SPECTROPHOTOMETRIC DETERMINATION OF CALCIUM IN ZIRCONIUM POWDER BY USE OF MUREXIDE

HERMAN GORDON and GEORGE NORWITZ
Frankford Arsenal, Philadelphia, Pa. 19137, U.S.A.

(*Received* 16 *April* 1971. *Accepted* 28 *August* 1971)

Summary—An accurate spectrophotometric method is proposed for the determination of calcium in zirconium powder by use of murexide. A 0·4-g sample is dissolved in hydrofluoric and sulphuric acids, the solution evaporated to fumes of sulphuric acid, and a mercury cathode electrolysis made if more than 0·05% copper or nickel is present. Ammoniacal precipitation in the presence of ammonium chloride separates zirconium and other elements and an aliquot of filtrate is collected, equivalent to 0·2 g of sample. The ammonium salts are destroyed with nitric and hydrochloric acids and the calcium is determined with murexide. The high reagent blank is shown to be due to the reagent grade nitric acid, hydrochloric acid, and ammonium hydroxide.

ZIRCONIUM powder is used in pyrotechnics, primers, and flashlight powder. It is usually manufactured by reacting zirconium oxide or halide with calcium metal,[1,2] so calcium is a common contaminant.

There is need for an improved method for the determination of calcium in zirconium powder. The U.S. Military Specification for zirconium powder[3] describes a method in which zirconium is separated by ammoniacal precipitation, and the calcium precipitated as calcium oxalate, which is then titrated with permanganate. Elwell and Wood[4] pass a hydrofluoric acid solution of the sample through a cation-exchange resin which retains the calcium. The calcium is eluted with hydrochloric acid and determined by flame photometry or atomic absorption. The recoveries are 65–75% and the method is recommended for the determination of 0·001–0·003% calcium. The direct determination by atomic absorption is not feasible because of the quenching effect of the zirconium. Because of the lack of data, ASTM does not describe limits or methods for calcium in zirconium.[5,6]

Much work has been performed on the calcium–murexide colour and this work has been summarized by Sandell[7], by Ivanova and Simova[8] and by Hunter.[9] Surprisingly, the method does not seem to have been applied to metallic materials such as zirconium powder.

EXPERIMENTAL

Reagents

Standard calcium solutions. No. 1 (1 ml ≡ 1·0 mg Ca): dry reagent grade calcium carbonate for 3 hr in an oven at 110°, transfer 1·2486 g to a covered 400-ml beaker, add 10 ml of dilute hydrochloric acid (1 + 3), wash down the sides of the beaker, boil for 3 min, cool, and dilute to 500 ml in a volumetric flask. No. 2 (1 ml ≡ 0·01 mg Ca): dilute 5 ml of solution No. 1 to 500 ml in a volumetric flask; prepare fresh daily.

Methyl Orange indicator solution 0·1 %w/v.

Murexide solution. Dissolve 40 mg of good grade murexide in 75 ml of water at 10° in a glass-stoppered 250-ml Pyrex bottle and add 175 ml of 95% ethyl alcohol. Store in a refrigerator at about 10°. This solution will keep for at least 20 days.

Preparation of calibration curve

Rinse all glassware with hydrochloric acid before use. Transfer 2·0, 4·0, 6·0, 8·0 and 10·0-ml portions of standard solution No. 2 to 800-ml beakers and add 50 ml of water, 2 ml of sulphuric acid, 2·5 g of ammonium chloride, and 3 drops of Methyl Orange indicator. Carry a reagent blank through the entire procedure (this is essential). While swirling the beaker add ammonia solution (1 + 1) until the solution turns yellow and then add 30 ml of nitric acid. Boil down, without cover glasses, at the highest heat of the hot-plate to fumes of sulphuric acid and continue heating till complete disappearance of fumes. Allow to cool, wash down the sides of the beaker, and add 25 ml of nitric acid and 25 ml of hydrochloric acid. Again heat at highest heat of the hot-plate till complete disappearance of fumes. Allow to cool, wash down the sides of the beaker, and boil down to dryness. Again allow to cool, add 30 ml of water, and boil down to 20 ml. Cool somewhat and wash into 50-ml volumetric flasks. Cool to 10–15° in a water-bath. Remove from the water-bath, add 2·0 ml of 0·1N sodium hydroxide and wash down with a little water. Add 10·00 ml of murexide solution, dilute to the mark, and within 30 min measure the absorbance at 505 nm with a spectrophotometer that has been set to 100% transmittance with the reagent blank. (With the Beckman Model B spectrophotometer it is necessary to work with a sensitivity of about 3 in order to set the instrument to 100% transmittance.) Plot mg of calcium against absorbance.

Procedure

Transfer a 0·4-g sample to a platinum dish and add 10 ml of water, 4 ml of sulphuric acid and 2 ml of hydrofluoric acid, and swirl. Carry a reagent blank through all steps of the procedure (this is essential). Wash down the sides, evaporate to fumes of sulphuric acid at moderate heat, and fume for 2 or 3 min. Allow to cool.

If heavy metals such as copper or nickel are present in amounts greater than 0·05%, perform a mercury cathode electrolysis; otherwise proceed as in the next paragraph. For the mercury cathode electrolysis, dilute the solution to about 150 ml, wash into a mercury cathode cell, and electrolyse at 5 V for 45 min. Filter through a Whatman No. 42 filter paper into a 400-ml beaker that has graduated markings.

Dilute to about 300 ml, add 5 g of ammonium chloride and 3 drops of Methyl Orange indicator, and heat to about 90°. Remove each beaker from the hot-plate individually, add ammonia solution (1 + 1) from a burette, with vigorous stirring, until the first sign of a precipitate, and then continue the addition dropwise until the solution just becomes yellow. Dilute to the 350-ml mark with hot water (temperature about 90°) and allow the beaker to stand near the edge of the hot-plate for 5 min so that the precipitate settles. Filter immediately through a Whatman No. 41 filter paper into a 400-ml beaker with graduated markings. Discard the first 25 ml and collect 175 ml.

If the manganese content is greater than 0·05% make a manganese dioxide precipitation; otherwise proceed as in the next paragraph. To make the manganese dioxide precipitation, add 10 ml of bromine water and 5 ml of ammonia solution (1 + 1) to the 175 ml of solution in the 400-ml beaker. Digest at about 95° for 15 min, filter through a Whatman No. 42 filter paper into an 800-ml beaker, and wash with water.

Add 30 ml of nitric acid to the solution (contained in an 800-ml beaker) and proceed with the evaporations and development of the colour as described for preparation of the calibration curve. Convert the absorbance reading into mg of calcium by referring to the calibration curve. Calculate as follows:

$$\% \text{ Ca} = \frac{\text{mg of Ca as read from curve}}{\text{g of sample in aliquot} \times 10}$$

DISCUSSION AND RESULTS

Effect of temperature

The use of murexide reagent stabilized by the use of alcohol, as recommended by Williams and Moser,[10] was found to be desirable. However, the addition of a 70% alcohol solution (even if cool) caused the temperature of the sample solution to rise 4–5°, owing to the high heat of dilution of alcohol. To prevent this heating effect and subsequent instability, it is recommended that the sample solution be cooled to about 10° before addition of the water–alcohol solution of the reagent. The use of 10 ml of the reagent is recommended, since excess of murexide must be present to react with the calcium in the blank. This will be discussed later.

Effect of amount of sodium hydroxide solution

From the work of previous investigators it was judged that an alkaline medium was preferable. To ascertain the optimum amount of sodium hydroxide, various amounts of 0·1 *M* sodium hydroxide were added to solutions containing 0·05 mg of calcium. Murexide reagent (10·00 ml) was added, the solutions were diluted to 50 ml, and the transmittance was measured (after 5 and 30 min) at 505 nm against the reagent blank. The results (Table I) show that the colour intensity was essentially the same over the range 0·4–3·0 ml of 0·1 *M* sodium hydroxide. The use of 2·0 ml of 0·1 *M* sodium hydroxide is recommended (this gave a pH of 10·8 before addition of the murexide solution). The colour intensity did not change significantly over the time interval 5–30 min. The colour started to change somewhat in hue after about 1 hr.

TABLE I.—EFFECT OF AMOUNT OF 0·1*M* SODIUM HYDROXIDE (0·05 mg OF Ca PRESENT)

0·1*M* NaOH, *ml*	Transmittance, %	
	After 5 min	After 30 min
0	97	97
0·2	59	59
0·4	48	47
0·7	48	48
1·0	48	48
2·0	47	47
3·0	47	48
5·0	54	56
10·0	58	69

Absorption curves

The absorption spectrum of murexide has the absorption maximum at about 550 nm; that of calcium murexide, has the maximum at about 505 nm. It is recommended that the calcium murexide colour be read at 505 nm.

Calcium from the blank

In applying the method to zirconium, fairly large amounts of nitric acid, hydrochloric acid, and ammonia solution had to be used and it was found that these reagents contained surprisingly large amounts of calcium. The source of this calcium is probably the soft glass bottles used for shipping these reagents (bottle glass contains 4·6–14% calcium oxide[11,12]). Therefore 100-ml portions of these reagents were evaporated to dryness in platinum dishes and also Pyrex beakers. The residues were dissolved in boiling water and the calcium was determined by the murexide reaction. The results (Table II) show that on the average there were 0·025, 0·032, and 0·039 mg of calcium in 100 ml of the nitric acid, hydrochloric acid, and ammonia solution

TABLE II.—CALCIUM IN REAGENTS

Reagent	Calcium found, *mg/100 ml*	
	Evaporated in platinum	Evaporated in Pyrex
Nitric acid	0·027	0·023
Hydrochloric acid	0·031	0·032
Ammonium hydroxide	0·040	0·038

respectively. The results did not differ significantly for samples evaporated in platinum dishes or Pyrex beakers (this was not unexpected, since Pyrex does not contain detectable amounts of calcium[13]).

Equilibrium conditions for the calcium murexide complex depend somewhat on the amount of calcium present. Hence, in preparing the calibration curve it is necessary to treat portions of standard calcium solution with nitric acid, hydrochloric acid, and ammonia solution as in the method, in order to compensate for the effect of the large amount of calcium contained in these reagents.

The blank from these materials could be reduced by use of specially purified reagents. However, this laboratory was interested in methods that would use ordinary analytical reagents.

Study of separations

The cupferron precipitation followed by chloroform extraction was ruled out because it did not eliminate several interfering metals. Ion-exchange was found to be open to the same objections. The separations finally decided upon were a mercury cathode electrolysis, followed by an ammoniacal precipitation in the presence of ammonium chloride to provide buffering.[13] It is known that zirconium and calcium hydroxides are precipitated at pH 3 and 12·5 respectively.[13] To avoid washing the precipitate a fraction of the hot filtrate is taken. This is readily done by using beakers with graduated markings. There is a small error caused by expansion, but because the fraction used is very large and the amount of calcium in zirconium is small (less than 0·05%), the error is not significant.

An important advantage of the use of the ammoniacal precipitation is that the zirconium hydroxide acts as scavenger to remove many possible interfering metals from solution. It would be expected that small or moderate amounts of the following would be completely co-precipitated with zirconium hydroxide: hafnium, titanium, chromium, vanadium, uranium, aluminium, iron, phosphorus, lead, bismuth, tin, arsenic, antimony, selenium, tellurium, gallium, germanium, niobium, tantalum, beryllium, cerium, thorium, indium, and platinum metals.

After the ammoniacal precipitation it was necessary to destroy the large amount of ammonium salts before the colour could be developed. Initially, this was done by evaporating the filtrate to dryness in a platinum dish and heating over an open flame to volatilize the ammonium chloride and ammonium sulphate. It was found that considerable calcium was lost in the cloud of vapours, so this technique was abandoned. The method finally adopted was the nitric–hydrochloric acid treatment to oxidize the ammonium ion to nitrogen. No ammonium salts remained after this treatment and no calcium was lost. The technique is fairly rapid since the evaporations are conducted at the highest heat of the hot-plate.

Study of interferences

The use of both the mercury cathode electrolysis and ammoniacal precipitation eliminates all except a few elements. Manganese and tungsten are partially removed, while calcium, sodium, potassium, lithium, magnesium, barium and strontium are not removed. Potassium and lithium are not found in zirconium. Sodium is occasionally found in traces in zirconium but does not interfere (the hydroxide is used in the procedure). The investigation of interferences was therefore confined to magnesium, barium, strontium, manganese, tungsten and mercury (possible contamination from the mercury cathode).

The results are shown in Table III. These indicate that there is a complex equilibrium involving calcium, the second metal and murexide. The following are suggested as the maximum permissible limits (per 50 ml) for the interfering ions: magnesium, 0·3 mg; barium, 0·2 mg; strontium, 0·01 mg; manganese, 0·1 mg; tungsten, 1 mg; mercury, 0·2 mg.

Williams and Moser,[10] using pH 11·2 and a different technique, found that the maximum permissible amounts of magnesium, barium, and strontium were 0·5, 0·25, and 0·05 mg per 50 ml, respectively.

The recommended interference limits would indicate that the proposed method would be applicable to samples (0·2 g aliquot) containing less than 0·15% magnesium, 0·1% barium, 0·005% strontium, 0·05% manganese, and 0·5% tungsten. These amounts of magnesium, barium, strontium, and tungsten are less than the amounts to be found in commercial zirconium powder. It is rare for a sample of zirconium powder to contain more than 0·05% manganese. However, to take care of all eventualities, it was decided to include a precipitation of the manganese dioxide,[14] when the manganese content is appreciable. Some of the manganese would, of course, be deposited at the mercury cathode. The maximum permissible amount of mercury is more than that which would be found in the solution after the electrolysis.

Results for calcium in zirconium powder

The results obtained for calcium in four samples of zirconium powder are shown in Table IV. The samples contained 0·000–0·042% calcium. Good recoveries were obtained on adding standard calcium solution to samples of calcium-free zirconium and carrying these synthetic samples through the procedure (Table V).

0·4 g of sample 3 + 0·100 mg of calcium	0·097

Zusammenfassung—Eine genaue spektrophotometrische Methode zur Bestimmung von Calcium in Zirkoniumpulver mittels Murexid wird vorgeschlagen. Eine Probe von 0,4 g wird in Flußsäure und Schwefelsäure gelöst, die Lösung bis zum Rauchen der Schwefelsäure eingedampft und, falls mehr als 0,05% Kupfer oder Nickel vorliegen, an einer Quecksilberkathode elektrolysiert. Eine Ammoniakfällung in Gegenwart von Ammoniumchlorid trennt Zirkonium und andere Elemente ab. Ein 0,2 g Probe entsprechender aliquoter Teil des Filtrats wird gesammelt, die Ammoniumsalze mit Salpetersäure und Salsäure beseitigt und das Calcium mit Murexid bestimmt. Es wird gezeigt, daß der hohe Blindwert von der analysenreinen Salpetersäure und Salzsäure sowie vom Ammoniumhydroxid herrührt.

Résumé—On propose une méthode spectrophotométrique précise pour le dosage du calcium dans la poudre de zirconium au moyen de murexide. On dissout un échantillon de 0,4 g dans les acides fluorhydrique et sulfurique, évapore la solution jusqu'à apparition des fumées d'acide sulfurique, et effectue une électrolyse à cathode de mercure s'il y a plus de 0,05% de cuivre ou de nickel. La précipitation ammoniacale en présence de chlorure d'ammonium sépare le zirconium et les autres éléments, et l'on recueille une partie aliquote du filtrat, équivalant à 0,2 g d'échantillon. Les sels d'ammonium sont détruits aux acides nitrique et chlorhydrique et l'on dose le calcium avec le murexide. On montre que la valeur élevée du témoin des réactifs est due à la qualité de l'acide nitrique, de l'acide chlorhydrique et de l'ammoniaque.

MICRODOSAGE DU SILICIUM DANS LES COMPOSES ORGANIQUES*

E. Debal
(avec la collaboration technique de M. Riocreux)
Service Central de Microanalyse du Centre National de la Recherche Scientifique, 2, rue Henry Dunant, 94–Thiais, France

(*Reçu le* 28 *juin* 1971. *Accepté le* 23 *août* 1971)

Résumé—Les composés organiques siliciés sont minéralisés en bombe de Würzschmitt par le peroxyde de sodium et le silicate formé est dosé par spectrophotométrie de l'ion silicomolybdique. La masse du prélèvement analytique varie de 2 à 6 mg. L'erreur absolue possible sur la teneur en silicium est de 0,3–0,4%.

Le microdosage du silicium à l'échelle microanalytique a donné lieu à quelques travaux dont Reverchon et Legrand[1] ont fait un bref rappel.

Minéralisation

En outre, Klimova et collaborateurs,[2] puis Klimova et Bereznitskaya,[3] Shostakovskii et collaborateurs,[4] Gel'man,[5] ont décrit des méthodes permettant les dosages simultanés du silicium, du carbone et de l'hydrogène, par combustion sous courant d'oxygène, comportant le pesage de la silice formée qui reste à l'intérieur de la cartouche en quartz où a brûlé le prélèvement analytique. Leur application n'a pas paru appropriée aux besoins de notre Service qui requéraient une méthode plus spécifique se prêtant mieux à une mise en oeuvre sporadique.

La méthode de calcination en creuset de platine en présence d'acide sulfurique (Ridge et Todd cités par Belcher[6]) avec dosage gravimétrique de la silice, mise en oeuvre à l'échelle milligrammique pendant quelques temps dans notre Service, malgré son défaut de spécificité, y a été abandonnée. Elle conduit en effet trop souvent à des erreurs systématiques portant sur plusieurs microgrammes de silicium et, en outre, elle ne convient pas à l'analyse de la plupart des substances liquides. De telles difficultés avaient d'ailleurs été déjà signalées notamment par Belcher[6] ainsi que par Brown et Fowles,[7] ces derniers effectuant une attaque initiale du prélèvement analytique par un mélange d'acide sulfurique et d'acide nitrique.

La méthode de minéralisation par combustion en fiole de Schöniger a été adoptée par quelques microanalystes tels que Burroughs[8] qui utilise une fiole en polyéthylène et Reverchon et Legrand[1] qui emploient une fiole en nickel.

Les quelques essais que nous avons effectués avec minéralisation en fiole de polypropylène (marque "Nalgène") dont nous disposions n'ont pas été encourageants: ils ont conduit à l'obtention de résultats erronés par défaut et à la perforation fréquente des fioles, par combustion, lorsque des particules enflammées viennent au contact de leur paroi de matière plastique. La fiole de nickel ne présente pas ce dernier inconvénient mais son opacité ne se prête pas non plus à un allumage simple en son sein. Ces essais ont donc été abandonnés au profit de l'étude de la minéralisation en bombe par le peroxyde de sodium à l'instar de quelques

---

* Communication présentée dans le cadre des Journées de microanalyses organisées par la Société Chimique de France et la Société de Chimie Industrielle, à Thiais, les 18 et 19 mars 1971.

microanalystes tels que Christopher et Fennell[9] qui utilisent 0,2 g de ce réactif et portent leur bombe à 500° pendant 15 min.

La méthode décrite ci-après est une variante de la méthode initiale de Würzschmitt.[10] Elle est associée à l'utilisation des sachets de "Scotch" décrits par Reverchon[1] pour le conditionnement, le pesage et l'attaque du prélèvement analytique dans la bombe; non seulement ces sachets sont indispensables dans le cas de la minéralisation de produits liquides mais, de plus, ils semblent faciliter la minéralisation de certaines substances solides dont les résultats d'analyse sont erronés par défaut lorsque les prélèvements analytiques sont déposés directement au fond de la bombe à l'aide d'un pèse-substance d'après le mode opératoire original de Würzschmitt.

Dosage

Le silicate formé est dosé par colorimétrie spectrophotométrique du complexe jaune silicomolybdique utilisé par de nombreux analystes tels que Reverchon.[1]

Cependant il n'est pas établi de courbes d'étalonnage; il est préférable de préparer des solutions étalons en même temps que les solutions inconnues qui leur sont directement comparées, comme nous l'avons indiqué par ailleurs.[11] Les calculs sont fondés sur l'application d'une simple règle de proportionnalité. En vue d'améliorer la précision, la loi de Lambert-Beer n'étant pas rigoureusement suivie dans les conditions opératoires décrites, les teneurs en silicium des solutions étalons doivent être voisines de celles des solutions à titrer (les écarts admissibles entre ces teneurs ne doivent pas excéder 60–80 μg de silicium par fiole jaugée de 200 ml).

Il est connu que le complexe silico-12-molybdique existe sous deux formes α et β, dont la seconde a un coefficient d'extinction double de celui de la première à $\lambda \sim 400$ nm et se transforme lentement et irreversiblement en forme α. Lorsqu'on effectue la mesure de densité optique une quinzaine de minutes après l'addition du molybdate, comme il est en général indiqué dans la littérature, le complexe existe alors, en principe, sous la forme β mais d'après Strickland cité par Hargis[12] il est impossible d'obtenir une solution d'isomère β seul. Nous avons effectué des séries de mesures de densités optiques 15 min, 45 min et 17 hr après l'addition de molybdate d'ammonium. Elles nous ont montré que les quantités de silicium trouvées sont en général très voisines dans le cas des mesures effectuées après 15 ou 45 min c'est à dire, sur le complexe β, en principe, mais que par contre elles sont quelquefois légèrement différentes au bout de 15 à 18 hr, c'est à dire sur le complexe α. Ce sont les dosages effectués sur le complexe α qui sont les plus exacts. Comme la quantité de peroxyde de sodium utilisée est définie à 0,1–0,2 g près, il s'en ensuit que le pH peut varier légèrement d'une fiole à l'autre puisque la quantité d'acide ajoutée est constante. Or la valeur du pH joue un rôle important dans la formation des complexes α et β; il est donc possible qu'après addition du molybdate d'ammonium, il se forme immédiatement des quantités faibles mais variables de complexe α ce qui expliquerait la meilleure reproductibilité des résultats lorsque l'ion silicomolybdique est entièrement sous la forme α, c'est à dire après 16 à 18 hr d'attente.

PARTIE EXPERIMENTLLE

Materiel

Microbombes de Würzschmitt en nickel avec joint de Téflon[13] et dispositif de chauffage et de protection.

Spectrophotomètre "graphi-spectral" Jouan à 2 cuves, sans enregistreur.
Béchers de 150 ml en Téflon.
Accessoires divers: pipettes de précision, bain de sable, fioles jaugées de précision de 200 ml.

Reactifs

Glycol éthylénique pour usages scientifiques.
Peroxyde de sodium en poudre pour analyses.
"Scotch" Minnesota en ruban de 19 mm de largeur.
Acide sulfurique ($d = 1{,}83$) pour analyses. Diluer pour obtenir de l'acide 7*N*.

Solution de molybdate d'ammonium. Dissoudre 106 g de molybdate d'ammonium, $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$, pour analyses, dans de l'eau distillée. Ajuster le pH à 7–7,5 en ajoutant environ 28 g de soude en pastilles pour analyses et en diluant à 1 litre avec de l'eau distillée. Conserver la solution en flacon de polyéthylène.

Solutions de silicate de sodium à 40 et 100 mg de silicium par litre (variante de la méthode de Reverchon[1]). Introduire soit 85,60 mg (solution à 40 mg/l), soit 214,00 mg (solution à 100 mg/l) de silice exempte de carbone, pour analyses métallurgiques, dans une capsule de platine. Ajouter soit environ 6 g (solution à 40 mg/l), soit environ 12 g (solution à 100 mg/l) de soude en pastilles pour analyses. Faire fondre en chauffant doucement, maintenir le chauffage pendant 30 min et après refroidissement reprendre par de l'eau distillée bouillante. Ajuster le pH à 1,5 (essai à la touche sur papier à pH) en ajoutant de l'acide sulfurique 7*N* (environ 20 ou 40 ml) et en diluant à 1 litre avec de l'eau distillée. Transvaser immédiatement dans un flacon en polyéthylène.

Mode opératoire

Préparer des sachets de "Scotch" revêtus intérieurement de papier filtre sans cendres analogues à ceux de Reverchon[1] mais d'environ 10 mm de hauteur totale et sans languette. Peser dans chacun de ces sachets 2 à 6 mg de substance de telle sorte que la masse de silicium y soit, si possible au plus égale à 0,7 mg.* Lors de l'analyse de substances liquides, introduire au préalable dans chaque sachet quelques carrés de papier filtre sans cendres d'environ 2 mm de côté et déposer le liquide sur le papier à l'aide d'une tige capillaire. Effectuer la minéralisation à l'aide de 2,6 g de peroxyde de sodium en présence de 2 à 3 gouttes d'éthylène-glycol selon la méthode de Würzschmitt.[10]

Après minéralisation et refroidissement, préparer, pour chaque bombe, un bécher de Téflon contenant un petit carré de toile de platine (36 mailles par mm^2) destiné à catalyser la décomposition ultérieure de l'eau oxygénée formée par dissolution dans l'eau du peroxyde de sodium. Introduire chaque bombe dans un bécher de Téflon; rincer le couvercle de la bombe à l'eau distillée bouillante et recueillir l'eau de rinçage dans le bécher; y ajouter de l'eau distillée bouillante jusqu'à ce que le corps de la bombe soit juste recouvert, ce qui donne lieu à la dissolution de la masse d'attaque. Couvrir le bécher avec un "verre de montre" en Téflon et le poser sur un bain de sable à 200° en vue de détruire l'eau oxygénée. Au bout de 45 min, rincer le "verre de montre", extraire le corps de la bombe et le rincer avec de l'eau distillée bouillante; recueillir toutes les eaux de rinçage dans le bécher. Ajouter lentement 9,5 ml d'acide sulfurique 7*N* pour que la solution soit portée à un pH voisin de 1,5 et laisser revenir à température ambiante. Transvaser la solution, en la filtrant sur papier filtre sans cendres à filtration rapide, dans une fiole jaugée de 200 ml préalablement garnie de 5,7 ml d'acide sulfurique 7*N* de telle sorte que le pH final reste égal à 1,5. On obtient ainsi une série de fioles correspondant à la série de prélèvements analytiques et de minéralisations effectués. Préparer en même temps des solutions étalons et un essai à blanc suivant le même mode opératoire mais en introduisant un sachet de "Scotch" vide dans chaque bombe puis *n* ml de solution de silicate de sodium dans la fiole jaugée correspondante avec $n = 0$ dans le cas de l'essai à blanc. Ajouter dans chacune des fioles 20 ml de solution de molybdate d'ammonium et ajuster le volume de la solution à 200 ml avec de l'eau distillée.

Effectuer la mesure spectrophotométrique par rapport à l'essai à blanc à 400 nm après 15 à 18 h de repos.

Calcul

Soit *d* la densité optique d'une solution inconnue, D, D', D'', D''' les densités optiques de 4 solutions étalons identiques correspondantes

$$\text{Si}\ \% = \frac{d \times m' \times 100}{\dfrac{D + D' + D'' + D'''}{4} \times m}$$

* Lorsque la masse croît au delà de 0,7 mg, la précision diminue souvent peu à peu.

m': masse de silicium introduite dans chaque solution étalon, exprimée en mg; m: masse du prélèvement analytique exprimée en mg.

(Pour 0,5 mg de silicium, d est de l'ordre de 0,24)

DISCUSSION

La méthode décrite est de longue durée et délicate à mettre en oeuvre par suite des nombreuses manipulations qu'elle comporte et de la perturbation susceptible d'être apportée par l'eau oxygénée au cas où celle-ci ne serait pas quantitativement détruite. Il est donc important que cette destruction soit opérée dans des conditions rigoureusement reproductibles pour toutes les solutions, que, par conséquent, les volumes de solutions à porter à l'ébullition soient les mêmes et que la température du bain de sable soit uniforme. Du fait de l'existence de ces différentes causes d'erreurs, il est recommandé de préparer simultanément 4 solutions étalons identiques afin de pouvoir éventuellement éliminer le résultat fourni par l'une d'elles s'il apparaît que celui-ci est manifestement erroné.

Afin de réduire au minimum le temps passé, grouper les substances par teneurs afin que la moyenne des résultats obtenus pour ces 3 ou 4 solutions étalons soit utilisable pour le calcul de la teneur en silicium de plusieurs substances soumises à l'analyse (les quantités de silicium à doser ne doivent pas différer de plus de 60 à 80 μg: *cf. Dosage*).

RESULTATS

Quelques exemples de résultats de microdosages du silicium sont reportés dans le Tableau I. Ils mettent en évidence l'exactitude et la reproductibilité que peut fournir

FLUORIMETRIC AND PHOSPHORIMETRIC CHARACTERISTICS OF SEVERAL VITAMINS*

JEAN-JACQUES AARON† and J. D. WINEFORDNER®
Department of Chemistry, University of Florida, Gainesville, Florida 32601, U.S.A.

(*Received* 10 *May* 1971. *Accepted* 18 *August* 1971)

Summary—The fluorescence and phosphorescence characteristics of 14 vitamins were evaluated. The existence or absence of fluorescence and phosphorescence was compared with predictions based upon molecular structure. Analytically useful fluorescence signals were obtained for *p*-aminobenzoic acid, folic acid, calciferol, pyridoxine hydrochloride, riboflavine, α-tocopherol and vitamin A, whereas analytically useful phosphorescence signals were obtained for *p*-aminobenzoic acid, folic acid, niacinamide, pyridoxine hydrochloride, and α-tocopherol. All other vitamins either did not fluoresce or phosphoresce or could not be measured, owing to experimental difficulties. The complementary nature of fluorimetry and phosphorimetry is evident in these studies.

NUMEROUS fluorimetric assays have been developed for vitamins.[1] Most of these studies have involved measurement of fluorescence characteristics, study of pH and solvent effects upon fluorescence signals and spectra, and development of extraction procedures for separation of vitamins from biological fluids and conversion of vitamins into fluorescent compounds.[1] In contrast to the rather extensive fluorescence studies, the knowledge of the phosphorescence characteristics of vitamins is quite limited, and, at present, no use of phosphorimetry[2–4] for analysis of vitamins has been reported. The lack of use of phosphorimetry for studies involving biological samples was impeded, until recently, by the difficulty of sample cell alignment and the need for organic solvents which would form clear, rigid glasses at liquid nitrogen temperatures; as a result of the rotating sample-cell assembly described by Zweidinger and Winefordner,[5] the previous problems have been minimized, and phosphorimetry is now capable of analytical use for measurement of trace species in biological samples.

The purpose of the present research was to evaluate the fluorescence and phosphorescence characteristics of 14 vitamins and to compare the usefulness of fluorimetry and phosphorimetry for quantitative analysis of these compounds.

EXPERIMENTAL

Instrumentation

Fluorescence measurements were performed with either a Baird Fluorispec (Model SF-100; Baird Atomic Inc., Bedford, Mass.) or an Aminco-Bowman SPF (Model 4-8202, American Instrument Co., Inc., Silver Spring, Md.) spectrophotofluorimeter. A 150 W Hanovia d.c. power supply was used to power the xenon arc lamp with the Baird unit, whereas a Harrison (Model 6268A, Hewlett-Packard, Palo Alto, Calif.) constant current d.c. power supply was used to power the xenon arc lamp with the Aminco unit. All spectra were recorded with an X-Y recorder.

Phosphorescence measurements were performed by using the Aminco-Bowman SPF with an Aminco-Keirs phosphoroscope attachment (Model, C27-62140, American Instrument Co., Inc.) and the rotating sample-cell described by Zweidinger and Winefordner.[5] Phototube signals were measured

† On leave from Laboratoire de Chimie Organique Physique, Paris, France.

by using the low noise nanoammeter described by O'Haver and Winefordner.[6] The stable Harrison power supply used for fluorescence studies was also used to power the 150-W xenon arc source.

Reagents

All vitamins studied here were purchased as a kit (Nutritional Biochemicals Corp., Cleveland, Ohio) and used as received. Solvents used were ethanol which was purified by distillation through a 1·5-m vacuum-jacketed column,[7] and demineralized water.

Procedure

Stock ethanolic solutions of all vitamins, except for inositol, calcium pantothenate, and riboflavin, which had to be prepared in water, were prepared. Inositol and calcium pantothenate are insoluble in ethanol, and riboflavin is known[8] to photolyse much faster in ethanolic than aqueous solutions. Lower concentrations of each vitamin were prepared by successive dilutions.

The spectrometric slit arrangements for fluorimetry were: 4, 1, 1, 3, 3, 3 for the Aminco instrument; and 1, 1, 1, 1 for the Baird instrument. The spectrometric slit arrangements for phosphorimetry were: 4, 3, 3, 3, 3, 3. The numbers refer to the slit dimensions (mm) and the sequence refers to the manufacturer's means of specifying slits within the spectrometric instrument. All excitation and emission spectra, analytical curves, and detection limits were obtained (for a given instrument) with the same slit arrangement. All spectra were uncorrected for instrumental response.

RESULTS AND DISCUSSION

Fluorescence and phosphorescence excitation and emission spectra

Eight of the 14 vitamins fluoresced or phosphoresced or exhibited both fluorescence and phosphorescence; the measured fluorescence and phosphorescence spectral characteristics of these eight are given in Table I. The reported fluorescence and phosphorescence characteristics of the parent compounds are also given in Table I for comparison. Six compounds, including ascorbic acid, biotin, calcium pantothenate, thiamine hydrochloride, inositol and choline chloride did not fluoresce or phosphoresce with sufficient intensity to be of analytical use.

The main reasons for the occurrence (or lack) of fluorescence and phosphorescence of vitamins may be attributed to the great variety of structures and to dissociation energy considerations.[9] It is well known that the existence of a conjugated system in the molecule is necessary for fluorescence because π–π^* singlet states are preferred; on the other hand, aromatic hydrocarbons, heterocycles, and carbonyl compounds involving n–π^* or π–π^* triplet states undergo phosphorescence. Vitamins (see Table II) usually contain several of these structural features. From the information in Table II, it would seem that all but 2 vitamins should fluoresce and/or phosphoresce. From the results in Table I, there are some cases of disagreement between predicted and observed fluorescence and phosphorescence. These might be a result of either particular geometrical arrangements of the molecule or a result of predissociation.

In Table III, the absorption maxima (in kJ/mole) of the vitamins with the bond dissociation energy (in kJ/mole) of their weakest bond are compared. The data show that generally the vitamins fluoresce only when they absorb at lower-energy frequencies than the dissociation energy of their least stable bond; under these conditions, there should be no predissociation and the vitamins are able to fluoresce. Niacinamide and thiamine hydrochloride (both were predicted to fluoresce, from their structural characteristics, but did not fluoresce experimentally—see Table II) have very much higher absorption energies (in kJ/mole) than the dissociation energies of their weakest bond and, therefore, they are probably predissociated and unable to fluoresce.

The fluorescence and phosphorescence bands of vitamins are generally broad and

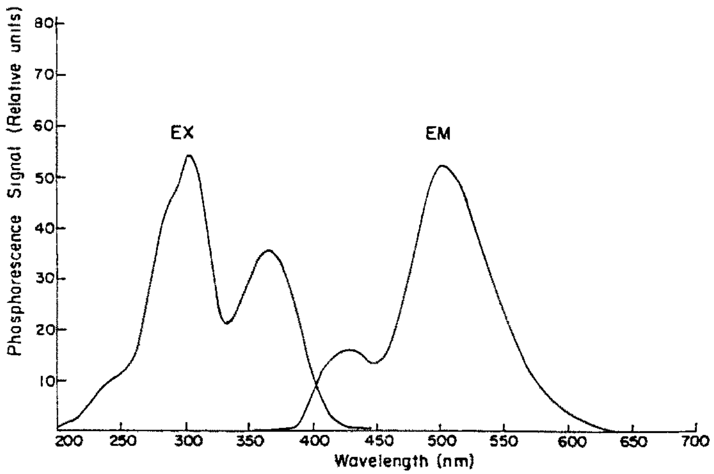

FIG. 1.—Phosphorescence excitation and emission spectra of folic acid in ethanol (77K).

structureless. In some cases, the excitation or the emission spectra exhibit several peaks. For instance, the phosphorescence excitation and emission spectra of folic acid include two peaks each (Fig. 1): the emission peak at 425 nm is attributed to the anilino part of the folic acid and the emission peak at 505 nm is related to the pteridin part of the molecule, as can be seen by comparing these wavelength values with those of the parent compounds (see Table I). Generally, the spectra of the vitamins resemble those of the parent compounds very closely (see Table I). However, in some cases, such as pyridoxine hydrochloride and α-tocopherol, a red shift of the fluorescence and phosphorescence bands is observed relative to the parent compound (Table I); this shift may be attributed to the effect of electron-donating alkyl and alkoxy substituents. In the case of the niacinamide, the parent compound pyridine does not phosphoresce, but the vitamin phosphoresces; the appearance of the phosphorescence is related to the substitution of the carbonyl group in the pyridine ring, which is known to favour the appearance of phosphorescence.[11]

Analytical studies

Fluorescence and phosphorescence analytical characteristics are given in Table IV. The linear portion of the analytical curves was much the same whether measured with the Aminco-Bowman or the Fluorispec instrument. The limit of detection was taken as the concentration giving a signal (located on the linear portion of the analytical curve) two times that of the background noise; the background signal was suppressed by means of the bias adjustment of the nanoammeter read-out or subtracted from the total signal value when the Fluorispec spectrophotofluorimeter was used. In Table IV, limits of detection obtained for the fluorescent and phosphorescent vitamins are given. These values are between 0·0001 and 8 μg/ml, depending to the structure of the vitamin. Practical "sensitivity" has been determined by fluorimetry for some compounds of biological interest,[10] but these values cannot be compared with our values because of the arbitrary definition of "sensitivity". For the vitamins which fluoresce and phosphoresce, the limits of detection are about the same for fluorimetry and phosphorimetry; however for *p*-aminobenzoic acid, the limit of detection in

‡ Value for the linear portion above the limit of detection.

§ NAU means no analytical use.

‖ In aqueous solution. All others in ethanol.

¶ No measurements possible because of aqueous solvent.

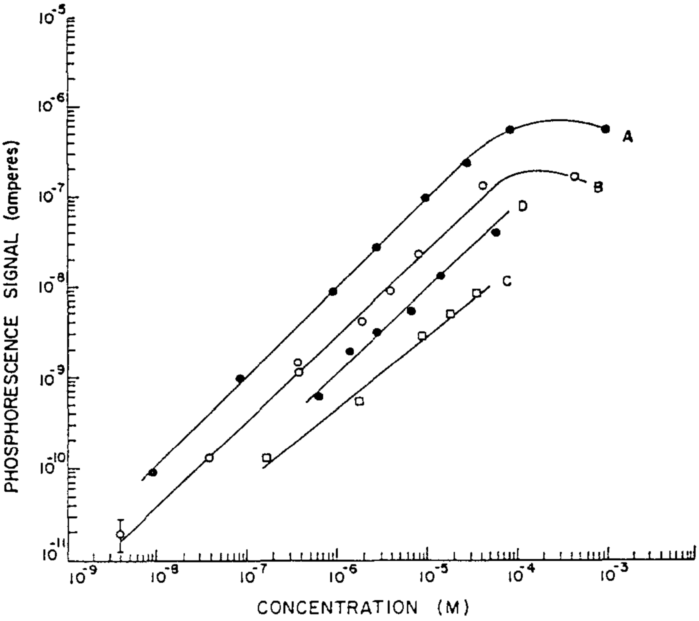

FIG. 3.—Several typical phosphorimetric analytical curves:
(a) *p*-Aminobenzoic acid
(b) Pyridoxine hydrochloride
(c) Folic acid
(d) α-Tocopherol.

phosphorimetry is lower by a factor of about 10 (see Table IV). The slopes of all analytical curves are very similar for fluorimetry and phosphorimetry and are close to unity (see Figs. 2 and 3) as expected.

In the past, fluorimetry was used for the analysis of vitamins,[1] but not phosphorimetry. However, our results show that the precision, linearity of the analytical curves, and limits of detection obtained by fluorimetry and phosphorimetry are very similar Therefore, it should be possible to use either fluorimetry or phosphorimetry for the routine determination of the nine vitamins in Table I. The choice of method will be primarily determined by the structural criteria discussed above.

Zusammenfassung—Die Fluoreszenz- und Phosphoreszenzeigenschaften von 14 Vitaminen wurden ermittelt. Auftreten oder Abwesenheit von Fluoreszenz und Phosphoreszenz wurden mit Voraussagen verglichen, die an Hand der Molekülstruktur getroffen wurden. Analytisch brauchbare Fluoreszenzen wurden gefunden bei p-Aminobenzoesäure, Folsäure, Calciferol, Pyridoxin-Hydrochlorid, Lactoflavin, α-Tocopherol und Vitamin A, analytisch brauchbare Phosphoreszenzen bei *p*-Aminobenzoesäure, Folsäure, Nicotinsäureamid, Pyridoxin-Hydrochlorid und α-Tocopherol. Alle anderen Vitamine fluoreszierten und phosphoreszierten nicht oder konnten wegen experimenteller Schwierigkeiten nicht gemessen werden. Die komplementäre Natur von Fluorimetrie und Phosphorimetrie kommt in diesen Untersuchgen zum Ausdruck.

Résumé—On a évalué les caractéristiques de fluorescence et de phosphorescence de 14 vitamines. On a comparé l'existence ou l'absence de fluorescence et de phosphorescence aux prévisions basées sur la

structure moléculaire. Des signaux de fluorescence analytiquement utiles ont été obtenus pour l'acide *p*-aminobenzoïque, l'acide folique, le calciférol, le chlorhydrate de pyridoxine, la riboflavine, l'α-tocophérol et la vitamine A, tandis que des signaux de phosphorescence analytiquement utiles ont été obtenus pour l'acide *p*-aminobenzoïque, l'acide folique, le niacinamide, le chlorhydrate de pyridoxine et l'α-tocophérol. Toutes les autres vitamines n'émettent pas de flourescence ou de phosphorescence, ou ne peuvent être mesurées à cause de difficultés expérimentales. La nature complémentaire de la fluorimétrie et de la phosphorimétrie est évidente dans ces études.

(*Received* 16 *April* 1971. *Accepted* 22 *June* 1971)

Summary—Micro-methods for spectrophotometric and oxidimetric determination of α-amino-acids are described. They are based on a reaction of the acids with *peri*-naphthindan-2,3,4-trione hydrate at pH 2.5 to give a red precipitate of dihydroxy-*peri*-naphthindenone. The red product is dissolved and measured either spectrophotometrically at 243 nm or titrimetrically by reaction with iodine or *N*-bromosuccinimide. The results obtained by the three methods are concordant, the average recovery being 98%.

MANY METHODS have been reported for the determination of α-amino-acids. Alkalimetric,[1] acidimetric,[2] manometric,[3] gasometric,[4] and chromatographic[5] measurements of nitrous oxide, nitrogen, ammonia, carbon dioxide and aldehydes produced by reactions with suitable reagents have been proposed. Direct alkalimetric[6] and complexometric[7] determination of the free acid after treatment with excess of formaldehyde and copper salts are employed. Enzymatic,[8] mass spectrometric[9] and conductometric[10] methods have been also utilized.

However, few colorimetric and redox reactions are known for amino-acid determination. Colorimetric reactions with ninhydrin,[11] 3,5-dibromosalicyldehyde[12] and *o*-diacetylbenzene[13] have been mentioned. A method based on a reaction of *N*-ethylmaleimide with carboxydithiocarbamate, formed by the action of carbon disulphide on the acid, is described.[14] An oxidimetric method based on deamination of the acid followed by oxidation of the resulting hydroxy-acid with vanadium(V) has been used.[15]

Peri-naphthindan-2,3,4-trione hydrate has been proposed for the determination of α-amino-acids by measuring the amount of carbon dioxide,[16] ammonia,[17] and aldehydes[18] produced. In the present work this reagent is used in the development of new colorimetric and redox methods for amino-acid determination.

EXPERIMENTAL

Reagents

All reagents were of analytical grade unless otherwise specified.

Peri-*naphthindan-2,3,4-trione hydrate* was prepared as described previously.[18,19]

*Dihydroxy-*peri*-naphthindenone* was prepared by reduction of the trione with ascorbic acid.[20]

Citrate buffer solution. Sodium citrate trihydrate (2·06 g) and 19·16 g of citric acid monohydrate were dissolved in 500 ml of water.

The α-amino-acids used were of purity not less than 99%.

Procedure

Spectrophotometric determination of α-amino-acids. Construct a standard calibration curve as follows. Dissolve 1·765 mg of dihydroxy-*peri*-naphthindenone in 50 ml of methanol. Then take 1·5, 2, 2·5, 3, 3·5, 4, 4·5 and 5 ml of this solution in 10-ml measuring flasks and make up to the mark with methanol. Measure the absorbance of these solutions at 342 nm in 10-mm cuvettes within 15 min, using methanol in the reference cell. Draw a graph of the absorbance against the concentration of amino-acid nitrogen (1 μg of dihydroxy-*peri*-naphthindenone ≡ 0·066 μg of amino-acid nitrogen).

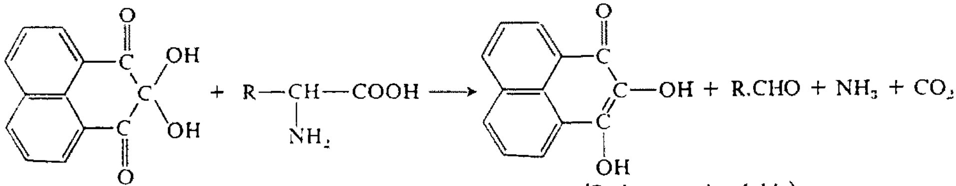
Into a 25-ml round bottom flask, introduce 4 ml of 0·1% *peri*-naphthindan-2,3,4-trione hydrate solution in distilled water and 1 ml of the citrate buffer solution. Add 0·4 ml of 8m*M* α-amino-acid solution in water (equivalent to 44·8 μg of amino-acid nitrogen). Heat the flask under reflux for 1 hr at 100°, cool in ice and filter (Whatman No. 42 paper). Wash several times with cold water. Dissolve the red precipitate of dihydroxy-*peri*-naphthindenone in methanol into a 50-ml graduated flask. Measure the absorbance at 342 nm in a 10-mm cell against a blank.

Titrimetric determination of α-amino-acids with iodine. Dissolve the dihydroxy-*peri*-naphthindenone precipitate in 25 ml of methanol in a 250-ml conical flask. Add 100 ml of water and 5 ml of 0·004*N* iodine. After 5 min titrate the excess of iodine with 0·004*N* sodium thiosulphate, using starch as indicator (1 ml of 0·004*N* iodine ≡ 21 μg of amino-acid nitrogen).

Titrimetric determination of α-amino-acid with N-*bromosuccinimide.* Dissolve the red precipitate in 50 ml of 1:1 acetic acid–water in a 250-ml conical flask. Dilute with water to 150 ml, add 5 ml of 4% potassium iodide solution and 1 ml of 1% starch solution and titrate with 0·004*N* *N*-bromosuccinimide (1 ml of 0·004*N* *N*-bromosuccinimide ≡ 21 μg of amino-acid nitrogen).

RESULTS AND DISCUSSION

Peri-naphthindan-2,3,4-trione hydrate (I) decomposes α-amino-acids quantitatively with the formation of the corresponding aldehyde having one carbon atom less, ammonia, carbon dioxide and dihydroxy-*peri*-naphthindenone (II) according to the equation:



(Colourless, water-soluble) (I)

(Red, water-insoluble) (II)

Since one molecule of dihydroxy-*peri*-naphthindenone is produced for each molecule of α-amino-acid, this reaction may be used for amino-acid determination. The reaction is quantitative in a citrate buffer solution at pH 2·5 and a low blank value is obtained.

Spectrophotometric methods

Absorption spectra. The absorption spectra show maxima at 320 nm (ε 1·22 × 10^3 $\text{l.mole}^{-1}.\text{mm}^{-1}$) for the naphthindantrione and 342 nm (ε 1·14 × 10^3 $\text{l.mole}^{-1}.\text{mm}^{-1}$) for the dihydroxynaphthindenone (Fig. 1). Because of the equal absorption by both compounds over a wide wavelength range, prior separation is necessary; in that case an excess of the reagent does not adversely affect the accuracy of the method.

Beer's law is obeyed (for dihydroxy-*peri*-naphthindenone) in the concentration range equivalent to 0·1–2 μg of amino-acid nitrogen per ml and only one calibration curve is required for all α-amino-acids.

Effect of pH. Dihydroxy-*peri*-naphthindenone dissolves in methanol to give a red

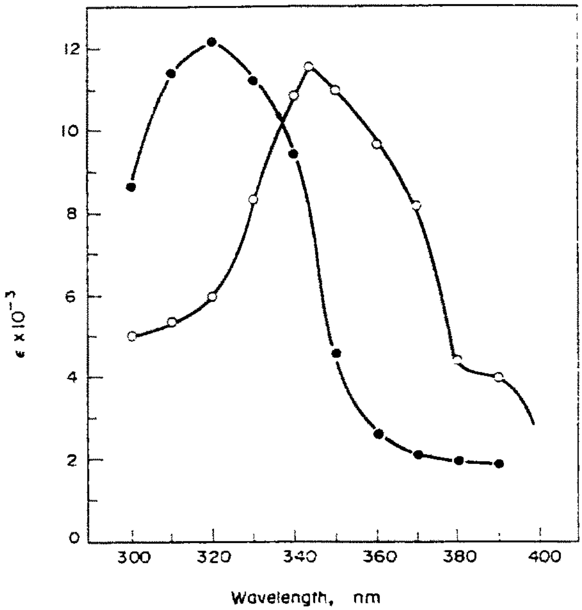


FIG. 1

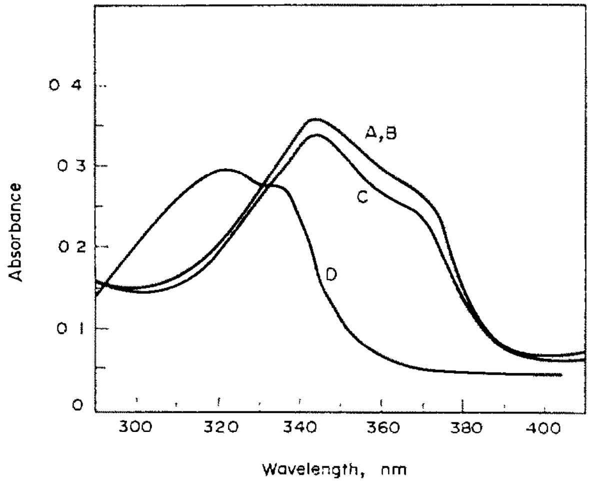

FIG. 2

solution and in glacial acetic acid to give a yellow one. Both solutions absorb at around 340 nm with equal molar absorptivity, indicating that the colour intensity at this wavelength is independent of the acidity.

Effect of standing time. The absorbance of methanolic solutions containing different concentrations (up to 12 μg/ml) of dihydroxy-*peri*-naphthindenone was measured after 1, 30 and 120 min and 24 hr. It was observed that the colour intensity

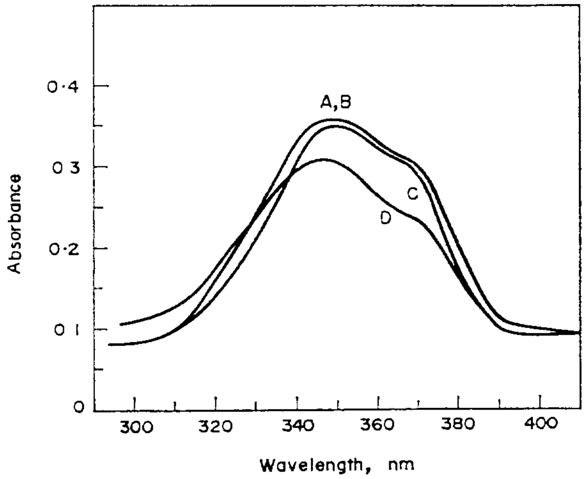

Fig. 3.

remained stable for 30 min, after which fading took place. On standing for 2 hr the intensity decreased by 5–10%. After 24 hr the dihydroxy-*peri*-naphthindenone changed (probably by air-oxidation) to *peri*-naphthindan-2,3,4-trione and the absorption maximum was shifted to 320 nm (Fig. 2). However, the dihydroxy compound was more stable in glacial acetic acid medium and 85% of the colour intensity remained after 24 hr (Fig. 3).

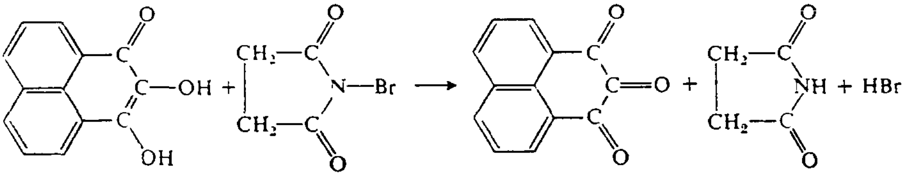
Determination of α-amino-acids. A number of α-amino-acids were analysed for amino-nitrogen content. The results (Table I) show an average recovery of 98·2% and a mean absolute error of ±0·3%. Amino-acids containing thiol groups (*e.g.*, cysteine hydrochloride) give high recoveries probably because of the interference of the thiol group in the reduction reaction.

Table I.—Microdetermination of α-amino-acids by reaction with *peri*-naphthindan-2,3,4-trione hydrate

Sample	Theory	Amino-acid nitrogen, %		
		Spectro-photometric	Titrimetric (iodine)	Titrimetric (*N*-bromosuccinimide)
Glycine	18·65	19·9	18·7	18·7
Phenylalanine	8·48	8·6	8·5	8·5
Glutamic acid monohydrate	8·48	8·4	8·4	8·4
Aspartic acid	10·52	10·2	10·1	10·2
Leucine	10·67	10·3	10·3	10·2
Methionine	9·38	9·2	9·2	9·2
Threonine	11·75	11·3	11·5	11·4
Serine	13·32	12·8	12·7	12·8

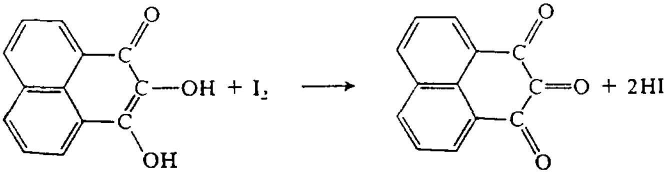
Titrimetric methods

Reaction with N-*bromosuccinimide. N*-Bromosuccinimide quantitatively oxidizes the ene-diol group in dihydroxy-*peri*-naphthindenone to give *peri*-naphthindan-2,3,4-trione. The reaction proceeds according to the equation:



For determining α-amino-acids, the equivalent amount of the dihydroxy compound is separated from the reaction medium by filtration, dissolved in acetic acid and titrated directly with standard *N*-bromosuccinimide solution.

Reaction with iodine. The ene-diol group of dihydroxy-*peri*-naphthindenone reacts with iodine quantitatively according to the equation:



Excess of iodine solution is added to the dihydroxy compound (itself equivalent to the amino-acid) and the iodine remaining after reaction is titrated with sodium thiosulphate.

Determination of α-amino-acids. Many samples of α-amino-acids were analysed by oxidimetric titration of the equivalent amount of dihydroxy-*peri*-naphthindenone obtained in the reaction with the trione. With *N*-bromosuccinimide, the results obtained show an average recovery of 97·8% and a mean absolute error of ±0·3%. With iodine, the mean absolute error is ±0·3%, the average recovery being 98·4% (Table 1).

Zusammenfassung—Mikromethoden zur spektrophotometrischen und oxidimetrischen Bestimmung von α-Aminosäuren werden beschrieben. Sie beruhen auf der Reaktion der Säuren mit *peri*-Naphthindan-2,3,4-trion-Hydrat bei pH 2·5; es entsteht ein roter Niederschlag von Dihydroxy-*peri*-naphthindenon. Das rote Produkt wird gelöst und entweder spektrophotometrisch bei 243 nm oder titrimetrisch durch Reaktion mit Jod oder *N*-Bromsuccinimid bestimmt. Die Ergebnisse der drei Methoden stimmen überein, im Durchschnitt beträgt die Ausbeute 98%.

Résumé—On décrit des microméthodes pour la détermination spectrophotométrique et oxydimétrique des α-amino acides. Elles sont basées sur une réaction des acides avec l'hydrate de *peri*-naphtindan-2,3,4-trione à pH 2,5, donnant un précipité rouge de dihydroxy-*peri*-naphtindéone. Le produit rouge est dissous et mesuré, soit spectrophotométriquement à 243 nm, soit titrimétriquement par réaction avec l'iode ou le N-bromosuccinimde. Les résultats obtenus par les trois méthodes sont concordants, la récupération moyenne étant de 98%.

INDIRECT NEAR-INFRARED SPECTROPHOTOMETRIC DETERMINATION OF SILICATE BY THE 2-AMINO-4-CHLOROBENZENETHIOL METHOD

LOUIS A. TRUDELL* and D. F. BOLTZ
Department of Chemistry, Wayne State University, Detroit, Michigan 48202, U.S.A.

(*Received* 1 *March* 1971. *Accepted* 3 *August* 1971)

Summary—An indirect near-infrared spectrophotometric method for the determination of silicate, based on the absorbance of an equivalent amount of molybdenum-2-amino-4-chlorobenzenethiol complex in chloroform solution, has been developed. The green chloroform solution has an absorbance maximum at 715 nm. The development of the spectrophotometric method for the determination of silicate included a study of a buffer system for the purpose of maintaining the pH within a narrow optimum pH range, complex stability, effect of diverse ions, and conformity to Beer's law. The limit of detection is 0·034 μg of silicon per ml of aqueous heteropoly acid solution.

THE MAJORITY of the spectrophotometric methods for the determination of silicate that have been reported in the literature are based on the heteropoly acid chemistry of silicate. The very sensitive indirect methods involve the partitioning of molybdosilic acid from excess of molybdate by extraction with organic solvents followed by the decomposition of the extracted heteropoly acid and subsequent measurement of the molybdate in the decomposition products. The molybdate, which is equivalent to the amount of silicon present in the original sample, can be measured without further treatment by spectrophotometry[1,2] and by atomic-absorption spectrometry.[2,3] Other methods have been reported in which the molybdate is reacted with thiocyanate,[4] ammonium 1-pyrrolidinecarbodithioate,[5] or hydrogen peroxide[6] and the resulting molybdenum products are measured spectrophotometrically.

The method proposed in this paper differs from all previous spectrophotometric heteropoly acid methods for silicate because it is an indirect near-infrared method. The method is based on the measurement of the absorptivity of the chloroform extract of a green complex that molybdenum forms with 2-amino-4-chlorobenzenethiol hydrochloride.[7] The absorptivity of the molybdenum-2-amino-4-chlorobenzenethiol complex, in chloroform, has been utilized successfully for the indirect determination of phosphorus.[8]

The procedure developed by Kirkbright and Yoe for the formation and extraction of the molybdenum complex and later used for the indirect determination of phosphorus has been improved as a result of the studies associated with the method reported in this paper.

EXPERIMENTAL

Reagents

Standard silicate solution. Dissolve 5·50 g of sodium metasilicate, $Na_2SiO_3{\cdot}9H_2O$, in water and dilute to 1 litre. The pH of this solution is about 11·5. Standardize this solution gravimetrically and use a microburette to transfer sufficient silicate solution to a 1-litre volumetric flask so that on dilution to the mark, the final silicate solution contains 2·0 μg of silicon per ml.

---

* Present address: Division of Mathematics and Science, Macomb County Community College, Warren, Michigan 48093, U.S.A.

Ammonium molybdate solution. Dissolve 25·0 g of ammonium paramolybdate, $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$, in water and dilute to 500 ml.

Dilute ammonia solution. Prepare a 0·25*M* ammonia solution by diluting 17·5 ml of concentrated ammonia solution to 1 litre with water.

Sulphate–bisulphate buffer solution. Dissolve 106·4 g of anhydrous sodium sulphate and 20·68 g of sodium bisulphate, $NaHSO_4\cdot H_2O$, in water and dilute to 1 litre.

2-Amino-4-chlorobenzenethiol hydrochloride solution. Dissolve 0·25 g of 2-amino-4-chlorobenzenethiol hydrochloride in 5·0 ml of 95% ethanol. Prepare the reagent solution fresh every two days.

Extractant mixture. Mix 1 volume of 1-pentanol with 5 volumes of diethyl ether. Prepare the mixture fresh each day.

All aqueous solutions were prepared with reagent grade chemicals and redistilled water. The solutions were stored in paraffin-lined bottles to avoid silica contamination. Reagent-grade organic solvents were used for the extractions that are specified in the procedure.

Procedure

Transfer to a 125-ml separatory funnel a sample containing 2–8 μg of silicon in the form of soluble silicate. Add 1·0 ml of hydrochloric acid (1 + 1) and dilute the acidified sample solution to 45 ml with redistilled water. Add 5·0 ml of the ammonium molybdate solution, mix, and allow the solution to stand for 20 min to ensure complete formation of the silicomolybdic acid. The pH of this solution should be about 1·4.

Add 30 ml of hydrochloric acid (1 + 1) and 20 ml of 5:1 ethyl ether–1-pentanol extractant mixture. Shake the separatory funnel vigorously on a mechanical shaker for 1 min. Rinse the stopper with 1–2 ml of fresh extractant mixture and collect the rinsings in the separatory funnel. Allow the layers to separate for 3 min, then withdraw the lower aqueous layer and discard it. Wash the organic phase twice, each time with 25 ml of hydrochloric acid.(1 + 10). Each washing consists of shaking the organic phase with the wash solution for 15 sec, allowing the two phases to separate, and withdrawing and discarding the lower aqueous phase. After the second wash is completed, rinse the funnel tip with distilled water.

Add 20 ml of 0·25*M* ammonia to the funnel and shake vigorously for 30 sec. After the layers have separated, carefully transfer the lower aqueous solution containing the decomposition products of silicomolybdic acid to a 100-ml volumetric flask. Rinse the funnel and funnel stopper several times with a total of 20–30 ml of distilled water and add the rinsings to the volumetric flask. Acidify the flask contents with 4·0 ml of hydrochloric acid solution (1 + 10). Add 25 ml of the sulphate–bisulphate buffer solution, dilute to the mark with distilled water, and mix well. The pH of this solution should be between 1·9 and 2·3.

Transfer a 25·00-ml aliquot of the buffered molybdate solution to a clean 125-ml separatory funnel that has a cotton plug inserted into its tip. Numerous samples may be simultaneously treated up to this point of the procedure and the aliquots of the buffered molybdate solutions may be allowed to stand in their respective separatory funnels until they are used to complete the procedure that follows.

Add 0·25 ml of the ethanolic reagent solution, swirl the funnel to mix its contents, and allow the solution to stand for 15–60 min. Add 10·00 ml of chloroform, start a mechanical timer, and shake the funnel vigorously on a mechanical shaker for 1 min. Allow the phases to separate for a few sec, then rinse a 10-mm silica cell with small portions of the chloroform extract that have been drained through the cotton plug. Finally, fill the cell with the green chloroform extract and exactly 3 min after the chloroform extraction step was begun, place the cell in the spectrophotometer and quickly measure the absorbance of the extract at 715 nm with chloroform in the reference cell. Correct for the absorbance of a reagent blank extract. Refer the corrected absorbance to a standard calibration graph

So that the analyst may use his time more efficiently, the following sequence of steps is recommended for the completion of the determination of a series of sample solutions: (1) add the ethanolic reagent solution to three of the separatory funnels containing 25·00-ml aliquots of the buffered molybdate solution; (2) after 15 min, add the ethanolic reagent solution to three other aliquots of the buffered molybdate solutions; (3) complete the extraction and measurement of each of the three solutions prepared in step (1) (these operations will require a total of 12–15 min); (4) add the ethanolic reagent solution to three more aliquots of buffered molybdate solutions; (5) complete the extraction and measurement of each of the three solutions prepared in step (2). Continue the sequence of steps until all molybdate aliquots have been taken completely through the recommended procedure.

RESULTS AND DISCUSSION

Absorption spectra

Figure 1 shows the near-infrared absorption spectra for the chloroform extracts of the molybdenum-2-amino-4-chlorobenzenethiol complex. The amount of the complex in chloroform solution is equivalent to a specific amount of silicon in the original

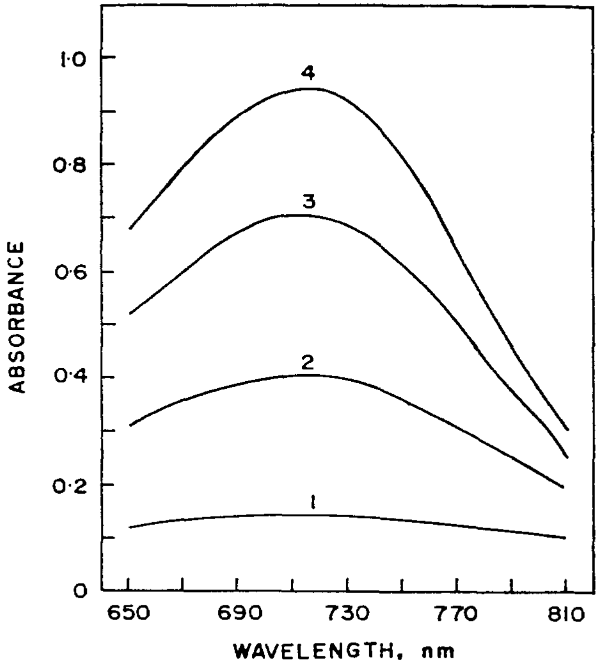

FIG. 1. Characteristic near-infrared spectra of molybdenum-2-amino-4-chlorobenzenethiol in chloroform *vs.* chloroform.
(1) Reagent blank equivalent in chloroform,
(2) 0·10 ppm of silicon equivalent in chloroform,
(3) 0·20 ppm of silicon equivalent in chloroform,
(4) 0·30 ppm of silicon equivalent in chloroform.

sample. The chloroform extract of the reagent blank exhibits significant absorbance and must be subtracted from the absorbances obtained for the silicate samples. The organic reagent used to form the molybdenum complex does not absorb in the spectral region 500–1000 nm.

Effects of solution variables

Silicon concentration. Conformity to Beer's law was observed for the molybdenum equivalent to 0·05–0·20 μg of silicon per ml of chloroform solution, *i.e.*, 2–8 μg of silicon in the original 50 ml of silocomolybdic acid solution. The optimum concentration range is equivalent to 0·075–0·175 μg of silicon per ml of chloroform, *i.e.* 3–7 μg of silicon in the original 50 ml of molybdosilicic acid solution.

The various silicon concentrations that have been or will be mentioned in this paper should be clarified and delineated. The basis of possible confusion lies in the fact that there are four solutions of importance, *viz.*, (1) the original 50 ml of aqueous silicomolybdic acid solution, (2) the 100 ml of buffered molybdate solution, (3) the 25·00 ml aliquot of the buffered molybdate solution that is taken for the molybdenum determination according to the recommended procedure, and (4) the 10·00 ml chloroform solution of the molybdenum complex formed from 25% of the total molybdenum recovered from the silicomolybdic acid. Table I indicates the equivalent silicon concentration in each of these solutions when a sample containing 4·0 μg of silicon is taken for analysis.

TABLE I.—EQUIVALENT SILICON CONCENTRATION IN VARIOUS PREPARED SOLUTIONS

Solution	Total amount of Si, μg	Equiv. Si concn., μg/ml
Original 50-ml silicomolybdic acid solution	4·0	0·080
100-ml buffered molybdate solution	4·0	0·040
25·00-ml aliquot of buffered molybdate solution	1·0	0·040
10·00-ml chloroform extract from 25% of recovered molybdate	1·0*	0·10†

* Theoretical amount of silicon extracted by chloroform.

† Theoretical concentration of silicon extracted by chloroform.

Conditions for the formation and extraction of molybdosilic acid. The effects of acidity and molybdate concentration on the formation of silicomolybdic acid,[1,2,9] the effect of the acidity on the extent of extraction[1,2] and the choice of the solvent system used for the extraction[1] have been previously investigated. The optimum conditions for the most efficient formation and extraction of the heteropoly acid were chosen for this study.

pH of the molybdate solution. Previous studies have shown that the optimum pH range for formation of the molybdenum-2-amino-4-chlorobenzenethiol complex is 1·9–3·3 whereas the optimum pH range for chloroform extraction of the complex is 1–2·3,[7] The procedure that has been used for the pH adjustment of the molybdate solution[7,8] was found to be quite unsatisfactory because of the amount of time required to complete the acidity adjustment. The difficulty that was encountered was to keep within the narrow optimum pH range and this was probably due to the fact that only 3·0 ml of a Clark and Lubs' buffer solution (0·006*M* in HCl and 0·05*M* in KCl) was used and it provided little, if any, buffer capacity. The tedium and inconvenience associated with having to carefully monitor the pH adjustment of the molybdate solutions with a pH-meter indicated the need for a more suitable means of adjusting and maintaining the pH of the solution. The sulphate–bisulphate buffer system, studied by Jeffreys and Swift,[10] was adapted for use in the acidity adjustment because other anions and organic reagents that are commonly used in buffer solutions for the pH 2 region are known to interfere with this method of molybdenum determination.

Several studies were made concerning the acidification step. One study showed that the final 100-ml molybdate solution had a pH of about 2·1 when 20·0 ml of the dilute ammonia solution were used to strip the molybdate from silicomolybdic acid and when the ammoniacal solution was treated with 4·0 ml and 25·0 ml of hydrochloric acid (1 + 10) and sulphate–bisulphate buffer solution, respectively. Another study showed that these volumes can be significantly varied with little effect on the resulting pH of the final solution. Table II summarizes the changes in pH observed corresponding to the indicated changes in the volumes of the individual solutions that were involved in the acidity adjustment. As a consequence of this study, it was predicted that the volumes of the dilute ammonia solution and the buffer solution could be measured accurately enough in a 25-ml graduated cylinder, and that of the hydrochloric acid solution with a measuring pipette, and the pH of the final buffered

TABLE II.—EFFECT OF CHANGE IN VOLUME OF SOLUTIONS INVOLVED IN THE ACIDITY ADJUSTMENT OF THE MOLYBDATE BACK-EXTRACT

Solution	Recommended volume, *ml*	Change in volume, *ml*	Average pH change
0·25*M* NH_3	20·0	±1·0	±0·05
HCl (1 + 10)	4·0	±0·5	±0·05
SO_4^{-2}–HSO_4^- buffer	25·0	±1·0	±0·11

molybdate solution would be within the limits necessary for optimum formation and extraction of the molybdenum complex. These predictions were tested by randomly selecting 12 molybdate solutions as they, among others, were prepared for use during a period of several days. The pH of each of these 12 solutions was measured with a pH-meter. The results of this random pH study are summarized in Table III and they demonstrate the effectiveness of the sulphate–bisulphate system for maintaining the molybdate solutions within the desired pH range of 1·9–2·3.

Extraction time for the molybdenum complex. A 1-min shaking period is sufficient for the complete extraction of the molybdenum complex.

Stability of the molybdenum complex. The green molybdenum-2-amino-4-chlorobenzenethiol complex in chloroform undergoes slow photodecomposition in room light and rapid photodecomposition when subjected to the radiation passing through the sample cell in the Cary spectrophotometer used. The rate of absorbance decrease is about 0·3% per min when the chloroform extract is allowed to stand in room light and 3·6% per min when the sample cell remains in the cell compartment of an instrument where the radiation emitted by the source passes continually through the cell. These observed rates of absorbance decrease do not agree with those reported for the determination of molybdenum with this reagent, *viz.*, a decrease of only 6% after 4 hr and 9% after 6 hr.[7] It should be mentioned that the larger rate of absorbance decrease cannot be attributed to the use of the sulphate–bisulphate buffer solution, because the instability of the complex was also observed when the molybdenum determinations were performed exactly as recommended in the original method.

It is postulated that the lower rate of absorbance decrease reported in the original method for molybdenum was because the sample was kept in relative darkness or in the cell compartment of the Beckman DK-2 spectrophotometer. The optical system of DK-2 spectrophotometer is different from that of the Cary 14 spectrophotometer when the latter is in the near-infrared mode of operation. In the former instrument, the radiation incident to the sample cell is monochromatic whereas the source radiation remains polychromatic in the Cary 14 spectrophotometer until after it has passed through the sample cell and then reaches the monochromator. Therefore, the flux reaching the sample cell and which is responsible for the photodecomposition of the green molybdenum complex is considerably less in the Beckman DK-2 spectrophotometer than in either room light or the Cary 14 spectrophotometer.

TABLE III.—SUMMARY OF pH VARIATIONS OF RANDOMLY-SELECTED BUFFERED MOLYBDATE SOLUTIONS

Number of solutions measured	12
pH range	2·07–2·11
Average pH	2·08
Average deviation	0·01

TABLE IV.—INTERFERING IONS

Ion	Added	Amount added, *μg of ion*	Relative error, %	Permissible amount*, *ppm*
Al^{3+}	$Al(ClO_4)_3$	5000	−8·0	50
Fe^{3+}	$FeNH_4(SO_4)_2$	250	−7·9	1
Pb^{2+}	$Pb(C_2H_3O_2)_2$	2500	−7·9	25
Zn^{2+}	$Zn(ClO_4)_2$	5000	−8·1	50
AsO_2^-	$NaAsO_2$	5000	+9·3	25
AsO_4^{3-}	Na_2HAsO_4	2500	+36	10
$Cr_2O_7^{2-}$	$K_2Cr_2O_7$	250	−7·9	1
F^-	KF	500	+16	5
NO_2^-	KNO_2	50	−13	0
PO_4^{3-}	KH_2PO_4	1250	+7·1	10
VO_3^-	NH_4VO_3	250	−14	1

* Causes less than 5·0 per cent relative error in determination of 4·0 μg of silicon per 50 ml of aqueous heteropoly acid solution.

Effect of diverse ions. The effect of 5000 μg of diverse ions in solutions containing 4·0 μg of silicon was investigated. The effect of larger amounts was not investigated. The following ions did not interfere with the determination of silicon: ammonium, calcium, chromium(III), cobalt(II), copper(II), magnesium, manganese(II), nickel, potassium, silver, sodium, acetate, bromide, chloride, molybdate, nitrate, oxalate, perchlorate, permanganate, sulphate and tungstate. The permissible amounts of the interfering ions are listed in Table IV. No attempt was made to avoid the interferences caused by these ions.

Precision

An estimate of the precision of the recommended procedure was obtained from the results of 6 samples, each containing 4·0 μg of silicon in the original 50 ml of aqueous silicomolybdic acid solution. The mean absorbance of the molybdenum complex in chloroform obtained from these samples was 0·698 when measured at 715 nm against chloroform. The standard deviation was 0·017 and the relative standard deviation 2·4%. The limit of detection was ascertained from a series of six determinations of reagent blank solutions. A mean absorbance value of 0·145 and a standard deviation of 0·024 were obtained. The limit of detection, when based on the equations cited by Kaiser,[11] is equivalent to about 0·043 μg of silicon per ml of chloroform or about 1·7 μg of silicon in the original 50-ml aqueous silicomolybdic acid solution (0·034 ppm of silicon).

Sensitivity

The effective molar absorptivity, based on the original 50 ml of aqueous silicomolybdic acid solution, is $1{\cdot}97 \times 10^4$ $l.mole^{-1}.mm^{-1}$ at 715 nm. The molar absorptivity is $1{\cdot}58 \times 10^4$ $l.mole^{-1}.mm^{-1}$ when based on the equivalent concentration of silicon in the chloroform extract.

Zusammenfassung—Zur Bestimmung von Silikat wurde eine indirekte spektrophotometrische Methode im nahen Infrarot entwickelt. Sie beruht auf der Messung der Extinktion einer äquivalenten Menge des Komplexes aus Molybdän und 2-Amino-4-chlorthiophenol in Chloroformlösung. Die grüne Chloroformlösung hat ein Absorptionsmaximum bie 715 nm. Bei der Entwicklung des spektrophotometrischen Verfahrens zur Silikatbestimmung wurde auch ein Puffersystem untersucht, das den pH in einem engen optimalen Bereich konstant hält, sowie die Stabilität des Komplexes, der Einfluß verschiedener Ionen und die Gültigkeit des Beerschen Gesetzes. Die Nachweisgrenze beträgt 0,034 μg Silicium pro ml wäßriger Heteropolysäurelösung.

Résumé—On a élaboré une méthode spectrophotométrique indirecte dans le proche infra-rouge pour le dosage du silicate, basée sur l'absorption d'une quantité équivalente du complexe molybdene-2-amino 4-chlorothiophénol en solution chloroformique. La solution chloroformique verte a un maximum d'absorption à 715 nm. Le développement de la méthode spectrophotométrique pour le dosage du silicate comprend une étude d'un systéme tampon dans le but de maintenir le pH dans un domaine optimal étroit de pH, de la stabilité du système, de l'influence de divers ions et de la conformité à la loi de Beer. La limite de détection est de 0,034 μg de silicium par ml de solution aqueuse d'hétéropolyacide.

STUDIES ON POTASSIUM CHLORATE AS A PRIMARY OXIDIMETRIC REAGENT

C. RADHAKRISHNA MURTY and G. GOPALA RAO
Department of Chemistry, Andhra University, Waltair, India

(*Received* 30 *October* 1970. *Revised* 1 *July* 1971. *Accepted* 23 *August* 1971)

Summary—Conditions have been established for the use of potassium chlorate as a primary oxidizing agent in the direct titration of vanadium(III), tin(II) and titanium(III) with visual or potentiometric end-points.

POTASSIUM CHLORATE is available in high purity, some commercial grades assaying as high as 99·7%, but has found little use as a titrimetric reagent. It may function in acid solution either as a 5- or a 6-electron oxidant, the redox potentials being 1·47 and 1·45 V respectively, but is relatively inert as an oxidant in dilute acid solution. The rate of reaction of potassium chlorate even with substances of very low redox potentials such as tin(II) and titanium(III) is very low. Potassium chlorate furnishes an excellent example of a reagent the practical function of which as an oxidant is governed more by kinetic considerations than by thermodynamics. We have now found conditions under which potassium chlorate can be used as a convenient oxidant for direct titrimetric determination of vanadium(III), tin(II) and titanium(III).

Potassium iodate is kinetically a more facile oxidant than bromate and chlorate, although thermodynamically the order of reactivity should be bromate > chlorate > iodate, as indicated by the redox potentials.[1] The kinetic order of reactivity, iodate > bromate > chlorate is exemplified by the reaction with iodide. The speed of the reaction increases with increasing hydrogen ion concentration. Iodate ion reacts rapidly and completely at a much lower hydrogen concentration than does bromate. According to Kolthoff and Hume,[2] at pH 4–5 the iodate–iodide reaction is complete whereas the bromate reaction is negligibly slow and iodate can be determined in the presence of bromate at pH 4. The bromate reaction requires a hydrochloric acid concentration of at least 0·5*M*, though catalysts such as ammonium molybdate can be used at lower acidity. According to Ferrey[3] the chlorate reaction is rapid only when the hydrochloric acid concentration is 7·5*M*, but under these conditions iodide is oxidized by aerial oxygen anyway so the reaction is not useful for analytical purposes.

More recent kinetic studies confirm these findings.[4] The variation in the rate of oxidation with the atomic number of the halogen is presumably related to the strength of the oxygen–halogen bond and the ability of the halogen atom to achieve an increased co-ordination number in the transition state. The halate oxidation rates show a similarity to the rates of halate oxygen-exchange reactions, iodate giving rapid exchange with water at room temperature even in neutral solution, whereas bromate and chlorate exchange slowly.[5] The rate of oxygen exchange of bromate and chlorate with water is dependent on the square of the hydrogen ion concentration, and is faster in D_2O than in H_2O. This suggests that protonation occurs rapidly and reversibly before the rate-determining step.

$$2H^+ + ClO_3^- \rightleftharpoons H_2ClO_3^+$$

$$X^- + H_2ClO_3^+ \rightarrow \text{products.}$$

The rates of oxidations with chlorate, bromate and iodate are largely dependent on the hydrogen ion concentration of the medium, showing either first-order or second-order dependence. The reaction of chlorate with a halide follows the rate law

$$\frac{-d[X^-]}{dt} = k[ClO_3^-][X^-][H^+]^2.$$

The protons are used in production of water from the halate, and this may occur by an S_N1 mechanism such as

$$ClO_3^- + H^+ \rightleftharpoons HOClO_2$$

$$HOClO_2 + H^+ \rightarrow ClO_2^+ + H_2O$$

$$ClO_2^+ + X^- \rightarrow XClO_2$$

or an S_N2 mechanism such as

$$ClO_3^- + 2H^+ \rightleftharpoons H_2OClO_2^+$$

$$H_2OClO_2^+ + X^- \rightarrow XClO_2 + H_2O.$$

It appears that on the addition of hydrogen ions the oxy-anions are converted into less stable forms which can easily react with other chemical entities. Another fact of importance to the rates of reactions involving oxy-anions is the oxidation state of the central atom. The rates of replacement reactions for a lower oxidation state are faster than for a higher oxidation state. Thus the rates of perchlorate reactions in aqueous solution are extremely slow, those of hypochlorite very rapid, and those of chlorite and chlorate are intermediate.

Taking into account these theoretical considerations, we have been able to establish conditions under which potassium chlorate reacts very rapidly with vanadium(III), tin(II) and titanium(III). The reactions of chlorate with vanadium(III), tin(II) and titanium(III) become fast enough for titration purposes at very high mineral acid concentrations; under the prescribed conditions the reactions have been found to be stoichiometric according to the equation:

$$ClO_3^- + 6H^+ + 6e^- \rightarrow Cl^- + 3H_2O$$

EXPERIMENTAL

Solutions

Potassium chlorate, 0·1*N*. Prepared from *pro analysi* reagent (Merck) dried at 100°; standardized as described by Vogel.[6]

Vanadium(III), 0·1*N*. Prepared by cathodic reduction of 0·1*N* sodium vanadate solution in 0·5*N* sulphuric acid.[7] Kept in a reservoir fitted with an automatic burette, and stored under carbon dioxide. The solution contains mostly vanadium(III) and a little vanadium(IV) and is standardized according to Murty and Rao.[8]

Tin(II) chloride and titanium(III) chloride, 0·1*N*. Prepared in hydrochloric acid, stored and standardized by the usual methods.

Titration of vanadium(III)

Preliminary studies showed that only 5–7*M* hydrochloric acid is a suitable medium for the potentiometric titration, but the potential requires 5 min to stabilize, and the end-point inflection is poor. However, addition of 0·3 ml of 0·1*M* iron(III) sulphate in a titration volume of 50 ml gave not only potential stabilization within 1 min, but also gave a good inflection in the titration curve. Phosphoric acid, osmium tetroxide and potassium iodide did not have this beneficial effect. A carbon dioxide atmosphere was used, owing to the instability of vanadium(III) solutions in air. Seven titrations gave a value of 6·01 ± 0·02 moles of vanadium(III) oxidized per mole of potassium chlorate used, confirming the stoichiometry.

Procedure

Take 27–31 ml of concentrated hydrochloric acid and 15–11 ml of distilled water in a 150-ml Pyrex titration cell so as to keep the overall acidity 6–7*M* on final dilution to 50–60 ml. The cell is fitted with a 5-holed rubber stopper accommodating the platinum electrode, porous salt bridge, microburette, and inlet and outlet tubes for carbon dioxide. A thick platinum wire is used as indicator electrode and a saturated calomel electrode as reference. Before the titration pass carbon dioxide through the mixture for 5–10 min to expel dissolved oxygen. Add a 3–6 ml portion of vanadium(III) solution to the titration vessel and pass carbon dioxide while the mixture is stirred by a magnetic stirrer Add 0·3 ml of 0·1*M* iron(III) sulphate. Titrate with 0·1*N* potassium chlorate, noting the potentials with a wait of 1 min after each addition of the titrant. The potential jump at the equivalence point is 200–270 mV per 0·04 ml of 0·1*N* potassium chlorate. Some representative results are presented in Table I

TABLE I.—TITRATION OF VANADIUM(III) WITH POTASSIUM CHLORATE

Condition	Vanadium(III), *mmole*	
	Taken	Found
Potentiometric,	0·2418	0·2424
6*M* HCl,	0·3650	0·3660
inert atmosphere	0·5024	0·5008
	0·5244	0·5230
Indicator	0·5352	0·5337
Methyl Orange,	0·5588	0·5571
6*M* HCl,		
inert atmosphere	0·5816	0·5840
	0·2876	0·2888

Visual titration

Methyl Orange can be used as redox indicator for this titration. Ferroin, diphenylbenzidine, diphenylaminesulphonate, Methyl Red and other dyes did not prove useful. More catalyst is necessary, at least 1 ml of 0·1*M* iron(III) sulphate for 50–60 ml of titration mixture. With a smaller amount of catalyst the indicator is bleached before the equivalence point.

Take 27 ml of concentrated hydrochloric acid, 18 ml of distilled water, 1 ml of 0·1*M* iron(III) and 3 drops of 0·1% Methyl Orange solution in the titration cell, and pass carbon dioxide through for 5–10 min. Then add the vanadium(III), pass carbon dioxide while the mixture is stirred magnetically, and titrate with 0·1*N* potassium chlorate, rapidly in the beginning and slowly towards the equivalence point, where 20–25 sec should be allowed between additions of a drop of the reagent. The end-point is denoted by the disappearance of the red colour. The indicator correction is 0·06 ml to be deducted. The average relative error is ±0·4%.

Titration of tin(II)

Kulwarskaja[3] determined tin(II) with chlorate, but had to titrate the solution at boiling temperature. We titrate tin(II) potentiometrically with potassium chlorate at room temperature in hydrochloric, sulphuric or phosphoric acid media. Conditions have also been found for the visual titration, using Phenosafranine, Neutral Red, Methylene Blue and Naphthol Blue Black as indicators in hydrochloric acid medium, and ferroin as indicator in sulphuric acid medium. None of these indicators functions in phosphoric acid medium.

Potassium chlorate reacts with tin(II) rapidly when the acid concentration is >5*M* for hydrochloric acid, >6*M* for sulphuric acid, and >12*M* for phosphoric acid, but the stabilization of potentials is slow, especially in phosphoric acid, in the vicinity of the end-point (4–6 min in HCl, 3–6 min in H_2SO_4, 4–6 min in initial stages and 10–12 min in final stages in H_3PO_4). The potential breaks are ~500 mV/0·04 ml of titrant in HCl and H_2SO_4 media but only ~350 mV in H_3PO_4. The average relative error is ±0·2% in hydrochloric acid medium and ±0·4% in the other two media. Some representative results are presented in Table II.

Satisfactory visual titrations have been made in an inert atmosphere, with Methylene Blue or

TABLE II.—TITRATION OF TIN(II) WITH POTASSIUM CHLORATE

Conditions	Tin(II), *mmole*	
	Taken	Found
Potentiometric, 5–6*M* HCl	0·2345	0·2340
	0·2535	0·2530
	0·2836	0·2842
	0·3325	0·3335
Indicator Methylene Blue, 6–7*M* HCl	0·2468	0·2476
	0·3147	0·3139
	0·4055	0·4043
	0·5454	0·5470
Indicator Phenosafranine, 6–7*M* HCl	0·2104	0·2098
	0·3231	0·3243
	0·3766	0·3750
	0·4566	0·4578

Phenosafranine in 6–7*M* hydrochloric acid medium, Neutral Red in 7–8*M* acid and Naphthol Blue Black in 6–8*M* hydrochloric acid. It is within these limits of acidity that both the reduction of the dye by stannous chloride and the reoxidation of the leuco dye are fast. The indicator corrections are negligible. The average relative error is ±0·3%. Typical results are presented in Table II.

None of these indicators functions satisfactorily in sulphuric acid medium. Only ferroin works satisfactorily, although it does not do so in hydrochloric acid medium. It is used in 6–7*M* sulphuric acid, with the addition of 10 ml of phosphoric acid for 50 ml of titration mixture. The indicator correction is 0·07 ml for 2 drops of 0·01*M* ferroin.

Titration of titanium(III)

Titanium(III) can be titrated with potassium chlorate solution at room temperature, using Neutral Red or Phenosafranine as indicator, in 6–8*M* hydrochloric acid. The average relative error is ±0·3%. Some representative results are presented in Table III.

TABLE III.—TITRATION OF TITANIUM(III) WITH POTASSIUM CHLORATE

A SPECTROPHOTOMETRIC METHOD FOR THE DETERMINATION OF COPPER IONS AND ITS APPLICATION TO THE CO-PRECIPITATION OF COPPER IN THE CRYSTALLIZATION OF SODIUM CHLORIDE*

A. GLASNER, S. SARIG, D. WEISS and M. ZIDON
Department of Inorganic and Analytical Chemistry, The Hebrew University of Jerusalem,
Jerusalem, Israel

(*Received* 29 *March* 1971. *Accepted* 27 *June* 1971)

Summary—The molar absorptivity of the cyanide complexes $[Cu(CN)_3]^{2-}$ and $[Cu(CN)_4]^{3-}$, at their isosbestic wavelength (235 nm) is $1{\cdot}13 \times 10^3$ l.mole^{-1}.mm^{-1} and can be used for the quantitative determination of micro-amounts of copper in the ppm range. The determination of 1–10 μg of Cu^{2+} per g of NaCl, or 0·25–2·5 μg/ml, is described in detail. The co-precipitation of copper with NaCl crystallizing from aqueous solutions has been studied by this method.

CUPRIC CHLORIDE is readily converted, on addition of cyanide, into the cuprous cyanide complex even in a concentrated alkali metal halide solution.[1] The cuprous cyanides have a distinct absorption in the 225–240 nm region which can serve for the identification and quantitative determination of micro-amounts of copper. However, the shape and position of the absorption band are affected by the concentration of copper, by the concentration of cyanide, and by the ratio between them.

Glasner and Avinur[1] have found that in order to obtain a well-developed narrow band with its peak at about 235 nm it is necessary to add cyanide in some excess to the concentrated alkali metal chloride solutions containing the copper(II) ions. This excess was assumed to be at least 20 moles of cyanide per mole of copper. However, the quantitative determination of copper, especially at very low concentrations in the ppm range, was not satisfactory.

Baxendale and Westcott[2] found that a $6 \times 10^{-6}M$ solution of $K_3Cu(CN)_4$ shows an absorption band with a peak at 234 nm, which they attributed to the $Cu(CN)_2^-$ species. This peak shifted to longer wavelengths on addition of either free cyanide or sodium hydroxide, the shift being ascribed to the formation of $Cu(CN)_3^{2-}$; the four-co-ordinated complex may not be attainable at the low concentrations mentioned. Kappenstein and Hugel[3] convincingly proved that both $Cu(CN)_4^{3-}$ and $Cu(CN)_3^{2-}$ absorb strongly in the 225–240 nm region, having an isosbestic point at 235 nm. They determined the stability constant of the tetracyano complex

$$CN^- + Cu(CN)_3^{2-} \rightleftharpoons Cu(CN)_4^{3-} \qquad (1)$$

in *ca.* $2M$ sodium perchlorate solution.

This constant (418 ± 12 l.mole^{-1} at 25°) was found to be valid for solutions ranging from $0{\cdot}2M$ to $10^{-4}M$ copper, when the mole fraction of $Cu(CN)_3^{2-}$ varied from 0·1 to 0·96 respectively, and the amount of other species present was negligible. They excluded from their study solutions of lower copper concentration, in the range $1\text{–}5 \times 10^{-5}M$, in which the calculated mole fraction of $Cu(CN)_3^{2-}$ would be above 0·96, and its dissociation to a lower co-ordinated complex most probable.

---

* This work was supported by an NBS Grant No. (G)-86

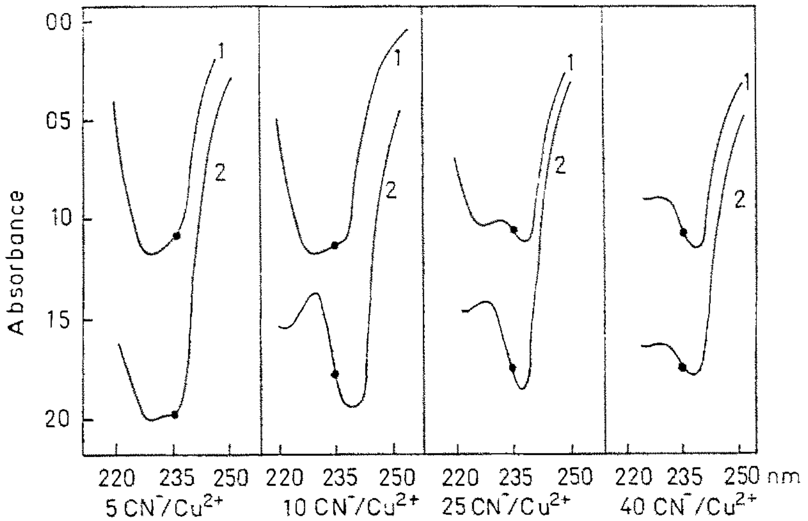

FIG. 1.—The absorption spectra of copper cyanide solutions of varying CN^-/Cu^{2+} ratio. Series 1 contained 1·5 μg Cu^{2+}/ml; series 2 contained 2·5 μg Cu^{2+}/ml.

As the range of copper concentrations of analytical interest to us coincided with the range excluded by Kappenstein and Hugel,[3] the prime aim of this work was to determine the excess of cyanide needed in order to keep the mole fraction of $Cu(CN)_3^{2-}$ sufficiently low to prevent further dissociation which would affect the value of the molar absorptivity at the isosbestic point.

A number of different values of the stability constant required for such a computation can be found in the literature;[2–6] virtually all of them are "concentration constants" determined at different ionic strengths. The reported values vary within an order of magnitude.[3] Experimental determination of the cyanide excess needed was therefore indicated.

EXPERIMENTAL

The test solutions contained 2·5 g of alkali metal halide (J. T. Baker, "Baker-Analyzed") per 10 ml of solution, and appropriate amounts of copper [1–10 μg of copper(II) per g of alkali metal halide]. Potassium cyanide solution was added in the desired excess before the flask was filled to the mark. A pure alkali metal halide solution of identical concentration, but without added copper and cyanide, served as the reference. The copper stock solution was prepared from $CuSO_4.5H_2O$ (J. T. Baker, "Baker-Analyzed") and its copper content was ascertained by electrolysis.

In order to determine the effect of other cations present, the chlorides of Zn^{2+}, Mn^{2+}, Cd^{2+}, Fe^{2+}, Ni^{2+}, Fe^{3+} and Au^{3+} were used.

The analytical method was applied to a series of sodium chloride samples crystallized by evaporation at 65° from solutions containing 490 or 980 μg of copper(II) per g of sodium chloride.

RESULTS

Figure 1 shows the absorption spectra of two series of copper solutions and their variation with the mole ratio CN^-/Cu^{2+}. All the solutions contained 0·25 g of sodium chloride and 1·5 or 2·5 μg of copper per ml, and 40-mm cells were used. With low CN^-/Cu^{2+} ratios the absorption bands are broad and ill-defined. As this ratio increases, a well-developed band, with a peak at 237 nm, reveals itself and the absorbance at 235 nm, the isosbestic point, is the same for equal copper concentrations, irrespective of the cyanide excess. Also, the greater the concentration of the copper

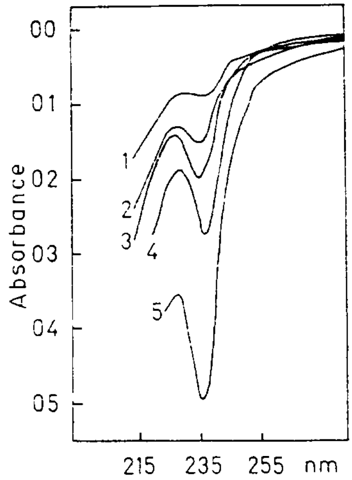

FIG. 2.—Absorption spectra of copper cyanide in NaCl solutions. Composition of solutions 1–5 was as given in Table I.

the smaller the ratio at which this constant value is attained; a tenfold molar ratio was sufficient for the solutions containing 2·5 μg of copper per ml.

Similarly, it has been established that solutions containing 10 μg of cyanide and 0·25 μg of copper per ml (*i.e.* 1 ppm of copper in the sodium chloride), will give the right band shape for a quantitative determination. This is equal to a mole ratio CN^-/Cu^{2+} of nearly 100, and hence 10 μg of cyanide were added per ml of test solution in the following experiments. The spectra obtained with varying amounts of copper (0·25–2·5 μg/ml) added to sodium chloride solutions (2·5 g/10 ml, weighed out separately) are recorded in Fig. 2 (10-mm cells were used). The shape of the absorption curves is satisfactory, but a plot of the absorbance values does not extrapolate to the origin, indicating the presence of 0·7 μg of Cu^{2+} per g of sodium chloride on the average.

As the copper content of the sodium chloride may vary from sample to sample, even if taken from the same bottle,[7] the series of measurements was repeated with solutions of similar composition, but the sodium or potassium chloride was taken by pipette from a single stock solution. The results are recorded in Table I.

Assuming that both salts were initially contaminated by a small amount of copper, we calculate the molar absorptivity as $1{\cdot}13 \times 10^3$ l.mole^{-1}.mm^{-1}, in close agreement

TABLE I.—THE ABSORBANCE OF COPPER CYANIDE SOLUTIONS AT THE ISOSBESTIC POINT, 235 nm

Cu^{2+}, *μg/ml*	Absorbance at 235 nm NaCl	Absorbance at 235 nm KCl
0·25	0·050	0·050

1·00	0·190	0·180
1·50	0·270	0·270
2·50	0·450	0·450

Cell path = 10 mm. All solutions contained 0·25 g of alkali metal chloride and 10 μg of cyanide per ml.

TABLE II.—THE ABSORBANCE OF 2·69 μg OF Cu^{2+}/ml, CYANIDE COMPLEXES IN NaCl SOLUTION, IN THE PRESENCE OF VARIOUS CATIONS, MEASURED AT 235 nm. EXPECTED ABSORBANCE VALUE: 0·483

Foreign cation	Au^{3+}	Mn^{2+}	Zn^{2+}	Cd^{2+}	Ni^{2+}	Fe^{3+}
Absorbance	0·24	0·470	0·515	0·495	0·450	0·477
Deviation, %	−50	−2·7	+6·6	+2·5	−6·8	−1·2

with the values recorded in the literature[1–3] for different salt solutions and ionic strengths. Further, we note that the samples of chlorides used contain only about 0·1 ppm copper.

The influence of a number of cations on the estimation of copper by the proposed method was also investigated. Table II gives some of the absorbance readings of a solution containing 2·69 μg of copper and 0·25 g of sodium chloride per ml, in the presence of 10 μg of the ions listed, or 2·5 μg per ml in the case of nickel and iron(III). The expected absorbance of the pure solutions, without the foreign ions, is 0·483. It may be observed that only gold ions interfere seriously. The spectrum indicated the formation of the $[Au(CN)_2]^-$ complex, which consumed a good part of the excess of cyanide ions required for the formation of the $[Cu(CN)_3]^{2-}$ species. Adding a larger surplus of cyanide ions does not help, as the absorption bands overlap. This measure was adopted in the case of the nickel and iron(III) ions; the latter solutions contained 20 μg of cyanide per ml. Under these conditions both nickel and copper could be determined simultaneously. Small amounts of iron(II) ions appear to be totally oxidized to iron(III), probably by dissolved oxygen.

The deviations, indicated in Table II, from the expected value are due to the sum of the experimental errors as well as to the inhomogeneous distribution of the copper ions in the sodium chloride sample. The presence of some copper ions in the zinc and cadmium chlorides used is also suspected.

Several potassium and sodium chloride products were analysed for copper content by the proposed spectrophotometric method; 2 μg of Cu^{2+} per g of salt were initially added to each of the test solutions, in order to improve the precision of the measurements. Copper may be determined in other "pure" salts in a similar manner, unless the solution absorbs light appreciably in the spectral range 230–240 nm. For example, the method was not applicable to bromide solutions.

Our attempts to determine copper by atomic-absorption spectroscopy in these salts, or in other copper-doped samples, failed as the readings were completely irreproducible and non-linear.

Recommended procedure

Test solution. Dissolve 25 g of solid sample in 80 ml of triply distilled water. Filter off foreign particles.

Reagents. Potassium cyanide solution, 0·26 g/l. If cyanide-complexing cations are present, or if the copper content of the final test solution is greater than 2·5 μg/ml, a proportionately more concentrated solution should be prepared.

Standards. Copper range 2·5–25 mg/l. Triply distilled water throughout. Mix 8 ml of test solution with 1 ml of reagent and 1 ml of water (or standard copper solution) giving a total of 10 ml. Transfer the solution to the photometric cell and record the absorbance at 235 nm, using 8·0 ml of test solution + 2·0 ml of water in the reference cell. If the spectrum does not reveal a distinct band with a peak at 237 nm, use a more highly concentrated cyanide solution. If the copper content of the test solution is low (about 0·25 μg/ml or less), add 1 ml of a standard copper solution.

The co-precipitation of copper with crystallizing sodium chloride

The cyanide method was applied to the estimation of the amount of copper in fractions of sodium chloride crystallized by evaporating a solution at constant temperature, 65 ± 1°, and constant pressure, 20 mbar. The results of two series of experiments are given in Table III: 126 g of pure recrystallized sodium chloride were dissolved in 360 g of water, with 0·98 and 0·49 mg of copper per g of sodium chloride added in the two series respectively. The Pyrex glass vessel containing the solution was immersed in a large oil-bath, and the solution evaporated by continuous regulated pumping. The water vapour was condensed in a cold trap, where its volume or weight could be determined. After fixed intervals the crystallized salt was filtered off by suction through a sintered glass filter. A few ml of water were added to the filtered supersaturated solution and the fractional crystallization was continued. The filtered crystals were thoroughly washed with saturated sodium chloride solution to remove all adhering copper-rich solution, weighed after suction, dried at 130° and then re-weighed.

* Total Cu present in initial solution was 0·1225 g.

† Total Cu present in initial solution was 0·0612 g.

It may be seen that the copper content (μg of Cu^{2+}/g of NaCl) of the first fraction is only 0·5–1·0% of that of the dissolved salt, *i.e.*, co-precipitation is largely independent of the copper concentration. However the copper content of the crystallized fractions increases in an inverse proportion to the amount of sodium chloride in the solution.[8] The latter observation is expressed by the equation $Y' = R \ln [X_H/(X_H - X')]$, where Y' is the total amount of copper co-precipitated by each fraction, R is a constant, X_H is the weight of sodium chloride in the solution, and X' is the weight of each fraction of salt. The fluctuations in the R values are rather small, considering the experimental difficulties involved. Two exceptionally high values, one in each series, are thought to be due to incomplete washing of these crystallized fractions, and the analytical method appears to be fairly satisfactory.

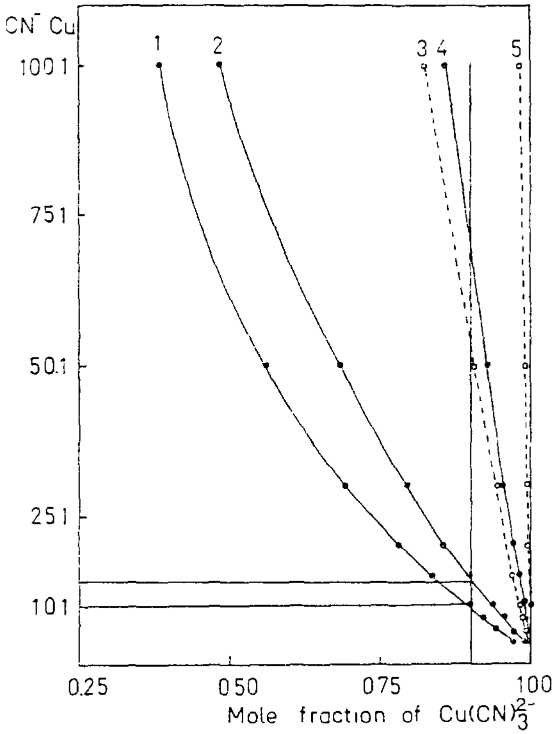

FIG. 3.—Calculated mole fraction of $[Cu(CN)_3]^{2-}$ as a function of the CN^-/Cu^{2+} ratio in the solution.
Assumed concentration of copper: *1*, *3*—2·5 μg/ml; *2*, *5*—1·5 μg/ml; *4*—0·25 μg/ml.
——$K = 418$; ---$K = 55$.

DISCUSSION

It has been proved experimentally that Beer's law is valid for the absorbance of the cyanide complexes $[Cu(CN)_3]^{2-}$ and $[Cu(CN)_4]^{3-}$ at the isosbestic wavelength 235 nm, in the copper concentration range of 0·25–2·5 μg/ml, if a sufficient excess of cyanide ions has been added to the solution. Our results are in good agreement with those of Kappenstein and Hugel.[3] These authors stated that if the mole fraction of the tricyano complex in the equilibrium equation (1) is calculated to be larger than 0·96 of the total copper concentration then the isosbestic point ceases to be reliable, because of the formation of complexes with lower co-ordination numbers. In Fig. 3 we plot the calculated mole fraction of the tricyano complex for three different concentrations of copper: 0·25, 1·5 and 2·5 μg/ml, as a function of the CN^-/Cu^{2+} mole ratio. The stability constants $K = 418$ from Ref. 3 and $K = 55$ from Ref. 2 (broken line) are used for these calculations. The mole fraction 0·90 of $[Cu(CN)_3]^{2-}$ is indicated by straight lines. This lower value (0·90) was adopted as an analytical safety margin. Comparison of Figs. 1 and 3 confirms the higher value of the two stability constants tested, and indicates that 0·25 μg Cu^{2+}/ml should be readily determinable in the presence of a minimum of a 70-fold excess of cyanide ions. However, the cyanide method would not be applicable to the determination of copper at lower concentrations.

No other metal ions except gold were found to interfere with the estimation of copper by the cyanide method. A larger excess of cyanide ions should however be added in the presence of cations giving stable cyanide complexes. In the procedure given here, a minimum concentration of cyanide was proposed so as to preclude the possibility of complications due to contamination.

The cyanide method was applied to a study of the co-precipitation of copper with sodium chloride crystallizing from aqueous solutions. Table III proves that the co-precipitation is largely independent of the concentration of copper ions in the solution or the amount of salt crystallized; it is inversely proportional to the amount of sodium chloride in the solution and can be expressed by an appropriate constant *R*. The *R* value of copper in sodium chloride is about $0{\cdot}56 \times 10^{-3}$, slightly less than that of calcium and magnesium ions.[9]

Zusammenfassung—Der molare Extinktionskoeffizient der Cyanidkomplexe $[Cu(CN)_3]^{2-}$ und $[Cu(CN)_4]^{3-}$ beträgt bei ihrer isosbestischen Wellenlänge (235 nm) $1.13{\cdot}10^3$ l mol^{-1} mm^{-1}; dies kann zur quantitativen Bestimmung von Mikromengen Kupfer im ppm-Bereich verwendet werden. Die Bestimmung von 1–10 μg Cu^{2+} pro g NaCl oder 0·25–2·5 $\mu g/ml$ wird in Einzelheiten beschrieben. Die Mitfällung von Kupfer beim Auskristallisieren von NaCl aus wäßrigen Lösungen wurde mit diesem Verfahren untersucht.

Résumé—Le coefficient d'absorption moléculaire des complexes du cyanure $[Cu(CN)_3]^{2-}$ et $[Cu(CN)_4]^{3-}$, à la longueur d'onde isobestique (235 nm) est de 1,13 × 10^3 l.mol.$^{-1}$ mm^{-1} et il peut être utilisé pour la détermination quantitative de micro-quantités de cuivre dans le domaine du ppm. On décrit en détail le dosage de 1–10 μg de Cu^{2+} par g de NaCl, ou de 0,25–2,5 $\mu g/ml$. On a étudié par cette méthode la coprécipitation du cuivre avec NaCl cristallisant de solutions aqueuses.

AMMONIUM HEXANITRATOCERATE(IV) AS AN OXIDIZING AGENT—V*

TITRIMETRIC DETERMINATION OF ARSENIC(III) AT ROOM TEMPERATURE

G. Gopala Rao, K. S. Murty and Muralikrishna Gandikota
Department of Chemistry, Andhra University, Waltair, India

(*Received* 16 *March* 1971. *Accepted* 20 *August* 1971)

Summary—Conditions have been established for the accurate titration of arsenic(III) with ammonium hexanitratocerate(IV) at room temperature in sulphuric, nitric and hydrochloric acid media, using suitable catalysts, and ferroin as indicator.

CERIUM(IV) SULPHATE in sulphuric acid medium is used for titration of arsenic(III), consequent on the work of Willard and Young[1,2] and Gleu,[3] and is nowadays often prepared from pure ammonium hexanitratocerate(IV). It would be an advantage if the ammonium hexanitratocerate(IV) could be used directly, especially as it is claimed to be of fixed composition and obtainable in high purity. Willard and Young[2] stated that arsenic(III) can be accurately determined in 3·0–4·2*M* hydrochloric acid with cerium(IV) sulphate at 50°, using iodine monochloride as catalyst and ferroin as indicator, but the procedure is rather inconvenient. Gleu[3] used three drops of 0·01*M* osmium tetroxide as catalyst and ferroin as indicator in about 0·5*N* sulphuric acid medium, but even then the oxidant should be added very slowly near the end. It is interesting that ferriin, the oxidized form of the indicator, is not readily reduced by arsenious acid; even in the presence of osmium catalyst only a faint red colour appears.

We have now established conditions for the rapid and accurate titration of arsenic(III) in 1–2*M* hydrochloric acid or 1–1·5*M* nitric acid, or 0·5–1·0*N* sulphuric acid at room temperature with ammonium hexanitratocerate(IV), using ferroin as indicator and a trace of iodine as catalyst. The titration can be done very rapidly even at the end-point, which is deemed to have been reached if the ferroin colour does not recur within 30 sec of the addition of the last fraction of a drop of the oxidant. Potassium iodide or iodate or iodine monochloride can also be used as catalysts, but corrections have to be made for the first two. At higher acid concentrations the results will be low by 0·05–0·1 ml of 0·1*M* cerate unless the titrations are carried out slowly towards the end. This is due to the slower reduction of ferriin by arsenic(III) at higher acid concentrations. The indicator correction is negligible in titrations with 0·1*M* cerium(IV) nitrate. With more dilute solutions of the oxidant indicator corrections are necessary.

A large number of titrations with varied acid concentrations showed that satisfactory conditions for the titration of arsenic(III) with ammonium hexanitratocerate(IV) with a potentiometric end-point are: (1) 1*N* sulphuric acid medium with trace amounts of iodide, iodine or iodine monochloride as catalyst, (2) 1*M* nitric acid with

---

* Part IV: *Talanta* 1964, **11**, 955.

0·1*M* potassium bromide or $10^{-5}M$ potassium iodide, $10^{-5}N$ I_2 or $10^{-6}M$ ICl as catalyst, (3) 1*M* hydrochloric acid with 0·1*M* potassium bromide or $10^{-5}M$ potassium iodide or $10^{-5}M$ iodine as catalyst. A negative correction has to be applied when potassium iodide is used, especially when working with dilute solutions of cerium(IV) nitrate.

Bromide failed to catalyse the reaction in sulphuric acid medium, but was effective at concentrations >0·1*M* in nitric or hydrochloric acid medium. In titrations using the bromide catalyst the potential break at the end-point is invariably much lower than in titrations using iodide, iodine or iodine monochloride catalyst in all the acid media tried. Moreover bromide is required at a much higher concentration than iodide. For these reasons the procedures using the iodine-based catalysts are recommended.

Some representative results are presented in Table I.

EXPERIMENTAL

Preparation of solutions

Ammonium hexanitratocerate(IV), 0·1*M*. Prepared in 1*M* nitric acid and standardized against arsenic(III).[4]

Sodium arsenite, 0·1*N*. Prepared from analytical grade arsenious oxide dried at 105–110° for 1 hr.

All other chemicals employed in this investigation were of analytical reagent quality. The nitric acid was heated long enough to drive off oxides of nitrogen, and stored in an amber-coloured bottle.

All solutions were prepared in demineralized water because of the high susceptibility of the cerium(IV)–arsenic(III) reaction to catalysis by trace impurities.

Apparatus

The potentiometric titration assembly is that described earlier.[5]

DISCUSSION OF RESULTS

Willard and Young titrated arsenic(III) with cerium(IV) sulphate in 3–4·2*M* hydrochloric acid at 50°, using 5–10 ml of 0·005*M* iodine monochloride as catalyst and ferroin as indicator. For successful potentiometric titration at room temperature they had to use 4·2*M* hydrochloric acid and at least 5 g of potassium bromide as the catalyst (per 100 ml of titrand). This corresponds to about 0·4*M* bromide. We observed that arsenic(III) can be titrated rapidly with ammonium hexanitratocerate(IV) in 1*M* hydrochloric acid at room temperature with lower catalyst concentrations. Under our conditions the formal redox potential of the Ce(IV)/Ce(III) couple is about 1·08 V. In 1·0*M* nitric acid medium the redox potential of the Ce(IV)/Ce(III) couple is very high, about 1·61 V, but a catalyst is still needed for rapid oxidation of arsenic(III). This is indeed interesting because the formal redox potential of Ce(IV)/Ce(III) in the presence of bromide falls to about 1·1 V. This result brings out the significant point that for a rapid reaction to occur between cerium(IV) and arsenic(III) the redox potential of the oxidant is not of such importance as is usually believed. It is the presence of environmental ions that matters.

The potentiometric titration of arsenic(III) with cerium(IV) is not possible without a catalyst in perchloric acid,[6] nitric acid, sulphuric acid or hydrochloric acid, in which the Ce(IV)/Ce(III) couple has formal redox potentials of about 1·7, 1·61, 1·44 and 1·28 V respectively, but is possible in the presence of 0·1*M* bromide catalyst. In 1*M* nitric acid or 1*M* hydrochloric acid medium sodium chloride can be used in place of bromide as catalyst, but the concentration required is very much higher (>4*M* is required). Iodide has an effective catalytic action at a very much lower concentration than bromide.

Our observations may be explained in terms of a substitution reaction giving hexahalocerate(IV) instead of hexanitratocerate. It appears that bromide displaces the nitrate from the complex more easily than chloride does. The mechanism of the catalytic effect of chloride or bromide may be explained as being due to electron transfer from the arsenic(III) to cerium(IV) *via* the halide ion. The halide ion may even be oxidized within the halide complex, and the resulting halogen atom oxidizes the arsenic(III):

$$\mathrm{Ce(IV)} + \mathrm{Cl^-} \rightarrow \mathrm{Ce(III)} + \mathrm{Cl^0} \qquad (1)$$

$$\mathrm{Cl^0} + \mathrm{As(III)} \rightarrow \mathrm{Cl^-} + \mathrm{As(IV)} \qquad (2a)$$

$$\mathrm{Cl^0} + \mathrm{As(IV)} \rightarrow \mathrm{Cl^-} + \mathrm{As(V)} \qquad (2b)$$

or

$$2\mathrm{Cl^0} + \mathrm{As(III)} \rightarrow 2\mathrm{Cl^-} + \mathrm{As(V)}. \qquad (3)$$

The transient formation of the unstable state As(IV) has been assumed by Csanyi,[7] and others. That electron transfer from arsenic(III) occurs *via* the halide ion is evident from the fact that bromide is effective at a much lower concentration than chloride. It is known that bromide is more rapidly oxidized than chloride by cerium(IV) nitrate. This mechanism also explains why cerium(IV) does not readily oxidize arsenic(III) in nitric acid or sulphuric acid media in the absence of a catalyst; nitrate and sulphate are already fully oxidized and cannot serve as electron transfer agents.

There are reports that in solutions of ammonium hexanitratocerate(IV) in <2*M* nitric acid, there may not be much of the cerium(IV) present in the complex anionic form, only free or hydrolysed and polymerized cerium(IV) ions being present. If that be the case a slight modification of the mechanism suggested above becomes necessary, invoking the work of Duke and Borchers.[8] They explained the kinetics of the oxidation of chloride by cerium(IV) by assuming the formation of chloro-complexes of the type $CeCl^{3+}$, $CeCl_2^{2+}$ *etc*, followed by:

$$CeCl_3^+ \rightarrow Ce^{3+} + Cl^- + Cl_2^- \qquad (4)$$

$$CeCl_2^{2+} \rightarrow Ce^{3+} + Cl_2^- \qquad (5)$$

The resulting Cl_2^- (or the Br_2^- from the bromide) may be assumed to oxidize arsenic(III) rapidly:

$$Cl_2^- + As(III) \rightarrow As(IV) + 2Cl^-. \qquad (6)$$

The mechanism of the action of iodide (iodine or iodine monochloride) appears to be somewhat different from that of bromide and chloride. Because iodide works at trace concentrations of the order of $10^{-5}M$ the mechanism may be believed to be truly catalytic and not necessarily involving any breaking of the complex nitratocerate. Both iodine and iodide may be converted by nitratocerate in nitric, sulphuric or hydrochloric acid medium into iodine(I) (as in iodine monochloride) which then acts as the catalyst:

$$As(III) + I(I) \rightarrow As(IV) + I^0 \qquad (7)$$

$$As(IV) + I(I) \rightarrow As(V) + I^0 \qquad (8)$$

$$I^0 + I^0 \rightarrow I_2 \qquad (9)$$

$$I^0 + Ce(IV) \rightarrow I(I) + Ce(III). \qquad (10)$$

This mechanism implies that if molecular iodine is formed according to reaction (9) the speed of oxidation of arsenic(III) would be retarded. Indeed we have observed that when the iodine monochloride concentration is increased beyond a certain limit the reaction becomes sluggish. In acid solution molecular iodine does not react with arsenic(III), because the As(III)/As(V) potential is pH dependent and increased by acidity, whereas that of the I^-/I_2 couple is not.

That the mechanism of catalytic action of iodine is somewhat different from that of chloride and bromide is also indicated by the fact that iodide is required as catalyst even in hydrochloric acid medium and has a pronounced catalytic action even in sulphuric acid medium where chloride has a negligible, and bromide a poor catalytic action; in sulphuric acid medium cerium(IV) forms very strong sulphate complexes which cannot be easily transformed into the chloro- and bromo-complexes unless very high concentrations of these ligands are added.

Résumé—On a établi des conditions pour le titrage précis de l'arsenic-(III) par l'hexanitratocérate(IV) d'ammonium à température ordinaire, dans des milieux acide sulfurique, acide nitrique et acide chlorhydrique, en utilisant des catalyseurs convenables et la ferroïne comme indicateur.

Zusammenfassung—Die Bedingungen für eine genaue Titration von Arsen(III) mit Ammoniumhexanitratocerat(IV) bei Zimmertemperatur in schwefelsaurer, salpetersaurer und salzsaurer Lösung unter Verwendung geeigneter Katalysatoren und Ferroin als Indikator wurden ermittelt.

SHORT COMMUNICATIONS

Ammonium hexanitratocerate(IV) as an oxidizing agent—VI
Determination of chromium(III) through oxidation to chromium(VI) at room temperature

(*Received* 16 *March* 1971. *Accepted* 20 *August* 1971)

THE DETERMINATION of chromium(III) is of importance in the assay of ores, alloys, chromium-plating solutions and chrome-tanning liquors, and is usually done by oxidizing the chromium(III) to chromium(VI), which is then titrated after destruction of excess of oxidizing agent. The classical method of oxidizing chromium(III) with hydrogen peroxide or sodium peroxide in hot alkaline medium is subject to the defect that, if all the peroxide is not removed, it may reduce some of the chromic acid formed during acidification before titration of the chromic acid, or may react with the iodide added if an iodometric estimation is used. To facilitate the complete removal of hydrogen peroxide, Feigl *et al.*[1] added nickel nitrate after oxidation of chromium(III). Schulek and Szakacs[2] proposed destroying the excess of hydrogen peroxide by adding chlorine water and destroying excess of chlorine with cyanide. Willard and Young[3] boiled the chromium(III) with concentrated perchloric acid, cooled, added a known and excessive amount of ferrous ammonium sulphate, and back-titrated with permanganate. Smith[4] stated that some of the chromic acid formed may be reduced by hydrogen peroxide, which is a by-product of the reaction. Lynn and Mason[5] boiled the chromium(III) solution with an excess of 72% perchloric acid in a mixed medium of nitric acid and sulphuric acid containing silver nitrate as catalyst. This procedure also appears to be subject to Smith's criticism, as is evidenced by the high negative errors (−0·8%). Jarvenin[6] oxidized chromium(III) with excess of bromine in alkaline solution, acidified and boiled to remove the excess of bromine. Schulek and Dosza[7] stated that in this method some chromic acid is lost by reaction with bromide during expulsion of the bromine. To avoid this error they oxidized with excess of hypobromite in alkaline medium and removed the excess with phenol. In our opinion some chromic acid may react with phenol during acidification. Kolthoff and Sandell[8] oxidized with an excess of potassium bromate in dilute sulphuric acid containing phosphoric acid and manganous chloride, decomposing the excess by boiling with ammonium persulphate and hydrochloric acid. This process also involves some loss of chromic acid as chromyl chloride or by reaction with bromite. Willard and Young[9] oxidized chromium(III) by boiling with excess of cerium(IV) sulphate in sulphuric acid, and back-titrated the excess with oxalate, or nitrite.[10] Both procedures must be subject to some error caused by reduction of cerium(IV) in a boiling solution, as has been established in recent years. Van der Meulen[11] oxidizes with excess of potassium persulphate in the presence of zinc sulphate, sodium sulphate and silver nitrate, boils to destroy excess of persulphate, adds manganous sulphate and heats until the supernatant liquid is a clear yellow, filters through a sintered glass crucible, cools and determines the chromium(VI) iodimetrically. This procedure is time-consuming and requires too many chemicals, though it is accurate.

We have now made the interesting new observation that ammonium hexanitratocerate(IV) oxidizes chromium(III) in dilute nitric acid at room temperature rapidly and stoichiometrically. The optimum conditions are 0·5–1M nitric acid and 50–100% excess of the reagent for a reaction time of 10–15 min.

EXPERIMENTAL

Reagents

Ammonium hexanitratocerate (IV) solution, 0·1M. Prepared according to Smith *et al.*[12] and standardized with sodium oxalate (ferroin indicator or potentiometrically[13]).

Sodium oxalate solution, 0·1N. Sodium oxalate was dried at 120° for 2 hr, dissolved in doubly distilled water tested for freedom from heavy metal ions, and stored in an amber glass bottle.

Chrome alum solution, 0·1N. Standardized by the method of van der Meulen.[11]

All other solutions were prepared from chemicals of analytical reagent quality. Nitric acid was heated long enough to drive off any oxides of nitrogen present and then stored in an amber coloured bottle.

Procedure

To 3–8 ml of chromium (III) solution (∼ 0·1N) add a known and excessive amout of ammonium hexanitratocerate(IV) (6–16 ml of 0·1M), 10 ml of 5·0M nitric acid, dilute with water to 50 ml, and set aside for 15–20 min. Then titrate the unreacted cerium(IV) slowly with 0·1N sodium oxalate potentiometrically.[13] The potential break at the equivalence point is ∼ 400 mV per 0·1 ml of oxalate.

RESULTS AND DISCUSSION

The stoichiometry was confirmed by taking an aliquot of chrome alum solution, oxidizing, adding the calculated amount of sodium oxalate equivalent to the unreacted Ce(IV) nitrate, letting stand for 5 min, making 2N in acid by addition of sulphuric acid, and titrating the chromium(VI) with iron(II) solution, using barium diphenylaminesulphonate as indicator.

Typical results are given in Table I. The good agreement between the results affords proof of the stoichiometric oxidation of chromium (III) with ammonium hexanitratocerate (IV) to chromium (VI) at room temperature.

Summary—A new method has been developed for the determination of chromium(III), depending on its oxidation to chromium(VI) at room temperature by treatment with 50–100% excess of ammonium hexanitratocerate(IV) in 1·0M nitric acid medium. The reaction is complete within 15 min. The unreacted cerium(IV) is titrated potentiometrically with sodium oxalate.

Zusammenfassung—Ein neues Verfahren zur Bestimmung von Chrom-(III) wurde entwickelt. Es beruht auf der Oxidation zu Chrom(VI) bei Zimmertemperatur mit einem 50–100%-igen Überschuß von Ammonium-hexanitratocerat(IV) in 1M salpetersäurer Lösung. Die Reaktion ist in 15 min abgeschlossen. Das nicht verbrauchte Cer(IV) wird potentiometrisch mit Natriumoxalat titriert.

Résumé—On a élaboré une nouvelle méthode pour le dosage du chrome-(III), basé sur son oxydation en chrome(VI) à température ordinaire par traitement avec un excés de 50–100% d'hexanitratocétate(IV) d'ammonium en milieu acide nitrique 1,0M. La reaction est complète en 15 mn. Le cerium(IV) qui n'a pas réagi est titré potentiométriquement à l'oxalate de sodium.

A rapid automatic method for the determination of oxygen in organic substances, using coulometry at controlled potential

(*Received* 15 *July* 1971. *Accepted* 28 *August* 1971)

SINCE 1954 we have performed routine determinations of oxygen in organic substances according to the procedure of Unterzaucher.[1] The final step in this method is the following. The iodine which is formed by the reaction of carbon monoxide with anhydroiodic acid is collected in a tube containing 20% sodium hydroxide solution. Bromine in acetate buffer is then added to this solution and all iodine is oxidized to iodate. Excess of bromine is removed by addition of formic acid, and bromine vapour in the flask is flushed out with a stream of air for 1 min. Sulphuric acid and potassium iodide are then added and the iodine formed is titrated with 0·02*N* thiosulphate.

The final step thus involves several manual operations. Many authors have tried to make the procedure more or less automatic and some of these methods will be briefly described. Fraisse and Levy[2] convert the carbon monoxide into carbon dioxide and titrate this with hydroxide ion generated coulometrically. Kan-Ichi Nakamura *et al.*,[3] using a rather complicated procedure, oxidize the carbon monoxide to carbon dioxide which is then reacted with lithium hydroxide to produce water, which is driven off and determined coulometrically in a Pt–P_2O_5 cell of the Keidel type. The accuracy of this method is, however, not very satisfactory. Calmè and Keyser[4] continuously titrate the iodine formed, with thiosulphate solution, in a special cell. Those methods which use gas chromatography in the final step, either for determination of carbon monoxide or of carbon dioxide, do not usually give such good values as Unterzaucher's original method.

The method which is described here is based on the continuous reduction of the iodine formed to iodide, at controlled potential.

Since iodine has been extensively studied in connection with coulometric measurements, and since with the help of modern electronic instrumentation quantities of electricity can be determined with very high accuracy, this procedure is very attractive.

Apparatus

The oxygen apparatus which is described here has been in use for about two years and is in principle the same as that of Unterzaucher up to and including the anhydroiodic acid tube. The iodine vapour which is formed here is led by the nitrogen gas stream (10 ml/min) through the electrically heated glass tube *A* (Fig. 1) down into the electrolysis cell *B*, also of glass, which contains 5 ml of 2*M* sodium iodide and 5 ml of 2*M* sodium perchlorate. To prevent the temperature from rising, the electrolysis cell is surrounded by a glass jacket through which cooling water is led in at *C* and out at *D*. *E* is a rotating platinum electrode consisting of a circular Pt gauze (36-mesh), diameter about 35 mm, fixed at one end to a rotating Teflon-coated shaft. The shaft rotates at about 400 rpm. *F* is a calomel reference electrode (Radiometer K 401). Electrolyte can be added to and removed from the cell through the hole stoppered by *G*. The nitrogen can leave the cell *via* a small hole in *G*. *H* is a circular Haldenwanger clay filter, diameter about 15 mm, fixed to the cell with special Haldenwanger cement. The anode, *K*, consists of a platinum gauze (36 mesh, 20 × 30 mm). The anode compartment contains 2*M* sodium perchlorate.

The platinum electrode, *E*, is connected *via* a mercury contact at the upper end of the rotating shaft with the positive input of an operational amplifier in a potentiostat of exactly the same construction as described by Karlsson and Karrman.[5] The reference electrode, *F*, is connected to the negative input of the operational amplifier, and the anode, *K*, to the output. The potential of the working electrode is always − 100 mV *vs.* the calomel electrode. The temperature of the tube *A* through which the iodine vapour is led from the anhydroiodic acid tube down to the working

electrode is about 120°. The quantity of electricity required to reduce the iodine is measured with an electronic integrator[5] and the value is read from a digital voltmeter (Solatron LM 1420·2).

Procedure

A 2–6 mg sample in a platinum boat is placed in the usual way in the pyrolysis tube. The cell is connected and a check made that the residual current is 15–20 μA before the movable furnace is put into position about 5 mm behind the boat. After about 3 min the current starts to increase rapidly and reaches a maximum value of 25–30 mA after 4–7 min. After about 13–14 min, depending on the nature of the sample, the residual current has again reached the 15–20 μA level, and the analysis is complete. The oxygen content is then calculated from the value U_0 read from the digital voltmeter, using the equation

$$\%\mathrm{O} = \frac{\mathrm{R}_1 \,.\, \mathrm{C} \,.\, (U_0 - U_\mathrm{B}) \,.\, 15 \,.\, 32}{R_2 \,.\, F \,.\, n \,.\, M \,.\, 6} \times 100 \qquad (1)$$

where R_1, R_2 and C are integrator components (see Fig. 2, Karlsson and Karrman[5]) and have in this case the values $R_1 = 0{\cdot}5\ \mathrm{M}\Omega$; $R_2 = 10\ \Omega$; $C = 10\ \mu\mathrm{F}$; $F = 96487$ C; $n = 2$ (number of electrons involved); M = weight of sample (mg); U_0 = integrator reading for sample (mV); U_B = integrator reading for blank (mV); 32 = molecular weight of oxygen.

The figures 15 and 6 come from the reaction between carbon monoxide and anhydroiodic acid. The electrical components have been accurately calibrated, and when the values are inserted in equation (1) the following simplified equation is obtained

$$\%\mathrm{O} = 0{\cdot}020718\,\frac{(U_0 - U_\mathrm{B})}{M} \qquad (2)$$

The integrator read-out for an analysis is 4000–5000 mV. The amount of sample is adjusted according to the oxygen content of the substance. The blank value in equation (1), U_B, is obtained by performing the analysis in the absence of the sample, and is 30 ± 3 mV. When the analysis is complete after 13–14 min (for certain substances which are more difficult to pyrolyse, a further

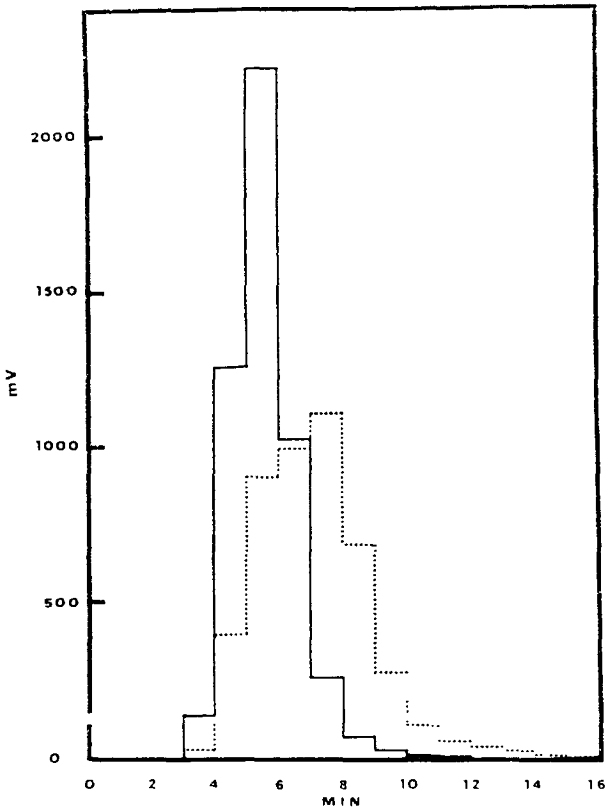

FIG. 2.—Histogram for the increase of the integrator read-out per unit time for the pyrolysis of benzoic acid (full line) and 3,5-dinitrobenzoic acid (dashed line).

1–2 min will be required) the residual current is 15–20 μA. This means that the residual current contributes about 2 mV/min to the integrator read-out.

RESULTS

The analyses can be carried out either by placing the movable furnace just behind the boat with the sample and then letting the furnace move over the boat, or by placing the furnace directly over the boat. With the latter procedure, the pyrolysis starts earlier and the total analysis time is reduced by 1–2 min. With the apparatus described here, the pyrolysis process can be followed continuously. Figure 2 shows 2 diagrams obtained by measuring the increase of the integrator read-out each whole minute, the time being counted from the moment the movable furnace was placed just behind the boat. It may be seen that benzoic acid is pyrolysed considerably faster than 3,5-dinitrobenzoic acid.

Table I gives the collected results from the determinations of oxygen on the milligram scale. It can be seen that the aromatic nitro-compounds give rise to a very small but significant systematic error. Some experiments have also been performed to determine the carbon dioxide and water evolved on heating calcium carbonate and barium chloride dihydrate (Table II). Thus when the amount of CO_2 is determined, only 2 of the 3 oxygen atoms in calcium carbonate are included in the calculated value. It has been shown previously, results not yet published, that the barium chloride contains 1·985 moles of H_2O which corresponds to an oxygen content of 13·02%; the measured value was 13·01%.

Table III shows some determinations made on the submilligram scale, where the weight of sample was 0·5–1·0 mg. The weighings were performed on a Rodder ultramicro torsion balance and a Sartorius electronic ultramicrobalance 4125. For these determinations, the diameters of the

Summary—An Unterzaucher apparatus for the determination of oxygen in organic compounds is used. The iodine vapour formed in the anhydroiodic acid tube is led by a stream of nitrogen to the cathodic chamber of an electrolysis cell. Here the iodine is reduced at controlled potential at a rotating Pt-electrode. The amount of electricity used is determined by an electronic integrator and read from a digital voltmeter. For weights of samples in the range 0·5–6 mg the standard deviation is about 0·08% oxygen.

Zusammenfassung—Zur Bestimmung von Sauerstoff in organischen Verbindungen wird ein Unterzaucher-Gerät verwendet. Der in der Röhre mit Anhydrojodsäure gebildete Joddampf wird mit einem Stickstoffstrom in die Kathodenkammer einer Elektrolysezelle überführt. Hier wird das Jod bei geregelter Spannung an einer rotierenden Pt-Elektrode reduziert. Die verbrauchte Elektrizitätsmenge wird durch einen elektronischen Integrator ermittelt und an einem Digitalvoltmeter abgelesen. Bei Probengewichten von 0,5–6 mg beträgt die Standardabweichung etwa 0,08% Sauerstoff.

Résumé—On utilise un appareil d'Unterzaucher pour le dosage de l'oxygène dans les composés organiques. La vapeur d'iode formée dans le tube à acide anhydroiodique est entrainée par un courant d'azote dans le compartiment cathodique d'une cellule à électrolyse. L'iode y est réduit à potentiel contrôlé sur une électrode tournante de platine. La quantité d'électricité utilisée est déterminée par un intégrateur électronique et lue sur un voltmètre digital. Pour des pesées d'échantillon comprises entre 0,5 et 6 mg, l'écart-type est d'environ 0,08% d'oxygène.

Successive complexometric determination of thorium and uranium in sulphuric acid media

(*Received* 12 *April* 1971. *Accepted* 21 *August* 1971)

THE SUCCESSIVE complexometric determination of thorium(IV) and uranium(VI) in nitrate solution has been reported in the literature,[1] but a large quantity of sulphate or phosphate interferes seriously. The method, therefore, requires separation of thorium and uranium by precipitation with carbonate-free sodium hydroxide. Very large amounts of sulphate are present when sintered thorium oxides or thorium-uranium oxides are brought into solution by fusion with potassium bisulphate, and the precipitation procedure is quite time-consuming.

We have recently described the selective extraction determination of thorium[2,3] with *N*-butylaniline or *N*-benzylaniline in chloroform from sulphuric acid media. Gagliardi and Illmaier[4] have reported the specific extraction of uranium(VI) with the same reagents.

The present investigation, therefore, was undertaken to combine the extraction procedure with the successive complexometric determination of thorium and uranium.[1] It was found that extraction of uranium with *N*-butylaniline or *N*-benzylaniline in the presence of ascorbic acid and EDTA resulted in the removal of the interference of many cations such as zirconium, scandium, gallium, indium, yttrium, osmium, rhodium, ruthenium and thallium; palladium and platinum remained in the organic phase. The reduction of uranium(VI) with sodium dithionite for the titration of uranium (VI) was preferred as this reductant was found to be superior to ascorbic acid,[5] which reduces uranium (VI) in boiling solutions. The reduction of uranium(VI) with sodium dithionite at room temperature was rapid and quantitative. The de Heer method[1] was also modified, it having been found that a lower pH gave a sharper end-point.

EXPERIMENTAL

Reagents

All solutions were prepared from analytical-grade reagents. Aqueous solutions were prepared with doubly distilled water.

Successive complexometric determination of thorium and uranium in sulphuric acid media

(*Received* 12 *April* 1971. *Accepted* 21 *August* 1971)

THE SUCCESSIVE complexometric determination of thorium(IV) and uranium(VI) in nitrate solution has been reported in the literature,[1] but a large quantity of sulphate or phosphate interferes seriously. The method, therefore, requires separation of thorium and uranium by precipitation with carbonate-free sodium hydroxide. Very large amounts of sulphate are present when sintered thorium oxides or thorium-uranium oxides are brought into solution by fusion with potassium bisulphate, and the precipitation procedure is quite time-consuming.

We have recently described the selective extraction determination of thorium[2,3] with *N*-butylaniline or *N*-benzylaniline in chloroform from sulphuric acid media. Gagliardi and Illmaier[4] have reported the specific extraction of uranium(VI) with the same reagents.

The present investigation, therefore, was undertaken to combine the extraction procedure with the successive complexometric determination of thorium and uranium.[1] It was found that extraction of uranium with *N*-butylaniline or *N*-benzylaniline in the presence of ascorbic acid and EDTA resulted in the removal of the interference of many cations such as zirconium, scandium, gallium, indium, yttrium, osmium, rhodium, ruthenium and thallium; palladium and platinum remained in the organic phase. The reduction of uranium(VI) with sodium dithionite for the titration of uranium (VI) was preferred as this reductant was found to be superior to ascorbic acid,[5] which reduces uranium (VI) in boiling solutions. The reduction of uranium(VI) with sodium dithionite at room temperature was rapid and quantitative. The de Heer method[1] was also modified, it having been found that a lower pH gave a sharper end-point.

EXPERIMENTAL

Reagents

All solutions were prepared from analytical-grade reagents. Aqueous solutions were prepared with doubly distilled water.

Co(II)	30	EDTA	186

* Reduced with ascorbic acid.
† Masked with boric acid.

Thorium(IV) *solution*, 0·05M. Dissolve the required amount of thorium nitrate tetrahydrate in 0·001M nitric acid, and standardize against EDTA (Xylenol Orange indicator). Prepare more dilute solutions from it by accurate dilution.

Uranium(VI) *solution*, 0·05M. Dissolve the required amount of uranyl nitrate hexahydrate in 0·001M nitric acid and standardize gravimetrically with 8-hydroxyquinoline.

N-*butylaniline*. Dissolve 9·0 g of reagent (b.p. 241–242°) in 100 ml of chloroform.

N-*benzylaniline*. Dissolve 7·0 g of purified reagent[6] (m.p 36°, b.p. 180°/16 mbar) in 100 ml of chloroform.

Procedure

To an aliquot of solution containing up to a total of 45 mg of thorium(IV) and uranium(VI) in a 50-ml separatory funnel, add enough sulphuric acid and water to give 1–2·5N acid in the case of N-butylaniline and 3–4N acid in the case of N-benzylaniline, and a total volume of 10 ml. Add 15 ml of either N-butylaniline or N-benzylaniline solution in chloroform, shake the funnel vigorously for about 1 min and allow the layers to separate. Run off the organic layer into a 50-ml beaker. Extract again with 10 ml of the extractant solution. Strip thorium and uranium from the combined organic layers by shaking for 2 min with 30–40 ml of water. Transfer the aqueous layer to a 250-ml conical flask and dilute to about 100 ml. Adjust the pH to 2·5 ± 0·5 with 2M ammonia solution (narrow-range pH paper or pH-meter). Add 8 drops of 0·1% Xylenol Orange solution and titrate with 0·01M EDTA (yellow end-point). Then add roughly 100% excess of EDTA with respect to uranium. Add sodium dithionite till the brown colour of the solution changes to green. Then add *ca.* 10 drops of 37% formaldehyde solution, followed by 8 drops of Xylenol Orange solution. Adjust the pH to 2·5 ± 0·5 and titrate with standard thorium solution (red end-point).

RESULTS AND DISCUSSION

Both thorium(IV) and uranium(VI) can be selectively and quantitatively extracted from sulphuric acid media. The extraction of uranium(VI) in the presence of ascorbic acid and sufficient 0·1M EDTA obviates the interference of most cations[2,3] and improves the selectivity of the Gagliardi method[4] (Table I). Excess of ascorbic acid does not interfere. Palladium(II) and platinum(II) or (IV) remain in the organic phase. Nitrate, chloride, borate, arsenate, citrate and tartrate do not interfere. Phosphate and oxalate, which interfere in most methods for the extraction of thorium and

11·56	11·90	11·62	+0·5	11·84	−0·5

uranium, do not interfere. Fluoride interferes seriously but can easily be masked with boric acid in dilute sulphuric acid.

Typical results obtained for mixtures are summarized in Table II. It was found that 25 ml of *N*-butylaniline or *N*-benzylaniline are sufficient to extract a total of 48 mg of thorium and uranium. Larger amounts can be extracted with an increased amount of extractant. None of the experimental conditions is critical. The method is simple, rapid, accurate and selective.

Summary—A selective analytical extraction method for rapid successive complexometric determination of thorium(IV) and uranium(VI) in sulphuric acid media is described. The method is based on the extraction of thorium and uranium from sulphuric acid media with *N*-butylaniline or *N*-benzylaniline in chloroform. Both thorium and uranium are selectively and quantitatively extracted in the presence of ascorbic acid and EDTA. Most cations and anions do not interfere. The reduction of uranium(VI) with sodium dithionite at room temperature is rapid and quantitative and superior to that with ascorbic acid, which reduces uranium(VI) in boiling solution. The method is simple, rapid and accurate, and the experimental conditions are not highly critical.

Zusammenfassung—Eine selektive analytische Extraktionsmethode zur raschen komplexometrischen Bestimmung von Thorium(IV) und Uran(IV) nacheinander in schwefelsaurer Lösung wird beschrieben. Die Methode beruht auf der Extraktion von Thoruim und Uran aus schwefelsaurer Lösung mit N-Butylanilin oder N-Benzylanilin in Chloroform. In Gegenwart von Ascorbinsäure und EDTA werden sowohl Thorium als auch Uran selektiv und quantitativ extrahiert. Die meisten Kationen und Anionen stören nicht. Die Reduktion von Uran(VI) mit Natriumdithionit bei Zimmertemperatur verläuft rasch und quantitativ und ist der Reduktion mit Ascorbinsäure überlegen, die Urban(VI) in siedender Lösung reduziert. Die Methode ist einfach, schnell und genau; die Versuchsbedingungen müssen nicht sehr kritisch eingehalten werden.

Résumé—On décrit une méthode d'extraction analytique sélective pour la détermination complexométrique successive rapide du thorium(IV) et de l'uranium(IV) en milieux acide sulfurique. La méthode est basée sur l'extraction du thorium et de l'uranium des milieux acide sulfurique par la N-butylaniline ou la N-benzylaniline en chloroforme. Le thorium et l'uranium sont tous deux sélectivement et quantitativement

extraits en la présence d'acide ascorbique et d'EDTA. La plupart des cations et des anions ne gênent pas. La réduction de l'uranium(IV) par le dithionite de sodium à température ordinaire est rapide et quantitative et supérieure à celle obtenue avec l'acide ascorbique, qui réduit l'uranium(IV) en solution bouillante. La méthode est simple, rapide et précise, et les conditions experimentales ne sont pas extrémement essentielles.

Titrimetric determination of arsenic(III) with potassium dichromate, using redox indicators

(*Received* 16 *April* 1971. *Accepted* 20 *August* 1971)

THE DETERMINATION of arsenic(III) is of importance in the assay of pharmaceuticals, insecticides, glasses, and alloys. Also, several oxidizing agents are estimated indirectly by treatment with excess of arsenite and back-titration of the excess with a suitable oxidant. Thus de Bacho[1] determined permanganate, manganese dioxide, barium peroxide, chlorate, hypochlorite, persulphate *etc.* and Schreyer *et al.*[2] determined potassium ferrate. Willard and Young[3] standardized dichromate solutions similarly, titrating the surplus arsenite with cerium(IV) sulphate, with osmium tetroxide as catalyst and ferroin as indicator. Van der Meulen[4] precipitated lead as chromate with a measured and excessive amount of dichromate solution and estimated the excess by reducing with excess of arsenite and back-titrating with bromate.

Arsenic(III) has been titrated with potassium permanganate, potassium iodate, iodine monochloride, iodine, potassium bromate, chloramine-T, sodium chlorite, sodium hypochlorite, potassium periodate, cerium(IV) sulphate and other oxidizing agents, most of which have disadvantages, such as unavailability in analytical grade purity, instability in solution or high cost. Potassium dichromate is unique in that it is free from these drawbacks, but has not previously been used successfully for titration of arsenic(III). (Pound[5] obtained high results, using diphenylamine as indicator.) We have now made an investigation of the use of potassium dichromate for determination of arsenic(III) and established conditions for accurate titrations using ferroin and *N*-phenylanthranilic acid as indicators.

EXPERIMENTAL

Solutions

Sodium arsenite solution, 0·1*N*. Prepared from arsenious oxide dried at 105–110° for 1 hr and stored in a Pyrex bottle kept in the dark. The solution was made acidic to avoid oxidation by atmospheric oxygen. Demineralized water was used for preparing the solution because traces of heavy metal ions are known to catalyse the oxidation.

Potassium dichromate solution, 0·1*N*. Stored in Pyrex.

All chemicals used were of analytical reagent quality.

Titration of arsenic(III)

In a preliminary study by photometric titration the rate of oxidation of arsenite by dichromate was found to increase with increasing acid concentration, becoming very fast in > 6*N* sulphuric acid. Oxidation of ferroin becomes fast enough in 7·5–8·5*N* sulphuric acid, but reduction of ferriin by extraits en la présence d'acide ascorbique et d'EDTA. La plupart des cations et des anions ne gênent pas. La réduction de l'uranium(IV) par le dithionite de sodium à température ordinaire est rapide et quantitative et supérieure à celle obtenue avec l'acide ascorbique, qui réduit l'uranium(IV) en solution bouillante. La méthode est simple, rapide et précise, et les conditions experimentales ne sont pas extrémement essentielles.

ferroin indicator	0·5260	0·5240	+0·4
	0·4060	0·4070	+0·2
	0·3280	0·3270	−0·3
10*N* H_2SO_4	0·9020	0·9020	0·0
+	0·8000	0·8000	0·0
1 ml of 0·005*N* KI	0·7020	0·7020	0·0
N-phenylanthranilic	0·6140	0·6140	0·0
acid indicator	0·5020	0·5010	−0·2
	0·4200	0·4200	0·0
	0·3160	0·3150	−0·3
	0·2160	0·2150	−0·5

arsenic(III) is then slow. To make this second reaction fast it was found necessary to add a catalyst, 0·05 ml of 0·1*M* potassium iodide for 50 ml of titration mixture. As iodide will be oxidized to iodine by potassium dichromate at the end of the titration, a suitable correction has to be made for it. Similar observations were made when *N*-phenylanthranilic acid was used as indicator, except that a wider range of acid concentration (8–11*N*) can be used.

Procedure

Dilute the arsenic(III) solution to about 30 ml, then add slowly and with stirring enough sulphuric acid (1+1) to make the mixture 7·5–8·5*N* in acid when diluted to 50 ml. Cool to room temperature, add 1 ml of 0·005*M* potassium iodide and 0·05 ml of 0·025*M* ferroin and dilute to 50 ml and titrate with dichromate, rapidly until within 0·2 ml of the end-point, then dropwise with a wait of 30–40 sec between drops; use a magnetic stirrer. The end point is indicated by the sharp change in colour from brown to blue-grey. If more catalyst is used, a brown turbidity appears, which is very likely due to an insoluble ferroin–iodine complex. Deduct 0·06 ml of 0·1*N* dichromate to allow for oxidation of the catalyst and indicator. Alternatively, adjust the acidity to 8–10*N* and use 2 drops of 0·2% *N*-phenylanthranilic acid solution as indicator.

RESULTS AND DISCUSSION

The reactions underlying the titration may be postulated a follows:

$$\text{ferroin} + \text{Cr(VI)} \xrightarrow{>7{\cdot}5N\ H_2SO} \text{ferriin} + \text{Cr(V)},\ \text{fast}$$

$$\text{Cr(V)} + \text{As(III)} \longrightarrow \text{Cr(III)} + \text{As(V)},\ \text{fast}$$

$$\text{ferriin} + \text{As(III)} \xrightarrow{7{\cdot}5N\ H_2SO_4} \text{ferroin} + \text{As(IV)},\ \text{slow}$$

$$\text{ferriin} + \text{I}^- \text{———} \text{I}^0 + \text{ferroin},\ \text{fast}$$

$$\text{I}^0 + \text{As(III)} \text{———} \text{As(IV)} + \text{I}^-,\ \text{fast}$$

$$\text{As(IV)} + \text{Cr(VI)} \text{———} \text{Cr(V)} + \text{As(V)},\ \text{fast}$$

$$\text{or As(IV)} + \text{ferriin} \text{———} \text{As(V)} + \text{ferroin},\ \text{fast}$$

We have also used 0·5 ml of 0·005*M* iodine monochloride as catalyst, and then the volume of dichromate solution consumed was about 0·05 ml less than the theoretical on account of the oxidizing action of iodine monochloride on arsenic(III). Some representative results are presented in Table I, with the corrections applied.

Interferences

Iron(III) (0·2–2·0 meq), chromium(III) (0·2–2·0 meq), aluminium(III) (0·2–2·0 meq) and manganese(II) (0·5–2·0 meq) do not interfere. Iron(II) and similar reductants interfere by reacting with the potassium dichromate.

The use of triethanolamine in a buffer for the determination of fluoride in calcium and transition metal orthophosphates, using a fluoride-selective electrode

(*Received* 26 *March*. *Accepted* 3 *July* 1971)

The use of a fluoride-selective electrode[1,2] has largely superseded, at least for inorganic analysis, the earlier spectrophotometric methods[3–8] for the determination of traces of fluoride. Whilst the fluoride electrode "senses" only ionic fluoride below pH 8, it is sensitive to hydroxide ions at higher pH values. In addition, the presence of undissociated hydrofluoric acid, or HF_2^- ions, (which can exist below about pH 3·5) results in an apparent loss of fluoride ions as sensed by the electrode. Further, the formation of complexes with metal cations reduces the concentration of free, ionic fluoride in the system. The electrode potential is also affected by changes in the ionic strength of the solution, which are often overcome by the addition of a buffer of high ionic strength, such that the variation in the ionic strength of the sample solution will have but a small effect on that of the buffered system. An early example of this type of buffer for fluoride determination is "Total Ionic Strength Adjustment Buffer"[9] (TISAB). Recently, criticisms have been advanced against the use of this buffer in calcium orthophosphate systems[10–12] on the grounds that the acetate ion forms an insoluble calcium complex. The use of the citrate ion, usually added as the trisodium salt, as a buffer in place of TISAB appears to overcome this objection. In a recent communication[11] we described a method utilizing hydrochloric acid to dissolve solid calcium orthophosphates, and trisodium citrate for pH control. Whilst this method has proved useful for the analysis of pure calcium orthophosphates, and has also been used with success on many other bivalent metal orthophosphates, it has been found

We have also used 0·5 ml of $0{\cdot}005M$ iodine monochloride as catalyst, and then the volume of dichromate solution consumed was about 0·05 ml less than the theoretical on account of the oxidizing action of iodine monochloride on arsenic(III). The use of triethanolamine in a buffer for the determination of fluoride in calcium and transition metal orthophosphates, using a fluoride-selective electrode

(*Received* 26 *March. Accepted* 3 *July* 1971)

The use of a fluoride-selective electrode[1,2] has largely superseded, at least for inorganic analysis, the earlier spectrophotometric methods[3–8] for the determination of traces of fluoride. Whilst the fluoride electrode "senses" only ionic fluoride below pH 8, it is sensitive to hydroxide ions at higher pH values. In addition, the presence of undissociated hydrofluoric acid, or HF_2^- ions, (which can exist below about pH 3·5) results in an apparent loss of fluoride ions as sensed by the electrode. Further, the formation of complexes with metal cations reduces the concentration of free, ionic fluoride in the system. The electrode potential is also affected by changes in the ionic strength of the solution, which are often overcome by the addition of a buffer of high ionic strength, such that the variation in the ionic strength of the sample solution will have but a small effect on that of the buffered system. An early example of this type of buffer for fluoride determination is "Total Ionic Strength Adjustment Buffer"[9] (TISAB). Recently, criticisms have been advanced against the use of this buffer in calcium orthophosphate systems[10–12] on the grounds that the acetate ion forms an insoluble calcium complex. The use of the citrate ion, usually added as the trisodium salt, as a buffer in place of TISAB appears to overcome this objection. In a recent communication[11] we described a method utilizing hydrochloric acid to dissolve solid calcium orthophosphates, and trisodium citrate for pH control. Whilst this method has proved useful for the analysis of pure calcium orthophosphates, and has also been used with success on many other bivalent metal orthophosphates, it has been found that certain metal ions are complexed preferentially with fluoride rather than with citrate under the conditions used in the determination, and therefore give rise to low readings for fluoride content of the solutions when this is determined electrometrically. Because many mineralogical and biological samples of calcium orthophosphates contain appreciable quantities of some of these ions, we have developed a method of minimizing the interference from them in fluoride determinations by employing triethanolamine in the presence of citric acid as the complexing ligands, at a pH in the range 4·5–7·5.

EXPERIMENTAL

Reagents

Dissolution acid—either *A* or *B*. *A*: 2*M* in each of hydrochloric and citric acids: 420 g of analytical-reagent grade citric acid dissolved in 700 ml of demineralized distilled water and 172·5 ml of analytical-reagent grade concentrated hydrochloric acid and diluted to 1 litre with demineralized distilled water. *B*: 2*M* in each of perchloric and citric acids: 166 ml of analytical-reagent grade perchloric acid (70–72%) in place of the hydrochloric acid in *A*.

Triethanolamine (*TEA*) *solution*. Reagent-grade TEA (266 ml) diluted to 1 litre with demineralized distilled water.

Instruments

For pH. Pye 290 pH meter with a Pye-Ingold E-07 combination pH electrode.

For pF. Orion 94-09 or 94-09A fluoride-selective electrode with a Cambridge Instrument 42528 ceramic plug calomel reference electrode, or a Radiometer K401 calomel reference electrode.

Radiometer mains-operated PHM 53 selective-ion meter.

Procedure

Between 0·2 and 0·3 g of solid calcium orthophosphate (or other orthophosphate) is dissolved in 5 ml of the dissolution acid, then 5 ml of demineralized distilled water are added followed by 15 ml of TEA. (The quantities may be scaled down or up as appropriate) The pH of the system should now be in the range 5·0–5·8. The pF is now measured after allowing sufficient time for the electrode to equilibrate. (N.B. A minor modification introduced after this procedure was developed, a Radiometer PHM 51 meter, which has a recorder output, may be connected to a suitable pen recorder to facilitate the taking of readings when the response time is long (this is only necessary when the fluoride content of the system is less than $5 \times 10^{-5}M$).) The PHM 51 is a combined pH and univalent-ion meter; whilst for many purposes it is as good as the PHM 53 for selective ion work, experience of both meters in these laboratories suggests that the PHM 53 meter, despite its longer response time, yields more reproducible results with fluoride-selective electrodes than does the PHM 51. The fluoride content of the solution may be determined by reference to a suitable calibration curve constructed by substitution of 5 ml of an appropriate standard fluoride solution (analytical-reagent grade sodium fluoride) for the 5 ml of demineralized distilled water. The calibration curve method also affords a method for the determination of fluoride in aqueous solutions. Higher pH up to 7·5 may be used if desired simply by increasing the amount of TEA used. Some decrease in the sensitivity occurs at pH higher than 6·0.

DISCUSSION

The technique described here differs from that developed earlier in these laboratories in that citric acid is substituted for trisodium citrate, and triethanolamine is used to buffer the system at the desired pH. A 2*M* solution of TEA has a pH of *ca* 9·2. The total ionic strength of the final solution is about 1·7–1·9, which is quite usual for fluoride determination. It is, however, unusual to carry out the determination at a pH much above 6·0 because interference from hydroxide ions is then more likely. We explored the extent of hydroxide interference in the system described here, by using 2*M* TEA solutions, and reducing the quantity of dissolution acid used, the total volume being kept constant by addition of demineralized distilled water. This had the effect of increasing the pH without greatly decreasing the ionic strength. Two standard fluoride solutions were used for these determinations: 5×10^{-3} and $10^{-4}M$. Hydroxide ion interference occurred in both cases when the pH exceeded 8·2. Thus in the range pH 5·0–7·5 which may be used in this work, no hydroxide ion interference should occur. However, if an alkaline solid sample or solution is being analysed it may be advisable to ascertain the pH of the sample solution before the fluoride determination is made and, if necessary, to reduce the pH to below 7·5. The optimum pH for the determination is pH 5·4.

Many transition metal ions form soluble complexes of the type MF_x^{x-y} (where x is the number of fluoride ions in the complex, and y is the charge on the metal cation M). Until recently, little was known of the nature of metal-ion interactions with fluoride ions. With the advent of the fluoride-selective electrode, more knowledge has been gained of these systems. Recently, the stability constants of fluoride complexes of H^{+},[13] Al(III) and Fe(III),[14] Sn(II)[15] and Cd, Mg, Ni, and Ag(II)[16] have been determined. Whilst bivalent transition metal fluoride complexes are relatively weak, they are nevertheless significant in that distinctly low values for fluoride are recorded in the presence of these metal ions. That these complexes are not entirely dissociated by hydrochloric acid–citric acid buffer at pH 4·8–5·5 is shown in Table I.

It has been shown recently[17] that TEA will form complexes with a number of bivalent transition metal ions, and under certain conditions, these can be obtained as solid compounds. We suggest that some complexing of these ions by TEA is occurring in aqueous solution, and that this, together with the higher pH used in this work for fluoride determination, results in a more complete recovery of the fluoride present (see Table I).

TABLE I.—DETERMINATION OF FLUORIDE IN THE PRESENCE OF VARIOUS METAL IONS WITH USE OF HYDROCHLORIC ACID–CITRATE OF PERCHLORIC ACID–CITRIC ACID–TEA BUFFERS

Metal ion (25 ppm)	Fluoride found, *ppm*			
	Hydrochloric acid–citrate buffer		Perchloric acid–citric acid–TEA, pH 7	
	A*	B†	A*	B†
None	48·5	4·9	48·5	4·92
Fe(II)	44·2	4·2	48·4	4·90
Zn	48·0	4·8	48·5	4·91
Ni	48·4	4·9	48·6	4·90
Co(II)	48·2	4·85	48·5	4·95
Mn(II)	47·5	4·8	48·5	4·95
Cr(III)	47·0	4·42	48·4	4·89
Cu(II)	46·5	4·5	48·4	4·89
Al (as SO_4^{2-})	10·7	0·0	15·5	0·0

* 47·5 ppm fluoride taken.

† 4·75 ppm fluoride taken.

Solutions prepared from 1 ml of 500-ppm metal ion solution + 10 ml of 100-ppm or 10-ppm sodium fluoride solution + 10 ml of buffer solution.

Of the ions investigated, only aluminium causes incomplete recovery of fluoride. This is not altogether surprising as the AlF_6^{3-} ion is one of the most stable complex ions known. With this proviso, the method described here appears to overcome the majority of the interferences in the electrometric determination of fluoride that arise from complexing with metal ions. Repeated determinations on samples gave a reproducibility of better than ±3%, similar to that obtained by our earlier method. There was no significant difference in the results obtained by using perchloric rather than hydrochloric acid for sample dissolution. Neither perchlorate nor chloride interfered when present in 5000-fold amounts nor calcium nor orthophosphate (as HPO_4^{2-} or $H_2PO_4^{-}$) when present in 3000-fold amounts. The method has also been used for the determination of fluoride in samples of transition metal orthophosphates (Table II).

A comparison was made to determine the lower limit of fluoride determination by this method and by our earlier method. A calibration curve was constructed for both methods, using freshly prepared solutions of sodium fluoride (analytical-reagent grade) of concentrations in the range 10^{-1}–$10^{-8}M$. The method described here gave a reproducible linear calibration curve to 7 × $10^{-5}M$, 1·7 × $10^{-5}M$, after which there was a gradual but reproducible curvature to 8 × $10^{-7}M$. At fluoride at pH 7·0 and circa 10^{-6} M at pH 5·4 after which it curved off sharply. The curve obtained by using our earlier method[11] was linear to concentrations below this, the curve fell away sharply. It would appear therefore, that this present method is not readily applicable for the determination of fluoride at concentrations much below $10^{-4}M$ at the higher pH which may be used, whereas our previous method may, and has been, used successfully down to $10^{-6}M$. (N.B. These concentrations represent the concentration of fluoride in the buffered solutions and not in the sample solution. At these very low concentrations, a response time of 30 min is required in order to obtain reproducible results.)

TABLE II.—DETERMINATION OF FLUORIDE IN VARIOUS METAL ORTHOPHOSPHATES

Compound	Fluoride found, *ppm*				
	In sample	With 10 *ppm* added fluoride	Relative std. devn., %	With 1000 *ppm* added fluoride	Relative std. devn., %
Cupric apatite	495	504	1	1502	3
Nickel orthophosphate	1064	—	—	2050	2
Cobalt orthophosphate	238	248	1	1241	1
$CuHPO_4$	8·2	17·9	1	1009	1
$Zn_3(PO_4)_2{\cdot}4H_2O$	3·7	13·6	1	1001	1
$Ni_3(PO_4)_2 7H_2O$	19·5	29·4	1	1021	1
$CaHPO_4$	8·2	19·0	1	1009	1
$CaHPO_4{\cdot}2H_2O$	20·2	30·1	1	1021	1
$Ca_5OH(PO_4)_3$*	58·2	68·3	1	1054	1
$Ca_5F(PO_4)_3$†	37·8 × 10^3	—	—	38·8 × 10^3	2

* Prepared by reaction from $CaHPO_4{\cdot}2H_2O$ in 0·1*M* sodium hydroxide solution.[18]
† Prepared by reaction from $CaHPO_4{\cdot}2H_2O$ in 0·1*M* sodium fluoride solution.[19]

Care of the electrodes

The sensitivity and response time of the fluoride-selective electrode appear to be directly related to the treatment received by the electrode immediately before the determination. It was found that optimum sensitivity and response could be obtained by storage of the electrode in a buffer solution made $10^{-3}M$ in sodium fluoride. Care should be taken that this solution does not evaporate, as it has been found that a solution more than 10*M* in TEA may damage the electrode. Immediately before use, and immediately after, the electrode should be washed with demineralized distilled water, and carefully dried with a tissue, after which the electrode is ready for use. Alternatively, the electrode may be stored in demineralized distilled water. It should be noted that although the Cambridge Instrument type 42528 calomel reference electrode appeared to survive storage under either of these conditions satisfactorily, the Radiometer type K401 calomel electrode suffered diffusion of KCl from the electrode to the storage solution. This electrode should therefore be stored dry. Repeated swings from low a_{F^-} samples to high a_{F^-} samples should be avoided, and if several samples are to be analysed which contain different fluoride levels, it is advisable to begin with those at the lower levels. Little difference was found between the sensitivity of the older Orion 94-09 fluoride-selective electrode, which has been used in these laboratories continuously for over 4 years, and a new example of the newer type of electrode, Orion 94-09A.

Summary—A method is described for the determination of fluoride in inorganic orthophosphates. Interference by complex-forming metal ions is avoided by the use of a citric acid–triethanolamine buffer, pH < 7·5.

Zusammenfassung—Ein Verfahren zur Bestimmung von Fluorid in anorganischen Orthophosphaten wird beschrieben. Eine Störung durch komplexbildende Metallion wird durch Verwendung eines Puffers aus Zitronensäure und Triäthanolamin bei pH < 7,5 vermieden.

Résumé—On décrit une méthode pour le dosage du fluorure dans les orthophosphates minéraux. On évite l'interférence des ions métalliques formant des complexes par l'emploi d'un tampon acide citrique-triéthanolamine, pH < 7,5.

Determination of phosphorus in coke by the oxygen-flask method

(*Received* 12 *January* 1971. *Accepted* 13 *July* 1971)

EARLIER[1] we described the determination of phosphorus in coke by oxygen-flask combustion followed by the method described in B.S. 1016 Part 9.[2] More recently a new reagent was proposed for the reduction of phosphomolybdate[3] and applied to the determination of phosphorus in coal,[4,5] the novel feature being reduction of phosphomolybdate by ascorbic acid, with potassium antimonyl tartrate as catalyst, the reagents being combined in a single solution. This paper shows how these developments were combined for determination of phosphorus in coke.

EXPERIMENTAL

Preliminary studies of the reducing agent suggested by Shafran *et al.*[3] led to minor modifications of the method, involving daily preparation of fresh batches of reagent solution, and an increase to 20 min in the time allowed for development of the colour.

A comparison was then made of the results obtained by the British Standard method[2] and the modified method using the catalysed ascorbic acid reagent. The mean results of duplicate tests are given in Table I for a series of commercially produced high-temperature metallurgical cokes. The phosphorus was extracted from the ash by the British Standard method.

It was concluded that the proposed reducing agent functioned successfully. Because of the volume of the $1N$ sulphuric acid used as absorbent in the flask-combustion method it was necessary to reduce the concentration of the acid used in the preparation of the reagent solution.

Reagents

Sulphuric acid, $5N$.

Ammonium molybdate solution, 6% w/v.

Ascorbic acid solution, 5% w/v.

Potassium antimonyl tartrate solution. Dissolve 0·34 g of reagent in 250 ml of water.

Reagent solution. Mix 125 ml of the sulphuric acid, 50 ml of the ammonium molybdate solution, 50 ml of the ascorbic acid solution and 25 ml of the antimony potassium tartrate solution. Prepare freshly each day before use.

Standard phosphorus solution. Dissolve 0·4392 g of potassium dihydrogen phosphate (dried at 110° for 1 hr) in water and dilute to 1 litre. Dilute 20 ml of this standard solution to 1 litre with water to obtain the working solution, which contains 2 μg of phosphorus/ml.

Eschka mixture. Analytical reagent quality.

Apparatus

A 250-ml combustion flask, fitted with a B24 stopper carrying a platinum wire 60 mm long and 1 mm in diameter. The sample carrier attached to the platinum wire is 20 mm long and 7·5 mm in diameter, fabricated from 36-mesh (422-μm) platinum gauze.

Procedure

Mix intimately 30 mg of coke, ground to pass a 240-mesh (63-μm) test-sieve with approximately 30 mg of Eschka mixture, wrap the mixture in filter paper and burn it in the oxygen flask, which contains 10 ml of $1N$ sulphuric acid as absorbent. Shake to absorb combustion products, wash the platinum basket with distilled water, boil the solution for a few min, cool and filter into a 50-ml standard flask. Dilute to 35 ml with distilled water, add 5 ml of fresh reagent solution by pipette, swirling the flask during the addition, dilute to the mark with distilled water, shake and stand for 20 min. Measure the absorbance at 680–710 nm in 40-mm cells against distilled water.

Run a blank determination and apply an appropriate correction.

RESULTS

Table II compares the mean values of duplicate determinations by the present standard method and the new method. The same operator carried out all the determinations.

The within-laboratory tolerance of the determination (95% limits) is 0·0013% phosphorus. The corresponding value for the tests carried out by the B.S. method was 0·0010%. These limits are

Spectrophotometric study of the determination of copper with ammonium 1-pyrrolidinecarbodithioate

(*Received* 3 *December* 1970. *Accepted* 3 *August* 1971)

A NUMBER of chromogenic agents have been proposed for the determination of micro amounts of copper. Dithizone gives a sensitive colour reaction but is not very specific.[1,2] Cuproine, 2,2′-biquinoline, is a more specific reagent for copper but is less sensitive.[3,4] Neocuproine, 2,9-dimethyl-1,10-phenanthroline, reacts with copper(I) to form an extractable metal chelate with a molar within those adopted in the current British Standard (0·002% for cokes with a phosphorus content of $\leqslant$0·02%, or 10% of phosphorus content >0·02%.)

The method is shorter, simpler and cheaper than that described in the present standard and is thus suitable for use in control or plant laboratories. The technique of reducing phosphomolybdate by ascorbic acid, with potassium antimonyl tartrate as catalyst in a single solution has been adopted in the revised version of the B.S. method for the determination of phosphorus in coal and coke.[6]

Spectrophotometric study of the determination of copper with ammonium 1-pyrrolidinecarbodithioate

(*Received* 3 *December* 1970. *Accepted* 3 *August* 1971)

A NUMBER of chromogenic agents have been proposed for the determination of micro amounts of copper. Dithizone gives a sensitive colour reaction but is not very specific.[1,2] Cuproine, 2,2′-biquinoline, is a more specific reagent for copper but is less sensitive.[3,4] Neocuproine, 2,9-dimethyl-1,10-phenanthroline, reacts with copper(I) to form an extractable metal chelate with a molar absorptivity of 7·95 × 10^2 l.mole^{-1}.mm^{-1}.[5] The copper(I) chelates of several bipyridyl derivatives have been studied: 6,6'-dimethyl-2,2'-bipyridine;[6] 2,6-bis(6-phenyl-2-pyridyl)-4-phenylpyridine;[7] and 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline, bathocuproine.[8]

One of the most widely used spectrophotometric reagents for copper is sodium diethyldithiocarbamate which forms an extractable complex exhibiting a molar absorptivity of 1·3 × 10^3 l.mole^{-1}.mm^{-1}.[9,10]

The main disadvantages of this reagent are its instability in acidic media and lack of specificity. However, the deleterious effect of many metals can be circumvented by masking the interfering cations with EDTA.[11] Zinc dibenzyldithiocarbamate has been used as an alternative reagent because it is more stable in acidic solutions and shows less interference by iron(III) and several other ions.[12,13] The extensive use of ammonium 1-pyrrolidinecarbodithioate, often designated ammonium pyrrolidinedithiocarbamate, as an extractant for copper before the determination of copper by atomic-absorption spectrometry,[14–16] and the superiority of this reagent in the ultraviolet spectrophotometric determination of cadmium, cobalt and bismuth,[17] resulted in the spectrophotometric study of the copper(II)–1-pyrrolidinecarbodithioate system. The proposed method is selective and more sensitive when ultraviolet absorbance measurements are made. The reagent is more stable, especially in acidic solutions, than its diethyl analogue.

EXPERIMENTAL

Reagents

Standard copper(II) *solution.* Transfer 0·1000 g of reagent grade copper metal to a small conical flask and add 3–5 ml of concentrated nitric acid to effect dissolution. Add 10–15 ml of water and heat to boiling. Rinse the inside of the flask with 10–15 ml of water and heat again to boiling to expel oxides of nitrogen. Transfer this solution and several rinsings of the flask to a 1-litre volumetric flask and dilute to volume with water. A tenfold dilution of this stock solution gives a standard solution containing 10·0 μg of copper per ml.

Ammonium 1-pyrrolidinecarbodithioate (APCDT) regent solution. Dissolve 0·150 g of pure ammonium 1-pyrrolidinecarbodithioate in 100 ml of water containing 0·1–0·3 ml of ammonia solution (1 + 1). Filter and store in an amber glass bottle. The reagent is stable for at least two weeks.

Acetate buffer solution. Dissolve 12·3 g of sodium acetate trihydrate in distilled water. Add 5·0 ml of glacial acetic acid and dilute to 1 litre with distilled water. The pH of this buffer solution is 4·7.

Phosphate buffer solution. Dissolve 0·40 g of potassium dihydrogen phosphate in approximately 900 ml of distilled water. Add sufficient potassium monohydrogen phosphate to adjust the pH to 8·0 and dilute to 1 litre.

Procedure

Transfer 10 ml of buffer solution to a 60-ml separatory funnel. (Use phosphate buffer if absorbance measurements are to be made at 269 nm; use the acetate buffer if absorbance measurements are to be made at 435 nm.) Add the sample solution containing about 1–80 μg of copper(II). Add 5 ml of the 0·15% APCDT solution, mix and allow to stand for 5 min. Add 10 ml of chloroform and shake vigorously for 1 min in a mechanical shaker. Prepare a reference blank solution by the same procedure but using distilled water instead of the sample solution (use the same total volume). Measure the absorbance at 269 nm (phosphate buffer) or 435 nm (acetate buffer) in 10-mm silica cells.

RESULTS AND DISCUSSION

Absorption spectra

Aqueous solutions of ammonium 1-pyrrolidinecarbodithioate exhibit ultraviolet absorbance maxima at 254,277 and 336 mn, whereas the chloroform extract of the reagent exhibits absorbance maxima at 280 nm and 336 nm. Absorbance maxima for the copper(II)–1-pyrrolidinecarbodithioate complex were found at 269 nm and 435 nm. Figure 1 shows the characteristic absorption spectrum of the copper–PCDT–chloroform system as measured against a chloroform extract of a reagent blank solution.

Effect of solution variables

Concentration of copper. Conformity to Beer's law was observed over a concentration range of 0·1–8 ppm of copper. The optimum concentration range is 0·2–4·0 μg of copper per ml when the phosphate buffer is used and the absorbance is measured at 269 nm and 0·4–4·0 μg of copper per ml when the acetate buffer is used and the absorbance is measured at 435 nm.

Concentration of reagent. The effect of adding varying amounts of the 0·15% APCDT solution to a solution containing 2 μg of copper per ml showed that when absorbance measurements were made at 435 nm the absorbance did not change when the mole ratio of reagent to copper varied from 6 : 1 to 240 : 1. The fact that the reagent does not absorb at 435 nm means that the exact amount of reagent used is not critical. Therefore, the 5 ml of 0·15% reagent used in the procedure provides for about a 20–30-fold excess of reagent for the highest concentration of copper which can be determined by this method. Because the reagent does absorb at 269 nm careful control of the concentration of the reagent is essential when this wavelength is used and necessitates the use of a reagent blank solution in the reference cell. Thus, the higher sensitivity achieved by making absorbance measurements at 269 nm is accompanied by some loss in precision because of slight variations in reagent concentration.

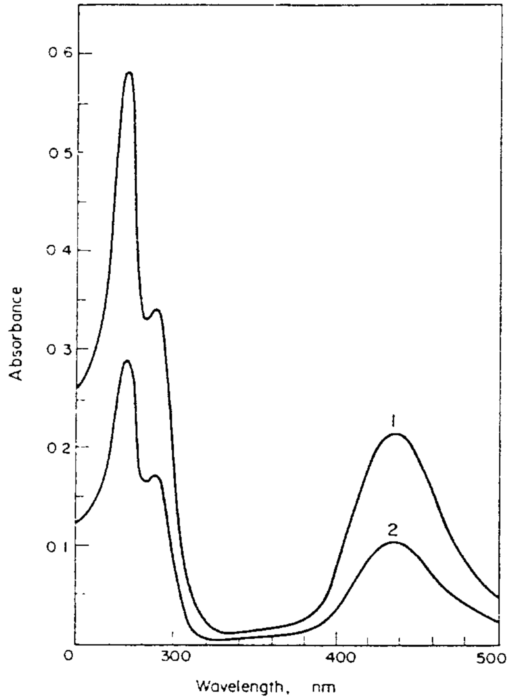

Fig. 1.–Characteristic absorption spectra for the Cu-PCDT complex in chloroform.
1. Copper 1 μg/ml
2. Copper 0·5 μg/ml

pH. The results of a study of the effect of pH on the determination of 2 μg of copper per ml showed that at pH of 4, 5, 6, 7, 8 and 9·5 the corresponding absorbance values at 435 nm were 0·429, 0·422, 0·422, 0·422, 0·420 and 0·418. Hence control of pH is not critical in the range 4–9·5, which is useful for trying to mask certain interfering ions. However, if the absorbance measurements are to be made at 269 nm, it is necessary to use the basic phosphate buffer solution because in acidic media the extraction of reagent is excessive and causes difficulty in using the external compensation technique of spectrophotometric measurement.

Extraction time. The effect of shaking time on the efficiency of the extraction was studied. When shaking times of 30, 45, 60, 90 and 120 sec were used the corresponding absorbances obtained were 0·419, 0·423, 0·423, 0·422 and 0·420. An extraction time of one minute was selected as being optimum. The volume of chloroform used is not critical, because of the very favourable distribution ratio for the copper(II)-PCDT system. Although the use of 10 ml of chloroform is designated in the recommended general procedure, the use of 5 ml of chloroform was found to be equally efficient and is recommended if less than 0·5 μg of copper is to be determined.

Co^{2+}	50	0	50
Fe^{3+}	50	0	50

* Causes an error of less than three times the standard deviation with 2·0 ppm of copper.

Composition of the complex

A study of the composition of the copper (II)–PCDT system was made by the mole-ratio method. A $4{\cdot}7 \times 10^{-7}M$ copper (II) solution and a $4{\cdot}7 \times 10^{-4}M$ reagent solution were used with absorbance being measured at 435 nm. As shown in Fig. 2 a 1 : 2 ratio was obtained for the Cu–PCDT complex.

Effect of diverse ions

A concentration of 500 ppm of the following anions caused no interference in the determination of 2 ppm of copper when absorbance measurements were made at 435 nm: acetate, bromide, carbonate, chloride, iodide, fluoride, molybdate, nitrate, perchlorate, phosphate, thiocyanate, silicate, sulphate, sulphite, selenite, vanadate, tungstate, tartrate and EDTA. Of the cations tested, the following can be tolerated at 500-ppm level: ammonium, aluminium, barium, calcium, magnesium, potassium and sodium.

Table I shows those ions which caused an error larger than 3 times the relative standard deviation when present at 500-ppm concentration. Most of the interfering ions form chelates with the excess of reagent. Although these other metal–PCDT complexes may have absorbance maxima considerably removed from that of the copper-PCDT system, interference results at relatively high concentrations of the diverse ion. Interference may be circumvented by the control of pH, the use of masking agents and by using a lower concentration of the reagent so that less of the interfering metal chelate is formed.

Precision

A statistical study of the 435-nm method was made to estimate the precision. Ten independent determinations on solutions containing 2·5 μg of copper per ml gave a mean absorbance value of 0·520, and a standard deviation of $3{\cdot}8 \times 10^{-3}$ absorbance unit or relative standard deviation of 0·7%. A similar statistical study of 6 independent determinations of the reagent blank solution gave a mean absorbance of 0·044, and a standard deviation of $2{\cdot}0 \times 10^{-3}$ absorbance unit or relative standard deviation of 4·7%

Sensitivity and detection limit

The molar absorptivities for the copper(II)–PCDT–chloroform system is $1{\cdot}35 \times 10^{3}$ $\text{l.mole}^{-1}.\text{mm}^{-1}$ at 435 nm and $3{\cdot}4 \times 10^{3}$ $\text{l.mole}^{-1}\text{mm}^{-1}$ at 269 nm. The detection limit based on Kaiser's[18] recommended criteria is 0·03 μg of copper when absorbance is measured at 435 nm.

Summary—A new spectrophotometric method for the determination of traces of copper has been developed. The method is based on the formation of a stable 1:2 complex of copper(II) and 1-pyrrolidinecarbodithioate and the isolation of this complex by extraction into chloroform. The absorbance is measured at either 269 nm or 435 nm. The detection limit is 0·03 μg of copper per ml for absorbance measurements at 435 nm.

Zusammenfassung—Ein neues spectrophotometrisches Verfahren zur Bestimmung von Kupferspuren wurde entwickelt. Es beruht auf der Bildung eines stabilen 1:2-Komplexes aus Kupfer(II) und 1-Pyrrolidincarbodithioat und der Isolierung dieses Komplexes durch Extraktion in Chloroform. Die Extinktion wird entweder bei 269 nm oder bei 435 nm gemessen. Die Nachweisgrenze beträgt 0,03 μg Kupfer pro ml, wenn die Extinktion bei 435 nm gemessen wird.

Résumé—On a élaboré une nouvelle méthode spectrophotometrique pour le dosage de traces de cuivre. La methode est basée sur la formation d'un complexe stable 1:2 entre le cuivre et le 1-pyrrolidine carbodithioate, et l'isolement de ce complexe par extraction en chloroforme. On mesure l'absorption à 269 ou à 435 nm. La limite de détection est de 0,03 μg de cuivre par ml pour les mesures d'absorption à 435 nm.

Stabilities of some cyclopentadienide metal complexes

(*Received* 11 *June* 1971. *Accepted* 21 *August* 1971)

During the last two decades the metal complexes of cyclopentadienide have been intensively studied in connection with the problems of organometallic chemistry.[1] For that reason, it may be of some interest to determine the stability of those complexes in solution.

EXPERIMENTAL

Reagents

Preparation of cyclopentadiene. Add dropwise sodium cyclopentadienide to a cooled (−5° to 0°) well stirred solution of 3*M* sulphuric acid. Separate the organic layer, dry it with anhydrous sodium sulphate and distil under normal pressure in an atmosphere of nitrogen. Collect the 39–41° fraction. Store the product in the dark in a solid carbon dioxide bath.

When stored under the given conditions, the product is stable for 2–3 weeks. The quality of the product was checked by measurement of the refractive index $n_D^{25°} = 1{\cdot}4471$ (1·4404) and density $d_D^{25°} = 0{\cdot}7969$ (0·7966). The values in brackets are due to Raistrik *et al.*[2]

To avoid the oxidation of cyclopentadiene and ions of iron(II), manganese(II) and cobalt(II), all solutions (including the buffer solutions) were prepared in a nitrogen atmosphere from solvents from which oxygen had been removed by distillation in nitrogen. Ethanolic and dimethylformamide solutions of cyclopentadiene ($1{\cdot}00 \times 10^{-2}M$) were prepared daily.

Metal ion solutions. The aqueous and dimethylformamide solutions of metal chlorides were $1{\cdot}00 \times 10^{-2}M$.

Buffers solutions. The pH was adjusted by means of borax and perchloric acid (pH 7·20–9·01), borax and sodium hydroxide (pH 9·26–10·82), and sodium hydroxide (pH 10·93–15·80). The ionic strength between pH 7·20 and 12·95 was kept constant (0·10*M*) by means of sodium perchlorate.[3] The data of Schwarzenbach and Sulzberger[4] were used to establish pH 13·00–15·80. The nitrogen used was washed with 10% chromium(II) chloride solution.

Measurement

A nitrogen atmosphere was used for the preparation of solutions to be measured and for the absorbance measurements. The sequence reagent, metal ion and buffer was adhered to during the preparation of all measured solutions; the temperature was kept at 25±1°. The absorbance of solutions was measured against a solvent–buffer blank.

† $c_M = 8{\cdot}00 \times 10^{-5} M$ throughout.

‡ $\Delta A = A - A_M - A_L$ where A is the absorbance of the solution with the complex, A_M and A_L are the absorbances of the metal ion and cyclopentadiene solution respectively. Subscript 1 refers to the basic total concentrations c_M, and c_L, subscript 2 to $c_M/2$ and $c_L/2$.

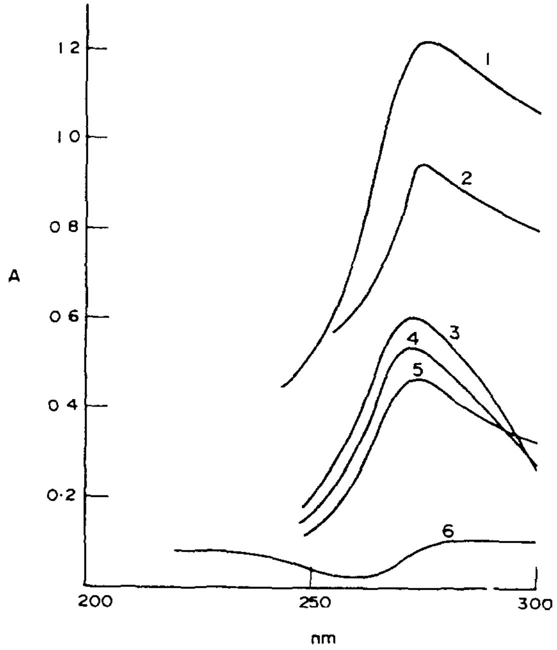

FIG. 3.—Absorption spectra of iron(II) (1), manganese(II) (2), cobalt(II) (3), palladium(II) (4) and nickel(II) (5) complexes of cyclopentadienide in dimethylformamide solution. Curve 6 is reagent alone.

$2c_M = c_L = 4{\cdot}00 \times 10^{-5} M$ was used throughout.

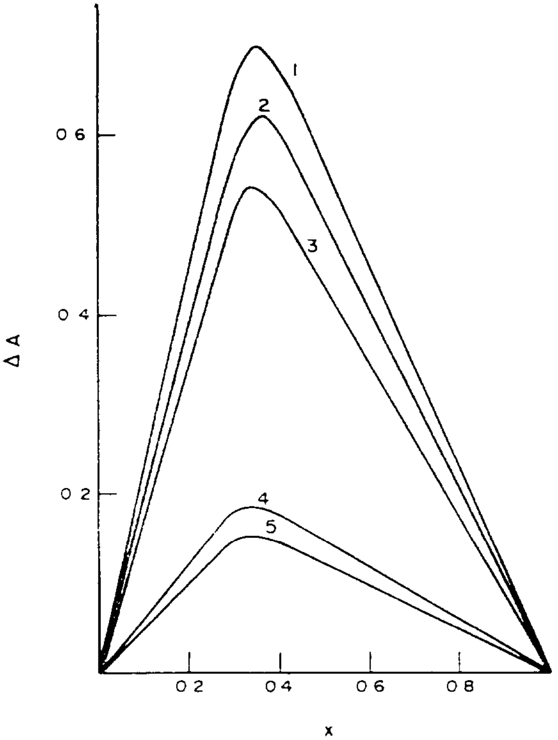

FIG. 4.—Continuous variation for iron(II) (1), manganese(II) (2), cobalt(II) (3), palladium(II) (4) and nickel(II) (5) with cyclopentadiene in aqueous solution. $c_M + c_L = 8{\cdot}00 \times 10^{-5}M$, $\lambda = 220$ nm, pH 12·07. The designation ΔA indicates that the absorbance was corrected for the absorption by cyclopentadiene and metal $x = c_M/(c_M + c_L)$.

RESULTS

Hydrogen complex

The stability of the hydrogen complex of cyclopentadienide was determined by the usual spectrophotometric method.[3] A typical absorption spectrum is shown in Fig. 1. The dependence of absorbance on pH is presented in Fig. 2. The value of the constant found is given in Table I.

Metal complexes

The dependence of complex formation on pH was investigated spectrophotometrically. Some representative absorption spectra in aqueous solution are given in Fig. 1. Spectra in dimethylformamide are shown in Fig. 3. The metal : ligand molar ratio of the complex was determined by the method of continous variation in equimolar solutions. Curves obtained are presented in Figs. 4 and 5. The effective stability constants K_n of the complexes were determined by the method of stoichiometric dilution.[5] From a set of effective stability constant values, the overall stability constant β_n was determined by means of the equation

$$\log \beta_n = \log K_n + \log \alpha_{M(OH)} + n \log \alpha_{L(H)} + j\,\text{pH} \qquad (1)$$

where $\alpha_{M(OH)}$ and $\alpha_{L(H)}$ designate the side-reaction coefficients of the metal with hydroxyl ions and of the ligand with hydrogen ions respectively. They are given by the equations

$$\alpha_{M(OH)} = 1 + \beta^*/[H] \qquad (2)$$

$$\alpha_{L(H)} = 1 + \beta_H[H] \qquad (3)$$

where

$$\beta^* = [M(OH)][H]/[M] \qquad (4)$$

$$\beta_H = [HL]/[H][L] \qquad (5)$$

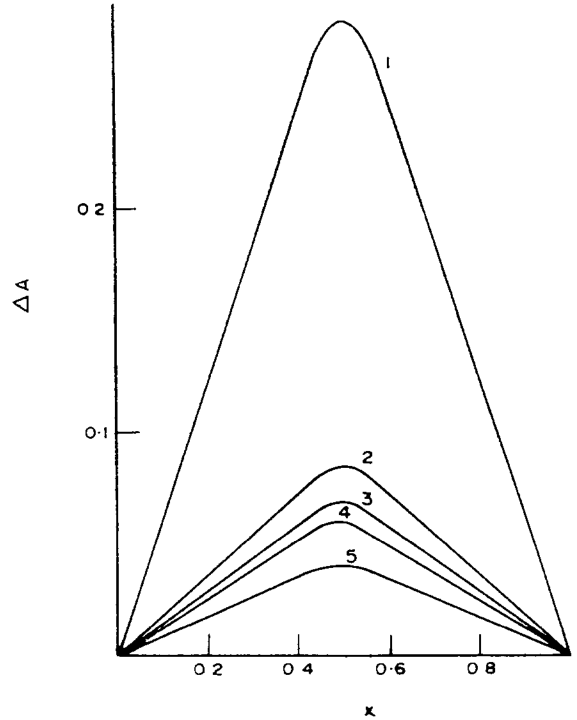

FIG. 5.—Continuous variation of iron(II) (1), manganese(II) (2), cobalt(II) (3), palladium(II) (4) and nickel(II) (5) with cyclopentadiene in dimethylformamide solution.

$c_M + c_L = 8{\cdot}00 \times 10^{-5}M$, $\lambda = 275$ nm. For ΔA and x see caption to Fig. 4.

The square brackets express the actual concentrations of the species. From possible complexes $M_i(OH)_i$ only the complex M(OH) was taken into account, owing to the low concentrations used. The values of β^* were taken from the monograph of Sillén and Martell.[7] The values of j designate the number of hydrogen ions in the complex MH_jL_n; L is the cyclopentadienide anion.

Results obtained are collected in Table I. They indicate that for metal complexes in aqueous solution j was always zero.

