} & -I \end{pmatrix}.$$

Observe that $\mathcal{M}_D^{-1}\mathcal{L}_T$ is nothing but $\mathcal{M}_T^{-1}$ and that $\mathcal{P}$ is symmetric with respect to the scalar product $\langle\cdot,\, \cdot\rangle$.

Theorem 3.2. *There exist constants $0 < c_0 \leq c_1$ independent of h and ν, such that*

$$c_0 \cdot \nu^2 \left\langle \begin{pmatrix} u \\ p \end{pmatrix}, \begin{pmatrix} u \\ p \end{pmatrix}\right\rangle \leq \left\langle \mathcal{P}\begin{pmatrix} u \\ p \end{pmatrix}, \begin{pmatrix} u \\ p \end{pmatrix}\right\rangle \leq c_1 \left\langle \begin{pmatrix} u \\ p \end{pmatrix}, \begin{pmatrix} u \\ p \end{pmatrix}\right\rangle$$

$\forall (u,p) \in V \times W$.

Proof. First, we shall prove the lower bound. As in the previous section, the upper bound will be easy to derive from the boundedness assumptions (see Lemma 2.1). For $(u,p) \in V \times W$ we have

$$\left\langle \mathcal{P}\begin{pmatrix} u \\ p \end{pmatrix}, \begin{pmatrix} u \\ p \end{pmatrix}\right\rangle = \left\langle \mathcal{M}_D^{-1}\mathcal{L}_T\mathcal{M}\begin{pmatrix} u \\ p \end{pmatrix}, \mathcal{L}_T\mathcal{M}\begin{pmatrix} u \\ p \end{pmatrix}\right\rangle \tag{3.7}$$

and

$$\mathcal{L}_T\mathcal{M} = \begin{pmatrix} A & B^* \\ B(A_0^{-1}A - I) & BA_0^{-1}B^* + C \end{pmatrix}.$$

Therefore,

$$\left\langle \mathcal{P}\begin{pmatrix} u \\ p \end{pmatrix}, \begin{pmatrix} u \\ p \end{pmatrix}\right\rangle = |||Au + B^*p|||^2_{A_0^{-1}} + |||BA_0^{-1}(A - A_0)u + (BA_0^{-1}B^* + C)p|||^2_{J_0^{-1}}. \tag{3.8}$$

Defining this time $\tilde{f} = Au + B^*p$ and $\tilde{g} = BA_0^{-1}(A - A_0)u + (BA_0^{-1}B^* + C)p$ we obviously have that the pair (u, p) satisfies the system

$$\left\{ \begin{array}{l} Au + B^*p = \tilde{f}, \\ Cp - Bu = \tilde{g} - BA_0^{-1}(Au + B^*p) = \tilde{g} - BA_0^{-1}\tilde{f}. \end{array} \right. \tag{3.9}$$

From stability estimates for the saddle point problem (see Lemma 2.1), it follows that the solution (u, p) of (3.9) satisfies

$$\nu \cdot (||u|| + |p|) \leq \text{const} \cdot (||\tilde{f}|| + |BA_0^{-1}\tilde{f} - \tilde{g}|) \leq \text{const} \cdot (|||\tilde{f}|||_{A_0^{-1}} + |||\tilde{g}|||_{J_0^{-1}}). \tag{3.10}$$

This estimate yields the lower bound on the spectrum of $\mathcal{P}$. To get the upper bound we return to (3.8) and use the estimates from section 2. □

REMARK 3.2. *Observe that the preconditioner discussed here is more costly to evaluate than the diagonal one: it requires three applications of A_0^{-1} per inner product, compared to only one A_0^{-1} for the diagonal preconditioner analyzed in the previous subsection.*

REMARK 3.3. *Again, the ellipticity assumption on A in Theorem* 3.2 *may be weakened. V^0-ellipticity of A (see* (3.5)*) is sufficient.*

4. Preconditioner for the GMRES method. It is well known that after symmetrizing the system, its condition number increases; moreover, the symmetrized preconditioned matrix is quite costly to apply, as it takes at least two preconditioner solves. This fact is also indicated by numerical experiments (see section 5). Therefore, rather than symmetrizing the system, we may use an efficiently preconditioned GMRES method for our problem. If the preconditioner works well enough so that satisfactory approximation is obtained after few iterations, then the GMRES memory consumption is less painful, and we can benefit from its better convergence properties.

For $k > 0$ to be specified later, let us consider the block triangular preconditioner,

$$\mathcal{M}_T = \begin{pmatrix} k \cdot A_0 & 0 \\ B & -k \cdot J_0 \end{pmatrix},$$

which was previously discussed (with another choice of scaling parameters), e.g., in [1], [10], [13] and [19], [23]. The convergence rate of the GMRES method for a system

$$\mathcal{M}_T^{-1}\mathcal{M}\begin{pmatrix} u \\ p \end{pmatrix} = \begin{pmatrix} F \\ G \end{pmatrix} = \mathcal{M}_T^{-1}\begin{pmatrix} f \\ g \end{pmatrix} \tag{4.1}$$

can be estimated by means of two parameters (see [8]),

$$\underline{c} = \inf_{(u,p)\neq 0} \frac{\left[\mathcal{M}_T^{-1}\mathcal{M}\begin{pmatrix} u \\ p \end{pmatrix}, \begin{pmatrix} u \\ p \end{pmatrix}\right]}{\left[\begin{pmatrix} u \\ p \end{pmatrix}, \begin{pmatrix} u \\ p \end{pmatrix}\right]}, \quad \bar{c} = \sup_{(u,p)\neq 0} \frac{\left[\mathcal{M}_T^{-1}\mathcal{M}\begin{pmatrix} u \\ p \end{pmatrix}, \mathcal{M}_T^{-1}\mathcal{M}\begin{pmatrix} u \\ p \end{pmatrix}\right]}{\left[\begin{pmatrix} u \\ p \end{pmatrix}, \begin{pmatrix} u \\ p \end{pmatrix}\right]}. \tag{4.2}$$

Recall that $[\cdot, \cdot]$ is defined by (2.7) and generates the norm in which the residual for GMRES is measured.

We shall prove that these parameters are bounded independently of h. Since they are strongly dependent on ν, the preconditioner use is practically limited to diffusion dominated flows.

LEMMA 4.1. *There exists $k > 0$ such that the symmetric part of A, $A_{symm} = (A + A^*)/2$, together with $A^* A_0^{-1} A$, satisfies*

$$\left(\left(\left(A_{symm} - \frac{1}{2k} A^* A_0^{-1} A\right) u,\ u\right)\right) \geq \delta((A_0 u,\ u)) \qquad \forall u \in V \tag{4.3}$$

for some constant $\delta \geq \text{const} \cdot \nu$. The scaling parameter k can be chosen independently of h, precisely, $k \geq \text{const} \cdot \nu^{-1}$.

Proof. Let λ be the smallest eigenvalue of the following generalized eigenproblem:

$$A_{symm} u = \lambda A_0 u,$$

and let μ be the largest eigenvalue of another generalized eigenproblem,

$$A^* A_0^{-1} A u = \mu A_0 u.$$

From (2.1) it follows that $\lambda \geq \text{const}\, \nu$, while from Lemma 2.1 we have $\mu \leq \text{const}$. Then

$$\left(\left(\left(A_{symm} - \frac{1}{2k} A^* A_0^{-1} A\right) u,\ u\right)\right) \geq \left(\lambda - \frac{\mu}{2k}\right) ((A_0 u,\ u)),$$

and for $k \geq \text{const} \cdot \nu^{-1} \geq \frac{\mu}{\lambda}$, (4.3) holds with $\delta = \frac{\lambda}{2}$. This gives the estimate $\delta \geq \text{const} \cdot \nu$. □

REMARK 4.1. *The scaling requirement is similar to that of Bramble and Pasciak* [1] *for the triangular preconditioner in the symmetric case. In the general case, the scaling parameter k would need to be computed from (rough) estimates of the above eigenvalues. In practice, however, the scaling is usually not essential for the convergence. For example, in our numerical experiments (see section 5) there was no significant difference between scaled and unscaled preconditioner convergence.*

THEOREM 4.2. *For any fixed $\nu > 0$ and for k as in Lemma 4.1, the convergence rate of the GMRES for (4.1) is independent of h, precisely,*

$$\underline{c} \geq \text{const} \cdot \nu^2, \qquad \bar{c} \leq \text{const}\,.$$

Proof. Our aim is to estimate the quantities $\underline{c}, \bar{c}$ in (4.2) independently of h. Since

$$\begin{pmatrix} kA_0 & 0 \\ 0 & kJ_0 \end{pmatrix} \cdot \mathcal{M}_T^{-1} = \begin{pmatrix} I & 0 \\ \frac{1}{k} B A_0^{-1} & -I \end{pmatrix},$$

then

$$\left[\mathcal{M}_T^{-1} \mathcal{M} \begin{pmatrix} u \\ p \end{pmatrix},\ \begin{pmatrix} u \\ p \end{pmatrix}\right] = \frac{1}{k}((Au,\ u)) + \frac{1}{k^2}((A_0^{-1} Au,\ B^* p)) + \frac{1}{k^2}((A_0^{-1} B^* p,\ B^* p)) + (Cp,\ p).$$

From (2.2) we estimate

$$\left[\mathcal{M}_T^{-1} \mathcal{M} \begin{pmatrix} u \\ p \end{pmatrix},\ \begin{pmatrix} u \\ p \end{pmatrix}\right] \geq \frac{1}{2k^2} |||Au + B^* p|||^2_{A_0^{-1}} + \frac{1}{k}\left(\left(\left(A_{symm} - \frac{1}{2k} A^* A_0^{-1} A\right) u,\ u\right)\right) + \frac{1}{2k^2} |||B^* p|||^2_{A_0^{-1}}.$$

Obviously, $|||Au + B^*p|||^2_{A_0^{-1}} \geq 0$ and $|||B^*p|||^2_{A_0^{-1}} = (BA_0^{-1}B^*p,\, p) \geq \mathrm{const}(J_0p,\, p)$, the latter from (2.6) and the LBB condition; see [1]. Therefore, for k and δ as in Lemma 4.1, we can conclude that

$$\left[\mathcal{M}_T^{-1}\mathcal{M}\begin{pmatrix}u\\p\end{pmatrix}, \begin{pmatrix}u\\p\end{pmatrix}\right] \geq \mathrm{const}\,\nu^2 \left[\begin{pmatrix}u\\p\end{pmatrix}, \begin{pmatrix}u\\p\end{pmatrix}\right].$$

In order to estimate $\bar{c}$, observe that

$$\begin{aligned}\left[\mathcal{M}_T^{-1}\mathcal{M}\begin{pmatrix}u\\p\end{pmatrix}, \mathcal{M}_T^{-1}\mathcal{M}\begin{pmatrix}u\\p\end{pmatrix}\right] &= \left\langle\begin{pmatrix}A_0 & \\ & J_0\end{pmatrix}\mathcal{M}_T^{-1}\mathcal{M}\begin{pmatrix}u\\p\end{pmatrix}, \mathcal{M}_T^{-1}\mathcal{M}\begin{pmatrix}u\\p\end{pmatrix}\right\rangle\\ &= \left\langle\mathcal{M}^*(\mathcal{M}_T^{-1})^*\mathcal{M}_D\mathcal{M}_T^{-1}\mathcal{M}\begin{pmatrix}u\\p\end{pmatrix}, \begin{pmatrix}u\\p\end{pmatrix}\right\rangle\\ &= ||\mathcal{M}^*|| \cdot ||(\mathcal{M}_T^{-1})^*|| \cdot ||\mathcal{M}_D|| \cdot ||\mathcal{M}_T^{-1}|| \cdot ||\mathcal{M}|| \cdot \left\langle\begin{pmatrix}u\\p\end{pmatrix}, \begin{pmatrix}u\\p\end{pmatrix}\right\rangle.\end{aligned}$$

As $k \geq \mathrm{const}\cdot\nu^{-1}$, then using estimates from section 2 and the factorization

$$\mathcal{M}_T^{-1} = \begin{pmatrix}I & \\ & \frac{1}{k}J_0^{-1}\end{pmatrix}\begin{pmatrix}I & 0\\ B & -I\end{pmatrix}\begin{pmatrix}\frac{1}{k}A_0^{-1} & \\ & I\end{pmatrix},$$

we have that $||\mathcal{M}_T^{-1}||, ||(\mathcal{M}_T^{-1})^*|| \leq \max\{1, \frac{1}{k^2}\}\cdot\mathrm{const} \leq \mathrm{const}$, and finally

$$\left[\mathcal{M}_T^{-1}\mathcal{M}\begin{pmatrix}u\\p\end{pmatrix}, \mathcal{M}_T^{-1}\mathcal{M}\begin{pmatrix}u\\p\end{pmatrix}\right] \leq \mathrm{const}\left[\begin{pmatrix}u\\p\end{pmatrix}, \begin{pmatrix}u\\p\end{pmatrix}\right],$$

which completes the proof. □

5. Numerical experiments. We implemented certain preconditioners considered in this paper and examined their applicability in the iterative solution of a nonsymmetric saddle point problem. The test problem was to solve the Oseen equations in a rectangle $\Omega = (-1, 1) \times (-1, 1)$

$$\begin{cases}-\nu\Delta u + (k\cdot\nabla)u + \nabla p = f,\\ \operatorname{div} u = 0,\end{cases}$$

with homogeneous Dirichlet boundary conditions on u. The function $k(\cdot,\cdot)$ was defined as in [10], [23], as a simple vortex,

$$k(x, y) = \begin{pmatrix}2y(1-x^2)\\ -2x(1-y^2)\end{pmatrix}.$$

For the right-hand side vector in our experiments, we always took a random vector with elements uniformly distributed between $(-1, 1)$. We discretized the equation using popular Q_2–Q_1 Taylor–Hood rectangular finite elements; see [6]. The mesh was uniform in both directions, with nx inner pressure nodes along the x-axis and ny inner pressure nodes in y-direction, so there were approximately twice as many inner nodes in each direction for each component of the discrete velocity. In all experiments presented below, $nx = ny$. To keep the pressure in L_0^2, we added to the system a discretized condition $\int p = 0$ using the Lagrange multipliers.

All algorithms were implemented on an unloaded Linux PC, using PETSc 2.0.29 library subroutines for the iterative solvers and additive Schwarz preconditioners [32]. We performed our tests in three different solver/preconditioner configurations.

Table 5.1

Iteration counts for different solvers and preconditioning strategies: results for A_0 = Laplacian, J_0 = mass matrix. Wall clock time (seconds) in parentheses.

nx	DOF[1]	GMRES/diag	GMRES/triang	CG/symm
10	1202	38 (0.4)	21 (0.2)	45 (0.7)
20	4182	39 (1.5)	21 (0.9)	46 (2.8)
40	15542	40 (8.0)	21 (3.8)	49 (12.8)
80	59862	39 (47.3)	21 (17.7)	49 (56.1)

Table 5.2

Timings relative to GMRES/triang for different solver/preconditioner strategies reported in Tables 5.1 *and* 5.3.

	nx	GMRES/diag	GMRES/triang	CG/symm
"best"	20	1.7	1.0	3.1
	40	2.1	1.0	3.4
	80	2.7	1.0	3.2
ASM	20	1.4	1.0	2.3
	40	1.4	1.0	1.9
	80	1.7	1.0	1.6

1. CG/symm: the symmetrized preconditioned conjugate gradient method with the block diagonal preconditioner; see section 3.1.
2. GMRES/triang: the GMRES method with the block triangular preconditioner; see section 4.
3. GMRES/diag: the GMRES method with the block diagonal preconditioner.

To compare the overall efficiency of the preconditioners, we report both the iteration counts and the wall clock times (in seconds) needed to reduce the initial residual by a factor of 10^6. We used a restarted version of GMRES, with restart after every 30 iterations.

Two simplifications to GMRES algorithms have been made, which, as it turns out in the preliminary set of experiments, hardly influences the convergence rate of the methods. Our GMRES algorithm minimizes the Euclidean norm of the residual, instead of the energy norm analyzed in section 4. For the same reason we always used $k = 1$ (see Theorem 4.2). All this makes the GMRES algorithm cheaper.

Except for the last set of experiments, we restrict ourselves to the case where the viscosity parameter $\nu = 1$. The influence of ν on the convergence rate will be reported at the end of this section. As it has been indicated in the above theorems and will be confirmed in Table 5.5 as well, the performance of our preconditioner deteriorates for small values of the viscosity parameter ν. This is the reason that we focus mainly on diffusion dominated flow.

First, we conducted experiments under the best available circumstances, that is, we used as the preconditioners A_0 = Laplacian, J_0 = mass matrix. Notice that, in contrast to [11] and [23], we restricted ourselves only to *symmetric* preconditioners. We refer to the above choice of preconditioners as the "best" preconditioners, since in this case we exactly solve the symmetric part of the relevant diagonal operators. Our results are presented in Tables 5.1 and 5.2 and Figure 5.1.

Next, we tested the same methods using inexact preconditioners for A_0, J_0, namely, the 1-level additive Schwarz method (ASM) with standard black-box decomposition

[1] DOF = the total number of degrees of freedom.

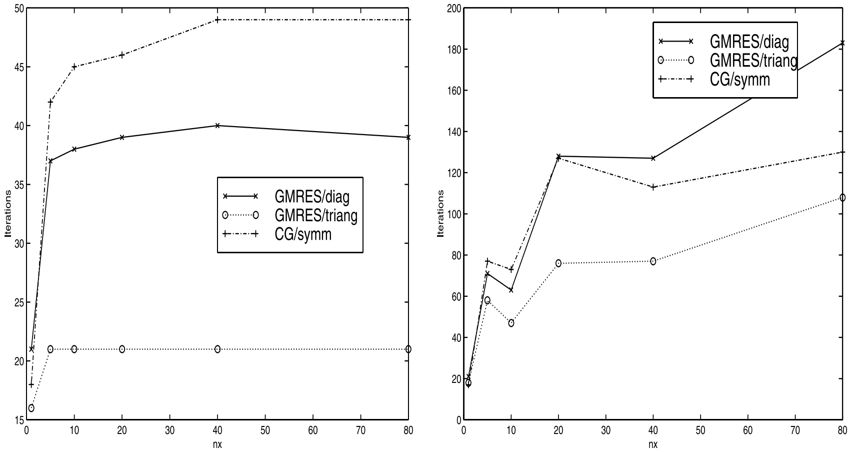

Fig. 5.1. *The growth of iterations as a function of the problem size for different solvers and preconditioning strategies. Left:* A_0 = *Laplacian,* J_0 = *mass matrix. Right: additive Schwarz preconditioners (fixed number of subdomains, small overlap, no coarse grid).*

Table 5.3

Iteration counts for different solvers and preconditioning strategies: The results for additive Schwarz preconditioners. (Timings in parentheses.)

nx	DOF	GMRES/diag	GMRES/triang	CG/symm
10	1202	63 (1.0)	51 (0.7)	73 (1.7)
20	4182	128 (6.0)	76 (4.2)	128 (9.8)
40	15542	127 (23.1)	77 (16.3)	113 (31.6)
80	59862	183 (155.0)	108 (91.8)	130 (146.7)

into 6 rectangular subdomains with small and fixed overlap (2 nodes) provided by PETSc. The results are presented in Tables 5.2 and 5.3 and Figure 5.1.

The experiments confirm theoretical results, showing that the number of iterations reflects the quality of the preconditioning blocks being used. This may be seen very clearly from the experiments with "best" solvers and implicitly from those for the inexact solvers (Figure 5.1). For $\nu = 1$, the number of iterations is moderate and, with "best" solvers, virtually independent of the mesh size. As one could expect, the triangular preconditioner is most effective, being usually more than two times faster than diagonal preconditioners. The CG/symm combination is even slower than GMRES/diag.

According to [31], for the ASM preconditioning blocks, with fixed number of subdomains, small overlap, and no coarse grid, the number of iterations in Table 5.3 should increase as the square root of nx, and this is approximately what we actually see. Theorems 3.1 and 4.2 ensure that the convergence rate would be fully independent of nx if a 2-level ASM were used.

Another experiment (Table 5.4) shows the performance of our preconditioners when the number of subdomains is scaled with the problem size, so that $\sqrt{N}/nx$ remains constant. As compared to [21, Table 1], the number of iterations of the GMRES/triang method is quite similar to a 1-level overlapping ASM for the whole system (1.1), despite the fact that our decomposition might suffer from subdomain bad aspect ratios (we did not have control over the shape of the subdomains). This indicates that a block 1-level ASM preconditioner may be an alternative to 1-level

Table 5.4

Iteration counts for different solvers and preconditioning strategies: the results for additive Schwarz preconditioners with number of subdomains scaled with problem size, so that $\sqrt{N}/nx = 4$. (Note: full GMRES used.)

$\sqrt{N}$	nx	DOF	GMRES/diag	GMRES/triang	CG/symm
1	4	279	34	21	40
2	8	823	66	51	96
4	16	2775	95	62	108
8	32	10135	165	124	139
10	40	15543	221	147	184

Table 5.5

Iteration counts for varying mesh size nx and viscosity ν with preconditioning blocks A_0 = Laplacian, J_0 = mass matrix.

	GMRES/diag			GMRES/triang			CG/symm		
ν	1.0	0.1	0.02	1.0	0.1	0.02	1.0	0.1	0.02
nx									
16	38	111	> 300	21	76	255	43	42	116
32	40	102	> 300	22	73	> 300	48	41	117
64	40	105	> 300	22	73	> 300	48	37	115

ASM designed in [21] for the full system, although it seems that 1-level ASM for the full system is still a bit cheaper. More comparisons of this type have recently been made in a paper by Klawonn and Pavarino [22].

Finally, we examined the behavior of our methods for decreasing values of the viscosity parameter ν. They confirm that symmetric-block-based preconditioners are competitive to those using nonsymmetric A solves only if the symmetric part dominates in A; for small ν, the convergence rate deteriorates very quickly, as indicated in Table 5.5.

Acknowledgments. The author wishes to thank Professor Maksymilian Dryja and Professor Krzysztof Moszyński for their valuable remarks. The comments of two anonymous referees also significantly helped to improve the paper.

VORTICITY-PRESERVING LAX–WENDROFF-TYPE SCHEMES FOR THE SYSTEM WAVE EQUATION[*]

K. W. MORTON[†] AND P. L. ROE[‡]

Abstract. In numerical solutions of fluid flow, vorticity can be generated by truncation errors. We analyze this phenomenon for linearized equations and give conditions for preventing it. The Lax–Wendroff method that meets these constraints is essentially unique, although there are two distinct interpretations, and also turns out to have optimal properties regarding stability and truncation error. The extension of the scheme to unstructured grids is given, together with some discussion of practical problems to which these schemes might bring improvement.

Key words. vorticity-preserving, system wave equation, discrete Kelvin's theorem

1. Introduction.

Much of computational fluid dynamics (CFD) is based on the analysis of simple "model problems." To an astonishing extent, the solution of problems governed by hyperbolic equations is based on analysis of the one-dimensional linear advection equation $u_t+au_x = 0$. However, neither this nor the multidimensional $u_t+\vec{a}\cdot\nabla u = 0$ really reflects the richness of fluid behavior, capturing merely advection and some aspects of wave propagation but ignoring, for example, all phenomena associated with vorticity, which are of vital importance in many three-dimensional situations.

The simplest model problem to combine wave propagation and vorticity is the system wave equation. We will write this in two space dimensions in the matrix form, using a notation corresponding to acoustic waves in a fluid that is stationary in the mean, with pressure p^* and velocity $\vec{u}^* = (u^*, v^*)$; thus

$$\partial_t \mathbf{u} + cL\mathbf{u} = 0. \tag{1}$$

Here $\mathbf{u} = (p^*/(\rho c^2), u^*/c, v^*/c) \equiv (p, u, v,)$, c is the sound speed in the mean flow, and

$$L = \begin{bmatrix} 0 & \partial_x & \partial_y \\ \partial_x & 0 & 0 \\ \partial_y & 0 & 0 \end{bmatrix}. \tag{2}$$

Restriction to two dimensions is merely for economy of notation; all of the analysis at the PDE level extends very straightforwardly to three dimensions, as does the numerical analysis on Cartesian grids. We study the wave equation in system rather than scalar ($\partial_{tt}u = c^2\nabla^2 u$) form for two reasons: first, because this is the form of

the wave equation that is hidden inside the Euler equations, whether in their two-dimensional unsteady or in their three-dimensional supersonic steady forms [1], and second, because the scalar form automatically implies vanishing vorticity, whereas the interaction of the waves with vorticity is one of the aspects we want to study.

Here the interaction is very simple, as befits a model problem. We easily deduce from (1), (2), if c is a constant, that

$$\partial_t \zeta = 0, \qquad \text{where} \qquad \zeta = \partial_x v - \partial_y u.$$

In other words, there is no interaction, and any initial distribution of vorticity is preserved. Maintaining this independence at the discrete level will be one of our objectives. In section 6, however, we consider more general, variable coefficient, problems, for which vorticity is created by the interaction of waves with density gradients. In this case, there is a very satisfying discrete parallel.

It is a trivial modification to change the notation so that (1), (2) describe Maxwell's equations, and the constraint of invariant vorticity becomes one of invariant (and vanishing) divergence of the magnetic field. The two cases differ, however, when nonconstant coefficients are involved, a case that will be treated in due course. The analysis also applies to the divergence constraint in magnetohydrodynamics and to maintaining the div-curl identity when using a velocity-vorticity formulation of the Navier–Stokes equations.

We study fully discrete schemes because of our personal conviction that transient hyperbolic problems are most naturally treated by such methods. More specifically, we study Lax–Wendroff schemes because the Taylor expansion of the evolution operator seems to be the most general technique available, applicable to the wave equation for any order of accuracy. However, Lax–Wendroff schemes are ambiguous in more than one dimension. For example, if we look to discretize $u_t + \vec{a} \cdot \nabla u = 0$ to second-order accuracy on the standard nine-point stencil, we have only six constraints on the nine coefficients and hence three degrees of freedom. There are even more degrees of freedom in discretizing a system of equations. One reason for the rise of finite-element and finite-volume methodologies is that by working within a more disciplined framework some of the ambiguity is removed, hopefully without at the same time losing valuable options.

In the early stages of the present analysis we consider mainly regular rectangular grids with uniform spacing h in both x and y. We do not impose any particular interpretation on the discrete solution $u^n_{i,j}$: the values could represent cell-averaged quantities as in a cell-centered finite-volume scheme, or nodal values as in a vertex-centered finite-difference scheme. One point of interest is that by initially taking a simple finite-difference viewpoint, the formulae that emerge as having distinguished properties are precisely those that have dual interpretations as each of the above. Subsequently, however, we find that only the finite-volume interpretation generalizes to unstructured grids but that the particular form of finite-volume scheme to emerge is not the one most commonly encountered.

In section 2 of the paper, we recall some simple formulae of the finite-difference calculus and some elementary properties of the wave equation. In section 3 we place constraints on the scheme such that some discrete measure of vorticity is preserved and in section 4 show that requiring an adjoint property on a minimal stencil results in a unique version of the Lax–Wendroff scheme, although one having two distinct implementations. In section 5 we analyze the stability and truncation error of this scheme. In section 6 we show that if the waves are being propagated in a uniformly

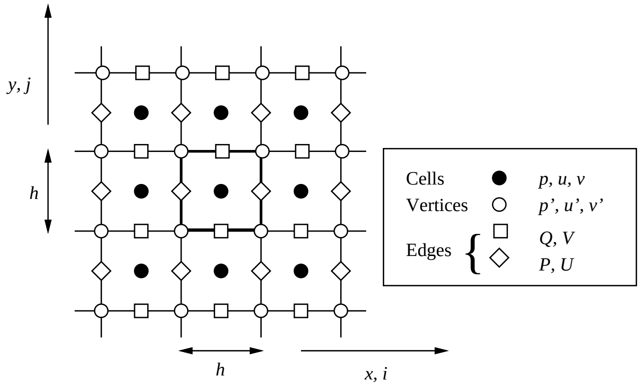

FIG. 1. *Grid definition.*

moving medium, then any vorticity present in the initial conditions will be propagated numerically according to the scalar version of our Lax–Wendroff method.

In section 7 we turn to irregular grids, and we find that there is still a measure of vorticity that is conserved, and in section 8 generalize further to the case of a problem with variable coefficients, although still linear. In this case the argument can be made global to yield a discrete Kelvin theorem.

2. Properties of the exact and discrete solution operators.

2.1. Discrete notation. As stated in the introduction, we concentrate at first on simple finite-difference formulations on uniform grids. These can be manipulated using a calculus that is almost as transparent as that of the differential operators. We exploit this simplicity to remove ambiguity from the finite-difference formulae by requiring certain algebraic properties. Then we ask what interpretations are compatible with the formulae.

We adopt a uniform square grid, such that the spacing in the x and y directions is h and the time step is Δt, with $u^n_{i,j}$ a discrete approximation located at $(x, y, t) = (ih, jh, n\Delta t)$. The standard discrete differencing and averaging operators are defined by

$$\delta_x()_{\cdot,\cdot} = ()_{\cdot+\frac{1}{2},\cdot} - ()_{\cdot-\frac{1}{2},\cdot}, \qquad \mu_x()_{\cdot,\cdot} = \tfrac{1}{2}\{()_{\cdot+\frac{1}{2},\cdot} + ()_{\cdot-\frac{1}{2},\cdot}\},$$

$$\delta_y()_{\cdot,\cdot} = ()_{\cdot,\cdot+\frac{1}{2}} - ()_{\cdot,\cdot-\frac{1}{2}}, \qquad \mu_y()_{\cdot,\cdot} = \tfrac{1}{2}\{()_{\cdot,\cdot+\frac{1}{2}} + ()_{\cdot,\cdot-\frac{1}{2}}\},$$

where it is understood that the result of any operator is located halfway between the two input points. Then the product $\Delta_{ox}()_{i,j} \equiv \mu_x\delta_x()_{i,j}$ is a central difference $\frac{1}{2}\{()_{i+1,j} - ()_{i-1,j}\}$ located at the grid point i, j, and the product $\mu_y\delta_x()_{i,j}$, which features frequently in what follows, involves four points $(i \pm \frac{1}{2}, j \pm \frac{1}{2})$ of a square centered at i, j.

The points with integer coordinates will be called *cells*, those with one integer and one half-integer coordinate *edges*, and those with two half-integer coordinates *vertices*. The variables stored at cells will be (p, u, v). The same variables stored at vertices will be distinguished by primes where necessary. The variables stored at vertical edges will be (P, U) and those stored at horizontal edges (Q, V), where both P and Q are approximations to the pressure. In a finite-volume interpretation the edge quantities are the fluxes (see Figure 1).

If it is recognized that each application of the above operators changes the centering of the mesh values to a different set of grid points, then arbitrarily long products of operators are allowed and all multiplications commute. It is simple to prove analogues of differential identities. For example, using $\langle\cdot,\cdot\rangle$ to denote an inner product,

$$\begin{aligned}\langle p, \delta_x U\rangle &\equiv \sum_{i,j} h^2 p_{i,j}\left(U_{i+\frac{1}{2},j} - U_{i-\frac{1}{2},j}\right)\\ &= -\sum_{i,j} h^2\left(p_{i+1,j} - p_{i,j}\right)U_{i+\frac{1}{2},j} \quad\equiv\quad -\langle\delta_x p, U\rangle\end{aligned}$$

and a similar argument leads to $\langle p, \mu_x U\rangle = \langle\mu_x p, U\rangle$. Thence we have

$$\langle p, \mu_x\delta_x u\rangle \equiv \langle p, \Delta_{ox} u\rangle = -\langle\Delta_{ox} p, u\rangle, \text{ etc.}$$

Also we can combine cell and vertex values; for example,

$$\begin{aligned}\langle p, \mu_y\delta_x u'\rangle &\equiv \sum_{i,j} \tfrac{1}{2}h^2 p_{i,j}(u'_{i+\frac{1}{2},j+\frac{1}{2}} - u'_{i-\frac{1}{2},j+\frac{1}{2}} + u'_{i+\frac{1}{2},j-\frac{1}{2}} - u'_{i-\frac{1}{2},j-\frac{1}{2}})\\ = -\sum_{i,j} \tfrac{1}{2}h^2&\left(p_{i+1,j+1} - p_{i,j+1} + p_{i+1,j} - p_{i,j}\right)u'_{i+\frac{1}{2},j+\frac{1}{2}} = -\langle\mu_y\delta_x p, u'\rangle.\end{aligned}$$

Thus inner products are meaningful provided each term has the same centering. Such products may be called compatible. Matrix-valued operators will be a useful way to describe schemes, and obey the usual rules of matrix multiplication, provided each matrix has compatible entries.

2.2. Symmetry of solutions. An obvious property of (1), (2) is that because it involves only the divergence and gradient operators, then any solution remains a solution under an arbitrary translation or rotation of the (x, y)-plane. Clearly this cannot be true of the discrete solution, but we should insist on the weaker condition that the solution remains a solution under any translation or rotation that maps the grid onto itself.

This will ensure that all truncation errors are symmetric functions of the wave numbers k_x, k_y; it would also be a desirable property (minimizing the anisotropy of the scheme) if the leading terms depended only on $(k_x^2 + k_y^2)$.

2.3. Power series form. A formal solution to the initial-value problem for (1) is

$$\mathbf{u}(t) = \mathrm{e}^{-cLt}\mathbf{u}(0). \tag{3}$$

Let e^{-cLt} be represented by its power series, separating the odd and even terms,

$$\mathrm{e}^{-cLt} = 1 - \sum_{p=1}^{p=\infty}\frac{(cLt)^{2p-1}}{(2p-1)!} + \sum_{q=1}^{q=\infty}\frac{(cLt)^{2q}}{(2q)!}.$$

We can easily verify that

$$L(L^2 - \nabla^2) = 0,$$

which implies that

$$L^{p+2} = \nabla^2 L^p, \qquad p \geq 1. \tag{4}$$

Then we can write

$$\mathbf{u}(t) = \left[1 - (cLt)\sum_{p=0}^{p=\infty}\frac{t^{2p}(c^2\nabla^2)^p}{(2p+1)!} + (cLt)^2\sum_{q=0}^{q=\infty}\frac{t^{2q}(c^2\nabla^2)^q}{(2q+2)!}\right]\mathbf{u}(0). \tag{5}$$

Truncating each sum at its first term will lead to a second-order Lax–Wendroff method. For extension to higher order it is useful to note that each term beyond the third merely represents continued applications of the Laplacian, either to L or to L^2. The structure of L is that its first row represents a divergence and its first column a gradient. As for L^2, we have

$$L^2 = \begin{bmatrix} \partial_x^2 + \partial_y^2 & 0 & 0 \\ 0 & \partial_x^2 & \partial_x\partial_y \\ 0 & \partial_x\partial_y & \partial_y^2 \end{bmatrix},$$

which displays the Laplacian and the grad-div operator. Most of these operators are ambiguous on the usual nine-point stencil of Lax–Wendroff schemes, and it is that ambiguity we seek to resolve.

2.4. Conservation form. In the cell-centered finite-volume method, discrete conservation is ensured by drawing a control volume around the grid point of interest and writing the update as an integral around this volume. In the generic case of a vector $\mathbf{U}$ of conserved variables, with fluxes $\mathbf{F}, \mathbf{G}$ in the (x, y)-directions, respectively, one has

$$h^2\left[\mathbf{U}^{n+1} - \mathbf{U}^n\right] + h\Delta t\left[\delta_x\mathbf{F}^* + \delta_y\mathbf{G}^*\right] = 0,$$

where $\mathbf{F}^*, \mathbf{G}^*$ are numerical fluxes evaluated from some formula to be determined. In the present case we can write, with $\nu = c\Delta t/h$ and following the notation of Figure 1,

$$p^{n+1} - p^n + \nu[\delta_x U + \delta_y V] = 0, \tag{6}$$

$$u^{n+1} - u^n + \nu\delta_x P = 0, \tag{7}$$

$$v^{n+1} - v^n + \nu\delta_y Q = 0. \tag{8}$$

It will usefully restrict the schemes to require that they can be written in this form. A second-order scheme of the Lax–Wendroff type follows from taking U, V, P, Q to be estimates halfway through the time step. However, we will find subsequently that it is a rather special type of conservation form that emerges from the analysis.

3. Preservation of discrete vorticity.

We will now require that some discrete measure of vorticity is preserved during a time step. There are two simple measures.

3.1. Centered vorticity. First define the "centered vorticity"

$$\zeta_{\Delta_1} = \mu_x\delta_x v - \mu_y\delta_y u = Z_1\mathbf{u}, \tag{9}$$

where $Z_1 = [0, -\mu_y\delta_y, \mu_x\delta_x]$, and require that $\zeta_{\Delta_1}^{n+1} = \zeta_{\Delta_1}^n$, so that

$$\begin{aligned} 0 &= Z_1(\mathbf{u}^{n+1} - \mathbf{u}^n) \\ &= -\nu Z_1[\delta_x U + \delta_y V, \delta_x P, \delta_y Q] \\ &= \nu\delta_x\delta_y(\mu_y P - \mu_x Q). \end{aligned}$$

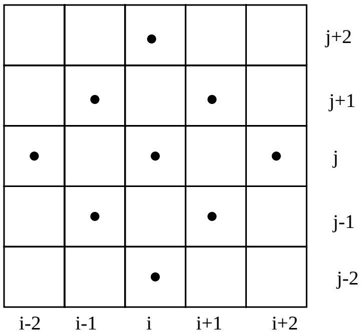

FIG. 2. *The stencil for Richtmyer's version of Lax–Wendroff.*

This measure of vorticity will therefore be preserved if the pressures assigned to the edges have the property that $\mu_y P = \mu_x Q$, and this is ensured if we take $P = \mu_x r, Q = \mu_y r$, where r is some quantity defined in cells. For consistency, it should be some local mean of the pressure, and to obey the symmetry principle (section 2.2) it must be evaluated by a symmetrical operator such as $[1 + \alpha(\delta_x^2 + \delta_y^2) + \beta\delta_x^2\delta_y^2]$. The smallest possible stencil comes from taking simply $r = p$, and hence

$$P = \mu_x r = \mu_x p, \qquad Q = \mu_y r = \mu_y p,$$

which corresponds to the simplest form of central differencing used in cell-centered finite-volume schemes, for example, [2]. However, this would lead to an unconditionally unstable scheme. Averaging just in the coordinate directions, as for the well-known Lax–Friedrichs difference scheme, leads to taking $\alpha = \frac{1}{4}, \beta = 0$.

To obtain second-order accuracy P, Q should be evaluated halfway through the time step, and to preserve vorticity we need to derive them from an r that has been evaluated halfway through the time step, so that $r = p + \frac{1}{2}\Delta t \partial_t p = p - \frac{1}{2}c\Delta t \mathrm{div}\vec{u}$.

On the most compact available stencil, and maintaining stability as for the Lax–Friedrichs scheme, this leads to

$$r = [1 + \tfrac{1}{4}(\delta_x^2 + \delta_y^2)]p - \tfrac{1}{2}\nu[\mu_x\delta_x u + \mu_y\delta_y v]$$

and hence, with $P = \mu_x r, Q = \mu_y r$, (7), (8) become

$$u^{n+1} = u^n - \nu\mu_x\delta_x\{[1 + \tfrac{1}{4}(\delta_x^2 + \delta_y^2)]p - \tfrac{1}{2}\nu[\mu_x\delta_x u + \mu_y\delta_y v]\}, \tag{10}$$

$$v^{n+1} = u^n - \nu\mu_y\delta_y\{[1 + \tfrac{1}{4}(\delta_x^2 + \delta_y^2)]p - \tfrac{1}{2}\nu[\mu_x\delta_x u + \mu_y\delta_y v]\}. \tag{11}$$

If we update the pressure with the same standard central-differences, together with a four-point averaging of p to give stability, we recover Richtmyer's form of the Lax–Wendroff method, usually written as a two-step scheme [3] (see also [4, pp. 360–365]). Its vorticity-preserving property does not seem to have been previously noticed. However, in other respects, it is less desirable. The stencil is shown in Figure 2 and can be seen to involve only points of one "parity" (value of $(i+j)(\mathrm{mod} 2)$). Therefore the method suffers from "odd-even decoupling." We do not consider this method further but turn to an alternative definition of discrete vorticity.

3.2. Compact vorticity. Next let us define the "compact vorticity"

$$\zeta_{\Delta_2} = \mu_y\delta_x v - \mu_x\delta_y u = Z_2\mathbf{u}. \tag{12}$$

Following the previous argument, we can preserve this if

$$\begin{aligned} 0 &= Z_2(\mathbf{u}^{n+1} - \mathbf{u}^n) \\ &= -\nu Z_2[\delta_x U + \delta_y V, \delta_x P, \delta_y Q] \\ &= \nu \delta_x \delta_y (\mu_x P - \mu_y Q), \end{aligned}$$

and the condition $\mu_x P = \mu_y Q$ will be met if we take $P = \mu_y r', Q = \mu_x r'$, where r' is some quantity defined at vertices. The only way to define a consistent local pressure while retaining a nine-point stencil is to take

$$r' = \mu_x \mu_y p. \tag{13}$$

In that case we have

$$P = \mu_x \mu_y^2 p, \qquad Q = \mu_x^2 \mu_y p. \tag{14}$$

To obtain second-order accuracy, r' must now be updated to halfway through the time step. The simple formula

$$r' = \mu_x \mu_y p - \tfrac{1}{2}\nu[\mu_y \delta_x u + \mu_x \delta_y v]$$

is the unique symmetrical formula to achieve this without enlarging the stencil, leading to

$$P = \mu_y r' = \mu_x \mu_y^2 p - \tfrac{1}{2}\nu[\mu_y^2 \delta_x u + \mu_x \mu_y \delta_y v], \tag{15}$$

$$Q = \mu_x r' = \mu_x^2 \mu_y p - \tfrac{1}{2}\nu[\mu_y \mu_x \delta_x u + \mu_x^2 \delta_y v]. \tag{16}$$

3.3. Two remarks on implementation. We insert here an important observation relating to the construction of nonlinear "limited" schemes that avoid nonphysical overshoots [5]. We do not attempt a thorough discussion of this issue in the present paper, because the objectives for such schemes are still unclear. For example, there is no maximum principle because waves may focus and increase in strength. However, we do note that any limiting applied to the intermediate quantity r' will still leave the vorticity exactly preserved. The limiter for such a scheme must, however, be centered on a vertex and therefore depend on values in the four neighboring cells. Schemes that are based, like most upwind schemes in current use, on one-dimensional reconstruction and interpolation cannot preserve vorticity in any of the above senses.

Our second remark deals with the application of boundary conditions, for example, to simulate the generation of acoustic waves by a moving boundary. In most finite-volume schemes one would derive from the boundary condition some expression for the unknown pressure at an interface (say, P, in Figure 1) in terms of the known normal velocity (say, U, for a vertical boundary). This would be incorrect. The correct procedure is to obtain vertex pressure p' in terms of given vertex velocities u'. If the condition is applied in this way one can easily show that vorticity at nodes adjacent to the wall is preserved; for any other procedure a vortical layer will be produced.

4. Construction and properties of evolution operator. We collect the results of section 3.2 into a prescription for the matrix operator that will update the solution, so that if

$$\mathbf{u}^{n+1} = \mathbf{u}^n - M_\Delta \mathbf{u}^n, \tag{17}$$

certain elements of the matrix M_Δ are already uniquely determined by insisting that the velocities are updated with second-order accuracy while preserving the discrete vorticity (12). We have in fact, from (7), (8), (15), (16),

$$M_\Delta = \begin{bmatrix} ?? & ?? & ?? \\ \nu\mu_x\mu_y^2\delta_x & \frac{1}{2}\nu^2\mu_y^2\delta_x^2 & \frac{1}{2}\nu^2\mu_x\mu_y\delta_x\delta_y \\ \nu\mu_x^2\mu_y\delta_y & \frac{1}{2}\nu^2\mu_x\mu_y\delta_x\delta_y & \frac{1}{2}\nu^2\mu_x^2\delta_y^2 \end{bmatrix}.$$

The adjoint property $\mathrm{div}_h = -\mathrm{grad}_h^*$ requires that this matrix be symmetric, hence

$$M_\Delta = \begin{bmatrix} ?? & \nu\mu_x\mu_y^2\delta_x & \nu\mu_x^2\mu_y\delta_y \\ \nu\mu_x\mu_y^2\delta_x & \frac{1}{2}\nu^2\mu_y^2\delta_x^2 & \frac{1}{2}\nu^2\mu_x\mu_y\delta_x\delta_y \\ \nu\mu_x^2\mu_y\delta_y & \frac{1}{2}\nu^2\mu_x\mu_y\delta_x\delta_y & \frac{1}{2}\nu^2\mu_x^2\delta_y^2 \end{bmatrix}$$

and only the $1,1$ element remains open. This can be determined by noting that the flux U, say, is implied by the above formula to be

$$U = \mu_x\mu_y^2 u = \mu_y(\mu_x\mu_y u) = \mu_y u',$$

where $u' = \mu_x\mu_y u$ is an average evaluated at the vertices, as in (13). To update this to $(n+\frac{1}{2})\Delta t$ we need to add a term $-\frac{1}{2}\Delta t\partial_x p$ which can only be $-\frac{1}{2}\nu\mu_y\delta_x p$. By considering V also, we finally arrive at

$$M_\Delta = \begin{bmatrix} \frac{1}{2}\nu^2(\mu_y^2\delta_x^2 + \mu_x^2\delta_y^2) & \nu\mu_x\mu_y^2\delta_x & \nu\mu_x^2\mu_y\delta_y \\ \nu\mu_x\mu_y^2\delta_x & \frac{1}{2}\nu^2\mu_y^2\delta_x^2 & \frac{1}{2}\nu^2\mu_x\mu_y\delta_x\delta_y \\ \nu\mu_x^2\mu_y\delta_y & \frac{1}{2}\nu^2\mu_x\mu_y\delta_x\delta_y & \frac{1}{2}\nu^2\mu_x^2\delta_y^2 \end{bmatrix}. \tag{18}$$

The scheme represented by this matrix has been uniquely determined by the requirements of conservation, vorticity preservation, symmetry of the solution under grid transformations, adjoint symmetry of the discrete operator, and second-order accuracy. Again, however, it is not a new scheme. It can be recognized by noting that M_Δ can be factored as

$$M_\Delta = \nu L_\Delta[\mu_x\mu_y I - \tfrac{1}{2}\nu L_\Delta], \tag{19}$$

where

$$L_\Delta = \begin{bmatrix} 0 & \mu_y\delta_x & \mu_x\delta_y \\ \mu_y\delta_x & 0 & 0 \\ \mu_x\delta_y & 0 & 0 \end{bmatrix}, \tag{20}$$

and therefore can be written as a two-step scheme. The operation

$$\mathbf{u}' = [\mu_x\mu_y I - \tfrac{1}{2}\nu L_\Delta]\mathbf{u}^n \tag{21}$$

gives a provisional solution at the vertices. The operation

$$\mathbf{u}^{n+1} = \mathbf{u}^n - \nu L_\Delta \mathbf{u}' \tag{22}$$

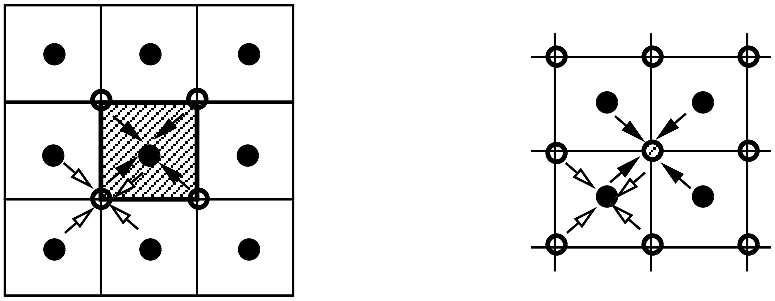

FIG. 3. *(left) The rotated Richtmyer scheme. In the first step, symbolized by white arrows, data from the cells are used to create a half time-step solution at the vertices. In the second step (black arrows) integration round the vertices updates the central cell. (right) Ni's cell-vertex scheme. In the first step (white arrows) we integrate around the cells to obtain a "cell-residual." In the second step (black arrows) these are distributed to the vertices.*

completes the update by integrating around the vertices. This is in fact the version of Lax–Wendroff known as the rotated Richtmyer scheme (see, e.g., [5, p. 125]). It is shown schematically on the left of Figure 3; comparing with Figure 2 we see the reason for the name. The original motivations for this scheme were compactness, computational economy, and stability. In the nonlinear case, as in all two-step Lax–Wendroff schemes, one avoids any multiplication by the Jacobian matrices. The vorticity-preserving property does not seem to have been previously noticed.

The second step of the method is of course a leapfrog scheme. Usually the dissipative first step is desirable to enhance stability, especially in the nonlinear case. However, we could, if we wished, construct the "pure" leapfrog method,

$$\mathbf{u}^{n+1} = \mathbf{u}^{n-1} - 2\nu L_\Delta \mathbf{u}^n, \tag{23}$$

and it is clear that this scheme would also be vorticity-preserving. So indeed would a multistage method of Runge–Kutta type [2] in which each stage employed the operator L_Δ.

4.1. Duality. Since both factors of M_Δ depend only on L_Δ they commute, and so the scheme may also be written as

$$\mathbf{u}^{n+1} - \mathbf{u}^n = -\nu[\mu_x\mu_y I - \tfrac{1}{2}\nu L_\Delta]L_\Delta \mathbf{u}^n. \tag{24}$$

In this form it is Ni's cell-vertex scheme [7], in which the variables are usually thought of as located at vertices of a grid, defining a bilinear interpolant over a square element. The first step L_Δ is to integrate $\partial_x\mathbf{F} + \partial_y\mathbf{G}$ over this element and the second step is to distribute this to the nodes of the element. It is easy to check that if some cell variable q is distributed to the nodes in the four ways shown in Figure 4, the updates to the vertices are, respectively,

$$\mu_x\mu_y q, \qquad \mu_y\delta_x q, \qquad \mu_x\delta_y q, \qquad \delta_x\delta_y q.$$

Ni's scheme was devised in the context of solving steady-state aerodynamic problems. If the transients are not required to be accurately resolved, one may consider variants of the form

$$\mathbf{u}^{n+1} - \mathbf{u}^n = -\nu[\mu_x\mu_y I - \tfrac{1}{2}\nu' L'_\Delta]L_\Delta \mathbf{u}^n,$$

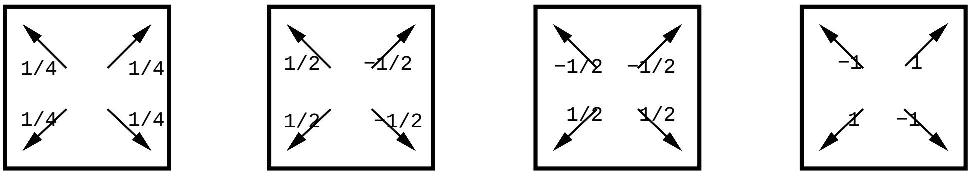

FIG. 4. *Distribution strategies.*

where ν' and L'_Δ may not be the same as ν and L_Δ. Such a scheme will not in general preserve vorticity.

However, vorticity is preserved by those schemes in which $L'_\Delta = L_\Delta$; smoother solutions are obtained by taking ν small and ν' large such that $\nu\nu' \leq 1$ (see [8] and the next section).

4.2. Energy conservation and stability. At the PDE level, we have in two dimensions the classical energy invariance

$$\begin{aligned}
\frac{d}{dt}\iint \tfrac{1}{2}(p^2+u^2+v^2)dxdy &= \iint (p\partial_t p + u\partial_t u + v\partial_t v)dxdy \\
&= -\langle p, \mathrm{div}(u,v)\rangle - \langle (u,v)^T, \mathrm{grad}p\rangle \\
&= -\langle 1, \mathrm{div}(pu,pv)\rangle \\
&= 0.
\end{aligned}$$

This proof turns on the relationship div $= -\text{grad}^*$, where $()^*$ denotes the adjoint operator.

To obtain stability in the discrete case we will require analogous discrete properties. In fact, the choices for $\mathbf{F}^*, \mathbf{G}^*$ derived above utilize discrete definitions $(\mathrm{div})_h$ and $(\mathrm{grad})_h$ which actually possess an adjoint relationship through the summation-by-parts formulae in section 2.1. In the following section we use this fact to prove energy stability of the scheme.

5. Stability and truncation error.

5.1. Stability. In this section, we consider a slight generalization of the update operator, taking

$$M_\Delta = \nu\mu_x\mu_y L_\Delta - \tfrac{1}{2}qL_\Delta^2, \tag{25}$$

where q is a parameter controlling the numerical dissipation. All schemes of this family preserve vorticity in the sense of section 3.2. In general they are first-order accurate unless $q = \nu^2$. Denoting Fourier transforms of $\mathbf{u}, M_\Delta, L_\Delta$ by $\widehat{\mathbf{u}}, \widehat{M_\Delta}, \widehat{L}_\Delta$ we write the stability condition as

$$\widehat{\mathbf{u}}^*[I - \widehat{M_\Delta^*}][I - \widehat{M_\Delta}]\widehat{\mathbf{u}} \leq \widehat{\mathbf{u}}^*\widehat{\mathbf{u}},$$

where $()^*$ denotes the Hermitian operator. We write

$$\widehat{L}_\Delta = 2\mathrm{i}\begin{bmatrix} 0 & \alpha & \beta \\ \alpha & 0 & 0 \\ \beta & 0 & 0 \end{bmatrix},$$

where $\alpha = \cos(\frac{1}{2}k_y h)\sin(\frac{1}{2}k_x h), \beta = \cos(\frac{1}{2}k_x h)\sin(\frac{1}{2}k_y h)$, and k_x, k_y are the wave numbers; note that $\widehat{L}_\Delta^* = -\widehat{L}_\Delta$. Then, abbreviating also $c_x = \cos(\frac{1}{2}k_x h), c_y = \cos(\frac{1}{2}k_y h)$ so that $\hat{\mu}_x\hat{\mu}_y = c_x c_y$, we have

$$\begin{aligned}[I - \widehat{M}_\Delta^*][I - \widehat{M}_\Delta] &= [I + \nu c_x c_y \widehat{L}_\Delta + \tfrac{1}{2}q\widehat{L}_\Delta^2][I - \nu c_x c_y \widehat{L}_\Delta + \tfrac{1}{2}q\widehat{L}_\Delta^2] \\ &= [I + (q - \nu^2 c_x^2 c_y^2)\widehat{L}_\Delta^2 + \tfrac{1}{4}q^2\widehat{L}_\Delta^4].\end{aligned}$$

After carrying out the multiplications, we have

$$\widehat{\mathbf{u}}^*[I - \widehat{M}_\Delta^*][I - \widehat{M}_\Delta]\widehat{\mathbf{u}} = \|\widehat{\mathbf{u}}\|^2 - 4[(q - \nu^2 c_x^2 c_y^2) - q^2(\alpha^2 + \beta^2)][(\alpha^2 + \beta^2)|\hat{p}|^2 + |\alpha\hat{u} + \beta\hat{v}|^2]$$

so that the stability condition is

$$(\alpha^2 + \beta^2)q^2 \le q - \nu^2 c_x^2 c_y^2 \tag{26}$$

for all modes.

Lemma 1. *The scheme is stable if*

$$\nu^2 \le q \le 1. \tag{27}$$

Proof. Necessity of the left inequality follows from considering $k_x = k_y = 0$, and necessity of the right inequality from $k_x h = \pi, k_y = 0$. Sufficiency follows from noting

$$\alpha^2 + \beta^2 = 1 - (1 - c_x^2)(1 - c_y^2) - c_x^2 c_y^2 \le 1 - c_x^2 c_y^2$$

so that

$$\begin{aligned}(\alpha^2 + \beta^2)q^2 - q + \nu^2 c_x^2 c_y^2 &\le (1 - c_x^2 c_y^2)q^2 - q + \nu^2 c_x^2 c_y^2 \\ &= (\nu^2 - q)c_x^2 c_y^2 + q(q - 1)(1 - c_x^2 c_y^2) \le 0. \qquad \square\end{aligned}$$

As well as the special choice $q = \nu^2$ leading to the second-order scheme, one may note other stable choices. Taking $q = 1$ gives a Lax–Friedrichs scheme, and $q = \nu$ gives a scheme that reduces to the first-order upwind scheme if the data is one-dimensional. It may be conjectured that this latter scheme will have an important role to play in the development of nonlinear, “limited” methods. Finally, the parameter q may be identified with the product $\nu\nu'$ mentioned in the previous section.

In the appendix we use Fourier analysis to estimate the rate of vorticity production by comparable schemes which have not been designed to preserve it. In particular, an expression is given for the vorticity production by the standard one-step Lax–Wendroff method.

5.2. Truncation error. The amplification factor that results from applying the operator L_Δ to an arbitrary Fourier mode is, using the above notation, $2\mathrm{i}\sqrt{\alpha^2 + \beta^2}$ and hence the amplification factor of the operator $1 - M_\Delta$ is, for $q = \nu^2$,

$$g = 1 - 2\mathrm{i}\nu\hat{\mu}_x\hat{\mu}_y\sqrt{\alpha^2 + \beta^2} - 2\nu^2(\alpha^2 + \beta^2).$$

This has a modulus given by

$$|g|^2 = 1 - 4\nu^2(1 - c_x^2 c_y^2)(\alpha^2 + \beta^2) + 4\nu^4(\alpha^2 + \beta^2)^2.$$

Expanding this as a Taylor series in k_x, k_y leads to

$$|g| = 1 - \frac{h^4}{8}\nu^2(1 - \nu^2)(k_x^2 + k_y^2)^2 + \mathcal{O}(h^6), \tag{28}$$

which is isotropic to leading order. The amplification error over a number of time steps proportional to h^{-1} (that is, over some fixed time independent of the grid) is $\mathcal{O}(h^3)$.

The phase error is given by the ratio of numerical to exact propagation speeds

$$\frac{\arg g}{\frac{1}{2}\sqrt{k_x^2+k_y^2 h}} = 1 - \frac{h^2}{8}(1-\nu^2)(k_x^2+k_y^2) - \frac{h^2}{24}\frac{k_x^2k_y^2}{k_x^2+k_y^2} + \mathcal{O}(h^4), \tag{29}$$

which is $\mathcal{O}(h^2)$ and is not isotropic.

6. Including advection. If the linearization is not with respect to a stationary flow but with respect to a uniform flow with velocity (u_0, v_0), the differential operator becomes

$$L^Q = \frac{1}{c}\begin{bmatrix} u_0\partial_x + v_0\partial_y & c\partial_x & c\partial_y \\ c\partial_x & u_0\partial_x + v_0\partial_y & 0 \\ c\partial_y & 0 & u_0\partial_x + v_0\partial_y \end{bmatrix}, \tag{30}$$

from which we may easily deduce that vorticity is a convected quantity,

$$(\partial_t + u_0\partial_x + v_0\partial_y)(\partial_x v - \partial_y u) = 0. \tag{31}$$

6.1. Discrete vorticity advection. This is very simply achieved. Define

$$L_\Delta^Q = \begin{bmatrix} Q_\Delta & \mu_y\delta_x & \mu_x\delta_y \\ \mu_y\delta_x & Q_\Delta & 0 \\ \mu_x\delta_y & 0 & Q_\Delta \end{bmatrix}, \tag{32}$$

where Q_Δ is any discrete operator consistent with $(u_0\partial_x + v_0\partial_y)/c$ that maps between the cell center and cell vertex meshes. Then the evolution of vorticity ζ_{Δ_2} under a first-order application of this operator is given by

$$\begin{aligned} \zeta_{\Delta_2}^{n+1} - \zeta_{\Delta_2}^{n} &= Z_2\mathbf{u}^{n+1} - Z_2\mathbf{u}^n \\ &= -\nu Z_2[Q_\Delta I + L_\Delta]\mathbf{u}' \\ &= -\nu Z_2 Q_\Delta \mathbf{u}' \\ &= -\nu Q_\Delta Z_2\mathbf{u}' \\ &= -\nu Q_\Delta \zeta'_{\Delta_2}. \end{aligned} \tag{33}$$

A Lax–Wendroff scheme defined by

$$\mathbf{u}^{n+1} - \mathbf{u}^n = -\nu L_\Delta^Q[\mu_x\mu_y I - \tfrac{1}{2}\nu L_\Delta^Q]\mathbf{u}^n$$

will lead to

$$\zeta_{\Delta_2}^{n+1} - \zeta_{\Delta_2}^{n} = -\nu Q_\Delta[\mu_x\mu_y I - \tfrac{1}{2}\nu Q_\Delta]\zeta_{\Delta_2}^n, \tag{34}$$

so that ζ_{Δ_2} is transported by the Lax–Wendroff version of Q_Δ.

6.2. Stability with advection. For consistency in our choice of difference operators we will take Q_Δ above to be

$$Q_\Delta = \frac{1}{c}(u_0 \mu_y \delta_x + v_0 \mu_x \delta_y) \tag{35}$$

so that the Fourier symbol of the update operator becomes

$$\widehat{L}^Q_\Delta = 2\mathrm{i} \begin{bmatrix} \gamma & \alpha & \beta \\ \alpha & \gamma & 0 \\ \beta & 0 & \gamma \end{bmatrix}, \tag{36}$$

where $\gamma = M_x \alpha + M_y \beta$ and $M_x = u_0/c, M_y = u_0/c$ are Mach numbers of the undisturbed flow in the (x, y)-directions.

In this section we use an alternative analysis in terms of the eigenvalues of the evolution operator, exploiting the fact that only powers of the first-order operator are involved. Suppose that $\widehat{L}^Q_\Delta$ has an eigenvalue $2\mathrm{i}\kappa$. Then the Fourier symbol of the second-order update operator

$$I - \nu \mu_x \mu_y L^Q_\Delta + \tfrac{1}{2} q (L^Q_\Delta)^2$$

has an eigenvalue

$$1 - 2\mathrm{i}\nu \hat{\mu}_x \hat{\mu}_y \kappa - 2q\kappa^2,$$

and this has modulus less than unity if

$$\kappa^2 q^2 \leq q - \nu^2 c_x^2 c_y^2. \tag{37}$$

Now, κ is actually equal to either γ or $\gamma \pm \sqrt{\alpha^2 + \beta^2}$ so that in either case

$$\kappa^2 \leq \gamma^2 + 2|\gamma|\sqrt{\alpha^2 + \beta^2} + \alpha^2 + \beta^2.$$

Using the fact that $|\gamma| \leq |M|\sqrt{\alpha^2 + \beta^2}$ we obtain

$$\kappa^2 \leq (|M| + 1)^2 (\alpha^2 + \beta^2)$$

so that from (37) the stability condition becomes

$$(1 + |M|)^2 (\alpha^2 + \beta^2) q^2 \leq q - \nu^2 c_x^2 c_y^2 \tag{38}$$

for all modes, which may be compared with (26). From the analysis of that equation it follows that the necessary and sufficient condition for stability of all modes in the presence of advection is

$$\nu^2 \leq q \leq \left(\frac{1}{1 + |M|} \right)^2. \tag{39}$$

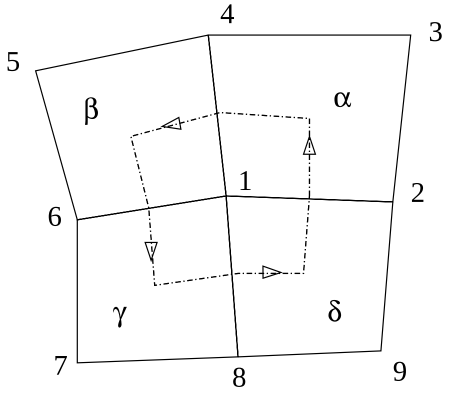

FIG. 5. *Cell and vertex numbering for a quadrilateral mesh.*

7. Irregular grids. We now turn our attention to irregular grids. Our aim is to find some measure of vorticity that is exactly preserved. More significantly, if that measure can be expressed as a line integral around some small control volume, and if many such control volumes can be united to make a large control volume, there will be a global conservation principle for circulation.

This is where the two interpretations of our scheme diverge. In the cell-centered finite-volume approach the velocities are piecewise constant within each cell so that circulation will be evaluated by a rectangle rule. In a vertex-centered finite-difference interpretation, velocities vary bilinearly within each element so that circulation will be evaluated by a trapezium rule. Even on a re-entrant path on a square grid these are equivalent so that both interpretations lead to a circulation-preserving scheme. On irregular grids the measures of circulation are different and it is not obvious that any correspondence exists.

In fact, we have only been able to prove preservation of circulation for the cell-centered finite-volume scheme, and have come to suspect rather strongly that there is no such result for the vertex-centered finite-difference method.

7.1. Quadrilateral cells. Suppose the square cells of Figure 1 are distorted to give the quadrilaterals of Figure 5, and the solution is updated by a two-step scheme as in (21), (22) with the intermediate quantities $\mathbf{u}'$ held at the vertices of the quadrilaterals. To calculate the update we suppose that $\mathbf{u}'$ is bilinearly interpolated over each quadrilateral from the vertex values. Then we show that a natural generalization of the discrete vorticity $Z_2\mathbf{u}$ is exactly preserved.

With the cell and vertex numbering of Figure 5, the update to the cell average $\mathbf{u}_\alpha$ is obtained by integrating $L\mathbf{u}'$ over the quadrilateral Ω_α of measure V_α and by applying Gauss's theorem to obtain a line integral around the perimeter of the cell. Thus for u we obtain

$$\begin{aligned} u_\alpha^{n+1} - u_\alpha^n &= -\frac{c\Delta t}{V_\alpha}\int_{\Omega_\alpha} \partial_x p' d\Omega = -\frac{c\Delta t}{V_\alpha}\oint_{\partial\Omega_\alpha} p' dy \\ &= -\frac{c\Delta t}{2V_\alpha}[(p'_1 - p'_3)(y_2 - y_4) + (p'_2 - p'_4)(y_3 - y_1)], \end{aligned} \tag{40}$$

where the integrals along each edge are given exactly by use of the trapezoidal rule. Similarly for v we obtain

$$\begin{aligned} v_\alpha^{n+1} - v_\alpha^n &= -\frac{c\Delta t}{V_\alpha}\int_{\Omega_\alpha} \partial_y p' d\Omega = \frac{c\Delta t}{V_\alpha}\oint_{\partial\Omega_\alpha} p' dx \\ &= \frac{c\Delta t}{2V_\alpha}[(p'_1 - p'_3)(x_2 - x_4) + (p'_2 - p'_4)(x_3 - x_1)]. \end{aligned} \tag{41}$$

The change in discrete vorticity at vertex 1 is then obtained by integrating the change in $\partial_x v - \partial_y u$ over an appropriate region and again turning this into a line integral of the form

$$\Delta\Gamma = \oint [(v^{n+1} - v^n)dy + (u^{n+1} - u^n)dx], \tag{42}$$

where (u, v) are constant in each quadrilateral and the line integral represents the circulation. Preservation of vorticity can be ensured by appropriately choosing a path for the line integral. We choose the part of the line in cell Ω_α to run from the midpoint of the side $(1, 2)$ to the centroid and then to the midpoint of side $(1, 4)$. In fact, since (u, v) are constant along this path, the integral is the same for any path joining the midpoints of the sides, but making it go through the centroid ensures that the control volumes can be joined together. The contribution to (42) at vertex 1 from (40) and (41) is then, after some crucial cancellation,

$$\begin{aligned} \Delta\Gamma_{1,\alpha} &= \tfrac{1}{2}[(v_\alpha^{n+1} - v_\alpha^n)(y_4 - y_2) + (u_\alpha^{n+1} - u_\alpha^n)(x_4 - x_2)] \\ &= \frac{c\Delta t}{4V_\alpha}(p'_2 - p'_4)[(y_4 - y_2)(x_3 - x_1) - (x_4 - x_2)(y_3 - y_1)] \\ &= \tfrac{1}{2}c\Delta t(p'_2 - p'_4), \end{aligned} \tag{43}$$

because the quantity in square brackets on the line above (43) is just $2V_\alpha$. It is now clear that as we add the contributions from cells $\Omega_\alpha, \Omega_\beta, \Omega_\gamma$, and Ω_δ, which meet at the vertex 1, they all cancel. Thus there is no change in the circulation around the contour chosen, and so the discrete vorticity defined by (42) and (43) is exactly preserved.

7.2. Mixed meshes. Suppose we have a mesh in which any combination of triangles and quadrilaterals meets at every vertex. Again we define the vorticity at that vertex through (42). Then, with the numbering of Figure 6, the line integrals for the update in triangular cell Ω_α can be computed as in (40), (41) to give

$$\begin{aligned} \begin{pmatrix} u \\ v \end{pmatrix}_\alpha^{n+1} - \begin{pmatrix} u \\ v \end{pmatrix}_\alpha^{n} &= -\frac{c\Delta t}{2V_\alpha}\left[p'_1\begin{pmatrix} y_2 - y_3 \\ x_3 - x_2 \end{pmatrix} + p'_2\begin{pmatrix} y_3 - y_1 \\ x_1 - x_3 \end{pmatrix} + p'_3\begin{pmatrix} y_1 - y_2 \\ x_2 - x_1 \end{pmatrix}\right] \\ &= \frac{c\Delta t}{2V_\alpha}\left[(p'_2 - p'_1)\begin{pmatrix} y_1 - y_3 \\ x_3 - x_1 \end{pmatrix} + (p'_3 - p'_1)\begin{pmatrix} y_2 - y_1 \\ x_1 - x_2 \end{pmatrix}\right]. \end{aligned} \tag{44}$$

It is also clear that the area of the triangle is given by

$$\begin{aligned} V_\alpha &= \tfrac{1}{2}[x_1(y_2 - y_3) + x_2(y_3 - y_1) + x_3(y_1 - y_2)] \\ &= -\tfrac{1}{2}[y_1(x_2 - x_3) + y_2(x_3 - x_1) + y_3(x_1 - x_2)]. \end{aligned} \tag{45}$$

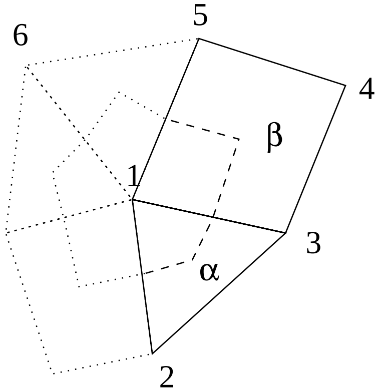

FIG. 6. *Cell and vertex numbering for a mixed mesh.*

Hence the vorticity change computed from all the triangular cells meeting at vertex 1 is in the form of a line integral,

$$\begin{aligned}&\oint [(v^{n+1}-v^n)dy+(u^{n+1}-u^n)dx]\\ &= c\Delta t \sum_{(\alpha)} \frac{1}{2V_\alpha}[(v_\alpha^{n+1}-v_\alpha^n)\Delta y_\alpha+(u_\alpha^{n+1}-u_\alpha^n)\Delta x_\alpha],\end{aligned} \tag{46}$$

into which the u and v updates are substituted from (44).

As in the quadrilateral case, we choose the line integrals to go from the midpoints of edges to the centroids of each triangle. Thus in cell Ω_α we have $\Delta x_\alpha = \frac{1}{2}(x_3+x_1)-\frac{1}{2}(x_2+x_1)=\frac{1}{2}(x_3-x_2)$. As a result, the contribution from Ω_α to the update of circulation around vertex 1 may be written

$$\begin{aligned}\Delta\Gamma_{1,\alpha} &= \frac{c\Delta t}{4V_\alpha}\left[\left\{(p_2'-p_1')(y_3-y_1)+(p_3'-p_1')(y_1-y_2)\right\}(x_3-x_2)\right.\\ &\qquad \left.+\left\{(p_2'-p_1')(x_1-x_3)+(p_3'-p_1')(x_2-x_1)\right\}(y_3-y_2)\right]\\ &= \frac{c\Delta t}{4V_\alpha}\left[p_2'\left\{(y_3-y_1)(x_3-x_2)+(x_1-x_3)(y_3-y_2)\right\}\right.\\ &\qquad \left.+p_3'\left\{(y_1-y_2)(x_3-x_2)+(x_2-x_1)(y_3-y_2)\right\}\right]\\ &= \frac{c\Delta t}{2}(p_2'-p_3').\end{aligned} \tag{47}$$

Since this is of exactly the same form as (43) the total update to the circulation around vertex 1 vanishes, and since the control volumes for any set of contiguous vertices can be merged into one large control volume as in Figure 7, the circulation around that remains unchanged also.

If cells with more than four vertices are considered, their contribution involves the values of p' at vertices that are not common to two cells and which therefore do not cancel. It seems that meshes made from a mixture of quadrilaterals and triangles are the most general for which this particular result holds.

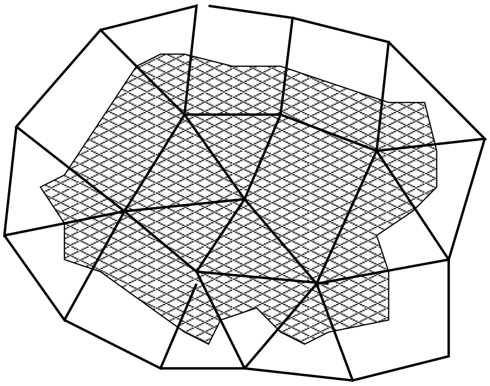

FIG. 7. *Contour for defining circulation.*

7.3. Three-dimensional unstructured grids. In three dimensions the circulation around some closed surface is the vectorial quantity

$$\vec{\Gamma} = \int\!\!\int \vec{u} \times d\vec{n}, \tag{48}$$

which evolves, for the three-dimensional version of (1), according to

$$\partial_t \vec{\Gamma} = -\int\!\!\int c\,\nabla p \times d\vec{n}, \tag{49}$$

and this vanishes if c is constant.

For finite-volume schemes, it is possible to show that a discrete version of (48) remains invariant for grids that are arbitrary combinations of tetrahedra and hexahedra if a suitable control volume is chosen around each vertex. This is constructed as shown in Figure 8 . For tetrahedral cells, one constructs the six planes defined by one edge and the midpoint of the opposite edge, thereby dissecting the tetrahedron into four hexahedra, one associated with each vertex. For hexahedral cells, one creates eight small hexahedra by constructing the three bilinear surfaces that bisect pairs of

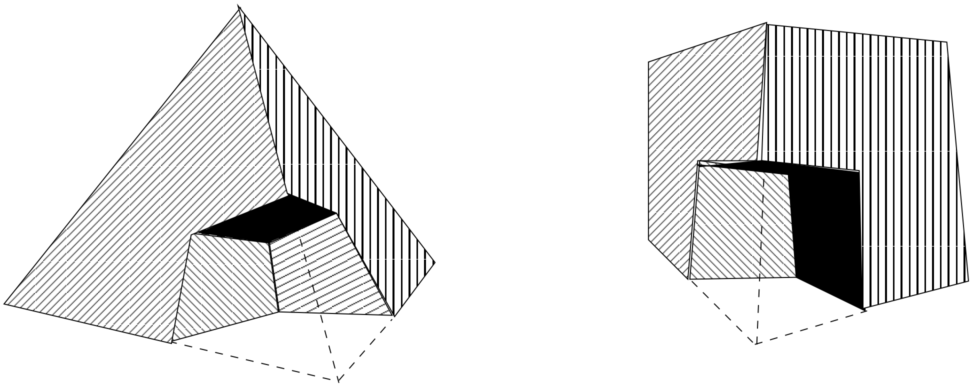

FIG. 8. *Elements of a mixed three-dimensional unstructured grid, showing a tetrahedral cell (left) and a hexahedral cell (right) with the subvolume corresponding to one vertex cut away.*

opposite faces. The control volume around any given vertex is the union of subcells so constructed. An appropriate measure for the circulation around this control volume is

$$\vec{\Gamma}_V = \sum \vec{u}_{\text{cell}} \vec{n}_{\text{cell}}, \tag{50}$$

where the sum is over all cells meeting at V, $\vec{u}_{\text{cell}}$ is the constant velocity associated with that cell, and $\vec{n}_{\text{cell}}$ is the "integrated normal" $\int\int \vec{n} dS$ over the boundary between the subvolume of the cell associated with V and the remainder of the cell. (Recall that $\vec{n}_{\text{cell}}$ depends only on the perimeter of that boundary and not on the surface spanning it; we choose a particular surface only to ensure that the control volumes fill the whole space.) We now sketch a proof that this circulation remains constant.

After some rather lengthy algebra, the contribution made by some cell α to the circulation around V can be written as a sum over a certain set of edges. Think of the cells meeting at V as defining some irregular polyhedron. The edges of this polyhedron that divide α from its neighbors may be called the boundary of α with respect to V and for the kind of grid considered will be either a triangle or a (probably nonplanar) hexahedron. Suppose that it is a hexahedron whose vertices have position vectors $\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \mathbf{r}_4, \mathbf{r}_5, \mathbf{r}_6$. The relationship is

$$\Delta \vec{\Gamma}_{V,\alpha} = \frac{c\Delta t}{4} \sum_{j=1}^{j=6} (p_j + p_{j+1})(\mathbf{r}_{j+1} - \mathbf{r}_j). \tag{51}$$

From this equation it is clear that if c is a constant, the sum over the boundaries of all cells surrounding V will vanish, because every edge appears twice with opposite sign. If c is not a constant, then the sum becomes a consistent discretization of $-\int\int c\nabla p \times \vec{n}_{\text{cell}}$, and hence the circulation around any assembly of these control volumes depends only on a surface summation. Noting that the formulae remain valid when the hexahedra are degenerate, in particular when they degenerate to tetrahedra, completes the outline of the proof.

8. Variable coefficients. As an example of how the techniques of the present paper may be extended to problems with variable coefficients, we consider the case of acoustic waves in a fluid of variable density ρ. Then the system (1) is replaced by

$$\partial_t p + \rho a^2(\partial_x u + \partial_y v) = 0, \;\; \partial_t u + (1/\rho)\partial_x p = 0, \;\; \partial_t v + (1/\rho)\partial_y p = 0, \tag{52}$$

and the change in vorticity, $\zeta = \partial_x v - \partial_y u$, is given by

$$\begin{aligned} \partial_t \zeta &= -\partial_x (1/\rho)\partial_y p + \partial_y (1/\rho)\partial_x p \\ &= [\rho_x p_y - \rho_y p_x]/\rho^2. \end{aligned} \tag{53}$$

This represents the barotropic effect through which an inviscid flow may acquire vorticity, unless the pressure and density gradients are parallel. The integral version of this effect is Kelvin's theorem,

$$\partial_t \Gamma = \oint \frac{dp}{\rho}, \tag{54}$$

where $\Gamma = \oint \vec{u} \cdot \vec{ds}$ is the circulation around some given contour.

Now let us consider the update of the velocities on the quadrilateral mesh of Figure 5 with an appropriate modification of (40) and (41). In fact, let us take R_α as the constant value of $1/\rho$ in cell Ω_α so that these update formulae need to be modified only by a factor R_α. The resulting change in the discrete vorticity $Z_2\mathbf{u}$ at vertex 1 is given by replacing c by R_α in (43) and summing over the cells. The result is

$$\begin{aligned} Z_2(\mathbf{u}^{n+1}-\mathbf{u}^n) = \tfrac{1}{2}\Delta t[&R_\alpha(p'_2-p'_4)+R_\beta(p'_4-p'_6)\\ &+R_\gamma(p'_6-p'_8)+R_\delta(p'_8-p'_2)]. \end{aligned} \tag{55}$$

Moreover, it is clear that the same argument applies on the mixed grid of Figure 6, and that if we merge any set of contiguous control volumes as in Figure 7, then a discrete version of Kelvin's theorem applies to such circuits of arbitrary size.

To relate this to the local formula (53), we note that (55) can be rearranged to give

$$\begin{aligned} &\tfrac{1}{4}\Delta t\{(R_\alpha-R_\gamma)[(p'_2-p'_4)+(p'_8-p'_6)]+(R_\beta-R_\delta)[(p'_4-p'_6)+(p'_2-p'_8)]\\ &\qquad+(R_\alpha-R_\beta+R_\gamma-R_\delta)(p'_2-p'_4+p'_6-p'_8)\}. \end{aligned} \tag{56}$$

Now if the mesh in Figure 5 is roughly rectangular, $R_\alpha - R_\gamma$ is a difference of R in the NW direction while $(p'_2-p'_4)+(p'_8-p'_6)$ is an averaged difference of p' in the roughly orthogonal NE direction; and $R_\delta - R_\beta$ is a difference of R in the NE direction while $(p'_4-p'_6)+(p'_2-p'_8)$ is an averaged difference of p' in the NW direction. Thus the first line of (56) will be close to zero when the gradients of R and p' are parallel, matching the behavior of (53). The second line of (56) is a product of crossed second derivatives of R and p' and will normally be two orders smaller.

This example demonstrates how properties of vorticity preservation in the differential system, even those that hold in the presence of variable coefficients, can still be reflected in our discrete schemes. With appropriate control volumes they still hold for three-dimensional unstructured grids, as in section 7.3. The case of variable coefficients in Maxwell's equations is actually easier, because the coefficients appear inside the derivative, meaning that the magnetic field remains curl-free in an arbitrary nonresistive medium. Our method will mimic this precisely.

9. Concluding discussion.

A great step forward in CFD was the casting of discrete representations into conservation form by Lax and Wendroff [9]. This ensured that any shock waves captured by the scheme would be in some sense "correct" and greatly extended the range of application of numerical methods. Conservation of derived quantities seems to have received much less attention since the early work of Arakawa [10] and Jesperson [11] on schemes that conserve total energy and enstrophy. In particular, there seems to have been little exploration of the conservation of local derivative quantities such as vorticity which is the object of study in this paper.

By starting with the simplest case of linear problems on square grids treated by Lax–Wendroff methods, we have been able to reduce the number of candidate schemes. In fact, insisting on conservation of the primary quantities and the derivatives, together with symmetry and compactness properties, makes the scheme essentially unique. We have analyzed the stability of the scheme and find that either with or without advective terms it is stable up to the largest time steps that the CFL condition allows.

Expressing the update operator as the product of two commuting factors allows just two interpretations, depending on the order of their execution. One interpretation is as a cell-centered finite-volume scheme, whereas the other is as a vertex-centered finite-difference scheme. On irregular grids the operators no longer commute, and the two interpretations are different. We show that the finite-volume interpretation continues to preserve vorticity, but it is a finite-volume scheme of a somewhat nontraditional kind. There is a unique flux through each interface, but it may not be evaluated by reference only to the pair of cells that it separates; it must be found by averaging the fluxes at its two end points and therefore involves four cell states. Apparently this is the price to be paid for incorporating the additional conservation properties.

Whether this price will buy worthwhile benefits remains to be seen. In [12] a number of alternative nine-point schemes are given, some of which have attractive properties, but they are not vorticity-preserving. These schemes are designed by approximating the exact evolution operator for the PDE (using the bicharacteristics of the wave equation in this case) and then projecting onto piecewise constant functions. Unfortunately these approximations to the evolution operator destroy the vorticity preservation. On the other hand the schemes generated in the present paper can be regarded as evolution Galerkin methods in which Taylor expansions in time are used to approximate the evolution operator; this has the advantage of preserving vorticity. For the schemes in [12] the changes in vorticity can be estimated and shown to be quite substantial relative to other truncation error terms. Vorticity production by a general class of schemes, which includes the standard one-step Lax–Wendroff method, is presented briefly in the appendix.

Moreover, there is one rather substantial practical problem to which the current approach might be relevant. This is the appearance in many shock-capturing codes of anomalous solutions, such as the "carbuncle" that often appears ahead of blunt bodies in supersonic flow computations, first reported in [13] and recently investigated thoroughly in [14]. Closely related to this is "Quirk's phenomenon" [15] that produces an odd-even decoupling in response to small mesh perturbations, and the kinks that sometimes appear in reflected Mach stems [15, 16]. It seems very probable that these are truly weak solutions, even entropy-satisfying weak solutions, of the Euler equations, even though not usually observed in practice.[1]

Very often, perhaps always, these anomalous solutions are marked by the presence of nonphysical vorticity; in the carbuncle this accumulates into two massive counter-rotating vortices. Robinet et al. [17] note a marked correspondence between the Quirk phenomenon and a previously overlooked form of shock instability involving resonance between vortical and acoustic modes. It is therefore a reasonable speculation that a method based to some extent on the control of vorticity might be less prone to producing anomalous solutions, and might even avoid them altogether. At the moment they are usually eliminated by adding numerical dissipation in a somewhat indiscriminate manner.

But as stated earlier, we regard the present paper merely as a beginning and hope to present various extensions, both theoretical and practical, in future publications. Some extensions are very easy, such as the consideration of Maxwell's equations or ideal MHD, where the differential constraint involves the divergence rather than the curl. We have begun to consider higher-order extensions and consistent finite-element versions. We have not yet seriously thought about fully nonlinear problems or moving meshes, both of which are necessary steps to take if these ideas are indeed to have

[1] The carbuncle phenomenon can be created in a wind tunnel. One inserts a thin splitter-plate ahead of the tip of the body. A Schlieren photograph of the resulting flow appears as Plate 272 in [18]. Quite possibly the vorticity created by the boundary layer on the plate is responsible, but the high Reynolds number limit of this flow is a valid solution of the Euler equations. We conjecture that anomalous Euler solutions result from the systematic creation of vorticity due to truncation error.

practical impact on complex problems. Neither have we ourselves yet conducted any numerical experiments, although we plan on doing so soon. In the meantime we are grateful to Professor Alain Lerat who has had some experiments carried out in his laboratory when the second author was visiting there [21]: these confirm the predictions of the analysis. For initial data representing a stationary vortex they show substantial vorticity losses in a variety of alternative schemes applied to the linear acoustic system. For the present scheme, such initial data are of course perfectly preserved. Moreover, when the fully nonlinear Euler equations are used, the initial data are almost perfectly preserved by the rotated Richtmyer scheme, which is a natural generalization of our scheme to this problem.

As a final remark, we wish to draw to the attention of our readers the work of Hyman and Shashkov (see [19, 20] and the references cited therein) with which our analysis has many points of similarity. They construct discrete operators on logically rectangular meshes that obey discrete analogues of the major vector identities, such as $CURL \times GRAD = 0$, which is another way of expressing what we do here. The starting points, and the style, of the two analyses are quite different, and although our results are less specific in one sense, being limited to the single identity above, they are more general in the sense of extending to (some) unstructured and multidimensional grids. An extended comparison of the two approaches may well prove profitable.

Appendix. Vorticity production by a general scheme. We consider a class of schemes that include Lax–Wendroff schemes and compute the vorticity that they generate. The schemes are written as (only the velocity updates are needed)

$$u^{n+1} = u^n - \nu\delta_x P - \nu\delta_y Q', \tag{57}$$

$$v^{n+1} = v^n - \nu\delta_x P' - \nu\delta_y Q, \tag{58}$$

where

$$\begin{aligned} P &= [a + (1-a)\mu_y^2]\mu_x p^n - \tfrac{1}{2}\nu[b + c\mu_y^2]\delta_x u^n - \tfrac{1}{2}\nu d\mu_x\mu_y\delta_y v^n, \\ Q &= [a + (1-a)\mu_x^2]\mu_y p^n - \tfrac{1}{2}\nu[b + c\mu_x^2]\delta_y v^n - \tfrac{1}{2}\nu d\mu_x\mu_y\delta_x u^n, \\ P' &= -e\delta_x v^n, \\ Q' &= -e\delta_y u^n. \end{aligned}$$

Such a scheme is properly centered in time, and hence second-order accurate, if

$$b + c = 1, \qquad d = 1, \qquad e = 0;$$

a particular case is $a = 1, c = 0$, which corresponds to the standard one-step Lax–Wendroff scheme. For the compact vorticity of (12), in general we have

$$\begin{aligned} \zeta^{n+1} - \zeta^n &= \nu\left\{\mu_x\delta_x\delta_y P - \mu_y\delta_x\delta_y Q + \mu_x\delta_y^2 Q' - \mu_y\delta_x^2 P'\right\} \\ &= \nu\left\{\mu_x^2\delta_x\delta_y[a + (1-a)\mu_y^2]p^n - \mu_y^2\delta_x\delta_y[a + (1-a)\mu_x^2]p^n\right. \\ &\quad -\tfrac{1}{2}\nu[b + c\mu_y^2]\mu_x\delta_x^2\delta_y u^n + \tfrac{1}{2}\nu d\mu_x\mu_y^2\delta_x^2\delta_y u^n \\ &\quad -\tfrac{1}{2}\nu d\mu_x^2\mu_y\delta_x\delta_y^2 v^n + \tfrac{1}{2}\nu[b + c\mu_x^2]\mu_y\delta_x\delta_y^2 v^n \\ &\quad \left.-e\mu_x\delta_y^3 u^n + e\mu_y\delta_x^3 v^n\right\} \\ &= \nu\left\{a(\mu_x^2 - \mu_y^2)\delta_x\delta_y p^n - \tfrac{1}{2}\nu b\delta_x\delta_y(\mu_x\delta_x u^n - \mu_y\delta_y v^n)\right. \\ &\quad \left.+\tfrac{1}{2}\nu(d-c)\mu_x\mu_y\delta_x\delta_y(\mu_y\delta_x u^n - \mu_x\delta_y v^n) - e(\mu_x\delta_y^3 u^n - \mu_y\delta_x^3 v^n)\right\}. \end{aligned}$$

This formula displays four different mechanisms for vorticity production. For all of their contributions to vanish, we require

$$a = 0, \qquad b = 0, \qquad c = d, \qquad e = 0,$$

and the unique second-order scheme meeting these constraints has

$$a = b = e = 0, \qquad c = d = 1. \tag{59}$$

If we now take Fourier transforms, we have, with the notation of section 5.1,

$$\begin{aligned}\hat{\zeta}^{n+1} - \hat{\zeta}^n = \nu \{ & a(s_y^2 - s_x^2)(-4s_x s_y)\hat{p}^n \\ & -\tfrac{1}{2}\nu b(-4s_x s_y)(2\mathrm{i}c_x s_x \hat{u}^n - 2\mathrm{i}c_y s_y \hat{v}^n) \\ & +\tfrac{1}{2}\nu(d-c)(-4s_x s_y)c_x c_y(2\mathrm{i}c_y s_x \hat{u}^n - 2\mathrm{i}c_x s_y \hat{v}^n) \\ & -e(-8\mathrm{i}c_x s_y^3 \hat{u}^n + 8\mathrm{i}c_y s_x^3 \hat{v}^n)\}.\end{aligned}$$

As the mesh size h approaches zero, the left-hand side tends to h times the vorticity, $c_x, c_y \to 1, s_x \to k_x h/2, s_y \to k_y h/2$, and hence

$$\begin{aligned}\frac{\hat{\zeta}^{n+1} - \hat{\zeta}^n}{h} \simeq {} & \mathrm{i}\frac{h^2}{2}\left[\nu^2(b+c-d)k_x k_y(k_x \hat{u}^n - k_y \hat{v}^n) + e\nu(k_x^3 \hat{u}^n - k_y^3 \hat{v}^n)\right] \\ & + \frac{h^3}{4} a\nu(k_x^2 - k_y^2)k_x k_y \hat{p}^n.\end{aligned} \tag{60}$$

This shows that most first-order members of the family produce vorticity at a rate proportional to h^2, unless $b + c = d$ and $e = 0$. It also shows that most second-order members will produce vorticity at a rate proportional to h^3 unless $a = 0$; note that the standard Lax–Wendroff scheme has $a = 1$. Finally, if also $b = 0$ and $c = d$, there is no vorticity production. This corresponds to the single-parameter family studied in section 5.1.

ALGEBRAIC MESH QUALITY METRICS[*]

PATRICK M. KNUPP[†]

Abstract. Quality metrics for structured and unstructured mesh generation are placed within an algebraic framework to form a mathematical theory of mesh quality metrics. The theory, based on the Jacobian and related matrices, provides a means of constructing, classifying, and evaluating mesh quality metrics. The Jacobian matrix is factored into geometrically meaningful parts. A nodally invariant Jacobian matrix can be defined for simplicial elements using a weight matrix derived from the Jacobian matrix of an ideal reference element. Scale and orientation-invariant algebraic mesh quality metrics are defined. The singular value decomposition is used to study relationships between metrics. Equivalence of the element condition number and mean ratio metrics is proved. The condition number is shown to measure the distance of an element to the set of degenerate elements. Algebraic measures for skew, length ratio, shape, volume, and orientation are defined abstractly, with specific examples given. Two combined metrics, shape-volume and shape-volume orientation, are algebraically defined and examples of such metrics are given. Algebraic mesh quality metrics are extended to nonsimplicial elements. A series of numerical tests verifies the theoretical properties of the metrics defined.

Key words. unstructured mesh generation, mesh quality metrics, condition number, shape measures

1. Introduction.

Mesh quality metrics for assessing the results of a meshing process have been in use almost since the beginning of meshing. Metrics are or can be used in a number of ways. First, metrics can serve as mesh *requirement specifications* prior to mesh creation. Element volume, shape, and orientation in various parts of the geometric domain can be specified in advance of meshing to enable the mesh generator to select proper algorithms and concentrate on the most difficult areas. Second, mesh improvement techniques such as *smoothing, optimization,* and *edge swapping* depend heavily on the use of quality metrics. Third, metrics often serve as a *quality control* mechanism. Given a mesh, is it of sufficient quality that it can be passed on to the consumer? Nonadaptive, a priori meshing of complex geometries is difficult, especially with nonsimplicial elements. As a result, mesh quality is not assured. Consumers of meshes for adaptive purposes should also be interested in quality metrics because h-adaptive mesh refinement will rarely improve initial mesh quality. R-type adaptive procedures, in which mesh nodes are moved, can also make good use of mesh quality metrics. Given these uses, mesh quality metrics will be needed for the foreseeable future.

For the most part, mesh quality metrics are based on geometric criteria. For example, does a given element possess positive volume and a good shape? Element volume, aspect ratio, skew, angles, stretching, and orientation are common geometric quality metrics. Surprisingly, a mathematical theory of geometric mesh quality metrics has not been developed until now. Such a theory should include a discussion of what a mesh quality metric is, what properties it should possess, a capability for analyzing and classifying various metrics, including a way to show how metrics are related and a means of identifying redundant metrics. This attempt at such a theory is based on element Jacobian matrices and an algebraic framework that uses matrix norm, trace, and determinant. A crucial feature introduced in this theory is the idea that metrics don't exist in a vacuum but need to be referenced to an ideal element. The metric then measures the deviation from the ideal. The ideal may vary from one application to another. For example, some applications can do well with isotropic elements while others may need anisotropic elements with particular orientations. We thus construct our theory for arbitrary reference elements.

We do not attempt a comprehensive survey of all the work that has been done on metrics but refer the reader to the early work of Robinson on quality metrics for quadrilaterals [22], [23], [24], the distortion measure of Oddy [20], the "flatness" measure of Ives [11], the summary of tetrahedral measures in [6], [21], the measures in Canann, Tristano, and Staten [3], and the paper [7]. The work reported here is an extension of the ideas of the author presented in [13], [14], [8], [15], and [16] in which the use of matrices, norms, and the condition number for mesh quality measures were introduced.

2. Preliminary observations. For both structured and unstructured meshes we can refer to mesh *nodes* and mesh *elements*. A mesh element is a geometric object topologically equivalent to some geometrically regular object such as a cube/square, tetrahedron/triangle, wedge, or pyramid. The boundary of the element is defined in terms of mesh nodes with given spatial coordinates.[1] Given a mesh element we define an element quality metric as follows.

Definition. *An element* quality metric *is a scalar function of node positions that measures some geometric property of the element.*

If a three-dimensional element has K nodes with coordinates $x_k \in R^3$, $k = 0, 1, \ldots, K-1$, then we denote a mesh quality metric by $\hat{f} \mid R^{3K} \to R$.

A host of mesh quality metrics have been defined over the years. Many of the metrics are redundant. Others may lack one or more of the following properties of quality metrics (also given in Table 1).

Definitions. *A metric is* dimension-free *if its definition in three dimensions is an unambiguous, natural generalization of its definition in two dimensions; otherwise it is* dimension-specific*. Example: Volume metrics are dimension-free while angle metrics are dimension-specific.*

A metric is element-free *if its definition on one element type is an unambiguous, natural generalization of its definition on another element type; otherwise it is* element-specific*. Example: Maximum angle is element-free on two-dimensional elements while the ratio of quadrilateral diagonal lengths is element-specific.*

A metric on a fixed element type is domain-general *if it is meaningful over a wide range of possible shapes of the element; otherwise it is* domain-specific*. Example: Aspect ratio is domain specific. Although aspect ratio may be defined for any quadri-*

[1] In this paper attention is restricted to linear elements having no midside nodes.

lateral [24] *it is not meaningful for any shape of quadrilateral. The minimum angle of a quadrilateral is domain-general.*

A metric on a fixed element type is versatile *if it is sensitive to more than one distortion mode (e.g., skew and aspect ratio); otherwise it is* specialized. *Example: Tetrahedral shape measures are versatile while skew is specialized. Versatile metrics are useful when one does not need to know the specific mode of distortion.*

A metric is scale-free *if its value does not depend on the volume of the element; otherwise it is* scale-sensitive. *A metric is* orientation-free *if its value does not depend on the orientation of the element in space; otherwise it is* orientation-sensitive. *Example: Rectangle aspect ratio is scale-free and orientation-free. Volume is orientation-free, but scale-sensitive.*

A metric is unitless *if it has no units. Example: Aspect ratio and skew are unitless while volume is not. Unitless measures do not depend upon the physical units of the problem (such as length in feet vs. meters).*

A metric is referenced *if it incorporates an explicit comparison to a reference element, which may determine volume, shape, or orientation; otherwise it is unreferenced. Example: Aspect ratio $h/(sw)$ is referenced to a rectangle with aspect ratio $s > 0$. By necessity, referenced metrics are unitless.*

Table 1
Quality metric property summary.

Property	Restricted metric	General metric
Dimension ($n = 2$ vs. $n = 3$)	dimension-specific (e.g., only applies to $n = 2$)	dimension-free (applies to both $n = 2$ and $n = 3$)
Element type (e.g., tri or quad)	element-specific (e.g., only defined for quad)	element-free (e.g., both tri and quad)
Domain (e.g., shape of quad)	domain-specific (e.g., rectangles only)	domain-general (e.g., all quads)
Versatility (# qualities measured)	specialized (only one)	versatile (e.g., volume-shape orientation)
Element size (or volume)	scale-sensitive (size-dependent)	scale-free (size-invariant)
Orientation	orientation-sensitive (orientation-dependent)	orientation-free (orientation-invariant)
Units (of metric)	has-units (dimensional)	unitless (nondimensional)
Reference (ideal element)	unreferenced (implicit ideal)	referenced (explicit ideal)

Before proceeding, we make a few general comments. First, many of the propositions noted have trivial proofs, which are omitted. Proofs are given for less straightforward results. Second, although many of the ideas presented in this paper can be generalized, we prefer to remain concrete since the meshing application demands it. Accordingly, we work over the field of real numbers, with objects in two or three dimensions ($n = 2$ or $n = 3$). We will work primarily with simplicial elements in mind and concentrate on three dimensions since this is more difficult than two dimensions. Most results we present hold in both two and three dimensions, even though only one case or the other is presented. Differences are noted. Extension of our results to nonsimplicial elements is given in section 14. We rely heavily on results from linear algebra to develop the theory of metrics. It is important to keep in mind that our emphasis differs from that of numerical linear algebra. The matrices with which we work are 2×2 or 3×3, so efficiency of computation is not the main issue. Instead, the issue is to define algebraic metrics having the desired properties and to show how they are related.

Various sets of matrices are used extensively in our presentation. Let $\mathcal{M}_n$ be the set of all $n \times n$ real matrices. Let $\mathcal{M}_n^+$ be the set of all $n \times n$ real matrices with positive determinant. The boundary of this latter set is $\partial\mathcal{M}_n^+$, the set of all $n \times n$ singular matrices. Let $\mathcal{I}_n$ be the $n \times n$ identity matrix and $\mathcal{O}$ the $n \times n$ zero-matrix. Let $\mathcal{Z}(n)$ be the set of all matrices in $\mathcal{M}_n^+$ whose determinant is unity. Let $\mathcal{SO}(n)$ be the set of all $n \times n$ orthogonal matrices with determinant 1. Let $\mathcal{D}(n)$ be the set of all $n \times n$ nonsingular diagonal matrices and $\mathcal{U}(n)$ the set of all $n \times n$ nonsingular upper triangular matrices. Let $\mathcal{SR}(n)$ be the set of all $n \times n$ nonsingular matrices of the form $\rho\,\Theta$, where $\rho > 0$ and $\Theta \in \mathcal{SO}(n)$. Each of these sets forms one of the classical matrix groups. Recognition of these groups is important because we rely heavily upon the closure, identity, and inverse properties of these matrix groups throughout this exposition.

Consider the affine map associated with a tetrahedron. Let $x_k \in R^3$, $k = 0, 1, 2, 3$, be the coordinates of the four vertices of the tetrahedron in physical space. Let ξ_k, with $0 \le \xi_k \le 1$ and $\xi_0 + \xi_1 + \xi_2 + \xi_3 = 1$, be four logical space coordinates and define the mapping from logical space to physical space by

$$x(\xi) = \sum \xi_k \, x_k$$

with $x \in R^3$.

This can be explicitly written as

$$x = (1 - \xi_1 - \xi_2 - \xi_3)\, x_0 + \xi_1\, x_1 + \xi_2\, x_2 + \xi_3\, x_3,$$

giving

$$x = A_0\, u_0 + x_0$$

with $x = (x, y, z)^t$, $u_0 = (\xi_1, \xi_2, \xi_3)^t$, and

$$A_0 = \begin{pmatrix} x_1 - x_0 & x_2 - x_0 & x_3 - x_0 \\ y_1 - y_0 & y_2 - y_0 & y_3 - y_0 \\ z_1 - z_0 & z_2 - z_0 & z_3 - z_0 \end{pmatrix}.$$

Written in this form, one sees that x is an affine map which takes points u_0 in the right tetrahedron with node coordinates $(0,0,0)$, $(1,0,0)$, $(0,1,0)$, and $(0,0,1)$ to points in a tetrahedron in physical space with the four nodes x_k. The vector x_0 controls translation of the element while the matrix A_0 controls volume, shape, and orientation of the element. We refer to A_0 as the Jacobian matrix because the columns $x_k - x_0$ of the matrix form the Jacobian of the affine map with respect to the logical variables, i.e., $A_{ij} = dx_i/d\xi_j$. The Jacobian matrix has units of length and is, in general, nonsymmetric. The formulation above also applies to triangular elements on a surface, provided the surface has a well-defined normal at every point.

3. Geometric significance of the Jacobian matrix. The Jacobian matrix of an element is important because it is well-defined for both $n = 2$ and $n = 3$. Basing element metrics on the Jacobian matrix thus makes it easy to devise metrics that are dimension-free. Furthermore, the Jacobian matrix contains information relating to the volume, shape, and orientation of an element. This can be understood more clearly by performing the QR factorization of the Jacobian matrix. The factorization decomposes the Jacobian matrix into several matrices with clear geometric interpretations. These matrices will be used to build mesh quality metrics in sections 9, 10, 11, 12, and 14.

Let A be the Jacobian matrix and $\lambda_{ij} = [A^t A]_{ij}$ be the elements of the "metric tensor." Let $\alpha = \det(A)$. It is assumed that $0 <\mid A \mid< \infty$ and $\alpha \geq 0$. Elements with $\alpha < 0$ are *inverted* and will not be considered.

PROPOSITION 3.1. *Let A be the $n = 2$ or $n = 3$ Jacobian matrix. Then one can decompose A as follows:*

$$A = RU = \mu RS = \mu RQD = RQ\Delta,$$

where

- *$R \in \mathcal{SO}(n)$ defines "orientation,"*
- *$U = \mu S$ with $U \in \mathcal{U}(n)$ and $U_{ii} > 0$,*
- *μ is a nonnegative scalar,*
- *$S = QD$ with $S \in \mathcal{U}(n)$, $S_{11} = 1$, and S defines "shape,"*
- *$Q \in \mathcal{U}(n)$ has unit column vectors, and defines "skew,"*
- *$D, \Delta \in \mathcal{D}(n)$ defines "aspect ratio."*

Proof. We explicitly construct the factorizations for $n = 2$ and $n = 3$, as they are needed for computation of the various metrics to be defined later. For $n = 2$,

$$R = \frac{1}{\sqrt{\lambda_{11}}} \begin{pmatrix} A_{11} & -A_{21} \\ A_{21} & A_{11} \end{pmatrix},$$

$$U = \begin{pmatrix} \sqrt{\lambda_{11}} & \lambda_{12}/\sqrt{\lambda_{11}} \\ 0 & \alpha/\sqrt{\lambda_{11}} \end{pmatrix},$$

$$\mu = \sqrt{\lambda_{11}},$$

$$S = \begin{pmatrix} 1 & \lambda_{12}/\lambda_{11} \\ 0 & \alpha/\lambda_{11} \end{pmatrix},$$

$$Q = \begin{pmatrix} 1 & \lambda_{12}/\sqrt{\lambda_{11}\lambda_{22}} \\ 0 & \alpha/\sqrt{\lambda_{11}\lambda_{22}} \end{pmatrix},$$

$$D = \begin{pmatrix} 1 & 0 \\ 0 & \sqrt{\lambda_{22}/\lambda_{11}} \end{pmatrix},$$

$$\Delta = \begin{pmatrix} \sqrt{\lambda_{11}} & 0 \\ 0 & \sqrt{\lambda_{22}} \end{pmatrix}.$$

For $n = 3$, let x_{ξ_k}, $k = 1, 2, 3$, be the kth column vector of A.

$$R = \left(\frac{x_{\xi_1}}{\sqrt{\lambda_{11}}}, \frac{\lambda_{11} x_{\xi_2} - \lambda_{12} x_{\xi_1}}{\sqrt{\lambda_{11}} \mid x_{\xi_1} \times x_{\xi_2} \mid}, \frac{x_{\xi_1} \times x_{\xi_2}}{\mid x_{\xi_1} \times x_{\xi_2} \mid} \right),$$

$$U = \begin{pmatrix} \sqrt{\lambda_{11}} & \frac{\lambda_{12}}{\sqrt{\lambda_{11}}} & \frac{\lambda_{13}}{\sqrt{\lambda_{11}}} \\ 0 & \frac{|x_{\xi_1} \times x_{\xi_2}|}{\sqrt{\lambda_{11}}} & \frac{\lambda_{11}\lambda_{23}-\lambda_{12}\lambda_{13}}{\sqrt{\lambda_{11}}|x_{\xi_1} \times x_{\xi_2}|} \\ 0 & 0 & \frac{\alpha}{|x_{\xi_1} \times x_{\xi_2}|} \end{pmatrix},$$

$$\mu = \sqrt{\lambda_{11}},$$

$$S = \begin{pmatrix} 1 & \frac{\lambda_{12}}{\lambda_{11}} & \frac{\lambda_{13}}{\lambda_{11}} \\ 0 & \frac{|x_{\xi_1} \times x_{\xi_2}|}{\lambda_{11}} & \frac{\lambda_{11}\lambda_{23}-\lambda_{12}\lambda_{13}}{\lambda_{11}|x_{\xi_1} \times x_{\xi_2}|} \\ 0 & 0 & \frac{\alpha}{\sqrt{\lambda_{11}}|x_{\xi_1} \times x_{\xi_2}|} \end{pmatrix},$$

$$Q = \begin{pmatrix} 1 & \frac{\lambda_{12}}{\sqrt{\lambda_{11}\lambda_{22}}} & \frac{\lambda_{13}}{\sqrt{\lambda_{11}\lambda_{33}}} \\ 0 & \frac{|x_{\xi_1} \times x_{\xi_2}|}{\sqrt{\lambda_{11}\lambda_{22}}} & \frac{\lambda_{11}\lambda_{23}-\lambda_{12}\lambda_{13}}{\sqrt{\lambda_{11}\lambda_{33}}|x_{\xi_1} \times x_{\xi_2}|} \\ 0 & 0 & \frac{\alpha}{\sqrt{\lambda_{33}}|x_{\xi_1} \times x_{\xi_2}|} \end{pmatrix},$$

$$D = \operatorname{diag}\left(1, \frac{\sqrt{\lambda_{22}}}{\sqrt{\lambda_{11}}}, \frac{\sqrt{\lambda_{33}}}{\sqrt{\lambda_{11}}}\right),$$

$$\Delta = \operatorname{diag}(\sqrt{\lambda_{11}}, \sqrt{\lambda_{22}}, \sqrt{\lambda_{33}}). \qquad \square$$

The *orientation matrix R* rotates the first column vector of A to the x-axis (and, for $n = 3$, rotates the second column vector to the x-y plane). The *volume matrix U* contains volume and shape information about the element, but not orientation. The *scale factor* μ is the length of the first column vector in the Jacobian matrix. The *shape matrix S* contains length ratio and skew information. The *length ratio matrix D* gives the ratio of element edge lengths while the *skew* matrix Q contains information about the angles in the element. The matrices *R, S, Q,* and D have units of $(length)^0$ while U, Δ, and μ have units of $(length)^1$.

Orientation, volume, shape, length ratio, and skew are a complete list of the element properties embodied in the Jacobian matrix. Other properties such as curvature or relationships between adjacent elements are not contained in this matrix.

4. Multiple Jacobian matrices. To obtain the Jacobian matrix A_0 of the affine map in the previous section we replaced ξ_0 with $1 - \xi_1 - \xi_2 - \xi_3$. A_0 is thus referenced to the node at x_0. One could just as well refer to any of the four nodes in the tetrahedron, giving four Jacobian matrices per tetrahedral element. Let $k = 0, 1, 2, 3$ and let

$$A_k = (-1)^k \begin{pmatrix} e_{k+1,k} & e_{k+2,k} & e_{k+3,k} \end{pmatrix}$$

be the kth Jacobian matrix, where $e_{k,\ell} = \mathbf{x}_k - \mathbf{x}_\ell$ with $k \neq \ell$ and $\ell = 0, 1, 2, 3$ (note that $e_{\ell,k} = -e_{k,\ell}$). Node k has three attached edge vectors, $e_{k+1,k}$, $e_{k+2,k}$, and $e_{k+3,k}$, where the indices are taken modulo four. The $(-1)^k$ factor ensures that $\alpha_k > 0$ according to the right-hand-rule.

Definitions. Let x_k be the nodes of a simplicial element ε_n. Let the centroid of the element be

$$x_c = \frac{1}{n+1}\sum_k x_k.$$

Element translation. Let $\tilde{x}_k$ be the corresponding nodes of the element translated in space by a vector b. Then $\tilde{x}_k = x_k + b$ and the centroid of the translated element, $\tilde{x}_c$, is $\tilde{x}_c = x_c + b$.

Element scaling. Let $\tilde{x}_k$ be the corresponding nodes of an element uniformly scaled by $\rho > 0$ about the centroid. Then $\tilde{x}_k = x_c + \rho(x_k - x_c)$ and the centroid is $\tilde{x}_c = x_c$.

Element rotation. Let $\tilde{x}_k$ be the corresponding nodes of the element rotated about its centroid. Then, if the rotation is given by $\Theta \in \mathcal{SO}(n)$, $\tilde{x}_k = x_c + \Theta\,(x_k - x_c)$ and the centroid of the rotated element is $\tilde{x}_c = x_c$.

Element scaling and rotation. Let $\tilde{x}_k$ be the corresponding nodes of the scaled and rotated element. Then $\tilde{x}_k = x_c + B(x_k - x_c)$ where $B \in \mathcal{SR}(n)$ and the centroid is preserved.

Proposition 4.1. *The Jacobian matrices A_k transform under element translation, scaling, rotation, or both scaling and rotation as $\tilde{A}_k = A_k$ (translation), $\tilde{A}_k = \rho A_k$ (uniform scaling), $\tilde{A}_k = \Theta A_k$ (rotation), and $\tilde{A}_k = BA_k$ (scaling and rotation).*

Proposition 4.2. *If A_k is given, the nodal coordinates are known relative to one another but not relative to the origin of the coordinate system.*

The fact that A_k is not invariant to k would appear to be a serious obstacle to using the Jacobian matrix as a basis for measuring element quality because metrics based on A_k will vary with k.[2] This difficulty will be addressed in the next section but first we show how the four Jacobian matrices are related.

Let $M \in \mathcal{Z}(n)$ be the following constant matrix

$$M = \begin{pmatrix} 1 & 1 & 1 \\ -1 & 0 & 0 \\ 0 & -1 & 0 \end{pmatrix}.$$

Proposition 4.3. *The set $\mathcal{I}_3, M, M^2, M^3$ is a cyclic group under matrix multiplication.*

Proposition 4.4. *The four Jacobian matrices are related to one another by $A_k = A_0\, M^k$. This can be verified by a direct calculation.*[3]

Proposition 4.5. *The Jacobian determinant α_k is invariant to k.*

Proof. This follows directly from Proposition 4.4 since the determinant of M equals 1. □

The result in Proposition 4.5 is to be expected since the volume of a tetrahedron is one-sixth of the Jacobian determinant [9], and hence α_k cannot depend on k.

[2] The matrices R, U, S, Q, D, and Δ in the factorization of A are also not invariant to k.

[3] For $n = 2$,

$$M = \begin{pmatrix} -1 & -1 \\ 1 & 0 \end{pmatrix}.$$

5. A nodally invariant Jacobian matrix. In this section we exhibit a weighted Jacobian matrix that is nodally invariant.[4] We consider linear transformations between certain simplicial elements. Figure 1 illustrates the situation in two dimensions. Three triangular elements are shown in the figure: the logical triangle, the reference triangle, and the physical triangle. The physical triangle is the triangle defined by an element of the mesh. The reference triangle is the ideal triangle one wants to obtain (for example, an equilateral triangle). The logical triangle is constructed by placing one node at the origin and the other nodes at unit lengths along Cartesian axes. The physical triangle has three Jacobian matrices A_k, defined in the previous section. Similarly, the reference triangle has three Jacobian matrices W_k, computed in the same manner. The logical triangle also has three Jacobian matrices, $\mathcal{I}_n$, M, and M^2, corresponding to $k = 0, 1, 2$. The three triangles can be related via the three matrices W_k, $T_k = A_k W_k^{-1}$, and A_k. The matrix W_k is taken to have the same units as A_k (length); therefore T_k is unitless.

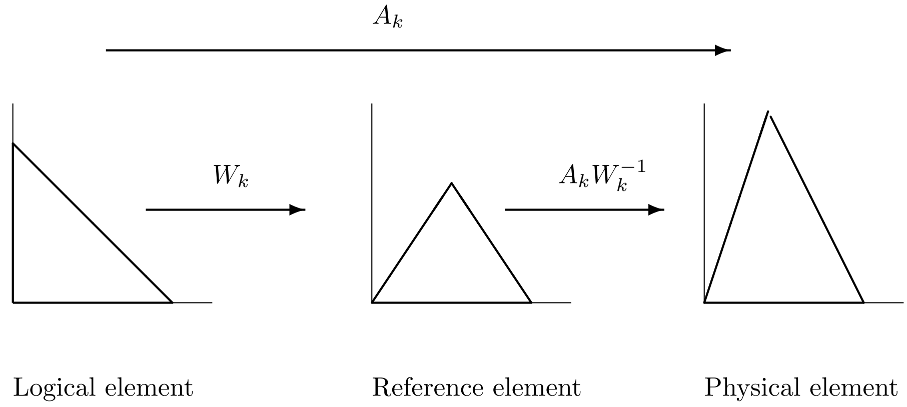

FIG. 1.

PROPOSITION 5.1. *Given any tetrahedron with Jacobian matrices A_k, $k = 0, 1, 2, 3$, let T_k be the linear transformation that takes W_k to A_k. Assume* $\det(W_k) \neq 0$. *Then $T_k = A_0\, W_0^{-1}$, that is, T_k is independent of k.*

Proof. By definition, $T_k W_k = A_k$. Proposition 4.4 applies to the matrices W_k. Thus $W_k = W_0\, M^k$. Since $A_k = A_0\, M^k$, we have the stated result. □

The matrix $T = AW^{-1}$ between the reference and physical elements does not depend on which node one chooses to compute; therefore one may use T (instead of A) to define nodally invariant element quality measures.

A consequence of the nodal invariance of T is that, unlike geometrically based tetrahedral metrics [21], we do not use all the edges of the tetrahedron, but only three (however, we also use three edges of the reference element).

From here on, then, we suppress the subscripts k, with the understanding that A and W must be computed with respect to the same node. This implies a one-to-one correspondence between the nodes of the reference element and the physical element. The matrix W is not only useful for making T nodally invariant but, as will be seen, it permits the construction of *referenced* quality metrics. Because W is derived from

[4] Some of the results of this section were foreshadowed in [19].

an ideal reference element, it is reasonable to assume that $w = \det(W) > 0$.

The following associated derived matrices are useful in a theory of quality metrics: T^t, T^{-1}, T^{-t}, $adj(T)$, T^tT (the metric matrix), $(T^tT)^{-1}$, and TT^tT.

6. Algebraic mesh quality measures. We have shown that, given W, the nodally invariant Jacobian matrix T can be computed using any node of a simplicial element. The Jacobian matrix A was factored into four matrices controlling orientation, volume, skew, and length ratio. We now turn to the question of how to build mesh quality metrics from these matrices. Determinant, trace, and norm are the most useful means to convert matrices to scalar quantities.

DEFINITION. *Let* $\tau = \det(T) = \det(AW^{-1}) = \det(A)\det(W^{-1}) = \alpha/w$.

PROPOSITION 6.1. α *and* τ *are invariant to element rotation because* $\det(\Theta T) = \det(T)$.

Another useful means to convert a matrix to a scalar is the trace function.

DEFINITION.

$$trace(T) = \sum_i T_{ii}.$$

PROPOSITION 6.2. $trace(T)$ *is a linear map from* $\mathcal{M}_n$ *to the real numbers, i.e.,* $trace(\rho T) = \rho\, trace(T)$ *and* $trace(T_1 + T_2) = trace(T_1) + trace(T_2)$.

The matrix inner product $B \cdot C$, defined in terms of the trace, is $trace(B^tC)$. For example, $A^t \cdot W^{-1} = trace(T)$. The inner product leads to the Frobenius matrix norm

$$\mid T \mid^2 = trace(T^tT).$$

The Frobenius norm is the sum of the squares of the matrix elements. The Frobenius norm is preferred for mesh quality metrics because (1) it is less expensive to compute than the p-norms and (2) many well-known mesh quality measures can be written in terms of the Frobenius norm. For some of the results in this paper it is necessary to use the 2-norm, which we will denote by $\mid T \mid_2$. The 2-norm of T is the square-root of the maximum eigenvalue of T^tT.

DEFINITION. *Let* $f \mid B_i \in \mathcal{M}_n, i = 0, \ldots, I \to R$, *be a continuous function from sets of real matrices to the real numbers. Then* f *is an* algebraic mesh quality metric *if* (1) *the matrices* B_i *are constructed from* A_k, W_k, *or factorizations thereof;* (2) *the matrices* B_i *are converted to scalars by means of the matrix norm, determinant, or trace; and* (3) f *is invariant to the element node at which the matrices are computed. The algebraic metric* f *is* referenced *if the domain of* f *is restricted to weighted matrices that make use of* W *or factorizations thereof.*

Let $\mathcal{A}$ be the set of all algebraic mesh quality metrics.

Examples of algebraic metrics are given in Table 2. They are inspired by the sources cited, but these sources did not pose the metrics in terms of the Jacobian matrix, nor were they explicitly referenced.

Algebraic mesh quality metrics are, in general, no more expensive to compute than geometrically based metrics, especially if the Frobenius norm is used.

An advantage of the algebraic metrics is that, using matrix theory and linear algebra, they are in general easier to analyze than are nonalgebraic metrics.

PROPOSITION 6.3. *Assume* $\det(W)$ *and* $\mid W \mid > 0$. *Then* (1) $\tau = 0$ *if and only if* $\alpha = 0$, (2) $\tau > 0$ *if and only if* $\alpha > 0$, (3) $\mid T \mid = 0$ *if and only if* $\mid A \mid = 0$, *and* (4) $\mid T \mid > 0$ *if and only if* $\mid A \mid > 0$.

Let $f(\{B_i\})$ be shorthand for $f(B_1, B_2, \ldots, B_I)$.

Table 2
Examples of algebraic mesh quality metrics.

Algebraic metric	Comments/source
$trace(T)$	
$T \cdot B$	with B some constant matrix
$\mid T \mid^2$	Laplace
$\mid T^t T \mid^2$	Liao [17]
τ^2	Volume [4]
$\mid adj(T) \mid^2$	Jacquotte and Cabello [12]
$\tau \mid T^{-1} \mid^2$	Winslow [2]
$\mid T \mid^2 / \tau$	Tinico-Ruiz and Barrera-Sanchez [1]
$\tau^{-4/3}\{\mid T^t T \mid^2 -(1/3) \mid T \mid^4\}$	Oddy et al. [20]
$\tau^{2/3} \mid T^{-1} \mid^2$	Nondimensional Winslow
$\tau^{-2/3} \mid T \mid^2$	Mean ratio^{-1} [18]
$\mid T \mid \mid T^{-1} \mid$	Condition number [16]

Definition. *f is* scale-invariant *if $f(\{\rho B_i\}) = f(\{B_i\})$ for $\rho > 0$.*

Example. For $n = 3$, $\tau^{-2/3} \mid T \mid^2$ is scale-invariant, while for $n = 2$ it is not.

Let $\Theta \in \mathcal{SO}(n)$. From the definition of the Frobenius norm it is easy to show that $\mid T\Theta \mid = \mid T \mid$ and $\mid \Theta T \mid = \mid T \mid$, i.e., the Frobenius norm is invariant to rotations of the element. Because of this property, many natural algebraic metrics are orientation-free.

Definition. *Let f be an algebraic metric. Then f is* orientation-invariant *if $f(\{\Theta_1 B_i \Theta_2\}) = f(\{B_i\})$ for $\Theta_1, \Theta_2 \in \mathcal{SO}(n)$.*[5]

Examples.

$$f(T) = \mid T \mid,$$
$$f(T) = \det(T).$$

Definition. *f is* scale and orientation-invariant *if $f(\{H_1 B_i H_2\}) = f(\{B_i\})$, where $H_1, H_2 \in \mathcal{SR}(n)$.*

Example. $\kappa(T) = \mid T \mid \mid T^{-1} \mid$.

Definition. *f is* positive *if $f(\{B_i\}) > 0$ for all $B_i \neq \mathcal{O}$.*

Example. $f(T) = \mid T \mid$.

Definition. *f is* even *if $f(\{-B_i\}) = f(\{B_i\})$. f is* odd *if $f(\{-B_i\}) = -f(\{B_i\})$.*

Example. $trace(T)$ is odd, $\mid T \mid$ is even, and $\det(T)$ is odd when n is odd and even when n is even.

Definition. *f is* transpose-invariant *if $f(\{B_i^t\}) = f(\{B_i\})$.*

Example. $f(T) = \mid T \mid$.

Since norm, determinant, and trace are all invariant to matrix transpose, the majority of mesh quality metrics are transpose-invariant. An example of a metric that is not transpose-invariant is $f(T) = \mid T - C \mid$, where C is an arbitrary constant matrix.

Definition. *The* conjugate *metric of $f(\{B_i\})$ is $f^*(\{B_i\}) = f(\{B_i^{-t}\})$. Note that $f^{**} = f$.*

Example. For $n = 3$, $\mu(T) = \tau^{-2/3} \mid T \mid^2$ has conjugate $\mu^*(T) = \tau^{2/3} \mid T^{-1} \mid^2$. Thus the mean ratio metric is conjugate to the modified Winslow metric.

Definition. *f is* self-conjugate *if $f^* = f$.*

[5] f is *left orientation-invariant* if $f(\{\Theta_1 B_i\} = f(\{B_i\})$. Example: $f(T) = \mid T^t T - I \mid$.

Examples.

$$f(T) = \kappa(T) = \mid T \mid \mid T^{-1} \mid,$$
$$f(T) = \tau^{-2/3} \mid T \mid^2 + \tau^{2/3} \mid T^{-1} \mid^2 .$$

7. Singular values. In this section we show that algebraic mesh quality metrics may be expressed in terms of singular values and that this provides a useful tool in analyzing properties of such metrics.

The singular value decomposition of a matrix T says there exists $\Theta, \Phi \in \mathcal{SO}(n)$ such that

$$T = \Theta^t \, D \, \Phi,$$

where $D = \text{diag}(\sigma_1, \sigma_2, \sigma_3) \in \mathcal{D}(n)$. The singular values $\sigma_k(T)$, $k = 1, 2, 3$, are real and positive. They are related to the eigenvalues of T^tT by $\sigma_k(T) = \sqrt{\lambda_k(T^tT)}$. Hence $\mid T \mid_2 = \sqrt{\lambda_{max}} = \sigma_{max}$.

Let $\sigma(T) = (\sigma_1, \sigma_2, \sigma_3)^t \in R^3$ be the vector of singular values of T. Let $\lambda(T^tT) = (\lambda_1, \lambda_2, \lambda_3)^t \in R^3$ be the vector of eigenvalues of T^tT. Then $\sigma(T)$ and $\lambda(T)$ map $T \in \mathcal{M}_n$ to vectors in R^3.

PROPOSITION 7.1. *For $\tau > 0$, $\Psi \in SO(n)$, and $\rho > 0$,*

$$\begin{aligned} \sigma(T^t) &= \sigma(T), \\ \sigma(\Psi T) &= \sigma(T), \\ \sigma(\rho T) &= \rho \, \sigma(T), \\ \sigma_k(T^{-1}) &= 1/\sigma_k(T), \\ \sigma_k(T^tT) &= \sigma_k^2(T). \end{aligned}$$

PROPOSITION 7.2.

$$\begin{aligned} \mid T \mid^2 &= \sum_k \sigma_k^2(T) = \sum_k \lambda_k(T^tT), \\ \tau &= \prod_k \sigma_k(T) = \sqrt{\prod_k \lambda_k(T^tT)}. \end{aligned}$$

Thus $\tau = 0$ if and only if $\sigma_{min} = 0$.

One can express algebraic metrics $f(T)$ as functions of the singular values $\tilde{f}(\sigma(T))$. Note that $\tilde{f}(\sigma)$ maps a vector in R^3 to a scalar. Thus $f = \tilde{f} \circ \sigma$ maps T to a scalar, i.e., it is the composition of the two maps. For example, if $\tilde{f}(\sigma) = \mid \sigma \mid^2$, then $f(T) = \mid T \mid^2$. Some other examples are

$$\begin{aligned} \mid T^tT \mid^2 &= \sum_k \sigma_k^4 = \sum_k \lambda_k^2, \\ \mid T \mid^4 = \mid \sigma \mid^4 &= \left(\sum_k \lambda_k \right)^2, \\ \mid adjT \mid^2 &= \sum_l \prod_{k \neq \ell} \sigma_k^2 = \sum_\ell \prod_{k \neq \ell} \lambda_k, \\ \mid T^{-1} \mid^2 &= \sum_k (1/\sigma_k)^2 = \sum_k 1/\lambda_k. \end{aligned}$$

Given $f(T)$, the corresponding function $\tilde{f}(\sigma)$ always exists because the SVD of T always exists. Thus, algebraic mesh quality metrics may always be expressed in terms of singular values. On the other hand, given some arbitrary function $\tilde{f}$ of σ, there may not correspond an algebraic mesh quality metric $f(T)$. For example, $\tilde{f}(\sigma) = \sum_k \sin \sigma_k$ cannot be derived from a mesh quality metric.

PROPOSITION 7.3. *$f(T) = trace(T)$ gives rise to a linear function $\tilde{f}$ of its singular values of the form $\tilde{f}(\sigma) = t \cdot \sigma$. The vector t has components $t_\ell = \sum_k \Theta_{\ell,k} \Phi_{\ell,k}$.*

DEFINITION. *f is* homogeneous of degree m *if for $\rho > 0$, $f(\{\rho\, B_i\}) = \rho^m\, f(\{B_i\})$. Metrics with no such property are inhomogeneous.*

Examples. $f(T) = \tau$ is homogeneous of degree n. $f(T) = trace(T)$ and $\mid T \mid$ are homogeneous of degree 1. $\mid T \mid^2 + \tau^2$ is inhomogeneous for both $n = 2, 3$.

PROPOSITION 7.4. *Let $f(T)$ be homogeneous of degree m. Then the product $f^* f$ is homogeneous of degree 0, i.e., scale-invariant.*

Example. $f(T) = \mid T \mid^2$ gives $(f^* f)(T) = \kappa^2(T)$.

DEFINITION. *Let $\mathcal{A}_H^m \subset \mathcal{A}$ be the set of all homogeneous algebraic metrics of degree m.*

PROPOSITION 7.5. *Let $f_1 \in \mathcal{A}_H^m$ and $f_2 \in \mathcal{A}_H^\ell$. Then $f_1 f_2 \in \mathcal{A}_H^{m+\ell}$. From this we observe that we can generate metrics having any degree of homogeneity.*

PROPOSITION 7.6. *Let $f_1 \in \mathcal{A}_H^m$ and $f_2 \in \mathcal{A}_H^m$. Then $f_1 + f_2 \in \mathcal{A}_H^m$.*

DEFINITION. *Let $\tilde{\mathcal{A}}$ be the set of functions $\tilde{f}(\sigma)$ derived from the set $\mathcal{A}$ of algebraic mesh quality metrics. Let $\tilde{\mathcal{A}}_H^m \subset \tilde{\mathcal{A}}$ be the set of functions in $\tilde{\mathcal{A}}$ that are homogeneous of degree m.*

PROPOSITION 7.7. *If $f \in \mathcal{A}_H^m$, then $\tilde{f} \in \tilde{\mathcal{A}}_H^m$.*

Proof. If $f(\{\rho B_i\}) = \rho^m\, f(\{B_i\})$, then by definition

$$\tilde{f}(\sigma(\{\rho B_i\})) = \rho^m\, \tilde{f}(\sigma(\{B_i\})).$$

However, Proposition 7.1 then implies

$$\tilde{f}(\rho\sigma) = \rho^m\, \tilde{f}(\sigma). \qquad \square$$

PROPOSITION 7.8. *If f is positive, so is $\tilde{f}$. If f is even/odd, so is $\tilde{f}$. If f is self-conjugate, so is $\tilde{f}$.*

Singular values can be used to prove two important identities which hold for Frobenius norms of 3×3 matrices:[6]

PROPOSITION 7.9.

$$\begin{aligned} \mid T^t T \mid^2 + 2\,\tau^2 \mid T^{-1} \mid^2 \;&\equiv\; \mid T \mid^4, \\ 3 \mid T \mid^2 \mid T^t T \mid^2 - \mid T \mid^6 + 6\,\tau^2 \;&\equiv\; 2 \mid T T^t T \mid^2 . \end{aligned}$$

These identities give the following bounds for $T_{3\times 3}$:

$$\begin{aligned} \mid adj T \mid \;\le\; \mid T^t T \mid \;\le\; \mid T \mid^2, \\ \mid T T^t T \mid^2 - \frac{1}{2} \mid T \mid^6 \;\le\; 3\tau^2 \;\le\; \mid T T^t T \mid^2 + \frac{1}{2} \mid T \mid^6 . \end{aligned}$$

[6] The corresponding identities for $T_{2\times 2}$ are

$$\begin{aligned} &\mid T \mid^2 \equiv \frac{1}{2} \mid T - T^t \mid^2 + trace(T^2), \\ &\mid T \mid^4 \equiv \mid T^t T \mid^2 + 2\tau^2. \end{aligned}$$

One can also relate $\kappa(T^tT)$ to $\kappa(T)$ using singular values:

$$\kappa^2(T^tT) \equiv \kappa^4(T) + 4\kappa^2(T) - 2(\tau^{-2} \mid T \mid^6 + \tau^2 \mid T^{-1} \mid^6).$$

Singular values have an important application in analyzing the equivalence of certain quality metrics.

8. Shape measures and equivalences. Tetrahedral *shape measures* for detecting distorted elements abound in the literature [6]. The list of measures includes such well-known quantities as the radius ratio [9], mean ratio [18], solid angle, and several aspect ratios [21].

A tetrahedral *shape measure* is formally defined in [6] as

> "... a continuous function that evaluates the quality of a tetrahedron. It must be invariant under translation, rotation, reflection, and uniform scaling of the tetrahedron. It must be maximum for the regular tetrahedron and it must be minimum for a degenerate tetrahedron. There is no local maximum other than the global maximum for a regular tetrahedron and there is no local minimum other than the global minimum for a degenerate tetrahedron. For the ease of comparison, it should be scaled to the interval [0,1], and be 1 for the regular tetrahedron and 0 for a degenerate tetrahedron."

This definition was used to show that mean ratio and radius ratio are shape measures while minimum dihedral angle and edge ratio are not [6].

Shape measures are clearly mesh quality metrics but, in general, they are not *algebraic* mesh quality metrics. One exception is the mean ratio shape measure η, whose definition is given in [18]:

$$\eta(T) = \frac{3\tau^{2/3}}{\mid T \mid^2}.$$

DEFINITION. *Let a, b, c be elements in a set. Recall that an equivalence relation $\sim$ on this set holds if*

- *$a \sim a$ for any a,*
- *$a \sim b$ if $b \sim a$,*
- *$a \sim b$ and $b \sim c$ implies $a \sim c$.*

DEFINITION (see Liu and Joe [18]). *Let M_1 and M_2 be tetrahedral shape measures. Then $M_1 \sim M_2$ if there exist constants $0 < c_1 \leq c_2$ and $0 < p \leq q$ such that*

$$c_1 M_1^p \leq M_2 \leq c_2 M_1^q.$$

The equivalence is strong *if $p = q$. We use the notation $M_1 \simeq M_2$ for strong equivalence.*

Informally, equivalent shape metrics sense the same shape distortions, grow large together, and grow small together. The original motivation for introducing the idea of equivalences was to reduce the list of shape measures to some manageable number. For example, the shape measures radius ratio, mean ratio, and sine of solid angle are equivalent [18].

DEFINITION. *The definition of shape measure equivalence can be generalized to include all positive algebraic mesh quality measures. The definition for the latter is the same as the former, except the phrase "tetrahedral shape measures" is replaced by "positive algebraic mesh quality measures."*

Proposition 8.1. *$\mid T\mid^2 \simeq \mid T^tT \mid$ and neither is a shape measure.*

Proof. From a well-known equivalence that can be found in [10],

$$\mid T \mid_2 \quad \leq \quad \mid T \mid \leq \sqrt{n} \ \mid T \mid_2,$$

we have

$$\mid T^tT \mid_2 \quad \leq \quad \mid T^tT \mid \leq \sqrt{n} \ \mid T^tT \mid_2,$$

that is,

$$\sigma^2_{max}(T) \leq \mid T^tT \mid \leq \sqrt{n}\, \sigma^2_{max}(T).$$

From Proposition 7.2 one can show

$$\sigma^2_{max}(T) \leq \mid T \mid^2 \leq n\, \sigma^2_{max}(T);$$

thus,

$$\frac{1}{n} \mid T \mid^2 \leq \mid T^tT \mid \leq \sqrt{n} \ \mid T \mid^2 . \qquad \square$$

Proposition 8.2. *Let $\nu > 0$ be given and M be an algebraic mesh quality measure. Then $M^\nu \simeq M$. Strong equivalence thus does not force homogeneous metrics to have the same degree of homogeneity.*

Proposition 8.3. *Let $\nu > 0$. Then $M_1 \sim M_2$ if and only if $M_1^\mu \sim M_2$.*

The statement that *if two metrics are equivalent, then it does not matter which one is used* is an exaggeration. For example,

$$\kappa(A)/\kappa(W) \leq \kappa(T) \leq \kappa(A)\,\kappa(W)$$

shows the strong equivalence of $\kappa(A)$ and $\kappa(T)$, yet the weight matrix W is a critical factor in assessing the quality of an element.

Metrics with the same degree of homogeneity need not be equivalent. For example, for $n = 3$, τ^2 and $\mid T \mid^6$ are homogeneous of degree 6 but are not equivalent.

Proposition 8.4. *$f_1 \sim f_2$ if and only if $\tilde{f_1} \sim \tilde{f_2}$.*

Proposition 8.5. *Using singular values, $\kappa^2(T) \simeq \kappa(T^tT)$, since*

$$\frac{1}{3}\,\kappa^2(T) \leq \kappa(T^tT) \leq \kappa^2(T).$$

Proposition 8.6. *Let $\kappa_2(T) = \mid T \mid_2 \mid T^{-1} \mid_2$. Then $\kappa \sim \kappa_2$.*

Proof. Using the first line of the proof of Proposition 8.1, one can readily show that

$$\kappa_2 \leq \kappa \leq n\kappa_2. \qquad \square$$

Proposition 8.7. *For $n = 3$, let $\mu(T) = \tau^{-2/3} \ \mid T \mid^2$ with conjugate $\mu^*(T) = \tau^{2/3} \mid T^{-1} \mid^2$. Then $\mu \sim \mu^* \sim \kappa$.*

Proof. Let $0 < \lambda_1 \leq \lambda_2 \leq \lambda_3$ be the eigenvalues of T^tT.

Part A. *$\mu \sim \kappa$.*

$$\mu = \frac{1 + \lambda_2/\lambda_1 + \lambda_3/\lambda_1}{[(\lambda_2/\lambda_1)(\lambda_3/\lambda_1)]^{1/3}}.$$

Therefore,

$$\begin{gathered}(\lambda_3/\lambda_1)^{1/3} \le \mu \le 3\,(\lambda_3/\lambda_1)^{2/3},\\ \kappa_2^{1/3} \le \mu \le 3\,\kappa_2^{2/3},\\ (\kappa/3)^{1/3} \le \mu \le 3^{5/3}\,(\kappa/3)^{2/3}.\end{gathered}$$

Part B. $\mu^* \sim \kappa$.

$$\mu^* = [(\lambda_2/\lambda_3)(\lambda_1/\lambda_3)]^{1/3}(1 + \lambda_3/\lambda_2 + \lambda_3/\lambda_1).$$

Therefore,

$$\begin{gathered}(\lambda_3/\lambda_1)^{1/3} \le \mu^* \le 3\,\lambda_3/\lambda_1,\\ \kappa_2^{2/3} \le \mu^* \le 3\,\kappa_2^2,\\ (\kappa/3)^{2/3} \le \mu^* \le 27\,(\kappa/3)^2.\end{gathered}$$

Then by the definition of equivalences, $\mu \sim \mu^*$. □

For $n = 2$, the corresponding scale-invariant metric is $\mu = \mid T \mid^2 / \tau$. In this case it is easy to show that $\mu = \mu^* = \kappa$.

We began this section by giving the definition of a tetrahedral shape measure. The definition is vague on the definition of a degenerate element. In the next section we fix this and define *algebraic shape metrics.*

9. Algebraic shape metrics and the condition number. We formalize the definition of a degenerate element by first defining a degenerate matrix.

DEFINITION. *Let $B \in \mathcal{M}_n^+ \cup \partial\mathcal{M}_n^+$. Then B is* degenerate *if B is singular but nonzero (i.e., $\mid B \mid > 0$ with* $\det(B) = 0$*). B is nondegenerate if* $\det B > 0$*, i.e., $B \in \mathcal{M}_n^+$. Let $\mathcal{DG}(n)$ be the set of degenerate $n \times n$ matrices. The set of singular matrices ∂M_n^+ then consists of $\mathcal{DG}(n)$ plus the zero matrix.*

DEFINITION. *A simplicial element ε_n is degenerate if and only if the matrices A_k, $k = 0, 1, \ldots, K-1$, are degenerate. Sliver elements are "near-degenerate" elements.*

PROPOSITION 9.1. *ε_n is degenerate if and only if the matrix T is degenerate.*

Proof. If ε_n is degenerate, then A_k is degenerate for all k. Since $T = A_k W_k^{-1}$, $\tau = \det(T) = \alpha_k/w_k = 0$. Hence T is singular. Suppose $T = \mathcal{O}$. Then $\mathcal{O} = A_k W_k^{-1}$, which gives $A_k = \mathcal{O}$ and $\mid A_k \mid = 0$. But since A_k is degenerate, its norm must be strictly positive. To avoid this contradiction we must have $\mid T \mid > 0$, i.e., T is degenerate. The proof in the other direction is similar. □

As a reminder, we assume here and in subsequent sections that $\alpha \ge 0$, $0 < \mid A \mid < \infty$ and that W is nondegenerate.

We return to the factorization of the Jacobian matrix discussed in section 3. As observed, the Jacobian matrix contains the following information: skew (Q), length ratio (D), shape (S), volume (U), and orientation (R). It should therefore be possible to define algebraic mesh quality metrics for each of these geometric quantities. In this section we will consider algebraic *shape* metrics. Let

$$\begin{aligned} A &= \mu R S,\\ W &= \mu_W R_W S_W. \end{aligned}$$

The shape of A will equal the shape of W if $S = S_W$. The shape of an element is a measure of element skew and aspect ratio, relative to the reference shape. We adapt the Dompierre definition of shape measures to the algebraic setting.[7]

Definition. *Let f be an algebraic mesh quality metric. Then f is an* algebraic shape metric *if*

- *the domain of f is restricted to the matrix T,*
- *f is scale and orientation invariant,*
- *$0 \leq f(T) \leq 1$ for all T,*
- *$f(T) = 1$ if and only if $T \in \mathcal{SR}(n)$,*[8]
- *$f(T) = 0$ if and only if T is degenerate.*

Proposition 9.2. *Algebraic shape metrics are invariant to uniform scalings and rotations of the physical element.*

Proof. Uniform scalings and rotations of an element mean that $A_k \to BA_k$, where $B \in \mathcal{SR}(n)$. Then $T = A_k W_k^{-1} \to BT$. But by definition, $f(BT) = f(T)$. □

Proposition 9.3. *$f(T) = n/\kappa(T)$ is an algebraic shape metric.*

Proof. The first criterion is immediate. Second, because T is nodally invariant, f is invariant to the node at which it is computed. Observe that

$$\kappa^2(T) = \sum_i \sum_j \frac{\lambda_i}{\lambda_j}$$

with λ_i the eigenvalues of T^tT. Setting $\partial\kappa/\partial\lambda_i = 0$ to find the extremum, one finds that $n \leq \kappa < \infty$; hence $0 \leq f \leq 1$. If $f = 1$, then $\kappa = n$, i.e., $\lambda_i = \lambda_j$ for all i, j. Therefore, by the singular value decomposition, $T = \lambda_i \Theta$, i.e., $T \in \mathcal{SR}(n)$. If $T \in \mathcal{SR}(n)$, then $\kappa = n$, so $f = 1$. This proves f meets the third and fourth requirements. Fifth, if T is degenerate, then $\lambda_1 = 0$ and so $\kappa \to \infty$ and $f = 0$. Finally, if $f = 0$, then $\kappa \to \infty$, and so $\lambda_1 = 0$ and $\lambda_3 > 0$, so T is degenerate. □

Similarly, one can prove $3/\mu(T)$ and $3/\mu^*(T)$ are algebraic shape metrics.[9]

The distinguishing property of the condition number is given in the following well-known result stated in Proposition 9.4 (see [5, pp. 33–34] for proof).

Proposition 9.4. *Let X and Y be 3×3 matrices with X nonsingular and $X + Y$ singular. Let*

$$d \equiv \min \{ \mid Y \mid_2 / \mid X \mid_2 \colon X + Y \mathit{singular} \}$$

be the distance between X and the set of singular matrices. The distance between X and the set of singular matrices is $1/\kappa_2(X)$.

Proposition 9.5. *$f = 3/\kappa$ is an equivalent measure of the minimum distance to the set of singular matrices.*

Proof. From Proposition 8.6, $\kappa_2 \sim \kappa$, i.e.,

$$\kappa_2 \leq \kappa \leq 3\,\kappa_2,$$

we have

$$\frac{f}{3} \leq d \leq f,$$

[7] In our definition we do not say anything about the metric lacking local minimae or maximae. The property is related to the convexity of f with respect to T. This condition, while highly desirable, is probably too restrictive in most cases, i.e., if added to the definitions, there will be no function that can satisfy all of the requirements. Numerical results in section 13 show that the metrics we suggest do not possess local extremae with respect to some parameters, but perhaps not all.

[8] This requirement forces $S = S_W$ when $f = 1$.

[9] Note that for $n = 3$ the Winslow metric $\tau \mid T^{-1} \mid^2$ is not a shape metric because it is not scale-invariant. From the definition in section 12, it is not a shape-volume metric either. This may explain why three-dimensional Winslow smoothing of structured grids has had only limited success.

i.e., f goes to zero if and only if d goes to zero. □

COROLLARY. *Since $\mathcal{DG}$ is a subset of the singular matrices, f also measures the distance to degenerate matrices and thus the distance to degenerate elements.*

10. Algebraic metrics for skew and length ratio. The algebraic shape metrics, as defined in the previous section, are invariant to the node at which they are computed. Unfortunately, the elegant way in which this is achieved by using the matrix T cannot be done for properties such as skew and length ratio. To create nodally invariant skew metrics, we can define functions that use matrices at all of the nodes.[10]

DEFINITION. *Let f be an algebraic mesh quality metric. Then f is an* algebraic skew metric *if*

- *the domain of f consists of the matrices $X_k = Q_k Q_{W_k}^{-1}$, $k = 0, 1, \ldots, K-1$, in the decompositions of A_k and W_k,*
- *$0 \le f(\{X_k\}) \le 1$ for all matrices X_k,*
- *$f(\{X_k\}) = 1$ if and only if $X_k = \mathcal{I}_n$ for all k,*
- *$f(\{X_k\}) = 0$ if and only if X_k is degenerate for at least one k.*

PROPOSITION 10.1. *Algebraic skew metrics are invariant to uniform scalings and rotations of the physical element.*

Proof. Under such an element transformation, $A_k \to BA_k$, where $B \in \mathcal{SR}(n)$. Then $Q_k = skew A_k \to skew BA_k = Q_k$. Thus X_k is unchanged under element scaling and rotation. □

PROPOSITION 10.2. *If $X_k = Q_k Q_{W_k}^{-1}$, then $f = \prod_k \frac{n}{\kappa(X_k)}$ is an algebraic skew metric.*

Proof. By construction, f is nodally invariant because it uses all nodes, so f is an algebraic metric. The remainder of the proof relies on the facts about n/κ noted in Proposition 9.3. If $f = 1$, then for all k, $X_k \in \mathcal{SR}(n)$, i.e., Q_k can differ from Q_{W_k} only by a rotation and scaling. But since these two matrics are both skew matrices, we must have $Q_k = Q_{W_k}$, hence $X_k = \mathcal{I}_n$. If $f = 0$, then $\det(X_k) = 0$ for some k. Furthermore, $\sqrt{n} \mid X_k \mid = \mid X_k \mid\mid Q_{W_k} \mid \ge \mid X_k Q_{W_k} \mid = \mid Q_k \mid = \sqrt{n} > 0$. Hence $\mid X_k \mid = 1$ and X_k is degenerate. □

PROPOSITION 10.3. $f = \min_k\{\frac{n}{\kappa(X_k)}\}$ *is an algebraic skew metric.*

DEFINITION. *Let f be an algebraic mesh quality metric. Then f is an* algebraic length ratio metric *if*

- *the domain of f consists of the matrices $X_k = D_k D_{W_k}^{-1}$, $k = 0, 1, \ldots, K-1$, in the decompositions of A_k and W_k,*
- *$0 \le f(\{X_k\}) \le 1$ for all X_k,*
- *$f(\{X_k\}) = 1$ if and only if $X_k = \mathcal{I}_n$ for all k,*
- *$f(\{X_k\}) = 0$ if and only if X_k is degenerate for at least one node.*

PROPOSITION 10.4. *Algebraic length ratio metrics are invariant to scalings and rotations of the element.*

PROPOSITION 10.5. *By this definition, $f = \prod_k n/\kappa(X_k)$ and $f = \min_k n/\kappa(X_k)$ are algebraic length ratio metrics.*

Proof. The proof is similar to that of Proposition 10.2. □

11. Algebraic metrics for volume and orientation. Roughly speaking, the orientation of an element is a measure of its orientation in space relative to the orientation of a reference element. Orientation is defined in terms of the matrix R in Proposition 3.1.

[10] Shape metrics can also be defined in this way, using $X_k = S_k S_{W_k}^{-1}$. Then if f is orientation-invariant, $f(\{X_k\}) = f(\{\mu R X_k R_W^{-1} \mu_W^{-1}\}) = f(\{A_k W_k^{-1}\}) = f(T)$.

For the definition of an orientation metric, let three diagonal matrices $\Psi^\ell \in \mathcal{SO}(3)$, $\ell = 1, 2, 3$, be defined as follows:

$$\Psi^\ell_{ij} = \begin{cases} 1, & i = j = \ell, \\ -1, & i = j \neq \ell, \\ 0, & i \neq j. \end{cases}$$

Definition. *Let f be an algebraic mesh quality metric. Then f is an* algebraic orientation metric *if*

- *the domain of f is restricted to matrix $X_0 = R_0 R_{W_0}^{-1}$,*
- *$0 \leq f(X_0) \leq 1$ for all X_0,*
- *$f(X_0) = 1$ if and only if $X_0 = \mathcal{I}_n$,*
- *$f(X_0) = 0$ if and only if $X_0 = -\mathcal{I}_n$ when $n = 2$, and $X_0 = \Psi^\ell$ for some ℓ when $n = 3$.*

The matrix R_0 is the orientation matrix in the factorization of A_0. It is assumed that $\det(R_0) = 1$ so that inverted elements are not considered. Algebraic orientation metrics are nodally invariant because the nodes on which they depend are specified (i.e., $k = 0$). However, they critically depend on the node-numbering scheme of the element (i.e., which node is numbered zero).

Proposition 11.1. *Algebraic orientation metrics are invariant to uniform scalings of the physical element.*

Proof. The proof is immediate since uniform scaling does not affect R_0 and thus X_0. □

Proposition 11.2. *$f(X_0) = 1 + (trace(X_0) - n)/4$ is an algebraic orientation metric. So is $f(X_0) = 1 - \frac{1}{8} \mid X_0 - \mathcal{I}_n \mid^2$.*

Proof. Consider the first statement. Since $X_0 \in \mathcal{SO}(n)$, $\mid X_{ii} \mid \leq 1$. Then we must have $n - 4 \leq trace(X_0) \leq n$, which gives $0 \leq f(X_0) \leq 1$. Suppose $f(X_0) = 1$. Then $traceX_0 = n$, which forces $X_0 = \mathcal{I}_n$. Suppose $traceX_0 = 0$. Then $traceX_0 = n - 4$, which, for $n = 2$, forces $X_0 = -\mathcal{I}_2$ and, for $n = 3$, forces $X_0 = \Psi^\ell$. The proof of the second statement is similar. □

The volume of an element depends both on edge lengths and element skew. A referenced volume metric is defined below.

Definition. *Let f be an algebraic mesh quality metric. Then f is an* algebraic volume metric *if*

- *the domain of f is restricted to the matrix T,*
- *f is orientation-invariant,*
- *f is homogeneous of degree n,*
- *$0 \leq f(T) < \infty$ for all T,*
- *$f(T) = 1$ if and only if $T \in Z(n)$,*
- *$f(T) = 0$ if and only if T is degenerate.*

A value of f greater (less) than one means the physical element has volume greater (less) than the volume of the reference element. Since element volume is unbounded, the upper limit of f is unbounded.

Proposition 11.3. *$f(T) = \det(T)$ is an algebraic mesh volume metric.*

If $f(T) = 1$, then $A_k = HW_k$, where $H \in \mathcal{Z}(n)$. Therefore the volume of the element is the same as the reference element, but the shape may differ.

12. Combination metrics. Combinations of the various metrics are often more useful than single metrics. Below we define algebraic volume-shape metrics.

Definition. *Let f be an algebraic mesh quality metric. Then f is an* algebraic volume-shape metric *if*

- *the domain of f is restricted to the matrix T,*
- *f is orientation-invariant,*
- $0 \leq f(T) \leq 1$ *for all T,*
- $f(T) = 1$ *if and only if $T \in \mathcal{SO}(n)$,*
- $f(T) = 0$ *if and only if T is degenerate or* $\det(T) \to \infty$.

Proposition 12.1. *Algebraic volume-shape metrics are invariant to rotations of the physical element.*

If the requirement that f be homogeneous of degree n is included in the definition of a volume-shape metric, we cannot find specific examples. For example, adding the homogeneity requirement in one attempt resulted in a discontinuous function, which is not allowed under the definition of an algebraic metric.

Proposition 12.2. *Define*

$$f(T) = \min(\tau, 1/\tau)\, n/\kappa(T).$$

Then $f(T)$ is an algebraic volume-shape metric.

Proof. f is continuous because $\lim_{\tau \to 1} f$ is the same whether one approaches from above or below. Suppose $\tau \leq 1$. Since $\det(T) \leq 1$ and $\det(T) n/\kappa(T) \leq 1$ for any T, $f(T) = 1$ forces $\det(T) = 1$ and $n/\kappa(T) = 1$. Thus $T \in \mathcal{Z}_n \cap \mathcal{SR}(n) = \mathcal{SO}(n)$. Similarly, if $\det(T) > 1$, $T \in \mathcal{SO}(n)$. If $f = 0$, then either $\tau = 0$, $\tau \to \infty$, or $n/\kappa(T) = 0$. Since $\mid T \mid > 0$, T is degenerate or $\tau \to \infty$. $\square$

f in the previous proposition is homogeneous of degree n when $\tau < 1$ and homogeneous of degree $-n$ when $\tau > 1$.

It is possible in a similar manner to define and give examples of combined shape-orientation and volume-orientation metrics. However, we skip forward to the following volume-shape orientation metric which is potentially useful in adaptive meshing schemes because it simultaneously measures element size, skew, aspect ratio, and degree of alignment (say, with a flow-field).

Definition. *Let f be an algebraic mesh quality metric. Then f is an* algebraic volume-shape orientation metric *if*

- *the domain of f is restricted to the matrices T and $X_0 = R_0 R_{W_0}^{-1}$,*
- $0 \leq f(T, X_0) \leq 1$ *for all T and X_0,*
- $f(T, X_0) = 1$ *if and only if $T = \mathcal{I}_n = X_0$,*
- $f(T) = 0$ *if and only if T is degenerate or $X_0 = -\mathcal{I}_n$ for $n = 2$ and $X_0 = \Psi^\ell$ for $\ell = 1, 2,$ or 3.*

Proposition 12.3. *Let $g(T) = n/\kappa(T)$, $h(X_0) = 1 + \frac{1}{4}(trace(X_0) - n)$, and*

$$f(T, X_0) = \min(\tau, 1/\tau)\, g(T)\, h(X_0).$$

Then $f(T, X_0)$ is an algebraic volume-shape orientation metric.

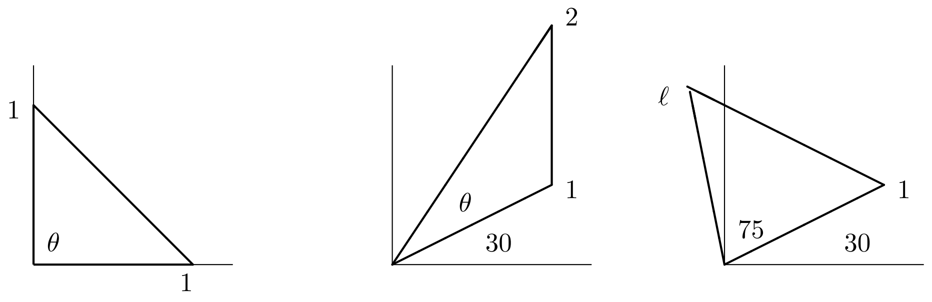
Proof. Suppose $\tau \leq 1$. Since $\det(T) \leq 1$, $n/\kappa(T) \leq 1$, and $h(X_0) \leq 1$ for any T, $f(T) = 1$ forces $\det(T) = 1$, $n/\kappa(T) = 1$, and $h(X_0) = 1$. Thus $T \in \mathcal{Z}_n \cap \mathcal{SR}(n) \cap \mathcal{I}_n = \mathcal{I}_n$. Similarly, if $\det(T) > 1$, $T = \mathcal{I}_n$. If $f = 0$, then either $\det(T) = 0$, $n/\kappa(T) = 0$, or $h(X_0) = 0$. Since $\mid T \mid > 0$, T is degenerate and $X_0 = \mathcal{I}_n$ for $n = 2$ and $X_0 = \Psi^\ell$ for $\ell = 1, 2,$ or 3. $\square$

Table 3 summarizes the metrics described so far (SC stands for scale, O for orientation, SK for skew, and AR for aspect ratio).

13. Numerical examples. We have given general definitions of algebraic metrics for simplicial elements including shape, skew, length ratio, volume, orientation, and combinations thereof. Using the specific examples given in sections 9, 10, 11,

Table 3
Summary of algebraic metrics for simplicial elements.

Metric	Invariants	Noninvariants	Example
Shape	SC, O	SK, AR	$n/\kappa(T)$
Skew	SC, O, AR	SK	$\prod_k n/\kappa(Q_k Q_{W_k}^{-1})$
Length-ratio	SC, O, SK	AR	$\prod_k n/\kappa(D_k D_{W_k}^{-1})$
Orientation	SC, SK, AR	O	$1 + (trace(X_0) - n)/4$
Volume	O, SK, AR	SC	$\det(T)$
Relative size	O, SK, AR	relative SC	$\min(\tau, 1/\tau)$
Volume-shape	O	SK, AR, relative SC	$\min(\tau, 1/\tau) n/\kappa(T)$
Volume-shape orientation	none	all	$\min(\tau, 1/\tau) n/\kappa(T)[1 + (trace(X_0) - n)/4]$



Test one Test two Test three

Fig. 2. *Triangle geometry for three test cases.*

and 12, we illustrate the behavior of these metrics with several test cases shown in Figure 2.

In the first test (see Figure 3) the metrics are plotted vs. the included angle of a triangular physical element with sides of unit length emanating from the origin. The first side lies on the x-axis, while the second side is oriented by a variable included angle. The reference triangle is the unit equilateral triangle with base on the x-axis. Figure 3 shows that all the metrics except volume vary between zero and unity, as desired. Shape and length ratio peak when the included angle matches the 60 degree angle of the reference triangle. The skew curve is not plotted, because it is nearly identical to the shape plot (because the relative lengths of sides of the physical triangle are the same as the reference triangle). The volume metric (p1-size) peaks at 1.15 when the included angle is 90 degrees, i.e., the area of the physical triangle is 1.15 times the area of the reference triangle. The orientation of the physical triangle was varied by an angle from the x-axis. The results for the orientation metric in Figure 3 show a cosine curve, which agrees with theory. The combined shape and volume metric (p1-ss) is similar to the shape metric, but less smooth and with lower values.

In the second test (Figure 4), the same physical triangle was used except that the length of the second side was increased to 2, the base of the triangle made an angle of 30 degrees with the x-axis, and the reference triangle was an isosceles triangle

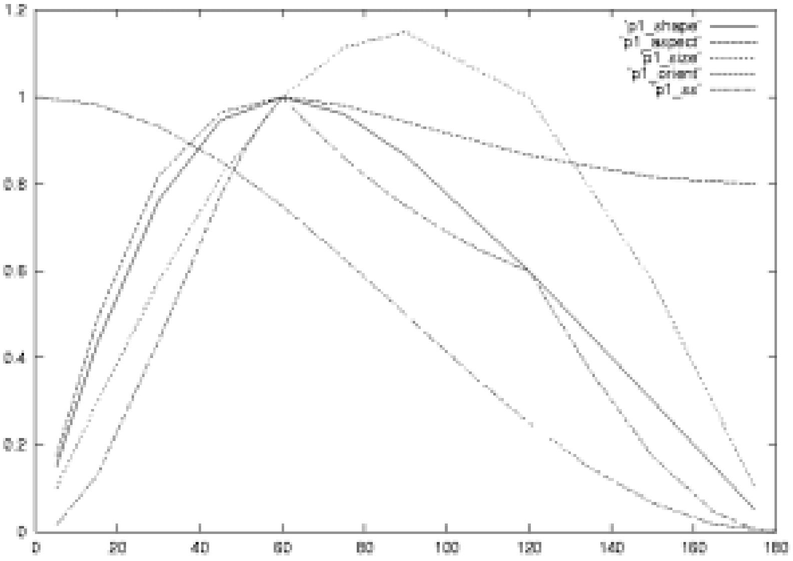


FIG. 3. *Unit equilateral reference triangle, included angle varied.*

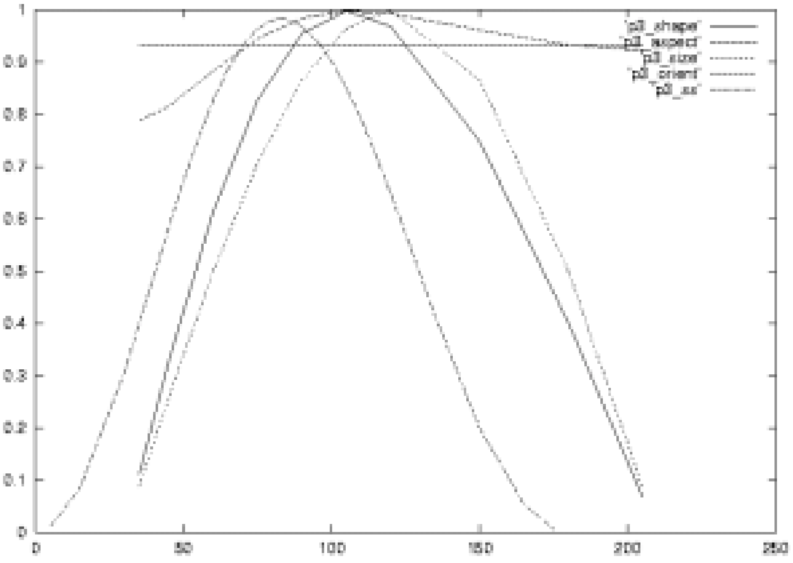

FIG. 4. *Isosceles reference triangle, included angle varied*

(perhaps describing some desired anisotropy in the mesh), with base 1 and height 2. As the included angle was varied from 0 to 180 degrees, the angle shown in the plots varied from 30 to 210 degrees. The metrics ranged between zero and unity, peaking around 105 degrees for shape and 120 degrees for volume. The skew curve again

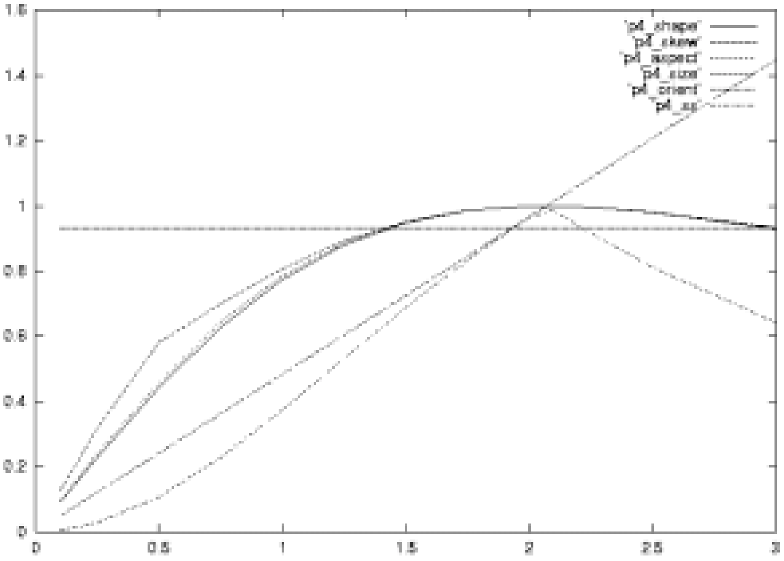

FIG. 5. *Isosceles reference triangle, second side length varied.*

overlaid the shape curve.

In the third test (Figure 5), the physical triangle had a unit length base which made an angle of 30 degrees with the x-axis. The included angle between the first and second sides was 75 degrees. The length of the second side was varied from 0 to 3. The reference triangle was the same as in the second test. The shape and skew curves differed from each other somewhat because of the differences in lengths between the physical and reference triangles. In general, however, shape, skew, and length ratio followed the same trend as one another, peaking when the second length matched the reference triangle. Volume varied linearly with the variation in the length of the second side, as expected.

In our opinion, shape, volume, and combined shape-volume are the most valuable of the metrics. Skew varies nearly the same as shape while length ratio is misleading because it is not the ratio of element width to breadth but rather the ratio of the lengths of consecutive sides. Orientation may be of use provided element nodes can be numbered in a consistent manner.

14. Nonsimplicial element metrics. Nonsimplicial elements such as quadrilaterals, hexahedra, and wedges fail to obey Propositions 4.4, 4.5, and 5.1.[11] There is no single nodally invariant matrix T which can represent all the geometric properties of nonsimplicial elements. To build algebraic quality metrics for such elements we can resort to the technique used in section 10, in which multiple matrices are used in the definition of the metric. Nonsimplicial elements for which Jacobian matrices A_k can be defined may be treated as follows. Choose a reference element and compute the reference weight matrices W_k. Let $T_k = A_k W_k^{-1}$, $k = 0, 1, \ldots, K-1$, be the

[11] Pyramids and other three-dimensional elements having more than three edges meeting in a node are still more problematic since the Jacobian matrix fails to exist.

weighted matrix, where K is the number of nodes in the element. The matrices are factored as $A_k = R_k U_k = R_k Q_k \Delta_k$ and similarly for W_k. Basic assumptions are that $\alpha_k = \det(A_k) \geq 0$, $0 < \mid A_k \mid < \infty$, and that W_k is nondegenerate for all k. The W_k should be self-consistent, i.e., computed from an element that exists.

Shape and volume metrics are defined for nonsimplicial elements, with the others left to the reader.

Definition. *Let f be an algebraic mesh quality metric. Then f is a* nonsimplicial algebraic shape metric *if*

- *the domain of f is the complete set of matrices $T_k = A_k W_k^{-1}$, $k = 0, 1, \ldots, K-1$,*
- *f is scale- and orientation-invariant,*
- *$0 \leq f(\{T_k\}) \leq 1$ for all T_k,*
- *$f(\{T_k\}) = 1$ if and only if $T_k \in \mathcal{SR}(n)$ for all k,*
- *$f(\{T_k\}) = 0$ if and only if T_k is degenerate for some k.*

Proposition 14.1. *$f(\{T_k\}) = \min_k\{n/\kappa(T_k)\}$ is an algebraic shape metric for nonsimplicial elements. So is $K/\sum_k(\kappa(T_k)/3)^2$.*

If the definition of a volume metric given for simplicial elements in section 11 is directly extended to nonsimplicial elements, the metric

$$f(\{T_k\}) = \min_k\{\det(T_k)\}$$

fails to satisfy the requirements because $f = 1$ does not force $T_k \in \mathcal{Z}(n)$ for all k. Other attempts to fix this also fail. We thus redefine algebraic volume metrics as follows.

Definition. *Let f be an algebraic mesh quality metric. Then f is an* algebraic volume metric *if*

- *the domain of f is restricted to the matrices T_k, $k = 0, 1, 2, \ldots, K-1$,*
- *f is orientation-invariant,*
- *$0 \leq f(\{T_k\}) \leq 1$ for all T_k,*
- *$f(\{T_k\}) = 1$ if and only if $T_k \in Z(n)$ for all k,*
- *$f(\{T_k\}) = 0$ if and only if T_k is degenerate for all k (or if $\det(T_k) \to \infty$ for all k).*

Proposition 14.2. *$f(\{T_k\}) = (1/K)\sum_k \min(\tau_k, 1/\tau_k)$ is an algebraic volume metric for nonsimplicial elements.*

For simplicial elements, if the value of the volume metric is say, 1/2, then either the physical element has half or twice the volume of the reference element.

The definition of volume-shape metrics given in section 12 readily extends to the nonsimplicial case.

Proposition 14.3. *$f(\{T_k\}) = (1/K)\sum_k \min(\tau_k, 1/\tau_k)\,\min_k\{n/\kappa(T_k)\}$ is an algebraic volume-shape metric for nonsimplicial elements.*

Figure 6 shows how such metrics vary for a quadrilateral element referenced to a unit square. The quadrilateral is a symmetric trapezoid, with a unit length base oriented in agreement with the reference element. The angle of the two vertical sides with respect to the base side was varied from 60 to 165 degrees.

15. Summary and conclusions. A theory of algebraic mesh quality metrics was proposed based on element Jacobian matrices. Jacobian matrices can be decomposed into geometrically meaningful factors representing element volume, orientation, and shape. The factor matrices are node-dependent and thus cannot be used to construct algebraic mesh quality measures unless all are used in a symmetric way.

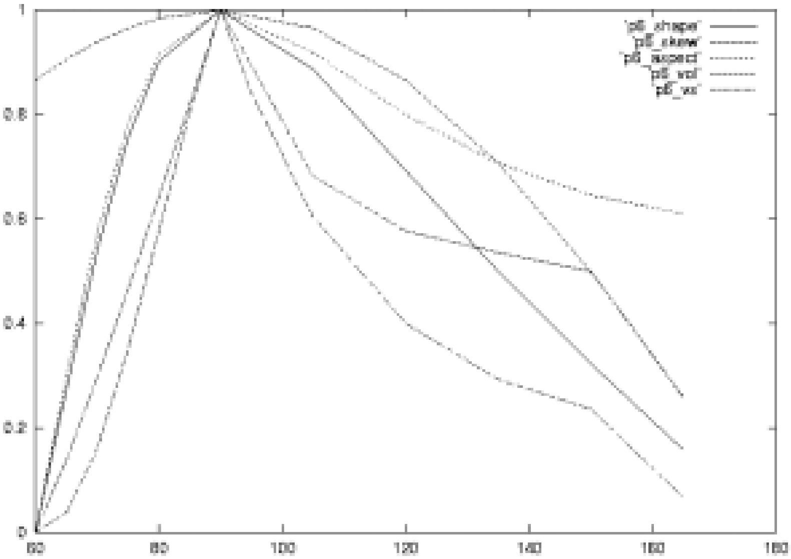

FIG. 6. *Square reference quadrilateral, trapezoid physical element.*

However, for simplicial elements one can define a single nodally invariant matrix T using the Jacobian matrices W_k of a reference element. We emphasize the point that mesh quality metrics should be explicitly referenced to a logical element. Thus, for example, shape metrics may be referenced to an isosceles, equilateral, or right-angled simplicial element, depending on the application. We list the properties which must be satisfied by an algebraic mesh quality metric. An algebraic definition of mesh quality metrics permits relatively easy analysis of the properties of a metric, for example, in terms of its singular values. Abstract definitions of metrics are given in terms of precise requirements for algebraic shape, length ratio, skew, volume, orientation, volume-shape, and volume-shape orientation metrics. The abstract definitions are slightly subjective, especially in the range and domain of the metrics, but are largely noncontroversial. The requirements in the abstract definitions clearly must be satisfied by any algebraic metric purporting to be of a particular type. Specific examples for each type of metric are given. The examples, for the most part, are conspicuous in that they are new. Few traditional metrics (even were they referenced) will qualify under the definitions given, with the notable exceptions of mean ratio and determinant. Shape, volume, and volume-shape metrics for simplicial elements can be posed in terms of the nodally invariant matrix T while the other metrics must use a set of nodally dependent matrices. Examples of volume-shape metrics are difficult to construct due to the large number of requirements they must satisfy. Volume-shape metrics are critical to adaptive meshing, and it is significant that a rigorous definition and example has been provided. Except for volume, the metrics are scaled between zero and unity for ease of comparison. Multiple Jacobian matrices are needed in the definitions of metrics for nonsimplicial elements due to the lack of an analogy to the matrix T. The rigorous definitions given for the various types of metrics have made it clear that it is not, in general, easy to devise metrics having all the right properties;

this is especially true for nonsimplicial element metrics. For example, to obtain the proper behavior for a volume metric for nonsimplicial elements, we sacrificed the homogeneity requirement. The difficulties encountered suggest that one reason why so many mesh quality metrics have been defined in the past is that few metrics satisfy all of the requirements. Although the metric definitions given require metrics to satisfy rigorous criteria to qualify being a metric of a particular type, there remains some freedom to define alternative metrics. Redundant metrics can be eliminated by investigating possible equivalences via singular values. It was shown that the algebraic shape metric, condition number, measures the distance to the set of degenerate elements. Not all geometric properties of potential interest can be given in terms of an algebraic metric. For example, nonalgebraic metrics based on solid angle or length-to-width ratios cannot be expressed as algebraic metrics. However, there seems to be little need for these additional metrics since, for example, solid-angle-based shape metrics are equivalent to the algebraically based mean ratio shape metric.

Future work may include extending the theory to higher-order finite elements having midside nodes as a means to measuring element curvature. Development of connections between algebraic element quality metrics and effects upon analysis error, efficiency, and robustness should be pursued. Finally, the metrics given are likely candidates for objective functions in mesh smoothing and optimization techniques.

SAMPLING AND EIGENVALUES OF NON-SELF-ADJOINT STURM–LIOUVILLE PROBLEMS[*]

AMIN BOUMENIR[†]

Abstract. In this work we extend the sampling method to the case of non-self-adjoint Sturm–Liouville problems generated by complex-valued potentials and boundary conditions. It is shown that the function which is recovered by sampling on the real line extends analytically into the complex plane. A direct connection with polynomial approximation is established.

Key words. eigenvalues, non-self-adjoint Sturm–Liouville, interpolation, sampling theory

1. Introduction.

We would like to extend the sampling method to the computation of eigenvalues of regular non-self-adjoint Sturm–Liouville problems defined by

$$\begin{cases} -y''(x,\mu)+q(x)y(x,\mu)=\mu^2 y(x,\mu), & 0\le x\le \pi,\\ a_1 y(0,\mu)+a_2 y'(0,\mu)=0, & \\ b_1 y(\pi,\mu)+b_2 y'(\pi,\mu)=0, & \end{cases}$$

where $q\in L^1(0,\pi),\ a_i,b_i,\ q\in\mathbb{C},\ |a_1|+|a_2|\neq 0$, and $|b_1|+|b_2|\neq 0$.

It is well known that eigenvalues, if they exist, are in general nonreal and scattered in the complex plane, which makes the task of computing them very arduous; see [3]. Classical methods relying on tracking the number of zeros of the eigenfunctions, such as the Prufer method, cannot deal with a complex potential. Thus new methods evaluating the miss-distance function by Cauchy-type integrals were developed for computing eigenvalues in the complex plane; see [4].

We recall that the sampling method (see [2]) is basically an interpolation of the characteristic function whose zeros are the eigenvalues. We show that although in the non-self-adjoint case this function is complex valued, it is still in a Paley–Wiener space; see [1] and [7]. Thus we need to interpolate a complex-valued function defined on the complex plane. This immediately raises a new question: Should we need a two-dimensional sampling strategy, or should we sample on the real line only and then use an analytic extension to reach those roots situated far from the real line? Surprisingly, we shall see that the latter alternative is sufficient. The fact that only a few values are needed to interpolate the characteristic function with computable error bounds (see [2]) makes the sampling method very attractive. The actual code or algorithm is very simple and consists of only a few lines. A discussion on the computational aspects of the spectral theory of Sturm–Liouville problems and a comparison between existing codes can be found in [5] and [6].

2. The characteristic function. We recall that the sampling method is basically a shooting data processing. If $y(x,\mu)$ denotes the solution of the initial value problem defined by

$$\begin{cases} -y''(x,\mu)+q(x)y(x,\mu)=\mu^2 y(x,\mu), \\ y(0,\mu)=a_2 \quad \text{and} \quad y'(0,\mu)=-a_1, \end{cases} \qquad 0\le x\le \pi,$$

then the characteristic function is simply defined by the second boundary condition

$$\Delta(\mu):=b_1 y(\pi,\mu)+b_2 y'(\pi,\mu), \tag{2.1}$$

and thus all zeros of Δ are the eigenvalues. We now study the analytic decomposition of Δ. The variation of parameters yields

$$y(x,\mu)=a_2\cos(x\mu)-a_1\frac{\sin(x\mu)}{\mu}+\int_0^x \frac{\sin((x-t)\,\mu)}{\mu}q(t)y(t,\mu)dt, \tag{2.2}$$

which implies that

$$y'(x,\mu)=-a_2\mu\sin(x\mu)-a_1\cos(x\mu)+\int_0^x \cos((x-t)\,\mu)q(t)y(t,\mu)dt.$$

Thus we deduce from (2.1) that

$$\begin{aligned}\Delta(\mu)&=b_1\left[a_2\cos(\pi\mu)-a_1\frac{\sin(\pi\mu)}{\mu}\right]+b_2\left[-a_2\mu\sin(\pi\mu)-a_1\cos(\pi\mu)\right]\\ &\quad+b_1\int_0^\pi \frac{\sin((\pi-t)\,\mu)}{\mu}q(t)y(t,\mu)dt+b_2\int_0^\pi \cos((\pi-t)\,\mu)q(t)y(t,\mu)dt. \end{aligned}\tag{2.3}$$

In order to find the roots of Δ, we need to approximate the last two integrals. To this end we use standard iterative methods to approximate the solution of the Volterra equation (2.2) as

$$y(x,\mu):=\sum_{n=0}^{\infty} y_n(x,\mu),$$

where

$$y_0(x,\mu)=a_2\cos(x\mu)-a_1\frac{\sin(x\mu)}{\mu}$$

and

$$y_n(x,\mu)=\int_0^x \frac{\sin((x-t)\,\mu)}{\mu}q(t)y_{n-1}(t,\mu)dt.$$

With the help of

$$\frac{|\sin(z)|}{|z|}\le\frac{c}{1+|z|}\exp\left(|\operatorname{Im} z|\right) \quad \text{and} \quad |\cos(z)|\le\exp\left(|\operatorname{Im} z|\right) \tag{2.4}$$

we successively obtain the following estimates:

$$|y_0(x,\mu)| \leq \left(|a_2| + |a_1| \frac{cx}{1+x|\mu|}\right) \exp(x|\operatorname{Im}\mu|),$$

$$\begin{aligned}|y_1(x,\mu)| &\leq \int_0^x \left|\frac{\sin((x-t)\mu)}{(x-t)\mu}\right| (x-t)|q(t)|\,|y_0(t,\mu)|\,dt \\ &\leq \left(|a_2| + |a_1| \frac{cx}{1+x|\mu|}\right) \int_0^x \frac{c(x-t)|q(t)|}{1+(x-t)|\mu|} dt \exp(x|\operatorname{Im}\mu|) \\ &\leq \left(|a_2| + |a_1| \frac{cx}{1+x|\mu|}\right) \frac{cx}{1+x|\mu|} \int_0^x |q(t)|\,dt \exp(x|\operatorname{Im}\mu|),\end{aligned}$$

which leads to

$$\begin{aligned}|y_2(x,\mu)| &\leq \frac{cx}{1+x|\mu|} \int_0^x |q(t)|\,|y_1(t,\mu)|\,dt \exp(x|\operatorname{Im}\mu|) \\ &\leq \left(|a_2| + |a_1| \frac{cx}{1+x|\mu|}\right) \frac{cx}{1+x|\mu|} \int_0^x \frac{ct}{1+t|\mu|} |q(t)| \int_0^t |q(\eta)|\,d\eta dt \exp(x|\operatorname{Im}\mu|) \\ &\leq \left(|a_2| + |a_1| \frac{cx}{1+x|\mu|}\right) \left(\frac{cx}{1+x|\mu|}\right)^2 \int_0^x |q(t)| \int_0^t |q(\eta)|\,d\eta dt \exp(x|\operatorname{Im}\mu|) \\ &\leq \left(|a_2| + |a_1| \frac{cx}{1+x|\mu|}\right) \left(\frac{cx}{1+x|\mu|}\right)^2 \left(\frac{1}{2}\int_0^x |q(t)|\,dt\right)^2 \exp(x|\operatorname{Im}\mu|).\end{aligned}$$

The successive integrations yield

$$\begin{aligned}|y_n(x,\mu)| &\leq \frac{cx}{1+x|\mu|} \int_0^x |q(t)|\,|y_{n-1}(t,\mu)| \exp((x-t)|\operatorname{Im}\mu|)\,dt \\ &\leq \left(|a_2| + \frac{|a_1|\,cx}{1+x|\mu|}\right) \frac{1}{n!} \left(\frac{cx}{1+x|\mu|} \int_0^x |q(t)|\,dt\right)^n \exp(x|\operatorname{Im}\mu|).\end{aligned}$$

Thus we recover the well-known exponential growth in μ,

$$|y(x,\mu)| \leq \left(|a_2| + \frac{|a_1|\,cx}{1+x|\mu|}\right) \exp\left(cx\int_0^x |q(t)|\,dt\right) \exp(x|\operatorname{Im}\mu|), \tag{2.5}$$

and the integrals appearing in (2.3) can be estimated:

$$\left|\int_0^\pi \frac{\sin((\pi-t)\mu)}{\mu} q(t)y(t,\mu)dt\right| \leq \frac{c\pi M(q)}{1+\pi|\mu|} \exp(\pi|\operatorname{Im}\mu|) \tag{2.6}$$

and similarly

$$\left|\int_0^\pi \cos((\pi-t)\mu) q(t)y(t,\mu)dt\right| \leq M(q) \exp(\pi|\operatorname{Im}\mu|), \tag{2.7}$$

where

$$M(q) := \left(|a_2| + \frac{|a_1|\,c\pi}{1+\pi|\mu|}\right) \int_0^\pi |q(t)| \exp\left(ct\int_0^t |q(\eta)|\,d\eta\right) dt.$$

Observe that the upper bound in (2.7) is not square integrable on the real line if $a_2 \neq 0$. In order to have a faster decay in μ, we use the difference $y(x,\mu) - y_0(x,\mu)$ instead of $y(x,\mu)$,

$$|y(x,\mu) - y_0(x,\mu)| \leq \frac{c\pi M(q)}{1+\pi|\mu|} \exp\left(x\left|\operatorname{Im}\mu\right|\right), \tag{2.8}$$

and so we can recast (2.7) as

$$\left|\int_0^\pi \cos((\pi-t)\,\mu)q(t)\left(y(t,\mu)-y_0(t,\mu)\right)dt\right| \leq \frac{c\pi M(q)}{1+\pi|\mu|}\int_0^\pi |q(t)|\,dt \exp\left(\pi\left|\operatorname{Im}\mu\right|\right). \tag{2.9}$$

This leads to a first practical decomposition of Δ,

$$\begin{aligned}
\Delta(\mu) &= b_1\left[a_2\cos(\pi\mu) - a_1\frac{\sin(\pi\mu)}{\mu}\right] - b_2\left[a_2\mu\sin(\pi\mu) + a_1\cos(\pi\mu)\right] \\
&\quad + a_2b_2\int_0^\pi \cos((\pi-t)\,\mu)\cos(t\mu)q(t)dt - a_1b_2\int_0^\pi \cos((\pi-t)\,\mu)\frac{\sin(t\mu)}{\mu}q(t)dt \\
&\quad + b_1\int_0^\pi \frac{\sin((\pi-t)\,\mu)}{\mu}q(t)y(t,\mu)dt + b_2\int_0^\pi \cos((\pi-t)\,\mu)q(t)\left(y(t,\mu)-y_0(t,\mu)\right)dt \\
&= G(\mu) + S(\mu),
\end{aligned}$$

where after a few algebraic simplifications

$$\begin{aligned}
G(\mu) &= \cos(\mu\pi)\left[a_2b_1 + b_2\left(-a_1 + a_2\int_0^\pi \cos^2(t\mu)\,q(t)dt - \frac{a_1}{2}\int_0^\pi \frac{\sin(2t\mu)}{\mu}q(t)dt\right)\right] \\
&\quad + \frac{\sin(\pi\mu)}{\mu}\left[-a_1b_1 + b_2\left(-a_2\mu^2 + \frac{1}{2}a_2\mu\int_0^\pi \sin(2t\mu)\,q(t)dt - a_1\int_0^\pi \sin^2(t\mu)\ \ q(t)dt\right)\right]
\end{aligned} \tag{2.10}$$

and

$$S(\mu) := b_1\int_0^\pi \frac{\sin((\pi-t)\,\mu)}{\mu}q(t)y(t,\mu)dt + b_2\int_0^\pi \cos((\pi-t)\,\mu)q(t)\left(y(t,\mu)-y_0(t,\mu)\right)dt.$$

Thus using (2.6) and (2.9) we obtain the following.

Proposition 1. *Assume that* $q \in L^1(0,\pi)$, $a_i, b_i,\ q \in \mathbb{C}$, $|a_1| + |a_2| \neq 0$, *and* $|b_1| + |b_2| \neq 0$; *then* $S(\mu) \in PW_\pi$.

The above proposition allows us to recover the function S by the Whittaker–Shannon–Kotelnikov (W.S.K.) theorem (see [7]):

$$S(\mu) = \sum_{n\in Z} S(n)\frac{\sin(\pi(\mu-n))}{\pi(\mu-n)}, \tag{2.11}$$

where the sampling values $S(n)$,

$$S(n) := \Delta(n) - G(n),$$

are computed by evaluating (2.1) and (2.10) at the integers only.

We now analyze the truncation error due to replacing S by a finite sum:

$$S_N(\mu) := \sum_{n=-N}^{N} S(n)\frac{\sin(\pi(\mu-n))}{\pi(\mu-n)}. \tag{2.12}$$

$$\begin{aligned}\Delta(\mu) &= G(\mu) + S(\mu)\\ &= G(\mu) + \sum_{n=-N}^{N} S(n)\frac{\sin(\pi(\mu-n))}{\pi(\mu-n)} + \sum_{|n|>N} S(n)\frac{\sin(\pi(\mu-n))}{\pi(\mu-n)}\\ &= G(\mu) + \sin(\pi\mu)\sum_{n=-N}^{N} \frac{(-1)^n S(n)}{\pi(\mu-n)} + \sin(\pi\mu)\sum_{|n|>N} \frac{(-1)^n S(n)}{\pi(\mu-n)}\\ &= G(\mu) + \sin(\pi\mu)\sum_{n=-N}^{N} \frac{(-1)^n S(n)}{\pi(\mu-n)} + \sin(\pi\mu)\sum_{|n|>N} \frac{(-1)^n S(n)}{\pi(\mu-n)}.\end{aligned}$$

Observe that $y(\pi,\mu)$ is an even function of μ, and thus $S(-n) = S(n)$, which further simplifies the above sums:

$$\begin{aligned}\Delta(\mu) &= G(\mu) + \mu\sin(\pi\mu)\frac{2}{\pi}\left(\frac{S(0)}{2\mu^2} + \sum_{n=1}^{N}\frac{(-1)^n S(n)}{(\mu^2-n^2)}\right) + \mu\sin(\pi\mu)\frac{2}{\pi}\sum_{n>N}\frac{(-1)^n S(n)}{(\mu^2-n^2)}\\ &= G(\mu) + \frac{\sin(\pi\mu)}{Q_N(\mu)}P_N(\mu) + T_N(\mu),\end{aligned}$$

where P_N and

$$Q_N(\mu) = \pi\mu\prod_{n=1}^{N}\left(1-\frac{\mu^2}{n^2}\right)$$

are polynomials of degree $2N$ and $2N+1$, respectively, and observe that the only zeros of the entire function $\frac{\sin(\pi\mu)}{Q_N(\mu)}$ are $\{n \in Z : |n| \geq N+1\}$, and furthermore

$$\frac{\sin(\pi\mu)}{Q_N(\mu)} \to 1 \text{ as } N \to \infty.$$

It is readily seen that if K is a compact set of the complex plane not containing large integers, i.e., $\{n \in Z : |n| > N\} \cap K = \emptyset$, then the truncation error T_N is bounded by

$$\sup_{\mu\in K}|T_N(\mu)| \leq \frac{2}{\pi}\sqrt{\sum_{n>N}|S(n)|^2}\,\sup_{\mu\in K}\left|\mu\sin(\pi\mu)\sqrt{\sum_{n>N}\frac{1}{(\mu^2-n^2)^2}}\right|.$$

Since $|S(\mu)| = o(\mu^{-1})$, the convergence of $\sum_{n\geq 0}|S(n)|^2$ implies that $\sup_{\mu\in K}|T_N(\mu)| \to 0$ as $N \to \infty$, and thus we can use the approximation provided by

$$\Delta_N(\mu) := G(\mu) + \frac{2}{\pi}\frac{\sin(\pi\mu)}{Q_N(\mu)}P_N(\mu) = 0 \tag{2.13}$$

to compute the roots of $\Delta(\mu)$ in the complex plane. Uniform convergence implies that $\Delta_N(\mu) \to 0$ as $N \to \infty$, and so the roots of Δ_N approximate the roots of $\Delta(\mu)$.

PROPOSITION 2. *Let $q \in L^1(0,\pi)$ and K be a compact set in the complex plane; then* $\sup_{\mu\in K}|\Delta_N(\mu)-\Delta(\mu)| \to 0$ *as* $N\to\infty$.

It is true that the integrals in the function G (2.10) may not be easy to compute. Can we avoid computing the Fourier transforms appearing in G? Observe that if $q\in L^2(0,\pi)$, then $\sin\mu\pi\int_0^\pi \sin(2t\mu)\,q(t)dt$ is square integrable for $\mu\in R$ since it is the Fourier transform of q. It is also an entire function, and its exponential growth is given by (2.4)

$$\left|\sin\mu\pi\int_0^\pi \sin(2t\mu)\,q(t)dt\right| = O\left(\exp\left(3\pi\left|\operatorname{Im}(\mu)\right|\right)\right),$$

and thus $\sin\mu\pi\int_0^\pi \sin(2t\mu)\,q(t)dt \in PW_{3\pi}$, and similarly we obtain

$$\cos\mu\pi\int_0^\pi \cos t\mu\frac{\sin(t\mu)}{\mu}q(t)dt,\ \sin\mu\pi\int_0^\pi \frac{\sin^2 t\mu}{\mu}q(t)dt \in PW_{3\pi}.$$

The last remaining integral needs a different treatment, namely,

$$\int_0^\pi \cos^2(t\mu)\,q(t)dt = \frac{1}{2}\int_0^\pi \cos(2t\mu)\,q(t)dt + \frac{1}{2}\int_0^\pi q(t)dt,$$

and we obviously have $\cos\mu\pi\int_0^\pi\cos(2t\mu)\,q(t)dt = O\left(\exp\left(3\pi\left|\operatorname{Im}(\mu)\right|\right)\right)$ and

$$\cos\mu\pi\int_0^\pi \cos(2t\mu)\,q(t)dt \in L^2(-\infty,\infty).$$

Thus we deduce again that

$$\cos\mu\pi\int_0^\pi \cos(2t\mu)\,q(t)dt \in PW_{3\pi}.$$

The remaining term $\frac{1}{2}\int_0^\pi q(t)dt\cos\mu\pi$ is easy to compute and can be included in G. Hence a simpler decomposition follows if we assume that $q\in L^2(0,\pi)$ instead of $q\in L^1(0,\pi)$.

PROPOSITION 3. *Assume that* $q\in L^2(0,\pi)$, $a_i, b_i, q\in\mathbb{C}$, $|a_1|+|a_2|\neq 0$, *and* $|b_1|+|b_2|\neq 0$; *then*

$$\Delta(\mu) := G_1(\mu)+S_1(\mu),$$

where

$$G_1(\mu) = \left(b_1a_2 - a_1b_2 + a_2b_2\frac{1}{2}\int_0^\pi q(t)dt\right)\cos(\pi\mu) - a_2b_2\mu\sin(\pi\mu)$$

and $S_1\in PW_{3\pi}$.

Here the cost of the simplification is that we need three times more sampling points since the step size is $\frac{1}{3}$ instead of 1. There is a further interesting simplification that will be crucial for computing purposes. In the Dirichlet case, e.g., a_2 and b_2 are nil; then Δ simplifies since $G_1(\mu)=0$.

We now summarize the main points of the above results. In the case where we are working with Proposition 1 then we use the space PW_π, step size = 1, and an approximation of Δ is given by

$$\Delta_N(\mu) = \cos(\pi\mu)F(\mu)+\sin(\pi\mu)H(\mu)+P_N(\mu)\sin(\pi\mu)/Q_N(\mu),$$

where F, H are Fourier transforms, P_N is a polynomial, $\sin(\pi\mu)/Q_N(\mu)$ is an entire function whose zeros are $\{n \in Z : |n| \geq N+1\}$ and converges to 1. If the functions F and H are too difficult to evaluate, then one could use Proposition 2 where the approximation takes place in $PW_{3\pi}$

$$\Delta_N(\mu) := \alpha\cos(\pi\mu) + \beta\mu\sin(\pi\mu) + P_N(\mu)\sin(3\pi\mu)/Q_N(\mu) = 0,$$

where α and β are constants and $\sin(3\pi\mu)/Q_N(\mu)$ is an entire function which converges to 1.

3. Examples. We examine the simplest case corresponding to the Dirichlet case. Indeed if

$$a_1 = b_1 = 1 \quad \text{and} \quad a_2 = b_2 = 0,$$

then the characteristic function given by (2.10) and Proposition 1 reduces to

$$\Delta(\mu) = -\frac{\sin(\pi\mu)}{\mu} + S(\mu)$$

and the approximation of S takes place in PW_π. The approximation is then given by (2.13):

$$\begin{aligned}\Delta_N(\mu) &= -\frac{\sin(\pi\mu)}{\mu} + \frac{\sin(\pi\mu)}{\pi\mu}S(0) + \frac{2}{\pi}\sum_{n=1}^{N}\frac{(-1)^n\,\mu S(n)}{\left(\frac{\mu^2}{n^2}-1\right)n^2}\\ &= \frac{\sin(\pi\mu)}{Q_N(\mu)}P_N(\mu),\end{aligned}$$

where $Q_N(\mu) = \pi\mu\prod_{n=1}^{N}(1-\frac{\mu^2}{n^2})$. Recall that by Weiestrass factorization theorem $\sin(\pi\mu) = \pi\mu\prod_{n=1}^{\infty}(1-\frac{\mu^2}{n^2})$ and so

$$\frac{\sin(\pi\mu)}{Q_N(\mu)} = \prod_{n=N+1}^{\infty}\left(1-\frac{\mu^2}{n^2}\right)$$

is an entire function whose zeros are on the real line. As $N \to \infty$, $\frac{\sin(\pi\mu)}{Q_N(\mu)} \to 1$, and hence the roots of Δ are given by the zeros of P_∞, which is easily approximated by P_N.

Example 1. We first use a simple example where the eigenvalues are known explicitly:

$$\begin{cases} -y''(x,\mu) + (3-2*I)y(x,\mu) = \mu^2 y(x,\mu),\\ y(0,\mu) = y(\pi,\mu) = 0.\end{cases}$$

In this case the eigenvalues are $\mu_n^2 = n^2 + 3 - 2*I$ for $n = 1, 2, \ldots$. With $y(0,\mu) = 0$, $y'(0,\mu) = 1$ as the initial condition, the differentials equation is integrated numerically with a precision set to 18 digits to obtain the sampling values $y(\pi,k)$ for $k = 0, 1, 2, \ldots, N$. We take $N = 40$ points and the first values are

$$\begin{aligned} y(\pi,0) &= 10.7815379571786450 - 78.7057658098574994I,\\ y(\pi,1) &= -2.28608041879586698 - 39.1205731809301484I.\end{aligned}$$

The eigenvalues recovered by sampling are

1299.0715154524844623686775442 3 – 2.1862736842674060080899925653 8 I,
1372.0830262152627467942839815 1 – 2.2204029731717988537688109878 1 I,
1447.0985667408315500147689169 5 – 2.2690302318731190889933998464 3 I,
1524.1216991431764869342294399 0 – 2.3485304385436856926755202546 3 I,
1603.1630623747688137832609560 6 – 2.5315296352398540224535584060 8 I.

Observe that the precision on the last 3 eigenvalues deteriorates. Although we evaluated Δ on the small set $\mu \in \{0, 1, \ldots, 40\}$, we have recovered all the eigenvalues up to $1603 - 2I$; see Figure 1.