DISCUSSION

The value of the stability constant of the hydrogen complex of cyclopentadienide is in good agreement with previously estimated values.[8] Also the composition of cyclopentadienide metal complexes in aqueous solution is in agreement with the known data obtained by analysis of solid samples. However, the values of the effective stability constants show the relatively poor stability of the complexes in aqueous solution. The sequence of the values of overall stability constants indicates the adherence to the 18-electron rule, so an 18-electron complex has the maximum stability [complex of iron(II)] and with increasing deviation from that number there is a proportional decrease of stability of complexes.

It was impossible to determine the value of the overall stability constant of the palladium complex because of lack of data on palladium(II) hydrolysis.

The absorbance maximum of the iron(II) complex is in agreement with that measured for commercially available ferrocene. To prevent the hydrolysis of metal ions, the concentrations were kept as low as possible, therefore the far ultraviolet maxima were used, which occur practically at the same wavelength.

The complexation in dimethylformamide is apparently influenced by the strong nucleophilic properties of that solvent. This may be the reason for the formation of complexes with 1:1 molar ratio metal:ligand. Dimethylformamide ligands complete the saturation of the co-ordinative capacity of individual metal ions.

Attempts to study the complexation in pyridine were unsuccessful because of the strong absorption in the ultraviolet by that solvent.

Acknowledgment—The authors are grateful to the National Research Council (Ottawa, Ontario) for a grant that made this work possible.

Summary—The composition and stabilities of hydrogen, manganese(II), iron(II), cobalt(II), nickel(II) and palladium(II) complexes with cyclopentadienide were investigated spectrophotometrically in aqueous and dimethylformamide solutions. Corresponding effective and overall stability constants were determined.

Zusammenfassung—Die Zusammensetzung und die Stabilität der Cyclopentadienidkomplexe von Wasserstoff, Mangan(II), Eisen(II), Kobalt(II), Nickel(II) und Palladium(II) wurden spektrophotometrisch an Lösungen in Wasser und in Dimethylformamid untersucht. Die entsprechenden effektiven und Gesamtstabilitätskonstanten wurden ermittelt.

Résumé—On a étudié spectrophotométriquement la composition et les stabilités des complexes de l'hydrogène, du manganèse(II), du fer(II), du cobalt(II), du nickel(II) et du palladium(II) avec le cyclopentadiénide en solution dans l'eau et le diméthylformamide. On a déterminé les constantes de stabilité effectives et globales correspondantes.

PUBLICATIONS RECEIVED

Principles of Radiochemistry: H. A. C. McKay. Butterworths, London, 1971. Pp. 550. £13.00.

Written by a world-renowned chemist of long and vast experience, here is everything for all users of radioactivity as a tool. Origin, theories, handling, applications, everything is there with the exception of a cost analysis. At the price, this will inevitably be a book for the library, for reference, but perhaps two copies will be necessary—one for borrowing and one permanently on the shelves.

Treatise on Titrimetry; Volume 1, Inorganic Titrimetric Analysis (Contemporary Methods): Walter Wagner and Clarence J. Hull (edited by Joseph Jordan). Dekker, New York, 1971. Pp. xii + 225. $13.50.

It is fair comment on this compilation of methods to say that "contemporary titrimetry" ceased in 1968, or at least that is what appears to be the case. The only reference dated later than that not only has the year wrong but succeeds in transposing the digits in the volume number as well. The arrangement by groups of the periodic table is not as helpful or convenient as the general editor supposes, and an alphabetical arrangement would have been better. It is difficult to decide which is the more surprising in some of the choices of method—the ones that have been included or the ones that have been left out. According to the jacket of the book, advantages and limitations are pointed out; it is difficult, however, to see the advantage in recommending a method for copper that gives an error of 1–3% (pp. 13–14) when the "classical" version of the same reaction gives much lower error (a point made in the original of ref. 12 on p. 16 but omitted in the quotation from it). In short, this book is useful as a rough and ready guide to the literature up to late 1968 (for some journals—apparently earlier for others), but is limited by the selectivity imposed by the authors.

Analytical Methods for Atomic Absorption Spectrophotometry: edited by J. Kerber. Third Edition, Perkin–Elmer, Norwalk, Connecticut, 1971. $20.00.

This new edition of the well-known Perkin–Elmer manual replaces the 1968 edition, and will prove as generally useful as its predecessors. Like them, it carries the bonus of free supplements as they are issued.

Selected Annual Reviews of the Analytical Sciences, Volume 1: edited by L. S. Bark. Society for Analytical Chemistry, London, 1971. Pp. 269. £5.00; $12.50.

This first fruit of a new venture by the Society for Analytical Chemistry contains authoritative reviews on molecular-sieve chromatography, photoluminescence and chemiluminescence, activation analysis, atomic-absorption spectroscopy and catalytic methods. Those who regret the demise of the analytical section of the Annual Reports of the Chemical Society will find some consolation in these pages, although they will still mourn the loss of the comprehensiveness of the Reports.

Gas Chromatography: D. Ambrose. Second Edition, Butterworths, London, 1971. Pp. 321. £4.00, hard cover; £2.50, limp cover.

This revised edition of an already well-known work is to be welcomed for its thorough updating (up to 1970) of what is essentially a working chemist's guide to gas chromatography. Users of the first edition will know they should buy this one as well; newcomers will find it indispensable.

Nomenclature of Organic Chemistry: IUPAC. Third Edition, Butterworths, London, 1971. Pp. xiii + 337. £8.00.

The well-known "Sections A, B and C" of the IUPAC definitive rules on organic nomenclature have been revised and combined into a single handy volume, which will be welcomed by all organic chemists and all editors of chemical journals.

Problems in Advanced Organic Chemistry: Jerry March. Dekker, New York, 1971. Pp: viii + 421. $9.75.

These problems, ranging from bonding, through kinetics, mechanism and so on to literature searching, come complete with answers and will be a boon to those teachers who believe that the only way to learn to solve problems is to solve problems.

Oxidation: Techniques and Applications in Organic Synthesis, Vol. 2: R. L. AUGUSTINE and D. J. TRECKER. Dekker, New York, 1971. Pp. x + 204. $17.50.

This book contains review articles on four oxidation techniques in current vogue in organic chemistry, namely sulphoxide–carbodi-imide reactions, photo-oxygenation, hydrogen peroxide as reagent for producing epoxides, and metal ion–peroxide oxidations. Mechanism and application are both covered, and the volume should prove useful to the organic chemist interested in modern methods of synthesis.

Microtechniques—6: edited by G. KAINZ. Butterworths, London, 1971. Pp. 74. £2.00.

This volume contains the plenary lectures delivered at the IUPAC VIth Symposium on Microtechniques, organized by the Austrian Society for Microchemistry and Analytical Chemistry, in Graz in 1970. They cover inorganic and organic microanalysis, modern methods of organic structure determination, trace analysis by atomic-absorption and atomic-fluorescence spectroscopy, and modern radioanalytical methods.

Analytical Chemistry, Budapest 1970: edited by F. SZABADVÁRY. Butterworths, London, 1971. Pp. v + 201. £5.50.

This book contains the plenary lectures delivered at the IUPAC 3rd International Analytical Conference in Budapest, organized by the Hungarian Chemical Society and Academy of Sciences in 1970. The themes were solvent extraction of metal chelates, separation in inorganic and organic chemistry, a history of French analytical chemistry, electrolytic chromatography, enzyme electrode probes, chromic acid as oxidant in organic analysis, chromatographic polarography, pH, complexometric analysis, ion-exchange, ion-selective electrodes, reflectance spectroscopy, and thermal analysis.

Analytical Geochemistry: LORD ENERGLYN and L. BREALEY. Elsevier, Amsterdam, 1971. Pp. XV + 426. £9.25.

This is an account of the methods used today in geochemistry and geophysics, and the interests of its authors are reflected to some extent in the material chosen. Thus we are treated to a chapter on the principles of geochemistry as well as to the chemical methods of analysis used, and the sections on instrumentation occupy roughly half the book. In the purely chemical analysis sections, there are some surprising omissions, and some methods are simply reproduced from the literature quite uncritically. The English is rather quaint in places, and the proof-reader has left in "automatic sample spitter," presumably having taken this as a cry from the heart.

Conformational Analysis, Brussels, Belgium, 1969: edited by G. CHIURDOGLU. Butterworths, London, 1971. Pp. vi + 201. £5.30.

This volume contains the plenary lectures delivered at the IUPAC symposium on conformational analysis, organized in Belgium in 1969 by the Belgian Chemical Society, The Federation of Belgian Chemical Industries, and the University of Brussels, in 1969. The topics covered include the scope and limitations of the method, means of studying the conformation of compounds, and application of the technique to various systems.

Fluorescence Spectroscopy; An Introduction for Biology and Medicine: AMADEO J. PESCE, CARL-GUSTAF ROSÉN and TERRY L. PASBY. Dekker, New York, 1971. Pp. xiii + 247. $16.50.

This is a very readable account of fluorescence and should prove useful to others besides those readers indicated in the subtitle. There is the occasional lapse into the obscurity of jargon—for example, what is meant by "derivation of polarization of fluorescence equations"?— but the literature coverage is up to date (though selective) and the diagrams clear and helpful.

Flame Emission and Atomic Absorption Spectrometry; Volume 2—Components and Techniques: edited by JOHN A. DEAN and THEODORE C. RAINS. Dekker, New York, 1971. Pp. xiv + 362. $22.75.

As the title implies, this is essentially a practical guide to the equipment for flame spectroscopy, and how to use it. It is therefore packed with useful information, and likely to prove a flame-spectroscopists *vade mecum*.

Talanta, 1972, Vol. 19, pp. 93 to 124. Pergamon Press. Printed in Northern Ireland

TALANTA REVIEW*

ORGANIC ANALYSIS BY LUMINESCENCE METHODS

J. Bartos and M. Pesez
Centre de Recherches Roussel-Uclaf, F.93-Romainville, France

(*Received* 17 *March* 1971. *Accepted* 27 *July* 1971)

Summary—This review presents the major features of luminescence methods relating to the estimation of organic compounds in solution. A notation for reporting fluorimetric determinations is proposed. The outstanding factors affecting the fluorescence of solutions are briefly reviewed, and determinations of compounds offering a native fluorescence are illustrated by selected examples. Special attention is paid to functional fluorimetry and to the determination of non-fluorescent compounds by means of chemical reactions giving rise to fluorescent species. Some enzymatic reactions are described, as far as they allow the estimation of definite chemicals. Phosphorimetry and chemiluminescence are exemplified. An appendix presents some new functional fluorimetric determinations developed by the authors.

From 1957 to 1965, some 2000 papers were published on fluorimetric analysis, and the last biennial review in *Analytical Chemistry*,[1] covering the period approximately from December 1967 to December 1969, contains 763 references. Even if it is taken into account that these references include inorganic chemistry, it is obvious that an exhaustive bibliography of studies dealing with organic analysis by luminescence methods could not be condensed within the pages allocated to this review, and would duplicate existing reviews. Moreover, various books and monographs have been issued these last five years, trying to keep the analyst's knowledge in this field up to date.[2-9]

This review is limited to the presentation of the features of luminescence methods relating to the estimation of organic compounds in solution, and its major part is obviously devoted to fluorimetry. A notation for reporting determinations is suggested which will facilitate comparisons between results obtained with different apparatus. The outstanding factors affecting the fluorescence of solutions are reviewed, and determinations of compounds offering a native fluorescence are illustrated by some selected examples. Particular emphasis is placed on estimations which involve chemical reactions: functional fluorimetry and determinations of definite compounds. One section deals with some enzymatic reactions. Phosphorimetry and chemiluminescence, which have been scarcely applied until now to the determination of organic compounds are briefly dealt with. Theories of luminescence methods, and instrumentation are not dealt with, these topics being already widely covered.[2-4,9]

FLUORIMETRY

Fluorescence is the emission of light from a molecule which returns to its normal ground state from the lowest vibrational level of an excited singlet state, the excitation being achieved by the absorption of light.

---

* For reprints see Publisher's announcement at end of issue.

When compared to absorptiometric methods, fluorimetry offers various advantages. The sensitivity is usually from 10- to 100-fold greater, and in many instances allows work at levels below 1 ppm. Fluorescence methods may be specific. Only a limited number of molecules fluoresce, and they have individual excitation and emission spectra. With selected excitation and emission wavelengths, it is possible to determine a fluorescent compound in mixtures without tedious separations. Slightly turbid or coloured solutions do not generally lead to serious interferences.

On the other hand, the intensities of the fluorescence spectra are proportional to the concentration of the species only in dilute solutions. At higher concentrations, the intensity falls off, owing to inner-filter effects. Determinations must therefore be limited to the range over which linearity is observed. Commercially available instruments do not allow one to obtain an absolute expression of the fluorescence intensity, analogous to absorbance, and the excitation and emission spectra recorded with the usual spectrofluorimeters are distorted. However, in order to determine the concentration of a compound in solution, it is not necessary to know the relationship between uncorrected and true spectra, since at given excitation and emission wavelengths, the correction coefficient is the same for the sample, the blank and the reference.

Reporting results

In reports of determinations problems arise from the lack of an absolute expression of the fluorescence intensity and from the fact that the blank almost always fluoresces, particularly when a chemical reaction is involved. Most spectrofluorimeters are equipped with a zero potentiometer which is utilized to set the meter at zero and to supply blank suppression, but the deflection given by the sample remains arbitrary, varying with the adjustments.

Different methods are used to overcome these problems, and standardization would be highly desirable in this field, permitting a ready comparison of results gathered by authors working with various apparatus.

The instrument can simply be adjusted to read 50 per cent of full scale for a given concentration of the compound to be determined.[10] The fluorescence intensities of the samples can also be expressed in terms of an intensity scale on which a standard solution gives a deflection of 100 meter divisions, at the same wavelengths of excitation and emission.[11] Standard solutions of quinine sulphate, sodium fluoresceinate or 2-aminopyridine have often been used. With these methods, the blank value is not taken into account, and it is worth knowing it, since impurities are of the highest importance in fluorimetric determinations. The blank can vary widely from one series of assays to another, even with analytical-grade solvents and reagents.

Some authors give the limits of the range over which a linear relationship between concentration and emission of light is observed, and they express the blank value in μg/ml of the compound to be determined.[12,13] When concentrations are plotted on the x axis and readings on the y axis, this equivalent is the abscissa of the point where the extrapolated straight line for concentration *vs.* reading reaches the x axis.

In our first paper on fluorimetric functional analysis,[14] we proposed another notation. The meter is set at zero with the photomultiplier shutter closed. We give two limit values for the determination, the upper corresponding to a deflection of 100 meter units, the lower to the smallest weight of compound which can be estimated with a reasonable accuracy. It is of course implied that the relationship of concentration to reading is linear over this range. We also report the sample weight and the concentration of a suitable standard both corresponding to a deflection of 50 units. Therefore, knowing the sample concentrations which give readings 100 and 50, and since linearity is observed, it is easy to calculate the blank deflection. On the other hand, the knowledge of the standard concentration corresponding to the deflection 50 permits the proper adjustment of any fluorimeter. It must be verified that the cells used do not afford a noticeable interfering fluorescence. If they do, the corresponding readings must be subtracted from the respective deflections given by the blank, the samples and the standard.

Comparison of results obtained with two instruments (Farrand equipped with xenon lamp and gratings, and Electrosynthèse* with low-pressure mercury lamp and filters) showed only very slight discrepancies, probably due to the widths of the spectral bands. Therefore, the numerical values given make our results readily reproducible with other instruments, and it also becomes easy to find out whether unexpected discrepancies are related to an abnormal fluorescence of the blank, caused by the solvents or reagents. We suggest this method for reporting results be adopted by analysts dealing with fluorimetric determinations in solution.

It must be pointed out that it is not always worth operating at the wavelengths corresponding to the most intense emission of light from the sample, but at those corresponding to the highest difference between sample and blank. In our procedures, whenever possible, we propose an excitation wavelength accessible to apparatus equipped with a low-pressure mercury lamp and glass cells, *i.e.*, 366, 405, 436 and 546 nm, so that our results can be reproduced even with very simple instrumentation. The study of excitation and emission spectra recorded on a Farrand spectrofluorimeter has shown that, in these instances, the selection of the true optimum excitation wavelength would multiply the sensitivity only by a coefficient lower than 2.

It must also be emphasized that, when chemical reactions are involved in fluorimetric estimations in solution, the lower limit of the determination is strictly dependent upon the blank fluorescence, which cannot be avoided. Even if the fluorescent species would allow determination at a level of, *e.g.*, 10 ng, the blank may afford a fluorescence intensity corresponding to, *e.g.*, 1 μg of the said species, and therefore accurate determinations become possible only at levels permitting an appreciable difference between the assay and blank signals.

Factors affecting the fluorescence of solutions

The main factors affecting the fluorescence of a compound in solution at concentrations usually used for determinations are: solvent, pH, oxygen, photodecomposition, temperature. These effects have already been described and discussed in various books and reviews,[2,4,6,15] and we have gathered here only some information exemplifying them.

Solvent effects. In many instances, for a given compound, the colour and intensity of fluorescence vary with the nature of the solvent. The interpretation of these effects is often complicated, because the observed changes may be the resultant of several quite different forces which may either reinforce or minimize each other. Some of these phenomena are still imperfectly understood.

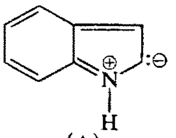
Changes in emission spectra may or may not be accompanied by modifications in the excitation spectrum. Changes in both spectra imply interaction with solvent in

---

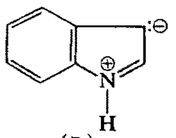
* Manufactured in France.

both ground and excited states of the molecule. Changes in only the emission spectrum mean that there is an interaction between solvent and the excited state of the molecule, but the ground state is not involved.

Provided that hydrogen-bonding does not take place, the effect of the solvent can often be related to its dielectric constant. Indole and substituted indoles show pronounced shifts to longer wavelengths in their fluorescence emission maxima with increasing dielectric constant of the solvent,[16] but comparable shifts are not observed in the fluorescence excitation spectrum. Polar mesomeric forms of indole such as (A) and (B) may make a larger contribution in the excited state of indole than in the ground state and such structures are expected to be more sensitive to the dielectric constant of the surrounding solvents. This explains why changes occur in emission spectra only.



(A)



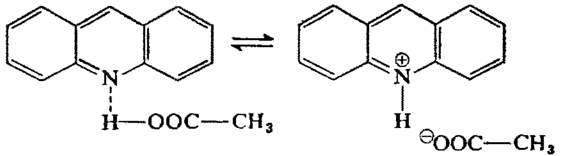
(B)

The quantum yield of dansyl DL-tryptophan increases with decreasing dielectric constant of the solvent: 0·068 in water, 0·35 in acetone and 0·70 in dioxan. At the same time, the fluorescence emission maximum shifts towards shorter wavelengths: 578, 513 and 500 nm respectively.[17]

In some instances, the refractive index of the solvent plays a role. In non-polar media, the shift of the fluorescence maximum of 1- and 2-acetylanthracenes increases with increasing refractive index of the medium.[18]

The viscosity of the solvent must also be taken into account. It is well known that increase in molecular rigidity and co-planarity of the rings increase fluorescence efficiency. It may thus be expected that substances possessing substituted phenyl groups which are capable of internal rotation will increase their fluorescence when dissolved in a medium which will rigidify them. For example, a diphenylmethane dye such as Auramine O becomes fluorescent when dissolved in a viscous medium (*e.g.*, glycerol).[19] Incidentally, it was found that this effect provides an extremely convenient means for measuring the viscosity of high-viscosity media.

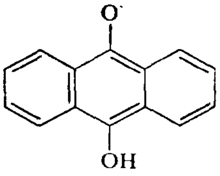
A compound may form hydrogen bonds with solvents in both the ground and excited states. In non-polar solvents such as benzene, chlorophyll shows only a weak fluorescence when water is rigorously excluded.[20] Addition of water or of a polar solvent causes a remarkable enhancement of fluorescence, due to hydrogen-bonding between the solvent and chlorophyll. The fluorescence of acridine in benzene solutions increases on addition of acetic acid,[21] and there are only minor changes in absorption. The hydrogen bond formation takes place in the ground state (C), but in the excited state an ion-pair (D) predominates, *i.e.*, in the excited state the equilibrium is shifted to the right as a result of the increased basicity.



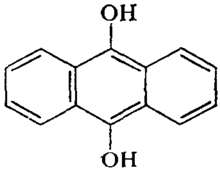
(C) (D)

Fluorescence quenching by solvent may permit selective determinations (see below under native fluorescence). Quenching processes divert the absorbed energy into channels other than fluorescence.

In its excited state, a molecule may react with the solvent. In alcohol solution, the singlet excited state of anthraquinone goes to the triplet state, which reacts with alcohol to form the semiquinone radical (E) and the alcohol radical which further reacts with a ground-state anthraquinone molecule to produce a second semiquinone radical and one aldehyde molecule. Through a disproportionation reaction, two semiquinone radicals give one molecule of anthraquinone and one molecule of 9,10-dihydroxyanthracene (F), which is highly fluorescent. Oxygen traps the radical (E), and the fluorescence is observed only in its absence.[22,23]



(E)



(F)

pH effects. It is obvious that for a compound which can undergo ionization, the neutral species, the anion and the cation may be differently excited, leading to different excitation and emission spectra. For example, the dibasic ion of quinine fluoresces blue, the monobasic ion fluoresces violet and the undissociated base does not fluoresce at all.

Compounds may be more acidic or more basic in the excited state than in the ground state. In acidic dimethylformamide, 8-aminofluoranthene absorbs as the cation and emits as the neutral amine. The deprotonation has taken place owing to collisions within the duration of excitation.[6] A methanol–trifluoroacetic acid solution of 9-acridanone shows the excitation spectrum of the neutral species and the emission spectrum of the cation. In strongly alkaline solution, the excitation and emission spectra are both derived from the anion.[24]

We shall not extend this paragraph beyond these examples, since a detailed study of pH effects has been given in a previous *Talanta* review.[6] Moreover, an account has been given recently of the theory of the effect of pH change on fluorescence of organic species which exhibit acid-base properties, and of the practical application of this effect.[25]

Effect of oxygen. Oxygen may decrease the fluorescence intensity of a compound by oxidizing it, and this reaction may be catalysed by ultraviolet irradiation. It may also accelerate the photodecomposition of the fluorescent species.[26] But often there is neither chemical decomposition nor catalysis of photodecomposition, and yet the fluorescence of almost all organic compounds is quenched at least slightly by oxygen. It is believed that, generally, the quenching is caused by a reaction between oxygen and the excited singlet state of the molecule, giving rise to a triplet state.[27]

Photodecomposition. Substances sensitive to ultraviolet light may of course suffer a photodecomposition during a prolonged fluorimetric examination. Reasonably rapid measurements are recommended in order to overcome this problem, particularly with very dilute solutions.

Temperature effects. Fluorescence intensity usually decreases with increasing temperature, owing to higher probabilities for the other means of deactivation of the excited molecule. Since most fluorimetric measurements are made at room temperature, it is best to take this temperature into account and to obviate heating of the sample chamber by excitation light, by using a suitable thermostatic arrangement whenever necessary.

Compounds possessing native fluorescence

De Ment[28] listed about 3000 compounds possessing native fluorescence. Some 600 are purely organic and fluoresce in solution. They can of course be determined without any prior reaction, usually at levels of 0·1–1·0 μg/ml, sometimes at much lower concentrations (*e.g.*, 0·1 ng/ml for quinine sulphate). Modern spectrofluorimeters permit detection and measurement of ultraviolet fluorescence, thus extending the field of these determinations. Suitable selection of pH, wavelength combinations and solvents are of the highest importance, and this section is limited to some selected examples pointing out these outstanding features.

Some phenols have been determined recently.[29] With one exception, they fluoresce in the ultraviolet region and, for each species, an optimum pH was proposed: phenol, excitation 276 nm, emission 365 nm, pyrocatechol 282/345 nm, hydroquinone, 298/350 nm, in 0·010–0·011M sulphuric acid; 4-hydroxybenzoic acid, 290/355 nm, in 0·10M sodium hydroxide; gentisic acid, 328/459 nm, in pH 5·5 buffer; protocatechuic acid, 300/370 nm, in pH 8·9 buffer.

Mixtures of 2- and 3-hydroxybenzoic acids can be analysed. At pH 12·0, both isomers fluoresce, whereas at pH 5·5 only the 2-isomer is fluorescent. 4-Hydroxybenzoic acid does not fluoresce at these two pH values and does not interfere.[30]

When excited at 295 nm, a neutral solution of serotonin exhibits an emission-peak at 330 nm. In acidic medium, this peak fades and another appears at 550 nm, reaching its maximum value in 3N hydrochloric acid.[31] An acid may intervene not only through its hydrogen ion, but also through its anion. For example, fluorescence of quinine sulphate is usually measured in 0·1N sulphuric acid. No fluorescence is observed in 0·1M hydrochloric acid. The fluorescences of fluorescein and Rhodamine are strongly diminished if the solutions contain a few per cent of salts such as potassium iodide or sodium chloride. Iodide ion also quenches the fluorescence of vitamin B_2.

Formaldehyde and acrolein both react with J-acid in sulphuric acid, yielding fluorescent chromogens which emit in the 500-nm region. Upon addition of water, the formaldehyde chromogen becomes virtually non-fluorescent at this wavelength.[32]

A suitable selection of excitation and emission wavelengths allows the determination of salicylic and acetylsalicylic acids in aspirin tablets.[33] The solvent is 1% acetic acid in chloroform. Salicylic acid is estimated at 308/450 nm, and acetylsalicylic acid at 280/335 nm, after a further dilution with the same solvent.

At the same excitation wavelength (365 nm), 1-naphthol and 2-naphthol in 0·2M sodium hydroxide were determined at emissions 480 nm and 426 nm respectively.[34]

A striking example of suitable selection of pH, wavelengths and solvent is given by the analysis of mixtures of morphine, codeine, narcotine and papaverine, the principal opium alkaloids.[11] A sample is dissolved in 0·1N sulphuric acid and most of the narcotine and papaverine are stripped from the acidic solution with chloroform. In the acidic medium, morphine and codeine both exhibit almost similar fluorescences.

In 0·1*M* sodium hydroxide, the fluorescence of codeine is only about 10% less intense than in 0·1*N* sulphuric acid, whereas that of morphine strongly weakens. Thus, a differential method allows the determination of these two species. Papaverine and narcotine are quantitatively extracted from a pH 9 buffer solution into chloroform. Papaverine fluorescence is measured at 320/348 nm. Narcotine does not interfere (maxima 335/400 nm). The addition of trichloroacetic acid to the chloroform solution intensifies the fluorescence of narcotine and shifts the maxima to 315/375 nm, whereas the fluorescence of papaverine is depressed and its maxima are shifted to 417/455 nm, thereby causing no interference in narcotine determination.

Quenchofluorimetric analysis[35] was applied to the selective estimation of various polynuclear compounds. For instance, in *o*-cresol solution, most of the aromatic amines remain fluorescent, whereas aza heterocyclic hydrocarbons and most of the heterocyclic imines are quenched. Nitromethane quenches the fluorescence of aromatic amines, heterocyclic imines, and most aromatic hydrocarbons except those containing a fluoranthene ring. With nitrogen dioxide–trifluoroacetic acid as the solvent, aza heterocyclic hydrocarbons remain fluorescent, aromatic amines, heterocyclic imines and polycyclic aromatic hydrocarbons are quenched.[36] A more detailed study of air pollutants was the subject of a previous *Talanta* review.[6]

A chemical reaction can also quench the fluorescence of one of the components of a mixture. For example, the Diels–Alder reaction of maleic anhydride with anthracene removes the lowest energy electronic transition of this hydrocarbon, permitting the fluorimetric measurement of pyrene, diphenylstilbene and perylene in the presence of the adduct.[37]

Raman effect. In determination of compounds possessing native fluorescence, with modern sensitive spectrofluorimeters, the limit of sensitivity is set by the magnitude of the blank. Some interferences can be avoided by choosing proper material for the cells, using efficient monochromators, high-purity solvents, *etc.* But in operations at high sensitivities, Raman emission from the solvent cannot be overcome.[38] For instance, when a solution of quinine sulphate in 0·1*N* sulphuric acid is excited at 365 nm, the main Raman band of water occurs at 416 nm and overlaps the edge of the fluorescence spectrum of the sample. At a dilution of 1 ng/ml, this band may be mistaken for part of the structure of the quinine sulphate band. The emission spectrum of a very dilute anthracene solution in *cyclo*hexane appears to have an additional band. Excitation spectra are also distorted, and these interferences can be even more important with filter fluorimeters.

All solvents containing hydrogen atoms interfere, and carbon tetrachloride is the most satisfactory solvent for high sensitivity spectrofluorimetry. The band shown by chloroform is less intense than those of water, ethanol or *cyclo*hexane. Raman bands are readily identified, since there is a constant difference between the wavenumber of the exciting light and the wavenumber of the Raman band.

For instance, with the excitation monochromator set at 365 nm, the wavelength of the main Raman band produced by water is 416 nm. With excitation at 405 nm, this band is shifted to 469 nm.

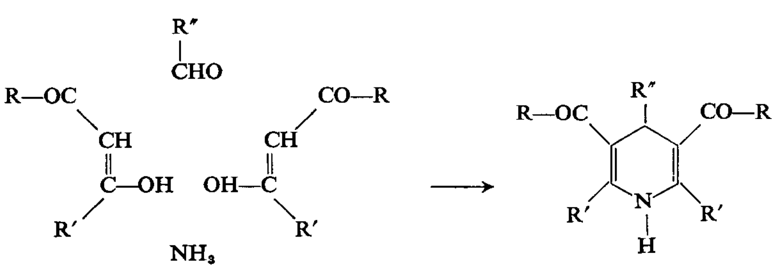
Functional organic fluorimetry

This branch of fluorimetry is based on chemical reactions characteristic of the various functional groups. A given reaction may therefore be applied to different molecules bearing the same group. Widely used in colorimetry for many years, this approach had until 1967 been but scarcely applied to fluorimetric determinations, probably because it is much easier to predict the development of a colour than of a fluorescence. But the knowledge of the compounds already described as being fluorescent, the study of their methods of preparation and the replacement, in the course of the synthesis, of one of the components by another molecule bearing the same functional group, recently led to an appreciable extension of this field of analysis. Furthermore, some unreactive groups can be converted into more reactive ones, or a molecule can be degraded, yielding a reactive species.

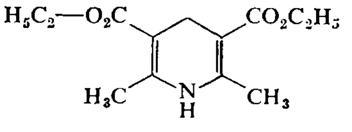
The following table summarizes the main references relative to the functional group determinations mentioned in this section.

Alcohols;[61] primary;[40] primary, α-amino-;[13,14] primary, 2-nitro-;[14] 1,2-diols[13,14]
Aldehydes, aliphatic;[13,14] α-methylenic-[66]
Alkylamines, primary, secondary and tertiary;[44] primary and secondary,[39,48] (appendix);[14,43] primary, (appendix); tertiary[39]
Arylamines, primary (appendix)
Carboxylic acids, α-amino-;[39,48] 2,3-dihydroxy-;[14] α-oxo-[77,78]
Dibenzazepine derivatives[84]
Ethylenic compounds, $R—CH=CH_2$[13,14]
Guanidines, monosubstituted and *N*,*N*-disubstituted;[50,51] monosubstituted (appendix)
Hexitols[13,14]
Hexuronic acids[14]
Indoles[39,81]
Ketones;[76] α-methylenic dialkyl-;[49] α-diketones[78]
Nitriles[14]
Phenols[14]
Phenothiazine derivatives[82,83]
gem-Polyhalogen derivatives[79]
Pyridine derivatives[80]
Steroids, Δ^4 and $\Delta^{1,4}$-3,11-dioxo;[39] guanylhydrazones;[91] hydroxy-;[61] 17-ketol-;[13,14] $\Delta^{5(10)}$-3-oxo-19-nor-[39]
Sugars: aldohexoses;[10,87,88] aldoses;[86] 2-amino-sugars;[90] carbohydrates;[85] 2-deoxyoses;[14] ketoses (appendix); pentoses[39]
Thiols[62,63]
Thioureas, *N*,*N'*-disubstituted[55]
Ureas, monosubstituted and *N*,*N'*-disubstituted.[55]

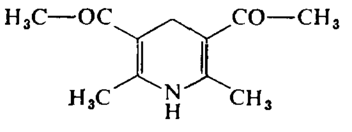
Dihydropyridine derivatives are formed through the Hantzsch reaction, by condensing two molecules of a β-keto ester or a β-diketone with one molecule each of aldehyde and ammonia:



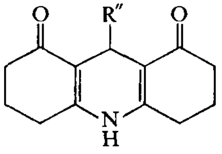
Derivatives obtained from ethyl acetoacetate (I), 2,4-pentanedione (II), 1,3-*cyclo*hexanedione (III) and dimedone (IV) are fluorescent.



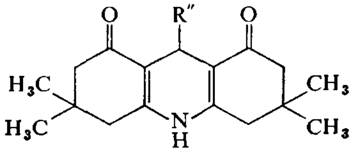
(I)



(II)



(III)



(IV)

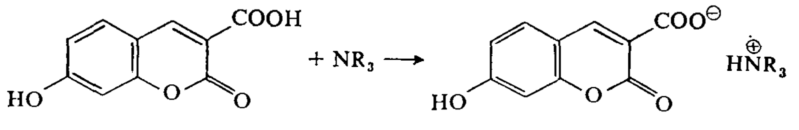
Thus, a mixture of ammonium acetate with ethylaceto acetate,[14] 2,4-pentanedione[13] or dimedone[13] allows the determination of formaldehyde, and hence of compounds which afford formaldehyde by suitable chemical reactions: 1,2-diols, hexitols, primary α-aminoalcohols, and 17-ketolsteroids oxidized with periodate ion,[13,14] ethylenic compounds of formula R—CH=CH_2 oxidized with a mixture of permanganate and periodate ions,[13,14] and aliphatic 2-nitro-1-hydroxy compounds decomposed in alkaline medium.[14]

The ethyl acetoacetate and 2,4-pentanedione methods are the most specific for formaldehyde, whereas the estimation of other aliphatic aldehydes is achieved with dimedone[12] or *cyclo*hexanedione.[12,14] The last reagent was also used for the determination of pentoses, after their dehydration into furfural,[39] and of primary alcohols,[40] oxidized to aldehydes with 2,6-dichloro-4-trimethylammonium phenyldiazonium ion.[41,42]

J-Acid (6-amino-1-naphthol-3-sulphonic acid) was also proposed for the estimation of formaldehyde obtained by oxidative degradations.[13] The fluorescent chromogen formed is a dibenzoxanthylium derivative.[32]

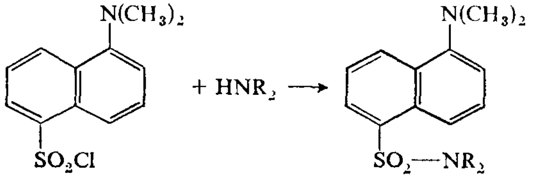
The Hantzsch reaction also allows the determination of primary alkylamines, α-amino acids[14,39,43] and nitriles, which are reduced to primary alkylamines by potassium borohydride in alkaline medium containing palladium.[14] The reagent is an aqueous solution of 2,4-pentanedione and formaldehyde.

Various other fluorimetric methods have been described for nitrogenous bases. The reaction of primary, secondary and tertiary aliphatic, and secondary and tertiary cyclic amines with 3-carboxy-7-hydroxycoumarin results in an increase in fluorescence, accompanied by a change in the activation wavelength of the mixture, permitting the measurement of the reaction product even in the presence of an excess of fluorescent coumarin reagent.[44]

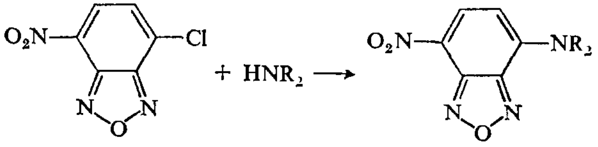


Aromatic amines and aromatic heterocycles do not react.

Dansyl chloride (1-dimethylaminonaphthalene-5-sulphonyl chloride) has been widely used in peptide and amino-acid studies,[45] and in fluorimetric estimation of amines after separation by thin-layer chromatography.[46] In non-aqueous medium, the chloride is much less fluorescent than the sulphonamide, thus allowing fluorimetric determination of primary and secondary alkylamines without any previous separation of the excess of reagent.[39]



4-Chloro-7-nitrobenzofurazan (identical with 7-chloro-4-nitrobenzofurazan or 4-chloro-7-nitro-2,1,3-benzoxadiazole) has been proposed for the determination of amines and amino-acids.[47]

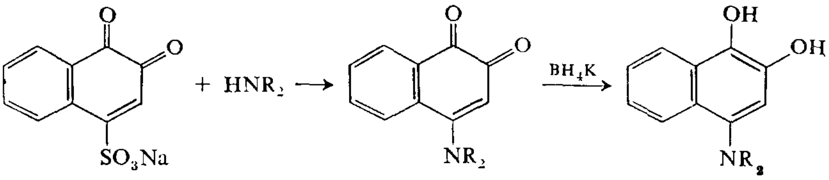


In ethanolic solution, it allows the determination of primary and secondary alkylamines (see Appendix). Amino-acids also react, but there is no linear relationship between concentration and light emission.

o-Diacetylbenzene, already used for colour and fluorescence detection of amines, amino-acids and proteins, also permits a sensitive fluorimetric estimation of primary alkylamines (see Appendix). The mechanism of this reaction is unknown.

A colour test has been proposed for the detection of tertiary alkylamines, using a solution of α,γ-anhydroaconitic acid in acetic anhydride. Under suitable conditions, the same reagent permits the fluorimetric determination of these amines.[39]

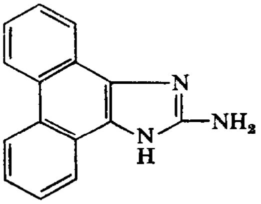
The dye obtained by reacting primary and secondary alkylamines with 1,2-naphthoquinone-4-sulphonic acid is extractable into methylene chloride. Reduction by potassium borohydride yields a fluorescent *o*-diphenol, allowing the fluorimetric estimation of these nitrogenous bases.[48]



Primary arylamines have also been determined, using a somewhat different procedure (see Appendix) which gave negative results with alkylamines. The same reagent allows the fluorimetric estimation of α-methylenic dialkylketones.[49]

In alkaline solution, ninhydrin is converted into *o*-carboxyphenylglyoxal which can give rise to fluorescent Schiff's bases with the free NH_2-group of guanidine or monosubstituted and *N,N*-disubstituted guanidines, permitting their fluorimetric determination.[50,51] The reaction has been applied to the determination of dihydrostreptomycin.[52]

Phenanthrenequinone has been proposed as an analytical reagent for arginine and other monosubstituted guanidines.[53] According to the authors, arginine, guanidine, methylguanidine and *p*-tosylarginine yield, upon reaction with this quinone, the same fluorescent species, identified as 2-amino-1*H*-phenanthro-[9,10-*d*]-imidazole-(V). The mechanism of this reaction as yet is unknown.

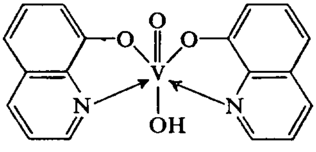


(V)

Under suitable conditions, there is a linear relationship between the concentration of a monosubstituted guanidine and light emission, which permits the fluorimetric determination of this class of compounds (see Appendix).

Although, as a general rule, fluorescence is quenched by nitro groups, one of us has shown that picric acid, on reaction with *N,N'*-dicyclohexylcarbodiimide or *N,N'*-dibenzylcarbodi-imide gives fluorescent guanylisoureas.[54] An excess of picric acid unfortunately quenches the fluorescence. When other aromatic trinitro derivatives were tested, it was found that 2,4,6-trinitrobenzoic acid also formed, with these carbodi-imides, a yellow fluorescent adduct, the structure of which has not yet been established. An excess of reagent did not interfere. Carbodi-imides are obtained by treating ureas with *p*-toluenesulphonyl chloride in pyridine, or thioureas with mercuric oxide. These reactions thus allow fluorimetric determination of urea, monosubstituted and *N,N'*-disubstituted ureas, and *N,N'*-disubstituted thioureas.[55] Derivatives with aromatic substituents do not react.

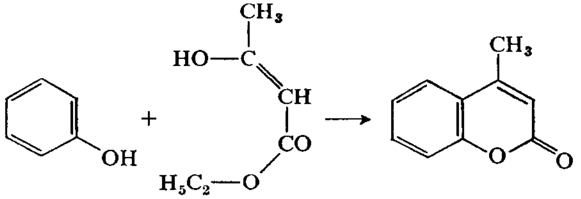
The blue-violet solution of di-(8-hydroxyquinolyl)orthovanadic acid (VI) in chloroform turns to red on addition of an alcohol. The excess of reagent is stripped



(VI)

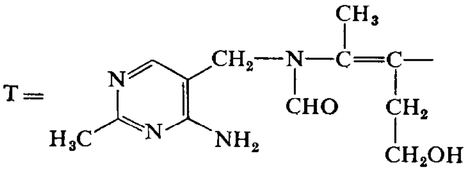
from the organic phase with an aqueous solution of sodium hydroxide, in which the red species, the structure of which is not known with certainty,[56–59] is insoluble.[60] This red form is then hydrolysed by adding hydrochloric acid to the organic phase, and the liberated 8-hydroxyquinoline, reacting with magnesium ion, yields a fluorescent complex. Primary, secondary and tertiary alcohols, as well as hydroxysteroids, are so determined.[61]

Fluorimetric determination of phenols is achieved by converting them into coumarins, with ethyl acetoacetate in sulphuric acid medium.[14]



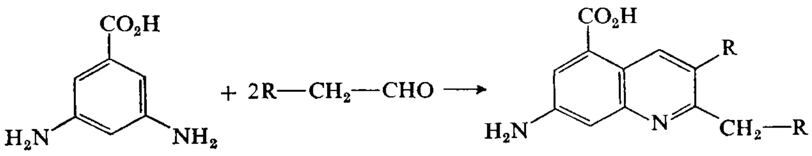
An exchange reaction occurs between symmetric thiamine disulphide and the —SH group of thiols. The liberated thiamine sulphide is oxidized to fluorescent thiochrome by ferricyanide in alkaline medium.[62,63] The following equations have been proposed:

$$\mathrm{R{-}SH + T{-}S{-}S{-}T \rightarrow R{-}S{-}S{-}T + T{-}SH}$$
$$\mathrm{2R{-}SH + T{-}S{-}S{-}T \rightarrow R{-}S{-}S{-}R + 2T{-}SH}$$



There is a linear relationship between the intensity of the fluorescence emitted by the thiochrome and the original concentration the thiol.

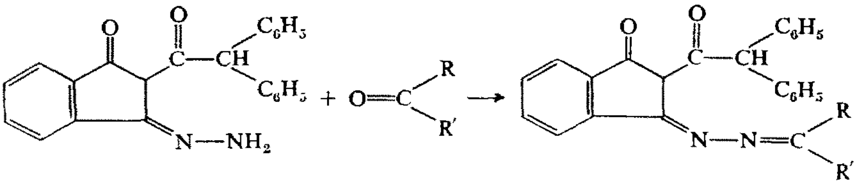
Through the Doebner–Miller synthesis for quinolines, aldehydes with an α-methylene group, reacting with 3,5-diaminobenzoic acid in acidic medium, afford a fluorescent 2,3-dialkyl-5-carboxy-7-aminoquinoline.



[For the mechanism of the reaction, see Refs. 64, 65]

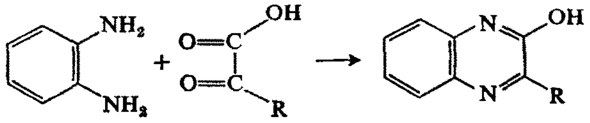
This method allows the determination of α-methylene aldehydes[66] and 2-desoxy-sugars.[14] It has been applied to the determination of acetaldehyde obtained by enzymatic decarboxylation of pyruvic acid,[67] of succinic semialdehyde produced from γ-aminobutyrate during incubation with a transaminase,[68] of deoxyribonucleic acid,[69,70] 2-deoxyglucose[71,72] and sialic acid,[73] which yields a 2-deoxy-4-aminooctose upon deacetylation and decarboxylation.

2-Diphenylacetyl-1,3-indandione-1-hydrazone was introduced in 1958 as a useful reagent for characterizing carbonyl compounds.[74]

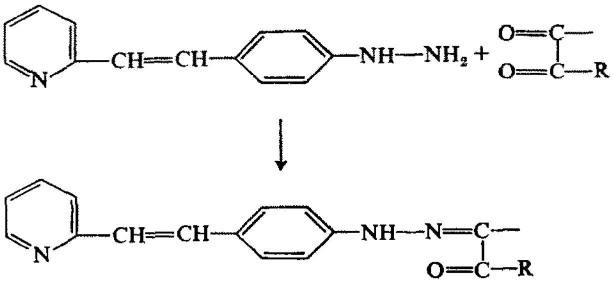


The fluorescent azine allowed the detection of acetone,[75] and was applied to the spectrofluorimetric determination of carbonyl compounds.[76] Unfortunately, the reagent itself strongly fluoresces in the same regions as the azine derivatives, and estimations are possible only after a chromatographic separation.

α-Oxo-acids give fluorescent hydroxyquinoxaline derivatives when condensed with *o*-phenylenediamine in sulphuric acid medium:[77]

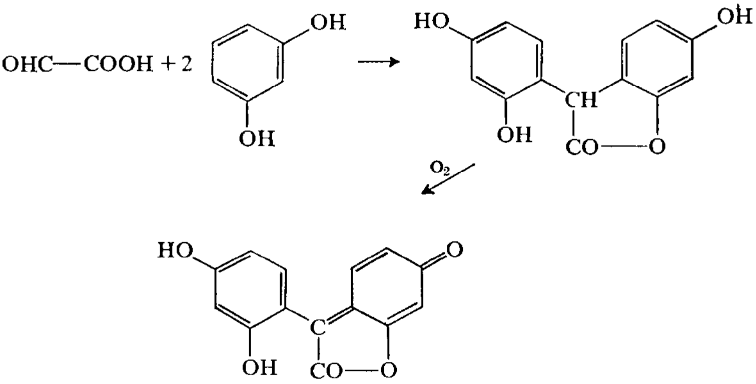


They also react with 4′-hydrazino-2-stilbazole, which is selective for α-oxo acids and α-diketones:[78]

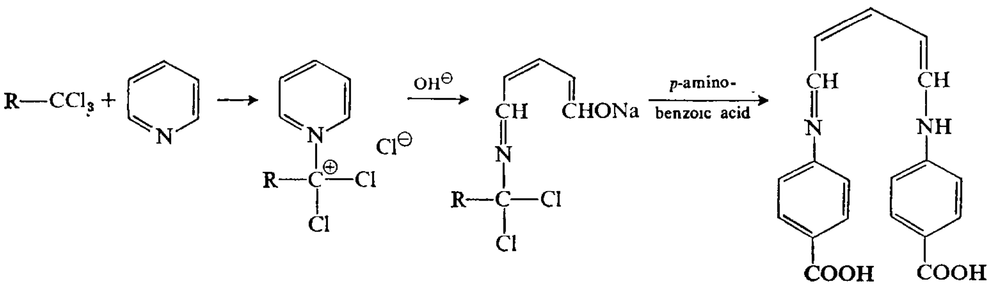


The reagent itself, and the hydrazones of monocarbonyl compounds such as acetone strongly fluoresce at pH 7–12, whereas those of α-oxo-acids and α-diketones fluoresce at pH lower than 2.

2,3-Dihydroxycarboxylic acids, such as tartaric acid, and hexuronic acids can be oxidized to glyoxylic acid which in acidic medium condenses with resorcinol, and the resultant lactone is oxidized in air to a fluorescent dye:[14]



According to the Fujiwara reaction, *gem*-polyhalogen compounds open up the pyridine ring to give a glutaconic dialdehyde derivative. This reacts with *p*-aminobenzoic acid, yielding a fluorescent Schiff's base, allowing the fluorimetry of the *gem*-polyhalogen derivatives.[79]



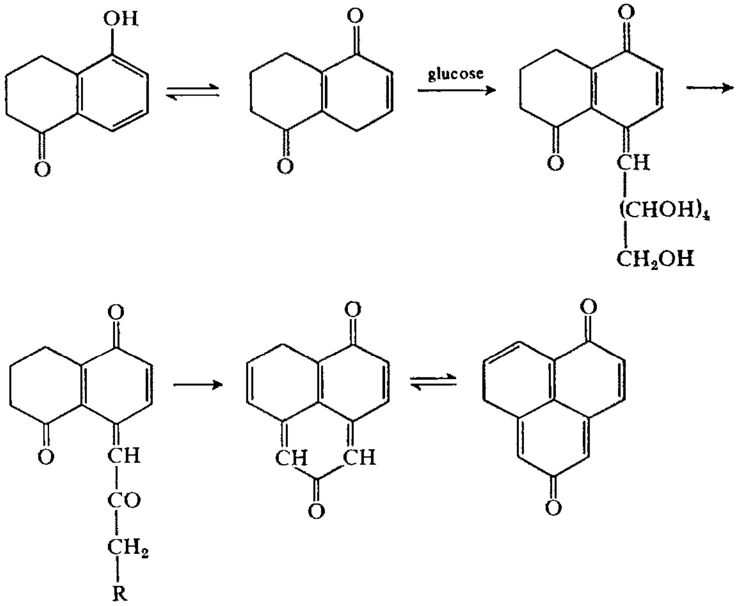
The pyridine ring is also opened up by cyanogen bromide. A further reaction with *p*-aminobenzoic acid thus permits the fluorimetric determination of pyridine derivatives.[80] 4-Hydroxypyridine and α-substituted derivatives do not react.

Upon condensing them with formaldehyde in the presence of an oxidizing agent, indole compounds develop a fluorescence.[39] The mechanism of this reaction is unknown. Some 3- and 5-substituted indoles were also determined with *o*-phthalaldehyde.[81]

Phenothiazine derivatives offer a native fluorescence. It is modified, and greatly increased, under the action of oxidizing agents such as potassium permanganate or hydrogen peroxide, thus allowing measurements in the submicrogram range.[82,83] Permanganate oxidation also permits the fluorimetric estimation of dibenz[*b,f*]-azepine derivatives.[84]

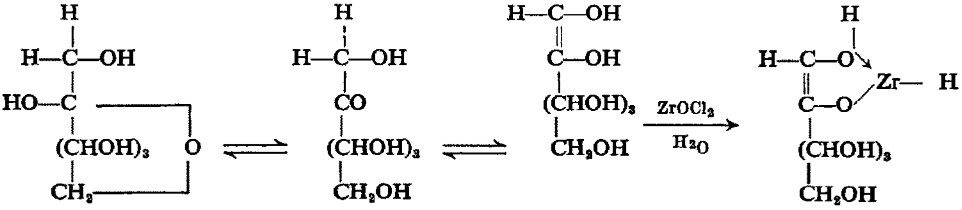
A variety of carbohydrates react with *o*-phenylenediamine to form fluorescent derivatives, which allow their determination.[85] The mechanisms of the reactions involved are still being discussed.

Aldoses are dehydrated in hydrochloric acid medium, and then condensed with resorcinol to yield presumably xanthenone derivatives.[86] The fluorescence is green for pentoses, blue for hexoses. Hexoses react with 5-hydroxytetralone, forming benzonaphthenone which permits their determination by fluorimetry.[10,87,88] The following mechanism has been proposed:



The step in which three carbon atoms from the hexose unit are eliminated is not explained.

Ketoses form a fluorescent adduct with zirconyl chloride[89]:

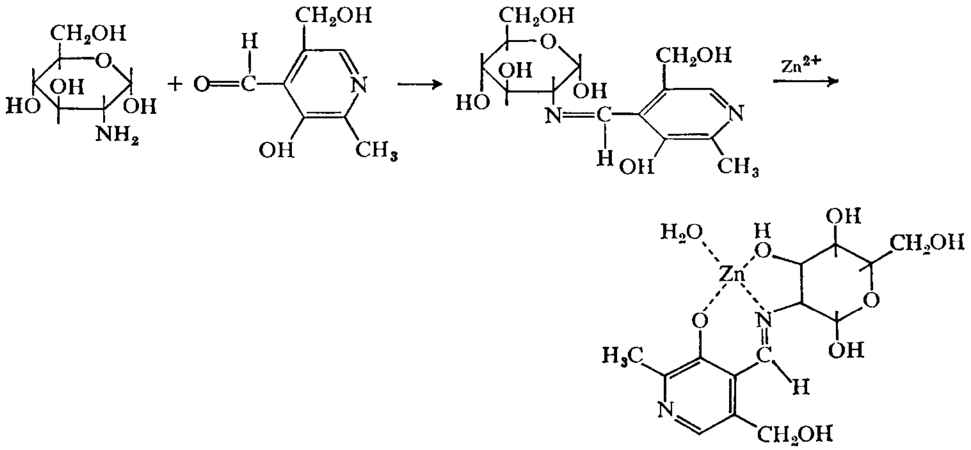


Under suitable conditions, the fluorimetric determination of these carbohydrates becomes possible (see Appendix). Aldopentoses and aldohexoses react but weakly.

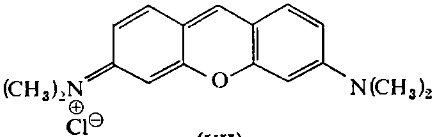
2-Amino-sugars reacting with pyridoxal and zinc ions form a fluorescent zinc chelate of pyridoxylideneamino-sugar containing a 1:1 ratio of amino-sugar to zinc.[90] (See p. 108.)

Steroid guanylhydrazones yield fluorescent derivatives upon reaction with phenanthrenequinone in alkaline medium.[91] Δ^4- and $\Delta^{1,4}$-3,11-dioxosteroids give fluorescent adducts, of unknown structure, with 2,6-di-t-butyl-*p*-cresol.[39]

It was shown that, under the action of $\Delta^{5(10)}$-3-oxo-19-norsteroids in alkaline medium, the colour of thionine or Methylene Blue rapidly changes. Under similar conditions, the fluorescence of Pyronine G (VII), the structure of which may be



compared to that of Methylene Blue, rapidly decreases, thus allowing the determination of this class of steroids by the decrease in fluorescence.[39]



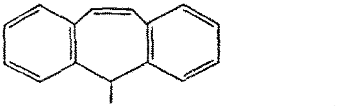
(VII)

Determinations of individual compounds

Obviously, it is not possible to cover here all the compounds which have been fluorimetrically determined and we have tried to present, in a fairly systematic fashion, some selected reactions in order to show that fluorimetry of individual compounds, as well as functional fluorimetry, is no longer a mere collection of purely empirical recipes. A definite compound has often been determined in various media (*e.g.*, biological assays), giving rise to sundry procedures based on the same reaction; quoting all the references would be but a compilation. As far as possible, we report the reference of the paper which, to the best of our knowledge, was the first dealing with this analytical reaction, or we refer to a paper reviewing it. We also mention some reactions which, until now, have only been used qualitatively, when we consider that they might readily be adapted to quantitative analysis.

It is well known that the main fluorescent species are either aromatic or heterocyclic compounds. Since it is usually easier to create a heterocyclic ring than an aromatic one, many determinations are based on the formation of a *O*- or *N*-heterocycle. Of course, some reactions are exceptions to this rule. For example, cerium(III) ions in dilute sulphuric acid medium exhibit a characteristic fluorescence, exc: 260 nm, em: 350 nm. Osmium(VIII) catalyses the redox reaction between cerium(IV) and oxalate, thus permitting a fluorimetric determination of oxalate ion by measurement of the cerium(III) produced.[92] Oxalate also quenches the fluorescence of a 1:1 zirconium–flavonol chelate in dilute sulphuric acid solution, the emission decreasing with increasing concentration of the ion.[93] In a similar manner, citrate quenches the fluorescence of the tungstate–flavonol complex.[94]

Some non-fluorescent acids and bases have been determined by ion-pair extraction with a fluorescent species as counter-ion. For example, dimethylprotriptyline (VIII) allowed the estimation of nonylbenzenesulphonate and tetradecansulphonate.[95]

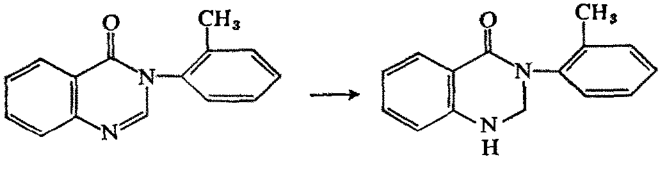


(VIII)

Protriptyline, nortriptyline, amitriptyline, imipramine and terodoline were determined with anthracene-2-sulphonate.[96]

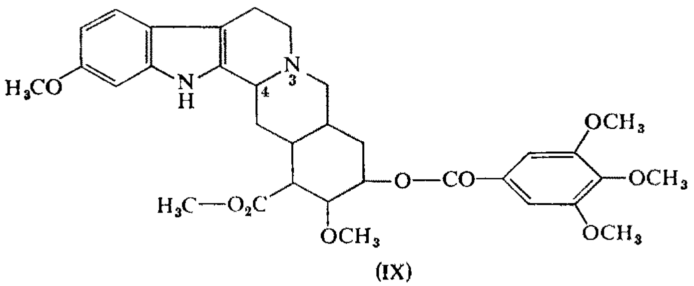
Obviously, some of the reactions described in the preceding section can be applied to the determination of a definite compound. For instance, J-acid or a mixture of ammonium acetate and ethyl acetoacetate or 2,4-pentanedione allow a selective determination of formaldehyde. The glyoxylic acid–resorcinol reaction[14] permits determination of oxalic acid, which can be reduced to glyoxylic acid by aluminium amalgam, a copper–zinc mixture,[97] or zinc and hydrochloric acid.[98] Glyoxylic acid is also obtained by saponifying dichloroacetic acid in the presence of hydrazine, which avoids formation of oxalic and glycolic acids. This reaction has been applied to the identification of the dichloroacetic group in chloramphenicol.[99]

A slight modification of the structure of a heterocyclic compound, such as a change in the degree of saturation can result in development or extinction of fluorescence. For example, methaqualone was determined as a tetrahydroquinazolinone derivative after reduction by lithium borohydride.[100]



Reserpine (IX) has a native fluorescence which permits direct measurements, but the emission maximum is at 375 nm. A more intense and yellow-green fluorescence (em: 510 nm) is obtained by a suitable 3-4 dehydrogenation, with hydrogen peroxide[101] or nitrous acid.[102,103]

Various heterocyclic compounds bearing a hydroxyl group fluoresce only in the free state. Esters must therefore be hydrolysed before fluorimetric determination. For instance, *O*,*O*-diethyl-*O*-(3-chloro-4-methyl-2-oxo-2*H*-1-benzopyran-7-yl)phosphorothioate (Coumaphos) affords fluorescent 3-chloro-4-methyl-7-hydroxycoumarin.[104] *O*,*O*-Diethyl-*O*-2-pyrazinyl phosphorothioate yields the sodium salt of 2-pyrazinol.[105] Tocopherol esters are also determined as free tocopherol. In order



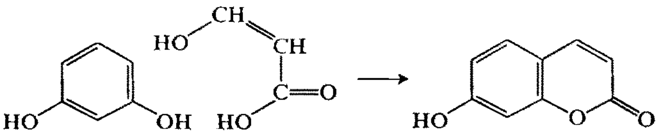
(IX)

to avoid oxidation, the esters are reduced to the free hydroxyl compound by lithium aluminium hydride.[106]

Diethyl phosphate ester and *O,O*-diethyl phosphorothioate *O*-ester with *N*-hydroxynaphthalimide (Maretin and Bayer 22408) are determined after alkaline hydrolysis followed by an oxidation step.[107,108]

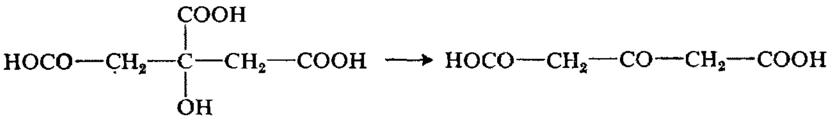
Formation of O-*heterocycles.* The von Pechmann reaction, used in functional fluorimetry for the estimation of phenols, has been applied to the determination of polycarboxylic acids which are unsaturated or bear hydroxyl groups. Malic acid, reacting with resorcinol in concentrated sulphuric acid, yields umbelliferone. In the first step, the acid is converted into formylacetic acid.

$$\mathrm{HOCO{-}CH_2{-}CHOH{-}COOH \rightarrow HOCO{-}CH_2{-}CHO}$$

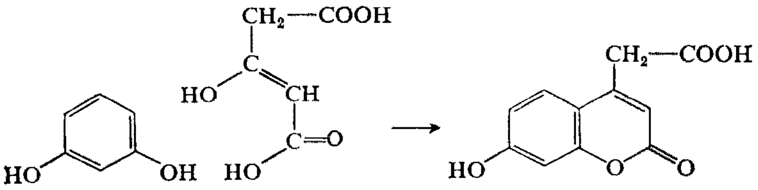


It has been claimed that umbelliferone-4-carboxylic acid is also formed.

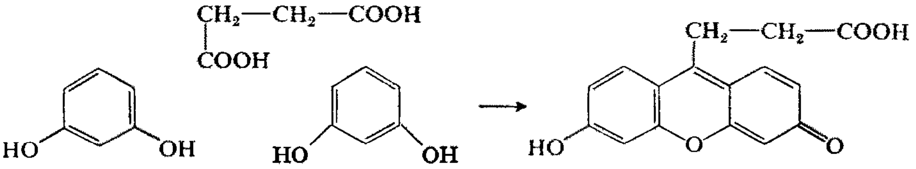
Likewise, citric acid gives a fluorescent species. The first step is probably to convert it into acetonedicarboxylic acid.



$$\mathrm{HOCO{-}CH_2{-}\underset{\displaystyle OH}{\overset{\displaystyle COOH}{C}}{-}CH_2{-}COOH \longrightarrow HOCO{-}CH_2{-}CO{-}CH_2{-}COOH}$$

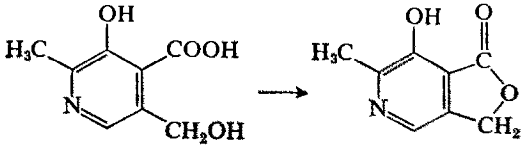


Fluorescences are also afforded by fumaric, α-oxoglutaric, oxalacetic acids, and polycarboxylic acids with no other functional groups. These react to produce compounds similar to fluorescein.



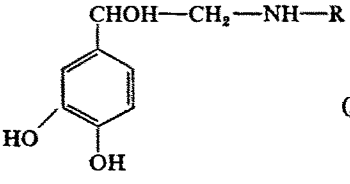
A convenient selection of pH and excitation and emission wavelengths allowed determination of malic and succinic acids in mixtures.[109] For a more selective determination of malic acid, orcinol[110,111] and 2-naphthol[112] have been proposed. With the last phenol, citric and succinic acids do not interfere at concentration ratios lower than 1:1. The fluorescent species is probably 5,6-benzocoumarin. With malic acid as the reagent, the same authors determined 2-naphthol.

Pyridoxic acid can be dehydrated in acidic medium to give a strongly fluorescent pyridoxic lactone.[113]



The lactone fluoresces 25 times as intensely as the acid. This is probably due to an increase in the quantum efficiency of fluorescence. Pyridoxic acid is obtained from pyridoxine oxidized with potassium permanganate, from pyridoxamine converted into pyridoxine with nitrous acid and then oxidized, and from pyridoxal oxidized with ammonical silver nitrate.[114] These three compounds can therefore be determined fluorimetrically.

Formation of N-*heterocycles.* One of the most studied determinations is probably that of catecholamines, mainly epinephrine (X) and norepinephrine (XI).

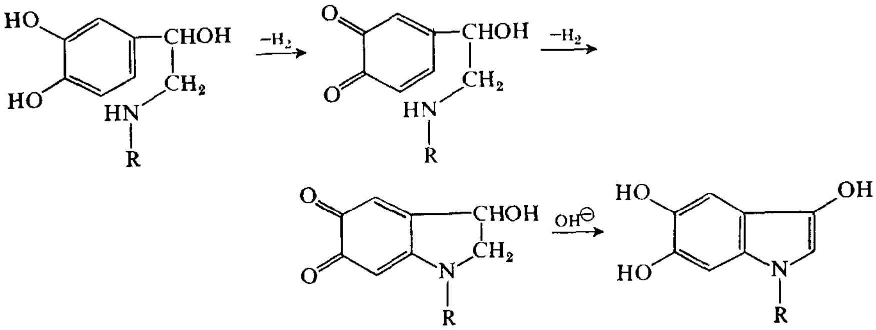


(X) $R = CH_3$
(XI) $R = H$

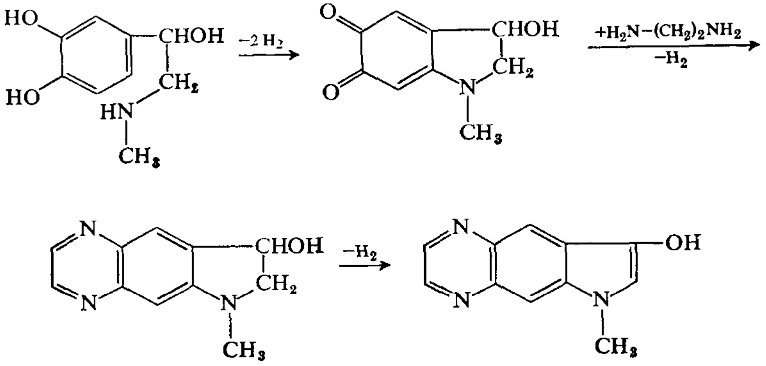
Epinephrine upon oxidation gives an *o*-quinone derivative, adrenochrome, which in alkaline medium is subjected to a rearrangement yielding adrenolutine, a strongly fluorescent trihydroxyindole derivative.[115]

The same reaction can of course be applied to norepinephrine. Differential determinations are possible, since both amines are oxidized at pH 6·5, whereas only epinephrine reacts at pH 3·5.[116]

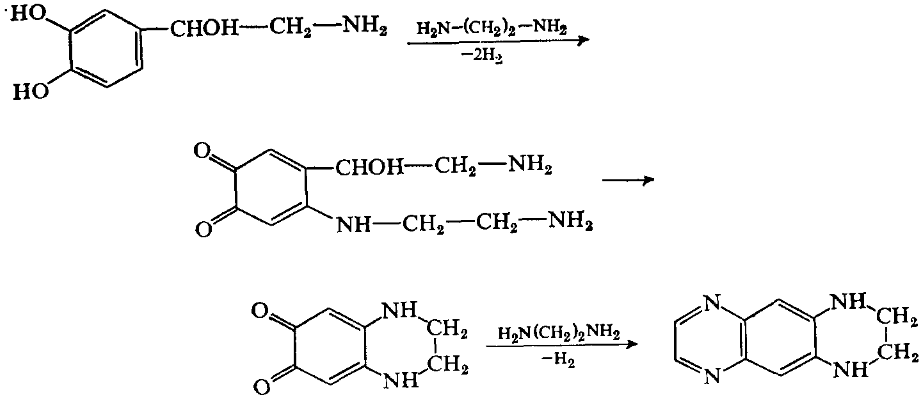
In the presence of ethylenediamine, other fluorescent species are obtained, and the mechanisms of the reactions are different for epinephrine and norepinephrine.[117]



Epinephrine

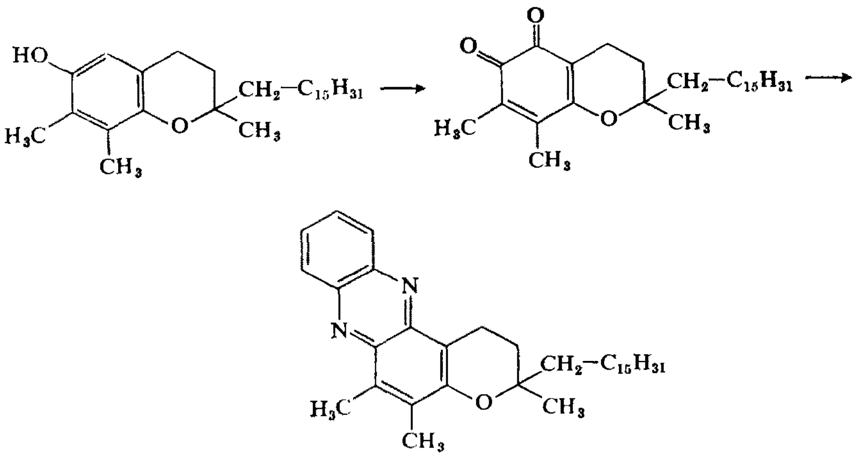


Norepinephrine

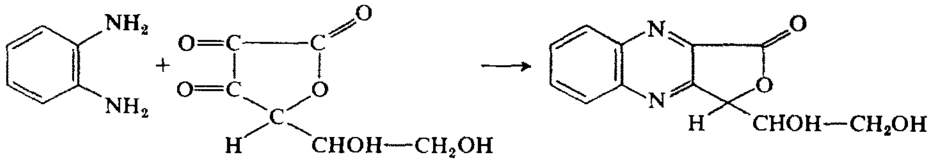


Another fluorescent product is also formed, the structure of which is not yet certain. By suitable selection of emission wavelengths, both compounds can be determined in mixtures. The method has recently been automated.[118] On the same basis, with adrenochrome as reagent, ethylenediamine has been determined in milk.[119]

Another diamine, *o*-phenylenediamine, reacts with some *o*-quinones and α-diketo derivatives, to yield strongly fluorescent species. Tocopherol, oxidized with nitric acid, gives a quinone which is then condensed with *o*-phenylenediamine to give a phenazine derivative.[120]

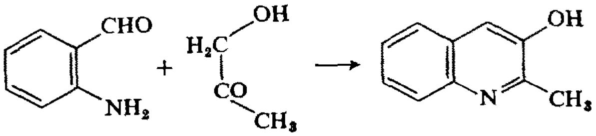


Ascorbic acid is oxidized to dehydroascorbic acid which, upon reacting with the same diamine, produces a fluorescent quinoxaline, thus permitting the determination of the vitamin.[121]



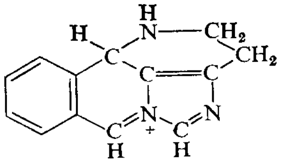
Alloxan was also determined by a similar reaction.[112]

Two other *o*-disubstituted benzenes have been used as reagents for various purposes. *o*-Aminobenzaldehyde reacts with acetol to form fluorescent 3-hydroxyquinaldine.[123]

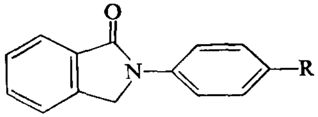


Thymine and 5-methylcytosine, when suitably oxidized, afford this ketol[124] and can therefore be determined as well as nucleosides and nucleotides of these pyrimidines, and deoxyribonucleic acid.[125] *o*-Phthalaldehyde gives a fluorescent adduct upon condensation with histamine. The formula (XII) has been tentatively proposed.[126]

Under suitable conditions, histamine can readily be determined in the presence of histidine, which normally interferes[127] and histidine has also been determined.[128]



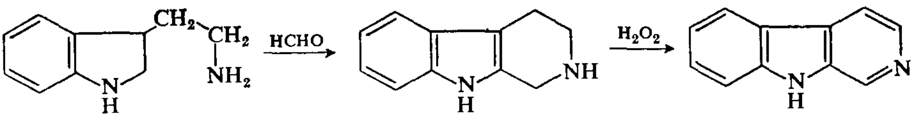
(XII)



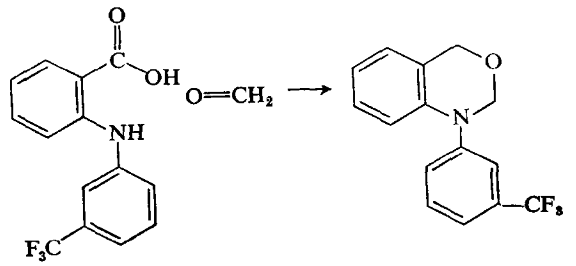
(XIII)

The same reagent has been applied to the determination of some sulphonamides, which give condensates of general formula (XIII),[129] of α,ε-diaminopimelic acid,[130] and of reduced gluthathione.[131] In pH 8 medium, this tripeptide yields a fluorescent product whereas little or no fluorescence is observed from oxidized glutathione and thiol-containing amino-acids.

One of the simplest organic compounds, formaldehyde, has often been applied to various determinations. Examples were described above in the section on functional fluorimetry. Tryptamine offers a native fluorescence, but in various extracts, other species may interfere. These interferences may be overcome by reacting tryptamine with formaldehyde, then oxidizing the tetrahydronorharman formed to fluorescent norharman.[132]



Flufenamic acid also reacts with formaldehyde, giving a fluorescent heterocyclic derivative.[133]

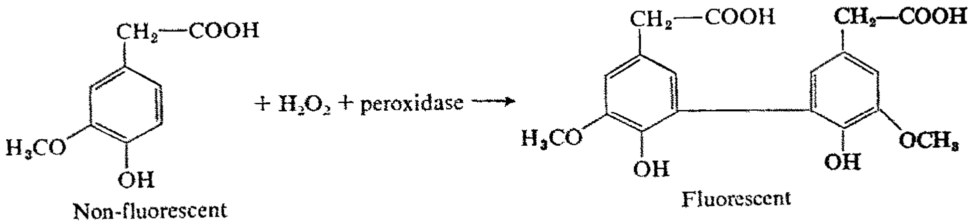


Many determinations, mainly in the field of steroid compounds, are conducted in strongly acidic media, such as concentrated sulphuric, phosphoric or perchloric acids. These "halofluoric" reactions are often due to various preferential mesomeric forms or to dehydrations which have mechanisms that are as yet not well understood. For these reasons, they are somewhat beyond the scope of this review. They have been already widely referred to in books and monographs.[5,9,116,134]

Enzymatic reactions

Studies on fluorimetric assay of enzymes, and enzyme kinetics and mechanisms are also beyond the scope of this review, since they are more closely related to biochemistry and biology. But recently, some enzymatic reactions have been applied to various fluorimetric determinations of organic compounds, thus paving the way to new methods which stand on the border of functional fluorimetry and fluorimetry of definite compounds.

Non-fluorescent homovanillic acid, reacting with hydrogen peroxide in the presence of horseradish peroxidase, gives a fluorophore by the following reaction:[135]

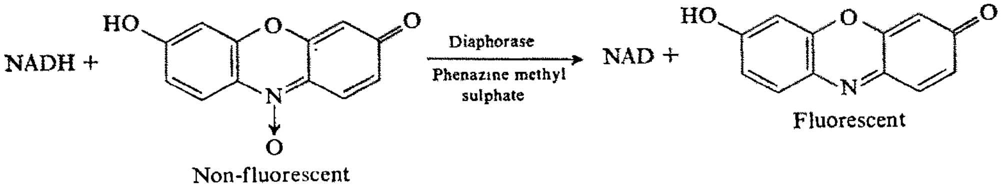


Compounds which upon action of suitable oxidases afford hydrogen peroxide, may therefore be determined. This is the case with xanthine and hypoxanthine when converted into uric acid by xanthine oxidase.[136]

The much cheaper *p*-hydroxyphenylacetic acid may be used instead of homovanillic acid. It allows the determination of *N*-acetyl-D-galactosamine, 2-deoxy-D-galactose, 2-deoxy-D-glucose, D-galactosamine, D-galactose, D-glucose, α-D-melibiose, methyl-β-D-galactopyranoside, D-raffinose, stachyose, sucrose. All these sugars, after invertase hydrolysis, are oxidized by glucose- or galactose-oxidase. The first is highly specific, whereas with galactose oxidase the C_1 position need not be free, for galactosides are readily attacked. The correct configuration at position 4 is essential, but that at position 2 is not so critical, for D-talose also reacts.[137]

Nicotinamide adenine dinucleotide (NAD), reacting with an acid under the action of a suitable dehydrogenase, is reduced to NADH which, under the catalytic action of diaphorase or phenazine methyl sulphate, reduces non-fluorescent resazurin to fluorescent resorufin. Six dehydrogenase systems were used for the determinations of 21 organic acids.[138]

$$\text{Acid} + \text{NAD} \xrightarrow{\text{Dehydrogenase}} \text{Keto acid} + \text{NADH}$$

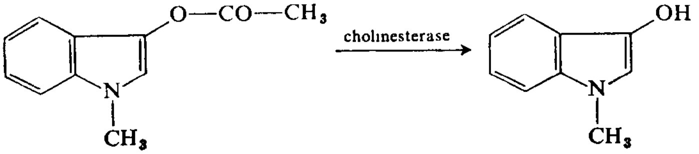


Monoamine and diamine oxidases allow the determination of benzylamine, cadaverine, furfurylamine, histamine, putrescine and tyramine,[139] hydrogen peroxide being formed.

$$R—CH_2—NH_2 + O_2 + H_2O \xrightarrow[\text{oxidase}]{\text{Amine}} R—CHO + NH_3 + H_2O_2$$

Methanol, ethanol, n-propanol and allyl alcohol have been determined with alcoholoxidase, which converts them into the corresponding aldehyde and hydrogen peroxide.[140]

Various pesticides have also been determined. Cholinesterase from rat liver and human serum is strongly inhibited by organophosphorus compounds, but the chlorinated pesticides have no effect. The enzyme from electric eel is sensitive to chlorinated pesticides only. Cholinesterases from both the bean-leaf beetle and white-fringe beetle are very strongly inhibited by paraoxon (diethyl-*p*-nitrophenylphosphate) and DDVP (phosphoric acid 2,2-dichlorovinyl dimethyl ester), but parathion and methyl parathion are very weak inhibitors. There is no interference either from the chlorinated or carbamate pesticides. The substrate *N*-methylindoxyl acetate is cleaved by all five cholinesterases to highly fluorescent *N*-methylindoxyl.



The various pesticides, when introduced into the reaction mixture, inhibit the hydrolysis of the substrate catalysed by cholinesterase, causing a decrease in the initial slope of the fluorescence-time curve. The decrease is a direct measure of the concentration of the inhibitor present.[141]

PHOSPHORIMETRY

Phosphorescence is the photon emission from a molecule which returns to its normal ground state from an excited triplet state, reached by a radiationless transfer from an excited singlet state. Whereas fluorescence decays almost immediately, usually within about 10^{-8} sec, the lifetime of phosphorescence is much longer, from 10^{-4} up to 20 sec. The first phosphoroscope was described a century ago,[142] but the qualitative identification of organic compounds by phosphorescence spectra was suggested only in 1944[143] and the first quantitave determinations were published in 1957.[144]

Since fewer compounds phosphoresce than fluoresce, phosphorimetry is still more selective than fluorimetry. In a solid solution, the phosphorescence decay process is of the first order. The mean decay time at constant temperature in a given solvent being characteristic of the compound studied (and independent of concentration), it can be used to identify phosphorescent compounds, thus introducing a complementary datum, besides the excitation and emission spectra. A pure substance alone will show a straight-line plot of the logarithm of intensity against time. With mixtures, a curved plot is obtained, since several decay processes with different rates are superimposed.[145]

Because of the long lifetime of phosphorescence, molecules can easily lose their energy by radiationless processes, mainly by collisional deactivation. Although some attempts were made at room temperature with rigid transparent organic glasses (polymeric matrices),[146] phosphorescence measurements are almost always performed at 77 K (liquid nitrogen). Until very recently, determinations were only possible in solvents and mixtures of solvents giving clear glasses at this temperature. Various mixtures have been proposed,[147] but they often tend to crack or form snows when they contain a small quantity of water. Absolute ethanol has proved very suitable, since its water content is not highly critical.[148] In 1970, the use of a rotating sample cell was proposed.[149] Combined with a more stable power supply and a better solvent clean-up procedure, it led to lowering of detection limits by more than a factor of 100, and to increased precision and accuracy. Moreover, these results have been obtained not only in clear rigid solvents, but also in cracked glasses and snowed matrices.

Up to now, and to the best of our knowledge, phosphorimetry has only been applied to the estimation of compounds offering a native phosphorescence. The potentialities of the method in the field of quantitative determinations were first exemplified with benzaldehyde, benzophenone and 4-nitrobiphenyl dissolved in EPA (ethyl ether–isopentane–ethanol 5:5:2).[144] In a mixture of these three compounds, 4-nitrobiphenyl could be resolved on the basis of its slower decay rate. Mixtures of acetophenone and benzophenone were also resolved, the mean lifetimes of these compounds being 0·008 and 0·006 sec respectively. Diphenylamine and triphenylamine were determined by selective excitation.

As a consequence of its selectivity and sensitivity, phosphorimetry has been mainly applied in the areas of biology and medicine. Aspirin was the first compound to be determined in blood and plasma, without interference, at concentrations of 1–100 mg per 100 ml of serum.[150] Salicylic acid, the only metabolic product of aspirin which phosphoresces, gave nearly 1/500 the sensitivity of aspirin. The use of ethanol allowed easy determinations of 22 organic compounds of pharmacological importance, with a limit of detectability of 10 ng/ml in ethanol for most drugs.[148] Procaine, cocaine, phenobarbital and chlorpromazine have been determined in blood serum, and cocaine and atropine in urine.[151] The proposed method is rapid and sensitive. For instance, it allows 83% recovery of 0·30 μg of procaine in 10 ml of blood, or 110% recovery of 30 ng of cocaine in 1 ml of blood. Sulphonamides have been determined.[152] and for sulphamerazine, sulphapyridine, sulphamethazine and sulphacetamide, the limit of detectability was 0·1 ng/ml of solvent.

Tobacco samples have been analysed for nicotine, nornicotine and anabasine.[153] The method involves a separation by thin-layer chromatography, and the time for a complete analysis of the three alkaloids in a commercial tobacco sample was less than 90 min, which is considerably less than by other methods previously used. In the field of pesticides, 32 compounds have been studied,[154] and biphenyl has been determined in oranges, with a limit of 1 ng/ml of ethanol.[155]

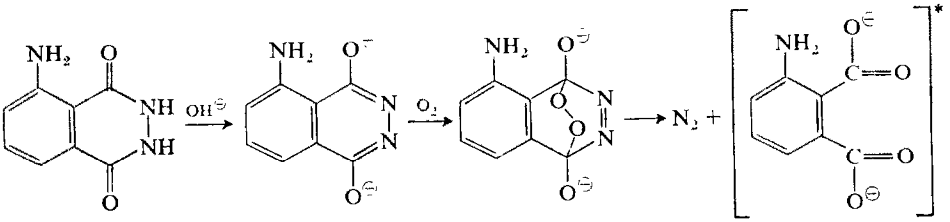
Mixtures of tryptophan and tyrosine in the presence of phenylalanine in various hydrolysed proteins have been analysed simultaneously.[156] The method is based on the fact that when two molecules differ by approximately a factor of 10 in their decay times, and when the concentrations of the species are about equal, a plot of the logarithm of the phosphorescence intensity *vs.* time is a combination of two straight lines.

This section is far from being exhaustive. Our purpose was only to illustrate the possibilities and potentialities of phosphorimetry. There is no doubt that commercially available phosphoroscope attachments, and the recent possibility of working with cracked glasses and snowed matrices will extend the usefulness of this method, both in the areas of biology and medicine, where sensitive, selective, accurate and rapid methods are needed, and in other areas for the study of trace impurities.

CHEMILUMINESCENCE

In fluorescence and phosphorescence, the activation of the molecule is obtained by the absorption of light. In chemiluminescence, the excitation is produced by a chemical reaction. Although this phenomenon has been widely studied,[157–159] only a few examples are within the scope of this review.

Luminol(5-amino-2,3-dihydro-1,4-phthalazinedione) emits light when oxidized in alkaline medium under suitable conditions. Various mechanisms have been proposed,[160–162] and it has been shown that, under aqueous conditions with hydrogen peroxide, the reaction products are complex.[163] Whatever may be the true mechanism, it is established that the luminescence is afforded by an excited singlet state of the aminophthalate ion. The following scheme seems possible:



When copper(II) is added to an alkaline solution of luminol in the presence of hydrogen peroxide, the mixture emits light, and this emission is inhibited by various compounds. The effect of small amounts of nitrophenols, aminophenols, trihydroxybenzenes, dinotrophenols, nitroanilines and phenylenediamines on the chemiluminescence of the system luminol-Cu-NH_3-H_2O_2 has also been studied.[164] All these compounds inhibit the luminescence and, for disubstituted derivatives, the order of the inhibiting action is *ortho* > *para* > *meta*. Small amounts of the compounds can be determined by means of a calibration graph. Polyhydric alcohols, unsaturated monohydric alcohols, mono- and disaccharides are also effective.[165] α-Amino-acids have been determined, the reaction being based on the reduction of the intensity of luminescence of luminol in the presence of cupric sulphate in dilute ammonia and hydrogen peroxide. The intensity of inhibition varies with the amino-acid tested.[166] Copper complexes of amino-acids have also been determined.[167]

Adenosine triphosphate reacts with luciferin in the presence of magnesium ion and luciferase, under the action of oxygen:

$$\text{Luciferin} + O_2 + \text{ATP} \xrightarrow[\text{Mg}^{2+}]{\text{Luciferase}} \text{Oxyluciferin} + \text{AMP} + h\nu.$$

Measurement of the light produced gives a direct determination of the ATP present.[168]

Ozone-induced chemiluminescence of organic compounds has also been studied, in the dry state as well as in acetone solution.[169] The peak intensity of the light emission is related quantitatively to the amount of compound.

Up to now, with the exception of the ATP determination, the proposed methods do not seem to be more sensitive than fluorimetric ones.

APPENDIX

Determination of primary and secondary alkylamines

Reagent. A 0·05% solution of 4-chloro-7-nitrobenzofurazan in ethanol.

Procedure. To 1 ml of an ethanol solution of the amine, add 0·75 ml of reagent. Heat at 60° for 30 min, in daylight, then let stand for 3 min at room temperature, dilute to 4 ml with ethanol and read at exc: 436 nm, em: 535 nm (yellow fluorescence). The fluorescence standard is an aqueous solution of sodium fluoresceinate

Results

	Determination limits, μg	Reading 50 Sample, μg	Standard, μg/ml
n-Propylamine	0·25–1·0	0·41	0·12
n-Butylamine	0·25–1·0	0·45	0·12
Benzylamine	0·25–1·0	0·41	0·083
Diethylamine	1–5	1·9	0·083
Di-n-propylamine	3–12	4·3	0·13
Di-n-butylamine	2–10	4·0	0·06

Determination of primary alkylamines

Buffer, pH 8·6. Dissolve 0·62 g of boric acid and 0·745 g of potassium chloride in 50 ml of water, add 12·0 ml of 0·2*M* sodium hydroxide and dilute with water to a final volume of 200 ml.

Reagent. A 0·25% solution of *o*-diacetylbenzene in ethanol.

Procedure. To 1 ml of an ethanol solution of the amine or amine hydrochloride, add 0·5 ml of buffer and 0·2 ml of reagent. Heat at 30° for 60 min, cool to room temperature and add 2 ml of ethanol. Read at exc: 366 nm, em: 430 nm (blue fluorescence). The fluorescence standard is a solution of quinine sulphate in 0·1*N* sulphuric acid.

Results

	Determination limits, μg	Reading 50 Sample, μg	Standard, μg/ml
Methylamine (hydrochloride)	0·2–1·0	0·43	0·256
Ethylamine	0·1–0·5	0·22	0·238
Ethylamine (hydrochloride)	0·2–1·0	0·44	0·227
n-Propylamine	0·1–0·5	0·21	0·164
n-Butylamine	0·2–1·0	0·44	0·222

Determination of primary arylamines

Reagents. (*a*) 0·50% aqueous solution of the sodium salt of 1,2-naphthoquinone-4-sulphonic acid. (*b*) Dissolve 0·050 g of potassium borohydride in 1 ml of 0·1*M* sodium hydroxide and dilute to 100 ml with water.

Procedure. To 1 ml of a neutral aqueous solution of the arylamine, add 0·2 ml of reagent *a*, mix, and transfer into a 10-ml separatory funnel which contains 2 ml of methylene chloride. Rinse the tube with 1 ml of water, adding the rinsings to the separatory funnel. Shake for about 5 sec, allow the layers to separate and drain all of the organic layer into a tube. With the tube protected from light, add 2 ml of ethanol, 0·1 ml of reagent *b*, mix, and let stand for 1 min at room temperature. Add 0·5 ml of 0·01*M* hydrochloric acid and mix. Read at exc: 366 nm, em: 470 nm (blue-green fluorescence). The fluorescence standard is a solution of 3,5-dicarbethoxy-1,4-dihydrolutidine in water containing 2% ethanol (see Ref. 14).

Results

	Determination limits, *μg*	Reading 50 Sample, *μg*	Standard, *μg/ml*
Aniline	0·2–1·0	0·48	1·89
o-Toluidine	0·3–1·5	0·72	1·92
m-Toluidine	0·2–1·0	0·48	1·64
p-Toluidine	0·2–1·0	0·48	1·67
p-Anisidine	0·3–1·5	0·73	1·85
o-Aminophenol	0·2–1·0	0·48	1·82

Arylamines bearing substituents which favour solubility in slightly alkaline water, such as *p*-aminobenzoic acid and sulphonamide, do not react.

Determination of monosubstituted guanidines

Reagent. A 0·05 % solution of phenanthrenequinone in ethanol.

Procedure. To 0·5 ml of an aqueous solution of the guanidine, add 0·1 ml of 40 % sodium hydroxide solution and 0·5 ml of reagent. Mix and let stand for 30 min at room temperature. Add 0·25 ml of concentrated hydrochloric acid and 2·5 ml of water. Mix and read at exc: 360 nm, em: 400 nm. Any slight turbidity in the solution does not interfere with measurements (violet-blue fluorescence). The fluorescence standard is a solution of quinine sulphate in 0·1*N* sulphuric acid.

Results

	Determination limits, *μg*	Reading 50 Sample, *μg*	Standard, *μg/ml*
Arginine	1·5–7·5	3·0	1·66
p-Chlorophenylguanidine	37·5–150	63·7	2·28
Dihydrostreptomycin (sulphate)	16–80	32	1·82
Guanethidine (sulphate)	2–10	4	2·27
Guanidine	1·5–6·0	2·5	2·7
Guanidoacetic acid	0·8–4·0	1·6	1·9
Streptomycin (sulphate)	15–60	22·5	2·1
3,4,5-Trimethoxybenzylguanidine	2–10	4·2	2·2

Determination of ketoses

Reagent. A 0·1 % aqueous solution of zirconyl chloride.

Procedure. To 1 ml of an aqueous solution of the ketose, add 0·7 ml of 0·01*M* hydrochloric acid and 0·5 ml of reagent, mix and add 2 ml of water. Heat at 70° for 60 min, cool in ice for 2 min and read at exc: 345 nm, em: 400 nm (blue fluorescence). The fluorescence standard is a solution of quinine sulphate in 0·1*N* sulphuric acid.

Results

	Determination limits, *μg*	Reading 50 Sample, *μg*	Standard *μg/ml*
Fructose (1 H_2O)	6–24	9·3	0·115
Sorbose	6–30	12·9	0·071

Zusammenfassung—In dieser Übersicht werden die wichtigen Aspekte der Lumineszenzverfahren behandelt, die zur Bestimmung organischer Verbindungen in Lösung dienen können. Ein Bezeichnungsschema für Berichte über fluorimetrische Bestimmungen wird vorgeschlagen. Es wird eine kurze Übersicht über die wesentlichen Faktoren gegeben, die die Fluoreszenz von Lösungen beeinflussen; ausgewählte Beispiele illustrieren die Bestimmung von Verbindungen, die von Hause aus fluoreszieren. Besonderer Wert wird auf die Fluorimetrie funktioneller Gruppen gelegt und auf die Bestimmung nicht fluoreszierender Verbindungen mit Hilfe chemischer Reaktionen, die zu fluoreszierenden Spezies führen. Einige enzymatische Reaktionen werden beschrieben, soweit sie die Bestimmung definierter chemischer Verbindungen erlauben. Beispiele für Phosphorimetrie und Chemilumineszenz werden angeführt. Ein Anhang zeigt einige neu von den Autoren entwickelte fluorimetrische Bestimmungsmethoden für funktionelle Gruppen.

Résumé—Cette revue présente les principaux caractères des méthodes de luminescence se rapportant au dosage de composés organiques en solution. On propose une notation pour rapporter les dosages fluorimétriques. On passe brièvement en revue les facteurs dominants qui affectent la fluorescence des solutions, et l'on illustre par des exemples choisis les dosages de composés à fluorescence native. On porte une attention particulière à la fluorimétrie fonctionnelle et au dosage de composés non fluorescents au moyen de réactions chimiques donnant naissance à des espèces fluorescentes. On décrit quelques réactions enzymatiques, dans la mesure où elles permettent le dosage de produits chimiques définis. La phosphorimétrie et la chimiluminescence sont illustrées par des exemples. Un appendice présente quelques nouveaux dosages de fluorimétrie organique fonctionnelle, développés par les auteurs.

ELECTRIFICATION OF GAS BUBBLES AS AN ANALYTICAL TOOL

D. A. PANTONY and D. C. STAGG
Department of Metallurgy, Imperial College of Science and Technology,
Prince Consort Road, London, S.W.7

(*Received* 15 *July* 1971. *Accepted* 2 *October* 1971)

Summary—When a gas passes through a liquid, a charge is produced and this is carried on in the droplets formed when the bubble bursts at the surface of the liquid. A theory to account for the relationship between the bubble charge and concentration of electrolyte, *viz.* $q \propto C^{-1/2}$, is derived and applied to a number of uni-univalent and multivalent electrolytes. The general agreement between theory and experiment and the reasonable reproducibility of the technique show that it could have analytical application. Such use is exemplified in laboratory simulations of flowing systems for continuous analysis and in bubble-charge indication of titration end-points.

IT HAS LONG been known that a gas bubble bursting from an aqueous solution forms droplets that carry a small electrical charge. Indeed, Townsend,[1] by generating a multitude of small bubbles electrolytically and thence a fog of tiny droplets, was able to show that each droplet carried a single electronic charge or a small integral number of such charges. More recently[2] it has been shown that a smaller population of bubbles and droplets carried charges, the sizes of which were appreciable and dependent on bubble radius and on the concentration of an electrolyte in the aqueous phase. The fact that moving colloidal particles, and both ionic and non-ionic liquids passing down a tube cause a current to flow is also well known.[3–5] The mechanism of bursting bubbles and droplet formation has been studied in connection with cloud physics studies[6] where it is known that the liquid cap of the emerging and bursting bubble drains back into the cavity and forms a jet causing ejection of droplets of liquid amounting to about 0·001 of the volume of the original bubble.[7] Mason and Iribarne[2] have proposed a theory to account for the relationship found between bubble charge, q, radius of bubble, r, and ionic concentration, C, namely

$$q = -7 \times 10^3 \, . \, 4\pi r^2 C^{1/2} \exp\{-\tfrac{1}{2} - 10^6 r C^{1/2}/9\}$$

Their experimental results tend to confirm the remarkable relationship between the square root of the ionic concentration and bubble charge, but the mixed terms in the expression make it sensitive to parameters that change the coefficient in the exponential term. In fact, it is possible to show that q becomes proportional to any small power of C under moderate changes of conditions. Nevertheless, the processes could form the basis of a sensitive method of analysis in dilute solution.

An alternative theoretical approach and the results of a systematic analytical investigation are given below.

THEORETICAL APPROACH

Gas bubbles rising through an insulating fluid can readily attain appreciable electrical charges. Present experiments show that these charges can reach between -3 and $+6$ e.s.u per bubble and that, after the bubble has become well detached from its forming orifice, the value is independent of the distance travelled. In the case of doubly distilled water, charges of -3×10^{-3} e.s.u., again independent of distance travelled, are obtained. Evidently the charge is related to the velocity of the bubble and although the movement of the bubble relative to the liquid may tend to cause further charging, the charge dissipates to the liquid if this is at ground potential. A steady state must soon be established between electrical charging and leakage, at least with organic liquids of reasonably high dielectric constant and with aqueous solutions.

In aqueous solution the position is complicated by the possibility of ionic conduction or dissipation of the charge and even in doubly-distilled water charges far less than those in non-conducting media are found, and as the concentration of any electrolyte is increased in the aqueous phase the measured charge decreases still further. Experimental demonstration of such a phenomenon where detector response increases with decreasing concentration is given in Figs. 1 and 2.

The flux of univalent ions causing transfer of charge under a potential gradient $\mathrm{d}E/\mathrm{d}x$ can be expressed as

$$f = \frac{DC}{kT}\frac{\mathrm{d}E}{\mathrm{d}x}$$

where D is diffusivity, C the ionic concentration, k is Boltzmann's constant and T the absolute temperature. But at the gas–liquid interface the distribution of charge will be that of the Gouy double layer. Hence the potential E will be given by

$$E = \frac{4\pi\sigma}{\epsilon\kappa}$$

where σ is the specific surface charge, ϵ the dielectric constant of the solvent and $1/\kappa$ is the measure of the effective double layer thickness irrespective of its type. Hence,

$$\frac{\mathrm{d}E}{\mathrm{d}x} = \frac{4}{\epsilon\kappa} \cdot \frac{\mathrm{d}\sigma}{\mathrm{d}x} = \frac{4\pi}{\epsilon\kappa} \cdot \rho$$

where ρ is the electrical charge density at distance x from the interface.

Substituting for ρ gives

$$\frac{\mathrm{d}E}{\mathrm{d}x} = \frac{-4}{\epsilon\kappa} \,.\, \exp\{-\kappa(x-a)\}$$

where a is the distance of closest approach of the ions to the gas surface.

Hence,

$$f = -\frac{4\pi DC\sigma}{kT\epsilon \exp\{\kappa(x-a)\}} \tag{1}$$

If, under steady state conditions, this is the flux of ions that exactly counterbalances the charging process described above, then it will reach a constant depending only on the velocity of the bubble in a particular medium.

The value of x cannot exceed the thickness, δ, of the film that contributes to the bubble, and accepting the value of κ as $(2C)^{1/2}/4{\cdot}31 \times 10^{-7}\,\mathrm{mm}^{-1}$ for a univalent electrolyte in water at room temperature, then on expanding the exponential term

$$\sigma = -\frac{fkT\epsilon\{\kappa\delta + \kappa^2\delta^2 + \ldots\}}{4\pi DC}$$

The thickness δ is known[2] to be $<10^{-3}$ mm for small ($\sim$0·15 mm radius) bubbles so that, in the range below $C = 10^{-4}M$, the second and later terms of the expansion can be neglected.

Hence,

$$\sigma = -\frac{fk^{1/2}T^{1/2}\epsilon^{1/2}eN^{1/2}\delta}{1000 \times 2^{1/2}\pi^{1/2}DC^{1/2}}$$

Allotting accepted values of Avogadro's number, N, as $6{\cdot}03 \times 10^{23}$, the electronic charge, e, as $4{\cdot}80 \times 10^{-10}$ e.s.u., $\epsilon_{H_2O} = 78{\cdot}6$ at $T = 298°$ K and $k = 1{\cdot}38 \times 10^{-16}$ erg. K^{-1} then $\sigma = -8{\cdot}44 \times 10^{-7} f\delta D^{-1}C^{-1/2}$ e.s.u. or as a charge, $q_{1,1}$, resulting from a bubble of radius r, in a uni-univalent electrolyte,

$$q_{1,1} = -1{\cdot}06 \times 10^{-5} f\delta D^{-1}C^{-1/2}r^2 \text{ e.s.u.}$$

A complementary approach employs the relationship for charge density,

$$\rho = \frac{\epsilon\kappa}{4\pi} \cdot \frac{d\psi}{dx}$$

where ψ is the potential in the double layer. Hence the flux of ions transporting the charge is

$$f = -\frac{DC}{kT} \cdot \frac{4\pi\rho}{\epsilon\kappa}$$

and since

$$\sigma = \int_0^\delta \rho \, dx$$

$$\sigma = -\frac{fkT\epsilon\kappa\delta}{4\pi DC}$$

$$= -8{\cdot}44 \times 10^{-7} f\delta D^{-1}C^{-1/2}$$

Experimental evidence suggests that δ is $\sim$5–10 $\times 10^{-4}$ mm for bubble radii of 0·15–0·3 mm and the flux, expressed as a current density, is about 0·59 e.s.u. cm^{-2}.[2,4] With a typical value of $D = 10^{-3}$ mm^2 sec^{-1} these data give charges per bubble as

$$\sigma = 4\pi r^2 \times 5{\cdot}0 \times 10^{-4}C^{-1/2} \text{ e.s.u.} \tag{2}$$

i.e.,

$$5{\cdot}7 \times 10^{-7}C^{1/2} \text{ e.s.u.} \quad \text{or} \quad 1{\cdot}9 \times 10^{-16}C^{-1/2} \text{ coulomb} \tag{3}$$

The general form of this equation, modified to accommodate different diffusivities and bubble radii is in agreement with results given below.

Mason and Iribarne observed more complex behaviour of charge with respect to bubble radius. This has not been found in the present work although only a small range of bubble sizes has been investigated.

However, these authors found that at electrolyte concentrations above $10^{-4{\cdot}5}M$ their formula for charge was not obeyed; this was also observed in the present work. It seems logical from the proposed theory that charges would be dissipated more efficiently in more concentrated electrolyte solutions, leaving a slight excess of positive ions in the neighbourhood of the bursting bubble to be carried up in the droplet. Reference to the first theoretical approach given in this paper also shows that the first approximation of the expansion of the exponential part of equation (1) is not valid at higher concentrations. Under such conditions the second term becomes significant and the charge should become virtually independent of concentration and fall to quite small values. At higher concentrations, therefore, it would be expected that the charge would fall to a small almost constant value perhaps with a positive sign as is found in practice.

The present state of theoretical treatment of the electrical double layer formed by multivalent ions is inadequate for formulation of a similarly straightforward relationship between charge and electrolyte concentration. If adsorption and flux of a bivalent ion followed the same pattern as that of a univalent ion, then the expression for the charge per bubble would be

$$q_{2,2} = -1{\cdot}49 \times 10^{-5} f \delta D^{-1} C^{-1/2} \text{ esu}$$

However, the double layer appears to be populated with bivalent ions less efficiently than with univalent ions.[8] As a consequence the charge may be smaller than expected and the power to which the concentration is raised is likely to become rather more negative. Presumably, a converse argument could be applied to the counter-ions to explain the similarity of behaviour between uni-bivalent and bi-univalent electrolytes which, in practice, differ only in size of charge and not power in the relationship with concentration.

At the same time, the argument implies that, in a mixture of uni-univalent and bi-bivalent ions the effect of the univalent ions is dominant and equation (2) is likely to hold until bivalent ions are present in considerable excess. Most of these predictions are borne out in practice.

If the process of electrification depended solely on adsorption and double-layer formation it would be expected that different ions, owing to their different surfactant properties, would offer distinctly different bubble charges. A glance at the results for the uni-univalent electrolytes shows that indeed they behave similarly. Moreover, addition of the preferentially adsorbed species should have a dominating effect if adsorption were the single mechanism. In this connection, the effect of non-ionic surfactants is interesting: addition of small quantities of the substances to water causes a marked increase of the negative charge until irreproducibility caused by foaming occurs at approximately $10^{-4}M$, as follows,

Concentration of surfactant, M	Charge per bubble, *esu*
0	$-2{\cdot}9 \times 10^{-3}$
$10^{-6}M$ Nonidet P40	$-1{\cdot}4 \times 10^{-2}$
$10^{-5}M$ Nonidet P40	$-1{\cdot}12$
$0{\cdot}9 \times 10^{-6}M$ Tergitol NPX	$-0{\cdot}303$
$0{\cdot}9 \times 10^{-5}M$ Tergitol NPX	$-7{\cdot}72$

However, the presence of 10^{-6} or $10^{-5}M$ surfactant in experiments with sodium chloride shows that the relationship between concentration of electrolyte and bubble charge, seen in the table above, is affected in terms of size of charge and slightly in terms of slope until the adsorbed surfactant layer becomes so thick in the more concentrated solutions that conduction becomes inefficient.

A ready explanation for the results in pure water lies in the formation of an insulating layer of the organic surfactant at the water-gas interface, thus inhibiting the already weak charge-dissipating effect of the hydronium and hydroxyl ions at their low concentrations. But the presence of an electrolyte again allows charge conduction along a double-layer ion distribution but with a smaller absolute effect. The $q \propto C^{-1/2}$ relationship should therefore still hold, but the negative charge should be larger when the non-ionic surfactant is present. Apart from a slight reduction of the size of the inverse power to which the concentration is raised, these predictions are borne out in practice and confirm that diffusive dissipation of charge is an essential feature of the processes. At the same time, presence of such a non-ionic surfactant makes the method analytically more sensitive provided that too high a concentration of the surfactant is not employed.

TABLE I.—BUBBLE CHARGES IN ORGANIC SOLVENTS

Solvent	Grade	Bubble charge $q \pm s_q$, *esu*
Dimethylformamide	Purified[9]	$+6{\cdot}4 \pm 0{\cdot}1$
Isopentanol	GCR, as supplied	$+2{\cdot}7 \pm 0{\cdot}1$
n-Butanol	GCR, as supplied	$+0{\cdot}38 \pm 0{\cdot}01$
1,4-Dioxan	GCR, as supplied	$-(4{\cdot}1 \pm 0{\cdot}1) \times 10^{-4}$
Dimethylsulphoxide	Commercial, as supplied	$-(1{\cdot}6 \pm 0{\cdot}1) \times 10^{-3}$
Water	Twice distilled	$-(2{\cdot}2 \pm 0{\cdot}1) \times 10^{-3}$
Petroleum ether, 80–100°	A.R., MS treated	$-(3{\cdot}2 \pm 0{\cdot}3) \times 10^{-3}$
Dimethylformamide	GPR, as supplied,	$-(4{\cdot}0 \pm 0{\cdot}2) \times 10^{-3}$
1,4-Dioxan	Karl Fischer grade, as supplied, MS treated	$-(6{\cdot}5 \pm 0{\cdot}1) \times 10^{-3}$
Dimethylsulphoxide	Purified	$-(9{\cdot}5 \pm 0{\cdot}3) \times 10^{-3}$
Benzene	GCR, as supplied, MS treated	$-(1{\cdot}03 \pm 0{\cdot}05) \times 10^{-2}$
Ethyl methyl ketone	GCR, as supplied, MS treated	$-0{\cdot}42 \pm 0{\cdot}02$
Nitrobenzene	AR, as supplied, MS treated	$-1{\cdot}83 \pm 0{\cdot}07$
Pyridine	GPR, anhydrous, as supplied, MS treated	$-3{\cdot}43 \pm 0{\cdot}03$

GCR = Griffin Certified Reagent.
AR = BDH Analytical Reagent Grade.
MS treated = a column of type 5A molecular sieves was included in the closed-circuit flow system.

A rapid survey was made to find the size and sign of charges developed on bubbles rising in organic solvents. Results, given in Table I, must be regarded as preliminary since in most cases no rigorous efforts were made to purify the solvents and in certain cases there was evidence of some solvent attack on the silicone rubber tubing of the apparatus, and no corrections have been made for the small changes of bubble radius due to the different surface tensions. Nevertheless, the wide variation of charge magnitude and its change of sign are noteworthy, and the technique may afford a method for checking purity of organic solvents. In the case of purified dimethylformamide, it was shown that its large positive charge did decrease with increasing concentration of sodium perchlorate but its behaviour was complex and will be the subject of a further communication. No obvious correlation could be found between charge and dielectric constant, donor power, surface tension, dipole moment or viscosity.

RESULTS

The charge per bubble, q, *vs.* concentration, C, relationships for a number of electrolytes are shown in Figs. 1 and 2 and Table II. Clearly, for uni-univalent

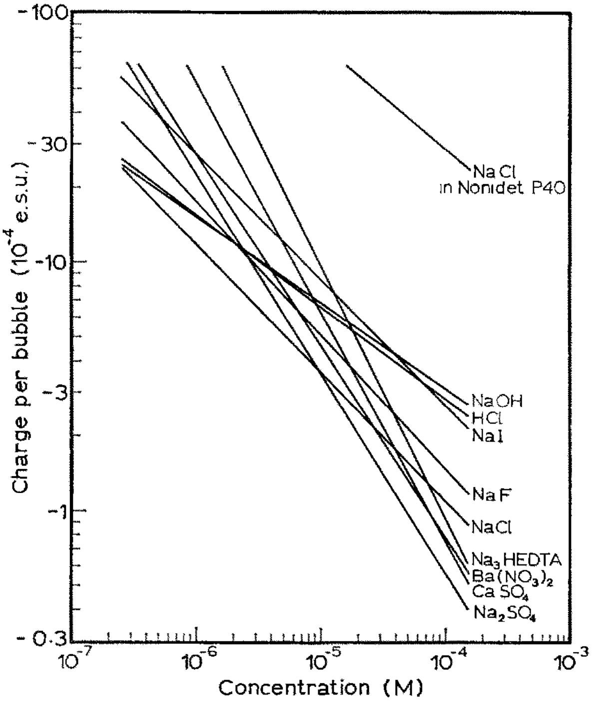

FIG. 1.—Charge-concentration relationships for various electrolytes.

electrolytes the $q \propto C^{-1/2}$ relationship holds well and predicted values for the charge are in reasonable agreement with experimental values, and incidentally, with those of Mason and Iribarne.[2] For multivalent electrolytes, illustrated by sodium sulphate, barium nitrate, calcium sulphate and the sodium salt of EDTA at pH 8, the power to which the concentration should be raised increases until almost a reciprocal relationship between charge and concentration holds. Mixtures of sodium sulphate and sodium chloride and of calcium sulphate and sodium chloride give intermediate values of the index, weighted towards one half, until the bivalent ion is in large excess, as shown in Table III.

It appears that the theory proposed above is essentially substantiated. The technique and results provide a novel method of analysis of dilute electrolyte solutions. There are two outstanding features that make the method attractive, based on the proportionality between detector response and the reciprocal of a power of electrolyte concentration. This gives an increasing signal with decreasing concentration, a property not found in other techniques. In practice the square-root relationship does not detract substantially from the sensitivity, and in the case of multivalent electrolytes where the function is almost reciprocal there is virtually no loss of sensitivity. Thus, sensitivity and precision, expressed as relative error, improve with decreasing concentration and the lower limit is set by the ionization of the solvent.

Hence concentrations of uni-univalent electrolytes, singly or in mixtures, can be measured by reference to equations (2) and (3) or to the straight line plots of log q *vs.* log C or to the parabolic curves of q *vs.* C. Since the equations analogous to (2) are not yet predictable for multivalent electrolytes, reference to calibration curves is necessary for their analysis. For many purposes mixtures of univalent and multivalent ions can be analysed with adequate precision in terms of concentration or ionic strength by using a calibration curve, especially when the univalent kind is not in proportionally minor concentration.

In the case of a method that yields a greater detector response with decreasing concentration and is highly sensitive to changes of ionic strength, one obvious application is in detection of titrimetric end-points. Figures 3–8 illustrate its usefulness

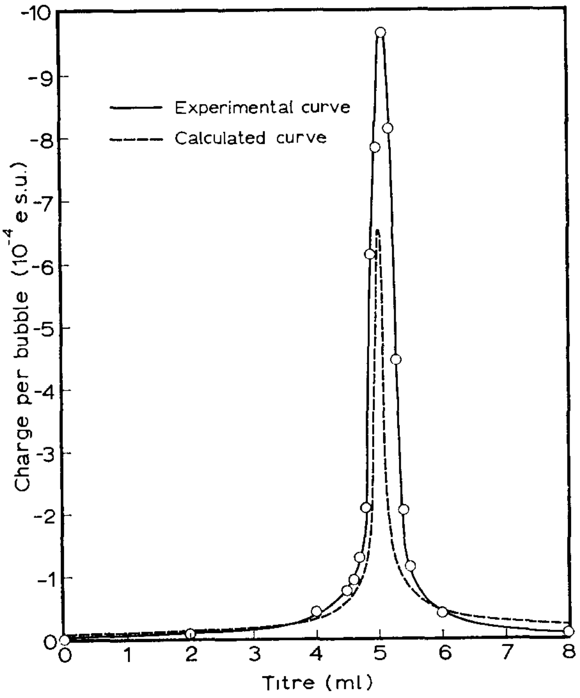

FIG. 3.—Titration of 250 ml of $10^{-3}M$ sulphuric acid with 0·05M barium hydroxide.

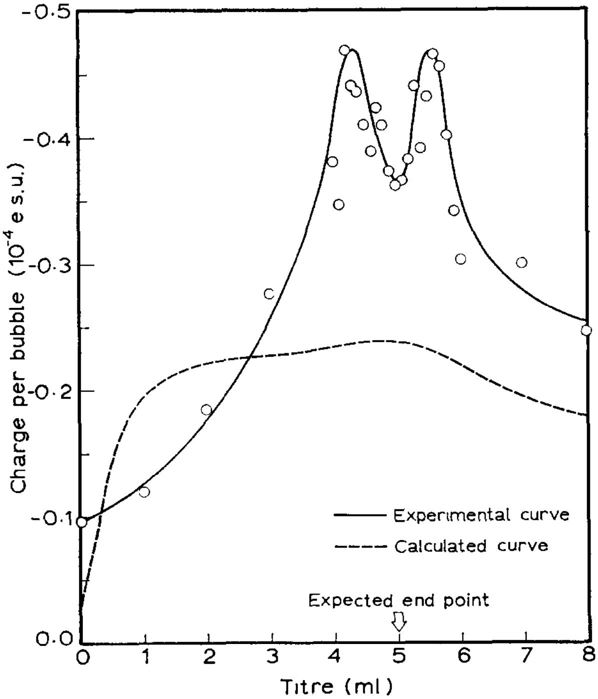

FIG. 4.—Titration of 250 ml of $10^{-3}M$ sodium sulphate with $0{\cdot}05M$ barium chloride.

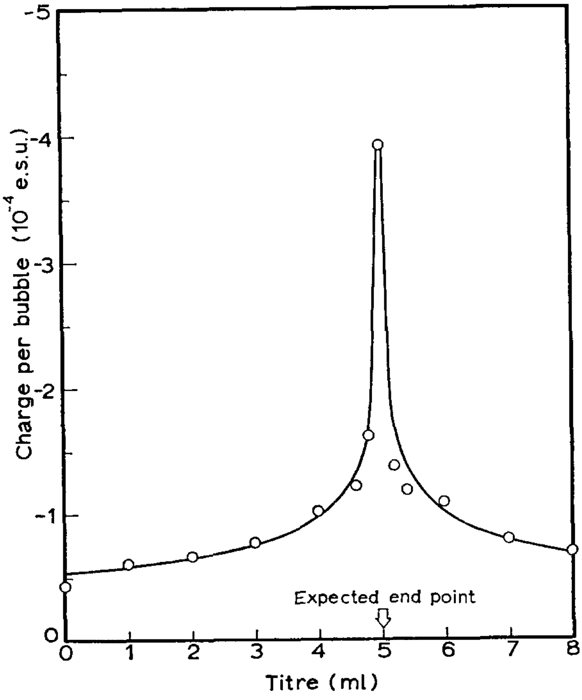

FIG. 5.—Titration of 250 ml of $10^{-3}M$ acetic acid with $0{\cdot}05M$ sodium hydroxide.

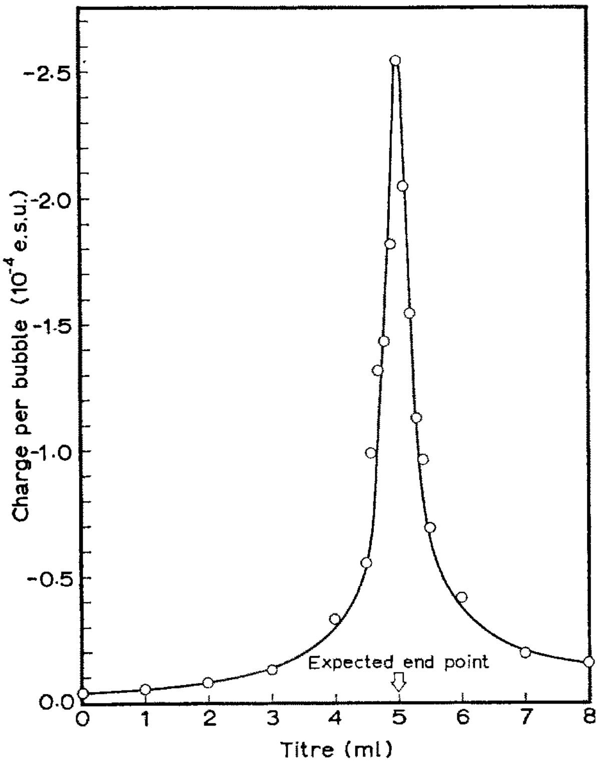

FIG. 6.—Titration of 250 ml of $10^{-3}M$ acetic acid with 0·05M ammonia.

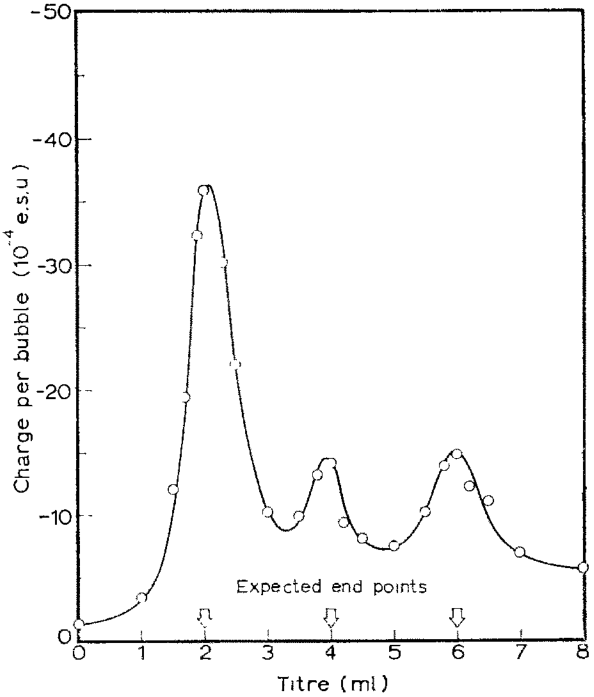

FIG. 7.—Titration of 200 ml of $10^{-3}M$ *ortho*phosphoric acid with 0·1M sodium hydroxide.

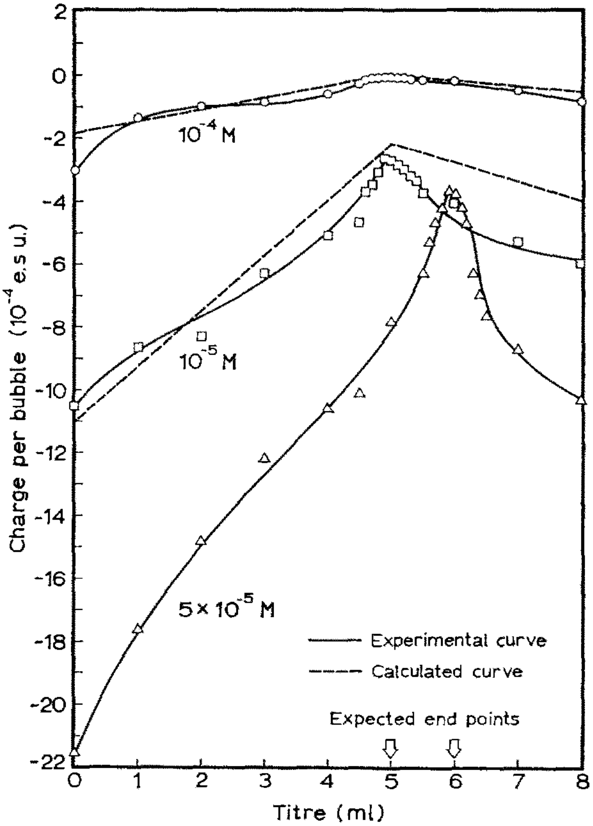

FIG. 8.—Titration of various concentrations of nickel with suitable concentrations of EDTA at pH 8.

in the following titration reactions:

$$H_2SO_4 + Ba(OH)_2 \rightarrow BaSO_4 + 2H_2O$$

$$Na_2SO_4 + BaCl_2 \rightarrow BaSO_4 + 2NaCl$$

$$NaOH + CH_3COOH \rightarrow CH_3COONa + H_2O$$

$$NH_4OH + CH_3COOH \rightarrow CH_3COONH_4 + H_2O$$

$$H_3PO_4 \xrightarrow{OH^-} H_2PO_4^- + H_2O \xrightarrow{OH^-} HPO_4^{2-} + 2H_2O \xrightarrow{OH^-} PO_4^{3-} + 3H_2O$$

$$Ni^{2+} + HY^{3-} \rightarrow NiY^{2-} + H^+ \ (pH \sim 8, Y = \text{EDTA ion})$$

These cover a wide range of changes of ionic strength during the course of a titration and in some cases the changes are extremely small. Nevertheless, the end-points occur at the expected values and are indicated with a clarity that is remarkable at $10^{-3}M$ concentrations and in some cases becomes even better at lower concentrations. End-points shown by analogous potentiometric methods are barely discernible even at the highest concentrations examined. It will be seen from Figs. 3 and 8 that the bubble-charge curves follow those calculated from calibration curves such as those shown in Figs. 1 and 2 with the exception of that for the precipitation of barium sulphate from barium chloride and sodium sulphate shown in Fig. 4. This displays a most remarkable shape and, while at the end-point the bubble charge tends towards that to be expected from solubility product, concentration of other ions and the charge/concentration relationships, the charges found on either side of the equivalence point are far larger than those expected. The results are the same if a filter is inserted in the liquid circuit. These observations imply that before and after the end-point the ionic concentrations of free ions are far smaller than those expected from thermodynamic and stoichiometric relationships. It would appear that adsorption on the almost colloidal barium sulphate and on the aging precipitate withdraws a great many ions from solution and that the technique offers a method of following nucleation, precipitation and adsorption processes.

EXPERIMENTAL

The apparatus, built essentially of Perspex and high density polythene, is illustrated in Figs. 9 and 10. The second kind is essentially that designed by Mason and Iribarne[3] and is particularly useful if control of gas atmosphere and prevention of dust contamination are required. Details of screening and earthing are important. However, a comparison between the apparatus using nitrogen and laboratory air atmospheres showed that they gave identical results.

The bubble charges were measured as a current on a Keithley Electrometer, type 602, by connecting the collecting funnel *A* to the solution *via* the screening at *B* and *via* a triaxial/coaxial adapter. Liquid was kept flowing to spill over the circular weir *C*, either fed from a large reservoir by gravity, thus simulating a continuous stream and providing a constantly renewed liquid surface, or by closed circuit peristaltic pumping with a Watson-Marlow type MHRE pump. The second system was of particular application in the bubble-charge titrations. A balance must be arranged between the inflow of gas as bubbles plus that entering at *E* and the withdrawal at the exit tube *F*. Rates of bubble generation were measured with a photoelectric device coupled to an Advance Instruments

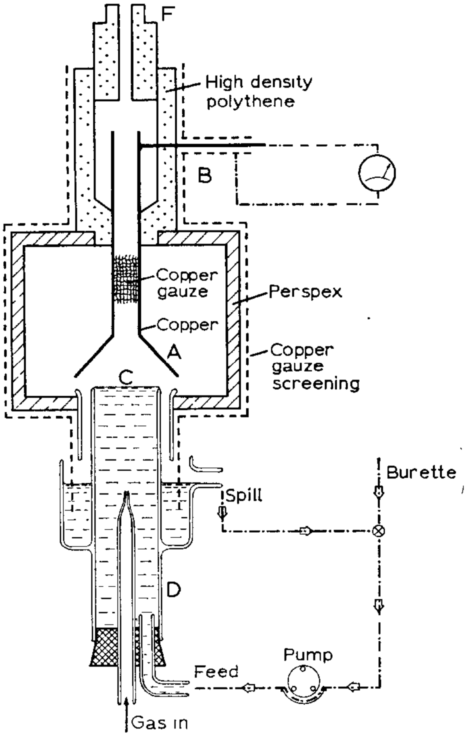

FIG. 9.—First bubble-chamber apparatus.

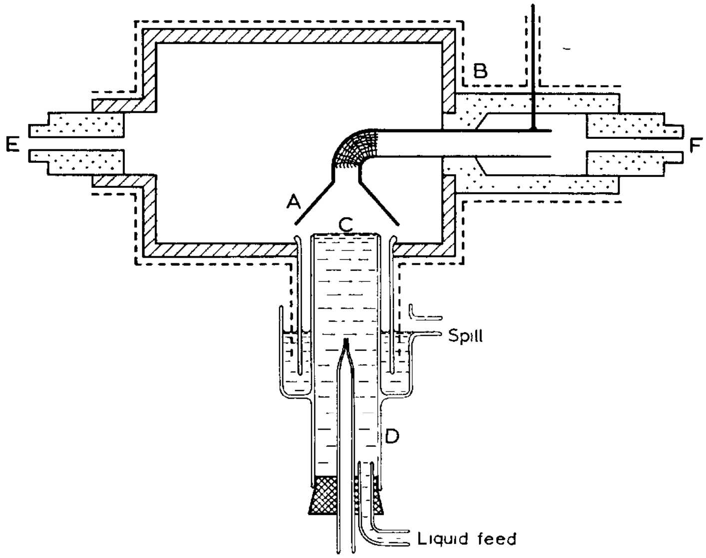

Fig. 10.—Second bubble-chamber apparatus.

Timer, type TC12A. In the present series of experiments the bubble-rate control was crude and was contrived by adjustment of the usual valve fittings on a nitrogen cylinder: undoubtedly this could be improved to some advantage but it was quite adequate for these experiments, the relative fluctuation in bubble rate being less than ±10%.

The current measured on the electrometer was converted into individual bubble charges from the

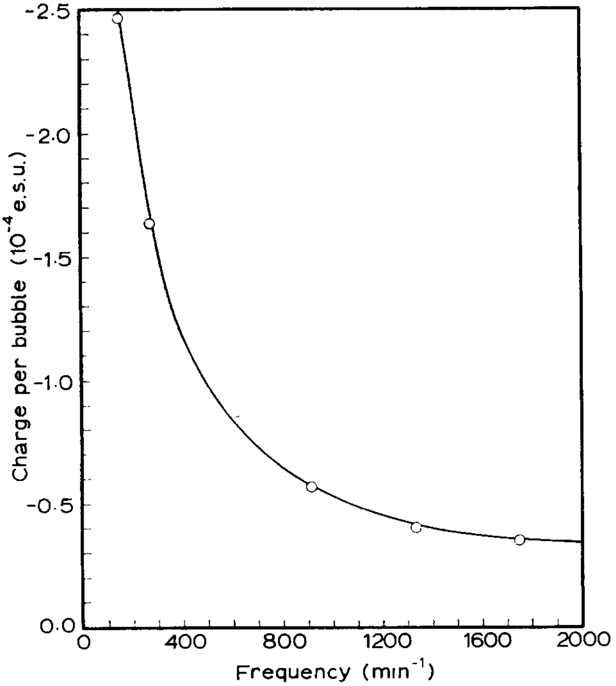

Fig. 11.—Effect of bubble frequency on charge per bubble in $10^{-5}M$ sodium chloride and with 0·1-mm radius bubbles.

measured bubble rate, which had been selected from previous experimentation. Lower bubble rates had the disadvantage that, while the bubble charges were larger, the electrometer needle oscillated wildly at the bubble bursting stage and, at the same time, results were of rather poor reproducibility. A plot of bubble charge against bubble rate is shown in Fig. 11 and most measurements were conducted at rates of 1000–1200 bubbles/min, where changes of rate had smaller effects. This procedure also had the advantage that meter readings became meaningful and the occasional spurious low currents, apparently caused by a bubble brushing against the glass wall of the flow tube *D* during upward traverse, became obvious and could be ignored. This charge-deficiency problem may set a lower limit to the solution capacity of the apparatus because a narrower tube *D* suffers more seriously from this disadvantage. Inclusive of small reservoirs and any molecular-sieve drying tubes, the capacity of the closed circuit system was about 250 ml in the apparatus used in the majority of this work.

Preliminary experiments established that over the practical bubble-paths available (60–150 mm) the distance traversed by a bubble in water or organic solvents had no effect on the bubble charge, and the rate of flow of liquid similarly had no significant effect, provided that it exceeded 50 ml/min. Bubble velocities were found to be reproducible in both designs of apparatus and in long columns of the liquids investigated, namely, for water 0·333 ± 0·046 m/sec and for dimethylformamide, 0·220 ± 0·008 m/sec. The lowering of charge observed when a bubble brushed the side of the tube was presumably to be attributed to a slowing down, to an increased dissipation of charge and perhaps to a disturbing of the double layer.

CONCLUSIONS

The electrification of gas bubbles affords a simple and comparatively inexpensive means of analysis of dilute solutions. The proposed theory is confirmed in practice and from the resulting formula it is possible to evaluate concentrations of electrolytes. The sensitivity and usefulness of the technique is demonstrated by the application to identification of titrimetric end-points and to analysis of continuously flowing solutions. Considerable extension of the applications seems possible in double layer, diffusion and analytical fields and work on continuous and titrimetric analysis is continuing.

Zusammenfassung—Wenn ein Gas durch eine Flüssigkeit strömt, bildet sich eine Ladung; diese geht in die Tröpfchen über, die beim Platzen der Blase an der Flüssigkeitsoberfläche entstehen. Eine Theorie wird abgeleitet, die die Beziehung zwischen Blasenladung und Elektrolytkonzentration beschreibt, nämlich $q \propto C^{1/2}$, und auf eine Anzahl ein-einwertiger und mehrwertiger Elektrolyte angewandt. Die allgemeine Übereinstimmung zwischen Theorie und Experiment und die zufriedenstellende Reproduzierbarkeit des Verfahrens zeigen, daß es analytisch angewandt werden könnte. Das wird an Beispielen gezeigt, wie simulierten fließenden Systemen zur kontinuierlichen Analyse und der Anzeige von Titrationsendpunkten mit Hilfe der Blasenladung.

Résumé—Lorsqu'un gaz passe à travers un liquide, il se produit une charge qui est transportée dans les gouttelettes formées lorsque la bulle éclate à la surface du liquide. Une théorie est établie pour rendre compte de la relation entre la charge de la bulle et la concentration de l'électrolyte, c'est-à-dire $q \propto \mathrm{C}^{-1/2}$, et appliquée à un certain nombre d'électrolytes mono-monovalents et multivalents. L'accord général entre la théorie et l'expérience et la reproductibilité raisonnable de la technique montre qu'elle peut avoir des applications analytiques. Un tel emploi est illustré par les simulations en laboratoire de systèmes en écoulement pour l'analyse en continu et par l'indication de points de fin de titrage par charge de bulle.

TITRIMETRIC DETERMINATION OF MICROGRAM AMOUNTS OF MANGANESE AFTER AMPLIFICATION

J. W. HAMYA and A. TOWNSHEND
Chemistry Department, Birmingham University, P.O. Box 363, Birmingham 15, England

(*Received* 17 *August* 1971. *Accepted* 21 *September* 1971)

Summary—Manganese (5–100 μg) is oxidized to permanganate by periodate in 3 or 6% nitric acid. After masking of the excess of periodate with molybdate the permanganate and iodate formed are titrated iodimetrically.

MANGANESE is conveniently determined titrimetrically after oxidation to permanganate. Various oxidants have been recommended. Sodium bismuthate[1,2] and lead(IV) oxide[3] give rapid oxidation, but the excess of reagent has to be filtered off before titration of the permanganate. Silver(II) oxide,[4] dissolved in cold nitric, perchloric or sulphuric acid also gives complete and rapid oxidation at room temperature, and the excess of silver(II) ions is completely destroyed by dilution and warming for a few minutes. Peroxydisulphate ions[5] are very effective with silver ions acting as a catalyst; the addition of phosphoric acid[6,7] has been suggested to prevent precipitation of manganese dioxide. The excess of oxidant is destroyed by prolonged boiling. Decomposition of permanganate at this stage is retarded by buffering the solution with disodium hydrogen phosphate, and keeping the boiling period as short as possible.[8] In all these methods, the permanganate may be determined titrimetrically, after removal of the excess of added oxidant, by using for example arsenic(III)[9] or iron(II) sulphate.

Willard and Greathouse[10] used periodate to oxidize manganese to permanganate:

$$2Mn^{2+} + 5IO_4^- + 3H_2O \rightarrow 2MnO_4^- + 5IO_3^- + 6H^+ \qquad (1)$$

The permanganate formed was measured colorimetrically. Attempts to apply a titrimetric finish have been hampered by the presence of periodate and iodate, both of which are also strong oxidants, and would interfere in the permanganate titration. Attempts to remove iodate and periodate by precipitation with mercury did not give satisfactory results.[11] Recently, it was found that periodate can be masked by molybdate, whereas iodate is unaffected.[12] In particular, this masking effect was used to achieve a 24-fold amplification for iodide, based on the reaction:

$$I^- + 3IO_4^- \rightarrow 4IO_3^-$$

The iodate formed could be determined iodimetrically, a titrimetric[13] or spectrophotometric[14] finish being used after masking of the excess of periodate. It seemed probable that the same masking effect could be utilized in the determination of permanganate formed by periodate oxidation of manganese(II). In this instance, the products of reaction (1) are reacted with iodide:

$$2MnO_4^- + 10\,I^- + 16H^+ \rightarrow 5I_2 + 2Mn^{2+} + 8H_2O \qquad (2)$$

$$5IO_3^- + 25I^- + 30\,H^+ \rightarrow 15I_2 + 15H_2O \qquad (3)$$

whereas the excess of periodate is masked by molybdate. As the amount of iodate formed in the reaction is stoichiometrically related to the amount of manganese present initially, the overall production of iodine can be represented by:

$$2Mn^{2+} \equiv 20\ I_2$$

Titration of the iodine produced gives an appreciable amplification of the manganese. The present paper describes the development of this amplification procedure.

EXPERIMENTAL

Aqueous solutions

All chemicals used were analytical reagent grade.

Potassium metaperiodate. Recrystallized from water and vacuum-dried in the dark. Dissolve 1·400 g in small portions of hot water and after cooling make up to 500 ml with water. Store in a dark glass bottle.

Manganese(II) nitrate solution. To contain 98·66 μg of manganese per ml.

Nitric acid (30%). Dilute 30 ml of conc. acid to 100 ml. Boil gently for 2 min, cool and store in a dark glass bottle.

Potassium carbonate solution, 30%.

Ammonium molybdate solution, 12·5%. Freshly prepared.

Potassium iodide solution, 10%. Freshly prepared.

Acetate buffer. Freshly prepared from 0·2M sodium acetate and glacial acetic acid to give a pH of 2.

Sodium thiosulphate solution, $2 \times 10^{-3}M$.

Procedure for determination of manganese (5–100 μg)

To the sample containing $<50\ \mu$g of manganese in a 10-ml graduated flask, add 1 ml of 30% nitric acid (2 ml for $>50\ \mu$g of manganese) and 2 ml of periodate solution and make up to the mark with distilled water. Hold down the stopper with plastic-covered wire and, after gentle mixing, lower the flask carefully into boiling water and leave for 30 min. Cool the reaction mixture, transfer it, with washing, to a conical flask, and add 1·5 ml (or 3 ml when 2 ml of acid were added) of 30% potassium carbonate solution, 5 ml of molybdate solution and 10 ml of buffer solution. Add 2·5 ml of 10% potassium iodide solution, allow to stand for about 2 min and titrate with $2 \times 10^{-3}M$ sodium thiosulphate, adding Thyodene as indicator near the end-point. Take a blank of distilled water through the whole process.

DISCUSSION

The periodate oxidation of manganese

The reaction between manganese(II) and periodate ions was studied by some early workers[15–18] with conflicting results, but Willard and Greathouse were the first to use it as the basis of a colorimetric method for the quantitative determination of manganese. Originally it was applied to the determination of manganese in steels and iron ores. Later its use was successfully extended, often with some modifications, to water,[19] to animal and vegetable materials[20–22] and to salt solutions.[23]

Willard and Greathouse emphasized the danger of having insufficient acid in the reaction mixture; and they stated that a very large concentration of acid does no harm to the development of the permanganate colour. However, the smallest amount of manganese they determined was 2·5 mg per 100 ml of solution. Richards[21] pointed out that if the amount of manganese present is very small, for example 5 μg or less, the danger lies in excessive acidity rather than in its insufficiency. He found that 15% sulphuric acid was sufficient to prevent full colour development or to cause it to fade rather rapidly, the solution gradually assuming a yellow tint.

The acids that have been used include nitric, sulphuric and phosphoric acids or any mixture of them. Hydrochloric acid is not recommended because chloride is oxidized by periodate and thus would interfere. Perchloric acid appears to prevent the oxidation of some manganese(II) and apart from its use in kinetic studies, has never come into general use.

Clark,[23] in determining manganese in salt solutions, preferred phosphoric acid as he found it more satisfactory than other acids for the rapid development of the permanganate colour. He used solutions at about pH 2 and states that a difference of 1 μg of manganese in 50 ml of solution can be observed, if Nessler tubes are used. Phosphoric acid is thought to play a role as a complexing agent for manganese(III) and manganese(IV). Richards found that for 25–500 μg of manganese, the rate of oxidation was a minimum in 9–10% sulphuric acid. With below 1% acid the colour developed very rapidly but the solutions showed the same yellow tint and tendency to rapid fading as are found when the acidity is too great. He recommended the use of 5–6% acid, unless manganese was present in very considerable amounts to justify the use of 15–20% acid, and applied the method to the colorimetric determination of very small amounts of manganese in certain biological materials.

These contradictory results led to investigations of the kinetics and mechanism of the formation of permanganate from manganese(II) by periodate in nitric, sulphuric and perchloric acid media.[24,25] The reaction was found to be autocatalytic, with an induction period, and its rate was proportional to the concentrations of manganese(II) and periodate and also increased with permanganate concentration. In perchloric acid, a violet manganese(III) complex is formed as an intermediate. The proposed mechanism may be represented as:

$$2\mathrm{Mn(II)} + \mathrm{IO_4^-} \xrightarrow{\text{slow}} 2\mathrm{Mn(III)} + \mathrm{IO_3^-} \tag{4}$$

$$\mathrm{Mn(III)} + 2\mathrm{IO_4^-} \longrightarrow \mathrm{MnO_4^-} + 2\mathrm{IO_3^-} \tag{5}$$

$$\mathrm{Mn(II)} + \mathrm{MnO_4^-} \longrightarrow \mathrm{Mn(III)} + \mathrm{MnO_4^{2-}} \tag{6}$$

$$\mathrm{Mn(II)} + \mathrm{MnO_4^{2-}} \longrightarrow 2\mathrm{Mn(IV)} \tag{7}$$

$$\mathrm{Mn(IV)} + \mathrm{Mn(II)} \longrightarrow 2\mathrm{Mn(III)} \tag{8}$$

In particular, the reactions show that manganese(IV) cannot be oxidized unless it is first reduced by manganese(II) [reaction (8)]. Thus some manganese may be trapped as manganese(IV), if its concentration ever exceeds that of manganese(II).

Establishment of optimal conditions

In the present work attempts were made to oxidize manganese(II) between pH 5 and 8, as it was thought that the reaction might be faster than at higher acidities. It was observed, however, that although permanganate was formed more or less instantaneously, there followed the formation of a permanent brown precipitate or colloidal suspension of manganese(IV) oxide [reaction (7)]. At pH 7–8, also, the titration volumes were always 20% greater than theoretical. It was clear that to avoid the permanent formation of manganese(IV), the mixture of periodate and manganese had to be optimally acidified.

The oxidation of 100 μg of manganese was investigated, using nitric, perchloric and sulphuric acids at different concentrations. Phosphoric acid was not used because the formation of phosphomolybdate in the final titration step is undesirable because of its colour and the rapid production of molybdenum blue. Sulphuric acid gave variable results, although this is the acid which most workers have used in this reaction. The permanganate colour developed quite slowly, especially in 3–9% acid. At acidities below 1% sulphuric acid, a brown colloidal suspension was produced. Nitric and perchloric acids were preferable to sulphuric acid; spectrophotometric measurements showed that nitric acid led to the stoichiometric formation of permanganate more rapidly than did perchloric acid. After oxidation in 6% nitric acid, 25–450 μg of manganese could be determined spectrophotometrically as permanganate at 525 nm. The calibration graph was rectilinear and comparable to that of standard amounts of permanganate in the presence of periodate and nitric acid at similar concentrations, showing that oxidation was stoichiometric. At this acidity, however, <25 μg of manganese required more than 30 min heating for complete oxidation. Lowering the acidity to 3% markedly improved the reaction rate and samples containing up to 100 μg of manganese could be quantitatively oxidized within 30 min, although for >50 μg of manganese the use of 6% acid gave a faster reaction. If the nitric acid contained nitrogen oxides little or no reaction took place, but nitrogen oxides were readily eliminated by boiling the acid before use.

The effect of periodate concentration on the rate and extent of reaction was much less pronounced than that of acidity, provided there was sufficient periodate present. Theoretically, 10·47 mg of potassium periodate are required to oxidize one mmole of manganese. Many early investigators used far greater excesses of solid periodates for the reaction than was necessary, and some workers[26,27] used silver salts as catalysts, so as to permit the use of less periodate. High,[28] using periodate dissolved in 0·5% nitric acid, found that as little as 50 mg of periodate sufficed for the oxidation of 2·3 mg of manganese 100 ml of solution. The oxidation was as rapid with this concentration of periodate as when larger amounts of a solid periodate were used. In the present work it was found that 5·6 mg of potassium periodate in 10 ml of aqueous solution is suitable for a wide range of manganese concentrations.

After quantitative oxidation of manganese to permanganate, the excess of periodate is masked by molybdate, iodide is added, and the iodine formed [reactions (2) and (3)] is titrated with thiosulphate solution. As little as 5 μg of manganese could be determined in this way. The results for the determination of 5–100 μg of manganese are summarized in Table I. The blank titration was 0·3–0·6 ml. Alternatively, the permanganate colour may be monitored by the established spectrophotometric procedure.

The induction period was not constant for apparently identical reaction mixtures, but was generally 3–5 min from the initial insertion of the reaction flask in the boiling water-bath. Methods for shortening the induction period have been suggested, for example, the use of a few μg of manganese dioxide and smooth metallic platinum or the use of small amounts of iodate and permanganate,[25] but such expedients were found to be unnecessary. Very small amounts of certain reductants such as nitrite, sulphite and hydrogen peroxide lengthen the induction period although the concentration of the reductant must exceed that of the manganese before the effect is appreciable. However, reductants consume periodate, and therefore interfere by giving a positive error. Many metals form iodates or periodates which are insoluble in dilute acids. However, addition of up to 100 μg of aluminium, antimony(III), silver, lead, bismuth, barium, calcium, magnesium, mercury(II), zinc, tin(II), iron(III), lithium or zirconium

TABLE I.—TITRIMETRIC DETERMINATION OF MANGANESE(II) AFTER AMPLIFICATION

Manganese taken, μg	Nitric acid used, %	Number of determinations	Mean recovery, %	Standard deviation, %
100*	6	10	$100{\cdot}1_8$	$0{\cdot}7_8$
50	6	6	$101{\cdot}5_2$	$0{\cdot}8_4$
25	6	6	$99{\cdot}8_5$	$1{\cdot}5_2$

20	3	5	$100{\cdot}2_3$	1·0
10	3	5	$100{\cdot}6_4$	1·9
5	3	8	$100{\cdot}2_2$	4·2

* 20 ml of $2 \times 10^{-3}M$ sodium thiosulphate solution required.

to the reaction mixtures had no deleterious effect on the determination of 100 μg of manganese. Cobalt(II) and nickel gave a hue that interfered with the colour change at the end-point of the final titration. Although the effects of halide and organic anions were not examined, these would undoubtedly be oxidized by periodate, but could be eliminated by wet ashing with acids.

The determination of 5–100 μg of manganese is readily achieved by utilizing the amplification resulting from the stoichiometric formation of 5 iodate ions for every 2 permanganate ions formed. Such a procedure is made possible by the masking of excess of periodate by molybdate. This amplification procedure should be of general application to all species that are oxidized by periodate to give an oxidizing species and iodate ions, for example:

$$2Cr^{3+} + 3IO_4^- + 4H_2O \rightarrow Cr_2O_7^{2-} + 3IO_3^- + 8H^+.$$

Acknowledgement—The authors thank Professor R. Belcher for his interest and encouragement. J. W. Hamya thanks the Association of Commonwealth Universities for a Commonwealth Scholarship, and the Uganda Government for study leave.

Zusammenfassung—Mangan (5–100 μg) wird mit Perjodat in 3 oder 6% Salpetersäure zu Permanganat oxidiert. Nach Maskierung des überschüssigen Perjodats mit Molybdat wird das gebildete Permanganat und Jodat jodometrisch titriert.

Résumé—On oxyde le manganèse (5–100 μg) en permanganate par le periodate en acide nitrique à 3 ou 6%. Après dissimulation de l'excès de periodate par le molybdate, le permanganate et l'iodate formé sont titrés par iodométrie.

APPLICATION DES METHODES COULOMETRIQUES AUX DOSAGES MICROANALYTIQUES DU MANGANESE ET DU CHROME DANS LES COMPOSES ORGANIQUES

M. BIGOIS
(avec la collaboration technique de M. MARCHAND)
Service Central de Microanalyse du Centre National de la Recherche Scientifique,
2, rue Henry Dunant, 94—Thiais, France

(*Reçu le* 12 *juillet* 1971. *Accepté le* 24 *août* 1971)

Résumé—La coulométrie à intensité constante est appliquée à la détermination microanalytique du manganèse et du chrome contenus dans les substances organiques après minéralisation appropriée. Les substances sont décomposées par un mélange d'acides sulfurique et nitrique. Le manganèse et le chrome sont respectivement oxydés en ions permanganiques par le persulfate d'ammonium, et en ions bichromiques par l'acide perchlorique. Les ions MnO_4^- et $Cr_2O_7^{2-}$ sont titrés par les ions Fe^{2+} formés électrolytiquement à courant constant à partir d'ions Fe^{3+} contenus dans la solution avec une fin de titrage ampérométrique.

LES HETEROELEMENTS rencontrés dans les molécules organiques sont de plus en plus nombreux et divers et, corrélativement, les problèmes de leurs dosages microanalytiques se posent à notre Service. Pour les résoudre, les méthodes appliquées, à cette èchelle, doivent être non seulement précises et rapides, mais également aussi sélectives que possible, ce qui élimine, entre autres, le recours à la gravimétrie classique d'oxydes et de sulfates (*cf.* Réf. 1).

Sous réserve de la comparer ultérieurement à d'autres méthodes de mesures finales susceptibles d'être mises en oeuvre, tant classiques (titrimétrie complexométrique) que modernes (spectrométrie de flamme, spectrométrie d'absorption atomique *etc.*), la méthode fondée sur la génération électrolytique des ions titrants et leur mesure coulométrique nous a semblé réunir les qualités requises.

En effet nous appliquons un principe classique de minéralisation préalable de la substance organique qui comporte une attaque sulfonitrique puis, si nécessaire, une oxydation des ions porteurs de l'élément à doser et qui peut être sélective; elle permet d'obtenir une espèce ionique unique dans laquelle cet élément possède une valence définie; il est alors possible de doser cette espèce ionique par des ions ou molécules appropriés, réducteurs ou oxydants, engendrés in situ par électrolyse de la solution et mesurés par coulométrie, dans des conditions qui peuvent également être sélectives.

L'ensemble de ces réactions d'oxydoréduction chimiques et électrochimiques peut conférer à la méthode un caractère de spécificité permettant de résoudre avec précision des problèmes d'analyse particuliers.

Les méthodes de dosages de métaux comportant un titrage coulométrique ont déjà donné lieu à de nombreuses publications, dans le cadre de l'analyse minérale, et notamment en vue du dosage du manganèse et du chrome dans les aciers.[2,3] Le présent travail a pour objet l'adaptation de ces méthodes aux dosages microanalytiques du manganèse et du chrome dans les composés organiques.

Les principes des titrages électrochimiques mis en oeuvre sont classiques et décrits dans les ouvrages généraux; il convient cependant de les rappeler brièvement.

L'attaque sulfonitrique initiale du prélèvement analytique fournit en solution des ions manganeux Mn^{2+} et chromique Cr^{3+}; leur titrage électrochimique exige leur oxydation préalable en ions permanganiques MnO_4^- et bichromiques $Cr_2O_7^{2-}$. Les réactifs oxydants utilisés à cette fin sont respectivement le persulfate d'ammonium,[2,3] dans le premier cas, et l'acide perchlorique[4] dans le second. Les ions MnO_4^- et $Cr_2O_7^{2-}$ sont titrés par des ions ferreux Fe^{2+} engendrés par électrolyse d'une solution d'ions ferriques Fe^{3+}, en milieu acide; le point final de titrage qui correspond à l'apparition d'un excès d'ions Fe^{2+} en solution est mis en évidence par ampérométrie.

PARTIE EXPERIMENTALE

Minéralisation

La minéralisation a pour objet la destruction de la matière organique et la production en solution des hétéroéléments à doser sous forme titrable. Comme il a été rappelé, elle comprend deux phases: l'attaque proprement dite du prélèvement analytique et l'oxydation éventuelle des ions porteurs de l'élément à doser en une autre forme ionique appropriée au titrage.

L'attaque proprement dite, effectuée par un mélange d'acides sulfurique et nitrique concentrés, est dérivée de celle qui a déjà été utilisée, dans notre Service, pour le dosage de l'arsenic dans les composés organiques;[5] elle est généralement applicable à la mise en solution des hétéroéléments portés par des molécules organiques. Seul varie, suivant la nature de la molécule organique et de l'hétéroélément à doser, le nombre des répétitions nécessaires de cette attaque sulfonitrique.

La variante de la méthode que nous avons mise au point comporte une évaporation par chauffage, à quasi-siccité, des acides nitrique et sulfurique dans un récipient réactionnel du type micromatras de Kjeldahl, ce qui implique, pour ce dernier, une forme et des dimensions adéquates et un dispositif d'aspiration et de chauffage progressif, à réglage fin, qui sont décrits dans le paragraphe ci-après.

Appareillage de minéralisation (Fig. 1)

Le micromatras, en verre Pyrex, dans lequel est effectuée l'attaque sulfonitrique comporte une partie sensiblement sphérique, d'une capacité d'environ 5 ml (diamètre = 25 à 26 mm) et un col de 50 mm de longueur, muni à son extrémité d'un rodage femelle normalisé (n° 0).

Le dispositif d'aspiration est une rampe tubulaire de verre Pyrex, de 40 mm de diamètre, à 6 ajutages tubulaires perpendiculaires à son axe, pourvus de 6 rodages mâles (n° 0) distants de 50–60 mm et sur lesquels peuvent être ajustés les rodages femelles des matras. La rampe est fermée à ses deux extrémités et comporte, en son centre, une tubulure d'aspiration pouvant être reliée à une trompe à eau et, à une extrémité, une tubulure de communication avec l'air ambiant pouvant être fermée par un robinet de verre à pointeau de Téflon. Sur la rampe est bobiné un cordon chauffant permettant d'élever les vapeurs d'extraction de la minéralisation à une température de l'ordre de 100°.

Le dispositif de chauffage électrique des matras est composé de six éléments chauffants constitués essentiellement par des petits fours électriques semblables aux fours mobiles de certains bancs de microanalyse utilisés pour les microdosages du carbone et de l'hydrogène[1] et dont la construction est inspirée des données de Zimmerman;[6] l'âme de chaque four est un tube de porcelaine réfractaire non vernissée, de 50 mm de diamètre intérieur, de 4 mm d'épaisseur et 50 mm de longueur, sur laquelle le fil chauffant, en nichrome, est enroulé suivant des génératrices des surfaces extérieure et intérieure du cylindre réfractaire. Le fil de nichrome a une longueur de 0,75 m et un diamètre de 0,43 mm. Le four est cimenté (ciment talc-silicate de soude) à l'intérieur d'un tube réfractaire de même longueur, de 50 mm de diamètre intérieur et de 4 mm d'épaisseur. Les éléments chauffants sont disposés verticalement et centrés sous six trous, de 50 mm de diamètre, d'une platine en amiantine horizontale. (*cf.* Fig. 1.)

Chaque élément chauffant est alimenté sous tension de 40 V par l'intermédiaire d'un rhéostat de 2,2 Ω, en série, permettant de faire varier l'intensité de chauffage de 2,7–4 A.

Les matras sont posés sur des petits carrés de toile métallique obturant les trous de la platine (*cf.* Fig. 1). La très faible inertie thermique des éléments chauffants et leur montage "en cheminée à air" permet d'obtenir un réglage fin et reproductible du chauffage des matras plus aisément qu'avec une rampe à gaz classique équipée de microbrûleurs.

Attaque sulfonitrique

Les prélèvements microanalytiques sont pesés (0,5 à 4 mg), les produits solides dans des pèse-substances classiques, les produits liquides dans des gélules* (*cf.* Ref 7) ou encore dans des sachets tubulaires de terphane[8] lorsqu'ils sont altérables à l'air, et introduits dans les matras.

* Gélules n° 5—Fabricant Parke Davis—U.S.A.

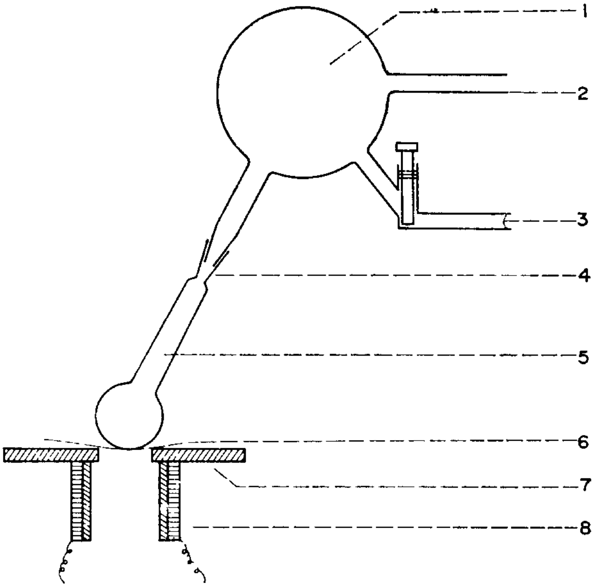

FIG. 1.—Dispositif de chauffage avec matras et rampe d'aspiration. Coupe verticale.

1 Rampe d'aspiration
2 Tubulure d'aspiration
3 Sortie tubulaire commandée par vanne en Téflon
4 Assemblage rodé
5 Matras
6 Toile métallique
7 Platine d'amiantine
8 Elément chauffant.

Sur ces prélèvements sont versées 1 ou 2 gouttes d'acide sulfurique concentré (pur pour toxicologie $d = 1{,}83$)† puis une goutte d'acide nitrique concentré (pur pour toxicologie $d = 1{,}40$).

Les matras sont posés sur les toiles métalliques des éléments chauffants et branchés par leurs rodages à la rampe d'aspiration, cette dernière étant à la pression atmosphérique, prise d'air ouverte; les éléments chauffants sont mis sous tension, les intensités étant réglées à l'aide des rhéostats à leur valeur minimale; au bout de 15 min les intensités sont réglées à leur valeur maximale de façon à chauffer les matras jusqu'à apparition des vapeurs sulfuriques.

Les éléments chauffants sont alors éteints; la prise d'air de la rampe d'aspiration est fermée et cette dernière remise sous dépression à l'aide de la trompe à eau afin de chasser des matras les vapeurs nitriques et une partie de l'acide sulfurique tandis que les composés des hétéroéléments à doser se déposent sous forme de sulfates métalliques (Mn) sur les fonds de matras ou restent en solution dans l'acide sulfurique (Cr).

Notons que nous appliquons également ce mode opératoire à la minéralisation de substances organiques contenant des hétéroéléments tels que Ni, Co, Cu, Mn, Cd, Mg, Ca, Zn, Fe et les métaux alcalins, en vue de leur dosage par complexométrie.

Oxydation des ions resultant de l'attaque sulfonitrique

Parmi les réactifs oxydants décrits dans la littérature, il importait de sélectionner pour l'usage proposé, ceux d'entre eux qui permettent d'obtenir *une vitesse d'oxydation élevée, dont simultanément l'excès peut être détruit sans nécessiter de chauffage, à cette fin, à une température trop élevée qui donnerait lieu à perte par volatilisation des composés chimiques porteurs de l'élément à doser, et dont, enfin, les produits de décomposition ne forment pas de composés volatils avec les éléments à doser et ne perturbent pas le dosage coulométrique ultérieur.*

---

† Dans le cas de substances organiques contenant du chrome il est nécessaire d'ajouter 5 gouttes supplémentaires d'acide sulfurique afin d'éviter la précipitation de sulfate chromique dont la dissolution ultérieure serait difficile.

Oxydation des ions porteurs du manganese en ions MnO_4^-

Nous avons essayé le bismuthate de sodium et le persulfate d'ammonium qui répondent aux précédentes caractéristiques.

Le premier réactif a été abandonné car son emploi implique, après réaction, une filtration[2] qui ne s'avère pas quantitative à l'échelle microanalytique du fait d'une rétention de permanganate dans le filtre. Par contre, le persulfate d'ammonium, en présence d'ions Ag^+, sous forme de nitrate[2,3] offre l'avantage d'être détruit par simple élévation de température à 80° avec dégagement d'oxygène. Cependant cette destruction s'accompagne de la formation de persels instables, mais électroactifs en solution, dont la nature n'a pu être déterminée et qui perturbent le dosage coulométrique en entachant les résultats analytiques d'une erreur soit positive soit négative correspondant à une quantité de manganèse de l'ordre de grandeur de 20 à 30 μg.

L'expérience nous a montré que la présence de quelques grains de magnésie ou d'alumine* en solution, lors de l'oxydation, permet de catalyser la destruction de ces persels.

Les produits de l'attaque sulfonitrique sont repris, dans chaque matras, par de l'eau distillée; la solution obtenue est ensuite transvasée dans un bécher de 100 ml, de forme haute, où les eaux de lavage quantitatif du matras, à l'eau distillée, sont également collectées. A la solution ainsi obtenue dont le volume doit être d'environ 10 ml sont ajoutés 200 à 300 mg de persulfate d'ammonium, une dizaine de milligrammes de nitrate d'argent et une pointe de microspatule de magnésie ou d'alumine granulée.

Le bécher est recouvert d'un verre de montre et la solution est portée puis maintenue à l'ébullition jusqu'à cessation complète du dégagement gazeux provoqué par la destruction du persulfate d'ammonium, ce qui requiert un temps de 20 à 30 min. La solution est alors refroidie sous un courant d'eau et transvasée quantitativement, dans le vase de titrage coulométrique (son volume total, dont les eaux de lavage du bécher, doit être de l'ordre de grandeur de 40 ml).

Oxydation des ions porteurs du chrome en ions $Cr_2O_7^{2-}$

Nous avons préféré l'acide perchlorique[4] au persulfate d'ammonium en présence d'argent pour effectuer cette oxydation, du fait de sa réaction sélective; il permet en effet d'oxyder les ions porteurs du chrome en ions $Cr_2O_7^{2-}$ sans oxyder les ions porteurs du manganèse en ions MnO_4^- et par conséquent de doser éventuellement le chrome en présence de manganèse.

En outre, l'action de l'acide perchlorique est rapide et ne nécessite pas, comme dans le cas du persulfate d'ammonium, la destruction de l'excès de réactif en vue du titrage coulométrique ultérieur.

Toutefois la présence d'ions Cl^- dans l'acide perchlorique du commerce donne lieu à la formation de chlorure de chromyle volatil avec perte de chrome; afin d'éviter cet inconvénient il suffit d'éliminer les ions Cl^- en les précipitant sous forme de chlorure d'argent par des ions Ag^+ (nitrate d'argent).

Aux produits de l'attaque sulfonitrique sont ajoutés, dans le matras, 1 ml d'acide perchlorique R. P. puis quelques cristaux de nitrate d'argent (environ 10 mg).

Le matras est alors chauffé, sur la veilleuse d'un bec Bunsen, avec précaution, afin de ne pas atteindre la température de décomposition de l'acide perchlorique se décelant par un fort dégagement gazeux, pendant 1–2 min, temps nécessaire pour l'oxydation du chrome sous forme d'ions bichromiques.

Il convient de remarquer qu'une prolongation du chauffage pendant 5 min ne donne par lieu à perte de chrome.

La solution obtenue dans le matras est alors transvasée directement, ainsi que les eaux de lavages, dans le récipient de titrage coulométrique. Le volume total de la solution doit être de l'ordre de grandeur de 40 ml.

Titrage coulométrique

Les principes des titrages coulométriques et les appareils permettant leur application ont été décrits par maints auteurs[5–12] qui mettent en oeuvre des sources variées de courant, avec régulation d'intensité et des méthodes et systèmes divers de détection de fin de titrage.

Il est aisé, par l'étude des courbes voltampéromètriques, en solution[10,11] de mettre en évidence les conditions électrochimiques dont la réalisation est requise en vue de la génération quantitative en solution, par simple électrolyse, d'un oxydant ou d'un réducteur.

Par contre, le choix de la méthode indicatrice de fin de titrage est plus délicat. En effet, la reproductibilité des résultats des dosages et la sensibilité globale de la méthode dépendent, en grande partie, de la reproductibilité et de la sensibilité de la réponse des électrodes utilisées pour la détection des espèces électroactives, en solution. La détection par ampérométrie entre électrodes bimétalliques (*cf.* Ref. 10) est à la fois fidèle et sensible sous réserve que la surface des électrodes en contact avec la solution soit inaltérable et de dimensions appropriées à la sensibilité requise, ce qui est compatible avec nos conditions opératoires; nous avons donc adopté cette méthode.

* Magnésie frittée en grains de 1 mm—Fournisseur Desmarquet—France. Alumine "ALCEL" en grains de 1 mm—Fournisseur Desmarquet—France.

Il convient cependant de remarquer qu'elle ne permet pas de déterminer le point final proprement dit d'un titrage; elle permet seulement d'arrêter ce dernier lorsqu'un paramètre de titrage, en l'occurence la concentration des ions ou du réactif titrants engendrés in situ par électrolyse, atteint une valeur déterminée et précise. Dans le présent travail il s'agit de la concentration des ions Fe^{2+}.

L'application de la méthode implique donc que soient déterminées, avant les titrages, les quantités d'électricité qui ont servi à la génération, dans les solutions à titrer, des excès d'ions Fe^{2+} correspondant aux concentrations de ces réactifs définissant les points d'arrêt de titrage. Elles doivent en effet être soustraites des quantités totales d'électricité consommées au cours des titrages coulométriques pour calculer les quantités d'électricité équivalentes aux espèces chimiques à titrer.

Ainsi, compte tenu des conditions électrochimiques à réaliser pour l'électrolyse et de celles qui sont inhérentes à la mesure finale ampérométrique, la reproductibilité des résultats des titrages dépend essentiellement des facteurs suivants:

—volume de la solution,

—concentration des acides et des sels en solution,

—agitation de la solution.

Il vient s'y ajouter la constance du courant d'électrolyse imposée par la méthode de mesure coulométrique mise en oeuvre qui est ramenée à une mesure de temps (*cf.* ci-après).

Appareillage de titrage coulométrique

L'appareillage que nous employons est semblable à celui qui a été déjà mis en oeuvre par d'autres auteurs.[11] Il comprend le coulomètre proprement dit, un détecteur de fin de titrage et une cellule électrochimique.

Coulométre. Cet instrument est un Chronoamperostat Tacussel, type CEAM D 3 qui réunit, en un seul appareil un ampèrostat et un chronomètre électronique. L'ampèrostat permet de régler (de 10^{-5} à 10^{-1} A), de choisir et de maintenir constante l'intensité i du courant d'électrolyse; le chronomètre permet de mesurer avec précision (à 0,01 sec près) le temps t de passage du courant d'intensité imposée i et par conséquent, de connaître, à chaque instant, la quantité d'électricité ($q = it$) consommée par l'électrolyse.

Détecteur de fin de titrage. Cet appareil est une Unité de détection ampérométrique Tacussel, type ALO4, qui permet d'établir une tension imposée (réglable de 0 à 1000 mV). Il comporte un ampèremètre à cadre mobile qui mesure l'intensité du courant qui passe entre les électrodes indicatrices et qui est pourvu d'un index à position réglable dans toute l'étendue de l'échelle de mesure (cadran). Le franchissement de l'index par l'aiguille de l'ampèremètre donne lieu à coupure du courant d'électrolyse par l'intermédiaire d'un relais.

Cellule èlectrochimique—(Fig. 2). La cellule électrochimique comprend essentiellement un récipient, deux électrodes d'électrolyse et deux électrodes indicatrices. Le récipient est un cylindre en verre Pyrex, à fond plat, à section carrée, d'une capacité de 50 ml dont l'orifice comporte un rodage plan sur lequel se pose un couvercle de même forme d'environ 35 mm de hauteur. Le fond du couvercle est pourvu de quatre ajutages à rodages coniques femelles qui permettent le passage de quatre électrodes et d'un courant d'un gaz inerte; il est en outre percé d'un trou de 3 mm de diamètre qui permet éventuellement l'injection d'un réactif dans la solution à titrer. Cet ensemble permet d'effectuer des réactions électrochimiques en solution en l'absence d'oxygène.

Les électrodes d'électrolyse comportent une électrode génératrice employée comme cathode (réduction des ions MnO_4^- et $Cr_2O_7^{2-}$) et une électrode auxiliaire. La premiére est constituée par une plaque de platine d'une superficie de 200 mm^2 (20 × 10 mm) soudée à un fil de platine de 0,1 mm de diamètre[4] qui plonge dans la solution à titrer; la seconde est un simple fil de platine de 1 mm de diamètre qui plonge dans une solution de l'électrolyte support utilisé au sein d'un compartiment (tube de verre Pyrex de 12 mm de diamètre porteur d'un rodage mâle s'adaptant sur un rodage femelle du couvercle de la cellule) isolé de la solution à titrer par une plaque de verre Pyrex fritté n° 4. Les deux fils de platine servent à connecter ces électrodes à l'ampérostat.

Les électrodes indicatrices sont deux fils de platine de 0,5 mm de diamètre isolés à leurs parties supérieures par des gaines de verre qui leur sont collées par chauffage. Leurs parties inférieures plongent dans la solution à titrer; l'une a la forme d'une hélice à quatre spires de 5 mm de diamètre (longueur de fil: 60 mm) tandis que l'autre, rectiligne, coïncide avec l'axe de cette hélice (longueur de fil: 10 mm). Les deux fils de platine (parties supérieures) servent à connecter les électrodes au détecteur de fin de titrage.

Titrage coulométrique des ions MnO_4^- et $Cr_2O_7^{2-}$

Les dosages des ions permanganiques et bichromiques sont basés sur le même principe. Les modes opératoires correspondants ne diffèrent que par l'intensité du courant d'électrolyse qui permet la réduction des ions Fe^{3+} en ions Fe^{2+}; elle est fixée a 10 mA dans le cas du manganèse et à 3 mA dans le cas du chrome afin que les durées d'électrolyse ne soient pas trop élevées et restent du même ordre de grandeur malgré les nombres différents d'électrons échangés par le manganèse et le chrome dans les réactions de réduction.

Determination du point final de titrage—mesure du "seuil"

L'excès d'ions Fe^{2+} qui apparaît en solution dès que tous les ions MnO_4^- et $Cr_2O_7^{2-}$ sont réduits, doit permettre de mettre en évidence le point final de titrage; afin que le titrage soit précis, il importe que la concentration des ions Fe^{2+} atteinte soit aussi faible que possible et corresponde à une quantité de manganèse ou de chrome ne dépassant pas 3–5 μg.

Par ailleurs, avec l'appareillage utilisé, l'ordre de grandeur du minimum de l'intensité du courant susceptible d'être décelé entre les deux électrodes indicatrices est de 2–3 μA.

En vue d'assurer une sensibilité suffisante du titrage coulométrique, l'étude des courbes intensités-potentiels, dans des solutions de compositions identiques à celles de nos solutions à titrer, montre qu'il est alors nécessaire d'imposer une tension de 600 mV entre les électrodes indicatrices.

Dans la pratique l'intensité du courant indicatrice du point final de titrage est fixée à 3 μA*;

---

* Dans le cas particulier du dosage de quantités de chrome correspondant à des concentrations inférieures à $10^{-5}N$, la réaction de réduction des ions $Cr_2O_7^{2-}$ par les ions Fe^{2+} n'est plus quantitative de sorte que la concentration en ions Fe^{2+} correspondant au "seuil" est atteinte avant le "point d'équivalence", ce qui conduit à l'obtention de résultats erronés par défaut. Pour pallier cet inconvénient, l'intensité de courant indicatrice de fin de titrage est alors fixée à un ordre de grandeur de 10–15 μA.

la quantité d'électricité qui est alors nécessaire lors de la simple réduction électrolytique des ions Fe^{3+} pour atteindre la concentration en ions Fe^{2+} correspondant au courant de 3 μA déclenchant l'arrêt de l'électrolyse est dénommée seuil coulométrique ou "seuil". Elle peut être exprimée en coulombs, ou plus simplement, à un coefficient près, l'intensité du courant d'électrolyse étant fixée et constante, en unités de temps (secondes).

Elle devra être retranchée de la quantité totale d'électricité consommée par la réduction quantitative des ions MnO_4^- ou $Cr_2O_7^{2-}$.

Le "seuil" est mesuré dans une solution aqueuse d'ions ferriques acidifiée et additionnée de nitrate d'argent oú plongent les électrodes. Celles-ci sont décapées par quelques gouttes d'acide nitrique ajoutées à la solution avant leur immersion. La solution est dégazée par barbotage d'un courant d'azote. Ce dégazage a pour double effet de chasser de la solution les gaz oxydants dissous, c'est à dire l'oxygène ainsi que, dans le cas du dosage du chrome, le chlore provenant de l'acide perchlorique utilisé pour l'oxydation des produits de l'attaque sulfonitriques. L'absence d'oxygène permet d'abaisser le courant résiduel à 0,5 μA* et corrélativement de déterminer la valeur du "seuil" avec une plus grande reproductibilité.

Le système des quatre électrodes est plongé dans une solution aqueuse dont le volume total est ajusté à 40 ml (à 5 ml près) et contenant 10 ml d'une solution d'acide sulfurique 4*N*, environ 10 mg de nitrate d'argent, 0,2 g de sulfate ferrique PA et 2 à 3 gouttes d'acide nitrique concentré (pour toxicologie: $d = 1,40$).

Le courant d'azote† est alors envoyé dans la solution pendant toute la durée de la détermination. Après 5 min de barbotage, l'électrolyse qui donne lieu à la réduction des ions Fe^{3+} est déclenchée et se poursuit jusqu'à son arrêt automatique. Le "seuil" est alors mesuré par le temps t_s indiqué par le coulomètre; il est de l'ordre de grandeur de 4 à 6 sec et doit être reproductible à 1 sec près; il est évidemment supérieur à cette valeur et atteint 20 à 30 sec dans le cas particulier ou l'intensité de courant indicatrice est fixée à 10–15 μA.

Titrage proprement dit

Le mode opératoire est semblable à celui qui vient d'être décrit pour la mesure du "seuil". A la solution obtenue par minéralisation du prélèvement analytique recueillie dans le vase de titrage coulométrique et dont le volume est préalablement ajusté à 40 ml à l'aide d'eau distillée, sont ajoutés 0,2 g de sulfate ferrique et 2 à 3 gouttes d'acide nitrique; le système d'électrodes est mis en place et la solution dégazée; l'électrolyse est alors déclenchée; lors de son arrêt automatique, le temps t_x mesuré par le coulomètre correspond à la quantité d'électricité consommée pour la réduction quantitative des ions MnO_4^- ou $Cr_2O_7^{2-}$.

Calcul des résultats. L'application de la loi de Faraday conduit aux formules de calcul suivantes:

$$\text{Mn}\ \% = \frac{113{,}86(t_x - t_s)}{m}$$

$$\text{Cr}\ \% = \frac{53{,}89\,(t_x - t_s)}{m}$$

dans lesquelles *m* est la masse du prélèvement analytique exprimée en microgrammes.

Elles ont été établies pour une intensité de courant d'électrolyse égale à 10 mA dans le cas du manganèse, à 3 mA dans le cas du chrome et les valeurs numériques suivantes des constantes: Faraday = 96480 C; Mn = 54,94; Cr = 52,00.

RESULTATS ET CONCLUSION

Il apparaît que les méthodes décrites pour les dosages du manganèse et du chrome, qui comportent une attaque sulfonitrique suivie d'une oxydation des ions formés et un titrage par électrolyse coulométrique à intensité constante, fournissent des résultats (Tableaux I et II) dont la précision est comparable à celle des méthodes classiques de la microanalyse organique élémentaire, caractérisée par l'ordre de grandeur des erreurs absolues.

Il est cependant certains cas extrêmes tels que celui du dosage du chrome dans le nitrure de chrome (dont la teneur élevée en élément à doser (78,79%) qui imposent d'effectuer des prélèvements analytiques décimilligrammiques, en vue de l'obtention

---

* Le courant résiduel est défini par le courant apparaissant entre les deux électrodes indicatrices plongées dans la solution en présence de toutes les espèces électroactives nécessaires au titrage, à l'exception de l'espèce oxydante ou réductrice produite électrochimiquement.

de minéralisations quantitatives), où l'ordre de grandeur de l'erreur absolue peut dépasser celui de l'erreur classique; cependant l'ordre de grandeur de l'erreur relative reste alors satisfaisant.

Dans les conditions définies dans cette étude, toutes quantités de métaux peuvent être dosées sous réserve de rester inférieures à 800 μg, masse qui définit, dans ce cas, la limite supérieure du domaine microanalytique; en ce qui concerne la limite inférieure elle peut être abaissée à un ordre de grandeur de 40–30 μg, sous réserve de définir un "seuil" de fin de titrage correspondant à une intensité de courant indicatrice voisine de 15 μA.

Par ailleurs certaines substances, figurant sur les tableaux de résultats et marqués d'un astérisque, ne sont pas analytiquement pures; elles ont été fournies par le "National Bureau of Standards" de Washington avec une teneur certifiée de l'élément à doser; cette dernière, également marquée d'un astérisque est reportée dans les tableaux au lieu de la teneur calculée; les écarts reportés sont, dans ce cas, les différences entre les teneurs trouvées et les teneurs certifiées.

Summary—Constant-current coulometric titration is applied to the determination of manganese and chromium contained in organic compounds. These compounds are decomposed in a mixture of sulphuric and nitric acids. The Mn and Cr are oxidized by ammonium persulphate to MnO_4^- and by perchloric acid to $Cr_2O_7^{2-}$ respectively. MnO_4^- and $Cr_2O_7^{2-}$ are titrated by Fe^{2+} electrolytically generated from Fe^{3+} by constant-current eletrolysis, with amperometric end-point detection,

Zusammenfassung—Mangan und Chrom in organischen Verbindungen werden mit Hilfe einer coulometrischen Titration bei konstantem Strom bestimmt. Die Verbindungen werden in einem Gemisch aus Schwefel- und Salpetersäure aufgeschlossen. Mn wird mit Ammoniumpersulfat zu MnO_4^- und Cr mit Überchlorsäure zu $Cr_2O_7^{2-}$ oxidiert. MnO_4^- und $Cr_2O_7^{2-}$ werden mit Fe^{2+} titriert, das elektrolytisch aus Fe^{3+} durch Elektrolyse bei konstantem Strom erzeugt wird. Der Endpunkt wird amperometrisch ermittelt.

(*Reçu le* 12 *juillet* 1971. *Accepté le* 23 *août* 1971)

Résumé—Une méthode de microdosage de l'arsenic, de l'antimoine et du cuivre dans les composés organométalliques est décrite. Les substances sont décomposées dans un mélange d'acides sulfurique et nitrique. Les produits de décomposition sont alors oxydés par l'eau oxygénée dans le cas de l'arsenic et par le permanganate de potassium dans le cas de l'antimoine afin d'obtenir respectivement les ions AsO_4^{3-} et SbO_4^{3-}. Dans le cas du cuivre, les ions Cu^{2+} sont obtenus directement comme produit de décomposition. L'iode engendré par l'électrolyse d'une solution aqueuse d'iodure de potassium est l'agent titrant, avec une solution de thiosulfate de sodium comme agent intermédiaire (fin de titrage ampérométrique). L'iode produit est mesuré coulométriquement.

LE CARACTÈRE réducteur des ions iodures en solution aqueuse peut être mis à profit pour le dosage de l'arsenic, de l'antimoine et du cuivre dans les composés minéraux comme l'ont montré de nombreux auteurs (*cf.* citation 1). Par ailleurs nous avons déjà mis en évidence l'intérêt de l'application des méthodes coulométriques au dosage microanalytique de certains métaux (Mn, Cr) dans les composés organiques.[2] En ce qui concerne le dosage microanalytique de l'arsenic, de l'antimoine et du cuivre dans les composés organiques, il est également possible d'appliquer les méthodes coulométriques sous forme de l'iodométrie coulométrique. Il convient alors de minéraliser les composés organiques porteurs de ces hétéroéléments en vue de l'obtention d'espèces ioniques représentatives de ces derniers et susceptibles d'être réduites par les ions I^-.

La mise en oeuvre, à cette fin, de réactions d'oxydoréduction appropriées permet, en outre, d'effectuer avec spécificité le titrage de ces éléments en présence de métaux susceptibles de se trouver simultanément présents dans les produits soumis à l'analyse.

Une attaque sulfonitrique fournit des mélanges d'ions porteurs d'arsenic et d'antimoine tri et pentavalents qui doivent être oxydés en ions arséniques AsO_4^{3-} et antimoniques SbO_4^{3-} en vue de leurs titrages. Les réactifs oxydants correspondants utilisés sont respectivement l'eau oxygénée, dans le premier cas[3] et le permanganate de potassium, dans le second.[4]

Les ions AsO_4^{3-} et SbO_4^{3-} sont réduits par des ions I^- (iodure de potassium) en milieu acide, avec formation d'iode libre; l'iode est à son tour réduit par un excès d'une solution titrée de thiosulfate de sodium et cet excès dosé par de l'iode engendré par électrolyse des ions I^- en solution; le point final de titrage qui correspond à l'apparition d'un excès d'iode libre, en solution est mis en évidence par ampérométrie. Le titre du thiosulfate employé est déterminé par l'iode électrolytique de façon identique. L'attaque sulfonitrique fournit directement les ions cuivriques Cu^{2+} qui sont titrés suivant le même principe que les ions AsO_4^{3-} et SbO_4^{3-}.

PARTIE EXPERIMENTALE

Minéralisation

L'appareillage de minéralisation est identique à celui que nous avons antérieurement decrit.[2]

Attaque sulfonitrique. Le mode opératoire d'attaque sulfonitrique des composés organiques précédemment décrit[2] (qui permet notamment de doser les métaux qu'ils contiennent par complexométrie) est directement applicable dans le cas du dosage du cuivre par iodométrie coulométrique.

Dans les cas de l'arsenic et de l'antimoine il est nécessaire d'employer des quantités supérieures d'acide sulfurique, soit 5 à 10 gouttes, afin d'éviter, surtout dans le cas de l'arsenic, la précipitation d'oxydes d'arsenic sublimables à température élevée.

Il importe en outre de noter que l'obtention de solutions parfaitement limpides contenant quantitativement l'arsenic et l'antimoine à doser peut nécessiter, parfois, trois attaques successives suivant le mode opératoire déjà cité.[2]

Oxydation des ions porteurs de l'arsenic en ions AsO_4^{3-}. Aux produits de l'attaque sulfonitrique, deux gouttes d'eau oxygénée (à 100 volumes) sont ajoutées, dans le matras. Ce dernier est alors replacé sur la rampe de minéralisation et chauffé lentement à la pression atmosphérique, jusqu'à cessation du bouillonnement dû à la décomposition de l'eau oxygénée. Les dernières traces de ce réactif doivent être détruites; à cette fin, il est nécessaire d'élever la température jusqua'à ébullition de l'acide sulfurique; cette dernière ne doit durer que quelques secondes afin d'éviter des pertes d'arsenic par volatilisation sous forme d'hémipentoxyde.

La solution obtenue dans le matras est alors transvasée dans le vase de titrage coulométrique ainsi que les eaux de lavage. Le volume total de liquide doit y être de l'ordre de grandeur de 40 ml.

Oxydation des ions porteurs de l'antimoine en ions SbO_4^{3-}. La faible quantité d'acide sulfurique utilisée lors de l'attaque sulfonitrique conduit à une précipitation d'une partie de l'antimoine sous forme d'oxydes. Les essais d'oxydation par l'eau oxygénée[5] visant simultanément la mise en solution se sont avérés infructueux; nous avons attribué cet échec au défaut de réaction de l'eau oxygénée sur le précipité antimonié. Par contre, nous avons pu effectuer quantitativement cette oxydation et la mise en solution grâce à l'emploi du permanganate de potassium.

Aux produits de l'attaque sulfonitrique sont ajoutés, dans le matras, une dizaine de gouttes d'eau distillée et 20 à 30 mg de permanganate de potassium cristallisé.

Le matras est alors replacé sur la rampe de minéralisation et chauffé lentement à la pression atmosphérique jusqu'à la température d'ébullition de l'acide sulfurique. Afin d'éliminer l'excès d'ions permanganiques et de solubiliser l'hémipentoxyde d'antimoine obtenu, 7 à 8 gouttes d'acide chlorhydrique (pur pour analyse) et quelques gouttes d'eau distillée sont ajoutées dans le matras. En vue de chasser le chlore formé par réaction de l'acide chlorhydrique sur le permanganate, le matras est à nouveau chauffé sur la rampe, à basse température, afin d'éviter les pertes d'antimoine par volatilisation du pentachlorure d'antimoine.

La solution obtenue dans le matras est alors transvasée ainsi que les eaux de lavage dans le récipient de titrage coulométrique. Le volume total du liquide doit y être de l'ordre de grandeur de 40 ml.

Titrage coulométrique

L'appareillage permettant le titrage coulométrique est identique à celui qui a été antérieurement décrit.[2] Le système oxydoréducteur qui permet de mettre en évidence la fin de titrage est, ici, le couple iode–iodure; il s'agit donc, dans ce cas, de détecter un excès d'iode dont la concentration est contrôlée par ampérométrie par l'apparition d'un courant passant entre deux électrodes de platine polarisées sous 150 mV.

Titrages coulométriques des ions AsO_4^{3-}, SbO_4^{3-} *et* Cu^{2+}. Les titrages des ions arséniques, antimoniques et cuivriques se ramènent tous à une iodométrique coulométrique. L'intensité du courant de l'électrolyse qui donne lieu à génération d'iode par oxydation des ions I^- est fixée à 3 mA. Les titrages des ions AsO_4^{3-} et SbO_4^{3-} sont effectués en milieu acidifié par l'acide chlorhydrique afin de faciliter la réaction ultérieure d'oxydoréduction. Le titrage des ions Cu^{2+} qui donne lieu à la précipitation d'iodure cuivreux est effectué en milieu acidifié par l'acide acétique et l'acide nitrique en présence de gélatine, comme d'aucuns[6] l'ont préconisé pour le dosage des ions Cl^- par argentométrie.

Par ailleurs, l'oxygène dissous dans les solutions à titrer est susceptible de fausser les dosages iodométriques du fait de l'oxydation facile des ions I^- en milieu acide. Afin d'éviter cette cause d'erreur les solutions sont désoxygénées avant l'addition d'iodure du potassium par barbotage d'un courant d'azote pendant un temps suffisant. L'expérience montre que ce dégazage permet d'abaisser suffisamment la concentration de l'oxygène dissous pour éliminer toute perturbation du titrage iodométrique.

Determination du point final de titrage—mesure du seuil

Le titrage électrochimique consiste à mesurer, à l'aide d'iode engendré par électrolyse coulométrique d'iodure de potassium (oxydation anodique des ions I^-), l'excès de thiosulfate introduit dans la solution à titrer après la libération d'iode par oxydation antérieure des ions I^- (iodure de potassium) par les ions AsO_4^{3-}, SbO_4^{3-} ou Cu^{2+}. L'excès d'iode libéré qui apparaît en solution dès que tous les ions $S_2O_3^{2-}$ sont réduits doit permettre de mettre en évidence le point final du titrage de l'excès de thiosulfate.

En vue d'assurer une sensibilité suffisante du titrage coulométrique, l'étude des courbes intensités-potentiels montre qu'avec l'appareil de détection utilisé[2] il est nécessaire, dans le cas du système iode-iodure et dans les conditions du titrage, d'imposer une tension de 150 mV entre les électrodes indicatrices.

Dans la pratique, l'intensité de courant indicatrice du point final de titrage est fixée à 3 à 4 μA; la quantité d'électricité qui est alors nécessaire, lors de la simple oxydation électrolytique d'ions I^-, pour atteindre la concentration en iode libre correspondant au courant de 3-4 μA déclenchant l'arrêt de l'électrolyse est le "seuil". Elle est exprimée en unités de temps puisque l'intensité du courant d'électrolyse est fixée et constante; son ordre de grandeur correspond à 5 à 6 μg d'arsenic et 9 à 10 μg d'antimoine ou de cuivre. Elle est retranchée de la quantité d'électricité consommée par l'oxydation quantitative de l'excès d'ions $S_2O_3^{2-}$.

Le système des quatre électrodes est plongé dans une solution dont le volume total est ajusté à 40 ml (à 3 à 4 ml près). Dans le cas des dosages de l'arsenic et de l'antimoine cette solution aqueuse contient un mélange de 10 ml d'une solution d'acide chlorohydrique 4N et de 10 ml d'une solution d'acide sulfurique 4N; dans le cas du dosage du cuivre elle est constituée par un mélange d'acide acétique (pur P. A.) et d'acide nitrique (pur pour toxicologie; $d = 1{,}4$),[6] dans un rapport volumique de 10/1, auquel sont ajoutés 5 g de gélatine par litre de solution.* Le courant d'azote est alors envoyé dans la solution où il barbote pendant 5 min; il est ensuite maintenu au dessus de la solution à titrer à laquelle est ajouté 1 g d'iodure de potassium. L'électrolyse qui donne lieu a l'oxydation des ions I^- est déclenchée et se poursuit jusqu'à son arrêt automatique. Le "seuil" est alors mesuré par le temps t_S indiqué par le coulomètre; il est de l'ordre de grandeur de 4 à 5 sec et doit être reproductible à moins d'une seconde près.

Determination du titre de la solution de thiosulfate de sodium

Suivant la pratique classique, les solutions de thiosulfate de sodium sont préparées un mois avant leur emploi à la concentration 10^{-1} N, et stabilisées par addition de carbonate de sodium.[5] Elles sont diluées à la concentration 10^{-2} N au moment de leur emploi par volumes de 1 litre.

Avant tous les dosages il est nécessaire de déterminer, par coulométrie, le titre exact de la solution de thiosulfate ainsi préparée. A cette fin, dans une solution venant de servir à la détermination du "seuil" et contenant donc la quantité d'iode correspondant au point final de titrage, il est ajouté 1 ml de la solution de thiosulfate à titrer, le courant d'azote étant maintenu au dessus de la solution. L'électrolyse se déclenche alors automatiquement.

Le temps t_N d'électrolyse sous intensité de courant de 3 mA, mesuré lors de l'arrêt automatique de celle-ci, correspond à la quantité d'électricité nécessaire à l'oxydation par l'iode électrolytique de la quantité de thiosulfate introduite; il est la mesure du titre électrochimique du thiosulfate. Si le titre du thiosulfate était exactement 10^{-2} N, ce temps devrait être égal à 321,6 sec; le temps réel doit être l'objet de 3 ou 4 déterminations et l'écart maximal des valeurs obtenues ne doit pas dépasser 1 seconde; le temps moyen est adopté comme titre électrochimique du thiosulfate.

Titrage proprement dit

La mode opératoire est semblable à celui qui vient d'être décrit pour la mesure du "seuil" et du titre du thiosulfate. Les solutions d'ions AsO_4^{3-} ou SbO_4^{3-} ont été transvasées dans le récipient de titrage coulométrique après le traitement oxydant (voir minéralisation). Dans le cas du dosage du cuivre la solution d'attaque sulfonitrique a été directement transvasée dans ce récipient ainsi que les eaux de lavage (à l'eau distillée) du matras.

Le volume de chacune de ces solutions a été ajusté à 40 ml (à 3 à 4 ml près) dans le récipient de titrage. La solution est alors dégazée par barbotage d'azote, pendant 5 min comme précédemment et 1 g d'iodure de potassium cristallisé lui est alors ajouté tandis que le courant d'azote est maintenu au dessus de la solution.

L'iode libéré est ensuite réduit par addition de la solution de thiosulfate de sodium précédemment titrée. Cette opération est effectuée manuellement ou automatiquement grâce à l'emploi d'une électroburette Tacussel commandée par le détecteur ampèrométrique de fin de titrage; l'introduction

---

* L'addition de sulfocyanure de potassium[7] (concentration de 10^{-2} M) à l'électrolyte permet de doser des quantités de cuivre de l'ordre de grandeur de 50 μg, grâce au faible produit de solubilité du sulfocyanure cuivreux qui est inférieur à celui de l'iodure cuivreux.

† Azote de qualité "R" fourni par la Société "L'Air liquide".

de la solution de thiosulfate est arrêtée dès que la concentration de l'iode en solution devient inférieure à celle qui correspond au "point final de titrage".

Après 10 min d'attente, temps nécessaire à la réaction des ions I^- sur les ions réductibles, l'électrolyse est déclenchée et s'arrête automatiquement au bout d'un temps t_x.

Calcul des résultats. L'application de la loi de Faraday conduit aux formules de calcul suivantes:

$$\text{As}\ \% = \frac{116{,}4[Vt_N - (t_x - t_B)]}{m}$$

$$\text{Sb}\ \% = \frac{189{,}25\ [Vt_N - (t_x - t_B)]}{m}$$

$$\text{Cu}\ \% = \frac{197{,}5\ [Vt_N - (t_x - t_B)]}{m}$$

dans lesquelles V est le volume de la solution de thiosulfate de sodium exprimé en ml, ajouté dans la solution à titrer et m est la masse du prélèvement analytique exprimé en microgrammes.

Elles ont été établies pour une intensité du courant d'électrolyse égale à 3 mA et les valeurs numériques suivantes des constantes Faraday = 96480C; As = 74,92; Sb = 121,7; Cu = 63,54.