Example 2. Consider by the following example:

$$\begin{cases} -y''(x,\mu) + (1+I)x^2 y(x,\mu) = \mu^2 y(x,\mu), \\ y(0,\mu) = y(\pi,\mu) = 0. \end{cases}$$

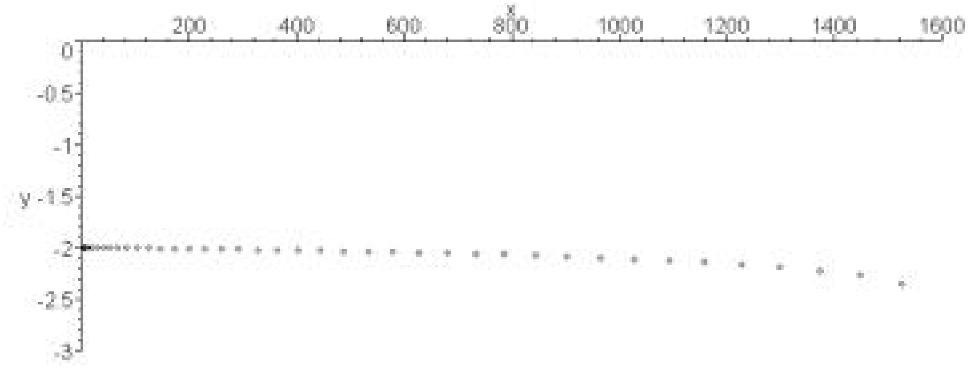

FIG. 1. *The eigenvalues when $q(x) = 3 - 2I$.*

The first values of $y(\pi, n)$ are computed with the same precision as previously:

$$y(\pi, 0) = -30.0194706498185406 + 76.7008318167070961I,$$
$$y(\pi, 1) = -22.3863633586727145 + 31.8682226573447697I,$$
$$y(\pi, 2) = -2.64524868593933849 - 4.08802765222044812I.$$

The polynomial P_{40} is easily factored and the eigenvalues are given by μ_n^2:

```

The characteristic function can be reduced to a hypergeometric series $\Delta(\mu) = c\mathrm{WhittakerM}(\frac{\mu^2}{4\sqrt{1+I}},\ \frac{1}{4},\ \pi^2\sqrt{1+I})$. Since its zeros are not known explicitly we can, for example, check the validity of the numerical results by evaluating $\Delta\left(\mu_n\right)$ numerically; for example,

μ^2	$\Delta(\mu)$
$3.292530378 + 1.366320846280 * I$	$-0.000129911013565507 - 0.0000337654876381 * I$
$103.2854503 + 3.339043664060 * I$	$-0.000080009701487999 + 0.0003554960921802 * I$
$679.28884246 + 3.39700479352 * I$	$-0.000140099029306098 + 0.0004554926139912 * I.$

This shows that N sampling values on the real line are enough to approximate N eigenvalues in the complex plane; see Figure 2. It is also clear that the precision improves as we take more sampling points.

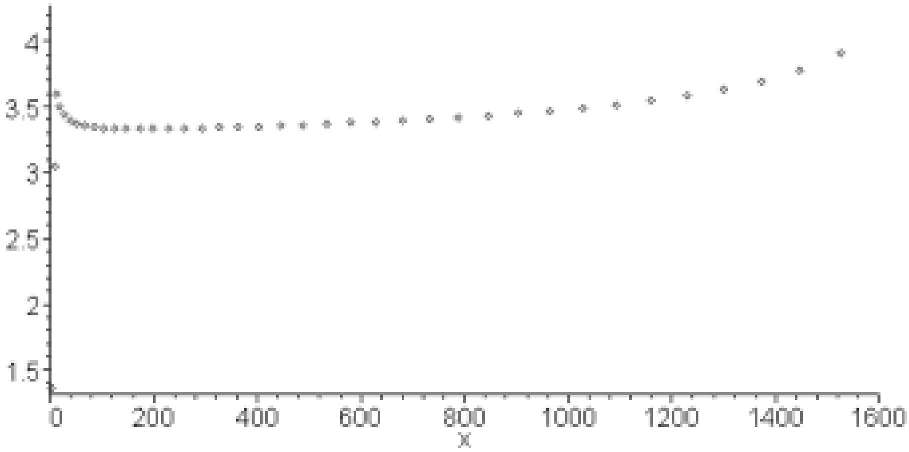

FIG. 2. *Eigenvalues when $q(x) = (1 + I)x^2$.*

SOME IMPROVEMENTS OF THE FAST MARCHING METHOD*

DAVID L. CHOPP†

Abstract. The fast marching method published by Sethian [*Proc. Natl. Acad. Sci. USA*, 93 (1996), pp. 1591–1595] is an optimally efficient algorithm for solving problems of front evolution where the front speed is monotonic. It has been used in a wide variety of applications such as robotic path planning [R. Kimmel and J. Sethian, *Fast Marching Methods for Computing Distance Maps and Shortest Paths*, Tech. Report 669, CPAM, University of California, Berkeley, 1996], crack propagation [M. Stolarska et al., *Internat. J. Numer. Methods Engrg.*, 51 (2001), pp. 943–960; N. Sukumar, D. L. Chopp, and B. Moran, *Extended finite element method and fast marching method for three-dimensional fatigue crack propagation*, J. Comput. Phys., submitted], seismology [J. Sethian and A. Popovici, *Geophysics*, 64 (1999), pp. 516–523], photolithography [J. Sethian, *Fast marching level set methods for three-dimensional photolithography development*, in Proceedings of the SPIE 1996 International Symposium on Microlithography, Santa Clara, CA, 1996], and medical imaging [R. Malladi and J. Sethian, *Proc. Natl. Acad. Sci. USA*, 93 (1996), pp. 9389–9392]. It has also been a valuable tool for the implementation of modern level set methods where it is used to efficiently compute the distance to the front and/or an extended velocity function.

In this paper, we improve upon the second order fast marching method of Sethian [*SIAM Rev.*, 41 (1999), pp. 199–235] by constructing a second order approximation of the interface generated from local data on the mesh. The data is interpolated on a single box of the mesh using a bicubic approximation. The distance to the front is then calculated by using a variant of Newton's method to solve both the level curve equation and the orthogonality condition for the nearest point to a given node. The result is a second order approximation of the distance to the interface which can then be used to produce second order accurate initial conditions for the fast marching method and a third order fast marching method.

1. Introduction.

The fast marching method published by Sethian [12] is an optimally efficient algorithm for solving general problems of front evolution where the front speed is monotonic. It has been used in a wide variety of applications such as robotic path planning [7], crack propagation [15, 16], seismology [14], photolithography [10], and medical imaging [8]. It has also been a valuable tool for the implementation of modern level set methods where it is used to efficiently compute the distance to the front and/or an extended velocity function. The fast marching method can trace its roots back to graph theoretical results first published by Dijkstra [4], and a review of the fast marching method can be found in Sethian's review article [13].

The fast marching method, presented in [12], was first order accurate, using a first order approximation of the derivatives. In [13], a second order fast marching method is constructed by using corresponding higher order approximations of the derivatives. For one to achieve higher order methods, the initial data must be more accurate. This is possible if the initial distance to the front is given explicitly, but it is more complicated if the initial front is given as a level curve of a function on the mesh, as

commonly arises in applications of the level set method. The method for initializing the fast marching data in [13] uses first order accurate linear interpolation limiting the global error to second order at best.

The level set method is a numerical method which has gained significant popularity in recent years for solving complex problems of evolving interfaces, particularly where the topology of the interface may change. The key advantages of the method are that it can change topology without special cases, can propagate sharp corners and cusps in the interface, and is easily extendible to any number of spatial dimensions. This compares with marker particle-type methods (see, e.g., [5]), where topology changes require collision detection and interface surgery, and the mesh itself requires node point redistribution for stability (and also smooths sharp edges formed by the flow). On the other hand, the interface is known only implicitly in a level set formulation, while it is known explicitly for a marker particle method. The results of this paper offer a way to close this latter gap between the two types of interface representations. Both methods have their uses, and a complete comparison between these two methods is beyond the scope of this paper. For a complete discussion of the level set method and reinitialization, see [9, 11].

One common application of the fast marching method is for implementing reinitialization within the framework of the level set method. Reinitialization, introduced in [3], is where the signed distance map to the zero level set of a function is computed. One common criticism of the level set method is its purported problem with mass conservation. Reinitialization techniques, such as those given in [3] and [18], are well known to have difficulty preserving mass. This is primarily due to the poor accuracy around the zero level set.

In this paper, we improve upon the second order fast marching method of Sethian [13] by constructing a second order approximation of the interface generated from local data on the mesh. The data is interpolated on a single box of the mesh using a bicubic approximation. The distance to the front is then calculated by using a variant of Newton's method to solve both the level curve equation and the orthogonality condition for the nearest point to a given node. The result is a second order approximation of the distance to the interface which can then be used to produce second order accurate initial conditions for the fast marching method and a third order fast marching method. We show with computed examples that the method appears to be second order accurate locally around the zero level set, can be used to build a globally third order accurate fast marching method, preserves mass markedly better during reinitialization than existing methods, and easily generalizes to any number of spatial dimensions—all without increasing the computational complexity of the fast marching method.

In section 2, we describe the fast marching method as presented in [12, 13]. In section 3 we describe the bicubic interpolation and how it is used to construct a second order approximation to the distance map. We also give the formulation for implementing a third order accurate fast marching method. In section 4 we compare the new bicubic approximation method with the second order method in [13] with a series of examples. Finally, in section 5 we summarize our results, discuss how this local approximation can be used for velocity extensions, and briefly describe a current application in crack propagation where this method is already successfully in use.

2. The fast marching method.

The fast marching method is an optimal method for solving an equation of the form

$$\|\nabla\phi\| = 1/F(\mathbf{x}), \tag{2.1}$$

where $F(\mathbf{x})$ is a monotonic speed function for an advancing interface. If $\phi^{-1}(0)$ represents the initial interface, and ϕ solves (2.1), then $\phi^{-1}(t)$ gives the location of the interface evolving with normal velocity $F(\mathbf{x}) > 0$ at time t. The advantage of this method over the original level set method is that the entire evolution of the front is computed in one pass over the mesh with an operation count of $O(N \log N)$ for N mesh points. It is also advantageous over other front tracking algorithms in that it uses techniques borrowed from hyperbolic conservation laws to properly advance fronts with sharp corners and cusps. We present here a basic description of the method; the interested reader is referred to [11, 12, 13].

In the fast marching method, (2.1) is solved numerically by using upwind finite differences to approximate $\nabla\phi$. The use of upwind finite differences indicates a causality, or a direction for the flow of information propagating from the initial contour $\phi^{-1}(0)$ outward to larger values of ϕ. This causality means that the value of $\phi(\mathbf{x})$ depends only on values of $\phi(\mathbf{y})$ for which $\phi(\mathbf{y}) \le \phi(\mathbf{x})$. Thus, if we solve for the values of ϕ in a monotonically increasing fashion, then the upwind differences are always valid and all the mesh points are eventually computed. This sequential procession through the mesh points is maintained by a heap sort which controls the order in which the mesh points are computed.

To begin, the mesh points are separated into three disjoint sets: the set of *accepted* points A, the set of *tentative* points T, and the set of *distant* points D. The mesh points in the set A are considered computed and are always closer to the initial interface than any of the remaining mesh points. The mesh points in T are all potential candidates to be the next mesh point to be added to the set A. The mesh points in T are always kept sorted in a heap sort so that the best candidate is always easily found. The mesh points in D are considered too far from the initial interface to be possible candidates for inclusion in A. Thus, if $\mathbf{x} \in A$, $\mathbf{y} \in T$, and $\mathbf{z} \in D$, then $\phi(\mathbf{x}) < \phi(\mathbf{y}) < \phi(\mathbf{z})$. Figure 2.1 shows the relationship between the different sets of mesh points.

To describe the main algorithm for the fast marching method, we will use the notation for discrete derivatives given by

$$\begin{aligned}
\phi_{i,j} &= \phi(\mathbf{x}_{i,j}),\\
D_x^+\phi_{i,j} &= \frac{1}{\Delta x}(\phi_{i+1,j} - \phi_{i,j}),\\
D_x^-\phi_{i,j} &= \frac{1}{\Delta x}(\phi_{i,j} - \phi_{i-1,j}),\\
D_y^+\phi_{i,j} &= \frac{1}{\Delta y}(\phi_{i,j+1} - \phi_{i,j}),\\
D_y^-\phi_{i,j} &= \frac{1}{\Delta y}(\phi_{i,j} - \phi_{i,j-1}),
\end{aligned}$$

where Δx, Δy are the space step sizes in the x and y directions, respectively. One of the key components in the fast marching method is the computation of the estimate of ϕ for points in T. Suppose, for example, mesh points $\mathbf{x}_{i-1,j}$, $\mathbf{x}_{i,j+1} \in A$ and $\mathbf{x}_{i,j} \in T$. Given the values of $\phi_{i-1,j}$, $\phi_{i,j+1}$, we must estimate the value of $\phi_{i,j}$. This is accomplished by looking at the discretization of (2.1) given by

$$(D_x^-\phi_{i,j})^2 + (D_y^+\phi_{i,j})^2 = \frac{1}{F_{i,j}^2}. \tag{2.2}$$

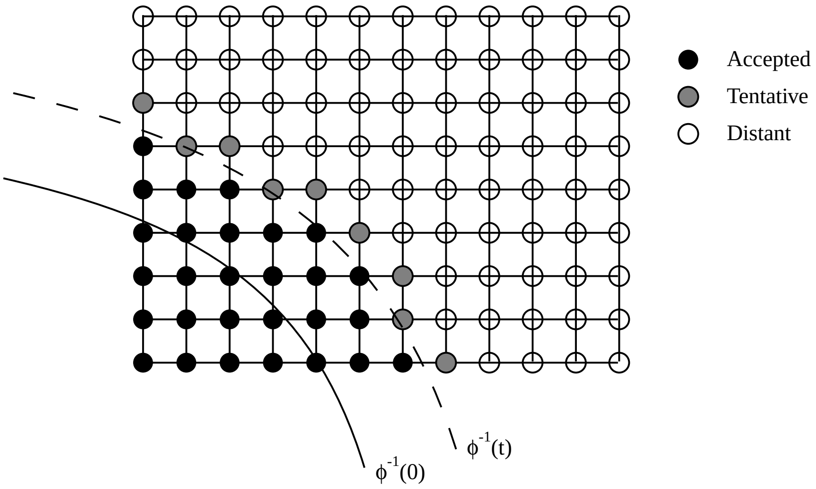

FIG. 2.1. *Illustration of the sets A, T, and D.*

Equation (2.2) reduces to a quadratic equation in $\phi_{i,j}$ given by

$$\left(\frac{1}{\Delta x^2}+\frac{1}{\Delta y^2}\right)\phi_{i,j}^2-2\left(\frac{\phi_{i-1,j}}{\Delta x^2}+\frac{\phi_{i,j+1}}{\Delta y^2}\right)\phi_{i,j}+\frac{\phi_{i-1,j}^2}{\Delta x^2}+\frac{\phi_{i,j+1}^2}{\Delta y^2}-\frac{1}{F^2}=0. \tag{2.3}$$

The new estimate for $\phi_{i,j}$ is given by the largest of the two roots of (2.3). The remaining configurations and the resulting quadratic equations can be derived in a similar fashion.

Note that (2.2) is a first order approximation of (2.1). The general second and third order approximations of (2.1) requires the use of switches determined by which points are in A:

$$\begin{aligned}&\max\Bigg(D_x^-\phi_{i,j}+s_{x,-1}\frac{\Delta x}{2}D_x^-D_x^-\phi_{i,j}+s_{x,-1}s_{x,-2}\frac{\Delta x^2}{6}D_x^-D_x^-D_x^-\phi_{i,j},\\&\qquad -D_x^+\phi_{i,j}+s_{x,1}\frac{\Delta x}{2}D_x^+D_x^+\phi_{i,j}+s_{x,1}s_{x,2}\frac{\Delta x^2}{6}D_x^+D_x^+D_x^+\phi_{i,j},0\Bigg)^2\\&+\max\Bigg(D_y^-\phi_{i,j}+s_{y,-1}\frac{\Delta y}{2}D_y^-D_y^-\phi_{i,j}+s_{y,-1}s_{y,-2}\frac{\Delta y^2}{6}D_y^-D_y^-D_y^-\phi_{i,j},\\&\qquad -D_y^+\phi_{i,j}+s_{y,1}\frac{\Delta y}{2}D_y^+D_y^+\phi_{i,j}+s_{y,1}s_{y,2}\frac{\Delta y^2}{6}D_y^+D_y^+D_y^+\phi_{i,j},0\Bigg)^2=\frac{1}{F_{i,j}^2},\end{aligned} \tag{2.4}$$

where the switches are

$$s_{x,k}=\begin{cases}1, & \mathbf{x}_{i+k,j}\in A,\\ 0 & \text{otherwise,}\end{cases}$$

$$s_{y,k}=\begin{cases}1, & \mathbf{x}_{i,j+k}\in A,\\ 0 & \text{otherwise.}\end{cases}$$

Now the fast marching method can be assembled as an algorithm:

1. Initialize all the points adjacent to the initial interface with an initial value; put those points in A. A discussion about initialization follows in section 3. All points $\mathbf{x}_{i,j} \notin A$ but are adjacent to a point in A are given initial estimates for $\phi_{i,j}$ by solving (2.4). These points are tentative points and put in the set T. All remaining points unaccounted for are placed in D and given initial value of $\phi_{i,j} = +\infty$.
2. Choose the point $\mathbf{x}_{i,j} \in T$ which has the smallest value of $\phi_{i,j}$ and move it into A. Any point which is adjacent to $\mathbf{x}_{i,j}$ (i.e., the points $\mathbf{x}_{i-1,j}$, $\mathbf{x}_{i,j-1}$, $\mathbf{x}_{i+1,j}$, $\mathbf{x}_{i,j+1}$) which is in T has its value $\phi_{i,j}$ recalculated using (2.4). Any point adjacent to $\mathbf{x}_{i,j}$ and in D has its value $\phi_{i,j}$ computed using (2.4) and is moved into the set T.
3. If $T \neq \emptyset$, go to step 2.

The algorithm presented in [12] is first order accurate and can be recovered from (2.4) by taking all the switches $s_{\bullet,\bullet} = 0$. The second order accurate method presented in [13] can also be recovered from (2.4) by taking all the switches $s_{\bullet,\pm 2} = 0$.

3. Locally second order approximation of the level set function.

In [13], it is shown that the fast marching method behaves as a globally second order accurate method. However, it is also noted in [13] that the method is only first order accurate in the set of nodes immediately adjacent to the initial front. This does not destroy the global accuracy because as the mesh shrinks, so too does the size of the region of first order accuracy. To achieve a fully second order accurate fast marching method, we must ensure that the initial data is at least second order accurate. Furthermore, we can also get a globally third order accurate fast marching method by virtue of having at least second order initial data.

The underpinning of this higher degree of accuracy around the initial front is the use of a bicubic interpolation function p which is a second order accurate local representation of a level set function ϕ (i.e., $p(\mathbf{x}) \approx \phi(\mathbf{x})$). The interpolation function $p(\mathbf{x})$ can serve many purposes including second order accuracy for the distance to the zero level set, subgrid resolution of the shape of the interface, as well as subgrid resolution of the level set function $\phi(\mathbf{x})$ itself.

3.1. The bicubic interpolation.

We begin with a description of the bicubic interpolation for a level set function given on a rectangular mesh. The approximation is done locally in a box of the mesh bounded by grid points; call them $\mathbf{x}_{i,j}$, $\mathbf{x}_{i+1,j}$, $\mathbf{x}_{i,j+1}$, and $\mathbf{x}_{i+1,j+1}$, as in Figure 3.1.

A bicubic interpolation $p(\mathbf{x})$ of a function $\phi(\mathbf{x})$ is a function

$$p(\mathbf{x}) = p(x,y) = \sum_{m=0}^{3}\sum_{n=0}^{3} a_{m,n} x^m y^n \tag{3.1}$$

which solves the following set of equations:

$$\begin{aligned} p(\mathbf{x}_{k,\ell}) &= \phi(\mathbf{x}_{k,\ell}), \\ \frac{\partial p}{\partial x}(\mathbf{x}_{k,\ell}) &= \frac{\partial \phi}{\partial x}(\mathbf{x}_{k,\ell}), \\ \frac{\partial p}{\partial y}(\mathbf{x}_{k,\ell}) &= \frac{\partial \phi}{\partial y}(\mathbf{x}_{k,\ell}), \\ \frac{\partial^2 p}{\partial x \partial y}(\mathbf{x}_{k,\ell}) &= \frac{\partial^2 \phi}{\partial x \partial y}(\mathbf{x}_{k,\ell}) \end{aligned}$$

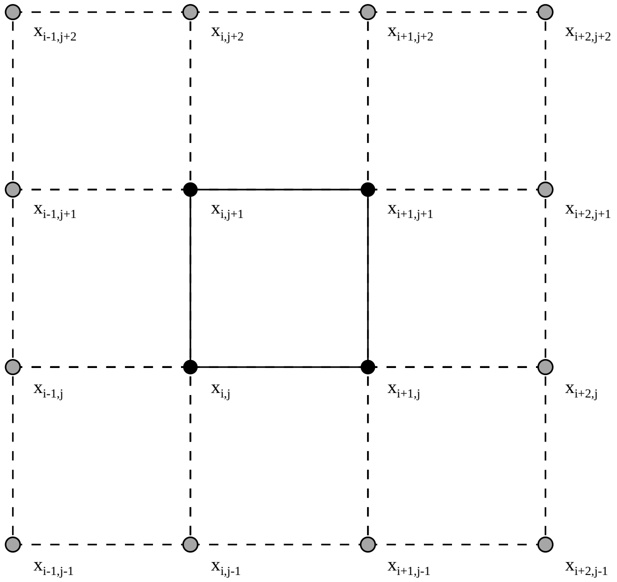

FIG. 3.1. *Sample portion of the mesh where a bicubic interpolation is used.*

for $k = i,\ i+1;\ \ell = j,\ j+1$. This gives sixteen equations for the sixteen unknown coefficients $a_{m,n}$. Solving for the $a_{m,n}$ makes $p(x, y)$ a bicubic interpolating function of $\phi(x, y)$ on the rectangle bounded by the corners $\mathbf{x}_{i,j}$, $\mathbf{x}_{i+1,j}$, $\mathbf{x}_{i,j+1}$, and $\mathbf{x}_{i+1,j+1}$.

Since ϕ is known only on the mesh points, the values for the derivatives of ϕ must be approximated. We use second order finite difference approximations for the derivatives of ϕ:

$$\begin{aligned}
\frac{\partial\phi}{\partial x}(\mathbf{x}_{m,n}) &\approx \frac{1}{2\Delta x}(\phi(\mathbf{x}_{m+1,n}) - \phi(\mathbf{x}_{m-1,n})),\\
\frac{\partial\phi}{\partial y}(\mathbf{x}_{m,n}) &\approx \frac{1}{2\Delta y}(\phi(\mathbf{x}_{m,n+1}) - \phi(x_{m,n-1})),\\
\frac{\partial^2\phi}{\partial x\partial y}(\mathbf{x}_{m,n}) &\approx \frac{1}{4\Delta x\Delta y}(\phi(\mathbf{x}_{m+1,n+1}) - \phi(\mathbf{x}_{m-1,n+1})\\
&\qquad\qquad - \phi(\mathbf{x}_{m+1,n-1}) + \phi(\mathbf{x}_{m-1,n-1}))
\end{aligned}$$

for $m = i, i+1$ and $n = j, j+1$. Thus, construction of the interpolant p requires all the points shown in Figure 3.1. The observant reader will note that the accuracy of this method is restricted to second order by our use of second order approximations for the derivatives of ϕ. In principle, higher order local approximations can be made using higher order finite difference approximations and using a larger set of grid points around the box where the interpolant is used.

One useful property of this local interpolation method is that interpolations in neighboring boxes match smoothly along their common edge. To see this, consider two interpolations $p(x, y)$ and $q(x, y)$ interpolating in two adjacent boxes as depicted in Figure 3.2. To show continuity, we must show $p(x_i, y) = q(x_i, y)$ for $y_j \leq y \leq y_{j+1}$. Now, $p(x_i, y)$ and $q(x_i, y)$ are both cubic polynomials in y. Furthermore, by construction, $p(x_i, y_j) = q(x_i, y_j)$, $p(x_i, y_{j+1}) = q(x_i, y_{j+1})$, $\frac{\partial p}{\partial y}(x_i, y_j) = \frac{\partial q}{\partial y}(x_i, y_j)$,

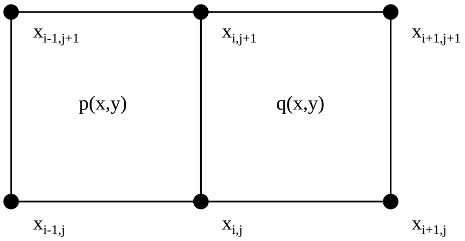

FIG. 3.2. *Two neighboring bicubic interpolants.*

and $\frac{\partial p}{\partial y}(x_i, y_{j+1}) = \frac{\partial q}{\partial y}(x_i, y_{j+1})$. These four conditions uniquely determine the cubic polynomial along the common edge; hence $p(x_i, y) \equiv q(x_i, y)$.

We can go one step further by noting that $\frac{\partial p}{\partial x}(x_i, y)$ and $\frac{\partial q}{\partial x}(x_i, y)$ are also cubic polynomials in y and by construction, $\frac{\partial p}{\partial x}(x_i, y_j) = \frac{\partial q}{\partial x}(x_i, y_j)$, $\frac{\partial p}{\partial x}(x_i, y_{j+1}) = \frac{\partial q}{\partial x}(x_i, y_{j+1})$, $\frac{\partial^2 p}{\partial x \partial y}(x_i, y_j) = \frac{\partial^2 q}{\partial x \partial y}(x_i, y_j)$, and $\frac{\partial^2 p}{\partial x \partial y}(x_i, y_{j+1}) = \frac{\partial^2 q}{\partial x \partial y}(x_i, y_{j+1})$. As above, these four equations uniquely determine the cubic polynomial $\frac{\partial p}{\partial x}(x_i, y) \equiv \frac{\partial q}{\partial x}(x_i, y)$.

If we differentiate the two results $p(x_i, y) \equiv q(x_i, y)$, $\frac{\partial p}{\partial x}(x_i, y) \equiv \frac{\partial q}{\partial x}(x_i, y)$ with respect to y, we get the additional equations $\frac{\partial p}{\partial y}(x_i, y) \equiv \frac{\partial q}{\partial y}(x_i, y)$, $\frac{\partial^2 p}{\partial x \partial y}(x_i, y) \equiv \frac{\partial^2 q}{\partial x \partial y}(x_i, y)$. Therefore, the combined bicubic interpolation over two adjacent boxes is at least $C^{(1)}$.

The approximation $p(x, y)$ is now a local subgrid representation of the level set function ϕ inside the box and can be used as an initializer for a fast marching or velocity extension method.

3.2. Reinitialization. Reinitialization is the construction of the distance map to the zero level set of a given level set function ψ. Thus, given $\psi(\mathbf{x})$, we want to construct $\phi(\mathbf{x})$ such that $\phi^{-1}(0) = \psi^{-1}(0)$ and $\|\nabla\phi\| = 1$. Reinitialization was first introduced in [3], where it was shown to improve the stability of the level set method. It continues to play a crucial role in many level set applications, for example, narrow-band level set methods [1], incompressible fluid flow [18], and computer-aided design [6], to name a few.

One of the main drawbacks of using reinitialization in level set methods is the difficulty in maintaining the original position of the interface, often leading to breakdown in conservation of area/volume. This problem surfaced in the original method proposed in [3] and persists today as observed in [17]. To overcome this problem with the level set method, different solutions have been proposed. Adalsteinsson and Sethian [2] used velocity extensions constructed with the fast marching method to drastically reduce or even eliminate the need for reinitialization in level set method applications. However, their velocity extension method is only first order accurate in a neighborhood of the interface. Sussman and Fatemi [17] proposed a mass correction procedure which artificially enforces mass conservation by modifying the front velocity. While this method forces mass conservation by construction, it comes at the price of modifying the original front velocity with a nonphysical correction term.

In this paper, we focus on reinitialization because it is a stepping stone to initializing the more general fast marching method, and also because it is important to the level set method on its own. The method for reinitialization we present here using bicubic interpolation has two very important properties that previous reinitialization techniques lack: very good front location preservation and, consequently, very good mass conservation. This will be demonstrated by showing that repeated reinitializations do not significantly degrade the location of the interface compared with existing first order methods. In the next section we will describe how this method of reinitialization can be used to solve more general fast marching method applications.

Given a function $\psi(\mathbf{x})$, we want to construct $\phi(\mathbf{x})$ such that $\phi^{-1}(0) = \psi^{-1}(0)$ and $\|\phi\| = 1$. We begin by passing through the mesh to locate all rectangles bounded by nodes which are not all of the same sign, indicating that the zero level set passes through that rectangle. Suppose the rectangle is bounded by the nodes $\mathbf{x}_{i,j}$, $\mathbf{x}_{i+1,j}$, $\mathbf{x}_{i,j+1}$, $\mathbf{x}_{i+1,j+1}$ as in Figure 3.1. Using the values of ψ at these nodes, we construct the bicubic interpolation function $p(\mathbf{x})$ as described above.

Now, let $\mathbf{x}^0$ be a point in the rectangle where we wish to compute the distance to the set $\psi^{-1}(0) \approx p^{-1}(0)$. Let $\mathbf{y}$ be a point in $p^{-1}(0)$ nearest to $\mathbf{x}^0$; then it follows that

$$p(\mathbf{y}) = 0, \tag{3.2}$$

$$\nabla p(\mathbf{y}) \times (\mathbf{x}^0 - \mathbf{y}) = 0. \tag{3.3}$$

Equation (3.2) is a requirement that $\mathbf{y}$ must be on the zero contour of p and (3.3) is a requirement that the normal to the zero contour, given by $\nabla p(\mathbf{y})$, must be aligned with the line through the points $\mathbf{x}^0$, $\mathbf{y}$.

To solve (3.2)–(3.3), we employ a variant of Newton's method to simultaneously solve the pair of conditions. We compute a sequence of iterates $\mathbf{x}^k$ with initial point $\mathbf{x}^0$. The update for the iterates is given by

$$\boldsymbol{\delta}_1 = -p(\mathbf{x}^k)\frac{\nabla p(\mathbf{x}^k)}{\nabla p(\mathbf{x}^k) \cdot \nabla p(\mathbf{x}^k)}, \tag{3.4}$$

$$\mathbf{x}_{k+1/2} = \mathbf{x}^k + \boldsymbol{\delta}_1, \tag{3.5}$$

$$\boldsymbol{\delta}_2 = (\mathbf{x}^0 - \mathbf{x}^k) - \frac{(\mathbf{x}^0 - \mathbf{x}^k) \cdot \nabla p(\mathbf{x}^k)}{\nabla p(\mathbf{x}^k) \cdot \nabla p(\mathbf{x}^k)}\nabla p(\mathbf{x}_k), \tag{3.6}$$

$$\mathbf{x}_{k+1} = \mathbf{x}_{k+1/2} + \boldsymbol{\delta}_2. \tag{3.7}$$

This method takes advantage of the orthogonality of the solution sets for (3.2) and (3.3). Equation (3.4) is the Newton step for the function $g_1(t) = p(\mathbf{x}^k + t\nabla p(\mathbf{x}^k))$. This step moves in the direction of ∇p, and hence holds the value of the left side of (3.3) approximately fixed. Equation (3.6) is the Newton step for the function $g_2(t) = \mathbf{k} \cdot (\nabla p(\mathbf{x}^k) \times (\mathbf{x}_0 - (\mathbf{x}^k + t(\mathbf{k} \times \nabla p(\mathbf{x}^k)))))$. This step moves in the direction normal to ∇p, and hence holds the value of p approximately fixed. Figure 3.3 illustrates this algorithm.

We found the number of iterations required to obtain convergence using this two-step Newton's method was half the standard Newton step or less, but we do not believe the convergence rate differs from the standard Newton iteration. Should this method prove more generally useful, a more complete study of this method will be undertaken by the author.

For the results presented in section 4, we used the convergence criterion

$$\sqrt{\|\boldsymbol{\delta}_1\|^2 + \|\boldsymbol{\delta}_2\|^2} < 10^{-3}\Delta x \Delta y,$$

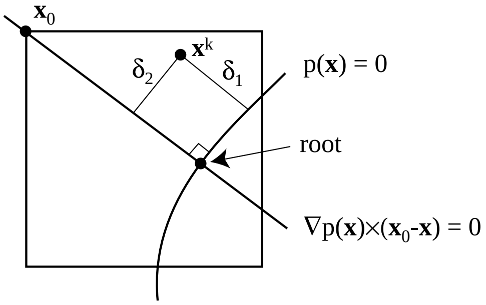

FIG. 3.3. *Example of solution sets for* (3.2) *and* (3.3).

where Δx, Δy are the space step sizes in the x and y directions, respectively. For nearly all evaluations, two or three iterations are necessary to meet the criterion. The distance to the front from the point $\mathbf{x}^0$ is now given by $\phi(\mathbf{x}^0) = \pm\|\mathbf{x}^0 - \mathbf{x}^\infty\|$, where the sign of $\phi(\mathbf{x}^0)$ is taken to be the same as that of $p(\mathbf{x}^0)$.

The above process gives more than just the distance to the zero level set of p; it also gives the location of the nearest point, $\mathbf{x}^\infty$. This will have important consequences later when we discuss the application of this method to velocity extensions and the general fast marching method.

Reinitialization now proceeds by using the above process to calculate the distance to the zero contour from each of the nodes $\mathbf{x}_{i,j}$, $\mathbf{x}_{i+1,j}$, $\mathbf{x}_{i,j+1}$, $\mathbf{x}_{i+1,j+1}$, i.e., each of these nodes plays the role of $\mathbf{x}^0$ above. Now, some of these nodes will be involved in multiple interpolation procedures, so the final value taken for ϕ at those nodes is the minimum of all computed distances to the front. To initialize the fast marching method to complete reinitialization, all nodes whose distance values are constructed using the bicubic interpolation are placed in the set A of accepted points.

The modified Newton iteration will not always converge. Divergence generally can happen when there is no solution for the pair of equations inside the box formed by the nodes $\mathbf{x}_{i,j}$, $\mathbf{x}_{i+1,j}$, $\mathbf{x}_{i,j+1}$, $\mathbf{x}_{i+1,j+1}$. In this event, the calculated distance is taken to be infinite. The iteration rarely requires more than five iterations, and hence twenty iterations is taken to be the maximum before divergence is determined.

3.3. Application to general fast marching method. The above construction was designed to solve the problem of reinitialization. To apply this method for more general fast marching methods, note that the initialization of the general fast marching method requires two components: the local front speed F and the initial distance to the front ϕ. The front speed is determined by the application, and the above process produces the initial distance to the front. Thus, the initial value for a point adjacent to the initial front for the general fast marching method solving (2.1) is ϕ/F. The same set of initially accepted points A are used for general fast marching as for reinitialization.

The fast marching method is also used to construct extension velocity fields for the level set method [2]. Extended velocity fields are used in the level set method when the front velocity F is defined only on the zero level set. In order to advance the level set method, a value of F must exist for the entire domain of the level set function ϕ, not just at the zero contour. The extended velocity field F_{ext} is a speed function defined on the domain of the level set function which satisfies the conditions

$$F_{\text{ext}}\big|_{\phi^{-1}(0)} = F\big|_{\phi^{-1}(0)}, \tag{3.8}$$

$$\nabla F_{\text{ext}} \cdot \nabla \phi = 0, \tag{3.9}$$

where ϕ is again the signed distance to the front. The solution of (3.9) is accomplished using a technique based on the fast marching method; for details, see [2]. In this application, the speed function F_{ext} must be initialized in the same way as for the fast marching method. In this case, the actual location on the front nearest a given node in the mesh is useful, because we can now set $F_{\text{ext}}(\mathbf{x}^0) = F(\mathbf{x}^\infty)$. This solves (3.9) because F_{ext} is now constant on a line between $\mathbf{x}^\infty$ and $\mathbf{x}^0$, which means that

$$\nabla F_{\text{ext}} \perp (\mathbf{x}^\infty - \mathbf{x}^0).$$

But by construction,

$$(\mathbf{x}^\infty - \mathbf{x}^0) \parallel \nabla \phi(\mathbf{x}^\infty).$$

Therefore,

$$F_{\text{ext}}(\mathbf{x}^0) \cdot \nabla \phi(\mathbf{x}^\infty) = 0.$$

Solving (3.9) at the remainder of the nodes is done using fast marching where the heap sort sorts points according to their ϕ value.

4. Results. In this section, we demonstrate the advantages of this new method for initializing the fast marching method.

4.1. Accuracy of the local distance map. The first test of this method is to show that the initialization method is second order accurate in a neighborhood of the initial zero level set. To test this, we show that the error in the computed distance function to a given zero level set is second order accurate. We measure the error in only those points which are computed via the bicubic interpolation method and exclude all points which are subsequently computed by the fast marching method.

The tests were conducted on three initial contours, which are shown in Figure 4.1. We see in Table 4.1 that the initialization method presented in [13] behaves as a first order approximation, and the bicubic interpolation method shows second order convergence as shown in Table 4.2 for smooth functions. Note that for test cases with corners or cusps (the second two examples), the bicubic interpolation also reduces to first order due to the local discontinuity in the derivatives of the level set function.

The computational cost of the new initialization method compared with the old method increased by 20% for an 80 × 80 mesh, down to less than a 4% increase for the 320 × 320 mesh. This is expected because the more refined the mesh, the quicker the iterative step converges on average, and the overall computational cost of the initialization procedure is $O(N)$ with the number of nodes N compared with the fast marching method which increases in cost by $O(N \log N)$.

4.2. Order of accuracy of the fast marching method. Since we now have an initialization procedure which is second order accurate, we should in theory be able to build a third order fast marching method as given in (2.4). For comparison purposes, Table 4.3 shows the results of applying the second order method from [13] with first order initialization. Table 4.4 shows the error measurements for the third

order method. This method appears to be third order from the error measurements for the circle example. Note that the higher rate of convergence does not apply to the second two test cases because the exact solution is not smooth. We show them only to illustrate how the method behaves for more difficult problems.

4.3. Conservation of mass. One common criticism of the level set method concerns the conservation properties of the method. The primary source of variation in mass is due to the process of reinitialization. In some applications of the level set method, such as narrow band methods, for example, frequent reinitializations are used. Repeated reinitializations eventually lead to problems in mass conservation. In Figure 4.2, we show that after twenty reinitializations, the location of the zero level set, and hence the measured value of the area bounded by the zero level set, is very well preserved. Table 4.5 shows the calculated area of the center circle after repeated reinitializations for both the old linear method and the new bicubic method.

4.4. Extension to higher dimensions. Another advantage of the initialization method presented in this paper concerns the extension to higher dimensions. The linear initialization method used does not easily extend to higher dimensions. The method presented in this paper is easily extended to any number of dimensions. For

N dimensions, we use an N-cubic interpolant

$$p(x_1, \dots, x_N) = \sum_{k_1=0}^{3} \cdots \sum_{k_N=0}^{3} a_{k_1,\dots,k_N} \prod_{\ell=1}^{N} x_\ell^{k_\ell}.$$

The iterative procedure given by (3.4)–(3.7) is still valid in this higher dimensional framework. We employed this method to reinitialize a sphere in $\mathbb{R}^3$ and used the second order fast marching method to get a second order accurate method including near the zero level set. Table 4.6 shows the errors from the original first order method from [12]. Table 4.7 shows the bicubic initialization method using second order fast marching. Table 4.8 shows the third order fast marching method results.

$40 \times 40 \times 40$	3.74×10^{-4}	6.25×10^{-4}	1.22×10^{-2}
$80 \times 80 \times 80$	6.62×10^{-5}	1.37×10^{-4}	6.12×10^{-3}

5. Conclusion. In this paper, we have presented a new interpolation method for initializing the fast marching method. This new method makes higher order accurate fast marching methods possible. Furthermore, the new method extends to higher dimensions much more readily than the old first order method. The new method is more accurate than existing methods and the additional cost is minimal. The additional accuracy also significantly improves the mass conservation of the level set method.

The additional accuracy has already proven useful in practice. We have used this new technique to do both reinitialization and front evolution using fast marching for fatigue crack growth modeling in three dimensions [16]. In this work, this higher order fast marching method is used in three different ways. First, reinitialization is used to construct the signed distance from the crack front. This is required to be as accurate as possible to obtain accurate crack front velocity values. Second, after the crack front velocities are obtained through a finite element calculation, the velocities are extended using the velocity extension method described above. Third, the crack front is advanced using the fast marching method and the extended velocity values. All three steps make use of the bicubic interpolation scheme. This approach is different than most uses of the level set method and is taken because the velocity calculation is by far the most expensive part of the process. By using the fast marching method instead of the level set method, arbitrarily large time steps can be taken to advance the front.

The application presented in [16] limits the crack to a single plane in a three-dimensional solid, and hence all the fast marching applications are done on a two-dimensional domain. When the crack front is allowed to move in arbitrary nonplanar directions, the fast marching method will be done in a three-dimensional domain. In that case, this higher order interpolation method will be critical because the refinement of the level set mesh will by necessity be much coarser than for two dimensions.

The bicubic interpolation presented here will produce at best a third order accurate fast marching method. Higher order fast marching methods are possible by using biquintic interpolation. The construction of the interpolant will require a larger stencil of nodes than shown in Figure 3.1 to approximate the additional derivative conditions, and the finite difference derivative approximations will require additional points to obtain sufficient accuracy. For initialization of the fast marching method, the iterative scheme (3.4)–(3.7) for computing the distance to the zero level set remains the same. The fast marching method would also have to be modified to be higher order by adding more terms and more switches.

There is a limit to the order of accuracy of the fast marching method. It is interesting to note that in one dimension, the fast marching method reduces to a backward difference formula method. These methods are known to be stable only for order less than seven. Convergence of the second and higher order fast marching methods is still not proven, and there is some question about their behavior in very dense meshes. The convergence of the higher order methods and their relationship to backward difference formulas is the subject of future research.

ON SOME MIXED FINITE ELEMENT METHODS WITH NUMERICAL INTEGRATION*

STEFANO MICHELETTI†, RICCARDO SACCO†, AND FAUSTO SALERI‡

Abstract. In this paper a new family of mixed finite volume methods is analyzed for the approximation of a reaction-diffusion problem. All the methods are obtained starting from the dual mixed formulation of the problem and then employing the lowest-order Raviart–Thomas finite element spaces plus a suitable quadrature formula for the mass matrix. This allows for the use of different averages of the inverse diffusion coefficient to enforce the constitutive law for the fluxes at the interelement boundary in a finite volume fashion. The soundness of the methods is supported by an error analysis which shows optimal $\mathcal{O}(h)$ convergence rate with respect to the standard mixed finite element norm in the case of both smooth and piecewise smooth coefficients. Numerical results on test problems with both smooth and nonsmooth coefficients support the theoretical estimates.

1. Introduction.

In this article we propose a unified framework for the analysis of a family of cell-centered finite volume schemes for the approximation of the Dirichlet problem for the reaction-diffusion operator $Lu = -\text{div}\ (\mu\underline{\nabla} u) + \sigma u$ on a polygonal domain $\Omega \subset \mathbb{R}^2$. The novel approach is based on the dual mixed discretization of the differential problem by the lowest-order Raviart–Thomas (RT) finite element space [35] on a given triangulation $\mathcal{T}_h$ of $\overline{\Omega}$.

Introducing the auxiliary flux variable $\underline{J} = \mu\underline{\nabla} u$ and denoting by u_h and $\underline{J}_h$ the RT approximations of u and $\underline{J}$, the linear system associated with the dual mixed discretization is of the form

$$\begin{pmatrix} A & B^T \\ -B & C \end{pmatrix} \begin{pmatrix} \mathbf{J} \\ \mathbf{u} \end{pmatrix} = \begin{pmatrix} \mathbf{0} \\ \mathbf{f} \end{pmatrix}, \tag{1.1}$$

where $\mathbf{J}$ and $\mathbf{u}$ are the vectors of the degrees of freedom for $\underline{J}_h$ and u_h. The dual mixed formulation provides the interelement continuity of the normal traces of $\underline{J}_h$ and yields the same order of accuracy for both u_h and $\underline{J}_h$ (see [35, 12, 36, 34]).

This is quite desirable in practical applications where there is the need of providing a good approximation of a vector field as it enters other equations as an input datum. See, for example, [15, 16] for the case of the semiconductor problem.

However, two kind of difficulties arise when dealing with system (1.1).

First, the solution procedure can be quite expensive since the matrix acting on u_h, obtained after eliminating the flux unknowns from the first equation of (1.1), is full. Moreover, such a matrix, although symmetric and positive-definite, is not in

general an M-matrix. (See [32] for an example in the one-dimensional case, and see [27] and [12, Remark 5.4, p. 195] in the special case where problem (1.1) arises from semiconductor device simulation.) This can be a serious drawback, especially in those applications where a discrete maximum principle is required (see, e.g., [39], [12, pp. 193–195]).

The usual way to circumvent the first difficulty is to resort to the hybridization of the mixed formulation, introducing Lagrange multipliers λ_h for u_h at the interelement boundaries. The matrix of the resulting system on λ_h, in the case when $\sigma = 0$, is symmetric and positive-definite and turns out to be an M-matrix provided that $\mathcal{T}_h$ is a weakly acute triangulation (see [12, p. 194]). However, to preserve the M-matrix property when $\sigma \neq 0$, it is necessary to change the RT finite element space for $\underline{J}_h$ [27].

An alternative approach that has been the object of several researches in the recent literature is to perform a *lumping* of the matrix A through some suitable quadrature formula.

Concerning the use of rectangular grids, this strategy was first proposed in [32] and was further investigated in [33] in the case when $\mu = 1$. Theoretical and implementation issues that link "nodal" finite elements, mesh-centered finite differences, and mixed-hybrid finite elements have been addressed in [22, 23]. In [31] a theoretical analysis shows that under appropriate smoothness assumptions, the quadrature error (in the evaluation of A and $\mathbf{f}$) does not spoil the accuracy of the mixed method with exact integration.

Passing to triangular elements, similar conclusions have been drawn in [9, 10], where a quadrature formula to diagonalize the matrix A is proposed and examined in the case of the Laplace operator on triangular grids. An extension of this latter lumping procedure has been carried out in [2] and [39] in the case of a diffusion problem with nonconstant coefficients, and in [40, 29] in the case of the convection-diffusion operator with a zero-order term. In particular, in [2] the case of piecewise constant diffusion coefficients is considered with only one harmonic average of μ computed over each triangle. We instead analyze in the present paper a family of averages, all characterized by being piecewise constant over the dual tessellation of the domain. Moreover, we also include in the analysis the zero-order term.

In the previous works [39, 40, 29] the philosophy is the same as in this paper but with two main differences. In the previous works, on the one hand, only a stability analysis was performed on u in a suitable mesh-dependent H^1-seminorm, and on the other hand, only one particular choice of the average of μ was considered, namely, the one corresponding to (8.3) in section 8. In the present work we carry out a complete error analysis for the mixed finite volume formulation in the standard mixed finite element norm.

The case of an elliptic problem where μ is a symmetric, positive-definite tensor has been studied in [5, 14], where RT mixed finite elements of lowest degree with numerical integration are considered on both rectangular and logically rectangular grids. Another numerical scheme on this subject has been proposed in [4], where an expanded mixed finite element method capable of handling the case of a discontinuous full tensor μ and general shape elements and geometry is derived. It can be checked that in the special case of a reference equilateral triangle and RT finite elements of lowest degree, the quadrature rule proposed in [4] to diagonalize the mass matrix yields the same result as the lumping formula of [9], which is at the basis of the discrete formulation proposed in the present article. However, the resulting method in [4] gives a ten-point finite difference stencil, while our method gives a four-point finite difference stencil. Moreover, the error analyses in [4] and in the present paper yield similar orders of convergence and superconvergence properties.

The common feature of the approaches based on a lumping procedure is that the mixed formulation using RT finite elements of lowest degree can be interpreted as a finite volume method acting on the primal unknown u_h. This connection has also been recently investigated in [20], where cell-centered finite difference schemes are constructed on triangular grids of regular shape (equilateral and isosceles right triangles). In this respect we also mention [45], where finite difference schemes on triangular cell-centered grids are derived under the assumption of weakly acute triangulation. In this case, and using the harmonic average of μ along the Voronoi edge, the methods of [45] and of the present paper coincide, although the error analysis in [45] is carried out only in the case when $\mu = 1$.

In the present paper, we provide a unified framework for a family of cell-centered finite volume schemes derived from the dual mixed formulation of the differential problem (see section 2). With this aim, the dual tessellation $\mathcal{L}_h$ associated with $\mathcal{T}_h$ is first introduced in section 3. Notice that $\mathcal{T}_h$ is required to be only a Delaunay triangulation, while previous schemes in the literature assume that $\mathcal{T}_h$ must be a weakly acute triangulation (see [13, 27, 8, 45]). The Delaunay property allows for the presence of obtuse triangles in the mesh, while in a weakly acute triangulation all the angles are required to be $\leq \pi/2$. Next, the RT discretization of the reaction-diffusion problem is considered in section 4, and the finite volume schemes are derived in section 5.

The methods are based on the combined use of a piecewise constant approximation $\overline{\alpha}$ of $\alpha \equiv \mu^{-1}$ over $\mathcal{L}_h$ and of the quadrature formula proposed in [9]. The resulting discretization is a cell-centered finite volume scheme where the degrees of freedom for u_h are picked up at the circumcenters of each element of $\mathcal{T}_h$, while the interelement fluxes are computed using the values of u_h at the circumcenters of two neighboring triangles of $\mathcal{T}_h$.

An abstract framework for the error analysis of the Galerkin discretization with numerical integration of saddle-point problems including zero-order terms is provided in section 6. The results of this section, based on the use of the Strang lemma, are a nontrivial extension to the case of an elliptic operator with zero-order term of the analysis carried out in [12, Chapter 2]. The abstract theory of section 6 is then used in section 7 to prove the (optimal) $\mathcal{O}(h)$ convergence of the new family of methods with respect to the $H(\text{div}; \Omega) \times L^2(\Omega)$-norm that is the standard norm for the analysis of dual mixed methods. We emphasize that the convergence analysis covers the case of both smooth and piecewise smooth coefficients.

The results of section 7 allow us to conclude that, provided $\overline{\alpha}$ is a suitable average of α, it is no longer necessary to resort to the modified RT finite element space introduced in [27]. We also emphasize that the derivation of the novel methods, as well as their convergence analysis, allows us in every respect to call them "mixed finite volume schemes" or, equivalently, "mixed finite element schemes with numerical integration."

Section 8 deals with the computational details of the novel mixed finite schemes. Three choices of $\overline{\alpha}$ are first considered; two averages are suitable approximations of the *harmonic average* of μ (see [7]), while the third one is the trapezoidal rule. The accuracy of the resulting discretization schemes is then examined and compared on two sets of numerical examples with both smooth and discontinuous diffusion coefficient

μ.

2. The continuous problem and its dual mixed formulation.

Let Ω be a bounded convex polygonal domain in $\mathbb{R}^2$ with boundary $\partial\Omega$, and denote by $\underline{n}$ the unit outward normal vector to $\partial\Omega$. We consider the second-order elliptic model problem with homogeneous Dirichlet boundary conditions

$$\left\{ \begin{array}{ll} -\text{div}\,(\mu\underline{\nabla} u) + \sigma u = f & \text{in } \Omega, \\ u = 0 & \text{on } \partial\Omega. \end{array} \right. \tag{2.1}$$

For any open set $\mathcal{S} \subset \mathbb{R}^d$ $(d = 1, 2)$, $|\mathcal{S}|$ and $\chi_{\mathcal{S}}$ will denote, respectively, the d-dimensional Lebesgue measure of $\mathcal{S}$ and the characteristic function of $\mathcal{S}$, while $(\cdot,\cdot)_{0,\mathcal{S}}$ will be the inner product in $L^2(\mathcal{S})$. Norms and seminorms for the spaces $W^{m,p}(\Omega)$ will be denoted by $\|\cdot\|_{m,p,\Omega}$ and $|\cdot|_{m,p,\Omega}$, respectively, with $p = 2$ omitted. Moreover, we shall denote henceforth by $H^m(\Omega)$ the spaces $W^{m,2}(\Omega)$. In particular, $H^0(\Omega) \equiv L^2(\Omega)$, and $H_0^1(\Omega)$ is the Sobolev space of functions of $H^1(\Omega)$ with vanishing traces on $\partial\Omega$ (see [1, 25]).

In (2.1), the diffusion coefficient $\mu \in L^\infty(\Omega)$ is such that $0 < \mu_0 \leq \mu \leq \mu_1$ almost everywhere (a.e.) in Ω, the absorption coefficient $\sigma \in L^\infty(\Omega)$ is nonnegative, and the source term f is a given function in $L^2(\Omega)$.

Using the Lax–Milgram lemma, it is immediate to check that the primal formulation associated with problem (2.1) admits a unique solution $u \in H_0^1(\Omega)$.

Let us introduce the Hilbert space

$$H(\text{div};\Omega) = \{\underline{\tau} \in \left[L^2(\Omega)\right]^2 \mid \text{div}\,\underline{\tau} \in L^2(\Omega)\} \tag{2.2}$$

and define the strictly positive function $\alpha = \mu^{-1} \in L^\infty(\Omega)$ such that $0 < \alpha_0 \leq \alpha \leq \alpha_1$ a.e. in Ω. Thanks to the regularity of u, μ, σ, and f, the vector field

$$\underline{J} = \mu\underline{\nabla} u \tag{2.3}$$

(henceforth denoted as the *flux*) turns out to belong to $H(\text{div};\Omega)$.

Let $V = H(\text{div};\Omega)$ and $Q = L^2(\Omega)$, and define the bilinear forms

$$\left\{ \begin{array}{ll} a(\underline{J},\underline{\tau}) = (\alpha\underline{J},\underline{\tau})_{0,\Omega} = \displaystyle\int_\Omega \alpha\underline{J}\cdot\underline{\tau}\,d\Omega & : V \times V \mapsto \mathbb{R}, \\ b(\underline{\tau},u) = (u,\text{div}\,\underline{\tau})_{0,\Omega} = \displaystyle\int_\Omega u\text{div}\,\underline{\tau}\,d\Omega & : Q \times V \mapsto \mathbb{R}, \\ c(u,v) = (\sigma u,v)_{0,\Omega} = \displaystyle\int_\Omega \sigma uv\,d\Omega & : Q \times Q \mapsto \mathbb{R}. \end{array} \right. \tag{2.4}$$

Then the dual mixed formulation of (2.1) reads

$$\left\{ \begin{array}{ll} \text{Find } \underline{J} \in V \text{ and } u \in Q \text{ such that} & \\ a(\underline{J},\underline{\tau}) + b(\underline{\tau},u) = 0 & \forall\underline{\tau} \in V, \\ -b(\underline{J},v) + c(u,v) = (f,v)_{0,\Omega} & \forall v \in Q. \end{array} \right. \tag{2.5}$$

The existence and uniqueness of $(\underline{J},u)$ will be addressed in section 6.

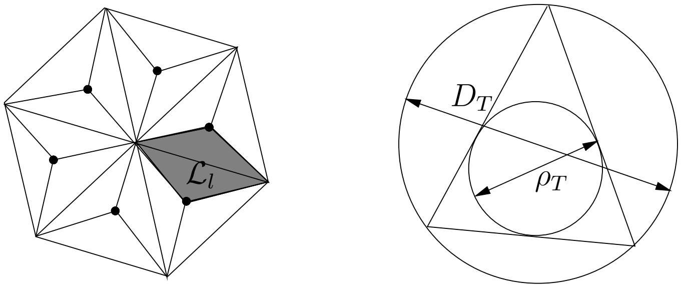

FIG. 1. *Primal triangulation $\mathcal{T}_h$ with the corresponding lumping regions $\mathcal{L}_l$ (left), mesh parameters (right).*

3. Geometry and notations. In view of the finite element discretization of problem (2.5), we introduce on the domain Ω a triangulation $\mathcal{T}_h$ and denote by T the generic triangle of $\mathcal{T}_h$, by h_T the diameter of T, and by h the maximum of h_T over $\mathcal{T}_h$.

Definition. $\mathcal{T}_h$ is a Delaunay triangulation if, for every $T \in \mathcal{T}_h$, the circumcircle of T contains no other vertices than those belonging to T (cf. [19]).

We assume henceforth that $\mathcal{T}_h$ is a Delaunay triangulation. Moreover, we shall indicate by N_h and M_h the total number of edges and triangles of $\mathcal{T}_h$, respectively. Throughout the article, any geometrical entity will always be understood as being an open bounded subset of $\mathbb{R}^d$. For any couple of neighboring triangles T_i and T_j of $\mathcal{T}_h$, let l_{ij} be the common edge, and let λ_{ij} be its corresponding numbering, with $1 \le \lambda_{ij} \le N_h$ for any $i, j = 1, \dots, M_h$. For brevity, we will write in this section l instead of l_{ij}.

We also consider the dual tessellation $\mathcal{L}_h$ of $\mathcal{T}_h$ and denote its elements by "lumping regions" (see Figure 1, left). The lumping region $\mathcal{L}_l$ corresponding to edge l is obtained by joining the common vertices and the two circumcenters C_i and C_j (see Figure 1, left). We also set $\mathcal{L}_{l,T_k} = \mathcal{L}_l \cap T_k$ for $k = i,\ j$. From now on we assume the following regularity constraint on $\mathcal{T}_h$:

$$\frac{D_T}{\rho_T} \le \mathcal{K} \qquad \forall T \in \mathcal{T}_h, \tag{3.1}$$

where D_T and ρ_T are the diameters of the circumscribed and inscribed circles of triangle T, respectively, and $\mathcal{K}$ is a suitable constant (see Figure 1, right). Inequality (3.1) immediately implies that

$$D_T \le \mathcal{K}\rho_T \le \mathcal{K}h_T \qquad \forall T \in \mathcal{T}_h, \tag{3.2}$$

from which it follows that, for an arbitrary triangulation $\mathcal{T}_h$,

$$h_{\mathcal{L}_l} \le D \le \mathcal{K}h \qquad \forall \mathcal{L}_l \in \mathcal{L}_h,$$

where $D = \max_T D_T$ (see Figure 2).

4. RT finite element discretization. Let us consider the Galerkin approximation of (2.5). For any integer $k \ge 0$ we denote by $\mathbb{P}_k$ the space of polynomials of degree $\le k$ in the space variables x, y and define for $k \ge 1$ the space of vector

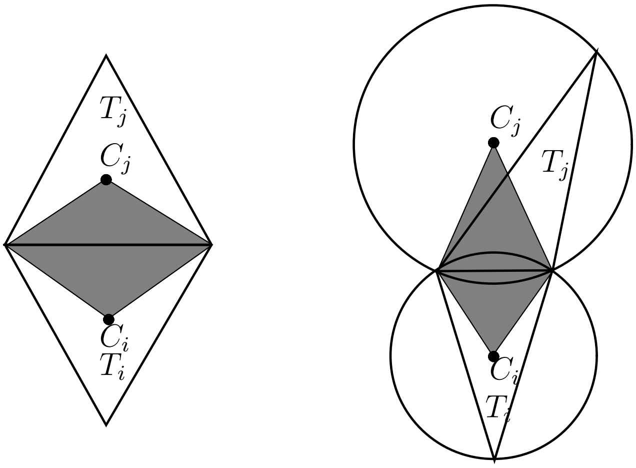

FIG. 2. *Geometrical dimensions (left) and a lumping region for an obtuse triangle.*

polynomials $\mathbb{D}_k = (\mathbb{P}_{k-1})^2 \oplus \underline{x}\mathbb{P}_{k-1}$, where $\underline{x} = (x, y)^T$. Then we introduce the RT finite element space of lowest order [35]

$$V_h = \{\underline{\tau}_h \in V \mid \underline{\tau}_h|_T \in \mathbb{D}_1, \forall T \in \mathcal{T}_h\},$$
$$Q_h = \{v_h \in Q \mid v_h|_T \in \mathbb{P}_0, \forall T \in \mathcal{T}_h\}. \tag{4.1}$$

The finite element discretization of (2.5) reads

$$\begin{cases} \text{Find } \underline{J}_h \in V_h \text{ and } u_h \in Q_h \text{ such that} \\ a(\underline{J}_h, \underline{\tau}_h) + b(\underline{\tau}_h, u_h) = 0 & \forall \underline{\tau}_h \in V_h, \\ -b(\underline{J}_h, v_h) + c(u_h, v_h) = (f, v_h)_{0,\Omega} & \forall v_h \in Q_h. \end{cases} \tag{4.2}$$

For any $\underline{\psi}_h \in V_h$ and $q_h \in Q_h$, we associate with $b(\underline{\psi}_h, q_h)$ an operator B_h from V_h into Q'_h (see [12, p. 51] for more details) and identify its kernel as the subspace $\mathcal{V}_h$ of V_h given by

$$\mathrm{Ker}(B_h) \equiv \mathcal{V}_h = \{\underline{\psi}_h \in V_h \mid b(\underline{\psi}_h, q_h) = 0 \quad \forall q_h \in Q_h\}. \tag{4.3}$$

Existence and uniqueness of the solution $(\underline{J}_h, u_h)$ of (4.2) are ensured by the fact that $a(\cdot,\cdot)$ is coercive on $\mathrm{Ker}(B_h)$ and positive-semidefinite on V_h (i.e., $a(\underline{\psi}_h, \underline{\psi}_h) \geq 0$ for all $\underline{\psi}_h \in V_h$), $c(\cdot,\cdot)$ is a continuous, symmetric, and positive-semidefinite bilinear form on $Q_h \times Q_h$ and that the spaces V_h and Q_h satisfy the inf-sup condition (see [12, Prop. 2.11] and [36, Thm. 10.4 and Remark 10.8, pp. 572-573]).

From previous notation it turns out that $N_h = \dim V_h$, $M_h = \dim Q_h$; let us introduce a basis on these spaces, namely, $\{\underline{\tau}_i\}_{i=1}^{N_h}$ for V_h and $\{v_i\}_{i=1}^{M_h}$ for Q_h. Next, we denote

$$a_{ij} = a(\underline{\tau}_j, \underline{\tau}_i), \qquad b_{ij} = b(\underline{\tau}_j, v_i), \qquad c_{ij} = c(v_j, v_i), \qquad f_i = (f, v_i)$$

and define the matrices $A = (a_{ij}) \in \mathbb{R}^{N_h \times N_h}$, $B = (b_{ij}) \in \mathbb{R}^{M_h \times N_h}$, $C = (c_{ij}) \in \mathbb{R}^{M_h \times M_h}$ and vectors $\mathbf{f} = (f_i) \in \mathbb{R}^{M_h}$, $\mathbf{J} = \{\Phi_i\} \in \mathbb{R}^{N_h}$, $\mathbf{u} = \{u_i\} \in \mathbb{R}^{M_h}$, where Φ_i and u_i are the degrees of freedom for $\underline{J}_h$ and u_h (the fluxes of $\underline{J}_h$ across each edge of

$\mathcal{T}_h$ and the values of u_h over each element $T \in \mathcal{T}_h$, respectively). Eliminating $\mathbf{J}$ from the first equation in (1.1), we end up with the following linear system on u_h:

$$(C + BA^{-1}B^T)\mathbf{u} = \mathbf{f}. \tag{4.4}$$

Solving (4.4) can be quite expensive since the matrix $W \equiv C + BA^{-1}B^T$ is full (due to the presence of A^{-1}); moreover, W is symmetric and positive-definite, but it is not in general an M-matrix (see [12, Remark 5.4, p. 195] and [32, 26]).

To circumvent these two difficulties, we construct in the next section, starting from (4.2), a family of cell-centered finite volume schemes characterized by a reduced computational cost and the same accuracy as the original mixed formulation.

5. A family of finite volume methods. For any $T_k \in \mathcal{T}_h$ and for any integrable function φ, define its mean value as

$$\varphi_k = \frac{(\varphi, 1)_{0,T_k}}{|T_k|} \qquad \forall T_k \in \mathcal{T}_h, \quad \varphi \in L^1(T_k). \tag{5.1}$$

Taking v_h equal to the characteristic function $\mathcal{X}_k$ of triangle T_k in the second equation of (4.2), we obtain

$$- \sum_{j \in \mathrm{adj}(T_k)} \Phi_{\lambda_{kj}} + u_k \sigma_k |T_k| = f_k |T_k| \qquad \forall T_k \in \mathcal{T}_h, \tag{5.2}$$

where $\mathrm{adj}(T_k)$ is the index set of the elements surrounding triangle T_k. Clearly, (5.2) is a genuine finite volume discretization for (2.1), provided that we are able to express each flux $\Phi_{\lambda_{kj}}$, $j \in \mathrm{adj}(T_k)$, in terms of the nodal values u_k and u_j only. With this aim, let us consider the first equation in (4.2) and denote by l_{ij} an edge of $\mathcal{T}_h$ and by T_i, T_j the couple of elements of $\mathcal{T}_h$ such that $\partial T_i \cap \partial T_j = l_{ij}$ (see Figure 2, left). Let also $\underline{n}_{l_{ij}}$ be the unit outward normal vector to ∂T_i (i.e., $\underline{n}_{l_{ij}}$ is positively oriented from T_i towards T_j).

Taking $\underline{\tau}_h = \underline{\tau}_{\lambda_{ij}}$ in the first equation in (4.2) and noting that $\mathrm{div}\, \underline{\tau}_{\lambda_{ij}}|_{T_i} = 1/|T_i|$ and $\mathrm{div}\, \underline{\tau}_{\lambda_{ij}}|_{T_j} = -1/|T_j|$, we get

$$\int_{T_i} \alpha \underline{J}_h \cdot \underline{\tau}_{\lambda_{ij}}\, dT + \int_{T_j} \alpha \underline{J}_h \cdot \underline{\tau}_{\lambda_{ij}}\, dT + u_i - u_j = 0. \tag{5.3}$$

For any $T_k \in \mathcal{T}_h$ let $i, j \in \{1, 2, 3\}$ be the local numbering of the edges of triangle T_k; we then introduce the following exact and approximate bilinear forms restricted over T_k:

$$\begin{aligned} a^{T_k}(\underline{\tau}_j, \underline{\tau}_i) &= \left(\alpha \underline{\tau}_j, \underline{\tau}_i\right)_{0,T_k} = \int_{T_k} \alpha \underline{\tau}_j \cdot \underline{\tau}_i\, dT, \\ a_h^{T_k}(\underline{\tau}_j, \underline{\tau}_i) &= \overline{\alpha}_{l_i} \left(\underline{\tau}_j, \underline{\tau}_i\right)_{h,0,T_k} = \delta_{ij} \frac{d_{k,i}}{|l_i|}, \end{aligned} \tag{5.4}$$

where δ_{ij} is the usual Kronecker symbol, $d_{k,i}$ is the distance between C_k and the edge l_i, and $\overline{\alpha}_{l_i}$ is a suitable average of α over $\mathcal{L}_{l_i}$.

Remark 5.1. *For each edge l_i the distance $d_{k,i}$ is computed using the formula*

$$d_{k,i} = \left(\underline{t}_i \times (\underline{x}_{C_k} - \underline{x}_{1,i})\right) \cdot \underline{n}_z, \qquad i = 1, 2, 3, \tag{5.5}$$

where the symbol "×" denotes the vector product, $\underline{n}_z$ is the unit vector orthogonal to the (x, y) plane, $\underline{x}_{C_k}$ is the coordinate vector of C_k, $\underline{x}_{1,i}$ is the coordinate vector of

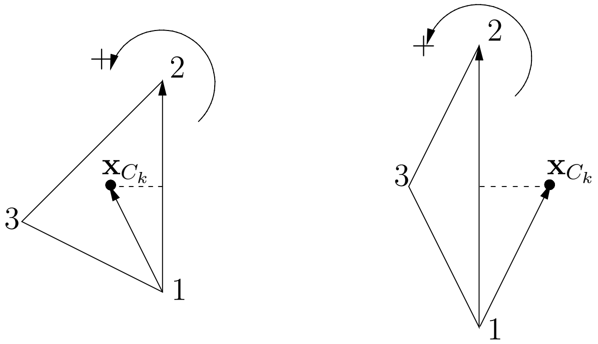

FIG. 3. *Distance of a triangle edge from the circumcenter. Acute triangle (left) and obtuse triangle (right).*

the first vertex of the edge, and $\underline{t}_i$ *is the unit tangent vector to edge* l_i *according to a counterclockwise orientation. From* (5.5) *it follows that the distance* $d_{k,i}$ *has actually a sign, being positive when the edge* l_i *is opposite to an acute angle (Figure* 3*, left) and negative when the angle is obtuse (Figure* 3*, right).*

The construction of the piecewise constant function $\overline{\alpha}$ addressed in the introduction will be fully discussed in sections 7.2 and 8; here we just emphasize the two basic properties of the average: (i) $\overline{\alpha}$ is constant on each lumping region; (ii) $\overline{\alpha}$ is some average of the restriction of α to a suitable subset of each lumping region.

We notice that in the case when $\alpha = 1$, the approximate bilinear form a_h^T coincides with the quadrature formula proposed in [9], where it is shown that the quadrature error is $\mathcal{O}(h_T)$. We let $(\underline{J}_h^*, u_h^*) \in (V_h \times Q_h)$ be henceforth the couple of discrete functions that are solutions of the dual mixed system (4.2) in presence of some quadrature error.

Using (5.4) in (5.3) and recalling that $\overline{\alpha}_{l_{ij}}$ is constant over *all* the lumping region $\mathcal{L}_{l_{ij}}$, we end up with the following equation for the approximate interelement flux $\Phi^*_{h,\lambda_{ij}}$:

$$\Phi^*_{h,\lambda_{ij}} = \overline{\alpha}_{l_{ij}}^{-1} \left(\frac{u_j^* - u_i^*}{d_{ij}} \right) |l_{ij}|, \qquad d_{ij} = d_{i,\lambda_{ij}} + d_{j,\lambda_{ij}}. \tag{5.6}$$

Equation (5.6) holds for any edge l_{ij} in the interior of Ω; if l_{ij} lies on the boundary $\partial\Omega$, it is understood that the value u_j^* is set equal to the average of the Dirichlet datum for u over l_{ij} and that d_{ij} is the distance between the circumcenter of T_i and l_{ij} (see [11]).

Substituting the exact fluxes $\Phi_{\lambda_{kj}}$ in (5.2) with the corresponding approximations (5.6), we finally obtain the family of cell-centered finite volume schemes in the new unknown u_h^*:

$$\begin{cases} \displaystyle\sum_{j \in \mathrm{adj}(T_k)} \overline{\alpha}_{l_{kj}}^{-1} \left(\frac{u_k^* - u_j^*}{d_{kj}} \right) |l_{kj}| + u_k^* \sigma_k |T_k| = f_k |T_k| & \forall T_k \in \mathcal{T}_h, \\ u_j^* = 0 & \forall l_{kj} \in \partial\Omega. \end{cases} \tag{5.7}$$

The set of linear algebraic equations (5.7) can be written in matrix form as

$$W^* \mathbf{u}^* = \mathbf{f}^*, \tag{5.8}$$

where the ith component of $\mathbf{f}^*$ is $f_i|T_i|$ and

$$W^*_{ij} = \begin{cases} \displaystyle\sum_{k\in \mathrm{adj}(T_i)} \overline{\alpha}^{-1}_{l_{ik}} \frac{|l_{ik}|}{d_{ik}} + \sigma_i|T_i| & \text{if } i = j, \\ \\ -\overline{\alpha}^{-1}_{l_{ij}} \dfrac{|l_{ij}|}{d_{ij}} & \text{if } i \neq j \end{cases} \tag{5.9}$$

for $i = 1, \dots, M_h$ and $j \in \mathrm{adj}(T_i)$.

Lemma 5.2. *Assume that $\mathcal{T}_h$ is a Delaunay triangulation. Then the matrix W^* in* (5.8) *is a symmetric, positive-definite, and irreducibly diagonally dominant M-matrix.*

Proof. We first notice that the Delaunay property for $\mathcal{T}_h$ implies that the quantity d_{ij} in (5.7) is positive. As a consequence, $W^*_{ii} > 0$ and $W^*_{ij} \leq 0$ in (5.9) for $i = 1, \dots, M_h$ and $j \in \mathrm{adj}(T_i)$. The expressions (5.9) show that W^* is a symmetric matrix with at most four nonzero entries on each row. Let s_i denote the sum of the entries of each row i of W^*; then

$$s_i = \begin{cases} \sigma_i|T_i| & \text{if } \partial T_i \cap \partial\Omega = \emptyset, \\ \\ \displaystyle\sum_{\substack{j\in \mathrm{adj}(T_i) \\ l_{ij}\notin \partial\Omega}} \overline{\alpha}^{-1}_{l_{ij}} \frac{|l_{ij}|}{d_{ij}} + \sigma_i|T_i| & \text{if } \partial T_i \cap \partial\Omega \neq \emptyset. \end{cases}$$

We see that the sum of the entries of the rows corresponding to boundary triangles is strictly positive, while it is nonnegative for the rows corresponding to internal triangles. Thus W^* is a symmetric, positive-definite, irreducibly diagonally dominant M-matrix (see [43, Corollary 1, p. 85]). □

Remark 5.3. *The M-matrix property ensures that system* (5.8) *is uniquely solvable and that the family of finite volume schemes* (5.7) *enjoys a discrete maximum principle (see* [17, 37]*). In particular, provided $f \geq 0$, the discrete solution u^*_h turns out to be nonnegative.*

The M-matrix property is very desirable in applications. As an example, consider the case where (2.1) is the linearized current continuity equation for semiconductor device simulation using the drift-diffusion or energy-balance transport models (see [13, 26, 39, 29]). In such a case, the unknown u (after a suitable scaling) has the physical meaning of a concentration, and therefore it must be a nonnegative function.

Notice that the M-matrix property guarantees that the solution is oscillation-free even if the ratio $\|\sigma\|_{\infty,\Omega}/\mu_0$ is arbitrarily large. This issue is also the case with a Galerkin finite element method, where it is well known that the performance of the method can be enhanced by lumping the mass matrix associated with the zero-order term.

Remark 5.4 (extension to the three-dimensional case). *Let us briefly comment about the extension of the finite volume formulation of the present paper to the case where Ω is a polygonal domain in $\mathbb{R}^3$.*

The extension is straightforward if Ω is of the form $\Omega = \Omega_{xy} \times (0, H)$ with $\Omega_{xy} \subset \mathbb{R}^2$ and $H > 0$, and $\mathcal{T}_h$ is a partition of Ω into prisms with three vertical edges parallel to the z-axis and two horizontal faces in the (x, y)-plane. We refer to [3] *for the definition and to* [30] *for the use of mixed approximations with RT finite elements on prismatic triangulations.*

The extension of the mixed finite volume method proposed in this paper to the case where $\mathcal{T}_h$ is a decomposition of Ω into simplices is less straightforward. In particular, *if the finite element mesh is made of tetrahedra, a condition for devising a consistent diagonalization of the mass matrix has been provided in* [10, sect. 4] *in the case of the Laplace operator. This condition is necessary and sufficient for a mesh element to be an orthocentered tetrahedron and, in particular, is satisfied if regular tetrahedra are employed in the discretization. Under such an assumption, the present mixed finite volume scheme can also be formulated in three dimensions.*

In the case of a general three-dimensional triangulation the method of the present paper, as well as the related approaches proposed in [9, 10, 2]*, cannot be extended, as pointed out in* [42].

In the following sections we are going to

(i) analyze the convergence in the $H(\mathrm{div};\Omega) \times L^2(\Omega)$-norm of the finite volume methods (5.7); and

(ii) consider a special choice of the average $\overline{\alpha}$ which extends to the two-dimensional case the generalized finite element methods proposed in [7].

6. Abstract theory of the saddle-point problem. In this section we set up an abstract framework for the error analysis of Galerkin methods with numerical quadratures to approximate saddle-point problems of the form

$$(6.1)\qquad \begin{cases} \text{Find } \underline{J} \in V \text{ and } u \in Q \text{ such that} \\ a(\underline{J}, \underline{\tau}) + b(\underline{\tau}, u) = \langle g, \underline{\tau} \rangle & \forall \underline{\tau} \in V, \\ -b(\underline{J}, q) + c(u, q) = \langle f, q \rangle & \forall q \in Q. \end{cases}$$

In (6.1), V and Q are Hilbert spaces with scalar products $(\cdot,\cdot)_V$ and $(\cdot,\cdot)_Q$, the norms $\|\cdot\|_V$ and $\|\cdot\|_Q$, $g \in V'$, $f \in Q'$ are given, and $\langle \cdot,\cdot \rangle$ denotes the duality pairing between V' and V or Q' and Q. The bilinear forms $a(\cdot,\cdot)$, $b(\cdot,\cdot)$, and $c(\cdot,\cdot)$ are assumed to fulfill all the requirements for (6.1) to admit a unique solution (see [12, Ch. 2, Thm. 1.2 and Prop. 2.11]).

In particular, defining the linear operator $B : V \to Q'$ by $\langle B\underline{\lambda}, q \rangle_{Q' \times Q} = b(\underline{\lambda}, q)$ for every $\underline{\lambda} \in V$, we assume that $a(\cdot,\cdot)$ is positive-semidefinite over V and coercive over $\mathrm{Ker}(B)$, $b(\cdot,\cdot)$ satisfies the inf-sup condition, and $c(\cdot,\cdot)$ is symmetric and positive-semidefinite over Q. Problem (2.5) is clearly a special instance of (6.1) provided that $g = 0$, $\langle f, q \rangle = (f, q)_{0,\Omega}$, and the forms $a(\cdot,\cdot)$, $b(\cdot,\cdot)$, and $c(\cdot,\cdot)$ are defined as in (2.4).

Concerning the approximation of (6.1) with the Galerkin method, error estimates and analysis can be found in [12, sect. II.2.4] and [36, Ch. 3, sect. 11]. Hereafter, we shall generalize these results to the case where the bilinear forms $a(\cdot,\cdot)$, $b(\cdot,\cdot)$, and $c(\cdot,\cdot)$ and the duality brackets $\langle \cdot,\cdot \rangle$ are replaced by suitable approximations $a_h(\cdot,\cdot)$, $b_h(\cdot,\cdot)$, $c_h(\cdot,\cdot)$, and $\langle \cdot,\cdot \rangle_h$ through the use of numerical quadratures. This leads us to considering the following Galerkin problem with numerical quadrature associated with (6.1):

$$(6.2)\qquad \begin{cases} \text{Find } \underline{J}_h \in V_h \text{ and } u_h \in Q_h \text{ such that} \\ a_h(\underline{J}_h, \underline{\tau}_h) + b_h(\underline{\tau}_h, u_h) = \langle g, \underline{\tau}_h \rangle_h & \forall \underline{\tau}_h \in V_h, \\ -b_h(\underline{J}_h, q_h) + c_h(u_h, q_h) = \langle f, q_h \rangle_h & \forall q_h \in Q_h. \end{cases}$$

The family of finite volume schemes (5.7) can be recovered setting into (6.2) $g = 0$, $b_h(\cdot,\cdot) = b(\cdot,\cdot)$, and

$$\begin{aligned} a_h(\underline{J}_h, \underline{\tau}_h) &= \sum_{T_k \in \mathcal{T}_h} a_h^{T_k}(\underline{J}_h, \underline{\tau}_h), \\ c_h(u_h, v_h) &= \sum_{T_k \in \mathcal{T}_h} \sigma_k \, (u_h, v_h)_{0,T_k}\,, \\ \langle f, q_h \rangle_h &= \sum_{T_k \in \mathcal{T}_h} f_k \, (q_h, 1)_{0,T_k}\,. \end{aligned} \tag{6.3}$$

(See section 5 for the definitions of all the discrete forms.)

As previously done in section 4, we associate with $b_h(\cdot,\cdot)$ an operator $\widehat{B}_h : V_h \to Q'_h$ whose kernel is the subspace $\widehat{\mathcal{V}}_h$ of V_h given by

$$\operatorname{Ker}(\widehat{B}_h) \equiv \widehat{\mathcal{V}}_h = \{ \underline{\tau}_h \in V_h \ \mid b_h(\underline{\tau}_h, q_h) = 0 \quad \forall q_h \in Q_h \} \,. \tag{6.4}$$

Moreover, following [12, pp. 46–47] and denoting by $\widehat{B}_h^t$ the transpose of $\widehat{B}_h$, we consider for every $\varepsilon > 0$ and for every $\bar{p}_h \in (\operatorname{Ker}(\widehat{B}_h^t))^\perp$ the equation in the unknown $p_{0h} \in \operatorname{Ker}(\widehat{B}_h^t)$,

$$\varepsilon \, (p_{0h}, q_h)_Q + c_h(p_{0h}, q_h) = -c(\bar{p}_h, q_h) \qquad \forall q_h \in \operatorname{Ker}(\widehat{B}_h^t), \tag{6.5}$$

and we assume henceforth that there exists $\gamma_0 > 0$ such that

$$\gamma_0 \|p_{0h}\|_Q \le \|\bar{p}_h\|_Q \qquad \forall \bar{p}_h \in \left(\operatorname{Ker}(\widehat{B}_h^t) \right)^\perp . \tag{6.6}$$

The next proposition ensures the existence and uniqueness of the solution to problem (6.2). It makes the counterpart to the case of numerical integration of the corresponding result given in section 4 and extends to the case $\sigma \ge 0$ the result in [12, Proposition 2.15].

PROPOSITION 6.1. *Assume that there exist positive constant $\mathcal{A}$, $\mathcal{B}$, and $\mathcal{C}$ such that*

$$\begin{aligned} &|a_h(\underline{\psi}_h, \underline{\tau}_h)| \le \mathcal{A} \|\underline{\psi}_h\|_V \|\underline{\tau}_h\|_V && \forall \underline{\psi}_h,\, \underline{\tau}_h \in V_h, \\ &|b_h(\underline{\psi}_h, q_h)| \le \mathcal{B} \|\underline{\psi}_h\|_V \|q_h\|_Q && \forall \underline{\psi}_h \in V_h, \quad q_h \in Q_h, \\ &|c_h(q_h, r_h)| \le \mathcal{C} \|q_h\|_Q \|r_h\|_Q && \forall q_h,\, r_h \in Q_h. \end{aligned} \tag{6.7}$$

Suppose also that $a_h(\cdot,\cdot)$ is coercive on $\operatorname{Ker}(\widehat{B}_h)$*, that is,*

$$a_h(\underline{\lambda}_h, \underline{\lambda}_h) \ge a_0 \|\underline{\lambda}_h\|_{0,\Omega}^2 \qquad \forall \underline{\lambda}_h \in \widehat{\mathcal{V}}_h, \tag{6.8}$$

that b_h satisfies the inf-sup condition independently of h, i.e., there exists $k_0 > 0$ such that

$$\sup_{\underline{\tau}_h \in V_h} \frac{b_h(\underline{\tau}_h, q_h)}{\|\underline{\tau}_h\|_V} \ge k_0 \|q_h\|_Q, \tag{6.9}$$

and that $c_h(\cdot,\cdot)$ is a symmetric positive-semidefinite bilinear form on $Q_h \times Q_h$ satisfying (6.6)*. Then, problem* (6.2) *has a unique solution and there exists a positive constant $\mathcal{M}$, independent of h and depending only on $\mathcal{A}$, $\mathcal{C}$, $1/a_0$, $1/k_0$, and $1/\gamma_0$ such that*

$$\|\underline{J}_h\|_V + \|u_h\|_Q \le \mathcal{M} \left(\|g\|_h + \|f\|_h \right), \tag{6.10}$$

where

$$\|g\|_h = \sup_{\underline{\tau}_h \in V_h} \frac{\langle g, \underline{\tau}_h \rangle_h}{\|\underline{\tau}_h\|_V}, \qquad \|f\|_h = \sup_{q_h \in Q_h} \frac{\langle f, q_h \rangle_h}{\|q_h\|_Q}. \tag{6.11}$$

We shall check later on conditions $(6.7)_1$ and (6.8). We merely notice that in the problem at hand $(6.7)_2$ trivially holds taking $\mathcal{B} = 1$ and that (6.9) is automatically satisfied by the RT finite element space. Moreover, using the Cauchy–Schwarz inequality, it is immediate to check that $(6.7)_3$ holds taking $\mathcal{C} = \|\sigma\|_{\infty,\Omega}$. Finally, condition (6.6) trivially holds since $\mathrm{Ker}(\widehat{B}_h^t) = \mathrm{Ker}(B_h^t) = \{\emptyset\}$.

We are in position to state the first main result of the section, which extends to the case $\sigma \geq 0$ [12, Proposition 2.16] and [36, Thm. 11.2].

THEOREM 6.2. *Let* $(\underline{J}, u)$ *be the solution of problem* (2.5)*, and let* $(\underline{J}_h, u_h)$ *be the solution of problem* (6.2)*. Assume that the hypotheses of Proposition* 6.1 *are satisfied; then the following a priori error bound holds:*

$$\begin{aligned}
&\|\underline{J} - \underline{J}_h\|_V + \|u - u_h\|_Q \leq (1 + \mathcal{M}(\mathcal{A} + \mathcal{B})) \inf_{\underline{w}_h \in V_h} \|\underline{J} - \underline{w}_h\|_V \\
&+ (1 + \mathcal{M}(\mathcal{B} + \mathcal{C})) \inf_{r_h \in Q_h} \|u - r_h\|_Q \\
&+ \mathcal{M} \sup_{\underline{v}_h \in V_h} \left[\frac{|a(\underline{J}, \underline{v}_h) - a_h(\underline{J}, \underline{v}_h)|}{\|\underline{v}_h\|_V} + \frac{|b(\underline{v}_h, u) - b_h(\underline{v}_h, u)|}{\|\underline{v}_h\|_V} \right] \\
&+ \mathcal{M} \sup_{q_h \in Q_h} \left[\frac{|b(\underline{J}, q_h) - b_h(\underline{J}, q_h)|}{\|q_h\|_Q} + \frac{|c(u, q_h) - c_h(u, q_h)|}{\|q_h\|_Q} \right] \\
&+ \mathcal{M} \left[\sup_{\underline{v}_h \in V_h} \frac{|\langle g, \underline{v}_h \rangle - \langle g, \underline{v}_h \rangle_h|}{\|\underline{v}_h\|_V} + \sup_{q_h \in Q_h} \frac{|\langle f, q_h \rangle - \langle f, q_h \rangle_h|}{\|q_h\|_Q} \right].
\end{aligned} \tag{6.12}$$

Proof. It is a nontrivial extension of the proof of [12, Proposition 2.11] which holds in the case of exact integration. For *any* couple of functions $(\tilde{\underline{J}}_h, \tilde{u}_h) \in (V_h \times Q_h)$, let us consider the following problem, which is completely equivalent to problem (6.2):

$$\left\{ \begin{array}{rcl}
a_h(\tilde{\underline{J}}_h - \underline{J}_h, \underline{\tau}_h) + b_h(\underline{\tau}_h, \tilde{u}_h - u_h) & = & a_h(\tilde{\underline{J}}_h, \underline{\tau}_h) + b_h(\underline{\tau}_h, \tilde{u}_h) - \langle g, \underline{\tau}_h \rangle \\
 & + & \langle g, \underline{\tau}_h \rangle - \langle g, \underline{\tau}_h \rangle_h \qquad \forall \underline{\tau}_h \in V_h, \\
-b_h(\tilde{\underline{J}}_h - \underline{J}_h, q_h) + c_h(\tilde{u}_h - u_h, q_h) & = & -b_h(\tilde{\underline{J}}_h, q_h) + c_h(\tilde{u}_h, q_h) - \langle f, q_h \rangle \\
 & + & \langle f, q_h \rangle - \langle f, q_h \rangle_h \qquad \forall q_h \in Q_h.
\end{array} \right.$$

Therefore, it turns out that the couple $(\tilde{\underline{J}}_h - \underline{J}_h, \tilde{u}_h - u_h) \in (V_h \times Q_h)$ is the solution of a problem in the form (6.2) with right-hand side $G = G_1 + G_2 \in V_h'$ and $F = F_1 + F_2 \in Q_h'$ (see [12] for a precise definition of these spaces) given by

$$\begin{aligned}
&G_1 : \underline{\tau}_h \to a_h(\tilde{\underline{J}}_h, \underline{\tau}_h) + b_h(\underline{\tau}_h, \tilde{u}_h) - \langle g, \underline{\tau}_h \rangle, \qquad && G_2 : \underline{\tau}_h \to \langle g, \underline{\tau}_h \rangle - \langle g, \underline{\tau}_h \rangle_h, \\
&F_1 : q_h \to -b_h(\tilde{\underline{J}}_h, q_h) + c_h(\tilde{u}_h, q_h) - \langle f, q_h \rangle, \qquad && F_2 : q_h \to \langle f, q_h \rangle - \langle f, q_h \rangle_h.
\end{aligned}$$

Using the stability estimate (6.10), we get

$$\begin{aligned}\|\tilde{\underline{J}}_h - \underline{J}_h\|_V + \|\tilde{u}_h - u_h\|_Q \leq \mathcal{M}\Bigg(&\sup_{\underline{v}_h \in V_h} \frac{\Big|a_h(\tilde{\underline{J}}_h, \underline{v}_h) + b_h(\underline{v}_h, \tilde{u}_h) - \langle g, \underline{v}_h\rangle\Big|}{\|\underline{v}_h\|_V} \\ + \sup_{q_h \in Q_h} \frac{\Big|-b_h(\tilde{\underline{J}}_h, q_h) + c_h(\tilde{u}_h, q_h) - \langle f, q_h\rangle\Big|}{\|q_h\|_Q} &+ \sup_{\underline{v}_h \in V_h} \frac{|\langle g, \underline{v}_h\rangle - \langle g, \underline{v}_h\rangle_h|}{\|\underline{v}_h\|_V} \\ + \sup_{q_h \in Q_h} \frac{|\langle f, q_h\rangle - \langle f, q_h\rangle_h|}{\|q_h\|_Q}\Bigg)&.\end{aligned} \tag{6.13}$$

Let us label the first two terms in the right-hand side of (6.13) by E_1, E_2; next, notice that since $V_h \subset V$ and $Q_h \subset Q$, we have $\langle g, \underline{v}_h\rangle = a(\underline{J}, \underline{v}_h) + b(\underline{v}_h, u)$ and $\langle f, q_h\rangle = -b(\underline{J}, q_h) + c(u, q_h)$. Concerning E_1, we have

$$E_1 = \sup_{\underline{v}_h \in V_h} \frac{\Big|a_h(\tilde{\underline{J}}_h, \underline{v}_h) + b_h(\underline{v}_h, \tilde{u}_h) - a(\underline{J}, \underline{v}_h) - b(\underline{v}_h, u)\Big|}{\|\underline{v}_h\|_V}. \tag{6.14}$$

Add and subtract $a_h(\underline{J}, \underline{v}_h)$ and $b_h(\underline{v}_h, u)$ in (6.14); this can be done since $a_h(\cdot,\cdot)$ and $b_h(\cdot,\cdot)$ are well defined on V and Q. Then, using the triangular and Cauchy–Schwarz inequalities and the continuity of a_h and b_h, we get

$$\begin{aligned}E_1 \leq &\sup_{\underline{v}_h \in V_h} \frac{|a(\underline{J}, \underline{v}_h) - a_h(\underline{J}, \underline{v}_h)|}{\|\underline{v}_h\|_V} + \mathcal{A}\|\underline{J} - \tilde{\underline{J}}_h\|_V + \sup_{\underline{v}_h \in V_h} \frac{|b(\underline{v}_h, u) - b_h(\underline{v}_h, u)|}{\|\underline{v}_h\|_V} \\ &+ \mathcal{B}\|u - \tilde{u}_h\|_Q.\end{aligned}$$

A completely analogous procedure on E_2 yields, adding and subtracting $b_h(\underline{J}, q_h)$ and $c_h(u, q_h)$,

$$\begin{aligned}E_2 \leq &\sup_{q_h \in Q_h} \frac{|b(\underline{J}, q_h) - b_h(\underline{J}, q_h)|}{\|q_h\|_Q} + \mathcal{B}\|\underline{J} - \tilde{\underline{J}}_h\|_V + \sup_{q_h \in Q_h} \frac{|c(u, q_h) - c_h(u, q_h)|}{\|q_h\|_Q} \\ &+ \mathcal{C}\|u - \tilde{u}_h\|_Q.\end{aligned}$$

Concluding, we obtain

$$\|\tilde{\underline{J}}_h - \underline{J}_h\|_V + \|\tilde{u}_h - u_h\|_Q \leq \mathcal{M}(\mathcal{A} + \mathcal{B})\|\underline{J} - \tilde{\underline{J}}_h\|_V + \mathcal{M}(\mathcal{B} + \mathcal{C})\|u - \tilde{u}_h\|_Q + \mathcal{M}\mathcal{E},$$

where $\mathcal{E}$ gathers all the other consistency error terms. Using the triangular inequality

$$\|\underline{J} - \underline{J}_h\|_V + \|u - u_h\|_Q \leq \|\underline{J} - \tilde{\underline{J}}_h\|_V + \|\tilde{\underline{J}}_h - \underline{J}_h\|_V + \|u - \tilde{u}_h\|_Q + \|\tilde{u}_h - u_h\|_Q,$$

we finally get

$$\|\underline{J} - \underline{J}_h\|_V + \|u - u_h\|_Q \leq (1 + \mathcal{M}(\mathcal{A} + \mathcal{B}))\|\underline{J} - \tilde{\underline{J}}_h\|_V + (1 + \mathcal{M}(\mathcal{B} + \mathcal{C}))\|u - \tilde{u}_h\|_Q + \mathcal{M}\mathcal{E},$$

from which, taking the infimum on $\tilde{\underline{J}}_h \in V_h$ and $\tilde{u}_h \in Q_h$, estimate (6.12) follows. □

In view of the error analysis, the following corollary can be derived from Theorem 6.2.

COROLLARY 6.3. *Under the same hypotheses as in Theorem* 6.2, *we have*

$$\begin{aligned}
&\|\underline{J}-\underline{J}_h\|_V + \|u-u_h\|_Q \le (1+\mathcal{M}(2(\mathcal{A}+\mathcal{B})+\gamma+\beta)) \inf_{\underline{w}_h\in V_h} \|\underline{J}-\underline{w}_h\|_V \\
&+ (1+\mathcal{M}(2(\mathcal{B}+\mathcal{C})+\beta+\delta)) \inf_{r_h\in Q_h} \|u-r_h\|_Q \\
&+\mathcal{M} \inf_{\underline{w}_h\in V_h} \sup_{\underline{v}_h\in V_h} \frac{|a(\underline{w}_h,\underline{v}_h)-a_h(\underline{w}_h,\underline{v}_h)|}{\|\underline{v}_h\|_V} + \mathcal{M} \inf_{r_h\in Q_h} \sup_{\underline{v}_h\in V_h} \frac{|b(\underline{v}_h,r_h)-b_h(\underline{v}_h,r_h)|}{\|\underline{v}_h\|_V} \\
&+\mathcal{M} \inf_{\underline{w}_h\in V_h} \sup_{q_h\in Q_h} \frac{|b(\underline{w}_h,q_h)-b_h(\underline{w}_h,q_h)|}{\|q_h\|_Q} + \mathcal{M} \inf_{r_h\in Q_h} \sup_{q_h\in Q_h} \frac{|c(r_h,q_h)-c_h(r_h,q_h)|}{\|q_h\|_Q} \\
&+\mathcal{M}\left[\sup_{\underline{v}_h\in V_h} \frac{|\langle g,\underline{v}_h\rangle - \langle g,\underline{v}_h\rangle_h|}{\|\underline{v}_h\|_V} + \sup_{q_h\in Q_h} \frac{|\langle f,q_h\rangle - \langle f,q_h\rangle_h|}{\|q_h\|_Q}\right],
\end{aligned}$$

where γ, β, and δ are the constants of continuity of $a(\cdot,\cdot)$, $b(\cdot,\cdot)$, and $c(\cdot,\cdot)$, respectively.

Proof. The proof follows by rewriting $(\underline{J},u)$ in the right-hand side of (6.12) as $(\underline{J}-\underline{w}_h+\underline{w}_h,\ u-r_h+r_h)$, respectively, where $\underline{w}_h$ and r_h are the same functions as those with respect to the infima in (6.12). □

We conclude the section with the error estimate that establishes the $\mathcal{O}(h)$ convergence of the family of mixed finite volume schemes (5.7).

THEOREM 6.4. *Assume that the solution $(\underline{J},u)$ of problem* (2.5) *is such that $(\underline{J},u)\in(H^1(\Omega))^2\times H^1(\Omega)$ and $\mathrm{div}\underline{J}\in H^1(\Omega)$. Then there exist two positive constants $\mathcal{C}_1$ and $\mathcal{C}_2$, depending on u, $\underline{J}$, α, σ, and f but independent of h, such that, for h sufficiently small, the solution $(\underline{J}_h,u_h)$ of problem* (6.2) *satisfies*

$$\|\underline{J}-\underline{J}_h\|_V + \|u-u_h\|_Q \le h\,(\mathcal{C}_1+\mathcal{C}_2 h)\,. \tag{6.15}$$

We emphasize that Theorem 6.4 holds irrespectively of the choice of the average $\overline{\alpha}_{l_{kj}}$ in (5.7), the only requirement being that

$$\min_{\underline{x}\in\mathcal{L}_{l_{kj}}}(\alpha(\underline{x})) \le \overline{\alpha}_{l_{kj}} \le \max_{\underline{x}\in\mathcal{L}_{l_{kj}}}(\alpha(\underline{x})) \qquad \forall\mathcal{L}_{l_{kj}}\in\mathcal{L}_h. \tag{6.16}$$

The proof of Theorem 6.4 is carried out in the next section.

7. Error analysis of the mixed finite volume methods.

To prove (6.15) we must first check the basic assumptions of Theorem 6.2 in the case of the family of mixed finite volume methods (5.7) and then give an estimate of the extra terms coming from numerical integration.

7.1. Analysis of the approximate bilinear form.

In this section we check continuity and coercivity on $\mathrm{Ker}(\widehat{B}_h)$ of the approximate bilinear form $a_h(\cdot,\cdot)$ in (6.3).

LEMMA 7.1. *There exist positive constants $\mathcal{A}$ and a_0, independent of h, such that*

$$\begin{aligned}
&|a_h(\underline{p}_h,\underline{q}_h)| \le \mathcal{A}\|\underline{p}_h\|_V\|\underline{q}_h\|_V \qquad \forall\underline{p}_h,\ \underline{q}_h\in V_h, \\
&a_h(\underline{w}_h,\underline{w}_h) \ge a_0\|\underline{w}_h\|^2_{0,\Omega}, \qquad \forall\underline{w}_h\in\widehat{\mathcal{V}}_h.
\end{aligned} \tag{7.1}$$

Proof. To prove (7.1), let us pick up a triangle $T_k\in\mathcal{T}_h$ and set $\underline{p}_h|_{T_k}=\sum_{i=1}^3 P_i\underline{\tau}_i$, $\underline{q}_h|_{T_k}=\sum_{i=1}^3 Q_i\underline{\tau}_i$, $\underline{w}_h|_{T_k}=\sum_{i=1}^3 W_i\underline{\tau}_i$, and $\gamma_{ki}=d_{k,i}/|l_i|$, where P_i, Q_i, and W_i are the fluxes of $\underline{p}_h$, $\underline{q}_h$, and $\underline{w}_h$ across edge l_i and $d_{k,i}$ is the distance between the circumcenter C_k of T_k and edge l_i (see section 5). We also let $\mathcal{R}_{T_k} = \cup_{i\,=\,1,3}\mathcal{L}_{l_i}$. Notice that here we will use a local numbering of the edges and the related quantities. Moreover, for brevity, the subscript k will be always dropped. The element approximate bilinear form $a_h^T(\cdot,\cdot)$ can be written as

$$a_h^T(\underline{p}_h, \underline{q}_h) = \sum_{i=1}^{3} \overline{\alpha}_{l_i} P_i Q_i \gamma_i.$$

Notice that, using (3.1), we have

$$\max_{i=1,3} |\gamma_i| \le \frac{D_T}{\rho_T} \le \mathcal{K},$$

which holds both for acute and obtuse triangles. Therefore, since $\overline{\alpha}$ is an average of α,

$$|a_h^T(\underline{p}_h, \underline{q}_h)| \|\alpha\|_{\infty,\mathcal{R}_T} \sum_{i=1}^{3} |P_i||Q_i| \le \mathcal{K}\|\alpha\|_{\infty,\Omega} \sum_{i=1}^{3} |P_i||Q_i|. \tag{7.2}$$

Let $\underline{x} = F_T(\widehat{\underline{x}}) = B_T\widehat{\underline{x}} + \underline{x}_0$ be the usual affine mapping between the reference unit triangle $\widehat{T}$ and T. Let also $\widehat{h} = \sqrt{2}$ be the diameter of $\widehat{T}$, and let $\mathcal{J}_T = \det(B_T)$ denote the (constant) Jacobian matrix of the transformation. Given any vector-valued function $\widehat{\underline{\psi}} \in (H^1(\widehat{T}))^2$, we associate with $\widehat{\underline{\psi}}$ the function $\underline{\psi}$ defined on T by

$$\underline{\psi} = \frac{1}{\mathcal{J}_T} B_T \widehat{\underline{\psi}} \circ F_T^{-1} \equiv \mathcal{P}\widehat{\underline{\psi}}(\widehat{\underline{x}}),$$

where $\mathcal{P}(\cdot)$ is the *Piola mapping* (see, e.g., [35, (3.17)] or, for a different definition, [12, (1.45)] and is such that

$$\int_{\widehat{l}_i} \widehat{\underline{\psi}} \cdot \widehat{\underline{n}} d\widehat{s} = \int_{l_i} \underline{\psi} \cdot \underline{n} ds, \qquad i = 1, 3, \tag{7.3}$$

as can be easily checked by taking $\widehat{\varphi} = \chi(\widehat{l}_i)$ in formula (3.19) of [35]. Then take $\widehat{\underline{\psi}} \in \mathbb{D}_1 \ \forall \widehat{\underline{x}} \in \widehat{T}$, i.e., $\widehat{\underline{\psi}} = \sum_{i=1}^{3} \widehat{\Psi}_i \widehat{\underline{\tau}}_i$; clearly, each edge flux $\widehat{\Psi}_i$ can be identified with a continuous linear functional on the space $(L^2(\widehat{T}))^2$, denoted as $L_i(\widehat{\underline{\psi}})$ and with norm

$$\|L_i\|_{\mathcal{L}(\mathbb{D}_1;\mathbb{R})} = \sup_{\substack{\widehat{\underline{\psi}} \in \mathbb{D}_1 \\ \widehat{\underline{\psi}} \neq \mathbf{0}}} \frac{\left| \int_{\widehat{l}_i} \widehat{\underline{\psi}} \cdot \widehat{\underline{n}} d\widehat{s} \right|}{\|\widehat{\underline{\psi}}\|_{0,\widehat{T}}}, \qquad i = 1, 3,$$

where, as usual, $\mathcal{L}(\mathcal{V};\mathcal{W})$ is the set of linear continuous functionals from $\mathcal{V}$ into $\mathcal{W}$. It can be checked that $\max_{i=1,3} \|L_i\|_{\mathcal{L}(\mathbb{D}_1;\mathbb{R})} = \sqrt{6}$, so that we get

$$\sum_{i=1}^{3} |\widehat{P}_i||\widehat{Q}_i| \le \sum_{i=1}^{3} \|L_i\|^2_{\mathcal{L}(\mathbb{D}_1;\mathbb{R})} \|\widehat{\underline{p}}_h\|_{0,\widehat{T}} \|\widehat{\underline{q}}_h\|_{0,\widehat{T}} \le 18 \|\widehat{\underline{p}}_h\|_{0,\widehat{T}} \|\widehat{\underline{q}}_h\|_{0,\widehat{T}}. \tag{7.4}$$

Next, we recall that for any function $\widehat{\underline{\psi}} \in (L^2(\widehat{T}))^2$ the following result holds (cf. formula (3.21) in [35] with $l = 0$):

$$\|\widehat{\underline{\psi}}\|_{0,\widehat{T}} \le \|B_T^{-1}\| |\mathcal{J}_T|^{1/2} \|\underline{\psi}\|_{0,T}, \tag{7.5}$$

where $\|\cdot\|$ is the spectral matrix norm. Using (7.3), (7.4), (7.5), standard scaling arguments (see, e.g., [34, p. 86]) and (3.1), we finally obtain

$$|a_h^T(\underline{p}_h, \underline{q}_h)| \leq 36\mathcal{K}^3\|\alpha\|_{\infty,\Omega}\|\underline{p}_h\|_{H(\mathrm{div};T)}\|\underline{q}_h\|_{H(\mathrm{div};T)}, \tag{7.6}$$

from which, summing over all the triangles of $\mathcal{T}_h$ and using the Cauchy–Schwarz inequality, the estimate $(7.1)_1$ follows with $\mathcal{A} = 36\mathcal{K}^3\|\alpha\|_{\infty,\Omega}$. The proof of $(7.1)_2$ is straightforward; for any function $\underline{w}_h$ such that $\underline{w}_h|_T \in (\mathbb{P}_0)^2$ we have

$$a_h^T(\underline{w}_h, \underline{w}_h) \geq \inf_{\underline{x}\in\mathcal{R}_T}(\alpha)\sum_{i=1}^{3} W_i^2\gamma_i \geq \alpha_0\sum_{i=1}^{3} W_i^2\gamma_i, \tag{7.7}$$

where $\alpha_0 = \inf_\Omega(\alpha)$ and W_i is the flux of $\underline{w}_h$ across edge l_i. In [9] it has been proved that $\sum_{i=1}^{3} W_i^2\gamma_i = (\underline{w}_h, \underline{w}_h)_{0,T} = \|\underline{w}_h\|_{0,T}^2$, so that, summing (7.7) over all the triangles in $\mathcal{T}_h$ and using the Cauchy–Schwarz inequality, we finally get $(7.1)_2$ with $a_0 = \alpha_0$ and $\widehat{\mathcal{V}}_h = \{\underline{w} \in (L^2(\Omega))^2 \,|\, \underline{w}|_T \in (\mathbb{P}_0)^2\ \forall T \in \mathcal{T}_h\}$. □

Recalling that the conditions in Proposition 6.1 about b_h and c_h have already been assessed, Theorem 6.2 applies for the convergence analysis of the family of generalized Galerkin methods (5.7).

7.2. Analysis of the quadrature error. In this section we deal with the quadrature errors occurring in the approximate linear and bilinear forms in the finite volume schemes (5.7). For this, we set $g = 0$ and $b_h(\cdot,\cdot) = b(\cdot,\cdot)$. Moreover, to avoid resorting to an interpolation-free approach (see [18], [36, pp. 132–133]) or to some suitable projection operator (see [34, sect. 3.5]), we require an extra regularity for the problem coefficients than asked for in section 2, i.e., assume henceforth that μ, σ, and f are given functions in $W^{1,\infty}(\Omega)$. We shall come back to the issue of coefficient regularity in Remark 7.4. Finally, throughout the section we denote by C a positive constant whose value is not necessarily the same at each occurrence.

We recall the interpolation estimate (see [36, formula (16.19)])

$$|v - \Pi v|_{m,\infty,T} \leq C\frac{h_T^{k+1}}{\rho_T^m}|v|_{k+1,\infty,T}, \tag{7.8}$$

where $v \in W^{k+1,\infty}(T)$ for $k \geq 0$, C is a positive constant, and $\Pi v : T \to \mathbb{R}$ is the local interpolation operator of v associated with the finite element space $\mathbb{P}_k$.

For any $T \in \mathcal{T}_h$, we denote by $\Pi_{0,T}$ the local $\mathbb{P}_0$-interpolation operator of σ such that $\Pi_{0,T}\sigma = \sigma(C_T)$. Using (7.8) with $m = 0$, $k = 0$ and letting C_c be a positive constant yields

$$\begin{aligned}|c(r_h, q_h) - c_h(r_h, q_h)| &\leq \sum_{T\in\mathcal{T}_h}|\sigma - \Pi_{0,T}\sigma|_{0,\infty,T}\left(\int_T |r_h||q_h|dT\right)\\ &\leq \sum_{T\in\mathcal{T}_h} C_c h_T|\sigma|_{1,\infty,T}\|r_h\|_{0,T}\|q_h\|_{0,T} \leq C_c h|\sigma|_{1,\infty,\Omega}\|r_h\|_Q\|q_h\|_Q\end{aligned}$$

so that the quadrature error for $c(\cdot,\cdot)$ can be estimated as

$$\sup_{q_h\in Q_h}\frac{|c(r_h, q_h) - c_h(r_h, q_h)|}{\|q_h\|_Q} \leq C_c h|\sigma|_{1,\infty,\Omega}\|r_h\|_Q. \tag{7.9}$$

In a similar way we obtain

$$\sup_{q_h\in Q_h}\frac{|\langle f, q_h\rangle - \langle f, q_h\rangle_h|}{\|q_h\|_Q} \leq C_f|\Omega|^{1/2}h|f|_{1,\infty,\Omega}. \tag{7.10}$$

Let us now give a bound for the quadrature error associated with $a_h(\cdot,\cdot)$. With this aim, let $\underline{p}_h$ and $\underline{q}_h$ be any two functions in V_h. Using the same notation as in section 7.1, for any $T \in \mathcal{T}_h$ we set $\underline{p}_h|_T = \sum_{i=1}^{3} P_i \underline{\tau}_i$ and $\underline{q}_h|_T = \sum_{i=1}^{3} Q_i \underline{\tau}_i$. Then we recall two approximation results that will be useful in the forthcoming analysis. The first one is an immediate consequence of Theorem 15.3 in [36] with $k = m = 0$ and $p = q = \infty$.

Lemma 7.2. *Let $\widehat{S}$ be an open subset of $\mathbb{R}^2$, and let $\widehat{\Pi}$ be a linear and continuous mapping from $W^{1,\infty}(\widehat{S})$ to $L^\infty(\widehat{S})$ which satisfies $\widehat{\Pi}\widehat{p} = \widehat{p}, \forall \widehat{p} \in \mathbb{P}_0(\widehat{S})$. For any open set S that is affine-equivalent to the set $\widehat{S}$, let Π_S be defined by $\Pi_S v = \widehat{\Pi}\widehat{v} \circ F^{-1}$ for all functions $\widehat{v} \in W^{1,\infty}(\widehat{S})$ and $v \in W^{1,\infty}(S)$ such that $v = \widehat{v} \circ F^{-1}$, where $F : \widehat{S} \mapsto S$ is an invertible affine mapping such that $F(\widehat{S}) = S$. Then there exists a constant C (depending on $\widehat{\Pi}$ and $\widehat{S}$) such that*

$$(7.11) \qquad \|v - \Pi_S v\|_{\infty,S} \le C h_S |v|_{1,\infty,S} \qquad \forall v \in W^{1,\infty}(S),$$

where $h_S = \operatorname{diam} S$.

The second result has been proved in [9]:

$$(7.12) \quad \left| \left(\underline{p}_h, \underline{q}_h\right)_{0,T} - \left(\underline{p}_h, \underline{q}_h\right)_{h,0,T} \right| \le \left(\frac{h_T}{2\sqrt{6}} + \frac{h_T^2}{48} \right) \|\underline{p}_h\|_{H(\mathrm{div};T)} \|\underline{q}_h\|_{H(\mathrm{div};T)}.$$

Let $\Pi_T \alpha = \widetilde{\alpha}_T$ be a suitable average of the function α over T satisfying Lemma 7.2. For instance, we can take $\widetilde{\alpha}_T$ equal to the value of α at the centroid of T. The quadrature error $a^T(\underline{p}_h, \underline{q}_h) - a_h^T(\underline{p}_h, \underline{q}_h)$ can then be split as

$$a^T(\underline{p}_h, \underline{q}_h) - a_h^T(\underline{p}_h, \underline{q}_h) = \mathcal{E}_1(\underline{p}_h, \underline{q}_h) + \mathcal{E}_2(\underline{p}_h, \underline{q}_h) + \mathcal{E}_3(\underline{p}_h, \underline{q}_h),$$

where

$$\mathcal{E}_1(\underline{p}_h, \underline{q}_h) = \left(\alpha \underline{p}_h, \underline{q}_h\right)_{0,T} - \left(\widetilde{\alpha}_T \underline{p}_h, \underline{q}_h\right)_{0,T} = \int_T (\alpha - \widetilde{\alpha}_T) \underline{p}_h \cdot \underline{q}_h dT,$$

$$\mathcal{E}_2(\underline{p}_h, \underline{q}_h) = \left(\widetilde{\alpha}_T \underline{p}_h, \underline{q}_h\right)_{0,T} - \left(\widetilde{\alpha}_T \underline{p}_h, \underline{q}_h\right)_{h,0,T} = \int_T \widetilde{\alpha}_T \underline{p}_h \cdot \underline{q}_h dT - \sum_{i=1}^{3} \widetilde{\alpha}_T P_i Q_i \gamma_i,$$

$$\mathcal{E}_3(\underline{p}_h, \underline{q}_h) = \left(\widetilde{\alpha}_T \underline{p}_h, \underline{q}_h\right)_{h,0,T} - a_h^T(\underline{p}_h, \underline{q}_h) = \sum_{i=1}^{3} (\widetilde{\alpha}_T - \overline{\alpha}_{l_i}) P_i Q_i \gamma_i.$$

Using (7.11) and the Cauchy–Schwarz inequality, we get

$$|\mathcal{E}_1(\underline{p}_h, \underline{q}_h)| \le C h_T |\alpha|_{1,\infty,T} \|\underline{p}_h\|_{H(\mathrm{div};T)} \|\underline{q}_h\|_{H(\mathrm{div};T)},$$

while (7.12) yields

$$|\mathcal{E}_2(\underline{p}_h, \underline{q}_h)| \le \widetilde{\alpha}_T \left(\frac{h_T}{2\sqrt{6}} + \frac{h_T^2}{48} \right) \|\underline{p}_h\|_{H(\mathrm{div};T)} \|\underline{q}_h\|_{H(\mathrm{div};T)}.$$

Recalling that $\widetilde{\alpha}_T$ and $\overline{\alpha}_{l_i}$ are averages of α over $T \subset \mathcal{R}_T$ and $\mathcal{L}_{l_i} \subset \mathcal{R}_T$, respectively, we can immediately conclude that

$$\begin{aligned} |\mathcal{E}_3(\underline{p}_h, \underline{q}_h)| &\le \left(\max_{\underline{x} \in \mathcal{R}_T} (\alpha) - \min_{\underline{x} \in \mathcal{R}_T} (\alpha) \right) \sum_{i=1}^{3} |P_i|\,|Q_i|\,|\gamma_i| \\ &\le |\alpha|_{1,\infty,\mathcal{R}_T} D_T \sum_{i=1}^{3} |P_i|\,|Q_i|\,|\gamma_i \le 36 \mathcal{K}^4 |\alpha|_{1,\infty,\mathcal{R}_T} h_T \|\underline{p}_h\|_{H(\mathrm{div};T)} \|\underline{q}_h\|_{H(\mathrm{div};T)}, \end{aligned}$$

where we have used (3.2) and (7.6) with $\alpha = 1$.

Gathering the previous estimates and overestimating the norms on local sets with the same norms over Ω yields $\forall T \in \mathcal{T}_h$

$$\begin{aligned}&|a^T(\underline{p}_h, \underline{q}_h) - a_h^T(\underline{p}_h, \underline{q}_h)|\\ &\quad \leq \left((C + 36\mathcal{K}^4)|\alpha|_{1,\infty,\Omega} + \|\alpha\|_{\infty,\Omega}\left(\frac{1}{2\sqrt{6}} + \frac{h}{48}\right)\right) h\|\underline{p}_h\|_{H(\mathrm{div};T)}\|\underline{q}_h\|_{H(\mathrm{div};T)}.\end{aligned}$$

Letting

$$\Phi = \Phi(h, \mathcal{T}_h, \alpha) = \left((C + 36\mathcal{K}^4)|\alpha|_{1,\infty,\Omega} + \|\alpha\|_{\infty,\Omega}\left(\frac{1}{2\sqrt{6}} + \frac{h}{48}\right)\right),$$

summing over all the mesh triangles, and using the Cauchy–Schwarz inequality finally gives

$$\sup_{\underline{q}_h \in V_h} \frac{|a(\underline{p}_h, \underline{q}_h) - a_h(\underline{p}_h, \underline{q}_h)|}{\|\underline{q}_h\|_V} \leq \Phi h \|\underline{p}_h\|_{H(\mathrm{div};\Omega)}. \tag{7.13}$$

Taking, in (7.9), r_h equal to the L^2-projection of u, we get

$$\sup_{q_h \in Q_h} \frac{|c(r_h, q_h) - c_h(r_h, q_h)|}{\|q_h\|_Q} \leq C_c h|\sigma|_{1,\infty,\Omega}\|u\|_Q. \tag{7.14}$$

Analogously, taking, in (7.13), $\underline{p}_h$ equal to the RT-interpolant to $\underline{J}$ of lowest degree $\pi_h\underline{J}$ and recalling that (see [36, p. 583])

$$\|\pi_h\underline{J}\|_V \leq C\left(h|\underline{J}|_{1,\Omega} + \|\mathrm{div}\underline{J}\|_{0,\Omega}\right),$$

we get

$$\sup_{\underline{q}_h \in V_h} \frac{|a(\underline{p}_h, \underline{q}_h) - a_h(\underline{p}_h, \underline{q}_h)|}{\|\underline{q}_h\|_V} \leq C\Phi h\left(h|\underline{J}|_{1,\Omega} + \|\mathrm{div}\underline{J}\|_{0,\Omega}\right). \tag{7.15}$$

From Corollary 6.3, using the estimates (7.14), (7.10), and (7.15), letting

$$M = \max\left((1 + \mathcal{M}(2(\mathcal{A} + \mathcal{B}) + \gamma + \beta)), (1 + \mathcal{M}(2(\mathcal{B} + \mathcal{C}) + \beta + \delta))\right),$$

and denoting by C_k, $k = 1, 3$, some positive constants, we finally obtain the convergence result (6.15):

$$\begin{aligned}&\|\underline{J} - \underline{J}_h\|_V + \|u - u_h\|_Q \leq Mh\left[|u|_{1,\Omega} + |\underline{J}|_{1,\Omega} + |\mathrm{div}\underline{J}|_{1,\Omega}\right]\\ &\quad + C_1\Phi h\left(h\|\underline{J}\|_{1,\Omega} + \|\mathrm{div}\underline{J}\|_{0,\Omega}\right)\\ &\quad + C_2 h|\sigma|_{1,\infty,\Omega}\|u\|_Q + C_3 h|\Omega|^{1/2}|f|_{1,\infty,\Omega}.\end{aligned} \tag{7.16}$$

REMARK 7.3. *We remark that the $\mathcal{O}(h)$ convergence proved above for the mixed finite volume methods* (5.7) *is optimal and that it has been obtained without giving up the M-matrix property of the schemes. This feature, together with the reduced computational cost, makes the novel methods quite attractive and competitive with respect to the standard dual mixed approaches with exact integration* [27, 26] *and to* *dual mixed schemes with numerical integration recently proposed for the approximation of problem* (2.1) *in the case* $\sigma = 0$ [9, 10]. *Finally, the genuine finite volume flavor of the novel methods allows for the basic conservation properties (mass and interelement fluxes) to be satisfied, even in the presence of jumps in the coefficient of the problem (as happens, for instance, in porous media flows governed by Darcy's law* [20]*) or steep internal/boundary layers in the scalar unknown* u *(as happens in semiconductor device simulation using the drift-diffusion model* [24, 28, 31, 39]*). Numerical evidences of the accuracy and stability of the new formulation will be exhibited in the next section.*

REMARK 7.4. *The error estimate* (6.15) *has been obtained under stringent regularity assumptions on the problem coefficients. This is quite a standard situation when trying to derive a convergence result (see, e.g.,* [3, sect. 7]*). However, a more careful analysis reveals that the convergence result* (6.15) *still holds under the sole assumption that the coefficients* μ, σ *and the right-hand side* f *be locally smooth functions. Actually, assuming that* $\mu|_T$, $\sigma|_T$ *and* $f|_T$ *belong to* $W^{1,\infty}(T)$ *for all* $T \in \mathcal{T}_h$ *and using the same arguments as above, one can prove the following analogue of* (7.16)*:*

$$\begin{aligned}\|\underline{J} - \underline{J}_h\|_V + \|u - u_h\|_Q \leq Mh &\left[|u|_{1,\Omega} + \left(\sum_{T\in\mathcal{T}_h} |\underline{J}|^2_{1,T} \right)^{1/2} + \left(\sum_{T\in\mathcal{T}_h} |\text{div}\underline{J}|^2_{1,T} \right)^{1/2} \right] \\ &+ C_1 \widetilde{\Phi} h \left[h \left(\sum_{T\in\mathcal{T}_h} |\underline{J}|^2_{1,T} \right)^{1/2} + \|\text{div}\underline{J}\|_{0,\Omega} \right] \\ &+ C_2 h \max_{T\in\mathcal{T}_h} |\sigma|_{1,\infty,T} \|u\|_Q + C_3 h |\Omega|^{1/2} \max_{T\in\mathcal{T}_h} |f|_{1,\infty,T},\end{aligned}$$

where

$$\widetilde{\Phi} = (C + 36\mathcal{K}^4) \max_{T\in\mathcal{T}_h} |\alpha|_{1,\infty,T} + \max_{T\in\mathcal{T}_h} \|\alpha\|_{\infty,T} \left(\frac{1}{2\sqrt{6}} + \frac{h}{48} \right).$$

8. Numerical results. In this section we are going to validate numerically the family of mixed finite volume methods introduced in the present paper. With this aim we first need to characterize the choice of the average $\overline{\alpha}$ of the inverse diffusion coefficient α. Being that this matter is one-dimensional, we restrict our attention on the affine-equivalent interval $\mathcal{I} = [0, h]$ for any $h > 0$.

The obvious candidate for $\overline{\alpha}$ is the mean value of α over $\mathcal{I}$. Since we are interested in the inverse of $\overline{\alpha}$ (see (5.7)) and $\alpha = \mu^{-1}$, it follows that

$$\overline{\alpha}^{-1} = \left(\frac{\displaystyle\int_0^h \mu^{-1}(x)dx}{h} \right)^{-1} \equiv \mathcal{H}_{\mathcal{I}}(\mu), \tag{8.1}$$

where $\mathcal{H}_{\mathcal{I}}(\mu)$ denotes the *harmonic average* of μ over the interval $\mathcal{I}$.

Use of harmonic averaging for the diffusion coefficient μ is quite natural in mixed methods (see [7, 12]) and has been proved in one dimension to provide better results than the mean value, in particular when μ exhibits sharp variations on $\mathcal{I}$ or is even discontinuous. Typical instances of such behavior are flows in porous media (see [20] and the references cited therein) or electron and hole carrier flow in a semiconductor device (see [24, 13]).

It is clear that, except in trivial cases, the evaluation of (8.1) cannot be carried out. This, of course, demands for the use of a suitable quadrature formula. With this aim, define for any function $\phi : \mathcal{I} \rightarrow \mathbb{R}^+$ the *exponential interpolant* to ϕ as

$$\Pi_e\phi(x) = \exp\left\{\Pi_1\left[\ln(\phi(x))\right]\right\} = \phi_0 \left(\frac{\phi_h}{\phi_0}\right)^{\frac{x}{h}}, \qquad x \in \mathcal{I}, \tag{8.2}$$

where $\phi_0 = \phi(0)$, $\phi_h = \phi(h)$, and $\Pi_1\phi$ is the $\mathbb{P}_1$-interpolant to ϕ. The quadrature formula approximating (8.1) can then be defined as

$$\begin{aligned}\overline{\alpha}^{-1} \simeq \left(\frac{\displaystyle\int_0^h \Pi_e\mu^{-1}(x)dx}{h}\right)^{-1} &= \frac{\ln(1/\mu_h) - \ln(1/\mu_0)}{1/\mu_h - 1/\mu_0} \\ &= \left(\frac{\ln(\mu_0) - \ln(\mu_h)}{\mu_0 - \mu_h}\right)\mu_0\mu_h,\end{aligned} \tag{8.3}$$

which clearly satisfies (6.16). Assuming $\alpha \in W^{1,\infty}(\mathcal{I})$, it is easy to prove the following bound for the interpolation error:

$$\|\alpha - \Pi_e\alpha\|_{\infty,\mathcal{I}} \leq Ch\frac{\alpha_M}{\alpha_m}|\alpha|_{1,\infty,\mathcal{I}},$$

where α_M and α_m are the maximum and the minimum values of α over $\mathcal{I}$, respectively. We remark that (8.3) is *exact* if $\mu = e^{ax+b}$, $a, b \in \mathbb{R}$, $x \in \mathcal{I}$, as typically happens in the numerical approximation of the drift-diffusion semiconductor device equations (see [8, 13, 39]).

In this latter application the mixed finite volume scheme (5.7) with the quadrature (8.3) can be regarded as a two-dimensional generalization of the classical exponentially fitted Scharfetter–Gummel method [41]. The resulting scheme can be proved to recover the *exact* solution (u, $\underline{J}$) at the nodes of the dual mesh when $\mu = e^{ax+by}$, $a, b \in \mathbb{R}$, $x, y \in \overline{\Omega}$, $\sigma = 0$, $f = 0$, and suitable Dirichlet–Neumann boundary conditions are assumed in problem (2.1) (see for the proof [40] and [44], respectively, in the case of triangles and rectangles). This nice property is a special instance of the "patch-test" (see [36, Chap. V, sect. 34] and [23]) and turns out to be a sound indication for good behavior of a numerical scheme to deal with advection-dominated flow problems, as previously remarked in [44, 38].

Our second choice for $\overline{\alpha}^{-1}$ is the harmonic average of the piecewise constant extension to μ over $\mathcal{I}$

$$\overline{\alpha}^{-1} \simeq \left(\frac{\displaystyle\int_0^{\overline{x}} \mu_0^{-1}dx + \int_{\overline{x}}^h \mu_h^{-1}dx}{h}\right)^{-1} = \frac{\mu_0\mu_h}{\mu_h\overline{x}/h + \mu_0(1 - \overline{x}/h)}, \tag{8.4}$$

where it is assumed that $\mathcal{I}$ represents the segment connecting the circumcenters of two neighboring triangles T and T' so that $\overline{x}$ is the intersection between $\mathcal{I}$ and the edge common to T and T'. The average (8.4) seems to be quite promising in the presence of discontinuities of μ.

The last choice that we consider for $\overline{\alpha}^{-1}$ employs linear interpolation for μ. This leads to the trapezoidal quadrature formula

$$\overline{\alpha}^{-1} \simeq \frac{\displaystyle\int_0^h \Pi_1\mu(x)dx}{h} = \frac{\mu_0 + \mu_h}{2}. \tag{8.5}$$

Let us now deal with the numerical experiments. We henceforth assume that in (2.1) Ω is the unit square. Two test problems with available exact solutions have been considered; in the first test case five unstructured grids of triangular elements have been employed with average mesh sizes of 2^{-k} for $k = 3, \ldots, 7$. For the second test problem, which is of one-dimensional nature, eight grids of rectangular elements have been used with mesh sizes of 2^{-k} in the x-direction for $k = 3, \ldots, 10$. When applied to this example, the mixed finite volume scheme (5.7) reduces to a five-point difference scheme with a special average of the diffusion coefficient.

Suitably accurate integration formulae have been used to evaluate the $L^2(\Omega)$ and $H(\text{div}; \Omega)$ norms of the discretization errors $u - u_h$ and $\underline{J} - \underline{J}_h$. Precisely, a symmetric formula using 10 nodes on each element of the triangular grid has been employed in the first test case, while the nine-point Simpson formula has been adopted on each element in the quadrilateral grid in the second test case. We emphasize that all the numerical results presented below have been obtained using the midpoint quadrature formula to approximate the right-hand side in (5.2). In all the reported figures the symbols have the following meaning: "*" refers to the scheme using the average (8.5), "o" refers to the use of the average (8.3), and "□" refers to use of the average (8.4).

Test case 1. This test problem basically aims at checking the theoretical convergence properties of the novel method. Therefore, we take as exact solution the smooth function

$$u(x, y) = 16xy(x - 1)(y - 1)$$

such that $\|u\|_{\infty,\Omega} = 1$. The diffusion coefficient μ is

$$\mu(x, y) = \left(\frac{\mu_a + \mu_b}{2}\right)\left(1 + \frac{\mu_b - \mu_a}{\mu_a + \mu_b}\tanh(K(y - x))\right),$$

where $\mu_b > \mu_a > 0$ and K is a suitable constant. Notice that for $\mu_b/\mu_a \gg 1$ and $K \gg 1$, μ tends to a step function with jump equal to $\mu_b - \mu_a$ across the main diagonal of the unit square.

The first set of numerical results refers to the case $\mu_a = 1$, $\mu_b = 10$, and $K = 2$. The maximum values of $|\underline{J}|$ and $\text{div}\underline{J}$ are 36.05 and 129.6, respectively. Figures 4(a) and 4(b) show the L^2-norm and the discrete L^∞-norm of the error $u - u_h$, this latter norm being evaluated as

$$\|u - u_h\|_{\infty,C} = \max_{T_k \in \mathcal{T}_h} |u(\underline{x}_{C_k}) - u_k|.$$

Linear convergence with respect to the mesh size h is clearly observed for all of the considered averages in the case of the L^2-norm, while second-order convergence is exhibited by the method when the discrete L^∞-norm is used to measure convergence. This appears to be a (nodal) superconvergence of the mixed finite schemes and is to be ascribed to the special choice of the point of measurement of the convergence (i.e., the circumcenter of the triangle) which coincides with the center of the stencil of the method.

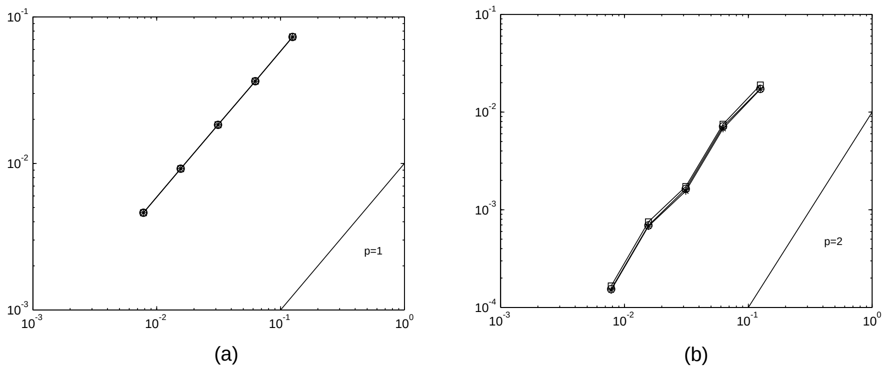

FIG. 4. *Discretization error $u - u_h$ for test case* 1: (a) *L^2-norm, $\mu_a = 1$, $\mu_b = 10$, $K = 2$;* (b) *discrete L^∞-norm, $\mu_a = 1$, $\mu_b = 10$, $K = 2$.*

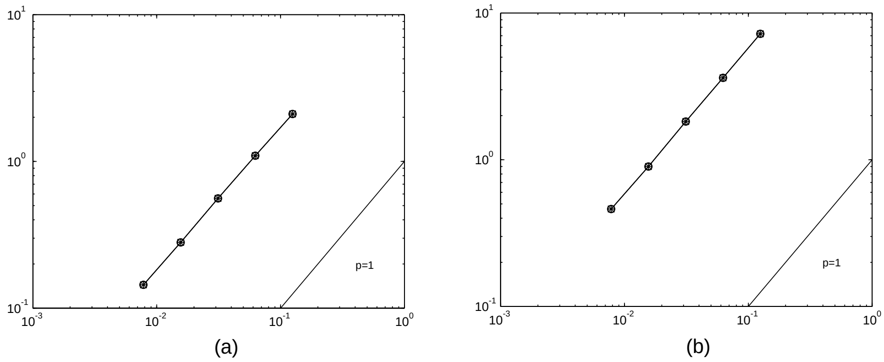

FIG. 5. *Test case* 1: (a) *L^2-norm of the discretization error $\underline{J} - \underline{J}_h$, $\mu_a = 1$, $\mu_b = 10$, $K = 2$;* (b) *graph norm of the discretization error $U - U_h = (u - u_h, \underline{J} - \underline{J}_h)$, $\mu_a = 1$, $\mu_b = 10$, $K = 2$.*

Figures 5(a) and 5(b) show the L^2-norm of the discretization error $\underline{J} - \underline{J}_h$ and the graph norm of the error $U - U_h \equiv (u - u_h, \underline{J} - \underline{J}_h)$ defined as

$$\|U - U_h\|_{V \times Q} = \left(\|u - u_h\|_{0,\Omega}^2 + \|\underline{J} - \underline{J}_h\|_{H(\mathrm{div};\Omega)}^2 \right)^{1/2}.$$

Linear convergence is clearly observed for all of the three averages.

The second set of numerical results refers to the case $\mu_a = 1$, $\mu_b = 1000$, and $K = 100$. The maximum values of $|\underline{J}|$ and $\mathrm{div}\underline{J}$ are 4000 and 16308.8, respectively (clearly much bigger than in the previous case). Figures 6(a) and 6(b) show that linear convergence in the L^2-norm is exhibited by all of the considered averages, while the schemes appear to be second-order accurate in the discrete L^∞-norm. Linear convergence is also observed for the discretization errors $\underline{J} - \underline{J}_h$ and $U - U_h$, as shown in Figures 7(a) and 7(b), respectively.

Test case 2. In the second test case, taken from [7], we check the performances of the three averages introduced in this section when the diffusion coefficient μ is discontinuous. With this aim, we consider the simple one-dimensional problem $-(\mu u')' =$

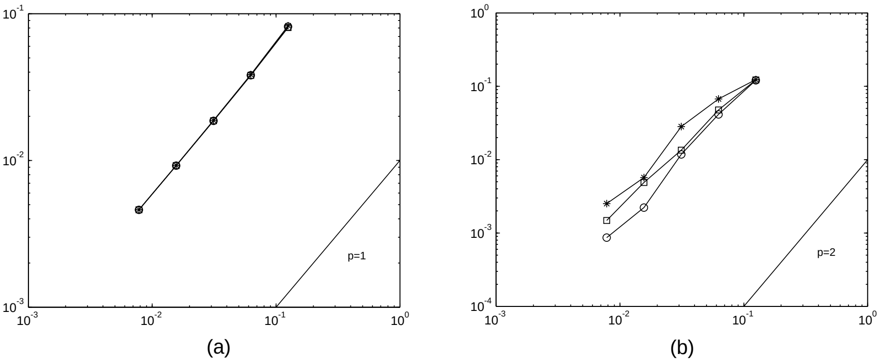

FIG. 6. *Discretization error $u - u_h$ for test case* 1: (a) *L^2-norm, $\mu_a = 1$, $\mu_b = 1000$, $K = 100$*; (b) *discrete L^∞ -norm, $\mu_a = 1$, $\mu_b = 1000$, $K = 100$.*

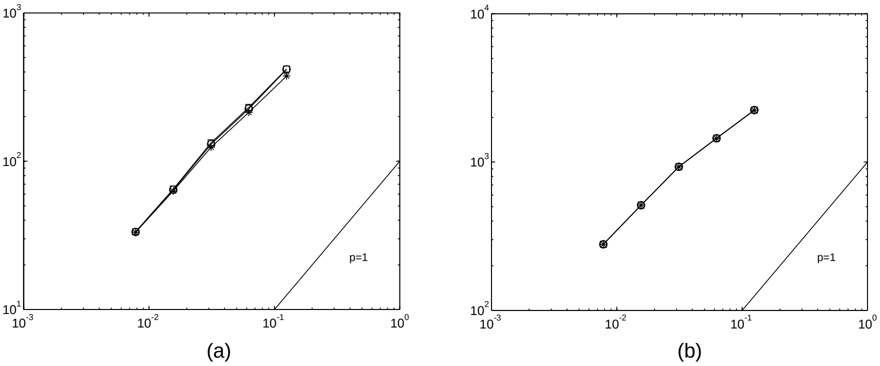

FIG. 7. *Test case* 1: (a) *L^2-norm of the discretization error $\underline{J} - \underline{J}_h$, $\mu_a = 1$, $\mu_b = 1000$, $K = 100$*; (b) *graph norm of the discretization error $U - U_h = (u - u_h, \underline{J} - \underline{J}_h)$, $\mu_a = 1$, $\mu_b = 1000$, $K = 100$.*

M^{-1} on the interval $(0, 1)$ with $u(0) = u(1) = 0$, where

$$M = \frac{\mu_a \beta^2}{2}, \quad \beta = \left(\frac{3}{4\mu_b} + \frac{1}{4\mu_a} - \gamma \right), \quad \mu(x) = \begin{cases} \mu_a, & 0 \le x < 0.5, \\ \mu_b, & 0.5 \le x \le 1, \end{cases}$$

again having $\mu_b > \mu_a > 0$ and having set $\gamma = (1 + 3\mu_a/\mu_b)/(4(\mu_a + \mu_b))$. The exact solution of this latter problem reads

$$u(x) = \frac{1}{M} \begin{cases} -\dfrac{x^2}{2\mu_a} + \beta x, & 0 \le x < 0.5, \\ -\dfrac{x^2}{2\mu_b} + \gamma x + \dfrac{1}{2\mu_b} - \gamma, & 0.5 \le x \le 1, \end{cases} \tag{8.6}$$

$$J(x) = \frac{1}{M} (\beta \mu_a - x), \quad x \in [0, 1], \tag{8.7}$$

and is such that $\|u\|_{\infty,\Omega} = 1$. Notice that the exact solution u, although continuous, does not belong to $H^2(0, 1)$.

Next we analyze a two-dimensional boundary value problem of the form (2.1) but with Dirichlet–Neumann boundary conditions, having as exact solution the function

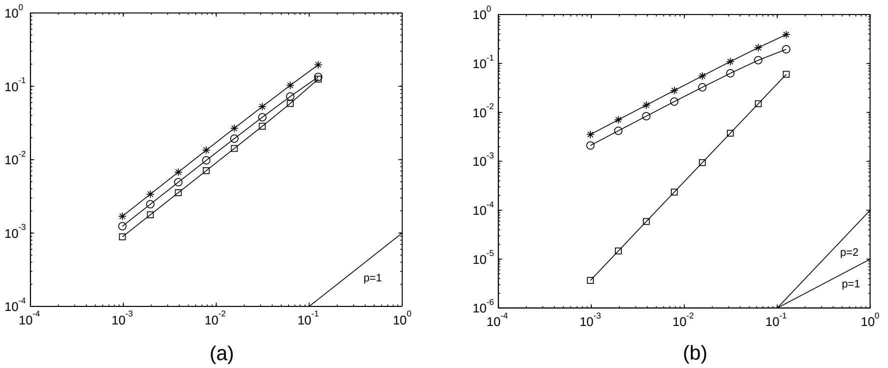

FIG. 8. *Discretization error* $u - u_h$ *for test case* 2: (a) L^2*-norm,* $\mu_a = 1, \mu_b = 100$; (b) *discrete* L^∞*-norm,* $\mu_a = 1, \mu_b = 100$.

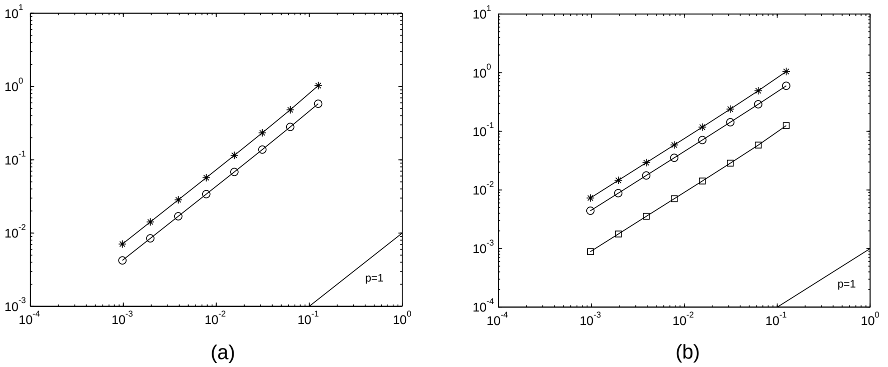

FIG. 9. *Test case* 2: (a) L^2*-norm of the discretization error* $\underline{J} - \underline{J}_h$*,* $\mu_a = 1, \mu_b = 100$; (b) *graph norm of the discretization error* $U - U_h = (u - u_h, \underline{J} - \underline{J}_h)$*,* $\mu_a = 1, \mu_b = 100$.

(8.6). Homogeneous Dirichlet data have been assumed for u along the vertical sides $x = 0$ and $x = 1$, while vanishing fluxes have been imposed for $\underline{J}$ on the rest of the boundary of Ω. The values of the diffusion coefficient μ are $\mu_a = 1$ and $\mu_b = 100$, respectively.

We show in Figures 8(a) and 8(b) the L^2-norm and the discrete L^∞-norm of the error $u - u_h$, this latter norm being evaluated as

$$\|u - u_h\|_{\infty,h} = \max_{T_k \in \mathcal{T}_h} |u(\underline{x}_{B_k}) - u_k|,$$

where $\underline{x}_{B_k}$ is the centroid of the element T_k. Linear convergence with respect to h is observed for all of the considered averages, except for the case of the convergence order in the discrete L^∞-norm of the method using the average (8.4), which proves to be *quadratic* with respect to h. This appears to be a (nodal) superconvergence of the scheme and is to be ascribed to the choice of the average which is *exact* if μ is a piecewise constant function as in the present case. The second-order convergence of the mixed finite volume method using the average (8.4) on quadrilaterals is in agreement with the theoretical results obtained in the literature for the RT finite element of lowest order (see [6, 3, 22, 21]).

Figures 9(a) and 9(b) show the L^2-norm of the discretization error $\underline{J} - \underline{J}_h$ and the graph norm of the error $U - U_h$. Linear convergence is clearly observed for all of the three averages; notice that the curve of the L^2-norm of $\underline{J} - \underline{J}_h$ is not shown for the method using the average (8.4) since in this test case the scheme furnishes the exact solution for $\underline{J}$ (due to the combination of the choice of the average and the fact that the flux is contained in the approximation space). We also point out that the quantity div$\underline{J}_h$ computed by all of the three schemes is *exact* (up to the roundoff error) since the right-hand side f is equal to a constant.

ON THE EFFICIENT PARALLEL COMPUTATION OF LEGENDRE TRANSFORMS*

MÁRCIA A. INDA[†], ROB H. BISSELING[‡], AND DAVID K. MASLEN[§]

Abstract. In this article, we discuss a parallel implementation of efficient algorithms for computation of Legendre polynomial transforms and other orthogonal polynomial transforms. We develop an approach to the Driscoll–Healy algorithm using polynomial arithmetic and present experimental results on the accuracy, efficiency, and scalability of our implementation. The algorithms were implemented in ANSI C using the BSPlib communications library. We also present a new algorithm for computing the cosine transform of two vectors at the same time.

Key words. orthogonal polynomials, Legendre polynomials, BSP, parallel computation, computational harmonic analysis

1. Introduction.

Discrete Legendre transforms (DLTs) are widely used tools in applied science, commonly arising in problems associated with spherical geometries. Examples of their application include spectral methods for the solution of partial differential equations, e.g., in global weather forecasting [3, 9], shape analysis of molecular surfaces [16], statistical analysis of directional data [18], and geometric quality assurance [17].

A direct method for computing a discrete orthogonal polynomial transform such as the DLT transform for N data values requires a matrix-vector multiplication of $O(N^2)$ arithmetic operations, though several authors [2, 28] have proposed faster algorithms based on approximate methods. In 1989, Driscoll and Healy introduced an exact algorithm that computes such transforms in $O(N \log^2 N)$ arithmetic operations [13, 14, 15]. They implemented the algorithm and analyzed its stability, which depends on the specific orthogonal polynomial sequence used.

Discrete polynomial transforms are computationally intensive, so for large problem sizes the ability to use multiprocessor computers is important, and at least two papers discussing the theoretical parallelizability of the algorithm have already been written [19, 32]. We are, however, unaware of any parallel implementation of the Driscoll–Healy algorithm at the time of writing.

In this paper, we derive a new parallel algorithm that has a lower theoretical time complexity than those of [19, 32], and we present a full implementation of this

algorithm. Another contribution is the method used to derive the algorithm. We present a method based on polynomial arithmetic to clarify the properties of orthogonal polynomials used by the algorithm and to remove some unnecessary assumptions made in [13, 14, 15].

The remainder of this paper is organized as follows. In section 2, we describe some important properties of orthogonal polynomials and orthogonal polynomial transforms, and we present a derivation of the Driscoll–Healy algorithm. In section 3, we introduce the bulk synchronous parallel (BSP) model and describe a basic parallel algorithm and its implementation. In section 4, we refine the basic algorithm by introducing an intermediate data distribution that reduces the communication to a minimum. In section 5, we present results on the accuracy, efficiency, and scalability of our implementation. We conclude with section 6 and two appendices describing a generalization of the algorithm and the precomputation of the data needed by the algorithm.

2. The Driscoll–Healy algorithm.

2.1. Orthogonal polynomials. A sequence of polynomials $p_0, p_1, p_2, \ldots$ is said to be an *orthogonal polynomial sequence* on the interval $[-1, 1]$ with respect to the weight function $\omega(x)$, if $\deg p_i = i$, and

$$\int_{-1}^{1} p_i(x)p_j(x)\omega(x)dx = 0 \quad \text{for } i \neq j,$$

$$\int_{-1}^{1} p_i(x)^2\omega(x)dx \neq 0 \quad \text{for } i \geq 0.$$

The weight function $\omega(x)$ is nonnegative and integrable on $(-1, 1)$.

Let $x_0, \ldots, x_{N-1}$ be a sequence of distinct real numbers called *sample points*, and let $f_0, \ldots, f_{N-1}$ be a sequence of real values. Then there exists a unique polynomial f of degree less than N such that

$$f(x_j) = f_j, \quad j = 0, \ldots, N-1. \tag{2.1}$$

This polynomial can be obtained by Lagrangian interpolation.

The *expansion transform* corresponding to the orthogonal polynomial sequence $\{p_k\}$ computes the coefficients c_k in the expansion

$$f = \sum_{k=0}^{N-1} c_k p_k, \tag{2.2}$$

where f is a polynomial given by function values f_j in the sample points x_j. (Note that we do not require any special relation between the sample points and the orthogonal polynomials.) The *inverse expansion transform* evaluates f at the sample points x_j, and this can be done by straightforward substitution:

$$f_j = \sum_{k=0}^{N-1} c_k p_k(x_j), \quad j = 0, \ldots, N-1. \tag{2.3}$$

In matrix-vector notation, the latter transform can be written as $\mathbf{f} = \mathbf{Pc}$, where $\mathbf{f} = (f_0, \ldots, f_{N-1})$ and $\mathbf{c} = (c_0, \ldots, c_{N-1})$ are column vectors, and the matrix $\mathbf{P}$ is defined by $P_{jk} = p_k(x_j)$. The matrix $\mathbf{P}$ is invertible, and $\mathbf{P}^{-1}$ represents the expansion transform. In general, $\mathbf{P}$ need not be orthogonal, and hence its inverse and transpose need not be the same.

EXAMPLE 2.1 (discrete Chebyshev transform (DChT)). *The Chebyshev polynomials of the first kind are the sequence of orthogonal polynomials defined recursively by*

$$T_{k+1}(x) = 2x \cdot T_k(x) - T_{k-1}(x), \quad T_0(x) = 1, \quad T_1(x) = x. \tag{2.4}$$

These are orthogonal with respect to the weight function $\omega(x) = \pi^{-1}(1-x^2)^{-\frac{1}{2}}$ *on* $[-1,1]$*, and they satisfy* $T_k(\cos\theta) = \cos k\theta$ *for all real* θ*.*

The DChT is the expansion transform for the Chebyshev polynomials at the Chebyshev points. The Chebyshev points *are the roots of* T_N*, and they are given by*

$$x_j^N = \cos\frac{(2j+1)\pi}{2N}, \quad j = 0, \ldots, N-1. \tag{2.5}$$

We denote the Chebyshev transform by a tilde. More specifically, the coefficient of T_k *in the Chebyshev expansion of a polynomial* f *is denoted by* $\tilde{f}_k$*.*

The inverse Chebyshev transform can straightforwardly be written as

$$f_j = \sum_{k=0}^{N-1} \tilde{f}_k T_k(x_j^N) = \sum_{k=0}^{N-1} \tilde{f}_k \cos\frac{(2j+1)k\pi}{2N}, \quad j = 0, \ldots, N-1. \tag{2.6}$$

Furthermore, it can be shown that the Chebyshev transform itself is given by

$$\tilde{f}_k = \frac{\epsilon_k}{N}\sum_{j=0}^{N-1} f_j T_k(x_j^N) = \frac{\epsilon_k}{N}\sum_{j=0}^{N-1} f_j \cos\frac{(2j+1)k\pi}{2N}, \quad k = 0, \ldots, N-1, \tag{2.7}$$

where

$$\epsilon_k = \begin{cases} 1 & \text{if } k = 0, \\ 2 & \text{if } k > 0. \end{cases} \tag{2.8}$$

In this work, we will study a slightly more general transform which includes weights. Given an orthogonal polynomial sequence $\{p_k\}$, a sequence of sample points $x_0, \ldots, x_{N-1}$, and a sequence of numbers $w_0, \ldots, w_{N-1}$ called *sample weights*, we define the *discrete orthogonal polynomial transform* of a data vector $(f_0, \ldots, f_{N-1})$ to be the vector of sums $(\hat{f}_0, \ldots, \hat{f}_{N-1})$, where

$$\hat{f}_k = \hat{f}(p_k) = \sum_{j=0}^{N-1} w_j f_j p_k(x_j). \tag{2.9}$$

The matrix of the discrete orthogonal polynomial transform (2.9) for the special case with sample weights 1 is $\mathbf{P}^T$.

EXAMPLE 2.2 (discrete cosine transform (DCT)). *The DCT, or DCT*-II *in the terminology of* [35]*, is the discrete orthogonal polynomial transform for the Chebyshev polynomials, with sample weights* 1 *and with the Chebyshev points as sample points. Thus, the matrix representing the DCT is* $\mathbf{P}^T$*. Since the matrix representing the DChT is* $\mathbf{P}^{-1}$*, the DCT is the inverse transpose of the DChT. The relation is even closer: by comparing* (2.9) *for the DCT with* (2.7) *for the DChT we see that the DChT is equivalent to a DCT followed by a multiplication of the kth coefficient by* $\frac{\epsilon_k}{N}$*.*

A DCT can be carried out in $O(N \log N)$ arithmetic operations using a fast Fourier transform (FFT) [1, 35] *or using the recent algorithm of Steidl and Tasche* [33]. *Such an $O(N \log N)$ algorithm is called a fast cosine transform (FCT). This also provides us with a fast Chebyshev transform (FChT). We use an upper bound of the form $\alpha N \log_2 N + \beta N$ for the number of floating point operations (flops) for one FChT of size N, or its inverse. The lower order term is included because we are often interested in small size transforms, for which this term may be dominant.*

Example 2.3 (DLT). *The Legendre polynomials are orthogonal with respect to the uniform weight function 1 on $[-1, 1]$, and they may be defined recursively by*

$$(2.10)\quad P_{k+1}(x) = \frac{2k+1}{k+1} x \cdot P_k(x) - \frac{k}{k+1} P_{k-1}(x), \quad P_0(x) = 1, \quad P_1(x) = x.$$

The Legendre polynomials are one of the most important examples of orthogonal polynomials, as they occur as zonal polynomials in the spherical harmonic expansion of functions on the sphere. Our parallel implementation of the Driscoll–Healy algorithm, to be described later, focuses on the case of Legendre polynomials. For efficiency reasons, we sample these polynomials at the Chebyshev points. In this paper, we call the discrete orthogonal polynomial transform for the Legendre polynomials, with sample weights $1/N$ and with the Chebyshev points as sample points, the DLT.

One of the important properties of orthogonal polynomials we will use is the following lemma.

Lemma 2.4 (Gaussian quadrature). *Let $\{p_k\}$ be an orthogonal polynomial sequence for a nonnegative integrable weight function $\omega(x)$, and let $z_0^N, \ldots, z_{N-1}^N$ be the roots of p_N. Then there exist numbers $w_0^N, \ldots, w_{N-1}^N > 0$, such that for any polynomial f of degree less than $2N$ we have*

$$\int_{-1}^{1} f(x)\omega(x)dx = \sum_{j=0}^{N-1} w_j^N f(z_j^N).$$

The numbers w_j^N are unique and are called the Gaussian weights for the sequence $\{p_k\}$.

Proof. See, e.g., [10, Theorem 6.1]. □

Example 2.5. *The Gaussian weights for the Chebyshev polynomials with weight function $\pi^{-1}(1-x^2)^{-\frac{1}{2}}$ are $w_j^N = 1/N$. So for any polynomial f of degree less than $2N$ we have*

$$(2.11)\qquad \frac{1}{\pi}\int_{-1}^{1} \frac{f(x)dx}{\sqrt{1-x^2}} = \frac{1}{N}\sum_{j=0}^{N-1} f(x_j^N),$$

where $x_j^N = \cos\frac{(2j+1)\pi}{2N}$ are the Chebyshev points.

Another property of orthogonal polynomials that we will need is the existence of a three-term recurrence relation, such as (2.4) for the Chebyshev polynomials and (2.10) for the Legendre polynomials.

Lemma 2.6 (three-term recurrence). *Let $\{p_k\}$ be an orthogonal polynomial sequence for a nonnegative integrable weight function. Then $\{p_k\}$ satisfies a three-term recurrence relation*

$$(2.12)\qquad p_{k+1}(x) = (A_k x + B_k)p_k(x) + C_k p_{k-1}(x),$$

where A_k, B_k, C_k are real numbers with $A_k \neq 0$ and $C_k \neq 0$.

Proof. See, e.g., [10, Theorem 4.1]. □

The Clebsch–Gordan property follows from, and is similar to, the three-term recurrence.

Corollary 2.7 (Clebsch–Gordan). *Let $\{p_k\}$ be an orthogonal polynomial sequence with a nonnegative integrable weight function. Then for any polynomial Q of degree m we have*

$$p_k \cdot Q \in \operatorname{span}_{\mathbf{R}}\{p_{k-m}, \dots, p_{k+m}\}.$$

Proof. Rewrite the recurrence (2.12) in the form $x \cdot p_k = A_k^{-1}(p_{k+1} - B_k p_k - C_k p_{k-1})$, and use induction on m. □

Iterating the three-term recurrence also gives a more general recurrence between polynomials in an orthogonal polynomial sequence. Define the *associated polynomials* $Q_{l,m}, R_{l,m}$ for the orthogonal polynomial sequence $\{p_l\}$ by the following recurrences on m, which are shifted versions of the recurrence for p_l. See, e.g., [4, 5].

$$\begin{aligned} Q_{l,m}(x) &= (A_{l+m-1}x + B_{l+m-1})Q_{l,m-1}(x) + C_{l+m-1}Q_{l,m-2}(x), \\ Q_{l,0}(x) &= 1, \quad Q_{l,1}(x) = A_l x + B_l, \\ R_{l,m}(x) &= (A_{l+m-1}x + B_{l+m-1})R_{l,m-1}(x) + C_{l+m-1}R_{l,m-2}(x), \\ R_{l,0}(x) &= 0, \quad R_{l,1}(x) = C_l. \end{aligned} \tag{2.13}$$

Lemma 2.8 (generalized three-term recurrence). *The associated polynomials satisfy* $\deg Q_{l,m} = m$, $\deg R_{l,m} \le m - 1$, *and for* $l \ge 1$ *and* $m \ge 0$,

$$p_{l+m} = Q_{l,m} \cdot p_l + R_{l,m} \cdot p_{l-1}. \tag{2.14}$$

Proof. Equation (2.14) follows by induction on m with the case $m = 1$ being the original three-term recurrence (2.12). □

In the case where the p_l are the Legendre polynomials, the associated polynomials should not be confused with the associated Legendre functions, which in general are not polynomials.

2.2. Derivation of the Driscoll–Healy algorithm. The Driscoll–Healy algorithm [13, 14] allows one to compute orthogonal polynomial transforms at any set of N sample points, in $O(N \log^2 N)$ arithmetic operations. The core of this algorithm consists of an algorithm to compute orthogonal polynomial transforms in the special case where the sample points are the Chebyshev points and the sample weights are $1/N$. For simplicity we restrict ourselves to this special case, and, furthermore, we assume that N is a power of 2. In Appendix A, we sketch extensions to more general problems.

Using the relation

$$f \cdot p_{l+m} = Q_{l,m} \cdot (f \cdot p_l) + R_{l,m} \cdot (f \cdot p_{l-1}), \tag{2.15}$$

derived from the three-term recurrence (2.14), we may formulate a strategy for computing all the polynomials $f \cdot p_l$, $0 \le l < N$, in $\log_2 N$ stages.

- At stage 0, compute $f \cdot p_0$ and $f \cdot p_1$.
- At stage 1, use (2.15) with $l = 1$ and $m = N/2 - 1$ or $m = N/2$ to compute
$$\begin{aligned} f \cdot p_{\frac{N}{2}} &= Q_{1,\frac{N}{2}-1} \cdot (f \cdot p_1) + R_{1,\frac{N}{2}-1} \cdot (f \cdot p_0), \\ f \cdot p_{\frac{N}{2}+1} &= Q_{1,\frac{N}{2}} \cdot (f \cdot p_1) + R_{1,\frac{N}{2}} \cdot (f \cdot p_0). \end{aligned}$$
- In general, at each stage $k, 1 \le k < \log_2 N$, similarly as before, use (2.15) with $l = 2q(N/2^k) + 1$, $0 \le q < 2^{k-1}$, and $m = N/2^k - 1$ or $N/2^k$, to compute the polynomial pairs

$$f \cdot p_{\frac{N}{2^k}},\ f \cdot p_{\frac{N}{2^k}+1};\ f \cdot p_{\frac{3N}{2^k}},\ f \cdot p_{\frac{3N}{2^k}+1};\ \cdots\ ; f \cdot p_{\frac{(2^k-1)N}{2^k}}, f \cdot p_{\frac{(2^k-1)N}{2^k}+1}.$$

The problem with this strategy is that computing a full representation of each polynomial $f \cdot p_l$ generates much more data at each stage than is needed to compute the final output. To overcome this problem, the Driscoll–Healy algorithm uses *Chebyshev truncation operators* to discard unneeded information at the end of each stage. Let $f = \sum_{k \geq 0} b_k T_k$ be a polynomial, of any degree, written in the basis of Chebyshev polynomials, and let n be a positive integer. Then the truncation operator $\mathcal{T}_n$ applied to f is defined by

$$\mathcal{T}_n f = \sum_{k=0}^{n-1} b_k T_k. \tag{2.16}$$

The important properties of $\mathcal{T}_n$ are given in Lemma 2.9.

LEMMA 2.9. *Let f and Q be polynomials. Then the following hold.*

1. $\mathcal{T}_1 f = \int_{-1}^{1} f(x)\omega(x)dx$, *where* $\omega(x) = \pi^{-1}(1-x^2)^{-\frac{1}{2}}$.
2. *If* $m \leq n$, *then* $\mathcal{T}_m \mathcal{T}_n = \mathcal{T}_m$.
3. *If* $\deg Q \leq m \leq n$, *then* $\mathcal{T}_{n-m}(f \cdot Q) = \mathcal{T}_{n-m}[(\mathcal{T}_n f) \cdot Q]$.

Proof. Part 1 follows from the orthogonality of Chebyshev polynomials, as $\mathcal{T}_1 f$ is just the constant term of f in its expansion in Chebyshev polynomials. Part 2 is a trivial consequence of the definition of truncation operators. For part 3 we assume that $f = \sum_{k \geq 0} b_k T_k$ is a polynomial and that $\deg Q \leq m \leq n$. By Corollary 2.7, $T_k \cdot Q$ is in the linear span of $T_{k-m}, \ldots, T_{k+m}$, so $\mathcal{T}_{n-m}(T_k \cdot Q) = 0$ for $k \geq n$. Therefore,

$$\mathcal{T}_{n-m}(f \cdot Q) = \mathcal{T}_{n-m}\left(\sum_{k \geq 0} b_k T_k \cdot Q\right) = \mathcal{T}_{n-m}\left(\sum_{k=0}^{n-1} b_k T_k \cdot Q\right) = \mathcal{T}_{n-m}[(\mathcal{T}_n f) \cdot Q]. \qquad \square$$

As a corollary of part 1 of Lemma 2.9, we see how we can retrieve the discrete orthogonal polynomial transform from the $f \cdot p_l$'s computed by the strategy above by using a simple truncation.

COROLLARY 2.10. *Let f be the unique polynomial of degree less than N such that $f(x_j^N) = f_j$, $0 \leq j < N$. Let $\{p_l\}$ be an orthogonal polynomial sequence. Then*

$$\hat{f}_l = \mathcal{T}_1(f \cdot p_l), \quad 0 \leq l < N,$$

where the $\hat{f}_l$ form the discrete orthogonal polynomial transform of f of size N with respect to the sample points x_j^N and sample weights $1/N$.

Proof. This follows from the definition of discrete orthogonal polynomial transforms, the Gaussian quadrature rule (2.11) for Chebyshev polynomials applied to the function $f \cdot p_l$, and Lemma 2.9,

$$\hat{f}_l = \frac{1}{N}\sum_{j=0}^{N-1} f(x_j^N) p_l(x_j^N) = \frac{1}{\pi}\int_{-1}^{1} \frac{f(x)p_l(x)}{\sqrt{1-x^2}}dx = \mathcal{T}_1(f \cdot p_l). \qquad \square$$

The key property of the truncation operators $\mathcal{T}_n$ is the "aliasing" property (part 3 of Lemma 2.9), which states that we may use a truncated version of f when computing a truncated product of f and Q. For example, if we wish to compute the truncated product $\mathcal{T}_1(f \cdot p_l)$ with $l, \deg f < N$ then, because $\deg p_l = l$, we may apply part 3 of Lemma 2.9 with $m = l$ and $n = l + 1$ to obtain

$$\hat{f}_l = \mathcal{T}_1(f \cdot p_l) = \mathcal{T}_1[(\mathcal{T}_{l+1} f) \cdot p_l].$$

Thus we need to know only the first $l+1$ Chebyshev coefficients of f to compute $\hat{f}_l$.

The Driscoll–Healy algorithm follows the strategy described at the start of this section, but it computes truncated polynomials

$$Z_l^K = \mathcal{T}_K(f \cdot p_l) \tag{2.17}$$

for various values of l and K, instead of the original polynomials $f \cdot p_l$. The input is the polynomial f, and the output is $\hat{f}_l = \mathcal{T}_1(f \cdot p_l) = Z_l^1$, $0 \le l < N$.

Each stage of the algorithm uses truncation operators to discard unneeded information, which keeps the problem size down. Instead of using the generalized three-term recurrence (2.15) directly, each stage uses truncated versions. Specifically, (2.15) with $m = K-1, K$ and part 3 of Lemma 2.9 with $m = K$ and $n = 2K$ imply the following recurrences for the Z_l^K:

$$Z_{l+K-1}^K = \mathcal{T}_K[Z_l^{2K} \cdot Q_{l,K-1} + Z_{l-1}^{2K} \cdot R_{l,K-1}], \tag{2.18}$$

$$Z_{l+K}^K \quad = \mathcal{T}_K[Z_l^{2K} \cdot Q_{l,K} + Z_{l-1}^{2K} \cdot R_{l,K}]. \tag{2.19}$$

The algorithm proceeds in $\log_2 N + 1$ stages, as shown in Algorithm 2.1. The organization of the computation is illustrated in Figure 2.1.

Algorithm 2.1 Polynomial version of the Driscoll–Healy algorithm.

```
INPUT  $(f_0, \ldots, f_{N-1})$: Polynomial defined by $f_j = f(x_j^N)$; $N$ is a power of 2.

               $\hat{f}_l \leftarrow Z_l^1$
```

2.3. Data representation and recurrence procedure. To complete our description of the Driscoll–Healy algorithm, we still need to specify how to represent the polynomials in the algorithm and to describe the methods used to multiply two polynomials and to apply the truncation operators $\mathcal{T}_K$. This is done in the following subsections.

2.3.1. Chebyshev representation of polynomials. Truncation of a polynomial requires no computation if the polynomial is represented by the coefficients of its expansion in Chebyshev polynomials. Therefore, we use the Chebyshev coefficients z_n^l defined by

$$Z_l^K = \sum_{n=0}^{K-1} z_n^l T_n \tag{2.20}$$

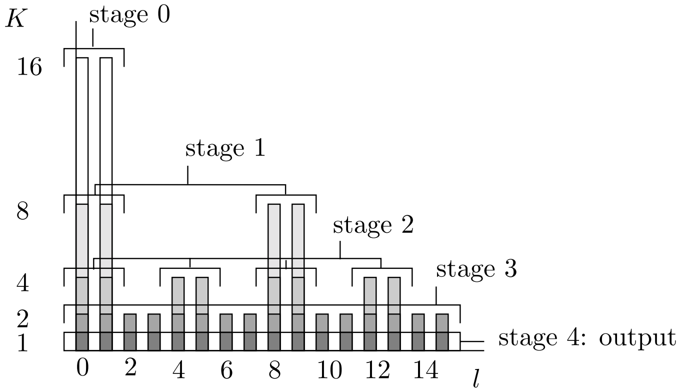

FIG. 2.1. *Computation of the truncated polynomials Z_l^K for $N = 16$. Each bar represents the polynomials Z_l^K for one value of l. The height of the bar represents the initial number of Chebyshev coefficients. At each stage, the number of coefficients is reduced as indicated by the gray scales.*

to represent all the polynomials Z_l^K appearing in the algorithm. Such a representation of a polynomial is called the *Chebyshev representation*.

The input polynomial f of degree less than N is given as the vector $\mathbf{f} = (f_0, \ldots, f_{N-1})$ of values $f_j = f(x_j^N)$. This is called the *point-value representation* of f. In stage 0, we convert $Z_0^N = \mathcal{T}_N(f \cdot p_0) = f \cdot p_0$ and $Z_1^N = \mathcal{T}_N(f \cdot p_1)$ to their Chebyshev representations. For $f \cdot p_0$ this can be done by a Chebyshev transform on the vector of function values with the input values multiplied by the constant p_0. For $f \cdot p_1$ we also use a Chebyshev transform of size N, even though $f \cdot p_1$ may have degree N, rather than $N - 1$. This poses no problem, because applying part 4 of Lemma 2.11 from the next subsection with $h = f \cdot p_1$ and $K = N$ proves that $f \cdot p_1$ agrees with Z_1^N at the sampling points x_j^N. Stage 0 becomes the following.

```
Stage 0. Compute the Chebyshev representation of $Z_0^N$ and $Z_1^N$.
         (a) $(z_0^0, \ldots, z_{N-1}^0) \leftarrow \text{Chebyshev}(f_0 p_0, \ldots, f_{N-1} p_0)$
         (b) $(z_0^1, \ldots, z_{N-1}^1) \leftarrow \text{Chebyshev}(f_0 p_1(x_0^N), \ldots, f_{N-1} p_1(x_{N-1}^N))$
```

Stage 0 takes a total of $2\alpha N \log_2 N + 2\beta N + 2N$ flops, where the third term represents the $2N$ flops needed to multiply f with p_0 and p_1.

2.3.2. Recurrence using Chebyshev transforms. To apply the recurrences (2.18) and (2.19) efficiently, we do the following.

1. Apply inverse Chebyshev transforms of size $2K$ to bring the polynomials Z_{l-1}^{2K}, Z_l^{2K} into point-value representation at the points x_j^{2K}, $0 \leq j < 2K$.
2. Perform the multiplications and additions.
3. Apply a forward Chebyshev transform of size $2K$ to bring the result into Chebyshev representation.
4. Truncate the results to degree less than K.

This procedure replaces the polynomial multiplications in the recurrences (2.18) and (2.19) by a slightly different operation. Because the multiplications are made in only $2K$ points, whereas the degree of the resulting polynomial could be $3K - 1$, we must verify that the end result is the same. To describe the operation formally, we introduce the *Lagrange interpolation operators* $\mathcal{S}_n$ for positive integers n. For any polynomial h, the Lagrange interpolation polynomial $\mathcal{S}_n h$ is the polynomial of degree less than n which agrees with h at the points $x_0^n, \dots, x_{n-1}^n$. The important properties of $\mathcal{S}_n$ are given in Lemma 2.11.

Lemma 2.11. *Let g and h be polynomials. Then the following hold.*

1. *If $\deg h < n$, then $\mathcal{S}_n h = h$.*
2. *$\mathcal{S}_n(g \cdot h) = \mathcal{S}_n((\mathcal{S}_n g) \cdot (\mathcal{S}_n h))$.*
3. *Let $m \leq n$. If $\deg h \leq m + n$, then $\mathcal{T}_{n-m} h = \mathcal{T}_{n-m}\mathcal{S}_n h$.*
4. *If $\deg h = n$, then $\mathcal{S}_n h = \mathcal{T}_n h$.*

Proof. Parts 1 and 2 are easy. To prove part 3 assume that $\deg h \leq m + n$. By long division, there is a polynomial Q of degree at most m such that $h = \mathcal{S}_n h + T_n \cdot Q$. Applying $\mathcal{T}_{n-m}$ and using part 3 of Lemma 2.9, we obtain

$$\mathcal{T}_{n-m}\mathcal{S}_n h = \mathcal{T}_{n-m} h - \mathcal{T}_{n-m}[T_n \cdot Q] = \mathcal{T}_{n-m} h - \mathcal{T}_{n-m}[(\mathcal{T}_n T_n) \cdot Q] = \mathcal{T}_{n-m} h,$$

since $\mathcal{T}_n T_n = 0$. For part 4 we note that $\deg \mathcal{S}_n h < n$, and we use part 3 with $m = 0$ to obtain $\mathcal{S}_n h = \mathcal{T}_n \mathcal{S}_n h = \mathcal{T}_n h$. □

From the recurrences (2.18) and (2.19) and part 3 of Lemma 2.11 with $m = K$ and $n = 2K$, it follows that

$$Z_{l+K-1}^K = \mathcal{T}_K[\mathcal{S}_{2K}(Z_l^{2K} \cdot Q_{l,K-1}) + \mathcal{S}_{2K}(Z_{l-1}^{2K} \cdot R_{l,K-1})], \tag{2.21}$$

$$Z_{l+K}^K \quad = \mathcal{T}_K[\mathcal{S}_{2K}(Z_l^{2K} \cdot Q_{l,K}) + \mathcal{S}_{2K}(Z_{l-1}^{2K} \cdot R_{l,K})]. \tag{2.22}$$

These equations are exactly the procedure described above. The inner loop of stage k of Algorithm 2.1 becomes the following.

```
(a) Compute the Chebyshev representation of $Z^K_{l+K-1}$ and $Z^K_{l+K}$.
    $(z_0^{l+K-1}, \dots, z_{K-1}^{l+K-1};\ z_0^{l+K}, \dots, z_{K-1}^{l+K})$
        $\leftarrow \mathrm{Recurrence}_l^K(z_0^{l-1}, \dots, z_{2K-1}^{l-1};\ z_0^l, \dots, z_{2K-1}^l)$
(b) Compute the Chebyshev representation of $Z^K_{l-1}$ and $Z^K_l$.
    Discard $(z_K^{l-1}, \dots, z_{2K-1}^{l-1})$ and $(z_K^l, \dots, z_{2K-1}^l)$
```

Algorithm 2.2 describes in detail the recurrence procedure, which takes $4(\alpha \cdot 2K \log_2 2K + \beta \cdot 2K) + 12K = 8\alpha K \log_2 K + (8\alpha + 8\beta + 12)K$ flops.

2.4. Early termination. At late stages in the Driscoll–Healy algorithm, the work required to apply the recursion amongst the Z_l^K is larger than that required to finish the computation using a naive matrix-vector multiplication. It is then more efficient to use the vectors Z_l^K computed so far directly to obtain the final result, as follows.

Let $q_{l,m}^n$ and $r_{l,m}^n$ denote the Chebyshev coefficients of the polynomials $Q_{l,m}$ and $R_{l,m}$, respectively, so that

$$Q_{l,m} = \sum_{n=0}^{m} q_{l,m}^n T_n, \quad R_{l,m} = \sum_{n=0}^{m-1} r_{l,m}^n T_n. \tag{2.23}$$

The problem of finishing the computation at the end of stage $k = \log_2(N/M)$, when $K = M$, is equivalent to finding $\hat{f}_l = z_0^l$ for $0 \leq l < N$, given the data z_n^l, z_n^{l-1}, $0 \leq n < M$, $l = 1, M + 1, 2M + 1, \dots, N - M + 1$. Our method of finishing the computation is to use part 1 of Lemma 2.12, which follows. Part 2 of this lemma can be used to halve the number of computations in the common case, where the polynomial recurrence (2.12) has a coefficient $B_k = 0$ for all k.

Algorithm 2.2 Recurrence procedure using the Chebyshev transform.

```
CALL Recurrence$_l^K(\tilde{f}_0,\dots,\tilde{f}_{2K-1};\ \tilde{g}_0,\dots,\tilde{g}_{2K-1})$.
INPUT $\tilde{\mathbf{f}} = (\tilde{f}_0,\dots,\tilde{f}_{2K-1})$ and $\tilde{\mathbf{g}} = (\tilde{g}_0,\dots,\tilde{g}_{2K-1})$: First $2K$ Chebyshev coefficients of input
polynomials $Z_{l-1}^{2K}$ and $Z_l^{2K}$; $K$ is a power of 2.
OUTPUT $\tilde{\mathbf{u}} = (\tilde{u}_0,\dots,\tilde{u}_{K-1})$ and $\tilde{\mathbf{v}} = (\tilde{v}_0,\dots,\tilde{v}_{K-1})$: First $K$ Chebyshev coefficients of output
polynomials $Z_{l+K-1}^K$ and $Z_{l+K}^K$.
STEPS
    1. Transform $\tilde{\mathbf{f}}$ and $\tilde{\mathbf{g}}$ to point-value representation.
       $(f_0,\dots,f_{2K-1}) \leftarrow \text{Chebyshev}^{-1}(\tilde{f}_0,\dots,\tilde{f}_{2K-1})$
       $(g_0,\dots,g_{2K-1}) \leftarrow \text{Chebyshev}^{-1}(\tilde{g}_0,\dots,\tilde{g}_{2K-1})$
    2. Perform the recurrence.
       for $j = 0$ to $2K-1$ do
           $u_j \leftarrow Q_{l,K-1}(x_j^{2K})\, g_j + R_{l,K-1}(x_j^{2K})\, f_j$
           $v_j \leftarrow Q_{l,K}(x_j^{2K})\, g_j + R_{l,K}(x_j^{2K})\, f_j$
    3. Transform $\mathbf{u}$ and $\mathbf{v}$ to Chebyshev representation.
       $(\tilde{u}_0,\dots,\tilde{u}_{2K-1}) \leftarrow \text{Chebyshev}(u_0,\dots,u_{2K-1})$
       $(\tilde{v}_0,\dots,\tilde{v}_{2K-1}) \leftarrow \text{Chebyshev}(v_0,\dots,v_{2K-1})$
    4. Discard $(\tilde{u}_K,\dots,\tilde{u}_{2K-1})$ and $(\tilde{v}_K,\dots,\tilde{v}_{2K-1})$.
```

LEMMA 2.12.

1. *If $l \geq 1$ and $0 \leq m < M$, then*

$$\hat{f}_{l+m} = \sum_{n=0}^{m} \frac{1}{\epsilon_n}(z_n^l q_{l,m}^n + z_n^{l-1} r_{l,m}^n). \tag{2.24}$$

2. *If p_l satisfies a recurrence of the form $p_{l+1}(x) = A_l x p_l(x) + C_l p_{l-1}(x)$, then*

$$\begin{aligned} q_{l,m}^n &= 0 \quad \textit{if } n-m \textit{ is odd, and} \\ r_{l,m}^n &= 0 \quad \textit{if } n-m \textit{ is even.} \end{aligned}$$

Proof. Applying $\mathcal{T}_{M-m}$ to both sides of (2.15) and using part 3 of Lemma 2.9 with $n = M$ gives $Z_{l+m}^{M-m} = \mathcal{T}_{M-m}(Z_l^M \cdot Q_{l,m} + Z_{l-1}^M \cdot R_{l,m})$. Truncating again, now using $\mathcal{T}_1$, we see that $\hat{f}_{l+m} = Z_{l+m}^1$ is the constant term of the Chebyshev expansion of $Z_l^M \cdot Q_{l,m} + Z_{l-1}^M \cdot R_{l,m}$. To find this constant term expressed in the Chebyshev coefficients of Z_l^M, Z_{l-1}^M and of $Q_{l,m}, R_{l,m}$, we substitute the expansions (2.20) and (2.23) and rewrite the product of sums by using the identity $T_j \cdot T_k = \frac{1}{2}(T_{|j-k|} + T_{j+k})$. For the second part, we assume that p_l satisfies the given recurrence. Then $Q_{l,m}$ is odd or even according to whether m is odd or even, and $R_{l,m}$ is even or odd according to whether m is odd or even, which can be verified by induction on m. This implies that the Chebyshev expansion of $Q_{l,m}$ must contain only odd or even coefficients, respectively, and the reverse must hold for $R_{l,m}$. □

Assuming that the assumptions of part 2 of the lemma are valid, i.e., each term of (2.24) has either $q_{l,m}^n = 0$ or $r_{l,m}^n = 0$, and that the factor $1/\epsilon_n$ has been absorbed in the precomputed values $q_{l,m}^n$ and $r_{l,m}^n$, the total number of flops needed to compute $\hat{f}_{l+m}$ is $2m+1$.

2.5. Complexity of the algorithm. Algorithm 2.3 gives the sequential Driscoll–Healy algorithm in its final form. The total number of flops can be computed as follows. Stage 0 takes $2\alpha N \log_2 N + (2\beta + 2)N$ flops. Stage k invokes $N/(2K)$ times the recurrence procedure, which has cost $8\alpha K \log_2 K + (8\alpha + 8\beta + 12)K$ flops, so that the total cost of that stage is $4\alpha N \log_2 K + (4\alpha + 4\beta + 6)N$ flops. Adding the costs for $K = N/2, \ldots, M$ gives $2\alpha N[\log_2^2 N - \log_2^2 M] + (2\alpha + 4\beta + 6)N[\log_2 N - \log_2 M]$ flops. In the last stage, output values have to be computed for $m = 1, \ldots, M - 2$, for each of the N/M values of l. This gives a total of $\frac{N}{M} \sum_{m=1}^{M-2} (2m + 1) = NM - 2N$ flops. Summing the costs gives

$$\begin{aligned} T_{\text{Driscoll-Healy}} =& N[2\alpha(\log_2^2 N - \log_2^2 M) + (4\alpha + 4\beta + 6) \log_2 N \\ & - (2\alpha + 4\beta + 6) \log_2 M + M + 2\beta]. \end{aligned} \tag{2.25}$$

Algorithm 2.3 Driscoll–Healy algorithm.

```

```

The optimal stage at which to halt the Driscoll–Healy algorithm and complete the computation using Lemma 2.12 depends on α and β and can be obtained theoretically. The derivative of (2.25) as a function of M equals zero if and only if

$$M \ln^2 2 - 4\alpha \ln M = (2\alpha + 4\beta + 6) \ln 2. \tag{2.26}$$

In our implementation $\alpha = 2.125$ and $\beta = 5$; thus the minimum is $M = 128$. In practice, the optimal choice of M will depend not only on the number of flops performed, but also on the architecture of the machine used. The machine-tuned basic linear algebra subprograms (BLAS) exploit the memory hierarchy of a computer, and using the BLAS may cause a shift in the optimal value for M. For example, early termination can be implemented by using a level 2 BLAS operation for matrix-vector multiplication, which is more efficient than the level 1 vector operations of a straightforward implementation of the Driscoll–Healy algorithm. This will increase the optimal value for M.

3. The basic parallel algorithm and its implementation.

We designed our parallel algorithm using the BSP model, which provides a simple and effective way of developing portable parallel algorithms. The BSP model does not favor any specific computer architecture, and it includes a simple cost function that enables us to choose between algorithms without actually having to implement them.

In the following subsections, we give a brief description of the BSP model, and then we present the framework in which we develop our parallel algorithm, including the data structures and data distributions used. This leads to a basic parallel algorithm. From now on we concentrate on the DLT instead of the more general discrete orthogonal polynomial transform.

3.1. The BSP model. In the BSP model [34], a computer consists of a set of p processors, each with a private memory, connected by a communication network that allows processors to access the memories of other processors. In the model, algorithms consist of a sequence of supersteps. In the variant of the model we use, a *superstep* is either a number of computation steps or a number of communication steps. Global synchronization barriers (i.e., places of the algorithm where all processors must synchronize with each other) precede and/or follow a communication superstep. Using supersteps imposes a sequential structure on parallel algorithms, and this greatly simplifies the design process.

A BSP computer can be characterized by four global parameters: p, the number of processors; s, the computing speed in flop/s; g, the communication time per data element sent or received, measured in flop time units; and l, the synchronization time, also measured in flop time units. Algorithms can be analyzed by using the parameters p, g, and l; the parameter s just scales the time. In this work, we are able to avoid all synchronizations at the end of computation supersteps. Therefore, the time of a computation superstep is simply w, the maximum amount of work (in flops) of any processor. The time of a communication superstep is $hg + l$, where h is the maximum number of data elements sent or received by any processor. The total execution time of an algorithm (in flops) can be obtained by adding the times of the separate supersteps. This yields an expression of the form $a + bg + cl$. For further details and some basic techniques, see [6]. BSPlib [21] is a standard library which enables parallel programming in BSP style. Available implementations are the Oxford BSP toolset [22] and the Paderborn University BSP library [8].

3.2. Data structures and data distributions. At each stage k, $1 \le k \le \log_2 \frac{N}{M}$, the number of intermediate polynomial pairs doubles as the number of expansion coefficients halves. Thus, at every stage of the computation, all the intermediate polynomials can be stored in two arrays of size N. We use an array $\mathbf{f}$ to store the Chebyshev coefficients of the polynomials Z_l^{2K} and an array $\mathbf{g}$ to store the coefficients of Z_{l+1}^{2K} for $l = 0, 2K, \ldots, N - 2K$ with $K = N/2^k$ in stage k. We also need some extra work space to compute the coefficients of the polynomials Z_{l+K}^{2K} and Z_{l+K+1}^{2K}. For this we use two auxiliary arrays, $\mathbf{u}$ and $\mathbf{v}$, of size N.

The data flow of the algorithm (see Figure 3.1) suggests that we distribute all the vectors by blocks, i.e., assign one block of consecutive vector elements to each processor. This works well if p is a power of two, which we will assume from now on. Since both N and p are thus powers of two, each processor obtains exactly N/p elements. For the general case, the block distribution is defined as follows.

Definition 3.1 (block distribution). *Let* $\mathbf{f}$ *be a vector of size* N. *We say that* $\mathbf{f}$ *is* block distributed *over* p *processors if, for all* j, *the element* f_j *is stored in* $\mathrm{Proc}(j \operatorname{div} b)$ *and has local index* $j' = j \bmod b$, *where* $b = \lceil N/p \rceil$ *is the block size.*

The precomputed data required to perform the recurrence of stage k are stored in two-dimensional arrays $\mathbf{Q}$ and $\mathbf{R}$, each of size $2\log_2(N/M) \times N$. Each pair of rows

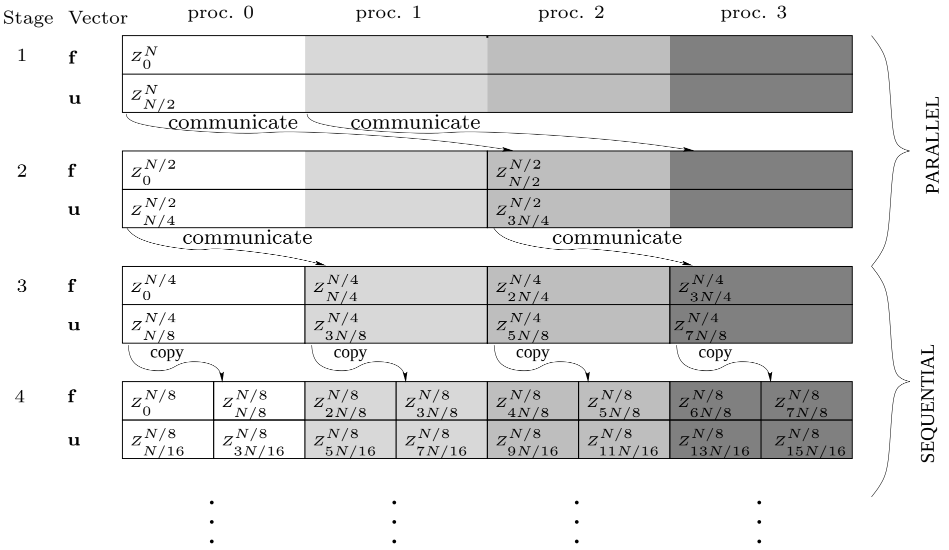

FIG. 3.1. *Main data structure and data distribution in the parallel fast Legendre transform (FLT) algorithm for $p = 4$. Arrays* **f** *and* **g** *contain the Chebyshev coefficients of the polynomials Z_l^{2K} and Z_{l+1}^{2K}, which are already available at the start of the stage. Arrays* **u** *and* **v** *contain Z_{l+K}^{2K} and Z_{l+K+1}^{2K}, which become available at the end of the stage. Arrays* **g** *and* **v** *are not depicted. Each array is divided into four local subarrays by using the block distribution.*

k	$K-1, K$	proc. 0	proc. 1	proc. 2	proc. 3
1	31	$l = 0$			
	32	$j = 0, \dots, 63$			
2	15	$l = 0$		$l = 32$	
	16	$j = 0, \dots, 31$		$j = 0, \dots, 31$	
3	7	$l = 0$	$l = 16$	$l = 32$	$l = 48$
	8	$j = 0, \dots, 15$	$j = 0, \dots, 15$	$j = 0, \dots, 15$	$j = 0, \dots, 15$

FIG. 3.2. *Data structure and distribution of the precomputed data needed in the recurrence with $N = 64$, $M = 8$, and $p = 4$. Data are stored in two-dimensional arrays* **Q** *and* **R**; *one such array is shown. Each pair of rows in an array stores the data needed for one stage k.*

in **Q** stores data needed for one stage k by

$$\begin{aligned} \mathbf{Q}[2k-2, l+j] &= Q_{l+1,K-1}(x_j^{2K}), \\ \mathbf{Q}[2k-1, l+j] &= Q_{l+1,K}(x_j^{2K}) \end{aligned} \tag{3.1}$$

for $l = 0, 2K, \dots, N-2K$, $j = 0, 1, \dots, 2K-1$, where $K = N/2^k$. Thus polynomials $Q_{l+1,K-1}$ are stored in row $2k-2$, and polynomials $Q_{l+1,K}$ are stored in row $2k-1$. This is shown in Figure 3.2. The polynomials $R_{l+1,K-1}$ and $R_{l+1,K}$ are stored in the same way in array **R**. Note that the indexing of the implementation arrays starts at zero. Each row of **Q** and **R** is distributed by the block distribution, i.e., $\mathbf{Q}[i,j], \mathbf{R}[i,j] \in \text{Proc}(j \text{ div } \frac{N}{p})$, so that the recurrence is a local operation.

The termination coefficients $q_{l,m}^n$ and $r_{l,m}^n$ for $l = 1, M+1, 2M+1, \dots, N-M+1$, $m = 1, 2, \dots, M-2$, and $n = 0, 1, \dots, m$ are stored in a two-dimensional array **T** of size $N/M \times (M(M-1)/2 - 1)$. The coefficients for one value of l are stored in row $(l-1)/M$ of **T**. Each row has the same internal structure: the coefficients are stored in increasing order of m, and coefficients with the same m are ordered by increasing n. (This format is commonly used to store lower triangular matrices.) By part 2 of

	$m = 1$	$m = 2$	$m = 3$	$m = 4$	$m = 5$	$m = 6$	
$l = 1$	$r^0\ q^1$	$q^0\ r^1\ q^2$	$r^0\ q^1\ r^2\ q^3$	$q^0\ r^1\ q^2\ r^3\ q^4$	$r^0\ q^1\ r^2\ q^3\ r^4\ q^5$	$q^0\ r^1\ q^2\ r^3\ q^4\ r^5\ q^6$	proc. 0
$l = 9$	$r^0\ q^1$	$q^0\ r^1\ q^2$	$r^0\ q^1\ r^2\ q^3$	$q^0\ r^1\ q^2\ r^3\ q^4$	$r^0\ q^1\ r^2\ q^3\ r^4\ q^5$	$q^0\ r^1\ q^2\ r^3\ q^4\ r^5\ q^6$	
$l = 17$	$r^0\ q^1$	$q^0\ r^1\ q^2$	$r^0\ q^1\ r^2\ q^3$	$q^0\ r^1\ q^2\ r^3\ q^4$	$r^0\ q^1\ r^2\ q^3\ r^4\ q^5$	$q^0\ r^1\ q^2\ r^3\ q^4\ r^5\ q^6$	proc. 1
$l = 25$	$r^0\ q^1$	$q^0\ r^1\ q^2$	$r^0\ q^1\ r^2\ q^3$	$q^0\ r^1\ q^2\ r^3\ q^4$	$r^0\ q^1\ r^2\ q^3\ r^4\ q^5$	$q^0\ r^1\ q^2\ r^3\ q^4\ r^5\ q^6$

FIG. 3.3. *Data structure and distribution of the precomputed data for termination with $N = 64$, $M = 8$, and $p = 4$. The coefficients $q^n_{l,m}$ and $r^n_{l,m}$ are stored in a two-dimensional array* $\mathbf{T}$. *In the picture, q^n denotes $q^n_{l,m}$, and r^n denotes $r^n_{l,m}$.*

Lemma 2.12, either $q^n_{l,m} = 0$ or $r^n_{l,m} = 0$ for each n and m, so we need to store only the value that can be nonzero. Since this depends on whether $n - m$ is even or odd, we obtain an alternating pattern of $q^n_{l,m}$'s and $r^n_{l,m}$'s. Figure 3.3 illustrates this data structure.

The termination stage can be kept local if $M \leq N/p$. This requires that each row of $\mathbf{T}$ is assigned to one processor, namely, to the processor that holds the subvectors for the corresponding value of l. Each column of $\mathbf{T}$ is in the block distribution, i.e., $\mathbf{T}[i, j] \in \text{Proc}(i \text{ div } \frac{N}{pM})$. As a result, the N/M rows of $\mathbf{T}$ are distributed in consecutive blocks of rows.

3.3. The basic parallel algorithm. To formulate our basic parallel algorithm, we introduce the following conventions and subroutines.

Processor identification. The total number of processors is p. The processor identification number is s with $0 \leq s < p$.

Supersteps. Labels indicate a superstep and its type: (Comp) computation superstep, (Comm) communication superstep, and (CpCm) subroutine containing both computation and communication supersteps. Global synchronizations are stated explicitly. Supersteps inside loops are executed repeatedly, though they are numbered only once.

Indexing. All the indices are global. This means that array elements have a unique index which is independent of the processor that owns it. This enables us to describe variables and gain access to arrays in an unambiguous manner, even though the array is distributed and each processor has only part of it.

Vectors and subroutine calls. All vectors are indicated in boldface. To specify part of a vector we write its first element in boldface, e.g., $\mathbf{f_j}$; the vector size is explicitly written as a parameter.

Communication. Communication between processors is done by using

$$\mathbf{g_j} \leftarrow \text{Put}(pid, n, \mathbf{f_i}).$$

This operation puts n elements of vector $\mathbf{f}$, starting from element i, into processor *pid* and stores them there in vector $\mathbf{g}$ starting from element j.

Copying a vector. The operation

$$\mathbf{g_j} \leftarrow \text{Copy}(n, \mathbf{f_i})$$

denotes the copy of n elements of vector $\mathbf{f}$, starting from element i, to a vector $\mathbf{g}$ starting from element j.

Subroutine name ending in 2. Subroutines with a name ending in 2 perform an operation on two vectors instead of one. For example,

$$(\mathbf{f_i}, \mathbf{g_j}) \leftarrow \text{Copy2}(n, \mathbf{u_k}, \mathbf{v_l})$$

is an abbreviation for

$$\begin{aligned} \mathbf{f_i} &\leftarrow \text{Copy}(n, \mathbf{u_k}) \\ \mathbf{g_j} &\leftarrow \text{Copy}(n, \mathbf{v_l}). \end{aligned}$$

FChT. The subroutine

$$\text{BSP\_FChT}(s_0, s_1, p_1, \mathit{sign}, n, \mathbf{f})$$

replaces the input vector $\mathbf{f}$ of size n by its Chebyshev transform if $\mathit{sign} = 1$, or by its inverse Chebyshev transform if $\mathit{sign} = -1$. A group of p_1 processors starting from processor s_0 work together; s_1 with $0 \leq s_1 < p_1$ denotes the processor number within the group. The original processor number equals $s = s_0 + s_1$. For a group of size $p_1 = 1$, this subroutine reduces to the sequential FChT.

Truncation. The subroutine

$$\mathbf{f} \leftarrow \text{BSP\_Trunc}(s_0, s_1, p_1, n, \mathbf{u})$$

truncates two polynomials of degree less than n which are stored as vectors $\mathbf{f}$ and $\mathbf{u}$ of length n. The subroutine copies the first half of $\mathbf{u}$ into the second half of $\mathbf{f}$. A group of p_1 processors starting from processor s_0 work together, similar to the BSP_FChT operation. For a group of size $p_1 = 1$, the subroutine reduces to a sequential truncation of one or more complete polynomials. In Figure 3.1, the truncation operation is depicted by arrows. Algorithm 3.1 describes subroutine BSP_Trunc2 which carries out two truncation operations simultaneously. In doing so, we save one synchronization.

Algorithm 3.1 Truncation procedure for the FLT.