RESULTATS ET CONCLUSIONS

Les méthodes coulométriques appliquées aux dosages microanalytiques de l'arsenic, de l'antimoine et du cuivre dans les substances organiques permettent de déterminer les teneurs centésimales de ces métaux avec la precision classique de la microanalyse organique élémentaire comme le montrent les tableaux I, II, et III.

* Teneur certifiée de la substance fournie par le National Bureau Standard.

Les conditions opératoires décrites dans cette étude montrent qu'il est possible de doser avec la même précision chacun des éléments considérés pour des quantités comprises entre 3000 et 400 μg.

Facilement mises en oeuvre, ces méthodes coulométriques alliées éventuellement à d'autres méthodes analytiques s'avèrent des plus appropiées à la résolution de problèmes toujours plus complexes qui sont posés aux microanalystes.

Summary—A method is described for the microanalytical determination of arsenic, antimony and copper in organic compounds. These compounds are decomposed in a mixture of sulphuric and nitric acids. The decomposition products are then oxidized by hydrogen peroxide in the case of arsenic and by potassium permanganate in the case of antimony in order to obtain AsO_4^{3-} or SbO_4^{3-} ions respectively. In the case of copper, Cu^{2+} ions are obtained directly as a decomposition product. Iodine generated by constant-current electrolysis of potassium iodide contained in the solution is the titrating reagent, with sodium thiosulphate solution as intermediate reagent, and amperometric end-point detection. The iodine consumption is measured coulometrically.

Zusammenfassung—Ein Verfahren zur mikroanalytischen Bestimmung von Arsen, Antimon und Kupfer in organischen Verbindungen wird beschrieben. Die Verbindungen werden in einem Gemisch aus Schwefel- und Salpetersäure aufgeschlossen. Die Aufschlußprodukte werden im Falle von Arsen mit Wasserstoffperoxid, im Falle von Antimon mit Kaliumpermanganat zu AsO_4^{3-} bzw. SbO_4^{3-} oxidiert. Cu^{2+}-Ionen werden direkt als Aufschlußprodukt erhalten. Als Titrationsmittel dient Jod, das durch Elektrolyse bei konstantem Strom aus in der Lösung enthaltenem Kaliumjodid erzeugt wird, als Zwischenreagens Natriumthiosulfat; der Endpunkt wird amperometrisch ermittelt. Der Jodverbrauch wird coulometrisch gemessen.

Summary—A review is given of the methods that have been proposed for enrichment of trace elements in samples that are to be analysed by neutron-activation methods. The emphasis is on classification of methods, with full illustrations by means of practical examples.

THE RECENT CONCERN over metal pollutants in the environment has resulted in increased efforts to develop satisfactory analytical procedures for determining trace metals in natural systems. The fact that many metals are found at low concentration levels in biological or other natural systems has imposed serious limitations on the analytical techniques that can be applied to direct determination of these trace metals.

Neutron-activation analysis (NAA), because of its inherent sensitivity, has become a prime technique for trace analysis.[1] The sensitivity of this technique for a number of elements is 1 part per milliard (ppM)[2,3] and under ideal conditions can be as low as one part in 10^{12}.[4] Despite this great sensitivity, the necessary procedures for using NAA for trace metal analysis will, in many cases, limit the actual concentration levels that can accurately be determined.

A good example of this is the use of NAA to determine metal ion concentrations in blood or sea-water samples where the metal species may be present in concentrations of 10^{-6}–$10^{-12}M$.[5,6] Since the metal or metals of interest are at such low concentrations, it is necessary to irradiate a large volume of sample in order to achieve a sufficient count rate. The bulk matrix, however, may absorb neutrons and thereby shield the trace elements of interest from activation.[7] Furthermore, the matrix itself may become highly radioactive and obscure the activity of the trace metals present. This latter fact is especially true for sea-water and biological samples in which large amounts of ^{24}Na are produced on irradiation. These various factors combine to reduce the sensitivity of NAA for trace metals in such systems.

One solution to such problems is to separate and isolate trace metals from the bulk matrix after irradiation. "Hot" chemical separation is a technique commonly employed to allow the determination of a metal when other interfering radionuclides may be present after irradiation.[6] While such a technique might be useful, there are significant difficulties associated with its use. Special facilities and equipment are required to handle radioactive samples for separation procedures. In the case of short-lived nuclides, the time required for chemical separation may be of such a length as to completely preclude the use of this technique.

An alternative procedure which has been effectively employed is to separate and

---

* Present address: BASF-Wyandotte Chemicals Corp., Wyandotte, Michigan 48192.

concentrate the desired species from the bulk matrix before irradiation. The problems of handling "hot" solutions are eliminated and the concentrated sample can more conveniently be determined by NAA. However, great care is necessary to avoid introducing impurities (at the level contained by the sample or even more) from reagents, etc, during the preconcentration procedure. Such preconcentration methods have been both widely and successfully used and are reviewed here.

Taylor[8] has discussed in detail several methods of preconcentration used in conjunction with NAA to analyse for trace elements in blood, cerebrospinal fluid and urine. Among the methods discussed were column chromatography, electrophoresis and ultracentrifugation. Joyner *et al.*[9] published a review and an evaluation of preconcentration methods used with a number of analytical techniques for the determination of trace metals in sea-water. These previous reviews have presented only a few examples of the application of preconcentration techniques to NAA. This paper is intended as a general review of the subject without including references cited in the reviews mentioned above.

CHROMATOGRAPHIC METHODS

Chromatographic methods are ideally suited for preconcentration and offer the added advantage of being able to isolate the concentrated species as pure components. The following describes the various chromatographic techniques that have been applied to the preconcentrating of species for determination by NAA.

Ion-exchange chromatography

Ion-exchange chromatography has been used extensively both alone and in conjunction with other techniques to concentrate and separate elements for NAA. In the biomedical field it has been used to determine protein-bound iodine in human blood and plasma. The usual technique involves passing the sample through an anion-exchanging resin[10] to remove inorganic iodide or through a mixed-bed resin[11] to remove iodide and non-protein-bound electrolytes. The effluent containing the protein-bound iodide is then irradiated and analysed. Hamada and co-workers[12] varied this procedure slightly by oxidizing the effluent with chromic acid and distilling the iodine produced into a potassium hydroxide solution. This solution was evaporated to dryness and the residue irradiated.

Total organic iodine,[13] free thyroxine[14] and total thyroxine[15] in human serum have been determined after separation by ion-exchange. Zaichik *et al.*[16] have designed a scheme for the determination of free iodide, and hormonal and non-hormonal iodide in blood serum. Free iodide is removed from the sample with Dowex-1 and eluted (A). Organic iodide is sorbed on Dowex 50. Non-hormonal iodide can be eluted from the resin with water (B) and hormonal iodide eluted with a buffer at pH 2 (C). Samples A, B and C are then lyophilized and irradiated.

Inorganic iodide has been separated from urine on an anion-exchanging resin.[17,18] In one example, the iodide can be selectively eluted for irradiation.[17] In another, after the elution of bromide and chloride ions, the resin is dried and irradiated directly.[18] Direct irradiation of the resin has also been applied to determine inorganic fluoride in urine.[19]

In another biochemical application,[20] selenocystathionine was extracted from nuts. The extract was passed through a Dowex-1 column and the fractions irradiated for determination.

Ion-exchange has been particularly useful in preconcentrating elements from natural water systems since essentially unlimited volumes can be passed through a column to obtain the desired sensitivity. Examples are given below.

Rubidium and caesium concentrations in the North Atlantic[21] and vanadium in the Colorado River[22] and in other natural water systems[23] have been determined by concentrating the elements on cation-exchanging resin. After elution from the column the sample is evaporated and irradiated. A similar technique has been used to determine silver ion present in samples of the rain water produced by cloud seeding with silver iodide.[24] A sensitivity of 10^{-10} g is reported. ^{230}Th and ^{232}Th have also been determined in natural water systems.[25] After cation-exchange concentration and elution with EDTA, the thorium is co-precipitated with titanium hydroxide for irradiation.

An anion-exchanging resin can be used for preconcentration of elements which form anionic complexes. Rhenium (as perrhenate ion) in sea-water,[26] and molybdenum and manganese present in solution as the molybdate and permanganate ions[27] have been determined by this method after elution from the column. Chromate ion in the ppM range in water[28] and mercury present in urine[29] have also been preconcentrated on anion-exchanging resin. In both cases the resin was irradiated directly without elution.

Similarly ion-exchanging membranes have been used as a preconcentration matrix for cations in aqueous solutions.[30–32] The procedure is to stir pieces of membrane in the solution, allowing sufficient time to reach equilibrium or to obtain sufficient metal concentration in the membrane for analysis. The membranes are then dried and irradiated. Green *et al.*[33] were able to determine ppM quantities of gold by using paper loaded with 50% Ionac SRXL resin (a resin specific for gold and the platinum group metals).

Paper chromatography

The technique of paper chromatography has also been widely used as a means of preconcentration. It offers an advantage in that the paper chromatogram containing the isolated species can itself be irradiated without further preparatory steps. This method has been notably successful in determining organic and biologically-related compounds.

While first row elements, such as hydrogen, carbon, oxygen, or nitrogen are not suitable for NAA, many of the organic and biologically related compounds contain elements such as sulphur, phosphorus, chlorine, or bromine that can be activated, and therefore be determined by NAA.

By this method phospholipids have been determined in human blood serum and spermatozoa,[34] in liver bile,[35] and in liver biopsy specimens and plasma.[36] Phospholipids have also been separated on paper and determined by NAA after extraction from cerebrospinal fluid and concentration on a silic acid column.[37] Strickland and Benson[38] were able to determine phosphatides after extracting them from cell fractions, converting them into phosphate diesters and separating them on paper. Phosphoryl peptides in protein[39] and mono- and oligonucleotides in calf thymus DNA and MS2-RNA have been determined after electrophoretic paper chromatography separation.[40] The purity of phosphate nutrient solutions for botanical use have even been determined with use of a paper chromatography preconcentration step.[41]

Schmeiser and Jerchel[42,43] have determined biologically-related compounds containing sulphur, chlorine, bromine and phosphorus. Skinner *et al.*[44] have determined chlorine- and bromine-containing drugs after separation and preconcentration by paper chromatography. Iodostyrine[45] and other iodo-compounds[46] in blood serum have been separated and determined. Certain organobromine compounds have been found in deproteinized spinal fluid.[47] Bromine analogues of DDT have also been separated for analysis.[48,49] Iodine and iodine compounds,[50] including isomers of di-iodobenzoles,[51] have been separated from aqueous solutions and determined by NAA.

If the compound to be determined does not contain an element suitable for activation, derivatives can be prepared which will contain a suitable nuclide. Steim and Benson[52] prepared bromine derivatives of amino-acids, carboxylic acids, keto-acids and sugars for paper chromatographic separation and irradiation. Unsaturated fatty acids in the form of mercury complexes have also been separated and determined by these authors.[52]

Metal ions and metal-containing compounds have also been isolated for analysis by paper chromatography. Cobalt and vanadium were determined on paper chromatograms after tissue samples were ashed, dissolved and chromatographed before NAA.[34] After homogenization and deproteinization of serum, muscle and liver tissue, selenomethionine was separated from other components and determined.[53] Sodium, uranium and the lanthanide elements have been separated by ascending paper chromatography on Whatman No. 1 filter paper with mixtures of alcohol and nitric acid to develop the chromatogram.[54,55] The chromatogram strips were irradiated for analysis.

Zinc[56] and magnesium[57,58] present in aqueous solutions were determined by NAA after chromatographic preconcentration. These metal ions were extracted from aqueous solutions into chloroform by complexation with 5,7-dibromo-8-hydroxyquinoline. The metal complexes were separated from excess of chelating agent by paper chromatography. Though zinc could be determined from the activity of the ^{65}Zn produced on irradiation, magnesium, having a low abundance of the isotope that can be activated and a low thermal neutron cross-section (^{26}Mg $= 11\%$, $\sigma = 0{\cdot}03$ barn),[59] could not be determined from ^{27}Mg. This difficulty was obviated by determining the activity of ^{82}Br produced (^{81}Br $= 50\%$, $\sigma = 3{\cdot}0$ barn)[59] when the magnesium complex was irradiated and hence indirectly the amount of magnesium present.

Miscellaneous chromatographic methods

Other chromatographic methods of preconcentration have also been applied to NAA. Column chromatography has been used to separate chlorine- and bromine-containing drugs[44] and to collect phospholipids extracted from cerebrospinal fluid.[37] Thin-layer chromatography has been used to separate mercurous and mercuric ions from other cations.[60] Following this, a section of the substrate containing these mercury species was taken for NAA.

Protein-bound elements have been separated from other materials present in blood serum by gel permeation chromatography. Fritze and Robertson[61] have determined a large number of protein-bound metals by freeze-drying the protein fraction of the eluate, irradiating and then either determining the activity directly or after a radiochemical separation. Protein-bound copper[62] and iodine[63] have also been preconcentrated for NAA by using gel permeation chromatography.

EXTRACTION METHODS

Solvent extraction has often been used as a means of preconcentration. Vanadium in blood samples[64,65] has been determined by extracting with 8-hydroquinoline, evaporating the solvent and irradiating the residue for analysis. Thenoyltrifluoroacetone has been used to extract calcium, copper, magnesium and manganese from serum[66] into a tetrahydrofuran/benzene solution. NAA of these metals was performed after re-extracting the metals into a small volume of nitric acid and irradiating. Selenium in biological materials[67] was isolated for analysis by first drying the sample and then oxidizing it with nitric acid and hydrogen peroxide and finally extracting the selenium with 8-mercaptoquinoline.

The use of solvent extraction in conjunction with other techniques for preconcentration has also been cited in the literature. As an initial step, before further fractionation, solvent extraction has been used to separate phospholipids from cerebrospinal fluid[37] and phosphatides from cell functions.[38] A determination of selenocystathionine in nuts[20] was obtained after an initial extraction followed by fractionation on an ion-exchange resin and irradiation.

Solvent extraction has proved to be useful in isolating metals from sea-water or aqueous solutions after chelation of the metal. Using sea-water samples, extractions have been made of copper, manganese and zinc with diethyldithiocarbamate into chloroform,[68,69] uranium with tri-n-octylphosphine oxide into cyclohexane[70] and vanadium with α-benzoinoxime into benzene.[71] In each case the solvent was evaporated and the residue irradiated for analysis. Zinc[56] and magnesium[57,58] were extracted from aqueous solutions into chloroform as the 5,7-dibromo-8-hydroxyquinolinates and separated from excess of chelating agent and solvent by paper chromatography before irradiation. In a similar application, a mercury dithizone complex was extracted into chloroform and the solution evaporated on plastic film which was irradiated directly.[72] This method appears to have the added advantage of preventing mercury volatilization losses since mercury tends to react with unsaturated bonds in the plastic film.[73]

Extraction methods can also be employed to remove impurities or interfering nuclides before determination. Uranium, for example, has been removed from solutions by complexing with tributyl phosphate and extracting. This allowed trace amounts of copper, cobalt and manganese in the original solution to be determined.[74]

PRECIPITATION METHODS

Both precipitation and co-precipitation have been used to remove trace elements from bulk solution. When irradiating a precipitate directly, it is necessary that neither the precipitating agent nor the co-precipitant contain nuclides with an activity which would interfere in the determination. A common procedure to circumvent this problem is the separation of the element of interest from the precipitate and its conversion into a form more suitable for analysis.

Rona *et al.*[75] coprecipitated manganese and zinc from sea-water with hydrous ferric oxide. After dissolution of the separated precipitate with hydrochloric acid, iron as the trichloride was removed from the solution by extracting with isopropyl ether. The aqueous phase was evaporated to dryness and the residue then irradiated and analysed. A similar procedure has been employed in the determination of ruthenium in sea-water.[76] After precipitation and extraction of the iron from the dissolved precipitate as described above, the hydrochloric acid solution is evaporated. The residue is redissolved in a potassium permanganate–sulphuric acid solution and from it ruthenium oxide is distilled into hydrochloric acid for subsequent irradiation and determination. The lanthanide elements have also been co-precipitated with hydrous ferric oxide.[77–80] After dissolution of the precipitate in hydrochloric acid and extraction of the iron, uranium and thorium are removed by anion-exchange and the eluate is evaporated for irradiation.

In a few instances it has been possible to irradiate the ferric hydroxide precipitates directly in order to determine co-precipitated metals without removal of the iron. This method has been applied to determine tantalum in sea-water,[81] thorium in mineral springs and Japanese coastal waters,[82] and indium in rain water.[83]

Calcium oxalate has been employed as a co-precipitant and used to precipitate barium and strontium from urine,[84] strontium from sea-water,[85] and several rare-earth elements from hot spring water.[86] After separation and drying, the precipitate was irradiated directly.

A number of instances have been reported of precipitating metal ions with an appropriate anion of a soluble salt. Cobalt, zinc and uranium in sea-water have been precipitated in this manner with disodium phosphate.[87] The precipitate was then dissolved in acid and passed through cation- and anion-exchanging columns to separate the metals for irradiation and NAA. Thorium in urine has been determined by adding ammonia solution to an acidified urine sample and irradiating the resultant precipitate.[88] By a precipitation method, uranium in milk has been determined to one part in 10^{12}.[89] The procedure entailed drying and ashing the milk, dissolving the residue in hydrochloric acid and precipitating the uranium with sodium ferrocyanide.

An unusual determination of ^{18}O in water has been accomplished by converting the oxygen into carbon dioxide and thence into solid ammonium carbonate which is irradiated.[90] With suitable modification, this method could be applied to the determination of tagged organic or biological materials in aqueous solutions.

DRYING AND ASHING METHODS

Perhaps the simplest methods of concentration are evaporation or freeze-drying of an aqueous sample and ashing of a solid sample. Evaporation and freeze-drying have been applied to the analyses of lake water,[91,92] sea-water,[93,94] mineral spring water[95] and Rhine river water.[96] Aluminium in reactor cooling water[97] and manganese in nitric and hydrochloric acids[98] have been determined by irradiating the residue after evaporation. Sodium and phosphorus have been determined in cervical mucus which has been dried and ashed.[99] Similar analyses have been reported for vanadium, arsenic, molybdenum, tungsten, rhenium and gold in dried marine organisms[100,101] and for gold in wine.[102]

Simple freeze-drying has been utilized to reduce sample size and to prevent the radiolysis of water present in a sample. Such a procedure facilitated the determination of selenium in eye lenses,[103] egg yolks[104] and sera and plasma,[105] of cadmium in biological tissue[106] and of bromine, chlorine, radium, mercury, chromium, phosphorus, rubidium, iron, cobalt and zinc in blood.[107] Freeze-drying has also been used as a final preconcentration step before irradiation of effluents from gel permeation[61] and ion-exchange chromatography[16] as cited above.

The methods of drying and ashing have certain disadvantages associated with their use. A sample, for example, may contain a species of interest that will volatilize during the drying or ashing process. A case in point is the determination of mercury and its compounds.[93] A recent paper,[72] however, reported a way to circumvent this problem. The procedure entailed the freeze-drying of an aqueous sample in a flask lined with a plastic film. The film itself was a convenient matrix for sample irradiation and good recovery of the mercury was reported as a result of the reaction of mercuric ion with unsaturated bonds present in the plastic film. Other problems associated with drying and ashing methods are cited in a paper describing the determination of several elements in sea-water.[93] Poor results were attributed to a combination of adsorption on storage container walls, interference from sodium and chloride gamma-spectra, and too rapid decay of short-lived nuclides.

ELECTROCHEMICAL METHODS

Electro-deposition is a very convenient way to concentrate trace metals for analysis. It offers the advantage of yielding a chemically and physically inert sample on a relatively small surface area that is suitable for analysis. Lux[108,109] initiated the idea of electrochemical preconcentration by the electrodeposition of silver on a rotating platinum disc electrode from a solution which also contained large amounts of cadmium. The deposited silver was irradiated and dissolved in *aqua regia* and a gamma-spectrum of the solution was taken. Direct counting of the silver film on the platinum electrode was not feasible, owing to the high background activity of the platinum itself. A relatively high background activity was also noted for the dissolved sample, owing to dissolution of some of the active platinum.

The problems associated with the use of a platinum substrate in NAA can be eliminated by choosing an electrode material that will not give rise to large interfering activity on irradiation. Such an approach was taken by Sion *et al.*[29] who determined mercury in aqueous solutions by electro-depositing it on aluminium wire. Since aluminium has a very short half-life, the electrode and deposited film could be irradiated directly and after approximately 30 min the mercury activity could be counted without background interference.

Pyrolytic graphite has also been used as an electrode material. Since pyrolytic graphite is totally carbon, it is not activated to yield a gamma-emitting isotope,[59] and since it can be obtained in a very pure form,[110] this substrate produces a very low background activity without any post-irradiation waiting period. Thus, counting can begin immediately after irradiation and even short-lived nuclides can be determined on this substrate. Several accounts of the application of this material to NAA have been published.[6,30–32,111–115]

MISCELLANEOUS METHODS

Other preconcentration techniques have also been reported. Sion *et al.*[29] have amalgamated mercury present in aqueous solutions on aluminium powder by stirring the powder in contact with the solution for several hours. After equilibrium has been achieved, the powder is filtered, dried and irradiated. After a brief waiting period, the activity of the aluminium declines and the mercury activity can be counted.

Total blood iodine[116] and protein bound iodine in serum[12] have been determined by NAA after oxidation of the sample and distillation from phosphoric acid solutions.

In biological materials the greatest potential interference for the NAA determination of trace metals is the presence of large amounts of sodium, potassium, chloride and bromide ions in the sample. These ions can be removed to an appreciable extent by dialysis of the sample. While heavy metals are usually complexed in biological materials, the uncomplexed interfering ions diffuse through the dialysis membrane, leaving the organically-bound heavy metals in the sample, which can then be irradiated. This technique has been used in the determination of manganese and copper in blood serum and cerebrospinal fluid,[117] protein-bound selenium in blood,[118] and brominated protein in serum.[119] Human serum has been dialysed before ion-exchange separation and irradiation for the determination of free thyroxine.[14]

Zusammenfassung—Es wird eine Übersicht über die Methoden gegeben, die zur Anreicherung von Spurenelementen in Proben für die Neutronenaktivierungsanalyse vorgeschlagen wurden. Der Nachdruck liegt auf der Klassifizierung der Methoden; praktische Beispiele dienen zur Illustration.

Résumé—On présente une revue des méthodes qui ont été proposées pour l'enrichissement d'éléments à l'état de traces dans des échantillons qui doivent être analysés par les méthodes par activation de neutrons. On insiste sur la classification des méthodes, avec illustrations complètes au moyen d'exemples pratiques.

(*Eingegangen am* 16. *April* 1971. *Angenommen am* 13. *September* 1971)

Zusammenfassung—Es wird ein neues Konzentrierungsverfahren für Elemente vor deren Spektralanalyse vorgeschlagen. Das Verfahren verkürzt wesentlich die Analysendauer und erhöht die Empfindlichkeit und Genauigkeit der Bestimmungen. Dem neuen Verfahren liegt die Eigenschaft des Diantipyrylmethans als Extraktionsmittel zugrunde, eine Entmischung des organischen Lösungsmittels in zwei Phasen während der Extraktion zu bewirken. In einer der Phasen, der sogenannten "dritten Phase", werden die zu extrahierenden Elemente bis auf 95–98% konzentriert. Das kleine Volumen der "dritten Phase" gestattet es, diese sofort auf die Elektroden zu bringen und dadurch solche langwierigen Operationen wie Verdampfung, Veraschen der Extrakte und Auffüllen der Elektroden vor der Spektralbestimmung zu vermeiden. Es sind spektralchemische Analysenmethoden mit genügender Selektivität und Empfindlichkeit für die Bestimmung von Hg, Sc, Sn, Cd, Bi, Zr, Hf ausgearbeitet worden (Nachweisgrenze 0,5–3 μg). Es wurde gezeigt, wie aussichtsreich das besagte Verfahren für die Konzentrierung von Mikromengen der Beimischungselemente bei der Analyse von Reinststoffen ist.

EINE HÖHERE EMPFINDLICHKEIT der Methoden der Spektralanalyse wird vor allem durch die Ausarbeitung von spektralchemischen Analysenmethoden erreicht, die die geringen Gehalte an Beimischungen von den Hauptbestandteilen durch Extraktion, Abscheidung auf einem Kollektor, Destillation u.a. abtrennen. Auf diese Weise wird der Gehalt der Beimischungselemente in den Konzentraten um einige Ordnungen erhöht.

Chemische Spektralanalysenmethoden besitzen aber einige Nachteile. Vor der Spektralanalyse wird das Konzentrat, z.B. das Extrakt, einer langwierigen Behandlung unterworfen, die aus Verdampfung, Veraschung, Verdünnung mit Graphit und Auffüllung der Elektroden besteht.

Eine wesentliche Vereinfachung und Beschleunigung der Analyse, eine höhere Genauigkeit und Empfindlichkeit der spektralanalytischen Bestimmungen wird durch Konzentrieren der Elemente mit Hilfe der Dreiphasensysteme der Extraktion ermöglicht.[1]

Solche Vorgänge wie die Entmischung der organischen Schicht und die Bildung von drei Phasen (zwei organische und eine wässerige) wurden bei der Extraktion der Elemente durch Diantipyrylmethan (DAM) und seine Homologen beobachtet. In einer der organischen Phasen, der sogenannten "dritten Phase," deren Volumen kaum einige Tropfen beträgt, werden die extraktionsfähigen Elemente praktisch vollständig (bis auf 95–98%) konzentriert. Für das Elementkonzentrat als dritte Phase sind keine langwierigen Operationen wie Trocknung und Veraschung nötig. Es kann unmittelbar auf die Elektroden gebracht werden. Dadurch wird die

Analysendauer wesentlich (2 bis 3 mal) verkürzt und die Genauigkeit sowie die Reproduzierbarkeit der Resultate erhöht.

Gegenwärtig wird DAM bereits für die Trennung und Bestimmung von über 30 Elementen des Periodischen Systems benutzt.[2–5] Trotz seiner allgemeinen Anwendbarkeit sind mit seiner Hilfe einige hoch selektive Verfahren für die Trennung der Elemente ausgearbeitet worden. So lassen sich damit, z.B., Zn–Cd, Sc–Seltene Erden, Se–Te, Sb–Bi, Co–Ni, Ga–In sehr leicht voneinander trennen.

Dieses Verfahren ermöglicht in der Spektralanalyse eine leichte und rasche Konzentrierung eines oder mehrerer der in Spuren vorhandenen Elemente, wenn als Hauptbestandteil ein analoges oder beliebig andere Elemente vorhanden sind, die unter den gegebenen Analysenbedingungen nicht mit dem DAM reagieren.

In manchen Fällen gestattet das DAM, große Gruppen von Elementen gleichzeitig zu konzentrieren, was sehr bequem ist, wenn Reinststoffe auf fremde Zusätze geprüft werden müssen. So lassen sich aus sauren Lösungen in Gegenwart von Rhoda-nid ionen über 20 Elemente (Fe, Cu, Co, Zn, Mo, W, Sn, Ti, Zr, Hf, Th, U, Ge, Sb, Bi, Ga, In, Hg, Nb, Se u.a.) gleichzeitig ausscheiden. Wenn also nur das Rhodanidsystem verwendet wird, kann man bereits die ganze Summe der genannten Elemente aus den zu prüfenden Objekten ausscheiden, die als Hauptbestandteile Magnesium, Aluminium, Chrom und andere Elemente anthalten, die sich mit DAM nicht extrahieren lassen.

In der vorliegenden Übersicht sind die Ergebnisse der unter Anwendung verschiedener Extraktionssysteme durchgeführten Bestimmungen der Elemente angegeben. Diese Beispiele zeigen, welch große Aussichten sich bei der Anwendung der Dreiphasensysteme für Konzentrierung und nachfolgende spektralanalytische Bestimmung geringer Mengen der Elemente ergeben. Besonders aussichtsreich sind diese Systeme bei der Analyse von Reinststoffen und Halbleitern.

RHODANIDSYSTEM

Bestimmung von Quecksilber, Scandium und Zinn

Die Gesetzmäßigkeiten der Extraktion von in Komplexen gebundenen Elementen mit Hilfe von DAM in dem Rhodanidsystem ist ausführlich beschrieben.[6–8] Nach ihrer Fähigkeit, extrahiert zu werden, sind die Elemente in eine bestimmte Reihenfolge, der "Rhodanidreihe," (d.H. nach der Abnahme deren Extrahierbarkeit) angeordnet, und zwar: Sn $>$ Zn $>$ Co $>$ Mo $>$ W $>$ Ga $>$ Fe $>$ In $>$ (Hf, Zr, Th, Ti, Hg, U, Sb, Bi) $>$ Sc $>$ V $>$ Cd $>$ Mn $>$ Be. In Klammern sind jene Elemente angegeben, deren gegenseitige Einordnung einige Schwierigkeiten bereitet, wegen eines starken und dabei nicht einheitlichen Einflusses der Rhodanidionenkonzentration, sowie der gewählten Arbeitsbedingungen auf die Vollständigkeit der Extraktion der Elemente.

Der Übergang von einem Zwei-Phasensystem zu einem System mit drei flüssigen Phasen wird mühelos erreicht, wenn das organische Lösungsmittel Chloroform durch ein Gemisch von Chloroform mit einem unpolaren Lösungsmittel wie Benzol ersetzt wird. Bei der Bildung solcher Systeme werden güngstige Voraussetzungen für die Extraktion der Elemente geschaffen. In der dritten Phase, die zu 40% aus dem Rhodanidsalz des Reagenzes besteht, ist eine hohe Konzentration zweier Komponenten vorhanden, die für die Komplexbildung sowie für die Extraktion unentbehrlich sind: diese Phase enthält einerseits Rhodanidionen, die für die Bildung von

Thiocyanato-metallanionen erforderlich sind, zum anderen hochmolekulare Ionen des Reagenzes, die mit diesen Anionen eine Reaktion eingehen.

Die Untersuchung der Dreiphasensysteme hat folgendes ergeben: obwohl die allgemeinen Gesetzmäßigkeiten der Extraktionsprozesse hier dieselben wie in den Zweiphasensystemen bleiben, treten jedoch einige interessante Eigenheiten auf. Dies hängt wahrscheinlich damit zusammen, daß in den Zweiphasensystemen die Konzentration der reagierenden Komponenten bedeutend geringer ist, als in den Drei-Phasensystemen.

Es ist vor allem notwendig zu betonen, daß die Zahl der extrahierbaren Elemente immer größer wird. Es ist bereits möglich, solche Elemente in die organischen Phasen überzuführen, für die die Bildung von Rhodanidkomplexe gar nicht spezifisch ist. Zu solchen Elementen gehören Beryllium, Aluminium, Nickel, Yttrium, Lanthanum und andere seltene Erden.

Als zweite Eigenart der Dreiphasensysteme ist eine ausgesprochen enge Beziehung zwischen der Vollständigkeit der Extraktion der Elemente und der Acidität des Mediums zu nennen. Elemente wie Aluminium, Yttrium, Lanthanum sind zwar aus den schwach-sauren Medien extrahierbar, es genügt aber, den Säuregehalt auf 2–3N zu steigern, um die Extraktion praktisch auf Null zu bringen. Dieses besondere Verhalten der Dreiphasensysteme läßt neue abgeänderte Verfahren zur Trennung der Elemente mittels Extraktion entstehen.

Um die Extraktion geringer Mengen, sowie Spuren von Elementen besser zu erforschen, wurde radioaktives Kobaltisotop verwendet. Die Untersuchungen haben ergeben, daß das Extraktionsprozent in der dritten Phase zusammen mit der zweiten Phase, wo auch geringe Mengen Kobalt extrahiert werden, insgesamt mehr als 99% beträgt. So hat man sogar bei der unter ziemlich extremen Bedingungen verlaufenden Extraktion—es wurde 1 μg ^{60}Co einem Liter 200 g Nickelchlorid enthaltender Lösung zugesetzt—in der wäßrigen Phase nur 0,001 μg ^{60}Co nachgewiesen.

Das Dreiphasen-Rhodanidsystem wurde zur Ausarbeitung eines hochempfindlichen Verfahrens für die Bestimmung geringer Mengen von Quecksilber, Scandium und Zinn verwendet.

Auf der Grundlage des Studiums der Bildungsbedingungen der drei flüssigen Phasen im Rhodanid-Extraktionssystem, der Verteilung des Quecksilbers, Scandiums und Zinns zwischen den Phasen in Abhängigkeit vom Säuregehalt des Mediums, der Konzentration der Rhodanidionen und der Zusammensetzung des organischen Lösungsmittels werden für das Konzentrieren von μg-Mengen dieser Elemente als Extraktionsmittel eine Lösung des DAM in einem Benzol–Chloroformgemisch (Volumenverhältnis 7:3) und als Vergleichselement Kobalt empfohlen. Das Kobalt wird dabei gemeinsam mit dem Quecksilber, Scandium und Zinn aus einer an Salz- oder Schwefelsäure 1–2N Lösung, die 4–5% Ammoniumrhodanid enthält, vollständig extrahiert.

Ausführung der Analyse

Die 2–50 μg Hg, Sc oder Sn enthaltende Einwaage wird in Salz oder Schwefelsäure gelöst. Die Lösung wird quantitativ in einen Scheidetrichter gebracht und eine Standardlösung von Kobalt als Vergleichselement (10 μg) zugegeben; danach werden Salz oder Schwefelsäure und eine 50%-ige Ammoniumrhodanidlösung zugesetzt, bis die wäßrige Phase bei einem Gesamtvolumen von 20–30 ml 1–2N an Säure und 5%-ig an Ammoniumrhodanid ist. Dann gibt man 15 ml Extraktionsreagenz (eine Lösung von 0,5 g DAM im 7: 3 v/v Benzol–Chloroformgemisch) hinzu. Die nach dem Schütteln und Absetzenlassen gebildete dritte Phase wird auf die Stirnflächen von 10 Kohlenelektroden gebracht. Die Elektroden werden an der Luft leicht getrocknet und die Spektren photografiert. Die optimalen Bedingungen für die Aufnahme der Spektren aller zu bestimmenden Elemente werden entsprechend den experimentellen Bedingungen ausgewählt und sind nach der Beschreibung der Methodik für die Abscheidung der Elemente mittels Extraktion angegeben.

Quecksilber, Scandium und Zinn lassen sich in verschiedenen Untersuchungsobjekten bestimmen, deren Hauptbestandteile Erdalkalien und Seltene Erden, Aluminium, Chrom(III), Nickel u.a. bilden. Von besonderem Wert ist die Möglichkeit, Scandium in Seltenen Erden zu bestimmen.

JODIDSYSTEM

Bestimmung von Kadmium und Wismut

Die Gruppe der im Jodidsystem extrahierbaren Elemente ist etwas anders als die der im Rhodanidsystem extrahierbaren; dies ermöglicht die Ausarbeitung neuer, abgeänderter Extraktionsverfahren für die Trennung der Elemente. So lassen sich bei der üblichen Analyse die Elemente Ga–In, Sc–Y, Zn–Cd u.a. leicht voneinander trennen.

Es wird beispielsweise ein Verfahren zur Bestimmung von Mikromengen von Kadmium und Wismut angegeben.[9]

Um die optimalen Bedingungen für die Abscheidung von Kadmium und Wismut in dem Dreiphasensystem der Extraktion auszuarbeiten, wurde der Einfluß der Azidität des Mediums, Konzentration der Jodid-Ionen, Volumenverhältnis der wäßrigen zur organischen Phase, Zusammensetzung des organischen Lösungsmittels, Reagenzmenge u.a. untersucht.

Es wurde festgestellt, daß die Extraktion aus den schwefelsauren Lösungen vorgenommen werden muß; dabei darf die Konzentration der Schwefelsäure nicht unter $0{,}5N$ sinken. Das Lösungsmittel stellt ein Benzol–Chloroformgemisch dar (Volumenverhältnis 7:3). Als Vergleichselement ist Quecksilber vorgeschlagen, das sich aus einer $0{,}5N$-schwefelsauren Lösung zusammen mit Kadmium und Wismut extrahieren läßt. Zwecks vollständiger Extraktion verwendet man 0,5 g DAM. Das Volumen der "dritten Phase" wird nach dem Reagenzgehalt ermittelt, wobei immer dieselbe Menge DAM eingesetzt wird, um ein konstantes Volumen der Phase zu erhalten.

Für die Analyse wird eine 2–100 μg Cd oder Bi enthaltende Einwaage (0,5–1,0 g) in Schwefelsäure gelöst. Die Lösung wird quantitativ in einen Scheidetrichter gegeben, eine Standardlösung von Quecksilber (44 μg) und Schwefelsäure hinzugesetzt, wobei die Konzentration der letzteren bei dem Gesamtvolumen der wäßrigen Phase von 20–30 ml nicht unter $0{,}5N$ sinken darf. Es wird Kaliumjodid hinzugegeben, damit dessen Konzentration in der Lösung 5–6% beträgt, darauf werden 0.1 g Ascorbinsäure und 15 ml Lösung von 0,5 g DAM in 7:3 v/v Benzol-Chloroformgemisch hinzugefügt. Man schüttelt mindestens 15 min (bei kürzerer Schütteldauer ist die Extraktion der Elemente unvollständig), läßt die Entmischung der Phasen zustandekommen und bringt die "dritte Phase" tropfenweise auf die Kohlenelektroden.

Die Bestimmung von Kadmium und Wismut wird nicht durch Fe, Mn, Al, Mg, Cr, Ni, Be, Ga, La, Ce und andere Seltene Erden gestört.

NITRATSYSTEM

Bestimmung von Zirkonium und Hafnium

Aus den nitrathaltigen Medien kann durch DAM nur eine beschränkte Gruppe von Elementen (Zr, Hf, Sc, U, Bi, Hg) extrahiert werden.[10] Dies veranlaßt zur Ausarbeitung einer Reihe von hochselektiven Analysenmethoden.[11,12] Es muß betont werden, daß es in manchen Fällen sogar im Rahmen eines einzigen Extraktionsystemes gelingt, zusätzliche Trennungen durch Regulieren der Konzentration der Salpetersäure zu verwirklichen. So führt die Steigerung der Konzentration von Salpetersäure in der wäßrigen Phase auf $6N$ zu einem praktisch vollständigen

Übergang von Zirkonium und Hafnium in die Schicht des organischen Lösungsmittels, bei Scandium dagegen zur Einstellung der Extraktion.

Um die optimalen Bedingungen für die Abscheidung von Zirkonium und Hafnium in dem Dreiphasen-Extraktionssystem auszuarbeiten, wurde der Einfluß der Acidität des Mediums, des Volumenverhältnisses der wäßrigen und der organischen Phasen, die Zusammensetzung des Lösungsmittels und die Reagenzmenge untersucht.[13]

Eine möglichst vollständige Konzentrierung der Elemente in der "dritten Phase" findet statt, wenn als organisches Lösungsmittel ein Benzol–Chloroformgemisch im Volumenverhältnis 7:3 verwendet wird. Die Extraktion muß aus Lösungen, die mindestens 6*N* an Salpetersäure sind, vorgenommen werden. Die Anwesenheit von Chloriden und Sulfaten ist unerwünscht, weil durch Chloridionen die Zahl der extrahierbaren Elemente größer wird, die Gegenwart von Sulfaten aber zur Maskierung von Zirkonium und Hafnium, sowie des Vergleichselements Thorium führt. Letzteres läßt sich mit den zu bestimmenden Elementen abscheiden und muß der zu analysierenden Lösung unmittelbar vor der Extraktion zugesetzt werden.

Die zu analysierende 5–300 μg Zr oder 9–600 μg Hf enthaltende Lösung wird in einen Scheidetrichter gegeben, dann 2 ml 5×10^{-4} *M* Lösung von Thoriumnitrat (264 μg Th) und Salpetersäure hinzugefügt, bis die Azidität 6*N* ist, wobei sas Gesamtvolumen der wäßrigen Phase 15–30 ml beträgt; darauf werden 10 ml 4%-iger Lösung von DAM im organischen Lösungsmittel zugesetzt. Man schüttelt den Inhalt des Trichters 20–25 min, läßt die Entmischung der Phasen zustandekommen und bringt dann die "dritte Phase" auf die Elektroden. Über die Selektivität des Verfahrens kann man an Hand der Tabelle I urteilen.

SPEKTRALANALYTISCHE BESTIMMUNG DER ELEMENTE

Die Elementenkonzentrate als "dritte Phase" wurden nach dem Auftragen auf die Elektroden und Trocknung an der Luft der Spektralanalyse unterworfen. Als Lichtquelle diente der Funke, weil in dieser Lichtquelle der Effekt der gegenseitigen Beeinflussung der Elemente minimal ist.[14,15] Wesentlich für die Funkquelle ist nur die Molekularform, in der das Element in den zu analysierenden Untersuchungsobjekten vorliegt. Bei der Extraktion mittels DAM entstehen strukturell gleichartige Elementkomplexe, so daß es möglich wird, durch kombinierte Ausnutzung des Funkens und der DAM-Extraktion, den nicht unbedeutenden Einfluß der Molekularform der Verbindungen auf die Genauigkeit der Analysenergebnisse zu beheben. Eine größere Genauigkeit und höhere Empfindlichkeit der empfohlenen Methoden wird auch bei dem Auftragen der "dritten Phase" auf mehrere Elektroden (10–12) und deren nachfolgendem Photographieren auf dasselbe Spektrum erreicht (je 10

TABELLE I.—CHARAKTERISTIK DER SPEKTRALCHEMISCHEN VERFAHREN FÜR DIE BESTIMMUNG DER ELEMENTE UNTER ANWENDUNG DER DREIPHASENSYSTEME

Extraktions system	Das zu bestimmende Element	Matrix	Absolute Empfindlichkeit, μg	Standardabweichung, %
1. Rhodanid system	Hg	Be, Mg, Al	2,0	11,2
	Sc	La, Ni, Cr	2,0	9,0
	Sn		4,0	5,0
2. Jodid system	Cd	Fe, Cr, Co	1-3	13,0
	Bi	Ni, Mn, Al, Zn, Ga		14,0
3. Nitrat system	Zr	Sc, Y, La, Ce	5,0	5,6
	Hf	Al, Be, Mg In Ga, Cu, Zn, Cd	9,0	7,4

bei der Bestimmung von Hg, Sc, Sn, Cd oder Bi und je 12 für Zr und Hf). Die Spektren wurden mit dem Spektrografen ISP-28 photographiert; die Spaltbreite betrug, 0,01 mm; der analytische Abstand, 3 mm; Belichtungsdauer, 20 sec (15 sec bei der Bestimmung von Hg, Sc, Sn). Anregungsquelle: Generator IG-3, einfaches Schema, V = 200 V, I = 2,6 A (und 3,0 A bei der Bestimmung von Quecksilber, Scandium und Zinn) C = 0,02 μF, L = 0,15 mH.

Für die Aufnahme der Eichkurven werden bekannte Mengen der Elemente extrahiert. Die Berechnung des Durchschnittwertes wird auf Grund von 10–15 Spektren durchgeführt. Um verschiedene Einwaagen je nach dem Gehalt der Elemente in den Proben ausnutzen zu können, werden die Eichkurven anhand folgender Koordinaten zusammengestellt: die Differenz zwischen der Schwärzung des zu bestimmenden Elementes und des Vergleichselementes, und Logarithmus der absoluten Menge des zu bestimmenden Elementes in Mikrogramm. Als analytische Paare gelten folgende Linien:

Das zu bestimmende Element	Vergleichselement
Hg 253,65 nm Sc 255,23 nm Sn 283,99 nm	Co 241,16 nm
Cd 226,50 nm Bi 293,83 nm	Hg 253,65 nm
Zr 267,86 nm Hf 263,87 nm	Th 287,04 nm

Um klarzustellen, ob es möglich ist, Elemente in verschiedenen Untersuchungsobjekten zu bestimmen, wurden bei der Bildung der Eichkurven für die Bestimmung von Kadmium und Wismut als Grundlage Zink, Chrom, Mangan, Eisen, Kobalt und Nickel genommen; für die Bestimmung von Zirkonium, Hafnium, u.a. werden Scandium, Yttrium, Lanthan, Cer, Aluminium, Beryllium, Magnesium als Grundlage genommen. Meistenteils ist der Einfluß der Grundlage unbedeutend und für die Bestimmung von Hg, Sc, Sn, Cd, Bi, Zr und Hf kann man einheitliche Eichkurven benutzen, die nach synthetischen Etalons gebildet sind.

Die Methoden sind hochempfindlich und liefern gut reproduzierbare Resultate (Tabelle I).

Summary—A new method for concentrating elements before their determination by spectrography is described, which achieves considerable saving in time and improvement in sensitivity and accuracy. The method depends on the separation of a mixed organic solvent into two phases when diantipyrylmethane is present as extracting reagent. In one of the phases—the so-called "third phase"—the extracted elements are concentrated in 95–98% yield. The small volume of the third phase permits it to be transferred quantitatively directly to the electrode and so to dispense with time-consuming evaporation and ashing procedures before the spectrographic determination. Spectrochemical methods with adequate selectivity and sensitivity for the determination of Hg, Sc, Sn, Cd, Bi, Zr and Hf have been developed. The new procedure is shown to be very promising for the concentration of traces and the analysis of high-purity materials.

Résumé—On décrit une nouvelle méthode de concentration des éléments avant leur détermination par spectrographie, qui mène à un gain de temps considérable et à une amélioration de la sensibilité et de la précision. La méthode repose sur la séparation d'un solvant organique mixte en deux phases lorsque le diantipyrylméthane est présent en tant que réactif d'extraction. Dans l'une des phases—dénommée "troisième phase"—le séléments extraits sont concentrés avec un rendement de 95–98%. Le petit volume de la troisième phase lui permet d'être transférée quantitativement directement à l'électrode et d'éviter ainsi les longues techniques d'évaporation et d'incinération avant le dosage spectrographique. On a élaboré des méthodes spectrochimiques de sélectivité et sensibilité convenables pour le dosage de Hg, Sc, Sn, Cd, Bi, Zr et Hf. On montre que la nouvelle technique est très intéressante pour la concentration de traces et l'analyse de produits de haute pureté.

INTERFERENCES AND THEIR ELIMINATION IN THE DETERMINATION OF THE NOBLE METALS BY ATOMIC-ABSORPTION SPECTROPHOTOMETRY

R. C. MALLETT, D. C. G. PEARTON, E. J. RING and T. W. STEELE
Analytical Division, National Institute for Metallurgy, Johannesburg

(*Received* 10 *March* 1971. *Accepted* 7 *July* 1971)

Summary—A number of serious interferences in the determination of the noble metals by atomic-absorption spectrophotometry have been investigated, and ways of eliminating them considered. The use of the nitrous oxide and acetylene flame reduced many of the interferences but also reduced the sensitivity. Additions of lanthanum, copper sulphate, copper + cadmium sulphate, uranium, and vanadium as releasing agents were effective in the removal of interferences for one or more of the noble metals in the air-acetylene flame. Uranium additions were found to be effective in removing mutual interferences associated with the noble metals (osmium and iridium were not tested) whereas vanadium removed mutual and base-metal interferences. The precision and accuracy of methods of analysis based on the use of uranium and vanadium were acceptable, and the application of these methods to the analysis of noble metals collected by various procedures is briefly discussed.

ATOMIC-ABSORPTION SPECTROSCOPY (AAS) was considered to be a suitable technique for the determination of noble metals. However, a survey of earlier studies indicated that the determinations were subject to many interferences, arising from the noble metals themselves (mutual interference) and also from other metals or non-metals. Some investigators have made use of releasing agents for the removal of interferences; others have resorted to the use of hot flames.

Strasheim and Wessels,[1] using a butane–propane–air flame, found that platinum and rhodium were particularly subject to interferences. They were able to remove mutual interference with platinum by the addition of copper sulphate, but rhodium had to be determined by the standard addition technique. Measurements were made on 10% hydrochloric acid media. Palladium and gold were not subject to serious mutual interference but the acidity (10% hydrochloric acid) had to be closely controlled. Base metals had to be separated before the measurement of the noble metals.

Van Loon[2] determined platinum, palladium and gold in silver assay beads and found that addition of lanthanum (1%) removed the interferences encountered. Measurements were made on a 6*M* hydrochloric acid medium, and it was noted that the lanthanum had caused an enhancement in the adsorption measurement of the various metals.

Schnepfe and Grimaldi,[3] in the determination of palladium and platinum, found that mutual and base-metal interferences were removed by the addition of a mixture of copper and cadmium sulphates.

Scarborough[4] reported that when uranium was present no interferences were encountered in the determination of molybdenum, ruthenium, palladium and rhodium and there was also an enhancement in the absorption measurement of the noble metals.

Many interferences that occur in the cooler flames can often be reduced or eliminated by the use of hotter flames. Atwell and Hebert[5] found that many of the interferences encountered with the air–acetylene flame when rhodium was being determined were not present when the nitrous oxide–acetylene flame was used.

Up to the present no suitable methods whereby all the noble metals can be determined in one solution have been reported. It was therefore decided to try to determine as many noble metals as possible in a single solution, and this paper describes the investigations into the determination of platinum, palladium, rhodium, ruthenium and gold, the interferences encountered, and the methods used to eliminate these interferences. Preliminary investigations had indicated that osmium and iridium would not be present in the materials to be analysed at levels suitable for atomic-absorption measurement, so these were not included in this investigation.

EXPERIMENTAL

Apparatus

Spectrometer. A Techtron AA4 spectrophotometer with a Dl-20 digital indicator or the normal meter indicator unit, and Varian-Techtron hollow-cathode lamps were used. The wavelengths, slitwidths, and operating lamp currents are shown in Table I.

TABLE I.—INSTRUMENTAL PARAMETERS FOR THE TECHTRON AA4 SPECTOPHOTOMETER

Parameter	Pt	Pd	Rh	Ru	Au
Wavelength, *nm**	265·9	244·8	343·5	349·9	242·8
Spectral band width, *nm*	0·17	0·17	0·17	0·33	0·33
Lamp current, *mA*	10	7	5	10	4
Flow-rate, *l. min*$^{-1}$	1·75	1·75	2·25	3	1·75

* The most sensitive lines were used.

Flame. Most of the investigational work was carried out with the air–acetylene flame and a Techtron 0·10-m grooved burner. Maximum sensitivity for platinum, palladium and gold was observed when a lean flame was used. Rhodium required a normal flame, and ruthenium a rich flame.

In the tests where the nitrous oxide–acetylene and air–acetylene flames were compared, the Techtron 60-mm grooved burner was used for all measurements. To obtain maximum sensitivity, the procedure adopted was to set the flow-rates of the air and nitrous oxide to those indicated in Fig. 2 and then, while a solution was being aspirated, to adjust the acetylene flow for maximum sensitivity. This often resulted in a very lean flame, but care was taken not to reduce the acetylene flow to the point where a flash-back might occur.

Reagents

Standard noble metal solutions. Stock solutions of platinum, palladium and gold were prepared by the dissolution of the individual noble metals in *aqua regia.* The nitrate was removed from platinum and platinum solutions by repeated evaporations with hydrochloric acid. Gold solutions were not treated in this way because gold can be easily reduced with this treatment. When nitrate-free gold solutions were required, they were made from "Specpure" ammonium chloroaurate (NH_4AuCl_4) dissolved in hydrochloric acid. The stock solutions of rhodium and ruthenium, and of osmium and iridium, when used, were made from the "Specpure" ammonium chloro-salts (previously assayed gravimetrically, except for osmium) dissolved in hydrochloric acid.

Uranium solution (1 ml ≡ 250 mg of U). Dissolve 29·5 g of pure U_3O_8 in 40 ml of nitric acid (1 + 1). Evaporate to dryness, dissolve in nitric acid, hydrochloric acid, or *aqua regia* as required, and dilute to 100 ml. (if solutions free from excess of nitric acid are required, evaporate several times with hydrochloric acid.)

Vanadyl chloride ($VOCl_2$) *solution* (1 ml ≡ 100 mg of V). Although this reagent can be purchased it was prepared in the laboratory in the following manner. To 8·39 g of V_2O_5 (analytical grade) add 50 ml of comc hydrochloric acid. Heat the mixture gently until the initial reaction ceases, then boil for 10 min. Add hydrazine hydrochloride solution dropwise to the boiling solution until the green colour disappears, indicating complete reduction to blue vanadyl chloride ($VOCl_2$). Evaporate the solution to 25 ml and dilute it to 50 ml with water.

Interference studies

Noble metals can be collected by several procedures, *e.g.*, assay fusion with lead, nickel sulphide, or tin as the collectors. Solutions of prills obtained by assay fusion with lead as a collector, followed by cupellation, would not contain appreciable amounts of base metals, whereas the solutions of noble metals resulting from the other collection procedures, or solutions obtained from the chlorination of the ore would contain large amounts of base metals and their salts. Because the materials could be divided into two categories according to the type of interferences likely to be encountered, *viz.* mutual and base-metal interferences, it was decided to study these separately, and, if necessary, use different methods to control them.

In terference effects were recorded by comparison of the absorption of solutions containing the noble metals, either present together or added individually, depending on the nature of the test, with the absorption of similar solutions in the presence of the interfering ion. The concentrations of acids and releasing agents when used were the same in the test and the reference solutions and both sets of solutions were measured under the same operating conditions.

RESULTS

Mutual interference

Mutual interferences of the noble metals, tested in 4% *aqua regia** and in 10% hydrochloric acid media are shown in Tables II and III where the seriousness of these interferences in very evident. Further evidence of mutual interference in 4% *aqua regia* can be seen in Fig. 1*a*–1*f* where the effect of one noble metal upon another is shown.† Although ruthenium, osmium and iridium were added (Table II) these were not measured in the 4% *aqua regia* medium because they were present at too low a concentration. From a comparison of Tables II and IV it appears at first sight that the interferences suffered by platinum and rhodium were more severe in 10% hydrochloric acid medium than in 4% *aqua regia*, a feature that may be associated with the relatively large amount of ruthenium present in the former medium. Figures 1*b* and 1*c* indicate that ruthenium in 4% *aqua regia* depresses the absorption of platinum and rhodium. A similar effect can therefore be expected in a hydrochloric acid medium. The absorption of ruthenium was itself enhanced in both a 4% *aqua regia* medium. (Fig. 1*e*) and a 10% hydrochloric acid medium (Table III) by the presence of relatively large amounts of gold. Gold in a 4% *aqua regia* solution had a similar effect on rhodium (Fig. 1*f*).

It is evident that the phenomenon of mutual interference is a very complex one and it was necessary therefore to find methods whereby it could be removed or at least controlled.

Experiments with the nitrous oxide–acetylene flame. Since Atwell and Hebert[5] reported that the interferences encountered in the air–acetylene flame when rhodium was being determined were not present in the nitrous oxide–acetylene flame, it was decided to test this flame for the measurement of the other noble metals. It was obvious that this flame, when used normally, lowered the sensitivity for rhodium, so arrangements were made to introduce air to modify the characteristics of the flame. It can be seen from Table IV and Fig. 2 that, although there was an improvement in the recovery of platinum and rhodium with an increase in the nitrous oxide content of the gas mixture, there was a progressive decrease in sensitivity for all the noble metals except ruthenium. Little improvement in recovery was observed for ruthenium over that obtained with the air–acetylene flame. The mutual interference with gold caused a higher absorption; with palladium there was no effect from interferences either in the nitrous oxide *or* the acetylene flame.

Experiments on the use of releasing agents

A number of recommended releasing agents were examined, *viz.* copper sulphate,[1] lanthanum,[2] copper sulphate plus cadmium sulphate,[3] and uranium.[4] Where possible, the reported methods were adhered to. An exception was the substitution of the

air–acetylene flame for the propane–butane–air flame used when copper[1] was added. Since the effects of these releasing agents on mutual interference had not been reported for all the noble metals, the present tests were related to all the noble metals that had sufficient sensitivity to enable them to be measured. The results of these tests are presented in Table V, together with absorption data from which the relative sensitivities in the various media can be estimated.

Lanthanum and uranium were the most effective releasing agents for the removal of mutual interferences of all the noble metals. A poor recovery for rhodium (55%) was obtained when copper plus cadmium was tested, and although a full recovery was

obtained by the use of copper sulphate the sensitivity for rhodium was significantly lowered. Palladium in this medium (copper sulphate) was subject to interference (110% recovery) and the sensitivity was lowered. Of the two releasing agents, lanthanum and uranium, the latter was preferred because of its slight superiority in removing mutual interference effects and because it offered the greater improvement in sensitivity.

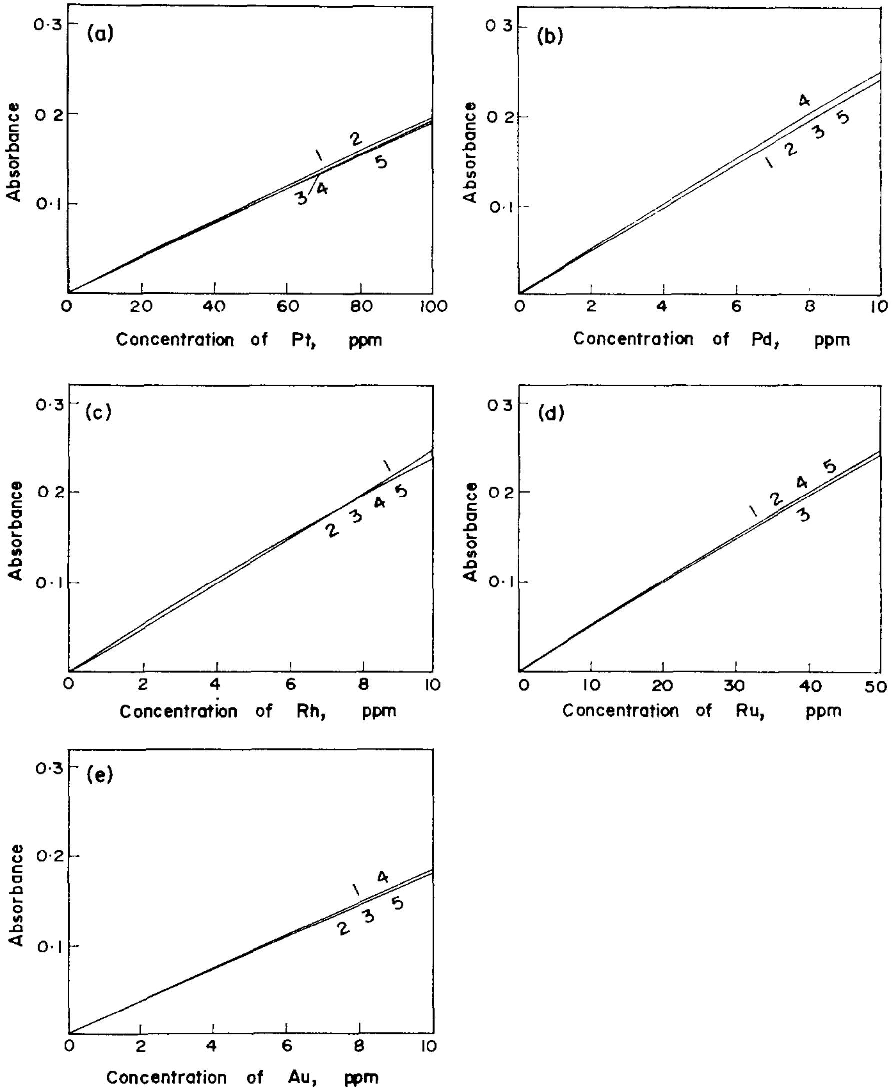

FIG. 3.—The effect of varying amounts of uranium on the calibration curves of the noble metals in a 4% *aqua regia* medium.

3. 20 g/l. of uranium.
4. 30 g/l. of uranium.
5. 30 g/l. of uranium.

Uranium as a releasing agent in various acid media.* Because the calibration curves obtained for the noble metals in 4% v/v *aqua regia* in the presence of 0·5–4% w/v uranium were virtually identical and essentially linear, and it had been shown that 1% w/v of U removed mutual interference effects, it was concluded that the addition of uranium was not critical over this range, and decided to use 1% w/v of uranium for all subsequent investigations.

* The uranium was added as a solution (250 mg of U per ml) of U_3O_8 in 10% *aqua regia* solution

TABLE V.—THE VARIATION OF ABSORBANCE OF THE NOBLE METALS AND MUTUAL INTERFERENCES WHEN VARIOUS RELEASING AGENTS ARE ADDED

La—1% lanthanum, 50% v/v hydrochloric acid medium.

Cu/Cd—0·5% copper and 0·5% cadmium (added as the sulphates), 10% v/v hydrochloric medium.

$CuSO_4$—2% copper (added as sulphate) 10% v/v hydrochloric acid medium.

U—1% U (added as a solution derived from U_3O_8) 4% *aqua regia* medium.

All solutions contain, *ppm*, Pt, 100 Pd, Rh and Au 10 each; Ru, 50.

* = Absorbance of the noble metal in the solution containing all the metals together. No scale expansion was used.

Tests on solutions containing the noble metals and uranium, with variation of the amounts of hydrochloric and nitric acids while maintaining the total acid concentration at 4% v/v, indicated that it was not necessary to remove nitric acid (Table VI).

High acid concentrations are necessary when an analysis is made of cupellation prills to which silver has been added, in order to maintain the silver in solution. Recovery tests (Table VII) on solutions of noble metals in 40% v/v hydrochloric acid–1% v/v nitric acid medium in the presence of 50 ppm of silver and 1% w/v of uranium,

showed that the uranium still removed the mutual interference effects and that this amount of silver could be tolerated.

Precision and accuracy of the uranium-addition method. Reproducibility tests carried out on 20 solutions of the noble metals in a 20% v/v hydrochloric acid + 1% v/v nitric acid medium containing 1% w/v of uranium, yielded coefficients of variation of 0·6, 0·5, 0·3, 5·0, 1·0, 1·3 and 1·3% respectively for platinum, palladium, rhodium, ruthenium, gold, silver and lead. The solutions tested contained the noble metals, silver and lead in the concentrations (ppm) associated with a solution of a typical cupellation prill, *viz.* Pt 80; Pd 45; Rh 10; Ru 1·5; Au 2·5; Ag 30; Pb 20. The high coefficient of variation for ruthenium was a function of the low concentration determined. As there was no reason to believe that the precision would be adversely affected by the use of a 40% v/v hydrochloric acid medium, no precision tests were carried out on this medium.

Because standard samples were not available, the accuracy of the method with uranium as a releasing agent was estimated by comparison of the results obtained by AAS with those obtained by chromatographic, chemical and spectrographic analyses (Table VIII). The ruthenium level of these samples, after suitable dilution for the

measurement of the other noble metals, was too low to be measured by AAS. The agreement between the various techniques was acceptable, and it is considered that the accuracy of the atomic-absorption technique, with uranium being used as a releasing agent for the removal of mutual interference effects, is at least as good as that of the other techniques.

Base-metal interferences in the presence of uranium

Although reliable results for the determination of the noble metals in solutions of prills were obtained, with uranium as a releasing agent, the presence of relatively large amounts of some base metals resulted in significant interferences, which were not removed by the uranium. The effects of those base metals likely to be encountered

were tested in 4% v/v *aqua regia* and 10% v/v hydrochloric acid media and are shown in Tables IX and X. Errors of less than ±3% were interpreted as not constituting a definite interference. Interference effects were usually more evident in the 4% *aqua regia* than in the 10% hydrochloric acid medium. It was observed that rhodium was particularly prone to serious interference (>10% error). Large amounts of copper and nickel resulted in poor recoveries for rhodium in both media, whereas cobalt and chromium affected rhodium to a greater extent in 4% *aqua regia* than in 10% hydrochloric acid. The effect of sulphate was marked in both media; the absorption of all the noble metals, with the exception of palladium in 10% hydrochloric acid, was seriously suppressed by sulphate equivalent to 5000 ppm of S. Where precipiation occurred, as with silver, lead and tellurium, losses of noble metals were attributed to occlusion in the precipitates. Many of the interferences listed were not serious (<5% error) and usually occurred at the highest levels of interferent concentration tested (5000 ppm).

The use of vanadium as a releasing agent in perchloric acid medium. Because several of the base metals that caused serious interference effects (*e.g.*, Cu, Ni, Cr) would be present in some materials requiring analysis, it was decided to investigate the use of a releasing agent other than uranium. It was found that a 1% w/v solution of vanadium in 20% v/v perchloric acid medium removed mutual interference effects (Fig. 1) and considerably improved the recoveries of the noble metals in the presence of relatively large amounts (5000 ppm) of base metals. The metals tested were those

* Added as SO_4^{2-}.

described in the previous section. The presence of 100 ppm of silver and 5000 ppm of lead resulted in significant losses of rhodium owing to occlusion in the chloride precipitates, and in replicate tests it was found that, on occasions, the presence of iron and tin caused a serious loss of gold, probably owing to reduction to the metal in the evaporation steps required for the removal of excess of nitric acid (to be discussed later). The presence of 5000 ppm of Mg, Cr, Co, Ni, Al, Se, Te, Cu, Na, or Ca and 100 ppm of Au usually resulted in errors of less than 5 %. Sulphate usually suppressed the absorption of rhodium to a larger extent than that of the other noble metals, (*e.g.*, 85 % recovery for rhodium in the presence of 1500 ppm S). However, up to 200 ppm of S had no effect on the absorption of any of the noble metals.

As mentioned earlier, unknown amounts of hydrochloric and nitric acids were undesirable when the vanadium–perchloric acid method was being used. This is shown in Table XI where the effect of various amounts of nitric acid, hydrochloric acid, and *aqua regia* is shown. Because, in this test, unknown amounts of these acids were first removed by fuming in perchloric acid, ruthenium was lost as RuO_4 and could not be measured. The addition of controlled amounts of the acids indicated that a certain amount of variability in the absorption measurements of gold and particularly of palladium could result if the concentration of the acids were not controlled.

In this method a solution of $VOCl_2$ in hydrochloric acid is added in definite amounts after removal, by evaporation, of any unknown amounts of hydrochloric or nitric acids, in order to control the concentration of hydrochloric acid. Noble metals and gold in particular, can be reduced when evaporated to dryness[9] so lithium chloride (10 mg Li) is added before evaporation on a water-bath and the salts are never baked. (These precautions did not always prevent the reduction of gold when iron or tin was present.)

Precision and accuracy of the vanadium–perchloric acid method. Tests of the precision of the method carried out on 48 solutions of noble metals in the absence of base metals, yielded coefficients of variation of 1·4, 1·4, 1·2, 1·4 and 1·1 % for platinum,

† Includes added ruthenium to give a measurable concentration.

DISCUSSION

It was confirmed that in the atomic-absorption measurement of the noble metals interferences from the noble metals themselves and from a number of base metals were serious.

The use of the nitrous oxide–acetylene flame as a means of reducing mutual interferences successfully eliminated such effects in the determination of rhodium, as found by Atwell and Hebert.[5] Interferences were also eliminated for platinum, and palladium and gold could be determined as effectively as with the air–acetylene flame. The nitrous oxide flame was not effective in the elimination of interferences in the determination of ruthenium and this, coupled with the overall reduction in sensitivity occurring with this flame, ruled out this approach as a simple means of determination of all the noble metals in one solution.

The observations on the use of various additives as releasing agents for the removal of mutual interferences confirm the published data. In general the additives have been found to be effective for more noble metals than were originally examined but only lanthanum and uranium were found to be effective for all of them. The observations on additives were at variance with the published data in only one instance—contrary to Strasheim and Wessels[1] it was found that the addition of copper sulphate removed the mutual interferences with rhodium. This difference can be attributed to the use of the hotter (air–acetylene) flame.

Base metal interferences, have previously been overcome by the addition of a mixture of copper and cadmium sulphate[4] or by the use of a nitrous oxide flame.[5] These methods were, however, shown to be inadequate in the removal of the mutual interferences associated with the determination of *all* the noble metals examined. The addition of vanadyl chloride as a releasing agent effectively eliminated both mutual and base metal effects even when the base metal concentration was appreciable. The relative merits of the uranium and vanadium methods are worth consideration. The uranium method is simple, requiring only that the sample be dissolved, uranium added and appropriate dilutions made. Acid and uranium concentrations are not critical. Up to 0·5 mg of silver can be maintained in solution by the use of a 40% v/v hydrochloric acid medium. Small amounts of base metals such as lead (20–50 ppm) cause no interference but the method is not applicable to solutions containing significant amounts of base metals.

The vanadium method, although eliminating both mutual and base-metal interferences, requires stricter control of the acid content of the final solution and care must be taken, when removing free nitric acid, to avoid a loss of gold by reduction, especially in the presence of iron and occasionally tin. Lead and silver interfere by occlusion of the noble metals in the precipitated chlorides, the degree of occlusion varying with the conditions of precipitation.

It has been shown by Beyerman[9] that appreciable losses of gold can occur if chloride solutions of this metal are evaporated to dryness. Thus, in the removal of free nitric acid the evaporation should be only to incipient dryness. If losses by reduction are to be avoided, especially in the presence of iron, either the presence of nitric acid should be avoided or the iron be removed before the evaporation step. The loss of gold and the other noble metals would be accelerated if easily reducible metals such as tellurium and selenium were present and the evaporation were taken too far.

Large amounts of lead and silver would need to be removed before measurement. Fortunately, silver and lead are normally only present in significant amounts in cupellation prills from the lead collection procedure, and such prills would be analysed by the uranium-addition technique.

It is apparent, therefore, that the uranium and vanadium methods are useful for different collection methods. Cupellation prills obtained from the lead collection procedure are relatively free from base metals and can best be analysed by the uranium-addition method. Solutions of the noble metals collected by the nickel sulphide procedure, or those obtained by acid extraction of the ores containing significant amounts of base metals, can best be analysed by the vanadium-addition method. Solutions freed from base metals by ion-exchange techniques could be analysed by the uranium-addition method.

The two approaches are therefore capable of being applied to the analysis of the noble metals collected from ores by a variety of procedures provided that the concentrations of the noble metals and any base metals in the solution used in the final analysis can be adjusted to suitable concentration levels.

Zusammenfassung—Eine Anzahl ernsthafter Störungen bei der Bestimmung der Edelmetalle durch Atomabsorptions-Spektrophotometrie wurden untersucht und Wege erörtert, um sie zu beseitigen. Die Verwendung einer Distickstoffoxid-Acetylen-Flamme verminderte viele Störungen, aber auch die Empfindlichkeit. Zugaben von Lanthan, Kupfersulfat, Kupfer + Cadmiumsulfat, Uran und Vanadium als Mittel zur Freisetzung der Edelmetalle waren bei der Beseitigung von Störungen für ein oder mehrere Edelmetalle in der Luft-Acetylen-Flamme wirksam. Zugaben von Uran erwiesen sich als wirksam beim Beseitigen gegenseitiger Störungen der Edelmetalle (Osmium und

Iridium wurden nicht geprüft), wogegen Vanadium gegenseitige Störungen und solche durch unedle Metalle beseitigte. Genauigkeit und Richtigkeit der Analysenmethoden mit Uran und Vanadium waren annehmbar; die Anwendung dieser Methoden auf die Analyse edler Metalle, die mit verschiedenen Verfahren angereichert wurden, wird kurz diskutiert.

Résumé—On a étudié un certain nombre d'interferences sérieuses dans la détermination des métaux nobles par spectrophotométrie d'absorption atomique, et l'on a envisagé des voies pour les éliminer. L'emploi de la flamme protoxyde d'azote-acetylène réduit nombre de ces interferences, mais réduit aussi la sensibilité. Des additions de lanthane, sulfate de cuiver, cuivre + sulfate de cadmium, uranium et vanadium comme agents d'élimination sont efficaces pour éliminer les interférence pour un ou plusieurs des métaux nobles dans la flamme air-acétylène. On a trouvé que des additions d'uranium sont efficaces pour l'élimination d'interférences mutuelles associées aux métaux nobles (l'osmium et l'iridium n'ont pas été essayés), tandis que le vanadium élimine les interférences mutuelles et les interférences base-métal. La fidélité et la précision des méthodes d'analyse basées sur l'emploi d'uranium et de vanadium sont acceptables, et l'on discute brièvement de l'application de ces méthodes à l'analyse de métaux nobles recueillis par diverses techniques.

RAPID SEPARATION AND DETERMINATION OF MERCURY*

IVAN KRESSIN
University of California, Los Alamos Scientific Laboratory
Los Alamos, New Mexico 87544, U.S.A.

(*Received* 4 *March* 1971. *Accepted* 12 *June* 1971)

Summary—An analytical procedure is described for the separation of mercury(II) by extraction into n-octanol from sulphuric acid solution and then back-extraction as the tetraiodo complex. The mercury is determined by measuring the absorbance of this complex at 322 nm (molar absorptivity $1{\cdot}95 \times 10^3$ l.mole^{-1}.cm^{-1}). The procedure is applicable to samples containing copper; the effects of a wide variety of other impurities are tabulated.

MANY ANALYTICAL METHODS have been reported for the determination of mercury. Neutron-activation analysis and spark-source mass spectrometry provide sensitive methods for the detection of mercury but also require expensive equipment and highly trained analysts.[1,2] Atomic-absorption spectrophotometry is commonly used in many modern laboratories.[3] Methods based on extraction with dithizone have probably received the greatest attention, but other reagents have also been reported.[4] Waterbury, for example, has reported the extraction of the mercury–diethyldithiocarbamate complex into carbon tetrachloride.[5] Rogers[6] suggested the use of iodide for the determination of mercury and Kressin and Coleman reported on the spectrophotometric determination of mercury as the tetraiodo complex.[7]

Mercury has an unusually great affinity for the iodide ion and the formation constants of the iodide complexes of mercury(II) (Table I) have been known for many years.[8] Although the formation constants are well known, it is less widely known that tetraiodomercurate(II) absorbs strongly in the near ultraviolet. The present paper reports the conditions required for the use of mercuric iodide complexes for an unusually simple and straightforward separation followed by a specific photometric determination of mercury. The method is based on the extraction of iodide–mercury(II) species into octanol from an acidic solution and back-extraction of the mercury as the tetraiodo complex which is then determined spectrophotometrically.

TABLE I.—FORMATION CONSTANTS OF Hg–I COMPLEXES*

$Hg^{2+} + I^- \rightleftharpoons HgI^+$	$\log K_1 = 12{\cdot}9$
$HgI^+ + I^- \rightleftharpoons HgI_2$	$\log K_2 = 10{\cdot}9$

$Hg^{2+} + 4I^- \rightleftharpoons HgI_4^{2-}$	$\log \beta_4 = 29{\cdot}8$

* See Ref. 8.

EXPERIMENTAL

Apparatus

A Cary Model 14 spectrophotometer was used for photometric measurements and all absorbances were read directly from the recorder scale. Aliquots of standard mercuric sulphate solutions were

---

* This work was performed under the auspices of the U.S. Atomic Energy Commission.

taken with a calibrated pipette. Other volumetric glassware was not calibrated. Extractions were performed in 60-ml separatory funnels, electric motors fitted with a glass stirring rod being used to mix the solutions.

Reagents

Mercuric oxide was used as the primary standard for the determination of molar absorptivities and for calibration curves. The mercuric oxide was dried in a vacuum desiccator before weighing and then dissolved in sulphuric acid. The standard mercuric solution was $0{\cdot}1M$ with respect to sulphuric acid. All reagents used in the preparation of solutions were of analytical grade.

Potassium iodide ($3M$) was found to be quite stable in 10% aqueous ammonia solution, and was used for the back-extraction. The solution was filtered before use, to avoid light-scattering by flocculent impurities.

The $0{\cdot}1M$ potassium iodide and $0{\cdot}1M$ sodium thiosulphate were prepared by dissolving the respective salts in water and used without further treatment.

The n-octanol, Eastman P-871, was used without further purification.

The $9M$ sulphuric acid was prepared by slowly diluting concentrated sulphuric acid with an equal volume of water.

Procedure

Transfer an aliquot of the sample solution containing 1–200 μg of mercury(II) to a separatory-funnel and add an equal volume of $9M$ sulphuric acid. Stir the mixture and add 0·5 ml of $0{\cdot}1M$ potassium iodide and 10 ml of n-octanol. Stir the mixture for one minute and discard the aqueous phase. Wash the alcohol phase twice with 3-ml portions of water to remove the excess of sulphuric acid, and discard the wash solution. Back-extract the mercury with three 3-ml portions of $3M$ potassium iodide, and collect the extracts in a volumetric flask (10-ml if the mercury content is expected to be in the 1–40 μg range, otherwise 25-ml). Add to the flask 0·5 ml of $0{\cdot}1M$ sodium thiosulphate and dilute to volume with water. Measure the absorbance of the mercuric tetraiodo complex at 322 nm against air in the reference beam. Correct for the absorbance of the reagents by performing the extraction on a volume of water equal to that of the sample.

DISCUSSION AND RESULTS

In the presence of iodide, mercury(II) is extracted rapidly from sulphuric acid solution into n-octanol, but as the tetraiodo complex is not extracted quantitatively a large excess of iodide should be avoided during the first extraction of the mercury. It is considered that the tri-iodo complex of mercury(II) is the mercury complex extracted, because increasing concentrations of iodide lowered the fraction of mercury extracted by the *n*-octanol. If this is the case, the complex is presumably protonated to give a neutral species. From the analytical point of view it is immaterial which species is extracted provided extraction is complete. The amount of iodide added before extraction of mercury may vary within ±50% of that recommended, without causing loss of mercury. The mercury(II) is quantitatively extracted into octanol from $>2M$ sulphuric acid but the convenience of adding a volume of $9M$ sulphuric acid equal to that of the sample aliquot justified using the larger volume of acid. Approximately 98% of the mercury is extracted from $1{\cdot}0M$ sulphuric acid. The mercury is not back-extracted by the water wash but the excess of sulphuric acid should be removed, otherwise the ammonium sulphate produced will inhibit phase separation during the back-extraction step. The water wash also removes any other ions which might interfere if present in the final solution. More than three washes with water may be required if copper or nitrate is present in the sample. After the water wash, mercury is back-extracted into $3M$ potassium iodide, three successive extractions being used for quantitative recovery. Iodide in acid solution is readily oxidized by air, therefore the tri-iodide ion (I_3^-) formed during the extraction is reduced by the addition of thiosulphate before the absorbance measurements are made.

Iodo-mercuric complexes, iodide and tri-iodide (I_3^-) all absorb strongly in the ultraviolet region. Mercuric iodide, Fig. 1A, has two absorbance maxima. The absorbance peak at 264 nm has a molar absorptivity of approximately 560 l.mole^{-1}.mm^{-1} and the sharp one at 210 nm an absorptivity of approximately 2·86 × 10^4 l.mole^{-1}.mm^{-1}. There are several reasons why the absorption by mercuric iodide at 210 nm is unsuitable for the spectrophotometric determination of mercury; from the formation constants it is apparent that its concentration will depend on the free iodide concentration, and the iodide itself absorbs strongly below 270 nm. The use of the absorption due to the mercuric tri-iodo complex was rejected for similar reasons.

The absorption spectrum of mercuric tetraiodo complex is shown in Fig. 1B. The absorption peak at 322 nm has a molar absorptivity of 1·95 × 10^4 l.mole^{-1}.cm^{-1}, and that at 270 nm about 3·50 × 10^4 l.mole^{-1}.cm^{-1}. Since iodide does not absorb

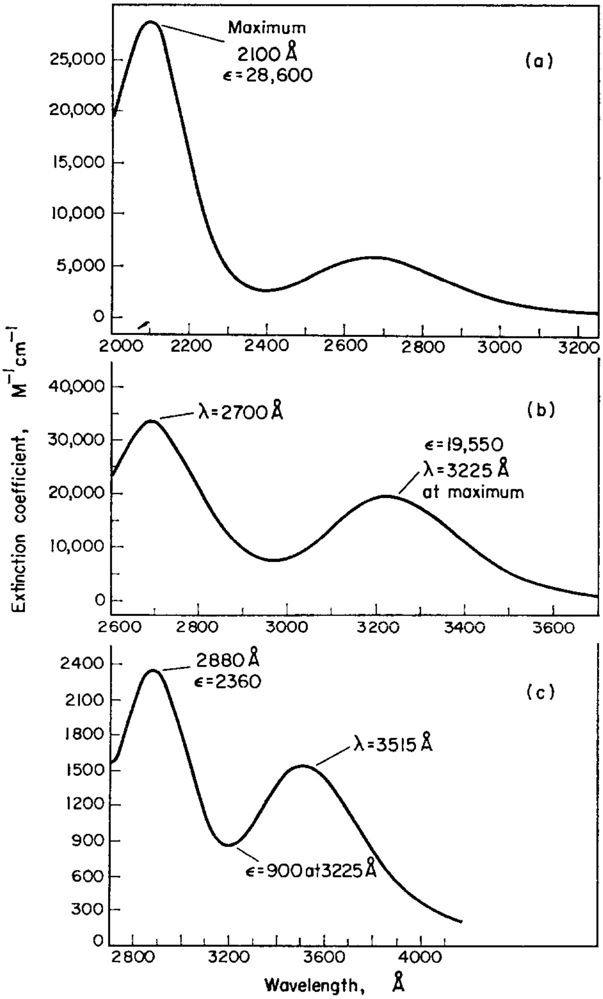

FIG. 1.—Absorption spectrum of (A) HgI$_2$; (B) HgI$_4^{2-}$ in 1*M* potassium iodide; (C) I$_3^-$.

at above 300 nm but does so appreciably below this wavelength, the analytical use of the 270-nm peak would require an accurate knowledge of the iodide concentration. For these reasons, the longer-wavelength peak at 322 nm was chosen.

From the formation constants, it is apparent that moderately high iodide concentrations are needed to drive the reaction, $HgI_3^- + I^- \rightleftharpoons HgI_4^{2-}$ to completion. Figure 2 shows the variation in the absorption spectrum of the mercuric tetraiodo complex with changes in the iodide concentration. The presence of the isosbestic points confirms the presence of just two absorbing species; namely HgI_3^- and HgI_4^{2-} and the results are in good accord with the reported equilibrium constant for this reaction. The use of a final potassium iodide concentration much lower than 0·6*M* clearly leads to a mixture of mercury complexes and should be avoided.

The tri-iodide ion has an absorption peak (Fig. 1C) on either side of 322 nm with a minimum very near this wavelength. A small concentration of this ion could be tolerated but the addition of 0·5 ml of 0·1*M* sodium thiosulphate effectively removes tri-iodide from the solution.

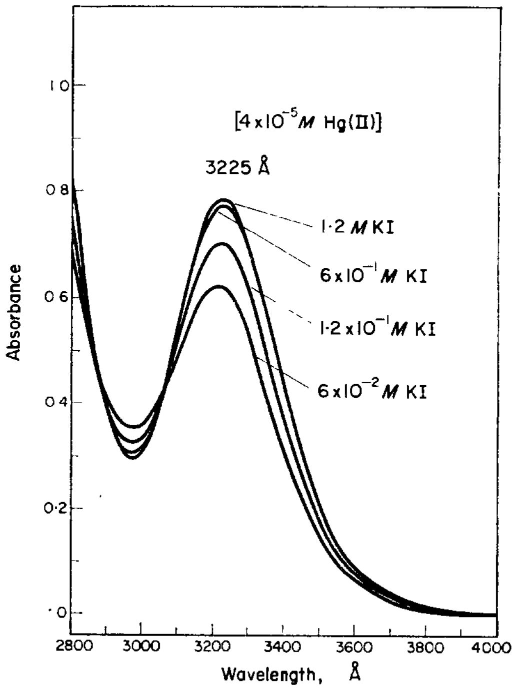

FIG. 2.—Effect of various concentrations of potassium iodide on the absorption spectrum of Hg(II) species in the region of the 322 nm peak of the HgI_4^{2-} complex.

Colour stability

The mercury tetraiodo complex is stable for long periods in 1·0*M* potassium iodide solution. With the addition of sodium thiosulphate to remove tri-iodide the absorbance is stable for more than 24 hr. The effect of varying the pH was investigated and no change was found over the pH range 1–14; however, as potassium iodide solutions are more stable at pH above 7, a higher pH was chosen.

Variations in temperature above 30° and below 20° do have a measurable effect, but no error is introduced if the solutions are maintained at 25° ± 5°.

The precision was checked in two ways. With samples of mercuric oxide weighed directly into volumetric flasks, 34 determinations yielded a molar absorptivity of $1{\cdot}95 \times 10^3$ l.mole^{-1}.cm^{-1} with a relative standard deviation of 0.4%. The final concentration of mercury varied from $1{\cdot}5 \times 10^{-5}$ to $4 \times 10^{-5}M$, corresponding to a net absorbance of 0·3–0·8. Another check on the precision was made by taking 34 aliquots containing from $3{\cdot}1 \times 10^{-7}$ to $8{\cdot}0 \times 10^{-6}$ mole of mercury, following the procedure, and determining the slope of the line by the linear regression method. The slope was 10·36 μg/ml per absorbance unit, with a correlation coefficient of 0·9998 and an intercept of −0·0015 ± 0·0005 at the 95% confidence interval. The data show that Beer's law is obeyed over the concentration range investigated and that mercury can be determined with a high degree of precision.

The recovery of mercury in the extraction procedure was checked in the following manner. Solutions of mercuric sulphate were added directly to 25-ml volumetric flasks and the absorbance due to the mercuric tetraiodo complex was measured. The extraction procedure was performed on equal amounts of mercuric sulphate and the absorbances were measured after the extraction. Within the experimental error, the absorbances of the two sets of solutions showed that the mercury was recovered in this extraction procedure.

Interferences

A detailed investigation of every conceivable type of sample which might contain mercury would be impossible, but a large number of ions were investigated. The ions tested for interference were present at concentrations one thousand times greater than that of the mercury and an ion was not considered as causing an interference unless the results for mercury were changed by more than 2%. The species which do not interfere are: Li, Na, K, Mg, Ca, Sr, Ba, La, Ti(IV), Zr, V(V), Nb, Ta, Cr(III), Mo(VI), W(VI), Fe, Co, Zn, Cd, Ce(III), Al, Sn(IV), As(V), Te, fluoride, chloride, phosphate, acetate and hydrogen peroxide. Those which necessitate some precautions are listed in Table II.

In general, ions that interfere are those that react with potassium iodide and absorb strongly at 322 nm. Strong reducing agents will also interfere. Many of the interfering elements listed in Table III could be tolerated at lower concentrations and would not be expected at such high concentrations in most samples. Cyanide, tin(II) and titanium(III) would interfere at any concentration.

TABLE II.—MASKING OF SOME POSSIBLE INTERFERENCES

Ion	Precaution
Ni(II)	Solution must be saturated with ammonium chloride before the extraction.
Cu(II)	Solution must be saturated with ammonium chloride before the extraction. Solid ammonium chloride must be present during the extraction.
Tl(I)	Solution must be saturated with ammonium chloride before the extraction.
Pb(II)	Solution must be saturated with ammonium chloride before the extraction.
Br^-	Concentrations above 1M interfere.
NO_3^-	This ion absorbs strongly in the ultraviolet, and must be stripped from the octanol by thorough washing before the back-extraction of the mercury.

TABLE III.—IONS THAT AFFECT THE DETERMINATION

$[Ion]/[Hg] = 10^3$	Comment
Ag(I)	Removes iodide and the precipitate interferes with extraction. Small amounts do not interfere.
Bi(III)	Concentrations equal to that of the mercury do not interfere.
Ce(IV)	Extracted; can be reduced with H_2O_2 to eliminate interference.
Mn(II)	Extracted and causes positive errors
Cr(VI)	Extracted; can be reduced with Fe(II)
CN^-	Complexes mercury.
Sn(II)	Reduces mercury.
Ru	Can be removed by fuming with HNO_3.
Pd	Extracted and causes positive errors.
Au	Causes negative errors.
V(III)	Can be oxidized to V(V) to eliminate interference.
Ti(III)	Reduces the mercury.

CONCLUSION

The spectrophotometric determination of mercury as the tetraiodo complex has several advantages to warrant its use. The procedure is applicable to samples containing copper and the method is sensitive, precise, rapid and easy to use. The procedure as described can be performed with chemicals and equipment usually found in a laboratory. Furthermore the method does not suffer from the instability of reagents, as does the dithizone extraction of mercury.

Zusammenfassung—Ein analytisches Verfahren zur Abtrennung von Quecksilber wird beschrieben. Es wird aus schwefelsaurer Lösung in n-Octanol extrahiert und als Tetrajodokomplex rückextrahiert. Quecksilber wird bestimmt durch Messung der Extinktion dieses Komplexes bei 320 nm (molarer Extinktionskoeffizient $1{,}95 \cdot 10^3$ l mol^{-1} mm^{-1}). Das Verfahren läßt sich auf kupferhaltige Proben anwenden; der Einfluß einer großen Vielfalt anderer Verunreinigungen wird tabellarisch dargestellt.

Résumé—On décrit une technique analytique pour la séparation du mercure(II) par extraction en *n*-octanol à partir d'une solution en acide sulfurique, puis extraction en retour à l'état de complexe tetraiodo. Le mercure est déterminé par mesure de l'absorption du complexe à 320 nm (coefficient d'absorption moléculaire $1{,}95 \times 10^3$ l.mole^{-1}.cm^{-1}). La technique est applicable aux échantillons contenant du cuivre; on présente sous forme de tableau les influences d'une large variété d'autres impuretés.

SHORT COMMUNICATIONS

A voltammetric and chronopotentiometric study of molten alkali acetates

(*Received* 6 *July* 1971. *Accepted* 19 *October* 1971)

MANY papers have been published in recent years regarding molten alkali metal acetates, dealing with characterization of the solvent,[1-3] polarography,[4-6] potentiometry,[7] spectrophotometry[8,9] and conductivity.[10,11] In this communication some preliminary results of a voltammetric and chronopotentiometric study in molten (Na, K) acetates (46·3 mole% sodium acetate) at 250° are reported.

The study deals with the reduction of water and acetic acid, and with the oxidation of hydrogen and hydroxide ions on bright platinum electrodes. Voltammetry was performed with an oscillating platinum microelectrode;[12-14] for chronopotentiometry a vertical platinum foil (61·7 mm^2) was used.

The electrochemically stable range of the solvent is represented by curve *1* in Fig. 1.

All the potentials are referred to an Ag/Ag$^+$(0·1 mole/kg) electrode in (Na, K)NO$_3$ enclosed in a soft glass bulb. This electrode has been used as a reference both in voltammetry and in chronopotentiometry, assuming its potential to be equal to zero.

Curve *1* may be obtained from a melt carefully dried for many hours under high vacuum or a stream of dry nitrogen. A good baseline is obtained only when oxygen is rigorously excluded from the melt, and when certain precautions are taken in pretreating the electrodes.

Normally the last traces of water are difficult to remove and the voltammograms are more like that represented by curve *2*. The wave at about −1·8 V is due to reduction of water according to the reaction

$$2H_2O + 2e^- \rightarrow H_2 + 2OH^-$$

as is demonstrated by the composite wave (curve *3*) obtained in a melt with added hydroxide ion and molecular hydrogen.

The height of the anodic wave is limited by the hydrogen pressure; the wave at about −0·8 V is associated with the oxidation of the hydroxide ion and may still be seen after removal of hydrogen gas by passing a stream of nitrogen.

The voltammograms obtained for melts of this kind are not reproducible over prolonged periods, owing to decomposition caused by reaction of the hydroxide ion with the solvent. Some attempts have been made to determine the kinetics of this reaction; it seems to be pseudo-monomolecular with a half-life of about 2 hr, referred to the hydroxide ion concentration.

If glacial acetic acid is added to the melt the shape of the voltammogram becomes that of curve *4*. The hydrogen ion reduction precedes that of water and there is evolution of hydrogen gas at the electrode according to the overall reaction.

$$2H^+ + 2e^- \rightarrow H_2.$$

In the presence of hydrogen gas a composite wave (curve *5*) is obtained.

Oxidation waves of molecular hydrogen, not represented in Fig. 1 for the sake of simplicity, are readily obtained; sometimes these waves show a maximum of the first kind, but this depends on the pretreatment of the electrode.

Chronopotentiometric experiments lead one to the same conclusion regarding the electrochemical behaviour of each species. In Figs. 2 and 3 are represented some typical chronopotentiograms for different solutes. Figure 2 represents a chronopotentiogram obtained in a partially dried melt; the potential break on the reverse branch corresponds to the anodic part of the composite wave of curve *3* (Fig. 1) with the difference that hydrogen gas and hydroxide ions are produced during the forward process.

The shape of the anodic wave remains the same as long as the amount of hydrogen gas produced does not exceed the total solubility in the melt and on the platinum electrode. When this happens gas evolution can be observed at the electrode and hence some hydrogen is lost by a process other than pure diffusion. This event causes the appearance on the anodic wave of a second potential break that corresponds to oxidation of the excess of hydroxide ion formed at the electrode surface.

Curves *a* and *b* in Fig. 3 represent the oxidation of molecular hydrogen and the reduction of hydrogen ion followed by the respective reverse processes.

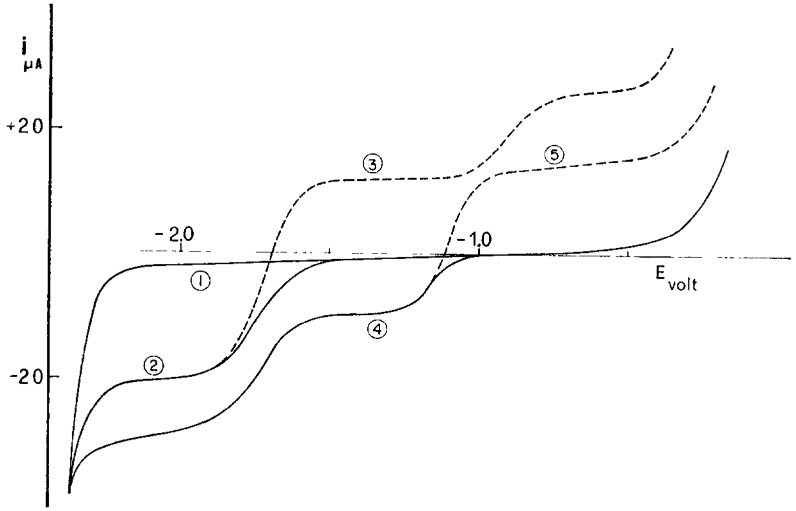

FIG. 1.—Current–potential curves for a platinum microelectrode: (*1*) dry solvent; (*2*) water reduction wave; (*3*) composite wave for the system H_2O/H_2, OH^-; (*4*) hydrogen ion reduction; (*5*) composite wave for the system H_2/H^+.

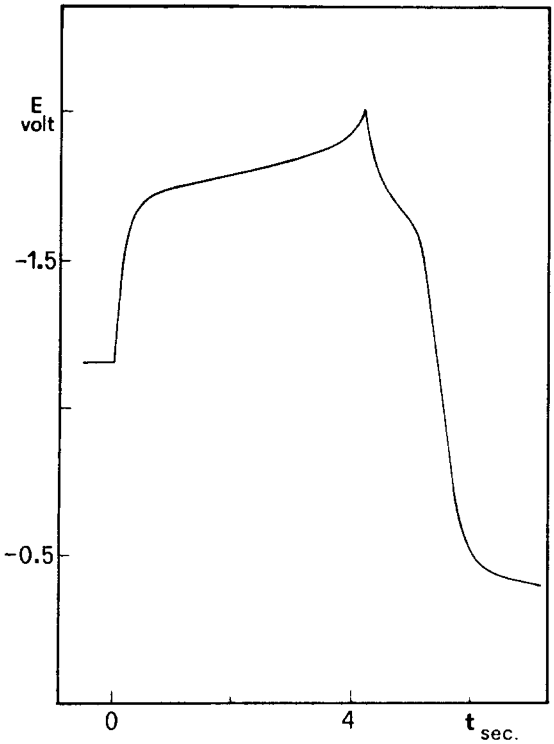

FIG. 2.—Chronopotentiogram with current reversal for water reduction.

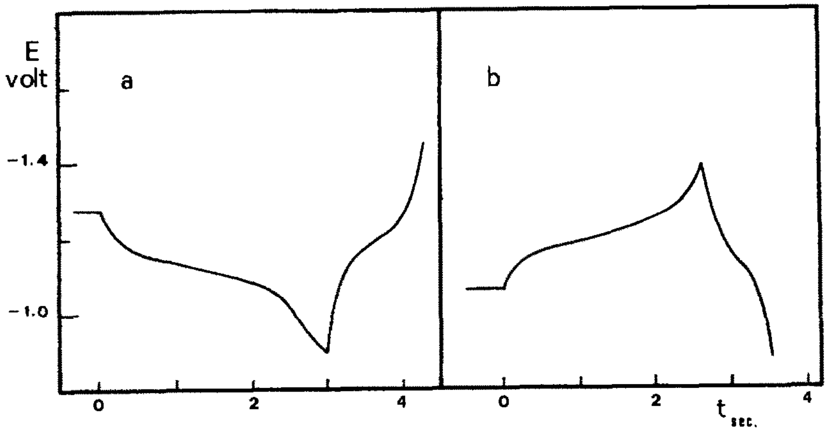

FIG. 3.—Chronopotentiograms with current reversal for: (a) hydrogen oxidation; (b) hydrogen ion reduction.

Both voltammetry and chronopotentiometry have been demonstrated to be suitable methods for the detection of water in acetate melts; this is important because water is the commonest impurity generally found in melts. In addition the reproducibility of the wave-height and of the transition times suggests that these techniques may be used for the determination of each species and hence their solubility. These studies are in progress and will be the subject of a later report.

Statocalcein, a stable Calcein indicator for the EDTA titration of calcium

(*Received* 24 *June* 1971. *Accepted* 15 *September* 1971)

THE COMPOUND $K_2Ca_5Calcein_2$ provides a stable aqueous solution of Calcein which is suitable as an indicator in the EDTA titration of calcium at high pH in the presence of magnesium. Two hundred and ten days after preparation, an aqueous solution of this compound still provided a sharp fluorometric endpoint, in contrast to solutions of Calcein in alkali which decompose within a day or so with the production of material, which gives a disturbing background fluorescence. We propose to call the new material *Statocalcein* (from *stato*, stable or fixed).

The theory of this development is based on the work of Hefley[1] who established the structure of Calcein and worked out the combining ratio and formation constants of the two calcium derivatives. Two ions of calcium combine, stepwise, with Calcein, each being bound by one iminodiacetate group (*i.e.*, both carboxylate groups and the nitrogen atom) and the adjacent phenolic oxygen atoms. The iminodiacetic acid groups and the resorcinol rings are thus tightly packed, minimizing free rotation and presenting a more spherical configuration which is less subject to attack. The idea was to take advantage of this for the preparation of a stock solution, it being immaterial for indicator purposes that the metal being determined is also present in the indicator.

In the union of calcium with Calcein hydrogen ions are displaced. As shown by Hefley, in the titration with alkali of Calcein in the presence of calcium, six hydrogen ions are neutralized per Calcein molecule and a sharp end-point is observed at pH 8. It was proposed simply to isolate from a solution brought essentially to this end-point the compound $K_2Ca_2Calcein$. A solid compound was isolated but it proved to be $K_2Ca_5Calcein_2$.

EXPERIMENTAL

Reagents

Statocalcein; K_2Ca_5*Calcein*$_2$*; dipotassium pentacalcium bis*(3′,6′-*dihydroxy*-4′,5′-*di*[N,N′-*di*(*carboxymethyl*)*aminomethyl*]*fluoran*). Calcein was prepared by the procedure of Hefley[1] starting with metal-free fluorescein obtained by the hydrolysis of diacetylfluorescein. The Calcein was dried in vacuum at 50° for 24 hr. To a slurry of 3·84 g (0·0060 mole) of Calcein in 25 ml of deionized water was added a solution of calcium chloride prepared by dissolving 1·50 g (0·0150 mole) of primary-standard calcium carbonate in hydrochloric acid. With vigorous mechanical stirring, 0·4*M* potassium hydroxide was added dropwise until the pH reached and remained at 8·5. The precipitate formed was filtered off, slurried with 100 ml of demineralized water, and again filtered off. Some of this material was air-dried. The major part was rinsed into a freeze-drying bulb, frozen in liquid nitrogen, and freeze-dried. Both solids were orange. Found: Ca, 13·26%; K, 5·18%; Calcein, 81·0%. Calculated for $K_2Ca_5C_{60}H_{40}O_{26}N_4$: Ca, 13·26%; K, 5·17%; Calcein ($C_{60}H_{40}O_{26}N_4$), 81·57%. (Calcium was determined by EDTA titration following wet ashing with nitric acid plus perchloric acid. Potassium was determined by conversion of Statocalcein into calcium hydroxide plus potassium hydroxide by passage over IRA-400 in the alkaline form, followed by titration with acid and successive and immediate determination of calcium by EDTA titration; potassium was then calculated by difference. Calcein was determined fluorometrically as the dicalcium salt at pH 12, by using a Turner Model 110 fluorometer with appropriate filters, and calibration with pure Calcein as obtained by Hefley.)

Procedure

Stability of indicator solution and evaluation as indicator. For comparison, four solutions were prepared: (1) Calcein, 0·02% in 0·01*M* potassium hydroxide (as recommended in the original paper of Diehl and Ellingboe);[2] (2) Calcein, 0·02% in 1:1 water–ethanol; (3) Statocalcein (air-dried), 0·02% in water; (4) Statocalcein (freeze-dried), 0·02% in water. All solutions were stored in

Statocalcein, a stable Calcein indicator for the EDTA titration of calcium

(*Received* 24 *June* 1971. *Accepted* 15 *September* 1971)

THE COMPOUND K$_2$Ca$_5$Calcein$_2$ provides a stable aqueous solution of Calcein which is suitable as an indicator in the EDTA titration of calcium at high pH in the presence of magnesium. Two hundred and ten days after preparation, an aqueous solution of this compound still provided a sharp fluorometric endpoint, in contrast to solutions of Calcein in alkali which decompose within a day or so with the production of material, which gives a disturbing background fluorescence. We propose to call the new material *Statocalcein* (from *stato*, stable or fixed).

The theory of this development is based on the work of Hefley[1] who established the structure of Calcein and worked out the combining ratio and formation constants of the two calcium derivatives. Two ions of calcium combine, stepwise, with Calcein, each being bound by one iminodiacetate group (*i.e.*, both carboxylate groups and the nitrogen atom) and the adjacent phenolic oxygen atoms. The iminodiacetic acid groups and the resorcinol rings are thus tightly packed, minimizing free rotation and presenting a more spherical configuration which is less subject to attack. The idea was to take advantage of this for the preparation of a stock solution, it being immaterial for indicator purposes that the metal being determined is also present in the indicator.

In the union of calcium with Calcein hydrogen ions are displaced. As shown by Hefley, in the titration with alkali of Calcein in the presence of calcium, six hydrogen ions are neutralized per Calcein molecule and a sharp end-point is observed at pH 8. It was proposed simply to isolate from a solution brought essentially to this end-point the compound K$_2$Ca$_2$Calcein. A solid compound was isolated but it proved to be K$_2$Ca$_5$Calcein$_2$.

EXPERIMENTAL

Reagents

Statocalcein; K$_2$Ca$_5$*Calcein*$_2$*; dipotassium pentacalcium bis*(3′,6′*-dihydroxy-*4′,5′*-di*[N,N′*-di*(*carboxymethyl*)*aminomethyl*]*fluoran*). Calcein was prepared by the procedure of Hefley[1] starting with metal-free fluorescein obtained by the hydrolysis of diacetylfluorescein. The Calcein was dried in vacuum at 50° for 24 hr. To a slurry of 3·84 g (0·0060 mole) of Calcein in 25 ml of deionized water was added a solution of calcium chloride prepared by dissolving 1·50 g (0·0150 mole) of primary-standard calcium carbonate in hydrochloric acid. With vigorous mechanical stirring, 0·4*M* potassium hydroxide was added dropwise until the pH reached and remained at 8·5. The precipitate formed was filtered off, slurried with 100 ml of demineralized water, and again filtered off. Some of this material was air-dried. The major part was rinsed into a freeze-drying bulb, frozen in liquid nitrogen, and freeze-dried. Both solids were orange. Found: Ca, 13·26%; K, 5·18%; Calcein, 81·0%. Calculated for $K_2Ca_5C_{60}H_{40}O_{26}N_4$: Ca, 13·26%; K, 5·17%; Calcein ($C_{60}H_{40}O_{26}N_4$), 81·57%. (Calcium was determined by EDTA titration following wet ashing with nitric acid plus perchloric acid. Potassium was determined by conversion of Statocalcein into calcium hydroxide plus potassium hydroxide by passage over IRA-400 in the alkaline form, followed by titration with acid and successive and immediate determination of calcium by EDTA titration; potassium was then calculated by difference. Calcein was determined fluorometrically as the dicalcium salt at pH 12, by using a Turner Model 110 fluorometer with appropriate filters, and calibration with pure Calcein as obtained by Hefley.)

Procedure

Stability of indicator solution and evaluation as indicator. For comparison, four solutions were prepared: (1) Calcein, 0·02% in 0·01*M* potassium hydroxide (as recommended in the original paper of Diehl and Ellingboe);[2] (2) Calcein, 0·02% in 1:1 water–ethanol; (3) Statocalcein (air-dried), 0·02% in water; (4) Statocalcein (freeze-dried), 0·02% in water. All solutions were stored in polyethylene bottles in the dark. The calcium in a stock solution of calcium chloride, 0·02000M, prepared by dissolving 4·0036 g of primary-standard calcium carbonate in hydrochloric acid and diluting to exactly 2 l., was determined periodically by EDTA titration, each of these indicators being used.

A 25·00-ml aliquot of the stock solution of calcium chloride was first treated with about 10 mg of ascorbic acid, 2·5 ml of 5% potassium cyanide solution, 5 ml of 20% triethanolamine solution, and then 5 ml of 5·0M potassium hydroxide, and finally with 1 or 2 drops of the indicator solution. The solution was then titrated with 0·01250M EDTA prepared by weight from primary-standard grade disodium dihydrogen ethylenediaminetetra-acetate dihydrate. The titrations were carried out in the dark (in a box with an amber glass window[3]) under radiation from an ultraviolet source housed in a box with a slit; the assembly is shown in the recent text by Diehl.[4] Best results were obtained with the very minimum amount of indicator.

RESULTS AND DISCUSSION

It was surprising that the compound isolated was $K_2Ca_5Calcein_2$ rather than $K_2Ca_2Calcein$. The composition of the filtrate from the crop of solid was consonant with this, being deficient in calcium. Each molecule of Calcein binds two calcium ions, so the fifth calcium ion, like the two potassium ions, is ionic. That is, the character of the compound is probably expressed by $K_2Ca[Ca_2Calcein]_2$.

The periodic titration of calcium with EDTA, using the various indicator solutions, showed that Calcein prepared according to the original directions deteriorated within two days, producing sufficient background fluorescence to obscure the end-point; by holding the pH at 7, the deterioration could be reduced, such a solution being useful for seven or eight days. Calcein in 1:1 water–ethanol is much more stable but deterioration did occur with the development of background fluorescence and although the results of titrations even with indicator 60 days old were satisfactory the background fluorescence was gradually increasing. Solutions of Statocalcein showed no deterioration and no background fluorescence over a period of 210 days. The end-points were sharp, and in the darkened room, as distinctive as turning off a light bulb. The results of the analyses made on the stock solution of calcium chloride (using 60-day old indicators) were excellent, the precision being that expected in good volumetric work without precise temperature control, the average titre being 40·02 ml of 0·0125M EDTA for titrations with each of indicators (2), (3) and (4), the standard deviations being 0·06, 0·03 and 0·04 ml respectively for these indicators (11 determinations each).

Rapid determination of traces of silver in sulphide ores by atomic absorption

(*Received* 7 *June* 1971. *Accepted* 18 *July* 1971)

SPECTROPHOTOMETRIC methods using *p*-dimethylaminobenzylidenerhodanine[1,2] and dithizone[3] for the determination of small quantities of silver are not entirely satisfactory though widely used. However, atomic-absorption spectrophotometry offers rapidity and accuracy for determination trace quantities of silver. A method involving this technique developed by Rawling *et al.*[4] for determination of silver in lead concentrates recommends addition of ammonium acetate and potassium cyanide to sample solutions to keep both silver and lead in solution before aspiration into the flame. Rubeška *et al.*[5] adopted various methods of digestion for different sulphide minerals (galena, tetrahedrite, sphalerite and antimonites) and recommend the use of tartaric acid to prevent precipitation of antimony. In addition, mercury(II) nitrate was added to overcome the effect of chloride ions which tend to decrease the signal, owing to adsorption of silver chloride on the walls of the glass container. Greaves[6] made use of alkylpolyamines such as diethylenetriamine to keep both lead and silver dissolved as stable soluble chelates in 8*M* hydrochloric acid.

We have achieved excellent results by adding an excess of ammonia to the sample solution obtained by digestion with *aqua regia*, and aspirating this ammoniacal solution into the flame of an atomic absorption spectrophotometer. This method ensures retention of all the silver in a soluble state in the supernatant liquid while throwing down most of the metallic ions as hydroxides.

EXPERIMENTAL

Reagents

A 100-ppm standard silver solution was prepared by dissolving 0·1575 g of silver nitrate in 800 ml of demineralized water and adding 5% ammonia solution drop by drop till a clear solution was obtained, and finally diluting to 1000 ml; 10-ppm and 1-ppm standard solutions were prepared by diluting this solution with 1% ammonia solution. All other reagents were analytical-reagent grade.

Apparatus

A model AA 100 Tectron Atomic Absorption Spectrophotometer with ASL hollow-cathode lamp was used. The most sensitive silver absorption line at a wavelength of 328·1 nm was chosen to measure the absorbance values. The working conditions were:

Lamp current:	4 mA
Acetylene pressure:	10 psi, flow-meter reading 4·5
Air pressure	15 psi
Slit	0·10 mm

A standard 0·10-m stainless-steel AB 51 burner with a 0·5-mm wide slit was used.

Calibration

Portions (3 ml) of 10-ppm silver standard solution were diluted to 20 ml after addition of various amounts of ammonia solution (1 + 1), and the absorbances of the solutions were measured. From Table I, it can be seen that addition of at least 3 ml of the ammonia solution is required to produce maximum absorbance. The atomic absorbance values of 0, 0·5, 1·0, 1·5 and 2·0 ppm silver solutions containing 1 ml hydrochloric acid (1 + 1) and 5 ml of ammonia solution (1 + 1) in a total volume of 20 ml were measured and a calibration curve was drawn.

TABLE I.—EFFECT OF AMMONIA ON ATOMIC ABSORBANCE OF SILVER AT 328·1 nm

Ammonia solution, *ml*	Absorbance	Ammonia solution, *ml*	Absorbance
0·1	0·095	2·0	0·135
0·2	0·105	3·0	0·145
0·5	0·11	5·0	0·145
1·0	0·12	10·0	0·145

Procedure

A 0·1–0·2 g sample was weighed into a dry graduated cylinder (of a type which could be stoppered), 3ml of *aqua regia* were added and the mixture was digested on a hot-plate for about an hour. After cooling to room temperature the solution was neutralized by dropwise addition of ammonia solution (1 + 1) till a permanent precipitate of iron and other hydroxides formed. Then 5 ml of the ammonia solution were added and the mixture was made up to 20 ml. The cylinder was stoppered and after vigorous shaking the solution was allowed to settle for an hour. The supernatant liquid was aspirated into the flame and the absorbance recorded.

RESULTS

Fe(III), Al, Cr(III), Sb(III), Bi, As(III), Cu(II), Pb, Zn, Co(II), Ni, Hg(II), Sn(IV), V(V), Mo(VI), W(VI), Ca, Mg, Na, K, Cl^- and SO_4^{2-} in concentrations ranging between 0·5 and 2·5 mg/ml were found to cause no change in the absorbance of 1·5 ppm of silver. Addition of Sn(II) lowered the absorbance considerably because it separated silver from the ammoniacal silver nitrate solution. However if sufficient Fe^{3+} is present in solution (as is often the case) the Sn^{2+} is oxidized before the addition of ammonia, and does not interfere.

Apart from this interference from Sn^{2+}, the metal hydroxides precipitated by ammonia do not seem to retain any silver if a sufficient excess of ammonia is present. Copper, nickel, cobalt, cadmium and zinc remain in solution along with silver but do not cause any interference.

A large number of silver-bearing samples analysed by this method yielded values for silver in close agreement with those obtained by the potassium cyanide-ammonium acetate method.[4]

The absorption of carbon dioxide in solutions of monoethanolamine

(*Received* 30 *August* 1971. *Accepted* 15 *September* 1971)

One of the more popular methods for the determination of carbon in steel and other materials involves combustion of the sample in a stream of oxygen and absorption and titration of the resulting carbon dioxide in non-aqueous media. A number of procedures have now been proposed which include both coulometric and volumetric addition of the titrant. An important condition of these methods is that the absorption of the carbon dioxide in the titration medium or titrand solution should be 100% efficient and the use of dilute solutions of monoethanolamine has been found satisfactory in many cases. One of the earlier groups of workers in this field, Blom *et al.*,[1] suggested that the efficiency of absorption of carbon dioxide by monoethanolamine solutions was due to the formation of 2-hydroxyethylcarbamic acid,

$$HO{\cdot}C_2H_4{\cdot}NH_2 + CO_2 \rightarrow HO{\cdot}C_2H_4{\cdot}NH{\cdot}COOH$$

but no evidence was put forward in support of this conclusion. A similar situation applies to the reactions of a number of other amines with carbon dioxide which have been explained on a similar basis.[2-5] Braid *et al.*[6] have reported some studies in which carbon dioxide was bubbled through pure amine solutions and the resulting syrupy liquids were examined by infrared spectroscopy. They concluded, 'It therefore seems likely that substituted ammonium carbamates are formed,' in agreement with an earlier suggestion by Smola.[2] Although the infrared evidence is useful, it is not conclusive and since it appears likely to be taken as establishing this reaction,[7] it seemed of some importance to attempt to obtain more precise information on the products of the reaction of carbon dioxide with, in particular, dilute solutions of monoethanolamine.

In the normal procedures for carbon analysis, monoethanolamine is used as a 0·5–5% v/v solution in pyridine[1,9] or dimethylformamide[6-8] and, under these conditions, no insoluble product separates out. To obtain the required information, two procedures were adopted. Slightly more concentrated solutions were taken (10%) and (*a*) strontium chloride was included to bring about precipitation of the strontium salt of the acid formed and (*b*) carbon dioxide was passed through a strontium-free solution for a long time, whereupon an oily phase separated out. The products from both (*a*) and (*b*) were analysed.

When carbon dioxide was bubbled into pyridine containing ethanolamine (10% v/v) and strontium chloride hexahydrate (5% w/v), a glutinous mass separated out which, after washing with pyridine and drying in a vacuum oven at 50°, gave a white solid which appeared to be strontium 2-hydroxyethylcarbamate contaminated with about 7% strontium carbonate and 6% strontium chloride. The use of the hydrate appeared to be the cause of the formation of strontium carbonate and, to avoid this contamination, the experiment was repeated with 3·5% w/v anhydrous strontium chloride solution. The material obtained (Compound A) was insoluble in water and readily decomposed by dilute mineral acids, evolving carbon dioxide, a characteristic property of carbamates. It was subjected to elemental microanalysis (Table I), thermogravimetric analysis (Fig. 1) and infrared analysis. The thermogravimetric curve shows three breaks. The weight loss up to 120° was due to loss of volatile material, presumably water absorbed by the sample after separation. The loss at 300° was 50% on a dry-weight basis and corresponds exactly to the loss expected from the reaction,

$$Sr(C_3H_6O_3N)_2 \xrightarrow{300^\circ} SrCO_3$$

The final weight loss, 29·5%, corresponds to the decomposition of the carbonate to the oxide,

$$SrCO_3 \xrightarrow{1000^\circ} SrO + CO_2$$

TABLE I.—COMPOSITION OF COMPOUNDS A AND B

(Theoretical figures are based on $Sr(C_3H_6O_3N)_2$ for A and $[HOC_2H_4NHCO_2]^-[H_3NC_2H_4OH]^+$ for B)

Compound		*Elemental analysis* Theory, %	Reported, %	Corrected, %	Atomic ratio
A	C	24·40	18·7	23·5	5·8
	H	4·06	4·5	4·3	12·5
	N	9·38	8·4	8·7	1·8
	Sr	29·70	28·6	29·7	1·0
	O	32·47	35·8*	33·8	6·2
B	C	36·16	36·8		5·2
	H	8·49	9·0		15·0
	N	16·88	16·7		2·0
	O	38·47	37·5*		3·9

* By difference.

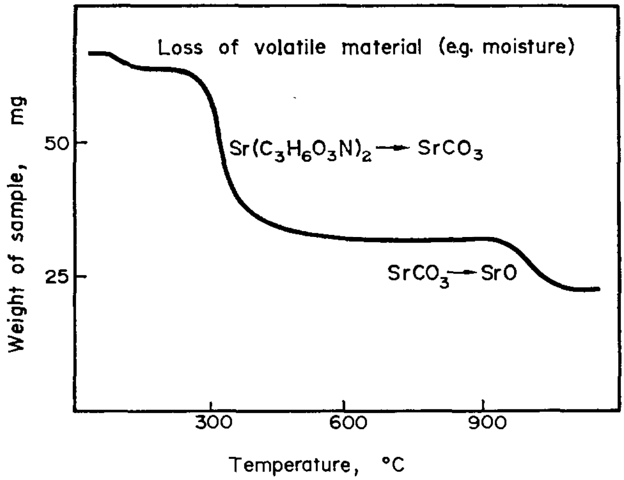

FIG. 1.—Thermolysis curve of compound A.

for which the theoretical weight loss is 29·8%. The thermogravimetric results show that strontium carbonate is formed at the temperature (800°) used for the ignition in the carbon determination and the carbon result will therefore be low. The thermogravimetric data also shows that 3·82% volatile material, presumed to be absorbed water, is present and difficult to exclude completely, owing to the hygroscopic nature of the material. Correction for both these errors is a simple matter and the corrected figures given in Table I are in reasonable agreement with the theoretical composition for $Sr(C_3H_6O_3N)_2$. Slight discrepancies are almost certainly due to small variations in the water content between different analyses.

Passing carbon dioxide through a 90:10 mixture of pyridine and ethanolamine in the *absence of strontium chloride* yielded a viscous oily phase (Compound B) which separated out at the bottom of the reaction vessel. This was also hygroscopic, was readily soluble in water and was also decomposed by dilute mineral acids with evolution of carbon dioxide. The material also appeared to give a pale violet fluorescence. The elemental analysis of Compound B is also given in Table I and suggests that it is in fact the monoethanolamine salt of 2-hydroxyethylcarbamic acid.

Infrared spectra of both Compound B and monoethanolamine itself were obtained from thin liquid films between KBr discs and that of Compound A from a pressed KBr pellet. All three spectra were generally similar but new bands were observed for both A and B in the region 1600–1300 cm^{-1} and at 800–850 cm^{-1}. These were in general agreement with the reported results of Braid *et al.*,[6] although less detail was observable in our case, possibly due to contamination by pyridine. Thus, the band at 1600 cm^{-1} in ethanolamine disappears and new bands appear at 1580 and 1390 cm^{-1}, as be expected for an ionized carboxyl group. The infrared evidence is not, however, particularly conclusive on its own.

CONCLUSION

It is established that the acidic species present in solutions of ethanolamine in pyridine after the absorption of carbon dioxide is the ethanolamine salt of 2-hydroxyethylcarbamic acid. This compound and the strontium salt of 2-hydroxyethylcarbamic acid have both been isolated from this medium and identified. As has been assumed previously, it is this acid which is titrated on addition of a strong base to the solution. Amines such as monoethanolamine therefore provide excellent absorption properties for carbon dixoide. The existence of the chemical reaction instead of simple dissolution means that the carbon dioxide is not easily removed, *e.g.*, by continued flushing of oxygen through the solution, and is available in acidic form for titration with bases.

Oxidimetric determination of ascorbic acid with potassium hexacyanoferrate(III) in acid medium

(*Received* 21 *April* 1971, *Revised* 20 *August* 1971. *Accepted* 4 *October* 1971)

According to Kolthoff and Belcher[1] hexacyanoferrate(III) is obtainable in a high state of purity and serves as its own primary standard. It is a convenient oxidimetric reagent because of its stability in aqueous solution and its large equivalent weight. It is mostly employed for the determination of organic substances in neutral or alkaline media. It has been used for the determination of ascorbic acid by Hubicka[2] at pH 7, employing an amperometric technique and by van Pinxteren and Verloop[3] with a dead-stop end-point procedure in bicarbonate medium. Erdey and Svehla[4] proposed the visual titration of ascorbic acid with this reagent in a slightly alkaline medium buffered with sodium acetate, using 2,6-dichlorophenolindophenol as redox indicator. In an attempt to determine the redox potentials of the ascorbic acid $\rightleftharpoons$ dehydroascorbic acid system from potentiometric titration curves, Ball[5] reported that at pH 5 not only ascorbic acid but also dehydroascorbic acid reduces hexacyanoferrate(III). Abramov and Kadyrov[6] proposed the indirect determination in a slightly acid medium. After an aliquot of the ascorbic acid solution was reacted with a known and excessive amount of hexacyanoferrate(III) in the presence of zinc sulphate, the unreacted oxidant was treated with an excess of potassium iodide and the iodine liberated titrated with sodium thiosulphate, with starch as indicator. Sant[7] improved the method by direct titration in a medium buffered with zinc acetate to pH 6, with a starch-iodide end-point. In both cases, the zinc salt raises the redox potential of the hexacyanoferrate system towards the end-point by precipitating the hexacyanoferrate(II). At the higher pH the titration is likely to be vitiated by the reaction of dehydroascorbic acid with the oxidizing titrant, as stated by Ball. We have, therefore, undertaken this investigation to ascertain the conditions under which potassium hexacyanoferrate(III) can be used for the direct titration of ascorbic acid in acid medium with visual and potentiometric end-points.

EXPERIMENTAL

Reagents

Potassium hexacyanoferrate(III) solution, 0·1*N*. Stored in an amber bottle, and diluted as required.

Oxidimetric determination of ascorbic acid with potassium hexacyanoferrate(III) in acid medium

(*Received* 21 *April* 1971, *Revised* 20 *August* 1971. *Accepted* 4 *October* 1971)

ACCORDING to Kolthoff and Belcher[1] hexacyanoferrate(III) is obtainable in a high state of purity and serves as its own primary standard. It is a convenient oxidimetric reagent because of its stability in aqueous solution and its large equivalent weight. It is mostly employed for the determination of organic substances in neutral or alkaline media. It has been used for the determination of ascorbic acid by Hubicka[2] at pH 7, employing an amperometric technique and by van Pinxteren and Verloop[3] with a dead-stop end-point procedure in bicarbonate medium. Erdey and Svehla[4] proposed the visual titration of ascorbic acid with this reagent in a slightly alkaline medium buffered with sodium acetate, using 2,6-dichlorophenolindophenol as redox indicator. In an attempt to determine the redox potentials of the ascorbic acid ⇌ dehydroascorbic acid system from potentiometric titration curves, Ball[5] reported that at pH 5 not only ascorbic acid but also dehydroascorbic acid reduces hexacyanoferrate(III). Abramov and Kadyrov[6] proposed the indirect determination in a slightly acid medium. After an aliquot of the ascorbic acid solution was reacted with a known and excessive amount of hexacyanoferrate(III) in the presence of zinc sulphate, the unreacted oxidant was treated with an excess of potassium iodide and the iodine liberated titrated with sodium thiosulphate, with starch as indicator. Sant[7] improved the method by direct titration in a medium buffered with zinc acetate to pH 6, with a starch-iodide end-point. In both cases, the zinc salt raises the redox potential of the hexacyanoferrate system towards the end-point by precipitating the hexacyanoferrate(II). At the higher pH the titration is likely to be vitiated by the reaction of dehydroascorbic acid with the oxidizing titrant, as stated by Ball. We have, therefore, undertaken this investigation to ascertain the conditions under which potassium hexacyanoferrate(III) can be used for the direct titration of ascorbic acid in acid medium with visual and potentiometric end-points.

EXPERIMENTAL

Reagents

Potassium hexacyanoferrate(III) solution, 0·1*N*. Stored in an amber bottle, and diluted as required.

Ascorbic acid solution, 0·1*N*. Stabilized with a small amount of sulphuric acid, and standardized against potassium iodate. Diluted as required and standardized with iodate.

Demineralized water was used throughout because of the decomposition of ascorbic acid by traces of metallic impurities.

Visual titration in sulphuric acid medium

Oxidation of barium diphenylaminesulphonate by hexacyanoferrate(III) is rapid only when the sulphuric acid concentration is greater than 4*M* and reduction of oxidized indicator by ascorbic acid is rapid at all sulphuric acid concentrations $<5M$ but retarded at concentrations $>5M$. For this reason the range of acidity for titration should be 4–5*M* at the equivalence point. To 40 ml of 8*M* sulphuric acid in a 250-ml conical flask add 3–8 ml ascorbic acid solution and 1 drop of 0·2% solution barium diphenylaminesulphonate and titrate with hexacyanoferrate(III). The equivalence point is heralded by transient appearance of a violet colour. Towards the equivalence point, the titrant is added dropwise at 3–4 sec. intervals. The end-point is indicated by a violet colour stable for 2–3 min. At low ascorbic acid concentration (20–200 μg/ml) the consumption of hexacyanoferrate(III) is low by 1–2% because of aerial oxidation of the ascorbic acid, but the results are accurate if a carbon dioxide atmosphere is used and an indicator correction of 0·02 ml of 0·01*M* titrant is deducted. No inert atmosphere is necessary for more concentrated solutions. Typical results are given in Table I.

TABLE I.—TITRIMETRIC DETERMINATION OF ASCORBIC ACID WITH HEXACYANOFERRATE(III)

Amount of ascorbic acid, *mg*			
Taken	Found	Taken	Found
72·74	72·70	8·166	8·167
57·73	57·61	7·705	7·691
48·21	48·39	6·742	6·751
43·42	43·25	5·780	5·792
36·38	36·47	5·154	5·140
25·14	25·18	3·992	3·987
		3·280	3·284
		1·919	1·920

Interferences

A tenfold excess of oxalic, citric, tartaric, succinic, malic and acetic acids, and glucose, fructose and sucrose does not interfere.

Visual titrations in other acidic media

Similar results are obtained in 7–10*M* hydrochloric acid or 9·0–11·0*M* phosphoric acid. The end point is sluggish (10–30 sec between additions) in phosphoric acid medium, but an advantage is that even dilute solutions of ascorbic acid (0·005*M*) can be titrated in air.

TABLE II.—POTENTIOMETRIC TITRATION OF ASCORBIC ACID WITH HEXACYANOFERRATE(III) IN 10*M* PHOSPHORIC ACID

Amount of ascorbic acid, *mg*	
Taken	Found
24·13	24·22
29·44	29·44
38·71	38·55
48·78	48·78
58·02	57·76
66·95	66·95
73·55	73·47

Potentiometric titrations

For potentiometric titration a bright platinum rod is used as indicator electrode and a saturated calomel cell as reference electrode. In 4·5–5·5M sulphuric acid medium the potential stabilizes within 1 min in the early stages and 5 min at the end-point. The potential break is 100–120 mV per drop (0·04 ml) of 0·1N hexacyanoferrate(III), but the end-point is 1–2% lower than the true equivalence point. However, with rapid titration in an inert atmosphere and immediate reading of potential in the early stages and a wait of 1 min before readings near the end-point, an inflexion occurs at the true equivalence point. This implies that in a slow titration some aerial oxidation occurs.

Potentiometric titration in 10–12M phosphoric acid gives an end-point that corresponds to the true equivalence point and there is no need to maintain an inert atmosphere. Table II shows the relative error is 0·4%. The results are not affected by the presence of a 10–20 fold excess of sucrose, dextrose, citric acid, tartaric acid, malic acid and oxalic acid.

Microtitrimetric determination of uranium in nitric acid medium in the presence of excess of iron, magnesium and aluminium

(*Received* 15 *March* 1971. *Revised* 5 *July* 1971. *Accepted* 30 *August* 1971)

Davies and Gray[1] developed a method for titration of uranium(VI) with iron(II) in phosphoric acid medium after reduction to U(IV) and eliminated the interference of nitrate. Their method also avoids the sluggishness of reaction near the end-point that is experienced with the Rao and Sagi method.[2] The Davies and Gray procedure was developed for 200–300 mg amounts of uranium, and has since been applied to smaller amounts.[3-6] However, our attempts to scale it down (by a factor of 20) to cover submilligram levels were not immediately successful, and this paper describes the modifications found necessary.

EXPERIMENTAL

Reagents

These were the same as for the Davies and Gray method[1] except that 0·005*N* potassium dichromate was also used, and was prepared by dilution of the 0·05*N* reagent and standardized by titration of uranium.

Orthophosphoric acid, analytical-reagent grade

Procedures

A—for 0·1–3·0 mg of U
B—for 0·02–0·3 mg of U

Transfer 100 μl of sample (in 0–9*M* nitric acid) to a tall 50-ml beaker and dilute to 500 μl with water. Add 0·25 ml of 1·5*M* sulphamic acid, 2 ml of 85% orthophosphoric acid and 0·25 ml of 1*M* ferrous sulphate, mixing thoroughly after each addition (magnetic stirrer). Some sulphamic acid settles out after addition of the phosphoric acid, and after a while a fine, green, layer of U(IV) appears at the surface if there is more than 300 μg of U present. Add 0·5 ml of 4·0*M* nitric acid–0·1*M* sulphamic acid mixture and stir; the sulphamic acid precipitate then redissolves. Add 0·15 ml of 1% ammonium molybdate reagent and stir till the reaction mixture becomes grey, then stop the stirring and let the reaction take place. Bubbles evolve from the dark brown solution, and nitrous gases can be smelt. When the reaction is over (2–5 min) no bubbles are evolved and the solution is green or colourless. Immediately stir twice for 30-sec periods with a short (~1 min) break in between. After the first stirring, intensive evolution of N_2 and/or NO bubbles from the solution takes place; after the second, the evolution of bubbles is less intensive or only sporadic. Then add 1·25 ml of 9*M* sulphuric acid and stir similarly for two 30-sec periods. Immediately before the titration dilute the reaction mixture with 10·0 ml of distilled water and add 0·10 ml of 0·04% barium diphenylamine-sulphonate indicator solution. No nitrogen bubbles should evolve from the solution at this stage and any remaining crystals at the bottom are dissolved. Stirring continuously, titrate the solution with 0·05*N* dichromate (*A*) or 0·005*N* dichromate (*B*) from a 0·5-ml microburette till an intense red-purple colour persists for 1 min without fading.

In the proximity of the end-point it is necessary to wait after each addition of titrant, to see whether the solution is decolorized.

DISCUSSION AND RESULTS

Effect of orthophosphoric acid

The reduction of U(VI) to U(IV) by ferrous sulphate is quantitative in phosphoric acid medium if the phosphoric acid concentration exceeds 9·8*M*.[2] Scaling down of the Davies and Gray method should permit use of up to 0·75 ml of sample but it was found that high results were obtained. The safe limit is 0·5 ml of sample, if 85% orthophosphoric acid is used.

Effect of nitric acid

In the sample aliquot. According to Davies and Gray the permissible amount of nitrate in the sample aliquot is 50 mmole. According to Lindner *et al.*[3] the concentration of nitric acid in the sample should be 2–3*M*. Eberle *et al.*[6] consider that 3 g of nitrate can be tolerated in 15 ml of sample provided <1 mg of molybdenum is present. Under our experimental conditions, satisfactory results were obtained for 0·5-ml samples in which the concentration of nitric acid was 0·5–1·8*M*; low results were obtained for nitric acid concentrations between 1·8 and 6*M*.

In oxidation of excess of Fe(II). The most suitable means[1] of destroying the excess of Fe(II) is oxidation with nitric acid in the presence of molybdenum.[7] The optimum conditions require a certain range of nitric acid concentration in the reaction mixture, achieved by adding a constant volume of nitric acid–sulphamic acid mixture.

The limitation imposed by the need to have less than 0·9 mmole of nitrate present from the initial sample was dealt with by taking 100 μl of sample and diluting it to 500 μl before addition of the reagents. In this way the initial sample could be up to 9*M* in nitric acid, and the procedure was satisfactory for 0·5–9*M* nitric acid. If the nitric acid concentration was below 0·5*M*, however, the oxidation of excess of iron(II) became very slow (20–30 min), and it was found necessary to increase the amount of nitric acid–sulphamic acid reagent by 100% and of molybdate by 50% to make the oxidation sufficiently rapid. The method was then applicable even in the absence of nitric acid in the sample.

The disappearance of the dark brown colour of the nitrosyl iron(II) complex, and the removal of nitric oxide from the solution (which we think is very important) can be accelerated by efficient stirring. Short sharp bursts of stirring were found most effective, and necessary to prevent unwanted oxidation of uranium(IV). We had found that in the Davies and Gray procedure nitrogen bubbles were evolved during the beginning of the titration, and that although evolution of nitrogen had apparently ceased after the recommended standing time, stirring caused an intense release of gas bubbles. To us, this indicated the presence of unreacted nitrous acid or nitrite at the beginning of the titration, or the presence of at least traces of nitric oxide. Such a possibility does not seem to have considered earlier,[1,3] but the presence of nitric oxide or nitrous acid could cause oxidation of uranium-(IV) according to Slade's mechanism:[8]

$$U^{4+} + NO_3^- + H_2O \rightarrow UO_2^{2+} + HNO_2 + H^+ \qquad (1)$$

$$U^{4+} + 2\,HNO_2 \rightarrow UO_2^{2+} + 2\,NO + 2\,H^+ \qquad (2)$$

$$2\,NO + HNO_3 + H_2O \rightarrow 3\,HNO_2 \qquad (3)$$

In nitric acid medium uranium(IV) is oxidized slowly at first because (1) is very slow, but the rates of the autocatalytic reactions (2) and (3) are high, and some uranium(IV) will be oxidized if the NO or HNO_2 is not removed or destroyed. The reaction of nitrous acid with sulphamic acid is likely to be slower at low concentrations, so we considered it best to try to remove NO by vigorous stirring, to prevent reaction (3) from occurring, and the method proved successful.

Titration conditions

Scaling down of the Davies and Gray procedure by a factor of 20 gave satisfactory results. Dilution with more water, or use of more indicator, gave positive errors of up to 5%.

Cherry[9] has described an amperometric end-point method that was reported to give better precision and accuracy. Eberle *et al.*[6] found that addition of a vanadyl salt sharpened the end-point and improved the precision and accuracy.

Time factors

To avoid aerial or other oxidation of uranium(IV) the earlier methods[1,3,6] specify time schedules, especially for the period between destruction of excess of iron(II) and completion of the titration. This can constitute a problem if several analyses are to be done together. However, we have found the presence of excess of iron(II) prevents the oxidation of uranium(IV) for at least 2 hr; contrary to Lindner's statement,[3] individual treatment of each sample after this stage is not necessary at all, if the procedure proposed above is followed.

Effect of other ions

In the determination of 2·4 mg of uranium, the presence of 2·7 mg of aluminium, 2·4 mg of magnesium, and 11 mg of iron(II) and 0·5 mg of molybdenum(VI) in addition to the amounts added as reagents, caused errors of less then ±1·5%. The effect of other ions was described earlier.[1]

Accuracy and precision

By procedure *A*, 8 replicate samples containing 2440 μg uranium gave a mean of 2442 μg (range 2404–2478 μg). By procedure *B*, the error was less than 2 μg for 120–240 μg of uranium, but increased to 4 μg for 24–48 μg in the sample. The end-point was more difficult to detect when these low concentrations were used. No blank correction was found necessary; when blanks were determined they were found to be less than the average error.

V. MAREŠKA

Summary—The Davies and Gray procedure for determination of uranium in presence of nitric acid has been scaled down to permit the analysis of solutions 0–9*M* in nitric acid and containing 20–3000 μg of uranium. The original method required modification in the scaled-down version, the main alterations being removal of NO by rapid stirring during the oxidation of excess of iron(II), and an increase in the amount of two of the reagents. Several analyses can be done together.

Zusammenfassung—Die Methode von Davies und Gray zur Bestimmung von Uran in Gegenwart von Salpetersäure kann auf kleinere Mengen angewandt werden. Man kann dann 0–9*M* salpetersaure Lösungen mit 20–3000 μg Uran analysieren. Die Anwendung auf kleinere Mengen bedingt Änderungen der Originalmethode: die wichtigsten sind Entfernen von NO durch rasches Rühren während der Oxidation von überschüssigem Eisen(II) sowie größere Mengen von zwei Reagentien. Man kann mehrere Analysen zugleich ausführen.

Résumé—La technique de Davies et Gray pour le dosage de l'uranium en présence d'acide nitrique a été réduite à plus petite échelle pour permettre l'analyse de solutions 0–9 *M* en acide nitrique et contenant 20–3000 μg d'uranium. La mé'hode originale a nécessité des modifications dans la version à échelle réduite, les principaux remaniements étant l'élimination deNO par agitation rapide pendant l'oxydation de l'excès de fer (II), et un accroissement de la quantité de deux des réactifs. Plusieurs analyses peuvent être menées en même temps.

TALANTA REVIEW*

SYNTHETIC INORGANIC ION-EXCHANGERS—I

HYDROUS OXIDES AND ACIDIC SALTS OF MULTIVALENT METALS

V. VESELÝ and V. PEKÁREK†
Nuclear Research Institute of the Czechoslovak Academy of Sciences, Řež near Prague, Czechoslovakia

(*Received* 22 *March* 1971. *Accepted* 12 *September* 1971)

Summary—An exhaustive literature survey is given of the hydrous oxides and acidic salts of multivalent metals that are used as ion-exchange materials, the survey covering the preparation, properties, uses and theory of these materials.

DURING the last 10–15 years the inorganic ion-exchangers have firmly occupied their own position among the ion-exchange materials. A rapid development in nuclear energy, hydrometallurgy of rare elements, preparation of high-purity materials, water purification, *etc.*, has enforced attempts to find and synthesize new, highly selective ion-exchanging materials resistant to chemicals, temperature changes and radiation, and of more convenient properties than commercial organic or natural inorganic (soils, clay minerals, *etc.*) ion-exchangers.

A large number of synthetic inorganic substances has been described which exhibit ion-exchanging properties. These materials may be divided into the following main groups:

1. Hydrous oxides
2. Acidic salts of multivalent metals
3. Salts of heteropolyacids
4. Insoluble ferrocyanides
5. Synthetic aluminosilicates
6. Certain other substances, *e.g.*, synthetic apatites, sulphides, alkaline earth sulphates

A large number of papers dealing with the ion-exchange properties of these substances has been published. The excellent book by Amphlett[1] and the reviews by Churms[2] and Materova *et al.*[3] have covered this field up to 1964–5. However, during the last five years great progress has been made in development and study of the basic properties of these materials. We found it reasonable to review the papers appearing within the period 1965–70, with an attempt to cover the data published by the end of 1970. The present review is divided into two parts, the first covering hydrous oxides and acidic salts of multivalent metals, which have been the most intensively studied groups of synthetic inorganic ion-exchangers. The ion-exchange properties of the other substances will be reviewed in the second part.

HYDROUS OXIDES

The adsorptive properties of hydrous oxides, such as alumina, silica and ferric oxide have been known for many years and it has been established that the adsorption of ions by them is presumably by ion-exchange. In that sense the hydrous oxides are of particular interest because most of them can function both as cation and anion-exchangers, and under certain conditions both cation and anion-exchange can occur simultaneously. These substances are mostly amphoteric and their dissociation may be schematically represented as follows:

$$\text{M—OH} \rightleftharpoons \text{M}^+ + \text{OH}^- \qquad \text{(I)}$$

$$\text{M—OH} \rightleftharpoons \text{M—O}^- + \text{H}^+ \qquad \text{(II)}$$

(M represents the central atom)

Scheme **I** is favoured by acid conditions, when the substance can function as an anion-exchanger, and scheme **II** by alkaline conditions, when the substance can function as a cation-exchanger. Near the isoelectric point of the oxide,[2] dissociation according to both schemes can take place and both types of exchange may occur simultaneously.

A large number of compounds of this type has been studied in recent years,[1,2,4] some more extensively than others, with particular attention to deeper knowledge of the adsorption mechanism as well as to their application in chemical processing of radioactive materials and in water desalination processes. The progress during the last five years in studying the exchange properties of hydrous oxides will be reviewed in this section.

Hydrous oxides of bi- and tervalent metals

Hydrous oxides of bivalent metals

This group of exchangers includes hydroxides of Be^{2+}, Mg^{2+}, Zn^{2+} and their mixtures with ferric hydroxide and hydrous alumina.

Hydrous BeO of composition $BeO.1{\cdot}7H_2O$ acts both as cation and anion-exchanger[5,6] with the selectivity for alkali metal cations following the order of decreasing ionic radii of the unhydrated ions.[6] Magnesium hydroxide exhibits anion-exchange properties.[5] However, there has also been found an adsorption of Zn^{2+}, which is more co-precipitation within the $Mg(OH)_2$ than ion-exchange. The adsorption process obeys the Langmuir equation and in the case of large amounts of the adsorbate, a sigmoid isotherm was verified.[7] Very interesting phenomena were observed for mixed hydrous oxides. The adsorption isotherm of a mechanical mixture of $Mg(OH)_2$–2 $Fe(OH)_3$ was a superposition of the isotherms of both pure oxides and its hysteresis loop consisted of two parts, the first corresponding to coarse pores of $Mg(OH)_2$, and the second to fine pores of $Fe(OH)_3$. The hysteresis loop of co-precipitated hydroxides in the same ratio as in the mechanical mixture revealed uniformly porous material with a considerably lower volume of micropores in comparison to pure $Fe(OH)_3$, and a lower surface than that of the mechanical mixture. Co-precipitated specimens are more probably anomalous solid solutions not subject to the law of isomorphism. The $Mg(OH)_2$ phase was always present and $Fe(OH)_3$ was deposited in the $Mg(OH)_2$ pores and in layers of the $Mg(OH)_2$ crystal lattice, partially distorted.[8]

The mixture of Zn^{2+} and Al^{3+} oxides was employed for ^{35}S and ^{32}P decontamination from waste solutions.[9]

Hydrous oxides of tervalent metals

The tervalent metal hydroxides are still extensively studied, even though their sorption and separation properties are well known and have been reported in detail in many earlier papers.

The sorption properties of pseudomorphic iron hydroxide were studied with respect to its isoelectric point, which was found at pH 7·1–7·2.[10] Surface charge characteristics of microcrystalline particles of ferric oxide were measured in indifferent electrolyte solutions by potentiometric titration methods[11] and the surface area of iron hydroxides was determined on the basis of nitrogen and argon adsorption.[12] The sorption ability of $Fe(OH)_3$ decreases with increase in the dehydration temperature[13] and is lost on heating at 600°. Strongly sorbed cations are better separated on $Fe(OH)_3$ dehydrated at $\sim$450°, whereas less strongly sorbed cations require sorbents dehydrated at 300° or less.[14] Higher sorbability of cations occurs if the drying temperature is $\sim$125° and decreases in the order $H > Fe > Al > Pb > Ag > Cu > Zn > Cd > Mn > Ni(Co) > Ba$.[15]

The adsorption of phosphates,[13,16,17] sulphates[9] and chlorides[5] on ferric oxide in the form of sol, gel or ignited and crystalline samples was studied at different pH values. The adsorption isotherms more or less obey the Freundlich adsorption law but clear evidence of phosphate exchange for OH^- ions was not obtained.[9,16] The sorption capacity for PO_4^{3-} decreases on heating the sorbents, in correlation to the loss of H_2O from the precipitate. However, some capacity remains even after sintering at 1000°.[13] The sorption of VO_3^-, WO_4^{2-}, $Cr_2O_7^{2-}$ and MoO_4^{2-} anions was studied[18] and the adsoption mechanism, especially for MoO_4^{2-}, was examined in detail.[19] Dissolution of iron occurred during sorption of molybdate at pH 3–5.[10] The sorption of ^{131}I and ^{35}S in the form of the corresponding anions was examined and correlated with pH and electrokinetic properties of colloidal $Fe(OH)_3$ particles.[20]

For the adsorption of Cs, Na,[20] K,[12] and Ag[9] an ion-exchange mechanism was proved to be operative. The co-precipitation of nickel with $Fe(OH)_3$ was determined at different pH values[21] and in the presence of sodium and magnesium salts. A hydrolytic mechanism was observed in the absence of electrolytes but the presence of magnesium salts enabled the ion-exchange process to operate.[22] Electrolytes markedly increased the sorption capacity for nickel.[22] The adsorption of Zn^{2+}, Hg^{2+}, Mn^{2+} and Sr^{2+} ions as well as of amine complex-forming cations such as Co^{2+} and Zn^{2+} has also been presented.[17,23,24,25,26,27,46] Both hydrolytic and ion-exchange mechanisms were proved for copper adsorption.[28]

Hydrous Fe_2O_3 was successfully applied for the decontamination of waste water from ^{35}S, ^{32}P,[9,20] $^{106}Ru^{3+}$, $^{106}Ru(NO)^{2+}$,[29] $^{131}I^-$,[28,30] ^{137}Cs, ^{22}Na,[20] for Zn^{2+} isolation from rock samples,[24] and for daughter separation of ^{99}Mo–^{99m}Tc and ^{132}Te–^{132}I mixtures.[10]

A modified form of sorbent was prepared by co-precipitation of hydrated Ag_2O with $Fe(OH)_3$. The high sorption activity for ^{106}Ru, $^{106}Ru(NO)^{2+}$ and radiocobalt was examined.[29]

Hydrous alumina was also studied quite intensively, although its ion-exchange properties were known many years ago. The isoelectric points of α-Al_2O_3, α-$AlOOH$ and β-$Al(OH)_3$ are at pH 5·59, 6·78, and 6·80, respectively. The isoionic point and the point of exchange neutrality are dependent on the type and concentration of electrolyte present. The relationship between electrokinetic potential and ion-adsorption properties has been derived.[31] Dielectric loss measurements were made for single crystals of β-alumina suspended in α-alumina.[32] Adsorption of H^+ and OH^- ions at the alumina water interface and the heats of immersion of alumina in H_2O were measured. The minimum heat of immersion occurred at the equiadsorption point.[33] The rate of Na^+–H^+ exchange on hydrated Al_2O_3 decreased with increase in pH whereas the rate of Cl^-–OH^- exchange increased.[34] Irradiation of alumina ($>10^{15}$n/mm^2 γ-radiation dose of 10^7–10^9 rad) caused an increase in adsorption capacity.[35]

The dissociation of hydrated alumina occurs in the following stages: $Al(OH)_3 \rightleftharpoons Al(OH)_2^+ + OH^-$, $Al(OH)_2^+ \rightleftharpoons Al(OH)^{2+} + OH^-$, $Al(OH)^{2+} \rightleftharpoons Al^{3+} + OH^-$. The acid dissociation occurs according to the scheme $Al(OH)_3 \rightleftharpoons H_2AlO_3^- + H^+$.[36] The effect of pH on the ion-exchange capacity and selectivity of hydrated alumina for alkali metal cations and for univalent anions was determined at pH 4–11.[36,37,38] Saturation capacity for anions increased with decreasing pH.[36,39] Alumina showed a slight preference for Cl^- over NO_3^-,[5,36] and the affinity series $Cl > Br > I$ was established.[40] The same saturation capacity at a given pH has been shown to hold for Li^+, Na^+ and K^+. The selectivity increased in the order ($Li < Na < K$) of decreasing ionic radii of the hydrated cations. Alumina exhibits a strong preference for Cs.[36] Retention of Ca, Sr, Ba,[37,38] Zn,[23] Ni,[21] and La^{3+},[38] has been studied as a function of pH. The sorption of LiCl, $NiCl_2$, and $Cu(NO_3)_2$ was found to be partially irreversible.[38]

Applications include the following separations on hydrous alumina: Cl–Br–I,[40] ^{99}Mo–^{99m}Tc,[41] ^{35}S and ^{32}P from waste water,[9] and some thin-layer chromatographic separations.[42] Systematic study of the retention of a series of cations from $1M$ and $7M$ nitric acid and $1M$ perchloric acid by hydrous alumina has been reported with respect to possible separation applications.[43]

The use and properties of other tervalent metal hydrous oxides, such as MnOOH, $La(OH)_3$, $Sb_2O_3{\cdot}3H_2O$, $In_2O_3{\cdot}3{\cdot}5H_2O$, Ga_2O_3,[5] $Bi_2O_3{\cdot}3H_2O$[5,44] and $Cr(OH)_3$,[45] have so far been of limited interest.

Hydrous oxides of quadrivalent elements

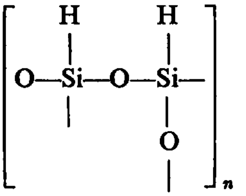
In recent years a systematic study has been made of the ion-exchange properties of quadrivalent ion oxides such as SiO_2, SnO_2, TiO_2, ThO_2, ZrO_2 and MnO_2. These oxides are usually described as hydrous oxides or hydrated hydroxy oxides and behave either as cation-exchangers in alkaline solutions or anion-exchangers in acid solutions, depending upon the basicity of the central atom and the strength of the M—O bond relative to that of the O—H bond in the hydroxyl group. Usually no sharp transition point from cation-exchange behaviour to anion-exchange behaviour exists, indicating the exchange sites to be heterogeneous. The basic ion-exchange properties of these materials have been described and reviewed earlier,[1,2,3] the recent progress in studying the exchange properties of these oxides will be reviewed in this section.

Hydrous silica

The use of silica gel as an ion-exchange substance has been extensively studied for many years.[47,48] The different types of hydrogels and xerogels are the compounds most studied, as compared with other ion-exchange materials of the oxide type.

Although the ionic adsorption mechanism on silica gel has not so far been fully established, it can be said that silica gel generally acts as a weakly acidic cation-exchanger.[49,50,51] The surface of this material is covered with OH–silanol groups, with a density of 4·6–8·0 groups per 10·0 nm,[52] ($\sim$7·8 μmole OH^-/m^2),[53] which are strong hydrogen-bond donors and may be determined by titration.[54] The conventional silica gel is an agglomeration of spheroids with diameters of the order of 10 nm, cemented by interparticle siloxane ($\equiv$Si—O—Si$\equiv$) links.[52] The aggregation is predominant near the gelation point. The aggregates, with a porous and sponge-like structure, grow to as much as 80 nm in diameter.[55] The porosity (of some hundred m^2/g) reflects this structure.[52]

A great variety in adsorption properties occurs as a result of different methods of preparation of the sorbents. Specific surfaces and porosities, which are mostly connected with the sorption activities of the sorbents, may vary widely.[56,57] High surface area silica gel was prepared by the controlled acid extraction of metal silicates and subsequent vacuum activation at 200°.[58] A soaking of preheated silica in hot hydrochloric acid was found to increase its silanol group content as well as its porosity.[59] Treating the hydrogel with higher hydrofluoric acid concentrations and subsequently aging it increases the pore volume of SiO_2 and diminishes its surface area.[60] Various geometrically modified wide-pore silica gels with low specific surface area have also been prepared by hydrothermal treatment of xerogels in an autoclave. Besides wide pores there are ultrapores accessible to H_2O but inaccessible to C_6H_6, CH_3OH and Kr molecules. Ultrapores are diminished by calcination in steam at 750°.[61] On hydrothermal treatment of hydrogels, no ultrapores were formed.[62] Modified silica sorbents with enhanced selectivity were prepared by the pretreatment of silicic acid hydrogels with various azo-dyes related to Methyl Orange, and with amines.[63,64] Silica gels with porous structure are formed by hydration of



$$\left[\begin{matrix} & H & & H & \\ & | & & | & \\ O- & Si & -O- & Si & - \\ & | & & | & \\ & & & O & \\ & & & | & \end{matrix}\right]_n$$

xerogels: $\equiv Si—H + H_2O \rightarrow \equiv Si—OH + H_2$.[65] Storage of the silicic acid xerogels makes their structure denser and decreases their adsorption activity, probably as a result of the influence of moisture.[66] Distinct cation-exchange properties with a capacity of 0·46 meq/g were obtained by treating SiO_2 with phenyltrichlorosilane in oleum.[67] Highly active silica gels were prepared by drying the wet gel (pH 7) in benzene, toluene or xylene and aging the product for 48 hr. The capacity of such a product was 2·5–3 times that of commercial silica gel.[68] On the other hand the dehydration pretreatment of silica gel by boiling with aromatic liquids leads to a decrease in capacity[69] and to deterioration of selectivity, even if surface homogenization has occurred.[70] The specific surface and porosity of silica gel are the decisive factors[71,72] influencing its sorption behaviour. For the determination of specific surface the sorption of $Zn(NH_3)_4{}^{2+}$ and $Zn(en)_3{}^{2+}$ complexes was recommended.[49] Specific surface charge density is closely connected with the surface phenomena of the sorbents. From surface charge-density measurements it was concluded that surface charge increased in the order $(C_6H_5)_4N^+ < Li^+ < Na^+ < K^+ < Cs^+$.[152] This series was in good agreement with the order of sorption affinities towards alkali metals for preparations having more than 50% of the surface area associated with pores with radii between 1·0 and 3·0 nm.[73,74]

Proton relaxation measurements of H_2O adsorbed on silica gel indicate that in most cases the proton relaxation of adsorbed liquids and gases is caused by the proton–proton dipole interaction and by the coupling between protons and paramagnetic impurities (*e.g.*, Fe^{3+}) in the sorbent.[75] The properties of adsorbed water were found to be different from those of interstitial water.[76] The molecular adsorption of H_2O on silica gel is based on hydrogen bridges formed between H_2O and hydroxylic groups on the sorbent surface.[77] The content of molecular and hydroxylic water was examined within the temperature range 100–1000° by infrared,[78] NMR,[79] and thermogravimetric methods. EPR measurements show the loss of the surface hydroxyl functional groups and the formation of $\equiv SiO^-$ radicals after γ-irradiation of SiO_2.[80]

The changes occurring in silica gel on thermal treatment have been widely examined. The adsorption ability of sorbents gradually decreases as they are heated to 100–300°, but in the temperature range 300–1000° substantially increases, *e.g.*, for Rb^+.[81] This increase is explained by the conversion of the original compound of $\equiv\mathrm{Si}\begin{smallmatrix}\diagup\mathrm{OH}\\ \diagdown\mathrm{OH^-}\cdots\mathrm{H_3O^+}\end{smallmatrix}$ by calcination at over 500°, probably to $=\mathrm{Si}\begin{smallmatrix}\diagup\mathrm{OH}\\ \diagdown\mathrm{OH}\end{smallmatrix}$ and $-Si(OH)_3$ compounds, which have higher capacities.[81] Great changes in the physical properties of the sorbent are caused by hydrothermal treatment[82,83] up to 1050°. Thus the surface area decreased from 580 to 25 m^2/g, mean particle size increased from 5 to 105 nm, and mean total pore volume increased from 0·74 to 2·31 ml/g.[83] On heating of silica gel at 200–400° in vacuum, the density of surface OH^- groups was lowered to a minimum value of 3·5 μmole OH^-/m^2, but at temperatures $>400°$ the destruction process was substantially retarded.[53] On the other hand the presence of Na^+ in the gel enhanced the calcination effect.[84] The degree of hydration can be determined by the interaction of $TiCl_4$ with the OH^- groups of SiO_2.[85] The solubility and the dissolution kinetics of precipitated amorphous silica in 1*M* $NaClO_4$ have been discussed.[86]

The adsorption mechanism of non-hydrolysing cations on silica gel is mostly interpreted in terms of ion-exchange:[71,87–90] $m(\equiv SiOH) + M^{n+} \rightleftharpoons [(\equiv SiO)_mM]^{m-n} + mH^+$ ($m = n$ for all systems examined).[87] There are some suggestions that besides this mechanism physical adsorption and ion exclusion from small pores may also occur even for alkali metal ions.[73] These conclusions, however, conflict with the results of other authors, where only ion-exchange is postulated, especially for alkali metals.[74] Special attention is paid to $Al(OH)_3$ impurities in the crystal lattice of SiO_2. In contradiction to earlier papers, the sorption process at pH $<8{\cdot}0$ is said to be unaffected by the presence of $Al(OH)_3$ in the sorbent.[91] Adsorbed cations are weakly bound to the surface sites of silica gel and are readily exchangeable.[52] Affinity for the surface is governed by the electron density distribution in the surface area and between $\equiv SiO^- \cdots M^{n+}$ bonds.[93] Generally, the affinity increases, going from univalent to tervalent elements.[51,94] For elements of the same charge, the adsorption is enhanced by decrease in the crystallographic diameter, *e.g.*, RbOH < KOH < NaOH < LiOH, $Ba^{2+} \sim Sr^{2+} < Mg^{2+} < Be^{2+}$, and $In^{3+} < Ga^{3+} < Al^{3+}$.[91,94,95] However, these affinity series may be dependent upon the type of the sorbent used or on the experimental conditions applied. There are great differences in the results presented, especially for univalent and bivalent cations, and quite opposite affinity series have been found.[73,91,94,96] The mechanism of ion-exchange is supported by the shift of the infrared vibration of the $\equiv SiO^- \cdots M^{n+}$ bond. The adsorbability of the transition metal ions on the Ca form of silica gel increases as their charge increases. The limiting value for the uptake of M^{3+} ions is 3·2–4·5 meq/g and of M^{2+} ions 1·8–2·5 meq/g. There is a steady increase in the adsorption of tervalent ions with an unfilled *f*-shell, in the order La < Ce < Nd < Gd < Tb < Y < Er < Tm < Yb < Lu < Sc, *i.e.*, with decrease in their ionic radius.[93] The results are in agreement with the idea of the possible contribution of covalent bonding as well as of electrostatic forces to the energy of the adsorption bond Si—OM. Labile co-ordination complexes, *e.g.*, *trans*-$Co(en)_2Cl_2^+$, are also adsorbed by SiO_2. Adsorbed inert complex cations which contain an aquo ligand react with surface silanol groups to bind $\equiv SiO^-$ in the co-ordination sphere, and in media of low dielectric constant $\equiv SiO^-$ can directly displace Cl^- in the absorbed *trans*-$Co(en)_2Cl_2^+$.[52]

The values of specific surface area as well as the pore diameter are decisive for the kinetics of exchange reactions. The rate of exchange in the case of colloidal silica was governed by both film and particle diffusion mechanisms. Preheated silica samples give a fast uptake process followed by a slow one. The first process is mainly chemically controlled, the second is governed by chemical reaction as well as by particle diffusion.[59]

Of the univalent cations, the sorption of alkali metals has been mostly studied.[57,73,74,81,90,94,95,97] Alkali metal dichromates react reversibly with the surface of silica gel. The reaction has been shown to occur either by adsorption or by equivalent exchange of cation and anion.[98] The adsorption of Ag^+ increases with increasing pH with a high uptake of 7·96 mmole per mole of SiO_2 at pH 7·86.[99] The Ag^+ adsorbed on SiO_2 is reduced to metallic Ag, as proved by EPR measurements.[157]

The sorption of bivalent cations on different SiO_2 preparations has been examined.[49,90,94,100,101,102] Ionic forms of hydrogels and the structure of the globules of polysilicic acid xerogels have been studied with respect to different forms of the sorbents (Ca^{2+}, Na^+, Li^+, and H^+) and to the sorption properties of bivalent and tervalent cations at pH 3.[103] Silica gel in the Mg form exhibits the following sorption affinity series: Cu > Ni > Zn > Mg.[104] The adsorption of *tris*-phenanthroline complexes with Zn^{2+}, Cu^{2+}, and Fe^{2+} was found to occur as a pure ion-exchange process.[105] Ion-exchange adsorption of $Zn(NH_3)_4^{2+}$ and $Zn(en)_3^{2+}$ complexes is independent of pH in the pH interval 6·00–9·20 and on the surface areas from 50 to 500 m^2/g.[49] The H^+–Cu^{2+} exchange[57,72] is strongly dependent on pH, specific surface and pore diameter of silica gel. Only 60% of the OH groups can react with the Cu^{2+} ion and the compound $0{\cdot}6$–$0{\cdot}9CuO{\cdot}SiO_2{\cdot}nH_2O$ is formed. In all the ion-exchange stages molecular sorption on the SiO_2 surface and skeleton occurs. Narrow-pore samples can adsorb Cu^{2+} ions less than can wide-pore silica; after Cu desorption the skeleton is capable of adsorbing more water molecules than it could originally. The electron reflectance and ESR spectra of a series of Cu^{2+}, Ni^{2+} and Co^{2+} complex cations with multidentate nitrogen ligands adsorbed on SiO_2 gel were examined and discussed in terms of adsorption mechanism.[153–156] The EPR method was applied to the study of Mn^{2+} ions adsorbed on silica gel sorbents.[106]

The adsorption of tervalent cations such as Al, Ga, In, Tl, Bi, Fe, and Cr has been studied over a wide range of pH and silica gel products.[90,94,97,103] The extent of adsorption of Al^{3+} from an acetate buffer by coarsely porous silica gel does not exceed significantly the number of the hydroxy groups present on the surface of the sorbent.

During the adsorption the sorbents depolymerize. The quality of the dissolved silicic acid is improved in proportion to how much Al^{3+} goes over into the composition of the solid phase.[107] For the adsorption of $FeCl_3$, $AlCl_3$, and $CaCl_2$ from $SnCl_4$ media, the differential adsorption heats were found to be 31·2, 47·7 and 23·8 kJ/mole, respectively.[101,108]

The adsorption of multivalent cations such as Pa, Zr, Nb, Ac, Th, U, from concentrated acid solutions has been studied.[51,59,100,109,110] The most favourable pH for Th adsorption was 2·5–2·9 and the adsorption process was irreversible.[111] Special attention was paid to Zr adsorption. The adsorption process and elution rate are highly dependent on the acidity of the original solution and the kind of anion.[51,112] Zr and Hf are probably hydrolysed after diffusion into the silica gel phase.[113] The break-through capacity corresponds to 0·6–0·7 mg atoms of Zr per g of SiO_2.[114] Zirconium adsorption is substantially increased in the presence of phosphoric acid, which is explained in terms of molecular adsorption of neutral phosphate complexes of Zr.[115]

The adsorption mechanism of hydrolysed cations on SiO_2 is very complicated and only qualitative conclusions are drawn from the experimental results. Besides the ion-exchange process, surface adsorption phenomena are supposed to occur with many hydrolysates,[71,88] *e.g.*, the adsorption of heavy metal ions on silica gel from solutions of high pH is treated as occurring in two stages: (1) ion-exchange of the acid H^+ on silica gel for a heavy metal ion; (2) establishment of adsorption equilibria for molecular adsorption of a slightly soluble metal silicate on the silica gel network. The law of mass action is then applied.[116] Hydroxides react with SiO_2, forming the following anions: $\equiv SiO^-$, $\left[\begin{array}{l}\equiv Si{-}O\\ \qquad\ \ |\\ \equiv Si{-}OH\end{array}\right]^-$, and $\left[\equiv Si\begin{array}{l}\diagup OH\\ \diagdown OH\end{array}\right]^-$.[52] The adsorption of $Ca(OH)_2$ on different silica gels with specific surfaces areas ranging from 51 to 693 m^2/g proceeds in two stages. The fast adsorption stage is connected with an ion-exchange process, the subsequent slow one with the formation of a new, $CaSiO_3$, phase.[117] The adsorption of hydrolytic products of Co, Mn, Cu, Ni and Zn tracers was found to increase with increase in pH. These hydroxo-complexes are adsorbed by an ion-exchange mechanism, except for Cu.[118] The same adsorption increase with pH was observed for Th^{4+}, Fe^{3+}, Al^{3+} and Cr^{3+} hydrolysates. Thorium was adsorbed as $[Th(OH)]^{3+}$ and $[Th(OH)_2]^{2+}$, and as $[Th(CH_3COO)_3]^+$, $[Th(OH)(CH_3COO)_2]^+$, and $[Th(OH)_2(CH_3COO)]^+$ from acetate buffers. Other hydrolytic complexes were adsorbed in the forms of $[Al(OH)(H_2O)_5]^{2+}$, $[Al(CH_3COO)(H_2O)_5]^{2+}$, $[Fe(CH_3COO)]^{2+}$ $[Fe(CH_3COO)_2]^+$, $[Fe(OH)(CH_3COO)]^+$, $[Cr(H_2O)_6]^{3+}$, $[Cr(OH)_6]^{3-}$ and $[Fe(CH_3COO)_3]$.[119,120] Zirconium hydroxo-complexes were found to be adsorbed even from highly concentrated nitric acid solutions.[112] The cationic and neutral hydroxo-complexes of Zr and Hf are supposed to be adsorbed by molecular adsorption.[113] In the case of protactinium the neutral or anionic hydroxo-complexes are quickly adsorbed over the acidity range 4–10*M* hydrochloric acid; at higher acidities the adsorption of $H_{(x-5)}PaCl_x$ is supposed to occur. The sorption of neutral bisulphate complexes was established for the concentration range 3–7*M* sulphuric acid. The cationic hydroxo-complexes are adsorbed much more slowly. The adsorption process for the compounds mentioned above has features of molecular adsorption.[110] Adsorption of Pa from hydrochloric and sulphuric acid media follows the Freundlich adsorption isotherm and decreases with increasing acidity.[121] The adsorption of Nb and Ta hydrolysates from hydrochloric, nitric, sulphuric and perchloric acid solutions onto hydrous and silicon-treated SiO_2 was observed. Lower adsorption occurred on silicon-treated sorbents. Mixed neutral complexes of niobium, $Ta(OH)_5$ and $Ta(OH)_mCl_{(5-m)}$ are supposed to be adsorbed.[122,123]

The sorption of different cations on silica gel from organic and mixed aqueous–organic media has also been studied. LiCl, $LiNO_3$ and NaI, dissolved in acetone, react reversibly with the sorbent without ion-exchange. The extent of reaction is enhanced by the addition of small amounts of water.[124] The mixed aqueous–organic solutions have the following important effects on the adsorption: solvation and complex formation, salting-out of the complexes from the liquid into SiO_2, and selective uptake of the solvents. The partition of Zr, Hf, Nb and Ta between SiO_2 and 1–10*M* hydrochloric acid in the presence of 0–90% v/v of methanol, ethanol, isopropanol, acetone and dioxan in water was determined.[125] The adsorption of Zr and Hf was increased with increase in the amount of organic component. At higher alcohol content in acid solutions no sorption occurred of the elements of groups I, II, and III and of U^{6+}, Fe, Al and Th.[114] On the other hand, a sudden drop of Nb adsorption was achieved in the presence of dioxan,[126] and a gradual decrease in adsorption of Pa and of the reaction rate was found with increase in the organic component concentration.[127,128]

Many papers deal with the use of silica gel for the separation of individual elements or groups of elements in different combinations. The following separations have been described: Na–Rb–Cs–Fr.[96,129] Tl–Bi;[97] LiCl, $LiNO_3$, NaI—isolation from acetone;[124] Cs–Hf;[114] Cs from waste water;[130,131] Sr from waste water;[92,130] Co–Ni;[87] Co–Cu, Zn, Ni, Tl;[132] Cu from waste water;[133] $Cu–Cr^{6+}$;[134] Zn—determination in Cu;[87] Zn–Cu, Ag, Ni, Cd, Co, Fe, Mn, W;[102] Al–Fe;[87,120] Fe, Al–Sr, Cu, Zn, Co, Ni, Mn;[120] Eu–Zr–Hf;[135] Ce from waste water;[130] Bi–Pd, Tb;[97] Zr–Nb;[126] Zr, Nb–Sr, Ce, Ru, Al;[136] Zr–K, Na, Ca, Mg, Zn, Mn, La, Al, Fe, Ti, Th;[137] Zr–Hf on the macro-scale;[138] Zr–Cs, Sr, Eu;[114] Zr, Hf–La, U^{6+}, Fe, Al;[114] Zr, Hf–alkali metals, alkaline earth metals, rare earth elements, Al, Fe, Th, U^{6+};[135] Zr–Pa–Hf–Nb;[128] Zr–minerals;[51] Zr–bulk concentration of Th;[139] Nb–Ta;[123] Hf–Eu;[114] Pa–U ores;[128] Pa–irradiated Th;[100,128,140,141] Pa–U;[141] $Pa^{4+}–Pa^{5+}$;[142] U–Pu–fission products;[143,144] Cr^{6+}–Cu, Ni, Zn, Cd;[134] Sr–Hf;[114] Fe^{2+}–Cu, Hg, Cd, Zn, Ni, Bi;[87] Co^{2+}–Cu, Hg, Cd, Zn, Bi.[87]

Thin-layer chromatography[42,71] has also been applied for studying the adsorption of Li, Na, K, Rb, Cs, Ca, Sr, Ba, Al, Zn, Cd and Hg^{2+} cations on SiO_2,[88,145] for mutual separation of phosphate, pyrophosphate, phosphite and hypophosphite,[146] and for Sr–Y, Ba–La and Ba–Cs[147] separations.

Special attention has been paid to those sorbents of which silica gel is one of the main structural components. Acid treatment of silicic acid gels co-precipitated with various metal hydroxides, such as $Fe(OH)_3$, $Pb(OH)_2$, $Co(OH)_2$, $Cr(OH)_3$ and $Mg(OH)_2$, gives samples of silica gels with essentially different porosity types. Mild acid treatment with diluted acids at room temperature retains a porous type of co-precipitate gel in the product. A more vigorous acid treatment at boiling point yields silica gels of mixed porosity.[148] Silica–alumina sorbents with the Al/Si ratio of 1/3 have cation-exchange properties.[149] The rates of exchange[150] as well as the adsorption isotherms for $H^+–NH_4^+$ and $H^+–Mg^{2+}$ ion-exchange[149] were studied with this sorbent. The protonic sites on the silica–alumina solid can form 2- or 3-co-ordinate bonds on the surface. The strongly protonic acid sites disappear when the product is calcined at 1000°. The weak, remaining protonic acid sites exchange only at pH > 8 with univalent cations such as NH_4^+.[151]

Stannic oxide

Hydrous stannic oxide is prepared by the acidification of sodium stannate solution or by the reaction of nitric acid with tin metal.[158] By the former procedure α-stannic acid is formed, and β-stannic acid by the latter. The products are stable towards highly concentrated nitric and sulphuric acid solutions.[158]

X-Ray, DTA and Mössbauer spectra measurements[158] suggest that the exchanger is "wet" SnO_2 and that SnO_2 is simply a host for adsorbed water, which itself must act as the exchanger.[158] Thus it may be formulated as $SnO_2 \cdot xH_2O$.

Hydrous stannic oxide behaves both as cation- and anion-exchanger,[158,159] especially selective for bivalent transition metal and uranyl ions. It is interesting that the selectivity series[158] $Cu > Zn > Co \geqslant Fe(II) > Ni > Mn$ closely parallels the order of the equilibrium constants of the hydrolytic reaction $M^{2+} + H_2O \rightleftharpoons MOH^+ + H^+$. Alkaline earth metal cations are weakly adsorbed[160] whereas tervalent metal ions such as Al^{3+} and Cr^{3+} are strongly adsorbed. A co-precipitation rather than an ion-exchange mechanism is suggested for the adsorption of the latter ions.[158] The selectivity series $PO_4^{3-} > C_2O_4^{2-} > SO_4^{2-} > Cr_2O_7^{2-} > Fe(CN)_6^{4-} > Fe(CN)_6^{3-} > Cl^- > MnO_4^- > Br^- > I^-$ has been reported[159] for the exchange of anions.

Hydrous stannic oxide is suitable for column separation of bivalent transition metal ions (Cu–Zn, Cu–Co, Cu–Fe, Cu–Ni, Cu–Mn, Mn–Zn, Mn–Ca, Co^{2+}–Fe^{3+}).[160] Separations of W(VI) from solutions containing Mo(VI) and Fe(III)[161] and the removal of UO_2^{2+} and transition metal ion contamination from aqueous solutions have been described.[159] The exchanger, in NH_4^+ from, is suitable for alkali metal and alkaline earth separations.[159] High selectivity for Cu^{2+} ions enables their separation to be made by co-precipitation with hydrous stannic oxide.[162] The anion-exchange behaviour of hydrous stannic oxide has been used for the separation of $Cr_2O_7^{2-}$–MnO_4^-.[159]

Titanium oxide

Hydrous titanium oxide is prepared by mixing titanyl oxalate or $TiCl_4$ solutions with sodium hydroxide.[163,164] The precipitates obtained are usually dried at room temperature[163] or at 400°.[163,165] White amorphous products are obtained which lose free or interstitial water up to 200° and chemically bound water at higher temperatures (200–500°). The amount of chemically bound water is very low (1–2%).[164] Infrared measurements[164,166] indicate the presence of H_2O molecules more or less bonded to the solid and also of OH groups bonded to the metal atom. Similar measurements made on analogous hydrous oxides of Zr, Hf and Th[166] have shown that the number of OH groups bonded to the metal atom is the lowest for Ti and the highest for Th. Further, a correspondence has been found between the infrared Ti–O absorption band (and also of Zr–O, Hf–O and Th–O bands) of the hydrous oxide and that in the crystal oxide after thermal treatment. Hydrous titanium oxide is thus formulated as a hydrated hydroxide oxide of a general formula $TiO_{(2-x)}(OH)_{2x} \cdot yH_2O$,[166–168] with x probably <1 However, the formula $TiO(OH)_2 \cdot nH_2O$ has also been proposed.[164]

Hydrous titanium oxide is insoluble in acid as well as in alkaline solutions.[163] The exchanger is very suitable for use in column operations and can be easily regenerated for reuse.[163]

Titration curves of this exchanger exhibit three characteristic points indicating the polyfunctional character of the exchanger.[169,170] There are three protons exchangeable for every 10 Ti atoms.[169,170] The constants for the successive dissociation of the three protons were determined.[169]

The exchange capacity of hydrous titanium oxide is dependent on pH, ranging from ~2·0 meq/g at pH ~12·5 for Ca^{2+} and Sr^{2+} to ~1·5 meq/g at pH ~4 for Co^{2+}, Ni^{2+} and Cu^{2+}.[164] Samples heated up to 400° still show a high exchange capacity.[164] Distribution coefficients for the exchange of Na^+, Rb^+, Cs^+, Sr^{2+}, Ni^{2+}, Co^{2+}, Fe^{3+} and Cr^{3+} have been determined.[164] The affinity series $Na < Rb < Cs$ has been found for alkali metal ions; the affinity series of transition metal ions coincides with the stability order of the respective complexes, *i.e.*, $Cu > Ni > Co$. The plots of $\log K_d$ *vs.* $\log [H^+]$ are linear for the exchange of univalent and bivalent cations, with slopes corresponding to the valency of the ion exchanged.[164] However, species such as $SrOH^+$ are adsorbed in the case of Sr^{2+}. In alkaline solutions the adsorption of Sr^{2+} led to the formation of a crystalline compound with a 1:1 Sr:Ti ratio.[169] Such behaviour was not observed for the sorption of alkali metal cations.[169] High adsorption of Fe^{3+} was ascribed to the formation of a stable chemisorption bond between the hydrated oxides of Ti and Fe.[171]

Thermodynamic equilibrium constants of the Cs^+–H^+ and Na^+–H^+ exchange[169,172] have been determined from the adsorption isotherms for the three exchange stages (Cs^+–H^+: $10^{-3\cdot29}$, $10^{-5\cdot47}$, $10^{-7\cdot60}$, Na^+–H^+: $10^{-3\cdot81}$, $10^{-6\cdot28}$, —). For the Tl^+–H^+ exchange, six exchange stages have been found with the following constants: $10^{-0\cdot52}$, $10^{-1\cdot97}$, $10^{-3\cdot42}$, $10^{-4\cdot87}$, $10^{-6\cdot32}$, $10^{-7\cdot77}$.[173]

Kinetic measurements on the Cu^{2+}–H^+ exchange[163] indicate that the rate of exchange is diffusion controlled, with the diffusion coefficient of ~2·5 . 10^{-4}mm^2/min and activation energy of 20·3 kJ/mole.

High chemical and radiation stability as well as good mechanical properties of hydrous titanium oxide permitted its application for the removal of Pu and certain fission products (Ru, Zr, Nb) from alkaline (Na_2CO_3) media[174] or from highly radioactive solutions[175] as well as for concentrating uranium from sea-water.[176] The use of papers impregnated with hydrous TiO_2 has been reported for the separation of U,Ni,Co,Cu and Fe(III).[177] Hydrous titanium oxide has been also described as a co-precipitating agent for small amounts of In^{3+}, SeO_2^{2-}, PO_4^{3-} and Cu^{2+}.[162,178,179,180]

Thorium oxide

Hydrous thorium oxide is usually prepared by mixing thorium nitrate solution with alkalis in various initial ratios of the reactants.[163] White, glassy-looking, amorphous products are obtained, which lose free or interstitial water on heating up to 200° and bonded water up to 500°.[164] The results of thermogravimetric (TGA), DTA, X-ray and infrared analyses suggest that the samples dried at room temperature contain Th-O and OH groups as well as H_2O molecules and that the general formula may be written as $ThO(OH)_n \, . \, nH_2O$.[164] On heating of the exchanger *n* decreases owing to the water loss, which is accompanied by a decrease in surface area.[164] The formation of cubic ThO_2 was observed on heating to over 300°.[181]

Hydrous thorium oxide behaves both as cation- and anion-exchanger. Relatively high capacities for Ca^{2+} and Sr^{2+} ions have been found at pH $\sim 12(\sim 2{\cdot}0$ meq/g), which decreased substantially with decreasing pH. An anion-exchange capacity of $\sim$1 meq/g has been reported for acid solutions.[163] The distribution coefficients determined for Na^+, Rb^+, Cs^+, Sr^{2+}, Cu^{2+}, Ni^{2+}, Co^{2+}, Fe^{3+} and Cr^{3+} show a regular selectivity series for alkali metal cations ($Cs > Rb > Na$). The selectivity series of transition metal ions ($Cu > Ni > Co$) coincides with the stability order of the respective hydroxo-complexes,[164] similarly to the behaviour of hydrous Sn and Ti oxides.[158,164]

Kinetic measurements have been made for the Cu^{2+} and Sr^{2+} exchange.[163] The Bt *vs.* t plots are linear[163] indicating a diffusion-controlled exchange process ($B = \pi^2 D/r^2$, where D is the effective diffusion coefficient of ions within the exchanger and r is the radius of the exchanger spherical particles; t = time). The reaction rate is very slow in comparison with other hydrous oxides.[163] The diffusion coefficient for the Cu^{2+} exchange ($2{\cdot}2 \times 10^{-5}$ mm^2/min) and activation energy (about 71 kJ/mole) have been estimated.[163]

It is interesting that heated ThO_2 possesses adsorption ability towards phosphates, the process being very probably solution diffusion-controlled with an activation energy of 12·5 kJ/mole.[182] The formation of thorium phosphate was found to occur on co-precipitation of phosphates with hydrous thorium oxide.[180]

Hydrous thorium oxide in mixture with other inorganic ion-exchangers has found good application in inorganic ion-exchange membranes. Thus membranes made from hydrous ThO_2 and CeO_2 are stable at high temperatures, are unaffected by corrosive and oxidizing agents and can be used for demineralization of saline water.[183] Similarly, combined anion/cation-exchange membrane systems consisting of ThO_2 and zirconium phosphate[184,185] or ThO_2 mixed with other oxides, and zirconium phosphate membranes have been reported for the same purpose.[186]

Zirconium oxide

Hydrous zirconium oxide is usually prepared by mixing zirconium salt solutions with alkalis. Well granulated materials are obtained by freeze-drying the gels at 268, 263 and 258 K.[187] This procedure does not affect the ion-exchange capacity and is suitable also for the preparation of other granular hydrous oxides.[187] An exchanger of suitable mechanical properties has also been prepared as a mixed hydrous ZrO_2–hydrous SiO_2 gel.[188]

Although the structure of amorphous hydrous zirconium oxide has not yet been properly resolved, a tetrameric structure is suggested, based on the known tetrameric species in hydrolysed Zr(IV) salt solutions, for the freshly prepared zirconium hydroxide—$[Zr(OH)_4]_4$. On aging, the $[ZrO(OH)_2]_4$ structure is formed.[189] The evidence for the presence of hydroxyl groups was found by Clearfield.[190] X-Ray data on crystalline zirconium hydroxide suggest a structure which is analogous to ZrO_2, *i.e.*, $[ZrO_2]_n$, with H_2O and OH groups.[191]

Hydrous zirconium oxide behaves both as cation- and anion-exchanger[192,193] with the zero-point of charge at pH 6·05.[194] Thermodynamic equilibrium constants of ion-exchange reactions of some alkali metal cations[195] and some anions[196,197] have been determined by Nancollas *et al.* and are summarized together with the corresponding thermodynamic quantities in Table I.

TABLE I.—THERMODYNAMIC QUANTITIES FOR ION-EXCHANGE ON HYDROUS ZrO_2[195–197]

System	*K*	$\Delta G°$ *kJ/mole*	$\Delta H°$ *kJ/mole*	$\Delta S°$ *J/mole/K*
Li^+–K^+	40·2	−3·4	1·0	15
Na^+–K^+	1 52	−1·0	0·3	5
Cl^-–NO_3^-	1·04	−0·6	4·1	16
SCN^-–NO_3^-	1·94	−1·6	−7·8	3
SCN^-–Cl^-	1·54	−1·2	−4·8	−13

The thermodynamic equilibrium constants for alkali metal cations show an unusual affinity series, Li > Na > K,[195] in contradiction to the earlier reported affinity series.[1] It has been found[195] that all the Li^+, Na^+ or K^+ forms of the exchanger contain the same percentual amount of water and it has been concluded that the ingoing ions should be substantially dehydrated within the exchanger. Thus the positive entropy changes, accompanying the release of H_2O molecules from the co-ordination spheres of ingoing ions may be responsible for this unusual affinity series. The equilibrium constants for the exchange of anions show a slightly higher selectivity towards chloride as compared with nitrate,[197] which is ascribed to an entropy effect, when the entropy change is sufficient to overcome the unfavourable endothermic enthalpy change. The exchange of SCN^- anions is exothermic, which probably reflects some covalency in the bonding between the exchanger matrix and SCN^- ion.[197]

In addition to the anions mentioned above, it is well known[1] that hydrous zirconium oxide is highly selective towards phosphate ions, even at high temperatures and pressures.[198] The adsorption of phosphates was found even on heated ZrO_2[199] as well as on heated ThO_2, HfO_2, CeO_2 and Zr powder.[200] A fixed stoichiometry between the adsorbed phosphates and the surface sites of the metal oxide has been found.[199]

Hydrous zirconium oxide has recently become important in the water desalination process by hyperfiltration. Dynamically formed membranes made from this material show promising salt-rejections by virtue of Donnan electrolyte exclusion.[201,202,203] Other applications such as quantitative mutual separation of I^-, Br^- and Cl^-[204] as well as a series of separation processes using co-precipitation of Pu,[205] Sc, Ti, V,[206] Mo, W,[207] Zn,[208] In^{3+},[178] and SeO_2^{2-},[179] with hydrous zirconium oxide have been described. Hydrous zirconium oxide, in mixture with hydrous alumina, is suitable for the determination of traces of V in Al matrices by neutron-activation analysis.[209] By treatment of the hydrous ZrO_2 with dithionite, phosphite, sulphide, thiosulphate, dichromate, permanganate and oxalate solutions, electron-exchanging ion-exchangers are obtained.[210]

Manganese dioxide

Hydrous manganese dioxide is prepared by mixing $KMnO_4$ and $MnSO_4$ solutions at 90°,[211] or by electrodeposition from a solution of $MnSO_4$ at ~100°.[212] Depending on the method of preparation and the drying temperature, different products are formed with structures close to β-, γ-, or ρ-MnO_2.[1,211,212] Non-stoichiometric composition has often been found (for example $MnO_{1.88}$[211]) which can be expressed by an empirical formula $(MnO_x)_2OH$,[213] where $x = 1{\cdot}70$–$1{\cdot}75$. It is supposed that the OH groups which are distributed through the whole volume of hydrous manganese dioxide differ in their acid-base properties.[213] Their pK values have been determined at an ionic strength of $0{\cdot}1M$(pK_1 = 3·6, pK_2 = 5·5 and pK_3 = 9·3).[213] The corresponding total capacity is 0·5 meq/g and decreases on heating of the exchanger.[213,214] This maximum capacity value indicates that there is one exchangeable OH group per two MnO_2 molecules, in accordance with the above-mentioned empirical formula.[213]

Hydrous manganese dioxide is more selective towards alkaline earth metal cations than alkali metal cations;[214] pyrolusite and γ-MnO_2 exhibit high adsorption capacity for NH_4^+ and Zn^{2+},[215] and bivalent transition metal ions.[216]

The adsorption mechanism on hydrous manganese dioxide seems to be rather complicated. An ion-exchange mechanism is reported for the adsorption of alkali metal ions on $(MnO_x)_2OH$[214] and for Ag^+, Ba^{2+}, Ca^{2+}, Sr^{2+}, Mg^{2+} and Nd^{3+} on colloidal manganese dioxide.[217,218] However, in the case of alkaline earth metal cations the adsorption of MCl^+ and at higher concentrations the molecular sorption of MCl_2 species has been observed.[214] In addition to the ion-exchange process, some other kinds of retention may occur. Thus chemical reaction of Cr^{3+} or Mn^{2+} ions with MnO_2,[211,219] formation of a colloidal suspension in the case of Fe^{3+} adsorption[211] or a redox process yielding insoluble products in the case of WO_4^{2-}, MoO_4^{2-} and AsO_4^{3-},[220] have been reported as factors causing some irregularities when these processes are treated as pure ion-exchange.

The isotherms for the Ba^{2+} and Mn^{2+} adsorption on β-MnO_2[219] and for Eu^{3+}, Tb^{3+}, Sc^{3+}, Mn^{2+} and Cr^{3+} on ρ-MnO_2[211] have been determined. For the latter, the isotherms (with the exception of that for Cr^{3+}) fit the Langmuir adsorption equation. Large differences in the adsorption capacities between the individual ions could be explained only by the Langmuir model and it was assumed that the number of adsorbing sites in MnO_2 was not the same for different ions, which, depending upon their size, could be more or less well accommodated in the irregular structure of the MnO_2 particles.[211]

A series of useful separations[43] on hydrous manganese dioxide have been described: ^{51}Cr retention and ^{60}Co–^{59}Fe separation for the neutron-activation analysis of Fe–Cr alloys;[211] carrier-free parent–daughter separations (^{49}Ca–^{49}Sc, ^{90}Sr–^{90}Y, ^{32}S–^{32}P);[211] separation of ^{140}Ba and ^{140}La from Ce,Zr and Nb;[211]; mutual separation of Na, K and Cs;[220]; separation of Tc from Mo for obtaining carrier-free ^{99m}Tc of high purity;[221] separation of Ra from liquid wastes.[222] Hydrous MnO_2 in mixture with hydrous Fe_2O_3 is suitable as a scavenger for ^{60}Co, ^{106}Ru and ^{65}Zn from sea water[223] or for the removal of various radionuclides from aqueous solutions.[224]

Hydrous oxides of quinquevalent and sexivalent metals

Hydrous oxides of Sb, V, Ta, Nb, Mo(VI) and W(VI) have been described as ion-exchanging materials. Among them hydrous antimony oxide (so-called antimonic or polyantimonic acid) has been the most intensively studied, owing to its considerable adsorption capacity and a reasonable rate of adsorption and desorption when used in column operations.

Antimonic acid

Various antimonic acid materials have been obtained with different chemical composition and ion-exchange properties, depending on the method of their preparation as well as on aging. The species can be divided into three groups —crystalline, amorphous and glassy.

The well defined *crystalline antimonic acid* is prepared by the hydrolysis of $SbCl_5$ with a large amount of water and aging of the gel in the mother liquor at 30° for 20 days.[225] The time of aging can be reduced by increasing the temperature to 80°,[226] or to 130–180°.[227] The other methods of preparation are based on passing an aqueous $KSb(OH)_6$ solution through a column filled with Dowex 50 or KU-2[227] followed by subsequent evaporation[228] or treating the effluent with nitric acid. Good sorbents were obtained by thermal polymerization of $NaSb(OH)_6$ at 250° and subsequent treatment with nitric acid.[229] The chemical composition of the crystalline antimonic acid corresponds to the empirical formula $Sb_2O_5{\cdot}4H_2O$[226,227,229,230] for samples dried at up to 50° and $Sb_2O_5{\cdot}3\text{–}4H_2O$ for species obtained after drying at 70–90°.[228] The acid is practically insoluble in water and 4*M* hydrochloric acid.[228]

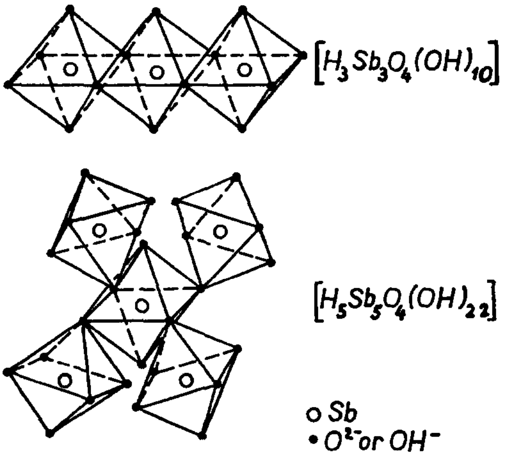


FIG. 1.—Tentative structure of crystalline polyantimonic acid.[230]

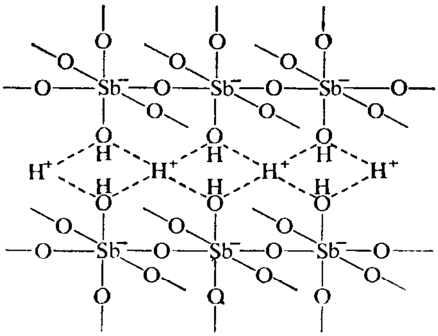
Contradictory statements have been reported for the structure of antimonic acid. X-Ray diffraction measurements lead to a cubic structure with an *a* parameter of 1·025,[230] 1·038[225] and 1·029 nm.[227] Baetslé and Huys,[230] on the basis of the empirical formula $Sb_2O_5{\cdot}4H_2O$, the density of 4·27 and the lattice parameter $a = 1{\cdot}03$ nm, deduced that the molecular weight was about 2800, implying 14 Sb atoms per unit cell. The structure proposed is built up of trimeric units [empirical formula $H_3Sb_3O_4(OH)_{10}$] with 4 oxygen atoms common to 3 Sb atoms, and a pentameric unit [empirical formula $H_5Sb_5O_4(OH)_{22}$] with 4 oxygen atoms of the central Sb octahedron linking four $Sb(OH)_6^-$ groups around it. Both structures are shown in Fig. 1. Three trimeric units and one pentameric form one unit cell of an empirical formula of $\{[H_3Sb_3O_5(OH)_8]_3\}[H_5Sb_5O_6(OH)_{18}]$. This empirical formula takes into account the interconnecting oxygen atoms which link the trimers to each other, as well as the trimers to the pentamer.[230] The fourteen hydrogen atoms are supposed to be exchangeable, corresponding to the theoretical exchange capacity of 5·05 meq/g. Capacities very close to this value have been found for Ag^+, Tl^+, Pb^{2+} and Sr^{2+}.[227,230,231]

Infrared measurements by Abe and Ito[225] led to the following structure with an empirical formula of $H_2Sb_2O_5(OH)_2$:



The hydrogen ions in the structure may be combined with H_2O molecules as H_3O^+ ions. It is supposed[225] that the hydrogen-bonding surface groups are constrained by rigid three-dimensional bonding and that the exchangeable hydrogen ions are surrounded by six oxygen atoms, as is Na^+ in $Na[Sb(OH)_6]$.* The presence of Sb–OH groups is confirmed by the occurrence of the infrared absorption band at 1280 cm^{-1} and that of the hydrogen bonds by a broad band at 2700–3800 cm^{-1}.[225] On the other hand, Novikov *et al.*[227,232] postulated the compound $H_3OSbO_3 \cdot 0 \cdot 48H_2O$ with molecules of adsorbed water. These authors support this conclusion by the isomorphism of antimonic acid with $AgSbO_3$ and a cubic $NaSbO_3$ as well as by infrared measurements.