```
CALL  $(\mathbf{f}, \mathbf{g}) \leftarrow \text{BSP\_Trunc2}(s_0, s_1, p_1, n, \mathbf{u}, \mathbf{v})$.
DESCRIPTION
              if $p_1 = 1$ then
$1^{\text{Comp}}$            Sequential truncation.
                  $(\mathbf{f}_{\frac{\mathbf{n}}{\mathbf{2}}}, \mathbf{g}_{\frac{\mathbf{n}}{\mathbf{2}}}) \leftarrow \text{Copy2}(\frac{n}{2}, \mathbf{u}, \mathbf{v})$
              else
$2^{\text{Comm}}$            Parallel truncation.
                  if $s_1 < \frac{p_1}{2}$ then
                      $(\mathbf{f}_{\mathbf{s_1}\frac{\mathbf{n}}{\mathbf{p_1}}+\frac{\mathbf{n}}{\mathbf{2}}}, \mathbf{g}_{\mathbf{s_1}\frac{\mathbf{n}}{\mathbf{p_1}}+\frac{\mathbf{n}}{\mathbf{2}}}) \leftarrow \text{Put2}(s_0 + s_1 + \frac{p_1}{2}, \frac{n}{p_1}, \mathbf{u}_{\mathbf{s_1}\frac{\mathbf{n}}{\mathbf{p_1}}}, \mathbf{v}_{\mathbf{s_1}\frac{\mathbf{n}}{\mathbf{p_1}}})$
                  Synchronize
```

Algorithm 3.2 Basic parallel algorithm for the FLT.

CALL BSP_FLT$(s, p, N, M, \mathbf{f})$.

ARGUMENTS

s: Processor identification; $0 \le s < p$.
p: Number of processors; p is a power of 2 with $p < N$.
N: Transform size; N is a power of 2 with $N \ge 4$.
M: Termination block size; M is a power of 2 with $M \le \min(N/2, N/p)$.
$\mathbf{f} = (f_0, \dots, f_{N-1})$: Real vector of size N (block distributed).

OUTPUT $\mathbf{f} \leftarrow \hat{\mathbf{f}}$.

DESCRIPTION

```

              $\mathbf{f}_\mathbf{l} \leftarrow$ Terminate$(l, M, \mathbf{f}_\mathbf{l}, \mathbf{g}_\mathbf{l})$
```

The basic parallel algorithm for the FLT is presented as Algorithm 3.2. At each stage $k \le \log_2(N/M)$ of the algorithm, there are 2^{k-1} independent problems. For $k \le \log_2 p$, there are more processors than problems, so the processors will have to work in groups. Each group of $p_1 = p/2^{k-1} > 1$ processors handles one subvector of size $2K$, $K = N/2^k$; each processor handles a block of $2K/p_1 = N/p$ vector components. In this case, the l-loop has only one iteration, namely, $l = s_0 \cdot N/p$, and the j-loop has N/p iterations, starting with $j = s_1 \cdot N/p$, so that the indices $l+j$ start with $(s_0 + s_1)N/p = s \cdot N/p$ and end with $(s_0 + s_1)N/p + N/p - 1 = (s+1)N/p - 1$. Interprocessor communication is needed, but it occurs only in two instances:

- inside the parallel FChTs (in supersteps 2, 5, 7); see section 4;
- at the end of each stage (in supersteps 3, 8).

For $k > \log_2 p$, the length of the subvectors involved becomes $2K \leq N/p$. In that case, $p_1 = 1$, $s_0 = s$, and $s_1 = 0$, and each processor has one or more complete problems to deal with, so that the processors can work independently and without communication. Note that the index l runs only over the local values sN/p, $sN/p+2K$, …, $(s+1)N/p - 2K$ instead of over all values of l.

The original stages 0 and 1 of Algorithm 2.3 are combined into one stage and then performed efficiently as follows. First, in superstep 1, the polynomials Z_1^N, $Z_{N/2}^N$, and $Z_{N/2+1}^N$ are computed directly from the input vector $\mathbf{f}$. This is possible because the point-value representation of $Z_1^N = \mathcal{T}_N(f \cdot P_1) = \mathcal{T}_N(f \cdot x)$ needed by the recurrences is the vector of $f_j \cdot x_j^N, 0 \leq j < N$; see subsection 2.3.1. In superstep 2, polynomials $Z_0^N = \mathbf{f}, Z_1^N = \mathbf{g}, Z_{N/2}^N = \mathbf{u}$, and $Z_{N/2+1}^N = \mathbf{v}$ are transformed to Chebyshev representation; then, in superstep 3, they are truncated to obtain the input for stage 2.

The main loop works as follows. In superstep 4, the polynomials Z_l^{2K}, with $K = N/2^k$ and $l = 0, 2K, \ldots, N-2K$, are copied from the array $\mathbf{f}$ into the auxiliary array $\mathbf{u}$, where they are transformed into the polynomials Z_{l+K}^{2K} in supersteps 5–7. Similarly, the polynomials Z_{l+1}^{2K} are copied from $\mathbf{g}$ into $\mathbf{v}$ and then transformed into the polynomials Z_{l+K+1}^{2K}. Note that $\mathbf{u}$ corresponds to the lower value of l, so that in the recurrence the components of $\mathbf{u}$ must be multiplied by values from $\mathbf{R}$. In superstep 8, all the polynomials are truncated by copying the first K Chebyshev coefficients of Z_{l+K}^{2K} into the memory space of the last K Chebyshev coefficients of Z_l^{2K}. The same happens to polynomials Z_{l+K+1}^{2K} and Z_{l+1}^{2K}.

The termination procedure, superstep 9, is a direct implementation of Lemma 2.12 using the data structure $\mathbf{T}$ described in subsection 3.2. Superstep 9 is a computation superstep, provided the condition $M \leq N/p$ is satisfied. This usually holds for the desired termination block size M. In certain situations, however, one would like to terminate even earlier, with a block size larger than N/p. This extension is discussed in [23].

4. Improvements of the parallel algorithm.

4.1. FChT of two vectors, FChT2. The efficiency of the FLT algorithm depends strongly on the FCT algorithm used to perform the Chebyshev transform. There exists a substantial amount of literature on this topic and many implementations of sequential FCTs are available; see, e.g., [1, 29, 30, 33]. Parallel algorithms or implementations have been less intensively studied; see [31] for a recent discussion.

In the FLT algorithm, the Chebyshev transforms always come in pairs, which led us to develop an algorithm that computes two Chebyshev transforms at the same time. The new algorithm is based on the FCT algorithm given by Van Loan [35, Algorithm 4.4.6] and the standard algorithm for computing the FFTs of two real input vectors at the same time (see, e.g., [29]). The new algorithm employs a complex FFT, which is advantageous in the sequential case because as a separate module the complex FFT can easily be replaced, for instance, by a newer, more efficient FFT. Even in the parallel case, where the parallel FFT module needs to be modified to reduce the communication cost of the FLT, we can still make use of the techniques developed for the parallel complex FFT and reuse parts of the FFT code; see subsection 5.4.

The Chebyshev transform is computed as follows. Let $\mathbf{x}$ and $\mathbf{y}$ be the input vectors of length N. We view $\mathbf{x}$ and $\mathbf{y}$ as the real and imaginary parts of a complex vector $(\mathbf{x} + i\,\mathbf{y})$. The algorithm has three phases. Phase 1, the packing of the input data into an auxiliary complex vector $\mathbf{z}$ of length N, is a simple permutation:

$$\left\{ \begin{array}{ll} z_j & = (x_{2j} + i\, y_{2j}), \\ z_{N-j-1} & = (x_{2j+1} + i\, y_{2j+1}), \qquad 0 \le j < N/2. \end{array} \right. \tag{4.1}$$

In phase 2, the complex FFT creates a complex vector $\mathbf{Z}$ of length N:

$$Z_k = \sum_{j=0}^{N-1} z_j e^{\frac{2\pi ijk}{N}}, \qquad 0 \le k < N. \tag{4.2}$$

This phase takes $4.25N \log_2 N$ flops if we use a radix-4 algorithm [35]. Finally, in phase 3 we obtain the Chebyshev transform by

$$(\tilde{x}_k + i\tilde{y}_k) = \frac{\epsilon_k}{2N}(e^{\frac{\pi ik}{2N}} Z_k + e^{-\frac{\pi ik}{2N}} Z_{N-k}), \qquad 0 \le k < N. \tag{4.3}$$

The value Z_N in (4.3) is defined as $Z_N = Z_0$ by periodic extension of (4.2). Phase 3 is efficiently performed by computing the components k and $N-k$ together and using symmetry properties. The cost of phase 3 is $10N$ flops. The total cost of the FChT2 algorithm is thus $4.25N \log_2 N + 10N$, giving an average $\alpha = 2.125$ and $\beta = 5$ for a single transform.

The verification that (4.1)–(4.3) indeed produce the Chebyshev transform is best made in two steps. First, we prove that

$$e^{\frac{\pi ik}{2N}} Z_k = \sum_{j=0}^{N/2-1} [(x_{2j} + iy_{2j})e^{\frac{\pi ik(4j+1)}{2N}} + (x_{2j+1} + iy_{2j+1})e^{-\frac{\pi ik(4j+3)}{2N}}], \tag{4.4}$$

and

$$e^{-\frac{\pi ik}{2N}} Z_{N-k} = \sum_{j=0}^{N/2-1} [(x_{2j} + iy_{2j})e^{-\frac{\pi ik(4j+1)}{2N}} + (x_{2j+1} + iy_{2j+1})e^{\frac{\pi ik(4j+3)}{2N}}]. \tag{4.5}$$

Second, we add (4.4) to (4.5) and multiply the result by $\frac{\epsilon_k}{2N}$ to obtain the desired equality (2.7).

The inverse Chebyshev transform is obtained by inverting the procedure described above. The phases are performed in the reverse order, and the operation of each phase is replaced by its inverse. The cost of the inverse FChT algorithm is the same as that of the FChT algorithm.

Efficient parallelization of this algorithm requires breaking open the parallel FFT inside the FChT2 and merging parts of the FFT with the surrounding computations. We explain this process in the following subsection.

4.2. Parallel FFT within the scope of the parallel FChT2. The FFT is a well-known method for computing the discrete Fourier transform (4.2) of a complex vector of length N in $O(N \log N)$ operations. It can concisely be written as a decomposition of the Fourier matrix F_N,

$$F_N = A_N \cdots A_8 A_4 A_2 P_N, \tag{4.6}$$

where F_N is an $N \times N$ complex matrix, P_N is an $N \times N$ permutation matrix corresponding to the so-called *bit reversal permutation*, and the $N \times N$ matrices A_L are defined by

$$A_L = I_{N/L} \otimes B_L, \quad L = 2, 4, 8, \ldots, N, \tag{4.7}$$

which is shorthand for a block-diagonal matrix $\mathrm{diag}(B_L, \ldots, B_L)$ with N/L copies of the $L \times L$ matrix B_L on the diagonal. The matrix B_L is known as the $L \times L$ *butterfly matrix.*

This matrix decomposition naturally leads to the *radix*-2 *FFT* algorithm [11, 35]. In a radix-2 FFT of size N, the input vector $\mathbf{z}$ is permuted by P_N and then multiplied successively by all the matrices A_L. The multiplications are carried out in $\log_2 N$ stages, each with N/L times a butterfly computation. One butterfly computation modifies $L/2$ pairs $(z_j, z_{j+L/2})$ at distance $L/2$ by adding a multiple of $z_{j+L/2}$ to z_j and subtracting the same multiple.

Parallel radix-2 FFTs have already been discussed in the literature; see, e.g., [25]. For simplicity, we restrict ourselves in our exposition to FFT algorithms where $p \leq \sqrt{N}$. This class of algorithms uses the block distribution to perform the short distance butterflies with $L \leq N/p$ and the cyclic distribution to perform the long distance butterflies with $L > N/p$. Figure 4.1(a) gives an example of the cyclic distribution, which is defined as follows.

Definition 4.1 (cyclic distribution). *Let* $\mathbf{z}$ *be a vector of size* N. *We say that* $\mathbf{z}$ *is* cyclically distributed *over* p *processors if, for all* j, *the element* z_j *is stored in* $\mathrm{Proc}(j \bmod p)$ *and has local index* $j' = j \operatorname{div} p$.

Using such a parallel FFT algorithm, we obtain a basic parallel FChT2 algorithm for two vectors $\mathbf{x}$ and $\mathbf{y}$ of size N.

1. PACK vectors $\mathbf{x}$ and $\mathbf{y}$ as the auxiliary complex vector $\mathbf{z}$ by permuting them, using (4.1).
2. TRANSFORM vector $\mathbf{z}$ using an FFT of size N.
   (a) Perform a bit reversal permutation in $\mathbf{z}$.
   (b) Perform the short distance butterflies of size $L = 2, 4, \ldots, N/p$.
   (c) Permute $\mathbf{z}$ to the cyclic distribution.
   (d) Perform the long distance butterflies of size $L = 2N/p, 4N/p, \ldots, N$.
   (e) Permute $\mathbf{z}$ to the block distribution.
3. EXTRACT the transforms from vector $\mathbf{z}$ and store them in vectors $\mathbf{x}$ and $\mathbf{y}$.
   (a) Permute $\mathbf{z}$ to put components j and $N - j$ in the same processor.
   (b) Compute the new values of $\mathbf{z}$ using (4.3).
   (c) Permute $\mathbf{z}$ to block distribution, and store the result in vectors $\mathbf{x}$ and $\mathbf{y}$.

The time complexity of this basic algorithm will be reduced by a sequence of improvements as detailed in the following subsections.

4.2.1. Combining permutations. By breaking open the FFT phase inside the parallel FChT2 algorithm, we can combine the packing permutation (1) and the bit reversal (2(a)), thus saving one complete permutation of BSP cost $2\frac{N}{p}g + l$. The same can be done for (2(e)) and (3(a)).

4.2.2. Increasing the symmetry of the cyclic distribution. We can eliminate permutation (2(e))/(3(a)) completely by restricting the number of processors slightly further to $p \leq \sqrt{N/2}$ and permuting the vector $\mathbf{z}$ in phase (2(e)) from block distribution to a slightly modified cyclic distribution, the zig-zag cyclic distribution, shown in Figure 4.1(b) and defined as follows.

Definition 4.2 (zig-zag cyclic distribution). *Let* $\mathbf{z}$ *be a vector of size* N. *We say that* $\mathbf{z}$ *is* zig-zag cyclically distributed *over* p *processors if, for all* j, *the element* z_j *is stored in* $\mathrm{Proc}(j \bmod p)$ *if* $j \bmod 2p < p$ *and in* $\mathrm{Proc}(-j \bmod p)$ *otherwise, and has local index* $j' = j \operatorname{div} p$.

In this distribution, both the components j and $j + L/2$ needed by the butterfly

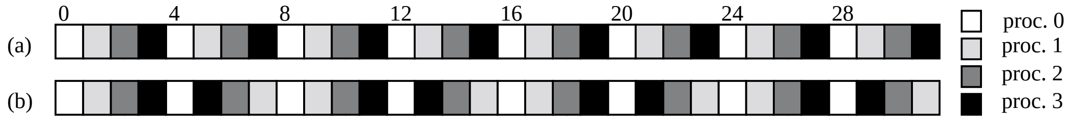

FIG. 4.1. (a) *Cyclic distribution and* (b) *zig-zag cyclic distribution for a vector of size* 32 *distributed over four processors.*

operations with $L > N/p$ and the components j and $N - j$ needed by the extract operation are in the same processor; thus we avoid the permutation (2(e))/(3(a)) above, saving another $2\frac{N}{p}g + l$ in BSP costs.

4.2.3. Reversing the stages for the inverse FFT. To be able to apply the same ideas to the inverse transform we perform the inverse FFT by reversing the stages of the FFT and inverting the butterflies, instead of taking the more common approach of using the same FFT algorithm but replacing the powers of $e^{\frac{2\pi i}{N}}$ by their conjugates. Thus we save $6\frac{N}{p}g + 3l$, both in the Chebyshev transform and its inverse.

4.2.4. Reducing the number of flops. Wherever possible we take pairs of stages $A_{2L}A_L$ together and perform them as one operation. The butterflies have the form $B_{2L}(I_2 \otimes B_L)$, which is a $2L \times 2L$ matrix consisting of 4×4 blocks, each an $L/2 \times L/2$ diagonal submatrix. This matrix is a symmetrically permuted version of the radix-4 butterfly matrix [35]. This approach gives both the efficiency of a radix-4 FFT algorithm and the flexibility of treating the parallel FFT within the radix-2 framework; for example, it is possible to redistribute the data after any number of stages and not only after an even number. The radix-4 approach reduces α from 2.5 to 2.125. An additional benefit of radix-4 butterflies is better use of the cache memory: 34 flops are performed on a quadruple of data, instead of 10 flops on a pair of data. Thus 8.5 flops are carried out per data word loaded into the cache, instead of five flops. This effect may be even more important than the reduction in flop count.

Since we do not use the upper half of the Chebyshev coefficients computed in the forward transform, we can alter the algorithm to avoid computing them. This saves $4N$ flops in (4.3).

4.3. Main loop. The discussion that follows is only relevant in the parallel part of the main loop, i.e., stages $k \le \log_2 p$, so we will restrict ourselves to these stages. Recall that in these stages a group of $p_1 = p/2^{k-1} > 1$ processors handles only one subproblem of size $2K = 2N/2^k$ corresponding to $l = s_0\frac{N}{p}$.

4.3.1. Modifying the truncation/copy operation. It is possible to reorganize the main loop of the FLT algorithm such that the end of stage k and the start of stage $k+1$ are merged into one, more efficient procedure. The current sequence of operations is as follows.

1. Permute from zig-zag cyclic to block distribution in stage k.
2. Truncate at the end of stage k.
3. Copy at the beginning of stage $k + 1$.
4. Permute from block to zig-zag cyclic distribution in stage $k + 1$.

In the new approach, we aim at removing permutations 1 and 4 by keeping the data in the zig-zag cyclic distribution of stage k during part of stage $k + 1$ as well. In the following discussion, we treat only operations on the arrays $\mathbf{f}$ and $\mathbf{u}$ because the operations on $\mathbf{g}$ and $\mathbf{v}$ are similar. The values of K and p_1 used in the discussion are those of stage k. Now assume that the second half of the $2K$ elements of $\mathbf{f_l}$ has been discarded. Recall that the second half of $\mathbf{u_l}$ has not even been computed; see subsection 4.2.4. Therefore, $\mathbf{f_l}$ and $\mathbf{u_l}$ are now in the zig-zag cyclic distribution of K elements (instead of $2K$) over p_1 processors. The new sequence of operations, illustrated in Figure 4.2, is as follows.

1. Prepare a working copy of the data needed at stage $k+1$.
   - (a) Copy vector $\mathbf{u_l}$ of size K into vector $\mathbf{u_{l+K}}$.
   - (b) Copy vector $\mathbf{f_l}$ of size K into vector $\mathbf{u_l}$.
2. Redistribute the data needed at stage $k+2$.
   - (a) Put the first $K/2$ elements of vector $\mathbf{u_l}$ into vector $\mathbf{f_l}$ in the zig-zag cyclic distribution over the first $\frac{p_1}{2}$ processors.
   - (b) Put the first $K/2$ elements of vector $\mathbf{u_{l+K}}$ into vector $\mathbf{f_{l+K}}$ in the zig-zag cyclic distribution over the next $\frac{p_1}{2}$ processors.

The synchronization at the end of the redistribution can be removed by buffering and delaying the communications until the next synchronization. The new approach reduces the BSP cost of the truncation/copy operation from $6\frac{N}{p}g + 3l$ to $\frac{N}{p}g$.

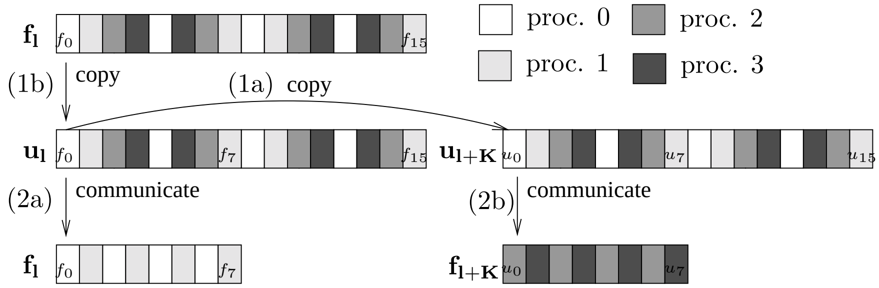

FIG. 4.2. *New truncation/copy operation of vectors* $\mathbf{f_l}$ *and* $\mathbf{u_l}$ *for* $K = 16$ *and* $p_1 = 4$.

As a result, vectors $\mathbf{u_l}$ and $\mathbf{u_{l+K}}$ contain all the data needed at stage $k+1$, and vectors $\mathbf{f_l}$ and $\mathbf{f_{l+K}}$ contain half the data needed at stage $k+2$; stage $k+1$ will produce the other half. We now verify that the operations on $\mathbf{u_l}$ and $\mathbf{u_{l+K}}$ at the start of stage $k+1$ remain local and hence do not require communication. The first operation is the inverse of operation (4.3), which acts on an array of size K. The pairs (u_{l+j}, u_{l+K-j}) and (u_{l+K+j}, u_{l+2K-j}) involved in this operation are indeed local. After that, the long distance butterflies of the inverse FFT have to be performed, and then the short distance ones have to be performed. The short distance butterflies, of size $L \leq K/(p_1/2)$, will be done after a suitable redistribution as in the original algorithm, using the block distribution over $p_1/2$ processors. The long distance butterflies operate on pairs $(u_{l+j}, u_{l+j+L/2})$ and $(u_{l+K+j}, u_{l+K+j+L/2})$ with $L \geq 4K/p_1$. The restriction $p \leq \sqrt{N/2}$ implies $p_1 \leq \sqrt{K}$ and hence $2p_1 \leq 2K/p_1$, which means that the period of the zig-zag cyclic distribution over p_1 processors does not exceed the minimum butterfly distance. As a result, the pairs involved are local.

4.3.2. Moving the bit reversal to the precomputation. Another major improvement is to avoid the packing/bit reversal permutation (1)/(2(a)) in the FChT2 just following the recurrence and its inverse preceding the recurrence, thus saving another $4\frac{N}{p}g + 2l$ in communication costs. This is done by storing the recurrence coefficients permuted by the packing/bit reversal permutation. This works because one permutation is the inverse of the other, so that the auxiliary vector $\mathbf{z}$ is in the same ordering immediately before and after the permutations.

4.4. Time complexity. After all the improvements, the total communication and synchronization cost is approximately $(5\frac{N}{p}\log_2 p)g + (2\log_2 p)l$. Only two communication supersteps remain: the zig-zag cyclic to block redistribution inside the inverse FFT, which can be combined with the redistribution of the truncation, and the block to zig-zag cyclic redistribution inside the FFT. To obtain this complexity, we ignored lower order terms and special cases occurring at the start and the end of the algorithm.

The total cost of the optimized algorithm without early termination is

$$T_{\mathrm{FLT,par}} \approx 4.25\frac{N}{p}\log_2^2 N + \left(5\frac{N}{p}\log_2 p\right) g + (2\log_2 p)\, l. \tag{4.8}$$

5. Experimental results and discussion. In this section, we present results on the accuracy and scalability of the implementation of the Legendre transform algorithm. We implemented the algorithm in ANSI C using the BSPlib library [21]. Our programs are completely self-contained, and we did not rely on any system-provided numerical software such as BLAS, FFTs, etc. Nonetheless, we used an optimized FFT package [27] to illustrate how to optimize the computation supersteps of the code; see section 5.4. We tested our programs using the Oxford BSP toolset [22] implementation of BSPlib running on two different machines:

1. a *Cray T3E* with up to 64 processors, each having a theoretical peak speed of 600 Mflop/s, with double precision (64-bit) accuracy of 1.0×10^{-15};
2. an *IBM RS/6000 SP* with up to 8 processors, each having a theoretical peak speed of 640 Mflop/s, which uses the more common IEEE 754 floating point arithmetic with double precision accuracy of 2.2×10^{-16}.

To make a consistent comparison of the results, we compiled all test programs using the `bspfront` driver with options `-O3 -flibrary-level 2 -bspfifo 10000 -fcombine-puts` (on the IBM we had to add the option `-fcombine-puts-buffer 256K,8M,256K`) and measured the elapsed execution times on exclusively dedicated CPUs using the system clock.

5.1. Accuracy. We tested the accuracy of our implementation by measuring the error obtained when transforming a random input vector $\mathbf{f}$ with elements uniformly distributed between 0 and 1. The relative error is defined as $||\hat{\mathbf{f}}^* - \hat{\mathbf{f}}||_2/||\hat{\mathbf{f}}||_2$, where $\hat{\mathbf{f}}^*$ is the FLT and $\hat{\mathbf{f}}$ is the exact DLT (computed by (2.9), using the stable three-term recurrence (2.10) and quadruple precision); $||\cdot||_2$ indicates the L^2-norm.

Table 5.1 shows the relative errors of the sequential algorithm for various problem sizes using double precision except in the precomputation of the last column, which is carried out in quadruple precision. This could not be done for the Cray T3E because quadruple precision is not available there. Note, however, that it is possible to precompute the values on another computer. The results show that the error of the FLT algorithm is comparable with the error of the DLT provided that the precomputed values are accurate. Therefore, it is best to perform the precomputation in increased precision. This can be done at little extra cost because the precomputation is done only once and its cost can be amortized over many FLTs. See [19, 20] for a discussion of other techniques that can be used to obtain more accurate results.

The errors of the parallel implementation are of the same order as in the sequential case. The only part of the parallel implementation that differs from the sequential implementation in this respect is the FFT, and then only if the butterfly stages cannot be paired in the same way. Varying the termination block size between 2 and 128 also does not significantly change the magnitude of the error.

Table 5.1

Relative errors for the sequential FLT algorithm. (QP indicates that the precomputation is carried out in quadruple precision.)

5.2. Efficiency of the sequential implementation. We measured the efficiency of our optimized FLT algorithm by comparing its execution time with the execution time of the direct DLT algorithm (i.e., a matrix-vector multiplication). Table 5.2 shows the times obtained by the direct algorithm and the FLT with various termination values: $M = N/2$ is the maximum termination value that our program can handle, and the resulting algorithm is similar to the seminaive algorithm [12]; $M = 64$ is the empirically determined value that makes the algorithm perform best for $N \leq 8192$ on the Cray T3E and for $N \leq 16384$ on the IBM SP (for larger values of N, the choice $M = 128$ gives slightly better results); $M = 2$ yields the pure FLT algorithm without early termination.

The results show that for the choice $M = N/2$ the behavior of the FLT is similar to that of the DLT. On the other extreme, the pure FLT algorithm with $M = 2$ becomes faster than the DLT algorithm at $N = 128$. Choosing the optimum value $M = 64$ further improves the performance of the FLT. This optimum is close to the theoretical optimum $M = 128$ calculated in section 2.4.

Another advantage of the FLT is its reduced need of storage space for the precomputed data. While the DLT must store $O(N^2)$ precomputed values, the FLT needs to store only $O(N \log N)$ precomputed values. Furthermore, these values can be computed in only $O(N \log^2 N)$ operations using Algorithm B.1, which is presented in Appendix B. Table 5.3 lists the storage and precomputation requirements for the DLT and the FLT for various input sizes, assuming a precomputation cost of $4N(N-2)$ for the direct transform and $12.75N \log_2^2 N + 76.25N \log_2 N$ for the fast transform; cf. (B.3).

5.3. Scalability of the parallel implementation. We tested the scalability of our optimized parallel implementation using our optimized sequential implementation as basis for comparison.

Tables 5.4 and 5.5 show the execution times on the Cray T3E for up to 64 proces-

sors and the IBM SP for up to eight processors, respectively. The tables list timing results for the sequential and parallel algorithms with $p < \sqrt{N}$ and $M = 2, 64$. The table for the Cray starts at a lower value of N because on the Cray parallelism is already advantageous for much smaller problem sizes. In general, the Cray T3E delivers better scalability than the IBM SP, but the execution on the IBM SP is faster. Qualitatively, this is in accordance with the BSP parameters for these machines given in Table 5.6: the parameters g and l are smaller for the Cray T3E, which means relatively faster communication and synchronization, whereas the parameter s is larger for the IBM SP, which means faster computation.

The BSP parameters presented in Table 5.6 reflect the way we implemented the communication subroutines of our programs. Our implementations divide the communication supersteps into three phases. In phase 1, the data are locally rearranged in such a way that the elements to be sent to the same processor are packed together. In phase 2, packets of data are exchanged between the processors. In phase 3, the data are unpacked locally so that the elements get to their final destination. This scheme generally saves communication time for regular communication patterns, because the overhead of sending corresponding address information together with the actual data is drastically reduced. Furthermore, we implemented the communication subroutines using `hpputs` (high performance put operations that dispense with the use of buffers). Therefore, the l and g values of Table 5.6 were measured for large data packets sent by using `hpputs`. For more details, see [23, Appendix A].

Figure 5.1 shows the behavior of our algorithm in terms of flop rate per processor:

$$F(N,p) = \frac{4.25N \log_2^2 N + 34.5N \log_2 N}{p \cdot T(N,p)}. \tag{5.1}$$

Here, the numerator represents the number of flops of the basic sequential FLT algorithm with only the two main terms included and without optimizations such as early termination. This gives a convenient reference count for the FLT, similar to the

common count of $5N \log_2 N$ for the FFT. Furthermore, $T(N, p)$ denotes the execution time of the parallel FLT algorithm. Ideally, the flop rates should be high and remain constant with an increase in p. As already pointed out, in absolute numbers, the IBM SP delivers more Mflops per second, but the Cray T3E maintains better flop rates as a function of p.

Normalizing $F(N, p)$ against the flop rate of the sequential algorithm, $F^{\text{seq}}(N)$ (the entry labeled "seq" in Figure 5.1), gives the absolute efficiency of a parallel algorithm:

$$E^{\text{abs}}(N, p) = \frac{F(N, p)}{F^{\text{seq}}(N)}. \tag{5.2}$$

The absolute efficiency can be used as a measure of the scalability of the parallel algorithm. Ideally, $E^{\text{abs}}(N, p) = 1$. As a rule of thumb, efficiencies larger than 0.8 are considered very good, while efficiencies of 0.5 are reasonable. From the nearly horizontal lines of $F(N, p)$ for large N, it is clear that the algorithm scales very well asymptotically (i.e., when N is large). The experimental results also show that on the Cray T3E with up to 64 processors a size of $N \geq 8192$ already gives reasonable to very good efficiencies, whereas on the IBM SP with up to eight processors, N must at least be equal to 32768. Note that on the Cray T3E, efficiencies larger than one are observed for $N \geq 16384$. This is a well-known phenomenon related to cache size.

The DLT is often used as part of a larger spherical harmonic transform. This means that, in practical applications, many independent FLTs of small size will be performed by a group of processors that could be only slightly larger than the number of transforms. For this reason, it is important that the FLT algorithm scales well for small N and p. Indeed, our algorithm already delivers reasonable to good efficiencies on the Cray T3E with up to eight processors for N as small as 512; on the IBM SP, larger problem sizes are needed.

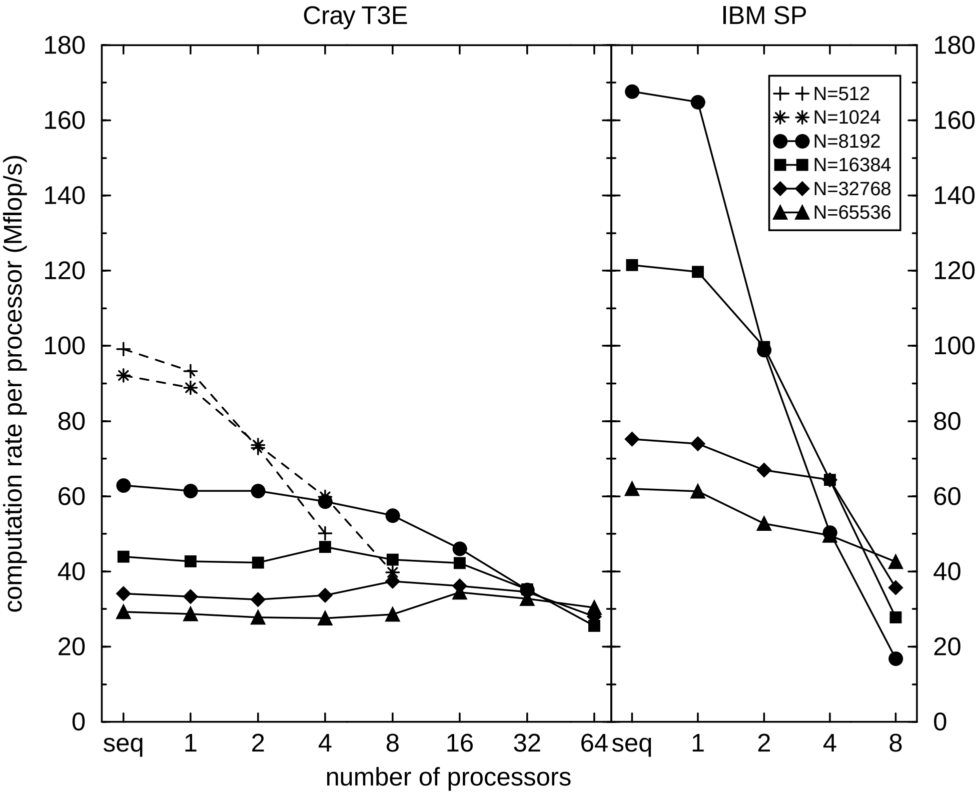

Fig. 5.1. *Mflop/s rate per processor of the FLT algorithm with termination parameter $M = 64$.*

5.4. Further optimizations. It is easy to modify our FLT algorithm to enable the use of complete FFTs instead of our own butterfly routines. In this subsection, we discuss the necessary modifications and demonstrate the possible gains by comparing our plain implementation with an optimized version that uses Ooura's FFT package `fft4g.c` [27]. This competitive FFT is on average 2.6 times faster than our butterflies and our FFT.

The sequential stages of our parallel algorithm involve complete FFTs, provided we do not move the bit-reversal permutation to the precomputation; see section 4.3.2. These FFTs can readily be replaced by highly optimized versions. Similarly, the short distance butterflies of the parallel stages can be replaced by a local bit-reversal permutation followed by a complete local FFT of size N/p. In stages 2 to $\log_2 p$, the extra permutation can be moved to the precomputation, so that it comes for free. (It is even possible to skip the extra permutation of the first stage; see [23, Section 2.3.2].)

Figure 5.2 shows the effect on the Cray T3E of optimizing the computation supersteps of the FLT algorithm. For small N, the main savings are already obtained by terminating early, while for large N they are achieved by using complete, faster FFTs. We also observe that computation is dominant for large values of N/p, which leaves in principle plenty of room for improvement of the FLT by optimizing the computation supersteps. For small N/p, however, such optimization will not have much

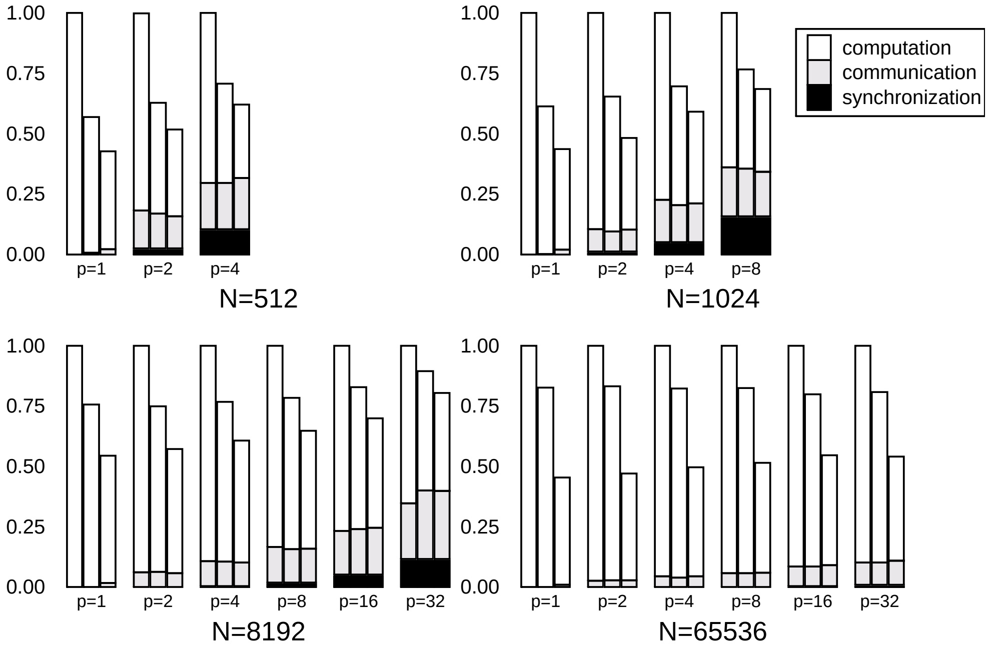

FIG. 5.2. *Gains achieved by optimizing the computational supersteps of the parallel FLT. Vertical bars represent the time of an FLT of length N executed on p processors of a Cray T3E, normalized with respect to our plain implementation with $M = 2$. The first bar of each triple represents the plain implementation with $M = 2$; the second bar represents the plain implementation optimized by early termination with $M = 64$; and the third bar represents the highly optimized version (with $M = 64$ and Ooura's FFT). Each bar is split into three parts, representing computation, communication, and synchronization time.*

effect because the dominant cost is that of communication and synchronization; we believe that these costs have already been reduced to the minimum.

Optimizing the FFTs of the sequential stages and the short distance butterflies of the parallel stages already covers most of the $O(N \log^2 N)$ computation operations of the algorithm. The only parts not yet optimized are as follows: the recurrence and pack/extract operations of the FChTs, with a total of $O(N \log N)$ flops, which can be carried out using level 1 BLAS; the $O(NM)$ termination routine which can be based on level 2 BLAS; and the long distance butterflies with a total of $O(N \log^2 p)$ flops. Since $p \ll N/p$ in practice, the long distance butterfly stages have a relatively small cost; if, however, $p \approx N/p$, this cost becomes significant. Fortunately, the long distance butterfly stages in the zig-zag cyclic distribution can also be carried out using FFTs at the expense of an extra $O(N \log p)$ flops and some local permutations. To do so, we first need to permute the vector to move the even elements to the front and then apply to both vector halves the method described in [23, sections 2.4 and 2.6], which performs cyclically distributed long distance butterflies using FFTs.

6. Conclusions and future work. As part of this work, we developed and implemented a sequential algorithm for the DLT, based on the Driscoll–Healy algorithm. This implementation is competitive for large problem sizes. Its complexity $O(N \log^2 N)$ is considerably lower than the $O(N^2)$ matrix-vector multiplication algorithms which are still much in use today for the computation of Legendre transforms.

Its accuracy is similar, provided the precomputation is performed in increased precision. The new algorithm is a promising approach for compute-intensive applications such as weather forecasting.

The main aim of this work was to develop and implement a parallel Legendre transform algorithm. Our experimental results show that the performance of our parallel algorithm scales well with the number of processors for medium to large problem sizes. The overhead of our parallel program consists mainly of communication, and this is limited to two redistributions of the full data set and one redistribution of half the set in each of the first $\log_2 p$ stages of the algorithm. Two full redistributions are already required by an FFT and an inverse FFT, indicating that our result is close to optimal. Our parallelization approach was first to derive a basic algorithm that uses block and cyclic data distributions and then to optimize this algorithm by removing permutations and redistributions wherever possible. To facilitate this we proposed a new data distribution, which we call the zig-zag cyclic distribution.

Within the framework of this work, we also developed a new algorithm for the simultaneous computation of two Chebyshev transforms. This is useful in the context of the FLT because the Chebyshev transforms always come in pairs, but such a double FChT also has many applications in its own right, as does the corresponding double FCT. Our algorithm has the additional benefit of easy parallelization. Our FFT, FChT, and FLT programs will be made available in the public domain as the package BSPFTpack, which can be obtained through the same Webpage as BSPEDUpack [7].

We view the present FLT as a good starting point for the use of fast Legendre algorithms in practical applications. However, to make our FLT algorithm directly useful in such applications, further work must be done: an inverse FLT must be developed; the FLT must be adapted to the more general case of the spherical harmonic transform where associated Legendre functions are used (this can be done by changing the initial values of the recurrences of the precomputed values and multiplying the results by normalization factors); and alternative choices of sampling points must be made possible. Lesur and Gubbins [26] have studied the accuracy of the generalization of the FLT to the spherical harmonic transform, and they found numerical instabilities for higher order transforms. Future research should investigate how techniques such as precomputation in quadruple precision and our method of truncation improve the accuracy in the general case. Driscoll, Healy, and Rockmore [15] have already shown how a variant of the Driscoll–Healy algorithm may be used to compute Legendre transforms at any set of sample points (see Appendix A), though the set of points chosen affects the stability of the algorithm.

Appendix A. Related transforms and algorithms.

The derivation of the Driscoll–Healy algorithm given in section 2 depends only on the properties of truncation operators $\mathcal{T}_n$ given in Lemma 2.9 and on the existence of an efficient algorithm for applying the truncation operators. In particular, Lemmas 2.9 and 2.11 hold as stated when the weight function $\omega(x) = \pi^{-1}(1-x^2)^{\frac{1}{2}}$ is changed, when the truncation operators are defined using a polynomial sequence which is orthogonal with respect to the new weight function and which starts with the polynomial 1, and when the Lagrange interpolation operators are defined using the roots of the polynomials from the sequence. In theory, this can be used to develop new algorithms for computing orthogonal polynomial transforms, though with different sample weights w_j. In practice, however, the existence of efficient Chebyshev and cosine transform algorithms makes these the only reasonable choice in the definition of the truncation operators. This situation may change with the advent of other fast transforms.

Theoretically, the basic algorithm works, with minor modifications, in the following general situation. We are given operators $\mathcal{T}_n^r$ for $1 \leq n \leq r$ such that the following hold.

1. $\mathcal{T}_n^r$ is a mapping from the space of polynomials of degree less than $2r$ to the space of polynomials of degree less than n.
2. If $m \leq n \leq r$, then $\mathcal{T}_m^n \mathcal{T}_n^r = \mathcal{T}_m^r$.
3. If $\deg Q \leq m \leq n \leq r$, then $\mathcal{T}_{n-m}^r(f \cdot Q) = \mathcal{T}_{n-m}^n\left[(\mathcal{T}_n^r f) \cdot Q\right]$.

The problem now is, given an input polynomial f of degree less than N, to compute the quantities $\mathcal{T}_1^N(f \cdot p_l)$ for $0 \leq l < N$, where $\{p_l\}$ is a sequence of orthogonal polynomials. This problem may be treated using the same algorithms as in section 2, but with the truncation operators $\mathcal{T}_n$ replaced by $\mathcal{T}_n^r$, where $r \leq N$ depends on the stage of the algorithm. Using $r = N$ retrieves our original algorithm. The generalized algorithm uses the quantities $Z_l^K = \mathcal{T}_K^N(f \cdot p_l)$, and the recurrences in this context are

$$Z_{l+K-1}^K = \mathcal{T}_K^{2K}[Z_l^{2K} \cdot Q_{l,K-1} + Z_{l-1}^{2K} \cdot R_{l,K-1}], \tag{A.1}$$

$$Z_{l+K}^K \quad = \mathcal{T}_K^{2K}[Z_l^{2K} \cdot Q_{l,K} + Z_{l-1}^{2K} \cdot R_{l,K}], \tag{A.2}$$

cf. (2.18) and (2.19).

This generalization of our approach may be used to derive the original algorithm of Driscoll and Healy in the exact form it was presented [13, 14], which uses the cosine transforms in the points $\cos(j\pi/K)$. For more details, see [24].

Driscoll, Healy, and Rockmore [15] describe another variant of the Driscoll–Healy algorithm that may be used to compute the Legendre transform of a polynomial sampled at the Gaussian points, i.e., at the roots of the Legendre polynomial P_N. Their method replaces the initial Chebyshev transform used to find the polynomial Z_0^N in Chebyshev representation by a Chebyshev transform taken at the Gaussian points. Once Z_0^N has been found in Chebyshev representation, the rest of the computation is the same.

The Driscoll–Healy algorithm can also be used for input vectors of arbitrary size, not only powers of two. Furthermore, at each stage, we can split the problem into an arbitrary number of subproblems, not only into two. This requires that Chebyshev transforms of suitable sizes are available.

Appendix B. The precomputed data.

In this appendix we describe algorithms for generating the point values of $Q_{l,m}, R_{l,m}$ used in the recurrence of the FLT algorithm and for generating the coefficients $q_{l,m}^n, r_{l,m}^n$ used in its termination stage.

Lemma B.1. *Let $l \geq 1$, $j \geq 0$, and $k \geq 1$. Then the associated polynomials $Q_{l,m}, R_{l,m}$ satisfy the recurrences*

$$Q_{l,j+k} = Q_{l+k,j} Q_{l,k} + R_{l+k,j} Q_{l,k-1}, \tag{B.1}$$

$$R_{l,j+k} = Q_{l+k,j} R_{l,k} + R_{l+k,j} R_{l,k-1}. \tag{B.2}$$

Proof. The proof is by induction on j. The proof for $j = 0$ follows immediately from the definition (2.13), since $Q_{l+k,0} Q_{l,k} + R_{l+k,0} Q_{l,k-1} = 1 \cdot Q_{l,k} + 0 = Q_{l,k}$ and similarly for $R_{l,k}$. The case $j = 1$ also follows immediately from the definition. For

$j > 1$, we have

$$\begin{aligned} Q_{l+k,j}Q_{l,k} + R_{l+k,j}Q_{l,k-1} &= \left[Q_{l+k+j-1,1}Q_{l+k,j-1} + R_{l+k+j-1,1}Q_{l+k,j-2}\right] Q_{l,k} \\ &\quad + \left[Q_{l+k+j-1,1}R_{l+k,j-1} + R_{l+k+j-1,1}R_{l+k,j-2}\right] Q_{l,k-1} \\ &= Q_{l+k+j-1,1}\left[Q_{l+k,j-1}Q_{l,k} + R_{l+k,j-1}Q_{l,k-1}\right] \\ &\quad + R_{l+k+j-1,1}\left[Q_{l+k,j-2}Q_{l,k} + R_{l+k,j-2}Q_{l,k-1}\right] \\ &= Q_{l+k+j-1,1}Q_{l,k+j-1} + R_{l+k+j-1,1}Q_{l,k+j-2} \\ &= Q_{l,k+j}, \end{aligned}$$

where we have used the case $j = 1$ to prove the first and last equality and the induction hypothesis for the cases $j-1, j-2$ to prove the third equality. In the same way we may show that $Q_{l+k,j}R_{l,k} + R_{l+k,j}R_{l,k-1} = R_{l,k+j}$. □

This lemma is the basis for the computation of the data needed in the recurrences of the Driscoll–Healy algorithm. The basic idea of the Algorithm B.1 is to start with polynomials of degree $0, 1$, given in only one point, and then repeatedly double the number of points by performing a Chebyshev transform, adding zero terms to the Chebyshev expansion, and transforming back, and also double the maximum degree of the polynomials by applying the lemma with $j = K-1, K$ and $k = K$.

```

Note that $\deg R_{l,m} \le m-1$, so the Chebyshev coefficients $r_{l,m}^n$ with $n \ge m$ are zero, which means that the polynomial is fully represented by its first m Chebyshev coefficients. In the case of the $Q_{l,m}$, the coefficients are zero for $n > m$. If $n = m$, however, the coefficient is nonzero, and this is a problem if $m = K$. The Kth coefficient which was set to zero must then be corrected and set to its true value, which can be computed easily by using (2.13) and (2.4).

The FLT algorithm requires the numbers

$$Q_{l,K}(x_j^{2K}),\quad Q_{l,K-1}(x_j^{2K}),\quad R_{l,K}(x_j^{2K}),\quad R_{l,K-1}(x_j^{2K}),\quad 0 \le j < 2K,$$

for $l = r \cdot 2K + 1$, $0 \le r < \frac{N}{2K}$, for all K with $M \le K \le N/2$. After the m-loop in stage $k = \log_2 K + 1$ of Algorithm B.1, we have obtained these values for $l = rK + 1$, $0 \le r < N/K$. We need only the values for even r, so the others can be discarded. The algorithm must be continued until $K = N/2$, i.e., $k = \log_2 N$.

The total number of flops of the precomputation of the point values is

$$T_{\text{precomp, point}} = 6\alpha N \log_2^2 N + (2\alpha + 12\beta + 12) N \log_2 N. \tag{B.3}$$

Comparing with the cost (2.25) of the Driscoll–Healy algorithm itself and considering only the highest order term, we see that the precomputation costs about three times as much as the Driscoll–Healy algorithm without early termination. This one-time cost, however, can be amortized over many subsequent executions of the algorithm.

Parallelizing the precomputation of the point values can be done most easily by using the block distribution. This is similar to our approach in deriving a basic parallel version of the Driscoll–Healy algorithm. In the early stages of the precomputation, each processor handles a number of independent problems, one for each l. At the start of stage k, such a problem involves K points. In the later stages, each problem is assigned to one processor group. The polynomials $Q_{l,K}$, $Q_{l,K-1}$, $R_{l,K}$, $R_{l,K-1}$, and $Q_{l+K,K}$, $Q_{l+K,K-1}$, $R_{l+K,K}$, $R_{l+K,K-1}$ are all distributed in the same manner, so that the recurrences are local. The Chebyshev transforms and the addition of zeros may require communication. For the addition of zeros, this is caused by the desire to maintain a block distribution while doubling the number of points. The parallel precomputation algorithm can be optimized following similar ideas as in the optimized main algorithm.

The precomputation of the coefficients $q_{l,m}^n, r_{l,m}^n$ required to terminate the Driscoll–Healy algorithm early, as in Lemma 2.12, is based on the following recurrences.

LEMMA B.2. *Let $l \ge 1$ and $m \ge 2$. The coefficients $q_{l,m}^n$ satisfy the recurrences*

$$q_{l,m}^n = \frac{1}{2} A_{l+m-1}(q_{l,m-1}^{n+1} + q_{l,m-1}^{n-1}) + B_{l+m-1} q_{l,m-1}^n + C_{l+m-1} q_{l,m-2}^n \text{ for } n \ge 2,$$

$$q_{l,m}^1 = A_{l+m-1}(q_{l,m-1}^0 + \frac{1}{2} q_{l,m-1}^2) + B_{l+m-1} q_{l,m-1}^1 + C_{l+m-1} q_{l,m-2}^1,$$

$$q_{l,m}^0 = \frac{1}{2} A_{l+m-1} q_{l,m-1}^1 + B_{l+m-1} q_{l,m-1}^0 + C_{l+m-1} q_{l,m-2}^0,$$

subject to the boundary conditions $q_{l,0}^0 = 1, q_{l,1}^0 = B_l, q_{l,1}^1 = A_l$, and $q_{l,m}^n = 0$ for $n > m$. The $r_{l,m}^n$ satisfy the same recurrences but with boundary conditions $r_{l,1}^0 = C_l$ and $r_{l,m}^n = 0$ for $n \ge m$.

Proof. These recurrences are the shifted three-term recurrences (2.13) rewritten in terms of the Chebyshev coefficients of the polynomials by using the equations $x \cdot T_n = (T_{n+1} + T_{n-1})/2$ for $n > 0$ and $x \cdot T_0 = T_1$. □

For a fixed l, we can compute the $q_{l,m}^n$ and $r_{l,m}^n$ by increasing m, starting with the known values for $m = 0, 1$, and finishing with $m = M - 2$. For each m, we need to compute only the $q_{l,m}^n$ with $n \le m$ and the $r_{l,m}^n$ with $n < m$. The total number of flops of the precomputation of the Chebyshev coefficients in the general case is

$$T_{\text{precomp, term}} = 7M^2 - 16M - 15. \tag{B.4}$$

When the initial values B_l are identically zero, the coefficients can be packed in alternating fashion into array $\mathbf{T}$, as shown in Figure 3.3. In that case the cost is considerably lower, namely, $2.5M^2 - 3.5M - 12$.

The precomputed Chebyshev coefficients can be used to save the early stages in Algorithm B.1. If we continue the precomputation of the Chebyshev coefficients two steps more and finish with $m = M$ instead of $m = M - 2$, we then can switch directly to the precomputation of the point values at stage $K = M$, just after the forward Chebyshev transforms.

Parallelizing the precomputation of the Chebyshev coefficients is straightforward, since the computation for each l is independent. Therefore, if $M \leq N/p$, both the termination and its precomputation are local operations.

Acknowledgments. We thank Dennis Healy, Daniel Rockmore, and Peter Kostelec for useful discussions. We thank the anonymous referees for valuable suggestions for improvement.

A LOCAL SPACE-TIME ADAPTIVE SCHEME IN SOLVING TWO-DIMENSIONAL PARABOLIC PROBLEMS BASED ON DOMAIN DECOMPOSITION METHODS[*]

HONGYI YU[†]

Abstract. We describe a local space-time adaptive refinement and derefinement method for solving systems of parabolic partial differential equations. Solutions are calculated on local space-time meshes using a domain decomposition finite element algorithm in space and an extrapolation algorithm in time. An a posteriori spatial error estimate controls a local spatial refinement strategy and an a posteriori temporal error estimate monitors temporal refinement and order of the integration. A multiplicative Schwarz algorithm is used to coordinate solutions between overlapping grids. We use nearly minimal fine meshes which follow the dynamics of the problems in an efficient manner.

Key words. local AMR scheme, domain decomposition, extrapolation methods, multiplicative Schwarz algorithm

1. Introduction.

Adaptive local refinement methods have been effectively used to solve a wide range of systems of partial differential equations [1, 3, 4, 5, 6, 7, 15, 16, 17, 18, 19]. Two basic strategies are structured and unstructured mesh refinement. Structured methods are further divided into cellular and noncellular methods, where cellular means that the fine mesh is aligned with the coarse mesh (see Figure 1a) and noncellular mesh means that the fine mesh can be skewed with respect to the coarse mesh (see Figure 1b).

Berger and Oliger [5] developed a noncellular overlapping uniform grid algorithm which allows alignment of fine grids with evolving dynamic structures. However, the data transition between coarse and fine grids is complicated. Multiple levels of overlapping refined grids, as shown in Figure 1b, require complicated data structures and data transition as well. Additionally, when using implicit methods in time, grids must not cross domain boundaries.

Arney and Flaherty [3] use cellular meshes to form fine grids with piecewise polygonal shapes. Data transition between fine and coarse grids is simplified with cellular refinement. However, the data structure is still complicated, since the refined grids are generally not rectangles. Thus, information associated with each node has to include pointers to the nodes above and below the node in the mesh. Further complications arise if high-order elements are used.

Moore and Flaherty [16] use rectangular meshes which are aligned with the coarse mesh to form overlapping patches. The problem is solved on the patches using a Schwarz alternating algorithm. The data structure is simplified in this case, but more work is required due to the large overlap between the rectangular meshes and over-refinement resulting from grids aligned with domain boundaries rather than solution features (see Figure 1a).

Another approach is to use unstructured meshes with triangular elements. These methods are more economical than the structured mesh methods in the sense that a

FIG. 1. *Cellular and noncellular overlapping grids.*

minimum region required for local solution is created. But the data structures are even more complicated, and so more memory is needed.

Domain decomposition methods have also become popular. The classical Schwarz alternating method has been extended to more than two subdomains and additive and multiplicative Schwarz methods have been developed [8, 11, 13, 21]. The methods have been widely used to solve elliptic partial differential equations as well as some simple, linear parabolic partial differential equations [11, 9, 10, 13]. The advantage of these methods is that each subdomain can be sent to a separate processor with communications needed only at the interfaces.

All the methods mentioned above use uniform time stepping when applied to solving parabolic partial differential equations. Herein, we develop a local space-time adaptive mesh refinement procedure coupled with a domain decomposition multiplicative Schwarz algorithm on structured meshes which has the advantage of using simple spatial grids, nearly minimal spatial overrefinement, and a variable time step over the spatial regions. By nearly minimal spatial overrefinement, we mean that the spatial overrefinement and resolution procedure are performed only in the regions that cover and are nearly as large as the regions that require a resolution as indicated by a posterior error estimator. Examples in section 5 show that our methods automatically create fine spatial meshes and small time steps (or fine space-time meshes) in regions of high activity based on the error estimates. Coarse spatial meshes and large time steps (or coarse space-time meshes) are used in regions of low activity.

Note: For clarity, we sometimes separate spatial meshes and time steps from space-time meshes as we did in the last paragraph.

In section 2, the model problem is defined and the underlying space discretization algorithm is presented. In section 3, we discuss the one- and two-level overlapping domain decomposition and the multiplicative Schwarz algorithm. We will give a detailed description of the local adaptive mesh refinement (AMR) procedure in section 4. Some examples that show the effectiveness of the method are presented in section 5. Concluding remarks are given in section 6.

2. The model problem and discretization.

Consider systems of nonlinear parabolic equations of the form

$$u_t + f(t, x, y, u, u_x, u_y) = [D_1(t, x, y, u)u_x]_x + [D_2(t, x, y, u)u_y]_y \tag{1}$$

for $(x, y) \in \Omega, t > 0$, together with the initial conditions

$$u(x, y, 0) = u_0(x, y), \quad (x, y) \in \overline{\Omega}, \tag{2}$$

and the mixed boundary conditions

$$u(t, x, y) = g_D(t, x, y), \quad (x, y) \in \partial\Omega_D, \quad t > 0, \tag{3}$$

$$D_1 u_x \eta^1 + D_2 u_y \eta^2 = g_N(t, x, y), \quad (x, y) \in \partial\Omega_N, \quad t > 0, \tag{4}$$

where (η^1, η^2) is the unit outer normal of $\partial\Omega$ and $\partial\Omega_D \bigcup \partial\Omega_N = \partial\Omega$, and $\Omega = [x_l, x_r] \times [y_l, y_r]$. The system is assumed to be well posed, i.e., D_1, D_2 are positive definite.

We solve the mixed boundary value problem (1)–(4) using a Galerkin finite element method with a hierarchical polynomial basis of degree $p \geq 1$ in space coupled with a variable-order, variable-step extrapolation method in time.

The Galerkin form of (1)–(4) is to find $u \in H_E^1$ such that

$$(u_t, v) + A(u, v) + (f, v) = \int_{\partial\Omega_N} v^T g_N ds \quad \forall v \in H_0^1, \quad t > 0, \tag{5}$$

$$A(u, v) = A(u^0, v) \qquad \forall v \in H_0^1, \quad t = 0, \tag{6}$$

where

$$(v, u) = \int_\Omega v(t, x, y)^T u(t, x, y) dx dy$$

and

$$A(u, v) = (D_1 u_x, v_x) + (D_2 u_y, v_y).$$

As usual, the Sobolev space $H^1(\Omega)$ consists of functions having square integrable first partial derivatives. The subscripts E and 0 further restrict this space to functions that satisfy (3) and a homogeneous version of (3), respectively.

Introduce partitions

$$\Omega_x = \{x_l = x_0 < x_1 < \cdots < x_{n_x} = x_r\},$$

$$\Omega_y = \{y_l = y_0 < y_1 < \cdots < y_{n_y} = y_r\}$$

of Ω into $m = n_x n_y$ elements. Let

$$h_x = \frac{x_r - x_l}{n_x}, \quad h_y = \frac{y_r - y_l}{n_y}, \quad h = \sqrt{h_x^2 + h_y^2}, \text{ and } \Delta^h = \Omega_x \times \Omega_y.$$

We approximate $H^1(\Omega)$ by a finite-dimensional subspace $S^{p,h}$ of piecewise polynomials of degree p, $p \geq 1$, defined on Δ^h. The finite element Galerkin approximation $U(t, x, y) \in S_E^{p,h}$ to $u(t, x, y) \in H_E^1(\Omega)$ is obtained by solving

$$(U_t, V) + A(U, V) + (f, V) = \int_{\partial\Omega_N} V^T g_N ds \quad \forall V \in S_0^{p,h}, \quad t > 0, \tag{7}$$

$$A(U, V) = A(u_0, V) \quad \forall V \in S_0^{p,h}, \quad t = 0. \tag{8}$$

A hierarchical basis is constructed for $S^{p,h}$ with rectangular elements using the tensor products of Legendre polynomials. We refer to Szabo and Babuska [20] for details.

3. Domain decomposition and multiplicative Schwarz methods.

3.1. One- and two-level decompositions with small overlap. Let Δ^H be a coarse mesh or H-level subdivision of Ω and let $\{\Omega_i\}_{i=1}^M$ be the elements of Δ^H with $M = N_x N_y$, where N_x and N_y are the number of subdivisions in the x- and y-directions, respectively. We further divide each coarse element Ω_i into smaller rectangles of lengths h_x and h_y, where $h_x = \frac{H_x}{r}$, $h_y = \frac{H_y}{r}$, and r is an integer (we take $r = 3$). The mesh Δ^h with $h = \sqrt{h_x^2 + h_y^2}$ is called the fine mesh or h-level subdivision of Ω. To obtain an overlapping decomposition, we extend each coarse element $\Omega_i = (x_i, x_{i+1}) \times (y_i, y_{i+1})$ to a slightly larger extended element $\Omega_i^{ext} = (x_i, x_{i+1} + \tilde{h}_x) \times (y_i, y_{i+1} + \tilde{h}_y)$, where

$$\tilde{h}_x = \begin{cases} h_x & \text{if } x_{i+1} < x_r, \\ 0 & \text{if } x_{i+1} = x_r, \end{cases} \qquad \tilde{h}_y = \begin{cases} h_y & \text{if } y_{i+1} < y_r, \\ 0 & \text{if } y_{i+1} = y_r. \end{cases}$$

We also require that $\Omega_i^{ext} \supset \overline{\Omega_i^{ext}} \bigcap \partial\Omega_N$, i.e., the Neumann boundary is included in $\bigcup_i \Omega_i^{ext}$.

The purpose of creating $\{\Omega_i^{ext}\}_{i=1}^M$ is to form overlapping subdomains of Ω. Using the extended elements, we can always form four overlapping subdomains as follows:

Let $m = (k-1)N_x + j$, the element number with $1 \le k \le N_y$ and $1 \le j \le N_x$. Define

$$\tilde{\Omega}_1 = \left\{ \bigcup \Omega_m^{ext}; \quad k, j \text{ are odd} \right\}, \qquad \tilde{\Omega}_2 = \left\{ \bigcup \Omega_m^{ext}; \quad k \text{ is odd and } j \text{ is even} \right\},$$

$$\tilde{\Omega}_4 = \left\{ \bigcup \Omega_m^{ext}; \quad k,\ j \text{ are even} \right\}, \qquad \tilde{\Omega}_3 = \left\{ \bigcup \Omega_m^{ext}; \quad k \text{ is even and } j \text{ is odd} \right\}.$$

Then we have

$$\bigcup_{i=1}^{4} \tilde{\Omega}_i = \bigcup_{i=1}^{M} \Omega_i^{ext}.$$

Each $\tilde{\Omega}_i$ is a union of disjoint extended elements, as illustrated in Figure 2 shown with their fine element structures. For convenience, each extended element Ω_i^{ext} with its fine element structure is called a local grid. Thus, $\tilde{\Omega}_1$ consists of 16 local grids, $\tilde{\Omega}_2$ and $\tilde{\Omega}_3$ both have 12, and $\tilde{\Omega}_4$ has 9 local grids. The overlaps between different $\tilde{\Omega}_i$'s have a width of one fine element. For each $\tilde{\Omega}_j, 1 \le j \le J$ (here $J = 4$), we define

$$V_j = \{v \in V^h; \quad v(x,y) = 0, (x,y) \notin \tilde{\Omega}_j\} \subset V^h$$

with $V^h = S_0^{p,h}$. If we denote $S_0^{p,H}$ by V_0, then we have the following two decompositions of V^h:

$$V^h = V_1 + \cdots + V_J$$

and

$$V^h = V_0 + V_1 + \cdots + V_J,$$

which will be referred to as the one-level and two-level uniformly overlapping decompositions of V^h, or as the decomposition without and with the coarse mesh space, respectively.

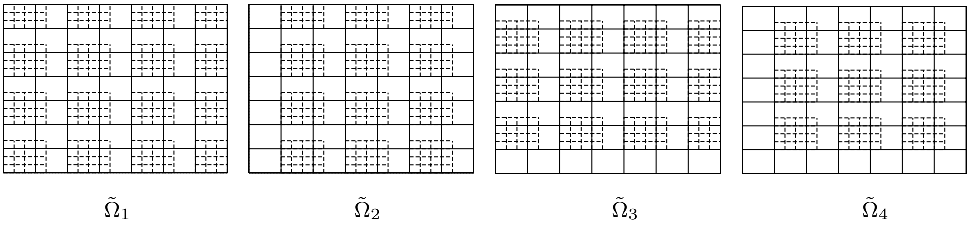

FIG. 2. *Partition of the entire domain into overlapping subdomains.*

We have eliminated the condition

$$\text{(9)} \qquad Distance\left(\partial\Omega_i^{ext}\bigcap\Omega, \partial\Omega_i\bigcap\Omega\right) \geq cH \quad \forall i, \quad c > 0,$$

proposed by Cai [9] and therefore achieved smaller overlaps between the local grids. The systems are made smaller, and in most cases the computational speed is increased [22]. The experiments also showed that the size of the overlap affects neither the accuracy of the solution nor the convergence of the multiplicative Schwarz algorithm.

3.2. Multiplicative Schwarz algorithms. We briefly describe the multiplicative Schwarz algorithm based on the two decompositions of V^h as described in section 3.1. We assume a set of triplets $\{W_i, P_i, w_i | i = 1, 2, \ldots, m\}$, where W_i are some subspaces of a normed linear space W, P_i are mappings from W to W_i, and $w_i \in W_i$. The multiplicative Schwarz algorithm can be described as follows:

MULTIPLICATIVE SCHWARZ $\{W_i, P_i, w_i\}$.

```
Given an initial guess $u^0 \in W$,
for $n = 0, 1, \ldots, n_{max}$;
    for $i = 1, \ldots, m$;
        $u^{n+\frac{i}{m}} = u^{n+\frac{i-1}{m}} + (w_i - P_i u^{n+\frac{i-1}{m}})$.
```

Remark 1. For linear problems, we have

$$u^{n+1} = Eu^n + g,$$

where

$$E = (I - P_m) \cdots (I - P_1),$$

and

$$g = (I - P_m) \cdots (I - P_2)w_1 + (I - P_m) \cdots (I - P_3)w_2 + \cdots + w_m.$$

The convergence rate of the multiplicative Schwarz algorithm is thus determined by the spectral radius of the operator E.

Remark 2. Let w be a fixed element in $S_E^{p,H}$. The Schwarz algorithm can be extended to the more general case where space W is replaced by $w + W$ and the mappings P_i are defined as $P_i : w + W \to W_i$. We will use the extended version of it.

The parabolic system is solved by dividing the time interval into several smaller ones. To apply the multiplicative Schwarz algorithm on interval $[t_j, t_{j+1}]$, we take W

to be $g_D + V^h$, W_i to be the subspace V_i of V^h, and $w_i \in W_i$ to be the solution of the ODE system

$$(10) \qquad (u_t, v) + A(u, v) + (f, v) = \int_{\partial\Omega_N \bigcap \tilde{\Omega_i}} v^T g_N ds \quad \forall v \in V_i, \quad t_j < t \le t_{j+1},$$

with the initial condition $u = u(t_j)$ for $t = t_j$. When $t_j = 0$, $u(0)$ is the solution from (8). The mapping $P_i : g_D + V^h \to V_i$ is defined by

$$(11) \qquad A(g_D + u, v) = A(P_i(g_D + u), v) \quad \forall v \in V_i, \quad \forall u \in V^h.$$

The ODE systems are solved independently in the interior of the local grids. While the projections P_i involve the information from the local grid boundaries, the multiplicative Schwarz algorithm merges the two sets of systems and passes information from grid to grid throughout the entire domain.

With a chosen base time step, $\Delta t_j = t_{j+1} - t_j$, on the entire domain, we solve the ODE systems (10) in the interior of each small local grid using the extrapolation method [12]. A variable time step and a variable integration order are used based on an a posteriori error estimate. Fine temporal meshes match fine spatial meshes in a consistent manner as shown in section 5. The examples in section 5 also show the commanding advantage, in terms of efficiency, of our adaptive space-time meshes over the adaptive space meshes with uniform time steps. For a detailed description of the time integration procedure, please refer to [22].

In applying the multiplicative Schwarz algorithm, we can use either the one-level or two-level decomposition. In general, the two-level decomposition requires fewer iterations than one-level decomposition, since the solution on the coarse grid improves the initial guess for the solutions on the fine grid and smooths the solution from the overlapping subdomains. Table 1 in section 5 compares the number of iterations via the two different ways of decomposition.

4. Local adaptive mesh refinement (AMR) procedure.

4.1. Local AMR procedure.

We start with a uniform grid in space and a base time step. The spatial grid is divided into some overlapping subgrids and the systems (10)–(11) are solved on each subgrid. Time steps are adaptively refined or derefined based on an a posteriori temporal error estimate on each subgrid independent of one another. The maximum of the local time steps is used for the next base time step.

At the end of each base time step, an a posteriori spatial error estimate is performed elementwise. A dichotomy principle of Babuska, Theorems 3.1 and 4.1 in [2], is used for the error estimate, which says that errors in finite element solutions in two space dimensions computed with odd-degree polynomials arise mainly near element edges, while those computed with even-degree approximations arise mainly in element interiors. Elements having "high" error are grouped into different error sets, called photo-clusters, using Berger and Oliger's nearest neighbor algorithm [5] with a predefined distance λ (we take $\lambda = 2h$). We use a linked list to store these photo-clusters. A list iterator is used to build up such a list. The first photo-cluster is created by adding the first high-error element to it. Then we check the next high-error element; if it is within the predefined distance from the first cluster, we will add it to the cluster. Otherwise, we will create the second photo-cluster with this element in it. Follow such a procedure; if an error element is "far" from any of the constructed photo-clusters, a new photo-cluster is created and added to the list. If the error element is within

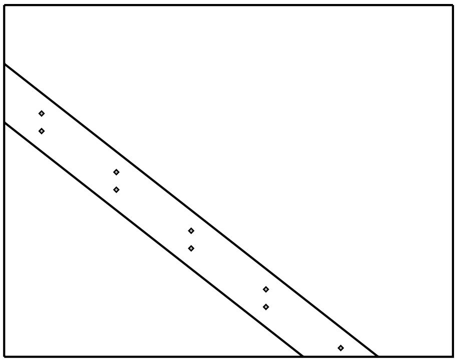

FIG. 3. *Cluster that intersects domain boundaries.*

a distance λ from two different photo-clusters, the two photo-clusters will be combined into one. By dividing the error elements into different photo-clusters, spatially distinct phenomena are separated.

For each photo-cluster, we form a local rectangle, called a cluster, using Berger and Oliger's procedure [5]. Each cluster is enlarged by increasing the length of its two sides so that the region between the enlarged and original clusters provides a buffer (we take the buffer-size to be $0.9h$) and artificial internal boundary conditions will be prescribed at low-error degrees of freedom, and thus fine-grid errors will not significantly propagate through the buffer. If we choose an appropriate λ and buffer zone (say, $\lambda > 2*$buffer-size), the different clusters will not overlap. Hence the solution procedure over different clusters will be independent.

Clusters may be skewed with respect to the coordinate axes. Thus, for each cluster, a second rectangle is formed, which we call a megagrid. The megagrid contains the cluster and is aligned with the coordinate axes. Its sides also overlap the grid-lines of the parent megagrid (the base grid is considered as a megagrid too). If the cluster intersects the parent megagrid boundaries, we take only the part inside the parent megagrid, as shown in Figure 3. The megagrids contain the information from the parent megagrid and pass the information to their clusters.

To keep the resolution region to a minimum we check the efficiency of each cluster which is measured by the ratio of the number of high-error elements to the total number of elements in the cluster. The cluster is considered as inefficient if the ratio is less than 0.3. Those clusters with six elements or less are assumed to be efficient. If the cluster is inefficient, we bisect it along the major side, then apply Berger and Oliger's procedure on each of the two parts separately to form two new clusters. This procedure is performed recursively until all the clusters are efficient. Figure 4a shows one example of such a case.

We refine each megagrid by a factor of 3, interpolate the data field on the refined megagrid, and decompose the megagrid into small rectangular grids. Those local grids that don't intersect any of the clusters in the megagrid are discarded to maximize the efficiency. This results in a piecewise polygonal region, as shown in Figure 4b, which is called a polygrid. The multiplicative Schwarz algorithm is then applied on the polygrid.

In some cases, different megagrids may overlap. But the polygrids within these intersecting megagrids are independent of each other, as shown in Figure 5. Since the re-solution process is on the polygrids, such procedures on different polygrids are

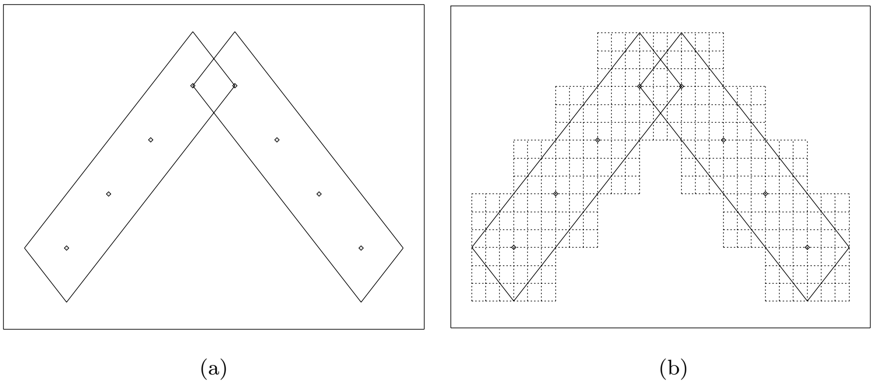

FIG. 4. *Cluster bisectioning and fine grids formation.*

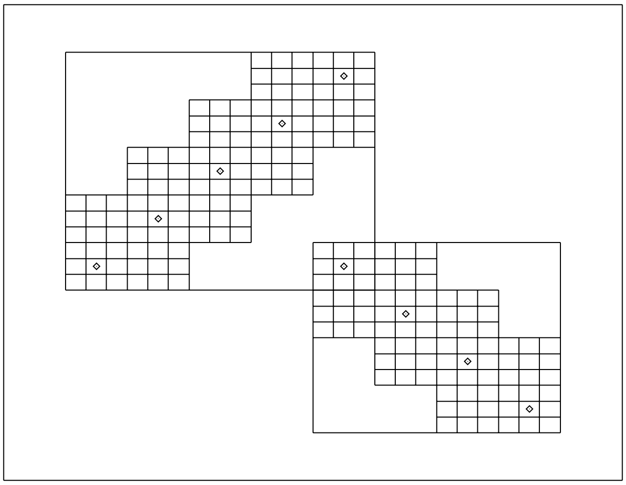

FIG. 5. *Grids formation for overlapping megagrids.*

independent of each other.

Each local grid is small with a maximum size of 4 × 4 and a minimum size of 3 × 3. If the mesh is fine enough, the refined polygrids will cover and possibly be slightly larger than the regions flagged with high error. Thus, a nearly minimal overrefinement and resolution is achieved. So our method has the advantage of both structured noncellular mesh and unstructured mesh methods. Since the megagrids are aligned with the problem domain and properly nested, the data structure is much simpler and data transition between megagrids is much easier. Compared to structured cellular grid methods, where solutions are computed over either the entire problem domain as in [3] or overlapping rectangular patches with large overlaps as in [16], we solve the problem on a smaller refined region with the same simplicity of data storage and data transition. Furthermore, the methods presented here enable us to solve the entire problem by solving many very small problems independently. It is therefore best suited for parallel computation. My next paper [23] will focus on issues of parallel computation using the methods provided here.

We use a recursive local AMR and derefinement procedure. A top level description

                group error points into different clusters
                form and refine rectangular megagrids
                do data transition and interpolation
                form polygrids for resolution
                update solution field outside the polygrids
                for $j := 1$ to number of polygrids do
                    begin
                        LocalAMR(polygrid($j$), $t$, $\Delta t$, $\epsilon_{sp}$, $\epsilon_t$)
                    end
            end
    end
```

FIG. 7. *Recursive local AMR procedure on polygrid G.*

of these procedures is presented in the following three algorithms, Figures 6–8. In the first algorithm, *Solve*, an initial base time step is chosen which will be modified when the program starts. A root grid which is also a polygrid is generated and will be refined adaptively. Initial solution is projected to the root grid with a L_2 projection. A domain decomposition procedure is performed to generate a finite number of subdomains (4 or 5 for two-dimensional problems) as well as a number of small local grids which are mostly in the size of 4×4 with a few smaller sizes near the megagrid boundaries. The solution proceeds from initial time, t_{start}, to the final time, t_{end}.

The second algorithm, *LocalAMR*, receives a solution from the algorithm *Schwarz* for one base time step and then performs an elementwise spatial error estimate. The elements with high error are grouped into different clusters. A polygrid is formed for each cluster and the solution procedure is repeated on each polygrid. The solution is updated before the resolution so that the solution outside the polygrids will not be

```

FIG. 8. *Multiplicative Schwarz algorithm.*

lost.

The algorithm *Schwarz* is called on each polygrid. It solves the ODE systems (10) and stores the solutions on each local grid. A temporal error estimator controls the local time steps that are refined or derefined automatically. This procedure is described in a previous paper [22] in more detail. Then the projection equations (11) are solved on each local grid and the multiplicative Schwarz procedure is performed on the polygrid. We prescribe a temporal error tolerance that is a factor of at least 100 less than the prescribed spatial error tolerance. Thus temporal error will not affect the spatial refinement.

Alternatively, we may form the polygrids without creating clusters. To do this, we form a megagrid for each photo-cluster. The megagrid contains the photo-cluster with a chosen buffer zone and is aligned with the coordinate axes. We then refine the megagrid by a factor of three and interpolate the data field on the refined megagrid. We decompose the megagrid to get a list of small local grids. For each local grid on the list, we check if there is an error element inside or with a distance less than γ from it, where γ is the buffer size chosen as the mesh size of the parent megagrid. If not, we remove this local grid from the list. By going over all the local grids on the list, we end up with a polygrid. Example 5.3 uses this procedure for the refinement. The pseudo-Pascal algorithm, Figure 9, describes this process.

Arney and Flaherty [3], Moore [15], and Moore and Flaherty [16] used a scheme that performed spatial refinement for each fine time step. This significantly increased the overhead of their methods, since spatial refinement is one of the most expensive procedures. We have improved this by performing spatial refinement once per base time step. This increases efficiency significantly. Grid changes is generally insignificant within one base time step. Therefore, such a strategy is very effective.

Spatial derefinement is performed if the spatial error is too small. For a given

```
Procedure. PolygridMaker(Megagrid MG, List<errNode> &Eset)
    begin
        remove := 1
        for i := 1 to number of local grids of MG do
            begin
                for j := 1 to number of error points in Eset do
                    begin
                        if distance( err_point(j), grid(i) ) < $\gamma$) do
                            begin
                                remove := 0
                                break
                            end
                    end

FIG. 9. *An alternative procedure of generating polygrid.*

local grid, if the estimated error on each of the m ($9 \leq m \leq 16$) elements inside the grid is less than $\beta\epsilon_{sp}$ (we choose $\beta = 0.3$), we delete the lower left 3×3 fine elements (see Figure 2), and a coarse element is returned. The remaining three or four fine elements on the right-most column of this local grid are deleted only if the errors on the elements of the neighbor local grid to the right are all less than $\beta\epsilon_{sp}$. The same is true for the three or four elements on the top-most row of the local grid and the neighbor local grid on the top. By going through all the local grids, we have formed some polygrids which are used for the next level of integration.

4.2. Data structures. We keep track of the data fields and grid structures by maintaining an extended tree structure of the megagrids with sibling pointers. We choose to store the megagrids because of their simple structures. Data transition between different levels of megagrids are simple since they are all aligned with the coordinate axes and properly nested. A polygrid within a megagrid is stored as a list of local grids. A local grid is composed of m ($9 \leq m \leq 16$) elements and lists of nodes and edges. Finite element procedure and time integration are performed on local grids. Intergrid information is propagated through the multiplicative Schwarz algorithm. The base grid Δ^h (which is also a megagrid and a polygrid) is the root of the tree. The megagrids created by the first level of refinement process are considered the offspring of the base grid and are said to be at the first level of the tree. Since LocalAMR is recursive, the tree structure continues, with a megagrid at level i having a parent coarse megagrid at level $i - 1$ and possible finer offspring megagrids at level $i + 1$ for each megagrid. We define pointers to its parent, to its first son, and to its next sibling megagrid. Information at a parent level megagrid is passed to its sons through interpolation. Sibling megagrids at the same level have polygrids which are independent of each other. The tree structure grows if further refinement is needed and shrinks if derefinement is performed.

The data structure as well as the major objects such as grid, megagrid, and polygrid are easily manipulated by using the object-oriented programming language C++. Iterators are used for the many linked lists defined in the program. The use of iterators makes adding or deleting elements easier when constructing clusters and polygrids.

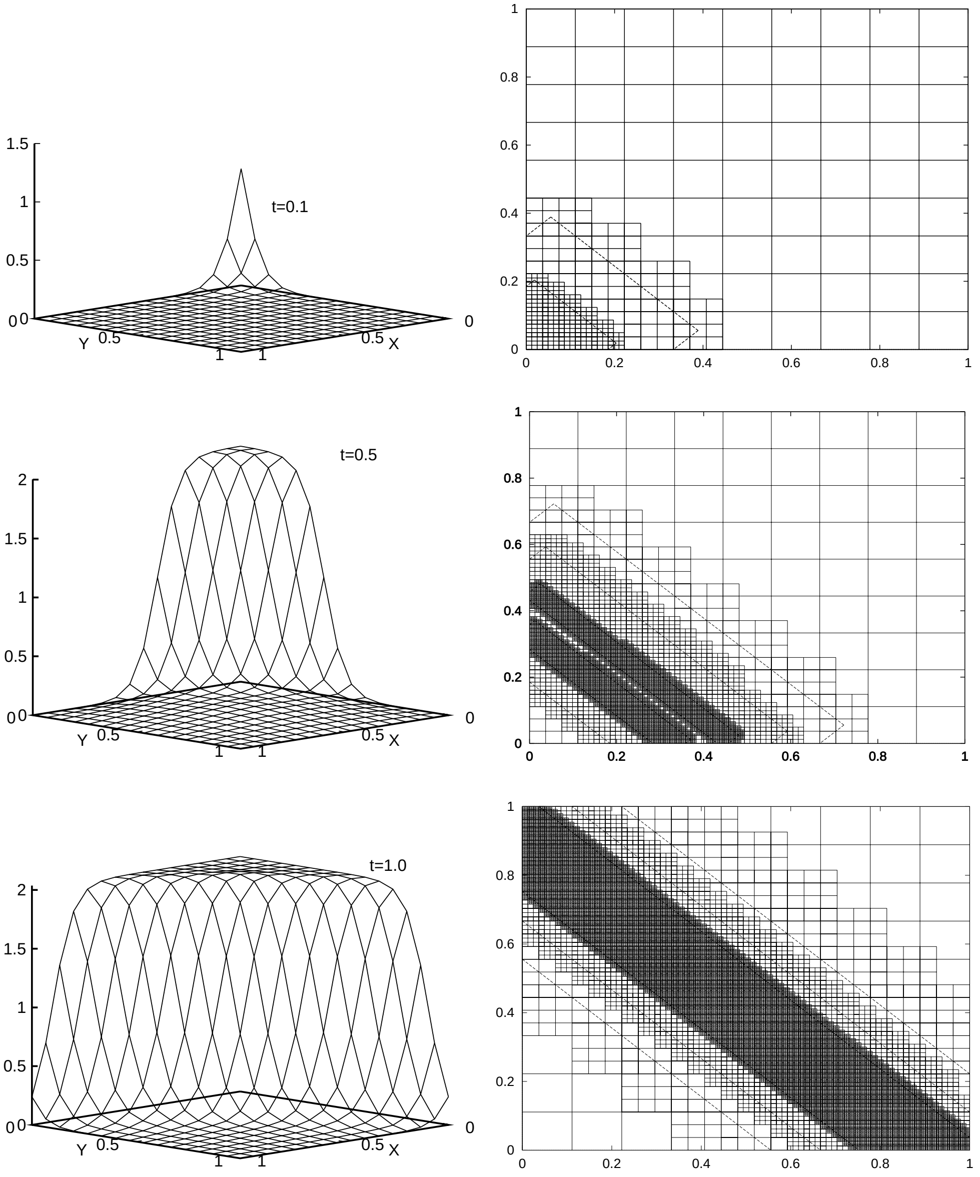

FIG. 10. *Surfaces and corresponding spatial meshes for Example* 5.1 *at* $t = 0.1, 0.5,$ *and* 1.0.

5. Numerical examples. We demonstrate the performance of our adaptive local space-time refinement procedure by applying our methods to three examples. The code is written in C++ and was run on a family of IBM RS6000 machines.

Example 5.1. Consider the forced heat conduction equation

$$u_t + f(x, y) = u_{xx} + u_{yy}, \qquad 0 \le x, y \le 1,\ 0 \le t \le t_f, \tag{12}$$

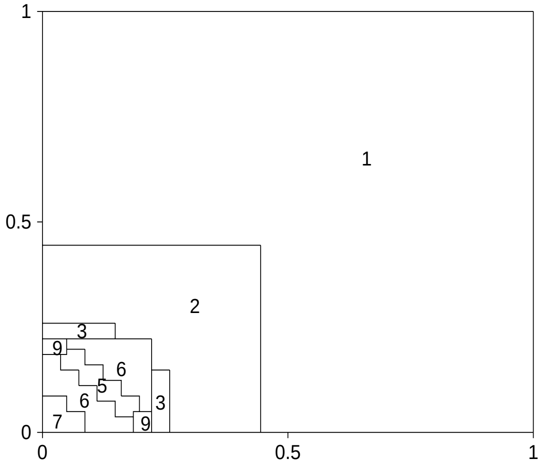

FIG. 11. *Number of time steps used in each region for Example* 5.1 *on* $0 \le t \le 0.1$.

with $f(t,x,y)$, the initial and boundary conditions specified so that the exact solution is

$$u(t,x,y) = 1.0 - \tanh[10(x+y-t+0.1)]. \tag{13}$$

We solved this problem for $0 \le t \le 1$. A 9×9 base spatial mesh with a uniform polynomial order 1 and an initial base time step of $\Delta t = 0.1$ are used. For the automatic error control, we use a spatial tolerance of 0.1 and a temporal error tolerance of 0.001. Surface plots and the adaptive meshes at $t = 0.1, 0.5$, and 1.0 are given in Figure 10. To get a better view of the surface plots, we rotated the coordinate plane 135^{o} clockwise. Figure 11 shows the number of time steps used in each spatial region for $0 \le t \le 0.1$ and a base time step $\Delta t = 0.1$. As can be seen from these figures, one large time step 0.1 and a very coarse spatial mesh are used in most of the domain. A fine mesh and a large number of time steps (9 in this case) are used only in a small fraction of the domain where changes are most rapid. Note that the time steps are not evenly divided. They are chosen automatically by the integration routine. The CPU times for the solution on $0 \le t \le 0.1$, with the same error tolerances, are 157.52 seconds with our space-time adaptive procedure and 1087.17 seconds using a spatially local adaptive procedure with uniform time stepping, a significant improvement in terms of computational efficiency.

Example 5.2. Consider the forced heat conduction equation (12) with $f(t,x,y)$ and the initial and boundary condition so that the exact solution is

$$u(t,x,y) = 0.8e^{-80[(x-r(t))^2+(y-s(t))^2]},$$

where

$$r(t) = 0.5 + 0.25 \sin \pi t$$

and

$$s(t) = 0.5 + 0.25 \cos \pi t.$$

The solution is a cone initially centered at $(0.5, 0.75)$ that rotates in a circle centered at $(0.5, 0.5)$ with a radius of 0.25 in a clockwise direction. The problem is solved on

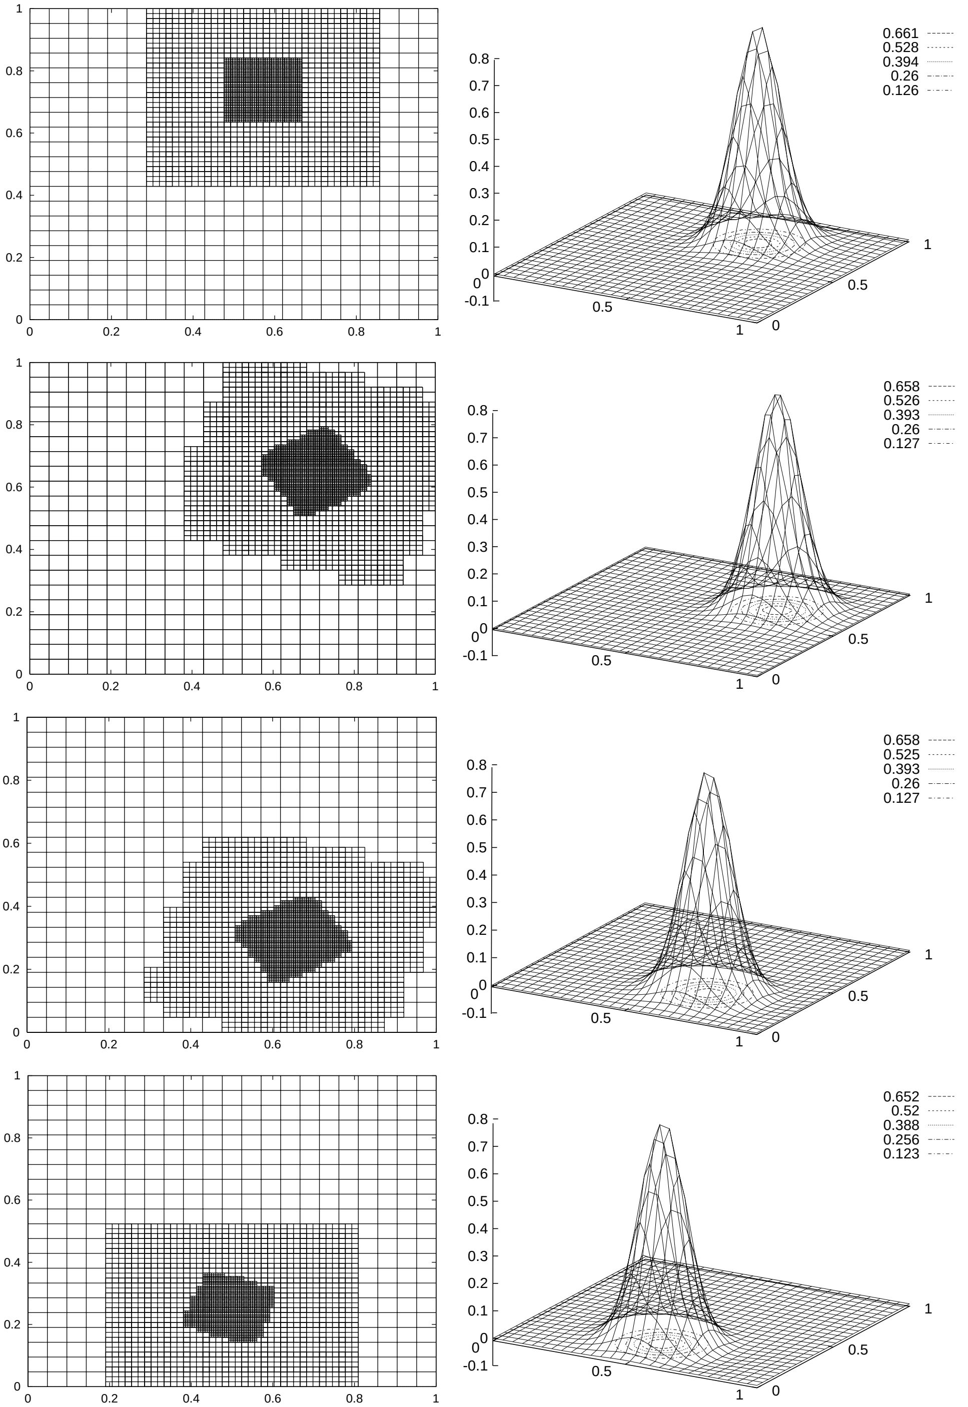

FIG. 12. *Spatial meshes and surface plots in Example* 5.2 *for* $t = 0.1, 0.3, 0.8,$ *and* 1.0.

Table 1
Convergence of multiplicative Schwarz algorithm.

# of iteration	H^1 error	# of iteration	H^1 error	# of iteration	H^1 error
1	0.829172	5	0.13051	9	0.0457369

3	0.271475	7	0.0695346	11	0.039111
4	0.185898	8	0.0544481	12	0.0382874
				13	0.0380543

(a) On one-level decomposition.

# of iteration	H^1 error
1	0.148836
2	0.0396165
3	0.034211

(b) On two-level decomposition.

$0 \le t \le 1$ with an initial spatial grid of 21×21 and base time step of 0.1. The spatial error tolerance is 0.1 and the temporal error tolerance is 0.001. The grids and the surface plots at $t = 0.1, 0.3, 0.8$, and 1.0 are shown in Figure 12. The H^1 errors at 0.1, 0.3, 0.8, and 1.0 are 0.0204886, 0.0206745, 0.02065328, and 0.0204843, respectively.

To demonstrate the convergence of the multiplicative Schwarz algorithms, we solve the problem for one base time step of 0.1 starting at $t = 0.7$ using both one- and two-level decompositions. A 15×15 spatial grid and uniform elements of order 3 are used. Table 1 shows that the two-level algorithm needs many fewer iterations than the one-level method. The one-level algorithm takes 20m 0.26s CPU time, while the two-level algorithm takes 18m 20.09s, which is 90% of that needed for the one-level algorithm. Thus, the two-level algorithm is also slightly faster.

Example 5.3. Consider the combustion problem in Kapila [14]:

$$u_t - D(1+\alpha-u)e^{-\frac{\delta}{u}} = u_{xx} + u_{yy}, \ (x,y) \in \Omega, \qquad t > 0, \tag{14}$$

$$u(0,x,y) = 1, \qquad (x,y) \in \overline{\Omega}, \tag{15}$$

$$u(t,x,1) = 1, \ 0 \le x \le 1, \ t > 0, \ u(t,1,y) = 1, \qquad 0 \le y \le 1, \ t > 0, \tag{16}$$

$$u_x(t,x,0) = 0, \ 0 \le x \le 1, \ t > 0 \ u_y(t,0,y) = 0, \qquad 0 \le y \le 1, \ t > 0, \tag{17}$$

where

$$D = \frac{Re^{\delta}}{\alpha\delta}$$

is the Damkohler number, δ is the activation energy, α is the heat release, and R is the reaction rate. The temperature increases slowly with a hot spot forming at the origin. After some time, ignition occurs and the temperature at $(0,0)$ jumps rapidly. A sharp reaction front forms and propagates toward the boundaries $x = 1$ and $y = 1$ where boundary layers form.

We solve (14)–(17) with $\alpha = 1$, $\delta = 20$, and $R = 5$. An initial spatial grid of 9×9 and base time step of 0.1 with uniform element of order 1 is used. Spatial and temporal tolerances are chosen to be 0.1 and 0.001. Surface plots at $t = 0.25, 0.28, 0.29, 0.30, 0.32, 0.35$ are shown in Figure 13. Figure 14 shows the refined spatial grids at $t = 0.28, 0.30, 0.32$, and 0.35. The number of time steps used for one base time step are shown in Figure 15.

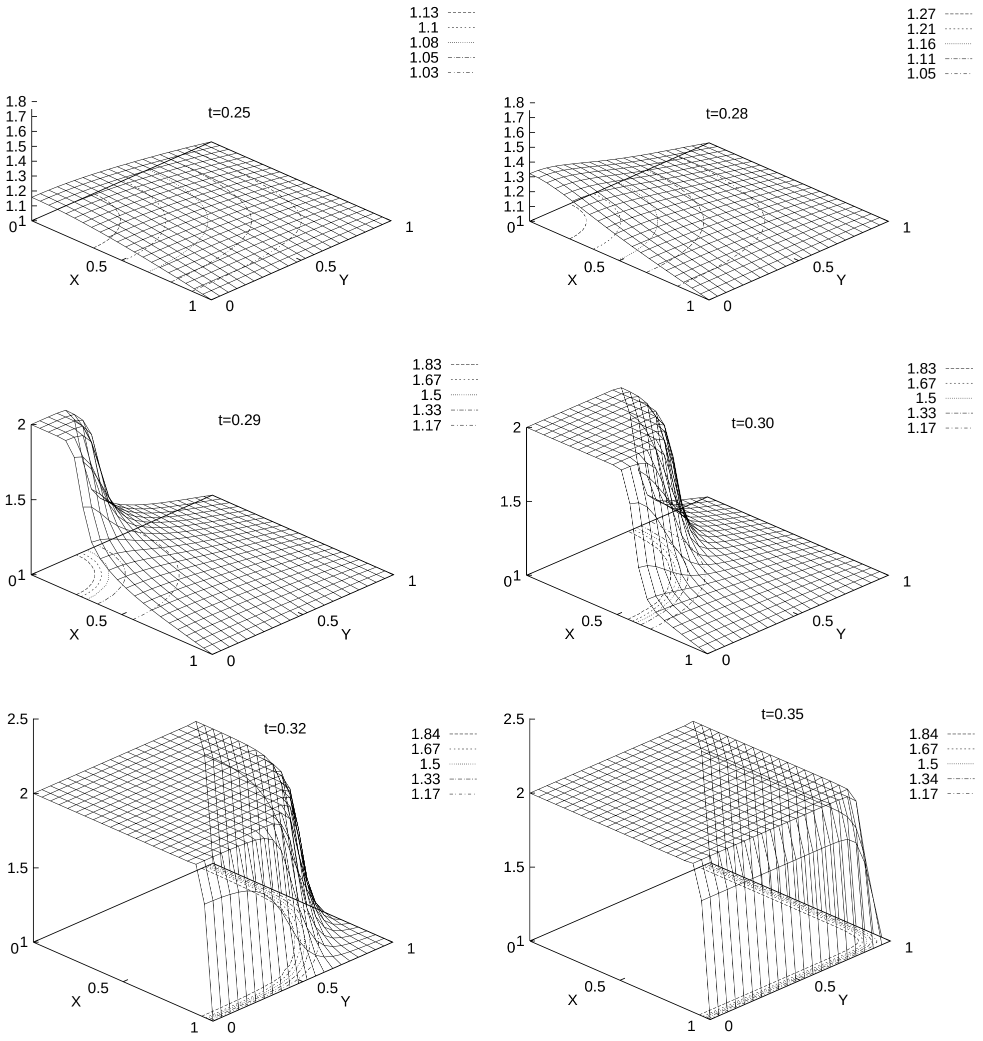

FIG. 13. *Surface and contour plots of Example* 5.3 *at* $t = 0.25, .28, .29, .30, .32, and .35$.

From these plots, we conclude that the temperature increases slowly from $t = 0$ to $t = 0.28$, where very coarse spatial mesh and time steps are used. At about $t = 0.28$, ignition occurs, the temperature at the origin increases rapidly to 2, and a sharp reaction front forms and propagates toward the Dirichlet boundaries $x = 1$ and $y = 1$. The space-time meshes follow the evolution process closely. We also note that, when the reaction front is close to the Dirichlet boundaries $x = 1$ and $y = 1$, the spatial mesh is fine near these boundaries since the spatial gradient is large there. But the changes with time become slow except at the corner $(1, 1)$. Thus, large time steps are used near these boundaries. Smaller time steps are used only near the corner as indicated in the plots for $0.34 \leq t \leq 0.35$.

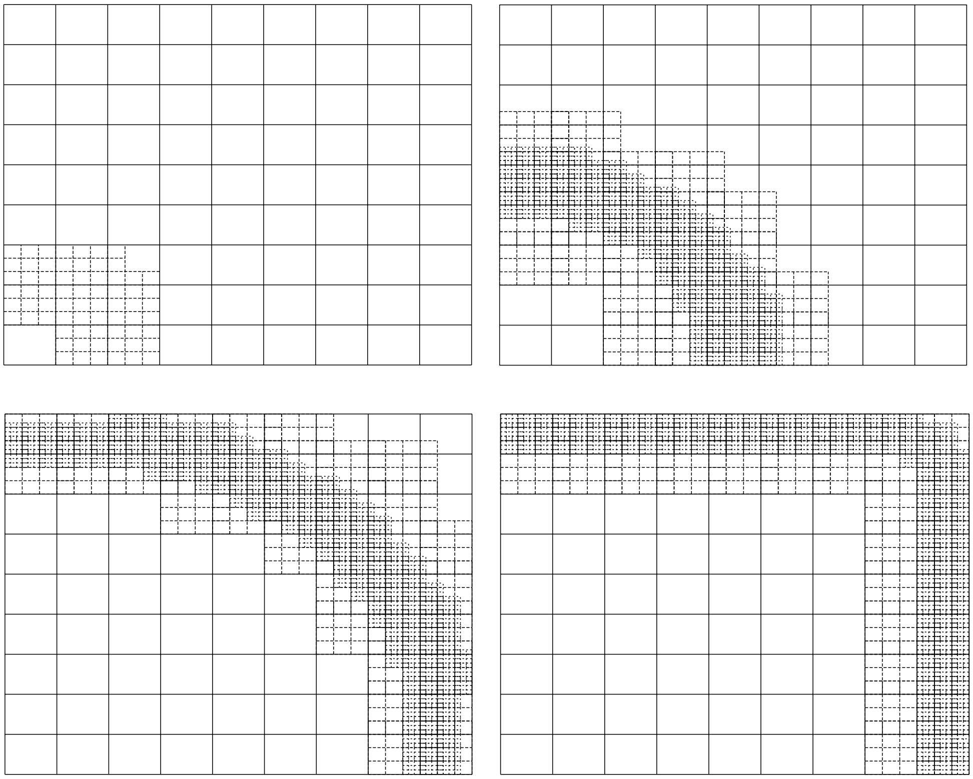

FIG. 14. *Spatial mesh used for Example* 5.3 *at* $t = .29, .30, .32,$ *and* .35.

We run this example from $t = 0.0$ to $t = 0.35$ with local space-time adaptive meshes and get a CPU time of 5 hours and 1763 seconds. We also run the example on the same interval with the same spatial and temporal error tolerances but with local adaptive spatial mesh and uniform time stepping; the CPU time is 51 hours and 3354 seconds, which is almost ten times longer. In most part of the domain, one step is enough to advance one base time step if our algorithm is used, while dozens of steps are needed if uniform time stepping is used.

6. Concluding remarks. An adaptive local space-time mesh refinement procedure was described for solving parabolic partial differential equations in two space dimensions. The test problems showed that fine time steps are used in regions with fine spatial meshes. The fine meshes follow the dynamics of the physical problems. The test problems given are all on rectangular domains, but the methods can be generalized to any domain with piecewise linear boundaries. Thus, with an appropriate mapping, we can generalize the method to solving any two-dimensional parabolic problem on an arbitrary domain. We will also generalize the methods to three-dimensional problems with some trivial changes. Since one of the most important benefits of domain decomposition methods is the ease with which the code can be run on parallel machines, an effort is being made in making the code running parallel.

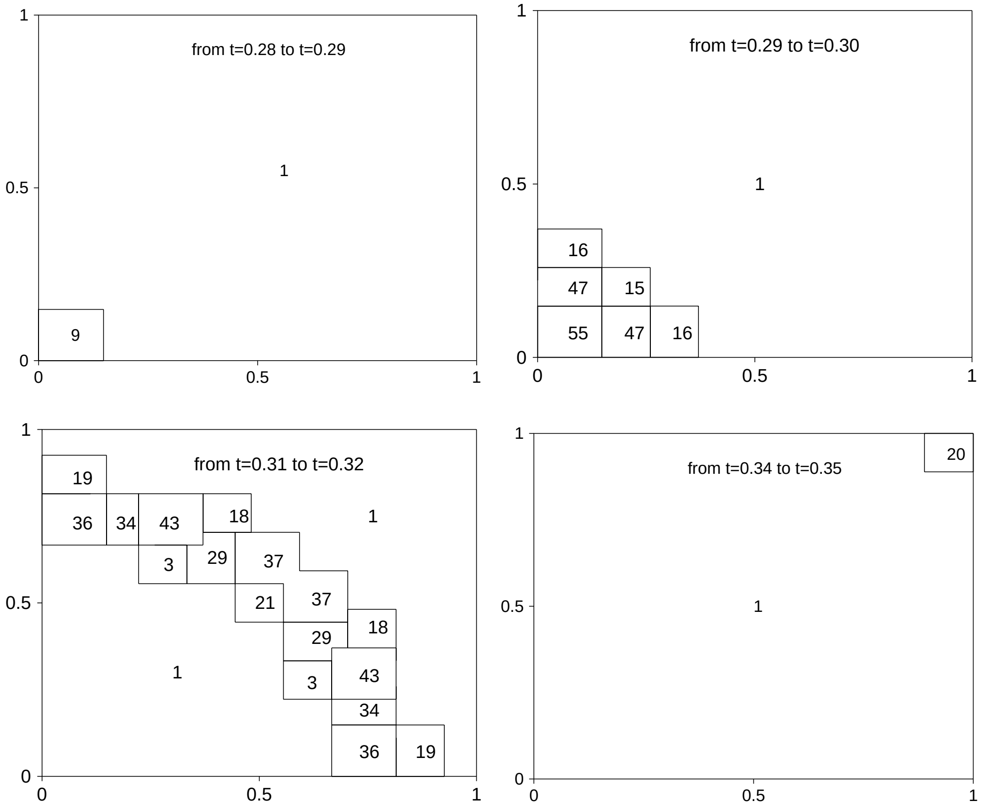

FIG. 15. *Number of time steps used for Example* 5.3 *start at* $t = .28, .29, .31,$ *and* .34 *with a base step* 0.01.

Acknowledgment. I wish to thank my thesis advisor Dr. Peter Moore for his inspiring guidance and constant encouragement.

ENUMERATION OF ALL EXTREME EQUILIBRIA OF BIMATRIX GAMES*

CHARLES AUDET†, PIERRE HANSEN‡, BRIGITTE JAUMARD§, AND GILLES SAVARD§

Abstract. The set of equilibrium points of a bimatrix game is the union of polytopes that are not necessarily disjoint. Knowledge of the vertices of these polytopes (extreme equilibria) is sufficient to identify all equilibria. We present an algorithm that enumerates all extreme equilibria by exploiting complementary slackness optimality conditions of two pairs of parameterized linear programming problems. The algorithm is applied to randomly generated problems of size up to 29×29 when both dimensions are equal, and up to 700×5 when the second dimension is fixed. The number of extreme equilibria grows exponentially with problem size but remains moderate for the instances considered. Therefore, the results could be useful for further study of refinements of Nash equilibria.

Key words. bimatrix game, extreme equilibrium, implicit enumeration, two-person nonzero-sum game

AMS subject classifications. 90D05, 90C27

PII. S1064827598339086

1. Introduction.

A bimatrix game (or two-person nonzero-sum game in strategic form) may be stated as follows: given a pair of $m \times n$ payoff matrices A and B, Player I attempts to maximize his payoff x^tAy by selecting the probability vector x in $\mathbb{R}^m$, and simultaneously, Player II attempts to maximize his payoff x^tBy by choosing the probability vector y in $\mathbb{R}^n$.

It is well known that there is always at least one *equilibrium point* (see Nash [18]) in such a game, i.e., a pair of strategies $(\hat{x}, \hat{y})$ that simultaneously solve the two parameterized linear programs

$$(\text{P1}) \quad \text{subject to} \quad \begin{array}{cl} \max\limits_{x} & x^tA\hat{y} \\ (\text{s.t.}) & x^t\mathbf{1} = 1, \\ & x \geq \mathbf{0}, \end{array} \qquad \text{and} \qquad (\text{P2}) \quad \begin{array}{cl} \max\limits_{y} & \hat{x}^tBy \\ \text{s.t.} & \mathbf{1}^ty = 1, \\ & y \geq \mathbf{0}, \end{array}$$

where $\mathbf{0}$ and $\mathbf{1}$, respectively, denote vectors whose components are all equal to zero and one. The strategy $\hat{x}$ is thus a best response to $\hat{y}$, as it is an optimal solution of (P1); and $\hat{y}$ is a best response to $\hat{x}$, as it is an optimal solution of (P2). Hence at

an equilibrium point neither player has an incentive to change his strategy unless the other player does so.

Linear programming duality theory yields the equivalent dual programs

$$(\mathrm{D1})\qquad \begin{array}{ll} \min\limits_{\alpha} & \alpha \\ \text{s.t.} & \mathbf{1}\alpha \geq A\hat{y}, \end{array} \qquad \text{and} \qquad (\mathrm{D2})\qquad \begin{array}{ll} \min\limits_{\beta} & \beta \\ \text{s.t.} & \beta\mathbf{1}^t \geq \hat{x}^t B, \end{array}$$

where α and β are dual variables in $\mathbb{R}$.

There are two classical and equivalent necessary and sufficient optimality conditions in linear programming theory and thus two equilibrium conditions in our framework. Both of these conditions require primal and dual feasibility: the pair of strategies $(\hat{x}, \hat{y})$ together with scalars $\hat{\alpha}$ and $\hat{\beta}$ must satisfy

$$\begin{aligned} (\hat{x}, \hat{\beta}) &\in X = \{(x, \beta) \in \mathbb{R}^{m+1} :\ x^t B \leq \beta\mathbf{1}^t,\ x^t\mathbf{1} = 1,\ x \geq \mathbf{0}\}, \\ (\hat{y}, \hat{\alpha}) &\in Y = \{(y, \alpha) \in \mathbb{R}^{n+1} :\ Ay \leq \mathbf{1}\alpha,\ \mathbf{1}^t y = 1,\ y \geq \mathbf{0}\}. \end{aligned}$$

The first optimality condition consists in the equality of primal and dual objective function values

$$(1.1)\qquad \hat{x}^t A\hat{y} = \hat{\alpha} \qquad \text{and} \qquad \hat{x}^t B\hat{y} = \hat{\beta}.$$

This means that the values of the dual variables must be equal to the payoffs. The second optimality condition is the complementary slackness condition

$$(1.2)\qquad \hat{x}^t(\mathbf{1}\hat{\alpha} - A\hat{y}) = 0 \qquad \text{and} \qquad (\hat{\beta}\mathbf{1}^t - \hat{x}^t B)\hat{y} = 0.$$

Equivalence of optimality conditions (1.1) and (1.2) appears when substituting $\hat{x}^t\mathbf{1}$ and $\mathbf{1}^t\hat{y}$ by 1.

There may be one, many, or an infinite number of equilibrium points. Indeed, for a given strategy $\hat{y}$, the set of optimal responses of Player I, i.e., the set of optimal solutions of (P1), denoted $X(\hat{y})$, is either a singleton or a polytope. The symmetric observation holds for (P2), where the set of optimal solutions is denoted $Y(\hat{x})$. In fact, the set E of all equilibrium points is the union of a finite number of polytopes called *maximal Nash subsets* [14]. Different equilibria possess different characteristics which make them unequally attractive. Identification of all equilibria of a bimatrix game would ease further refinement and classification of them. Discussion of equilibrium refinements can be found in Kohlberg [7] and in Van Damme [19], [20].

The contribution of this paper is to present a new algorithm that enumerates all vertices of every maximal Nash subset of a bimatrix game. Knowledge of these *extreme equilibria* allows identification of all equilibrium points.

The key feature of the algorithm is that it enumerates only a subset of the vertices of the polyhedra X and Y. To this effect, the complementary slackness conditions (1.2) of the primal and dual problems are exploited while the enumeration proceeds, and this allows early pruning of many branches of the search tree. Nondegeneracy of the bimatrix game is not required in order to show that the proposed algorithm enumerates in finite time all extreme equilibria.

The paper is organized as follows. The next section briefly reviews previous work on enumeration of equilibrium points of bimatrix games. Section 3 presents a detailed description of an algorithm that enumerates all extreme equilibria. Numerical results for much larger problems than those previously solved are presented in section 4.

2. Previous work on enumeration of equilibria. The classical algorithm to find a single equilibrium point of a bimatrix game is that of Lemke and Howson [9]. It is a path-following method designed primarily for nondegenerate games, but it can also be applied to degenerate games after a slight perturbation. Aggarwal [1] shows that this algorithm cannot be directly modified to enumerate all extreme equilibria, as some of them may be inaccessible to the path.

A complete listing of equilibrium points is impossible, as their number may be infinite, since Nash subsets are polytopes. However, given the vertices of all maximal Nash subsets (the extreme equilibria), one can fully describe the nonconvex set E of all equilibria. Let S_x be a set containing any number of extreme strategies of Player I, and let $\hat{x}$ be a convex combination of these strategies. Vorob'ev [23] shows that if $\hat{y}$ solves (P2) for each extreme strategy of S_x, then $(\hat{x}, \hat{y})$ is an equilibrium point. Let $Y(x)$ denote the set of optimal solutions of (P2) for $\hat{x} = x$. The set E is obtained by considering the union of such sets S_x over all possible subsets of extreme strategies of Player I:

$$E = \bigcup_{S_x \subseteq \{x:(x,y) \in V\}} \left\{ \operatorname{conv}(S_x) \times \bigcap_{x \in S_x} Y(x) \right\},$$

where V is the set of all extreme equilibria, and $\operatorname{conv}(S_x)$ denotes the convex envelope of S_x.

From symmetry we can also obtain the following characterization of E:

$$E = \bigcup_{S_x \subseteq vert(X),\, S_y \subseteq vert(Y),\, S_x \times S_y \subseteq E} \operatorname{conv}(S_x) \times \operatorname{conv}(S_y),$$

which shows that the equilibrium condition need only be checked for extreme points of X and Y, expressed by the conditions under the $\bigcup$ sign. See Winkels [24] and Jansen [6] for additional information.

In order to obtain all equilibrium points, it is therefore sufficient to find all extreme equilibria. The problem addressed in this paper is to enumerate all of them. Only a few algorithms are designed to do so. We briefly present their main ideas. The first one is due to Vorob'ev [23] and was later simplified by Kuhn [8], in which extreme equilibria are characterized in terms of square submatrices of the payoff matrices.

Mangasarian [11] suggests enumerating all vertices of X and Y (using Balinski's algorithm [2]) and then checking for each pair of vertices x of X and y of Y if the bilinear optimality condition $x^t(A+B)y = \alpha + \beta$ is satisfied. Mills [15] and Mangasarian and Stone [12] show that this condition is equivalent to (1.1). Winkels [24] proposes an algorithm which differs from the previous one only in the optimality test: it consists in checking the complementary slackness conditions (1.2). Mukhamediev [17] enumerates all vertices of a linear maxmin problem derived from the above mentioned bilinear optimality condition.

Another algorithm consists in enumerating each of the $(2^n - 1)(2^m - 1)$ possible supports (the sets of pure strategies that are assigned a positive probability) and then checking for equilibria. For a given support, the set of equilibria can either be empty, a singleton, or a polytope. In this last case, all vertices of that polytope must be enumerated. Different implementations are discussed in Dickhaut and Kaplan [3] and in McKelvey and McLennan [13].

Von Stengel [22] is currently exploring an algorithm that enumerates the vertices of X only while directly computing the complementary vertices of Y (if they exist). This is advantageous if one player has much less pure strategies than the other.

All these methods rely more or less directly on enumeration of all vertices of polyhedra. The number of such vertices typically increases exponentially with problem size and can be high even for low dimensional polyhedra. Moreover, important computational difficulties arise when degeneracy is encountered, i.e., when there are multiple basic representations of the same vertex. See Von Stengel [21] for equivalent definitions of degeneracy. For more information on computation of equilibria in finite games, the reader can refer to the recent surveys of McKelvey and McLennan [13], and Von Stengel [21].

Note that if X and Y are nondegenerate, it follows from the facts that (i) Dyer's [4] vertex enumeration algorithm for polyhedra is polynomial in input size and number of vertices, and (ii) the equilibrium conditions can be checked in polynomial time, that a similar property holds for Mangasarian's algorithm [11], after substitution of the vertex enumeration routine. We do not know if such a property holds for the algorithm proposed in this paper.

3. Enumeration method. Enumeration of all extreme equilibria is done through exploration of a search tree. To each node of the tree correspond two linear subproblems whose feasible regions are derived from X and Y. They differ through conversion of inequalities into equalities. Two types of branching rules govern these conversions.

The first type of rule relies on an equivalent formulation of the complementary slackness condition (1.2). At an equilibrium point, the feasibility conditions insure that the vectors $\hat{x}$ and $\hat{y}$ are nonnegative and that $\hat{x}^t B \leq \hat{\beta}\mathbf{1}^t$ and $A\hat{y} \leq \mathbf{1}\hat{\alpha}$. Therefore, condition (1.2) can be written through the $m+n$ complementary slackness conditions

$$\hat{x}_i = 0 \ \text{ or } \ A_{i\cdot}\hat{y} = \hat{\alpha} \quad \text{and} \quad \hat{y}_j = 0 \ \text{ or } \ \hat{x}^t B_{\cdot j} = \hat{\beta}, \tag{3.1}$$

where $A_{i\cdot}$ denotes the ith row of A and $B_{\cdot j}$ denotes the jth column of B for $i = 1, 2, \ldots, m$ and $j = 1, 2, \ldots, n$. The first type of branching rule splits the current node of the tree through two branches. In one branch, a pure strategy is forced to be played with probability zero (a variable is fixed to zero), and in the second, a pure strategy is forced to have maximum payoff, so it is a best response (a slack variable is fixed to zero). This rule is invoked by the algorithm until all complementary slackness conditions (3.1) are forced to be satisfied and thus for all nodes whose depth in the search tree is less than or equal to $m + n$.

When the depth of the current node exceeds $m+n$, the second type of branching rule is used. At such a node, all complementary slackness conditions (3.1) are guaranteed to be satisfied by the first type of branching rule, and thus any solution of the current converted equalities is necessarily an equilibrium point. This branching rule consists in splitting the current node through as many branches as there are strictly positive variables and slack variables of X and Y corresponding to the equilibrium point. In each branch the variable or slack variable is fixed to zero. All degenerate solutions are reached, possibly several times, and thus elimination of duplicates is required.

Backtracking occurs when conversion of inequalities into equalities reduces the feasible region to the empty set. Let us now introduce more formal definitions in order to fully describe the algorithm.

3.1. Notation. As discussed above, every new branch is obtained by converting a single inequality of X or Y to an equality. In order to efficiently select which inequality to take, we introduce the following linear programming problems, parameterized in the objective functions

$$P(y) \equiv \max_{(x,\beta)\in X} x^tAy - \beta,$$
$$Q(x) \equiv \max_{(y,\alpha)\in Y} x^tBy - \alpha.$$

Problem $P(y)$ is an aggregation of the primal and dual problems (P1) and (D2), and $Q(x)$ is an aggregation of (P2) and (D1). Indeed, the constraints appearing in the definition of X and Y are those of the primal and dual problems. Moreover, the objective functions $x^tAy - \beta$ and $x^tBy - \alpha$ are the sum of the primal and dual objective functions. Therefore, it is likely that an optimal solution of $P(y)$ solves (P1) and (D2), and one of $Q(x)$ solves (P2) and (D1). The search for equilibria is done through the feasible regions X and Y, and thus any objective functions could be used. The intuitive motivation behind this choice of objective functions is to guide the algorithm toward equilibrium points.

At each node of the search tree is associated a pair of current subproblems $\tilde{P}$ and $\tilde{Q}$ that are identical to P and Q, except that some of the inequality constraints or nonnegativity constraints are converted to equalities. The depth of the root node is as follows.

1. At each node, one of the three following cases occurs as follows:
   (i) Either $\tilde{P}$ or $\tilde{Q}$ is infeasible.
   (ii) Both $\tilde{P}$ and $\tilde{Q}$ are feasible, but there is not enough information to obtain an equilibrium point. (The depth of the current node is less than or equal to $m + n$.)
   (iii) Both $\tilde{P}$ and $\tilde{Q}$ are feasible and there is sufficient information to deduce an extreme equilibrium point. (The depth of the current node is greater than $m + n$.)

In the first case, the current node is discarded. In the two other cases, the current node is split into others through new branches. The subproblems of the new nodes are identical to the current ones except for one additional constraint converted into an equality in either $\tilde{P}$ or $\tilde{Q}$, chosen according to the branching rules. Thus for each new branch, only one of the two subproblems needs to be checked for feasibility.

In the first type of branching rule, the selected pair of complementary inequalities to be converted into equalities corresponds to the largest complementary product $x_i(\alpha - A_{i\cdot}y)$ or $(\beta - x^tB_{\cdot j})y_j$, where $i = 1, 2, \ldots, m$ and $j = 1, 2, \ldots, n$. Of course, the pair of inequalities must be chosen among those that were not already converted in $\tilde{P}$ or $\tilde{Q}$.

A node is not only characterized by the pair of current subproblems $\tilde{P}$ and $\tilde{Q}$. One of the two vectors x or y is also associated to each node. This vector describes a feasible strategy for the current subproblem that does not differ from its predecessor in the tree. We now introduce the notation that specifies which constraint is converted. This notation will be used when formally defining both types of branching rule. Given the current subproblems $\tilde{P}$ and $\tilde{Q}$, we define

P^i to be $\tilde{P}$ in which the constraint $x_i \geq 0$ is converted to $x_i = 0$,

P_j to be $\tilde{P}$ in which the constraint $x^tB_{\cdot j} \leq \beta$ is converted to $x^tB_{\cdot j} = \beta$,

Q^j to be $\tilde{Q}$ in which the constraint $y_j \geq 0$ is converted to $y_j = 0$, and

Q_i to be $\tilde{Q}$ in which the constraint $A_{i\cdot}y \leq \alpha$ is converted to $A_{i\cdot}y = \alpha$,

where $i \in \{1, 2, \ldots, m\}$ and $j \in \{1, 2, \ldots, n\}$.

3.2. Algorithm EEE (enumeration of extreme equilibria). The algorithm is now briefly stated, followed by a more intuitive discussion of several important steps and a proof of its validity.

Step a. Initialization.
Initialize the set of nodes to be explored to $T = \{(x, P, Q)\}$, where x is set to an arbitrary feasible value (typically, $x = (\frac{1}{m}, \frac{1}{m}, \dots, \frac{1}{m})$). Go to Step b.

Step b. Selection of a node.
If the set T of nodes to be explored is empty, then stop. Otherwise, choose and remove a node N from T. Either $N = (x, \tilde{P}, \tilde{Q})$ or $N = (y, \tilde{P}, \tilde{Q})$. In the first case go to Step c; in the second case, go to Step d.

Step c. Direct feasibility test ($\tilde{\boldsymbol{Q}}$).
If $\tilde{Q}(x)$ is infeasible, then go to Step b; otherwise, choose $(\tilde{y}, \tilde{\alpha})$ that solves $\tilde{Q}(x)$ and $(\tilde{x}, \tilde{\beta})$ that solves $\tilde{P}(\tilde{y})$. If the depth of the current node is not greater than $m + n$, go to Step e; otherwise, go to Step f.

Step d. Direct feasibility test ($\tilde{\boldsymbol{P}}$).
If $\tilde{P}(y)$ is infeasible, then go to Step b; otherwise, choose $(\tilde{x}, \tilde{\beta})$ that solves $\tilde{P}(y)$ and $(\tilde{y}, \tilde{\alpha})$ that solves $\tilde{Q}(\tilde{x})$. If the depth of the current node is not greater than $m + n$, go to Step e; otherwise, go to Step f.

Step e. Dichotomous branching.
Let

$$\tau_i = \begin{cases} \tilde{x}_i(\alpha - A_{i\cdot}\tilde{y}) & \text{if the variable } x_i \text{ of } \tilde{P} \text{ is not forced to be null, and} \\ & \text{the constraint } A_{i\cdot}y \le \alpha \text{ of } \tilde{Q} \text{ is not fixed at equality,} \\ -1 & \text{otherwise,} \end{cases}$$

$$\pi_j = \begin{cases} (\beta - \tilde{x}^t B_{\cdot j})\tilde{y}_j & \text{if the variable } y_j \text{ of } \tilde{Q} \text{ is not forced to be null,} \\ & \text{the constraint } x^t B_{\cdot j} \le \beta \text{ of } \tilde{P} \text{ is not fixed at equality,} \\ -1 & \text{otherwise,} \end{cases}$$

and then select the indices ĩ and j̃ that maximize the values τ_i and π_j (ties are broken arbitrarily) for $i = 1, 2, \dots, m$ and $j = 1, 2, \dots, n$. In the case where $\tau_{\tilde{\imath}} \ge \pi_{\tilde{\jmath}}$, add

$$(\tilde{y}, P^{\tilde{\imath}}, \tilde{Q}) \text{ and } (\tilde{x}, \tilde{P}, Q_{\tilde{\imath}})$$

to T, and in the case where $\tau_{\tilde{\imath}} < \pi_{\tilde{\jmath}}$, add

$$(\tilde{x}, \tilde{P}, Q^{\tilde{\jmath}}) \text{ and } (\tilde{y}, P_{\tilde{\jmath}}, \tilde{Q})$$

to T. Go to Step b.

Step f. Polychotomous branching.
The solution $(\tilde{x}, \tilde{y})$ is an equilibrium strategy since the complementary slackness conditions are satisfied. Record it on the list of equilibria if not already there, and add to T all nodes corresponding to a strictly positive variable or slack variable. These nodes are in the four sets

$$\{(\tilde{y}, P^i, \tilde{Q}) : \tilde{x}_i > 0\}, \qquad \{(\tilde{x}, \tilde{P}, Q_i) : A_{i\cdot}\tilde{y} < \alpha\},$$
$$\{(\tilde{x}, \tilde{P}, Q^j) : \tilde{y}_j > 0\}, \text{ and } \{(\tilde{y}, P_j, \tilde{Q}) : \tilde{x}^t B_{\cdot j} < \beta\}.$$

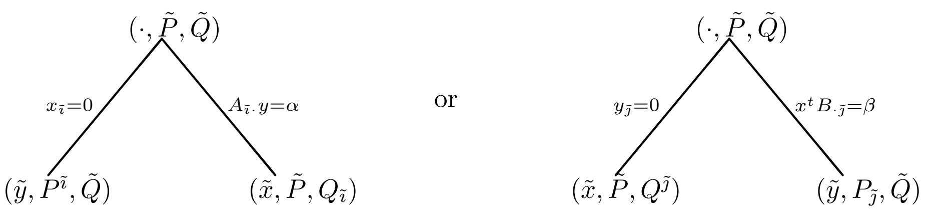
Go to Step b.

We now discuss each step of the enumeration method. The initialization step places the original bimatrix game into the set of nodes to be explored, together with a feasible strategy for Player I, and sets the depth of this node to one.

The order in which the nodes are chosen from the set T (in Step b) is not important since all of them must eventually be selected to ensure that no extreme equilibria are missed. Our implementation uses a depth-first strategy.

Steps c and d are the backtracking steps. In each of them, only one subproblem among $\tilde{P}$ and $\tilde{Q}$ is checked for feasibility, as only one problem differs in its feasible region from its predecessor (identification of the modified problem is done through the vector x or y associated to the node). When the feasible region is nonempty, these steps end with a feasible strategy $(\tilde{x}, \tilde{y})$. The parameterized linear programs are solved by a Simplex algorithm, and so the solutions are vertices of the polyhedra X and Y. (This might not be so with an interior point algorithm.) In order to reduce the number of pivots, the optimal bases found when solving $\tilde{P}$ and $\tilde{Q}$ are kept in memory and reused at the next node.

The last two steps define the branching structure of the algorithm. New nodes are added to the search tree. Step e is invoked when the depth of the current node in the search tree is less than or equal to $m+n$ (i.e., when at least one of the complementary conditions is not forced to be satisfied). It follows that $\tau_{\bar{\imath}}$ and $\pi_{\bar{\jmath}}$ will not both be equal to -1. Based on the complementary slackness conditions, two new branches are created: one in which either a variable $x_{\bar{\imath}}$ is fixed at 0 or a constraint $x^t B_{\cdot\bar{\jmath}} \leq \beta$ is replaced by $x^t B_{\cdot\bar{\jmath}} = \beta$, and the other in which either a variable $y_{\bar{\jmath}}$ is fixed at 0 or a constraint $A_{\bar{\imath}\cdot} y \leq \alpha$ is replaced by $A_{\bar{\imath}\cdot} y = \alpha$. Figure 3.1 summarizes this dichotomous branching rule using the above notation for the subproblems.



$(\cdot, \tilde{P}, \tilde{Q})$
$x_{\bar{\imath}}=0$
$A_{\bar{\imath}\cdot}y=\alpha$
$(\tilde{y}, P^{\bar{\imath}}, \tilde{Q})$
$(\tilde{x}, \tilde{P}, Q_{\bar{\imath}})$
or
$(\cdot, \tilde{P}, \tilde{Q})$
$y_{\bar{\jmath}}=0$
$x^tB_{\cdot\bar{\jmath}}=\beta$
$(\tilde{x}, \tilde{P}, Q^{\bar{\jmath}})$
$(\tilde{y}, P_{\bar{\jmath}}, \tilde{Q})$

FIG. 3.1. *Dichotomous branching rule.*

Step f is reached only when the depth of the current node in the search tree is greater than $m + n$. The corresponding current solution $(\tilde{x}, \tilde{y})$ is necessarily an extreme equilibrium strategy since all the complementary conditions are satisfied, and feasibility is ensured by Steps c and d. A new branch is created for each strictly positive variable or slack variable of the current solution of $\tilde{P}$ and $\tilde{Q}$. This implies that any equilibria found in the subtree rooted at the current node will differ from $(\tilde{x}, \tilde{y})$.

An important aspect of either of these two branching rules is that every new branch obtained from the current node has one additional inequality constraint converted into an equality, thus reducing the size of one subproblem of each branch. This reduction ensures that every branch of the tree will eventually terminate with an infeasible subproblem, even when degeneracy is encountered. In the degenerate case, it is possible that the same equilibrium is obtained at more than one node of the enumeration tree, but it is recorded only once.

THEOREM 3.1. *Algorithm EEE enumerates in finite time all extreme equilibrium points of a bimatrix game.*

Proof. Let $(\hat{x}, \hat{y})$ be an extreme equilibrium point, and let $\hat{\alpha}$ and $\hat{\beta}$ be the payoffs $\hat{x}^t A \hat{y}$ and $\hat{x}^t B \hat{y}$, respectively. The point $\hat{s} = (\hat{x}, \hat{y}, \hat{\alpha}, \hat{\beta})$ is a vertex of $X \times Y$. We define the following sets of indices indicating binding constraints at that point:

$$I^x = \{i : \hat{x}_i = 0\}, \quad J^y = \{j : \hat{y}_j = 0\}, \quad I^y = \{i : A_{i\cdot}\hat{y} = \alpha\}, \quad J^x = \{j : \hat{x}^t B_{\cdot j} = \beta\}.$$

Clearly, the point $\hat{s}$ belongs to the set

$$S = \left\{ \begin{array}{lrr} (x, \beta, y, \alpha) \in X \times Y : & x_i = 0 \ \forall i \in I^x; & y_j = 0 \ \forall j \in J^y; \\ & A_{i\cdot} y = \alpha \ \forall i \in I^y; & x^t B_{\cdot j} = \beta \ \forall j \in J^x; \end{array} \right\}.$$

Suppose that the set S is not a singleton, i.e., that there is an s' in S such that $s' \neq \hat{s}$. For a given ϵ, consider the point $s_\epsilon = s' + \epsilon(\hat{s} - s')$. If $\epsilon \in [0, 1]$, then convexity of S implies that s_ϵ belongs to S. Recall that $\hat{s}$ is a vertex of $X \times Y$; therefore, for $\epsilon > 1$, s_ϵ does not belong to $X \times Y$ nor to S. It follows that there must be a binding constraint at the point $\hat{s}$ that is free at s'. Since S is defined through all binding constraints at $\hat{s}$, s' cannot belong to S. Therefore, the set S consists of the singleton $\{(\hat{x}, \hat{\beta}, \hat{y}, \hat{\alpha})\}$.

Furthermore, the complementary slackness conditions (3.1) ensure that these sets of indices satisfy $I^x \cup I^y = \{1, 2, \ldots, m\}$ and $J^x \cup J^y = \{1, 2, \ldots, n\}$. If the equilibrium point is nondegenerate, then these pairs of sets are disjoint, i.e., $I^x \cap I^y = \emptyset$ and $J^x \cap J^y = \emptyset$. In the degenerate case, multiple basic representations imply nonempty intersections.

Consider a current node of the enumeration tree where the extreme equilibrium point $(\hat{x}, \hat{y})$ has not yet been detected by the algorithm. If the depth is less than or equal to $|I^x| + |I^y| + |J^x| + |J^y|$ (this sum is equal to $m + n$ in the nondegenerate case), the branching rules select a variable $\tilde{\imath}$ or $\tilde{\jmath}$ in such a way that a new branch of this node will necessarily impose one of the following constraints:

$$\begin{array}{llll} x_{\tilde{\imath}} = 0, \text{ where } \tilde{\imath} \in I^x, & \text{or} & y_{\tilde{\jmath}} = 0, \text{ where } \tilde{\jmath} \in J^y, & \text{or} \\ A_{\tilde{\imath}\cdot} y = \alpha, \text{ where } \tilde{\imath} \in I^y, & \text{or} & x^t B_{\cdot\tilde{\jmath}} = \beta, \text{ where } \tilde{\jmath} \in J^x. & \end{array}$$

If $(\hat{x}, \hat{y})$ is an extreme equilibrium of the problem of the predecessor's node, then it is also one for the current problem as addition of this constraint does not render the current problem infeasible.

There will therefore be a node of depth $|I^x| + |I^y| + |J^x| + |J^y| + 1$ containing the constraints appearing in the set S. At that node, Step e of the algorithm discovers the extreme equilibrium $(\hat{x}, \hat{y})$.

The number of constraints and variables in the sets X and Y are finite. In the enumeration tree, each node contains a problem that has one more variables or slack variables fixed at 0 than its predecessor, and thus, in view of the constraints appearing in (P1), every branch of the tree is bound to end up with an infeasible problem. Therefore, the number of nodes is finite.

Moreover, processing each node is done in finite time as it basically reduces to the resolution of two parameterized linear programs bounded in size by P and Q. It follows that the algorithm is finite. □

We now illustrate the algorithm EEE on a small example and then on a slightly larger but degenerate example.

3.3. A small example. Consider Nash's [18] 2 × 2 example

$$A = \begin{bmatrix} 1 & -10 \\ 10 & -1 \end{bmatrix}, \quad B = \begin{bmatrix} 1 & 10 \\ -10 & -1 \end{bmatrix}.$$

Even though this example contains dominated strategies (see e.g., Luce and Raiffa [10]) and could be solved directly by inspection, it is analyzed here to illustrate the steps of the algorithm.

At the initialization step, the problems

$$\begin{aligned} P(y) = \max_{x\geq 0,\beta}\ & (y_1 - 10y_2)x_1 + (10y_1 - y_2)x_2 - \beta \\ \text{s.t.}\quad & x_1 + x_2 = 1, \\ & x_1 - 10x_2 \leq \beta, \\ & 10x_1 - x_2 \leq \beta, \\ Q(x) = \max_{y\geq 0,\alpha}\ & (x_1 - 10x_2)y_1 + (10x_1 - x_2)y_2 - \alpha \\ \text{s.t.}\quad & y_1 + y_2 = 1, \\ & y_1 - 10y_2 \leq \alpha, \\ & 10y_1 - y_2 \leq \alpha, \end{aligned}$$

together with $x^t = (\frac{1}{2}, \frac{1}{2})$, constitute the first node placed into the stack T. This node is selected in Step b and removed from T. Step c solves $Q(\frac{1}{2}, \frac{1}{2})$, obtaining $\tilde{y}_1 = 0, \tilde{y}_2 = 1$, and then solves $P(0,1)$, getting $\tilde{x}_1 = 0, \tilde{x}_2 = 1$. At the end of this step, $\tilde{x}^t = \tilde{y}^t = (0,1)$, $\tilde{\alpha} = \tilde{\beta} = -1$, and the slack variables associated with the constraints $A\tilde{y} \leq \mathbf{1}\tilde{\alpha}$ and $\tilde{x}^t B \leq \tilde{\beta}\mathbf{1}^t$ are both $(9,0)$.

The branching step selects the index $\tilde{\imath} = 1$. The stack T now contains two nodes, one in which the constraint $x_1 = 0$ is added to $\tilde{P}$ (with feasible starting point $\tilde{y}^t = (0,1)$ for $\tilde{Q}$), and the other in which the constraint $A_{1\cdot}y = \alpha$ is added to $\tilde{Q}$ (with feasible starting point $\tilde{x}^t = (0,1)$ for $\tilde{P}$).

Figure 3.2 displays the complete search tree generated by the algorithm. Selection of the nodes in Step b is done following a depth-first strategy. The circled numbers indicate the order in which the nodes are selected.

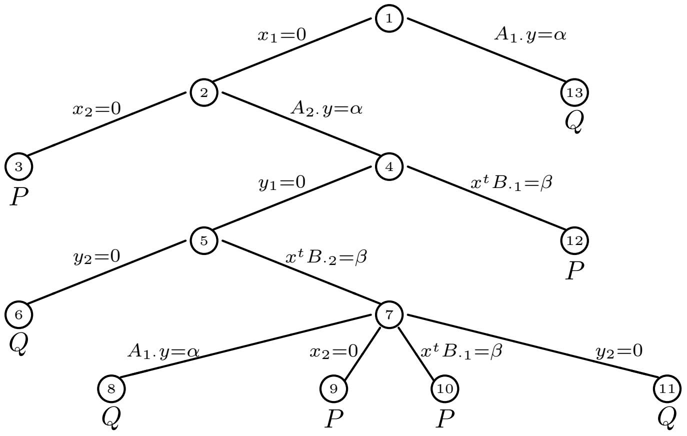


FIG. 3.2. *Search tree.*

We discuss a few important nodes of the search tree. At the third node, subproblem $\tilde{P}$ is found to be infeasible as the constraint $x_1 + x_2 = 1$ is violated by the added constraints $x_1 = x_2 = 0$. Step d detects this infeasibility and backtracks to Step b. The stack T now only contains the problems corresponding to the nodes 4 and 13.

At the seventh node, an equilibrium point is found since all complementary conditions are satisfied, and the current subproblems $\tilde{P}$ and $\tilde{Q}$ are both feasible. Although this point $\tilde{x}^t = \tilde{y}^t = (0,1)$ was obtained at the first node of the search tree, it is recorded only as an equilibrium point at this deeper node. This reduces the time spent in checking if a point is an equilibrium or not. Therefore, the time required to find a first equilibrium could be reduced, but this is not our goal. In Step e, a total of four new nodes are added to the stack T. One corresponds to the strictly positive slack variable of the constraint $A_{1\cdot}\tilde{y} = y_1 - 10\tilde{y}_2 \leq \tilde{\alpha}$, a second to $\tilde{x}_2 \geq 0$, another to the slack variable of the constraint $\tilde{x}^tB_{\cdot 1} = \tilde{x}_1 - 10\tilde{x}_2 \leq \beta$, and a last one to $\tilde{y}_2 \geq 0$. Each of these nodes yields infeasible problems which are detected in either Step c or d. The stack T now contains the problems corresponding to the nodes 12 and 13; all other nodes are completely processed.

At the thirteenth node, subproblem $\tilde{Q}$ is found to be infeasible. Indeed the addition of $y_1 - 10y_2 = \alpha$ to nine times $y_1 + y_2 = 1$ violates the constraint $10y_1 - y_2 \leq \alpha$. Step c detects this infeasibility and backtracks to Step b. The stack T is now empty, thus ending execution of the algorithm.

The use of the complementary slackness conditions is the key to the efficiency of the algorithm. For example, consider node 13. As mentioned above, the complementary condition $A_{1\cdot}y = \alpha$ obtained from the branching rule allows immediate pruning of the branch. If that rule was replaced by $x_1 = 0$ versus $x_1 > 0$, then pruning of the branch is not immediately possible since there is a vertex $(x^t, \beta) = (1, 0, 10)$ of the set X that satisfies the constraint $x_1 > 0$. That point is therefore a candidate for an extreme equilibrium strategy. Under this weakened branching rule, node 13 should be further investigated. For larger problems, this significantly reduces the number of nodes visited by the algorithm.

3.4. A degenerate example. Winkels's [24] 6×2 example is next discussed to illustrate how algorithm EEE behaves when degeneracy occurs:

$$A^t = \begin{bmatrix} 1 & 1 & 3 & 3 & \frac{5}{2} & \frac{5}{2} \\ 3 & 3 & 1 & 1 & \frac{5}{2} & \frac{5}{2} \end{bmatrix}, \quad B^t = \begin{bmatrix} 1 & 0 & -2 & 4 & -1 & 6 \\ 2 & -1 & 2 & -1 & 6 & -1 \end{bmatrix}.$$

The first node of depth greater than $m + n = 8$ where both subproblems are feasible is the nineteenth. To reach that node, the first branching rule converted eight complementary slackness conditions into

$$x_1 = x_2 = x_3 = x_4 = 0, \; A_{5\cdot}y = A_{6\cdot}y = \alpha, \quad \text{and} \quad x^tB_{\cdot 1} = x^tB_{\cdot 2} = \beta.$$

The extreme equilibrium point obtained by solving the current subproblems is

$$\begin{aligned} \tilde{x}^t &= (0,0,0,0,\tfrac{1}{2},\tfrac{1}{2}), & \tilde{y}^t &= (\tfrac{3}{4},\tfrac{1}{4}), & \tilde{\alpha} &= \tfrac{5}{2}, \\ (A\tilde{y} - \mathbf{1}\tilde{\alpha})^t &= (1,1,0,0,0,0), & (\tilde{x}^tB - \tilde{\beta}\mathbf{1}^t) &= (0,0), & \tilde{\beta} &= \tfrac{5}{2}. \end{aligned}$$

Both alternatives of the complementary slackness condition $\tilde{x}_3 = 0$ or $A_{3\cdot}\tilde{y} = \tilde{\alpha}$ are satisfied. (The same is true for $\tilde{x}_4 = 0$ or $A_{4\cdot}\tilde{y} = \tilde{\alpha}$.) The solution is therefore degenerate. Figure 3.3 displays the subtree rooted at node 19, obtained with the second branching rule.

A second extreme equilibrium point is obtained at node 20:

$$\begin{aligned} \tilde{x}^t &= (0,0,0,0,\tfrac{1}{2},\tfrac{1}{2}), & \tilde{y}^t &= (\tfrac{1}{4},\tfrac{3}{4}), & \tilde{\alpha} &= \tfrac{5}{2}, \\ (A\tilde{y} - \mathbf{1}\tilde{\alpha})^t &= (0,0,1,1,0,0), & (\tilde{x}^tB - \tilde{\beta}\mathbf{1}^t) &= (0,0), & \tilde{\beta} &= \tfrac{5}{2}. \end{aligned}$$

The same extreme equilibrium is found at node 27 but is not recorded again. Nodes 21 to 26 and 28 to 37 are discarded through the infeasibility criterion of Steps c or d. Processing of these nodes is rapid since infeasibility is detected in the first phase of the Simplex algorithm. All twelve equilibria were obtained with 417 nodes.

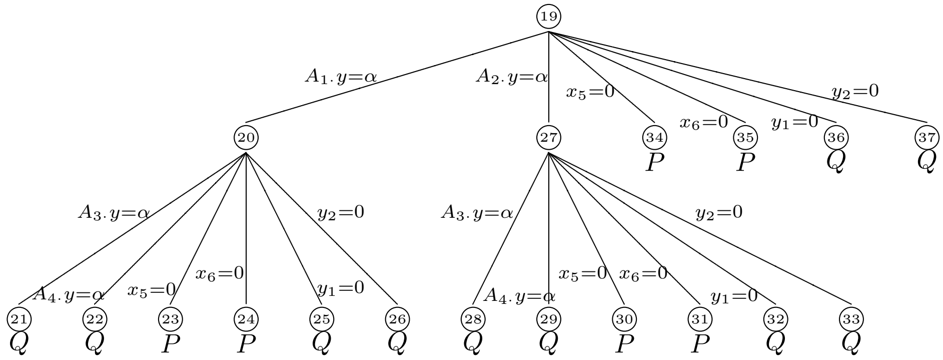

FIG. 3.3. *Search tree.*

4. Numerical results. We have shown that the algorithm EEE enumerates all extreme equilibria of bimatrix games. However, the size of the instances that can be solved and the precision to which computations are made depend on the implementation and on the computers on which the experiments are made. The algorithm is coded in C, and the CPLEX library is used to solve the parameterized linear programs $\tilde{P}$ and $\tilde{Q}$. Computational experiments are made on a SPARC station SS20/514MP under Solaris 2.4-27 using double precision floating point arithmetic.

The entries in Table 4.1 are mean values (μ) and standard deviations (σ) for ten randomly generated problems where the coefficients of the matrices A and B are drawn from a uniform distribution over the real interval $[0, 10]$. This process is unlikely to produce degenerate bimatrix games. Note that algorithm EEE may be inefficient for degenerate games (as illustrated by the fact that it requires 417 nodes for Winkels's small example discussed above). Indeed, the same equilibrium will be found many times at a level greater than $n + m$. The columns *time* and *nodes* are the average computing times in seconds and average total number of nodes explored in the search tree. The *equilibrium* columns display the average *total* number of extreme equilibria and the average number of the node at which the *first* extreme equilibrium point is detected.

The total number of extreme equilibrium points does not increase very rapidly. It remains almost stable for large problems with m fixed at 5. This is due in part to the large number of dominated strategies inherent to such randomly generated games. That number goes down when both dimensions are close. When $m = n$, there appears to be an exponential growth in the number of extreme equilibria, but it remains, however, moderate. The average node at which the first extreme equilibria is detected is fairly large as the method only checks for equilibria at nodes of depth greater than $m + n$. The logarithm of the execution times is plotted on the graphs of Figure 4.1.

It appears that the time required when $m = n$ grows exponentially with n. For large values of n, some of the problems were difficult to solve, yielding large standard deviations. One of the ten problems generated for $n = 21$ was very difficult and required 2140 seconds and 272034 nodes. When m is fixed at $5, 10$, or 15, the execution time seems to grow asymptotically towards an exponential since the logarithm of the computational times approaches linearity for large values of n. It also appears that the time spent by the algorithm at each node is roughly proportional to the product of m and n.

Figure 4.2 suggests that the total execution time of algorithm EEE is polynomial in the total number of extreme equilibria. The figure displays the logarithm of the execution times on the y-axis and the logarithm of the total number of extreme equilibria on the x-axis for the randomly generated games of Table 4.1 where $m = n$.

When m and n differ significantly, analysis of dominated strategies prior to the execution of algorithm EEE can improve computational time for problems generated as above. We used McKelvey and McLennan's [13] package GAMBIT v0.94 to solve various instances. Computational results are summarized in Table 4.2, where a single instance corresponds to each line. Problems are randomly generated as above and solved by EEE, then dominated strategies are identified and removed, and, finally, EEE is executed again on these smaller games.

The first five columns display characteristics of the instances considered and of the execution of EEE, as in the other tables. The columns ElimDom are derived from the strongly dominated strategy removal routine of the GAMBIT package. The columns m' and n' indicate the size of the resulting reduced bimatrix game. The last columns detail execution of the algorithm EEE on these smaller instances, where the bracketed entries are the sum of the execution times of EEE and ElimDom.

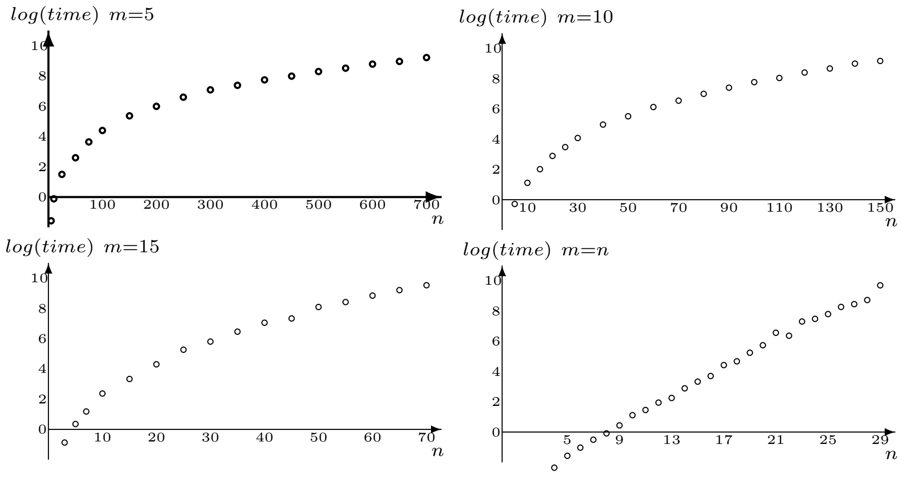

FIG. 4.1. *Logarithm of the execution times of algorithm EEE.*

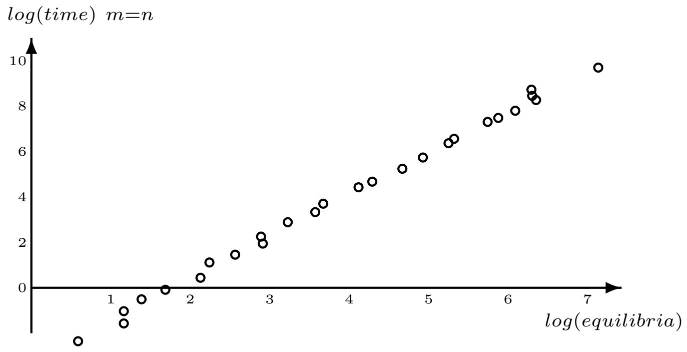

FIG. 4.2. *Logarithm of the execution times of algorithm EEE versus logarithm of the number of equilibria.*

Enumeration of all extreme equilibria using GAMBIT's *EnumMixed* procedure is possible in reasonable time (less than three hours) only for the smallest instances considered. For example, the time required for that procedure (excluding that of ElimDom), for the problem where the dimensions are reduced from 100×5 to 17×5, is 70.6 seconds, and the time required for the one reduced from 200×5 to 29×5 is 1803.5 seconds. However, for the next instance, the one where the size is reduced from 300×5 to 47×5, the time required is more than 17.5 hours. This computational time is more than 1700 times longer than the 36.1 seconds required by algorithm EEE on the same reduced game.

A significant gain in computing time occurs when there is an important difference between the dimensions and when the largest dimension is not too high. For such randomly generated games that contain many dominated strategies, it appears that their identification and removal prior to the execution of the algorithm EEE reduces the total computational time.

The alternative straightforward approach consisting in enumerating in a first step all vertices of the polyhedra X and Y and then checking for equilibrium may be

efficient for small problems. However, the number of vertices grows much more rapidly than the number of nodes visited by algorithm EEE. Table 4.3 displays the mean and the standard deviation of the number of nodes required by the search tree as well as the number of vertices of the polyhedron Y for ten problems randomly generated as above. Computational times, including those of the GAMBIT package, are also reported.

Table 4.3
Comparison of algorithms in terms of times, nodes and vertices.

Fukuda's [5] state-of-the-art implementation in C of the double description method of [16] is used for vertex enumeration. The number of vertices of Y grows much more rapidly than the number of nodes visited by algorithm EEE. Computational time required for enumerating all vertices follows their number. Even if another algorithm or a different implementation were used, the time would quickly exceed that required by algorithm EEE. Moreover, vertex enumeration of Y is only the first step of the straightforward approach. Thus it does not appear that this approach is competitive.

In a second step (as long as the first one), all vertices of the polyhedron X should be enumerated, and a final step would verify complementary conditions for each pair of vertices. This approach does not seem reasonable even for midsized problems, e.g., the average number of vertices for the 15×15 problems is over 5×10^4 for both polyhedra, and thus approximately 2.5×10^9 equilibrium conditions should be checked. (These conditions require the knowledge of slack variables.) Moreover, additional difficulties arise in vertex enumeration procedures when degeneracy is encountered. Table 4.3 shows that algorithm EEE is more than 1000 times faster than GAMBIT for a problem of size 11×11, and that factor grows with problem size. For those problems, GAMBIT's procedure for eliminating dominated strategies always took less than 2.1 seconds for each instance considered; thus the most computational time is needed for the extreme equilibria enumeration procedure.

In conclusion, the proposed algorithm allows enumeration of all extreme equilibrium points of substantially larger bimatrix games than done by previous ones. The key to the efficiency of the algorithm is the systematic use of complementary slackness conditions in the branching rule. This allows joint use of information concerning the polyhedra X and Y, unlike vertex enumeration based procedures that treat them as two distinct entities.

MAXIMUM PRINCIPLE PRESERVING SCHEMES FOR INTERFACE PROBLEMS WITH DISCONTINUOUS COEFFICIENTS[*]

ZHILIN LI[†] AND KAZUFUMI ITO[†]

Abstract. New finite difference methods using Cartesian grids are developed for elliptic interface problems with variable discontinuous coefficients, singular sources, and nonsmooth or even discontinuous solutions. The new finite difference schemes are constructed to satisfy the sign property of the discrete maximum principle using quadratic optimization techniques. The methods are shown to converge under certain conditions using comparison functions. The coefficient matrix of the resulting linear system of equations is an M-matrix and is coupled with a multigrid solver. Numerical examples are also provided to show the efficiency of the proposed methods.

Key words. elliptic interface problems, finite difference methods, discontinuous coefficients, singular source term, discrete maximum principle, quadratic optimization, multigrid methods

1. Introduction.

Many important practical problems lead to partial differential equations (PDEs) whose solutions or derivatives have discontinuities across some interfaces within the solution domains. In this paper, we propose a class of numerical methods that preserve the discrete maximum principle for the interface problems defined below:

$$(\beta u_x)_x + (\beta u_y)_y - \kappa(x,y)\,u = f(x,y), \qquad (x,y) \in \Omega = \Omega^+ \cap \Omega^-, \tag{1.1}$$

with a boundary condition on $\partial\Omega$, where $\beta \geq \beta_{min} > 0$, $\kappa \geq 0$, and f are *piecewise* continuous but may have a jump discontinuity across some *smooth* curve Γ in the domain Ω; see Figure 1(a) for an illustration. The source term f can also contain singular sources as reflected in the following jump conditions:

$$[u]\Big|_{\mathbf{X}\in\Gamma} = w(s), \qquad [\beta u_n]\Big|_{\mathbf{X}\in\Gamma} = v(s), \tag{1.2}$$

where $\mathbf{X} = (X, Y)$ is a point on the interface Γ, s is the arc-length parameterization of the interface Γ, and the jump is defined as the difference of the limiting values of two different sides of the interface, for example,

$$[u]\Big|_{\mathbf{X}\in\Gamma} = \lim_{\mathbf{x}\to\mathbf{X},\mathbf{X}\in\Omega^+} u(\mathbf{x}) \;-\; \lim_{\mathbf{x}\to\mathbf{X},\mathbf{X}\in\Omega^-} u(\mathbf{x}),$$

where $\mathbf{x} = (x, y) \in \Omega$. The interface Γ can be arbitrary, but it is assumed to be a smooth closed curve[1] lying in Ω. In the case that κ is continuous and $w(s) \equiv 0$, the

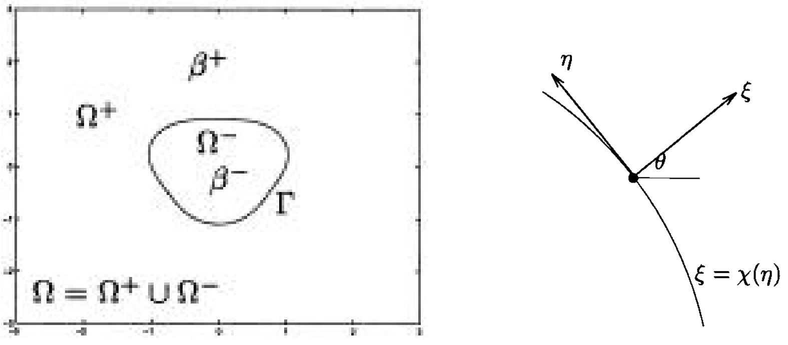
[1] We impose some conditions on β, κ, and Γ for simplicity, especially for theoretical discussions. Nevertheless, most of these conditions can be relaxed when we apply the algorithms discussed in this paper.



(a) (b)

FIG. 1.1. (a) *A diagram of a rectangular domain* $\Omega = \Omega^+ \cup \Omega^-$ *with an immersed interface* Γ. *The coefficient* $\beta(\mathbf{x})$ *may have a jump across the interface.* (b) *A diagram of the local coordinates in the normal and tangential directions, where* θ *is the angle between the* x*-axis and the normal direction.*

interface problem can be written as the boundary value problem below:

$$\begin{aligned} &\nabla \cdot (\beta \nabla u(\mathbf{x})) - \kappa\, u(\mathbf{x}) = f(\mathbf{x}) + \int_\Gamma v(s)\delta_2(\mathbf{x} - \mathbf{X}(s))ds, \\ &\text{with a given boundary condition on} \quad \partial\Omega, \end{aligned}$$

where δ_2 is the two-dimensional Dirac delta function; the second term at the right-hand side is a distribution which satisfies

$$\iint_\Omega \int_\Gamma v(s)\delta_2(\mathbf{x} - \mathbf{X}(s))\Psi(\mathbf{x})ds\, d\mathbf{x} = \int_\Gamma v(s)\Psi(\mathbf{X}(s))ds \tag{1.3}$$

for any arbitrary smooth function $\Psi(x, y)$. The discussion of the existence and the regularity of the solution can be found, for example, in [2, 3]. In general, if β, κ, and f are piecewise smooth in Ω, $w = 0$, and v is continuous along Γ, then the solution to the interface problem exists and is in $H^1(\Omega)$.

There are several numerical methods in the literature designed for the interface problems discussed in this paper. We just mention a few here: the finite element methods using body fitting grids [3]; the fast solvers based on integral equations for piecewise constant coefficients including the fast multipole method; the first order ghost fluid method [11]. In this paper, our new methods are based on the immersed interface method (IIM) [7, 8].

The IIM is a second order finite difference method based on Cartesian grids for interface problems in which the jump conditions across the interface are known. The IIM gives sharp solutions (no smear-out) across the interfaces since the jump conditions are enforced. Generally the IIM uses only local information, specifically, the PDEs, the jump conditions, the interface, and the underlying grid. The IIM has been successfully coupled with evolution schemes such as the particle approach and the level set method for moving interface and free boundary problems.

For an interface problem with a variable coefficient that has discontinuity across the interface, the resulting linear system of equations from the original IIM is not symmetric positive definite. While it is stable for one-dimensional and certain two-dimensional problems [6], the stability of the algorithm depends on the choice of one or more extra grid points in addition to the standard five-point stencil [5]. In other words, it is not always guaranteed that the original IIM will converge and satisfy the maximum principle. Many efficient linear solvers may not work or may work poorly for the linear system of equations derived from the original IIM.

In this paper, we will develop new methods for *arbitrary $\beta(x,y)$ using direct finite difference discretization*. The new methods satisfy the sign property that guarantees the discrete maximum principle. The sign property is enforced through a constrained quadratic optimization problem. The coefficient matrix of the resulting linear system of equations is diagonally dominant and its symmetric part is negative definite. Such a matrix is an M-matrix that guarantees some iterative methods such as the SOR method converge. Two specific schemes using the optimization approach are discussed. One is a first order method that uses the standard five-point stencil. The other one is a second order method that uses a standard nine-point stencil. The convergence of the methods is warranted if the solution to the optimization problem exists and certain bounds are satisfied. The existence of the solution to the optimization problem is proved for the first order method and verified numerically for the second order method.

The idea in this paper actually was proposed and tested by Z. Li (1993) and S. Moskow and F. Santosa (1996–1997). However, due to various reasons, it has never been written up and published.

The paper is organized as follows. In section 2, we lay down some theoretical fundamentals for interface problems that are needed in deriving the new methods. We derive the new methods using optimization techniques in section 3. Convergence analysis for the first order and second order methods is given in section 4 and 5, respectively. The numerical results are presented in section 6.

2. Preliminaries.

2.1. The local coordinates. Given a point (x_i^*, y_j^*) on the interface, it is convenient to use the local coordinates in the normal and the tangential directions:

$$\xi = (x - x_i^*)\cos\theta + (y - y_j^*)\sin\theta, \qquad \eta = -(x - x_i^*)\sin\theta + (y - y_j^*)\cos\theta, \tag{2.1}$$

where θ is the angle between the x-axis and the normal direction, pointing to the direction of a specified side, say, the $+$ side in Figure 1(b). We use the superscripts $-$ or $+$ to denote the limiting values of a function from one side or the other. Under the local coordinates, the limiting differential equation approaching the interface from a particular side, for example, from the $-$ side, can be written

$$\beta^-\left(u_{\xi\xi}^- + u_{\eta\eta}^-\right) + \beta_\xi^- u_\xi^- + \beta_\eta^- u_\eta^- - \kappa^- u^- = f^-. \tag{2.2}$$

In a neighborhood of the point (x_i^*, y_j^*), the interface Γ can be parameterized as

$$\xi = \chi(\eta), \quad \text{with} \quad \chi(0) = 0, \quad \chi'(0) = 0. \tag{2.3}$$

The curvature of the interface at (x_i^*, y_j^*) is $\chi''(0)$.

2.2. The interface relations. Let $u(x,y)$ be the solution to (1.1) and (1.2). Let (x_i^*, y_j^*) be a point on the interface. We have derived the following interface relations in [7, 8] that represent the limiting quantities of the solution of (1.1)–(1.2) and its derivatives from one side of the interface in terms of the other.

$$\begin{aligned}
& u^+ = u^- + w, \qquad u_\xi^+ = \rho\, u_\xi^- + \frac{v}{\beta^+}, \qquad u_\eta^+ = u_\eta^- + w', \\
& u_{\xi\,\xi}^+ = \left(\frac{{\beta_\xi}^-}{\beta^+} - \chi'' \right) u_\xi^- + \left(\chi'' - \frac{{\beta_\xi}^+}{\beta^+} \right) u_\xi^+ + \frac{{\beta_\eta}^-}{\beta^+}\, u_\eta^- - \frac{{\beta_\eta}^+}{\beta^+}\, u_\eta^+ \\
& \qquad\qquad + (\rho - 1)\, u_{\eta\,\eta}^- + \rho u_{\xi\,\xi}^- - w'' + \frac{[f]}{\beta^+} + \frac{[\kappa]\, u^- + \kappa^+\, [u]}{\beta^+}, \\
& u_{\eta\,\eta}^+ = u_{\eta\,\eta}^- + (u_\xi^- - u_\xi^+)\, \chi'' + w'', \\
& u_{\xi\,\eta}^+ = \frac{{\beta_\eta}^-}{\beta^+}\, u_\xi^- - \frac{{\beta_\eta}^+}{\beta^+} u_\xi^+ + \left(u_\eta^+ - \rho u_\eta^- \right) \chi'' + \rho\, u_{\xi\,\eta}^- + \frac{v'}{\beta^+},
\end{aligned} \tag{2.4}$$

where $\rho = \beta^-/\beta^+$. These interface relations are used in deriving the new finite difference methods in the next section.

3. The algorithm description. We assume the domain Ω is a rectangle, say, $[a, b] \times [c, d]$. We take a uniform grid with

$$x_i = a + ih, \quad y_j = a + jh, \qquad i = 0, 1, \ldots, m, \quad j = 0, 1, \ldots, n,$$

where $h = (b - a)/m$ and $h = (d - c)/n$. The discussions are easily generalized to the cases in which the spatial step sizes are different in each direction. Our goal is to develop a finite difference equation of the form

$$\sum_{k=1}^{n_s} \gamma_k\, U_{i+i_k, j+j_k} - \kappa_{ij}\, U_{ij} = f_{ij} + C_{ij} \tag{3.1}$$

at any grid point (x_i, y_j), where n_s is the number of grid points in the finite difference stencil, and U_{ij} is the solution to the linear system of equations (3.1) and an approximation to the solution $u(x, y)$ of (1.1) and (1.2) at (x_i, y_j). The sum over k involves a finite number of points neighboring (x_i, y_j). So each i_k, j_k will take values in the set $\{0, \pm 1, \pm 2, \ldots\}$. The coefficients γ_k and the indices i_k, j_k, and n_s will depend on (i, j), so these should really be labeled γ_{ijk}, etc., but for simplicity of notation we will concentrate on a single grid point (x_i, y_j) and drop these indices.

The local truncation error at a grid point (x_i, y_j) is defined as

$$T_{ij} = \sum_{k=1}^{n_s} \gamma_k\, u\left(x_{i+i_k}, y_{j+j_k}\right) - \kappa_{ij}\, u(x_i, y_j) - f(x_i, y_j) - C_{ij}. \tag{3.2}$$

We say (x_i, y_j) is a *regular grid point* if all the grid points in the standard five-point stencil are in the same side of the interface. At regular grid points, we use the standard five-point ($n_s = 5$) central finite difference scheme with $C_{ij} = 0$. The local truncation error at regular grid points is $O(h^2)$.

We need to determine formulas of the form (3.1) for *irregular grid points* around which the standard five-point stencil contains grid points from both sides of the interface. First we choose a point (x_i^*, y_j^*) on the interface Γ near the grid point (x_i, y_j). Usually, we take (x_i^*, y_j^*) either as the orthogonal projection of (x_i, y_j) on the interface or the intersection of the interface and one of the axes. We then expand each $u(x_{i+i_k}, y_{j+j_k})$ about (x_i^*, y_j^*) under the local coordinates,

$$u(x_{i+i_k}, y_{j+j_k}) = u(\xi_k, \eta_k) = u^\pm + \xi_k u_\xi^\pm + \eta_k u_\eta^\pm + \frac{1}{2}\xi_k^2 u_{\xi\xi}^\pm + \xi_k \eta_k u_{\xi\eta}^\pm + \frac{1}{2}\eta_k^2 u_{\eta\eta}^\pm + O(h^3),$$

where the + or − sign is chosen depending on whether (ξ_k, η_k) lies on the + or − side of Γ. If we do this expansion at each point involved in the finite difference equation (3.1), then the local truncation error T_{ij} can be expressed as a linear combination of the values $u^{\pm}, u_\xi^{\pm}, u_\eta^{\pm}, u_{\xi\xi}^{\pm}, u_{\xi\eta}^{\pm}, u_{\eta\eta}^{\pm}$ as the following:

$$\begin{aligned} T_{ij} &= a_1\, u^- + a_2\, u^+ + a_3\, u_\xi^- + a_4\, u_\xi^+ + a_5\, u_\eta^- + a_6 u_\eta^+ + a_7\, u_{\xi\,\xi}^- + a_8\, u_{\xi\,\xi}^+ \\ &\quad + a_9\, u_{\eta\,\eta}^- + a_{10}\, u_{\eta\,\eta}^+ + a_{11}\, u_{\xi\,\eta}^- + a_{12}\, u_{\xi\,\eta}^+ - \kappa^- u^- - f^- - C_{ij} + O(h). \end{aligned}$$

The quantities $f^{\pm}$, $\kappa^{\pm}$, $\beta^{\pm}$ are the limiting values of the functions at (x_i^*, y_j^*) from the + side or − side of the interface. The coefficients a_j depend only on the position of the stencil relative to the interface. They are independent of the functions u, κ, and f. If we define the index sets K^+ and K^- by

$$K^{\pm} = \{k : \ (\xi_k, \eta_k) \text{ is on the } \pm \text{ side of } \Gamma\},$$

then the a_j are given by

$$\begin{aligned} &a_1 = \sum_{k\in K^-} \gamma_k, && a_2 = \sum_{k\in K^+} \gamma_k, && a_3 = \sum_{k\in K^-} \xi_k\gamma_k, \\ &a_4 = \sum_{k\in K^+} \xi_k\gamma_k, && a_5 = \sum_{k\in K^-} \eta_k\gamma_k, && a_6 = \sum_{k\in K^+} \eta_k\gamma_k, \\ &a_7 = \frac{1}{2}\sum_{k\in K^-} \xi_k^2\gamma_k, && a_8 = \frac{1}{2}\sum_{k\in K^+} \xi_k^2\gamma_k, && a_9 = \frac{1}{2}\sum_{k\in K^-} \eta_k^2\gamma_k, \\ &a_{10} = \frac{1}{2}\sum_{k\in K^+} \eta_k^2\gamma_k, && a_{11} = \sum_{k\in K^-} \xi_k\eta_k\gamma_k, && a_{12} = \sum_{k\in K^+} \xi_k\eta_k\gamma_k. \end{aligned} \tag{3.3}$$

Using the interface relations (2.4), we eliminate the quantities from one side, say, the + side, using the quantities from the other side, say, the − side, and collect terms to get an expression of the form

(3.4)
$$\begin{aligned} T_{ij} \;=\; & \left(a_1 + \frac{a_8\,[\kappa]}{\beta^+} + a_2\right) u^- + \left\{ a_3 + a_8\left(\frac{\beta_\xi{}^-}{\beta^+} - \chi''\right) + a_{10}\chi'' + a_{12}\frac{\beta_\eta{}^-}{\beta^+} \right. \\ & \left. +\ \rho\left(a_4 + a_8\left(\chi'' - \frac{\beta_\xi{}^+}{\beta^+}\right) - a_{10}\chi'' - a_{12}\frac{\beta_\eta{}^+}{\beta^+}\right) - \beta_\xi{}^- \right\} u_\xi^- \\ & + \left\{ a_5 + a_6 + a_8\left(\frac{\beta_\eta{}^-}{\beta^+} - \frac{\beta_\eta{}^+}{\beta^+}\right) + a_{12}(1-\rho)\,\chi'' - \beta_\eta{}^- \right\} u_\eta^- \\ & + \left\{a_7 + a_8\rho - \beta^-\right\} u_{\xi\,\xi}^- + \left\{a_9 + a_{10} + a_8\,(\rho - 1) - \beta^-\right\} u_{\eta\,\eta}^- \\ & + \{a_{11} + a_{12}\rho\}\, u_{\xi\,\eta}^- - \kappa^- u^- - f^- + (\hat{T}_{ij} - C_{ij}) + O(h), \end{aligned}$$

where

$$\begin{aligned} \hat{T}_{ij} &= a_2\, w + a_{12}\,\frac{v'}{\beta^+} + \left(a_6 - \frac{a_8\,\beta_\xi{}^+}{\beta^+} + a_{12}\chi''\right) w' \\ &\quad + a_{10}\, w'' + \frac{1}{\beta^+}\left(a_4 + a_8(\chi'' - \frac{\beta_\xi{}^+}{\beta^+}) - a_{10}\chi'' - a_{12}\frac{\beta_\eta{}^+}{\beta^+}\right) v \\ &\quad + a_8\left\{\frac{[f]}{\beta^+} + \frac{\kappa^+\, w}{\beta^+} - w''\right\}. \end{aligned} \tag{3.5}$$

We want to make the magnitude of the truncation error as small as possible by choosing γ_k's so that some of coefficients of u^-, u_ξ^-, u_η^-, $\ldots$ vanish:

$$\begin{aligned}
a_1 + a_2 + a_8 \frac{[\kappa]}{\beta^+} &= 0, \\
a_3 + \rho a_4 + a_8 \frac{{\beta_\xi}^- - \rho {\beta_\xi}^+ - [\beta]\chi''}{\beta^+} + a_{10} \frac{[\beta]\chi''}{\beta^+} + a_{12} \frac{{\beta_\eta}^- - \rho {\beta_\eta}^+}{\beta^+} &= {\beta_\xi}^-, \\
a_5 + a_6 - a_8 \frac{[\beta_\eta]}{\beta^+} + a_{12} (1-\rho)\, \chi'' &= {\beta_\eta}^-, \\
a_7 + a_8\, \rho &= \beta^-, \\
a_9 + a_{10} + a_8\, (\rho - 1) &= \beta^-, \\
a_{11} + a_{12}\, \rho &= 0.
\end{aligned} \tag{3.6}$$

Once the γ_k's are chosen, we set $C_{ij} = \hat{T}_{ij}$, where $\hat{T}_{ij}$ is given by (3.5). If we use a six-point stencil and equations (3.6) hold, then this leads to the original IIM [7].

3.1. An optimization approach. In order to obtain finite difference schemes that satisfy the discrete maximum principle, see section 6.5 of Morton and Mayers [12] for the definition. We need to impose the sign restriction on the coefficients γ_k's in (3.1)

$$\gamma_k \geq 0 \quad \text{if} \quad (i_k, j_k) \neq (0,0), \qquad \gamma_k < 0 \quad \text{if} \quad (i_k, j_k) = (0,0), \tag{3.7}$$

along with several equations in (3.6). At regular grid points, the standard central finite difference scheme satisfies the sign restriction and the equations in (3.6). So we will concentrate our discussion only on an irregular grid point (x_i, y_j). We form the following constrained quadratic optimization problem to determine the coefficients of the finite difference scheme

$$\min_{\gamma} \left\{ \frac{1}{2} \|\gamma - g\|_2^2 \right\} \qquad \text{subject to} \tag{3.8}$$

$$A\gamma = b, \quad \gamma_k \geq 0 \quad \text{if} \quad (i_k, j_k) \neq (0,0), \quad \gamma_k < 0 \quad \text{if} \quad (i_k, j_k) = (0,0), \tag{3.9}$$

where $\gamma = [\,\gamma_1, \gamma_2, \ldots, \gamma_{n_s}\,]^T$ is the vector composed of the coefficients of the finite difference scheme, $g \in R^{n_s}$, and $A\gamma = b$ is the system of linear equations that contains several or all equations in (3.6). Naturally we want to choose $\{\gamma_k\}$ in such a way that they become the coefficients of the standard five-point central difference scheme if $\beta^+ = \beta^-$ is a constant. This can be done by selecting the vector g as

$$\begin{aligned}
g_k &= \frac{\beta_{i+i_k, j+j_k}}{h^2} \quad \text{if} \quad (i_k, j_k) \in \{(-1,0), (1,0), (0,-1), (0,1)\,\}; \\
g_k &= -\frac{4\beta_{i,j}}{h^2} \quad \text{if} \quad (i_k, j_k) = (0,0); \qquad g_k = 0 \quad \text{otherwise}.
\end{aligned} \tag{3.10}$$

There are two parameters in the optimization algorithm (3.8)–(3.9) that are to be determined. The first one is the set of grid points (x_{i_k}, y_{j_k}), whose total number is n_s, involved in the finite difference scheme. The second one is the set of equations from (3.6), which is used as the equality constraint in (3.9). The solution $\{\gamma_k\}$ to the constrained optimization problem is the coefficients of the finite difference scheme at the particular irregular grid point. We will discuss a first, as well as a second, order method in this paper.

3.2. The first order method. In this section we describe the first order method. Note that $A_i\gamma = b_i$, $1 \le i \le 3$, the first three equations in (3.6) represent the leading terms in (3.4), and the last three equations $A_l\gamma = b_l$, $4 \le l \le 6$ in (3.6) are one order higher in terms of h than the first three equations. To obtain a first order method, it is sufficient to select the first three equations as the equality constraints. Moreover, since the $O(h^2)$ terms have little effect on the convergence order, we neglect them to get simplified equality constraints

$$a_1 + a_2 + a_8\frac{[\kappa]}{\beta^+} = 0, \qquad a_3 + \rho a_4 = {\beta_\xi}^-, \qquad a_5 + a_6 = {\beta_\eta}^- \tag{3.11}$$

for the first three equations. We take $n_s = 5$, and the standard five-point stencil

$$\{(i_1,j_1),(i_2,j_2),(i_3,j_3),(i_4,j_4),(i_5,j_5)\} = \{(-1,0),(0,0),(1,0),(0,-1),(0,1)\}\,.$$

Thus, the optimization problem (3.8) is written as

$$\min_{\gamma} \left\{ \frac{1}{2}\|\gamma - g\|_2^2 + \sum_{l=4}^{6} w_l \left(A_l\gamma - b_l\right)^2 \right\} \qquad \text{subject to (3.11) and} \tag{3.12}$$
$$\gamma_k \ge 0 \quad \text{if} \quad (i_k, j_k) \ne (0,0), \qquad \gamma_k < 0 \quad \text{if} \quad (i_k,j_k) = (0,0),$$

where w_l are predefined weights for $l = 4, 5, 6$ (we often simply take $w_l = 0$). It will be shown in section 4 that the resulting finite difference scheme is of first order.

3.3. The second order method. In order to get a second order method, we require all six equations in (3.6) to be satisfied plus the sign restriction (3.7) for the optimization problem. Therefore $n_s \ge 6$. In the conforming finite element method for interface problems with a uniform triangulation [10], a nonstandard nine-point stencil is used for the second order method and the stiffness matrix is symmetric positive definite. Since we do not require symmetry in the linear system of the finite difference equations described in this paper, we expect that for the standard nine-point stencil ($n_s = 9$) the optimization problem has solutions. We will see this through numerical verifications in section 5. Moreover, we prefer to use the standard nine-point stencil so that the resulting linear system of equations is block tridiagonal and a multigrid solver DMGD9V (developed for the standard nine point stencil) can be used.

3.4. Solving the optimization problems. There are several commercial and educational software packages that are designed to solve constrained quadratic optimization problems, for example, the *QP* function in Matlab; the *QL* program using Fortran computer language developed by Schittkowski [13]; and the *IQP* Fortran code from *Port* managed by Lucent Technologies. The information about these software packages can be found through the Internet.

Most of the quadratic optimization solvers require users to provide an initial guess, lower and upper bounds, and other information. We take the initial guess as the vector g, and the lower and upper bounds as

$$0 < \gamma_k < \frac{\beta_{\max}}{h^2} \quad \text{if} \quad (i_k,j_k) \ne (0,0); \qquad -\frac{4\beta_{\max}}{h^2} < \gamma_k < 0 \quad \text{if} \quad (i_k,j_k) = (0,0),$$

where $\beta_{\max}$ is an estimation of the upper bound of the coefficient $\beta(x,y)$.

In case that the optimization solver fails to give a solution, we can either increase the number of grid points or switch to a first order scheme that satisfies the discrete maximum principle, such as the smoothing method, without affecting global accuracy. If the optimization solver fails to return a feasible solution, it may mean either the *curvature* or the *jump* in β is too large relative to the underlying grid.

4. Convergence analysis for the first order method.

4.1. Existence of the solution to the optimization problem. In this subsection, we assume that $\beta(x, y)$ is piecewise constant in the solution domain although the method itself does not have such a restriction; see Example 6.1. We first show that the constrained optimization problem (3.12) has a solution and then show that the resulting finite difference scheme is of first order.

Since we use the standard five-point stencil ($n_s = 5$), the stencil at an irregular grid point (x_i, y_j) is composed of (x_{i+i_k}, y_{j+j_k}) with

$$(i_k, j_k) = \{\, (i-1, j), (i, j), (i+1, j), (i, j-1), (i, j+1)\, \} \tag{4.1}$$

corresponding to $k = 1, 2, 3, 4, 5$. Since the linear system of equations is obtained from the Taylor expansion at (x_i^*, y_j^*), a point on the interface, we need only use the limiting value of $\beta(x, y)$ at (x_i^*, y_j^*), which we denote as β^+ and β^-, respectively. Assuming $\kappa = 0$ in (1.1), we can eliminate γ_2 from the first equation in (3.11) to get

$$\gamma_2 = -\sum_{k=1,k\neq 2}^{5} \gamma_k. \tag{4.2}$$

The equality constraints from $a_3 + \rho a_4 = 0$ and $a_1 + a_2 = 0$ in (3.11) with high order terms of h being neglected and the inequality constraints of the optimization problem are the following:

$$\sum_{k=1,k\neq 2}^{5} \left(\frac{\xi_k}{\beta^\pm} - \frac{\xi_2}{\beta^\pm} \right) \gamma_k = 0, \qquad \sum_{k=1,k\neq 2}^{5} (\eta_k - \eta_2)\, \gamma_k = 0, \tag{4.3}$$

$$\gamma_k \geq 0, \quad k = 1, 3, 4, 5, \tag{4.4}$$

where $\beta^\pm$ takes either β^+ or β^- depending on which side of the interface the grid point (x_{i+i_k}, y_{j+j_k}) is. We will prove the following theorem.

THEOREM 4.1. *Let (x_i^*, y_j^*) be a point on a smooth interface Γ that satisfies*

$$|x_i^* - x_i| + |y_j^* - y_j| < \sqrt{2}\, h. \tag{4.5}$$

Assume that the interface Γ cuts through the axes at no more than two points within $[x_i - h,\, x_i + h] \times [y_j - h,\, y_j + h]$, and the tangent line at (x_i^*, y_j^*) separates the grid points in the five-point stencil in the same way as the interface does. Then there is at least one set of solutions $\gamma_k > 0$, $k = 1, 3, 4, 5$, that satisfies (4.3).

Proof. Without loss of generality, and for simplicity for indexing, we assume that $x_i^* - x_i \geq 0$, $y_j^* - y_j \geq 0$, the angle between the x-axis and the normal direction θ is in the interval $[\,0, \pi/2)$. There are two different cases depending on which side the grid point (x_i, y_{j+1}) is. We will prove one of the cases as shown in Figure 4.1 in which the condition (4.5) is assumed. The proof of the other case is technically similar and will be omitted. From Figure 4.1, it is easy to see that

$$\begin{aligned} &\xi_1 < 0, \quad \xi_3 > 0, \quad \xi_4 \leq 0, \quad \xi_5 \geq 0, \\ &\eta_1 \geq 0, \quad \eta_3 \leq 0, \quad \eta_4 < 0, \quad \eta_5 > 0. \end{aligned}$$

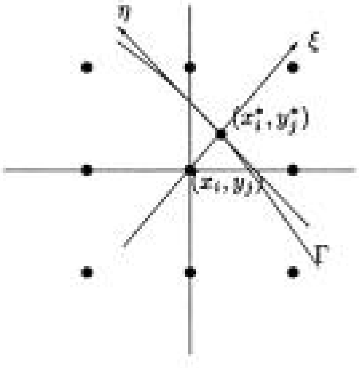


FIG. 4.1. *A diagram of the geometry at an irregular grid point if h is sufficiently small.*

With such a geometry, the two equations (4.3) are

$$\left(\frac{\xi_1}{\beta^-}-\frac{\xi_2}{\beta^-}\right)\gamma_1+\left(\frac{\xi_3}{\beta^+}-\frac{\xi_2}{\beta^-}\right)\gamma_3+\left(\frac{\xi_4}{\beta^-}-\frac{\xi_2}{\beta^-}\right)\gamma_4+\left(\frac{\xi_5}{\beta^+}-\frac{\xi_2}{\beta^-}\right)\gamma_5=0,$$

$$(\eta_1-\eta_2)\,\gamma_1+(\eta_3-\eta_2)\,\gamma_3+(\eta_4-\eta_2)\,\gamma_4+(\eta_5-\eta_2)\,\gamma_5=0. \tag{4.6}$$

Introduce the parameters α_{ij} as in the following:

$$\alpha_{11}=-\left(\frac{\xi_1}{\beta^-}-\frac{\xi_2}{\beta^-}\right)>0,\quad \alpha_{13}=\frac{\xi_3}{\beta^+}-\frac{\xi_2}{\beta^-}>0,$$
$$\alpha_{14}=-\left(\frac{\xi_4}{\beta^-}-\frac{\xi_2}{\beta^-}\right)\geq 0,\quad \alpha_{15}=\frac{\xi_5}{\beta^+}-\frac{\xi_2}{\beta^-}\geq 0,$$
$$\alpha_{23}=-(\eta_3-\eta_2)\geq 0,\quad \alpha_{21}=(\eta_1-\eta_2)\geq 0,$$
$$\alpha_{24}=-(\eta_4-\eta_2)>0,\quad \alpha_{25}=(\eta_5-\eta_2)>0.$$

We can rewrite the equations (4.6) as[2]

$$\alpha_{13}\gamma_3-\alpha_{11}\gamma_1=\alpha_{14}\gamma_4-\alpha_{15}\gamma_5,\qquad \alpha_{23}\gamma_3-\alpha_{21}\gamma_1=-\alpha_{24}\gamma_4+\alpha_{25}\gamma_5. \tag{4.7}$$

We are ready to prove the theorem by distinguishing the following cases.

- $\alpha_{23}=0$. In this case, we also have $\alpha_{21}=0$. We choose

$$\gamma_5=\frac{\beta^+}{h^2}>0,\qquad \gamma_4=\frac{\alpha_{25}}{\alpha_{24}}\gamma_5>0,$$
$$\gamma_1=\frac{2\beta^-}{h^2}+\frac{|\,\alpha_{14}\gamma_4-\alpha_{15}\gamma_5\,|}{\alpha_{11}}>0,\qquad \gamma_3=\frac{1}{\alpha_{13}}\left(\alpha_{11}\gamma_1+\alpha_{14}\gamma_4-\alpha_{15}\gamma_5\right)>0.$$

- $\alpha_{14}=0$. In this case, we also have $\alpha_{15}=0$. We choose

$$\gamma_1=\frac{\beta^-}{h^2}>0,\qquad \gamma_3=\frac{\alpha_{11}}{\alpha_{13}}\gamma_1>0,$$
$$\gamma_4=\frac{2\beta^-}{h^2}+\frac{|\,\alpha_{23}\gamma_3-\alpha_{21}\gamma_1\,|}{\alpha_{24}}>0,\qquad \gamma_5=\frac{1}{\alpha_{25}}\left(\alpha_{24}\gamma_4+\alpha_{23}\gamma_3-\alpha_{21}\gamma_1\right)>0.$$

[2] It is also easy to show that $\alpha_{23}=\alpha_{21}$ and $\alpha_{24}=\alpha_{25}$.

- $\dfrac{\alpha_{11}}{\alpha_{21}} = \dfrac{\alpha_{13}}{\alpha_{23}} = \tau > 0$. We choose

$$\gamma_4 = \frac{\beta^-}{h^2} > 0, \qquad \gamma_5 = \frac{\alpha_{14} + \tau\alpha_{24}}{\alpha_{15} + \tau\alpha_{25}}\,\gamma_4.$$

With such choice of γ_4 and γ_5, we have

$$\alpha_{14}\gamma_4 - \alpha_{15}\gamma_5 = -\tau\alpha_{24}\gamma_4 + \tau\alpha_{25}\gamma_5.$$

Then we choose

$$\gamma_1 = \frac{2\beta^-}{h^2} + \frac{|\,\alpha_{14}\gamma_4 - \alpha_{15}\gamma_5|}{\alpha_{11}}, \qquad \gamma_3 = \frac{1}{\alpha_{13}}\left(\alpha_{11}\gamma_1 + \alpha_{14}\gamma_4 - \alpha_{15}\gamma_5\right).$$

- $\dfrac{\alpha_{11}}{\alpha_{13}} > \dfrac{\alpha_{21}}{\alpha_{23}}$. This is one of the general cases. Consider the following two functions:

$$g_1(\gamma_4, \gamma_5) = \alpha_{14}\gamma_4 - \alpha_{15}\gamma_5, \qquad g_2(\gamma_4, \gamma_5) = -\alpha_{24}\gamma_4 + \alpha_{25}\gamma_5.$$

In the first quadrant of the γ_4-γ_5 plane, there are three different regions where $g_1 > g_2$, $g_1 = g_2$, and $g_1 < g_2$, respectively. Choose a point $\gamma_4^* > 0$, $\gamma_5^* > 0$ in the first quadrant of the γ_4-γ_5 plane in such a way that $g_1 < g_2$. Let γ_1^*, γ_2^* be the solution to the system of equations (4.7) with γ_4 and γ_5 being substituted by γ_4^* and γ_5^*; since $\frac{\alpha_{11}}{\alpha_{13}} > \frac{\alpha_{21}}{\alpha_{23}}$, we can conclude that $\gamma_1^* > 0$ and $\gamma_2^* > 0$.

- $\dfrac{\alpha_{11}}{\alpha_{13}} < \dfrac{\alpha_{21}}{\alpha_{23}}$. The proof is almost exactly the same as the previous case except we choose $\gamma_4^* > 0$, $\gamma_5^* > 0$ such that $g_1 > g_2$. This completes the proof. □

COROLLARY 4.2. *From the proof of the existence of the optimization problem, we can conclude that*

$$|\gamma_k| \le \frac{C}{h^2}, \quad k = 1, 2, \dots, 5,$$

and there is at least one of γ_k from each side of the interface such that

$$|\gamma_k| \ge \frac{\bar{C}}{h^2},$$

where the constants are $O(1)$ and independent of the grid points involved but depend on the coefficient β.

These results of the corollary imply the condition (4.12) in Theorem 4.4 in the next subsection.

4.2. Convergence proof of the first order method. We need the following lemma which is a generalization of Theorem 6.1 and Theorem 6.2 of Morton and Mayers [12] for multiple subregions J_i.

LEMMA 4.3. *Given a finite difference scheme L_h defined on a discrete set of interior points J_Ω for a Dirichlet elliptic PDE, assume the following conditions hold:*

1. *J_Ω can be partitioned into a number of disjoint regions*

$$J_\Omega = J_1 \cup J_2 \cup J_3 \cup \cdots \cup J_{N_\Omega}, \quad J_i \cap J_k = \emptyset \quad \text{if } i \ne k. \tag{4.8}$$

2. *The truncation error of the finite difference scheme at a grid point p satisfies*

$$|T_p| \le T_i \quad \forall p \in J_i, \quad i = 1,\, 2,\, \dots,\, N_\Omega. \tag{4.9}$$

3. *There exists a nonnegative mesh function ϕ defined on $\cup_{i=1}^{N_\Omega} J_i$ satisfying*

$$L_h\phi_p \geq C_i > 0 \quad \forall p \in J_i, \qquad i = 1, 2, \ldots, N_\Omega. \tag{4.10}$$

Then the global error of the approximate solution U_{ij} from the finite difference scheme at mesh points is bounded by

$$||E_h||_\infty \leq \left(\max_{A\in J_{\partial\Omega}} \phi_A \right) \max_{1\leq i\leq N_\Omega} \left\{ \frac{T_i}{C_i} \right\}, \tag{4.11}$$

where E_h is the difference of the exact solution of the differential equation and the approximate solution of the finite difference equations at the mesh points, and $J_{\partial\Omega}$ is the set that contains the boundary points.

The proof of this lemma is trivial and is omitted.

Theorem 4.4. *Let $u(x, y)$ be the exact solution to* (1.1) *and* (1.2) *with $\kappa = 0$ and a Dirichlet boundary condition. Assume that* (1) *$u(x, y)$ has* piecewise *continuous second order derivatives;* (2) *h is sufficiently small;* (3) *at all irregular grid points, the following is true:*

$$|\gamma_k| \leq \frac{C_1}{h^2}, \quad k = 1, 2, \ldots, 5, \quad \text{and} \sum_{\xi_k\geq 0} \gamma_k\xi_k \geq \frac{C_2}{h}. \tag{4.12}$$

Then we have the following error estimate for U_{ij}, the solution of the finite difference equations obtained from the first order optimization method

$$\|u(x_i, y_j) - U_{ij}\|_\infty \leq Ch, \tag{4.13}$$

where $C = O(1)$ depends on the underlying grid and the interface, f, u, and the coefficient β.

Proof. If $h > 0$ is sufficiently small, we have proved that the optimization problem has solutions. Consider the solution to the following interface problem:

$$\begin{aligned} &\nabla \cdot \beta\nabla\phi = 1, \\ &\qquad [\phi] = 0, \qquad [\beta\phi_n] = 1, \qquad \phi_{\partial\Omega} = 1. \end{aligned} \tag{4.14}$$

From the results in [2, 3], we know that the solution ϕ exists, and it is unique and piecewise continuous. Therefore the solution is also bounded. Let

$$\bar\phi(x, y) = \phi(x, y) + \left| \min_{(x,y)\in\Omega} \phi(x, y) \right|. \tag{4.15}$$

Then $\bar\phi(x, y) \geq 0$ and still satisfies the differential equation and the jump conditions in (4.14). We define the discrete finite difference operator as

$$L_h u(x_i, y_j) = \sum_k^{n_s} \gamma_k\, u(x_{i+i_k}, y_{j+j_k}). \tag{4.16}$$

Let (x_i, y_j) be an irregular grid point. If h is small enough, then we know that γ_k is bounded by C/h^2. Therefore we have

$$\begin{aligned}
L_h\bar{\phi}(x_i,y_j) &= \sum_k^{n_s} \gamma_k\,\bar{\phi}(x_{i+i_k}, y_{j+j_k}) \\
&= (a_1+a_2)\bar{\phi}^- + \left(a_3+\rho a_4 - a_8\frac{[\beta]\chi''}{\beta^+}\right)\bar{\phi}_\xi^- \\
&\quad + \left(a_5+a_6-a_8\frac{[\beta_\eta]}{\beta^+}+a_{12}(1-\rho)\,\chi''\right)\bar{\phi}_\eta^- + \sum_{\xi_k\ge 0}\gamma_k\xi_k + O(1) \\
&= \sum_{\xi_k\ge 0}\gamma_k\xi_k + O(1),
\end{aligned}$$

where a_k are defined in (3.3). Note that $a_8\beta\chi''/\beta$, $a_8\beta_\eta/\beta$, and $a_{12}(1-\rho)\,\chi''$ are $O(1)$ provided that $\gamma_k \le C_1/h^2$. Thus from (4.12), the comparison function $\bar{\phi}$ satisfies

$$L_h\bar{\phi}(x_i,y_j) = \begin{cases} 1+O(h^2) & \text{if } (x_i,y_j) \text{ is a regular grid point,} \\ \displaystyle\sum_{\xi_k\ge 0}\gamma_k\xi_k \ge \frac{C_1}{h}+O(1) & \text{if } (x_i,y_j) \text{ is an irregular grid point.} \end{cases}$$

At a *regular* grid point we have

$$\frac{|T_{ij}|}{L_h\bar{\phi}(x_i,y_j)} \le \frac{C_2h^2}{1} = C_2h^2. \tag{4.17}$$

At an irregular grid point we have

$$\frac{|T_{ij}|}{L_h\bar{\phi}(x_i,y_j)} \le \frac{C_3}{C_1/h} = \frac{C_3}{C_1}h. \tag{4.18}$$

From Lemma 4.3, we conclude the global error then satisfies

$$\|u(x_i,y_j)-U_{ij}\|_\infty \le \left(\max_{(x,y)\in\partial\Omega}\phi(x,y)\right)\max\left\{\frac{C_3}{C_1}, C_2h\right\}h \le Ch.$$

Remarks. Although the theorem is proved for the case $\kappa = 0$, we should be able to claim that the condition (4.12) is also true when $\kappa \ge 0$ and so is the theorem, since $\kappa \ge 0$ increases the diagonal dominance of the resulting linear system of equations. When $\kappa < 0$, the original differential equation may not be well-posed, and the condition may not be satisfied.

5. Convergence of the second order method. In this section we first show the existence of the solution to the optimization problem numerically and then argue that the resulting finite difference scheme is of second order.

5.1. Numerical verification of the existence of the solution to the optimization problem. We again assume that $\kappa = 0$ in (1.1) (see the remarks in the previous section), and h is small enough so that the interface behaves like a straight line relative to the underlying grid. Under these conditions, those terms that contain χ'' in (3.6) are high order terms compared to those in a_3 and ρa_4 in terms of h and therefore can be neglected. For the second order method, if we scale the system of equations (3.6), then β_ξ^- and β_η^- in the second and third equations in (3.6) are high order terms compared with β^- in the fourth and fifth equations in (3.6) in terms of h, therefore we can simply set $\beta_\xi^- = \beta_\eta^- = 0$ as long as h is sufficiently small.

CONJECTURE 5.1. *Let (x_i, y_j) be an irregular grid point, and let (x_i^*, y_j^*) be its orthogonal projection on the interface. Then the optimization problem defined in* (3.8)–(3.9) *has solutions. The solution of the coefficients $\{\gamma_k\}$ also satisfies*

$$\left|\frac{\gamma_k}{\beta^-}\right| \le \frac{C}{h^2}, \quad k = 1, \dots, 9. \tag{5.1}$$

Furthermore there are γ_k's from each side of the interface such that

$$\left|\frac{\gamma_k}{\beta^-}\right| \ge \frac{C_1}{h^2}, \tag{5.2}$$

and thus

$$\sum_{\xi_k \ge 0} \gamma_k \xi_k \ge \frac{C_2}{h} \tag{5.3}$$

provided that $\max_{\xi_k \ge 0}\{\,\xi_k\} \ge C_3\, h$ *for some* $C_3 > 0$. *The constants are* $O(1)$ *which depend on the coefficient* β.

Numerical verification of Conjecture 5.1. First we shift and scale the problem in the following way:

$$\bar{x} = \frac{x - x_i}{h}, \qquad \bar{y} = \frac{y - y_j}{h}, \qquad \bar{\gamma}_k = \frac{\gamma_k}{h^2}.$$

For simplicity, we will use the same notation without bars. The nine-point stencil then corresponds to the square $-1 \le x, y \le 1$. With the local coordinates (2.1), we can just consider the case that the orthogonal projection is in the first quadrant.

Given any point (x^*, y^*) on the interface, and an angle θ

$$0 \le x^* \le 1, \qquad 0 \le y^* \le 1 - x^*, \qquad 0 \le \theta < \frac{\pi}{2}. \tag{5.4}$$

The tangent line of the interface at (x^*, y^*),

$$(x - x^*)\,\cos\theta + (y - y^*)\,\sin\theta = 0, \tag{5.5}$$

is a good approximation to the interface if $h > 0$ is sufficiently small so that $\chi''\,h^2$ is negligible.

The interface cuts the square $-1 \le x,\ y \le 1$ into two parts. We denote the side which contains the origin as $-$ side and the other half as $+$ side. We also scale the coefficient β either as $\beta^- = 1$, $\beta^+ = 1/\rho$, or $\beta^+ = 1$, $\beta^- = \rho$. The optimization problem is

$$\min_\gamma \frac{1}{2}\sum_{k=1}^{9} (\gamma_k - g_k)^2 \qquad \text{subject to}$$

$$A\gamma = b, \quad \gamma_k \ge 0 \quad \text{if} \quad (i_k, j_k) \ne (0,0); \quad \gamma_k < 0 \quad \text{if} \quad (i_k, j_k) = (0,0),$$

where

$$g_k = \beta^\pm \quad \text{if} \quad (i_k, j_k) \in \{(-1,0), (1,0), (0,-1), (0,1)\,\};$$

$$g_k = -4 \quad \text{if} \quad (i_k, j_k) = (0,0); \qquad g_k = 0 \quad \text{otherwise},$$

and $A\gamma = b$ is the following system of equations from (3.6):

$$\begin{aligned} &a_1 + a_2 = 0, && a_3 + \rho a_4 = 0, && a_5 + a_6 = 0,\\ &a_7 + a_8\,\rho = \beta^-, && a_9 + a_{10} + a_8\,(\rho - 1) = \beta^-, && a_{11} + a_{12}\,\rho = 0. \end{aligned}$$

To solve the optimization problem numerically, we use a uniform grid:

$$r_i = i\,\Delta r, \quad \Delta r = \frac{1}{M}, \quad i = 0, 1, \ldots, M, \quad \theta_j = j\,\Delta\theta, \quad \Delta\theta = \frac{\pi}{2N}, \quad j = 0, 1, \ldots, N,$$

$$\rho_k = 10^{-N_1 + k\,\Delta\rho}, \quad \Delta\rho = \frac{N_2 + N_1}{L}, \quad k = 0, 1, \ldots, L.$$

The projection then is $x_i^* = r_i\,\cos\theta_j$, $y_i^* = r_i\,\sin\theta_j$ excluding those $y_i^* > 1 - x_i^*$ that are outside of the five-point stencil. Define

$$\gamma_{max}(\rho) = \max_{r_i,\theta_j}\max_{1\le k\le 9}\frac{|\gamma_k|}{\beta^-} = \max_{r_i,\theta_j}\frac{|\gamma_5|}{\beta^-}, \qquad \gamma_{min}(\rho) = \min_{r_i,\theta_j}\frac{|\gamma_5|}{\beta^-},$$

$$S_{min}(\rho) = \min_{r_i,\theta_j,\ \max\limits_{\xi_k\ge 0}\{\xi_k\}\,\ge\, C_3 h}\ \sum_{\xi_k\ge 0}\xi_k\gamma_k.$$

Our numerical results show that the solution to the optimization problem always exits. Figure 5.1 summarizes the numerical verification results for Conjecture 5.1. In Figures 5.1(a) and (b), the dashed line is $\gamma_{max}(\rho)$ and it is bounded by $|\gamma_k|\,h^2 \le 10$. The solid line is $\gamma_{min}(\rho)$ and $|\gamma_5|\,h^2 \ge 1$. If $\beta^- = \beta^+$, we will have $\gamma_5 h^2 = 4$ exactly as we can see from Figure 5.1. Figures 5.1(a) and (b) confirm the inequalities (5.1) and (5.2).

In Figures 5.1(c) and (d), we plot $hS_{min}(\rho)/C_2$, where

$$C_2 = \frac{\max\{\beta^-/\beta^+, \beta^-/\beta^+\}}{\max\{\,1,\ \beta^-\}\ \max\{\,1,\ \beta^+\}}. \tag{5.6}$$

This constant was found by numerical experiments. The minimum of $\sum_{\xi_k\ge 0}\gamma_k\xi_k$ is taken in all cases except for the point $(1, 0)$ where the interface actually is $x = 1$. In this case, the grid point touches the interface and the finite difference scheme is the standard centered scheme using the five-point stencil with possible nonzero correction C_{ij} for the jump in the solution and the flux. In Figures 5.1(a) and (b), we have

$$\sum_{\xi_k\ge 0}\gamma_k\xi_k \ge \frac{0.01\,C_2}{h} \quad \text{if} \quad \max_{\xi_k\ge 0}\{\xi_k\} \ge C_3 h.$$

Thus the numerical verification confirms the inequalities (5.1)–(5.3). We have tried different grid sizes and all the results showed the same conclusions. The ratio ρ of the jump in β ranges from 10^{-9} to 10^{10}, which should cover most applications.

The complete theoretical proof of the theorem is still an open problem. Although we are able to prove the conjecture for special values of ρ, for example, $\rho \ge 1$, we omit those proofs due to the space limitation.

5.2. Convergence analysis of the second order method. Parallel to the convergence result for the first order method, we have the following theorem.

THEOREM 5.1. *Let $u(x, y)$ be the exact solution to* (1.1) *and* (1.2) *with $\kappa \ge 0$ and a Dirichlet boundary condition. Assume* (1) *the optimization problem* (3.8)–(3.9)

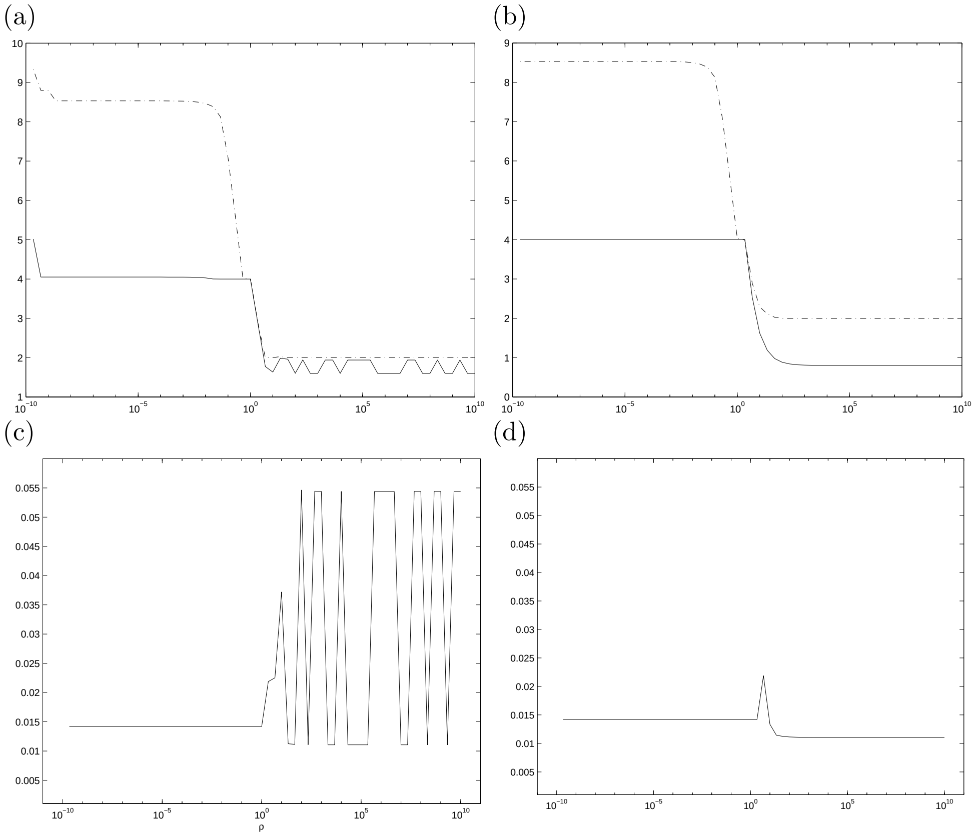

FIG. 5.1. *Numerical verification of Conjecture* 5.1 *with $m = n = L = 60$, $N_1 = 9$, and $N_2 = 10$.* (a) *Plots of $\gamma_{max}(\rho)$ (dash-dotted line) and $\gamma_{min}(\rho)$ (solid line) versus ρ in log scale with $\beta^+ = 1$, $\beta^- = \rho$.* (b) *The same plots as* (a) *with $\beta^- = 1$, $\beta^+ = 1/\rho$.* (c) *Plot of $S_{min}(\rho)$, whose minimum is* 0.0111*, with $\beta^+ = 1$, $\beta^- = \rho$.* (d) *Plot of $S_{min}(\rho)$, whose minimum again is* 0.0111*, with $\beta^- = 1$, $\beta^+ = 1/\rho$.*

with the six-equation constraint (3.6) *using the standard nine-point stencil has a set of solutions $\{\gamma_k\}$ at every irregular grid point;* (2) *$u(x, y)$ has* piecewise *continuous third order derivatives;* (3) *h is sufficiently small;* (4) *the following is true:*

$$|\gamma_k| \le \frac{C_1}{h^2} \quad \textit{and} \quad \sum_{\xi_k \ge 0} \gamma_k \xi_k \ge \frac{C_2}{h}. \tag{5.7}$$

Then we have the following error estimate for U_{ij}, the solution of the finite difference scheme obtained from the second order method

$$\|u(x_i, y_j) - U_{ij}\|_\infty \le Ch^2, \tag{5.8}$$

where the constant C depends on the underlined grid and interface, as well as u, f, and β.

Proof. If (5.7) is true, then we know that

$$L_h\bar{\phi}(x_i, y_j) \ge \left\{ \begin{array}{ll} 1 + O(h^2) & \text{if } (x_i, y_j) \text{ is a regular grid point,} \\ \displaystyle\sum_{\xi_k \ge 0} \gamma_k \xi_k \ge \frac{C_1}{h} + O(1) & \text{if } (x_i, y_j) \text{ is an irregular grid point,} \end{array} \right.$$

where $\bar{\phi}(x,y)$ is defined in (4.15). Note that at some regular grid points, $L_h\tilde{\phi}(x_i,y_j)$ can be very large, but it is nonnegative. Thus, the first inequality above still holds. Therefore at a regular point we have

$$\frac{|T_{ij}|}{L_h\bar{\phi}(x_i,y_j)} \le \frac{C_3h^2}{1}.$$

At an irregular grid point where (5.7) is satisfied, we have

$$\frac{|T_{ij}|}{L_h\bar{\phi}(x_i,y_j)} \le \frac{C_4h}{C_2/h} = \frac{C_4}{C_2}h^2$$

since the truncation error is bounded by

$$|T_{ij}| \le C_4h$$

for some constant C_4 that depends on the second derivatives of the solution on each side of the interface. Thus, from Lemma 4.3, we have proved the quadratic convergence.

Remarks. We have numerically verified that equation (5.7) holds as long as $\max_{\xi_k\ge 0}\{\xi_k\} > C_3h$. The second condition in (5.7) may be violated when the interface is very close to a grid point involved in the stencil other than (x_i,y_j) and almost parallel to a grid line in the neighborhood of (x_i,y_j). In this case, the finite difference scheme actually is very close to the standard finite difference scheme using the five-point stencil with a correction term to the right-hand side. This fact can be stated in the following theorem (the proof of the theorem is given in the appendix).

Theorem 5.2. *If the conditions* (1)–(3) *in Theorem* 5.1 *are satisfied and either* (5.7) *or*

$$\max_{\xi_k\ge 0}\{\xi_k\} \le C_5h^{1+\sigma} \quad \textit{with } C_5>0 \textit{ and } \sigma>0 \tag{5.9}$$

is true, then

$$\|u(x_i,y_j)-U_{ij}\|_\infty \le Ch^2, \tag{5.10}$$

where the constants depend on the underlying grid and the interface, u, f, and β.

6. Numerical results.

We have performed a number of numerical experiments for both the first order and the second order methods. The results agree with our analysis in sections 4 and 5. The computations are done using either Sun's Ultra-1 workstations or IBM SP2 machines. The code has not been parallelized. The linear system of equations is solved using the multigrid method DMGD9V developed by de Zeeu [4]. The interface is a closed curve in the solution domain and is expressed in terms of the periodic cubic spline interpolation as in [8]. The implementation of the methods is sequential and not optimized. In this section, the following notations are used: m and n with $m=n$ are the number of grid lines in the x- and y-directions; n_1 is the number of control points used in the cubic spline interpolation to represent the interface Γ; n_{coarse} and n_{finest} are the number of the coarsest and finest grid lines, respectively, when the multigrid solver DMGD9V is used; n_l is the number of levels used for the multigrid method.

Table 6.1

6.1. The grid refinement analysis.

Example 6.1. This example is the same as the Example 2 in [7]. The interface is the circle $x^2 + y^2 = \frac{1}{4}$ within the computation domain $-1 \le x, y \le 1$. The equations are

$$(\beta u_x)_x + (\beta u_y)_y = f(x,y) + C \int_\Gamma \delta(\vec{x} - \vec{X}(s))\, ds, \tag{6.1}$$

with $\quad f(x,y) = 8\,(x^2+y^2) + 4 \quad$ and

$$\beta(x,y) = \begin{cases} x^2 + y^2 + 1 & \text{if } x^2 + y^2 \le \frac{1}{4}, \\ b & \text{if } x^2 + y^2 > \frac{1}{4}. \end{cases}$$

Dirichlet boundary conditions are determined from the exact solution

$$u(x,y) = \begin{cases} r^2 & \text{if } r \le \frac{1}{2}, \\ \left(1 - \frac{1}{8\,b} - \frac{1}{b}\right)/4 + \left(\frac{r^4}{2} + r^2\right)/b + C\,\log(2r)/b & \text{if } r > \frac{1}{2}. \end{cases} \tag{6.2}$$

In this example, we have *variable* and discontinuous coefficients. Tables 6.1 and 6.2 show the results of the grid refinement analysis using the first and second order methods for different choices of b and c. The maximum error over all grid points,

$$\parallel E_n \parallel_\infty = \max_{i,j} \mid u(x_i, y_j) - U_{ij} \mid,$$

is presented. The order of convergence is computed from

$$\text{order} = \left| \frac{\log\left(\parallel E_{n_1} \parallel_\infty / \parallel E_{n_2} \parallel_\infty\right)}{\log(n_1/n_2)} \right|,$$

TABLE 6.3

The grid refinement analysis of the second order method for Example 6.2 *with* $n_{coarse} = 9$*; second order convergence is confirmed.*

			$\beta^+ = 1000$, $\beta^- = 1$		$\beta^+ = 1$, $\beta^- = 1000$

130	160	5	$4.5814\ 10^{-5}$	3.0090	$7.1981\ 10^{-4}$	2.1238
258	320	6	$1.4240\ 10^{-5}$	1.7049	$1.6876\ 10^{-4}$	2.1162
514	640	7	$3.1501\ 10^{-6}$	2.1887	$2.7407\ 10^{-5}$	2.6371

which is the solution of the equation

$$\parallel E_n \parallel_\infty = C\, h^{\text{order}}$$

with two different n's.

As explained in [9], for interface problems, the errors usually do not decline monotonously. Instead it depends on the relative location of the grid and the interface. However, the average of the orders approaches 1 and 2 for the first and second order methods in Tables 6.1 and 6.2. Compared with the result in [7], the new second order method gives a slightly better result. Notice that as the parameter b gets smaller, the solution in the outside of the interface becomes larger and the problem becomes harder to solve. But our second order method still converges quadratically.

Example 6.2. In this example, the coefficients of the differential equation are $\kappa = 0$ and β is piecewise constant, β^- and β^+. The jumps $[u]$ in the solution, $[\beta u_n]$ in the flux, and $[f]$ in the source term are chosen so that the following function is the exact solution:

$$u(x,y) = \begin{cases} x^2 - y^2 & \text{if } x^2 + 4y^2 \le 1, \\ \sin(x)\cos(y) & \text{if } x^2 + 4y^2 > 1. \end{cases} \tag{6.3}$$

Unlike Example 6.1, the solution in this example is *discontinuous* and independent of the coefficient β. Table 6.3 shows the results of the grid refinement analysis using the second order method. Again we see clearly second order convergence. Figure 6.1(a) plots the solution which is composed of two pieces.

Compared with the original IIM, the advantages of the new methods, especially the second order method, are the following: (a) The SOR method always converges for the new methods since the resulting linear system of equations is diagonally dominant. The system obtained from the original IIM, however, does not have this property. As the result, an iterative method including the SOR and the multigrid DMGD9V either does not converge or has significantly more iterations. (b) When both old and new methods converge, the errors of the solution obtained from the new methods are more evenly distributed; see, for example, Figure 6.1(b).

6.2. Algorithm efficiency analysis. A natural concern about the new methods proposed in this paper is how much extra cost is needed in solving the quadratic optimization problem at each irregular grid point. In Figure 6.2(a), we plot the percentage of the computational time used in the interface treatment versus the ratio of the jump in the coefficients $\log(\beta^+/\beta^-)$. The interface in polar coordinates is

$$r = r(\theta) = \frac{1}{2} + 0.1\,\sin(5\theta), \quad 0 \le \theta \le 2\pi. \tag{6.4}$$

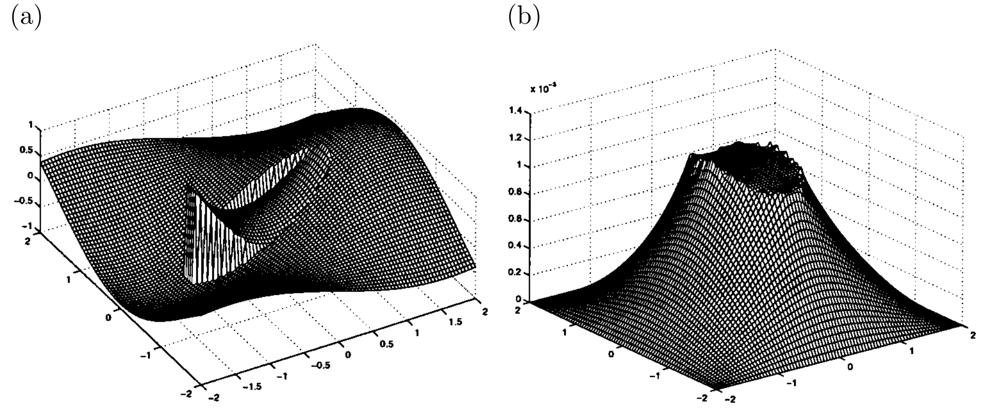

Fig. 6.1. (a) *The solution of Example* 6.2 *with jumps in the solution as well as in the normal derivatives. The parameters are* $\beta^+ = 1$*,* $\beta^- = 100$*, and* $n_{finest} = 82$*.* (b) *The error plot with the same parameters. The error distribution is better than that obtained from the original immersed interface method.*

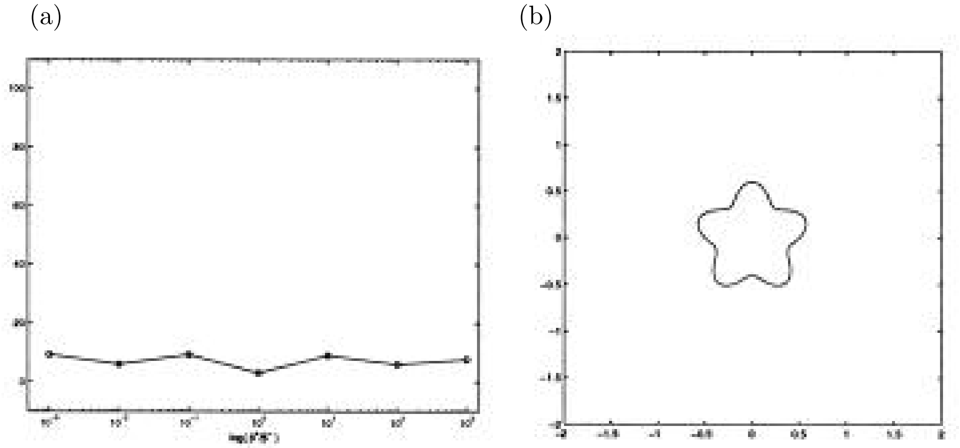

Fig. 6.2. (a) *Plot of percentage of the CPU time used for dealing with interfaces versus* $\log(\beta^+/\beta^-)$*.* (b) *The domain of the test example.*

For this interface, the curvature is quite large; see Figure 6.2(b). The cost for dealing with the irregular grid points includes solving the quadratic optimization problem, interpolating the cubic spline, indexing the irregular grid points, and finding (x_i^*, y_j^*). For regular problems, the multigrid solver is as fast as the fast Poisson solver using FFT.[3] Therefore the multigrid method that we used is indeed a fast solver but it does depend on the jump in β. In all our simulations, the cost for dealing with the irregular grid points near or on the interface is less than 10%. The ratio may increase when a better multigrid solver is used; see [1], for example. When $\beta^- = \beta^+$, the finite difference coefficients become the standard five-point stencil scheme and the cost for the interface treatment reaches its minimum.

The CPU time used in the entire solution process depends on the geometry and the jump in the coefficient β. Table 6.4 lists some statistics for Example 6.2 on an IBM

[3] Generally the fast Poisson solver using FFT can only be used for constant coefficients.

Table 6.4

CPU time for Example 6.2 *with different parameters using an IBM SP*2 *machine. The outputs vary with machines and time.*

n_{finest}	n_1	n_l	n_{coarse}	β^-	β^+	CPU time (s)
130×130	160	5	9	10	1	0.03
258×258	320	6	9	1	1	0.03
258×258	320	6	9	1	100	0.05
258×258	320	6	9	1	10000	0.06
258×258	320	6	9	100	1	0.06
258×258	320	6	9	10000	1	3.29
514×514	640	7	9	1	1000	0.15
514×514	640	7	9	1000	1	0.35

SP2 machine. In this example, when $\beta^- < \beta^+$, the CPU time is just a little more than that needed for one fast Poisson solver. When $\rho = \beta^-/\beta^+ > 1$ gets bigger, we see the CPU time grows slowly. The DMGD9V cannot return a solution in reasonable time when $\rho > 10^6$ with a 258×258 grid; see the remarks below. Generally we see that the second order method converges very fast if DMGD9V does work for the interface problem.

Remark 6.1. The linear system of equations using the finite difference methods proposed in this paper is irreducible and diagonally dominant. The multigrid solver DMGD9V is designed for systems of equations with standard nine-point stencil. The method requires the system of equations to have positive/negative symmetric part and works well for problems with large variation in the coefficients. So it is natural that we choose to use DMGD9V. The multigrid method converges very fast for the system of equations obtained from our algorithms, if it converges. However, we do observe occasionally that the multigrid stops before it returns a convergent result. In these cases, we still can make the multigrid method work by changing some built-in parameters such as the number of maximum iterations on the coarse grid, the number of smoothing operations, etc. Other DMGD9V users[4] have had similar experiences. We are currently working with L. Adams of the University of Washington to develop better multigrid methods for elliptic and parabolic interface problems.

7. Conclusions.

In this paper, we have proposed two finite difference methods that preserve the discrete maximum principles for elliptic interface problems. The methods have been shown to converge provided that the solution to the optimization problem exists and certain bounds are satisfied, which is proved for the first order method and numerically verified for the second order method. The methods can be easily generalized to parabolic interface problems. We would strongly recommend the second order method over the first order method. A Fortran package for a single closed interface and a Dirichlet boundary condition is available upon request (zhilin@math.ncsu.edu).

Appendix. Complete proof of Theorem 5.2.

At an irregular grid point, if (5.7) is true, then we know that

$$L_h\bar{\phi}(x_i, y_j) = \sum_{\xi_k \geq 0} \gamma_k \xi_k + \text{high order terms} \geq \frac{C_2}{h},$$

[4] Private communication with Dr. X. Wu from Caltech and Exxon Company.

where $\bar{\phi}(x,y)$ is defined in (4.15) in section 4. If (5.7) is violated but (5.9) is true, then all the grid points from the other side of the interface other than (x_i, y_j) are very close to the interface. For the nine-point stencil, this can happen only when the interface is very close to one of the grid lines, $x = x_{i-1}$, or $x = x_{i+1}$, or $y = y_{j-1}$, or $y = y_{j+1}$. Without loss of generality, we assume that the interface cuts the grid line $y = y_j$ at x_i^*, where $x_i < x_i^* \le x_{i+1}$, $x_{i+1} - x_i^* \le C_5 h^{1+\sigma}$. The normal direction is nearly parallel to the x-axis. Since $\max_{\xi_k \ge 0} \{\xi_k\} \le C_5 h^{1+\sigma}$, we know that (x_{i+1}, y_j), (x_{i+1}, y_{j-1}), and (x_{i+1}, y_{j+1}) are only three grid points in the nine-point stencil that are on the different side from (x_i, y_j). Since there is no interface involved in the y-direction, we can decompose the equations (3.6) in the x- and y-directions. In the y-direction, assuming (x_i, y_j) is on the $-$ side, we have

$$\frac{\beta_{i,j-\frac{1}{2}} u(x_i, y_{j-1}) - (\beta_{i,j-\frac{1}{2}} + \ \beta_{i,j+\frac{1}{2}}) u(x_i, y_j) + \beta_{i,j+\frac{1}{2}} u(x_i, y_{j+1})}{h^2} = (\beta u_y)_y + O(h^2),$$

which is the standard three-point difference scheme.

The equations in the x-direction are

$$\tilde{a}_1 + \tilde{a}_2 = \beta_x^-, \qquad \tilde{a}_3 + \rho \tilde{a}_4 = 0, \qquad \tilde{a}_7 + \tilde{a}_8\, \rho = \beta^-,$$

where we use $\tilde{a}_i$ to represent those terms in x-directions in a_i's in (3.6). We define a function

$$\text{(A.1)} \qquad \psi_{ij}^x(x) = \begin{cases} \dfrac{(x_i^* - x_i)(x_i - x)}{\gamma_{ij}^{(2)} h^3} & \text{if } x \le x_i^*, \\ \dfrac{(x_{i+1} - x_i^*)(x - x_{i+1})}{\gamma_{i+1,j}^{(8)} h^3} & \text{if } x > x_i^*, \end{cases}$$

where $\gamma_{ij}^{(2)}$ is the coefficient of the finite difference scheme centered at (x_i, y_j) corresponding to the grid point (x_{i-1}, y_j); $\gamma_{i+1,j}^{(8)}$ is the coefficient of the finite difference scheme centered at (x_{i+1}, y_j) corresponding to the grid point (x_{i+2}, y_j). Notice that $\psi_{ij}^x(x_i) = \psi_{ij}^x(x_{i+1}) = 0$ and $\psi_{ij}^x(x_j) > 0$ for $j \ne i,\ i+1$ and that $\psi_{ij}^x(x) \le M\ \forall\, (x,y) \in \Omega$. More important, we can easily derive

$$\text{(A.2)} \qquad L_h \psi_{ij}^x(x_i, y_j) = \frac{x_i^* - x_i}{h^2} (1 + O(C_6 h^\sigma)),$$

$$\text{(A.3)} \qquad L_h \psi_{ij}^x(x_{i+1}, y_j) = \frac{x_{i+1} - x_i^*}{h^2} (1 + O(C_7 h^\sigma)).$$

The high order terms are due to the fact that L_h may not be exactly the standard five-point finite difference scheme, although it is close. Therefore when all $\xi_k \ge 0$ is very small, $x_i^* - x_i$ is close to h and $L_h \psi_{ij}^x(x_i, y_j) \ge \frac{1 - C_8 h^\sigma}{h}$.

Similarly we can construct such $\psi_{ij}^x(x)$ or $\psi_{ij}^y(y)$ at the few irregular grid points where (5.9) holds. Define the comparison function as

$$\tilde{\phi}(x,y) = \bar{\phi}(x,y) + \sum \psi_{ij}^x(x) + \sum \psi_{ij}^y(y),$$

where $\bar{\phi}$ is the same as defined in (4.15). Then

$$L_h\tilde{\phi}(x_i,y_j) \geq \begin{cases} 1+O(h^2) & \text{if } (x_i,y_j) \text{ is a regular grid point,} \\ \displaystyle\sum_{\xi_k\geq 0} \gamma_k\xi_k \geq \frac{C_2}{h}+O(1) & \text{if (5.7) is true,} \\ \dfrac{1-C_8h^\sigma}{h} & \text{if } \displaystyle\max_{\xi_k\geq 0}\{\xi_k\} \leq C_5h^{1+\sigma}, \text{ with } \sigma>0. \end{cases}$$

Note that at some regular grid points, $L_h\tilde{\phi}(x_i,y_j)$ can be very large but it is nonnegative. Thus, the first inequality above still holds. Therefore at a regular point we have

$$\frac{|T_{ij}|}{L_h\tilde{\phi}(x_i,y_j)} \leq \frac{C_3h^2}{1}.$$

At an irregular grid point where (5.7) is satisfied, we have

$$\frac{|T_{ij}|}{L_h\tilde{\phi}(x_i,y_j)} \leq \frac{C_4h}{C_2/h} = \frac{C_4}{C_2}h^2$$

since the truncation error is bounded by

$$|T_{ij}| \leq C_4h$$

for some constant C_4 that depends on the third derivatives of the solution on each side of the interface. At an irregular grid point where (5.9) is true, we also have

$$\frac{|T_{ij}|}{L_h\tilde{\phi}(x_i,y_j)} \leq \frac{C_4h}{(1-C_8h^\sigma)/h} = \frac{C_4}{1-C_8h^\sigma}h^2.$$

Thus from Lemma 4.3, we have again proved the quadratic convergence.

Acknowledgments. We would like to thank K. Schittkowski for his quadratic optimization code and P. de Zeeuw for his multigrid solver. We are also grateful for the discussion with them and L. Adams and R. LeVeque.

SPECIAL ISSUE: 2000 COPPER MOUNTAIN CONFERENCE

The Copper Mountain Conferences, organized annually by the University of Colorado in cooperation with SIAM, focus alternately on multigrid methods and iterative methods. The conferences have built a reputation for the relaxed atmosphere that makes it *the* place for young researchers to present their ideas and for the older celebrities to listen to so many exciting, often still unpolished, ideas. This development of young researchers is further stimulated by the Student Paper Competition, through which the best work of doctoral students is highlighted.

On April 3–7, 2000, we saw the sixth conference in the series on iterative methods, and the research area was as fresh, lively, and inspiring as ever. The Program Committee quickly agreed that it would be very attractive for the entire research community to have the best contributions collected as papers in a special issue of *SIAM Journal on Scientific Computing*. We are very grateful to SIAM for graciously accepting our proposal. SIAM handed the responsibility for this special issue to the Program Committee, and those present at the meeting accepted the invitation to act as guest associate editors. The next step was to invite all speakers to submit a paper, which led to 31 submissions. All papers underwent the usual SIAM review process, maintaining the high SIAM standards for acceptance. Eventually, 18 papers were accepted for publication, among them the top 2 in the Student Paper Competition, by Judith Vogel (with Daniel Szyld) and Michiel Hochstenbach.

A special thanks should go to all those anonymous referees who helped us meet the deadlines through their very constructive efforts. I consider this a strong sign that we are members of a friendly research family rather than individuals in an impersonal community.

The 18 accepted papers are distributed over the following categories:

- 6 papers related to preconditioning,
- 6 related to eigenvalue computation,
- 3 on multigrid techniques,
- 2 on nonlinear problems,
- and 1 with a new variant of an iterative method (TQMR).

This shows that preconditioning continues to attract much research attention, with many more challenging problems left open rather than being solved. Eigenvalue computation continues to gain more attention after initial emphasis in these conferences on linear systems.

We expect that the readers of these papers will enjoy reading them as much as we did and that it will help many of us make further progress in research. We thank all the authors for their efforts to get their papers ready under often very tight time constraints. I thank my colleagues the associate editors for their dedication and help. Above all, we are indebted to Tom Manteuffel and Steve McCormick for organizing such excellent conferences.

FQMR: A FLEXIBLE QUASI-MINIMAL RESIDUAL METHOD WITH INEXACT PRECONDITIONING*

DANIEL B. SZYLD† AND JUDITH A. VOGEL‡

Abstract. A flexible version of the QMR algorithm is presented which allows for the use of a different preconditioner at each step of the algorithm. In particular, inexact solutions of the preconditioned equations are allowed, as well as the use of an (inner) iterative method as a preconditioner. Several theorems are presented relating the norm of the residual of the new method with the norm of the residual of other methods, including QMR and flexible GMRES (FGMRES). In addition, numerical experiments are presented which illustrate the convergence of flexible QMR (FQMR), and show that in certain cases FQMR can produce approximations with lower residual norms than QMR.

Key words. Krylov subspace methods, flexible preconditioning, inner-outer iterations

AMS subject classification. 65F10

PII. S106482750037336X

1. Introduction.

The quasi-minimal residual (QMR) method [11] is a well-established Krylov subspace method for solving large systems of non-Hermitian linear equations of the form

$$A\mathbf{x} = \mathbf{b}, \tag{1}$$

where the $n \times n$ matrix A is assumed to be nonsingular. The algorithm makes use of a three-term recurrence, and thus, unlike some other Krylov methods for non-Hermitian systems, e.g., GMRES [23], storage requirements are fixed and known a priori.

The strength of Krylov subspace methods is most apparent when a preconditioner is used. For a general introduction to these methods see, e.g., [17], [22]. In the case of right preconditioning, one solves the equivalent linear system

$$AM^{-1}(M\mathbf{x}) = \mathbf{b}$$

with some appropriate preconditioner M. The matrix AM^{-1} is never formed explicitly. Instead, when $\mathbf{z} = M^{-1}\mathbf{v}$ is required, one solves the corresponding system

$$M\mathbf{z} = \mathbf{v}. \tag{2}$$

In an analogous manner, left preconditioning consists of solving $M^{-1}A\mathbf{x} = M^{-1}\mathbf{b}$.

In this paper we present a flexible version of QMR, where the matrix M in (2) can vary from one iteration to the next. Let us denote by M_i the preconditioner used at the ith iteration. The need to allow for a variable preconditioner arises, e.g., when the solution of (2) is not obtained exactly (say, by a direct method), but is approximated by the use of a second (inner) iterative method. This is the case, e.g., when the preconditioner used is some version of multigrid, such as in [10].

‡Richard Stockton College, Pomona, NJ 08240 (judith.vogel@stockton.edu).

In recent years, several authors worked on the idea of preconditioning with a different matrix at each outer iteration of a Krylov subspace method [1], [16], [20], [21], [25]; see also [6], [14], [15] for other instances of inner-outer iterations. Preconditioning of this form is referred to as flexible preconditioning, also known as variable or inexact preconditioning. Our approach to a flexible version of QMR, which we call FQMR, is similar to that of Saad for FGMRES [21]. In addition, we were influenced by ideas presented by Golub and Ye for inexact conjugate gradients [16].

The new FQMR method, in the same way as the other inexact methods just mentioned, is not strictly speaking a Krylov subspace method. This is because the minimization at each step is done over a subspace which is not in general a Krylov subspace; also cf. [7]. Nevertheless, the convergence theory developed by Eiermann and Ernst [9] applies to these methods as well.

We emphasize that FQMR can be used whenever FGMRES is used, with the advantage that FQMR has a fixed low memory requirement.

FQMR is not intended as an alternative to QMR when the latter works well but rather as an option when no fixed preconditioner is available, as in [10] and in [18], or when the preconditioner can be improved from one step to the next with newly available information; cf. [2]. Nevertheless, we have found in our numerical experiments that FQMR can produce approximations with lower residual norms than QMR.

In the next section we briefly review the QMR method and present the new flexible version. We describe several properties of this new version, including the quasi-minimization property over a certain subspace. In section 3 we present our main theorem relating the residual norm of FQMR with that of FGMRES, in a way analogous to the well-known relation between QMR and GMRES. As a corollary we obtain a new relation between the residual norm of FGMRES and that of QMR.

The same techniques are used in section 4 to obtain bounds for the FQMR residual norm. As is to be expected, these bounds are in terms of how inexactly each preconditioned step is solved. In a similar way new bounds for the FGMRES residual norm are obtained.

Finally, in section 5 numerical experiments are reported which describe the convergence behavior of FQMR using several different iterative methods as flexible preconditioners. Furthermore, a comparison is made between FQMR and the corresponding version of QMR with fixed preconditioner. This comparison shows that in many cases the maximal attainable accuracy of FQMR, i.e., the minimum relative residual norm, is better than that of QMR.

2. The FQMR algorithm.

We begin this section by first considering the standard QMR algorithm with a fixed right preconditioner M; for full details see [11], [17], or [22]. An analogous description can be given for QMR with fixed left preconditioning. Let $\mathbf{x}_0$ be the initial guess and let $\mathbf{r}_0 = \mathbf{b} - A\mathbf{x}_0$ be the initial residual. In QMR, the two-sided Lanczos algorithm is used to construct biorthogonal bases corresponding to the Krylov subspaces generated by AM^{-1} and $(AM^{-1})^H$, namely,

$$K_m(AM^{-1}, \mathbf{r}_0) = \text{span}\{\mathbf{r}_0, AM^{-1}\mathbf{r}_0, \ldots, (AM^{-1})^{m-1}\mathbf{r}_0\}$$

and

$$K_m((AM^{-1})^H, \mathbf{r}_0) = \text{span}\{\mathbf{r}_0, M^{-H}A^H\mathbf{r}_0, \ldots, (M^{-H}A^H)^{m-1}\mathbf{r}_0\}.$$

Let the basis vectors for $K_m(AM^{-1}, \mathbf{r}_0)$ and $K_m(M^{-H}A^H, \mathbf{r}_0)$ be $\{\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_m\}$ and $\{\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_m\}$, the columns of V_m and W_m, respectively. The approximation to the solution of (1) at the mth QMR iteration is of the form

$$\mathbf{x}_m = \mathbf{x}_0 + M^{-1}V_m\mathbf{y}_m, \quad \mathbf{y}_m = \arg\min_{\mathbf{y}} \| \|\mathbf{r}_0\|\mathbf{e}_1 - T_{m+1,m}\mathbf{y}\|, \tag{3}$$

where $T_{m+1,m}$ is the $(m+1)\times m$ tridiagonal matrix of recurrence coefficients associated with two-sided Lanczos, namely,

$$T_{m+1,m} = \begin{bmatrix} \alpha_1 & \beta_1 & & \\ \gamma_1 & \ddots & \ddots & \\ & \ddots & \ddots & \beta_{m-1} \\ & & \gamma_{m-1} & \alpha_m \\ & & & \gamma_m \end{bmatrix};$$

see Algorithm 2.1 below. In (3) and throughout the paper the norm is the 2-norm.

By the construction of the two-sided Lanczos, the following relation holds:

$$AM^{-1}V_m = V_{m+1}T_{m+1,m}, \tag{4}$$

from which it follows that

$$\begin{aligned} \mathbf{r}_m &= \mathbf{b} - A\mathbf{x}_m \\ &= \mathbf{r}_0 - AM^{-1}V_m\mathbf{y}_m \qquad (5)\\ &= V_{m+1}(\|\mathbf{r}_0\|\mathbf{e}_1 - T_{m+1,m}\mathbf{y}_m). \qquad (6) \end{aligned}$$

This establishes that QMR produces the approximation $\mathbf{x}_m$ in such a way as to minimize the norm of the second factor of the residual (6); see (3). Thus, a quasi-minimization of the residual norm takes place. One can see from (5) that the residual at the mth step is of the form $\mathbf{r}_0 - AM^{-1}\mathbf{v}$ with $\mathbf{v} \in K_m(AM^{-1}, \mathbf{r}_0)$. Relation (4) can be rewritten

$$AZ_m^Q = V_{m+1}^Q T_{m+1,m}, \tag{7}$$

where $Z_m^Q = M^{-1}V_m$. We use superscripts Q and FQ to distinguish the vectors and matrices generated by QMR and FQMR, respectively. Correspondingly, rewriting (3), the approximate solution is of the form

$$\mathbf{x}_m = \mathbf{x}_0 + Z_m^Q\mathbf{y}_m, \quad \mathbf{y}_m = \arg\min_{\mathbf{y}} \| \|\mathbf{r}_0\|\mathbf{e}_1 - T_{m+1,m}\mathbf{y}\|.$$

Relation (4) illustrates that the action of AM^{-1} on a vector $\mathbf{v}$ of the Krylov subspace is in $K_{m+1}(AM^{-1}, \mathbf{r}_0)$ a basis of which are the columns of V_{m+1}^Q, while relation (7) will be useful in comparing QMR with FQMR. With this background in place, we present the following algorithm for FQMR.

Algorithm 2.1 (FQMR).

```
    Given $\mathbf{x}_0$, form $\mathbf{r}_0$ and choose $\hat{\mathbf{r}}_0$ such that $\langle \mathbf{r}_0, \hat{\mathbf{r}}_0 \rangle \neq 0$
    set $\mathbf{v}_1 = \mathbf{r}_0/\|\mathbf{r}_0\|$ and $\mathbf{w}_1 = \hat{\mathbf{r}}_0/\langle \hat{\mathbf{r}}_0, \mathbf{v}_1 \rangle$
    set $\beta_0 = \gamma_0 = 0$ and $\mathbf{v}_0 = \mathbf{w}_0 = 0$
    For $i = 1, 2, \ldots$
(8)     Set $\mathbf{z}_i = M_i^{-1}\mathbf{v}_i$
```

```
(9)     Compute: $A\mathbf{z}_i$ and $M_i^{-H}A^H\mathbf{w}_i$
        $\alpha_i = \langle A\mathbf{z}_i, \mathbf{w}_i\rangle$
(10)    $\tilde{\mathbf{v}}_{i+1} = A\mathbf{z}_i - \alpha_i\mathbf{v}_i - \beta_{i-1}\mathbf{v}_{i-1}$
        $\tilde{\mathbf{w}}_{i+1} = M_i^{-H}A^H\mathbf{w}_i - \bar{\alpha}_i\mathbf{w}_i - \gamma_{i-1}\mathbf{w}_{i-1}$
        $\gamma_i = \|\tilde{\mathbf{v}}_{i+1}\|$
(11)    $\mathbf{v}_{i+1} = \tilde{\mathbf{v}}_{i+1}/\gamma_i$
        $\beta_i = \langle \mathbf{v}_{i+1}, \tilde{\mathbf{w}}_{i+1}\rangle$
        $\mathbf{w}_{i+1} = \tilde{\mathbf{w}}_{i+1}/\bar{\beta}_i$
(12)    $\mathbf{x}_i = \mathbf{x}_0 + Z_i^{FQ}\mathbf{y}_i$,   where $\mathbf{y}_i = \arg\min_{\mathbf{y}} \|\|\mathbf{r}_0\|\mathbf{e}_1 - T_{i+1,i}\mathbf{y}\|$
                                and $Z_i^{FQ} = [\mathbf{z}_1, \ldots, \mathbf{z}_i]$
```

In this algorithm, $\bar{\alpha}_i$ and $\bar{\beta}_i$ stand for the conjugate of the complex numbers α_i and β_i, respectively. Note that the above algorithm represents a theoretical rendition of FQMR and not a full description of its implementation. In the actual implementation of FQMR the minimization in (12) is solved by performing a QR factorization of $T_{i+1,i}$. Using Givens rotations, this factorization of $T_{i+1,i}$ is easily updated from that of $T_{i,i-1}$, thus eliminating the need to save and construct $Z_i^{FQ} = [\mathbf{z}_1, \ldots, \mathbf{z}_i]$ at each step.

If we replace M_i with M, a fixed preconditioner, the above algorithm reduces to the standard QMR method. Thus, implementation of FQMR requires only a slight modification of the code for QMR, and this is one of the strengths of this new algorithm.

Let us discuss the variable preconditioned step (8) in some detail. If the preconditioned equations $M\mathbf{z} = \mathbf{v}$ are solved approximately by a second iterative solver, then we can write (8) in terms of M^{-1} and $\boldsymbol{\varepsilon}_i$, where $\boldsymbol{\varepsilon}_i$ is the error associated with the inner solve at step i. Thus, for this case we write

$$\mathbf{z}_i = M_i^{-1}\mathbf{v}_i = M^{-1}\mathbf{v}_i + \boldsymbol{\varepsilon}_i. \tag{13}$$

This description of flexible preconditioning is used in [16] for investigating inexact conjugate gradient.

A consequence of flexible preconditioning is the relation

$$AZ_m^{FQ} = V_{m+1}^{FQ}T_{m+1,m}, \tag{14}$$

where Z_m^{FQ} is the matrix whose ith column is $\mathbf{z}_i$, the vector constructed by FQMR in (8); cf. (7). Let us denote by $\hat{K}_m$ the subspace spanned by the columns of Z_m^{FQ}, which, in general, is not a Krylov subspace. Consequently, relation (14) cannot be simplified into a form similar to relation (4) since the action AM_i^{-1} on a vector $\mathbf{v}$ of the Krylov subspace is no longer in the span of the columns of V_{m+1}. Using (14), however, we can still display a quasi-minimization property held by $\mathbf{x}_m$ over this new $\hat{K}_m$, and this is why the convergence theory in [9] applies to FQMR. The proof is identical to the one for QMR as we show in what follows. For an arbitrary vector in the space $\mathbf{x}_0 + \hat{K}_m$, i.e., of the form $\mathbf{z} = \mathbf{x}_0 + Z_m^{FQ}\mathbf{y}$, for some $\mathbf{y} \in \mathbb{C}^m$, we have the following identities

$$\begin{aligned}\mathbf{b} - A\mathbf{z} = \mathbf{b} - A(\mathbf{x}_0 + Z_m^{FQ}\mathbf{y}) &= \mathbf{r}_0 - AZ_m^{FQ}\mathbf{y}\\ &= V_{m+1}^{FQ}(\|r_0\|\mathbf{e}_1 - T_{m+1,m}\mathbf{y}).\end{aligned}$$

Now, since $\mathbf{x}_m$ is chosen to minimize the norm of $\|r_0\|\mathbf{e}_1 - T_{m+1,m}\mathbf{y}$, we see that FQMR maintains the quasi-minimal residual property over the affine space $\mathbf{x}_0 + \hat{K}_m$.

We remark that FQMR with left preconditioning does not follow an analogous construction. For flexible left preconditioning, relation (14) no longer holds, and therefore $\mathbf{x}_i$ cannot be updated as in (12).

Another noteworthy observation is that FQMR, by construction, maintains the three-term recurrence of QMR. However, in so doing, there is a loss of the global biorthogonality held by the bases generated by QMR. However, a local biorthogonality property is maintained, as shown in the following theorem. That is, consecutive Lanczos vectors constructed by the flexible two-sided Lanczos process are biorthogonal. We note, however, that for the results of this theorem to hold, we are assuming that at each step of the outer iteration the matrix M_i is the same matrix used in (8) and in (9). Theoretically this is a logical assumption, and in some cases this is also true in practice, but in general this assumption does not necessarily hold.

THEOREM 2.2. *If the two-sided Lanczos vectors are defined at steps* $1, \ldots, k+1$ *in Algorithm* 2.1*, i.e., if* $\langle \mathbf{v}_i, \mathbf{w}_i \rangle \neq 0$ *for* $i = 1, \ldots, k+1$*, then*

$$\langle \mathbf{v}_{k+1}, \mathbf{w}_k \rangle = 0 \qquad \textit{and} \qquad \langle \mathbf{w}_{k+1}, \mathbf{v}_k \rangle = 0. \tag{15}$$

Proof. We first note that $\|\mathbf{v}_i\| = 1$ for all i by the choice of γ_{i-1}. Likewise $\langle \mathbf{v}_i, \mathbf{w}_i \rangle = 1$ for all i by the choice of γ_{i-1} and $\bar{\beta}_{i-1}$. We prove (15) by induction. For $k = 0$ the result is obvious since $\mathbf{v}_0 = \mathbf{w}_0 = 0$. Assume that (15) holds for $i \leq k-1$; then

$$\begin{aligned} \langle \tilde{\mathbf{v}}_{k+1}, \mathbf{w}_k \rangle &= \langle AM_k^{-1}\mathbf{v}_k, \mathbf{w_k} \rangle - \alpha_k \langle \mathbf{v}_k, \mathbf{w}_k \rangle - \beta_{k-1} \langle \mathbf{v}_{k-1}, \mathbf{w}_k \rangle \\ &= \langle AM_k^{-1}\mathbf{v}_k, \mathbf{w_k} \rangle - \alpha_k = 0 \end{aligned}$$

and

$$\begin{aligned} \langle \tilde{\mathbf{w}}_{k+1}, \mathbf{v}_k \rangle &= \langle M_k^{-H} A^H \mathbf{w}_k, \mathbf{v}_k \rangle - \bar{\alpha}_k \\ &= \langle M_k^{-H} A^H \mathbf{w}_k, \mathbf{v}_k \rangle - \overline{\langle AM_k^{-1}\mathbf{v}_k, \mathbf{w}_k \rangle} \\ &= \langle M_k^{-H} A^H \mathbf{w}_k, \mathbf{v}_k \rangle - \overline{\langle \mathbf{v}_k, M_k^{-H} A^H \mathbf{w}_k \rangle} = 0. \qquad \square \end{aligned}$$

3. FQMR and FGMRES.

Generalized minimal residual (GMRES) [23] is another successful Krylov subspace method for solving non-Hermitian systems of linear equations. Like QMR, GMRES can be implemented with a flexible preconditioner, and the flexible version is called FGMRES [21]. In this section we establish a relationship between FQMR and FGMRES which is reminiscent of a relationship held by QMR and GMRES [19]. As a precursor to the statement of this relationship, we give a brief summary of GMRES with a fixed right preconditioner; see [17], [22], or [23] for a full description.

At the mth iteration, preconditioned GMRES produces an approximation $\mathbf{x}_m$ to the solution of (1) in $\mathbf{x}_0 + K_m(AM^{-1}, \mathbf{r}_0)$ in such a way as to minimize the norm of the residual over $K_m(AM^{-1}, \mathbf{r}_0)$, i.e.,

$$\mathbf{x}_m = \mathbf{x}_0 + \arg \min_{\mathbf{z} \in K_m(AM^{-1}, \mathbf{r}_0)} \| \mathbf{r}_0 - AM^{-1}\mathbf{z} \|.$$

This minimization is accomplished by constructing an orthonormal basis for $K_m(AM^{-1}, \mathbf{r}_0)$ using the Arnoldi method [17]. In the Arnoldi method the basis vectors, $\{\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_m\}$, are formed recursively by orthogonalizing a new vector, $\hat{\mathbf{v}}_{i+1}$, in $K_{i+1}(AM^{-1}, \|\mathbf{r}_0\|)$ against the previous vectors $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_i$ in $K_i(AM^{-1}, \|\mathbf{r}_0\|)$ and then normalizing it, so that $\mathbf{v}_{i+1} = \hat{\mathbf{v}}_{i+1}/\|\hat{\mathbf{v}}_{i+1}\|$. Thus,

$$\mathbf{v}_{i+1} = \frac{1}{h_{i+1,i}} \left(AM^{-1}\mathbf{v}_i - \sum_{k=1}^{i} h_{k,i}\mathbf{v}_k \right), \tag{16}$$

where the coefficients $h_{k,i},\ k = 1, \ldots, i+1$, are appropriately chosen to orthogonalize and normalize $\mathbf{v}_{i+1}$. From (16) we get the relation

$$AM^{-1}V_m = V_{m+1}H_{m+1,m}, \tag{17}$$

where $H_{m+1,m}$ is the upper-Hessenberg matrix whose nonzero entries are the coefficients $h_{k,i},\ k = 1, \ldots, i+1$, from (16), $i = 1, \ldots, m$.

With this groundwork in place, we can now establish that GMRES computes the approximation $\mathbf{x}_m = \mathbf{x}_0 + V_m\mathbf{y}_m$ such that

$$\begin{aligned} \mathbf{y}_m &= \arg\min_{\mathbf{y}} \|\mathbf{r}_0 - AM^{-1}V_m\mathbf{y}\| = \arg\min_{\mathbf{y}} \|\mathbf{r}_0 - V_{m+1}H_{m+1,m}\mathbf{y}\| \\ &= \arg\min_{\mathbf{y}} \| \|\mathbf{r}_0\|\mathbf{e}_1 - H_{m+1,m}\mathbf{y}\|. \end{aligned} \tag{18}$$

Observe that while in (3) QMR only minimizes the norm of a factor of the residual, in (18) we have that GMRES minimizes the norm of the actual residual, since V_{m+1} is unitary.

We end this introduction of GMRES by pointing out that when the preconditioner changes from step to step, i.e., when one uses M_i instead of M in (16), we have FGMRES [21]. In what follows, we use superscripts G and FG to distinguish the vectors and matrices generated by GMRES and FGMRES, respectively.

Let $\mathbf{z}_i = M_i^{-1}\mathbf{v}_i$, and let Z_m^{FG} be the matrix with columns $\mathbf{z}_1, \ldots, \mathbf{z}_m$; then the following relation analogous to (17) holds for FGMRES:

$$AZ_m^{FG} = V_{m+1}^{FG}H_{m+1,m}. \tag{19}$$

When QMR and GMRES are implemented with fixed preconditioning, we have the following result due to Nachtigal [19], where κ_2 denotes the condition number using the 2-norm; see also [17], [22].

Theorem 3.1. *If $\mathbf{r}_m^G$ denotes the GMRES residual at step m and $\mathbf{r}_m^Q$ denotes the QMR residual at step m, then*

$$\|\mathbf{r}_m^Q\| \le \kappa_2(V_{m+1}^Q)\|\mathbf{r}_m^G\|, \tag{20}$$

where V_{m+1}^Q is the matrix whose columns are the basis vectors generated by QMR.

This inequality works out nicely since V_{m+1}^G constructed by GMRES and V_{m+1}^Q constructed by QMR are both a basis for the same Krylov subspace. When flexible preconditioning is used, this is no longer the case. To avoid confusion, let us denote by $\mathbf{v}_{i+1}^{FQ}$ and $\mathbf{v}_{i+1}^{FG}$ the vectors computed by FQMR in (11) and by FGMRES in (16), respectively. We can, however, prove a relation similar to (20) for FGMRES and FQMR, but to do so we first need the following lemma relating Z_m^{FG} and Z_m^{FQ}, the basis of the subspaces constructed by FGMRES and FQMR, respectively; see (19) and (14).

Lemma 3.2. *Let $\mathbf{z}_i^{FG}$ be the ith column of Z_m^{FG} satisfying* (19). *Likewise, let $\mathbf{z}_i^{FQ}$ be the ith column of Z_m^{FQ} satisfying* (14). *If $\boldsymbol{\varepsilon}_i^{FQ}$ is the ith error vector defined by*

$$\mathbf{z}_i^{FQ} = M^{-1}\mathbf{v}_i^{FQ} + \boldsymbol{\varepsilon}_i^{FQ} \tag{21}$$

and if $\boldsymbol{\varepsilon}_i^{FG}$ is the ith error vector defined by

$$\mathbf{z}_i^{FG} = M^{-1}\mathbf{v}_i^{FG} + \boldsymbol{\varepsilon}_i^{FG}, \tag{22}$$

then

$$\mathbf{z}_i^{FG} \in S^m, \quad i = 1, \dots, m, \tag{23}$$

where

$$S^m = \operatorname{span}\{\mathbf{z}_i^{FQ}, (M^{-1}A)^j\boldsymbol{\varepsilon}_i^{FQ}, (M^{-1}A)^j\boldsymbol{\varepsilon}_i^{FG};\ i = 1, \dots, m,\ j = 0, \dots, m-1\}.$$

Proof. We show (23) by induction on m. For $m = 1$, since $\mathbf{v}_1^{FG} = \mathbf{v}_1^{FQ} = \mathbf{r}_0/\|\mathbf{r}_0\|$, we have $\mathbf{z}_1^{FG} = M^{-1}\mathbf{v}_1^{FG} + \boldsymbol{\varepsilon}_1^{FG} = M^{-1}\mathbf{v}_1^{FQ} + \boldsymbol{\varepsilon}_1^{FG} = \mathbf{z}_1^{FQ} - \boldsymbol{\varepsilon}_1^{FQ} + \boldsymbol{\varepsilon}_1^{FG} \in S^1$. Assuming that (23) holds for $n \le m$, then

$$\begin{aligned}
\mathbf{z}_{m+1}^{FG} &= M^{-1}\mathbf{v}_{m+1}^{FG} + \boldsymbol{\varepsilon}_{m+1}^{FG} \\
&= M^{-1}(\tfrac{1}{h_{m+1,m}})\left(Az_m^{FG} - \sum_{k=1}^{m} h_{k,m}\mathbf{v}_k^{FG}\right) + \boldsymbol{\varepsilon}_{m+1}^{FG} \\
&= (\tfrac{1}{h_{m+1,m}})\left(M^{-1}A\mathbf{z}_m^{FG} - \sum_{k=1}^{m} h_{k,m}M^{-1}\mathbf{v}_k^{FG} + h_{m+1,m}\boldsymbol{\varepsilon}_{m+1}^{FG}\right) \\
&= (\tfrac{1}{h_{m+1,m}})\left(M^{-1}A\mathbf{z}_m^{FG} - \sum_{k=1}^{m}(h_{k,m}\mathbf{z}_k^{FG} - h_{k,m}\boldsymbol{\varepsilon}_k^{FG}) + h_{m+1,m}\boldsymbol{\varepsilon}_{m+1}^{FG}\right),
\end{aligned}$$

where the first and last equalities follow from (22) and the second equality follows from the definition of $\mathbf{v}_{m+1}^{FG}$.

By the induction hypothesis and the observation that $S^r \subseteq S^t$ for $r \le t$, we have that $\mathbf{z}_i^{FG} \in S^{m+1}$ for $i \le m$. By the definition of S^{m+1}, $\boldsymbol{\varepsilon}_i^{FG} \in S^{m+1}$ for $i \le m+1$. Therefore, all that remains to be shown is that the first term $M^{-1}A\mathbf{z}_m^{FG} \in S^{m+1}$. Again by the induction hypothesis, we know that $\mathbf{z}_m^{FG} \in S^m$; hence, there are scalars $a_i, b_{i,j}, c_{i,j},\ i = 1, \dots m,\ j = 0, \dots, m-1$, such that

$$\mathbf{z}_m^{FG} = \sum_{i=1}^{m} a_i\mathbf{z}_i^{FQ} + \sum_{k=0}^{m-1}\left(\sum_{i=1}^{m} b_{i,k}(M^{-1}A)^k\boldsymbol{\varepsilon}_i^{FQ}\right) + \sum_{k=0}^{m-1}\left(\sum_{i=1}^{m} c_{i,k}(M^{-1}A)^k\boldsymbol{\varepsilon}_i^{FG}\right),$$

and therefore

$$\begin{aligned}
M^{-1}A\mathbf{z}_m^{FG} = {} & \sum_{i=1}^{m} a_i(M^{-1}A)\mathbf{z}_i^{FQ} + \sum_{k=0}^{m-1}\left(\sum_{i=1}^{m} b_{i,k}(M^{-1}A)^{k+1}\boldsymbol{\varepsilon}_i^{FQ}\right) \\
& + \sum_{k=0}^{m-1}\left(\sum_{i=1}^{m} c_{i,k}(M^{-1}A)^{k+1}\boldsymbol{\varepsilon}_i^{FG}\right).
\end{aligned}$$

Since $(M^{-1}A)^j\boldsymbol{\varepsilon}_i^{FG} \in S^{m+1}$ and $(M^{-1}A)^j\boldsymbol{\varepsilon}_i^{FQ} \in S^{m+1}$ for $j = 0, \dots, (m+1)-1$, $i = 1, \dots, m+1$ by definition of S^{m+1}, all that remains to be shown is $(M^{-1}A)\mathbf{z}_i^{FQ} \in S^{m+1}$ for $i = 1, \dots, m$. Solving in (10) for $A\mathbf{z}_j$ and multiplying through by M^{-1} gives

$$(M^{-1}A)\mathbf{z}_i^{FQ} = \gamma_i M^{-1}\mathbf{v}_{i+1}^{FQ} + \alpha_i M^{-1}\mathbf{v}_i^{FQ} + \beta_{i-1}M^{-1}\mathbf{v}_{i-1}^{FQ}. \tag{24}$$

Next, solving (21) for $M^{-1}\mathbf{v}_i^{FQ}$ and substituting this into (24) gives

$$(M^{-1}A)\mathbf{z}_i^{FQ} = \gamma_i\mathbf{z}_{i+1}^{FQ} - \gamma_i\boldsymbol{\varepsilon}_{i+1}^{FQ} + \alpha_i\mathbf{z}_i^{FQ} - \alpha_i\boldsymbol{\varepsilon}_i^{FQ} + \beta_{i-1}\mathbf{z}_{i-1}^{FQ} - \beta_{i-1}\boldsymbol{\varepsilon}_{i-1}^{FQ} \in S^{m+1}. \qquad \square \tag{25}$$

We can now prove our main result.

THEOREM 3.3. *Assume that V_{m+1}^{FQ}, the matrix satisfying* (14), *is of full rank. Let $\mathbf{r}_m^{FQ}$ and $\mathbf{r}_m^{FG}$ be the residuals obtained after m steps of the FQMR and FGMRES algorithms, respectively, and let $\mathcal{E}_m^{FQ} = [\boldsymbol{\varepsilon}_1^{FQ}, \ldots, \boldsymbol{\varepsilon}_m^{FQ}]$ and $\mathcal{E}_m^{FG} = [\boldsymbol{\varepsilon}_1^{FG}, \ldots, \boldsymbol{\varepsilon}_m^{FG}]$, where $\boldsymbol{\varepsilon}_i^{FQ}$ and $\boldsymbol{\varepsilon}_i^{FG}$ are the error vectors in* (21) *and* (22), *respectively. Then there exist vectors $\mathbf{y}_k^{FQ}, \mathbf{y}_k^{FG} \in \mathbb{R}^m$, $k = 1, \ldots, m-1$, such that the following holds:*

$$\|\mathbf{r}_m^{FQ}\| \le \kappa_2(V_{m+1}^{FQ}) \left[\|\mathbf{r}_m^{FG}\| + \sum_{k=0}^{m-1} \|A(M^{-1}A)^k\mathcal{E}_m^{FQ}\mathbf{y}_k^{FQ}\| + \sum_{k=0}^{m-1} \|A(M^{-1}A)^k\mathcal{E}_m^{FG}\mathbf{y}_k^{FG}\| \right].$$

Proof. Step 1. Consider the set defined by

$$\mathcal{R} = \{\mathbf{r} : \ \mathbf{r} = V_{m+1}^{FQ}\mathbf{t}; \ \mathbf{t} = \beta\mathbf{e}_1 - T_{m+1,m}\mathbf{y}; \ \mathbf{y} \in \mathbb{C}^m\}.$$

Let $\mathbf{y}_m$ denote the vector $\mathbf{y}$ that minimizes $\|\beta e_1 - T_{m+1,m}\mathbf{y}\|$, and denote by $\mathbf{t}_m = \beta e_1 - T_{m+1,1}\mathbf{y}_m$. Then by definition we have $\mathbf{r}_m^{FQ} = V_{m+1}^{FQ}\mathbf{t_m}$. By hypothesis, V_{m+1}^{FQ} is of full rank. Therefore, there is an $(m+1) \times (m+1)$ nonsingular matrix S such that $W_{m+1} = V_{m+1}^{FQ}S$ is unitary. Then for any element of the set $\mathcal{R}$,

$$\mathbf{r} = W_{m+1}S^{-1}\mathbf{t} \ , \qquad \mathbf{t} = SW_{m+1}^H\mathbf{r},$$

and, in particular, $\mathbf{r}_m^{FQ} = W_{m+1}S^{-1}\mathbf{t}_m$, which implies

$$\|\mathbf{r}_m^{FQ}\| \le \|S^{-1}\|\|\mathbf{t}_m\|. \tag{26}$$

From (3), it follows that the norm $\|\mathbf{t}_m\|$ is the minimum of $\|\beta e_1 - T_{m+1,m}\mathbf{y}\|$ over all vectors $\mathbf{y}$, and therefore

$$\|\mathbf{t}_m\| = \|SW_{m+1}^H\mathbf{r}_m^{FQ}\| \le \|SW_{m+1}^H\mathbf{r}\| \le \|S\|\|\mathbf{r}\| \quad \text{for all } \mathbf{r} \in \mathcal{R}. \tag{27}$$

Step 2. We now consider

$$\mathbf{r}_m^{FG} = \mathbf{r}_0 - AZ_m^{FG}\mathbf{y}_m^{FG}, \qquad \text{where } \mathbf{y}_m^{FG} \text{ minimizes } \|\mathbf{r}_0 - AZ_m^{FG}\mathbf{y}\|. \tag{28}$$

By Lemma 3.2 there exists vectors $\mathbf{y}_z$, $\mathbf{y}_k^{FQ}$, $\mathbf{y}_k^{FG} \in \mathbb{R}^m$; $k = 0, \ldots, m-1$, such that

$$\begin{aligned}
\mathbf{r}_m^{FG} &= \mathbf{r}_0 - AZ_m^{FQ}\mathbf{y}_z - \sum_{k=0}^{m-1} A(M^{-1}A)^k\mathcal{E}_m^{FQ}\mathbf{y}_k^{FQ} - \sum_{k=0}^{m-1} A(M^{-1}A)^k\mathcal{E}_m^{FG}\mathbf{y}_k^{FG} \\
&= \mathbf{r}_0 - V_{m+1}^{FQ}T_{m+1,m}\mathbf{y}_z - \sum_{k=0}^{m-1} A(M^{-1}A)^k\mathcal{E}_m^{FQ}\mathbf{y}_k^{FQ} - \sum_{k=0}^{m-1} A(M^{-1}A)^k\mathcal{E}_m^{FG}\mathbf{y}_k^{FG}.
\end{aligned}$$

By rearrangement of terms,

$$\mathbf{r}_0 - V_{m+1}^{FQ}T_{m+1,m}\mathbf{y}_z = \mathbf{r}_m^{FG} + \sum_{k=0}^{m-1} A(M^{-1}A)^k\mathcal{E}_m^{FQ}\mathbf{y}_k^{FQ} + \sum_{k=0}^{m-1} A(M^{-1}A)^k\mathcal{E}_m^{FG}\mathbf{y}_k^{FG}.$$

Let $\hat{\mathbf{r}} = V^{FQ}_{m+1}(\|\mathbf{r}_0\|e_1 - T_{m+1,m}\mathbf{y}_z)$; then

$$\begin{aligned} \|\hat{\mathbf{r}}\| &= \|V^{FQ}_{m+1}(\|\mathbf{r}_0\|\mathbf{e}_1 - T_{m+1,m}\mathbf{y}_z)\| = \|\mathbf{r}_0 - V^{FQ}_{m+1}T_{m+1,m}\mathbf{y}_z\| \\ &\le \|\mathbf{r}^{FG}_m\| + \sum_{k=0}^{m-1}\|A(M^{-1}A)^k\mathcal{E}^{FQ}_m\mathbf{y}^{FQ}_k\| + \sum_{k=0}^{m-1}\|A(M^{-1}A)^k\mathcal{E}^{FG}_m\mathbf{y}^{FG}_k\|. \end{aligned} \tag{29}$$

Since $\hat{\mathbf{r}} \in \mathcal{R}$, by (27),

$$\|\mathbf{t}_m\| \le \|S\|\|\hat{\mathbf{r}}\|. \tag{30}$$

Hence, by (26), (29), and (27),

$$\begin{aligned} \|\mathbf{r}^{FQ}_m\| &\le \|S^{-1}\|\|\mathbf{t}_m\| \\ &\le \|S^{-1}\|\|S\|\left[\|\mathbf{r}^{FG}_m\| + \sum_{k=0}^{m-1}\|A(M^{-1}A)^k\mathcal{E}^{FQ}_m\mathbf{y}^{FQ}_k\| + \sum_{k=0}^{m-1}\|A(M^{-1}A)^k\mathcal{E}^{FG}_m\mathbf{y}^{FG}_k\|\right] \end{aligned}$$

and since $\kappa_2(V^{FQ}_{m+1}) = \kappa_2(S) = \|S^{-1}\|\|S\|$, the theorem follows. □

We comment that as $\boldsymbol{\varepsilon}_i$ goes to $\mathbf{0}$, the bound on $\|\mathbf{r}^{FQ}_m\|$ in Theorem 3.3 is reduced. However, we cannot know how sharp this bound is due to the existence of vectors $\mathbf{y}^{FQ}_k, \mathbf{y}^{FG}_k$ in the right-hand side of the inequality.

By considering exact solutions of the preconditioned equations (13), i.e., if $\boldsymbol{\varepsilon}_i = 0$ in (13), or equivalently if $M_i = M$ for all i, then FQMR and FGMRES are reduced to QMR and GMRES with fixed preconditioners and Theorem 3.3 reduces to Theorem 3.1. There are two other special situations, which we want to highlight. If $\mathcal{E}^{FG}_m = 0$, i.e., $\boldsymbol{\varepsilon}^{FQ}_i = 0$ for all i, then FGMRES reduces to GMRES, and we have the following corollary.

Corollary 3.4. *Let V^{FQ}_{m+1}, $\mathcal{E}^{FQ}_m$, and $\mathbf{r}^{FQ}_m$ be as described in Theorem* 3.3*, and let $\mathbf{r}^G_m$ be the residual obtained after m steps of the GMRES algorithm. Then there exists vectors $\mathbf{y}^{FQ}_k \in \mathbb{R}^m$, $k = 1, \ldots, m-1$, such that the following holds:*

$$\|\mathbf{r}^{FQ}_m\| \le \kappa_2(V^{FQ}_{m+1})\left(\|\mathbf{r}^G_m\| + \sum_{k=0}^{m-1}\|A(M^{-1}A)^k\mathcal{E}^{FQ}_m\mathbf{y}^{FQ}_k\|\right).$$

Likewise, if $\mathcal{E}^{FQ}_m = 0$, i.e., $\boldsymbol{\varepsilon}^{FQ}_i = 0$ for all i, then the following corollary, which is a new result for FGMRES, is also established.

Corollary 3.5. *Let V^Q_{m+1}, $\mathcal{E}^{FG}_m$, and $\mathbf{r}^{FG}_m$ be as described in Theorems* 3.1 *and* 3.3*, and let $\mathbf{r}^Q_m$ be the residual obtained after m steps of the QMR algorithm. Then there exists vectors $\mathbf{y}^{FG}_k \in \mathbb{R}^m$, $k = 1, \ldots, m-1$, such that the following holds:*

$$\|\mathbf{r}^Q_m\| \le \kappa_2(V^Q_{m+1})\left(\|\mathbf{r}^{FG}_m\| + \sum_{k=0}^{m-1}\|A(M^{-1}A)^k\mathcal{E}^{FG}_m\mathbf{y}^{FG}_k\|\right).$$

We end this section with a comment on the hypothesis in Theorem 3.3 that V^{FQ}_{m+1} be of full rank. This implies that the subspace $\hat{K}_m$ has dimension m, i.e., that at each step we are minimizing over increasingly larger subspaces. Note that this hypothesis implies that the subspaces $\hat{K}_m$ are nested, and this is precisely the assumption made in [9] for the convergence proofs.

4. Bounds on residual norms. Using the same techniques used in Lemma 3.2 and Theorem 3.3, we provide bounds on the norm of the residual of FQMR in terms of the norm of the residual of QMR. The following lemma relates Z_m^{FQ} to Z_m^Q, the matrices whose columns are the basis of the subspaces generated by FQMR and QMR, respectively; see (14) and (7). We first establish an auxiliary lemma.

LEMMA 4.1. *Let* $\mathbf{z}_i^{FQ}$ *be the ith column of* Z_m^{FQ}*, and let* $\mathbf{z}_i^Q$ *be the ith column of* Z_m^Q*. If* $\boldsymbol{\varepsilon}_i^{FQ}$ *is the ith error vector defined by* (21)*, then*

$$\mathbf{z}_i^Q \in S^m, \quad i = 1, \ldots, m, \tag{31}$$

where $S^m = \operatorname{span}\{\mathbf{z}_i^{FQ}, (M^{-1}A)^j \boldsymbol{\varepsilon}_i^{FQ};\ i = 1, \ldots, m,\ j = 0, \ldots, m-1\}$.

Proof. We show (31) by induction on m. For $m = 1$, we have $\mathbf{z}_1^Q = M^{-1}\mathbf{v}_1^Q = M^{-1}\mathbf{v}_1^{FQ} = \mathbf{z}_1^{FQ} - \boldsymbol{\varepsilon}_1^{FQ} \in S^1$. Assuming that (31) holds for $n \leq m$, then

$$\begin{aligned}
\mathbf{z}_{m+1}^Q &= M^{-1}\mathbf{v}_{m+1}^Q \\
&= M^{-1}(\tfrac{1}{\gamma_m})(A\mathbf{z}_m^Q - \alpha_m \mathbf{v}_m^Q - \beta_{m-1}\mathbf{v}_{m-1}^Q) \\
&= (\tfrac{1}{\gamma_m})(M^{-1}A\mathbf{z}_m^Q - \alpha_m M^{-1}\mathbf{v}_m^Q - \beta_{m-1}M^{-1}\mathbf{v}_{m-1}^Q) \\
&= (\tfrac{1}{\gamma_m})(M^{-1}A\mathbf{z}_m^Q - \alpha_m \mathbf{z}_m^Q - \beta_{m-1}\mathbf{z}_{m-1}^Q),
\end{aligned}$$

where the first and last equalities follow from the relation (2), and the second equality follows from the definition of $\mathbf{v}_{m+1}^Q$; see (10). By the induction hypothesis and the observation that $S^r \subseteq S^t$ for $r \leq t$, we have that $\mathbf{z}_i^Q \in S^{m+1}$ for $i \leq m$. Therefore, all that remains to be shown is that $M^{-1}A\mathbf{z}_m^Q \in S^{m+1}$. Again by the induction hypothesis, we know that $\mathbf{z}_m^Q \in S^m$; hence, there are scalars $a_i, b_{i,j},\ i = 1, \ldots m,\ j = 0, \ldots, m-1$, such that

$$\mathbf{z}_m^Q = \sum_{i=1}^m a_i \mathbf{z}_i^{FQ} + \sum_{k=0}^{m-1} \left(\sum_{i=1}^m b_{i,k} (M^{-1}A)^k \boldsymbol{\varepsilon}_i^{FQ} \right),$$

and therefore

$$M^{-1}A\mathbf{z}_m^Q = \sum_{i=1}^m a_i (M^{-1}A)\mathbf{z}_i^{FQ} + \sum_{k=0}^{m-1} \left(\sum_{i=1}^m b_{i,k} (M^{-1}A)^{k+1} \boldsymbol{\varepsilon}_i^{FQ} \right).$$

Since $(M^{-1}A)^j \boldsymbol{\varepsilon}_i^{FQ} \in S^{m+1}$ for $j = 0, \ldots, (m+1)-1,\ i = 1, \ldots, m+1$, all that remains to show is $(M^{-1}A)\mathbf{z}_i^{FQ} \in S^{m+1}$ for $i = 1, \ldots, m$, but this follows from (25). □

Using Lemma 4.1, we now present the following theorem.

THEOREM 4.2. *Assume that* V_{m+1}^{FQ}*, the matrix satisfying* (14)*, is of full rank. Let* $\mathbf{r}_m^{FQ}$ *and* $\mathbf{r}_m^Q$ *be the residuals obtained after m steps of the FQMR and QMR algorithms, respectively, and let* $\mathcal{E}_m^{FQ} = [\boldsymbol{\varepsilon}_1^{FQ}, \ldots, \boldsymbol{\varepsilon}_m^{FQ}]$*, where* $\boldsymbol{\varepsilon}_i^{FQ}$ *are the error vectors defined by* (21)*. Then there exists vectors* $\mathbf{y}_k^{FQ} \in \mathbb{R}^m$*,* $k = 1, \ldots, m-1$*, such that the following holds:*

$$\|\mathbf{r}_m^{FQ}\| \leq \kappa_2(V_{m+1}^{FQ}) \left(\|\mathbf{r}_m^Q\| + \sum_{k=0}^{m-1} \|A(M^{-1}A)^k \mathcal{E}_m^{FQ} \mathbf{y}_k^{FQ}\| \right).$$

Proof. Step 1 of the proof is identical to Step 1 of the proof of Theorem 3.3.

Step 2. Consider

$$\mathbf{r}_m^Q = \mathbf{r}_0 - AZ_m^Q \mathbf{y}_m^Q, \qquad \text{where } \mathbf{y}_m^Q \text{ minimizes } \|\mathbf{r}_0 - AZ_m^Q \mathbf{y}\|. \tag{32}$$

By Lemma 4.1 there exists vectors $\mathbf{y}_z$, $\mathbf{y}_k^{FQ}$, $k = 0, \dots, m-1$, such that

$$\begin{aligned}\mathbf{r}_m^Q &= \mathbf{r}_0 - AZ_m^{FQ}\mathbf{y}_z - \sum_{k=0}^{m-1} A(M^{-1}A)^k \mathcal{E}_m^{FQ}\mathbf{y}_k^{FQ} \\ &= \mathbf{r}_0 - V_{m+1}^{FQ} T_{m+1,m}\mathbf{y}_z - \sum_{k=0}^{m-1} A(M^{-1}A)^k \mathcal{E}_m^{FQ}\mathbf{y}_k^{FQ}.\end{aligned}$$

By rearrangement of terms,

$$\mathbf{r}_0 - V_{m+1}^{FQ} T_{m+1,m}\mathbf{y}_z = \mathbf{r}_m^Q + \sum_{k=0}^{m-1} A(M^{-1}A)^k \mathcal{E}_m^{FQ}\mathbf{y}_k^{FQ}.$$

Let $\hat{\mathbf{r}} = V_{m+1}^{FQ}(\|\mathbf{r}_0\|\mathbf{e}_1 - T_{m+1,m}\mathbf{y}_z) = \mathbf{r}_0 - V_{m+1}^{FQ}T_{m+1,m}\mathbf{y}_z$; then

$$\|\hat{\mathbf{r}}\| \le \|\mathbf{r}_m^Q\| + \sum_{k=0}^{m-1} \|A(M^{-1}A)^k \mathcal{E}_m^{FQ}\mathbf{y}_k^{FQ}\|.$$

Since $\hat{\mathbf{r}} \in \mathcal{R}$, by (27)

$$\|\mathbf{t}_m\| \le \|S\|\|\hat{\mathbf{r}}\|. \tag{33}$$

Hence, by (26) and (33) we obtain

$$\|\mathbf{r}_m^{FQ}\| \le \|S^{-1}\|\|\mathbf{t}_m\| \le \|S^{-1}\|\|S\| \left(\|\mathbf{r}_m^Q\| + \sum_{k=0}^{m-1} \|A(M^{-1}A)^k \mathcal{E}_m^{FQ}\mathbf{y}_k^{FQ}\| \right),$$

and since $\kappa_2(V_{m+1}^{FQ}) = \kappa_2(S) = \|S^{-1}\|\|S\|$, the theorem follows. □

Using identical techniques as in Lemma 4.1 and Theorem 4.2 one can prove the following new result relating the norm of the residuals associated with GMRES and FGMRES.

THEOREM 4.3. *Assume that V_{m+1}^{FG}, the matrix satisfying* (19), *is of full rank. Let $\mathbf{r}_m^{FG}$ and $\mathbf{r}_m^G$ be the residuals obtained after m steps of the FGMRES and GMRES algorithms, respectively, and let $\mathcal{E}_m^{FG} = [\boldsymbol{\varepsilon}_1^{FG}, \dots, \boldsymbol{\varepsilon}_m^{FG}]$, where $\boldsymbol{\varepsilon}_i^{FG}$ are the ith error vectors given by* (22). *Then there exists vectors $\mathbf{y}_k^{FG} \in \mathbb{R}^m$, $k = 1, \dots, m-1$, such that the following holds:*

$$\|\mathbf{r}_m^{FG}\| \le \kappa_2(V_{m+1}^{FG}) \left(\|\mathbf{r}_m^G\| + \sum_{k=0}^{m-1} \|A(M^{-1}A)^k \mathcal{E}_m^{FG}\mathbf{y}_k^{FG}\| \right).$$

5. Numerical experiments.

To illustrate the behavior of FQMR we performed several numerical experiments. We begin by considering a set of examples from [21] given by a finite difference discretization of the partial differential equation

$$-\Delta u + \gamma(xu_x + yu_y) + \beta u = f \tag{34}$$

on a unit square, where f is such that the exact solution to the discretized equation $A\mathbf{x} = \mathbf{b}$ is $\mathbf{x}^H = (1, \ldots, 1)$. The parameters γ and β are chosen in one case to make the system indefinite ($\gamma = 10$ and $\beta = -100$) and in another to have a highly nonsymmetric matrix ($\gamma = 1000$ and $\beta = 10$). For $\gamma \neq 0$, A is non-Hermitian, and it is appropriate to use FQMR. The mesh is chosen as in [21] of equal size in both dimensions (32 nodes), and the corresponding matrix is thus of order 1024.

In our experiments, we ran FQMR preconditioned with the standard QMR method (FQMR-QMR), FQMR preconditioned with QMR which, in turn, is preconditioned with ILU(0) (FQMR-QMR(ILU(0))), and FQMR preconditioned with CGNE (FQMR-CGNE); see, e.g., [17], [22] for descriptions of these preconditioners. When possible, each of these was run with an outer relative residual norm tolerance of 10^{-7} and an inner relative residual tolerance ranging from 10^{-1} to 10^{-6}. In all of our experiments, our stopping criteria uses the 2-norm in computing the relative residual norm $\|\mathbf{r}_k\|/\|r_0\|$, which is consistent with our theoretical analysis. Our FORTRAN code is derived from the existing code for QMR taken from [12], and ILU(0) and CGNE are taken from [3]. Our experiments were run on a DEC-alpha machine; however, for easy comparisons with runs on other machines, in our tables and figures we report number of operations and not computer times. The trends observed in our tables and figures are very similar to those one would observe using CPU times.

TABLE 1

Tables 1 and 2 display the results of FQMR-QMR, Tables 3 and 4 display the results of FQMR-QMR(ILU(0)), and Tables 5 and 6 display the results of FQMR-CGNE. We list the average number of inner iterations needed to reach the inner tolerance, the exact number of outer iterations needed to reach the outer tolerance, and the number of operations used to complete the solution. In Tables 3 and 4, we point out that, for an inner tolerance of 10^{-1}, FQMR cannot achieve full accuracy in the outer iteration; thus for this case, QMR(ILU(0)) is not a good preconditioner. For these tables we list the outer tolerance separately at each step. We remark that a more efficient implementation of FQMR-QMR is possible where steps (8) and (9)

10^{-6}	2	441	6.52×10^{7}

of Algorithm 2.1 are performed with a single call to QMR, but we have not used this feature here.

As it can be observed, reducing the inner tolerance produces a better preconditioner, and the overall convergence is improved. As is to be expected, the average number of inner iterations increases. An important observation comes from looking at the progression of total number of operations as the inner tolerance decreases from 10^{-1} to 10^{-6}. For our given outer tolerance of 10^{-7}, the amount of required operations in relation to the inner tolerance will decrease to a point and then begin to increase.

TABLE 7
FQMR-QMR: $\beta = -100, \gamma = 10$, outer tol.= 10^{-4}.

Inner tol.	Matrix dimension	Out. it.	Inner it.	Operations
10^{-1}	1024	5	96	5.63×10^{7}
10^{-1}	4096	5	187	4.38×10^{8}
10^{-1}	10000	5	276	1.58×10^{9}
10^{-1}	40000	5	1055	2.41×10^{10}
10^{-2}	1024	2	113	3.88×10^{7}
10^{-2}	4096	8	828	3.10×10^{9}
10^{-2}	10000	3	1134	3.88×10^{9}
10^{-2}	40000	3	1527	2.09×10^{10}
10^{-3}	1024	2	124	2.91×10^{7}
10^{-3}	4096	2	249	4.38×10^{8}
10^{-3}	10000	3	1181	4.05×10^{9}
10^{-3}	40000	2	2294	2.09×10^{10}

This phenomenon is consistent with the behavior of other inner-outer methods; see e.g., [5], [24]. In Tables 1, 2, 4, and 6, the smallest amount of work was achieved for an inner tolerance of 10^{-4}; in Table 5 the smallest amount of work was achieved for an inner tolerance of 10^{-5}; while in Table 3 an inner tolerance of 10^{-6} yielded the least amount of work. This demonstrates that the inner iterative method need not, in every case, be solved to the fullest precision in order to have a good preconditioner; see [4] for other examples of this occurrence. Thus, for a given flexible preconditioner and a specific outer residual norm tolerance, we can find an optimal choice of inner tolerance for minimizing work. It can be observed that this optimal choice is problem dependent. Note also that choosing an inner tolerance equal to the outer one, say, 10^{-7} in most of our cases, would imply only one outer iteration. This is equivalent to just running the inner iterative method.

We next give the results of our experiments with larger matrices A. We solve the indefinite problem, $\beta = -100, \gamma = 10$, using FQMR-QMR with varying grid sizes of 32, 64, 100, and 200, giving us matrices of dimension 1024, 4096, 10000, and 40000, respectively. Table 7 records the results for an outer tolerance of 10^{-4}. We give the results for each of the matrix sizes using the inner tolerances 10^{-1}, 10^{-2}, and 10^{-3}. We point out that for the total number of outer iterations there is little or no change. Thus, the increase in the work per variable is wholly a result of an increase in the number of inner iterations.

We present now several figures which display that in many cases the maximum attainable accuracy of FQMR is better than that of the corresponding QMR. By this we mean the smallest possible relative residual norm. Figure 1 shows the maximum attainable accuracy of FQMR-QMR(ILU(0)) and QMR(ILU(0)) for the indefinite problem, $\beta = -100$, $\gamma = 10$. Here FQMR-QMR(ILU(0)) was able to achieve a relative residual norm of 10^{-7}, while QMR(ILU(0)) terminated at 10^{-4}. This observation is typical of all our experiments with FQMR. One particularly strong example of this behavior is observed for the matrix created with $\beta = -1000.1$ and $\gamma = 10.0$. The convergence curves of QMR and FQMR-QMR for this matrix are shown in Figure 2. Notice that while QMR stagnates at 10^{-2}, we achieve a relative residual norm of 10^{-9} using FQMR-QMR for the same number of operations. FQMR-QMR can achieve an even lower relative residual norm if we allow for additional work. A value of 10^{-15} is reached in 7.42×10^{8} operations.

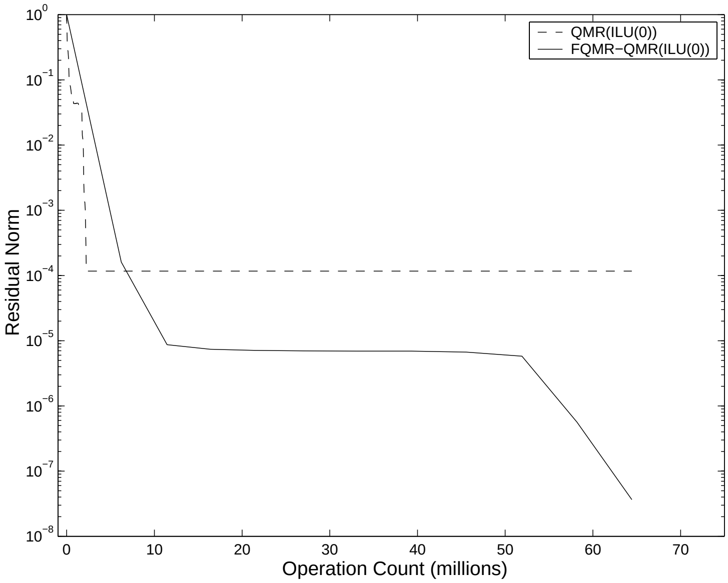

Fig. 1. *FQMR convergence:* $\beta = -100, \gamma = 10$*, inner tol.* $= 0.01$.

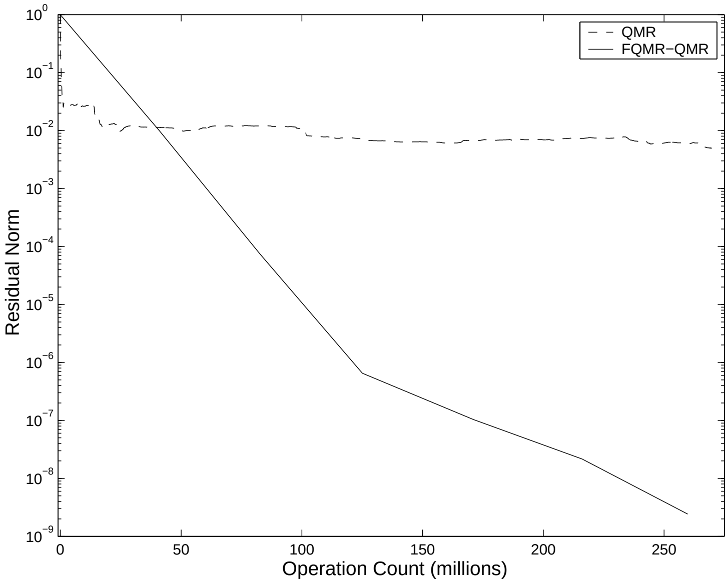

Fig. 2. *FQMR convergence:* $\beta = -1000.1, \gamma = 10$.

In Table 8, we further confirm these findings by recording achievable relative residual norms of FQMR and QMR for other choices of the matrix A. Notice that even when QMR performs well, i.e., it successfully converges to an appropriately small relative residual norm before reaching a plateau, FQMR can be shown to perform better by reaching an even smaller value. The ability to reach a lower relative residual norm by using a flexible preconditioner was observed both in the case of breakdown and stagnation. At the present time, we do not have a full explanation for this

Table 8
Comparison of achievable residual norms for FQMR-QMR and QMR.

β	γ	Res. norm - QMR	Res. norm - FQMR-QMR
-1000	10	10^{-8}	5.2×10^{-15}
1000	10	10^{-8}	6.1×10^{-15}
100	10	10^{-13}	1.42×10^{-15}
-100	10	10^{-11}	1.64×10^{-15}
10	1000	10^{-12}	5.9×10^{-15}

Table 9
*FQMR-QMR: Sherman*1 *matrix. Out. tol.* $= 10^{-7}$.

Inner tol.	Out. it.	Avg. inner it.	Oper.
10^{-1}	111	98	1.07×10^9
10^{-2}	10	148	1.47×10^8
10^{-3}	4	189	7.50×10^7
10^{-4}	2	180	$\mathbf{3.56\times10^7}$
10^{-5}	2	272	5.40×10^7
10^{-6}	2	327	6.28×10^7

phenomenon.

We comment that there are of course several ways of going beyond the point where QMR stagnates, for example, by using iterative refinement or restarting QMR. Also, if one uses the coupled two-term recurrences version of QMR, the maximum attainable residual norm is better than with the three-term recurrence version of QMR used here; see [13].

To emphasize the robustness of the new FQMR method, we ran FQMR on two matrices whose structure is different from the previous examples. These are the Sherman1 matrix and the Sherman5 matrix from [8]. They are the first and fifth matrices from the Sherman collection, respectively. Both represent oil reservoir simulations, with Sherman1 coming from a black oil simulation with shale barriers on a $10 \times 10 \times 10$ grid with one unknown per grid point, and Sherman5 coming from a fully implicit black oil simulator on a $16 \times 23 \times 3$ grid with three unknowns per grid point. The Sherman1 matrix is of dimension 1000 and has 3750 nonzeros, and the Sherman5 matrix is of dimension 3312 and has 20793 nonzeros.

Table 9 displays the convergence behavior of FQMR-QMR for the Sherman1 matrix, and Table 10 displays the convergence behavior of FQMR-QMR for the Sherman5 matrix. Notice that for both of these matrices the convergence behavior of FQMR-QMR remains comparable to what we have seen in all of the previous examples. Tables 9 and 10, also, display a consistency with our other examples in that the total work required for solving these problems with an outer tolerance of 10^{-7} reaches a minimum when the inner tolerance is 10^{-4} for Table 9 and 10^{-5} for Table 10. Thus, once more we see an optimal preconditioner for our implementation is achieved when using a less precise inner iteration.

To emphasize the property that we have observed in FQMR of achieving a lower relative residual norm than QMR, we display full convergence results of both QMR and FQMR-QMR on the Sherman5 matrix in Figure 3. Here QMR can achieve a tolerance of only 2.0×10^{-8}, while FQMR-QMR reaches 3.5×10^{-16}. Therefore, once again, FQMR can outperform QMR when an extremely low residual norm is required.

10^{-7}	10^{-6}	2	2069	1.77×10^{9}

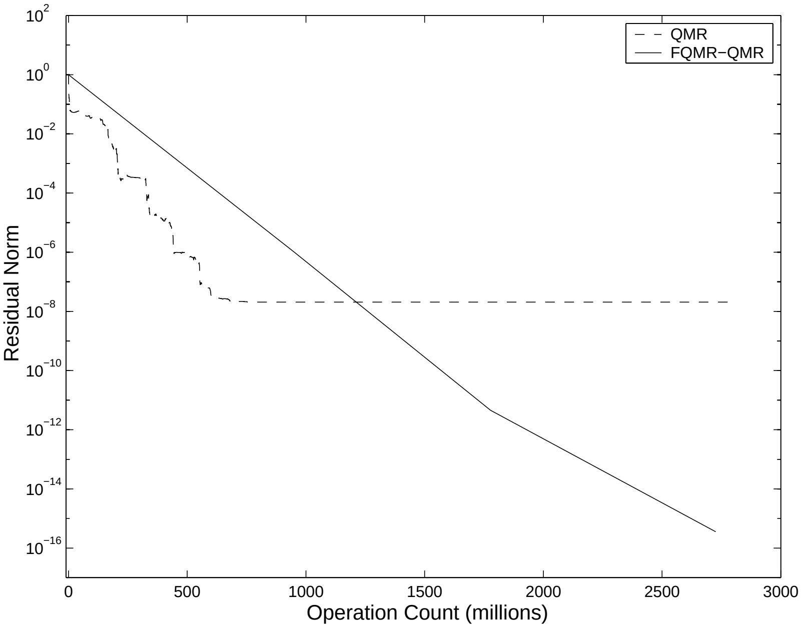

Fig. 3. *QMR vs. FQMR-QMR: Sherman5 matrix.*

6. Conclusions. We have formulated a flexible version of QMR for the solution of large sparse non-Hermitian nonsingular systems of linear equations. This new method, FQMR, converges to the solution of the linear system, as long as the new vectors generated at each step are linearly independent of the previous ones. Theoretical bounds on the norm of the residual at each step were given. These bounds are (as is to be expected) not as good as those obtained using the same preconditioner at each step. The advantage is that the variable preconditioner can be less onerous. Furthermore, there is the potential of great gains in cases of an adaptive preconditioner. One of the advantages of FQMR over FGMRES is the fact that the low memory requirements are fixed from the beginning.

Using the methodology developed to produce the mentioned bounds, we have also contributed to the analysis of FGMRES [21].

Numerical experiments of the type found in [21] illustrate the convergence behavior of FQMR and demonstrate that FQMR is capable of attaining lower residual norms than the standard QMR with three-term recurrence. Other experiments presented show a similar behavior.

Acknowledgments. We thank the referees, as well as Michele Benzi and Valeria Simoncini, for their valuable comments and suggestions. We greatly benefited from them.

Abstract. Solidifying flow equations can be used to model industrial metallurgical processes such as casting and welding, and material science applications such as crystal growth. These flow equations contain locally stiff nonlinearities at the moving phase-change interface. We are developing a three-dimensional parallel simulation tool for such problems using a Jacobian-free Newton–Krylov solver and unstructured finite volume methods. A segregated (distributed, block triangular) preconditioning strategy is being developed for the Newton–Krylov solver. In this preconditioning approach we are only required to approximately invert matrices coming from a single field variable, not matrices arising from a coupled system. Additionally, simple linearizations are used in constructing our preconditioning operators. The preconditioning strategy is presented along with the performance of the methods. We consider problems in phase-change heat transfer and the thermally driven incompressible Navier–Stokes equations separately. This is a required intermediate step toward developing a successful preconditioning strategy for the fully coupled physics problem.

Key words. Newton–Krylov methods, preconditioning, solidifying flow

1. Introduction.

Numerical simulation of solidifying flow equations plays an important role in the analysis of industrial metallurgical processes such as casting and welding and material science applications such as crystal growth. These flow equations contain locally stiff nonlinearities at the moving phase-change interface. The typical equation set is a combination of the incompressible Navier–Stokes equations and an energy equation which includes phase-change and latent heat evolution. Examples of numerical solutions to solidifying flow equations are [VCM87, Dan89].

There are many challenges to numerically integrating the equations of solidifying flow. We focus here on fixed-grid approaches, although moving mesh methods can also be used. In constructing a solution algorithm one must choose a set of dependent variables. In most applications temperature is used as the dependent variable for the energy equation, whereas we use total enthalpy [KKL99]. One may chose to iteratively converge the heat transfer phase-change evolution within a time step as in [VCM87] or approximately linearize this coupling within a time step using an "effective heat capacity" method as in [Dan89]. Additionally, one may choose a segregated solution procedure to couple the flow equations and the energy equation within a time step, as is done in [VCM87], or one can solve this system with a Newton based approach, as is done in [Dan89]. Note that while [Dan89] has demonstrated the applicability of a Newton based approach to solidifying flow, the more modern Jacobian-free Newton–Krylov (JFNK) approach was not applied in that study. However, the convergence of a Newton based approach applied to solidifying flow has been established in [Dan89].

Our algorithmic approach will use total enthalpy as a dependent variable, accurately capturing the latent-heat exchange within a time step [KKL99]. We employ a fully coupled Newton–Krylov method to integrate the system in a Jacobian-free approach [CJ84, BS90]. We have recently had success using this approach for boundary value problems involving coupling between fluid flow and phase-change or finite rate chemistry [Kno98, KMK96]. We use the "effective heat capacity" method and a segregated flow solver approach to precondition our outer Newton–Krylov solver. In this study, the scalar elliptic systems which arise in the preconditioner will be approximately inverted using low-complexity multilevel methods [KR00, MKR00, KM00].

Our equation system is comprised of a continuity equation,

$$\nabla \cdot \mathbf{u} = 0, \tag{1.1}$$

a set of momentum equations,

$$\frac{\partial[\rho \mathbf{u}]}{\partial t} + \nabla \cdot (\rho_l \mathbf{u}\mathbf{u}) - \nabla \cdot (\nu \nabla \mathbf{u}) = -\nabla P + \rho \mathbf{g} \beta (T - T_{ref}) - \alpha(\epsilon_s)\mathbf{u}, \tag{1.2}$$

and an energy equation for total mixture enthalpy,

$$\frac{\partial[\rho H]}{\partial t} + \nabla \cdot ([\rho H]\mathbf{u}) - \nabla \cdot (\kappa(\epsilon_s, T)\nabla T) = 0. \tag{1.3}$$

Here the mixture density and volumetric enthalpy are

$$[\rho] = \epsilon_s \rho_s + (1 - \epsilon_s)\rho_l, \;\; [\rho H] = \epsilon_s \rho_s h_s + (1 - \epsilon_s)\rho_l h_l. \tag{1.4}$$

The subscript s indicates solid, and the subscript l indicates liquid. The phase enthalpies and total enthalpy are

$$h_s = C_{p,s}T, \;\; h_l = C_{p,l}T + L, \;\; H = C_p T + (1 - \epsilon_s)L. \tag{1.5}$$

ρ is density, $\mathbf{u}$ is velocity, T is temperature, P is pressure, ϵ_s is the solid volume fraction, κ is the thermal conductivity, ν is the kinematic viscosity, α is a solid-liquid friction coefficient, β is the thermal expansion coefficient, $\mathbf{g}$ is the gravity vector, C_p is the mixture heat capacity ($C_p = \epsilon_s C_{p,s} + (1 - \epsilon_s)C_{p,l}$), and L is the latent heat of fusion. T_{ref} is the temperature around which the density is linearized for the Boussinesq approximation. The functional form for the mixture thermal conductivity is

$$\kappa(\epsilon_s, T) = \epsilon_s \kappa_s(T) + (1 - \epsilon_s)\kappa_l(T). \tag{1.6}$$

The solid phase, assumed to be stationary in this model, has the ability to absorb momentum from the fluid. The drag (friction) at the solid-liquid interface is modeled as a loss term in the momentum equations, although an artificially increased viscosity has also been used for this purpose [Dan89]. For simplicity of presentation we have also ignored the effects of solute transport and solutal buoyancy effects, which are important for alloys.

In section 2 we outline our proposed solution algorithm. It is this section which will isolate the two individual components of our preconditioning strategy to be studied in this paper. In section 3 we study separate components of the algorithm as applied to phase-change heat transfer and thermally driven incompressible flow. It is this section which contains our new results and lays the foundation for the fully coupled preconditioning strategy. Conclusions are given in section 4.

2. Solution algorithm. We use a JFNK method with segregated solution method (only scalar inversions) as a preconditioner. We have recently applied a similar approach to time dependent reaction-diffusion systems [MKR00]. Much of the material in this section is not new; however, we include it for completeness. Newton's method requires the solution of the linear system

$$\mathbf{J}^k \delta w^k = -\mathbf{F}(\mathbf{w}^k), \qquad \mathbf{w}^{k+1} = \mathbf{w}^k + S^k \delta w^k, \tag{2.1}$$

where $\mathbf{J}$ is the Jacobian matrix, $\mathbf{F}(\mathbf{w})$ is the nonlinear system of equations, $\mathbf{w}$ is the state vector, S is a damping scalar, and k is the nonlinear iteration index. The Newton iteration continues until $||\mathbf{F}(\mathbf{w}^k)||_2/||\mathbf{F}(\mathbf{w}^0)||_2$ falls below a specified tolerance. We will use 1.0×10^{-6} for this tolerance. When using a Krylov method to solve (2.1) (we are using GMRES [SS86]), the action of the Jacobian is only required in the form of matrix-vector products which can be approximated with finite differences [CJ84, BS90]. The right preconditioned form of this approximation, where $\mathbf{v}$ is a general Krylov vector, is

$$\mathbf{J}\mathbf{P}^{-1}\mathbf{v} \approx \left[\mathbf{F}(\mathbf{w} + \epsilon \mathbf{P}^{-1}\mathbf{v}) - \mathbf{F}(\mathbf{w})\right] / \epsilon, \tag{2.2}$$

where $\mathbf{P}$ is our preconditioning matrix. In this study ϵ, the perturbation parameter, is given by

$$\epsilon = \frac{1}{N||\mathbf{v}||_2} \sum_{m=1}^{N} b|w_m|, \tag{2.3}$$

where N is the linear system dimension and b is a constant whose magnitude is within a few orders of magnitude of the square root of machine roundoff ($b = 10^{-5}$ for this study), and w_m is the mth component of $\mathbf{w}$.

In the JFNK method only the matrix $\mathbf{P}$ is formed, and only the matrix $\mathbf{P}$ is iteratively inverted. There are two important decisions to make regarding $\mathbf{P}$.

1. What linearization should be used to form $\mathbf{P}$?
2. What linear iterative method should be used to solve $\mathbf{P}y = \mathbf{v}$?

It is in answering these questions where our approach becomes novel in its application to solidifying flow problems.

Additionally, we use an inexact Newton method, where the required linear convergence tolerance on a given nonlinear iteration is proportional to the nonlinear residual,

$$\parallel \mathbf{J}^k \delta w^k + \mathbf{F}(\mathbf{w}^k) \parallel_2 < \gamma \parallel \mathbf{F}(\mathbf{w}^k) \parallel_2 . \tag{2.4}$$

For this work we use a constant $\gamma = 5.0 \times 10^{-3}$.

As indicated above, we allow for damping in each Newton iteration. This damping limits the maximum change in $\mathbf{w}$ to a fixed percent per Newton iteration. This process allows for an increase in nonlinear residual but prevents thermodynamic variables from becoming unphysical (i.e., becoming negative). Our expression for the damping scalar, S, is

$$S = \min[1, \min_i(f * w_i/\delta w_i)], \tag{2.5}$$

where f is a user supplied fraction for a 20 percent allowed change, $f = 0.2$. Only the thermodynamic variables in $\mathbf{w}$ are used to evaluate S. It can be seen that S approaches unity as the Newton method produces updates which are small.

Next our preconditioning strategy is described. First, we present the strategy in general, and in the next section we present specifics. Our segregated preconditioning strategy can be viewed as belonging to a broader class of lower block triangular preconditioners, examples of which include [ES96, Kla98]. However, it is most closely related to the recent preconditioning methods put forth for thermally driven flows in [PT01]. The relationship between these approaches will be discussed more at the end of this section.

We are interested in time accurate simulation and expect, for the most part, to integrate with time steps which respect the advective time scales. This allows us to perform a simple Picard-type linearization of advection in the preconditioner without a significant increase in outer GMRES iterations. When evaluating the preconditioning operator, the advecting velocity is evaluated at the previous nonlinear iteration level. This is similar to the approach used in [ES96], except that in our approach the nonlinearity of the advection operator is treated with an outer Newton–Krylov iteration. This simplified linearization applied in the preconditioner should not be viewed as restricting the application of the method to some limited range of Reynolds numbers. It may be viewed as restricting the time step to some small multiple (say, 10) of the explicit advection stability limit. However, in practice, it has worked well on steady-state problems [KR00, KM00]. Within a time step we expect that stiffness will come from phase-change, solid-liquid friction, pressure-velocity (or stream function–vorticity) coupling, thermal body forces, and possibly the conduction and viscous operators. In this study we focus on constructing effective preconditioning for phase-change and stream function–vorticity–thermal body force coupling separately. These methods will form the foundation of a total preconditioning strategy. Again, we feel that the convergence of a Newton based method on the complete problem can be inferred from the success of [Dan89]. Our goal is to construct an effective preconditioning strategy for a more modern JFNK approach.

Consider a two-dimensional (2D) Newton system where the dependent variables are u, v, P, and H in each control volume with $\mathbf{w} = [u, v, P, H]^T$, $\delta\mathbf{w}^k = [\delta u, \delta v, \delta P, \delta H]^T$, and $\mathbf{F}(\mathbf{w}^k) = [F_u, F_v, F_P, F_H]^T$, in matrix form

$$\begin{bmatrix} J_{uu} & J_{uv} & J_{uP} & J_{uH} \\ J_{vu} & J_{vv} & J_{vP} & J_{vH} \\ J_{Pu} & J_{Pv} & 0 & 0 \\ J_{Hu} & J_{Hv} & 0 & J_{HH} \end{bmatrix} \begin{bmatrix} \delta u \\ \delta v \\ \delta P \\ \delta H \end{bmatrix} = - \begin{bmatrix} F_u \\ F_v \\ F_P \\ F_H \end{bmatrix}.$$

Here $J_{uu} = \frac{\partial F_u}{\partial u}$ (this submatrix has a dimension equal to the number of finite volumes), and F_u is the nonlinear function for the u momentum equation. The system has been written in block form, blocked by a conservation equation. The preconditioning "process" requires the mapping of a vector in a similar manner:

$$[\delta u, \delta v, \delta P, \delta H]^T = \mathbf{P}^{-1}(-[F_u, F_v, F_P, F_H]^T). \tag{2.6}$$

$\mathbf{P}$, however, has only to approximate $\mathbf{J}$. Assuming a Picard linearization for the advecting velocity, $J_{uv} = J_{vu} = J_{Hu} = J_{Hv} = 0$, and the preconditioner will be

$$\begin{bmatrix} P_{uu} & 0 & P_{uP} & P_{uH} \\ 0 & P_{vv} & P_{vP} & P_{vH} \\ P_{Pu} & P_{Pv} & 0 & 0 \\ 0 & 0 & 0 & P_{HH} \end{bmatrix} \begin{bmatrix} \delta u \\ \delta v \\ \delta P \\ \delta H \end{bmatrix} = - \begin{bmatrix} F_u \\ F_v \\ F_P \\ F_H \end{bmatrix}.$$

P_{uu} is an approximation to J_{uu}, formed by a Picard linearization, not a Newton linearization. It is a linear convection diffusion operator with a diagonal contribution from the time derivative. We need to approximate the action of $\mathbf{P}^{-1}$ on a vector. The first step of the preconditioning process is to approximately invert the phase-change heat transfer problem:

$$P_{HH}\delta H = -F_H.$$

We will focus on this step and the formation of P_{HH} in the next section. Incorporating approximate phase-change effects into P_{HH} is one of the main contributions of this paper. P_{HH} is a linear convection diffusion operator with a diagonal contribution from the time derivative, as well as phase-change. With δH, we are left with a pressure-velocity coupling problem, given by

$$\begin{bmatrix} P_{uu} & 0 & P_{uP} \\ 0 & P_{vv} & P_{vP} \\ P_{Pu} & P_{Pv} & 0 \end{bmatrix} \begin{bmatrix} \delta u \\ \delta v \\ \delta P \end{bmatrix} = - \begin{bmatrix} F_u - P_{uH}\delta H \\ F_v - P_{vH}\delta H \\ F_P \end{bmatrix}.$$

Solutions to this problem can be obtained in a number of ways. For example, a few passes of the segregated SIMPLE algorithm [Pat80] could be used. In fact, the SIMPLE algorithm has recently been used as a smoother for a multigrid (MG) preconditioner inside a JFNK method [PT01]. As is shown in [PT01], the SIMPLE algorithm effectively puts the above linear system in lower block triangular form with a required outer iteration. This can also be seen in [Wes92], where SIMPLE is discussed as an MG smoother. The performance of the SIMPLE algorithm as a solver is well documented in the enginering community, although frequently several iterations are required for convergence. When used as a preconditioner to JFNK, only a few iterations of the segregated solver are employed.

The philosophy behind our segregated preconditioner is the same as in [MKR00]. One can use an operator split, or a segregated, solution method (a non-Newton approach) as a preconditioner to an outer JFNK solver. The resulting preconditioner will have a block triangular form with an outer iteration. The individual blocks are only approximately inverted in each outer iteration of the preconditioner. This is a different approach to producing a lower block triangular preconditioner as compared to [ES96], although the resulting preconditioners are similar. Further investigation of the similarities between these approaches is clearly warranted, but it is out of the scope of current study.

In the next section we will apply a segregated (block triangular) preconditioner to a time dependent thermally driven flow problem and compare its performance to a coupled MG based preconditioner.

3. Algorithm specifics.

We have described our JFNK method and our preconditioning philosophy as applied to solidifying flow. In this section we give specific examples of algorithm application and performance, considering the phase-change heat conduction problem and thermally driven incompressible flow separately.

3.1. The phase-change heat conduction problem.

In this subsection we ignore fluid flow, assume constant density, heat capacity, and thermal conductivity, and focus on JFNK as applied to the phase-change heat conduction problem. Our initial work on this problem is detailed in [KKL99]. Here we focus on significant improvements to the formation of the preconditioner, and we demonstrate the applicability of the JFNK algorithm to a problem with multiple phase transitions. Additionally, we will briefly describe the method used for time step control on phase change problems. As stated, we use total enthalpy as a dependent variable, and thus we need to express temperature as a function of enthalpy, $T = \mathcal{T}(H)$, to perform implicit conduction. Given our assumptions, a one-dimensional (1D) version of the energy equation is

$$\frac{\partial H}{\partial t} - \frac{\kappa}{\rho}\frac{\partial}{\partial x}\left[\frac{\partial \mathcal{T}(H)}{\partial x}\right] = 0 \tag{3.1}$$

with $H = C_pT + (1-\epsilon_s)L$. An implicit discrete version of this equation is

$$F_{H,i} = \frac{H_i^{n+1} - H_i^n}{\Delta t} - \frac{\kappa}{\rho \Delta x^2}[\mathcal{T}(H_{i+1}^{n+1}) - 2\mathcal{T}(H_i^{n+1}) + \mathcal{T}(H_{i-1}^{n+1})] = 0, \tag{3.2}$$

where the diffusion operator is approximated with second order centered differences.

For a pure material (Stefan problem, isothermal solidification) with a melting temperature T_m, the function $\mathcal{T}(H)$ is given by

$$\mathcal{T}(H) = \begin{cases} H/C_p, & H < C_pT_m, \\ T_m, & C_pT_m \le H \le C_pT_m + L, \\ (H-L)/C_p, & H > C_pT_m + L, \end{cases}$$

where $\epsilon_s = 1 - \frac{H - C_pT_m}{L}$. With this function one can evaluate the nonlinear residual given a guess for H_i^{n+1}. For a more complex multicomponent system, such as a binary eutectic alloy (nonisothermal solidification), the function $\mathcal{T}(H)$ becomes more complex:

$$\mathcal{T}(H) = \begin{cases} H/C_p, & H < C_pT_{eut}, \\ T_{eut}, & C_pT_{eut} \le H \le C_pT_{eut} + (1-\epsilon_{s,eut})L, \\ (H-(1-\epsilon_s)L)/C_p, & C_pT_{eut} + (1-\epsilon_{s,eut})L \le H \le C_pT_l + L, \\ (H-L)/C_p, & H > C_pT_l + L, \end{cases}$$

where T_{eut} is the eutectic temperature, T_l is the liquidus temperature, and $\epsilon_{s,eut}$ is the solid volume fraction at T_{eut}. The region of nonisothermal solidification ($T_{eut} < T < T_l$) is referred to as the "mushy zone," where solid and liquid can coexist. In the "mushy zone," one must simultaneously satisfy the energy balance, the phase diagram, and a local scale model. In this region a small nonlinear system must be solved to extract T as a function of H.

The local scale model is a subgrid model used to account for solute diffusion in the solid. For example, if the Schiel local scale model (no solute diffusion in the solid) is being used, then the two-equation nonlinear system becomes

$$C_pT + (1-\epsilon_s)L - H = 0,$$

$$\epsilon_s + \left(\frac{T_f - T_l}{T_f - T}\right)^{-(1-k)} - 1.0 = 0. \tag{3.3}$$

Solutions to this system must be found in each finite volume in the "mushy zone." (k, T_f, T_l, and H are known.) We are solving for T and ϵ_s, using a local Newton method.

Next we need to form a preconditioning matrix, $\mathbf{M}$, which is an approximation to $\mathbf{J}$. In this subsection we refer to the preconditioning operator as $\mathbf{M}$, not $\mathbf{P}$. We do this to symbolize that we are only considering the phase-change heat conduction problem. The Jacobian for the constant property Stefan problem (isothermal solidification) is easy to form analytically [KR90].

$$\begin{aligned} J_{i,i-1} &= \frac{\partial F_i}{\partial H_{i-1}} = -\frac{\kappa}{\rho \Delta x^2}\mathcal{T}'(H_{i-1}),\\ J_{i,i} &= \frac{\partial F_i}{\partial H_i} = \frac{1}{\Delta t} + 2\frac{\kappa}{\rho \Delta x^2}\mathcal{T}'(H_i),\\ J_{i,i+1} &= \frac{\partial F_i}{\partial H_{i+1}} = -\frac{\kappa}{\rho \Delta x^2}\mathcal{T}'(H_{i+1}). \end{aligned} \tag{3.4}$$

Here, $\mathcal{T}'$ is the derivative of the temperature function with respect to enthalpy for the Stefan problem, given by

$$\mathcal{T}'(H) = \begin{cases} 1/C_p, & H < C_pT_m,\\ 0, & C_pT_m \le H \le C_pT_m + L,\\ 1/C_p, & H > C_pT_m + L. \end{cases}$$

Forming the Jacobian is not as simple for alloys (nonisothermal solidification). The simplest approximation, which we call M1, results from assuming a constant value, $\mathcal{T}'(H) = 1/C_p$, for all values of enthalpy when evaluating the preconditioning matrix $\mathbf{M}$. This is equivalent to ignoring phase change in the preconditioner and preconditioning only heat conduction. Thus each row of the preconditioning matrix becomes

$$\begin{aligned} M_{i,i-1} &= -\frac{\kappa}{\rho C_p \Delta x^2},\\ M_{i,i} &= \frac{1}{\Delta t} + 2\frac{\kappa}{\rho C_p \Delta x^2},\\ M_{i,i+1} &= -\frac{\kappa}{\rho C_p \Delta x^2}. \end{aligned} \tag{3.5}$$

This preconditioning matrix is used in [KKL99]. Here we also consider a simple improvement to this preconditioning matrix obtained by using the "effective heat capacity" approach [Dan89]. In the effective heat capacity approach the time derivative of enthalpy is transformed into a time derivative of temperature. The effective heat capacity, $\frac{dH}{dT}$, is evaluated at the previous time step.

$$\left(\frac{dH}{dT}\right)^n \frac{\partial T}{\partial t} - \frac{\kappa}{\rho}\frac{\partial}{\partial x}\left[\frac{\partial T}{\partial x}\right]^{n+1} = 0, \quad \left(\frac{dH}{dT}\right)^n = \frac{H^n - H^{n-1}}{T^n - T^{n-1}}. \tag{3.6}$$

In evaluating the improved preconditioner, M2, $\mathcal{T}'(H)^{n+1} = (\mathcal{T}(H^n+\delta H)-\mathcal{T}(H^n))/\delta H$. For both M1 and M2 five passes of symmetric Gauss–Seidel (SGS) are used to approximate $\mathbf{M}^{-1}$.

Before studying algorithm performance we briefly describe the time step control used to follow solidification fronts which we have borrowed from [RK99]. Assume that our nonlinear parabolic equation can be expressed as a hyperbolic equation, i.e.,

$$\frac{\partial H}{\partial t} - \frac{\kappa}{\rho}\frac{\partial}{\partial x}\left[\frac{\partial \mathcal{T}(H)}{\partial x}\right] = 0 \tag{3.7}$$

as

$$\frac{\partial H}{\partial t} + V_f \frac{\partial H}{\partial x} = 0. \tag{3.8}$$

We are motivated to make this assumption since many nonlinear parabolic problems, such as radiation diffusion [RK99] and phase-change heat transfer produce a solution with a hyperbolic character (a transporting front). Here V_f is the effective velocity with which the solidification front moves. If one can approximately evaluate V_f, then it can used to set a time step which does not allow the front to propagate more than one mesh spacing in one time step. We use

$$V_f = \frac{\parallel \frac{\partial H}{\partial t} \parallel_1}{\parallel \frac{\partial H}{\partial x} \parallel_1}, \quad \Delta t = C\frac{\Delta x}{V_f}, \tag{3.9}$$

evaluated on the discrete solution at the previous time step, and we choose $C \leq 1$. We have found this method for choosing the time step for solidification problems a robust way to maintain temporal accuracy.

As a first model problem we consider a 1D binary eutectic problem, which has been adapted from [SV96], in the region $0 \leq x \leq 0.4$. This problem is done in dimensional form with $C_p = 1000\frac{J}{kgK}$, $L = 4.0 \times 10^5 \frac{J}{kg}$, $\rho = 2400\frac{kg}{m^3}$, and $\kappa = 100\frac{W}{mK}$. The liquidus temperature, at an initial solute concentration of 5.0 percent, is $T_l = 904.2\ K$. The eutectic temperature is $T_{eut} = 821.2\ K$, and the melting temperature of the pure solvent is $T_f = 921.2\ K$. The slope of the liquidus line is $m_l = 3.4$, and the partition coefficient is $k = 0.15$. The initial condition for temperature is $905.2\ K$. At time equal to zero, the left boundary is set to a temperature of $621.2\ K$, and solidification proceeds. The accuracy of the solution to this problem was demonstrated in [KKL99]. Here we demonstrate the efficiency gained from the improved preconditioner (M2).

Table 1 presents results for different fixed time step sizes with the Scheil local scale model, with nx (the number of finite volumes)= 100 . We can see that M2 performs significantly better than M1. Tables 2 and 3 present results for a 2D version of this problem on different grids using a variable time step with $C = 0.25$. For this problem $0 \leq x \leq 0.4$ and $0 \leq y \leq 0.4$. The temperature on all four boundaries is set to $621.2\ K$. Again, M2 is significantly better than M1. We see the impact on the 2D problem being greater than on the 1D problem. This is because there is a larger fraction of grid cells in the solidification front. Comparing Tables 2 and 3 for the 60×60 grid, M2 has reduced the required GMRES iterations by a factor of five and has reduced the CPU time by a factor of four. It should be mentioned that over the course of the 2D simulation the variable time step increased by nearly two orders of magnitude.

Figure 1 shows the solution of the 1D problem at three different times. It is normalized to show the effect of phase change on the enthalpy field. In these plots temperature is equal to $\frac{T}{621.2}$, and enthalpy is equal to $\frac{H}{621.2C_p}$. With this normalization temperature is equal to enthalpy in the solidified region. In the pure liquid

region temperature is equal to enthalpy plus $\frac{L}{621.2C_p}$. Note that M1 ignores the jump in the enthalpy field, while M2 attempts to incorporate it.

Finally, consider a material which goes through both a solid-liquid phase transformation and then a solid-solid phase transformation. For a pure material (Stefan problem, isothermal solidification) with two phase transitions we have the following function:

$$\mathcal{T}(H) = \begin{cases} H/C_p, & H < C_pT_{m,2}; \\ T_{m,2}, & C_pT_{m,2} \leq H \leq C_pT_{m,2} + L_2; \\ (H - L_2)/C_p, & C_pT_{m,2} + L_2 \leq H \leq C_pT_{m,1} + L_2; \\ T_{m,1}, & C_pT_{m,1} + L_2 \leq H \leq C_pT_{m,1} + L_2 + L_1; \\ (H - L_2 - L_1)/C_p, & H > C_pT_{m,1} + L_1 + L_2. \end{cases}$$

Here $T_{m,1} > T_{m,2}$. Phase transition 1 occurs at temperature $T_{m,1}$ with latent heat

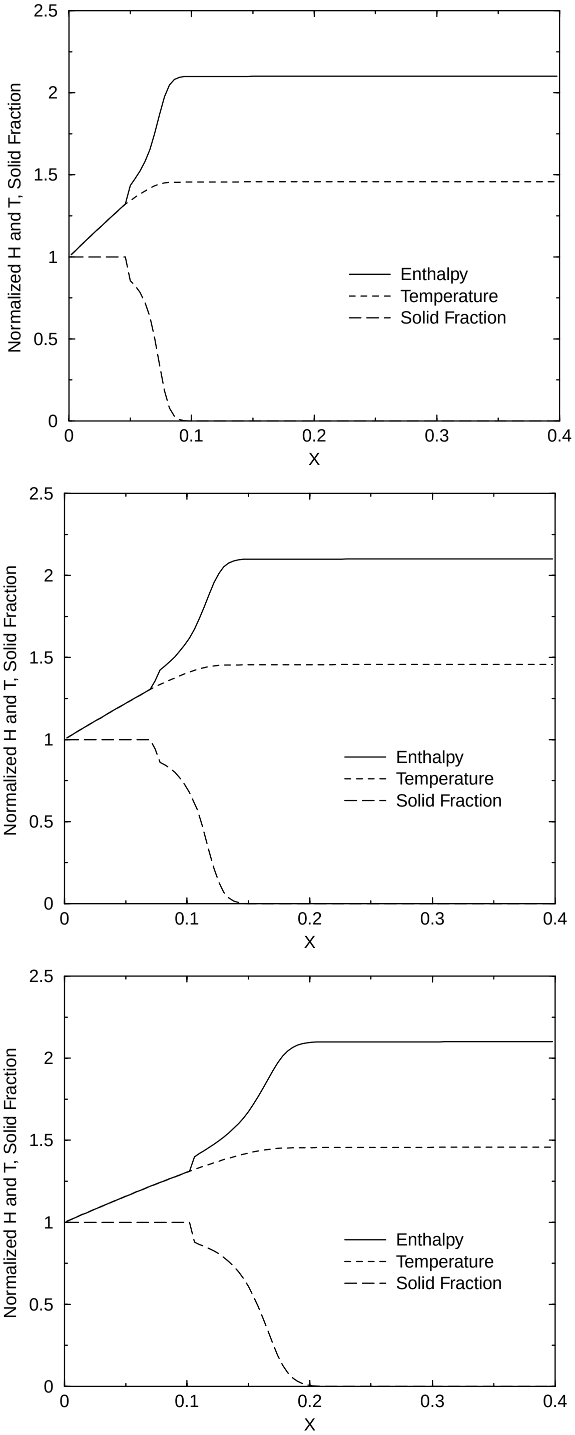

FIG. 1. *Normalized solutions of temperature, enthalpy, and solid fraction for the* 1*D binary alloy problem at* $t = 100$, 250, *and* 500.

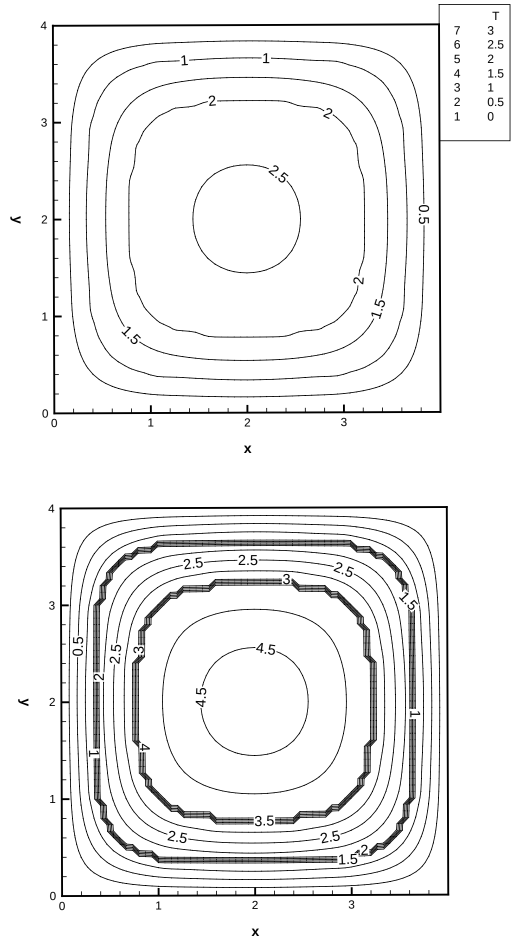

FIG. 2. *Solution of the two phase transition Stefan problem; temperature (top) and enthalpy (bottom).*

L_1. Simulation of this problem will result in the propagation of two sharp fronts. We consider a 2D model problem with an initial temperature of 3.0, $T_{m,1} = 2.0$, $T_{m,2} = 1.0$, $L_1 = L_2 = 1.0$, and $\kappa = C_p = \rho = 1.0$. At time equal to zero the boundary conditions are a zero applied temperature. Figure 2 depicts the temperature and enthalpy solution at time equal to 0.5. We see the two fronts in the enthalpy solution. The results of Table 4 show that the improved preconditioner (M2) makes a positive impact on this problem as well, decreasing the required CPU time by as much as a factor of two.

3.2. Prototype flow solver. In this subsection we demonstrate algorithmic performance of our distributed preconditioner on a thermally driven incompressible flow problem. We consider a time dependent version of the natural convection model problem in stream function (ψ), vorticity (ω), and temperature (T) form [Dav83]. Here the pressure-velocity coupling has been transfromed into a stream function–vorticity coupling. The boundary conditions on the ω equation are a function of ψ, and the source term for the ψ equation is ω. This is a stiff coupling, and our pre-

TABLE 4

60x60, M2	50	3.67	2.0	10.9

conditioning strategy must contain an iteration on this coupling to be effective. The Newton–Krylov method is used for the solution of the fully coupled system (including implicit advection).

$$\nabla^2\psi = \omega, \tag{3.10}$$

$$\frac{\partial\omega}{\partial t} + \nabla\cdot(\vec{V}\omega) - \frac{1}{Re}\nabla^2\omega = \frac{Gr}{Re^2}\nabla_x T, \tag{3.11}$$

$$\frac{\partial T}{\partial t} + \nabla\cdot(\vec{V}T) - \frac{1}{Re\;Pr}\nabla^2 T = 0 \tag{3.12}$$

with $\vec{V} = u\hat{x} + v\hat{y}$, $u = \frac{\partial\psi}{\partial y}$, and $v = -\frac{\partial\psi}{\partial x}$. Here Re is the Reynolds number, Gr is the Grashof number, and Pr is the Prandtl number. As in [Dav83], we use $Re = 1$ and $Pr = 0.71$. Note that in this nondimensionalization the maximum velocity is proportional to Gr. Thus, for large Gr, convection will dominate diffusion even for $Re = 1$. We use centered differences in space and forward differences in time. Time step size will be such that the explicit limit based on advection is not severely violated. This choice of time step is motivated by time accuracy not stability. The preconditioner employs a Picard linearization for the advection terms in (3.11) and (3.12), and $\mathbf{P}^{-1}$ results from an approximate inverse of a segregated system. Note that (3.10) has no time derivative and is therefore purely elliptic. A low-complexity MG method [KR00, MKR00, KM00] is used to solve the separate (scalar) elliptic problems. Our preconditioning system is

$$\begin{bmatrix} P_{\psi\psi} & P_{\psi\omega} & 0 \\ P_{\omega\psi} & P_{\omega\omega} & P_{\omega T} \\ 0 & 0 & P_{TT} \end{bmatrix} \begin{bmatrix} \delta\psi \\ \delta\omega \\ \delta T \end{bmatrix} = - \begin{bmatrix} F_\psi \\ F_\omega \\ F_T \end{bmatrix}.$$

Here $P_{\psi\psi} = \nabla^2$, $P_{\psi\omega}$ is the source term coupling in (3.10), and $P_{\omega\psi}$ results from boundary condition on (3.11) being a function of ψ. The coupling from $P_{\psi\omega}$ and $P_{\omega\psi}$ can be represented as a 2 x 2 matrix at each finite volume. The two parabolic operators are

$$P_{TT} = \frac{I}{\Delta t} + \vec{V}^n\cdot\nabla - \frac{1}{Re\;Pr}\nabla^2$$

and

$$P_{\omega\omega} = \frac{I}{\Delta t} + \vec{V}^n\cdot\nabla - \frac{1}{Re}\nabla^2,$$

where $\vec{V}^n$ is the velocity at the previous Newton step.

The approximation to

$$\begin{bmatrix} \delta\psi \\ \delta\omega \\ \delta T \end{bmatrix} = -\mathbf{P}^{-1} \begin{bmatrix} F_\psi \\ F_\omega \\ F_T \end{bmatrix}$$

proceeds as follows.

Step 1. One MG V-cycle on

$$P_{TT}\delta T = -F_T.$$

Step 2. This step requires the solution of

$$\begin{bmatrix} P_{\psi\psi} & P_{\psi\omega} \\ P_{\omega\psi} & P_{\omega\omega} \end{bmatrix} \begin{bmatrix} \delta\psi \\ \delta\omega \end{bmatrix} = - \begin{bmatrix} F_\psi \\ F_\omega - P_{\omega T}\delta T \end{bmatrix},$$

which is similar to pressure-velocity coupling, since it has an elliptic constraint. With $\bar{F}_\omega = F_\omega - P_{\omega T}\delta T$, step 2 proceeds in three separate steps (a,b,c).

2a. Solve

$$\begin{bmatrix} 0 & P_{\psi\omega} \\ P_{\omega\psi} & 0 \end{bmatrix} \begin{bmatrix} \delta\psi^* \\ \delta\omega^* \end{bmatrix} = - \begin{bmatrix} F_\psi \\ \bar{F}_\omega \end{bmatrix},$$

which is a 2 × 2 matrix at each control volume.

2b. Next, approximately solve

$$P_{\omega\omega}\delta\omega^{**} = \bar{F}_\omega - P_{\omega\psi}\delta\psi^*,$$

$$P_{\psi\psi}\delta\psi^{**} = F_\psi - P_{\psi\omega}\delta\omega^*,$$

which requires two separate MG solves, each only one V-cycle.

2c. Finally, solve

$$\begin{bmatrix} 0 & P_{\psi\omega} \\ P_{\omega\psi} & 0 \end{bmatrix} \begin{bmatrix} \delta\psi \\ \delta\omega \end{bmatrix} = - \begin{bmatrix} F_\psi - P_{\psi\psi}\delta\psi^{**} \\ \bar{F}_\omega - P_{\omega\omega}\delta\omega^{**} \end{bmatrix},$$

which is again a 2 x 2 matrix at each control volume. Thus approximating the action of $\mathbf{P}^{-1}$ on a vector requires three separate (scalar) MG V-cycles and two sweeps of a block 2 × 2 matrix on the fine grid. The 2 × 2 matrix solves which incorporate the stiff stream function–vorticity coupling in the preconditioner (and their placement) is crucial to the performance of this approach. As in [KR00, MKR00], the MG here uses piecewise constant restriction and prolongation and a Galerkin coarse grid operator. SGS is used as the smoother. We have also used a coupled MG method for this problem. Here the smoother is a block SGS, where the block is a 3 × 3 matrix coupling the unknowns at a cell [KR00, KM00].

Our model problem is a fixed number of time steps for a simulation with $Gr = 1.0 \times 10^6$. The initial conditions are a steady-state solution for $Gr = 1.0 \times 10^3$. We take a fixed number of constant time steps and collect performance data. Since we wish to have the same advective Courant number $(u\frac{\Delta t}{\Delta x})$ on each grid, the time step is reduced as the grid is refined. Figure 3 shows the steady-state temperature for $Gr = 1.0 \times 10^3$ and $Gr = 1.0 \times 10^6$.

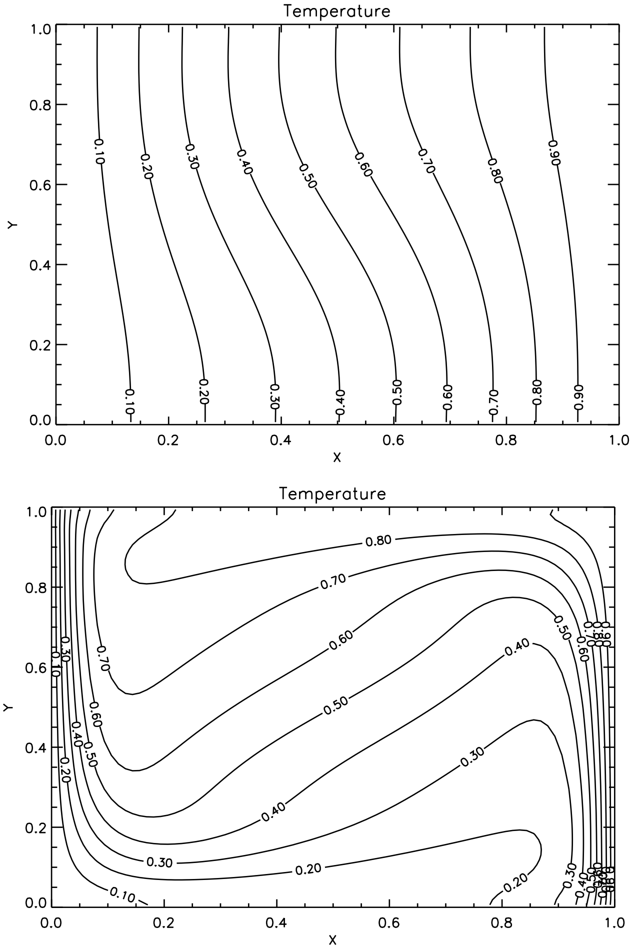

FIG. 3. *Temperature solution of natural convection problem; Gr* $= 1.0 \times 10^3$ *(top) and* 1.0×10^6 *(bottom).*

The performance on 40 × 40, 80 × 80, and 160 × 160 grids is given in Tables 5 through 7. In the nondimensionalization of this problem the maximum "effective" Reynolds number is equivalent to the peak velocity. For the problem considered this is approximately 1000 at the end of the simulation. Both algorithmic and CPU scalings are good for the MG methods. The coupled MG results in the fewest Krylov iterations per Newton iteration, while the segregated MG method produces the lowest

Table 6

MG coup.	10	4.0	3.6	3.2

CPU times. Both MG methods outperform an ILU(0) preconditioner. Note that both the coupled MG and ILU(0) preconditioners are approximately inverting a $3N \times 3N$ matrix, while the segregated MG method is approximately inverting three $N \times N$ matrices. For interest, Table 8 presents data for the 80×80 grid using a time step which is four times larger than that of Table 6. We can see that the CPU savings, for using a time step which is four times larger, are slightly better than a factor of two. We mention that this segregated preconditioner has previously been shown to perform well for a steady-state version for this problem with $Gr = 1.0 \times 10^7$ on a 320×320 grid [KM00] (a maximum Reynolds number of approximately 5000). Also, results in [PT01] have shown a similar segregated preconditioner to perform well on the lid-driven cavity problem at a Reynolds number of 10,000.

4. Conclusions. We have presented a model set of equations for solidifying flow and have presented a JFNK method for the solution of these equations. We have discussed a segregated solution procedure as a preconditioner, and we have studied specific issues of algorithmic performance on the phase-change heat conduction problem and thermally driven incompressible flow separately. These results will form the foundation of a preconditioning strategy for the fully coupled problem

In the phase-change heat conduction problem, a preconditioner which incorporated the effective heat capacity method was shown to be superior to a preconditioner which only used heat conduction. Comparing Tables 2 and 3 for the 60×60 grid, the effective heat capacity preconditioner reduced the required GMRES iterations by a factor of five and reduced the CPU time by a factor of four. Additionally, the JFNK method was shown to perform well on a problem which contained two phase transitions.

In the thermally driven incompressible flow problem, a segregated preconditioner using a low-complexity MG on each equation was presented. The relationship to other block triangular preconditioners for the Navier–Stokes equations was briefly discussed. The segregated preconditioner was compared to a coupled MG based preconditioner. The segregated preconditioner was shown to be competitive in terms of outer GMRES iterations while being superior in terms of CPU perfromance. The CPU advantage of the segregated preconditioner was shown to grow with increasing problem size, growing to nearly a factor of two on the 160 × 160 grid.

Acknowledgment. The authors would like to thank Mike Pernice for his discussions on block triangular preconditioners for the Navier–Stokes equations.

A MULTIGRID-PRECONDITIONED NEWTON–KRYLOV METHOD FOR THE INCOMPRESSIBLE NAVIER–STOKES EQUATIONS[*]

M. PERNICE[†] AND M. D. TOCCI[‡]

Abstract. Globalized inexact Newton methods are well suited for solving large-scale systems of nonlinear equations. When combined with a Krylov iterative method, an explicit Jacobian is never needed, and the resulting matrix-free Newton–Krylov method greatly simplifies application of the method to complex problems. Despite asymptotically superlinear rates of convergence, the overall efficiency of a Newton–Krylov solver is determined by the preconditioner. High-quality preconditioners can be constructed from methods that incorporate problem-specific information, and for the incompressible Navier–Stokes equations, classical pressure-correction methods such as SIMPLE and SIMPLER fulfill this requirement. A preconditioner is constructed by using these pressure-correction methods as smoothers in a linear multigrid procedure. The effectiveness of the resulting Newton–Krylov-multigrid method is demonstrated on benchmark incompressible flow problems.

Key words. Newton–Krylov methods, multigrid preconditioning, pressure-correction smoothers

1. Introduction.

Efficient solution of the steady-state incompressible Navier–Stokes equations

$$\begin{aligned} (uu)_x + (uv)_y - \tfrac{1}{Re}\Delta u + p_x &= f_1, \\ (uv)_x + (vv)_y - \tfrac{1}{Re}\Delta v + p_y &= f_2, \\ u_x + v_y &= 0, \end{aligned} \tag{1.1}$$

where Re is the Reynolds number, has been a problem of central importance in computational science and engineering since its inception. Methods for solving (1.1) can also be leveraged to solve the systems of nonlinear equations that arise when an implicit method is used to solve the unsteady incompressible Navier–Stokes equations. Early efforts were constrained by limited memory capacity and were often based on strategies that involved solving a series of simplified and lower-dimensional problems. The simplifications generally arose from application of operator-splitting strategies, and solutions of individual equations were often built from iterative methods based on line solves. Pressure-correction algorithms such as SIMPLE [29] and SIMPLER [28] are typical of these approaches. While frugal in their use of memory, these methods lack theoretical foundations and converge slowly. Moreover, these convergence rates degrade with increasing problem size. Despite these drawbacks, pressure-correction methods are still in widespread use in production engineering

codes. Consequently, there is great interest in exploring strategies for accelerating the convergence of pressure-correction methods while minimizing changes in software and data structures.

Recent decades have seen considerable progress in the development of new approaches for solving large-scale nonlinear problems, in particular, globalized inexact Newton methods [11, 12, 13]. The major shortcoming of classical Newton methods is the need to solve a large-scale system of linear equations at each iteration. Inexact Newton methods address this by using an iterative method to solve this system of equations to less than full accuracy. Inexact Newton methods can be considerably more expensive than the classical pressure-correction techniques, but rapid increases in both the speed and capacity of computing resources make it practical to consider inexact Newton methods for incompressible flow problems. At the same time, the desire to address new classes of problems sometimes makes it necessary to consider these methods.

Since their introduction, inexact Newton methods have been successfully applied to a large variety of nonlinear problems: integral equation descriptions of equilibrium states of liquid surfaces [3], multiphase flow in porous media [9, 43], radiation-diffusion problems [32, 27, 5], reacting flows [20, 21, 35], aerodynamics calculations [7, 6], and incompressible flow problems [25, 19, 22, 23]. While by no means exhaustive, these applications represent a cross-section of preconditioning strategies currently in use. Incomplete LU (ILU) factorizations [26, 33] are popular choices, but they require information about the Jacobian that may be difficult to determine in a matrix-free inexact Newton method. Depending on the amount of element fill-in that is allowed, ILU preconditioners can have high storage requirements. Calculating an ILU preconditioner can also be computationally expensive, and this cost is multiplied by the number of times the preconditioner is updated during the nonlinear solution process.

A notable trend reflected in this list of applications of Newton–Krylov methods is the use of multigrid methods as preconditioners [43, 32, 5, 22, 23]. While multigrid methods are highly efficient solvers on their own, they also serve as excellent preconditioners, and their use in this context makes the performance and robustness of the multigrid method less sensitive to the selection of components such as intergrid transfers and coarse grid solvers. Multigrid methods can be tailored to specific problems by selection of an appropriate smoother; it has been known for some time that SIMPLE can be used as a multigrid smoother [36, 37], and it has recently been demonstrated that SIMPLER can also be used as a smoother in a multigrid procedure [30]. In contrast to prior work on Newton–Krylov-multigrid (NK-MG) methods [22, 23], pressure-correction methods work directly on the primitive variable formulation (1.1) and so are readily extendible to problems in three dimensions. Also in contrast to prior work applying Newton–Krylov methods to incompressible flow problems [25], a multigrid preconditioner represents a considerable savings in storage and setup time over an ILU-based preconditioner. The combination of an NK-MG method with a pressure-correction smoother may also be regarded as a means for accelerating the convergence of the pressure-correction scheme; however, patterns of use of the pressure-correction methods must be reexamined in order to use them effectively in this context.

This paper is organized as follows. First, some notation is introduced. Following this, the relevant algorithmic components are described in section 3. The effectiveness of combining Newton–Krylov methods with multigrid preconditioners equipped with pressure-correction smoothers is examined in section 4. These results are summarized and some conclusions are drawn in section 5.

2. Notation. Pressure-correction methods have traditionally been developed for staggered grid discretizations [29, 28], and that convention is adhered to in this work. In this arrangement of variables, originally presented in [18], the domain is divided into a number of cells, with the horizontal component of velocity centered on vertical cell faces, vertical components of velocity centered on horizontal cell faces, and pressure located at cell centers. A second-order centered discretization of the Navier–Stokes equations (1.1) on a staggered grid produces a set of nonlinear equations $F(\mathbf{u}, p) = 0$, which may be written in block matrix form as

$$F(\mathbf{u}, p) = \mathcal{Q}[\mathbf{u}] \begin{pmatrix} \mathbf{u} \\ p \end{pmatrix} - \begin{pmatrix} \mathbf{f} \\ 0 \end{pmatrix}, \tag{2.1}$$

where

$$\mathcal{Q}[\mathbf{u}] = \begin{pmatrix} \mathbf{Q}[\mathbf{u}] & \nabla^h \\ \nabla^h\cdot & 0 \end{pmatrix}.$$

In this,

$$\mathbf{Q}[\mathbf{u}] = \begin{pmatrix} Q_1[\mathbf{u}] & 0 \\ 0 & Q_2[\mathbf{u}] \end{pmatrix} \tag{2.2}$$

is the discrete momentum operator, ∇^h is a discrete gradient operator, $\nabla^h\cdot$ is a discrete divergence operator,

$$\mathbf{u} = \begin{pmatrix} u \\ v \end{pmatrix}$$

is the discrete velocity field, and

$$\mathbf{f} = \begin{pmatrix} f_1 \\ f_2 \end{pmatrix}$$

represents the body force.

Implicit methods for solving the time dependent version of the Navier–Stokes equations can be accommodated with a few minor modifications. If a backward Euler method is used to discretize the time derivative, the discrete momentum operator becomes

$$\mathbf{Q}[\mathbf{u}] = \begin{pmatrix} Q_1[\mathbf{u}] + u/\Delta t & 0 \\ 0 & Q_2[\mathbf{u}] + v/\Delta t \end{pmatrix},$$

and the set of nonlinear equations to be solved at each time step is

$$F(\mathbf{u}, p) = \mathcal{Q}[\mathbf{u}] \begin{pmatrix} \mathbf{u} \\ p \end{pmatrix} - \frac{1}{\Delta t} \begin{pmatrix} \mathbf{u}^n \\ 0 \end{pmatrix} - \begin{pmatrix} \mathbf{f} \\ 0 \end{pmatrix},$$

where $\mathbf{u}^n$ is the velocity at the previous time step.

3. Algorithms. This section describes the basic ingredients that are used to construct the NK-MG method. The discussion begins with a description of the inexact Newton method that will be used. This is followed by a discussion of classical pressure-correction methods and their use as smoothers in the multigrid preconditioner.

3.1. Inexact Newton methods. Newton's method for solving a system of nonlinear equations

$$F(x) = 0$$

requires, at the kth step, the solution of the linear *Newton equation*

$$F'(x_k)\, s_k = -F(x_k), \tag{3.1}$$

where x_k is the current approximate solution and F' is the Jacobian matrix of the system. Once the Newton step s_k is determined, the current approximation is updated via

$$x_{k+1} = x_k + s_k.$$

This process is continued until a satisfactory solution is found, which is usually judged by making $\|F(x_k)\|$ or $\|s_k\|$ (or both) sufficiently small. Traditionally, Newton's method was considered to be inappropriate for the solution of large-scale systems of nonlinear equations because of the high computational and storage costs of solving (3.1). However, Newton's method will still converge even if (3.1) is not solved exactly; indeed, under some circumstances an exact solution of (3.1) is undesirable. This can be seen by noting that (3.1) is obtained from a linearization of $F(x_k) = 0$ around x_k, which is valid only in a neighborhood of x_k. If the solution of (3.1) produces an s_k that is too large, there may be poor agreement between F and its local linear model, and the effort expended to accurately compute s_k may be wasted. Examples that illustrate this behavior appear in [13, 35].

Newton iterative methods relax the requirement to solve (3.1) exactly to an *inexact Newton condition* [11]

$$\|F(x_k) + F'(x_k)\, s_k\| \le \eta_k \|F(x_k)\|, \tag{3.2}$$

in which the "forcing term" $\eta_k \in (0, 1)$ can be specified either statically or dynamically [13] to enhance efficiency and convergence. The optimal choice of η_k is somewhat problem-specific; see, for example, [35] for some comparative studies. Nevertheless, superlinear and even quadratic convergence of the inexact Newton method can be obtained under certain choices of the forcing terms [11, 13]. In this work, an initial η_k is dynamically determined using a slight modification of the strategy from [13] labeled Choice 1. There, safeguards that prevent η_k from getting too small too quickly are disabled once η_k drops below a certain threshold. In this work, these safeguards are retained throughout the computation.

There are many ways to compute an inexact Newton step s_k that satisfies (3.2), and the efficiency of an inexact Newton method is strongly affected by this choice. Krylov subspace methods [15] are especially well suited for this purpose since they require only matrix-vector products $F'(x_k)v$. This further specialization of inexact Newton methods leads to the class of methods referred to as *Newton–Krylov methods.* The matrix-vector products needed in a Newton–Krylov method may be approximated with finite differences of function values

$$F'(x_k)v \approx \frac{F(x_k + \epsilon v) - F(x_k)}{\epsilon}, \tag{3.3}$$

and so the Jacobian F' never needs to be explicitly formed. Because the Jacobian matrix is neither formed nor stored, this approach is frequently referred to as a *matrix-free Newton–Krylov* method. While this greatly reduces storage requirements and simplifies implementation, the differencing parameter ϵ must be chosen carefully. Furthermore, some information about the Jacobian is still needed to construct a preconditioner. Finally, a matrix-free Newton–Krylov method generally requires more nonlinear iterations than a Newton–Krylov method that uses the Jacobian directly.

Among Krylov subspace methods, GMRES [34] is generally preferred, since it minimizes the residual at every iteration. Unfortunately, in order to enforce this, the work and storage requirements per iteration grow linearly with the number of iterations. In practice, this is dealt with by restarting the method, which can potentially slow down convergence or even cause divergence if restarting is done too frequently. Alternatives such as BiCGSTAB [38] and transpose-free QMR [14] can be used; however, they do not share the minimum residual property and, when used in a matrix-free Newton–Krylov method, are generally not as robust as GMRES [24], provided a sufficiently large restart value is used.

Finally, another traditional objection to using Newton's method for large-scale problems is the need to find a good initial approximation x_0. Newton's method (and its inexact counterpart) can fail to converge if x_0 is not chosen carefully. Fortunately, classical strategies for improving the likelihood of convergence from a poor initial approximation also apply to inexact Newton methods [12]. The backtracking globalization strategy given in Algorithm Inexact Newton Backtracking (INB) from [12] is employed in this work.

ALGORITHM 3.1 (INB [12]).

```
Let $x_0$, $\eta_{\max} \in [0,1)$, $t \in (0,1)$, and $0 < \theta_{\min} < \theta_{\max} < 1$ be given.
For $k = 0, 1, \ldots$ (until convergence) do:
    Choose initial $\eta_k \in [0, \eta_{\max}]$ and $s_k$ such that
        $\|F(x_k) + F'(x_k)\, s_k\| \le \eta_k \|F(x_k)\|$.
    While $\|F(x_k + s_k)\| > [1 - t(1 - \eta_k)]\, \|F(x_k)\|$ do:
        Choose $\theta \in [\theta_{\min}, \theta_{\max}]$.
        Update $s_k \longleftarrow \theta s_k$ and $\eta_k \longleftarrow 1 - \theta(1 - \eta_k)$.
    Set $x_{k+1} = x_k + s_k$.
```

In this, backtracking is invoked when the trial Newton iterate $x_k + s_k$ fails to adequately reduce $\|F\|$. This is determined by comparing the *actual reduction* in $\|F\|$,

$$\|F(x_k)\| - \|F(x_k + s_k)\|,$$

with the *predicted reduction*

$$\|F(x_k)\| - \eta_k \|F(x_k)\| = (1 - \eta_k)\|F(x_k)\|.$$

If the actual reduction exceeds some fraction t of the predicted reduction, then the step is accepted. The value $t = 10^{-4}$ is used to judge sufficient reduction, leading to acceptance of a step that produces even minimal reduction in $\|F\|$. If this criterion is not met, the step is damped by a factor θ that is chosen to minimize a quadratic that interpolates $\|F\|$ in the direction of s_k. Backtracking safeguard values $\theta_{\min}$ and $\theta_{\max}$ provide bounds on the step reduction and are given by 0.1 and 0.5, respectively. Once the Newton step is damped, the predicted reduction in $\|F\|$ is then approximated by noting

$$\begin{aligned}\|F(x_k+\theta s_k)\| &\approx \|F(x_k)+\theta F'(x_k)s_k\| \\ &\leq \theta\|F(x_k)+F'(x_k)s_k\|+(1-\theta)\|F(x_k)\| \\ &\leq (1-\theta(1-\eta_k))\|F(x_k)\|.\end{aligned}$$

This leads to the adjustment in the forcing term indicated in Algorithm INB, which is used either in the next pass through the backtracking loop or as an initial value in the selection of the forcing term for the next Newton iteration.

3.2. Pressure-correction methods. The pressure-correction methods SIMPLE and SIMPLER can be used to incorporate information that is specific to the incompressible Navier–Stokes equations into the preconditioner. These methods are described in this section. In the following, the dependence of the momentum transport operator (2.2) on $\mathbf{u}$ is suppressed.

3.2.1. SIMPLE. The SIMPLE algorithm, introduced in [29], begins by approximately solving the momentum equations, and then uses the discretized form of the continuity equation to derive an equation whose solution is used both to update the pressure field and to correct the velocity field so that mass is conserved. To begin with, the discrete momentum transport operator $\mathbf{Q}$ is updated to reflect the current approximate solution $\mathbf{u}^{(n)}$ to the momentum equations. The resulting linearized momentum equations can then be solved to determine an intermediate velocity field $\mathbf{u}^{(n+\frac{1}{2})}$ using the current approximate pressure field $p^{(n)}$:

$$\mathbf{Q}\mathbf{u}^{(n+\frac{1}{2})} = \mathbf{f} - \nabla^h p^{(n)}. \tag{3.4}$$

The resulting velocity field $\mathbf{u}^{(n+\frac{1}{2})}$ does not satisfy the continuity equation, and the residual of this equation is used to compute a correction δp to the pressure field whose gradient is also used to correct $\mathbf{u}^{(n+\frac{1}{2})}$.

To derive an equation for δp, let

$$\mathbf{D} = \operatorname{diag}\mathbf{Q}, \tag{3.5}$$

and introduce the approximations

$$\begin{array}{ccccc}\mathbf{u}^{(n+\frac{1}{2})} & \approx & \mathbf{D}^{-1}\mathbf{Q}\mathbf{u}^{(n+\frac{1}{2})} & = & \mathbf{D}^{-1}(\mathbf{f}-\nabla^h p^{(n)}), \\ \mathbf{u}^{(n+1)} & \approx & \mathbf{D}^{-1}\mathbf{Q}\mathbf{u}^{(n+1)} & = & \mathbf{D}^{-1}(\mathbf{f}-\nabla^h p^{(n+1)}).\end{array} \tag{3.6}$$

Subtracting these equations and changing the approximation to equality leads to

$$\delta\mathbf{u} \equiv \mathbf{u}^{(n+1)} - \mathbf{u}^{(n+\frac{1}{2})} = -\mathbf{D}^{-1}\nabla^h\delta p, \tag{3.7}$$

where $\delta p = p^{(n+1)} - p^{(n)}$. Applying the discrete divergence operator to these equations gives

$$\nabla^h\cdot(\mathbf{u}^{(n+1)} - \mathbf{u}^{(n+\frac{1}{2})}) = \nabla^h\cdot\mathbf{D}^{-1}\nabla^h\delta p.$$

Finally, requiring $\nabla^h\cdot\mathbf{u}^{(n+1)} = 0$ leads to

$$S\delta p = \nabla^h\cdot\mathbf{u}^{(n+\frac{1}{2})}, \tag{3.8}$$

where

$$S = -\nabla^h\cdot\mathbf{D}^{-1}\nabla^h \tag{3.9}$$

is symmetric. Equation (3.8) is a generalized Poisson equation which must be solved for the pressure correction δp. Since the intended correction (3.7) should be 0 at locations where the velocity field is specified, (3.8) is supplemented with homogeneous boundary conditions at these locations. In particular, for problems where the velocity field is specified at the boundaries, δp is determined only up to an additive constant, and S is positive semidefinite. Summarizing, we have the following algorithm.

ALGORITHM 3.2 (SIMPLE).

Determine $\mathbf{u}^{(n+\frac{1}{2})}$ *by solving* (3.4).

Find the pressure correction δp *from* (3.8).

Calculate the velocity corrections $\delta\mathbf{u}$ *using* (3.7).

Update the pressure

$$p^{(n+1)} = p^{(n)} + \delta p$$

and the velocities

$$\mathbf{u}^{(n+1)} = \mathbf{u}^{(n+\frac{1}{2})} + \delta\mathbf{u}.$$

Remark 3.1. In practice the pressure update is damped by a factor $\alpha \in (0,1]$:

$$p^{(n+1)} = p^{(n)} + \alpha\delta p.$$

Remark 3.2. SIMPLEC is a variation that replaces the entries in the diagonal matrices D_i with absolute rowsums from Q_i [39]. This variation is used in this work.

Remark 3.3. Observe that

$$\begin{pmatrix} \mathbf{u}^{(n+1)} \\ p^{(n+1)} \end{pmatrix} = \begin{pmatrix} \mathbf{u}^{(n)} \\ p^{(n)} \end{pmatrix} + \begin{pmatrix} \mathbb{I} & -\mathbf{D}^{-1}\nabla^h \\ 0 & \alpha\mathbb{I} \end{pmatrix} \begin{pmatrix} \mathbf{Q} & 0 \\ \nabla^h\cdot & S \end{pmatrix}^{-1} \mathbf{r}^{(n)}, \tag{3.10}$$

where $\mathbb{I}$ is an identity operator of the appropriate dimension and

$$\mathbf{r}^{(n)} = \begin{pmatrix} \mathbf{f} \\ 0 \end{pmatrix} - \mathcal{Q}\begin{pmatrix} \mathbf{u}^{(n)} \\ p^{(n)} \end{pmatrix}$$

is the residual of the system. This representation can be derived by employing the notion of transforming smoothers; see [42, 41].

Remark 3.4. When SIMPLE is used as a solver, the inversion in (3.10) is not computed exactly. This practice is followed when using SIMPLE as a smoother: the momentum equations are approximately solved with five sweeps of the point Gauss–Seidel method, and the pressure correction equation is solved with twenty sweeps of point Gauss–Seidel. These values were empirically determined to strike a good balance between cost and effectiveness of the preconditioner.

3.2.2. SIMPLER. SIMPLER is a variation due to Patankar [28]. It is similar to SIMPLE, but it determines $p^{(n+1)}$ from $\mathbf{u}^{(n)}$ and uses a separate potential field ϕ to enforce continuity in a manner similar to projection methods [8, 2].

As with SIMPLE, each cycle begins with an update of the momentum transport operator (2.2) to reflect the latest approximate solution $\mathbf{u}^{(n)}$. For the next iteration the pressure and velocity field should satisfy

$$\mathbf{Q}\mathbf{u}^{(n+1)} = \mathbf{f} - \nabla^h p^{(n+1)}.$$

To determine an equation for $p^{(n+1)}$, introduce the splitting $\mathbf{Q} = \mathbf{D} - (\mathbf{L} + \mathbf{U})$, where $\mathbf{D}$ is again given by (3.5) and $-(\mathbf{L} + \mathbf{U})$ are the off-diagonal elements of $\mathbf{Q}$. It follows that

$$\begin{aligned} \mathbf{u}^{(n+1)} &= \mathbf{D}^{-1}(\mathbf{f} + (\mathbf{L} + \mathbf{U})\mathbf{u}^{(n+1)} - \nabla^h p^{(n+1)}) \\ &\approx \mathbf{D}^{-1}(\mathbf{f} + (\mathbf{L} + \mathbf{U})\mathbf{u}^{(n)} - \nabla^h p^{(n+1)}). \end{aligned} \tag{3.11}$$

Taking the divergence of both sides of (3.11), requiring that $\nabla^h \cdot \mathbf{u}^{(n+1)} = 0$, changing the approximation to equality, and rearranging terms lead to

$$Sp^{(n+1)} = -\nabla^h \cdot \mathbf{D}^{-1}(\mathbf{f} + (\mathbf{L} + \mathbf{U})\mathbf{u}^{(n)}), \tag{3.12}$$

where S is again given by (3.9).

Once the updated pressure field is known, the updated velocity field is found by first solving

$$\mathbf{Q}\mathbf{u}^{(n+\frac{1}{2})} = \mathbf{f} - \nabla^h p^{(n+1)} \tag{3.13}$$

and then correcting $\mathbf{u}^{(n+\frac{1}{2})}$ so that the updated velocity field conserves mass. This is done using the gradient of an auxiliary variable ϕ. To determine an equation for ϕ, the following *ansatz* is made for the correction:

$$\mathbf{u}^{(n+1)} = \mathbf{u}^{(n+\frac{1}{2})} - \mathbf{D}^{-1}\nabla^h \phi. \tag{3.14}$$

An equation for ϕ is then determined by requiring that $\nabla^h \cdot \mathbf{u}^{(n+1)} = 0$:

$$\begin{aligned} 0 &= \nabla^h \cdot \mathbf{u}^{(n+1)} \\ &= \nabla^h \cdot \mathbf{u}^{(n+\frac{1}{2})} + S\phi, \end{aligned} \tag{3.15}$$

where S is again given by (3.9). Summarizing, we have the following algorithm.

Algorithm 3.3 (SIMPLER).
Determine $p^{(n+1)}$ by solving (3.12).
Determine $\mathbf{u}^{(n+\frac{1}{2})}$ by solving (3.13).
Determine ϕ by solving (3.15).
Correct $\mathbf{u}^{(n+\frac{1}{2})}$ using (3.14).

Remark 3.5. The correction (3.14) may be described in terms of a projection:

$$\begin{aligned} \mathbf{u}^{(n+1)} &= \mathbf{u}^{(n+\frac{1}{2})} + \mathbf{D}^{-1}\nabla^h S^{-1}\nabla^h \cdot \mathbf{u}^{(n+\frac{1}{2})} \\ &= \left(\mathbb{I} + \mathbf{D}^{-1}\nabla^h S^{-1}\nabla^h \cdot\right)\mathbf{u}^{(n+\frac{1}{2})} \\ &\equiv \mathbb{P}\mathbf{u}^{(n+\frac{1}{2})}. \end{aligned}$$

From (3.9) it follows that $\mathbb{P}^2 = \mathbb{P}$. Thus $\mathbb{P}$ is actually a *projection* (though it is not an *orthogonal* projection with respect to the standard inner product).

3.2.3. Alternative description. In order to employ SIMPLER as either a preconditioner or a smoother in a linear multigrid method, the method must be recast in a form that operates on residuals, analogous to (3.10). To derive such a representation, observe that

$$\begin{pmatrix} \mathbf{u}^{(n+\frac{1}{2})} \\ p^{(n+1)} \end{pmatrix} = \mathcal{M}^{-1} \begin{pmatrix} \mathbf{f} \\ -\nabla^h \cdot \mathbf{D}^{-1}(\mathbf{f} + (\mathbf{L} + \mathbf{U})\mathbf{u}^{(n)}) \end{pmatrix}, \tag{3.16}$$

where

$$\mathcal{M} = \begin{pmatrix} \mathbf{Q} & \nabla^h \\ 0 & S \end{pmatrix}.$$

The residual $\mathbf{r}^{(n)}$ may be partitioned into components r_1, r_2 that correspond, respectively, to the momentum and continuity equations. Then note that

$$\mathbf{Q}\mathbf{u}^{(n)} + \nabla^h p^{(n)} + r_1 = \mathbf{f}$$

so that

$$\mathbf{D}^{-1}(\mathbf{f} + (\mathbf{L} + \mathbf{U})\mathbf{u}^{(n)}) = \mathbf{u}^{(n)} + \mathbf{D}^{-1}\nabla^h p^{(n)} + \mathbf{D}^{-1} r_1.$$

Thus (3.16) may be rewritten as

$$\begin{aligned} \begin{pmatrix} \mathbf{u}^{(n+\frac{1}{2})} \\ p^{(n+1)} \end{pmatrix} &= \mathcal{M}^{-1}\left[\begin{pmatrix} \mathbf{f} \\ 0 \end{pmatrix} - \begin{pmatrix} 0 & 0 \\ \nabla^h\cdot & -S \end{pmatrix}\begin{pmatrix} \mathbf{u}^{(n)} \\ p^{(n)} \end{pmatrix} - \begin{pmatrix} 0 & 0 \\ \nabla^h\cdot\mathbf{D}^{-1} & 0 \end{pmatrix}\mathbf{r}^{(n)}\right] \\ &= \mathcal{M}^{-1}\left[\begin{pmatrix} \mathbf{f} \\ 0 \end{pmatrix} + (\mathcal{M} - \mathcal{Q})\begin{pmatrix} \mathbf{u}^{(n)} \\ p^{(n)} \end{pmatrix} - \begin{pmatrix} 0 & 0 \\ \nabla^h\cdot\mathbf{D}^{-1} & 0 \end{pmatrix}\mathbf{r}^{(n)}\right] \\ &= \begin{pmatrix} \mathbf{u}^{(n)} \\ p^{(n)} \end{pmatrix} + \mathcal{M}^{-1}\begin{pmatrix} \mathbb{I} & 0 \\ -\nabla^h\cdot\mathbf{D}^{-1} & \mathbb{I} \end{pmatrix}\mathbf{r}^{(n)}. \end{aligned}$$

Finally, add the projection step to obtain the complete update:

$$\begin{aligned} \begin{pmatrix} \mathbf{u}^{(n+1)} \\ p^{(n+1)} \end{pmatrix} &= \begin{pmatrix} \mathbb{P} & 0 \\ 0 & \mathbb{I} \end{pmatrix}\begin{pmatrix} \mathbf{u}^{(n+\frac{1}{2})} \\ p^{(n+1)} \end{pmatrix} \\ &= \begin{pmatrix} \mathbb{P} & 0 \\ 0 & \mathbb{I} \end{pmatrix}\left[\begin{pmatrix} \mathbf{u}^{(n)} \\ p^{(n)} \end{pmatrix} + \mathcal{M}^{-1}\begin{pmatrix} \mathbb{I} & 0 \\ -\nabla^h\cdot\mathbf{D}^{-1} & \mathbb{I} \end{pmatrix}\mathbf{r}^{(n)}\right]. \end{aligned}$$

Now note that

$$\begin{aligned} \mathbb{P}\mathbf{u}^{(n)} &= \mathbf{u}^{(n)} + \mathbf{D}^{-1}\nabla^h S^{-1}\nabla^h\cdot\mathbf{u}^{(n)} \\ &= \mathbf{u}^{(n)}, \end{aligned}$$

provided that each iterate $\mathbf{u}^{(n)}$ is calculated to accurately satisfy the continuity equation. Thus

$$(3.17)\quad \begin{pmatrix} \mathbf{u}^{(n+1)} \\ p^{(n+1)} \end{pmatrix} = \begin{pmatrix} \mathbf{u}^{(n)} \\ p^{(n)} \end{pmatrix} + \begin{pmatrix} \mathbb{P} & 0 \\ 0 & \alpha\mathbb{I} \end{pmatrix}\mathcal{M}^{-1}\begin{pmatrix} \mathbb{I} & 0 \\ -\nabla^h\cdot\mathbf{D}^{-1} & \mathbb{I} \end{pmatrix}\mathbf{r}^{(n)},$$

where a damping factor $\alpha \in (0, 1]$ has been included as in Remark 3.1.

Remark 3.6. Remark 3.4 also applies to (3.17).

Remark 3.7. In order to satisfy the condition $\mathbb{P}\mathbf{u}^{(n)} = \mathbf{u}^{(n)}$, it is necessary to compute the action of $\mathbb{P}$ to high accuracy. In light of (3.15), it is apparent that

$$\|\nabla^h\cdot\mathbf{u}^{(n+1)}\| = \|\nabla^h\cdot\mathbf{u}^{(n+\frac{1}{2})} + S\phi\|,$$

so that accurate computation of the action of $\mathbb{P}$ can be accomplished by solving (3.15) to a tight absolute tolerance; here an absolute tolerance of $\epsilon_{abs} = 10^{-10}$ was used. Since S is symmetric and positive semidefinite, a preconditioned conjugate gradient method can be used. The preconditioner was a multigrid method composed of volume-averaged restriction, piecewise constant prolongation, symmetric Gauss–Seidel smoothing, V(1,1) cycles, and a Galerkin coarse grid version of (3.9). This latter choice was made necessary by the fact that $\mathbf{D}$ is not conveniently available on the coarser grids, and was made easy to implement because of the choices made for intergrid transfers. The semidefiniteness was treated by requiring ϕ to have a 0 average value, which amounts to a least-squares projection against the null space of S. These choices led to a highly efficient solver with convergence rates of less than 0.1 that were observed to be independent of grid size.

3.3. Multigrid preconditioners with pressure-correction smoothers. Solving the Newton equations (3.1) with a preconditioned iterative method requires computing the action of the inverse of a preconditioner M,

$$z = M^{-1}r, \tag{3.18}$$

at every iteration of the linear solver. In this, r is some vector in the Krylov subspace generated by the Jacobian $F'(x_k)$, M, and the initial residual $F(x_k)$. In a matrix-free Newton–Krylov method, constructing M can be a challenge since the matrix entries of the Jacobian are not available. A good choice for solving the Navier–Stokes equations is

$$M = \mathcal{Q}[\mathbf{u}_k],$$

where $\mathbf{u}_k$ is the current Newton approximation to the velocity field. This captures most of the important features of the Jacobian. Moreover, $\mathcal{Q}[\mathbf{u}_k]$ is readily available since it is generally formed and stored at the beginning of each nonlinear iteration so that it can be used in (2.1) to evaluate F. Alternatively, it is possible to construct M from a lower-order discretization of the Navier–Stokes system. This entails a higher setup cost since it requires a rediscretization, but it can also lead to a system (3.18) that is easier to solve. This does not sacrifice accuracy in the solution, since convergence of the overall procedure is determined by $\|F\|$, which is based on a higher-order discretization.

Once M is chosen, a means for approximating the action of its inverse (3.18) is needed. Multigrid methods [4, 41] provide an efficient means for performing this operation. These approaches compute the solution to a problem discretized on a given grid by approximately solving related problems on coarser grids. The following is a recursive version of a V-cycle, where the h is used to indicate different grid levels and h_c denotes the coarsest grid that is used.

ALGORITHM 3.4 (MG-V(h, M^h, z^h, r^h)).