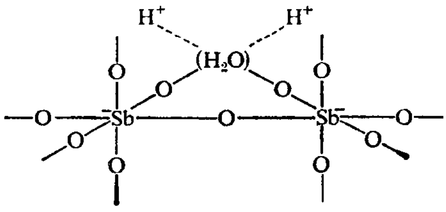
TGA, DTA and X-ray studies[233] of thermal decomposition of the crystalline antimonic acid show a reversible loss of 2 molecules of water up to 200° with formation of crystalline $Sb_2O_5 \cdot 2H_2O$ without change in the adsorption capacity. On further heating the loss of bonded water occurs with stepwise formation of Sb_2O_5, Sb_6O_{13} and Sb_2O_4. Another scheme of thermal decomposition, leading to the stepwise formation of H_3OSbO_3, Sb_3O_6OH, Sb_6O_{13} and Sb_2O_4, has been proposed by Novikov *et al.*[227]

Amorphous forms of antimonic acid ($Sb_2O_5 \cdot nH_2O$) are prepared by hydrolysis of $SbCl_5$ and aging of the gel in the mother liquor for 4 hr,[226] by hydrolysis at low temperature,[234] or by low-temperature treatment of antimonic acid solutions.[235] The composition of the gels prepared varies, depending on the time of drying, from $Sb_2O_5 \cdot 6 \cdot 4H_2O$ to $Sb_2O_5 \cdot 3 \cdot 4H_2O$.[235] The wet precipitates are easily dissolved in H_2O[226,227,236] or are peptized. It is difficult to dissolve products dried for a long period,[226] and also to reach equilibrium between the solid and the solution.[226] The latter phenomenon is caused by depolymerization, involving hydration, from a higher polymer to a lower one. On prolonged aging in H_2O or in Sb(V) solutions,[226,227,236,237,238] a gradual change to the crystalline form occurs, which is connected with a spontaneous condensation of OH groups.[227] The amorphous gels gradually dehydrate on heating,[233]

---

* This is the statement made by the authors of the paper cited and appears to be based on the fact that the unit cell contains 6 OH^- groups per Na^+ [Ed.].

and this change is accompanied by a decrease in the exchange capacity.[226] The following structure is proposed for the amorphous material:[225]



The exchange capacity varies, depending on the composition of the exchanger and the nature of the exchanging ion (Na^+—4·2 meq/g, Sr^{2+}—1·8 meq/g).[234]

The glassy form of antimonic acid ($Sb_2O_5{\cdot}nH_2O$) is prepared by hydrolysis of $SbCl_5$ solutions and dissolution of the fresh precipitate in hot water, followed by rapid cooling.[225,226] The glassy gel obtained gives five weak X-ray powder pattern lines and its properties are very similar to those of amorphous antimonic acid.[225,226]

Some other methods of preparation leading to products of different properties have been described.[239] (Oxidation of $SbCl_3$ with nitric acid or *aqua regia* and subsequent hydrolysis or neutralization of the acid solutions of Sb(V) salts with ammonia).[239]

Antimonic acid acts as a cation-exchanger. An equivalent exchange has been found for various univalent and bivalent metal cations.[227,228,239,240,241] Titration curves show one inflection point[239,248] with p*K* values varying from 2·34 to 3·18, depending on the method of preparation.[239] The shape of the titration curves does not depend on the strength of the base.[228] Ion-exchange equilibria of alkali metal ions, alkaline earth, metal ions Ag^+, Ce^{3+}, La^{3+}, Eu^{3+} and Th^{4+} have been studied.[230,231,238,239,243] The affinity series for alkali and alkaline earth metal cations vary depending on the crystalline form of the exchanger as well as on the sorption media. The series $Li < Na < K < Rb < Cs$ in acid solutions and $Li < Na \sim Cs < K = Rb$ in NH_4NO_3 solutions were found for both the amorphous and glassy exchangers.[238] For the crystalline material the following series were found: $Li < K < Cs < Rb < Na$ in acid solutions, $Li < K < Rb < Cs < Na$ in NH_4NO_3 solutions.[238,243] The affinity series for micro amounts of alkali metal cations confirms the decreased order of the lattice constants of various alkali metal forms of the exchanger[238] except for Li^+. However, slightly different affinity series have been reported by other authors for crystalline antimonic acid: $Cs < Li < Rb < NH_4 < K < Na$[231] and $Rb{=}Cs < Na$.[230] Similar disagreement between various authors exists for the alkaline earth metal cation series: $Mg < Ca < Sr < Ba$,[231] $Ra < Ba < Ca < Sr$.[230]

Ion-exchange isotherms measured for the systems alkali metal ion $-H^+$, Ag^+-H^+, $Ca^{2+}-H^+$, $Sr^{2+}-H^+$, $Ba^{2+}-H^+$, $Pb^{2+}-H^+$ and $La^{3+}-H^+$ are mostly S-shaped,[230,231,238,239] indicating selectivity reversal. From the dependence of selectivity coefficients on the exchanger loading, thermodynamic equilibrium constants and ΔG values have been calculated[230] for various systems and are presented in Table II. The selectivity coefficients decrease with exchanger loading. Plots of log selectivity coefficient *vs.* exchanger composition are linear up to 65% of available capacity, indicating that 9 of the 14 hydrogen ions in the unit cell are attached by the exchange. In terms of the proposed

TABLE II.—THERMODYNAMIC EXCHANGE DATA FOR CRYSTALLINE ANTIMONIC ACID.[230]

System	ln K	ΔG, *kJ/g ion*
Na^+–H^+	−7·4	+18·1

Sr^{2+}–H^+	0	0
Ba^{2+}–H^+	−8·7	+10·6
Pb^{2+}–H^+	2·30	−3·2
La^{3+}–H^+	−64	+52

polymeric structure[230] this is explained as follows: the 9 exchange sites on the trimeric antimony species are the most reactive and may be considered as ionized sites neutralized by free hydrogen ions, while the 5 remaining sites associated with the pentameric unit consist of covalently-bound hydrogen ions which can only be exchanged by large ions at rather low acidity. Ions such as Ag^+ are covalently bound with formation of Ag–O–Sb bonds attaching the 5 remaining sites having a covalent bond nature.[230] The exchange is then partly irreversible (the residual amount of ~2 meq of Ag per g cannot be eluted).[230]

Owing to the large differences in the selectivity for individual alkali metal cations, these ions can be separated on a small column with nitric acid or ammonium nitrate solution as eluent.[243] However, the glassy and crystalline materials are more favourable for column separations, owing to their low solubility and suitable granular form.[238] Li, Na and K can be separated on amorphous and glassy materials, and a mixture of Li, K and Cs on the crystalline material by elution with nitric acid. Similarly, neighbouring pairs, except Rb–Cs, are easily separated[238] by NH_4NO_3 elution.

Miscellaneous applications[43] of antimonic acid such as column separation of ^{90}Sr from the fission products mixture,[244] ^{90}Sr recovery from acid solutions after nuclear fuel reprocessing[242,245] and separation of Na^+ in activation analysis,[246] have been reported.

Phosphoantimonic acid

A highly temperature- and radiation-resistant exchanger based on antimonic acid—phosphoantimonic acid—is formed by pouring $SbCl_5$ into phosphoric acid[241,247] or by treating Sb(V) salt solutions with phosphoric acid and then neutralizing with ammonia.[248,249] The resulting glassy solid, with variable P/Sb ratio, is not attacked by water, salt solutions or strong acids.[247,250] The selectivity of this exchanger depends on the P/Sb ratio in the solid.[251,252,253] Samples with a high P content are selective for univalent cations such as Na^+, K^+, NH_4^+ and Ag^+.[252] Reversible exchange was found for various systems, *i.e.*, alkali metal ion–H^+, NH_4^+–H^+, Ag^+–H^+, alkaline earth metal cations –H^+, Cu^{2+}–H^+, Ce^{3+}–H^+, K^+–NH_4^+, $Ag(NH_3)_2^+$–NH_4^+.[242,247,250] The titration curve of phosphoantimonic acid shows one sharp inflection point, indicating the exchanger to be a strong monobasic acid.[250,253] This exchanger (as well as the exchanger with H_2TeO_4 incorporated instead of H_3PO_4) has been reported[248,249] as a suitable material for the separation of alkaline earth metals and lanthanides from alkali and transition metals.

Other hydrous oxides of this group

Little attention has been given to other hydrous oxides of quinque- and sexi-valent metals. Hydrous V_2O_5[254] in mixture with hydrous zirconia adsorbs K^+, Na^+, Ba^{2+}, Ca^{2+}, Mg^{2+}, Cd^{2+}, Fe^{3+}, Co^{2+}, Ni^{2+}, Pb^{2+}, Zn^{2+}, Cu^{2+} and Ag^+. Its total exchange capacity is between 1·42 and 1·95 meq/g, depending on the V content of the mixture, and is reduced by thermal treatment. Hydrous Nb_2O_5 acts both as cation-[241] and anion-exchanger[255,256,257] selective for $Cr_2O_7^{2-}$, paramolybdates, tungstates and ferrocyanides. Hydrous Ta_2O_5 is a cation-exchanger[241,258,259] suitable for the purification of nuclear reactor cooling-waters at high temperatures up to 300°.[258,259] The hydrous oxides of Mo(VI) and W(VI) act as cation-[241] or as anion-exchangers in mixtures with basic hydrous oxides.[260]

ACIDIC SALTS OF MULTIVALENT METALS

A wide range of compounds of this type has been described as ion-exchangers. Among the metals studied have been zirconium, thorium, titanium, cerium(IV), tin(IV), aluminium, iron(III), chromium(III), uranium(VI) *etc*, and the anions employed include phosphate, arsenate, antimonate, vanadate, molybdate, tungstate, tellurate, silicate, oxalate *etc*. These salts, acting mostly as cation-exchangers, are gel-like or microcrystalline materials, with the composition and properties depending upon the method of preparation, and possess mostly a high chemical, temperature and radiation stability.[1,2,3] The cation-exchange properties arise from the presence of readily exchangeable hydrogen ions, associated with the anionic groups present in the salts. Some of these materials also exhibit electron-exchange properties.

Recent developments in study of these materials have led to a successful preparation of defined crystalline compounds of the type $M^{IV}(HX^{V}O_4)_2 \cdot yH_2O$ and to recognition of their crystal structure. The structure is layered and the crystalline compounds exhibit ion-sieve properties.[286] Knowledge of the crystal structure gave a deeper understanding of the ion-exchange processes and their reversibility[314] as well as a solid basis for the interpretation of thermodynamic measurements.[293,322] Besides possible application of these exchangers in chemical processing of radioactive materials and in treatment of contaminated moderator- and cooling-water in nuclear reactors working at high temperatures and pressures, new applications have recently been found, such as in water desalination processes and in fuel-cells employing ion-exchange membranes for transport of hydrogen ions.

Acidic salts of quadrivalent metals

These substances have been the most intensively studied group of synthetic inorganic ion exchangers. Most of the work to date has been concerned with zirconium phosphate exchangers, which have been more thoroughly studied than any of the other materials.

Zirconium salts

Zirconium phosphate. The earlier studies on zirconium phosphates (ZrP) were mostly concerned with the amosphous materials.[1,2,3,261] The interest during the last five years has been primarily in the semicrystalline and crystalline forms of zirconium phosphates. Owing to their definite structure, a more exact interpretation of the sorption phenomena might be achieved. However, the applications of amorphous materials are still of great interest.

The preparation of gelatinous amorphous sorbents was carried out by the usual mixing of Zr salt solutions with phosphoric acid at room temperature. According to the preparation conditions, materials with P/Zr ratios of 0·5–2·1 were formed.[1,262–267,373] A granular material was prepared by freezing the gels at up to $-22°$.[268,269] Thermal treatment of amorphous materials with phosphoric acid[270,271,272] or refluxing them with $\geqslant 2{\cdot}5M$ phosphoric acid[1,271,273–275] leads to the formation of semicrystalline or crystalline forms, respectively. In the latter case, the well developed crystalline phase of the so-called α-ZrP was prepared, corresponding to the formula $Zr(HPO_4)_2{\cdot}H_2O$. The same compound resulted after evaporation of suitable Zr salt solutions with hydrofluoric acid.[276] A β-phase and a γ-phase, corresponding to $Zr(HPO_4)_2$ and $Zr(HPO_4)_2{\cdot}2H_2O$ respectively, were prepared by refluxing the solutions of $ZrOCl_2$ with NaH_2PO_4 in $3M$ hydrochloric acid. Drying over anhydrous $CaSO_4$ leads to the formation of β-ZrP; air-dried products correspond to γ-ZrP.[277] The surface area of the crystalline preparations is about 1000 times that of the amorphous ones.[278,279]

The composition of amorphous or poorly crystalline materials is mostly interpreted in terms of compounds for which the P/Zr ratio is freely variable, without existence of distinct, more definite intermediate products,[280] and the P/Zr ratio found is then speculatively ascribed to corresponding hypothetical formulae such as $Zr(OH)(PO_4)$, $ZrO(HPO_4)$, $Zr_3(PO_4)_4$, $Zr(HPO_4)_2{\cdot}xH_2O$ and $Zr(HPO_4)(H_2PO_4)(OH)$.[270,271,281]

An attempt has been made to solve the structure of α-ZrP.[282–285] A three-dimensional study on $Zr(HPO_4)_2{\cdot}H_2O$ single crystals, presented by Clearfield and Smith[286,287,288] resolved this structure completely from the integrated precession data; α-ZrP crystals are monoclinic with $a = 0{\cdot}9076$, $b = 0{\cdot}5298$, $c = 1{\cdot}622$ nm and $\beta = 111{\cdot}5°$. There are 4 formula units per unit cell and the space group is $P2_1/c$. The structure is layered and consists of a sheet of roughly coplanar Zr atoms sandwiched between two sheets of monohydrogen phosphate groups. Each Zr atom is co-ordinated octahedrally to 6 oxygen atoms. Each of these 6 oxygen atoms belongs to one of six different monohydrogen phosphate groups. This group acts as a 3-way bridging ligand, co-ordinating 3 different Zr atoms through 3 of its oxygen atoms. The fourth non-co-ordinating oxygen atom points towards an adjacent layer in the structure and presumably bears the H atom. The forces between layers are very weak long hydrogen-bonds or van der Waals forces and the interlayer distance is 0·76 nm. The layers are arranged relative to each other in such a way that the Zr atoms in one layer lie over the P atoms in an adjacent layer and *vice versa*. Zeolitic type cavities are thus formed. There is exactly one such cavity per formula unit of α-ZrP. A water molecule resides in the centre of each cavity and is hydrogen-bonded to phosphate groups. A schematic illustration of two adjacent layers in α-ZrP with the formed cavity is presented on Fig. 2.[286] One possible speculative arrangement of the hydrogen-bonds is that in which one H atom of a phosphate group is directed towards the H_2O molecule  $\left(P{-}O{-}H\ldots O\!\begin{smallmatrix}\diagup H\\ \diagdown H\end{smallmatrix}\right)$ forming the interlayer bonds. The remaining hydrogen-bonds form very weak interlayer bonds (P–O–H . . . O–P) and form a zigzag array running parallel to the *b*-axis.[286] This

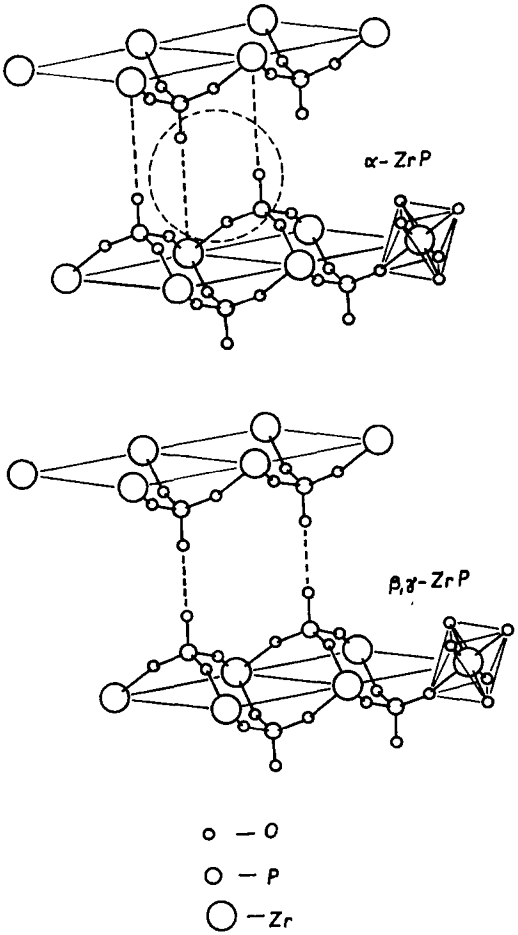

FIG. 2.—Schematic illustration of the structures of α-, β-, and γ-ZrP.[277]
Dashed circle—inter-layer cavity.

idea is in agreement with the infrared measurements on α-ZrP and its deutero-analogues.[289] Structural features of the β-phase are essentially the same as those of α-ZrP but with a different interlayer distance, 0·928 nm. It has been proposed that the layer packing sequence is such that neighbouring HPO_4 groups from adjacent layers are aligned opposite one another (Fig. 2) to allow interlayer hydrogen-bonds of the type  $O_3P{-}O\langle\overset{H}{\underset{H}{}}\rangle O{-}PO_3$. The structure of γ-ZrP is very closely related to that of β-ZrP. The interlayer attractions are probably hydrogen-bonds between the aligned HPO_4 groups through the interagency of the water molecules. The interlayer separation must be thus substantially larger than that in β-ZrP.[277]

The hydrolytic behaviour of these ion-exchangers is closely connected with their structure. The tendency towards hydrolysis decreases from amorphous to crystalline ZrP.[283,290] The stability of the H^+ forms of amorphous ZrP with respect to phosphate release increases with decreasing P/Zr ratio.[291,373] The stability increases in the presence of ions, in the following order: Li $<$ Na $<$ Ag $<$ K $<$ Rb $<$ NH_4 $<$ Cs. With the Li and Na forms of the ZrP cation release prevails, while with the K, Rb, and Cs forms, phosphate release predominates.[264,292] At low pH, the phosphate release is not primarily due to a "hydrolysis," but rather to washing out of phosphoric acid, which adheres very stubbornly to the gel,[272] or to a conversion into a less acidic compound on aging the gel: $2Zr(HPO_4)_2 \rightleftharpoons Zr_2H(PO_4)_3 + H_3PO_4$.[293] In this way a linear dependence of the equilibrium phosphate concentration in the solution on the weight of amorphous solid material, may be explained.[289,290] The solubility data of crystalline ZrP in strong phosphoric acid have been determined.[294]

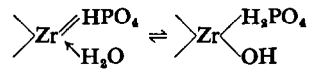
The changes occurring on heating the ZrP sorbents have been studied quite intensively.[267,295,374] Anhydrous $Zr(HPO_4)_2$ was obtained by heating at up to 130°.[278,296] The loss of constitutional water and formation of pyrophosphate groups start at $\sim$180°.[296,297] At 200° about 13·8% of the total capacity is lost,[296] but the degree of cross-linking increases and variations in selectivity occur.[267,289,297,298,299] No condensation was observed on similar thermal treatment of crystalline and semicrystalline materials, even on autoclaving under pressure at 270°. However, $Zr_3(PO_4)_4$ formation was found in the case of amorphous materials.[290,300,301] By 450° the capacity of crystalline samples has decreased to 58·8% of the starting value[296] and at 550° ZrP_2O_7 is formed.[278] Crystalline ZrP in the K^+ form is converted into $Zr(KPO_4)_2$ after heating to 1000°. Ammonium forms are decomposed at elevated temperatures and the pure H^+-form of the sorbent is created.[266,302]

Sorption properties of both amorphous and crystalline ZrP have been extensively studied by many authors. Great attention has been paid to the alkali metal cations.

The adsorption on the amorphous ZrP gels, especially those of high P/Zr ratio ($>$1·5), is an ideal cation-exchange.[292] The capacity increases with the P/Zr ratio.[262] It is supposed from the titration curves that monobasic[303] as well as dibasic[262,271,304] acid groups are present in these gels. The points of zero charge vary significantly with the composition of the gels.[305] At lower P/Zr ratios, however, these gels retain part of the amphoteric character which is connected with the presence of the hydrous ZrO_2 functional groups.[292,318] It has been proved that K^+ and Li^+ are attracted electrostatically to the surface of the solid only when the solid is negatively charged; on the other hand, ions which form insoluble phosphates, such as Ag^+, are chemisorbed even when the solid is positively charged.[306] The adsorption phenomena are closely connected with the water content of the sorbents. It has been confirmed by Ahrland[298] that the affinity of amorphous ZrP for Cs adsorption considerably increases when the gels are dehydrated to one mole of water per mole of Zr in the sorbent. A similar but less marked increase occurs for Na.[272,374] The selectivity for K, Rb and Cs adsorption is rather higher than that for Li, Na and Ag and increases with increasing P content in the sorbent.[292,307] The Cs adsorption is very little influenced by temperature increase[198] and diffusion phenomena are the decisive factors for the rate of exchange.[309] Cs adsorption substantially increases in the presence of the phosphate ions in the solution. The ion-exchange process is thus more complicated than simple ion-exchange and structural changes in the sorbent during the adsorption process have to be taken into account.[290]

Very interesting phenomena have been found on studying the adsorption on α-ZrP. The titration curves for the exchange of Li^+, Na^+ and K^+ for H^+ exhibit a hysteresis loop. A marked hysteresis has also been found in the Na–Li and Li–K exchange processes.[310] The hysteresis results from the presence of different phases in the forward and reverse titrations. When α-ZrP is titrated with NaOH, two solid phases are present up to 50% exchange, *i.e.*, α-ZrP and the compound $Zr(NaPO_4)(HPO_4)\cdot 5H_2O$. At higher levels of exchange another two-phase region is obtained, *i.e.*, the latter compound and a fully exchanged phase with composition $Zr(NaPO_4)_2\cdot 3H_2O$. The interconversion of these phases is fully reversible. However, when the half-exchanged phase takes up protons it forms an unexchanged phase, which is more highly hydrated than the original α-ZrP.[311] In the case of Li^+ exchange, phases of composition $Zr(LiPO_4)_{1\cdot 33}(HPO_4)_{0\cdot 67}\cdot 4H_2O$ and $Zr(LiPO_4)_2\cdot 4H_2O$ are formed.[312] The process of H^+–Li^+ exchange is accompanied by a substantial particle size decrease with increasing loading of the exchanger.[276] Kinetic measurements by Nancollas *et al.*[313] led to the conclusion that the Na^+–H^+ exchange process rate is governed by the diffusion rate of ions through the exchanger particles. The diffusion coefficients of alkali metal cations decreased in the order K > Na > Li.[305]

The detailed ion-exchange mechanism for crystalline ZrP has now been presented by Clearfield. Even though the existence of two tautomeric forms[278]



or formation of different functional groups as a function of pH[271] can be used to explain some sorption phenomena, the model based on the layer structure properties of crystalline ZrP was found to be the most exact. The zeolitic nature of the crystals and the weak forces between layers provide a basis for explaining their sieving behaviour and the ready expansion of the lattice during exchange.[286] Both phosphate hydrogen ions are replaceable by cations, so the capacity of the exchanger is 6·64 meq/g. One proton is exchanged at the relatively low pH of 2–4 by alkali metal cations, and the interlayer distances remained unchanged (0·76 nm). Thus at half the exchange capacity, all the cavities contain one univalent cation and can accommodate no more. The second proton exchanges at higher pH and the cations insert themselves between the layers, with consequent spreading apart of the layers. Thus the mechanism of exchange is thought to involve the diffusion of unhydrated (or partially hydrated) ions into the cavities (0·24 nm in diameter), replacing the more acidic phosphate protons. This is followed by diffusion of water molecules into the crystal lattice and subsequent rehydration of the cations. Further exchange can then occur by diffusion of hydrated ions into the sorbent cavities.[314] Li^+ and Na^+ are exchanged as the hydrated ions and K^+ as the unhydrated ion.[305] The interlayer separation of 0·76 nm disappears when Sr^{2+} is sorbed and the unhydrated ions immediately occupy sites between the layers rather than inside the cavities. The exchange of Ba^{2+}, however, involves breaking of hydrogen bonds, hydration of the resultant protons, dehydration of the incoming cations, and co-ordination of the cations within the crystal lattice with consequent enlargement of the interlayer separation.[287] The interlayer distances in the half-exchanged forms decrease in the order Li > Na > K[305] and have the following values (in nm) for substitution of the species named: Sr–1·02,[287] n-hexylammonium–2·28,[315] n-octadecylammonium–4·70,[315] $Zr(LiPO_4)_{1\cdot 33}(HPO_4)_{0\cdot 67}\cdot 4H_2O$–1·00,[312] $Zr(LiPO_4)_2\cdot 4H_2O$–1·01,[312] $Zr(NaPO_4)(HPO_4)\cdot 5H_2O$–1·18,[314] and $Zr(NaPO_4)_2\cdot 4H_2O$–0·98.[314] The interlayer separation in the γ-ZrP is large enough to permit the exchange of larger cations such as Cs and Ba ions, which are rather excluded by α-ZrP.[277] It is interesting to note that the α-ZrP has the ability to exchange ions directly with solids or gases.[316] The exchanger, in the hydrogen form, is heated (~150°) with an anhydrous metal salt (LiCl, NaCl, $ZnCl_2$, $MnCl_2$, $CoCl_2$, $AlCl_3$, $HfCl_4$) which on exchange forms a volatile acid (HCl). The exchange reaction proceeds by continuous removal of the volatile acid. Exchanged cations may be eluted with dilute acid solutions or removed by gaseous HCl.[316]

The selectivity of zirconium phosphates towards the bivalent cations is rather low.[292,304] Higher adsorption was found for Sr^{2+} at elevated temperature.[198] The cations such as Co^{2+}, Ni^{2+}, Cu^{2+} and Zn^{2+} are sorbed to about the same extent, and their affinity is not very different from that of Sr^{2+}.[272] UO_2^{2+} is easily adsorbed at high temperatures on amorphous ZrP.[317] The adsorption of Sr on crystalline ZrP was found to be independent of ionic strength and the interdiffusion coefficients were found to be constant.[305]

Cr^{3+} is adsorbed on amorphous ZrP a little more strongly than the bivalent ions, while the affinity towards Fe^{3+} was found to be extremely high. The uptake of this ion is not a simple exchange reaction but rather a process involving the introduction of Fe^{3+} ions into the matrix of the sorbent.[272] Small differences in selectivity of sorption on amorphous ZrP were found for Am^{3+}, Cm^{3+}, Cf^{3+}, Ce^{3+} and Eu^{3+} at 75°.[291,292] Very low adsorption of Ru occurred over the entire concentration range (0–9M) of perchloric nitric and hydrochloric acids.[304] Some of the multivalent cations, such as U^{4+}, Th^{4+}, Pu^{4+}, *etc*, are adsorbed irreversibly, probably because of precipitation of the corresponding phosphates during the adsorption process.[290,292,300,304,319] In the case of UO_2^{2+} adsorption on semicrystalline and crystalline ZrP the formation of a $UO_2HPO_4{\cdot}4H_2O$ phase has been proved by X-ray analysis.[290,300] Similarly, a relatively strong uptake of WO_4^{2-} and $Mo_7O_{24}^{6-}$ anions on amorphous ZrP may be explained by the chemical interaction between these anions and the phosphate group.[320] The thermodynamics of ion-exchange on different types of zirconium phosphates have been studied for various systems.[293,301,303,321,322] The ΔG, ΔH and ΔS values determined are summarized in Table III. Generally, the free energy changes become more positive going from amorphous to crystalline materials (for the same exchange system) indicating the latter to be less favourable for the exchange. The free-energy changes for the alkali metal ion $-H^+$ exchange[322] as a function of the radius of the ingoing cation show a departure from a linear relationship. This behaviour is interpreted in terms of increasing distortion of the ion-exchanger matrix with size of the ingoing ion. The enthalpy changes are negative for alkali and alkaline earth metal cations,[1,301,321,322] and positive for UO_2^{2+},[293] Ce^{3+} and Eu^{3+}.[1]

Even though ZrP has been the most extensively examined of all inorganic ion-exchangers of this type, there still appear new fields for its application.

First of all, the knowledge of the selectivities[323,324,325] and affinity sequences is useful for rough evaluation of the separation possibilities. The affinity sequences can be summarized as follows: amorphous ZrP: $Cs > Rb \gg K > Na$,[267] $Cs > Rb > Eu^{3+} > Sr^{2+}$,[303] $Co < Ni < Cu > Zn$,[272] $Ce > Y > Cr$,[272] and $Cf > Eu > Cm > Am > Ce$;[291] semicrystalline ZrP: $Li < K < H < Cs$;[322] crystalline ZrP: $Sr \geqslant UO_2 \geqslant Ce^{3+} > Na > Cs$.[284]

The following separation applications have been presented: purification of reactor coolants;[326] decontamination of D_2O;[198] decontamination of radioactive

waste water;[327] ^{137}Cs from reprocessing solutions;[328–331] Cs–Sr–UO_2;[332] Cs–Sr, UO_2, Ce, Y, $RuNO^{3+}$, Ru^{4+};[319] Cs–Ba;[329] Na–K–Rb–Cs;[267] ^{45}Ca–^{46}Sc;[333,334] Ca–Sr–Ba;[335] Ca–Sr;[334] Sr from radioactive waste water;[303] Sr–Cs[269] Sr–Ba;[269] Sr–Ce, Eu, Zr^{4+}, Pu^{4+};[319] Sr–Y–Cs;[317] Sr–Y;[269] ^{137m}Ba–^{137}Cs;[336] Ni–Co;[337] Ni–Co–UO_2–Fe^{3+};[337] Cd–Zn–UO_2–Fe^{3+};[337] UO_2–Sr;[319] UO_2, Ce, Eu–Zr^{4+}, Pu^{4+};[319] Fe^{3+}, Mn, Ni, Pb, Al, Cr^{3+}, Co–Zn, Ag, Cd;[338] Pu^{4+} from irradiated U;[319] Pu–Cs, Sr, Eu, Ce, Ru^{4+};[319] Pu, U, Cm–Yb, Fe^{3+};[339] Bk^{4+}–Cm^{3+};[291] U^{6+}–Am^{3+};[291] $CH_3(CH_2)_7NH_3{}^+Cl^-$–$CH_3CH_2NH_3{}^+Cl^-$–$CH_3NH_3{}^+Cl^-$–$Cl^-NH_3{}^+CH_2CH_2NH_3{}^+Cl^-$;[340] $(OHCH_2CH_2)_3NH_3{}^+Cl^-$–$OHCH_2CH_2NH_3{}^+Cl^-$–$NH_4{}^+Cl^-$;[340] XeO_3–HIO_3.[341]

Various applications have been made of ZrP materials used in ion-exchange membranes especially in H/O fuel cells and electrodialysis.[342–350]

Attempts have also been made to prepare inorganic ion-exchangers consisting of a combination of the zirconium phosphate compounds with another organic or inorganic component. The selectivity of such materials is supposed to be increased. The following combinations have been described: zirconium phthalophosphate,[338] zirconium sulphosalicylophosphate,[351] zirconium phosphate-silicate,[339] zirconium-niobium phosphate,[352] zirconium phosphate–ammonium molybdophosphate,[330,466] and zirconium phosphate-tungstophosphate.[328,329]

Zirconium pyrophosphate, polyphosphates and hypophosphate. Zirconium pyrophosphate is prepared by mixing zirconyl salt solutions with $Na_4P_2O_7$ in nitric acid media.[308,353] Glass-like gels of different compositions ($P/Zr = 2{\cdot}0, 2{\cdot}5–2{\cdot}8$) are formed. By freezing of the precipitated gel, products of better mechanical properties may be obtained.[354] The exchange capacities vary according to the drying temperature, time of aging[465] and the exchanger composition.[353] The selectivity for various cations follows the order $Cu > Ni > Ca > Na \gg Fe^{3+} > Mg$[353] and an ion-exchange mechanism has been shown to operate for adsorption of Cs^+ and Sr^{2+}.[308] The following separations have been successfully achieved with this exchanger: ^{90}Sr–^{90}Y; ^{90}Sr from ^{90}Y, ^{137}Cs; $UO_2{}^{2+}$–^{234}Th; Pu^{4+} from $UO_2{}^{2+}$, ^{95}Zr, ^{95}Nb, ^{106}Ru, ^{144}Ce, ^{90}Sr, ^{137}Cs;[308] Cd^{2+}–Cu^{2+}; Pb^{2+}–Hg^{2+}; Mg^{2+}–Cd^{2+}; Ag^+–Hg^{2+}; Ni^{2+}–Fe^{3+}; Fe^{3+}–Zn^{2+}; Fe^{3+}–Cu^{2+}.[355]

Various *zirconium polyphosphate* products are obtained by mixing zirconyl salt solutions with sodium polyphosphates of various degree of polymerization.[356,357] The exchange capacity increases with increasing degree of polymerization of the starting phosphate material.[356] However, a higher amount of polyphosphate in the solid affects the kinetics of the adsorption, owing to a higher degree of cross-linking.[357] The $NH_4{}^+$ form of the exchanger is selective for alkali metal cations,[358] and has been used for their separation and purification.[359] The H^+ form is selective for Fe^{3+}, Cu^{2+}, Ca^{2+}, Ba^{2+}, Sr^{2+}, Ni^{2+}, Sn^{2+} and Sb^{3+} ions.[360]

By mixing $ZrOCl_2$ and $Na_2H_2P_2O_6$ solutions in hydrochloric acid, amorphous *zirconium hypophosphate* ($Zr:P = 1:1{\cdot}75$) is formed, which is highly selective for multivalent cations.[361,362,363] Support-free thin sheets made from zirconium hypophosphate have been used for the chromatographic separation of Sn^{2+}, Pb^{2+} and tervalent cations from alkali, alkaline earth and bivalent transition metal cations.[361]

Zirconium arsenate and antimonate. Zirconium arsenate is prepared either as an amorphous substance by mixing zirconium salt solutions with arsenic acid[364,365,366] or as a crystalline material by refluxing the amorphous zirconium arsenate with H_3AsO_4 for a prolonged period.[364,365]

The amorphous materials, of various As/Zr ratios (1·53–1·96), in comparison with the crystalline materials exhibit very low stability towards hydrolysis at higher pH[364] and their titration curves do not exhibit any particular inflection point, suggesting that the exchangeable hydrogen ions display a range of acidities.[364] The affinity series for alkali metal cations changes with pH (Cs > K > Na at pH 2·6, Na > K > Cs at pH 4·65).[365]

The crystalline zirconium arsenate, $Zr(HAsO_4)_2 \cdot H_2O$,[364,365] is isomorphous with α-zirconium phosphate. The parameters of its monoclinic lattice are $a = 0·9178$ nm, $b = 0·5378$ nm, $c = 1·655$ nm, $\beta = 111·30°$, and the average As–O and Zr–O distances are close to those in α-zirconium phosphate.[367] One molecule of water is reversibly lost on heating at 110°, without changing the X-ray patterns;[364,365] on heating to 500°, the second water molecule is lost owing to the condensation of $HAsO_4^{2-}$ groups. On titration with LiOH, NaOH and KOH, two end-points occur in the titration curves, corresponding to the replacement of the two hydrogen ions of the two $HAsO_4^{2-}$ groups.[364,365] Practically no adsorption of Cs^+ occurs in acid solutions up to pH 7; at higher pH, however, some exchange is observed, accompanied by remarkable hydrolysis of the exchanger and destruction of its crystal structure.

The ion-exchange process is assumed to proceed as follows: during the replacement of the first hydrogen ion the exchanging ions occupy the zeolitic cavities in the crystal (one cavity per Zr atom) and the interlayer distance remains unchanged.[364] Only Li^+, Na^+ and K^+ are small enough to enter these cavities.[365] When one mole of hydrogen ions per formula weight of the exchanger has been replaced, the ingoing cations must insert themselves between the layers, which is demonstrated by the increase in interlayer distances of the totally exchanged Li^+, Na^+ and K^+ forms as compared with the H^+ form. These distances indicate that the unhydrated cations are exchanged, since the increased interlayer distances are only slightly larger than the diameters of the inserted cations.[364] Such a behaviour indicates that crystalline zirconium arsenate exhibits ion-sieve properties, similarly to the other crystalline salts of this type.

The Na^+–H^+, Tl^+–H^+ and Ba^{2+}–H^+ exchange processes have been found to be irreversible,[365] owing to the structural rearrangement when going from the H^+ to M^+ form or to a possible precipitation of barium arsenate within the exchanger.

Amorphous zirconium arsenate has been reported as a suitable material for concentrating caesium from a mixture containing multivalent and alkali metal ions.[368]

Zirconium antimonate is prepared as an amorphous substance by mixing $ZrOCl_2$ solutions with an excess of Sb_2O_5 dissolved in hydrochloric acid.[369] From the exchange isotherm measurements the affinity series Na ⩾ K > NH_4 > Rb > Cs > Li has been established.[370] The exchange reaction rate increases from Li^+ to Cs^+.[370] Mutual separation of Rb^+ and Cs^+ [371] and separation of microquantities of Na^+ from macroamounts of Al^{3+} have been described.[369]

Zirconium molybdate and tungstate. Zirconium molybdate is prepared by mixing zirconyl salt solutions with ammonium molybdate and subsequent neutralization with ammonia. Amorphous products of various composition with the Zr/Mo ratio ranging from 0·5 to 2·0 are obtained, depending upon the pH of the precipitation.[263,372] Their ion-exchange capacities for K^+ and Cs^+ lie between 2·18 and 2·43 meq/g.[372] Zirconium molybdate also exhibits electron-exchange properties, *e.g.*, its ability to oxidize $SnCl_2$ solutions. The mean value of the electron-exchange capacity is 0·18 meq/g.[372]

Zirconium tungstate is prepared by mixing zirconium salt solutions with Na_2WO_4[373,375] or by passing a concentrated Na_2WO_4 solution through an anion-exchange column filled with hydrous ZrO_2. Amorphous products of various composition (Zr:W = 1·0–0·44)[263,375] and properties were obtained. They are easily soluble in strong acids.[373,374] The selectivity for alkali metal cations decreases in the order Cs > Rb > K > Na > Li.[376] An equivalent UO_2^{2+}–H^+ exchange has been reported for gels pretreated with 1*M* nitric acid.[374] Similarly to zirconium molybdate, zirconium tungstate can act as an electron-exchanger.[375] It is reduced by $SnCl_2$ solutions, probably to products containing tervalent W. The reduced form can be reoxidized by Fe^{3+}, Ce^{4+}, V(V) or H_2O_2 solutions. The electron-exchange capacity is 0·26 meq/g.[375]

Zirconium tellurate, oxalate and silicate. Zirconium tellurate is prepared by refluxing $ZrOCl_2$ and Na_2TeO_4 solution in 1*M* hydrochloric acid[377] and its composition corresponds to the formula $Zr(H_2TeO_6)·4H_2O$.[377] Four molecules of water are lost on heating to 100–500°; at 650–700° condensation to $Zr(TeO_5)·H_2O$ occurs.[377] The exchange capacity determined from the titration curves (~2·8 meq/g)[377,378] is approximately one half of the formula capacity, indicating that only 50% of the H^+ ions are exchangeable in the pH range of 2·5–12.[277]

Gel-like and crystalline *zirconium oxalates* of empirical formula $ZrO(OH)C_2O_4H$ were prepared from $ZrOCl_2$ and $(NH_4)_2C_2O_4$ solutions.[379] An unusual affinity series has been reported for alkali metal cations: Na < Cs < Rb < K.[379]

Zirconium silicate with total exchange capacity 3·18 meq/g[380] has been used for the separation of Th^{4+} from Sm^{3+} and of Ca^{2+} from Sr^{2+}.[381]

Thorium salts

Of the thorium salts only phosphate, arsenate and molybdate have been reported as ion-exchangers.

Thorium phosphate with variable composition, low stability towards hydrolysis and low exchange capacity is prepared by precipitation at room temperature. However, by precipitation at 100° and subsequent digestion for 40 hr, fibrous crystalline materials (similar to fibrous cerium phosphate) are obtained.[382] The exchange capacity for Na^+ (3·7 meq/g) is closed to that corresponding to the stoichiometric formula $Th(HPO_4)_2·3H_2O$. This material is suitable for preparing support-free ion-exchange sheets having potential application in electrophoresis.[382]

Thorium arsenate is prepared by prolonged refluxing of thorium nitrate solution in arsenic acid at 110°.[383] Crystalline material of composition $Th(HAsO_4)_2·H_2O$[384] is not readily dissolved at pH < 12.[383] The exchanger is highly selective towards Li^+ ions; Na^+, K^+, Rb^+, Cs^+ and Tl^+ are not adsorbed at all. This behaviour is due to an ion-sieve effect of this compound, which has the smallest interlayer distance of all the compounds of this type. A comparison of ion-sieve behaviour of various compounds of the type of $M^{IV}(HXO_4)_2·yH_2O$ is given in Table IV. The Li^+ form of thorium arsenate possesses a similar crystal structure to that of the H^+ form, and the exchange process, unlike that of other salts of this type is completely reversible.[384] Two phases, $Th(HAsO_4)_2·H_2O$ and $Th(LiAsO_4)_2·H_2O$, are present at each stage of the exchange process.

Thorium molybdate is prepared by mixing $Th(NO_3)_4$ and Na_2MoO_4 solutions.

TABLE IV.—COMPARISON BETWEEN THE FIRST INTERPLANAR DISTANCE AND ION-EXCHANGE PROPERTIES OF THE SALTS OF THE TYPE $M^{IV}(HXO_4)_2yH_2O$

Exchanger	First interplanar distance, *nm*	Alkali metal cation exchanged by the H^+ form
$Zr(HPO_4)_2 \cdot 2H_2O$(γ–ZrP)	1·220	Na—Cs
$Th(HPO_4)_2 \cdot 3H_2O$	1·147	Na—Cs
$Ce(HPO_4)_2 \cdot H_2O$	1·095	Li, Na, K, Rb, Cs
$Zr(HPO_4)_2$ (β–ZrP)	0·940	Na—Cs
$Ce(HAsO_4)_2 \cdot H_2O$	0·910	Li, Na, K (partly)
$Zr(HAsO_4)_2 \cdot H_2O$	0·780	Li, Na, K, Cs (partly)
$Sn(HAsO_4)_2 \cdot H_2O$	0·777	Li, Na, K (partly) Cs (partly)
$Ti(HAsO_4)_2 \cdot 2H_2O$	0·777	Li, Na, K
$Sn(HPO_4)_2 \cdot H_2O$	0·776	Li, Na, K, Cs (partly)
$Zr(HPO_4)_2 \cdot H_2O$ (α–ZrP)	0·760	Li, Na, K
$Ti(HPO_4)_2 \cdot H_2O$	0·756	Li, Na,
$Th(HAsO_4)_2 \cdot H_2O$	0·705	Li

Various conditions of preparation lead to formation of different products.[385] This exchanger is readily dissolved in mineral acids and on heating to 100° its capacity (~0·57 meq/g) is lost. Total adsorption of Fe^{3+}, Zr^{4+} and Pb^{2+} has been observed and Co^{2+}–Fe^{3+}, Zn^{2+}–Fe^{3+} and Cu^{2+}–Fe^{3+} separations have been achieved with this exchanger.[385]

Titanium salts

Titanium phosphate. Various methods have been described for the preparation of titanium phosphate ion-exchangers, leading to formation of amorphous,[265,386,387] granular amorphous[388,389] and crystalline[276,366,390,391] products. The composition of the amorphous materials varies between P/Ti ratios of 0·6 and 2·0, and different empirical formulae such as $[(TiO)_{0\cdot535}(H_2PO_4)_{0\cdot369}(OH)_{1\cdot77}]\cdot 1\cdot 11\ H_2O$,[386] $TiH_2(PO_4)_2 \cdot 4H_2O$ and $Ti_3(PO_4)_4$[387] have been proposed for these materials. High exchange capacity has been found (~7·5 meq/g)[386] and is not appreciably affected by calcination.[392,393] The exchanger can be easily regenerated[386] and exhibits a high selectivity towards Cs^+.[386] Selectivity series for alkali metal cations reported by various authors[263,265,394] differ substantially, probably owing to different products being used.

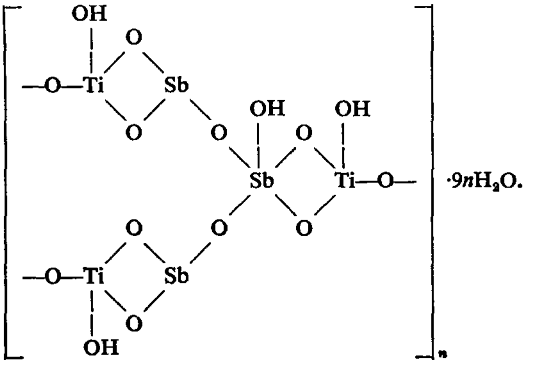
A formula $Ti(HPO_4)_2 \cdot H_2O$[366,390,391] for crystalline titanium phosphate has been proposed on the basis of chemical and X-ray analysis. One molecule of water was lost reversibly on heating this material to 120°.[366,390,391] A further molecule of water was taken up on standing in a water-saturated atmosphere at 0–20°,[366] and the product showed higher resistance than the amorphous materials towards hydrolysis.[390] The total ion-exchange capacity is 7·15 meq/g.[390] However, crystallization of the exchanger permits the exclusion of ions with larger ionic radii. This effect is more noticeable for this compound than for the zirconium phosphate, since K^+ ions are also excluded in acid solutions. By conversion into the Na^+ form, the crystallographic *d*-values are increased and the material exhibits a lower degree of crystallinity. A special behaviour has been observed for the Li^+ form, when no changes in X-ray pattern occurred on the conversion of the H^+ form into the Li^+ form, and difficulties arose in converting the Li^+ form into the K^+ and even into the Na^+ forms.[390] Crystalline titanium phosphate also exhibits a unidimensional intercrystalline swelling,[366] when amines are incorporated into the crystals either from the gaseous phase or from solution. The incorporation of amines leads to an increase in one lattice parameter only.[366]

Titanium phosphate has been used for the separation of radioactive Cs from strongly acidic nuclear-fuel reprocessing solutions,[395,396] to separations of Curie-level activities of ^{228}Th and ^{227}Ac from traces of ^{226}Ra,[397] and to the thin-layer chromatographic separation of Na from K.[398]

Titanium arsenate and antimonate. By mixing sodium arsenate solution with $TiCl_4$, glassy amorphous *titanium arsenate* with composition $Ti(HAsO_4)_2{\cdot}2{\cdot}5H_2O$ is formed[399] which has an exchange capacity of about 1 meq/g. The exchanger is highly selective towards Pb^{2+}, Cu^{2+}, Ba^{2+}, Sr^{2+}, Zn^{2+}, Mn^{2+} and Cd^{2+} and can be used for the separation of Pb^{2+} from a series of bivalent metals as well for Ba–Mg, Ba–Ca and Ba–Sr separations.[399]

Crystalline titanium arsenate of composition $Ti(HAsO_4)_2{\cdot}H_2O$ is prepared by dissolving the freshly prepared amorphous titanium arsenate in 8*M* arsenic acid and subsequent refluxing for 45 hr.[400] The compound is hydrolysed considerably at $pH > 5$, so the total exchange capacity (5·8 meq/g) cannot be completely utilized.

Titanium antimonate is prepared by mixing $TiCl_4$ and $SbCl_5$ solutions and subsequently neutralizing with ammonia.[401] Amorphous products with Sb:Ti ratio ~1·0 and exchange capacity ~0·7 meq/g are obtained. The structure of the exchanger is built up from TiO_2 and Sb_2O_5, which are condensed together, giving the polymer



The hydrogen of the Sb-OH group is considered to be responsible for the cation-exchange capacity.[401] Separations such as Mg–Sr, Mg–Ca, Mg–Al, and Mn^{2+}–Al^{3+} have been achieved with this exchanger.[401]

Titanium molybdate and tungstate. Titanium molybdate is prepared by mixing $TiO(SO_4)_2$ or $TiCl_4$ solutions with an acidic solution of sodium molybdate. Amorphous products with Mo/Ti ratio ranging from 0·5 to 2·0 have exchange capacity between 0·8 and 1·6 meq/g. The capacity is substantially changed by heating the exchanger to 200°.[402] High selectivity of this exchanger towards Pb^{2+}, Ba^{2+}, Tl^{+} and K^{+} has been found and numerous separations such as Zn^{2+}–Pb^{2+}–Tl^{+}, Bi^{3+}–Pb^{2+}–Tl^{+},[402] Na–Rb, K–Cs, Ba–Ca and Na–Cs[403] have been achieved.

Titanium tungstate, prepared in a similar way to titanium molybdate, is an amorphous material which is highly stable towards mineral acids.[404] The exchange capacities vary between 0·42 and 0·76 meq/g depending upon the exchanger composition, and are higher for bivalent than univalent cations. Higher selectivity towards Ca^{2+} than other alkaline earth metal cations has been found, permitting the separation of Ca from Sr,Mg and Ba.[403,404] Other separations such as Na–Rb, K–Cs, Na–Cs,[403] and of Ga^{3+} from Fe^{3+}, Al^{3+} and In^{3+},[405] with this exchanger have been described. A paper impregnated with titanium tungstate is suitable for the separation of Au^{3+}, Tl^{3+}, Ag^{+}, Mo^{6+}, K^{+}, Rb^{+}, Cs^{+}, Ni^{2+}, Sb^{3+}, Bi^{3+}, Be^{2+} and Tl^{+} from numerous metal ions in aqueous and mixed-solvent media.[406]

Cerium salts

Cerium phosphate. When a solution of phosphoric acid is mixed with a solution containing a Ce(IV) salt a precipitate of cerium phosphate is formed, the composition, degree of crystallinity and structure of which are strongly dependent on experimental conditions such as precipitation medium, temperature, digestion time, PO_4/Ce ratio in the solution, rate and order of mixing, stirring *etc.* The products obtained may be divided into four groups: amorphous, microcrystalline, fibrous crystalline and crystalline cerium phosphate-sulphate.

The composition of the *amorphous* materials varies, with PO_4/Ce ratios between 1·03 and 1·95.[407,408] For some products an empirical formula $Ce_3(OH)_8(H_2PO_4)_4$ has been postulated.[409] If the precipitation is carried out in sulphuric acid media, the PO_4/Ce ratio decreases and the product contains 2–6% of sulphate.[407] The maximum exchange capacity of 2·9 meq/g[410] is totally lost on heating the exchanger to 200°.[410,411] The selectivity series for alkali metal cations follows the order of hydrated ionic radii, *ie.*, $Cs > Rb > K > Na > Li$.[409,410,412] Standard enthalpy changes have been determined for the Li–H, Na–H and K–H exchanges (+3·6, +3·1, −0·63 kJ/mole).[409]

The amorphous cerium phosphate also exhibits electron-exchange properties.[409] The oxidation of Mn^{2+} according to the equation

$$\begin{aligned} Ce_3^{IV}(OH)_8(H_2PO_4)_4 + 3Mn^{2+} \rightleftharpoons\ & Ce_3^{IV}(OH)_8Mn_3^{II}(HPO_4)_2(PO_4)_2 + 6H^+ \\ & \qquad\qquad\downarrow \\ & Ce^{III}(OH)_8Mn^{III}(HPO_4)_2(PO_4)_2 \end{aligned}$$

and the oxidation of I^- according to the equation

$$2Ce_3^{IV}(OH)_8(H_2PO_4)_4 + 9I^- \rightleftharpoons 2Ce_3^{III}(OH)_5(H_2PO_4)_4 + 3I_3^- + 6OH^-$$

have been observed.[409]

Microcrystalline cerium phosphate with a PO_4/Ce ratio of 1·5,[407,413] corresponding to the formula $(Ce{-}O{-}Ce)(HPO_4)_3{\cdot}H_2O$,[407] exhibits low ion-exchange capability.[412,413] Its affinity towards univalent cations increases in the order $Cs < Na < Ag$.[412]

Fibrous *crystalline* cerium phosphate, formulated as $Ce(HPO_4)_2{\cdot}H_2O$,[413] is stable towards hydrolysis[413,414] and exhibits a higher theoretical capacity (~5·2 meq/g) than the amorphous material. However, its capacity is lower at low pH (<3·3) than that of amorphous cerium phosphate. Similar behaviour has also been observed for zirconium and titanium phosphates and has been explained by the fact that in the amorphous materials the exchangeable hydrogen ions display a larger range of acidities than in the crystalline materials, so that some exchange may occur at lower pH values.[413]

Crystalline *cerium phosphate-sulphates* are obtained by precipitation from sulphuric acid solutions.[407] Products containing at least 0·75% w/w of sulphate exhibit their own crystal structure, which does not change till one HPO_4^{2-} group has been exchanged for an SO_4^{2-} group. Another crystal structure was found at higher SO_4^{2-} content up to a Ce:P:S ratio of 2:1:2.[415] These compounds may be formulated as $Ce_2O(HPO_4)_{3-x}(SO_4)_x \cdot 4H_2O$, where $0 < x < 1$. It is supposed that they possess a zeolytic structure, which is demonstrated by the fact that on Na^+ or Ag^+ exchange for H^+ no change in the crystal structure occurs.[412] The exchange capacity decreases with increasing SO_4^{2-} content[415] owing to the replacement of an active HPO_4^{2-} group for an inactive SO_4^{2-} group. However, products with Ce:P:S ratios up to 2:2:1 exhibit very good mechanical as well as ion-exchange properties. The selectivity towards various cations decreases in the order Na > Ag > Sr > Ba > Cs > Ca, the Be^{2+}, Co^{2+}, Fe^{3+} and Y^{3+} ions being not adsorbed at all.[415] It is concluded that only ions having an effective ionic radius $\lessdot 0{\cdot}6$ nm can enter the exchanger, which behaves as an ion-sieving material.

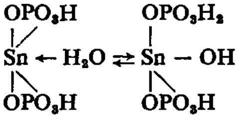
Cerium phosphates have been used for the column separations of Na from Cs and of Cs from Ba;[416,417] Li–Na–K, Ni–Ag–Tl and Co^{2+}–Eu^{3+}–Fe^{2+} separations have been carried out on a cellulose–cerium phosphate paper.[418] Fibrous cerium phosphate is suitable for preparing thin-layer membranes resistant to high temperature, ionizing radiation and oxidants.[419]

Cerium arsenate. Cerium arsenate is prepared by mixing a solution of cerium sulphate in sulphuric acid with arsenic acid and refluxing. A crystalline product of composition $Ce(HAsO_4)_2 \cdot 2H_2O$ is obtained, which loses one molecule of water at 60° and the second at 110°. A total exchange of Li^+ and Na^+ for H^+ has been achieved,[420] which was not the case with larger cations. The first interplanar distance increases with the degree of conversion into the Li^+ or Na^+ forms, similarly to the behaviour of other crystalline salts of this type. Hydrated cations enter the exchanger at low exchanger loading, whereas partly or totally dehydrated cations enter the exchanger at higher loading, and this is accompanied by selectivity reversal. The exchange isotherms show good reversibility for the Li^+–H^+ exchange, probably owing to the crystal structure of the starting and back-exchanged H^+ forms being the same.[420] However, small and remarkable hystereses were found for the total Na^+–H^+ and K^+–H^+ half-exchange.[420]

Stannic salts

Stannic phosphate. Stannic phosphate is prepared by mixing $SnCl_4$ solutions with NaH_2PO_4 solutions of different acidities.[421,422] Amorphous products with P/Sn ratio from 1·25[422] to 1·50[386] are highly stable towards ionizing radiation as well as in hydrothermal conditions.[422] Granular materials are obtained by mixing $Sn(SO_4)_2$ solution with concentrated phosphoric acid at 20°.[464] The ion-exchange capacity of stannic phosphate increases with increasing P/Sn ratio,[421] reaching maximum values between 1·2 and 1·44 meq/g,[386,422] and is lost on heating the exchanger.[422] The titration curves of this exchanger show a series of irregular kinks, indicating several dissociable hydrogen ions with a range of pK values.[422] The affinity for alkali metal cations follows the order Cs > Rb > K > Na > Li[422] and for the bivalent transition metals the order Cu > Zn > Ni > Co.[386] Irregularities were found in the alkaline earth metal series, where Ca^{2+} was preferred to Sr^{2+},[422] and for the adsorption of Zr^{4+}, where the K_d values did not depend upon the nitric acid concentration.[423,424] This behaviour of Zr^{4+} is explained either by the formation of a stable zirconium compound in the interior of the exchanger particles or by Zr exchange for Sn.[423,424]

Recently, crystalline stannic phosphate of composition $Sn(HPO_4)_2{\cdot}H_2O$ has been prepared by refluxing solutions containing $SnCl_4$, HNO_3 and H_3PO_4.[425] This exchanger is readily hydrolysed in alkaline solutions and loses its chemically bound water at a rather lower temperature (<350°) than the other crystalline phosphates of this type. The total exchange capacity for Na^+ corresponds to the stoichiometric formula. However, for the exchange of Li^+ a higher total capacity has been reached (7·9 meq/g), indicating probably the presence of more than two exchangeable hydrogen equivalents per formula weight of the exchanger. This is explained by the following tautomeric equilibrium in the solid:[425]



Stannic phosphate has found a wide range of useful separation applications, especially in the processing of radioactive effluents. Thus uranium can be separated from Sr,Cs and rare earths with a decontamination factor of $\sim 3{\cdot}10^3$,[424,426] as well as Sr and Cs from fission product solutions.[396,427] Complete separations such as K–Rb, Na–Cs, K–Cs, K–Na,[422,424] ^{89}Sr–^{137}Cs, ^{89}Sr–^{144}Ce, ^{137}Cs–^{144}Ce, ^{90}Sr–^{90}Y[428] have been described. Papers impregnated with stannic phosphate are suitable for chromatographic separation of a great number of cations.[429–432]

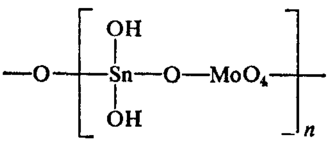
Stannic arsenate and antimonate. By mixing $SnCl_4$ solutions with Na_2HAsO_4[433] or H_3AsO_4,[434] amorphous *stannic arsenate* (Sn/As ~ 1·8) is formed. This material is stable in dilute acids and exhibits relatively high temperature stability.[433] The exchange capacity is between 0·79 and 0·94 meq/g, depending upon the As/Sn ratio in the solid. The distribution coefficients measured for a series of bi- and tervalent cations[433,434] show selectivity series corresponding to the order of ionic radii in the cases of alkaline earth metals, Al^{3+}, Ga^{3+} and In^{3+}. A disagreement found in the case of bivalent transition metals is explained by the decisive role of the solubility products of the corresponding arsenates of the metal ions in the adsorption process.[434]

Crystalline stannic arsenate is prepared either by refluxing the amorphous material with H_3AsO_4[434] or by refluxing solutions containing $SnCl_4$, HNO_3 and H_3AsO_4.[425] This material, of composition $Sn(HAsO_4)_2{\cdot}H_2O$,[425] is readily hydrolysed in alkaline media and exhibits ion-sieve properties, adsorbing only Li^+ and Na^+ ions from acid solutions. The exchange capacity found for Li^+ exceeds the formula capacity, which is explained similarly as in the case of crystalline stannic phosphate.[425]

A series of separations with stannic arsenate, such as Cu–Pb, Cu–Fe^{3+}, Fe^{2+}–Pb^{2+}, Fe^{2+}–Cu,$^{2+}$ Fe^{2+}–Fe^{3+},[433] Sr–Ba, Mg–Ba, Ca–Ba, Co^{2+}–Fe^{3+}, Al^{3+}–Fe^{3+}, Mn^{2+}–Fe^{3+}, Ca^{2+}–Fe^{3+}, Ni^{2+}–Fe^{3+}, Al–In and Mg–Al[434] has been described.

Stannic antimonate, prepared from $K_2H_2Sb_2O_7$ and $SnCl_4$ solutions, forms glass-like materials (Sb/Sn = 1:4–2:1) which are highly resistant towards mineral acids[435,436] and are suitable for use in column separation of alkali metal cations.

Stannic molybdate and tungstate. Stannic molybdate is prepared by mixing $SnCl_4$ with ammonium molybdate solutions.[437] Semitransparent amorphous granules with Sn:Mo ratio 1:1 and an exchange capacity of about 1·0 meq/g are obtained. The structure of this exchanger is tentatively postulated as



$$-\mathrm{O}-\left[\begin{matrix}\mathrm{OH}\\ |\\ -\mathrm{Sn}-\mathrm{O}-\mathrm{MoO_4}-\\ |\\ \mathrm{OH}\end{matrix}\right]_n-$$

The exchanger exhibits rather low stability towards hydrolysis (the Na^+ form being more stable than the H^+ form). High selectivity for Pb^{2+} ions has been found, which can be used for the separation of Pb^{2+} from a series of metal ions.[437]

Hard, semitransparent granules of *stannic tungstate* are prepared by mixing $SnCl_4$ with sodium tungstate solutions.[438] The product, with Sn/W ratio 1:3, is much more stable towards hydrolysis than stannic molybdate, and has an exchange capacity of ~0·58 meq/g which decreases on heating the exchanger to 100°. The selectivity for Co^{2+}, Ba^{2+}, Ni^{3+}, Pb^{2+}, Mn^{2+}, Cu^{2+} and Sr^{2+} ions has been established.[438] Papers impregnated with stannic tungstate are suitable for the separation of Zn^{2+}, Cd^{2+}, Au^{3+}, Ga^{3+}, Mg^{2+}, K^+, Rb^+, Cs^+ and Zr^{4+}.[431,439]

Other Acidic Salts

This group of ion-exchangers includes phosphates, polyphosphates and vanadates of tervalent and some bivalent cations, such as chromium, aluminium, iron, uranyl, alkaline earth metals, zinc, copper and tin.

Chromium phosphate is a polyfunctional gel-like radiation-resistant[440] cation-exchanger[441] with different PO_4/Cr ratios ranging from 0·6 to 1·0.[265] Empirical formulae such as $Cr_2O_2HPO_4$, $Cr_2O(HPO_4)_2$[265] and $CrPO_4$[441] have been proposed for these compounds. The maximum exchange capacity is 5·9 meq/g,[265,442] decreasing with increasing ionic radius of the ingoing ion.[265] The selectivities towards alkali and alkaline earth metal cations decrease in the orders $Na > K > Rb > Cs$ and $Ca \geqslant Sr > Ba$, respectively.[265] Separations of alkali metals and some transition metals such as K^+–Cs^+, Rb^+–Cs^+, Rb^+–Sr^{2+}, $Mn^{2+}Fe^{3+}$, Co^{2+}, –Fe^{3+}, Tc(IV)–Mo(VI) ,Sn^{2+}–In^{3+},[443] as well as the isolation of ^{59}Fe from Co,[442] have been described.

Chromium tripolyphosphate is prepared by mixing sodium tripolyphosphate with $CrCl_3$ solutions. Green glassy products with Cr/P ratio of 1:2·48 are obtained, exhibiting poor solubility in acids.[444] Their composition corresponds to the empirical formula $Cr_5(P_3O_{10})_3{\cdot}xH_2O$.[444] The exchange capacity for alkali metal cations is linearly dependent upon the pH of the external solution. The substance is highly selective towards alkali metal cations ($Cs > Rb > K > Na > H$), the uptake of bi-, ter- and quadrivalent cations being negligible.[444] A complete separation of Na, K, Rb and Cs has been achieved with this material, even in the presence of bi-, ter- and quadrivalent cations.[445,446] By evaporating $CrCl_3$ solution in phosphoric acid at 200–280°[447] another product, with composition $H_2CrP_3O_{10}{\cdot}2H_2O$, is formed, which is highly selective towards Ag^+.[447] The infrared spectra indicate that the water molecules are partly dissociated into H_3O^+ and OH^- groups.[448] The exchange of K^+ for H^+ led to the formation of an anhydrous compound, $K_2CrP_3O_{10}$.[447]

Aluminium and ferric triphosphates have been prepared with M/P ratios of 0·5–0·66 and can be used as selective ion-exchangers for K^+ ions within a limited pH range (2·5–6·0).[449] *Ferric pyrophosphate* $Fe_4(P_2O_7)_3$, has been studied for the adsorption of In^{3+}. It is noticeable that Fe^{3+} was displaced by In^{3+} ions during this process.[450]

Aluminium vanadate with composition $(Al_2O_3)_n(V_2O_5)_m(n/m = 2{\cdot}0\text{–}0{\cdot}5,\ m = 2\text{–}10)$ can be used as an ion-exchange membrane or may be sintered with a ceramic material without significant loss of exchange capability. The membranes operate efficiently up to 900°.[451]

Uranyl hydrogen phosphate ($UO_2HPO_4{\cdot}4H_2O$) and its salts with univalent and bivalent cations act as cation-exchangers, the exchange involving hydrogen (or M^+, M^{2+}) ions from the phosphate groups.[452,453] An unusual affinity series has been found for univalent cations, $NH_4 > Cs \sim Rb \sim K \gg Na$, which follows the series of increasing solubility products of the corresponding alkali metal uranyl phosphates.[454] High affinity for the ammonium ion is explained by the solubility product of ammonium uranyl phosphate having the lowest value.[454] On heating uranyl hydrogen phosphate to 300° a conversion into uranyl orthophosphate and liberation of the phosphoric acid occurs,[455] which causes substantial changes in the selectivity, bi-, ter- and quadrivalent cations being preferred. Na^+ can be separated from K^+, Rb^+ and Cs^+, but a complete separation of the alkali metals is impossible.[452] Separations of Co^{2+} from Zn^{2+}, Ce^{3+} from Cs^+, Co^{2+} from Cs^+ and Y^{3+} from Sr^{2+} have also been achieved with this exchanger.[452] For the adsorption of quadrivalent cations (Th^{4+}, Pu^{4+}, Zr^{4+}) on ammonium uranyl phosphate a precipitation mechanism has been found,[456,457] leading to the formation of insoluble phosphates of the type $(NH_4)_xH_yM^{IV}_{3-x-y}(PO_4)_{4-x-y}$, where $0 < x,y < 2$ and $(x + y) < 2$. Thus the formation of $NH_4M_2^{IV}(PO_4)_3$ was found on adsorption of Th^{4+} and Pu^{4+} and the formation of $Zr_3(PO_4)_4$ on adsorption of Zr^{4+}.[456,457]

A precipitation mechanism rather than ion-exchange has also been reported for other phosphates of bivalent metals, such as *calcium phosphate*,[458,459,460] *ammonium magnesium phosphate*,[461] *zinc phosphate*[462,463] and *copper phosphate*.[463]

Stannous polyphosphate exhibits electron-exchange properties,[360] reducing I_2, Fe^{3+} and Ag^+. The electron-exchange capacity varies between 0·44 and 0·59 meq/g.

Zusammenfassung—Eine ausführliche Literaturübersicht ist gegeben von hydratisierten Oxyden und sauren Salzen von vielwertigen Metallen die als Ionenaustauschsubstanzen anwendbar sind. Die Übersicht schliesst die Herstellung, Eigenschaften, Anwendbarkeit und Theorie von diesen Substanzen ein.

Résumé—Une revue complété est présenté sur les oxides hydratés et sels acides de métaux multivalents qui sont usés en qualité de matériaux échangeurs d'ions. La revue couvre la preparation, les qualités, usages et théorie de ces matériaux.

LE MICRODOSAGE COLORIMETRIQUE DES PHOSPHATES DANS DES MILIEUX DIVERS (PRODUITS BIOLOGIQUES, PHARMACEUTIQUES ET ALIMENTAIRES)

GH. GHIMICESUC et VASILE DORNEANU
Institut de Médecine et de Pharmacie de Iassy, Roumanie

(*Reçu le 7 juillet* 1971. *Accepté le* 2 *octobre* 1971)

Résumé—On propose une microméthode colorimétrique pour le dosage des phosphates dans divers milieux (produits biologiques, pharmaceutiques et alimentaires). Elle est fondée sur leur précipitation à l'état de phosphate double d'uranyle et de magnésium. Le précipité est dissous dans l'acide sulfurique dilué, et l'on dose l'ion uranyle par formation d'une coloration rouge foncé avec le ferrocyanure de potassium, puis mesure au spectrophotomètre. La sensibilité de la méthode est de 0,01 mg de P dans la prise d'essai, l'erreur moyenne est de ±1%. La méthode proposée est très simple et peut être appliquée dans les domaines les plus divers.

DANS LEUR majorité, les techniques couramment utilisées pour le dosage de l'ion phosphate sont fondées sur la formation d'acide phosphomolybdique, ensuite réduit en bleu de molybdène. Ces méthodes diffèrent entre elles par la nature du réducteur utilisé: hydroquinone,[1] acide aminonaphtolsulfonique en milieu sulfitique,[2-4] sulfate d'hydrazine,[5] chlorure stanneux,[6-8] hydroxyquinoléine,[9] *etc.*

Les colorimétries de l'acide phosphomolybdique[10] ou du complexe phosphovanadomolybdique,[11] tous deux colorés en jaune, ont été préconisées ainsi que celle mettant à profit la réaction entre le phosphate d'uranyle et le ferrocyanure de potassium.[12]

D'autres méthodes utilisent le titrage des phosphates par l'acétate d'uranyle en présence de ferrocyanure comme indicateur.

En vue d'établir un procédé unique, applicable à tous les cas considérés, nous avons d'abord étudié la méthode classique avec formation d'un bleu de molybdène. Nous avons constaté que la coloration bleue obtenue est instable, qu'elle s'intensifie dans le temps, et que les résultats ne sont pas reproductibles. Même dans l'intervalle de temps indiqué dans les diverses techniques, la variation d'intensité est appréciable, entraînant des erreurs qui peuvent atteindre 33%.

Notre étude s'est alors orientée vers la colorimétrie du ferrocyanure d'uranyle.[12]

En examinant la précipitation des phosphates à l'état de phosphate d'uranyle, nous avons constaté que la réaction est plus sensible avec l'acétate double d'uranyle et de magnésium (0,01 mg P) qu'avec l'acétate d'uranyle simple (0,1 mg P). Il y a formation de phosphate double d'uranyle et de magnésium, et la réaction n'est gênée par aucun ion.

L'analyse chimique de ce phosphate double, isolé et séché à température ambiante, a conduit à lui attribuer la formule suivante: $Mg(UO_2)_2(PO_4)_2$, 8,5 H_2O. L'analyse thermogravimétrique met en évidence une perte partielle de l'eau de cristallisation vers 105°, et une déshydratation totale vers 200°. Le composé est stable jusqu'à 620°.

Nos essais ont permis l'élaboration d'une technique de dosage des phosphates applicable dans tous les cas considérés (produits biologiques, pharmaceutiques, alimentaires, eaux).

Le principe de la méthode est le suivant: on précipite l'ion PO_4^{3-} sous forme de phosphate double d'uranyle et de magnésium.

$$2\ Na_3PO_4 + 2\ Mg(UO_2)(CH_3CO_2)_4 = Mg(UO_2)_2(PO_4)_2 + 6\ NaCH_3CO_2 + Mg(CH_3CO_2)_2$$

Le précipité est solubilisé dans l'acide sulfurique, libérant les ions UO_2^{2+} d'après la réaction:

$$Mg(UO_2)_2(PO_4)_2 + 3\ H_2SO_4 = 2(UO_2)SO_4 + MgSO_4 + 2\ H_3PO_4$$

Ces ions réagissent alors avec $K_4Fe(CN)_6$, formant $(UO_2)Fe(CN)_6$, sous forme d'une suspension colloïdale rouge foncé qui est mesurée spectrophotométriquement:

$$2(UO_2)SO_4 + K_4[Fe(CN)_6] = (UO_2)_2[Fe(CN)_6] + 2\ K_2SO_4$$

PARTIE EXPERIMENTALE

Réactifs

Etalon de phosphate monopotassique. On dissout 0,1098 g de KH_2PO_4 (désséché pendant 24 h sur acide sulfurique) dans l'eau distillée, q.s.p. 250 ml; 1 ml de cette solution contient 0,1 mg de P ou 0,25 mg de P_2O_5.

Réactif uranyle-magnésium. Solution *a*: on dissout, en chauffant au bain-marie, 10 g d'acétate d'uranyle dans 50 ml d'eau distillée, et ajoute 2 ml d'acide acétique cristallisable. Solution *b*: on dissout, en chauffant au bain-marie, 30 g d'acétate de magnésium dans 50 ml d'eau distillée, et ajoute 1 ml d'acide acétique cristallisable. On mélange à chaud les solutions *a* et *b*, refroidit à température ambiante, et ajoute 400 ml d'alcool 96%. On abandonne pendant quelques heures, filtre, et conserve dans des flacons teintés. La récupération des résidus d'acétate d'uranyl est effectuée selon les indications de E. Kahane (cité d'après la Réf. 13).

Solutions à 10% et 1% d'acide acétique.
Solution à 10% d'acide sulfurique.
Solution à 20% de ferrocyanure de potassium.
Solution à 10% d'acétate de potassium.
Solution à 20% d'acide trichloracétique.
Solution à 5% de soude.
Solution à 5% de persulfate de potassium.

Etablissement de la courbe d'étalonnage

Dans des tubes à centrifuger, on introduit 0,25; 0,5; 1,0; 2,0; 3,0; ... ml de solution étalon de phosphate. On ajoute 1 ml d'acide acétique à 1% et 3 ml de réactif uranyle-magnésium. On agite, puis lave l'agitateur avec 2 ml de réactif. On laisse reposer pendant 30 mn, puis centrifuge. On décante la liqueur claire surnageante, lave le précipité par 3 ml d'eau distillée et répète l'opération jusqu'à ce que la dernière eau de lavage ne donne plus la coloration rouge-brun avec le ferrocyanure de potassium. Après la dernière décantation, on reprend par 1 ml d'acide sulfurique à 10% et agite jusqu'à dissolution complète du précipité. On transvase, en rinçant avec 10–15 ml d'eau distillée, dans une fiole jaugée de 20 ml. On ajoute 2,0 ml de solution à 20% de ferrocyanure de potassium, complète au trait par l'eau distillée, agite, laisse reposer pendant 15 minutes et effectue la lecture à $\lambda = 479$ nm. Les courbes γ-sont des droites passant par l'origine et suivant la loi de Lambert-Beer.

Dosage du phosphore total dans le sang et l'urine

Dans une petite capsule en platine, on introduit 2 ml d'urine diluée au dixième, ou 1 ml de sang ou de sérum, ajoute 1 ml de KOH à 5%, 2 ml de $(NH_4)_2S_2O_8$ à 5% et calcine pendant 1 h dans un four électrique à 700–800. On transfère les cendres obtenues dans un tube à centrifuger avec 1 ml d'acide acétique à 10% et 4 ml d'eau distillée, ajoute 3 ml de réactif uranyle-magnésium et procède ensuite comme déja décrit.

Dosage du phosphore minéral dans le sang (sérum) ou l'urine

Dans un tube à centrifuger de 5 ml, on introduit 1 ml de sang ou de sérum, ou 2 ml d'urine diluée au dixième, ajoute 3 ml d'acide trichloracétique à 20%, agite et centrifuge. La liqueur claire est transvasée dans un autre tube à centrifuger. On lave le précipité à trois reprises avec chaque fois 1 ml d'eau, et les liqueurs surnageantes sont également transvasées dans le tube à centrifuger précédent. On ajoute alors 1 ml d'acétate de potassium à 10%, 5 ml de réactif uranyle-magnésium, et procède ensuite comme déja décrit.

Dosage du phosphore acido-soluble total du sang

A 1 ml de sang, on ajoute 3 ml d'acide trichloracétique à 20% pour éliminer les substances protéiques. On agite et filtre à travers un petit filtre dans une capsule en platine. On lave le précipité à trois reprises avec chaque fois 2 ml d'eau distillée et verse les eaux de lavage dans la capsule. On procède ensuite comme décrit pour phosphore minéral.

Dosage du phosphore lipidique du sang

On verse goutte à goutte 1 ml de sang dans un mélange 3:1 d'alcool éthylique et d'éther sulfurique, agite et filtre à travers un petit filtre dans une capsule en platine. On lave le filtre à trois reprises avec 5 ml du mélange alcool–éther, en recueillant le liquide de lavage dans la capsule. On ajoute 1 ml de KOH à 5%, évapore à sec et calcine dans un four électrique à 700–800. On procède ensuite comme décrit pour phosphore minéral.

La méthode proposée a été vérifiée sur le sang et l'urine, avec ou sans addition d'étalon de phosphate. Les résultats obtenus avec le spectrophotomètre sont consignés dans les Tableaux I–V et montrent que l'erreur relative varie de 0,0 à 2,6%.

Dosage du phosphore dans les produits pharmaceutiques contenant du phosphore organique

Dans une capsule en platine, on pèse 0,1 g de produit, ajoute 5 ml de KOH à 5%, évapore à sec au bain-marie et calcine dans un four électrique à 700–800 pendant 1 h. On reprend les cendres par 2 ml d'acide acétique à 10% agite jusqu'à dissolution totale. On transvase quantitativement, au moyen d'eau distillée, dans une fiole jaugée de 100 ml et complète au trait par l'eau distillée.

On introduit 2 ml de cette solution dans un tube à centrifuger, ajoute 3 ml de réactif uranyle-magnésium, et procède comme déja décrit.

La méthode a été vérifiée sur le glycérophosphate de calcium; on a trouvé 14,55% de P au lieu de 14,70 en théorie, soit une erreur de ±1%.

trait par l'eau distillée, et agite. On introduit 2 ml de cette solution dans un tube à centrifuger, ajoute 3 ml de réactif uranyle-magnésium, et procède comme déja décrit.

La méthode a été vérifiée sur la farine de blé, avec ou sans addition d'étalon de phosphate. Les résultats sont consignés dans le Tableau VI.

CONCLUSIONS

Après étude des méthodes de dosage des phosphates dans les produits biologiques, pharmaceutiques et alimentaires, une mise au point, en tant que technique unique, a été faite de la méthode au phosphate double d'uranyle et de magnésium. Elle comporte la précipitation du phosphate au moyen de l'acétate double d'uranyle et de magnésium, la dissolution du précipité par l'acide sulfurique dilué et le dosage spectrophotométrique de l'ion uranyl après action du ferrocyanure de potassium.

La sensibilité est de 0,01 mg de P dans la prise d'essai, l'erreur moyenne est de ±1 %. La méthode proposée est très simple et peut être aisément appliquée dans les domaines les plus divers.

Summary—A colorimetric micromethod is proposed for determination of phosphates in various materials (biological substances, pharmaceuticals and food). It is based on precipitation of magnesium uranyl phosphate, which is then dissolved in dilute sulphuric acid, and the uranyl ion is determined spectrophotometrically *via* the dark red colour of uranyl ferrocyanide. The sensitivity is 0·01 mg of P, and the average error 1 %. The method is very simple and applicable to many types of sample.

Zusammenfassung—Es wird eine kolorimetrische Mikrometode für die Dosierung der Phosphaten aus verschiedenen Umfängen (biologische, farmazeutische und Nahrungserzengnisse) vor geschlagen. Sie begründet sich auf das Niederchlagen unter doppelter Farm des Magnesiumsphosphates und uranyl. Der Niederschlag wird in verdünnter Schwefelsäure gelöst unddas uranyl ion wird dosiert durch die Bildung einer dunkelroten Färbung mit K_4 $Fe(CN)_6$ dem welche beim spektrophotometer gemessen wird. Die Empfindlichkeit der Metode ist 0,01 mg P mit einem durchschwittlichen. Fehler von ±1 %. Die vorgeschlagene Metode ist sehr einfach und kann in verschiedenen Umfängen angewendet werdew.

THE TIN-COLLECTION SCHEME FOR THE DETERMINATION OF PLATINUM-GROUP METALS, GOLD AND SILVER

G. H. FAYE and P. E. MOLOUGHNEY
Mineral Sciences Division, Mines Branch, Department of Energy, Mines and Resources, Ottawa, Canada

(*Received* 30 *March* 1971. *Accepted* 2 *October* 1971)

Summary—A comprehensive analytical scheme is presented for the determination of the six platinum-group metals, gold and silver. It is the result of the integration of separate procedures that have been described previously, in part, over the course of several years. The analytical scheme has been thoroughly tested in umpire and standards work on a wide variety of materials and, as a consequence, is of increasing interest to many laboratories. The precious metals are collected in molten tin when the sample is fused at 1200–1250° with a flux containing stannic oxide, sodium carbonate, silica, borax and flour. The resultant tin alloy is dissolved and the precious metals are isolated by ion-exchange, solvent extraction and/or distillation procedures. With the exception of the usual facilities required in the fusion step of fire assaying, standard equipment can be used in the wet-chemical operations for the isolation and determination of the individual precious metals.

THE LITERATURE reveals numerous problems associated with the determination of gold and silver and the individual members of the platinum-group of metals in ores, rocks, and mineralogical and metallurgical concentrates. Many of the difficulties arise from the use of the time-honoured method of fire assaying in which molten lead is used to collect the precious metals from the fused sample material. The classical lead-collection method is satisfactory for the determination of gold and silver in most commonly encountered materials of mineralogical origin, but there are many instances where it is unsuitable for the determination of the platinum-group metals, and for gold and silver in complex platiniferous materials. The interested reader may refer to certain works by Beamish and co-workers[1–8] for an understanding of many of the problems in the classical method of fire assaying.

To overcome some of these difficulties, certain of the larger mining and metallurgical laboratories employ spectrographic techniques to analyse precious-metal beads produced by the classical method of fire assaying. Although reliable results can be obtained for platinum, palladium, rhodium, and gold, this approach has been unsatisfactory for iridium, ruthenium, and osmium.[8] Further drawbacks to the spectrographic finish, at least for some laboratories, are the cost of equipment and the need for highly trained operators.

Because of the problems indicated above, attempts have been made to develop methods other than those based on the collection of precious metals in lead. Among these are: purely wet-chemical methods, neutron-activation analysis and fire assay methods using a metal other than lead as a collector. Although the first two of these approaches are useful in particular situations, they cannot, as yet, fulfil the need for a versatile method that can be used routinely in a modestly equipped laboratory.

In the early 1960's a new analytical scheme was developed in the Mines Branch for the determination of the platinum metals and gold in ores and other mineralogical materials. This scheme was originally outlined, in part, in 1965 in Research Report R 154 and is based on the preconcentration of the precious metals by a fire assay using tin as the collector.

As at present used, the scheme (Fig. 1) involves the collection of the precious metals in molten tin when the sample is fused at 1200–1250° with a flux containing stannic oxide, sodium carbonate, silica, borax and flour. The resultant tin alloy (containing the precious metals as intermetallic compounds with tin) is then treated by relatively simple wet-chemical techniques to prepare solutions in which the individual precious metals can be determined by methods of atomic-absorption spectrophotometry or classical absorption spectrophotometry. For details of the developmental work involving platinum and palladium,[10] rhodium[11], iridium,[12] ruthenium and osmium,[13] gold,[14] and silver,[15] the reader should refer to the cited papers.

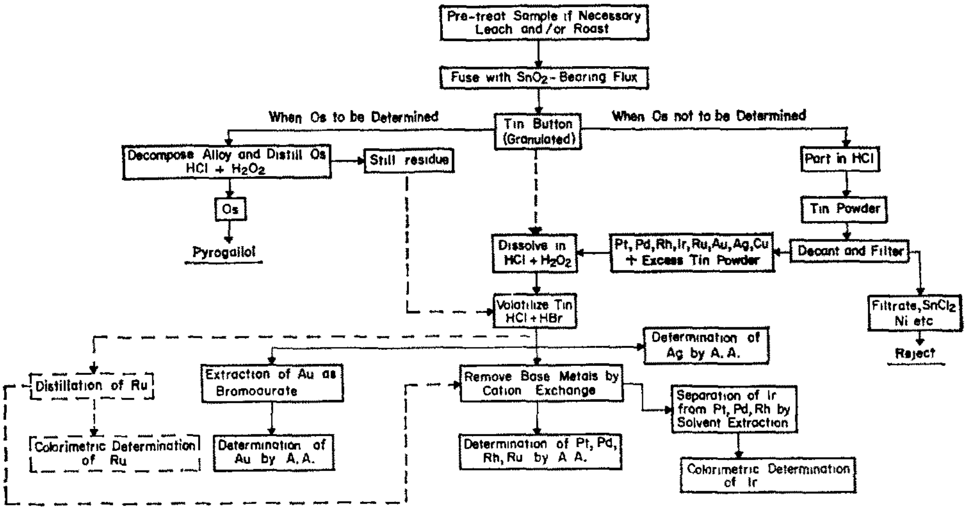

FIG. 1.—Flow-sheet outlining analytical scheme.

The tin-collection scheme has been used routinely in the Mines Branch for about seven years and has been successfully applied to a wide variety of materials including silicate rocks, copper–nickel ores, concentrates and matte, magnetite concentrates, precious metals concentrates, osmiridium and meteorites. In addition to routine applications, the tin-collection scheme of analysis has been used in umpire and standards work where it has been demonstrated, unequivocally, that the results obtained are in good agreement with those obtained by highly developed but less comprehensive methods in other laboratories.

The determination of silver was not part of the scheme described in 1965. Although it was recognized that silver was completely collected in tin, a suitable means was not then available for measuring its concentration in solutions obtained on dissolving the tin button. However, with the combined use of atomic-absorption techniques and tin-collection, silver can now be determined simply and quickly in the most complex materials.[15] Indeed, the silver method seems superior to other methods and, with the exception of materials high in lead, it is highly recommended for most geological and mineralogical samples even if they are not platiniferous.

Atomic-absorption techniques have also been introduced for finishing the determination of gold, platinum, palladium, rhodium and ruthenium; in general this eliminates the need for certain separations necessary before use of colorimetric finishes.

With respect to gold, the combined tin-collection and atomic absorption finish offers the advantages of speed and simplicity over similar procedures using lead as the collector. Again, the former approach is also suitable for many kinds of non-platiniferous materials.

In addition to the inclusion of silver and the introduction of finishes based on atomic-absorption spectrophotometry, a number of other modifications and improvements have been made in the tin-collection method for the precious metals. Because of the continued interest by outside agencies, this paper has been prepared to present the procedural details of the modified and updated tin-collection scheme of analysis for the whole family of precious metals.

GENERAL COMMENTS ON THE ANALYTICAL SCHEME

Certain types of materials such as copper–nickel matte, precious metals concentrates, meteorites and osmiridium may necessitate the determination of all six platinum metals plus gold and silver; Fig. 1 indicates the steps required for these determinations to be made on a single sample. However, many of the operations can be omitted when only partial analysis is required. For example, it is often necessary to determine only platinum and/or palladium because the abundance of these elements in some materials is considerably greater than the abundance of the other precious metals.

There are situations where it may be convenient, and perhaps more rapid, to perform some of the determinations on one portion of sample material (*e.g.*, osmium and/or ruthenium) and proceed simultaneously with the determination of other members of the group on a second portion.

If the sample contains *milligram* amounts of the platinum-group metals, consideration must be given to the recovery and analysis of insoluble residues that may be encountered after the decomposition of the tin button. It is to be emphasized however, that this complication arises only with special materials such as refinery products and bulk samples of native iridium–osmium alloys.

EXPERIMENTAL

Apparatus

The apparatus described below is recommended primarily because it has proved satisfactory in this laboratory; however, it is not necessary to adhere rigidly to the specifications given.

Assay furnace. A 15-kW Globar type with suitable thermocouple and temperature controller. The furnace should be capable of accommodating 6 assay crucibles and maintaining their temperature at 1250°.

Jelrus "Handy-Melt" portable electric furnace. This small vertical furnace is equipped with removable graphite crucibles and is used for melting tin-base assay buttons before their granulation in water. After 4–6 months of relatively constant use, it is recommended that the bottom of the crucibles be examined for small holes.

Atomic-absorption spectrophotometer. It is recommended that this spectrophotometer have a scale expansion facility. An oxidizing air–acetylene flame is used for the determination of gold, silver, platinum, palladium and rhodium; a slightly fuel-rich air–acetylene flame is used for the determination of ruthenium.

Spectrophotometer. The spectrophotometer should be capable of making absorbance measurements in the range 300–800 nm.

Distillation apparatus. The design of the apparatus is shown in Fig. 2. Vessel A is a 500-ml round-bottomed distillation flask and receiver B is a 250-ml, two-necked, round-bottomed flask which, during the ruthenium distillation, is fitted with a 250-ml "Glas-Col" heating mantle. Receivers C and D are 125-ml, tall-form gas-washing bottles with fritted cylinders at the end of the inlet tubes. Each fritted cylinder is pierced to make a 1·5-mm hole to permit free flow of gases through the apparatus.

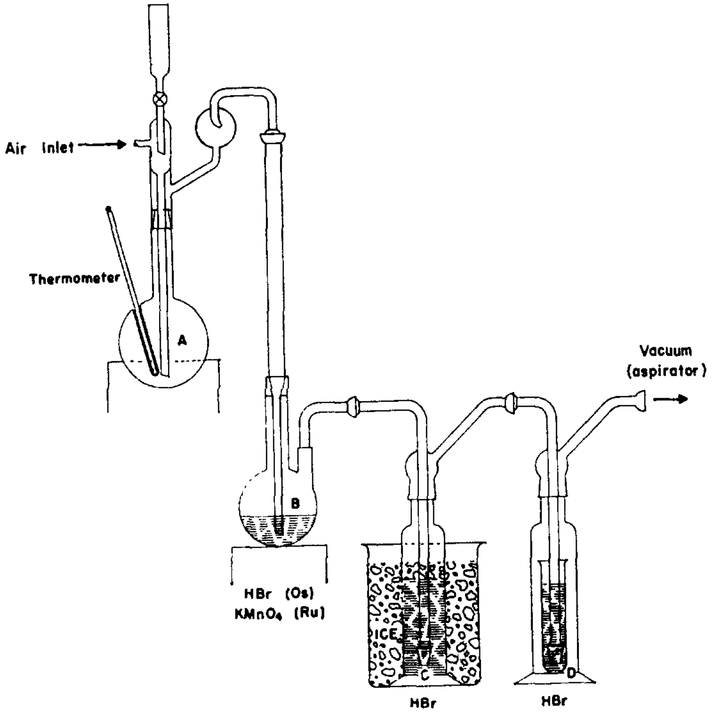

FIG. 2.—Distillation apparatus for osmium and ruthenium. Scale ~ 1/9. Reprinted from *Anal. Chem.*, by permission of the copyright holder (American Chemical Society).

Note. The diameter of the air-cooled, condensing bulb on vessel A should not be less than about 50 mm. A smaller bulb may not be efficient in condensing stannic chloride, which might then be troublesome in the analysis of the distillate.

Cation-exchange columns. It is recommended that both "large" (25 × 450 mm) and "small" (15 × 15 mm) columns be prepared with water-washed, 20–50 mesh, Dowex 50 W-X8 cation-exchange resin. Columns of these dimensions are suitable for the removal of approximately 4 and 0·5 g, respectively, of combined base metals (mainly copper and nickel).

To remove base metals and regenerate the resin, pass 4*M* hydrochloric acid through the column until the effluent solution is free from copper and nickel (test with ammonia solution). Wash the resin with water until the effluent is neutral to litmus paper.

Assay crucibles. Catalogued as "40-gram" type.

Reagents

Details of the preparation of special reagents will be given under *Procedures* in the sections describing their use.

Procedures

A. *Pre-treatment of sample*

Depending upon the nature of the sample, a pretreatment is frequently required to remove certain constituents or convert them into a form that will not lead to difficulties in subsequent operations.

Roasting is used primarily to convert sulphides into oxides, but also to volatilize arsenic and antimony, when present, and thus prevent the formation of matte or speiss during the subsequent fusion. It is recommended that samples other than alloys and copper-nickel matte be roasted before being mixed with the flux. It is known that osmium (but not ruthenium) is lost by volatilization during the roasting operation. Fortunately, this step can be omitted when certain types of platiniferous materials are to be analysed for osmium (*e.g.*, copper-nickel matte).

Place the sample (200-mesh), weighing up to 1 assay ton, in a shallow fire-clay dish and roast at 750–800° for approximately 1 hr with intermittent stirring. In cases where only a few grams of material (particularly sulphides) are to be roasted, place the sample on a thin bed of silica to prevent possible loss of the resultant calcine to the surface of the dish (include the silica used as part of the total quantity required for fluxing–see B1). When the calcine is cool, mix it with the flux and proceed with the fusion process as indicated below in B6.

Leaching of copper-nickel matte can be conveniently achieved in the following manner to remove the bulk of the copper and nickel and to leave the precious metals in a concentrated form in the leach residue. Place the sample, weighing up to 2 assay tons, in a 1500-ml beaker and treat it with approximately 25 g of ammonium chloride and 100–200 ml of 12*M* hydrochloric acid. Heat the covered beaker and contents until the amount of insoluble matter appears not to exceed approximately 2 g. If dealing with large sample weights, it may be necessary to retreat the leach residue once or twice with fresh acid after intervening filtrations.

Dilute the combined sample solution (approximately 100 ml) with an equal volume of water, heat to approximately 70° and then stir the solution and dissolved residue with a polyethylene-coated, electrically-driven stirrer. Add approximately 5 g of tin powder (200-mesh or finer) and stir the suspension for approximately 15 min. Filter the solution, containing most of the nickel, through a moderately fast paper. Completely wash the solids onto the paper with dilute (~5%) hydrochloric acid. Dry the washed residue and paper at ~110° for about 1 hr and then mix them with the flux for fusion (B6). [*Note.* After the fusion of the matte leach residue, a small amount of a sulphide phase will adhere to the tin button but this will ultimately be decomposed during the chemical treatment of the button (C1).]

Acid attack of the metallic phase from meteorites is necessary because the meteoritic iron–nickel alloy would not be attacked appreciably during the fusion process on account of the relatively low temperature and the reducing conditions that prevail. This problem can be avoided by dissolving the alloy in hydrochloric acid and then fusing the resultant chloride salts as in B6 below. The net result is to slag off the iron and collect the precious metals in the tin button.

Dissolve the meteoritic alloy (preferably more than 5 g of granules or turnings) in the requisite amount of boiling 12*M* hydrochloric acid. Evaporate the solution to dryness directly on the hot-plate and near the end of the operation stir the crystallizing salts with a glass stirring rod. The heating should be carried out in such a way as to drive off as much free acid as possible yet keep the mass from baking; this is to lessen the possible danger of losing osmium as the volatile tetroxide.

Scrape the dried salts from the beaker and add to the flux as described in B6(*a*). Using small portions of water and a rubber policeman, dissolve and dislodge the remaining material adhering to the beaker and pour the solution (suspension) into a bed of the standard flux.

B. *Crucible fusion process (preparation of buttons)*

1. *Flux.* The flux that has proven most satisfactory for nearly all materials so far encountered, contains the following materials in the indicated quantities:

	g
SnO_2	35–40
Na_2CO_3	50
SiO_2	10–20
$Na_2B_4O_7$	10
Flour	40

The quantity of silica is adjusted according to the amount of silica in the sample (for details see B4 below).

Note. Powdered coke (100–325 mesh) is also satisfactory as a reducing agent, 6–8 g being required. In early work[9–15] coke was used as reducing agent because experiments had shown that the use of relatively small quantities of flour (~10 g) resulted in the formation of inordinately small buttons. Subsequently however, it was learned that by increasing the amount of flour to 40 g, essentially complete reduction of stannic oxide is achieved. With 120 g of the flux, 40 g of flour, and samples weighing up to 1 assay ton (29·17 g), tin buttons weighing 27–29 g are obtained. This represents 85–90% recovery of the tin.

2. *Amount of sample required for analysis.* Usually the analyst has some prior knowledge of the range of the platinum metal and base metal values to be expected and can make a choice of sample weight according to the following considerations.

With the atomic-absorption methods described later in this paper, the smallest amounts of the individual precious metals that can be determined with reasonable accuracy are, in μg: Pt $\sim$ 5, Pd $\sim$ 1, Rh $\sim$ 1, Ru $\sim$ 5, Au $\sim$ 2, Ag $\sim$ 1. If the colorimetric methods are used for the platinum metals, the corresponding values are $\sim$3 μg each for Pt, Pd, Rh, Ir, Ru and $\sim$10 μg for Os.

To determine smaller quantities of the precious metals than indicated above, replicate buttons from 1-assay-ton samples, for example, can be combined and analysed by the methods to be described.

3. *Behaviour of copper and nickel during fusion.* During the crucible fusion process, virtually all of the nickel and copper in the charge form an alloy with the tin, while the iron remains in the silicate slag. Experience has shown that it is desirable to keep the combined nickel and copper content of the button to less than approximately 4 g.

Copper and, particularly, nickel increase the melting point of the assay button. Therefore, when more than 1–2 g of the base metals is expected to be present, approximately 10 g of tin (stick-tin is a convenient form) can be added to the charge to reduce the melting point of the button and thus facilitate the granulation process [B6(*c*)].

4. *Variation of composition of flux with nature of samples.* In contrast to the classical method of fire assaying, the flux and the proposed fusion process need not be modified greatly when processing materials of a diverse nature. However, minor variations in the charge are made with certain types of materials; these are indicated below together with a general description of the kinds of material to which the proposed analytical scheme may be applied.

Siliceous ores and rocks. For a 1-assay-ton sample of such materials, the quantity of silica used in the flux may be varied from 20 to 10 g, depending on the estimated silica content of the sample. Platiniferous rocks are frequently of the ultrabasic type such as dunite, pyroxenite, *etc*, and these contain the precious metals in minute, widely dispersed blebs of native platinum or perhaps minerals such as iridosmine. Because of the possible heterogeneity of samples of such rocks, reproducible results may not be obtained.

Magnetite and ilmenite. Experiments have shown that essentially complete decomposition is achieved with charges containing as much as 15 g of either of these minerals. The relatively large amount of iron or titanium in these minerals to be reduced to lower states of oxidation requires the use of approximately 40 g of flour in the fusion of a 1-assay-ton sample. Usually platinum is the predominant precious metal in these minerals.

Copper–nickel sulphide ores and concentrates. Because of the relatively large amounts of base metal oxides that may be present (after roasting) and must undergo reduction, 40 g of flour are required in the fusion of a 1-assay-ton sample.

Copper–nickel sulphide ores are among the most commonly encountered naturally platiniferous materials. Although minute grains of platinum metal-bearing minerals, such as sperrylite ($PtAs_2$), michenerite ($PdBi_2$), and froodite ($PdBi_2$) are known to occur in these sulphides, it is considered by some workers that the platinum metals are present, not as discrete compounds or minerals but, rather, in solid solution in the base metal minerals pentlandite, pyrrhotite and chalcopyrite.

All members of the platinum metals group are known to occur in certain copper–nickel sulphide deposits; however, palladium and platinum are the predominant metals. Other members of the group are usually less abundant by a factor of 5–10.

Iiridosmine (*osmiridium*). This native alloy, as the name suggests, is composed mainly of osmium and iridium and occurs in placer deposits in the form of flattened grains. Iridosmine is among the most chemically inert minerals known, but it seems to be completely attacked by molten tin during the crucible fusion process[12,13] of the proposed analytical scheme, the osmium and iridium forming intermetallic compounds with tin (shown by electron microprobe analysis of tin buttons). Thus, the precious metals in minute grains of iridosmine occurring in ores or concentrates would be reported together with the values from other minerals.

It is to be emphasized that the accurate, complete analysis of *bulk* samples of native alloys such as those of the osmium–iridium series would involve specialized methods of decomposition such as dry chlorination, rather than the procedures outlined here.

Chromite. Chromite is not completely decomposed during the fusion process, and samples containing an appreciable proportion of it must be subjected to a pretreatment that will decompose it. This can be done by sintering with sodium peroxide. The sample is mixed with 1·5 times its weight of sodium peroxide; placed on a 10-g bed of silica in a roasting dish and roasted at 700° for about 1 hr. The sinter cake and underlying silica are ground together in a mortar and mixed with the flux for the crucible fusion process. The weights of sodium peroxide and silica are subtracted from the weights of sodium carbonate and silica, respectively, in the flux described in B1.

5. *Gold and silver content of stannic oxides and tin powder.* Experience has shown that both stannic oxide and tin powder invariably contain a significant concentration of both gold and silver (*e.g.*, ~0·1–2·0 ppm). It is therefore imperative that the gold and/or silver value of each batch of these materials be determined and subtracted as a blank when the determination of either of these metals is included in the analytical scheme. Despite the necessity of making corrections for the blank, accurate and reproducible results are easily obtained with the procedures to be described.

6. *Procedures for preparation of buttons.*

(*a*) *Mixing the charge.* For dry samples follow the standard assay practice by blending the dry samples with the flux on glazed paper and transfer the charge to a "40-gram" crucible.

When solutions or suspensions (*e.g.*, from acid decomposition of meteorites) are to be mixed with the flux, place approximately one third of the standard flux in the crucible and press a square of thin, commercial, plastic wrapping-film into the crucible to form an envelope, and into this envelope transfer the remainder of the flux. With a spatula, form a cavity in the bed of flux and transfer the sample slowly into the depression so as to avoid wetting the film or crucible walls. Heat the crucible and contents in a drying oven at 110° for at least 2 hr. After the sample has dried, remove the material in the wrapping-film envelope and grind it in a mortar, mix well, and place back in the film in the crucible.

(*b*) *Fusion.* Place the crucible in an assay furnace maintained at approximately 1250° and fuse the contents for 1 hr. During the first 15 min, inspect the crucible several times to ensure that evolution of gases, or frothing, is not excessive. On the few occasions when this situation arises, swirl the molten material in the crucible several times with tongs until the melt becomes quiescent, then continue the fusion. At the completion of the fusion period, the melt should not be viscous or lumpy nor should there be extensive crust formation at the top of the melt.

Pour the melt into a conical steel mould and, when it is cool, separate the tin button from adhering slag by tapping with a small hammer. (A small file can sometimes be used to advantage in removing tenaciously adhering encrustations of slag, but loss of metal should be avoided.)

(*c*) *Granulation of buttons.* Place the button in the graphite crucible of the Jelrus furnace (see *Apparatus*), from which air is purged by nitrogen gas delivered through a suitable ceramic tube placed directly over the button. After melting the button (which may require a temperature of 600–700° for buttons particularly rich in nickel), withdraw the nitrogen delivery tube and, using tongs to hold the crucible, quickly pour the molten tin-alloy into approximately 1 gallon of water contained in an enamel pail. Decant the water; dry the alloy on the hot-plate (avoid remelting). Any large lumps produced can easily be reduced in size with metal shears.

Reserve the granulated alloy for analysis according to the appropriate procedures described below and outlined in Fig. 1.

C. *Wet chemical procedures for isolation, separation and determination of precious metals*

1. *Decomposition of tin buttons (except when osmium is to be determined).* Two procedures for the decomposition of the tin button may be used, the choice being largely dependent on the nature of the sample.

The procedure used by the authors for most materials involves treatment (parting) of the tin-alloy with concentrated hydrochloric acid. A major proportion of each of the precious metals, as intermetallic compounds of tin, remains undissolved; however, a significant fraction especially of rhodium, iridium and ruthenium, dissolves along with the tin matrix. The soluble species are readily recovered by cementation with tin powder.

The major advantage of the hydrochloric acid parting-procedure is that much of the excess of tin, as stannous chloride, can be eliminated before the tin-volatilization procedure.

If the sample contains *milligram* amounts of the platinum-group metals it is advantageous to decompose the tin-alloy directly with a mixture of hydrochloric acid and hydrogen peroxide. Insoluble matter which may remain is easy to recover and treat chemically. A minor disadvantage of this approach is that subsequently all the tin of the original button may have to be volatilized.

(*a*) *Parting in hydrochloric acid.* Transfer the granulated tin alloy to a 600-ml beaker and treat it with approximately 150 ml of concentrated hydrochloric acid. Cover the beaker with a clock-glass and heat until the alloy has been decomposed and vigorous evolution of bubbles from the black insoluble residue has ceased. Dilute the resulting suspension to about 400 ml with water and heat to approximately 70°. While the suspension is being stirred with a motor-driven polyethylene-coated stirrer or magnetic stirrer, sprinkle approximately 5 g of powdered tin (200-mesh or finer) into the beaker to precipitate any precious metals that had dissolved during the parting operation. Stir the contents of the beaker for approximately 15 min.

If iridium and/or ruthenium are to be determined, again heat the beaker to approximately 70° and add a second 5-g portion of powdered tin; stir for an additional period of 15 min.

If silver only is to be determined, the hydrochloric acid solution need not be heated and not more than 0·5 g of tin powder is required.

The insoluble matter produced in these operations should contain essentially all the copper in the sample, the excess of tin powder, and all of the precious metals. Nickel remains in solution and is ultimately discarded.

Decant the supernatant solution through a pad of paper pulp (from Whatman No. 31 paper) supported on a filter disk. Wash the solids several times by decantation with $1M$ hydrochloric acid and pass the washings through the filter pad.

Add 25–30 ml of $12M$ hydrochloric acid to the solids in the beaker, and then cautiously add 30% hydrogen peroxide in small portions until the solids have dissolved and excess of peroxide is present. A small amount of siliceous matter from the slag may be present, but can be ignored. After the mixture has been heated to the boil for a few minutes to ensure complete dissolution of the residue, place the beaker under the filter pad and wash the pad with a mixture of approximately 10 ml of $12M$ hydrochloric acid and 2–3 ml of 30% hydrogen peroxide to dissolve any fines caught on the filter during decantation.

Analyse the solution obtained in these operations for silver as in C2, or treat directly as in C3 to voltilize tin if silver is not to be determined.

(*b*) *Decomposition in hydrochloric acid and hydrogen peroxide* (primarily for samples containing milligram amounts of the platinum-group metals). Place the granulated tin alloy in an 800-ml beaker immersed in an ice-bath. Add approximately 200 ml of $12M$ hydrochloric acid, then with stirring cautiously add 30% hydrogen peroxide in relatively small portions until the tin alloy has decomposed and the effervescence from excess of peroxide is evident. Add an additional 50 ml of hydrochloric acid and 10 ml of hydrogen peroxide then heat the beaker and contents until the volume of the solution has been reduced to approximately 100–150 ml.

Dilute the solution with approximately 100 ml of water and allow any dense, dark-coloured residue to settle for about 30 min. Decant the supernatant solution through an appropriate filter paper into a 500-ml volumetric flask. Wash the beaker and residue, by decantation, with several small portions of dilute hydrochloric acid.

Treat any residue left in the beaker with approximately 10 ml of $12M$ hydrochloric acid and 5 ml of 30% hydrogen peroxide. Evaporate the solution to a small volume, then add 5–10 ml of *aqua regia*. Again evaporate the solution to 1–2 ml and, by repeated treatments with $12M$ hydrochloric acid, destroy nitrogen-containing compounds and ensure that the platinum metals are present as their chloro-complexes. Dilute the acid solution with a small volume of water then filter into the 500-ml flask through the paper used previously.

Dry the paper and residue and then fuse as in B6, to produce a second tin button. Decompose this, in turn, with hydrochloric acid and hydrogen peroxide. Filter off any siliceous matter from the resulting solution and receive the filtrate in the 500-ml flask containing the solution from the first button. Dilute to volume with water.

Because this method of decomposition is used primarily for materials rich in platinum-group metals, it is often sufficient to take an aliquot of the sample solution for analysis by the procedures described below.

If the solution obtained by C1(*b*) is to be analysed for silver, take an appropriate aliquot and adjust to approximately $2M$ hydrochloric acid before atomization as in C2. When a large aliquot is taken and it must be reduced in volume to concentrate silver, it may be necessary to volatilize tin by procedure C3 before the determination of silver by atomic absorption.

2. *Determination of silver by atomic absorption.*[15] To prevent possible blockage of the atomizer by particulate matter, filter the combined solution obtained by the procedure C1 through a fast paper (*eg*., Whatman No. 31) into a 200-ml volumetric flask. Wash the filter paper several times with water, and dilute the combined filtrate and washing to volume. The resultant solution for atomization should be approximately $2M$ in hydrochloric acid.

If milligram quantities of silver are present, filter this solution into a 500-ml flask and adjust the hydrochloric acid and concentration to approximately $3M$ to prevent precipitation of silver as the chloride.

Take an appropriate aliquot, and adjust to $2M$ hydrochloric acid before atomization. The aliquot may contain up to 4 ppm of silver. Reserve the remainder of the solution from the tin-button decomposition for the determination of the platinum metals and/or gold by the procedures to be described below.

Determine the silver content of the aliquot by atomic absorption, using a wavelength of 328·1 nm, a 0·10-m narrow-slit burner and an oxidizing air–acetylene flame. Subtract the silver content of the blank from that of the sample.

3. *Volatilization of tin before the determination of gold and platinum-group metals.* Evaporate the solution from either C1 or C2, above, to a relatively small volume on the hot-plate, then place the beaker in an aluminium "no-bump" solution evaporator. Heat the evaporator from below with the hot-plate and from above with an infrared heat lamp to volatilize as much tin as possible.

Copious fumes of stannic halide are evolved at this point, and, when relatively large amounts of copper and/or nickel are present, care should be taken to avoid spattering caused by local intense heating.

When it appears that the evolution of fumes has nearly ceased, remove the beaker from the evaporator and cool for a short time. Wash down the sides of the beaker with approximately 10 ml of a mixture (7:2) of hydrochloric and hydrobromic acids and again evaporate to dryness under the heat lamp. Repeat the treatment with the mixed halogen acids (5–10 ml) and the evaporation twice or until it is evident that essentially all of the tin has been volatilized.

If gold is to be determined, simply evaporate the mixed halogen acid solution as in C4 below.

If gold is not to be determined, cool the beaker and residue, add 10–15 ml of $12M$ hydrochloric acid, and then, while swirling the beaker in a fume cupboard, cautiously add 30% hydrogen peroxide until it is evident that an excess of peroxide is present and that the evolution of bromine vapour is not vigorous. Evaporate the solution to small volume and process according to requirements (see flow sheet) for the removal of base metals or the extraction of gold and/or the distillation of ruthenium.

4. *Isolation and determination of gold.* Evaporate the solution to 2–3 ml. If the solution does not contain an appreciable quantity of base-metal chlorides, place the beaker in a hot water-bath and, with the aid of a jet of compressed air, evaporate the solution gently to dryness to prevent baking of the gold salts on the beaker walls. When a substantial amount of base-metal chlorides is present, the solution can be evaporated gently to dryness directly on the cooler part of the hot-plate.

Take up the salts in 5 ml of $2M$ hydrobromic acid and wash into a 60-ml separatory funnel with a further 10 ml of $2M$ hydrobromic acid. Extract the gold by shaking the solution with two separate 15-ml portions of diethyl ether. Double the volume of hydrobromic acid and ether if the sample contains a relatively large quantity of copper. Combine the ether extracts and wash with three separate 5-ml portions of $2M$ hydrobromic acid. Strip the gold from the ether phase by shaking it with three separate 15-ml portions of water. Treat the aqueous gold solution with approximately 2 ml of *aqua regia* and evaporate to a small volume. Transfer the gold solution to a volumetric flask of appropriate size, depending upon the expected gold content, and dilute to volume with water. Determine the gold content of the solution by atomic-absorption as described below.

Evaporate to dryness the aqueous phase from the ether extraction of gold and, with a small volume of hydrochloric acid–30% hydrogen peroxide mixture (2:1), destroy bromides and convert the metals into their chlorocomplexes. Reserve the resulting solution for the determination of platinum-group metals according to the procedures given below.

Determine the gold content of the final solution, containing at least 0·2 ppm of gold, by atomic absorption at a wavelength of 242·8 nm, a 0·10-m narrow-slit burner, and an oxidizing air–acetylene flame. Subtract the gold content of the blank charge from that of the sample.

5. *Some comments on the anaytical scheme for the platinum-group metals.* Most samples to which the proposed methods will be applied will require the determination of one or more of platinum, palladium, and rhodium with or without the prior determination of gold and/or silver. When this is the case, the procedures described immediately below for removing base metals by cation-exchange, followed by the individual determination of platinum palladium, and rhodium by atomic absorption or colorimetric techniques, can be followed directly.

However, as will be seen subsequently, the scheme must be altered somewhat when osmium, and possibly ruthenium, is to be determined on the same assay buttons as the other precious metals. The distillation procedures for isolating osmium and ruthenium (only when ruthenium is to be determined colorimetrically) must be applied before the determination of gold, platinum, palladium, rhodium and iridium. Although this is a perfectly feasible analytical path, it may be more convenient, if sufficient material is available, to determine osmium and ruthenium (colorimetrically) on a separate sample.

It should be noted that the comments above pertain to ruthenium only if this element is to be determined colorimetrically; if atomic-absorption spectrometry is to be used for ruthenium, then this element need not be isolated by distillation and can be determined in the same solution as that containing platinum, palladium and rhodium.

The atomic-absorption sensitivity for iridium is low, therefore the proposed analytical scheme involves the use of the more sensitive colorimetric determination of iridium after it has been separated from other platinum-group metals by solvent extraction. If the iridium content of the sample is relatively high, however, as in precious metal concentrates, then iridium too can be determined by atomic-absorption.

6. *Removal of base metals by cation-exchange*[16,17,18] *before the determination of the platinum-group metals.* Evaporate the solution of metal chlorides to dryness. Take up in 5–10 ml of 12 M hydrochloric acid and again evaporate to a residue of salts. When more than approximately 0·5 g of base metals (usually copper) is present, stir the crystallizing salts with a stirring rod to aid in the removal of free hydrochloric acid. Cool the beaker and, depending on the amount of base metals estimated to be present, add 0·25 or 0·50 ml of $12M$ hydrochloric acid and then dissolve the salts with 50 or 100 ml of water, to give a solution with a pH of 1·0–1·5.

Notes: (1) At this point the analyst should be aware of the possibility of hydrolysis of the anionic chloro-complexes of rhodium, iridium and, especially, ruthenium during the ion-exchange process. In the operating time required, hydrolysis can be prevented by maintaining the chloride ion concentration at 0·1*M* or higher, which is normally provided by the base metal salts present. However, when it is apparent that these are in low concentration, it is advisable to add approximately 0·5 g of sodium chloride per 50 ml of solution.

(2) If the sample solution contains appreciable quantities of base-metal chloro-salts, *i.e.*, a relatively high chloride ion concentration, any silver present may remain in solution until a later stage when the chloride ion concentration has been reduced, for example in 8(*c*).

Pass the sample solution through a cation-exchange column at the rate of approximately 5 ml/min. If the sample contains less than approximately 0·5 g of base metals, use a "small" column; otherwise use a "large" column as described under *Apparatus.* Collect the effluent solution in a 400-ml beaker and wash the column with sufficient dilute hydrochloric acid (pH approx. 1) to quadruple the original volume of the sample solution.

To the effluent solution, add approximately 25 mg of sodium chloride and 10 ml of 12*M* hydrochloric acid and reserve for the separation of platinum, palladium, rhodium and iridium or for the isolation of ruthenium by distillation (see Fig. 1).

Notes: (1) In certain cases it may become apparent, from the colour developed during the subsequent evaporation of the effluent solution, that leakage of base metals has occurred. This can generally be ignored if the solution is to be analysed by atomic absorption for one or more of platinum, palladium and rhodium. However, it is necessary to repeat the cation-exchange operation (using the small column) to remove the contaminants if colorimetric finishes are to be used.

(2) If tin were not completely volatilized in earlier steps, it would precipitate in a gelatinous or flocculent form during the ion-exchange process and might contaminate both the resin bed and the effluent solution. If the amount of precipitate is relatively small (slightly cloudy suspension), then the danger of losing platinum metals by occlusion or co-precipitation is slight and, therefore, any solid material retained on the resin bed can be neglected. The small amount of tin in the effluent can be removed ultimately by repeating the volatilization procedure given above in C3. When more than a few milligrams of tin appear to be present, strip the column with 4*M* hydrochloric acid, combine the stripping solution with the original effluent and treat the whole, as above, for the volatilization of tin before repeating the ion-exchange procedure.

7. *Atomic-absorption determination of platinum, palladium, rhodium and ruthenium.*

Mixed cadmium–copper sulphate. Prepare a solution[19] by dissolving 98·0 g of $CuSO_4 . 5H_2O$ and 57·0 g of $3CdSO_4 . 8H_2O$ in 500 ml of 12*M* hydrochloric acid and 300 ml of water. Dilute to 1 litre with water.

Evaporate the sample solution, containing a mixture of the platinum metals as their chloro-complexes, from C6 above, to incipient dryness in the presence of a few milligrams of sodium chloride. Add 5 ml of the cadmium–copper sulphate solution and dilute to 25 ml with water. Filter the solution if a cloudiness develops.

In certain cases it may be necessary to prepare a more concentrated solution for the determination of the minor elements, followed by dilution of aliquots for the determination of the other metals.

The aliquot taken for analysis should contain at least 1 ppm of each of platinum and ruthenium or 0·2 ppm of each of palladium and rhodium. The wavelengths used for these elements are respectively 266·1, 349·9, 247·8 and 343·6 nm. An oxidizing air–acetylene flame is used for the determination of gold, silver, platinum, palladium and rhodium; a slightly fuel-rich air–acetylene flame is used for the determination of ruthenium.

8. *Separation of platinum, palladium, rhodium and iridium*[20] (before colorimetric determination).

(*a*) *General comments.* Previously it was mentioned that the atomic-absorption sensitivity for iridium is relatively low, therefore it is often necessary to determine this metal colorimetrically. This necessitates the separation of iridium from the other platinum-group metals, each of which interferes with its determination. The following solvent extraction scheme is used for such a separation.

Procedures are also given for the fractionation of mixtures of platinum, palladium and rhodium because they are required if these metals must also be determined colorimetrically rather than by the more convenient atomic-absorption technique. Because the determination and separation of palladium with *p*-nitrosodimethylaniline are so closely related, the procedure for its colorimetric determination is included.

(*b*) *Special reagents. Equilibrated tri-n-butyl phosphate TBP)* prepared by shaking the purified grade of TBP with an equal volume of 6*M* hydrochloric acid in a separatory funnel for approximately 1 min. *Buffer, pH* 2·2, prepare by mixing 50 ml of 4*M* sodium acetate (33 g/100 ml) with 53 ml of 4*M* hydrochloric acid. *Ethanolic* p-*nitrosodimethylaniline solution* 0·5%, prepared by mixing 0·5 g of *p*-nitrosodimethylaniline with 100 ml of 95% ethyl alcohol, leaving over-night (or placing in an ultrasonic bath for a few minutes), and filtering off any solids on Whatman paper No. 30.

(*c*) *Separation of platinum and palladium from rhodium and iridium.* Evaporate the sample solution, containing a mixture of the platinum metals as their chloro-complexes, from C6 above, to incipient dryness in the presence of a few mg of sodium chloride. Dissolve the salts in 8–10 ml of approximately 1*M* hydrochloric acid, and allow to stand for a few minutes to allow any silver that may be present to precipitate as the chloride. If necessary, remove the silver chloride by filtering the solution through a No. 40 paper, directly into a 60-ml sepatatory funnel. Adjust the volume of solution to 20 ml and the hydrochloric acid concentration to 6*M*. Shake the sample solution with 5 ml of an aqueous 4% w/v solution of sodium iodide and allow the mixture to stand for about 30 min. Extract the platinum and palladium iodide complexes with two separate 15-ml portions of a 15% solution of TBP in hexane. Withdraw the aqueous phase, wash it with 10 ml of hexane in a separatory funnel, and then reserve it for the separation of rhodium and iridium as in (*f*) below.

Combine the TBP-hexane extracts and strip the mixture of platinum and palladium by shaking it with three separate 10-ml portions of concentrated nitric acid for approximately 20 sec each. Place the nitric acid stripping solution in a separatory funnel, dilute with an equal volume of water, and shake with 10 ml of hexane to wash out as much TBP as possible.

If the sample solution is expected to contain 50 μg or less of palladium, transfer it to a beaker and treat as in (*d*) and (*e*) for the determination and/or separation of palladium. When the sample solution is expected to contain more than 50 μg of palladium, dilute it to a known volume and remove a suitable aliquot for the separate determination of palladium. In the latter case, place both the aliquot and the remainder of the solution in separate beakers and treat as in the following procedure.

(*d*) *Determination of palladium with* p-*nitrosodimethylaniline.*[21] Treat the platinum–palladium solution obtined in (*c*) with a few mg of sodium chloride and evaporate to incipient dryness. To convert platinum and palladium into their chloro-complexes, add 2–3 ml of 12*M* hydrochloric acid, evaporate the solution just to dryness, then repeat these operations twice ensuring that all excess of acid has been removed by evaporation. Add 2 ml of the sodium acetate-hydrochloric acid buffer solution and approximately 10 ml of water to the residue in the beaker. Warm the mixture gently for a few minutes and, with aid of a rubber policeman, loosen any sticky deposits that may be adhering to the bottom of the beaker.

When palladium is to be determined (in the whole sample solution or an aliquot), add 1 ml of the 0·5% solution of *p*-nitrosodimethylaniline and transfer the red solution to a 50-ml volumetric flask. Wash the original beaker with 15 ml of 95% ethyl alcohol, add the washings to the flask, and dilute to volume with water. Measure the absorbance of the solution at 525 nm, and then determine the palladium content of the sample by reference to a calibration curve prepared from spectrophotometric data obtained from standard solutions that have been taken through the TBP extraction procedure.

(*e*) *Separation of palladium from platinum. Note*: This separation is based on the fact that at room temperature platinum does not react appreciably with *p*-nitrosodimethylaniline[18] and thus it remains in the aqueous phase when the palladium–*p*-nitrosodimethylaniline complex is extracted with chloroform.

Combine the portion of solution taken for spectrophotometric measurement with the remainder of the platinum–palladium solution and transfer the whole to a 60-ml separatory funnel and reserve for the separation of palladium from platinum. When the sample contains 50 μg or more of palladium, add 2 ml of the *p*-nitrosodimethylaniline reagent and 15 ml of ethyl alcohol, and transfer the mixture to a 60-ml separatory funnel.

Extract the palladium–*p*-nitrosodimethylaniline complex with two or three separate 10–15-ml portions of chloroform. If mg amounts of palladium are to be separated, add an additional 1–2 ml of *p*-nitrosodimethylaniline reagent and continue the extraction with further portions of chloroform until the aqueous phase is light yellow or colourless.

Filter the aqueous phase (or an aliquot) through a Whatman No. 31 paper into a 400-ml beaker, add approximately 2 ml of concentrated sulphuric acid and approximately 10 ml of concentrated perchloric acid. Reserve this solution for the spectrophotometric determination of platinum by a suitable colorimetric method.[10,22]

(*f*) *Separation of iridium from rhodium.* Transfer the rhodium–iridium fraction obtained in (*c*) to a 250-ml beaker, evaporate nearly to dryness, and treat with a few drops of concentrated nitric acid to destroy iodides. Convert the rhodium and iridium into chloro-complexes by the repeated addition and evaporation of 2–3-ml portions of 12*M* hydrochloric acid and 1 ml of 30% hydrogen peroxide (to ensure that iridium remains in the quadrivalent state) and wash the resultant solution into a 60-ml separatory funnel with an additional 5 ml of 6*M* hydrochloric acid. Add 5 ml of equilibrated TBP and 5 ml of hexane and shake the funnel and contents for 1 min. Transfer the lower (aqueous) phase to a second funnel and repeat the extraction step. Drain the aqueous phase into a clean separatory funnel, wash with approximately 10 ml of hexane, and reserve for the determination of rhodium by a suitable colorimetric method.[11,23]

Combine the two TBP-hexane extracts in a separatory funnel and strip the mixture by shaking it with three separate 15-ml portions of dilute hydrobromic acid (1 + 9). Reserve the combined strippings for the spectrophotometric determination of iridium as in (*h*) or treat for the removal of ruthenium as in (*g*).

(*g*) *Removal of ruthenium interference before determination of iridium.* If ruthenium is present in the sample material and was not removed previously by the distillation procedure given in C10, it will accompany iridium through the TBP extraction step and subsequently interfere in the spectrophotometric determination of iridium. In such cases, treat the hydrobromic acid stripping solution with approximately 1 ml of concentrated sulphuric acid and evaporate the solution to fumes of sulphur trioxide. To volatilize ruthenium, add approximately 1 ml of concentrated perchloric acid dropwise, with swirling, to the fuming solution. After the excess of perchloric acid has evaporated, cool the solution, take up the residue in approximately 10 ml of hydrobromic acid, and boil down in a covered beaker to a small volume to ensure that iridium is present as its bromo-complex.

(*h*) *Determination of iridium.*[12,24] The reagent is a 5% solution of stannous chloride in hydrobromic acid, prepared by dissolving 12·5 g of $SnCl_2.H_2O$ in 50 ml of redistilled concentrated hydrobromic acid with gentle warming. Cool the solution to room temperature and dilute to 100 ml with water. The solution should be prepared fresh daily and should be nearly colourless immediately after preparation.

Experience has shown that, to obtain a colourless reagent solution, only clear stannous chloride crystals that dissolve readily in hydrobromic acid should be used. Stannous chloride crystals that have a dull frosted appearance and are difficultly soluble in hydrobromic acid produce an intensely coloured solution that is unsuitable as a reagent for iridium.

Transfer the hydrobromic acid solution of iridium from (*f*) or (*g*) to a 250-ml beaker and evaporate it to dryness in the presence of a few mg of sodium chloride. Add 7 ml of concentrated hydrobromic acid (which should not be coloured), cover the beaker with a watch-glass and boil the solution until it has evaporated to 2·0–2·5 ml (as judged visually, or by using comparison solution). Transfer the solution to a 25-ml volumetric flask by washing with 3 ml of concentrated hydrobromic acid and 7 ml of 25% (v/v) phosphoric acid. Place the flask in a boiling water-bath and, after 10 min, add 5 ml of stannous chloride reagent. Exactly 2 min after reagent addition, remove the flask, and cool to room temperature in a cold water-bath. Dilute the solution to the mark and measure the absorbance of the iridium complex at 402 nm against a reagent blank.

9. *Isolation and determination of osmium.* Because of the volatility of osmium compounds, the tin assay button cannot be treated by the chemical methods above to produce a solution containing osmium together with the other precious metals. Therefore osmium must be isolated directly from the tin button by distillation. The techniques for determining osmium by atomic absorption have not been established, at least in this laboratory, consequently a colorimetric method is described.

When osmium is to be determined, in copper-nickel matte for example, the sample must be fused directly, without roasting, to avoid the loss of osmium by volatilization. As indicated earlier, the other precious metals may be determined in the same assay button after distillation of osmium or, if more convenient, a separate sample may be used for their determination. Although a 25-g granulated tin button can be handled in the distillation apparatus, for simplicity and the convenience of smaller volumes, it is recommended that a 15-g portion of the tin alloy be taken for the determination of osmium whenever possible.

To distil osmium place the granulated tin button, or portion thereof, (B6) in a 500-ml distillation flask. Connect the flask to the distillation apparatus (Fig. 2) in which receivers B, C, and D contain 25, 40 and 15 ml of concentrated hydrobromic acid respectively. Receiver C is cooled in an ice-bath.

By means of a water-pump or aspirator connected to vessel D, draw air through the distillation train at the rate of 3-4 bubbles/sec. For every gram of tin alloy taken, add approximately 5 ml of 12*M* hydrochloric acid. Next, add 30% hydrogen peroxide, dropwise through the delivery tube, until the tin alloy has been decomposed and a small excess of peroxide is present. Some care must be taken during the addition of peroxide to prevent gases from sucking back up the delivery tube of the distillation head; this can be achieved by adjusting the flow of air through the distillation apparatus.

After the tin alloy has been decomposed, apply heat and evaporate the solution in the flask until its temperature rises to 115–118°. While maintaining the temperature in this range, add approximately 15 ml of 30% hydrogen peroxide in small portions in the manner described above. Next, add rapidly 30–35 ml of 12*M* hydrochloric acid through the funnel and continue the distillation until the temperature again reaches 115°. To ensure complete distillation of osmium, repeat twice more the alternate addition of 15 and 30 ml of peroxide and hydrochloric acid, respectively, with the intervening evaporations necessary to bring the temperature to at least 115° before addition of the peroxide. Do not allow the temperature to exceed 120° because higher temperatures may result in the volatilization of stannic halide.

After heating has been discontinued and the apparatus allowed to cool somewhat, disconnect the receivers and combine their contents in a 400-ml beaker containing 25 mg of sodium chloride and sufficient hydrobromic acid to make its concentration 5 *M*.

When the samples are known to contain more than 300 μg of osmium, dilute the combined receiver solutions to a known volume with hydrobromic acid and take an aliquot for the determination of osmium.

Evaporate the solution first at a low heat to prevent violent evolution of bromine; then take it to incipient dryness (without baking) at a more rapid rate. Determine the osmium content of the residue spectrophotometrically as described below.

When other precious metals in the original button are to be determined, reserve the solution remaining in the flask after the distillation of osmium and proceed with the appropriate part of the analytical scheme (Fig. 1).

When the sample is known to contain milligram amounts of native iridium–osmium alloys for example, any insoluble residue remaining in the distillation flask should be recovered by filtration and subsequently analysed for osmium by the procedures used for the first button. Experiments have shown that approximately 10% of the osmium and iridium, as intermetallic compounds of tin, may remain undissolved if the tin button is rich in these metals.

For determination of osmium the reagent is 2% pyrogallol solution prepared by dissolving 2 g of reagent-grade pyrogallol in 100 ml of distilled water containing 2 or 3 drops of 12*M* hydrochloric acid (to inhibit atmospheric oxidation). This reagent should be prepared fresh daily. A pH 2·2 buffer is also needed (prepared as in C8).

Place the hydrobromic acid solution of osmium from above (containing up to 350 μg of osmium) in a 250-ml beaker. Add 1 ml of a 2·5% sodium chloride solution and evaporate the sample just to dryness. Dissolve the salts in 10 ml of water and then add 1 ml of buffer solution (pH 2·2) and 5 ml of 2% pyrogallol solution. Using a pH meter, adjust the pH to 2·9–3·1 by the dropwise addition of a saturated solution of sodium bicarbonate. Transfer the sample solution to a 25-ml volumetric flask (without washing) and heat it in a boiling water-bath for about 30 min. The maximum colour develops within 10–15 min, but as a precaution the longer heating time is preferable. Cool the flask to room temperature (in running water) and dilute the contents to volume with water. After mixing, allow the sample to stand for 15 min and then measure its absorbance at 585 nm against either water or a reagent blank.

When less than 100 μg of osmium is to be determined, transfer the 25 ml of blue solution to a 60-ml separatory funnel and extract the osmium complex with two separate 5-ml portions of n-pentanol. Combine the extracts and centrifuge for a short time to remove water droplets. Measure the absorbance against water or a reagent blank at 585 nm, and from this determine the amount of osmium present.

Note: Ruthenium interferes in the determination of osmium. Therefore, if the solution to be analysed by the procedures given above was derived from a sample in which the ratio of ruthenium to osmium was high (*e.g.*, greater than 100, as in a precious-metals concentrate), it is recommended that the distillation of osmium be repeated to ensure that the two metals have been completely separated.

10. *Isolation of ruthenium by distillation*[13] *before colorimetric determination.*

Note: The following procedure is generally applied directly after the tin-volatilization step. However, when the sample solution contains more than about 2 g of base metals and is to be analysed subsequently for one or more of platinum, palladium, rhodium and iridium, then it is recommended that the base metals be removed by cation-exchange (C6) before the perchloric acid distillation of ruthenium. By using this approach, the subsequent task of decomposing relatively large amounts of perchlorate is avoided.

Evaporate the solution to dryness on the hot-plate to drive off as much free hydrochloric acid as possible. Cool the beaker, take up the residue in a small volume of water, and transfer to a 500-ml distillation flask by washing with several small portions of water. Connect the flask to the distillation assembly (Fig. 2) in which receiver B contains a saturated potassium permanganate solution, prepared by mixing 2 g of solid permanganate and 25 ml of water; receivers C and D contain 40 and 15 ml respectively of concentrated hydrobromic acid. Cool receiver C in an ice-bath. While air is drawn through the apparatus at the rate of 2–3 bubbles/sec, add about 50 ml of perchloric acid through the delivery funnel and apply heat to both the distillation flask and the permanganate receiver with their separate heating elements. Continue heating until the reaction mixture boils and the white fumes disappear (about 30 min). Boil the permanganate receiver solution (essentially a trap for perchloric acid) virogously until its volume is aproximately 10–15 ml; then shut off, and remove, the heating mantle.

Combine the hydrobromic acid receiver solutions, treat with about 25 mg of sodium chloride, and

evaporate the whole solution or an aliquot, just to moist salts, before the spectrophotometric determination of ruthenium with *p*-nitrosodimethylaniline.[26]

To remove perchloric acid (only after ruthenium distillation), transfer the perchloric acid solution from the ruthenium distillation to a 600-ml beaker and heat strongly to drive off as much free perchloric acid as possible. Stir the residue with a small volume of 6*M* hydrochloric acid and again evaporate to dryness. Repeat these operations until most of the perchlorates have been destroyed (as evidenced by the absence of white fumes).

To ensure that the platinum metals are in a soluble form, treat the residue with approximately 15 ml of *aqua regia*, heat, and evaporate to dryness in a covered beaker. Remove the watch-glass and, by repeated additions of 12*M* hydrochloric acid and subsequent evaporations, convert the metals into their chloro-salts. Analyse the solution for their precious metals content by the procedure described above.

RESULTS

Table I presents results obtained by the proposed tin-collection scheme of analyses on a number of materials. It is apparent that these are in relatively good agreement with analyses obtained by independent laboratories which, collectively, used a wide variety of methods.

Zusammenfassung—Ein umfassendes Analysenschema zur Bestimmung der sechs Metalle der Platingruppe sowie von Gold und Silber wird angegeben. Es besteht in der Vereinigung einzelner Verfahren, die teilweise im Laufe mehrerer Jahre schon beschrieben wurden. Das Analysenschema wurde in Schieds- und Standardanalysen an einer großen Vielfalt von Material überprüft und ist folglich von zunehmendem Interesse für viele Laboratorien. Die Probe wird bei 1200–1250° mit einem Schmelzfluß aus Zinndioxid, Natriumcarbonat, Kieselsäure, Borax und Kokspulver geschmolzen; dabei sammeln sich die Edelmetalle im geschmolzenen Zinn an. Die erhaltene Zinnlegierung wird gelöst und die Edelmetalle durch Ionenaustausch-, Extraktions- und Destillationsverfahren isoliert. Mit Ausnahme der für den Schmelzaufschluß notwendigen Einrichtungen kann man bei den naßchemischen Operationen zur Isolierung und Bestimmung der einzelnen Edelmetalle herkömmliches Gerät verwenden.

Résumé—On présente un schéma analytique complet pour le dosage des six métaux du groupe du platine, de l'or et de l'argent. Il est le résultat de l'intégration de techniques séparées qui ont été décrites antérieurement, en partie, dans le courant de plusieurs années. Le schéma analytique a été totalement mis à l'épreuve sur une large variété de produits par un travail arbitré et normalisé et, en conséquence, il est d'un intérêt croissant pour de nombreux laboratoires. Les métaux précieux sont rassemblés dans de l'étain fondu lorsque l'échantillon est fondu à 1200°–1250° avec un fondant contenant de l'oxyde stannique, du carbonate de sodium, de la silice, du borax et de la farine. L'alliage d'étain résultant est dissous et les métaux précieux sont isolés par des techniques d'échange d'ions, d'éxtraction par solvant ou de distillation. A l'exception des conditions usuelles requises au stade de la fusion de l'essai par voie sèche, l'équipement type peut être utilisé dans les opérations chimiques par voie humide pour l'isolement et le dosage des différents métaux précieux.

KINETIC METHOD OF ANALYSIS BY ANALOGUE COMPUTER SIMULATION

MASAKI NAKANISHI
Department of Chemistry, Ochanomizu University
Bunkyo-ku, Tokyo, Japan

(*Received* 15 *July* 1971. *Accepted* 15 *September* 1971)

Summary—The simulation by an analogue computer of slow reactions used for the purpose of chemical analysis is described. Bromination of maleic and fumaric acids is used for illustration. The concentration of bromine is traced spectrophotometrically as a function of time and the trace simulated with an analogue computer by the trial and error method. The initial concentration of the substance in question and the rate constant of the reaction are determined from the values given to the computer variables to obtain the best fit. Only a single experiment is required for the analysis. The procedure can be followed easily without laborious mathematical or graphical treatment.

KINETIC methods of chemical analysis have been applied successfully to a number of inorganic and organic substances. In spite of various advantages, the methods are hardly general and only restricted applications have been reported. Most of the reactions employed are first-order or pseudo first-order (*viz.* a second-order reaction, with a large excess of one reactant). When a mixture of two unknown components is to be analysed, it is usually a prerequisite that the sum of the concentrations of the two components is known or that the rate constants are considerably different from each other. Sometimes the rate constant involved in the particular reaction has to be determined in a separate run under rigorously controlled experimental conditions. In addition, the majority of the methods proposed require a rather laborious graphical or mathematical treatment of the results.

A differential equation expressing a kinetic reaction can be most readily solved graphically by means of an analogue computer. Although little use has been made of the analogue computer technique in chemical problems, some successful applications to the study of reaction kinetics of a complex system have been demonstrated.[1-4]

In these studies the technique was employed mostly to determine the rate constant and the order of reaction by the simulation method, but it also offers a means of determining the reacting component in the system. It should be faster and easier to use than graphical methods.

In this paper, the application of an analogue computer to chemical analysis is described. Simple bromination reactions of unsaturated compounds, maleic and fumaric acids, which obey second-order kinetics, have been selected and the processes followed spectrophotometrically. Reaction kinetic methods which employ bromination reactions to determine organic unsaturation have been reported previously.[5-8] In this earlier work extensive graphical or mathematical treatment of the results was important, but in this study the absorbance curve of the reacting mixture as a function of time is simulated with an analogue computer by a curve-fitting procedure and the initial concentration of the sample compound is determined from the machine variable. It is to be expected that even if the reaction proceeds slowly and a relatively long time is required before completion, observation of only the initial stage of reaction will suffice for the simulation. As is evident in the following section, the method is applicable without modification to a system in which the concentration of the sample substance is equal to that of the bromine.[9]

THEORY

Throughout this work a reaction between substances A and B which obeys second-order kinetics is considered:

$$\frac{dx}{dt} = k(a - x)(b - x) \tag{1}$$

where t is time in sec, k is the rate constant in l.mole^{-1}.sec^{-1}, a and b are the concentrations in mole.l.$^{-1}$ of substances A and B, respectively, at $t = 0$, and x is the amount of the substances consumed in time t, expressed in concentration units. A is supposed to be the substance to be determined and B is the reactant added.

If the concentration of B could be followed by any means during the course of reaction, a curve showing the variation of $(b - x)$ as a function of time would be obtained.

On the other hand, the differential equation (1), the so-called physical equation expressing the real physical phenomenon, or the chemical reaction could be simulated with an analogue computer. As a result, a curve entirely identical in shape and magnitude with the experimental curve, $(b - x)$ *vs.* t, could be reproduced on the computer output as a function of the machine time T. The circuit diagram relevant to equation (1) is shown as a block scheme in Fig. 1. The voltages shown are those that appear at any part of the circuit at time t when known voltages $-A$ and $-B$ are applied to the adders II and III, respectively, and the circuit is closed at $t = 0$.

The analogue computer circuit represents the following so-called machine equation:

$$\frac{dX}{dT} = \frac{K}{10}(A - X)(B - X) \tag{2}$$

where T is the machine time and the coefficient $K/10$ originates from the characteristics of the multiplier that the output voltage is a tenth of the product, with inverted sign, of two input voltages.

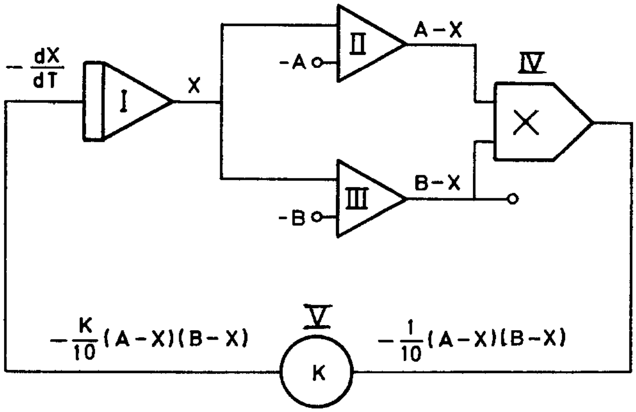

FIG. 1.—Analogue computer circuit diagram for the second-order reaction (1).
I, integrator; II, III, adders; IV, function multiplier; V, coefficient potentiometer.

The voltage $(B - X)$ that appears at the output of the adder III as a function of T can be obtained as a curve on a recorder. This fits with the experimental curve $(b - x)$ *vs.* t, as is evident from the similarity of equations (1) and (2), provided certain relationships [equations (3) and (6) below] hold.

Because curves fit at $t = 0$, at which $x = 0$, the following relationship is valid:

$$B = \alpha b \tag{3}$$

where α is a conversion factor in V.l.mole^{-1}. Consequently, fitting at any point of the curves leads to the expressions,

$$X = \alpha x \tag{4}$$

$$A = \alpha a \tag{5}$$

Also T is related to t by the equation

$$T = \beta t \tag{6}$$

where β is a conversion factor.

Thus, equation (2) can be rewritten as

$$\frac{dx}{dt} = \frac{\alpha \beta K}{10}(a - x)(b - x) \tag{7}$$

Because the two curves fit, equation (7) should be identical with equation (1). Hence,

$$k = \frac{\alpha \beta K}{10} \tag{8}$$

In conclusion, if the two curves which correspond to the physical and machine equations fit each other, the initial concentration, a, of the substance A and the rate constant, k, can be obtained from (5) and (8), respectively.

EXPERIMENTAL

Apparatus

Spectrophotometer. Hitachi, Model 101-003. To accommodate a reaction vessel in the cell compartment and agitate a solution inside the vessel with a magnetic stirrer, the cell compartment was reconstructed with aluminium plates lined with dark woollen cloth. A magnetic stirrer was placed immediately under the cell compartment. The case plates of the spectrophotometer were removed as a precaution to avoid accumulation of heat inside the compartment.

The reaction vessel was a 100-ml cylindrical glass vessel which was fitted with a silicone rubber stopper and placed in the cell compartment as shown in Fig. 2. Two Teflon strips were attached to the stopper to prevent the solution from forming a convex surface. A deep hole was bored in the stopper so that a layer that could be punctured with a needle was left at the bottom of the stopper. Correspondingly, a hole was drilled in the lid of the compartment and covered with dark woollen cloth. A vinylidene chloride sheet was placed between the stopper and the glass vessel to avoid the reaction of bromine with the stopper material.

The electrical output of the spectrophotometer, proportional to the transmittance and having a value of 10 mV at 100% transmittance, was amplified by a factor of slightly over 100 with an amplifier, Model PM-17A, Toa Electronics, of which the output voltage was attenuated to exactly 1.000 V for 100% transmittance. The overall drift in several hours amounted to less than 1% transmittance.

Values of transmittance thus obtained were converted into absorbance by means of a logarithmic converter which was constructed in the author's laboratory from a logarithmic module, Model LGP-3, and operational amplifiers, Models SA-3a and SQ-10a, supplied by Philbrick/Nexus. A detailed description of the circuitry is omitted, but it provided logarithmic output voltages of 0·00 and 1·00 V for input voltages of 0·100 and 1·000 V, respectively. The working range covered approximately two decades.

The absorbance value was recorded on a 2-pen potentiometric recorder, Model EPR-3T, Toa Electronics. The absorbance estimated on the trace was precise to 0·002.

The syringe pipette for delivering sample solutions through the hole in the rubber stopper was a 250-μl Hamilton syringe. Water was used for calibration.

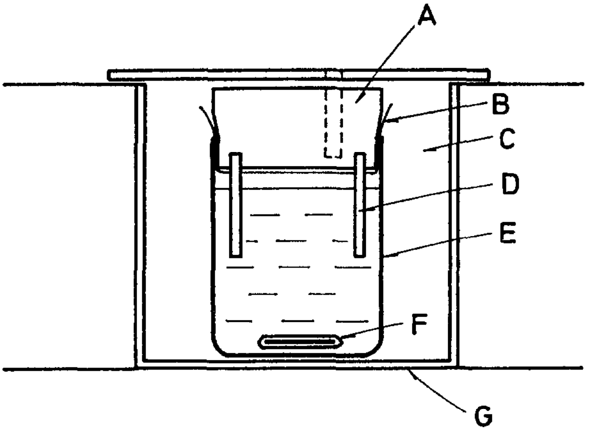

FIG. 2.—Reaction vessel and cell compartment.
A, silicone rubber stopper; B, vinylidene chloride sheet; C, cell compartment; D, Teflon strip; E, reaction vessel; F, stirrer rod; G, aluminium plate.

Analogue computer. This was also constructed in the author's laboratory. A Philbrick/Nexus operational amplifier SA-3a was used for the integrator and SQ-10a operational amplifiers for adders. A Burr-Brown Model 4030/25 quarter-square multiplier was used for the function multiplier and a Beckman-Toshiba Helipot, 10 kΩ, for the coefficient potentiometer. The capacitor was a 10-μF sintered anode solid electrolytic tantalum condenser, J5NSSA, Nippon Chemical Condensers. Resistors were commercially available 5%-grade products. The performance of the analogue computer was tested on an individual-parts basis, and the corrections thus obtained were applied to the final evaluations of concentration of the sample substance and the rate constant.

Reagents

All reagents used were of guaranteed grade. Allyl alcohol was distilled and the 95–97° fraction was used. Solutions were made up with distilled water except for the ethanolic solution of allyl alcohol. Accurate concentrations were calculated from the weight of solute and the volume. A blank test was carried out with respect to bromine consumption for each run before a sample solution was added.

Procedure

Calibration graph of bromine concentrations. The concentration of bromine was determined from the absorbance of the solution. A known volume (90 ml for the particular reaction vessel used) of 0·05*M* potassium bromide adjusted to pH 4·2 with acetic acid–acetate buffer was placed in the reaction vessel shown in Fig. 2. This was then settled in the cell compartment. An arbitrary amount of bromine was added through the lid of the compartment and the rubber stopper by use of a syringe pipette, while the solution was being stirred with a magnetic stirrer. The absorbance, A_0, of the resulting solution was measured at 370 nm against a blank solution. A known amount of allyl alcohol was then added in the same manner with a syringe pipette, and the absorbance, A, was measured. The decrease in the concentration of bromine due to the fast reaction with allyl alcohol could be calculated from the amount of allyl alcohol added, an equimolar reaction being assumed. With the amount of allyl alcohol expressed in terms of concentration, C, a plot of A_0 against $CA_0/(A_0 - A)$ for different values of A_0 and different amounts of allyl alcohol gave a straight line, which showed the relationship between concentration and absorbance of the bromine solutions in the particular vessel.

No particular effort was made to maintain a constant temperature in the solution under reaction, because the primary object was not the determination of the rate constant. Nevertheless, the temperature was essentially constant during the several minutes of the reaction period.

RESULTS AND DISCUSSION

Analytical bromination of unsaturated compounds has been carried out mainly under strongly acid conditions, to prevent hydrolysis of bromine.[10–12] However, in such an acid solution the bromination reactions of maleic and fumaric acids proceed much more slowly than those of the corresponding ionic species.[6,13] Since the hydrolysis of bromine did not substantially occur at pH below 4.5, for this work pH 4.2 was selected and maintained with an acetic acid–acetate buffer.

Several precautions had to be taken against the loss of bromine. It could be considerably reduced by adding potassium bromide to the solution to give the less volatile tribromide ion species. Also the volume of solution in the reaction vessel should be increased so as to minimize the space above the solution, since it was found that the absorbance of the solution continued to decrease until the head-space was saturated with bromine vapour. Continuous stirring of the solution accelerated volatilization, and it took 10 min at most before the decrease in absorbance substantially ceased.

The aqueous bromine solution has a maximum absorption at 390 nm whilst that of the tribromide ions is at a much shorter wavelength, so a solution containing both bromine and potassium bromide shows a plateau on its absorbance curve between 360 and 380 nm. For this reason the absorbance was measured at 370 nm.

The three bromine species, Br_2, Br^- and Br_3^-, are connected by the relationship

$$Br_2 + Br^- \rightleftharpoons Br_3^- \tag{9}$$

Each of them may take part in the bromination of maleic and fumaric acids, and therefore should be taken into consideration, although the participation of tribromide ions in the bromination reactions of 8-quinolinols[4] and phenetole[10] is unimportant. However, when the concentration of potassium bromide is large enough, as in the present work, the ratio of $[Br_2]$ to $[Br_3^-]$ remains substantially constant. As a result, total possible participation of the three species in the reaction kinetics is considered to be proportional to the concentration of Br_2, or to the absorbance measured at 370 nm.

To achieve the most reliable fit of the two traces, a sufficiently curved trace of absorbance was desired, since prominently curved traces are more easily checked for congruence. Consequently, it was better, with a slow chemical reaction, to reduce the chart speed. The analogue computer trace could be more rapidly drawn by using a value of β less than unity.

Another important factor for obtaining a trace of larger curvature is the ratio of the initial concentrations of reacting substances, b/a. The effect of the ratio b/a on the curve shape will be discussed in terms of the reaction of fumaric acid with bromine.

Initial portions of the absorbance traces, $(b - x)$ *vs.* t, for a certain constant value of a and different values of b/a are shown in Fig. 3. The curves are arbitrarily displaced along the ordinate axis only to illustrate the curvature of the traces. The rate constant and the time scale, which are related to each other according to equation (8), are not referred to since they are unimportant in this discussion.

Curve I, for which the ratio b/a is 5, is sufficiently curved to be useful, but poor curvature results for smaller values of b/a, even when a more sensitive recorder range is used. Thus a higher concentration ratio of bromine to unsaturated compound is preferable.

However, when traces from larger values of b/a were still not sufficiently curved, the curvature could be emphasized if a certain constant voltage was subtracted from the trace at the input of the recorder and the remainder was recorded in a more sensitive range. The effect of this differential procedure on the curve shape is apparent

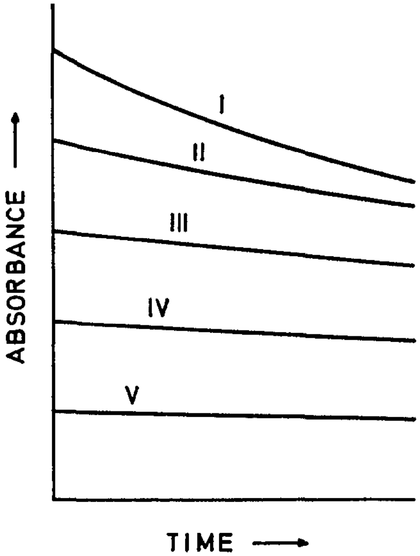

FIG. 3.—Dependence of the initial portion of absorbance trace, $(b - x)$ *vs.* t, on the ratio b/a, when a and k remain constant.
Values of b/a: I, 5; II, 2; III, 1; IV, $\frac{1}{2}$; V, $\frac{1}{5}$.

in Fig. 4. Curves I′, III′ and V′ represent magnification of the traces I, III and V in Fig. 3 from which 80% of the initial absorbance has been subtracted. The curves were drawn at sensitivities 2·5, 10 and 25 times those used for the respective traces in Fig. 3. The curvature of V′ is still poor, but the pronounced curvature of I′ and III′ permitted the method to be applied to a relatively slower reaction.

The initial concentration of bromine, b, in the real chemical experiment could be determined from the absorbance before addition of sample. The corresponding value, B, to be given to the analogue computer might be decided arbitrarily, and would determine α in equation (3).

The values of A and K needed to give exact fit of the machine curve with the experimental curve gives the values of a and k, according to equations (5) and (8). However, small changes in A and K might produce no appreciable effect on the machine curve, if the changes compensated each other. Thus, the graphical simulation method gives ranges of A and K instead of definite values. This is the most serious limitation to the precision of the method.

The most probable values of a and k were estimated as the mid-point of the ranges a and k thus obtained, and the precision was taken as half the range.

Maleic acid in aqueous solutions of different concentrations was treated at room temperature by the proposed method. Although the temperature was not controlled, it remained substantially constant during each run. Results are shown in Table I. The results seem to be tolerable, but errors as great as $0{\cdot}1 \times 10^{-4}$ mole.l.$^{-1}$ may occur. The temperature ranged from 19 to 23° for different runs. However, the estimated values of rate constant were apparently not correlated with the temperature.

The reaction of fumaric acid with bromine required a longer time to produce a sufficiently curved trace on a recorder owing to the lower rate of reaction. A lengthy experiment is undesirable, not only for reasons of time but also because of increased loss of bromine by volatilization. Consequently, to obtain well-curved traces, about

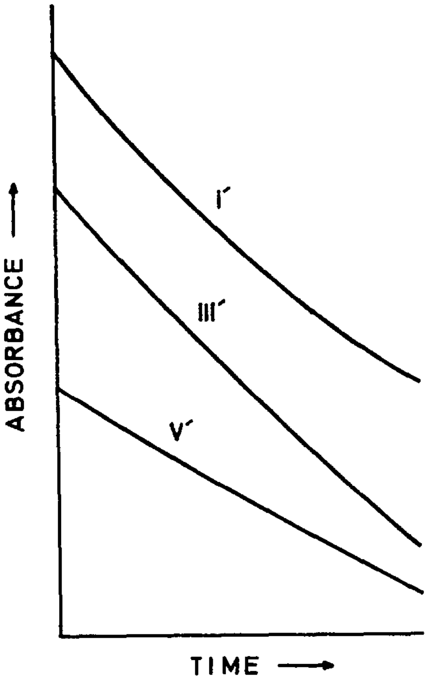

FIG. 4.—Magnification of the curves I, III and V in Fig. 3. Values of b/a: I′, 5; III′, I; V′, $\frac{1}{5}$.

TABLE I.—DETERMINATION OF MALEIC ACID

Concentration of maleic acid, 10^{-4} *mole.l.*$^{-1}$		Rate constant, *k*, *l.mole*$^{-1}$*.sec*$^{-1}$
Calc.	Found	
1·03	1·04 (±0·04)	9·2 (±0·6)
1·54	1·54 (±0·05)	8·4 (±0·4)
1·67	1·73 (±0·06)	8·9 (±0·5)
2·05	1·95 (±0·08)	7·7 (±0·5)
2·50	2·41 (±0·07)	9·0 (±0·4)
2·56	2·57 (±0·07)	8·6 (±0·6)
3·34	3·39 (±0·07)	8·0 (±0·3)
4·17	4·09 (±0·12)	8·6 (±0·5)

80% of the voltage was subtracted at the input of the recorder by applying a negative voltage and the remaining input was recorded at higher sensitivity. The same treatment was applied to the simulation process. Thus, a voltage α times as large as the subtracted voltage was subtracted from the analogue computer output and the resulting trace was used to find appropriate values of A and K.

Some examples of the kinetic analysis of fumaric acid are shown in Table II. The differences between the calculated and experimental values are tolerable, but the precision is poorer than for maleic acid, probably because of the more complex procedure.

Advantages of the proposed method are the ease with which the experimental results can be treated without laborious mathematical or graphical treatment, that

TABLE II.—DETERMINATION OF FUMARIC ACID

Concentration of fumaric acid, 10^{-4} *mole.l.*$^{-1}$		Rate constant, *k*, *l.mole*$^{-1}$*.sec*$^{-1}$
Calc.	Found	
2·56	2·59 (±0·15)	2·0 (±0·2)
3·38	3·38 (±0·27)	2·0 (±0·2)
4·19	4·27 (±0·42)	1·8 (±0·2)

only a single experiment is needed and that the nature of the reaction and the substances involved need not be known except for the type of differential equation which represents the kinetics of the reaction. Conversion of the time scale, as expressed by equation (6), is an additional feature of the method, by use of which results for a slow reaction could be treated in a shorter time.

Application of the method is not restricted to second-order kinetics nor to a spectrophotometric process. Extension of the method to a mixed component system is also promising.

Acknowledgement—I would like to thank Miss Yumiko Masaki for her helpful collaboration.

Zusammenfassung—Die Simulierung langsamer Reaktionen, die man zur chemischen Analyse verwerten kann, mit Hilfe eines Analogrechners wird beschrieben. Als Beispiel wird die Bromierung von Malein- und Fumarsäure angeführt. Die Bromkonzentration wird spektrophotometrisch in Abhängigkeit von der Zeit verfolgt und die Registrierkurve nach einem trial-and-error-Verfahren mit dem Analogrechner simuliert. Die Anfangskonzentration der zu bestimmenden Substanz und die Geschwindigkeitskonstante der Reaktion werden aus den Werten berechnet, die man dem Rechner eingegeben hat, um die beste Übereinstimmung zu erzielen. Für die Analyse wird nur ein Experiment benötigt. Man kann dem Verfahren ohne großen mathematischen oder graphischen Aufwand leicht folgen.

Résumé—On décrit la simulation par une calculatrice analogique de réactions lentes utilisées en vue d'analyse chimique. On utilise la bromuration des acides maléique et fumarique comme illustration. La concentration du brome est tracée spectrophotométriquement en fonction du temps et le tracé simulé avec une calculatrice analogique par la méthode des approximations successives. La concentration initiale de la substance en question et la constante de vitesse de la réaction sont déterminées à partir des valeurs données aux variables de la calculatrice pour obtenir le meilleur degré d'accord. Une seule expérience est nécessitée pour l'analyse. La technique peut être suivie aisément sans traitement mathématique ou graphique laborieux.

MÖGLICHKEITEN UND GRENZEN BEI DER VERWENDUNG VON FILTERPAPIER ALS TRÄGER BEI DER RÖNTGENSPEKTROMETRISCHEN ANALYSE

G. Ackermann, R.-K. Koch,[1] H. Ehrhardt und G. Sanner

(*Eingegangen am* 20. *August* 1970. *Revidiert am* 4. *Mai* 1971. *Angenommen am* 13. *September* 1971)

Zusammenfassung—Die Untersuchungen haben gezeigt, daß sich Filterpapier als Trägermaterial für die Röntgenfluoreszenz-Analyse prinzipiell eignet und daß man bei Einsatz der Ringofen-Technik nach Weisz eine hohe Empfindlichkeit bei einer hinreichend reproduzierbaren Probengeometrie erreichen kann. Die Konzentrations-Intensitätsbeziehungen sind für Ag, Pd, Rh, Pt, Au, Cu, Fe und Ca im Bereich von 0 bis 100 μg linear. Die relativen Standardabweichungen schwanken bei Gegenwart aller Elemente zwischen 7 und 30%, die Nachweisgrenzen liegen zwischen 8 μg/ml (für Eisen) und 35 μg/ml (für Calcium). Die Arbeitszeit beträgt für 5 Parallelproben *ca.* 30 min. Mit Hilfe der Wachsringtechnik läßt sich bei vergleichbarer Reproduzierbarkeit der Meßwerte, allerdings bei verringerter Empfindlichkeit, die Analysendauer auf etwa 15 min senken.

Da bei manchen Röntgenspektrometern die direkte Analyse von Flüssigkeiten wegen ungünstiger geometrischer Anordnung des Probenhalters Schwierigkeiten bereitet, verwendet man Trägermaterialien zur Fixierung solcher Proben. Sowohl bei der Untersuchung von Lösungen als auch bei der Verwendung von Trägern hat man den Vorteil, daß sich die Eichproben verhältnismäßig einfach präparieren lassen und die Verwendung innerer Standards kaum Mühe macht. Als Trägermaterialien werden in der Literatur z.B. Cellulose, PVC-Pulver, Polyäthylenpulver usw. empfohlen.

Als besonders zweckmäßig hat sich Cellulose, sowohl in Pulverform wie auch als Filtrierpapier erwiesen. Bei Einsatz von Papier erscheint zur Konzentrierung der Probe und damit zur Erhöhung der Meßempfindlichkeit die Kombination mit der Ringofentechnik nach Weisz[2] besonders empfehlenswert. Erstmalig ist darüber von Püschel[3] berichtet worden. Der Autor stellt fest, daß Filtrierpapier als organische Matrix eine geringe Untergrundstrahlung liefert und infolge seiner Saugfähigkeit eine genügend große Aufnahmefähigkeit für die zu untersuchende Lösung aufweist. Auch die Oberflächenbeschaffenheit und seine mechanische Widerstandsfähigkeit lassen es als Träger für röntgenspektrometrische Untersuchungen geeignet erscheinen. Über eine Kombination von Röntgenspektroskopie und Ringofentechnik berichten u.a. nach Natelson und Sheid,[4] die auf diesem Wege kleine Calcium-Mengen bestimmten.

Ziel der Untersuchungen war es, den Einsatz der Ringofentechnik zur Probenvorbereitung für die röntgenspektrometrische Bestimmung von Palladium, Rhodium, Gold und Platin neben Silber, Kupfer, Eisen und Calcium zu prüfen.

EXPERIMENTELLER TEIL

Meßbedingungen

Einkanalvakuum-Röntgenspektrometer "Fluroprint" V150 (Hilger und Watts, London)
Anregungsbedingungen: 50 kV, 30 mA; W-Anode
Analysatorkristall: LiF
Kollimator: 0,25 mm
Impulsvorwahl: 10^5 Imp. (für Ca-$K_{\alpha 1,2}$: $3 \cdot 10^5$ Imp.)
Probekammer: Titaneinsatz
Probehalterung: PVC-Block
Chromatographiepapier: FN 15 des VEB Spezialpapierfabrik Niederschlag
Probendurchmesser: 18 mm

Probenpräparation

Auf einem Ringofen, dessen Bohrung den Abmessungen des Fensters im Spektrometer angepaßt ist, wird das gewünschte Volumen der Probelösung eingedampft. Dabei ist darauf zu achten, daß der vorgegebene Ring-Durchmesser nicht überschritten wird. Es ist aber nicht erforderlich, daß die gesamte Menge in dem Ring konzentriert wird.

Eichreihen der reinen Lösungen

Vorversuche dienten zur Aufnahme der Eichkurven für die reinen Komponenten, von denen der Bereich von 0 bis 100 μg/ml geprüft wurde. Man erhält bei allen untersuchten Elementen für die Konzentrations-Intensitäts-Beziehung Geraden mit unterschiedlichem Anstieg. Die Anstiegsfaktoren sind in Tabelle I zusammengefaßt.

TABELLE I.—ANSTIEGSFAKTOREN DER EICHGERADEN UND NACHWEISGRENZEN FÜR DEN BEREICH 0–100 μg DER GEPRÜFTEN ELEMENTE

Element	Ca	Fe	Cu	Au	Pt	Rh	Pd	Ag
Anstieg	0,90	0,76	0,49	0,17	0,15	0,11	0,10	0,06
Nachweisgrenze, *μg/ml*	35	8	13	22	37	24	27	31

Eichreihen für die Mehrkomponentengemische

Unter Verwendung entsprechender Stammlösungen wurden im Bereich von 0 bis 100 μg über die Meßpunkte 0, 5, 25, 50, 75 und 100 μg für jedes Element Eichkurven aufgenommen, bei denen die Begleitelementmatrix, bestehend aus weiteren 6 Elementen, in 3 Stufen (1, 50 und 100 μg) zugemischt wurde. Der Gehalt an Matrix blieb dann für die ganze Reihe konstant.

Durch Vergleich mit den Meßwerten für die reinen Lösungen kann dann auf den Einfluß der Matrixelemente geschlossen werden. Als Beispiel zeigt Abb. 1 das Verhalten von Eisen in einer reinen Lösung und in Gegenwart von je 50 und 100 μg des Gemisches der Matrixelemente. Es ist zu erkennen, daß der Anstieg der Eichgeraden erwartungsgemäß vom Gehalt an Matrixelementen beeinflußt wird. Um Schwankungen durch die Meßanordnung zu beseitigen, sind die Messungen mit äußerem Standard vorgenommen worden.

Um die Interelementeffekte zu verringern, arbeitet man häufig mit einem inneren Standard. Für unsere Messungen bot sich dazu Zink an. Als Beispiel sind in Tabelle II die Anstiegsfaktoren fur die Bestimmung von Eisen in Gegenwart der Begleitelemente zusammengestellt. Man sieht deutlich, daß Zink als Standard geeignet ist, weil durch dessen Zusatz der Einfluß der Partner auf die Meßwerte vermindert wird.

TABELLE II.—WIRKUNG VON ZINK ALS INNERER STANDARD BEI DER BESTIMMUNG VON 0 BIS 25 μg EISEN

	Anstiegsfaktoren
Innerer Standard ohne Begleitelemente	0,46
Äußerer Standard ohne Begleitelemente	0,37
Äußerer Standard mit Begleitelemente	0,28

Für Palladium und Rhodium erzielten wir durch Verwendung des Untergrundes als inneren Standard sehr günstige Ergebnisse. Dieses Verfahren hat noch den Vorteil, daß ein zusätzlicher Zeitaufwand für das Zumischen der Bezugslösung entfällt.

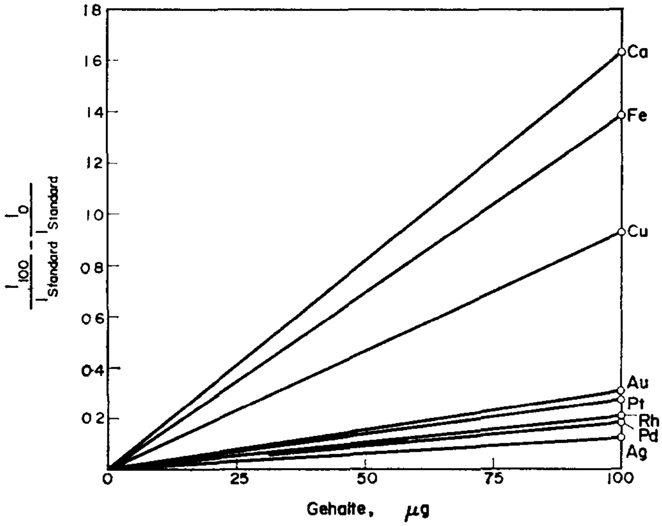

ABB. 1.—Eichkurven für die Bestimmung von Silber, Palladium, Rhodium, Platin, Gold, Kupfer, Eisen und Calcium

DISKUSSION DER ERGEBNISSE

Reproduzierbarkeit und Nachweisgrenzen

Um den durch das Spektrometer hervorgerufenen Meßfehler zu erfassen, wurden von jedem Element bei einer mittleren Menge von der gleichen Probe 11 (bzw. 10) Messungen durchgeführt. Wie Tabelle III zeigt, liegen die Variationskoeffizienten für die einzelnen Elemente zwischen 1,0 und 5,5%.

Um den Einfluß der Probenvorbereitung mit zu erfassen, sind (in Gegenwart aller anderen genannten Elemente) jeweils an 11 (bzw. 10) individuellen Proben bei einer mittleren Menge Messungen vorgenommen worden. Die Ergebnisse enthält Tabelle IV. Aus den zwischen 6,8 und 23% liegenden Variationskoeffizienten kann man ableiten, daß zur Erhöhung der Präzision der Messungen die Präparationstechnik vervollkommnet werden muß.

Wie Tabelle I zeigt, liegen die aus statistischen Berechnungen[6] für Pd und Pt bzw. aus den Regressionsgeraden[6] für alle anderen Elemente berechneten Nachweisgrenzen zwischen 8 µg/ml (Eisen) und 35 µg/ml (Calcium). Durch Verwendung eines inneren Standards können diese Werte verbessert werden.

TABELLE III.—REPRODUZIERBARKEIT BEIM MESSVORGANG

Element	Ag	Pd	Rh	Au	Pt	Cu	Fe	Ca
Gemessene Linie	$K_{\alpha,Ag}$	$K_{\alpha,Pd}$	$K_{\alpha,Rh}$	$L_{\beta,Au}$	$L_{\beta,Pt}$	$K_{\alpha,Cu}$	$K_{\alpha,Fe}$	$K_{,Ca}$
Mittelwert $\bar{X}$, µg	47,1	44,7	56,4	54,0	68,3	45,4	49,4	48,3
Anzahl n der Messungen	11	11	11	10	11	11	11	11
Variationskoeffizient V, %	4,8	1,5	3,7	4,1	5,5	3,4	3,2	1,0

Es wurde das Verhältnis $I_{K\alpha}/I_{K\alpha(std)}$ bzw. $I_{L\beta}/I_{L\beta(std)}$ für jede Messung berechnet. Die Intensität $I_{K\alpha(std)}$ bezieht sich auf einen äußeren Standard.

Die unter Verwendung des Ringofens erhaltenen Ergebnisse stimmen annähernd mit den von McNevin und Hakkila erhaltenen Werten[7] für die Reproduzierbarkeit

TABELLE IV.—REPRODUZIERBARKEIT BEI DER PROBENVORBEREITUNG

Element	Ag	Pd	Rh	Au	Pt	Cu	Fe	Ca
Meßverfahren	$\frac{I_{\mathrm{Ag-K}\alpha}}{I_{\mathrm{Ag-K}\alpha(\mathrm{std})}}$	$\frac{I_{\mathrm{Pd-K}\alpha}}{I_{\mathrm{U}(15\cdot 00)}}$	$\frac{I_{\mathrm{Rh-K}\alpha}}{I_{\mathrm{U}(19\cdot 00)}}$	$\frac{I_{\mathrm{Au-L}\beta}}{I_{\mathrm{Au-L}\beta(\mathrm{std})}}$	$\frac{I_{\mathrm{Pt-L}\beta}}{I_{\mathrm{Pt-L}\beta(\mathrm{std})}}$	$\frac{I_{\mathrm{Cu-K}\alpha}}{I_{\mathrm{Cu-K}\alpha(\mathrm{std})}}$	$\frac{I_{\mathrm{Fe-K}\alpha}}{I_{\mathrm{Fe-K}\alpha(\mathrm{std})}}$	$\frac{I_{\mathrm{Ca-K}\alpha}}{I_{\mathrm{Ca-K}\alpha(\mathrm{std})}}$
Mittelwert $\bar{X}$, μg	46,1	42,8	55,1	46,5	42,7	46,7	45,4	43,1
Anzahl n der Proben	11	10	11	10	11	11	11	10
Variationskoeffizient V, %	21,5	15,2	6,8	13,2	14,2	9,3	9,3	23,0

Std = äußerer Standard; U = Untergrund.

überein. Die Autoren brachten jeweils 1 ml der zu untersuchenden Lösung auf Filterpapier und dampften die Lösung dann auf einer Heizplatte ein. Auf diesem Wege bestimmten sie 100 μg/ml Palladium, 140 μg/ml Rhodium, 20 μg/ml Iridium und 200 μg/ml Platin, wobei die Variationskoeffizienten zwischen 7 und 13 % lagen. Die Verfasser verwendeten für ihre Untesuchungen teilwise eine Anregungsspannung von 100 kV, wodurch die Empfindlichkeit für Platin and Iridium (Anregung der K-Spektren) erheblich gesteigert und die Reproduzierbarkeit für alle Elemente verbessert werden konnte.

Auswahl der Papiersorte

Die Wahl der Papiersorte wird in erster Linie durch den Einsatz des Ringofens bestimmt. Für das Verfahren eignen sich besonders mittelstarke, gut saugende, säuregewaschene Qualitäten. Um aber den Einfluß der Papiereigenschaft auf die Fluoreszenzstrahlung zu prüfen, ist von einer Reihe säuregewaschener Chromatographiepapiere die Untergrundstrahlung für die Elemente Eisen, Kupfer und Calcium geprüft worden, die von der Herstellung her noch im Papier zu erwarten sind. Die Ergebnisse sind in Tabelle V zusammengestellt.

TABELLE V.—IMPULSVERHÄLTNIS FÜR DIE UNTERGRUNDSTRAHLUNG EINIGER PAPIERSORTEN

Sorte	Flächengewicht, *$\mu g/mm^2$*	Papierstärke, *mm*	Impulsverhältnis Kupfer	 Eisen	 Calcium
FN 15	93	0,18	0,493	0,292	0,435
FN 13	94	0,18	0,950	0,289	0,436
FN 11	98	0,18	0,503	0,294	0,447
FN 12	182	0,20	0,508	0,287	0,326
WF 16	161	0,20	0,496	0,273	0,269
FN 17	160	0,28	0,492	0,271	0,264
FN 18	290	0,51	0,504	0,243	0,165

Bei der Kupfer-Linie ist kein Zusammenhang zwischen Papierstärke und Fluoreszenzstrahlung des Untergrundes feststellbar. Dagegen zeichnet sich aber etwas beim Eisen und deutlich beim Calcium ein Gang ab. Mit zunehmender Papierstärke und damit mit steigendem Flächengewicht nimmt die Blindstrahlung dieser Elemente ab, wobei der Intensitätsrückgang der Ca–K$\alpha_{1,2}$ Linie erwartungsgemäß stärker ausgeprägt ist. Diese Tatsache kann durch zunehmende Absorption der Sekundärstrahlung in der Papierschicht erklärt werden, da die Fluoreszenzstrahlung von Eisen und Calcium schon ziemlich langwellig ist. Aus diesen Untersuchungen resultiert, daß man auch für die röntgenspektrometrische Analyse keine zu dicken Papiersorten verwenden darf.

Zeitlich-ökonomische Betrachtungen

Bei Anwendung der Ringofentechnik benötigt man zum Auftragen von 1 ml einer Lösung etwa 60 min. Da man aber ohne Schwierigkeit—auch ohne Verwendung automatischer Dosiervorrichtungen—fünf Ringöfen gleichzeitig bedienen kann, sinkt die Präparationsdauer auf etwa 12 min pro Probe.

Die Meßzeit beträgt—in Abhängigkeit vom verwendeten Gerät—etwa 10 min für 7 Linien. Einschließlich der Auswertung der ausgedruckten Impulse resultiert daraus eine Gesamtarbeitszeit von 80 min für eine Probe und von 30 min bei gleichzeitigem Einsatz von 5 Ringöfen. Aus dieser Betrachtung geht deutlich hervor, daß das Verhältnis von Dauer der Probenvorbereitung zu Meßzeit noch recht ungünstig ist.

Wachsringtechnik

Abschließend soll deshalb noch kurz auf einige Untersuchungen zur "Wachsringtechnik" nach Johnson und Nagel[8] hingewiesen werden. Man verfährt dabei so, daß man auf einem Blatt eines geeigneten Filtrierpapiers (z.B. FN 12 des VEB Spezialpapierfabrik Niederschlag) die saugfähige Fläche mit Wachs auf einen innerem Durchmesser von 18 mm begrenzt. In das Innere des Kreises gibt man mit Hilfe einer geeigneten Dosierspritze die zu untersuchende Lösung und trocknet an der Luft. Gegenüberder oben beschriebenen Präparationstechnik ist dabei von Nachteil, daß man nur etwa 50 μl auftragen kann. Vorteilhaft ist aber die sehr kurze Auftragezeit von etwa 1,5 min. Der für Cu-$K_{\alpha 1,2}$ ermittelte Variationskoeffizient betrug 8,3%. Für Ag-$k_{\alpha 1,2}$ erhielten wir 11%.

Summary—It has been shown that filter paper is a suitable support material for X-ray fluorescence analysis, but that the use of the Weisz ring-oven enables a higher sensitivity to be obtained with a sufficiently reproducible sample geometry. Linear calibration plots are obtained for Ag, Pd, Rh, Pt, Au, Cu, Fe and Ca in the range 8–100 μg. The relative standard deviations vary between 7 and 35, and the limits of detection range from 8 to 35 μg/ml (for iron and calcium respectively). Five samples may be analysed in 30 min. Use of the wax-ring technique enables the analysis time to be halved, but the sensitivity is then less.

Résumé—On a montré que le papier filtre est une matière support convenable pour l'analyse par fluorescence de rayons X, mais que l'emploi du four annulaire de Weisz permet d'obtenir une sensibilité plus élevée avec une géométrie d'échantillon suffisamment reproductible. On a obtenu des courbes d'étalonnage linéaires pour Ag, Pd, Rh, Pt, Au, Cu, Fe et Ca dans le domaine 8–100 μg. Les écartes types relatifs varient entre 7 et 35, et les limites de détection vont de 8 à 35 μg/ml (pour le fer et le calcium respectivement). On peut analyser cinq échantillons en 30 mn. L'emploi de la technique à l'anneau de cire permet de diviser le temps de l'analyse par deux, mais la sensibilité est alors plus faible.

(*Received* 28 *December* 1970. *Revised* 13 *April* 1971. *Accepted* 3 *August* 1971)

Summary—The pK-values of Xylenol Orange, Pyrocatechol Violet, Thorin and Alizarin Complexone were determined electrophoretically on the basis of the Kiso equation. The colour changes of Xylenol Orange and Alizarin Complexone were found to take place at slightly higher pH values than the electrophoretically determined pK-values. The Kiso-equation for determination of the pK values by electrophoresis yielded reproducible results and the method is useful for complicated substances because the procedure is simple, the equipment inexpensive and only microamounts of the substances are needed.

UNTIL recently paper electrophoresis was applied only to the qualititative separation of various organic and inorganic substances, mainly because of lack of theoretically predictable migration distances. There seemed to be too many variables for a generally applicable theory to be developed. Recently, however, some attempts at a mathematical treatment have been made.[1] A general equation was derived by Kiso *et al.*,[2] calculating the relative electrophoretic mobilities of substances from their molecular weight and pK, and the pH of the background solution. Waldron-Edward had earlier determined the pK-values of a few monobasic amino-acids[3] on the basis of an equation published by Consden, Gordon and Martin.[4] This equation permitted the determination of the pK-values of a monobasic acid, and of both pK-values of a dibasic acid if the difference between them was at least 4 units. The Kiso-equation is applicable to substances with several dissociable protons. The Kiso-equation is:

$$U = \frac{1}{2} \sum_{i=1}^{n} \frac{a}{\sqrt{M}} \left\{1 + \tanh\left[\frac{2.303}{2}(\text{pH} - \text{p}K_i)\right]\right\}$$

where U is the relative mobility of the substance, M the molecular weight, a a constant depending on the substance used as migration standard, and $\text{p}K_i$ the ith dissociation constant of the substance. The migration distance L is directly proportional to U:

$$L = UEt$$

where E is the potential gradient and t the migration time.

From this equation the mobility *vs.* pH or migration distance *vs.* pH curves for various substances can be drawn. From the latter it should be possible to read the pK-values of substances of known molecular weight. This could be confirmed by applying the equation to simple acids such as the various phosphorus acids.[2] We have tried to show that this theory can be applied not only to simple acids but also complex substances such as indicators. The indicators tested were Xylenol Orange, Pyrocatechol Violet, Thorin, Alizarin Complexone, Calcon and Eriochrome Black T.

EXPERIMENTAL

A 10-chamber Toyo Model MC-10K electrophoresis apparatus was used. Cooling water thermostatically controlled at 10° was passed through cooling pipes to keep the coolant, carbon tetrachloride, at constant temperature. Toyo Roshi Paper No. 51A was used in 0·40-m strips as supporting material. The paper was soaked with the buffer solution and a few μl of the indicator solution were applied with a capillary. Picric acid was the migration standard on every strip. Generally 1000 V (Toyo Kagaku Sangyo Model IV power supply) were applied for 60 min. The current was 2–80 mA, depending on the pH of the background buffer solution. The corrected migration distance was derived from the formula

$$L_{\mathrm{corr}} = L_{\mathrm{exp}} \frac{L_{\mathrm{p.t}}}{L_{\mathrm{p.exp}}}$$

where L_{corr} is the corrected migration distance, L_{exp} the experimental migration distance, $L_{\mathrm{p.t}}$ the theoretical migration distance of picric acid (the mean for the particular series of experiments) and $L_{\mathrm{p.exp}}$ the experimental migration distance of picric acid.

The pK of picric acid is 0·38. Between pH 0 and 2 an equilibrium exists between undissociated picric acid and its anion. Only the anion shows the well-known yellow colour which in the electrophoretic experiments was visible only at pH > 1·8. Hence in the pH range 0·5–1·8 no migration standard could be used. The concentration of the solutions was 0·1M. The buffer mixtures used were: pH 0·5–2·0, glycine and hydrochloric acid (0·1M; 2·0–5·4, citric acid and hydrochloric acid or sodium hydroxide; 5·0–7·4, disodium hydrogen phosphate and potassium dihydrogen phosphate; 7·2–9·1, borax and sodium hydroxide; 9·0–12·0, glycine and sodium hydroxide.

RESULTS AND DISCUSSION

Xylenol Orange

The pK values for Xylenol Orange reported by Murakami *et al.*[5] differ slightly from those given by Rehak and Körbl,[6] mainly in the acidic pH range. This was attributed by the former to the use of an impure sample by the latter authors. The values reported by Akhmedli and Imamverdieva[7] were very different.

	Murakami *et al.*[5]	Rehak and Körbl[6]	Akhmedli and Imamverdieva[7]
	(1967)	(1960)	(1966)
pK_1	<1·5	—	—
pK_2	2·32	2·6	—
pK_3	2·85	3·2	4·15
pK_4	6·67	6·4	—
pK_5	10·39	10·5	7·21
pK_6	12·23	12·3	10·72

Our experimentally obtained migration distance *vs.* pH curve is given in Fig. 1. The pH differences for the first three dissociations are only 0·9 and 1·05 pH units, and hence too small to allow separate detection of these steps by electrophoresis. However the increase in the migration distance is about three times that for each of the two further dissociations, indicating a charge increase of three units. According to this assumption the three pK values can be estimated as pK_1 = 1·25, pK_2 = 2·15 and pK_3 = 3·2, which is in agreement with the reported data. These three dissociation steps do not cause any colour change. The solution is yellow and has an absorption maximum at 435 nm. At pH 6·5 another maximum appears at 580 nm, becoming prominent at pH 7·0 and being the only one at pH > 8·0. The colour is then red. The corresponding dissociation equilibrium can be easily detected by electrophoresis, though the value pK_4 = 6·1 determined electrophoretically seems to be too low compared with the optical data and the reported values. The pK_5 determined by electrophoresis is 10·0. This step causes no colour change, and the pK value also seems to be rather low. The pK_6 cannot be determined by electrophoresis. Murakami *et al.*[5] report that the Dotite reagent, which we used for our experiments, contains impurities, but this should not cause shifts of the electrophoretically determined

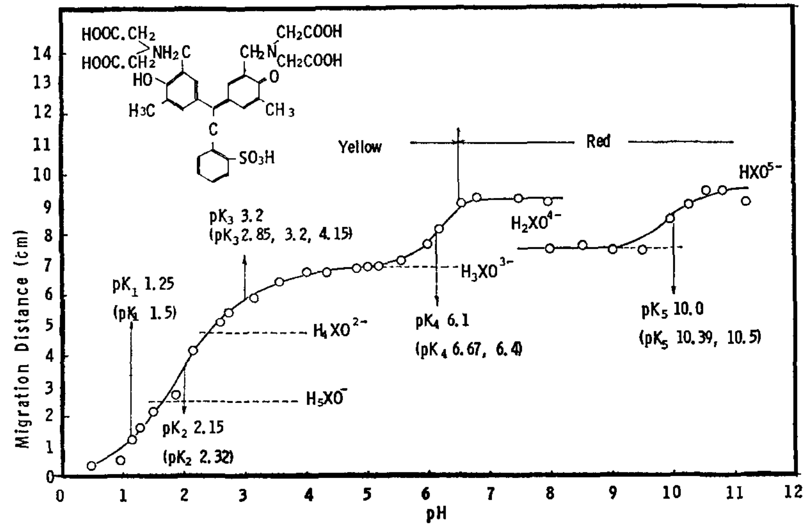

FIG. 1.—Corrected migration distance plotted against pH for Xylenol Orange. pK values are marked and previously published values given in brackets. The colours of the solution are indicated above the curve.

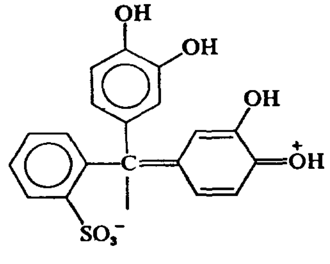
pK-values, as the impurities should have different mobilities and hence be separated from the main compound in our experiment. The reason for the lower values of the electrophoretically determined pK-values has still to be found.

The discontinuity in Fig. 1 and other figures is caused mainly by the change of temperature and ionic strength in the supporting medium. The mobility depends on the ionic strength $I = \frac{1}{2} . c_i z_i^2$, where c_i, the concentration and z_i the charge of the ions. In our experiments the concentration of the buffer solutions was kept constant but the mean charge of the buffer ions varied from buffer solution to buffer solution thus causing differences in the ionic strength and hence in the temperature. We repeated our experiments several times and used chemically different buffer solutions with identical pH values to try to avoid any mistakes. We are further improving the experimental conditions, mainly by keeping constant the ionic strength as well as the concentration of the buffers. If the ionic strength is kept constant the migration distance *vs.* pH curve become a continuous line. It was assumed that when a discontinuity occurred the lower curve could simply be shifted vertically until it became an extension of the upper curve.

Pyrocatechol Violet

The mobility *vs.* pH curve is given in Fig. 2. The reported pK values[8] are also shown. Suk and Malát[9] report the existence of a zwitterion at pH < 1·5:



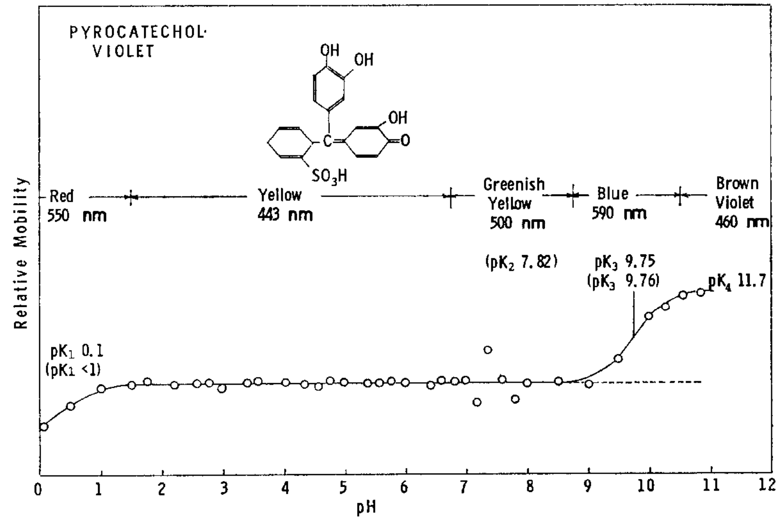


FIG. 2.—Corrected migration distance *vs.* pH for Pyrocatechol Violet. Dotted line; theoretical curve, full line: experimentally obtained.

Electrophoretic evidence for the existence of this species can be found, as the species shows a rather low mobility at pH < 1. Under these conditions the electro-osmotic flow does not lower the migration distance, so all neutral species should have zero mobility. In our experiments the species moved as an anion with low charge. At pH 1·5 the absorption maximum is at 443 nm and the solution is yellow. The zwitterion is reported to be red[10] with an absorption maximum at about 550 nm[9] which can be detected at about pH 0·12, the maximum at 443 nm still being prominent. Only below pH 0 does the maximum at 443 nm completely disappear.

For pH 1·5–7·0 the experimental results are in good agreement with calculation, showing no change in migration distance, and the experimental error is small. The dissociation of the first phenolic hydrogen, with pK = 7·82,[9] cannot be detected by this method. However, at pH = 7·2 the experimental error suddenly increases a great deal. In the absorption spectrum (Fig. 3) a small shoulder with a maximum at 590 nm is found at pH 6·5. Below pH 7·0 the colour appears yellow; at pH 7·0 it is greenish-yellow and besides the maximum at 443 nm a small one is found at 590 nm. At pH 7·5 these maxima are equal in height and the solution is greyish green. At pH 7·7 the 590 nm peak is higher than the one at 443 nm and the colour is grey; at pH 8·0 the solution is red and there is only the maximum at 500 nm. These colours are all stable for 1–2 weeks; after about a month they change slowly. These frequent colour changes and the very poor reproducibility of the electrophoretic results indicate an equilibrium of at least two species with different charges and hence different electrophoretic mobilities. The results also indicate that the transition is not a simple dissociation of a proton as stated by Suk and Malát[9] but a rearrangement within the molecule. The red species obtained at pH 8·0 (λ_{max} 500 nm) is stable up to pH 9·0. At pH 9·3 the solution is deep blue, λ_{max} 590 nm. This blue colour is stable between pH 9·3 and 10·0; at higher pH values the blue colour appears immediately the indicator is added to the buffer but changes within 2 min to violet, there being a broad absorption band with a flat maximum at 460 nm. This is in

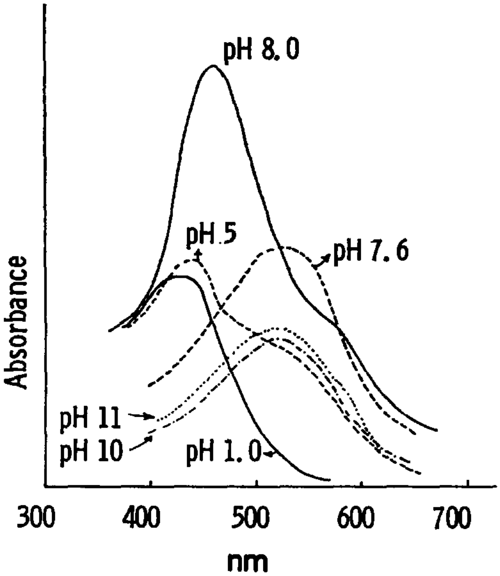

FIG. 3.—Spectra of Pyrocatechol Violet at different pH values (visible region).

agreement with the electrophoretic results, where an increase in migration distance starts at pH 9·0. The electrophoretically determined p*K* of 9·75 is in excellent agreement with the reported value[9] of 9·76. Our investigations did not always confirm the results of Suk and Malát, especially the spectra, and the electrophoretic results in the neutral and alkaline region seemed to show that the dissociation equilibria suggested by them are over-simplified.