```
If $h = h_c$ then:
    Solve $M^h z^h = r^h$.
else
    Presmooth $z^h \longleftarrow z^h + B(r^h - M^h z^h)$ $\nu_1$ times.
    Restrict $r^{2h} = I_h^{2h}(r^h - M^h z^h)$.
    Set $z^{2h} = 0$.
    MG-V($2h$, $M^{2h}$, $z^{2h}$, $r^{2h}$).
    Correct $z^h = z^h + I_{2h}^h z^{2h}$.
    Postsmooth $z^h \longleftarrow z^h + B(r^h - M^h z^h)$ $\nu_2$ times.
```

A multigrid algorithm is constructed by supplying the following components:

- a *grid coarsening* strategy,

- a *restriction* operation I_h^{2h} to transfer the problem from a fine grid to a coarser grid,
- a *prolongation* operation I_{2h}^h to transfer the problem from a coarse grid to a finer grid,
- a *coarse grid operator* M^{2h},
- a *coarse grid solver* for solving the problem on the coarsest grid, and
- a *smoother* B that effectively reduces high frequency components of the error.

Grid coarsening is readily achieved by defining each coarse cell to be a union of underlying fine cells. Restriction and prolongation of both velocity and pressure on a staggered grid are accomplished via bilinear interpolation; these are rather standard choices [40]. While coarse grid operators M^{2h} can be computed using a Galerkin coarse grid approximation [44], for simplicity they are determined here by recomputing $M^{2h} = \mathbf{Q}[\mathbf{u}_k^{2h}]$ on the coarser grid. The solution on the coarsest grid h_c is obtained with a fixed number of sweeps of the smoother. Finally, the action of the smoother B is given by either (3.10) or (3.17), once again with $\mathbf{Q}$ fixed at the current inexact Newton approximation.

One additional consideration is required when SIMPLER is used as a smoother. While the projection $\mathbb{P}$ is used to ensure $\nabla^h \cdot \mathbf{u}^h = 0$ to machine accuracy on each grid level, the interpolated coarse grid correction $I_{2h}^h \mathbf{u}^{2h}$ does not satisfy this constraint. An additional application of the projection $\mathbb{P}$ must be applied to the coarse grid correction, so that the velocity portion of the coarse grid correction becomes

$$\mathbf{u}^h = \mathbf{u}^h + \mathbb{P} I_{2h}^h \mathbf{u}^{2h}.$$

4. Numerical evaluations.

The combination of multigrid methods, Newton–Krylov methods, and pressure-correction methods offer a wide range of algorithmic choices. Since these combinations embed iterative methods within iterative methods, it is difficult to predict the most effective combination. Numerical experimentation is necessary to help determine which combinations merit further investigation. This section illustrates effective combinations of these approaches. Except where noted, all reported execution times were measured on a MIPS R10000 processor with a 1 MB L2 cache running at 195 Mhz using the MipsPro 7.2 Fortran compiler and level 2 optimization. Solutions to steady-state problems were obtained using NITSOL [31] on a 128 × 128 grid using an initial approximation $x_0 = 0$ and a GMRES restart value of 100. Such a large restart value is too large for practical computation and is used here only to study the behavior of the preconditioner without the influence of restarting. The nonlinear iterations were terminated when $\|F(x_k)\| \leq 10^{-6}\|F(x_0)\|$.

4.1. Flow in a lid driven cavity.

The driven cavity problem is a classic difficult fluid dynamics benchmark problem. The governing equations consist of the incompressible Navier–Stokes equations (1.1) defined on the unit square $\Omega = [0,1]^2$ with boundary conditions

$$\begin{aligned} u = 1,\ v = 0, &\quad y = 1, \\ u = v = 0 &\quad \text{elsewhere on } \partial\Omega. \end{aligned}$$

In applying the NK-MG method to this problem, convergence difficulties were encountered when the preconditioner was based on the same second-order differences used to discretize the problem. Consequently, all results reported here use a first-order upwind discretization to construct the operator used by the preconditioner. Solutions

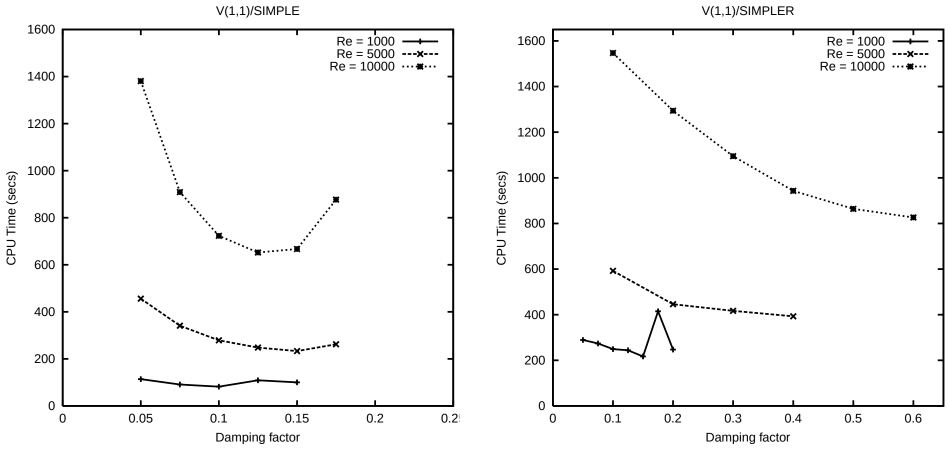

FIG. 4.1. *Sensitivity of multigrid preconditioner to variation in pressure damping factor for Reynolds numbers* 1000, 5000, *and* 10,000.

for Reynolds numbers up to 10,000 were obtained on a 128×128 grid and were within 10% of results published elsewhere [17].

The sensitivity of the performance of the multigrid preconditioners to the pressure damping factor α was investigated. The results for V(1,1) cycles and 2 grid coarsenings are summarized in Figure 4.1; results for larger numbers of pre- or postsmoothing sweeps and for more grid coarsenings are qualitatively similar.

In general, SIMPLER smoothing allowed larger values for the damping factor α. Increasing α beyond those shown in Figure 4.1 caused the inexact Newton method to fail to converge in 200 iterations. Sensitivity to α increased as the Reynolds number was increased. For $Re = 1000$, performance varies by around 25%, excluding the result obtained for SIMPLER smoothing with $\alpha = 0.175$. For this case, backtracking was invoked four times, twice as many as the other cases tested. At $Re = 5000$ performance with SIMPLE smoothing varied by 95%, whereas performance with SIMPLER smoothing varied by 50%; at $Re = 10,000$ the variations were 112% and 87%, respectively.

While multigrid preconditioning with SIMPLE smoothing produced solutions in less CPU time than when SIMPLER smoothing was used, this was the result of a larger number of less expensive iterations. This is due to the need to compute $\mathbb{P}$ to high accuracy: profiling showed that the net cost of this operation was around 20% of the calculation. Note that, by doing so, the preconditioner takes on all the responsibility for enforcing continuity. This is in contrast to the SIMPLE-based preconditioners, where the corrections that are designed to drive the velocity field to conserve mass are not computed with very high accuracy, and the outer Newton iteration is responsible for enforcing $\nabla \cdot \mathbf{u} = 0$. Some consequences of this division of labor are illustrated in Table 4.1, which compares the number of times the preconditioner was applied for the optimal value of α determined above. At lower Reynolds numbers, multigrid preconditioning with SIMPLE smoothing outperforms SIMPLER smoothing by a substantial margin. This gap narrows at $Re = 10,000$, however, as the total number of applications of the SIMPLER-based multigrid preconditioner grows at a slower rate.

SIMPLER smoothing in the multigrid preconditioner also appears to scale better with problem size. This is illustrated in Table 4.2, which shows the usual figures-of-

Table 4.1

Number of applications of multigrid preconditioner (NPRE) *and CPU times* (T) *for different smoothers.*

	SIMPLE		SIMPLER	
Re	NPRE	T	NPRE	T

NNI	32	23	24	31	30	28
NBT	7	6	6	7	6	6
T	31	108	719	47	187	826

merit for evaluating the performance of an inexact Newton method. These results were obtained with the optimal value for α found above. As problem size increases, multigrid with SIMPLE smoothing requires fewer nonlinear iterations but an increasing number of linear iterations than when SIMPLER smoothing is used. While many factors contribute to the peformance of a globalized Newton–Krylov method as problem size increases, the final arbiter is CPU time. In this regard, the CPU time for the case of SIMPLER scales more favorably, owing to the fact that NLI is nearly constant as problem size is increased.

Finally, performance of the linear solver is examined. When a variable forcing term is used, it is difficult to simply characterize the performance of the linear solver. Table 4.3 summarizes some performance statistics for the linear solver over the entire inexact Newton solve. The minimum number of iteration counts occurs early in the computation, when a conservative value for the forcing term is used. During the course of the iteration, a more aggressive value for the forcing term is attempted, generally leading to a higher iteration count for solving the Newton equations. The maximum values always occurred in the last or next-to-last Newton iteration. Overall, the performance of the linear solver with SIMPLER smoothing is better than when SIMPLE smoothing is used, allowing a smaller restart value to be used. However, this is offset by the higher cost per iteration.

4.2. Buoyancy driven flow. Natural convection in an enclosed cavity is a standard benchmark problem that is frequently used to test different numerical schemes and solution methods [10]. The governing equations consist of the incompressible Navier–Stokes equations (1.1) coupled to an energy transport equation,

$$(uT)_x + (vT)_y - \frac{1}{RePr}\Delta T = 0,$$

together with a body force on the fluid that, under the Boussinesq approximation, is proportional to the temperature

$$\mathbf{f} = \begin{pmatrix} 0 \\ \frac{Ra}{Re^2 Pr}T \end{pmatrix},$$

Table 4.3

Performance statistics for solving the Newton equations with multigrid preconditioning and pressure-correction smoothers. The preconditioner is a V(1,1) cycle with two grid coarsenings.

	SIMPLE			SIMPLER

NLI	285	221	193	155	133
NNI	19	18	18	19	16
NBT	4	3	3	3	2
T	313	308	329	368	400

where *Pr* is the Prandtl number and *Ra* is the Rayleigh number. Following [25], *Re* is fixed at 1, *Pr* is fixed at 0.71, and the Rayleigh number is varied. The problem is defined on the unit square $\Omega = [0,1]^2$ with boundary conditions

$$\begin{aligned} u = v &= 0 \quad \text{on } \partial\Omega, \\ T(0,y) = 0,\ T(1,y) &= 1, \quad y \in [0,1], \\ T_y(x,0) = T_y(x,1) &= 0, \quad x \in [0,1]. \end{aligned}$$

The additional transport equation is readily accommodated by the SIMPLE and SIMPLER smoothers. Five sweeps of the point Gauss–Seidel method are applied to the discretized energy equation prior to solving the momentum equations. The updated temperature field is then incorporated as a source term before solving the equation governing the vertical component of momentum.

Results for $Ra = 100,000$ using SIMPLE smoothing in the multigrid preconditioner are summarized in Table 4.4, which contains the usual figures-of-merit for evaluating a Newton–Krylov method. Use of a multigrid preconditioner reduces both the number of nonlinear iterations and the number of backtracking steps that were needed. Reducing the number of backtracking steps when employing a variable forcing term is particularly desirable, since each backtracking step increases the forcing term and delays onset of superlinear convergence behavior. In general, V(2,1) cycles in the preconditioner seem to provide a performance "sweet spot." Use of more pre- and/or postsmoothing sweeps decreases NLI, but these reductions are not always enough to offset the resulting higher cost of the preconditioner. Finally, note that use of a multigrid preconditioner improves the performance of GMRES to the extent that a smaller restart value can be used. Thus the high-quality multigrid preconditioner has an additional benefit of reducing the storage costs associated with the Newton–Krylov method. Similar results were obtained for Rayleigh numbers ranging from 20,000 to 500,000.

Results for the same problem that were obtained with the SIMPLER-based preconditioners are summarized in Table 4.5, which reports the same figures-of-merit that appear in Table 4.4. Here only two grid coarsenings were used. Note that the SIMPLER-based preconditioners generally require fewer linear iterations than their SIMPLE-based counterparts. Yet, as observed for the driven cavity problem, the CPU

times are somewhat higher. Another interesting trend to note is that, while increasing the number of pre- or postsmoothing sweeps generally decreases the total number of linear iterations, it also increases the total execution time. This reflects the tradeoff between the cost and effectiveness of the preconditioner. Both of these observations can be attributed to the cost of enforcing $\nabla^h \cdot \mathbf{u} = 0$ in the preconditioner.

Next, the performance of the NK-MG method using different smoothers is compared with stand-alone versions of the pressure-correction methods. Figure 4.2 shows this comparison for $Ra = 20,000$. The NK-MG method with SIMPLE smoothing is nine times faster than SIMPLE as a stand-alone solver; the NK-MG method with SIMPLER smoothing is nearly seven times faster than SIMPLER as a solver. With SIMPLE smoothing, the largest number of linear iterations taken in an inexact Newton step was 27, so these same results could be obtained by storing only a maximum of 27 Krylov subspace basis vectors. Using a smaller restart value of 10 increases the solution time by roughly a third. On the other hand, when SIMPLER smoothing was used, the largest number of linear iterations taken in an inexact Newton step was 46; using a smaller restart value of 10 increases the solution time by almost 15%.

Dynamic selection of forcing terms as described in [13] employs a safeguard that prevents η_k from getting too small too quickly. More specifically, Choice 1 from [13] uses the safeguard

$$\eta_k \leftarrow \max\{\eta_k, \eta_{k-1}^{(1+\sqrt{5})/2}\} \text{ if } \eta_{k-1}^{(1+\sqrt{5})/2} > \text{threshold}. \tag{4.1}$$

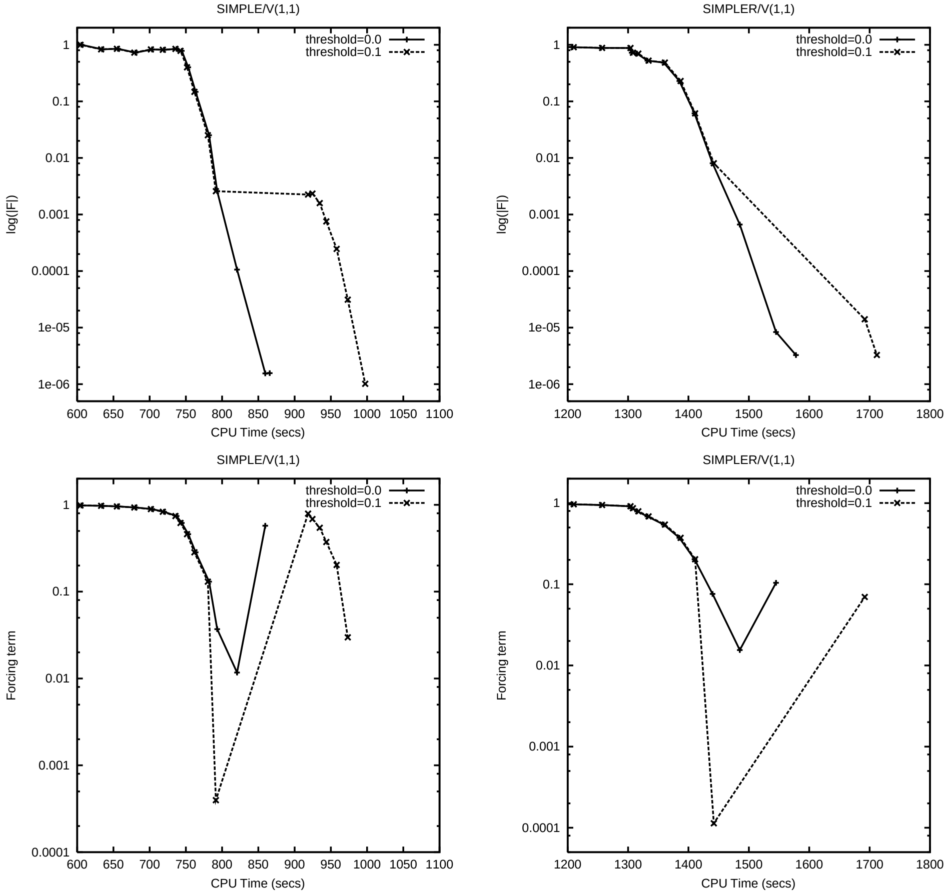

FIG. 4.3. *Convergence histories and forcing terms of the NK-MG method with and without safeguard* (4.1)*. When the threshold is set to* 0*, the safeguard is never disabled. SIMPLE smoothing is on the left, while SIMPLER smoothing is on the right.*

The motivation for this safeguard is that it is possible to request too much accuracy in the solution of the Newton equations, which can happen, for example, when there is serendipitously good agreement between the linear model and the nonlinear function. This safeguard is disabled once the forcing term drops below the threshold value. The choice of a threshold value is somewhat arbitrary, and the implementation of Algorithm INB in NITSOL allows a user to specify this while supplying a default value of 0.1 [31]. The safeguard can be retained by using a threshold value of 0.

While previous studies of the performance of Newton-GMRES with dynamic selection of forcing terms [13, 35, 31] disabled this safeguard, it was found that, when using a multigrid preconditioner, doing so sometimes led to undesirable behavior, as illustrated in Figure 4.3. These plots show the final stages in the solution of the buoyancy-driven flow problem at $Ra = 1,000,000$. The top two plots show $\|F(x_k)\|$, while the bottom two plots show the corresponding η_k. The bottom plots show that, with the safeguard disabled at a threshold of 0.1, a very small value for η_k is generated. For SIMPLE smoothing, the linear solver fails to converge in 100 iterations. Further, sufficient reduction in $\|F\|$ is not achieved, which triggers backtracking, increases the forcing term, and delays convergence of the nonlinear iterations. (The increase in η that is seen on the last iteration when the safeguard is retained is the result of a second safeguard implemented in NITSOL to prevent unnecessary work in reducing $\|F\|$ beyond the requested tolerance [31].) When SIMPLER smoothing is used, backtracking is not triggered, but when (4.1) is disabled, a smaller η is produced in the next to last iteration. While this saves one nonlinear iteration over the case where (4.1) is retained, overall it results in 49 more linear iterations and a higher overall cost to solve the problem.

4.3. Unsteady thermal convection. The issues that are important in a time dependent simulation are somewhat different than was the case for the steady-state case. One major difference is that unlike the steady-state case, there will usually be a very good initial guess for the Newton iteration. This means that globalization strategies are not as important as they were for steady-state problems. For the set of runs shown in this section, SIMPLE was used as the smoother in a multigrid preconditioner, point Gauss–Seidel relaxation was replaced by red-black Gauss–Seidel relaxation, and V(4,2) cycles were used. All of the tests were run over ten time steps using a constant time step size. The test problem is the threee-dimensional analogue of the natural convection problem described in section 4.2. The problem is defined on the unit square $\Omega = [0,1]^3$ with boundary conditions

$$\begin{aligned} u = v = w = 0 &\quad \text{on } \partial\Omega, \\ T(0,y,z) = 0,\ T(1,y,z) = 1, &\quad y,z \in [0,1], \\ T_y(x,0,z) = T_y(x,1,z) = 0, &\quad x,z \in [0,1], \\ T_z(x,y,0) = T_z(x,y,1) = 0, &\quad x,y \in [0,1]. \end{aligned}$$

Before presenting the numerical results, the structure of the computer program that is used is described. The package PETSc [1] is used to implement the inexact Newton solver that was described in section 3.1. In order to define the grid, the package SAMRAI [16] is used. SAMRAI is an object oriented framework for implementing structured adaptive mesh refinement (SAMR). Although adaptive mesh refinement is not used for the work presented in this paper, it is a feature that will be vital in future work.

In order to use PETSc to solve nonlinear systems that are defined on SAMRAI grids, either the data must be copied into a format that PETSc understands or the PETSc vector functions must be extended to act on SAMRAI grids. The former strategy will likely be very inefficient, as large amounts of data must be moved in memory. Instead, SAMRAI provides an interface to PETSc that redirects PETSc vector operations, such as norms and dot products, to act directly on the data that is stored in SAMRAI format. This solver structure is used to solve the natural convection problem and test several aspects of the algorithms.

First the effect of using a better initial iterate on the performance of the linear and nonlinear solver is examined. For this time integrator, the initial conditions are used as the initial iterate for the first time step, and then a linear predictor based on the previous two time steps is used for the remaining time steps in a simulation. The linear predictor should perform much better than the initial iterate for the first time step. The results shown in Table 4.6 are for a 128 × 128 × 128 grid, and they show that the solvers have to work much harder to solve the initial time step because of the poor initial iterate. Also, for all the results shown here, the backtracking scheme was never activated.

Table 4.6
Performance of the linear and nonlinear solvers per time step for the three-dimensional natural convection problem on a grid of $128 \times 128 \times 128$.

		First time step		10 time steps	
Ra	Δt	NNI	NLI	NNI	NLI
10^6	10^{-4}	5	14	4.1	10.4
10^7	10^{-5}	9	24	4.0	8.0
10^8	10^{-6}	8	19	2.8	4.2

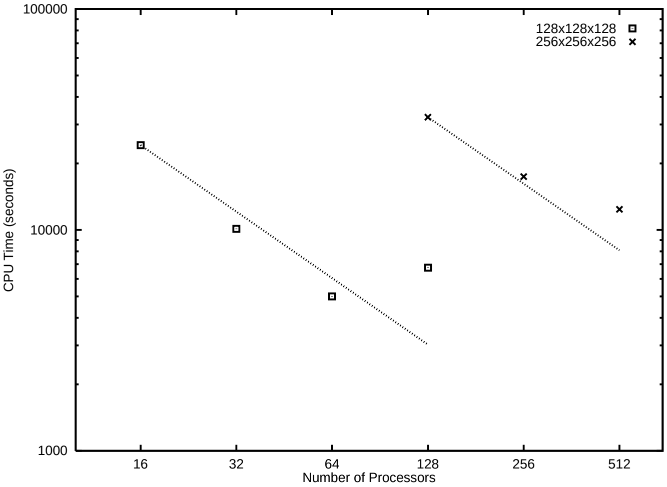

Fig. 4.4. *Parallel performance on an SGI Origin* 2000 *for the natural convection problem.*

The parallel performance of these algorithms is also very important, so the same test problem was run on the SGI Origin 2000 at Los Alamos National Laboratory with $Ra = 10^6$ and $\Delta t = 10^{-4}$ for the $128 \times 128 \times 128$ problem and $Ra = 10^6$ and $\Delta t = 10^{-5}$ for the $256 \times 256 \times 256$ problem. The results, shown in Figure 4.4, indicate that you can get very good scalability for the small problem until the problem size on each processor becomes too small. Then increasing the problem size allows us to get good scalability up to 512 processors. This type of behavior is typical of parallel algorithms for solving PDEs.

5. Summary and conclusions. The pressure-correction methods SIMPLE and SIMPLER have been adapted for use in preconditioning a matrix-free Newton–Krylov method applied to the incompressible Navier–Stokes equations. Application to both two- and three-dimensional problems, as well as unsteady problems, was demonstrated. NK-MG methods with pressure-correction smoothers substantially accelerate the convergence of the pressure-correction methods, albeit at an increase in storage cost, and their performance scales well as problem size is increased. The performance of both methods was found to be sensitive to damping the pressure update; analysis of this behavior will be the subject of future work and will be facilitated by the development of a new correction-oriented version of SIMPLER. SIMPLE-based preconditioning was found to require less CPU time. While SIMPLER-based preconditioning generally led to fewer total linear iterations to complete the inexact Newton solve, this reduction in iteration counts was offset by the additional expense of enforcing continuity at each step. However, SIMPLER-based preconditioning displayed some favorable robustness trends with respect to problem size and Reynolds number, so further investigation of ways to reduce the cost per iteration is warranted. Finally, these methods were found to be straightforward to parallelize, and encouraging initial parallel results have been obtained.

Acknowledgments. Thanks to Dana Knoll of Los Alamos National Laboratory for pointing out that **Q** could be directly reused in the Newton–Krylov preconditioner. The comments of an anonymous referee led to numerous improvements in the presentation. The computations presented in this paper were conducted on facilities provided by the University of Utah Center for High Performance Computing and by Los Alamos National Laboratory.

ON THE INCOMPLETE CHOLESKY DECOMPOSITION OF A CLASS OF PERTURBED MATRICES*

GÉRARD MEURANT†

Abstract. We consider how to cheaply compute an incomplete Cholesky decomposition of symmetric perturbed matrices $C = \epsilon I + A$ with a small ϵ when knowing an incomplete decomposition of A. Numerical examples are provided that show the effectiveness of the proposed approach.

Key words. incomplete factorization, conjugate gradient

AMS subject classifications. 65F10, 65F50

1. Introduction.

In this paper we are mainly concerned with the incomplete Cholesky decomposition of symmetric M-matrices

$$C = \epsilon I + A,$$

where A arises from the discretization of an elliptic partial differential equation, ϵ being a "small" positive real parameter. Such problems arise, for instance, from discretizing parabolic equations.

As a model problem we can use the two-dimensional heat equation

$$\frac{\partial u}{\partial t} - \Delta u = f$$

in the unit square with Dirichlet boundary conditions and an initial condition $u(x,0) = u_0(t)$. We discretize in space with finite differences with a stepsize h and a time implicit scheme. Then we obtain

$$\left(\frac{I}{k} + \frac{1}{h^2}A\right) u^{n+1} = \frac{u^n}{k} + f^{n+1},$$

where k is the time step and $1/h^2\, A$ is the matrix of the corresponding elliptic problem. For some problems it makes sense to choose $k \simeq h$. After multiplication by h^2 the matrix of the problem is $C = kI + A$, where k is "small."

Since the matrix C is symmetric positive definite, we would like to solve the linear system at each time step with the preconditioned conjugate gradient algorithm. A very popular preconditioner is the incomplete Cholesky decomposition without any fill-in IC(1,1) (sometimes also denoted as IC(0)); c.f. [3], [4] or [5], [6] for a review. Usually the time step k must be small to obtain the convergence of the approximation. Therefore, it is interesting to know if one can compute an approximation of the incomplete decomposition of C knowing the decomposition of A. Moreover, very often the time step is not constant, and therefore one cannot compute the decomposition of C once for all. It has to be recomputed at each time step. Hence it would be interesting to find a way to cheaply update the incomplete decomposition from one time step to the next.

†CEA/DIF, DCSA/ED, BP 12, 91680 Bruyères le Chatel, France (gerard.meurant@cea.fr).

Matrices of this type have been considered in previous works, mainly to stabilize the incomplete factorization of A (see [2], [1]) when the straightforward factorization of A gives some small pivots.

In section 2, we describe algorithms corresponding to perturbations of order 0 and 1 in ϵ. Section 3 gives numerical examples for several problems with comparisons between the incomplete decomposition of C, that of A, and the SSOR preconditioning. For a definition of these algorithms, see [5]. We will also give some results for problems not arising from parabolic partial differential equations, even for cases where A is not an M-matrix. Then in section 4, we apply the previous results to the solution of the heat equation. Section 5 deals with another problem where $C = I + \epsilon A$.

2. Approximate preconditioners. We first recall the first step of the incomplete Cholesky decomposition of a matrix C whose elements are denoted $c_{i,j}$. Let G be a set of indices corresponding, for instance, to the nonzero structure of A and

$$C = C_1 = \begin{pmatrix} c_{1,1} & c_1^T \\ c_1 & E_2 \end{pmatrix} = \begin{pmatrix} c_{1,1} & f_1^T \\ f_1 & E_2 \end{pmatrix} - \begin{pmatrix} 0 & r_1^T \\ r_1 & 0 \end{pmatrix} = M_1 - R_1,$$

with

$$c_1 = f_1 - r_1,$$

$$(f_1)_i = 0, \text{ if } (i,1) \notin G \Rightarrow (r_1)_i = -(c_1)_i,$$

$$(f_1)_i = (c_1)_i, \text{ if } (i,1) \in G \Rightarrow (r_1)_i = 0.$$

Then, we factorize M_1:

$$M_1 = \begin{pmatrix} c_{1,1} & 0 \\ l_1 & I \end{pmatrix} \begin{pmatrix} c_{1,1}^{-1} & 0 \\ 0 & C_2 \end{pmatrix} \begin{pmatrix} c_{1,1} & l_1^T \\ 0 & I \end{pmatrix} = L_1 \Sigma_1 L_1^T.$$

We obtain

$$l_1 = f_1,$$

$$C_2 = E_2 - \frac{1}{c_{1,1}} f_1 f_1^T.$$

The next step is applying the same decomposition on C_2,

$$C_2 = \begin{pmatrix} c_{2,2}^{(2)} & c_2^T \\ c_2 & E_3 \end{pmatrix} = \begin{pmatrix} c_{2,2}^{(2)} & f_2^T \\ f_2 & E_3 \end{pmatrix} - \begin{pmatrix} 0 & r_2^T \\ r_2 & 0 \end{pmatrix} = M_2 - R_2,$$

where f_2 is obtained from c_2 by setting to zero the elements for which the indices $(i,2)$ do not belong to G. Let

$$L_2 = \begin{pmatrix} c_{1,1} & 0 \\ 0 & \begin{pmatrix} c_{2,2}^{(2)} & 0 \\ l_2 & I \end{pmatrix} \end{pmatrix}.$$

Note that $l_2 = f_2$ and that we shall never throw away a diagonal entry.

At the end of the second step, we have

$$C = L_1 L_2 \Sigma_2 L_2^T L_1^T - L_1 \begin{pmatrix} 0 & 0 \\ 0 & R_2 \end{pmatrix} L_1^T - R_1,$$

but

$$L_1 L_2 = \begin{pmatrix} c_{1,1} & 0 \\ l_1 & \begin{pmatrix} c_{2,2}^{(2)} & 0 \\ l_2 & I \end{pmatrix} \end{pmatrix} \quad \text{and } L_1 \begin{pmatrix} 0 & 0 \\ 0 & R_2 \end{pmatrix} L_1^T = \begin{pmatrix} 0 & 0 \\ 0 & R_2 \end{pmatrix}.$$

Therefore, we have a factor with the desired structure and we can go on as long as the pivots $c_{i,i}^{(i)}$ are nonzero. It has been proven that IC is feasible whatever the set G is when C is an H-matrix. We apply this algorithm to $C = \epsilon D + A$, where D is a diagonal matrix with nonzero diagonal elements d_i. We use a matrix $D \neq I$ because with the order 1 algorithm to be described soon, the diagonal entries are going to be modified so that we do not get the identity for all steps of the algorithm. We have

$$c_{1,1} = \epsilon d_1 + a_{1,1},$$

$$l_1 = f_1,$$

$$C_2 = \epsilon D_2 + A_2 - \frac{1}{\epsilon d_1 + a_{1,1}} f_1 f_1^T,$$

where these matrices are defined by

$$C = \begin{pmatrix} \epsilon d_1 + a_{1,1} & a_1^T \\ a_1 & \epsilon D_2 + A_2 \end{pmatrix}.$$

Rather than computing C_2 exactly, we would like to use an asymptotic expansion related to ϵ for the ratio. For the order 0 we have

$$C_2 = \epsilon D_2 + A_2 - \frac{1}{a_{1,1}} f_1 f_1^T;$$

that is to say, we add ϵD_2 to what we would have obtained for the incomplete decomposition of A.

The order 1 gives

$$C_2 = \epsilon \left(D_2 + \frac{d_1 f_1 f_1^T}{a_{1,1}^2} \right) + A_2 - \frac{1}{a_{1,1}} f_1 f_1^T.$$

To motivate the choices we are going to make later on, let us look at what we get for a two-dimensional finite difference matrix. As an example, we take the Poisson equation in a square with a mesh size $h = 1/(m+1)$. This leads to a matrix of order $n = m^2$, which can be written blockwise as

$$A = \begin{pmatrix} T & -I & & & \\ -I & T & -I & & \\ & \ddots & \ddots & \ddots & \\ & & -I & T & -I \\ & & & -I & T \end{pmatrix}$$

with blocks of order m

$$T = \begin{pmatrix} 4 & -1 & & & \\ -1 & 4 & -1 & & \\ & \ddots & \ddots & \ddots & \\ & & -1 & 4 & -1 \\ & & & -1 & 4 \end{pmatrix}.$$

The matrix A has five nonzero diagonals. For a generic row i and more general problems, the nonzero coefficients are $a_{i,i-m}, a_{i,i-1}, a_{i,i}, a_{i+1,i}, a_{i+m,i}$. When we compute the incomplete decomposition IC(1,1) (with no fill-in) of this matrix obtaining $M = (\Sigma + L)\Sigma^{-1}(\Sigma + L^T)$, it is easy to see that we only need to compute the diagonal matrix Σ whose elements are denoted by $\sigma_{i,i}$. The matrix L is the strictly lower triangular part of A. The diagonal elements are given by

$$\sigma_{i,i} = a_{i,i} - \frac{a_{i,i-1}^2}{\sigma_{i-1,i-1}} - \frac{a_{i,i-m}^2}{\sigma_{i-m,i-m}}.$$

In this formula, entries of A (resp., Σ) whose indices do not exist are taken to be 0 (resp., 1). The two ratios arise from the two nonzero elements in each column of L and from the upper triangular part of A in each row of L^T.

Let us look at what we obtain in the first step of the decomposition of $C = \epsilon D + A$. For order 0 there is no problem as we have just to compute $\sigma_{i,i}$ as before and to add ϵd_i.

Handling order 1 is a little more tricky. We obtained

$$C_2 = \epsilon \left(D_2 + \frac{d_1 f_1 f_1^T}{a_{1,1}^2} \right) + A_2 - \frac{1}{a_{1,1}} f_1 f_1^T.$$

To what we would have obtained for A, that is,

$$A_2 - \frac{1}{a_{1,1}} f_1 f_1^T,$$

which corresponds to the computation of $\sigma_{i,i}$, we have to add the correction of order ϵ. That is,

$$\epsilon \left(D_2 + \frac{d_1 f_1 f_1^T}{a_{1,1}^2} \right).$$

Since there are only two nonzero elements in f_1 for the model problem, the outer product $f_1 f_1^T$ gives two diagonal modifications for indices $(2,2)$ and $(m+1, m+1)$ (when these terms exist). Therefore, we add

$$\epsilon \left(d_2 + d_1 \frac{a_{2,1}^2}{a_{1,1}^2} \right)$$

to the element of index $(2,2)$ and

$$\epsilon \left(d_{m+1} + d_1 \frac{a_{m+1,1}^2}{a_{1,1}^2} \right)$$

to the element of index $(m+1, m+1)$. This modifies the diagonal terms of order ϵ. Therefore, we see that the modification of the diagonal terms is recursive. This means that there is no gain from doing the decomposition of C from scratch. Consequently, we decided to bypass the recursion. We apply only the modifications to the initial D. For example, the correction of the element $(3,3)$ will be

$$\epsilon \left(d_3 + d_2 \frac{a_{3,2}^2}{\sigma_{2,2}^2} \right).$$

This will work when ϵ is small but not with larger values of the parameter. In the latter case we have

$$\frac{1}{\epsilon d_1 + a_{1,1}} \simeq \frac{1}{\epsilon d_1}.$$

Therefore, in the formulas for order 1 we replace $\sigma_{i,i}$ by $\sigma_{i,i} + \epsilon d_i$. This does not make too much of a difference when ϵ is small and gives asymptotically the exact answer when it is large. For instance, the final correction for the element $(3,3)$ in the second step will be

$$\epsilon \left(d_3 + d_2 \frac{a_{3,2}^2}{(\sigma_{2,2} + \epsilon d_2)^2} \right).$$

This algorithm is what we call order 1 in the numerical experiments. This has the additional advantage that all the corrections can proceed in parallel. In this way we get rid of the recursion of the incomplete Cholesky factorization which is not easily parallelizable. However, note that there is still a recursion when solving the triangular systems.

In the case of a matrix arising from a diffusion equation with a constant coefficient, we can perform an asymptotic analysis of the diagonal elements of the incomplete factors. If $a_{i,i} = a, a_{i,i-1} = b, a_{i,i-m} = c$, then the elements of the incomplete decomposition $\sigma_{i,i}$ (within a block) converge rapidly to σ:

$$\sigma = \frac{a+s}{2}, \quad s = \sqrt{a^2 - 4(b^2 + c^2)}.$$

If the diagonal coefficients of A are perturbed by ϵ, we obtain a limit $\bar{\sigma}$:

$$\bar{\sigma} \simeq \frac{a+s}{2} + \frac{\epsilon}{s} \frac{a+s}{2}.$$

The fact that the difference between the exact factorization and the approximate one is small is also illustrated in Figure 2.1, where we show the relative differences between the exact and approximate order 0 values of the second block of diagonal coefficients for the perturbed Poisson equation with a 30×30 mesh as a function of the relative index in the block. The solid line is $\epsilon = 10^{-2}$, the dashed line is $\epsilon = 10^{-1}$, the dot-dashed line is $\epsilon = 1$, the dotted line is $\epsilon = 10$, the plus signs are $\epsilon = 100$, and the circles are $\epsilon = 1000$. Over all values of ϵ the maximum relative difference is 4%.

This technique can be generalized to any nonzero structure for A. For order 0 we just add ϵD to the diagonal. For the order 1 we modify only the diagonal, neglecting the recursiveness, and we add an order of ϵ term in the denominator to obtain the correct behavior when ϵ is large. The method can also be applied to matrices arising from finite element methods. In case mass lumping is used we can do exactly the same thing. If the mass matrix is not diagonal, we can do modifications to the nonzero entries but neglecting the recursiveness that is using the initial values of the entries of the mass matrix.

3. Numerical experiments. We denote by IC the incomplete Cholesky decomposition without fill-in. We use several examples to compare the following preconditioners:

1. IC for $C = \epsilon I + A$,
2. approximate IC of C order 0,
3. approximate IC of C order 1,
4. IC for A,
5. SSOR with $\omega = 1$.

We first consider matrices arising from diffusion equations in the unit square with homogeneous Dirichlet boundary conditions. The first example is the Poisson equation we described in section 2. We solve a linear system whose solution is $x = \{1, 1, \ldots, \}^T$. The initial iterate is chosen at random, and we stop the iterations as soon as the relative norm residual is less 10^{-10}. We use a regular 30×30 cartesian mesh. We start with $\epsilon = 320$, and we divide it by 4 several times. The results are given in Table 1.

For this example, the two approximate decompositions give almost the same number of iterations as the "exact" incomplete decomposition. The results of the approximate decompositions are also quite good for large ϵ's. This is linked to the fact that

$4.882\ 10^{-3}$	41	41	41	41	47

Table 3
Diffusion problem with anisotropic coefficients.

ϵ	IC(C)	Order 0	Order 1	IC(A)	SSOR
320	4	8	8	143	6
80	5	12	9	92	10
20	7	15	11	53	18
5	10	14	12	28	33
1.25	15	15	15	16	57
0.325	25	26	26	25	97
$7.812\ 10^{-2}$	34	34	34	33	126
$1.953\ 10^{-2}$	38	38	38	38	134
$4.882\ 10^{-3}$	39	39	39	39	136

in this case the matrix is diagonally dominant and that we add a proper correction for the order 1. We also note that in this case the results of the order 1 are the same as those of order 0. Of course, when ϵ is small we obtain the same number of iterations when we only use IC(A).

The second example is a diffusion problem with discontinuous diffusion coefficients and Dirichlet boundary conditions on the unit square. The diffusion coefficient is 1000 in $[1/4, 3/4] \times [1/4, 3/4]$ and 1 elsewhere. We use the same mesh and parameters as before. Results are provided in Table 2. The conclusions are the same as for the first example.

The third example is a diffusion problem with an anisotropic coefficient and Dirichlet boundary conditions on the unit square. The x diffusion coefficient is 100 in $[1/4, 3/4] \times [0, 1]$ and 1 elsewhere. The y diffusion coefficient is 1 everywhere. The parameters are the same as before. Results are given in Table 3.

This is a difficult problem, and we can see there are differences between IC and the approximate decompositions. For this problem we get an improvement when going from order 0 to order 1 for middle range values of ϵ . However, the differences are small, and we can still conclude that it could be useful to use the approximate decomposition.

We now consider some matrices from the Harwell–Boeing collection or from the Boeing collection arising from Tim Davis's Web site (http://www.cise.ufl.edu). We had to normalize some of these matrices in order for the perturbations ϵI to be meaningful. We use the following examples.

1. 1138-bus. An admittance matrix of order 1138 with 4054 nonzeros. It was normalized. Note that the unperturbed matrix is close to being singular.
2. bcsstk01. A stiffness matrix of order 48 with 400 nonzeros. It was normalized.

Table 4
1138-bus.

ϵ	IC(C)	Order 0	Order 1	IC(A)	SSOR
1000	1	2	2	205	1
250	2	3	3	249	2
62.5	2	3	3	249	2
15.625	2	4	4	242	3
3.51	3	5	5	215	4
0.98	6	8	8	163	6
0.24	10	14	13	110	10
0.0610	18	22	21	93	19
0.0015	30	34	33	86	34
0.0038	46	48	48	81	62
$9.54\ 10^{-4}$	65	65	65	80	108
$2.38\ 10^{-4}$	83	83	83	86	175
$5.963\ 10^{-5}$	101	101	101	102	250
$1.490\ 10^{-5}$	114	114	114	114	320

This matrix is not diagonally dominant, nor an M-matrix, but nevertheless positive definite.

3. gr3030. A matrix arising from a nine point approximation to the Laplacian on the unit square with a 30×30 mesh. It has order 900 and 7744 nonzeros.

4. msc00726. A matrix of order 726 with 34518 nonzeros from Nastran. This matrix was normalized.

We ran the different problems and preconditioners with values of ϵ ranging from 1000 to $1.49\ 10^{-5}$. In Tables 4 to 7 we report the number of iterations obtained by using a stopping criterion of 10^{-6} on the relative residual norm in CG.

For 1138-bus there is no gain by using order 1 over order 0. The SSOR preconditioner gives better results than the approximate ICs for large ϵ, but for small ones the SSOR results are much worst. We can see that although this is a different kind of problem the approximate preconditioners still give very good results. Note that ϵ has to be very small for having good results with IC(A). The conclusions for bcsstk01 are the same as for the previous example. For the last two problems gr3030 and msc00726 we can also draw the same conclusions. We can obtain a very good preconditioner by just modifying the diagonal elements in a parallel way. A general remark is that using IC(A) is fine when $\epsilon \to 0$, but with the perturbed factorizations we can also get good results when ϵ is large. Moreover, the results are generally better than using straight SSOR.

4. Application to the heat equation.

We consider the following problem:

$$\frac{\partial u}{\partial t} - \frac{\partial^2 u}{\partial x^2} - \frac{\partial^2 u}{\partial y^2} = f, \quad \text{in } \Omega =]0,1[^2,$$

with Dirichlet boundary conditions and a given initial condition.

We discretize with finite differences and a time implicit scheme as shown in the introduction. We use the conjugate gradient algorithm to solve the linear system we obtain at each time step.

We solved a problem whose exact solution is $u = (1+t^3)\sin(\pi x)\sin(\pi y)$. We use 30 discretization points in each direction and $k = h$. We obtained exactly the same total number of CG iterations using either the "exact" incomplete Cholesky decomposition recomputed at each time step or the approximate one of order 0. Therefore,

$1.953\ 10^{-2}$	5	12	7	13	12
$4.882\ 10^{-3}$	4	7	4	9	7

this shows that in this case it is useless to recompute the decomposition at each time step; we just have to update the diagonal of the decomposition of A which is computed during the initialization phase. Of course, updating the incomplete factorization was much cheaper than recomputing at every time step. We do not give any computer times since this computation was done using Matlab for which computer times depend very much on how the programs are written.

5. Perturbation of a diagonal matrix. For completeness, we now consider the incomplete Cholesky decomposition of a matrix $C = I + \epsilon A$, although this case has much less practical applications than the case we handle in section 2. Let $c_1 = f_1 - r_1$, $l_1 = \epsilon f_1$. For the first step we get

$$C_2 = I + \epsilon A_2 - \frac{1}{1 + \epsilon a_{1,1}} l_1 l_1^T = I + \epsilon \left(A_2 - \frac{\epsilon}{1 + \epsilon a_{1,1}} f_1 f_1^T \right).$$

Now we use an asymptotic expansion of the ratio. The order 1 expansion gives $l_1 = \epsilon f_1$, $C_2 = I + \epsilon A_2$. This is nothing else than the SSOR preconditioner with $\omega = 1$. For the order 2 expansion we obtain

$$C_2 = I + \epsilon A_2 - \epsilon^2 f_1 f_1^T.$$

Looking at this formula, we may already think that this correction cannot give good results for large ϵ. It may even happen that the preconditioner is not positive definite. To obtain something which can work for both small and large ϵ, it makes sense to use a weighting factor. Therefore, we propose to use

$$C_2 = I + \epsilon A_2 - \frac{\epsilon^2}{\epsilon a_{1,1} + 1} f_1 f_1^T.$$

This is what is denoted as order 2 in the results. As in section 2, we neglect the recursion when we compute the diagonal corrections.

Another way is to use the incomplete decomposition of A which computes a diagonal d and to set the diagonal elements of the approximate decomposition to $1 + \epsilon d_{i,i}$. We denote this method as ICd. We consider the third example from section 3 for which results are given in Table 8.

The results in Table 8 show that the order 1 approximation indeed gives the same results as SSOR with $\omega = 1$. The order 2 gives better results than order 1. For small ϵ it gives almost the same results as IC(C). Finally, ICd always gives good results. These are not too far from those of IC(C) for all values of ϵ although order 2 gives better results for very small ϵ. Therefore, ICd seems to be the method of choice for this case.

6. Conclusion. In this paper we have shown that we can efficiently and easily compute incomplete Cholesky-like preconditioners of $\epsilon I + A$ and $I + \epsilon A$ when we know the incomplete decomposition of A. The proposed methods work for a large range of values of the perturbation parameter ϵ. These approximate factorizations can be useful when solving time dependent partial differential equations since we do not anymore have to recompute the factorization at each time step but only have to update it, which is a cheap and parallel operation.

Acknowledgment. Thanks to Henk van der Vorst for helpful comments on a preliminary draft of this paper.

AN AGGREGATION-BASED DOMAIN DECOMPOSITION PRECONDITIONER FOR GROUNDWATER FLOW*

E. W. JENKINS[†], C. E. KEES[‡], C. T. KELLEY[§], and C. T. MILLER[‡]

Abstract. We consider theoretical and computational issues associated with an aggregation-based domain decomposition preconditioner applied to a Bi-CGSTAB iterative solver used to solve both Laplace's equation and an important nonlinear model from hydrology used to simulate unsaturated flow, Richards' equation. Theoretical results for Laplace's equation provide estimates of the condition number and the rate of convergence for a two-level Schwarz domain decomposition preconditioner. Computational results for Laplace's equation and Richards' equation show excellent scalability, although no theory is yet available to support the results for the difficult nonlinear problem.

Key words. domain decomposition, Newton–Krylov–Schwarz methods, Richards' equation, nonlinear equations, aggregation

1. Introduction.

In this paper we report on a scalability study and derive condition number estimates for a two-level additive Schwarz preconditioner. In our previous work we have applied this preconditioner to a set of problems in hydrology [8, 9, 7]. We build the coarse mesh problem with aggregation, an approach used in both algebraic multigrid [2, 21] and domain decomposition methods [11, 12, 13, 3]. In the case of minimal overlap, we implement this as a simple unweighted sum of nodal values. This implementation permits a simple construction of a two-level preconditioner on unstructured grids.

Our methods were developed for use in the adaptive hydrology model (ADH) [18], a production code being developed at the U.S. Army Engineer Research and Development Center. The use of aggregation arose from necessity. In the applications reported in [8, 9, 7] the subdomains were irregular, and a coarse mesh based on "hat functions" over the subdomains was impractical. For the same reason, we needed minimal overlap between subdomains. Unlike the method from [5], we do not need to create a coarse mesh geometry or use geometric information about the subdomains. Neither theoretical analysis of this algorithm applied to any problem nor in-depth scalability studies have been performed to date to our knowledge.

The overall goal of this work is to advance our understanding of this aggregation-based domain decomposition method. The specific objectives are (1) to develop estimates of the condition number as a function of coarse and fine grid size for Laplace's

equation; (2) to evaluate computationally the scalability of this algorithm for Laplace's equation and to compare to theoretical estimates; and (3) to apply this algorithm to a difficult and important problem in hydrology, the flow of water in the unsaturated zone modeled by Richards' equation [16]. The first two objectives will advance and test the current theory of this algorithm for a simple equation, while the latter objective will provide some evidence of the applicability of this algorithm to a challenging class of applications for which improved solution algorithms are badly needed. We consider the theoretical analysis of this algorithm applied to Richards' equation and other nonlinear models as open issues and beyond the scope of this effort.

The use of smoothed aggregation elements in an additive Schwarz scheme was originally proposed in [2, 3]. In these papers this idea was tested on a variety of elliptic problems with complicated geometries. Construction of coarse mesh problems by aggregation was critical to the results reported in [8, 9, 7], where computations were done on unstructured grids in three space dimensions. Our coarse mesh basis functions are nonsmoothed, which means that the square of the H^1 bound on the basis functions is $O(\frac{H^{d-1}}{\delta})$ instead of $O(H^{d-1})$. Note that we do, for generality, include the possibility of overlap $\delta > h$. The method in [2, 3], however, assumes a physical overlap of $O(h)$ and obtains the benefits of overlap (i.e., bounds on the condition number independent of H and h) by smoothing the basis functions. These differences lead to a change in the energy of the coarse mesh operator so that $|Qu|^2_{H^1} \leq C\frac{H}{\delta}|u|^2_{H^1}$. Thus instead of having a condition number bound by a constant we get a condition bound that is $O(\frac{H^2}{\delta^2})$.

In our previous work [8, 9, 7], we used nonsmoothed aggregation elements with minimal overlap and exact subdomain solves. Similarly, in section 3 the overlap is h, where h is the fine mesh length scale, and we solve the subdomain problems exactly with sparse Gaussian elimination. The convergence results in section 2 allow for more flexibility in overlap and subdomain solvers.

The analysis in section 2 uses the standard finite element framework from [17, 23]. The preconditioner also works well in the context of finite differences, however, as the example in section 3.2 illustrates.

Richards' equation [16] is a model of flow through unsaturated porous media. In this paper we consider the head-based form of the equation and for a homogeneous media in two space dimensions,

$$\left[\frac{\partial \theta}{\partial \psi} + \frac{S_s}{\theta_s}\theta\right]\frac{\partial \psi}{\partial t} = \nabla \cdot \left[K_s k_r \nabla\left(\psi + z\right)\right], \tag{1.1}$$

where ψ is the pressure head, θ is the volume fraction of the wetting phase, and k_r is the relative permeability of the wetting phase. The remaining terms are scalar coefficients given in Table 1.1, along with their values for the test problem. θ and k_r are functions of ψ given by

$$\theta = (\theta_s - \theta_r)(1 + |\alpha\hat{\psi}|^n)^{-m} + \theta_r, \tag{1.2}$$

$$k_r = (1 + |\alpha\hat{\psi}|^n)^{-m/2}[1 - |\alpha\hat{\psi}|^{n-1}(1 + |\alpha\hat{\psi}|^n)^{-m}]^2, \text{ and} \tag{1.3}$$

$$\hat{\psi} = \min(\psi, 0), \tag{1.4}$$

where $m = 1 - 1/n$. These functions are derived from the van Genuchten [20] and Mualem [14] empirical relations among pressure, saturation, and relative permeability. We discretize (1.1) in space with finite differences and integrate the resulting system of differential algebraic equations in time with the fixed leading coefficient backward

Table 1.1
Richards' equation parameters.

Description	Symbol	Value
Saturated volume fraction	θ_s	3.01×10^{-1}
Residual volume fraction	θ_r	9.30×10^{-2}
Specific storage	S_s	1.00×10^{-6} (1/m)
Hydraulic conductivity	K_s	5.04×10^{0} (m/day)
Mean pore size	α	5.47×10^{0} (1/m)
Pore size uniformity	n	4.26×10^{0}

difference formulas of orders one to five [4, 10]. Within the implicit temporal integration is a Newton iteration, and we solve the nonsymmetric linear equation for the Newton step with a preconditioned Bi-CGSTAB [19] linear iteration.

2. Theory for an elliptic model problem.

The convergence theory in this paper is for the weak form of an elliptic boundary value problem with Dirichlet boundary conditions on a domain $\Omega \subset R^d$ with boundary Γ, with spatial dimension d. We will restrict our attention to piecewise linear nodal finite element spaces.

The goal is to find $u \in V$ such that

$$a(u, v) = l(v) \text{ for all } v \in V, \tag{2.1}$$

where a is a strongly elliptic bilinear form on V, l is a linear functional on V, and V is an appropriate function space.

We let $V^h \subset V$ be the appropriate space of piecewise linear functions. The approximating problem at level h is to find $u^h \in V^h$ such that

$$a(u^h, v) = l(v) \text{ for all } v \in V^h. \tag{2.2}$$

The problem (2.2) is equivalent to a linear system

$$Au^h = f \tag{2.3}$$

on V^h, where $a(u, v) = (Au, v)$ for all $u, v \in V^h$. Here $(\cdot, \cdot)$ is the l^2 inner product.

Schwarz preconditioners are designed to accelerate Krylov space iterative methods for the solution of (2.3).

2.1. One-level method.

We begin with the one-level additive Schwarz preconditioner. We divide Ω into subdomains $\{\Omega_j\}_{j=1}^J$ with an overlap width of δ and assume that $\bigcup_{j=1}^J \Omega_j = \Omega$.

Let R_j be the restriction map from an element of V^h to the subspace V_j of functions in V^h with support on Ω_j. Let

$$A_j = R_j A R_j^T$$

be the subdomain operator. We assume that A_j is nonsingular on V_j and define

$$B_j = R_j^T \tilde{A}_j^{-1} R_j,$$

where $\tilde{A}_j$ is an approximation of A_j. The one-level additive Schwarz preconditioner is

$$M = \sum_{j=1}^{J} B_j. \tag{2.4}$$

2.2. Two-level method. The two-level additive Schwarz method adds a coarse mesh term

$$B_0 = R_0^T \tilde{A}_0^{-1} R_0$$

to the one-level preconditioner. Here $\tilde{A}_0$ is an approximation of A_0. We let V^H denote the space of coarse mesh basis functions. If the coarse mesh restriction map R_0 and the coarse mesh operator A_0 are well designed, the condition number of MA is significantly reduced.

One way to define a coarse mesh problem is to discretize the continuous problem on a coarser mesh. There are a few difficulties associated with forming the coarse problem this way. First, for unstructured meshes, such as the ones considered in [7, 9, 8], the interpolation operators between the fine mesh and the coarse mesh are difficult to define. Second, a coarse mesh must be generated, stored, and parallelized. Finally, the PDE must be discretized and recomputed on the coarse mesh.

Alternatively, the discretization of the coarse mesh operator may be defined in terms of the existing fine mesh discretization. A Galerkin or variational coarse grid correction uses the fine grid matrix to obtain the coarse grid operator as $A_0 = R_0 A R_0^T$, where R_0^T is the interpolation operator from the coarse mesh function space, and R_0 is the restriction operator. If the coarse mesh basis functions are obtained from the fine mesh basis functions, then the coarse mesh space V^H is contained in the fine grid space V^h.

In this section we use the aggregation-based basis from [2, 3, 7, 8, 9], where one coarse mesh basis function is defined for each subdomain as the sum of the fine mesh basis functions for that subdomain.

To set the notation that we will need in section 2.4, let the expansion of a function $u \in V^h$ in the finite element basis be

$$u = \sum_l u_l \psi_l, \tag{2.5}$$

where the ψ_l's are the nodal basis functions for the fine mesh. A function $u_C \in V^H$ can be represented on the coarse mesh space as

$$u_C = \sum_K u_{C_K} \Psi_K, \tag{2.6}$$

where the Ψ_K's are the basis functions for the coarse mesh space. Since $V^H \subset V^h$, Ψ_K can be written as

$$\Psi_K = \sum_l R_{Kl} \psi_l. \tag{2.7}$$

The index K represents the subdomain number. The value of $R_{Kl} \geq 0$ is constrained by the conditions that $\nabla \Psi_K = O(\delta)$ and the requirement of the theory that the coarse mesh basis functions provide a partition of unity, i.e.,

$$\sum_K \Psi_K = 1.$$

In the case of minimal overlap, where $\delta = O(h)$, $R_{Kl} = 1$ if the support of the fine mesh basis function ψ_l is contained in subdomain K; otherwise, $R_{Kl} = 0$.

Further expanding the representation of u_C gives

$$\begin{aligned} u_C &= \sum_K u_{C_K} \Psi_K, \\ &= \sum_K u_{C_K} \sum_j R_{Kl} \psi_l, \\ &= \sum_l \left(\sum_K u_{C_K} R_{Kl} \right) \psi_l, \\ &= \sum_l \left(R^T u_C \right)_l \psi_l. \end{aligned}$$

Thus R^T is the operator which interpolates from the coarse mesh to the fine mesh. Any function on the coarse mesh can be represented solely in terms of the already existing fine mesh functions, making the formulation of a separate coarse mesh unnecessary.

2.3. Condition number estimate. In Assumption 2.1 we make precise the idea that H is the characteristic diameter of a subdomain. In Assumption 2.2 we make precise the overlap δ between the subdomains and the properties of the coarse mesh basis functions. These assumptions are based on assumptions given in [2, 3], but ours differ in the fact that an overlap parameter of δ is considered and the square of the energy of our coarse mesh basis function is bound by $\frac{H^{d-1}}{\delta}$ instead of H^{d-2}, where d is the dimension of the problem.

ASSUMPTION 2.1.

1. *There is* $C > 0$ *such that* $diam(\Omega_j) \leq CH$ *for all* $j = 1, \ldots, J$.
2. *There is* $c > 0$ *such that for all* $x \in \Omega$ *there exists* $j \geq 1$ *such that* $x \in \Omega_j$ *and*

$$\text{dist}\,(x, \partial\Omega_j \backslash \partial\Omega) \geq c\delta.$$

3. *There are* $C_R, C_1, C_2 > 0$ *such that for all* $x \in \Omega$ *the ball*

$$B\,(x, C_R H) = \{y \in \Omega : \text{dist}\,(y, x) \leq C_R H\}$$

intersects at most $C_1 + C_2^d$ *subdomains* Ω_j *(i.e., an object of diameter* $O\,(H)$ *intersects at most* $O(1)$ *subdomains* Ω_i*).*

4. $\mu\,(\Omega_j) \geq CH^d$, $j = 1, \ldots, J$.

In Assumption 2.1, μ denotes the Lebesgue measure.

ASSUMPTION 2.2. *Assume the basis functions* Ψ_i *of the coarse space satisfy the following.*

1. $|\Psi_i|^2_{H^1(\Omega)} \leq C\frac{H^{d-1}}{\delta}$,
   $\|\Psi_i\|^2_{L^2} \leq CH^d$.
2. *There is a domain* $\Omega^{int} \subset \Omega$ *such that* $\sum_i \Psi_i\,(x) = 1$ *for every* $x \in \Omega^{int}$ *and* $\text{dist}(x, \partial\Omega) \leq C\delta$ *for every* $x \in \Omega \backslash \Omega^{int}$.
3. $\text{supp}\,(\Psi_i) \subset \bar{\Omega}_i$.

In section 2.4 we prove the following theorem.

THEOREM 2.1. *Let* $V^h = \sum_{j=0}^J V_j \subset C(\bar{\Omega})$, *and let Assumptions* 2.1 *and* 2.2 *hold. Assume that there is* $\omega \geq 1$ *such that*

$$(v, v) \leq (\tilde{A}_j^{-1} A_j v, v) \leq \omega(v, v)$$

for all $v \in V^h$ *and* $0 \le j \le J$. *Let*

$$M = \sum_{j=0}^{J} B_j; \tag{2.8}$$

then there is $C > 0$, *independent of* H *and* h *such that*

$$\kappa(MA) \le C\omega(1 + (H/\delta)^2). \tag{2.9}$$

2.4. Convergence theory. The bound on the condition number for the system preconditioned using two-level additive Schwarz methods is given in [23, 22]. We use this theory to calculate our bound.

THEOREM 2.2. *Let* K_0 *be a positive constant so that, for any* $v \in V^h$, *there exists a decomposition* $v = \sum_{i=0}^{J} v_i$ *such that* $v_i \in V_i$ *and*

$$\sum_{i=0}^{J} (A_i v_i, v_i) \le K_0 (Av, v) . \tag{2.10}$$

Let

$$K_1 = \max_{1 \le j \le J} \sum_{i=1}^{J} \varepsilon_{ij}, \tag{2.11}$$

where, for $1 \le i, j \le J$, $\varepsilon_{ij} = 0$ *if* $V_i \perp V_j$; $\varepsilon_{ij} = 1$ *otherwise. Then*

$$\kappa (MA) \le \omega K_0 (1 + K_1) , \tag{2.12}$$

where

$$\omega = \max_{0 \le j \le J} \lambda_{\max} \left(\tilde{A}_j^{-1} A_j \right) .$$

We assume that the energy norm is equivalent to the H^1 seminorm, and we can therefore replace (2.10) by

$$\sum_{i=0}^{J} |u_i|^2_{H^1(\Omega)} \le K_0 |u|^2_{H^1(\Omega)}. \tag{2.13}$$

Our estimate for K_0 will be based on (2.13).

The value of K_1 is an indicator of the number of subdomains which contain any given point in Ω; we assume our partition is such that $K_1 = O(1)$. We solve the subdomain problems exactly in our numerical results, so $\tilde{A}_j = A_j$ for all j and $\omega = 1$ in section 3. Thus our condition number estimate is based on the estimate of K_0, which we obtain using Lemmas 2.3 and 2.4.

We define the coarse mesh projection $Q : V^h \to V^H$ by

$$Qu = \sum_{i=1}^{J} \alpha_i \Psi_i, \quad \alpha_i = \alpha_i (u) = \frac{1}{\mu (\Omega_i)} \int_{\Omega_i} u (x) \, dx,$$

where $u \in V^h$.

The value of K_0 depends on the bound of the energy of Qu and on the L^2 bound of the error in the coarse mesh operator, i.e., $u - Qu$. These bounds are provided in Corollary 2.3. This analysis is a modification of the results in [2, 3] for nonsmoothed aggregates.

Here, as in the remainder of this section, C is a constant that is independent of H and h. C may increase as the analysis progresses.

COROLLARY 2.3. *If Assumptions* 2.1 *and* 2.2 *hold, then*

$$\|u - Qu\|_{L^2}^2 \leq CH^2 |u|_{H^1}^2 , \tag{2.14}$$

$$|Qu|_{H^1}^2 \leq C\frac{H}{\delta} |u|_{H^1}^2 . \tag{2.15}$$

Proof. We give here the main results where our work differs from that in [2, 3], and we refer the reader to the details of the proof in those papers.

Since we have $\|\Psi_i\|_{L^2}^2 \leq CH^d$ by construction of our coarse mesh basis functions, we get

$$\|Qu\|_{L^2(\Omega)}^2 \leq C \|u\|_{L^2(\Omega)}^2 .$$

Therefore, by Poisson's inequality [6],

$$\|u - Qu\|_{L^2(\Omega)} \leq \|u\|_{L^2(\Omega)} + \|Qu\|_{L^2(\Omega)} \leq C \|u\|_{L^2(\Omega)} \leq CH |u|_{H^1(\Omega)} . \tag{2.16}$$

Since by construction we also have $|\Psi_i|_{H^1}^2 \leq C\frac{H^{d-1}}{\delta}$, we obtain

$$|Qu|_{H^1(\Omega)}^2 \leq C\tfrac{H}{\delta} |u|_{H^1(\Omega)}^2 . \qquad \square \tag{2.17}$$

We use these bounds in the following lemma.

LEMMA 2.4. *Under Assumptions* 2.1 *and* 2.2*, for every finite element function $u \in V^h$, there exists a decomposition $\{u_i\}_{i=0}^J$, $u_i \in V_i$, such that*

$$u = \sum_{i=0}^{J} u_i, \tag{2.18}$$

$$\sum_{i=0}^{J} |u_i|_{H^1(\Omega)}^2 \leq C \left(1 + \frac{H}{\delta}\right)^2 |u|_{H^1(\Omega)}^2 . \tag{2.19}$$

Proof. Define the fine mesh pointwise projection $I_h : C(\Omega) \to V^h$ by

$$I_h (u) = \sum_{l=1}^{n} u (x_l) \psi_l,$$

where $\{\psi_l\}_{l=1}^n$ is the finite element basis on the fine mesh, and $\{x_l\}_{l=1}^n$ are the fine mesh nodal points. Let u be partitioned such that

$$u_0 = Qu \text{ and } u_i = I_h (\theta_i(u - Qu)) ,$$

where, as in [17], $\{\theta_i\}$ is a smooth partition of unity such that

$$\begin{aligned} \theta_i &= 1 \text{ if } x \in \Omega_i \cup \Omega^{int},\ x \notin \Omega_j \text{ for } j \neq i, \text{ and} \\ \theta_i &= 0 \text{ if } x \notin \Omega_i. \end{aligned}$$

Hence $|\nabla\theta_i| \le \frac{1}{\delta}$. Clearly, by construction, for all $u \in V^h$,

$$\sum_{i=0}^{J} u_i = u.$$

The standard arguments [17] imply that

$$\sum_{i=0}^{J} |u_i|^2_{H^1(\Omega)} \le C\left(\frac{1}{\delta^2}\|u - Qu\|^2_{L^2(\Omega)} + |u - Qu|^2_{H^1(\Omega)} + |Qu|^2_{H^1(\Omega)}\right). \tag{2.20}$$

We complete the proof by applying Lemma 2.3 to estimate $|Qu|^2_{H^1(\Omega)}$ and $\|u - Qu\|^2_{L^2(\Omega)}$. □

If we let

$$K_0 = C\left(1 + \frac{H}{\delta}\right)^2,$$

we obtain the result in Theorem 2.1.

3. Numerical results.

In the two examples we used minimal overlap. Hence the coarse mesh problem is constructed by simply adding the matrix contributions for the nodes in a subdomain. The matrix representation for the restriction operator R_0 given minimal overlap h is

$$R_0 = \begin{bmatrix} 1 & 1 & \ldots & 1 & 0 & 0 & 0 & 0 & 0 & \ldots & 0 \\ 0 & 0 & \ldots & 0 & 1 & 1 & \ldots & 1 & 0 & \ldots & 0 \\ \vdots & & & & & & & & & & \end{bmatrix},$$

where the length of 1's in row i is determined by the number of unknowns in subdomain i.

Subdomain solves were exact, meaning that $\tilde{A}_j = A_j$ for all j and, therefore, that $\omega = 1$.

3.1. Laplace equation.

In this section we consider the simple test problem

$$\nabla^2 u = 0 \tag{3.1}$$

on the unit square $[0,1] \times [0,1]$ with zero Dirichlet boundary conditions. We use the function identically equal to one on the mesh as the initial iterate for a preconditioned conjugate gradient iteration. We terminated the iterations when the residual had been reduced by a factor of 10^{-4}. This example fully conforms to the theory from section 2.4.

In Table 3.1 we report results for a piecewise linear finite element discretization of (3.1). From the theory, one would expect the condition number κ to increase by a factor of 4 as either H is doubled or h is halved and to remain constant along the diagonals where H/h is constant. If, as is the case with the unpreconditioned problem, the iteration count is $O(\sqrt{\kappa})$, we would expect the iteration count to double if either H is held fixed and h is reduced by a factor of two or h is held fixed and H is increased by a factor of two.

If the iteration count is proportional to the square root of the condition number, as it is in the unpreconditioned case, then Table 3.1 shows that the growth in the number of iterations for fixed H and decreasing h is slower than predicted by the theory and is consistent with an $O(H/h)$ growth in the condition number. The rate of reduction in the iteration count as h is held fixed and as H is decreased is smaller still.

3.2. Richards' equation. The test domain is the unit square $[0, 1m] \times [0, 1m]$ with boundary and initial conditions

$$\begin{array}{rclll} \psi(x,0) & = & 0.0, & x \in [0,1], & t > 0, \\ \psi(x,1) & = & 0.1, & x \in [1/3, 2/3], & t > 0, \\ \dfrac{\partial \psi}{\partial z}(x,1) & = & -1.0, & x \in [0,1/3) \cup (2/3,1], & t > 0, \\ \dfrac{\partial \psi}{\partial x}(x,z) & = & 0.0, & x = 0,1 \quad z \in [0,1], & t > 0, \\ \psi(x,z) & = & -z, & x,z \in [0,1] \times [0,1], & t = 0. \end{array} \tag{3.2}$$

3.2.1. Finite difference discretization with minimal overlap. We discretized (1.1) by applying cell-centered finite differences to the spatial operator, thereby yielding the system of differential-algebraic equations,

$$\begin{aligned} F_{i,j}(t, \psi, \frac{\partial \psi}{\partial t}) = & \left(\frac{d\theta}{d\psi}_{i,j} + \frac{S_s}{\theta_s} \theta_{i,j} \right) \frac{\partial \psi_{i,j}}{\partial t} \\ & - \frac{1}{\Delta z^2} \left[K_{i+\frac{1}{2},j}(\psi_{i+1,j} - \psi_{i,j}) - K_{i-\frac{1}{2},j}(\psi_{i,j} - \psi_{i-1,j}) \right] \\ & - \frac{1}{\Delta z}(K_{i+\frac{1}{2},j} - K_{i-\frac{1}{2},j}) \\ & - \frac{1}{\Delta x^2} \left[K_{i,j+\frac{1}{2}}(\psi_{i,j+1} - \psi_{i,j}) - K_{i,j-\frac{1}{2}}(\psi_{i,j} - \psi_{i,j-1}) \right], \end{aligned} \tag{3.3}$$

where $i = 0, \ldots, N-1$, $j = 0, \ldots, N-1$, $\Delta z = \Delta x = 1/N$, and

$$K_{i\pm\frac{1}{2},j} = \left[(K_s k_r)_{i\pm1,j} + (K_s k_r)_{i,j} \right] /2, \tag{3.4}$$

$$K_{i,j\pm\frac{1}{2}} = \left[(K_s k_r)_{i,j\pm1} + (K_s k_r)_{i,j} \right] /2. \tag{3.5}$$

The semidiscrete system was integrated in time over [0, 0.0149 days]. Order and step-size were selected via local truncation error estimates, and the local truncation error tolerance was set to $10\Delta x^2$, thereby balancing temporal and spatial truncation error. A secondary effect of this choice is that the number of iterations needed for convergence grows more slowly as Δx is reduced than would be the case for a steady-state problem. This effect is clearly visible in all the results reported in Tables 3.2, 3.3, and 3.4.

At a given step t_{n+1}, the application of the integration method yielded a nonlinear system of the form

$$F[t_{n+1}, \psi_{n+1}, g(\psi_{n+1})] = G(\psi_{n+1}) = 0,$$

where $g(\psi)$ is a the backward difference formula for $\partial\psi/\partial t$. We solved the nonlinear system with an inexact Newton iteration that terminated when the 2-norm of the nonlinear residual was reduced by a factor of 10^{-5}.

At each Newton iteration we obtained the Newton step δ^{m+1}, by solving the linear system

$$\left[\frac{\partial G}{\partial \psi}(\psi^m_{n+1})\right]\delta^{m+1} = -G(\psi^m_{n+1})$$

with scaled, preconditioned BiCGstab. The scaling was obtained from the integration method's weighted root mean squared norm [15, 10, 1, 4]. In real applications, such a scaling would allow termination of the linear iteration according to tolerances specified by the integration scheme. However, for this test we computed the l^2 norm of the true linear residual for each linear iteration and terminated the linear iteration when that norm had been reduced by a factor of 10^{-7}. We did this both to more accurately estimate the effects of the preconditioner and to insure that errors in the Newton step were insignificant with respect to the Newton iteration and integration. The choices of termination criteria for the linear and nonlinear solvers imply that the time steps that the code uses are independent of the choice of preconditioner.

The preconditioner was two-level additive Schwarz using (3.1). The subdomains had the minimal overlap of $\Delta x = 1/N$. Table 3.2 gives the average BiCGstab iterations per Newton iteration for two-level additive Schwarz. The iteration count is constant as H and h are reduced simultaneously, as was the case with the simple example from section 3.1.

The iteration counts in Table 3.2 increase more slowly than the theory would predict if, as would be the case with a discretized elliptic problem and conjugate gradient iteration, the iteration count increased as the square of the condition number. In that case, if the condition number is $O(1 + H^2/h^2)$, then the iteration count would double as either H doubled or as h was halved.

For comparison we include similar statistics for a one-level additive Schwarz preconditioner in Table 3.3 and for no preconditioning in Table 3.4. Point Jacobi preconditioning is the $H = h$ diagonal in Table 3.3. Neither of these scale well as H and h are reduced together.

4. Conclusions. In the context of Richards' equation, a model for subsurface flow through the unsaturated zone, we have demonstrated the effectiveness of the two-level additive Schwarz preconditioner using nonsmoothed aggregates for the coarse space on a temporally dependent, nonlinear problem. Our convergence estimates for a simpler model problem are consistent with the observations for Richards' equation, a problem to which the theory does not apply.

Acknowledgments. We wish to thank Marian Brezina, Jim Jones, Van Henson, David Keyes, Andrea Toselli, Mary Wheeler, Carol Woodward, and Jun Zou for many helpful discussions and Dave Klepacki, Matt Matthews, Mark Reed, Eric Sills, and Bob Walkup for their help with the computations. We are particularly grateful to our collaborators at the U.S. Army Engineer Research and Development Center: Charlie Berger, Jackie Hallberg, Stacy Howington, John Peters, Joe Schmidt, and Alan Stagg. We also wish to thank the referees for their helpful suggestions.

ON THE CONSTRUCTION OF DEFLATION-BASED PRECONDITIONERS*

J. FRANK† AND C. VUIK‡

Abstract. In this article we introduce new bounds on the effective condition number of deflated and preconditioned-deflated symmetric positive definite linear systems. For the case of a subdomain deflation such as that of Nicolaides [*SIAM J. Numer. Anal.*, 24 (1987), pp. 355–365], these theorems can provide direction in choosing a proper decomposition into subdomains. If grid refinement is performed, keeping the subdomain grid resolution fixed, the condition number is insensitive to the grid size. Subdomain deflation is very easy to implement and has been parallelized on a distributed memory system with only a small amount of additional communication. Numerical experiments for a steady-state convection-diffusion problem are included.

Key words. deflation, preconditioners, optimal methods, parallel computing, conjugate gradients

1. Background: Preconditioning and deflation.

It is well known that the convergence rate of the conjugate gradient method is bounded as a function of the condition number of the system matrix to which it is applied. Let $A \in \mathbb{R}^{n\times n}$ be symmetric positive definite. We assume that the vector $f \in \mathbb{R}^n$ represents a discrete function on a grid Ω and that we are searching for the vector $u \in \mathbb{R}^n$ on Ω which solves the linear system

$$Au = f.$$

Such systems are encountered, for example, when a finite volume/difference/element method is used to discretize an elliptic partial differential equation (PDE) defined on the continuous analogue of Ω. In particular our goal is to develop efficient serial and parallel methods for applications in incompressible fluid dynamics; see [28, 27].

Let us denote the spectrum of A by $\sigma(A)$ and the ith eigenvalue in nondecreasing order by $\lambda_i(A)$ or simply by λ_i when it is clear to which matrix we are referring. After k iterations of the conjugate gradient method, the error is bounded by (cf. [10, Thm. 10.2.6]

$$\|u - u_k\|_A \leq 2\,\|u - u_0\|_A \left(\frac{\sqrt{\kappa}-1}{\sqrt{\kappa}+1}\right)^k, \tag{1.1}$$

where $\kappa = \kappa(A) = \lambda_n/\lambda_1$ is the spectral condition number of A and the A-norm of u is given by $\|u\|_A = (u^T A u)^{1/2}$. The error bound (1.1) does not tell the whole story, however, because the convergence may be significantly faster if the eigenvalues of A are clustered [23].

When A is the discrete approximation of an elliptic PDE, the condition number can become very large as the grid is refined, thus slowing down convergence. In this case it is advisable to solve, instead, a preconditioned system $K^{-1}Au = K^{-1}f$, where the symmetric positive definite preconditioner K is chosen such that $K^{-1}A$ has a more clustered spectrum or a smaller condition number than that of A. Furthermore, K must be cheap to solve relative to the improvement it provides in convergence rate. A final desirable property in a preconditioner is that it should parallelize well, especially on distributed memory computers. Probably the most effective preconditioning strategy in common use is to take $K = LL^T$ to be an incomplete Cholesky (IC) factorization of A [18]. For discretizations of second order PDEs in two dimensions, defined on a grid with spacing h, one finds, with IC factorization, $\kappa \sim h^{-2}$; with a modified IC factorization [11, 1], $\kappa \sim h^{-1}$; and with a multigrid cycle, $\kappa \sim 1$. Preconditioners such as multigrid and some domain decomposition methods, for which the condition number of the preconditioned system is independent of the grid size, are termed *optimal*.

Another preconditioning strategy that has proven successful when there are a few isolated extremal eigenvalues is *deflation* [20, 16, 17]. Let us define the projection P by

$$P = I - AZ(Z^TAZ)^{-1}Z^T, \quad Z \in \mathbb{R}^{n\times m}, \tag{1.2}$$

where Z is the deflation subspace, i.e., the space to be projected out of the residual, and I is the identity matrix of appropriate size. We assume that $m \ll n$ and that Z has rank m. Under this assumption $A_c \equiv Z^TAZ$ may be easily computed and factored and is symmetric positive definite. Since $u = (I - P^T)u + P^Tu$ and because

$$(I - P^T)u = Z(Z^TAZ)^{-1}Z^TAu = ZA_c^{-1}Z^Tf \tag{1.3}$$

can be immediately computed, we need only compute P^Tu. In light of the identity $AP^T = PA$, we can solve the deflated system

$$PA\tilde{u} = Pf \tag{1.4}$$

for $\tilde{u}$ using the conjugate gradient method and premultiply this by P^T. Obviously (1.4) is singular, and this raises a few questions. First, the solution $\tilde{u}$ may contain an arbitrary component in the null space of PA, i.e., in span$\{Z\}$.[1] This is not a problem, however, because the projected solution $P^T\tilde{u}$ is unique. Second, what consequences does the singularity of (1.4) imply for the conjugate gradient method?

Kaasschieter [14] notes that a positive semidefinite system can be solved as long as the right-hand side is consistent (i.e., as long as $f = Au$ for some u). This is certainly true for (1.4), where the same projection is applied to both sides of the nonsingular system. Furthermore, he notes (with reference to [23]) that because the null space never enters the iteration, the corresponding zero-eigenvalues do not influence the convergence. Motivated by this fact, we define the *effective condition number* of a positive semidefinite matrix $C \in \mathbb{R}^{n\times n}$ with corank m to be the ratio of its largest to smallest *positive* eigenvalues:

$$\kappa_{\text{eff}}(C) = \frac{\lambda_n}{\lambda_{m+1}}.$$

[1] We will use the notation span$\{Z\}$ to denote the column space of Z.

Example. To see that the condition number of PA may be better than that of A, consider the case in which Z is the invariant subspace of A corresponding to the smallest eigenvalues. Note that $PAZ = 0$, so that PA has m zero-eigenvalues. Furthermore, since A is symmetric positive definite, we may choose the remaining eigenspace Y in the orthogonal complement of span$\{Z\}$, i.e., $Y^T Z = 0$ so that $PY = Y$. However, $AY = YB$ for some invertible B; therefore, $PAY = PYB = YB$, and span$\{Y\}$ is an invariant subspace of PA. Evidently, when Z is an invariant subspace of A,

$$\kappa_{\text{eff}}(PA) = \frac{\lambda_n(A)}{\lambda_{m+1}(A)}.$$

In summary, deflation of an invariant subspace cancels the corresponding eigenvalues, leaving the rest of the spectrum untouched.

This idea has been exploited by several authors. For nonsymmetric systems, approximate eigenvectors can be extracted from the Krylov subspace produced by GMRES. Morgan [19] uses this approach to improve the convergence after a restart. In this case, deflation is not applied as a preconditioner, but the deflation vectors are augmented with the Krylov subspace, and the minimization property of GMRES ensures that the deflation subspace is projected out of the residual. For more discussion on deflation methods for nonsymmetric systems, see [15, 8, 6, 21, 5, 2]. Other authors have attempted to choose a subspace a priori that effectively represents the slowest modes. In [29] deflation is used to remove a few stubborn but *known* modes from the spectrum. Mansfield [16] shows how Schur-complement-type domain decomposition methods can be seen as a series of deflations. Nicolaides [20] chooses Z to be a piecewise constant interpolation from a set of m subdomains and points out that deflation might be effectively used with a conventional preconditioner. Mansfield [17] uses the same "subdomain deflation" in combination with damped Jacobi smoothing, obtaining a preconditioner which is related to the two-grid method.

In this article we introduce new bounds on the effective condition number of deflated and preconditioned-deflated symmetric positive definite linear systems. For the case of a subdomain deflation such as that of Nicolaides [20], these theorems can provide direction in choosing a proper decomposition into subdomains. If grid refinement is done keeping the subdomain grid resolution fixed, the condition number is insensitive to the grid size. Subdomain deflation is very easy to implement and has been parallelized on a distributed memory system with only a small amount of additional communication. Numerical experiments for a steady-state convection-diffusion problem are included.

2. A condition number bound for deflation.

Nicolaides [20] proves the following bound on the spectrum of PA:

$$\lambda_{m+1}(PA) = \min \frac{v^T v}{v^T A^{-1} v}, \quad \lambda_n(PA) = \max \frac{v^T v}{v^T A^{-1} v},$$

where v is taken in span$\{Z\}^\perp$. In this section we give a bound of a different flavor which will be used in the subsequent sections to construct a preconditioning strategy with an optimal convergence property.

First we need the following result on the preservation of positive semidefiniteness under deflation.

LEMMA 2.1. *Let R be positive semidefinite and P be a projection ($P^2 = P$); then if PR is symmetric, it is positive semidefinite.*

Proof. By hypothesis, $0 \leq u^T R u$ for all u. In particular, $0 \leq (P^T u)^T R (P^T u) = u^T P R P^T u$ so that $PRP^T = P^2 R = PR$ is positive semidefinite. $\square$

The next theorem provides a bound on the condition number of PA and is our main result.

THEOREM 2.2. *Let A be symmetric positive definite, let P be defined by* (1.2), *and suppose there exists a splitting $A = C + R$ such that C and R are symmetric positive semidefinite with $\mathcal{N}(C) = \text{span}\{Z\}$ the null space of C. Then*

$$\lambda_i(C) \leq \lambda_i(PA) \leq \lambda_i(C) + \lambda_{\max}(PR). \tag{2.1}$$

Moreover, the effective condition number of PA is bounded by

$$\kappa_{\text{eff}}(PA) \leq \frac{\lambda_n(A)}{\lambda_{m+1}(C)}. \tag{2.2}$$

Proof. From (1.2) it is obvious that PA is symmetric. Since Z is in the null space of C, we have that $PC = C$ and is therefore also symmetric by hypothesis. Symmetry of $PR = PA - C$ follows immediately; and by assumption R is positive semidefinite, so we can apply Lemma 2.1 to arrive at $\lambda_{\min}(PR) \geq 0$, with equality holding in any case due to singularity of P. The bound (2.1) now follows from Theorem 8.1.5 of [10]:

$$\lambda_i(PC) + \lambda_{\min}(PR) \leq \lambda_i(PA) \leq \lambda_i(PC) + \lambda_{\max}(PR).$$

Furthermore, because $PA = A - AZ(Z^T AZ)^{-1}(AZ)^T$ is the difference of positive (semi-)definite matrices, the same theorem (Theorem 8.1.5 of [10]) gives $\lambda_{\max}(PA) \leq \lambda_{\max}(A)$. This upper bound together with the lower bound in (2.1) proves (2.2). $\square$

There is also a preconditioned version of the previous theorem.

THEOREM 2.3. *Assume the conditions of Theorem* 2.2 *and let K be a symmetric positive definite preconditioner with Cholesky factorization $K = LL^T$. Then*

$$\lambda_i(L^{-1}CL^{-T}) \leq \lambda_i(L^{-1}PAL^{-T}) \leq \lambda_i(L^{-1}CL^{-T}) + \lambda_{\max}(L^{-1}PRL^{-T}), \tag{2.3}$$

and the effective condition number of $L^{-1}PAL^{-T}$ is bounded by

$$\kappa_{\text{eff}}(L^{-1}PAL^{-T}) \leq \frac{\lambda_n(L^{-1}AL^{-T})}{\lambda_{m+1}(L^{-1}CL^{-T})}. \tag{2.4}$$

Proof. Define $\hat{A} = L^{-1}AL^{-T}$, $\hat{C} = L^{-1}CL^{-T}$, $\hat{R} = L^{-1}RL^{-T}$ (all congruence transformations), $\hat{Z} = L^T Z$, and

$$\hat{P} = I - \hat{A}\hat{Z}(\hat{Z}^T \hat{A}\hat{Z})^{-1}\hat{Z}^T = L^{-1}PL.$$

Note that $\hat{P}$ is a projection and $\hat{P}\hat{A}$ is symmetric, and also that $\hat{Z}$ is in the null space of $\hat{C}$ so that $\hat{P}\hat{C} = \hat{C}$. Thus, Theorem 2.2 applies directly to the deflated system matrix $\hat{P}\hat{A}$. The conclusions follow immediately from the definitions of $\hat{A}$ and $\hat{C}$. $\square$

Remark. Experience with discretized PDEs indicates that the greatest improvement in convergence is obtained by removing the smallest eigenvalues from the spectrum. It is therefore the lower bounds of (2.1) and (2.3) which are of most concern. Theorem 2.3 suggests that it might be better to construct a preconditioner for C rather than for A in this case. However, care should be taken that a good preconditioner for C does not increase the upper bound in (2.3) when applied to A. See Kaasschieter [14] for a discussion about preconditioning indefinite systems.

In the next section we consider applications of Theorems 2.2 and 2.3 in lieu of a specific choice of the subspace of deflation Z.

3. Subdomain deflation. The results of the previous section are independent of the choice of deflation subspace Z in (1.2). As mentioned in section 1, deflation of an eigenspace cancels the corresponding eigenvalues without affecting the rest of the spectrum. This has led some authors to try to deflate with "nearly invariant" subspaces obtained during the iteration, and led others to try to choose in advance subspaces which represent the extremal modes.

For the remainder of this article we make a specific choice for the subspace Z in (1.2), based on a decomposition of the domain Ω with index set $\mathcal{I} = \{i \,|\, u_i \in \Omega\}$ into m nonoverlapping subdomains Ω_j, $j = 1, \ldots, m$, with respective index sets $\mathcal{I}_j = \{i \in \mathcal{I} \,|\, u_i \in \Omega_j\}$. We assume that the Ω_j are simply connected graphs covering Ω. Define Z by

$$z_{ij} = \begin{cases} 1, & i \in \mathcal{I}_j, \\ 0, & i \notin \mathcal{I}_j. \end{cases} \tag{3.1}$$

With this choice of Z, the projection (1.2) will be referred to as *subdomain deflation*. Such a deflation subspace has been used by Nicolaides [20] and Mansfield [16, 17].

This choice of deflation subspace is related to domain decomposition and multigrid methods. The projection P can be seen as a subspace correction in which each subdomain is agglomerated into a single cell; see, for example, [13]. Within the multigrid framework, P can be seen as a coarse grid correction using a piecewise constant interpolation operator with very extreme coarsening.

Note that the matrix $A_c = Z^T AZ$, the projection of A onto the deflation subspace Z, has sparsity pattern similar to that of A. We will see that the effective condition number of PA improves as the number of subdomains is increased (for a fixed problem size). However, this implies that the dimension of A_c also increases, making direct solution expensive. By analogy with multigrid, it might be advantageous in some applications to solve A_c recursively.[2] In a parallel implementation this would lead to additional idle processor time, as it does with multigrid.

3.1. Application to Stieltjes matrices. Using subdomain deflation, we can identify matrices C and R needed for application of Theorems 2.2 and 2.3 to the class of irreducibly diagonally dominant Stieltjes matrices (i.e., symmetric M-matrices). Such matrices commonly arise as a result of discretization of symmetric elliptic and parabolic PDEs. For our purposes the following characteristics are important:

- A is symmetric positive definite and irreducible.
- $a_{ii} > 0$, $a_{ij} \leq 0$ for $i \neq j$.
- $a_{ii} + \sum_{j \neq i} a_{ij} \geq 0$ with strict inequality holding for some i.

For a matrix A, define the subdomain block-Jacobi matrix $B(A) \in \mathbb{R}^{n \times n}$ associated to A by

$$b_{ij} = \begin{cases} a_{ij} & \text{if } i, j \in \mathcal{I}_k, \text{ for some } k, \\ 0 & \text{otherwise.} \end{cases} \tag{3.2}$$

Notice that since each block B_{jj} is a principle submatrix of A, it is symmetric positive definite. Also, since B is obtained from A by deleting off-diagonal blocks containing only negative elements, the B_{jj} are at least as diagonally dominant as the corresponding rows of A. Furthermore, the irreducibility of A implies that A itself cannot be

[2] A referee pointed out to us that the two-level method with direct solution of A_c has suboptimal complexity. On the other hand, for the examples considered in this article, A_c is too small for a second coarsening.

written in block diagonal form, so to construct B it is necessary to delete at least one nonzero block from each block-row. As a result, at least one row of each B_{jj} is strictly diagonally dominant. We will further assume that the so-constructed B_{jj} are irreducible.[3] It follows from Corollary 6.4.11 of [12] that the B_{jj} are again Stieltjes matrices.

Additionally, define $\mathbf{1} = (1, \ldots, 1)^T$ with the dimension following from the context, such that $A\mathbf{1}$ is the vector of row sums of A. Let the matrix C be defined by

$$C = B - \operatorname{diag}(B\mathbf{1})\,. \tag{3.3}$$

Each block C_{jj} of C has zero row sums—so $\mathbf{1}$ is in the null space of each block—but is further irreducible and weakly diagonally dominant and has the M-matrix property. According to Theorem 4.16 of [3], a singular M-matrix has a null space of rank exactly 1. It follows that the matrix Z defined by (3.1) is a basis for the null space of C.

Putting these ideas together we formulate the following.

Theorem 3.1. *If A is an irreducibly diagonally dominant Stieltjes matrix and C defined by* (3.3) *has only irreducible blocks, then the hypotheses of Theorem* 2.2 *are met.*

Example. Consider a Poisson equation on the unit square with homogeneous Dirichlet boundary conditions

$$-\Delta u = f, \quad u = 0, u \in \partial\Omega, \quad \Omega = [0,1] \times [0,1]. \tag{3.4}$$

The problem is discretized using central finite differences on a 9×9 grid, and subdomain deflation is applied with a 3×3 decomposition into blocks of resolution 3×3. The system matrix A is pre- and postmultiplied by the inverse square root of its diagonal. Figure 3.1 shows the eigenvalues of A, PA, and C. The extreme positive eigenvalues of these three matrices are

	$\lambda_{\min}$	$\lambda_{\max}$
A	0.06	1.94
PA	0.27	1.91
C	0.25	1.50

Both the table and the figure support the conclusions of Theorem 2.2; namely, that the largest eigenvalue of A and the smallest nonzero eigenvalue of C bound the spectrum of PA. (Note that each eigenvalue of C has multiplicity equal to the number of blocks—9 in this case.) We observe also that the bounds are reasonably sharp.

Each diagonal block C_{jj} of the matrix C as defined by (3.3) can be interpreted as the discretization of a related Neumann problem on the jth subdomain. By Theorem 2.2, the effective condition number of the deflated matrix PA is determined by the smallest nonzero eigenvalue of C—in this case, the smallest nonzero eigenvalue over the set of related Neumann problems on the subdomain grids, i.e.,

$$\lambda_{m+1}(PA) = \min_j \lambda_2(C_{jj}).$$

[3] This is generally the case with matrices arising from discretization of PDEs on simply connected domains. If a block B_{ii} *is* reducible, then it may be possible to decompose B_{ii} into additional subdomains which *are* irreducible.

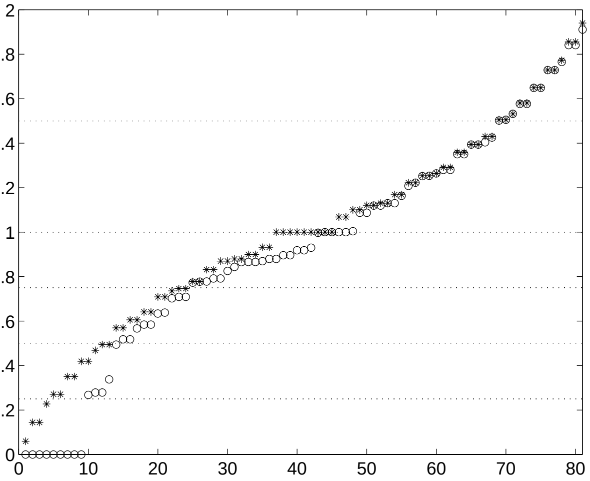

FIG. 3.1. *The eigenvalues of A (*), PA ($\circ$), and C ($\cdots$).*

Theorem 2.2 thus says that *subdomain deflation effectively decouples the original system into a set of independent Neumann problems on the subdomains,* with convergence governed by the "worst-conditioned" Neumann problem. This implies an optimality result, since—if we can somehow refine the grid without affecting the worst-conditioned Neumann problem—the condition number will also remain unchanged. For an isotropic problem on a uniform grid, for example, this can be achieved by simply fixing the subgrid resolutions and performing refinement by adding more subdomains. The numerical experiments of section 6 support this observation.

3.2. Application to finite element stiffness matrices. A result similar to the above discussion on M-matrices holds for finite element stiffness matrices. We briefly describe it here. Suppose we have a domain Ω whose boundary is given by $\partial\Omega = \partial\Omega^D \cup \partial\Omega^N$, with Dirichlet boundary conditions on $\partial\Omega^D$ and Neumann boundary conditions on $\partial\Omega^N$. Let Ω be decomposed into m nonoverlapping subdomains Ω_j, $j = 1, \ldots, m$, and define the finite element decomposition of Ω by

$$\bar{\Omega} = \cup_{i\in\mathcal{I}} \bar{e}_i.$$

Let the index set $\mathcal{I}$ be divided into $m+1$ disjoint subsets $\mathcal{I}_1, \ldots, \mathcal{I}_m$ and $\mathcal{I}_r$, defined by

$$\mathcal{I}_j = \left\{ i \in \mathcal{I} \,|\, e_i \subset \Omega_j \text{ and } \bar{e}_i \cap \partial\Omega^D = \varnothing \right\},$$

and $\mathcal{I}_r = \mathcal{I} \backslash \cup_j \mathcal{I}_j$. Figure 3.2 shows an example of a domain with quadrilateral elements and two subdomains.

The stiffness matrix A is defined as the sum of elemental stiffness matrices A_{e_i}:

$$A = \sum_{i\in\mathcal{I}} A_{e_i},$$

where the elemental matrices are assumed to be positive semidefinite. This is always the case when the integrals in the element matrices are computed analytically. We assume that A is symmetric positive definite. This is normally true if the solution

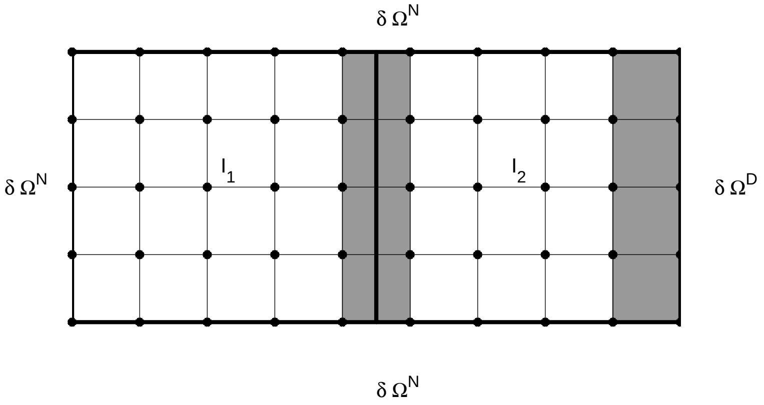

FIG. 3.2. *The domain Ω is decomposed into two subdomains (the shaded region is $\mathcal{I}_r$).*

is prescribed somewhere on the boundary. The matrix C needed for Theorem 2.2 is defined by

$$C = \sum_{i \in \mathcal{I} \backslash \mathcal{I}_r} A_{e_i}.$$

Note that C is block diagonal and the blocks C_{jj} can be interpreted as a finite element discretization of the original system on the subdomain Ω_j with homogeneous Neumann boundary conditions. This implies that $\lambda_1(C_{jj}) = 0$ and that Z is in the null space of C. Clearly C is positive semidefinite, as is

$$R = \sum_{i \in \mathcal{I}_r} A_{e_i}.$$

To ensure that $\lambda_{m+1}(C) \neq 0$, it is necessary that every grid point $x_k \in \bar{\Omega} \backslash \partial\Omega^D$ be contained in a finite element e_i with $i \in \cup_{j=1}^m \mathcal{I}_j$; otherwise the ith row of C contains only zero elements.

4. Guidelines for selecting subdomains.

We can use the results of the previous section to give guidance in choosing a good decomposition of the domain Ω such that the "worst-conditioned related Neumann problem" is as well conditioned as possible. We consider two cases: a Poisson equation on a stretched uniform grid, and a diffusion equation with a discontinuity in the diffusion coefficient.

4.1. Large domain/grid aspect ratios.

Consider the Poisson equation with homogeneous Neumann boundary conditions on a rectangular domain Ω:

$$-\Delta u = f, \quad \partial u / \partial \hat{n} = 0, \; u \in \partial\Omega,$$

where $\hat{n}$ denotes the unit normal vector to the boundary. This equation is discretized using cell-centered, central finite volumes on a uniform $N_x \times N_y$ grid having cell dimensions $h_x \times h_y$:

$$\frac{1}{h_x^2}(-u_{j-1,k} + 2u_{j,k} - u_{j+1,k}) + \frac{1}{h_y^2}(-u_{j,k-1} + 2u_{j,k} - u_{j,k+1}) = f_{j,k}$$

for $j = 0, \ldots, N_x$ and $k = 0, \ldots, N_y$. Assume central discretization of the boundary conditions

$$u_{-1,k} = u_{0,k}, \text{ etc.};$$

then, the eigenvalues of the discretization matrix are given by

$$\lambda_{j,k} = \frac{4}{h_x^2} \sin^2\left(\frac{j\pi}{2(N_x+1)}\right) + \frac{4}{h_y^2} \sin^2\left(\frac{k\pi}{2(N_y+1)}\right). \tag{4.1}$$

The largest eigenvalue is λ_{N_x,N_y} and the smallest nonzero eigenvalue is the minimum of $\lambda_{0,1}$ and $\lambda_{1,0}$. Substituting into (4.1), and assuming $N_x, N_y \gg 1$, we find

$$\begin{aligned}\lambda_{N_x,N_y} &\approx \frac{4}{h_x^2} + \frac{4}{h_y^2},\\ \lambda_{0,1} &\approx \frac{4}{h_y^2}\left(\frac{\pi}{2(N_y+1)}\right)^2 = \frac{\pi^2}{h_y^2(N_y+1)^2},\\ \lambda_{1,0} &\approx \frac{4}{h_x^2}\left(\frac{\pi}{2(N_x+1)}\right)^2 = \frac{\pi^2}{h_x^2(N_x+1)^2}.\end{aligned} \tag{4.2}$$

The decomposition problem can be stated as follows: For a fixed cell aspect ratio $\mathcal{Q}_c \equiv h_x/h_y$ and a fixed total number of cells $\gamma \equiv N_x N_y = \text{const}$, find the grid aspect ratio $\mathcal{Q}_g \equiv N_x/N_y$ minimizing the effective condition number

$$\begin{aligned}\kappa_{\text{eff}} &= \max\left\{\frac{\lambda_{N_x,N_y}}{\lambda_{0,1}}, \frac{\lambda_{N_x,N_y}}{\lambda_{1,0}}\right\}\\ &= 4/\pi^2 \max\left\{(1+\mathcal{Q}_c^{-2})(\gamma/N_x+1)^2, (1+\mathcal{Q}_c^2)(N_x+1)^2\right\}.\end{aligned}$$

Since both arguments of the maximum are monotone functions of positive N_x, one increasing and the other decreasing, the condition number is minimized when these arguments are equal:

$$\begin{gathered}(1+\mathcal{Q}_c^{-2})(\gamma/N_x+1)^2 = (1+\mathcal{Q}_c^2)(N_x+1)^2,\\ \frac{1}{\mathcal{Q}_c^2} = \frac{1+\mathcal{Q}_c^{-2}}{1+\mathcal{Q}_c^2} = \frac{(N_x+1)^2}{(N_y+1)^2} \approx \mathcal{Q}_g^2.\end{gathered}$$

Thus, for constant coefficients and a uniform grid, one should choose a decomposition such that the subdomain grid aspect ratio is the reciprocal of the cell aspect ratio; that is, one should strive for a subdomain aspect ratio $\mathcal{Q}_d \equiv (N_x h_x)/(N_y h_y)$ of 1:

$$\mathcal{Q}_d = \mathcal{Q}_g \mathcal{Q}_c = 1.$$

Example. Again take the Poisson equation on the unit square (3.4), with a grid resolution $N_x = 16$, $N_y = 32$. We compare the condition number of PA for three decompositions into 16 subdomains as shown in Figure 4.1:

	$\lambda_{\min}(C)$	$\lambda_{\min}(PA)$	$\kappa(PA)$
2×8	0.013	0.024	83.0
4×4	0.053	0.062	32.2
8×2	0.014	0.024	81.8

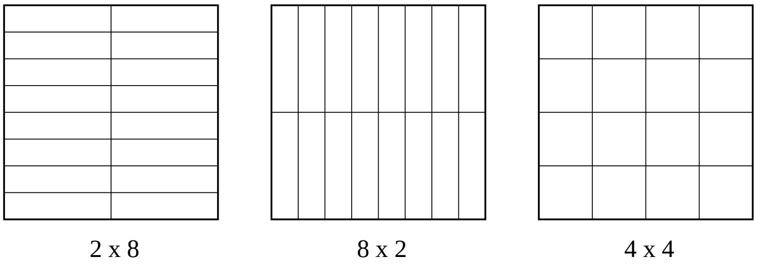

FIG. 4.1. *Three decompositions of the unit square into* 16 *subdomains.*

The 4×4 decomposition yields a subdomain aspect ratio of $\mathcal{Q}_d = 1$, and this is the best-conditioned case, as predicted.

The decomposition problem described above assumes that the grid size and the number of domains is given, and that one would like to choose the decomposition for optimal convergence rate. This would be the case, for example, if a parallel decomposition is desired on a prescribed number of processors. For a serial computation, or if there is an unlimited number of available processors, a better approach would be to ask what number of domains gives the fastest solution. Suppose we decompose into subdomains of unit aspect ratio, as described above. By comparison with (4.2), the smallest positive eigenvalue of C scales as $1/N_x^2$, with N_x the number of grid cells in the x direction for the worst-conditioned Neumann problem. Thus if we split each subdomain horizontally and vertically into four equivalent smaller subdomains, the condition number of C is improved by a factor of 4, roughly speaking. On the other hand, the dimension of the coarse grid matrix A_c will be increased by a factor of 4, causing the direct (or recursive) solution of this system to be relatively more expensive. In the extreme case of one unknown per subdomain, $A_c = A$, so that solving A_c is as expensive as solving A. Clearly, there must be an optimal value for the number of subdomains; however, this will depend on the convergence of the conjugate gradients process, and therefore also on the distribution of eigenvalues.

4.2. Discontinuous coefficients. When a problem has a large jump in coefficients at some location, poor scaling may result in slow convergence. It may be possible to improve the convergence by applying subdomain deflation, choosing the subdomain interface at the discontinuity. Since the related Neumann problems are decoupled, a diagonal scaling preconditioner is sufficient to make the condition number independent of the jump in coefficients. This is best illustrated with an example.

Consider a one-dimensional diffusion problem with Neumann and Dirichlet boundary conditions

$$-\frac{d}{dx}\alpha(x)\frac{du}{dx} = f(x), \quad x \in (0,1), \quad \frac{du}{dx}(0) = 0, \ u(1) = 1,$$

and a jump discontinuity in the coefficient

$$\alpha(x) = \begin{cases} 1, & x \leq 0.5, \\ \epsilon, & x > 0.5 \end{cases}$$

for some $\epsilon > 0$. Choose an even number n and define $h = 1/n$. The grid points are given by $x_i = ih, i = 0, \ldots, n$ and u_i is the numerical approximation for $u(x_i)$. For all $i \in \{0, 1, \ldots, n-1\} \setminus \{n/2\}$ we use the standard central difference scheme.

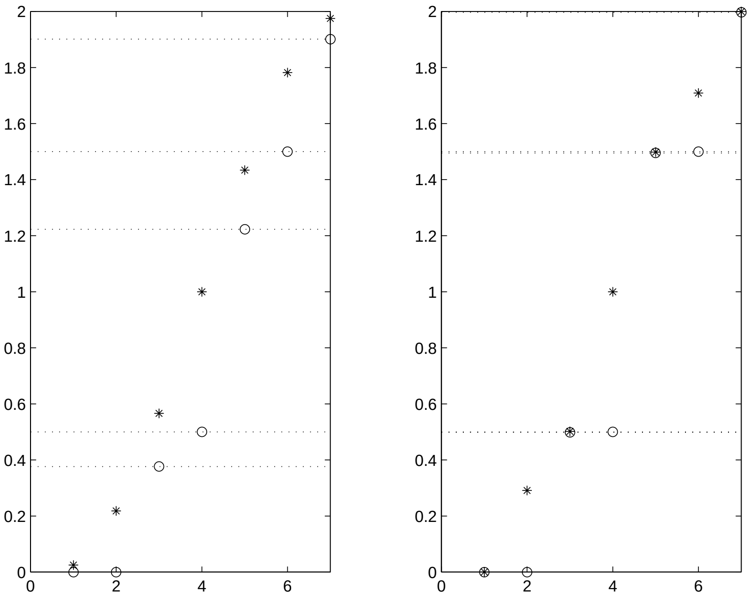

FIG. 4.2. *Eigenvalues of $D^{-1}A$ ($*$) and $D^{-1}PA$ ($\circ$) for $\epsilon = 1$ (left) and $\epsilon = 0.01$ (right). The spectrum of $D^{-1}C$ is indicated by the dotted lines.*

The unknown u_n is eliminated from the system of equations by using the Dirichlet boundary condition. For $i = 0$ the value u_{-1} is eliminated by a central discretization of the Neumann boundary condition. The resulting equation is multiplied by 1/2 to make the coefficient matrix symmetric. Finally for $i = n/2$ the discrete equation is

$$\frac{\frac{u_{n/2}-u_{n/2-1}}{h} - \epsilon\frac{u_{n/2+1}-u_{n/2}}{h}}{h} = f(x_{n/2}).$$

The domain $\Omega = [0, 1]$ is subdivided into two subdomains $\Omega_1 = [0, 0.5]$ and $\Omega_2 = (0.5, 1]$. Note that grid point $x_{n/2} = 0.5$ belongs to Ω_1. The subdomain deflation space Z is defined by (3.1).

To construct C from A we decouple the matrix A according to the subdomains, so

$$c_{n/2+1,n/2} = c_{n/2,n/2+1} = 0.$$

The other off-diagonal elements of A and C are identical. Finally the diagonal elements of C are made equal to minus the sum of the off-diagonal elements, so

$$\sum_{j=1}^{n} c_{ij} = 0.$$

Let D be the diagonal of A. The eigenvalues of $D^{-1}A$ and $D^{-1}PA$ (equivalent to the eigenvalues of the symmetrically preconditioned case $D^{-1/2}AD^{-1/2}$, etc.) with $n = 8$ are shown in Figure 4.2 for $\epsilon = 1$ and $\epsilon = 0.01$ with the eigenvalues of $D^{-1}C$ appearing as dotted lines. Note that the smallest positive eigenvalue of $D^{-1}C$ bounds from below the smallest positive eigenvalue of $D^{-1}PA$, as predicted by Theorem 2.3.

In the following table we give the effective condition numbers relevant for convergence of the preconditioned conjugate gradient method.

ϵ	$\lambda_1(D^{-1}A)$	$\kappa(D^{-1}A)$	$\lambda_3(D^{-1}PA)$	$\kappa_{\text{eff}}(D^{-1}PA)$
1	$2.5 \cdot 10^{-2}$	$7.9 \cdot 10^{1}$	$3.8 \cdot 10^{-1}$	5.0
10^{-2}	$4.1 \cdot 10^{-4}$	$4.8 \cdot 10^{3}$	$5.0 \cdot 10^{-1}$	4.0
10^{-4}	$4.2 \cdot 10^{-6}$	$4.8 \cdot 10^{5}$	$5.0 \cdot 10^{-1}$	4.0

Due to diagonal preconditioning, the smallest nonzero eigenvalue of $D^{-1}C$ is independent of ϵ. As predicted by Theorem 2.3, the same holds for $D^{-1}PA$. The smallest eigenvalue of $D^{-1}A$, however, decreases proportionally to ϵ, leading to a large condition number and slow convergence of the conjugate gradient method applied to $D^{-1}Au = D^{-1}f$.

5. Additional considerations.

In this section we discuss extension of deflation methods to the nonsymmetric case and describe an efficient parallel implementation of the subdomain deflation method.

5.1. The nonsymmetric case.

A generalization of the projection P for a nonsymmetric matrix $A \in \mathbb{R}^{n\times n}$ is used in [29]. In this case there is somewhat more freedom in selecting the projection subspaces. Let P and Q be given by

$$P = I - AZ(Y^TAZ)^{-1}Y^T, \quad Q = I - Z(Y^TAZ)^{-1}Y^TA,$$

where Z and Y are suitable subspaces of dimension $n \times m$. The operator A_c on the projection subspace is given by $A_c = Y^TAZ$.[4] We have the following properties for P and Q:

- $P^2 = P$, $Q^2 = Q$.
- $PAZ = Y^TP = 0$, $Y^TAQ = QZ = 0$.
- $PA = AQ$.

To solve the system $Au = f$ using deflation, note that u can be written as

$$u = (I - Q)u + Qu$$

and that $(I-Q)u = Z(Y^TAZ)^{-1}Y^TAu = Z(Y^TAZ)^{-1}Y^Tf$ can be computed immediately (cf. (1.3)). Furthermore Qu can be obtained by solving the deflated system

$$PA\tilde{u} = Pf \tag{5.1}$$

for $\tilde{u}$ (cf. (1.4)) and premultiplying the result with Q.

Also in the nonsymmetric case, deflation can be combined with preconditioning. Suppose K is a suitable preconditioner of A, then (5.1) can be replaced by the following: solve $\tilde{u}$ from

$$K^{-1}PA\tilde{u} = K^{-1}Pf \tag{5.2}$$

and form $Q\tilde{u}$, or solve $\tilde{v}$ from

$$PAK^{-1}\tilde{v} = Pf \tag{5.3}$$

and form $QK^{-1}\tilde{v}$. Both systems can be solved by one's favorite Krylov subspace solver, such as GMRES [22], GCR [7, 25], Bi-CGSTAB [24], etc.

The question remains how to choose Y. We consider two possibilities:

[4] In multigrid terminology, Z is the projection or interpolation operator, and Y^T is the restriction operator.

1. Suppose Z consists of eigenvectors of A. Choose Y as the corresponding eigenvectors of A^T.
2. Choose $Y = Z$.

For both choices we can prove some results about the spectrum of PA.

ASSUMPTION 5.1. *We assume that A has real eigenvalues and is nondefective.*

Whenever A satisfies Assumption 5.1 there exists a matrix $X \in \mathbb{R}^{n\times n}$ such that $X^{-1}AX = \mathrm{diag}(\lambda_1, \dots, \lambda_n)$. For the first choice, which is related to Hotelling deflation (see [30, p. 585]), we have the following result.

LEMMA 5.1. *If A satisfies Assumption 5.1, $Z = [x_1 \cdots x_m]$, and Y is the matrix composed of the first m columns of X^{-T}, then*

$$X^{-1}PAX = \mathrm{diag}(0, \dots, 0, \lambda_{m+1}, \dots, \lambda_n).$$

Proof. From the definition of P we obtain $PAZ = 0$, so $PAx_i = 0,\ i = 1, \dots, m$. For the other vectors $x_i,\ i = m + 1, \dots, n$, we note that

$$PAx_i = Ax_i - AZ(Y^TAZ)^{-1}Y^TAx_i = \lambda_ix_i - AZ(Y^TAZ)^{-1}\lambda_iY^Tx_i = \lambda_ix_i. \qquad \square$$

The second choice $Y = Z$ has the following properties.

LEMMA 5.2. *For $Y = Z$ one has the following:*

(i) *If A is positive definite and Z has full rank, $A_c = Z^TAZ$ is nonsingular.*

(ii) *If A satisfies Assumption 5.1 and $Z = [x_1 \cdots x_m]$, the eigenvalues of PA are $\{0, \lambda_{m+1}, \dots, \lambda_n\}$, where the zero-eigenvalue has multiplicity m.*

Proof. (i) For $Y = Z$ the matrix $A_c = Z^TAZ$ is nonsingular since $s^TA_cs > 0$ for all $s \in \mathbb{R}^m$ and $s \neq 0$.

(ii) Again $PAx_i = 0$ for $i = 1, \dots, m$. For the other eigenvalues we define the vectors

$$v_i = x_i - AZA_c^{-1}Z^Tx_i = x_i - ZD_mA_c^{-1}Z^Tx_i, \quad i = m + 1, \dots, n,$$

where $D_m = \mathrm{diag}(\lambda_1, \dots, \lambda_m)$. These vectors are nonzero, because $x_1, \dots, x_n$ form an independent set. Multiplication of v_i by PA yields

$$PAv_i = PA(x_i - ZD_mA_c^{-1}Z^Tx_i) = PAx_i = Ax_i - AZA_c^{-1}Z^TAx_i = \lambda_iv_i,$$

which proves the lemma. $\square$

From these lemmas we conclude that both choices of Y lead to the same spectrum of PA. The second choice has the following advantages: when A is positive definite we have proven that A_c is nonsingular; it is not necessary to determine (or approximate) the eigenvectors of A^T; and finally only one set of vectors $z_1, \dots, z_m$ has to be stored in memory. This motivates us to use the choice $Y = Z$. In our applications Z is not an approximation of an invariant subspace of A but is defined as in (3.1).

Theorems 2.2 and 2.3 do not apply to the nonsymmetric case. However, our experience has shown that the convergence of (5.1) is similar to that of (1.4) as long as the asymmetric part of A is not too dominant.

5.2. Parallel implementation. In this section we describe an efficient parallel implementation of the subdomain deflation method with Z defined by (3.1). We distribute the unknowns according to subdomain across available processors. For the discussion we will assume one subdomain per processor. The coupling with neighboring domains is realized through the use of virtual cells added to the local grids. In this way, a block-row of $Au = f$ corresponding to the subdomain ordering

$$A = \begin{bmatrix} A_{11} & \cdots & A_{1m} \\ \vdots & \vdots & \vdots \\ A_{m1} & \cdots & A_{mm} \end{bmatrix} \tag{5.4}$$

can be represented locally on one processor: the diagonal block A_{ii} represents coupling between local unknowns of subdomain i, and the off-diagonal blocks of block-row i represent coupling between local unknowns and the virtual cells.

Computation of element $A_{c_{ij}}$ of $A_c = Z^TAZ$ can be done locally on processor i by summing the coefficients corresponding to block A_{ij} of (5.4): $A_{c_{ij}} = \mathbf{1}^T A_{ij}\mathbf{1}$.

Use of the deflation P within a Krylov subspace method involves premultiplying a vector v by PA:

$$PAv = (I - AZ(Z^TAZ)^{-1}Z^T)Av.$$

Assuming A_c^{-1} has been stored in factored form, this operation requires two multiplications with A. However, the special form of Z given by (3.1) allows some simplification. Since Z is piecewise constant, we can efficiently compute and store the vectors

$$w_j = Az_j = \begin{bmatrix} A_{1j} \\ \vdots \\ A_{mj} \end{bmatrix} \mathbf{1} \tag{5.5}$$

corresponding to row sums of the jth block-column of A. Note that for the ith block system the local block of w_j is nonzero only if there is coupling between subdomains i and j, and only the nonzero blocks of w_j need be stored. Thus, for a five-point stencil the number of nonzero vectors w_j which have to be stored per block is five. Furthermore, for many applications, the row sums are zero, and w_j is only nonzero on subdomain boundaries.

With the w_j stored, local computation of $AZ\tilde{e}$ for a given (m-dimensional) vector $\tilde{e}$ consists of scaling the nonzero w_j by the corresponding $\tilde{e}_j$ and summing them up: $AZ\tilde{e} = \sum_j \tilde{e}_j w_j$. The number of vector updates is five for a five-point stencil.

In parallel, we first compute and store the (nonzero parts of the) w_j and $(Z^TAZ)^{-1}$ (factored) on each processor. In particular, on processor i we store the local part $w_j = A_{ij}\mathbf{1}$ for all nonzero A_{ij}. Then to compute PAv we first perform the matrix-vector multiplication $\tilde{q} = Av$, requiring nearest neighbor communications. Next we compute the local contribution to the restriction $q = Z^T\tilde{q}$ (local summation over all grid points) and distribute the result to all processes. With this done, we solve for $\tilde{e}$ from $A_c\tilde{e} = q$ and finally compute $AZ\tilde{e} = \sum_j \tilde{e}_j w_j$ locally.

The total parallel communication involved in the matrix-vector multiplication and deflation are a nearest neighbor communication of the length of the interfaces and a global gather-broadcast of dimension m.

The computational and communication costs plus storage requirements of subdomain deflation are summarized in Table 5.1, assuming a five-point discretization stencil on an $N_x \times N_y$ grid with $M_x \times M_y$ decomposition into blocks of revolution $n_x \times n_y$ ($N_x = n_xM_x$, $N_y = n_yM_y$). The abbreviation *GaBr* (m) refers to a gather-broadcast operation in which a set of m distributed floating point numbers is gathered from the participating processors and then the whole set is returned to each processor. The construction costs are incurred only once, whereas the iteration costs are in each conjugate gradient iteration. Also included in the table are the costs of an (in the parallel case, blockwise) incomplete factorization preconditioner with zero fill-in, ILU(0).

TABLE 5.1
Work, storage, and communication costs for deflation-based preconditioning.

	Sequential		Parallel		
	Work	Storage	Work	Storage	Comms.
Construction:					
ILU(0)	$6N_xN_y$	N_xN_y	$6n_xn_y$	n_xn_y	0
A_c	$5N_xN_y$	$5M_xM_y$	$5n_xn_y$	$5M_xM_y$	GaBr $(5M_xM_y)$
Band-factor A_c	$2M_x^3My$	$2M_x^2M_y$	$2M_x^3M_y$	$2M_x^2M_y$	0
AZ	$9N_xN_y$	$5N_xN_y$	$9n_xn_y$	$9n_xn_y$	0
Iteration:					
Backsolve IC(0):	$10N_xN_y$		$10n_xn_y$		0
Restriction: $q = Z^TAv$	N_xN_y		n_xn_y		0
Backsolve: $A_c\tilde{e} = q$	$4M_x^2M_y$		$4M_x^2M_y$		GaBr (M_xM_y)
Prolongation: $AZ\tilde{e}$	$5N_xN_y$		$5n_xn_y$		0
Vector update: $Av - AZ\tilde{e}$	N_xN_y		n_xn_y		0

Besides the items tabulated above, there are computation and communication costs associated with the matrix-vector multiplication and inner products as well as computational costs of vector updates, associated with the CG method. Based on this table, we expect the added iteration expense of deflation to be less expensive than an ILU(0) factorization, and that the method will parallelize very efficiently on a distributed memory computer.

6. Numerical experiments. All experiments in this section are conducted with PDEs discretized using cell-centered, central finite volumes on Cartesian grids in rectangular regions. The theory discussed until now makes no such assumptions, however, and should hold in a more general, unstructured setting.

In conducting numerical experiments, we are interested in the following issues: (i) verification of the theoretical results of this article, (ii) the properties of subdomain deflation for nonsymmetric systems, and (iii) the parallel performance of the method. To this end we consider three test cases:

I. Poisson equation: $-\Delta u(x,y) = f$.

II. Diffusion equation: $-\nabla \cdot \nu(x,y)\nabla u(x,y) = f$.

III. Steady-state convection-diffusion equation: $\nabla\cdot(\mathbf{a}(x,y)u(x,y)) - \Delta u(x,y) = f$.

In most examples we take $f \equiv 1$, having checked that similar results are observed for a random right-hand side function. We use a global grid resolution $N_x \times N_y$, with decomposition into $M_x \times M_y$ subdomains, each of resolution $n_x \times n_y$ (thus, $N_x = n_xM_x$ and $N_y = n_yM_y$).

We solve the resulting discrete (symmetric) system using the CG method and subdomain deflation. The initial iterate is chosen to be $u^{(0)} = 0$, and convergence is declared when, in the Jth iteration, $\|r_J\| \leq tol \cdot \|r_0\|$ for $tol = 10^{-6}$.

When classical preconditioning is included, we solve $K^{-1}PAu = K^{-1}Pf$, where the preconditioner K used on the blocks is the relaxed incomplete Cholesky (RIC) factorization of [1], with relaxation parameter $\omega = 0.975$. We choose this preconditioner because it is simple to implement (for a five-point stencil, modifications occur only on the diagonal) and is reasonably effective. Certainly, more advanced preconditioners could be employed on the blocks of C.

6.1. Convergence results. In this section we give convergence results with problems I, II, and III to illustrate the insensitivity of the convergence to the number of subdomains, the optimal decomposition on stretched grids, the effectiveness of the method for problems with discontinuous coefficients, and the convergence behavior for nonsymmetric problems.

6.1.1. Near grid independence. First we illustrate the sense in which subdomain deflation can lead to nearly grid-independent convergence. The symmetric discretization matrix of problem I on $(0,1)\times(0,1)$ with homogeneous Dirichlet boundary conditions is used without preconditioning. Keeping the resolution of each subdomain fixed, the number of subdomains is increased. In so doing, the blocks of C remain roughly the same as the grid is refined, and the bound in (2.1) becomes insensitive to the number of blocks m for large enough m.

Assume $M_x = M_y$ and $n_x = n_y$. Figure 6.1 shows the scaled number of CG iterations J/n_x (note that n_x is constant along each line in the figure) for problem I as the grid is refined keeping the subdomain resolution n_x fixed at values of 10, 50, and 200. The lines are almost indistinguishable from one another. It is apparent from the figure that—using only subdomain deflation—the number of iterations required for convergence is bounded independent of the number of subdomains. The same qualitative behavior is observed with preconditioning.

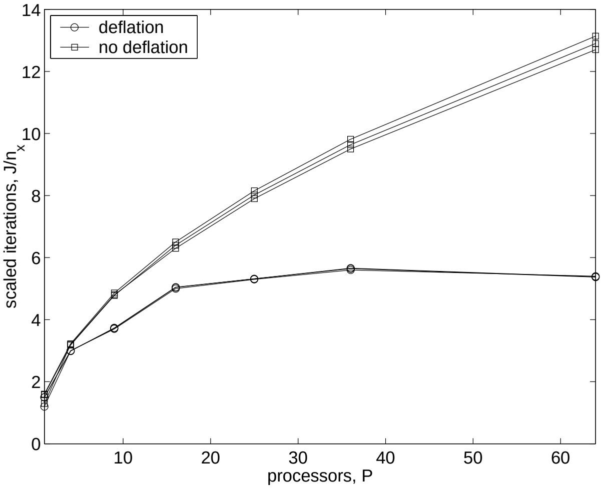

FIG. 6.1. *Number of iterations J divided by the subdomain resolution $n_x \equiv n_y \in \{10, 50, 200\}$ with and without deflation.*

6.1.2. Stretched grid. We consider problem I on $(0,3)\times(0,1)$ with homogeneous Dirichlet boundary conditions, and $N_x = 36$ and $N_y = 72$. The cell aspect ratio is $\mathcal{Q}_c = h_x/h_y = (3/36)/(1/72) = 6$. Based on the discussion of section 4.1, the best condition number is expected for a subdomain aspect ratio $\mathcal{Q}_d = 1$, associated with a subdomain grid aspect ratio of $\mathcal{Q}_g = \mathcal{Q}_d/\mathcal{Q}_c = 1/6$. Table 6.1 gives the number of iterations required for convergence for 5 different decompositions into 12 equally sized subdomains. The solution tolerance of the nonpreconditioned CG algorithm was set to $tol = 10^{-2}$, prior to the onset of superlinear convergence, to obtain these results. The 6×2 decomposition with $\mathcal{Q}_d = 1$ gives the minimum number of iterations, in keeping with the discussion. We note that if iteration is continued to high tolerance, the superlinear convergence effect may give quite different results than shown here. This domain decomposition selection strategy is most useful when the condition number governs the convergence rate.

Table 6.1
Iterations required for problem I *for different decompositions.*

$M_x \times M_y$	$n_x \times n_y$	Q_d	J
2×6	18×12	9	73
3×4	12×18	4	63
4×3	9×24	9/4	56
6×2	6×36	1	48
12×1	3×72	1/4	50

6.1.3. Discontinuous coefficients. To further illustrate the discussion of section 4.2 we give results for problem II on $(0,1) \times (0,1)$ with boundary conditions $u_x(0,y) \equiv u_y(x,0) \equiv u_y(x,1) \equiv 0$, $u(1,y) \equiv 0$. We define the diffusion coefficient to have value $\nu(x,y) = 1$ on the lower left subdomain, including its interfaces, and $\nu(x,y) = \epsilon$ elsewhere. Table 6.2 lists the iterations for the CG method with diagonal preconditioning for $M_x = M_y = 3$ and $n_x = n_y = 30$, as ϵ is decreased.

One observes that this is a very effective strategy for eliminating the effect of the jump in coefficients.

Table 6.2
Iterations for problem II *with discontinuous coefficients.*

ϵ	No deflation	Deflation
1	295	151
10^{-2}	460	183
10^{-4}	521	189
10^{-6}	628	189

6.1.4. A nonsymmetric example. We also illustrate the convergence of the deflation method for a convection dominated problem III on $(0,1) \times (0,1)$ with recirculating wind field $a_1(x,y) = -80xy(1-x)$, $a_2(x,y) = 80xy(1-y)$ and boundary conditions $u(x,0) \equiv u(y,0) \equiv u(x,1) \equiv 0$, $u_x(1,y) = 0$. The grid parameters are $N_x = N_y$, $M_x = M_y$, $n_x = n_y$ with grid spacing given by

$$x_i = (i/N_x)^2(3 - 2(i/N_x)).$$

The resulting system is solved using GCR truncated to a subspace of 20 vectors by dropping the vector most nearly orthogonal to the current search direction [26]. Classical preconditioning in the form of RILU(0.975) is incorporated. The restriction matrix for deflation is chosen to be $Y = Z$.

Table 6.3 compares the required number of GCR iterations as the number of subdomains is increased keeping the subdomain resolution fixed at $n_x = 50$. Although the number of iterations is not bounded in the deflated case, it grows much slower than the nondeflated case.

6.2. Parallel performance. For the results in this section, problem I will be solved on $(0,1) \times (0,1)$ with homogeneous Dirichlet boundary conditions everywhere.

The resulting equations are solved with CG preconditioned with RIC(0.975). Our implementation does not take advantage of the fact that some of the row sums may

be zero in (5.5). Each processor is responsible for exactly one subdomain. Parallel communications were performed with MPI, using simple point-to-point and collective communications. No exploitation of the network topology was used. Parallel results were obtained from a Cray T3E. Wall-clock times in seconds were measured using the MPI timing routine.

6.2.1. Speedup for fixed problem size. To measure the speedup, we choose $p = M_x^2$ processors for $M_x \in \{1, 2, 3, 4, 5, 6, 8\}$. The results are given in Tables 6.4 and 6.5 for $N_x = 120$ and $N_x = 480$, respectively. The total number of iterations is denoted by J; the time to construct the incomplete factorization and deflation operator is denoted by t_{const}; and the time spent in iterations is denoted by t_{iter}. The speedup is determined from $s = (t_{\text{iter}}|_{p=1}) / (t_{\text{iter}}|_{p=M_x^2})$ and parallel efficiency by $\mathit{eff} = s/p$.

In Table 6.4 the parallel efficiency decreases from 58% on 4 processors to only 19% on 64 processors, whereas in Table 6.5 efficiency increases slightly from 77% to 88%. We expect that the poorer performance in the first table is due to both a relatively large cost of solving the coarse operator A_c and a large communication-to-computation ratio for small subdomains. The following factors contribute to the parallel performance:

- As more subdomains are added, the relative size of the deflation system A_c

increases, making it more expensive to solve, but at the same time, its solution becomes a better approximation of the global solution.
- As the size of the subdomain grids decreases, the *RILU* preconditioner becomes a better approximation of the exact solution of the subdomain problems.
- Global communications become more expensive for many subdomains.
- Additionally there may be architecture-dependent effects in play.

6.2.2. Scaled performance for fixed subdomain size. Table 6.6 gives the computation times in seconds obtained with and without deflation, keeping the subdomain size fixed at $n_x \in \{5, 10, 20, 50, 100, 200\}$ as the number of processors is increased. It is clear that the effect of deflation is to make the parallel computation time less sensitive to the number of processors.

We have already seen that the number of iterations levels off as a function of the number of subdomains. The results of this table show that also the parallel iteration time becomes relatively insensitive to an increase in the number of blocks. Some overhead is incurred in the form of global communications and in solving the deflation subsystem. As a result, the computation times are not bounded independent of the number of subdomains.

Comparing the iteration counts for this problem, we note that the ratio of iterations with and without deflation is very similar to that of Figure 6.1 without preconditioning. Furthermore, the cost per iteration scales with n_x^2 for $n_x \geq 20$ (for smaller n_x, the cost of deflation offsets the advantage gained). The effect of preconditioning is to reduce the necessary number of iterations in both the deflated and undeflated cases such that the ratio of iterations remains fixed. We therefore expect that the ratio of computation times with and without deflation should reflect the ratios of Figure 6.1 as well.

7. Conclusions. In this paper we have given new effective condition number bounds for deflated systems, both with and without conventional preconditioning. Specifically, we show that choosing the deflation subspace to be piecewise constant on subdomains effectively decouples the problem into a set of related Neumann problems, with the convergence governed by the "worst-conditioned" Neumann problem. This knowledge can help to choose an effective decomposition of the domain and is especially useful for problems with large discontinuities in the coefficients. Numerical experiments illustrate that the convergence rate is nearly independent of the number of subdomains for some problems, and that the method can be very efficiently implemented on distributed memory parallel computers.

We see the deflation approach presented here as offering improved convergence rate at a small additional cost for parallel computations using blockwise application of conventional preconditioners. The reader is referred to [9] for a comparison of blockwise incomplete factorization in the framework of nonoverlapping domain decomposition. In that reference is also a comparison of blockwise incomplete factorization with single-block incomplete factorization. In turn, to put these results in perspective, Botta et al. [4] compare a number of modern strategies including ICCG and multigrid methods.

MULTIRESOLUTION APPROXIMATE INVERSE PRECONDITIONERS[*]

ROBERT BRIDSON[†] AND WEI-PAI TANG[‡]

Abstract. We introduce a new preconditioner for elliptic PDEs on unstructured meshes. Using a wavelet-inspired basis we compress the inverse of the matrix, allowing an effective sparse approximate inverse by solving the sparsity vs. accuracy conflict. The key issue in this compression is to use *second generation* wavelets which can be adapted to the unstructured mesh, the true boundary conditions, and even the PDE coefficients. We also show how this gives a new perspective on multiresolution algorithms such as multigrid, interpreting the new preconditioner as a variation on node-nested multigrid. In particular, we hope the new preconditioner will combine the best of both worlds: fast convergence when multilevel methods can succeed but with robust performance for more difficult problems.

The rest of the paper discusses the core issues for the preconditioner: ordering and construction of a factored approximate inverse in the multiresolution basis, robust interpolation on unstructured meshes, automatic mesh coarsening, and purely algebraic alternatives. Some exploratory numerical experiments suggest the superiority of the new basis over the standard basis for several tough problems, including discontinuous anisotropic coefficients, strong convection, and indefinite reaction problems on unstructured meshes, with scalability like hierarchical basis methods achieved.

Key words. preconditioner, multilevel, multigrid, hierarchical basis, unstructured mesh, elliptic PDEs

1. Motivation.

Approximate inverses are becoming increasingly popular preconditioners for the iterative solution of large sparse linear systems. The main reason is that they can be efficiently applied (with just matrix-vector products) on high-performance hardware; they are also a valuable general-purpose alternative to ILU for tough problems where ILU breaks down from instabilities.

Several algorithms for computing sparse approximations to $\mathbf{A}^{-1}$, or to its inverse triangular factors $\mathbf{L}^{-1}$ and $\mathbf{U}^{-1}$, have been proposed; see, e.g., [5, 6, 7, 19, 27, 30, 36]. Unfortunately, for linear systems arising from elliptic PDEs, there appears to be an inherent problem in the explicit nature of these preconditioners, a fundamental conflict between accuracy and sparsity. As problem sizes increase, their performance (either in terms of convergence rate at a fixed number of nonzeros per row, or storage required for a fixed convergence rate) quickly decreases.[1]

For a simple heuristic analysis of this problem, ignore boundary conditions. Suppose the elliptic PDE $\mathcal{L}u = f$ on domain Ω is discretized to $\mathbf{Au} = \mathbf{f}$ on points x_1, …, x_n in Ω, where the matrix $\mathbf{A}$ is the discrete form of the elliptic operator $\mathcal{L}$,

[1] Of course, switching to an implicit preconditioner isn't guaranteed to solve the scalability problem; for example, standard ILU does not scale any better than no preconditioner, and the question of how best to use matrix orderings, dropping strategies, and numerical modifications to improve the scalability of ILU is still open [3, 4, 9, 14, 32, 33, 34].

and $u_i \approx u(x_i)$. (The discretization may use finite elements, finite volumes, or any other reasonable scheme.) The continuous solution may be written with the Green's function $\mathcal{G}(x,y)$ on $\Omega \times \Omega$ satisfying $\mathcal{L}\mathcal{G}(x,y) = \delta(x-y)$:

$$u(x) = \int_\Omega \mathcal{G}(x,y) f(y)\, dy$$

(assuming this exists, as one would expect for an elliptic problem well-posed enough to permit numerical solution). The discrete solution is similarly found with the matrix $\mathbf{A}^{-1}$ satisfying $\mathbf{A}\mathbf{A}^{-1} = \mathbf{I}$:

$$u_i = \sum_{j=1}^{n} A^{-1}_{ij} f_j.$$

Through this analogy, it is clear that $\mathbf{A}^{-1}$ is the discrete approximation to the Green's function.

Unfortunately, it is well known that though the Green's function decays away from its diagonal singularity, the decay may be slow especially for convective or indefinite problems (in fact, for problems with Neumann boundaries, $\mathcal{G}$ might not even decay to zero at all). The decay of the true Green's function is independent of the mesh size in the discretization, and so as the mesh is refined the number of large nonzeros in $\mathbf{A}^{-1}$ also increases, roughly like $O(n^{1+1/d})$, where n is the number of mesh nodes and d is the dimensionality of the problem.[2] This means an approximate inverse preconditioner cannot scale effectively with the problem size.[3]

To be more precise, one cannot scale in the standard basis, where u_i approximates $u(x_i)$. In [11, 18], the realization that the Green's function is smooth away from the diagonal suggested wavelets as alternate bases: they can compress smooth functions into high-quality sparse approximations, handle nonsmooth points (e.g., at the diagonal singularity, or arising from discontinuous coefficients), and provide fast and parallelizable transforms to and from the standard basis. The finer the mesh, the better the smoothness of $\mathcal{G}(x,y)$ can be exploited for compression, so the preconditioner may scale much more effectively.

The original paper [18] considered only classical wavelets, treating the discrete Green's function as a two-dimensional, regularly sampled, periodic image. For problems of dimensions greater than one (so the Green's function is of dimension greater than two) on irregular meshes with nonperiodic boundaries, this leads to significant problems. In particular, these "first generation" wavelets are constructed on regularly sampled one-dimensional periodic domains and so cannot hope to perform well on data coming from more complicated situations. This motivated the use of second generation wavelets [35] in [11] that naturally match such domains, while retaining the attractive properties of compression, tolerance of singularities, and fast transforms. The present article describes the multiresolution approximate inverse preconditioner of [11] and more recent developments.

[2] There are n columns in $\mathbf{A}^{-1}$, with column i containing a discrete approximation to $G(\cdot, x_i)$. There is a d-dimensional subregion $\Omega_L \subset \Omega$ such that $G(x, x_i)$ is large for $x \in \Omega_L$. There are $O(n^{1/d})$ mesh nodes contained in Ω_L, so column i of $\mathbf{A}^{-1}$ has roughly $O(n^{1/d})$ large entries, for a total of $O(n^{1+1/d})$ in $\mathbf{A}^{-1}$.

[3] Of course, this reasoning applies directly only to fully explicit approximate inverses: preconditioners in factored form perhaps may be more effective, since their product may be dense, though at the time of writing this has yet to be demonstrated.

The initialization phase

- Determine multiresolution bases α and β.
- Use a standard operator-based approximate inverse algorithm to find $\widetilde{\mathbf{Q}} \approx (\mathbf{M}_\beta^{-T}\mathbf{A}\mathbf{M}_\alpha^{-1})^{-1}$.

The application phase (called by a Krylov solver)

- Apply preconditioner to x by $y = \mathbf{M}_\alpha^{-1}(\widetilde{\mathbf{Q}}(\mathbf{M}_\beta^{-T}x))$.

FIG. 1. *The multiresolution approximate inverse method.*

Other authors have proved that discretizing elliptic PDEs with a wavelet basis in the finite element method (and using point or block diagonal preconditioners) can give optimal scalability, primarily working with classical wavelets and generalizations to handle boundaries and even dyadically refined unstructured meshes (see, e.g., [15, 16, 21, 22, 23, 24]) but also, e.g., with approximate wavelets derived from an existing hierarchical basis [37, 38]. The work in [21] actually worked with a full approximate inverse rather than just diagonal preconditioners and found significant improvements by taking into account interactions between different levels. The present paper differs by combining second generation wavelets with a more sophisticated approximate inverse, with an emphasis on heuristically finding good multilevel algorithm components (regrettably without theoretical results to confirm the promising first few numerical experiments).

2. Outline of the method. Since the Green's function is defined on the product space $\Omega \times \Omega$, it is natural to look for a wavelet basis that is a tensor product $\alpha \otimes \beta$ of wavelet bases α and β on Ω. In the discrete case, this means representing $\mathbf{A}^{-1}$ as

$$A_{ij}^{-1} = \sum_{k=1}^{n}\sum_{l=1}^{n} Q_{kl} a_i^k b_j^l,$$

where the separable basis functions are the product of elements $a^k \in \alpha$ and $b^l \in \beta$, and the coefficients are stored in matrix $\mathbf{Q}$. Equivalently,

$$\mathbf{A}^{-1} = \mathbf{M}_\alpha^{-1}\mathbf{Q}\mathbf{M}_\beta^{-T},$$

where $\mathbf{M}_\alpha^{-1}$ and $\mathbf{M}_\beta^{-1}$ have the basis functions of α and β, respectively, as their columns. Applying these operators to the standard basis vectors shows that $\mathbf{M}_\alpha$ and $\mathbf{M}_\beta$ are the transforms from the wavelet bases to the standard basis.

The transformed $\mathbf{A}^{-1}$, ready for compression, is $\mathbf{Q} = \mathbf{M}_\alpha\mathbf{A}^{-1}\mathbf{M}_\beta^T$. For the preconditioner, a highly sparse approximation $\widetilde{\mathbf{Q}}$ will be used. Rewriting $\mathbf{Q} = (\mathbf{M}_\beta^{-T}\mathbf{A}\mathbf{M}_\alpha^{-1})^{-1}$ shows that $\widetilde{\mathbf{Q}}$ can be obtained by applying a standard sparse approximate inverse algorithm to the transformed operator $\mathbf{M}_\beta^{-T}\mathbf{A}\mathbf{M}_\alpha^{-1}$—in particular, without knowledge of the true inverse $\mathbf{A}^{-1}$. Note that to avoid forming $(\mathbf{M}_\beta^{-T}\mathbf{A}\mathbf{M}_\alpha^{-1})$ explicitly, which may incur significant fill-in, an approximate inverse algorithm that works on a linear operator (not necessarily a matrix) is required. One example, used in this research, is SAINV [7].

To summarize, an overview of the multiresolution approximate inverse method is given in Figure 1.

The forward transform (standard basis → multiresolution basis)

- Start with the function values $f_1, \ldots, f_n$ at sample points $x_1, \ldots, x_n$.
- Let $\lambda_i^0 = f_i$ for all i, $\mathcal{C}^0 = \{x_1, \ldots, x_n\}$, and $j = 0$.
- Begin loop:
  - Split up the sample points $\mathcal{C}^j$ into two disjoint subsets, the fine nodes $\mathcal{F}^{j+1}$ and the coarse nodes $\mathcal{C}^{j+1}$.
  - Predict λ_F^j, the values at the fine nodes, from λ_C^j, the values at the coarse nodes, with some linear prediction operator $\mathbf{P}^j$: $\lambda_F^j \approx \mathbf{P}^j \lambda_C^j$.
  - Store the wavelet coefficient $\gamma_i^{j+1} = \lambda_i^j - (\mathbf{P}^j \lambda_C^j)_i$ for each fine node $x_i \in \mathcal{F}^{j+1}$.
  - Update the value at each coarse node by $\lambda_i^{j+1} = \lambda_i^j + (\mathbf{U}^j \gamma^{j+1})_i$ for each $x_i \in \mathcal{C}^{j+1}$ so that the required moments will be preserved. This update operator $\mathbf{U}^j$ must also be linear.
  - If $|\mathcal{C}^{j+1}|$ is small enough, below some constant, break out of the loop. Otherwise, set $j \leftarrow j + 1$ and continue.
- Return λ^j from the coarsest level along with the wavelet coefficients $\gamma^1, \ldots, \gamma^j$ from each level.

The inverse transform (multiresolution basis → standard basis)

- Start with λ^j and the wavelet coefficients $\gamma^1, \ldots, \gamma^j$.
- Begin loop:
  - Reconstruct λ_C^{j-1} at the coarse nodes by $\lambda_i^{j-1} = \lambda_i^j - (\mathbf{U}^{j-1}\gamma^j)_i$ for each $x_i \in \mathcal{C}^j$.
  - Reconstruct λ_F^{j-1} at the fine nodes by $\lambda_i^{j-1} = \gamma_i^j + (\mathbf{P}^{j-1}\lambda_C^{j-1})_i$ for each $x_i \in \mathcal{F}^j$.
  - Continue with $j \leftarrow j - 1$ until $j = 1$.
- Return $f_i = \lambda_i^0$ for all i.

FIG. 2. *The transform algorithms of the lifting scheme.*

3. The general algorithm.

3.1. The basis construction. The goal of the new basis $\alpha \otimes \beta$ is to convert "smoothness" in the standard basis to small coefficients that can be accurately approximated by zero. For irregular domains, the lifting scheme [35] for second generation wavelets is a natural choice. In this scheme, the basis is not constructed explicitly, but rather the forward transform algorithms (from the standard basis to the multiresolution basis, called $\mathbf{M}_\alpha$ and $\mathbf{M}_\beta$ above) are designed to directly achieve good compression along with easy invertibility. Figure 2 gives summaries of the transform algorithms.

The essential idea is that where a function is smooth, its values can be accurately predicted from nearby neighbors, and so storing the prediction error results in small coefficients except near "rough" regions. Doing this in a hierarchy of levels gives rise to a multiresolution representation: wavelet coefficients at level j correspond to features on the scale of the grid resolution of the set of nodes $\mathcal{C}^j$ at level j. It should be noted that on unstructured meshes (and possibly for other reasons mentioned below) the prediction operator for each fine node may have different weights—unlike classical wavelets, where one set of convolution weights is used throughout the domain.

The update step is required in signal processing to prevent aliasing, where for example a high-resolution singularity is propagated unchanged to lower resolutions; the update step is an averaging designed to make sure the signal is smooth enough to be faithfully represented at the next coarser level. However, in this context of compressing discrete Green's functions, this seems to be a liability, as demonstrated in [11]. In the ideal case, all wavelet coefficients in $\mathbf{Q}$ will be very small except on the diagonal, where the discrete Green's function must have a singularity: finding a sparse approximate inverse for a nearly diagonal matrix is simple. However, the update step smooths out this inherent singularity, smearing the large diagonal entries to off-diagonals, resulting in a harder task for a sparse approximate inverse algorithm.

On the other hand, without the update step the basis can be viewed as just a generalization of the standard hierarchical basis [1, 40] (if regular refinement and linear interpolation for prediction are used, it is exactly the hierarchical basis; see section 4 for more details). While optimal scalability has been demonstrated with classical wavelets in [15, 16, 21, 22, 23, 24], it is well known that with just diagonal or block diagonal preconditioning the hierarchical basis is not optimal: the condition number of the preconditioned system slowly grows with the number of unknowns, particularly in higher dimensions. To get the optimal performance of methods such as multigrid, the basis must be stabilized [37, 38], making the basis functions from different levels at least approximately orthogonal. This is essentially what the update step does, smoothing the function at each level so that coarser levels don't see the high-resolution features picked up at finer levels. Thus perhaps a theoretical analysis, beyond the scope of this paper, will show that the update step can be of value for multiple dimensions. However, the issue is further complicated by the fact that approximate inverses can be more effective in higher dimensions, where the Green's function decays faster and a sparse approximation is more feasible. For the rest of this paper we will not use the update step, leaving these questions for future research.

Without the update step, the forward transform is simplified, and in fact all wavelet coefficients at all levels can be computed simultaneously. The forward transform $\mathbf{M}$ can easily be written explicitly as a triangular matrix multiply and the inverse transform as a triangular solve, as in Figure 3. As long as each prediction operation can be done in constant time, i.e., each $\mathbf{P}^j$ has a bounded number of nonzeros per row, it is clear that the forward and inverse transforms can both be done in $O(n)$ time in serial. In terms of parallel computation, the forward transform is as good as a single sparse matrix multiply, whereas the inverse transform can naturally be done in $O(\log n)$ steps (with smaller and smaller matrix multiplies) assuming a geometric decline in the size of the $\mathcal{C}^j$.

There are two big issues that need to be resolved when constructing the basis. The first is how to coarsen; how to select the sets $\mathcal{C}^j$ of coarse nodes at each level. So far, we have concentrated on independent set heuristics similar to those used in unstructured multigrid [17] and algebraic multigrid [31]. The second issue is how to define the prediction operators $\mathbf{P}^j$ at each level. Standard linear interpolation or higher order polynomial interpolation is a possibility, but for robustness in difficult problems we have found more sophisticated techniques are necessary [11].

Looking at the compressed inverse $\mathbf{Q} = \mathbf{M}_\alpha \mathbf{A}^{-1} \mathbf{M}_\beta^T$, notice that the transform $\mathbf{M}_\alpha$ is being applied to each of the columns of $\mathbf{A}^{-1}$. From the equation $\mathbf{A}\mathbf{A}^{-1} = \mathbf{I}$, observe that column i of $\mathbf{A}^{-1}$ is actually the discrete solution to the PDE $\mathcal{L}u(x) = \delta(x - x_i)$. Thus the functions compressed by α satisfy the homogeneous PDE $\mathcal{L}u = 0$ almost

The forward transform (standard basis → multiresolution basis)

$$\begin{pmatrix}\gamma^1\\ \gamma^2\\ \vdots\\ \gamma^j\\ \lambda^j\end{pmatrix} = \mathbf{Mf} = \left(\begin{array}{c|c} \mathbf{I} & -\mathbf{P}^1 \\ \hline & \begin{array}{c|c} \mathbf{I} & -\mathbf{P}^2 \\ \hline & \begin{array}{c|c} \ddots & \vdots \\ \hline & \begin{array}{cc}\mathbf{I} & -\mathbf{P}^j\\ & \mathbf{I}\end{array}\end{array}\end{array}\end{array}\right) \begin{pmatrix}\mathbf{f}_{F1}\\ \mathbf{f}_{F2}\\ \vdots\\ \mathbf{f}_{Fj}\\ \mathbf{f}_{Cj}\end{pmatrix}$$

The inverse transform (multiresolution basis → standard basis)

$$\mathbf{f} = \mathbf{M}^{-1}\gamma = \left(\begin{array}{c|c} \mathbf{I} & -\mathbf{P}^1 \\ \hline & \begin{array}{c|c} \ddots & \vdots \\ \hline & \begin{array}{cc}\mathbf{I} & -\mathbf{P}^j\\ & \mathbf{I}\end{array}\end{array}\end{array}\right)^{-1} \begin{pmatrix}\gamma^1\\ \vdots\\ \gamma^j\\ \lambda^j\end{pmatrix}$$

FIG. 3. *The multiresolution basis transforms without update steps expressed in terms of triangular matrices.*

everywhere, which we can take as our definition of "smooth." Predicting the value at a fine node i from nearby coarse nodes can be done by solving a discrete form of $\mathcal{L}u(x_i) = 0$ using the coarse nodes as specified "boundary" data.

Similarly, the β transform is applied to the rows of $\mathbf{A}^{-1}$, which are discrete solutions to the adjoint problems, so β may be constructed with the adjoint operator $\mathcal{L}^*$ in mind. In particular, for self-adjoint problems it makes sense to take $\alpha = \beta$; for highly non-self-adjoint problems it will be important to have $\alpha \neq \beta$.

Finally it should be noted that for some problems—e.g., with oscillatory coefficients, strong indefiniteness, or complicated convection streamlines—it may be too difficult to construct very coarse yet useful representations of the Green's function. Though ideas from homogenization theory may help, it's likely that there will be a lower limit to the resolutions that are useful to consider. In this case, it is probably wisest to limit the multiresolution bases to a few levels and instead concentrate resources on the approximate inverse.

3.2. The approximate inverse. The transformed operator $\mathbf{M}_\beta^{-T}\mathbf{A}\mathbf{M}_\alpha^{-1}$ may be multiplied out explicitly at which point any approximate inverse algorithm may be used. However, in doing so substantial extra fill-in is incurred, increasing the cost of the preconditioner construction and application as well as storage requirements. A more attractive route is to use an approximate inverse algorithm that doesn't require explicit knowledge of the matrix and thus can precondition an operator known only in this factored form.

Many popular algorithms can, in their simplest form, be adapted to this context. One example is the minimal residual (MR) method of [19] which requires no modification. However, other approximate inverses require more thought. For example,

```
• Take as input matrix $\mathbf{A}$ of dimension $n$ and a drop tolerance $\delta$, generally
  around 0.1 or 0.01.
• Set $\mathbf{W} \leftarrow \mathbf{I}$ and $\mathbf{Z} \leftarrow \mathbf{I}$.
• for $j = 1$ to $n$ do
    • Compute $l = \mathbf{A}Z_{:,j}$ and $u = \mathbf{A}^T W_{:,j}$.
    • Set $D_{jj} \leftarrow (u^T Z_{:,j})^{-1}$, the inverse pivot.
    • Rescale $L = lD_{jj}$ and $U = uD_{jj}$.
    • Compute the biconjugation coefficients
      $C_W = L^T W_{:,j+1:n}$ and $C_Z = U^T Z_{:,j+1:n}$.
    • Update the remaining columns of $\mathbf{W}$ and $\mathbf{Z}$ with sparsified outer-
      products (i.e., only updating with the entries of magnitude greater
      than $\delta$): $W_{:,j+1:n} \leftarrow W_{:,j+1:n} - \mathit{sparsify}(W_{:,j}C_W)$
      and $Z_{:,j+1:n} \leftarrow Z_{:,j+1:n} - \mathit{sparsify}(Z_{:,j}C_Z)$.
```

FIG. 4. *The SAINV algorithm, using MATLAB colon notation for submatrices.*

a sparsity pattern must be specified a priori for some methods, and it is not clear how to do so for efficient and robust performance here. Avoiding this issue, we have chosen to adopt SAINV [5, 6, 7] for this first study, which constructs the sparsity pattern during construction. In particular we use an outer-product-based version of the algorithm [13] that doesn't require any knowledge of the sparsity pattern of the operator for efficient performance. We note that for efficiency during the construction phase, the basis transforms and matrix multiplies must be done in fully sparse mode. Figure 4 gives the algorithm, which by biconjugation (along the lines of modified Gram–Schmidt) applied to two copies of the identity matrix constructs upper triangular matrices $\mathbf{W}$ and $\mathbf{Z}$ and a diagonal matrix $\mathbf{D}$ such that $\mathbf{A}^{-1} \approx \mathbf{ZDW}^T$. It can be simplified in the case of symmetric matrices to construct just $\mathbf{Z}$ (which is equal to $\mathbf{W}$) with half the work and storage. It has the advantage that for positive definite matrices it is guaranteed to produce a positive definite preconditioner, though breakdown is possible in the general case, and has generally been shown to be very robust [7].

One important issue for factored approximate inverses is the ordering of the rows and columns of the matrix. As demonstrated in [8, 12, 13], performance can be significantly improved by an appropriate reordering—e.g., nested dissection (we use the Metis routine [29]). On the other hand, one might argue that if the multiresolution bases here are constructed correctly, the transformed $\mathbf{A}$ will be well enough conditioned that ordering isn't needed. However, it seems doubtful that the multiresolution framework will be robust enough to handle all problems on its own. What we desire for tough problems is a multiresolution basis construction algorithm which "fails gracefully," i.e., never makes $\mathbf{A}$ worse conditioned even though it may not provide adequate improvement. In this case, the power of the approximate inverse will hopefully show through, provided we have taken care of the ordering.

3.2.1. Ordering. Unfortunately, typical ordering algorithms require the explicit structure of the matrix, so this is a nontrivial step in this context; some analysis is required.

Before going further, recall the graph theory notation often used in sparse matrix ordering. With a given $n \times n$ matrix $\mathbf{B}$, associate the graph $G_{\mathbf{B}}$, or simply G if the context makes it clear, defined on nodes $\{1,\dots,n\}$ with a directed edge $i \to j$ if and only if $B_{ij} \neq 0$ (for $i \neq j$). Thus the nonzero structure of $\mathbf{B}$ and the graph $G_{\mathbf{B}}$ may be identified. As an abbreviation, write $i \to j$ to mean the statement that the directed edge $i \to j$ exists in G. The neighborhood of a node i is the set of nodes j such that $i \to j$. A path is a sequence of distinct nodes $i_1, \dots, i_k$ such that $i_1 \to i_2$, $i_2 \to i_3, \dots,$ and $i_{k-1} \to i_k$, often written $i_1 \to \cdots \to i_k$, or simply $i_1 \rightsquigarrow i_k$. The transitive closure G^* of a graph G is one constructed on the same nodes but having $i \to j$ whenever $i \rightsquigarrow j$ in G. For a fuller treatment, see [25, 26].

As is shown in [26], assuming here and for the rest of this section that there is no felicitous cancellation, the structure of $\mathbf{B}^{-1}$ is given by the transitive closure of the graph of $G_{\mathbf{B}}$. As shown before, the forward transform $\mathbf{M}_\alpha$ can be simply expressed as a triangular matrix (when there are no update steps). Then the graph of $\mathbf{M}_\alpha$ satisfies $i \to j$ if and only if at some level i there is a fine node whose prediction uses coarse node j. Therefore the graph of $\mathbf{M}_\alpha^{-1}$ has $i \to j$ if and only if there is a chain of prediction dependencies $i \rightsquigarrow j$.

Define the support of a node j to be the set $\operatorname{supp}(j)$ of nodes i such that $(\mathbf{M}_\alpha^{-1})_{ij} \neq 0$—this is actually the support of the jth multiresolution basis function. From the transitive closure characterization of inverses, observe that the supports have a nested structure: if $i \in \operatorname{supp}(j)$, then $\operatorname{supp}(i) \subset \operatorname{supp}(j)$. Notice that if j is a fine node at the highest resolution level, $\operatorname{supp}(j) = \{j\}$, but that if j is at the lowest resolution level, its support may be very dense—showing that it is important to not multiply out the inverse transform explicitly.

Now examine the structure of $\mathbf{M}_\beta^{-T}\mathbf{A}\mathbf{M}_\alpha^{-1}$. Assume that $\mathbf{A}$ has symmetric structure ($A_{ij} \neq 0$ if and only if $A_{ji} \neq 0$) and $\mathbf{M}_\beta$ and $\mathbf{M}_\alpha$ have the same structure, i.e., that the two bases have the same hierarchy of levels and the same prediction dependencies.[4] Then the product has symmetric structure, and one can speak unambiguously about coarse/fine nodes and the support of a node. Observe

$$\begin{aligned}(\mathbf{M}_\beta^{-T}\mathbf{A}\mathbf{M}_\alpha^{-1})_{ij} &= \sum_{k=1}^{n}\sum_{l=1}^{n}(\mathbf{M}_\beta^{-T})_{ik}A_{kl}(\mathbf{M}_\alpha^{-1})_{lj}\\ &= \sum_{k=1}^{n}\sum_{l=1}^{n}(\mathbf{M}_\beta^{-1})_{ki}A_{kl}(\mathbf{M}_\alpha^{-1})_{lj}.\end{aligned}$$

Then $(\mathbf{M}_\beta^{-T}\mathbf{A}\mathbf{M}_\alpha^{-1})_{ij} \neq 0$ if and only if there exist nodes k and l with $k \in \operatorname{supp}(i)$, $l \in \operatorname{supp}(j)$, and $k \to l$ in $\mathbf{A}$. In other words, $i \to j$ in the product if and only if their supports are adjacent in $\mathbf{A}$. Using the nested structure of the supports, it is then clear that the neighborhood of any node j contains the neighborhoods of all nodes in $\operatorname{supp}(j)$.

Now, the location of nonzeros in column i of the upper inverse triangular factor $\mathbf{Z}$ of a symmetrically structured matrix $\mathbf{B}$ can be characterized as follows [12]: $\mathbf{Z}$ has a nonzero for each node before i and reachable from i via paths in $\mathbf{B}$ using nodes before i.

Consider the effect of swapping the positions of $i \neq j$ in some ordering, when $i \in \operatorname{supp}(j)$. Clearly the number of nonzeros in columns in $\mathbf{Z}$ ordered before both

[4] So far, relatively good results have been obtained under this assumption, which makes the following analysis much easier. However, it may prove useful to relax this requirement for convection-dominated problems, where predicting from the upwind nodes suggests that the structure of M_α and M_β should be different: convection for the adjoint problem (handled by β) is in the opposite direction from the original problem (handled by α).

```
• Take as input the structure of $\mathbf{M}_\alpha$ or $\mathbf{M}_\beta$ (multiplied out).
• For $i = 1, \ldots, n$
    • Set $numdep(i)$ = number of nodes $j$ with $j \to i$, not including $i$ itself.
    • Set $waiting(i)$ to false.
• Initialize a queue with room for $n$ entries, empty at first.
• Set $i = 1$, the first node to attempt to order.
• Set $j = 1$, the first index into the modified ordering $p$.
• While $j \leq n$
    • If the queue is not empty then
        • Remove the first node $k$ from the front of the queue.
        • Set $p_j = k$ and $j \leftarrow j + 1$.
        • Consider, in order, each $l \neq k$ with $k \to l$ and $waiting(l)$ true;
          decrement $numdep(l)$, and if this is 0 set $waiting(l)$ to false and
          append $l$ to the queue.
    • Else if $numdep(i) = 0$ then
        • Set $p_j = i$, $j \leftarrow j + 1$, and $i \leftarrow i + 1$.
        • Consider, in order, each $l \neq i$ with $i \to l$ and $waiting(l)$ true;
          decrement $numdep(l)$, and if this is 0 set $waiting(l)$ to false and
          append $l$ to the queue.
    • Else $(numdep(i) > 0)$
        • Set $waiting(i)$ to true, and $i \leftarrow i + 1$.
• Return the modified ordering $p$.
```

FIG. 5. *Modifying an ordering to respect the multiresolution basis.*

i and j or after both will not be changed. However, the columns in between may be altered. Since the neighborhood of j contains the neighborhood of i, any nodes reachable on paths through i are reachable through j, but not necessarily the other way around. Therefore ordering i before j can't result in more nonzeros in $\mathbf{Z}$, but putting j before i might.

Thus any ordering of the nodes should respect j ordered after all other nodes in $\operatorname{supp}(j)$. Since $\operatorname{supp}(j)$ is the set of i such that $(\mathbf{M}_\alpha^{-1})_{ij} \neq 0$, this is equivalent to requiring that i be ordered before j whenever $i \rightsquigarrow j$ in $\mathbf{M}_\alpha$. This is clearly equivalent to ordering i before j whenever $i \to j$ in $\mathbf{M}_\alpha$, which can be enforced by the algorithm in Figure 5.

Essentially the algorithm outputs the nodes in the existing order except when a coarse node comes before any of its fine dependents. Then the coarse node is made to wait until all the fine dependents have been ordered, at which point it's put on a queue to be ordered as soon as possible. The value $numdep(i)$ serves as a counter of how many fine nodes dependent on i have yet to be ordered—since i is put into p only when this reaches zero, the ordering must be consistent.

The initialization loop, assuming sparse storage of the matrix, takes time on the order of the number of nonzeros in the matrix, which should be $O(n)$. The complexity of the main loop is a little more difficult to prove.

First note that both i and j begin at 1 and are never decremented. Let $d = \sum_{i=1}^{n} numdep(i)$, so before the main loop begins $d = nnz(\mathbf{M}_\alpha) - n$, the number of off-diagonal nonzeros in $\mathbf{M}_\alpha$. Values in *numdep* are never incremented, so d never increases.

A node can only be marked as waiting in the final else clause, and since i is incremented there it can never be marked as waiting again. The only way an entry in *numdep* can be decremented to zero is if it had been marked as waiting, and when it hits 0 its marked as not waiting, so it can never be decremented past 0. Therefore d is always nonnegative.

Suppose i is incremented past $n+1$—this can only happen if $i = n+1$ at the start of an iteration with the queue empty. There must be some unordered nodes left, as otherwise j would have been incremented past n and the loop would have stopped. If any of the unordered nodes had *numdep* equal to zero, they either would have started at zero, in which case the first else clause would have been executed for that value of i, or would have been decremented to zero and added to the queue—in either case implying that they must now be ordered, a contradiction. Thus all the unordered nodes have positive *numdep* counters. However, some unordered node v must be from the finest resolution level of all unordered nodes and so cannot have any unordered dependent fine nodes—and so must have $\mathit{numdep}(v) = 0$, a contradiction. Therefore i never is incremented past $n + 1$.

Clearly j can never be incremented past $n + 1$ thanks to the loop condition. Therefore, since in each iteration either j is incremented, i is incremented, or at least one of the values in *numdep* is decremented, there can be at most $n + \mathit{nnz}(\mathbf{M}_\alpha)$ iterations. In fact, assuming constant time queue operations (e.g., as in a simple array implementation) the time spent in the main loop is $O(n) + O(\mathit{nnz}(\mathbf{M}_\alpha))$, which again should be $O(n)$. Thus the entire algorithm runs in $O(n)$ time.

Now consider the following simple scheme: order $\mathbf{A}$ with nested dissection and then run the above algorithm to make the ordering consistent with the multiresolution basis. The only worry is that the modification will destroy the good fill-reducing qualities of the original ordering. However, the bulk of the nodes should be at the finest level and thus have trivial supports, so the modification can't change their relative order. The only nodes that can be greatly affected by the ordering modification are the very coarse nodes, which are in a very small minority. Thus the potential damage is very limited. Experiments have confirmed that this isn't much worse (but far cheaper) than applying nested dissection to the multiplied out $\mathbf{M}_\beta^{-T}\mathbf{A}\mathbf{M}_\alpha^{-1}$.

4. Relationships with other methods. Before proceeding to our actual implementation and testing for unstructured two-dimensional problems, it is instructive to compare the new algorithm with some other multiresolution methods.

As mentioned before, the basis transforms can be expressed as triangular matrices with unit block diagonals, so the algorithm could be viewed as a highly parallel variant of multilevel ILU (e.g., [4, 3, 9, 32, 33, 34]) with an approximate inverse replacing $\mathbf{D}^{-1}$ for the approximate LDU factorization.

Another viewpoint comes from noting that the operators $\binom{\mathbf{P}_\alpha}{\mathbf{I}}$ and $(\mathbf{P}_\beta^T\ \mathbf{I})$ within the transforms for α and β correspond to node-nested multigrid's prolongation and restriction, respectively. The application of the preconditioner can then be thought of as the multigrid-like algorithm in Figure 6. The key difference between this and multigrid is that the smoothing is performed in one step, and only at the coarsest level for each variable, instead of being interleaved with restriction and prolongation. (See [36] for an example of approximate inverses used as smoothers in multigrid.) This is similar to but not exactly the same as additive multigrid, i.e., BPX [10].

The hierarchical basis preconditioners (see, e.g., [1, 2, 40]) are very similar to the

- Successively restrict the function to coarser and coarser levels by $\mathbf{M}_\beta^{-T}$.
- Smooth all variables at their coarsest level only—including couplings between variables at different levels—by $\widetilde{\mathbf{Q}}$, possibly doing an exact solve on the coarsest level if the approximate inverse is dense enough there.
- Prolong the smoothed multiresolution representation back to the original variables by $\mathbf{M}_\alpha^{-1}$.

FIG. 6. *A multigrid-like interpretation of the multiresolution approximate inverse algorithm.*

new preconditioner. In these, the original system is transformed into a new multiresolution basis, and a simple preconditioner such as block Jacobi is applied. Extending this, the multiresolution approximate inverse naturally works with unsymmetric bases ($\alpha \neq \beta$) better adapted to the problem and also allows for coupling between variables at different levels in the preconditioner $\widetilde{\mathbf{Q}}$.

More sophisticated multiresolution bases (but otherwise essentially the same algorithm as the hierarchical basis method) are used in wavelet methods; see, e.g., [15, 16, 21, 22, 23, 24, 37, 38]. In particular, these bases are more stable than simple hierarchical bases, in the sense that the multiresolution norm is equivalent to the standard norm, which results in optimal scalability. As we mentioned before when discussing the update step in the present method, this issue hasn't been resolved here, and it appears that we currently achieve only the suboptimal scalability of the hierarchical basis method.

Finally, there have already been proposed wavelet–approximate inverse combinations in [18] and [21]. Both of these works used classical wavelets, though the latter featured a generalization which correctly treats nonperiodic boundary conditions.

5. Implementation.

This section illustrates two ways to generate the multiresolution basis, one geometric and one algebraic. The important thing to keep in mind here is not the exact heuristics used but rather that exactly the same techniques used for other node-nested unstructured multilevel methods are used here. The new viewpoint of compressing the discrete Green's function provides additional insight, but this part of the problem is the same.

5.1. Geometric implementation in two dimensions.

In this section, we describe a geometric-oriented implementation for scalar second-order elliptic problems on unstructured triangular meshes. We restrict ourselves to two dimensions since the geometric complexity of remeshing in three dimensions is daunting.

The first issue to be dealt with is discretization. In this geometric implementation, the PDE is rediscretized on coarser and coarser meshes, so it is imperative to have a discretization which is stable and reasonably accurate even for large meshes. In this paper upwinding is used for convection and harmonic averaging for diffusion; more accurate schemes such as [39] could be used instead. Obviously there could be aliasing problems with highly oscillatory coefficients with the simple rediscretization used here—without resorting to algebraic methods, the only solution would be an analytic homogenization, but we have not investigated this.

The second issue is how to choose coarse nodes. Of course, in some applications an appropriate hierarchy of nested meshes is already available, but in general an automatic procedure for generating the hierarchy is needed. The simplest approach, used for multigrid in [17], is to consider the graph of a triangulation of the current set of nodes and to select a greedily chosen maximal independent subset as the next coarser level. These nodes can then be retriangulated for the next coarsening. Under the assumption that the edges of the triangulation represent strong couplings between unknowns, the maximality condition ensures that every fine node has at least one strongly coupled coarse node from which it can be predicted, and the independence condition ensures that there won't be too many coarse nodes.

This assumption breaks down for anisotropic PDEs or anisotropic meshes; "semicoarsening" is needed here, where coarsening takes place only in the directions of strong coupling. Heuristically this can be implemented by rediscretizing the PDE on the coarser mesh and then disregarding the edges corresponding to small off-diagonal nonzeros when constructing the maximal independent set. Then every fine node is guaranteed to have a strongly coupled coarse node, where the strength of coupling is measured by the size of the nonzero in the discretization. A reasonable measure of coupling strength is, for example,

$$|A_{ij}| + |A_{ji}| > \epsilon||(|A_i| + |A_j|)||$$

for some norm of the matrix columns, and with $\epsilon = 0.1$, say. All reasonable heuristics appear to work equally well after a little tuning of ϵ on small test problems.

The other problem with anisotropic PDEs lies in retriangulation of the coarse nodes. At coarse levels with anisotropically distributed nodes, Delaunay triangulation (which ignores the PDE, of course) may produce very poor meshes which don't reflect the anisotropy. Some form of coefficient-adapted triangulation is needed, such as breaking the region into subregions with more-or-less constant coefficients, changing coordinates in each subregion to make the PDE isotropic, Delaunay triangulating in the new coordinates, and then stitching the triangulated subregions back together.

The final issue concerns how to do prediction. The most robust technique is PDE prediction, where as discussed earlier the value at a fine node is taken from the approximate solution of the homogeneous PDE or its adjoint with neighboring coarse nodes as Dirichlet boundary data. With unstructured triangular meshes this is easily done by triangulating the fine node together with the few surrounding coarse nodes, then rediscretizing the PDE at just the fine node to give a single linear equation for the value there. To guarantee sparsity in the prediction operator, the coarse nodes are selected as the vertices of the coarse triangle containing the fine node, possibly with any of the three vertices on the other sides of the triangle's edges according to the Delaunay criterion for edge-swapping. If the fine node is on a convex boundary, the coarse triangle that comes nearest to containing it is used. Note that these neighboring coarse nodes can be found in $O(1)$ time by doing a breadth-first search from the fine node in the fine mesh. Also we restrict the retriangulation so that at most six coarse nodes are used to predict the fine node, thus guaranteeing a fast (linear time) construction, sparse basis transforms, and agreement with stretched meshes (see Figure 7 for what could go wrong with unrestricted retriangulation).

These same issues appear in any unstructured multilevel algorithm and, in particular, algorithms developed for coarsening and interpolation in multigrid, etc., can be used here, just as the algorithms given above could be used for other multilevel methods.

5.1.1. Sample results. In [11] several example problems were given, showing that for a variety of two-dimensional problems the new method is superior to a plain approximate inverse. For the same storage (including the basis transforms as well as the approximate inverse) and similar flop counts per iteration, the multiresolution

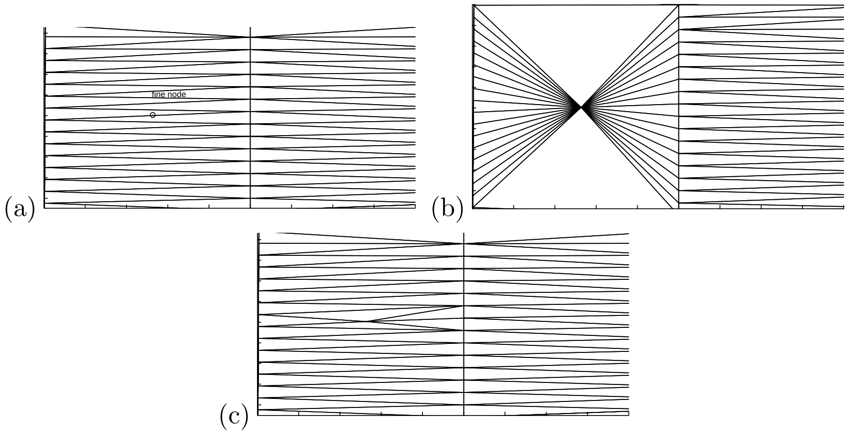

Fig. 7. *When retriangulating around a fine node in a stretched mesh* (a)*, problems can arise if no limits are put on the Delaunay insertion algorithm since many distant coarse nodes are connected to the fine node* (b)*, but a restricted retriangulation solves this issue and is also more efficient* (c)*.*

algorithm provided convergence that was several times faster, even on the smallest problems. As problem sizes increased, the number of iterations for the multiresolution method grew much more slowly than for the plain approximate inverse. (Regrettably the convergence still wasn't mesh-independent but appeared to grow like the number of levels squared, similar to hierarchical basis methods. As noted in the first part, perhaps further analysis of the update step will produce an optimal preconditioner.)

We first present results for three problems from [11] in Table 1. HEAT is a large (10 units) backward-Euler timestep of the heat equation $u_t = \nabla^2 u$ on the unit disc with Neumann boundary conditions $\nabla u \cdot \hat{n} = \mathrm{sign}(\cos(20\theta))$ and a previous timestep of $u = 0$ for $x < 0$ and $u = 1$ for $x > 0$ on an exponentially stretched mesh. ANISO is an anisotropic discontinuous problem from [20], with $1000u_{xx} + u_{yy} = f$ on the southwest and northeast quarters of the unit square, $u_{xx} + 1000u_{yy} = f$ on the others, $f = \sin(10\pi y)$, homogenous Neumann boundaries for $y > 0.25$, and the Dirichlet boundary condition $u = x$ for $y < 0.25$. REACTOR is a discontinuous indefinite problem on the unit disc of the form $\nabla \cdot K\nabla u + cu = f$, with $K = 1$, $c = 0.3$, $f = -1$ in 21 small interior discs, $K = 0.005$, $c = -0.2$, $f = -1$ for the rest of the inner disc $r < 0.9$, and $K = 10^{-6}$, $c = 0$, $f = 0$ for $r > 0.9$.

The multiresolution bases included enough levels so that the coarsest had about 100 nodes. Drop tolerances in AINV were selected to give approximately the same storage (including prediction operators) for each preconditioner: $\approx 7n$ nonzeros for a problem with n nodes. CG was used for the SPD problems and Bi-CGSTAB for the rest, with convergence flagged when the 2-norm of the residual was reduced by a factor of 10^{-6} from a starting guess of all zeros, giving up at 1000 iterations.

However, two examples of difficulties for the geometric approach arose in ANISO without the special coefficient-adapted retriangulation and in ROTATE. The latter is a non-self-adjoint, convection-dominated problem based on a solid-body rotation of a disc (circular streamlines); see Table 2. ROTATE couldn't be effectively solved with a complete hierarchy; the best results were obtained with only two coarse levels, precluding any improvement in the asymptotic rate of convergence.

5.2. An algebraic alternative. Some of the difficulties encountered in solving ANISO and ROTATE are really just artifacts of trying to rediscretize the problem

Table 1

Iteration counts for example problems of varying sizes, with the standard basis and a problem-adapted multiresolution basis for AINV. The number of unknowns starts at $n = 4939$ for HEAT, $n = 900$ for ANISO, and $n = 4195$ for REACTOR.

Problem	Method	n	$\approx 4n$	$\approx 16n$
HEAT	Standard	125	215	432
	Multiresolution	23	25	28
ANISO	Standard	37	67	111

	Multiresolution	89	141	132

Table 2

Iteration counts for examples of difficulties in geometric approach. Delaunay retriangulation ignoring anisotropy causes problems for ANISO; attempting to coarsely discretize curved streamlines causes problems for ROTATE. The number of unknowns starts at $n = 900$ for ANISO and at $n = 1195$ for ROTATE.

Problem	n	$\approx 4n$	$\approx 16n$	$\approx 64n$
ANISO	350	545	*	*
ROTATE	73	135	297	879

on very coarse triangular meshes. A simple triangular mesh cannot easily match the changing anisotropies of ANISO or curved streamlines of ROTATE, yet both of these problems would appear to permit very coarse representations. This motivates the use of algebraic methods for basis construction, where no auxiliary meshes are used; everything is generated from the original matrix alone, hopefully avoiding geometric pitfalls in doing so. This is also an advantage in three dimensions, where unstructured remeshing can be difficult.

For the prediction operators, we first decide which coarse nodes will be used to predict each fine node: we select the strongly coupled coarse nodes that are adjacent to either the fine node or one of its fine neighbors. Next we determine the weights for each coarse node in the prediction.

The simplest method we try, labeled M1, is to predict the fine node value as a weighted mean of the coarse node values, with (positive) weights proportional to the magnitude of the appropriate off-diagonal entries in the matrix $\mathbf{A}$.

A potentially more accurate method, M2, is based on solving the homogeneous PDE at the fine node with boundary values specified at the surrounding coarse nodes, as in the geometric approach. In fact, the matrix gives us an equation for each node involving it and its neighbors. Unfortunately, the equation at the fine node in general involves neighboring fine nodes as well as coarse nodes, and so we cannot stop here. Including the equations at those fine nodes would again, in general, involve more fine nodes or coarse nodes we're not using in the prediction, so the system still won't be closed. However, we can use method M1 to interpolate these unknown values from the coarse neighbors instead and then solve the closed system for the desired fine value. This is similar to element-free AMGe [28], where an additional layer of nodes is used.

The next issue is how to generate the discretized matrix at coarser levels than the original. While these matrices are not used in the preconditioner, they are required to generate the prediction operators using the above schemes and allow us to use the maximal independent set algorithm for coarse node selection from the previous section. The most natural choice for these coarser versions of $\mathbf{A}$ is the Petrov–Galerkin approximation to the Schur complement, as in multigrid:

$$\mathbf{A}_{coarse} = (\mathbf{P}_\beta^T\ \mathbf{I})\mathbf{A}\begin{pmatrix}\mathbf{P}_\alpha \\ \mathbf{I}\end{pmatrix}.$$

Unfortunately we encountered a difficulty with this approach: for unstructured problems with a reasonable number of coarse nodes used to predict each fine node, the coarse versions of **A** quickly become dense. From a finite element perspective, the supports of the coarse basis functions have too much overlap. Perhaps with more tuning of the strong connection heuristic in the coarse node selection this could have been averted, but we looked for a more automatic approach instead.

The bulk of the extra nonzeros in the coarse versions of **A** are very small, and thus a viable approach is to simply filter out the small nonzeros at each level (perhaps with diagonal compensation) as is done in multilevel ILU [4, 3, 9, 32, 33, 32]. However, for anisotropic problems such a filter may be unreliable, destroying essential topology in the problem—it cannot distinguish between the small, negligible entries resulting from excessive overlap of coarse basis functions and the small but nonnegligible entries representing weak couplings in the original PDE (that increase in relative strength as semicoarsening proceeds).

Our solution is to use two sets of prediction operators. One is stored for the basis transform, and the other is used temporarily just to generate the coarsened matrices. The prediction operators in the second set are much sparser, with structures chosen so that excessive fill-in is impossible (e.g., if the initial matrix has a planar graph, so do the coarsened matrices). They are poorer quality than the operators in the first set, but since they are better adapted to the problem than simple polynomial interpolation they should be superior to a standard rediscretization on the coarse nodes.

The nonzero structure of the second set of prediction operators is determined in two stages. In the first stage, each fine node is assigned the coarse node to which it is most strongly coupled, giving one nonzero per row in the prediction operator. In this way, the fine nodes are disjointly partitioned into clusters around the coarse nodes. From the finite element method perspective this guarantees at most unit element overlap between coarse basis functions. From the graph theory perspective this guarantees that the graph of the coarse matrix is the result of a sequence of edge contractions (the edges coupling each fine node to its chosen coarse node) from the original matrix—and this means that graph properties such as planarity or being a triangulation are preserved. In the second stage, additional nonzeros are added to improve the quality of prediction but only when they don't incur any extra fill in the coarse matrix. A greedy algorithm is used, considering the coarse nodes in order of how few fine dependencies they have, adding as many connections to the neighboring fine nodes (in order of connection strength) as possible.

5.2.1. Sample results. We now present the results of using the algebraic approach in solving ANISO and ROTATE. Table 3 gives iteration counts for these problems with both prediction methods. Clearly there is more research to be done as M2 is better than M1 for ANISO but unexpectedly worse for ROTATE.

6. Conclusions.

We have presented a new preconditioner designed for the high-performance solution of linear systems derived from elliptic PDEs. We combine the scalability of multiresolution methods with the robustness of approximate inverses to give something useful for large problems on unstructured meshes with anisotropies, strong convection, or even indefinite reaction terms. The key idea is to create a

Table 3

Iteration counts for example problems of varying sizes, solved with algebraic methods. The number of unknowns starts at $n = 961$ for ANISO and at $n = 307$ for ROTATE.

Problem	Method	n	$\approx 2n$	$\approx 4n$	$\approx 8n$
ANISO	M1	12	15	17	19
	M2	10	10	13	13
ROTATE	M1	10	14	19	23
	M2	24	32	41	63

sparse approximate inverse expressed in a multiresolution basis which compresses the discrete Green's function.

In implementing the method we have worked with a factored approximate inverse algorithm, solving the problem of ordering the unknowns in the new basis. We have also investigated both geometrical and algebraic methods for constructing the basis for unstructured problems.

Unfortunately it appears that the method doesn't scale any better than hierarchical basis methods; while this is much better than simple approximate inverses, it is suboptimal. However, the power of the approximate inverse in addition to problem-adapted interpolation means convergence is generally better than hierarchical basis methods. Robustness is particularly gained for problems, where an effective complete multilevel decomposition cannot be found: the new method can truncate the hierarchy at an appropriate level and the approximate inverse can take care of the rest.

As a result, we don't expect the method to be competitive with a well-tuned multigrid algorithm for well-behaved problems, but it may be of use for more difficult problems where robustness is critical.

SOLVING COMPLEX-VALUED LINEAR SYSTEMS VIA EQUIVALENT REAL FORMULATIONS*

DAVID DAY† AND MICHAEL A. HEROUX†

Abstract. Most preconditioned iterative methods apply to both real- and complex-valued linear systems. At the same time, most iterative linear solver packages available today focus exclusively on real-valued systems or deal with complex-valued systems as an afterthought. By recasting the complex problem in a real formulation, a real-valued solver can be applied to the equivalent real system.

On one hand, real formulations have been dismissed due to their unfavorable spectral properties. On the other hand, using an equivalent preconditioned real formulation can be very effective. We give theoretical and experimental evidence that an equivalent real formulation is useful in a number of practical situations. Furthermore, we show how to use the advanced features of modern solver packages to formulate equivalent real preconditioners that are computationally efficient and mathematically identical to their complex counterparts.

The effectiveness of equivalent real formulations is demonstrated by solving ill-conditioned complex-valued linear systems for a variety of large scale applications. Moreover, the circumstances under which certain equivalent real formulations are competitive is more clearly delineated.

Key words. complex linear systems, iterative methods, sparse matrices, preconditioning

1. Introduction.

We describe a simple yet effective extension of a real-valued preconditioned iterative solver package to solve complex-valued linear systems such as

$$Cw = d, \tag{1.1}$$

where C is an m-by-n known complex matrix, d is a known right-hand side, and w is unknown. Although most preconditioners and iterative methods apply to either complex-valued or real linear systems [4], most preconditioned iterative solver packages treat only real-valued systems. Packages that deal with complex-valued linear systems include QMRPACK [8], PETSc [3, 2, 1], and work done at CERFACS [6]. However, even in these cases, the breadth, depth, and performance capabilities of the complex-valued solvers are not as complete as the collective set of real-valued solvers. Because of these apparent deficiencies, we are compelled to consider using the vast body of real-valued solver packages to solve complex-valued systems. This work explains when and how to leverage the existing real-valued solver packages for use with complex-valued systems.

1.1. Potential equivalent real formulations.

We begin our study of equivalent real formulations by writing (1.1) in its real and imaginary terms:

$$(A + iB)(x + iy) = b + ic. \tag{1.2}$$

Table 1.1
Spectral properties of the K formulations. $\sigma(K)$ denotes the spectrum of K and $i = \sqrt{-1}$.

Matrix	Spectral properties
K_1	(i) If $\lambda \in \sigma(C)$, then $\lambda, \bar{\lambda} \in \sigma(K_1)$. (ii) If C is Hermitian (positive definite), then K_1 is symmetric (positive definite).
K_2	(i) If $\lambda \in \sigma(K_2)$, then $-\lambda, \bar{\lambda}, -\bar{\lambda} \in \sigma(K_2)$. (ii) If C is symmetric, then K_2 is symmetric.
K_3	(i) If $\lambda \in \sigma(K_3)$, then $-\lambda, \bar{\lambda}, -\bar{\lambda} \in \sigma(K_3)$. (ii) If C is symmetric, then K_3 is symmetric. (iii) $\sigma(K_3) = \sigma(K_2)$.
K_4	(i) If $\lambda \in \sigma(C)$, then $-i\lambda, i\bar{\lambda} \in \sigma(K_4)$. (ii) If C is Hermitian (positive definite), then K_4 is skew symmetric (with eigenvalues that have positive imaginary parts).

Equating the real and imaginary parts of the expanded equation, respectively, gives rise to four possible 2-by-2 block formulations, listed in (1.3)–(1.6). We call these K1 to K4, respectively.

K1 *formulation.*

$$\begin{pmatrix} A & -B \\ B & A \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} b \\ c \end{pmatrix}. \tag{1.3}$$

K2 *formulation.*

$$\begin{pmatrix} A & B \\ B & -A \end{pmatrix} \begin{pmatrix} x \\ -y \end{pmatrix} = \begin{pmatrix} b \\ c \end{pmatrix}. \tag{1.4}$$

K3 *formulation.*

$$\begin{pmatrix} B & A \\ A & -B \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} c \\ b \end{pmatrix}. \tag{1.5}$$

K4 *formulation.*

$$\begin{pmatrix} B & -A \\ A & B \end{pmatrix} \begin{pmatrix} x \\ -y \end{pmatrix} = \begin{pmatrix} c \\ b \end{pmatrix}. \tag{1.6}$$

For future reference, we denote the matrix associated with the K1 to K4 formulations by K_1 to K_4, respectively. For any pair of bases for R^{2m} and R^{2n}, there is a different equivalent real formulation of (1.1). K1 to K4 are representative of the many different formulations.

The convergence rate of an iterative method applied directly to an equivalent real formulation is often substantially worse than for the corresponding complex iterative method (see [7] and section 2). The slower convergence rate is due to the spectral properties of the equivalent real formulation. Table 1.1 summarizes the spectral properties of K_1 to K_4.

We digress briefly to justify certain relations in Table 1.1 that are not discussed in the following sections. The K_2 and K_3 matrices satisfy $K_2J = -JK_2$ and $K_3J = -JK_3$, where

$$J = \begin{pmatrix} 0 & I \\ -I & 0 \end{pmatrix}. \tag{1.7}$$

In fact, $-JK_2$ has the same eigenvalues as K_2 and is similar to K_3. Thus $\sigma(K_3) = \sigma(K_2)$ is symmetric with respect to the origin. ($\sigma(K)$ denotes the spectrum of K.)

The configuration of the eigenvalues of K_2 and K_3 is problematic for Krylov methods. If a matrix has positive eigenvalues, then augmenting that matrix in a way that reflects the spectrum through the origin degrades the convergence rate of an iterative method such as the generalized minimum residual (GMRES) method. The convergence rate for a matrix whose spectrum is symmetric with respect to the origin is the square root of the rate for the same method applied to a linear system whose spectrum lies in a half plane (see section 3.2, Example 2). Similarly, convergence rates in the K2 or K3 formulations tend to be the square root of the rates in the K1 or K4 formulations.

For the K1 formulation, if all the eigenvalues of C are on one side of the imaginary axis, then the spectrum of K_1 should not present a major problem to an iterative method such as GMRES. However, if C has eigenvalues on both sides of the imaginary axis, a property that degrades the GMRES convergence rate, then K_1 will have twice as many problematic eigenvalues. Moreover, the convex hull containing the eigenvalues of K_1 will also contain the origin. For the K4 formulation, if all the eigenvalues of C are in the upper half plane, then the eigenvalues of K_4 will be in the right half plane.

It is noteworthy that the K4 formulation of (1.1) is the same as the K1 formulation of

$$i\,\overline{C}\overline{w} = i\,\overline{d}. \tag{1.8}$$

Similarly, the K3 formulation of (1.1) is the same as the K2 formulation of (1.8). Because of these relationships, we need to consider only the K1 and K2 formulations if we are interested in the convergence properties of *unpreconditioned* Krylov methods. In fact, most of the remaining discussion is focused on the K1 and K2 formulations with K3 and K4 being special cases. However, if we want to consider the preconditioned case, especially preconditioners such as the incomplete lower/upper factorization (ILU), then K4 deserves more attention than we present in section 2.2.

If C is Hermitian, then K_1 is symmetric, and, as we will demonstrate below, the convergence rate with an equivalent real formulation is identical to the convergence rate with the original complex formulation. If C is complex symmetric, then K_2 and K_3 are also complex symmetric. Nevertheless, we still recommend K_1 for complex symmetric linear systems (see section 3.2, particularly Examples 1 and 2) because of the problem mentioned above. The best way known to the authors to precondition K_2 or K_3 is to permute back to K_1.

In view of their spectral properties, the K1 to K4 formulations have been justly criticized. Particularly, the K2 and K3 formulations appear to be unusable. However, in spite of these properties, we have found that a variation of the K1 formulation has merit. Success with the K1 formulation depends on the quality of the preconditioner to the *same* extent that success with the original complex formulation depends on the quality of the complex preconditioner. In fact, our experience shows that for the classes of problems we are solving, in particular, eigenvalue problems for computational fluid dynamics using complex valued shift parameters, if a good preconditioner is used, then the iteration count of the K formulation (discussed below) is generally comparable (within 50%) to that of solving the original complex problem with a true complex preconditioned iterative solver and has the same robustness as a true complex solver. Given the wide availability of excellent real-valued solver packages, we view our results as noteworthy.

2. Preconditioning equivalent real systems.

In trying to solve the original complex system in (1.1) via the K1 formulation in (1.3), the most interesting question is how to precondition K_1. Standard real-valued preconditioners such as Jacobi, Gauss–Seidel, or ILU applied directly to K_1 are not robust enough for our needs. Furthermore, the ordering of the unknowns is unsuitable for sparse matrix operations related to factorization, particularly ILU preconditioning.

Another preconditioner we experimented with is

$$M = \begin{pmatrix} M_A & 0 \\ 0 & M_A \end{pmatrix}, \tag{2.1}$$

where M_A is a real-valued preconditioner determined from the real part of $C = A+iB$. This approach can be viewed as a special form of block Jacobi preconditioning that may be effective if terms in A are generally larger in magnitude than those in B. However, for the problems we tested, the preconditioner in (2.1) was also not robust enough. We observed large increases in iteration count and outright failure to converge, while the solution of the complex system via a complex solver succeeded. Preconditioning by the imaginary part of C (by using the K4 formulation in (1.6)) also failed.

2.1. The K formulation.

The approach that consistently gives us good results is based on preserving the sparsity pattern of C. A *block entry* matrix is a sparse matrix whose entries are all (small) dense (sub)matrices. An alternative formulation, which we call the K formulation, preserves the nonzero pattern of the block entries at the expense of doubling the size of each dense submatrix.

In the K formulation, $c_{pq} = a_{pq} + ib_{pq}$ corresponds, via the scalar K1 formulation, to the 2-by-2 block entry of the $2m$-by-$2n$ real matrix K given by

$$\begin{pmatrix} a_{pq} & -b_{pq} \\ b_{pq} & a_{pq} \end{pmatrix}. \tag{2.2}$$

For example, if

$$C = \begin{pmatrix} c_{11} & 0 & c_{13} & 0 & c_{15} \\ 0 & c_{22} & c_{23} & 0 & 0 \\ c_{31} & 0 & c_{33} & c_{34} & 0 \\ 0 & 0 & c_{43} & c_{44} & 0 \\ c_{51} & 0 & 0 & 0 & c_{55} \end{pmatrix}, \tag{2.3}$$

then

$$K = \left(\begin{array}{cc|cc|cc|cc|cc} a_{11} & -b_{11} & 0 & 0 & a_{13} & -b_{13} & 0 & 0 & a_{15} & -b_{15} \\ b_{11} & a_{11} & 0 & 0 & b_{13} & a_{13} & 0 & 0 & b_{15} & a_{15} \\ \hline 0 & 0 & a_{22} & -b_{22} & a_{23} & -b_{23} & 0 & 0 & 0 & 0 \\ 0 & 0 & b_{22} & a_{22} & b_{23} & a_{23} & 0 & 0 & 0 & 0 \\ \hline a_{31} & -b_{31} & 0 & 0 & a_{33} & -b_{33} & a_{34} & -b_{34} & 0 & 0 \\ b_{31} & a_{31} & 0 & 0 & b_{33} & a_{33} & a_{34} & -b_{34} & 0 & 0 \\ \hline 0 & 0 & 0 & 0 & a_{43} & -b_{43} & a_{44} & -b_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & b_{43} & a_{43} & a_{44} & -b_{44} & 0 & 0 \\ \hline a_{51} & -b_{51} & 0 & 0 & 0 & 0 & 0 & 0 & a_{55} & -b_{55} \\ b_{51} & a_{51} & 0 & 0 & 0 & 0 & 0 & 0 & b_{55} & a_{55} \end{array}\right). \tag{2.4}$$

In a related real formulation, also preserving the block entry structure, the K2 formulation of c_{pq} forms the corresponding 2-by-2 block entry

$$\begin{pmatrix} b_{pq} & a_{pq} \\ a_{pq} & -b_{pq} \end{pmatrix}. \tag{2.5}$$

The K3 and K4 versions are generated similarly.

2.2. Implementation within existing software packages. The properties of the K formulation defined in section 2.1 enable us to implement efficient and robust preconditioned iterative solvers for complex linear systems. We can efficiently compute and apply the exact equivalent of a complex-valued preconditioner. If the complex preconditioned linear system has nice spectral properties, then the K formulation leads to convergence that is competitive with the true complex solver.

Solvers with block entry support. There are a number of general-purpose parallel sparse iterative solver packages that do not require special matrix properties, e.g., structured grids, and thus can be applied to a wide range of problems. These packages are usually freely available and have been used in a variety of applications. Several of these packages, including Aztec [19] and PETSc [2], support block entry matrices. The matrix K in the K formulation has a natural 2-by-2 block structure that can be exploited by using block entry data structures. Using the block entry features of these packages has the following benefits.

1. Applying 2-by-2 block Jacobi scaling to K corresponds exactly to applying point Jacobi scaling to C.
2. The block sparsity pattern of K exactly matches the point sparsity pattern of C. Thus any pattern-based preconditioners such as block ILU(l) applied to K correspond exactly to ILU(l) applied to C. See section 4 for definitions of block ILU(l) and ILU(l).
3. Any drop tolerance-based complex preconditioner has a straightforward K formulation since the absolute value of a complex entry equals the scaled Frobenius norm of the corresponding block entry in K.

Other solver packages. For existing solvers that do not have block entry support, it is still possible to exploit many of the benefits of the K formulation with the following considerations.

1. It is still possible to form the K matrix, even though its underlying block structure will not be explicitly available. Many preconditioners, especially incomplete factorizations, will closely approximate the block preconditioners listed above. Ideally, a real or imaginary nonzero in C corresponds to four entries in K, two of which are zero and may fill in during an incomplete factorization.
2. If any diagonal entries of the complex matrix C have zero or very small real parts, then pointwise incomplete factorization preconditioners may fail. (Note that this is not a problem for block entry factorization if pivoting is done within the diagonal block entries.) In this situation, one might consider using the K4 equivalent of the K formulation, or one may interleave the K1 and K4 formulations at the equation level depending on the relative magnitude of the real and imaginary parts of the complex diagonal entries. In certain situations, this leads to better ILU factors. However, we have not fully explored this approach, and its overall effectiveness remains an open question to us.

As noted above, by using block entry features, we can easily and efficiently construct preconditioners for K that are equivalent to those we would form for C using a true complex preconditioner formulation. As a result, the equivalent real preconditioned matrix operation is *identical* to the true complex preconditioned operator up to a permutation. Thus solving the real equivalent form via the K formulation using a preconditioned iterative method is identical to solving the original complex system using a corresponding preconditioned complex solver, except that the two approaches use different inner product spaces. Section 3 expands upon these comments.

3. Properties of the K formulation.

The K formulation of a preconditioned iterative method is comparable to the original complex formulation. Section 3.1 presents an equivalence between a preconditioned complex linear system and the corresponding K formulation. Next, the properties of K and C that influence convergence of iterative linear solvers are contrasted. The critical difference between K and C is that the eigenvalues of K are the eigenvalues of C together with their conjugates; $\sigma(K) = \sigma(C) \cup \overline{\sigma(C)}$. Section 3.2 contains a detailed survey of the influence of the spectrum of the convergence rate. The theoretical results of sections 3.1 and 3.2 are summarized in section 3.3 and illustrated using an example from computational chemistry in section 3.4.

3.1. Homomorphic properties of the K formulation.

The K formulation of a coefficient matrix C results in a symmetric permutation $K = PK_1P^T$ that preserves the block entry structure of C. Note that K and K_1 are orthogonally similar and share many properties.

We use the function $f()$ to denote the matrix K that corresponds to C in the K formulation, $f(C) = K$. The *key to understanding the K formulation is that f is a homomorphism*:

$$\begin{cases} f(I) = I, \\ f(XY) = f(X)f(Y). \end{cases}$$

This observation appears not to have been made before in this context. In the K formulation of an iterative method for solving a linear system with coefficient matrix C and preconditioner M, the linear system $f(C)$ is preconditioned with preconditioner $f(M)$. The K formulation of a preconditioned iterative method inherits from the preconditioned complex iterative method through

$$f(M^{-1}C) = f(M)^{-1}f(C)$$

all the properties that K_1 inherits from C.

We use the following framework to compare preconditioned iterative linear solvers. For clarity, a zero initial guess is assumed. A left-preconditioned Krylov solver is an algorithm that determines a sequence of approximations from the corresponding expanding Krylov subspaces

$$\mathcal{K}^k(M^{-1}C, M^{-1}d) = \text{span}(M^{-1}d, \ldots, (M^{-1}C)^{k-1}M^{-1}d). \tag{3.1}$$

Right preconditioning is similar. A preconditioned Krylov solver succeeds to the extent that the algorithm converges in a small number of iterations.

Characterizing successful preconditioners is difficult. The convergence rate of conjugate gradient methods applied to the left or right normal equations is bounded in terms of the square of the condition number

$$\text{cond}(M^{-1}C). \tag{3.2}$$

The convergence rate of GMRES is bounded in terms of the eigenvalues and condition number of the matrix of eigenvectors of $M^{-1}C$ [15]. For many problems, the maximum absolute value of the ratio of eigenvalues, the *spectral* condition number, best correlates with preconditioner effectiveness. The Krylov subspace, (3.1), the condition number of C, (3.2), and the condition number of the matrix of eigenvectors of C are all invariant under the K formulation (see below).

The K formulation preserves Krylov subspaces in the sense that

$$f((M^{-1}C)^k M^{-1}) = (f(M)^{-1}f(C))^k f(M)^{-1}$$

for left preconditioning and a similar equation applies with a right preconditioner. A prerequisite to discussing condition numbers is to relate the singular value decomposition (SVD) of C,

$$C = U\Sigma V^*,$$

to the SVD of K_1. Problem 8.6.4 in [9] is to show that if $U = U_r + iU_u$ and $V = V_r + iV_u$, where U_r,U_u,V_r,V_u are real, then K has the SVD

$$K = \begin{bmatrix} U_r & -U_u \\ U_u & U_r \end{bmatrix} \begin{bmatrix} \Sigma & \mathbf{0} \\ \mathbf{0} & \Sigma \end{bmatrix} \begin{bmatrix} V_r & -V_u \\ V_u & V_r \end{bmatrix}^T.$$

In particular, f preserves condition numbers. This implies the second property, that conditioning is preserved from the complex case:

$$\begin{aligned} \text{cond}(M^{-1}C) &= \text{cond}(f(M^{-1}C)) \\ &= \text{cond}(f(M)^{-1}f(C)). \end{aligned}$$

For clarity, we discuss eigenvalues in the unpreconditioned case. However, as above, these results to extend to the preconditioned case. As mentioned in section 3, eigenvalues of K are the eigenvalues of C together with their conjugates. Thus, for

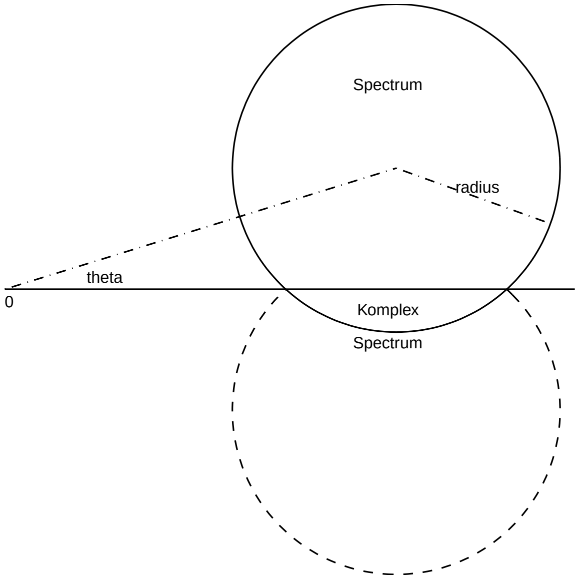

FIG. 3.1. *Asymmetric preconditioned spectrum.*

example, $M^{-1}C$ and $f(M)^{-1}f(C)$ also have the same *spectral* condition number. More precisely, Proposition 5.1 of [7] states that if C has Jordan normal form,

$$C = XJX^{-1},$$

then $K_1 = W\text{diag}(J, \overline{J})W^{-1}$ for

$$W = \left[\begin{array}{cc} X & \overline{X} \\ -iX & i\overline{X} \end{array} \right].$$

An observation not made explicitly in [7] is that it immediately follows that

$$\text{cond}(W) = \text{cond}(X).$$

As mentioned earlier, eigenvalue-based bounds on the convergence rate involve the condition number of the matrix of eigenvectors. (See also (3.3) below.)

3.2. Convergence of the K formulation. Augmenting the spectrum of C to $\sigma(K) = \sigma(C) \cup \overline{\sigma(C)}$ may or may not change the convergence rate of an iterative method. Examples 1–4 below compare the convergence rates of iterative methods in the K formulation and the original complex formulation applied to representative classes of model problems. Based on these examples, we conclude the following.

- For Hermitian linear systems, the K formulation preserves the convergence rate of the original complex formulation.
- For linear systems with an asymmetric preconditioned spectrum (see Figure 3.1), the convergence rate degrades mildly in a K formulation.

We review the prerequisite mathematical tools to keep this work self-contained.

Preliminary remarks. We selected four examples to illustrate the influence of recasting a complex linear system in an equivalent real form on the convergence rate of the linear solver. Examples 1 and 3 are paraphrased from [5]. Example 2 is classical and reviewed here in detail. Example 4 appears to be new. Examples 1 and 2 illustrate the best and the worst properties of the K1 formulation. In Example 1 the spectral condition number is preserved, and in Example 2 the spectral condition number is squared. Fortunately, the K formulation of a successfully preconditioned system is more like Example 1 than Example 2.

Examples 3 and 4 relate the convergence rates of the K formulation of a preconditioned iterative method to the corresponding complex preconditioned iterative method if the spectrum is nearly symmetric with respect to the real axis. Successful preconditioning transforms the spectrum into a disk far from 0. Example 3 shows that the convergence rate for the complex formulation is the ratio of the radius of the disk to the distance from the center of the disk to the origin. In the K formulation the convergence rate also depends on the angle between the disk and the real axis. Example 4 shows how the convergence rate gently increases as the disk rotates away from the positive real axis.

The asymptotic convergence factor for polynomial-based methods, including preconditioned Krylov subspace methods, is κ if the nth residual norm is proportional to κ^n for some constant κ. A sharp upper bound for the asymptotic convergence factor can be determined using the complex Green's function for the convex hull of the spectrum. Following [5, pp. 90–93], an iterative method for $Cw = d$ determines $\{w_k\}$ that (hopefully) converges to w and residuals, $r_k = d - Cw_k$, such that $\{r_k\}$ converges to zero. Consider the polynomial-based iterative solution method

$$r_n = p_n(C)r_0, \quad p_n(0) = 1,$$

where each $p_n \in \Pi_n$, the space of nth degree polynomials. Next let Ω be a set containing $\sigma(C)$, and define

$$\|p_n\|_\Omega = \max_{\omega\in\Omega} |p_n(\omega)|.$$

Common choices for Ω are the convex hull of $\sigma(C)$, a disk, or an ellipse with a major axis along a ray through the origin. For clarity, we assume that C is diagonalizable: $CV = V\Lambda$. The reduction in the residual norm

$$\|r_n\|_2 = \|p_n(C)r_0\|_2 \leq \text{cond}(V)\|p_n\|_{\sigma(C)}\|r_0\|_2 \leq \text{cond}(V)\|p_n\|_\Omega\|r_0\|_2 \tag{3.3}$$

is bounded above by the spectral condition number of V and $\|p_n\|_\Omega$. A residual polynomial p_n that minimizes $\|p_n\|_\Omega$ is an *optimal polynomial* $\mathcal{P}_n(t;\Omega,0)$ and solves

$$\|\mathcal{P}_n(t;\Omega,0)\|_\Omega = \min\{\|p\|_\Omega : p \in \Pi_n, p(0) = 1\}, \quad 0 \notin \Omega.$$

The convergence of an iteration $r_n = p_n(C)r_0$ is related to the asymptotic convergence factor for the polynomial iterative method induced by $\{p_n\}$,

$$\kappa(C;p_n) = \limsup_{n\to\infty}\left(\sup_{r_0\neq 0}\frac{\|r_n\|_2}{\|r_0\|_2}\right)^{1/n}.$$

The asymptotic convergence factor for Ω is defined by

$$\kappa(\Omega) = \inf_{p_n}\sup_{\sigma(C)\subset\Omega}\kappa(C;p_n).$$

The asymptotic convergence factor corresponding to the K formulation is $\kappa(\Omega\cup\overline{\Omega})$.

Next we determine the asymptotic convergence factor for C and K in several characteristic cases. $\kappa(\Omega)$ is determined from Green's function $G(z;\Omega^c)$ for the complement Ω^c of Ω with pole at infinity

$$\kappa(\Omega) = |G(0;\Omega^c)|.$$

If Ω is connected, then G is a conformal mapping from Ω^c to the open unit disk such that $G(\infty) = 0$. In general, G has the following properties.

- $G(z;\Omega^c)$ is an analytic function on Ω^c with a single-valued modulus $|G(z;\Omega^c)| < 1$ in Ω^c.
- $G(z;\Omega^c)$ has precisely one zero at ∞.
- If $z \in \partial\Omega$, then $|G(z;\Omega^c)| = 1$.

Example 1. If C is Hermitian positive definite, then the convex hull of $\sigma(C) = \sigma(K)$ is $\Omega = [\alpha, \beta]$ for $0 < \alpha < \beta$. The first step is to derive Green's function for the complement of the interval $G(z; I^c)$, an inverse of $\phi(z) = (z + z^{-1})/2$, where I denotes the interval $[-1, 1]$. We select the square root function with a branch cut along the negative real axis and

$$\phi^{-1}(z) = \begin{cases} z + \sqrt{z^2 - 1}, & 0 \le \arg(z) \le \pi, \\ z - \sqrt{z^2 - 1}, & \pi < \arg(z) < 2\pi. \end{cases}$$

Note that the branch cut for the argument function is along the positive real axis, and for $\rho > 1$,

$$\lim_{z \to \rho, \Im(z) < 0} \arg(z^2 - 1) = 2\pi.$$

Here $\Im(z)$ denotes the imaginary part of the complex number z. In this case, the singularity in ϕ^{-1} along $[1, \infty]$ has been removed, and because ϕ^{-1} is odd, ϕ^{-1} is analytic on I^c. To show that ϕ^{-1} maps I^c to the open unit disk, note that the equation $\phi(z) = w$ is a quadratic polynomial in z and $\phi(z) = \phi(z^{-1})$.

Now for $\Omega = [\alpha, \beta]$ such that $0 < \alpha < \beta$, $G(z;\Omega^c) = \phi^{-1}(\ell(z))$ for $\ell(t) = (2t - \alpha - \beta)/(\beta - \alpha)$, and

$$\kappa([\alpha, \beta]) = |G(0)| = \frac{1}{-\ell(0) + \sqrt{\ell^2(0) - 1}} = \frac{\beta - \alpha}{\beta + 2\sqrt{\beta\alpha} + \alpha}.$$

Example 2. If iC is Hermitian positive definite, then the convex hull of $\sigma(C)$ is $[i\alpha, i\beta]$ for $0 < \alpha < \beta$ and $\kappa(i[\alpha, \beta]) = \kappa([\alpha, \beta])$. However, $\sigma(K) \subset [-i\beta, -i\alpha] \cup [i\alpha, i\beta]$, and $\kappa([-i\beta, -i\alpha] \cup [i\alpha, i\beta]) = \kappa([-\beta, -\alpha] \cup [\alpha, \beta])$. The first step is to derive Green's function for the complement of symmetric intervals $\Omega = [-1, -\eta] \cup [\eta, 1]$ for $\eta = \alpha/\beta < 1$. Green's function is a branch of the solution of

$$\psi^2 + 2\frac{2z^2 - (1 + \eta^2)}{1 - \eta^2}\psi + 1 = 0.$$

The two branches

$$\psi_\pm = \frac{2}{1 - \eta^2}\left(\pm\sqrt{(z^2 - 1)(z^2 - \eta^2)} - z^2 + \frac{1 + \eta^2}{2}\right)$$

satisfy $\psi_+\psi_- = 1$, and we seek a branch whose range is the open unit disk. We choose the branch of $\pm\sqrt{(z^2 - 1)(z^2 - \eta^2)}$ that is nearest to z^2. The branch cut for $\sqrt{}$ is along the negative real axis, and

$$\arg\left((z^2 - 1)(z^2 - \eta^2)\right) = \pm\pi \leftrightarrow z = x + iy \;\text{ and }\; x^2 - y^2 = \frac{1 + \eta^2}{2}.$$

This gives us Green's function

$$G(z) = \begin{cases} \frac{2}{1-\eta^2}\left(\sqrt{(z^2-1)(z^2-\eta^2)} - z^2 + \frac{1+\eta^2}{2}\right), & x^2 - y^2 \geq \frac{1+\eta^2}{2}, \\ \frac{2}{1-\eta^2}\left(-\sqrt{(z^2-1)(z^2-\eta^2)} - z^2 + \frac{1+\eta^2}{2}\right), & x^2 - y^2 < \frac{1+\eta^2}{2}. \end{cases}$$

To show that the range of G is the open unit disk, note that ψ is a quadratic polynomial and $|\psi_\pm| = 1$ if and only if $\eta^2 \leq z^2 \leq 1$. In this case, $\kappa(\Omega) = (1-\eta)/(1+\eta) = (\beta-\alpha)/(\beta+\alpha)$.

To contrast Examples 1 and 2 as in the preliminary remarks, note that β/α is the spectral condition number of C. In Example 1 the asymptotic reduction factor depends on the square root of the spectral condition number,

$$\kappa_1 \approx 1 - 2\sqrt{\frac{\alpha}{\beta}}.$$

In Example 2 the asymptotic reduction factor depends on the spectral condition number and is much larger:

$$\kappa_2 \approx 1 - 2\,\frac{\alpha}{\beta} \gg \kappa_1.$$

Examples 3 and 4 quantify the penalty for using the K formulation instead of the true complex formulation if the convex hull of the preconditioned spectrum lies inside a disk in the left half plane rotated by θ from the positive real axis. Our analysis applies in the case in which the disk intersects its conjugate. Example 3 shows that in complex arithmetic, the asymptotic convergence factor is independent of θ. Comparing (3.4) with $|w| = 1$ to (3.6) shows that, in the K formulation, the asymptotic convergence factor increases mildly with θ.

Example 3. Here $\Omega = \{z : |z - w| < r\}$ is the disk in the complex plane of radius r about a point w that is the distance $\rho = |w|$ from the origin. The asymptotic convergence factor is $\eta = r/\rho$. A conformal mapping of Ω onto the open unit disk is $G(z;\Omega) = \frac{r}{z-w}$ and

$$\kappa(\Omega) = \frac{r}{|w|} = \eta. \tag{3.4}$$

Example 4. Here Ω comes from rotating the disk $\{z : |z - \rho| < r\}$ with center $\rho > 0$ by θ and then from reflecting though the real axis as illustrated in Figure 3.1. The circles intersect: $\sin\theta < \eta = r/\rho$.

Figure 3.2 illustrates the conformal mapping from two intersecting disks to a disk. The upper left graph corresponds to Figure 3.1. In the upper right figure the two disks are transformed to a wedge by the fractional linear transformation $w(z) = (z-\mu)/(z-\nu)$ for μ and ν defined in (3.5). Next, in the lower left figure, the wedge is opened up into the imaginary axis via $v(w) = w^{\pi/\alpha}$ for α defined in (3.5). In the lower right figure, the half plane is transformed to a disk by another fractional linear transformation $u(v) = (v-1)/(v+1)$.

To sum up, the conformal mapping of the exterior of two intersecting circles to the open unit disk is given by

$$G(z) = \frac{\left(\frac{z-\mu}{z-\nu}\right)^{\pi/\alpha} - 1}{\left(\frac{z-\mu}{z-\nu}\right)^{\pi/\alpha} + 1},$$

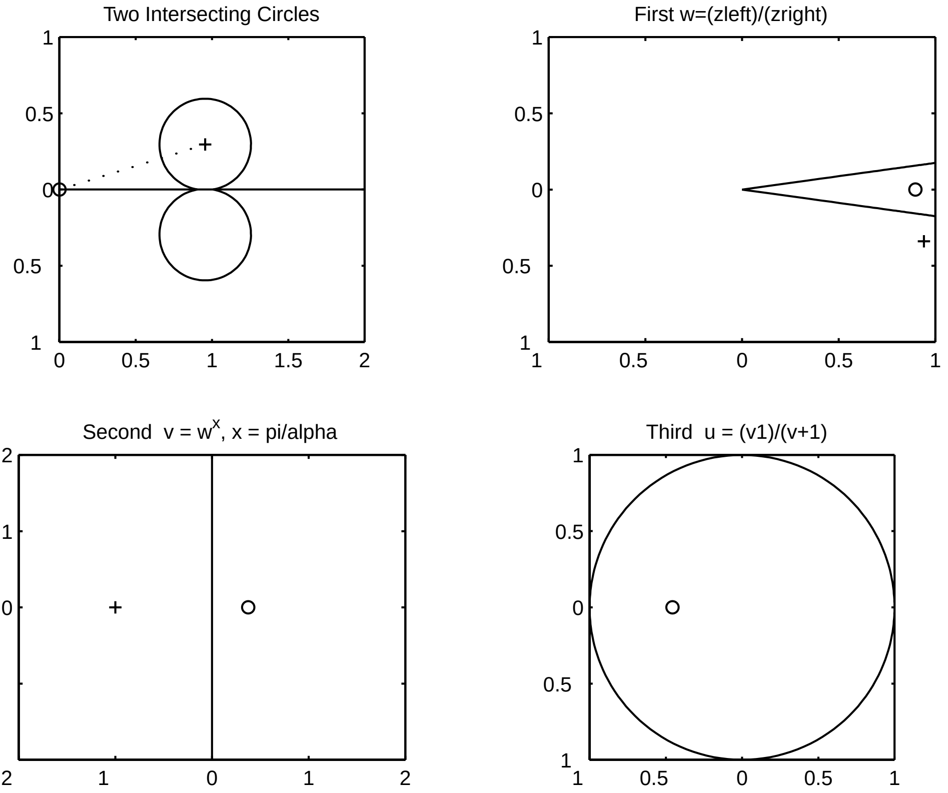

Fig. 3.2. *A conformal mapping between two intersecting disks (upper left) and a disk (lower right).*

where

$$\mu = \cos\theta - \sqrt{\eta^2 - \sin^2\theta}, \quad \nu = \cos\theta + \sqrt{\eta^2 - \sin^2\theta}, \quad \alpha = \pi - 2\tan^{-1}\left(\frac{\sin\theta}{\sqrt{\eta^2 - \sin^2\theta}}\right). \tag{3.5}$$

Also $w^{\pi/\alpha} = \exp(\frac{\pi}{\alpha}\log w)$ for $\log w = \log|w| + i\arg w$, and the branch for the argument function is placed along the negative real axis, $-i\pi < \arg w \leq i\pi$. In this case,

$$\kappa(\Omega) = (1 - (\mu/\nu)^{\pi/\alpha})/(1 + (\mu/\nu)^{\pi/\alpha}) = \eta + \frac{|\sin\theta|}{\eta\pi}(1-\eta)^2 + O(\theta^2). \tag{3.6}$$

3.3. Summary of K formulation properties. Based on the results of this section, we see that the K formulation differs from a true complex iterative solver only in the inner product space used by the iterative method. In other words, by utilizing the block entry data structures mentioned in section 2.2, we are able to provide the identical preconditioned matrix-multiply computations using the K formulation as we would for a true complex solver.

Furthermore, for complex Hermitian problems, there is no difference in asymptotic convergence rates. In fact, as is well known (e.g., see Problem 8.3.6 in [9]), if a complex matrix C is Hermitian (positive definite), the corresponding K matrix has the same eigenvalues, each with doubled multiplicity. Given the ability of the conjugate gradient

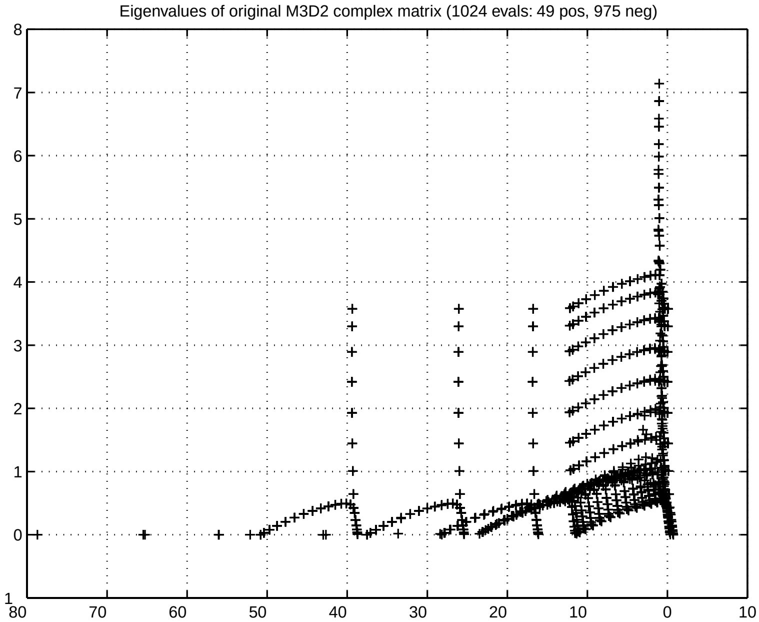

FIG. 3.3. *Eigenvalues of the original complex matrix in problem $M3D2$.*

method for linear systems to resolve multiple eigenvalues simultaneously, we observe in practice that the K formulation has identical convergence properties as a true complex solver for complex Hermitian problems.

For the non-Hermitian case, we saw from Examples 3 and 4 above that if the disk enclosing the spectrum of the preconditioned matrix C is not far from the point (1,0) in the complex plane, then the asymptotic convergence rate of the K formulation is close to the convergence rate of a true complex solver with the rate dictated by the size of the angle θ in Figure 3.1. As we will see in section 3.4, a high quality preconditioner tends to move the spectrum of C toward (1,0), setting up very favorable conditions for the K formulation.

3.4. Spectral case study. For problem M3D2 listed in Table 4.1, we computed the spectrum of the original and preconditioned matrix using the `eig` function of MATLAB. Figure 3.3 shows the distribution of the eigenvalues of the original matrix.[1] Figure 3.4 shows the eigenvalues of the K matrix, and, as expected, the eigenvalues of the K matrix are the eigenvalues of the complex matrix plus their reflection about the real axis.

Figure 3.5 shows the spectrum of the preconditioned matrix using `luinc(A,1e-1)` from MATLAB. `luinc` computes an incomplete LU factorization of a given sparse matrix. It provides several means to reduce the fill that would occur with an exact factorization. We chose to specify a drop tolerance. Given this drop tolerance, `luinc` will perform the LU factorization column by column as though it were doing an exact factorization, but as each column is computed, the terms in the column that are smaller in magnitude than the drop tolerance times the norm of the column are set to

[1] A note of thanks to Tom Wright and Nick Trefethen. They analyzed the pseudospectra of this matrix and determined that the eigenvalues of this matrix obtained via `eig` would be accurately computed.

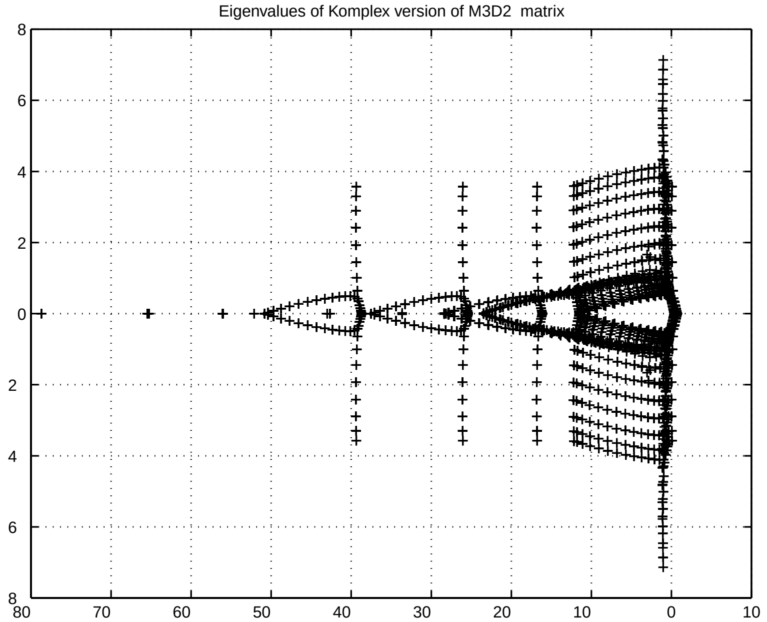

FIG. 3.4. *Eigenvalues of the K formulation matrix in problem M3D2.*

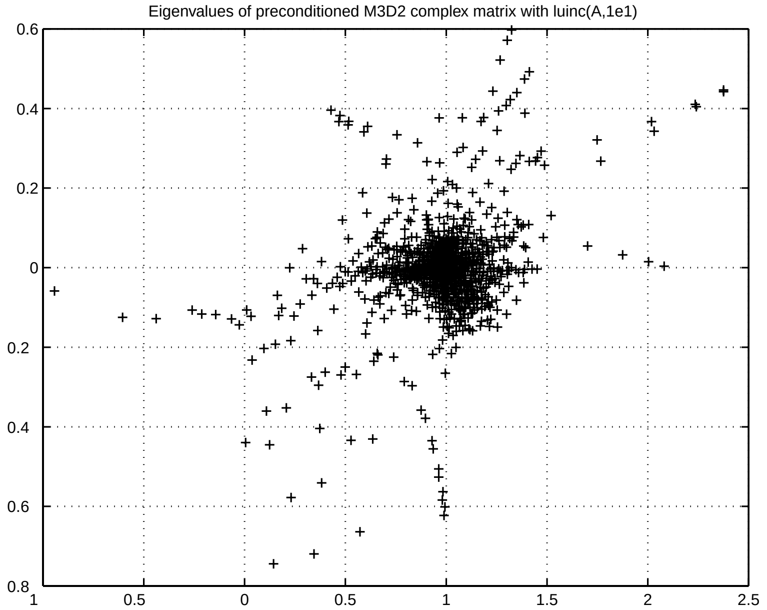

FIG. 3.5. *Eigenvalues of the complex matrix in problem M3D2, preconditioned by* `luinc(A,1e-1)`.

zero. `luinc(A,1e-1)` uses a drop tolerance of 10^{-1}. Note that the eigenvalues start to cluster around the point (1,0) in the complex plane.

Figure 3.6 shows the spectrum using `luinc(A,1e-2)`, which uses a drop tolerance of 10^{-2}. This preconditioner will typically keep more entries than `luinc(A,1e-1)` and

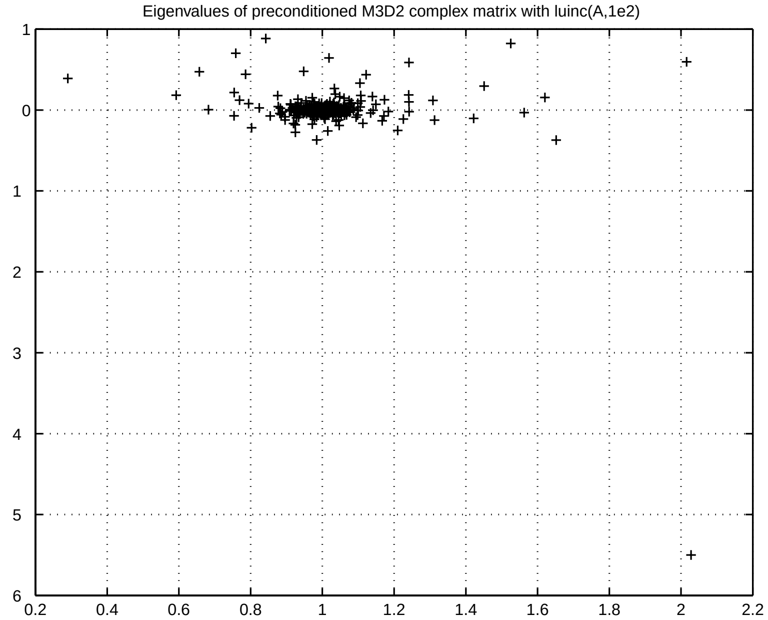

FIG. 3.6. *Eigenvalues of the complex matrix in problem M3D2, preconditioned by* `luinc(A,1e-2)`.

will be a better approximation to the exact LU factorization. With the exception of one outlyer, the eigenvalues in this case are closely clustered around (1,0).

Coupling this observation with the analysis from section 3.2, we see that high quality preconditioning, which tends to cluster the eigenvalues around the point (1,0), additionally minimizes the differences in asymptotic convergence rates between the true complex formulation and the K formulation. Thus, it simultaneously improves the convergence of both formulations and reduces the differences in convergence rates between them.

4. Computational results.

We have used the K formulation to solve complex linear systems coming from two application areas (see Table 4.1). Each system comes from a real application. These problems are very ill conditioned in the sense that inexpensive preconditioners like Jacobi or block Jacobi are not sufficient for convergence. Eigenvalue problems with complex eigenvalues are important applications for complex linear solvers. Complex linear systems arise first in computing the eigenvalue using a complex shift-invert implicitly restarted Arnoldi method [11] and next in tracking the eigenvalues as a function of a parameter using Newton's method. Selecting a shift near to the eigenvalues of interest to accelerate the convergence of Arnoldi's method creates a linear system with a large spectral condition number. We have found the K formulation with ILU preconditioning to be very effective.

4.1. Overview of problems and solution methods.

Our computational problems come from molecular dynamics and fluid dynamics. The first two problems listed in Table 4.1 come from given data sets where we are unfamiliar with the details of the applications. The last two problems come from efforts to understand the stability of a computed solution to a particular computational fluid dynamics problem using MPSalsa [18, 17]. The stability problems are representative of the linear

Table 4.1

systems solved in a complex shift-invert formulation of the eigenvalue problem.

MATLAB results were obtained using version 5.3.1 [12]. In particular, we used the built-in functions `luinc`, described in section 3.4, and `gmres`. `gmres` solves a linear system using the GMRES method [16] preconditioned by the ILU preconditioner computed by `luinc`.

The remaining results come from the Komplex Solver Package [10], an add-on module to Aztec 2.1 [19] that forms equivalent real systems from complex systems, uses Aztec to solve the real systems, and returns the complex results. For each of the problems we use overlapping domain decomposition preconditioning, specifically, additive Schwarz with one level of overlap, and we use GMRES(∞). For the M4D2 problem, the matrix has a natural block structure, and we used a block ILU preconditioner with a level fill of l (BILU(l)) on the subdomains, where we view the matrix as a sparse matrix whose entries are dense 8-by-8 matrices. The level fill parameter l refers to the pattern of the BILU factors. A level fill of $l = 0$ means that the only block entries kept are those that correspond to the pattern of the original matrix. A level fill of $l > 0$ is defined recursively to allow the BILU factors to have entries that correspond to the terms from the level fill $l - 1$ and any fill-in that comes directly from these terms. For LINSTAB1 and LINSTAB2 we replace BILU(l) with a variation of ILUT [14], a dual-threshold ILU preconditioner, as the subdomain preconditioner. The ILUT factors are computed row by row, dropping terms that fall below the threshold parameter multiplied by the norm of the row, and then keeping (at most) a prescribed number of the largest terms in the row. Details of the solvers and preconditioners can be found in [19].

Table 4.2
MATLAB test results using GMRES(∞) with luinc(droptol) preconditioning.

Problem	droptol	*nz(ILU)/nz(A)*	$\|r\|/\|b\|$	*C Iters*	*K Iters*

4.2. Results. The first set of results (in Table 4.2) were obtained using a MATLAB code where we compare a true complex preconditioned iterative solver to the K formulation. For these problems, the preconditioned operators are exactly equivalent; i.e., using the notation from section 3, if M_C and M_K are the C and K preconditioners, respectively, then $M_K = f(M_C)$. Thus what we are comparing are the differences due to having a complex inner product over n-space versus a real inner product over $2n$-space. Note that, as the quality of the preconditioner improves, the difference in iteration counts between the two approaches diminishes.

Our MATLAB results did not have any relevant solution time statistics, so we cannot precisely measure the relative costs. However, the results in Table 4.3 show that higher quality preconditioners also provide the best time to solution, up to a point where the time spent constructing and applying the higher quality preconditioner exceeds the reduction in time due to fewer iterations. These results are from the Komplex Solver Package [10], an add-on module to Aztec. We used a BILU preconditioner with 8-by-8 blocks and GMRES(∞). The best time to solution comes from BILU with a level fill of 2. This result suggests a general observation that a high quality preconditioner provides both the best time to solution and makes the difference in iteration counts between the true complex and the K formulations minimal.

Table 4.3
Komplex test results for M4D2 using GMRES(∞) with block ILU preconditioning, 8-by-8 blocks.

Problem	l	$\|r\|/\|b\|$	*K Iters*	Time(s)
M4D2	0	1×10^{-11}	322	354
	1	1×10^{-11}	179	182
	2	1×10^{-11}	75	95
	3	1×10^{-11}	60	125

The final set of results (in Table 4.4) comes from using the Komplex Solver Package to solve linear stability problems in computational fluid dynamics. The primary purpose of these results is to illustrate that, with a modest amount of new software development, we are able to provide a general-purpose parallel preconditioned iterative solver for complex-valued linear systems by leveraging existing real-valued solvers. Results are given for 1, 2, 4, 8, and 16 processors of an 8-node, 16-processor PC-based Beowulf [13] cluster. The second column of this table lists the ratio of nonzero entries in the ILU factors to the original matrix. In all cases we iterated until the scaled residual (the norm of the residual divided by the norm of the right-hand side) was below 10^{-13}. The increase in the ILU fill is due to the effect of overlap used by our parallel overlapping Schwarz preconditioners. Another trend we see is that the iterations increase as we add processors, an additional effect that is common with these preconditioners. However, even with these increasing serial costs, the parallel timings are quite reasonable.

Table 4.4

5. Conclusions.

In this paper we presented a discussion of how to solve complex-valued linear systems via equivalent real formulations. We listed approaches that failed and presented the K formulation, which works very well. Although it is clear from our results that the K formulation is not superior to a true complex solver, and clearly if you have easy access to a complex-valued solver you should use it, we do think that equivalent real formulations should receive more attention than they have in the past.

For many challenging problems, a high quality preconditioner is a requirement for convergence. Such a preconditioner has the tendency to map the spectrum around the point (1,0) in the complex plane. This, in turn, as the analysis in section 3.2 shows, minimizes the spectral difference between a true complex-valued iterative solver and the K formulation and leads to our observation that the requirement of a high quality preconditioner simultaneously provides the best solution times and diminishes the convergence differences between a true complex iterative solver and the K formulation.

Finally, for applications such as linear stability analysis, where all operators are real-valued except for the presence of complex shift value, the equivalent real formulation can be very attractive since it utilizes the native real-valued solver, and installation of the K formulation usually involves a modest amount of extra effort on the part of the application developer.

PRECONDITIONING STRATEGIES FOR FULLY IMPLICIT RADIATION DIFFUSION WITH MATERIAL-ENERGY TRANSFER*

PETER N. BROWN† and CAROL S. WOODWARD†

Abstract. In this paper, we present a comparison of four preconditioning strategies for Jacobian systems arising in the fully implicit solution of radiation diffusion coupled with material energy transfer. The four preconditioning methods are block Jacobi, Schur complement, and operator splitting approaches that split the preconditioner solve into two steps. One splitting method includes the coupling of the radiation and material fields that appears in the matrix diagonal in the first solve, and the other method puts this coupling into the second solve. All preconditioning approaches use multigrid methods to invert blocks of the matrix formed from the diffusion operator. The Schur complement approach is clearly seen to be the most effective for a large range of weightings between the diffusion and energy coupling terms. In addition, tabulated opacity studies were conducted where, again, the Schur preconditioner performed well. Last, a parallel scaling study was done showing algorithmic scalability of the Schur preconditioner.

1. Introduction.

In this paper, we present a comparison of preconditioners for a new numerical approach to the solution of very large-scale radiation diffusion problems. In this model, energy can be transferred to a material through coupling terms in both the radiation and material energy equations. These problems are important in modeling photon energy progression through an optically thick regime, a situation common in some laser and stellar fusion applications. Traditionally, solutions for these problems have been developed using operator split and time-lag techniques to reduce the coupled system of nonlinear equations to the solution of a series of linear problems. These solution techniques, however, lead to requirements of unacceptably small time steps. Furthermore, as computers have become faster, researchers have attempted to simulate larger problems despite existing solution methods that did not scale well for increased numbers of unknowns.

For these reasons, we have developed a solution method for solving radiation diffusion problems formulated in a fully implicit manner [5]. The fully implicit formulation allows larger time steps to be taken without sacrificing accuracy. Furthermore, recent work in iterative methods has provided computational scientists with new tools for solving these problems—tools that scale well to large numbers of unknowns. In order to solve this fully implicit formulation, we employ ODE time integration techniques which then require an implicit solve for the solution at each time step. We use an inexact Newton method for these solves, with a preconditioned Krylov method for solving the linear Jacobian systems that arise within the Newton iterations. The

Newton method provides fast nonlinear convergence, and the Krylov method gives a robust linear solver.

We consider four methods for solving the Jacobian preconditioning step in the Krylov method. All four schemes neglect the nonlinearity in the diffusion coefficient. The four methods primarily differ in how they approximate the coupling between the radiation and material energies. The first scheme is just to use the block diagonal part of the Jacobian matrix, thereby neglecting the majority of the coupling between the two fields. The second scheme is to factor the Jacobian and use a Schur complement preconditioner. The remaining methods use operator splitting approaches to split the preconditioner solve into two steps. One method includes the coupling of the radiation and material fields that appears in the matrix diagonal in the first solve, and the other method puts this coupling into the second solve. All preconditioning approaches use multigrid methods to invert blocks of the matrix formed from the diffusion operator.

Recent work by Mousseau, Knoll, and Rider [15] has considered the fully implicit formulation of radiation diffusion using an operator splitting preconditioner similar to the second splitting method mentioned above. They saw this preconditioner to be quite effective in solving one- and two-dimensional problems. In addition, earlier work by Knoll, Rider, and Olson [14] showed that the fully implicit form of the one-dimensional radiation diffusion problem gave greater accuracy in shorter times than did traditional methods. In previous work, we found that the block Jacobi preconditioning method was effective for test problems in three dimensions on parallel computers [5]. Further work has shown that this method is not as effective as we would like for cases where the material coupling dominates the diffusion operator. In this paper, we will compare the four preconditioning methods mentioned above on three-dimensional test problems. We will show an effective, fully implicit, parallel solution strategy for these problems.

The rest of this paper is organized as follows. In the next section, we present the mathematical models we are considering for this work. In sections 3 and 4 we discuss the spatial and temporal discretization techniques used, and in section 5 we detail the four preconditioning methods compared and show analysis indicating what qualitative behavior we expect of each for different problem parameters. We briefly discuss multigrid methods in section 6. In section 7 we give some numerical results showing algorithm performance on problems with various degrees of difficulty and in parallel on problems in three dimensions. Section 8 provides some concluding remarks.

2. Problem formulation. Our model for radiation diffusion is a simplification of the full radiation transport equation given in [16]. We assume isotropic radiation (no angular dependence), Fick's law of diffusion, no scattering effects, and that the photon energy is Planckian, and then integrate the transport equation in frequency to get the diffusion model [2],

$$\frac{\partial E_R}{\partial t} = \nabla \cdot \left(\frac{c}{3\rho\kappa_R(T_R)} \nabla E_R \right) + c\rho\kappa_P(T_M) \cdot \left(aT_M^4 - E_R \right), \tag{2.1}$$

where $E_R(\mathbf{x}, t)$ is the radiation energy density ($\mathbf{x} = (x, y, z)$), $T_M(\mathbf{x}, t)$ is the material temperature, $\rho(\mathbf{x})$ is the material density, c is the speed of light, and $a = 4\sigma/c$, where σ is the Stephan–Boltzmann constant. The Rosseland opacity, κ_R, is a nonlinear function of the radiation temperature, T_R, which is defined by the relation $E_R = aT_R^4$. The Planck opacity, κ_P, is a nonlinear function of material temperature, T_M, which is related to the material energy through an equation of state, $E_M = EOS(T_M)$. In many instances, the two opacities will take on similar values.

We also consider a spatially dependent source term in this equation expressing sources or sinks in the radiation field given by

$$\chi(\mathbf{x}) c a T_{\text{source}}^4, \tag{2.2}$$

where T_{source} is a given source temperature and $\chi(\mathbf{x})$ is a function of the spatial variable $\mathbf{x}$. Computed solutions to (2.1) may result in photon velocities which exceed the speed of light. To prevent this nonphysical phenomenon, a flux-limiter is often added to the diffusion term [2]. We use a flux-limiter of the form $\frac{\|\nabla E_R\|}{E_R}$, where the norm $\|\cdot\|$ is just the l^2 norm of the gradient vector.

The resulting radiation diffusion equation we use as our model is

$$\begin{aligned} \frac{\partial E_R}{\partial t} &= \nabla \cdot \left(\frac{c}{3\rho\kappa_R(T_R) + \frac{\|\nabla E_R\|}{E_R}} \nabla E_R \right) \\ &\quad + c\rho\kappa_P(T_M) \cdot \left(a T_M^4 - E_R \right) + \chi(\mathbf{x}) c a T_{\text{source}}^4. \end{aligned} \tag{2.3}$$

This equation is coupled to an equation expressing conservation of material energy given by

$$\frac{\partial E_M}{\partial t} = -c\rho\kappa_P(T_M) \cdot \left(a T_M^4 - E_R \right). \tag{2.4}$$

We will focus on the development of solution methods for the system (2.3)–(2.4) in what follows.

3. Solution method.

We apply a method of lines approach to the solution of (2.3)–(2.4). The spatial discretization used is as follows. We use a tensor product grid with N_x, N_y, and N_z cells in the x, y, and z directions, respectively. Define $E_{R,i,j,k}(t) \approx E_R(\mathbf{x}_{i,j,k}, t)$ and $E_{M,i,j,k}(t) \approx E_M(\mathbf{x}_{i,j,k}, t)$, with $\mathbf{x}_{i,j,k} = (x_i, y_j, z_k)$ the cell centers. Next, define

$$\mathbf{E}_R \equiv \begin{pmatrix} E_{R,1,1,1} \\ \vdots \\ E_{R,N_x,N_y,N_z} \end{pmatrix} \text{ and } \mathbf{E}_M \equiv \begin{pmatrix} E_{M,1,1,1} \\ \vdots \\ E_{M,N_x,N_y,N_z} \end{pmatrix}.$$

We employ a cell-centered finite difference scheme over the computational mesh and write our discrete equations in terms of a discrete diffusion operator given by $\mathbf{L}(\mathbf{E}_R) \equiv \left(L_{1,1,1}(\mathbf{E}_R), \ldots, L_{N_x,N_y,N_z}(\mathbf{E}_R) \right)^T$, where

$$\begin{aligned} L_{i,j,k}(\mathbf{E}_R) = &\left(\frac{c}{3\rho_{i+1/2,j,k}\kappa_{R,i+1/2,j,k} + \frac{\|\nabla E_R\|_{i+1/2,j,k}}{E_{R,i+1/2,j,k}}} \frac{E_{R,i+1,j,k} - E_{R,i,j,k}}{x_{i+1} - x_i} \right. \\ &\left. - \frac{c}{3\rho_{i-1/2,j,k}\kappa_{R,i-1/2,j,k} + \frac{\|\nabla E_R\|_{i-1/2,j,k}}{E_{R,i-1/2,j,k}}} \frac{E_{R,i,j,k} - E_{R,i-1,j,k}}{x_i - x_{i-1}} \right) \\ &/(x_{i+1/2} - x_{i-1/2}) + \ y \text{ and } z \text{ terms,} \end{aligned} \tag{3.1}$$

and a local operator $\mathbf{S}(\mathbf{E}_R, \mathbf{E}_M) \equiv (S_{1,1,1}(\mathbf{E}_R, \mathbf{E}_M), \ldots, S_{N_x,N_y,N_z}(\mathbf{E}_R, \mathbf{E}_M))^T$, where

$$S_{i,j,k}(E_{R,i,j,k}, E_{M,i,j,k}) = c\rho_{i,j,k}\kappa_{P,i,j,k} \left(a T_{M,i,j,k}^4 - E_{R,i,j,k} \right). \tag{3.2}$$

Thus, our discrete scheme is to find $\mathbf{E}_R(t)$ and $\mathbf{E}_M(t)$ such that

$$\frac{d\mathbf{E}_R}{dt} = \mathbf{L}(\mathbf{E}_R) + \mathbf{S}(\mathbf{E}_R, \mathbf{E}_M) + \mathbf{Q}, \tag{3.3}$$

$$\frac{d\mathbf{E}_M}{dt} = -\mathbf{S}(\mathbf{E}_R, \mathbf{E}_M), \tag{3.4}$$

where $\mathbf{Q} \equiv caT^4_{\text{source}}(\chi(\mathbf{x}_{1,1,1}), \ldots, \chi(\mathbf{x}_{N_x,N_y,N_z}))^T$. The system (3.3)–(3.4) is an ODE system and our time integration technique will be based on ODE time integration methods.

4. Time integration. We have developed a three-dimensional, parallel simulator that employs a fully implicit formulation and solution process for the radiation diffusion model in (3.3)–(3.4) and with which algorithms for radiation diffusion can be studied. In order to allow for accurate time-stepping as well as larger steps than what traditional methods allow, we use an ODE time integrator to handle the temporal discretization. This simulator uses the parallel ODE solver, PVODE [8], developed at Lawrence Livermore National Laboratory and based on the VODPK package (variable order ODE solver with preconditioned Krylov methods; see [7]). PVODE employs the fixed leading coefficient variant of the backward differentiation formula (BDF) method [4, 12] and allows for variation in the order of the time discretization as well as in the time step size. Time step sizes are chosen to minimize the local truncation error and thus give a solution that obeys a user-specified accuracy bound.

This time integration technique leads to a coupled, nonlinear system of equations that must be solved at each time step. For the solution of this system, we use an inexact Newton–Krylov method with Jacobian-vector products approximated by finite differences. As the methods in PVODE are predictor-corrector in nature, an explicit predictor is used for an initial guess in the nonlinear solve.

In the methods discussed above, we use the scaling technique incorporated into PVODE. Thus, we include an absolute tolerance (ATOL) for each unknown and a relative tolerance (RTOL) which is applied to all unknowns. These tolerances are then used to form a weight which is applied to each solution component during the time step from t_{n-1} to t_n. This weight is given as

$$w_i = RTOL|y^i_{n-1}| + ATOL_i \tag{4.1}$$

and is also used to weight a root mean square norm which is applied to all error-like vectors within the solution process. This scaling gives each vector component equal weight when calculating norms. For our application, we supply two absolute tolerances, one to be used with the radiation energy unknowns and one to be used with the material energy unknowns.

5. Preconditioners. The use of Newton–Krylov methods necessitates the use of preconditioning, and we consider several strategies. Before detailing the four preconditioning strategies we compare in this work, we consider the content and structure of the Jacobian matrix we are trying to precondition. We formulate our system of ODEs as $\dot{y} = f(t, y)$, set $y = (\mathbf{E}_R^T, \mathbf{E}_M^T)^T$, and then form f using the right-hand sides of (3.3)–(3.4). The Jacobian matrices used in the Newton method are of the general form $F'(y) = (I - \gamma J)$, where $J = \partial f/\partial y$ is the Jacobian of the nonlinear function f, and the parameter $\gamma \equiv \Delta t\beta$ with Δt the current time step value and β a coefficient depending on the order of the BDF method. Recalling the definitions of the discrete divergence and source operators, defined in (3.1) and (3.2), the block form of the Jacobian of f is

$$J = \begin{pmatrix} \partial \mathbf{L}/\partial \mathbf{E}_R + \partial \mathbf{S}/\partial \mathbf{E}_R & \partial \mathbf{S}/\partial \mathbf{E}_M \\ -\partial \mathbf{S}/\partial \mathbf{E}_R & -\partial \mathbf{S}/\partial \mathbf{E}_M \end{pmatrix} = \begin{pmatrix} A+G & B \\ C & D \end{pmatrix},$$

where $A = \partial \mathbf{L}/\partial \mathbf{E}_R$, $G = \partial \mathbf{S}/\partial \mathbf{E}_R$, $B = \partial \mathbf{S}/\partial \mathbf{E}_M$, $C = -\partial \mathbf{S}/\partial \mathbf{E}_R$, and $D = -\partial \mathbf{S}/\partial \mathbf{E}_M$. We note that G, B, C, and D are all diagonal matrices.

Since Jacobian approximations can be expensive to compute, the preconditioner is not updated with every Newton iteration. Preconditioner updates occur only when the Newton iteration fails to converge, when 20 time steps pass without an update, or when there is a significant change in the time step size and order of the ODE method.

On close inspection of the nonlinear diffusion operator $\mathbf{L}(\mathbf{E}_R)$, we can write

$$\mathbf{L}(\mathbf{E}_R) = \hat{\mathbf{L}}(\mathbf{E}_R)\mathbf{E}_R,$$

where $\hat{\mathbf{L}}$ is a nonlinear matrix-valued function of $\mathbf{E}_R$. In all of our preconditioning strategies, we neglect the nonlinearity in the diffusion term and use the approximation

$$A = \partial \mathbf{L}(\hat{\mathbf{E}}_R)/\partial \mathbf{E}_R \approx \hat{\mathbf{L}}(\hat{\mathbf{E}}_R) \equiv \tilde{A},$$

where $\partial \mathbf{L}(\hat{\mathbf{E}}_R)/\partial \mathbf{E}_R$ is the Jacobian of $\mathbf{L}$ evaluated at a radiation energy, $\hat{\mathbf{E}}_R$. The size of the neglected term is related to the derivatives of the Rosseland opacity and the flux-limiter. Our motivation for neglecting this term arises from the fact that $-\tilde{A}$ is symmetric and positive definite, whereas A has a first-order term that leads to nonsymmetries in its discretized form. This first-order term includes derivatives of the Rosseland opacity and flux-limiter. By neglecting the nonlinearity, this term is removed from the preconditioner, and a symmetric approximation results. In addition, calculation of $\tilde{A}$ is much cheaper than for A, as no derivatives of the flux-limiter need be computed. We also note that computation of the derivative of the flux-limiter may lead to numerical errors if $\nabla \mathbf{E}_R$ approaches 0.

Our preconditioning strategies differ in how they approximately solve systems with the matrix

$$M = I - \gamma \begin{pmatrix} \tilde{A}+G & B \\ C & D \end{pmatrix}.$$

In all cases, multigrid methods are used to invert the $\tilde{A}$ blocks. We will discuss the specifics of the multigrid scheme after detailing the four strategies.

In the following discussion, we will be examining the preconditioner performance responses to changes in the κ_P, κ_R, and Δt parameters in the problem. For these discussions, it will be useful to consider the same radiation diffusion model as given in (3.3)–(3.4) but neglecting flux-limiting and assuming κ_P and κ_R constant. In this case, we see that $\tilde{A} = O(1/\kappa_R)$ and that B, C, and D are all $O(\kappa_P)$.

5.1. Block Jacobi. Our first strategy is to approximate the Jacobian system with

$$M_{\text{Jacobi}} = I - \gamma \begin{pmatrix} \tilde{A}+G & 0 \\ 0 & D \end{pmatrix}.$$

This method effectively neglects the coupling between the radiation and material energy fields.

We now examine the error, $Err_{\text{Jacobi}} = (I - \gamma J) - M_{\text{Jacobi}}$. We see that

$$Err_{\text{Jacobi}} = \gamma \begin{pmatrix} \tilde{A} - A & -B \\ -C & 0 \end{pmatrix}.$$

Thus, the error for this block Jacobi preconditioning strategy is $O(\Delta t)$. In addition, for the non-flux-limited, constant opacity case, we see that $\tilde{A} = A$ and the error is $O(\Delta t \times \kappa_P)$ since both B and C are $O(\kappa_P)$. When $\Delta t \times \kappa_P$ gets large, we would expect this preconditioner to perform poorly.

5.2. Schur complement. Our second preconditioning strategy is to factor the matrix

$$\begin{pmatrix} P & Q \\ R & T \end{pmatrix} \equiv \begin{pmatrix} I - \gamma(\tilde{A} + G) & -\gamma B \\ -\gamma C & I - \gamma D \end{pmatrix} = M$$

into the following:

$$M_{\text{Schur}} = \begin{pmatrix} I & QT^{-1} \\ 0 & I \end{pmatrix} \begin{pmatrix} P - QT^{-1}R & 0 \\ 0 & T \end{pmatrix} \begin{pmatrix} I & 0 \\ T^{-1}R & I \end{pmatrix}.$$

Letting $S = P - QT^{-1}R$, we write the solution to $M_{\text{Schur}}x = b$ as

$$\begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \begin{pmatrix} S^{-1}(b_1 - QT^{-1}b_2) \\ T^{-1}(-Rx_1 + b_2) \end{pmatrix}.$$

The error in this preconditioner, $Err_{\text{Schur}} = (I - \gamma J) - M_{\text{Schur}}$, is given by

$$Err_{\text{Schur}} = \gamma \begin{pmatrix} \tilde{A} - A & 0 \\ 0 & 0 \end{pmatrix}.$$

If the Schur complement, S, is exactly inverted, there will be no error associated with this preconditioner for the non-flux-limited, constant opacity case. In addition, because D and hence T are diagonal, there is no penalty associated with inverting T for every iteration of a method that inverts S, as there would be if a material energy diffusion term were added to the equations. Also note that S is formed by modifying the diagonal of P, so we can still employ multigrid methods to invert this Schur complement, as we would to invert the $\tilde{A}$ matrix.

5.3. Matrix split. Our third strategy is motivated by a preconditioner developed in [11] where a splitting of the Jacobian matrix is used. Our preconditioner is written as

$$M_{\text{matrix\_split}} = (I - \gamma J_{\text{diag}})(I - \gamma J_{\text{border}}), \tag{5.1}$$

where

$$J_{\text{diag}} = \begin{pmatrix} \tilde{A} + G & 0 \\ 0 & 0 \end{pmatrix} \text{ and } J_{\text{border}} = \begin{pmatrix} 0 & B \\ C & D \end{pmatrix}.$$

Solving systems of the form $M_{\text{matrix\_split}}x = b$ requires two steps. The first step consists of a solve with the system $(I - \gamma J_{\text{diag}})y = b$, and the second step consists of a solve with the system $(I - \gamma J_{\text{border}})x = y$. Multigrid methods can be used to solve the first system.

To see how the second system can be easily inverted, we consider a reordering of the unknowns and equations of the system, so that unknowns are first ordered by space and then by energy type for each spatial point. Equations are reordered similarly. With this new ordering, $I - \gamma J_{\text{border}}$ will be a block diagonal matrix with 2×2 blocks. Each of these blocks can be written as

$$(I - \gamma J_{\text{border}})_i = \begin{pmatrix} 1 & b_i \\ c_i & d_i \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ c_i & 1 \end{pmatrix} \begin{pmatrix} 1 & b_i \\ 0 & d' \end{pmatrix},$$

where $d' = d_i - b_i c_i$. Solutions of the second step in the application of $M_{\text{matrix\_split}}$ are easily obtained with this factorization.

The error in this preconditioner, $Err_{\text{matrix\_split}} = (I - \gamma J) - M_{\text{matrix\_split}}$, is given by

$$Err_{\text{matrix\_split}} = \gamma \begin{pmatrix} -A + \tilde{A} & 0 \\ 0 & 0 \end{pmatrix} - \gamma^2 \begin{pmatrix} 0 & (\tilde{A} + G)B \\ 0 & 0 \end{pmatrix}. \tag{5.2}$$

For the non-flux-limited, constant coefficient case, $\tilde{A} = A$. The term $(\tilde{A} + G)B$ is of order $O((\frac{1}{\kappa_R} + \kappa_P)\kappa_P) \approx O(\kappa_P^2)$. Thus, this preconditioner has error $O((\Delta t)^2 \times \kappa_P^2)$. So, as $\Delta t \times \kappa_P$ gets large, we would expect this preconditioner's effectiveness to deteriorate rapidly.

5.4. Operator split. Our last strategy is motivated by a preconditioner developed in [6] where an operator splitting of the Jacobian operator is used to split the preconditioning into two steps. This preconditioner is very similar to the previous strategy except that the G term is part of the second step, rather than the first. This preconditioner is written as

$$M_{\text{operator\_split}} = (I - \gamma J_{\text{diff}})(I - \gamma J_{\text{coupling}}), \tag{5.3}$$

where

$$J_{\text{diff}} = \begin{pmatrix} \tilde{A} & 0 \\ 0 & 0 \end{pmatrix} \text{ and } J_{\text{coupling}} = \begin{pmatrix} G & B \\ C & D \end{pmatrix}.$$

Again, the first step consists of a solve with the system $(I - \gamma J_{\text{diff}})y = b$, and the second step consists of a solve with the system $(I - \gamma J_{\text{coupling}})x = y$. Multigrid methods can be used to solve the first system.

The second system here is also easily inverted by a simple LU decomposition of a reordered problem. However, the 2×2 blocks have a nonidentity upper left entry, so that the decomposition is

$$(I - \gamma J_{\text{coupling}})_i = \begin{pmatrix} g_i & b_i \\ c_i & d_i \end{pmatrix} = \begin{pmatrix} g_i & 0 \\ c_i & 1 \end{pmatrix} \begin{pmatrix} 1 & b_i/g_i \\ 0 & d' \end{pmatrix},$$

where $d' = d_i - (b_i c_i)/g_i$.

The error associated with this preconditioner, $Err_{\text{operator\_split}} = (I - \gamma J) - M_{\text{operator\_split}}$, is given by

$$Err_{\text{operator\_split}} = \gamma \begin{pmatrix} -A + \tilde{A} & 0 \\ 0 & 0 \end{pmatrix} - \gamma^2 \begin{pmatrix} \tilde{A}G & \tilde{A}B \\ 0 & 0 \end{pmatrix}. \tag{5.4}$$

Again, for the non-flux-limited, constant coefficient case, $\tilde{A} = A$ and the terms $\tilde{A}G$ and $\tilde{A}B$ are of order $O(\frac{\kappa_P}{\kappa_R})$. Thus, this preconditioner has $O((\Delta t)^2 \times \frac{\kappa_P}{\kappa_R})$ error.

If $\kappa_R \approx \kappa_P$, we would expect this preconditioner to show minimal deterioration in effectiveness as the opacities get large.

Note that $G = -C$ and $B = -D$ so that as $\Delta t \to \infty$, the second stage of this preconditioner $I - \gamma J_{\text{coupling}}$ becomes singular. As a result, we may expect this preconditioner to deteriorate for extremely large time steps.

6. Multigrid methods. The Rosseland opacity will exhibit large changes where material interfaces exist in the domain. The temperature dependence gives rise to large value changes as well. These changes imply that the problem can be very heterogeneous. As a result, to invert matrix blocks formed from the diffusion operator, we use a multigrid method designed to handle large changes in problem coefficients. In particular, we use 1 V-cycle of the ParFlow multigrid (PFMG) algorithm developed by Ashby and Falgout [1] as our multigrid solver. Other multigrid methods have been developed for highly heterogeneous problems. A comparison of PFMG and another of these methods can be found in [13]. We use PFMG here because it is fast and scales extremely well. More information about multigrid methods can be found in [3].

7. Numerical results. To understand how these preconditioning strategies perform for problems with varying degrees of difficulty, we performed a number of studies. Our first study looked at the effects of changing the relative weighting of the diffusion and coupling terms in the radiation equation by setting the two opacities constant and equal and then investigating preconditioner responses to increasing the value. Our second study looked at the effects of tabulated opacities, as are currently used in applications of interest, on these preconditioners. Last, we performed a parallel scaling study with the most effective preconditioner to verify algorithmic scalability of the solution method.

For all runs, we used the PVODE package default settings, with the following exception. Some of our tests led to nonstable solutions with higher-order methods, so we have limited the ODE method order to 2 for all cases, except where explicitly noted. We are presently looking into why these situations occur. Some work has been done in the area of avoiding these sorts of instabilities [10], and we will investigate its applicability here. Note that the default setting for the maximum number of GMRES iterations for PVODE is 5. No restart is performed.

7.1. Constant opacity results. In our first study, we set the Rosseland and Planck opacities equal to a single parameter, κ. We then changed the value of this parameter from $\kappa = 1$ to $\kappa = 100{,}000$.

For this problem, we set $E_M = T_M$. The system (2.3)–(2.4) is solved on the box $\mathcal{D} \equiv \{\mathbf{x} = (x, y, z) : 0 \le x, y, z \le 1\text{cm}\}$. The function $\chi(\mathbf{x})$ in (2.3) is defined by

$$\chi(\mathbf{x}) = \begin{cases} 1 & \text{if } 0.4 \le x, y, z \le 0.6, \\ 0 & \text{otherwise.} \end{cases} \tag{7.1}$$

The parameter T_{source} was 3,481,440 $°K$ (approximately $300eV$), and the initial conditions were taken as $E_R = aT_{R,0}^4$ and $E_M = T_{M,0}$, where $T_{R,0} = T_{M,0} = 300\ °K$. Dirichlet boundary conditions were consistent with the initial conditions. The density was taken to be 1.0g/cc. The spatial grid was uniform with $N_x = N_y = N_z = 20$.

We examined solver statistics at 50 intervals of about 0.1002s with a final simulation time of about 5.0104s. Flux-limiting was applied to the problem as discussed above. We asked for a relative tolerance on each solution component of 10^{-4} and an absolute tolerance on each of the energies of 200.

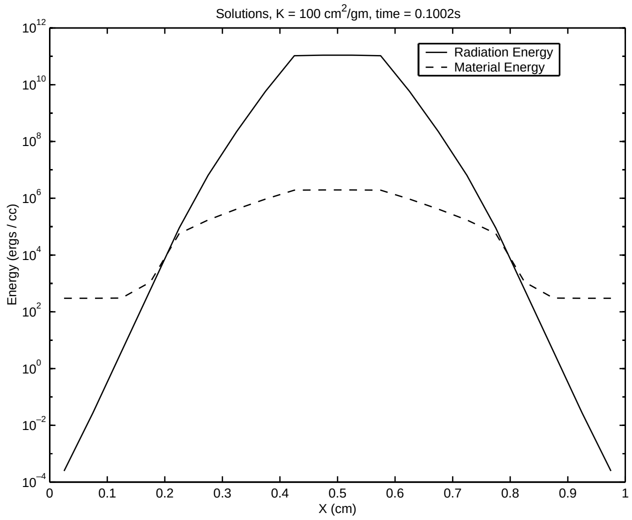

FIG. 7.1. *Radiation and material energies for* $\kappa = 100$*, time* $= 0.1002\text{s}, y = z = 0.475\text{cm}$.

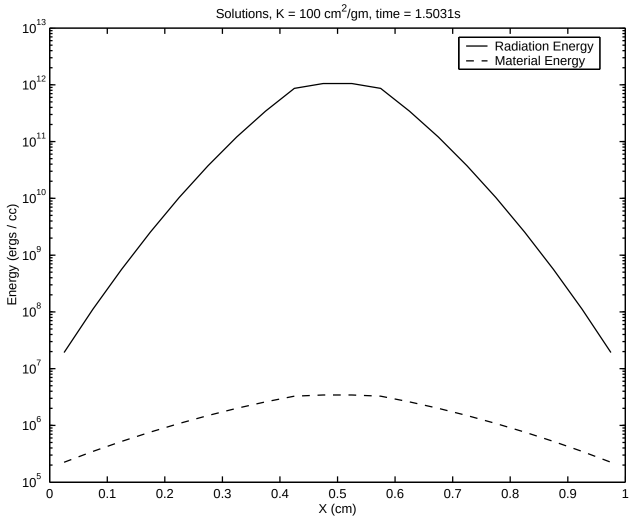

FIG. 7.2. *Radiation and material energies for* $\kappa = 100$*, time* $= 1.5031\text{s}, y = z = 0.475\text{cm}$.

Figures 7.1 and 7.2 show the solutions over the x-line for $y = z = 0.475\text{cm}$ at times 0.1002s and 1.5031s for the value $\kappa = 100\text{cm}^2/\text{g}$. The time 0.1002s is the first output time we recorded. The solutions have felt the effects of the source at this point. By 1.5031s, the energies have increased due to the source at the domain center. We also see the effects of the diffusion operator spreading out the radiation energy.

Figures 7.3 and 7.4 show the solutions at these times but for $\kappa = 10^5\text{cm}^2/\text{g}$. Here the "bump" in the domain center is much more pronounced. This difference from the lower κ case is due to the increased coupling between the two energy fields. For higher values of κ, the radiation energy diffuses much less, and more of its energy is transferred to the material. For these cases, the local physics is clearly dominating the calculation.

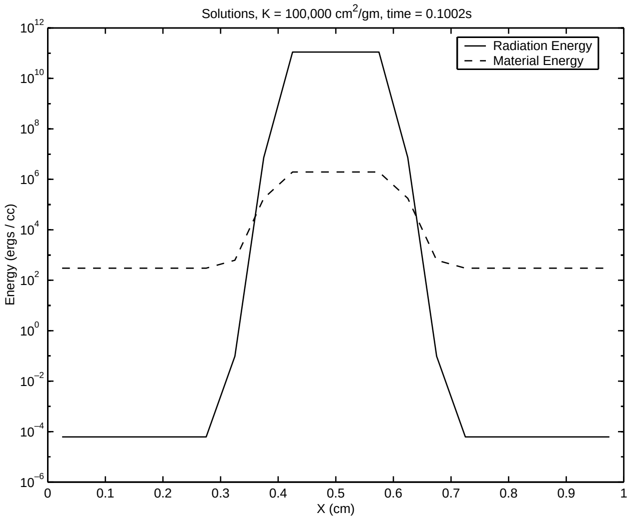

FIG. 7.3. *Radiation and material energies for* $\kappa = 10^5$*, time* $= 0.1002$s*,* $y = z = 0.475$cm.

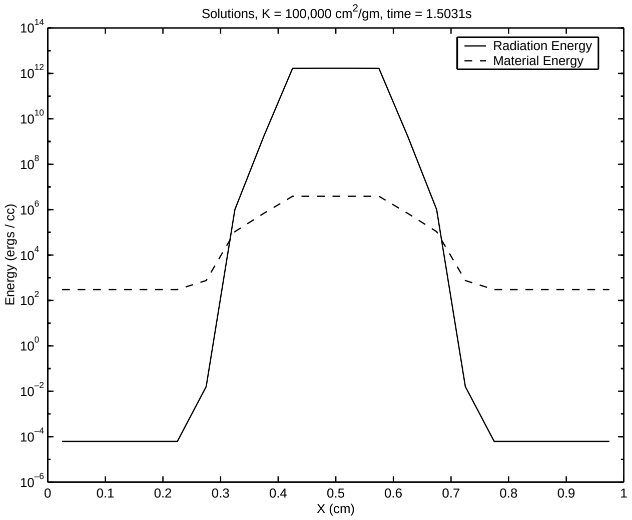

FIG. 7.4. *Radiation and material energies for* $\kappa = 10^5$*, time* $= 1.5031$s*,* $y = z = 0.475$cm.

NST = total number of time steps,
NNI = total number of nonlinear iterations,
NLI = total number of linear iterations,
NFE = total number of $f(t, y)$ evaluations,
NPE = total number of preconditioner evaluations,
NPS = total number of preconditioner solves,
HU = step size that was used on the last step (scaled by c),
RT = run time in seconds,
NCFN = total number of nonlinear convergence failures, and
NCFL = total number of linear convergence failures.

We see that the Schur preconditioner is consistently performing better and faster than the others. As the coupling term between the radiation and material grows in weight relative to the diffusion term, we see that the matrix split preconditioner is the first to show significant signs of struggle. This degradation in the matrix split preconditioner performance is expected since its error was on the order of κ_P^2. However, all but the Schur preconditioner are struggling for $\kappa = 10^4$ and $\kappa = 10^5$. The operator split preconditioner shows the second best performance, which is also expected since its error is on the order of κ_P/κ_R. For lower opacity values, the preconditioners all perform fairly well.

Figure 7.5 shows the cumulative numbers of nonlinear iterations taken by each of the preconditioners for the 50 output times for the two cases of $\kappa = 100\text{cm}^2/\text{g}$ and $\kappa = 10^5\text{cm}^2/\text{g}$. For the lower κ value, all preconditioners result in about the same number of nonlinear iterations at each time step. For the higher κ value, however, the preconditioners show distinctly different performances. During the transition to steady state, the matrix split preconditioner has the most degradation with the block Jacobi preconditioner also showing degradation, but less. These results bear out the analysis given above in that these two preconditioners have the strongest dependence on the κ value with the matrix split the strongest. After the solution gets close to steady state, however, the four preconditioners all require very few nonlinear iterations to resolve the physics. Similar results bear out for the linear iteration counts.

7.2. Tabular opacities results. In this section we give results of using the above preconditioners on several problems involving the use of tabular opacities. We

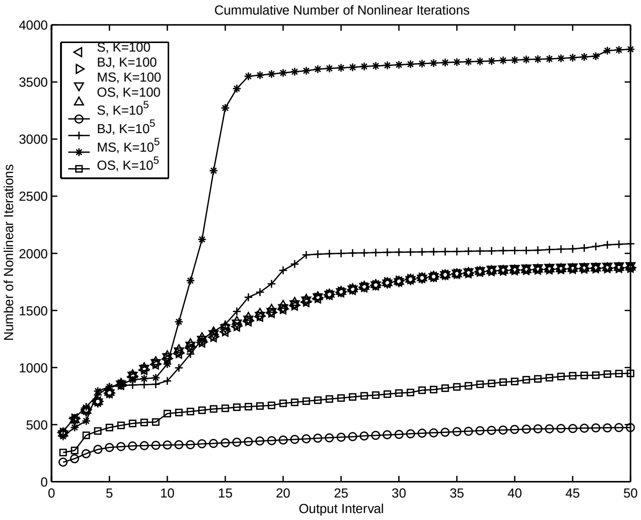

FIG. 7.5. *Cumulative nonlinear iteration counts for all four preconditioners for* $\kappa = 100\text{cm}^2/\text{g}$ *and* $\kappa = 10^5\text{cm}^2/\text{g}$.

use the LEOS package (Livermore Equation of State; see [9]) to give the Rosseland and Planck opacities as nonlinear functions of the radiation temperature T_R and material temperature T_M, respectively. The system (2.3)–(2.4) is solved on the box $\mathcal{D} \equiv \{\mathbf{x} = (x, y, z) : 0 \leq x, y, z \leq 1\text{cm}\}$ with Dirichlet boundary conditions. The function $\chi(\mathbf{x})$ in (2.3) is defined by

$$\chi(\mathbf{x}) = \begin{cases} 1 & \text{if } 0.3 \leq x, y, z \leq 0.7, \\ 0 & \text{otherwise.} \end{cases} \tag{7.2}$$

The parameter T_{source} was 3,481,440 °K (approximately $300eV$), and the initial conditions were taken as $E_R = aT_{R,0}^4$ and $E_M = EOS(\rho, T_{M,0})$, where $T_{R,0} = T_{M,0} =$ 116,100 °K (approximately $10eV$), and $EOS(\rho, T_M)$ is the equation of state function in the LEOS package giving E_M as a function of ρ and T_M. The Dirichlet boundary values for E_R and E_M are taken to be consistent with the initial conditions. The material used was carbon at a reference density of $\rho = 1.05\text{g/cc}$. The spatial grid was uniform with $N_x = N_y = N_z = 20$.

For this problem, the time behavior consists of an initial transient in which the material heats up in the region of the source (from 0 to .01 microseconds), followed by a radiation front traveling to the boundary (continuing to .41 microseconds), and then a final phase in which the solution approaches a steady state (integrated to about 1.33 microseconds). Figures 7.6 and 7.7 show the solutions plotted on the line $y = z = 0.475\text{cm}$ at .01 and .03 microseconds. The only preconditioner that was effective for the entire course of the simulation was the Schur preconditioner. We note that for the initial conditions, the starting values of the Rosseland and Planck opacities are on the order of 10^4 and 10^5, respectively. Table 7.2 compares the statistics of the PVODE solver at .01 microseconds.

At this early output time, the matrix split preconditioner is actually performing the best. However, in the next phase of the solution all the preconditioners start having large numbers of linear convergence failures except for the Schur preconditioner. It has zero linear and nonlinear convergence failures for this problem. When a linear

convergence failure occurs and the preconditioner is current, the PVODE solver reduces the step size and tries the step over. This has the effect of increasing the total number of steps for the simulation. Also note that the step sizes used by PVODE are much larger than one would expect for the split and Jacobi preconditioners to be effective. With step sizes of order 1, the errors in the split and Jacobi preconditioners are extremely large. Hence, it is not hard to understand the failure of these preconditioners (or their high cost since the step sizes must be kept small) for the latter part of the simulation. Figures 7.8 and 7.9 show the step size behavior as a function of output times for the Schur and block Jacobi preconditioners. While the step sizes change

fairly smoothly for the Schur preconditioner, the behavior has a sawtooth flavor for the block Jacobi preconditioner. The final statistics for the Schur preconditioner are given in Table 7.3, as well as the final computed statistics for the other preconditioners. For this problem, we requested 400 output snapshots. The Schur preconditioner finished the computation in under a 2-hour limit, while the block Jacobi reached 285 output points, the operator split reached 14, and the matrix split reached only 7. For the Schur preconditioner, there were on average 1.1 nonlinear iterations per time step and 2.0 linear iterations per nonlinear iteration.

For this first problem, we also investigated the effect of restricting the ODE solver to first order (i.e., backward Euler). While this had a significant effect on reducing the number of linear and nonlinear convergence failures for all but the matrix split preconditioner, the number of time steps increased dramatically. As a result, all of the preconditioners failed to produce the requested 400 output points within the 2-hour run time limit. Table 7.4 gives statistics and final times reached for each preconditioner. From these results, it is apparent that the higher-order time integration methods can be extremely effective in reducing overall run time costs.

A second problem was run with hydrogen as the material at a reference density of $\rho = .874$g/cc. This problem has the same general behavior as the first, except that the time to reach steady state is an order of magnitude lower, i.e., the simulation was run to .133 microseconds. Figures 7.10, 7.11, and 7.12 show the solutions plotted on the line $y = z = 0.475$cm at .01, .02, and .133 microseconds. Table 7.5 contains the statistics for this problem. As before, the Schur preconditioner was the only effective preconditioner for the entire run. There were on average 1.1 nonlinear iterations per time step, and 2.15 linear iterations per nonlinear iteration. Note that there were 13 linear convergence failures and 1 nonlinear failure.

7.3. Scalability study with tabulated opacities. A scalability study was performed on a third problem. The system (2.3)–(2.4) was solved on the box $\mathcal{D} \equiv \{\mathbf{x} = (x, y, z) : 0 \leq x, y, z \leq 1\text{cm}\}$ with Dirichlet boundary conditions. The function $\chi(\mathbf{x})$ in (2.3) is defined by (7.1). The parameter T_{source} was 3,481,440 °K, and the initial conditions were obtained using $T_{R,0} = T_{M,0} = 300$ °K. The Dirichlet boundary values were taken to be consistent with the initial conditions. The material used was carbon at a reference density of $\rho = 1.05$g/cc, and the spatial grid per processor was uniform with $N_x = N_y = N_z = 40$. Thus, problem size and computational resources

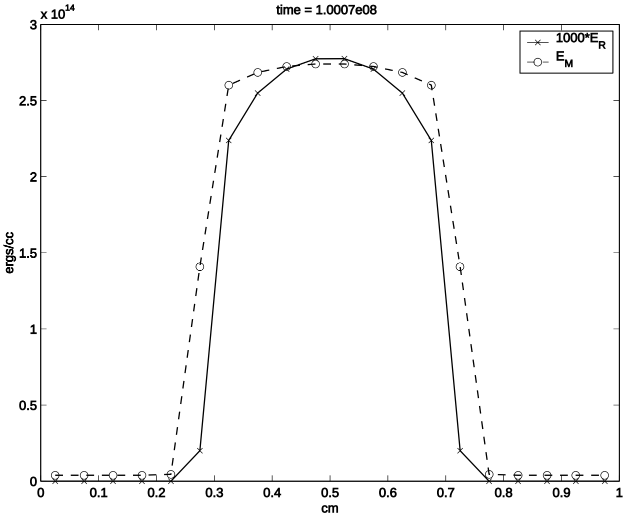

FIG. 7.10. *Snapshot of E_R and E_M for the second LEOS problem on the line $y = z = 0.475$cm at .01 microseconds.*

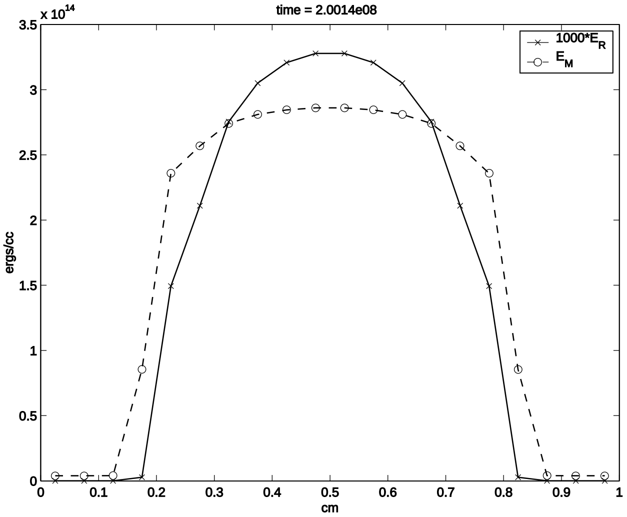

FIG. 7.11. *Snapshot of E_R and E_M for the second LEOS problem on the line $y = z = 0.475$cm at .02 microseconds.*

were simultaneously increased for this study. Only the Schur preconditioner was used. Table 7.6 contains the results of the scalability study. The reported scaled efficiency for a run on N processors was calculated by dividing the run time for the single processor case by the run time for the N processor case. As can be seen, except for the run times, all the statistics scaled extremely well. (We note that when this study was performed, the run time environment on the IBM ASCI Blue Pacific machine at LLNL was under a state of flux. Earlier scalability studies performed showed a much better scalability of run times.) The simulation was run until approximately .001 microseconds, which is very early in the time history.

8. Conclusions. We have presented a comparison of four preconditioning strategies for Jacobian systems arising in the fully implicit solution of radiation diffusion coupled with material energy transfer. The four preconditioning methods are block Jacobi, Schur complement, and operator splitting approaches that split the preconditioner solve into two steps. From our results, it is apparent that the Schur complement approach is clearly seen to be the most effective for a large range of weightings between the diffusion and energy coupling terms. For problems using tabulated opacities, the Schur preconditioner outperformed the other preconditioners by a wide margin. One conclusion we can draw from our studies is that it appears to be more effective to use full matrix approaches to developing preconditioners for radiation transport problems rather than approaches based on splittings or on only parts of the matrix.

While limiting the time integration methods to first order helps lower the number of step failures, there is a marked increase in the number of steps. At least for the problems we have considered, the better preconditioner allows for much larger step sizes within the allowed error bounds used by the PVODE solver, and this significantly reduces the overall work. Our parallel scaling study demonstrated good algorithmic scalability of our solution approach. Finally, when material diffusion is added to equation (2.4), the Schur approach may fail to be competitive. In addition, extending the physics in the problem to include multigroup diffusion (where the radiation energy spectrum is resolved) leads to a Schur complement that is a full matrix. Our future work will include exploring the use of system-based multigrid solvers as preconditioners, as well as other multilevel methods, to address material energy diffusion and multigroup energy resolution.

TOWARD THE OPTIMAL PRECONDITIONED EIGENSOLVER: LOCALLY OPTIMAL BLOCK PRECONDITIONED CONJUGATE GRADIENT METHOD*

ANDREW V. KNYAZEV†

Abstract. We describe new algorithms of the locally optimal block preconditioned conjugate gradient (LOBPCG) method for symmetric eigenvalue problems, based on a local optimization of a three-term recurrence, and suggest several other new methods. To be able to compare numerically different methods in the class, with different preconditioners, we propose a common system of model tests, using random preconditioners and initial guesses. As the "ideal" control algorithm, we advocate the standard preconditioned conjugate gradient method for finding an eigenvector as an element of the null-space of the corresponding homogeneous system of linear equations under the assumption that the eigenvalue is known. We recommend that every new preconditioned eigensolver be compared with this "ideal" algorithm on our model test problems in terms of the speed of convergence, costs of every iteration, and memory requirements. We provide such comparison for our LOBPCG method. Numerical results establish that our algorithm is practically as efficient as the "ideal" algorithm when the same preconditioner is used in both methods. We also show numerically that the LOBPCG method provides approximations to first eigenpairs of about the same quality as those by the much more expensive global optimization method on the same generalized block Krylov subspace. We propose a new version of block Davidson's method as a generalization of the LOBPCG method. Finally, direct numerical comparisons with the Jacobi–Davidson method show that our method is more robust and converges almost two times faster.

1. Introduction.

We consider a generalized *symmetric definite* eigenvalue problem of the form $(A-\lambda B)x = 0$ with real symmetric n-by-n matrices A and B, assuming that A is positive definite. That describes a regular matrix pencil $A - \lambda B$ with a discrete spectrum (set of eigenvalues λ). It is well known that such a generalized eigenvalue problem has all real eigenvalues λ_i, and corresponding (right) eigenvectors x_i, satisfying $(A - \lambda_i B)x_i = 0$, can be chosen orthogonal in the following sense: $(x_i, Ax_j) = (x_i, Bx_j) = 0,\ i \neq j$. In some applications, the matrix B is simply the identity $B = I$, and then we have the standard symmetric eigenvalue problem with matrix A, which has n real positive eigenvalues

$$0 < \lambda_{\min} = \lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_n = \lambda_{\max}.$$

In general, when $B \neq I$, the pencil $A - \lambda B$ has n real, some possibly infinite, eigenvalues. If B is nonsingular, all eigenvalues are finite. If B is positive semidefinite, some eigenvalues are infinite, all other eigenvalues are positive, and we consider the

†Department of Mathematics, University of Colorado at Denver, P.O. Box 173364, Campus Box 170, Denver, CO 80217-3364 (andrew.knyazev@cudenver.edu, http://www-math.cudenver.edu/~aknyazev).

problem of computing the smallest m eigenvalues of the pencil $A - \lambda B$. When B is indefinite, it is convenient to consider the pencil $\mu A - B$ with eigenvalues

$$\mu = \frac{1}{\lambda},\ \mu_{\min} = \mu_n \leq \cdots \leq \mu_1 = \mu_{\max},$$

where we want to compute the largest m eigenvalues, $\mu_1, \ldots \mu_m$, and corresponding eigenvectors.

An important class of eigenproblems is the class of *mesh eigenproblems*, arising from discretizations of boundary value problems with self-adjoint differential operators of mathematical physics. Such problems appear, e.g., in structural mechanics, where it is usual to call A a *stiffness* matrix and B a *mass* matrix. A mass matrix is usually positive definite, but in some applications, e.g., in buckling, the matrix B is only nonnegative, or even indefinite, while A is positive definite.

Typical properties of mesh eigenproblems are well known; see, e.g., [22]. We just want to highlight that the desired eigenpairs of the matrix pencil $B - \mu A$ are rarely needed with high accuracy as the pencil itself is just an approximation of the original continuous problem and the approximation error may not be small in practice. It means that the typical ratio of the number of iterations and the number of unknowns should be small when a preconditioner is of a reasonable quality. For that reason, in the present paper we are not much interested in such properties of eigensolvers, e.g., in superlinear convergence, which could be observed only after large number of steps.

In the rest of the paper, for brevity, we deal with the pencil $B - \mu A$ mostly. With $B = I$ and $\lambda = 1/\mu$, our results and arguments are readily applied for the pencil $A - \lambda I$.

The paper is organized as follows.

In section 2, we introduce, following [21, 22], preconditioning for eigenvalue solvers and give general definitions of preconditioned single-vector and block, or simultaneous, iterative eigensolvers. We describe the global optimization method on the corresponding generalized Krylov subspace. No efficient algorithm is presently known to perform a global optimization of the Rayleigh quotient on the generalized Krylov subspace. We shall show numerically in section 8, however, that the method we suggest in section 4 provides approximations often quite close to those of the global optimization, at a small fraction of the cost.

In section 3, we outline the "ideal" control algorithm, namely, the standard preconditioned conjugate gradient method, for finding an eigenvector as an element of the null-space of the corresponding homogeneous system of linear equations under assumption that the eigenvalue is known. The algorithm cannot, of course, be used in practice as it requires knowledge of the extreme eigenvalue, but it seems to be a perfect choice as a benchmark for preconditioned eigensolvers for computing the extreme eigenpair.

In section 4, we describe, in some details, a new algorithm of the locally optimal preconditioned conjugate gradient method, based on the local optimization of the three-term recurrence suggested by the author in [19, 21, 22]. In the original algorithm of [19], the three-term recurrence contains the current eigenvector approximation, the current preconditioned residual, and the previous eigenvector approximation. As the current eigenvector approximation and the previous eigenvector approximation get closer in the process of iterations, special measures need to be used in the algorithm to overcome the potential instability. In our new algorithm, the three-term recurrence contains the current eigenvector approximation, the current preconditioned residual, and the implicitly computed difference of the current and previous eigenvector approximations. Such choice resolves instability issues and allows us to write a much simpler and more efficient code.

We present block versions of the method, the locally optimal block preconditioned conjugate gradient (LOBPCG) methods for symmetric eigenvalue problems, in section 5.

To be able to compare numerically different methods in the class, with different preconditioners, we suggest, in section 6, a common system of model tests, using random preconditioners and initial guesses. We recommend that every new preconditioned eigensolver for computing the extreme eigenpair be compared with our "ideal" algorithm on our model test problems in terms of the speed of convergence, costs of every iteration, and memory requirements. We also recommend a comparison with the global optimization method in terms of accuracy.

We provide such comparison for our LOBPCG method in sections 7 and 8. Numerical results of section 7 establish that our algorithm is practically as efficient as the "ideal" algorithm when the same preconditioner is used in both methods. In section 8 we show numerically that the block version of our method comes close to finding the global optimum of the Rayleigh quotient on the corresponding generalized block Krylov subspace.

Section 9 contains an informal discussion of the block Davidson method. We describe a nonstandard restart strategy that makes the block Davidson method a generalization of our LOBPCG method. We argue, however, that such generalization may not be beneficial for symmetric eigenvalue problems.

In section 10, we compare directly our method with a version of the Jacobi–Davidson method [14] for $B = I$. No MATLAB code of the Jacobi–Davidson method for a generalized eigenvalue problem is currently publicly available. We find that our method is much more robust and typically converges almost two times faster. This is not very surprising, as the MATLAB version of the Jacobi–Davidson method available to us for testing is not apparently optimized for symmetric eigenvalue problems, while our method takes full advantage of the symmetry by using a three-term recurrence.

Finally, section 11 contains references to some relevant software written by the author.

We note that the simplicity, robustness, and fast convergence of preconditioned eigensolvers we propose make them a more and more popular choice in applications, e.g., in band structure calculations in two- and three-dimensional photonic crystals [6, 7] and eigenvalue problems for thin elastic structures [32]. Some eigenvalue problems in mechanics, e.g., vibration of a beam supported by springs, lead to equations with nonlinear dependence on the spectral parameter. Preconditioned eigensolvers for such equations are analyzed in [39, 40], where, in particular, a generalization of the theory of a preconditioned subspace iteration method of [9, 10] is presented.

2. Preconditioning for eigenvalue problems.

First, we briefly review a traditional approach for large symmetric generalized eigenproblems, based on using classical methods, e.g., the Lanczos method, for a shifted-and-inverted operator $(B - \nu A)^{-1}A$. It typically lets us quickly compute the eigenvalues closest to the shift ν, assuming that this operation may be implemented with an efficient factorization of $B - \nu A$. However, for very large problems such factorizations are usually too expensive. An inner iterative solver is often used to somewhat circumvent this difficulty; see a review and references in [21, 22] and a recent paper [38].

If B is efficiently factorizable, e.g., $B = I$, so that we can multiply vectors by

AB^{-1}, or $B^{-1}A$, we take $\nu = 0$. In this case, a single iteration may not be expensive, but eigenvalues μ close to zero are usually not of practical interest, and the convergence for eigenvalues of interest is often very slow.

Thus, the traditional approach is inefficient for very large mesh eigenproblems. Preconditioning is the key for significant improvement of the performance as it allows one to find a path between the Scylla of expensive factorizations and the Charybdis of slow convergence.

Preconditioned methods are designed to handle the case when the only operation we can perform with matrices A and B of the pencil is multiplication of a vector by A and B. To accelerate the convergence, we introduce a *preconditioner* T.

In many engineering applications, preconditioned iterative solvers for linear systems $Ax = b$ are already available, and efficient preconditioners $T \approx A^{-1}$ are constructed. It is important to realize that the same preconditioner T can be used to solve an eigenvalue problem $Ax = \lambda x$, or $Bx = \mu Ax$.

We assume that the preconditioner T is *symmetric positive definite.* As A is also symmetric positive definite, there exist positive constants $\delta_1 \geq \delta_0 > 0$ such that

$$\delta_0(T^{-1}x, x) \leq (Ax, x) \leq \delta_1(T^{-1}x, x). \tag{2.1}$$

The ratio δ_1/δ_0 can be viewed as the spectral condition number $\kappa(TA)$ of the preconditioned matrix TA and measures how well the preconditioner T approximates, up to a scaling, the matrix A^{-1}. A smaller ratio δ_1/δ_0 usually ensures faster convergence.

We want to highlight that the assumption we just made on T is essential for the theory (see [21]) but may not be an actual limitation in numerical computations for some methods. In particular, our own method of section 5 is quite robust in practice with respect to the choice of the preconditioner, even when the assumptions above are not satisfied; see Figure 5.2 below as an example of using an indefinite preconditioner.

As we want to discuss an optimality of preconditioned eigensolvers, we need to have a formal definition of the whole class of such methods. We first define, following [21], a preconditioned single-vector iterative solver for the pencil $B - \mu A$, as a generalized polynomial method of the following kind:

$$x^{(k)} = P_k(TA, TB)x^{(0)}, \tag{2.2}$$

where P_k is a polynomial of the kth degree of two independent variables, $x^{(0)}$ is an initial guess, and T is a fixed preconditioner.

We need only choose a polynomial, either a priori or during the process of iterations, and use a recursive formula which leads to an iterative scheme. For an approximation $\mu^{(i)}$ $(\lambda^{(i)})$ to an eigenvalue of the pencil $B - \mu A$ $(A - \lambda B)$ for a given eigenvector approximation $x^{(i)}$ the Rayleigh quotient $\mu(x)$ $(\lambda(x))$ defined as

$$\mu(x^{(i)}) = \frac{(x^{(i)}, Bx^{(i)})}{(x^{(i)}, Ax^{(i)})} \quad \left(\lambda(x^{(i)}) = \frac{(x^{(i)}, Ax^{(i)})}{(x^{(i)}, Bx^{(i)})}\right) \tag{2.3}$$

is typically used.

Let us now define the generalized Krylov subspace:

$$K_k\left(TA, TB, x^{(0)}\right) = \left\{P_k(TA, TB)x^{(0)}\right\}, \tag{2.4}$$

where P_k runs through the set of all polynomials of the kth degree of two independent variables and $x^{(0)}$ is a fixed initial vector. In particular,

$$\begin{aligned} &K_2\left(TA, TB, x^{(0)}\right) \\ &\quad = \operatorname{span}\left\{x^{(0)}, TAx^{(0)}, TBx^{(0)}, (TA)^2x^{(0)}, TATBx^{(0)}, TBTAx^{(0)}, (TB)^2x^{(0)}\right\}. \end{aligned}$$

We notice that in our definition (2.2) of the preconditioned eigensolver

$$x^{(k)} \in K_k\left(TA, TB, x^{(0)}\right).$$

Having definition (2.2) of the whole class of preconditioned eigensolvers, we can introduce, as in [21], the *global optimization* method for computing the first eigenpair simply by maximizing the Rayleigh quotient $\mu(x)$ on the Krylov subspace (2.4):

$$x_o^{(k)} = \operatorname{argmax}_{x \in K_k\left(TA, TB, x^{(0)}\right)} \mu(x). \tag{2.5}$$

We want to highlight that an efficient algorithm for finding $x_o^{(k)}$, e.g., based on short-term recurrences, is not presently known, and that the number of vectors in the basis of the Krylov subspace (2.4) grows exponentially, which makes the method very expensive in practice, similarly to the situation with Davidson's method (see discussion in [21, 22]), unless restarts are used. Therefore, the global optimization method (2.5) is optimal only in the sense that it provides the global maximum of the Rayleigh quotient on the Krylov subspace, but it may not be optimal if we also count computational costs.

For block methods, we introduce the generalized block Krylov subspace:

$$K_k\left(TA, TB, X^{(0)}\right) = \operatorname{span}\left\{P_k(TA, TB)x_j^{(0)},\ j = 1, \dots, m\right\}, \tag{2.6}$$

where P_k runs through the set of all polynomials of the kth degree of two independent variables and $X^{(0)} = \operatorname{span}\{x_j^{(0)},\ j = 1, \dots, m\}$.

A general preconditioned block eigensolver is a generalization of method (2.2) with a single vector being replaced with several ones. Using the Rayleigh–Ritz method is typical for block methods; see [21, 22].

Here, we only want to define the *block global optimization* method, Algorithm 2.1, as we use it later in our numerical experiments.