Thorin

Thorin has been studied in detail by Margerum *et al.*,[11] who gave the dissociation constants of the two protons of the arsonic group as $pK_3 = 3{\cdot}7$ and $pK_4 = 8{\cdot}3$, and the constant for the naphtholic group as $pK_5 = 11.6$; they could not determine the dissociation constants of the two sulphonic groups. Figure 4, based on the electrophoretic experiments, shows dissociation steps at pK 3·6, 7·4 and 10·2. The migration distance at pH 1 is rather large, suggesting that the migration species has two negative charges; hence the pK values of the two sulphonic groups are less than 0·5. This confirms the assumption of Margerum and his co-workers. The value p*K* 3·6 for dissociation of the first arsonic proton agrees with Margerum's results but pK_4 and pK_5 are lower. The increase in mobility between pH 6 and 9 is rather large, and indicative of a charge increase of two units rather than one. This large increase in migration distance and the discrepancy between Margerum's results and ours will be further studied.

Thorin is red-orange in solution and the absorption maximum at 445 nm is not affected by pH change.

Alizarin Complexone

For Alizarin Complexone we could not find p*K* values in the literature. From our experiments we obtained reproducible values of 3·7, 6·7 and 10·5 (Fig. 5). We ascribe the first two steps to dissociation of the two carboxylic proton and the third to

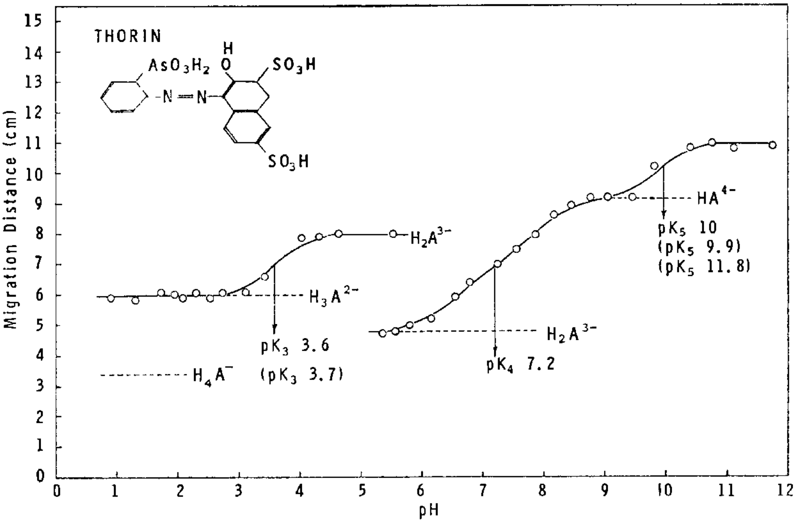

FIG. 4.—Thorin: corrected migration distance *vs*. pH.

dissociation of the first phenolic proton. The solution is yellow below pH 5·0, with an absorption maximum at 425 nm (Fig. 6). At pH 5·0, another maximum appears at 510 nm and is the only one between pH 6·0 and 7·6, the solution being red. Belcher *et al.*[12] reported the colour to be yellow below pH 4·5, red at pH 7–10, mauve at pH 11·5 and violet at pH 12. Unlike these authors we found another colour change from red to yellow at pH 8·0 (absorption maximum 455–460 nm). This yellow colour is stable between pH 8·0 and 9·0. At pH 9·6 it changes back to red (λ_{max} 507 nm), At pH 11 we found a slight shift of the absorption maximum, the peak being rather broad and having a shoulder (the colour being red violet). The colour changes from yellow to red, red to yellow and red to red-violet are all sharp, but the pH values at which they occur are higher than the pK values measured by electrophoresis. The

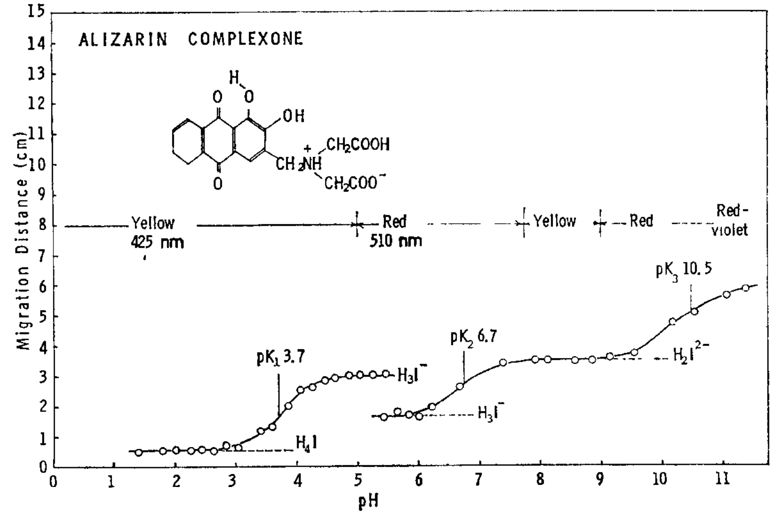

FIG. 5.—Alizarin Complexone: corrected migration distance *vs*. pH.

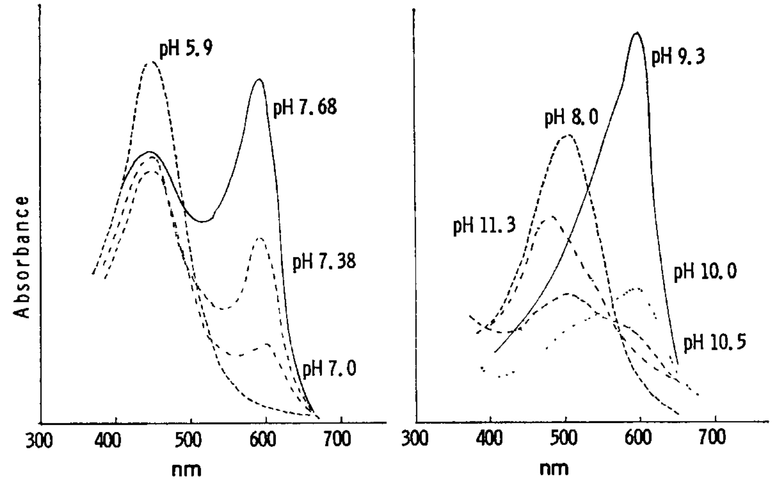

FIG. 6.—Spectra of Alizarin Complexone at different pH values (visible region).

reason seems to be that the colour change can be seen only when the dissociation is nearly complete.

Calcon and Eriochrome Black T

The pK values of these two substances could not be determined by electrophoretic experiments. Each has two naphthyl groups within the molecule, and these cause such strong adsorption on the chromatographic paper that the indicators do not move under our experimental conditions even at the highest pH used.

Zusammenfassung—Die pK-Werte von Xylenolorange, Brenzcatechinviolett, Thorin und Alizarinkomplexon wurden elektrophoretisch auf Grund der Kiso-Gleichung ermittelt. Es wurde gefunden, daß die Farbänderungen von Xylenolorange und Alizarinkomplexon bei geringfügig höheren pH-Werten stattfinden als bei den elektrophoretisch bestimmten pK-Werten. Die Kiso-Gleichung zur Bestimmung von pK-Werten durch Elektrophorese ergab reproduzierbare Ergebnisse. Die Methode ist für komplizierte Substanzen nützlich, da das Verfahren einfach und die Ausrüstung nicht teuer ist und nur Mikromengen Substanz benötigt werden.

Résumé—On a déterminé électrophorétiquement les valeurs de pK des composés Orangé Xylénol, Violet de Pyrocatéchol, Thorin et Alizarine Complexon, sur la base de l'équation de Kiso. On a trouvé que les changements de coloration de l'Orangé Xylénol et de l'Alizarine Complexon se produisent à des valeurs de pH légèrement plus élevées que les valeurs de pK déterminées électrophorétiquement. L'équation de Kiso pour la détermination des valeurs de pK par électrophorèse fournit des résultats reproductibles et la méthode est utile pour les substances compliquées car la technique est simple, l'équipement peu onéreux et des microquantités seulement de substances sont nécessaires.

APPLICATION OF DISPLACEMENT REACTIONS IN FLAME PHOTOMETRY—II

EMISSION FLAME PHOTOMETRIC DETERMINATION OF ALKALINE EARTH METALS IN THE PRESENCE OF INTERFERING ANIONS

P. J. Slevin, E. Györy-Szebényi* and G. Svehla
Department of Chemistry, Queen's University, Belfast, U.K.

(*Received* 15 *July* 1970. *Revised* 30 *September* 1971 *Accepted* 7 *October* 1971)

Summary—For the emission flame photometric determination of strontium and barium in the presence of interfering ions such as phosphate, sulphate, arsenate and oxalate, calibration or simple standard addition methods cannot be used. Greatly reduced errors can be achieved by dividing the sample solution into four equal parts and adding to each certain known amounts of two metal ions. One of these is identical to the determinand (*e.g.*, strontium or barium) the other has similar characteristics to it (*e.g.*, calcium). The amounts of these metals are chosen so that the total (molar) concentration of these should be identical in all solutions, but the ratio of the concentrations of the two metals should be different. The emission of the determinand metal must be measured, and a standard addition plot produced. The amount of determinand present in the sample can be obtained from the intersection of the emission *vs.* concentration line with the concentration axis.

Although the depressive anion interference effects in the flame photometric determination of the alkaline earths have been well documented, they continue to be of interest. Several authors made detailed studies of these in the early 1950's[1–4] with particular reference to the phosphate and sulphate effects. Excellent reviews of the nature of these effects have been made by Fukushima[5] and Herrmann and Alkemade[6] and the depressive effects have been attributed to the formation of compounds with high vaporization temperatures in the evaporating droplets of the aerosol. More recently attempts have been made to establish the exact identity of these involatile compounds[7,8] and the mechanisms by which they are formed.

For the practical analyst, many techniques have been proposed to eliminate such commonly encountered depressive effects as those of phosphate, sulphate, borate, silicate and arsenate on the emission of alkaline earth metals and on that of calcium in particular. The simplest of these methods is the addition of the interferent in excess. This method is based on the well-known fact that the depressing effect of the interferent increases proportionally with the concentration of the latter only up to a certain well-defined value; above this concentration the emission becomes constant. The decrease of the emission signal may be as high as 80%. A similar difficulty arises when the sample is diluted with water. In less concentrated solutions the relative decrease of emission becomes less, but of course the actual signals are weakened. The use of simulated standards is another possibility, but is commendable only if samples of similar composition are analysed in great numbers. Chemical separation methods, based mainly on the removal of interfering ions by ion-exchange is more attractive

---

* On leave from the Department of Applied Chemistry, Technical University, Budapest, Hungary.

than any of these, but it requires time and skill and the efficiency of the separation has to be checked in order to obtain reliable results. The application of a releasing agent (to which our proposed displacement technique is distantly related) is very simple as it requires only the addition of a further reagent to the sample. but it also has its limitations. Quantitative release is not necessarily attained when making up the solution and in accurate work this has to be checked. The use of large excesses of the releasing agent can also have undesirable side-effects.[9]

These interferences are especially marked if the flame temperature is not too high (*e.g.*, in the air–acetylene premixed laminar flame). At higher temperatures, for example with the nitrous oxide–acetylene flame and with measurement of the emission at a sufficient distance above the burner head, errors due to such interferences can be substantially reduced, if not completely eliminated.[10–12] It is relatively simple to remove this remaining marginal interference by any of the techniques mentioned above when hot flames are used; our displacement method works very efficiently under such circumstances. To illustrate the technique, however, we chose a low-temperature flame for several reasons. As the interferences are more marked under such circumstances, the efficiency of the displacement technique can be better judged. Furthermore, though the application of hot flames would certainly ease the difficulties, this cannot be implemented in all cases without altering or replacing existing instruments. Quite a number of commercial flame photometers are based on the application of the premixed acetylene–air flame. These are in routine use and give satisfactory performance if maintained correctly. For the users of such instruments our method may be the simplest and safest.

The proposed technique is based on a shift of the chemical equilibrium by the addition of a third species, keeping, however, the overall concentration ratio of metal to interferent constant. A complete release of the determinand is not necessary and thus errors due to an assumed complete release or to a large excess of releasing agent do not arise. The sensitivity of the method should be at least as good as a normal calibration procedure using a releasing agent, owing to the fact that the displacement is incorporated in a standard addition procedure. Experimentally the technique is very simple, requiring mixtures of the sample solution and solutions which can be prepared and stored in large amounts. The flame photometric readings are made by using a simple air–acetylene flame and all operations require no specially trained personnel.

Principle of the method

The problem facing the analyst when determining alkaline earth metals by flame photometry in the presence of interfering ions can be appreciated from the lowest curve of Fig. 1 where the emission of calcium is plotted as a function of the concentration of phosphate ions present.

This curve was obtained with a Unicam SP 90 spectrophotometer, operated in its emission mode. Solutions were made up from calcium chloride, phosphoric acid and an excess of hydrochloric acid and water so that the calcium concentration in each solution was $0{\cdot}01M$. An acetylene–air flame was used. A similar curve was obtained with a Zeiss (Jena) Model III flame photometer, using an interference filter with a transmission maximum at 630 nm.

The curve indicates clearly the well-known fact that the emission of calcium decreases considerably with increasing phosphate concentration, until the composition corresponding to the formula $Ca_3(PO_4)_2$ is reached; from then onwards the emission

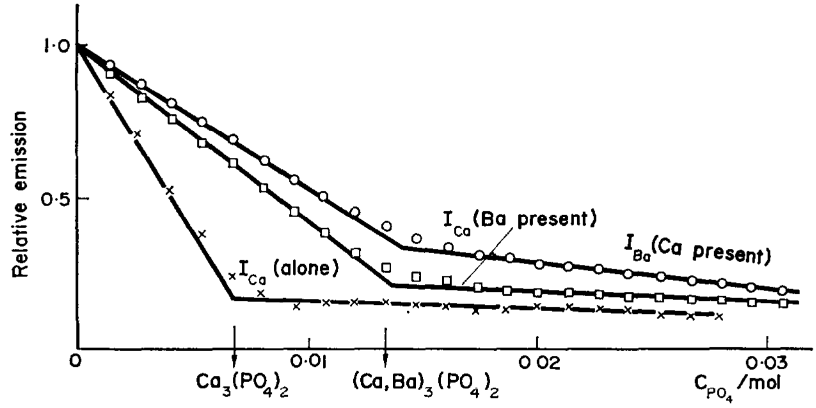

FIG. 1.—Variation of the emission of calcium and barium as a function of the concentration of phosphate.

remains constant. The determination of calcium in the presence of phosphate by making a single emission measurement and using a calibration curve is therefore out of the question. Even the well-known technique of standard addition will not help, because, if calcium ions are added, the relative amounts of calcium and phosphate will change and therefore the degree of interference of phosphate will be different, unless the latter is present in an overwhelming excess.

Such samples can be analysed by using the displacement technique, which is based on the phenomenon that if there are other metal ions present in the sample which will react with the interfering ion in a similar way, a stiuation may arise in which the interferent will react simultaneously with both metals. (An alternative is that the interferent reacts preferentially with one metal; in such a case the displacement technique is not applicable.)

Evidence of such a simultaneous reaction is shown in the upper two curves of Fig. 1. Phosphate was added to mixtures of calcium and barium together with an excess of hydrochloric acid, and the solutions were diluted to a known volume. In each solution the concentrations of calcium and barium ions were 0·01*M*, and the concentrations of phosphate varied between 0 and 0·04*M*. The flame photometric emissions of calcium (at 625 nm) and barium (at 515 nm) were measured separately and the relative emissions plotted as a function of the concentration of phosphate. Both curves show one break-point, corresponding to the formation of a mixed compound, $(Ca,Ba)_3(PO_4)_2$, showing that phosphate was reacting simultaneously with the two metals. (Had phosphate been reacting preferentially with barium, the barium curve would have one break-point where the one was observed with the calcium only, while the calcium curve would have two break-points; first a horizontal line would have been observed up to the break-point of barium, then a decrease would have been observed in the emission up to the second break-point, from which the emission would again have remained constant.)

The displacement technique makes use of the fact that the interfering ion reacts simultaneously with both metals present. This indicates that an equilibrium exists between the determinand *A*, the interfering ion *B* and the displacing agent *M*:

$$AB + M \rightleftharpoons MB + \mathrm{A}$$

where *AB* and *MB* are the refractory compounds which are formed. Such an equilibrium can be shifted in either direction by adding more or less displacing agent to the solution. If we ensure that the ratio of the total concentration of the metal ions and the concentration of the interfering ion is kept constant, we can apply a technique resembling the standard addition method which will provide more reliable results with improved accuracy.

The displacement technique can be applied in the following way. The sample is dissolved and diluted to a known value. Equal aliquots of this stock solution are taken which, (after final dilution) have equal concentrations of the determinand *A* (C_X) and of the interferent *B* (C_B) which are unknown. (All concentrations are expressed in mole/l.) To each of these solutions known amounts of *A* and of the displacing agent *M* are added. The individual amounts must vary, but the addition must be made in such a way that the total concentration of the added ions in the final solutions is equal. Denoting the four aliquots taken from the sample by 1,2,3 and 4, the condition

$$C_{A1} + C_{M1} = C_{A2} + C_{M2} = C_{A3} + C_{M3} = C_{A4} + C_{M4} = \text{constant}$$

must be fulfilled. The purpose of this operation is to keep the ratio $(C_X + C_A + C_M)/C_B$ constant for each aliquot. The flame photometric emission of *A* is then measured. Plotting these emission values as a function of C_A (the known concentrations of the added analyte) gives a straight line which, when extrapolated to the ordinate zero will intersect the abscissa at a point which corresponds to the unknown concentration C_X. These conditions are better seen on the (idealized) diagrams of Fig. 2. The four upper

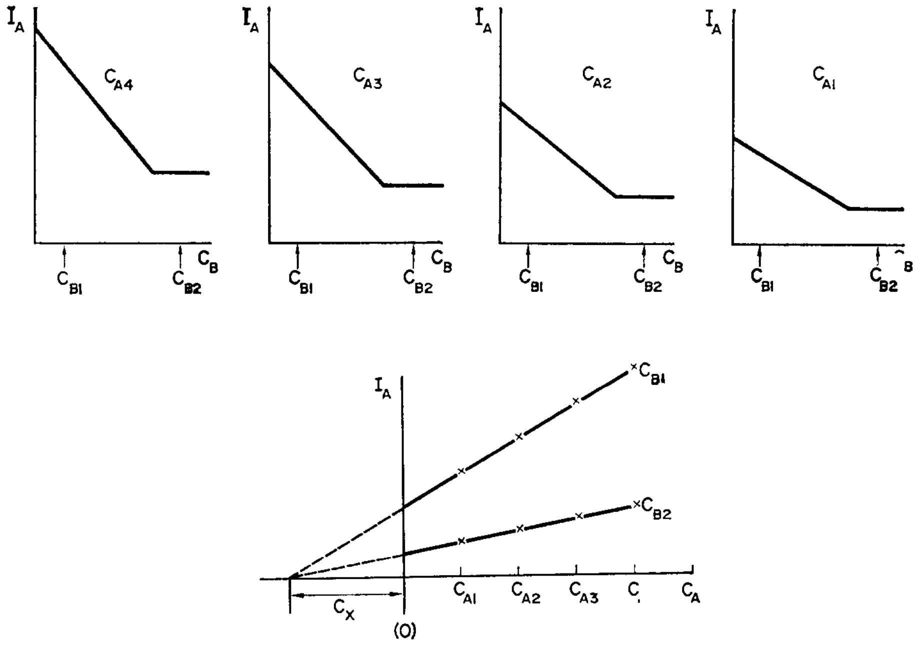

Fig. 2.—Principle of the displacement technique.

curves represent the variation of the emission of the analyte with the concentration of the interfering ions. It is to be noted that if the known concentration C_A is varied, the emission readings will vary proportionally at any fixed concentration C_{B1} or C_{B2} of the interfering ion, but the position of the break-point remains the same because of the presence of the displacing agent. Thus, the emission of the solution at any concentration (C_{B1} or C_{B2}) will be proportional to the total concentration $C_X + C_A$ of the determinand. Thus, intersection of the line with the C_A axis will correspond to the distance of C_X from the origin.

EXPERIMENTAL

Apparatus

A Unicam SP 90 combined emission and atomic-absorption spectrophotometer was used to measure the emission of the solutions. The instrument was equipped with an AEI 10S potentiometer recorder. Readings were made using the standard Méker air–acetylene burner head with the instrument operating in the emission mode. The following parameters were held constant: air flow-rate 5 l./min, burner-height 20 mm (as measured on the scale of the instrument), slit-width 0·1 mm, damping 4. The acetylene flow-rate was adjusted to give the optimum signal in each case, *i.e.*, a maximum signal for a sodium solution at 589 nm. The gain was adjusted as required.

Reagents

Calcium chloride, 0·1*M*. Analytical grade calcium carbonate was dissolved in the minimum amount of dilute hydrochloric acid necessary.

Strontium chloride, 0·1*M*. Prepared from analytical grade strontium chloride hexahydrate by dissolution in water.

Barium chloride, 0·1*M*. Prepared from analytical grade barium chloride dihydrate by dissolution in water.

Lanthanum chloride, 0·1*M*. Prepared by dissolving lanthanum chloride heptahydrate in dilute hydrochloric acid. The lanthanum content was determined by complexometric titration.

Cerium(III) chloride, 0·1*M*. Prepared by dissolving cerous chloride heptahydrate in dilute hydrochloric acid. The cerous content was determined by complexometric titration.

Diammonium hydrogen phosphate, 0·1*M*. Prepared by dissolving the analytical-grade reagent in water.

Sulphuric acid, 0·05*M*. Prepared from concentrated acid by dilution and standardized by acidimetric titration.

Oxalic acid, 0·1*M*. Prepared from analytical grade oxalic acid dihydrate by dissolution in water.

Arsenic acid, 0·1*M*. Prepared from arsenic pentoxide by dissolving in water. The arsenic content estimated by iodimetric titration.

All solutions were made up in demineralized water and stored in polythene containers.

Determination of strontium

Wavelengths. With a monochromator of medium resolution, strontium shows three characteristic emission maxima. The first, at 460·7 nm, is the resonance line of atomic strontium. A strong band system, originating from the emission of SrOH molecules, appears with a maximum at 610 nm, and this peak is closely followed by another, with a maximum at 680 nm. (The latter maximum is the unresolved resultant of four bandheads at 650, 662, 668 and 683 nm respectively.) When the displacement technique is used, the 610-nm band cannot be used because both calcium and lanthanum show a considerable emission in this region. Both the 460·7-nm resonance line and the 690-nm bandhead can be used for the determinations, and it is the characteristics of the photomultiplier which determine the choice between the two wavelengths. In the Unicam SP 90 spectrophotometer the 680-nm bandhead appears to be approximately three times as sensitive as the other, but the precision of the results is equal at both wavelengths.

Choice of the displacing agent. Comprehensive studies were made, using barium, calcium, cerium(III) and lanthanum as displacing agents. Since phosphate showed the most marked interference of those anions examined, the effectiveness of the displacement technique has been checked on solutions containing phosphate alone; the recommended procedures were then applied in the presence of other ions. The displacing agents were introduced as their chlorides, and each solution contained a sufficient (but constant at each concentration range) amount of hydrochloric acid. Three different concentrations 5, 1 and 0·1m*M* strontium, were examined. For each of these concentrations six different molar ratios of phosphate to strontium were investigated, ranging from 0 to 1·25. Four solutions were used in each individual determination, containing $X/2$, X, $3X/2$ and $2X$ amounts of added strontium (where X is the molar concentration of strontium to be determined), and $2X$, $3X/2$, X and $X/2$ amounts of the displacing agent respectively. These values were chosen on the basis of an error calculation, published elsewhere,[18] where it has been shown that for maximum accuracy the ratio of added determinand to unknown should be at least 2. When the solutions were made up, their strontium emission was measured at both the wavelengths mentioned above. Zero emission was adjusted by spraying demineralized water into the flame, as it had been proved that a blank containing $3X$ moles of the displacing agent (plus hydrochloric acid) did not produce any measurable emission at these wavelengths. The solution containing the $2X$ amount of strontium was used to adjust the scale to almost full deflection (about 95%). All the other solutions were then measured and results plotted as shown on the lower curve of Fig. 2. Each determination was repeated three times and the mean result calculated. Results indicated that calcium is the most suitable displacing agent, allowing the determination of strontium with an average error of 5%. For 0·1mM strontium lanthanum(III) is even more suitable, but at higher concentrations lanthanum (and also cerium) gave curved calibration graphs which could not be extrapolated with good accuracy.

In the procedure given below, calcium is therefore recommended as a generally suitable displacing agent. If the results indicate that the unknown concentration of strontium is in the 0·1mM region, a second experiment using lanthanum as a displacing agent might be feasible.

Procedure. Dissolve a sample containing a maximum of 100 mg of strontium and a maximum of 100 mg of phosphate in hydrochloric acid and dilute to 100 ml. Mix, take four 20-ml aliquots in 100-ml volumetric flasks marked A, B, C and D. To A add 10 ml of 0·005M strontium chloride and 40 ml of 0·005M calcium chloride (or less concentrated solutions if the amount of strontium is less). Add 20 + 30 ml for B, 30 + 20 ml for C and 40 + 10 ml for D respectively. Add sufficient hydrochloric acid to each flask to prevent precipitation (using the same amount in each case). Dilute the solutions to the mark and measure the emission of these solutions at 460·7 or 680 nm. Plot the results *vs.* the concentration of added strontium. Draw a straight line through the points and extrapolate until the line intercepts the concentration axis (at "negative" concentration values). The distance from the intercept to the zero point on the concentration axis gives the concentration of the unknown in the final solution.

Results. Results are tabulated in Table I. Note that while the errors obtained by using the standard addition technique alone are as high as ± 20% (depending on the relative concentrations of strontium and the interferent), the displacement method offers much more accurate results. These results also indicate that the determination can be carried out most accurately if the concentration of strontium is kept at the 0·1mM (10 ppm) level and lanthanum is used as a displacing agent.

Determination of barium

Wavelengths. The flame emission spectrum of barium chloride solutions shows the resonance line of barium at 553·6 nm, surrounded by bandheads of BaO emissions. The bandhead at 515 nm is the most sensitive in the air–acetylene flame: it is also a wavelength where there is the least interference from calcium or lanthanum (though the latter shows a considerable background radiation). The 515-nm bandhead was used therefore for the determinations.

Choice of the displacing agent. Calcium, strontium, lanthanum and cerium (III) were used as displacing agents. The pattern of the investigation was similar to that described under strontium. Calcium was again found the most satisfactory displacing agent, but again lanthanum was found to be superior at lower concentrations.

Procedure. Dissolve the sample, containing 0–100 mg of barium and 0–100 mg of the interferent, in hydrochloric acid. Proceed as described for strontium, but use barium chloride solutions instead of strontium chloride and measure the emission at 515 nm. If possible, repeat the experiment at the 0·1mM (10–15 ppm) level with lanthanum as a displacing agent.

Results. Table II shows the results. Sulphate was omitted as an interferent, because at all concentration levels barium sulphate precipitates under these circumstances. Note the advantage of the displacement technique over the simple standard addition method.

Determination of calcium

Experiments on the determination of calcium were made along the lines mentioned above, using strontium, barium, cerium(III) and lanthanum. Of these, strontium seemed to be the best displacing agent, but the errors of the determination were too high (in the 10–20% range) and though these errors were still less than those obtained with the ordinary standard addition technique, the method cannot be recommended for practical analyses. The main difficulty is that because of spectral overlaps, at all feasible wavelengths (the 422·7 nm atomic resonance line and the band heads at around

550 and 625 nm) there is a measurable contribution of the displacing agent in almost all combinations. The possibility of improving the results by the use of a better monochromator cannot be ruled out, provided that width of emission lines or bands can be decreased considerably.

A method has been worked out —a method based on a different type of displacement reaction—for the determination of calcium. This method is based on the addition of an excess of sulphate to the solution, whereupon all the calcium present is transformed into calcium sulphate. When the solutions are sprayed into an acetylene–air flame, well-defined emissions are obtainable, which with the

aid of a suitable calibration curve permit the determination of calcium in the presence of phosphate, arsenate and oxalate with an error less than 3–5%. Details of the method have been published elsewhere.[14]

Acknowledgments—The authors wish to thank Professor Cecil L. Wilson for encouragement of this work and the Government of Northern Ireland for a research grant to P. J. S.

Zusammenfassung—Bei der emissionsphotometrischen Bestimmung von Strontium und Barium in Gegenwart störender Ionen wie Phosphat, Sulfat, Arsenat und Oxalat können Eichverfahren oder ein einfaches Zumischverfahren nicht angewandt werden. Man erreicht eine starke Verminderung der Fehler, wenn man die Probenlösung in vier gleiche Teile teilt und jedem bekannte Mengen zweier Metallionen zusetzt. Eines davon ist identisch mit dem zu bestimmenden Ion (z.B. Strontium oder Barium), das andere hat ähnliche Eigenschaften (z.B. Calcium). Die Mengen dieser Metalle werden so gewählt, daß die (molare) Gesamtkonzentration in allen Lösungen gleich, jedoch das Verhältnis der beiden Metalle verschieden ist. Die Emission des zu bestimmenden Metalls wird gemessen und eine Standardzugabekurve aufgezeichnet. Die Menge des in der Lösung anwesenden zu bestimmenden Metalls erhält man aus dem Schnittpunkt der Emissions-Konzentrations-Kurve mit der Konzentrationsachse.

Résumé—On ne peut utiliser les méthodes d'étalonnage ou d'addition d'étalon simples pour le dosage photométrique par émission du strontium et du baryum en la présence d'ions gênants tels que phosphate, sulfate, arséniate et oxalate. On peut obtenir des erreurs fortement réduites en divisant la solution échantillon en quatre parts égales et en ajoutant à chacune certaines quantités connues de deux ions métalliques. L'un de ceux-ci est identique à celui que l'on détermine (par exemple strontium ou baryum), l'autre à des caractéristiques qui lui sont similaires (par exemple calcium). Les quantités de ces métaux sont choisies de sorte que leur concentration totale (molaire) soit identique dans toutes les solutions, mais le rapport des concentrations des deux métaux doit être différent. L'émission du métal que l'on dose doit être mesurée, et l'on doit établir un graphique d'addition type. La quantité de produit à doser présente dans l'échantillon peut être obtenue à partir de l'intersection du tracé de l'émission en fonction de la concentration avec l'axe des concentrations.

Summary—A new approach to the automated determination of sodium hypochlorite and hydrogen peroxide is described, based on the use of a porous catalytic silver electrode. The principle of both methods involves the quantitative liberation of oxygen, which is measured coulometrically by the electrode. The procedures are suitable for the continuous monitoring of the contents of bleaching baths.

AN EFFICIENT bleaching process must impart to textile goods a pure and permanent white and level-dyeing properties without "tendering" or diminishing the tensile strength. Much of the early work on bleaching processes suffered from lack of sufficiently accurate methods of testing both the bleaching solution and the bleached product. Satisfactory chemical methods of estimating damage of textile material resulting from an inefficiently controlled bleaching process have now been definitely established and have been incorporated in a number of standard methods.[1–4] These include the copper number determination,[1,5] the fluidity test and the solubility test.[4,6] In order to obtain high-quality bleached textile goods which satisfy the relevant specifications, constant surveillance and control at each step of the bleaching process are required.

The two bleaching agents most commonly employed in the textile industry are sodium hypochlorite and hydrogen peroxide, both of which are useful for bleaching cotton, rayon, linen and other cellulosic fibres. Hypochlorite bleach has the advantage of having a long history and hence a well-developed methodology. It is also relatively cheap and capable of giving good results provided that the process has been closely controlled. Hydrogen peroxide has the advantage of being able to deal with unscoured or partially scoured cotton, thus requiring less manipulation of fabric. Another advantage is that it has a much lower degrading action on cellulose and can also be used for bleaching wool, silk and other animal fibres. A comprehensive account of the bleaching procedures based on these bleaching agents has been given by Marsh[7] and Trotman.[8] In general, the most important factors in both bleaching processes are pH, temperature and concentration of the bleaching agent. The first two factors can be readily controlled by using suitable buffers and a thermostatic bleaching bath respectively. In the past, concentration of the bleaching solution has been monitored by conventional titrimetric analyses of grab samples, with obvious shortcomings in time, economy and human error. Adelman[9] has described an automated method for hypochlorite determination, based on measuring the absorbance of the iodine formed by the reaction between hypochlorite and potassium iodide in an acetic acid medium. Automated analysis on a continuous basis offers not only increases in economy, speed and precision but also offers possibilities of continuous monitoring in a process stream. Furthermore, the continuous analytical system can be incorporated into an automated control system in which the controller compares the signal from the sensor with a set signal—any deviation would bring about a corrective action (in this case) by controlling the addition of a concentrated bleach solution from a reservoir. As a result, the concentration of the bleaching bath is maintained at a constant predetermined level.

Although AutoAnalyser systems involving colour development have been very popular, there is no reason to believe that the spectrophotometer is superior to other sensor systems in continuous analysis. Tenygl *et al.*[10] have recently described automated methods for determining dichromate and permanganate, based on the reaction with hydrogen peroxide to liberate oxygen which, in turn, is measured by a new type of coulometric oxygen analyser.[11] An extension of these two methods was found to be satisfactory for the automated determination of dichromate (C.O.D.) and permanganate value of sewage and effluents[12] and also for oxygen determination in clinical analysis.[13] The analytical system involved in all these procedures consisted basically of an oxygen sensor and the Technicon AutoAnalyser. Such a system is highly versatile and can be used to monitor any reaction which is well-defined, reasonably rapid, stoichiometric and does not involve the formation of a precipitate, provided that oxygen is either liberated or consumed. The reactions between hydrogen peroxide and permanganate (or dichromate) and between oxyhaemoglobin and ferricyanide are thus important but not exclusive examples of a large class of reactions which can be monitored by this relatively simple analytical system.

In this study, automated methods for determining hypochlorite and hydrogen peroxide are described. The first is based on the reaction between hypochlorite and hydrogen peroxide in an alkaline medium to liberate oxygen, which is monitored by the coulometric oxygen analyser. With the hydrogen peroxide method, there should theoretically be a wide range of choice of reagent as hydrogen peroxide reacts with several substances, some in acidic medium, others in alkaline medium, to liberate oxygen. Reactions in acid media, however, are not suitable for the present procedure, as the hydrogen peroxide bleach is normally buffered with bicarbonate and the large quantities of carbon dioxide liberated by dilute acids would damage the silver working electrode. Reagents which react with hydrogen peroxide in alkaline medium to liberate oxygen include hypochlorite and periodate. Potassium periodate is used in the present procedure since it is more stable than hypochlorite.

The automated hypochlorite method, as described here, is useful in the textile industry since it permits efficient control of the contents of the hypochlorite bath. This is especially important in bleaching viscose rayon and other regenerated cellulosic fibres since they are more prone to damage than the native cellulosic fibres such as cotton.[7] Although there is less information correlating chemical damage with excess of hydrogen peroxide bleach, the automated hydrogen peroxide method is useful since the reagent is relatively expensive and hence correct control of the bleach bath concentration can lead to appreciable economy by using not more than the required amount of bleach.

EXPERIMENTAL

Apparatus

AutoAnalyser modules (Technicon Corp., Tarrytown, N.Y.) consisting primarily of a sampler and a proportioning pump with associated pump tubes and glass fittings, were used. For procedures in which the integrated current response was used, samples were presented at the rate of 20/hr at a ratio of sample to water wash of 1:2. When the non-integrated current response was used as analytical signal, a sampling rate of 10/hr was used at a ratio of sample to water wash of 1:1.

The oxygen analyser. A detailed description of the construction of the oxygen analyser has already been reported.[11] Basically, it consists of a three-electrode cell (Fig. 1) consisting of a porous catalytic silver electrode (Fig. 2) which is immersed in a 25% potassium hydroxide solution and maintained at −0·85 V *vs.* an Hg/HgO reference electrode by means of a potentiostat; a schematic circuit for this is shown in Fig. 3. The third counter electrode is a platinum wire isolated from the rest of the solution by a glass tube with a sintered-glass base. The gaseous sample stream is analysed by passing through an inlet-outlet manifold into the annular space within the silver working electrodes, where the oxygen is reduced. The electrode reactions involved are:

$$\text{at Ag working electrode: } O_2 + 2H_2O + 4e = 4OH^-$$
$$\text{at Pt counter-electrode: } 4OH^- = O_2 + 2H_2O + 4e$$

The pressure regulator. Efficient working of the porous silver electrodes requires that equilibrium be maintained between the gas and electrolyte-filled pores. This is achieved with the aid of a gas over-pressure against the capillary pressure of the electrode. For the Type LD848 electrodes (Heyrovský Inst. of Polarography, Prague) used in the present study, the hydrodynamic resistance is 10–15 mm Hg and the gas over-pressure used must be greater than this value. There are two simple ways by which a constant gas over-pressure within the electrodes can be maintained. One method depends on differential pumping, with the total (pre-sensor + post-sensor) waste-lines pumping at a rate slower than that of the total feed-in lines. Another method is to place a pressure control valve in line behind the sensor. In the latter method, the flow-rate of the post-sensor waste line is automatically regulated and the gas over-pressure within the electrodes remains constant even when the flow-rates of the feed-in lines are changed. Another advantage is that problems due to pump overloading and pump pulses are much

reduced because the use of the pressure regulator dispenses with the need to pass the post-sensor waste lines through the pump.

Flow diagram

The flow chart for the automated hypochlorite and hydrogen peroxide methods is shown in Fig. 4. Sample (hypochlorite or hydrogen peroxide), reagent (hydrogen peroxide or potassium periodate) and nitrogen are mixed; the oxygen liberated in the reaction is then carried along in the nitrogen stream and presented to the sensor after the liquid phase has been removed by passing the gas-liquid mixture through two consecutive phase separators. A sample-pump tube of very small bore is used for the hydrogen peroxide method because of the relatively high "available" oxygen content of the sample. Manifolds in which only part of a prediluted sample is presented, thus permitting larger initial volume intake of sample, have been tried but were found to be less satisfactory since carry-over tends to increase with increasing complexity of the manifold.

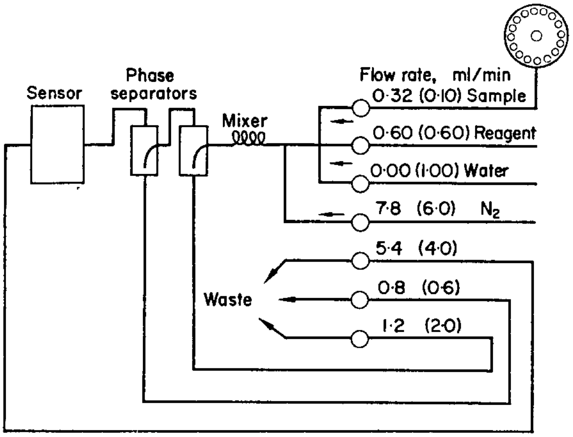

FIG. 4.—Flow diagram for the automated hypochlorite method and hydrogen peroxide method. Tube dimensions in brackets refer to the hydrogen peroxide procedure.

Reagents

All chemicals used were of analytical grade.

Sodium hypochlorite stock solution (~2 *g of Cl/l.*). A strong concentrated sodium hypochlorite solution was diluted with the appropriate amount of distilled water, and 5 g of sodium carbonate were added to make the pH approximately 11. The solution was then standardized against arsenious acid, with Bordeaux as indicator.

Hydrogen peroxide solution (*for the hypochlorite method*). Ten ml of 100-volume hydrogen peroxide were diluted to 1 litre with distilled water. The solution was stored in the dark in a dark glass bottle.

Stock hydrogen peroxide bleach solution (*2-volume standard*). Hydrogen peroxide (100-vol, 20 ml) was added to a solution containing 7 g of sodium silicate (78° Tw), 0·5 g of sodium hydroxide and 1·75 g of sodium carbonate. The solution was diluted to 1 litre with distilled water and standardized iodometrically, with molybdate catalyst, the iodine being titrated in an atmosphere of carbon dioxide or nitrogen. The stock solution was adjusted to exactly 2-volume strength.

Diluent for hydrogen peroxide bleach standards. Prepared by dissolving 7 g of sodium silicate (78° Tw), 1·75 g of sodium carbonate and 0·5 g of sodium hydroxide and diluting to 1 litre with distilled water.

Potassium periodate solution. Potassium periodate (2·3 g) was dissolved in 10 ml of 20% potassium hydroxide solution and the solution made up to 100 ml.

RESULTS AND DISCUSSION

Theory

Sodium hypochlorite reacts with hydrogen peroxide in an alkaline medium to liberate oxygen.

$$NaOCl + H_2O_2 = NaCl + H_2O + O_2$$

Assuming hydrolysis of sodium hypochlorite, this can be written as:

$$OH^- + HOCl + H_2O_2 = Cl^- + 2H_2O + O_2$$

Potassium periodate reacts with hydrogen peroxide in an alkaline medium according to the equation:

$$KIO_4 + H_2O_2 = KIO_3 + H_2O + O_2$$

Assuming hydrolysis of potassium periodate, this can be written as:

$$OH^- + HIO_4 + H_2O_2 = IO_3^- + H_2O + O_2$$

The concentration of available chlorine required in the hypochlorite bleach liquor varies between 1 and 3 g of Cl/l., depending on the type of yarn and the amount of impurities present. The bleach liquor is normally buffered between pH 10 and 11 by the addition of 5 g of sodium carbonate per l. because the active bleaching component varies with the pH of the bath. At pH 10–11, the active component is sodium hypochlorite, but as the pH decreases to 5–8·5, the solution would consist predominantly of free hypochlorous acid, and on further lowering of the pH to below 3, free chlorine would be evolved.[13] The last two situations are undesirable because free hypochlorous acid causes a rapid oxidation and degradation of cellulose and hence excessive damage to the textile material being bleached. In the present study, hypochlorite standards were prepared simulating bleach liquors both in concentration and in pH.

In the case of hydrogen peroxide bleach, the most important factor is to achieve the right degree of stability so that sufficient oxidizing (bleaching) power is attained without danger of rapid exhaustion of hydrogen perioxide through decomposition. The liquor is normally buffered between pH 8 and 10·9 with a mixture of sodium carbonate and sodium hydroxide. Sodium silicate is added as a stabilizer. The basic formula for making up a 1-volume bleach liquor is: water 98 gallons (98 litres); sodium silicate 78° Tw 7 lb (0·7 kg); caustic soda ½ lb (0·05 kg); soda ash 1¾ lb (0·175 kg) and hydrogen peroxide "100 volume" solution, 1 gallon (1·0 litre).[15] Many variations of this basic formula can be used according to the nature of the material, the degree of whiteness called for and the construction of the plant. In this study, however, hydrogen peroxide bleach standards of different strengths were prepared according to the formula above, only the amount of hydrogen peroxide being varied.

Hypochlorite method

Integrated response. The integrated current obtained from hypochlorite standards is summarized in Table I. Samples contained 20·0, 40·0, 60·0, 80·0 and 100·0 ml of stock hypochlorite solution, made up to 100 ml with distilled water. These concentration standards then covered the range from 0·44 to 2·22 g of Cl/l., which is the range normally found in bleach baths. A linear relationship between the integrated response and concentration over the range studied is obtained. The integrated signals obtained for replicate analyses of a series of standards were evaluated statistically (Table I). The reproducibility of the method was found to be satisfactory, with standard deviation 0·40 and coefficient of variation 1·1%.

† Weighted mean: ‡ Total of sum of squares/total of degree of freedom.

Non-integrated response. The non-integrated response obtained with hypochlorite standards is summarized in Table II. The same samples were used as for the integrated method. A rectilinear relationship between signal and concentration is again obtained. The reproducibility of the method was found to be slightly better than that of the integrated method, with standard deviation 0·27 and coefficient of variation 0·8% (Table II).

Discrete sample analysis vs. *continuous monitoring.* In analysis of discrete samples with the present apparatus, the integrated method is the obvious choice since the number of samples which can be handled (20/hr) is twice that of the non-integrated method. Because of the simplicity of the manifold, the current-time profile is well-defined and regular. Hence, there should be no problem in linking the integrator to a "super-timer" which governs both the sampling probe and the integrator. In the case of continuous monitoring, however, it is preferable to use the non-integrated method, which is simpler and at the same time exercises a minute-to-minute close control of the process stream. A semi-continuous method may also be useful at times when a less rigorous albeit continuous control of the process stream is desired and this will be discussed below in the hydrogen peroxide method.

TABLE II.—NON-INTEGRATED RESPONSE AT VARYING CONCENTRATIONS OF HYPOCHLORITE. A STATISTICAL EVALUATION OF THE RESULTS OBTAINED

Dynamic response of the system. The total time-lag between the introduction of sample and the sensor read-out can be divided into two components—the dead-time of the system, which is the time required for the processing of the sample before measurement, and the transition time of the sensor, which is the time required for the sensor to change from the steady state for one sample to that for the next. In analysis of discrete samples, it is the latter factor which controls the sampling rate and hence in such systems efforts have been made to minimize sensor hold-up and hence reduce the transition time. In the case of continuous monitoring, the dead-time is just as important as the sensor transition time because the total response time must be small if close control of the process stream is to be achieved. The dynamic response of the present analytical system as a whole is assessed by stepwise changes (at 5-min intervals) in the concentration of the sample solution which is continuously fed in. Figure 5 shows a recording of the current-time response for five such steps. The dead-time of the system was found to be 2½ mins. The sensor transition (95%) time was about 2 min for a change in concentration Δ[NaOCl] = 0·444 g of Cl/l. This means that any variation in the concentration of the bleach bath can be detected within 2½ mins whereas the full impact of the variation would be felt within another 2 min. Further improvements towards a faster dynamic response of the present system can be achieved by using better manifold designs to minimize hold-up in the processing units and flow-system preceding the sensor. It may also be possible to reduce the transition time by using flow-through sensor electrodes of smaller capacity. For most practical purposes, however, the dynamic response of the present system should be good enough for bleach liquor control.

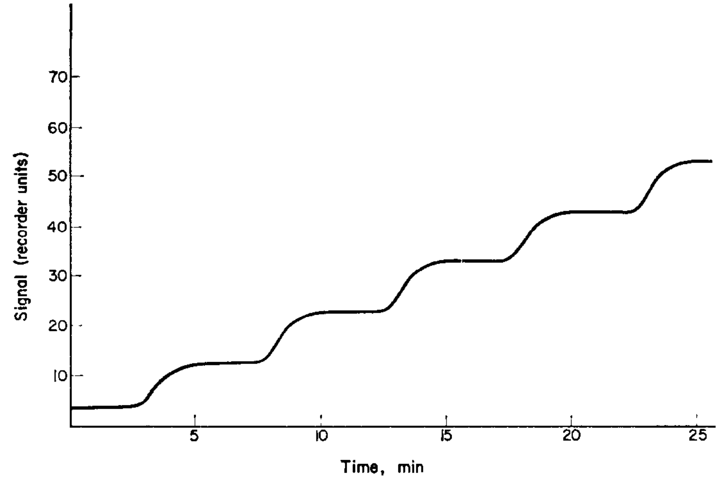

Fig. 5.—Current-time waves obtained with stepwise increase in concentration of the hypochlorite sample at 5-minute intervals.

Hydrogen peroxide method

Integrated response. The integrated current response obtained with hydrogen peroxide bleach standards is shown in Table III. Samples contained 10·0, 20·0, 30·0, 40·0, 50·0 and 60·0 ml of the stock 2-volume standard, made up to 100 ml with the diluent solution. These concentration standards then covered the range of 0·2–1·2 volume hydrogen peroxide. A rectilinear relationship between the integrated signal and concentration over the range studied is obtained. The reproducibility of the

method was found to be satisfactory, with a standard deviation $s = 0{\cdot}82$ and coefficient of variation of 1·5%.

Non-integrated response. Figure 6 is a typical recording of the non-integrated current response, obtained with hydrogen peroxide bleach standards. The results are summarized in Table IV. The same samples were used as for the integrated method. A rectilinear relationship between signal and concentration is again obtained. The reproducibility of this method was found to be slightly better than that of the integrated method, with $s = 0{\cdot}58$ and coefficient of variation 1·0%.

Standard deviation 0·58; coefficient of variation, 1·0%

fluctuations in bleach liquor concentrations are, however, rarely observed in bleach baths, which normally show a gradual drift towards lower concentrations. Minute-to-minute close control of the bleach liquor concentrations is, therefore, often superfluous, and a less rigorous form of continuous monitoring would be sufficient. Fleet *et al.*[12] have recently described a semicontinuous form of monitoring in which a constant sample stream is introduced while the reagent, interspersed with water wash, is supplied from a standard sampler. A series of current-time waves would be obtained which would vary in height with any change in the concentration of the sample. Figure 7 is a typical recording of the signals obtained when the potassium periodate reagent was supplied at the rate of 10/hr (1:1 wash ratio). The first four waves correspond to signals obtained when a continuous stream of a 0·4 volume hydrogen peroxide bleach standard was supplied. The next two sets of four waves correspond to continuous

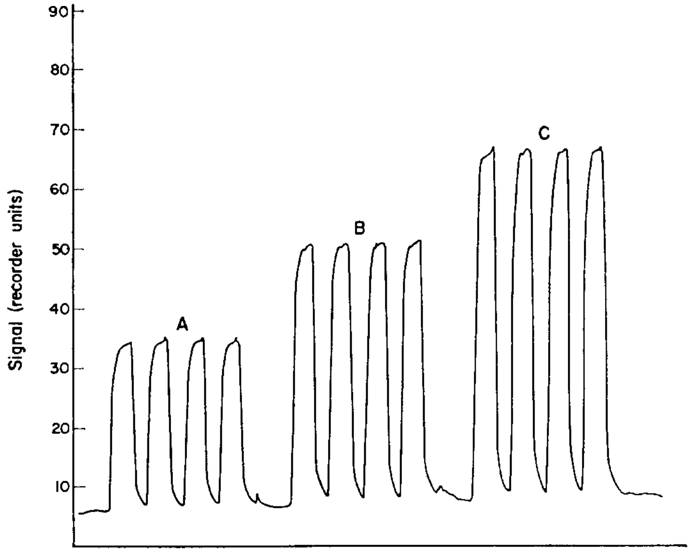

Fig. 7.—Current-time waves obtained when the hydrogen peroxide sample was continuously supplied whereas the potassium periodate reagent was supplied at the rate of 10/hr., interspersed with water wash at a ratio of 1:1. Sample concentration *A*, 0·40; *B*, 0·60; *C*, 0·80 volume H_2O_2.

streams of 0·6 and 0·8 volume hydrogen peroxide bleach standards respectively. By use of this semicontinuous method, the cost of the reagent is reduced by half and the response is easier to interpret since a definite step is obtained rather than a continuous record. Although only 10 readings are obtained per hour, that should be sufficient for bleach liquor control purposes

Dynamic response of the system. As discussed in the hypochlorite method, it is the total response time—dead-time plus transition time—which is important in continuous monitoring. The dynamic response of the system is assessed in the same way as described above. The dead-time of the system was found to be 2¾ minutes for a change in concentration equal to 0·2 volume hydrogen peroxide.

Conclusion

The dual objective of an ideal bleaching process—an excellent white with no significant damage to the textile material—can only be achieved by close control of the bleaching bath, its contents and conditions. The automated methods described in the present work enable one of these parameters, the bleach-bath concentration, to be effectively controlled and hence would be useful in the textile industry.

Zusammenfassung—Ein neues Verfahren zur automatischen Bestimmung von Natriumhypochlorit und Wasserstoffperoxid wird beschrieben; es beruht auf der Verwendung einer porösen katalytischen Silberelektrode. Das Prinzip beider Methoden besteht in der quantitativen Freisetzung von Sauerstoff, der coulometrisch an der Elektrode gemessen wird. Die Vorschriften sind zur kontinuierlichen Gehaltskontrolle von Bleichbädern geeignet.

Résumé—On décrit une nouvelle voie d'accès au dosage automatisé de l'hypochlorite de sodium et de l'eau oxygénée, basée sur l'emploi d'une électrode d'argent catalytique poreuse. Le principe des deux méthodes comprend la libération quantitative de l'oxygène, qui est mesuré coulométriquement par l'électrode. Les techniques conviennent au contrôle continu des teneurs de bains de blanchiment.

Summary—Reduction rates of Pu(IV) and oxidation rates of Pu(III) have been studied in sulphuric acid and nitric acid media, as functions of acid concentration, plutonium concentration and kind of acid. A flow-coulometric method was used in this work. This procedure has many merits, namely, the sample size required is very small, special reagents are not used, fewer limitations are imposed by the type and concentration of acid, and the method is rapid.

PLUTONIUM exists in aqueous solution as Pu^{3+}, Pu^{4+}, PuO_2^+ and PuO_2^{2+}. The standard oxidation-reduction potentials of their couples are close to each other,[1] so disproportionation reactions occur easily. It is reported that the oxidation of Pu^{3+} occurs in the presence of oxygen.[2] Up to the present, the oxidation states of plutonium in solution have been studied by solvent extraction, co-precipitation or spectrophotometric measurement of special ionic species. However, extraction or co-precipitation methods have many disadvantages:

(1) the oxidation state may be changed by chemical reaction between plutonium and the reagent added;
(2) the acid concentration must be chosen in a limited range and a certain kind of acid must be employed;
(3) the operations require a time ranging from 10 min to a few hours.

On the other hand, spectrophotometric methods are excellent for identification of the oxidation states, but useful only when plutonium concentrations are relatively high. In this work, a flow-coulometric method which was investigated by Fujinaga and others[3] has been used to study oxidation states of plutonium in sulphuric and nitric acid media. This method has the following merits:

(1) the sample size required is 10–50 μl,
(2) limitations imposed by acid concentrations, kind of acid, or plutonium concentrations are fewer than in other methods,
(3) special solvents or co-precipitants are not needed, so the side-reactions with plutonium cannot occur,
(4) the time needed is only a few minutes.

In this work, we were concerned with the behaviour of Pu^{3+} and Pu^{4+} in the sulphuric or nitric acid media which are commonly used in solution chemistry and studied correlations between the concentrations of acid or plutonium and transformation of the oxidation states. Such correlations for perchloric and hydrochloric acid media have been studied by Rabideau,[4] Rabideau and Cowan,[5] and Connick and McVey,[6] and in nitric acid media by Artyukin *et al.*[7]

EXPERIMENTAL

Reagents

Plutonium metal. A product of Nuclear Materials and Equipment Co., U.S.A., was used. Its isotopic composition was ^{239}Pu 91·3, ^{240}Pu 7·81, ^{241}Pu 0·85, ^{242}Pu 0·04 atom %.

(7) Porcelain cylinder (8) Ag–AgCl reference electrode
(9) Sample inlet (10) Supporting electrolyte inlet
(11) Supporting electrolyte outlet
▬ Silicone rubber.

Plutonium sulphate solutions. Plutonium metal was dissolved in 0·5*M* sulphuric acid after electrorefining and weighing.

Plutonium nitrate solutions. Plutonium metal was dissolved in 1·0*M* hydrochloric acid. The plutonium chloride solution was evaporated almost to dryness at 100–150°. Small amounts of 1·0*M* nitric acid were added to the residue and evaporated almost to dryness at 100–150°; this procedure was repeated three times. The final nitrate solution was prepared by dissolving the residue with 1·0*M* nitric acid.

From the results of colorimetry and coulometry plutonium is expected to be present as a mixture of Pu(IV), Pu(III) and a negligibly small amount of Pu(VI) in both sulphuric and nitric acids immediately after the above-mentioned preparation procedures.

The oxidation state of plutonium is adjusted by batch electrolysis with a glassy carbon[8] working electrode, just before measurements.

All other reagents used were of extra-pure grade.

Apparatus

An electrolytic cell for flow-coulometry is shown in Fig. 1. Glassy carbon grains (80–100 mesh), which act as a working electrode, are packed in a 7-mm bore porcelain cylinder, which is the electrolytic diaphragm. A glassy carbon cylinder is used as the counter electrode and the silver–saturated silver chloride electrode (SSE) is used as the reference electrode. The supporting electrolyte, the acid solution, flows from the supporting-electrolyte solution reservoir to the drain tank *via* the sample injection port and working electrode. Sample solutions are injected by a micro-syringe or through a rotating cock from the sample injection port. The supporting electrolyte flows through 3-mm vinyl tubing.

A Hokuto Denko Co. model PS-500B potentiostat was used. The current-time curve of electrolysis was recorded by a Yokogawa Electric Works type 3047 recorder. The current integration was made with a Koizumi Sokki Co. model KP-30 polar disk planimeter.

Pretreatment of glassy carbon electrode. The glassy carbon working electrode is oxidized at 1·2 V *vs.* SSE for 5 min and reduced at −1·0 V *vs.* SSE for the same time in 0·5*M* sulphuric acid or 1·0*M* nitric acid and this procedure is repeated five times.

Procedure

Flow-coulometric measurement. Supporting electrolyte (0·5*M* sulphuric acid for sulphate sample or 1*M* nitric acid for nitrate sample) is passed through the flow-coulometric column electrode, at a flow-rate of 5 ± 0·5 ml/min, regulated by varying the height of solution reservoir; the flow-rate is not critical (20% tolerance). The potential of the working electrode is adjusted to an appropriate value, then 10–50 μl of plutonium solution are injected and the current–time curve for electrolysis is recorded. The amount of plutonium electrolysed is determined by integrating the current–time curve and converting the number of coulombs into weight or concentration.

The supporting electrolyte and sample solution are not deaerated, for the following reasons: it was confirmed by preliminary experiments that there is no electrolytic reaction of air at the potential range used in this work, and for later practical application the behaviour of plutonium ions should be observed in the presence of oxygen.

Determinations are reproducible to within ±3% and blank corrections are not needed for more than 1 μg of plutonium. The total time required to determine the amount of plutonium (from sample injection to recording of current-time curve) is 10–40 sec, depending on the plutonium concentration.

RESULTS AND DISCUSSION

Plutonium in sulphuric acid solution

Voltage *vs.* quantity of electricity curves (*E–Q* curves) for the Pu(III)/Pu(IV) system in 0·5*M* sulphuric acid are shown in Fig. 2. Ten μl of 1·00 mg/ml plutonium solution (41·8 nmole of Pu) were taken each time. Curve 1 shows the reduction curve of Pu(IV) to Pu(III) obtained by varying the working potential of the flow-coulometric column electrode from +1·20 to −0·20 V *vs.* SSE. The Pu(IV) solution was prepared by batch electrolysis at +1·10 V *vs.* SSE. Similarly, curve 2 shows the oxidation curve of Pu(III) to Pu(IV). The Pu(III) solution was prepared by batch electrolysis at +0·30 V *vs.* SSE. Curve 3 shows the *E–Q* curve of plutonium that had been left for five months after the plutonium metal had been dissolved in 0·5*M* sulphuric acid.

It is confirmed by comparing curve 3 with curve 2 in Fig. 2 that the amount of Pu(VI) or Pu(V) is small (less than 2% of the total plutonium) in 0·5*M* sulphuric acid. The sum of the quantity of electricity (Q_3) for reduction at +0·35 V *vs.* SSE and that for oxidation at +0·75 V *vs.* SSE in curve 3 is nearly equal to the quantity of electricity (Q_2) at +0·75 V *vs.* SSE in curve 2. If Pu(VI) is present, Q_3 should be larger than Q_2 because, at +0·35 V *vs.* SSE, Pu(VI) should be reduced to Pu(III) and hence a three-electron change should be involved. The reason why Pu(VI) generated by disproportionation of Pu(IV) disappears is not clear. But it can be considered that the reduction of Pu(VI) by hydrogen peroxide[9,10] or α-ray direct reduction[11] and the complex-formation between Pu(IV) and sulphate make Pu(VI) unstable. Hydrogen

(The solution was left for five months after dissolution of the plutonium metal.)

peroxide is generated by radiolysis of water[10] or reduction of dissolved oxygen by Pu(III).[2] The formal oxidation-reduction potential of the H_2O_2/O_2 couple is +0·68 V and that of the Pu(IV)/Pu(VI) couple is between +1·2 and +1·4 V in 0·5*M* sulphuric acid at 25°.[1]

Plutonium in nitric acid solution

E–Q curves for the Pu(III)/Pu(IV) and Pu(III)/Pu(VI) couples in 1·0*M* nitric acid are shown in Fig. 3. Ten μl of 5·40 mg/ml plutonium solution (0·226 μmole of Pu) were taken in each case. Curve 1 shows the reduction curve of Pu(IV) to Pu(III) obtained by varying the column electrode potential from +1·20 to 0·00 V *vs.* SSE. Pu(IV) solution was prepared by batch electrolysis at +0·90 V *vs.* SSE. Similarly, curve 2 shows the oxidation curve of Pu(III) to Pu(IV). Pu(III) solution was prepared by batch electrolysis at +0·30 V *vs.* SSE. A comparison of the sum of the quantity of electricity at +0·30 and +1·20 V *vs.* SSE (Fig. 3) with the theoretical value indicates that the amount of Pu(VI) or Pu(V) is less than 2% of the total plutonium, in 1·0*M* nitric acid, immediately after preparation of the plutonium nitrate solution from chloride solution. After controlled potential electrolysis at +0·90 V *vs.* SSE, the quantity of electricity for reduction, at +0·30 V *vs.* SSE, is nearly equal to the theoretical value calculated for a one-electron reduction and it is estimated that almost all the plutonium is converted into Pu(IV) by controlled potential electrolysis.

Curve 3 shows the *E–Q* curve of plutonium that has been left for two months in

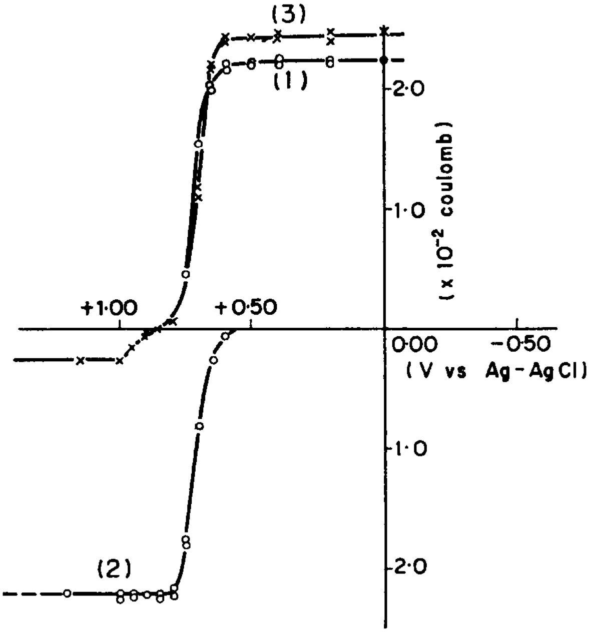

FIG. 3.—Coulomb-potential curves of plutonium

(1) Pu(IV) + *e* = Pu(III). (2) Pu(III) − *e* = Pu(IV)
(3) Oxidation and reduction of Pu(III), Pu(IV) and Pu(VI) mixtures.
(The nitrate solution was left for two months after preparation.)

1·0*M* nitric acid. It was reported[7] that in 0·1–0·5*M* nitric acid Pu(III), Pu(IV) and Pu(VI) ions were generated by the disproportionation reaction

$$3\text{Pu(IV)} + 2H_2O \rightarrow 2\text{Pu(III)} + \text{Pu(VI)} + 4H^+. \qquad (1)$$

It is found, by comparing the quantity of electricity at +0·30 V *vs.* SSE (Q_1) in curve 1 with the quantity of electricity at +0·30 V *vs.* SSE (Q_{3-r}) and at +1·20 V *vs.* SSE (Q_{3-o}) in curve 3 that Pu(III), Pu(IV) and Pu(VI) ions are generated in 1·0*M* nitric acid medium. It can be considered that some of the Pu(III) is reoxidized to Pu(IV) by dissolved oxygen or nitrate, because Q_{3-r} is larger than Q_1. If only the reaction of equation (1) occurs, Q_{3-r} should be equal to Q_1. The amount of Pu(III) is calculated from Q_{3-o} to be 0·026 μmole and the amounts of Pu(VI) and Pu(IV) are calculated to be 0·024 and 0·176 μmole respectively:

$$\text{Pu(VI) (mole)} = \frac{1}{2}\cdot\frac{1}{96500}\left\{Q_{3-r}(\text{coul.}) - [Q_1(\text{coul.}) - Q_{3-o}(\text{coul.})]\right\} \qquad (2)$$

$$\text{Pu(IV)} = \text{total Pu} - \text{Pu(III)} - \text{Pu(VI)} \qquad (3)$$

In the study of oxidation of Pu(III), the concentration of dissolved oxygen was found to be 2–3 × 10^{-4}*M*, by a polarographic method. The concentration of oxygen was maintained constant by bubbling solution-saturated air through the sample solution. In the reduction study of Pu(IV), solutions were not deaerated and were allowed to stand in contact with air.

Reduction reactions of Pu(IV)

The disproportionation reaction, α-ray reduction, oxidation or reduction of reaction products by solvent or atmosphere, and complex-formation by Pu(IV) are the main factors in the rate of transformation of oxidation state of Pu(IV). It has been reported that the disproportionation reaction is the most important and rate-determining factor.[5,12]

In the present work, on the assumption that the rate of generation of Pu(III) is nearly proportional to the apparent rate of transformation of oxidation state of Pu(IV), the ratio of Pu(III) to total plutonium is plotted as a function of time.

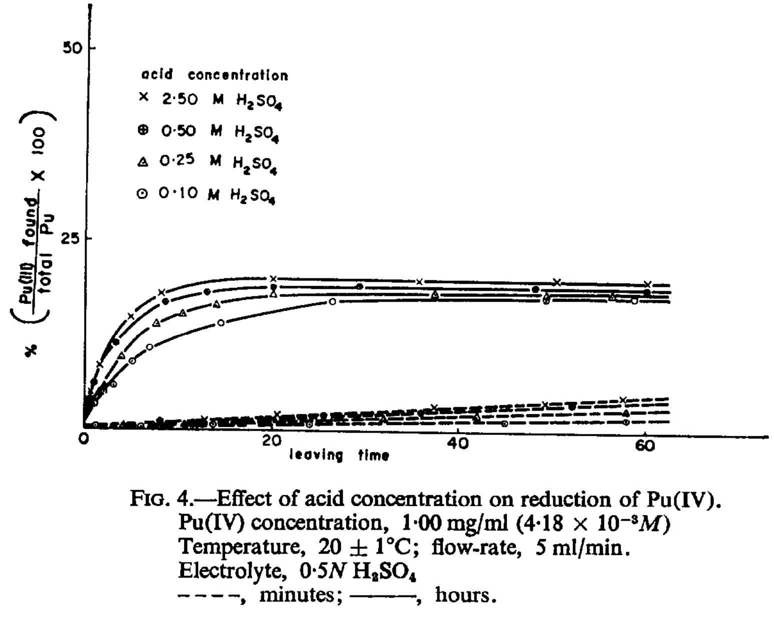

Fig. 4.—Effect of acid concentration on reduction of Pu(IV).

Temperature, 20 ± 1°C; flow-rate, 5 ml/min.
Electrolyte, 0·5*N* H_2SO_4
– – – –, minutes; ———, hours.

The relationship between time and reduction of Pu(IV) at various sulphuric acid concentrations is shown in Fig. 4. The plutonium concentration was 1·00 mg/ml. Figure 4 shows that the higher the concentration of sulphuric acid, the larger the degree of reduction. After 30 hr, the equilibrium is nearly established and about 17–20% of Pu(IV) is reduced. The influence of plutonium concentration is shown in Fig. 5, for a concentration of sulphuric acid of 0·5*M*; the lower the plutonium concentration, the easier the reduction. At Pu = 1·00 mg/ml, only about 10% of Pu(IV) was reduced after 20 hr. Similar relationships for nitric acid medium are shown in Figs. 6 and 7.

Disproportionation reactions of Pu(IV) in perchloric or hydrochloric acid have been studied by Rabideau,[4] Connick and McVey[6] and other authors. For sulphuric or nitric acid media, however, data on transformation of the oxidation state of Pu(IV) are scarce. The disproportionation equilibrium constants $K = [\mathrm{Pu(III)}]^2[\mathrm{Pu(VI)}][\mathrm{H}^+]^4/[\mathrm{Pu(IV)}]^3$, were determined in 0·2–1·0*M* perchloric acid[4] and 0·2–1·0*M* hydrochloric acid.[6] In obtaining these results, the effects of the anion were not taken into account, and results on the relationship between disproportionation and time are insufficient. In the present work, however, it is found that transformation of the oxidation state of

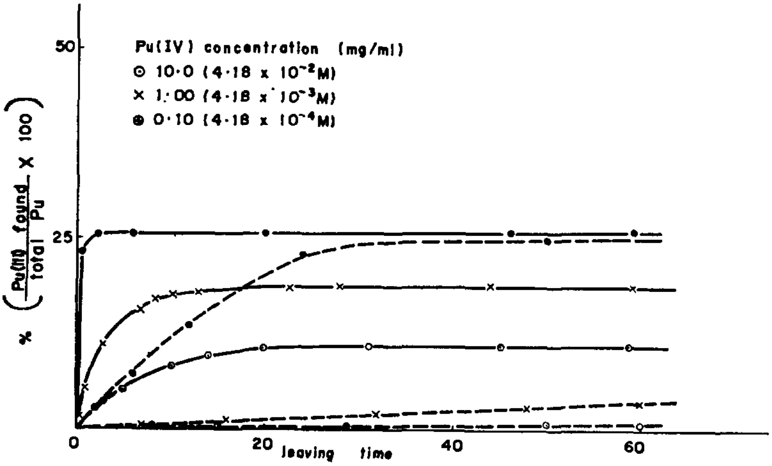

Fig. 5.—Effect of Pu(IV) concentration on reduction of Pu(IV). Acid concentration, 0·5M H_2SO_4, electrolyte; 0·5M H_2SO_4 Temperature, 20 ± 1°C: flow-rate, 5 ml/min. ----, minutes; ——, hours.

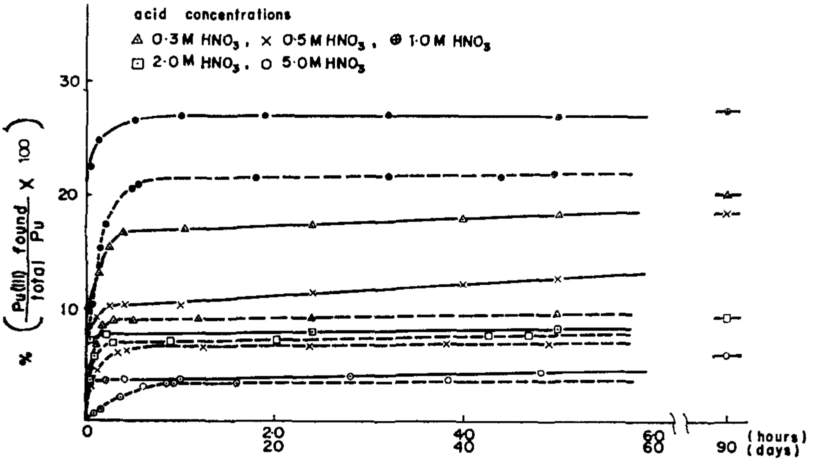

Fig. 6.—Effect of acid concentration on reduction of Pu(IV). Pu(IV) concentration, $1{\cdot}23_6$ mg/ml (5·17 × $10^{-3}M$) Temperature, 20 ± 1°C; flow-rate, 5 ml/min. Electrolyte: 1·0M HNO_3 ----, hours; ——, days.

Pu(IV) is scarcely affected by acid concentration in the range 0·1–2·5M sulphuric acid. On the other hand, the rate of transformation of the oxidation state of Pu(IV) decreases with increasing acid concentration in the range 1·0–5·0M nitric acid, and is also lower in 0·3–0·5M than in 1·0M nitric acid. It is considered that the oxidizing power of nitrate or nitrite ions may stabilize Pu(IV) at higher nitric acid concentration. In 0·5M sulphuric acid medium, the rate of transformation of oxidation state of Pu(IV) decrease with increasing plutonium concentration in the range 0·1–10 mg/ml. In nitric acid, however, plutonium concentrations in the range 0·332–1·24 mg/ml have

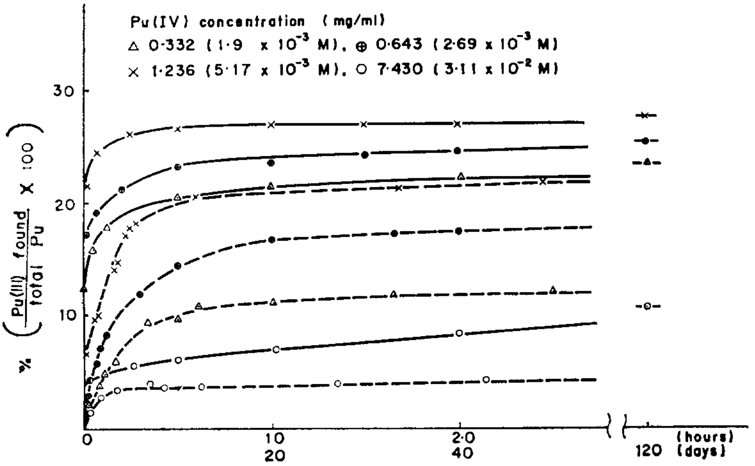

FIG. 7.—Effect of Pu(IV) concentration on reduction of Pu(IV). Acid concentration, 1·0*M* HNO_3; electrolyte, 1·0*M* HNO_3 Temperature, 20 ± 1°C; flow-rate, 5 ml/min. ----, hours, ———, days.

little influence on the transformation rate but at high plutonium concentration (7·43 mg/ml) Pu(IV) becomes more stable. Equilibrium is much more rapidly reached in sulphuric acid than in nitric acid, and takes longer with increasing concentration of plutonium and decreasing acid concentration.

From Figs. 4–7 it seems that transformation of Pu(IV) is induced by complexation reactions and that equation (1), obtained for perchloric, hydrochloric and 0·1–0·5*M* nitric acid media does not apply for the transformation in sulphuric and nitric acids.

In 0·5*M* hydrochloric acid, 0·002*M* plutonium solution (478 μg/ml) at 25° was found by Connick and others[13] to disproportionate to give about 26·3% Pu(III), 62·8% Pu(IV), 0·5% Pu(V) and 10·5% Pu(VI) at equilibrium. A 2 mg/ml solution of Pu(IV) in 0·5*M* nitric acid at 25° was found by Hall[14] to give 12% Pu(III), 66% Pu(IV) and 22% Pu(VI) at equilibrium. In the present study, in 0·5*M* nitric acid, 18·5% Pu(III), 68·8% Pu(IV) and 10·7% Pu(VI) were found for 1·24 mg/ml plutonium solution at equilibrium at 20°. Pu(IV) and Pu(VI) are calculated from the quantity of electricity used at +1·20 V and +0·30 V *vs.* SSE [equations (2) and (3)].

Oxidation reactions of Pu(III)

For the oxidation mechanism of Pu(III), it is supposed that dissolved oxygen plays an important role.[2] If the Pu(III) solution is deaerated by passage of pure nitrogen gas, the oxidation of Pu(III) solution is very slow and Pu(IV) cannot be detected after 6 hr, in either sulphuric or nitric acid. Pu(III) (1·0 mg/ml) in 0·5*M* sulphuric acid or 1·0*M* nitric acid were used in this study. In 1·0–5·0*M* nitric acid, however, nitrate or nitrite oxidation may be involved. Dukes[14] reported that in the presence of nitrite ion the oxidation of Pu(III) is faster in nitric acid than in perchloric or hydrochloric acid.

The relationship between time and oxidation of Pu(III) for different sulphuric acid concentrations is shown in Fig. 8. The concentration of plutonium was 50 μg/ml.

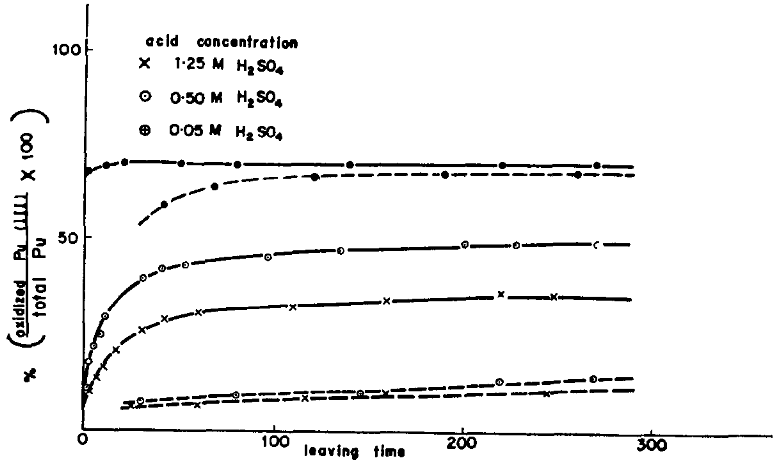

FIG. 8.—Effect of acid concentration on oxidation of Pu(III).

Temperature, 20 ± 1°C; flow-rate: 5 ml/min.
Electrolyte, 0·5N H_2SO_4
– – – –, seconds; ———, minutes.

Figure 8 shows that the lower the acid concentration, the more easily the oxidation of Pu(III) occurs. In 0·05M sulphuric acid, the equilibrium of Pu(III)/Pu(IV) is established immediately, but in 1·25M sulphuric acid about 2 hr is needed. The effect of plutonium concentration is shown in Fig. 9. The concentration of sulphuric acid was 0·5M. Figure 9 shows that the lower the plutonium concentration, the easier the oxidation of Pu(III). Pu(III) oxidizes rapidly within the first 1 hr and then slowly to equilibrium. After 10 hr, in the case of 50 μg/ml Pu, about 55% of Pu(III) is oxidized, but in the case of 10 mg/ml, only 12%.

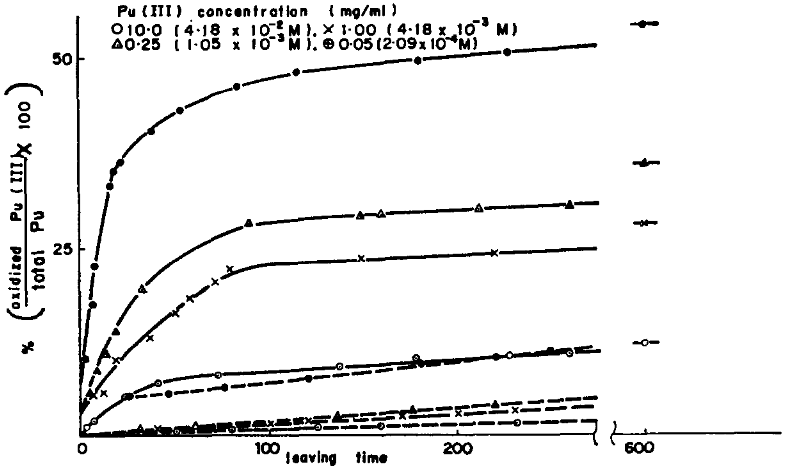

FIG. 9.—Effect of Pu(III) concentration on oxidation of Pu(III).

Temperature, 20 ± 1°C; flow-rate, 5 ml/min.
Electrolyte, 1·0*M* HNO_3
– – – –, hours; ———, days.

Similar relationships for nitric acid media are shown in Figs. 10 and 11. Figure 10 shows that in 0·5*M* nitric acid the oxidation of Pu(III) (1·24 mg/ml) is at a minimum and even after 120 days only 3% of Pu(III) is oxidized. When the nitric acid concentration is more than 5·0*M*, Pu(III) is oxidized to Pu(IV) as soon as the pre-electrolysis is stopped, because nitrite ion is generated in the solution by the pre-electrolysis. Figure 11 shows that when the plutonium concentration is 1·24 mg/ml (in 1·0*M* nitric acid), the oxidation is slowest and at higher plutonium concentration the equilibrium

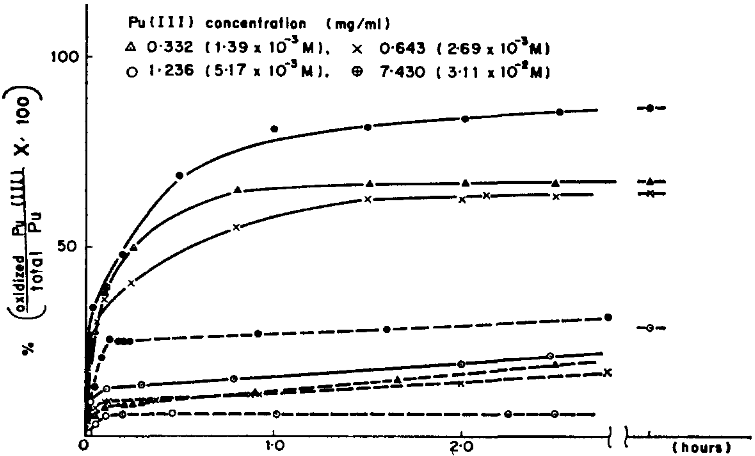

FIG. 11.—Effect of Pu(III) concentration on oxidation of Pu(III).

Temperature, 20 ± 1°C; flow-rate, 5 ml/min.
– – – –, hours: ———, days.

is established more quickly. It was confirmed that the amount of Pu(VI) generated from oxidized Pu(IV) was negligible.

In both $0{\cdot}5M$ sulphuric acid and $1{\cdot}0M$ nitric acid, oxidation of Pu(III) becomes faster with decreasing plutonium concentration, but in $1{\cdot}0M$ nitric acid at a relatively high plutonium concentration (7·43 mg/ml), an extremely large fraction of Pu(III) is oxidized. The rate of oxidation of Pu(III) decreases with increasing acid concentration in $0{\cdot}3$–$0{\cdot}5M$ nitric acid and $0{\cdot}05$–$1{\cdot}25M$ sulphuric acid. In $1{\cdot}0$–$5{\cdot}0M$ nitric acid, on the contrary, the rate of oxidation increases with acid concentration. Pu(III) may be oxidized by nitrate, nitrite and dissolved oxygen at higher nitric acid concentrations.

The oxidation mechanism of Pu(III) in sulphate media was discussed by Newton and Baker.[2] They reported that 58·5% of Pu(III) was oxidized after 100 min under the following conditions; temperature 25°, $P_{O_2} = 750$ mbar, total Pu $= 5{\cdot}36 \times 10^{-3}M$, $0{\cdot}3M$ $HClO_4$, $0{\cdot}4M$ Na_2SO_4. In the present work, 23·1% of Pu(III) was oxidized after 100 min under the conditions; 20°, $P_{O_2} = 200$ mbar, total Pu $= 4{\cdot}18 \times 10^{-3}M$, $0{\cdot}5M$ H_2SO_4.

Oxidation of Pu(III) in sulphuric acid is much faster than in nitric acid. It is known that the oxidation is very slow in solutions of hydrochloric and perchloric acids.[12] The potential for oxidation of Pu(III) to Pu(IV), complex-formation of the anion with Pu(IV) and the oxidizing potential of the medium may affect the oxidation rate of Pu(III).

In the present work, apparent transformations of Pu(IV) and Pu(III) are studied, but more detailed studies are required to elucidate the mechanisms of these reactions.

Acknowledgement—The authors thank Dr. H. Onishi and Mrs. N. Tamura for their helpful discussions.

Zusammenfassung—Die Reduktionsgeschwindigkeit von Pu(IV) und die Oxidationsgeschwindigkeit von Pu(III) wurden in schwefelsaurem und salpetersaurem Medium in Abhängigkeit von Säurekonzentration, Plutoniumkonzentration und Art der Säure untersucht. Es wurde eine durchflußcoulometrische Methode verwendet. Sie hat viele Vorteile: man braucht nur sehr kleine Proben, es werden keine speziellen Reagentien verwendet, die durch Art und Konzentration der Säure gegebenen Einschränkungen sind geringer, und die Methode geht rasch.

Résumé—On a étudié les vitesses de réduction de Pu(IV) et les vitesses d'oxydation de Pu(III) en milieux acide sulfurique et acide nitrique, en fonction de la concentration de l'acide, de la concentration du plutonium et de la nature de l'acide. On a utilisé dans ce travail une méthode coulométrique par écoulement. Cette technique a de nombreux avantages, la prise d'essai nécessitée est très petite, on n'utilise pas de réactifs spéciaux, moins de limitations sont imposées par le type et la concentration de l'acide, et la méthode est rapide.

SPECTROPHOTOMETRIC DETERMINATION OF 0–50 ng OF CHROMIUM IN 1 ml OF HUMAN SERUM

J. AGTERDENBOS, L. VAN BROEKHOVEN, B. A. H. G. JÜTTE and J. SCHURING
Analytisch-Chemisch Laboratorium, Rijksuniversiteit, Croesestraat 77A,

(*Received* 27 *August* 1971. *Accepted* 25 *October* 1971)

Summary—A method is described for the determination of chromium in 1 ml of human serum or plasma. It is based on a wet decomposition and a spectrophotometric determination with diphenylcarbazide after extraction with methyl isobutyl ketone. A 40-mm cuvette with less than 1 ml sample volume is described. Results are lower than expected from the literature, most samples from healthy persons containing less than 2 or 3 ng/ml. The reproducibility is about 1 ng/ml.

IN MANY BIOLOGICAL systems chromium is present, generally in extremely low concentrations. In the last two decades the functions and occurrence of chromium in these systems have been extensively studied. A comprehensive survey of this work has been given recently by Mertz.[1] It shows that chromium probably plays a role in biological processes in human beings. Some points are that the element is accumulated in high concentrations in certain areas of the brain, in nucleic acids and in hair, and that during the first weeks or months of life, the chromium concentration in many organs is higher than for the rest of life. Correlation may exist between certain diseases and the chromium content of human tissues and organs. Plasma undergoes significant changes in chromium content after an oral glucose load.

Mertz[1] reports values for the chromium concentration in blood (or serum or plasma) ranging from 0 to 520 ng/ml, and concludes that most of the values are between 20 and 50 ng/ml, and that plasma chromium levels considerably below 20 ng/ml may be suggestive of a low dietary intake, but do not necessarily mean chromium deficiency. Niedermeier *et al.*[2] recently described a direct-reading emission spectrographic method. They report that 50% of the 105 sera analysed have a chromium content below their detection-limit of 10 ng/ml. They report a mean value of 30 ng/ml.

In order to make further studies of the subject, further development of analytical methods is necessary, however. If these methods have to be applied in clinical laboratories they have to be performed with apparatus generally available there. In the present work the possibility of the development of such a method, applicable to the determination of chromium in 1 ml of human serum, was studied. Of the techniques used for the determination of metals at such levels, emission spectrography is not sensitive enough (except perhaps if special techniques[2] are used) and it is not available at most clinical laboratories. The latter objection may also be made against X-ray fluorescence. This technique was used by Beyermann *et al.*[3] for the determination of chromium in urine (down to 15 ng) after extraction with 8-quinolinol into chloroform. The use of atomic absorption for purposes similar to ours was described by Feldman *et al.*[4,5] but it seems not sensitive enough (down to 30 ng) for the present problem. Volatile metal chelates have recently been used for the determination of metals in the subnanogram range. Measurements were made with gas chromatographs (with electron-capture detectors) and with mass spectrometers. The latter method has not so far been applied to practical problems of a similar nature to ours. The chromium content of the plasma of rats has been measured by GLC, but the animals had been injected with Na_2CrO_4 and the chromium content was about 50 ng/ml (Hansen *et al.*[6]).

A technique readily available in clinical laboratories is spectrophotometry, and therefore we tried to find a procedure using this technique. Except for some catalytic procedures which we did not study, the diphenylcarbazide reaction with chromium(VI) combined with methyl isobutyl ketone (MIBK) extraction seemed the most sensitive. Its application has often been described, *e.g.*, by Koch and Koch-Dedic,[7] Beyermann,[8] and Morsches and Tölg.[9] The method of decomposition entailed some modifications to the method of determination, which may be useful in other applications, too. Suitable apparatus is present in many clinical laboratories, except perhaps the cuvettes and the slit-attachment which may, however, be obtained commercially.

EXPERIMENTAL

Apparatus and reagents

Absorption measurements were made with the Uvispek H 700 (Hilger and Watts) with a slit-attachment H 742. A cuvette was made from a 50 × 34 × 12 mm Teflon block. A groove was milled, 17 mm deep, 36 mm long, and 2 mm wide. In both side-walls at the end of the groove a circular hole was drilled, the holes were threaded, and a perforated screw was placed in each hole (perforation 5 mm diameter). Quartz windows were placed in the holes and Buna-N O-rings used for sealing. The optical path was about 37 mm, the volume used for measurements about 0·9 ml. The H 742-slit was used with an aperture 2 mm high and 1 mm wide. Small volume 40-mm cuvettes are commercially available.

Pyrex and quartz tubes with glass stoppers were used both for sample decomposition and centrifugation. They were 15 mm in bore and 100 mm long and were heated in a copper block, in holes (6 in the block) with the proper diameter and about 20 mm deep. The block contained a small hole for a thermometer and was heated on an electric plate. A quartz tube, 3 mm outer and 1 mm inner diameter and 120 mm long, was sealed 2 mm above one of its ends and placed in the decomposition tube as a "stirring rod" to prevent bumping.

Doubly distilled demineralized water, distilled acetone, distilled methyl isobutyl ketone and "Suprapur" (Merck) acids were used, except for hydrochloric acid which was prepared by isothermic distillation.[10] The dichromate standard (100 μg/ml) was made from solid $K_2Cr_2O_7$; more dilute solutions were prepared daily. A chromium(III) solution was prepared from this standard by reduction with alcohol and sulphuric acid. Diphenylcarbazide solution (50 mg/25 ml) in MIBK was prepared fresh every week. MIBK–hydrochloric acid mixture was prepared by diluting 1 ml of 10*M* hydrochloric acid to 100 ml with MIBK. The decomposition mixture was prepared from nitric acid (65%) perchloric acid (70%) and sulphuric acid (96%) in the volume-ratio 3:1:1.

Procedure

Take a 1·0-ml sample in the decomposition tube, add 1·0 ml of the decomposition mixture, mix, add a stirring rod. Place the tubes in the block (at 60–70°) and after 5 min mix the foam formed with the rest of the contents. Heat the block to 90° in 25 min, then in 20 min more to 120° for the dissolution, in another 30 min to 150° for the predecomposition, in the next 45 min to 275° for the final decomposition and in 15 min to 330° for the removal of perchloric acid. Remove the tubes from the block and cool them. If the contents are yellow, heat again at 330° for 5 min.

Wash the wall and the stirring-rod each with 0·5 ml of 0·12*M* perchloric acid, add 0·2 ml of 0·01*M* potassium permanganate and place for 5 min on a water-bath (100°). Cool in ice, add 0·10 ml of 10*M* hydrochloric acid, keep at 0° until the permanganate colour disappears, add 1·00 ml of MIBK–hydrochloric acid solution (at 0°), extract for 1 min and then immediately centrifuge for 1 min at 2000 rpm. Take 0·85 ml of the organic phase in another centrifuge tube, add 0·10 ml of diphenylcarbazide solution, 0·01 ml of MIBK–hydrochloric acid solution and 0·10 ml of acetone. Mix, place in the dark, and measure the absorbance against water at 540 nm in a 40-mm microcuvette between 20 and 30 min after addition of the diphenylcarbazide. Substract the value of a blank obtained in the same way without the addition of serum.

Calibration curves without preliminary decomposition are prepared by the same procedure. Aliquots of a dichromate solution containing 0–100 ng of chromium are used, 0·2 ml of 96% sulphuric acid and 1 ml of 0·12*M* perchloric acid are added and the volume is adjusted to about 1·2 ml before the oxidation with permanganate.

DISCUSSION

The decomposition mixture described was also used by Feldman *et al.*[5] Its advantage over some other mixtures tried is that a small and constant amount is used. This eliminates the influence of impurities in the reagents. Moreover the decomposition does not take much work. There was some indication that blanks obtained with Pyrex tubes were slightly higher than those with quartz tubes but the difference—if any—was small. New tubes may cause loss of some chromium when first used. The oxidation of chromium(III) to chromium(VI) and the extraction with hydrochloric acid and MIBK (as $HCrO_3Cl.2MIBK$) have been described with slight variations by several others.[4,5,7,8,9,11]. Some of these authors[7,8,9] also describe the photometric determination. The method is very selective[8] and therefore not much work was done to investigate interferences. An exception was made for iron but at the levels normally present in serum the absorbance due to the iron contribution was found to be roughly equivalent to that of 0·1 ng of chromium.

Preliminary experiments gave some irregular results which suggested that perchloric acid left on the walls of the decomposition tube might affect the absorbance. It was found in experiments without the decomposition step that the addition of perchloric acid greatly enhanced the absorbance. Addition of 10 μl of 70% perchloric acid gave a constant and maximum absorbance value. Therefore the walls and the stirring rod were rinsed with the equivalent of this amount of acid. The rinsing with perchloric acid greatly improved the reproducibility of the complete procedure. Another modification is the addition of 0·1 ml of acetone to the organic phase. This addition prevents turbidity in the coloured solution.

For the blanks a mean value of zero was expected, and was found in about half the experiments, but all the others gave high blanks. The results suggest that the equivalent of 4 (or 2) ng of chromium are introduced in part of the experiments, but not in others. Statistical conclusions based on the Gaussian curve may therefore be incorrect. The mean value of the blanks is 1·4 ng, the standard deviation is 1·6 ng. This value is higher than the value of 1·0 ng found for the standard deviation in the measurement of samples, but it should be noted here that duplicate or triplicate samples were always analysed within one day, whereas the blanks were taken over a period of more than a week. The recovery experiments show recoveries of 96%, 103%, 93% and 94% (mean 97%) if a blank of 1·4 ng is substracted.

A calibration curve for the range 0–100 ng of chromium, obtained without application of the decomposition mixture and procedure, was linear, obeying the equation $1000A = 2{\cdot}16x + 1{\cdot}7$, where A was the absorbance and x the number of ng of chromium. A similar curve prepared with 1 ml of a serum and 0–50 ng of chromium was also linear, with the equation $1000A = 2{\cdot}15x + 8{\cdot}4$. The standard deviation was 0·6 ng in both cases.

From the analytical point of view it is concluded that the procedure described allows the determination of chromium in serum or plasma at the 0–50 ng level with a standard deviation of about 1 ng, but that blanks and samples should preferably be run at the same time. Fourteen experiments a day are possible.

BIOCHEMICAL APPLICATION

A total of 27 heparinized plasma samples and 10 sera samples from healthy adults were analysed for chromium, with the results given in Table I. Youden's formulae[12] were used to determine the standard deviations.

TABLE I.—CHROMIUM CONTENT OF THE SERUM OF 37 HEALTHY PERSONS FROM UTRECHT AND ROTTERDAM, AND RESULTS OF 14 BLANKS.

Cr found, *ng/ml*	Number of persons*	Number of blanks†
<1	3	7
1	10	1
2	16	2
3	2	0
4	1	4
5	4	0
6	1	0

* Most results were mean values for two (or three) analyses.

† Single experiments.

Most of the values given for the samples in the table are mean values of duplicate experiments; in a few cases only a single determination was made, in a few others triplicate experiments were run. From each set of duplicate or triplicate experiments (made on the same day) the standard deviation was calculated and a pooled value of 1·0 ng/ml was found with 31 degrees of freedom. No differences due to age or sex could be detected in the results. No difference was found between serum and plasma. Twelve blanks (including decomposition) and four recovery experiments were also run. Results for the blanks are given in Table I. Recovery experiments with 10 or 20 ng of Cr(VI) and 20 or 40 ng of Cr(III) gave measured values of 11, 22, 20 and 39 ng respectively. From a biochemical point of view we have to conclude that results for healthy persons are lower than might be expected from the review of Mertz[1] and the work of Niedermeier *et al.*[2] The best conclusion seems that practically all values are below 5 ng/ml and that 80 or 90% are below even 2 or 3 ng/ml. Clinical chemists are left to draw further conclusions but before they do so, repetition of the experiments may be useful. Two points are mentioned here, however. One is that Mertz[1] reports large geographical variation in the chromium content of several human organs. Another is that the loss of considerable amounts of chromium during storing of the sample, before the analysis, seems improbable, no decrease in chromium content being found during experiments on the same deep-frozen serum analysed at intervals during a fortnight.

Acknowledgement—The authors thank Drs. B. G. Blijenberg, Academic Hospital Rotterdam Dijkzigt for his suggestion to do this work, for discussions on the clinical aspects and for supplying some samples. Thanks are also due to the blood-transfusion service of the Sint Antonius Hospital in Utrecht for supplying the other samples.

Zusammenfassung—Ein Verfahren zur Bestimmung von Chrom in 1 ml menschlichem Blutserum oder -plasma wird beschrieben. Es beruht auf nasser Zersetzung und spektrophotometrischer Bestimmung mit Diphenylcarbazid nach Extraktion mit Isobutylmethylketon. Eine 40 mm-Küvette mit weniger als 1 ml Probenvolumen wird beschrieben.

Die Ergebnisse sind niedriger als nach Literaturangaben erwartet; die meisten Proben von gesunden Personen enthalten weniger als 2 oder 3 ng/ml. Die Reproduzierbarkeit beträgt etwa 1 ng/ml.

Résumé—On décrit une méthode pour le dosage du chrome dans 1 ml de sérum ou de plasma humain. Elle est basée sur une décomposition par voie humide et un dosage spectrophotométrique avec le diphénylcarbazide après extraction en méthylisobutylcétone. On décrit une cuvette de 40 mm avec un volume d'échantillon moindre que 1 ml. Les résultats sont plus faibles que ceux attendus de la littérature, la plupart des échantillons de personnes en bonne santé contenant moins de 2 ou 3 ng/ml. La reproductibilité est d'environ 1 ng/mil.

DICHLORAMINE-T AS A NEW OXIDIMETRIC TITRANT IN NON-AQUEOUS AND PARTIALLY AQUEOUS MEDIA

T. J. Jacob and C. G. R. Nair
University Department of Chemistry, Kerala University, Trivandrum-1, India

(*Received* 31 *August* 1971. *Accepted* 24 *October* 1971)

Summary—A new oxidimetric titrant, dichloramine-T, is proposed for redox titrations in glacial acetic acid medium. The general analytical conditions for using this oxidant and the procedures for potentiometric determination of ascorbic acid, iodide, arsenic(III) and iron(II) are described.

Redox titrimetry in non-aqueous media has received comparatively scant attention,[1] although considerable work has been done in acid-base titrimetry in non-aqueous media. Tomiček and co-workers carried out redox titrations in glacial acetic acid, using bromine, iodine, iodine monochloride, lead tetra-acetate, chromic acid *etc.*[2,3] Rao and Murthy used ammonium hexanitratocerate in acetonitrile as an oxidimetric reagent.[4,5,6] Our preliminary experiments indicated that a solution of dichloramine-T (*N,N'*-dichloro-*p*-toluenesulphonamide, hereafter abbreviated to DCT) in anhydrous acetic acid could be used to titrate several types of reductant. This is the first time that a metal-free organic substance has been used as an oxidimetric titrant in non-aqueous medium, as pointed out in our preliminary communication announcing this new reagent.[7] Details of individual determinations with this new oxidant are now communicated, *viz.*, potentiometric titration of ascorbic acid, iodide, arsenic(III) and iron(II).

EXPERIMENTAL

Apparatus

Smooth, clean platinum electrodes were used as indicator electrodes. A saturated calomel electrode with a potassium chloride–agar gel salt-bridge was used as reference electrode.[2–6] All titrations were done at room temperature (29 ± 2°).

Reagents

Preparation of DCT. DCT was prepared by further chlorination of chloramine-T.[8] Orton and Bradfield prepared DCT by dissolving *p*-toluenesulphonamide in acetic acid, adding bleaching powder solution, filtering off the precipitate, dissolving it in acetic acid and reprecipitating it with bleaching powder solution.[3] We found that a simpler method, passing chlorine through an aqueous solution of chloramine-T, gives good samples of DCT.

Recrystallized chloramine-T (30 g) was dissolved in water (500 ml) and pure chlorine was bubbled through the solution for about 3 hr. The fine white precipitate was filtered off, dried on the filter by sucking dry air through it and kept in a blackened vacuum desiccator for 24 hr. The sample was subsequently stored in brown bottles. The dry sample melted at 71–72° (lit.[8] 71–75°). The available chlorine was determined by dissolving an accurately weighed sample in glacial acetic acid, adding excess of 10% potassium iodide solution, diluting with water and titrating the iodine with thiosulphate solution (found 29·0%; theoretical 29·6%).

Stock solutions of DCT. Approximately 0·1*M* (∼0·4*N*) solutions were prepared by dissolving *ca.* 12 g of DCT in about 500 ml of glacial acetic acid containing 10% v/v acetic anhydride, and kept in brown or dark-painted bottles fitted with automatic burettes and guard-tubes for the exclusion of moisture. These solutions were found to be comparatively stable. The normality of a typical stock solution over a period of 15 days is given in Table I. This stability is equal or superior to the stability of other oxidimetric reagents employed in non-aqueous media.[2,3,4,5] The DCT solutions are, however, slightly decomposed by exposure to light; hence they are preserved in brown bottles. For accurate

TABLE I. STABILITY OF STOCK SOLUTIONS OF DICHLORAMINE-T IN GLACIAL ACETIC ACID, KEPT IN BROWN BOTTLES.

No. of days keeping	0	1	2	3	4	5	7	15
Normality	0·4603	0·4603	0·4603	0·4603	0·4571	0·4571	0·4571	0·4463

work, daily standardization is recommended, the method involving addition of aqueous potassium iodide solution and titrating the liberated iodine with thiosulphate.[4,5]

Determination of ascorbic acid

Standard solutions of ascorbic acid were prepared in (*a*) water, and (*b*) anhydrous acetic acid containing acetic anhydride, and standardized iodometrically.[10] Both solutions were titrated potentiometrically with DCT in glacial acetic acid. With DCT as titrant, the potential increased slightly at first; there was a sharp potential jump at the equivalence point. The attainment of equilibrium was quick. The values were found to be highly reproducible.

Reverse titrations, with ascorbic acid as titrant, give premature end-points and are therefore unsatisfactory.

Determination of potassium iodide

In view of the very low solubility of potassium iodide in glacial acetic acid and the susceptibility of iodide to aerial oxidation in presence of acid, solutions of KI in glacial acetic acid were not prepared; instead, standard aqueous solutions were used. Carbon dioxide was bubbled through the solution to exclude atmospheric oxygen during the titration. Glacial acetic acid (20 ml) and acetic anhydride (~5 ml—slightly more than the amount theoretically required to react with the water present in the KI solution) were added. The DCT solution was added from a microburette to the magnetically stirred titrand. The stirring and the carbon dioxide flow were momentarily stopped while readings were taken.

In a few titrations, 5 ml of perchloric acid were also added before the titration was started.

Determination of arsenic

Arsenious oxide was weighed out, dissolved in sodium hydroxide solution, neutralized with glacial acetic acid, and made up to standard volume with glacial acetic acid. The solution was standardized by diluting aliquots with water, adding excess of bicarbonate and titrating with standard iodine solution.

Aliquots were taken in the titration cell and slightly more than the required amounts of acetic anhydride were added. Then 20 ml of acetic acid and 5 ml of perchloric acid were added and the solution was titrated with DCT.

Determination of iron(II)

Aqueous solutions were made direct from ferrous ammonium sulphate. Glacial acetic acid solutions were prepared as follows. Solid ferrous carbonate was prepared from ferrous ammonium sulphate and sodium carbonate in aqueous solution in a carbon dioxide atmosphere. The ferrous carbonate was filtered off, washed several times with distilled water, then with alcohol and ether, and finally dried in a desiccator in an atmosphere of carbon dioxide. This ferrous carbonate was dissolved in glacial acetic acid and 5% v/v of acetic anhydride was added. Both aqueous and acetic acid ferrous solutions were standardized by permanganate titration.

Aliquots of ferrous solution were taken in the titration cell and 20 ml of glacial acetic acid were added. Preliminary experiments showed that the presence of perchloric acid is essential for the titration. Moreover, the presence of finely powdered solid potassium bromide was found to give quicker attainment of stable potentials. It was also found necessary to have phosphoric acid present to remove iron(III) by complex formation as soon as it is formed, and thereby keep the potential low till the end-point.

RESULTS AND DISCUSSION

Typical results are presented in Tables II–V. The end-points were read from the potentiometric curves, and also checked by calculations employing the Hostetter-Roberts equation.[11]

TABLE II.—POTENTIOMETRIC DETERMINATION OF ASCORBIC ACID WITH DICHLORAMINE-T

Series	Conditions	Ascorbic acid taken, *mmole*	DGT consumed, *mequiv*	Equiv. DCT per mole ascorbic acid	Error %*
(*a*)	Ascorbic acid in water	0·437$_5$	0·869	1·987	−0·6
		0·465$_4$	0·933	2·004	+0·2
		0·519$_2$	1·035	1·993	−0·3

0·989$_3$	0·988	0·999	−0·1
0·989$_3$	0·992	1·002	+0·3

* Assuming that 1 equivalent of oxidant is consumed per mole of potassium iodide.

TABLE IV.—POTENTIOMETRIC DETERMINATION OF As(III) WITH DICHLORAMINE-T

As_2O_3 taken, *mmole*	DCT consumed, *mequiv.*	Equiv. DCT per mole As_2O_3	Error %*
0·514$_0$	2·057	4·002	+0·1
0·514$_0$	2·054	3·996	−0·1
0·616$_8$	2·464	3·994	−0·1
0·616$_8$	2·469	4·002	+0·1

* Assuming that 4 equivalents of oxidant are consumed per mole of As_2O_3

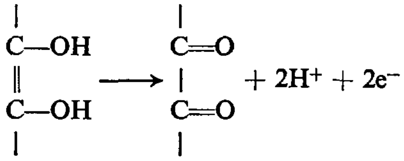
TABLE V.—POTENTIOMETRIC DETERMINATION OF Fe(II) WITH DICHLORAMINE-T

Conditions	Fe(II) taken, *mmole*	DCT consumed, *mequiv*	Equiv. DCT per mole Fe(II)	Error %*
Ferrous salt in water	0·806$_5$	0·809	1·003	+0·3
	0·806$_5$	0·809	1·003	+0·3
	0·806$_5$	0·814	1·009	+0·9
Ferrous salt in glacial acetic acid	0·995$_6$	0·994	0·998	−0·2
	0·995$_6$	0·994	0·998	−0·2
	1·245$_0$	1·243	0·998	−0·2

* Assuming that 1 equivalent of oxidant is consumed per mole of Fe(II)

Abscorbic acid

From Table II two equivalents of oxidant are consumed per mole of ascorbic acid, in agreement with the reaction



$$\begin{array}{c} | \\ \mathrm{C{-}OH} \\ \| \\ \mathrm{C{-}OH} \\ | \end{array} \longrightarrow \begin{array}{c} | \\ \mathrm{C{=}O} \\ | \\ \mathrm{C{=}O} \\ | \end{array} + 2\mathrm{H}^+ + 2e^-$$

The potential jump at the equivalence point is of the order of 600 mV for series (*a*) and 450 mV for series (*b*). The presence of water is therefore immaterial and, indeed, improves the accuracy by giving a greater potential break. Earlier workers have also remarked that small amounts of water do not cause any interference in redox titrations in non-aqueous media.[2] The lower potential break in non-aqueous medium is understandable in view of the reported inhibition of the reducing capacity of ascorbic acid in such media.[12,13]

Potassium iodide

During the titration, from the first addition of titrant, the solution becomes reddish owing to the liberation of iodine. The red colour reaches a maximum intensity and then fades to lemon yellow. Analysis of the yellow solution shows that it contains iodine in the +1 oxidation state. The fading of the red colour to lemon yellow therefore signifies the oxidation of iodine to iodine(I). Since the ICl/I couple has a standard potential $E^\circ = +1{\cdot}19$ V, it was considered desirable to raise the redox potential of the DCT/sulphonamide couple as much as possible. This potential increases with increasing acidity,[14] so perchloric acid was added.

Two breaks were observed in the titration curve. The first was sharp and corresponds to complete oxidation of iodide to iodine. The potential break was about 300 mV. Further oxidation to iodine(I) is represented by the second break (about 150 mV), which occurred much earlier than expected. This is due to loss of iodine from the solution by volatilization. In the absence of perchloric acid the second break was not satisfactory.

Arsenic

Arsenic(III) is quantitatively oxidized to arsenic(V) if perchloric acid is present; the potential break is about 50 mV.

Iron(II)

The potential break is about 200 mV for both aqueous and acetic acid solutions. As with arsenic(III) the presence of perchloric acid is necessary. This is not surprising because the Fe(III)/Fe(II) couple has a standard potential of $E^\circ = 0{\cdot}77$ V and it is advantageous to increase the potential of the DCT/sulphonamide couple by increasing the acidity. Phosphoric acid helps to give a sharper break, by complexing with the ferric iron formed. It was observed that in the absence of potassium bromide the attainment of steady potentials was slow and sluggish.

DCT

The formal redox potential of the DCT/sulphonamide couple in glacial acetic acid medium has been measured and found to be $E^\circ = 1{\cdot}2$ V.[14] This indicates that DCT is a moderately strong oxidant. The behaviour of DCT towards hydrazine, oxine, hydroquinone, and many other reductants, and back-titrations of water-insoluble organic reductants with DCT in glacial acetic acid medium are under investigation.

Zusammenfassung—Ein neues oxidimetrisches Titrationsmittel, Dichloramin-T, wird für Redoxtitrationen in Eisessig vorgeschlagen. Die allgemeinen analytischen Bedingungen zum Gebrauch dieses Oxidationsmittels und die Arbeitsvorschriften zur potentiometrischen Bestimmung von Ascorbinsäure, Jodid, Arsen(III) und Eisen(II) werden beschrieben.

Résumé—On propose un nouvel agent de titrage oxydimétrique, la dichloramine T, pour les titrages redox en milieu acide acétique glacial. On décrit les conditions analytiques générales d'emploi de cet oxydant et la technique de dosage potentiométrique de l'acide ascorbique, de l'iodure, de l'arsenic(III) et du fer(II).

Determination of purity of compounds by extraction-solubility

(*Received* 16 *August* 1971. *Accepted* 29 *October* 1971)

THE USE of differential scanning calorimetry permits mole% purity of organic compounds to be determined conveniently on small samples.[1-3] The method is applicable to any organic compound which is thermally stable at its melting point, and having impurities which dissolve in the liquid phase and do not form solid solutions. If either the compound or one of its impurities is thermally unstable or if for some other reason results by differential scanning calorimetry appear to be in doubt, verification by another method is desirable. The extraction-solubility method as described by Stenger, Crummett and Kramer[4] offers an alternative. Although this approach has been reviewed by several authors[5,6,7] and in one case modified extensively by using smaller equipment, an azeotrope as a solvent, and refractive index as a measuring device in the determination of the purity of naphthalene,[8] further work showing its general applicability to the determination of the purity of compounds has not been published. Phase-solubility analysis has been reviewed by Higuchi and Conners[9] while some problems connected with this method have been studied by Wilkinson and Wragg[10]

In this paper we have applied the original technique[4] to a large number of organic compounds of high purity, tabulated the results, and made some comparisons with other methods. All results were obtained in the course of solving practical analytical problems rather than in a deliberate attempt to show the applicability of the method.

EXPERIMENTAL

In carrying out this work the method of Stenger *et al.*[4] was modified slightly. The flask and filter crucible were weighed immediately after filtering to obtain the weight when wet with solvent. (This avoids the need to wash the crystals.) Subtracting the dry weight gave the weight of solvent remaining with the crystals. When the amount of soluble impurities which remained with the crystals was high enough to affect the results, the weight was calculated from the weight of solvent and added to the amount of soluble impurities calculated to be in the residue. Other modifications and conditions are reported in the tables. The purity results in Table I were calculated as follows. "Purity from recovery" is 100 × weight recovered/sample weight. "Purity by difference" is 100—(volatiles + insolubles + solubles).

RESULTS AND CONCLUSIONS

Of the 33 compounds considered, 21 were found to be suitable for the determination of purity by extraction-solubility, 5 failed to show solubilities in the required range, and 7 were unsuitable for extraction-solubility purity determinations owing to other factors.

Successful determinations of purity are tabulated in Table I. The results compare favourably with those obtained by other methods such as infrared spectrophotometry and differential scanning calorimetry (DSC). The results are reproducible as is shown by duplicate analyses of several lots of the same compound. Also extraction-solubility was found to be an effective way to follow purification methods in several instances—piperazine hydrochloride; 4-amino-2,3,5-trichloropyridine; 3,5-dichloro-2,6-dimethyl-4-pyridinol; and 3,5-dinitro-*o*-toluamide. Surprisingly good results were obtained in some instances at low purity levels (95–99%), although the method was designed for compounds having a purity of 99·5% or better. Nine different solvents were used with equal effectiveness.

Table II lists those compounds for which no suitable solvent was found. Some solubilities are given to define the problem.

Table III identifies those compounds for which solvents showing appropriate solubilities were found but the extraction-solubility method failed owing to other difficulties. Some of these were compound decomposition, impurities more soluble in the crystals than in the solvent, formation of solid solutions, and solubility of impurity in solvent too low. Greater effort could possibly have found ways to avoid some of these difficulties, but the table serves to illustrate some of the problems associated with the practical use of the method.

TABLE II.—COMPOUNDS FOR WHICH A SUITABLE SOLVENT COULD NOT BE FOUND (EXTRACTION-SOLUBILITY METHOD INAPPLICABLE)

Compound	Observations
3,5-Dichloro-4-methoxy-2,6-lutidine	Solubility > 10 mg/ml of acetone, benzene, carbon disulphide, carbon tetrachloride, chloroform, cyclohexane, or n-hexane; 140 mg/ml of methanol; 0·1 mg/ml of water at 23°C.
Phosphoric acid, diethyl-(3,5,6-trichloro-2-pyridyl) ester	Solubility too high in organic solvents—100 mg/ml of iso-octane, 180 mg/ml of n-hexane at 23°C. Solubility in water 0·5 mg/ml is in range but compound hydrolyses in water.
Phosphorothioic acid, *O*,*O*-diethyl-*O*-(3,5,6-trichloro-2-pyridyl) ester	Solubility in n-hexane 89 mg/ml at 0°C. Other hydrocarbons and methanol about the same. Other organic solvents greater amounts. Solubility in water 0·0004 mg/ml at 24°C.
Phosphorothioic acid, *O*,*O*-dimethyl-*O*-(3,5,6-trichloro-2-pyridyl) ester	Lowest solubility in an organic solvent was 160 mg/ml in n-hexane at 23°C (0·004 mg/ml in water).
4,4′-(2,3-dimethyltetramethylene)dipyrocatechol (nordihydroguaiaretic acid)	Solubility too low except in alcohols and ether, in which it is too high.

TABLE III.—COMPOUNDS FOR WHICH SOLUBILITY SUITABLE BUT RESULTS UNSATISFACTORY

Compound	Solvent	Solubility *mg/ml*	*°C*	Observations
2,4,5-Trichlorophenoxyacetic acid	carbon tetrachloride	0·48	23	Methoxy impurity not detected.
	benzene	2·2	23	Methoxy impurity not detected.
Methylcarbamic acid, 4-dimethylamino-3,5-xylyl ester	water	0·1	25	Decomposed on extraction with water. Solubility in other solvents too high.
Dehydroacetic acid (3-acetyl-6-methyl-2H-pyran-2,4-(3H)-dione)	n-hexane	2·9	23	No difference in total weight of soluble impurities between 1-g and 2-g samples although these were detected by TLC.
4-Amino-3,5-dichloro-2,6-lutidine	n-hexane	1·8	23	Impurities concentrated on the recrystalized material.
5-Chloro-4-hydroxy-2,6-dimethylnicotinic acid	acetone	0·25	23	2, 6-Dimethyl-4-hydroxynicotinic acid impurity not in soluble impurities although shown to be present by ion-exchange–UV method.
N, *N*′-Dimethylphosphorodiamidic acid, 4-t-butyl-2-chlorophenyl ester	n-hexane	0·44	23	0·3% Soluble impurities found. By GLC 0·9% unchlorinated phenyl ester found. Purity by DSC 99·4%
Tricyclohexylhydroxystannane	n-hexane	0·20	25	Compound decomposed, losing water during extraction

Summary—Thirty-three organic compounds prepared for use as analytical standards were examined for purity by the extraction-solubility method. Of these, twenty-one gave satisfactory results, seven behaved non-ideally, and five were not soluble in the useful range. Results on the twenty-one satisfactory samples compared favourably with those obtained by differential scanning calorimetry and other analytical methods. The method was found to be useful for following the improvement of compounds undergoing purification.

Zusammenfassung—Dreiunddreißig zur Verwendung als analytische Standards hergestellte organische Verbindungen wurden mit der Extraktions-Löslichkeitsmethode auf Reinheit untersucht. Darunter gaben einundzwanzig befriedigende Ergebnisse, sieben verhielten sich nicht ideal, und fünf waren im nutzbaren Bereich nicht löslich. Die Ergebnisse von den einundzwanzig zufriedenstellenden Proben schneiden beim Vergleich mit solchen von Untersuchungen mit registrierender Differentialkalorimetrie und anderen analytischen Methoden gut ab. Die Methode wurde zur Kontrolle der Verbesserung von Verbindungen während des Reinigungsprozesses für nützlich befunden.

Résumé—On a examiné la pureté de trente trois composés organiques préparés pour l'emploi comme étalons analytiques par la méthode d'extraction-solubilité. De ceux-ci, vingt et un donnent des résultats satisfaisants, sept se comportent de maniére non idéale, et cinq ne sont pas solubles dans le domaine utile. Les résultats obtenus avec les vingt et un échantillons satisfaisants sont favorablement comparables à ceux obtenus par l'analyse enthalpique différentielle et d'autres méthodes analytiques. On a trouvé que la méthode est utile pour suivre l'amélioration de composés soumis à purification.

Determination of phosphorus in lubricating oils by cool-flame emission spectroscopy

(*Received* 2 *August* 1971. *Accepted* 14 *October* 1971)

An analytical procedure, based on the cool-flame technique of Dagnall *et al.*,[1] has been developed for the determination of phosphorus in lubricating oils; phosphorus is commonly present in these oils in the form of the additive zinc dialkyldithiophosphate and the present method forms an alternative to procedures published elsewhere[2] for this determination.

Brite[3] and Davis *et al.*[4] have shown that phosphorus in organophosphorus compounds may be detected by measurement at 540 nm of the flame emission continuum produced when solutions of the material in various organic solvents are aspirated into an oxy-hydrogen flame. In our experience, it is difficult to obtain specific and quantitative measurements under these conditions and a more certain indication of phosphorus is obtained by using the emission from the HPO species at 528 nm, produced when aqueous solutions containing phosphorus are aspirated into a cool hydrogen–nitrogen

range. Results on the twenty-one satisfactory samples compared favourably with those obtained by differential scanning calorimetry and other analytical methods. The method was found to be useful for following the improvement of compounds undergoing purification.

Determination of phosphorus in lubricating oils by cool-flame emission spectroscopy

(*Received* 2 *August* 1971. *Accepted* 14 *October* 1971)

AN ANALYTICAL PROCEDURE, based on the cool-flame technique of Dagnall *et al.*,[1] has been developed for the determination of phosphorus in lubricating oils; phosphorus is commonly present in these oils in the form of the additive zinc dialkyldithiophosphate and the present method forms an alternative to procedures published elsewhere[2] for this determination.

Brite[3] and Davis *et al.*[4] have shown that phosphorus in organophosphorus compounds may be detected by measurement at 540 nm of the flame emission continuum produced when solutions of the material in various organic solvents are aspirated into an oxy-hydrogen flame. In our experience, it is difficult to obtain specific and quantitative measurements under these conditions and a more certain indication of phosphorus is obtained by using the emission from the HPO species at 528 nm, produced when aqueous solutions containing phosphorus are aspirated into a cool hydrogen–nitrogen diffusion flame.[1] Since, as reported by Aldous *et al.*,[5] the HPO emission in the cool flame is completely quenched by the introduction of organic liquids, it is impracticable to work directly with a solution of the oil sample in an organic solvent; the only strong emission we have observed with certainty under these conditions can be attributed to the C_2 band at 516 nm.

Investigation of possible chemical pretreatments of the oil, to provide an aqueous solution suitable for cool-flame analysis, indicated that severe interference effects were present in solutions prepared by either the wet-oxidation process of IP 148/58[2] or the zinc oxide ashing technique of IP 149/58;[2] high residual contents of mineral acid or of bivalent cations are not readily removed. A new pretreatment was devised, in which the oil was ashed in the presence of potassium hydroxide; the residual melt was dissolved in water and treated with cation-exchange resin, and the phosphorus content of the final solution was measured, using the general procedure described in other published applications.[6,7]

EXPERIMENTAL

Reagents

Potassium hydroxide. Pellets, analytical reagent grade.

Orthophosphoric acid. Analytical reagent grade was used to prepare the reference standard. An accurate 0·001*M* solution, containing 31 μg of P/ml, was prepared by dilution of a standardized stock solution.

Dowex 50W-X8 *cation-exchange resin.* A resin bed 0·25 m long and 20 mm in diameter was found satisfactory for 3 sample treatments. Resin stocks were regenerated by stirring for 8 hr with 0·3*M* hydrochloric acid, followed by decantation and washing until acid-free.

Apparatus

Unicam SP 900 flame photometer, fitted with standard 13-hole air–propane burner head, or with an open Pyrex glass tube, 10 mm bore, attached by a short polythene sleeve to a standard burner shaft. In both cases, the burner head was sited 10 mm below the bottom of the monochromator entrance slit. Nitrogen, at 105 kN/m^2 (15 psi) (2·5 l./min), was fed through the SP 900 nebulizing system and hydrogen, at 20 mm pressure on the dibutyl phthalate manometer (1·2 l./min), was fed through the fuel system. The solution uptake rate was 2·5 ml/min. Other instrument settings were: slitwidth 0.35 mm; electrical bandwidth 3; gain control 4–5, as necessary.

Procedure

Transfer 1 ± 0·005 g of oil to a small nickel or platinum crucible and add 0·5 g of potassium hydroxide pellets. Heat gently over a low flame until the potassium hydroxide melts and the oil ignites. Continue heating until the oil has burned off, then ignite more strongly until a clean white residue is obtained, taking care to avoid loss by spitting. Cool, add 10 ml of water and transfer the dissolved melt, with washings, to a 100-ml beaker. Add 5 g of wet resin and stir mechanically for 10 min or until the solution loses all turbidity. Transfer to the resin column and collect the effluent in a 250-ml graduated flask. Wash with successive 25-ml portions of water, at a flow-rate of 10 ml/min, to a final total volume of 250 ml.

Measure, by pipette, two 50-ml aliquots of this solution into two 100-ml graduated flasks and to one aliquot add a suitable volume (*V* ml) of the standard phosphorus solution (Note 1). Dilute both solutions to volume.

Measure the emission at the peak response wavelength (approx. 528 nm) for both solutions alternately, and record the mean galvanometer deflections for each from at least 3 replicate readings. (Note 2). Spray distilled water after each pair of readings to restore the galvanometer to zero. Any blank determination required should be carried out by the same procedure (Note 3).

From the mean readings for the sample (S_0) and the sample with added phosphorus (S_1), calculate the phosphorus content of the sample from the expression:

$$\% \mathrm{P} = \frac{(S_0) \times V \times 31 \times 250 \times 100 \times 100}{(S_1 - S_0) \times \text{weight of oil (g)} \times 10^6 \times 50 \times 100}$$

For a fixed sample weight of 1 g this reduces to:

$$\% \mathrm{P} = \frac{(S_0)}{(S_1 - S_0)} \times V \times 0{\cdot}0155$$

Notes. 1. Ascertain the approximate phosphorus content of the sample solution by spraying the first 50-ml aliquot—diluted to volume—and, with the SP 900 settings unaltered, spray a series of standards to determine the concentration giving about the same response. The volume (*V* ml) to be added to the second 50-ml aliquot can then be estimated, and should make $S_0/(S_1 - S_0)$ approximately unity.[8]

2. Adjust the gain control, on a trial spraying, so that the phosphorus-doped aliquot gives a galvanometer deflection of about 80–90% full scale.

3. Blank determinations on the reagents, including potassium hydroxide, have not shown any measurable response. If it is desired to measure any blank contribution by the base oil, as distinct from the phosphorus-containing additive, ash 1 g of base oil in the same way as for the sample and apply the result as a correction to the total phosphorus result. Provided that fresh resin is used, this correction has not been found to exceed 0·002% P, but high and variable blanks may be obtained if the resin is not fresh.

RESULTS AND DISCUSSION

The method was tested on a series of synthetic oil blends prepared in the laboratory, on a weight/weight basis, from OMD 370 base oil and analysed oil additives. The compositions of the blends and the phosphorus contents found are listed in Table I; these results were obtained at various intervals over a period of 5–6 weeks.

Since the procedure measures total phosphorus in the oil, a separate determination was run on the base oil, so that the added phosphorus could be obtained by difference and it was the application of this correction that revealed, in the early stages of the work, that high and variable blanks were likely to be recorded unless fresh resin was used and adequate stirring given in the initial treatment. Once this point was established, blank corrections dropped from a level of about 0·008–013% P to a steady figure of about 0·002% and this latter correction was applied to the results given in Table I. In fact, there was no evidence that the blank signal was actually due to phosphorus; spectral scans on solutions concentrated from larger (5 g) samples of base oil did not show the three characteristic HPO peaks at 512, 528 and 560 nm and the correction could therefore be regarded as a background compensation.

There was no indication that the phosphorus results shown in Table I were subject to interference by the other metals—calcium, barium and zinc—present in the oil additives.

A further series of analyses was made on 8 samples available through the Institute of Petroleum Atomic Absorption Sub-Panel ST-G-4E. The results, given in Table II, are shown in comparison with the nominal phosphorus contents; eventually, analytical results obtained by a range of techniques will become available on these oil blends.

In a separate precision test, 10 replicate analyses were performed on blend C.3 (Table I); the mean result was 0·039% P, with a coefficient of variation of ±5%.

TABLE II.—ANALYSIS OF I.P. OIL BLENDS

CONCLUSIONS

The cool-flame technique provides a rapid alternative to the standard chemical methods[2] for the determination of phosphorus in lubricating oils. A single determination can be completed in approximately 2½ hr and for a batch of 8 samples the time is reduced to approximately 1 hr per sample. The precision is acceptable in terms of the repeatability and reproducibility criteria laid down in the alternative methods,[2] and the accuracy is satisfactory as measured by the results shown in Table I, which indicate an average deviation of 0·0025% P from the true result.

Summary—The phosphorus content of lubricating oils is determined by measurement of the emission from the HPO molecular species at 528 nm in a cool hydrogen–nitrogen diffusion flame. The oil is ashed in the presence of potassium hydroxide and an aqueous extract of the melt is treated with ion-exchange resin to remove interferents, before aspiration into the flame. Analytical results are presented on samples containing phosphorus in the range 0·009–0·2%. The precision of the method is ±5% at the 0·04% phosphorus level.

Zusammenfassung—Der Phosphorgehalt von Schmierölen wird durch Messung der Emission des HPO-Moleküls bei 528 nm in einer kühlen Wasserstoff-Stickstoff-Diffusionsflamme bestimmt. Das Öl wird in Gegenwart von Kaliumhydroxid verascht und ein wäßriger Extrakt der Schmelze mit Ionenaustauschharz behandelt, um vor dem Ansaugen in die Flamme störende Bestandteile zu entfernen. Analysenergebnisse von Proben mit Phosphorgehalten im Bereich 0·009–0·2% werden angegeben. Die Genauigkeit der Methode beträgt ±5% bei 0·04% Phosphorgehalt.

Résumé—On dose la teneur en phosphore d'huiles de lubrification par mesure de l'émission de l'espèce moléculaire HPO à 528 nm dans une flamme de diffusion hydrogène-azote froide. L'huile est incinérée en la présence de potasse et l'on traite un extrait aqueux de la masse fondue par une résine échangeuse d'ions pour éliminer les substances gênantes, avant aspiration dans la flamme. On présente les résultats analytiques pour des échantillons contenant 0,009–0,2% de phosphore. La précision de la méthode est de ±5% pour une teneur en phosphore de 0,04%.

Neutron-activation analysis for thorium in zircon

(*Received* 26 *July* 1971. *Accepted* 19 *October* 1971)

NEUTRON-ACTIVATION analysis is a sensitive method for the determination of traces of thorium in geological specimens.[1-5] It is, therefore, surprising that the technique has not been applied for the determination of this element in zircon, although this analysis is of great geochemical interest.[6-8] Recently Mantel and co-workers,[9] Gordon *et al.*[10] and Meyer[11] have reported non-destructive neutron-activation determination of thorium in silicate rock samples, using Ge(Li) detectors. When attempts were made to analyse zircon samples for thorium by using a 3 ml Ge(Li) detector, the 299 and 311 keV gamma-rays of ^{233}Pa were barely identifiable over the high intensity Compton continuum from the prominent gamma-rays of ^{181}Hf. Hence it was not investigated further.

Preliminary experiments revealed that the radiochemical methods reported in the literature, based on ion-exchange separations of ^{233}Pa[5,12,13] or solvent extraction with *N*-benzoyl-*N*-phenylhydroxylamine (NBPHA),[14] when applied to zircons, did not give radiochemically pure ^{233}Pa. It was particularly difficult to remove ^{95}Nb, ^{182}Ta and ^{181}Hf produced in significant amounts on irradiation of zircons.[15]

Sill[16] has separated ^{233}Pa on barium sulphate. This procedure was applied in the present study and its adequacy for giving radiochemically pure ^{233}Pa was evaluated by the analysis of U.S.G.S. standard rock samples and then applied for the analysis of a number of zircons.

EXPERIMENTAL

Apparatus

Gamma-ray spectra were taken with a 400-channel analyser coupled to a 75 × 75 mm NaI(Tl) detector system.

Reagents

Thorium standard. Thorium dioxide (1·138 g) was dissolved by boiling with 50 ml of nitric acid (1 + 1). A few drops of 2% hydrofluoric acid were occasionally added to facilitate the dissolution. After repeated evaporation with nitric acid to remove residual fluoride, the solution was made up to 100 ml. The solution was further diluted to give a standard solution containing 100 μg of Th/ml.

Manganese carrier. Potassium permanganate (2·87 g) was dissolved in nitric acid (1 + 20), 2 or 3 drops of 30% hydrogen peroxide were added, the solution was boiled to remove excess of hydrogen peroxide, and diluted to give a solution containing 10 mg of Mn/ml.

Barium carrier. Barium chloride dihydrate (6·6 g) was dissolved in 100 ml of distilled water.

Zirconium carrier. Hydrated zirconyl nitrate (3·66 g) was heated with 5–10 ml of concentrated sulphuric acid, cooled and made up to 100 ml to give a solution containing 5 mg of Zr/ml.

Irradiation of samples

Samples were wrapped in high-purity aluminium foil. Thorium standard solution (100 μl) was evaporated on a small piece of aluminium foil and then wrapped in a second foil. The sample and standard were sealed in an aluminium can and irradiated for 2–3 days in the CIRUS reactor (natural uranium, heavy-water moderated reactor of the NRX type) at a flux of 3×10^{10} n.mm^{-2}.sec^{-1} and then cooled for a week.

Chemical procedure

Evaporate 1 ml of the barium carrier solution in a nickel crucible. Transfer 50–100 mg of irradiated sample, weighed to ±0·2 mg, to the crucible. Fuse with 1–2 g of sodium peroxide. Cool the fused mass and leach it with water in a 100-ml beaker, wash the crucible with water and with

Neutron-activation analysis for thorium in zircon

(*Received* 26 *July* 1971. *Accepted* 19 *October* 1971)

NEUTRON-ACTIVATION analysis is a sensitive method for the determination of traces of thorium in geological specimens.[1–5] It is, therefore, surprising that the technique has not been applied for the determination of this element in zircon, although this analysis is of great geochemical interest.[6–8] Recently Mantel and co-workers,[9] Gordon *et al.*[10] and Meyer[11] have reported non-destructive neutron-activation determination of thorium in silicate rock samples, using Ge(Li) detectors. When attempts were made to analyse zircon samples for thorium by using a 3 ml Ge(Li) detector, the 299 and 311 keV gamma-rays of ^{233}Pa were barely identifiable over the high intensity Compton continuum from the prominent gamma-rays of ^{181}Hf. Hence it was not investigated further.

Preliminary experiments revealed that the radiochemical methods reported in the literature, based on ion-exchange separations of ^{233}Pa[5,12,13] or solvent extraction with *N*-benzoyl-*N*-phenylhydroxylamine (NBPHA),[14] when applied to zircons, did not give radiochemically pure ^{233}Pa. It was particularly difficult to remove ^{95}Nb, ^{182}Ta and ^{181}Hf produced in significant amounts on irradiation of zircons.[15]

Sill[16] has separated ^{233}Pa on barium sulphate. This procedure was applied in the present study and its adequacy for giving radiochemically pure ^{233}Pa was evaluated by the analysis of U.S.G.S. standard rock samples and then applied for the analysis of a number of zircons.

EXPERIMENTAL

Apparatus

Gamma-ray spectra were taken with a 400-channel analyser coupled to a 75 × 75 mm NaI(Tl) detector system.

Reagents

Thorium standard. Thorium dioxide (1·138 g) was dissolved by boiling with 50 ml of nitric acid (1 + 1). A few drops of 2% hydrofluoric acid were occasionally added to facilitate the dissolution. After repeated evaporation with nitric acid to remove residual fluoride, the solution was made up to 100 ml. The solution was further diluted to give a standard solution containing 100 μg of Th/ml.

Manganese carrier. Potassium permanganate (2·87 g) was dissolved in nitric acid (1 + 20), 2 or 3 drops of 30% hydrogen peroxide were added, the solution was boiled to remove excess of hydrogen peroxide, and diluted to give a solution containing 10 mg of Mn/ml.

Barium carrier. Barium chloride dihydrate (6·6 g) was dissolved in 100 ml of distilled water.

Zirconium carrier. Hydrated zirconyl nitrate (3·66 g) was heated with 5–10 ml of concentrated sulphuric acid, cooled and made up to 100 ml to give a solution containing 5 mg of Zr/ml.

Irradiation of samples

Samples were wrapped in high-purity aluminium foil. Thorium standard solution (100 μl) was evaporated on a small piece of aluminium foil and then wrapped in a second foil. The sample and standard were sealed in an aluminium can and irradiated for 2–3 days in the CIRUS reactor (natural uranium, heavy-water moderated reactor of the NRX type) at a flux of 3×10^{10} n.mm^{-2}.sec^{-1} and then cooled for a week.

Chemical procedure

Evaporate 1 ml of the barium carrier solution in a nickel crucible. Transfer 50–100 mg of irradiated sample, weighed to ±0·2 mg, to the crucible. Fuse with 1–2 g of sodium peroxide. Cool the fused mass and leach it with water in a 100-ml beaker, wash the crucible with water and with nitric acid (1 + 1). Acidify the solution carefully with nitric acid. If silica separates, centrifuge and separate the residue. Transfer the residue to a platinum dish and volatilize the silica with a hydrofluoric–nitric acid mixture. Remove the fluorides by repeated evaporation with nitric acid. Dissolve the residue in nitric acid (1 + 1) and transfer to the main solution. Add 20 mg of manganese carrier to the solution and heat on a water-bath. Add about 2 g of solid potassium bromate to precipitate manganese dioxide. Boil, centrifuge and reject the supernatant liquid. Transfer the precipitate to a beaker and dissolve the manganese dioxide with nitric acid (1 + 1) and 2 or 3 drops of dilute hydrogen peroxide. Boil the solution and reprecipitate the manganese dioxide. Dissolve the precipitate in nitric acid (1 + 1) and a few drops of dilute hydrogen peroxide, add 1 ml of the barium solution, and 7 ml of concentrated sulphuric acid. Heat the solution on a hot-plate to fumes of sulphur trioxide. Cool and add 25–30 ml of water to precipitate barium sulphate. Boil the solution for 5 min, cool, centrifuge and reject the supernatant. Slurry the barium sulphate with water and transfer to the same beaker, wash the centrifuge tube with 7 ml of sulphuric acid and add the washings to the beaker. Evaporate the solution on a hot-plate to fumes of sulphur trioxide. Cool the solution to 50–70°, add 150–200 mg of potassium dichromate to oxidize ^{239}Np, and heat the beaker on a boiling water-bath for 5 min. Cool to about 50°, dilute to 40–50 ml with water, boil for 5 min. Filter the solution through a demountable filtering unit containing a small circle of Whatman No. 42 filter paper. Take out the filter circle, with the precipitate, dry it and mount it on an aluminium card, and count the activity of ^{233}Pa under the 310 keV photopeak. Check the decay curve.

Dissolve with dilute hydrochloric acid the aluminium foil containing the thorium standard and evaporate to dryness. Dissolve the residue in 10 ml of nitric acid (1 + 1) and dilute the solution to a known volume. Treat a suitable aliquot as described above.

RESULTS AND DISCUSSION

The hydrolytic nature of protactinium and the non-availability of suitable carriers have led many earlier workers to employ ^{231}Pa for evaluating the yield of ^{233}Pa in radiochemical methods.[4,17,18] Others[5,19–23] established that high and nearly constant yields are obtained in their procedures before the analysis of samples by these methods. The results of Sill[16] and the preliminary studies made in the present work indicated the nearly quantitative recovery of ^{233}Pa during its co-precipitation on barium sulphate. The method was, therefore, applied to the determination of Th in U.S.G.S. standard samples. The results given in Table I indicate the adequacy of the method. However, it was felt desirable to establish that similar recoveries were obtained in the analysis of matrices such as zircon. Hence one portion of the irradiated zircon was spiked with a known amount of the thorium standard and the thorium content computed by the standard addition technique. This value was comparable with that obtained by direct comparison of the activities from the sample and the

standard. Replicate analyses of a zircon from Chavara gave an overall relative standard deviation of 6.4% for the method. A number of other zircons were also analysed by this method and the results are given in Table II.

The radiochemical purity of the ^{233}Pa isolated from the sample was established from the γ-ray spectrum, which revealed the absence of any peak not attributable to ^{233}Pa, the decay under the 310 keV photo-peak which gave a half-life of 27–28 days comparable with 27 days reported in the literature,[28] and the absence of gamma-active radio nuclides emitting photons of energy greater that 400 keV.

Spectrophotometric molybdenum determination with thiolactic acid*

(*Received* 15 *July* 1971. *Accepted* 22 *October* 1971)

THE DETERMINATION of molybdenum by estimating the yellow complex formed with thioglycollic acid was first described by Will and Yoe.[1] They found, however, that numerous ions interfere at concentrations less than 25 ppm. Přibil and Adam[2] eliminated many of these interferences by extracting the complex into a 5% Alamine 336-S solution and measuring the absorbance of the organic phase at 370 nm. Bismuth(III), mercury(II), tungsten(VI), chloride, fluoride and nitrate ions interfered.

Busev, Nacu and Redzit[3] used thiolactic acid (TLA) and some of its anilides for the colorimetric estimation of molybdenum. The molybdenum complex with TLA was extracted into an organic solvent in the presence of benzylthiuronium chloride. Molybdenum was successfully determined in the presence of any of nine different metal ions.

We have developed a simple spectrophotometric method for molybdenum that is more selective than the thioglycollic acid method[1] and is quicker and requires less manipulation than the extraction procedures.[2,3] The present method is also very selective.

EXPERIMENTAL

Reagents

α-Thiolactic acid (TLA) was obtained from Evans Chemetics, Inc. and used as received. The assay was reported as 99.4%.

Molybdenum(VI) solutions were prepared by dissolving MoO_3 in 7*M* ammonia solution and diluting to 500 ml. The 0.05*M* solutions of other metal ions were made by dissolving the appropriate salts in distilled water (slightly acidified). Tartaric acid (0.05*M*) was added to antimony(V), tin(IV), titanium(IV) and tungsten(VI) solutions to prevent hydrolysis.

* Work was performed in the Ames Laboratory of the U.S. Atomic Energy Commission. Contribution No. *3057*.

Procedure

Take a sample containing 120–1920 μg of molybdenum and dilute to about 35 ml. Add a masking agent if copper, tungsten, iron or bismuth are present (Table I). Adjust the pH to between 1.0 and 1.6 with sulphuric acid, perchloric acid or sodium hydroxide. Transfer to a 50-ml volumetric flask, add 0.5 ml of TLA and dilute to volume with water. Measure the absorbance at 365 nm *vs* a blank.

TABLE I.—MASKING AGENTS USED IN REDUCING INTERFERENCE IN THE ABSORPTION OF THE TLA–Mo COMPLEX

Ion	Added, *mmole*	Masking agent	Added, *mmole*
Cu*	0.25	thiourea	2.4
Fe	0.25	H_3PO_4	1.5
Bi	0.25	EDTA	2.5
W	0.25	tartrate	1.0

* Absorbance must be measured within 10 min.

RESULTS AND DISCUSSION

Absorption spectra

Spectra of α-thiolactic acid and the TLA–molybdenum complex at pH 1.0 are shown in Fig. 1. The shoulder on the TLA–molybdenum spectrum is useful in the determination of molybdenum. A wavelength of 365 nm was found to be the most free from foreign ion interferences.

Effect of pH

Figure 2 shows the effect of pH on the absorbance of the TLA–Mo complex at a molybdenum concentration of $2 \times 10^{-4}M$. The chemistry of molybdenum is complex because of the polymerized species formed in acidic solutions. Therefore, no attempt was made to determine the cause for the deviation between pH 1.6 and 2.6. This phenomenon occurred in three separate experiments using perchloric, hydrochloric and sulphuric acid, respectively. A pH range of 1.0–1.6 was selected. The absorbance is less dependent on small changes in acidity within this range and there are fewer interferences than at higher pH values.

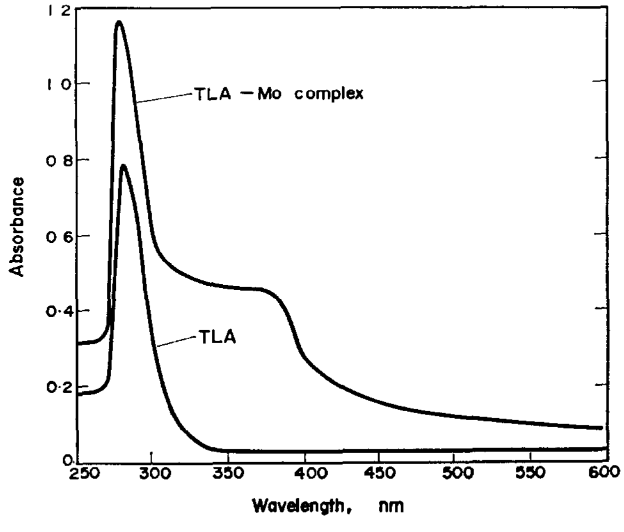

FIG. 1.—Absorption spectra of TLA and TLA–Mo complex in perchloric acid solution. (Mo = $2 \times 10^{-4}M$)

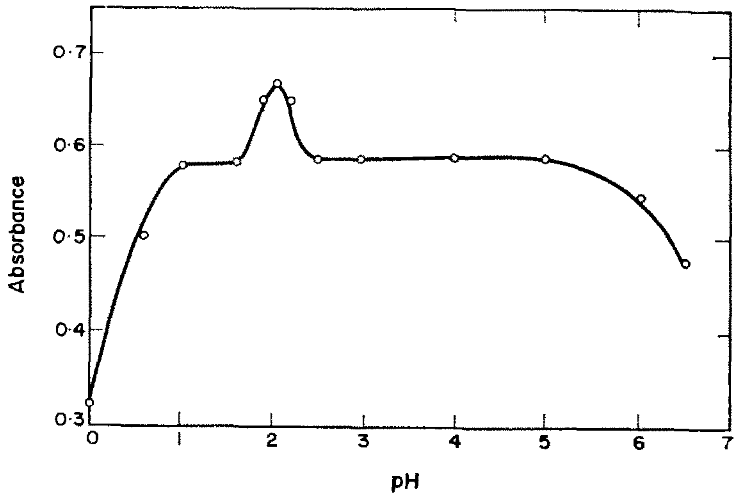

FIG. 2.—Effect of pH on the absorbance of the TLA-Mo complex. (Mo = 2 × $10^{-4}M$)

Stability

With thioglycollic acid as a colour-forming reagent for molybdenum, the solution became slightly turbid and this turbidity increased on standing. This did not occur when TLA was used. The TLA-molybdenum complex formed at pH 1.0–1.6 gave constant absorbance readings for more than 24 hr with no evidence of turbidity.

Beer's law

The complex obeyed Beer's law for molybdenum concentrations between 2.5×10^{-5} and $4 \times 10^{-4}M$. The molar absorptivity was 280 $\text{l.mole}^{-1}.\text{mm}^{-1}$ at 365 nm. At a pH of 1.0–1.6 this compares with a value of approximately 210 $\text{l.mole}^{-1}.\text{mm}^{-1}$ as calculated from the results of Will and Yoe at pH 1 for thioglycollic acid.

Effect of foreign ions

The absorbance of solutions containing 5 μmole of molybdenum and 500 times as much (2.5 mmole) of a foreign metal ion was measured. The following ions caused no interference: Na, Al, K, Ca, Cr(III), Ni, Zn, Ga, Sr, Y, Zr, Cd, La, Yb, Hf, Hg(II), Pb, Th. In sulphuric acid solution 2.5 mmole of tin(IV), antimony(V), or uranium(VI) caused no interference, but did interfere seriously in hydrochloric acid solution. Vanadium(V) and chromium(VI) were reduced to vanadium(IV) and chromium(III), respectively. These did not interfere with the determination of molybdenum if sufficient TLA was added to compensate for the amount consumed in the reduction.

Copper(II), tungsten(VI), iron(III) and bismuth caused some error in the molybdenum determination unless a suitable masking agent was added as listed in Table I. Phosphoric acid effectively masked iron(III), and thiourea masked copper(II) if the absorbance in the latter case was read within 10 min. Tungsten(VI) caused no error if tartrate was added, and bismuth did not interfere if EDTA was present. The effect of any combination of masking agents was not studied. Of the metal ions investigated, only gold(III), platinum(IV) and silver(I) interfered with the molybdenum determination.

The effect of several anions was investigated. Sulphate, perchlorate, phosphate or chloride (5.0 mmole), EDTA (2.5 mmole) and acetate, nitrate, tartrate, citrate (1.0 mmole) caused no error. Fluoride interfered by causing low results.

Determination of traces of iron(II) in the presence of iron(III) by the bathophenanthroline method

(*Received* 4 *May* 1971. *Accepted* 17 *October* 1971)

THE BATHOPHENANTHROLINE method is generally used for determination of the sum of iron(II) and (III) in boiler water. In investigation of the deposition mechanism of iron oxides and corrosion of boiler tubes, it is necessary to know the concentration of the iron(II). Titration methods,[1] Clark's bathophenanthroline method[2] and the ammonium thiocyanate–thioglycol method[3] cannot be applied to boiler water, because the concentration of iron(II) is too low, of the order of ppM (parts per milliard). Lee's bathophenanthroline method[4] gave a positive error for solutions with a high ratio of iron(III) to iron(II).

The present paper describes attempts to determine iron(II) with bathophenanthroline after masking of iron(III).

EXPERIMENTAL

Reagents

A standard solution of iron(II) was prepared by dissolving reagent-grade ferrous ammonium sulphate in water acidified with sulphuric acid, and diluting with demineralized water. This solution was prepared daily, and was saturated with carbon dioxide and kept in an atmosphere of carbon dioxide. Bathophenanthroline (4,7-diphenyl-1,10-phenanthroline) was dissolved in isopropanol. Other chemicals were chemically pure or reagent-grade.

Procedure

Sample solution [200 ml, 0·2–6 μg of iron(II)] was adjusted to a pH between 4·2 and 4·7 with 2 ml of $3M$ hydrochloric acid and 5 ml of $2{\cdot}6M$ ammonium acetate, and transferred to a 300-ml separatory funnel; 2 ml of 2·5% w/v sodium pyrophosphate solution were added and the solution was left standing for 5 min for the iron(III) pyrophosphate complex to form. Then 2 ml of $0{\cdot}25M$ bathophenanthroline in isopropanol were added and the solution was shaken mechanically for 1 min; 25 ml of n-butanol were added and the shaking continued for 1 min. After settling (for 5 min) the aqueous phase was discarded, and 10 ml of methanol were added to the organic phase, which was then shaken to dissolve any water adherent to the funnel. The absorbance of the organic phase was measured in a 100-mm cell at 533 nm against a reagent blank.

RESULTS AND DISCUSSION

Choice of stabilizing agent

A major problem was to establish a solution environment that would keep the iron species in their original oxidation states. Several potential stabilizing agents including citrate, tartrate, oxalate, malonate, salicylate, phosphate and pyrophosphate were tested.

The absorbance of the organic phase was measured in a 100-mm cell at 533 nm against a reagent blank.

RESULTS AND DISCUSSION

Choice of stabilizing agent

A major problem was to establish a solution environment that would keep the iron species in their original oxidation states. Several potential stabilizing agents including citrate, tartrate, oxalate, malonate, salicylate, phosphate and pyrophosphate were tested.

Only pyrophosphate masked iron(III) without suppressing the colour reaction or reducing iron(III).

Choice of solvent

The ferrous bathophenanthroline complex has usually been extracted with isopentanol and any droplets of water in the extract have been dissolved with isopropanol. However, when pyrophosphate is used, the colour of the isopentanol–isopropanol extract is unstable. Chloroform, carbon tetrachloride, n-hexanol, n-butanol, ketones and esters were tested as extraction solvents, and isopropanol, ethanol and methanol as solvents for residual water.

With solvents other than alcohols no coloured product was extracted. Even with alcohols as solvents, the colour faded with time, and a relationship existed between the rate of fading and the molar concentration of hydroxyl groups (sum of alcohol and water OH groups) in the organic phase. Although no explanation for this relationship was forthcoming, it appeared that the lower alcohols gave the more stable colour. Therefore n-butanol and methanol were the solvents selected.

The shaking time required for the complete formation of ferrous bathophenanthroline complex was about 2 min and after shaking, its colour showed no change for 15 min and then increased.

Effect of sodium pyrophosphate

Figure 1 shows the effect of sodium pyrophosphate on the absorbance for solutions containing iron(II) with and without iron(III). In the range from 2·6 to 60 mg sodium pyrophosphate masked iron(III) and permitted iron(II) to react with bathophenanthroline. Therefore, 25 mg (1 ml of 2·5% solution) were used in further work. This amount was adequate to prevent interference of iron(III) in up to 20-fold ratio to iron(II) if a 10% error could be tolerated (Table I). However, the masking reaction is not instantaneous, taking ~3 min at 15° and ~2 min at 20°. At 32° the absorbance begins to fall at ~6 min reaction time, so 5 min were allowed at room temperature. The time needed for

complete extraction was 2 min; the absorbance remained constant for 15 min but then gradually increased.

Effect of pH

The absorbance was unaffected by pH in the range 3·0–4·7 if iron(III) was originally present and 4·2–4·7 if it was absent (Fig. 2). The latter range was therefore used.

Absorption spectrum and stability of the colour

The absorption maximum was at 533 nm and the molar absorptivity was $2 \cdot 03 \times 10^3$ $\text{l.mole}^{-1}.\text{mm}^{-1}$, slightly less than in isopentanol-isopropanol medium. Beer's law was obeyed for iron(II) concentrations up to 30 ppM in the aqueous solution (coefficient of variation 4% for 5 ppM). The absorbance in n-butanol is constant for 20 min and for at least 3 hr in butanol-methanol.

Effect of diverse ions

As shown in Table I, nickel, zinc, manganese(II) and chromium(III) had little effect on the absorbance. Copper(II) gave a negative error, because it catalysed the oxidation of ferrous ion with oxygen. Cobalt(II) gave a positive error, because cobalt reduced ferric ion in the presence of bathophenanthroline.[3] Only 25 ppM of copper and 5 ppM of cobalt could be tolerated.

Summary—Traces of iron(II) (1–30 ppM) in the presence of iron(III) were determined (error <10%) by the bathophenanthroline method. Interference of iron(III) was eliminated by masking with sodium pyrophosphate (2·5–60 mg). The iron(II) complex was extracted with n-butanol, at pH 4·2–4·7.

Zusammenfassung—Spuren des Eisen(II) (1–30 ppM) in Gegenwart des Eisen(III) wurden mit Bathophenanthrolin Methode bestimmt (Fehler <10%). Störung von Eisen(III) wurde mittels Maskierung mit Natriumpyrophosphate (2,5–60 mg) beseitigt. Eisen(II) Komplex wurde in n-butanol, at pH 4,2–4,7 extrahiert.

Résumé—On a déterminé trace de fer(II) (1–30 ppM) en présence de fer(III) (erreur 10%) par la méthode de bathopénanthroline. On a éliminé l'interférence de fer(III) par la dissimulation avec pyrophosphate de sodium (2,5–60 mg). On a extrait la complexe de fer(II) avec n-butanol à pH 4,2–4,7.

Determination of inorganic impurities in vinyl chloride by activation analysis

(*Received* 15 *March* 1971. *Accepted* 24 *June* 1971)

THE LACK of experimental data concerning the traces of inorganic compounds found in vinyl chloride is due to the difficulties in using classical analytical methods on gases or liquids at low temperature for the detection of trace impurities. The object of this paper is to examine the estimation of trace inorganic impurities in vinyl chloride. The high sensitivity of the activation method compared with the usual chemical methods makes it suitable for this purpose. The vinyl chloride obtained by synthesis from acetylene and hydrogen chloride (mercuric chloride as catalyst) is likely to be contaminated by such inorganic constituents as arsenic and phosphorus which are present in acetylene as AsH_3 and PH_3.

A vinyl chloride sample irradiated with a thermal neutron flux gives mainly one radioactive isotope, ^{38}Cl, *via* an (n, γ) reaction, in high yield.[1] For an irradiation time of a few hours all other nuclear reactions may be neglected. The presence of elements other than C, H and Cl (*e.g.*, As) might lead to the formation of radioisotopes which could be determined.

A slow neutron flux of $1{\cdot}2 \times 10^9$ n/mm²/sec with a fast neutron component of $6{\cdot}2 \times 10^7$ n/mm²/sec was used. Under these conditions the existence of nuclear reactions such as (n, α) and (n, p) for chlorine are possible and could result in the formation of ^{32}P and ^{35}S, the first of which would interfere in the determination of phosphorus by β-counting. The (n, p) reaction occurs even with slow neutrons but a cross-section for reactor neutrons of 590 ± 90 mb is given.[2] The effect of ^{35}S is easily eliminated, owing to its low β-energy of 0·2 MeV. ^{32}P may result either from the $^{31}P(n, \gamma)^{32}P$ reaction (which is directly related to the phosphorus present as impurity) or from $^{35}Cl(n, \alpha)^{32}P$. The contribution of the latter nuclear reaction is low, owing to the subcadmium neutron spectrum having a cross-section of 0·08 mb.[3] In the presence of fast neutrons this value might be higher.

EXPERIMENTAL

Sample irradiation

Vinyl chloride samples were introduced into quartz vials cooled with liquid nitrogen in a special aluminium vessel insulated with expanded polystyrene. In order to keep the sample cool the facility of adding further refrigerant was required and the only reactor channel suitable for this purpose had the low neutron flux of 10^7 n/mm²/sec and could not be used for analytical determinations. This difficulty was overcome by taking advantage of the tendency of the liquid monomer to polymerize. This polymer is solid and stable at 25° and could be used as the sample in the normal channel which has a neutron flux of $1{\cdot}2 \times 10^9$ n/mm²/sec.

The industrial synthesis of vinyl chloride uses acetylene and hydrogen chloride. Acetylene is contaminated by AsH_3 and PH_3 generated from calcium arsenide and phosphide present in calcium carbide. The acetylene and hydrogen chloride are also contaminated with traces of oxygen, which can give oxygenated compounds. Other organic contaminants of the monomer may be produced during the reaction process. These organic compounds and, more efficiently, vinyl chloride react with arsine and phosphine, resulting in the retention of these elements in the polymer. The same is true for bromine (existing as HBr in HCl).

Determination of inorganic impurities in vinyl chloride by activation analysis

(*Received* 15 *March* 1971. *Accepted* 24 *June* 1971)

THE LACK of experimental data concerning the traces of inorganic compounds found in vinyl chloride is due to the difficulties in using classical analytical methods on gases or liquids at low temperature for the detection of trace impurities. The object of this paper is to examine the estimation of trace inorganic impurities in vinyl chloride. The high sensitivity of the activation method compared with the usual chemical methods makes it suitable for this purpose. The vinyl chloride obtained by synthesis from acetylene and hydrogen chloride (mercuric chloride as catalyst) is likely to be contaminated by such inorganic constituents as arsenic and phosphorus which are present in acetylene as AsH_3 and PH_3.

A vinyl chloride sample irradiated with a thermal neutron flux gives mainly one radioactive isotope, ^{38}Cl, *via* an (n, γ) reaction, in high yield.[1] For an irradiation time of a few hours all other nuclear reactions may be neglected. The presence of elements other than C, H and Cl (*e.g.*, As) might lead to the formation of radioisotopes which could be determined.

A slow neutron flux of $1{\cdot}2 \times 10^9$ n/mm²/sec with a fast neutron component of $6{\cdot}2 \times 10^7$ n/mm²/sec was used. Under these conditions the existence of nuclear reactions such as (n, α) and (n, p) for chlorine are possible and could result in the formation of ^{32}P and ^{35}S, the first of which would interfere in the determination of phosphorus by β-counting. The (n, p) reaction occurs even with slow neutrons but a cross-section for reactor neutrons of 590 ± 90 mb is given.[2] The effect of ^{35}S is easily eliminated, owing to its low β-energy of 0·2 MeV. ^{32}P may result either from the $^{31}P(n, \gamma)^{32}P$ reaction (which is directly related to the phosphorus present as impurity) or from $^{35}Cl(n, \alpha)^{32}P$. The contribution of the latter nuclear reaction is low, owing to the subcadmium neutron spectrum having a cross-section of 0·08 mb.[3] In the presence of fast neutrons this value might be higher.

EXPERIMENTAL

Sample irradiation

Vinyl chloride samples were introduced into quartz vials cooled with liquid nitrogen in a special aluminium vessel insulated with expanded polystyrene. In order to keep the sample cool the facility of adding further refrigerant was required and the only reactor channel suitable for this purpose had the low neutron flux of 10^7 n/mm²/sec and could not be used for analytical determinations. This difficulty was overcome by taking advantage of the tendency of the liquid monomer to polymerize. This polymer is solid and stable at 25° and could be used as the sample in the normal channel which has a neutron flux of $1{\cdot}2 \times 10^9$ n/mm²/sec.

The industrial synthesis of vinyl chloride uses acetylene and hydrogen chloride. Acetylene is contaminated by AsH_3 and PH_3 generated from calcium arsenide and phosphide present in calcium carbide. The acetylene and hydrogen chloride are also contaminated with traces of oxygen, which can give oxygenated compounds. Other organic contaminants of the monomer may be produced during the reaction process. These organic compounds and, more efficiently, vinyl chloride react with arsine and phosphine, resulting in the retention of these elements in the polymer. The same is true for bromine (existing as HBr in HCl).

Standards

Preliminary qualitative determinations identified the inorganic contaminants as arsenic, bromine and phosphorus.

Standards of As_2O_3, KBr, HCl and Na_2HPO_4 were irradiated at the same time as the samples, under similar conditions to avoid errors due to neutron flux fluctuations, shielding effects, geometry and time interval.

Radioactivity measurements

Most of the radioactivity measurements were based on gamma spectrometry with a 42 × 45 mm NaI(Tl) scintillation counter associated with a 400-channel pulse-height analyser (SA-40 B, Intertechnique). A 25 $\mu g/mm^2$ end-window GM counter for β-measurements was also used for ^{32}P. Liquefied samples were counted in a special apparatus cooled with liquid nitrogen.

RESULTS AND DISCUSSION

When liquefied monomer has been irradiated (usually for 3 hr) the resulting γ-ray spectrum is similar to that shown in Fig. 1. The presence of ^{38}Cl(37·3-min half-life) from the nuclear reaction $^{37}Cl(n, \gamma)$ ^{38}Cl is evident and does not permit an estimation of any inorganic component. When ^{38}Cl has completely decayed, the existence of the peaks is revealed at energies of 0·56, 0·78, 1·04, 1·2, 1·7, and 2·17 MeV (spectrum 2).

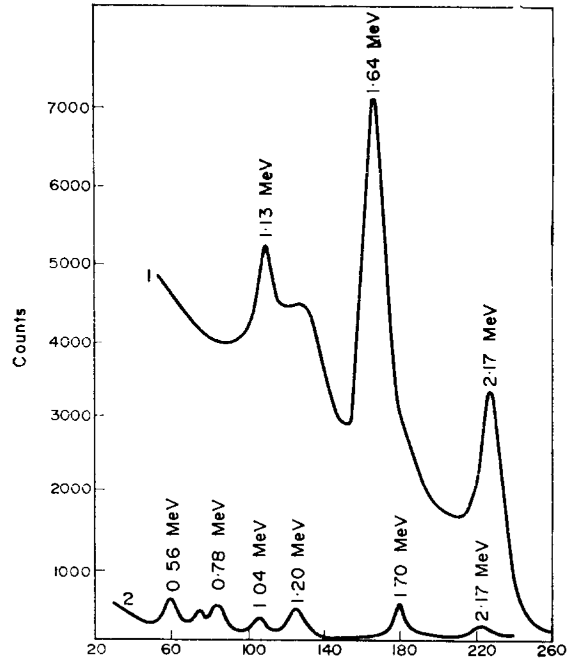

FIG. 1.—Liquefied monomer gamma-spectra.
1. In the presence of ^{38}Cl.
2. In the absence of ^{38}Cl.

From nuclear data,[1,4] the peaks at 0·56, 0·66 and perhaps 1·2 MeV are ascribed to ^{76}As. The remaining peaks cannot be ascribed to ^{76}As because of the low activities involved. The height of the 0·56-MeV peak is inexplicable,[4] but the low neutron flux resulted in bad counting statistics. The alternative method of irradiation of polyvinyl chloride was therefore used. The counting statistics were thus improved owing to an increased neutron flux and a larger sample size. The γ-spectra obtained for sample and standard are illustrated in Fig. 2.

By comparison with literature data it is clear that ^{76}As obtained in the nuclear reaction[1,4] $^{75}As(n, \gamma)$ ^{76}As is not the only component involved. The ^{82}Br must also be taken into consideration with its

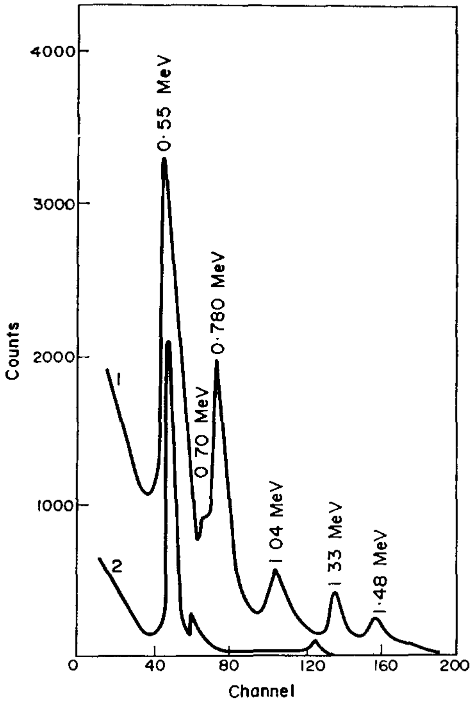

Fig. 2.—Gamma-spectra.
1. Solid polymerized sample.

characteristic peaks at 0·55, 0·70, 0·78, 1·04, 1·33 and 1·48 MeV (higher energies are neglected),[4] as shown in Fig. 2. This proves the existence of the nuclear reaction ^{81}Br(n, γ) ^{82}Br. The target element abundance 49·46% ^{81}Br and $\sigma = 3{\cdot}3$ b explain the presence of this component.[1] A decay curve for the 0·78 and 1·04-MeV peaks, which except for the 0·55-MeV peak are the most important, gave a half-life of 35·4 hr, characteristic of ^{82}Br.

The 0·55-MeV peak results from the superposition of the ^{76}As 0·56-MeV peak and the ^{82}Br 0·55-MeV peak. A decay curve for the ^{76}As peak gave a half-life of 31 hr. Because of the half-lives of ^{76}As of 26·4 hr,[1] and ^{82}Br of 35·4 hr,[1] it is clear that both components are present and this fact is reflected in the half-life of 31 hr found. If this peak alone is used the two activities must be determined separately, which is not possible from the decay curve obtained. A mathematical treatment permits the estimation of the activities of two components at time $t = 0$ when their half-lives are known.[5] The total activity I (measured) is a resultant of the two components I_1 and I_2 given in equation (1)

$$I = I_1 \exp(-\lambda_1 t) + I_2 \exp(-\lambda_2 t) \tag{1}$$

where the λ's are the disintegration constants.

Dividing this equation by $\exp(-\lambda_1 t)$ gives

$$I \exp(\lambda_1 t) = I_1 + I_2 \exp[(\lambda_1 - \lambda_2)t] \tag{2}$$

A plot of $I \exp(\lambda_1 t)$ against $\exp[(\lambda_1 - \lambda_2)t]$ gives the total activity at $t = 0$, when $I = I_1^0 + I_2^0$, as an intercept on the ordinate. The slope gives I_2^0.

The values obtained for one example were ^{76}As, $I_1^0 = 1{\cdot}7 \times 10^4$ c/Δt; ^{82}Br, $I_2^0 = 3{\cdot}60 \times 10^4$ c/Δt. The results for 3 experiments are given in Table I. In this case the value of I_1^0 for ^{76}As from equation (2) was compared with the corresponding 0·56-MeV peak activity of the standard.

For the bromine determination two methods have been used. In the first, potassium bromide was used as the standard and the peak at 0·78 MeV was the most suitable to use because it involved the highest activity (except for the 0·55-MeV peak). The corresponding peaks of sample and standard were compared and the results are given in Table I. The second method was employed to check the

results obtained for bromine, starting with the ^{76}As determination. The activity dN/dt induced in the target is given by the formula:

$$dN/dt = N\sigma\phi[1 - \exp(-\lambda t_1)] \qquad (3)$$

where N refers to the target quantity (abundance included) σ is the cross-section, ϕ the flux and t_1 the time of irradiation. The activity A measured with a scintillation counter for the time interval Δt at time t_2 is given by:

$$A = N\sigma\phi[1 - \exp(-\lambda t_1)] \exp(-\lambda t_2)\Omega\eta\Delta t \qquad (4)$$

where Ω includes the geometry and the scattering effects and η is the photopeak efficiency.

It would be convenient to write two equations of type (4); one for arsenic and one for bromine. Their ratio would eliminate several constants which are the same in both cases. The only unknown would be the quantity of bromine, which is deduced from the amount of arsenic previously determined (Table I) and the activities of ^{76}As and ^{82}Br found from equation (2). The results are given in Table II.

It must be emphasized that this alternative method is a check on the values obtained but the differences between the bromine results obtained by the two methods result from variations in cross-sections, geometry and statistics. The cross-section is referred to thermal neutrons, not to reactor neutrons, and a substantial error might thereby result. The fluctuations from the mean value in Tables I and II are acceptable under the given experimental conditions.

A note of caution must be introduced in estimating ^{76}As. In the presence of fast neutrons ($6{\cdot}2 \times 10^7$ n/mm^2/sec) and bromine as contaminant, the following nuclear reaction is theoretically possible: $^{79}Br(n, \alpha)\,^{76}As$. However, owing to the low amount of bromine present (the same order of magnitude as the arsenic), the lower fast-neutron flux and the much lower cross-section, the presence of this nuclear reaction is certainly not detectable. The neutron spectrum of energies, combined with the reaction threshold, leads to the virtual absence of (n, α) reactions.

When all other radioactive products have decayed, the only components supposed to be present are ^{35}S and ^{32}P. The former was obtained in the $^{35}Cl(n, p)^{35}S$ reaction even with slow neutrons. The second radioisotope is more likely to result with fast neutrons in the $^{35}Cl(n, \alpha)\,^{32}P$ nuclear process. Interference of the last reaction with the $^{31}P(n, \gamma)\,^{32}P$ reaction which permits the estimation of the phosphorus impurity may be expected and steps taken to avoid this contribution.

The vinyl chloride sample was irradiated at the same time as hydrogen chloride and Na_2HPO_4 as standards. The pure hydrochloric acid leads to ^{35}S and ^{32}P following (n, p) and (n, α) nuclear reactions. The same is true for the sample, including the $^{31}P(n, \gamma)\,^{32}P$ reaction which occurs in the presence of phosphorus as impurity. The Na_2HPO_4 standard is used for the (n, γ) reaction of phosphorus. In all

TABLE III.—DETERMINATION OF PHOSPHORUS
(Sample weight 302 mg, using Na_2HPO_4 and HCl solution as standards. P = 4·3 mg and Cl = 172 mg)

No. of sample	Sample activity	HCl activity	Sample activity due to P	Activity of 4·3–mg P standard	P impurity in sample
	counts/172 *mg* Cl		*counts*/172 *mg* Cl	*counts*	%
1	3250	2970	280	21600	$1{\cdot}85 \times 10^{-2}$
2	3050	2760	290	19300	$2{\cdot}14 \times 10^{-2}$

Mean value $(2{\cdot}0 \pm 0{\cdot}15) \times 10^{-2}$ %

cases a reasonable decay time was allowed before counting, in order to eliminate the effect of interfering radioactive products.

Beta-counting was later employed and a decay and absorption curve followed. When the decay curve was measured, an absorber (aluminium) was used to eliminate the effect of ^{35}S. The half-life determined in the classical way gave a value of 14·3 d ± 5%.

When hydrochloric acid activity was subtracted from that of the sample, the ^{32}P and ^{35}S contributions were eliminated. The residual activity was ascribed to the (n, γ) reaction of the phosphorus impurity, which is compared with the standard activity. For the purposes of calculation, it was preferred to eliminate some undesirable weak activities by absorption with aluminium. Results of the phosphorus determination are given in Table III.

CONCLUSIONS

The thermal-neutron activation method used has permitted the estimation of arsenic and bromine by gamma-spectrometry and phosphorus by beta counting. In each case the fluctuations from the mean value are 10–20%. Discrepancies between the values obtained by the two methods of calculation are explained by side-effects and the influence of the cross-sections.

SANDA MURGALESCU

Summary—Trace impurities in vinyl chloride have been determined by activation analysis in a reactor thermal neutron flux of $1{\cdot}2 \times 10^9$ n/mm²/sec. Irradiations were carried out on liquid and solid samples at the same time as a standard. Gamma-spectrometry was used to reveal the presence of arsenic and bromine, the quantitative estimation being based on two calculus methods., The impurities determined were: arsenic $8{\cdot}0 \pm 0{\cdot}6 \times 10^{-4}$%, bromine $3{\cdot}07 \pm 0{\cdot}2 \times 10^{-3}$% and phosphorus $2{\cdot}0 \pm 0{\cdot}15 \times 10^{-2}$%.

Zusammenfassung—Spuren-Verunreinigungen in Vinylchlorid wurden aktivierungsanalytisch bei einem thermischen Neutronenfluß von $1{,}2 \times 10^9$ n/mm²/sec im Reaktor bestimmt. Die Bestrahlungen wurden an flüssigen und festen Proben gleichzeitig mit einem Standard ausgeführt. Mit Hilfe der Gamma-Spektrometrie wurde Arsen und Brom nachgewiesen, wobei für die quantitative Auswertung zwei Verfahren zur Anwendung kamen. Folgende Verunreinigungen wurden bestimmt: Arsen $8{,}0 \pm 0{,}6 \times 10^{-4}$%, Brom $3{,}07 \pm 0{,}2 \times 10^{-3}$% und Phosphor $2{,}0 \pm 0{,}15 \times 10^{-2}$%.

Résumé—On a déterminé des impuretés à l'état de traces dans le chlorure de vinyle par analyse par activation dans un flux de neutrons thermiques de réacteur de $1{,}2 \times 10^9$ n/mm²/s. Les irradiations ont ete effectuées sur des échantillons liquides et solides en même temps que sur un étalon. On a utilisé la spectrométrie gamma pour révéler la présence d'arsenic et de brome, l'estimation quantitative étant basée sur deux méthodes de calcul. On a déterminé les impuretés suivantes: arsenic $8{,}0 \pm 0{,}6 \times 10^{-4}$%, brome $3{,}07 \pm 0{,}2 \times 10^{-3}$% et phosphore $2{,}0 \pm 0{,}15 \times 10^{-2}$%.

Organic and inorganic ion-exchange beads as indicators in redox and precipitation titrations

(*Received* 30 *April* 1971. *Accepted* 21 *October* 1971)

RECENTLY ion-exchange resins have found some new analytical applications in the detection of metal ions.[1] Resin beads, loaded with indicators, have also been used for the titration of acids and bases,[2,3] but, so far as we are aware, have not been used as indicators in precipitation titrations.

Some inorganic ion-exchangers show great selectivity towards some metal ions, and adsorb them irreversibly. In these cases the metal ion is probably incorporated in the matrix and the bead of the exchanger in this particular form can be used advantageously as an indicator. Thus stannic arsenate adsorbs iron(III) irreversibly,[4] and in this form can be used for titration of metal ions with ferrocyanide.

EXPERIMENTAL

Reagents

Potassium ferrocyanide. The trihydrate was dried at 100° for 1 hr. A $0{\cdot}10M$ ferrocyanide solution was prepared by exact weighing and 1 g of sodium carbonate was added per litre.

Zinc sulphate, $0{\cdot}1M$. Standardized with EDTA.

Ferrous ammonium sulphate, $0{\cdot}1M$.

Potassium dichromate, $0{\cdot}1N$.

Silver nitrate, $0{\cdot}1M$.

Ceric sulphate solution. Standardized against arsenious oxide. Nitrates of other metal ions were used.

Resin beads. Dowex 50W × 8 (20–50 mesh) resin beads in Na^+ form were soaked in alcoholic diphenylamine solution, and in H^+ form were soaked in *p*-dimethylaminobenzylidenerhodanine, for use in redox and argentometric titrations respectively.

Procedures

Determination of Zn, Pb, Ag *and* Cd. To the metal ion solutions were added 5 ml of appropriate acid solution ($1M$ acetic for lead, silver and cadmium and $1M$ hydrochloric for zinc), 1 ml of distilled alcohol and 3 or 4 beads in the Fe(III) form. The solutions were titrated with potassium ferrocyanide from a 5-ml microburette. Near the end-point the solution was vigorously shaken after the addition of each drop. A sharp change from yellow to blue on the beads occurred at the end-point owing to the formation of Prussian Blue. For titrant concentrations of $0{\cdot}005$–$0{\cdot}1M$ and metal ion amounts of 0·01–1 m mole the titration error was from 0 to +0·4%.

Titration of Fe(II) *or* $Na_2S_2O_3$. To 5 ml of Fe(II) solution were added 5 ml of $5N$ sulphuric acid, 1 ml of 85% phosphoric acid and 3 or 4 beads in the diphenylamine form. The solution was titrated with potassium dichromate, ceric sulphate, or potassium permanganate from a 5-ml microburette with vigorous shaking after each drop. The end-point colour change from yellow to blue on the resin surface is sharp. The titrant concentration was varied between 0·005 and $0{\cdot}1N$, but the error remained more or less constant in the range +0·2–0·5%,

Determination of Cl^-, Br^-, I^-. To 5 ml of metal halide solution were added a few *p*-dimethylaminobenzylidenerhodanine beads. In the case of chloride and bromide 5 ml of alcohol were also added. On titration with silver nitrate there was a sharp colour change from yellow to violet orange at the end-point. The results are in error by +0·1–0·3%

Successive determination of Zn^{2+} *and* Cl^-. To a mixture of zinc chloride and sodium chloride 5 ml of alcohol and a few *p*-dimethylaminobenzylidenerohdanine beads were added. The solution

Organic and inorganic ion-exchange beads as indicators in redox and precipitation titrations

(*Received* 30 *April* 1971. *Accepted* 21 *October* 1971)

RECENTLY ion-exchange resins have found some new analytical applications in the detection of metal ions.[1] Resin beads, loaded with indicators, have also been used for the titration of acids and bases,[2,3] but, so far as we are aware, have not been used as indicators in precipitation titrations.

Some inorganic ion-exchangers show great selectivity towards some metal ions, and adsorb them irreversibly. In these cases the metal ion is probably incorporated in the matrix and the bead of the exchanger in this particular form can be used advantageously as an indicator. Thus stannic arsenate adsorbs iron(III) irreversibly,[4] and in this form can be used for titration of metal ions with ferrocyanide.

EXPERIMENTAL

Reagents

Potassium ferrocyanide. The trihydrate was dried at 100° for 1 hr. A 0·10*M* ferrocyanide solution was prepared by exact weighing and 1 g of sodium carbonate was added per litre.

Zinc sulphate, 0·1*M*. Standardized with EDTA.

Ferrous ammonium sulphate, 0·1*M*.

Potassium dichromate, 0·1*N*.

Silver nitrate, 0·1*M*.

Ceric sulphate solution. Standardized against arsenious oxide. Nitrates of other metal ions were used.

Resin beads. Dowex 50W × 8 (20–50 mesh) resin beads in Na^+ form were soaked in alcoholic diphenylamine solution, and in H^+ form were soaked in *p*-dimethylaminobenzylidenerhodanine, for use in redox and argentometric titrations respectively.

Procedures

Determination of Zn, Pb, Ag *and* Cd. To the metal ion solutions were added 5 ml of appropriate acid solution (1*M* acetic for lead, silver and cadmium and 1*M* hydrochloric for zinc), 1 ml of distilled alcohol and 3 or 4 beads in the Fe(III) form. The solutions were titrated with potassium ferrocyanide from a 5-ml microburette. Near the end-point the solution was vigorously shaken after the addition of each drop. A sharp change from yellow to blue on the beads occurred at the end-point owing to the formation of Prussian Blue. For titrant concentrations of 0·005–0·1*M* and metal ion amounts of 0·01–1 m mole the titration error was from 0 to +0·4%.

Titration of Fe(II) *or* $Na_2S_2O_3$. To 5 ml of Fe(II) solution were added 5 ml of 5*N* sulphuric acid, 1 ml of 85% phosphoric acid and 3 or 4 beads in the diphenylamine form. The solution was titrated with potassium dichromate, ceric sulphate, or potassium permanganate from a 5-ml microburette with vigorous shaking after each drop. The end-point colour change from yellow to blue on the resin surface is sharp. The titrant concentration was varied between 0·005 and 0·1*N*, but the error remained more or less constant in the range +0·2–0·5%,

Determination of Cl^-, Br^-, I^-. To 5 ml of metal halide solution were added a few *p*-dimethylaminobenzylidenerhodanine beads. In the case of chloride and bromide 5 ml of alcohol were also added. On titration with silver nitrate there was a sharp colour change from yellow to violet orange at the end-point. The results are in error by +0·1–0·3%

Successive determination of Zn^{2+} *and* Cl^-. To a mixture of zinc chloride and sodium chloride 5 ml of alcohol and a few *p*-dimethylaminobenzylidenerohdanine beads were added. The solution was titrated with silver nitrate till a sharp colour change from yellow to violet on the resin phase was observed. Then 5 ml of 1M hydrochloric acid were added. The slight excess of silver ions present at the equivalence point, was precipitated as the chloride, and a few Fe(III)-form beads were added and zinc was titrated with ferrocyanide. The results are reasonable, the errors for Cl^- being in the range from −3·0 to +0·2% and for zinc(II) from −1·2 to +0·5%.

Simultaneous determination of silver and lead. A silver nitrate–lead nitrate mixture was taken in a burette and added drop by drop to a known volume of sodium chloride solution containing 5 ml of ethanol and resin beads in the *p*-dimethylaminobenzylidenerhodanine form. At the equivalence point silver was precipitated as the chloride and lead nitrate remained in solution. A few drops of sodium chloride were added at the equivalence point to precipitate excess of silver (to minimize the error in the determination of lead), 5 ml of 1M acetic acid were added and lead was titrated with potassium ferrocyanide, with Fe(III) beads as indicator. The errors are from 0 to +0·3% for silver and from −0·7 to 0·90 for lead. Chloride solutions (0·001N) can be titrated with 0·005–0·001N silver with an error of +0·3–0·9%.

Determination of chloride in a coloured solution. The chloride in a cobalt(II)–chloride mixture is determined as above. The addition of a few ml of saturated cobalt nitrate solution intensifies the colour but does not effect the end-point.

Effect of diverse ions in Zn *determination.* To 5 ml of 0·002M zinc solution the following ions were added in the quantities (in mg) given in parentheses. No interference in the zinc determination was noticed when *p*-dimethylaminobenzylidenerhodanine was used as an indicator: Ba^{2+}(100), Sr^{2+}(100), Na^+(240), Al^{3+}(40), Ca^{2+}(120), NH_4^+(40). Thiosulphate, chlorate, perchlorate, sulphite, thiosulphate and thiocyanate do not interfere.

The following ions did not interfere at the levels indicated when stannic arsenate beads were used: Ba^{2+}(120), Al^{3+}(60), NH_4^+(60), Na^+(320) Ca^{2+}(140).

Care must be taken that a drop of titrant does not fall on the resin beads. A blank correction was made in each case. The results are summarized in Table I.

TABLE I.—COMPARISON OF THE BEAD METHOD WITH VOLHARD'S METHOD IN THE TITRATION OF Cl^- IN $CoCl_2$

Volhard method			Proposed method		
Chloride taken, *mg*	Chloride found, *mg*	Error %	Chloride taken, *mg*	Chloride found, *mg*	Error, %
6·35	3·19	−49	6·35	6·30	−0·7
12·78	9·58	−25	12·78	12·80	+0·1
9·58	6·55	−30	9·58	9·60	+0·2

DISCUSSION

In the determination of halides the method is superior to the Mohr method since chloride, bromide and iodide can be accurately titrated, and Mohr's method is not applicable to the determination of iodides and thiocyanates. Further the Mohr titration is possible only in the pH range of 7–10·5, whereas the bead method can be used with accuracy from pH 2 to 7. At pH less than 2 the method is inaccurate. Volhard's method is undoubtedly superior to Mohr's method, but it cannot be used if the solution itself has an intense colour. Thus in the titration of cobalt chloride the Volhard method gives wrong results whereas the bead method is accurate. It is also superior to the adsorption indicator method, since it is possible to titrate 0·001M chloride solution by this method. It is not possible to titrate chloride solution more dilute than 0·005M, using fluoroscein as indicator.

Another novel feature is that resin beads can be used for the successive determination of two substances. Thus zinc and chloride or silver and lead can also be determined without prior separation. This is feasible because it is possible to add different indicators in succession. This is not the case with the conventional indicators.

Another advantage is that selective, specific and sensitive spot test reagents can be appropriately used for volumetric titrations. The use of *p*-dimethylaminobenzylidenerhodanine is a case in point. It has been used for the titration of silver nitrate with potassium chloride or bromide in 6M nitric acid or 5M sulphuric acid.[5]

The greatest advantage of resin bead indicators is that a single indicator can be used when different species are titrated with the same titrant. Thus Zn, Pb, Ag, Cd and Cu have been titrated, using resin beads in the Fe(III) form as the indicator.

The method is particularly useful in dilute solutions, where the precipitates are not so dense and the colour change on the beads can be easily detected at the equivalence point. In more concentrated solutions, the beads are not visible through the thick precipitate, but the colour change on the resin phase can be seen by raising the beaker above eye level and viewing the beads at the bottom.

As zinc ferrocyanide is more soluble than Prussian Blue, the end-point is obtained rather early when zinc is titrated with ferrocyanide in aqueous medium and the results are erroneous. However if alcohol is added before the titration is started, accurate results are obtained, because the alcohol lowers the solubility product of zinc ferrocyanide. It will also lower the solubility product of iron(III) ferrocyanide but presumably to a lesser extent. Addition of alcohol may similarly improve the end-point for Pb, Ag and Cd titration. The addition of alcohol has a remarkable effect on the interference by diverse ions. Thus without alcohol barium interfered in the zinc titration even in 1:1 ratio, but in the presence of alcohol even 100 times as much did not interfere. The same is true for other ions. This is because the addition of alcohol suppresses the ionization of these electrolytes and prevents their interference. Stannic arsenate beads give even better results. Since Fe(III) is irreversibly adsorbed, the addition of large quantities of interfering ions does not affect the titrations.

Summary—Resin beads in the Fe(III) or *p*-dimethylaminobenzylidenerhodanine form are used as indicators in precipitation titrations with $K_3Fe(CN)_6$ and Ag^+. Resin beads with diphenylamine adsorbed on them can be used as indicators in cerimetric titrations. They have some advantages over conventional indicators.

Zusammenfassung—Harzperlen in der Fe(III)- oder in der p-Dimethylaminobenzylidenrhodamin-Form werden als Indikatoren bei Fällungstitrationen mit $K_3Fe(CN)_6$ und Ag^+ verwendet. Harzperlen mit adsorbiertem Diphenylamin können als Indikatoren bei cerimetrischen Titrationen verwendet werden. Sie haben gegenüber herkömmlichen Indikatoren einige Vorteile.

Résumé—On utilise des perles de résine sous la forme Fe(III) ou *p*-diméthylaminobenzylidène rhodamine comme indicateurs dans les titrages par précipitation avec $K_3Fe(CN)_6$ et Ag^+. On peut utiliser les perles de résine ayant adsorbé de la diphénylamine comme indicateurs dans les titrages cérimétriques. Elles ont quelques avantages par rapport aux indicateurs usuels.

ANNOTATION

On the analytical utility of quasi-linear molecular emission spectra

(*Received* 15 *July* 1971. *Accepted* 21 *October* 1971)

A UNIQUE development regarding the spectra of aromatic hydrocarbons was reported by a Russian spectroscopist, E. V. Shpol'skii about two decades ago.[1] Certain aromatic molecules, when frozen in a crystalline matrix of selected n-paraffin solvents, gave unusually well-resolved fine-structured luminescence emission spectra. This phenomenon, known as the Shpol'skii effect, was soon confirmed by others.[2] Two review articles appeared a few years later and generated considerable interest.[3,4]

The appearance of very sharp lines (5–10 cm^{-1} half-bandwidth) in the luminescence emission spectra of molecules in rigid n-paraffin solvents at low temperatures has been attributed to the embedding of a solute molecule in the crystalline lattice of the solvent, thereby rendering it much like an oriented gas molecule. When the molecular dimensions of the solute and solvent are very similar, the probability of observing quasi-linear spectra is greatly enhanced.[4,5]

In the last three years, more than 40 scientific papers have appeared on the subject of the Shpol'skii effect. Several[6,7] have strongly suggested widespread analytical application; few, however, have presented a detailed description of a specific analytical method along with the usual data stating reproducibility, accuracy and precision. Perhaps the closest approach to a true utilization of the Shpol'skii effect for an analytical determination is that of Muel and Lacroix;[8] 3,4-benzopyrene in cigarette smoke was determined, with octane used as solvent at −190°. A standard addition procedure was employed, using the sharp emission line of 3,4-benzopyrene at 403·0 nm. The reported limit of detection was 0·1 ng/ml with a relative precision of 10%. Some question, however, remains whether (under the experimental conditions used for the analysis) the fine structure, *i.e.*, "quasi-line spectra" observed, differed significantly from that obtained in an ordinary low-temperature fluorescence spectrum, because 3,4-benzopyrene exhibits fine structure in many solvents at low temperature.

We wish to offer some possible explanations for the absence of widespread utilization of the Shpol'skii effect in analytical chemistry. On the basis of much experimental evidence and a survey of the recent literature, we have reached the following conclusions regarding the analytical utility of the Shpol'skii effect.

(*i*) The availability of suitable commercial luminescence instrumentation severely limits analytical applications. Because quasi-line spectra generally exhibit half-band widths smaller than 0·1 nm, an instrument of very high resolution is necessary. To be analytically useful, the instrument must also have a high light-gathering power. Such an instrument can be prohibitively expensive. When spectra are obtained with instruments having lesser resolving power, little difference in the width of lines of the emission spectra is observed for the same molecule in many different solvents. In addition, molecules exhibiting the Shpol'skii effect generally give luminescence emission spectra possessing a reasonable amount of structure in many different solvents anyway, and so the gain in recorded spectral structure of molecules in solvents exhibiting the Shpol'skii effect is minimal with most analytical luminescence spectrometric systems.

(*ii*) At the present time, the efforts necessary for preparation of the unknown sample,[8] choice of solvent[4,5] and consideration of little studied matrix effects[9] on the intensity of low-temperature quasi-linear luminescence spectra must be unduly great.

(*iii*) Intensity of luminescence of quasi-line spectra often has an irregular and non-reproducible concentration dependence. Shpol'skii *et al.*[10] and Bolotonikova[11] have discussed the effects of molecular aggregation and energy transfer on the intensity of quasi-line spectra. They reported a reasonable luminescence intensity due to the Shpol'skii effect in the 10^{-3}–$10^{-2}M$ concentration region. At lower concentrations, band spectra from molecules aggregated inhomogeneously in the sample and not incorporated into the crystalline matrix may obscure the line spectra. Also, at concentrations above about $10^{-2}M$, the molecular aggregates absorb strongly but do not emit, whereas quasi-line spectra can only be observed from molecules incorporated in the solvent crystal lattice.

(*iv*) In addition to the solvent–solute restrictions regarding molecular size, and formation of molecular aggregates, problems arise with respect to the rate of freezing of solutions. Dokunikhin *et al.*[12] reported on the dependence of both intensity and width of quasi-lines as a function of the rate of freezing.

In light of the findings by the Russian workers[10-12] regarding the dependence of the intensity and width of quasi-lines, and of the results of a concerted effort on our part, we feel that under the experimental conditions normally employed in luminescence analysis there exists little difference between low-temperature emission spectra and the spectra expected as a result of the Shpol'skii effect. We feel at the same time that there are advantages of low-temperature luminescence in analysis but that one must be careful to distinguish between true quasi-line spectra and fine-structured emission resulting from a simple temperature effect.

It is our belief that combined instrumental and theoretical restrictions limit the usefulness of true quasi-line spectra for analytical determinations. Use of the Shpol'skii effect for qualitative identification purposes may prove to be of much greater use, although considerable caution must still be used in the interpretation of spectra.

LETTER TO THE EDITOR

A rapid volumetric method for determination of thallium(I)

SIR,

During investigation of the complexation tendency of thallium(I) and (III) with certain sulphur compounds such as thiourea, thioglycollic acid, dithio-oxamide and thiosemicarbazide, it became necessary to develop a rapid and accurate method for the determination of thallium(I). In the bromine method[1] use is made of phenol or sulphosalicylic acid to destroy the excess of bromine remaining after oxidation of thallium(I) to thallium(III). This involves formation of undesirable precipitates. We have found that dimethylsulphoxide (DMSO) destroys almost immediately the excess of bromine, in the cold. DMSO and its oxidation product dimethylsulphone remain in solution and cause no interference in the iodometric titration of thallium(III). Based on this, a rapid and accurate method for the determination of thallium(I) in many oxide and co-ordination systems has been developed and satisfactorily used in these laboratories for over two years. The results obtained are correct to within 0·5%.

The recommended method is as follows. A sample containing 0·5–1 mmole of thallium(I) is dissolved or suspended in about 50 ml of 0·5*M* hydrochloric acid. Excess of bromine water (15–30 ml of 0·1*N*) is added, the mixture is swirled for a minute, then 2–3 ml of dimethylsulphoxide are added to destroy the unutilized bromine. After a minute, 15 ml of 10% potassium iodide solution are added and the iodine liberated by the thallium(III) is titrated with standard thiosulphate, after addition of 10 ml of 2% starch solution.

ANALYTICAL CHEMISTRY IN JAPAN

TAITIRO FUJINAGA
Department of Chemistry, Faculty of Science, University of Kyoto, Kyoto, Japan

IN JAPAN, "Chemistry" did not exist until 1837, when Yoan Utagawa, an official scholar of the Tokugawa Government, published the first chemistry book, *Shamitsu Kaiso*. He writes in its introduction as follows.

"What is chemistry? It is a field of science in Western countries. Japan and China have not had such learning. It is chemistry that makes the characteristics of materials clear by decomposing and synthesizing them. It can be said that chemists are able not only to clarify the scheme designed by Nature, but also to participate in the work of Nature. The domain of chemistry is quite extensive and is neighbour to physics; when the physicist is unable to clarify the characteristics of a material by observing it from without, the chemist analyses it and makes clear Nature's scheme."

Shamitsu Kaiso is believed to be the translation of *Elements of Experimental Chemistry*, written by W. Henry, which had been translated into Dutch. At that time Dutch was the only foreign language permitted by the Tokugawa Government and this book was imported and translated into Japanese. Therefore, chemistry in Japan can be said to have arisen in England. The book contains five main chapters and one additional chapter. In the additional chapter qualitative analysis, preparative chemistry and mineral water analysis are described. The names of persons and substances were coined by Utagawa in Chinese characters. For example nitrogen was written as azoticum 亞曹知究母. This way of thinking has become the basis for the contemporary chemical terms of Japan. Owing to this fact, we are able to learn not only chemistry but also all fields of science in our mother tongue, a condition which has not always been realized in most of the nations of Asia.

For example, *Handbook of Analytical Chemistry*, edited by Prof. Kenjiro Kimura and published last year by the Japan Society for Analytical Chemistry, presents a tremendous amount of analytical data together with precise descriptions of most of the analytical methodologies, in 1,610 pages. *Encyclopedia of Analytical Chemistry*, edited by Prof. Soichiro Musha and published also last year by Kyoritsu Shuppan Co. Ltd., contains 12,000 terms with 2,544 figures in 2,228 pages, the equivalent of which may not be found even in the Western languages.

Education

In 1868, right after the Meiji Restoration, the government founded the Imperial Institute of Chemistry and later successively nine Imperial Universities, beginning with Tokyo in 1877, followed by various local main cities. There the course of chemistry was initiated and studied from the beginning at the Faculty of Science. In analytical chemistry, a professorial chair was first introduced in 1918 at the Department of Chemistry, Faculty of Science in the Imperial University of Tohoku, next in 1922 in Kyoto, in 1925 in Tokyo, in 1932 in Hokkaido, in 1941 in Kyushu, in 1942 in Nagoya and finally in Osaka. Likewise at most of the universities the course of analytical chemistry was introduced and studied similarly to the other fields of chemistry.

Meanwhile, in many universities courses of analytical chemistry were initiated in the faculties of engineering, pharmacology, medicine, agriculture and liberal arts. For instance, at the Faculty of Engineering of the University of Tokyo they have three chairs of analytical chemistry in their Department of Industrial Chemistry. Besides faculties, some ancillary institutes in the universities have chairs of analytical chemistry. Thus in one university there are more than ten professors working in the field of analytical chemistry, with an equivalent number of associate professors and twice as many instructors and assistants.

Before World War II there were nine Imperial Universities, including those in Souel and Taipei. General MacArthur, at the time of the occupation of Japan, thought that seven Imperial Universities were too few and status-prone: he felt the necessity of establishing universities in every prefecture of Japan, which can be compared to the state university system in the United States. In spite of Japan being a small country, the number of prefectures is almost the same as the number of states in the U.S.A. and seventy-five governmental universities and thirty-two other public universities were established (after the War the adjective "Imperial" was replaced by "governmental"). He also thought that private universities should have equal authority with the governmental universities, and so two hundred and eighty-one private universities have been founded. Most of these universities have more than one chair of analytical chemistry. This university policy as well as the establishment of the Japanese Constitution can be said to be one of the most successful decisions which have greatly contributed to today's peace and prosperity in Japan. Needless to say, this decision also contributed basically to the development of analytical chemistry: the Japanese Government and her Ministry of Education going along with the policy, advised the establishment of a division of analytical chemistry in the Department of Chemistry for all universities, irrespective of whether they were public or private. Even at present many leading chemists in Japan believe that analytical chemistry is the basis of chemistry, and that the "systematic qualitative analysis" originated by Noyes should be the first step of practice for students to become capable researchers. However, in spite of the fact that the educational level and the research facilities for analytical chemistry have made a remarkable progress both in quality and quantity, recent students seem to have lost interest in learning and researching on the methodology of analytical chemistry.

Research

Thanks to the increase of universities and hence the number of analytical professors, analytical chemistry has been greatly developed, followed by great progress in instrumentation in this field. However, it is hardly possible to describe the whole picture of the development of analytical chemistry in Japan, so the lineage in the Faculties of Science in the former Imperial Universities will be briefly introduced. At the University of Tohoku, Professor Emeritus Matsusuke Kobayshi, who is the foundation-holder of the chair, initiated the use of liquid amalgam for the reduction of metals in place of the solid amalgam of the Jones reductor: this modification has been applied to many practical analyses after thorough experimental and theoretical treatment. Professor Em. Shinichiro Hakomori, who introduced electrometric methods and cathode ray luminescence analysis, succeeded to this position, followed by Professor

Em. Yoshinaga Oka, who introduced γ-ray activation analysis besides many investigations in the field of chemical analysis. The position is now held by Professor Nobuo Suzuki, who is studying mainly the solvent effect in the extraction process, and substoichiometric determinations. At the University of Kyoto the late Professor Em. Motooki Matsui developed electrochemistry as applied to oragnic synthesis and inorganic analysis. Professor Em. Masayoshi Ishibashi succeeded to this position and contributed to the development of instrumental analysis, especially in the field of inorganic polarography. He also applied co-precipitation phenomena and instrumental analysis to the study of oceanography, determining more than 50 elements in sea-water, among which 17 elements were discovered there for the first time. After Prof. Ishibashi's retirement Professor Taitiro Fujinaga succeeded to his chair, and is mainly studying new electrochemical methodologies such as current-scan polarography, electrolytic chromatography, non-aqueous solvent voltammetry, *etc.* At the University of Tokyo Professor Em. Kenjiro Kimura was the first holder of the chair of analytical chemistry and performed extensive instrumental research, especially in the fields of X-ray and emission spectroscopy, and radiochemical analysis with his colleague Professor Em. Eiichi Minami, who succeeded to his position. They have also contributed to the development of geochemistry, especially that of hot springs in Japan. After their retirement, Professor Shizuo Fujiwara succeeded to the position and is studying mainly the nuclear magnetic and electron spin resonance spectroscopy as applied to analytical chemistry. At the University of Hokkaido, Professor Em. Yasumitsu Uzumasa initiated the analytical chemistry division and studied mainly emission and absorption spectroscopy, applied to geochemical analysis of hot springs and volcanic substances. The position then passed to Professor Tomihiko Kambara who is mainly studying the diffusion processes related to polarography and gas chromatography. At the University of Kyushu, Professor Sakae Shinoda, who mainly studied X-ray analysis of rare earth elements, Professor Iwaji Iwasaki who developed trace analysis applied to geochemical samples, and Professor Jun Yoshimura who mainly investigated the use of ion-exchange resins applied to inorganic analysis, have occupied the chair of analytical chemistry. Professor Shigeru Ohashi is now working mainly on gel-permeation chromatography as applied to the analysis of inorganic complexes. At the University of Nagoya, Professor Em. Ken Sugawara founded the division and concentrated on the development of trace analysis applied to the analysis of lake, river and spring water. The position is now held by Professor Motoharu Tanaka who is mainly interested in equilibrium studies on various titration and extraction processes. At the University of Osaka, Professor Shigero Ikeda is working on various problems in electron spectroscopy (ESCA) and electroanalytical chemistry in non-aqueous solvents. It should be emphasized that many achievements in the development of analytical chemistry have also been realized in other faculties and universities. Here let me quote one example. At the Faculty of Agriculture of the University of Kyoto, the late Professor Masuzo Shikata devised the polarograph with Professor Jaroslav Heyrovský in Prague in 1924, and next year the first commercial model was made by the Yanagimoto Mfg. Co. under his guidance. Professor Shikata with his successor Professor Em. Isamu Tachi initiated the study of organic polarography and contributed much to the development of polarography in this country: they established the Polarographic Society of Japan in 1960 and publish bimonthly the *Review of Polarography* in English.

Industrial analysis

In 1900 the Tokyo Industrial Research Institute (IRI) was established and later several IRI's were founded in Osaka and other main cities, which have taken charge of the analyses requested by the public. In the Tokyo IRI, the Analytical Chemistry Centre was established in 1957. There are many kinds of new analytical instruments and up-to-date machinery on display and used for furthering research. President Dr. Yoichiro Mashiko is making a big effort for its further development.

In 1925 the first Japanese Engineering Standard (JES), on the *Analysis of Copper-base Alloys*, appeared, and was followed by many series of other JES. After World War II these standards have been succeeded by the Japanese Industrial Standards (JIS). The JIS give criteria for various practical methods of analysis to be applied to raw materials and industrial products. Professor Em. Takayuki Somiya of the University of Tokyo, Faculty of Engineering, contributed much to the development of applied analytical chemistry and process control in industry. This position was then held by Professor Hitoshi Kamata, who is working mainly on emission spectroscopy and mass spectroscopy applied to industrial analysis. Professor Em. Hidehiro Goto of the University of Tohoku made a big contribution to the study of trace analysis, using spectrophotometric and catalytic methods, which were applied to the analysis of iron and steel. Overall, the analytical laboratories of industrial factories, research institutes and universities have been rapidly improved in these decades. For example most of the iron and steel works are equipped with an automatic emission spectrometric analyser, the so-called "Quantometer" together with a pneumatic sample conveyer and telephone reply system between smelting furnace and laboratory. With this facility, the production quality is finely controlled while the melt is still hot. This kind of rapid analysis is widely adopted in various industries and even further automated by use of computers. The contribution of analytical chemistry to the study of environmental science is also worth mentioning: such analytical information on flowing water as degree of transparency (photometric), chemical oxygen demands (coulometric), pH (glass electrode), dissolved oxygen (amperometric), cyanide (ion-selective electrode) and electrical conductivity, *etc*, are automatically recorded at unmanned stations on rivers and lakes. The records are sent to the central analytical laboratory, through cable if necessary. Air pollution due to carbon monoxide, sulphur dioxide (infrared absorption) and oxidants (coulometric) is also analysed automatically and in many cities shown to the public with a digital electric sign.

Analytical instrument industries

Most of the large analytical instruments and pure chemicals for analytical purposes had to be imported before World War II. On the other hand the first model of a polarograph, designed by Professor Shikata, was commercialized in 1925 almost at the same time that Nejedley in Czechoslovakia sold the world's first commercial model. Likewise the background of the present prosperity in the industry of analytical instruments had been slowly growing up. The expansion of analytical instruments in the market is remarkable in these decades: Yanagimoto Mfg. Co. is now selling a series of polarographs which can be linked in a single frame unit to give the complete range of direct current, alternative current, square-wave and radiofrequency-modulated square-wave polarograms. Shimazu Mfg. Co. manufactures X-ray fluorescence spectrometers, including an electron microprobe analyser and various kinds of automated emission and absorption spectrometers. Hitachi Mfg. Co. produces a mass spectrometer, electron microscope and other chromatographic and optical instruments. Japan Electronics and Optical Laboratories Inc. is well known for its nuclear magnetic and electron spin resonance spectrometers. In the field of reagent chemicals, Wakojunyaku Co., Tokyo Kasei Kogyo Co. and Dojindo Co. have developed many kinds of organic reagents, especially chelating agents, which are supplied to overseas customers. It is difficult to cover all the manufactures of instruments and chemicals in this short article: it can be said that almost any analytical tools which have appeared in the literature are available in the domestic markets.

The Japan Analytical Instruments Manufacturers' Association was organized in 1960. At that time the annual gross output of analytical instruments was less than ten million U.S. dollars. However by 1970 it reached one hundred million dollars and one fifth was exported throughout the world.

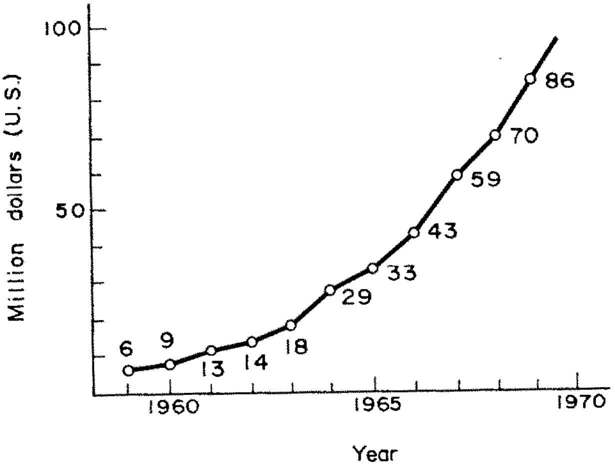

FIG 1.—Growth of Analytical Instrument Production.

TABLE I.—PRODUCTION AND EXPORT OF ANALYTICAL INSTRUMENTS (APRIL 1969–MARCH 1970)

	Output		Export

Chemical societies

Finally, let me introduce briefly the Japan Society for Analytical Chemistry (JSAC), which celebrated its 20th anniversary last year. Most of the analytical chemists in Japan belong to the Chemical Society of Japan which was established about one hundred years ago, and some others to the Society of Agricultural Chemistry of Japan or the Pharmaceutical Society Japan as well as to the CSJ. After twenty years, the number of members of the JSAC exceeds 6,000; there are 31 honorary members, 850 company associates, 315 public members and 6,510 regular members. They publish their organ *Bunseki-Kagaku*, the "*Japan Analyst*", in Japanese with English abstracts every month, and the members and the subscribers receive the organ every month plus one annual review. Each issue carries an average of 20 original research papers. Altogether some 600 papers on analytical chemistry are published each year in Japanese journals. The JSAC holds one regular annual meeting and two local discussion meetings a year and at the annual meeting they grant the Society Prize to a few members who have contributed to the development of analytical chemistry and Progress Prizes to some promising young members. Besides these, they also award the Distinguished Service Prize to those who have served more than 25 years as chemical analysts in a company or research institute: the total number of D. S. Prize winners reached 710 in 1971. The JSAC has organized an International Congress on Analytical Chemistry in Kyoto in April, 1972 (from 3rd to 7th) sponsored by the International Union of Pure and Applied Chemistry, and the Science Council of Japan. Professor Em. Yuji Shibata, ex-president and member of the Japanese Academy of Science, who acted as the first President of the JSAC in 1951, is taking the presidentship of the International Congress. The Congress is hoped to be a fruitful meeting of 700 analytical chemists, including 300 overseas participants.

In conclusion, present-day Japan has been provided with all things abundantly, and it is not exceptional in the field of analytical chemistry either. However, it is most important now for the Japanese analytical chemists to make greater efforts to create new methodologies based on unique principles in order to contribute to analytical chemistry as a science as Mr. Utagawa described 145 years ago.

ION-SELECTIVE CHALCOGENIDE ELECTRODES FOR A NUMBER OF CATIONS

HIROSHI HIRATA and KENJI HIGASHIYAMA
Wireless Research Laboratory, Matsushita Electric Industrial Co. Ltd.
Kadoma, Osaka, Japan

(*Received* 7 *June* 1971. *Accepted* 2 *December* 1971)

Summary—Ion-selective chalcogenide disc electrodes have been developed which are responsive to cations such as silver, lead, chromium(III), nickel, cobalt(II), cadmium, zinc, copper(II) and manganese(II) ions. Each was prepared by using the corresponding metal chalcogenide with silver sulphide. An electrode was assembled with both a compacted and a sintered disc. The sintered electrodes were more sensitive and stable than the compacted ones. Response to silver ion was 59·5 mV/pAg, to lead, nickel, cadmium, zinc and copper(II) 29·5 mV/pM and to chromium(III) 20 mV/pM. Cobalt(II) and manganese(II) electrodes had a non-Nernstian response of 25 mV/pM. Both selenides and tellurides can be used for potentiometric determination, but the manganese(II) electrode serves as an analytical tool only when the disc consists of manganese(II) telluride and silver sulphide.

ION-SELECTIVE solid-state membrane electrodes have been developed for a number of cations and anions.[1] They may be classified into four main groups; single crystal membrane electrodes; compacted polycrystalline electrodes; heterogeneous membrane electrodes; glass electrodes. Strictly speaking, the sintered electrodes to be dealt with in the present paper belong to a fifth class.

A range of commercial solid-state membrane electrodes which respond to such cations as silver, copper(II) lead and cadmium has been introduced by Orion Research Inc. They are based on the corresponding metal sulphide with silver sulphide in the form of compacted discs.[1]

In our laboratory, a new type of ceramic electrode has been prepared by using sintering and hot-pressing methods; copper(I) sulphide ceramic electrode for copper(II),[2] lead sulphide–silver sulphide–copper(I) sulphide electrode for lead,[3] and cadmium sulphide–silver sulphide–copper(I) sulphide electrode for cadmium[4] have been developed in succession.

They proved to have several excellent characteristics, especially in their long-range stability and their reproducibility of response, and in their mechanical properties such as abrasion-resistance and breakage-strength.

Heterogeneous membrane electrodes for cations have also been developed in our laboratory; electrodes fabricated from silicone rubber membranes impregnated with copper(I) sulphide,[5] lead sulphide[6] and cadmium sulphide–silver sulphide.[7]

There are limitations in employing metal sulphides; the use of other sulphides is not possible because they are insufficiently conducting or are appreciably soluble in neutral and acidic solutions, or at least rather hygroscopic. Consequently, the use of metal chalcogenides other than sulphides has been investigated. As a result, metal chalcogenide electrodes were found to be applicable to a considerably wide variety of cations such as silver, lead, copper(II), cadmium, nickel, cobalt(II), manganese(II), zinc and chromium(III) ions.[8]

In this paper, the sensitivities of these disc electrodes are described.

EXPERIMENTAL

Apparatus

Measurements of e.m.f. to 0·1 mV were made on an Orion 801 pH-meter with the ion-selective electrode in conjunction with a double-junction reference electrode to prevent contamination from test solution.

Chemicals

Starting materials for preparing the electrodes, such as silver, lead, copper, nickel, cobalt, zinc, cadmium, manganese, chromium, sulphur, selenium and tellurium were commercially available and as pure as possible. All chemicals were analytical-reagent grade and used without further purification.

Stock metal in solutions (1*M*) were made by dissolving weighed amounts of the nitrates in distilled water, with no inert electrolytes added to maintain constant ionic strength, and diluted as required. All solutions were prepared from water which had been both demineralized and distilled.

Preparation of ceramic electrodes

Metal selenides or tellurides were prepared by the direct reaction of the elements in a high-vacuum sealed quartz tube. Silver sulphide, the carrier material, was obtained by direct reaction of silver with sulphur in a hydrogen sulphide gas stream.

A mixture of metal selenide (or telluride) and silver sulphide was compressed at a pressure of 10 ton/cm^2 to form a tablet with a diameter of 15 mm and a thickness of 2–3 mm, and then sintered at 100–600° for 3 hr in a stream of nitrogen.

Preparation of electrode

A cross-section of the electrode is shown in Fig. 1. The disc was fastened directly to a lead wire, and then mounted with epoxy resin adhesive in a stem of unbreakable epoxy resin which was highly resistant to acids, bases and organic solvents. An internal solution and an internal electrode were eliminated to avoid internal contamination and to simplify the structure of the electrode. The surface of the sintered disc was polished with diamond paste and washed with an ultrasonic cleaner.

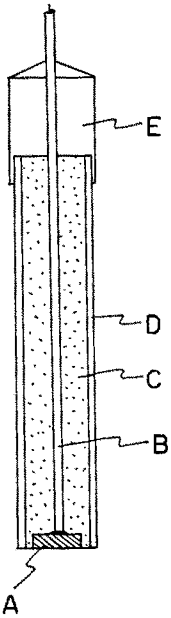

FIG. 1.—Cross-section of metal chalcogenide electrode.

A, Electrode disc
B, Lead wire
C, Insulator (epoxy resin)
D, Epoxy resin stem
E, Cap

Procedure

Potentiometric measurements were made in the conventional manner. The inner chamber of the double junction reference electrode was drained and filled once every two weeks, and the outer chamber was filled daily with saturated potassium nitrate solution. No potential changes were observed on filling. Between measurements, the electrode pair was rinsed several times with distilled water and wiped with filter paper. In the calibrations, the solutions were magnetically stirred at a constant, slow rate and readings were taken when equilibrium was reached (0·1–2 min).

RESULTS

Silver electrodes

Commercially available silver-selective electrodes contain a compacted disc of silver sulphide or a silicone rubber membrane impregnated with silver sulphide. The limit of detection may be restricted by the solubility of silver sulphide. Silver selenide and telluride are less soluble and therefore of potential use.

Figure 2 shows the potential *vs.* concentration curves of silver chalcogenide electrodes. The lower limit of the Nernstian slope is 10^{-7}–$10^{-8}M$ when silver selenide is used in place of the sulphide.[9]

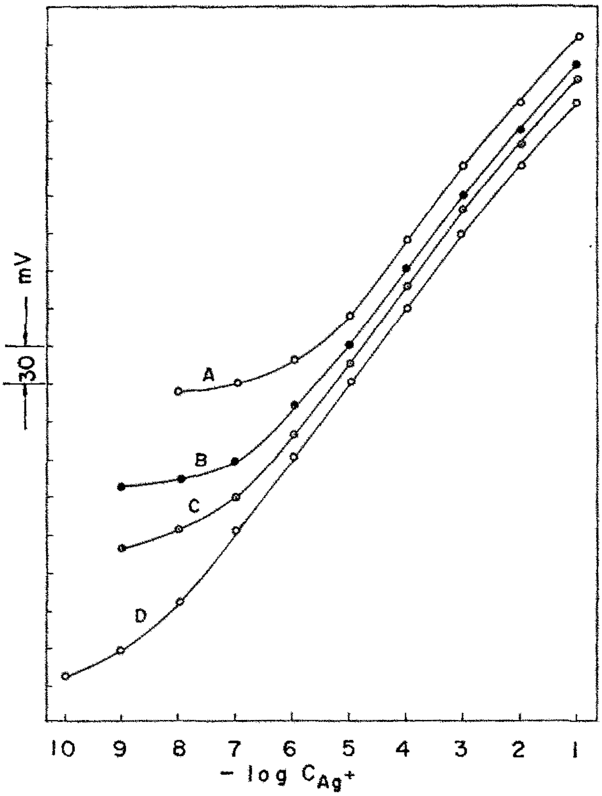

FIG. 2.—Potential responses of silver chalcogenide electrodes.

A. Compacted silver selenide
B. Sintered silver sulphide
C. Sintered silver telluride
D. Sintered silver selenide

The response rate of a silver selenide or telluride electrode is as fast as that of a sulphide one to $[Ag^+] > 10^{-6}M$, although the selenide or telluride has more covalent character than the sulphide. A ceramic chalcogenide electrode has better stability and reproducibility than a compacted one, and also better abrasion-resistance.

Other electrodes

The chalcogenides of the other metals investigated has to be mixed with silver sulphide in order to obtain electrodes that worked satisfactorily. These electrodes were compared with each other and with other membrane electrodes for the same elements. In general the metal sulphide electrodes were about as sensitive as commercial sulphide-type electrodes (which are usually made with a compacted mixture of metal sulphide and silver sulphide), and some orders of magnitude more sensitive than impregnated silicone-rubber electrodes. They also had better resistance to abrasion, had fast response, and gave stable and reproducible potentials.

Copper(I). The copper(I) selenide and telluride electrodes gave nearly the same performance as the sulphide electrode (which had the advantage that silver sulphide was not necessary for its functioning) with copper(II). The response slope was Nernstian down to $10^{-6}M$ copper(II) and the analytical range 10^{-8}–$10^{-1}M$.

Lead. The lead sulphide electrode gave Nernstian response down to $10^{-6}M$ lead, and so did the selenide and telluride electrodes, but the latter two gave a more sensitive response at lower concentrations than this. The response rates proved highly dependent on the nature of the active material, the composition of the disc and the temperature of sintering. The rate increased with lead chalcogenide content over the range 5–50%, and decreased if the sintering temperature was above the optimum of 300°.

Cadmium. Cadmium selenide electrodes behaved similarly to the sulphide electrodes, but the telluride electrode was superior both in linear response range and in sensitivity. The optimum composition was 10–50% w/w of chalcogenide, and the sintering temperature below 300° for a fast response to be obtained. Electrodes outside this range of composition were unsatisfactory. The response is Nernstian down to $10^{-6}M$.

Zinc. There was no commercial electrode available. Zinc orthophosphate and zinc sulphide were first tried as electrode materials but both were unsatisfactory for various reasons (drift, non-selectivity of the phosphate electrode) and this was attributed to the hygroscopic nature of these materials. The selenide and telluride were therefore tried and the selenide was found to give the best response if it was sintered with silver sulphide in a high-vacuum sealed quartz tube. The response is Nernstian down to $10^{-5}M$.

Manganese(II). Few investigations have been made of electrodes responsive to manganese(II). Buchanan and Seago[10] studied impregnated silicone-rubber electrodes and found that they were not selective; electrodes fabricated from membranes impregnated with manganese(II) carbonate and hydrogen phosphate trihydrate responded toward manganese(II) ion, but the presence of an additional electrolyte in the test solution levelled the response towards manganese(II) to that corresponding to the concentration of the added salt.

In the present study, manganese(II) chalcogenide disc electrodes were tried. However, manganese(II) sulphide could not be used, since it was very soluble in neutral and acidic solutions. Manganese(II) selenide mixed with silver sulphide was also moderately soluble in water and the surface became porous after several measurements, even when sintered. Consequently, only manganese(II) telluride could be used. Figure 3 shows the response of a manganese(II) telluride–silver sulphide disc sintered at 400°. This electrode exhibited fairly good response toward manganese(II) over the concentration range 10^{-1}–$10^{-5}M$ with an observed slope of 25 mV/pMn^{2+}. Moreover, there was no levelling effect from additional electrolytes such as alkali metal and alkaline earth metal ions in the test solution.

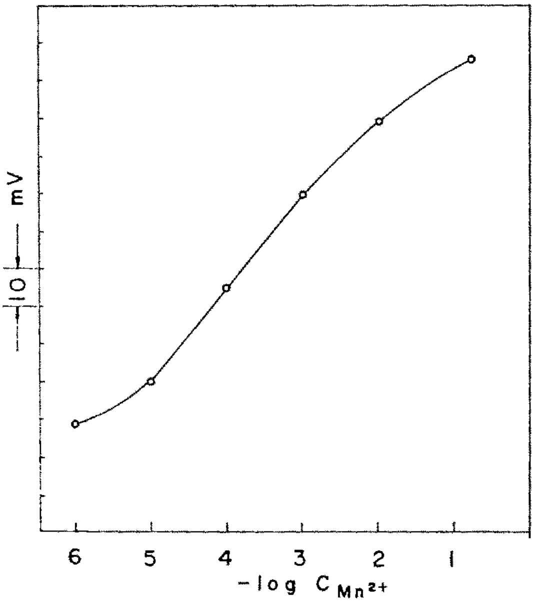

FIG. 3.—Potential response of sintered manganese(II) telluride electrode.

Chromium(III). No electrode has ever been studied which is responsive toward chromium(III), because of the lack of suitable active materials.

Chromium(III) selenide and telluride electrodes were studied, but did not respond rufficiently to chromium(III) ion, whether the chalcogenide was alone or incorporated with silver sulphide, in the form of compacted or sintered discs.

On the other hand, chromium(III) was found to interfere more or less for most of the cation-sensitive electrodes, the most remarkable interference being with a nickel selenide ceramic electrode. The potential *vs.* concentration curves for this electrode, as shown in Fig. 4, satisfies Nernst's law, but interferences from nickel by other ions which interfere with the potentiometric determination of nickel, cannot be avoided.

Cobalt(II). Few studies have been made on electrodes responsive to cobalt(II). Chatterjee[11] obtained a clay membrane that responded to copper(II), molybdenum, and cobalt(II). Buchanan and Seago[10] prepared a silicone-rubber membrane impregnated with cobalt(II) salts such as the carbonate and orthophosphate (octahydrate and anhydrous). These membranes, however, proved unsatisfactory, either by not giving the desired response or by having no selectivity toward cobalt(II).

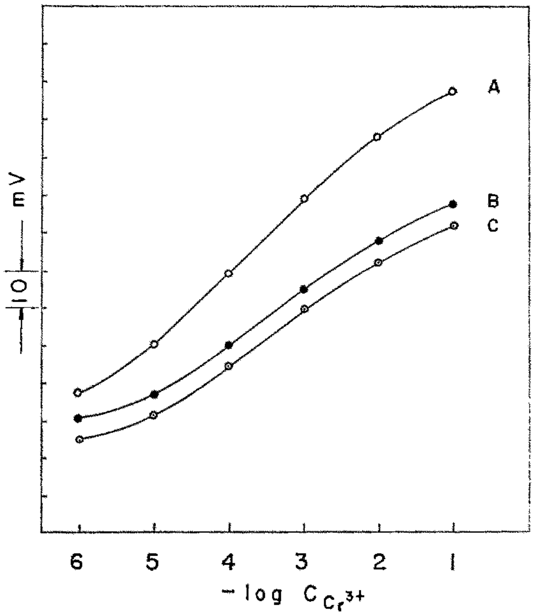

FIG. 4.—Potential responses of chromium(III) ion-sensitive electrodes.
A. Sintered nickel selenide
B. Sintered chromium(III) selenide
C. Sintered chromium(III) telluride

Cobalt(II) sulphide was found here to show no response toward cobalt(II). Cobalt(II) selenide added to silver sulphide and sintered in an inert gas stream responded nicely to cobalt(II), but compacted cobalt(II) selenide or telluride and sintered cobalt(II) telluride electrodes, proved unsatisfactory (Fig. 5).

The response characteristics seem highly dependent on the nature of the chalcogenide and silver sulphide, the temperature and time of sintering, and the inert gas used in the sintering.

Nickel. Several electrodes responsive toward nickel have been investigated. Morazzani-Pelletier and Baffier[12] studied collodion and paraffin membranes embedded with nickel salts. Buchanan and Seago[10] prepared silicone-rubber membranes impregnated with nickel dimethylglyoximate, nickel acetylacetonate (dihydrate and anhydrous), nickel carbonate and nickel orthophosphate heptahydrate. Dobbelstein and Diehl[13] investigated membranes of collodion, of epoxy polyester, and of phenol-formaldehyde, containing nickel dimethylglyoximate, and a membrane prepared by polymerizing phenol, formaldehyde, ammonia and nickel nitrate.

Only membrane electrodes impregnated with nickel salts, and not chelates, responded towards nickel ion, but were non-selective.

Nickel sulphide electrodes were found by us to be so poor in response to nickel that after several measurements they no longer responded properly. Nickel selenide and telluride, however, gave sensitive and selective response to nickel, which were linear over the range 10^{-5}–$10^{-1}M$, with a slope of 29·5 mV. The sintered disc gave a more Nernstian response than a compacted one did.

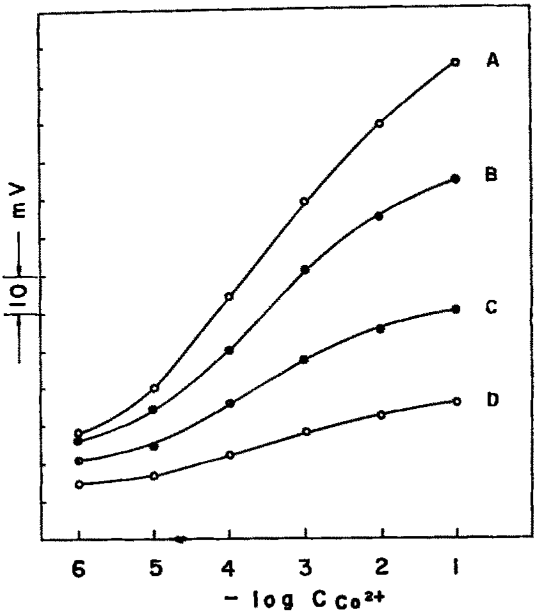

FIG. 5.—Potential responses of cobalt(II) chalcogenide electrodes.
A. Sintered cobalt(II) selenide
B. Sintered cobalt(II) telluride
C. Compacted cobalt(II) selenide
D. Compacted cobalt(II) telluride

The response rates varied with composition and the temperature of sintering. Among the common ions, silver, copper(II), mercury(II), iron(III), sulphide and chloride interfered seriously. But over 1000-fold amounts of alkali metal, alkaline earth metal, aluminium, zinc, cadmium, cobalt, manganese(II) and nitrate did not interfere at all. At constant ionic strength, the potentials did not change over a pH range from below zero to the pH at which nickel hydroxide precipitated. The discs showed Nernstian slopes at temperatures from 0° to 95°.

DISCUSSION

The mechanism of the response by a mixed crystalline electrode is not so well understood as that of a single crystal or a liquid ion-exchanger membrane electrode. Up to the present, the behaviour of these electrodes has been explained on the basis of ion-exchange occurring at the interface between electrode and solution, plus some mechanisms for conduction through the bulk of the electrode disc. Recently Brand and Rechnitz[14] made impedance measurements on mixed crystalline electrodes such as the lead-selective electrode, which has a compacted disc containing a mixture of lead sulphide and silver sulphide. As a result, charge was found to build up at the membrane–solution interface, producing a capacitative effect. However, it is very difficult, in terms of only the capacitative effect, to explain the role played by the silver sulphide.

Most metal sulphides other than silver sulphide can only be used as active material if mixed with the latter. For example, a highly-purified lead sulphide electrode, in which no traces of silver could be detected by qualitative emission spectroanalysis, proved non-responsive toward lead, whereas, an impure lead sulphide electrode containing trace amounts of silver was much more sensitive than a pure one. Cadmium sulphide behaves similarly, and it seems that silver sulphide must be incorporated in both compacted and sintered electrodes.

As seen in this paper, a number of metal selenides and tellurides, when incorporated with silver sulphide, function in a similar manner to sulphide electrodes.

From the experimental results, it seems that particular silver ions arising from imperfections in the crystal lattice play a predominant role in ion-selective solid-state electrodes. The presence of silver ions, especially interstitial ones, renders the disc conductive and capable of providing sensitivity, fast response and the other response characteristics suitable for potentiometric measurements.

Acknowledgement—The authors thank Dr. S. Kisaka, Dr. K. Sugihara, Dr. S. Hayakawa and Dr. S. Mori for their encouragement in this work.

Zusammenfassung—Es wurden ionenselektive Scheibenelektroden aus Chalkogeniden entwickelt, die auf Kationen wie Silber, Blei, Chrom(III), Nickel, Kobalt(II), Cadmium, Zink, Kupfer(II) und Mangan(II) ansprechen. Jede Elektrode wurde sowohl mit einer gepreßten als auch mit einer gesinterten Scheibe aufgebaut. Die gesinterten Elektroden waren empfindlicher und stabiler als die gepreßten. Die Elektroden sprechen auf Silber mit 59,5 mV/pAg, auf Blei, Nickel, Cadmium, Zink und Kupfer(II) mit 29,5 mV/pM und auf Chrom(III) mit 20 mV/pM an. Kobalt(II)- und Mangan(II)-Elektroden gehorchten der Nernstschen Beziehung nicht und zeigten 25 mV/pM. Sowohl Selenide als auch Telluride konnen zur potentiometrischen Bestimmung verwendet werden; die Manganelektrode ist jedoch analytisch nur dann nutzbar, wenn die Scheibe aus Mangan(II)-tellurid und Silbersulfid besteht.

Résumé—On a mis au point des électrodes de chalcogénure sélectives aux ions, qui répondent à des cations tels que les ions argent, plomb, chrome(III), nickel, cobalt(II), cadmium, zinc, cuivre(II) et manganèse(II). On a préparé chacune d'elles en utilisant le chalcogénure métallique correspondant avec le sulfure d'argent. On a assemblé l'électrode avec un disque aggloméré ou fritté. Les électrodes frittées sont plus sensibles et stables que les électrodes compactes. La réponse est de 59,5 mV/pAg pour l'ion argent, de 29,5 mV/pM pour les plomb, nickel, cadmium, zinc et cuivre(II), et de 20 mV/pM pour le chrome(III). Les électrodes de cobalt(II) et manganèse(II) ont une réponse non-Nernstienne de 25 mV/pM. On peut utiliser tant les séléniures que les tellurures pour le dosage potentiométrique, mais l'électrode de manganèse(II) ne sert comme outil analytique que lorsque le disque est constitué de tellurure de manganèse(II) et de sulfure d'argent.

STALAGMOMETRIC TITRATIONS

TOMIHITO KAMBARA and TOMOE KIBA
Department of Chemistry, Faculty of Science, Hokkaido
University, Sapporo, Japan

(*Received* 7 *June* 1971. *Accepted* 19 *October* 1971)

Summary—End-point detection in some precipitation titrations is achieved by measurement of the surface tension between mercury and the solution ("stalagmometric" titration). The drop-time of a polarographic dropping mercury electrode in open circuit is plotted against volume of surface-active titrant added, and shows a break or a peak at the end-point. The stalagmometric titration of sodium tetraphenylborate with Zephiramine (tetradecyldimethylbenzylammonium chloride) was satisfactory and made possible the determination of potassium by back-titration. Potassium was also titrated directly with tetraphenylborate and with calcium dipicrylaminate. Sodium dodecylbenzenesulphonate was titrated directly with Zephiramine and the results were compared with those obtained by the *p*-toluidine method and Epton's method.

ACCORDING to Kolthoff and Stenger,[1] the "stalagmometric" method of end-point detection was applied as far back as 1841 by Clark to the determination of water hardness, with a soap solution as the titrant. At that time, the end-point was detected by observing the appearance of foaming of the solution. Then the stalagmometer was introduced by Traube[2] in 1914. Later, the capillary–manometric method[3] and also the ring method[4] were employed for surface tension measurements, and some investigations on acid-base titrations with long-chain fatty acids or certain alkaloids have been reported.

Very little has been done in this field recently, presumably because of the lack of a convenient and suitable method of surface tension measurement.

The authors have developed an interfacial tensiometric titration method, based on measurement of the drop-time for a dropping mercury electrode immersed in the solution being titrated (stalagmometric titration). The drop-time gives an approximate relative value of surface tension between mercury and the solution according to Tate's law.

EXPERIMENTAL

Reagents

Sodium tetraphenylborate.

Zephiramine. (Tetradecyldimethylbenzylammonium chloride; Zeph-Cl).

Potassium chloride standard solution. Potassium chloride (reagent grade), dried for 3 hr in air at 110°, was used.

Calcium dipicrylaminate $Ca[N\{C_6H_2(NO_2)_3\}_2]_2$.

Sodium dodecylbenzenesulphonate.

Water. Distilled and demineralized.

Apparatus

Dropping mercury capillary. The capillary characteristics at 0·50-m mercury column height were: $m = 0{\cdot}839_4$ mg/sec and $t = 17{\cdot}0_7$ sec in pure water at 21·6°. The electrode was used in open circuit.

Measurement of the drop time. A stop-watch readable to 0.1 sec was used.

General procedure

Figure 1 shows the assembly used for the stalagmometric titration. The titrant is added to the beaker from the burette as usual, and the solution in the beaker is stirred and allowed to stand for a while after each addition. The time for five mercury drops to fall is measured with a stop-watch, and a further volume of titrant is added. A plot of drop-time against volume of titrant added gives the stalagmometric titration curve. The point of the maximum drop-time is taken as the end-point.

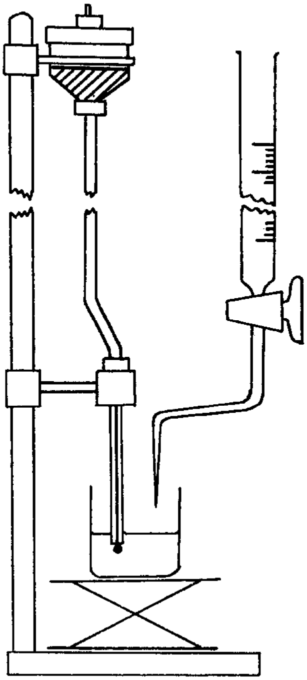

FIG. 1.—Assembly used for the stalagmometric titration.

RESULTS AND DISCUSSION

Titration of sodium tetraphenylborate with Zephiramine

Sodium tetraphenylborate reacts stoichiometrically with Zeph-Cl, forming a white precipitate. Bromophenol Blue or Titan Yellow as adsorption indicator has been used in this reaction for the indirect determination of potassium.[5-7]

In the present work, the relationship between the surface tension and the concentration of these reagents has been studied. Series of solutions of both $Na(C_6H_5)_4B$ and Zeph-Cl covering the concentration range from $10^{-6}M$ to $10^{-2}M$ in $10^{-3}M$ sodium chloride were prepared. The drop-time for each solution was measured and plotted against the logarithm of the concentration. Figure 2 clearly indicates that both of these reagents are surface-active.

The titration curves for the stalagmometric titration of $Na(C_6H_5)_4B$ with Zeph-Cl are shown in Fig. 3. A sharp peak, *i.e.*, a sudden increase in surface tension, was seen in each curve, and was taken as the end-point. This new method was compared with the ordinary Bromophenol Blue method (adsorption indicator),[5] and the results are given in Table I. By the familiar *F*- and *t*-tests, it has been confirmed that there is no significant difference between the variances and means of these two groups of results.

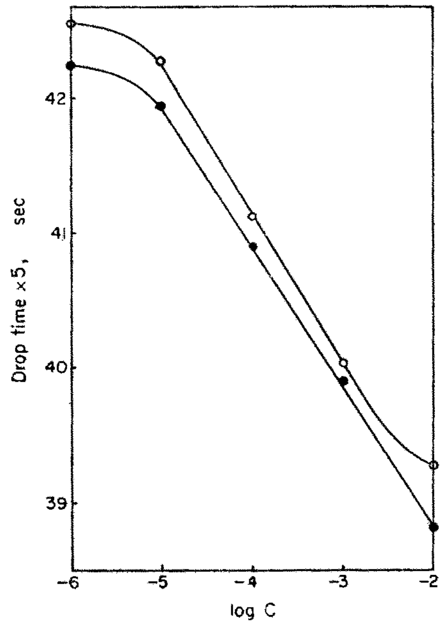

FIG. 2.—Change of drop-time of the dropping mercury capillary with the concentration *C* of surface-active substance.

Open circle Zeph-Cl; closed circle $Na(Ph)_4B$; environment (supporting electrolyte or blank solution) $10^{-3}M$ NaCl.

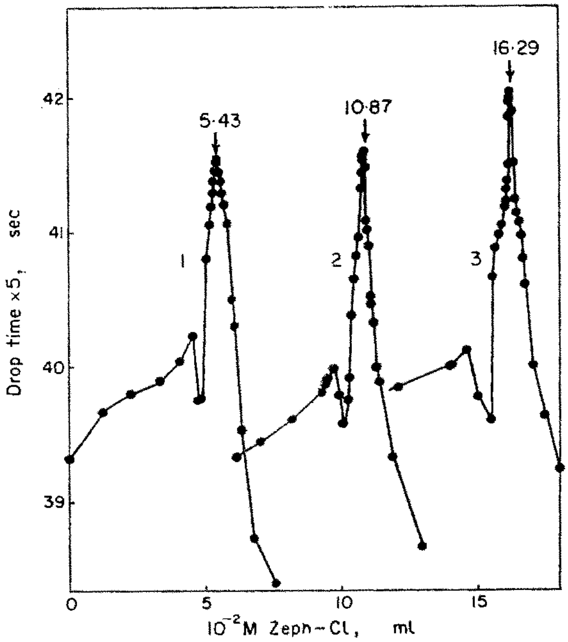

FIG. 3.—Stalagmometric titration curves of $Na(Ph)_4B$ with $10^{-2}M$ Zeph-Cl solution. $10^{-2}M$ $Na(Ph)_4B$ solution taken: (1) 5·00 ml; (2) 10·00 ml; (3) 15·00 ml.

TABLE I.—RESULTS OF TITRATIONS

Titration	Titrant volume used for 5-ml of sample solution, and its standard deviation, *ml*	Number of titrations
$10^{-2}M$ $Na(C_6H_5)_4B$ with $10^{-2}M$ Zeph-Cl		
by stalagmometric method	$5{\cdot}42_9 \pm 0{\cdot}00_4$	6
by BPB method	$5{\cdot}43_0 \pm 0{\cdot}01_0$	3
$10^{-1}M$ KCl with $10^{-1}M$ $Na(C_6H_5)_4B$		
by stalagmometric method	$4{\cdot}94_8 \pm 0{\cdot}02_0$	7
calculated value*	$4{\cdot}93_5 \pm 0{\cdot}01_4$	3
$10^{-2}M$ KCl with $10^{-2}F$ Ca-dipicrylaminate		
by stalagmometric method	$2{\cdot}47_7 \pm 0{\cdot}00_4$	9

* Calculated from the factor of the $Na(C_6H_5)_4B$ solution which was standardized against the standard Zeph-Cl solution by the Bromophenol Blue method.

Back-titration of potassium

A known volume of $10^{-2}M$ aqueous potassium solution was transferred to a 25-ml volumetric flask, a known excess of $Na(C_6H_5)_4B$ solution was added, and the flask was filled up to the mark with water. The white precipitate was allowed to stand in contact with the mother liquor for some time before being separated by filtration. A 20-ml portion of the filtrate was titrated stalagmometrically with $10^{-2}M$ Zeph-Cl. Titration curves similar to those in Fig. 3 were obtained, and complete recovery of potassium from potassium chloride was achieved.

Direct titration of potassium with sodium tetraphenylborate

The direct titration of potassium with $Na(C_6H_5)_4B$ is an interesting problem and has been realized through the use of various techniques including conductometric,[8] potentiometric,[9] amperometric[10] and high-frequency measurements.[11]

The solubility product of the salt being not so small ($pK_{sp} = 7{\cdot}7$), $0{\cdot}1M$ solutions were used, the $0{\cdot}1M$ tetraphenylborate solution being standardized by the Bromophenol Blue method against standard $10^{-2}M$ Zeph-Cl. A few examples of the titration curves obtained by the direct titration are given in Fig. 4. Only one component is surface-active, so the titration curve shows quite a different shape from those in Fig. 3. Satisfactory results were obtained, as summarized in Table I.

Direct titration of potassium with calcium dipicrylaminate

Dipicrylaminate, which forms a sparingly soluble salt with potassium ion, has been used for the separation and gravimetric determination of potassium. The mercury drop-time was plotted against the logarithm of the concentration (Fig. 5), showing that dipicrylaminate is remarkably surface-active.

The direct stalagmometric titration of potassium was tried with $10^{-2}M$ calcium dipicrylaminate solution as titrant. Some titration curves are reproduced in Fig. 6, and the results in Table I.

Titration of sodium dodecylbenzenesulphonate with Zephiramine

The anionic surfactant Na-DBS may be titrated with $10^{-2}M$ Zeph-Cl by the stalagmometric method.[12] In the present study, Zeph-Cl was titrated with $10^{-2}M$ Na-DBS solution (Fig. 7). As would be expected from the fact that both components are surface-active agents, the plot has a sharp peak at the equivalence point.

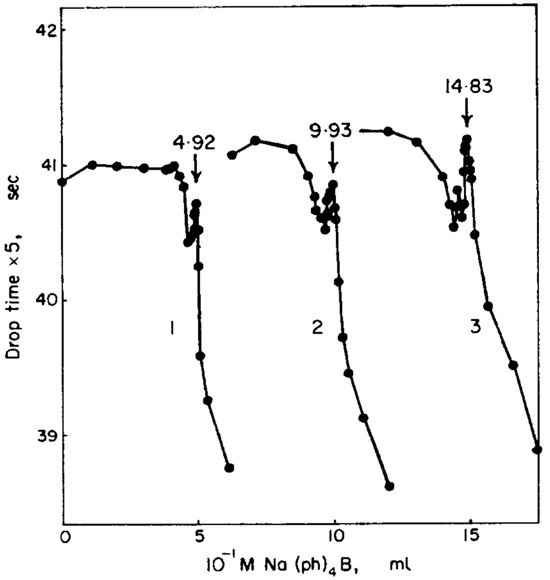

FIG. 4.—Stalagmometric titration curves of KCl with $10^{-1}M$ Na(Ph)$_4$B solution. $10^{-1}M$ KCl solution taken: (1) 5·00 ml; (2) 10·00 ml; (3) 15·00 ml.

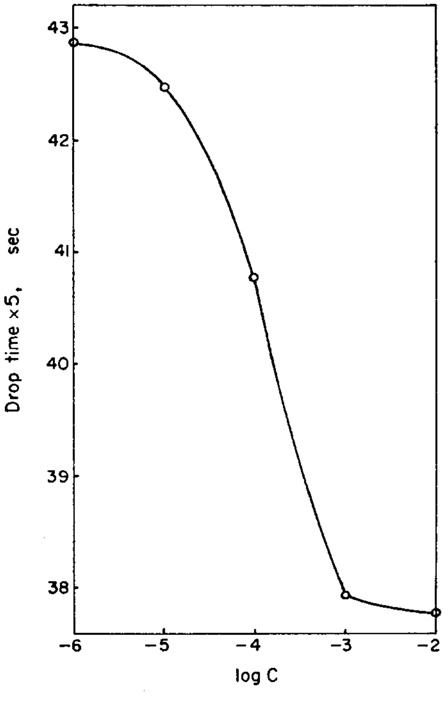

FIG. 5.—Change of drop-time of the dropping mercury capillary with the concentration C of calcium dipicrylaminate in $10^{-3}M$ NaCl environment.

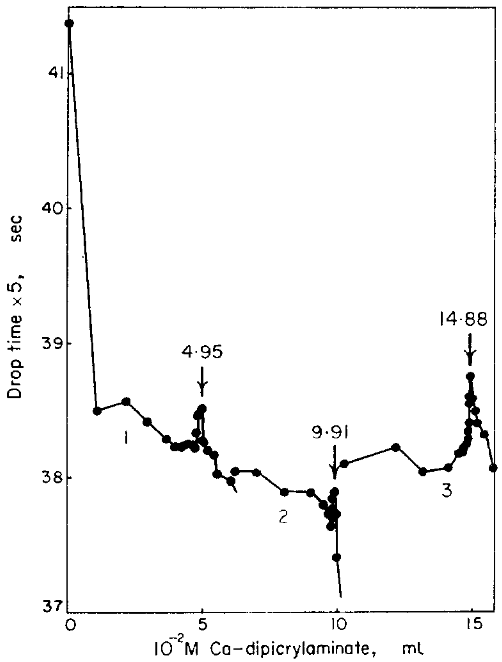

FIG. 6.—Stalagmometric titration curves of KCl with $10^{-2}M$ calcium dipicrylaminate solution.
$10^{-2}M$ KCl solution taken: (1) 5·00 ml; (2) 10·00 ml; (3) 15·00 ml.

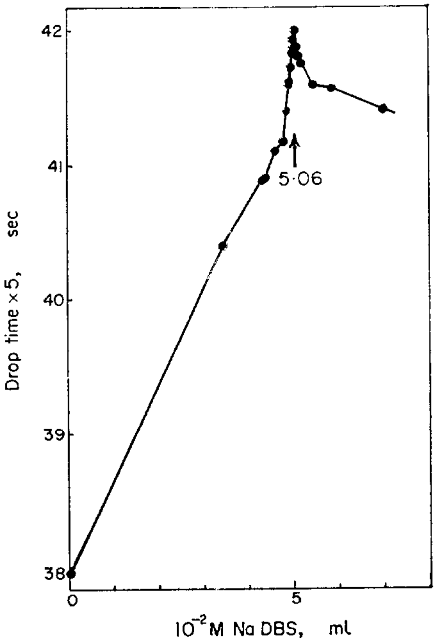

FIG. 7.—Stalagmometric titration curve of Zeph-Cl with $10^{-2}M$ Na-DBS solution.
$10^{-2}M$ Zeph-Cl solution taken: 5·00 ml.

TABLE II.—DETERMINATION OF Na-DBS CONTENT

Method	Na-DBS content found, %	Number of determinations
Stalagmometric titration	$90{\cdot}3_8 \pm 0{\cdot}2_0$	9
p-Toluidine method	$90{\cdot}2_1 \pm 0{\cdot}2_1$	3
Epton's method	$92{\cdot}7_2 \pm 0{\cdot}3_8$	3

In Table II, the content of Na-DBS obtained from the stalagmometric titration is compared with that from the *p*-toluidine method, *i.e.*, the Wickbold method,[13] in which the toluidinium salt is extracted into ether and titrated with standard sodium hydroxide solution. There is no significant difference between the variances and means of these two sets of results.

By Epton's method,[14] *i.e.*, two-phase titration with quaternary ammonium salt, with Methylene Blue as indicator, the Na-DBS content was found to be about 2% higher than these values.

Zusammenfassung—Die Endpunktsbestimmung in einigen Fällungstitrationen wird durch Messung der Oberflächenspannung zwischen Quecksilber und der Lösung bewerkstelligt ("stalagmometrische" Titration). Die Tropfzeit einer polarographischen Quecksilbertropfelektrode bei offenem Stromkreis wird gegen das Volumen des zugegebenen oberflächenaktiven Titranten aufgetragen; sie zeigt beim Endpunkt einen Knick oder eine Spitze. Die stalagmometrische Titration von Natriumtetraphenyloborat mit Zephiramin (Tetradecyl-dimethyl-benzyl-ammoniumchlorid) war zufriedenstellend und ermöglichte die Bestimmung von Kalium durch Rücktitration. Kalium wurde auch direkt mit Tetraphenyloborat und Calciumdipikrylaminat titriert. Natrium-dodecylbenzolsulfonat wurde direkt mit Zephiramin titriert und die Ergebnisse mit denen der p-Toluidinmethode und des Verfahrens nach Epton verglichen.

Résumé—La détection du point de fin de dosage dans certains titrages par précipitation est réalisée par la mesure de la tension superficielle entre du mercure et la solution (titrage "stalagmométrique"). Le temps de goutte d'une électrode polarographique à goutte de mercure en circuit ouvert est tracé en fonction du volume d'agent de titrage tensio-actif ajouté, et montre une brisure ou un pic au point de fin de dosage. Le titrage stalagmométrique du tétraphénylborate de sodium par la Zephiramine (chlorure de tétradécyldiméthylbenzylammonium) est satisfaisant et rend possible le dosage de potassium par titrage en retour. On a aussi dosé le potassium directement par le tétraphénylborate et par le dipicrylaminate de calcium. On a titré le dodécylbenzène sulfonate de sodium directement par la Zéphiramine et les résultats ont été comparés à ceux obtenus par la méthode à la *p*- toluidine et la méthode d'Epton.

INVESTIGATION OF MANGANESE(III) FLUORIDE FOR COULOMETRIC TITRATION

M. KATOH and T. YOSHIMORI
Faculty of Engineering, Science University of Tokyo, Shinjuku-ku, Tokyo, Japan

(*Received* 19 *June* 1971. *Accepted* 30 *August* 1971)

Summary—A study has been made of the use of electrogenerated manganese(III), in an electrolyte containing fluoride, for coulometric titration. The addition of fluoride prevented the deposition of manganese dioxide on the anode, and was responsible for increase of the current efficiency and for extension of the feasible range of current density, owing to complex formation between manganese(III) and fluoride. The bonding ratio, the apparent stability constant and the redox potential of the complex were also estimated from the Nernst equation and the current-potential curves.

SEVERAL investigations[1–4] have been reported dealing with the generation of manganese(III) for coulometric titration. The electrolytes used mainly consisted of manganese(II) sulphate and sulphuric acid, sometimes with phosphoric acid added. In the present study, potassium fluoride was also added to the electrolyte and a distinct improvement was found.

Tutundžić first used manganese(II) sulphate solution as the electrolyte for coulometric oxidimetry.[1] He considered the anodically oxidized product in the electrolyte to be permanganate. Subsequent investigators,[2–4] however, pointed out that manganese(III) was the most likely species to be produced. One of the disadvantages of these procedures was the formation of manganese dioxide on the anode surface. Although the earlier authors did not refer to the phenomenon, the current efficiency at the anode should be diminished by the formation of the dioxide. The other problem was the small current feasible, which was less than 40 $\mu A/mm^2$ under optimum conditions [$0{\cdot}2M$ manganese(II) sulphate and 2–$7M$ sulphuric acid].

Manganese(III) forms several complexes. The fluoride,[5] metaphosphate[6] and pyrophosphate[7] complexes have already been used in the determination of this element. It may therefore be expected that these anions can be used to prevent the deposition of manganese dioxide on the anode, and may also raise the upper limit of the current density for the electrogeneration of the oxidant.

In the present study, the formation of manganese dioxide has been found to be largely prevented by addition of potassium fluoride to the electrolyte, and the limiting current density has been increased several fold.

Meta- and pyrophosphates are not considered here, because metaphosphate sometimes produces precipitates with tervalent cations, and the pyrophosphate complex is not stable in acidic media. The mechanism of the reaction has also been elucidated, by interpretation of the absorption spectra and the current–potential curves for the generator electrode. The composition and stability of the fluoromanganese(III) complex are also deduced from the potential variations of the indicator electrode with time during a constant-current electrolysis.

EXPERIMENTAL

Apparatus

Cell and electrodes. The main electrolysis cell consisted of two tall-form lipless beakers. They were used for an anolyte and for a catholyte, and were connected by means of a saturated potassium sulphate agar-agar bridge. Both beakers were fitted with silicone rubber stoppers. The reference electrode of Hg–Hg_2SO_4–H_2SO_4 (0·615 V *vs.* N.H.E. at 25°) was joined to the anolyte cell, through an intermediate beaker containing 1*N* sulphuric acid, with the same kind of sulphate bridges as just described. A platinum plate (200 mm^2) was used as a cathode. An anode (generator electrode) consisting of a platinum plate (250 mm^2), an indicator electrode made of a platinized platinum plate (250 mm^2) and a nitrogen inlet were set in the anolyte cell. An electronic constant-current source (d.c.) was used for the electrolysis. When a resistance inserted between the output terminals of this supply was changed from 0 to 100 ohm, the variation of the current was 0·6 mA at 220 mA and 0·17 mA at 100 mA. The stability of the current was ±0·01 % during 60 min. The current was measured from the *IR* drop across a standard series resistor (100 ohm ± 0·01 %) by using a precision potentiometer. The potential between the reference electrode and the anode or the indicator electrode was measured with an electronic potentiometer (Yokokawa Electric Co. Tupe PM-20). The time of the electrolysis was measured with a stop-clock having a synchronous motor.

Reagents

Sulphuric acid, (1*N*, 55 ml), was used for both the intermediate solution and the catholyte. Two electrolytes (55 ml) were generally used as the anolyte: *A*, 0·5*M* manganese(II) sulphate–1*N* sulphuric acid; *B*, 0·5*M* manganese(II) sulphate–1*N* sulphuric acid–0·1–0·5*M* potassium fluoride. All electrolytes were prepared from chemicals of analytical grade. Before the electrolysis the anolyte was deaerated by passage of purified nitrogen for half an hour. The temperature of the electrolyte was maintained at 25° by a thermostat.

RESULTS AND DISCUSSION

Behaviour of the anode during the electrolysis

During the electrolysis of anolyte *A*, which contained no fluoride, a brownish black deposit was formed on the anode surface irrespective of the current density applied. The deposit is presumed to be manganese dioxide because the Pourbaix diagram[8] shows stable regions of MnO_2 (between 1·16 and 1·67 V *vs.* N.H.E. near pH 0·3, corresponding to our experimental conditions). Outside this region, manganese(II) on the less noble and permanganate on the more noble side are shown to be stable species. When anolyte *B*, which was more than 0·1*M* in fluoride was used, no deposit was formed on the electrode.

The formation of manganese dioxide on the anode may cause serious difficulties in the coulometric titration. As the electricity will be partly consumed for formation of this compound, the current efficiency may be decreased. On this basis addition of fluoride was considered to be effective for obtaining higher current efficiency. Further study, therefore, was directed to identify the anodic products from *A* and *B*.

Absorption spectra of the anolyte after electrolysis

In order to identify the products of the anode, absorption spectra were measured. A standard solution of manganese(III) was prepared by the following method.[9] A solution that was 0·2*M* in manganese(II) sulphate, 0·05*M* in potassium permanganate and 0·6*M* in sulphuric acid was allowed to stand for a day, then filtered, and the absorption spectrum of the filtrate was measured.

A solution that was 1m*M* in potassium permanganate and 1*N* in sulphuric acid was used as the standard permanganate solution. Both spectra are shown in Fig. 1, and are almost the same as those reported by Lingane *et al.*[2]

Solution *A* was electrolysed at 2·50 mA for 1800 sec. The spectrum of the anolyte after the electrolysis is also shown in Fig. 1. The spectrum was identical with that

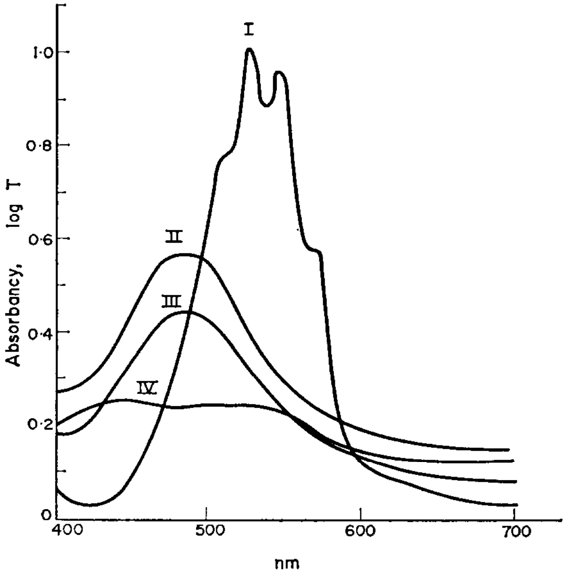

FIG. 1.—Absorption spectra
[I] : 1m*M* $KMnO_4$.
[II] : 0·56 m*M* Mn^{3+}.
[III] : Solution A after electrolysis for 1800 sec at 2·5 mA.
[IV] : Solution B (0·1*M* KF) after electrolysis for 1800 sec at 2·5 mA.

of manganese(III), showing the anodically oxidized product was not permanganate but manganese(III). In this case manganese dioxide was also formed on the anode.

The absorption spectrum of solution *B*(0·1*M* fluoride) after electrolysis under the same conditions was quite different from that of permanganate or manganese(III). This indicates that a manganese(III) fluoride complex may be formed in the solution.

Both solutions were then electrolysed for various time intervals at constant current (2·50 mA). The results obtained are shown in Fig. 2.

The curve for solution *A* was slightly convex, which indicated that the formation of

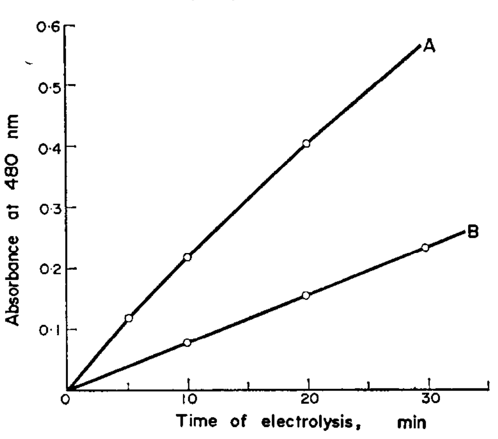

FIG. 2.—Increase of the absorbance as a function of the time of electrolysis
A : Solution *A*
B : Solution *B* (0·1*M* KF)

manganese dioxide on the anode would be slower in the initial stages of the electrolysis than in the later ones. This phenomenon is probably due to the formation of manganese dioxide. In the case of the solution *B*, on the other hand, strict proportionality was observed between the time of the electrolysis and the concentration of manganese(III) fluoride complex.

Further study on the fluoro-manganese(III) complex

Solution *A* and four types of solution *B* which differed in potassium fluoride concentration were anodically oxidized for 600 sec at 2·5 mA, while being stirred magnetically at constant rate. After cessation of the current, the stirring was continued for an additional 40 min. The potentials of the indicator electrode (platinized platinum) were measured every minute during these 50 min. The platinized platinum electrode was preferable to smooth platinum foil because of its good response. Figure 3 shows the results of the measurements. The potential became almost constant within 5 min after cessation of the current in all cases.

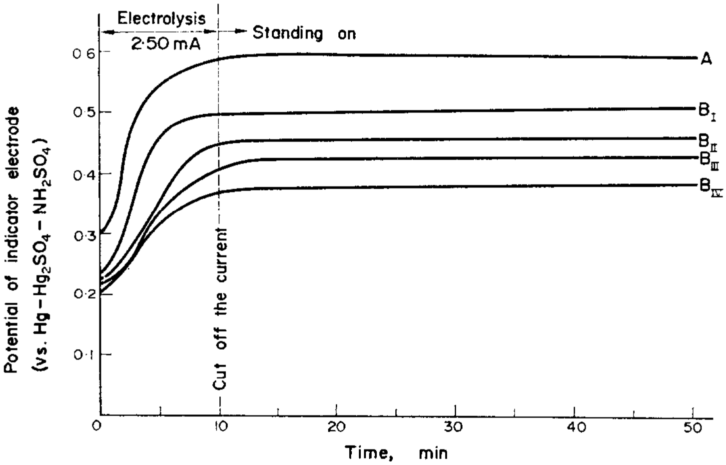

FIG. 3.—Build-up of the potential and the response of the indicator electrode.
A; Solution *A*:
B$_{I}$; Solution *B* (0·1*M* KF): B$_{II}$; Solution *B* (0·2*M* KF):
B$_{III}$; Solution *B* (0·3*M* KF): B$_{IV}$; Solution *B* (0·5*M* KF).

The results of Fig. 3 were interpreted as follows. The complex-formation reaction is given by equation (1).

$$\mathrm{Mn}^{3+} + x\mathrm{HF} \rightarrow \mathrm{MnF}_x^{3-x} + x\mathrm{H}^+ \tag{1}$$

The stability constant is

$$K = [\mathrm{MnF}_x^{3-x}][\mathrm{H}^+]^x/[\mathrm{Mn}^{3+}][\mathrm{HF}]^x \tag{2}$$

Although each term should be an activity, molar concentrations were used for convenience. Therefore *K* is the apparent stability constant.

Mass balance for manganese(III) gives equation (3).

$$[\mathrm{Mn}^{3+}] + [\mathrm{MnF}_x^{3-x}] = C \tag{3}$$

where C is the total concentration of manganese(III). Substituting (3) into (2), we obtain

$$K = \{C - [\mathrm{Mn}^{3+}]\}[\mathrm{H}^+]^x/[\mathrm{Mn}^{3+}][\mathrm{HF}]^x \tag{4}$$

In (4), $[\mathrm{Mn}^{3+}]$ can be obtained from the following relationship at 25°:

$$E = E^\circ + 0{\cdot}059 \log [\mathrm{Mn}^{3+}]/\mathrm{Mn}^{2+}] \tag{5}$$

where $[\mathrm{Mn}^{2+}]$ is almost constant because the concentration of manganese(III) formed by the electrolysis is only $2{\cdot}83 \times 10^{-4}M$ and is negligibly small compared with the total concentration of manganese(II) ($0{\cdot}5M$). E° is known to be 1·50 V *vs.* N.H.E. and E can be determined from Fig. 3. The term $C - [\mathrm{Mn}^{3+}]$ in equation (4) is nearly equal to C provided that the fluoro-manganese(III) complex is very stable. Such an assumption is reasonable because of the spectra (Fig. 1, curves III and IV) and this is confirmed by the high stability constant obtained later. Hence (4) can be rearranged as follows:

$$\log [\mathrm{Mn}^{3+}] - \log C = -\log K - x\{\log [\mathrm{HF}] + \mathrm{pH}\} \tag{6}$$

where $[\mathrm{Mn}^{3+}]$ can be obtained from (5) and C is calculated from the number of coulombs passed (and found to be $2{\cdot}83 \times 10^{-4}M$). The left-hand side of (6) can be designated q. In the right-hand side of (6), the pH was calculated to be about 0·3, from the dissociation constants of sulphuric acid, $k_1 = \infty$ and $k_2 = 1{\cdot}3 \times 10^{-2}$ at 25°. The next problem is the estimation of [HF]. The following equilibria exist in the solution B:

$$[\mathrm{H}^+][\mathrm{F}^-]/[\mathrm{HF}] = k_1 \tag{7}$$

$$[\mathrm{HF}_2{}^-]/[\mathrm{HF}][\mathrm{F}^-] = k_2 \tag{8}$$

$$2[\mathrm{HF}_2{}^-] + [\mathrm{HF}] + [\mathrm{F}^-] + x[\mathrm{MnF}_x^{3-x}] = C' \tag{9}$$

where C' represents the total concentration of fluoride; k_1 and k_2 are given[10] as $6{\cdot}71 \times 10^{-4}$ and 3·86 respectively, at 25°. In this case $x[\mathrm{MnF}_x^{3-x}]$ is again neglected owing to its negligibly small concentration. According to the relationships (7), (8) and (9), HF was the main species at present pH 0·3. $[\mathrm{HF}_2{}^-]$ and $[\mathrm{F}^-]$ can then be neglected, to a first approximation, and [HF] equated with C'. Therefore plots of q against $\{\log [\mathrm{HF}] + \mathrm{pH}\}$ are possible from the values of Fig. 3, the potentials for use in (5) being the values 30 min after the current had been cut off. The resultant straight line gave x and $\log K$ from the slope and intercept respectively, $x = 3{\cdot}0$ and $\log K = 5{\cdot}1$ being obtained. This means that the composition of the complex is MnF_3, under the experimental conditions used, and the stability is moderately high even in such a strongly acidic solution. The value of $\log K$ is only an apparent value because activity coefficients were ignored, but serves as an estimate of the stability. The formal redox potential for equation (10) may also be calculated from this value.

$$\mathrm{MnF}_3 + 3\mathrm{H}^+ + e \rightleftharpoons \mathrm{Mn}^{2+} + 3\mathrm{HF} \tag{10}$$

$$E^\circ = 1{\cdot}20\ \mathrm{V}\ vs.\ \mathrm{N.H.E.}$$

This couple is apparently less noble than that of equation (11),

$$\mathrm{Mn}^{3+} + e \rightleftharpoons \mathrm{Mn}^{2+} \tag{11}$$

$$E^\circ = 1{\cdot}50\ \mathrm{V}\ vs.\ \mathrm{N.H.E.}$$

Since the standard redox potential of (10) is almost the same as that of (12) below, no interaction will occur between the two, that is, no manganese dioxide is formed.

$$\begin{gathered} MnO_2 + 4H^+ + 2e \rightleftharpoons Mn^{2+} + 2H_2O \\ E^\circ = 1{\cdot}23 \text{ V } vs. \text{ N.H.E.} \end{gathered} \tag{12}$$

In the absence of potassium fluoride, the following disproportionation reaction will occur:

$$2Mn^{3+} + 2H_2O \rightarrow MnO_2 + Mn^{2+} + 4H^+ \tag{13}$$

This was confirmed in the present experiment.

Anodic behaviour

The anodic polarization curves of solutions *A* and *B* were measured from the stepwise increase of the electrolytic current. In this experiment, only a small amount of manganese(III) is formed in the first period of the electrolysis. This causes, however, an appreciable potential change in the solution, and disturbs the measurements of the potential of the anode. Therefore the electrolyte (*A* or *B*) was pre-electrolyzed for 15 min at a current of 2·5 mA before the first measurement of the potential. The pregenerated manganese(III) depressed the appreciable change of the equilibrium potential of the solution, as can be predicted from the Nernst equation. Thus, the over-potential of the anode could be obtained more easily.

The limiting currents were observed by this method, and are shown in curves *A*, B_1, B_2 and B_3 of Fig. 4. The curve for solution *A* is nearly the same as the results obtained previously.[2,3,11] We consider that the currents in solutions *A* and *B* are limited by the kinetics and not by a diffusion process. The biamperometric titration

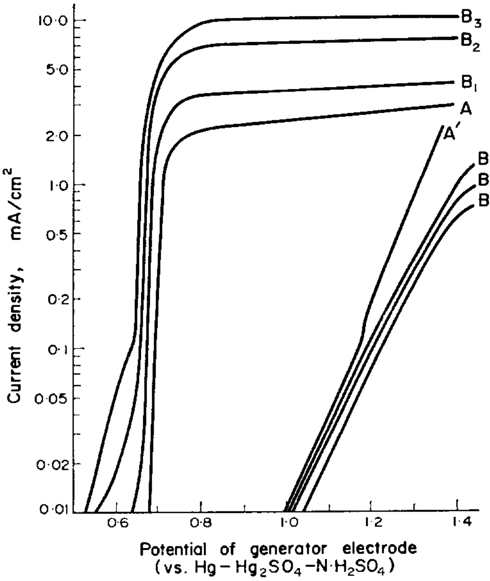

FIG. 4.—Anodic polarization curves in various electroyltes

curve of iron(II) with this electrolyte also indicated the irreversibility of this electrode reaction. The results will be shown in the next report.

Lingane *et al.*[3] concluded from their chronopotentiometric study that the anodic process is kinetically controlled. T. Sekine *et al.*[8] also derived the same explanation from the activation energy (38·5 kJ/mole) for this process, which is higher than that for a diffusion process. It is interesting to note that the limiting current increases linearly with increase of fluoride concentration. When the concentration of sulphuric acid in solution *B* (0·5*M* fluoride) was increased to 6*N*, the current density was further increased (up to 0·15 mA/mm^2).,

In Fig. 4 the curves marked with a "dashed" letter were measured for solutions without manganese(II) sulphate. The current efficiency for the generation of manganese(III) was calculated from the difference of the currents at the same potential with and without manganese(II). It is assumed that the current consumed in the absence of manganese will also be consumed in addition to that required to oxidize manganese(II) when the latter is present. The efficiencies are shown in Fig. 5. It can be concluded from these curves that a higher current density for generation of manganese(III) is obtained in the fluoride-containing solutions; *i.e.*, the feasible range of current is wider when fluoride is present than when it is absent.

Acknowledgement—The authors wish to thank Mr. T. Shibuya and Mr. K. Shimizu for their assistance in the experiments.

Zusammenfassung—Die Verwendung von elektrolytisch in einem fluoridhaltigen Elektrolyten erzeugtem Mangan(III) zur coulometrischen Titration wurde untersucht. Die Zugabe von Fluorid verhinderte durch Komplexbildung mit Mangan(III) die Abscheidung von Mangandioxid an der Anode und ergab eine Erhöhung der Stromausbeute sowie eine Ausdehnung des nutzbaren Stromdichtebereichs. Das Bindungsverhältnis, die scheinbare Bildungskonstante und das Redoxpotential des Komplexes wurden aus der Nernstschen Gleichung und aus den Stromspannungskurven berechnet.

Résumé—On a effectué une étude sur l'emploi du manganèse(III) électrogénéré, dans un électrolyte contenant du fluorure, pour le titrage coulométrique. L'addition de fluorure prévient le dépôt de bioxyde de manganèse sur l'anode et est responsable de l'accroissement de l'efficacité du courant et de l'extension du domaine praticable de densité de courant, du fait de la formation de complexe entre le manganèse(III) et le fluorure. Le taux de liaison, la constante de stabilité apparente et le potentiel redox du complexe ont aussi été estimés à partir de l'équation de Nernst et des courbes courant-potentiel.

(*Received* 14 *June* 1971. *Accepted* 29 *August* 1971)

Summary—A new colorimetric method is proposed for the determination of maleic acid. Among aliphatic dicarboxylic acids tested, maleic acid was found to be selectively extracted into nitrobenzene as the red ion-association complex (λ_{max} 516 nm) formed between the hydrogen maleate anion and the tris(1,10-phenanthroline)iron(II) cation. At least a 32-fold molar excess of tris(1,10-phenanthroline)iron(II) relative to maleic acid is needed and the optimal pH range is 3–5. A linear relationship is obtained over the concentration range 10^{-5}–10^{-4} M maleic acid. The relative standard deviation was 1·0%. The colour intensity of the extract remains constant at room temperature for at least 24 hr. A large amount of fumaric acid, the *trans*-isomer of maleic acid, is not extracted under the same conditions. This makes it possible to determine maleic acid in the presence of fumaric acid.

MALEIC ACID or maleic anhydride is one of the important raw materials for industrial production of polyester resins, alkyd resins, *etc.* Several procedures for the determination of maleic acid have been published, especially regarding the separation from fumaric acid. Markman and Chikryzova[1] presented a simultaneous determination of maleic acid and fumaric acid by polarography with 0·1M hydrochloric acid in 90% ethanol as a supporting electrolyte. Funasaka *et al.*[2] proposed an ultraviolet spectrophotometric method combined with a salting-out chromatographic separation from fumaric acid, but the procedure seems to be somewhat tedious. Burger and Schulek[3] devised a new titrimetric method for the determination of maleic acid and fumaric acid, using bromine monochloride and mercury(II), and Kreshkov *et al.*[4] reported on the analysis of mixtures of 2 or 3 dicarboxylic acids by potentiometric titration in non-aqueous solution.

In our previous papers of this series, certain aromatic organic acids such as pentachlorophenol,[5,6] picric acid[7] and phthalic acid,[8,9] the structures of which are relatively symmetrical, were found to be selectively extracted into particular organic solvents with cationic metal chelates such as tris(1,10-phenanthroline)iron(II), tris(2,2′-bipyridyl)iron(II), bis(cuproine)copper(I) or bis(neocuproine)copper(I). Such extraction systems have been successfully utilized for the spectrophotometric determination of the organic acids. In connection with these investigations, we also studied the extraction behaviour of various aliphatic dicarboxylic acids, and found

that among them maleic acid can also be selectively extracted into nitrobenzene with tris(1,10-phenanthroline)iron(II). This work was undertaken in order to establish a new colorimetric method for the determination of maleic acid in the presence of fumaric acid. The method has the advantage of being not only sensitive and accurate but also free from interference by the organic acid homologues.

EXPERIMENTAL

Reagents

All solutions were prepared from analytical-reagent grade chemicals and demineralized water.

Standard maleic acid solution, $2{\cdot}5 \times 10^{-4}M$.

Other carboxylic acid solutions, $2{\cdot}5 \times 10^{-4}M$. Stock solutions ($0{\cdot}01M$) of these acids (adipic, crotonic, fumaric, glutaric, DL-malic, malonic, oxalic, succinic and L-tartaric) were diluted as required before use.

Tris(1,10-phenanthroline)iron(II) sulphate solution, $1{\cdot}6 \times 10^{-2}M$. Prepared by dissolving 6·343 g of 1,10-phenanthroline monohydrate and 3·187 g of ferrous ammonium sulphate hexahydrate in dilute sulphuric acid and diluting the mixture to 500 ml with water. The resulting solution (pH 3·5) is $1{\cdot}6 \times 10^{-4}M$ in tris(1,10-phenanthroline)iron(II) sulphate and $1{\cdot}6 \times 10^{-4}M$ with respect to excess of 1,10-phenanthroline.

Buffer solution. The phosphate buffers for pH 4–9 were prepared by mixing $0{\cdot}3M$ potassium dihydrogen phosphate and $0{\cdot}3M$ disodium hydrogen phosphate in suitable ratios. More acidic or alkaline solutions were prepared by mixing $0{\cdot}3M$ potassium dihydrogen phosphate with $0{\cdot}5M$ sulphuric acid, or $0{\cdot}3M$ disodium hydrogen phosphate with $0{\cdot}5M$ sodium hydroxide.

General procedure

Transfer by pipette into a 100-ml separating funnel 5 ml of a carboxylic acid solution ($2{\cdot}5 \times 10^{-4}M$), 5 ml of the phosphate buffer solution and 5 ml of the tris(1,10-phenanthroline)iron(II) sulphate solution ($1{\cdot}6 \times 10^{-2}M$). Dilute the mixture to 25 ml with water and add 10 ml of nitrobenzene. Shake the funnel for 1 min with a mechanical shaker. After 30 min, transfer the nitrobenzene extract to a 15-ml glass tube with a stopper and dry it with 1 g of anhydrous sodium sulphate. Measure the absorbance at 516 nm, using a reagent blank extract or nitrobenzene as a reference.

Recommended procedure for the determination of maleic acid

Calibration curve. Transfer by pipette into 100-ml separating funnels 0–10 ml of the standard maleic acid solution ($2{\cdot}5 \times 10^{-4}M$) and 5 ml of pH 3·5 phosphate buffer solution, and then proceed as for the general procedure.

Determinations. Proceed as above, taking an amount of sample containing no more than 7 mg of maleic acid in a total volume less than 15 ml.

RESULTS AND DISCUSSION

Extraction behaviour of aliphatic dicarboxylic acid homologues

Absorption spectra. Figure 1 shows the visible absorption spectra of the extracts from the pH 3·5 phosphate-buffered solutions which contained maleic acid or one of its homologues. The presence of maleic acid leads to a considerable increase in the absorbance; malonic acid is slightly extracted and gives a similar absorption spectrum. These spectra are characterized by the absorbance maximum at 516 nm.

pH study. Figure 2 shows the influence of pH on the degree of extraction of maleic acid and malonic acid from the phosphate-buffered solutions. The absorbance of the extract from a solution of maleic acid is maximal and constant if the pH of the aqueous phase is 3–5. The degree of the extraction of malonic acid is fairly low and the other seven dicarboxylic acids mentioned above are not scarcely extracted at all under the same conditions.

The distribution curves for maleic acid species (calculated from $\mathrm{p}K_{a_1}$ 1·92, $\mathrm{p}K_{a_2}$ 6·22)[10] indicate that the hydrogen maleate anion predominates in pH range 3–6

(Fig. 3); it is probable that this singly-charged anion participates in the extraction. A possible reason for the specificity of the extraction of maleic acid is the formation by this anion of a seven-membered symmetric ring through an intramolecular hydrogen bond, which results in good charge distribution and a lower hydration energy. In order to confirm the composition of the extracted species, continuous

MA = maleic acid.

variation plots for maleic acid were made, at wavelengths of 490 and 516 nm. As shown in Fig. 4, the maximum absorbance occurred at a ratio of *ca.* 0·65. This fact together with the result of the pH study suggests that a 1:2 ion association complex is formed between the tris(1,10-phenanthroline)iron(II) cation and the hydrogen maleate anion, and is transferred into nitrobenzene.

It is of interest that fumaric acid, the *trans*-isomer of maleic acid, is not extracted even in the pH range 3·5–4, where the hydrogen fumarate anion is predominant (Fig. 5). This behaviour may be accounted for as follows. The charge distribution on the singly-charged anion may be assumed to be localized, because of the lack of hydrogen-bonding, and the resultant selective hydration may be strong enough to prevent the ion-association complex from forming.

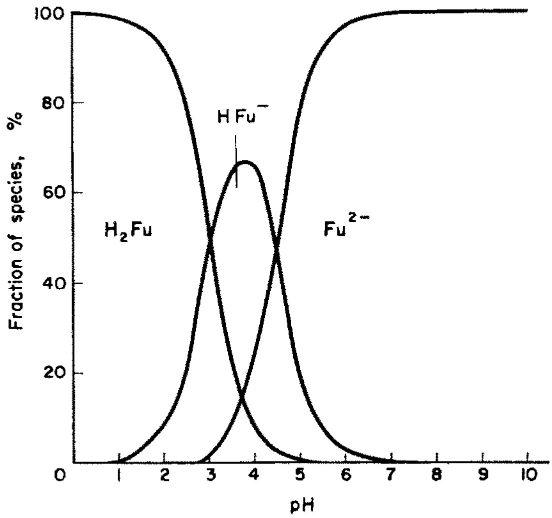

FIG. 5.—Distribution of fumarate species as a function of pH: H_2Fu = fumaric acid.

Development of analytical method for maleic acid

By utilization of the selective solvent extraction of tris(1,10-phenanthroline)iron(II) hydrogen maleate, it may be possible to determine maleic acid colorimetrically.

Effect of reagent concentration. With other variables constant, different amounts of tris(1,10-phenanthroline)iron(II) sulphate were added to an aqueous solution of maleic acid and extraction was done as described above. To obtain the maximum colour response it was found necessary to maintain a minimum 32-fold molar excess of the tris(1,10-phenanthroline)iron(II) cation relative to maleic acid. Therefore, the chelate concentration was usually kept at $3{\cdot}2 \times 10^{-3}M$ and the maximum maleic acid concentration at $10^{-4}M$. Large amounts of the pH 3·5 phosphate buffer solution are without deleterious effect.

Effect of shaking time. The shaking time for the extraction was varied from 0·5 to 10 min, while the other variables were kept constant. Extraction was quantitative with 15 sec of shaking. Continued shaking up to 10 min produced no further change of absorbance.

Colour stability of the extracts. Extractions were made on a series of maleic acid solutions in the usual way, after which the absorbances were measured as a function of time. The colour intensity of the extracts remained almost constant for at least 24 hr under normal laboratory conditions. This extraction system is negligibly affected by temperature over the range tested, 15–30°.

Calibration curve and precision. The recommended procedure for the calibration curve was established on the basis of the results above. The calibration curve was found to be linear over the concentration range 1–10 × $10^{-5}M$ maleic acid in the initial aqueous phase. Under these conditions, 29 μg of maleic acid give an absorbance of 0·033 in a 10-mm cell and at 516 nm, when extracted into 10 ml of nitrobenzene. The precision was estimated from ten results for 1·0 × $10^{-4}M$ maleic acid. The mean absorbance was 0·326 with a standard deviation of $0{\cdot}003_4$ (relative standard deviation 1·0%).

Effect of diverse substances. The influence of diverse substances on the extraction was studied under experimental conditions similar to those used for the calibration curve. The tolerance for a given substance was defined as the maximum concentration which could be present without causing a deviation of about 0·01 in the absorbance of the extract from 1·0 × $10^{-4}M$ maleic acid. Tolerances for several maleic acid homologues are listed in Table I. Large amounts of sulphate, phosphate, carbonate, fluoride, and moderate amounts of chloride and nitrate did not interfere. Interference of larger amounts of chloride, bromide or iodide could be eliminated by precipitation with silver sulphate. Nitrite should be decomposed by boiling with sulphamic acid. Metal ions interfere only if they form relatively stable maleate complexes, but can be masked by addition of non-interfering stronger complexing agents such as EDTA.[11–14]

TABLE I.—EFFECT OF MALEIC ACID HOMOLOGUES

Substance		Tolerance, $10^{-4}M$

DL-Malic acid	 $\begin{array}{l}\text{CH(OH)COOH}\\ \vert\\ \text{CH}_2\text{COOH}\end{array}$	5
L-Tartaric acid	 $\begin{array}{c}\text{HC(OH)COOH}\\ \vert\\ \text{HOCHCOOH}\end{array}$	100
Crotonic acid	 $\begin{array}{c}\text{H}_3\text{CCH}\\ \|\\ \text{HCCOOH}\end{array}$	25

Maleic acid taken: 1·0 × $10^{-4}M$.

Application of the method. To make sure that maleic acid could be determined in the presence of fumaric acid, the procedure was applied to known sample solutions containing both isomers in various ratios. The results obtained are summarized in Table II.

The fumaric acid has a negligible effect on the absorbance. Thus maleic acid can be determined in the presence of fumaric acid.

Zusammenfassung—Eine neue kolorimetrische Methode zur Bestimmung von Maleinsäure wird vorgeschlagen. Unter den geprüften aliphatischen Dicarbonsäuren wird nur Maleinsäure selektiv als rotes Ionenassoziat (λ_{max} 516 nm) aus Hydrogenmaleat und Tris(1,10-phenanthrolin)eisen(II) in Nitrobenzol extrahiert. Man braucht mindestens einen 32-fachen molaren Überschuß an Tris(1,10-phenanthrolin)eisen(II) über Maleinsäure; der optimale pH-Bereich ist 3–5. Eine lineare Beziehung findet man bei 10^{-5}–$10^{-4}M$ Maleinsäure. Die relative Standardabweichung beträgt 1,0%. Die Farbintensität des Extrakts bleibt bei Raumtemperatur mindestens 24 h stabil. Eine große Menge von Fumarsäure, dem trans-Isomeren der Maleinsäure, wird unter den selben Bedingungen nicht extrahiert. Damit wird es möglich, Maleinsäure in Gegenwart von Fumarsäure zu bestimmen.

Résumé—On propose une nouvelle méthode colorimétrique pour le dosage de l'acide maléique. On a trouvé que, parmi les acides aliphatiques dicarboxyliques essayés, l'acide maléique est extrait sélectivement en nitrobenzène en tant que complexe d'association ionique rouge (λ max. 516 nm) formé entre l'anion hydrogénomaléate et le cation tris(1,10-phénanthroline)fer(II). Une quantité molaire au moins 32 fois supérieure de tris (1,10-phénanthroline)fer(II) par rapport à l'acide maléique est nécessaire, et le domaine de pH optimal est de 3–5. On obtient une relation linéaire dans le domaine de concentrations 10^{-5}–10^{-4} M en acide maléique. L'écart type relatif est de 1,0%. L'intensité de coloration de l'extrait reste constante à température ordinaire pendant au moins 24 h. Une grande quantité d'acide fumarique, l'isomère *trans* de l'acide maléique, n'est pas extraite dans les mêmes conditions. Ceci rend possible le dosage de l'acide maléique en la présence d'acide fumarique.

Summary—Sedimentation potentials under a centrifugal field are studied with the disperse system titanium dioxide, alkyd resin and xylene. The relationships between the sedimentation potential and the rotation speed, the distance apart of the electrodes in the cell and the total weight of particles in the disperse system are examined. From the theoretical evaluation of the initial sedimentation potential, the zeta potential of the pigment in the disperse system is calculated. The calculated value was almost coincident with that obtained by the electrophoretic method. As the sedimentation potential is proportional to the total weight of pigment in the space between the electrodes in the cell, the particle-size distribution of pigment can be obtained from the sedimentation potential-time curve. The particle-size distribution in the above-mentioned disperse system was examined with respect to the effect of rotation speed and the pigment content. The modal diameter for the particle-size distribution obtained by this method had almost the same value as that obtained by the electron microscope method. By use of this method for particle-size analysis, the particle-size distribution for particles of diameter <1 μm can be obtained in a short time (*ca.* 10–30 min) and the zeta potential of the particles in the disperse system can be calculated.

MEASUREMENT OF SEDIMENTATION POTENTIAL IN NON-AQUEOUS DISPERSE SYSTEMS AND ITS THEORETICAL EVALUATION

PREVIOUSLY, one of the authors has measured the electrophoretic velocities of particles in a non-aqueous disperse system and from those results calculated the zeta potential by using the Helmholtz equation, and pointed out that the stability of a disperse system is dependent on the charges of the particles even in a non-aqueous system of low dielectric constant.[1,2]

This paper describes the measurement of sedimentation potential of particles in a non-aqueous disperse system under a centrifugal field.[3]

EXPERIMENTAL

Instrument

The centrifuge was driven by a belt connecting it to a motor *via* a set of interchangeable pulleys giving speeds of 250, 520, 1050 and 1560 rpm. The input impedance of the amplifier for measurement of the sedimentation potential was $>10^{12}$ ohm and the total sensitivity of the amplifier and the recorder was 1 mV for full-scale deflection. The sensitivity could be reduced by means of voltage dividers applied to the input and output signals of the amplifier.

The construction of the sample cell is shown in Fig. 1. The cell is made of Teflon, and the platinum ring-shaped electrodes have an inner diameter of 8 mm. The distance between the two electrodes is variable in 5 steps: 20, 25, 30, 35 and 40 mm.

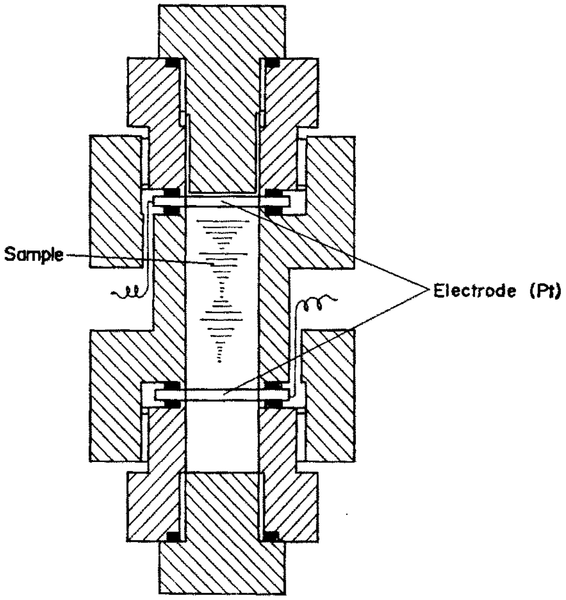

FIG. 1.—Construction of the cell.

Materials and sample preparation

An oily short-chain alkyd resin dissolved in xylene was used as the dispersion medium and titanium dioxides *A*, *B* and *C* as the dispersed phase. *A* was a non-surface-treated grade, *B* was treated with aluminium oxide, zinc oxide and silica, and *C* was for use in paint.

The disperse systems were prepared at several concentrations, after dispersing 10% pigment in 5% resin solution with a ball mill. The final disperse system was agitated for at least 30 min (usually 30–60 min) to give a reproducible dispersion of the particles in each run.

Procedure

The validity of the following equations was examined [for symbolism see below; *cf.* appendix, equations (6) and (12′)].[4]

$$(E_{\text{sed}})_{t=0} = k_2 \cdot \frac{r_1 + r_2}{2} \cdot \omega^2 \cdot \frac{3W}{4\pi\rho} \tag{1}$$

$$k_2 = \frac{(\rho - \rho_0)D_0\zeta f}{3K\eta_0} \tag{2}$$

It was assumed that each particle had the same zeta potential. Other values of the factors of the sedimentation potential were measured as follows. The viscosity of the dispersion medium was measured with an Ostwald viscometer and the electric conductivity by the current flowing on applying a d.c. voltage across the cell electrodes. The dielectric constant was measured with 1 kHz. As the dielectric constant used for calculation of the zeta potential should be that at the interface between the particle and the medium, but we assumed for convenience that the dielectric constant was almost constant in the whole liquid phase.

The distance between the rotating axis and the electrodes was designed to be large enough to be taken as practically equal for both electrodes. This is necessary for the simple treatment, because the centrifugal force acting on the particles is proportional to the distance between the rotating axis and the particle. In this instrument the distance between the furthest electrode and the rotating axis was 0·20 m. The time required to reach steady rotation was observed to be 2·5 sec at 1560 rpm, 2·0 sec at 1050 rpm, or 1·0 sec at 520 rpm.

RESULTS AND DISCUSSION

The initial sedimentation potential

An example of the sedimentation potential–time curve obtained with this instrument is shown in Fig. 2. The time required to reach the maximum potential

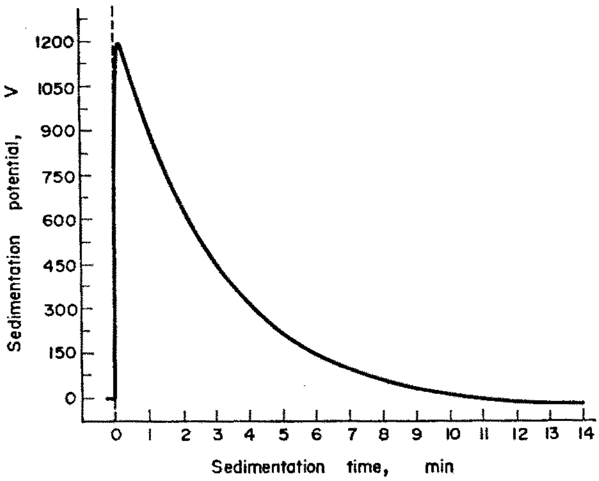

FIG. 2.—Sedimentation potential–time curve.
Suspension: TiO$_2$ *B* 5%, alkyd resin 3%, xylene 92%; 1560 rpm; 30-mm cell

was about 7 sec. Therefore the capacitance of the cell is considered to contribute to the potential decay. This consideration was supported by the fact that the time required for a steady current to flow was 7–8 sec after the voltage had been applied across the cell.

As it is very difficult to determine the amount of pigment during the sedimentation, the initial sedimentation potential should be used to calculate the zeta potential from equations (1) and (2). The authors tried to determine the initial potential by extrapolation of the curve, using two methods of filling the cell with suspension, as shown in Fig. 3. One mode is to fill with suspension just to the level of the upper

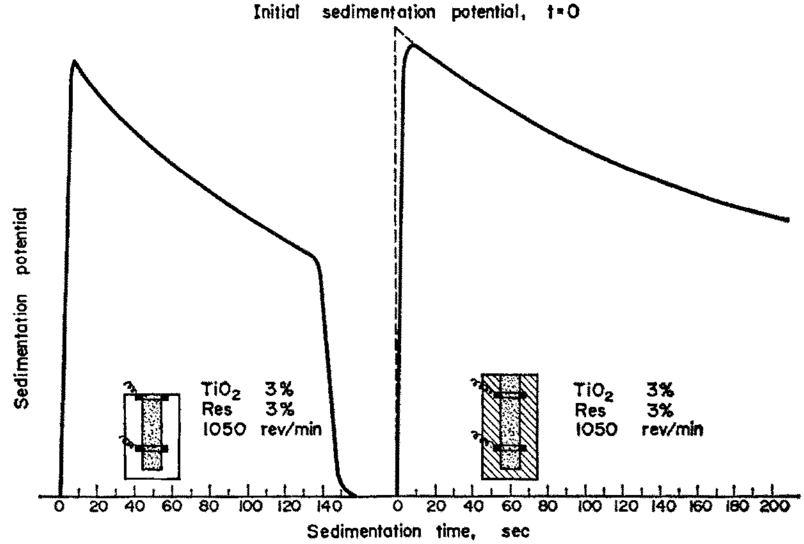

FIG. 3.—Relationship between settling rate and initial sedimentation potential, for two types of cell filling.
Sample: TiO$_2$ 3%, alkyd resin 3%; measured at 1050 rpm.

electrode (nearer to the rotating axis) as shown at the left of Fig. 3, and the other to fill it to above this level, as shown on the right. In the first mode, particles will be removed more and more from the space between the electrodes as the time elapses, and so the particle-size distribution changes immediately after the beginning of rotation. In the other, as the particles above the level of the upper electrode enter the space between the electrodes for some time after the beginning of rotation, the particle-size distribution will not change and only the distances between the particles will decrease to $1/\alpha$ of the initial distance, where $\alpha = \exp k_1\omega^2a^2t$ [*cf.* appendix equation (8)].

Therefore the sedimentation potential, E_{sed}, decreases according to the equation

$$E_{\mathrm{sed}} = \sum_{a=0}^{\infty} \frac{k_2\omega^2}{2(r_2 - r_1)} [a^3\phi(a)e^{-k_1\omega^2a^2t}({r_2}^2 - {r_1}^2e^{2k_1\omega^2a^2t})] \tag{3}$$

As $a^3\phi(a)$ for each particle size is regarded as constant for some time after the beginning of rotation, E_{sed} is expressed as the summation of linear equations of t. That is,

$$E_{\mathrm{sed}} = \sum_{a=0}^{\infty} \frac{k_2\omega^2(r_2 - r_1)}{2} a^3\phi(a)\left(1 - \frac{{r_1}^2 + {r_2}^2}{{r_2}^2 - {r_1}^2} \cdot k_1\omega^2a^2t\right) \tag{4}$$

From (4) it is obvious that the extrapolation of the sedimentation potential–time curve for the second mode of filling gives the initial sedimentation potential. This initial sedimentation potential is proportional to $(r_1 + r_2)/2$ [*cf.* appendix equation (12′)] and so we can calculate the zeta potential by equation (1). However, both extrapolation values were experimentally almost the same, when the particles were very fine and the rotation speed was small.

Relationship between the sedimentation potential and the amount of pigment particles in the space between the electrodes

Assuming that the specific gravity of the particles is independent of the diameter, the relationship between the sedimentation potential and the total weight of particles should be linear, from (4). The total weight of particles was determined by weighing the amount of solid matter obtained by drying at 105° for 3 hr a sample of suspension from the space between the electrodes, taken when the rotation was stopped. The points plotted for pigment weight *vs.* sedimentation potential lay on straight lines for various rotation speeds, the slope increasing with rotation speed, but the lines did not pass through the origin, and the value extrapolated to zero potential was 0·005 g (the initial amount of pigment was *ca.* 0·06 g). The potential decay after the centrifuge was switched off is shown at the left of Fig. 3. It took about 20 sec for rotation to cease. The error caused by sedimentation after switching off is therefore considered to be small. The inequality in centrifugal forces in the cell cannot explain the fact that the straight lines do not pass through the origin, because this effect might decrease the weight found. The discrepancy may be due to the inequality of zeta potentials for the particle systems, or to other causes. However, as the intercept was very small, the experimental results were taken as agreeing with equation (1) within experimental error.

Relationship between initial sedimentation potential and the electrode distance as well as the rotation speed

The relationship between the initial sedimentation potential and the total weight of particles at the beginning can be obtained by using cells with various electrode distances. From (1),

$$\frac{2(E_{\text{sed}})_{t=0}}{r_1 + r_2} = k_2\omega^2 W \frac{3}{4\pi\rho} \tag{5}$$

As the total weight, W, of particles in the space between the electrodes is proportional to the distance l between the two electrodes, the left-hand side (LHS) of the expression should be proportional to l and ω^2. The results obtained with various rotation speeds and distances between the electrodes gave straight-line plots which passed through the origin, showing equation (5) to be consistent with the experimental results [LHS plotted *vs.* l and $(\text{LHS})^{1/2}$ *vs.* ω].

Resistance of the cell

When the resistance of the cell containing the suspension is R,

$$R = \frac{r_2 - r_1}{\lambda} \cdot C_l \tag{6}$$

where λ is the specific conductivity of the suspension and C_l is a constant. When the electrode distance was changed, the change in R for various concentrations of particles was small. The calculated values of C_l were constant within ±3%.

Relationship between initial sedimentation potential and concentration of particles

This relationship is shown in Fig. 4. When the amount of the potential-determining alkyd resin is small compared with the amount of pigment, the special adsorption layer of alkyd resin cannot cover the particles and so the zeta potential is considered to become lower.

Relationship between zeta potential and the resin content

The zeta potential of titanium dioxide was calculated for various concentrations of alkyd resin. The results are shown in Fig. 5. Generally speaking, the lower the resin content, the higher the zeta potential. Below 0·3%, the amount of resin dissolved in the xylene becomes so small that the stability of the suspension is reduced and measurements become very difficult. These effects have been reported by van der Minne and Hermanie.[5,6]

The results shown in Fig. 5 show the same trend as those calculated[1] by the electrophoretic method. Although the former are a little lower, they are satisfactory, considering the difference in the methods.

MEASUREMENT OF PARTICLE-SIZE DISTRIBUTION IN NON-AQUEOUS DISPERSE SYSTEMS BY MEANS OF THE SEDIMENTATION POTENTIAL

In industries handling disperse systems of micro-size particles, it is very important to measure the state of dispersion. Among many methods defining this, the particle-size distribution is the most useful. Both the rheological and the optical properties

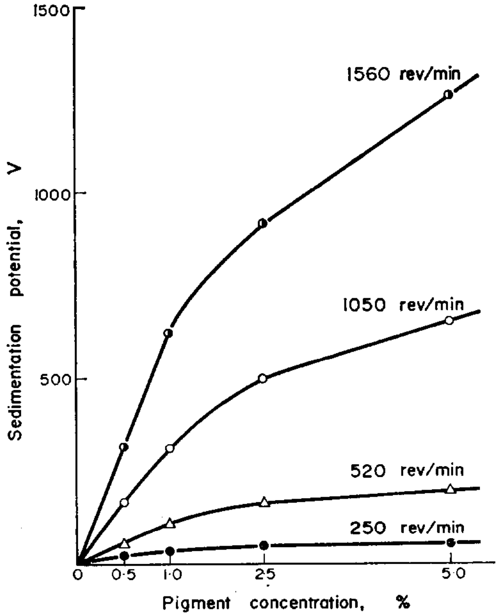

FIG. 4.—Relationship between pigment concentration and initial sedimentation potential.
Resin 3%; 30 mm-cell

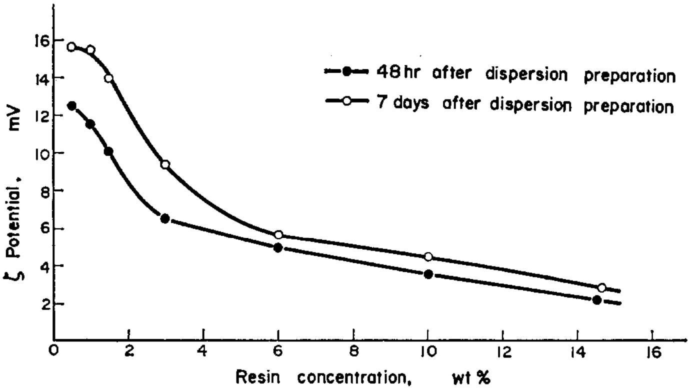

FIG. 5.—Relationship between resin concentration and zeta potential.
Pigment 1%

of the dispersed system change with the particle-size distribution. In industrial applications it is most desirable to know this distribution. Several methods for determining the particle-size distribution are known, but some problems still exist in the preparation of samples and in the measuring systems. Here we describe the method for calculating the particle-size distribution from measurements of the sedimentation potential, where the state of the sample is the same or nearly the same as in industrial use.

It was shown above that the sedimentation potential is proportional to the total weight of particles existing in the space between the electrodes in the cell. Therefore the sedimentation potential–time curve can reflect the curve for total weight of sedimented particles *vs.* time. Then the particle-size distribution obtained from the sedimentation potential–time curve is based on the weight of particles. Strictly speaking it is based on the product of zeta potential and weight of particles, but assuming the specific gravity and the zeta potential of particles in the disperse system are independent of the diameter of the particles, the statement just made will hold true.

EXPERIMENTAL

Sample and preparation

Titanium dioxide *C* was used as before.

Conditions for measurement

All measurements were made at 25°. Because in the two-liquid-layer method the sedimentation potential in the second layer should be different from the initial sedimentation potential, and so the particle-size distribution should deviate from the initial distribution, the homogeneous liquid method was used. In the homogeneous liquid method it must be noted that the dispersed state of the sample and the time required for measurement play the most important parts.

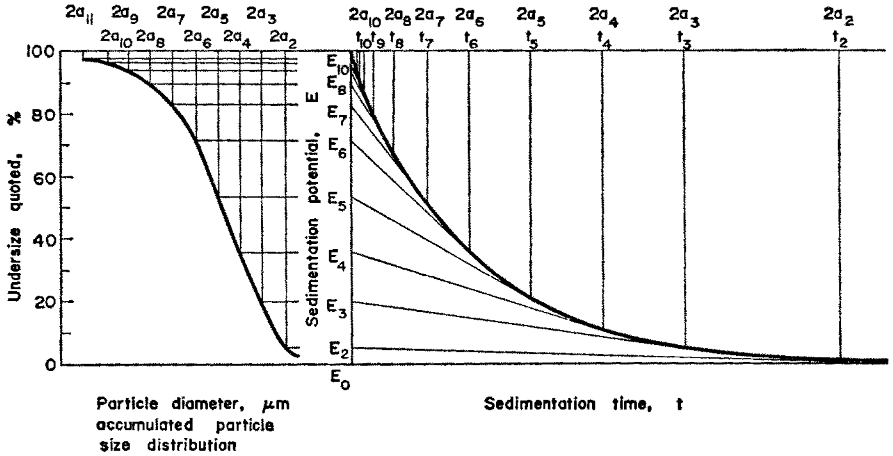

FIG. 6.—Construction of cumulative particle-size distribution diagram from sedimentation potential–time curve.

Configuration of particle-size distribution curve

When the radius of the largest particles still existing in the space between the electrodes at time t after the beginning of centrifugation is a_m, t can be calculated for each given a_m from $t = ln\,(r_2/r_1)/k_1\omega^2 a_m^2$ [cf. appendix equation (12)]. So the first step for obtaining the particle-size distribution curve is to calculate t for each increment of 0·05 μm in a_m <0·5 μm and of 0·1 μm in a_m > 0·5 μm. Then the extrapolation to $t = 0$ of the tangent to the sedimentation potential–time curve at t gives the ordinate of the cumulative particle-size distribution curve at a_m. An example is shown in Fig. 6.

RESULTS AND DISCUSSION

Theoretical calculation of the particle-size distribution from the sedimentation potential

In sedimentation under a centrifugal field, the centrifugal force on a particle is proportional to the distance between the particle and the rotating axis. Therefore the force is a function of sedimentation time. On this basis equation (7) can be derived relating the particle-size distribution to the sedimentation potential [*cf.* appendix equation (12)].

$$E_{\text{sed}} = \frac{k_2\omega^2}{2(r_2 - r_1)} \times \int_0^{a_t} a^3\phi(a)(r_2{}^2e^{-k_1\omega^2a^2t} - r_1{}^2e^{k_1\omega^2a^2t})\,da \qquad (7)$$

where $a_t = (\ln (r_2/r_1)/k_1\omega^2t_2)^{1/2}$, and k_1 is a constant related to the viscosity and density of the dispersion medium or the suspension; k_2 is a constant related to the viscosity, density, dielectric constant and electric conductivity of the dispersion medium and zeta potential of the particles in suspension; r_1 and r_2 are the radii of rotation of the electrodes. On putting $t = 0$ we obtain

$$(E_{\text{sed}})_{t=0} = k_2\omega^2 \frac{r_1 + r_2}{2} \int_0^{\infty} a^3\phi(a)\,da \qquad (8)$$

Therefore the initial sedimentation potential is equal to the potential which all particles would exhibit if they were gathered at the middle plane between the two electrodes.

Dependence of the particle-size distribution on the conditions of measurement

Typical sedimentation potential–time curves for titanium dioxide *C* in various concentrations are shown in Fig. 7 and the particle-size distribution curves derived are shown in Fig. 8. Table 1 gives the model and median diameters for each rotation speed and pigment content.

Effect of the pigment content. The pigment content has no large effect on the cumulative particle-size distribution curve, but there is a tendency for the number

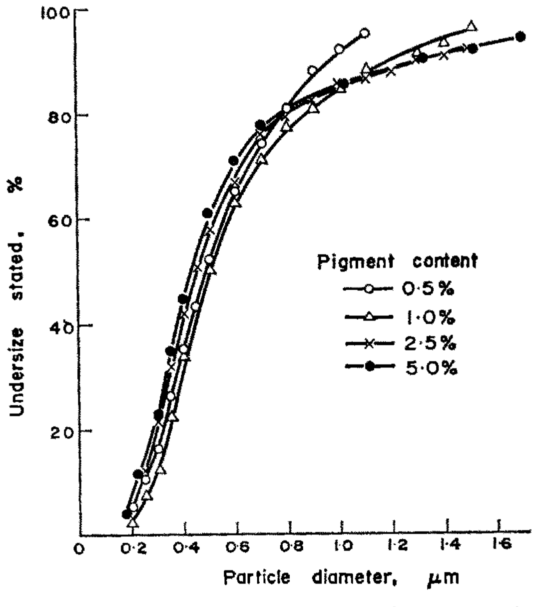

FIG. 7.—Cumulative particle-size distribution measured at 520 rpm.

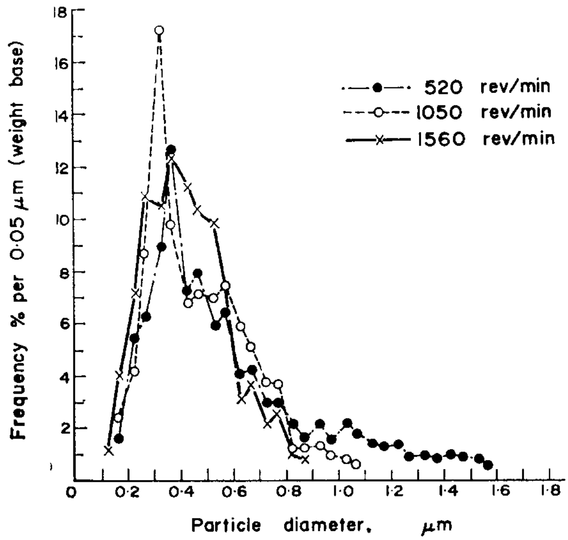

FIG. 8.—Particle-size distribution measured on a 1% suspension of pigment.

of large particles to increase as the pigment concentration increases. This may be caused by an increase in the number flocculated particles, but both the model and median diameters coincide within 0·1 μm, though the latter are inclined to decrease with increase in pigment concentration.

TABLE I.—RELATIONSHIPS OF THE MODAL AND MEDIAN DIAMETERS TO THE ROTATION SPEED AND PIGMENT CONTENT

Pigment concentration %		Diameter, μm 520 rpm	1050 rpm	1560 rpm
0·5	Mode	0·30–0·35	0·35–0·40	0·35–0·40
	Median	0·48	0·48	0·38
1·0	Mode	0·35–0·40	0·30–0·35	0·35–0·40
	Median	0·49	0·45	0·42
2·5	Mode	0·30–0·35	0·35–0·40	0·35–0·40
	Median	0·44	0·43	0·39
5·0	Mode	0·30–0·35	0·30–0·35	0·35–0·40
	Median	0·42	0·42	0·38

Effect of the rotation speed. The rotation speed is recognized as having little effect on the distribution curve. In the figures the distribution was plotted for 0·05 μm intervals. If the distribution at 0·1 μm intervals had been plotted, the curves would have agreed better. The differences for the larger particles are perhaps due to errors in drawing.

Comparison between the distribution curves obtained by the sedimentation potential and the electron microscope methods. In Fig. 9 are shown the distribution curves based on particle weight and on number of particles. Figure 10 shows the distribution

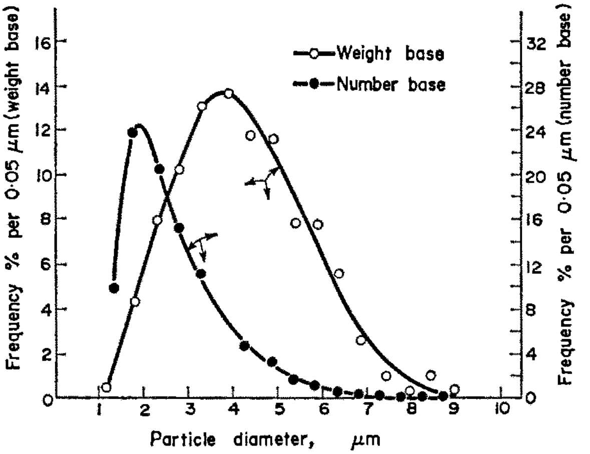

FIG. 9.—Relationship between particle-size distributions on weight base and number base.
Measured at 1560 rpm, 0.5% pigment, sedimentation potential method

curve obtained by the measurement of the fixed-direction diameter for 1000 particles by electron microscope.

The distribution-curve obtained by the electron microscope method is based on number of particles and that from the sedimentation potential method is based on particle weight (strictly, on the product of the weight and zeta potential of the particle). For comparison, weight-base and number-base distribution curves are both plotted in Figs. 9 and 10.

In the electron microscope method, combined images of particles are not counted, as the images of aggregated particles cannot be distinguished from overlapping images of separate particles. Because aggregated particles are not counted, the

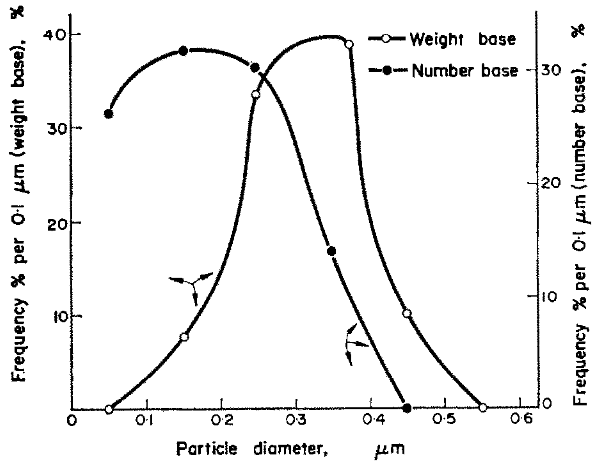

FIG. 10.—Relationship between particle-size distribution on weight and number base.
Electron microscope method.

single particle concentration becomes higher. For this reason the particle-size distribution curve deviates noticeably from a logarithmic normal distribution curve. On the other hand, in the sedimentation potential method the particle size means the diameter of particle which moves as a kinetic unit in the disperse system. Therefore the distribution curve is similar to the logarithmic normal distribution curve, because the aggregated particles are counted. The model diameters (two methods of measurement) were 0·3–0·4 μm based on the particle weight and about 0·2 μm based on the number of particles.

Zusammenfassung—Sedimentationspotentiale in einem Zentrifugalfeld wurden an der Dispersion aus Titandioxid, Alkydharz und Xylol studiert. Die Beziehungen zwischen Sedimentationspotential und Rotationsgeschwindigkeit, Abstand von den Elektroden in der Zelle und Gesamtgewicht der Teilchen in der Dispersion werden untersucht. Aus der theoretischen Berechnung des anfänglichen Sedimentationspotentials wird das Zeta-Potential des Pigments in der Dispersion berechnet. Der berechnete Wert fiel mit dem elektrophoretisch ermittelten fast zusammen. Da das Sedimentationspotential proportional ist zum Gesamtgewicht des Pigments im Raum zwischen den Elektroden in der Zelle, kann man aus der Kurve, die das Sedimentationspotential in Abhängigkeit von der Zeit wiedergibt, die Teilchengrößenverteilung des Pigments erhalten. Die Teilchengrößenverteilung in der erwähnten Dispersion wurde im Hinblick auf den Einfluß von Rotationsgeschwindigkeit und Pigmentanteil untersucht. Der äquivalente Durchmesser der Teilchengrößenverteilung, der auf diese Weise erhalten wurde, war fast gleich dem elektronenmikroskopisch ermittelten. Verwendet man dieses Verfahren für die Teilchengrößenanalyse, so kann man die Größenverteilung bei Teilchen mit Durchmessern <1 μm in kurzer Zeit (*ca.* 10–30 min) erhalten und das Zeta-Potential der Teilchen in der Dispersion berechnen.

Résumé—On étudie les potentiels de sédimentation dans un champ centrifuge avec le système dispersé dioxyde de titane, résine alkyde et xylène. On examine les relations entre le potentiel de sédimentation et la vitesse de rotation, l'éloignement des électrodes dans la cellule et le poids total des particules dans le système dispersé. De l'évaluation théorique du potentiel de sédimentation initial, on calcule le potentiel dzéta du pigment dans le système dispersé. La valeur calculée coïncide presque avec celle obtenue par la méthode électrophorétique. Comme le potentiel de sédimentation est proportionnel au poids total de pigment dans l'espace entre les électrodes dans la cellule, la répartition du pigment par dimensions de particules peut être obtenue à partir de la courbe potentiel de sédimentation—temps. La répartition par dimensionsde particules dans le système dispersé mentionné ci-dessus a été examinée par rapport à l'influence de la vitesse de rotation et de la teneur en pigment. Le diamètre modal pour la répartition par dimensions de particules obtenu par cette méthode a presque la même valeur que celle obtenue par la méthode au microscope électronique. En utilisant cette méthode pour l'analyse de dimensions de particules, on peut obtenir la répartition par dimensions de particules en un temps court (environ 10–30 mn) pour des particules de diamètre <1 μm, et l'on peut calculer le potentiel dzéta des particules dans le système dispersé.

APPENDIX

The sedimentation potential and the particle-size distribution

The following five assumptions were made for the theoretical derivation of the sedimentation potential under the centrifugal field as a function of the particle-size distribution.

(1) The particle is a sphere and is not combined.
(2) The particle is very small and settles out in a laminar flow.
(3) The retardation of the sedimentation velocity induced by the particle charge can be neglected.
(4) All particles have equal density and equal zeta potential.
(5) The electrical conductivity of the suspension is not affected by the pigment content.

When the particles settle out from the dispersion medium, the kinetic equation for the stationary velocity of particles is

$$\frac{4}{3}\pi(\rho - \rho_0)a^3\omega^2x = 6\pi\eta_0 a\frac{\mathrm{d}x}{\mathrm{d}t} \tag{1}$$

where x is the distance between the rotating axis and a particle at time t. From (1),

$$\frac{\mathrm{d}x}{\mathrm{d}t} = \frac{2}{9}\cdot\frac{\rho - \rho_0}{\eta_0}\omega^2a^2x \tag{2}$$

$$= k_1\omega^2a^2x \tag{2'}$$

where

$$k_1 = \frac{2(\rho - \rho_0)}{9\eta_0} \tag{3}$$

Solving the differential equation (2′),

$$\ln x = k\omega^2a^2t + \text{constant}$$

If the distance of the particle from the axis is r_1 when $t = 0$,

$$\text{constant} = \ln r_1$$

and

$$\ln\frac{x}{r_i} = k_1\omega^2a^2t \tag{4}$$

$$x = r_ie^{k_1\omega^2a^2t} \tag{4'}$$

On the other hand, when the homogeneously dispersed spherical particles settle out, the gradient of sedimentation potential is,[4]

$$V = \frac{a^3(\rho - \rho_0)n_0gD_0\theta}{3K\eta_0}$$

When the ratio of the radius of the particle to the thickness of the electrical double layer, χa, is negligible compared to unity, this equation should be written as

$$V = \frac{a^3(\rho - \rho_0)n_0gD_0\theta f}{3K\eta_0}$$

where if the particle is a sphere, f is equal to 2/3.

The sedimentation potential, E_{sed}, *i.e.*, the difference between the potentials of the two electrodes is

$$E_{\text{sed}} = V(r_2 - r_1)$$

$$= \frac{a^3(\rho - \rho_0)n_0(r_2 - r_1)gD_0\theta f}{3K\eta_0}$$

When the cross-sectional area of the cell is A, the total number of particles in the space between the two electrodes, n, is $An_0(r_2 - r_1)$. When n is used instead of n_0 in the equation above, KA should be used instead of K.

Therefore

$$E_{\text{sed}} = \frac{a^3(\rho - \rho_0)ngD_0\theta f}{3K\eta_0}$$

When the number of particles existing in the space between x and $x + \mathrm{d}x$ away from the rotating axis is Δn, the sedimentation potential ΔE_{sed} across this space is given by

$$\Delta E_{\text{sed}} = \frac{a^3(\rho - \rho_0)\Delta n \cdot \omega^2xD_0\theta f}{3K\eta_0} \tag{5}$$

$$= k_2a^3\Delta n \cdot \omega^2x \cdot f \tag{5'}$$

where

$$g = \omega^2x$$

$$k_2 = \frac{(\rho - \rho_0)D_0\theta f}{3K\eta_0} \tag{6}$$

The total weight of particles W in the space between the electrodes is

$$W = \frac{4}{3}\pi\rho\int_0^\infty a^3\phi(a)\,\mathrm{d}a \tag{7}$$

From (4′), writing x_t for the distance (at time t) between the axis and the particle which was initially at a distance x from the axis,

$$x_t = xe^{k_1\omega^2a^2t}$$

and putting $x_t + \alpha\Delta x$ for the distance (at time t) between the axis and the particle which was initially $x + \Delta x$ from the axis,

$$x_t + \alpha\Delta x = (x + \Delta x)e^{k_1\omega^2a^2t}$$

Therefore

$$\alpha = e^{k_1\omega^2a^2t} \tag{8}$$

This equation shows that the rate of change of the number of particles in a differential space during centrifuging is $1/\alpha$ and independent of the initial distance x. Hence the number of particles existing in a thickness $\mathrm{d}x$ of suspension at t can be expressed by

$$\phi(a)\cdot\frac{\mathrm{d}x}{\alpha(r_2 - r_1)} = \frac{\phi(a)\,\mathrm{d}x}{(r_2 - r_1)e^{k_1\omega^2a^2t}}$$

Then the sedimentation potential of a particle of radius a at time t can be written as follows from (5′):

$$(E_{\mathrm{sed}})_{a.} = \int_{x_1}^{x_2} k_2 a^3 \omega^2 x \cdot \frac{\phi(a)}{(r_2 - r_1) e^{k_1 \omega^2 a^3 t}} \cdot \mathrm{d}x$$

$$= \frac{k_2 \omega^2}{2(r_2 - r_1)} \left[\frac{a^3 \phi(a)}{e^{k_1 \omega^2 a^2 t}} (r_2^2 - x_1^2) \right] \tag{9}$$

where x_1 is the distance between the rotating axis and the particle initially nearest to it at t. So from (4′)

$$x_1 = r, e^{k_1 \omega^2 a^2 t}$$

Substituting this expression for x_1 into (9) we have,

$$(E_{\mathrm{sed}})_{a,t} = \frac{k_2 \omega^2}{2(r_2 - r_1)} \left[\frac{a^3 \phi(a) (r_2^2 - r, e^{2k_1 \omega^2 a^2 t})}{e^{k_1 \omega^2 a^2 t}} \right] \tag{10}$$

The largest particles among those existing in the space between the electrodes at t reach a distance r_2 from the axis, if they were at distance r_1 initially. Putting the largest radius as a_{m}, from (4′), we have

$$r_2 = r_1, e^{k_1 a_m^2 \omega^2 t}$$

$$A_{\mathrm{m}} = \sqrt{\frac{\ln (r_2/r_1)}{k_1 \omega^2 t}} \tag{11}$$

Therefore the sedimentation potential for all particles at t is obtained by integrating (10) with respect to the radii of the particles.

$$(E_{\mathrm{sed}})_t = \frac{k_2 a^2}{2(r_2 - r_1} \int_0^{a_m} \frac{a^3 \phi(a)(r_2^2 - v_1^2 e^{2k_1 \omega^2 a^2 t}}{e^{k_1 \omega^2 a^2 t}} \, \mathrm{d}a$$

$$= \frac{k \omega^2}{2(r_2 - r_1)} \int_0^{a_m} a^3 \phi(a)(r_2^2 e^{-k_1 \omega^2 a^2 t} - r_1^2 e^{k_1 \omega^2 a^2 t}) \, \mathrm{d}a \tag{12}$$

And when $t = 0$, a_{m} is infinity from (11), and so (12) is written as follows, from (7).

$$(E_{\mathrm{sed}})_{t=0} = \frac{k_2 \omega^2}{2(r_2 - r_1)} \cdot (r_2^2 - r_1^2) \int_0^{\infty} a^3 \phi(a) \, \mathrm{d}a$$

$$= k_2 \cdot \frac{r_1 + r_2}{2} \cdot \omega^2 \cdot \frac{3\overline{W}}{4\pi\rho} \tag{12′}$$

This equation shows that the sedimentation potential at $t = 0$ is equal to the sedimentation potential which would be generated if all the particles were at the middle plane between the two electrodes.

Derivation of the equation for the sedimentation potential

The curve for the potential distribution round a particle in the dispersion medium is very complex, even if the particle is spherical, but it can be expressed approximately as follows:

$$\theta = \theta_0 \frac{a}{y} e^{-\chi(y-a)} \tag{13}$$

where θ is the potential in the medium at a distance y from the centre of the particle and θ_0 is the potential of the particle. On the other hand, the charge per unit area around the particle is as follows, by the Poisson equation:

$$z = -\frac{D_0}{4\pi} \frac{\partial^2 \phi}{\partial y^2} \tag{14}$$

Since $\partial\theta/\partial y = 0$ inside the particle, the charge at the interface of the particle and medium, z_0, is expressed by

$$z_0 = -\frac{D_0}{4\pi} \left(\frac{\partial \theta}{\partial y} \right)_{y=a} \tag{15}$$

By substituting (13),

$$\frac{\partial\theta}{\partial y} = \frac{\theta_0 a}{y}(1 + \chi y)e^{-\chi(y-a)} \tag{16}$$

From (15) and (16)

$$z_0 = \frac{D_0\theta_0}{4\pi a}(1 + \chi a)$$

Therefore the total charge, Q, of the particle is

$$Q = \theta_0 D_0 a(1 + \chi a) \tag{17}$$

When the dispersion medium is a non-aqueous solution, the zeta potential is nearly equal to the surface potential. Then substituting ζ for θ_0 in (17), we have

$$Q = \zeta D_0 a(1 + \chi a) \tag{17'}$$

Assuming χa is negligible compared to unity, for non-aqueous medium,

$$Q = \zeta D_0 a \tag{18}$$

and the number of particles passing across the cross-section of the cell in unit time is $An_0(dx/dt)$. Then from (18) and (2) the streaming current, I_{str}, is given by

$$I_{str} = \frac{2An_0(\rho - \rho_0)a^3\omega^2 x\zeta D}{9\eta_0} \tag{19}$$

This streaming current is responsible for the streaming potential, E_{str}. At steady state it must be balanced by a current which accords with Ohm's law. This back-current is expressed by

$$I' = -\frac{AKE_{str}}{l} \tag{20}$$

where l is the distance between the two electrodes with which the potential is measured.

When the input impedance of the amplifier for the measurement of potential large enough for the current flowing out of the cell, to be neglected,

$$I_{str} + I' = 0 \tag{21}$$

Substituting (19) and (20) into (21),

$$E_{sed} = \frac{2n_0 a^3 l(\rho - \rho_0)\omega^2 x\zeta D_0}{9K\eta_0}$$

Putting $n = n_0 l$

$$E_{sed} = \frac{2a^3 n(\rho - \rho_0)\omega^2 x\zeta D_0}{9K\eta_0} \tag{22}$$

For a spherical particle, the retardation coefficient (or shape factor) f is 2/3. Hence

$$E_{sed} = \frac{a^3 n(\rho - \rho_0)\omega^2 x\zeta D_0}{3K\eta_0} \tag{23}$$

(*Received* 19 *June* 1971. *Accepted* 24 *November* 1971)

Summary—The polarogram of tellurium(IV) in weakly basic solution has a sharp maximum on the diffusion current plateau. The electrode process causing this maximum has been examined by means of various techniques such as semiconductor catalysis, "block" polarography and ultraviolet irradiation of the dropping mercury electrode. The maximum was found to be caused by the catalytic wave of hydrogen produced by the tellurium deposited on the mercury surface. Part of the tellurium is reduced to hydrogen telluride by nascent hydrogen formed catalytically. The brown mist which usually appears in the vicinity of the surface of the dropping mercury cathode consists of elemental tellurium produced by the decomposition of the hydrogen telluride near the electrode. The sudden decrease in the current maximum at a potential more negative than the peak potential of the maximum is due to desorption of tellurium, caused by movement of mercury.

THE POLAROGRAPHIC MAXIMUM of tellurium was found in 1935 by Schwaer and Suchy,[1] who said that this maximum seemed to be closely connected with the reduction of the hydrogen ion. Lingane and Niedrach[2,3] reported that this maximum was probably due to catalytic reduction of the hydrogen ion in acidic solution, and they found that a brown mist formed in the vicinity of the dropping mercury electrode (d.m.e.). Von Stackelberg *et al.*[4,5] reported on the mechanism of the generation of brown mist and the polarographic maximum. Since then, several papers[6–8] concerning the polarographic reduction of Te(IV) have appeared.

The polarographic reduction of Te(VI) was described by Norton *et al.*[9] in 1953, and again a maximum appeared which depended on the nature of the sample solution. Further reports[5,10,11] on the polarographic reduction of Te(VI) discuss the nature of the maximum.

In earlier papers,[12,13] we reported obtaining a maximum wave of similar kind when polarographing a suspension of tellurium powder in ammonium chloride solution. When a piece of tellurium block was put into contact with the d.m.e., the same kind of maximum wave was observed. Irradiation of the d.m.e. with ultraviolet light depressed the maximum current, and when the irradiation was stopped the current recovered. On the basis of these results, the mechanism of the tellurium maximum has to be reconsidered.

EXPERIMENTAL

Tellurium ingot (99·9999% purity; Osaka Asahi Metal Mfg. Co. Ltd.) was cut into pieces or ground into powder in an agate mortar.

Tellurium in the form of TeO_2, TeO_3, H_2TeO_3, K_2TeO_3, $(NH_4)_2TeO_3$, H_6TeO_6 and $NH_4HTeO_4{\cdot}2H_2O$ was obtained in chemically pure grade.

A Yanagimoto P-8 type polarograph was used for the d.m.e. work, and a Yanagimoto VE-3 type automatic apparatus for constant-potential electrolysis was used for the work with a mercury pool cathode and a carbon rod anode.

In the "suspension polarography" the sample solution was prepared by adding powdered metallic tellurium or a tellurium compound to the electrolyte solution, and current–potential curves were recorded with use of the d.m.e. while the sample solution was stirred magnetically. Rate of stirring, temperature of the solution (25° ± 0·1°) and other experimental conditions were kept constant. The conditions for the d.m.e. were: $t = 6{\cdot}0$ sec (open circuit in $1M$ ammonium chloride), $m = 0{\cdot}60$ mg/sec, and $h = 45$ cm. All batches of the electrolytic solution were deaerated with nitrogen before the electrolyses.

A piece of tellurium block was pasted on an end of a glass rod. The block was kept in contact with the hanging mercury drop (see Fig. 3A), and the current–potential curves were recorded by polarograph. This will be called the "block polarograph."

Instantaneous current–time curves were recorded oscillographically with an Iwasaki Synchroscope Model SS-5302 with SP-20 DF-A preamplifier and the Shimadzu Electropotentiostat Model SP-1.

An Ushio Uniarc-250 UR-3 apparatus was used to irradiate the d.m.e. The sample solution was deaerated with nitrogen before use. Experiments were carried out in the dark.

The hydrogen content of the evolved gas was measured with a Yanagimoto Gas-Chromatograph, Model GCG-3.

RESULTS AND DISCUSSION

General characteristics of polarographic maximum of tellurium

Figure 1[(*a*)–(*c*)] shows the polarograms of Te(IV) and Te(VI) in $1M$ ammonium chloride. In the polarogram of Te(IV), the potential range A involves the reduction current due to Te(IV) → Te^0 and the ranges B, C, D, and E have been thought[14] to involve the reduction current due to Te(IV) → Te^{2-}, where B and C involve also the catalytic current.[3,5]

If the concentration of K_2TeO_3 is increased up to $3 \times 10^{-4}M$ in $1M$ ammonium chloride, i_d increases linearly, while i_{max} attains a saturation value, comforming to the Langmuir adsorption isotherm, but shows a kink of the curve at the concentration at which the brown mist appears around the d.m.e. The values of E_{decomp} and E_{max} become a little more negative with increase in Te(IV) concentration, settling at almost $-1{\cdot}15$ and $-1{\cdot}3$ V respectively (all potentials are quoted *vs.* S.C.E.). The values of $(E_{1/2})_p$ and $E_{1/2}$ are $-0{\cdot}32$ and $-0{\cdot}55$ V respectively and independent of the concentration.

With a concentration of ammonium chloride between 0·2 and $1{\cdot}2M$, there is no change in $(E_{1/2})_p$, $E_{1/2}$, E_{decomp}, E_{max}, and i_d, but i_{max} shows a two-step saturation curve, *e.g.*, plateaux at 40 μA for 0·3–$0{\cdot}7M$ NH_4Cl and at 60 μA at $>1M$ NH_4Cl, for $5 \times 10^{-4}M$ K_2TeO_3.

According to Zhdanov and Pats[7] or Lingane and Niedrach,[2] a decrease in pH makes the height of the Te(IV) maximum higher. On the other hand, in strong alkaline solution there is no maximum.[3,8]

"Suspension polarography" of tellurium powder

Figure 1[(*d*) and (*e*)] shows the polarograms for $1M$ ammonium chloride with tellurium powder (150–200 mesh). Curve (*d*) shows what happens during magnetic stirring, and (*e*) what happens after the stirring stops. Curve (*f*) shows the decay curve of i_{max} with time after the stirring stops. These techniques may be called "suspension polarography."

In the case of the suspension polarogram of tellurium powder, the reduction step Te(IV) → Te^0 as in Fig. 1(*a*) cannot be obtained, but a similar maximum is seen on curves (*d*) and (*e*). It indicates that the existence of Te(IV) in the solution is not the necessary condition for the maximum. Combining this with the further experimental

facts to be mentioned later, it is thought that the contact of tellurium with the surface of the mercury electrode is the decisive factor in production of the maximum. So, it is considered that in ordinary polarography the elemental tellurium, reduced from Te(IV), deposits on the mercury drop and plays a role in causing the maximum.

Figure 2 shows the effects of Triton-X-100 and gelatin on the height of the maxima in suspension polarography of tellurium powder with stirring. The effects of those maximum suppressors[3,5,8] on the ordinary maximum of tellurium are illustrated for contrast, showing the same nature of the maximum, whatever its origin. The results of the current–time curves of Kuta's parabola[15] at several applied potentials are shown in Table I.

Besides elemental tellurium, TeO_2, H_2TeO_3 and $(NH_4)_2TeO_3$ powders give analogous typical maxima, but TeO_3, H_6TeO_6 or $NH_4HTeO_4{\cdot}2H_2O$ give a small maximum or none. With potassium or sodium chloride solution as supporting electrolyte a very

large maximum appears, but with potassium[8] or sodium[3] hydroxide the maximum is very small or non-existent.

Block polarography of elemental tellurium

A piece of elemental tellurium is placed in contact with the d.m.e. as shown in Fig. 3. The current begins at the same E_{decomp} as in suspension polarography, but increases linearly with potential sweep in accordance with Ohm's law until the block is detached from the electrode (see Fig. 3-B). It can be seen that the brown mist is spreading out and gas evolving from the whole surface of the tellurium block.

The same kind of phenomenon is seen in suspension polarography with a large particle of tellurium which might hit the mercury electrode by inertia and let the current flow even at potentials from −1·4 to −1·8 V, as shown in Fig. 4.

Adsorption of elemental tellurium on the cathode

In constant-potential electrolysis of Te(IV) in 1*M* ammonium chloride, black deposit of elemental tellurium is seen on the surface of the mercury pool cathode at more negative potentials than —0·5 V. Tellurium deposited on the mercury cathode deforms the electrocapillary curve for suspended tellurium powder (Fig. 5). The

100–150 mesh

depression of the electrocapillary curve is observed just in the potential range between the beginning of the reduction wave of Te(IV) and the maximum. A small peak, *C* in Fig. 5, appears in the depression of the electrocapillary curve at the same time as sudden evolution of hydrogen from the cathode, and it is thought that desorption of elementary tellurium from the electrode makes the electrocapillary process recover synchronously. However, in the presence of gelatin in the solution the catalytic evolution of hydrogen disappears and a depression, without the small peak, is obtained. The shape of this electrocapillary curve is very similar to that of a solution composed of Te(IV), 0·3*M* ammonia and 0·1*M* ammonium chloride, given by von Stackelberg *et al.*[4,5] According to their report,[5] the presence of gelatin does not prevent the adsorption of tellurium which is electrolytically deposited, but does so with telluride.

On the other hand, according to studies at the stationary mercury electrode by Jamieson and Perone,[8] during the reduction Te(IV) → Te^0 at the d.m.e., elemental tellurium remains adhered to the electrode and this desorbs from the electrode at potentials more negative than the maximum.

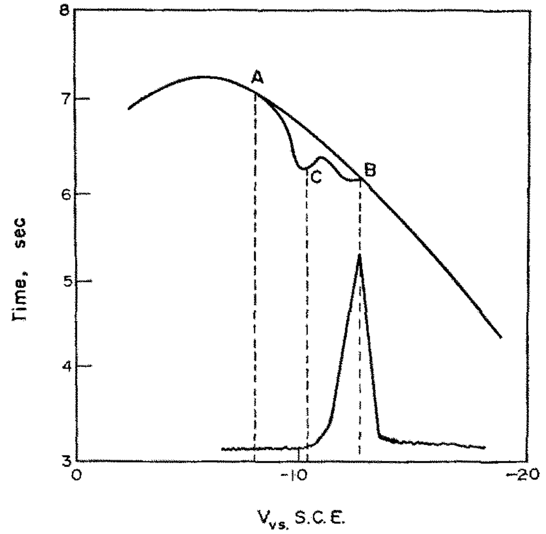

FIG. 5.—Electrocapillary curve for 1*M* NH_4Cl solution with suspended tellurium powder, compared with a "suspension polarogram" of the same solution.

By the adsorption of elemental tellurium on the mercury cathode, a "tellurium electrode" is established over the potential range between the reduction wave of Te(IV) and the maximum of the polarogram, that is the potential range *A* in Fig. 1. At a potential more negative than the maximum, already deposited tellurium departs from the mercury drop as Jamieson and Perone[8] observed for the stationary mercury electrode. This is caused by the relaxation of surface tension of mercury due to the mutual repulsion of negatively charged mercury atoms. Thus mercury moves to the circumference from the site facing the anode, leaving a bright mercury surface at the starting area as shown in Fig. 6. This opinion is different from that of Antwelier and von Stackelberg.[16] The particles of elemental tellurium which have been desorbed and suspended in the bulk of the solution are seen moving rapidly along the surface of the mercury cathode in three types of flow according to the applied potentials, as shown in Fig. 7. Jones and Kaye[17] observed this kind of mercury movement by using a dilute suspension of coal particles.

At the potentials of the positive half of the maximum, the brown mist has an umbrella shape (Fig. 7-*A*), and the surface of the mercury drop is covered with a

tellurium deposit. Especially when it is in a saturated solution of potassium chloride, the mercury drop is apparently black. As soon as the potential reaches the value of E_{max}, the brown mist begins to flow suddenly upward (Fig. 7-*B*). This phenomenon also means that the mercury surface begins to move suddenly at the potential of E_{max}. This is distinctly seen by sudden clearance of the mercury drop from black to bright metallic when it is in a saturated solution of potassium chloride. The mist of elemental tellurium is also observed at the final increase of the current (Fig. 7-*C*).

Catalytic reaction of hydrogen evolution

On increase of the negative potential of the tellurium cathode established on the mercury drop by the electrode process of Te(IV) → Te^0, hydrogen begins to evolve from the tellurium surface at the decomposition potential.

The solution side of the electric double layer at the interface of the tellurium electrode and the solution is negatively charged, and its electrostatic potential equals the work function of the solution, Φ_{sol}, less the electron affinity of tellurium, χ_{Te}. Taking Φ_{Te} as the work function of tellurium, the potential barrier which hinders electron-flow from tellurium to the solution is expressed by $\Phi_{sol} - \Phi_{Te}$. When a cathodic potential V is applied to tellurium the barrier amounts to $\Phi_{sol} - \Phi_{Te} - eV$.[14] So if this value becomes enough to give rise to the maximum, the surface of the tellurium electrode is relatively rich in electrons and has the character of telluride. According to Lingane and Niedrach[3] telluride is present as H_2Te at pH 4, and as HTe^- at $4 < pH < 11$. The adsorbed hydrogen will be very quickly reduced, as follows.

$$\begin{tikzcd}[column sep=small] \mathrm{HTe}^-_{ads} & + e^- \longrightarrow \tfrac{1}{2}\mathrm{H}_2 + & \mathrm{Te}^{2-}_{ads} \arrow[ll, bend left, "\mathrm{H}^+"] \end{tikzcd} \tag{1}$$

The Te^{2-}_{ads} thus formed again combines with hydrogen ions to form HTe^-, and so on; this cycle is repeated to evolve hydrogen catalytically. Some part of the hydrogen may reduce the electrode substrate and form HTe^- in the solution at $4 < pH < 11$ as follows.

$$\mathrm{Te}^0 + 2\mathrm{H} = \mathrm{HTe}^- + \mathrm{H}^+ \tag{2}$$

The HTe^- thus formed or telluride ion originally present gives the same cycle as in (1) and makes hydrogen evolve. The reason why the catalytic wave of hydrogen does not appear in strongly alkaline solution is that tellurium cannot exist in the elemental form but dissolves in the alkaline medium. On the other hand, some of the HTe^- either in the solution or in the adsorbed state is oxidized instantaneously to elemental tellurium by dissolved oxygen or by ultraviolet rays.

$$\begin{aligned} &\mathrm{HTe}^- \xrightarrow{h\nu} \mathrm{H}^+ + \mathrm{Te}^0 + 2e^- \\ &2\mathrm{HTe}^- + \mathrm{O}_2 + 2\mathrm{H}^+ \longrightarrow 2\mathrm{H}_2\mathrm{O} + 2\mathrm{Te}^0 \end{aligned} \tag{3}$$

Elemental tellurium thus produced forms the brown mist which appears in the vicinity of the dropping mercury surface in the potential range of the polarographic maximum.

Photochemical effect on the electrode process

Irradiation of the surface of the mercury cathode with ultraviolet light promotes the photodecomposition and increases the amount of the brown mist but decreases the height of the polarographic maximum, because of the decrease of the amount of hydrogen telluride near the electrode.

Figure 8 shows the experimental result of an "on–off" test of ultraviolet irradiation at the d.m.e. The current is higher when it is dark and lower when it is bright. This on–off effect on the maximum current begins to appear about more than half an hour after the electrolysis has been carried out at E_{max}. For this reason, it is thought that the amount of telluride near the electrode increases enough to show the effect. The small fluctuations of the current which appear in the current–time curves in Fig. 8 seem due to the lack of uniform distribution of the effective ions near the electrode. In fact, on stirring of the solution the fluctuation of current becomes very small.

The response time of the current when the light is off is shorter than when it is on. The former is within 1 sec, while the latter is within 10 secs. This suggests the necessity of above-mentioned half an hour pre-electrolysis.

On the other hand, the telluride formed on the electrode reacts in the diffusion

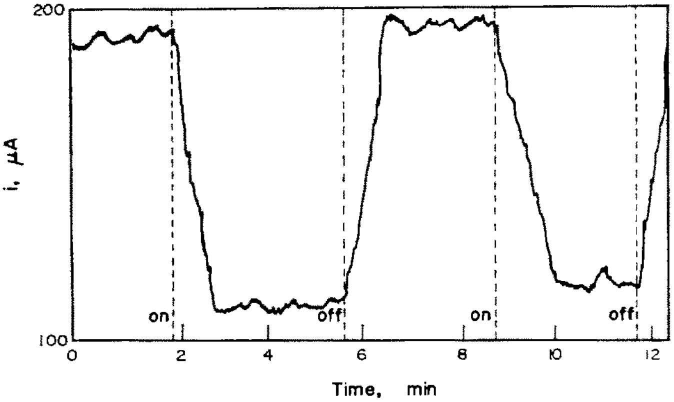

FIG. 8.—Effect of ultraviolet irradiation of d.m.e. on the catalytic current of hydrogen at constant voltage of $-1{\cdot}2$ V (E_{max}) in $1M$ NH_4Cl with $0{\cdot}15 \times 10^{-3}M$ H_2TeO_3.

layer according to equation (4):

$$2HTe^- + Te(IV) = 3Te^0 + 2H^+ \tag{4}$$

This has been reported to be the cause of the brown mist.[4,5,8] However, according to our experimental results, the brown mist appears in spite of the absence of Te(IV), especially in the case of suspension polarography of elemental tellurium powder or block polarography using an elemental tellurium block, so that the theory which needs the presence of Te(IV) is not always acceptable.

The descending branch of the maximum

At a potential where the maximum is over (region E in Fig. 1), the brown mist disappears. At still more negative potentials than E_f, however, the brown mist begins to appear again (Fig. 7C), because hydrogen telluride begins to be formed again owing to the reduction of tellurium by the nascent hydrogen produced electroreductively, *e.g.*, by $NH_4^+ + e^- \rightarrow NH_3 + H$. This flow of brown mist is more speedy than at B in Fig. 7, and it means that the movement of the mercury at C is more rapid than at B.

Because of the desorption of tellurium due to the above-mentioned mercury movement from the surface of the d.m.e., the tellurium electrode which has been established is cancelled and becomes simply a mercury cathode, so the catalytic wave of hydrogen on the tellurium electrode disappears at more negative potentials than E_{max} and at the same time i_{max} suddenly falls.

If the tellurium deposited on the mercury cathode is not desorbed at more negative potentials than E_{max}, the catalytic hydrogen wave does not vanish at any potential. The experiments shown in Figs. 3 and 4 illustrate this.

Minimum after the maximum

In the polarogram of Te(IV), a small current minimum appears at the potential immediately after the descent of the maximum (D in Fig. 1). The larger the height of the maximum, the deeper the following minimum, but it cannot be seen when the sample solution is agitated or in suspension polarography. Figure 9A shows a polarogram of Te(IV) and B shows a polarogram of the same solution, but with the potential sweep reversed. In B, the minimum at the negative side of the maximum disappears, while a new minimum appears at the positive side of the maximum. This shows that this minimum does not essentially correspond to the potential, but is a kind of after-effect of the maximum wave.

It is thought that the cause of the appearance of the minimum is the screening effect, on Te(IV) diffusion toward the electrode, of the products which remain in the vicinity of the mercury surface. These products are thought to be composed of HTe^-, H_2 *etc*, which remain near the electrode and react reductively with the Te(IV) ions [see equation (4)] to cause the temporal decrease of the current. This kind of redox reaction is suggested by Schmidt and von Stackelberg,[5] who made use of this phenomenon for the explanation of the plateaux before and after the Te(IV) maximum being at the same level of current.

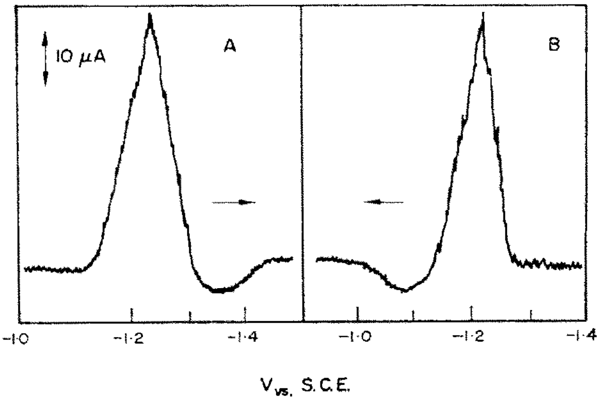

FIG. 9.—Polarograms of $0 \cdot 5 \times 10^{-3}M$ K_2TeO_3 in $1M$ NH_4Cl–$1M$ NH_4OH.
A: swept from positive to negative potential
B: swept from negative to positive potential

Current before and after the maximum

Schmidt and von Stackelberg[5] considered the problem of the plateaux before and after the Te(IV) maximum being at the same level, though the electrode process before the maximum is $Te(IV) + 4e^- \rightarrow Te^0$, while after the maximum it is $Te(IV) + 6e^- = Te^{2-}$. The apparent anomaly is explained by them in terms of telluride, formed on the electrode, reacting with Te(IV) in the diffusion layer according to equation (4), to produce tellurium. Therefore one third of the Te(IV) concentration in the diffusion layer is cancelled to make the $n = 6$ process look like an $n = 4$ process.

On the other hand, according to our experimental results, in spite of the absence of Te(IV), especially in the case of the suspension polarography of elemental tellurium powder or the block polarography using an elemental tellurium block, the currents before and after the maximum are equal. In the case of the polarography of Te(IV), the reduction proceeds in steps $Te(IV) \xrightarrow{4e^-} Te^0_{ads} \xrightarrow{H_2} HTe^- + H^+$. After the reduction of $Te(IV) \rightarrow Te^0$, the processes on the d.m.e. are as explained above by equations (1), (2) and (3). Even if elemental tellurium could adhere to the mercury electrode at a potential more negative than the peak potential of the maximum, it produces hydrogen to reduce itself to telluride. Consequently, since the latter half-step $Te^0 \rightarrow HTe^-$ is not faradaic, it shows no current, while the first half-step gives a current corresponding to n as high as 4. In the case of strongly alkaline medium, reductively produced elemental tellurium is successively dissolved in the medium as alkali metal polytelluride at potentials more positive than the maximum, while at the more negative potentials the polytelluride is reduced to simple telluride, showing a reductive current higher than in the mild alkaline medium, as shown in Fig. 10*b*.

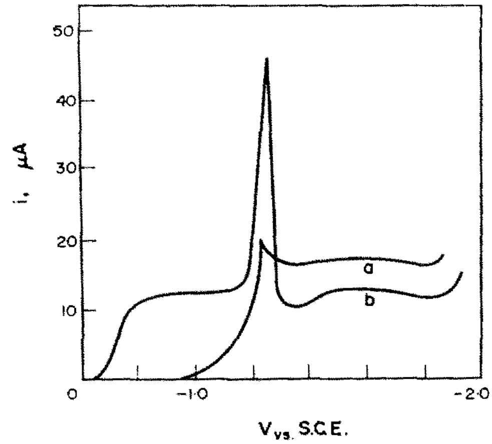

FIG. 10.—Polarograms of $1 \times 10^{-3}M$ K_2TeO_3 in (*a*) $1M$ KOH; (*b*) $0{\cdot}1M$ NH_4Cl–$0{\cdot}1M$ NH_4OH.

Schmidt and von Stackelberg,[5] like Norton, Stoenner and Medalia[9] reported that in the case of the Te(VI) wave the reduction ($n = 8$) leading to Te^{2-} is modified ($n = 6$) by the side-reaction of Te(VI) with Te^{2-} in the diffusion layer. We do not agree with this opinion, however, for the same reason as in the case of Te(IV). Here the reduction $Te(VI) \rightarrow Te^0$ ($n = 6$) provides the net current after the maximum. This supports the result reported by Issa *et al.*[10]

POSSIBILITIES OF ANALYTICAL APPLICATION

On the basis of the results of this survey of the tellurium maximum, we can list the analytical possibilities, though further examination is necessary.

1. The peak-height of the maximum is linearly proportional to the concentration of Te(IV) in the regions of $0{\cdot}5$–$1{\cdot}0 \times 10^{-3}M$ and $1{\cdot}0$–$1{\cdot}5 \times 10^{-3}M$. Though these two regions are adjacent, the slopes of the curves are different, so calibration curves are necessary.

2. Qualitative analysis for tellurium in insoluble form, *e.g.*, Te, TeO_2, H_2TeO_3, or $(NH_4)_2TeO_3$, can be carried out by suspension polarography or by block polarography. By suspension polarography the relative concentration of the powder could be found semiquantitatively.

3. For the determination of tellurium, the amperometric application of the maximum current seems to be more sensitive and specific than measurement of the $Te(IV) \rightarrow Te^0$ wave.

4. The photochemical effect on the maximum current of tellurium can be utilized for the "on–off" indication of ultraviolet light.

5. The maximum current for tellurium can be utilized for indication of the contact of mercury with tellurium.

6. Besides the usual constancy of analytical conditions needed in polarography, the illumination of the laboratory should also be kept constant, because of the photochemical effect on the electrode process corresponding to the current maximum.

Besides the surface-active substances shown in Fig. 2, ultraviolet irradiation of the electrode is effective to some extent for the suppression of the maximum in order to obtain a better background for analysis.

Zusammenfassung—Das Polarogramm von Tellur(IV) in schwach alkalischer Lösung hat im Diffusionsstrom-Plateau ein scharfes Maximum. Der dieses Maximum hervorrufende Elektrodenprozeß wurde auf verschiedene Weise untersucht; mit Hilfe der Halbleiterkatalyse, der "Block"-Polarographie und ultravioletter Bestrahlung der Quecksilbertropfelektrode. Es wurde gefunden, daß das Maximum durch die katalytische Stufe des Wasserstoffs verursacht wird, der durch das auf der Quecksilberoberfläche abgeschiedene Tellur freigesetzt wird. Ein Teil des Tellurs wird durch den katalytisch gebildeten naszierenden Wasserstoff zu Tellurwasserstoff reduziert. Der gewöhnlich in der Nähe der Oberfläche der Quecksilbertropfelektrode auftretende braune Nebel besteht aus elementarem Tellur, das durch Zersetzung von Tellurwasserstoff entsteht. Der plötzliche Abfall des Stroms bei negativerem Potential als dem des Strommaximums beruht auf Tellurdesorption, die durch die Bewegung des Quecksilbers bedingt ist.

Résumé—Le polarogramme du tellurium(IV) en solution faiblement basique a un maximum accentué sur le palier de courant de diffusion. On a examiné le processus à l'électrode qui provoque ce maximum au moyen de diverses techniques telles que la catalyse au semi-conducteur, la polarographie de "blocage" et l'irradiation ultra-violette de l'électrode à goutte de mercure. On a trouvé que le maximum est causé par la vague catalytique de l'hydrogène produit par le tellurium déposé sur la surface du mercure. Une partie du tellurium est réduite en hydrogène telluré par l'hydrogène naissant formé catalytiquement. Le brouillard brun qui apparaît habituellement au voisinage de la surface de la cathode à goutte de mercure se compose de tellurium élémentaire produit par la décomposition de l'hydrogène telluré près de l'électrode. La chute brusque dans le maximum du courant à un potentiel plus négatif que le potentiel du pic du maximum est dûe à la désorption du tellure, causée par le mouvement du mercure.

(*Received* 7 *June* 1971. *Accepted* 7 *October* 1971)

Summary—Ruthenium in various chemical forms can be evolved as the tetroxide from insoluble matrix materials by heating the sample with chromium(VI)-condensed phosphoric acid reagent (abbreviated as Cr(VI)-CPA). Because of its excellent decomposing power for various solid samples, condensed phosphoric acid is very useful in the chemical analysis of various insoluble materials, and when an oxidizing agent such as potassium dichromate is added in the CPA medium, drastic oxidation proceeds on heating. This method is now extended to the separation of ruthenium from marine sediments. During the reaction with Cr(VI)-CPA ruthenium tetroxide is evolved and collected in an absorbent solution of 6*M* hydrochloric acid and ethanol (1:1), and the ruthenium is then determined spectrophotometrically with thiourea or radiometrically by counting the β- or γ-activity. Osmium, which can be evolved as the tetroxide by the same treatment, can be eliminated beforehand by heating the sample with Ce(IV)-CPA, which removes osmium but not ruthenium. The successive distillations by means of Ce(IV)-CPA and Cr(VI)-CPA give satisfactory results for the separation between osmium and ruthenium. This method might be useful for the separation of ruthenium in geochemical or neutron-activation analysis.

SINCE 1951 Toshiyasu Kiba and his co-workers[1] have worked on development of a new chemical treatment for decomposition of various solid samples by use of condensed conc. phosphoric acid. The so-called condensed phosphoric acid (abbreviated as CPA) is also called dehydrated phosphoric acid, strong phosphoric acid or polyphosphoric acid, and prepared by dehydration of commercial orthophosphoric acid or the hydration of phosphorus pentoxide. This anhydrous material is a mixture of various kinds of phosphoric acid such as ortho-, pyro-, tri-, tetra-, and so on, the P_2O_5 content being generally $>72{\cdot}4\%$. The composition of the CPA depends on the temperature used for the dehydration.[2] In this study the CPA used was prepared by heating reagent grade orthophosphoric acid to 300°. It is a stable and inactive viscous liquid at room temperature, but heated it loses its viscosity and becomes very reactive. By simple heating with CPA, powdered glasses, insoluble silicates,[3,4] alumina,[5] clays,[5] and insoluble sulphates[6] can be decomposed readily, giving a transparent or slightly turbid liquid. Furthermore, when an oxidizing agent such as potassium iodate or potassium dichromate is added with CPA to various inorganic or organic samples, a drastic oxidation reaction occurs along with the decomposition of the sample, and some resistant samples such as elemental carbon,[7] graphite,[8] and powdered coal[9] can be decomposed easily, *e.g.*, with the evolution of carbon dioxide and iodine equivalent to the oxygen consumed when KIO_3-CPA is used. Simple organic and biochemical compounds can be decomposed with oxidant-CPA with

accompanying evolution of carbon dioxide, nitrogen, and halogen, depending on the composition of the sample. On the other hand, a reducing CPA medium has been prepared by heating a mixture of tin(II) chloride dihydrate and CPA to 300° to expel water and hydrogen chloride from the medium. This is called Sn(II)–CPA and can be stored in contact with the atmosphere without any loss of its reducing power. When samples containing sulphur, such as insoluble sulphates, sulphide ores and organic sulphur compounds, are heated with Sn(II)–CPA, hydrogen sulphide is evolved quantitatively. Hydrogen selenide and mercury can also be evolved from samples containing selenium and mercury by heating with Sn(II)–CPA. Thus, new sample treatment with various CPA systems has been developed and the method is highly popular in Japan, more than fifty articles having appeared on chemical analysis with the use of CPA, some of which are listed in Table I. In appreciation of this work the Japan Society for Analytical Chemistry awarded the Society Prize in 1963 to Prof. Toshiyasu Kiba. It must be noted that CPA is not only useful for analytical purposes but also for organic synthesis[10] and electrochemical investigations[11,12] in anhydrous media. The unusual reactivity of ordinary oxidants and reductants in CPA media has been exploited by Gopala Rao and his collaborators.[13]

A further application is in establishment of a simple method for ruthenium in marine sediments with use of CPA, since this element has never been examined in CPA medium. The ruthenium should be oxidized to Ru(VIII) and evolved as the

gaseous tetroxide from the matrix. After various experiments Cr(VI)–CPA was preferred for this purpose. Osmium was found to behave similarly to ruthenium with Cr(VI)–CPA, but another CPA medium, Ce(IV)–CPA, was found to separate osmium from ruthenium by evolving only osmium tetroxide. Separation by evolution of gaseous inorganic compounds has been described by Sandell,[32] especially for metal chlorides, but these processes are based on evolution from aqueous solution, not from a solid sample. Although ruthenium has been separated by distillation by heating an acidic solution containing various oxidizing agents, a tedious treatment of a solid sample by fusion and dissolution with acids must be done first.[33] The present method can be directly applied to soil samples without fusion or dissolution of the samples, and ruthenium in various chemical forms can be distilled as tetroxide by only one or two operations. Ruthenium and osmium are apt to be lost during the usual operations of distillation and fusion in acidic media, but this CPA treatment can be applied in a closed system from the start of the analytical process without any loss of the elements.

EXPERIMENTAL

Reagents

Condensed phosphoric acid (CPA). Place 300–400 g of commercial orthophosphoric acid of extra pure reagent grade in a 300-ml conical beaker, and dehydrate it by heating on a 500-W electric heater until a thermometer dipped in the liquid indicates 300°. During the heating the vapour coming off should be rapidly removed from the neighbourhood of the liquid surface through a glass tube, one end of which is held near the liquid surface, the other end being connected to a suction pump. Continue the suction until no further vapour emerges. The sirupy liquid thus obtained should be stored in a closed vessel.

Ruthenium standard solution. Dissolve ruthenium(III) trichloride monohydrate in $2M$ hydrochloric acid. Standardize the solution gravimetrically as follows: take an aliquot of the solution and dilute it to about $1M$ in hydrochloric acid. Then precipitate metallic ruthenium with magnesium metal powder and gentle heating. Add just enough concentrated hydrochloric acid to dissolve the excess of magnesium metal, and heat gently to coagulate the precipitate. Filter off the precipitate with a filter stick and glass-fibre filter paper. Wash with hydrochloric acid, ethanol and ether, successively, and dry at room temperature for 2 hr under reduced pressure, and weigh.

Osmium standard solution. Dissolve osmium tetroxide in $0{\cdot}2M$ sodium hydroxide solution. Standardize the solution volumetrically by Klobbie's method:[34] add potassium iodide to the osmium tetroxide in dilute sulphuric acid and titrate the liberated iodine with standard sodium thiosulphate solution potentiometrically.

Thiourea solution, 10%.

Other chemicals. Potassium dichromate, cerium (IV) sulphate, hydrochloric acid and sodium hydroxide, all of extra pure grade, were used without further purification. Doubly distilled water was used except for the radiochemical processes.

Radioactive tracer. Ruthenium-106 as trichloride from The Radio Chemical Centre, England, and osmium-185 as osmates prepared by sodium peroxide fusion of irradiated osmium metal in the Research Reactor Institute, Kyoto University, were employed as tracers to examine the behaviour of the two elements in the course of the reaction with CPA.

Apparatus

Radioactivity measurements. EA-14 NaI(Tl) crystal of well-type, scaler SA-250 and timer TM-2, all from Kobe Kogyo Co., for γ-counting. Multichannel pulse-height analysers, EDS-34208, Toshiba Co., (200 channels) and RCL (512 channels); Ge(Li)-detector, ORTEC Model 8100-45, having a resolution of about 2·5 keV for the 1333-keV gamma-peak of ^{60}Co; gas-flow counter (ALOKA LBG-21 U, Nippon Irigaku Co.).

Reaction vessel and absorbing tubes. The apparatus used is shown in Fig. 1; the reaction vessel (A) and absorbing tubes (B) are connected together by ground-glass ball-joints. The reaction vessel is a round-bottomed flask having a glass cap fitted to its top and provided with inlet and outlet tubes. A glass tube closed at one end is inset in the cap to take a thermometer for measuring the temperature of the reaction medium. A few drops of silicone oil are put in the tube to reduce the time-lag of temperature indication.

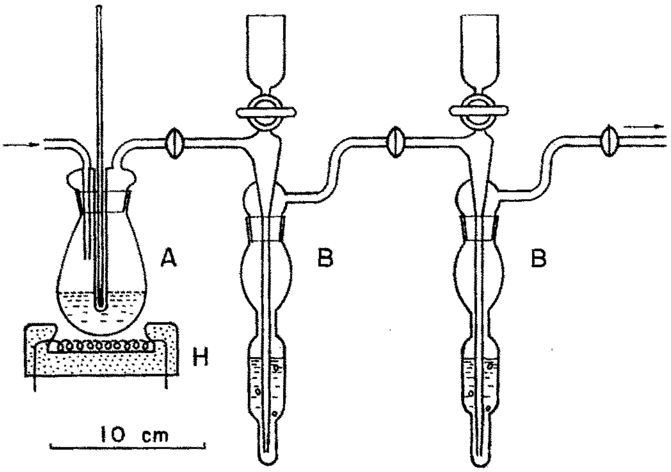

FIG. 1.—Reaction vessel (A), absorbing tubes (B) and electric heater (H).

Samples

Test solutions. To establish generally useful procedures ruthenium and osmium compounds in various chemical forms were submitted to test. Radioactive tracers of the two elements were also employed to estimate recovery and separation factor.

Sample to be analysed. Marine sediment was preferred for the study on the environmental radioactive contamination of the Japan Sea. The samples were parts of cores taken from the bottom of the Japan Sea, and surface sediments from Nanao Bay near Kanazawa, and their locations are shown in Table VI.

Experimental procedure

Place a sample solution in the reaction vessel and add a few drops of dilute sodium hydroxide solution to keep the solution alkaline. Evaporate the solution to dryness on a water-bath. Add about 20 g of CPA and 1–4 g of cerium(IV) sulphate; put 10 ml of the absorbing solution [9 ml of a mixture of 6*M* HCl and C_2H_5OH (1:1 v/v), plus 1 ml of 10% thiourea solution] into each of the absorbing tubes. Then connect all the joints as shown in Fig. 1. Suck the air slowly from the last outlet tube with a suction pump and heat the reaction vessel with an electric heater to start the reaction. The time needed to complete the oxidation and distillation is that needed to raise the temperature to that appropriate for osmium. After the distillation, stop the heating and disconnect all the connections. Combine the absorbing solutions in a 25- or 50-ml standard flask, together with the washings and dilute to the mark with a 1:1 v/v mixture of 6*M* hydrochloric acid and ethanol. Measure the absorbance of the red solution at 480 nm. Determine the osmium content from a working curve pre-prepared in the same way with a series of solutions of osmic acid. For tracer work, gamma-count a portion (usually 3 ml) of the absorbing solution.

After the separation of osmium as described above put about 2 g of potassium dichromate (in 2 or 3 portions) into the reaction vessel, which must be cooled to below 100° after the osmium distillation. Heat and cool the vessel whenever the reagent is added, to make the dissolution of the reagent uniform in the CPA medium. Distil the ruthenium by heating the reaction vessel to 240° The absorbing solution is 1:1 v/v 6*M* hydrochloric acid and ethanol mixture. After distillation transfer the absorbing solution into a standard flask together with the washings and dilute to volume. For spectrophotometric determination of ruthenium, use the thiourea method. In a 25-ml flask take an aliquot of the solution, add 1 ml of 10% thiourea solution and dilute to just below the mark with the mixed hydrochloric acid–ethanol solution. Stand the vessel for 10 min at 85° in a water-bath to develop the colour. Cool, dilute to the mark with acid–ethanol mixture, and measure the absorbance of the blue solution at 620 nm. Determine the ruthenium content from a working curve prepared by the same spectrophotometric procedure with a series of solutions of ruthenium chloride. The colour is very stable.[35]

For the tracer method use a portion (usually 3 ml) of the absorbing solution for γ-counting.

When marine sediments are to be analysed the sample should be dried at 110° for an hour and ground in a mortar, and a 1-g portion should be used in the reaction vessel. The analytical procedure is the same as for solutions.

RESULTS AND DISCUSSION

Distillation recovery of ruthenium

The choice of a suitable oxidizing agent useful in the CPA decomposition and distillation method was the first problem. Various oxidizing agents were tested according to the procedure described above, and the amount of ruthenium distilled was determined spectrophotometrically in each case. The recovery of ruthenium by various oxidizing agent–CPA treatments is shown in Table II, from which potassium dichromate is found the most useful for the purpose. Cerium(IV) sulphate was found not to react with ruthenium, and ruthenium tetroxide did not appear at all in the absorbing solution. This fact shows that potassium dichromate acts more powerfully than cerium(IV) sulphate in CPA, in contrast to the order of their oxidation potentials in aqueous solution. This result is compatible with that obtained by Rao for the formal redox potentials in phosphoric acid of increasing concentrations.[36] This reversal of the redox potential order in CPA may be attributed to the strong complex-forming behaviour of chromium(III) with CPA. The ideas of Charlot[37] on acid-base equilibrium involving oxide complexes in a melt may be extended to the reaction in CPA, a non-aqueous medium resembling a melt.

TABLE II.—RECOVERY OF RUTHENIUM WITH VARIOUS CPA REAGENTS

	4	0
Hydrogen peroxide, 30%	2 ml	0

* ($1{\cdot}69_8$ mg of Ru, taken as $RuCl_3$).

$$Cr_2O_7^{2-} + 6e^- \rightleftharpoons 2\,Cr^{3+} + 7\,O^{2-}$$

The equilibrium potential is

$$E = E_0 + \frac{RT}{nF}\log\frac{[Ox]}{[Red]} - \frac{RT}{nF}\log\,[O^{2-}]$$

In this equation, if an O^{2-} acceptor exists in the system, $[O^{2-}]$ decreases and the value of E should therefore be higher. CPA is itself an O^{2-} acceptor with the equilibria

$$P_2O_7^{4-} + O^{2-} \rightleftharpoons 2PO_4^{3-}$$

$$P_3O_{10}^{5-} + 2O^{2-} \rightleftharpoons 3PO_4^{3-}$$

Hence, an apparently anomalous formal redox potential may occur for chromium (VI) and cerium(IV).

The recovery of ruthenium from ruthenium(III) chloride by distillation from Cr(VI)–CPA was achieved as described above, and further examination for other ruthenium compounds was tried as follows. Standard ruthenium chloride solution was put in the reaction vessel and sodium hydroxide solution, sodium sulphide solution or magnesium powder was added. Thus the ruthenium was transformed into the hydroxide, sulphide, or the metal. After evaporation of the contents to dryness, the Cr(VI)–CPA treatment was applied. The time required for completion of reaction was examined by changing the absorbing solution for fresh at intervals of several minutes. The results are shown in Fig. 2. The chloride was the most easily decomposed, taking only about 5 min, but sulphide and metallic ruthenium were somewhat resistant, since it took about 30 min to complete the distillation of ruthenium tetroxide. In this case chromium(VI) dioxychloride was also sometimes evolved from the chloride-rich sample, but it caused no interference with the determination of ruthenium.

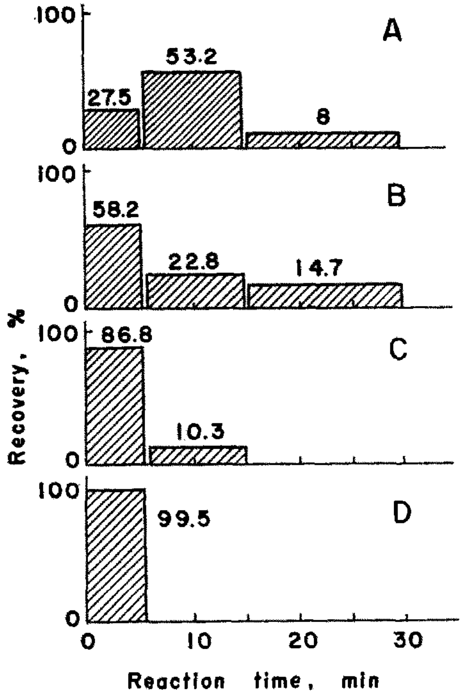

FIG. 2.—Recovery of RuO$_4$ during the Cr(VI)–CPA treatment.
Sample: (A) Ru metal, (B) Ru$_2$S$_3$, both with 2 g of K$_2$Cr$_2$O$_7$ in 20 g of CPA; (C) Ru(OH)$_3$, (D) RuCl$_3$, both with 1 g of K$_2$Cr$_2$O$_7$ in 20 g of CPA.

Distillation recovery of osmium

Osmium was distilled along with ruthenium on treatment with Cr(VI)–CPA, but was even more readily distilled from mixtures of weaker oxidizing agents with CPA. To find a suitable CPA system to separate osmium from ruthenium, the recovery of osmium by distillation from various reagent–CPA systems was examined, using osmium samples in various forms. Spectrophotometric and radioisotopic tracer methods were used. The results are summarized in Table III, from which it is seen

	2	Os	$0{\cdot}12_1$	$0{\cdot}12_0$	99·5*

Osmium in different chemical forms was prepared in the same way as for ruthenium.

* Radioactive tracer, ^{185}Os, was added as osmates, and the recovery was estimated by counting the activity.

that osmium can be distilled quantitatively by means of Ce(IV)–CPA in all cases. Of the oxidizing agents used, hydrogen peroxide seems to be rather useful for the purpose when it is added in a series of small portions, but its 30% solution brings a significant amount of water into the anhydrous CPA system and the temperature is considerably lowered and there is bumping of the reaction-vessel contents. Hence this reagent cannot be recommended for the CPA treatment.

Temperature control

Precise temperature control during the process was not necessary, as the temperature was simply raised from room temperature to the uppermost appropriate to each CPA reagent. Decomposition of samples and distillation of the tetroxides proceeded with the rise in temperature and was complete by the time the temperature reached its highest point. Therefore additional heating or extended heating time should be avoided since the CPA is apt to solidify if the temperature rises over 300°. In Table IV the recovery of ruthenium and osmium is given as a function of temperature. From these results it is also seen that ruthenium is not evolved at all by Ce(IV)–CPA treatment.

Behaviour of other elements

Elements having chlorides which are believed to be vaporized from their acidic solutions by heating[32] were submitted to the CPA treatment. Among them Fe(III), Mn(II), Sn(II, IV), Sb(III, V), Te(VI), Re(VII), and Ir(IV) could not be found in the distillate. Halogen gas was evolved from halides, and selenium, mercury, technetium, and arsenic have a tendency to yield gaseous compounds. By the use of tracers it was found that about 30–40% of selenium(VI), 10–20% of mercury(I, II) and 0–2% of arsenic(III) was lost from samples containing 10 mg of each element, on treatment with Cr(VI)–CPA. Technetium(VII) in tracer amounts lost 10–20% to the distillate after the same treatment. When the Ce(IV)–CPA treatment was used before the Cr(VI)–CPA treatment, the elements that could be volatilized were all removed by the former

* Ten milligrams of ruthenium and osmium.

treatment, and hence did not appear in the absorbing solution of the second distillation with Cr(VI)–CPA. Thus ruthenium could be separated quantitatively without contamination except that it was unavoidable that some chromium was transferred as chromium dioxychloride into the absorbing solution when chloride was present in the sample.

Successive distillations for osmium and ruthenium

Successive distillations were tried for synthesized samples containing the two elements. A mixed solution was placed in the reaction vessel, and tracers were added if necessary. An appropriate reagent to produce the desired chemical compounds of the elements was added as described in the case of ruthenium. The sample was evaporated to dryness on a water-bath, and 20 g of CPA and 1–4 g of cerium(IV) sulphate were added. The first distillation was done with the osmium absorbing solution in the absorber. Then the reaction vessel was cooled to below 100°, the ruthenium absorbing solution substituted for the osmium absorbent, 1–2 g of potassium dichromate added to the reaction vessel, and the second distillation started. The amount of the element in the absorbing solution after each distillation was determined by spectrophotometry or by γ-counting of the tracer. The results in Table V show the advantage of this CPA method. In Fig. 3 the γ-spectra of the Ce(IV)–CPA and Cr(VI)–CPA distillates, and of the residual CPA in the original reaction vessel are shown together to verify the separation. Identical spectra were obtained, not only with tracers but also with a few milligrams of carriers; hence separation by successive distillation was achieved successfully, with good recoveries of both tracers and carriers.

Separation and determination of ruthenium-106 *in marine sediment*

The separation and determination of ^{106}Ru, a fission-product nuclide, in marine sediment samples from the Japan Sea was tried by the proposed method. A 1-g sample was taken in the reaction vessel and a ruthenium chloride carrier solution containing 15 mg of ruthenium was added. The sample mixture was dried on a water-bath and subjected to successive distillation as described above. The final absorbing solution after the Cr(VI)–CPA treatment was transferred to a beaker and diluted with water to be about 1*M* in hydrochloric acid. Magnesium powder was then put in to reduce Ru(III) to Ru(0), followed by heating to coagulate the precipitate. The excess of magnesium was dissolved by dropwise addition of the minimum of concentrated hydrochloric acid required, and the solution was heated gently. The ruthenium metal

To estimate the recovery, spectrophotometric determination of both elements was employed, except where shown by an asterisk (which denotes radiometric counting).

(A) Os-fraction, (B) Ru-fraction, (C) distillation residue.

thus obtained was collected on a glass fibre filter paper on a filter stick and washed several times with hydrochloric acid, ethanol and ethyl ether, successively. The precipitate was dried at room temperature for two hours under reduced pressure, and weighed. The recovery of ruthenium carrier was estimated as the ratio of this weight to that added to the sample. Thereafter, the precipitate was wrapped with a thin film of Mylar or Kurehalon (a commercial polyethyleneterephthalate product) and additionally with aluminium foil (75 μg/mm^2) to cut off the weak β-ray generated from ^{106}Ru. The β-ray from the daughter nuclide ^{106}Rh was counted. The content of ^{160}Ru in the sediment was evaluated in the usual way.

The efficiency of the counter was estimated by counting a ^{90}Sr–^{90}Y standard. The results are shown in Table VI, where the values obtained are in fair agreement with those obtained by a method involving fusion of the solid sample with sodium peroxide, solvent extraction of ruthenium tetroxide into carbon tetrachloride, back-extraction into an aqueous phase, precipitation of metallic ruthenium with magnesium, and weighing of the carrier before the counting of the radioactivity.

TABLE VI.—RUTHENIUM-106 IN MARINE SEDIMENTS FROM THE JAPAN SEA

No.	Sample location (sample number)		^{106}Ru *pCi/g*
1	Nanao Bay,	North Bay (29)	$2{\cdot}7_6 \pm 0{\cdot}1_1$ $(3.0 \pm 0{\cdot}1)^*$
2		North Bay (22)	$4{\cdot}0_3 \pm 0{\cdot}2_4$
3		South Bay (44)	$4{\cdot}0_8 \pm 0{\cdot}1_7$ $(3.9 \pm 0{\cdot}1)^*$
4		West Bay (11)	$3{\cdot}1_3 \pm 0{\cdot}1_1$
5	39°47′N	139°18′E (#31)	$5{\cdot}4_8 \pm 0{\cdot}2_7$
6	42°35′N	135°29′E (#33)	$3{\cdot}8_7 \pm 0{\cdot}2_4$
7	40°27′N	135°47′E (#37)	$2{\cdot}2_1 \pm 0{\cdot}1_7$
8	36°51′N	132°18′E (#39)	$4{\cdot}4 \pm 0{\cdot}2_1$
9	38°35′N	131°00′E (#43)	$1{\cdot}7_8 \pm 0{\cdot}1_5$ $1{\cdot}9_8 \pm 0{\cdot}2_0$
10	30°40′N	130°44′E (#49)	$2{\cdot}8_8 \pm 0{\cdot}1_8$

Samples 5–10 were the top 20 mm of the cores.
* The value obtained by fusion of the sample with Na_2O_2, solvent extraction, *etc*, as in text.

Radiochemical analysis usually requires correction of the measured counting rate for the chemical recovery of the carrier added. In the present case, none of the ruthenium, either ^{106}Ru or carrier, was lost during the entire process, and the recovery of the carrier might always be taken as 100%. Therefore, determination of the chemical recovery can be omitted. Isotopic exchange between ^{106}Ru and the carrier is also no problem, because the results obtained by this method are fairly identical to those by the fusion method.

Confirmation of the separations, by neutron activation

When it is desired to determine the amounts of non-radioactive ruthenium and osmium in marine sediment, neutron-activation analysis will be preferred, since these amounts are too minute to be determined by spectrophotometry. In such a case CPA treatment of the irradiated sample may be accepted. The possibility of separation of active ruthenium and osmium from activated marine sediment was examined. A 0·5-g sample of marine sediment was loaded in a quartz ampoule and the end of the vessel was sealed. Reference standards of ruthenium and osmium were prepared by sealing a known amount of ruthenium chloride solution ($\sim 10^{-2}$ μg as Ru) and osmic acid solution ($\sim 10^{-2}$ μg as Os) in quartz ampoules, after evaporation to dryness with small portions of sodium hydroxide solution.[38] All these ampoules were put into another larger ampoule and the end of this was sealed. The ampoule was wrapped in aluminium foil and put into an aluminium capsule which was then irradiated for 80 hr in the Research Reactor of Kyoto University with a thermal neutron flux of about 4×10^{11} n/mm^2/sec. After cooling for a week, the ampoules were taken out of the capsule. Each ampoule was broken and its contents put into the CPA reaction vessel together with non-radioactive carriers. The decomposition and distillation processes were applied as described for ruthenium. The typical γ-spectra of each fraction of distillate from the irradiated sample standards are shown in Figs. 4 and 5, respectively. From these spectra, the osmium fraction after the Ce(IV)–CPA treatment is seen to be contaminated with other radioactive nuclides, mainly with ^{75}Se, and the ruthenium fraction after the Cr(VI)–CPA treatment is contaminated with ^{77}As, ^{51}Cr and ^{82}Br.

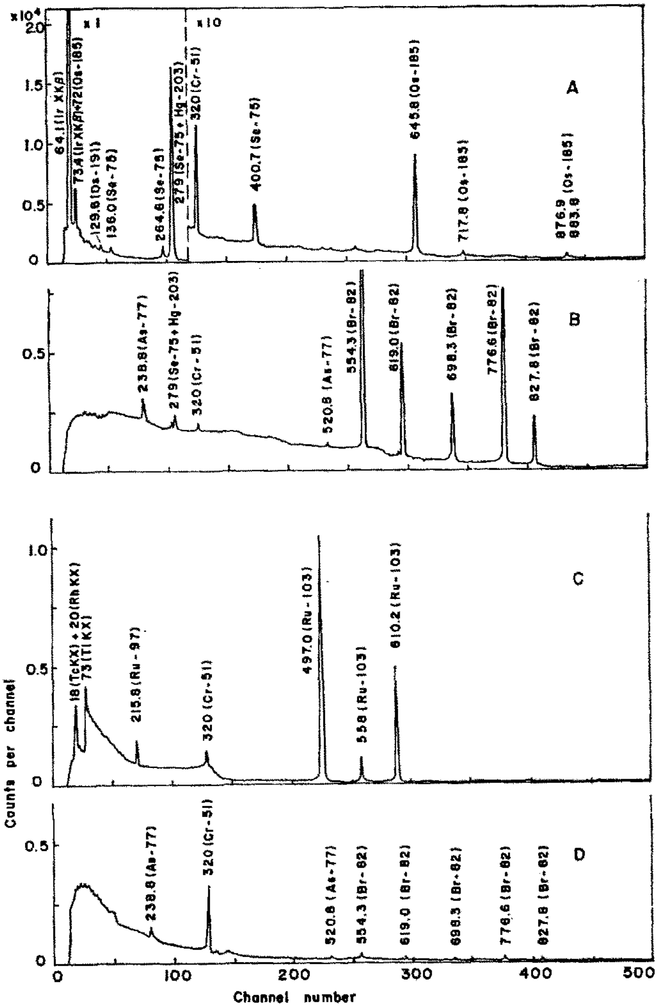

FIG. 4.—γ-Spectra of each fraction after the separation by CPA-method, obtained by Ge(Li) detector with 500-channel analyser.

Sample: irradiated marine sediment. (A) Os metal precipitated from Os-distillate. (B) Filtrate after (A). (C) Ru metal precipitated from Ru-fraction. (D) Filtrate after (C).

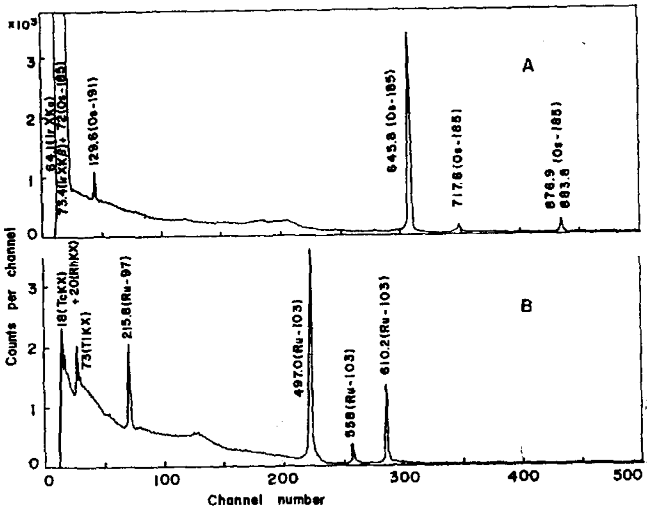

FIG. 5.—γ-Spectra of each reference standard of activated Ru and Os after being subjected to the Ce(IV)–CPA and Cr(VI)–CPA treatments, respectively.

The main radioactive nuclide generated after the neutron activation of marine sediment is ^{82}Br which shows its γ-ray spectrum especially in the osmium fraction after Ce(IV)–CPA treatment of the sample. Although some contaminating nuclides were distilled when metallic ruthenium was precipitated for radioactivity counting most of them passed into the filtrate, as shown in Figs. 4 and 5. The radioactive ruthenium consists of that from the ruthenium initially present in the marine sediment and that produced by fission of uranium in the sample. The spectra presented here refer to the separation of ruthenium from the marine sediment, not the determination of ruthenium present in the sample. In the osmium fraction, selenium and mercury are apt to be co-distilled, and they should be removed when this method is to be used for the activation determination of osmium. The activation determination of ruthenium and osmium by the use of this CPA treatment and some improved techniques[39] will be described elsewhere. However, it can be said now that this CPA method is specific for ruthenium and osmium in the separation of noble metals and more useful than other methods such as distilled from an aqueous solution.[40,41]

Acknowledgement—We are grateful to the members of the Research Reactor Institute of Kyoto University for their help with the activation of the samples and the radiochemical treatment.