```
ALGORITHM 2.1. THE BLOCK GLOBALLY OPTIMAL PRECONDITIONED EIGENSOLVER.
Input: $m$ starting vectors $x_1^{(0)}, \dots x_m^{(0)}$, devices to compute: $Ax$, $Bx$, and $Tx$ for
    a given vector $x$, and the vector inner product $(x, y)$.
  1. Start: select $x_j^{(0)}$, $j = 1, \dots, m$.
  2. Iterate to compute the basis of the generalized block Krylov subspace (2.6).
  3. Use the Rayleigh–Ritz method for the pencil $B - \mu A$ in the subspace
       to compute the Ritz values $\mu_j^{(k)}$ and the corresponding Ritz vectors $x_j^{(k)}$.
Output: the approximations $\mu_j^{(k)}$ and $x_j^{(k)}$ to the largest eigenvalues
    $\mu_j$ and corresponding eigenvectors, $j = 1, \dots, m$.
```

In our code of the block global optimization method, we do not even try to minimize computation costs and simply compute recursively

$$K_{k+1} = K_k + TAK_k + TBK_k, \tag{2.7}$$

followed by complete orthogonalization. The only purpose of the code is to provide a comparison, in terms of accuracy, for the actual block method we suggest in section 5.

3. The "ideal" preconditioned conjugate gradient method.

In this section, we outline the "ideal" control algorithm, namely, the standard preconditioned conjugate gradient (PCG) method for finding an eigenvector, corresponding to the minimal eigenvalue, as an element of the null-space of the corresponding homogeneous system of linear equations under the assumption that the eigenvalue is known.

We assume $B > 0$ in this section. Let us *suppose* that the minimal eigenvalue λ_1 is *already known*, and we just need to compute the corresponding eigenvector x_1, an element of the null-space of the homogeneous system of linear equations

$$(A - \lambda_1 B)x_1 = 0,$$

where the matrix of the system is symmetric and nonnegative definite. What would be an *ideal* preconditioned method of computing x_1? As such, we choose the *standard PCG method.* It is well known that a PCG method can be used to compute a nonzero element of the null-space of a homogeneous system of linear equations with a symmetric and nonnegative definite matrix if a nonzero initial guess is used. While fitting perfectly the definition of a single-vector preconditioned eigensolver of the previous section, this ideal method *cannot be used in practice* as it requires knowledge of the eigenvalue.

We suggest using the method as a *control* in numerical comparison with practical eigenvalue solvers, in particular, with PCG eigensolvers, e.g., with our locally optimal PCG method. If an eigensolver finds the eigenvector u_1 with the same accuracy and costs as the ideal method, we have reasons to call such an eigensolver "optimal" for computing the eigenvector u_1.

For our numerical tests, we write a code PCGNULL.m, which is a slightly modified version of the built-in MATLAB code PCG.m, revision 1.11, of the standard PCG method to cover solution of homogeneous systems of linear equations with symmetric and nonnegative definite system matrices.

The standard theory of the PCG method for computing an element of the null-space of a symmetric nonnegative definite matrix implies convergence to the eigenvector x_1, which is the T^{-1}-orthogonal projection of the initial guess $y^{(0)}$ to the null-space of the matrix $A - \lambda_1 B$. On the $(i+1)$st step, the "energy" norm of the error, in our case it's actually the seminorm based on $A - \lambda_1 B$, i.e.,

$$\sqrt{(y^{(i+1)}, (A - \lambda_1 B)y^{(i+1)})}, \tag{3.1}$$

is minimized over the hyperplane

$$H_{i+1} = y^{(0)} + K_i(T(A - \lambda_1 B),\ T(A - \lambda_1 B)y^{(0)}), \tag{3.2}$$

where K_i is the standard Krylov subspace. As x_1 is in the null-space of the matrix $A - \lambda_1 B$, we have

$$(y, T^{-1}x_1) = (y^{(0)}, T^{-1}x_1) \quad \forall y \in H_i, \tag{3.3}$$

in particular, $(y^{(i)}, T^{-1}x_1)$ does not change in the process of iterations, while (3.1) converges to zero at least linearly with the asymptotic average convergence factor $(1-\sqrt{\xi})/(1+\sqrt{\xi})$, where ξ is an upper bound for the ratio of the largest and smallest nonzero eigenvalues of the preconditioned matrix $T(A - \lambda_1 B)$. Using estimates of [18] of eigenvalues of $T(A - \lambda_1 B)$ in terms of eigenvalues λ of the pencil $A - \lambda B$ and constants of (2.1), we can obtain such an upper bound and get the following upper bound of the asymptotic average convergence factor:

$$q = \left(\frac{1 - \sqrt{\xi}}{1 + \sqrt{\xi}}\right), \ \xi = \frac{1}{\kappa(TA)}\left(1 - \frac{\lambda_1}{\lambda_2}\right). \tag{3.4}$$

Finally, we would like to remind the reader of a long forgotten version of the PCG method based on optimization of a three-term recurrence, e.g., [35]:

$$y^{(i+1)} = y^{(i)} + \alpha^{(i)} v^{(i)} + \beta^{(i)}(y^{(i)} - y^{(i-1)}), \ v^{(i)} = T(A - \lambda_1 B)y^{(i)}, \ \beta^{(0)} = 0, \tag{3.5}$$

with both scalar parameters $\alpha^{(i)}$ and $\beta^{(i)}$ computed by minimizing seminorm (3.1) of $y^{(i+1)}$. This version is mathematically equivalent, in exact arithmetic, to the standard version implemented in PCGNULL, which uses two linked two-term recurrences.

This provides an insight into the locally optimal PCG eigensolver [19] we discuss in the next section, where we simply replace in (3.5) exact λ_1 with its approximation, and instead of minimizing seminorm (3.1) of $y^{(i+1)}$ we compute $y^{(i+1)}$ by using the Rayleigh–Ritz method on the subspace

$$y^{(i+1)} \in \text{Span}\ \left\{v^{(i)},\ y^{(i)},\ y^{(i-1)}\right\}. \tag{3.6}$$

An investigation of a possible connection between the two methods is in progress. As we see in section 7, they behave quite similarly in our numerical tests.

4. The PCG methods.

In this section, we propose a new version of the *locally optimal PCG method* [19].

In [19], the author suggested the following PCG method for the pencil $B - \mu A$:

$$x^{(i+1)} = w^{(i)} + \tau^{(i)} x^{(i)} + \gamma^{(i)} x^{(i-1)}, \ w^{(i)} = T(Bx^{(i)} - \mu^{(i)} Ax^{(i)}), \ \mu^{(i)} = \mu(x^{(i)}), \ \gamma^{(0)} = 0, \tag{4.1}$$

with scalar iteration parameters $\tau^{(i)}$ and $\gamma^{(i)}$ chosen using an idea of *local optimality* [19], namely, select $\tau^{(i)}$ and $\gamma^{(i)}$ that maximize the Rayleigh quotient $\mu(x^{(i+1)})$ by using the Rayleigh–Ritz method. As the current eigenvector approximation $x^{(i)}$ and the previous eigenvector approximation $x^{(i-1)}$ are getting closer to each other in the process of iterations, special measures need to be used in the algorithm to overcome the potential instability.

Formula (4.1) has been used in an earlier revision of our MATLAB code LOBPCG. In our numerical tests, it often led to so ill-conditioned Gram matrices that the Rayleigh–Ritz method would produce spurious eigenpairs. As a cure, we had to use an A-based orthogonalization of the three-dimensional trial subspace, which increased computational costs as had to multiply by A more often.

In our new algorithm, the three-term recurrence contains the current eigenvector approximation, the current preconditioned residual, and the implicitly computed difference between the current and the previous eigenvector approximations:

$$\begin{aligned} x^{(i+1)} &= w^{(i)} + \tau^{(i)} x^{(i)} + \gamma^{(i)} p^{(i)}, \quad w^{(i)} = T(Bx^{(i)} - \mu^{(i)} Ax^{(i)}), \\ p^{(i+1)} &= w^{(i)} + \gamma^{(i)} p^{(i)}, \quad p^{(0)} = 0, \quad \mu^{(i)} = \mu(x^{(i)}), \end{aligned} \tag{4.2}$$

with scalar iteration parameters $\tau^{(i)}$ and $\gamma^{(i)}$ chosen using the idea of *local optimality* as above, namely, select $\tau^{(i)}$ and $\gamma^{(i)}$ that maximize the Rayleigh quotient $\mu(x^{(i+1)})$

by using the Rayleigh–Ritz method. We see that

$$p^{(i+1)} = x^{(i+1)} - \tau^{(i)} x^{(i)};$$

thus,

$$x^{(i+1)} \in \text{Span}\,\{w^{(i)},\ x^{(i)},\ p^{(i)}\} = \text{Span}\,\{w^{(i)},\ x^{(i)},\ x^{(i-1)}\},$$

and therefore the new formula (4.2) is mathematically equivalent to the previous one, (4.1), in exact arithmetic.

We describe the actual algorithm of the method given by (4.2) as Algorithm 4.1.

Our experiments confirm that Algorithm 4.1 is much more numerically stable compared to the previous version (4.1) and that it can be used without extra A-orthogonalization in most situations. However, for ill-conditioned problems and when a high accuracy is required, even our new choice of the basis $w^{(i)}, x^{(i)}, p^{(i)}$ of the trial subspace of the Rayleigh–Ritz method may lead to ill-conditioned 3-by-3 Gram matrices, which makes necessary orthogonalization prior to the use of the Rayleigh–Ritz method. In the actual code of LOBPCG, we check for ill-conditioned Gram matrices on every iteration and implement A-orthogonalization if necessary. Since by our assumptions matrix B may not be positive definite, there is no other option except to use the A-based scalar product for the orthogonalization. This typically increases the cost of iterations, but it makes the algorithm more robust.

Algorithm 4.1. The locally optimal PCG method.

```
Input: devices to compute: $Ax$, $Bx$, and $Tx$ for a given vector $x$, the vector inner
    product $(x, y)$, and a starting vector $x^{(0)}$.
 1. Start: select $x^{(0)}$ and set $p^{(0)} = 0$.
 2. Iterate: For $i = 0, \ldots,$ Until Convergence Do:
 3.     $\mu^{(i)} := (x^{(i)}, B\,x^{(i)})/(x^{(i)}, A\,x^{(i)})$
 4.     $r := B\,x^{(i)} - \mu^{(i)} A x^{(i)}$
 5.     $w^{(i)} := Tr$
 6.     Use the Rayleigh–Ritz method for the pencil $B - \mu A$
        on the trial subspace Span $\{w^{(i)}, x^{(i)}, p^{(i)}\}$
 7.     $x^{(i+1)} := w^{(i)} + \tau^{(i)} x^{(i)} + \gamma^{(i)} p^{(i)}$,
        (the Ritz vector corresponding to the maximal Ritz value)
 8.     $p^{(i+1)} := w^{(i)} + \gamma^{(i)} p^{(i)}$
 9. EndDo
Output: the approximations $\mu^{(k)}$ and $x^{(k)}$ to the largest eigenvalue $\mu_1$ and its
    corresponding eigenvector.
```

We want to highlight that the algorithm can be implemented with only one application of the preconditioner T, one matrix-vector product Bx, and one matrix-vector product Ax, per iteration.

Storage requirements for Algorithm 4.1 are small—only several n-vectors and no n-by-n matrices at all. Such methods are sometimes called *matrix-free*.

For the stopping criterion, we compute some norms of the preconditioned residual $w^{(i)}$ on every iteration. Such norms may provide accurate two-sided bounds for eigenvalues and a posteriori error bounds for eigenvectors; see [18]. For brevity, we do not consider it in the present paper.

Let us also mention the possibility of avoiding the residual in method (4.1) by splitting it into two vectors:

$$x^{(i+1)} \in \text{Span}\ \left\{TAx^{(i)}, TBx^{(i)}, x^{(i)}, x^{(i-1)}\right\}. \tag{4.3}$$

In this new method, the trial subspace is enlarged, which may lead to somewhat faster convergence. However, we need to apply the preconditioner two times now on every iteration; therefore, in our opinion, method (4.3) will not be more efficient for computing the extreme eigenpair than our favorite method, Algorithm 4.1, since the latter already converges practically with the optimal speed; see sections 7 and 8.

Other known CG methods for eigenproblems, e.g., [41, 12, 15, 11, 42, 13, 1, 26], starting from Bradbury and Fletcher [3], are usually constructed as general CG minimization methods, applied to the Rayleigh quotient or to a quadratic form (x, Bx) under the constrain $(x, Ax) = 1$. They are often based on (now standard for linear systems) two linked two-term recurrences,

$$p^{(i)} = -w^{(i)} + \beta^{(i)}p^{(i-1)},\ x^{(i+1)} = x^{(i)} + \alpha^{(i)}p^{(i)},$$

where $\alpha^{(i)}$ is chosen using a line search to minimize the Rayleigh quotient of $x^{(i+1)}$, which leads to a quadratic equation for $\alpha^{(i)}$, but $\beta^{(i)}$ is computed to make directions $p^{(i)}$ to be conjugate in some sense. These methods *do not utilize* the specific property of the Rayleigh quotient, i.e., that the local minimization of the Rayleigh quotient can be cheaply carried out using the Rayleigh–Ritz method not just in two dimensions, for line search for finding $\alpha^{(i)}$, but in three-dimensional or larger dimensional subspaces as well.

Let us now discuss theoretical convergence rate results for Algorithm 4.1.

The basic fact is that the locally optimal version of the PCG method trivially converges not slower on every step than the preconditioned steepest ascent in terms of the maximizing the Rayleigh quotient [19]; thus, we can use known and well-developed convergence theory of the latter method (e.g., [19]; see also very recent results by Klaus Neymeyr [29, 30]). Our numerical comparison in [21, 22] shows, however, that the PCG method converges much faster in practice than the preconditioned steepest ascent. A ten-fold increase of δ_1/δ_0 leads to the increase in number of iterations, ten-fold for the preconditioned steepest ascent, but only about three-fold for the PCG method, exactly as we would expect for a genuine PCG solver.

No comprehensive convergence theory that would explain such a fast convergence is available yet. Moreover, no even similar results are apparently known at present, e.g., there is no adequate convergence theory of CG methods in nonquadratic optimization. Even if one considers the simplest version of (4.1) for the standard eigenproblem and with no preconditioning, $T = A = I$ when it is reduced to the following trivial method, suggested in [17, 18, 25]: find

$$x^{(i+1)} \in \text{Span}\ \left\{Bx^{(i)}, x^{(i)}, x^{(i-1)}\right\} \tag{4.4}$$

by maximizing the Rayleigh quotient $(x, Bx)/(x, x)$ on every step. There is still no convergence theory currently known that would be able to compare (4.4) with the optimal method, in this case, with the Lanczos method for the global maximization of Rayleigh quotient $(x, Bx)/(x, x)$ on the corresponding standard Krylov subspace.

One possible approach to develop an adequate convergence theory may be based on comparison of method (4.4) with the following stationary three-term recurrence:

$$x^{(i+1)} = \alpha Bx^{(i)} + \beta x^{(i)} + \gamma x^{(i-1)},$$

where α, β, γ are fixed scalar parameters, sometimes called the *heavy ball method* in optimization [35]. However, for this simpler method, no accurate convergence theory in terms of the Rayleigh quotient apparently exists yet; cf. [25].

In this paper, we do not prove any new theoretical convergence rate results for Algorithm 4.1, but we suggest a different kind of remedy: numerical comparisons using the benchmark routines we propose; see sections 7 and 8.

We present block versions of Algorithm 4.1 in the next section.

5. Preconditioned simultaneous iterations. The well-known idea of using *simultaneous*, or *block*, iterations provides an important improvement over single-vector methods, and permits us to compute an $(m > 1)$-dimensional invariant subspace, rather than one eigenvector at a time. It can also serve as an acceleration technique over single-vector methods on parallel computers, as convergence for extreme eigenvalues usually increases with the size of the block, and every step can be naturally implemented on wide varieties of multiprocessor computers.

As in other block methods, the block size should be chosen, if possible, to provide a large gap between first m eigenvalues and the rest of the spectrum as this typically leads to a better convergence; see (5.5) below. Let us also mention that block methods generally handle clusters in the spectrum and multiple eigenvalues quite well; and the block methods we propose below are no exceptions. An attempt should be made to include the whole cluster of eigenvalues into the block, while for multiple eigenvalues this is not essential at all; e.g., if $\mu_{m-1} > \mu_m = \mu_{m+1} > \mu_{m+2}$, then the convergence rate will be determined by the gap $\mu_{m+1} - \mu_{m+2}$ even though the block size is only m; however, only one vector of the two-dimensional eigenspace corresponding to $\mu_m = \mu_{m+1}$ will be computed, as we observe in numerical experiments.

A block version of the locally optimal PCG method [19] was suggested in [21, 22]:

$$x_j^{(i+1)} \in \text{Span } \left\{x_1^{(i-1)},\ x_1^{(i)},\ T(B - \mu_1^{(i)} A)x_1^{(i)}, \dots,\ x_m^{(i-1)},\ x_m^{(i)},\ T(B - \mu_m^{(i)} A)x_m^{(i)}\right\}, \tag{5.1}$$

where $x_j^{(i+1)}$ is computed as the jth Ritz vector. It shares the same problem, as the single-vector version of [19] discussed in the previous section, of having close vectors in the trial subspace.

Our new block Algorithm 5.1 is a straightforward generalization of the single-vector Algorithm 4.1 and is combined with the Rayleigh–Ritz procedure. Here we present two different variants of the algorithm. They differ in the way that the Rayleigh–Ritz method is used. The first version is mathematically equivalent (without round-off errors) to that of [21, 22], but uses directions $p_j^{(i)}$ instead of $x_j^{(i-1)}$, similar to that of Algorithm 4.1.

Here, the column-vector

$$\left(\alpha_1^{(i)}, \dots, \alpha_m^{(i)},\ \tau_1^{(i)}, \dots, \tau_m^{(i)}\ \gamma_1^{(i)}, \dots, \gamma_m^{(i)}\right)^T$$

is the jth eigenvector corresponding to the jth largest eigenvalue of the $3m$-by-$3m$ eigenvalue problem of the Rayleigh–Ritz method, so it should have had an index j also, but we run out of space for indexes.

We observe that

$$p_j^{(i+1)} = x_j^{(i+1)} - \sum_{k=1,\dots,m} \tau_k^{(i)} x_k^{(i)},$$

```
ALGORITHM 5.1. THE LOBPCG METHOD I.
Input: $m$ starting vectors $x_1^{(0)}, \dots x_m^{(0)}$, devices to compute: $Ax$, $Bx$, and $Tx$
    for a given vector $x$, and the vector inner product $(x, y)$.
Start: select $x_j^{(0)}$, and set $p_j^{(0)} = 0,\ j = 1, \dots, m$.
Iterate: For $i = 0, \dots,$ Until Convergence Do:
    $\mu_j^{(i)} := (x_j^{(i)}, B\,x_j^{(i)})/(x_j^{(i)}, A\,x_j^{(i)}),\ j = 1, \dots, m$;
    $r_j := B\,x_j^{(i)} - \mu_j^{(i)} A x_j^{(i)},\ j = 1, \dots, m$;
    $w_j^{(i)} := T r_j,\ j = 1, \dots, m$;
    Use the Rayleigh–Ritz method for the pencil $B - \mu A$ on the trial subspace
    Span $\{w_1^{(i)}, \dots, w_m^{(i)}, x_1^{(i)}, \dots, x_m^{(i)}, p_1^{(i)}, \dots, p_m^{(i)}\}$;
    $x_j^{(i+1)} := \sum_{k=1,\dots,m} \alpha_k^{(i)} w_k^{(i)} + \tau_k^{(i)} x_k^{(i)} + \gamma_k^{(i)} p_k^{(i)}$,
    (the $j$th Ritz vector corresponding to the $j$th largest Ritz value),
    $j = 1, \dots, m$;
    $p_j^{(i+1)} := \sum_{k=1,\dots,m} \alpha_k^{(i)} w_k^{(i)} + \gamma_k^{(i)} p_k^{(i)}$;
EndDo
Output: the approximations $\mu_j^{(k)}$ and $x_j^{(k)}$ to the largest eigenvalues $\mu_j$ and
    corresponding eigenvectors, $j = 1, \dots, m$.
```

and thus,

$$\begin{aligned} x_j^{(i+1)} &\in \text{Span}\,\{w_1^{(i)}, \dots, w_m^{(i)}, x_1^{(i)}, \dots, x_m^{(i)}, p_1^{(i)}, \dots, p_m^{(i)}\} \\ &= \text{Span}\,\{w_1^{(i)}, \dots, w_m^{(i)}, x_1^{(i)}, \dots, x_m^{(i)}, x_1^{(i-1)}, \dots, x_m^{(i-1)}\}, \end{aligned}$$

and, indeed, the new Algorithm 5.1 is mathematically equivalent to method (5.1).

We note that Algorithm 5.1 without preconditioning, i.e., with $T = I$, appears in [25] as a "W-accelerated simultaneous gradient method."

Example 5.1. Let us consider the problem of computing first eigenpairs of the standard five-point finite-difference approximation of the Laplacian Δ_h in a $[-1, 1] \times [-1, 1]$ square on a uniform mesh with the step $h = 1/10$, such that the total number of the unknowns is 361. We set $B = I$ and $A = \Delta_h$. The initial approximations are random. No preconditioning is used in the first test, i.e., $T = I$. We plot in Figure 5.1 on a semilog scale relative errors in this example defined as $\|Ax_j^{(i)} - \lambda_j^{(i)} x_j^{(i)}\|_A / \|x_j^{(i)}\|_A$, where we use the standard notation of an A-based norm, $\|\cdot\|_A^2 = (\cdot, A\cdot)$.

Figure 5.1 shows a clear superlinear convergence. This is quite important as some authors, e.g., [34], consider a superlinear convergence as a sign of a genuine CG method. We see that a larger block size in the method improves convergence in this example. We also observe different convergence speed for different eigenpairs on Figure 5.1—the convergence is faster for smaller eigenvalues λ, in particular, λ_1 converges first.

In the second test, we use a preconditioner $T = A - \nu I$ with the shift $\nu = 20$, which is approximately in the middle of the group of the first ten eigenvalues that we compute, starting with random initial approximations. We plot $\|Ax_j^{(i)} - \lambda_j^{(i)} x_j^{(i)}\| / \|x_j^{(i)}\|$, using the Euclidean norm, in Figure 5.2 on a semilog scale. Figure 5.2 shows a superior convergence of the preconditioning. Now, we have a better convergence for eigenvalues close to the shift on the right part of Figure 5.2.

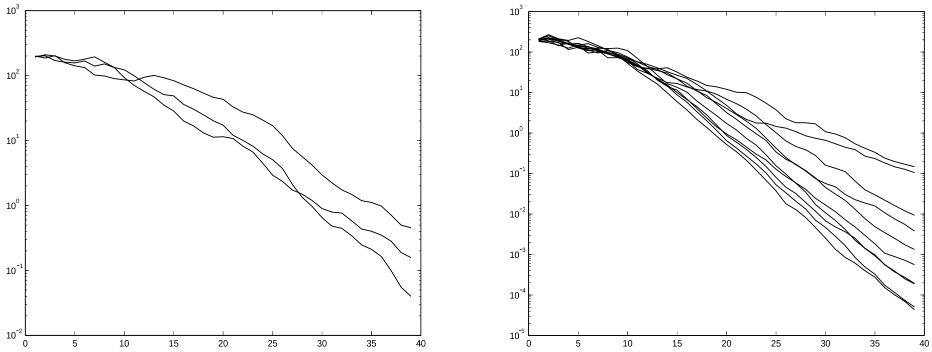

FIG. 5.1. *Errors for the Laplace operator in a square without preconditioning for three (left) and ten (right) first eigenpairs.*

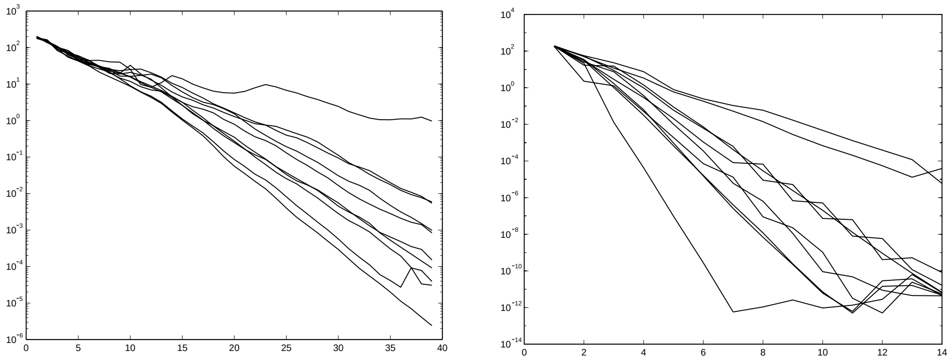

FIG. 5.2. *Errors for the Laplacian operator in a square without preconditioning (left) and with an indefinite preconditioner(right).*

The example thus illustrates that our method works without preconditioning and may even work with an indefinite preconditioner.

Example 5.2. As our next example, we solve a similar eigenvalue problem, but in the L-shaped domain—a union of three unit squares with a mesh uniform in both directions with the step 1/8, such that the total number of unknowns is 161. A specialized domain-decomposition without overlap method for such problem is suggested in [23]. Our numerically computed eigenvalues are consistent with those found in [23]. We compare the performance of the method without preconditioning and with preconditioning based on an incomplete Choleski decomposition of A with a drop tolerance of 10^{-3}. We plot $\|Ax_j^{(i)} - \lambda_j^{(i)} x_j^{(i)}\| / \|x_j^{(i)}\|$ in Figure 5.3. We see that preconditioning leads to approximately quadruple acceleration.

The actual MATLAB code LOBPCG of Algorithm 5.1 that we wrote uses the basis of the trial subspace exactly the way it appears in Algorithm 5.1 until this choice leads to ill-conditioned Gram matrices in the Rayleigh–Ritz method. When such an ill-conditioning shows up, we perform a selected orthogonalization. If this does not fix the problem, as a last resort we apply a complete orthogonalization prior to the Rayleigh–Ritz method. By our assumptions, A may be the only positive definite

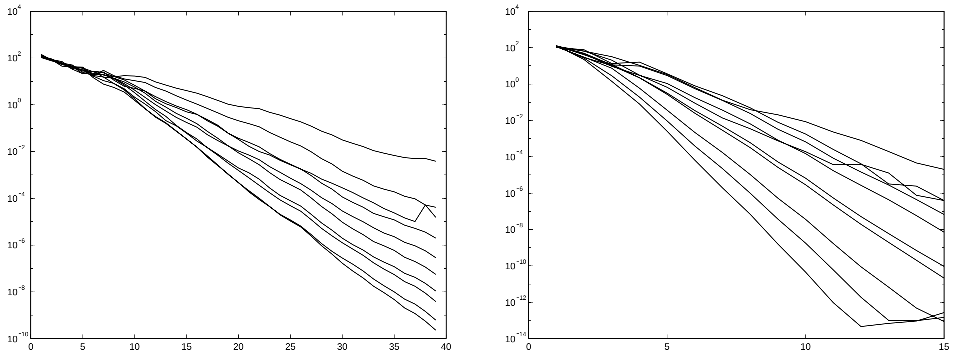

FIG. 5.3. *Residuals for the Laplacian operator in the L-shaped domain with no preconditioning (left) and an ILU preconditioning (right).*

matrix of the pencil; thus, the A-based scalar product is used for the orthogonalization.

There is no theory available yet to predict accurately the speed of convergence of Algorithm 5.1. Similarly to the single-vector case of the previous section, we can easily see that Algorithm 5.1 does not converge slower than the block steepest ascent on every step. Unfortunately, earlier known convergence results [9, 10, 4] for block preconditioned eigensolvers cannot be used to take advantage of this fact. Only the very recent result by Neymeyr [28] for the block preconditioned simple iterations allows us to conclude that Algorithm 5.1 converges linearly with the average asymptotic convergence factors

$$q_j = 1 - \frac{2}{\kappa(TA)+1}\frac{\mu_j - \mu_{j+1}}{\mu_j - \mu_{\min}},\ j = 1,\dots,m. \tag{5.2}$$

Let us formulate and prove this as the following.

THEOREM 5.1. *For simplicity, let*

$$\mu_j > \mu_j^{(i)} > \mu_{j+1},\ j = 1,\dots,m.$$

Then

$$\frac{\mu_j - \mu_j^{(i+1)}}{\mu_j^{(i+1)} - \mu_{j+1}} \le q_j^2 \frac{\mu_j - \mu_j^{(i)}}{\mu_j^{(i)} - \mu_{j+1}}, \tag{5.3}$$

with q_j given by (5.2).

Proof. The proof is straightforward and is based on a possibility of using the convergence rate estimate of [28] recursively and on the fact that our Algorithm 5.1 does not converge slower than the method of [28] in terms of Ritz values as our trial subspace is enlarged compared to that of [28].

The first step is to notice that all results of [28], written for the pencil $A - \lambda B$ with $B = I$, can be trivially applied to a more general case of $B \neq I,\ B > 0$ by using substitutions involving $B^{1/2}$. Secondly, we take the main convergence result of [28], presented as a nasty looking inequality for $\lambda_j^{(i+1)}$, and after tedious but elementary algebraic manipulations we show that it can be reduced to (5.3) with

$$q_j = 1 - \frac{2}{\kappa(TA)+1}\left(1 - \frac{\lambda_j}{\lambda_{j+1}}\right) = 1 - \frac{2}{\kappa(TA)+1}\frac{\mu_j - \mu_{j+1}}{\mu_j}. \tag{5.4}$$

Here, T is optimally scaled such that $\|I - TA\|_A \leq (\kappa(TA) - 1)/(\kappa(TA) + 1)$ to be consistent with assumptions of [28]. Neymeyr has recently found (private communication) an easier proof that takes only two pages.

Now, we use a trick, suggested in [17] and reproduced in [8]; namely, we substitute our actual matrix B, which is not necessarily positive definite with positive definite $B_\alpha = B - \alpha A > 0$ with a scalar $\alpha < \mu_{\min}$ and apply the previous estimate to the pencil $B_\alpha - \mu_\alpha A$ with eigenvalues $\mu_\alpha = \mu - \alpha$, which gives (5.3) with

$$q_j = 1 - \frac{2}{\kappa(TA) + 1} \frac{\mu_j - \mu_{j+1}}{\mu_j - \alpha}.$$

Finally, we realize that the block method of [28], which is the same as that of [4], itself is invariant with respect to α, and everything depends continuously on $\alpha < \mu_{\min}$, so we can take the limit $\alpha = \mu_{\min}$ as well. This proves estimate (5.3) with q_j given by (5.2) for the block method used in [4, 28] for the general pencil $B - \mu A$ satisfying assumptions of the present paper. However, in Algorithm 5.1 the trial subspace is enlarged compared to that of the method of [4, 28]; thus, the convergence rate estimate (5.3) with q_j given by (5.2) holds for our method, too. □

This result, however, does not appear to be sharp for our method, while it is sharp for the method of [28] in a certain sense.

First, if the computed eigenvalues form, or include, a cluster, the factor given by (5.2) is quite pessimistic as it depends on $\mu_j - \mu_{j+1}$, which may be small. For a block method, we expect to have a term $\mu_j - \mu_{m+1}$ instead, where m is the block size.

Second, for a genuine CG method we should count on having $\sqrt{\kappa(TA)}$ instead of $\kappa(TA)$ in the expression for q.

In [21, 22], we demonstrate numerically that our method is much faster than that of [4, 28]. Having in mind estimate (3.4) we have for the PCGNULL and results of [20] on the Rayleigh–Ritz method used in [4], which informally speaking allows us to analyze the error in jth Ritz vector $x_j^{(i)}$ ignoring components $(x_j^{(i)}, x_k)_A,\ k = 1, \dots, m,\ k \neq j$, we should expect convergence of norms of residuals to be asymptotically linear with the average asymptotic convergence factors

$$q_j = \left(\frac{1 - \sqrt{\xi_j}}{1 + \sqrt{\xi_j}} \right),\ \xi_j = \frac{1}{\kappa(TA)} \frac{\mu_j - \mu_{m+1}}{\mu_j - \mu_{\min}},\ j = 1, \dots, m. \tag{5.5}$$

Thus, convergence of $\mu_j^{(i)}$ to μ_j should be linear with the ratio q_j^2.

All our numerical tests (see some selected results in sections 7 and 8 below) support our expectation of having asymptotically linear convergence with the ratio (5.5).

A potential disadvantage of Algorithm 5.1 can manifest itself when the number m of eigenpairs of interest is large, as we need to form $3m$-by-$3m$ matrices and solve the corresponding eigenvalue problem of the size $3m$ in the Rayleigh–Ritz method on every step. It seems that vectors $w_j^{(i)}$ and $p_j^{(i)}$ may not always be helpful as basis vectors of the trial subspace of the Rayleigh–Ritz method to improve the approximation of $x_k^{(i+1)}$ for $j \neq k$. And adding unnecessary vectors in the trial subspace increases computational costs. Even more importantly, it may make the algorithm less stable, as the $3m$-by-$3m$ eigenvalue problem of the Rayleigh–Ritz method is likely to inherit ill-conditioning of the original eigenvalue problem when m is large.

In our second variant, Algorithm 5.2, we apply the Rayleigh–Ritz method in two stages: first, as in Algorithm 4.1, for individual indices j, and, second, we include only the minimal set of vectors, namely, just current approximations to different eigenvectors into the trial subspace.

Thus, on the first stage of an iteration of Algorithm 5.2 we solve m three-dimensional eigenproblems, and on the second stage we solve one m-dimensional eigenproblem. But this m-dimensional eigenproblem is constructed using approximate eigenvectors, corresponding to extreme eigenvalues, as a basis of the trial subspace. Therefore, this eigenvalue problem should not be ill-conditioned and no orthogonalization would be required.

We note that arguments of the previous theorem cannot be applied to Algorithm 5.2. Theoretical investigation of accurate convergence estimates of Algorithm 5.2 does not seem to be a trivial exercise.

Our numerical comparison using model problems described in section 6 below shows that Algorithm 5.2 converges with practically the same speed as Algorithm 5.1, except for the case of finding a cluster of eigenvalues with high accuracy. For eigenvalues in a cluster, Algorithm 5.2 at first converges similarly to Algorithm 5.1, but it then slows down and soon after may hit a plateau, i.e., may stop improving the quality of approximations. See Figure 5.4, which shows convergence history of eigenvalue errors of a one run of Algorithms 5.1 (solid) and 5.2 (dotted) with block size $m = 3$. The left picture is for well-separated eigenvalues, and errors for different algorithms are not possible to distinguish. The right picture corresponds to the cluster of three eigenvalues with $(\mu_1 - \mu_3)/(\mu_1 - \mu_{\text{min}}) \approx 10^{-11}$.

```
ALGORITHM 5.2. THE LOBPCG METHOD II.
Input: $m$ starting vectors $x_1^{(0)}, \dots x_m^{(0)}$,devices to compute: $Ax$, $Bx$, and $Tx$ for a
    given vector $x$,and the vector inner product $(x, y)$,
  Start: select $x_j^{(0)}$, and set $p_j^{(0)} = 0,\ j = 1, \dots, m$.
  Iterate: For $i = 0, \dots,$ Until Convergence Do:
      $\mu_j^{(i)} := (x_j^{(i)}, B x_j^{(i)})/(x_j^{(i)}, A x_j^{(i)}),\ j = 1, \dots, m$;
      $r_j := B x_j^{(i)} - \mu_j^{(i)} A x_j^{(i)},\ j = 1, \dots, m$;
      $w_j^{(i)} := T r_j,\ j = 1, \dots, m$;
      Use the Rayleigh–Ritz method $m$ times for the pencil $B - \mu A$ on the trial
        subspaces Span $\{w_j^{(i)},\ x_j^{(i)},\ p_j^{(i)}\},\ j = 1, \dots, m$;
      $\widehat{x}_j^{(i+1)} := w_j^{(i)} + \tau_j^{(i)} x_j^{(i)} + \gamma_j^{(i)} p_j^{(i)}$,
        (the Ritz vector corresponding to the maximal Ritz value), $j = 1, \dots, m$;
      $p_j^{(i+1)} := w_j^{(i)} + \gamma_j^{(i)} p_j^{(i)}$;
      Use the Rayleigh–Ritz method for the pencil $B - \mu A$ on the trial
        subspaces $\{\widehat{x}_1^{(i+1)}, \dots, \widehat{x}_m^{(i+1)}\}$;
      $x_j^{(i+1)} :=$ the $j$th Ritz vector corresponding to the $j$th largest Ritz value,
        $j = 1, \dots, m$;
  EndDo
Output: the approximations $\mu_j^{(k)}$ and $x_j^{(k)}$ to the largest eigenvalues $\mu_j$ and
    corresponding eigenvectors, $j = 1, \dots, m$.
```

For mesh eigenproblems, when high accuracy of computed eigenvalues and eigenvectors is not often required, Algorithm 5.2 can be recommended. For a general purpose method, it seems best to use a mix of Algorithms 5.1 and 5.2 such that eigenvalues, which have already formed a cluster, are treated together using Algorithm 5.1,

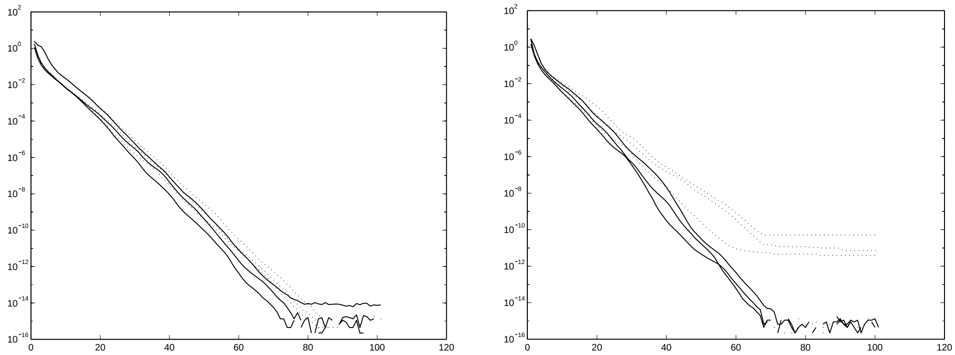

FIG. 5.4. *LOBPCG* I *(solid) vs. LOBPCG* II *(dotted): well-separated eigenvalues (left) and eigenvalue cluster (right).*

while all other eigenvalues in the block are treated separately, as in Algorithm 5.2. This approach will be implemented in the code LOBPCG.m in future revisions.

In the rest of the paper, all our numerical results are for Algorithm 5.1 only.

As theoretical investigation and comparison of preconditioned eigensolvers are quite tedious ([4] provides a perfect example of this), a possibility of a fair numerical comparison becomes even more important than usual. In the next section, we suggest a numerical benchmark for preconditioned eigensolvers.

6. Model test problems with random preconditioners. To be able to compare numerically different methods in the class with different preconditioners, we suggest the following system of model tests, with random preconditioners and initial guesses, be used for benchmarking.

For simplicity, we take the mass matrix $B = I$.

The stiffness matrix A is in our model tests a diagonal matrix with the minimal entry 1 and the maximal entry 10^{10}; therefore, all eigenvalues μ of the pencil $B - \mu A$ lie on the semiclosed interval $(0, 1]$. We are interested in finding a group of the largest eigenvalues and corresponding eigenvectors. In most of the tests of the present paper, we compute only one, the largest eigenvalue $\mu = 1$.

For preconditioned eigensolvers, we expect that the convergence does not slow down when the condition number of A gets larger [18, 19, 4, 21, 22], with a properly chosen preconditioner. Because of this, we simply use a fixed large value, 10^{10}, for the maximal entry of A. Our code seems to work robustly for condition number of A as large as 10^{16} in double precision arithmetic.

The gap between computed and excluded parts of the spectrum is known to play an important role in the convergence speed. It seems necessary to fix the gap within a series of tests. We do it with the gap ranging from 1 to 0.01 in different series. A small value of the gap may or may not lead to slow convergence, depending on several factors, the first of which is the distribution of eigenvalues in the excluded part of the spectrum close to the desired part. This makes comparison of different methods somewhat unreliable when the gap is small.

It is also necessary to choose a distribution of eigenvalues. The desired eigenvalues, if there is more then one, are distributed randomly on a given interval, as their distribution should not affect performance significantly. In the rest of the spectrum, the distribution of eigenvalues does not noticeably affect the speed of convergence in our tests for a general preconditioner. If, however, the preconditioner commutes with A, e.g., $T = I$, or $T = A^{-1}$, we do observe a strong influence of the distribution on convergence. For such cases, we choose a distribution that mimics that of an ordinary differential equation of the fourth order, but with the given maximal entry 10^{10} (see above). The initial guess is fixed for every run of the actual and the control codes but is changed for every new run as a vector with random entries, chosen from a normal distribution with mean zero and variance one.

The preconditioner T is also fixed for every run of the actual and the control programs but is modified for every new run as a random symmetric positive definite matrix with the fixed value of $\kappa(TA) = \delta_1/\delta_0$ of (2.1). We construct T as follows.

First, we chose a diagonal matrix D with random diagonal entries, chosen from a uniform distribution on the interval $(0, 1)$. Then we find minimal $\min D$ and maximal $\max D$ values of D and do a linear scaling $D = 1+(D-\min D)/(\max D-\min D)*(\kappa-1)$, where $\kappa = \kappa(TA)$ is the desired fixed value of the spectral condition number of TA. That makes diagonal entries of D uniformly distributed on the interval $(1, \kappa)$ with minimal and maximal values exactly at the end points of the interval; thus, the condition number of D equals exactly κ.

Second, we take a square matrix with random entries, chosen from a normal distribution with mean zero and variance one, and perform the standard orthogonalization procedure on it. That produces a random orthogonal matrix Q. We now scale it, $S = QA^{-1/2}$, keeping in mind that Q is orthogonal and A is diagonal, and therefore, $S^T = A^{-1/2}Q^{-1}$.

Finally, we form $T = S^T DS$. The matrix T is clearly symmetric. Moreover, the diagonal entries of D and columns of Q are eigenpairs of the matrix $A^{1/2}TA^{1/2} = Q^{-1}DQ$, which completes our argument.

There are two reasons for using random preconditioners for our model test problems. First, it is a natural choice when solving eigenvalue problems for diagonal matrices. Second, it allows us to make a fair numerical comparison of different eigensolvers and gives a simple opportunity to check that the best method in the class consistently outperforms other methods independently of the choice of the preconditioner for a fixed value of κ.

The size of the problem varies from 1000–4000.

The upper bound, 4000, is simply determined by our computer resources. The above algorithm of constructing a random preconditioner is quite expensive and leads to a full matrix T. The total cost grows cubically with the size of the problem. We find in our tests that small problems may lead to unreliable conclusions when the number of iterations is large enough. Namely, in some tests, depending on distribution of excluded eigenvalues of the original pencil, we observe a superlinear convergence of our methods when the total number of steps was more than 30% of the size of the problem. However, in practical applications of interest, eigenvalue problems are so large that the number of steps should not usually exceed 20% of the size of the problem, taking also into account that the high accuracy of desired eigenpairs of the algebraic pencil is rarely needed, as the pencil itself is just an approximation of the original continuous problem and the approximation error may not be small. Thus, one should not count in practice on having a superlinear convergence; and we try to rule such a possibility out by choosing the size of the problem large enough.

We recommend every new preconditioned eigensolver be compared with our "ideal" algorithm in our model test problems in terms of the speed of convergence, costs of every iteration, and memory requirements. We provide such comparison for our

LOBPCG method in the next section.

7. Numerical results: LOBPCG vs. PCGNULL. Here, we solve a model eigenvalue problem with $\lambda_1 = 1,\ \lambda_2 = 2$ and take the condition number of A to be 10^{10}.

For simplicity, the mass matrix equals the identity $B = I$.

We compute only the first eigenpair, i.e., the smallest eigenvalue $\lambda_1 = 1$ and the corresponding eigenvector. Thus, we set the block size $m = 1$ in our LOBPCG Algorithm 5.1.

The initial guess is fixed for every run of the actual and the control codes but is modified randomly for every new run. The preconditioner T is also fixed for every run of the actual and the control programs but is modified for every new run as a random symmetric positive definite matrix with the fixed value of the condition number $\kappa(TA)$; see above. We vary $\kappa(TA)$ in different series of tests.

The straight (and green on a color print) line corresponds to linear convergence with the residual reduction rate (3.4), which is the same as (5.5) with $m = 1$ and $\mu_{\min} = 0$. To be consistent with MATLAB's built-in code PCG.m, we measure the error as the Euclidean norm of the residual, i.e., $\|(A-\lambda_1 B)x^{(i)}\|/\|x^{(i)}\|$ in PCGNULL and $\|(A-\lambda^{(i)} B)x^{(i)}\|/\|x^{(i)}\|$ in our code. With these definitions, norms of the residuals are quite large on the first few iterations in our tests as our matrix A is very ill-conditioned.

The average slope is the most important. We observe in Figure 7.1 that the average residual reduction rate is about the same for the "ideal" method, PCGNULL, and for our LOBPCG, and is quite close to the theoretical prediction. Convergence history lines for every method are tightly bundled together, with the bundle for our LOBPCG (colored red in the electronic version of the paper) consistently a bit lower than the bundle for the PCGNULL (dotted and blue). We present here, because of space limitations, only cases $\kappa(TA) = 4$ and $\kappa(TA) = 1000$. Pictures with other values of κ are similar to those shown in Figure 7.1. Thus, our code converges essentially as fast as the "ideal" method.

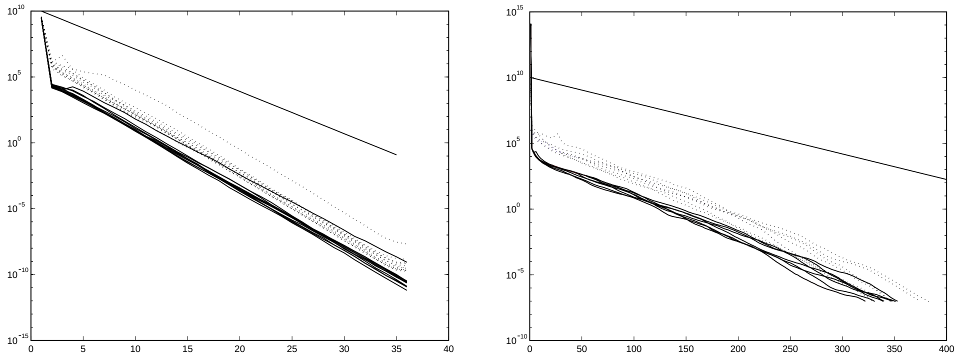

FIG. 7.1. *LOPCG (solid) vs. ideal (dotted):* $\kappa(TA) = 4$ *(left) and* $\kappa(TA) = 1000$ *(right).*

Let us now compare computational costs of a single iteration. PCGNULL involves one application of the preconditioner T, and one multiplication of A and a vector. LOBPCG (revision 3.2.9) has exactly the same major costs; however, for very ill-conditioned problems and when a very high accuracy is required, to increase stability we perform A-based orthogonalization of basis vectors of the trial subspace, which may require matrix A be multiplied two times instead of one on every iteration.

In terms of memory use, both methods are similar, as they require only several vectors, but no large matrices, to be stored.

To conclude, numerical results establish that our algorithm is practically as efficient as the "ideal" algorithm when preconditioners and initial approximations are the same in both methods.

8. Numerical results: LOBPCG vs. GLOBALMIN.

In the previous section, we compare our LOBPCG with the benchmark based on PCGNULL and show that LOBPCG is practically the optimal preconditioned method for finding the extreme eigenvalue and the corresponding eigenvector. LOBPCG can also be used, of course, for computing a group of extreme eigenvalues when the block size $m > 1$.

What benchmark do we advocate for preconditioned eigensolvers for finding several eigenpairs? We do not have an answer to this question as satisfactory as that for a single extreme eigenpair, because we are not yet able to suggest a convincing "ideal" (in terms of speed and costs) solver. We do have, however, the block globally optimal solver, Algorithm 2.1, which computes optimal approximations on the block generalized Krylov subspace.

Let us highlight again that the number of vectors in the basis of the block Krylov subspace (2.6) grows exponentially, which makes Algorithm 2.1 very expensive. On the other hand, it provides the global optimization of the Rayleigh quotient on the block Krylov subspace and, thus, can be used for numerical comparison with actual block preconditioned eigensolvers to check if they provide approximations close to those of the global optimization.

We write a MATLAB code of Algorithm 2.1, called GLOBALMIN.m, using recursion (2.7), followed by complete orthogonalization.

We tested LOBPCG vs. GLOBALMIN on model problems described in section 6 with $n = 3000$. The gap between computed and excluded parts of the spectrum is one. The condition number of A is chosen to be 10^8 as GLOBALMIN fails in some tests for larger condition numbers.

We find in the present section that putting only one run on a figure is more illustrative, as LOBPCG and GLOBALMIN produce very similar results, but they change greatly with different random initial guesses. We remove the initial value of the error from all pictures as it is typically too large to fit the chosen scale. LOBPCG is presented by a solid (and red in a color version of the paper) line, while GLOBALMIN is dashed (and blue). The straight (and green) line corresponds, as in section 7, to the average error reduction predicted by (5.5).

The residual-based error is measured as $\|(A-\lambda_j^{(i)}B)x_j^{(i)}\|/\|x_j^{(i)}\|$ on a corresponding Ritz vector $x_j^{(i)}$. The eigenvalue error is simply measured as the difference of the Ritz value $\lambda_j^{(i)}$ and the corresponding eigenvalue λ_j. Both methods, LOBPCG and GLOBALMIN, should monotonically decrease the eigenvalue error. GLOBALMIN provides the global minimum of the Rayleigh quotient; therefore, the eigenvalue error of GLOBALMIN should be always not larger than that of LOBPCG.

We first compare, on Figure 8.1, errors just for the smallest eigenvalue λ_1 for the LOBPCG and GLOBALMIN both with block size one as in section 7. Figure 8.1 displays errors for the same problems as Figure 7.1, but we also add the eigenvalue error. We highlight again that dimension of the generalized Krylov subspace global (2.4) grows exponentially with the number of iterations. For numerical tests

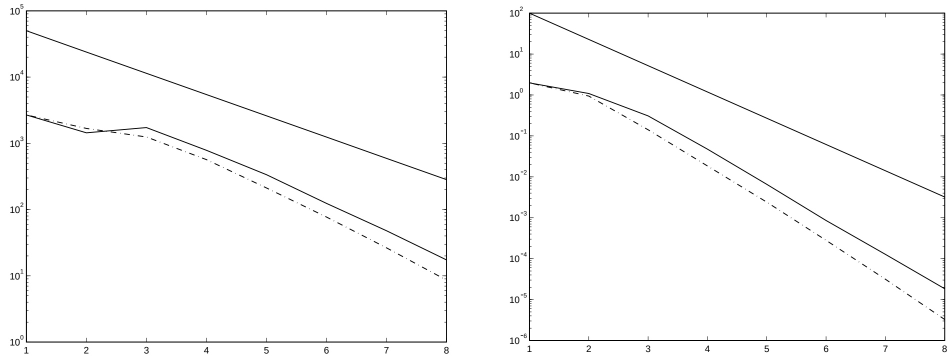

FIG. 8.1. *LOBPCG (solid) vs. GLOBALMIN (dashed), $\kappa(TA) = 4$, $m = 1$: residuals (left) and eigenvalue errors (right).*

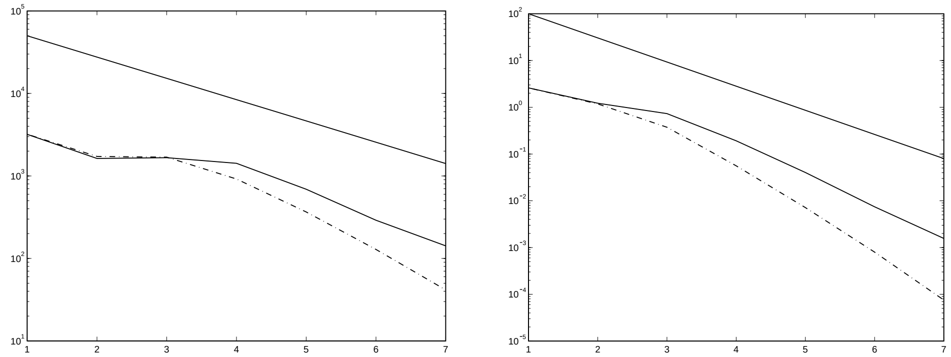

FIG. 8.2. *LOBPCG (solid) vs. GLOBALMIN (dashed), $\kappa(TA) = 4$, $m = 3$: residuals (left) and eigenvalue errors (right).*

presented in Figure 8.1, typical dimensions are $3, 7, 15, 31, 63, 127, 255, 511$, e.g., on the last (eighth) iteration, GLOBALMIN minimizes the Rayleigh quotient on a trial subspace of dimension 511.

In Figures 8.2 and 8.3, we compare the error for the third smallest eigenvalue λ_3 for the LOBPCG and GLOBALMIN, both with block size three. In these experiments, dimensions of the block generalized Krylov subspace global (2.6) typically are $9, 21, 45, 93, 189, 381, 765$. As our code GLOBALMIN is based on complete orthogonalization that filters out possible linearly dependent vectors in the trial subspace, in different tests we observe slightly different dimensions.

The trial subspace in GLOBALMIN is getting large enough—about 10%–20% of the size of the problem—to lead to a superlinear convergence of GLOBALMIN when $\kappa(TA)$ is not too large; see Figure 8.2. We believe that this effect is artificially created by the fact that our problem is of a small size, only 3000, and should be disregarded. Our computer resources do not allow us to solve larger problems.

We first observe that LOBPCG and GLOBALMIN produce almost the same approximations on the first two steps. Most importantly, by comparing the slopes on the figures, we come to the conclusion that our LOBPCG provides approximations close to those of the global optimization method on the generalized block Krylov

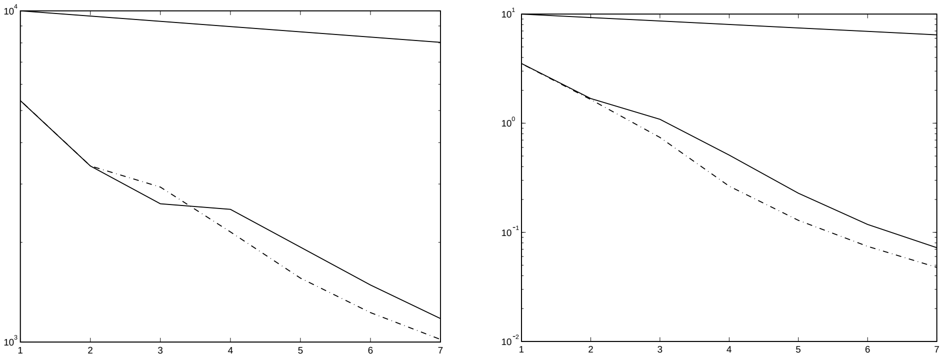

FIG. 8.3. *LOBPCG (solid) vs. GLOBALMIN (dashed),* $\kappa(TA) = 1000$*,* $m = 3$*: residuals (left) and eigenvalue errors (right).*

subspace and has a similar convergence speed.

9. LOBPCG vs. Davidson's method.

The discussion above allows us to make some conclusions on LOBPCG vs. Davidson's method, though we do not have a numerical comparison. The block Davidson method without restarts can be presented (cf. [5, 27, 37]) as the Rayleigh–Ritz method on the trial subspace spanned on vectors:

$$\left\{ \begin{array}{l} x_1^{(0)},\ T(B-\mu_1^{(0)}A)x_1^{(0)},\ T(B-\mu_1^{(1)}A)x_1^{(1)},\dots,\ T(B-\mu_1^{(i)}A)x_1^{(i)},\dots \\ x_m^{(0)},\ T(B-\mu_m^{(0)}A)x_m^{(0)},\ T(B-\mu_m^{(1)}A)x_m^{(1)},\dots,\ T(B-\mu_m^{(i)}A)x_m^{(i)} \end{array} \right\}, \tag{9.1}$$

and $x_j^{(i+1)}$ is computed as the jth Ritz vector. All vectors (9.1) are in the block generalized Krylov subspace (2.6) (assuming a fixed preconditioner), so such defined block Davidson method cannot converge faster than the GLOBALMIN. But our LOBPCG converges with about the same rate as the GLOBALMIN. Therefore, we can expect that LOBPCG is more efficient than Davidson's method, since the former should not converge much slower than, but is significantly less expensive than, the latter.

To make Davidson's method more competitive with our LOBPCG, one needs to restart after every k steps in the following special way: the Rayleigh–Ritz method is now used on the trial subspace spanned by vectors

$$\begin{aligned} &\Big\{x_1^{(i-1)},\ x_1^{(i)},\ T(B-\mu_1^{(i)}A)x_1^{(i)},\ T(B-\mu_1^{(i+1)}A)x_1^{(i+1)},\dots,\ T(B-\mu_1^{(i+k)}A)x_1^{(i+k)},\dots, \\ &\quad x_m^{(i-1)},\ x_m^{(i)},\ T(B-\mu_m^{(i)}A)x_m^{(i)},\ T(B-\mu_m^{(i+1)}A)x_m^{(i+1)},\dots,\ T(B-\mu_m^{(i+k)}A)x_m^{(i+k)}\Big\}, \end{aligned} \tag{9.2}$$

and $x_j^{(i+k+1)}$ is computed as the jth Ritz vector. The new trial subspace is still a subset of the block generalized Krylov subspace (2.6), but its dimension does not depend on the number of iterations.

Compared to a naive method of restarts, we have extra vectors, $x_j^{(i-1)}$, $j = 1,\dots,m$, in the basis of the trial subspace, which we expect will make method (9.2) much faster. We now notice that Davidson's method based on (9.2) with $k = 0$ coincides with our earlier method (5.1). Thus, our Algorithm 5.1 can be viewed as a specially-restarted-at-every-step block Davidson method.

Is there any benefit to using block Davidson method, based on (9.2) with $k > 0$? In our opinion, for symmetric eigenproblems, the answer seems to be no. We expect methods with $k = 0$ and $k > 0$ to be quite similar to each other in terms of speed of convergence, as the method with $k = 0$ already provides approximations practically close to those of the global optimization method on the block Krylov subspace. At the same time, method (9.2) with $k > 0$ will be somewhat more computationally expensive and less stable for ill-conditioned problems simply because the dimension of its trial subspace for the Rayleigh–Ritz method is larger. A direct numerical comparison is yet to be done.

10. Numerical results: LOBPCG vs. JDQR. Here, we present numerical results for the MATLAB code JDQR.m of the inexact Jacobi–Davidson method [14], written by Gerard Sleijpen, which is publicly available on the Internet (http://www.math.uu.nl/people/sleijpen/JD_software/JDQR.html). We are not able to compare it with PCGNULL, as recommended, because norms of the actual residuals are not available in JDQR on every inner iteration. Instead, we provide results of direct numerical comparison of JDQR with our method LOBPCG.

As in the previous two sections, the comparison is made using model eigenvalue problems with $B = I$ (a revision of JDQR code for generalized eigenproblems is not yet available) and random preconditioners, suggested in section 6. JDQR is used with the default tolerance. The number of iterations of our LOBPCG is chosen to match the accuracy of eigenvector approximations provided by the JDQR. We measure the accuracy as the angle between computed and exact invariant subspaces in the two-norm.

First, we find that JDQR is not as robust as our method with respect to ill-conditioning of the matrix A and the number of required eigenpairs. JDQR consistently fails to find even one eigenpair for condition number of A above 10^8. JDQR becomes even more sensitive to ill-conditioning when we increase the number of required eigenpairs. With $cond(A) = 10^6$, JDQR typically fails to compute all ten required eigenpairs in another series of tests, and in some of the tests outputs only one eigenpair out of ten. Attempts to compute forty eigenpairs using JDQR even with $cond(A) = 10$ produce no more than 16 eigenpairs.

JDQR does not handle random initial guess very well. In some tests it converges to the second eigenpair instead of the desired first one, with the smallest eigenvalue λ.

Our LOBPCG is much more robust and successfully computes all required eigenpairs in all tests mentioned above without any difficulties. Moreover, LOBPCG always converges about one-and-a-half to two times faster than JDQR if we count the number of iterations as the number of times the preconditioner is invoked. This may not be very surprising, as the only MATLAB version of the inexact Jacobi–Davidson method available to us for testing can be used for nonsymmetric eigenproblems as well and is not apparently optimized for symmetric eigenvalue problems, while our method takes full advantage of the symmetry by using a three-term recurrence.[1]

Both methods are scalable, as expected, with respect to the size of the problem and the quality of the preconditioner used.

A comparison of LOBPCG with JDQR has also been made for some practical problems, e.g., for an eigenvalue problem describing vibrations of a slender beam,

[1] A new MATLAB package, JDCG by Yvan Notay, was released in 2001; see http://mnsgi.ulb.ac.be/pub/docs/jdcg. It implements the Jacobi–Davidson method with a PCG inner solver, specifically tuned for the symmetric case [31]. According to our numerical tests, while JDCG does accelerate JDQR, it still converges slower than—and for clusters of eigenvalues is not as reliable as—our LOBPCG.

with a domain-decomposition-based preconditioner. This is outside of the scope of the present paper and will be reported elsewhere. Let us just highlight that the conclusions based on these practical comparisons are the same as above for our model diagonal eigenproblem with random preconditioners.

11. Availability of software for the preconditioned eigensolvers. The Internet page http:// www-math.cudenver.edu/~aknyazev/software/CG/ is maintained by the author. It contains all the software used for numerical experiments of the present paper, including benchmarking codes written in MATLAB by the author.

12. Conclusion. Let us formulate here the main points of the paper:

- Numerical results establish that our algorithm LOBPCG is practically as efficient as the "ideal" algorithm for computing an extreme eigenpair and provides approximations close to those of the global optimization method on the generalized block Krylov subspace.
- Our method is much more robust and typically converges about one and a half to two times faster than the inexact Jacobi–Davidson method.
- We provide a system of test problems with random preconditioners that we suggest be used for benchmarking. Every new preconditioned solver for finding an extreme eigenpair should be compared with the "ideal" algorithm in terms of the speed of convergence, costs of every iteration, and memory requirements. As the number of publications on different preconditioned eigenvalue solvers and their applications, e.g., recent papers [36, 43, 44, 24, 2, 34, 33], keeps growing rapidly, a need for such benchmarking becomes evident.

A SYMMETRIC BAND LANCZOS PROCESS BASED ON COUPLED RECURRENCES AND SOME APPLICATIONS*

ZHAOJUN BAI† AND ROLAND W. FREUND‡

Abstract. The symmetric band Lanczos process is an extension of the classical Lanczos algorithm for symmetric matrices and single starting vectors to multiple starting vectors. After n iterations, the symmetric band Lanczos process has generated an $n \times n$ projection, $\mathbf{T}_n^{\mathrm{s}}$, of the given symmetric matrix onto the n-dimensional subspace spanned by the first n Lanczos vectors. This subspace is closely related to the nth block-Krylov subspace induced by the given symmetric matrix and the given block of multiple starting vectors. The standard algorithm produces the entries of $\mathbf{T}_n^{\mathrm{s}}$ directly. In this paper, we propose a variant of the symmetric band Lanczos process that employs coupled recurrences to generate the factors of an $\mathrm{LDL}^{\mathrm{T}}$ factorization of a closely related $n \times n$ projection, rather than $\mathbf{T}_n^{\mathrm{s}}$. This is done in such a way that the factors of the $\mathrm{LDL}^{\mathrm{T}}$ factorization inherit the "fish-bone" structure of $\mathbf{T}_n^{\mathrm{s}}$. Numerical examples from reduced-order modeling of large electronic circuits and algebraic eigenvalue problems demonstrate that the proposed variant of the band Lanczos process based on coupled recurrences is more robust and accurate than the standard algorithm.

1. Introduction.

In recent years, suitable extensions of the classical Lanczos process [23] for single right and left starting vectors to multiple right and left starting vectors have proven to be powerful tools for reduced-order modeling of large-scale multi-input multi-output linear dynamical systems. The most general such Lanczos-type algorithm is the one proposed in [1]. Given a square matrix $\mathbf{A}$ and two blocks of right and left starting vectors, the algorithm in [1] generates two sequences of biorthogonal basis vectors for the right and left block-Krylov subspaces induced by the given data. The algorithm can handle the most general case of right and left starting blocks of arbitrary sizes, say, m and p. In [12, 13], it was shown that this Lanczos-type algorithm can be employed to generate reduced-order models of m-input p-output linear dynamical systems and that these reduced-order models correspond to matrix-Padé approximants of the system's transfer function. The resulting computational procedure is called the MPVL (matrix-Padé via Lanczos) algorithm. For recent surveys on MPVL, related methods, and their use in VLSI circuit simulation, we refer the reader to [14, 16].

In circuit simulation, an important special case is linear dynamical systems that describe large RCL subcircuits consisting of only resistors, capacitors, and inductors. In this case, by employing so-called modified nodal analysis, the circuit equations can be formulated so that the matrix $\mathbf{A}$ is symmetric and the blocks of right and left starting vectors are identical; for details of such a symmetric formulation, see,

e.g., [18]. The SyMPVL algorithm [17, 18] is a variant of MPVL that exploits this symmetry and as a result requires only half the computational costs and storage of MPVL. The Lanczos-type algorithm underlying SyMPVL is essentially the symmetric band Lanczos process first proposed in [26], with some additional features, such as deflation of Krylov vectors; see [15]. It generates a sequence of $n \times n$ projections $\mathbf{T}_n^{\mathrm{s}}$, $n \geq 1$, of the symmetric matrix $\mathbf{A}$ onto the n-dimensional subspace spanned by the first n Lanczos vectors. This subspace is closely related to the nth block-Krylov subspace induced by $\mathbf{A}$ and the given block of multiple starting vectors. As the classical Lanczos process, the symmetric band Lanczos process generates the entries of $\mathbf{T}_n^{\mathrm{s}}$ directly.

In this paper, we propose a new variant of the symmetric band Lanczos process that employs coupled recurrences to produce the factors of an $\mathrm{LDL}^{\mathrm{T}}$ factorization of an $n \times n$ matrix, $\mathbf{T}_n$, closely related to $\mathbf{T}_n^{\mathrm{s}}$, rather than $\mathbf{T}_n^{\mathrm{s}}$ itself. This work was motivated mainly by numerical experiences with the SyMPVL algorithm applied to RC subcircuits. In this case, the matrix $\mathbf{A}$ is symmetric positive semidefinite, and in order to ensure passivity of the reduced-order models produced by SyMPVL, it is crucial that the projection of $\mathbf{A}$ preserves the positive semidefiniteness of $\mathbf{A}$. In exact arithmetic, the projection $\mathbf{T}_n^{\mathrm{s}}$ of a positive semidefinite matrix $\mathbf{A}$ is guaranteed to be positive semidefinite. However, in finite-precision arithmetic, round-off may cause the computed projection $\mathbf{T}_n^{\mathrm{s}}$ to be slightly indefinite; see [4] for such examples. These problems are clearly due to the direct computation of $\mathbf{T}_n^{\mathrm{s}}$. Indeed, when the projection is obtained via the $\mathrm{LDL}^{\mathrm{T}}$ factorization produced by the proposed symmetric band Lanczos process based on coupled recurrences, the computed projection preserves the positive semidefiniteness of $\mathbf{A}$. In addition, the new variant also produces more accurate reduced-order models with the same number of iterations.

The idea of enforcing positive semidefiniteness of a matrix by generating it via a factorization is of course not new. Indeed, the very same issue arises in Kalman filtering where numerical round-off in the standard update formula of the covariance matrices may result in slightly indefinite matrices. The remedy there is to update suitable factors, rather than the covariance matrices, resulting in so-called square-root filtering; see, e.g., [3, Chapter 6.5]. The idea of square-root filtering seems to have originated with James E. Potter in 1962; see [3, Chapter 6.5] and [8, section 13.7]. The use of square-root filtering was crucial in eliminating problems in the Apollo navigation systems caused by numerical round-off; see [8] and the references given there. The same issue also arises in the computation of positive semidefinite solutions of Lyapunov equations; see [22] and the references therein. In [22], an algorithm is proposed that directly generates the Cholesky factor of the solution matrix, rather than the solution matrix.

Finally, in the context of employing the classical Lanczos process for single starting vectors to the solution of systems of linear equations, it has been observed that coupled two-term recurrences are more robust than the mathematically equivalent three-term recurrences; see, e.g., [19] and the references given there. Some recent analysis of this phenomenon can be found in [21].

The remainder of this paper is organized as follows. In section 2, we describe the governing equations of the symmetric band Lanczos process based on coupled recurrences and discuss connections with the standard algorithm. In section 3, we present a complete statement of the algorithm based on coupled recurrences and establish some of its properties. In sections 4 and 5, we discuss applications of the new variant of the symmetric band Lanczos process to reduced-order modeling and to eigenvalue computations, respectively, and we report results of numerical experiments. In section 6, we make some concluding remarks.

Throughout this article, we use boldface letters to denote vectors and matrices. Unless stated otherwise, vectors and matrices are assumed to have real entries. As usual, $\mathbf{M}^{\mathrm{T}} = [\, m_{kj} \,]$ denotes the transpose of the matrix $\mathbf{M} = [\, m_{jk} \,]$, and $\mathbf{M} \geq \mathbf{0}$ ($\mathbf{M} > \mathbf{0}$) means that $\mathbf{M} = \mathbf{M}^{\mathrm{T}}$ is symmetric positive semidefinite (symmetric positive definite). The vector norm $\|\mathbf{x}\| := \sqrt{\mathbf{x}^{\mathrm{T}}\,\mathbf{x}}$ is always the Euclidean norm, and $\|\mathbf{M}\| := \max_{\|\mathbf{x}\|=1} \|\mathbf{M}\,\mathbf{x}\|$ is the corresponding induced matrix norm. We use $\mathbf{I}_n$ to denote the $n \times n$ identity matrix and $\mathbf{0}_{n\times m}$ to denote the $n \times m$ zero matrix; we will omit these indices whenever the actual dimensions of $\mathbf{I}$ and $\mathbf{0}$ are apparent from the context. The sets of real and complex numbers are denoted by $\mathbb{R}$ and $\mathbb{C}$, respectively. For $s \in \mathbb{C}$, $\mathrm{Re}(s)$ is the real part of s.

2. The symmetric band Lanczos process based on coupled recurrences.

In this section, we describe the governing equations of the symmetric band Lanczos process based on coupled recurrences and discuss connections with the standard algorithm.

2.1. Preliminaries.

In what follows, we assume that

$$\mathbf{A} = \mathbf{A}^{\mathrm{T}} \in \mathbb{R}^{N\times N} \quad \text{and} \quad \mathbf{R} = [\, \mathbf{r}_1 \quad \mathbf{r}_2 \quad \cdots \quad \mathbf{r}_m \,] \in \mathbb{R}^{N\times m} \tag{2.1}$$

are given matrices. The columns of $\mathbf{R}$ are the multiple starting vectors. The purpose of the symmetric band Lanczos process is to generate orthogonal basis vectors for the subspaces spanned by the leading columns of the *block-Krylov matrix*,

$$\mathbf{K}(\mathbf{A}, \mathbf{R}) := [\, \mathbf{R} \quad \mathbf{A}\,\mathbf{R} \quad \mathbf{A}^2\,\mathbf{R} \quad \cdots \quad \mathbf{A}^{N-1}\,\mathbf{R} \,], \tag{2.2}$$

associated with the matrices (2.1) and to compute the projection of $\mathbf{A}$ onto these subspaces. A proper definition of these subspaces is necessarily quite involved; see the discussion in [1]. The main reason is that the columns of the matrix $\mathbf{K}(\mathbf{A}, \mathbf{R})$ in (2.2) are all vectors of length N, and thus at most N of them are linearly independent. As a result, in the symmetric band Lanczos process, one needs to perform so-called *deflation* of linearly dependent or in some sense almost linearly dependent vectors. As we will describe below, the symmetric band Lanczos process has a very simple built-in deflation procedure. In exact arithmetic, only the linearly dependent vectors have to be removed, and we refer to this as *exact* deflation. In the case of exact deflation, the subspaces spanned by the leading columns of the matrix (2.2) can be easily defined, and we will do so in section 2.5 below.

2.2. Governing equations.

The symmetric band Lanczos algorithm is an iterative procedure. After n iterations, the algorithm has generated the first n *Lanczos vectors*,

$$\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n \in \mathbb{R}^N, \tag{2.3}$$

as well as the $m_{\mathrm{c}} = m_{\mathrm{c}}(n)$ vectors,

$$\hat{\mathbf{v}}_{n+1}, \hat{\mathbf{v}}_{n+2}, \ldots, \hat{\mathbf{v}}_{n+m_{\mathrm{c}}} \in \mathbb{R}^N, \tag{2.4}$$

that are the candidates for the next m_{c} Lanczos vectors, $\mathbf{v}_{n+1}, \mathbf{v}_{n+2}, \ldots, \mathbf{v}_{n+m_{\mathrm{c}}}$. Here, $m_{\mathrm{c}} = m_{\mathrm{c}}(n)$ is the *current block size* defined as follows. In the initialization phase, i.e., for $n = 0$, $m_{\mathrm{c}} := m$ is set to be the number of starting vectors in (2.1), and the candidate vectors (2.4) are set to be the starting vectors from (2.1), i.e., $\hat{\mathbf{v}}_i = \mathbf{r}_i$, $1 \le i \le m$. Within the algorithm, $m_{\rm c}$ is then reduced by 1 every time a deflation occurs. Moreover, in the algorithm, the vectors (2.4) are used to detect and perform deflation. More precisely, it can be shown that an exact deflation occurs during the $(n+1)$st iteration of the algorithm if and only if $\hat{\mathbf{v}}_{n+1} = \mathbf{0}$. Therefore, in the algorithm, one simply checks if the first of the candidate vectors is the zero vector or in some sense close to the zero vector, and if so, one performs deflation by removing that first candidate vector.

We remark that due to the use of the candidate vectors (2.4), we need only generate $n \times n$ Lanczos matrices. This is in contrast to approaches such as the symmetric algorithm [26] and the nonsymmetric algorithm [1], which only involve Lanczos vectors, but no candidate vectors, and generate $(n+m_{\rm c})\times n$ Lanczos matrices. Since for the applications we have in mind only the leading $n \times n$ part of the Lanczos matrices is needed anyway, the approach using candidate vectors is more economical.

In addition to (2.3), the symmetric band Lanczos process based on coupled recurrences also generates a second set of vectors,

$$\mathbf{p}_1, \mathbf{p}_2, \ldots, \mathbf{p}_n \in \mathbb{R}^N, \tag{2.5}$$

that span the same subspaces as (2.3), i.e.,

$$\operatorname{span}\{\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_j\} = \operatorname{span}\{\mathbf{p}_1, \mathbf{p}_2, \ldots, \mathbf{p}_j\} \quad \text{for all} \quad 1 \le j \le n. \tag{2.6}$$

The vectors (2.3)–(2.5) are constructed to satisfy (in exact arithmetic) the following orthogonality conditions:

$$\mathbf{V}_n^{\rm T}\,\mathbf{V}_n = \mathbf{I}_n, \tag{2.7}$$

$$\mathbf{V}_n^{\rm T}\,[\,\hat{\mathbf{v}}_{n+1} \quad \hat{\mathbf{v}}_{n+2} \quad \cdots \quad \hat{\mathbf{v}}_{n+m_{\rm c}}\,] = \mathbf{0}, \tag{2.8}$$

$$\mathbf{P}_n^{\rm T}\,\mathbf{A}\,\mathbf{P}_n = \boldsymbol{\Delta}_n := \operatorname{diag}(\delta_1, \delta_2, \ldots, \delta_n)\,. \tag{2.9}$$

Here and in what follows,

$$\mathbf{V}_n := [\,\mathbf{v}_1 \quad \mathbf{v}_2 \quad \cdots \quad \mathbf{v}_n\,] \quad \text{and} \quad \mathbf{P}_n := [\,\mathbf{p}_1 \quad \mathbf{p}_2 \quad \cdots \quad \mathbf{p}_n\,] \tag{2.10}$$

denote the matrices whose columns are just the vectors (2.3) and (2.5), respectively. Furthermore, in (2.9), we assume that $\delta_i \neq 0$ for all i. This implies that

$$\boldsymbol{\Delta}_n \quad \text{is nonsingular.} \tag{2.11}$$

Note that, by (2.7), the Lanczos vectors (2.3) are an orthonormal basis of the subspaces (2.6), while, by (2.9), the vectors (2.5) are an $\mathbf{A}$-orthogonal basis of (2.6).

The recurrence relations that are used in the algorithm to generate the vectors (2.3)–(2.5) can be stated as follows. The first m_1 vectors in (2.3) are obtained by applying a modified Gram–Schmidt procedure [20] (with deflation) to the m columns of the block $\mathbf{R}$ to eliminate any linearly dependent or almost linearly dependent starting vectors. This procedure can be summarized in a relation of the form

$$\mathbf{R} = \mathbf{V}_{m_1}\,\boldsymbol{\rho}_{m_1} + \widehat{\mathbf{V}}_0^{\rm df}. \tag{2.12}$$

Here, $m_1\,(\le m)$ denotes the number of columns of the block $\mathbf{R}$ that have not been deflated, the matrix $\widehat{\mathbf{V}}_0^{\rm df} \in \mathbb{R}^{N \times m}$ contains the $m - m_1$ deflated starting vectors and m_1 zero vectors as columns, and

$$\boldsymbol{\rho}_{m_1} = [\,\rho_{i,j}\,]_{i=1,2,\ldots,m_1;\,j=1,2,\ldots,m} \in \mathbb{R}^{m_1 \times m} \tag{2.13}$$

is an upper triangular matrix whose entries are chosen such that the columns of $\mathbf{V}_{m_1}$ are orthonormal. The main relations for generating the vectors (2.3)–(2.5) are coupled recurrences that can be summarized as follows:

$$\mathbf{A}\,\mathbf{P}_n = \mathbf{V}_n\,\mathbf{L}_n\,\boldsymbol{\Delta}_n + \bigl[\,\underbrace{\mathbf{0} \quad \mathbf{0} \quad \cdots \quad \mathbf{0}}_{n-m_{\mathrm{c}}} \quad \underbrace{\hat{\mathbf{v}}_{n+1} \quad \hat{\mathbf{v}}_{n+2} \quad \cdots \quad \hat{\mathbf{v}}_{n+m_{\mathrm{c}}}}_{m_{\mathrm{c}}}\,\bigr] + \widehat{\mathbf{V}}_n^{\mathrm{df}}, \tag{2.14}$$

$$\mathbf{V}_n = \mathbf{P}_n\,\mathbf{U}_n. \tag{2.15}$$

Here, $\boldsymbol{\Delta}_n$ is the diagonal matrix defined in (2.9), and

$$\mathbf{L}_n = [\,\ell_{ij}\,]_{i,j=1,2,\dots,n} \in \mathbb{R}^{n\times n} \quad \text{and} \quad \mathbf{U}_n = [\,u_{ij}\,]_{i,j=1,2,\dots,n} \in \mathbb{R}^{n\times n} \tag{2.16}$$

are unit lower and upper triangular matrices, respectively. The entries of the matrices $\boldsymbol{\Delta}_n$, $\mathbf{L}_n$, and $\mathbf{U}_n$ are chosen such that the vectors (2.3)–(2.5) satisfy the orthogonality conditions (2.7)–(2.9). Furthermore, any candidate vector $\hat{\mathbf{v}}_j$ that was deflated at the jth iteration, where $1 + m_{\mathrm{c}}(j) \le j \le n$, appears as the $(j - m_{\mathrm{c}}(j))$th column of the matrix $\widehat{\mathbf{V}}_n^{\mathrm{df}}$ in (2.14); all other columns of $\widehat{\mathbf{V}}_n^{\mathrm{df}}$ are zero vectors. In the actual Algorithm 3.1 below, we use the index set $\mathcal{I}$ to record the positions of the potentially nonzero columns of $\widehat{\mathbf{V}}_n^{\mathrm{df}}$ due to deflation. If no deflation has occurred or if only exact deflation is performed, then clearly

$$\widehat{\mathbf{V}}_0^{\mathrm{df}} = \mathbf{0} \quad \text{and} \quad \widehat{\mathbf{V}}_n^{\mathrm{df}} = \mathbf{0} \tag{2.17}$$

in (2.12) and (2.14), respectively.

2.3. The Lanczos matrix. By multiplying (2.9) from the left by $\mathbf{U}_n^{\mathrm{T}}$ and from the right by $\mathbf{U}_n$, and by using (2.15), it follows that

$$\mathbf{T}_n := \mathbf{V}_n^{\mathrm{T}}\,\mathbf{A}\,\mathbf{V}_n = \mathbf{U}_n^{\mathrm{T}}\,\boldsymbol{\Delta}_n\,\mathbf{U}_n. \tag{2.18}$$

The matrix $\mathbf{T}_n$ defined in (2.18) is the so-called *nth Lanczos matrix.* It represents the projection of $\mathbf{A}$ onto the subspaces spanned by the Lanczos vectors (2.3). Recall that $\mathbf{U}_n$ is a unit upper triangular matrix and that $\boldsymbol{\Delta}_n$ is a diagonal matrix. Thus, in view of (2.18), the symmetric band Lanczos process based on coupled recurrences computes the factors of an LDL$^{\mathrm{T}}$ decomposition of the Lanczos matrix $\mathbf{T}_n$, rather than $\mathbf{T}_n$ itself.

In the important special case $\mathbf{A} \ge \mathbf{0}$, in view of (2.9), the diagonal entries of $\boldsymbol{\Delta}_n$ satisfy

$$\delta_i = \mathbf{p}_i^{\mathrm{T}}\,\mathbf{A}\,\mathbf{p}_i \ge 0 \quad \text{for all} \quad i, \tag{2.19}$$

and hence $\boldsymbol{\Delta}_n \ge \mathbf{0}$. Thus, for $\mathbf{A} \ge \mathbf{0}$, generating $\mathbf{T}_n$ via the factorization (2.18) always results in a positive semidefinite matrix.

The triangular matrices $\mathbf{L}_n$ in (2.14) and $\mathbf{U}_n$ in (2.15) are closely related. Indeed, by multiplying (2.14) from the left by $\mathbf{V}_n^{\mathrm{T}}$ and from the right by $\mathbf{U}_n$, and by using (2.7), (2.8), and (2.15), we get

$$\mathbf{V}_n^{\mathrm{T}}\,\mathbf{A}\,\mathbf{V}_n = (\mathbf{L}_n\,\boldsymbol{\Delta}_n + \boldsymbol{\Sigma}_n)\,\mathbf{U}_n, \quad \text{where} \quad \boldsymbol{\Sigma}_n := \mathbf{V}_n^{\mathrm{T}}\,\widehat{\mathbf{V}}_n^{\mathrm{df}}. \tag{2.20}$$

By comparing (2.18) and (2.20), it follows that

$$\mathbf{U}_n = \mathbf{L}_n^{\mathrm{T}} + \boldsymbol{\Delta}_n^{-1}\,\boldsymbol{\Sigma}_n^{\mathrm{T}}. \tag{2.21}$$

In particular, if no deflation has occurred or if only exact deflation is performed, then, in view of (2.17), we have $\boldsymbol{\Sigma}_n = \mathbf{0}$ in (2.20) and thus $\mathbf{U}_n = \mathbf{L}_n^{\mathrm{T}}$.

2.4. Structure of the triangular factor $\mathbf{U}_n$. In this subsection, we describe the sparsity structure of the matrix $\mathbf{U}_n$.

The unit upper triangular $\mathbf{U}_n$ consists of a banded part with bandwidth decreasing from $m+1$ to $m_{\mathrm{c}}+1$ and a "spiked" part with potentially nonzero elements only in rows with index $i \in \mathcal{I}$ and to the right of the banded part. Recall that the index set $\mathcal{I}$ records deflation. It turns out that in the additive splitting (2.21) of $\mathbf{U}_n$, the first term, $\mathbf{L}_n^{\mathrm{T}}$, is the banded part, while the second term, $\mathbf{\Delta}_n^{-1}\,\mathbf{\Sigma}_n^{\mathrm{T}}$, is the spiked part.

Next, we present an example that illustrates this structure of $\mathbf{U}_n$. Consider the case that $m = 5$ and that the three candidate vectors $\hat{\mathbf{v}}_8$ (when $m_{\mathrm{c}} = 5$), $\hat{\mathbf{v}}_{11}$ (when $m_{\mathrm{c}} = 4$), and $\hat{\mathbf{v}}_{13}$ (when $m_{\mathrm{c}} = 3$) have been deflated. The associated index set is $\mathcal{I} = \{\,3, 7, 10\,\}$. After $n = 15$ iterations, we then have $m_{\mathrm{c}} = 2$, and the matrix $\mathbf{U}_{15}$ has the following structure:

$$\mathbf{U}_{15} = \begin{bmatrix}
1 & \times & \times & \times & \times & \times & & & & & & & & & \\
 & 1 & \times & \times & \times & \times & \times & & & & & & & & \\
 & & 1 & \times & \times & \times & \times & * & * & * & * & * & * & * & * \\
 & & & 1 & \times & \times & \times & \times & & & & & & & \\
 & & & & 1 & \times & \times & \times & \times & & & & & & \\
 & & & & & 1 & \times & \times & \times & \times & & & & & \\
 & & & & & & 1 & \times & \times & \times & * & * & * & * & * \\
 & & & & & & & 1 & \times & \times & \times & & & & \\
 & & & & & & & & 1 & \times & \times & \times & & & \\
 & & & & & & & & & 1 & \times & \times & * & * & * \\
 & & & & & & & & & & 1 & \times & \times & & \\
 & & & & & & & & & & & 1 & \times & \times & \\
 & & & & & & & & & & & & 1 & \times & \times \\
 & & & & & & & & & & & & & 1 & \times \\
 & & & & & & & & & & & & & & 1
\end{bmatrix}.$$

Here, potentially nonzero off-diagonal entries in the banded part of $\mathbf{U}_{15}$ are marked by "×", and potentially nonzero entries in the spiked part are marked by "$*$".

2.5. Block-Krylov subspaces in the case of exact deflation. It can be shown that performing only exact deflation in the symmetric band Lanczos process is equivalent to scanning the columns of the block-Krylov matrix (2.2) from left to right and deleting each column that is linearly dependent on earlier columns; see [1]. The result of such a deletion of columns in (2.2) is the *deflated* block-Krylov matrix

$$\mathbf{K}^{\mathrm{df}}(\mathbf{A},\mathbf{R}) := [\,\mathbf{R}_1 \quad \mathbf{A}\,\mathbf{R}_2 \quad \mathbf{A}^2\,\mathbf{R}_3 \quad \cdots \quad \mathbf{A}^{j_{\max}-1}\,\mathbf{R}_{j_{\max}}\,].$$

By the structure of (2.2), a column $\mathbf{A}^{j-1}\,\mathbf{r}_i$ being linearly dependent on earlier columns implies that all $\mathbf{A}$-multiples, $\mathbf{A}^k\mathbf{r}_i$, $k \geq j$, of that column are also linearly dependent on earlier columns. As a result, for each $j = 1, 2, \ldots, j_{\max}$, $\mathbf{R}_j$ is a submatrix of $\mathbf{R}_{j-1}$, where, for $j = 1$, we set $\mathbf{R}_0 := \mathbf{R}$.

By construction, all columns of the matrix $\mathbf{K}^{\mathrm{df}}(\mathbf{A},\mathbf{R})$ are linearly independent. The *nth block-Krylov subspace*, $\mathcal{K}_n(\mathbf{A},\mathbf{R})$, induced by $\mathbf{A}$ and $\mathbf{R}$ is now defined as the n-dimensional subspace of $\mathbb{R}^N$ spanned by the first n columns of the matrix $\mathbf{K}^{\mathrm{df}}(\mathbf{A},\mathbf{R})$. When only exact deflation is performed in the symmetric band Lanczos process, then the Lanczos vectors (2.3) span the nth block-Krylov subspace, i.e.,

$$\operatorname{span}\{\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n\} = \mathcal{K}_n(\mathbf{A},\mathbf{R}). \tag{2.22}$$

2.6. The standard symmetric band Lanczos process. In this subsection, we review the standard symmetric band Lanczos process. The standard process only generates Lanczos vectors (2.3) and candidate vectors (2.4), but not the second set of vectors (2.5). We stress that our notion of "standard" process includes the same proper deflation procedure as used in the coupled algorithm. Moreover, all numerical comparisons reported in this paper were run with deflation turned on in both algorithms. In particular, the difference in the numerical behavior is indeed due to the use of coupled vs. standard recurrences, and not due to one algorithm being run with deflation and the other without deflation.

In the standard algorithm, the Lanczos vectors (2.3) and candidate vectors (2.4) are constructed to satisfy the orthogonality conditions (2.7) and (2.8). The first m_1 Lanczos vectors again satisfy a relation of the form (2.12). The main recurrences used in the standard algorithm can be summarized in the form

$$\mathbf{A}\,\mathbf{V}_n^{\mathrm{s}} = \mathbf{V}_n^{\mathrm{s}}\,\widetilde{\mathbf{T}}_n^{\mathrm{s}} + \big[\,\underbrace{\mathbf{0}\quad\mathbf{0}\quad\cdots\quad\mathbf{0}}_{n-m_{\mathrm{c}}}\quad\underbrace{\hat{\mathbf{v}}_{n+1}^{\mathrm{s}}\quad\hat{\mathbf{v}}_{n+2}^{\mathrm{s}}\quad\cdots\quad\hat{\mathbf{v}}_{n+m_{\mathrm{c}}}^{\mathrm{s}}}_{m_{\mathrm{c}}}\,\big] + \widehat{\mathbf{V}}_n^{\mathrm{s,\,df}}. \tag{2.23}$$

Here, the upper index "s" is used to differentiate the vectors and matrices generated by the standard process from those generated by the coupled process.

In (2.23), $\widetilde{\mathbf{T}}_n^{\mathrm{s}}$ is an $n\times n$ matrix whose entries are chosen such that the vectors (2.3) and (2.4) satisfy the orthogonality conditions (2.7) and (2.8). By multiplying (2.23) from the left by $(\mathbf{V}_n^{\mathrm{s}})^{\mathrm{T}}$, and by using (2.7) and (2.8), it follows that

$$\mathbf{T}_n^{\mathrm{s}} := (\mathbf{V}_n^{\mathrm{s}})^{\mathrm{T}}\,\mathbf{A}\mathbf{V}_n^{\mathrm{s}} = \widetilde{\mathbf{T}}_n^{\mathrm{s}} + (\mathbf{V}_n^{\mathrm{s}})^{\mathrm{T}}\,\widehat{\mathbf{V}}_n^{\mathrm{s,\,df}}. \tag{2.24}$$

It turns out that $\mathbf{T}_n^{\mathrm{s}}$ consists of a symmetric banded part with bandwidth decreasing from $2m+1$ to $2m_{\mathrm{c}}+1$ and a "spiked" part with potentially nonzero elements only in rows and columns with index $i \in \mathcal{I}$ and outside of the banded part. This means that the matrix $\mathbf{T}_n^{\mathrm{s}}$ has the same "fish-bone" sparsity structure as $\mathbf{U}_n^{\mathrm{T}} + \mathbf{U}_n$, where $\mathbf{U}_n$ is the triangular factor of $\mathbf{T}_n$ described in section 2.4.

For the example considered in section 2.4, the corresponding matrix $\mathbf{T}_n^{\mathrm{s}}$ produced by the standard algorithm has the following structure:

$$\mathbf{T}_{15}^{\mathrm{s}} = \begin{bmatrix}
\times & \times & \times & \times & \times & \times & & & & & & & & & \\
\times & \times & \times & \times & \times & \times & \times & & & & & & & & \\
\times & \times & \times & \times & \times & \times & \times & * & * & * & * & * & * & * & * \\
\times & \times & \times & \times & \times & \times & \times & \times & & & & & & & \\
\times & \times & \times & \times & \times & \times & \times & \times & \times & & & & & & \\
\times & \times & \times & \times & \times & \times & \times & \times & \times & \times & & & & & \\
 & \times & \times & \times & \times & \times & \times & \times & \times & \times & * & * & * & * & * \\
 & & * & \times & \times & \times & \times & \times & \times & \times & \times & & & & \\
 & & * & & \times & \times & \times & \times & \times & \times & \times & \times & & & \\
 & & * & & & \times & \times & \times & \times & \times & \times & \times & * & * & * \\
 & & * & & & & * & \times & \times & \times & \times & \times & \times & & \\
 & & * & & & & * & & \times & \times & \times & \times & \times & \times & \\
 & & * & & & & * & & & * & \times & \times & \times & \times & \times \\
 & & * & & & & * & & & * & & \times & \times & \times & \times \\
 & & * & & & & * & & & * & & & \times & \times & \times
\end{bmatrix}.$$

Here, potentially nonzero entries in the banded part of $\mathbf{T}_{15}^{\mathrm{s}}$ are marked by "×", and potentially nonzero entries in the spiked part are marked by "$*$".

For further details and properties of the standard symmetric band Lanczos algorithm, we refer the reader to [15]. We would also like to point the reader to the earlier work [9, 10, 26] on symmetric band or block Lanczos algorithms. The symmetric band Lanczos algorithm proposed in [26] identifies Lanczos vectors that need to be deflated in a similar fashion as described above. However, the deflated vectors are then simply discarded, and, as a result, a relation such as (2.24) holds true only approximately for this algorithm. The symmetric block Lanczos algorithm described in [9] and [10, Chapter 7] is a block and not a band procedure. At each block iteration, a new block of m_{c} vectors is computed so that it is orthogonal to the earlier blocks. Similar to the deflation procedure described above, vectors in the new block that are in some sense close to the zero vector are properly deflated, and not just discarded, before the remaining columns in the new block are orthogonalized.

2.7. Connection with the standard process. The standard band Lanczos process and the algorithm based on coupled recurrences are mathematically equivalent in the case that no deflation occurs or that only exact deflation is performed. Indeed, in this case, the first n Lanczos vectors (2.3) generated by both algorithms are identical and, in view of (2.22), span the nth block-Krylov subspace $\mathcal{K}_n(\mathbf{A}, \mathbf{R})$. Hence, the associated projected Lanczos matrices $\mathbf{T}_n$ and $\mathbf{T}_n^{\mathrm{s}}$ given by (2.18) and (2.24) are identical. Moreover, in (2.14) and (2.23), we have $\widehat{\mathbf{V}}_n^{\mathrm{df}} = \widehat{\mathbf{V}}_n^{\mathrm{s,\,df}} = \mathbf{0}$. This implies that the spiked parts of both $\mathbf{T}_n$ and $\mathbf{U}_n$ are actually zero matrices. Thus both $\mathbf{T}_n$ and $\mathbf{U}_n = \mathbf{L}_n^{\mathrm{T}}$ are banded matrices, and (2.18) reduces to the LDL$^{\mathrm{T}}$ factorization

$$\mathbf{T}_n = \mathbf{T}_n^{\mathrm{s}} = \mathbf{L}_n \, \boldsymbol{\Delta}_n \, \mathbf{L}_n^{\mathrm{T}}$$

of the Lanczos matrix associated with both variants of the symmetric band Lanczos process.

As soon as deflation of almost linearly dependent vectors is performed, the two processes are no longer mathematically equivalent in general. In this case, the spiked parts of both $\mathbf{T}_n$ and $\mathbf{U}_n$ are nonzero, and thus

$$\mathbf{T}_n^{\mathrm{s}} \neq \mathbf{T}_n = \mathbf{U}_n^{\mathrm{T}} \, \boldsymbol{\Delta}_n \, \mathbf{U}_n$$

in general. Indeed, $\mathbf{T}_n^{\mathrm{s}}$ has a “fish-bone” sparsity structure, while $\mathbf{T}_n$ is a full matrix in general, even though $\mathbf{U}_n$ is sparse. However, one can show that $\|\mathbf{T}_n - \mathbf{T}_n^{\mathrm{s}}\|$ is bounded by the tolerance used to check for deflation.

3. The algorithm and its properties. In this section, we present a detailed statement of the symmetric band Lanczos process with coupled recurrences, and establish some of its properties.

3.1. Statement of the algorithm. At each pass n through the main loop of the algorithm, one first checks if the candidate vector $\hat{\mathbf{v}}_n$ needs to be deflated. If yes, it is deleted, the indices of all the remaining candidate vectors are reduced by 1, and the deflation check is repeated. If no, the candidate vector $\hat{\mathbf{v}}_n$ is normalized to become the nth Lanczos vector $\mathbf{v}_n$. In the remaining steps of pass n, the algorithm orthogonalizes the candidate vectors against $\mathbf{v}_n$, generates the potentially nonzero entries of the nth column of $\mathbf{U}_n$ and, if $n \leq m_1$, of the nth row of $\boldsymbol{\rho}_{m_1}$, and computes the vector $\mathbf{p}_n$, the scalar δ_n, and a new candidate vector $\hat{\mathbf{v}}_{n+m_{\mathrm{c}}}$.

A detailed statement of the algorithm is as follows.

Algorithm 3.1 (symmetric band Lanczos process with coupled recurrences).

```
INPUT: A matrix $\mathbf{A} = \mathbf{A}^{\mathrm{T}} \in \mathbb{R}^{N \times N}$, and a block $\mathbf{R} = [\, \mathbf{r}_1 \quad \mathbf{r}_2 \quad \dots \quad \mathbf{r}_m \,] \in \mathbb{R}^{N \times m}$
        of $m$ starting vectors.
OUTPUT: Matrices $\mathbf{U}_n$, $\mathbf{\Delta}_n$, and (if $n \geq m_1$) $\boldsymbol{\rho}_{m_1}$.
    (0) Set $\hat{\mathbf{v}}_i = \mathbf{r}_i$ for $i = 1, 2, \dots, m$.
        Set $m_{\mathrm{c}} = m$.
        Set $\mathcal{I} = \emptyset$.
For $n = 1, 2, \dots,$ do:
    (1) (If necessary, deflate.)
        Decide if $\hat{\mathbf{v}}_n$ should be deflated.
        If no, continue with step 2.
        If yes, deflate $\hat{\mathbf{v}}_n$ by doing the following:
         (a) If $n - m_{\mathrm{c}} > 0$, set $\mathcal{I} = \mathcal{I} \cup \{n - m_{\mathrm{c}}\}$ and $\hat{\mathbf{v}}^{\mathrm{df}}_{n-m_{\mathrm{c}}} = \hat{\mathbf{v}}_n$.
         (b) Set $m_{\mathrm{c}} = m_{\mathrm{c}} - 1$. If $m_{\mathrm{c}} = 0$, set $n = n - 1$ and stop.
         (c) For $i = n, n+1, \dots, n + m_{\mathrm{c}} - 1$, set $\hat{\mathbf{v}}_i = \hat{\mathbf{v}}_{i+1}$.
         (d) Repeat all of step 1.
    (2) (Normalize $\hat{\mathbf{v}}_n$ to become the $n$th Lanczos vector $\mathbf{v}_n$.)
        Set $\mathbf{v}_n = \dfrac{\hat{\mathbf{v}}_n}{\|\hat{\mathbf{v}}_n\|}$.
        If $n - m_{\mathrm{c}} > 0$, set $u_{n-m_{\mathrm{c}},n} = \dfrac{\|\hat{\mathbf{v}}_n\|}{\delta_{n-m_{\mathrm{c}}}}$.
        If $n - m_{\mathrm{c}} \leq 0$, set $\rho_{n,n-m_{\mathrm{c}}+m} = \|\hat{\mathbf{v}}_n\|$.
        If $n = m_{\mathrm{c}}$, set $m_1 = m_{\mathrm{c}}$.
    (3) (Orthogonalize the vectors $\hat{\mathbf{v}}_{n+j}$, $1 \leq j < m_{\mathrm{c}}$, against $\mathbf{v}_n$.)
        For $j = 1, 2, \dots, m_{\mathrm{c}} - 1$, do:
            Set $\tau = \mathbf{v}_n^{\mathrm{T}} \hat{\mathbf{v}}_{n+j}$ and $\hat{\mathbf{v}}_{n+j} = \hat{\mathbf{v}}_{n+j} - \mathbf{v}_n \, \tau$.
            If $n + j - m_{\mathrm{c}} > 0$, set $u_{n+j-m_{\mathrm{c}},n} = \dfrac{\tau}{\delta_{n+j-m_{\mathrm{c}}}}$.
            If $n + j - m_{\mathrm{c}} \leq 0$, set $\rho_{n,n+j-m_{\mathrm{c}}+m} = \tau$.
    (4) (Update the spiked part of $\mathbf{U}_n$.)
        For each $j \in \mathcal{I}$, set $u_{jn} = \dfrac{\mathbf{v}_n^{\mathrm{T}} \hat{\mathbf{v}}^{\mathrm{df}}_j}{\delta_j}$.
    (5) (Compute the vector $\mathbf{p}_n$.)
        Set $j_0 = \max\{1,\, n - m_{\mathrm{c}}\}$ and

(3.1)          $\mathbf{p}_n = \mathbf{v}_n - \sum_{j \in \mathcal{I}} \mathbf{p}_j \, u_{jn} - \sum_{j=j_0}^{n-1} \mathbf{p}_j \, u_{jn}$.

        Set $u_{nn} = 1$.
    (6) (Advance the block-Krylov subspace.)
        Set $\hat{\mathbf{v}}_{n+m_{\mathrm{c}}} = \mathbf{A} \, \mathbf{p}_n$.
    (7) Set $\delta_n = \mathbf{p}_n^{\mathrm{T}} \hat{\mathbf{v}}_{n+m_{\mathrm{c}}}$.
        If $\delta_n = 0$, stop: look-ahead would be needed to continue.
    (8) Set $\hat{\mathbf{v}}_{n+m_{\mathrm{c}}} = \hat{\mathbf{v}}_{n+m_{\mathrm{c}}} - \mathbf{v}_n \, \delta_n$.
    (9) Test for convergence.
```

Remark 3.1. In Algorithm 3.1, only the potentially nonzero entries of the matrices $\mathbf{U}_n$ and $\boldsymbol{\rho}_{m_1}$ and the diagonal entries of the diagonal matrix $\boldsymbol{\Delta}_n$ are computed. All other entries of these matrices are set to be zero.

Remark 3.2. The entries of $\mathbf{U}_n$ generated in step 3 of Algorithm 3.1 are just the potentially nonzero off-diagonal entries of the banded part of the unit upper triangular matrix $\mathbf{U}_n$. In view of (2.21), the unit lower triangular matrix $\mathbf{L}_n$ can be obtained by simply transposing the banded part of $\mathbf{U}_n$.

Remark 3.3. A practical criterion for deflation in step 1 of Algorithm 3.1 is as follows. The vector $\hat{\mathbf{v}}_n$ is deflated if and only if

$$\|\hat{\mathbf{v}}_n\| \leq \mathtt{dtol}_n.$$

Here,

$$\mathtt{dtol}_n := \mathtt{dtol} \times \begin{cases} \|\mathbf{r}_{n+m-m_\mathrm{c}}\| & \text{if} \quad n \leq m_1, \\ \mathrm{nest}(\mathbf{A}) & \text{if} \quad n > m_1 \end{cases} \tag{3.2}$$

is the product of an absolute deflation tolerance `dtol` and a scaling factor that makes the deflation check independent of the actual scaling of the columns $\mathbf{r}_i$ of $\mathbf{R}$ and of the matrix $\mathbf{A}$. Ideally, we would like to set $\mathrm{nest}(\mathbf{A}) = \|\mathbf{A}\|$ in (3.2). However, if $\|\mathbf{A}\|$ is not available, then $\mathrm{nest}(\mathbf{A})$ is set to be an estimate of $\|\mathbf{A}\|$. For example, we can use the estimate

$$\mathrm{nest}(\mathbf{A}) := \max_{1 \leq i \leq m_1} \frac{\|\mathbf{A}\,\mathbf{p}_i\|}{\|\mathbf{p}_i\|} \leq \|\mathbf{A}\|\,,$$

which can be obtained from the vectors generated in Algorithm 3.1 at the expense of $2m_1$ additional vector-norm computations. Based on our numerical experiences with Algorithm 3.1, we recommend the absolute deflation tolerance $\mathtt{dtol} = \sqrt{\mathtt{eps}}$, where `eps` is the machine precision.

Remark 3.4. If $\mathbf{A} \geq 0$, then $\delta_n > 0$ for all n and so Algorithm 3.1 never stops in step 7. If $\mathbf{A}$ is indefinite, then it cannot be excluded that Algorithm 3.1 terminates prematurely due to $\delta_n = 0$ in step 7. In this case, look-ahead can be used to continue the process, but in order to keep the algorithm relatively simple, we opted to treat only the no-look-ahead case in this paper. However, we stress that Algorithm 3.1 can be extended to include look-ahead. Such an extension again generates an LDL^T factorization (2.18), where $\boldsymbol{\Delta}_n$ is a block-diagonal matrix in general. Furthermore, the nonsingularity (2.11) of $\boldsymbol{\Delta}_n$ is guaranteed only for the values of n that correspond to the end of a look-ahead step.

Remark 3.5. Algorithm 3.1 requires storage of the vector $\mathbf{v}_n$, the m_c candidate vectors $\hat{\mathbf{v}}_{n+1}, \hat{\mathbf{v}}_{n+2}, \ldots, \hat{\mathbf{v}}_{n+m_\mathrm{c}}$, the m_c vectors $\mathbf{p}_{n-m_\mathrm{c}+1}, \mathbf{p}_{n-m_\mathrm{c}+2}, \ldots, \mathbf{p}_n$, and all the vectors $\mathbf{p}_i$ and $\hat{\mathbf{v}}_i^{\mathrm{df}}$ with $i \in \mathcal{I}$. Since the set $\mathcal{I}$ contains at most $m - m_\mathrm{c}$ elements, the total number of vectors to be stored is at most

$$1 + m_\mathrm{c} + m_\mathrm{c} + 2(m - m_\mathrm{c}) = 2m + 1,$$

which is identical to the storage requirement of the standard symmetric band Lanczos process.

3.2. Properties. We now show that the quantities generated by Algorithm 3.1 indeed satisfy the governing equations stated in section 2.2.

THEOREM 3.2. *The vectors and matrices generated by n iterations of Algorithm* 3.1 *satisfy the recurrence relations* (2.14), (2.15), *and* (*if* $n \geq m_1$) (2.12).

Proof. Using the matrices introduced in (2.9), (2.10), (2.13), and (2.16), it is straightforward to verify that all the recurrences employed in the first n iterations of Algorithm 3.1 can indeed be summarized as the matrix relations (2.12), (2.14), and (2.15). □

THEOREM 3.3. *The vectors and matrices generated by n iterations of Algorithm* 3.1 (*run in exact arithmetic*) *satisfy the orthogonality conditions* (2.7)–(2.9).

Proof. From steps 2, 6, and 7 of Algorithm 3.1, it follows that

$$\mathbf{v}_i^{\mathrm{T}}\,\mathbf{v}_i = 1 \quad \text{and} \quad \mathbf{p}_i^{\mathrm{T}}\,\mathbf{A}\,\mathbf{p}_i = \delta_i \quad \text{for all} \quad 1 \leq i \leq n. \tag{3.3}$$

Next, we use induction on $n\,(\geq 0)$ to show that

$$\mathbf{v}_i^{\mathrm{T}}\,\mathbf{v}_n = 0 \quad \text{for all} \quad 1 \leq i < n, \tag{3.4}$$

$$\mathbf{p}_i^{\mathrm{T}}\,\mathbf{A}\,\mathbf{p}_n = 0 \quad \text{for all} \quad 1 \leq i < n, \tag{3.5}$$

$$\mathbf{v}_i^{\mathrm{T}}\,\hat{\mathbf{v}}_{n+j} = 0 \quad \text{for all} \quad 1 \leq i \leq n,\ 1 \leq j \leq m_{\mathrm{c}}(n). \tag{3.6}$$

Note that the relations (3.4)–(3.6), together with (3.3), are equivalent to the orthogonality conditions (2.7)–(2.9).

The assertions (3.4)–(3.6) are trivially satisfied for $n = 0$, since the sets of indices i in (3.4)–(3.6) are all empty in this case. Now let $n \geq 1$, and as induction hypothesis, assume that for all $0 \leq n' < n$, we have

$$\mathbf{v}_i^{\mathrm{T}}\,\mathbf{v}_{n'} = 0 \quad \text{for all} \quad 1 \leq i < n',$$

$$\mathbf{p}_i^{\mathrm{T}}\,\mathbf{A}\,\mathbf{p}_{n'} = 0 \quad \text{for all} \quad 1 \leq i < n', \tag{3.7}$$

$$\mathbf{v}_i^{\mathrm{T}}\,\hat{\mathbf{v}}_{n'+j} = 0 \quad \text{for all} \quad 1 \leq i \leq n',\ 1 \leq j \leq m_{\mathrm{c}}(n'). \tag{3.8}$$

We need to show that the relations (3.4)–(3.6) are satisfied.

Since $\mathbf{v}_n = \hat{\mathbf{v}}_n / \|\hat{\mathbf{v}}_n\|$, the orthogonality condition (3.4) for $\mathbf{v}_n$ is an immediate consequence of (3.8) (with $n' = n - 1$ and $j = 1$).

We now turn to (3.5). Note that at the end of the ith iteration of Algorithm 3.1, we have

$$\hat{\mathbf{v}}_{i+m_{\mathrm{c}}(i)}^{(i)} := \hat{\mathbf{v}}_{i+m_{\mathrm{c}}(i)} = \mathbf{A}\,\mathbf{p}_i - \mathbf{v}_i\,\delta_i. \tag{3.9}$$

Here, the upper index "(i)" indicates that $\hat{\mathbf{v}}_{i+m_{\mathrm{c}}(i)}^{(i)}$ is the $(i + m_{\mathrm{c}}(i))$th candidate vector at the end of the ith iteration. Note that, by (3.9) and (3.4), we have

$$\mathbf{v}_n^{\mathrm{T}}\,\mathbf{A}\,\mathbf{p}_i = \mathbf{v}_n^{\mathrm{T}}\left(\hat{\mathbf{v}}_{i+m_{\mathrm{c}}(i)}^{(i)} + \mathbf{v}_i\,\delta_i\right) = \mathbf{v}_n^{\mathrm{T}}\,\hat{\mathbf{v}}_{i+m_{\mathrm{c}}(i)}^{(i)} \quad \text{for all} \quad 1 \leq i < n. \tag{3.10}$$

Let $1 \leq i < n$ be arbitrary, but fixed, and consider the transformations that are performed on the candidate vector $\hat{\mathbf{v}}_{i+m_{\mathrm{c}}(i)}^{(i)}$ during iterations $i + 1, i + 2, \ldots, n$ of Algorithm 3.1. Note that there are only two types of transformations: shift of the (lower) index of the candidate vector by -1, and orthogonalization against previous Lanczos vectors. For the transformed vector resulting from $\hat{\mathbf{v}}_{i+m_{\mathrm{c}}(i)}^{(i)}$, there are the following three cases:

(I) The transformed vector is deflated during iteration $\tilde{n}$ for some $i < \tilde{n} \le n$.

(II) The transformed vector is one of the candidate vectors $\hat{\mathbf{v}}_n, \hat{\mathbf{v}}_{n+1}, \dots, \hat{\mathbf{v}}_{n-m_{\rm c}-1}$ before steps 2 and 3 are performed within the nth iteration of Algorithm 3.1.

(III) The transformed vector is normalized to become the kth Lanczos vector $\mathbf{v}_k$ for some $k < n$.

Case I occurs if and only if $i \in \mathcal{I}$. Indeed, let $\tilde{m}_{\rm c}$ be the value of $m_{\rm c}$ when the transformed vector $\hat{\mathbf{v}}_{\tilde{n}}$ is checked for deflation during iteration $\tilde{n}$. Since $\hat{\mathbf{v}}_{\tilde{n}}$ resulted from $\hat{\mathbf{v}}^{(i)}_{i+m_{\rm c}(i)}$, we have

$$\tilde{n} = i + m_{\rm c}(i) - (m_{\rm c}(i) - \tilde{m}_{\rm c}) = i + \tilde{m}_{\rm c},$$

and thus $i = \tilde{n} - \tilde{m}_{\rm c} > 0$. By step 1(a) of Algorithm 3.1, deflation of the vector $\hat{\mathbf{v}}_{\tilde{n}}$ is equivalent to $i = \tilde{n} - \tilde{m}_{\rm c} \in \mathcal{I}$. Moreover, note that $\hat{\mathbf{v}}^{\rm df}_i = \hat{\mathbf{v}}_{\tilde{n}}$ and that $\hat{\mathbf{v}}_{\tilde{n}}$ was obtained by orthogonalizing $\hat{\mathbf{v}}^{(i)}_{i+m_{\rm c}(i)}$ against Lanczos vectors $\mathbf{v}_k$ with $k < \tilde{n} \le n$. In view of (3.4) and step 4 of Algorithm 3.1, it follows that

$$\mathbf{v}_n^{\rm T}\, \hat{\mathbf{v}}^{(i)}_{i+m_{\rm c}(i)} = \mathbf{v}_n^{\rm T}\, \hat{\mathbf{v}}^{\rm df}_i = \delta_i\, u_{in} \quad \text{if} \quad i \in \mathcal{I}. \tag{3.11}$$

Case II occurs if and only if $i \ge j_0 := \max\{1,\, n - m_{\rm c}\}$. Indeed, the transformed vector has index $i + m_{\rm c}$ and is thus one of the candidate vectors $\hat{\mathbf{v}}_n, \dots, \hat{\mathbf{v}}_{n-m_{\rm c}-1}$ if and only if

$$n \le i + m_{\rm c} \le n - m_{\rm c} - 1. \tag{3.12}$$

Since $1 \le i < n$, the condition (3.12) is equivalent to $i \ge j_0$. Note that, in view of (3.4) and steps 2 and 3 of Algorithm 3.1, we have

$$\mathbf{v}_n^{\rm T}\, \hat{\mathbf{v}}^{(i)}_{i+m_{\rm c}(i)} = \mathbf{v}_n^{\rm T}\, \hat{\mathbf{v}}_{i+m_{\rm c}} = \delta_i\, u_{in} \quad \text{if} \quad i \ge j_0. \tag{3.13}$$

Case III complements cases I and II, and thus occurs if and only if $i < j_0$ and $i \notin \mathcal{I}$. In this case, in view of (3.4), we have

$$\mathbf{v}_n^{\rm T}\, \hat{\mathbf{v}}^{(i)}_{i+m_{\rm c}(i)} = \mathbf{v}_n^{\rm T}\, \hat{\mathbf{v}}_k = \left(\mathbf{v}_n^{\rm T}\, \mathbf{v}_k\right)\, \|\hat{\mathbf{v}}_k\| = 0. \tag{3.14}$$

Here, $k < n$ is the index of the Lanczos vector $\mathbf{v}_k$ that resulted from $\hat{\mathbf{v}}^{(i)}_{i+m_{\rm c}(i)}$.

By combining (3.10) with (3.11), (3.13), and (3.14), we get

$$\mathbf{v}_n^{\rm T}\, \mathbf{A}\, \mathbf{p}_i = \mathbf{v}_n^{\rm T}\, \hat{\mathbf{v}}^{(i)}_{i+m_{\rm c}(i)} = \begin{cases} \delta_i\, u_{in} & \text{if} \quad i \in \mathcal{I} \quad \text{or} \quad j_0 \le i < n, \\ 0 & \text{if} \quad i < j_0 \quad \text{and} \quad i \notin \mathcal{I}. \end{cases} \tag{3.15}$$

On the other hand, by transposing the relation (3.1), multiplying it from the right by $\mathbf{A}\, \mathbf{p}_i$, and using (3.3) and (3.7), it follows that

$$\mathbf{p}_n^{\rm T}\, \mathbf{A}\, \mathbf{p}_i = \mathbf{v}_n^{\rm T}\, \mathbf{A}\, \mathbf{p}_i - \begin{cases} \delta_i\, u_{in} & \text{if} \quad i \in \mathcal{I} \quad \text{or} \quad j_0 \le i < n, \\ 0 & \text{if} \quad i < j_0 \quad \text{and} \quad i \notin \mathcal{I}. \end{cases} \tag{3.16}$$

Inserting (3.15) into (3.16) gives (3.5).

Finally, we show (3.6). Note that $m_{\rm c}(i)$ is a nonincreasing function of i, and in particular, $m'_{\rm c} \ge m_{\rm c}(n) =: m_{\rm c}$. By (3.8) (for $n' = n - 1$ and $2 \le j \le m_{\rm c}$), the candidate vectors $\hat{\mathbf{v}}_{n+1}, \dots, \hat{\mathbf{v}}_{n+m_{\rm c}-1}$ are orthogonal to $\mathbf{v}_1, \dots, \mathbf{v}_{n-1}$ before step 3 is performed within the nth iteration of Algorithm 3.1. The update

$$\hat{\mathbf{v}}_{n+j} = \hat{\mathbf{v}}_{n+j} - \mathbf{v}_n\, \left(\mathbf{v}_n^{\rm T}\, \hat{\mathbf{v}}_{n+j}\right), \quad 1 \le j < m_{\rm c}, \tag{3.17}$$

in step 3 then makes these candidate vectors also orthogonal to $\mathbf{v}_n$. Moreover, in view of (3.4), the update (3.17) does not destroy the orthogonality to $\mathbf{v}_1, \ldots, \mathbf{v}_{n-1}$, and thus (3.6) is satisfied for all $1 \leq j < m_{\rm c}$. In order to prove (3.6) for $j = m_{\rm c}$, we first note that, by (3.9) (for $i = n$),

$$\hat{\mathbf{v}}_{n+m_{\rm c}} = \mathbf{A}\,\mathbf{p}_n - \mathbf{v}_n\,\delta_n.$$

Multiplying this relation from the left by $\mathbf{v}_i^{\rm T}$ and using (2.6), (3.4), and (3.5), it follows that

$$\mathbf{v}_i^{\rm T}\,\hat{\mathbf{v}}_{n+m_{\rm c}} = \mathbf{v}_i^{\rm T}\,\mathbf{A}\,\mathbf{p}_n - \left(\mathbf{v}_i^{\rm T}\,\mathbf{v}_n\right)\,\delta_n = 0 \quad \text{for all} \quad 1 \leq i < n.$$

We have thus established all three relations (3.4)–(3.6), and the proof of Theorem 3.3 is complete. □

4. Application to passive reduced-order modeling.

In this section, we discuss the application of the band Lanczos process with coupled recurrences to construct passive reduced-order models.

4.1. The problem.

Consider *symmetric* m-input m-output time-invariant linear dynamical systems of the form

$$\begin{aligned} \mathbf{C}\,\frac{d}{dt}\mathbf{x}(t) &= -\mathbf{G}\,\mathbf{x}(t) + \mathbf{B}\,\mathbf{u}(t), \\ \mathbf{y}(t) &= \mathbf{B}^{\rm T}\,\mathbf{x}(t). \end{aligned} \tag{4.1}$$

Here, $\mathbf{C} = \mathbf{C}^{\rm T}$, $\mathbf{G} = \mathbf{G}^{\rm T} \in \mathbb{R}^{N \times N}$, and $\mathbf{B} \in \mathbb{R}^{N \times m}$ are given matrices. Moreover, we assume that the matrix pencil $\mathbf{G} + s\,\mathbf{C}$ is *regular*, i.e., $\det(\mathbf{G} + s\,\mathbf{C}) = 0$ for only finitely many values of $s \in \mathbb{C}$. In (4.1), the components of the given vector-valued function $\mathbf{u}\colon [0,\infty) \mapsto \mathbb{R}^m$ are the inputs, $\mathbf{y}\colon [0,\infty) \mapsto \mathbb{R}^m$ is the unknown function of outputs, the components of the unknown vector-valued function $\mathbf{x}\colon [0,\infty) \mapsto \mathbb{R}^N$ are the state variables, and N is the state-space dimension. Systems of the form (4.1) can be used to model so-called RCL electrical networks consisting of resistors, capacitors, and inductors; see, e.g., [14] and the references given there. An important special case is RC networks consisting of only resistors and capacitors; in this case, the matrices $\mathbf{C}$ and $\mathbf{G}$ in (4.1) are sparse and positive semidefinite.

A *reduced-order model* of (4.1) is a system of the same form as (4.1) but of smaller state-space dimension $n < N$. A reduced-order model of dimension n is thus of the form

$$\begin{aligned} \mathbf{C}_n\,\frac{d}{dt}\mathbf{z}(t) &= -\mathbf{G}_n\,\mathbf{z}(t) + \mathbf{B}_n\,\mathbf{u}(t), \\ \mathbf{y}(t) &= \mathbf{B}_n^{\rm T}\,\mathbf{x}(t), \end{aligned} \tag{4.2}$$

where $\mathbf{C}_n = \mathbf{C}_n^{\rm T}$, $\mathbf{G}_n = \mathbf{G}_n^{\rm T} \in \mathbb{R}^{n \times n}$, and $\mathbf{B}_n \in \mathbb{R}^{n \times m}$. These three matrices should be chosen such that the input-output mapping $\mathbf{u}(t) \mapsto \mathbf{y}(t)$ of (4.2) somehow approximates the input-output mapping of the original system (4.1).

The input-output behavior of the original system (4.1), respectively, the reduced-order model (4.2), can be described by the associated *transfer function*

$$\mathbf{Z}(s) = \mathbf{B}^{\rm T}(\mathbf{G} + s\,\mathbf{C})^{-1}\mathbf{B}, \quad \text{respectively,} \quad \mathbf{Z}_n(s) = \mathbf{B}_n^{\rm T}(\mathbf{G}_n + s\,\mathbf{C}_n)^{-1}\mathbf{B}_n, \tag{4.3}$$

where $s \in \mathbb{C}$ is a complex variable. Note that both $\mathbf{Z}$ and $\mathbf{Z}_n$ are $(m \times m)$-matrix-valued rational functions.

Now, let $s_0 \in \mathbb{C}$ be any expansion point such that the matrix $\mathbf{G} + s_0\,\mathbf{C}$ is nonsingular. The transfer function $\mathbf{Z}_n$ is called an *nth matrix-Padé approximant* of $\mathbf{Z}$ (about the expansion point s_0) if the matrices $\mathbf{C}_n$, $\mathbf{G}_n$, and $\mathbf{B}_n$ in (4.3) are chosen such that

$$\mathbf{Z}_n(s) = \mathbf{Z}(s) + \mathcal{O}\big((s - s_0)^{q(n)}\big), \tag{4.4}$$

where the integer $q(n)$ is as large as possible; see, e.g., [7, pp. 429–466]. The condition (4.4) means that the Taylor expansions of $\mathbf{Z}_n$ and $\mathbf{Z}$ about s_0 agree in as many leading ($(m \times m)$-matrix-valued) coefficients as possible. In what follows, we call the reduced-order model (4.2) of (4.1) a *matrix-Padé model* (associated with the expansion point s_0) if its transfer function $\mathbf{Z}_n$ is an nth matrix-Padé approximant of $\mathbf{Z}$.

4.2. Reduced-order models via the symmetric band Lanczos process. In what follows, we assume that the matrices $\mathbf{C}$ and $\mathbf{G}$ in (4.1) are sparse and positive semidefinite. Moreover, let $s_0 \geq 0$ be any real expansion point such that $\mathbf{G}+s_0\,\mathbf{C} > 0$, and let

$$\mathbf{G} + s_0\,\mathbf{C} = \mathbf{M}\,\mathbf{M}^{\mathrm{T}} \tag{4.5}$$

be a sparse Cholesky factorization of $\mathbf{G} + s_0\,\mathbf{C}$. Note that, in general, $\mathbf{M}$ is a product of a permutation matrix, which records any pivoting for sparsity, and a sparse lower triangular matrix. Using (4.5), the transfer function $\mathbf{Z}$ in (4.3) can be recast as follows:

$$\begin{gathered} \mathbf{Z}(s) = \mathbf{R}^{\mathrm{T}}\,(\mathbf{I} + (s - s_0)\,\mathbf{A})^{-1}\,\mathbf{R}, \\ \text{where} \quad \mathbf{A} := \mathbf{M}^{-1}\,\mathbf{C}\,\mathbf{M}^{-\mathrm{T}} \geq 0 \quad \text{and} \quad \mathbf{R} := \mathbf{M}^{-1}\,\mathbf{B}. \end{gathered} \tag{4.6}$$

In [17, 18], it was proposed to obtain reduced-order models via the symmetric band Lanczos process applied to the matrix $\mathbf{A}$ and the block of starting vectors $\mathbf{R}$ given in (4.6). More precisely, after $n\,(\geq m_1)$ iterations of the algorithm, a reduced-order transfer function of dimension n is defined as follows:

$$\mathbf{Z}_n(s) = \boldsymbol{\rho}_n^{\mathrm{T}}\,(\mathbf{I}_n + (s - s_0)\,\mathbf{T}_n))^{-1}\,\boldsymbol{\rho}_n, \quad \text{where} \quad \boldsymbol{\rho}_n = \begin{bmatrix} \boldsymbol{\rho}_{m_1} \\ \mathbf{0}_{n-m_1\times m} \end{bmatrix}. \tag{4.7}$$

Here, $\mathbf{T}_n$ is the $n\times n$ projected Lanczos matrix and $\boldsymbol{\rho}_n$ is the $m_1\times m$ matrix containing the coefficients used to orthogonalize the starting block $\mathbf{R}$. In [17, 18], the standard symmetric band Lanczos process was used to generate $\mathbf{T}_n$ and $\boldsymbol{\rho}_n$, and the resulting algorithm was termed SyMPVL.

Here, we propose to employ the symmetric band Lanczos process based on coupled recurrences, instead of the standard algorithm, and we call the resulting computational procedure SyMPVL2.

Algorithm 4.1 (SyMPVL2).