Zusammenfassung—Ruthenium kann in verschiedenen chemischen Formen als Tetroxid aus unlöslichem Grundmaterial ausgetrieben werden. Man erhitzt dazu die Probe mit einem Reagens aus Chrom(VI) und kondensierter Phosphorsäure (abgekürzt als Cr(VI)-CPA). Wegen ihrer ausgezeichneten Zersetzungsfähigkeit für verschiedene feste Proben ist kondensierte Phosphorsäure sehr nützlich bei der chemischen Analyse verschiedener unlöslicher Materialien; gibt man ein Oxidationsmittel wie Kaliumdichromat zu dem CPA-Medium, dann tritt beim Erhitzen drastische Oxidation ein. Dieses Verfahren wird jetzt auf die Abtrennung von Ruthenium aus marinen Ablagerungen ausgedehnt. Während der Reaktion mit Cr(VI)-CPA wird Rutheniumtetroxid entwickelt und in einer Absorptionslösung aus 6*M* Salzsäure und Äthanol (1:1) gesammelt; Ruthenium wird dann spektrophotometrisch mit Thioharnstoff oder radiometrisch durch Zählen der β- oder, γ-Aktivität bestimmt. Osmium, das auf dieselbe Weise als

Tetroxid verflüchtigt werden kann, wird vorab durch Erhitzen der Probe mit Ce(IV)-CPA beseitigt; dieses Reagens entfernt Osmium, nicht aber Ruthenium. Die aufeinander folgenden Destillationen mit Ce(IV)-CPA und Cr(VI)-CPA geben zufriedenstellende Ergebnisse für die Trennung von Osmium und Ruthenium. Dieses Verfahren könnte sich zur Abtrennung von Ruthenium bei geochemischen oder Neutronenaktivierungsanalysen als nützlich erweisen.

Résumé—Le ruthénium sous des formes chimiques diverses peut être dégagé à l'état de tétroxyde de matières de matrice insolubles par chauffage de l'échantillon avec le réactif chrome(VI)-acide phosphorique condensé [en abrégé Cr(VI)-CPA]. En raison de son excellent pouvoir décomposant pour divers échantillons solides, l'acide phosphorique condensé est très utile dans l'analyse chimique de diverses matières insolubles, et lorsqu'un agent oxydant tel que le bichromate de potassium est ajouté au milieu CPA, une oxydation énergique se développe par chauffage. Cette méthode est maintenant étendue à la séparation du ruthénium des sédiments marins. Pendant la réaction avec Cr(VI)-CPA, le tétroxyde de ruthénium se dégage et est recueilli dans une solution d'aborption, mélange 1:1 d'acide chlorhydrique 6*M* et d'éthanol, et l'on dose alors le ruthénium spectrophotométriquement par la thiourée ou radiométriquement par comptage de l'activité β ou γ. L'osmium, qui peut être dégagé à l'état de tétroxyde par le même traitement, peut être éliminé auparavant par chauffage de l'échantillon avec Ce(IV)-CPA, qui élimine l'osmium, mais non le ruthénium. Les distillations successives au moyen de Ce(IV)-CPA et Cr(VI)-CPA donnent des résultats satisfaisants pour la séparation de l'osmium et du ruthénium. Cette méthode peut être utile pour la séparation du ruthénium en analyse géochimique ou par activation de neutrons.

(*Received* 7 *June* 1971. *Accepted* 14 *September* 1971)

Summary—The operating conditions of an atomic-absorption system based on flameless atomization have been investigated for trace analysis for Al, Cr, Cu, Fe, Mg and Mn. The sample solution on a tantalum strip was atomized by electrical heating in an inert atmosphere within an absorption chamber. This technique allows the use of small sample sizes and results in a higher sensitivity than that with the conventional flame technique. Some interference effects and applications were investigated.

THE FLAME TECHNIQUE is normally used for the production of atomic populations in atomic–absorption spectrometry, because the nebulizer–burner systems provide simple, rapid, and accurate means of introducing sample solutions into the flame. However, the flame has some disadvantages as an atomizer. The atomization within the flame is very inefficient and the elements which form refractory oxides are extremely difficult to atomize even with a nitrous oxide–acetylene flame. Furthermore, flames contain sufficient free radical concentrations to combine with many elements to produce stable compounds, resulting in a lower degree of atomization and giving an absorption background at certain wavelengths. The low efficiency of nebulizers also affects the sensitivity. For most commercially available pneumatic nebulizing units, only 5–15% of the solution uptake finally reaches the flame, and very few elements are completely atomized in the flame.

Therefore, some new methods of atomization have been developed to improve sensitivity. Gatehouse and Walsh[1] described the use of a hollow-cathode sputtering device for the direct atomization of solid samples. Goleb and Brody[2] used a similar technique, in which the sample solution was evaporated on the walls of a suitable cathode. This technique is, however, cumbersome and limited in application. Nelson and Kuebler[3] atomized the sample by flash heating from a capacitor discharge lamp wound round a silica chamber which contained quartz or graphite strips to locate the sample and was purged by an inert gas. L'vov[4] described the use of a graphite furnace which was heated by an a.c. current in an atmosphere of argon. This technique required only a few μl of solution and promised to have a higher sensitivity, of the order of 10^{-9}–10^{-7} g. Massmann[5] has used an electrically heated graphite cell, and reported some sensitivities below 10^{-12} g. West and Williams[6] devised an efficient carbon filament reservoir, the sample solution being placed on the filament and atomized by means of passing a current. These authors have determined 10^{-10} g of silver and magnesium in a few μl of solution. Dogena and Burgess[7] also described a similar system in which atomization took place in the pressure range in the range of

1–400 mbar. Welz and Wiedeking[8] used a graphite tube furnace in analysis of copper and other elements in serum.

These flameless atomization methods demonstrate that only a few μl of liquid sample are required and that detection limits may be reached which are well below those obtained by conventional flame atomization. The electrothermal heating device should be useful for trace analysis.

This paper describes the parameters required to optimize the atomic absorption of various elements in an electrothermal heating device for flameless atomization. Further application possibilities for trace analysis are also discussed.

EXPERIMENTAL

Apparatus

A Nippon Jarrell-Ash AA-1E emission and atomic-absorption spectrophotometer, with the nebulizer–burner system removed, was used. The radiation from a hollow-cathode lamp (Hitachi, Hamamatsu TV and Westinghouse) was electronically modulated at 60 Hz, and the output from an R106 photomultiplier tube was connected to a Yanagimoto recorder (1-sec full-scale deflection). The instrument settings were adjusted to give the optimum working conditions. The following resonance lines were used: magnesium 285·2 nm, manganese 279·5 nm, copper 324·8 nm, iron 248·3 nm, chromium 357·9 nm, and aluminium 309·3 nm.

Absorption chamber. The absorption chamber used in this work is shown in Fig. 1. It was made of Pyrex glass and optical-quality silica end-windows were sealed onto the sides of the chamber. The tantalum strip was mounted between two copper rods which were insulated from each other and from the cork by binding Teflon round them and inserting them into quartz tubes passing through the cork in the bottom of the absorption chamber. Taps were sealed on the top of the chamber to allow the passage of a stream of inert gas through the chamber. A stopper at the top of the chamber allowed sample solutions to be deposited in a depression in the strip. The chamber was placed on the optical bench so that the beam from the hollow-cathode lamp was focused midway above the strip and then refocused on the entrance slit of the monochromator. The strip could be of nickel, tungsten, tantalum or platinum, and was heated by passing an electric current from a low voltage

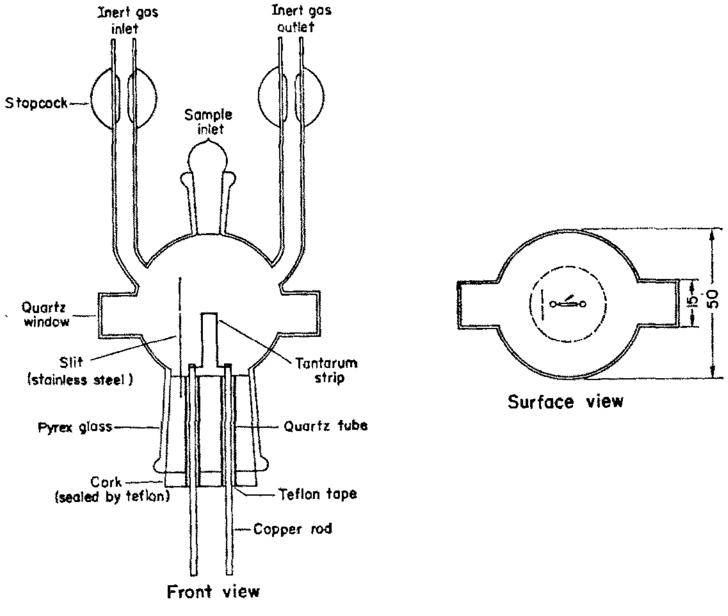

FIG. 1.—Atomization chamber.

transformer. The voltage was varied between 0 and 110 V with a maximum load current of 20 A. The temperature attained by the strip was measured with an optical pyrometer. The inert gas was supplied to the absorption chamber *via* a conventional flow-meter.

Procedure

The sample solution (2 μl) was placed in the depression in the strip with a Hamilton 10-μl microsyringe. The chamber was freed from air by flushing it with argon for 2 min. By passage of a low current through the strip in an atmosphere of inert gas, the solvent was evaporated without vaporization of the sample salts. The strip was then heated to vaporize and atomize the sample salts into the inert gas stream. All atomic-absorption signals were recorded and only peak signals were measured.

RESULTS AND DISCUSSION

Optimum analytical conditions

Strip material and voltage applied for atomization. The relationship between absorption signal and strip voltage is shown in Fig. 2. The absorption signal observed

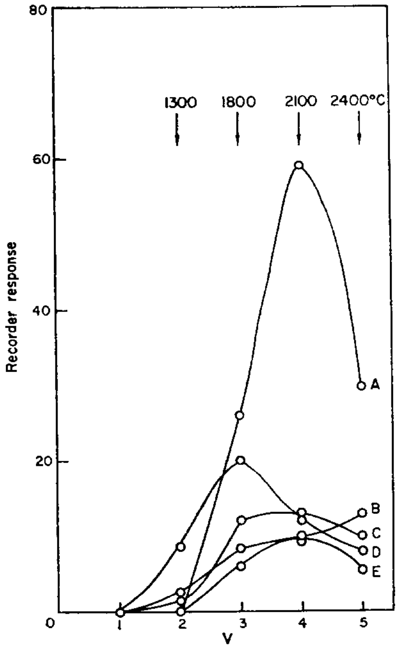

FIG. 2.—Effect of strip voltage (temperature) on atomic-absorption signal (chloride salts used).
A, 0·2 ng Mg; B, 0·6 ng Fe; C, 0·4 ng Mn;
D, 0·6 ng Cu; E, 0·8 ng Cr (flow-rate of argon: 3 l./min)

was transient, lasting a few seconds. The temperature attained by the strip is indicated in the figure. It can be seen that the optimum voltage differs for each element, and this may be due to a difference in the energy requirements for free atom production. The rate at which a sample was vaporized, and the atomization, were related to the temperature of the strip. Copper gave a narrower absorption signal than did magnesium, presumably because of the rapid atomization rate for copper; the width of the absorption signals for other elements was related to the atomization rates. Changing the temperature also broadened the signals. Increasing the voltage beyond the optimum value resulted in low peak signals owing to evaporation of the sample too quickly for monitoring by the amplifier. Although integration of the absorption signal might improve the sensitivity, the peak height was a reproducible measure of the concentration of the element.

Nickel, tungsten, tantalum and platinum were compared as strip material. Tantalum and tungsten showed similar results, but the tantalum strip was easier to fabricate. Only small signals were obtained with platinum, and neither nickel nor platinum could be used at very high temperature, so tantalum was chosen as the strip material. A continuous emission was observed, particularly in the wavelength range above 400 nm when the tantalum strip alone was heated, owing to light from the glowing strip entering the monochromater. Therefore, high precision was not obtained for elements having resonance lines in the longer wavelength range, because of the background.

Attempts were made to cover the strip with a small quartz tube, through which the beam from the hollow-cathode lamp passed. The sensitivity was improved, while the reproducibility was reduced because of the difficulty in accurate positioning of the strip in the tube.

Effect of inert gases and their flow-rate. An inert atmosphere is necessary within the absorption unit to prevent oxidation of the sample. Helium, argon and nitrogen were compared as inert gases, and reproducible results were obtained for a flowing system at atmospheric pressure as reported earlier.[6] The atomic-absorption signals were found to be unchanged for low concentrations of copper when different inert gases were used (Fig. 3). However, helium and nitrogen had a somewhat larger cooling effect upon the strip, as would be predicted from their thermal properties.

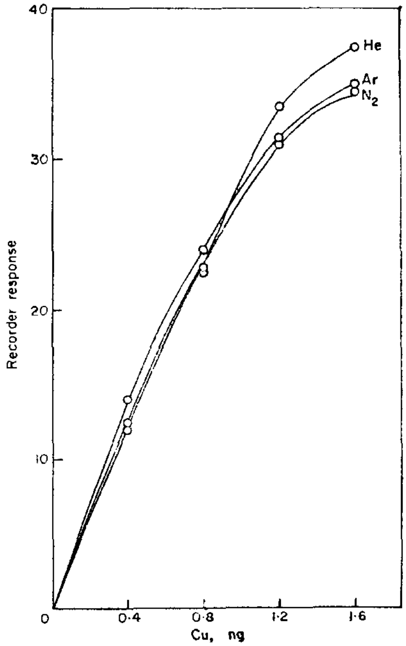

FIG. 3.—Effect of different inert gases (flow-rate of inert gas: ~2 l./min). Chlorides were used.

The temperature of the strip in nitrogen and helium was 8 and 16% lower, respectively, than that in argon at the same applied voltage. The cooling effect had little effect on the absorption signal, in contrast to the effect of strip temperature. No explanation can be found for this. As shown in Fig. 4, the magnesium absorption changed with increase in the flow-rate of argon. High inert gas flow-rates may have an adverse cooling effect on the atomic vapour. The argon flow-rate had different effects on measurement of other elements. The iron absorption was decreased with increasing flow rate whereas the chromium absorption was increased.

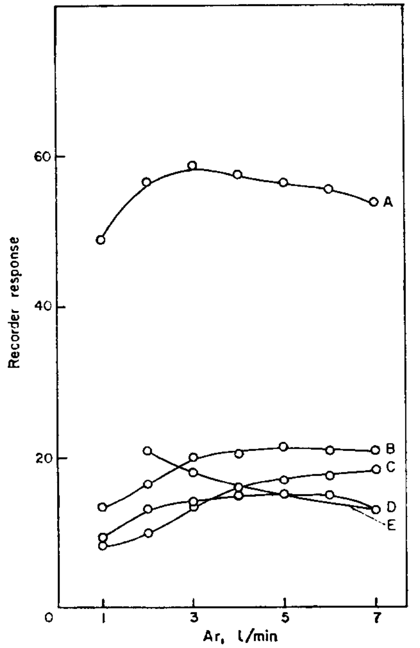

FIG. 4.—Effect of argon flow-rate on atomic-absorption signal.
A, 0·2 ng Mg; B, 0·6 ng Cu; C, 1·0 ng Cr;
D, 0·4 ng Mn; E, 1·0 ng Fe (used as chlorides)

The largest absorption signals were obtained when the light beam passed immediately above the strip.

Effect of the chemical composition of the sample. The chemical composition of the sample is important because thermal decomposition followed by atomization takes place before absorption. The nitrates and chlorides exhibited identical responses for copper, manganese and magnesium, while higher responses were obtained for chromium in the form of chromic salts than as chromate.

Reproducibility

The reproducibility of the method was determined by repetitively measuring standard solutions under optimized conditions, and calculating the coefficient of variation for each set of data. The coefficient of variation was 3–5% for all elements except iron (~7%). The volume delivered by the microsyringe had a coefficient of variation of 3%, so the main source of error was probably in delivery of the sample solution. Preheating of the strip was necessary before each analysis to remove any unwanted contamination on its surface.

Sensitivity

The absorption was plotted against the weight for each of the elements under conditions for maximum sensitivity. The curves obtained are shown in Fig. 5. The sensitivities (concentration which gives 1% absorption) were then calculated and are shown in Table I. The calibration curves showed increasing curvature at higher temperatures.

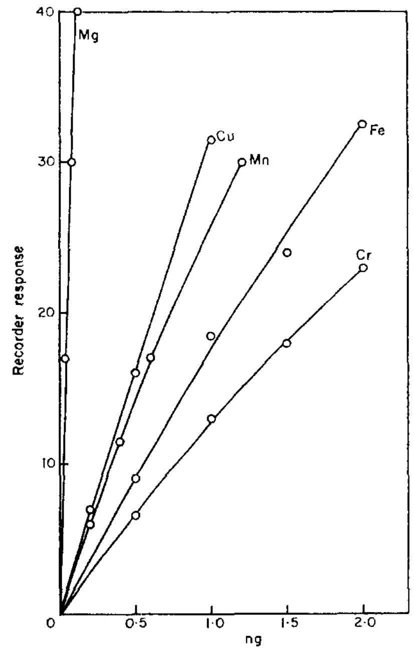

FIG. 5.—Calibration curves for magnesium, copper, manganese, iron and chromium (used as chlorides).

TABLE I.—SENSITIVITY

Element	Sensitivity, *g*
Mg (285·2 nm)	$3{\cdot}0 \times 10^{-12}$
Mn (279·5 nm)	$1{\cdot}0 \times 10^{-11}$
Cu (324·8 nm)	$1{\cdot}4 \times 10^{-11}$
Fe (248·3 nm)	$2{\cdot}0 \times 10^{-11}$
Cr (357·9 nm)	$3{\cdot}6 \times 10^{-11}$
Al (309·3 nm)	$6{\cdot}0 \times 10^{-11}$

Interferences

Interferences from aluminium and phosphate are encountered in the determination of magnesium, using a conventional flame. By the present technique, no such interferences were observed for [interferent]/[Mg] ratios up to 10. Higher concentrations of phosphate depressed the magnesium absorption. The interference due to aluminium depended on the magnesium concentration and the temperature as shown in Fig. 6. The presence of copper did not affect the magnesium absorption, but the absorption due to copper was affected by the presence of magnesium. No coherent theory can

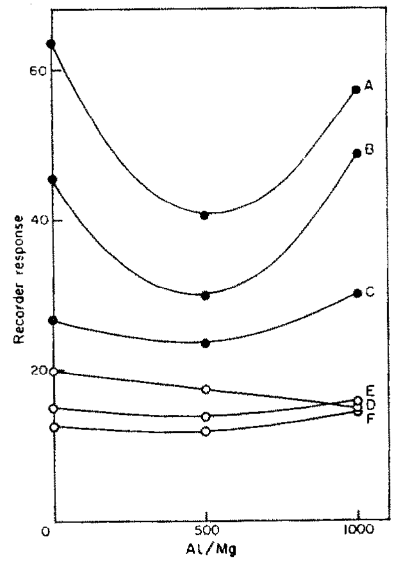

FIG. 6.—Interferences of aluminium in magnesium absorption (chlorides used).
A, 0·15 ng Mg(2100°); B, 0·10 ng Mg(2100°);
C, 0·05 ng Mg(2100°); D, 0·15 ng Mg(1800°);
E, 0·10 ng Mg(1800°); F, 0·05 ng Mg(1800°).

be advanced to explain these interferences, and much more work is needed on this aspect.

Potassium iodide (7 *μg*) was vaporized to examine molecular absorption in the wavelength region between 217·0 and 553·5 nm. Molecular absorption was observed at lower temperatures (1000°) as described previously by L'vov. Molecular absorption was not observed at higher temperatures (~2100°).

Applications

The value of the method was tested by selecting specific analytical applications. The magnesium concentration of control serum was measured by diluting 400-fold with water, and atomizing aliquots of the sample solution (2 *μl*) in the absorption device. Calibration was accomplished with known amounts of magnesium. The results are presented in Table II together with the certificate values.

TABLE II.—DETERMINATION OF MAGNESIUM IN SERUM

Sample	Mg found, *μg/ml*	Certificate value, *μg/ml*
A	24	23
B	59	61
C	25	21
D	34	31

A: Moni-Trol I (DADE Division, American Hospital Supply Corp., Miami, Fla.).

B: Moni-Trol II.

C: Versatol (General Diagnostics Division, Warner-Chilcott Lab., Morris Plain, N.J.).

D: Chemitrol (Clinton Lab., Los Angeles, Calif.).

An aluminium alloy (BCS 216/1) was also analysed for magnesium. With triplicate analyses, the values of 0·77, 0·80 and 0·78% were obtained. Calibration was accomplished using pure magnesium. These values were somewhat higher than the certified value of 0·74% (probably owing to interference by the aluminium). In this case the accuracy would be expected to be improved by the addition of aluminium to the standards. The standard addition method gave a value of 0·76% for magnesium.

This technique would appear to have considerable advantages in trace analysis where sample size is a limitation. Moreover, a solvent extraction method followed by atomization from the thermal strip could be suitable for determining trace amounts without a matrix effect.

Zusammenfassung—Die Arbeitsbedingungen eines Atomabsorptionssystems, das auf flammenloser Atomerzeugung beruht, wurden im Hinblick auf die Spurenanalyse nach Al, Cr, Cu, Fe, Mg und Mn untersucht. Die Probenlösung wurde auf einen Tantalstreifen aufgetragen und durch elektrische Heizung in inerter Atmosphäre in einer Absorptionskammer in den atomaren Zustand gebracht. Das Verfahren erlaubt geringe Probengrößen und erreicht eine höhere Empfindlichkeit als das herkömmliche Flammenverfahren. Einige Störeffekte und Anwendungen wurden untersucht.

Résumé—On a étudié les conditions de fonctionnement d'un système d'absorption atomique basé sur l'atomisation sans flamme pour l'analyse de traces de Al, Cr, Cu, Fe, Mg et Mn. La solution échantillon sur une lamelle de tantale est atomisée par chauffage électrique dans une atmosphère inerte à l'intérieur d'une chambre d'absorption. Cette technique permet l'emploi d'échantillons de petite dimension et conduit à une sensibilité plus grande que celle obtenue avec la technique de flamme ordinaire. On a étudié quelques effets d'interférences et applications.

SPECTROPHOTOMETRIC DETERMINATION OF ZIRCONIUM, URANIUM, THORIUM AND RARE EARTHS WITH ARSENAZO III AFTER EXTRACTIONS WITH THENOYLTRIFLUOROACETONE AND TRI-n-OCTYLAMINE*

HIROSHI ONISHI and KEIICHI SEKINE
Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki-ken, Japan

(*Received* 7 *June* 1971. *Accepted* 7 *July* 1971)

Summary—A method is described for the spectrophotometric determination of microgram amounts of zirconium, uranium(VI), thorium and rare earths with Arsenazo III after systematic separation by extraction. First zirconium is extracted into a xylene solution of thenoyltrifluoroacetone (TTA) from about 4*M* hydrochloric acid. Uranium(VI) is then extracted into a xylene solution of tri-n-octylamine from about 4*M* hydrochloric acid. Thorium is next extracted into TTA solution at pH about 1·5, and finally rare earths are extracted into TTA solution at pH about 4·7. Each metal is back-extracted from the organic phase before determination.

ARSENAZO III (2,2′-[1,8-dihydroxy-3,6-disulpho-2,7-naphthylenebis(azo)]dibenzenearsonic acid) is an extremely sensitive colorimetric reagent for thorium, uranium, and zirconium and a sensitive one for rare earths.[1–3] Although microgram amounts of thorium and zirconium can be determined without separation,[4] determination of zirconium, uranium, thorium, and rare earths in their mixtures is difficult because of interference. Methods have been described for the separation of 5 μg of zirconium from 3 mg of thorium,[5] 20 μg of uranium from 10 mg of thorium or 10 mg of zirconium,[6,7] and for the separation of microgram amounts of thorium and uranium.[8] In each method, Arsenazo III has been used for determination.

The purpose of the present work is to develop a method for the systematic separation of zirconium, uranium, thorium, and rare earths and subsequent photometric determination with Arsenazo III. The separation method described herein will be generally useful.

EXPERIMENTAL

Reagents

Standard zirconium solution. A stock solution, containing 1·00 mg of zirconium/ml, was prepared by dissolving 3·533 g of $ZrOCl_2 \cdot 8H_2O$ in 2*M* hydrochloric acid, and diluting to exactly 1 litre with 2*M* hydrochloric acid. This solution was standardized by titration with EDTA, using Xylenol Orange as indicator.[9] A working standard solution was prepared by diluting the stock solution with 2*M* hydrochloric acid.

Standard uranium solution. A stock solution, containing 1·00 mg of uranium/ml, was prepared by dissolving 0·500 g of pure uranium metal in 10 ml of concentrated nitric acid and 12 ml of 30% hydrogen peroxide by heating. The solution was evaporated to near dryness. The residue was dissolved in 0·2*M* nitric acid and the solution was diluted to exactly 1 litre with 0·2*M* nitric acid. From this stock solution a working standard solution containing 10 μg of uranium/ml was prepared by diluting with water.

Standard thorium solution. A stock solution, containing 1·00 mg of thorium/ml, was prepared by dissolving 2·379 g of $Th(NO_3)_4 \cdot 4H_2O$ in 2*M* hydrochloric acid, and diluting to exactly 1 litre with

2*M* hydrochloric acid. This solution was standardized by titration with EDTA, using Xylenol Orange as indicator.[9] A working standard solution was prepared by diluting the stock solution with 2*M* hydrochloric acid.

Stock solutions of lanthanum, dysprosium, and ytterbium. Each solution, containing 1·00 mg of metal/ml, was prepared by dissolving the previously ignited oxide in a slight excess of nitric acid (1 + 1) and diluting with water. Working standard solutions were prepared by diluting the stock solutions with water.

Standard cerium(III) *solution.* Water (10 ml), 70% perchloric acid (10 ml) and 30% hydrogen peroxide (1 ml) were added to 0·1228 g of previously ignited CeO_2. On heating, the oxide dissolved and the resulting solution was evaporated to dryness. Then 11 ml of sulphuric acid (1 + 1) and 1 ml of 30% hydrogen peroxide were added, and the solution was evaporated to white fumes. After cooling, the solution was diluted to exactly 100 ml with water. A working standard solution (10 μg of cerium/ml) was prepared by diluting this stock solution with water.

Thenoyltrifluoroacetone, 0·5*M*. TTA (45 g) was dissolved in 400 ml of xylene.

Tri-n-octylamine solution. TNOA (5 g) was dissolved in 100 ml of xylene.

Cresol Red solution. Cresol Red (100 mg) was dissolved in 26 ml of 0·01*M* sodium hydroxide and the solution was diluted to 250 ml with water.

Aqueous Arsenazo III solution, 0·10% *w/v*.

Procedure

An outline of the procedure is shown in Fig. 1.

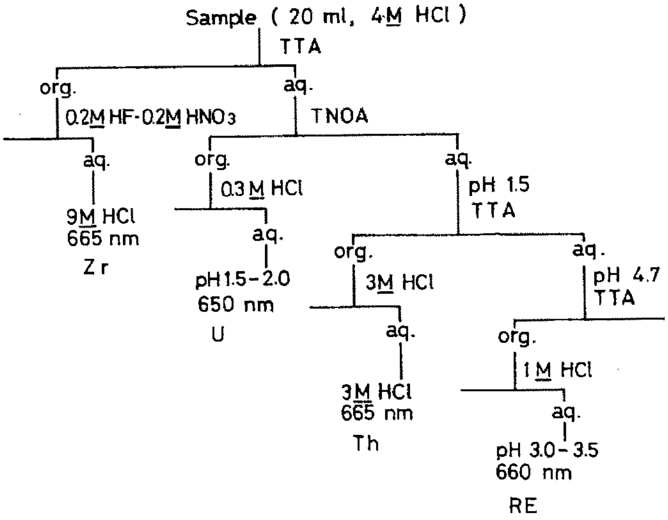

FIG. 1.—Outline of procedure.

Separation and determination of zirconium. Transfer the sample solution (4*M* in hydrochloric acid and containing 0–15 μg of zirconium, 0–50 μg of uranium, 0–30 μg of thorium, and 0–50 μg of a rare-earth element in a volume of approximately 20 ml) to a 100-ml separatory-funnel. Shake the solution for 10 min with 10 ml of TTA solution. When the layers have separated, drain off the aqueous phase into a second separatory-funnel. Wash the organic phase by shaking it for 5 min with 3 ml of 4*M* hydrochloric acid. Add this aqueous phase to the second separatory-funnel.

Add 10 ml of 0·2*M* hydrofluoric acid–0·2*M* nitric acid to the organic phase and shake for 3 min to back-extract the zirconium. Transfer the aqueous phase to a 50-ml quartz dish. Shake the organic phase for 30 sec with 3 ml of 0·2*M* hydrofluoric acid–0·2*M* nitric acid. Transfer the aqueous phase to the quartz dish and evaporate to dryness. (Discard the organic phase.) To the residue add 1 ml of concentrated nitric acid and 1 ml of 70% perchloric acid. Evaporate the solution to dryness, and dissolve the residue in 10 ml of concentrated hydrochloric acid.

Transfer the solution to a 25-ml volumetric flask, washing in with 8·5 ml of concentrated hydrochloric acid, add 1·0 ml of 0·1% Arsenazo III solution, and dilute to the mark with water. Measure the absorbance of the solution in a 1-cm cell at 665 nm, using the reagent blank as the reference.

Separation and determination of uranium. To the aqueous phase in the second separatory-funnel add 10 ml of TNOA solution and shake for 2 min. When the layers have separated, drain off the aqueous phase into a third separatory-funnel. Wash the organic phase by shaking it for 2 min with 3 ml of $4M$ hydrochloric acid. Add this aqueous phase to the third separatory-funnel.

Add 10 ml of $0{\cdot}3M$ hydrochloric acid to the organic phase and shake for 2 min to back-extract the uranium. Transfer the aqueous phase to a fourth separatory-funnel. Shake the organic phase for 1 min with 3 ml of $0{\cdot}3M$ hydrochloric acid. Add the aqueous phase to the fourth separatory-funnel. (Discard the organic phase.) Shake the aqueous phase containing uranium for 1 min with 5 ml of xylene.

Transfer the solution to a 25-ml volumetric flask through filter paper. Add 1 ml of 1% ascorbic acid solution [to reduce iron(III) if present], 1 drop of Cresol Red solution, dilute ammonia solution (1 + 9) until the colour turns to red from yellow (pH of the solution must be 1·5–2·0), 1·0 ml of Arsenazo III solution, and dilute to the mark with water. Measure the absorbance of the solution at 650 nm, using the reagent blank as the reference.

Separation and determination of thorium. To the aqueous phase in the third separatory-funnel add 1 drop of Cresol Red solution, concentrated ammonia solution until the colour of the aqueous phase turns to red from yellow (pH of the solution must be 1·5 – 2·0), and 10 ml of $0{\cdot}5M$ TTA, and shake the system for 15 min. When the layers have separated, drain off the aqueous phase into a fifth separatory-funnel.

Shake the organic phase for 10 min with 10 ml of $3M$ hydrochloric acid to back-extract the thorium. Transfer the aqueous phase to a sixth separatory-funnel. Shake the organic phase for 5 min with 5 ml of $3M$ hydrochloric acid. Add the aqueous phase to the sixth separatory-funnel. (Discard the organic phase.) Shake the combined aqueous phases for 1 min with 5 ml of xylene.

Transfer the aqueous solution to a 25-ml volumetric flask through filter paper. Wash the organic phase by shaking it for 30 sec with 5 ml of $3M$ hydrochloric acid. Transfer the aqueous solution to the same volumetric flask through the filter paper. Add 1 ml of concentrated hydrochloric acid and 1·0 ml of Arsenazo III solution and dilute to the mark with water. Measure the absorbance of the solution at 665 nm, using the reagent blank as the reference.

Separation and determination of a rare earth. To the aqueous phase in the fifth separatory-funnel, add 50% w/v ammonium acetate solution until the pH of the solution becomes 4·7 ± 0·2 (pH test paper) and 15 ml of $0{\cdot}5M$ TTA, and shake the system for 5 min. When the layers have separated, drain off the aqueous phase into a seventh separatory-funnel. Add 15 ml of TTA solution to the seventh separatory-funnel, and shake the system for 5 min. Discard the aqueous phase. Combine the second extract with the first and wash the extracts by equilibrating them for 1 min with 10 ml of $0{\cdot}1M$ acetate buffer solution of pH 4·7. Discard the aqueous phase.

Shake the organic phase for 5 min with 25 ml of $1M$ hydrochloric acid to back-extract the rare earth. Transfer the aqueous phase to a 50-ml quartz dish and evaporate to dryness. To the residue add 1 ml of concentrated nitric acid and 1 ml of 70% perchloric acid. Evaporate the solution to dryness.

Dissolve the residue in 15 ml of water and transfer the solution to a 25-ml volumetric flask. Add 1 ml of 50% ammonium acetate solution and $4M$ hydrochloric acid until the pH of the solution becomes 3·0–3·5 (pH test paper). Add 1·0 ml of Arsenazo III solution and dilute to the mark with water. Measure the absorbance of the solution at 660 nm, using the reagent blank as the reference.

Calibration curves. Construct calibration curves for zirconium (0–15 μg), uranium (0–50 μg), thorium (0–30 μg), and rare earth (0–50 μg) by omitting the separation steps.

RESULTS AND DISCUSSION

Determination of zirconium, uranium, thorium, and rare earths

The conditions for the spectrophotometric determination of zirconium,[4] uranium,[7] and thorium[4] have been already described. The addition of gelatin in the determination of zirconium[4] has been found unnecessary. Although uranium can be determined more sensitively by making use of the uranium(IV)–Arsenazo III complex,[6,10] the present work is based on the uranium(VI)–Arsenazo III complex,[7,10] because of simpler manipulation. In the present work, molar absorptivities of $12{\cdot}9 \times 10^3$, $4{\cdot}4 \times 10^3$, and $10{\cdot}2 \times 10^3$ $\mathrm{l.mole^{-1}.mm^{-1}}$ have been obtained for zirconium, uranium, and thorium, respectively.

The conditions for the determination of rare earths (dysprosium has been chosen to represent rare earths) have been examined. The absorption curves are shown in Fig. 2. A wavelength of 660 nm has been adopted for the determination of rare earths.

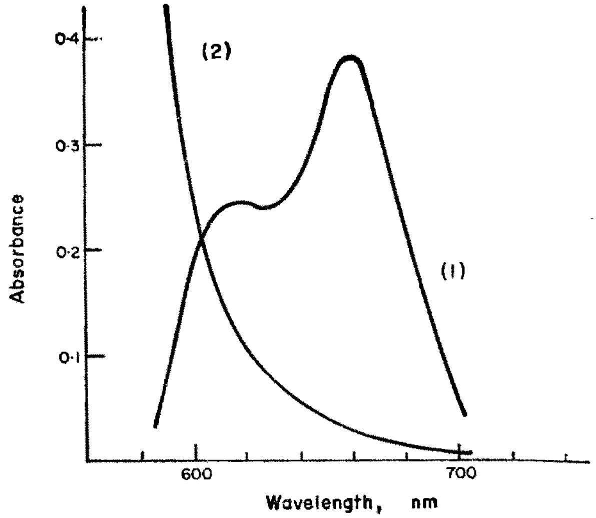

FIG. 2.—Absorption curves at pH 3·0.
(1) Dy (40 μg/25 ml) and Arsenazo III (1 mg/25 ml) *vs.* reagent blank.
(2) Reagent blank *vs.* water.

The effect of pH on the absorbance of the dysprosium–Arsenazo III complex is shown in Fig. 3. A suitable pH range is 3·0–3·5. The molar absorptivities at 660 nm are $4{\cdot}1 \times 10^3$, $4{\cdot}0 \times 10^3$, $4{\cdot}2 \times 10^3$, and $3{\cdot}4 \times 10^3$ $\text{l.mole}^{-1}.\text{mm}^{-1}$ for La, Ce, Dy, and Yb, respectively. These values are a little lower than those given by Savvin.[3]

(2) Reagent blank *vs.* water.

Separation of zirconium, uranium, thorium, and rare earths

The conditions for the separation of zirconium from thorium,[5] uranium from thorium,[6,7] and thorium and uranium[8] have been already clarified. Separation of rare earths by TTA extraction was previously studied.[11] On the basis of these investigations a scheme has been evolved for the analysis of mixtures of zirconium, uranium, thorium, and rare earths (Fig. 1).

TABLE I.—DETERMINATION OF Zr, U, Th, AND RARE EARTHS

Taken, *μg*				Found, *μg*			
Zr	U	Th	Dy	Zr	U	Th	Dy

* La instead of Dy.

Results obtained in applying the proposed procedure are collected in Table I. Recoveries of uranium are a little low (~ 90%). After extraction of uranium with TNOA solution, the organic phase was diluted with an equal volume of xylene, and uranium was back-extracted with 0·3*M* hydrochloric acid. The recovery of uranium was not improved by this procedure.

Occasionally high blank values for zirconium were obtained. This was due to traces of zirconium in the glass of the separatory-funnels. Separatory-funnels can be found which do not yield appreciable amounts of zirconium on treatment with 0·2*M* hydrofluoric acid–0·2*M* nitric acid. However, if such separatory-funnels are not available, plastic separatory-funnels may be necessary for the back-extraction step.

* Not determined.

Smaller amounts of uranium may be determined if uranium(VI) is reduced to uranium(IV) with zinc and then the colour is developed with Arsenazo III in hydrochloric acid solution.[6]

As shown in Table I, the recovery of lanthanum is the same as that of dysprosium. It is believed that other rare-earth elements will give similar results.[11]

Interference study. The effect of selected foreign ions on the separation and determination of zirconium, uranium, thorium, and dysprosium is shown in Table II. Although scandium will accompany thorium in the separation step,[12] it does not interfere with the determination of thorium. One mmole of phosphate does not interfere with the analysis for uranium, but it does with the analysis for the other elements; 0·05 mmole of phosphate still interferes with the analysis for thorium, but 0·01 mmole of phosphate does not.

Zusammenfassung—Es wird ein Verfahren zur spektrophotometrischen Unter scheidung von Mikrogrammengen von Zirkonium, Uran(VI), Thorium und seltenen Erden mit Arsenazo III nach systematischer Trennung durch Ausscheidung beschrieben. Zuerst wird Zirkonium in eine Xylollösung von Thenoyltrifluoroaceton (TTA) aus etwa 4M Chlorhydratsäure ausgeschieden. Dann wird Uran(VI) in eine Xylollösung von Tri-n-oktylamin aus etwa 4*M* Chlorhydratsäure ausgeschieden. Danach wird Thorium in eine TTA Lösung bei etwa pH 1,5 und zum Schluss seltene Erden in eine TTA Lösung bei etwa pH 4,7 ausgeschieden. Jedes Metall wird vor Unterscheidung von der organischen Phase zurück titriert.

Résumé—On décrit une méthode pour la détermination spectrophotométrique de quantités de l'ordre du microgramme de zirconium, uranium(VI), thorium et terres rares avec l'Arsenazo III après séparation systématique par extraction. On extrait d'abord le zirconium de l'acide chlorhydrique environ 4*M* dans une solution en xylène de thenoyltrifluoracétone (TTA). On extrait alors l'uranium(VI) de l'acide chlorhydrique environ 4*M* dans une solution en xylène de tri-*n*-octylamine. Le thorium est ensuite extrait par la solution de TTA à un pH d'environ 1,5 et, finalement, les terres rares sont extraites par la solution de TTA à un pH d'environ 4,7. Chaque métal est extrait en retour de la phase organique avant le dosage.

FORMATION AND COMPOSITION OF THE PRECIPITATES OF VARIOUS METAL 8-SELENOQUINOLINE COMPLEXES

Eiichi Sekido, Isamu Fujiwara and Yoshitaka Masuda
Department of Chemistry, Faculty of Science, Kobe University, Nada, Kobe, Japan

(*Received* 19 *June* 1971. *Accepted* 1 *December* 1971)

Summary—The effect of acidity on the precipitation of various bivalent metal 8-selenoquinoline and 8-mercaptoquinoline complexes has been systematically studied and compared. The metal ions were Zn^{2+}, Cd^{2+}, Pb^{2+}, Mn^{2+}, Ni^{2+}, Cu^{2+} and Co^{2+}. Most of the metal ions, except copper(II) and cobalt(II), precipitate as a 1:2 complex, metal:ligand. However, in hydrochloric acid solution cadmium precipitates as $CdR_2 \cdot 2HCl$ and lead as $PbR_2 \cdot 2HCl$ or $PbR \cdot Cl$. Copper(II) is reduced to copper(I) and precipitates as $CuR \cdot RH$ at pH above 2·0 and as CuR in strongly acidic solution. Cobalt(II) does not give a precipitate of composition but appears to precipitate as a mixture of $CoR_2 \cdot RH$ and fixed CoR_2 or as other complexes. The reasons for the formation of the various types of precipitate are considered.

From the viewpoint of selectivity of organic reagents it is particularly interesting to investigate the change of reactivity of 8-hydroxyquinoline with a metal ion when the donor oxygen atom is replaced by a sulphur or a selenium atom. The formation of 8-hydroxyquinoline precipitates with various metal ions was systematically studied by Goto,[1] and the various metal 8-mercaptoquinoline complexes were formed by Kuznetsov, Bamkovsky and Ievin'sh[2] for the first time. For 8-selenoquinoline, systematic studies have not been made although qualitative results for the formation of precipitates and their chloroform extraction were reported by Sekido, Fernando and Freiser.[3] The present paper is concerned with stoichiometric studies on the formation and composition of the precipitates of various bivalent metal 8-selenoquinoline complexes, and comparisons with those of 8-mercaptoquinoline and 8-hydroxyquinoline.

EXPERIMENTAL

Reagents

Sodium salts of 8-selenoquinoline and 8-mercaptoquinoline. 8-Selenoquinoline was synthesized by the modified method of Sekido, Fernando and Freiser,[4] and its sodium salt monohydrate was prepared by the method of Sekido and Fujiwara.[5] The sodium salt of 8-mercaptoquinoline anhydride was prepared by the method of Nakamura and Sekido.[6] Both of the reagent solutions were prepared as follows. An amount of 8-selenoquinoline corresponding to 50% excess over that required stoichiometrically for complete precipitation of a known quantity of metal ion was dissolved in a mixed solution of 2 ml of 50% hypophosphorous acid, 2 ml of 6*M* hydrochloric acid and 10 ml of water. 8-Mercaptoquinoline solution was prepared in the same manner but without hypophosphorous acid.

Buffer solutions. A 1*M* acetic acid–1*M* sodium acetate buffer was used for weakly acidic medium and 1*M* ammonia–1*M* ammonium chloride and Clark-Lubs buffer solution for weakly basic medium. Hydrochloric acid and sodium hydroxide solution were used for strongly acidic and basic media respectively.

Stock solutions of bivalent metal ions, 0·1*M*. Stock solutions of Zn^{2+}, Cd^{2+}, Pb^{2+}, Ni^{2+}, Mn^{2+}, Cu^{2+} and Co^{2+} were prepared by dissolving their salts in demineralized water. Their concentrations were determined with EDTA.

All reagents, including masking reagents, were of analytical-reagent grade.

Precipitation of the complexes

In order to find the effect of pH on the formation of the 8-selenoquinoline or 8-mercaptoquinoline complexes other conditions must be kept the same. Thus the conditions such as excess of reagent, temperature, aging time, use of reducing agents, washing and drying of the precipitates, were first examined.

The following procedures were adopted. Metal solution (0·1*M*, 10 ml) and 50 ml of water were taken in a 200-ml Erlenmeyer flask and adjusted to a definite pH with 20 ml of 1*M* buffer solution. If necessary, a masking reagent such as tartaric acid was added to prevent alkaline hydrolytic precipitation. The resulting solution was heated to 65–75° under nitrogen, and the reagent solution (50% excess) was added. After aging for about 10 min, the precipitate was collected and washed with 50 ml of hot solution at 80° adjusted approximately to the desired pH with hydrochloric acid or sodium hydroxide and then with 50 ml of hot water. All the operations were conducted under a blanket of nitrogen gas. The precipitate was dried to constant weight, in a desiccator charged with silica gel.

Determination of composition of the precipitates

About 0·1 g of the precipitate was weighed into a crucible and decomposed by heating with 18 ml of concentrated nitric acid and 6 ml of 60% perchloric acid. The procedure was repeated until the organic matter was completely destroyed. The resulting clear solution was titrated with 0·1*M* EDTA.

RESULTS AND DISCUSSION

The effect of acidity on the formation of the precipitates of the bivalent metal 8-selenoquinoline and 8-mercaptoquinoline complexes is shown in Figs. 1–6. The results for the formation of the precipitates are summarized in Table I. Most of the metal ions except for copper(II) and cobalt(II) precipitate stoichiometrically as the 1:2 complex, MR_2. However, in hydrochloric acid solution cadmium precipitates as $CdR_2 \cdot 2HCl$ and lead as $PbR_2 \cdot 2HCl$ or $PbR \cdot Cl$ for 8-selenoquinoline, and lead precipitates as $PbR \cdot Cl$ for 8-mercaptoquinoline. Copper(II) seems to precipitate as $CuR \cdot RH$ at pH > 2·0 and as CuR in strongly acidic solution. Cobalt(II) does not give precipitates of a definite composition, but appears to precipitate as a mixture of $CoR_2 \cdot RH$ and CoR_2 or as other complexes (*e.g.* CoR_3). The 8-seleno- and 8-mercaptoquinoline precipitates have no co-ordinated water although most of the bivalent metal 8-hydroxyquinoline complexes have two molecules of water of co-ordination.

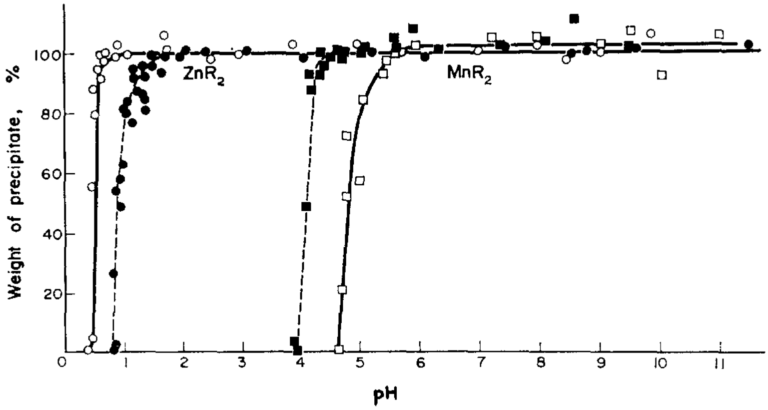

Fig. 1.—The effect of acidity on formation of zinc and manganese 8-selenoquinoline precipitates (———) and 8-mercaptoquinoline precipitates (– – – –). ○ and ●: zinc complexes; □ and ■: manganese complexes. The term "weight of precipitate (%)" *refers to the precipitate weight relative to the theoretical weight corresponding to the species indicated.*

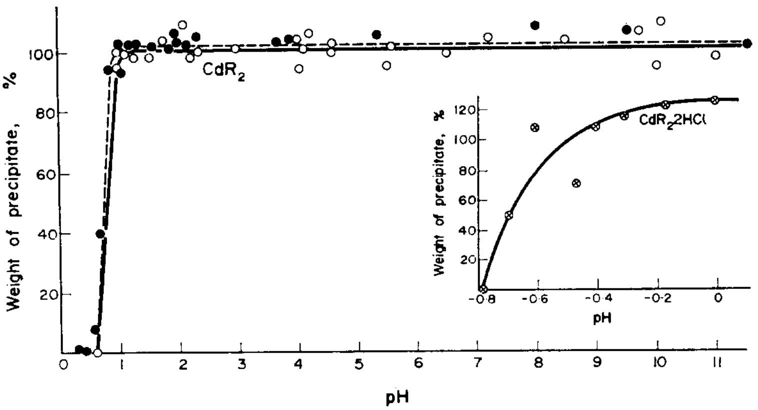

FIG. 2.—The effect of acidity on formation of cadmium 8-selenoquinoline (—○—) and cadmium 8-mercaptoquinoline (- -●- -) precipitates. ⊗ indicates precipitates formed on cooling or standing at low temperature.

The minimum pH for complete precipitation of the 1:2 metal complex increases in the order Zn < Cd < Ni < (Co) < Pb < (Cu) < Mn for 8-selenoquinoline complexes and Cd < Ni < (Co) < Zn < (Cu) < Pb < Mn for 8-mercaptoquinoline complexes. The values for cobalt and copper are those for $CoR_2 \cdot RH$ and $CuR \cdot RH$ respectively. In order to compare these orders qualitatively with that for 1:2 metal 8-hydroxyquinoline complexes, Goto's data[1] are cited below although the conditions of the formation of these precipitates is a little different from those used for this study.

Metal:	Cu	Ni	Zn	Co	Cd	Mn	Pb
pH:	2·7	4·0	4·1	4·2	5·4	5·9	8·4

On the basis of proton affinity, the pH of formation of the precipitate of the same metal would be expected to decrease in the order of the value of $pK_{a_1} + pK_{a_2}$ for the three reagents, 15·01 for 8-hydroxyquinoline,[7] 10·40 for 8-mercaptoquinoline[4] and 8·67 for 8-selenoquinoline.[4] This relation seems to hold between the 8-hydroxyquinoline complex and either of the other two reagent complexes but not between the

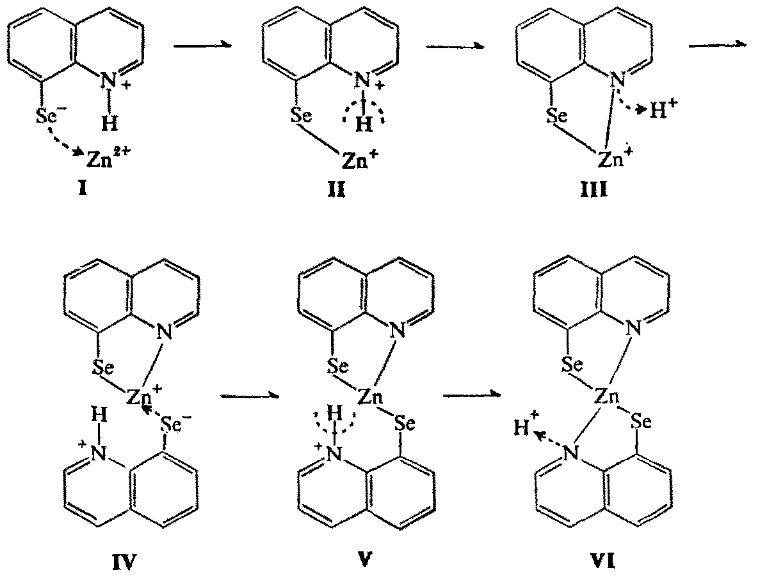
8-mercaptoquinoline and 8-selenoquinoline complexes themselves. The order for the 8-hydroxyquinoline precipitates is almost the Irving-Williams order,[8] but that for 8-selenoquinoline and 8-mercaptoquinoline complexes is not.

Taking into account the electronegativities of selenium, sulphur and oxygen atoms, the covalent character of the metal–selenium bond is probably the same as or slightly greater than that of the metal–sulphur bond and is greater than that of the metal–oxygen bond. Therefore, copper(I), zinc and cadmium ions, classified as group B metals having filled *d* orbitals, will form the strongest covalent bonds, followed by copper(II), nickel and cobalt ions, which are the latter half of the first transition metal group having group B character. In addition to the covalent bond these metal ions, especially the group B metal ions, probably form π-bonds with the selenium or sulphur atom. Manganese, with increasing group A character forms a weak bond with selenium or sulphur, and alkaline earth metal and aluminium ions, being group A, do not form such complexes even in alkaline solution, although they do form complexes with 8-hydroxyquinoline.

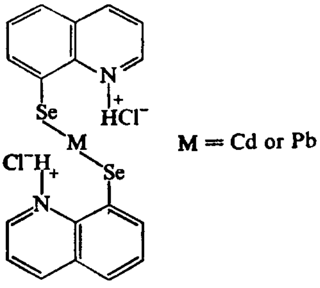
When zinc reacts with 8-selenoquinoline at $\text{pH} > 0{\cdot}75$, a hydrated zinc ion will approach the anionic selenium ($-\text{Se}^-$) of the zwitterion form of 8-selenoquinoline (step I), and will bond with it (step II). The value of pK_a corresponding to the dissociation of $\gt\text{N}-\text{H}^+$ is quite sensitive to the charge on the selenium atom.[9] That is, the neutralization of the selenium anion by a proton results in a remarkable decrease of the pK_a value from 8·75 to 3·26 as seen in Table II. Consequently, the formation of an Se–Zn bond makes the basicity of the nitrogen atom decrease significantly, so that the proton will dissociate at fairly low pH, and then the nitrogen atom will co-ordinate with the zinc ion even at pH 0·75 (step III). Then the second zwitterion form of 8-selenoquinoline approachs the 1:1 complex (step IV), and forms the second Se–Zn bond (step V), and then will complete the 1:2 complex (step VI).



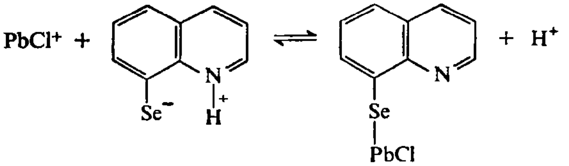
When the acidity of the solution increases, there is competition between zinc and hydrogen ions to bond with the nitrogen atom. At pH lower than 0·75 both Zn–N and Zn–Se bonds will be replaced by H–N and H–Se bonds respectively.

If the covalent character of an M–Se bond is higher than that of Zn–Se bond, for example Cd–Se or Pb–Se, the M–Se bond will still be preserved even if the M–N bond is replaced by an M–H bond. Consequently, in the case of cadmium and lead the red-orange precipitate of $MR_2 \cdot 2HCl$ as shown in formula I will be formed in a strongly acidic solution. The following reasons support the conclusion that the red-orange precipitate of cadmium is represented by formula I. (1) The theoretical weight of the precipitate is in the range of observed values. (2) This red-orange precipitate dissolves partly in hot water and then changes to a yellow-orange compound which may be the CdR_2 complex. (3) The metal-bonding infrared band for the 1:2 cadmium complex, CdR_2, 657 cm^{-1}, shifts to lower frequency, 645 cm^{-1}, for the red-orange compound. It is known that the metal-bonding bands which appear in the range of 600–700 cm^{-1} for the various metal 8-selenoquinoline and 8-mercaptoquinoline complexes shift to lower frequency when the chelate linkage is cleaved.[10] (4) The difference in colour of the two kinds of precipitate corresponds to the change of the visible absorption spectra of cadmium 8-selenoquinoline complex (1:1) in 50% dioxan–perchloric acid solution.[9]

In the case of lead, the existence of $PbR \cdot 2HCl$ in strongly acidic solution is confirmed by the same reasons as for cadmium. However, in addition to the formation of PbR_2 and $PbR_2 \cdot 2HCl$, the gray–green precipitate (of which the composition almost corresponds to $PbR \cdot Cl$) is formed in the range of pH 0·8–2·5. The following reaction will take place in this pH range, because the Pb–N bond is probably very weak:

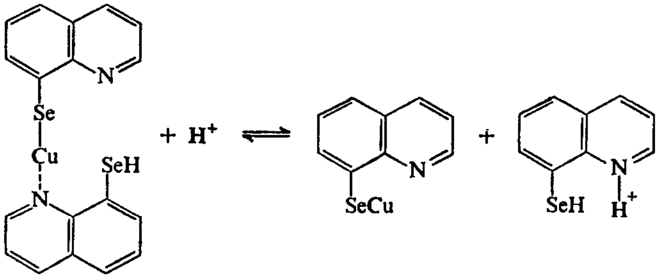


Formula I



If the M–Se bond and M–N bond are weaker than the Zn–Se bond and Zn–N bond respectively, for example in the manganese complex, the 1:2 complex will be formed at a higher pH than that for the formation of the zinc complex. That the stability of the manganese complex is less than that of other metal complexes is supported by the easy change to a white–brown substance even on gentle drying by heating.

Copper(II) seems to be reduced to copper(I) by 8-selenoquinoline whether in the presence of hypophosphorous acid or not, as shown in Fig. 5. However, in the absence of hypophosphorous acid, the equivalent amount of 8-selenoquinoline required to reduce copper(II) to copper(I) is oxidized to 8,8′-diquinolyldiselenide which does not dissolve in the solution at pH $>$ 1·5. Thus the composition of the precipitate obtained with 8-selenoquinoline at pH $>$ 3·0 will be $\mathrm{CuR{\cdot}RH}$, not $\mathrm{CuR_2}$, and in strongly acidic solution the following dissociation will occur:



This supposition is supported by the following facts. (1) The observed weight of precipitate agrees with the theoretical. (2) This reaction occurs at pH below 2·9, which is slightly less than $\mathrm{p}K_{\mathrm{B}}$, 3·26, for the neutral form of 8-selenoquinoline in aqueous solution as shown in Table II.[4] (3) The precipitates obtained with and without hypophosphorous acid present both have a metal-indicative band at 656 cm^{-1} and in addition those obtained in its absence have a band at 642 cm^{-1}, which also appears with 8,8′-diquinolyldiselenide.

The weight of the precipitate of copper(I) 8-mercaptoquinoline complex, CuR formed in the pH range from about 0·5 to —0·55, almost agrees with the theoretical value. Of the metal ions dealt with in this study copper(I) will form the strongest

TABLE II.—ACID DISSOCIATION CONSTANTS FOR 8-SELENOQUINOLINE IN WATER.*

$\mathrm{p}K_{\mathrm{C}}$	8.75	$\mathrm{p}K_{\mathrm{B}}$	3.26	$\mathrm{p}K_{\mathrm{D}}$	5.41	$\mathrm{p}K_{\mathrm{A}}$	—0.08

* Reference 4.

covalent bond because it is extremely deformable. In fact, the 8-selenoquinoline complex precipitates completely at pH −0·88 (7·6*M* hydrochloric acid) and is 70% precipitated even from 12*M* hydrochloric acid. Similarly, 8-mercaptoquinoline complex precipitates in strongly acidic solution although no precipitate of CuR forms in 12*M* hydrochloric acid. If the $pH_{1/2}$ is defined as the pH at which the complex is 50% precipitated, the values of $pH_{1/2}$ for the 8-selenoquinoline and 8-mercaptoquinoline complexes are −0·95 and −0·71 respectively. This may be attributed to the covalent bond for Se–Cu being stronger than that for S–Cu.

The weight of the precipitate of the cobalt 8-selenoquinoline complex varies widely from the theoretical, and it is impossible to decide whether it is CoR_2, CoR·RH or CoR_3, as elemental analysis shows the composition to be highly variable and not corresponding to any of these formulae. The precipitates obtained from ammoniacal solution (pH 9–11) are almost constant in composition but do not correspond to CoR_3. Although the weight of the precipitate of the cobalt 8-mercaptoquinoline complex obtained at pH above 1·25 is not so variable as that of 8-selenoquinoline complex, it is not stoichiometric either.

Acknowledgement—The authors acknowledge the assistance of Mr. Y. Mido with the infrared measurements.

Zusammenfassung—Der Säureeinfluß auf die Fällung der Komplexe von 8-Selenochinolin und 8-Mercaptochinolin mit verschiedenen zweiwertigen Metallionen wurde systematisch untersucht und verglichen. Die verwendeten Metallionen waren Zn^{2+}, Cd^{2+}, Pb^{2+}, Mn^{2+}, Ni^{2+}, Cu^{2+} und Co^{2+}. Die meisten Metallionen außer Kupfer(II) und Kobalt(II) fallen als Komplexe mit dem Metall:Ligand-Verhältnis 1:2 aus. In salzsaurer Lösung fällt jedoch Cadmium als CdR_2·2HCl und Blei als PbR_2·2HCl oder PbR·Cl aus. Kupfer(II) wird zu Kupfer(I) reduziert und fällt bei einem pH über 2,0 als CuR_2·RH, in stark saurer Lösung als CuR aus. Kobalt(II) gibt keinen definiert zusammengesetzten Niederschlag; anscheinend fällt es als ein Gemisch aus CoR_2·RH und CoR_2 oder als andere Komplexe aus. Die Gründe für die Bildung der verschiedenen Niederschlagstypen werden erörtert.

Résumé—On a systématiquement étudié et comparé l'influence de l'acidité sur la précipitation de divers complexes de métaux divalents avec la 8-sélénoquinoléine et la 8-mercaptoquinoléine. Les ions métalliques étaient Zn^{2+}, Cd^{2+}, Pb^{2+}, Mn^{2+}, Ni^{2+}, Cu^{2+} et Co^{2+}. La plupart des ions métalliques, à l'exception du cuivre(II) et du cobalt(II), précipitent à l'état de complexe 1:2, métal:ligand. Toutefois, en solution dans l'acide chlorhydrique, le cadmium précipite à l'état de CdR_2·2HCl et le plomb à l'état PbR_2·2HCl on PbRCl. Le cuivre(II) est réduit en cuivre(I) et précipite à l'état CuR_2·RH à pH supérieur à 2,0 et à l'état CuR en solution fortement acide. Le cobalt(II) ne donne pas de précipité de composition définie mais précipite sous forme de mélange de CoR_2·RH et CoR_2 ou sous forme d'autres complexes. On considère les raisons de la formation des divers types de précipités.

DETERMINATION OF PHOSPHORUS IN HYPEREUTECTIC ALUMINIUM–SILICON ALLOYS

KOHICHI MUKAI
Nippon Light Metal Research Laboratory, Ltd., Kambara, Shizuoka, Japan

(*Received* 15 *June* 1971. *Accepted* 30 *August* 1971)

Summary—A reproducible method is described for determination of small amounts of phosphorus (from 0·0005% to 0·02%) in hypereutectic aluminium–silicon complex alloys. The method permits the separate determination of phosphorus in acid-soluble and acid-insoluble fractions. Phosphomolybdate is extracted with n-butanol–chloroform solvent mixture and back-extracted with a stannous chloride reducing solution. The phosphorus content of a sample cut into small pieces decreases during storage; loss of phosphorus is negligible on acid dissolution under oxidizing conditions.

ALUMINIUM–SILICON alloys are of considerable technical importance in casting processes. In casting of such alloys in the hypereutectic region, a uniform distribution of fine silicon particles in the material, which results in better tensile properties, is ensured by the addition of a small amount of phosphorus. The phosphorus reacts with the aluminium to produce aluminium phosphide, an efficient nucleating agent for the silicon. Since the amount of phosphorus retained in the alloys is of considerable metallurgical significance, an accurate method is required for the determination of this element, which is present in the form of aluminium phosphide both in the primary silicon particles and probably in the aluminium matrix.

The analytical method for the determination of phosphorus is usually based on the formation of phosphomolybdate or the corresponding reduced complex. Many basic investigations on these methods have been published.[1,2] Various methods have been developed for the determination of phosphorus in aluminium alloys, and found successful. However, the distillation separation of phosphorus in the acid-soluble fraction, as described by Kuhn,[3] is extremely laborious, and a direct photometric method for the determination of total phosphorus, described by Davey,[4] in which the alloys are dissolved in a nitric–hydrofluoric acid mixture, is simple but less reproducible and apt to give low results for the complex alloys. By Davey's method, of course, a separate determination of phosphorus in acid-soluble and acid-insoluble fractions is impossible.

Generally, hypereutectic aluminium–silicon complex alloys contain around 20% silicon, 1–2% copper, 1% magnesium, 1–1·5% nickel and/or 0·5% chromium. The phosphorus content is usually less than 0·01%.

The purpose of this study was to investigate an accurate and reproducible method for the separate determination of 0·0005–0·02% phosphorus in the acid-soluble and acid-insoluble fractions of hypereutectic aluminium–silicon complex alloys, as well as the errors caused by the form of the sample, period of storage and manner of dissolution.

The possibility of using emission spectrometric or X-ray fluorescence procedures for the total phosphorus was first considered. It was found, however, that in the case of the former there was interference from neighbouring iron or manganese lines with the phosphorus doublets at 253·5 and 255·4 nm and with the latter, interference with phosphorus K_α from copper $K_{\alpha 1}$ (fourth order). Therefore it was concluded that absorptiometric procedures were preferable.

Several authors have pointed out both silicon and aluminium can cause severe interference in the development of the phosphomolybdenum blue colour. In the present work, in order to obtain the most reproducible result, the silicon was removed completely and the phosphomolybdate was separated from aluminium by extraction with an organic solvent. On the basis of preliminary tests, phosphomolybdate was extracted with n-butanol–chloroform mixture and back-extracted with a stannous chloride reducing solution. This procedure has already been applied for the determination of phosphorus in copper,[5] lead[6] and pure iron[7] but not to aluminium alloys.

EXPERIMENTAL

Reagents

Standard phosphorus solution, 0·1 mg/ml. Dissolve 0·4263 g of diammonium hydrogen phosphate in water and dilute to 1 litre. Prepare working solutions by appropriate dilution.

Ammonium molybdate solution 10% w/v. Store in a polythene bottle for at least 24 hr before use.

Stannous chloride solution. Dissolve 1·5 g of $SnCl_2 \cdot 2H_2O$ in 5 ml of conc. hydrochloric acid, with heating, then dilute to 100 ml with water. Prepare just before use.

Solvent mixture. Mix 3 volumes of chloroform with 1 of n-butanol.

Recommended procedure

Transfer accurately about 0·5 g of the sample in massive form, each piece about 100 mg or more in weight and washed with acetone, to a 250-ml beaker. Add 30 ml of nitric acid (2 + 1) and 2 ml of conc. hydrochloric acid, cover with a watch-glass and heat gently. After the initial reaction has subsided, add further hydrochloric acid in two 4-ml portions to maintain a moderate rate of decomposition of the alloy. Avoid too rapid an addition and violent a reaction. Break the sample into smaller pieces with a glass rod to accelerate the dissolution if necessary.

After the dissolution, add 20 ml of water, filter through a Whatman No. 40 filter paper or equivalent, previously washed with 50 ml of warm 7*M* nitric acid and rinsed several times with hot water to guard against phosphorus contamination. Receive the filtrate in a 250-ml beaker. Wash the filter paper with hot water. Keep the black silicon residue for the determination of P in the acid-insoluble fraction.

Acid-soluble phosphorus content. Add 7 ml of perchloric acid (60%) and evaporate carefully to dryness until fumes are no longer evolved, on an asbestos pad on a hot-plate. This takes about 2 hr. Allow to cool, add 14 ml of 7*M* nitric acid and warm for about 5 min. Rinse the inside of the beaker with water. Add 5 ml of 3% EDTA solution, then heat to just below boiling and dissolve the residue. Transfer the solution to a 150-ml separatory funnel with water to make the final volume 50 ml. Add 4 ml of ammonium molybdate solution, mix and allow to stand for 5 min. Extract first with 20 ml and then 10 ml of solvent mixture, shaking for 3 min each time. Combine the extracts in another separatory funnel and add an appropriate volume of the stannous chloride reducing solution, (10 ml for <15 μg of P, 30 ml for <50 μg of P and 60 ml for <100 μg of P). Shake for 30 sec, allow to stand, discard the organic layer (bottom) and measure the absorbance of the blue colour against water in a 10-mm cell at 720 nm within 40 min from the addition of the stannous chloride solution.

If the blue solution is turbid, filter it through sanitary cotton plugged in the end of a separatory funnel.

Apply the whole procedure to a reagent blank determination, but with only 10 ml of 7*M* nitric acid, and subtract the absorbance from that of the sample.

For construction of the calibration curve, transfer 0–100 μg of P to separatory funnels, add 10 ml of 7*M* nitric acid, dilute to 50 ml with water, add 4 ml of ammonium molybdate solution and follow the procedure. Beer's law is obeyed up to at least 1·7 μg of P/ml and the molar absorptivity for phosphorus is $1 \cdot 39 \times 10^3$ l.mole^{-1}.mm^{-1}.

Acid-insoluble phosphorus content. Place the residue with the filter paper in a 50-ml platinum crucible. Add several drops of nitric acid, dry, and ignite at 600° until the paper has been burned. Remove from the flame and allow to cool. Add 5 ml of nitric acid (2 + 1) and 1 ml of perchloric acid (60%). Add hydrofluoric acid dropwise from a small polythene beaker, agitating the crucible during the addition, until all silicon has dissolved. Finally, add 3 ml of hydrofluoric acid and evaporate to dryness, until fumes are no longer evolved, on an asbestos pad on a hot-plate. Process a reagent blank in the same manner.

Cool and add 10 ml of 7*M* nitric acid and heat the contents of the crucible to nearly boiling. Transfer the resulting solution to a 150-ml separatory funnel with water and dilute to 50 ml. Add 4 ml of ammonium molybdate solution and treat as outlined above.

If only total phosphorus is required, add the resulting solution to the filtrate from the dissolution step, and apply the procedure.

RESULTS AND DISCUSSIONS

Form of sample

The form of sample used for determination of phosphorus is extremely important. If the sample is in the form of drillings, turnings or millings, a strong smell of gaseous phosphorus compounds is detected during machining. These finely divided samples give a low phosphorus result. Drillings of the hypereutectic aluminium–silicon complex alloys, for instance, gave a result which was lower by 0·006% than the true value of 0·021%. Therefore, the sample was cut into slices 2–3 mm thick from the cross-section of a test-piece, 80 × 10 × 40 mm book-type mould, or an ingot, with a clean saw-blade without lubricant, rapid cutting being avoided. The use of "as cast" surfaces should be avoided, since these are usually rich in phosphorus. When a sample slice, 0·5 g in weight and 2 mm in thickness, was cut into 5 pieces, the phosphorus content, decreased slightly to 0·019% from 0·020%.

TABLE I.—PHOSPHORUS CONTENT FOLLOWING LONG-TERM STORAGE

Sample	Form	P, % Oct. 1968	March 1970	Feb. 1971
A	Wafer	0·0038		0·0040
B	Wafer	0·0064		0·0063
C	Wafer	0·0069		0·0072
D	Wafer	0·0086		0·0085
E	Wafer	0·0144		0·0142
F	Book type		0·0043	0·0040
G	Book type		0·0082	0·0083
H	Book type		0·0167	0·0170

If sampling from a liquid alloy is possible, pour a small quantity of the molten alloy upon a clean, cold, smooth metal surface from a height of approximately 0·3 m. The resulting wafer of the alloy should be uniform and not more than 1 mm in thickness. The sample is cut off in pieces of suitable size just before analysis.

Stability of phosphorus in the alloy during storage

As stated above, phosphorus in the alloy seems to be unstable during machining. Absence of a standard aluminium-base alloy sample for phosphorus suggests the instability of this element on long-term storage. No work has been done on this problem, and confirmation of the stability of the phosphorus in the alloy during storage was necessitated.

Samples in wafer form and book-type form stored in paper envelopes had stable phosphorus content during storage for a year or more (Table I). On the other hand, the phosphorus content in samples cut into pieces (2 × 2 × 10 mm), even when stored in a desiccator, decreased gradually within a week as shown in Fig. 1.

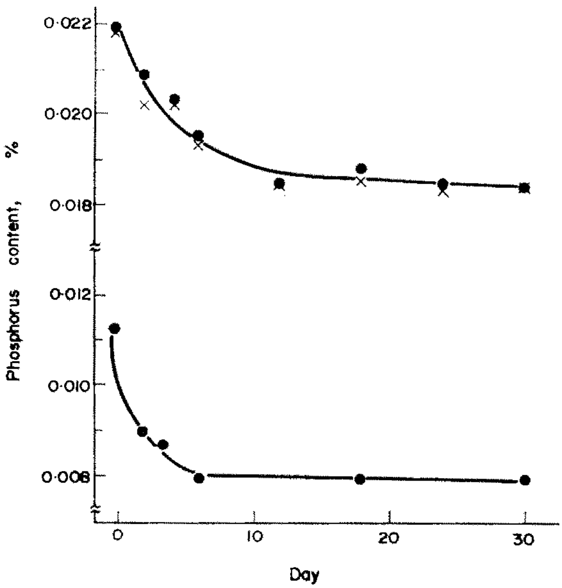

FIG. 1.—Phosphorus content in sample pieces over a period of a month.
●: Stored in desiccator ×: Left in atmosphere.

A sample of lower P content, 0·0076%, showed a slower decrease, to 0·0072% after a week.

Loss of phosphorus on acid dissolution

Phosphorus is readily liberated as phosphine by the action of nascent hydrogen. Kuhn's procedure[3] consists of absorbing (in brominated hydrobromic acid in a closed system) the phosphine liberated during hydrochloric acid attack upon the alloy. In Davey's procedure,[4] the alloy is completely decomposed by nitric–hydrofluoric acid mixture in an open system, which is quite simple to use compared with the closed system. Blackburn and Peters[8] confirmed by a neutron-activation method that the loss of phosphorus is negligible on complete dissolution of aluminium alloy in 3:1 nitric–hydrofluoric acid mixture but that a considerable amount of phosphine is released on use of hydrochloric acid. Mills *et al.*,[9] and Matelli and Vincentini,[10] however, still insisted upon hydrochloric acid dissolution in a closed system for the determination of phosphorus in the acid-soluble fraction. Pakalns,[11] for aluminium alloys with <2% silicon, adopted 10:3 nitric–hydrofluoric acid mixture for dissolving the sample for total phosphorus determination.

Because of the lack of precise descriptions, the manner of acid dissolution was evaluated again in terms of loss of phosphorus. Addition of 15 ml of 1:3 nitric–hydrochloric acid mixture and the same volume of water to 0·5 g of wafer sample (0·014% P) cut into pieces, did not cause any practical loss of P under rather vigorous reaction. In fact, in closed-system dissolution, less than 2 μg of P was found in the absorbing solution. In contrast, dissolution with 30 ml of hydrochloric acid (1 + 1) caused a remarkable loss of P in the acid-soluble fraction with a result 0·0024% lower than the true value of 0·0036%; nevertheless, in the acid-insoluble fraction the phosphorus content was almost the same as the result, 0·0104%, obtained by the

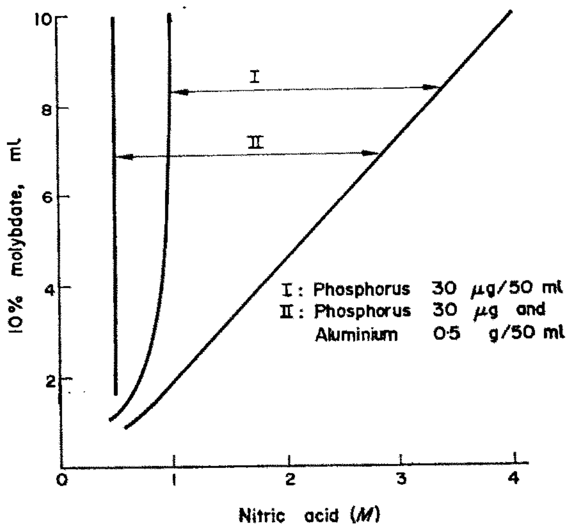

FIG. 2.—Optimum concentration ranges of reagents.

recommended procedure. To confirm the loss of P in the acid-soluble fraction, samples of pure aluminium in fine pieces, containing about 0·03% P, were dissolved under violent reaction conditions. The results obtained were 0·030% and 0·0015% of P from *aqua regia* and hydrochloric acid dissolution, respectively.

For a skilful analyst, not too much caution is required in dissolution of a slice sample under oxidizing conditions. In the present work, however, careful dissolution of a 0·5-g sample with 30 ml of nitric acid (2 + 1) and a total of 10 ml of conc. hydrochloric acid was adopted to prevent losses of phosphine as well as of spray. There is no need to use a distillation separation for the determination of phosphorus in the acid-soluble fraction.

Effect of concentration of nitric acid on extraction

Phosphate (30 μg of P) in a solution (50 ml) having an acidity of 0·3–2*M* with respect to nitric acid and containing 0·5 g of aluminium as nitrate, was subjected to the extraction and stripping procedure.

It was found that the optimum acidity before extraction is 0·6–1·7*M* in nitric acid when 4 ml of 10% ammonium molybdate solution are used, and that the extraction efficiency >95% in a single extraction from 0·8–1·3*M* nitric acid medium.

Generally, the range of optimum acid concentration depends on the amount of molybdenum solution added. This was reconfirmed in the present work and is shown in Fig. 2. However, in the determination of <5 μg of phosphorus, addition of too much ammonium molybdate should be avoided, because the resulting blue colour is unstable.

Stability of colour

The molybdenum blue obtained by the recommended procedure was stable at 20° for at least 40 min, after which the absorbance gradually decreased.

Influence of foreign ions

There is no known interference by alloying elements up to 2% or by the aluminium matrix. Certainly less than 5 mg of ionic Si, As and Ge have no influence. There is about 2 mg of Si in the acid-soluble fraction after acid dissolution of the alloys, and this is dehydrated by fuming in this procedure.

Among the impurity elements investigated, vanadium and zirconium decreased the absorbance if EDTA was not added. Commercial aluminium sometimes contains about 0·01% vanadium as impurity, but seldom contains more than 0·001% zirconium. There is no trouble caused by Zr at this level, but the presence of 0·05 or 0·1 mg of V causes a result low by 4 or 8 μg respectively in the determination of 10–50 μg of P. Addition of 5 ml of 3% EDTA solution prevents interference by up to 0·5 mg of V (equivalent to 0·1% V in the present work) or 2 mg of Zr if present.

TABLE II.—TYPICAL PHOSPHORUS RESULTS

Sample	Phosphorus, % Soluble fraction	Insoluble fraction	Total
1	0·0003	0·0020	0·0023
2	0·0002	0·0021	0·0023
3	0·0002	0·0030	0·0032

17	0·0049	0·0120	0·0169

Contamination

Much care must be exercised at all times to avoid contamination, because there are many sources of microgram-level phosphorus contamination, such as cigarette ash, perspiration, filter paper and dust from fume hoods. All containers should be thoroughly rinsed both inside and out with 10% w/v ammonium hydrogen fluoride solution, and then with demineralized water. Clean samples and filter paper should not be handled with the naked fingers.

Determination of the phosphorus content

Typical results obtained on a number of aluminium–21% silicon complex alloy samples, covering a phosphorus range of 0·002–0·017%, are given in Table II. In general, most of the P existed in the acid-insoluble fraction. Phosphorus (0·0006%) was found in alloys made without addition of P, for in this case the metallic silicon contained 0·003% P.

The standard deviation was about 0·0002% for the range 0·001–0·010% of phosphorus. A set of 6 samples may be analysed in 6 hr for acid-soluble and acid-insoluble phosphorus. Reagent blank levels were of the order of 0·0002% P.

CONCLUSION

Conventional spectrophotometric methods available for the determination of phosphorus in separate fractions in hypereutectic aluminium–silicon complex alloys have been improved. Compared with the direct dissolution procedure, a little more time is consumed in processing the soluble and insoluble phosphorus fractions separately, but in this way, it is possible to correlate the phosphorus content of the two fractions with the properties of the alloy. It is possible, however, to combine the two fractions at a convenient stage before extraction and to obtain more reproducible and reliable results for total phosphorus without difficulty, because most of the silicon is preliminarily separated and removed by fuming.

Even on rather vigorous acid dissolution of the alloys containing a considerable amount of acid-soluble phosphorus, little loss of phosphorus was detected. The conditions used did not require a distillation separation to be made and so saved time.

It was also confirmed that the phosphorus in the alloys was stable over a long storage term unless the alloy was cut into small pieces.

The method may be extended to other aluminium-base alloys.

Acknowledgement—It is a pleasure to acknowledge the assistance given by Mr. S. Yagi and Mr. I. Izumi in the experimental work.

Zusammenfassung—Eine reproduzierbare Methode zur Bestimmung kleiner Phosphormengen (0,0005%–0,02%) in hypereutektischen Aluminium–Silicium–Mehrstofflegierungen wird beschrieben. Die Methode erlaubt die getrennte Bestimmung von Phosphor in säurelöslichen und säureunlöslichen Fraktionen. Phosphomolybdat wird mit einem Lösungsmittelgemisch aus n-Butanol und Chloroform extrahiert und mit einer Zinn(II)-chlorid-Reduktionslösung rückextrahiert. Der Phosphorgehalt einer in kleine Stücke zerteilten Probe nimmt bei der Aufbewahrung ab; beim Lösen in Säure unter oxidierenden Bedingungen ist der Verlust an Phosphor zu vernachlässigen.

Résumé—On décrit une méthode reproductible pour le dosage de petites quantités de phosphore (de 0,0005% à 0,02%) dans les alliages complexes aluminium-silicium hypereutectiques. La méthode permet la détermination séparée du phosphore dans les fractions acido-soluble et acido-insoluble. On extrait le phosphomolybdate par un mélange *n*-butanol-chloroforme, et extrait en retour avec une solution réductrice de chlorure stanneux. La teneur en phosphore d'un échantillon taillé en petites pièces décroît durant la conservation; la perte en phosphore est négligeable par dissolution acide dans des conditions oxydantes.

ENHANCEMENT OF POLAROGRAPHIC REDUCTION CURRENTS BY A STATIC MAGNETIC FIELD

SHIZUO FUJIWARA and YOSHIO UMEZAWA
Department of Chemistry, Faculty of Science, University of Tokyo, Hongo 113, Tokyo, Japan

(*Received* 19 *June* 1971. *Accepted* 9 *September* 1971)

Summary—The effect of a magnetic field on d.c. polarographic reduction currents was studied with a static magnetic field applied perpendicularly to the dropping mercury electrode. In the presence of the magnetic field, diffusion or migration currents show a slight but distinct increase. The factors which can influence this effect have been examined experimentally. The effect is interpreted in terms of suppression of transfer of concentration polarization from one drop to the next. It is shown that certain types of maxima are enhanced by application of a magnetic field.

IT WAS FOUND in this laboratory that the maximum wave current in d.c. polarography decreases on application of a static magnetic field.[1,2] The decrease in current is always observable for the second kind of maxima, whereas for the first kind of maxima it occurs only with certain types of chemical systems. The magnetic field does not influence the drop-time and the flow-rate of mercury. The phenomenon has been interpreted in terms of retardation, by the magnetic field, of tangential motion at the surface of a mercury drop. The effect has also been examined in a.c. polarography[3] and oscillopolarography.[7]

In all these investigations[1–4] the magnetic field effect was to decrease the maximum wave current, and this can be interpreted in terms of magnetohydrodynamics. However, it has also been found[2] that a magnetic field causes a small *increase* in the limiting current. This paper gives the experimental details and interpretation of this effect, and shows that certain types of the maxima of the first kind are enhanced by the magnetic field. The effect of the magnetic field may be useful in elucidation of reaction processes at the surface of the dropping mercury electrode (DME).

EXPERIMENTAL

The d.c. polarograms were obtained with a Yanagimoto Polarograph Model PA-102 with a scan-rate of 0·2 V/min. Current-time curves during a single drop-life at fixed potential were obtained by using a potentiostat constructed in this laboratory and a spectrum computer (Model JRA-5, Japan Electron Optics Co.). A magnetic field of $5{\cdot}6 \times 10^5$ A/m was applied perpendicularly to the DME. The magnetic field is homogeneous within about 10 ppm over the whole volume of the glass cell. Some sample solutions were passed through a charcoal filter bed before measurement in order to eliminate surface-active substances. Potentials were measured *vs.* the mercury pool anode.

RESULTS AND DISCUSSION

The magnetic field often increases the limiting current by only a small amount (typically[2] 1 %) and can be observed only if the current is magnified to some extent. This enhancement implies that mass transport from the bulk solution to the electrode surface is increased by application of the magnetic field, presumably because of a stirring motion of electrolytes at the mercury/solution interface, brought about by the magnetic field. This statement is consistent with the results obtained by others. Leont'ev and Smirnov found that application of a magnetic field resulted in mixing of the electrolyte during electrolysis, which in turn caused a redistribution of cathodic current density.[5] Center *et al.* studied the effect of a magnetic field on electrolysis at a mercury pool cathode and found that the mercury/solution interface is hydrodynamically stirred by the magnetic field.[6] In the present system, it is assumed that the surface of a mercury drop is stirred hydrodynamically by a force F, defined as

$$F = JB \tag{1}$$

(where B is the magnetic field, and J the electrolytic current flowing at the mercury/solution interface) and that this results in an increase, in some cases, in mass transport to the electrode surface. The possibility that the force is due to direct interaction of the magnetic field with a diamagnetic mercury drop is considered very slight.

Effect on diffusion current

With the system 5mM lysine in 1M lithium chloride at pH 2·5, we observed a current minimum, *i.e.*, lowering of the diffusion current just after the fall of the maximum of the first kind; in the region of this current minimum, a magnetic field affects the current intensity appreciably as shown in Fig. 1. Similar results are observed for 1mM nickel or cobalt chloride with no supporting electrolyte. The current minimum following a maximum of the first kind has been studied by several workers,[7,8] and is attributed to the transfer of concentration polarization (TCP) from one drop to the next, which causes depletion of the depolarizer in the neighbourhood of the electrode. After the fall of the negative maximum (of the first kind, *i.e.*, a maximum which appears at a potential negative with respect to the electrocapillary zero potential), the depletion of the solution is especially enhanced,

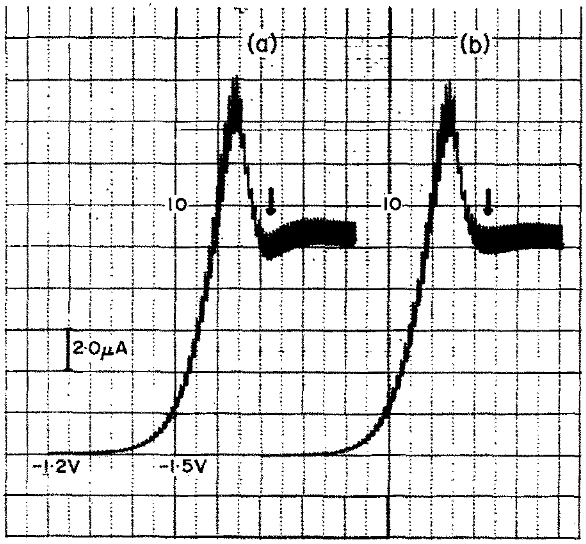

FIG. 1.—Effect of magnetic field on the minimum following the first kind of maximum.
5mM lysine and 1M LiCl, pH 2·5
(*a*): Without magnetic field
(*b*): Application of magnetic field

since at the maximum the depleted solution is transferred upwards and accumulates under the capillary in the vicinity of the drop, resulting in the current intensity being decreased after the maximum to less than the limiting diffusion current. Hence it may be concluded that the magnetic field can partially suppress the TCP, through the stirring action produced by F at the surface of the DME. This is consistent with the result obtained by Smoler,[7,9,10] who found that the current minimum does not appear when the capillary orifice is bent at an angle of 90° or 45°. He interpreted this in terms of removal of depleted solution from the capillary orifice, brought about by a falling drop. He observed a feeble downward streaming of the solution along the capillary orifice when the drop falls, which is a characteristic phenomenon of the inclined capillary and not observed in the case of the ordinary capillary.

As shown in Fig. 2, the magnetic field effect varies for different parts of the polarogram. It is most pronounced at the region of limiting diffusion current,

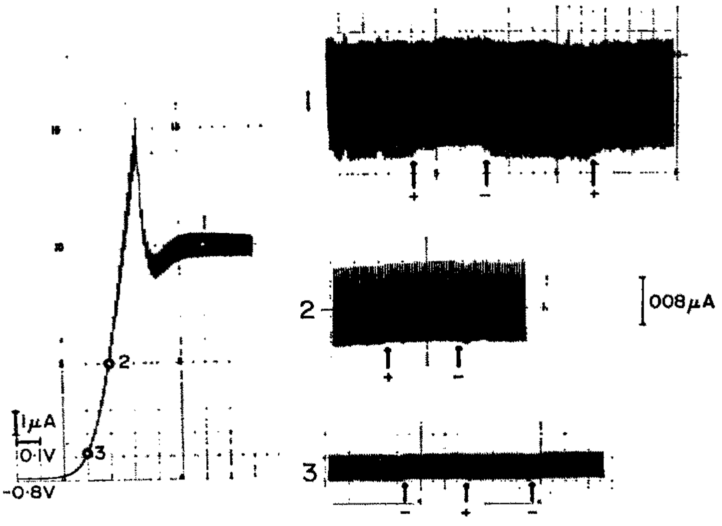

Fig. 2.—Comparison of magnetic field effect at various portions of the polarogram. 2mM $NiCl_2$ and no supporting electrolyte drop-time 3·49 sec (at −1·40 V, h = 0·70 m).

and almost imperceptible on the wave itself (as might be expected since depletion increases with wave-height). At the beginning of the wave the current is slightly *decreased* by the applied field (3 in Fig. 2).[2] The enhancement of the limiting diffusion current (1 in Fig. 2) is most marked at the beginning of growth of a mercury drop. This is consistent with the results of Hans *et al.* [11] who found the contribution from TCP is somewhat greater during the early growth of the drop. Because of difficulty in reproducing the hydrodynamic conditions,[7] the results are poorly reproducible, however (*cf.* Fig. 3).

Effect of surface-active substances. Addition of 0·001% of gelatin eliminates the increase in the limiting current caused by the magnetic field. It has been established[7,10] that the addition of surface-active substances lowers the TCP, and

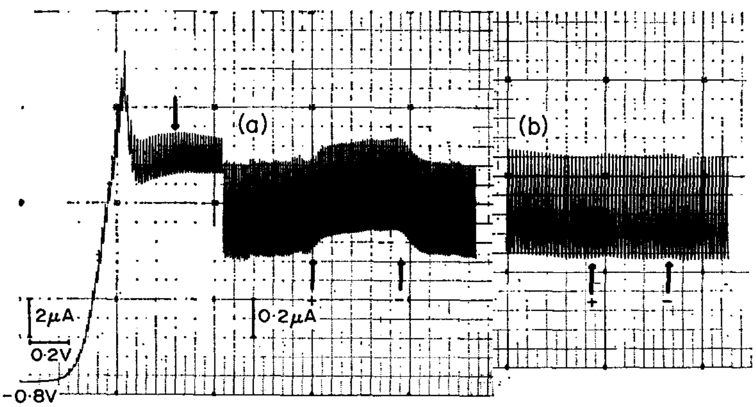

Fig. 3.—Effect of the drop-time on the magnetic field effect.
2mM NiCl$_2$ and no supporting electrolyte at −1·60 V (indicated by arrow on the d.c. polarogram)
(*a*): $t = 4{\cdot}28$ sec, (*b*): $t = 7{\cdot}87$ sec
+: magnetic field switched on
−: magnetic field off
Sample solution was passed through a charcoal filter bed before measurement.

this has been explained in terms of formation of a film of surface-active substance round the drop, this film being retained by the falling drop and carrying with it the depleted layer of the solution. As the surfactant has already suppressed the TCP, the magnetic field of necessity has no effect.

Influence of the drop-time. As shown in Fig. 3, the magnetic field enhancement of the limiting diffusion current is more pronounced when the drop-time is reduced. Smoler[7] found that the minimum after a negative maximum becomes more marked if the drop-time is shortened. When the drop grows slowly, the TCP effect is nullified because there is enough time for diffusion to occur. Rapid growth enhances TCP, which in turn is reduced by the magnetic field.

Concentration of supporting electrolyte. Increasing the concentration of supporting electrolyte diminishes the enhancement and may even cause a decrease in the limiting current when a magnetic field is applied. This may be explained as follows. TCP is expected to appear almost irrespective of the concentration of supporting electrolyte. However, addition of too much supporting electrolyte results in appearance of the second kind of maxima (which are due to the tangential motion brought about at the surface of a mercury drop by high flow-rate[9]). It has been shown that the second kind of maxima are reduced appreciably by application of a magnetic field.[2] According to Hans *et al.*[11] the second kind of maxima result in an increase in TCP (for the reasons given for the first kind). An increase in concentration of supporting electrolyte therefore results in formation of the second kind of maximum and then two opposing effects occur: (*a*) the effect of the magnetic field is enhanced because of the increase in TCP due to the maximum of the second kind, but (*b*) the magnetic field appreciably decreases the current of the second kind of maximum.

With the Smoler-type capillary, *i.e.*, a capillary inclined at 45°, the magnetic field decreased the limiting current when the concentration of supporting electrolyte was decreased, which can be explained in terms of the second kind of maxima, caused by the high flow-rate of mercury which is characteristic of this capillary.

The dependence of the magnetic field effect on the magnitude of current intensity, *i.e.*, a test of equation (1), was also studied. However, the results were poorly reproducible, because of differences in adsorbability of reaction products, which may determine the hydrodynamic conditions at the interface (*cf.* effect of surface-active substances, above).

Enhancement of the first kind of maxima

As shown in Fig. 4, (2mM uranyl sulphate, no supporting electrolyte), a maximum of the first kind may be enhanced appreciably by a magnetic field. Increasing the mercury head, however, increases the current at the maximum and the magnetic field effect becomes unobservable. A similar result is obtained for oxygen in $10^{-3}M$ potassium chloride with a trace of sodium polyacrylate, where the potential at which the maximum falls abruptly becomes more negative when the magnetic field is applied or the mercury head increased. This effect has been examined for a variety of chemical systems, but only a few show enhancement. Indeed, many show a decrease instead,[1,2] and their current–time curves during growth of a mercury drop fluctuate violently, that will be discussed elsewhere. The enhancement can be correlated with the anomalous shape of the current–time curve (*i–t* curve) during growth of a mercury drop at the maximum. For example, for 5mM copper(II) chloride in 0·1M ammonia–ammonium chloride, the current at the maximum increases with time, according to $i = Kt^{1/3}$, but falls abruptly at the later stages of drop growth until the diffusion current ($i = kt^{1/6}$) is attained (Fig. 5). A similar trend is observed for the uranyl sulphate and oxygen systems. The abrupt fall is probably due to formation of a weakly absorbed layer of surface-active substance,

or an electrolysis product at the surface of the DME, resulting in disappearance of the maximum. Coverage of the surface of a DME by adsorbents is especially pronounced in the later stages of drop growth, the rate of expansion of surface area then being small.*

The magnetic field is clearly demonstrated in Fig. 5, the abrupt fall of the i–t curve being eliminated by the magnetic field. A possible explanation is that the force F disturbs the surface layer and removes any surface-active substances from the neighbourhood of the capillary orifice, resulting in a continuation of the current at a value $i = Kt^{1/3}$ until the drop falls. When the mercury head is increased, the abrupt fall of current is reduced by the increased rate of expansion of the surface area of the DME.

---

* The surface area A of the growing mercury drop can be represented as a function of time,[11] $A = kt^{2/3}$, and $dA/dt = \frac{2}{3}\,kt^{-1/3}$. From this it can be concluded that dA/dt becomes small with increase in t.

It appears that the present model for the effect of the magnetic field is reasonable; further study of this effect may be useful in exploration of the structure of the electrode double layer and the mechanism of transport phenomena at the DME.

Acknowledgement—The authors thank Teruhiko Kugo, Yanagimoto Co., Kyoto, for his valuable discussions and help in the experimental work.

Zusammenfassung—Der Einfluß eines Magnetfelds auf gleichstrom-polarographische Reduktionsströme wurde untersucht. Ein statisches Magnetfeld wurde senkrecht zur Quecksilbertropfelektrode angelegt. In Gegenwart des Magnetfeldes nehmen Diffusions- und Wanderungsströme um einen kleinen, aber deutlichen Betrag zu. Die Faktoren, die diesen Prozeß beeinflussen können, wurden experimentell untersucht. Der Effekt wird dadurch erklärt, daß die Übertragung der Konzentrationspolarisation von einem Tropfen zum nächsten unterdrückt wird. Es wird gezeigt, daß beim Anlegen eines Magnetfeldes bestimmte Typen von Maxima verstärkt werden.

Résumé—On a étudié l'effet d'un champ magnétique sur les courants de réduction polarographique en courant continu avec un champ magnétique statique appliqué perpendiculairement à l'électrode à goutte de mercure. En la présence du champ magnétique, les courants de diffusion ou de migration montrent un accroissement léger mais net. On a examiné expérimentalement les facteurs qui peuvent influer sur cet effet. L'effet a été interprété en fonction de la suppression du transfert de la polarisation de concentration d'une goutte à la suivante. On montre que certains types de maximums sont renforcés par l'application d'un champ magnétique.

SPECTROPHOTOMETRIC DETERMINATION OF WATER IN ORGANIC SOLVENTS WITH SOLVATOCHROMIC DYES—II*

SADAKATSU KUMOI, HIROSHI KOBAYASHI and KEIHEI UENO®
Department of Organic Synthesis, Faculty of Engineering, Kyushu University,
Fukuoka 812, Japan

(*Received* 22 *June* 1971. *Accepted* 29 *September* 1971)

Summary—The correlation between the absorbance of a merocyanine dye in an organic solvent and the water content of the solvent has been investigated. The merocyanine dyes investigated are 1-methyl-4-[(4-oxo*cyclo*hexa-2,5-dienylidene)-ethylidene]-1,4-dihydropyridine (I), 1-methyl-4-[(2-oxo*cyclo*hexa-3,5-dienylidene)-ethylidene]-1,4-dihydropyridine, 1-methyl-2-[(4-oxo*cyclo*hexa-2,5-dienylidene)-ethylidene]-1,2-dihydropyridine and 1-methyl-2-[(oxo*cyclo*hexa-3,5-dienylidene)-ethylidene]-1,2-dihydropyridine, and the organic solvents are isopropanol, acetone, acetonitrile and pyridine. The possibility of determining a trace amount of water in an organic solvent is demonstrated, and a procedure is proposed for the determination of trace water in pyridine. The sensitivity of the method depends on the solvent, being more sensitive in an aprotic solvent than in a protic one; for example, 0·05 or 0·27 mg of water in 1 ml of acetonitrile or of isopropanol respectively can be detected with I, by use of an ordinary spectrophotometer.

SINCE Kosower [1] attempted to define solvent polarity by the change in the position and intensity of absorption band of 1-alkylpyridinium iodide, several empirical parameters to characterize the solvent polarity have been proposed.[2–4]

The susceptibility of an absorption band to solvent polarity is known as solvatochromism, and marked solvatochromism is noticed especially in the charge-transfer band of a compound having a polarized structure in its ground state. The physicochemical basis of this phenomenon has been extensively studied.[5] Dyes and mixtures of dyes with betaine and merocyanine structures have been studied in various solvents.[6–9] A betaine dye in a ground state can be represented by a zwitterion structure, while a merocyanine dye is shown as a resonance hybrid of a zwitterion and an unpolarized structure in a solution.

Merocyanine

SCHEME 1

The polarity of organic solvents is affected by their water content and we reported the possibility of the determination of water in organic solvents by spectral change of some betaine dyes.[10] Similar determinations have been reported by others.[6–9] In this paper we consider the possibility of determining a minute amount of water in a range of organic solvents by the solvatochromatic effect of a group of merocyanine

---

* Contribution No. 245 from the Department of Organic Synthesis, Kyushu University. Part I, *Talanta*, 1970, **17**, 319.

dyes having homologous structures, such as 1-methyl-4-[(4-oxo*cyclo*hexa-2,5-dienylidene)-ethylidine]-1,4-dihydropyridine (4,4-M), 1-methyl-4-[(2-oxo*cyclo*hexa-3,5-dienylidene)-ethylidene]-1,2-dihydropyridine (4,2-M), 1-methyl-2-[(4-oxo*cyclo*hexa-3,5-dienylidene)-ethylidene]-1,2-dihydropyridine (2,4-M) and 1-methyl-2-[(2-oxo*cyclo*hexa-3,5-dienylidene)-ethylidene]-1,2-dihydropyridine (2,2-M). A procedure is proposed for the determination of trace water in reagent grade pyridine, and the sensitivities of water determination in various organic solvents with merocyanine dyes as well as betaine dyes are discussed in relation to the molecular structures of the dyes.

EXPERIMENTAL

Reagents

Solvatochromic dyes. The dyes used in this investigation are listed in Table I and their structural formulae in Fig. 1. The precursor hydroiodides were synthesized by the procedure of Phillips[11] and aqueous methanol solutions of the respective hydroiodides were treated on a column of hydroxyl-type anion-exchange resin to give the final merocyanine dyes, which were purified by recrystallization from aqueous acetone or methanol-acetone mixture. They were identified by elemental analyses and spectroscopy.

TABLE I.—APPEARANCES AND PROPERTIES OF SOLVATOCHROMIC DYES

Dye	Hydroiodide (solvent for recryst.)	Desiccated merocyanine dye*
4,4-M	red (water), m.p. 257–9°C	0·6 H_2O, violet†
2,4-M	yellow (methanol), m.p. 265°C	0·1 H_2O, deep green
4,2-M	violet needles (methanol) m.p 215–30°C	0·15 H_2O, greenish violet
2,2-M	yellow plates (methanol) m.p. 257–8°C	H_2O, green

* All the dyes showed no melting points, instead decomposing at various temperature above 200°C, depending upon the content of water of crystallization.

FIG. 1.—Structures of merocyanine dyes.

In the solid state, they usually contained many molecules of water of crystallization. The desiccated samples were obtained by drying at 60°/10 nbar for 10 hr, but the last trace of water was very hard to remove.

Organic solvents. Isopropanol as a protic solvent and acetone, acetonitrile and pyridine as aprotic solvents were used. All were of reagent grade, and were dried by appropriate methods as summarized in Table II. The trace water content in each dried solvent was determined by Karl Fischer titration, the end-point being determined amperometrically.

TABLE II.—ORGANIC SOLVENTS AND THEIR WATER CONTENTS

Solvent	Method of drying	Water content of dried solvent, *mg/ml*
Isopropanol	reflux over calcium hydride	0·15
Acetone	reflux over Drierite	0·71
Acetonitrile	reflux over phosphorus pentoxide and over anhydrous calcium carbonate successively	0·45
Pyridine	reflux over potassium hydroxide pellets	0·41

Procedure for spectral study

The procedure was essentially the same as that described in the previous paper.[10] The stock solution for a dye was prepared so that the concentration was *ca.* $10^{-4}M$, and it was diluted to give the final solution, *ca.* $10^{-5}M$, in which the water content was determined.

Recommended procedure for determining trace water in pyridine with 4, 4-*M dye*

The stock dye solution was prepared by dissolving a weighed amount of dried 4,4-M dye (1·38 mg or 6·21 μmole) in dry pyridine to make 50 ml. A calibration curve of this dye was prepared by measuring the absorbance of pyridine solutions containing 2 ml of the stock dye solution and a known amount of water (50–250 mg) in 25 ml.

Two ml of the stock dye solution were transferred by pipette into a 25-ml dry volumetric flask, and made up to the mark with a pyridine sample of unknown water content. After mixing, solution was transferred into an air-tight spectrophotometric cell for absorption measurement at 610 nm against distilled water. Another 5-ml aliquot was transferred into a titration cell for determination of the water content by Karl Fischer titration. The results are summarized in Table III.

TABLE III.—DETERMINATION OF WATER CONTENT IN REAGENT GRADE PYRIDINE BY SPECTROPHOTOMETRIC METHOD AND KARL FISCHER TITRATION METHOD

Sample	Absorbance at 610 nm*	Water content, *mg/ml*	
		Spectrophotometric method†	Karl Fischer titration
Dry pyridine	0·748	—	0·32
No. 1	0·723	0·80	0·80
No. 2	0·647	2·7	2·60
No. 3	0·578	4·7	5·11

* The final dye concentration was $9{\cdot}95 \times 10^{-6}M$.

† The dry pyridine used in preparation of calibration curve was found to contain 0·32 mg of water per ml by Karl Fischer titration. Therefore, the calibration curve was connected for this amount.

RESULTS AND DISCUSSION

Applicability of the dyes

Before quantitative evaluation, applicability of the dyes to trace water determination was checked in respect to their solubilities in various organic solvents, chemical stabilities and analytical sensitivities. The solubility had to be at least $10^{-4}M$ for the preparation of the stock solution. Table IV summarizes the dissolution behaviour of the dyes in the solvents used, including water.

TABLE IV.—DISSOLUTION BEHAVIOR OF THE DYES

Dye	Solvent				
	Water	Isopropanol	Acetonitrile	Pyridine	Acetone
4,4-M	good*	good	fair†	good	poor‡
2,4-M	good	good	good	good	fair
4,2-M	good	good	fair	poor	poor
2,2-M	good	good	good	good	fair

* good: sufficiently soluble for absorption spectrophotometry.
† fair: sufficiently soluble but dissolving slowly.
‡ poor: insufficiently soluble or insoluble.

Generally the dyes were fairly soluble in a protic solvent, and the dyes 2,4-M and 2,2-M were soluble enough in the protic and aprotic organic solvents so far studied. Water determination in this work was carried out in isopropanaol, acetonitrile and pyridine, acetone being excluded because of its poor dissolving power for the dyes.

The dyes were chemically stable and not photosensitive in solution, but they appeared to exhibit a stronger thermochromic effect[12,13] than the betaine dyes reported earlier,[10] though no systematic investigation was carried out. Therefore, analytical operations were carried out under an ordinary fluorescent lamp and photometric measurements were performed at a temperature as invariable as possible.

Quantitative evaluation of the dyes

The dyes were evaluated by comparing the spectral change in an organic solvent containing a known amount of water. Figure 2 shows the visible absorption spectra of 4,4-M in isopropanol and in acetonitrile. Substantial changes in the spectra can be observed with the change of water content in the range of 0–20 mg/ml for isopropanol and 0–10 mg/ml for acetonitrile. The spectral change observed in pyridine is of intermediate degree.

The change in absorbance at certain wavelengths (560 and 570 nm for isopropanol and 580 nm for acetonitrile) when plotted *vs.* water content gives calibration curves for the determination of water, as shown in Fig. 3. The curves are not necessarily linear, because the method is not based on Beer's law.

Figure 4 shows the absorption spectra of dye 2,4-M in aprotic solvents such as acetonitrile and pyridine. Again acetonitrile gives the strongest spectral change, that in isopropanol being of similar to that in pyridine. When the change of absorbance at 550 and 560 nm is plotted against the water content, calibration curves for the range 0–10 mg/ml are obtained.

In order to compare analytical sensitivities of the dyes, we define the sensitivity as $S = \Delta A/\Delta W$, where ΔA is the change in absorbance for a change of water content of ΔW.* S-values of the dyes are summarized in Table V, as are the analytical limits of detection, D, defined by $D = 0{\cdot}004/S$, the coefficient 0·004 being based on the fact that an ordinary spectrophotometer can measure absorbance with a precision of ±0·002. Table V indicates that the S-value is generally higher in aprotic than in protic solvents.

---

* In the previous paper,[10] the term "sensitivity, S" was the inverse of that used here, and corresponds to the limit of detection D. Also the equation[10] defining S was misprinted, and should be corrected to $S = 0{\cdot}004\Delta W/\Delta A$. S is now redefined (at the suggestion of the referee), since it seems more sensible that a large S value should mean a higher sensitivity.

TABLE V.—SENSITIVITY, *S*, OF WATER DETERMINATION

Solvent	Dye	ΔA	ΔA *mg/ml*	*S*, *ml/mg*	*D*, *mg/ml*	λ, *nm*
Isopropanol	4,4-M	0·291	20	0·015	0·27	560
	2,4-M	0·250	20	0·013	0.32	540
	4,2-M	0·232	20	0·012	0·34	570
	2,2-M	0·138	20	0·007	0·58	540
Acetonitrile	4,4-M	0·493	6	0·082	0·05	580
	2,4-M	0·357	6	0.059	0.07	550
	4,2-M	0·365	6	0·061	0.07	610
	2,2-M	0.232	6	0·039	0·10	570
Pyridine	4,4-M	0.290	10	0·029	0.14	610
	2,4-M	0.253	12	0·021	0·19	590
	4,2-M	0.260	12	0·022	0·18	640
	2,2-M	0.309	12	0·026	0·15	600

Dye 4,4-M is the most sensitive for both protic and aprotic solvents. Dye 2,2-M exhibits the poorest sensitivity, half that of dye 4,4-M. Dyes 2,4-M and 4,2-M show similar analytical sensitivities midway between those of the other two.

Determination of trace water in pyridine

As a typical example, the proposed procedure was applied to the determination of a trace amount of water in reagent grade pyridine, and the result was compared with that obtained by the Karl Fischer titration method.

In this procedure, the dye concentration has to be kept constant for the standard solutions employed in the preparation of calibration curve as well as for the samples. Therefore, it is desirable to use the same stock dye solution for both purposes, because the same volume of stock solution can be used in preparing the final solutions throughout the procedure. As 2 ml of dye solution could be manipulated fairly accurately, a satisfactory reproducibility was obtained by the proposed method. It does not seem necessary to use a non-solvachromic dye as an internal standard to correct the solvatochromic dye concentration, such as was proposed in our previous paper.

As it was noticed that these dyes showed a noticeable thermochromism, the calibration and sample measurements should be done at the same temperature. Accordingly, our experiments were carried out in a constant-temperature room.

Table III shows fairly good agreement between the results obtained by the two methods. However, the dry pyridine used in the preparation of the calibration standard was found to contain 0·32 mg of water per ml by the Karl Fischer method, and the calibration curve had to be corrected.

As discussed previously, the method is not as sensitive as the Karl Fischer method, and is subject to interference by polar impurities. However, the procedure is far simpler than the titrimetric method, and may find wide application.

Correlation of S-value with molecular structure of the dye

Table VI lists the *S*-values of the betaine dyes, which are the most sensitive to water content among those investigated in the previous work,[6] including the 4,4-M merocyanine dyes for comparison. In aprotic solvents these dyes show comparable sensitivities for water determination. In protic solvents, however, the merocyanine dye is much more sensitive. Thus, at present, the 4,4-M has a wider applicability than the betaine dyes.

TABLE VI.—COMPARISON OF *S*-VALUES OF THE BETAINE AND MEROCYANINE DYES

Dye	Solvent		
	Isopropanol	Acetonitrile	Pyridine
P-2*	0·004	0·040	0·017
1,6-Q†	0·004	0·067	0·030
4,4-M	0·015	0·082	0·029

* 2,4,6-triphenyl-*N*-(3,5-diphenyl-4-hydroxyphenyl)-pyridinium betaine.

† 1-methyl-6-hydroxyquinolinium betaine.

In the dye molecules the distance between the cationic (R_3N^+) and anionic (RO^-) centres in the zwitterion structure is considered to increase in the order 2,2-M < 4,2-M $\sim$ 2,4-M < 4,4-M, though a definite conformation of the dye molecule in solution is not clear. This order parallels the increase in S-values. A similar relationship is also observed with the betaine dyes, 1,6-Q, 1,8-Q (1-methyl-8-hydroxyquinolinium betaine) and 2,5-IQ (2-methyl-5-hydroxyisoquinolinium betaine),[10] in which distances between oppositely polarized sites on aromatic nuclei are definite.

Results of the measurements of transition energy, E_T, of the merocyanine dyes in various solvents are tabulated in Table VII. Plots of E_T (measured in the protic solvents) *vs.* $f(\varepsilon)$ were linear, with slopes of 163·8, 146·8 and 140·1 for 4,4-M, 4,2-M and 2,2-M respectively, giving the spectral susceptibility of the dye to solvent polarity. The dye 4,4-M is the most susceptible, indicating it should have the highest solvatochromic effect among the four dyes. In aprotic media a similar tendency can be observed.

TABLE VII.—TRANSITION ENERGY, E_T, OF MEROCYANINE DYES IN VARIOUS SOLVENTS

Protic solvent	ε	$f(\varepsilon)$	E_T, *kJ*. mole^{-1}			
			4,4-M	2,4-M	4,2-M	2,2-M
Water	78·5	0.982	271	—*	266	274
Methanol	32·6	0·954	247	254	245	251
Ethanol	24·3	0·940	233	240	233	240
n-Propanol	20·1	0·928	228	235	227	236
Isopropanol	18·3	0·920	218	227	218	231
n-Butanol	17·1	0·914	225	231	226	235
Aprotic solvent						
Acetonitrile	37·5	0·960	209	219	206	216
Acetone	20·5	0·928	201	214	196	209
Pyridine	12·3	0·882	197	210	193	206

ε: Dielectric constant of solvent, $f(\varepsilon) = 2(\varepsilon - 1)/2\varepsilon + 1$.

E_T: Transition energy.

* λ_{max} is not clear on the absorption spectra of 2,4-M dye in aqueous solution.

These results suggest that in a group of dyes having homologous polar structures the extent of the solvatochromic effect depends upon the distance between the oppositely polarized sites, which presumably affects the difference between the dipole moments of a dye molecule in the ground and excited states. A larger blue shift, however, would not necessarily be obtained with longer distance between the oppositely polarized sites in a dye molecule. There must be an optimal distance for a certain chromophore system.

Analytical sensitivity is not solely dependent upon the gradient, $\Delta E_T/\Delta f(\varepsilon)$. For example, despite the S-value ratio of 4,4-M to 2,2-M being about 2:1, the gradient, $\Delta E_T/\Delta f(\varepsilon)$, for the former is only 15% steeper than that for the latter. Another example is presented in Table VIII, which shows the spectral change of 1,6-Q betaine and 4,4-M merocyanine in isopropanol. Although both dyes show a virtually equal extent of blue shift with an equal increase of water content, the hypochromic shift with water content of the latter dye is several times that of the former. In comparison with the merocyanine dyes, the betaine dyes generally show a rather small change in intensity at absorption maximum with increase of water content. The S-value depends upon the spectral shift in terms of both wavelength and absorption intensity.

TABLE VIII.—SPECTRAL CHANGE OF 1,6-Q AND OF 4,4-M IN ISOPROPANOL

Dye	λ_{max} *nm*		$\Delta\lambda$,† *nm*	A‡		ΔA§
	I*	II*		I	II	
1,6-Q	460	453	7	1·000	0·980	0·020
4,4-M	546	539	7	1·000	0·750	0·250

* Aliquot I is of a dried solvent, II contains an additional 2% of water.

† $\Delta\lambda = \lambda_{max}(I) - \lambda_{max}(II)$.

‡ A: absorbance at λ_{max}.

§ $\Delta A = A(I) - A(II)$.

The higher sensitivity of the merocyanine dye in protic solvents is mainly due to the change in absorption intensity.

Zusammenfassung—Die Beziehung zwischen der Extinktion eines Merocyaninfarbstoffs in einem organischen Lösungsmittel und dem Wassergehalt des Lösungsmittels wurde untersucht. Die untersuchten Farbstoffe sind 1-Methyl-4-[(4-oxo*cyclo*hexa-2,5-dienyliden)-äthyliden]-1,4-dihydropyridin (I), 1-Methyl-4-[(2-oxo*cyclo*hexa-3,5-dienyliden)-äthyliden]-1,4-dihydropyridin, 1-Methyl-2-[(4-oxo*cyclo*hexa-2,5-dienyliden)-äthyliden]-1,2-dihydropyridin und 1-Methyl-2-[(2-oxo-*cyclo*hexa-3,5-dienyliden)-äthyliden]-1,2-dihydropyridin, die organischen Lösungsmittel Isopropanol, Aceton, Acetonitril und Pyridin. Es wird gezeigt, daß man eine Spurenmenge Wasser in einem organischen Lösungsmittel bestimmen kann; eine Vorschrift zur Bestimmung von Wasserspuren in Pyridin wird vorgeschlagen. Die Empfindlichkeit des Verfahrens hängt vom Lösungsmittel ab, sie ist in einem protonenfreien Lösungsmittel höher als in einem protonenhaltigen. Z. B. kann man mit I in einem gewöhnlichen Spektrophotometer in 1 ml Acetonitril oder Isopropanol 0,05 bzw. 0,27 mg Wasser nachweisen.

Résumé—On a étudié la corrélation entre l'absorption d'un colorant de type merocyanine dans un solvant organique et la teneur en eau du solvant. Les colorants de type merocyanine étudiés sont les 1-méthyl 4-[(4-oxo*cyclo*hexa-2,5-diénylidène)-éthylidène] 1,4-dihydropyridine (I), 1-méthyl 4-[(2-oxo*cyclo*hexa 3,5-diénylidène)-éthylidène] 1,4-dihydropyridine, 1-méthyl 2-[(4-oxo*cyclo*hexa 2,5-diénylidène)-éthylidène] 1,2-dihydropyridine, et 1-méthyl 2-[(2-oxo*cyclo*hexa 3,5-diénylidène)-éthylidène] 1,2-dihydropyridine, et les solvants organiques sont l'isopropanol, l'acétone, l'acétonitrile et la pyridine. La possibilité de détermination d'une trace d'eau dans un solvant organique est démontrée, et l'on propose une technique pour le dosage de l'eau à l'état de traces dans la pyridine. La sensibilité de la méthode dépend du solvant, étant plus sensible dans un solvant aprotique que dans un solvant protique; par exemple, on peut détector 0,05 our 0,27 mg d'eau dans 1 ml d'acétonitrile ou d'isopropanol, respectivement, au moyen de (I), en utilisant un spectrophotomètre ordinaire.

YIELDS OF PHOTONUCLEAR REACTIONS FOR PHOTON-ACTIVATION ANALYSIS WITH HIGH-ENERGY BREMSSTRAHLUNG

TOYOAKI KATO and YOSHINAGA OKA*
Department of Chemistry, Faculty of Science, Tohoku University,
Sendai, Japan

(*Received* 7 *June* 1971 *Accepted* 16 *September* 1971)

Summary—Experimental reaction yields have been determined for various types of photonuclear reactions, induced in 52 elements by means of Bremsstrahlung irradiation with maximum energies ranging from 30 to 72 MeV, and of detection of the resultant activities with a lithium-drifted germanium detector. From the results obtained, sensitivities in photon-activation analysis were evaluated and the reactivity of high-energy photons with nuclei in a wide range of atomic number is discussed. Some nuclear considerations in photon-activation analysis, involving the relative probability of forming each product as a result of the (γ,$xn\gamma p$) reactions are also given.

IN RECENT YEARS photon-activation analysis has been exploited as a useful analytical method for the determination of trace amounts of a number of elements in the periodic table. A cyclic or linear electron accelerator capable of producing a high-current electron beam has been used as the irradiation facility, and several reports concerning the experimental or calculated sensitivities with bremsstrahlung of moderate maximum energies (~35 MeV) have been published.[1-6] Sensitivities well below 1 μg are obtained for many elements, and the emphasis is on the determination of those elements having nuclear properties unfavourable for thermal-neutron activation analysis, such as carbon, nitrogen, oxygen and fluorine. These elements can also be determined at very low levels by means of charged-particle activation analysis. In addition, severe difficulties due to sample self-shielding are encountered when a mixture to be analysed contains substantial amounts of elements with large thermal-neutron capture cross-sections. In these cases, photon-activation analysis is found to be very promising.

A general feature of the photon absorption cross-section for a nucleus is characterized by a peak 5–6 MeV wide at an energy located between the photodisintegration threshold and about 30 MeV, and, in this energy region, the main nuclear events are the emission of one neutron or one proton. A considerable amount of work has been done in the past on the determination of the (γ,n), (γ,p) and (γ,α) reaction yields for many elements with Bremsstrahlung produced by 20-MeV electons.[7-9]

Since yield is a function of photon energy, it should be noted that higher sensitivities can be expected with an accelerator giving Bremsstrahlung of higher maximum energies. The excitation of a nucleus by gamma-rays with higher energies, however, gives rise to more complex events. Apart from the reactions described above, those with the emission of two or more nucleons become important, thereby causing difficult interference problems in photon-activation analysis. A basic problem in photon-activation analysis under such conditions is, therefore, the necessity to investigate the production rates or yields of various photonuclear reactions induced

---

* Present address: Department of General Education, Kitasato University, Sagamihara, Kanagawa, Japan.

simultaneously in a sample to be analysed, over the energy range of given bremsstrahlung. It should also be mentioned that the production rates of those reactions depend on a specific target-sample configuration used for activation. Recently, Engelmann[10] determined the distribution of the 25–45 MeV electron-induced Bremsstrahlung beam spectrum by activating silver and carbon monitors arranged behind platinum and aluminium targets, and the longitudinal and transverse distribution patterns have been presented in terms of amounts of (γ,n) activation.

The work described here was undertaken in order to evaluate the potential for determining trace amounts of many elements by inducing the (γ,$xnyp$) reactions with bremsstrahlung from a linear electron accelerator and by detecting the resultant activities with a lithium-drifted germanium detector. Thus, first, sensitivities were obtained for some 13 elements at two different Bremsstrahlung maxium energies, 30 and 60 MeV, and secondly, the yield values at 30 MeV for 138 different reactions were obtained and discussed in terms of some nuclear considerations for photon-activation analysis, involving the relative probability of forming each reaction product, and, finally, dependences of Bremsstrahlung maximum energies on the yields for various types of the reactions were obtained, so that the more general applicability of photon-activation analysis to sensitive and accurate determination of many elements in a wide variety of materials can be considered.

EXPERIMENTAL

Accelerator

The 300-MeV linear electron accelerator of Tohoku University was used as the Bremsstrahlung source. The machine was operated with the "high current" accelerating section which provided a high intensity electron current, the peak current being at least 90 mA with energies up to 75 MeV. In many cases the pulse repetition rate was 200/sec with a pulse width of 3 μsec. The beam was deflected 90° from the original beam path of the accelerating section, and again deflected 45° onto the beam exit window. The spread of electron energies in this operating condition is 3% from the selected value. The electron beam produced Bremsstrahlung in a platinum converter with a thickness of 3 mm located 30 mm from the beam exit window. The average beam currents were measured at the position of the converter, by using a current monitor, and found, in typical operating conditions, to be 70 and 100 μA at 30 and 40–75 MeV, respectively.

Sample materials and irradiation

Samples of 52 elements, either in the form of metals or simple compounds, with chemical purity of 99·9% or better, were used. Metallic samples were small discs 6 mm in diameter with a thickness of about 0·1 mm. The powdered samples were individually wrapped in small pieces of aluminium foil and made into small discs 6 mm in diameter with a thickness of 2 mm. The amount loaded was between 10 and 100 mg, depending on the production rate of the desired activity. The sample was placed in a water-cooled sample holder on the Bremsstrahlung beam axis immediately behind the converter, for irradiation.

The distribution of the Bremsstrahlung flux behind the converter was far from homogeneous. In order to monitor the flux under such conditions, accurately weighed discs of copper, 0·1mm thick, were placed on the front and back of each sample and irradiated together with the sample. The ^{64}Cu activities produced by the ^{65}Cu(γ,n)^{64}Cu reaction were used for comparison. A mean specific activity was used for determining the dose rate of Bremsstrahlung to which the sample was exposed. The experimental results showed that the vertical spread of flux did not have a pronounced effect on the results, if the samples were limited to dimensions of the size given, and that the flux gradient along the length of the sample was less than 5%, even in the case of a sample of high atomic number. A typical irradiation was complete in 30–60 min.

Radioactivity measurement

The counting equipment consisted of a lithium-drifted germanium detector with a sensitive volume of 24 ml, ORTEC Model 8001–30, and its associated electronics, coupled to a TMC 1024-channel pulse-height analyser. The counting system had a resolution of 4 keV for the 661·6 keV gamma-line of ^{137}Cs. Energy calibration and photopeak counting efficiences were determined by counting a series of calibrated sources of known activities. The sample and copper monitor to be measured were separately sandwiched between 10-mm thick Lucite plates to absorb positrons from any positron emitters, and they were counted at a fixed position, 20 mm in most cases, from the active surface of the detector. Because of the high resolving power of the detector, no chemical separations were required for the present purposes, unless otherwise noted.

Nuclides were identified from a knowledge of the target nuclide, the gamma-ray spectra, decay data, data listed in the Table of Isotopes,[11] and current literature data. The initial decay rates of the various products were determined from decay curve analyses of the specified gamma-ray photopeak areas and normalizations were applied to them for the dose rate and sample weight.

Yield determination

The yield values were computed from the activity data by using the detection efficiency and the decay scheme parameters from the literature[11] for each nuclide. A yield was defined as the production rate of a nuclide due to a certain photonuclear reaction, in disintegrations/sec at the end of irradiation of one mole of a parent nucleus. This was converted into the corresponding saturation rate and expressed relative to that of the ^{65}Cu(γ,n)^{64}Cu process which occurred in the copper discs used for flux monitoring. In obtaining the yield data for 30-MeV Bremsstrahlung, a dose rate was determined by using the yield value of 2·8 × 10^{6}/mole/roentgen for the ^{63}Cu(γ,n)^{62}Cu reaction reported by Katz *et al.*,[12] and a yield was expressed in the form of dps/mole/R. In a typical operating condition at 30 MeV a dose rate of 4·41 × 10^{6} R/min was obtained at the sample position.

RESULTS AND DISCUSSION

Experimental sensitivity

Of the many product nuclides identified in this work, some 13 nuclides were selected for the sensitivity evaluations at two different Bremsstrahlung maximum energies, 30 and 60 MeV. The elements chosen for the sensitivity determinations were those having nuclear properties unfavourable for thermal-neutron activation analysis or those proved to be highly activated when irradiated with 20-MeV Bremsstrahlung.[2]

Table I lists the results. In Table I, all activity data have been expressed in counts/min/mg of the element at the end of 1 hr irradiation at each Bremsstrahlung maximum

TABLE I.—EXPERIMENTAL SENSITIVITIES FOR PHOTON ACTIVATION ANALYSIS WITH 30 AND 60 MeV BREMSSTRAHLUNG

Element	Reaction	Half-life of product	γ-ray energy, *MeV*	30 MeV		60 MeV	
				Photopeak activity,† *cpm/mg*	Limit of detection, μg	Photopeak activity, † *cpm/mg*	Limit of detection μg

* Annihilation γ-rays.

† At the end of 1-hr irradiation with a standard dose rate of Bremsstrahlung photons. With this dose rate, 2·4 μCi of ^{64}Cu or 60·1 μCi of ^{62}Cu are produced in 1 mg of Cu at 30 MeV, or 4·7 μCi of ^{64}Cu per mg Cu at 60 MeV.

energy, when a standard amount of Bremsstrahlung photons had passed through the sample. With this dose rate, 2·4 μCi of ^{64}Cu were produced in 1 mg of copper with 30-MeV Bremsstrahlung, or 4·7 μCi with 60-MeV Bremsstrahlung.

The limit of detection was then calculated on the basis of minimum detectable photopeak area. The limit was assumed, depending on the half-life of the product in question, to be the quantity of the element needed to give either 100($t_{1/2} < 1$ hr) or 10 ($t_{1/2} > 1$ hr) cpm under the present experimental conditions. Sensitivities for light elements can be improved significantly by Bremsstrahlung irradiation with higher maximum energies. With our accelerator, most of the elements listed here can be detected in amounts well below 1 μg with 30-MeV Bremsstrahlung and these amounts are generally reduced by one-half with 60-MeV Bremsstrahlung. In practical analysis using non-destructive methods, however, these amounts should be altered, owing to difficulties in resolution of the complex spectra.

The yield as a function of atomic number

For most nuclei, an excitation energy of 30 MeV is sufficient to cause the emission of one or two particles, and, especially for heavy nuclei, of three particles. In this work, the yields for 138 different photonuclear reactions could be measured separately in 52 elements from carbon up to lead with 30-MeV Bremsstrahlung. These totalled 69(γ,n), 31(γ,p), 18(γ,2n), 13(γ,pn), 4(γ,α) and 3(γ,3n) reactions. Several of the (γ,γ') reaction products were also measured but are excluded from the present compilation because of their low production rates. The individual yield was plotted against the atomic number (Z) of the target element as shown in Fig. 1. The yield values for the (γ,n) reactions lie in the range 10^5–10^8/mole/R, and increase regularly with atomic number. The (γ,2n) yield values become important at around chromium and, rising rapidly with increasing atomic number, reach about 10% of those of the (γ,n) reactions with high-Z nuclei. The (γ,3n) reactions were only measured for the elements of high atomic numbers. For low-Z nuclides, the (γ,n) and (γ,p) yields are of the same order of magnitude. With increasing Z, however, the (γ,p) yield drops rapidly since proton emission is more and more hindered by the Coulomb barrier, It is seen that the (γ,p) yield curve levels off at a roughly constant value for elements with atomic number greater than 50. The presence of direct effects in the photoproton emission from heavier nuclei will be responsible for this behaviour as has been suggested by several workers.[13,14] The shape of the curve for the (γ,pn) reactions is very similar to that for the (γ,p) reactions, which shows an initial rise, reaches a maximum and then drops rapidly with increasing atomic number, with tailing around $Z = 60$.

For light elements both (γ,n) and (γ,p) reactions can be used for analytical purposes, whereas for heavier elements the (γ,n) reaction is the most widely used. Other types of reactions are generally of little practical use and are mainly considered only in interference studies.

Isotopic yield ratio

The cross-section for photoneutron emission from a neutron-excess isotope is expected to be large, and *vice versa* for photoproton emission. From the yield data obtained with 30-MeV Bremsstrahlung, several examples of this sort were selected and are listed in Table II. For the (γ,n) processes in antimony isotopes, the total cross-section for the formation of the excited state of ^{121}Sb is shared between two

different ^{120}Sb isotopes, 16-min ^{120}Sb(1$^+$) and 5·8-d ^{120}Sb(8$^-$). The yield of the 5·8-d isotope was determined to be 4 % of that of the 16-min isotope as a result of the small probability of formation, owing to the large spin change.

As seen in Fig. 1, anomalously small yield values were obtained for the reactions on parent nuclides with "magic" neutron or proton numbers. These are the (γ,n) reactions on ^{16}O($Z = 8$), ^{52}Cr($N = 28$), ^{54}Fe($N = 28$), ^{58}Ni($Z = 28$), ^{89}Y($N = 50$), ^{90}Zr($N = 50$), ^{123m}Sn($Z = 50$), ^{141}Pr($N = 82$), ^{144}Sm($N = 82$) and ^{204}Pb($Z = 82$), the (γ,2n) reactions on ^{54}Fe, ^{59}Ni, ^{89}Y, ^{90}Zr, ^{141}Pr and ^{144}Sm, and the (γ,p) reactions on ^{43,44}Ca ($Z = 20$), the (γ,pn) reactions on ^{54}Fe, ^{58,60}Ni and ^{89}Y, and the (γ,α) reaction on ^{51}V($N = 28$).

Isomeric yield ratio

As seen in Fig. 1, the yields of metastable state isomers are low in general. The yield ratios of several isomeric pairs determined with 30-MeV Bremsstrahlung are given in Table III together with their spins and half-lives. The yield ratios favour those isomers having spin closer to that of the target nucleus, although the results for ^{89}Zr and ^{95}Nb isomers are exceptions. Similar results have been reported earlier.[15,16] Dependences of excitation energy on the isomeric yield ratios were not significant over the energy range investigated (see Fig. 3).

TABLE III.—THE YIELD RATIOS OF SEVERAL ISOMERIC PAIRS WITH 30 MeV BREMSSTRAHLUNG

Parent		Reaction	Residual					Yield ratio $\frac{Y_m}{(Y_m + Y_g)}$

The yield as a function of excitation energy

Reactions of the type (γ,xn). For most of the medium and heavy weight nuclei, the energy range of 30-MeV bremsstrahlung covers a substantial part of the excitation function of the (γ,n) reaction, and hence the yield reaches an almost constant value beyond 30 MeV. Typical yield curves for the (γ,n) reactions are given in Fig. 2. The yield curve for the ^{12}C(γ,n)^{11}C reaction ($-Q = 18{\cdot}72$ MeV), however, rises at 60 MeV to a value three times higher than that at 30 MeV.

The yield of a reaction with the emission of more than one neutron appears to be strongly energy-dependent. Several yield curves for the types (γ,2n), (γ,3n) and (γ,4n) are shown in Fig. 3. The relative yields of forming each nuclide by the (γ,xn) reactions appear likely to show almost an order of magnitude decrease with each unit increasing in x. Figure 4 gives the relative yields for the (γ,xn) reactions on ^{89}Y and ^{169}Tm.

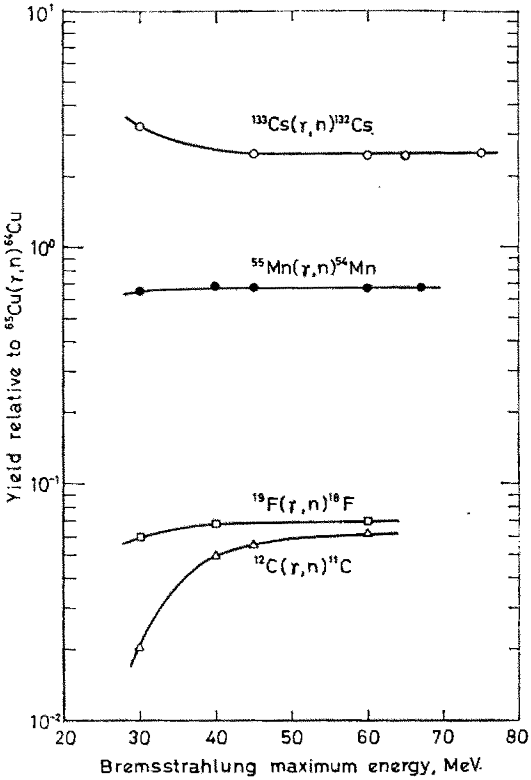

FIG. 2.—The yield curves for several (γ,n) reactions.

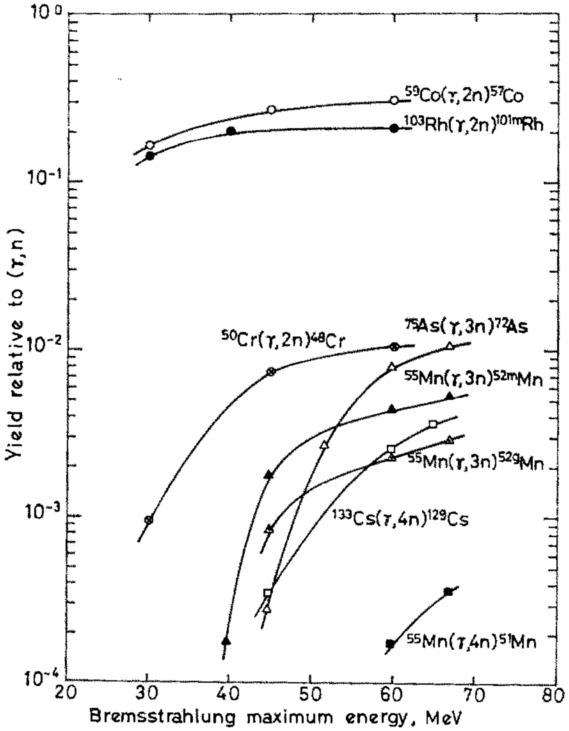

FIG. 3.—The yield curves for several (γ,2n), (γ,3n) and (γ,4n) reactions.

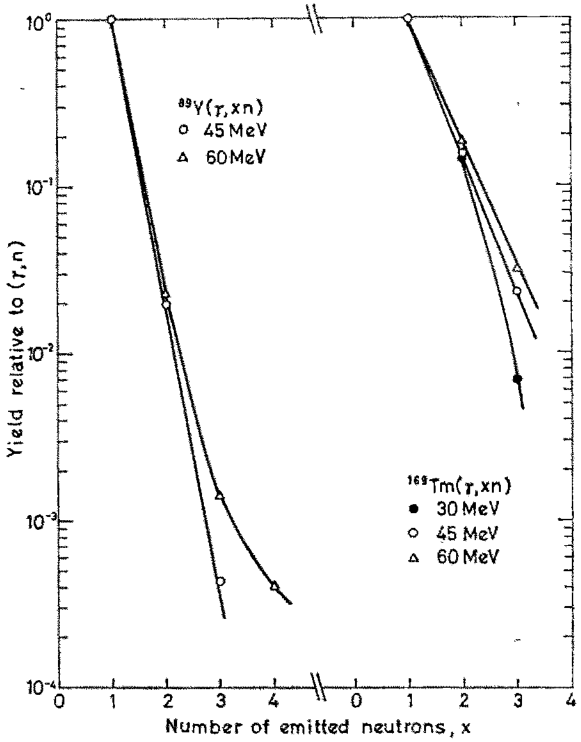

FIG. 4.—The relative yields of the (γ, xn) reactions on ^{89}Y and ^{169}Tm as functions of x.

Reactions of the type (γ,pxn). The yield curves for the (γ,p) reactions on ^{44}Ca, ^{96}Mo and ^{152}Sm are shown in Fig. 5. Over the energy range investigated, the yield increases gradually with increasing energy. The contribution of the direct photoproton emission mechanism will become more inportant at high energies, thereby causing the enhancement of the yield values. The enhancement of the yield values is more significant for the (γ,pn), (γ,p2n) and (γ,p3n) reactions as shown in Fig. 6. For the production of reactions of such types, the quasi-deuteron effect plays an important role, depending on the atomic number of the reacting nucleus and on the incident photon energy.[17] At high energies this process can be responsible for the increase in the yield values.

Other complex reactions. Other reactions with the emission of more particles are substantially forbidden from mass-threshold considerations for most of the light nuclei in the energy range covered in this experiment, but in some heavy nuclei they can still occur.

When iodine activities were chemically separated from an irradiated caesium sample, the ^{126}I activity formed by the (γ,2p5n) reaction on ^{133}Cs ($-Q = 55{\cdot}4$ MeV) was measured together with the ^{131}I and ^{130}I activities. The yields of these reactions are given as a function of Bremsstrahlung maxium energy in Fig. 7. The reaction paths other than (γ,2p5n) would also occur simultaneously; the reactions (γ,α3n) ($-Q = 27{\cdot}1$ MeV), (γ,dt2n) ($-Q = 44{\cdot}7$ MeV), (γ,^{3}He4n) ($-Q = 47{\cdot}7$ MeV), (γ,2d3n) ($-Q = 51{\cdot}0$ MeV) and (γ,pd4n) ($-Q = 53{\cdot}2$ MeV).

Although the yield values for such types of reactions are very small, a difficult

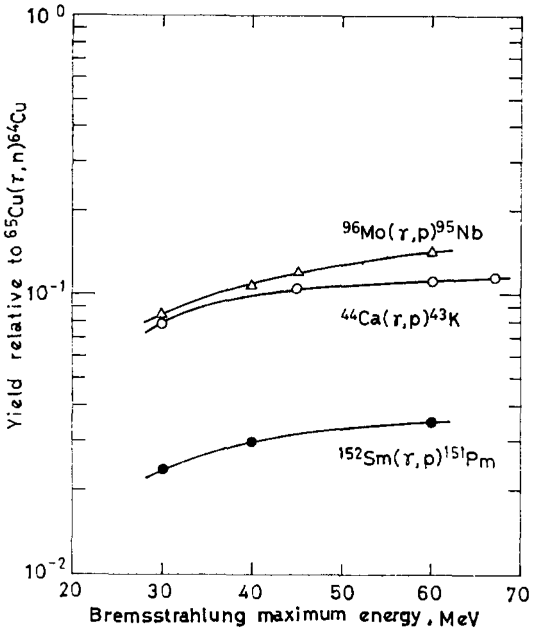

FIG. 5.—The yield curves for several (γ,p) reactions.

interference problem will occur when these reactions produce a nuclide identical to that in the activation analysis.

CONCLUSION

Although considerable effort has been devoted to photon-activation analysis for traces of light elements, it appears to be quite promising to apply this method to the determination of many other elements at trace levels. Under the present experimental conditions with our accelerator, sensitivities well below 1 μg were obtained for many elements. These sensitivities would be improved with an accelerator giving Bremsstrahlung of a much higher dose rate, and with better counting efficiencies. The amount of activation is very dependent on electron energy, and the (γ,2n) reactions, besides the (γ,n) and (γ,p) reactions, become useful in analysis. The interference problem, however, becomes serious under such conditions, but the yield data for various photonuclear reactions which occur simultaneously at a given electron energy should serve as a useful guide. The combination of an efficient chemical separation and solid-state detection technique will also improve sensitivity, accuracy and versatility in the determination of the heavier elements in photon activation analysis.

Acknowledgment—The authors express their appreciation to members of the Institute of Nuclear Science, Tohoku University, for their very fine service with the irradiations.

Zusammenfassung—Experimentelle Reaktionsausbeuten wurden für verschiedene Typen von Kern-Photoreaktionen ermittelt. Sie wurden in 52 Elementen durch Bestrahlung mit Bremsstrahlung (Maximalenergien zwischen 30 und 72 MeV) ausgelöst und die entstandenen Aktivitäten mit einem Lithium-gedrifteten Germaniumdetektor nachgewiesen. Aus den Ergebnissen wurden Empfindlichkeiten der Photoaktivierungsanalyse berechnet; die Reaktionsfähigkeit von hochenergetischen Photonen mit Kernen in einem weiten Bereich von Ordnungszahlen wird diskutiert. Einige kernchemische Überlegungen, etwa die relative Wahrscheinlichkeit der Bildung eines bestimmten Produkts als Folge der ($\gamma, xnyp$)-Reaktionen, werden ebenfalls mitgeteilt.

Résumé—On a déterminé les rendements de réaction expérimentaux pour divers types de réactions photonucléaires, induites dans 52 éléments au moyen d'irradiation "Bremsstrahlung" avec énergies maximales allant de 30 à 72 MeV, et détection des activités résultantes par un détecteur au germanium modifié au lithium. Des résultats obtenus, on a évalué les sensibilités en analyse par activation de photons et l'on discute de la réactivité des photons de haute énergie avec les noyaux dans un large domaine de nombres atomiques. On présente aussi quelques considérations nucléaires en analyse par activation de photons, comprenant la probabilité relative de formation de chaque produit comme résultat des réactions (γ, $xnyp$).

SOLID-LIQUID EXTRACTION AS A PRECONCENTRATION TECHNIQUE IN TRACE ELEMENT ANALYSIS

EXTRACTION OF TRACE IMPURITIES FROM METAL CHLORIDES

ATSUSHI MIZUIKE®, KATSUAKI FUKUDA and YOJI OCHIAI
Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya, Japan

(*Received* 14 *June* 1971. *Accepted* 29 *August* 1971)

Summary—Microgram quantities of iron, cobalt, copper, zinc and cadmium are extracted with various aqueous, organic and mixed solvents from chlorides of sodium, potassium, nickel, cadmium, barium and lead prepared by evaporation of aqueous sample solutions. An ultrasonic field accelerates the extraction, and satisfactory trace recoveries and separation factors are achieved in several systems within a reasonable time. The application to a polarographic determination and a two-stage separation technique are also described.

VARIOUS methods of separation have been applied to the preconcentration of trace elements from matrix elements before the trace determination, to make the sensitivity, precision and accuracy better than those which direct determination would achieve.[1,2] The most commonly used methods include volatilization, liquid-liquid extraction, precipitation, electrodeposition and ion-exchange. Solid-liquid extraction of trace elements from solids, with appropriate solvents, can also be employed for the same purpose, but very few applications have been made to date. Rynasiewicz *et al.*[3] extracted traces of boron from solid sodium chloride with 95% ethanol for the photometric determination of boron in sodium metal. Morrison and Rupp[4] employed the solid-liquid extraction of traces of boron from crystalline silicic acid with water, as a preconcentration technique in the emission spectrographic determination of boron at the parts per milliard level (ppM) in silicon. The same preconcentration technique was also applied to the determination by the isotope-dilution method with a mass spectrometer.[5] In this laboratory, the extraction of nanogram or microgram quantities of iron, cobalt, copper and zinc from solid basic bismuth nitrate with 0·07M phosphoric acid-0·12M hydrochloric acid or water was studied and applied in the square-wave polarographic or the emission spectrographic determination of these impurity elements in high-purity bismuth and reagent-grade bismuth nitrate pentahydrate.[6-8] Because very little information has hitherto been available on this subject, more work should be done to evaluate solid-liquid extraction as a preconcentration technique in trace element analysis in the light of criteria such as trace recoveries, separation factors,* contamination hazards, simplicity, rapidity and cost. The present paper reports the extraction of microgram quantities of impurity elements from several solid metal chlorides, with various solvents.

---

* The separation factor S for a matrix element M with respect to a desired trace element T is defined as follows:

$$S = (Q_M/Q_T)/(Q_M^0/Q_T^0)$$

where Q_T^0 = the quantity of T in the sample; Q_M^0 = the quantity of M in the sample; Q_T = the quantity of T after the separation; Q_M = the quantity of M after the separation.

EXPERIMENTAL

Apparatus

A Fujitsu NaI(Tl) well-type scintillation counter (44 × 50 mm). A Yanaco PF-501 polarograph. A Hirama model VI spectrophotometer with matched 20-mm cells. A Kaijo Denki model 4335 ultrasonic generator (29 kHz, 150 W).

Reagents

Tracer solutions. Hydrochloric acid solutions (0·1 *M*) containing 1 μg/ml of ^{59}Fe-labelled Fe(III), ^{60}Co-labelled Co(II), ^{64}Cu-labelled Cu(II), ^{65}Zn-labelled Zn(II), ^{110m}Ag-labelled Ag(I) and 10 μg/ml of ^{115}Cd-labelled Cd(II).

Matrix solutions. NaCl, KCl, $NiCl_2 \cdot 6H_2O$, $CdCl_2 \cdot 2{\cdot}5H_2O$, $BaCl_2 \cdot 2H_2O$ and $Pb(NO_3)_2$ dissolved in water (0·1 or 0·2 g of the matrix metal elements per ml).

Water was purified by distillation and ion-exchange. All the reagents used were of reagent grade and were used without further purification.

Standard procedure

Place 5 or 10 ml of matrix solution (containing 1 g of the matrix element) and 1 ml of tracer solution in a 50-ml beaker. In case of the lead matrix, add 4 ml of 12*M* hydrochloric acid. Evaporate the solution to dryness on a water-bath and then on an electric hot-plate at ca. 130°, rotating the beaker rapidly to prevent loss by spattering. Add 2 ml of water, stir, and evaporate again to dryness as described above. Cool to room temperature, and triturate the residue with a glass rod. Transfer the triturate to a 50-ml glass-stoppered Erlenmeyer flask. Rinse the beaker with 20 ml (or 40 ml for the cadmium matrix) of a solvent, and add the washings to the flask. Fasten the stopper, suspend the flask by a string in a 35-litre tank containing water and a transducer, and apply ultrasonics for 30 min (or 5 min for the lead matrix) to effect vigorous stirring. Transfer the contents of the flask quantitatively to a 50-ml round-bottomed centrifuge tube, and centrifuge for 3 min (or 6 min for the cadmium matrix) at 4000 rpm. Transfer the supernatant liquid into a second 50-ml beaker. Rinse the flask with 5 ml (or 10 ml for the cadmium matrix) of the solvent, and add the washings to the centrifuge tube. Immerse the tube in the tank, and apply ultrasonics for 30 sec while stirring with a glass rod. Centrifuge for 3 min (or 6 min for the cadmium matrix). Transfer the supernatant liquid to the beaker containing the first extract. If the combined liquid is turbid, filter it through a Millipore filter (Polyvic BS, mean pore size 2·0 μm, diam. 25 mm) or a glass fibre filter (Toyo Roshi, diam. 25 mm; for solvents containing acetone). Dilute the liquid to 25 ml (or 50 ml for the cadmium matrix) with the solvent in a volumetric flask, and measure the gamma-activity of a 2-ml aliquot to obtain the trace recovery.

Determine the matrix element dissolved in the solvent by the following methods after evaporation of the solvent; gravimetry for sodium, potassium and lead, polarography for lead and cadmium, EDTA titration for cadmium and barium, and spectrophotometry for nickel.

RESULTS

Effect of extraction time and ultrasonics on the extraction

Typical results are shown in Fig. 1. The application of a sound field accelerates the extraction of trace elements as well as dissolution of the matrix element, and the apparent equilibrium is achieved in about 30 min. The solvent is saturated with the matrix element before the trace recoveries reach their maxima. The same results were also obtained in the extractions of zinc from sodium chloride and barium chloride with a 1:1 n-butanol–12*M* hydrochloric acid mixture and from cadmium chloride with a 999:1 acetone–12*M* hydrochloric acid mixture. However, the extraction of iron and zinc from lead chloride with a 999:1 ethanol–12*M* hydrochloric acid mixture was completed within 5 min.

Table I lists the change in particle size during the extraction in a sound field. Without a sound field, much larger particles remained after the extraction. Although pulverization by ultrasonics is very effective, a preliminary crushing with a glass rod is essential to obtain a sufficiently small particle size after the extraction for a perfect trace recovery, especially in the extraction from sodium chloride, as shown in Table II.

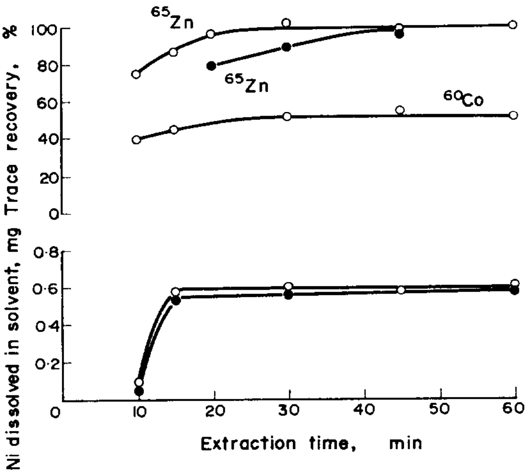

Fig. 1.—Extraction of cobalt and zinc from nickel chloride. 1 g of Ni + 1 μg of labelled Co or Zn; 25 ml of acetone–12*M* HCl (99:1). ○ with sound field ● with mechanical stirring.

Table I.—Pulverization of solids during extraction in a sound field

Matrix element (1 g)	Solvent	Particle size,* *μm*, after extraction for			
		0 min	3 min	10 min	30 min
Na	n-butanol–12*M* HCl (1:1), 25 ml	40–150	40–100	20–60	10–20
Ni	acetone–12*M* HCl (99:1), 25 ml	—	~20	~5	~1

‡ 5 min extraction.

which was established on the basis of the experimental results above. Trace recovery is always quite reproducible at greater than 90% yields. Negligible amounts of nitrate and free acids were found in solid lead chloride prepared by the standard procedure. Loss of trace elements due to adsorption or adhesion on the walls of the 50-ml beaker used for evaporation of sample solutions was always less than 1%. Fifty ml of solvent was employed for the cadmium matrix, because cadmium chloride swells in acetone and acetylacetone, forming voluminous addition compounds, which makes the extraction difficult with only 25 ml of solvent. Filtration of the extracts was necessary in the extractions from lead chloride with water, and from barium chloride with solvents containing n-butanol (sometimes with solvents containing acetone).

Effect of matrix quantity on the extraction

Table IV shows that trace recoveries decrease with increase of the quantity of matrix elements in extractions with a fixed amount of solvent. Because stirring due to a sound field was insufficient when larger quantities of solids were used, mechanical stirring was used simultaneously. Nevertheless, trace recoveries were poor for more than 3 g of matrix elements.

TABLE IV.—EFFECT OF QUANTITY OF MATRIX ELEMENT ON TRACE RECOVERY

Solvent 25 ml of n-butanol–12*M* HCl (9:1) for K, 25 ml of n-butanol–12*M* HCl (1:1) for Ba; 30 min extraction.

Repeated extractions

Extraction of traces of cobalt from nickel chloride with a 99:1 acetone–12*M* hydrochloric acid mixture was incomplete (Fig. 1 and Table III). Therefore, repeated extractions with portions of fresh solvent were carried out, with the results given in Table V. The cobalt recovery is directly proportional to the amount of nickel dissolved, up to the 5th extraction, and nearly perfect recovery is attained by the use of about 50 ml of the solvent.

Effect of water in organic solvents on the extraction

Organic solvents such as ethanol and acetone usually contain small amounts of water, and also absorb water from air. For example, in this study the ethanol contained 0·2% w/w of water and absorbed about 0·3% w/w of water during the extraction procedure, and the acetone contained 0·5% w/w of water (Karl Fischer

determination). Table VI shows the effect of water in organic solvents on the extraction of zinc.

DISCUSSION

In Fig. 2 are plotted the curves for recovery of a particular trace element as a function of the quantity of matrix element dissolved, from the data given in Table III. In each case, the points obviously fell on one universal curve irrespective of the solvents used. Also, the curves resemble each other for iron, cobalt, copper and zinc in any matrix except for nickel.

The results shown in Fig. 2 and Tables IV and V suggest that the following inequality must be satisfied for nearly perfect trace recoveries within 30 min of extraction:

$$\Delta m/m > k \tag{1}$$

where Δm is the quantity of the matrix element dissolved in the solvent, m the total amount of the matrix element, and k a constant independent of the quantity of the matrix element and the kind and quantity of the solvent, provided that the state of the solid phase is invariant.

We infer the following mechanism for the present solid–liquid extraction systems from the experimental results described previously. After evaporation of the sample solution, trace elements are present on the surfaces of crystals (or their agglomerates)

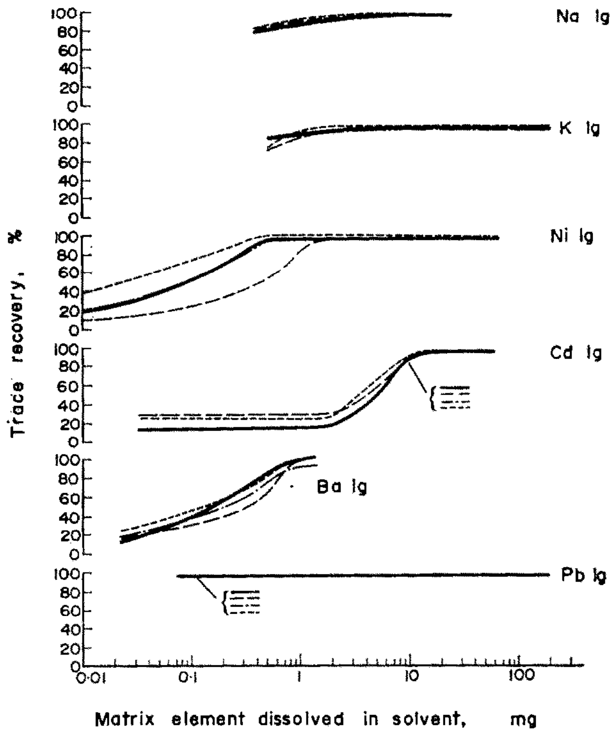

FIG. 2.—Relationship between quantity of matrix element dissolved in solvent and trace recovery.
Fe (—), Co (— —), Cu (— — — —), Zn (- - -), 1 μg added; 25 ml of solvent, except for Cd (50 ml); 30 min extraction, except for Pb (5 min).

of pure chlorides of the matrix element (anhydrous, for sodium, potassium and lead; hydrated, for nickel, cadmium and barium), or in the interstitial space in the agglomerates. During the extraction in a sound field, the agglomerates are pulverized, and the trace elements are brought into good contact with the solvent and dissolved together with part of the matrix.

Extremely low recoveries of silver are presumably due to its adsorption on the solid phase during the evaporation or the extraction step. The adsorption during the latter step was proved by a separate adsorption experiment, in which about 80% of silver was adsorbed on solid lead chloride from a mixed solution of 1 ml of tracer solution (^{110m}Ag) and 24 ml of a 999:1 ethanol–12*M* hydrochloric acid mixture within 10 min of ultrasonic irradiation. Similarly, adsorption of copper on barium chloride from acetone and of iron on lead chloride from ethanol was observed. Therefore, low recoveries of iron and copper in the extraction with pure organic solvents or water might be partly ascribed to adsorption on the solid phase. Formation of mixed crystals of matrix and trace elements during the evaporation and recrystallization during the extraction appear to be negligible in the present extraction systems. To explain the discrepancies among curves in Fig. 2, especially for nickel chloride, more detailed investigations on the formation of the solid phase, adsorption phenomena, and various factors affecting the constant *k* would be necessary.

The following suggestions will be useful as a guide for designing solid–liquid extraction methods for trace element analysis.

(1) Prepare larger crystals to make k smaller.
(2) Select the solvent and its quantity so that $\Delta m/m$ is a little larger than k. Also, consider adsorption of trace elements on the solid phase and ease in stripping for the subsequent determination or separation step.
(3) Apply ultrasonics during the extraction.
(4) If the separation factors for matrix elements with respect to desired trace elements are insufficient, use the two-stage separation technique described later.

At present, it is difficult to evaluate fully solid–liquid extraction as a preconcentration technique in trace element analysis. However, by choosing favourable solid phases, solvents and manipulations, quite satisfactory trace recoveries and separation factors may be easily obtained by this technique. Precipitation of 1 g of barium or lead as chloride from 25 ml of aqueous sample solution is also applicable to the preconcentration of impurity elements such as zinc at the microgram level. After the precipitation, 95–97% of zinc remains in the supernatant solution with 2 mg of barium or 40 mg of lead. These results are inferior to those obtained by the present technique (see Table III).

APPLICATIONS

Determination of impurities in lead

The proposed preconcentration technique was successfully applied in the square-wave polarographic determination of ppM levels of zinc and cadmium in high-purity lead and reagent-grade lead nitrate.

Recommended procedure. Transfer 2·5 g of lead to a 50-ml beaker, add 15 ml of 7*M* nitric acid, cover with a watch-glass, and heat gently to dissolve. Evaporate the solution to dryness, and then dissolve the residue in 15 ml of water. (For lead nitrate, dissolve 4 g of sample in 15 ml of water.) Dilute the solution to 25 ml with water in a volumetric flask. Place a 5- or 10-ml aliquot in another 50-ml beaker and add 4 ml of 12*M* hydrochloric acid. Evaporate the solution to dryness, and extract zinc and cadmium from the residue with a 999:1 ethanol–12*M* hydrochloric acid mixture, as described under *Standard procedure*. Filter the extract through a Millipore filter, and evaporate to near dryness in a 50-ml fused silica beaker on a water-bath. Add 1 ml of 60% perchloric acid, and evaporate to dryness. Dissolve the residue in 1 ml of 5*M* phosphoric acid, and dilute to 5 ml with water. Transfer the solution to a polarographic cell, deaerate with nitrogen for 5 min, and record the square-wave polarogram from −0·8 to −1·5 V *vs.* the mercury pool.

The calibration curve was linear up to at least 2 μg of zinc or cadmium with a maximum deviation of 0·02 μg. No interference results from the presence of 150 μg of lead(II), and 10 μg each of iron(III), cobalt(II), nickel(II), antimony(III, V), arsenic(III, V), tin(IV) and bismuth(III) in the determination of 0·2 μg of zinc or cadmium. Analytical results are given in Table VII. The blank values for the entire procedure were 0·05 μg of zinc and 0·00 μg of cadmium. A determination requires about 2 hr.

Two-stage separations

According to inequality (1), the total amount of a matrix element (m) must be reduced to minimize the amount of it dissolving in a solvent (Δm), if k is constant. Therefore, two-stage separation appears to be a promising means of improving the

TABLE VII.—POLAROGRAPHIC DETERMINATION OF IMPURITIES IN LEAD

* 1 μg of Zn and 0·1 μg of Cd added before extraction.

separation factors for the matrix element with respect to the trace elements of interest. In this technique, after the first solid–liquid extraction, the solvent is stripped by evaporation, and then the second extraction is carried out on the residue with another solvent. For the selection of the solvent used in the first extraction, perfect trace recoveries and ease in evaporation are prime considerations.

Procedure. Evaporate to dryness 5–10 ml of a sample solution containing 1 g of matrix element and 1 μg of labelled zinc, and extract zinc from the residue with 5 ml of a solvent in a test-tube (14 mm bore, 80 mm long, with a silicone rubber stopper) for 20 min in a sound field, as described under *Standard procedure*. Centrifuge for 5 min, using the same test-tube. Transfer the supernatant liquid to another test-tube. Wash the residue in the first test-tube twice with 3 and then 2 ml of the solvent, with the aid of a centrifuge, and add the washings to the extract in the second test-tube. Evaporate the solution to dryness on a water-bath and then heat the residue in an air-oven at about 110° for 10 min. Cool, and triturate the residue with a glass rod. Add 4 ml of another kind of solvent, and extract zinc from the residue for 30 min in a sound field. Centrifuge for 3 min. Transfer the supernatant liquid to a 10-ml volumetric flask. Add 1 ml of the second solvent to the second test-tube, and apply ultrasonics for 30 sec. Centrifuge, and transfer the supernatant liquid to the volumetric flask. Dilute to the mark with the second solvent, and measure the gamma-activity of a 1-ml aliquot. Determine the matrix element dissolved in the solvent, as described previously.

The results are summarized in Table VIII. The separation factors were improved by a factor of 5–10 as compared with those obtained by the standard procedure with

the second solvent (*cf.* Table III). More improvement may be achieved by choosing more suitable conditions.

Acknowledgement—We would like to thank Messrs. T. Kono, M. Hayashi and M. Hayakawa for their assistance in the experimental work.

Zusammenfassung—Mikrogrammengen Eisen, Kobalt, Kupfer, Zink und Cadmium werden mit verschiedenen wäßrigen, organischen und gemischten Lösungsmitteln aus den Chloriden von Natrium, Kalium, Nickel, Cadmium, Barium und Blei extrahiert, die durch Eindampfen wäßriger Probenlösungen gewonnen wurden. Ein Ultraschallfeld beschleunigt die Extraktion. In mehreren Systemen erreicht man in annehmbarer Zeit zufriedenstellende Trennfaktoren und Ausbeuten an Spurenelement. Anwendungen auf eine polarographische Bestimmung und ein zweistufiges Abtrennverfahren werden beschrieben.

Résumé—On extrait des quantités de l'ordre du microgramme de fer, cobalt, cuivre, zinc et cadmium avec divers solvants aqueux, organiques et mixtes à partir des chlorures de sodium, potassium, nickel, cadmium, baryum et plomb préparés par évaporation de solutions aqueuses d'échantillons. Un champ ultra-sonore accélère l'extraction, et l'on obtient des récupérations de traces et des facteurs de séparation satisfaisants pour plusieurs systèmes dans un temps raisonnable. On décrit aussi l'application à un dosage polarographique et une technique de séparation à deux stades.

SELECTIVE GAS-CHROMATOGRAPHIC DETECTION USING AN ION-SELECTIVE ELECTRODE—II*

SELECTIVE DETECTION OF FLUORINE COMPOUNDS

TSUGIO KOJIMA, MITSUNOJO ICHISE and YOSHIMITSU SEO
Department of Industrial Chemistry, Faculty of Engineering,
Kyoto University, Kyoto, Japan

(*Received* 7 *June* 1971. *Accepted* 17 *September* 1971)

Summary—Components in samples are separated on a gas chromatography column using hydrogen as carrier gas. The individual components from the column are passed through a platinum tube heated at 1000°, where they undergo hydrogenolysis, and fluorine compounds are converted into hydrogen fluoride. The hydrogen fluoride is dissolved in a slow stream of an absorption solution, and the fluoride ion concentration in the resulting solution is monitored in a flow-cell with a fluoride ion electrode. The potentiometric output of the cell is converted into a signal, which is proportional to the concentration of fluoride ion, by an antilogarithmic converter, and recorded. The response of the detector to fluorine compounds was about 10,000 times that to an equal quantity of other organic compounds, and 5×10^{-11} mole of fluorobenzene could be detected.

SEPARATE components from a gas chromatographic column are generally identified by determining the retention value. In practice, however, identification by the retention value alone is difficult and the final confirmation is often possible only after information on the elemental composition, functional groups and structure is obtained by simultaneously using other analytical means. One method used for this purpose is to transfer the eluates of pure components from the chromatograph into a spectrometer (infrared, mass or nuclear magnetic resonance), which thus produces the spectrum of each pure component in turn. The most effective is the combination of gas chromatograph and mass spectrometer.

Another method, which dispenses with expensive instruments uses the retention value and additional information obtained from the gas chromatogram above. Volatile injected compounds are reacted with non-volatile reagents to form non-volatile products in the gas chromatographic system and a comparison of chromatograms run in the presence and absence of the reagent is used to identify the kind of functional group or the structure of the carbon skeleton. Another method of this type is based on the selective detection of the compound containing a specific element or having a specific functional group, by means of a selective detector.

We have searched[1-3] for a method of this type which will give information on the elemental composition as well as the retention value. This is achieved by the selective detection of compounds containing halogens, sulphur, nitrogen and oxygen, with a reaction column and a selective detector. A new detection system for a gas chromatograph was recently devised, using an ion-selective electrode as a detecting element.[4] This system will not only detect organic compounds selectively but also furnish information on the composition.

---

* Part I: *Bunseki Kagaku*, 1971, 20, 20.

It is difficult to detect fluorine compounds selectively, and the only method[5] known so far is to monitor the intensity of the atomic emission spectrum of fluorine, using a d.c. discharge detector. The present method uses a simpler apparatus.

EXPERIMENTAL

Principle of the method

The sample components are separated on a gas chromatographic column using hydrogen as carrier gas and the effluent is passed through a platinum tube at 1000° where the separated components undergo hydrogenolysis and the fluorine in the fluorine compound is converted into hydrogen fluoride. The decomposition gases are introduced into an absorption tube where solution (flowing at a constant rate) absorbs the hydrogen fluoride. The solution emerging from the absorption tube is passed into a micro-cell equipped with a fluoride ion electrode. Changes in the fluoride ion concentration in the solution are detected by the corresponding changes in the ion electrode potential.[6] When the ionic strength is kept constant, a Nernst relationship exists between the electrode potential and the logarithm of the ion concentration. The difference in potential between the ion electrode and a reference electrode is fed to an antilog converter circuit and a signal directly proportional to the ion concentration is recorded. A chromatogram composed of only the peaks due to fluorine compounds is obtained.

Apparatus and procedure

A schematic diagram is shown in Fig. 1: (*a*) is the carrier gas source (hydrogen at a flow-rate of 25–48 ml/min), (*b*) and (*c*) represent a Yanagimoto Model GCG-II gas chromatograph, and (*d*) is an electric furnace, 200 mm in length, for elemental analysis which was operated at 1000°. A platinum tube, 2 m long and 1·5 mm inside diameter, was used as a pyrolysis tube (*e*); (*f*) is a glass absorption tube consisting of a gas-liquid contact area, 1 mm inside diameter and 0·15 m high, and a gas-liquid separation area, 13 mm inside diameter and 25 mm high. The pyrolysis tube and absorption tube are connected with 1 mm bore polyethylene tubing. Absorption solution (*g*) is pumped by a micro-pump (*h*) at a constant flow-rate (0·6 ml/min) *via* a stream buffer (*i*) to the absorption tube where it absorbs hydrogen fluoride *etc* from the hydrogenolysis gases. The unabsorbed gases such as methane are separated, together with the carrier gas, from the absorption solution in the gas-liquid separator and vented from the system. The emerging absorption solution is led through a measuring cell equipped with a fluoride ion electrode (*j*) as a detecting element and is then discarded. The absorption solution and the reference electrode (*k*) (a sleeve-type saturated calomel electrode) are connected by means of a saturated potassium chloride solution–agar bridge. The measuring cell is shown in detail in Fig. 2. Since the volume of the cell is about 0·05 ml, the dead time is about 5·0 sec when the flow rate of the absorption solution is 0·6 ml/min.

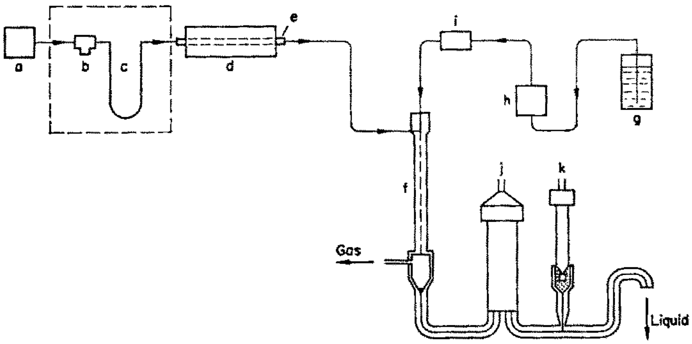

FIG. 1.—Schematic diagram of the apparatus.

The fluoride ion electrode used was an Orion Model 94-09A constructed from a single crystal membrane of lanthanum fluoride and it shows a potential *E* for a fluoride ion activity a_{F^-} in the vicinity of the electrode, in accordance with the Nernst equation as follows:

$$F = E_0 - 2{\cdot}303 \frac{RT}{\mathrm{F}} \log a_{F^-} \qquad (1)$$

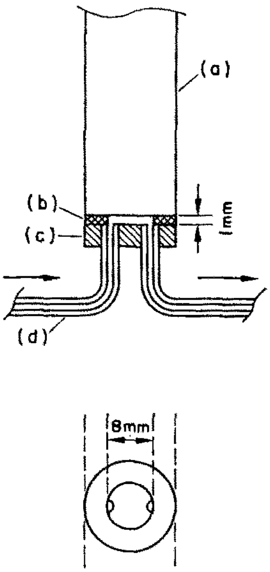

FIG. 2.—Cell details.
(*a*) Fluoride ion electrode body; (*b*) silicone rubber packing; (*c*) polyethylene plate; (*d*) glass capillary

If the ionic strength of the absorption solution is kept constant, a negative potential proportional to the logarithm of the fluoride ion concentration C_{F^-} is obtained:

$$E = E_0' - 0{\cdot}0592 \log C_{F^-} \quad \text{(at 25°)} \tag{2}$$

The circuit for measuring the electrode potential is shown in Fig. 3, where (*a*) is a voltage follower using a QFT-2a amplifier (Philbrick/Nexus Research) as an impedance converter, (*b*) is an adjustable-coefficient inverter (Philbrick PF-85AU inversion type negative feedback coupling) as an adapter for (*c*), an antilog converter, (Philbrick/Nexus Model 4351); (*d*) is a 1-mV recorder (Shimadzu R201) and (*e*) is the signal input.

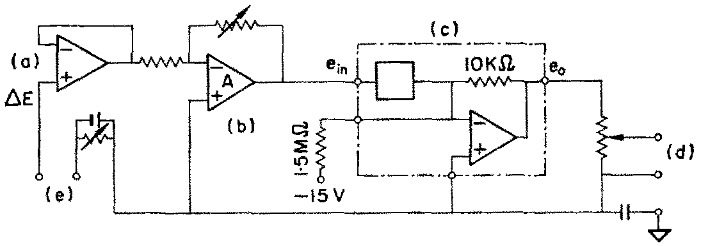

FIG. 3.—Circuit for ion electrode detector.

In order to use the fluoride ion electrode in the Nernstian range, a small amount of sodium fluoride was added to the absorption solution to make the concentration of fluoride ion approximately $10^{-5}M$. If this concentration of fluoride ion is C_b, the electrode potential is

$$E = E_0' - 0{\cdot}0592 \log C_b \tag{3}$$

The potential E' when hydrogen fluoride is absorbed in this solution and the concentration of fluoride ion is increased by ΔC is given by

$$E' = E_0' - 0{\cdot}0592 \log (C_b + \Delta C) \tag{4}$$

From equations (3) and (4), the change in the potential, ΔE, corresponding to the change in the fluoride ion concentration is given by

$$\Delta E = (E' - E) = -0\cdot0592 \log \left(1 + \frac{\Delta C}{C_b}\right) \tag{5}$$

In this apparatus, the potential change is recorded after antilog conversion to give an output signal proportional to the concentration, as in the case of an ordinary detector, the antilog converter used having the following conversion characteristics:

$$e_0 = -\frac{1}{10} \,.\, 10^{0\cdot5}e_{in} \tag{6}$$

The change in potential, ΔE, enters as input e_{in} to the antilog converter (*c*) after undergoing impedance conversion in the voltage follower (*a*) and is then amplified A times in the amplifier (*b*). Therefore,

$$e_{in} = -A \,.\, \Delta E \tag{7}$$

The following equation is derived from equations (5), (6) and (7):

$$\begin{aligned} e_0 &= -\frac{1}{10} \,.\, 10^{-0\cdot5} \,.\, A \,.\, \Delta E \\ \log(-e_0) &= -1 + 0\cdot5 \,.\, A \,.\, 0\cdot0592 \log \left(1 + \frac{\Delta C}{C_b}\right) \end{aligned} \tag{8}$$

Adjustment of the gain A in the amplifier (*b*) in such a manner as to make the coefficient of the second term of the right-hand side of equation (8) unity, that is to make $A = 33\cdot78$, gives the relationship

$$e_0 = -\frac{1}{10}\left(1 + \frac{\Delta C}{C_b}\right) \tag{9}$$

and the output e_0 of the antilog converter begins to change in direct proportion to the change in the fluoride ion concentration in the absorption solution.

RESULTS AND DISCUSSION

Samples containing hydrocarbons, nitrogen and oxygen compounds in addition to fluorine compounds were prepared and the possibility of selective detection of fluorine compounds was investigated.

Aliphatic compounds

In Fig. 4 is shown a chromatogram obtained by injecting into the column 0·1–0.2 μl of sample consisting of a mixture of 0·01 mole each of ethylmercaptan, n-octane, 1,2-dibromoethane and 1-nitropropane and 0·1 mmole of ethyl trifluoroacetate. In Fig. 4, (*a*) is an ordinary non-selective chromatogram obtained by passing the effluent component from the separation column through a hydrogen flame ionization detector while by-passing the hydrogenolysis tube, and the number in parentheses indicates the mole ratio; (*b*) is a chromatogram obtained by subjecting the same sample to hydrogenolysis absorbing the decomposition gas in the TISAB solution[7] (a mixture of 57 ml of glacial acetic acid, 58 g of sodium chloride and 0·3 g of sodium citrate, diluted to 2 l.) which is about $10^{-5}M$ in sodium fluoride as mentioned above. The ethyl trifluoroacetate is selectively detected in the measuring cell.

In measurements of fluoride ion concentration with the aid of the fluoride ion electrode, it should be noted that the interfering OH^- ions will show their effect as the pH of the solution rises whereas the apparent F^- concentration will decrease owing to formation of HF or HF_2^- as the pH drops. The useful range of pH is 5–7

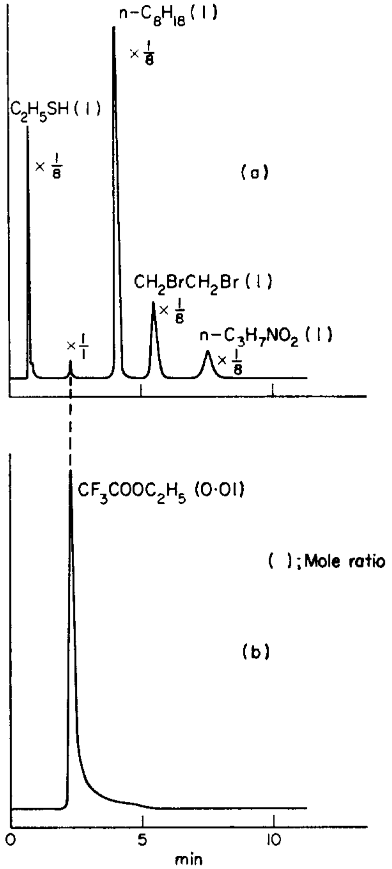

FIG. 4.—Chromatogram of a test mixture.
Column—Durapak-Carbowax 400/Porasil C (100–120 mesh), 1 m; temperature—90°; carrier gas—H_2 28 ml/min. (*a*) Non-selective detection by use of FID; (*b*) selective detection of fluorine compound by use of fluoride ion electrode detector.

when the concentration of F^- is $10^{-5}M$, according to Bock,[8] and a TISAB solution of pH 5 is used as an absorption solution.

By use of the same procedure, 0·1 mmole in 1,1,2,2-tetrachloro-1,2-difluoroethane was detected selectively in a mixture with 0·01 mole each of ethyl iodide, n-propyl acetate, 1,1,2-trichloroethane and ethyl thiocyanate.

Aromatic compounds

A chromatogram of a mixture of 0·01 mole each of ethylbenzene, bromobenzene, benzonitrile and thioanisole and 0·1 mmole of *o*-fluorotoluene is shown in Fig. 5. For further confirmation, a mixture of 0·01 mole each of *o*-xylene, *o*-chlorotoluene, methyl benzoate, phenyl isothiocyanate and 0·1 mmole of benzotrifluoride was chromatographed. It was confirmed from these experiments that selective detection of fluorine compounds is complete.

Quantitative results

The results shown in Fig. 4 and Fig. 5 indicated that fluorine compounds could be detected selectively, and the quantitativeness of response of the detector was next investigated. The results are shown in Table I.

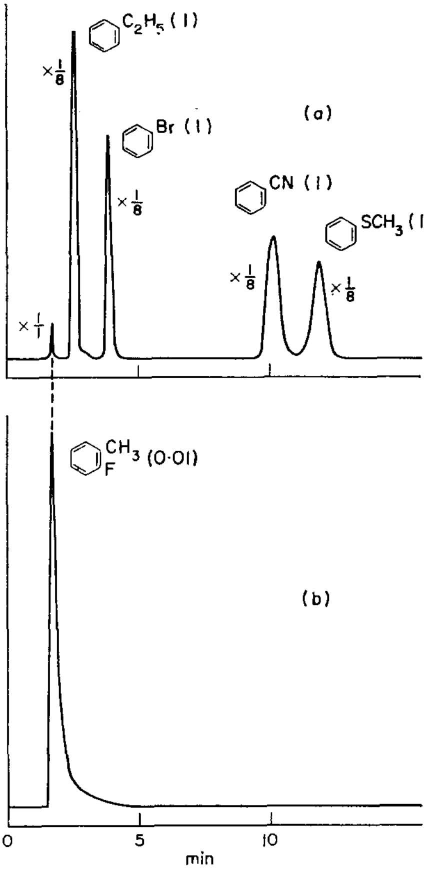

FIG. 5.—Chromatogram of a test mixture.
Column temperature 128°; see Fig. 4 for other conditions. (*a*) Non-selective detection by use of FID, (*b*) selective detection of fluorine compound by use of fluoride ion electrode detector.

Fluorobenzene, *o*-fluorotoluene, and benzotrifluoride were chosen as the first group of compounds; a sample containing 0·01 mole each of these compounds was prepared, diluted 10,000-fold with n-hexane, and 2 μl were injected into a column (Durapak-Carbowax 400/Porasil C, 100–120 mesh, 1 m, 60°), and chromatographed. The relative size of each peak area was determined by the method of cutting out the recorded peaks and weighing the paper. Taking benzotrifluoride as the standard, the ratio of the peak area of each of two other components to the peak area of the standard was measured repeatedly. 1,1,2,2-Tetrachloro-1,1-difluoroethane, *o*-fluorotoluene, and *p*-chlorofluorobenzene were chosen as the second group of compounds; a sample containing 0·01 mole each of these compounds and diluted 10,000-fold with n-hexane, was chromatographed as before. The same procedure as for the first

group was repeated with 1,1,2,2-tetrachloro-1,2-difluoroethane as the standard. Perfluoro-compounds were chosen as the third group of compounds; a sample containing 1/350 mole of perfluoromethylcyclohexane, 1/150 mole of perfluorobenzene and 1/50 mole of *m*-difluorobenzene was prepared and diluted 1000-fold with n-hexane, and 0·8 μl was chromatographed. The perfluorobenzene was used as the standard.

If the hydrogenolysis reaction, the absorption of hydrogen fluoride, and the response of the detector to fluoride ions are quantitative, the ratio of the peak areas of the three components for each group should be proportional to the number of fluorine atoms in each molecule. The average of the experimentally determined ratio of peak areas is close to the theoretical value. It is thus shown that fluorine bonded to an aromatic nucleus (which has been said to be particularly resistant to quantitative decomposition), perfluoro-compounds of the third group, and compounds containing other halogens in addition to fluorine can be determined quantitatively.

As mentioned previously, a proportionality to the fluoride ion concentration in the absorption solution should exist in the present apparatus in the range where the ionic strength of the absorption solution is constant. To confirm this, experiments were carried out with fluorobenzene as a sample.

The output e_0 of the antilog converter is confined to the range from 0 to -10 V. Therefore, supposing the concentration of the fluoride ion added to the absorption solution is $10^{-5}M$, the permissible range of the fluoride ion concentration in the absorption solution becomes 10^{-5}–$10^{-3}M$ from equation (9). The ionic strength μ of the absorption solution is 0·820, and this changes merely to 0·821 when the fluoride ion concentration reaches $10^{-3}M$ upon absorption of hydrogen fluoride. As a consequence, the changes in the activity coefficient of the fluoride ion may be ignored. Moreover, the changes in the pH are negligible. Therefore, if the amount of sample is adjusted so that the fluoride ion concentration falls within the range 10^{-5}–$10^{-3}M$, there should exist a linear relationship between the amount of sample injected and the peak area. Accordingly, solutions of fluorobenzene in n-hexane with a concentration of 0·0001–0·05M were prepared, 2 μl of each were injected into the column, and the relationship between the amount of sample injected and the peak area was examined. An absolute calibration curve was obtained and the existence of a linear relationship between the amount of sample injected (2×10^{-10}–10^{-7} mole) and the peak area in the concentration range indicated above was found.

CONCLUSION

A gas chromatographic detector with using an ion-selective electrode has been developed and applied to the selective detection of fluorine compounds. It has the following advantages: the limit of detection is 5×10^{-11} mole (for fluorobenzene), the detector sensitivity is high, the degree of selectivity is 10,000 or more with an extremely high sensitivity, the drift of the base line is 0·02 mV/hr with good stability.

The response time of the detector is about 10 sec when the concentration of F^- is about $10^{-5}M$ and several seconds when it is more than $10^{-4}M$. Such slow responses distort the early peaks slightly but the effect is negligible for peaks having retention times greater than 5 min.

A platinum tube was used as a hydrogenolysis tube in the present study, but could be replaced by a quartz tube.

Zusammenfassung—Die Proben werden an einer Gaschromatographiesäule mit Wasserstoff als Trägergas in ihre Komponenten getrennt. Die einzelnen von der Säule kommenden Komponenten werden durch ein auf 1000° geheiztes Platinrohr geleitet; dort werden sie hydrierend gespalten. Fluorverbindungen werden in Fluorwasserstoff übergeführt. Der Fluorwasserstoff wird in einem langsamen Strom einer Absorptionslösung gelöst und die Fluoridkonzentration in der Lösung in einer Durchflußzelle mit einer Fluoridionen-Elektrode verfolgt. Das potentiometrische Verhalten der Zelle wird mit Hilfe eines antilogarithmischen Umsetzers in ein Signal umgesetzt, das der Fluoridkonzentration proportional ist, und registriert. Der Detektor sprach auf Fluorverbindungen etwa 10 000-mal stärker an als auf eine gleiche Menge anderer organischer Verbindungen; $5 \cdot 10^{-11}$ Mol Fluorbenzol konnten nachgewiesen werden.

Résumé—On sépare des composants dans des échantillons sur une colonne de chromatographie en phase gazeuse en utilisant l'hydrogène comme gaz vecteur. On fait passer les composants individuels provenant de la colonne à travers un tube de platine chauffé à 1000°, où ils subissent l'hydrogénolyse, et les composés fluorés sont convertis en acide fluorhydrique. L'acide fluorhydrique est dissous dans un lent courant d'une solution d'absorption, et la concentration en ion fluorure dans la solution résultante est contrôlée dans une cellule à écoulement avec une électrode à ion fluorure. L'émission potentiométrique de la cellule est convertie en un signal, qui est proportionnel à la concentration en ion fluorure, par un convertisseur antilogarithmique, et enregistré. La réponse du détecteur aux composés fluorés est d'environ 10 000 fois celle fournie par une égale quantité d'autres composés organiques, et l'on a pu détecter 5×10^{-11} mole de fluorobenzène.

POLAROGRAPHIC STUDIES OF CADMIUM, ZINC AND MANGANESE(II) IODIDE COMPLEXES IN ACETONITRILE

S. Misumi and M. Aihara
Inorganic Chemistry Laboratory, Faculty of Science
Kyushu University, Fukuoka, Japan

(*Received* 15 *June* 1971. *Accepted September* 1971)

Summary—Cadmium, zinc and manganese(II) iodide complexes have been studied polarographically in acetonitrile and the electrode reactions for these complexes discussed. The overall stability constants of the iodide complexes of these metal ions were evaluated and corrected for the effect of the ion-pairing electrolyte. The values for log β_4 of CdI_4^{2-} and ZnI_4^{2-} are 26·2 and 18·4 respectively and the values found for the Mn(II) iodide complex are log $\beta_1 = 3·5$, log $\beta_2 = 5·6$, log $\beta_3 = 7·8$, log $\beta_4 = 10·0$, log $\beta_5 = 12·2$ and log $\beta_6 = 14·4$. Within certain limits, the wave-height for each complex is proportional to the metal concentration.

THE POLAROGRAPHIC behaviour of some halide complexes in dimethylsulphoxide and dimethylformamide has been studied by Pool[1] and by Furlani *et al.*[2] respectively, but there are very few investigations on the stability constants of halide complexes in these non-aqueous solvents, because of the problems associated with the unknown activities. This work deals with the electrode reactions for iodide complexes of cadmium, zinc and manganese(II) and the stability constants of iodide complexes of these metal ions in acetonitrile (which has the low donor number[3] of 14·1).

EXPERIMENTAL

Materials

Acetonitrile (AN) (Wako Junyaku Co., extra pure reagent grade) was purified[4] and the water content was found by Karl Fischer titration to be 0·01%. There was no impurity causing a detectable polarographic current at potentials less than −2·8 V *vs.* SCE.

Reagent-grade cadmium, zinc and manganese(II) perchlorate hexahydrates were dried *in vacuo* at 60° for 5–6 days.

Tetraethylammonium iodide, Et_4NI, was prepared, purified three times and dried *in vacuo* at 60° for 5–6 days. Et_4NClO_4 (TEAP) was used as the supporting electrolyte.

Apparatus

The electrolysis cell consists of three electrodes as shown in Fig. 1. The dropping mercury electrode had the following characteristics: $m = 1·425$ mg/sec, $t = 3·79$ sec in 0·1*M* TEAP–AN medium at −0·5 V *vs.* SCE. A platinum wire was used as the counter-electrode. The reference electrode was SCE with a salt bridge ($NaClO_4$–NaCl–KCl agar bridge). The temperature was controlled at 25·0 ± 0·1°. The junction potential was about 10 mV.

Procedure

A sample solution in TEAP–AN, 0·5m*M* in metal(II) perchlorate and containing an appropriate amount of Et_4NI, was taken in a cell. Since there is appreciable ion-pairing of the tetraethylammonium ion with iodide, the concentration of Et_4N^+ was kept constant (0·1*M*) for each metal iodide solution by adding an appropriate amount of Et_4NClO_4 instead of using constant ionic strength. The concentration of free iodide was calculated by using the ion-dissociation constant[5,6]

$$(K_d)_{Et_4NI} = 0·2.$$

Et_4NClO_4 was assumed to be almost completely dissociated.[7,8]

The dissolved oxygen in the solution was removed by bubbling for 20 min with pure nitrogen presaturated with acetonitrile vapour; the polarogram was then recorded.

THEORY

DeFord and Hume[9] derived the equation for the shift of the half-wave potential at constant ionic strength and defined the function $F_p(X)$, assuming that the complex species, $(MX_p^{(n-p)+} \ldots)$ dissociate to M^{n+} rapidly and are reduced reversibly to amalgam, that is

$$F_0(X) = \sum_0^p \beta_p[X]_0^p = \text{antilog}\left\{\frac{n}{0{\cdot}0591}\left[(E_{1/2})_s - (E_{1/2})_c\right] + \log\frac{k_s}{k_c}\right\} \tag{1}$$

where $(E_{1/2})_s$ and $(E_{1/2})_c$, k_s and k_c are the half-wave potentials and diffusion-current constants of the simple ion and complex ion, respectively, n denotes the number of electrons involved in the reduction, β_p is the overall formation constant of the pth complex and $[X]_0$ is the concentration of the complexing ligand at the electrode surface; concentrations are used instead of activities. The $F_p(X)$ functions can be written in the following forms if the ionic strength is kept constant.

$$F_1(X) = \frac{F_0(X) - \beta_0}{[X]_0}\ (\beta_0 = 1),$$

$$F_2(X) = \frac{F_1(X) - \beta_1}{[X]_0}$$

$$F_p(X) = \frac{F_{p-1}(X) - \beta_p}{[X]_0} \tag{2}$$

According to Bjerrum[10] the average number $\bar{p}$ of ligands attached is then given by equation (3).

$$\bar{p} = \frac{\mathrm{d}\ln F_0(\mathrm{X})}{\mathrm{d}\ln [\mathrm{X}]_0} = -\frac{\mathrm{d}(E_{1/2})_c}{\mathrm{d}\log [\mathrm{X}]_0}\Big/\frac{0{\cdot}0591}{n} \tag{3}$$

Values of $F_p(\mathrm{X})$ for various concentrations $[\mathrm{X}]_0$ of the complexing ligand can be determined experimentally and equations (1) and (2) solved graphically for β_1, $\beta_2, \ldots, \beta_p$.

If $\mathrm{MX}_p^{(n-p)+}$ is predominant in the solution because of a large value of β_p, equation (1) can be simplified to the equation derived by Lingane.[11]

$$\beta_p[\mathrm{X}]_0^p = \operatorname{antilog}\left\{\frac{n}{0{\cdot}0591}\,[(E_{1/2})_s - (E_{1/2})_c] + \log\frac{k_s}{k_c}\right\} \tag{4}$$

The values of p and β_p are then obtained from plots of $\Delta E_{1/2}$[i.e. $(E_{1/2})_s - (E_{1/2})_c$] *vs.* log $[\mathrm{X}]_0$.

In a solvent of low dielectric constant, the concentration of ligand must be corrected for ion-pair formation by the ligand. The total concentration C_x of the complexing ligand is given by

$$C_x = [\mathrm{X}]_0 + [\mathrm{M}]_0 \sum_1^p p\beta_p[\mathrm{X}]_0^p + [\text{ion-pair}]_0 \tag{5}$$

where $[\text{ion-pair}]_0$ is the concentration of the complexing ligand ion-pairs at the electrode surface. When $E = E_{1/2}$, equation (5) becomes

$$C_x = [\mathrm{X}]_0 + \frac{[\mathrm{M}]_t}{2F_0} \sum_1^p p\beta_p[\mathrm{X}]_0^p + [\text{ion-pair}]_0 \tag{6}$$

where subscript t means total concentration. The dissociation constant k_d of $\mathrm{Et_4NX}$ is given by $k_d = [\mathrm{Et_4N^+}]_t[\mathrm{X}]_0/[\mathrm{Et_4NX}]_t$. For a given series of experiments at constant $[\mathrm{Et_4N^+}]$, the ion-pair concentration is given by

$$[\text{ion-pair}]_0 = [\mathrm{Et_4NX}]_t = [\mathrm{Et_4N^+}]_t[\mathrm{X}]_0/k_d. \tag{7}$$

From equations (6) and (7):

$$[\mathrm{X}]_0 = \left\{C_x - \frac{[\mathrm{M}]_t}{2F_0}\sum_1^p p\beta_p[\mathrm{X}]_0^p\right\}\Big/\left(1 + \frac{[\mathrm{Et_4N^+}]_t}{k_d}\right). \tag{8}$$

A simultaneous solution to equations (1) and (8) cannot easily be obtained. However, when $\mathrm{MX}_p^{(n-p)+}$ is predominant in solution, equation (8) simplifies to

$$[\mathrm{X}]_0 = \left\{C_x - \frac{p}{2}\,[\mathrm{M}]_t\right\}\Big/\left(1 + \frac{[\mathrm{Et_4N^+}]_t}{k_d}\right). \tag{9}$$

Assuming the free halide ion concentration to be

$$[\mathrm{X}]_0 \sim [\mathrm{X}]_t = C_x/\{1 + [\mathrm{Et_4N^+}]_t/k_d\},$$

the value of p is obtained graphically [equation (3)] and the approximate $[\mathrm{X}]_0$ is calculated by using equation (9). This procedure is repeated and finally with the refined $[\mathrm{X}]_0$ the true values of the β's are obtained graphically from the $F_p(\mathrm{X})$ plots.