```
INPUT: Matrices $\mathbf{C}$, $\mathbf{G} \in \mathbb{R}^{N\times N}$ such that $\mathbf{C}$, $\mathbf{G} \geq \mathbf{0}$ and $\mathbf{G}+s\,\mathbf{C}$ is a regular pencil.
       A matrix $\mathbf{B} \in \mathbb{R}^{N\times m}$.
OUTPUT: Transfer function $\mathbf{Z}_n$ of a reduced-order model of dimension $n$.
    (1) Select expansion point $s_0 \geq 0$ with $\mathbf{G} + s_0\,\mathbf{C} > \mathbf{0}$.
    (2) Compute Cholesky decomposition $\mathbf{G} + s_0\,\mathbf{C} = \mathbf{M}\,\mathbf{M}^{\mathrm{T}}$.
    (3) Run $n\,(\geq m_1)$ iterations of Algorithm 3.1 (applied to $\mathbf{A} := \mathbf{M}^{-1}\,\mathbf{C}\,\mathbf{M}^{-\mathrm{T}}$
        and $\mathbf{R} := \mathbf{M}^{-1}\,\mathbf{B}$) to generate matrices $\mathbf{U}_n$, $\boldsymbol{\Delta}_n$, and $\boldsymbol{\rho}_{m_1}$.
```

(4) *Set*

$$\mathbf{Z}_n(s) = \boldsymbol{\rho}_n^{\mathrm{T}} \left(\mathbf{I}_n + (s - s_0)\, \mathbf{U}_n^{\mathrm{T}}\, \boldsymbol{\Delta}_n\, \mathbf{U}_n\right)^{-1} \boldsymbol{\rho}_n, \quad \textit{where} \quad \boldsymbol{\rho}_n = \begin{bmatrix} \boldsymbol{\rho}_{m_1} \\ \mathbf{0}_{n-m_1 \times m} \end{bmatrix}.$$

Remark 4.1. As we mentioned in section 2.7, the standard band Lanczos process and the algorithm based on coupled recurrences are mathematically equivalent in the case that no deflation occurs or that only exact deflation is performed. Consequently, in this case, SyMPVL and SyMPVL2 are mathematically equivalent. Furthermore, in [13, 18], it was shown that the reduced-order model defined by the transfer function (4.7) is a matrix-Padé model.

4.3. Passivity. Linear dynamical systems of the form (4.1) with $\mathbf{C}$, $\mathbf{G} \geq \mathbf{0}$ are *passive*. Roughly speaking, a system (4.1) is passive if it does not generate energy. In terms of the transfer function (4.3), $\mathbf{Z}$, passivity of (4.1) is equivalent to the *positive realness* of $\mathbf{Z}$; see, e.g., [2, 27]. A precise definition of positive realness is as follows.

Definition 4.2 (positive realness). *An* $(m \times m)$*-matrix-valued rational function* $\mathbf{Z}$ *is called positive real if*

(i) $\mathbf{Z}$ *has no poles in* $\mathbb{C}_+ := \{\, s \in \mathbb{C} \mid \mathrm{Re}(s) > 0 \,\}$*;*

(ii) $\mathbf{Z}(\bar{s}) = \overline{\mathbf{Z}(s)}$ *for all* $s \in \mathbb{C}$*;*

(iii) $\mathrm{Re}\left(\mathbf{x}^{\mathrm{H}}\, \mathbf{Z}(s)\, \mathbf{x}\right) \geq 0$ *for all* $\mathbf{x} \in \mathbb{C}^m$ *and all* $s \in \mathbb{C}_+$*.*

Passivity is a stronger condition than stability of a linear dynamical system. When reduced-order models of passive linear subsystems are used within a simulation of a (not necessarily linear) system, then passivity of the reduced-order models is needed to guarantee stability of the overall simulation; see the references given in [16].

By [16, Theorem 13], a reduced-order model (4.2) with transfer function $\mathbf{Z}_n$ given by (4.3) is passive if $\mathbf{C}_n \geq \mathbf{0}$ and $\mathbf{G}_n \geq \mathbf{0}$. By applying this result to the reduced-order transfer function (4.7), it follows that passivity is guaranteed if

$$\mathbf{T}_n \geq \mathbf{0} \quad \text{and} \quad \mathbf{I}_n - s_0\, \mathbf{T}_n \geq \mathbf{0}. \tag{4.8}$$

In exact arithmetic, the two conditions (4.8) are always fulfilled. Indeed, the first relation in (4.8) follows from $\mathbf{T}_n = \mathbf{V}_n^{\mathrm{T}}\, \mathbf{A}\, \mathbf{V}_n$ and $\mathbf{A} \geq \mathbf{0}$, and the second relation in (4.8) follows from

$$\mathbf{M}\ (\mathbf{I}_N - s_0\, \mathbf{A})\ \mathbf{M}^{\mathrm{T}} = \mathbf{G} \geq \mathbf{0}$$

and

$$\mathbf{I}_n - s_0\, \mathbf{T}_n = \mathbf{V}_n^{\mathrm{T}}\ (\mathbf{I}_N - s_0\, \mathbf{A})\ \mathbf{V}_n \geq \mathbf{0}.$$

Unfortunately, in finite-precision arithmetic, round-off may cause the matrix $\mathbf{T}_n$ generated by the standard band Lanczos process to be indefinite. The negative eigenvalues of $\mathbf{T}_n$ translate into positive poles of $\mathbf{Z}_n$, causing the reduced-order model given by (4.7) to be nonpassive; see the examples given in section 4.4 below. This problem can easily be remedied by employing the SyMPVL2 Algorithm 4.1. Instead of $\mathbf{T}_n$, it generates an $\mathrm{LDL}^{\mathrm{T}}$ factorization, $\mathbf{U}_n^{\mathrm{T}}\, \boldsymbol{\Delta}_n\, \mathbf{U}_n$, of $\mathbf{T}_n$. In view of (2.9) and (2.19), we have $\boldsymbol{\Delta}_n \geq \mathbf{0}$ and thus the first relation in (4.8) is satisfied.

An important practical issue for the SyMPVL2 Algorithm 4.1 is to determine if the reduced-order model $\mathbf{Z}_n$ is a sufficiently good approximation to $\mathbf{Z}$ for some prescribed range of s. By applying the technique in [6] to the reduced-order transfer function $\mathbf{Z}_n$ generated by Algorithm 4.1, it is easy to verify the following result; see [5] for more details. For all s with $|s - s_0| < 1/\,\|\mathbf{A}\|$, we have

$$(4.9)\quad \|\mathbf{Z}(s) - \mathbf{Z}_n(s)\| \;\le\; |s - s_0|^2\, \|\mathbf{F}_m(s - s_0)\|^2\, \frac{\|\widehat{\mathbf{V}}_{m_{\mathrm{c}}}\|^2}{1 - |s - s_0|\;\|\mathbf{A}\|} + \mathcal{O}\left(\mathtt{dtol}_n\right).$$

Here, we set

$$\begin{aligned} \mathbf{F}_n(s - s_0) &:= \left[\, \mathbf{0}_{m_{\mathrm{c}} \times n - m_{\mathrm{c}}} \quad \mathbf{I}_{m_{\mathrm{c}}} \,\right] \left(\mathbf{I}_n + (s - s_0)\, \mathbf{U}_n^{\mathrm{T}}\, \boldsymbol{\Delta}_n\, \mathbf{U}_n\right)^{-1} \begin{bmatrix} \boldsymbol{\rho}_m^{\mathrm{T}} \\ \mathbf{0}_{n-m\times m} \end{bmatrix}, \\ \widehat{\mathbf{V}}_{m_{\mathrm{c}}} &:= \left[\, \hat{\mathbf{v}}_{n+1} \quad \hat{\mathbf{v}}_{n+2} \quad \cdots \quad \hat{\mathbf{v}}_{n+m_{\mathrm{c}}} \,\right]. \end{aligned}$$

In practice, we drop the last term, $\mathcal{O}\left(\mathtt{dtol}_n\right)$, in the error bound (4.9), and evaluate only the remaining terms. The $(m_{\mathrm{c}} \times m)$-matrix-valued function $\mathbf{F}_m(s - s_0)$ can be computed explicitly, and sufficiently good approximations of the norms $\|\mathbf{F}_m(s - s_0)\|$ and $\|\widehat{\mathbf{V}}_{m_{\mathrm{c}}}\|$ can easily be obtained, for instance, using the Matlab function `normest`. The norm $\|\mathbf{A}\|$ can be estimated by using the largest eigenvalue of the projected Lanczos matrix $\mathbf{U}_n^{\mathrm{T}}\, \boldsymbol{\Delta}_n\, \mathbf{U}_n$; see, e.g., [20, section 9.1.4].

We have performed extensive numerical tests with SyMPVL2 using the convergence check based on evaluating the error bound (4.9). We found that, typically, the computational costs for this convergence check is about 5% to 8% of the cost of the underlying symmetric band Lanczos process.

4.4. Numerical examples. In this subsection, we present results of three numerical examples that demonstrate the superiority, in terms of both robustness and accuracy, of the SyMPVL2 Algorithm 4.1 based on coupled recurrences over the original SyMPVL algorithm [17, 18] based on the standard symmetric band Lanczos process.

All three examples are passive linear dynamical systems (4.1) describing RC networks arising in VLSI circuit simulation. The frequency range of interest is always $s = 2\pi\,\mathtt{i}\,\omega$, where $1 \le \omega \le 10^9$. The goal is to compute a reduced-order transfer function $\mathbf{Z}_n$ that approximates the transfer function $\mathbf{Z}$ of (4.1) well in this frequency range. In all three examples, $\mathbf{C} \ge \mathbf{0}$, $\mathbf{G} > 0$, and the expansion point $s_0 = 0$ is used. All experiments were performed in Matlab. The symmetric band Lanczos process was run with deflation tolerance (3.2), where $\mathtt{dtol} = \sqrt{\mathtt{eps}}$ and `eps` is the machine precision.

Example 4.1. In this example, $\mathbf{C}$ and $\mathbf{G}$ are matrices of order $N = 1346$, and $m = 10$. Both SyMPVL and SyMPVL2 required $n = 60$ iterations. However, the reduced-order model generated via SyMPVL is not passive, and not even stable. The reason is that the computed matrix $\mathbf{T}_{60}$ is indefinite, causing some positive poles of the transfer function $\mathbf{Z}_{60}$. On the other hand, SyMPVL2 generates a diagonal matrix $\boldsymbol{\Delta}_{60}$ with only positive diagonal entries, and the matrix $\mathbf{U}_{60}^{\mathrm{T}}\, \boldsymbol{\Delta}_{60}\, \mathbf{U}_{60}$ is positive definite. In particular, the transfer function $\mathbf{Z}_{60}$ does not have any positive poles. In Figure 1, we show the dominant poles of the reduced-order models obtained from SyMPVL and SyMPVL2, as well as the dominant poles of the transfer function $\mathbf{Z}$ of the original linear dynamical system. Note that SyMPVL not only generated two unstable poles, but also that one of the negative poles close to zero is wrong. In Figure 2, we plot the SyMPVL and SyMPVL2 errors $\|\mathbf{Z}(s) - \mathbf{Z}_{60}(s)\|$ for all $s = 2\pi\,\mathtt{i}\,\omega$, $1 \le \omega \le 10^9$. Clearly, the SyMPVL2 model is also more accurate than the SyMPVL model.

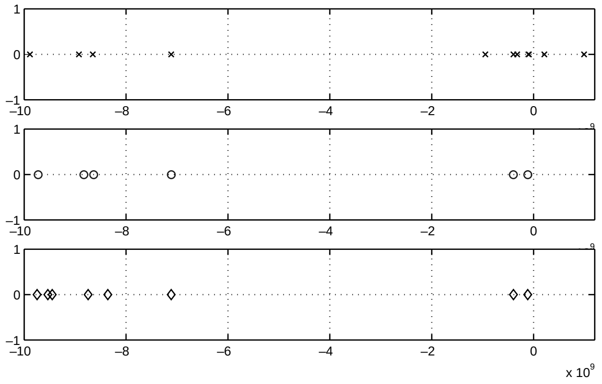

FIG. 1. *Dominant poles of SyMPVL reduced-order model* (*top*), *SyMPVL*2 *reduced-order model* (*middle*), *and the exact dominant poles* (*bottom*) *for Example* 4.1.

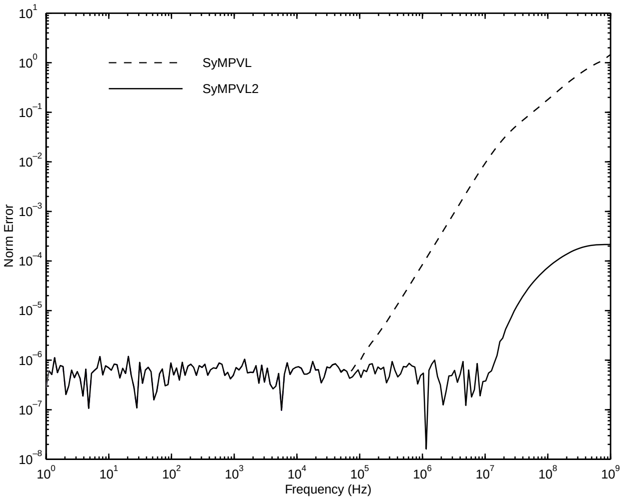

FIG. 2. *Error* $\|\mathbf{Z}(s) - \mathbf{Z}_n(s)\|$ *of SyMPVL and SyMPVL*2 *models for Example* 4.1.

Example 4.2. In this example, $\mathbf{C}$ and $\mathbf{G}$ are matrices of order $N = 13875$, and $m = 150$. A reduced-order model of dimension $n = 300$ is needed to achieve convergence in the frequency range of interest. Again, SyMPVL produced an indefinite matrix $\mathbf{T}_{300}$, resulting in some positive poles of $\mathbf{Z}_{300}$, while the reduced-order model generated via SyMPVL2 has no positive poles and is indeed passive. In Figure 3, we show the dominant poles of the reduced-order models obtained from SyMPVL and SyMPVL2.

Example 4.3. This example illustrates the behavior of the error bound (4.9). We use the same matrices $\mathbf{C}$ and $\mathbf{G}$ as in Example 4.2, but now $\mathbf{B}$ has only $m = 50$ columns. The left plot in Figure 4 shows the norm of the reduced-order transfer function $\mathbf{Z}_{300}(2\pi\, \mathtt{i}\, \omega)$ for the frequency range $1 \leq \omega \leq 10^9$. The right plot in Figure 4 shows the upper bound (4.9) for the corresponding error norm $\|\mathbf{Z}(s) - \mathbf{Z}_n(s)\|$ obtained after $n = 100$, 200, and 300 iterations of Algorithm 3.1.

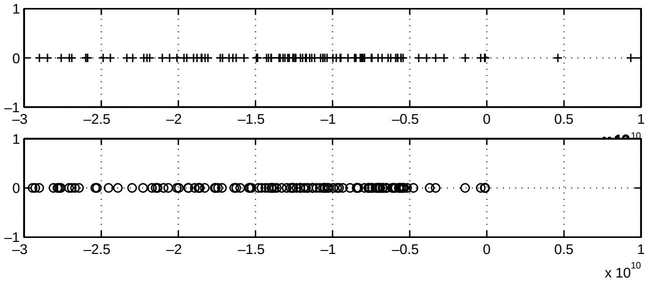

FIG. 3. *Dominant poles of SyMPVL reduced-order model* (*top*) *and SyMPVL*2 *reduced-order model* (*bottom*) *for Example* 4.2.

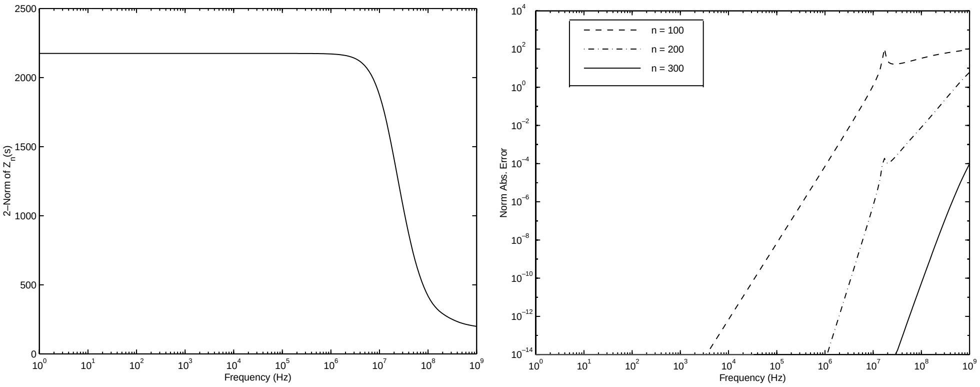

FIG. 4. $\|\mathbf{Z}_{300}(s)\|$ (*left*) *and upper bounds for* $\|\mathbf{Z}(s) - \mathbf{Z}_n(s)\|$ (*right*) *for Example* 4.3.

5. Application to eigenvalue computations. In this section, we present some preliminary numerical examples to illustrate the application of Algorithm 3.1 to the solution of generalized symmetric definite eigenvalue problems of the form

$$\mathbf{K}\,\mathbf{x} = \lambda\,\mathbf{M}\,\mathbf{x}, \tag{5.1}$$

where $\mathbf{K} = \mathbf{K}^{\mathrm{T}} \in \mathbb{R}^{N\times N}$, $\mathbf{M} = \mathbf{M}^{\mathrm{T}} \in \mathbb{R}^{N\times N}$, and $\mathbf{M} > \mathbf{0}$.

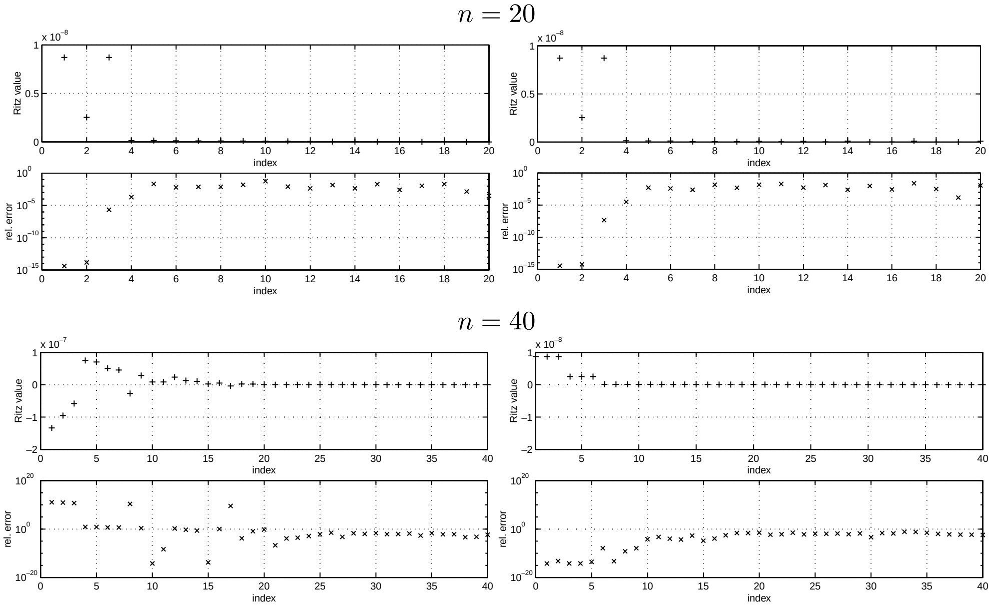
The usual approach is first to compute a Cholesky decomposition $\mathbf{M} = \mathbf{L}\,\mathbf{L}^{\mathrm{T}}$ of $\mathbf{M}$, and then convert (5.1) to the standard eigenvalue problem

$$\left(\mathbf{L}^{-1}\,\mathbf{K}\,\mathbf{L}^{-\mathrm{T}}\right)\,\mathbf{y} = \lambda\,\mathbf{y}, \quad \text{where} \quad \mathbf{y} := \mathbf{L}^{\mathrm{T}}\,\mathbf{x}. \tag{5.2}$$

The band Lanczos process is then applied to the symmetric matrix $\mathbf{A} := \mathbf{L}^{-1}\,\mathbf{K}\,\mathbf{L}^{-\mathrm{T}}$ and a random block $\mathbf{B} \in \mathbb{R}^{N\times m}$ of m starting vectors. Note that the Lanczos process requires only matrix-vector products with $\mathbf{A}$. These can be computed by means of multiplications with $\mathbf{K}$ and backsolves with $\mathbf{L}$ and $\mathbf{L}^{\mathrm{T}}$, without explicitly forming $\mathbf{A}$.

Next, we present two numerical examples. These experiments were performed in Matlab, and in both cases $m = 2$ starting vectors were used. In both examples, $\mathbf{K} \geq \mathbf{0}$, and hence the eigenvalues λ_k, $1 \leq k \leq N$, of (5.2) are all real and nonnegative.

Example 5.1. The matrices $\mathbf{K}$ and $\mathbf{M}$ in this example are of order $N = 1346$, and are taken from an application in circuit simulation. We ran both the standard symmetric band Lanczos process and the coupled Algorithm 3.1 for $n = 20$ and $n = 40$



$n = 20$

$n = 40$

FIG. 5. *The standard* (*left*) *and the coupled* (*right*) *band Lanczos process for Example* 5.1.

iterations. The Ritz values are then computed as the eigenvalues of the matrices $\mathbf{T}_n$ (for the standard algorithm) and $\mathbf{U}_n^{\mathrm{T}}\,\boldsymbol{\Delta}_n\,\mathbf{U}_n$ (for Algorithm 3.1). In Figure 5, we plot the computed Ritz values θ_i and their relative errors vs. their index i, $i = 1, 2, \ldots, n$, for both variants of the Lanczos process, and for $n = 20$ and 40. Here, the relative error of a computed Ritz value θ_i is defined as

$$\frac{\min_{1\le k\le N} |\theta_i - \lambda_k|}{|\lambda_{k_i}|}, \quad \text{where} \quad k_i := \operatorname{argmin}_{1\le k\le N} |\theta_i - \lambda_k|. \tag{5.3}$$

Note that for $n = 20$, the computed Ritz values and their relative errors for both variants of the band Lanczos process are essentially the same. However, for $n = 40$, the standard algorithm is significantly worse than the coupled algorithm, and even has generated negative Ritz values. On the other hand, all the Ritz values from the coupled Algorithm 3.1 are positive.

Example 5.2. In this example, **K** and **M** are 834 × 834 stiffness and mass matrices arising in a structural analysis within MSC's NASTRAN application. In Figure 6, we show the computed Ritz values, as well as their relative errors (5.3), that were obtained after $n = 40$ iterations of both variants of the band Lanczos process. Note that the standard algorithm produced one negative Ritz value, namely, θ_{30}, while all Ritz values from the coupled Algorithm 3.1 are positive.

6. Concluding remarks. We proposed a variant of the band Lanczos process for symmetric matrices and multiple starting vectors that uses coupled recurrences involving two sets of basis vectors, instead of the recurrences involving only one set in the standard algorithm. The new variant generates the factors of an LDL$^{\mathrm{T}}$ factorization of the Lanczos matrix, rather than the Lanczos matrix directly. Numerical experiments suggest that the coupled algorithm is superior to the standard algorithm both in terms of accuracy and robustness. However, a precise round-off error analysis

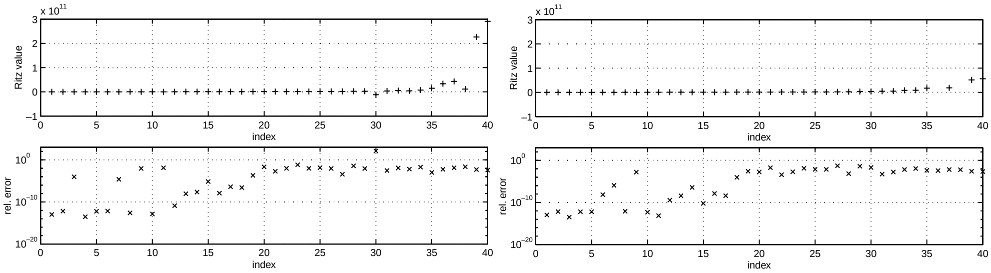


FIG. 6. *The standard* (*left*) *and the coupled* (*right*) *band Lanczos process for Example* 5.2.

that would provide a theoretical basis for the superiority of the coupled algorithm still remains to be done.

For a single starting vector, the symmetric band Lanczos process reduces to the classical symmetric Lanczos algorithm [23] and the Lanczos matrix is tridiagonal. In the last few years, it has gradually become clear that the standard representation of a tridiagonal matrix via its entries is an unfortunate one, and that it is better, for both accuracy and efficiency, to represent the matrix as a product of bidiagonals; see, e.g., [11, 24, 25]. This paper has demonstrated that the same is true for the Lanczos matrix associated with the symmetric band Lanczos process. Instead of representing that matrix via its entries, it is preferable to present it via the entries of an $\mathrm{LDL}^{\mathrm{T}}$ factorization.

Acknowledgments. We would like to thank Peter Feldmann for his help with some of the numerical examples. We are also grateful to an anonymous referee, whose constructive comments helped us to improve the presentation of the paper.

LARGE-SCALE NORMAL COORDINATE ANALYSIS FOR MOLECULAR STRUCTURES*

CHAO YANG[†], BARRY W. PEYTON[‡], DONALD W. NOID[§], BOBBY G. SUMPTER[§], AND ROBERT E. TUZUN[¶]

Abstract. We apply truncated RQ-iteration (TRQ) and the Jacobi–Davidson (JD) method to perform vibrational (eigenvalue) analysis for large-scale molecular systems. Both algorithms employ a preconditioned iterative solver to construct a low-dimensional subspace that contains desired vibrational modes. We discuss several strategies for speeding up the eigenvalue calculation. In particular, we illustrate how to construct effective preconditioners and analyze the quality of these preconditioners. We show that convergence can be improved by choosing appropriate shifts and deflating the translational and rotational modes. Numerical examples are provided to demonstrate the efficiency of our computation.

1. Introduction.

Normal coordinate analysis (NCA) [17, 26] plays an important role in the study of vibrational and thermal properties of various molecular structures at the atomic level. The molecular vibration at low temperatures can be analyzed by examining a collection of fundamental (normal) vibrational modes. These modes are essentially eigenvectors of a matrix that describes the atomic force interaction within the molecular system under study. Once NCA information is obtained, it becomes easier to link theoretical models to experimentally accessible macroscopic data to provide a straightforward interpretation of molecular events in the absence of classical chaos. The immediate applications of NCA include characterizing thermal stability of polymer materials [7] and assessing the dynamic role protein plays in the photosynthetic center of green plants [19]. The long-term benefits include the development of new materials that can be used for nano-manufacturing and bioengineering [8].

Until recently, the use of NCA has been limited to relatively small systems. This is partly due to the lack of efficient numerical algorithms and the limited computing

power on traditional sequential and parallel machines. In [16], we presented a numerical scheme that was based on a shift-invert Lanczos iteration. We reported the success of using this scheme to compute the lowest 100 vibrational modes for a 6000-atom (18000 degrees of freedom) polyethylene particle. This computation was performed on a single processor of NEC SX-4, a powerful vector machine with 2 Gflops peak performance and 2 GB of main memory. Although the performance we achieved on the SX-4 is quite satisfactory, the large amount of memory (450 MB) required to carry out this calculation makes it difficult to extend the current computation to larger molecular systems. To solve problems that are 10 or 100 times larger on existing machines, we must modify the algorithm to reduce memory usage.

Although force field modeling and calculation are crucial components of NCA, extracting eigenvalues and eigenvectors from the force interaction matrix constitutes the majority of the computational work. Therefore, the efficiency of NCA relies on fast algorithms for solving matrix eigenvalue problems. As will be shown in section 2, the force interaction matrix encountered in NCA is sparse, symmetric, and positive (semi-)definite.

In this paper we investigate the possibility of applying two recently developed algorithms—the truncated RQ-iteration (TRQ) [23, 27] and the Jacobi–Davidson (JD) method [20, 4]—to perform large-scale NCA. Both algorithms require far less memory than a shift-inverted Lanczos iteration. The experiments shown in section 6 demonstrate that these methods are quite effective in capturing the desired vibrational modes of a large-scale polymer system.

The paper is organized as follows. In the next section, we provide some mathematical background for NCA. Various approaches to the solution of large-scale eigenvalue problems are discussed in section 3. We point out the limitation of the Lanczos-type algorithms for this particular problem. We review TRQ and JD in section 4. The efficiency of TRQ and JD depends largely on the quality of preconditioners used to solve a linear system with a special structure. We discuss the construction of effective preconditioners and the use of deflation techniques in section 5. We show numerical results in section 6 to demonstrate the efficiency of these methods on NCA problems and point out additional techniques that can be used to improve the convergence rate. Finally, we give a few concluding remarks in section 7.

2. Problem formulation. The dynamics of a molecular system consisting of m atoms can be described by

$$\frac{d}{dt}\left(\frac{\partial T}{\partial \dot{q}_j}\right) + \left(\frac{\partial V}{\partial q_j}\right) = 0,$$

where T and V are total kinetic and potential energy of the system, respectively, and q_j is the mass adjusted displacement of an atom in one of the Cartesian coordinate directions. If we assume molecules vibrate near an equilibrium configuration, the equation of motion can be simplified to yield

$$\ddot{q} + Fq = 0,$$

where F is obtained by taking the second derivative of the potential with respect to the Cartesian coordinates, i.e.,

$$F_{i,j} = \frac{\partial^2 V}{\partial q_i \partial q_j}.$$

The standard technique for solving this second-order ODE is first to diagonalize F by computing its eigenvalues and eigenvectors. This allows us to decouple the system and solve each equation independently. Each eigenvector of F is called a normal (vibrational) mode and the corresponding eigenvalue is proportional to the vibrational frequency associated with that particular mode. This procedure of decomposing molecular vibration into a number of linearly independent modes is thus called normal coordinate (mode) analysis. It is well known that the near-equilibrium motion can often be captured by a linear combination of several low-frequency modes. Thus, our primary interest is to compute a number of smallest eigenvalues and corresponding eigenvectors of F.

Throughout this paper, we will focus on performing NCA on computer-generated polyethylene (PE) particles of various sizes. These particles are named as *pe*3*k*, *pe*6*k*, *pe*12*k*, and *pe*24*k*, where the trailing number represents the number of atoms in the particle. A 6000-atom particle model (*pe*6*k*) is shown in Figure 2.1. The structure of this model closely resembles droplet streams that can be generated experimentally [1, 11]. An m-atom particle involves $n = 3m$ degrees of freedom. Thus the dimension of the force interaction matrix F for the 6000-atom model is 18000.

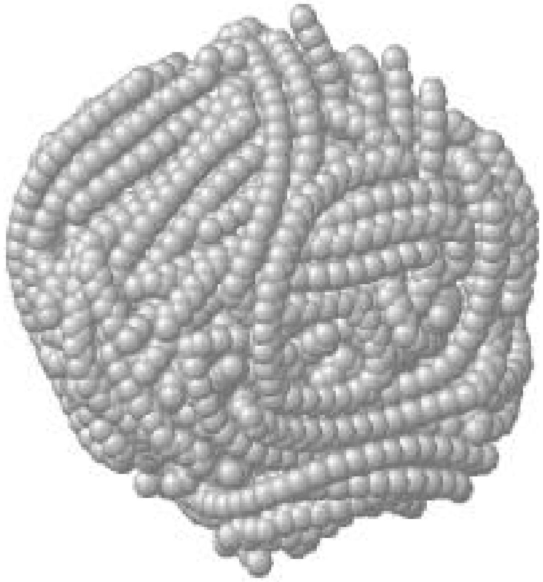

FIG. 2.1. *The structure of the pe6k particle.*

The potential field of PE particles is well understood. The interactions between atoms are categorized as either bonded or nonbonded. These interactions are often measured in terms of various angles and internal stretches. For example, the bonded interaction contributed by the ith atom can be expressed by

$$\begin{aligned} V_b^i(r_{i,i+1}, \theta_{i,i+1,i+2}, \tau_{i,i+1,i+2,i+3}) &= \frac{1}{2}k_r(r_{i+1,i} - r_0)^2 \\ &+ \frac{1}{2}k_\theta(\theta_{i,i+1,i+2} - \theta_0)^2 \\ &+ 8.77 + \alpha \cos \tau_{i,i+1,i+2,i+3} + \beta \cos^3 \tau_{i,i+1,i+2,i+3}, \end{aligned}$$

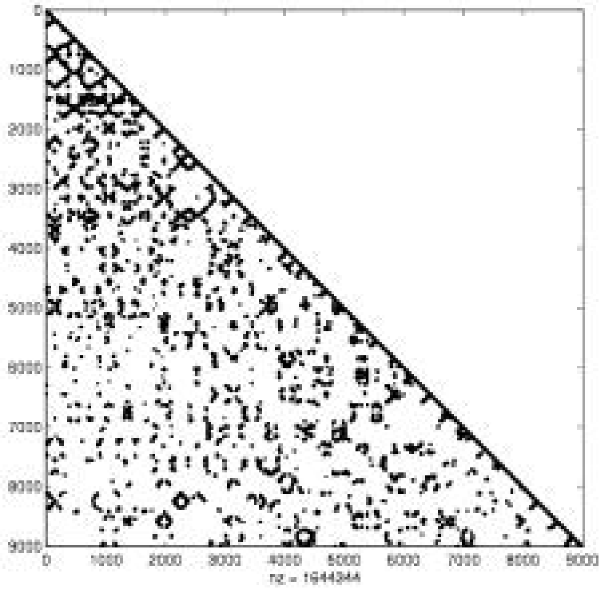

FIG. 2.2. *The nonzero pattern of the lower triangular part of F for pe3k.*

where k_r, k_θ, α, and β are force constant parameters and r_0 and θ_0 are equilibrium values of the bond length and angle. The 2-atom bonded stretch $r_{i,i+1}$ measures the displacement along the line segment connected by atom i and $i+1$. Atoms i, $i+1$, and $i+2$ form a bending angle $\theta_{i,i+1,i+2}$ centered at atom $i+1$. The quantity $\tau_{i,i+1,i+2,i+3}$ represents a 4-atom torsional angle.

The interaction between two atoms not directly bonded is represented by the following Lennard–Jones type of potential function:

$$\hat{V}_{nb} = 4\epsilon\left[\left(\frac{\sigma}{r_{ij}}\right)^{12} - \left(\frac{\sigma}{r_{ij}}\right)^{6}\right],$$

where r_{ij} is the distance between atom i and j, and σ and ϵ are Lennard–Jones parameters. The nonbonded interaction is often neglected when the distance between two atoms is beyond a certain threshold. The cutoff distance we used for PE particle in our experiment is 10 angstrom.

To form the force interaction matrix, one must calculate the derivatives of V with respect to the Cartesian coordinates (x,y,z). The brute force approach of expressing V in terms of x, y, and z before taking derivatives is very time-consuming. A more efficient computational scheme is presented in [24] to speed up the calculation. The details on efficient derivative calculation is beyond the scope of this paper. We refer readers to [24, 25] for more information.

Because the long-range nonbonded interactions are neglected, the force constant matrix is sparse. Since the second derivative of our potential is independent of the order in which it is taken, F is symmetric. The nonzero structure of the lower triangular portion of F for a 3000-atom PE particle is shown in Figure 2.2. The sparsity of F allows us to perform the matrix-vector mulitplication $y \leftarrow Fx$ efficiently.

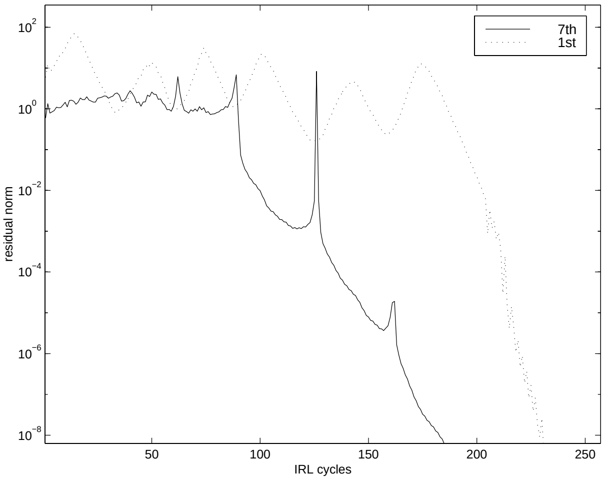

FIG. 3.1. *The relative residual history of the* 1*st and* 7*th approximate eigenpairs of* F *computed by IRL.*

3. Implicitly restarted Lanczos and shift-invert. Because F is fairly sparse, and because we are only interested in a small number of eigenpairs of F (around 100), it is natural to apply the Lanczos algorithm [12] to calculate the desired vibrational modes. The implicit restarting mechanism [21] implemented in the ARPACK software [13] allows us to further reduce memory usage by maintaining and repeatedly updating a *Krylov subspace* of low dimension. The approximate eigenpairs of F are obtained by projecting F into this low-dimensional subspace and solving a smaller eigenvalue problem.

Our first attempt at using ARPACK to perform large-scale NCA turned out to be somewhat disappointing. In Figure 3.1, we plot the convergence history of the first and the seventh approximate eigenpairs (θ_1, u_1) and (θ_7, u_7). Each curve records relative residual norms

$$\frac{\|Fu_i - \theta_i u_i\|}{|\theta_i|}$$

measured at the end of each implicit restarting cycle. The dimension of the Krylov subspace constructed in the implicitly restarted Lanczos (IRL) process is $\mathtt{ncv} = 100$. For this particular run, we requested $\mathtt{nev} = 50$ eigenpairs. The convergence tolerance is set to $\mathtt{etol} = 10^{-8}$. Thus, the number of matrix-vector products used in each IRL cycle is roughly 50. At the end of 300 IRL cycles, only 20 eigenpairs converged. The residual curves show some irregular bumps during the course of convergence. This phenomenon usually indicates that IRL detects nearby eigenpairs first before it converges to the desired one. It is not difficult to see, after examining the full spectrum of F, why IRL converges slowly. We observe from Figure 3.2 that the relative gaps between adjacent eigenvalues at the low end of the spectrum are tiny. The lowest six eigenvalues are nearly zero. The small magnitude of these eigenvalues is expected. In fact, if F is formed exactly, these eigenvalues should be exactly zero. The corresponding eigenvectors represent the pure translational and rotational motion of the entire molecular system. It is well known that small relative gaps between eigenvalues at the low end of the spectrum make it harder for IRL to construct a

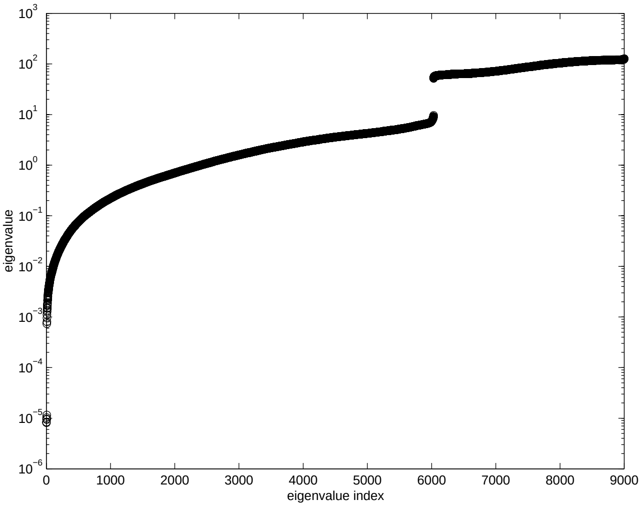

FIG. 3.2. *The full spectrum of pe3k.*

polynomial filter that can effectively separate the desired vibrational modes from the unwanted ones [13].

A commonly used strategy for speeding up the calculation of clustered or interior eigenvalues is to apply IRL to the shifted and inverted matrix $(F - \sigma I)^{-1}$, where σ is a target shift near the eigenvalues of interest. Instead of performing a sparse matrix-vector multiplication, we must solve sparse triangular systems at each Lanczos step using the sparse triangular factors computed in advance. The shifted matrix is often decomposed as $F - \sigma I = LDL^T$, where L is unit lower triangular and D is diagonal. The matrix L contains nonzero "fill-ins" produced by Gaussian elimination and thus requires more memory than that for F. Although significant progress has been made in the past few years on direct algorithms for solving large sparse linear systems [3, 9], decomposing $F - \sigma I$ into sparse triangular factors and solving sparse triangular systems still constitute a large portion of the computational effort in shift-invert Lanczos. However, our experiments show that, at least for problems of moderate size, shift-invert Lanczos is quite efficient compared to the straightforward application of IRL to F. In Table 3.1, we list CPU seconds and memory usage required to compute the lowest 100 vibrational modes of *pe*6*k*. The computation is carried out on a NEC SX-4 vector processor with 2 Gflop peak performance and 8 GB of shared memory. We observe that shift-invert is almost 20 times faster than the direct usage of IRL. Unfortunately, the large amount of memory required to store L makes it more difficult to perform NCA for larger molecular systems on current high-performance computers. Table 3.2 shows the CPU time and memory required to perform NCA on PE particles with various sizes. The first column of the table represents the dimension of F. A multilevel nested dissection matrix ordering scheme is used to reduce the amount of fill-ins in the sparse matrix factorization [10]. We observe that more than 3 GB of memory is needed to carry out NCA for a PE particle with 24000 atoms. Multifrontal codes require even more memory for intermediate stacks. This is quite demanding for a problem that is still relatively small compared to what we would like to tackle (molecular systems with 300,000 atoms).

An alternative to shift-invert is to apply IRL to $p(F)$, where $p(\lambda)$ is a polynomial

Table 3.1

The CPU time and memory required to compute the lowest 100 *vibrational modes of a* 6000-*atom PE particle.*

n	CPU time (seconds)	Memory (MB)
9000	145	224
18000	515	459
36000	1472	1333
72000	3432	3213

constructed to enhance the eigenvalue distribution. Typically, $p(\lambda)$ is chosen to map the small eigenvalues F to dominant eigenvalues of $p(F)$ [22]. However, when the condition number of F is large, it is difficult to find a low degree polynomial that can effectively separate the desired eigenvalues from the unwanted ones. Nevertheless, Table 3.1 indicates that polynomial transformation appears to be a reasonable compromise between the direct-use IRL and shift-invert IRL.

Another potential way to overcome the memory limitation is to parallelize the eigenvalue calculation on distributed-memory multiprocessors or a network of workstations [28]. We will not discuss parallelization issues in this paper.

4. JD and TRQ.

In the last few years, several algorithms [4, 20, 23] have been developed to address the computation of clustered or interior eigenvalues of large-scale problems without performing complete sparse matrix factorizations. The JD algorithm [4, 20] and the inexact TRQ (ITRQ) iteration [23, 27] are among the most successful ones. Both algorithms use preconditioned iterative solvers to generate and update a subspace similar to the one that is produced by a shift-invert Lanczos iteration. Neither method requires linear systems to be solved to high accuracy. In JD, the approximation subspace is no longer a Krylov subspace, and basis vectors are generated through a successive eigenvector correction process. The ITRQ iteration uses a preconditioned iterative solver to modify the starting vector of a restarted Lanczos process so that the leading columns of the Lanczos basis matrix converge quickly to desired eigenvectors. We review some of the basic concepts of these methods in this section.

4.1. The JD algorithm.

Suppose an approximate eigenvector $u \in \mathbb{R}^{n\times 1}$, $\|u\| = 1$, and its associated Rayleigh quotient

$$\theta = u^T F u$$

have been computed. One way to improve the current approximation is to seek a correction pair (γ, z), where $\gamma \in \mathbb{R}$ and $z \in \mathbb{R}^{n\times 1}$, such that

$$F(u+z) = (\theta+\gamma)(u+z) \quad \text{and} \quad u^T z = 0. \tag{4.1}$$

It follows that

$$(F - \theta I)z - \gamma u = -r + \gamma z,$$

```
Algorithm. Jacobi–Davidson.

Input: jmin, jmax, matrix $F$, initial eigenvector approximation $u$.
Output: approximate eigenpair $(\theta, u)$ such that $\|Fu - \theta u\|$ is small.

1. $u \leftarrow u/\|u\|$, $\theta \leftarrow u^H Fu$; converged $\leftarrow$ FALSE;
2. $V \leftarrow (u)$; $H \leftarrow (\theta)$; jstart $\leftarrow 1$;
3. while not converged do
  3.1 for $j =$ jstart, jstart + 1, ..., jmax
    3.1.1 Solve the correction equation (4.2) to obtain $z$;
    3.1.2 $z \leftarrow (I - VV^H)z$;
    3.1.3 $V \leftarrow (V, z)$; $H \leftarrow V^H FV$;
    3.1.4 Compute all eigenpairs of $H$, and select a desired pair $(\theta, s)$;
    3.1.5 Put $u \leftarrow Vs$;
    3.1.6 if $\|Fu - \theta u\| <$ some tolerance, converged $\leftarrow$ TRUE, goto 4;
  3.2 end for;
  3.3 Restart: replace $V$ with jmin desired Ritz vectors;
  3.4 $H \leftarrow V^H FV$; jstart $\leftarrow$ jmin $+ 1$; goto 3;
4. end while;
```

Fig. 4.1. *The JD iteration.*

where $r = Fu - \theta u$. If we drop the second order correction γz, z and γ can be determined by solving the following linear equation:

$$\begin{pmatrix} F - \theta I & u \\ u^T & 0 \end{pmatrix} \begin{pmatrix} z \\ -\gamma \end{pmatrix} = \begin{pmatrix} -r \\ 0 \end{pmatrix}. \tag{4.2}$$

The solution to this equation may be viewed as a Newton correction to the initial approximation to the solution of the nonlinear equation (4.1). Once z is computed, it can be adjoined to the approximate eigenvector u to form an augmented subspace

$$\mathcal{S} = \text{span}\{u, z\},$$

from which a better approximation, (θ^+, u^+), to the desired eigenpair of F can be extracted. If the new residual $r^+ = Fu^+ - \theta^+ u^+$ remains large, we can repeat the correction procedure and further expand $\mathcal{S}$ with an additional correction vector. To promote numerical stability, the new correction vector is orthogonalized against all previously generated basis vectors of $\mathcal{S}$. As the dimension of $\mathcal{S}$ becomes large, it may be necessary to truncate the correction sequence and retain only a few basis vectors of $\mathcal{S}$. The correction process then continues, and new correction vectors are appended to the truncated subspace $\mathcal{S}$. The details of this algorithm are described in [4, 20]. For completeness, we list the main steps of this subspace correction procedure in Figure 4.1.

Clearly, the most time-consuming part of this correction scheme is to solve the bordered linear system (4.2). One can easily show that if (4.2) is solved exactly, then

$$z = -u + \gamma(F - \theta I)^{-1}u,$$

```
ALGORITHM. IMPLICITLY SHIFTED RQ-ITERATION.

Input: $(F, V, H)$ with $FV = VH$, $V^H V = I$, and $H$ is upper
          Hessenberg.
Output: $(V, H)$ such that $FV = VH, V^T V = I$ and $H$ is upper triangular.

1. for $j = 1, 2, 3, \ldots$ until converged,
   1.1. Select a shift $\mu \leftarrow \mu_j$;
   1.2. Factor $H - \mu I = RQ$; ($R$ is triangular and $Q$ is orthogonal)
   1.3. $H \leftarrow QHQ^T$ ; $V \leftarrow VQ^T$;
2. end;
```

Fig. 4.2. *Implicitly shifted RQ-iteration.*

where $\gamma = \frac{u^T(F-\theta I)^{-1}r}{u^T(F-\theta I)^{-1}u}$. If we simply add the correction vector to u, it follows that

$$u \leftarrow \gamma(F - \theta I)^{-1}u,$$

which indicates the close relationship between the above correction procedure and an inverse iteration.

To reduce the cost associated with solving (4.2), Sleijpen and Van der Vorst [20] suggested solving the correction equation by a preconditioned iterative method. They expressed z as the solution to the projected equation

$$(I - uu^T)(F - \theta I)(I - uu^T)z = -(I - uu^T)r. \tag{4.3}$$

Since z is merely used as a basis vector of $\mathcal{S} = \operatorname{span}\{V\}$, it is not necessary to solve (4.3) to full accuracy. Thus JD can be viewed as an inner-outer iteration. The outer iteration provides eigenvalue and eigenvector approximations through the standard Rayleigh–Ritz procedure [18]. Each inner iteration provides a new basis vector of $\mathcal{S}$ by solving (4.3).

4.2. The ITRQ iteration. The TRQ iteration brings in the flavor of inverse iteration in a different way. A full RQ-iteration is similar to the familiar QR algorithm [5, 6]. The algorithm begins with a Hessenberg reduction

$$FV = VH, \tag{4.4}$$

where $V^T V = I$ and H is upper Hessenberg. This reduction is followed by a procedure described in Figure 4.2, which eventually drives H into an upper triangular form with eigenvalues exposed on the diagonal. Since our matrix F is symmetric, H is symmetric and tridiagonal. As convergence takes place, H becomes diagonal. If we let $V_+ = VQ^T$, $H_+ = QHQ^T$, $v_1^+ = V_+e_1$, and $v_1 = Ve_1$, it is easy to verify that in a single RQ iterate

$$(F - \mu I)v_1^+ = v_1\rho_{1,1},$$

where $\rho_{1,1} = e_1^T Re_1$. This implies that the first column V_+ is what one would have obtained by applying one step of inverse iteration to v_1 with the shift μ. This property is preserved in all subsequent RQ iterates. Thus, one would expect very rapid convergence of leading columns of V to an invariant subspace of A.

To avoid carrying out the full RQ-iteration involving $n \times n$ orthogonal similarity transformations on large-scale problems, it is desirable to truncate this update procedure after k steps to maintain and update only the leading portion of the factorizations occurring in this sequence.

The truncation scheme developed in [23] leads to a procedure that maintains and updates the following set of equations:

$$(F - \mu I)(V_k, v_+) = (V_k, v) \begin{pmatrix} T_k - \mu I_k & h \\ \beta_k e_k^T & \alpha \end{pmatrix}, \tag{4.5}$$

where T_k is symmetric and tridiagonal, $V_k^T V_k = I_k$, $V_k^T v = 0$, $V_k^T v_+ = 0$, and $\|v\| = \|v_+\| = 1$.

Clearly, the first k columns of the above equation satisfy a Lanczos reduction

$$FV_k = V_k T_k + \beta_k v e_k^T.$$

The vectors v_+, h, and the scalar variable α can be determined by solving the *TRQ equation*

$$\begin{pmatrix} F - \mu I & V_k \\ V_k^T & 0 \end{pmatrix} \begin{pmatrix} v_+ \\ h \end{pmatrix} = \begin{pmatrix} v\alpha \\ 0 \end{pmatrix}, \quad \|v_+\| = 1. \tag{4.6}$$

Once the solution of the above equation is obtained, the TRQ algorithm proceeds by performing an RQ decomposition

$$\begin{pmatrix} T_k - \mu I_k & h \\ \beta_k e_k^T & \alpha \end{pmatrix} = \begin{pmatrix} R_k & r \\ 0 & \rho \end{pmatrix} \begin{pmatrix} Q_k & q \\ \sigma e_k^T & \gamma \end{pmatrix}$$

and updating V_k, T_k, and v by applying appropriate orthogonal transformations. We refer readers to [23] for a detailed derivation of the algorithm.

Again, the major cost for carrying out a TRQ iteration is in solving the TRQ equation. To avoid enormous memory usage, we prefer to solve the TRQ equation by a preconditioned iterative solver. Just as it was for the correction equation that appeared in JD, it is easy to verify that v_+ also satisfies the following equation:

$$(I - V_k V_k^T)(F - \mu I)(I - V_k V_k^T) v_+ = v\alpha. \tag{4.7}$$

If the equation is not solved to full accuracy, the residual error will be mixed into all columns of V_k so that they will no longer form a basis of a Krylov subspace. However, it is shown in [27] that the error is damped by the orthogonal transformation applied to columns of V_k. After the RQ update is complete, the first column of the updated V_k, v_1^+ satisfies the equation

$$(F - \mu I) v_1^+ = \rho_{11} v_1 + z\delta,$$

where z is the residual error produced by the iterative solver used to solve (4.7), and δ is the product of sines generated from the Givens rotations used in the RQ update. Therefore the error associated with the above inexact inverse iteration is likely to be considerably smaller than $\|z\|$. Consequently, we expect v_1^+ to converge rapidly to a desired eigenvector of F. However, to continue the next cycle of ITRQ, we must restart a k-step Lanczos iteration from v_1^+ to generate a new set of T_k, V_k, v, β_k. We outline the basic steps of ITRQ in Figure 4.3. A convergence analysis for ITRQ is provided in [27].

```
ALGORITHM. ITRQ ITERATION.

Input: $(F, V_k, T_k, f_k)$ with $FV_k = V_k T_k + f_k e_k^T, V_k^T V_k = I$,
        $T_k$ is tridiagonal.
Output: $(V_k, T_k)$ such that $FV_k = V_k T_k, V_k^T V_k = I$ and $T_k$ is
        diagonal.

1. Put $\beta_k = \|f_k\|$ and put $v = f_k/\beta_k$;
2. for $j = 1, 2, 3, ...$ until convergence,
    2.1. Select a shift $\mu \leftarrow \mu_j$;
    2.2. Solve $(I - V_k V_k^T)(F - \mu I)(I - V_k V_k^T)w = v$ approximately;
    2.3. $w \leftarrow (I - V_k V_k^T)w$, $v_+ \leftarrow w/\|w\|$;
    2.4. $h \leftarrow V_k^T F v_+$,  $\alpha \leftarrow v^T(F - \mu I)v_+$ ;
    2.5. Factor $\begin{pmatrix} T_k - \mu I_k & h \\ \beta_k e_k^T & \alpha \end{pmatrix} = \begin{pmatrix} R_k & r \\ 0 & \rho \end{pmatrix} \begin{pmatrix} Q_k & q \\ \sigma e_k^T & \gamma \end{pmatrix}$;
    2.6. $v_1 \leftarrow V_k Q_k^T e_1 + v_+ q^T e_1$;
    2.7. $(T_k, V_k, v, \beta_k) \leftarrow$ Lanczos$(F, v_1, k)$;
3. end;
```

FIG. 4.3. *ITRQ iteration.*

5. Deflation and preconditioning.

The overall performance of TRQ and JD depends largely on the efficiency of the preconditioned iterative solver used to solve a sequence of projected linear systems of the form (4.7) (inner iteration). Although these equations do not need to be solved to full accuracy, some level of convergence is needed to ensure improvement of the approximate eigenpair in the outer iteration. In this section, we will discuss techniques for accelerating the convergence of the inner iteration.

5.1. Deflation.

Because the eigenvectors corresponding to the lowest six eigenvalues of F represent translational and rotational modes, the invariant subspace associated with these modes can be easily constructed. For example, a translational mode can be fixed by specifying 1 in the x direction and 0 in the other two directions. Deflating these modes from JD and ITRQ iteration helps improve the convergence of the eigenvalue calculation. In JD, deflation essentially amounts to solving a correction equation

$$(I - QQ^T)(F - \theta I)(I - QQ^T)z = -r,$$

where $Q = (U, u)$ consists of both the converged eigenvectors (including the translational and rotational modes) U and the approximation to a desired vibrational mode u. Deflation in ITRQ can be achieved by *locking* the converged eigenvectors in the leading columns of V_k. We refer readers to [4, 23] for implementation details.

5.2. Preconditioner for *F*.

Recall that each nonzero entry of the matrix F corresponds to either a bonded or a nonbonded force interaction between a pair of atoms. Because the bonded interaction is typically stronger than the nonbonded interaction, a natural candidate for a preconditioner is a matrix B that contains only the bonded entries of F. For PE particles, bonded interaction occurs among four adjacent atoms. Since each atom has three degrees of freedom (x, y, z), the full bonded interaction can be represented by a 12×12 dense matrix block. If atoms are numbered appropriately, these dense blocks will appear (with some overlap) on the diagonal of F. If we also include some of the nonbonded interactions between atoms that belong to different but nearby molecules, B can be made into a banded matrix. One of the preconditioners used in our experiments is a banded matrix formed by extracting nonzero entries between the 12th super- and subdiagonals of F.

A precise analysis of the effects of this preconditioner appears to be difficult. The following observation provides an intuitive explanation on why this preconditioner works well for PE particles.

It follows from our construction that

$$F = B + E.$$

The norm of E is relatively small compared to that of F and B. For the 3000-atom PE particle (*pe*3*k*) used in our experiments, $\|F\|_2 = 127.6$, $\|B\|_2 = 127.6$, and $\|E\|_2 = 1.3$. Thus, one may view E as a perturbation. Since $B^{-1}F = I + B^{-1}E$, the spectrum of the preconditioned system depends solely on the eigenvalue distribution of $B^{-1}E$. Because the removal of nonbonded interaction essentially eliminates the possibility of rigid body motion (i.e., translations and rotations), B is unlikely to contain eigenvalues that are extremely close to zero. Therefore, we expect eigenvalues of $B^{-1}E$ to be small. We observed from numerical experiments that the eigenvalues of $B^{-1}E$ lie within the interval $(-1.0, 1.5)$ for *pe*3*k*.

In Figure 5.1, we plotted the estimated spectrum of $B^{-1}F$ (computed by a simple Lanczos run) and compared it with that of F. Clearly, the preconditioner is quite effective in reducing condition number by two orders of magnitude.

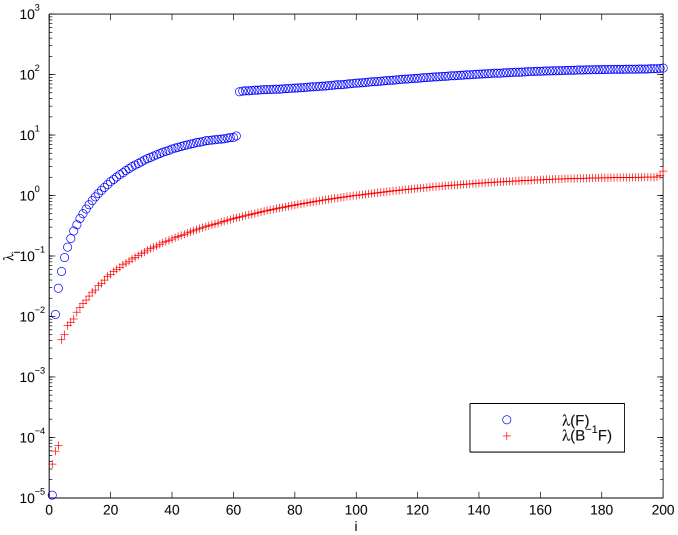

FIG. 5.1. *The estimated spectrum of F and $B^{-1}F$.*

To use the preconditioner in a symmetric iterative solver such as the conjugate gradient (CG) or the minimum residual (MINRES) method, B is required to be positive definite so that the Cholesky factors of B can be applied to preserve symmetry.

When this fails to be true, we add a small shift to the diagonal of B to make it positive definite.

Another technique we use to construct a preconditioner for F is *incomplete Cholesky factorization* [14, 15]. The factorization produces a lower triangular matrix L such that

$$E = F - LL^T$$

is small componentwise. If F is partitioned as

$$F = \begin{pmatrix} \alpha & \ell^T \\ \ell & \hat{F} \end{pmatrix},$$

the first step of the factorization leads to

$$\begin{pmatrix} \alpha & \ell^T \\ \ell & \hat{F} \end{pmatrix} \approx \begin{pmatrix} \sqrt{\alpha} & \\ \tilde{\ell}/\sqrt{\alpha} & I \end{pmatrix} \begin{pmatrix} \sqrt{\alpha} & \tilde{\ell}^T/\sqrt{\alpha} \\ & \hat{F} - \tilde{\ell}\tilde{\ell}^T/\alpha \end{pmatrix},$$

where $\tilde{\ell}$ is obtained by setting some small entries in ℓ to zero. Because most of the nonzero entries outside of the 12th subdiagonal element in ℓ correspond to weaker nonbonded interactions between atoms, their magnitude can be significantly smaller than $\sqrt{\alpha}$. Therefore it is reasonable to set some of these entries to zero to reduce the amount of fill-ins in $\hat{F} - \tilde{\ell}\tilde{\ell}^T/\alpha$. A heuristic threshold is often used to determine whether to keep or drop the nonzero entries in ℓ. When a fill-in is created in $\hat{F} - \tilde{\ell}\tilde{\ell}^T/\alpha$ its magnitude is likely to be small compared to the diagonal entry. Therefore, it is likely to be dropped from L as the factorization proceeds. As we will show in section 6, with a proper choice of drop tolerance, the number of nonzeros in L can be less than that in the lower triangular part of F.

5.3. Preconditioner for the projected system. We discussed how to construct preconditioners for F in section 5.2. However, in both JD and ITRQ, preconditioners must be applied to the projected system

$$(I - V_kV_k^T)(F - \theta I)(I - V_kV_k^T)x = \hat{b}, \tag{5.1}$$

where $V_k^T\hat{b} = 0$ and $V_k^Tx = 0$. In this section, we will provide a procedure for applying a pair of symmetric preconditioners to the projected system.

Suppose $B = LL^T$ is a good preconditioner for $F - \theta I$. It is reasonable to expect that

$$\hat{L} = (I - V_kV_k^T)L(I - V_kV_k^T),$$

together with $\hat{L}^T$, can be used to enhance the eigenvalue distribution of

$$C = (I - V_kV_k^T)(F - \theta I)(I - V_kV_k^T).$$

To apply these preconditioners in an iterative solver, we must find a convenient way to solve

$$\hat{L}\hat{x} = \hat{b} \quad \text{and} \quad \hat{L}^T\hat{y} = \hat{b},$$

where $V_k^T\hat{x} = 0$, $V_k^T\hat{y} = 0$, and $V_k^T\hat{b} = 0$. Because the solution to $\hat{L}\hat{x} = \hat{b}$ also satisfies

$$\begin{pmatrix} L & V_k \\ V_k^T & 0 \end{pmatrix} \begin{pmatrix} \hat{x} \\ -g \end{pmatrix} = \begin{pmatrix} b \\ 0 \end{pmatrix}$$

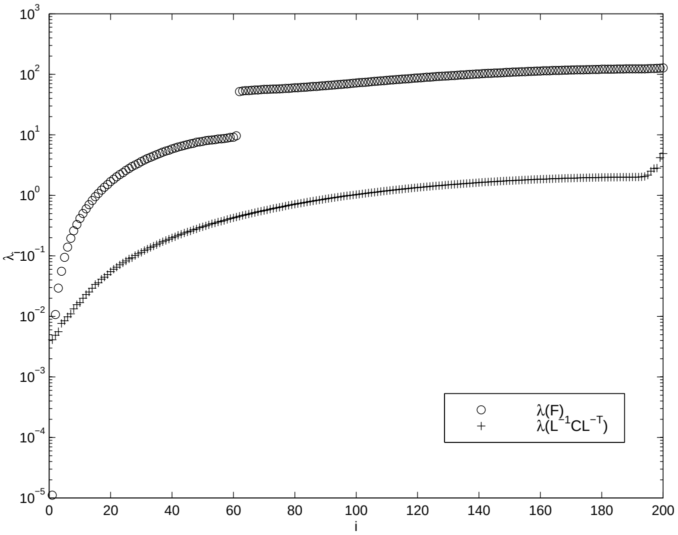

FIG. 5.2. *The estimated spectrum of F and $\hat{L}^{-1}(I - V_6V_6^T)F(I - V_6V_6^T)\hat{L}^{-T}$.*

for some $g \in \mathbb{R}^{k\times 1}$, block Gaussian elimination yields

$$\hat{x} = \hat{L}^{-1}\hat{b} = (I - Y_kG^{-1}V_k^T)L^{-1}\hat{b},$$

where $Y_k = L^{-1}V_k$ and $G = V_k^TY_k$. It follows that

$$\hat{L}^{-1}C\hat{L}^{-T} = \left(I - Y_kG^{-1}V_k^T\right)L^{-1}(F - \theta I)L^{-T}\left(I - V_kG^{-T}Y_k^T\right). \tag{5.2}$$

In Figure 5.2, we plotted the estimated spectrum of $\hat{L}^{-1}(I-V_6V_6^T)F(I-V_6V_6^T)\hat{L}^{-T}$ restricted to the subspace $V_6^{\perp}$, where V_6 consists of six vectors that describe the translational and rotational motions of *pe*3*k*. The estimated spectrum of the preconditioned and deflated matrix is compared to that of F. We observed that the combination of preconditioning and deflation effectively reduces the condition number of the linear system (in the inner iteration) from 10^8 to 10^2. Most eigenvalues of the preconditioned system have been clustered around 1.0.

Equation (5.2) defines a sequence of `matvec` operations that must be performed in one step of CG or MINRES iteration. One may follow the procedure provided below to modify a standard preconditioned iterative solver to compute an approximate solution of (5.1).

1. Solve $LY_k = V_k$.
2. Compute $G_k = V_k^TY_k$.
3. $\hat{b} \leftarrow L^{-1}\hat{b}$.
4. $\hat{b} \leftarrow \hat{b} - Y_kG_k^{-1}V_k^T\hat{b}$.
5. Apply an iterative solver to $(I-Y_kG^{-1}V_k^T)L^{-1}(F-\theta I)L^{-T}(I-V_kG^{-T}Y_k^T)y = \hat{b}$ to obtain an approximate solution y.
6. Compute $y \leftarrow y - V_kG^{-T}Y_k^Ty$.
7. Solve $L^T\hat{x} = y$.

6. Performance. In this section we present our computational experience applying JD and ITRQ to PE particles of various sizes. We found both algorithms are quite efficient at extracting a small number of low-frequency vibrational modes. The total number of floating point operations (flops) required to obtain the lowest 100 vibrational modes is kn^2 for some $k \ll n$. The JD algorithm appears to be more efficient than ITRQ when a set of optimal parameters is identified. These parameters include the following:

1. Preconditioner. We found that it is extremely expensive to solve the linear systems (4.2) and (4.7) without use of a preconditioner. We choose between two preconditioners of the linear systems. The first is a standard incomplete Cholesky preconditioner, which we call `IC`. The second is the banded submatrix of the original matrix obtained by ignoring the nonbonded interactions; we call this preconditioner `band`.
2. The convergence tolerance `tol` used to control the accuracy of the linear systems solved. The values of `tol` looked at here are $\sqrt{10^{-1}}$, 10^{-1}, 10^{-2}, 10^{-4}, and 10^{-6}. We also investigated the possibility of using a dynamic tolerance in which the `tol` value is gradually tightened in the outer iteration as the approximate eigenvector becomes more accurate.
3. The maximum dimension (`jmax`) of the approximating subspace constructed in the outer iteration and the minimum number (`jmin`) of vectors retained when restarting takes place.
4. Choice of shift θ. In the JD algorithm the linear systems are shifted using the most recent estimate of the eigenvalue. We can choose, alternatively, to refrain from shifting the linear system, and work directly with F. Shifting produces linear systems that are generally more ill-conditioned; however, it potentially obtains greater reduction in the eigenresidual per solve because shifting preserves the Newton-like solution process.

We ran our implementation of JD on three PE particle models *pe*3*k*, *pe*6*k*, and *pe*12*k* of orders 9000, 18000, and 36000, respectively. Problem statistics are given in Table 6.1, which includes statistics for the two preconditioners.

TABLE 6.1
Problem statistics.

Problem	n	nnz(F)	`nonzero` percentage(F)	`IC` nnz(L)	`band` nnz(L)
*pe*3*k*	9000	3,279,690	3.7%	903,510	106,161
*pe*6*k*	18000	6,897,316	1.8%	1,876,009	211,946
*pe*12*k*	36000	14,220,946	1.1%	3,540,453	423,517

Throughout we will use approximate counts of flops to measure performance. We count just the flops required by matrix-vector products and application of the preconditioners. We ignore the relatively small number of flops required by BLAS operations used in deflation, projection, and other MINRES operations. A flop refers to a multiply-add pair. An approximate eigenpair is declared converged when its residual norm drops below 10^{-6}.

6.1. `IC` and `band` preconditioners. To compute the `IC` preconditioner we used a drop-tolerance-based code provided to us by Edmond Chow [2], which provides a number of options that we found useful or even necessary. We used the option that scales the matrix before factorization so that it has unit main diagonal. We needed to shift the main diagonal to preserve positive definiteness. We tried a number of combinations of shifts and drop tolerances, and found that a drop tolerance of 10^{-4} and shift of 2×10^{-4} are very near optimal for all three problems under consideration.

Table 6.2

Average iterations per solve, flops per iterations, and flops per solve for MINRES using two different preconditioners during JD runs to calculate leading twenty eigenvalues. Linear systems are shifted; `tol` $= 10^{-1}$*; and* `jmin` $= 20$ *and* `jmax` $= 40$.

Problem	Iter/solve		Flops/iter		Flops/solve	
	`IC`	`band`	`IC`	`band`	`IC`	`band`
*pe*3*k*	10.5	23.6	1.02e7	6.84e6	1.08e8	1.61e8
*pe*6*k*	11.8	32.0	2.12e7	1.44e7	2.50e8	4.61e8
*pe*12*k*	12.4	34.7	4.21e7	2.96e7	5.21e8	1.03e9

Table 6.3

Approximate total flops during JD runs to calculate leading twenty eigenvalues using two different preconditioners. Linear systems are shifted; `tol` $= 10^{-1}$*; and* `jmin` $= 20$ *and* `jmax` $= 40$.

Problem	`IC`	`band`
*pe*3*k*	1.05e10	1.58e10
*pe*6*k*	2.38e10	4.27e10
*pe*12*k*	4.96e10	9.28e10

In Table 6.1 notice that each `IC` factor is considerably sparser than the lower triangle of the corresponding coefficient matrix. There are many very small entries in the coefficient matrices, and it is vital that the `IC` algorithm allows many of these small original entries to be dropped from the IC factors.

Observe in Table 6.1 that the `band` factors are much sparser than their `IC` counterparts, and hence much cheaper to apply. In Table 6.2 the number of flops per iteration is significantly smaller for `band`. But there are significant entries outside the band that need to play a role in the preconditioner.

`IC` permits entries to enter the preconditioner based on size alone and not position in the matrix (i.e., physical classification). While `IC` produces a much denser factor L, it is nonetheless much sparser than the lower triangle of the originating coefficient matrix. The number of iterations per solve in Table 6.2 shows that `IC` is a much more powerful preconditioner; the number of flops per solve in the same table show that it is much more efficient.

Finally, Table 6.3 shows approximate total flops for JD runs using `IC` and `band`. `IC` is clearly superior and has been in all the tests we have run. Henceforth we drop `band` and work with `IC` alone.

6.2. Accuracy in the linear equations. Using a “factorization-free” approach, we can choose how accurately to solve the linear systems. This turns out to be important. We tried various tolerances `tol` to control the relative reduction in the MINRES residuals. Table 6.4 shows approximate total work for the various values of `tol`.

Table 6.4

Approximate total flops during JD runs to calculate leading twenty eigenvalues using various settings of `tol`. `IC` *is used; linear systems are shifted; and* `jmin` $= 20$ *and* `jmax` $= 40$.

Problem	Tolerance					
	$\sqrt{10^{-1}}$	10^{-1}	10^{-2}	10^{-4}	10^{-6}	Dynamic
*pe*3*k*	1.22e10	**1.05e10**	1.45e10	1.81e10	2.14e10	**1.09e10**
*pd*6*k*	2.73e10	**2.38e10**	3.43e10	4.53e10	5.37e10	**2.36e10**
*pe*12*k*	5.50e10	**4.96e10**	7.28e10	1.01e11	1.16e11	**4.95e10**

Roughly one digit of accuracy (`tol` $= 10^{-1}$) is preferable for all three problems. The superiority of `tol` $= 10^{-1}$ manifested itself in all the tests we ran, which includes many runs not recorded in the table. One pays a fairly high price for solving the linear systems too accurately. In general, our experience has been that high accuracy in the linear system does not lead, with sufficient consistency, to commensurate reductions in the eigenresiduals in the JD algorithm. We have also observed that the cost of an average linear solve increases faster than accuracy as shift becomes closer to an eigenvalue.

Following the strategy proposed in [4], we also experimented with a dynamic tolerance $\texttt{tol}_j = \texttt{tol}_0/2^j$, where j is the outer iterate number, and $\texttt{tol}_0$ is the initial residual. This is motivated by the fact that JD can be viewed as an inexact Newton iteration in which a higher accuracy is required near the solution of the correction equation. However, for this scheme to be competitive with the fixed tolerance approach, we must limit the maximum number of MINRES iterations to a small number ($10 \sim 15$ in most cases). We observed that this limit is almost always reached before the residual error of the approximate solution falls below the dynamic tolerance. Henceforth the following results are obtained by using $\texttt{tol} = 10^{-1}$ in our runs.

6.3. Projection subspace size in JD. Our experience verified our expectation that the larger the space from which approximate eigenvectors are taken, the more efficiently the algorithm runs. Table 6.5 shows that increasing the maximum size jmax of the basis from 10 to 20 to 40 (along with the minimum size jmin from 5 to 10 to 20) reduces approximate total work when either shifted or unshifted linear systems are used.

Table 6.5
Approximate total flops during JD runs to calculate leading twenty eigenvalues using various settings of jmax *and* jmin *and shifted and unshifted linear systems.* IC *and* $\texttt{tol} = 10^{-1}$ *are used.*

	Shifted			Unshifted		
	(jmin,jmax)			(jmin,jmax)		
Problem	(5,10)	(10,20)	(20,40)	(5,10)	(10,20)	(20,40)
*pe*3*k*	1.26e10	1.13e10	1.05e10	1.88e10	1.47e10	1.26e10
*pe*6*k*	2.89e10	2.50e10	2.38e10	4.42e10	3.31e10	2.79e10
*pe*12*k*	6.05e10	5.32e10	4.96e10	9.10e10	7.14e10	5.90e10

It is interesting to note that the effect of increasing jmax is far more pronounced when the linear systems are unshifted rather than shifted. Unshifted is far more competitive with shifted when jmax = 40 rather than jmax = 10. In all our tests jmax = 40 outperformed the lower alternative values. The primary cost in increasing jmax is extra space for the basis vectors. The cost in storage of using jmax = 40 is not too large, and in the table it appears to be a reasonable point of diminishing returns. Hence, we choose jmax = 40.

6.4. Shifted versus unshifted linear systems. Table 6.5 also shows that shifting the linear systems is superior to the alternative of using unshifted linear systems. When jmax is large, the advantage of shifting is modest but significant; when jmax is small, the advantage of shifting can be quite large. Our experience with other runs not shown in the table also corroborate the conclusions we draw here.

6.5. A closer look at an optimal run. Let us now consider in more detail a single run of JD to compute the leading 20 eigenpairs for the smallest problem (*pe*3*k*) using the optimal parameters IC, $\texttt{tol} = 10^{-1}$, jmax = 40, jmin = 20, and shifted linear systems. Figure 6.1 displays the convergence history of the leading 20 eigenpairs. The residual norm of each approximate eigenpair is plotted against the flops mea-

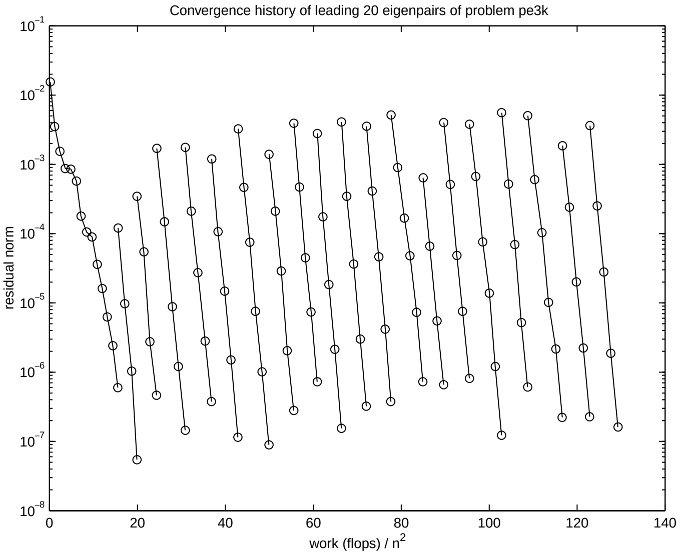

FIG. 6.1. *The residual history of the first* 20 *eigenpairs in a JD run.*

sured at each outer iteration of JD. The first eigenpair is computed without shifting because in our experience shifting is always completely ineffective for this eigenpair; moreover, shifting is always considerably more expensive for this eigenpair. The convergence histories for the other 19 eigenpairs are remarkably regular. The thing we would like to emphasize here is that with great regularity reducing the residual in the linear system by one order of magnitude results in reducing the eigenresidual by close to one order of magnitude. The average number of iterations per linear system solve is 10.5 iterations. The average number of MINRES iterations per eigenpair is 47.5 iterations.

It is important that some attention is paid to tuning the linear equation solver and JD for this application. Using `IC`, unshifted linear systems, `tol` $= 10^{-6}$, `jmax` $= 10$, and `jmin` $= 5$ it takes approximately 4.24×10^{10} flops to compute the leading 20 eigenpairs for problem *pe*3*k*. This is 4.0 times more flops than required by the optimal run. Using `band`, unshifted linear systems, `tol` $= 10^{-6}$, `jmax` $= 10$, and `jmin` $= 5$ it takes approximately 1.04e11 flops to compute the leading 20 eigenpairs for problem *pe*3*k*. This is 9.9 times more flops than required by the optimal run.

6.6. Comparison with ITRQ. Our preliminary results show that ITRQ is less efficient than JDQR for the PE problems. The convergence history of the first 20 eigenpairs is displayed in Figure 6.2. The residual norm of each approximate eigenpair is plotted against the flops measured at each RQ update step. We observe that the total number of flops required to capture the lowest 20 eigenpairs is significantly larger than that required by an optimal JD run. Part of the reason why ITRQ takes more flops is that our current implementation solves the full bordered system (4.2) by preconditioned MINRES. This may not be necessary because (4.2) can be rearranged into an equation that involves no V_k by exploiting the Lanczos relation $FV_k = V_k T_k + f e_k^T$ [23]. However, our experience seems to indicates that ITRQ requires a tighter convergence tolerance (`tol` $= 10^{-7}$) for the preconditioned iterative solver to obtain sufficient reduction in the residual norm in approximate eigenpairs.

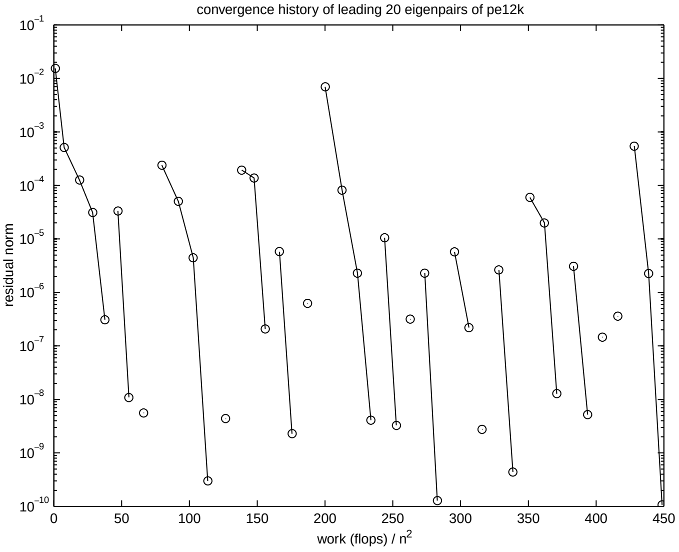

FIG. 6.2. *The residual history of the first* 20 *eigenpairs in an ITRQ run.*

Figure 6.2 also indicates that the convergence pattern of ITRQ is quite different from that of JD. Several approximate eigenpairs converge almost at the same time, whereas in JD an almost equal amount of time is spent on computing each eigenpair.

7. Conclusion. In this paper, we presented our computational experience in applying JD and ITRQ algorithms to obtain fundamental vibrational modes of large-scale molecular structures. The key to the efficiency of our computation is the choice of preconditioners used in the inner iteration of both JD and ITRQ. We found that both the banded preconditioner that contains mainly the bonded interaction and an incomplete Cholesky preconditioner are quite effective. We presented additional tuning techniques for improving the performance of JD. We believe both algorithms can be developed into general software tools for performing NCA on large-scale molecular structures.

Acknowledgments. We would like to thank Drs. Charles H. Romine and Eduardo D'Azevedo for carefully reading the manuscript and providing us with corrections and suggestions. We would also like to thank Prof. Ralph Byers for a helpful discussion on preconditioners during his visit to Oak Ridge National Laboratory. We are grateful for comments from the referees that helped improve the quality of this paper.

GENERALIZING EIGENVALUE THEOREMS TO PSEUDOSPECTRA THEOREMS[*]

MARK EMBREE[†] AND LLOYD N. TREFETHEN[†]

Abstract. Analysis of nonsymmetric matrix iterations based on eigenvalues can be misleading. In this paper, we discuss sixteen theorems involving ε-pseudospectra that each generalize a familiar eigenvalue theorem and may provide more descriptive information in some cases. Our organizing principle is that each pseudospectral theorem reduces precisely to the corresponding eigenvalue theorem when $\varepsilon = 0$.

Key words. eigenvalues, pseudospectra, matrix iterations

1. Introduction.

Though we speak of linear algebra, matrix iterative methods belong to the realm of linear analysis. Convergence of errors or residuals to zero is the concern, and this process has meaning because the algebraic problem is embedded in a normed space. Except for questions concerning finite termination, the appropriate tools for analyzing convergence are not the tools of algebra, such as eigenvalues, which are basis-independent, but those of analysis, such as singular values, which are defined via norms and necessarily change with the basis.

In this paper we consider the particular tools of linear analysis known as pseudospectra, which were invented to give information about matrices that lack a well-conditioned basis of eigenvectors. For simplicity, our norm $\|\cdot\|$ will always be the vector 2-norm and the matrix 2-norm that it induces. With this choice of norm, the matrices of interest are those that are far from normal in the sense that their eigenvectors, if a complete set exists, are far from orthogonal. Many of our results can be extended to other norms and also to operators as well as matrices, but we will not discuss these generalizations.

Throughout the article, A is an $N \times N$ matrix, and $\Lambda(A)$ denotes its spectrum, i.e., its set of eigenvalues, a subset of the complex plane $\mathbb{C}$. The pseudospectra of A are nested subsets of $\mathbb{C}$ that expand to fill the plane as $\varepsilon \to \infty$.

Definition. *For each $\varepsilon \ge 0$, the ε-pseudospectrum $\Lambda_\varepsilon(A)$ of A is the set of numbers $z \in \mathbb{C}$ satisfying any of the following equivalent conditions:*

(i) $\|(z-A)^{-1}\| \ge \varepsilon^{-1}$;

(ii) $\sigma_{\min}(z-A) \le \varepsilon$;

(iii) $\|Au - zu\| \le \varepsilon$ *for some vector u with* $\|u\| = 1$;

(iv) *z is an eigenvalue of $A+E$ for some matrix E with* $\|E\| \le \varepsilon$.

Here $\sigma_{\min}$ denotes the smallest singular value, and we employ the convention that $\|(z-A)^{-1}\| = \infty$ for $z \in \Lambda(A)$.

Pseudospectra were introduced as early as 1975 [12] and became a popular tool during the 1990s. We will not give detailed references here, but we refer the reader to [23] and [24] for examples, to [25] for algorithms and a list of applications, and to [26]

for history. For extensive online information about pseudospectra, including examples and a bibliography of papers by many authors, see the Pseudospectra Gateway [3].

This brief article is devoted to a simple idea:

Many theorems about eigenvalues are special cases $\varepsilon = 0$ of theorems about ε-pseudospectra.

Our whole content consists of the presentation of sixteen examples of theorems of this kind. These theorems are for the most part neither mathematically deep nor even new, though in some cases they have not been stated in the language of pseudospectra before. Nevertheless, for practical applications involving highly nonnormal matrices, they may sometimes be more useful than their eigenvalue special cases. This will tend to be so in situations where the eigenvalues of A are misleading, filling a region of $\mathbb{C}$ smaller than where A actually "lives." For an example illustrating the limitations of eigenvalue analysis for Krylov subspace methods for linear systems of algebraic equations, see [6]. Here is another extreme example. If A is nilpotent, with $A^K = 0$ for some $K \geq 1$, then $\Lambda(A) = \{0\}$. Some such matrices will have norms $\|A^k\|$ that diminish steadily toward 0 as $k \to K$, while for others, there may be no reduction until $k = K$ or great transient growth before the eventual decay. Eigenvalues alone cannot distinguish between these behaviors, but pseudospectra can.

Our presentation will adhere to a fixed pattern. In each case, we first list a theorem about eigenvalues, without proof, that is either elementary or well known. We follow this with a generalized theorem for pseudospectra together with an outline of a proof. Some pointers to the literature are included along the way, but we do not aim to be exhaustive, as it is often hard with this essentially elementary material to track down the first appearance of a result in print.

We hope that this article may provide a useful compendium for those concerned with nonnormal matrices and associated iterations, but we emphasize that this collection does not include all potentially useful theorems involving pseudospectra. By confining our attention to theorems that reduce for $\varepsilon = 0$ to valid statements about eigenvalues, we exclude some of the subtler estimates that may be obtained from pseudospectra, notably those based on contour integrals. One example is the Kreiss matrix theorem, which contains a constant eN that does not reduce cleanly to 1 as $\varepsilon \to 0$ [11, 19]. Another is the bound on a polynomial norm $\|p(A)\|$, of immediate relevance to iterations such as GMRES, that can be obtained by integrating $p(z)$ over the boundary contour(s) of $\Lambda_\varepsilon(A)$ [22]. For new results comparing such contour integral techniques to other approaches, see [5].

2. Sixteen theorems.

Our first theorem indicates the connection between the ill-conditioning of solving a linear system with A and the existence of a pseudoeigenvalue near the origin. This result has been attributed to Gastinel (see [21, pp. 120, 133], [28, p. 248]).

THEOREM 1. A is singular $\iff 0 \in \Lambda(A)$.

THEOREM 1ε. $\|A^{-1}\| \geq \varepsilon^{-1} \iff 0 \in \Lambda_\varepsilon(A)$.

Proof. The proof is immediate from the definitions. □

Pseudospectra possess the satisfying property that every connected component of the ε-pseudospectrum must contain at least one eigenvalue. This property forms the basis for the following result.

THEOREM 2. *A has N distinct eigenvalues $\Longrightarrow$ A is diagonalizable.*

THEOREM 2ε. *$\Lambda_\varepsilon(A)$ has N distinct components $\Longrightarrow$ A is diagonalizable.*

Proof. From definition (iv) of pseudospectra it is clear that for any $\delta > 0$, $\Lambda_\varepsilon(A)$ is contained in the interior of $\Lambda_{\varepsilon+\delta}(A)$. By the continuity of matrix eigenvalues with respect to perturbations, the same condition (iv) implies that if $\Lambda_\varepsilon(A)$ has N distinct components, so does $\Lambda_{\varepsilon+\delta}(A)$ for sufficiently small $\delta > 0$. Thus we see that $\|(z - A)^{-1}\|$ must achieve local maxima strictly in the interior of each of the N components of $\Lambda_{\varepsilon+\delta}(A)$. Now $\log \|(z - A)^{-1}\|$ is a subharmonic function of z throughout the complex plane except at the eigenvalues of A (see, e.g., [7, Thm. 3.13.1], [4]), and thus $\log \|(z-A)^{-1}\|$ and likewise $\|(z-A)^{-1}\|$ satisfy the maximum principle away from the eigenvalues of A. Putting these facts together, we see that each component of $\Lambda_\varepsilon(A)$ must contain an eigenvalue of A, which implies that A has N distinct eigenvalues and thus is diagonalizable. □

Gallestey has developed an algorithm for computing pseudospectra based on the maximum principle property used in the above proof [4]. A simpler exclusion algorithm, recently proposed by Koutis and Gallopoulos [10], is based upon the next result.

Theorem 3. $\|(z - A)^{-1}\| \ \ge\ \frac{1}{\operatorname{dist}(z,\Lambda(A))}$.

Theorem 3ε. $\|(z - A)^{-1}\| \ \ge\ \frac{1}{\operatorname{dist}(z,\Lambda_\varepsilon(A))+\varepsilon}$.

Proof. A perturbation of A of norm $\operatorname{dist}(z, \Lambda_\varepsilon(A)) + \varepsilon$ could make z an eigenvalue. □

The Koutis–Gallopoulos algorithm utilizes Theorem 3ε rewritten in the form

$$\operatorname{dist}(z, \Lambda_\varepsilon(A)) \ \ge\ \frac{1}{\|(z - A)^{-1}\|} - \varepsilon.$$

In our next theorem, S is an arbitrary nonsingular matrix and $\kappa(S)$ is its condition number, $\kappa(S) \equiv \|S\|\|S^{-1}\|$. Though the theorem is stated as an inclusion in one direction only, it applies in the other direction too, and in that sense Theorem 4 maintains our usual pattern of being the special case $\varepsilon = 0$ of Theorem 4ε. The result demonstrates that pseudospectra are invariant under unitary transformations, and also reflects the extent to which an ill-conditioned similarity transformation can alter pseudospectra. When B is diagonal, so that SBS^{-1} represents a diagonalization of A, Theorem 4ε is equivalent to the most familiar version of the Bauer–Fike theorem [1].

Theorem 4. $A = SBS^{-1} \implies \Lambda(A) = \Lambda(B)$.

Theorem 4ε. $A = SBS^{-1} \implies \Lambda_\varepsilon(A) \subseteq \Lambda_{\kappa(S)\varepsilon}(B)$.

Proof. Since $(z - A)^{-1} = S(z - B)^{-1}S^{-1}$, $\|(z - A)^{-1}\| \le \kappa(S)\|(z - B)^{-1}\|$. Therefore if $\|(z - A)^{-1}\| \ge \varepsilon^{-1}$, then $\|(z - B)^{-1}\| \ge (\kappa(S)\varepsilon)^{-1}$. □

The following theorem makes use of the idea of the "average pseudoeigenvalue" of a matrix, $\operatorname{mean}_{\lambda_\varepsilon\in\Lambda_\varepsilon(A)}\lambda_\varepsilon$. Of course, this quantity needs to be defined. We could be very specific and make use of, say, Haar measure (isotropy in $\mathbb{C}^N$) on the space of $N \times N$ matrices, but for the purposes of this theorem it is enough to say that $\operatorname{mean}_{\lambda_\varepsilon\in\Lambda_\varepsilon(A)}\lambda_\varepsilon$ is the mean of the eigenvalues of $A + E$ averaged over any fixed distribution on the matrices E with $\|E\| \le \varepsilon$ with the property that each matrix entry e_{ij} has mean 0.

Theorem 5. $\operatorname{tr}(A) \ =\ N \cdot \operatorname{mean}_{\lambda\in\Lambda(A)}\lambda$.

Theorem 5ε. $\operatorname{tr}(A) \ =\ N \cdot \operatorname{mean}_{\lambda_\varepsilon\in\Lambda_\varepsilon(A)}\lambda_\varepsilon$.

Proof. The theorem looks deep but is elementary. All we need to do is consider traces of perturbed matrices. Since each e_{jj} has mean 0 by assumption, so does their sum, and thus $\operatorname{tr}(A) = \operatorname{mean}_{\|E\|\le\varepsilon}\operatorname{tr}(A + E) = N \cdot \operatorname{mean}_{\lambda_\varepsilon\in\Lambda_\varepsilon(A)}\lambda_\varepsilon$. □

Our next pair of results requires a definition of the *condition number* $\kappa_A(\Sigma(A))$ of a compact set $\Sigma = \Sigma(A) \subset \mathbb{C}$ depending on A with respect to perturbations of A. If Σ_1 and Σ_2 are compact subsets of $\mathbb{C}$, let $d(\Sigma_1, \Sigma_2)$ denote the Hausdorff distance $d(\Sigma_1, \Sigma_2) = \max\{\max_{s\in\Sigma_1} d(s, \Sigma_2), \max_{s\in\Sigma_2} d(s, \Sigma_1)\}$, where $d(s, \Sigma)$ is the usual distance of a point s to a set Σ. Then

$$\kappa_A(\Sigma(A)) \equiv \limsup_{\delta\to 0}\left(\delta^{-1}\sup_{\|D\|\le\delta} d(\Sigma(A+D), \Sigma(A))\right).$$

THEOREM 6. $\Lambda(A)$ *depends continuously on* A*, with condition number* $\kappa_A(\Lambda(A)) = 1$ *if* A *is normal.*

THEOREM 6ε. $\Lambda_\varepsilon(A)$ *depends continuously on* A*, with condition number* $\kappa_A(\Lambda_\varepsilon(A)) = 1$ *if* A *is normal.*

Proof. The continuity of $\Lambda_\varepsilon(A)$ in the Hausdorff metric follows from the analogous continuity of $\Lambda(A)$. Suppose now that A is normal, so that its ε-pseudospectrum is the union of ε-disks centered at each eigenvalue. For any $\delta \ge 0$ and $D \in \mathbb{C}^{N\times N}$ with $\|D\| \le \delta$, we have $\max_{s\in\Lambda_\varepsilon(A+D)} d(s, \Lambda_\varepsilon(A)) \le \delta$ and similarly $\max_{s\in\Lambda_\varepsilon(A)} d(s, \Lambda_\varepsilon(A+D)) \le \delta$. Thus,

$$\sup_{\|D\|\le\delta} d(\Lambda_\varepsilon(A+D), \Lambda_\varepsilon(A)) \le \delta.$$

Since $\cup_{\|D\|\le\delta}\Lambda_\varepsilon(A+D) = \Lambda_{\varepsilon+\delta}(A)$, there always exists some D with $\|D\| \le \delta$ such that $\max_{s\in\Lambda_\varepsilon(A+D)} d(s, \Lambda_\varepsilon(A)) = \delta$, and for such a D we must have $\|D\| = \delta$, since the pseudospectra are strictly nested sets. It follows that

$$\kappa_A(\Lambda_\varepsilon(A)) \equiv \limsup_{\delta\to 0}\left(\delta^{-1}\sup_{\|D\|\le\delta} d(\Lambda_\varepsilon(A+D), \Lambda_\varepsilon(A))\right) = 1. \qquad \square$$

Eigenvalues can change dramatically with small perturbations, a warning that analysis based on them can be misleading. The following theorem hints that pseudospectra may be more robust.

THEOREM 7. $\Lambda(A+E) \subseteq \Lambda_{\|E\|}(A)$.

THEOREM 7ε. $\Lambda_\varepsilon(A+E) \subseteq \Lambda_{\varepsilon+\|E\|}(A)$.

Proof. If $z \in \Lambda_\varepsilon(A+E)$, then there exists a matrix F with $\|F\| \le \varepsilon$ such that $(A+E+F)u = zu$ for some $u \ne 0$. Since $\|E+F\| \le \varepsilon + \|E\|$, $z \in \Lambda_{\varepsilon+\|E\|}(A)$. □

We now turn to the problems of estimating the behavior of a matrix from its spectrum and pseudospectra.

THEOREM 8. $\lambda \in \Lambda(A) \implies \|A\| \ge |\lambda|$.

THEOREM 8ε. $\lambda_\varepsilon \in \Lambda_\varepsilon(A) \implies \|A\| \ge |\lambda_\varepsilon| - \varepsilon$.

Proof. If $\lambda_\varepsilon \in \Lambda_\varepsilon(A)$, then $Au = \lambda_\varepsilon u + \varepsilon v$ for some vectors $u, v \in \mathbb{C}$ with $\|u\| = \|v\| = 1$. It follows that $\|Au\| \ge |\lambda_\varepsilon| - \varepsilon$. □

The convergence analysis of stationary iterative methods is based on the behavior of powers of the iteration matrix. It has long been known that transient growth can occur even when the spectral radius of the iteration matrix is less than one (see, e.g., [27, p. 63]). The following two theorems use pseudospectra to describe this transient growth. The first is the "easy half of the Kreiss matrix theorem," that is, the half of that theorem that does not depend on N and whose proof is elementary [11].

THEOREM 9. $\max_{\lambda\in\Lambda(A)} |\lambda| > 1 \implies \sup_{k>0} \|A^k\| = \infty$.

THEOREM 9ε. $\max_{\lambda_\varepsilon\in\Lambda_\varepsilon(A)} |\lambda_\varepsilon| > 1 + C\varepsilon \implies \sup_{k\ge 0} \|A^k\| > C$.

Proof. Since $\|A^0\| = 1$, the result is trivial for $C < 1$, so assume $C \ge 1$. If $\max_{\lambda\in\Lambda(A)} |\lambda| > 1$, then the conclusion certainly holds, so assume $\max_{\lambda\in\Lambda(A)} |\lambda| \le 1$, in which case we have the convergent series representation

$$(z-A)^{-1} \;=\; z^{-1}(I + z^{-1}A + z^{-2}A^2 + \cdots),$$

which is valid for all z with $|z| > 1$. We now argue the contrapositive. If $\|A^k\| \le C$ for all $k \ge 0$, then

$$\|(z-A)^{-1}\| \;\le\; \frac{|z^{-1}|C}{1-|z^{-1}|} \;=\; \frac{C}{|z|-1}$$

for any z with $|z| > 1$. This implies that $\Lambda_\varepsilon(A)$ is contained in the disk about the origin of radius $1 + C\varepsilon$, i.e., $\max_{\lambda_\varepsilon \in \Lambda_\varepsilon(A)} |\lambda_\varepsilon| \le 1 + C\varepsilon$. □

THEOREM 10. $\lambda \in \Lambda(A) \implies \|A^k\| \ge |\lambda|^k$ *for all* k.

THEOREM 10ε. $\lambda_\varepsilon \in \Lambda_\varepsilon(A) \implies \|A^k\| \ge |\lambda_\varepsilon|^k - \frac{k\varepsilon\|A\|^{k-1}}{1-k\varepsilon/\|A\|}$ *for all* k *such that* $k\varepsilon < \|A\|$.

Proof. Pick E such that $\|E\| \le \varepsilon$ and $\lambda_\varepsilon \in \Lambda(A+E)$. Then $\|(A+E)^k\| \ge |\lambda_\varepsilon|^k$, which implies

$$\begin{aligned}\|A^k\| &\ge |\lambda_\varepsilon|^k - k\varepsilon\|A\|^{k-1} - \binom{k}{2}\varepsilon^2\|A\|^{k-2} - \cdots \\ &\ge |\lambda_\varepsilon|^k - k\varepsilon\|A\|^{k-1}\left(1 + k\varepsilon/\|A\| + (k\varepsilon)^2/\|A\|^2 + \cdots\right).\end{aligned}$$

Provided $k\varepsilon < \|A\|$, the series in this last equation converges, giving

$$\|A^k\| \ge |\lambda_\varepsilon|^k - \frac{k\varepsilon\|A\|^{k-1}}{1-k\varepsilon/\|A\|}. \qquad \square$$

Theorems 9 and 9ε have exact analogues for continuous time (see [14, 15]).

THEOREM 11. $\max_{\lambda\in\Lambda(A)} \mathrm{Re}\lambda > 0 \implies \sup_{t>0} \|e^{tA}\| = \infty$.

THEOREM 11ε. $\max_{\lambda_\varepsilon\in\Lambda_\varepsilon(A)} \mathrm{Re}\lambda_\varepsilon > C\varepsilon \implies \sup_{t>0} \|e^{tA}\| > C$.

Proof. As in the proof of Theorem 9ε, the conclusion is immediate if $C < 1$ or if $\max_{\lambda\in\Lambda(A)} \mathrm{Re}\lambda > 0$, so we assume that $C \ge 1$ and $\max_{\lambda\in\Lambda(A)} \mathrm{Re}\lambda \le 0$ and use the Laplace transform identity

$$(z-A)^{-1} \;=\; \int_0^\infty e^{-zt}e^{tA}dt,$$

which is valid for $\mathrm{Re}\, z > 0$. Again arguing the contrapositive, we note that if $\|e^{tA}\| \le C$ for all $t > 0$, then $\|(z-A)^{-1}\| \;\le\; C/\mathrm{Re}\, z$ for z with $\mathrm{Re}\, z > 0$, implying that $\Lambda_\varepsilon(A)$ is contained in the half-plane defined by $\mathrm{Re}\, z \le C\varepsilon$. □

Our next result is a pseudospectral generalization of Gerschgorin's theorem, which we believe to be new. It implies that if $\Lambda_\varepsilon(A)$ contains points distant from $\Lambda(A)$ for sufficiently small ε, then the bounds given by Gerschgorin's theorem will be more sharply descriptive of the pseudospectra than of the spectrum. Coupling this with Theorems 9ε and 10ε, one sees that Gerschgorin eigenvalue estimates may sometimes lead to more accurate predictions of transient behavior of iterative matrix processes than would be obtained from the exact eigenvalues! As has been pointed out in [13], this curious robustness phenomenon is of practical importance, for it sheds light on how it is that iterations such as GMRES may sometimes converge handily even when the associated Ritz values or harmonic Ritz values are far from accurate eigenvalue estimates. For these theorems, define $d_j = a_{jj}$ and $r_j = \sum_{k\ne j} |a_{jk}|$, and for any complex number z and real number $r \ge 0$, let $D(z, r)$ denote the closed disk about z of radius r.

THEOREM 12. $\Lambda(A) \;\subseteq\; \bigcup_j D(d_j, r_j)$.

THEOREM 12ε. $\Lambda_\varepsilon(A) \;\subseteq\; \bigcup_j D(d_j, r_j + \sqrt{N}\varepsilon)$.

Proof. Applying Gerschgorin's theorem to $A+E$ with $\|E\| \le \varepsilon$ yields inclusion disks centered at $d_j + e_{jj}$ with radius $\sum_{k\neq j} |a_{jk} + e_{jk}| \le r_j + \sum_{k\neq j} |e_{jk}|$. Each such disk is contained in the disk centered at d_j with radius $r_j + \sum_{k=1}^{N} |e_{jk}| = r_j + \|E_j\|_\infty$, where E_j denotes the matrix equal to E in the jth row and zero elsewhere. The term $\sqrt{N}\varepsilon$ comes from the inequality $\|E_j\|_\infty \le \sqrt{N}\|E_j\|_2 \le \sqrt{N}\|E\|_2$. □

The next result concerns the numerical range or field of values, which we denote by $W(A)$. In the context of iterative methods, the theorem indicates how analysis based on the field of values (see, e.g., [2]) relates to pseudospectral analysis. We write conv(S) for the convex hull in $\mathbb{C}$ of a set $S \subseteq \mathbb{C}$. The notation "$S \setminus \varepsilon$-border" also requires some explanation. By this we mean the set of points $z \in \mathbb{C}$ such that $D(z,\varepsilon) \subseteq S$. Perhaps Reddy, Schmid, and Henningson were the first to formulate this result in the language of pseudospectra [15, Thm. 2.2].

Theorem 13. *$W(A) \supseteq \operatorname{conv}(\Lambda(A))$.*

Theorem 13ε. *$W(A) \supseteq \operatorname{conv}(\Lambda_\varepsilon(A)) \setminus \varepsilon$-border.*

Proof. This result follows from a familiar result in functional analysis: that $W(A)$ is the intersection of all convex sets S that satisfy the condition

$$\|(z-A)^{-1}\| \le \frac{1}{\operatorname{dist}(z,S)}.$$

See, for example, Kato [9, p. 268]. □

The spectral mapping theorem (see, e.g., [9, p. 45]) is a jewel in the crown of eigenvalue theorems; it is theoretically appealing and practically relevant, forming the basis for rational transformation techniques for computing eigenvalues. The numerical range obeys a similar, though one-sided, mapping theorem [8]. Theorems 13 and 13ε suggest that a similar result might hold for pseudospectra. Our next theorem is a modest step in this direction, a precise mapping theorem for linear transformations [26, Thm. 2.4].

Theorem 14. *$\Lambda(\alpha + \beta A) = \alpha + \beta\Lambda(A)$ for $\alpha, \beta \in \mathbb{C}$.*

Theorem 14ε. *$\Lambda_{\varepsilon|\beta|}(\alpha + \beta A) = \alpha + \beta\Lambda_\varepsilon(A)$ for $\alpha, \beta \in \mathbb{C}$.*

Proof. The result is trivial when $\beta = 0$. Otherwise, note that

$$|\beta|\,\|(z-(\alpha+\beta A))^{-1}\| = \|(\beta^{-1}(z-\alpha) - A)^{-1}\|. \qquad □$$

For Theorems 15 and 16, let V denote an $N \times k$ rectangular matrix with orthonormal columns for some $k \le N$, as might be obtained by Arnoldi or subspace iteration, and let H denote a $k \times k$ square matrix. In the Arnoldi iteration, H would have Hessenberg form, but this is not necessary for these theorems. First, we assume that the columns of V exactly span an invariant subspace of A. The resulting theorem forms the basis for algorithms that compute pseudospectra by projecting A onto a carefully chosen invariant subspace [15, 25, 29].

Theorem 15. *$AV = VH \implies \Lambda(H) \subseteq \Lambda(A)$.*

Theorem 15ε. *$AV = VH \implies \Lambda_\varepsilon(H) \subseteq \Lambda_\varepsilon(A)$.*

Proof. If $\|Hu - zu\| \le \varepsilon$ for some $u \in \mathbb{C}^N$ with $\|u\| = 1$, then $\|VHu - Vzu\| \le \varepsilon$ too, and this implies $\|AVu - zVu\| \le \varepsilon$. □

Practical algorithms such as the implicitly restarted Arnoldi method [18] or subspace iteration (see, e.g., [16, section V.1]) may not easily yield an exact basis for the invariant subspace. Rather, the columns of V form an orthonormal basis for some *approximate* invariant subspace of A. Let H denote the generalized Rayleigh quotient this basis forms, $H \equiv V^*AV$. With this notation, eigenvalue Theorem 15 has an alternative, more practical pseudospectral generalization. This theorem is a fundamental result in the perturbation theory of invariant subspaces; see [20] and references therein.

THEOREM 16. $AV = VH \implies \Lambda(H) \subseteq \Lambda(A)$.

THEOREM 16ε. $AV = VH + R \implies \Lambda(H) \subseteq \Lambda_\varepsilon(A)$ *for* $\varepsilon = \|R\|$.

Proof. Consider the square matrix $E = -RV^*$. Then $(A+E)V = AV - R = VH$, so by Theorem 15, the eigenvalues of H are eigenvalues of $A+E$ and hence ε-pseudoeigenvalues of A for $\varepsilon = \|-RV^*\| = \|R\|$. □

For an Arnoldi factorization with k basis vectors, $V \in \mathbb{C}^{n\times k}$, Theorem 16$\varepsilon$ reduces to a well-known result: $\varepsilon = \|R\| = |h_{k+1,k}|$, where $h_{k+1,k}$ is the $(k+1, k)$ entry in the extended upper Hessenberg matrix (see, e.g., [17, Lem. 2.1]).

Acknowledgments. We thank Anne Greenbaum for carefully reading an earlier version of this manuscript and pointing out several corrections. We also appreciate helpful comments from Albrecht Böttcher, Nick Higham, and the referees. We especially thank Yvan Notay for noting that the constant in Theorem 12ε could be improved from N to $\sqrt{N}$.

LARGE-SCALE COMPUTATION OF PSEUDOSPECTRA USING ARPACK AND EIGS[*]

THOMAS G. WRIGHT[†] AND LLOYD N. TREFETHEN[†]

Abstract. ARPACK and its Matlab counterpart, `eigs`, are software packages that calculate some eigenvalues of a large nonsymmetric matrix by Arnoldi iteration with implicit restarts. We show that at a small additional cost, which diminishes relatively as the matrix dimension increases, good estimates of pseudospectra in addition to eigenvalues can be obtained as a by-product. Thus in large-scale eigenvalue calculations it is feasible to obtain routinely not just eigenvalue approximations, but also information as to whether or not the eigenvalues are likely to be physically significant. Examples are presented for matrices with dimension up to 200,000.

Key words. Arnoldi, ARPACK, eigenvalues, implicit restarting, pseudospectra

1. Introduction.

The matrices in many eigenvalue problems are too large to allow direct computation of their full spectra, and two of the iterative tools available for computing a part of the spectrum are ARPACK [10, 11] and its Matlab counterpart, `eigs`.[1] For nonsymmetric matrices, the mathematical basis of these packages is the Arnoldi iteration with implicit restarting [11, 23], which works by compressing the matrix to an "interesting" Hessenberg matrix, one which contains information about the eigenvalues and eigenvectors of interest. For general information on large-scale nonsymmetric matrix eigenvalue iterations, see [2, 21, 29, 31].

For some matrices, nonnormality (nonorthogonality of the eigenvectors) may be physically important [30]. In extreme cases, nonnormality combined with the practical limits of machine precision can lead to difficulties in accurately finding the eigenvalues. Perhaps the more common and more important situation is when the nonnormality is pronounced enough to limit the physical significance of eigenvalues for applications, without rendering them uncomputable. In applications, users need to know if they are in such a situation. The prevailing practice in large-scale eigenvalue calculations is that users get no information of this kind.

There is a familiar tool available for learning more about the cases in which nonnormality may be important: pseudospectra. Figure 1 shows some of the pseudospectra of the "Grcar matrix" of dimension 400 [6], the exact spectrum, and converged eigenvalue estimates (Ritz values) returned by a run of ARPACK (seeking the eigenvalues of largest modulus) for this matrix. In the original article [23] that described the algorithmic basis of ARPACK, Sorensen presented some similar plots of difficulties encountered with the Grcar matrix. This is an extreme example where the nonnormality is so pronounced that even with the convergence tolerance set to its lowest possible value, machine epsilon, the eigenvalue estimates are far from the true spectrum. From the Ritz values alone, one might not realize that anything was

[1] In Matlab version 5, `eigs` was an M-file adapted from the Fortran ARPACK codes. Starting with Matlab version 6, the `eigs` command calls the Fortran ARPACK routines themselves.

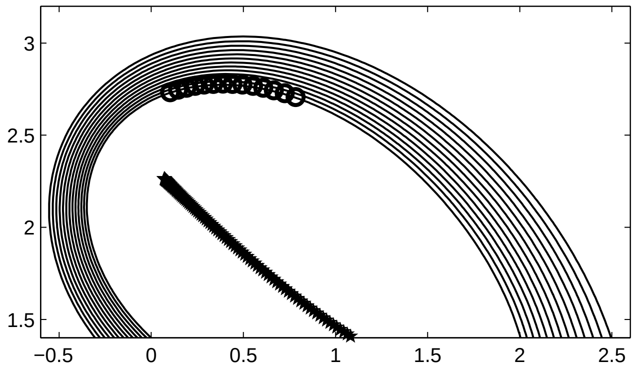

FIG. 1. *The ϵ-pseudospectra for $\epsilon = 10^{-5}, 10^{-6}, \ldots, 10^{-17}$ of the Grcar matrix (dimension 400), with the actual eigenvalues shown as solid stars and the converged eigenvalue estimates (for the eigenvalues of largest modulus) returned by ARPACK shown as open circles. The ARPACK estimates lie between the 10^{-16} and 10^{-17} pseudospectral contours.*

amiss. Once the pseudospectra are plotted too, it is obvious.

Computing the pseudospectra of a matrix of dimension N is traditionally an expensive task, requiring an $\mathcal{O}(N^3)$ singular value decomposition at each point in a grid. For a reasonably fine mesh, this leads to an $\mathcal{O}(N^3)$ algorithm with the constant of the order of thousands. Recent developments in algorithms for computing pseudospectra have improved the constant [28], and the asymptotic complexity for large sparse matrices [3, 12], but these are still fairly costly techniques. In this paper we show that for large matrices, we can cheaply compute an approximation to the pseudospectra in a region near the interesting eigenvalues. Our method uses the upper Hessenberg matrix constructed after successive iterations of the implicitly restarted Arnoldi algorithm, as implemented in ARPACK. Among other things, this means that after performing an eigenvalue computation with ARPACK or `eigs`, a user can quickly obtain a graphical check to indicate whether the Ritz values returned are likely to be physically meaningful. Our vision is that every ARPACK or `eigs` user ought to plot pseudospectra estimates routinely after their eigenvalue computations as a cheap "sanity check."

Some ideas related to ours have appeared in earlier papers by Nachtigal, Reichel, and Trefethen [17], Ruhe [19], Sorensen [23], Toh [24], and Toh and Trefethen [25]. For example, Sorensen plotted level curves of filter polynomials and observed that they sometimes approximated pseudospectra, and Ruhe showed that pseudospectra could be approximated by a rational Krylov method. What is new here is the explicit development of a method for approximating pseudospectra based on ARPACK. Of course, one could also consider the use of different low-dimensional compressions of a matrix problem such as those constructed by the Jacobi–Davidson algorithm [22]. Preliminary experiments, not reported here, show that this kind of Jacobi–Davidson approximation of pseudospectra can also be effective.

We start by giving an overview of pseudospectra calculations and the implicitly restarted Arnoldi iteration, followed by the practical details of our implementation along with a discussion of some of the problems we have had to deal with. After this we give some examples of the technique in practice. We also mention our MATLAB graphical user interface (GUI), which automates the computation of pseudospectra after the eigenvalues of a matrix have been computed by `eigs` in Matlab.

The computations presented in this paper were all performed using `eigs` in Matlab version 6 (which essentially is ARPACK) and our GUI rather than the Fortran ARPACK, although our initial experiments were done with the Fortran code.

2. Pseudospectra. There are several equivalent ways of defining $\Lambda_\epsilon(A)$, the ϵ-pseudospectrum of a matrix A. The two most important (see, e.g., [27]) are perhaps

$$\Lambda_\epsilon(A) = \{z \in \mathbb{C} : \|(zI - A)^{-1}\| \geq \epsilon^{-1}\} \tag{2.1}$$

and

$$\Lambda_\epsilon(A) = \{z \in \mathbb{C} : z \in \Lambda(A + E) \text{ for some } E \text{ with } \|E\| \leq \epsilon\}. \tag{2.2}$$

When the norms are taken to be the 2-norm, the definitions are equivalent to

$$\Lambda_\epsilon(A) = \{z \in \mathbb{C} : \sigma_{\min}(zI - A) \leq \epsilon\}, \tag{2.3}$$

where $\sigma_{\min}(\cdot)$ denotes minimum singular value. This provides the basis of many algorithms for computing pseudospectra. The most familiar technique is to use a grid over the region of the complex plane of interest and calculate the minimum singular value of $zI - A$ at each grid point z. These values can then be passed to a contour plotter to draw the level curves. For the rest of this paper, we consider the 2-norm; other norms are discussed in [8, 28].

The reason for the cost of computation of pseudospectra is now clear: the amount of work needed to compute the minimum singular value of a general matrix of dimension N is $\mathcal{O}(N^3)$ (see, e.g., [5]). However, several techniques have been developed to reduce this cost [28]. Here are two important ones.

(I) Project the matrix onto a lower dimensional invariant subspace via, e.g., a partial Schur factorization (Reddy, Schmid, and Henningson [18]). This works well when the interesting portion of the complex plane excludes a large fraction of the eigenvalues of the matrix. In this case, the effect of the omitted eigenvalues on the interesting portion of the pseudospectra is typically small, especially if the undesired eigenvalues are well conditioned. Projection can significantly reduce the size of the matrix whose pseudospectra we need to compute, making the singular value computation dramatically faster. In general, the additional cost of projecting the matrix is much less than the cost of repeatedly computing the smallest singular value for the shifted original matrix.

(II) Perform a single matrix reduction to Hessenberg or triangular form before doing any singular value decompositions (Lui [12]), allowing the singular value calculations to be done using a more efficient algorithm.

One way of combining these ideas is to do a complete Schur decomposition of the matrix, $A = UTU^*$, and then to reorder the diagonal entries of the triangular matrix to leave the "wanted" eigenvalues at the top. The reordered factorization can then be truncated leaving the required partial Schur factorization. We can now find the singular values of the matrices shifted for each grid point z using either the original matrix A or the triangular matrix T:

$$\sigma(zI - A) = \sigma(zUIU^* - UTU^*) = \sigma(U(zI - T)U^*) = \sigma(zI - T). \tag{2.4}$$

This allows us to work solely with the triangular matrix T once the $\mathcal{O}(N^3)$ factorization has been completed. The minimum singular value of $zI - T$ can be determined in $\mathcal{O}(N^2)$ operations[2] using the fact that $\sigma_{\min}(zI - T) = \sqrt{\lambda_{\min}((zI - T)^*(zI - T))}$. This can be calculated using either inverse iteration or inverse Lanczos iteration, which require solutions to systems of equations with the matrix $(zI - T)^*(zI - T)$. These can be solved in two stages, each using triangular system solves.

By combining these techniques with more subtle refinements we have an algorithm which is much more efficient than the straightforward method. It is suggested in [28] that the speedup obtained is typically a factor of about $N/4$, assuming the cost of the Schur decomposition is negligible compared with that of the rest of the algorithm. This will be the case on a fine grid for a relatively small matrix (N of the order of a thousand or less), but for larger matrices the Schur decomposition is relatively expensive, and it destroys any sparsity structure.

3. Arnoldi iteration.

The Arnoldi iteration for a matrix A of dimension N works by projecting A onto successive Krylov subspaces $\mathcal{K}_j(A, v_1) \subseteq \mathbb{C}^N$ of dimension j for some starting vector v_1 [1, 20]. It builds an orthonormal basis for the Krylov subspace by the Arnoldi factorization

$$AV_j = V_j H_j + f_j e_j^* = V_{j+1}\widetilde{H}_j, \tag{3.1}$$

where H_j is an upper Hessenberg matrix of dimension j, the columns of V_j form an orthonormal basis for the Krylov subspace, and f_j is orthogonal to the columns of V_j. The residual term $f_j e_j^*$ can be incorporated into the first term $V_j H_j$ by augmenting the matrix H_j with an extra row, all zeros except for the last entry, which is $\|f_j\|$, and including the next basis vector, $v_{j+1} = f_j/\|f_j\|$, in the matrix V_j. The matrix $\widetilde{H}_j$ is now rectangular, of size $(j+1) \times j$.

The matrix $\widetilde{H}_j$, being rectangular, does not have any eigenvalues, but we can define its pseudospectra in terms of singular values by (2.3). (With $\epsilon = 0$, we recover the definition occasionally used that λ is an eigenvalue of a rectangular matrix A if $A - \lambda I$ is rank-deficient, where I is the rectangular matrix of appropriate dimension with 1 on the diagonal and 0 elsewhere. In general, a rectangular matrix will have no eigenvalues, but it will have nonempty ϵ-pseudospectra for large enough ϵ.) It can then be shown [14, 25] that the pseudospectra of successive $\widetilde{H}_j$ are nested.

THEOREM 3.1. *Let A be an $N \times N$ matrix which is unitarily similar to a Hessenberg matrix H, and let $\widetilde{H}_j$ denote the upper left $(j+1) \times j$ section (in particular $\widetilde{H}_j$ could be created using a restarted Arnoldi iteration). Then for any $\epsilon \geq 0$,*

$$\Lambda_\epsilon(\widetilde{H}_1) \subseteq \Lambda_\epsilon(\widetilde{H}_2) \subseteq \cdots \subseteq \Lambda_\epsilon(A). \tag{3.2}$$

Thus as the iteration progresses, the pseudospectra of the rectangular Hessenberg matrices better approximate those of A, which gives some justification for the approximation $\Lambda_\epsilon(A) \approx \Lambda_\epsilon(\widetilde{H}_j)$. Unfortunately, this is only the case for the rectangular matrices $\widetilde{H}_j$. There do not appear to be any satisfactory theorems to justify a similar approximation for the square matrices H_j, and of course for ϵ sufficiently small the ϵ-pseudospectra of H_j must be disjoint from those of A, since they will be small sets surrounding the eigenvalues of H_j, which are in general distinct from those of A. This is not the case for the rectangular matrix as there will not be points in the complex plane with infinite resolvent norm unless a Ritz value exactly matches an

[2] An $\mathcal{O}(N^2)$ algorithm can also be used for Hessenberg matrices [12], but for those we do not have the advantage of projection.

eigenvalue of the original matrix. That is, $\Lambda_\epsilon(\widetilde{H}_j)$ is typically empty for sufficiently small ϵ.

Although the property (3.2) is encouraging, theorems guaranteeing rapid convergence in all cases cannot be expected. The quality of the approximate pseudospectra depends on the information in the Krylov subspace, which in turn depends on the starting vector v_1. Any guarantee of rapid convergence could at best be probabilistic.

3.1. Implicitly restarted Arnoldi. In its basic form, the Arnoldi process may require close to N iterations before the subspace contains good information about the eigenvalues of interest. However, the information contained within the Hessenberg matrix is very dependent on the starting vector v_1: if v_1 contains relatively small components of the eigenvectors corresponding to the eigenvalues which are *not* required, convergence may be quicker and the subspace size need not grow large. To avoid the size of the subspace growing too large, practical implementations of the Arnoldi iteration restart when the subspace size j reaches a certain threshold [20]. A new starting vector $\hat{v}_1$ is chosen which has smaller components in the directions of eigenvectors corresponding to unwanted eigenvalues, and the process is begun again.

Implicit restarting [11, 23] is based upon the same idea, except that subspace is only implicitly compressed to a single starting vector $\hat{v}_1$. What is explicitly formed is an Arnoldi factorization of size k based on this new starting vector, where k is the number of desired eigenvalues, and this Arnoldi factorization is obtained by carrying out $p - k$ implicitly shifted steps of the QR algorithm, with shifts possibly corresponding to unwanted eigenvalue estimates. The computation now proceeds in an accordion-like manner, expanding the subspace to its maximum size p, then compressing to a smaller subspace.[3] This is computationally more efficient than simple restarting because the subspace is already of size k when the iteration restarts, and in addition, the process is numerically stable due to the use of orthogonal transformations in performing the restarting. This technique has made the Arnoldi iteration competitive for finding exterior eigenvalues of a wide range of nonsymmetric matrices.

3.2. Arnoldi for pseudospectra. In a 1996 paper, Toh and Trefethen [25] demonstrated that the Hessenberg matrix created during the Arnoldi process can sometimes provide a good approximation to the pseudospectra of the original matrix. They provided results for both the square matrix H_j and the rectangular matrix $\widetilde{H}_j$. We choose to build our method around the rectangular Hessenberg matrices $\widetilde{H}_j$, even though this makes the pseudospectral computation harder than if we worked with the square matrix. The advantage of this is that we retain the properties of Theorem 3.1, and the following in particular:

For every $\epsilon \geq 0$, the approximate ϵ-pseudospectrum generated by our ARPACK algorithm is a subset of the ϵ-pseudospectrum of the original matrix,

$$\Lambda_\epsilon(\widetilde{H}_p) \subseteq \Lambda_\epsilon(A). \tag{3.3}$$

This is completely different from the familiar situation with Ritz values, which are, after all, the points in the 0-pseudospectrum of a square Hessenberg matrix. Ritz values need not be contained in the true spectrum. Simply by adding one more row to consider a rectangular matrix, we have obtained a guaranteed inclusion for every ϵ.

The results presented by Toh and Trefethen focus on trying to approximate the full pseudospectra of the matrix (i.e., around the entire spectrum) and they do not use

[3] Our use of the variable p follows `eigs`. In ARPACK and in Sorensen's original paper [23], this would be $p + k$.

any kind of restarting in their implementation of the Arnoldi iteration. While this is a useful theoretical idea, we think it is of limited practical value for computing highly accurate pseudospectra since good approximations are often obtained generally only for large subspace dimensions.

Our work is more local; we want a good approximation to the pseudospectra in the region around the eigenvalues requested from ARPACK or `eigs`. By taking advantage of ARPACK's implicit restarting, we keep the size of the subspace (and hence $\widetilde{H}_p$) reasonably small, allowing us to compute (local) approximations to the pseudospectra more rapidly, extending the idea of [25] to a fully practical technique (for a more restricted problem).

4. Implementation. In deciding to use the rectangular Hessenberg matrix $\widetilde{H}_j$, we have made the post-ARPACK phase of our algorithm more difficult. While the simple algorithm of computing the minimum singular value of $zI-A$ at each point has approximately the same cost for a rectangular matrix as a square one, the speedup techniques described in section 2 are difficult to translate into the rectangular case.

The first idea, projection to a lower dimensional invariant subspace, does not make sense for rectangular matrices because there is no such thing as an invariant subspace. The second idea, preliminary triangularization using a Schur decomposition, also does not extend to rectangular matrices, for although it is possible to triangularize the rectangular matrix while keeping the same singular values (by performing a QR factorization, for example), doing so destroys the vital property of shift-invariance (see (2.4)).

However, our particular problem has a feature we have not yet considered: the matrix is Hessenberg. One way to exploit this property is to perform a QR factorization of the matrix obtained after shifting for each grid point. The upper triangular matrix R has the same singular values as the shifted matrix, and they are also unchanged on removing the last row of zeros, which makes the matrix square. We can now use the inverse Lanczos iteration as in section 2 to find its smallest singular value. The QR factorization can be done with an $\mathcal{O}(N^2)$ algorithm (see, e.g., [5, p. 228]), which makes the overall cost $\mathcal{O}(N^2)$. Unfortunately, the additional cost of the QR factorization at each stage makes this algorithm slightly slower for the small matrices (dimensions 50–150) output from ARPACK than for square matrices of the same size, but this appears to be the price to be paid for using matrices which have the property of (3.3).

4.1. Refinements. In some cases we have found that inverse iteration to find the minimum eigenvalue of $(zI-R)^*(zI-R)$ is more efficient than inverse Lanczos iteration but only when used with continuation (Lui [12]). Continuation works by using the vector corresponding to the smallest singular value from the previous grid point as the starting guess for the next grid point.

This sounds like a good idea; if the two shifted matrices differ by only a small shift, their singular values (and singular vectors) will be similar. When it works, it generally means that only a single iteration is needed to satisfy the convergence criterion. However, as Lui indicates, there is a problem with this approach if the smallest and second smallest singular values "change places" between two values of z: the iteration may converge to the second smallest singular value instead of the smallest, since the starting vector had such a strong component in the direction of the corresponding singular vector. This leads to the convergence criterion being satisfied for the wrong singular value (even after several iterations).

```
Choose max subspace size $p$—larger $p$ for better pseudospectra.
Choose number of eigenvalues $k$—larger $k$ for better pseudospectra.
Run ARPACK($A, p, k$) to obtain $\widetilde{H}_p$.
Define a grid over a region of $\mathbb{C}$ enclosing converged Ritz values.
For each grid point $z$:
    Perform reduced QR factorization of shifted matrix: $z\tilde{I} - \widetilde{H}_p = \widetilde{Q}_p R$.
    Get $\lambda_{\max}(z)$ from Lanczos iteration on $(R^*R)^{-1}$, random starting vector.
    $\sigma_{\min}(z) := 1/\sqrt{\lambda_{\max}(z)}$.
end.
Start GUI and create contour plot of the $\sigma_{\min}$ values.
Allow adjustment of parameters (e.g., grid size, contour levels) in GUI.
```

FIG. 2. *Pseudocode for our algorithm.*

In the course of our research, we have found several test matrices which suffer from this problem, including the so-called Tolosa matrix [4]. Accordingly, because of our desire to create a robust algorithm, we do not use inverse iteration. In theory it is also possible to use continuation with inverse Lanczos iteration, but our experiments indicate that the benefit is small and it again brings a risk of misconvergence.

Our algorithm (the main loop of which is similar to that in [28]) is summarized in Figure 2.

5. Practical examples.

While one aim of our method is to approximate the pseudospectra of the original matrix accurately, this is perhaps no more important than the more basic mission of exhibiting the degree of nonnormality the matrix has, so that the ARPACK or `eigs` user gets some idea of whether the Ritz values returned are likely to be physically meaningful. Even in cases where the approximations of the sets $\Lambda_\epsilon(A)$ are inaccurate, a great deal may still be learned from their qualitative properties.

In the following examples, ARPACK was asked to look for the eigenvalues of largest real part except where otherwise indicated. However, the choice of region of the complex plane to focus on is unimportant for our results and is determined by which eigenvalues are of interest for the particular problem at hand. The number of requested eigenvalues k was chosen rather arbitrarily to be large enough so that the approximate pseudospectra clearly indicate the true behavior in the region of the complex plane shown, and the maximum subspace size p was chosen to ensure convergence of ARPACK for the particular choice of k. Experiments show that the computed pseudospectra are not very sensitive to the choices of k and p, provided they are large enough, but we have not attempted to optimize these choices.

5.1. Two extremes.

Our first example (Figure 3), from Matrix Market [15], shows a case where the approximation is extremely good. The matrix is the Jacobi matrix of dimension 800 for the reaction-diffusion Brusselator model from chemical engineering [7], and one seeks the rightmost eigenvalues. The matrix is not highly nonnormal, and the pseudospectra given by the approximation almost exactly match the

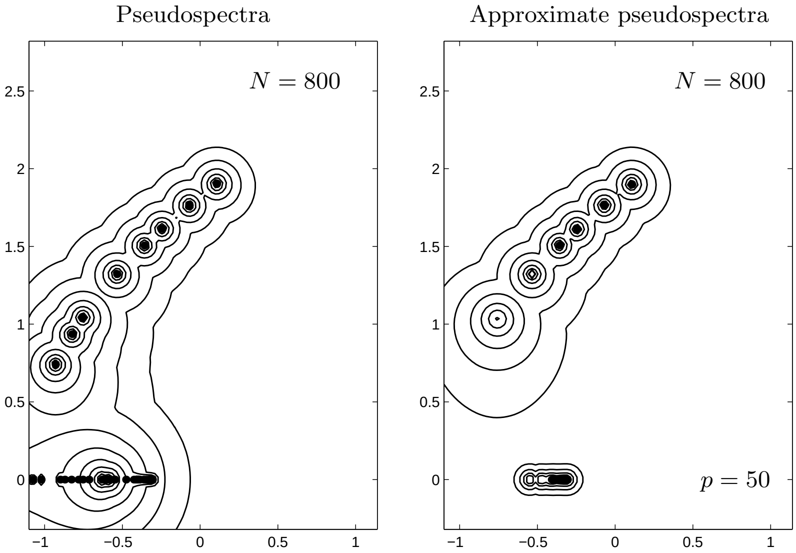

FIG. 3. *Pseudospectra for the matrix* `rdb800l` *(left) computed using the standard method, and pseudospectra of the upper Hessenberg matrix of dimension* $p = 50$ *computed using ARPACK (right) in about* 9% *of the computer time (on the fine grid used here). Levels are shown for* $\epsilon = 10^{-1}, 10^{-1.2}, \ldots, 10^{-2.4}$. *The number of matrix-vector products needed by ARPACK* (n_v) *is* 1,493.

true pseudospectra around the converged Ritz values. This is a case where the pseudospectra computed after running ARPACK indicate that the eigenvalues returned are both accurate and physically meaningful, and that no further investigation is necessary. In this computation we used a maximum subspace dimension of $p = 50$ and requested $k = 30$ eigenvalues.

The second case we consider is one where the matrix has a high degree of nonnormality—the Grcar matrix. As seen in Figure 1, ARPACK can converge to Ritz values which are eigenvalues of a perturbation of order machine precision of the original matrix, and the nonnormality of this particular matrix (here of dimension 400) means that the Ritz values found can lie a long way from the spectrum of the matrix. Figure 4 shows that the pseudospectra of the Hessenberg matrix (computed using $p = 50$, $k = 45$, and asking for eigenvalues of largest modulus) in this case are not good approximations to the pseudospectra of the original one.

This is typical for highly nonnormal matrices—the Hessenberg matrix cannot capture the full extent of the nonnormality, particularly when more than p eigenvalues of the original matrix lie within the region of the complex plane in which the pseudospectra are computed. In other words, the approximation is typically not so good in areas away from the Ritz values computed, and then only accurately approximates the pseudospectra of the original matrix when the Ritz values are good approximations to the eigenvalues. Despite this, a plot like that of Figure 4 will instantly indicate to the ARPACK user that the matrix at hand is strongly nonnormal and needs further investigation.

5.2. A moderately nonnormal example. While the above examples show two extreme cases, many important applications are more middle-of-the-range, where

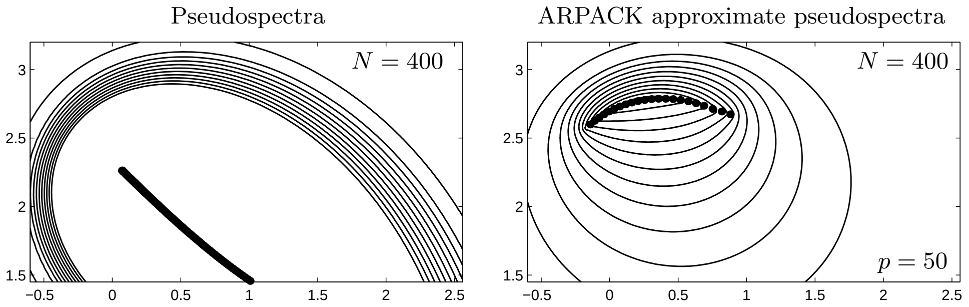

Fig. 4. *The pseudospectra of the Grcar matrix of dimension* 400 *(left) computed using the standard method, and the pseudospectra of the upper Hessenberg matrix of dimension* 50 *computed using ARPACK (right) in about* 8% *of the computer time (on this fine grid). Contours are shown for* $\epsilon = 10^{-1}, 10^{-2}, \ldots, 10^{-11}$*, and* $n_v =$ 8,284.

machine precision is sufficient to accurately converge the eigenvalues, but pronounced nonnormality may nevertheless diminish the physical significance of some of them. A good example of a case in which this is important is the matrix created by linearization about the laminar solution of the Navier–Stokes equations for fluid flow in an infinite circular pipe [26]. (Our matrix is obtained by a Petrov–Galerkin spectral discretization of the Navier–Stokes problem due to Meseguer and Trefethen [16]. The axial and azimuthal wave numbers are 0 and 1, respectively, and the matrix dimension is 402.) The pseudospectra are shown in Figure 5, and although the eigenvalues all have negative real part, implying stability of the flow, the pseudospectra protrude far into the right half-plane. This implies pronounced transient growth of some perturbations of the velocity field in the pipe, which in the presence of nonlinearities in practice may lead to transition to turbulence [30]. The approximate pseudospectra also highlight

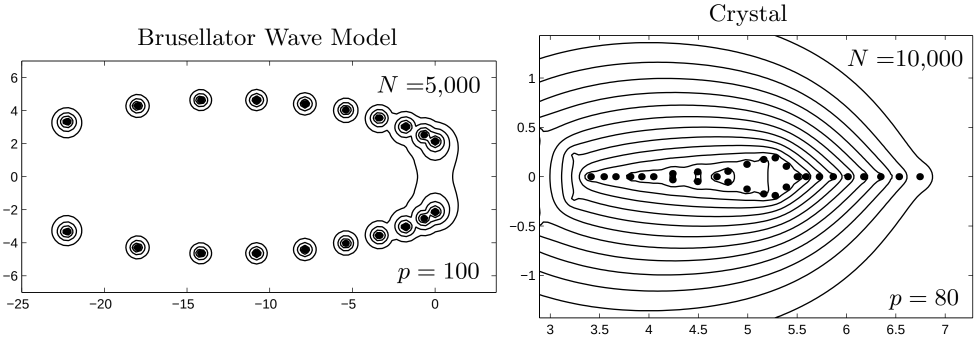

FIG. 6. *Left: The* $\epsilon = 10^{-0.2}, 10^{-0.4}, \ldots, 10^{-1.6}$ *pseudospectra for the Brusselator wave model,* $n_v = 16{,}906$*. this behavior. The parameters used here were $p = 50$ and $k = 25$.

5.3. Larger examples. We now consider four larger examples. The first is the Brusselator wave model from Matrix Market (not to be confused with the very first example), which models the concentration waves for reaction and transport interaction of chemical solutions in a tubular reactor [9]. Stable periodic solutions exist for a parameter when the rightmost eigenvalues of the Jacobian are purely imaginary. For a matrix of dimension 5,000, using a subspace of dimension 100 and asking ARPACK for 20 eigenvalues, we obtained the eigenvalue estimates and approximate pseudospectra shown in Figure 6 (left). The departure from normality is evidently mild, and the conclusion from this computation is that the Ritz values returned by ARPACK are likely to be accurate and the corresponding eigenvalues physically meaningful.

Figure 6 (right) shows approximate pseudospectra for a matrix of dimension 10,000, taken from the Crystal set at Matrix Market, which arises in a stability analysis of a crystal growth problem [32]. The eigenvalues of interest are the ones with largest real part. The fact that we can see the 10^{-13} pseudospectrum (when the axis scale is $\mathcal{O}(1)$) indicates that this matrix is significantly nonnormal, and although the matrix is too large for us to be able to compute its exact pseudospectra for comparison, this is certainly a case where the nonnormality could be important, making all but the rightmost few eigenvalues of dubious physical significance in an application. The ARPACK parameters we used in this case were $p = 80$ and $k = 30$, and the computation took about one hour on our Sun Ultra 5 workstation. Although we do not have the true pseudospectra in this case, we would expect that the rightmost portion should be fairly accurate where there is a good deal of Ritz data and relatively little nonnormality. We expect that the leftmost portion is less accurate where the effect of the remaining eigenvalues of the matrix unknown to the approximation begins to become important.

The third example, Figure 7 (left), shows the Airfoil matrix created by performing transient stability analysis of a Navier–Stokes solver [13], also from Matrix Market. In this case the matrix appears fairly close to normal, and the picture gives every reason to believe that the eigenvalues have physical meaning. Using $p = 80$ and $k = 20$, ARPACK took about 9 hours to converge to the eigenvalues, while we were able to plot the pseudospectra in about 3 minutes (even on the fine grid used here).

Our final example is a matrix which is bidiagonal plus random sparse entries

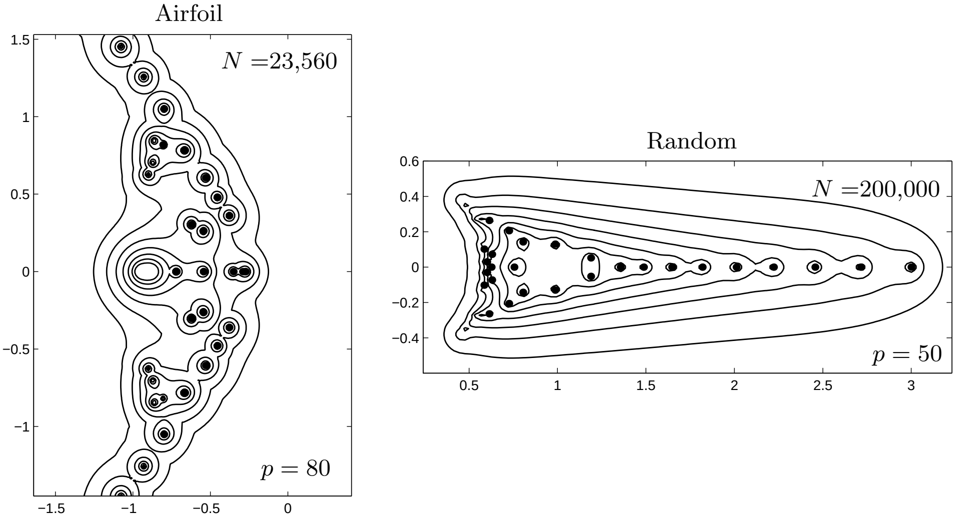

FIG. 7. *Left: The* $\epsilon = 10^{-1}, 10^{-1.25}, \ldots, 10^{-2.5}$ *pseudospectra for the Airfoil matrix from Matrix Market of dimension* 23,560*,* $n_v = 72{,}853$*. Right: The* $\epsilon = 10^{-1}, 10^{-1.5}, \ldots, 10^{-4.5}$ *pseudospectra for our random matrix, with* $n_v = 61{,}347$*.*

elsewhere, created in MATLAB by

```
A = spdiags([3*exp(-(0:N-1)'/10) .5*ones(N,1)], 0:1, N, N)
      + .1*sprandn(N,N,10/N);
```

The approximation to the pseudospectra of the matrix of dimension 200,000 is shown in Figure 7 (right), from which we can conclude that the eigenvalue estimates returned are probably accurate, but that the eigenvalues toward the left of the plot would likely be of limited physical significance in a physical application, if there were one, governed by this matrix. We used a subspace size of 50 and requested 30 eigenvalues from this example, and the whole computation took about 26 hours.

6. MATLAB GUI. We have created a MATLAB GUI to automate the process of computing pseudospectra, and Figure 8 shows a snapshot after a run of ARPACK. Initially the pseudospectra are computed on a coarse grid to give a fast indication of the nonnormality of the matrix, but the GUI allows control over the number of grid points if a higher quality picture is desired. Other features include the abilities to change the contour levels shown without recomputing the underlying values, and to select parts of the complex plane to zoom in for greater detail. The GUI can also be used as a graphical front end to our other pseudospectra codes for computing pseudospectra of smaller general matrices. The codes are available on the World Wide Web from http://web.comlab.ox.ac.uk/oucl/work/nick.trefethen/.

7. Discussion. The examples of section 5 give an indication of the sort of pictures obtained from our technique. For matrices fairly close to normal, the approximation is typically a very close match to the exact pseudospectra, but for more highly nonnormal examples the agreement is not so close. This is mainly due to the effect of eigenvalues which the Arnoldi iteration has not found: their effect on the pseudospectra is typically more pronounced for nonnormal matrices.

The other point to note is that if we use the Arnoldi iteration to look (for ex-

ample) for eigenvalues of largest real part, the rightmost part of the approximate pseudospectra will be a reasonably good approximation. This can clearly be seen in Figure 4 where we are looking for eigenvalues of largest modulus: the top parts of the pseudospectra are fairly good and only deteriorate lower down where the effect of the "unfound" eigenvalues becomes important.

However, as mentioned in the introduction, creating accurate approximations of pseudospectra was only part of the motivation for this work. Equally important has been the goal of providing information which can help the user of ARPACK or `eigs` decide whether the computed eigenvalues are physically meaningful. For this purpose, estimating the degree of nonnormality of the matrix is more important than getting an accurate plot of the exact pseudospectra.

One of the biggest advantages of our technique is that while the time spent on the ARPACK computation grows as the dimension of the matrix increases, the time spent on the pseudospectra computation remains roughly constant. This is because the pseudospectra computation is based just on the final Hessenberg matrix, of dimension typically in the low hundreds at most. Figure 9 shows the proportion of time spent on the pseudospectra part of the computation for the examples we have presented here. These timings are based on the time to compute the initial output from our

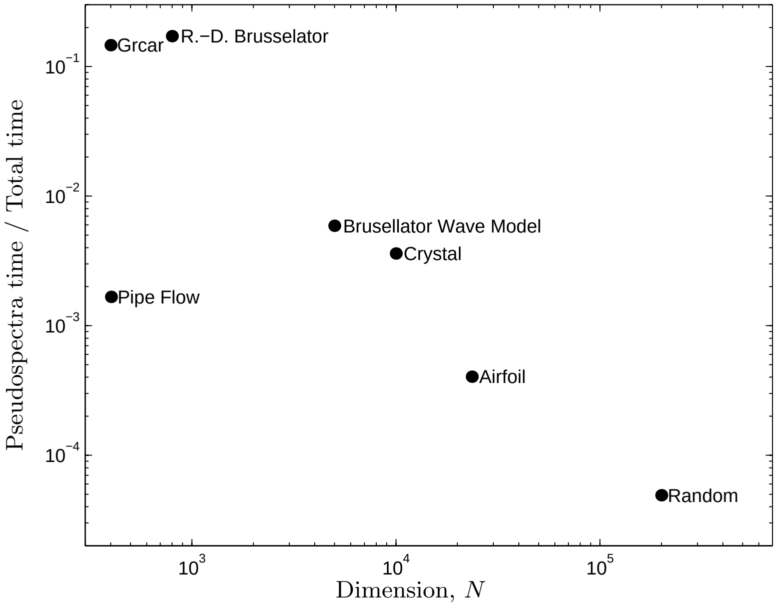

FIG. 9. *The proportion of the total computation time spent on computing the pseudospectra for the examples presented in this paper. For large N, the pseudospectra are obtained at very little additional cost.*

Figure* 4*).*

GUI using a coarse grid such as those illustrated in Figure 10, which is our standard resolution for day-to-day work. For the "publication quality" pseudospectra of the resolution of the other plots in this paper, the cost is about thirty times higher, but this is still much less than the cost of ARPACK for dimensions N in the thousands.

Acknowledgments. We would like to thank Rich Lehoucq for his advice on ARPACK beginning during his visit to Oxford in October–November 1999, Penny Anderson of The MathWorks, Inc., for her help with the beta version of the new `eigs` command, and Mark Embree for his comments on drafts of the paper.

A JACOBI–DAVIDSON TYPE SVD METHOD*

MICHIEL E. HOCHSTENBACH†

Abstract. We discuss a new method for the iterative computation of a portion of the singular values and vectors of a large sparse matrix. Similar to the Jacobi–Davidson method for the eigenvalue problem, we compute in each step a correction by (approximately) solving a correction equation. We give a few variants of this Jacobi–Davidson SVD (JDSVD) method with their theoretical properties. It is shown that the JDSVD can be seen as an accelerated (inexact) Newton scheme. We experimentally compare the method with some other iterative SVD methods.

Key words. Jacobi–Davidson, singular value decomposition (SVD), singular values, singular vectors, norm, augmented matrix, correction equation, (inexact) accelerated Newton, improving singular values

1. Introduction.

Suppose that we want to compute one or more singular values, and the corresponding singular vectors, of the real $m \times n$ matrix A. This subject has already been studied from a number of different viewpoints [5, 6, 1, 19, 20, 13], for example, to determine a few of the largest or smallest singular triples. This partial SVD can be computed in two different ways using equivalent eigenvalue decompositions.

The first is to compute some eigenvalues and eigenvectors of the $n \times n$ matrix A^TA or the $m \times m$ matrix AA^T. For large (sparse) matrices, direct methods like the QR method are unattractive, but there exist several iterative methods. In [13], for example, (block) Lanczos [10] and Davidson [2] are applied to A^TA. Another candidate is Jacobi–Davidson [15]. Note that it is in general not advisable (or necessary) to explicitly form the product A^TA. The nonzero eigenvalues of A^TA and AA^T are the squares of the nonzero singular values of A. This works positively for the separation of large singular values, but it forces a clustering of small ones. Moreover, it can be hard to find very small singular values (relative to the largest singular value) accurately. Apart from this, the approaches via A^TA or AA^T are asymmetric: in the process we approximate only one of the two singular vectors. The second vector can be obtained from the first by a multiplication by A or A^T, but this may introduce extra loss of accuracy. Besides, when we have approximations to both the left and right singular vector, we can use only one of them as a starting vector for an iterative method.

A second approach is to compute some eigenvalues and eigenvectors of the *augmented matrix*

$$\begin{pmatrix} 0 & A \\ A^T & 0 \end{pmatrix}. \tag{1.1}$$

This approach has its own advantages and disadvantages. The eigenvalues of the augmented matrix are plus and minus the singular values of A, and we can extract the left and right singular vectors from the eigenvectors by just taking the first and second part (see section 2). This makes an extra multiplication by A or A^T unnecessary. We

†Mathematical Institute, Utrecht University, P.O. Box 80.010, NL-3508 TA Utrecht, The Netherlands (hochstenbach@math.uu.nl, www.math.uu.nl/people/hochstenbach).

do not have the drawback of squaring small singular values. On the negative side, the augmented matrix is larger in size, and the smallest singular values are in the interior of the spectrum.

The Lanczos method for the augmented matrix has been studied by a number of authors [5, 6, 1]. The Lanczos process does not exploit the special (block or "two-cyclic") structure of the matrix, unless the starting vector is of the form $(u, 0)$ or $(0, v)$. This is essentially Lanczos bidiagonalization of A; see [7, p. 495].

We can also consider the Jacobi–Davidson method [15] for the augmented matrix. This is an efficient method for the computation of a few eigenpairs, and it is of a different nature in comparison to Lanczos. The essence of Jacobi–Davidson is its correction equation, where the shifted operator is restricted to the subspace orthogonal to the current approximation to an eigenvector. When we solve this equation exactly, we can show that the updated vector is the same as the one we would get by one step of Rayleigh quotient iteration (RQI). But in practice one solves the Jacobi–Davidson correction equation only approximately, and one accelerates the convergence by projecting the matrix onto the subspace spanned by all iterates. Therefore, Jacobi–Davidson can also be viewed as an inexact accelerated RQI.

"Standard" Jacobi–Davidson does not make use of the structure of the augmented matrix. In this paper we propose a Jacobi–Davidson variant that *does* take advantage of the special structure of the matrix. Instead of searching the eigenvector in one subspace, we search the left and right singular vectors in separate subspaces. We still solve a correction equation for the augmented matrix, but we use different projections, and we split the approximate solution of this equation for the expansion of the two search spaces. More similarities and differences are discussed in section 7.3.

After some preparations in section 2, we introduce the new approach, which we call the Jacobi–Davidson SVD (JDSVD), in section 3. In section 4, a few variants of the algorithm with their properties are presented. In section 5, we show that the JDSVD process can be viewed as an (inexact) accelerated Newton scheme, and in section 6 we focus on convergence. Various aspects of the method are discussed in section 7, and after numerical examples in section 8, we finish with conclusions in section 9.

2. Preparations. Let A be a real $m \times n$ matrix with SVD $A = U_* \Sigma V_*^T$ and singular values

$$0 \le \sigma_{\min} = \sigma_p \le \sigma_{p-1} \le \cdots \le \sigma_2 \le \sigma_1 = \sigma_{\max},$$

where $p := \min\{m, n\}$. Denote the corresponding left and right singular vectors by $u_{*,j}$ $(1 \le j \le m)$ and $v_{*,j}$ $(1 \le j \le n)$.

Throughout the paper, $\|\cdot\|$ stands for $\|\cdot\|_2$, and we write $\sigma_j(B)$ for the jth largest singular value of a real matrix B and simply σ_j for the jth largest singular value of A. Furthermore, $\Lambda(B)$ is the spectrum of B, and $\Sigma(B)$ is the set of singular values of B. If B is a real symmetric matrix, then $\lambda_j(B)$ denotes the jth largest eigenvalue of B.

If $a \in \mathbb{R}^m$ and $b \in \mathbb{R}^n$, then, for convenience, we write $\binom{a}{b} \in \mathbb{R}^{m+n}$ also as (a, b). If X is a matrix, then we denote the subspace spanned by the columns of X by $\mathcal{X}$. We use the notation $\mathcal{K}_l(B, x)$ for the Krylov subspace of dimension l generated by B and x.

DEFINITION 2.1. *Let $u \in \mathbb{R}^m$, $v \in \mathbb{R}^n$, $\mathcal{X} \subset \mathbb{R}^m$, and $\mathcal{Y} \subset \mathbb{R}^n$. We say that $\binom{u}{v} \in \mathbb{R}^{m+n}$ is double-orthogonal to the pair of subspaces $(\mathcal{X}, \mathcal{Y})$ if both $u \perp \mathcal{X}$*

and $v \perp \mathcal{Y}$, *which is denoted by* $\binom{u}{v} \perp\perp \binom{\mathcal{X}}{\mathcal{Y}}$. *By* $(u,v)^{\perp\perp}$ *we denote the subspace* $\{(a,b) \in \mathbb{R}^m \times \mathbb{R}^n : u^T a = v^T b = 0\}$.

The following lemma gives a relation between the singular triples of A and the eigenpairs of the augmented matrix.

LEMMA 2.2 (Jordan–Wielandt; see Theorem I.4.2 of [18]). *The augmented matrix* (1.1) *has eigenvalues*

$$-\sigma_1, \ldots, -\sigma_p, \underbrace{0, \ldots, 0}_{|m-n|}, \sigma_p, \ldots, \sigma_1$$

and eigenvectors

$$\begin{pmatrix} u_{*,j} \\ \pm v_{*,j} \end{pmatrix} \quad (1 \le j \le p)$$

corresponding to the $\pm\sigma_j$ *and, if* $m \neq n$, *additionally,*

$$\textit{either} \begin{pmatrix} u_{*,j} \\ 0 \end{pmatrix} \ (n+1 \le j \le m) \quad \textit{or} \quad \begin{pmatrix} 0 \\ v_{*,j} \end{pmatrix} \ (m+1 \le j \le n),$$

depending on whether $m > n$ *or* $n > m$.

The next definition is the natural analogue of the definition of a simple eigenvalue (see, e.g., [18, p. 15]).

DEFINITION 2.3. *We call* σ_i *a simple singular value of* A *if* $\sigma_i \neq \sigma_j$ *for all* $j \neq i$.

The following lemma gives a link between a simple singular value of A and a simple eigenvalue of A^TA and AA^T.

LEMMA 2.4. *Let* $\sigma > 0$. *Then* σ *is a simple singular value of* A *if and only if* σ^2 *is a simple eigenvalue of* A^TA *and* AA^T.

Proof. The nonzero eigenvalues of A^TA and AA^T are just the squares of the nonzero singular values of A (see, for example, [18, p. 31]). □

Note that the condition $\sigma > 0$ in the previous lemma is necessary. For example, 0 is a simple singular value of the 1×2 matrix $A = (0\ 0)$, but it is not a simple eigenvalue of A^TA.

For future use, we mention the following well-known results.

LEMMA 2.5 (Weyl; see pp. 101–102 of [21], Corollary IV.4.9 of [18], and Theorem 10.3.1 of [12]). *Let* B *and* E *be real symmetric* $n \times n$ *matrices. Then for all* $1 \le j \le n$

$$\lambda_j(B) + \lambda_n(E) \le \lambda_j(B+E) \le \lambda_j(B) + \lambda_1(E).$$

LEMMA 2.6 (see (3.3.17) of [9]). *If* B *and* E *are* $m \times n$ *matrices, then for* $1 \le i,\ j \le p$, *and* $i + j \ \le p+1$,

$$\sigma_{i+j-1}(B+E) \le \sigma_i(B) + \sigma_j(E).$$

In particular, for $j = 1$ *this yields* $\sigma_i(B+E) \le \sigma_i(B) + \sigma_1(E)$ *for* $i = 1, \ldots, p$.

LEMMA 2.7 (see (7.3.8) of [8]). *Let* B *and* E *be real* $m \times n$ *matrices. Then*

$$\sum_{j=1}^{p} (\sigma_j(B+E) - \sigma_j(B))^2 \le \|E\|_F^2.$$

LEMMA 2.8. *If* U *and* V *are orthogonal* $m \times m$ *and* $n \times n$ *matrices, respectively, then for all* $1 \le j \le p$ *we have* $\sigma_j(U^TAV) = \sigma_j(A)$. *In particular,* $\|U^TAV\| = \|A\|$.

Proof. The SVD of U^TAV is just $(U^TU_*)\Sigma(V^TV_*)^T$. The final statement follows from the characterization of the matrix two-norm as the largest singular value. □

LEMMA 2.9 (see (3.1.3) of [9]). *Let B be an $m \times n$ matrix, and let B_l denote a submatrix of B obtained by deleting a total of l rows and/or columns from B. Then*

$$\sigma_j(B) \geq \sigma_j(B_l) \geq \sigma_{j+l}(B)$$

for $1 \leq j \leq p$, where for a $q \times r$ matrix X we set $\sigma_j(X) = 0$ if $j > \min\{q, r\}$.

3. The JDSVD correction equation. Suppose that we have k-dimensional *search spaces* $\mathcal{U} \subset \mathbb{R}^m$ and $\mathcal{V} \subset \mathbb{R}^n$ and *test spaces* $\mathcal{X} \subset \mathbb{R}^m$ and $\mathcal{Y} \subset \mathbb{R}^n$. To determine approximations θ, η to a singular value, and $u \in \mathcal{U}, v \in \mathcal{V}$ (of unit norm) to the corresponding left and right singular vectors, we impose the *double Galerkin condition* with respect to $\mathcal{X}$ and $\mathcal{Y}$ on the *residual* r:

$$r = r(\theta, \eta) := \begin{pmatrix} Av - \theta u \\ A^Tu - \eta v \end{pmatrix} \perp\perp \begin{pmatrix} \mathcal{X} \\ \mathcal{Y} \end{pmatrix}. \tag{3.1}$$

Because $u \in \mathcal{U}$ and $v \in \mathcal{V}$, we can write $u = Uc$ and $v = Vd$, where the columns of the $m \times k$ matrix U and the columns of the $n \times k$ matrix V form bases for $\mathcal{U}$ and $\mathcal{V}$, respectively, and $c, d \in \mathbb{R}^k$. Then we want to find θ, η, c, and d that are solutions of

$$\left\{ \begin{array}{lcl} X^TAVd & = & \theta\, X^TUc, \\ Y^TA^TUc & = & \eta\, Y^TVd, \end{array} \right. \tag{3.2}$$

where X and Y are matrices with columns that form bases for $\mathcal{X}$ and $\mathcal{Y}$. For *test vectors* $x \in \mathcal{X}$ and $y \in \mathcal{Y}$, we have, in particular, that $r \perp\perp (x, y)$; so if $x^Tu \neq 0$ and $y^Tv \neq 0$,

$$\theta = \frac{x^TAv}{x^Tu}, \qquad \eta = \frac{y^TA^Tu}{y^Tv}. \tag{3.3}$$

This shows that the approximations θ and η may differ. We discuss possible choices for $\mathcal{X}$ and $\mathcal{Y}$ and the resulting relations for u and v in the following section. For now, suppose that we have approximations (u, v, θ, η). We would like to have a double-orthogonal correction $(s, t) \perp\perp (u, v)$ to (u, v) such that

$$\left\{ \begin{array}{lcl} A(v + t) & = & \sigma(u + s), \\ A^T(u + s) & = & \tau(v + t), \end{array} \right. \tag{3.4}$$

where $\sigma > 0$ and $\tau > 0$ need not be equal because the vectors are not normalized. However, since $A^TA(v+t) = \sigma\tau(v+t)$, we have $\sigma\tau = \sigma_i^2$ for some $1 \leq i \leq p$. Equations (3.4) can be rearranged to obtain

$$\begin{pmatrix} -\sigma I_m & A \\ A^T & -\tau I_n \end{pmatrix} \begin{pmatrix} s \\ t \end{pmatrix} = -\begin{pmatrix} Av - \theta u \\ A^Tu - \eta v \end{pmatrix} + \begin{pmatrix} (\sigma - \theta)u \\ (\tau - \eta)v \end{pmatrix} = -r + \begin{pmatrix} (\sigma - \theta)u \\ (\tau - \eta)v \end{pmatrix}.$$

Because σ and τ are unknown, we do not know the differences $(\sigma - \theta)u$ and $(\tau - \eta)v$ either. Therefore, we can consider the projection of the last equation onto $(x, y)^{\perp\perp}$ along (u, v). This projection is given by

$$\begin{pmatrix} I_m - \frac{ux^T}{x^Tu} & 0 \\ 0 & I_n - \frac{vy^T}{y^Tv} \end{pmatrix},$$

and it fixes r. Projecting the previous equation, we get

$$\begin{pmatrix} I_m - \frac{ux^T}{x^Tu} & 0 \\ 0 & I_n - \frac{vy^T}{y^Tv} \end{pmatrix} \begin{pmatrix} -\sigma I_m & A \\ A^T & -\tau I_n \end{pmatrix} \begin{pmatrix} s \\ t \end{pmatrix} = -r, \qquad \text{where } (s,t) \perp\perp (u,v). \tag{3.5}$$

Since σ and τ are unknown, an obvious choice is to replace them by θ and η. This can be considered as "throwing away second order terms" ($\sigma - \theta$, $\tau - \eta$, s, and t will all be asymptotically small) and suggests that the JDSVD is in fact a Newton method, which is true indeed (see section 5). Furthermore, since for every $\widetilde{x} \in \mathbb{R}^m$ and $\widetilde{y} \in \mathbb{R}^n$ such that $u^T\widetilde{x} \neq 0$ and $v^T\widetilde{y} \neq 0$

$$\begin{pmatrix} I_m - \frac{\widetilde{x}u^T}{u^T\widetilde{x}} & 0 \\ 0 & I_n - \frac{\widetilde{y}v^T}{v^T\widetilde{y}} \end{pmatrix} \begin{pmatrix} s \\ t \end{pmatrix} = \begin{pmatrix} s \\ t \end{pmatrix},$$

(3.5) leads to the *JDSVD correction equation*

$$\begin{pmatrix} I_m - \frac{ux^T}{x^Tu} & 0 \\ 0 & I_n - \frac{vy^T}{y^Tv} \end{pmatrix} \begin{pmatrix} -\theta I_m & A \\ A^T & -\eta I_n \end{pmatrix} \begin{pmatrix} I_m - \frac{\widetilde{x}u^T}{u^T\widetilde{x}} & 0 \\ 0 & I_n - \frac{\widetilde{y}v^T}{v^T\widetilde{y}} \end{pmatrix} \begin{pmatrix} s \\ t \end{pmatrix} = -r, \tag{3.6}$$

where $(s,t) \perp\perp (u,v)$. We see that the operator in (3.6) is symmetric if and only if $\widetilde{x}$ and $\widetilde{y}$ are a nonzero multiple of x and y. It maps $(u,v)^{\perp\perp}$ to $(x,y)^{\perp\perp}$. In sections 5 and 6 we explain why this process may lead to fast convergence, and we meet a generalized version of the correction equation. In the next section we examine several choices for the Galerkin conditions (3.1).

4. Choices for the Galerkin conditions.

Consider the eigenvalue problem for a symmetric matrix B, where we have one subspace $\mathcal{W}$ that is used both as search space and test space. If the columns of W form an orthonormal basis for $\mathcal{W}$, then the projected matrix W^TBW has some nice properties; see [12, section 11.4]. We will see that searching in two spaces, as in the JDSVD, spreads those properties over a few Galerkin choices. In this section we examine some obvious choices.

4.1. The standard choice $\mathcal{X} = \mathcal{U}$ and $\mathcal{Y} = \mathcal{V}$.

Consider the situation where the search spaces $\mathcal{U}$ and $\mathcal{V}$ are of equal dimension k. Let us first take the test spaces $\mathcal{X}$ and $\mathcal{Y}$ equal to the search spaces $\mathcal{U}$ and $\mathcal{V}$.

If the columns of U and V form orthonormal bases for $\mathcal{U}$ and $\mathcal{V}$, then with the notation $H := U^TAV$, (3.2) reduces to

$$Hd = \theta c \quad \text{and} \quad H^Tc = \eta d. \tag{4.1}$$

This gives approximations $u = Uc$ and $v = Vd$, where c and d are, respectively, left and right singular vectors of H. With the requirement $\|c\| = \|d\| = 1$ and test vectors $x = u$ and $y = v$, we get

$$\theta = \eta = u^TAv. \tag{4.2}$$

For reasons of symmetry, we choose $\widetilde{x} = x$ $(= u)$ and $\widetilde{y} = y$ $(= v)$. The resulting algorithm for the computation of $\sigma_{\max}$ is given in Algorithm 4.1.

In step 2 of the algorithm, RMGS stands for repeated modified Gram–Schmidt (see, for example, [7, pp. 231–232]), used to make s and t orthogonal to U_{k-1} and

```
Input: a device to compute $Av$ and $A^Tu$ for arbitrary $u$ and $v$, starting vectors $u_1$ and $v_1$,
    and a tolerance $\varepsilon$.
Output: the approximate singular triple $(\theta, u, v)$ for the largest singular value
    $\sigma_{\max}$ and its corresponding singular vectors satisfying $\|\binom{Av-\theta u}{A^Tu-\theta v}\| \le \varepsilon$.

1.    $s = u_1,\ t = v_1,\ U_0 = [\ ],\ V_0 = [\ ]$
      for $k = 1, \ldots$
2.        $U_k = \mathrm{RMGS}(U_{k-1}, s)$
          $V_k = \mathrm{RMGS}(V_{k-1}, t)$
3.        Compute $k$th column of $W_k = AV_k$
          Compute $k$th row and column of $H_k = U_k^T AV_k = U_k^T W_k$
4.        Compute largest singular triple $(\theta, c, d)$ of $H_k$, $(\|c\| = \|d\| = 1)$
          $u = U_k c,\ v = V_k d$
5.        $r = \binom{Av-\theta u}{A^Tu-\theta v} = \binom{W_k d-\theta u}{A^Tu-\theta v}$
6.        Stop if $\|r\| \le \varepsilon$
7.        Solve (approximately) an $(s,t) \perp\perp (u,v)$ from
      $\begin{pmatrix} I_m - uu^T & 0 \\ 0 & I_n - vv^T \end{pmatrix} \begin{pmatrix} -\theta I_m & A \\ A^T & -\theta I_n \end{pmatrix} \begin{pmatrix} I_m - uu^T & 0 \\ 0 & I_n - vv^T \end{pmatrix} \begin{pmatrix} s \\ t \end{pmatrix} = -r$
```

ALG. 4.1. *The JDSVD algorithm for the computation of* $\sigma_{\max}(A)$ *with Galerkin conditions* $\mathcal{X} = \mathcal{U}$, $\mathcal{Y} = \mathcal{V}$. *The approximations* (θ, η, u, v) *satisfy* $\theta = \eta = u^TAv$.

V_{k-1}, and to expand the search spaces with the normalized vectors. Furthermore, [ ] stands for the empty matrix, and we omit the index k of all variables that are overwritten in every step. If we are interested in another singular value, for example, the smallest, or the one closest to a specific target, we should adjust our choice in step 4 of the algorithm accordingly. The variant of Algorithm 4.1 is the only variant of the JDSVD for which the operator in (3.6) is symmetric and maps $(u,v)^{\perp\perp}$ in itself. Other choices imply that the operator is not symmetric or maps $(u,v)^{\perp\perp}$ to a different space. See also section 7.2.

4.2. Optimality of this choice. The following two results indicate that the method resulting from this standard Galerkin choice is optimal in some sense. Suppose we have an $m \times k$ matrix U and an $n \times k$ matrix V. Then for any $k \times k$ matrices K and L there are associated an $m \times k$ residual matrix $R(K)$ and an $n \times k$ residual matrix $\widetilde{R}(L)$:

$$R(K) := AV - UK \quad \text{and} \quad \widetilde{R}(L) := A^TU - VL.$$

If there exist K and L such that these residual matrices are zero, then we have found left and right singular subspaces, i.e., invariant subspaces of A^TA and AA^T. The following theorem states that if both U and V have orthonormal columns, then $H := U^TAV$ and $H^T = V^TA^TU$ minimize the norm of these residual matrices, which is a desirable property. It is a generalization of a result in the theory for eigenproblems (see [12, Theorem 11.4.2] and [18, Theorem IV.1.15]), which deals with residuals of the form $AV - VK$.

THEOREM 4.1 (cf. Theorem 11.4.2 of [12]). *For given* $m \times k$ *matrix* U *and* $n \times k$ *matrix* V, *let* $H = U^TAV$.

(a) *If the columns of* U *are orthonormal, then for all* $k \times k$ *matrices* K *we have* $\|R(H)\| \le \|R(K)\|$. *Moreover,* H *is unique with respect to the Frobenius norm* $\|R(H)\|_F \le \|R(K)\|_F$ *with equality only when* $K = H$.

(b) *If the columns of V are orthonormal, then $H^T = V^T A^T U$ minimizes the norm of $\widetilde{R}(L)$, and H^T is unique with respect to the Frobenius norm.*

Proof. Suppose that the columns of U are orthonormal; then $U^T U = I$, so

$$\begin{aligned} R(K)^T R(K) &= V^T A^T A V + K^T K - K^T H - H^T K \\ &= V^T A^T A V - H^T H + (K-H)^T (K-H) \\ &= R(H)^T R(H) + (K-H)^T (K-H). \end{aligned}$$

Since $(K-H)^T(K-H)$ is positive semidefinite, it follows that

$$\|R(K)\|^2 = \lambda_{\max}(R(K)^T R(K)) \geq \lambda_{\max}(R(H)^T R(H)) = \|R(H)\|^2,$$

where we used Lemma 2.5 in the inequality. For uniqueness, we realize that $\|B\|_F^2 = \text{Trace}(B^T B)$ for every real matrix B. Part (b) can be proved using the same methods. □

Proposition 4.2. *Let u and v be approximations of unit norm. Then*

$$(\theta, \eta) = (u^T A v, u^T A v) \text{ minimizes } \|r(\theta, \eta)\|.$$

Proof. This can be shown by differentiating $\|r(\theta,\eta)\|^2$ with respect to θ and η. □

Because of these two results, it is a natural idea to take the k singular values $\theta_j^{(k)}$ of H_k as approximations to the singular values of A. When U_k and V_k have orthonormal columns, we see by Lemma 2.8 that these approximations converge in a finite number of steps to the singular values of A. In the following theorem we show that the approximations converge monotonically increasing.

Theorem 4.3. *Let $\theta_k^{(k)} \leq \cdots \leq \theta_1^{(k)}$ be the singular values of $H_k := U_k^T A V_k$, where U_k and V_k have orthonormal columns. Then for all fixed j and increasing k, the $\theta_j^{(k)}$ converge monotonically increasing to the σ_j.*

Proof. H_k is a submatrix of H_{k+1}, so according to Lemma 2.9 $\theta_j^{(k+1)} \geq \theta_j^{(k)}$ for $1 \leq j \leq k$. Because of the orthogonality of U_k and V_k, the $\theta_j^{(k)}$ converge to the σ_j. □

Remark 4.4. *In practice, one often observes that the $\theta_j^{(k)}$ converge strictly monotonically to the σ_j. With the aid of* [21, pp. 94–98]*, conditions could be formulated under which the convergence is strict.*

Note that the theorem does *not* say that the smallest approximations $\theta_k^{(k)}$ converge monotonically (decreasing) to σ_p, because Lemma 2.9 only gives us $\theta_{k+1}^{(k+1)} \leq \theta_{k-1}^{(k)}$. For example, if $u_k \approx u_{*,p}$ and $v_k \approx v_{*,p-1}$, then $\theta_k^{(k)} \approx 0$, so we see that the smallest approximation can in fact be (much) smaller than σ_p. Experiments show that the convergence of the $\theta_k^{(k)}$ can be irregular and slow (see section 8). This is a serious difficulty of working with the augmented matrix, because the smallest singular values are in the interior of its spectrum. We discuss this matter further in sections 4.3, 4.4, and 7.5. The following theorem gives some relations between the singular values of H_k and those of A. For clarity, we leave out the index k as much as possible.

Theorem 4.5 (cf. Theorems 11.5.1 and 11.5.2 of [12] and Corollary IV.4.15 of [18]). *For $j = 1, \ldots, k$, there exist singular values $\sigma_{j'}$ of A which can be put in one-one correspondence with the singular values θ_j of H in such a way that*

$$|\sigma_{j'} - \theta_j| \leq \max\{\|R(H)\|, \|\widetilde{R}(H^T)\|\} \qquad (1 \leq j \leq k).$$

Moreover,

$$\sum_{j=1}^{k} (\sigma_{j'} - \theta_j)^2 \le \|R(H)\|_F^2 + \|\widetilde{R}(H^T)\|_F^2.$$

Proof. Let the columns of $\widetilde{U}$ and $\widetilde{V}$ be orthonormal bases for the orthogonal complements of U and V, respectively. Then both $[U\ \widetilde{U}]$ and $[V\ \widetilde{V}]$ are orthogonal and

$$[U\ \widetilde{U}]^T A [V\ \widetilde{V}] = \begin{pmatrix} H & 0 \\ 0 & \widetilde{U}^T A \widetilde{V} \end{pmatrix} + \begin{pmatrix} 0 & U^T A \widetilde{V} \\ \widetilde{U}^T A V & 0 \end{pmatrix}. \tag{4.3}$$

Using Lemmas 2.8 and 2.6, respectively, we obtain for $1 \le j \le p = \min\{m, n\}$

$$\sigma_j(A) = \sigma_j\left([U\ \widetilde{U}]^T A [V\ \widetilde{V}]\right) \le \sigma_j \begin{pmatrix} H & 0 \\ 0 & \widetilde{U}^T A \widetilde{V} \end{pmatrix} + \sigma_{\max} \begin{pmatrix} 0 & U^T A \widetilde{V} \\ \widetilde{U}^T A V & 0 \end{pmatrix}.$$

Now

$$[U\ \widetilde{U}]^T R(H) = \begin{pmatrix} 0 \\ \widetilde{U}^T A V \end{pmatrix} \qquad \text{and} \qquad [V\ \widetilde{V}]^T \widetilde{R}(H^T) = \begin{pmatrix} 0 \\ \widetilde{V}^T A^T U \end{pmatrix},$$

so, because of the orthogonal invariance of the norm (see Lemma 2.8), $\|R(H)\| = \|\widetilde{U}^T A V\|$ and $\|\widetilde{R}(H^T)\| = \|\widetilde{V}^T A^T U\| = \|U^T A \widetilde{V}\|$. Because

$$\Sigma \begin{pmatrix} H & 0 \\ 0 & \widetilde{U}^T A \widetilde{V} \end{pmatrix} = \Sigma(H) \ \cup \ \Sigma(\widetilde{U}^T A \widetilde{V}),$$

there exist indices j' such that

$$\sigma_{j'} \begin{pmatrix} H & 0 \\ 0 & \widetilde{U}^T A \widetilde{V} \end{pmatrix} = \theta_j.$$

So the theorem's first inequality is obtained by

$$\sigma_{\max} \begin{pmatrix} 0 & U^T A \widetilde{V} \\ \widetilde{U}^T A V & 0 \end{pmatrix} = \max\ \{\|\widetilde{U}^T A V\|, \|U^T A \widetilde{V}\|\} = \max\ \{\|R(H)\|, \|\widetilde{R}(H^T)\|\}.$$

For the second inequality, apply Lemma 2.7 to the splitting of (4.3). □

For the following proposition, we need the minimax theorem for singular values [9, Theorem 3.1.2]

$$\sigma_j = \max_{\mathcal{X}^j \subset \mathbb{R}^n} \ \min_{0 \ne x \in \mathcal{X}} \frac{\|Ax\|}{\|x\|}, \tag{4.4}$$

where $\mathcal{X}^j$ ranges over all subspaces of $\mathbb{R}^n$ of dimension j.

The following proposition states that the singular values of $U_k^T A V_k$ are also *not* optimal in another sense.

Proposition 4.6. *Let U_k and V_k have orthonormal columns. For $1 \le j \le k$,*

$$\sigma_j(U_k^T A V_k) \le \sigma_j(A V_k) \qquad \textit{and} \qquad \sigma_j(U_k^T A V_k) \le \sigma_j(A^T U_k).$$

Proof. This follows from (4.4) and the inequalities $\|U_k^T A V_k y\| \le \|A V_k y\|$ and $\|V_k^T A^T U_k x\| \le \|A^T U_k x\|$. □

We have seen that the $\sigma_j(U_k^T A V_k)$ increase monotonically and that they are bounded above by both $\sigma_j(AV_k) = \lambda_j^{1/2}(V_k^T A^T A V_k)$ and $\sigma_j(A^T U_k) = \lambda_j^{1/2}(U_k^T A A^T U_k)$. This forms one motivation to study other Galerkin choices. A second is the possibly irregular convergence of the smallest singular value of $U_k^T A V_k$.

4.3. Other choices. Suppose that the columns of V form an orthonormal basis for $\mathcal{V}$. By the Galerkin choice $\mathcal{X} = A\mathcal{V}$, $\mathcal{Y} = \mathcal{V}$, with test vectors $x = Av$, $y = v$, and $u = Uc$, $v = Vd$, and $\|v\| = 1$, (3.2) reduces to

$$\left\{ \begin{array}{lcl} V^T A^T A V d & = & \theta\, V^T A^T U c, \\ V^T A^T U c & = & \eta\, d. \end{array} \right. \tag{4.5}$$

One can check that to satisfy the Galerkin conditions, $(\theta\eta, d)$ should be an eigenpair of $V^T A^T A V$. Now first suppose that $V^T A^T U$ is nonsingular. Note that in this case $\eta \neq 0$; otherwise, $V^T A^T U$ would be singular. It follows that $c = \eta (V^T A^T U)^{-1} d$, $\eta = v^T A^T u$, and $\theta = v^T A^T A v / v^T A u$. When $V^T A^T U$ is singular, then this construction is impossible, but in this case we can simply restart the process or add extra vectors to the search spaces (see section 7.6).

With this Galerkin choice, θ and η do not converge monotonically in general, but we can apply well-known results from eigenvalue theory to ensure that their product does converge monotonically to the squares of the singular values and also to the smallest. In section 7.2 we discuss the resulting correction equation.

Likewise, if the columns of U form an orthonormal basis for $\mathcal{U}$, the Galerkin choice $\mathcal{X} = \mathcal{U}$, $\mathcal{Y} = A^T\mathcal{U}$ leads to the determination of $(\theta\eta, c)$, an eigenpair of $U^T A A^T U$. These two approaches are natural with respect to minimax considerations, as we will see now.

LEMMA 4.7. *Let $\xi \in [0,1]$. Then we have the following minimax property for singular values:*

$$\sigma_j = \max_{\substack{\mathcal{S}^j \subset \mathbb{R}^m \\ \mathcal{T}^j \subset \mathbb{R}^n}} \min_{\substack{0 \neq s \in \mathcal{S}^j \\ 0 \neq t \in \mathcal{T}^j}} \xi \frac{\|At\|}{\|t\|} + (1-\xi) \frac{\|A^T s\|}{\|s\|} \qquad (1 \le j \le p). \tag{4.6}$$

Proof. This follows from (4.4) and the observation that A and A^T have the same singular values. □

When we have search spaces $\mathcal{U}$ and $\mathcal{V}$, it is a natural idea to substitute $\mathcal{U}$ for $\mathbb{R}^m$ and $\mathcal{V}$ for $\mathbb{R}^n$ in (4.6), as a generalization of a similar idea in the theory of eigenproblems; see [12, p. 236]. This gives the following approximations for the singular values:

$$\tau_j = \max_{\substack{\mathcal{S}^j \subset \mathcal{U} \\ \mathcal{T}^j \subset \mathcal{V}}} \min_{\substack{0 \neq s \in \mathcal{S}^j \\ 0 \neq t \in \mathcal{T}^j}} \xi \frac{\|At\|}{\|t\|} + (1-\xi) \frac{\|A^T s\|}{\|s\|}. \tag{4.7}$$

The following theorem relates these approximations to the Ritz values of $A^T A$ and AA^T.

THEOREM 4.8. $\tau_j = \xi(\lambda_j^{1/2}(V^T A^T A V)) + (1-\xi)(\lambda_j^{1/2}(U^T A A^T U))$.

Proof. We have that $\mathcal{T}^j \subset \mathcal{V}$ if and only if $\mathcal{T}^j = V\widetilde{\mathcal{T}}^j := \{Vt : t \in \widetilde{\mathcal{T}}^j\}$ and $\widetilde{\mathcal{T}}^j \subset \mathbb{R}^k$. So for the first term of the expression for the τ_j we have that

$$\max_{\mathcal{T}^j \subset \mathcal{V}} \min_{0 \neq t \in \mathcal{T}^j} \frac{\|At\|^2}{\|t\|^2} = \max_{\widetilde{\mathcal{T}}^j \subset \mathbb{R}^k} \min_{0 \neq t \in \widetilde{\mathcal{T}}^j} \frac{t^T V^T A^T A V t}{\|t\|^2} = \lambda_j(V^T A^T A V).$$

For the second term we have a similar expression. □

When we take $\xi = 0$ and $\xi = 1$ in Theorem 4.8, we recognize the Galerkin approaches described in (4.5) and the discussion after that. They can essentially be viewed as a two-sided approach to A^TA or AA^T, in the sense that we have approximations to both the left and the right singular vector during the process.

As a generalization, we can consider the test spaces $\mathcal{X}$ and $\mathcal{Y}$ with bases $\alpha u_i+\beta Av_i$ and $\gamma v_i + \delta A^Tu_i$, respectively, where $\alpha^2 + \beta^2 = \gamma^2 + \delta^2 = 1$. Every choice other than $\alpha = \gamma = 1$ (the standard Galerkin choice discussed in section 4.1) involves the computation of additional projected matrices and more work per iteration.

Another possibility is to take search spaces of unequal dimension, that is, $\mathcal{U}_k$ and $\mathcal{V}_l$, where $k \neq l$. However, in view of the symmetric role of $\mathcal{S}_j$ and $\mathcal{T}_j$ in (4.6), this is probably not very useful.

4.4. Harmonic singular triples. As observed in section 4.2, the standard Galerkin choice leads to monotone convergence for the largest singular value, but it can imply irregular behavior for the smallest singular value. A related problem is the selection of the best approximate vectors. Suppose that $u = \sum_{j=1}^m \gamma_j u_{*,j}$ and $v = \sum_{j=1}^n \delta_j v_{*,j}$ are approximate vectors; then $\theta = u^TAv = \sum_{j=1}^p \gamma_j\delta_j\sigma_j$. (We may assume θ is nonnegative; otherwise, take $-u$ instead of u.) Now suppose that $\theta \approx \sigma_1$, in the sense that $\sigma_2 < \theta < \sigma_1$ and that $\sigma_1 - \theta$ is (much) smaller than $\theta - \sigma_2$. Then we conclude that $\gamma_1 \approx 1$ and $\delta_1 \approx 1$, so u and v are good approximations to $u_{*,1}$ and $v_{*,1}$. But when $\theta \approx \sigma_p$, u and v are not necessarily good approximations to $u_{*,p}$ and $v_{*,p}$. For example, u could have a large component of $u_{*,p-1}$ and a small component of $u_{*,1}$, and v could have a large component of $v_{*,p-2}$ and a small component of $v_{*,1}$. In conclusion, when we search for the largest singular value, it is asymptotically safe to select the largest singular triple of H, but for the smallest singular value the situation is more subtle.

Suppose for the moment that A is square and invertible. If the minimal singular value is the one of interest, the above discussion suggests to study the singular values of A^{-1}. Based on the SVD of A^{-1}

$$A^{-1} = V_*\Sigma^{-1}U_*^T,$$

we try to find the largest singular values of A^{-1} with respect to certain search spaces $\widehat{\mathcal{U}}, \widehat{\mathcal{V}}$ and test spaces $\widehat{\mathcal{X}}, \widehat{\mathcal{Y}}$. The new Galerkin conditions become (cf. (3.1))

$$\begin{pmatrix} A^{-1}\widehat{u} - \widehat{\theta}\widehat{v} \\ A^{-T}\widehat{v} - \widehat{\eta}\widehat{u} \end{pmatrix} \perp\perp \begin{pmatrix} \widehat{\mathcal{Y}} \\ \widehat{\mathcal{X}} \end{pmatrix},$$

where $\widehat{u} \in \widehat{\mathcal{U}}$ and $\widehat{v} \in \widehat{\mathcal{V}}$, say, $\widehat{u} = \widehat{U}\widehat{c}$ and $\widehat{v} = \widehat{V}\widehat{d}$. To avoid having to work with A^{-1}, we take for the search spaces $\widehat{\mathcal{U}} = A\mathcal{V}$ and $\widehat{\mathcal{V}} = A^T\mathcal{U}$ (cf. [15]). This gives the system

$$\left\{ \begin{array}{rcl} \widehat{Y}^TV\widehat{c} & = & \widehat{\theta}\,\widehat{Y}^TA^TU\widehat{d}, \\ \widehat{X}^TU\widehat{d} & = & \widehat{\eta}\,\widehat{X}^TAV\widehat{c}. \end{array} \right.$$

Taking $\widehat{\mathcal{X}} = \mathcal{U}$ and $\widehat{\mathcal{Y}} = \mathcal{V}$ results in equivalent conditions as in the standard choice (4.1); only now $(\widehat{\eta}, \widehat{\theta})$ and $(\widehat{c}, \widehat{d})$ play the role of (θ^{-1}, η^{-1}) and (d, c). The choices $(\widehat{\mathcal{X}}, \widehat{\mathcal{Y}}) = (A\mathcal{V}, \mathcal{V})$, $(\mathcal{U}, A^T\mathcal{U})$, and $(A\mathcal{V}, A^T\mathcal{U})$ lead to different approximations: to (4.5) and other systems described in section 4.3, only the roles of the variables differ. We can call these approximations *harmonic singular triples*, in analogy to the harmonic

Ritz pairs in the eigenproblem [11]. So these harmonic approximations have two advantages: the monotone behavior of the approximations to the smallest singular value, and the selection of a good approximate "smallest" vector.

The conclusion is that the nondefault Galerkin choices, as presented in section 4.3, can also be seen as a "harmonic" approach to the problem. Finally, when A is singular or even nonsquare, we can consider A^+ with respect to the test and search spaces $A\mathcal{V}$ and $A^T\mathcal{U}$, exploiting the fact that $AA^+A = A$.

5. The JDSVD as an (inexact) accelerated Newton scheme. In [16], it is shown that the Jacobi–Davidson method can be interpreted as an inexact accelerated Newton scheme [4] for the eigenvalue problem. Here we show that the same is true for the JDSVD applied to the singular value problem. Define $F : \mathbb{R}^m \times \mathbb{R}^n \to \mathbb{R}^m \times \mathbb{R}^n$ as

$$F(u, v) := \begin{pmatrix} Av - \theta u \\ A^T u - \eta v \end{pmatrix},$$

where $\theta = \theta(u, v)$ and $\eta = \eta(u, v)$ are as in (3.3). Thus the function F is nonlinear. Consider the singular value problem where we require the singular vectors u_*, v_* to be scaled such that $u_*^T a = 1$ and $v_*^T b = 1$ for certain vectors $a \in \mathbb{R}^m$ and $b \in \mathbb{R}^n$. So we look for solutions u_*, v_* of the equation $F(u, v) = 0$ in the "hyperplane"

$$\left\{(u, v) \in \mathbb{R}^m \times \mathbb{R}^n : u^T a = 1,\ v^T b = 1\right\}.$$

We introduce these a and b to derive a more general form of the correction equation (3.6). If (u_k, v_k) are approximations to the singular vectors, then the next Newton approximations (u_{k+1}, v_{k+1}) are given by $(u_{k+1}, v_{k+1}) = (u_k, v_k) + (s_k, t_k)$, where $(s_k, t_k) \perp\perp (a, b)$ satisfies

$$DF(u_k, v_k)(s_k, t_k) = -F(u_k, v_k) = -r_k.$$

Omitting the index k, one may check (remembering that $\theta = \theta(u, v)$ and $\eta = \eta(u, v)$ are as in (3.3)) that the Jacobian $DF(u, v)$ of F is given by

$$DF(u, v) = \begin{pmatrix} I_m - \frac{ux^T}{x^T u} & 0 \\ 0 & I_n - \frac{vy^T}{y^T v} \end{pmatrix} \begin{pmatrix} -\theta I_m & A \\ A^T & -\eta I_n \end{pmatrix}.$$

Hence the correction equation of the Newton step is given by

$$\begin{pmatrix} I_m - \frac{ux^T}{x^T u} & 0 \\ 0 & I_n - \frac{vy^T}{y^T v} \end{pmatrix} \begin{pmatrix} -\theta I_m & A \\ A^T & -\eta I_n \end{pmatrix} \begin{pmatrix} s \\ t \end{pmatrix} = -r, \qquad \text{where } (s, t) \perp\perp (a, b).$$

For every $\widetilde{x}, \widetilde{y}$ so that $a^T \widetilde{x} \neq 0$ and $b^T \widetilde{y} \neq 0$, this is equivalent to the slightly more general form of the JDSVD correction equation (in comparison with (3.6)),

$$\begin{pmatrix} I_m - \frac{ux^T}{x^T u} & 0 \\ 0 & I_n - \frac{vy^T}{y^T v} \end{pmatrix} \begin{pmatrix} -\theta I_m & A \\ A^T & -\eta I_n \end{pmatrix} \begin{pmatrix} I_m - \frac{\widetilde{x} a^T}{a^T \widetilde{x}} & 0 \\ 0 & I_n - \frac{\widetilde{y} b^T}{b^T \widetilde{y}} \end{pmatrix} \begin{pmatrix} s \\ t \end{pmatrix} = -r, \tag{5.1}$$

where $(s, t) \perp\perp (a, b)$. Note that the substitution $a = u$ and $b = v$ gives (3.6).

If we keep $a, b, x, \widetilde{x}, y$, and $\widetilde{y}$ fixed during the process, and if $x^T u_*, y^T v_*, a^T \widetilde{x}$, and $b^T \widetilde{y}$ are nonzero, then Newton iteration produces a series (u_k, v_k) that converges asymptotically quadratically towards (u_*, v_*) if the starting vector (u_1, v_1) is sufficiently close to (u_*, v_*).

But if we take $a, b, x, \widetilde{x}, y$, and $\widetilde{y}$ variable but converging to certain vectors, such that the denominators in (5.1) do not vanish, we get asymptotically quadratic convergence as well. The choice $a = x = \widetilde{x} = u_k$ and $b = y = \widetilde{y} = v_k$ leads to Algorithm 4.1. With other Galerkin choices described in section 4, the test vectors (x, y) are, in general, not equal to the approximations (u, v), and in this situation the vectors a and b can be useful; see sections 6 and 7.2.

We see that the JDSVD is a Newton scheme, accelerated by the usage of all previous iterates and the projection of A on the subspace that they span. This *subspace acceleration* accelerates the "prequadratic" phase of the method and ensures that we find a singular triple in a finite number of steps. It may be expensive to solve the correction equation exactly. Instead we may solve (5.1) approximately (see section 7.1); the resulting method is an inexact accelerated Newton scheme.

In [14], it is proved that if the correction equation is solved exactly, then Jacobi–Davidson applied to a symmetric matrix has asymptotically cubic convergence. Because the augmented matrix (1.1) is symmetric, we expect that the JDSVD can also reach cubic convergence. The next section shows that this expectation is correct indeed.

6. Convergence. In the previous section we have already seen that the correction equation represents a Jacobian system in a Newton step. Now we focus on the convergence (see [14] for similar observations for Jacobi–Davidson applied to the eigenvalue problem).

In a mathematical sense, it is not meaningful to speak of asymptotic convergence, because we know that the process ends in a finite number of steps. However, in many practical situations a singular triple will be approximated well, long before the dimension of the search spaces reaches p. At that stage, these approximations display a behavior that looks like a converging infinite sequence close to its limit. When speaking of asymptotic convergence, we think of this situation. In other words, by the word "asymptotically" we mean the situation where we have a (very) good approximation to the singular triple, rather than the situation where $k \to \infty$.

In the correction equation (5.1), u and v are the current approximations and x and y are test vectors, but we have not said much about choosing $\widetilde{x}$, $\widetilde{y}$, a, and b. They can vary per step. The next lemma and proposition show that the exact JDSVD (that is, the JDSVD where we solve the correction equation exactly) has asymptotically cubic convergence for specific choices of the test vectors x and y and the vectors a and b. To be precise, with ε small enough, if

$$|\angle(u_k, u_*)| = \mathcal{O}(\varepsilon) \text{ and } |\angle(v_k, v_*)| = \mathcal{O}(\varepsilon) \tag{6.1}$$

and if

$$a = x \text{ and } b = y \qquad \text{and} \qquad |\angle(x, u_*)| = \mathcal{O}(\varepsilon) \text{ and } |\angle(y, v_*)| = \mathcal{O}(\varepsilon), \tag{6.2}$$

then $|\angle(u_{k+1}, u_*)| = \mathcal{O}(\varepsilon^3)$ and $|\angle(v_{k+1}, v_*)| = \mathcal{O}(\varepsilon^3)$. Then the approximate singular values (see (3.3)) converge cubically as well.

LEMMA 6.1 (cf. Lemma 3.1 of [14]). *Assume that $Av_* = \sigma u_*$ and $A^T u_* = \tau v_*$, where $\sigma, \tau > 0$, and that $\sqrt{\sigma\tau}$ is a simple singular value of A. Let a, b, x, $\widetilde{x}$, y, and*

$\widetilde{y}$ be such that x^Tu_*, y^Tv_*, $a^T\widetilde{x}$, $b^T\widetilde{y}$, a^Tu_*, and b^Tv_* are all nonzero. Then the map

$$G := \begin{pmatrix} I_m - \frac{u_*x^T}{x^Tu_*} & 0 \\ 0 & I_n - \frac{v_*y^T}{y^Tv_*} \end{pmatrix} \begin{pmatrix} -\sigma I_m & A \\ A^T & -\tau I_n \end{pmatrix} \begin{pmatrix} I_m - \frac{\widetilde{x}a^T}{a^T\widetilde{x}} & 0 \\ 0 & I_n - \frac{\widetilde{y}b^T}{b^T\widetilde{y}} \end{pmatrix}$$

is a bijection from $(a,b)^{\perp\perp}$ onto $(x,y)^{\perp\perp}$.

Proof. Suppose $(z_1,z_2) \perp\perp (a,b)$ and $G(z_1,z_2)=0$. We show that $z_1=z_2=0$. We have

$$\begin{pmatrix} -\sigma I_m & A \\ A^T & -\tau I_n \end{pmatrix} \begin{pmatrix} z_1 \\ z_2 \end{pmatrix} = \begin{pmatrix} \mu u_* \\ \nu v_* \end{pmatrix}$$

for certain μ,ν. Then

$$\begin{cases} Az_2 &= \sigma z_1 + \mu u_*, \\ A^Tz_1 &= \tau z_2 + \nu v_*. \end{cases}$$

Multiplying the first equation by A^T and the second by A, we find

$$\begin{cases} (A^TA - \sigma\tau)z_2 &= (\sigma\nu + \tau\mu)v_*, \\ (AA^T - \sigma\tau)z_1 &= (\sigma\nu + \tau\mu)u_*. \end{cases}$$

So both z_1 and u_* belong to the kernel of $(AA^T-\sigma\tau)^2$, and both z_2 and v_* belong to the kernel of $(A^TA-\sigma\tau)^2$. From the simplicity of $\sigma\tau$ using Lemma 2.4, we have that z_1 and z_2 are multiples of u_* and v_*, respectively. Because $z_1 \perp a$, $z_2 \perp b$, and $a^Tu_* \neq 0$, $b^Tv_* \neq 0$, we conclude $z_1=z_2=0$. The bijectivity follows from comparing dimensions. □

Proposition 6.2 (cf. Theorem 3.2 of [14]). *With the assumptions of Lemma 6.1, if the initial vectors are close enough to the singular vectors corresponding to a simple nonzero singular value (i.e., if (6.1) holds), and if the correction equation is solved exactly, then for fixed vectors x, y, a, and b, the JDSVD process has quadratic convergence. Moreover, if (6.2) holds, then the JDSVD has even cubic convergence.*

Proof. For convenience write

$$P = \begin{pmatrix} I_m - \frac{ux^T}{x^Tu} & 0 \\ 0 & I_n - \frac{vy^T}{y^Tv} \end{pmatrix}, \ B = \begin{pmatrix} -\theta I_m & A \\ A^T & -\eta I_n \end{pmatrix}, \ Q = \begin{pmatrix} I_m - \frac{\widetilde{x}a^T}{a^T\widetilde{x}} & 0 \\ 0 & I_n - \frac{\widetilde{y}b^T}{b^T\widetilde{y}} \end{pmatrix}.$$

Then the correction equation (5.1) reads, for $(s,t) \perp\perp (a,b)$,

$$PBQ(s,t) = PB(s,t) = -r = -B(u,v).$$

Suppose that $\widetilde{u}$ and $\widetilde{v}$ are scalar multiples of the singular vectors u_* and v_* and that $(\widetilde{u},\widetilde{v}) = (u,v) + (e,f)$, where $(e,f) \perp\perp (a,b)$, and $\|e\| = \mathcal{O}(\varepsilon)$, $\|f\| = \mathcal{O}(\varepsilon)$. Our first goal is to show that $\|(e-s,f-t)\| = \mathcal{O}(\varepsilon^2)$. We know that there are $\sigma,\tau > 0$ such that

$$0 = \begin{pmatrix} -\sigma I_m & A \\ A^T & -\tau I_n \end{pmatrix} \begin{pmatrix} \widetilde{u} \\ \widetilde{v} \end{pmatrix} = \begin{pmatrix} -\theta I_m & A \\ A^T & -\eta I_n \end{pmatrix} \begin{pmatrix} \widetilde{u} \\ \widetilde{v} \end{pmatrix} - \begin{pmatrix} (\sigma-\theta)\widetilde{u} \\ (\tau-\eta)\widetilde{v} \end{pmatrix}.$$

Therefore, we have

$$\begin{pmatrix} -\theta I_m & A \\ A^T & -\eta I_n \end{pmatrix} \begin{pmatrix} e \\ f \end{pmatrix} = -\begin{pmatrix} -\theta I_m & A \\ A^T & -\eta I_n \end{pmatrix} \begin{pmatrix} u \\ v \end{pmatrix} + \begin{pmatrix} (\sigma-\theta)\widetilde{u} \\ (\tau-\eta)\widetilde{v} \end{pmatrix}. \tag{6.3}$$

We multiply this on the left side by P and use the fact that $PB(u, v) = B(u, v)$:

$$PB(e, f) = -B(u, v) + P((\sigma - \theta)\widetilde{u}, (\tau - \eta)\widetilde{v}). \tag{6.4}$$

Subtracting $PB(s, t) = -B(u, v)$ from (6.4), and noting that $P(u, v) = 0$, we get

$$PB(e - s, f - t) = P((\sigma - \theta)e, (\tau - \eta)f). \tag{6.5}$$

Multiplying (6.3) on the left by $\left(\begin{smallmatrix} x & 0 \\ 0 & y \end{smallmatrix}\right)^T$ leads to

$$\begin{pmatrix} \sigma - \theta \\ \tau - \eta \end{pmatrix} = \begin{pmatrix} (x^T\widetilde{u})^{-1} & 0 \\ 0 & (y^T\widetilde{v})^{-1} \end{pmatrix} \begin{pmatrix} -\theta x^T & x^T A \\ y^T A^T & -\eta y^T \end{pmatrix} \begin{pmatrix} e \\ f \end{pmatrix}. \tag{6.6}$$

So for fixed x, y, a, and b we have $\|PB(e - s, f - t)\| = \mathcal{O}(\varepsilon^2)$. Using Lemma 6.1 and the assumption that the initial vectors are close enough to the singular vectors, we see that PB in (6.5) is invertible, so $\|(e - s, f - t)\| = \mathcal{O}(\varepsilon^2)$, which implies quadratic convergence. But, if additionally, (6.2) holds, then

$$\left\| \begin{pmatrix} -\theta x^T & x^T A \\ y^T A^T & -\eta y^T \end{pmatrix} \begin{pmatrix} e \\ f \end{pmatrix} \right\| = \left\| \begin{pmatrix} a^T A f \\ b^T A^T e \end{pmatrix} \right\| = \sigma \left\| \begin{pmatrix} b^T f \\ a^T e \end{pmatrix} \right\| + \mathcal{O}(\varepsilon^2) = \mathcal{O}(\varepsilon^2),$$

so from (6.6) we see that $\|(\sigma - \theta, \tau - \eta)\| = \mathcal{O}(\varepsilon^2)$. We conclude that in this case the convergence is even cubic. □

One may check that the hypotheses on x and y in the theorem are true if we choose $x_k = u_k$ or $x_k = Av_k$, and $y_k = v_k$ or $y_k = A^T u_k$ in the process. The cubic convergence can be observed in practice; see section 8.

7. Various aspects of the method.

7.1. Solving the correction equation.

We now translate a number of observations for Jacobi–Davidson in [15, 14] to the JDSVD context. Consider the situation after k steps of the JDSVD algorithm. For easy reading, we again leave out the index k. In this section we take for simplicity the Galerkin spaces used in section 4.1, but most arguments carry over to other choices. First we rewrite the correction equation. Because of $(s, t) \perp\perp (u, v)$, we can eliminate the projections and write (3.6) as

$$\begin{pmatrix} -\theta I_m & A \\ A^T & -\theta I_n \end{pmatrix} \begin{pmatrix} s \\ t \end{pmatrix} = -r + \begin{pmatrix} \alpha u \\ \beta v \end{pmatrix}, \tag{7.1}$$

where α and β are determined by the requirement that $(s, t) \perp\perp (u, v)$. If we have a nonsingular preconditioner $M \approx \left(\begin{smallmatrix} -\theta I_m & A \\ A^T & -\theta I_n \end{smallmatrix}\right)$, then we can take an approximation

$$(\widetilde{s}, \widetilde{t}) = -M^{-1} r + M^{-1}(\alpha u, \beta v). \tag{7.2}$$

1 (cf. [15, p. 406, point 1]). If we approximate (s, t) simply by $\pm r$ (by taking $M = \mp I$ and $\alpha = \beta = 0$), then, because of the orthogonalization at step 2 of Algorithm 4.1, this is equivalent to taking $(\widetilde{s}, \widetilde{t}) = (Av, A^T u)$. By induction one can prove that for the special case where we take this simple approximation in every step, we have

$$\mathcal{U}_{2k} = \mathcal{K}_k(AA^T, u_1) \oplus \mathcal{K}_k(AA^T, Av_1), \qquad \mathcal{V}_{2k} = \mathcal{K}_k(A^T A, v_1) \oplus \mathcal{K}_k(A^T A, A^T u_1),$$

as long as the Krylov subspaces have a trivial intersection. Compare this with bidiagonalization, where

$$\mathcal{U}_k = \mathcal{K}_k(AA^T, Av_1), \qquad \mathcal{V}_k = \mathcal{K}_k(A^T A, v_1).$$

2 (cf. [15, p. 408, point 3]). If θ is not equal to a singular value, then $M = \left(\begin{smallmatrix} -\theta I_m & A \\ A^T & -\theta I_n \end{smallmatrix}\right)$ is nonsingular and $M^{-1}r = (u, v)$. So for the updated vectors $\widetilde{u}, \widetilde{v}$ we have

$$\begin{pmatrix} \widetilde{u} \\ \widetilde{v} \end{pmatrix} = \begin{pmatrix} u+s \\ v+t \end{pmatrix} = \begin{pmatrix} -\theta I_m & A \\ A^T & -\theta I_n \end{pmatrix}^{-1} \begin{pmatrix} \alpha u \\ \beta v \end{pmatrix}. \tag{7.3}$$

We conclude that exact the JDSVD can be seen as an accelerated scaled RQI.

3 (cf. [15, p. 409, point 4]). If we take $M \neq \left(\begin{smallmatrix} -\theta I_m & A \\ A^T & -\theta I_n \end{smallmatrix}\right)$, M nonsingular, then with $(\widetilde{s}, \widetilde{t}) = M^{-1}(\alpha u, \beta v)$ we obtain an inexact shift and invert method. This may be an attractive alternative if (7.3) is expensive.

4. When we are interested in a singular value close to a specific *target* τ, we can replace this in the left-hand side of the correction equation (3.6):

$$\begin{pmatrix} I_m - uu^T & 0 \\ 0 & I_n - vv^T \end{pmatrix} \begin{pmatrix} -\tau I_m & A \\ A^T & -\tau I_n \end{pmatrix} \begin{pmatrix} I_m - uu^T & 0 \\ 0 & I_n - vv^T \end{pmatrix} \begin{pmatrix} s \\ t \end{pmatrix} = -r.$$

The advantage of this approach is that we avoid misconvergence to some unwanted singular value "on the way." For example, if we want to compute the largest singular value, we can use a known approximation of $\sigma_{\max}$ as a target. In practice, $\tau \approx \|A\|_\infty$ may be a good guess (see section 8). For the minimal singular value, we can take $\tau = 0$ or a small positive number as target. As soon as we notice that the process starts to converge, we may replace the target in the correction equation by the current approximation to the singular value again.

5. In practice we often solve (5.1) approximately by an iterative method: for example, a few steps of GMRES or MINRES if the operator is symmetric (in case of the standard Galerkin choice). We may use a (projected) preconditioner; see section 7.8.

7.2. The correction equation with nonstandard Galerkin choices. In the case of nonstandard Galerkin choices (see section 4.3), we may have the situation that $(x, y) \neq (u, v)$. Now we exploit the flexibility of (a, b) in (5.1): by the choice

$$(a, b) = (x, y) \text{ and } (\widetilde{x}, \widetilde{y}) = (u, v), \tag{7.4}$$

we ensure that the operator in (5.1) maps $(x, y)^{\perp\perp}$ onto itself, and that the asymptotic convergence is cubic according to Theorem 6.2 (if the correction equation is solved exactly). Another option is

$$(a, b) = (u, v) \text{ and } (\widetilde{x}, \widetilde{y}) = (x, y) \tag{7.5}$$

to make the operator in (5.1) symmetric. In this case the operator maps $(u, v)^{\perp\perp}$ to $(x, y)^{\perp\perp}$. Therefore, we should use a left "preconditioner" that maps the image space $(x, y)^{\perp\perp}$ bijectively onto the domain space $(u, v)^{\perp\perp}$ (see also section 8 and [14, 17]).

7.3. Comparison with Jacobi–Davidson on the augmented matrix. It is interesting to compare the JDSVD with Jacobi–Davidson on the augmented matrix, starting with the "same" starting vector $w_1 = (u_1, v_1)/\sqrt{2}$.

There are some analogies between Jacobi–Davidson and the JDSVD. When their correction equations are solved exactly, both converge asymptotically cubically to a simple eigenvalue of the augmented matrix. Moreover, the costs per iteration are almost the same; the only difference is that in each step the JDSVD needs a small SVD, while Jacobi–Davidson needs a small eigenvalue decomposition. The storage requirements are also comparable.

The main difference is the fact that the JDSVD, by construction, searches in two (smaller) subspaces, while Jacobi–Davidson has one search space. If Jacobi–Davidson solves its correction equation exactly, then in fact it solves (7.3) with $\alpha = \beta$ [15]. This suggests that the JDSVD can cope better with "unbalanced" vectors, that is, vectors (u, v), where $\|u\| \neq \|v\|$. An extreme example of this can be seen by taking a starting vector of the form $(u_*, \delta v_*)$ for $0 < \delta < 1$. In contrast to Jacobi–Davidson, the JDSVD terminates after computing a zero residual.

Another (mostly theoretical) difference is the fact that the JDSVD terminates for every starting vector after at most $\max\{m, n\}$ iterations, and Jacobi–Davidson terminates on the augmented matrix after at most $m + n$ iterations. In section 8, we compare the methods experimentally.

7.4. Refinement procedure. Suppose that we have found an approximate minimal right singular vector $v = (1 - \varepsilon^2)^{1/2} v_{\min} + \varepsilon v_{\max}$ by an iterative method applied to $A^T A$, so that $\sin \angle(v, v_{\min}) = \varepsilon$. Then, in the absence of other information, $u = Av = (1 - \varepsilon^2)^{1/2} \sigma_{\min} u_{\min} + \varepsilon \sigma_{\max} u_{\max}$ is the best approximation to the left singular vector we have to our disposal. But $\tan \angle(u, u_{\min}) \approx \varepsilon \frac{\sigma_{\max}}{\sigma_{\min}} = \kappa(A)\varepsilon$, and this can be large. Moreover, $\|u\|^2 = (1 - \varepsilon^2)\sigma_{\min}^2 + \varepsilon^2 \sigma_{\max}^2$ can be an inaccurate approximation to $\sigma_{\min}^2$, and so may $\|A^T u\|^2 / \|u\|^2$.

Hence the approximations to small singular values, resulting from working with $A^T A$, may be inaccurate. In this situation, we may try to improve the approximate singular triple by a two-sided approach like the JDSVD. The following lemma gives a link with [3], where a system with a matrix of the form

$$\begin{pmatrix} -\theta I_m & A & -u & 0 \\ A^T & -\theta I_n & 0 & -v \\ 2u^T & 0 & 0 & 0 \\ 0 & 2v^T & 0 & 0 \end{pmatrix} \tag{7.6}$$

is used for improving an approximate singular triple.

Lemma 7.1 (cf. Theorem 3.5 of [14]). *The JDSVD correction equation* (5.1) *is equivalent to*

$$\begin{pmatrix} -\theta I_m & A & -u & 0 \\ A^T & -\eta I_n & 0 & -v \\ a^T & 0 & 0 & 0 \\ 0 & b^T & 0 & 0 \end{pmatrix} \begin{pmatrix} s \\ t \\ \alpha \\ \beta \end{pmatrix} = \begin{pmatrix} \theta u - Av \\ \eta v - A^T u \\ 0 \\ 0 \end{pmatrix}; \tag{7.7}$$

that is, if (s, t, α, β) *is a solution of* (7.7)*, then* (s, t) *is a solution of the correction equation* (5.1)*, and if* (s, t) *is a solution of* (5.1)*, then there exist unique* α, β *such that* (s, t, α, β) *is a solution of* (7.7)*.*

Proof. We use the same notation as in the proof of Theorem 6.2. The system (7.7) is equivalent to

$$B(s, t) - (\alpha u, \beta v) = -r \qquad \text{and} \qquad (s, t) \perp\!\!\perp (a, b).$$

By splitting the first equation in $(x,y)^{\perp\perp}$ and its complement, we obtain

$$\left\{\begin{array}{ccc} PB(s,t) & = & -r, \\ \begin{pmatrix} \alpha \\ \beta \end{pmatrix} & = & \begin{pmatrix} (x^Tu)^{-1} & 0 \\ 0 & (y^Tv)^{-1} \end{pmatrix} \begin{pmatrix} x^T & 0 \\ 0 & y^T \end{pmatrix} B \begin{pmatrix} s \\ t \end{pmatrix}, \\ (s,t) & \perp\perp & (a,b). \end{array}\right.$$

Note that we have used $Pr = r$, $P(\alpha u, \beta v) = 0$, and $r \perp\perp (x,y)$. The first and third equation together are equivalent to the correction equation (5.1), and the second equation determines α, β uniquely. □

REMARK 7.2. *Of course, this equivalence is valid only when both* (7.7) *and* (5.1) *are solved exactly, not when we solve them approximately.*

In particular, when we substitute $\eta = \theta$ and $(a,b) = 2(u,v)$, the matrix in (7.7) becomes (7.6).

7.5. Smallest singular value. As mentioned in section 4.1, the standard variant of the JDSVD may have difficulties with finding the smallest singular value of a matrix. This is not surprising, because the small singular values of A correspond to the interior eigenvalues of the augmented matrix. But in many applications, e.g., the computation of pseudospectra, the smallest singular value is just what we want to compute.

We can use the JDSVD with the nonstandard Galerkin (harmonic) variants, mentioned in sections 4.3 and 4.4, starting with zero, or a small positive number as a target, and solve the correction equation rather accurately, possibly with the aid of a preconditioner; see section 8. In this way the method is close to a shift and invert iteration but less expensive. Of course it is hereby advantageous to have a good initial triple (e.g., coming from an iterative method on A^TA); the JDSVD (with nonstandard Galerkin) can then be used as refinement procedure.

7.6. Restart. A nice property of Jacobi–Davidson is its flexibility in restarting. The JDSVD, too, has this advantage: we can restart at every moment in the process with any number of vectors, only keeping those parts of the search spaces that look promising, or possibly adding some extra vectors. All we have to do is compute the new resulting $H = U^TAV$ and continue. This is practical when the search spaces become large or to avoid a breakdown in case of the nonstandard Galerkin choices. Of course, the JDSVD can also be *started* with search spaces of dimension larger than one.

7.7. Deflation. We can compute multiple singular triples of A by using a deflation technique. If we have found a singular triple of A, and we want to find another, we can deflate the augmented matrix to avoid finding the same triple again. For the JDSVD, this can be done as follows. Suppose that U_f and V_f contain the already found singular vectors. Then it can be checked that, if we found the exact vectors,

$$\begin{pmatrix} I_m - U_fU_f^T & 0 \\ 0 & I_n - V_fV_f^T \end{pmatrix} \begin{pmatrix} 0 & A \\ A^T & 0 \end{pmatrix} \begin{pmatrix} I_m - U_fU_f^T & 0 \\ 0 & I_n - V_fV_f^T \end{pmatrix}$$

has the same eigenvalues as the original augmented matrix, except that the found eigenvalues are transformed to zeros. The method can then be restarted with another approximate triple.

7.8. Preconditioning the correction equation. The correction equation of the JDSVD can be preconditioned in a manner similar to Jacobi–Davidson (see, for example, [17]). We use the same notation as in the proof of Theorem 6.2 for the important case $Q = P$. Suppose that we have a preconditioner M for B. For left preconditioning we are given $(s, t) \perp\perp (x, y)$, and we have to solve for $(z_1, z_2) \perp\perp (x, y)$ from

$$PMP(z_1, z_2) = PBP(s, t).$$

Note that we project the preconditioner as well. Hence, for some α, β,

$$(z_1, z_2) = M^{-1}B(s, t) - M^{-1}(\alpha u, \beta v),$$

and by using the test vectors we obtain

$$\begin{pmatrix} x & 0 \\ 0 & y \end{pmatrix}^T M^{-1} \begin{pmatrix} u & 0 \\ 0 & v \end{pmatrix} \begin{pmatrix} \alpha \\ \beta \end{pmatrix} = \begin{pmatrix} x & 0 \\ 0 & y \end{pmatrix}^T M^{-1}B \begin{pmatrix} s \\ t \end{pmatrix}.$$

A recipe for computing (z_1, z_2) is given by the following four steps.

(1) Compute $(\widetilde{u}_1, \widetilde{u}_2) = M^{-1}(u, 0)$ and $(\widetilde{v}_1, \widetilde{v}_2) = M^{-1}(0, v)$.
(2) Compute $(\widetilde{s}, \widetilde{t}) = M^{-1}B(s, t)$.
(3) Compute (α, β) from $\left(\begin{smallmatrix} x^T\widetilde{u}_1 & x^T\widetilde{v}_1 \\ y^T\widetilde{u}_2 & y^T\widetilde{v}_2 \end{smallmatrix}\right)\left(\begin{smallmatrix} \alpha \\ \beta \end{smallmatrix}\right) = \left(\begin{smallmatrix} x^T\widetilde{s} \\ y^T\widetilde{t} \end{smallmatrix}\right)$.
(4) Compute $(z_1, z_2) = (\widetilde{s}, \widetilde{t}) - \alpha(\widetilde{u}_1, \widetilde{u}_2) - \beta(\widetilde{v}_1, \widetilde{v}_2)$.

An important observation is that step (1) and the computation of the 2×2 matrix in step (3) have to be performed only once at the start of the iterative solution process of the correction equation. The right-hand side of the correction equation, minus the residual, is handled similarly.

8. Numerical experiments. Our experiments are coded in MATLAB and are executed on a SUN workstation. The following lemma implies that up to rounding errors, it is not a loss of generality to consider (rectangular) diagonal matrices A.

LEMMA 8.1. *If there are no rounding errors, and the JDSVD's correction equation* (5.1) *in step k is solved by l_k steps of GMRES, then the JDSVD applied to*

(a) $A = U_*\Sigma V_*^T$, *with starting vectors u_1 and v_1,*
(b) Σ, *with starting vectors $\widetilde{u}_1 := U_*^T u_1$ and $\widetilde{v}_1 := V_*^T v_1$,*

gives "the same" results; that is,

$$\widetilde{\theta}_k = \theta_k \qquad \textit{and} \qquad \|\widetilde{r}_k\| = \|r_k\|.$$

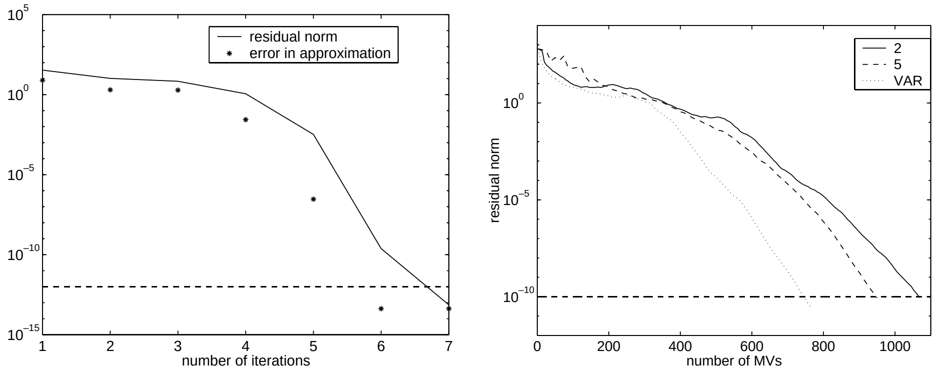
Proof. Define

$$Q = \begin{pmatrix} U_*^T & 0 \\ 0 & V_*^T \end{pmatrix};$$

then Q is orthogonal, and one may verify that $(\widetilde{u}_1, \widetilde{v}_1) = Q(u_1, v_1)$, $\widetilde{\theta}_1 := \widetilde{u}_1^T\Sigma\widetilde{v}_1 = u_1^TAv_1 =: \theta_1$, and $\widetilde{r}_1 = Qr_1$. A well-known property of Krylov subspaces ensures that (see [12, p. 264])

$$Q^T\mathcal{K}_l\left(\begin{pmatrix} 0 & \Sigma \\ \Sigma^T & 0 \end{pmatrix}, \widetilde{r}\right) = \mathcal{K}_l\left(Q^T\begin{pmatrix} 0 & \Sigma \\ \Sigma^T & 0 \end{pmatrix}Q, Q^T\widetilde{r}\right) = \mathcal{K}_l\left(\begin{pmatrix} 0 & A \\ A^T & 0 \end{pmatrix}, r\right).$$

With little extra work one can check that the same relation holds for the shifted and projected matrices that are present in the correction equation (5.1), where one



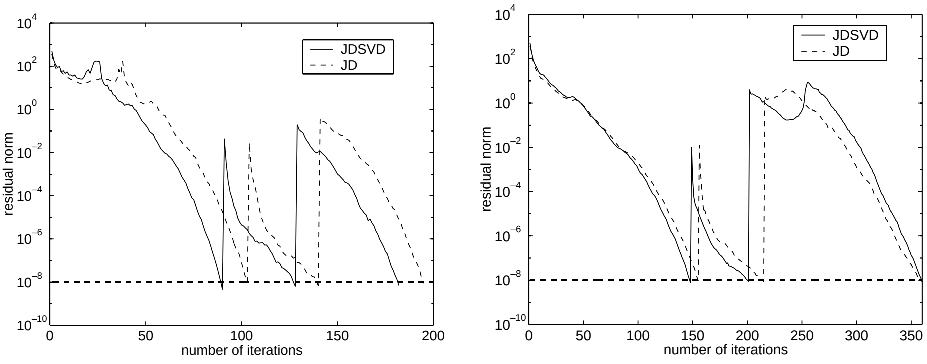
(a) (b)

FIG. 8.1. (a) *The convergence history of the exact JDSVD algorithm for* diag(1..100) *as in Algorithm* 4.1: *residual norm (solid line) and error in the approximations to* $\sigma_{\max}$ *(dots). The horizontal dotted line indicates the stopping tolerance.* (b) *Convergence for* diag(1..1000) *using, respectively,* 5, 2, *and a variable number of GMRES steps to solve the correction equation.*

should bear in mind that all other vectors involved in the projectors (a, b, x, y, $\widetilde{x}$, and $\widetilde{y}$) must also be altered for the Σ-system in the obvious way. So the approximate solutions from the correction equations satisfy $(\widetilde{s}_1, \widetilde{t}_1) = Q(s_1, t_1)$. By induction we can prove that $\widetilde{U}_k = U_*^T U_k$ and $\widetilde{V}_k = V_*^T V_k$, so the projected matrices are the same in both cases: $\widetilde{H}_k := \widetilde{U}_k^T \Sigma \widetilde{V}_k = U_k^T A V_k = H_k$. In particular, the approximations to the singular values are the same, and the approximations (u_k, v_k) and $(\widetilde{u}_k, \widetilde{v}_k)$ are orthogonal transformations of each other: $(\widetilde{u}_k, \widetilde{v}_k) = Q(u_k, v_k)$ and $\widetilde{r}_k = Qr_k$, so $\|\widetilde{r}_k\| = \|r_k\|$. □

For this reason, we first study some phenomena on $A = \text{diag}([1 : 100])$ and $A = \text{diag}([1 : 1000])$. In Figure 8.1(a), the solid line is the convergence history of (the standard variant of Algorithm 4.1 of) the JDSVD for the computation of the largest singular triple of $A = \text{diag}([1 : 100])$. The starting vectors are the normalized $v_1 = v_{\max} + 0.1r$, where r is a vector with random entries, chosen from a uniform distribution on the unit interval, and $u_1 = Av_1/\|Av_1\|$. The dots represent the error in the approximation $\sigma_{\max} - \theta_k^{(k)}$. In all figures, a horizontal dotted line indicates the stopping tolerance. We solve the correction equation by 200 steps of GMRES. Because the (augmented) matrices in the correction equation (step 7 of Algorithm 4.1) are of size 200×200, this means (theoretically) exactly, so according to Theorem 6.2 we expect cubic convergence. In Figure 8.1(a) we see, for instance, that the error in the approximation in iteration number 5 decreases from $\approx 10^{-2}$ to $\approx 10^{-7}$.

In Figure 8.1(b), we take $A = \text{diag}([1 : 1000])$, and u_1 and v_1 random vectors (as described above) with unit norm. We experiment with the number of GMRES steps. For the solid line, we solve the correction equation approximately by five steps of GMRES, which we denote by GMRES$_5$, for the dashed line by GMRES$_2$, and for the dotted line by a variable number equal to $\max\{2 \cdot (\lceil -\log \|r\| \rceil + 1), 0\}$. Measured in terms of matrix-vector products (MVs), the variable choice is best, followed by GMRES$_5$. An explanation of this is that when the initial approximations are not good (as in this case), it is of no use to try hard to solve the correction equation in the beginning. When we are almost converging, it may make sense to solve it more



(a) (b)

FIG. 8.2. (a) *The JDSVD (solid) and Jacobi–Davidson (dashed) for the three largest* σ*s of* diag(1..1000)*.* (b) *The same as Figure* 8.2(a)*, only with GMRES*$_2$ *to solve the correction equation.*

accurately to get fast convergence. See also [17].

In Figure 8.2(a) we compare, for $A = \mathrm{diag}([1 : 1000])$, the standard JDSVD for the three largest singular triples (solid), with Jacobi–Davidson on the augmented matrix for the computation of the three largest eigenpairs (dashed), each with GMRES$_5$. For the JDSVD, we take v_1 as a random vector, and $u_1 = Av_1/\|Av_1\|$. For Jacobi–Davidson we take the "same" starting vector $(u_1, v_1)/\sqrt{2}$. We see that the JDSVD is faster for the first triple; for the second and third we restart with a good approximation, and then the histories are similar.

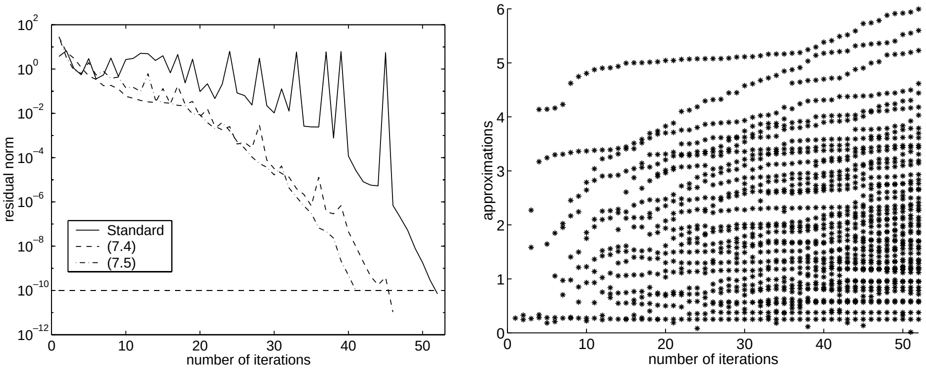
In Figure 8.2(b), we do the same, but now using GMRES$_2$. For the first two triples, the JDSVD is somewhat faster than Jacobi–Davidson, for the third JDSVD in the first instance (mis)converges to the fourth largest singular value 997. Other experiments also suggest that the JDSVD is generally (somewhat) faster than Jacobi–Davidson on the augmented matrix.

Next, we take some examples from the Matrix Market (these matrices can be downloaded from `http://math.nist.gov/MatrixMarket`). For Figure 8.3(a), we apply different JDSVD variants to find the smallest singular triple of PDE225, using two random starting vectors and GMRES$_{10}$ (no preconditioning). In all variants, we take initially target 0, but when $\|r\| < 10^{-3}$, we replace the target by the best approximations again (see section 7.1, point 4). The solid line is the standard choice; we see an irregular convergence history, as could be expected (see section 4). The dashed line represents the Galerkin choice (4.5), where in the correction equation (5.1) we substitute (7.4). Finally, the dash-dotted line is (4.5) with (7.5) substituted in (5.1). In the last case, as seen in section 7.2, the operator in (5.1) maps $(u, v)^{\perp\perp}$ to $(x, y)^{\perp\perp}$. Since in this case $v = y$ but $u \neq x$, we use a left "preconditioner" to handle the correction equation correctly. The preconditioned identity

$$\begin{pmatrix} I_m - \frac{xu^T}{u^Tx} & 0 \\ 0 & I_n \end{pmatrix} I_{m+n} \begin{pmatrix} I_m - \frac{ux^T}{x^Tu} & 0 \\ 0 & I_n \end{pmatrix}$$

maps $(x, y)^{\perp\perp}$ back to $(u, v)^{\perp\perp}$.

In Figure 8.3(b), the standard JDSVD's approximations to the singular values during this process are plotted. These are "regular," nonharmonic estimates. Note



(a) (b)

FIG. 8.3. (a) *Three different JDSVD variants for the computation of* $\sigma_{\min}$ *of* PDE225: *standard,* (4.5) + (5.1) + (7.4), *and* (4.5) + (5.1) + (7.5). (b) *(Nonharmonic) approximations to the singular values by the standard variant.*

the monotone convergence of the approximations to the largest singular values but the irregular behavior of the approximations to the smallest singular value.

Next, we compare the JDSVD with Lanczos applied to A^TA for the computation of $\sigma_{\max}$. These methods are of a different nature. The Lanczos method can be viewed as an accelerated power method, while the JDSVD can be seen as an accelerated inexact RQI. An advantage of the JDSVD is that we may use preconditioning for the correction equation. Therefore, we expect that if we have a reasonable preconditioner, and if preconditioning is relatively cheap in comparison to a multiplication by A or A^T, then the JDSVD can be cheaper than Lanczos. On the other hand, if $m \gg n$, or if there is no good or cheap preconditioner available, then we expect that Lanczos will be better. Table 8.1 shows some test results. For the JDSVD, we take a target $\tau \approx \|A\|_\infty$, in the hope that $\tau \approx \sigma_{\max}$. We make an incomplete LU-decomposition (using a drop tolerance displayed in the table) of the augmented matrix (1.1) minus τ times the identity, and we use $M = LU$ as a preconditioner. The starting vector v_1 is the vector with all coordinates equal to one, and is then normalized, and u_1 is a random vector. We solve the correction equation by only preconditioning the residual ("0 steps of GMRES"). The process is continued until $\|r\| < 10^{-8}$. Lanczos's method uses v_1 as starting vector and continues until $\|(A^TA - \theta^2)v\| < 10^{-8}$. The matrix A_1 stands for $\mathrm{diag}(1:100) + 0.1 \cdot \mathrm{rand}(n,n)$, where $\mathrm{rand}(n,n)$ denotes an $n \times n$-matrix with random entries, chosen from a uniform distribution on the unit interval. See [13] for more information on the origin and singular values of the other matrices. For the JDSVD, a pair is given, consisting of the number of MVs and the number of systems with L or U. For Lanczos we show the number of MVs.

For HOR131, the target τ is relatively far from $\sigma_{\max} \approx 0.66$. We see that although the JDSVD uses fewer MVs than Lanczos, Lanczos is cheaper when we take the preconditioning into account. Although for PORES3 ($\sigma_{\max} \approx 1.5 \cdot 10^5$) Lanczos finds a good approximate vector, its residual does not reach the required 10^{-8} due to the high condition number of the matrix. The JDSVD does converge, so this is an example of a situation where the JDSVD could be used as refinement. For SHERMAN1, the target is a reasonable approximation to $\sigma_{\max} \approx 5.05$. When we

Table 8.1
Some experiments with the JDSVD to compute $\sigma_{\max}$, using incomplete LU-factorizations of the shifted augmented matrix. The number of MVs, and the number of systems with L or U is displayed in the 5th column. The shift (or target) τ (6th column) for the preconditioning is roughly taken to be $\|A\|_\infty$. The last three columns give information on the incomplete LU-factorization: the drop tolerance of ILU, and the resulting number of nonzeros of L and U. We compare the JDSVD's results with the MVs of Lanczos applied to A^TA (4th column).

Matrix	Size	nnz(A)	Lan(A^TA)	JDSVD	τ	tol	nnz(L)	nnz(U)
HOR131	434 × 434	4182	30	(28, 65)	0.90	10^{-2}	1792	1792
PORES3	532 × 532	3474	–	(72, 175)	$2 \cdot 10^5$	10^{-1}	1301	1300
SHERMAN1	1000 × 1000	3750	74	(24, 66)	5	10^{-2}	4805	4803
A_1	100 × 100	10000	102	(38, 108)	106	10^{-2}	299	299

take the preconditioning into account, Lanczos is cheaper than the JDSVD. The last row of the table is an example where preconditioning is relatively cheap. The reason for this is that we now take the diagonal of A, instead A itself, to form an augmented matrix of the form (1.1) and to make an ILU-decomposition. Using far more MVs, Lanczos is (also counting the preconditioning) more expensive.

Finally, in Table 8.2, we compare the JDSVD for the computation of $\sigma_{\min}$ with Lanczos applied to $(A^TA)^{-1}$. We use the Galerkin choice (4.5) for the JDSVD. Note that the comparison with Lanczos is mainly meant to get an idea of how well the JDSVD performs. In practice, for large (sparse) A, it is too expensive to work with A^{-1} and A^{-T} or $(A^TA)^{-1}$. For the JDSVD, we take a small target $\tau = 10^{-5}$, drop tolerance 10^{-3}, and again we make an incomplete LU-decomposition based on this target. The starting vectors are the same as for Table 8.1. We solve the correction equation by preconditioning only the residual ("0 steps of GMRES"). Both processes are continued until $\|r\| < 10^{-7}$.

Table 8.2
Some experiments with the JDSVD to compute $\sigma_{\min}$. The numbers of MVs and systems with L or U (3rd column), and the number of nonzeros of L and U are displayed. We compare the JDSVD's results with the number of MVs of Lanczos applied to $(A^TA)^{-1}$.

Matrix	Lan(A^TA)$^{-1}$	JDSVD	nnz(L)	nnz(U)
HOR131	–	(26, 72)	20593	21167
PORES3	12	(36, 108)	3683	5491
SHERMAN1	20	(20, 54)	11575	11738
A_1	14	(28, 78)	200	200

We see that although the JDSVD may in general use more MVs, it may be much cheaper than Lanczos, due to the sparsity of A, L, and U. For HOR131, Lanczos does not converge to the required 10^{-7}. Again A_1 serves as an example for the situation where preconditioning is relatively cheap, which makes the JDSVD attractive. We also tried Lanczos applied to A^TA for the computation of $\sigma_{\min}$, but the results were bad (262 MVs for A_1, and more than 500 MVs for the other matrices).

9. Conclusions. We have discussed an alternative approach for the computation of a few singular values and vectors of a matrix. The JDSVD method searches in two separate subspaces, and it can be interpreted as an inexact Newton method for the singular value problem. The JDSVD can also be seen as an inexact accelerated scaled RQI method. Therefore, the best results may be expected when we have a good initial starting triple (refinement), but we can start with any approximations. While the asymptotic convergence is cubic if the correction equation is solved exactly, in practice we solve it approximately, and then the convergence typically looks (super)linear. Although we mainly discussed the application of the JDSVD for the largest and smallest singular value, the method is in principle suitable for all singular values. We may use preconditioning for the solution of the correction equation. This can be a decisive factor for fast convergence. Experiments indicate that the JDSVD is a good competitor to other iterative SVD methods, in particular when A is (almost) square and we have a reasonable, relatively cheap preconditioner for the correction equation.

Acknowledgments. The author thanks Henk van der Vorst and Gerard Sleijpen for interesting discussions, and the referees for many helpful comments.

ELEMENT-FREE AMGe: GENERAL ALGORITHMS FOR COMPUTING INTERPOLATION WEIGHTS IN AMG[*]

VAN EMDEN HENSON[†] AND PANAYOT S. VASSILEVSKI[†]

Abstract. We propose a new general algorithm for constructing interpolation weights in algebraic multigrid (AMG). It exploits a proper extension mapping outside a neighborhood about a fine degree of freedom (dof) to be interpolated. The extension mapping provides boundary values (based on the coarse dofs used to perform the interpolation) at the boundary of the neighborhood. The interpolation value is then obtained by matrix dependent harmonic extension of the boundary values into the interior of the neighborhood.

We describe the method, present examples of useful extension operators, provide a two-grid analysis of model problems, and, by way of numerical experiments, demonstrate the successful application of the method to discretized elliptic problems.

Key words. algebraic multigrid, interpolation weights, sparse matrices, finite elements, unstructured meshes

1. Introduction.

The classical algebraic multigrid (AMG) algorithm [2, 3, 9] was developed for operators represented by symmetric, positive definite M-matrices. While the algorithm works well for many real-world problems [10, 6, 11], there are situations in which it does not perform particularly well. One reason for this is that in some instances the classical definition of interpolation does not adequately interpolate the smooth modes of the error. More specifically, standard AMG interpolation makes certain assumptions about the nature of the smooth error which may not be valid for operators that are not M-matrices. A more sophisticated characterization of smooth error is required to develop an adequate interpolation formula.

To provide a better characterization of smooth error, a method known as AMGe, for element-based algebraic multigrid, was developed recently [4] for finite element discretizations. AMGe provides an accurate interpolation formula by using the individual element stiffness matrices to construct a neighborhood matrix for each fine degree of freedom (dof). The neighborhood matrix—the sum of the individual stiffness matrices for all the elements containing the point at which the dof is defined—acts as a local “Neumann”-type version of the original operator. According to AMGe theory, once the local matrix is developed and coarse-grid points are chosen, solving a simple minimization problem yields the optimal interpolation operator for each dof. It is shown in [4] that the method indeed produces superior interpolation and leads to improved convergence rates on several types of problems, including both scalar problems and systems of PDEs, such as elasticity problems.

An obvious drawback to AMGe, naturally, is that it requires that the element stiffness matrices be available. While this is often the case, their storage can be expensive. Further, AMGe requires that coarse level elements be constructed and

their individual stiffness matrices be available. Determining the coarse elements is a difficult and laborious task.

In this paper we examine the construction of the interpolation operator in both classical AMG and AMGe and present them within a common framework. Our purpose is to extend and generalize the classical interpolation, which was originally motivated for *M*-matrices, to develop a rule applicable in more general settings. Accordingly, we propose a new method for determining the interpolation weights that attempts to capture the benefits of AMGe interpolation without requiring access to the individual element stiffness matrices. This method is applicable to finite difference, finite element, or finite volume discretizations, and we concentrate on the symmetric positive definite case. Essentially, it seeks to determine, for each fine dof, a neighborhood matrix that can be utilized in the same manner that the local assembled stiffness matrix is used in AMGe. We do this by defining a neighborhood for the fine dof and examining the rows of the original matrix that correspond to the points in that neighborhood. A set of exterior dofs is defined and a mapping developed that extends functions on the neighborhood to the exterior dofs. This essentially imposes a set of boundary conditions on the neighborhood. Here we propose a unified way of building these boundary conditions. One may view them as an extension (extrapolation) of a vector defined on the neighborhood to its immediate exterior. This extension can be performed using constant vectors or any other vectors that may be of interest (such as the rigid body motions in elasticity problems). The extension can be built for each dof in the exterior based on the matrix sparsity pattern.

By incorporating the action of the extension operator into the local connections of the neighborhood, a modified local matrix is created. This matrix is then used in a manner similar to that employed in AMGe, that is, by solving a minimization problem, to create the interpolation operator. We consider the construction of the extension operator and the respective minimization procedure to build the interpolation weights as our main contribution. We give examples of several extension operators and show how they relate to both classical AMG and other, more recently proposed algorithms. A two-grid model analysis of the properties of the resulting interpolation mappings is provided as well. In particular, we prove that they exhibit approximately "harmonic" properties as well as "partition of unity" properties, desirable in standard two-grid analyses of the AMG methods.

Numerical results are presented to demonstrate the method. We include both scalar problems and systems of PDEs in the form of elasticity problems. Finally, we draw some conclusions and comment on the direction that continued research will take.

It is important to note that while the choice of coarse-grid points, like the construction of the interpolation operator, is crucial to the success of the AMG method, we do not consider the coarse-grid selection here; rather, we leave that topic to future research while focusing on the interpolation problem here. Furthermore, we observe that neither AMGe nor the method proposed here are intended to replace or compete with classical AMG on problems characterized by simple *M*-matrices, such as the model Laplacian problem on a regular grid. Instead, they are intended for complicated problems, such as thin-body elasticity, posed typically on unstructured grids. Nonetheless, we apply the new method (and AMGe) to model problems because they illustrate, in simple fashion, the features of the methods. We therefore compare results of our method with AMGe on these problems but do not include comparisons to classical AMG, which would be used in practice.

Some notational conventions follow: to denote a vector we will use boldface, e.g., $\mathbf{v}, \mathbf{w}, \ldots$. The ith component of $\mathbf{v}$ will be denoted in different contexts as $\mathbf{v}(i)$, $v(i)$, or v_i. In the latter two cases v (i.e., not in boldface) will have a meaning of a "grid" function.

2. A framework for AMG interpolation.

Assume that the problem $A\mathbf{x} = \mathbf{f}$ is to be solved, where A is a sparse, symmetric, positive definite matrix. AMG is a multigrid method in which no geometric grid information is used (and often isn't available or doesn't even exist). Accordingly, all of the components of a multigrid algorithm, the hierarchy of grids, interpolation and restriction operators, and the coarse-grid versions of the original operator must be constructed using only the information contained in the entries of A. For any multigrid algorithm, several basic components are required. In the case of AMG, they can be described as follows:

- A fine grid is required. For AMG, this is generally a set D comprising the degrees of freedom of the original problem.
- A coarse grid D_c is necessary. This set of dofs is typically a subset of D.
- An interpolation operator P is necessary to map vector functions defined on the coarse grid D_c to the fine grid D, $P: D_c \longrightarrow D$.
- A restriction operator $R: D \longrightarrow D_c$, mapping fine-grid functions to the coarse grid, is needed. For AMG the restriction is frequently defined by $R = P^T$, and we will use that definition here.
- A coarse-grid version of the original operator A is needed. For AMG the coarse operators are generally defined by the Galerkin relation $A_c = P^TAP$.
- A smoothing iteration, G, is used. It is typical to use a point-relaxation method such as Gauss–Seidel or Jacobi relaxation.

The basic two-grid algorithm can then be described as follows: Begin with an initial approximation $\mathbf{x}_0$ to the solution of $A\mathbf{x} = \mathbf{f}$.

1. Smooth the error by $\mathbf{x}_0 \leftarrow G(A, \mathbf{f}, \mathbf{x}_0)$.
2. Compute the residual $\mathbf{r} = \mathbf{f} - A\mathbf{x}_0$.
3. Restrict the residual to the coarse grid $\mathbf{f}_c = R\mathbf{r}$.
4. Solve the coarse-grid residual equation $\mathbf{e}_c = A_c^{-1}\mathbf{f}_c$.
5. Interpolate the coarse-grid error to the fine grid and correct the fine-grid approximation $\mathbf{x}_0 \leftarrow \mathbf{x}_0 + P\mathbf{e}_c$.

For a multigrid method, a hierarchy of coarse grids $D \equiv D_0 \supset D_1 \supset D_2 \supset \cdots \supset D_J$ is present, and the two-grid algorithm is applied recursively, i.e., the two-grid algorithm is repeated each time step 4 is encountered, except that a direct solve is employed at the coarsest grid.

For the multigrid method an interpolation operator P_i is required mapping functions on each grid (level i) to the next finer grid (level $i-1$). Unlike many conventional (geometric) multigrid algorithms, in AMG the interpolation operators are rarely the same for different levels. Similarly, the Galerkin relation is employed to define versions of the original operator A on all levels, thusly: $A_{i+1} \equiv R_iA_iP_i$.

There are many ways in which to select the coarse-grid dofs in AMG [9, 11, 5]. Commonly, the coarse set D_c is a maximally independent subset of D, but this is not required. We will not discuss the question of coarse-grid selection further, except to note that each fine-grid dof i is connected to its nearest neighbors (e.g., j) by way of having a nonzero coefficient a_{ij}, and that the value of a interpolated function at i is typically a weighted average of the values of its nearest neighbors that are coarse-grid dofs. For the remainder of this paper, we shall simply assume that a coarse grid has been selected and that the coarse neighbors are known for any fine dof.

With this description of the basic components of AMG, we can describe a simple framework for computing the entries of the interpolation operator. Let $i \in D$ be a fine-grid dof whose value is to be interpolated. We first define a subset $\Omega(i) \subset D$ to be the *neighborhood* of i. For now we place no particular restrictions on what dofs can be in $\Omega(i)$. For example, the set $\Omega(i)$ could consist of i and all of its nearest neighbors, or i and its nearest coarse neighbors, or i, its neighbors, and all of their neighbors. Indeed, within the framework we describe here, the exact character of the interpolation operator will depend largely on what sort of neighborhood is defined. Since the value at i will be interpolated from coarse points in the neighborhood, it is useful to denote the set of coarse dofs in the neighborhood to be $\Omega_c(i)$.

To construct the interpolation for i, we examine the entries of the operator A in the following way. We begin, without loss of generality, by permuting the rows and columns of A and partitioning it so the first set of rows and columns corresponds to i and the fine dofs in the neighborhood, that is, to $\Omega(i)\backslash\Omega_c(i)$. The next set of rows and columns corresponds to the coarse neighbors $\Omega_c(i)$, while the final set of rows and columns corresponds to the rest of the grid $D\backslash\Omega(i)$. Hence the partitioning of A, along with the identity of the rows corresponding to the partitions, appears as

$$A = \begin{pmatrix} A_{ff} & A_{fc} & * \\ * & * & * \\ * & * & * \end{pmatrix} \begin{array}{l} \}\ \Omega(i)\backslash\Omega_c(i), \\ \}\ \Omega_c(i), \\ \}\ D\backslash\Omega(i). \end{array}$$

For our purposes we are concerned only with two blocks of the partitioned matrix. The block A_{ff} gives the connections among i and the fine-grid neighbors while the block A_{fc} links i and the fine neighbors to the coarse neighbors.

Armed with these concepts of neighborhood partitioning of the operator, we can examine classical AMG, AMGe, and our proposed method in terms of choices of neighborhood and definition of the neighborhood matrices.

3. Interpolation in classical AMG. For classical AMG [9], the interpolation is computed in the following fashion. The neighborhood $\Omega(i)$ is defined to be the dof i and all dofs connected to it (all j for which $a_{ij} \neq 0$). We then replace both A_{ff} and A_{fc} with modified versions, $\widehat{A}_{ff}$ and $\widehat{A}_{fc}$, respectively.

A_{ff} is modified in two ways. Let S_i denote the set of dofs that are *strongly connected* to the dof i, let C_i denote the set of C-points in the neighborhood $\Omega(i)$, and let W_i denote the dofs that are *weakly connected* to the dof i. (By strongly (weakly) connected we mean that the magnitude of a_{ij} is greater (smaller) than some predefined threshold. A common choice is that if the magnitude of a_{ij} is less than θ times the largest magnitude of all off-diagonal entries in the ith row, then j is considered to be weakly connected to i.) Then we modify the row of A_{ff} corresponding to the dof i (which we will hereafter refer to as the ith row, regardless of the actual numerical ordering) by

$$\widehat{a}_{ii} = a_{ii} + \sum_{j \in W_i} a_{ij}, \tag{3.1}$$

$$\widehat{a}_{i,j} = \begin{cases} 0, & j \in W_i, \\ a_{i,j}, & j \in S_i. \end{cases} \tag{3.2}$$

For $j \in W_i$ we replace the jth row of A_{ff} by a zero row and then place a 1 in column j and -1 in column i. For all other rows of A_{ff}, i.e., for $j \in S_i$, we zero out the off-diagonal entries, and replace the diagonal entry a_{jj} with

$$\widehat{a}_{jj} = -\sum_{k \in C_i} a_{j,k}.$$

The block A_{fc} is modified to $\widehat{A}_{fc}$ by zeroing the jth row for $j \in W_i$.

Once the modified blocks $\widehat{A}_{ff}$ and $\widehat{A}_{fc}$ are computed, the entries of the ith row of the interpolation matrix P are determined by taking the entries of the ith row of the matrix

$$-\left(\widehat{A}_{ff}^{-1}\widehat{A}_{fc}\right).$$

4. Interpolation in AMGe. For AMGe a similar description of the interpolation is easily given. In this setting, the neighborhood $\Omega(i)$ is defined naturally as the union of all finite elements having i as a vertex (Figure 4.1). In the figure, the set $\Omega(i)$ consists of all vertices in the shaded region, including i (the open circle in the center). The shaded region consists of the six triangular finite elements having i as a vertex. Members of $\Omega_c(i)$ are indicated by the square vertices. Since AMGe gives us access to the individual element stiffness matrices, we may create a neighborhood matrix $A_{\Omega(i)}$ simply by summing together all the individual element stiffness matrices of the elements in the neighborhood. In AMGe the interpolation operator for the dof i is determined by solving a constrained min-max problem, that is, by finding interpolation coefficients that minimize a certain measure from finite element theory. The solution to the min-max problem can be computed in several ways, one of which fits into the framework we are developing here. We partition the neighborhood matrix into the rows and columns associated with the fine dofs in the neighborhood and the rows and columns associated with the coarse dofs, as

$$A_{\Omega(i)} = \begin{pmatrix} A_{ff} & A_{fc} \\ * & * \end{pmatrix} \begin{array}{l} \} \; \Omega(i) \setminus \Omega_c(i), \\ \} \; \Omega_c(i). \end{array}$$

Again, our only interest is in the rows of the neighborhood matrix corresponding to the fine dofs, including i. With this partitioning, it turns out that one way to solve the min-max problem is to take, as the coefficients for the interpolation operator for i, the entries of the ith row of the matrix

$$-\left(A_{ff}^{-1}A_{fc}\right).$$

It is useful to note that, unlike the classical AMG case, there is no need to modify the matrix A_{ff} prior to computing the interpolation coefficients. Essentially, this is because the element stiffness matrices have built into them local versions of the null space and near-null space of the operator; we do not need to make alterations to the local matrices to ensure that these spaces are represented.

For many problems the AMGe method produces a superior interpolation and results in good convergence rates [4]. In the remainder of this paper our goal is to accomplish a superior interpolation without the knowledge (and hence, expense) of the individual stiffness matrices.

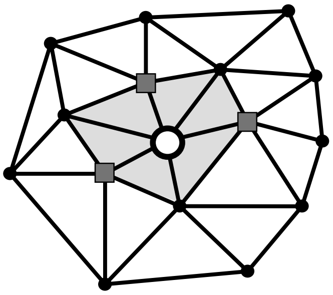

FIG. 4.1. *The neighborhood of the fine dof i (large open circle).*

5. Interpolation for element-free AMGe. The process we propose for building the interpolation operator is very similar to the processes described for AMG and AMGe. Once again, we will proceed by defining a neighborhood of the fine dofs and an associated neighborhood matrix. Let ψ be a set of fine dofs whose values we wish to interpolate. We define $\Omega(\psi)$ to be the neighborhood of ψ, which includes the coarse dofs that will be used to interpolate the dofs in ψ. The set of coarse dofs in the neighborhood we denote $\Omega_c(\psi)$.

Now, however, we define a third set of dofs:

$$\Omega_{\mathcal{X}}(\psi) = \{j \notin \Omega(\psi) \mid a_{ij} \neq 0 \text{ for some } i \in \Omega(\psi) \backslash \Omega_c(\psi)\}\,.$$

That is, $\Omega(\psi)$ can be viewed as the interior of the set $\overline{\Omega}(\psi) \equiv \Omega(\psi) \cup \Omega_{\mathcal{X}}(\psi)$. Figure 5.1 gives an example of such a neighborhood.

We begin the construction of a neighborhood matrix by examining the rows of the matrix A that correspond to the fine dofs in $\Omega(\psi)$; that is, we will be concerned with the following partitioning of A:

$$A = \begin{pmatrix} A_{ff} & A_{fc} & A_{f\mathcal{X}} & 0 \\ * & * & * & * \\ * & * & * & * \\ * & * & * & * \end{pmatrix} \begin{array}{l} \} \ \Omega(\psi)\ \backslash \Omega_c(\psi), \\ \} \ \Omega_c(\psi), \\ \} \ \Omega_{\mathcal{X}}(\psi), \\ \} \ \text{everything else on grid.} \end{array}$$

5.1. Local (neighborhood) quadratic form. Our next task is to define a matrix associated with ψ that yields a local version of the operator A, performing the same function as does the neighborhood matrix in AMGe. To do this we first build an extension mapping (matrix) $E(\psi)$ that maps a vector defined on $\Omega(\psi)$ to $\overline{\Omega}(\psi)$,

$$E(\psi) : \begin{pmatrix} \mathbf{v}_f \\ \mathbf{v}_c \end{pmatrix} \longrightarrow \begin{pmatrix} \mathbf{v}_f \\ \mathbf{v}_c \\ \mathbf{v}_{\mathcal{X}} \end{pmatrix},$$

using the relation

$$\mathbf{v}_{\mathcal{X}} = E_{\mathcal{X}f}(\psi)\mathbf{v}_f + E_{\mathcal{X}c}(\psi)\mathbf{v}_c.$$

That is, the extension operator looks like

$$E = \begin{pmatrix} I & 0 \\ 0 & I \\ E_{\mathcal{X}f}(\psi) & E_{\mathcal{X}c}(\psi) \end{pmatrix}.$$

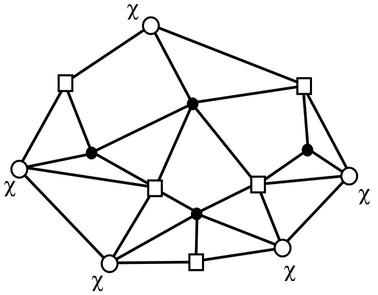

FIG. 5.1. *The extended neighborhood $\overline{\Omega}(\psi)$, including the fine dofs to be interpolated (solid circles), the coarse interpolatory set $\Omega_c(\psi)$ (squares), and the extension dofs (open circles marked $\mathcal{X}$).*

For now we will not be specific about the exact nature of the extension operator. Rather, we will describe how it may be used to develop an interpolation formula, after which we shall discuss desirable properties of the operator.

We construct a neighborhood matrix from the first block of rows of the partitioned matrix

$$\left(\widehat{A}_{ff}, \widehat{A}_{fc}\right) = (A_{ff}, A_{fc}, A_{f\mathcal{X}}) \begin{pmatrix} I & 0 \\ 0 & I \\ E_{\mathcal{X}f}(\psi) & E_{\mathcal{X}c}(\psi) \end{pmatrix}$$

so that

$$\widehat{A}_{ff} = A_{ff} + A_{f\mathcal{X}} E_{\mathcal{X}f}(\psi) \qquad \text{and} \qquad \widehat{A}_{fc} = A_{fc} + A_{f\mathcal{X}} E_{\mathcal{X}c}(\psi).$$

For any vector $[\begin{smallmatrix}\mathbf{v}_f \\ \mathbf{v}_c\end{smallmatrix}]$, consider its extension

$$\mathbf{v} = \begin{bmatrix} \mathbf{v}_f \\ \mathbf{v}_c \\ \mathbf{v}_{\mathcal{X}} \end{bmatrix},$$

where $\mathbf{v}_{\mathcal{X}}$ is given by $\mathbf{v}_{\mathcal{X}} = E_{\mathcal{X}f}(\psi)\mathbf{v}_f + E_{\mathcal{X}c}(\psi)\mathbf{v}_c$. Let

$$\widehat{\mathbf{v}} = \begin{bmatrix} -A_{ff}^{-1}\left(A_{fc}\mathbf{v}_c + A_{f\mathcal{X}}\mathbf{v}_{\mathcal{X}}\right) \\ \mathbf{v}_c \\ \mathbf{v}_{\mathcal{X}} \end{bmatrix}$$

be the so-called harmonic extension of $\mathbf{v}|_{\Omega_c(\psi)\cup\Omega_{\mathcal{X}}(\psi)}$ into $\Omega(\psi) \setminus \Omega_c(\psi)$. That is, one extends $\mathbf{v}$, restricted to the "boundary" $\Omega_c(\psi) \cup \Omega_{\mathcal{X}}(\psi)$, into the "interior" $\Omega(\psi) \setminus \Omega_c(\psi)$.

We use the $\mathbf{v}_f$ that minimizes the difference $\mathbf{v} - \widehat{\mathbf{v}}$ in energy norm in the interpolation procedure. Since

$$\mathbf{v} - \widehat{\mathbf{v}} = \begin{bmatrix} \mathbf{v}_f - (\widehat{\mathbf{v}})_f \\ 0 \\ 0 \end{bmatrix},$$

its energy norm is computable and equals

$$\begin{aligned} ||\mathbf{v} - \widehat{\mathbf{v}}||_A^2 &= (\mathbf{v}_f - (\widehat{\mathbf{v}})_f)^T A_{ff}(\mathbf{v}_f - (\widehat{\mathbf{v}})_f) \\ &= (\mathbf{v}_f + A_{ff}^{-1}\left(A_{fc}\mathbf{v}_c + A_{f\mathcal{X}}\mathbf{v}_{\mathcal{X}}\right))^T A_{ff}(\mathbf{v}_f + A_{ff}^{-1}\left(A_{fc}\mathbf{v}_c + A_{f\mathcal{X}}\mathbf{v}_{\mathcal{X}}\right)). \end{aligned}$$

Since A_{ff} is positive definite, this implies that if we solve the equation

$$\begin{aligned} 0 &= A_{ff}\mathbf{v}_f + (A_{fc}\mathbf{v}_c + A_{f\mathcal{X}}\mathbf{v}_{\mathcal{X}}) \\ &= (A_{ff} + A_{f\mathcal{X}}E_{\mathcal{X}f})\mathbf{v}_f + (A_{fc} + A_{f\mathcal{X}}E_{\mathcal{X}c})\mathbf{v}_c \\ &= \widehat{A}_{ff}\mathbf{v}_f + \widehat{A}_{fc}\mathbf{v}_c, \end{aligned}$$

the minimization of $||\mathbf{v}_f - (\widehat{\mathbf{v}})_f||_A$ is attained with zero minimum by $\mathbf{v}_f = -\widehat{A}_{ff}^{-1}\widehat{A}_{fc}\mathbf{v}_c$.

We can actually show (see Remark 7.1 and Lemma 7.1) that in the model finite element case considered in section 7 the minimization procedure is equivalent to a quadratic functional minimization involving Neumann assembled matrices, as in the AMGe method (cf. [4]).

It is natural to ask whether $\widehat{A}_{ff}$ is invertible. If $E_{\mathcal{X}f} = 0$, there is no difficulty, since then $\widehat{A}_{ff} = A_{ff}$. In general, if $E_{\mathcal{X}f}$ is sufficiently small in norm, $A_{ff} + A_{f\mathcal{X}}E_{\mathcal{X}f}$ will be invertible.

6. Examples of extension operators. We describe here four extension operators E that can be used to construct the interpolation operator in the element-free approach. These are by no means all the useful extensions that we could concoct; they form, however, a simple set of examples that will allow us to demonstrate the efficacy of the method and its underlying philosophy.

The first we call the L_2-*extension* because it is a simple averaging method. Given $\mathbf{v}$ defined on $\Omega(i)$, we wish to extend it to $\mathbf{v}_{\mathcal{X}}$, defined on $\Omega_{\mathcal{X}}(\psi)$. Suppose that $i_{\mathcal{X}}$ is an exterior dof, that is, a point from $\Omega_{\mathcal{X}}(\psi)$ whose value we wish to determine from the values of the dofs in $\Omega(i)$. Let $S = \{j \in \Omega(i) : a_{i_{\mathcal{X}},j} \neq 0\}$; that is, S comprises those dofs in $\Omega(i)$ to which the point $i_{\mathcal{X}}$ is connected. It seems natural to consider using a simple average over these dofs as the extension at $i_{\mathcal{X}}$. Thus, the extension formula, for the dof $i_{\mathcal{X}}$, is given by

$$\mathbf{v}_{\mathcal{X}}(i_{\mathcal{X}}) = \frac{1}{\sum\limits_{j\in S} 1} \sum_{j\in S} \mathbf{v}(j).$$

A somewhat more sophisticated extension we call the A-*extension* because it is a simple operator-induced method. The A-extension operator for the dof $i_{\mathcal{X}}$ is given by the formula

$$\mathbf{v}_{\mathcal{X}}(i_{\mathcal{X}}) = \frac{1}{\sum\limits_{j\in S} |a_{i_{\mathcal{X}},j}|} \sum_{j\in S} \left(|a_{i_{\mathcal{X}},j}|\mathbf{v}(j)\right).$$

It may be seen that in this case the extension to the exterior is a simple weighted average of the values of the neighborhood dofs to which the exterior point is connected. The weights in the average are given by the absolute values of the matrix coefficients.

The two methods just described share the property that they are computed point by point. That is, the extension formulas for the dofs in $\Omega_{\mathcal{X}}(\psi)$ are determined independently. A second feature shared by the methods is that if the neighborhood vector $\mathbf{v}$ is constant, then the extended values are also constant and have the same value as the entries of the neighborhood vector. This feature is clearly desirable for many elliptic PDEs, where the constant vector is in the null space or near-null space of the operator A.

The third example we describe is based on the minimization of a quadratic functional. Again, let $\mathbf{v}$ be a vector defined on $\Omega(i)$ that we wish to extend to $\Omega_{\mathcal{X}}(\psi)$. We construct the extension to be that operator which produces $\mathbf{v}_{\mathcal{X}}$ that minimizes the functional $Q(\mathbf{v}_{\mathcal{X}})$, where

$$Q(\mathbf{v}_{\mathcal{X}}) = \sum_{\substack{i_{\mathcal{X}} \in \Omega_{\mathcal{X}}(\psi) \\ j \in \Omega(i)}} |a_{i_{\mathcal{X}},j}| \left(v_{i_{\mathcal{X}}} - v_j\right)^2 . \tag{6.1}$$

It is evident that, like the previous extension operators, if $\mathbf{v}$ is constant on $\Omega(i)$ then the dofs in $\Omega_{\mathcal{X}}(\psi)$ will also have the same constant value. Unlike the previous extension operators, which are determined one dof at a time, this is a "simultaneous" extension, computing formulas for extending to all of the exterior dofs together. As such, it is necessarily more expensive to compute. We also note that this extension, and the interpolation it generates, is equivalent to the method recently proposed in [1].

A final example is given by minimizing the following "cut-off" quadratic functional:

$$(\theta \mathbf{v})^T A_{\overline{\Omega}(\psi)} (\theta \mathbf{v}) \mapsto \min,$$

where $\overline{\Omega}(\psi) \equiv \Omega(\psi) \cup \Omega_{\mathcal{X}}(\psi)$ subject to $\mathbf{v}_f,\ \mathbf{v}_c$ fixed. Here

$$\theta = \left[\begin{array}{cc} I & 0 \\ 0 & \theta_{\mathcal{X}} \end{array} \right] \begin{array}{l} \} \, \Omega(\psi), \\ \} \, \Omega_{\mathcal{X}}(\psi) \end{array}$$

is a diagonal matrix. A good choice is a diagonal matrix $\theta_{\mathcal{X}}$ formed from the vector

$$\underline{\theta}_{\mathcal{X}} = -(A_{\mathcal{X}\mathcal{X}})^{-1} \left[A_{\mathcal{X}f},\ A_{\mathcal{X}c} \right] \left[\begin{array}{c} (1)_f \\ (1)_c \end{array} \right] .$$

Here we used the blocks of A corresponding to its $\Omega_{\mathcal{X}}(\psi)$ rows.

It is easily seen that the extension mapping is actually defined as

$$\begin{aligned} \mathbf{v}_{\mathcal{X}} &= E_{\mathcal{X}c} \mathbf{v}_c + E_{\mathcal{X}f} \mathbf{v}_f \\ &= -\theta_{\mathcal{X}}^{-1} (A_{\mathcal{X}\mathcal{X}})^{-1} \left[A_{\mathcal{X}f},\ A_{\mathcal{X}c} \right] \left[\begin{array}{c} \mathbf{v}_f \\ \mathbf{v}_c \end{array} \right] . \end{aligned}$$

Note that this extension mapping is also a simultaneous extension operator and an averaging one; i.e., if $\mathbf{v}_c = (1)_c$ and $\mathbf{v}_f = (1)_f$, then $\mathbf{v}_{\mathcal{X}} = (1)_{\mathcal{X}}$.

6.1. Classical AMG as an extension method. The interpolation method of the classical AMG algorithm popularized by Ruge and Stüben [9] may be viewed as an extension method. Here the neighborhood is just the dof to be interpolated together with the dofs that will be used to compute the interpolated value. That is, $\Omega(i) = \{i\} \cup \Omega_c(i)$. The extended neighborhood then includes all fine dofs that are connected to i:

$$\Omega_{\mathcal{X}}(\psi) = \{ j \notin \Omega(i) \, : \, a_{ij} \neq 0 \} .$$

An A-extension is defined in the following manner. For each $i_{\mathcal{X}} \in \Omega_{\mathcal{X}}(\psi)$, set $v_{i_{\mathcal{X}}} = v_i$ if $i_{\mathcal{X}}$ is weakly connected to i. (Recall that in classical AMG, as developed for M-matrices, the dof i is said to be strongly connected to the dof j if

$$-a_{ij} > \theta \max_{k \neq i} (-a_{ik}),$$

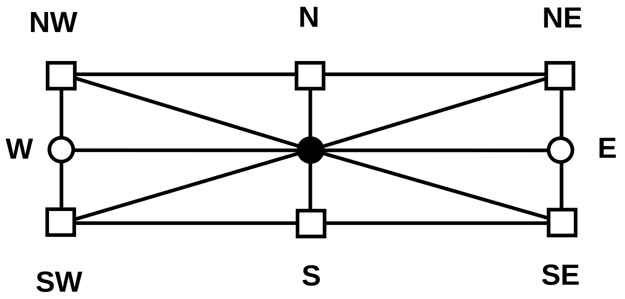

Fig. 6.1. *The neighborhood of the fine dof i (large solid circle) for the stretched quadrilateral element problem. The problem is semicoarsened; squares denote the coarse neighbors $\Omega_c(i)$ while the open circles are the exterior points $\Omega_{\mathcal{X}}(\psi)$.*

where θ is a user-specified parameter, and weakly connected otherwise.) If $i_{\mathcal{X}}$ is strongly connected to i, the extension is defined by

$$v_{i_{\mathcal{X}}} = \frac{1}{\displaystyle\sum_{j\in\Omega_c(\psi)} a_{i_{\mathcal{X}},j}} \sum_{j\in\Omega_c(\psi)} a_{i_{\mathcal{X}},j} v_j.$$

6.2. An example of the extensions. A simple example should suffice to illustrate these extension methods. Suppose the problem $-U_{xx} - U_{yy} = f(x,y)$ is discretized using a regular Cartesian grid of points making up the vertices of quadrilateral elements. Suppose further that the elements had dimension $h_x \times h_y$ where $h_x \gg h_y$. As $h_y/h_x \to 0$ the operator stencil tends toward

$$\begin{bmatrix} -1 & -4 & -1 \\ 2 & 8 & 2 \\ -1 & -4 & -1 \end{bmatrix}.$$

Since there is effectively no coupling between a given point and its neighbors to the east or west, the appropriate choice is to semicoarsen, selecting every other line of points with constant y-coordinate to be coarse points. Using the same logic, the natural interpolation is to have each fine dof interpolated using only the values to the north and south of it, each with equal weighting of 1/2. Consider the interpolation of one point, i, shown in the center of its neighborhood in Figure 6.1. For either the L_2- or A-extensions, we might select $\Omega(i) = \{i\} \cup \Omega_c(i)$, where, in this instance, $\Omega_c(i) = \{N, S, SW, NW, SE, NE\}$. Then $\Omega_{\mathcal{X}}(\psi) = \{W, E\}$. We see then that $A_{ff} = [8]$, $A_{fc} = [\ -4 \quad -4 \quad -1 \quad -1 \quad -1 \quad -1\ ]$, and $A_{f\mathcal{X}} = [\ 2 \quad 2\ ]$. For the A-extension it is easy to compute the extension operators

$$E_{\mathcal{X}c} = \frac{1}{12}\begin{pmatrix} 1 & 1 & 4 & 4 & & \\ 1 & 1 & & & 4 & 4 \end{pmatrix} \qquad \text{and} \qquad E_{\mathcal{X}f} = \frac{1}{12}\begin{pmatrix} 2 \\ 2 \end{pmatrix},$$

from which

$$\widehat{A}_{ff} = \left(\frac{104}{12}\right) \qquad \text{and} \qquad \widehat{A}_{fc} = \frac{1}{3}\left(\ -11 \quad -11 \quad -1 \quad -1 \quad -1 \quad -1\ \right),$$

which yields an interpolation operator

$$P_A = \frac{1}{26}\left(\ 11 \quad 11 \quad 1 \quad 1 \quad 1 \quad 1\ \right).$$

We see that the values to the north and south are used in the interpolation with weights $11/26 \approx 0.423$ and that the four points diagonally adjacent to i are all weighted $1/26 \approx 0.038$. The ideal weights, of course, are 0.5 and 0, respectively, so the interpolation weights computed by the A-extension method, while quite good, are not perfect.

A similar calculation for the weights using the L_2-extension yields the interpolation operator

$$P_{L_2} = \frac{1}{44}\left(\begin{array}{cccccc} 16 & 16 & 3 & 3 & 3 & 3 \end{array}\right).$$

Here the dofs to the north and south are weighted $16/44 \approx 0.364$ while the diagonally adjacent dofs are weighted by $3/44 \approx 0.068$. For this problem, then, the A-extension is significantly better than the L_2-extension.

By contrast, it is a straightforward calculation to show that classical AMG produces the interpolation operator

$$P_{AMG} = \frac{1}{12}\left(\begin{array}{cccccc} 4 & 4 & 1 & 1 & 1 & 1 \end{array}\right),$$

where the north and south dofs are weighted by $4/12 \approx 0.333$ and the diagonally adjacent dofs are weighted by $1/12 \approx 0.083$; these weights are farther from the ideal than the weights produced by either the A- or L_2-extension.

Finally, consider the extension operator based on minimizing the "cut-off" quadratic functional. The additional matrix blocks involved read

$$\begin{aligned} A_{\mathcal{X}\mathcal{X}} &= \begin{bmatrix} 8 & 0 \\ 0 & 8 \end{bmatrix}, \\ A_{\mathcal{X}f} &= \begin{bmatrix} 2 \\ 2 \end{bmatrix}, \\ A_{\mathcal{X}c} &= \begin{bmatrix} -1 & -1 & -4 & -4 & 0 & 0 \\ -1 & -1 & 0 & 0 & -4 & -4 \end{bmatrix}. \end{aligned}$$

The vector $\underline{\theta}_{\mathcal{X}} = -A_{\mathcal{X}\mathcal{X}}^{-1}[A_{\mathcal{X}f}\ A_{\mathcal{X}c}][\begin{smallmatrix}(1)_f \\ (1)_c\end{smallmatrix}] = (1)_{\mathcal{X}}$. This is seen as follows:

$$A_{\mathcal{X}f}(1)_f = 2(1)_{\mathcal{X}}, \qquad A_{\mathcal{X}c}(1)_c = -10(1)_{\mathcal{X}},$$

and hence

$$A_{\mathcal{X}f}(1)_f + A_{\mathcal{X}c}(1)_c = -8(1)_{\mathcal{X}},$$

which implies

$$\underline{\theta}_{\mathcal{X}} = -A_{\mathcal{X}\mathcal{X}}^{-1}(A_{\mathcal{X}f}(1)_f + A_{\mathcal{X}c}(1)_c) = -\frac{1}{8}[-8(1)_{\mathcal{X}}] = (1)_{\mathcal{X}}.$$

That is, the diagonal matrix θ is the identity and hence the extension matrices then read

$$\begin{aligned} E_{\mathcal{X}f} &= -A_{\mathcal{X}\mathcal{X}}^{-1}A_{\mathcal{X}f} &&= -\tfrac{1}{4}\begin{bmatrix} 1 \\ 1 \end{bmatrix}, \\ E_{\mathcal{X}c} &= -A_{\mathcal{X}\mathcal{X}}^{-1}A_{\mathcal{X}c} &&= \tfrac{1}{8}\begin{bmatrix} 1 & 1 & 4 & 4 & 0 & 0 \\ 1 & 1 & 0 & 0 & 4 & 4 \end{bmatrix}. \end{aligned}$$

The modified matrices $\widehat{A}_{ff}$ and $\widehat{A}_{fc}$ take the form

$$\begin{aligned}
\widehat{A}_{ff} &= A_{ff} + A_{f\mathcal{X}} E_{\mathcal{X}f} &&= 8 - [2,\ 2]\tfrac{1}{4}\begin{bmatrix} 1 \\ 1 \end{bmatrix} \\
& &&= 7, \\
\widehat{A}_{fc} &= A_{fc} + A_{f\mathcal{X}} E_{\mathcal{X}c} &&= [-4,-4,-1,-1,-1,-1] + [2,\ 2]\tfrac{1}{8}\begin{bmatrix} 1 & 1 & 4 & 4 & 0 & 0 \\ 1 & 1 & 0 & 0 & 4 & 4 \end{bmatrix} \\
& &&= [-4,-4,-1,-1,-1,-1] + [\tfrac{1}{2},\tfrac{1}{2},1,1,1,1] \\
& &&= [-\tfrac{7}{2},-\tfrac{7}{2},0,0,0,0].
\end{aligned}$$

That is, the interpolation coefficients are the "perfect" ones (corresponding to semicoarsening):

$$\left((-\widehat{A}_{ff})^{-1}\widehat{A}_{fc}\right)_i = \left[\frac{1}{2},\frac{1}{2},0,0,0,0\right].$$

7. Two-grid analysis for a model finite element problem. Before providing numerical results, we present an analysis of the quality of the "element-free AMGe" interpolation. That is, we prove an "approximate" harmonic property of the interpolation mapping and show that it provides a partition of unity. Specifically, we assume that the problem is a standard finite element discretization of a second-order elliptic problem

$$a(u,\ v) \equiv \int a(x)\nabla u \cdot \nabla v \, dx = (f,\ v), \qquad v \in V,$$

where V is a finite element space of piecewise linear functions over quasi-uniform triangular elements that cover a given two-dimensional polygonal domain. For simplicity, we assume that homogeneous Neumann boundary conditions are imposed and that $(f,\ 1) = 0$ (to ensure solvability).

Let us denote, for any element e,

$$\varrho(e) = \sup_{x\in e} \max_{\underline{\xi}\in\mathbb{R}^2} \frac{\underline{\xi}^T a(x)\underline{\xi}}{\underline{\xi}^T\underline{\xi}}. \tag{7.1}$$

In the following, we assume that the differential operator coefficients are essentially constant in each element, so that $\varrho(e)$ gives rise to the local ellipticity constant.

Further, we assume (only for simplicity) that the neighborhood $\overline{\Omega}(i) \equiv \Omega(i) \cup \Omega_{\mathcal{X}}(i)$ for any fine dof i is formed by a union of triangles that share dof i as a common vertex. Thus we will use i instead of ψ to denote the neighborhoods ($\Omega(i)$, $\Omega_{\mathcal{X}}(i)$, and $\Omega_c(i)$) and the extension mappings. In particular, we denote $E_i = [E_{\mathcal{X}f},\ E_{\mathcal{X}c}]$ where for brevity $E_{\mathcal{X}f} = E_{\mathcal{X}f}(i)$ and $E_{\mathcal{X}c} = E_{\mathcal{X}c}(i)$. A closer look at the analysis to follow, however, shows that it applies as well to more general (i.e., larger) neighborhoods.

In what follows, for any subdomain (union of triangles) G, we let $a_G(.,.)$ denote the bilinear form a restricted to G. The corresponding subdomain matrix (assembled from the individual element matrices A_e) will be denoted by A_G^N. We omit the superscript N when there is no confusion between A_G^N and A_G, the submatrix of the original matrix A (corresponding to G). Note that in the latter case A_G corresponds to a matrix with homogeneous Dirichlet boundary conditions imposed on $\partial(G \cup \{\text{elements neighboring } G\})$.

For this discussion we assume that E_i, the local extension mapping used to build the interpolation coefficients, is based on averaging, although no specific rule is assumed. We do, however, assume that $E = E(i)$ has the particular form

$$\begin{bmatrix} I & 0 \\ 0 & I \\ 0 & E_{\mathcal{X}c} \end{bmatrix} \begin{matrix} \}\Omega(i), \\ \}\Omega_c(i), \\ \}\Omega_{\mathcal{X}}(i). \end{matrix}$$

That is, $E_{\mathcal{X}f} = 0$ and $E_i = [0,\ E_{\mathcal{X}c}]$.

REMARK 7.1. *The general case of $E_i = [E_{\mathcal{X}f},\ E_{\mathcal{X}c}]$ can be reduced to the particular case above by using the modified extension mapping $\widehat{E}_i = [0,\ \widehat{E}_{\mathcal{X}c}]$, where*

$$\widehat{E}_{\mathcal{X}c} = E_{\mathcal{X}f}\left(-\widehat{A}_{ff}^{-1}\widehat{A}_{fc}\right) + E_{\mathcal{X}c}.$$

To see this, recall that $\widehat{A}_{ff} = A_{ff} + A_{f\mathcal{X}}E_{\mathcal{X}f}$ and $\widehat{A}_{fc} = A_{fc} + A_{f\mathcal{X}}E_{\mathcal{X}c}$, and note that the modified extension mapping extends a constant vector defined on $\Omega_c(i)$ to be the same constant on $\Omega_{\mathcal{X}}(i)$, that is,

$$\begin{aligned} \widehat{E}_{\mathcal{X}c}(1)_c &= -E_{\mathcal{X}f}\widehat{A}_{ff}^{-1}\widehat{A}_{fc}(1)_c + E_{\mathcal{X}c}(1)_c \\ &= E_{\mathcal{X}f}(1)_f + E_{\mathcal{X}c}(1)_c \\ &= (1)_{\mathcal{X}}. \end{aligned}$$

Here we have used the fact that since (for the model second-order elliptic problem) $A_{ff}(1)_f + A_{f\mathcal{X}}(1)_{\mathcal{X}} + A_{fc}(1)_c = 0$, then $A_{ff}(1)_f + A_{f\mathcal{X}}\left(E_{\mathcal{X}f}(1)_f + E_{\mathcal{X}c}(1)_c\right) + A_{fc}(1)_c = 0$. That is, $\widehat{A}_{ff}(1)_f + \widehat{A}_{fc}(1)_c = 0$, implying that $(1)_f = -\widehat{A}_{ff}^{-1}\widehat{A}_{fc}(1)_c$.

We still must show that the modified extension mapping $\widehat{E}_i$ leads to the same interpolation as does E_i, i.e., that

$$-A_{ff}^{-1}\left(A_{f\mathcal{X}}\widehat{E}_{\mathcal{X}c} + A_{fc}\right) = -\widehat{A}_{ff}^{-1}\widehat{A}_{fc}.$$

For this we observe that

$$\begin{aligned} -A_{ff}^{-1}(A_{f\mathcal{X}}\widehat{E}_{\mathcal{X}c} + A_{fc}) &= -A_{ff}^{-1}\left[A_{f\mathcal{X}}\left(E_{\mathcal{X}f}(-\widehat{A}_{ff}^{-1}\widehat{A}_{fc}) + E_{\mathcal{X}c}\right) + A_{fc}\right] \\ &= -A_{ff}^{-1}\left[A_{f\mathcal{X}}E_{\mathcal{X}c} + A_{fc} - A_{f\mathcal{X}}E_{\mathcal{X}f}\widehat{A}_{ff}^{-1}\widehat{A}_{fc}\right] \\ &= -A_{ff}^{-1}\left[\widehat{A}_{fc} - A_{f\mathcal{X}}E_{\mathcal{X}f}\widehat{A}_{ff}^{-1}\widehat{A}_{fc}\right] \\ &= -A_{ff}^{-1}\left[\widehat{A}_{ff} - A_{f\mathcal{X}}E_{\mathcal{X}f}\right]\widehat{A}_{ff}^{-1}\widehat{A}_{fc} \\ &= -A_{ff}^{-1}\left(A_{ff}\right)\widehat{A}_{ff}^{-1}\widehat{A}_{fc} \\ &= -\widehat{A}_{ff}^{-1}\widehat{A}_{fc}. \end{aligned}$$

Consider the minimization problem

$$\text{(7.2)} \qquad \text{find } v_f \text{ such that } \begin{bmatrix} v_f \\ v_c \\ E_i v \end{bmatrix}^T A^N_{\overline{\Omega}(i)} \begin{bmatrix} v_f \\ v_c \\ E_i v \end{bmatrix} = \inf_{\substack{w:\ w_c = v_c \\ w_{\mathcal{X}} = E_i w}} a_{\overline{\Omega}(i)}(w,\ w).$$

Thus we seek v_f, the value of w on $\Omega(i) \setminus \Omega_c(i)$, which minimizes the quadratic form $a_{\overline{\Omega}(i)}(w,\ w)$ when the values of w are fixed at the coarse points and are "slave" at the exterior points ($\Omega_{\mathcal{X}}(i)$); that is, they are extrapolated from the interior $\Omega(i)$ and the coarse points $\Omega_c(i)$ by $E_i w$.

LEMMA 7.1. *The solution to the minimization problem* (7.2) *produces the same interpolation coefficients as does element-free AMGe, namely, those given by* $-A_{ff}^{-1}(A_{f\mathcal{X}}E_{\mathcal{X}c}+A_{fc})$. *That is, the minimizer is given by* $w_f = v_f \equiv -A_{ff}^{-1}(A_{f\mathcal{X}}E_{\mathcal{X}c}+A_{fc})v_c$.

Proof. Consider the Neumann matrix

$$A^N_{\overline{\Omega}(i)} = \begin{bmatrix} A_{ff} & A_{fc} & A_{f\mathcal{X}} \\ A_{cf} & A^N_{cc} & A^N_{c\mathcal{X}} \\ A_{\mathcal{X}f} & A^N_{\mathcal{X}c} & A^N_{\mathcal{X}\mathcal{X}} \end{bmatrix}.$$

We use the superscript N for the blocks which differ from the corresponding blocks of $A_{\overline{\Omega}(i)}$, the principal submatrix of the original matrix A corresponding to the subdomain $\overline{\Omega}(i)$. Note that the "N" blocks are not accessible (available) and not used in our algorithm. We have $E_i v|_{\Omega_{\mathcal{X}}(i)} = E_{\mathcal{X}c}v_c$. Hence, $a_{\overline{\Omega}(i)}(w,\ w)$ for $w_c = v_c$ and $w_{\mathcal{X}} = E_i w|_{\Omega_{\mathcal{X}}(i)}$ leads to the following matrix expression:

$$\begin{aligned} a_{\overline{\Omega}(i)}(w,\ w) &= \begin{bmatrix} w_f \\ v_c \\ E_{\mathcal{X}c}v_c \end{bmatrix}^T \begin{bmatrix} A_{ff} & A_{fc} & A_{f\mathcal{X}} \\ A_{cf} & A^N_{cc} & A^N_{c\mathcal{X}} \\ A_{\mathcal{X}f} & A^N_{\mathcal{X}c} & A^N_{\mathcal{X}\mathcal{X}} \end{bmatrix} \begin{bmatrix} w_f \\ v_c \\ E_{\mathcal{X}c}v_c \end{bmatrix} \\ &= \begin{bmatrix} w_f \\ v_c \end{bmatrix}^T \begin{bmatrix} A_{ff} & A_{fc} + A_{f\mathcal{X}}E_{\mathcal{X}c} \\ A_{cf} + E^T_{\mathcal{X}c}A_{\mathcal{X}f} & A^N_{cc} + A^N_{c\mathcal{X}}E_{\mathcal{X}c} + E^T_{\mathcal{X}c}(A^N_{\mathcal{X}c} + A^N_{\mathcal{X}\mathcal{X}}E_{\mathcal{X}c}) \end{bmatrix} \\ &\quad \times \begin{bmatrix} w_f \\ v_c \end{bmatrix}. \end{aligned}$$

Minimizing this symmetric positive semidefinite quadratic form with respect to w_f is equivalent to solving the equation

$$A_{ff}w_f + (A_{fc} + A_{f\mathcal{X}}E_{\mathcal{X}c})v_c = 0,$$

which is the same equation that specifies v_f in the element-free AMGe interpolation procedure. □

In the next lemma we will remove the constraint on v being fixed at the $\Omega_{\mathcal{X}}(i)$ points.

LEMMA 7.2. *The following quadratic forms are spectrally equivalent:*

$$q_1(v_c,\ v_c) \equiv \inf_{v:\ v|_{\Omega_c(i)}=v_c} a_{\overline{\Omega}(i)}(v,\ v), \qquad \textit{and} \qquad q_2(v_c, v_c) \equiv \inf_{\substack{v:\ v_c\ \textit{fixed} \\ v_{\mathcal{X}}=E_i v}} a_{\overline{\Omega}(i)}(v,\ v).$$

That is, there exists a positive constant η *such that*

$$q_1(v_c, v_c) \le q_2(v_c, v_c) \le \eta\, q_1(v_c, v_c) \quad \textit{for all } v_c.$$

Proof. We show the proof for two-dimensional domains. For other domains, we must scale ϱ by the local mesh size appropriately; otherwise, the proof remains the same. It suffices to show that the two quadratic forms have the same null-space. The null-space of q_1 is $v_c = \text{const}$ and the null-space of q_2 is the same as that of $a_{\overline{\Omega}(i)}(v,\ v)$

with $v:\ v_c = \text{const}$ and $E_i v = $ const on $\Omega_{\mathcal{X}}(i)$. Note that $a_{\overline{\Omega}(i)}(v,\ v) = 0$ implies v_f is the same constant as v_c. Then $E_i v$ is also the same constant, since it is an averaging operator based on the values of v_c and v_f. Hence the forms q_1 and q_2 both vanish only for constant v_c. In order to show that the constant η is bounded independently of E_i, one first easily sees that

$$a_{\overline{\Omega}(i)}(v,v) \le C \sum_{e\subset\overline{\Omega}(i)} \varrho(e) \sum_{l,\ k\in e} (v(l) - v(k))^2.$$

The constant C depends only on the number of points used in the averaging procedure (E_i), i.e., it is bounded by the total number of coarse points $\Omega_c(i)$ (plus the interior point i). The dofs l and k in the summation are either coarse dofs or i, and $\varrho(e)$ is defined in (7.1) to be the maximal value of the local ellipticity bound associated with the original elliptic operator coefficient $a(x)$. More specifically, for each $i_{\mathcal{X}} \in \Omega_{\mathcal{X}}(i)$

$$v(i_{\mathcal{X}}) \equiv (E_i v)(i_{\mathcal{X}}) = \sum_{k\in\Omega_c(i)\cup\{i\}} \alpha_{i_{\mathcal{X}},\ k} v(k),$$

where

$$\sum_{k\in\Omega_c(i)\cup\{i\}} \alpha_{i_{\mathcal{X}},\ k} = 1, \quad \text{and} \quad \alpha_{i_{\mathcal{X}},\ k} \ge 0.$$

Then, for any $j \in \Omega_c(i) \cup \{i\}$,

$$(v(i_{\mathcal{X}}) - v(j)) = \sum_{k\in\Omega_c(i)\cup\{i\}} \alpha_{i_{\mathcal{X}},\ k}(v(k) - v(j)),$$

and hence

$$\begin{aligned}(v(i_{\mathcal{X}}) - v(j))^2 \ &\le \sum_{k\in\Omega_c(i)\cup\{i\}} \alpha^2_{i_{\mathcal{X}},\ k} \sum_{k\in\Omega_c(i)\cup\{i\}} (v(k) - v(j))^2 \\ &\le \sum_{k\in\Omega_c(i)\cup\{i\}} (v(k) - v(j))^2.\end{aligned}$$

As a result we see that, for $v_{\mathcal{X}} = E_i v$,

$$\begin{aligned} q_2(v_c,\ v_c)\ &\le a_{\overline{\Omega}(i)}(v,\ v) \\ &\le C \sum_{e\subset\overline{\Omega}(i)} \varrho(e) \sum_{l,k\in e} (v(l) - v(k))^2 \\ &\le C\, \frac{\max\limits_{e\in\overline{\Omega}(i)} \varrho(e)}{\min\limits_{e\in\overline{\Omega}(i)} \varrho(e)} \sum_{e\subset\overline{\Omega}(i)} \varrho(e) \sum_{k,j\in e\cap(\Omega_c(i)\cup\{i\})} (v(k) - v(j))^2.\end{aligned}$$

Finally, since v_f is arbitrary on the right-hand side of this inequality,

$$q_2(v_c,\ v_c) \le C\, \frac{\max\limits_{e\in\overline{\Omega}(i)} \varrho(e)}{\min\limits_{e\in\overline{\Omega}(i)} \varrho(e)} \inf_{v_f} \left(\sum_{e\subset\Omega_c(i)} \varrho(e) \sum_{k,j\in e\cap(\Omega_c(i)\cup\{i\})} (v(k) - v(j))^2 \right).$$

It is also true that

$$q_1(v_c, v_c) \simeq \inf_{v:\, v_c \text{ fixed}} \left(\sum_{e \subset \overline{\Omega}(i)} \varrho(e) \sum_{l,\, k \in e} (v(l) - v(k))^2 \right).$$

This shows that η can be chosen bounded independently of the actual averaging extension mapping E_i. □

The above estimates involve the factor

$$\frac{\max\limits_{e \in \overline{\Omega}(i)} \varrho(e)}{\min\limits_{e \in \overline{\Omega}(i)} \varrho(e)}.$$

Whether it is large or small depends on the selection of the coarse grid (the coarse grid reflects the form of the neighborhood $\Omega(i)$), which we do not consider in the present paper.

Then the following corollary, involving the element-free AMGe interpolated vector Pv_c, is proved in the same way as Lemma 7.2.

COROLLARY 7.3. *Consider the extended neighborhood of i,* $\widehat{\Omega}(i) = \cup\{e,\ e \subset \overline{\Omega}(i)$ *or* $e \subset \overline{\Omega}(j)$ *for all* $j \in \Omega_{\mathcal{X}}(i)\}$. *There is a constant* $\kappa = \kappa_{\widehat{\Omega}(i)} > 0$, *locally estimated, such that the following bound holds:*

$$a_{\overline{\Omega}(i)}(Pv_c,\ Pv_c) \le \kappa \inf_{w:\ w_c = v_c} a_{\hat{\Omega}(i)}(w,\ w).$$

Proof. Let v be defined on $\widehat{\Omega}(i)$ as follows:

$$v(k) = \begin{cases} (Pv_c)(k), & k \in \overline{\Omega}(i), \\ v_c(k), & k \text{ is a coarse dof outside } \overline{\Omega}(i), \\ (E_j v)(k), & k \in \Omega_{\mathcal{X}}(j), \text{ for some } j \in \Omega_{\mathcal{X}}(i). \end{cases}$$

We see that v at every fine dof k in $\widehat{\Omega}(i)$ is an average value of some neighboring coarse dofs from $\widehat{\Omega}(i)$. Hence, in the same way as in the proof of Lemma 7.2, we establish the inequality

$$a_{\hat{\Omega}(i)}(v, v) \le \kappa \inf_{w:\ w_c = v_c} a_{\hat{\Omega}(i)}(w,\ w).$$

Since $a_{\overline{\Omega}(i)}(Pv_c,\ Pv_c) \le a_{\hat{\Omega}(i)}(v, v)$, the desired result follows. □

For each fine dof i, define $\mathcal{Z}(i)$ to be the number of overlapping domains on $\hat{\Omega}(i)$, that is, the number of domains $\hat{\Omega}(j)$ such that $\hat{\Omega}(j) \cap \hat{\Omega}(i) \ne \emptyset$. Then we may state the following theorem.

THEOREM 7.4. *The element-free interpolation mapping P exhibits the following approximate harmonic property:*

$$a(Pv_c,\ Pv_c) \le \kappa \inf_{w:\ w_c = v_c} a(w,\ w),$$

where the constant $\kappa = \max\limits_{i = \text{fine dof}} \kappa_{\hat{\Omega}(i)} \mathcal{Z}(i)$, *and the* $\kappa_{\hat{\Omega}(i)}$ *are the local constants from Corollary* 7.3.

Proof. The proof simply follows from the fact that

$$a(Pv_c,\ Pv_c) \le \sum_{i = \text{fine dof}} a_{\overline{\Omega}(i)}(Pv_c,\ Pv_c)$$

and by summation of the local estimates from Corollary 7.3. □

Another important property of the element-free interpolation mapping P is that it partitions unity, as we show in the following theorem.

THEOREM 7.5. *P provides a partition of unity. Specifically, the row sums of P are* 1.

Proof. Let $v_f = Pv_c$ be given by $v_f = \sum_{i_c \in \Omega_c(i)} \alpha_{i,\, i_c} v_c(i_c)$. Assume that $v_c(i_c) = 1$ on $\Omega_c(i)$. Now, P uses the formula that minimizes (7.2) and the minimum (zero) is achieved for $E_i v(j) = 1$ at $\Omega_{\mathcal{X}}(i)$ and $v_f = 1$. That is, we find that

$$1 = \sum_{i_c \in \Omega_c(i)} \alpha_{i,\, i_c},$$

which is the desired unity row-sum property of P. □

REMARK 7.2. *Theorems* 7.4 *and* 7.5 *are the main goals of many two-grid convergence analyses and they imply convergence of the respective two-grid AMG methods, cf., e.g.,* [14], [8], [13], *and* [7].

8. Numerical experiments. We describe here several sets of numerical experiments designed to test the efficacy of the element-free AMGe methods described above. For each of several problems, we apply a set of interpolation rules within an AMG code. The problems are then solved using a CG solver, preconditioned with one V-cycle of AMG.

The interpolation rules are

- the AMGe rule [7] for the finite element problems;
- three element-free AMGe rules from section 6:
  1. L_2-extension;
  2. A-extension;
  3. (only for scalar PDE) the simultaneous extension based on minimizing the quadratic functional (6.1) described in section 6.

For system problems the unknowns are split into physical variables. That is, for scalar problems the rule is as described in section 6, while for two-dimensional elasticity, with physical variables u and v (displacement in the x- and y-directions, respectively), we perform the extensions (and associated interpolation) of exterior dofs of type u using only neighborhood dofs of type u; similarly, the extension to exterior dofs of type v are carried out using neighborhood dofs of type v; this applies both to L_2- and A-extensions. The local neighborhood about a point is defined by the sparsity pattern of the matrix about that point, and the averaging involves only dofs from the sparsity pattern set S (see section 6).

8.1. An elliptic problem on a triangular element mesh. We apply the various interpolation rules to a second-order elliptic PDE

$$-\nabla \cdot (A(x,y)\nabla u) = f(x,y) \quad \text{on } G, \tag{8.1}$$

$$u(x,y) = g(x,y) \quad \text{on } \partial G, \tag{8.2}$$

where G is the unit square. The matrix of diffusion coefficients includes functions with relatively benign characteristics—there are both spatial variability and jump discontinuity in the coefficients, but the jumps are of relatively small magnitude and the variation is mild. The discretization is by a finite element method on an unstructured triangular mesh. The coarsening algorithm is one of element agglomeration. That is, the coarse grids are the vertices of coarse elements produced by an agglomeration algorithm proposed in [7]. Figure 8.1 displays the coarsening sequence for a typical

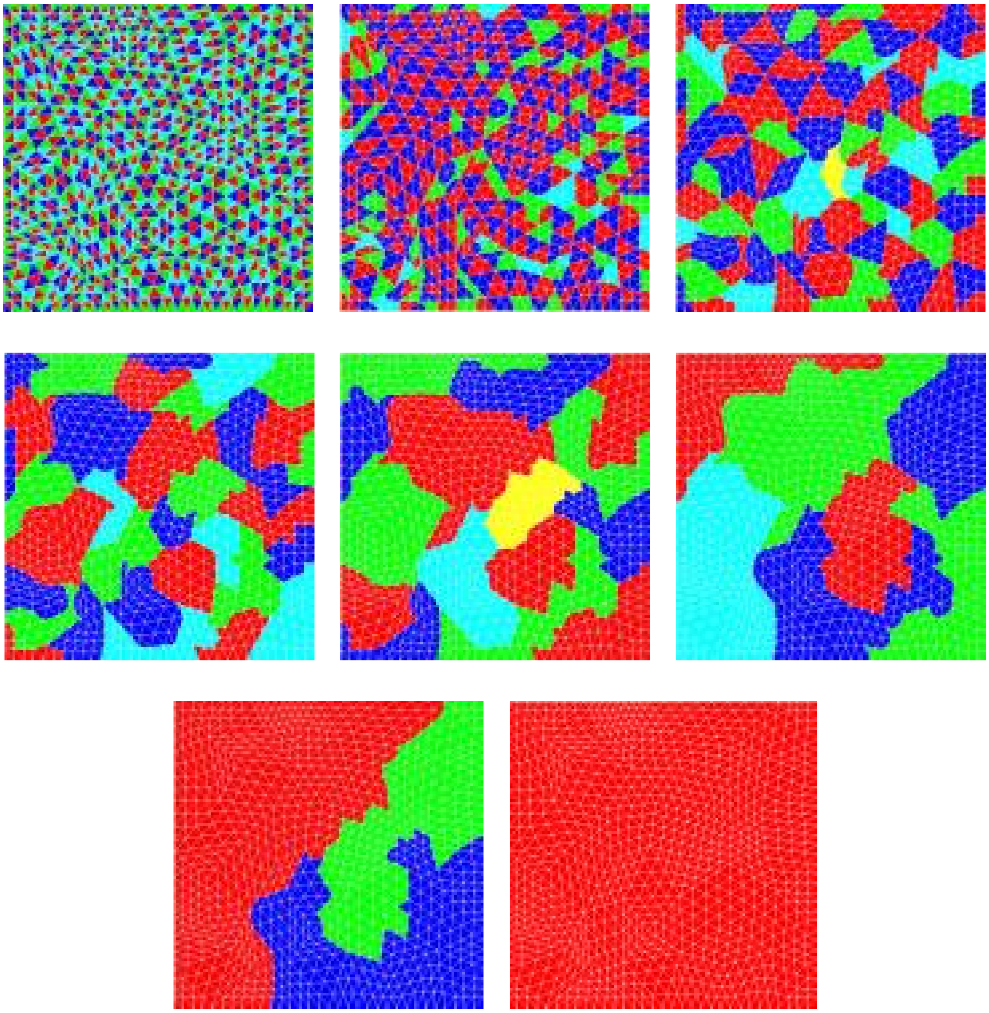

Fig. 8.1. *Sequence increasingly coarse elements, formed by element agglomeration.*

problem. Here the fine grid comprises 1600 elements, the first coarse grid has 382 elements, and the remaining grids have 93, 33, 15, 7, 3, and 1 elements. Table 8.1 gives the coarsening details for four different versions of this problem. It may be seen that the number of elements decreases by about 75% at each coarsening for the first few coarsenings, after which it decreases by about 50% per level. The number of nonzero entries in the matrix decreases by approximately 50% per level, while the number of dofs tends to decrease by 50–60% with each successive level.

For each of the four interpolation rules, the problem is solved using a preconditioned CG method, where the preconditioning consists of a single V(1,1)-cycle of AMG, with a Gauss–Seidel smoother. The iteration is run until the residual is less than 10^{-8} in norm. We report the results in Table 8.2. For each problem size, we display, for each interpolation rule, the number of preconditioned CG iterations required to achieve the desired residual size and ϱ, the average convergence factor over the iterations.

Table 8.1

Coarsening history for the problem $-\nabla \cdot A(x.y)\nabla u = f$ on an unstructured triangular fine grid. For each level of each problem size, "nz" is the number of nonzero entries in the operator matrix, "dofs" gives the number of degrees of freedom, and "elts" gives the number of finite elements in the agglomerated grid.

Interp. rule		400 elts	1600 elts	6400 elts	25600 elts
AMGe	iterations	14	16	21	23
	ϱ	0.115	0.172	0.252	0.289
A-extension	iterations	13	15	19	20
	ϱ	0.118	0.158	0.218	0.247
L_2-extension	iterations	13	16	19	21
	ϱ	0.119	0.161	0.227	0.249
Quadratic funct.	iterations	13	15	19	19
min.	ϱ	0.105	0.152	0.222	0.231

Examination of the results reveals that all three of the extension methods, A-extension, L_2-extension, and quadratic functional minimization, perform at least as well on this problem as does AMGe. In some cases the performance of the extension methods is marginally better than AMGe. The amount of work entailed for the A-extension and the L_2-extension methods is comparable to that of AMGe, provided that the neighborhoods are selected to be of comparable size to the element neighborhoods (which is the case in these experiments). For the quadratic functional minimization the work is somewhat greater but still comparable. The advantage of the element-free methods is, of course, that there is no requirement to have the actual individual stiffness matrices that are required in AMGe. For this experiment this represents a considerable savings in storage.

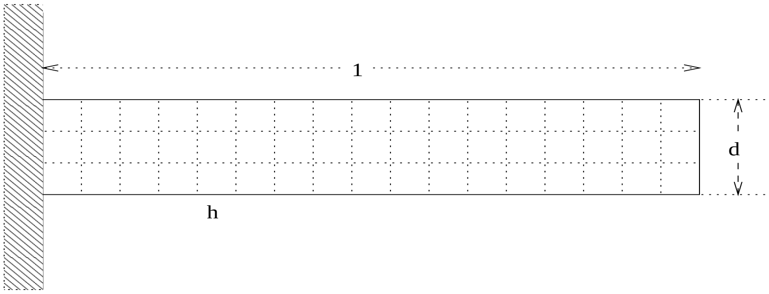

FIG. 8.2. *The thin-beam elasticity problem domain. Homogeneous Dirichlet boundary conditions are applied at $x = 0$.*

8.2. Two-dimensional elasticity: The thin beam. We consider next the two-dimensional plane-stress elasticity problem on a cantilevered beam, fixed at one end (see Figure 8.2). The domain of the problem is $G = (0,1) \times (0,\ d)$ with $d \le 1$. For $d \ll 1$ this is the thin beam problem. The problem is

$$\begin{aligned} u_{xx} + \frac{1-\nu}{2}\, u_{yy} + \frac{1+\nu}{2}\, v_{xy} &= f_1, \\ \frac{1+\nu}{2}\, u_{xy} + \frac{1-\nu}{2}\, v_{xx} + v_{yy} &= f_2, \end{aligned}$$

where u and v are displacements in the x and y directions, respectively. This can be a difficult problem for standard multigrid methods, especially when the domain is long and thin [6]. The problem is discretized using uniform square finite elements of size h. Nodal coarsening is used, with the coarse nodes being the vertices of elements created by the agglomeration algorithm from [7]. After certain levels of coarsening the algorithm agglomerates only along the x direction.

We present results in both the thick beam ($d = 1.0$) and thin beam ($d = 0.05$) cases. In both cases we use $\nu = 1/3$. For each case we present results for three sizes of the discretization parameter: $h = 0.05, 0.025$, and 0.0125 for the thick beam and $h = 0.025, 0.0125$, and 0.00625 for the thin beam. The coarsening histories of the agglomeration algorithm are shown in Table 8.3. Table 8.4 shows the results of the experiments for the beam problem. As in section 8.1, preconditioned CG is used as the solver, with a single V(1,1)-cycle of AMG as the preconditioner, with a Gauss–Seidel smoother. For this problem we show the number of iterations required to achieve a residual norm less than 10^{-8}, and also the convergence factor of the final iteration. For this problem we do not implement the quadratic minimization method

described in section 6. That method is for scalar problems, while this problem is a system of PDEs. We use the AMGe method described in [4] and compare it with the A- and L_2-extension methods described above. Our expectation is that AMGe should outperform the element-free methods, at least on the thin beam problem; this is the problem for which AMGe was originally developed. We observe, however, that for the thick beam problems the element-free methods both outperform AMGe. First, we note that it takes fewer iterations to reach the tolerance. It is also apparent that the element-free methods are more scalable, in that the number of iterations does not grow with the problem size. The AMGe method requires more iterations for larger problems.

For the thin beam problem, we observe the results we naturally expect. That is, AMGe outperforms the element-free methods, requiring fewer iterations. Further, AMGe appears to be more scalable on this problem than the extension methods. The L_2-extension method exhibits a distinct lack of scalability as the problem grows larger.

9. Conclusions. In this paper we propose a general rule for building interpolation weights in AMG, thus extending the applicability of AMG to more general settings than the traditional M-matrix case. The applications include elliptic problems on unstructured finite element grids, where both scalar problems and systems (like elasticity) are considered. The element-free AMGe method seems as competitive as the AMGe methods but entails much less overhead. The element information and the element matrices, in particular, are essential for the AMGe methods but are not required for element-free AMGe. If we assume more information is available (such as the rigid body modes in the case of elasticity) it may be incorporated into the construction of the extension mappings. Thus element-free AMGe can be made to reproduce the extra modes in the interpolation from their coarse values. This property is important in the AMG methods for elasticity problems (cf. [12]), and incorporating it into element-free AMGe is a subject of ongoing research.

ON THREE-GRID FOURIER ANALYSIS FOR MULTIGRID[*]

ROMAN WIENANDS[†] AND CORNELIS W. OOSTERLEE[†]

Abstract. In this paper, we present three-grid Fourier analysis for multigrid methods. Due to the recursive structure of a multigrid iteration, this analysis can be deduced from the well-known two-grid Fourier analysis. The coarse grid correction part of multigrid algorithms can be more accurately evaluated with the three-grid analysis. We apply the analysis to several scalar equations and discretizations with an emphasis on problems with a multigrid coarse grid correction difficulty like upwind discretizations of the convection diffusion equation. The main focus lies on possible improvements by carefully chosen Galerkin operators and/or by an additional acceleration with restarted GMRES, GMRES(m). Numerical test calculations validate the theoretical predictions.

Key words. Fourier analysis, multigrid, coarse grid correction, restarted GMRES

1. Introduction.

Fourier one-grid (smoothing) and two-grid analysis [2, 20, 21] are well-known tools in the multigrid community. The two-grid analysis is the basis for classical asymptotic multigrid convergence estimates [20, 21]. Moreover, it is the main analysis tool for nonsymmetric problems.

For several multigrid components or cycle variants, however, the asymptotic multigrid convergence factor cannot be predicted accurately by the Fourier two-grid factors. For example, one may use different discretizations on different grids. It can be beneficial to replace the direct $2h$-, $4h$-, etc. discretizations on the coarser grids by other discretizations. The most prominent example of this kind is the Galerkin coarse grid operator. As the entries of the Galerkin coarse grid discretizations are in general not known in advance, they may not be favorable for the smoothing method applied. Investigations of the two-grid iteration cannot display possible smoothing difficulties on coarser grids induced by the different discretizations, since the direct solution of the $2h$-problem is assumed. Furthermore, if one is interested in the influence on the asymptotic convergence factor of V-cycles versus W-cycles, of different numbers of pre- and postsmoothing, or of different smoothers on different grids, one needs to consider at least three grids.

To investigate these additional phenomena we carry out a *three*-grid Fourier analysis, which is usually sufficient to obtain a comprehensive insight into a *multi*grid method. In section 2, we outline the theoretical background of the three-grid analysis. Instead of (4×4)-blocks for the two-grid iteration matrix [2, 20, 21, 24] in the case of standard grid coarsening, the three-grid iteration matrix is transformed into a (16×16)-block matrix by Fourier analysis in the two-dimensional scalar case. This means that the calculation of three-grid asymptotic convergence factors is reduced to the calculation of the spectral radii of certain (16×16)-matrices.

In section 3, we apply the three-grid analysis to several equations and multigrid components. We focus on singular perturbation problems like the convection diffusion equation discretized by first or higher order difference schemes and the rotated

anisotropic diffusion equation. For these problems a variety of nonstandard coarse grid discretizations is evaluated. Some of them are discussed in [26]. For example, Galerkin coarsenings based on the transfer operators from [7] and [27] are analyzed.

This analysis can be generalized to the situation where multigrid is a preconditioner for GMRES(m) [15] in the same way as it was done in [24] for the two-grid analysis. The different multigrid algorithms are not only evaluated as a solver but also as a preconditioner for GMRES(m).

2. Fourier analysis of multigrid.

In this section we introduce the three-grid Fourier analysis of multigrid as a solver and as a preconditioner for GMRES(m); see sections 2.3 and 2.4, respectively. We restrict ourselves to the two-dimensional scalar case and standard coarsening, i.e., the grid coarsening is performed by doubling the mesh size in each direction, in order to keep the presentation as simple as possible. However, the generalization to three dimensions or to systems of equations is obvious but somewhat more technically involved, as explained in Remark 2. Other coarsening techniques like semicoarsening can be treated in a similar way by some appropriate changes concerning the coarse grid correction in the multigrid process.

2.1. Notation and basic principles.

The rigorous theoretical foundations for the Fourier analysis of multigrid, which is also commonly called *local mode analysis*, can be found, for example, in [4] and [18]. Basically, the local mode analysis is valid if the influence of a domain boundary is negligible [4]. Often, this requirement can be fulfilled by performing some extra local relaxations near and at the boundary.

For a k-grid cycle, we consider k discrete linear operators L_n $(n = 1, \dots, k)$ with constant coefficients on k infinite grids G_n with mesh sizes $h_n = 2^{k-n}h$:

$$\begin{gathered} L_n u_n(\boldsymbol{x}) = f_n(\boldsymbol{x}) \\ \text{on } \; G_n := \{\boldsymbol{x} = h_n \boldsymbol{j} = (h_n j_x, h_n j_y) = (x, y) \; \text{ with } \; \boldsymbol{j} \in \mathbb{Z}^2\}\,. \end{gathered} \tag{2.1}$$

Obviously, the grids become finer with an increasing index n, and L_k is defined on the finest grid with mesh size $h_k = h$. In stencil notation [20], (2.1) looks like

$$L_n u_n(\boldsymbol{x}) = \sum_{\boldsymbol{\kappa} \in J} (l_n)_{\boldsymbol{\kappa}} u_n(\boldsymbol{x} + \boldsymbol{\kappa} h_n) = f_n(\boldsymbol{x}) \;\text{ on }\; G_n \tag{2.2}$$

with stencil coefficients $(l_n)_{\boldsymbol{\kappa}}$ and a finite index set $J \subset \mathbb{Z}^2$. For compact 9-point stencils $[L]$ we have, for example,

$$J := \{\boldsymbol{\kappa} = (\kappa_x, \kappa_y) \;\text{ with }\; \kappa_x, \kappa_y \in \{-1, 0, 1\}\,\} \quad \text{and} \quad [L] = \begin{bmatrix} l_{-1,1} & l_{0,1} & l_{1,1} \\ l_{-1,0} & l_{0,0} & l_{1,0} \\ l_{-1,-1} & l_{0,-1} & l_{1,-1} \end{bmatrix}.$$

From (2.2), it can be deduced that the continuous eigenfunctions, the *Fourier components*, of the fine grid operator L_k are given by

$$\phi(\boldsymbol{\theta}, \boldsymbol{x}) := e^{i\boldsymbol{x}\boldsymbol{\theta}/h} = e^{i\boldsymbol{j}\boldsymbol{\theta}} = e^{i(j_x\theta_x + j_y\theta_y)} \;\text{ with }\; \boldsymbol{x} \in G_k\,,$$

where the *Fourier frequencies* $\boldsymbol{\theta} = (\theta_x, \theta_y)$ vary continuously in $\mathbb{R}^2$. The corresponding eigenvalues or *Fourier symbols* of L_k read as

$$\widetilde{L}_k(\boldsymbol{\theta}) = \sum_{\boldsymbol{\kappa} \in J} (l_k)_{\boldsymbol{\kappa}} e^{i\boldsymbol{\theta}\boldsymbol{\kappa}}\,. \tag{2.3}$$

On G_k, we introduce the scaled Euclidean inner product [20]

$$\langle v_k, w_k \rangle := \lim_{m\to\infty} \frac{1}{4m^2} \sum_{|\boldsymbol{\kappa}|\le m} v_k(\boldsymbol{\kappa}h)\,\overline{w_k(\boldsymbol{\kappa}h)} \quad \text{with}$$
$$|\boldsymbol{\kappa}| = \max\{|\kappa_1|, |\kappa_2|\} \quad \text{and} \quad v_k, w_k : \; G_k \longrightarrow \mathbb{C},$$

leading to a norm $||v_k|| := \sqrt{\langle v_k, v_k\rangle}$. Note that the Fourier components are orthonormal with respect to this inner product [20]. We define the space of bounded infinite grid functions by

$$\mathcal{F}(G_k) := \{v_k \mid \; v_k(\,.\,) : \; G_k \longrightarrow \mathbb{C} \; \text{ with } \; ||v_k|| < \infty\}.$$

For each $v_k \in \mathcal{F}(G_k)$, there exists a Fourier transformation, i.e., each v_k can be written as a linear combination of Fourier components [4, 11, 23]. Fourier components with $|\hat{\boldsymbol{\theta}}| := \max\{|\hat{\theta_x}|, |\hat{\theta_y}|\} \ge \pi$ are not visible on G_k, since they coincide with components $e^{i\boldsymbol{j}\boldsymbol{\theta}}$, where $\boldsymbol{\theta} = \hat{\boldsymbol{\theta}}(\operatorname{mod} 2\pi)$, due to the periodicity of the exponential function. Therefore, the *Fourier space*

$$\mathcal{F} := \operatorname{span}\{e^{i\boldsymbol{j}\boldsymbol{\theta}} : \boldsymbol{\theta} \in \Theta = (-\pi, \pi]^2\} \tag{2.4}$$

contains any bounded infinite grid-function.

It is convenient to explain the three-grid analysis (or, more generally, the k-grid analysis) by a recursive adaptation of the two-grid case. The discrete fine grid solution u_k and a current approximation u^i can be represented by linear combinations of Fourier components $e^{i\boldsymbol{j}\boldsymbol{\theta}} \in \mathcal{F}$ because of $\mathcal{F}(G_k) \subset \mathcal{F}$. The same holds for the error $v^{i-1} = u^{i-1} - u_k$ before and $v^i = u^i - u_k$ after the ith k-grid cycle. It can be easily established by induction that the error transformation by a k-grid cycle is given by the following recursion [10, 20, 21]:

$$M_2^1 = S_2^{\nu_2} K_2^1 S_2^{\nu_1} = S_2^{\nu_2}(I_2 - P_1^2 (L_1)^{-1} R_2^1 L_2) S_2^{\nu_1}, \tag{2.5}$$

$$\begin{aligned} M_{\ell+2}^1 &= S_{\ell+2}^{\nu_2} K_{\ell+2}^1 S_{\ell+2}^{\nu_1} \\ &= S_{\ell+2}^{\nu_2}(I_{\ell+2} - P_{\ell+1}^{\ell+2}(I_{\ell+1} - (M_{\ell+1}^1)^\gamma)(L_{\ell+1})^{-1} R_{\ell+2}^{\ell+1} L_{\ell+2}) S_{\ell+2}^{\nu_1} \\ &\text{for} \quad \ell = 1, \dots, k-2\,, \end{aligned} \tag{2.6}$$

where the sub- and superscripts of the different operators are abbreviations for the related mesh sizes of the k involved grids. S_n is a smoothing operator on G_n, ν_1 and ν_2 indicate the number of pre- and postsmoothing iterations, K_n^1 is the coarse grid correction operator, I_n is the G_n-identity, L_n is the approximation of L_k on a coarse grid G_n, P_{n-1}^n and R_n^{n-1} are transfer operators from coarse to fine grids and reversed, and γ is the cycle index (for example, $\gamma = 1$ denotes a V-cycle and $\gamma = 2$ denotes a W-cycle). Of course, it is possible to vary the number of pre- and postsmoothing steps on the different grids leading to $\nu_1(n)$ and $\nu_2(n)$. L_{n-1} may be defined by Galerkin coarsening, $L_{n-1} = \check{R}_n^{n-1} L_n \check{P}_{n-1}^n$, or simply by a straightforward application of L_k on G_{n-1}. Note that the transfer operators in the Galerkin process do not necessarily have to match with R_n^{n-1} and P_{n-1}^n from the multigrid iteration.

For the coarse grid discretization operators, the prolongation, and the restriction, similar stencil notations as in (2.2) exist. The corresponding Fourier symbols, denoted by a tilde $\tilde{}$, are calculated as in (2.3) with a suitable index set J related to the operator under consideration; see (2.8). A detailed representation of the Fourier symbols for many prolongations, restrictions, and discretizations is given, for instance, in [10, 20, 21, 23].

In the following, we often use a more instructive notation for the operators from (2.5), (2.6), the related Fourier symbols, and the infinite grids G_n. For example, their indices are replaced by the corresponding mesh sizes $h_n = 2^{k-n}h$. For example, we write P^h_{2h}, $\widetilde{P}^h_{2h}(\boldsymbol{\theta})$, and G_h instead of P^k_{k-1}, $\widetilde{P}^k_{k-1}(\boldsymbol{\theta})$, and G_k, respectively; see, e.g., (2.7), (2.8), or (2.11). Some basic elements of the three-grid analysis already appear in the two-grid analysis. Here, the sub- or superscript $2g$ always stands for two-grid. The index $3g$ is used accordingly for three-grid in section 2.3.

2.2. Two-grid Fourier analysis. If standard coarsening is selected, it is convenient to divide the Fourier space (2.4) into the following four-dimensional subspaces.

DEFINITION 2.1 ($2h$-harmonics). *The $2h$-harmonics $\mathcal{F}^{2g}_{\boldsymbol{\theta}}$ are given by*

$$\mathcal{F}^{2g}_{\boldsymbol{\theta}} := span\{\phi(\boldsymbol{\theta}^{\alpha_x\alpha_y}, \boldsymbol{x}) \quad with\ \ \alpha_x, \alpha_y \in \{0,1\}\ \}, \quad where$$
$$\boldsymbol{\theta} = \boldsymbol{\theta}^{00} \in \Theta_{2g} := (-\pi/2, \pi/2]^2 \quad and\ \ \boldsymbol{\theta}^{\alpha_x\alpha_y} := \boldsymbol{\theta}^{00} - (\,\alpha_x sign(\theta_x), \alpha_y sign(\theta_y)\,)\,\pi\,.$$

This distinction is motivated by the fact that each *low-frequency* $\boldsymbol{\theta}^{00} \in \Theta_{2g}$ is coupled with three *high-frequencies* $\boldsymbol{\theta}^{\boldsymbol{\alpha}}$ with $\boldsymbol{\alpha} \neq (00)$ in the transition from G_h to G_{2h}. For example, the three high-frequency components are not visible on the coarse grid as they coincide with the corresponding low-frequency component.

In order to ensure that we deal with nonsingular Fourier symbols $\widetilde{L}_h(\boldsymbol{\theta})$ and $\widetilde{L}_{2h}(2\boldsymbol{\theta})$, we restrict our considerations to the following slightly shrunken subspace of the Fourier space (2.4), as in [20]:

$$\mathcal{F}^{2g} := \mathcal{F}\backslash \bigcup_{\boldsymbol{\theta}\in\Psi_{2g}} \mathcal{F}^{2g}_{\boldsymbol{\theta}} \quad \text{with} \quad \Psi_{2g} := \{\boldsymbol{\theta} \in \Theta_{2g} :\ \widetilde{L}_{2h}(2\boldsymbol{\theta}^{00}) = 0 \ \text{ or } \ \widetilde{L}_h(\boldsymbol{\theta}^{\boldsymbol{\alpha}}) = 0\}.$$

The crucial observation is that the coarse grid correction operator K^{2h}_h (see (2.5)) leaves the spaces of $2h$-harmonics invariant for an arbitrary Fourier frequency $\boldsymbol{\theta} \in \widetilde{\Theta}_{2g} := \Theta_{2g}\backslash\Psi_{2g}$. The same invariance property holds for many well-known smoothing methods, e.g., Jacobi point- or line-relaxation, lexicographical Gauss–Seidel point- or line-relaxation, and certain pattern relaxation methods such as red-black Gauss–Seidel or zebra line Gauss–Seidel. Especially for pattern relaxations, the calculation of the related Fourier symbols is not as simple as it is for the different operators of the coarse grid correction. In general, certain Fourier components within the spaces of $2h$-harmonics may be coupled by the smoothing operator, which means that the calculation of the corresponding Fourier symbol cannot be done separately for each component $\phi(\boldsymbol{\theta}, \boldsymbol{x})$, as in (2.3). On the contrary, it is represented by a general (4×4)-matrix $S^{2g}(\boldsymbol{\theta}, h) = S^{2g}(\boldsymbol{\theta}^{00}, \boldsymbol{\theta}^{11}, \boldsymbol{\theta}^{10}, \boldsymbol{\theta}^{01}, h) \in \mathbb{C}^{4\times 4}$. For the explicit representation of several relaxation methods, we refer to [10, 20, 21, 23].

Summarizing, we have that the two-grid operator (see (2.5)) leaves the spaces of $2h$-harmonics invariant, i.e., for each $\boldsymbol{\theta} \in \widetilde{\Theta}_{2g}$ it holds that

$$\begin{aligned} &M^{2h}_h|_{\mathcal{F}^{2g}_{\boldsymbol{\theta}}} \overset{\wedge}{=} M^{2g}(\boldsymbol{\theta}, h) \\ &= (S^{2g}(\boldsymbol{\theta}, h))^{\nu_2}(\,I^{2g} - P^{2g}(\boldsymbol{\theta}, h)(\mathcal{L}^{2g}(\boldsymbol{\theta}, h))^{-1}R^{2g}(\boldsymbol{\theta}, h)L^{2g}(\boldsymbol{\theta}, h)\,)(S^{2g}(\boldsymbol{\theta}, h))^{\nu_1}\,. \end{aligned} \tag{2.7}$$

The representation of the coarse grid correction block matrices is given by

$$\begin{aligned} I^{2g} &= \operatorname{diag}\{1,1,1,1\} \in \mathbb{C}^{4\times 4}\,, \quad \mathcal{L}^{2g}(\boldsymbol{\theta},h) = \widetilde{L}_{2h}(2\boldsymbol{\theta}^{00}) \in \mathbb{C}^{1\times 1}\,,\\ L^{2g}(\boldsymbol{\theta},h) &= \operatorname{diag}\{\widetilde{L}_h(\boldsymbol{\theta}^{00}), \widetilde{L}_h(\boldsymbol{\theta}^{11}), \widetilde{L}_h(\boldsymbol{\theta}^{10}), \widetilde{L}_h(\boldsymbol{\theta}^{01})\} \in \mathbb{C}^{4\times 4}\,,\\ R^{2g}(\boldsymbol{\theta},h) &= (\, \widetilde{R}_h^{2h}(\boldsymbol{\theta}^{00})\; \widetilde{R}_h^{2h}(\boldsymbol{\theta}^{11})\; \widetilde{R}_h^{2h}(\boldsymbol{\theta}^{10})\; \widetilde{R}_h^{2h}(\boldsymbol{\theta}^{01})\,) \in \mathbb{C}^{1\times 4}\,,\\ P^{2g}(\boldsymbol{\theta},h) &= (\, \widetilde{P}_{2h}^{h}(\boldsymbol{\theta}^{00})\; \widetilde{P}_{2h}^{h}(\boldsymbol{\theta}^{11})\; \widetilde{P}_{2h}^{h}(\boldsymbol{\theta}^{10})\; \widetilde{P}_{2h}^{h}(\boldsymbol{\theta}^{01})\,)^T \in \mathbb{C}^{4\times 1}\,. \end{aligned} \tag{2.8}$$

Using the simple block representation from (2.7), the spectral radius of the two-grid iteration matrix and thus the asymptotic two-grid convergence factor can be approximated by

$$\rho_{2g}(h) := \sup_{\boldsymbol{\theta}\in\tilde{\Theta}_{2g}} \rho(M^{2g}\,(\boldsymbol{\theta},h))\,. \tag{2.9}$$

Remark 1 (boundedness of $\rho_{2g}(h)$). In all the examples considered in section 3, we have $\tilde{\Theta}_{2g} = (-\pi/2,\pi/2] \setminus \{(0,0)\}$, as only $\widetilde{L}_h((0,0))$ and $\widetilde{L}_{2h}(2(0,0))$ are zero. However, the suprenum in (2.9) remains finite, since $\widetilde{R}_h^{2h}((0,0))\widetilde{L}_h((0,0))$ is rank deficient too, in such a way that $\lim_{\boldsymbol{\theta}\to(0,0)} \rho(M^{2g}(\boldsymbol{\theta},h)\,)$ is bounded; see [4].

The smoothing or one-grid convergence factor $\rho_{1g}(h)$, based on the "ideal" coarse grid correction operator Q_h^{2h} with $Q_h^{2h}|_{\mathcal{F}_{\boldsymbol{\theta}}^{2g}} \overset{\wedge}{=} Q = \operatorname{diag}\{0,1,1,1\}$ from [20], reads as

$$\rho_{1g}(h) := \sup_{\boldsymbol{\theta}\in\tilde{\Theta}_{2g}} \rho(\, Q(S^{2g}(\boldsymbol{\theta},h))^{\nu_1+\nu_2}\,)\,. \tag{2.10}$$

Q_h^{2h} annihilates the low-frequency error components and leaves the high-frequency components unchanged. $\rho_{1g}(h)$ yields reasonable convergence estimates as long as Q_h^{2h} is a good approximation of the real coarse grid correction operator.

2.3. Three-grid Fourier analysis. From (2.6), the error transformation by a three-grid cycle is given by $v_i = M_h^{4h} v_{i-1}$ with

$$\begin{aligned} M_h^{4h} &= S_h^{v_2} K_h^{4h} S_h^{v_1}\\ &= S_h^{v_2}(I_h - P_{2h}^h(I_{2h} - (M_{2h}^{4h})^\gamma)(L_{2h})^{-1} R_h^{2h} L_h) S_h^{v_1}\,, \end{aligned} \tag{2.11}$$

where M_{2h}^{4h}, defined by (2.5), reads as

$$M_{2h}^{4h} = S_{2h}^{\nu_2}(I_{2h} - P_{4h}^{2h}(L_{4h})^{-1} R_{4h}^{2h} L_{2h}) S_{2h}^{\nu_1}\,. \tag{2.12}$$

Instead of inverting L_{2h}, as is done in the two-grid cycle (2.5), the $2h$-equation is solved approximately by performing γ two-grid iterations M_{2h}^{4h} with zero initial approximation. This is reflected by the replacement of $(L_{2h})^{-1}$ from (2.5) by the expression

$$(\mathcal{L}_{2h}^{4h})^{-1} = (I_{2h} - (M_{2h}^{4h})^\gamma)(L_{2h})^{-1} \tag{2.13}$$

in (2.11). To see this, consider an arbitrary nonsingular system $Lu = f$ which is approximately solved by γ steps of an iterative method, $Cu^j = (C-L)u^{j-1} + f$, based on the splitting $L = C + (L - C)$. If a multigrid method is applied, we obtain $u^j = Mu^{j-1} + C^{-1}f$ with $C^{-1} = (I - M)L^{-1}$. M denotes the error transformation matrix by one multigrid cycle; see (2.6). Starting with $u^0 = 0$, the γth iterate can easily be written as $u^\gamma = (I - M^\gamma)L^{-1}f$. In a numerical algorithm, however, L^{-1} (and, in particular, $(L_{2h})^{-1}$) is, of course, not applied explicitly.

FIG. 2.1. *A set of Fourier frequencies that are coupled by a three-grid iteration; see Definition* 2.2.

Considering three-grid cycles, it is appropriate to divide the Fourier space $\mathcal{F}$ into a direct sum of the following 16-dimensional subspaces.

DEFINITION 2.2 ($4h$-harmonics). *The $4h$-harmonics are defined by*

$$\begin{aligned} \mathcal{F}^{3g}_{\boldsymbol{\theta}} := span\Big\{ \phi(\boldsymbol{\theta}^{\boldsymbol{\alpha}}_{\boldsymbol{\beta}}, \boldsymbol{x}) \quad & with \;\; \boldsymbol{\alpha} = (\alpha_x\, \alpha_y)\,, \;\; \boldsymbol{\beta} = (\beta_x\, \beta_y), \\ & and \;\; \alpha_x, \alpha_y \in \{0,1\}\,, \;\; \beta_x, \beta_y \in \Big\{0, \frac{1}{2}\Big\} \;\Big\}, \\ where \quad \boldsymbol{\theta} = \boldsymbol{\theta}^{00}_{00} & \in \Theta_{3g} := (-\pi/4, \pi/4]^2 \quad and \\ \boldsymbol{\theta}^{00}_{\beta_x\beta_y} &= \boldsymbol{\theta}^{00}_{00} - (\, \beta_x sign(\theta_x), \beta_y sign(\theta_y)\,)\pi\,, \\ \boldsymbol{\theta}^{\alpha_x\alpha_y}_{\boldsymbol{\beta}} &= \boldsymbol{\theta}^{00}_{\boldsymbol{\beta}} - (\, \alpha_x sign(\theta_{\beta_x}), \alpha_y sign(\theta_{\beta_y})\,)\pi\,. \end{aligned}$$

Figure 2.1 illustrates this somewhat technical definition by indicating the location of the 16 different frequencies $\boldsymbol{\theta}^{\boldsymbol{\alpha}}_{\boldsymbol{\beta}}$. It can be motivated in the same way as it was done in the two-grid analysis concerning the $2h$-harmonics. In the transition from G_{2h} to G_{4h}, a low frequency $\boldsymbol{\theta}^{00}_{00} \in \Theta_{3g}$ is coupled with three high frequencies $\boldsymbol{\theta}^{00}_{\boldsymbol{\beta}}$ with $\boldsymbol{\beta} \neq (00)$. We collect four such components in the following subspaces.

DEFINITION 2.3.

$$\mathcal{F}^{\boldsymbol{\beta}}_{\boldsymbol{\theta}} := span\Big\{ \phi(\boldsymbol{\theta}^{00}_{\beta_x\beta_y}, \boldsymbol{x}) \quad with \;\; \beta_x, \beta_y \in \Big\{0, \frac{1}{2}\Big\} \;\Big\} \quad for \;\; \boldsymbol{\theta}^{00}_{00} \in \Theta_{3g}\,.$$

Furthermore, each $\boldsymbol{\theta}^{00}_{\boldsymbol{\beta}}$ is coupled with three high-frequency components $\boldsymbol{\theta}^{\boldsymbol{\alpha}}_{\boldsymbol{\beta}}$ with $\boldsymbol{\alpha} \neq (00)$ in the transition from G_h to G_{2h}; see Figure 2.1. It follows that a three-grid cycle couples 16 frequencies, i.e., the 15 high-frequency components alias on G_{4h} with the low-frequency component $\phi(\boldsymbol{\theta}^{00}_{00}, \boldsymbol{x})$.

Again, we exclude certain frequencies from the calculation to obtain a well-defined three-grid operator and consider the following slightly smaller spaces:

$$\mathcal{F}^{3g} := \mathcal{F} \backslash \bigcup_{\boldsymbol{\theta} \in \Psi_{3g}} \mathcal{F}^{3g}_{\boldsymbol{\theta}} \quad \text{and} \quad \tilde{\Theta}_{3g} := \Theta_{3g} \backslash \Psi_{3g} \quad \text{with}$$

$$\Psi_{3g} := \left\{ \boldsymbol{\theta} \in \Theta_{3g} : \ \widetilde{L}_{4h}(4\boldsymbol{\theta}^{00}_{00}) = 0 \ \text{ or } \ \widetilde{L}_{2h}(2\boldsymbol{\theta}^{00}_{\boldsymbol{\beta}}) = 0 \ \text{ or } \ \widetilde{L}_{h}(\boldsymbol{\theta}^{\boldsymbol{\alpha}}_{\boldsymbol{\beta}}) = 0 \right\}.$$

Comparing Definitions 2.1 and 2.2, it immediately follows that each space of $4h$-harmonics consists of four spaces of $2h$-harmonics, i.e., for an arbitrary $\boldsymbol{\theta} \in \tilde{\Theta}_{3g}$ we have

$$\mathcal{F}^{3g}_{\boldsymbol{\theta}} = \mathcal{F}^{2g}_{\boldsymbol{\theta}^{00}_{00}} \cup \mathcal{F}^{2g}_{\boldsymbol{\theta}^{00}_{\frac{1}{2}\frac{1}{2}}} \cup \mathcal{F}^{2g}_{\boldsymbol{\theta}^{00}_{\frac{1}{2}0}} \cup \mathcal{F}^{2g}_{\boldsymbol{\theta}^{00}_{0\frac{1}{2}}} . \tag{2.14}$$

As a fundamental statement for the three-grid analysis, we find that the three-grid operator M_h^{4h} (2.11) leaves the spaces of $4h$-harmonics invariant. Using Definition 2.3, (2.14), and the considerations from the last subsection, it follows for every $\boldsymbol{\theta} \in \tilde{\Theta}_{3g}$ that

$$\begin{aligned} &S_h \ : \ \mathcal{F}^{3g}_{\boldsymbol{\theta}} \longrightarrow \mathcal{F}^{3g}_{\boldsymbol{\theta}} \ , \quad L_h \ : \ \mathcal{F}^{3g}_{\boldsymbol{\theta}} \longrightarrow \mathcal{F}^{3g}_{\boldsymbol{\theta}} \ , \\ &R_h^{2h} \ : \ \mathcal{F}^{3g}_{\boldsymbol{\theta}} \longrightarrow \mathcal{F}^{\boldsymbol{\beta}}_{\boldsymbol{\theta}} \ , \quad \mathcal{L}^{4h}_{2h} \ : \ \mathcal{F}^{\boldsymbol{\beta}}_{\boldsymbol{\theta}} \longrightarrow \mathcal{F}^{\boldsymbol{\beta}}_{\boldsymbol{\theta}} \ , \quad P^{h}_{2h} \ : \ \mathcal{F}^{\boldsymbol{\beta}}_{\boldsymbol{\theta}} \longrightarrow \mathcal{F}^{3g}_{\boldsymbol{\theta}} \ . \end{aligned} \tag{2.15}$$

The relation for $\mathcal{L}^{4h}_{2h}$ reads in more detail as (see (2.13) and (2.12))

$$\begin{aligned} &L_{2h} \ : \ \mathcal{F}^{\boldsymbol{\beta}}_{\boldsymbol{\theta}} \longrightarrow \mathcal{F}^{\boldsymbol{\beta}}_{\boldsymbol{\theta}} \ , \quad S_{2h} \ : \ \mathcal{F}^{\boldsymbol{\beta}}_{\boldsymbol{\theta}} \longrightarrow \mathcal{F}^{\boldsymbol{\beta}}_{\boldsymbol{\theta}} \ , \quad R^{4h}_{2h} \ : \ \mathcal{F}^{\boldsymbol{\beta}}_{\boldsymbol{\theta}} \longrightarrow \operatorname{span}\{\phi(\boldsymbol{\theta}^{00}_{00}, \boldsymbol{x})\} \ , \\ &L_{4h} \ : \ \operatorname{span}\{\phi(\boldsymbol{\theta}^{00}_{00}, \boldsymbol{x})\} \longrightarrow \operatorname{span}\{\phi(\boldsymbol{\theta}^{00}_{00}, \boldsymbol{x})\} \ , \quad P^{2h}_{4h} \ : \ \operatorname{span}\{\phi(\boldsymbol{\theta}^{00}_{00}, \boldsymbol{x})\} \longrightarrow \mathcal{F}^{\boldsymbol{\beta}}_{\boldsymbol{\theta}} \ . \end{aligned}$$

As a consequence of (2.15), one obtains the following (16×16)-block matrices:

$$\begin{aligned} M_h^{4h}|_{\mathcal{F}^{3g}_{\boldsymbol{\theta}}} &\overset{\wedge}{=} M^{3g}(\boldsymbol{\theta}, h) \\ = (S^{3g}(\boldsymbol{\theta}, h))^{\nu_2} (I^{3g} &- P^{3g}(\boldsymbol{\theta}, h)(\mathcal{L}^{3g}(\boldsymbol{\theta}, h))^{-1} R^{3g}(\boldsymbol{\theta}, h) L^{3g}(\boldsymbol{\theta}, h) \ )(S^{3g}(\boldsymbol{\theta}, h))^{\nu_1} \ . \end{aligned} \tag{2.16}$$

The different operators of the block-matrices $M^{3g}(\boldsymbol{\theta}, h)$ can be expressed by the two-grid representations from section 2.2; see $S^{2g}(\boldsymbol{\theta}, h)$ and (2.8):

$$\begin{aligned} I^{3g} &= \operatorname{diag}\{I^{2g}, I^{2g}, I^{2g}, I^{2g}\} \in \mathbb{C}^{16\times 16} \ , \\ S^{3g}(\boldsymbol{\theta}, h) &= \operatorname{diag}\{S^{2g}(\boldsymbol{\theta}_{00}, h), S^{2g}(\boldsymbol{\theta}_{\frac{1}{2}\frac{1}{2}}, h), S^{2g}(\boldsymbol{\theta}_{\frac{1}{2}0}, h), S^{2g}(\boldsymbol{\theta}_{0\frac{1}{2}}, h)\} \in \mathbb{C}^{16\times 16} \ , \\ L^{3g}(\boldsymbol{\theta}, h) &= \operatorname{diag}\{L^{2g}(\boldsymbol{\theta}_{00}, h), L^{2g}(\boldsymbol{\theta}_{\frac{1}{2}\frac{1}{2}}, h), L^{2g}(\boldsymbol{\theta}_{\frac{1}{2}0}, h), L^{2g}(\boldsymbol{\theta}_{0\frac{1}{2}}, h)\} \in \mathbb{C}^{16\times 16} \ , \\ R^{3g}(\boldsymbol{\theta}, h) &= \operatorname{diag}\{R^{2g}(\boldsymbol{\theta}_{00}, h), R^{2g}(\boldsymbol{\theta}_{\frac{1}{2}\frac{1}{2}}, h), R^{2g}(\boldsymbol{\theta}_{\frac{1}{2}0}, h), R^{2g}(\boldsymbol{\theta}_{0\frac{1}{2}}, h)\} \in \mathbb{C}^{4\times 16} \ , \\ P^{3g}(\boldsymbol{\theta}, h) &= \operatorname{diag}\{P^{2g}(\boldsymbol{\theta}_{00}, h), P^{2g}(\boldsymbol{\theta}_{\frac{1}{2}\frac{1}{2}}, h), P^{2g}(\boldsymbol{\theta}_{\frac{1}{2}0}, h), P^{2g}(\boldsymbol{\theta}_{0\frac{1}{2}}, h)\} \in \mathbb{C}^{16\times 4} \ , \\ (\mathcal{L}^{3g}(\boldsymbol{\theta}, h))^{-1} &= \ (\ I^{2g} - (M^{2g}(2\boldsymbol{\theta}, 2h))^{\gamma} \ ) \\ &\quad (\ \operatorname{diag}\{\mathcal{L}^{2g}(\boldsymbol{\theta}_{00}, h), \mathcal{L}^{2g}(\boldsymbol{\theta}_{\frac{1}{2}\frac{1}{2}}, h), \mathcal{L}^{2g}(\boldsymbol{\theta}_{\frac{1}{2}0}, h), \mathcal{L}^{2g}(\boldsymbol{\theta}_{0\frac{1}{2}}, h)\} \ )^{-1} \in \mathbb{C}^{4\times 4} \ . \end{aligned} \tag{2.17}$$

Of course, $M^{2g}(2\boldsymbol{\theta}, 2h)$ can be calculated using $S^{2g}(\boldsymbol{\theta}, h)$ and (2.8) if we replace h by $2h$ and $\boldsymbol{\theta}$ by $2\boldsymbol{\theta}$.

Analogous to the two-grid factor $\rho_{2g}(h)$ from (2.9), we obtain the three-grid convergence factor as the suprenum of the spectral radii from certain block-matrices:

$$\rho_{3g}(h) := \sup_{\boldsymbol{\theta} \in \tilde{\Theta}_{3g}} \rho(M^{3g}(\boldsymbol{\theta}, h)) \,. \tag{2.18}$$

The considerations from Remark 1 concerning the boundedness of $\rho_{2g}(h)$ carry over to the three-grid factors calculated in section 3.

Remark 2 (generalization to d dimensions, k grids, and systems of equations). In the most general case, we consider a d-dimensional problem and apply k-grid cycles to a system of q equations. Then, every low-frequency $\boldsymbol{\theta} \in \Theta_{kg} := (-2^{1-k}\pi, 2^{1-k}\pi]^d$ is coupled with $2^{d(k-1)} - 1$ high frequencies. Accordingly, the related $2^{k-1}h$-harmonics are of dimension $2^{d(k-1)}$. Each operator of the k-grid cycle acts on the whole system and the dimensions of the corresponding block-matrices (see (2.8) and (2.17) for the two-dimensional scalar case with two- and three-grid cycles, respectively) are given by

$$I^{kg},\ S^{kg}(\boldsymbol{\theta}, h),\ L^{kg}(\boldsymbol{\theta}, h) \in \mathbb{C}^{2^{d(k-1)}q \times 2^{d(k-1)}q}, \quad R^{kg}(\boldsymbol{\theta}, h) \in \mathbb{C}^{2^{d(k-2)}q \times 2^{d(k-1)}q},$$
$$P^{kg}(\boldsymbol{\theta}, h) \in \mathbb{C}^{2^{d(k-1)}q \times 2^{d(k-2)}q}, \quad \mathcal{L}^{kg}(\boldsymbol{\theta}, h) \in \mathbb{C}^{2^{d(k-2)}q \times 2^{d(k-2)}q}.$$

The evaluation of k-grid cycles appears to be quite complicated and costly for many-level cycles, but one should take into account that the k-grid operators (2.6) are recursively defined and can be expressed in terms of two-grid operators. This means that the entries of a k-grid Fourier matrix representation are given by certain two-grid Fourier symbols; see (2.17). *In practice, however, it should usually be enough to perform a three-grid analysis to obtain sufficient insight into a multigrid method.*

Remark 3 (finite-dimensional Fourier space). Note that the Fourier space (2.4) has a nondenumerable basis as $\boldsymbol{\theta}$ varies continuously in $(\pi, \pi]^2$. The use of infinite-dimensional spaces and operators leads to some technical simplifications in the analysis; see [20]. However, in general, the suprema from (2.9), (2.10), and (2.18) cannot be calculated analytically. Therefore, we restrict our practical computations in section 3 to a finite-dimensional Fourier space which is related to the mesh size h under consideration:

$$\mathcal{F}_{finite} := \text{span}\{e^{i\boldsymbol{j}\boldsymbol{\theta}} : \boldsymbol{\theta} \in \Theta_{finite} := (-\pi, \pi]^2 \cap G_{h_{\boldsymbol{\theta}}}\}$$
$$\text{with } G_{h_{\boldsymbol{\theta}}} := \{\boldsymbol{\theta} = h_{\boldsymbol{\theta}}\boldsymbol{j} = (h_{\boldsymbol{\theta}}j_x, h_{\boldsymbol{\theta}}j_y) \text{ with } h_{\boldsymbol{\theta}} = 2\pi h \,, \boldsymbol{j} \in \mathbb{Z}^2\} \,.$$

The definitions of $\tilde{\Theta}_{2g}$, $\tilde{\Theta}_{3g}$, $\mathcal{F}^{2g}$, and $\mathcal{F}^{3g}$ have to be changed accordingly. Hence the suprema are replaced by maxima, which can easily be calculated numerically. Using this finite-dimensional Fourier space, the infinite Fourier analysis becomes an exact analysis for certain model problems on rectangular domains with periodic boundary conditions. Pure periodic boundary conditions lead to a singular boundary value problem in general. This necessitates a compatibility condition for every iterative solution method, which directly corresponds to the exclusion of the "zero" frequency in the analysis; see Remark 1. More details can be found, for example, in [20, 21].

2.4. Generalization for multigrid as a preconditioner for GMRES(m). In this section, we briefly describe the generalization of the above analysis to multigrid as a right preconditioner for GMRES(m). For a detailed discussion with respect to the two-grid analysis, we refer to [24].

As Krylov subspace methods are commonly described using matrix and vector notation, we consider the linear system $Lu = f$, related to (2.1) with $n = k$. A three-grid (or, more generally, a multigrid) cycle can be described by the matrix splitting, $Cu_j + (L - C)u_{j-1} = f$, where u_j and u_{j-1} represent a new and a previous approximation. This formulation is equivalent to

$$u_j = u_{j-1} + C^{-1}(f - Lu_{j-1}) \quad \text{and} \quad r_j = (I - LC^{-1})r_{j-1}$$

with the residual vectors r_j, r_{j-1} and the residual transformation matrix

$$I - LC^{-1} = LML^{-1}, \tag{2.19}$$

where M denotes the three-grid iteration matrix. GMRES(m) searches for a new approximation u_j with corresponding residual r_j in the Krylov subspace

$$K^m(LC^{-1}, r_{j-m}) := \text{span}[r_{j-m}, (LC^{-1})r_{j-m}, \dots, (LC^{-1})^{m-1}r_{j-m}] \ .$$

It selects the new solution by minimizing the residual in the discrete Euclidean 2-norm

$$||r_j||_2 = \min\{||P_m(LC^{-1})r_{j-m}||_2 \ | \ P_m \in \Pi_m\}, \tag{2.20}$$

where Π_m denotes the set of all polynomials of degree at most m with $P_m(0) = 1$. For convenience, $j \geq m$ is assumed. Since we are interested in the asymptotic convergence of multigrid preconditioned GMRES with a restart after m iterations, we focus on the residuals $r_m, r_{2m}, \dots, r_{i \cdot m}$. Then a "complete" iteration with iteration index i consists of m multigrid preconditioned GMRES(m) steps. The GMRES(m)-polynomial which characterizes the ith complete iteration is denoted by P_m^i, leading to the following recursion for the corresponding residual:

$$r_{i \cdot m} = P_m^i(LC^{-1})r_{(i-1)\cdot m}. \tag{2.21}$$

As unitary transformations do not affect the convergence properties of GMRES, we consider the Fourier representations $\widetilde{M}^{3g}$ and $\widetilde{L}^{3g}$ instead of the representations M and L with respect to the Euclidean basis. More precisely, we use the finite-dimensional variants

$$\widetilde{M}^{3g} := [M^{3g}(\boldsymbol{\theta}, h)]_{\boldsymbol{\theta} \in \tilde{\Theta}_{3g} \cap G_{h_{\boldsymbol{\theta}}}} \quad \text{and} \quad \widetilde{L}^{3g} := [L^{3g}(\boldsymbol{\theta}, h)]_{\boldsymbol{\theta} \in \tilde{\Theta}_{3g} \cap G_{h_{\boldsymbol{\theta}}}}$$

to allow an explicit calculation; see Remark 3. Assuming a repeated application of preconditioned GMRES(m), the following function g has to be minimized in order to find the coefficients α_k^i ($k = 1, ..., m$) of the ith GMRES(m)-polynomial P_m^i (see (2.19), (2.20), and (2.21)):

$$g(\alpha_1^i, \dots, \alpha_m^i) := (P_m^i(I - \widetilde{L}^{3g}\widetilde{M}^{3g}(\widetilde{L}^{3g})^{-1})\tilde{r}_{(i-1)m}, P_m^i(I - \widetilde{L}^{3g}\widetilde{M}^{3g}(\widetilde{L}^{3g})^{-1})\tilde{r}_{(i-1)m}).$$

The α_k^i are obtained by solving the linear system

$$\begin{aligned} \frac{\partial g}{\partial \alpha_\ell^i} &= 2\sum_{k=1}^{m} \alpha_k^i((I - \widetilde{L}^{3g}\widetilde{M}^{3g}(\widetilde{L}^{3g})^{-1})^\ell \tilde{r}_{(i-1)m}, (I - \widetilde{L}^{3g}\widetilde{M}^{3g}(\widetilde{L}^{3g})^{-1})^k \tilde{r}_{(i-1)m}) \\ &+ 2((I - \widetilde{L}^{3g}\widetilde{M}^{3g}(\widetilde{L}^{3g})^{-1})^\ell \tilde{r}_{(i-1)m}, \tilde{r}_{(i-1)m}) = 0 \qquad \text{for } \ell = 1, \dots, m. \end{aligned} \tag{2.22}$$

The solution of (2.22) can easily be computed for every iteration index i due to the sparse block structure of $(I - \widetilde{L}^{3g}\widetilde{M}^{3g}(\widetilde{L}^{3g})^{-1})^\ell$ ($\ell = 1, \dots, m$) if the previous

Fourier transformed residual $\tilde{r}_{(i-1)m}$ is given. We simply prescribe a randomly chosen initial residual $\tilde{r}_0$. This allows the calculation of $\alpha^1_\ell(\ell = 1,\dots,m)$ by (2.22) and gives $\tilde{r}_{1\cdot m} = P^1_m(I - \widetilde{L}^{3g}\widetilde{M}^{3g}(\widetilde{L}^{3g})^{-1})\tilde{r}_0$. Then the computation of $\tilde{r}_{i\cdot m}$ for $i > 1$ is straightforward due to its recursive definition; see (2.21). This leads to an average reduction factor $\rho^{acc}_{3g}(i,m)$ for a complete iteration, which can be obtained by the three-grid Fourier analysis

$$\rho^{acc}_{3g}(i,m) := \left[\left(\frac{||\tilde{r}_{i\cdot m}||_2}{||\tilde{r}_0||_2}\right)^{1/m}\right]^{1/i} . \tag{2.23}$$

The superscript "acc" is used as an abbreviation for "accelerated," since the combination of multigrid and GMRES(m) can be interpreted as an acceleration of the multigrid convergence speed by an additional application of GMRES(m).

In all tests, presented in section 3, $\rho^{acc}_{3g}(i,m)$ tends to a constant for $i \geq 20$. The particular choice of the initial residual $\tilde{r}_0$ does not influence the average reduction factors for $i \gg 1$, which is confirmed by systematic test calculations. Thus it is expected that $\rho^{acc}_{3g}(m) := \rho^{acc}_{3g}(20,m)$ matches well with numerical reference values.

If we use the above Fourier representation $I - \widetilde{L}^{3g}\widetilde{M}^{3g}(\widetilde{L}^{3g})^{-1}$, the corresponding spectrum can be calculated numerically. The common way (see, for example, [15, 16]) to analyze the convergence of GMRES is to exploit information about the spectrum σ of the iteration matrix LC^{-1}.

Suppose that all eigenvalues of $I - \widetilde{L}^{3g}\widetilde{M}^{3g}(\widetilde{L}^{3g})^{-1}$ are located in an ellipse $E(c,d,a)$ which excludes the origin. $(c,0)$ denotes the center, d denotes the focal distance, and a denotes the major semiaxis. Note that σ is always symmetric with respect to the real axis, so we only consider ellipses which are aligned with the axes and where the ordinate of the center equals zero. Then it is known [16] that the absolute value of the polynomial

$$t_m(z) := T_m\Big(\frac{c}{d} - \frac{1}{d}\,z\Big)\Big/T_m\Big(\frac{c}{d}\Big) = T_m(\widehat{z})\Big/T_m\Big(\frac{c}{d}\Big) \quad \text{with} \quad z,\, \widehat{z} := \Big(\frac{c}{d} - \frac{1}{d}\,z\Big) \in \mathbb{C}$$

is small on the spectrum of $I - \widetilde{L}^{3g}\widetilde{M}^{3g}(\widetilde{L}^{3g})^{-1}$. Here T_m represents the Chebychev polynomial of degree m of the first kind; see [16]. If $I - \widetilde{L}^{3g}\widetilde{M}^{3g}(\widetilde{L}^{3g})^{-1}$ is diagonalizable, $I - \widetilde{L}^{3g}\widetilde{M}^{3g}(\widetilde{L}^{3g})^{-1} = XDX^{-1}$, then (2.20) yields

$$\begin{aligned} ||\tilde{r}_{i\cdot m}||_2 &\leq ||t_m(I - \widetilde{L}^{3g}\widetilde{M}^{3g}(\widetilde{L}^{3g})^{-1})||_2\; ||\tilde{r}_{(i-1)m}||_2 \\ &\leq [||t_m(I - \widetilde{L}^{3g}\widetilde{M}^{3g}(\widetilde{L}^{3g})^{-1})||_2]^i\; ||\tilde{r}_0||_2 \;\leq\; \left[\kappa_2(X)\, T_m\Big(\frac{a}{d}\Big)/T_m\Big(\frac{c}{d}\Big)\right]^i ||\tilde{r}_0||_2, \end{aligned}$$

where $\kappa_2(X)$ denotes the spectral condition number of the transformation matrix X [16]. Using these inequalities, we obtain for an arbitrary complete iteration i

$$\rho^{acc}_{3g}(i,m) \;\leq\; N^E_m \;\leq\; (\kappa_2(X))^{1/m}\, T^E_m \quad \text{with} \tag{2.24}$$

$$N^E_m := (||t_m(I - \widetilde{L}^{3g}\widetilde{M}^{3g}(\widetilde{L}^{3g})^{-1})||_2)^{1/m} \quad \text{and} \quad T^E_m := \left(T_m\Big(\frac{a}{d}\Big)/T_m\Big(\frac{c}{d}\Big)\right)^{1/m} \tag{2.25}$$

as approximations for the average reduction factors of m multigrid preconditioned GMRES(m) steps (see (2.23)).

Remark 4 (determination of ellipses). There seems to be no simple way to determine the "optimal" ellipse for a given spectrum σ which minimizes T_m^E and N_m^E from (2.25). Thus it is proposed in [8] to compute a rectangle containing the spectrum σ and then to calculate the ellipse of smallest area which encloses this rectangle. Both steps of this two-stage strategy are rather simple and straightforward (see [8]), but the resulting ellipses may cover much too large an area due to the first "auxiliary" step. The resulting estimates reflect the qualitative convergence behavior of GMRES(m), but the explicit values are far too pessimistic in general. Therefore, we tune the ellipses by hand. It is well known that each ellipse is uniquely defined if we prescribe three points that should lie on the ellipse. As a first guess, we select those three eigenvalues contained in σ with maximal real part (λ_{max}^{Re}), with minimal real part (λ_{min}^{Re}), and with maximal imaginary part (λ_{max}^{Im}). Then the semiaxis in the x-direction a_x, the semiaxis in the y-direction a_y, and the center $(c, 0)$ of the ellipse are given by

$$a_x = \frac{\mathrm{Re}(\lambda_{max}^{Re}) - \mathrm{Re}(\lambda_{min}^{Re})}{2}, \quad c = \mathrm{Re}(\lambda_{min}^{Re}) + a_x, \quad \text{and} \quad a_y = \frac{\mathrm{Im}(\lambda_{max}^{Im})}{\sqrt{1 - \frac{\mathrm{Re}(\lambda_{max}^{Im}) - c}{a_x^2}}}.$$

$\mathrm{Re}(\lambda)$ and $\mathrm{Im}(\lambda)$ denote the real and imaginary part of the complex eigenvalue λ. (In this way, the ellipse from Figure 3.2b is calculated.) If this first guess does not contain the whole spectrum, the ellipse is carefully enlarged until it covers σ. (An example is given in Figure 3.2a.) Although this strategy might not be very satisfactory from a mathematical viewpoint, it yields sharper estimates which can be easily calculated.

In [17] it is stated that (2.24) is an asymptotic result and that the actual residual norm should rather behave like T_m^E without $\kappa_2(X)$. This presumption, in connection with the two-grid Fourier analysis, is validated in [24], where it is found that the heuristic estimate T_m^E gives a certain insight into the asymptotic accelerated two-grid convergence, whereas the upper bound N_m^E is too pessimistic in general. Therefore, some explicit values for T_m^E based on the spectra of three-grid iteration matrices are given in section 3 and compared with asymptotic numerical convergence results. However, the main focus lies on $\rho_{3g}^{acc}(m)$.

3. Applications of three-grid Fourier analysis.

In order to demonstrate the benefits of the three-grid analysis, we consider several equations, discretizations, and multigrid components. The applications range from the nicely elliptic Poisson equation in connection with standard components to singular perturbation problems with more advanced multigrid components. By considering a large number of smoothers and transfer operators, we intend to show the large range of applicability of the three-grid analysis. In each of the following three subsections, we consider coarse grid correction problems which can often be solved by algebraic multigrid (AMG) [19], because AMG implicitly selects the "correct" coarsening strategy for the problem under consideration, or by a special relaxation method. Of course, it is possible to adapt the Fourier analysis from section 2 to nonstandard coarsenings or to sophisticated smoothers. However, we try to keep the multigrid method simple and search for possible improvements by carefully chosen transfer operators and Galerkin coarse grid discretizations. Furthermore, we investigate the use of an additional acceleration with GMRES(m) of nonoptimal but easy-to-program multigrid methods. The main purpose is to evaluate the additional insights coming from the three-grid Fourier analysis.

The theoretical estimates are compared with numerical experiments whose convergence is indicated by $\rho_n(k\mathrm{g})$, which denotes the average defect reduction after 100

Table 3.1
*MG*1 *applied to the Poisson equation,* $h = 1/128$.

Cycle	$\rho_{1g}(h)$	$\rho_{2g}(h)$	$\rho_{3g}(h)$	ρ_n(3g)	ρ_n(7g)
V(1,1)	0.063	0.074	0.106	0.105	0.119
V(2,0)	0.063	0.074	0.133	0.132	0.170

W(1,1), W(2,0), W(0,2)	0.063	0.074	0.074	0.073	0.073

iterations for the corresponding solution method involving k grids. We choose such a large number of iterations because the theoretical values $\rho_{2g}(h)$ and $\rho_{3g}(h)$ refer to asymptotic convergence factors. For nonsymmetric problems like the convection-dominated examples from section 3.3, it might take a large number of iterations before the asymptotic behavior is observed. An alternative is to consider norms of the three-grid operator, like the defect reduction norm

$$\sigma_{3g}(h) := \sup_{\boldsymbol{\theta}\in\tilde{\Theta}_{3g}} \sqrt{\rho(L^{3g}(\boldsymbol{\theta},h)M^{3g}(\boldsymbol{\theta},h)(L^{3g}(\boldsymbol{\theta},h))^{-1}(L^{3g}(\boldsymbol{\theta},h)M^{3g}(\boldsymbol{\theta},h)(L^{3g}(\boldsymbol{\theta},h))^{-1})^{*})}, \tag{3.1}$$

which can be obtained straightforwardly by the above analysis. The star * in (3.1) denotes, as usual, the adjoint of the matrix.

3.1. Poisson equation. The first example deals with the well-known 5-point discretization of the Poisson equation,

$$-\Delta u(\boldsymbol{x}) = 1 \quad \text{on } \Omega = (0,1)^2, \qquad u(\boldsymbol{x}) = 0 \quad \text{on } \Gamma = [0,1]^2 \setminus \Omega. \tag{3.2}$$

An efficient multigrid method [20] for this problem, denoted by $MG1$, consists of

- direct $2h$-, $4h$-, etc. coarse grid discretizations,
- bilinear interpolation of coarse grid corrections and full weighting of residuals, and
- red-black Gauss–Seidel relaxation.

Table 3.1 compares the analytical predictions from the one-, two-, and three-grid analysis with numerical reference values ρ_n(3g) and ρ_n(7g) for several 3- and 7-grid cycles. This table illustrates that even for such a simple and well-understood problem there is a difference between the performance of a V-cycle and a W-cycle and pre- and postsmoothing which cannot be displayed by Fourier two-grid analysis, whereas the different behavior of the cycle variants is very accurately predicted by the three-grid estimates $\rho_{3g}(h)$.

Remark 5 (maintaining the two-grid convergence). As it is seen in Table 3.1, one has to choose the multigrid W-cycle to obtain the two-grid convergence factor. This is indicated by the Fourier analysis. The theoretical predictions for the two- and three-grid factors are equal only for the W-cycle. If we replace the 5-point discretizations on the coarse grids by operators based on Galerkin coarsening with full weighting and bilinear interpolation, the V-cycle also leads to k-independent fast convergence. Using a four-color Gauss–Seidel relaxation for the resulting symmetric 9-point operators, we get for a V(1,1)-cycle $\rho_{1g}(h) = \rho_{2g}(h) = \rho_{3g}(h) = 0.063$. This value is validated by the corresponding numerical calculation for a 7-grid method.

A second multigrid variant, $MG2$ [1], with a simplified coarse grid correction is given by

TABLE 3.2

FIG. 3.1b. $\alpha = 2$

FIG. 3.1. *Eigenvalue spectra from Fourier analysis for three-grid $W(1,1)$-cycles of MG2* [1] *with and without rescaling applied to the Poisson equation, $h = 1/128$.*

- Galerkin coarse grid discretizations,
- piecewise constant interpolation and its transpose as transfer operators, and
- symmetric lexicographical Gauss–Seidel relaxation.

Modified versions of this strategy are used in the so-called aggregation-type AMG approaches, which might be useful for problems on unstructured grids; see, for example, [1, 22]. A direct application of this method to the Poisson equation leads to inefficient and strongly h-dependent V- (and W-) cycles. It can be easily shown that each of the coarse grid operators is off by a factor of 2 compared to the discretization on the next finer grid [1, 19]. A simple recursive argument yields that the V-cycle convergence on k grids is limited by $\rho_{kg}(h) \geq 1 - 2^{-k+1}$ ($\rho_{2g}(h) \geq 0.5$, $\rho_{3g}(h) \geq 0.75, \dots$) [19]. Table 3.2 shows that these limiting values can be confirmed by Fourier two- and three-grid analysis.

The above considerations motivate us to rescale the coarse grid Galerkin operators by $1/\alpha$ with α close to 2, $L_{n-1} = 1/\alpha \, \check{R}_n^{n-1} L_n \check{P}_{n-1}^n$, as it is proposed in [1]. For $\alpha = 2$, the Galerkin operators coincide with the standard 5-point discretizations on all grids. Figure 3.1 demonstrates the strong influence of this rescaling on the eigenvalue distribution of a $W(1,1)$ three-grid cycle from Fourier analysis.

Comparing Tables 3.2 and 3.3, one observes the improvement of the two- and three-grid factors due to the rescaling. However, the coarse grid correction problem is not completely solved for V-cycles which can be deduced from the big differences between the one-, two-, and three-grid estimates and which is validated by the further increasing numerical reference value $\rho_n(7\text{g})$ for a 7-grid cycle. This behavior might refer to the fact that the order of the transfer operators (see, for example, [10, 12, 23])

Table 3.3
$MG2$ [1] with a rescaling by $\alpha = 2$ applied to the Poisson equation, $h = 1/128$.

	$MG2$ as a solver				
Cycle	$\rho_{1g}(h)$	$\rho_{2g}(h)$	$\rho_{3g}(h)$	ρ_n(3g)	ρ_n(7g)
V(1,1)	0.06	0.44	0.68	0.66	0.82
W(1,1)	0.06	0.44	0.52	0.50	0.51

	$MG2$ as a preconditioner, $m = 5$		
Cycle	$\rho_{3g}^{acc}(m)$	ρ_n(3g)	ρ_n(7g)

W(1,1)	0.36	0.34	0.35

in the multigrid process is too low compared to the order of the partial differential equation.

By combining $MG2$ with GMRES(m), one finds satisfactory convergence factors with a rather small Krylov subspace. The actual improvement for a three-grid method can be accurately predicted by $\rho_{3g}^{acc}(m)$; see Table 3.3.

Remark 6 (acceleration on coarse grids, F-cycle convergence). As the coarse grid difficulty occurs on all coarser grids, it seems reasonable to incorporate the Krylov acceleration into the multigrid cycle, like in [14], or to apply it *only on the coarse grids.* In the present example, one obtains ρ_n(7g)=0.52 for a V(1,1)-cycle if GMRES($m = 5$) is applied only on the coarse grids. In this way, it is possible to reduce the storage because on coarser grids much less storage is needed for a Krylov subspace. Furthermore, the multigrid F-cycle yields very similar convergence factors as the W-cycle, both as a solver and as a preconditioner.

Of course, these simple transfer operators are not at all an optimal choice for problem (3.2), especially compared to $MG1$ (see Table 3.1) or to AMG [19]. But it is a first example of a multigrid method with a coarse grid correction difficulty already for the Poisson equation and therefore an illustrative starting example. Furthermore, the method is easy to program and can be seen as a basis for more advanced aggregation-type AMG methods.

3.2. Rotated anisotropic diffusion equation. Next we discuss the standard 9-point discretization (see, for example, [23]) of the rotated anisotropic diffusion equation

$$-(c^2 + \varepsilon s^2)\, u_{xx}(\boldsymbol{x}) - 2(\varepsilon - 1)cs\, u_{xy}(\boldsymbol{x}) - (\varepsilon c^2 + s^2)\, u_{yy}(\boldsymbol{x}) = 1 \quad \text{on} \;\; \Omega = (0,1)^2$$
$$\text{with} \quad c = \cos(\beta),\;\; s = \sin(\beta), \quad u(\boldsymbol{x}) = 0 \quad \text{on} \;\; \Gamma = [0,1]^2 \setminus \Omega.$$

This differential operator corresponds to $-u_{\xi\xi} - \varepsilon u_{\eta\eta}$ in a (ξ, η)-coordinate system which can be obtained by rotating the (x, y)-system by an angle of β [23]. We set $\beta = 45°$. For $\varepsilon \to 0$ this equation is no longer elliptic. Using standard grid coarsening and Gauss–Seidel smoothing, this leads to coarse grid correction difficulties which limit the two-grid convergence to a factor of 0.75; see, for instance, [24]. The same recursive argument as in the previous subsection yields a lower bound for the V-cycle convergence on k grids which is given by $\rho_{kg}(h) \geq 1 - 4^{-k+1}$ ($\rho_{2g}(h) \geq 0.75$, $\rho_{3g}(h) \geq 0.9375, \dots$). These bounds can be established by Fourier two- and three-grid analysis as can be seen from Table 3.4, where $MG1$ is applied to the rotated anisotropic diffusion equation. Switching to a W-cycle leads to a slight improvement, which is well predicted by the three-grid analysis.

If $MG1$ is used as a preconditioner, it is possible to obtain an acceptable W-cycle

TABLE 3.4
$MG1$ applied to the rotated anisotropic diffusion equation, $\beta = 45°, \varepsilon = 10^{-5}$, $h = 1/128$.

	$MG1$ as a solver				
Cycle	$\rho_{1g}(h)$	$\rho_{2g}(h)$	$\rho_{3g}(h)$	$\rho_n(3\text{g})$	$\rho_n(7\text{g})$
$V(1,1)$	0.35	0.76	0.94	0.92	0.95

convergence, whereas the V-cycle convergence for a 7-grid method remains unsatisfactory. Again, the analytical values $\rho_{3g}^{acc}(m)$ yield reliable predictions that are more accurate than those indicated by T_m^E. As an example, Figure 3.2a shows the $V(1,1)$-cycle spectrum of $I - \widetilde{L}^{3g}\widetilde{M}^{3g}(\widetilde{L}^{3g})^{-1}$ from Fourier analysis for $MG1$ and the corresponding ellipse which is used to calculate T_m^E. For a more detailed discussion of such values and spectra, see [24], as the main focus in this paper lies on the three-grid analysis.

In the context of Galerkin coarsening for the rotated anisotropic diffusion equation, it is interesting to investigate the multigrid method, $MG3$,

- Galerkin coarse grid discretizations,
- matrix-dependent prolongation and restriction by de Zeeuw [27], and
- four-color Gauss–Seidel relaxation.

Comparing Tables 3.4 and 3.5, we see a remarkable improvement of the two-grid convergence factor. For this example, however, Fourier one- and two-grid analysis yield somewhat misleading results. At first sight, the coarse grid correction problem seems to be solved since the two-grid value nearly recovers the smoothing factor. But if we look at the increased three-grid values, one has to expect that the multigrid convergence deteriorates further, which is validated by the numerical reference values

TABLE 3.5
MG3 applied to the rotated anisotropic diffusion equation, $\beta = 45°, \varepsilon = 10^{-5}$, $h = 1/128$.

for the related 7-grid iterations.

On the other hand, we see that the three-grid methods can be nicely accelerated by GMRES(m) with a small Krylov subspace. Thus it can be expected also that the corresponding multigrid iterations are appropriate preconditioners, which is confirmed by the numerical values. The actual performance of the accelerated three-grid methods is very accurately estimated by $\rho_3^{acc}(m)$ and T_m^E. The V(1,1)-cycle spectrum of $I - \widetilde{L}^{3g}\widetilde{M}^{3g}(\widetilde{L}^{3g})^{-1}$ from Fourier analysis for $MG3$ and the related ellipse are pictured in Figure 3.2b.

Remark 7 (other Galerkin coarsenings). If the prolongation and restriction from [27] in $MG3$ are replaced by the transfer operators from the nonsymmetric blackbox multigrid by Dendy [7], we find very similar results. These transfer operators are investigated in the next subsection. The application of $MG2$ to this problem cannot be recommended. $MG2$ is mainly developed for elliptic problems and does not converge well for the rotated anisotropic diffusion equation.

Finally, we would like to mention that there are other multigrid components like ILU-type smoothers or nonstandard coarsening to overcome the coarse grid correction difficulty efficiently. De Zeeuw [27], for example, combines his matrix-dependent Galerkin coarsening with a powerful smoother, the incomplete line LU decomposition (ILLU), and obtains very fast multigrid convergence. These improvements might be verified by a straightforward adaption of the presented three-grid analysis.

3.3. Convection diffusion equation. As a third example, we discuss the convection diffusion equation with dominant convection in some detail. Here, it is important to distinguish between *entering* flows with an inflow and outflow boundary and *recirculating* flows for which no real inflow and outflow boundary exist and where the boundary information is mainly diffusing into the domain. In principle, efficient multigrid iterations can be constructed for upstream discretizations if relaxation methods are used with a downstream ordering of grid points. Then the relaxation acts not only as a smoother but also partly as a solver and takes care of problematic characteristic low-frequency error components; see [5]. For entering flows such smoothers can be found among standard relaxation methods, whereas for recirculating flows it is very difficult to construct a smoother with the desired property. Channel-type flows employing higher order upwind discretizations are treated successfully in [13].

For convection-dominated rotating flow problems like

$$-\varepsilon\Delta u(\boldsymbol{x}) + a(x,y)\,u_x(\boldsymbol{x}) + b(x,y)\,u_y(\boldsymbol{x}) = 1 \quad \text{on } \ \Omega = (0,1)^2 \tag{3.3}$$

$$\text{with } \ \varepsilon = 10^{-5}, \ \ a(x,y) = -\sin(\pi x)\cos(\pi y), \ \text{ and } \ b(x,y) = \sin(\pi y)\cos(\pi x)\,,$$

$$u(\boldsymbol{x}) = \sin(\pi x) + \sin(13\pi x) + \sin(\pi y) + \sin(13\pi y) \quad \text{on } \ \Gamma = [0,1]^2 \setminus \Omega,$$

the situation changes if standard smoothers are used, and we observe a similar coarse grid correction difficulty as in the previous subsection. If the direct $2h$-, $4h$-, etc. discretizations are applied on the coarser grids combined with standard coarsening, the two-grid convergence is limited by the factor

$$\rho_{2g}(h) \geq 1 - 2^{-p}, \tag{3.4}$$

where p denotes the order of the discretization [6]. This results in a deterioration of the V-cycle multigrid convergence on k grids given by $\rho_{kg}(h) \geq 1 - 2^{-(k-1)\cdot p}$; see above.

Remark 8 (reliability of the Fourier analysis). Dirichlet boundary effects are neglected by the Fourier analysis as it is presented in this paper. For entering flows, high-frequency boundary data may propagate far into the domain, and thus it should be taken into account by a reliable analysis. This is done by the so-called *half-space* full multigrid (FMG) analysis in [5]. For recirculating flows, however, the influence of the domain boundary is negligible in the limit of small mesh size, and the (*infinite-space*) Fourier analysis is again useful [6].

Remark 9 (Fourier analysis for operators with variable coefficients). A direct application of the Fourier analysis is not possible if we deal with operators $L_h(\boldsymbol{x})$ that are characterized by variable coefficients. However, the analysis can be applied to the locally frozen operator at a fixed grid point $\boldsymbol{\xi}$. Replacing the variable $\boldsymbol{x}$ by a constant $\boldsymbol{\xi}$, one obtains an operator $L_h(\boldsymbol{\xi})$ with *constant frozen* coefficients. In [3] it is motivated that the smoothing or two-grid factor for $L_h(\boldsymbol{x})$ can be bounded by the suprenum over the smoothing or two-grid factors for the locally frozen operators. Thus one may define the following convergence factors in the case of variable coefficients:

$$\rho_{kg}\left(h, L_h(\boldsymbol{x})\right) := \sup_{\boldsymbol{\xi}\in\Omega} \rho_{kg}\left(h, L_h(\boldsymbol{\xi})\right) \quad \text{for} \quad k = 1, 2, 3. \tag{3.5}$$

This means for (3.3) that one has to investigate the whole range of convection angles that occur in the problem. For an explicit calculation, we approximate (3.5) by a repeated application of the Fourier analysis to discretizations of $-\varepsilon\Delta u + a\,u_x + b\,u_y$ with fixed $a = \cos\beta$ and $b = \sin\beta$ for multiples of 3° until the range of possible convection angles $\beta \in [0^\circ, 360^\circ]$ is passed through, as is proposed in [23]. Then, the maximal values for $\rho_{1g}(h,\beta)$, $\rho_{2g}(h,\beta)$, $\rho_{3g}(h,\beta)$, and $\sigma_{3g}(h,\beta)$ are assumed to be upper bounds for problem (3.3).

In this section, we do not consider the acceleration by GMRES(m) in the Fourier analysis. For problems with varying coefficients the analysis from section 2.4 can be adapted in the same way as it is explained in Remark 9, but it has to be interpreted with care, as it has a more qualitative character. In the numerical experiments, however, we often observe a considerable improvement, especially for rotating flow problems.

3.3.1. First order discretization. A first order upwind discretization of (3.3) is given by the following stencil:

$$\frac{\varepsilon}{h^2}\begin{bmatrix} & -1 & \\ -1 & 4 & -1 \\ & -1 & \end{bmatrix} + \frac{1}{2h}\begin{bmatrix} -a-|a| & 2|a| & a-|a| \end{bmatrix} + \frac{1}{2h}\begin{bmatrix} b-|b| \\ 2|b| \\ -b-|b| \end{bmatrix}. \tag{3.6}$$

This discretization is studied in many papers, for instance, in [5, 14, 19, 26], where the coarse grid correction difficulty for geometric multigrid with direct coarse grid

Table 3.6
$MG4$ applied to the convection diffusion equation discretized by a first order upwind scheme, $\varepsilon = 10^{-5}$, $h = 1/256$.

Cycle	$\rho_{1g}(h,\beta)$	$\rho_{2g}(h,\beta)$	$\rho_{3g}(h,\beta)$	$\sigma_{3g}(h,\beta)$	$\rho_n(8g)$
$W(1,1)$	0.29 ($\beta = 3°$)	0.22 ($\beta = 6°$)	0.22 ($\beta = 6°$)	0.24 ($\beta = 6°$)	0.20
$W(2,1)$	0.15 ($\beta = 3°$)	0.17 ($\beta = 6°$)	0.18 ($\beta = 6°$)	0.20 ($\beta = 6°$)	0.17

discretizations is overcome by different remedies, like an overweighting of residuals [5], an additional Krylov acceleration [14], an application of AMG [19], or a special higher order choice of coarse grid discretizations [26]. Many of these approaches can be well analyzed by the Fourier three-grid analysis from section 2.

The convergence factors of the multigrid method by de Zeeuw [27] based on matrix-dependent transfer operators gets worse for discretization (3.6) with an increasing number of grids, even with a powerful relaxation like ILLU. This can be confirmed by the Fourier three-grid analysis. It is possible to improve the convergence properties with another Galerkin coarse grid operator applied in $MG4$:

- Galerkin coarse grid discretizations,
- transfer operators from the nonsymmetric blackbox multigrid by Dendy [7], and
- damped ($\omega = 0.7$) alternating zebra line Gauss–Seidel relaxation.

It was already stated in [26] that the application of this Galerkin coarsening should be useful. The symmetric prolongation, based on the symmetric part of the respective discretization operator $1/2(L_n + L_n^*)$, is similar to the well-known matrix-dependent prolongations for jumping coefficients; see, for instance, [10, 23, 27]. The nonsymmetric restriction, however, is defined as the transpose of a prolongation operator that is based on L_n^* leading to an upstream restriction. This is particularly useful because the coarse-grid operators remain upstream as well and tend to a second order compact upstream discretization. This agrees with the observation that the coarse grid operators must become higher order, at least in the cross-stream direction, to provide a good coarse grid approximation; see [26].

Table 3.6 shows the maximal one-, two-, and three-grid factors for $MG4$ with the corresponding convection angles in brackets; see Remark 9. As the two- and three-grid factors are very similar or even equal, it can be expected that the multigrid convergence for discretization (3.6) is close to these estimates, which is confirmed by the numerical reference for an 8-grid method. The maximal norm values $\sigma_{3g}(h,\beta)$ differ only slightly from the corresponding $\rho_{3g}(h,\beta)$, which indicates that the convergence speed for a single iteration is not much larger than the asymptotic convergence factor. Thus, $\rho_{3g}(h,\beta)$ is a "satisfactory" prediction for the multigrid convergence. This is observed in the numerical convergence history. Furthermore, we see that the damped alternating zebra line relaxation which is a robust smoother for the fine grid discretization [23] keeps this property for the Galerkin coarse grid discretizations resulting from the blackbox transfer operators.

3.3.2. Fourth order compact discretization. We continue with the fourth order compact discretization of (3.3) from [9]. With respect to the Fourier analysis, it is convenient to investigate the difference scheme for constant coefficients; see Remark

Table 3.7

$MG4$ is applied to the convection diffusion equation discretized by a compact fourth order scheme [9], $\varepsilon = 10^{-5}$, $h = 1/128$.

Cycle	$\rho_{1g}(h,\beta)$	$\rho_{2g}(h,\beta)$	$\rho_{3g}(h,\beta)$	$\sigma_{3g}(h,\beta)$
W(1,1)	0.53 ($\beta = 6°$)	0.59 ($\beta = 3°$)	0.77 ($\beta = 6°$)	> 20 ($\beta = 45°$)
W(2,2)	0.27 ($\beta = 6°$)	0.54 ($\beta = 9°$)	0.74 ($\beta = 9°$)	0.85 ($\beta = 18°$)

Table 3.8

The convection diffusion equation is discretized by a compact fourth order scheme [9] *using Galerkin coarsening based on the restriction from nonsymmetric blackbox multigrid* [7] *and biquintic interpolation, alternating zebra line Gauss–Seidel relaxation* ($\omega = 0.7$), $\varepsilon = 10^{-5}$, $h = 1/128$.

Cycle	$\rho_{1g}(h,\beta)$	$\rho_{2g}(h,\beta)$	$\rho_{3g}(h,\beta)$	$\sigma_{3g}(h,\beta)$
W(1,1)	0.53 ($\beta = 6°$)	0.46 ($\beta = 6°$)	0.60 ($\beta = 9°$)	0.69 ($\beta = 9°$)
W(2,2)	0.27 ($\beta = 6°$)	0.29 ($\beta = 3°$)	0.46 ($\beta = 9°$)	0.53 ($\beta = 9°$)

Cycle	$\rho_{3g}(h,\beta)$	$\sigma_{3g}(h,\beta)$
W(1,1), $\nu_1(2h) = \nu_2(2h) = 3$	0.46 ($\beta = 6°$)	0.50 ($\beta = 6°$)
W(2,2), $\nu_1(2h) = \nu_2(2h) = 4$	0.31 ($\beta = 9°$)	0.35 ($\beta = 9°$)

9, which reads in stencil notation [25]

$$\frac{\varepsilon}{6h^2}\begin{bmatrix} -1 & -4 & -1 \\ -4 & 20 & -4 \\ -1 & -4 & -1 \end{bmatrix} + \frac{1}{12h}\begin{bmatrix} a-b & -4b & -a-b \\ 4a & 0 & -4a \\ a+b & 4b & -a+b \end{bmatrix} + \frac{1}{24\varepsilon}\begin{bmatrix} ab & -2b^2 & -ab \\ -2a^2 & 4a^2+4b^2 & -2a^2 \\ -ab & -2b^2 & ab \end{bmatrix}.$$

Here, a two-grid convergence factor of 0.9375 is predicted by (3.4) for the direct coarse grid discretizations. Applying $MG4$ to this discretization, we find a remarkable improvement of the two-grid factor compared to the standard variant, but the coarse grid problem is not really solved, as is indicated by the increase of the two- and three-grid factors compared to the one-grid values; see Table 3.7. This can be explained by considering the orders of the transfer operators in a Galerkin process for singularly perturbed problems [26]. The sum of these orders ($m_r + m_p$, where the subscripts are abbreviations for restriction and prolongation, respectively) should be greater than the order of the differential equation M plus the order of the discretization p, i.e.,

$$m_r + m_p > M + p. \tag{3.7}$$

This requirement is fulfilled for the multigrid method from Table 3.6 for the first order discretization of (3.3) ($m_r = 1, m_p = 2, M = 1, p = 1$) but is violated in Table 3.7 ($m_r = 1, m_p = 2, M = 1, p = 4$). Note that we set $M = 1$ in this situation because of the dominating convection term. It is already indicated by the large value of σ_{3g} for the W(1,1)-cycle from Table 3.7 that this multigrid method has to be handled with care.

We keep the restriction from $MG4$ in order to maintain the upstream properties of the discretizations on the coarser grids (see [7]) but replace the prolongation by biquintic interpolation ($m_p = 6$). Thus, the above rule (3.7) is satisfied, which leads to a considerable improvement of the multigrid method, as is shown in Table 3.8. Regarding the norm values $\sigma_{3g}(h,\beta)$, one obtains a reliable multigrid method. However, although the one- and two-grid factors are similar, the three-grid factors still increase in the upper part of Table 3.8. This is due to a deterioration of the smoothing property on the coarse grids because there we have larger stencils resulting from the very accurate interpolation in the Galerkin process. The three-grid convergence factors can be improved if we increase the numbers $\nu_1(2h)$ and $\nu_2(2h)$ of pre- and postsmoothing steps on G_{2h}, as is shown in the lower part of Table 3.8. In this way, it is possible to recover the two-grid factors, which indicates that the coarse grid correction difficulty is solved. From section 3.3.1, it can be expected that the analytical estimates match closely with numerical test calculations, and also for the fourth order discretization. Because of the large stencils, however, this multigrid method cannot be recommended for a practical implementation despite its good (regarding the highly accurate discretization) convergence behavior.

4. Conclusions. We have presented Fourier three-grid analysis for multigrid as a solver and as a preconditioner for GMRES(m). Applying this analysis, it is possible to obtain accurate convergence estimates for elliptic operators and to predict the performance of V- and W-cycles or pre- and postsmoothing. For singularly perturbed problems with coarse grid correction difficulties, the three-grid analysis yields additional valuable insight into the nature of the multigrid convergence problem and allows for an investigation of the benefits of possible remedies, for example, based on certain choices of Galerkin coarse grid discretizations. One can verify the qualitative rule concerning the order of the transfer operators in a Galerkin process for singularly perturbed problems from [26] by quantitative asymptotic convergence and norm estimates.

SOLUTION METHODS FOR THE POISSON EQUATION WITH CORNER SINGULARITIES: NUMERICAL RESULTS*

ZHIQIANG CAI†, SEOKCHAN KIM‡, AND BYEONG-CHUN SHIN§

Abstract. In [Z. Cai and S. Kim, *SIAM J. Numer. Anal.,* 39 (2001), pp. 286–299], we developed a new finite element method using singular functions for the Poisson equation on a polygonal domain with re-entrant angles. Such a method first computes the regular part of the solution, then the stress intensity factor, and finally the solution itself. This paper studies solution methods for solving the system of linear equations arising from the discretization and focuses on numerical results including the finite element accuracy and the multigrid performance.

Key words. corner singularity, finite element, multigrid

1. Introduction.

Solutions of elliptic boundary value problems on a domain with corners have singular behavior near the corners. This occurs even when data of the underlying problem are very smooth. Such singular behavior affects the accuracy of the finite element method throughout the whole domain. In [5], we developed a new finite element method using singular and dual singular functions for the Poisson equation with homogeneous Dirichlet boundary conditions on a polygonal domain with re-entrant angles. By using the dual singular function and a cut-off function with a bigger support, we derived a new extraction formula for the stress intensity factor λ in terms of the regular part w of the solution u. This enables us to deduce a well-posed problem for w, which is then approximated by the continuous piecewise linear finite element method. Approximations to the intensity factor λ and the solution u are straightforward, so we concentrate in this paper on the computation of w. It was shown in [5] that we achieve $O(h)$ optimal accuracy for w and u in the H^1 norm. We established the $O(h^{1+\frac{\pi}{\omega}})$ error bound for w in L^2, which, in turn, implies the same error bounds for u in L^2 and for λ in the absolute value, where ω is the internal angle. This error bound for w in L^2 is not optimal. The reason is the simplified adjoint problem used in the duality argument, which does not have full regularity. But w is H^2 regular; it is then interesting to see if such error bound is sharp numerically.

The problem determining w is no longer the nice Poisson equation but is perturbed by integral terms which are only nonzero on a strip away from the corner. Because of such a perturbation, the problem is nonsymmetric and probably indefinite. To solve the nonsymmetric algebraic equations arising from the discretization, we observe that the perturbation is rank one and that its pseudodifferential order is -1. The

former leads to the first approach which uses the Sherman–Morrison (SM) formula (see section 4.1). This approach requires *two* (approximate) inversions of the discrete Laplace operator, which will be done by multigrid (MG) methods. It is well known (see, e.g., [10, 1]) that the MG for the discrete Poisson problem has a fast convergence rate. The latter suggests that the nonsymmetric perturbation is well controlled by the Laplace operator whose pseudodifferential order is 2, and, hence, MG can be applied efficiently. In particular, the second approach adopted in this paper is the V-cycle MG that uses the exact coarsest grid solver and in which smoothing operators depend only on the discrete Laplace operator. Application of the convergence theory in [6] guarantees that the MG $V(1, 0)$ cycle and, hence, the $V(\nu_1, \nu_2)$ cycles for $\nu_1 \geq 1$ and $\nu_2 \geq 0$ converge uniformly in the finest mesh size and the number of refinement levels, provided that the coarsest mesh size is sufficiently small. This condition indicates that the direct MG is probably expensive because it requires us to solve a relatively large coarse grid problem. The coarsest mesh size used in our experiments for both approaches is 1/4. Hence, it is clear that such a condition is not essential for our problem.

The present paper attempts to confirm theories numerically on the accuracy of finite element approximation and the performance of solution methods. For the Dirichlet problem on the L-shape domain, we show here that finite element approximations using continuous piecewise linear elements converge to the exact solution with $O(h^2)$ errors in the *discrete* H^1 seminorm and L^2 norm, respectively. The theoretically predicted error bounds are $O(h)$ in the H^1 norm and $O(h^{\frac{5}{3}})$ in the L^2 norm. We appear to have obtained superconvergence in the discrete H^1 seminorm for this particular case. We seem to achieve the optimal L^2 accuracy, which is better than what is predicted by our theory. We show that the SM formula using the MG V-cycles and the direct MG V-cycle converge independently of the finest mesh size h and the number of refinement levels. We also show that the full MG computes a final approximation with accuracy on the order of a discretization error in a total amount of work equal to about nine relaxation sweeps on the finest grid.

The paper is organized as follows. The finite element method and related results from [5] are introduced in sections 2 and 3, and the solution methods are described in section 4. We present the results of numerical experiments in section 5. Some conclusions and final remarks are contained in section 6.

2. The problem and preliminaries.

As a model problem, we consider the Poisson equation with homogeneous Dirichlet boundary conditions

$$\left\{ \begin{array}{rcll} -\Delta u & = & f & \text{in } \Omega, \\ u & = & 0 & \text{on } \partial\Omega, \end{array} \right. \tag{2.1}$$

where f is a given function in $L^2(\Omega)$ and Ω is an open, bounded polygonal domain in $\mathcal{R}^2$ with one re-entrant angle. Extension to the domain with the finite number of re-entrant angles is straightforward. We use the standard notation and definition for the Sobolev spaces $H^t(B)$ for $t \geq 0$; the standard associated inner products are denoted by $(\cdot, \cdot)_{t,B}$, and their respective norms and seminorms are denoted by $\| \cdot \|_{t,B}$ and $| \cdot |_{t,B}$. The space $L^2(B)$ is interpreted as $H^0(B)$, in which case the inner product and norm will be denoted by $(\cdot, \cdot)_B$ and $\| \cdot \|_B$, respectively.

Let ω be the internal angle of Ω satisfying $\pi < \omega < 2\pi$. Without loss of generality, assume that the corresponding vertex is at the origin. Define the *singular* and the *dual singular* functions by

$$s = r^{\frac{\pi}{\omega}} \sin \frac{\pi\theta}{\omega} \quad \text{and} \quad s_{-} = r^{-\frac{\pi}{\omega}} \sin \frac{\pi\theta}{\omega}, \tag{2.2}$$

respectively, in the polar coordinates (r, θ). The coordinates are chosen at the origin so that the internal angle ω is spanned by the two half-lines $\theta = 0$ and $\theta = \omega$. Set

$$B(r_1; r_2) = \{(r, \theta) : \ r_1 < r < r_2 \text{ and } 0 < \theta < \omega\} \cap \Omega \quad \text{and} \quad B(r_1) = B(0; r_1).$$

Define a family of cut-off functions of r, $\eta_\rho(r)$ as follows:

$$\eta_\rho(r) = \begin{cases} 1 & \text{in } B(\frac{\rho R}{2}), \\ \frac{15}{16}\Big\{\frac{8}{15} - \big(\frac{4r}{\rho R} - 3\big) + \frac{2}{3}\big(\frac{4r}{\rho R} - 3\big)^3 - \frac{1}{5}\big(\frac{4r}{\rho R} - 3\big)^5\Big\} & \text{in } \bar{B}(\frac{\rho R}{2};\, \rho R), \\ 0 & \text{in } \Omega \setminus \bar{B}(\rho R), \end{cases} \tag{2.3}$$

where ρ is a parameter in (0, 2] and $R \in \mathcal{R}$ is a fixed number so that the $\eta_2 s$ vanishes identically on $\partial\Omega$. It is well known (see, e.g., [8, 9]) that the solution of (2.1) has the singular function representation

$$u = w + \lambda \eta_\rho s, \tag{2.4}$$

where $w \in H^2(\Omega) \cap H_0^1(\Omega)$ is the regular part of the solution and $\lambda \in \mathcal{R}$ is the so-called *stress intensity factor*.

In [5], by using a new *extraction formula* in terms of w,

$$\lambda = \frac{1}{\pi}(w, \Delta(\eta_2 s_{-}))_{B(R;2R)} + \frac{1}{\pi}(f, \eta_2 s_{-})_{B(2R)}, \tag{2.5}$$

we are able to deduce a well-posed integro-differential equation of w,

$$-\Delta w - \frac{1}{\pi}(w, \Delta(\eta_2 s_{-}))_{B(R;2R)} \Delta(\eta_\rho s) = f + \frac{1}{\pi}(f, \eta_2 s_{-})_{B(2R)} \Delta(\eta_\rho s) \quad \text{in } \Omega, \tag{2.6}$$

where $0 < \rho \le 1$. Its variational formulation is to find $w \in H_0^1(\Omega)$ such that

$$a(w, v) = g(v) \quad \forall\, v \in H_0^1(\Omega), \tag{2.7}$$

where the bilinear form $a(\cdot, \cdot)$ and linear form $g(\cdot)$ are defined by

$$a(w, v) = a^s(w, v) + b(w, v), \quad b(w, v) = -\frac{1}{\pi}(w, \Delta(\eta_2 s_{-}))_{B(R;2R)} (\Delta(\eta_\rho s), v)_{B(\frac{\rho R}{2};\rho R)},$$
$$a^s(w, v) = (\nabla w, \nabla v)_\Omega, \quad \text{and} \quad g(v) = (f, v)_\Omega + \tfrac{1}{\pi}(f, \eta_2 s_{-})_{B(2R)} (\Delta(\eta_\rho s), v)_{B(\frac{\rho R}{2};\rho R)}.$$

Note that the bilinear form $b(\cdot, \cdot)$ is not symmetric. It was shown in [5] that (2.7) has a unique solution $w \in H_0^1(\Omega) \cap H^2(\Omega)$. The following continuity and coercivity bounds were also established:

$$|a^s(w, v)| \le C\, |w|_{1,\Omega}\, |v|_{1,\Omega}, \quad |b(w, v)| \le C\, \|w\|_\Omega\, \|v\|_\Omega \quad \forall\, w,\ v \in H_0^1(\Omega), \tag{2.8}$$

$$\text{and} \quad |v|_{1,\Omega}^2 - C\|v\|_\Omega^2 \le a(v, v) \quad \forall\, v \in H_0^1(\Omega). \tag{2.9}$$

Here and henceforth, we use C with or without script to denote a generic positive constant independent of the mesh size h and the number of levels J introduced in section 4.

3. Finite element approximation. Let $\mathcal{T}_h$ be a partition of the domain Ω into triangular finite elements; i.e., $\Omega = \cup_{K\in\mathcal{T}_h} K$ with $h = \max\{\operatorname{diam} K\colon\ K \in \mathcal{T}_h\}$. Assume that the triangulation $\mathcal{T}_h$ is regular. Set

$$\mathcal{V}_h = \{\phi_h \in C^0(\Omega)\colon\ \phi_h|_K \text{ is linear, } \forall\ K \in \mathcal{T}_h,\ \phi_h = 0 \text{ on } \partial\Omega\} \subset H_0^1(\Omega).$$

Then the finite element approximation to (2.7) in $H_0^1(\Omega)\cap H^2(\Omega)$ becomes as follows: find $w_h \in \mathcal{V}_h$ such that

$$a(w_h, v) = g(v) \quad \forall\ v \in \mathcal{V}_h. \tag{3.1}$$

Approximations to the stress intensity factor and the solution of (2.1) can be computed according to (2.5) and (2.4) as follows:

$$\lambda_h = \frac{1}{\pi}(w_h, \Delta(\eta_2 s_-))_{B(R;2R)} + \frac{1}{\pi}(f, \eta_2 s_-)_{B(2R)} \tag{3.2}$$

$$\text{and} \quad u_h = w_h + \lambda_h \eta_\rho s. \tag{3.3}$$

The following error estimates were established in [5].

THEOREM 3.1. *Assume that* $w \in H^2(\Omega)$ *and* u *are the solutions of* (2.7) *and* (2.1), *respectively. Then the following error estimates hold:*

$$\|w - w_h\|_{1,\Omega},\ \|u - u_h\|_{1,\Omega} \le C\, h \|f\|_\Omega, \tag{3.4}$$

$$\textit{and} \quad \|w - w_h\|_\Omega,\ \|u - u_h\|_\Omega,\ |\lambda - \lambda_h| \le C\, h^{1+\frac{\pi}{\omega}} \|f\|_\Omega. \tag{3.5}$$

4. Solution methods. Let $\{\phi_j(x)\}_{j=1}^N$ be nodal bases for $\mathcal{V}_h$, write $w_h = \sum_{j=1}^N w_j^h \phi_j(x)$, and then the matricial form of (3.1) is

$$\sum_{j=1}^{N} w_j^h a(\phi_j,\ \phi_i) = g(\phi_i) \tag{4.1}$$

for $i = 1, \dots, N$. Let A_h^s and B_h be $N \times N$ matrices with $(i,\ j)$ entries $a^s(\phi_j,\ \phi_i)$ and $b(\phi_j,\ \phi_i)$, respectively, let W_h be the unknown vector with components w_i^h, and let F_h be the right-hand side vector with components $g(\phi_i)$. Then (4.1) may be written as

$$A_h W_h = F_h, \tag{4.2}$$

where $A_h = A_h^s + B_h$. Note that B_h is a nonsymmetric and rank-one matrix. In this section, we discuss two approaches for solving the system of linear equations in (4.2). The first approach is to use the SM formula which requires two inversions of the discrete Laplace operator A_h^s. The second approach is the application of the MG V-cycle with smoothers depending only on A_h^s.

4.1. The SM formula. Any rank-one matrix B_h can be written as the product of the column and row vectors. In particular, we have

$$B_h = -UV^t,$$

where U and V are column vectors with ith components

$$U_i = \frac{1}{\pi}(\Delta(\eta_\rho s), \phi_i)_{B(\frac{\rho R}{2};\rho R)} \quad \text{and} \quad V_i = (\phi_i,\ \Delta(\eta_2 s_-))_{B(R;\,2R)},$$

respectively. By the SM formula, the inverse of A_h has the form

$$A_h^{-1} = (A_h^s)^{-1} + \alpha\,(A_h^s)^{-1}UV^t(A_h^s)^{-1}, \quad \text{where} \quad \alpha = \frac{1}{1 - V^t(A_h^s)^{-1}U}.$$

Therefore, the solution of the system of linear equations in (4.2), $W_h = A_h^{-1}F_h$, can be computed by the following algorithm.

1. Solve $A_h^s X = F_h$ for X.
2. Solve $A_h^s Y = U$ for Y.
3. Compute $\alpha = \frac{1}{1-V^tY}$ and $\beta = V^tX$.
4. Set $W_h = X + \alpha\,\beta\,Y$.

Note that the above algorithm requires *two* (approximate) inversions of the discrete Poisson equations, which will be done by using MG. It is well known that MG applied to the discrete Poisson equation has a fast convergence rate.

4.2. MG algorithms. In this subsection, we describe the MG for solving the discrete problem in (4.2); the MG uses the exact coarsest grid solver, and smoothing operators on the fine grids depend only on A_h^s. To this end, we start with an intentionally coarse triangulation $\mathcal{T}_0$ of $\bar{\Omega}$ with the properties that the boundary $\partial\Omega$ is composed of edges of some triangles K in $\mathcal{T}_0$ and that every triangle of $\mathcal{T}_0$ is shape regular. Each triangle K of $\mathcal{T}_0$ is regularly refined several times, giving a family of nested triangulations $\mathcal{T}_0, \mathcal{T}_1, \dots, \mathcal{T}_J \equiv \mathcal{T}$, such that each triangle of $\mathcal{T}_{k+1}$ is generated by subdividing a triangle of $\mathcal{T}_k$ into four congruent triangles. Let h_k be the mesh size for the corresponding triangulation $\mathcal{T}_k$; we then have $h_k = 2h_{k+1}$. Denote by h the mesh size of the finest grid. We associate the triangulation $\mathcal{T}_k$ with the continuous piecewise linear finite element space $\mathcal{V}_k$. It is easy to see that the family of spaces $\{\mathcal{V}_k\}$ is nested.

For $k = 0, 1, \dots, J$, define the nonsymmetric and symmetric elliptic operators $\mathcal{A}_k$, $\mathcal{A}_k^s : \mathcal{V}_k \longrightarrow \mathcal{V}_k$ by

$$(\mathcal{A}_k w, \phi) = a(w, \phi) \quad \forall\, \phi \in \mathcal{V}_k \quad \text{and} \quad (\mathcal{A}_k^s w, \phi) = a^s(w, \phi) \quad \forall\, \phi \in \mathcal{V}_k,$$

respectively. Also, define the L^2-projection operator $\mathcal{P}_k : \mathcal{V}_{k+1} \longrightarrow \mathcal{V}_k$ by

$$(\mathcal{P}_k w, \phi) = (w, \phi) \quad \forall\, \phi \in \mathcal{V}_k.$$

The smoothing operators $\mathcal{R}_k : \mathcal{V}_k \longrightarrow \mathcal{V}_k$ adopted in this paper are the exact solver on the coarsest grid and the Gauss–Seidel iteration based on the symmetric operator $\mathcal{A}_k^s$ for $k = 1, 2, \dots, J$. Now we define the MG operator $\mathcal{B}_k : \mathcal{V}_k \longrightarrow \mathcal{V}_k$ of the V(ν_1, ν_2)-cycle by induction (see [1]).

V(ν_1, ν_2)-Algorithm. *Set $\mathcal{B}_0 = \mathcal{A}_0^{-1}$. Assume that $\mathcal{B}_{k-1}$ has been defined, and define $\mathcal{B}_k\, g$ for $g \in \mathcal{V}_k$ as follows.*

1. *Set an initial guess x_0.*
2. *Define x^ℓ for $\ell = 1, \dots, \nu_1$ by $x^\ell = x^{\ell-1} + \mathcal{R}_k(g - \mathcal{A}_k x^{\ell-1})$.*
3. *Define x^{ν_1+1} by $x^{\nu_1+1} = \mathcal{B}_{k-1}\mathcal{P}_{k-1}(g - \mathcal{A}_k x^{\nu_1})$.*
4. *Set $\mathcal{B}_k g = x^{\nu_1+\nu_2+1}$, where x^ℓ is defined for $\ell = \nu_1 + 2, \dots, \nu_1 + \nu_2 + 1$ by $x^\ell = x^{\ell-1} + \mathcal{R}_k(g - \mathcal{A}_k x^{\ell-1})$.*

It was shown in [6] that if the bilinear forms $a(\cdot,\cdot)$ and $b(\cdot,\cdot)$ satisfy the continuity and coercivity bounds in (2.8) and (2.9), then the MG $V(1,0)$-cycle and, hence, the $V(\nu_1, \nu_2)$-cycles for $\nu_1 \geq 1$ and $\nu_2 \geq 0$ converge independently of the mesh size h and the number of levels J, provided that the coarsest mesh size h_0 is sufficiently small. This condition on h_0 indicates that this direct MG approach is probably expensive because it requires us to solve a relatively large coarse grid problem. Numerical experiments presented in the next section use $h_0 = 1/4$. Hence, it is clear that such a condition is not essential for our problem.

Finally, we will also consider the full MG scheme FMG(nV(ν_1, ν_2)), which proceeds from the coarsest to the finest grid, invoking n $V(\nu_1, \nu_2)$ cycles on each level along the way with $n \geq 1$ (see [4]). Thus, each coarse level serves to provide a good initial approximation to the next finer level, with the intent of producing a final approximation on the finest grid that is accurate to the level of discretization error.

5. Numerical experiments.

In this section, we present the results of numerical experiments. Performance of the solution methods and the finite element discretization accuracy are first analyzed individually, and then the overall FMG performance is assessed.

We consider the Poisson equation in (2.1) over the L-shaped domain

$$\Omega = ((-1, 1) \times (-1, 1)) \setminus ([0, 1) \times (-1, 0]) .$$

The domain Ω is first partitioned into $3(n \times n)$ square subdomains of side length $h = 1/n$. The $3(n\times n)$ subsquares are then divided into pairs of triangles by connecting the bottom right and upper left corners. We use continuous piecewise linear finite element space for the approximation of the regular part w of the solution with respect to the triangulation with the grid interval h ranging from 2^{-2} to 2^{-7} for each direction. In the performances of the MG V-cycles and the full MG V-cycles, the mesh size of the coarsest grid is chosen to be $h_0 = 2^{-2}$. To increase the accuracy of numerical quadratures, all integrations, involving singular and dual singular functions, on a given triangle $K \in \mathcal{T}_k$ are computed by the composite three points quadrature rule using small triangles of the side length 2^{-11}. These small triangles are generated by $(9 - k)$-times subdividing the triangles K of the side length $2^{-(k+2)}$. We will use the following discrete L^2-norm and H^1-seminorm for the vector $V_h \in \Re^N$:

$$\|V_h\|_h := \sqrt{\left(M_h V_h, V_h\right)} \quad \text{and} \quad |V_h|_{1,h} := \sqrt{\left(A_J^s V_h, V_h\right)},$$

where M_h is the mass matrix associating with $\mathcal{V}_h$ and A_J^s is the stiffness matrix of the Laplace operator defined in section 4.

5.1. Performance of the solution methods.

To study the performance of the solution methods, we begin with the Poisson equation in (2.1) with the homogeneous right-hand side; i.e.,

$$\begin{cases} -\Delta u &= 0 \quad \text{in } \Omega, \\ \quad u &= 0 \quad \text{on } \partial\Omega. \end{cases}$$

It is obvious that the exact solution is zero. With the initial guess of one, we report asymptotic convergence factors for the MG V-cycle defined in section 4.2 (referring to the direct MG) and the iterative Sherman–Morrison algorithm (SMA). Let X^k and Y^k denote, respectively, the kth V(ν_1,ν_2) iterates of the discrete Poisson problems in the first two steps of the SMA defined in section 4.1. The iterative SMA is defined as follows:

$$W_h^k = X^k + \alpha^k \beta^k Y^k$$

TABLE 1
Convergence factors for direct MG V(ν_1, ν_2) cycle.

	$\rho = 1.00$			$\rho = 0.50$		
Mesh size	V(1,0)	V(2,0)	V(1,1)	V(1,0)	V(2,0)	V(1,1)
$h = \frac{1}{8}$	0.3971	0.1822	0.1830	0.3988	0.1720	0.1694
$h = \frac{1}{16}$	0.4415	0.2460	0.2369	0.4564	0.2793	0.2758
$h = \frac{1}{32}$	0.4417	0.2696	0.2524	0.4504	0.2574	0.2866
$h = \frac{1}{64}$	0.4642	0.3113	0.2924	0.4360	0.2691	0.2598
$h = \frac{1}{128}$	0.4719	0.3081	0.2612	0.4777	0.3242	0.2831

TABLE 2
Convergence factors for the iterative SMA with $\rho = 1.0$.

Mesh size	V(1,0)	V(2,0)	V(1,1)
$h = \frac{1}{8}$	0.4005	0.1709	0.1691
$h = \frac{1}{16}$	0.4588	0.2722	0.2780
$h = \frac{1}{32}$	0.4563	0.2421	0.2680
$h = \frac{1}{64}$	0.4638	0.2285	0.2553
$h = \frac{1}{128}$	0.4369	0.3072	0.2474

with $\alpha^k = \frac{1}{1-V^tY^k}$ and $\beta^k = V^tX^k$. Convergence factors σ_h^k here are defined as ratios of a successive discrete H^1-seminorm of errors,

$$\sigma_h^k := \frac{|e_h^{k+1}|_{1,h}}{|e_h^k|_{1,h}} \qquad \text{with} \quad e_h^k = W_h - W_h^k,$$

where $W_h = 0$ and W_h^k are the exact solution and the kth iterate of (4.2) with $f = 0$, respectively. It is clear that the convergence factor of the iterative SMA does not depend on ρ and the mesh size h since the MG iterations apply to two discrete Poisson problems.