The method can be applied to reversible electrode reactions of simple and complex ions. For the quasi-reversible electrode process, the reversible half-wave potential, $(E_{1/2})^r$ can be calculated by applying the Matsuda–Ayabe theory.[12]

RESULTS AND DISCUSSION

For each metal iodide complex system the electrode reaction was reversible or quasi-reversible, two-electron and diffusion-controlled. The ion-pair dissociation constant for $Et_4N^+I^-$ was used to correct the free iodide ion concentration. The overall stability constants obtained are concentration constants rather than activity constants.

Cd–I⁻ system

The reduction wave of 0·5m*M* cadmium was split into two waves by addition of iodide (Fig. 2). The height of the first wave (simple ion) and that of the second wave (complex ion) were almost the same at $[I^-]_t/[Cd]_t = 1$. The first wave disappeared at $[I^-]_t/[Cd]_t = 4$, but the second wave was left (reciprocal slope: 0·044 V). The reciprocal slope for the complex wave was about 0·030 V at $[I^-]_t/[Cd]_t \gg 10$ and the electrode reaction was reversible. As shown in Table I, the half-wave potential was shifted to more negative values with increasing concentration of iodide ion and the height of this wave decreased slightly.

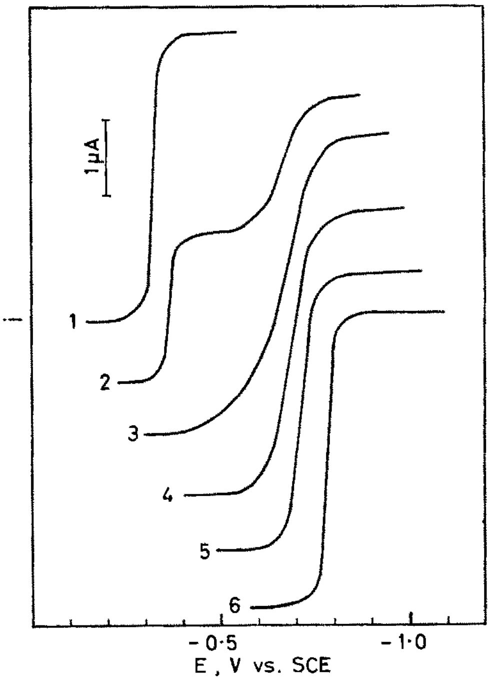

FIG. 2.—Polarograms of 0·50m*M* Cd in the presence of iodide. $[I^-]_t/[Cd]_t$: *1*—0; *2*—1; *3*—2; *4*—3; *5*—4; *6*—10.

The plot of log $[I^-]$ *vs.* $\Delta E_{1/2}$ is shown in Fig. 3. The dashed line shows a plot of the values obtained by using $[I^-]_t = C_{Et_4NI}/(1 + [Et_4N^+]_t/k_d)$ and this plot was found to be linear at $[I^-]_t > 4$m*M*. The value of *p* was calculated to be about 4·3.

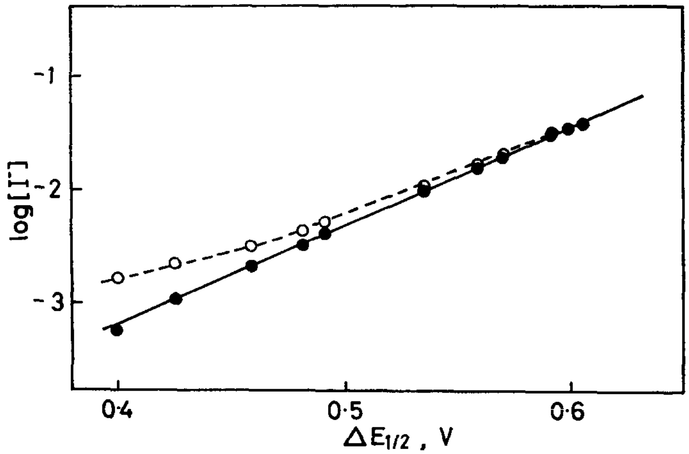

FIG. 3.—Plot of log $[I^-]$ *vs.* $\Delta E_{1/2}$ for Cd–I^- system.
--○-- log $[I^-]_t$ *vs.* $\Delta E_{1/2}$
—●— log $[I^-]_0$ *vs.* $\Delta E_{1/2}$

Then $[I^-]_0$ was calculated again by using equation (9) with $p = 4$. The full line shows the plot of these values to be linear. The value of p was calculated to be $3{\cdot}9_7$. As $0{\cdot}059/2 \log k_s/k_c < 0{\cdot}005$ V under these conditions, this term can be neglected within experimental error.

Extrapolation of the plot of log $[I]_0$ *vs.* $\Delta E_{1/2}$ to $1M$ concentration of $[I]_0$ gave the value of $\Delta E_{1/2}$ for use in equation (4), and thence $\log \beta_4 = 26{\cdot}2$.

In AN, the values of successive formation constants for the cadmium–iodide complexes could not be obtained, because of the large formation constant of CdI_4^{2-}. The value of β_4 was found to be much larger in AN than that $(7{\cdot}17)^{13}$ in formamide.

Zn–I⁻ system

This system behaved similarly to the cadmium system, and gave the value $\log \beta_4 = 18{\cdot}4$ for ZnI_4^{2-}.

There are few data for zinc–iodide complexes, and this complex seems, in general, to be unstable in aqueous solution. The polarographic data are given in Table II.

* Ill-defined.

Mn(II)–I⁻ system

Polarograms of 0·5m*M* manganese(II) in the presence of iodide ion did not exhibit the wave-splitting. The half-wave potential was constant (−1·14 V *vs.* SCE) at $[I^-]_t/[Mn(II)]_t \leqslant 4$ (Table III), but shifted to more negative potentials at $[I^-]_t/[Mn(II)]_t \geqslant 6$ and the height of the wave decreased slightly. A plot of *E vs.* $\log i/(i_d - i)$ indicates that the electrode reaction is quasi-reversible.

A plot of $[E + (2{\cdot}3RT/nF) \log i/(i_d - i)]$ *vs.* *E* is shown in Fig. 4. The reversible half-wave potential, $(E_{1/2})^r$, was obtained by extrapolation to a positive enough potential.

* Plot curved.

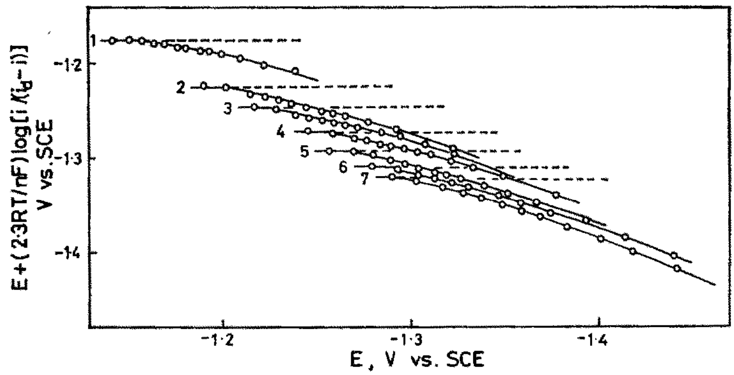

FIG. 4.—Plot of $\{E + 2{\cdot}3RT/nF \log i(i_d - i)\}$ *vs.* E for Mn(II) in the presence of iodide. $[\mathrm{I}^-]_t$: *1*—5·0; *2*—10·0; *3*—15·0; *4*—20·0; *5*—25·0; *6*—30·0; *7*—35·0m*M*.

The plot of $\Delta E_{1/2}[= (E_{1/2})_s - (E_{1/2})_c^{r}]$ *vs.* log $[\mathrm{I}^-]$ is shown in Fig. 5. The dashed line shows the plot of the values obtained by using $[\mathrm{I}^-]_t = C_{\mathrm{Et_4NI}}/(1 + [\mathrm{Et_4N^+}]/k_d)$. This plot is curved and indicates that some species of Mn(II)–iodide complex co-exist in acetonitrile. The value of $\bar{p}$ was calculated by using equation (3) at each point of the curve. Then the values of $[\mathrm{I}^-]_0$ were obtained by using equation (9), and $\Delta E_{1/2}$ *vs* log $[\mathrm{I}^-]_0$ was plotted. This procedure was repeated till the each value of $[\mathrm{I}^-]_0$ became constant. The full line in Fig. 5 shows the final plot. On substitution of these experimental data into the right-hand side of equation (1), the $F_0(\mathrm{X})$ function was calculated, and the $F_p(\mathrm{X})$ function was calculated from the previous $F_{p-1}(\mathrm{X})$ function by equation (2). Figure 6 shows the plot of F_p functions against iodide concentration, $[\mathrm{I}^-]_0$. By extrapolation of the $F_p(\mathrm{X})$ function to $[\mathrm{I}^-]_0 = 0$, the value of β_p was obtained.

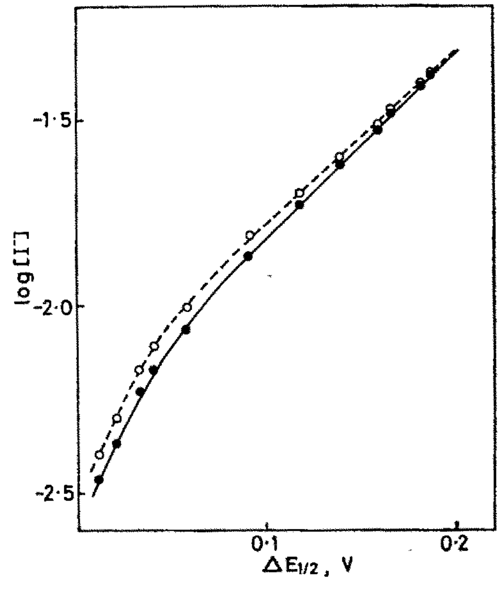

FIG 5.—Plot of log $[\mathrm{I}^-]$ *vs.* $\Delta E_{1/2}$ for Mn(II)-I⁻ system.
--○-- log $[\mathrm{I}^-]_t$ *vs.* $\Delta E_{1/2}$
—●— log $[\mathrm{I}^-]_0$ *vs.* $\Delta E_{1/2}$

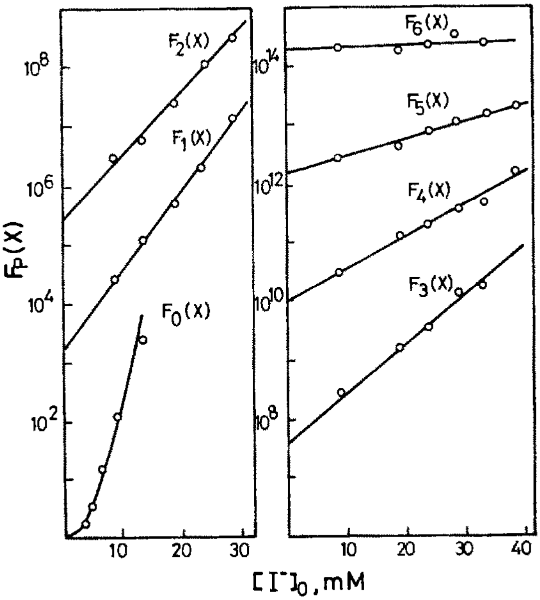

Fig. 6.—Plot of $F_p(X)$ *vs.* $[I^-]_0$ for Mn(II)–I^- system.

The logarithms of the overall formation constants for this system are:

$$\log \beta_1 = 3{\cdot}5, \quad \log \beta_2 = 5{\cdot}6, \quad \log \beta_3 = 7{\cdot}8$$
$$\log \beta_4 = 10{\cdot}0, \quad \log \beta_5 = 12{\cdot}2, \quad \log \beta_6 = 14{\cdot}4$$

In this procedure, extrapolation to zero concentration of complex is used so that the values of β_p can be obtained without using the value of the activity coefficient of the complexing ligand.

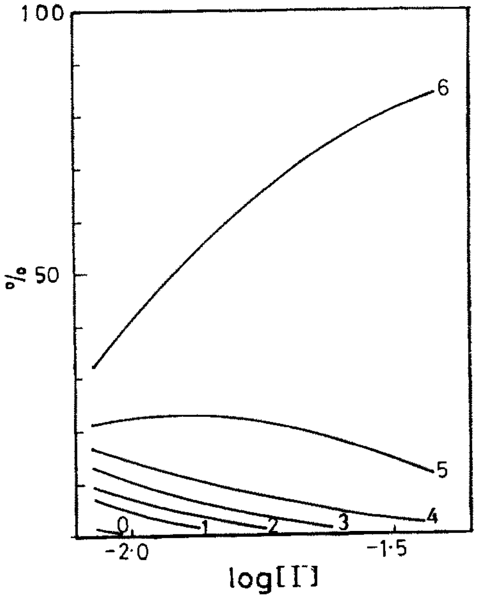

Fig. 7.—Distribution diagram for manganese iodide system. Number on the curve indicates number of ligands bound in complex

The value of p was calculated to be 6 in the range of high concentration of iodide ion as shown in Fig. 5. By use of equation (4), log β_6 was calculated at $[I^-]_0 =$ 38·5mM and found to be 14·8, in good agreement with the value obtained by the DeFord and Hume method. MnI_6^{4-} is the predominant species in acetonitrile medium.

The distribution of manganese(II)-iodide complexes in acetonitrile was calculated as a function of ligand concentration and is shown in Fig. 7.

In a mixture of cadmium, zinc and manganese(II) iodide complexes, each wave is clearly separated from the others and the wave-height for each complex is proportional to the metal concentration in the range from 0·1 to 1·0mM in acetonitrile medium.

Acknowledgements—The authors wish to express their sincere thanks to the Ministry of Education for its financial support of this work.

Zusammenfassung—Jodidkomplexe von Cadmium, Zink und Mangan(II) wurden polarographisch in Acetonitril untersucht und die Elektrodenreaktionen dieser Komplexe diskutiert. Die Bruttostabilitätskonstanten der Jodidkomplexe dieser Metallionen wurden ermittelt und für den Einfluß des ionenpaarbildenden Elektrolyten korrigiert. Die log β_4-Werte von CdI_4^{2-} und ZnI_4^{2-} betragen 26,2 bzw. 18,4; beim Mangan(II)-Jodidkomplex wurden log $\beta_1 = 3,5$, log $\beta_2 = 5,6$, log $\beta_3 = 7,8$, log $\beta_4 = 10,0$, log $\beta_5 = 12,2$ und log $\beta_6 = 14,4$ gefunden. In gewissen Grenzen ist die Stufenhöhe jedes Komplexes proportional zur Metallkonzentration.

Résumé—Les complexes d'iodure de cadmium, zinc et manganèse(II) ont été étudiés polarographiquement en acétonitrile et l'on discute des réactions à l'électrode de ces complexes. On a évalué les constantes de stabilité globales des complexes iodure de ces ions métalliques et les a corrigées pour l'influence d'appariement d'ions de l'électrolyte. Les valeurs de log β_4 de CdI_4^{2-} et ZnI_4^{2-} sont de 26,2 et 18,4 respectivement et les valeurs trouvées pour le complexe d'iodure de Mn(II) sont log $\beta_1 = 3,5$; log $\beta_2 = 5,6$; log $\beta_3 = 7,8$; log $\beta_4 = 10,0$; log $\beta_5 = 12,2$ et log $\beta_6 = 14,4$. Dans certaines limites, la hauteur de vague pour chaque complexe est proportionnelle à la concentration du métal.

USE OF LIGAND BUFFERS FOR IMPROVED SELECTIVITY IN THE POLAROGRAPHIC DETERMINATION OF METALS

POLAROGRAPHIC DETERMINATION OF ZINC IN THE PRESENCE OF A LARGE AMOUNT OF CADMIUM

Summary—The use of ligand buffers composed of a chelating agent and an excess of polarographically inert metal is recommended for the selective polarographic determination of a metal in the presence of a second metal, which has a polarographic wave at a less negative potential than the metal to be determined. Theoretical considerations on the optimum ligand concentration and the optimum composition of the ligand buffer are followed by the determination of zinc in cadmium as an example.

IN THE POLAROGRAPHIC determination of a metal M_I, difficulties are encountered in the presence of a large amount of a second metal M_{II}, which gives a polarographic wave at a more positive potential. In such a case, one can avoid the interference of M_{II} by utilizing a ligand L which forms more or less stable complexes with M_{II}. In the presence of such a masking agent, the wave of M_{II} either diminishes or moves to a more negative potential.[1] However, this method cannot be useful when the ligand L affects the polarographic wave of M_I: if the ligand L forms complexes with M_I, the half-wave potential of M_I moves to a more negative potential and sometimes the diffusion current of M_I diminishes.

In this paper, the use of ligand buffers composed of a chelating agent and an excess of inert metal M_{III} is recommended for the selective polarographic determination of M_I in the presence of a second metal M_{II}. The determination of zinc in cadmium will be given as an example.

THEORETICAL CONSIDERATIONS

Suppose that a chelating agent L forms complexes with metals M_I and M_{II} and that the complexes M_IL and $M_{II}L$ do not give polarographic waves at the potentials where M_I and/or M_{II} give polarographic waves. In order to mask only the M_{II} wave by the chelating agent L, the conditional formation constant of $M_{II}L$, $K_{M_{II}'L}$, should be larger than that for M_IL, $K_{M_I'L}$. When an excess of the ligand L is added to a solution containing M_I and M_{II}, the wave of M_{II} is masked and, the excess of L forming M_IL_I with M_I, the wave-height of M_I diminishes too. However the determination of M_I would be possible, if one could find a third metal M_{III},* for which

---

* M_{III} should not interfere with the polarographic wave of M_I.

$K_{M_{II}'L} > K_{M_{III}'L} > K_{M_I'L}$: in the presence of an excess of M_{III} (ligand buffer[2] of L with an excess of M_{III}), the excess of ligand L forms $M_{III}L$ and liberates M_I from M_IL.

Optimum ligand concentration

The total concentrations of metals M_I and M_{II} are denoted as C_{M_I} and $C_{M_{II}}$ respectively. $[M_I']$ and $[M_{II}']$ refer to the total concentrations of M_I and M_{II} not combined with L. From the conditional formation constant of M_IL, $K_{M_I'L}$, we have

$$\frac{[M_IL]}{[M_I']} = K_{M_I'L}[L] \qquad (1)$$

The wave-height of M_I being proportional to $[M_I']$, $[M_IL]$ should not exceed 1% of C_{M_I} for successful quantitative polarographic determination of M_I: $[M_IL]/[M_I']$ should be smaller than 10^{-2}. Then from equation (1), we have

$$K_{M_I'L}[L] \leqslant 10^{-2}$$

or

$$[L] \leqslant 10^{-2}/K_{M_I'L} \qquad (2)$$

Now we consider the masking of M_{II}. From the conditional formation constant of $M_{II}L$, $K_{M_{II}'L}$, we have

$$\frac{[M_{II}L]}{[M_{II}']} = K_{M_{II}'L}[L] \qquad (3)$$

Thus in order to mask M_{II} as completely as possible, most of M_{II} should be in the form of $M_{II}L$: $[M_{II}L]/[M_{II}']$ or $K_{M_{II}'L}[L]$ should be sufficiently high. It should be noted, however, that the upper limit of [L] is given by equation (2).

Substitution of equation (2) into (3) yields

$$\frac{[M_{II}L]}{[M_{II}']} \leqslant \frac{K_{M_{II}'L}}{10^2 K_{M_I'L}} \qquad (4)$$

From equation (4) we realize that $K_{M_{II}'L}/K_{M_I'L}$ should be sufficiently large if a large amount of M_{II} is to be masked: when $K_{M_{II}'L}/K_{M_I'L} = 10^4$, the wave-height of M_{II} diminishes by a factor of 100 at the ligand concentration [L] given by equation (2′), whereas the decrease in the wave-height of M_I is only 1% of C_{M_I} at the same ligand concentration.

$$[L] = 10^{-2}/K_{M_I'L} \qquad (2')$$

Even though the wave-height of a second metal M_{II} (which is supposed to give rise to a wave at a potential less negative than that of M_I) attains several times that of M_I, the presence of the metal M_{II} does not make any difficulty in the polarographic determination of the metal M_I. Therefore when the condition $K_{M_{II}'L}/K_{M_I'L} = 10^4$ can be realized, the polarographic determination of M_I is possible in the presence of several hundred times as high a concentration of M_{II} as that of M_I.

Optimum composition of the ligand buffer[2]

The metal M_{III} to be added as a component of the ligand buffer for masking the metal M_{II} should not interfere with the polarographic wave of the metal M_I and should satisfy the condition: $K_{M_{II}'L} > K_{M_{III}'L} > K_{M_I'L}$. The optimum concentration of M_{III} is calculated as follows.

Denoting by C_L and $C_{M_{III}}$ the total concentrations of the added chelating agent L and the metal M_{III} respectively, we have

$$C_L = [M_IL] + [M_{II}L] + [M_{III}L] + [L'] \tag{5}$$

In equation (5) $[M_IL]$ and $[L']$ are very small in the presence of excess of M_{III} and can be neglected. Moreover, when masking of M_{II} is complete, $[M_{II}L]$ can be regarded as $C_{M_{II}}$. Then from equation (5) we have

$$[M_{III}L] = C_L - C_{M_{II}} \tag{5'}$$

From equation (5′) and the conditional formation constant of $M_{III}L$, $K_{M'_{III}L}$, we get

$$C_{M_{III}} = (C_L - C_{M_{II}})\left(1 + \frac{1}{[L]K_{M'_{III}L}}\right) \tag{6}$$

where [L] should be fixed at an optimum value as determined in the preceding section. Then the favourable value of $C_{M_{III}}$ is found from equation (6) for given values of C_L and $C_{M_{II}}$.*

DETERMINATION OF ZINC IN THE PRESENCE OF CADIUM

Cadmium and zinc give rise to a well-defined polarographic wave in NH_3–NH_4Cl supporting electrolyte. The half-wave potential of the former in this solution is about −0·8 V and that of the latter is about −1·3 V *vs*. SCE. Thus it is not difficult to determine cadmium in the presence of a large amount of zinc, but a large amount of cadmium makes difficult the polarographic determination of zinc. The formation constants of EGTA [ethyleneglycol-*bis*(2-aminoethyl ether)-*N*,*N*,*N′*,*N′*-tetra-acetic acid] complexes of cadmium and zinc are:[3] $K_{CdL} = 10^{16\cdot7}$ and $K_{ZnL} = 10^{14\cdot5}$. The difference of these two constants is larger than that of the corresponding EDTA complexes. Thus EGTA was chosen for the selective masking of cadmium in the presence of zinc.

In Fig. 1, logarithmic conditional formation constants $\log K_{M'L}$ are plotted for cadmium, zinc, calcium and barium as a function of $\log [NH_3]$.† As calcium and barium do not form ammine complexes, we can realise the following condition for a certain favourable value of $[NH_3]$: $K_{Cd'L} > K_{Ba'L}(K_{Ca'L}) > K_{Zn'L}$.

In Fig. 2 are given polarograms of cadmium and zinc in NH_3–NH_4Cl supporting electrolyte with and without added EGTA. In the presence of EGTA the cadmium wave disappears and the zinc wave-height diminishes.

---

* When masking of M_{II} is not quantitative and $C_{M_{II}}$ cannot be regarded as $[M_{II}L]$, (5′) is rewritten as:

$$C_L = [M_{II}L] + [M_{III}L]$$

Then from this equation and the conditional formation constants of $M_{II}L$ and $M_{III}L$, we have

$$C_{M_{III}} = \left\{C_L - C_{M_{II}}\left(\frac{[L]K_{M_{II}'L}}{1 + [L]K_{M_{II}'L}}\right)\right\}\left(\frac{1 + [L]K_{M'_{III}L}}{[L]K_{M'_{III}L}}\right)$$

for the favourable value of $C_{M_{III}}$ in the selective determination of M_I in the presence of M_{II}.

† We know of the formation of such a mixed ligand complex as $ZnLNH_3$ for L = EDTA. Though in this case also such mixed ligand complexes are expected, they are not taken into consideration, because we have no available data for their formation constants. The stepwise formation constants used to calculate the conditional formation constants are $\log K_1 = 2{\cdot}37$, $\log K_2 = 2{\cdot}44$, $\log K_3 = 2{\cdot}50$ and $\log K_4 = 2{\cdot}15$ for zinc ammine complexes, and $\log K_1 = 2{\cdot}65$, $\log K_2 = 2{\cdot}10$, $\log K_3 = 1{\cdot}44$ and $\log K_4 = 0{\cdot}93$ for cadmium ammines.

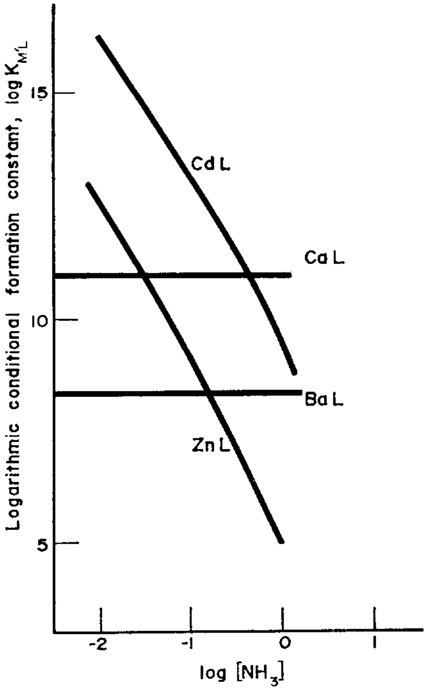

FIG. 1.—Logarithmic conditional formation constants of EGTA complexes of cadmium, zinc, calcium and barium as a function of log [NH$_3$].

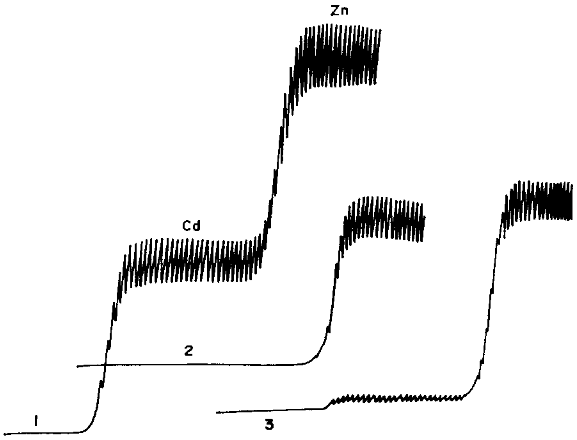

FIG. 2.—Polarograms of cadmium and zinc.

(1) Cd: 0·9 × $10^{-3}M$; Zn: 1 × $10^{-3}M$ in 0·5M NH_3–0·1M NH_4Cl and 0·01% gelatine.

(2) Solution (1) + 1·3 × $10^{-3}M$ EGTA.

(3) Solution (2) + 2 × $10^{-3}M$ $BaCl_2$.

Log $K_{Zn'L}$ being 6·2 in 0·5M NH_3 (Fig. 1), [L] should be smaller than $10^{-8 \cdot 2}$ in order to avoid diminution of the zinc wave in the presence of EGTA. Then we consider the masking of cadmium for $[L] = 10^{-8 \cdot 2}$. Log $K_{Cd'L}$ being 10·6 in 0·5M NH_3 (Fig. 1), we have immediately from equation (3): $[CdL]/[Cd'] = 10^{2 \cdot 4}$. Thus cadmium would be completely masked in this medium. As a metal to be added as a component of ligand buffer, barium is suitable, because $K_{Ba'L} = 10^{8 \cdot 4}$ (Fig. 1).* When barium is added in twice as much as the excess amount of EGTA ($[Ba^{2+}] = [BaL]$), $[L] = 10^{-8 \cdot 4}$ (see Ref. 2 for details).

Table I summarizes the wave-heights of zinc and cadmium in 0·5M NH_3–NH_4Cl

TABLE I.—DIFFUSION CURRENT OF ZINC AND CADMIUM

1·3	5	0·42	6·04
1·3	10	0·66	6·06

$C_{Cd} = 1 \cdot 0 \times 10^{-3}M$; $C_{Zn} = 1 \cdot 0 \times 10^{-3}M$; $C_{EGTA} = 1 \cdot 1$–$1 \cdot 3 \times 10^{-3}M$; $C_{Ba} = 2$–$30 \times 10^{-4}M$; 0·5M NH_3–0·1M NH_4Cl; 0·01% gelatine.

containing EGTA and $BaCl_2$ in different proportions. When $C_{Ba}/(C_{EGTA} - C_{Cd})$ is 2, the wave-height of zinc is a little too low, while the recovery of zinc is quantitative for $C_{Ba}/(C_{EGTA} - C_{Cd}) \geqslant 5$. Under these conditions the wave-height of cadmium diminishes to between 1/10 and 1/20 of its normal value.

Figure 3 demonstrates the good linearity of the wave-height of zinc plotted *vs.* zinc concentration under the following conditions: $C_{Cd} = 5 \times 10^{-3}M$; $C_{Zn} = 0 \cdot 1$–$1 \times 10^{-3}M$; $C_{EGTA} = 5 \cdot 5 \times 10^{-3}M$ and $C_{Ba} = 5 \times 10^{-3}M$. In the same figure, the wave-height of cadmium is given as a broken line. Thus by the present method we can determine zinc in the presence of cadmium in concentrations 10–50 times that of the zinc.

Experiments revealed that the masking of cadmium was less complete than expected from the equilibrium considerations, and that a concentration of barium higher than calculated was necessary to realize a quantitative wave-height for zinc. This is because dissociations such as

$$CdL^{2-} + 4NH_3 \rightarrow Cd(NH_3)_4^{2+} + L^{2-}$$

would proceed at the electrode surface and some *kinetic* nature would be involved in the cadmium wave. The free ligand produced at the electrode surface suppresses the

---

* For 0·1M NH_3 a ligand buffer containing excess of calcium can be used for our purpose. However, the conditional formation constant being proportional to about the fourth power of $[NH_3]$, the concentration of ammonia should strictly be adjusted in the ligand buffer with excess of calcium. Thus we prefer the ligand buffer with excess of barium, for which the optimum concentration of ammonia is higher (0·5M) and easily kept constant.

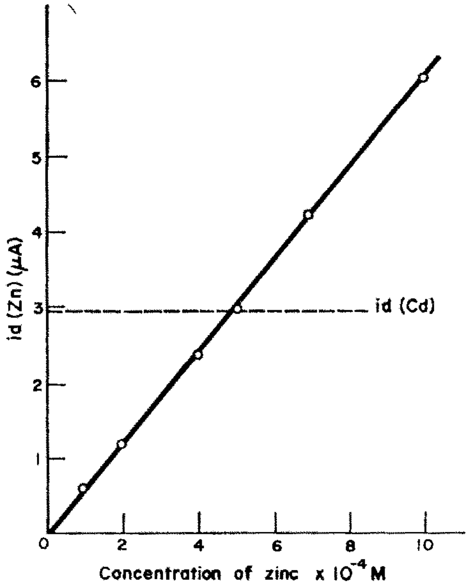

FIG. 3.—Wave-height of zinc as a function of zinc concentration.
$C_{Cd} = 5 \times 10^{-3}M$; $C_{Zn} = 0{\cdot}1\text{–}1 \times 10^{-3}M$; $0{\cdot}5M$ NH_3–$0{\cdot}1M$ NH_4Cl; $C_{EGTA} = 5{\cdot}5 \times 10^{-3}M$ and $C_{Ba} = 5 \times 10^{-3}M$.
Broken line indicates the wave height of cadmium under the same conditions.

zinc wave. Thus it is necessary to use a higher concentration of barium than calculated for the quantitative recovery of zinc.

Of metals giving rise to polarographic waves in ammoniacal solution, copper gives a wave at a more positive potential and the other metals such as nickel and cobalt do not give polarographic wave in the ammonia–EGTA supporting electrolyte. Therefore these metals do not interfere in the present method.

The use of ligand buffers can solve many problems in polarographic analysis, for example, polarographic determinations of cadmium in indium and lead in bismuth.

Cadmium and indium give polarographic waves at the same potential in many supporting electrolytes. In EDTA–Th ligand buffer, the indium wave disappears, while the cadmium wave is not affected and can be determined.

Bismuth gives a wave at a potential a little more positive than that of lead. The ligand buffer EDTA–Th masks the bismuth wave, while the lead wave remains unchanged ($\log K_{Bi'Y} > \log K_{Th'Y} > \log K_{Pb'Y}$). The method would thus be applicable to the determination of lead in crude copper after separation of bismuth and lead from copper by co-precipitation with ferric hydroxide.

EXPERIMENTAL

Reagents

EGTA solution, 0·10. Ten ml of $1M$ sodium hydroxide are added to 3·804 g of the pure reagent, and the whole is diluted to 100 ml.

Cadmium solution, $0{\cdot}01M$. Metallic cadmium (99·99%, 0·562 g) is dissolved in a small amount of hydrochloric acid. The excess of acid is expelled by evaporation and the solution is diluted to 500 ml.

Zinc solution, $0{\cdot}01M$. Metallic zinc (0·327 g) is dissolved in a small amount of hydrochloric acid and the same procedure is followed as for the cadmium solution.

Barium solution, 0·10*M*. Reagent grade $BaCl_2 \cdot 2H_2O$ (2·44 g) is dissolved in 100 ml of distilled water. The solution is standardized by EDTA titration.

Recommended procedure

In a 50-ml measuring flask take a 10-ml sample containing 20–25 mg of cadmium and 0·3–5 mg of zinc. Add 5 ml of 5*M* NH_3–1*M* NH_4Cl supporting electrolyte, and 3 ml of $10^{-1}M$ EGTA solution, 5 ml of $10^{-1}M$ $BaCl_2$ solution and 5 ml of 0·1% gelatine solution. Then dilute to the mark (the optimum barium concentration is 5–10 times the concentration of excess of EGTA). Take an aliquot of the solution in a polarographic cell and remove the dissolved oxygen with nitrogen gas which has passed through 0·5*M* ammonia solution. Record the polarogram from −0·5 to −1·5 V.

Zusammenfassung—Die Verwendung von Ligandenpuffern aus einem Chelatbildner und einem Überschuß von polarographisch inaktivem Metall wird vorgeschlagen für die selektive polarographische Bestimmung eines Metalls in Gegenwart eines zweiten Metalls, das eine polarographische Stufe bei einem weniger negativen Potential besitzt als das zu bestimmende Metall. Theoretische Erwägungen über die optimale Ligandenkonzentration werden angestellt sowie die Bestimmung von Zink in Cadmium als Beispiel ausgeführt.

Résumé—On recommande l'emploi de tampons à base de ligand, composés d'un agent chélatant et d'un excès d'un métal polarographiquement inerte, pour le dosage polarographique sélectif d'un métal en la présence d'un second métal qui a une vague polarographique à un potentiel moins négatif que le métal à doser. Des considérations théoriques sur la concentration optimale du ligand et la composition optimale du tampon à base de ligand sont suivies par le dosage du zinc dans le cadmium en tant qu'exemples.

SHORT COMMUNICATIONS

Flow method in high-resolution nuclear magnetic resonance

(*Received* 7 *June* 1971. *Accepted* 2 *September* 1971)

RAPID CHEMICAL EXCHANGES have been studied by the variation in nuclear magnetic resonance (NMR) line shape, whereas slow reactions have been examined by the integration of NMR spectra. No paper has appeared on a device to follow reactions with a half-life in the range 1–10^3 sec, although low-resolution NMR flow-cells have been examined by many investigators.[1–7] The present paper deals with designs of flow-cells and their application in the observation of labile intermediates such as the yellow thiol forms of thiamine and monoethyl carbonate in alkaline solutions.

EXPERIMENTAL

A Varian A-60A spectrometer with a room-temperature probe was used. Five types of flow-cell were examined: (*A*) a straight glass tube, 1·6 mm bore, (*B*) a pipette-type tube, 1 and 3 mm bore, (*C*) a spiral capillary, 1 mm bore, in a conventional sample tube, 4·25 mm bore, with carbon tetrachloride, (*D*) a jet in the base of a conventional tube, (*E*) the conventional spinning tube with an inlet at the base and an outlet at a height of about 50 mm. Samples were fed from 100-ml syringes through plastic tube to the inlet. A glass Y-tube or a conventional jet mixing chamber was used to mix two kinds of fluid.

An ultraviolet spectrum of the yellow thiol form of thiamine was measured with a Perkin–Elmer 450 spectrometer in a 1-mm flow-cell at 8 sec after mixing 1m*M* thiamine hydrochloride and 1*M* sodium hydroxide in equal proportions. The molar absorptivities were $8{\cdot}5 \times 10^2$ l.mole.$^{-1}$ mm^{-1} at λ_{max} 335 nm, $1{\cdot}3 \times 10^3$ at 245 nm (shoulder) and $1{\cdot}6 \times 10^3$ at 230 nm. On the flow being stopped, the absorbance at 335 nm decreased at a rate of $8{\cdot}8 \times 10^{-4}$ sec^{-1} at 23° to form the colourless thiol (λ_{max} 235 and 263 nm).

RESULTS

Test of the flow-cells

The best results were obtained with flow-cell (*E*). The half-height width (*W*) of the methyl triplet in ethanol increased slightly from 1 to 1·5 Hz at a flow-rate of 3 ml/min. The peak height (*h*) and the intensity of the integrated curve (*i*) decreased rapidly with increase in the field (H_1). The values of *h* and *i* in the flow system were smaller than those in the stopped-flow system at low H_1 whereas the values at higher H_1 were nearly equal. The inhomogeneities of the static field (ΔH_0) in the directions of the flow (*y*) and the plane of spinning (*xz*) were averaged by the movements of the sample.

The resolution and intensities in cells *A*–*D* (without spinning) were decreased by the flow: *W* by 2–7 Hz, *h* by 1/10 and *i* by 1/5 at $H_1 = 0{\cdot}02$ mG. The circular flow in cells *C* and *D* was not sufficient to average ΔH_0 in the plane.

Labile intermediate in reaction of thiamine with alkali

It has been established from the ultraviolet absorption spectrum that the thiazolium form of thiamine (I) is converted by alkali into the colourless thiol form (III) *via* the pseudo-base and the yellow thiol form (II). Conventional NMR[9] gave a spectrum of a mixture of the colourless and yellow thiols for an alkaline solution of thiamine. Flow NMR with cell *E* was successfully applied to this reaction.

A yellow mixture of 1*M* thiamine hydrochloride and 4*M* potassium hydroxide at 5 sec after mixing gave an NMR spectrum corresponding to the pure yellow thiol. When the flow was stopped, the colourless thiol was formed at the expense of the yellow thiol form. The first-order rate constant of the reaction was estimated to be $1{\cdot}7 \times 10^{-3}$ sec^{-1} at 38°.

The structure of the yellow thiol form (II) proposed by Maier[8] is in accord with the chemical shifts. The peaks due to the protons on the thiazolium ring shift upfield during the reaction, whereas the peaks due to the protons on the pyrimidine ring remain almost constant. These shifts correspond to the change of a quaternary nitrogen atom (I) into a tertiary nitrogen atom (II and III).

Alkaline hydrolyses of ethoxacarbonyl compounds

When a mixture (1:1) of 1*M* urethane and 1*M* potassium hydroxide was flowing through the cell, only the NMR spectrum of urethane (τ: 8·78*t*, 5·92*q*) was observed. On stoppage of the flow, ethanol (τ: 8·84*t*, 6·36*q*) was formed from the urethane. The rate constant was $1{\cdot}6 \times 10^{-4}$ sec^{-1} at 38°.

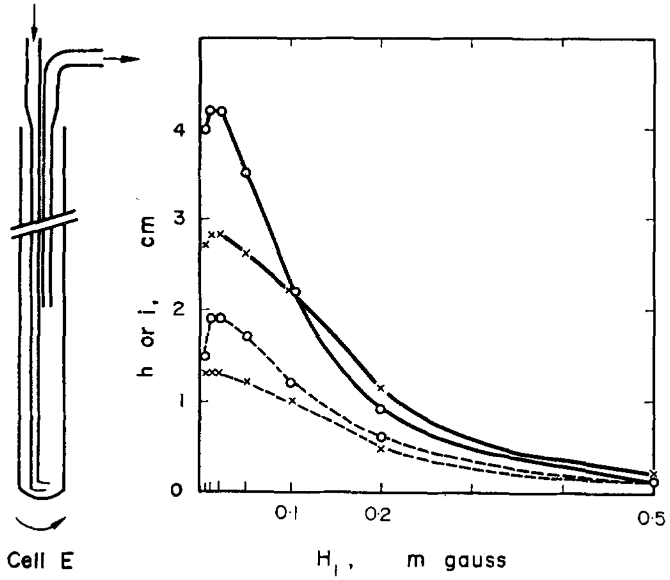

FIG. 1.—Dependence of the peak height (*h*, ———) and the integrated height (*i*, - - -) for the methyl triplet of ethanol on the radiofrequency field (H_1). ×, in flow-cell *E* at a flow-rate of 3 ml/min; ○, without flow.

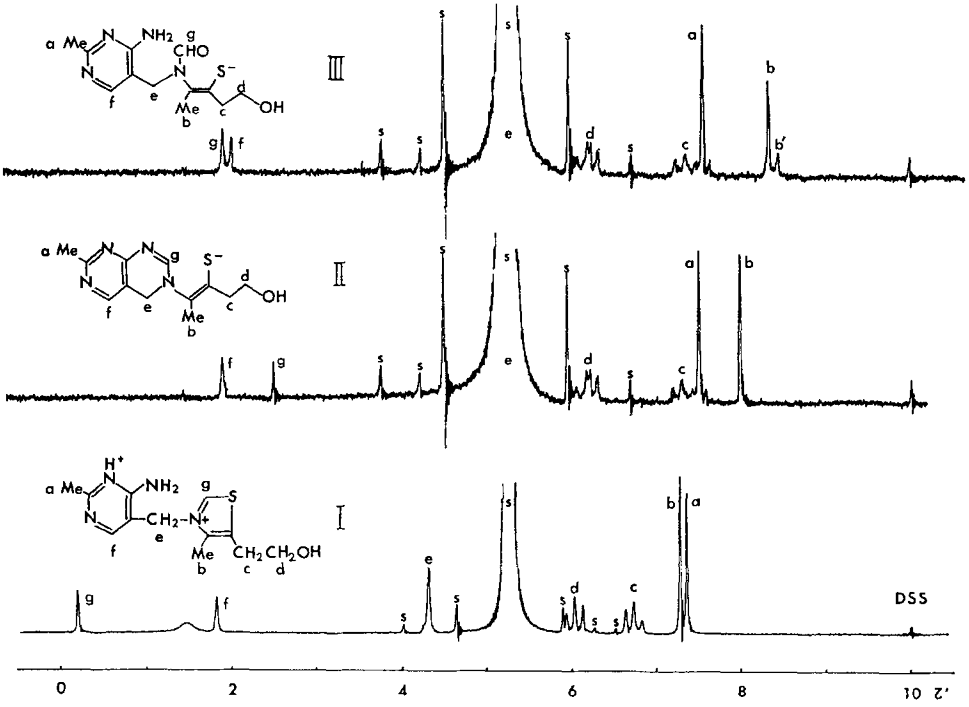

FIG. 2.—60-MHz NMR spectra of 1*M* thiamine hydrochloride (I) flowing in the cell *E*, the yellow thiol form (II) at 5 sec after mixing (I) with 4*M* KOH (1:1), and the colourless thiol form (III) at 20 min after the flow has stopped. *s*—solvent (water); *b*′—rotational isomer, 23%; DSS—sodium 2,3-dimethyl-2-silapentane-5-sulphonate as internal standard.

Any intermediate such as monoethyl carbonate or the complex of urethane with hydroxide ions was not observed. In the course of the alkaline hydrolysis of diethyl carbonate (τ: 8·74*t*, 5·80*q*) to ethanol, monoethyl carbonate (τ: 8·8*t*, 6·06*q*) was obtained as an intermediate.

DISCUSSION

Moderately rapid reactions with a half-life of 1–10^3 sec can be studied by high-resolution NMR spectroscopy, using the flow-cell *E*. A large flow-rate is necessary. To obtain the maximum signal from a flowing liquid, it is necessary to work at a relatively high field (H_1), which results in a broadening of the peaks. Saturation with increasing H_1 in the non-flow system was more rapid than that in the flow system, where rates of relaxation are comparable with the flow rate. The conventional instrument takes about 5 min to cover the range of 10 ppm and so requires large amounts of sample. Fourier NMR is expected to reduce this amount and decrease the time.

Zhernovoi[4] has studied a flow-through probe consisting of 2 successive coils in a static field, using broad-line NMR ($W = 60$–120 Hz). In such a flow probe for high-resolution NMR, reaction of prepolarized molecules in the first coil will be followed by depolarization in the second coil.

Application of urease to the precipitation of manganese(II) oxinate from homogeneous solution with urea in the presence of calcium

(*Received* 7 *June* 1971. *Accepted* 19 *June* 1971)

SINCE 1937 when Willard *et al.* proposed precipitation from homogeneous solution (PFHS) for the precipitation of aluminium hydroxide,[1] the method has been utilized for the gravimetric determination of many metallic and non-metallic ions. In the PFHS method, the hydrolysis of urea has often been applied to raise the pH of the solution. We have found that urease can be used in the hydrolysis of urea in the PFHS method and have applied it in the precipitation of nickel dimethylglyoximate[2] and of cobalt 8-hydroxyquinaldinate.[3] Although precipitation of manganese(II) oxinate had not been recommended as a gravimetric method, it has been found satisfactory.[4] In this study, it was found that rate of increase of pH depends on the amount and purity of urease used and the concentration of citric acid, *etc.*[4] The rate of pH increase can be regulated by changing the urease concentration if other experimental conditions are kept constant.

The pH ranges for precipitation of calcium and manganese oxinates are similar.[5,6] Therefore the effect of calcium on the precipitation of manganese(II) oxinate was investigated.

EXPERIMENTAL

Reagents

Manganese solution. A solution containing 0·25–3 g of manganese(II) per litre was prepared by dissolving manganese(II) sulphate in water. The manganese solution was standardized with EDTA solution which had been standardized with metallic zinc (99·999% pure), Eriochrome Black T being used as indicator.

Calcium solution. Aqueous solution, 1 mg/ml.

Ascorbic acid. Used as the dry powder.

Citric acid. Aqueous solution, 10%.

Urea. Aqueous solution, 20%.

Oxine. Ethanolic solution (2%) prepared immediately before use.

Urease. Aqueous solution (0·01%) prepared immediately before use (activity 8300 units/g, Sigma Chem. Co. Type VI).

All chemicals used were analytical-reagent grade.

Procedure

To a solution containing 24·46 mg of manganese(II) and 20 mg of calcium were added 100 mg of ascorbic acid, 1 ml of 10% citric acid solution, 50 ml of 20% urea solution, and 7 ml of 2% ethanolic oxine solution. The solution was diluted to *ca.* 200 ml and the pH was adjusted to 5·0 with ammonia solution. Four series of such solutions (eight solutions per series) were prepared and then urease was added: 0·6 mg (series *a*), 0·3 mg (series *b*), 0·2 mg (series *c*) and 0·1 mg (series *d*). These solutions were kept at 35°. After a measured time the pH of the solution was measured and the precipitate formed was filtered off, washed, dried and weighed.

RESULTS AND DISCUSSION

The effect of the urease concentration on the rate of pH increase is shown in Fig. 1. If the pH of the solution rises rapidly (Fig. 1*a*), the precipitates formed are similar to those produced by the

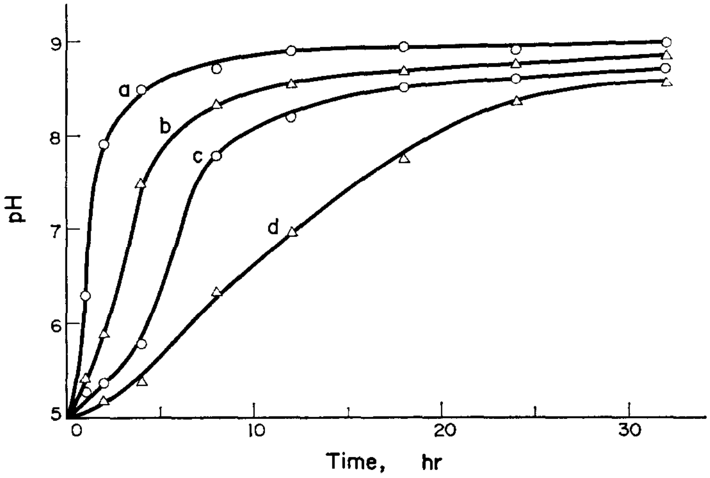

FIG. 1.—pH-time curves. *a*, urease 0·6 mg; *b*, urease 0·3 mg; *c*, urease 0·2 mg; *d*, urease 0·1 mg.

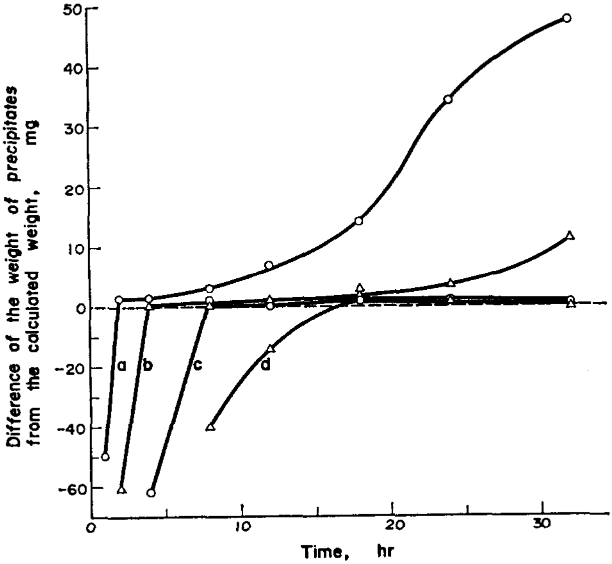

FIG. 2.—Effect of the reaction time on the formation of precipitates. (Expected weight of Mn(II) oxinate: 152·86 mg.)

ordinary method. When the pH takes 6–10 hr to reach a value of >8, satisfactory precipitates are obtained.

The weights of the precipitates are plotted against the reaction time in Fig. 2. The broken line in Fig. 2 shows the calculated weight of manganese(II) oxinate from the amounts of manganese taken. The amount of precipitate formed increases with reaction time. When the increase in pH is rapid, the weight of precipitate increases above the calculated value (Fig. 2*a*), but when the pH increases slowly, the weight excess is small (Fig. 2*b*–*d*).

Calcium in the precipitates

It was assumed that the increased weights of precipitates were due to calcium. To prove this, the precipitates were dissolved in dilute hydrochloric acid and the calcium contents were determined by atomic-absorption spectroscopy. The results are shown in Fig. 3.

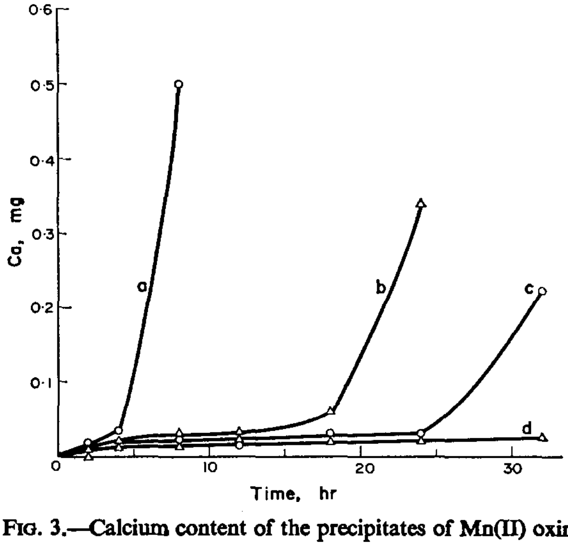

FIG. 3.—Calcium content of the precipitates of Mn(II) oxinate.

TABLE I.—DETERMINATION OF MANGANESE

		PFHS method		Conventional method	
Mn taken, *mg*	Ca taken, *mg*	Mn found, *mg*	Difference, *mg*	Mn found, *mg*	Difference, *mg*
19·38	5	19·39	+0·01	19·54	+0·16
19·38	10	19·42	+0·04	19·54	+0·07
19·38	20	19·41	+0·03	20·21	+0·83
19·38	40	19·42	+0·04	22·88	+3·50
22·91	60	23·06	+0·15	—	—
22·91	100	23·87	+0·16	—	—

When the pH of the solution rose rapidly (Fig. 3*a*), the calcium content in the precipitate increased rapidly with reaction time. However, when the pH rose more slowly, the calcium content of the precipitates stayed within limits comparable with the experimental error. The calcium contained in the precipitate increases rapidly at pH >8·5. This rapid increase in calcium content may be due to the precipitation of calcium carbonate. The presence of calcium carbonate may be proved by the fact that when the precipitate was dissolved in dilute hydrochloric acid, carbon dioxide was evolved. Carbon dioxide was generated by decomposition of urea and dissolved in the solution. When a solution of calcium containing urea was heated, calcium carbonate was precipitated at pH values over 8·5, and the weights of the precipitates increased rapidly at pH >8·5, which agrees with the literature values of the pH at which calcium carbonate is precipitated.

Determination of manganese(II) as oxinate in the presence of calcium

Manganese(II) was determined satisfactorily as the oxinate in the presence of calcium by the procedure given, using 0·3 mg of urease and keeping the mixed solution for 8 hr at 35°. The results are shown in Table I with the results obtained by the conventional wet method.[7]

Qualitative analysis of ultraviolet-absorbing substances by use of fluorescent materials

(*Received* 7 *June* 1971. *Accepted* 23 *November* 1971)

THE SPECTRAL REGION to which the human eye responds is restricted to the narrow range of about 400–800 nm. Consequently, a great number of colour reactions have been developed for detection of colourless substances, and many new reactions are proposed every year. On the other hand, for detection of colourless substances absorbing ultraviolet light, use of fluorescent materials has been developed, and recently a mixed fluorescent material was proposed for detection of these substances as coloured compounds, and thus to increase the selectivity of detection.

USE OF FLUORESCENT MATERIALS FOR DETECTION OF ULTRAVIOLET-ABSORBING SUBSTANCES

Brockman and Volpers[1] were the first to separate colourless substances on adsorption columns impregnated with a fluorescent material. The adsorption zones appeared under monochromatic ultraviolet light as dark bands against a brilliant background. They used Morin, a pentahydroxyflavone, to make alumina fluoresce (300 mg per 500 g of alumina), berberine for silica gel, diphenylfluoridine sulphonic acid for calcium carbonate, and Morin for magnesium oxide. This method is applicable to those substances which absorb ultraviolet light in the wavelength region causing fluorescence.

Sease[2] described the use of silica gel mixed with 2·5 % of fluorescent zinc sulphide, and Brockmann[1] suggested its slight adsorptivity. The usable wavelength range was limited to 330–390 nm. Sease[3] extended the range to 230–390 nm by admixture with 2·5 % of fluorescent zinc silicate. On columns of the fluorescent silica gel he separated 40 binary mixtures involving 25 different compounds, and detected the zones by illuminating the columns with a hydrogen lamp which provides continuous ultraviolet light. With such a light-source, however, the detection limit for an individual compound should be higher than that with suitable monochromatic light.

Kirchner *et al.*[4] made fluorescent chromatostrips with a mixture of 19 g of adsorbent, 1 g of starch, 0·15 g of zinc silicate and 0·15 g of zinc cadmium sulphide, to separate and detect some unsaturated organic compounds. The technique has grown into thin-layer chromatography with fluorescent adsorbents, the most popular nowadays among these being Merck's Silica Gel F_{254} containing fluorescent zinc silicate.

Fluorescent materials have also been used to make fluorescent screens which are mainly useful for detecting spots of ultraviolet-absorbing substances on paper.

Although the combinations of some fluorescent materials mentioned above are usable for a wide wavelength range, they have poor selectivity since the substances appear as dark and uncoloured spots. In contrast, by the method described here, the substances show different colours, depending on their ultraviolet absorbing spectra, and thus the selectivity is much increased.

Light source

Various kinds of mercury lamps of different pressure have been used for the light source, in combination with suitable filters, the simplest and most popular among them being a low-pressure lamp which emits a strong line at 254 nm and some weak lines, and a fluorescent lamp which is made from a similar lamp coated with fluorescent barium metasilicate and emits a band spectrum around 350 nm.

Sease[3] used a hydrogen lamp to obtain an ultraviolet continuum. Tamura *et al.*[5] improved the low-pressure mercury lamp to supplement the energy of wavelength longer than 254 nm. Three kinds of fluorescent materials which absorb light at 254 nm and emit ultraviolet light of longer wavelength—$(Zn,Ca)_3(PO_4)_2/Tl$ (fluorescence maximum, 310 nm), $BaSi_2O_5/Pb$ (350 nm) and $(Ba,Sr,Mg)SiO_3{\cdot}SO_4/Pb$ (370 nm)—were mixed in the proportions 26·0, 33·2 and 40·8 % respectively; the mixture was bound with acetylcellulose to make a film which was placed behind the mercury lamp, and a Toshiba UV-D25 filter was attached in front of the lamp. The emission spectrum of the light source thus obtained is shown in Fig. 1.

Since the fluorescent film gradually deteriorates, the light source was further improved by coating half of the inner surface of the discharging tube with the same fluorescent mixture (Fig. 2).*

---

* The light source is to be manufactured by Tokyo Kogaku Kikai K.K.

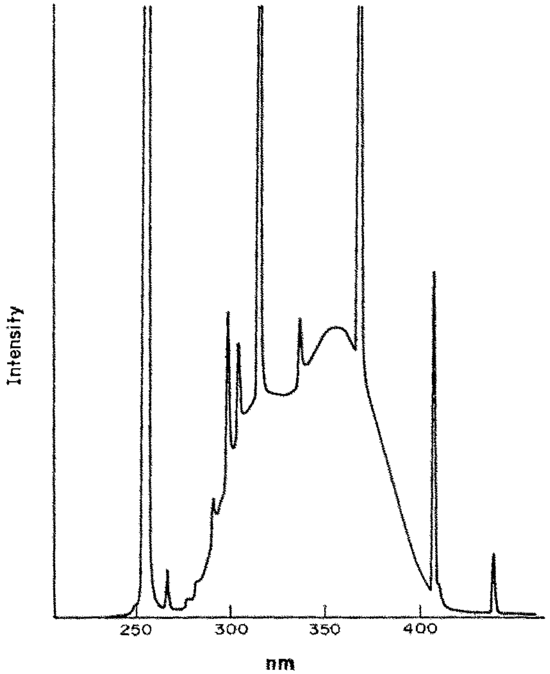

FIG. 1.—Emission spectrum of the light source (uncorrected).

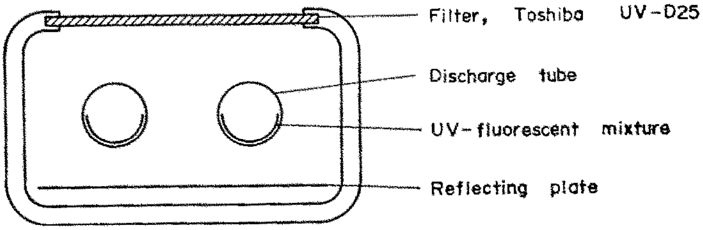

FIG. 2.—Cross-section of the light source.

Use of mixed fluorescent materials

Tamura *et al.*[5] selected three kinds of fluorescent materials which have different excitation spectra and fluorescent colours (blue, green and red) from the products of Tokyo Shibaura Electric Co. (Fig. 3), and mixed them so as to obtain white fluorescence on irradiation with continuous ultraviolet light (Fig. 3, Table I).

The mixed fluorescent materials display different colours according to the wavelengths of the irradiating ultraviolet light. The mixed fluorescent materials A and B change their colour from blue, through green, yellow and orange, to red on changing the excitation wavelength from 250 to 350 nm. Thus the visible spectrum seems to be transferred to the ultraviolet region.

Tamura *et al.* applied the mixed fluorescent material A to detection of ultraviolet absorbing substances as coloured substances.

Fluorescent screen. The mixed fluorescent material was mixed with an equal quantity of 1% starch solution and spread on a glass plate with an applicator, or mixed with several times its quantity of 5% acetylcellulose solution in acetone and spread on a polyvinyl chloride plate, to produce a fluorescent screen.*

* A fluorescent screen made from mixture A is commercially available under the name of Lumicolor-Plate (Wako Pure Chemical Industries, Ltd.).

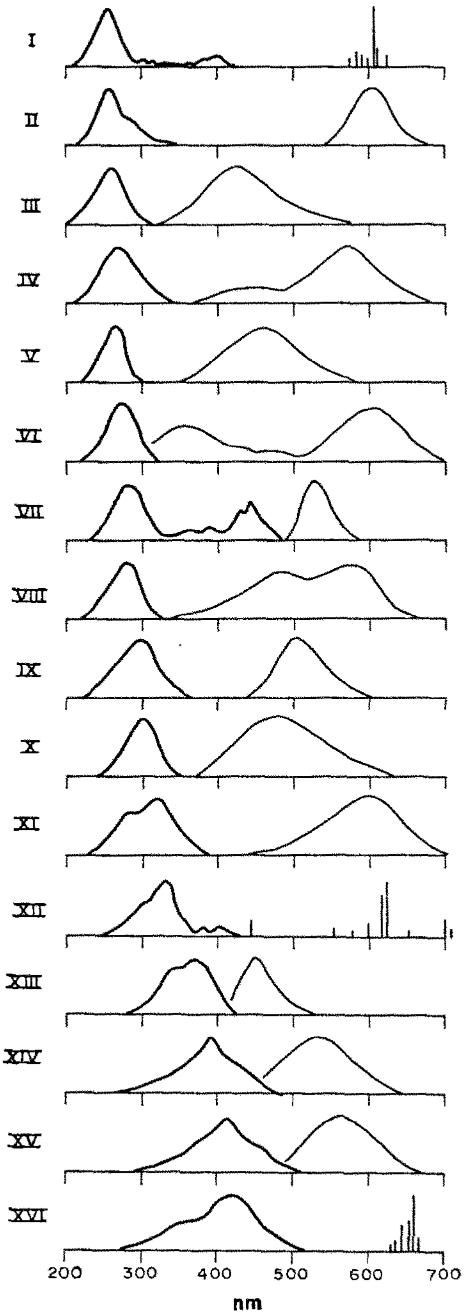

FIG. 3.—Spectra and fluorescent colours of inorganic fluorescent materials.

TABLE I.—COMPOSITION OF SOME MIXED FLUORESCENT MATERIALS

Symbol	Component	Mixing ratio
A	V, VII, XII	20:5:1
B	V, VII, XVI	12:3:2
C	VII, XII, XIII	5:1:2
D	I, IX, XIII	3:5:1

After chromatographic or electrophoretic separation, the filter paper was placed on the light source and covered with the fluorescent screen. Then the ultraviolet-absorbing compounds were observed as coloured spots on the white background.

The colour of a spot corresponds to the absorption spectrum of the compounds in it, and vitamin C, which has an absorption maximum at 265 nm, gives a red spot on a chromatogram, as expected from the spectrum of A. In some cases, however, the colour does not correspond to the absorption spectrum in the solution, because of changes caused by adsorption or solidification, or because of overlap with the fluorescence of the compound as in the case of vitamin B_6. A colour change from red to brown during irradiation was observed in the case of vitamin B_1, and this was the result of photochemical decomposition. The limits of detection depend on the molar absorptivities of the compounds, and those of vitamin B_1, C and nicotinamide were found to be 0·1, 0·5, 0·5 and 0·4 μg respectively in chromatography with n-butanol, acetic acid and water (4:1:5 v/v; upper phase).

Gases and liquids are observed by placing them in a quartz cell and putting this between the light source and the fluorescent screen. The vapour of benzene then looks red and aromatic impurities in a solvent can be detectable.

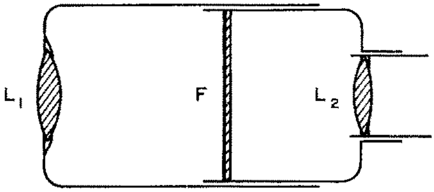

FIG. 4.—A viewer for ultraviolet-absorbing substances. L_1—quartz lens; F—fluorescent screen, L_2—glass lens.

A viewer for ultraviolet-absorbing substances has been developed, as shown in Fig. 4. An object is irradiated with the light source, the image is focused on the screen, and the fluorescent image is observed through the lens L_2.

Thin-layer and column chromatography. The fluorescent screen is scarcely applicable for thin-layer chromatography since ordinary adsorbents and glass absorb light of wavelength shorter than 300 nm, and therefore 5–10% of the mixed fluorescent material is added to the adsorbent.* The colour is better if observed from the back of the thin layer.

The detection limits on thin layers are generally lower than on paper, and 0·1 μg of vitamin B_1 and 0·3 μg of nicotinamide are sufficient for detection.

A similar fluorescent adsorbent in a quartz tube has been used for column chromatography, for example, an adsorbent was made by hydrolysis of ethyl silicate containing fluorescent material A, to achieve homogeneous distribution of the fluorescent components through the adsorbent.

Takitani *et al.* studied separation of hypnotics[6] and other drugs[7] on thin layers and columns of silica gel containing the mixed fluorescent material.

DISCUSSION

Strong acids or alkalis should not be applied to the mixed fluorescent material, for some of the components would be decomposed. Ultraviolet-absorbing solvents, if present, should be removed completely before the observation. The irradiation time should be kept as short as possible to avoid photochemical decomposition of unstable compounds.

* Silica gel containing the fluorescent material A, Wakogel B-5 UA is available (Wako Pure Chemical Industries, Ltd.).

Subject to these conditions, the mixed fluorescent material should be widely applicable not only to qualitative analysis of natural products, biological substances, drugs, synthetic materials *etc*, but also to their purification and for tracing their chemical reactions.

Automatic ion-exchange chromatograph for analysis of alkali and alkaline earth metal mixtures

(*Received* 7 *June* 1971. *Accepted* 28 *November* 1971)

FLAME PHOTOMETRY has been widely used for determination of alkali and alkaline earth metals, but a sample solution of several millilitres is necessary. A new method for ultramicro determination of these metals had been developed by the authors.[1–3] A hydrogen flame-ionization detector is used as sensor and the sample solution required for analysis is only several microlitres. This detector, in which an electric current is caused by ionization of the metals in the flame, has high sensitivity but lacks selectivity. Use of this detector with automatic ion-exchange chromatography on an inorganic ion-exchanger has been studied.

EXPERIMENTAL

Chromatograph

A block diagram of the automatic chromatograph is shown in Fig. 1 and some details in Fig. 2. The chromatograph consists of a hydrogen flame-ionization detector, an ion-exchange column, a motor-driven turntable, a photoelectric monitor, and a heater chamber to evaporate the eluate. The detector had double jets for two hydrogen flames (Fig. 3). Salts of alkali and alkaline earth metals were evaporated in the lower flame (the evaporating flame) and electrical responses corresponding to ionization of these metals were measured in the upper flame (the ionizing flame). The ion-exchange

Subject to these conditions, the mixed fluorescent material should be widely applicable not only to qualitative analysis of natural products, biological substances, drugs, synthetic materials *etc*, but also to their purification and for tracing their chemical reactions.

Automatic ion-exchange chromatograph for analysis of alkali and alkaline earth metal mixtures

(*Received* 7 *June* 1971. *Accepted* 28 *November* 1971)

FLAME PHOTOMETRY has been widely used for determination of alkali and alkaline earth metals, but a sample solution of several millilitres is necessary. A new method for ultramicro determination of these metals had been developed by the authors.[1–3] A hydrogen flame-ionization detector is used as sensor and the sample solution required for analysis is only several microlitres. This detector, in which an electric current is caused by ionization of the metals in the flame, has high sensitivity but lacks selectivity. Use of this detector with automatic ion-exchange chromatography on an inorganic ion-exchanger has been studied.

EXPERIMENTAL

Chromatograph

A block diagram of the automatic chromatograph is shown in Fig. 1 and some details in Fig. 2. The chromatograph consists of a hydrogen flame-ionization detector, an ion-exchange column, a motor-driven turntable, a photoelectric monitor, and a heater chamber to evaporate the eluate. The detector had double jets for two hydrogen flames (Fig. 3). Salts of alkali and alkaline earth metals were evaporated in the lower flame (the evaporating flame) and electrical responses corresponding to ionization of these metals were measured in the upper flame (the ionizing flame). The ion-exchange

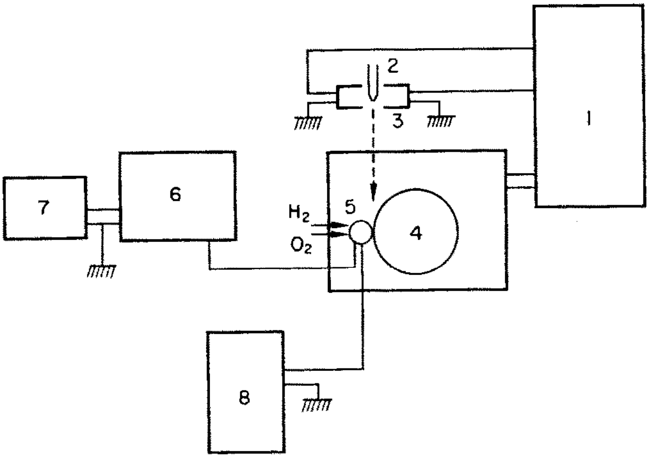

FIG. 1.—Schematic diagram of chromatograph. ① Control box; ② ion-exchange column; ③ device for monitoring a drop of eluate; ④ turntable (sample holders); ⑤ hydrogen flame-ionization detector; ⑥ d.c. amplifier; ⑦ recorder; ⑧ constant-voltage stabilizer.

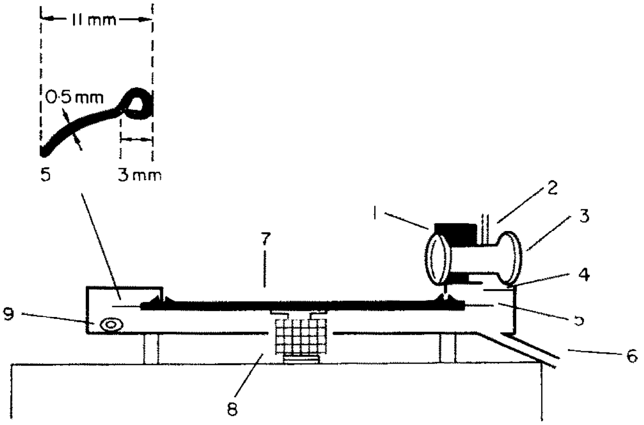

FIG. 2.—Vertical plane of chromatograph. ① Detector; ② ion-exchange column; ③ device for monitoring a drop of eluate; ④ shock absorber; ⑤ sample holder (Pt); ⑥ drain; ⑦ turntable (160 mm diameter); ⑧ screw for setting the height of sample holder; ⑨ heater for evaporating eluate.

column was a silica tube of 4·2 mm bore packed with zirconium phosphate (Bio-Rad, 100–200 mesh) to a height of 20 mm. The turntable had 47 platinum sample holders. A net or ring, made of fine platinum wire (0·1 mm diameter) was placed below the column to reduce the speed of a falling drop of effluent and ensure successful loading on a sample holder. The photoelectric monitor was the same as one used for a fraction collector. The heater chamber was set to evaporate eluates, especially those containing ammonium chloride, on the sample holders before they were inserted into the evaporating flame. Optimum temperatures of the heating zone are shown in Fig. 4. The chromatographic and sampling devices are shown in Fig. 5.

When a drop of effluent from the column is loaded on a sample holder, the motor begins to rotate as a result of a signal from the monitor, and drives the turntable clockwise until the next sample

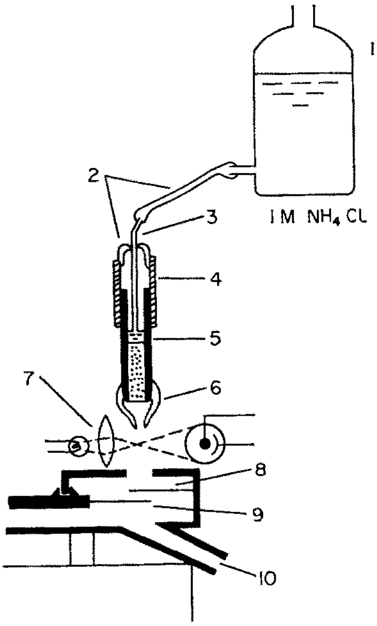

Fig. 5.—Chromatographic column and sampling device. ① Polyethylene bottle; ② polyethylene tube; ③ Pt tube (0·6 mm bore); ④ vinyl chloride tube; ⑤ ion-exchange column (silica tube 4 mm bore); ⑥ polyethylene; ⑦ device for monitoring a drop of eluate; ⑧ shock absorber; ⑨ sample holder; ⑩ drain.

holder is positioned just below the column. Simultaneously a drop of effluent on another holder moves into the heater chamber. In the heating zone, the eluate is evaporated, leaving a solid metal salt on the sample holder. When the metal salt is inserted into the evaporating flame, a response from the collector electrode is obtained and recorded. Thus the elution chromatogram is obtained.

Reagents

Salts of alkali and alkaline earth metals used were analytical grade reagents and ammonium chloride was prepared from hydrogen chloride and ammonia. They were dissolved in demineralized water and their solutions were kept in polyethylene bottles. Hydrochloric acid was prepared by dissolving hydrogen chloride in demineralized water.

RESULTS

Characteristics of the ionization detector were investigated in detail. The detector showed a good response to microamounts of the metals, as shown in Table I.

TABLE I.—LIMIT OF DETERMINATION AND LINEAR DYNAMIC RANGE

Sample	Limit of determination (*mole*)	Linear dynamic range	Remarks
LiCl	5×10^{-12}	1:100	Mixing HCl
NaCl	4×10^{-13}	1:50	Mixing HCl
KCl	5×10^{-14}	1:100	
RbCl	3×10^{-14}	1:100	
CsCl	3×10^{-14}	1:100	
$CaCl_2$	3×10^{-12}	1:100	
$SrCl_2$	3×10^{-13}	1:50	
$BaCl_2$	3×10^{-13}	1:70	

Evaporating flame temp. 1430°C; ionizing flame temp. 1380°C.

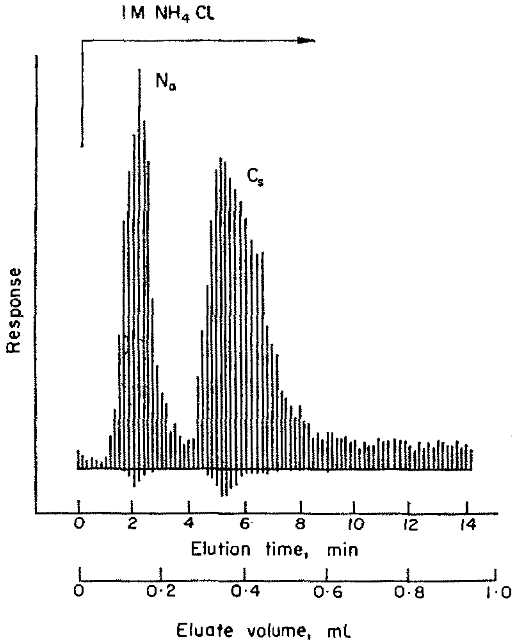

FIG. 6.—Ion-exchange chromatogram of sodium and caesium ions. Column, zirconium phosphate (20 mm × 13 mm^2); pretreatment with 2*M* HCl; eluent, 1*M* NH_4Cl; flow-rate, 0·072 ml/min. Sample: NaCl 2×10^{-9} mole, CsCl $2{\cdot}1 \times 10^{-10}$ mole.

An elution chromatogram (Fig. 6) of sodium and caesium ions was obtained with the chromatograph, with 1*M* ammonium chloride as eluent. Sodium and caesium could be determined from either the peak heights or the peak areas. The response did not return to zero after elution. It was considered that these baseline shifts occurred because of contamination with trace amounts of sodium or potassium in the preparation of the eluent. Therefore, the ammonium chloride, hydrochloric acid and demineralized water used should be highly purified.

Spectrophotometric studies on 5,7-dibromo-8-aminoquinoline chelates of some bivalent transition metals

(*Received* 19 *June* 1971. *Accepted* 21 *October* 1971)

WE HAVE BEEN studying 8-aminoquinoline and its derivatives in contrast with 8-quinolinol and as an example of an *N*,*N*-co-ordinately bonding organic reagent,[1-3] and now report on the 5,7-dibromo derivative.

EXPERIMENTAL

Reagents

Synthesis of 5,7-dibromo-8-aminoquinoline. Though 5,7-dibromo-8-aminoquinoline was obtainable by the reduction[4] of 5,7-dibromo-8-nitroquinoline, we synthesized it *via* the acetylation of 8-aminoquinoline.[5]

Commercial 8-aminoquinoline (2 g) was dissolved in glacial acetic acid (8–10 g) and placed in a 500-ml Erlenmeyer flask. In like manner, 4·47 g of bromine were separately dissolved in glacial acetic acid (18–23 g) by weight and stored in a separating funnel. The 8-aminoquinoline solution was vigorously agitated while being ice-cooled, and the bromine solution was added from the separating funnel dropwise. A fine yellowish-orange precipitate of 5,7-dibromo-8-acetylquinoline was obtained. Care was taken to cause it to agglomerate as little as possible. The precipitate was filtered off and dissolved in 50–100 ml of concentrated hydrochloric acid. The solution was poured into sufficient cooled water to yield a yellowish precipitate. This precipitate was recrystallized from methanol. The m.p. was 120–121°, and the yield 30%. Elemental analysis was as follows. Found: C 36·4%, H 2·1%, N 9·5%, Br 52·7%; calcd. for $C_9H_6N_2Br_2$: C 35·79%, H 1·99%, N 9·28%, Br 52·94%.

Metal ion solutions and solvents, *etc.*, to be used in the experiments were the same as previously reported.[2]

Dissociation constant of 5,7-dibromo-8-aminoquinoline (DBA)

The absorption spectra of $2{\cdot}02 \times 10^{-4}M$ DBA in 50% v/v aqueous dioxan were taken at various acidities (Fig. 1). At pH $>$ 1·9, the shape of the absorption spectrum was constant, with absorption maximum at 356 nm. At acidities of 0·05–1·0*N* (perchloric acid), the absorption spectra varied, with an isosbestic point at about 400 nm, and finally a new absorption maximum at 438 nm. The low-acidity spectrum is considered to be that of the neutral reagent and the high-acidity spectrum that of protonated reagent. Since it was thought that both chemical species were co-existent up to at least 0·50*N* acidity, the dissociation constant could be calculated.

For comparison, the absorption spectra of 8-aminoquinoline and 5,7-dibromo-8-aminoquinoline are shown in Fig. 2. The absorption spectrum of the reagent is shifted to longer wavelengths by the introduction of bromine atoms.

If HL^+ is the protonated form of the neutral reagent, L, the acid dissociation constant, K_a, is

$$K_a = \frac{[H^+][L]}{[HL^+]}\,. \tag{1}$$

If the absorbance at the determined wavelength of the solution is A, ε_{HL} and ε_L are the molar absorptivities of HL^+ and L respectively, C is the total concentration of L (*i.e.*, $C_L = [HL^+] + [L]$) and $A_0 = C_L\varepsilon_L$,

$$\frac{C_L}{(A - A_0)} = \frac{1}{(\varepsilon_{HL} - \varepsilon_L)} + \frac{K_a}{[H^+](\varepsilon_{HL} - \varepsilon_L)} \tag{2}$$

sensibilité avec la chromatographie d'échange d'ions. On a choisi le phosphate de zirconium comme échangeur d'ions.

$$K_a = \frac{[H^+][L]}{[HL^+]}\,. \tag{1}$$

If the absorbance at the determined wavelength of the solution is A, ε_{HL} and ε_L are the molar absorptivities of HL^+ and L respectively, C is the total concentration of L (*i.e.*, $C_L = [HL^+] + [L]$) and $A_0 = C_L\varepsilon_L$,

$$\frac{C_L}{(A - A_0)} = \frac{1}{(\varepsilon_{HL} - \varepsilon_L)} + \frac{K_a}{[H^+](\varepsilon_{HL} - \varepsilon_L)} \tag{2}$$

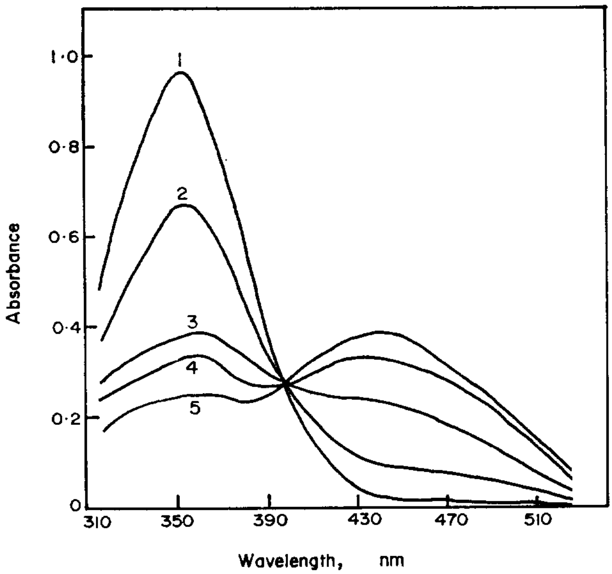

FIG. 1.—Absorption spectra of 2·02 × $10^{-4}M$ 5,7-dibromo-8-aminoquinoline. *1*—pH 1·85; *2*—0·10*M* $HClO_4$; *3*—0·25*M* $HClO_4$; *4*—0·50*M* $HClO_4$; *5*—1·00*M* $HClO_4$.

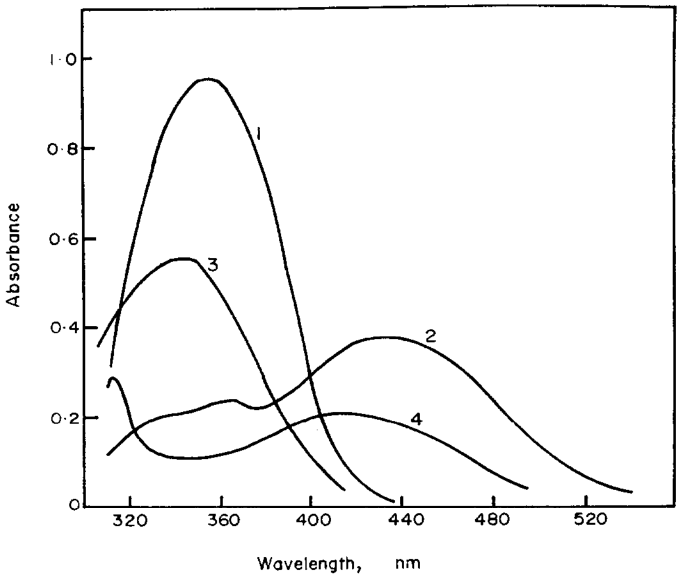

FIG. 2—Absorption spectra of 8-aminoquinoline and 5,7-dibromo-8-aminoquinoline. *1*—5,7-Dibromo-8-aminoquinoline; *2*—5,7-Dibromo-8-aminoquinoline (protonated form); *3*—8-Aminoquinoline; *4*—8-Aminoquinoline (protonated form). Concentrations 2·02 × $10^{-4}M$.

If the concentration of the reagent is kept at $2{\cdot}02 \times 10^{-4}M$, and the concentration of perchloric acid is varied from 0·10 to 0·25M, a linear relationship is found between $C_a/(A - A_0)$ and $1/[H^+]$. From these results, the acid dissociation constant of 5,7-dibromo-8-aminoquinoline can be found by the method of least squares. An average value, K_a, $7{\cdot}54 \times 10^{-2}$ (pK_a 1·1) was obtained, the individual values being 7·73, 7·72 and 7·18 (all $\times 10^{-2}$) from measurements at 430, 460 and 470 nm respectively.

This is large compared with that of the constant of 8-aminoquinoline ($1{\cdot}58 \times 10^{-4}$) because the electron-attracting power of the bromine atoms in the 5th and 7th positions reduces the electron density on the ring nitrogen atoms.

Absorption spectra of 5,7-dibromo-8-aminoquinoline chelate of copper

With $2{\cdot}02 \times 10^{-4}M$ DBA in 50% v/v dioxan–water at an acidity of 1·0M perchloric acid, variation of the copper(II) concentration from $2{\cdot}19 \times 10^{-4}$ to $2{\cdot}19 \times 10^{-2}M$ gave variation of the absorption spectra, relative to a solvent blank (Fig. 3). The absorption maximum was at 316 nm and the isosbestic point at 348 nm. It is considered that when copper is in excess only one type of chelate is formed in 1·0M perchloric acid.

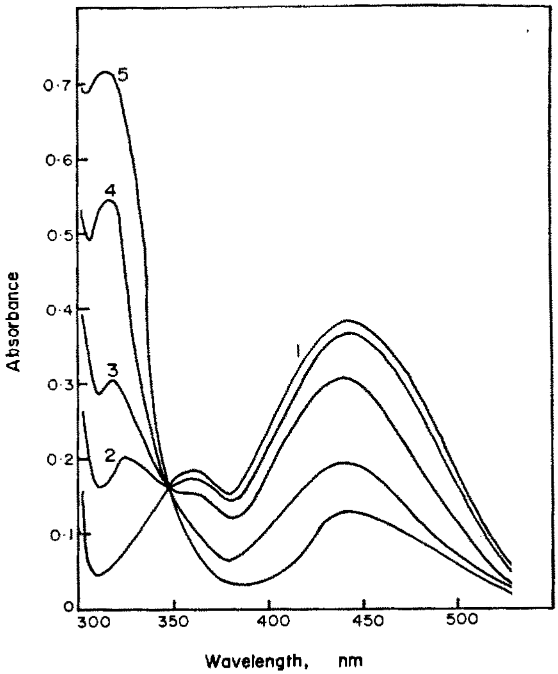

FIG. 3.—Absorption spectra of copper chelate of 5,7-dibromo-8-aminoquinoline. Reagent $2{\cdot}02 \times 10^{-4}M$, *1*—Reagent only; *2*—[Cu] $1{\cdot}09 \times 10^{-3}M$; 3—[Cu] $3{\cdot}29 \times 10^{-3}M$; *4*—[Cu] $1{\cdot}09 \times 10^{-2}M$; *5*—[Cu] $2{\cdot}19 \times 10^{-2}M$.

Composition and stability constant of 5,7-dibromo-8-aminoquinoline chelate of copper

If the reagent reacts with copper according to

$$Cu^{2+} + nHL^+ \rightleftharpoons CuL_n^{2+} + nH^+ \tag{3}$$

then

$$K_1 = \frac{[CuL_n^{2+}][H^+]^n}{[Cu^{2+}][HL^+]^n} \tag{4}$$

If the initial concentrations of copper and reagent are C_{Cu} and C_L and the concentration of the chelate is x (all in mole/l.),

$$K_1 = \frac{x[H^+]^n}{(C_{Cu} - x)(C_L - nx)^n} \tag{5}$$

Under these conditions, as the isosbestic point in Fig. 3 and the molar ratio method show, the composition of the chelate is 1:1. Thus when L as well as HL^+ is taken into account

$$K_1 = \frac{x\{[H^+] + K_a\}}{C_{Cu}/(C_L - x)} \tag{5a}$$

If ε_{CuL}, ε_L and ε_{HL} are the molar absorptivities of the chelate, L and HL^+, the total absorbance is A and the absorbances of L and HL^+ are A_L and A_{HL^+} respectively, it follows that

$$A = \varepsilon_{CuL}x + \varepsilon_{HL}\left\{\frac{[H^+](C_L - x)}{[H^+] + K_a}\right\} + \varepsilon_L\left\{\frac{K_a(C_L - x)}{[H^+] + K_a}\right\} \tag{6}$$

and

$$\frac{C_L}{\left(A - \frac{A_{HL}[H^+]}{[H^+] + K_a} - \frac{A_L K_a}{[H^+] + K_a}\right)} = \frac{[H^+] + K_a}{C_{Cu}K_1\left(\varepsilon_{CuL} - \frac{\varepsilon_{HL}[H^+]}{[H^+] + K_a} - \frac{\varepsilon_L K_a}{[H^+] + K_a}\right)} + \frac{1}{\left(\varepsilon_{CuL} - \frac{\varepsilon_{HL}[H^+]}{[H^+] + K_a} - \frac{\varepsilon_L K_a}{[H^+] + K_a}\right)} \tag{7}$$

If the concentration of the reagent is $2{\cdot}02 \times 10^{-4}M$ and the concentration of copper(II) ion varies from $7{\cdot}07 \times 10^{-3}$ to $1{\cdot}52 \times 10^{-2}M$, the acidity is maintained at $0{\cdot}45N$ with perchloric acid and the relationship between the left-hand side and $1/C_{Cu}$ in formula (7) is plotted, a linear relationship is obtained. Values of the equilibrium constant for the system were obtained by applying the methods of least squares to this curve. They were 14, 16 and 18 (mean 16) for measurements at 320, 325 and 330 nm. Log $k_1 = 2{\cdot}3$ was obtained as the stability constant of the 1:1 complex when K_a was taken as $7{\cdot}54 \times 10^{-2}$, and an ionic strength of 0·50 and a temperature of 25·0 ± 0·1° were maintained.

Absorption spectra and stability constant of 5,7-dibromo-8-aminoquinoline chelates of other metals

The method was also applied to the determination of the equilibrium constants for the 1:1 chelates formed with nickel, zinc, cobalt and cadmium (Table I). The stability constants are in Table II.

CONCLUSION

The results are summarized in Table II, which also includes those for 8-aminoquinoline and 8-quinolinol. It is seen that the electron-withdrawing effect of the bromine atoms leads to relatively

low stability constants. The absorption curve of the chelate is shifted to longer wavelengths and greater molar absorptivities. The stability constants almost follow the Irving-Williams order, but that of the cobalt(II) chelate is greater than expected.

5,7-Dibromo-8-aminoquinoline is not thought to be particularly superior to 8-quinolinol as an analytical reagent, but it seems to provide information on the influence that different atoms exert on the formation of chelates.

KATSUMI YAMAMOTO
HIROSHI TABATA

Summary—The acid dissociation constant of 5,7-dibromo-8-aminoquinoline and the stability constant of 1:1 chelates of some bivalent transition metals were determined spectrophotometrically in 50% v/v dioxan-water medium at an ionic strength of 0·50 at 25·0 ± 0·1° and compared with those of 8-aminoquinoline. The dissociation constant was found to be $7{\cdot}54 \times 10^{-2}$ and the stability constants (log K_1) were 2·3 (copper), 1·8 (nickel), 1·8 (zinc), 2·2 (cobalt) and 1·6 (cadmium), respectively. The dissociation constants are greater and the stability constants smaller than the corresponding values for 8-aminoquinoline and 8-quinolinol.

Zusammenfassung—Die Säuredissoziationskonstante von 5,7-Dibrom-8-aminochinolin und die Stabilitätskonstanten von 1:1-Chelaten einiger zweiwertiger Übergangsmetalle wurden spektrophotometrisch in 50 Vol.-% Dioxan-Wasser bei einer Ionenstärke von 0,50 bei 25,0 ± 0,1° gemessen und mit denen von 8-Aminochinolin verglichen. Die Dissoziationskonstante beträgt $7{,}54 \cdot 10^{-2}$ und die Stabilitätskonstanten (log K_1) 2,3 (Kupfer), 1,8 (Nickel), 1,8 (Zink), 2,2 (Kobalt) und 1,6 (Cadmium). Die Dissoziationskonstante ist größer und die Stabilitätskonstanten kleiner als die entsprechenden Werte bei 8-Aminochinolin und 8-Hydroxychinolin.

Résumé—On a déterminé spectrophotométriquement la constante de dissociation acide de la 5,7-dibromo 8-aminoquinoléine et les constantes de stabilité de chélates 1:1 de quelques métaux de transition bivalents dans le milieu dioxane-eau 50% v/v, à une force ionique de 0,50 à 25,0 ± 0,1°, et on les a comparées à celles de la 8-aminoquinoléine. On a trouvé que la constante de dissociation est de $7{,}54 \times 10^{-2}$ et les constantes de stabilité (log K_1) sont 2,3 (cuivre), 1,8 (nickel), 1,8 (zinc), 2,2 (cobalt) et 1,6 (cadmium) respectivement. Les constantes de dissociation sont plus grandes et les constantes de stabilité plus petites que les valeurs correspondantes pour la 8-aminoquinoléine et la 8-hydroxyquinoléine.

Summary—A review is made of the basic theory, instrumentation and application of mass spectrometry, with special reference to the development of the equipment and its impact on the scope of application.

THE IONIZATION PROCESS

ANALYSIS by mass spectrometry depends upon the segregation of ionized molecules in magnetic, electric or radiofrequency fields. The ionization process which precedes this separation must take place in the gas phase and this imposes certain limitations on the technique, which are discussed later. Mass spectrometry is best introduced by using its relationship to other physical techniques based upon ionization. The ionization process may be described most generally by the interaction of a species M, which may be a molecule, an atom or a free radical, with a second species X, which may be an electron, a photon, an ion, a fast molecule or even a high potential gradient. M may be considered to be in thermal equilibrium with its surroundings but X must have a certain minimal energy content (E) which is greater than the binding energy of the electron in the lowest energy orbital in M, *i.e.*, the lowest ionization potential (I) of M. As a result of this interaction the lowest-energy electron is ejected and an ion M^+ is formed. For cases in which E is greater than I the excess of energy will be partitioned between the ion (E_1) and the electron (E_2). As the free electron is so light when compared with even a small polyatomic ion, any translational energy released in the process will be almost completely retained by the electron, which can of course retain no other form of energy. The ion M^+ on the other hand, although it has no translational energy, may have excitation energy (E_1) which may be electronic, vibrational or rotational.

$$\begin{array}{ccccccc} M & + & X(E) & \rightarrow & \mathrm{M}^+(E_1) & + & e(E_2) \\ n_\mathrm{M} & & n_\mathrm{X} & & n_1 & & n_2 \end{array}$$

In order to examine the consequences of this interaction in a real environment we must assume an assembly of particles of species M, their number being n_M. The number of particles of species X, which will most normally be measured as a flux, is n_X and the numbers of ions and electrons produced will be n_1 and n_2 respectively. Except in the case of multiple ionization n_1 and n_2 will be equal.

There are obviously two ways of investigating the ionization process experimentally: either the number of ions or the number of electrons may be measured. Such measurements are most commonly made by collecting the charged species with electrode assemblies across which the appropriate potential gradients are applied.

---

† For reprints of this review, see Publisher's announcement near end of this issue.

It is most convenient to investigate ionization as a continuous process so that n_M is kept constant by maintaining a flux or current of X through the assembly of molecules, atoms or radicals M. The resulting numbers of ions and electrons may now also be measured as fluxes, *i.e.*, numbers of ions or electrons per second or, more familiarly, electric currents. Let us suppose that n_M and n_X are kept constant while E is varied. The electron current n_2/t (where t is time) is now measured, for example, by inserting a pair of polarized electrodes into the cell in which M and X are interacting. If the electron current n_2/t is plotted against the energy E, the result is a typical ionization curve with a very steep rise in n_2/t as E rises above the ionization potential of M. When X is a photon then E may be very sharply defined by the wavelength of X and the ionization potential may be measured with considerable precision. When X is an electron, E is not precisely defined, as it is not very easy to obtain a beam of monochromatic electrons of suitable intensity. As electrons are normally produced from a white hot tungsten or rhenium filament they retain a Boltzmann distribution of energy $\pm\Delta E$ which is an appreciable fraction of a volt. As a result the inflection in the ionization curve is less precisely defined and the value of the ionization potential less certain. Now let us consider an alternative experiment in which the energy E is kept constant and considerably greater than the ionization potential of M. Instead of the total ionization current n_2/t being measured, the energy distribution in the emitted electrons is determined. This may be achieved experimentally by interposing a retarding potential grid between the two collecting electrodes or more elaborately by passing a beam of the emitted electrons through a transverse electric field and dispersing them according to their velocity. A plot is now made of E_2' against n_2'/t where E_2' is the energy in any emitted electron and n_2' is the number of electrons having such a translational energy. Then $\sum n_2' = n_2$. The difference between the energy of the projectile (E) and the translational energy of the emitted electron (E_2') is equal to that energy retained by the ion M^+. When X is a photon of high energy, this curve may be recognized as the photoelectron spectrum. Such a curve will have several maxima corresponding to the ionization of electrons in orbitals of different energies. In addition, for simple molecules, the maxima may reveal structure due to the formation of the ion in a variety of excited states. This experiment gives information about the energies of orbitals in polyatomic molecules in addition to the lowest ionization potential. Similar information is theoretically available if X is not a photon but an electron. Once again however, there is the problem of the energy spread experienced with electron beams. Electron monochromators are now being developed, however, giving currents as high as 10^{-8} A with an energy spread of as little as 20 mV. Combinations of two of these devices have been used to provide determinations of the energy distribution of emitted electrons, and a new spectroscopic technique, electron energy loss spectroscopy, is being developed. Once again the information available with this technique is concerned with the energies of orbitals in simple polyatomic molecules rather than with structures.

The alternative method of investigating the ionization process is by measuring the ion current rather than the electron current. A plot of n_1/t against E once again provides a method of determining the ionization potential of M. The results are more precise when X is a photon rather than an electron but the measurement of ionization potentials from the ionization efficiency curves obtained with mass spectrometers is common practice and various extrapolation procedures and deconvolution devices are used to increase precision of the determination. When X is an ion, the situation is complicated by the involvement of the recombination energy of the projectile ion with an electron. This complication also arises with the other techniques mentioned above. A measurement of the ratio n_1/n_M gives a measure of the ionization cross-section of the molecule M. The ionization efficiency curve, which is a plot of n_1/t against E does not give any information about the higher ionization potentials of polyatomic molecules because it is not possible to identify the variation of cross-section with E for any specific ionization process in which an electron of particular energy is being removed, except in the simplest possible case of the hydrogen atom or possibly the hydrogen molecule. Energy analysis of the ion current reveals no information, because the translational energy is all removed by the electron and at present there is little or no possibility of the determination of the nature of the excited states of ions.

While however, little information of this type is available from an examination of the ion current, the technique of mass spectrometry is based on an alternative way of looking at the ion current. This arises because it is possible to segregate ions not according to their energy content but according to their relative mass. The various methods by which this segregation is achieved are discussed below and it is only necessary to point out that the assembly of the species M may now consist of a number of different molecules, atoms or radicals. Each of these will be converted into the appropriate ions M^+ and it is now possible to measure all the individual ion currents n_1/t and to plot n_1/t against the mass of the ion m. Such a plot constitutes a mass spectrum.

$$m \sum_{0}^{M} n_1' = n_1$$

If the assembly of species is, for example, a mixture of rare gases so that the only ionization processes possible were the production of the singly-charged rare gas ions then it is possible to analyse the mixture by mass spectrometry. Both n_M and n_X must be kept constant so that the rate of production of ions is constant. The individual ion currents of the species M are then proportional to the partial pressures of the species M in the mixture and the sum of all these currents is equal to the total ion current n_1/t. This situation is rather similar to the conditions of fluorescence analysis where the incident radiation is analogous to the electron beam and the fluorescent radiation is analogous to the ion beam, the wavelength and mass being characteristic of the species M. There are very few cases in which this very simple form of mass spectrometry has a modern application. There are two examples worth recording however, the first medical and the second cosmochemical. The most readily available gas mixture is the atmosphere and a mass spectrum of air readily reveals the separation of the ion currents due to oxygen, nitrogen, carbon dioxide and argon. The efficiency of a patient's respiration may be assessed by taking samples of the atmosphere from his lungs. This process can be carried out continuously and can show not only the state of the patient's breathing but also the concentration of any foreign gas introduced to induce anaesthesia.

The second application also deals with the analysis of atmospheres, but in extra-terrestrial situations. The development of very small light mass spectrometers, now referred to as "flyable" instruments, permits their transportation by rocketry to a number of remote situations. The molecule and ion concentrations in the outer layers of the earth's atmosphere may be examined by carrying a small mass spectrometer on a rocket and relaying the information which it gathers to a remote ground station by radio. An extension of this principle will allow the examination of a number of planetary atmospheres.

The dissociation of excited ion-molecules

The great value of mass spectrometry as an analytical technique does not derive from simple applications such as these, but from a quite distinct and separate result of the initial ionization process. For ionization to take place the energy in the electron must exceed the lowest ionization potential of the molecule. It must therefore have a value of E which is at least 15 eV since the ionization potentials of all molecules lie between 6 and 15 eV. It is common practice, in order to obtain sufficiently high values of the cross-section n_I/n_M which determines the sensitivity, to choose values of E in the 50–100 eV range. The cross-section n_I/n_M does not vary significantly above 100 eV but falls off rapidly below 50 eV. Although not all of the energy in the projectile electron is transferred to the molecule, the result of the ionization process may be the production of an ion with a considerable excess of energy (E_I). As the excited molecule ion is normally produced under high vacuum conditions (approximately 10^{-6} mm Hg) this excess of energy cannot be lost by collision with other molecules. It can thus only be reduced by the emission of a photon, a comparatively unlikely event, or by the molecule ion undergoing dissociation or rearrangement. As the bond dissociation energy of all chemical single bonds lies between 2 and 5 eV the transfer of a small fraction of the translational energy of the incident electron can result in the fission of a number of chemical bonds with the production of radicals and smaller ions. Because of the large excess of energy the dissociation process has two important features. The first is that there are a number of alternative modes of dissociation available and the diversity of these decompositions is further enhanced by the fact that the electrons have an energy spread $\pm\Delta(E)$ and may transfer a variable amount of their translational energy to the molecule, depending on the nearness of approach and the consequent intensity of interaction. As a result the excited molecule ion may dissociate in a number of parallel and consecutive reactions. If E is high, the molecule ion is most likely to react by breaking chemical bonds; if E is low the molecule ion is most likely to rearrange. The second feature is that the rate constants for the dissociation processes are very high and the reactions have negligible energies of activation. As a result the rates of reaction are almost totally unaffected by experimental parameters other than E. This means that the ratios of the ion currents for the molecule, fragment and rearrangement ions will have constant values over wide variations of n_M or n_X or the temperature of the ionization cell. The relative intensities of the ion currents, which are responsible for the peaks in a mass spectrum, constitute what has come to be known as the cracking pattern of the molecule. It is the cracking pattern which is therefore substantially invariant and constitutes a fingerprint of the molecule in the same way that the infrared absorption spectrum does. It is thus possible to match the cracking pattern observed with a chemical compound measured upon one instrument with that of the same compound measured on a machine with a completely different geometry. This match is not as complete as that obtained with infrared or NMR spectra, but the usefulness of this near identity has led to the collection both privately and by industrial and government organizations of large libraries of mass spectral cracking patterns. The best known collection of spectra has been made by the American Petroleum Institute Research Project 44. A second rapidly growing collection is being amassed by the Mass Spectrometry Data Centre situated at Aldermaston. The reduction of these cracking patterns to digital form permits a direct comparison by computer, and several schemes are in operation by which the mass spectrum of an unknown compound may be compared with a library of the spectra of known compounds, held upon a disc in a computer memory.

One of the most severe problems encountered in the matching of spectra is the necessity of matching the purity of the standard and unknown samples. The presence of a substantial impurity in either may cause a mismatch so severe that the identity is lost. The effect of the minor constituent in distorting the mass spectrum may be further magnified by a difference in the rate of evaporation of the two components. With volatile samples this effect may be minimized by evaporating all of the sample into a reservoir from which the vapour flows into the ion source. When solid samples are being introduced into the source by the insertion-probe technique this is not possible. The situation is at its worst when isomers are being studied. There are only very small differences in the mass spectra of structural isomers and it is only possible to match the spectra of unknown and standard if the purity and method of sample admission are kept the same. Fortunately, there are two ways of dealing with this problem. The first is to use the technique of differential evaporation as discussed in the section describing quantitative methods, and the second is to combine mass spectrometric identification with some other technique of physical separation such as chromatography. Chromatography in one form or other is to be preferred because in general the resolution obtainable with chromatographic methods rises with the lowering of sample size, and mass spectrometry is capable of dealing with very small sample sizes, in some cases well below the detection limit of the normal colorimetric or fluorometric methods.

Chromatographic separation

It is not difficult to separate small quantities (micrograms) of complex organic compounds by paper chromatography. The area containing the spot of the unknown is eluted with an organic solvent, the solution is concentrated by evaporation, and the concentrate admitted directly to the mass spectrometer. It is unfortunate that this process is surprisingly variable: sometimes the resulting mass spectrum can be matched very well with that of a standard, at other times the solvent may extract from the paper not only the sample material but also a great deal of contamination from the paper itself. The amount and nature of this contamination are dependent not only on the nature of the paper but also on its previous history, *i.e.*, which solvents it has already been exposed to during the chromatographic separation. Some improvements are observed when paper chromatography is replaced by thin-layer chromatography, on silica gel, cellulose *etc.* It has been possible, for example, to separate drugs from whole blood by a single separation upon cellulose and to identify the drug by removing a small area of the thin layer with a spatula and extracting with the appropriate eluent, filtering the slurry, evaporating the solvent and transferring the residue to the ion source in the manner described in the experimental section. Further, in the case of some compounds it has been possible to show that this process may be quantitative, so that submicrogram quantities of the components of complex mixtures may be separately identified and determined.[1]

When the sample components are sufficiently volatile they may be separated by gas chromatography. The very high efficiencies of separation obtainable with these methods, which greatly exceed those possible with fractionating columns, and their ability to deal with very small sample sizes, have encouraged experimenters to combine them with mass spectrometry. The separation of a pair of compounds by gas–liquid chromatography depends not only upon differences in the volatility of the two components but also upon differences in their interaction with the involatile liquid into which they are partitioned from the gas phase. As a result it is possible to take advantage not only of simple solution forces but of specific chemical interactions. It is thus possible, for example, to separate the *cis* and *trans* isomers of many simple hydrocarbons by using an involatile liquid containing a silver salt with which the unsaturated compounds form transient complexes. In a similar fashion the isomers of aromatic hydrocarbons may be separated by including in the involatile liquid some polynitro compound capable of forming molecular complexes with the aromatic. In each case some small difference in the stability of these complexes is exploited and quite small quantities of the involatile liquid are required. On the other hand, separations involving conventional solution forces may be made possible by having a very much larger quantity of the involatile liquid, maintained as a very thin film, and considerably multiplying the number of equilibrations of the sample mixture with the liquid. The limit to this is set only by purely experimental considerations of size and carrier gas inlet pressure. However, by an appropriate choice of column length and involatile liquid composition, it is possible to separate the components of complex mixtures of chemically very similar compounds. As an example, with the most efficient columns (either glass capillaries lined with squalane, or narrow packed columns with the same material dispersed upon small mesh size inert support) it is possible to separate deuterated hydrocarbons from their protonated counterparts. Dodecadeuterocyclohexane may be separated from normal cyclohexane with a relatively inefficient column of about 2000 theoretical plates, hexadeuterobenzene is separated from benzene, and trideuterotoluene from toluene[2] with packed or capillary columns with an efficiency of 10,000–15,000 plates, and with the highest efficiency columns of above 100,000 plates, monodeuterobenzene can be separated from benzene. The success of separations has in the past been limited by the inability of the gas chromatographic technique to provide an unequivocal means of identifying the separated species. The idea of specific retention volumes as a unique physical property which could be used for identification purposes has not been enthusiastically accepted by gas chromatographers. The determination of this constant, which is independent of temperature, gas flow-rate, involatile liquid concentration and sample size, required such precisely defined operating conditions that it was seldom used. A more successful compromise was the relative retention volume in which the retention volume of the unknown was expressed as a fraction of that of some similar known substance. Some variations in the experimental parameters were rendered less important but the uncertainties remained. Uncertainty could be removed by segregating the components of the mixture as they emerged from the chromatographic column, by adsorption on silica gel or alumina or by the passage of the effluent through a trap cooled in liquid air. A separate adsorbent tube or liquid-air trap was required for each component of the mixture requiring identification. The sample components recovered in this way were then identified by a second technique. Such a two-stage separation and identification does, however, involve difficulties, mainly resulting from the problem of manipulating small amounts of volatile material. This has resulted in the development of a direct coupling of the effluent from the gas chromatograph to the inlet system of the mass spectrometer, so that there is no handling process after the injection of the sample mixture into the inlet of the gas chromatograph. The manner in which this has been achieved is discussed in the section dealing with instrumentation and it is only necessary to point out that the problem of matching unknown and standard spectra is considerably simplified when the purity of the specimen is so assured. Further, although the retention volume is not normally determined with sufficient precision to make it a primary means of identification, it provides a useful additional piece of evidence to back up the mass spectra identification.

In all the foregoing it has been assumed that there exists a library spectrum of the unknown, and the only problem is that of matching. While this may be the case for some experimentalists, even in a routine analytical laboratory there will be times when the analyst will be faced with the identification of a completely new compound from its mass spectrum.

As outlined earlier, the mass spectrum presents a record of the unimolecular decomposition of an assembly of highly excited molecular ions. The chemistry of the decomposition is unique, and no great reward is obtained by comparisons with ground state chemistry or with radiolysis. And yet the only structural information available from a mass spectrum is that which can be gleaned from an understanding of the way in which the molecule ion breaks down. There are three distinct approaches to the problem of extracting this information. The analyst may attempt to understand this novel type of chemistry so that he may deduce the structure of the molecule ion from recognized decomposition processes. This approach is analogous to that by which many natural products were identified by classical organic chemical degradations, *e.g.*, pyrolysis or dehydrogenation. The second approach is to change the ionization process so that a different dissociation route is traversed. The third approach, which will commend itself most readily to the analytical chemist since he may make use of much of his armoury of chemical identification methods, is to modify the sample itself by means of a known chemical reaction and to infer the structure from a comparison of the mass spectrum before and after the chemical process. This method is analogous to the preparation of a derivative with a known physical property such as a melting point, absorption spectrum, R_f value or cryoscopic molecular weight. Our present understanding of the chemistry of the decomposition of ions has in fact been largely accumulated by studies involving the second and third approaches, and Beynon[3] in this country and McLafferty[4] in the United States have been particularly successful in expanding our understanding of the mechanisms involved. While it has been stressed that the chemistry of ion decomposition cannot be interpreted with the aid of an understanding of ground state mechanisms alone, there are certain features or underlying principles of chemical theory which must apply with equal force to these very fast reactions. It would be expected that the effect of neighbouring groups upon each other would be reflected in the rates of decomposition. An extreme example of this would be the so-called "*ortho* effect" where much stronger interactions would be expected between groups when they are adjacent to each other as substituents on a benzene ring than when they are more remote. Such an effect is observed and the spectra of isomers such as those of the nitrophenols or the hydroxybenzaldehydes are appreciably different (Fig. 1).

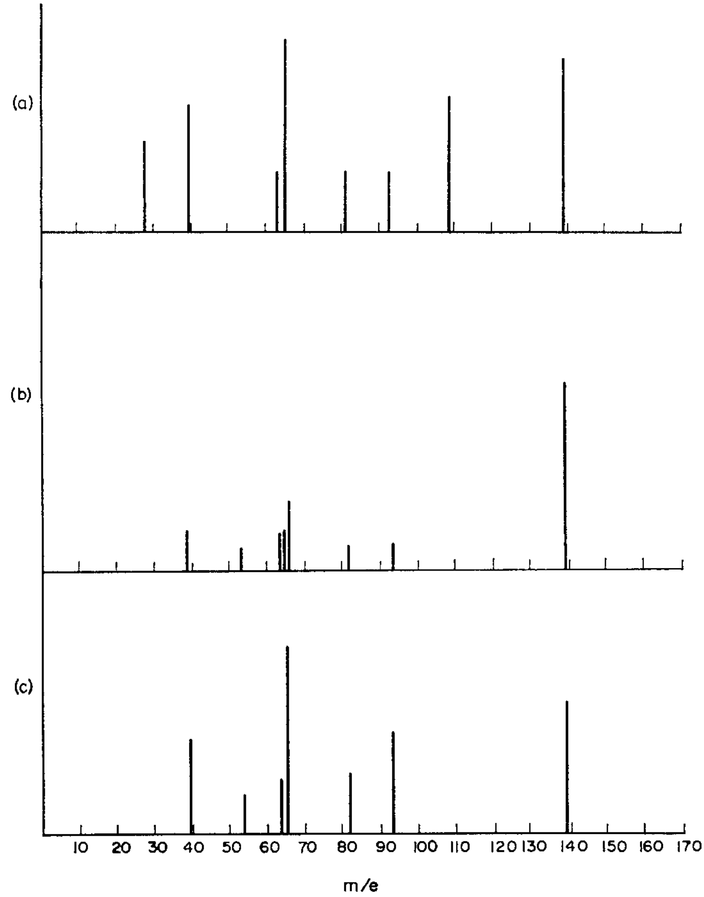

Fig. 1.—Mass spectra of nitrophenols: *a*, *p*-nitrophenol; *b*, *o*-nitrophenol; *c*, *m*-nitrophenol.

Since the energy is lost from the excited ion by breaking chemical bonds the strength of these bonds must have an effect upon the rate. As a result the rate of production of an ion from the molecule ion by the fission of a carbon–bromine bond would be expected to be much faster than if the same ion were being produced by the fission of a carbon–hydrogen bond, which has twice the bond dissociation energy. There are many examples in which this may be clearly demonstrated. The nature of the second species must also play a part in determining the rate of decomposition. Where the un-ionized fragment is a stable radical such as benzyl or allyl, then this dissociation is favoured. A very common example of the effect of the second species is when that species has a high electron affinity and so may readily form a negative ion with the release of up to 3 eV of energy. The most commonly observed example is the production of ion-pairs when compounds containing fluorine atoms are ionized. The high electron affinity of the fluorine atom results in the rapid dissociation of the molecule ion, and the mass spectra of most saturated fluorocarbons have negligibly small molecule ion peaks.[5] The most valuable information from a fundamental point of view would be the thermodynamic heats of formation of the ions, but although many values are available the thermochemical relationships have only been constructed for the simplest cases, and the main obstacle to their use in more complex systems is the lack of information about the excited states of the ions involved. If the mass spectrum represented only the results of the bond-breaking processes then the interpretation of most spectra would be greatly simplified. However, there are in addition a number of other processes occurring, leading to the formation of ions which could not arise by simple bond-breaking. The peaks in the mass spectra corresponding to ions produced in these processes were originally considered as noise, but recent improvements in instrumentation have provided more information about them and their recognition may actually aid structural analysis. These processes, which are normally called rearrangements, usually occur at low energies and result in the formation of an even-electron neutral species and an odd-electron ion, (*cf.* the bond-breaking process leads to the formation of an even-electron radical ion and an odd-electron atom or radical). An exception to this is when hydrogen atoms are involved. Hydrogen atoms appear to be quite mobile in the excited ion molecule and substantial rearrangements occur. Thus in the spectrum of 1,1,1-trideuterodimethyl sulphide[2] there are substantial peaks corresponding to the ions CD_2H^+ and CDH_2^+.[6] Another example of the mobility of atoms is the transfer to metal observed in the mass spectra of metal chelates. The spectrum of the titanium derivative of the diketone benzoyltrifluoroacetone exhibits peaks corresponding to ions in which one or two fluorine atoms have been transferred to the metal atom (Fig. 2). The elimination reactions referred to previously however may be more useful once they are understood. Certainly the most widely known of these rearrangement processes is the McLafferty rearrangement[7] in which the hydrogen atom gamma to a carbonyl or other electronegative group is transferred to the heteroatom with beta-cleavage of the molecular

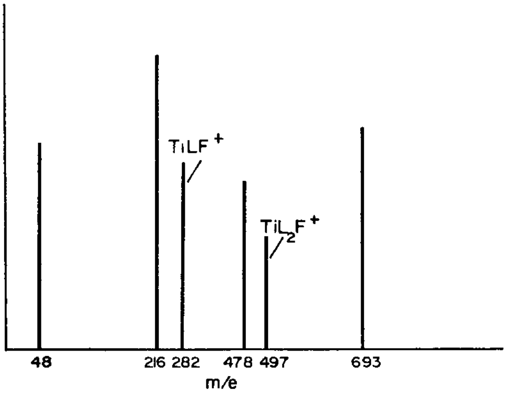

FIG. 2.—Mass spectrum of titanium benzoylacetonate, illustrating fluorine transfer to metal.

ion and the elimination of an unsaturated compound or a diradical (Fig. 3). Other examples include the elimination of CF_2 from atomatic compounds containing a CF_3 group, such as benzotrifluoride,[8] or the elimination of CO from aromatic ketones such as anthraquinone.[9]

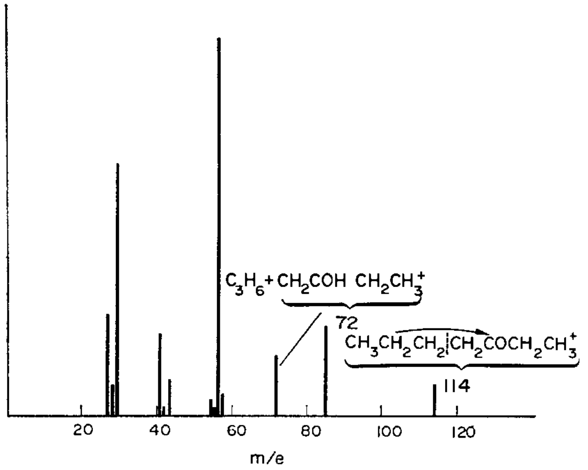

FIG. 3.—Mass spectrum of heptanone-3, illustrating the McLafferty rearrangement.

All these rearrangements lead to the formation of ions having an even mass (provided they do not contain an odd number of nitrogen atoms) and even-mass peaks other than molecule ion peaks are comparatively rare, so that it is easy to pick out the peaks due to rearrangement processes and to infer the structures from which they are formed.

In carrying out identification of unknown species by their mass spectrum alone, there are two techniques now available as a result of modern instrumentation, which are of the greatest assistance. The first of these is precise mass analysis which has been made possible by the development of high resolution instruments. The presently accepted mass scale uses carbon 12 as its standard, assigning it a mass of 12.000000. On this scale the mass of the hydrogen atom is 1.007825 while that of the oxygen atom is 15.994914. It follows that there is an appreciable difference in mass between ions having the same integral mass. Thus both carbon dioxide and propane ions have an integral mass of 44 but their precise masses of 43.989828 and 44.062600 differ by about 1 in 600. As a result a mass spectrometer with a resolution of 1000 can resolve the beams of carbon dioxide and propane ions when they are produced simultaneously and from the mass scale it is possible to say which is which. A higher resolution is required to resolve the mass doublet due to carbon monoxide and nitrogen molecule ions. It can be seen that an assembly of carbon, hydrogen and oxygen atoms gives a unique precise mass and this is true for any other atomic assembly. At the time of writing commerical mass spectrometers are available which have a mass resolution of 100,000 and masses of ions can be measured with a precision of 1 ppm. As a result it is possible to determine the atomic constitution of ions with a high degree of certainty. Taking, for example, the molecule ion of adrenaline, its precise mass is 183.089541 and the nearest precise mass to this which can be envisaged is 183.088195 which differs by one part in 180,000, which is considerably greater than the uncertainty of measurement. The atomic constitution is thus unequivocally determined as $C_9H_{13}O_3N$. The identification of the atomic composition from the precise mass can be carried out by the use of tables of the precise masses of atomic assemblies or may be done automatically with quite a simple computer programme. The atomic constitution of all ions represented in a mass spectrum can be identified provided that either the time or the instrumentation is available. It should be stressed, however, that despite the very great advance in understanding that such information provides, there is still at this stage no direct evidence as to the manner in which the atoms are linked together in the ions. It would be considered a reasonable assumption, on finding that peaks of mass 91 and 77 in the spectra of aromatic compounds were due to the atomic species $C_7H_7^+$ and $C_6H_5^+$, that these were in fact the benzyl and phenyl ions. There is evidence to the contrary, mainly arising from labelling studies, that these are seven membered ring and open-chain structures, respectively. Quantitative evidence about the structure of ions is scanty but there is good reason for believing that the doubly-charged ion of benzene no longer retains its cyclic structure.

The second technique which has been found useful in the study of ionic decomposition is that of metastable defocusing. It was pointed out in the earlier paragraphs that the reactions of ionic decomposition were extremely rapid and that the result of this was the consistency of the cracking pattern. In fact most of the chemistry is complete before the ion has left the source region of the instrument and proceeded to the analysis region, this journey taking a time of the order of a μsec. Some molecules in the ion source have relatively inefficient encounters with the ionizing electrons and as a result have lower amounts of excitation energy in the ions produced. The rate of dissociation of such ions is slower and weakly excited ions may escape from the source region of the instrument before undergoing reaction. The experimental result of this situation is that the ion, having acquired a velocity appropriate to its mass from the accelerating voltage gradient in the instrument, now changes its mass by the loss of a neutral fragment before being subjected to mass analysis. The magnetic field therefore brings this ion to a focus on the mass scale at a position which is neither the focus of the parent or the daughter ion but lower than either. In many cases the masses of the ions are related by the simple equation.

$$m^* = m_2^2/m_1$$

where m_1 is the parent mass, m_2 the daughter mass and m^* the apparent or metastable mass. The ions so produced have been erroneously named metastable ions and the peaks metastable peaks. These peaks may easily be identified in a mass spectrum by their appearance. They are most commonly very much wider than the normal peaks. This is due to the fact that the ionic decomposition is usually associated with the release of kinetic energy, which effectively increases the energy spread of the ion beam for that species only, and hence decreases the resolution, giving wider peaks. In fact there is a quantitative relationship between peak width and kinetic energy release and there have been a number of studies on this relationship, but of more general use is the facility of identifying the parent and daughter ion responsible for the metastable peak. Since the mass of each of these ions must be greater than that of the metastable peak position on the mass scale, and because there is normally a large ion current due to the parent ion, it is a fairly simple matter to find values of m_1 and m_2 which satisfy the equation. As an example, the mass spectra of most saturated hydrocarbons exhibit a peak at $m/e = 39{\cdot}1$ and the appropriate values of m_1 and m_2 for this metastable mass are 43 and 41 respectively. This means that the mode of decomposition can be identified, and on combining this technique with precise mass measurement it can be shown that the decomposition pathway is

$$C_3H_7^+ \rightarrow C_3H_5^+ + H_2$$

This of course does not imply that the $C_3H_7^+$ ion is either a propyl or an isopropyl ion; in fact, what evidence there is, arising from labelling studies, suggests a cyclic structure. In general, metastable peaks are less intense than those produced conventionally and the technique of metastable defocusing allows the operator to overcome this sensitivity problem and eliminate the difficulty of disentangling the normal and metastable spectra. The instrument is so adjusted that only those ions which have suffered a change in velocity as a result of a dissociation process taking place outside the ion source are able to pass a diaphragm situated after the energy selector of a double focusing instrument. The ion current due to ions formed within the ion source is not detected and the spectrum consists only of a series of metastable peaks, the intensity of which can be increased by increasing the amplification of the instrument, without at the same time increasing the signal due to the normal ion processes.[10] It is also possible to scan the spectrum in such a way as to identify all those decompositions associated with one particular ion.

The second approach in the identification of unknown compounds from their mass spectra is to gain additional information by varying the ionization process. The simplest way in which this may be achieved is to vary the energy in the ionizing electron beam. Many of the processes which are possible at energies of 70 eV cannot take place if the electron voltage is reduced to say 10 eV (see *e.g.*, Fig. 4). In some cases it may be possible to eliminate all the dissociation processes and obtain a spectrum which represents only the molecule ions of the sample components. This is however, easiest to achieve if the normal mass spectrum reveals a large molecule ion peak. Reducing the electron energy does not increase the total molecule ion current and may substantially reduce it, but it does increase the relative importance of the parent peak. An alternative to the reduction of electron energy is the substitution of the electron impact source by what has been called the field ionization source. If a molecule is exposed to a potential gradient which is similar to that existing at the outer electronic shells of the molecule then the outer low-energy electrons can escape and the molecule becomes ionized without the transfer of large amounts of excitation energy to the ion. A value of 10^8 V/cm is sufficient for this purpose and this can be created experimentally by a voltage of 10^5 V applied upon a sharp edge with a radius of a few hundred Å, such as a razor blade. The ions accelerated away from this edge are not highly excited and it is possible to create ions from molecules having weak chemical bonds, such as hydrates. Such species would not survive ionization by an electron impact source. Thus the spectrum produced by a field ionization source is very much simpler than that obtained with a conventional electron impact source and it is very much easier to identify the molecule ion.[11]

A further way in which ionization can take place has been studied by Field and relies upon ion–molecule interactions.[12] A conventional ion source is normally

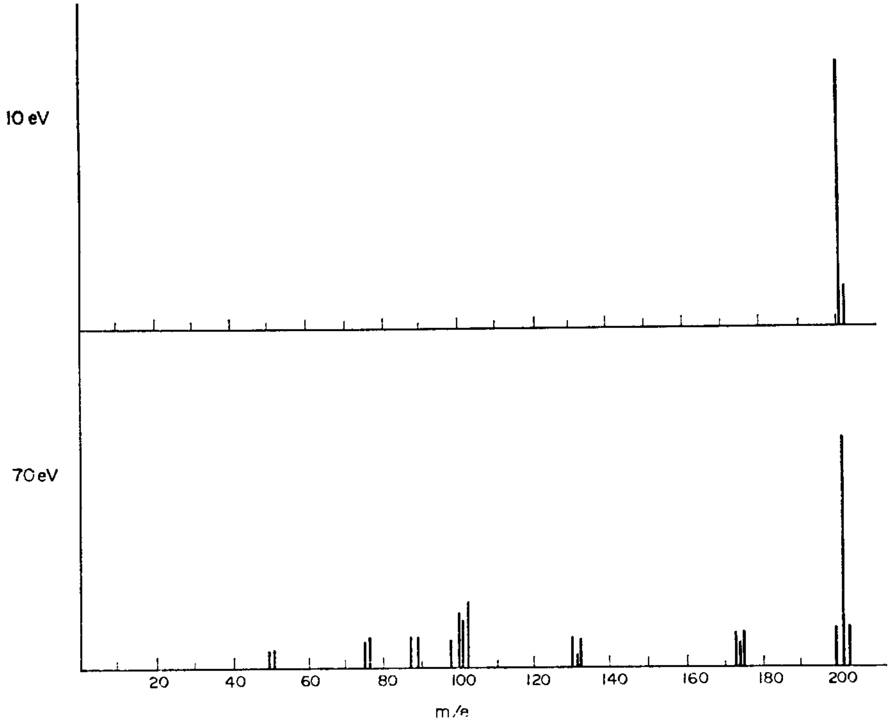

Fig. 4.—Mass spectrum of fluoranthene at 70 and 10 eV.

operated at a very low pressure so that the molecules have a long mean free path and secondary reactions are rendered insignificant. If, however, the pressure is allowed to rise above about 10^{-5} mm Hg the ion may interact with un-ionized gas molecules before it leaves the ion source. It has now become possible to eliminate the danger of producing gas discharges caused by the earthing of ion-accelerating voltages through a high pressure gas and to operate ion sources safely at pressures up to 1 mm Hg. If methane is ionized in such a source, then the methane ion, which is the initial result of the electron impact, abstracts a hydrogen atom from the methane gas to form CH_5^+.

$$CH_4 + CH_4^+ \rightarrow CH_5^+ + CH_3$$

If now a trace of a substance having a higher proton affinity is added to the methane, the proton is transferred to this molecule. The protonated molecule then decomposes in such a way that the charge remains with the fragment radicals. In this way an assembly of molecules gives rise to a mass spectrum with a different cracking pattern from that obtained by normal electron impact.

Finally, there is the purely chemical approach in which the sample substance is subjected to known reactions, the results of which are assessed by running additional mass spectra. The reactions chosen should be those which occur at room temperature (if possible) and lead to the formation of a derivative having a higher molecular weight than the original sample substance. There are a number of such reactions described in the literature, for the quantitative analysis of small amounts of compounds containing functional groups. The simplest possible reaction is that of deuteration. The sample is merely mixed with heavy water and allowed to equilibrate. Any labile hydrogen atoms such as those attached to oxygen atoms in hydroxyl or carboxyl groups will be replaced by deuterium. The result is that the mass spectrum, while retaining its overall pattern, will move to higher *m/e* values for those peaks which correspond to ions which have suffered deuteration. It is thus an easy matter to determine the number of hydrogen atoms replaced and which therefore were attached to oxygen. A second specific reaction which may be used with advantage is the conversion of aldehydes into aldoximes with hydroxylamine hydrochloride solution. For each aldehyde group converted the spectrum moves 15 mass units. The simplicity of this approach is that these reactions may be carried out on the microgram scale on the probe of the mass spectrometer, and the reaction products analysed without any pretreatment. As an example, the following three spectra (Fig. 5) show the spectrum of an alkaloid precursor[13] and its reaction products with heavy water and hydroxylamine hydrochloride. The presence of one hydroxyl and one aldehyde group is clearly indicated and the structure of the compound has been shown to be

INSTRUMENTATION

Mass spectrometry shares with the technique of molecular beams the distinction of being the physical method slowest to receive widespread acceptance and exploitation by the chemist. Both were being used by the physicist before the last war and it is only recently that the mass spectrometer has taken its place beside optical spectrometers in the laboratory for routine sampling and analysis. In no other technique has there been such widespread proliferation of instrumentation or so wide an application to diverse analytical problems. In this section the main types of instrument will be discussed and examples given. A more complete review has been made by Beynon and Fontaine.[14]

At the present time, because of the very diverse nature of the instruments which may be classed as mass spectrometers, it is necessary to define the instrument in the most general terms. The one feature which all instruments have in common is that ionization and mass analysis take place in a high vacuum system. Briefly then, a mass spectrometer is a device which is capable of introducing a sample into a high vacuum and converting a proportion of the molecules in the resulting vapour into ions. The ions so produced are classified according to their mass to charge ratio (m/e) and the abundances of each ionic species is measured and recorded. As will be discussed in a later section, because such measurement and recording takes an appreciable interval of time, ion abundances must be detected as ion currents n_1/t. In order to give any significance to such ion currents, it is necessary to maintain a constant partial pressure n_{M} of the sample in the source and to keep a constant rate of ionization n_X/t. These considerations are unimportant in the design of a mass spectrograph, where only the masses of the individual ions are to be measured. These instruments, however, are comparatively rare.

The story of the development of the modern mass spectrometer is an account of continued efforts to improve the sensitivity of the machine, to increase its ability to distinguish between ions of closely similar mass, *i.e.*, its mass resolution ($m/\Delta m$) and to decrease the time taken to record the magnitude of the ion currents, *i.e.*, the mass spectrum. At the same time there have been attempts to increase the range of the instrument both in the production of ions of higher m/e values and in the classification and recording of such ion currents.

180°-*Focusing instruments*

An ion moving with uniform velocity in a magnetic field at right angles to the plane of its motion describes a circular path provided that the magnetic field is constant and uniform. This principle was exploited in the earliest form of mass spectrometer described by Dempster[15] in 1918, and it is of considerable interest that an instrument of this type is still in an active stage of development today. Positive ions are accelerated in a potential gradient V and enter a uniform magnetic field H which is perpendicular to the direction of their motion. The ions of mass m aquire a velocity v and so have an energy given by $\frac{1}{2}mv^2 = \mathrm{e}\mathrm{V}$, where e is the electronic charge. The radius R of the circular path which the ions describe is then given by the equation

$$Hev = \frac{mv^2}{R}$$

On combination of these two equations the field and potential gradient requirements for an ion with mass to charge ratio m/e travelling in an orbit of radius R are given by

$$m/e = \frac{H^2R^2}{2V}$$

The uniform magnetic field has a focusing action equivalent to that of a cylindrical lens so that beams of ions issuing from a slit are brought to a focus after suffering a deflection of 180° to form a first-order image of the slit with ions of the appropriate m/e values for the given field strength and potential gradient. This system is thus direction-focusing so that it is not necessary to inject a parallel beam of ions into the magnetic field. On the other hand, it requires that all ions having the same m/e value should have the same velocity v, that is to say this is not an energy-focusing system. The resolution of this type of instrument depends upon the homogeneity of the magnetic field over the whole of the ion path, the stability of the ion-accelerating potential difference and the width of the entrance and exit slits. The optimum values for slitwidths are those in which a successful compromise is achieved between the increase in resolution obtained by reducing slitwidth and the accompanying reduction in sensitivity.

Before giving any actual values of mass resolution achieved by various instruments, it is necessary to make a satisfactory definition of the term $m/\Delta m$. The original definition used by Dempster is expressed in the formula

$$m/\Delta m = R/(S_1 + S_2)$$

where S_1 and S_2 are the entrance and exit slitwidths. This makes the assumption that a perfect image of the entrance slits is formed in the plane of the exit slit and that the adjacent beams of ions are resolved when one image occupies the exit slit while none of the ion current due to the adjacent image enters the exit slit. Owing to imperfections of the experimentally attainable ion optics system, this simple equation cannot be retained as an adequate definition of mass resolution. The image will be distorted, having chromatic aberration due to variations in the kinetic energy of ions of the same mass and would have "wings" on either side due to the gas scattering in the ion path. These aberrations are taken into account by assuming a constant β such that the effect of the aberrations is shown to be proportional to the radius of curvature of the ion path as in

$$m/\Delta m = R/(S_1 + S_2 + \beta R)$$

Despite the obvious value of this equation it is more common to apply an empirical definition of mass resolution in which unit resolution is said to be achieved when there is a valley between adjacent peaks in a mass spectrum record. The peaks should be of equal height and the depth of the valley is chosen arbitrarily; the height of the valley above the base-line is expressed as a fraction of the peak height. When comparing the advertised performance of commercial instruments or the published figures for mass resolution of experimental instruments, it is important to identify the criterion which has been applied for unit mass resolution, as this can range over two orders of magnitude. Alternative criteria for resolution which have been suggested are based on peak width or contribution to a mass peak from an adjacent peak of the same height. The effect of slitwidth on mass resolution in a modern 180°-focusing mass spectrometer is illustrated in Fig. 6 which shows a mass spectrum for krypton recorded with slitwidths of 0·25 and 0·50 mm.

The stability and simplicity of this method of mass selection has led to its adoption and development in a range of low-resolution instruments. In particular, Associated Electrical Industries have produced a number of commercial instruments under the generic name of M.S. 10 and 20, based on a design with a radius (*R*) of 5 cm. These instruments are still in a state of active development and improvement. The original design used a large permanent magnet with a field strength (*H*) of 1840 gauss. Scanning of a mass range of 1–200 was achieved by varying the accelerating voltage (*V*) either continuously or in steps. The resolution which could be achieved with a slitwidth of 0·50 mm was 40 with a 2% peak valley between adjacent peaks of equal height. This type of instrument is suitable for use as a sophisticated ionization gauge, when it may be bolted directly to the vacuum system being monitored. Alternatively, it may be used for leak testing, by using a gas with a characteristic mass spectrum as the test gas for tracing the leak in a vacuum system. The resolution is adequate for the identification of most of the residual gases found in high-vacuum systems.

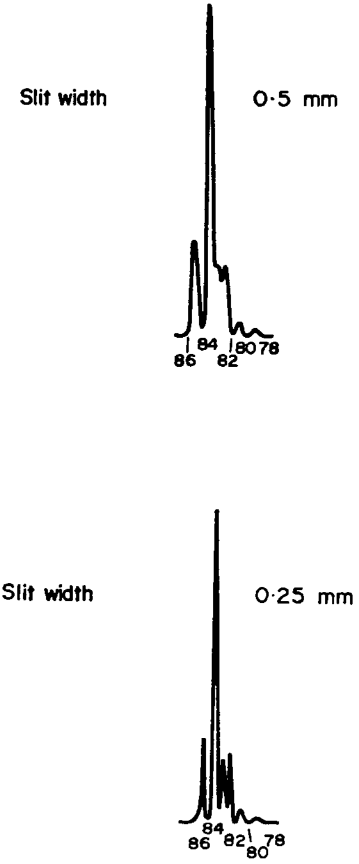

FIG. 6.—Effect of slitwidth on resolution: mass spectrum of krypton.

Recently, this design has been modified so as to convert the instrument into a versatile mass spectrometer for low-resolution general analytical studies. The mass range has been extended to 1000 by replacing the permanent magnet with a large electromagnet capable of providing fields up to 11,000 gauss. The resolution has been increased to approximately 550 by reducing the slitwidths to 0·025 mm and increasing the detector sensitivity. This design is particularly flexible since it permits the magnetic field to be swept at a number of alternative accelerating potentials.

The same company also produced a greatly simplified design in the Minimass Partial Pressure Gauge. The radius has been reduced to 1 cm and a small permanent magnet with a field strength of 4000 gauss is employed. Voltage scanning up to mass 240 permits the identification of each mass on a linear scale and the mass resolution is approximately 28 with 50% peak valley between adjacent peaks. This inexpensive compact model is intended for monitoring vacuum systems.

Similar models to the M.S. 10 range have been produced by the Atlas Co.* of Germany ($R = 28$ mm, $H = 2750$–4000 gauss, $m/\Delta m$ 18–44) and the Consolidated Electrodynamics Corporation of the U.S.A. ($H = 800$–6000 gauss, $m/\Delta m$ up to 600 with an electrostatic slit).

The chief advantage of the 180°-focusing system has been its comparative simplicity and consequent low price. The chief disadvantage in the past has been the necessity to scan the mass range by adjusting the ion-accelerating potential (V) so that ions are collected with varying efficiencies, the heavier ions requiring low potentials. Thus the sensitivity is lowest for ions with the highest m/e value and since in general such ion currents will give the most information from an analytical point of view, this reduction in sensitivity is a disadvantage. The recent substitution of large pole-face area electromagnets for the conventional permanent magnet has eliminated this disadvantage, permitting magnetic scanning. Although there is a corresponding rise in cost, the resulting flexibility has made this type of instrument the most important of the low-resolution magnetic series. The limiting factors in any further improvement of performance with this type of machine are the mechanical difficulties associated with providing source slitwidths of less than 0·025 mm and the resulting problem of providing additional detector sensitivity.

Sector field instruments

It was shown in 1940 that the phenomenon of the focusing of ion beams by causing deflection through 180° in a homogeneous magnetic field was in fact a special case of focusing by means of an inhomogenous field.[16] The ion beam should leave and enter the magnetic field at right angles to the field boundary and inside the field the ion describes a path which is a sector of a circle. The angle subtended by this sector may be 60°, 90° or in the limiting case above, 180°. The separation of ions of different mass to charge ratios takes place in an exactly analogous manner and beams of ions from the source situated some distance from the field boundary are brought to a focus at a collector symmetrically disposed on the other side of the sector magnetic field. The disadvantages of this type of geometry are the long path with consequent greater probability of collisional scattering, and the difficulties associated with the precise alignment of the sector magnetic field to obtain satisfactory focusing. On the other hand, there are considerable advantages in having both source and collector in

---

* Now Varian Mat.

field-free regions. The source is more readily accessible so that a variety of modifications may be carried out and the collector may be fitted without difficulty with an electron multiplier to increase detector sensitivity.

The most successful machine of this type was first introduced by the Metropolitan-Vickers Company (now G.E.C./A.E.I.) just before 1950. The M.S. 2 was a 90°-sector 15-cm radius instrument issued originally with a mechanically adjustable collector slit providing a maximum resolution of about 300. This resolution was later doubled by the use of a collector slit having an effective width which could be altered by giving it a high positive potential. For quantitative studies the collector slit was set at 0·62 mm to give a lower resolution but increased reproducibility, the record being in the form of a series of flat-topped rather than pointed mass peaks. A greatly improved version using the same basic geometry with a 90° sector of radius 15 cm was the M.S. 2H. The addition of an electron multiplier at the collector provided increased sensitivity, permitting a further increase in resolution to above 650. The mass range with the normal accelerating voltage of 2 kV was extended to 650 by increasing the magnetic field.

There have been a number of variations on this type of instrument, the most notable being the Atlas CH_4 with a resolution in excess of 1000.

A further stage in the improvement of the performance of the 90°-sector field instrument was provided by the A.E.I. M.S. 12 design in which the radius of curvature had been increased to 30 cm. A further decrease in slitwidth to 0·0125 mm was made possible by increasing the ion accelerating potential to 8 kV and with an electron multiplier detector a mass resolution of 7500 was achieved. In this design, which is now obsolete, both magnetic and voltage scanning facilities were provided, the latter permitting a mass spectrum to be displayed in less than 1/5 sec.

Double-focusing instruments

A beam of positive ions may also be analysed according to the velocity which the ions have attained. This velocity is proportional to the square root of the mass, provided that all the ions have suffered the same acceleration in a potential gradient, and velocity analysis is normally achieved by passage through transverse electrostatic fields. The principle of combining velocity and mass analysis to provide instruments having both direction and velocity focusing of beams of ions was discussed by a number of mass spectrometrists but little progress was made until Mattauch and Herzog[17] formulated their theory of double focusing, employing a radial electrostatic field for which $R\,dV/dR =$ constant where R is the radius and V the potential, and there is a homogeneous sector magnetic field. The improvements in the definition of the ion optic image made possible by the application of this principle stimulated the construction of a number of double-focusing instruments, culminating in the commercial development of two different types.

The first of these commercial double-focusing mass spectrometers was described in 1958 by Craig and Errock.[18] It was based upon the geometry suggested by Nier and Johnson[19] and was marketed as the first instrument specifically designed for the qualitative analysis of organic compounds. The commercial version became the A.E.I. M.S. 9 mass spectrometer.* It combined a magnetic sector of 90° with a radius

---

* Similar instruments have been developed by the Hitachi Organization in Japan and marketed by Perkin–Elmer.

of 15 cm, with an electrostatic analyser of radius 18·25 cm. A source slitwidth of 6·25 μm was used to give a resolution of 10,000. The instrument had the novel features of oscilloscope peak-matching, by which the precise masses of known and unknown ions were compared, with an accuracy sufficient to permit the identification of the atomic constitution of the unknown ion provided it had a mass of about 200. A further feature was the ability to record the spectra of compounds of low volatility by direct sample insertion into the ion source. There has been a steady improvement in the performance of the double-focusing instrument over the past ten years and the most recent models have a magnetic sector of 30 cm radius and an electrostatic sector of 38 cm radius with a source slit that can be reduced to 0·1 μm to give a resolving power of 100,000. At lower resolving powers the scan duration can be reduced to 2 sec. Additional features have included combined electron bombardment, field emission and water-cooled sources to permit the study of labile organic compounds. With a spectrometer having these characteristics it is possible to determine the atomic constitution of almost all the ions normally responsible for the peaks in a mass spectrum. However, making a number of precise mass determinations by the peak comparison technique is time-consuming and the most recent development is to carry out these determinations automatically by the aid of a small computer. The output from the spectrometer is digitized and the centroid of each mass peak determined from a score of ion current measurements or by differentiation. The centroids of known and unknown peaks are then compared not in terms of accelerating voltage as in the manual technique, but in terms of time with the aid of a megacycle clock. The spectra may be stored on magnetic tape to be played back in analogue form or they may be printed out in the form of a table of atomic constitution and ion abundance.

Double-beam mass spectrometer

The most recent development in instrument design has been the production of a double-beam instrument by the A.E.I. organization (M.S. 30). The beams from two ion sources are bent so as to pass through a single mass-analyser system and then allowed to diverge to two separate detectors. With such an arrangement it is possible to compare the spectra of two compounds recorded at the same time on a single chart recorder. The spectra may be of known and unknown compounds, permitting direct chemical mass marking or matching of spectra. The two spectra may equally well be those of a single compound ionized and analysed under different conditions, e.g., high and low resolution or electron voltage. The operation of this instrument has been simplified so as to make it appeal to the routine analyst. The multiplicity of controls on older models has been replaced by a few interlocked push buttons.

Spark-source mass spectrography

In the double-focusing high-resolution mass spectrometers described above, the deflection due to the electrostatic and magnetic sectors is in the same sense. In an alternative geometry, ion optic image corrections and double focusing may also be achieved if the two deflections have opposite senses.[20] In addition to providing high resolution, this geometry has the further advantage that all ions are brought to a focus in one plane. The result is that a complete mass spectrum may be recorded simultaneously by placing a photographic plate in this plane. These features were exploited successfully in instruments produced by the A.E.I. company in this country and the Atlas Co. in Germany. The ability of the double focusing system to accommodate ions with a large spread of kinetic energy made it possible to use an instrument for elemental analysis in which the ionization was carried out with a high-frequency spark. In the A.E.I. M.S. 7 the substances to be submitted to elemental analysis were incorporated into carbon electrodes if they were themselves non-conducting and submitted to the action of a high-frequency spark in the ion source region. The resulting vapour was then ionized and the ions submitted to mass analysis. Detection was by means of a photographic plate which not only permitted the simultaneous recording of ion currents at all masses but also compensated for variations in spark intensity by integrating ion current with time. The final measurement of ion abundance was made by developing the plate and measuring the density of the appropriate line. Comparisons with standards permitted quantitation of the technique and made it a competitor to emission spectrography. The great advantage of spark-source mass spectrometry is its ability to give a quantitative analysis of a large number of trace elements at the same time with only a few exposures. The limit of detection is very much lower than that of any other technique except activation analysis. Limits of detection of 1 in 10^9 are frequently quoted and the sample size may be as small as 50 mg.

While this type of instrument is eminently suitable for photoplate detection, the plate can be replaced by a slit and the ion current detected electrically. The spectrum may be scanned past the slit as in other instruments. This versatility has been made use of in designs developed by the Atlas company, who have marketed models which can be used with either electron bombardment or spark sources and with either photographic or electrical detection.

Mass filters

There are three types of non-magnetic mass analysers which can be classed as mass filters, that is devices in which radiofrequency fields are used to selectively exclude ions from a detector; they are classed according to their electrode systems and have been given the names of the quadrupole, the monopole and the three-electrode mass filters.

The quadrupole system consists of four rods which are mounted along the direction of the ion path between the ion source and the collector. The ions enter the space between the rods where they experience a radiofrequency field. Paul was the first to describe such an arrangement and in his design the rods were collinear and symmetrically disposed around the ion path, with opposite pairs being interconnected.[21] The potentials applied to the rods are as follows

$$V_x = U + V \cos \omega t$$

and

$$V_x = -V_y$$

where V is the amplitude of an RF sinewave of frequency ω, U is a superimposed d.c. voltage and x and y are planes at right angles to the ion path. Theoretically the rods should have a hyperbolic cross-section; in practice, with the exception of the instrument marketed by Industrial and Technical Equipment Co. Ltd., the cross-section is circular, and it is usual to make the distance between opposite pairs of rods smaller than the rod diameter by a factor of 1·16.

Under the conditions that $U/V < \frac{1}{6}$ for a given value of the RF amplitude V, only ions within a very small mass range can execute stable trajectories along the length of the rods and escape to the detector. All other ions have unstable trajectories which end in a collision with the rods. In order to scan a mass spectrum either the frequency or the RF amplitude V may be swept and for wide scans a combination has been preferred. Rods are about 20 cm long and 0·6 cm in diameter, so the assembly provides a very compact mass analyser. The upper frequency range is determined by power requirements and is about 5 MHz. The great advantage of this type of analyser is that it is insensitive to variations in ion energy, so quite crude sources can be used. On the other hand, it has the disadvantage of requiring very precise rod alignment and stability, of the order of a few thousandths of a centimeter. The power supplies must also be very stable and for the highest resolution the U/V ratio must be kept constant within at least 1 in 20,000. The first commercial mass filter was produced by the Atlas Co. in Germany in 1963. It has a resolution of 100 and a mass range of 2–100. More elaborate instruments have been produced by the E.A.I. Co. and most recently by the Finnegan Instrument Corporation. The latter organization has produced the mass filter with the highest performance, it being capable of scanning up to a mass of 750 with a resolution of 1000. Other instruments with more modest performances have been introduced by GEC/AEI, Vacuum Generators, Baltzers, 20th Century Electronics and Varian. The ability of the mass filter to scan a wide mass-range in a very short time interval has been exploited in the mass spectrometer/gas chromatograph combination described later. While in theory very high resolutions are accessible with the mass filter, at present it is in the stage of being an inexpensive low- and medium-resolution device having the virtue of rapid scan and small size.

The monopole

It was first pointed out by von Zahn that one quarter of the geometry of the quadrupole could be replaced by a single rod and a grounded electrode with a right angle cross-section.[22] The operation is the same, both RF and d.c. voltages being applied to the rod and scanning achieved by sweeping either the RF frequency or amplitude. As in the case of the quadrupole, the monopole suffers from the disadvantage of giving spiked peaks rather than the flat-topped peaks produced by magnetic sector instruments. On the other hand the monopole has the advantages of providing spatial separation of ions so that it is feasible to record several ion currents at the same time. In addition, the stability requirement of the U/V ratio is greatly reduced so that simple power supplies can be used while good resolution can be achieved without the same mechanical requirements. The chief disadvantage of the design is the sensitivity to contamination by particulate matter, which causes peak splitting, while small changes in the operating conditions may introduce large variations in the relative intensities of the ion currents. Nevertheless, a successful monopole partial pressure gauge *i.e.*, a low-resolution monopole, has been marketed by Veeco Instruments Ltd. It has a mass scan of 1–200, a resolution of 50 and a minimum detectable total pressure of 5×10^{-9} mm Hg.

The three-electrode analyser

This was first described by Fischer.[23] It is a very compact arrangement, each electrode being part of a hyperboloid of rotation. In practice this amounts to a ball-bearing being placed above and below a ring of the same cross-section. It will be at once realized that the quadrupole and three-electrode assemblies have the same cross-section geometries but the latter is in fact a three-dimensional device so that ions cannot escape from a field between the electrodes once they have entered it. The ions circulate continuously around the axis of the field, unstable ions being lost as before by collision with the electrodes. The stable ion current is detected by means of the inductive load which it presents to an external oscillator. High sensitivity has been obtained for the three-electrode system in experimental models, which have detected as few as 10,000 ions. There is also the possibility of storing ions for relatively long periods and hence integrating weak ion currents.

Time-of-flight mass spectrometers

In the time-of-flight mass spectrometer first described by Stevens[24] the ionizing electron beam was intermittent rather than continuous. The electron pulse lasted about 0·1 μsec and the time of a complete cycle was about 100 μsec. The ions formed during the pulse were accelerated into a drift tube which they traversed on their way to a detector. The rate of travel was inversely proportional to the square root of the mass to charge ratio, and with sufficiently good time resolution of the signal obtained from the detector it was possible to isolate the individual pulses produced by the separated bunches of ions. An oscilloscope was the most suitable means of displaying such a spectrum, provided that the time-base was coupled to the pulsing circuits. The original designs were rather insensitive but later instruments stored ions in the source for a few μsec before initiating the analysis, and commercial instruments such as that manufactured by the Bendix Co. have sensitivities which are comparable with those of other instruments. While repetition rates as high as 100,000 per sec at resolutions approaching 1000 are possible, it is important to stress the fact that the dynamic range under such conditions is low and good analytical operation is only possible by integration over some hundreds of cycles.

The great advantage of this type of mass analyser is the simplicity of the source and non-critical nature of the source and flight-tube geometry. Apart from the ability of the detector circuits to resolve smaller and smaller time intervals the only way of increasing the resolution of time-of-flight instruments is to increase the length of the path between source and collector. In order to prevent the size of the drift tube becoming unmanageably long the ions may be constrained by magnetic fields to move in a helix. A device of this type was recently described under the name of the Spiratron.[25] It is interesting that under these flight conditions the more energetic ions move in longer paths and arrive at the detector later, thus providing the possibility of a two-stage instrument. In this a helical path is coupled with a straight path in which the more energetic ions arrive first, thus eliminating the reduction in resolution caused by energy spread of the ion beam.

APPLICATIONS

Coupling with the gas chromatograph

The advantages of the direct coupling of the effluent of a gas chromatographic apparatus with the inlet system of a mass spectrometer were outlined in the introduction. The methods of carrying out the combination are discussed briefly here; for a more detailed discussion the reader is directed to earlier reviews.[26,27] There are two problems associated with such a combination, the first being the necessity of recording the mass spectrum during the period in which the sample is emerging from the base of the chromatographic column. This time may vary from about 10 sec to above 1 min, but during this time, in which the signal is rising and falling on the chromatograph detector, the concentration of the sample in the effluent carrier gas stream is rising and falling also. It is advantageous to record the mass spectrum with a constant sample pressure since otherwise the relative intensities of the ion currents will not be constant and the matching procedure referred to earlier will not be possible. For these reasons it is important to record the spectrum in a fraction of the time required for the whole of the sample to emerge and to make this record when the concentration is at its maximum. (Or alternatively to use a normalizing procedure based on a total ion-current measurement.) It is easier to change the accelerating voltage rapidly than to alter the magnetic field, and in many simple combination instruments the mass decade can be scanned in a second or less. Recent advances in instrumentation of magnetic instruments have made it possible to scan a mass decade magnetically in about 2 sec. This eliminates the disadvantage (associated with voltage scanning) of the lower efficiency of collection of the heavier ions. Much faster times of scanning are available with non-magnetic instruments and no problems are encountered with their use, for these reasons. A rapid scan allows the experimenter to examine partially resolved chromatographic peaks by recording the mass spectrum at the beginning and end of the chromatographic peak. In these spectra the role of the two sample components in the two spectra will be revealed.

The second problem associated with the direct coupling of the two instruments is the carrier gas. Even when the sample is at its highest concentration in the carrier gas effluent from the column, it is still present as only a small fraction of the carrier gas concentration. The direct admission of the carrier gas stream to the ion source would therefore result in the production of a high source pressure and in the recording of a mass spectrum which was largely that of the carrier gas itself. In order to overcome this problem it is necessary to achieve a segregation of the sample and to admit only it to the ion source, preferably without any loss of the sample. This ideal case has never been achieved in practice but there have been three successful compromises.

The first of these was developed by Ryhage and relied upon the effusion of the gas mixture from a narrow orifice for its separation.[28] The carrier gas used was helium and together with the sample the effluent passed through such a jet into a chamber at a reduced pressure. Immediately opposite to the jet was a small aperture leading to a second jet. The helium, because of its low gas density, had a high component of velocity at right angles to the line of flow and so collided with the chamber walls and was pumped away. The heavier sample molecules entered the aperture and issued together with a reduced amount of helium to the second jet where the process was repeated, the final aperture leading directly to the ion source and the second chamber being held at a pressure lower than that in the first chamber. Recoveries of the order of 50% of the original sample were achieved and the carrier gas concentration was reduced to 2%.

The second method also depended for its success on the exploitation of the low density of helium. The Watson-Biemann separator[29] allowed the effluent to pass into a tube made of glass frit or sinter. An outer jacket surrounded the frit and the annular space was continuously pumped out. The helium diffused through while the sample passed along the tube to the ion source. Recoveries of about 15% were achieved and the carrier gas concentration was reduced to a few per cent.

The third separator, which is now promising to oust all the others (although at present the majority use a glass frit separator) because of its cheapness and simplicity, was originally suggested by several investigators and is called the membrane separator. It uses a thin film of a polymer, usually silicone rubber, to divide the effluent stream from the ion source. The sample components are soluble in the membrane and diffuse through it into the ion source while the carrier gas is excluded. To eliminate memory effects and to increase the rate of diffusion and hence the response time, the film must be made as thin as possible. The recovery can be as high as 25% and the residual carrier gas concentration as low as 5%. All three separators are usually heated in order to increase the rate of the separation process and to reduce adsorption. There are a number of commercial instruments sold as a gas chromatograph–mass spectrometer package. The first successful design was the LKB 9000 which used the Ryhage separator, had a resolution of about 1000 and required a total sample size of only 0·1 μg. The GEC/AEI Co. used the glass frit separator in their M.S. 12 which in its final stages of development had a resolution of 7500 and required a sample size of only 2 μg. The M.S. 12 has now been replaced by the M.S. 30 double-beam instrument described previously, which uses a membrane separator. Lower resolution magnetic sector combinations have been developed by Edwards High Vacuum Ltd., and Vacuum Generators Ltd. The GEC/AEI Co. have combined their 180°-focusing instrument (the M.S. 20) with a gas chromatograph. The rapid-scan facility and low cost of the quadrupole mass filter have made it an attractive gas chromatograph detector and the EAI Co. and the Finnegan Instrument Co. in the U.S.A. have manufactured competitors to the magnetic instruments, using both frit and membrane separators. The resolution is in the 500–1000 range and the sensitivity is 3×10^{-11} g/sec. They have a very high scan-rate and indeed the scan-rate of all the instruments described is sufficiently fast to permit oscilloscope presentation of spectra. This is a useful facility because whether chromatographic peak detection is made by an external detector or by the ionization facilities of the instrument operating at an electron voltage below that of the ionization potential of the carrier gas, no peak identification is possible until the spectrum is run. The use of the oscilloscope obviates the need for the recording of unrequired mass spectra merely for peak identification purposes. In an analysis of a complex sample mixture this could be a costly undertaking.

The determination of isotopic constitution

The examination of any mass spectrum of an organic compound immediately reveals the polyisotopic nature of naturally occurring carbon, sulphur, chlorine, bromine and boron. The small proportions of the heavier stable isotopes of hydrogen, nitrogen and oxygen are less obvious. All these isotopes are stable and should not be confused with artificially produced radioactive isotopes such as carbon-14. The very great success of labelling techniques based on radioactive isotopes may be shared to some extent by the use of artificially enriched stable isotopes. The ability of the mass spectrometer to detect stable isotopes can never be as great as the ability of the counter to detect radioactive isotopes, but the great advantage is that the stable isotopes may be handled with none of the precautions inherent in the handling of radioactive compounds. The principles involved in tracing with stable isotopes are, however, exactly the same, the change in the isotopic constitution of samples (drawn from a dynamic or reacting system) being assayed by the mass spectrometer, and the signal at the abnormal isotope peak being analogous to the signal derived from the counter.

There is, however, a further advantage in the mass spectrometer method, because the ionization is followed by a dissociation process in which the labelling atoms are combined with fewer and fewer of the other atoms in the molecule. Thus an examination of the spectrum can give information not only on the extent of labelling but also on the position of labelling within the structure. In order to do this of course it may be necessary to use all the techniques which have already been outlined in previous paragraphs, such as precise mass determination.

If now the spectra of the labelled and unlabelled molecules are compared and the atomic constitution of the fragment ions is determined, it will be seen that the labelled atom is concentrated in one part of the molecule. This of course can only be achieved when the label atom is part of the backbone of the molecule. As has been observed earlier, hydrogen and deuterium atoms are notoriously labile in the ions and it is difficult to draw any but statistical conclusions from such labelling. This determination of the site of introduction of the label atom depends upon the ionization of a compound sufficiently volatile to permit evaporation into the source of the mass spectrometer. In some cases, because of the complexity of the reaction mixture or the intractable nature of the products, it may not be possible to make such a determination. It may still be feasible to get tracing information by conversion of the reaction mixture or some part of it into a volatile product which contains the stable isotope. In the case of carbon-14, radioactive tracing of the labelled compound is achieved by conversion into carbon dioxide or even methane. A similar conversion may be carried out with compounds containing carbon-13 and the ion current at $m/e = 45$ used as a measure of the total carbon-13 content. In a similar way the nitrogen-15 content of, for example, excreted urea, may be determined by Kjeldahl digestion followed by a hypobromite treatment to release molecular nitrogen. The ion current at $m/e = 29$ is a measure of the enrichment of the sample. Oxygen-18 may be assayed by pyrolysis followed by the oxidation of the carbon monoxide to carbon dioxide. The ^{18}O concentration is measured at $m/e = 46$. The precision of these measurements can be quite high and is improved by integrating the results of a number of measurements. The sensitivity depends upon the dynamic range of the instrument and can have a value of 0·01 atom %. When determinations of the isotopic concentration of both carbon and nitrogen are required the mass spectrometer may be connected directly to a conventional C, H, N analyser.

The very great advantage of the stable isotope method of tracing is that quite highly labelled material may be fed to experimental animals or patients without fear of the side-effects arising from the administration of similar doses of radioactive material. With the increasing availability of compounds labelled with ^{13}C, ^{15}N and ^{18}O and the wide distribution of moderately priced instruments capable of analysing them, a large increase may be expected in the use of stable isotope tracing in the biochemical and medical fields.

Quantitative analysis

With an ion source with a constant ionizing electron beam current and with a constant source pressure of the sample gas it is possible to determine the sensitivity of an instrument for any particular substance. Since in general any substance will produce ion currents at a number of different m/e values the sensitivity at any one of these values may be chosen. In the absence of any reason to the contrary the value chosen will be that at which the most intense ion current is produced, that is to say the m/e value corresponding to the highest peak in the mass spectrum. It is however difficult to record the pressure of the sample vapour in the ion source by any other than some form of ionization gauge, because of the very low pressures involved. It is therefore common practice to establish a constant flow of sample vapour through a capillary or sinter into the ion source from a reservoir of the sample gas maintained at a higher pressure. The sample pressure in the reservoir and hence the pressure in the ion source remain substantially constant during the time in which measurements are made. Once the instrument has been calibrated by measuring the sensitivities on selected m/e values for pure sample vapours the analyst is in a position to deal with any mixture of those compounds for which he has recorded sensitivities. For every component in the mixture the analyst must measure the intensity of one ion current or peak height in the mixture spectrum. While it is sometimes possible to calculate the mixture composition by a spectrum-stripping technique, a more general method is to express the values of the ion currents or peak heights as sums of the products of sensitivities and partial pressures, obtaining a series of linear simultaneous equations and to invert the matrices. For complex mixtures this is best carried out by computer. It is sometimes impossible to carry out this routine because the resolution of the instrument is not sufficient to enable separation of ion currents at closely similar m/e values. If this is the case then a solution to the problem is to record two spectra of the mixture, one before and one after the quantitative conversion of one of the components of the mixture into a second substance. As an example the masses of carbon monoxide and nitrogen differ only by 1 part in 2800 and if the instrument available cannot achieve this resolution then a low-resolution spectrum is recorded and then the sample vapour in the inlet system is exposed to iodine pentoxide which converts the carbon monoxide into carbon dioxide quantitatively. A second spectrum is then recorded and in this spectrum the ion current at mass 28 is due only to nitrogen. From a comparison of the two spectra the concentration of carbon monoxide can be deduced.[30]

Analyses such as those described can only be carried out if a few milligrams of the sample are available and if the sample is sufficiently volatile to permit the achievement of suitable reservoir pressures. Much modern mass spectrometry is carried out, however, with solid samples of low volatility and these are normally analysed by introducing them directly into the ion source on the end of a ceramic or glass probe which is inserted into the instrument through a vacuum lock and within a few mm of the ionizing electron beam. In the most recent developments the probe may be heated or cooled to control evaporation. The resulting vapour molecules move only a short distance before they become ionized and so substances with extremely low vapour pressures may be analysed. Under these circumstances the sample pressure within the source is controlled only by the rate of evaporation and can only be adjusted crudely by altering the temperature or the position of the sample. It is thus not easy to calibrate the instrument or to analyse quantitatively. Further, since sample sizes have tended to diminish, the sample pressure may vary widely during evaporation, owing to the exhaustion of the solid on the probe. For this reason an alternative system has been devised in which the ion current due to the sample is integrated while the whole of a known amount of the sample is being evaporated. It is then possible to relate the integrated ion current to the amount of sample evaporated and to determine a sensitivity for the instrument with that sample.[31] One method of doing this would be to scan the whole mass spectrum repetitively at as rapid a rate as possible, while evaporating the sample, and to measure the corresponding peak height on each scan and plot peak height against time for each significant *m/e* value. This is possible experimentally and Fig. 7 shows the results of such a determination, using 60 ng of *p*-tyramine as the sample. The total evaporation time is about 100 sec. However, the recording of a large number of spectra is an expensive process and measurement of the spectra is tedious. The system only becomes practical if the mass spectrometer output is digitized and stored either on tape or in a core for processing by computer.

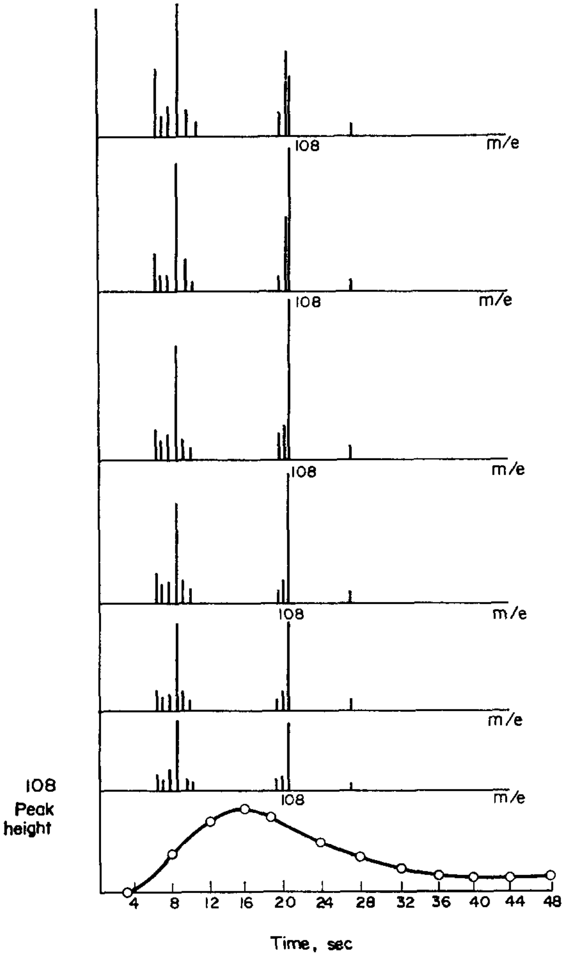

FIG. 7.—Mass spectrum scanned at 8-sec intervals during the evaporation of 60 ng of *p*-tyramine.

However, a compromise may be made in which not all of the spectrum but only a small part of it is repetitively scanned during the course of evaporation. The simplest possible situation is when only one ion current is recorded, for example the molecule ion-current since that will give most information about the molecule, although the argument would apply with equal force to a characteristic fragmentation peak in the mass spectrum. If the instrument is tuned to the selected *m/e* value before the evaporation begins and the ion current is recorded during the whole course of the evaporation of a small sample, then the record of the ion current at the selected *m/e* value is a measure of the rise and fall of the sample vapour concentration in the ion source, and the area under the curve so obtained is directly proportional to the integrated ion current and hence to the weight of sample evaporated. Thus an inexpensive and greatly simplified record is obtained and computer analysis is unnecessary. The problem of tuning in to a specific *m/e* value before an ion current is established at this value, *i.e.*, before evaporation has begun, is not always a simple matter. If voltage scanning, time-of-flight or radiofrequency instruments are being used, it is not too difficult, but with magnetic sector instruments without a very accurate mass-marking system it may not be possible to achieve. Further, it is often the case that an instrument of the latter type will go off tune during the course of an evaporation. For these reasons a system has been developed in which the single mass is repetitively scanned by means of peak switching facilities. Since this may be carried out in about 1 sec, only a short inexpensive recording is required and this consists of a series of peaks, the heights of which are proportional to the instantaneous ion current at the selected *m/e* value. These peaks rise and fall as the evaporation proceeds and it is the envelope of these peaks which constitutes the integrated ion current curve. Further, it is the area under this envelope which is proportional to the amount of sample evaporated. The problem of tuning to the *m/e* value with sector instruments may be solved by using a second calibrating substance in a second inlet system of the instrument, usually a reservoir of the type described above. The compound used is most commonly heptacosafluoro-tri-n-butylamine, which is allowed to flow into the source, and a peak in its spectrum is selected which is close to the *m/e* value which is being used for integration. This peak is then tuned in on the instrument by adjusting the magnet scan and the accelerating voltage is then altered so as to tune in the desired *m/e* value. The reference supply may then be cut off and evaporation initiated. If it is suspected that the sensitivity of the instrument is varying during the course of the evaporation then the ion currents due to the reference sample peaks may be recorded alternately with the sample peak currents. Any change in the height of the reference peaks would be due to a change in instrument sensitivity alone, since the sample source pressure of the reference compound is constant. In quantitative analysis by this technique the machine is first calibrated with known weights of pure samples of the compound. Comparison of the sample integrated ion-current curve area with the calibration graph gives a direct determination of the amount of unknown evaporated. Figure 8 shows such a calibration graph and it can be seen that there is linearity of response over several orders of magnitude. The limits of detection are very low indeed and detection of as little as 10^{-14} g has been achieved in favourable cases.[31] The effect of the matrix from which the sample is evaporated has been studied by making mixtures of two compounds, the major component being present in up to a million times the concentration of the minor component. It was found that provided the total sample size did not

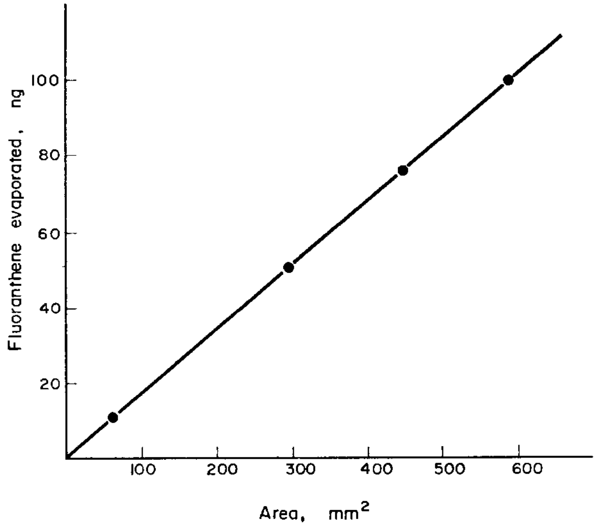

FIG. 8.—Calibration graph for fluoranthene.

exceed 5 μg, thus ensuring that the ion source pressure did not rise above 10^{-5} mm Hg, a plot of the integrated ion-current curve area for a characteristic m/e value of the minor component was linear down to the detection limit. The sensitivity of this technique varies with the compound and also with the characteristic m/e value selected. While it may be felt that the molecule ion peak is the most characteristic in the spectrum this sometimes carries only a very tiny fraction of the total ion current and thus can only give a low sensitivity. In such cases a characteristic fragment ion peak may provide a suitable m/e value for integration.

The analysis of metals

The most efficient method of analysing for trace metals is by the use of the spark-source double-focusing mass spectrometer such as the A.E.I. M.S. 7. Although the accuracy is limited by photoplate detection the ion currents due to all the ionized species are recorded at the same time and a limit of detection of one part in 10^9 has been claimed. Where the analytical requirements are less stringent it is sometimes possible to use the integrated ion current method with a general purpose mass spectrometer. Some metal salts such as mercuric chloride are themselves sufficiently volatile to permit their evaporation into the ion source directly. Figure 9 shows a portion of the mass spectrum for mercuric chloride, including the molecule ion region. It can be seen that the isotopic complexity has resulted in the distribution of the ion current over a number of isotopic ions and the sensitivity is thus much lower than that which can be achieved for a monoisotopic substance. However, amounts of mercuric chloride down to 1 ng can be determined with an error of 5%.[32]

Where no simple salt can be prepared it is necessary to convert the metal into a volatile form by making a chelate such as the acetylacetonate. The volatile nature of such chelates was first demonstrated by Morgan[33] over 40 years ago and more recently their properties have been exploited in an elegant and extensive study by Sievers,[34] using gas chromatography. The volatility of many metal chelates is improved by

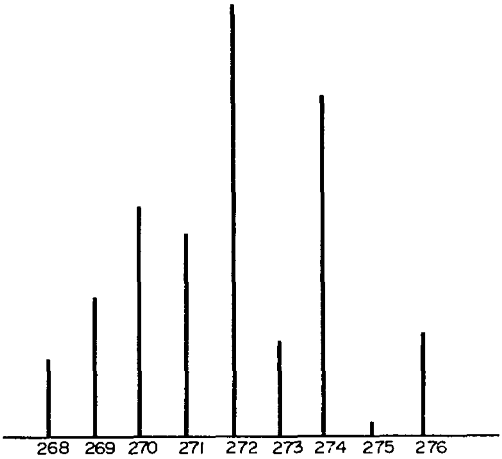

FIG. 9.—Mass spectrum of mercuric chloride.[31]

the substitution of fluorine and sulphur atoms in the diketone molecule. Although it is debatable whether alkali metal derivatives of diketones and keto esters can be classified as chelates, they may be evaporated from a probe into the ion source at temperatures below 200°.[35] Although it is possible to detect very small quantities of these compounds by the integrated ion current method the procedure is complicated by the fact that alkali metal chelates undergo two types of reaction upon evaporation—association and exchange.[36] Thus the mass spectra exhibit ions of the form $M_xL_y^+$ and the introduction of a large amount of a sodium chelate followed by, for example, a potassium derivative of a second diketone may result in the production of a spectrum revealing ions in which the two alkali metals have exchanged diketones. More complex association reactions are revealed if the chelates of alkali and alkaline earth metals are evaporated together.[37] Double chelates of the form $MM'L_3$ have been shown to exist. In the absence of the alkali metals however it is possible to estimate as little as 10^{-9} g of alkaline earth metals as their chelates with trifluoro-5,5-dimethylhexan-2,4-dione even though the mass spectrum exhibits polymeric peaks. Similar association reactions have been shown to occur between the chelates of alkali and rare-earth metals with the formation of binary chelates having the general formula $MM'L_4$.[35] In the absence of the alkali metals, however, very small quantities of rare-earth metals may be estimated as their chelates with heptafluoro-7,7-dimethyloctan-4,6-dione by the integrated ion current method.

1,3-Diketones or keto-esters have been used to make volatile derivatives of a number of other metals, the most volatile of these being the transition metal chelates, and detection limits for these species in the subnanogram range have been claimed. The power of the integrated ion current technique is, however, best demonstrated by the determination of mixtures of zirconium, hafnium and titanium as their trifluoroacetylbenzoylmethane chelates at the nanogram level–a formidable task by any other method.[39] There are many other chelating agents which form metal derivatives sufficiently volatile for their ready evaporation into the ion source and among these are 8-hydroxyquinoline, dipyridyl, dimethyl- and phenylglyoxime and the thio and amino derivatives of acetylacetone. A notable exception to this list is benzoylphenylhydroxylamine which forms derivatives which are not sufficiently stable to survive evaporation.

The integrated ion current method has been applied to the determination of a variety of organic compounds. It is perhaps very well suited to the analysis of polycyclic hydrocarbons obtained as air pollutants from automobile exhausts or the soot of smoky flames. The limit of detection for compounds such as the benzpyrenes is several orders of magnitude lower than that of any other technique. Further the spectrum of a complex mixture may be reduced to a number of molecule ion peaks by reducing the ionizing electron voltage to about 10 eV. Drugs have been assayed in blood and urine, and the distribution of non-catecholic amines in the human brain has been plotted.

A final feature of the integrated ion current technique is provided fortuitously by the differential rates of evaporation of closely similar compounds from the surface of a mass spectrometer probe. If the sample consists of a pair of isomers such as for example *o*- and *p*-nitrophenol, and if the curve is plotted for the molecule ion, then instead of the gaussian curve obtained for most sample evaporations a curve with two distinct maxima is obtained. This is because one isomer is being evaporated before the other. In all cases where isomerism can occur the integrated ion current curves have been shown to have fine structure. In the case of the chlorinated hydrocarbon "Chloran" no less than five maxima are visible. Structure has been demonstrated in curves obtained for *cis-trans* isomers, dioximes, polycyclic hydrocarbons, and very convincingly for metal chelates. By this means, the existence of *cis-trans* isomerism in the 8-hydroxyquinoline derivatives of bivalent metals has been demonstrated and complete separation of the isomers has been achieved in the 8-hydroxyquinoline derivatives of tervalent metals.[40]

An interesting application of the integrated ion current technique is in the assessment of the efficiency of decontamination agents and the cleaning of surfaces. For this application the probe is replaced by a small cylinder made of the material on which decontamination studies are to be made. The surface is then coated with a substance which is sufficiently volatile to be evaporated into the ion source at a high temperature. The amount adhering is determined in the normal way. The probe is then recontaminated and before assay is washed in the appropriate decontamination agent. The amount remaining is then assayed as before.

In the original study it was found that washing in cold solutions of efficient decontamination agent removed the contamination down to the level where it existed as a monolayer on the surface. This monolayer was only removed by treatment with the agent at elevated temperatures. More recently a phosphate-free decontamination agent, Decon 90, has been shown to break through the monolayer even in the cold and to leave no detectable film of contamination on the mass spectrometer probe after treatment at 50°.

Zusammenfassung—Es wird ein Überblick über die elementare Theorie, die Technik und die Anwendung der Massenspektrometrie gegeben. Besonders wird auf apparative Entwicklungen und dadurch bedingte neue Anwendungsmöglichkeiten hingewiesen.

Résumé—On a effectué une revue de la théorie fondamentale, de l'instrumentation et de l'application de la spectrométrie de masse, spécialement en ce qui concerne le développement de l'équipement et sa répercussion sur le cadre l'application.

TALANTA REVIEW†

ANALYTICAL MASS SPECTROMETRY

J. R. MAJER
Chemistry Department, University of Birmingham, P.O. Box 363, Birmingham 15, U.K.

(*Received* 12 *July* 1971. *Accepted* 11 *November* 1971)

Summary—A review is made of the basic theory, instrumentation and application of mass spectrometry, with special reference to the development of the equipment and its impact on the scope of application.

THE IONIZATION PROCESS

ANALYSIS by mass spectrometry depends upon the segregation of ionized molecules in magnetic, electric or radiofrequency fields. The ionization process which precedes this separation must take place in the gas phase and this imposes certain limitations on the technique, which are discussed later. Mass spectrometry is best introduced by using its relationship to other physical techniques based upon ionization. The ionization process may be described most generally by the interaction of a species M, which may be a molecule, an atom or a free radical, with a second species X, which may be an electron, a photon, an ion, a fast molecule or even a high potential gradient. M may be considered to be in thermal equilibrium with its surroundings but X must have a certain minimal energy content (E) which is greater than the binding energy of the electron in the lowest energy orbital in M, *i.e.*, the lowest ionization potential (I) of M. As a result of this interaction the lowest-energy electron is ejected and an ion M^+ is formed. For cases in which E is greater than I the excess of energy will be partitioned between the ion (E_1) and the electron (E_2). As the free electron is so light when compared with even a small polyatomic ion, any translational energy released in the process will be almost completely retained by the electron, which can of course retain no other form of energy. The ion M^+ on the other hand, although it has no translational energy, may have excitation energy (E_1) which may be electronic, vibrational or rotational.

$$\begin{array}{ccccccc} M & + & X(E) & \rightarrow & \mathrm{M}^+(E_1) & + & e(E_2) \\ n_{\mathrm{M}} & & n_{\mathrm{X}} & & n_1 & & n_2 \end{array}$$

In order to examine the consequences of this interaction in a real environment we must assume an assembly of particles of species M, their number being n_{M}. The number of particles of species X, which will most normally be measured as a flux, is n_{X} and the numbers of ions and electrons produced will be n_1 and n_2 respectively. Except in the case of multiple ionization n_1 and n_2 will be equal.

There are obviously two ways of investigating the ionization process experimentally: either the number of ions or the number of electrons may be measured. Such measurements are most commonly made by collecting the charged species with electrode assemblies across which the appropriate potential gradients are applied.

---

† For reprints of this review, see Publisher's announcement near end of this issue.

It is most convenient to investigate ionization as a continuous process so that n_M is kept constant by maintaining a flux or current of X through the assembly of molecules, atoms or radicals M. The resulting numbers of ions and electrons may now also be measured as fluxes, *i.e.*, numbers of ions or electrons per second or, more familiarly, electric currents. Let us suppose that n_M and n_X are kept constant while E is varied. The electron current n_2/t (where t is time) is now measured, for example, by inserting a pair of polarized electrodes into the cell in which M and X are interacting. If the electron current n_2/t is plotted against the energy E, the result is a typical ionization curve with a very steep rise in n_2/t as E rises above the ionization potential of M. When X is a photon then E may be very sharply defined by the wavelength of X and the ionization potential may be measured with considerable precision. When X is an electron, E is not precisely defined, as it is not very easy to obtain a beam of monochromatic electrons of suitable intensity. As electrons are normally produced from a white hot tungsten or rhenium filament they retain a Boltzmann distribution of energy $\pm\Delta E$ which is an appreciable fraction of a volt. As a result the inflection in the ionization curve is less precisely defined and the value of the ionization potential less certain. Now let us consider an alternative experiment in which the energy E is kept constant and considerably greater than the ionization potential of M. Instead of the total ionization current n_2/t being measured, the energy distribution in the emitted electrons is determined. This may be achieved experimentally by interposing a retarding potential grid between the two collecting electrodes or more elaborately by passing a beam of the emitted electrons through a transverse electric field and dispersing them according to their velocity. A plot is now made of E_2' against n_2'/t where E_2' is the energy in any emitted electron and n_2' is the number of electrons having such a translational energy. Then $\sum n_2' = n_2$. The difference between the energy of the projectile (E) and the translational energy of the emitted electron (E_2') is equal to that energy retained by the ion M^+. When X is a photon of high energy, this curve may be recognized as the photoelectron spectrum. Such a curve will have several maxima corresponding to the ionization of electrons in orbitals of different energies. In addition, for simple molecules, the maxima may reveal structure due to the formation of the ion in a variety of excited states. This experiment gives information about the energies of orbitals in polyatomic molecules in addition to the lowest ionization potential. Similar information is theoretically available if X is not a photon but an electron. Once again however, there is the problem of the energy spread experienced with electron beams. Electron monochromators are now being developed, however, giving currents as high as 10^{-8} A with an energy spread of as little as 20 mV. Combinations of two of these devices have been used to provide determinations of the energy distribution of emitted electrons, and a new spectroscopic technique, electron energy loss spectroscopy, is being developed. Once again the information available with this technique is concerned with the energies of orbitals in simple polyatomic molecules rather than with structures.

The alternative method of investigating the ionization process is by measuring the ion current rather than the electron current. A plot of n_1/t against E once again provides a method of determining the ionization potential of M. The results are more precise when X is a photon rather than an electron but the measurement of ionization potentials from the ionization efficiency curves obtained with mass spectrometers is common practice and various extrapolation procedures and deconvolution devices are used to increase precision of the determination. When X is an ion, the situation is complicated by the involvement of the recombination energy of the projectile ion with an electron. This complication also arises with the other techniques mentioned above. A measurement of the ratio n_1/n_M gives a measure of the ionization cross-section of the molecule M. The ionization efficiency curve, which is a plot of n_1/t against E does not give any information about the higher ionization potentials of polyatomic molecules because it is not possible to identify the variation of cross-section with E for any specific ionization process in which an electron of particular energy is being removed, except in the simplest possible case of the hydrogen atom or possibly the hydrogen molecule. Energy analysis of the ion current reveals no information, because the translational energy is all removed by the electron and at present there is little or no possibility of the determination of the nature of the excited states of ions.

While however, little information of this type is available from an examination of the ion current, the technique of mass spectrometry is based on an alternative way of looking at the ion current. This arises because it is possible to segregate ions not according to their energy content but according to their relative mass. The various methods by which this segregation is achieved are discussed below and it is only necessary to point out that the assembly of the species M may now consist of a number of different molecules, atoms or radicals. Each of these will be converted into the appropriate ions M^+ and it is now possible to measure all the individual ion currents n_1/t and to plot n_1/t against the mass of the ion m. Such a plot constitutes a mass spectrum.

$$m \sum_{0}^{M} n_1' = n_1$$

If the assembly of species is, for example, a mixture of rare gases so that the only ionization processes possible were the production of the singly-charged rare gas ions then it is possible to analyse the mixture by mass spectrometry. Both n_M and n_X must be kept constant so that the rate of production of ions is constant. The individual ion currents of the species M are then proportional to the partial pressures of the species M in the mixture and the sum of all these currents is equal to the total ion current n_1/t. This situation is rather similar to the conditions of fluorescence analysis where the incident radiation is analogous to the electron beam and the fluorescent radiation is analogous to the ion beam, the wavelength and mass being characteristic of the species M. There are very few cases in which this very simple form of mass spectrometry has a modern application. There are two examples worth recording however, the first medical and the second cosmochemical. The most readily available gas mixture is the atmosphere and a mass spectrum of air readily reveals the separation of the ion currents due to oxygen, nitrogen, carbon dioxide and argon. The efficiency of a patient's respiration may be assessed by taking samples of the atmosphere from his lungs. This process can be carried out continuously and can show not only the state of the patient's breathing but also the concentration of any foreign gas introduced to induce anaesthesia.

The second application also deals with the analysis of atmospheres, but in extra-terrestrial situations. The development of very small light mass spectrometers, now referred to as "flyable" instruments, permits their transportation by rocketry to a number of remote situations. The molecule and ion concentrations in the outer layers of the earth's atmosphere may be examined by carrying a small mass spectrometer on a rocket and relaying the information which it gathers to a remote ground station by radio. An extension of this principle will allow the examination of a number of planetary atmospheres.

The dissociation of excited ion-molecules

The great value of mass spectrometry as an analytical technique does not derive from simple applications such as these, but from a quite distinct and separate result of the initial ionization process. For ionization to take place the energy in the electron must exceed the lowest ionization potential of the molecule. It must therefore have a value of E which is at least 15 eV since the ionization potentials of all molecules lie between 6 and 15 eV. It is common practice, in order to obtain sufficiently high values of the cross-section n_1/n_M which determines the sensitivity, to choose values of E in the 50–100 eV range. The cross-section n_1/n_M does not vary significantly above 100 eV but falls off rapidly below 50 eV. Although not all of the energy in the projectile electron is transferred to the molecule, the result of the ionization process may be the production of an ion with a considerable excess of energy (E_1). As the excited molecule ion is normally produced under high vacuum conditions (approximately 10^{-6} mm Hg) this excess of energy cannot be lost by collision with other molecules. It can thus only be reduced by the emission of a photon, a comparatively unlikely event, or by the molecule ion undergoing dissociation or rearrangement. As the bond dissociation energy of all chemical single bonds lies between 2 and 5 eV the transfer of a small fraction of the translational energy of the incident electron can result in the fission of a number of chemical bonds with the production of radicals and smaller ions. Because of the large excess of energy the dissociation process has two important features. The first is that there are a number of alternative modes of dissociation available and the diversity of these decompositions is further enhanced by the fact that the electrons have an energy spread $\pm\Delta(E)$ and may transfer a variable amount of their translational energy to the molecule, depending on the nearness of approach and the consequent intensity of interaction. As a result the excited molecule ion may dissociate in a number of parallel and consecutive reactions. If E is high, the molecule ion is most likely to react by breaking chemical bonds; if E is low the molecule ion is most likely to rearrange. The second feature is that the rate constants for the dissociation processes are very high and the reactions have negligible energies of activation. As a result the rates of reaction are almost totally unaffected by experimental parameters other than E. This means that the ratios of the ion currents for the molecule, fragment and rearrangement ions will have constant values over wide variations of n_M or n_X or the temperature of the ionization cell. The relative intensities of the ion currents, which are responsible for the peaks in a mass spectrum, constitute what has come to be known as the cracking pattern of the molecule. It is the cracking pattern which is therefore substantially invariant and constitutes a fingerprint of the molecule in the same way that the infrared absorption spectrum does. It is thus possible to match the cracking pattern observed with a chemical compound measured upon one instrument with that of the same compound measured on a machine with a completely different geometry. This match is not as complete as that obtained with infrared or NMR spectra, but the usefulness of this near identity has led to the collection both privately and by industrial and government organizations of large libraries of mass spectral cracking patterns. The best known collection of spectra has been made by the American Petroleum Institute Research Project 44. A second rapidly growing collection is being amassed by the Mass Spectrometry Data Centre situated at Aldermaston. The reduction of these cracking patterns to digital form permits a direct comparison by computer, and several schemes are in operation by which the mass spectrum of an unknown compound may be compared with a library of the spectra of known compounds, held upon a disc in a computer memory.

One of the most severe problems encountered in the matching of spectra is the necessity of matching the purity of the standard and unknown samples. The presence of a substantial impurity in either may cause a mismatch so severe that the identity is lost. The effect of the minor constituent in distorting the mass spectrum may be further magnified by a difference in the rate of evaporation of the two components. With volatile samples this effect may be minimized by evaporating all of the sample into a reservoir from which the vapour flows into the ion source. When solid samples are being introduced into the source by the insertion-probe technique this is not possible. The situation is at its worst when isomers are being studied. There are only very small differences in the mass spectra of structural isomers and it is only possible to match the spectra of unknown and standard if the purity and method of sample admission are kept the same. Fortunately, there are two ways of dealing with this problem. The first is to use the technique of differential evaporation as discussed in the section describing quantitative methods, and the second is to combine mass spectrometric identification with some other technique of physical separation such as chromatography. Chromatography in one form or other is to be preferred because in general the resolution obtainable with chromatographic methods rises with the lowering of sample size, and mass spectrometry is capable of dealing with very small sample sizes, in some cases well below the detection limit of the normal colorimetric or fluorometric methods.

Chromatographic separation

It is not difficult to separate small quantities (micrograms) of complex organic compounds by paper chromatography. The area containing the spot of the unknown is eluted with an organic solvent, the solution is concentrated by evaporation, and the concentrate admitted directly to the mass spectrometer. It is unfortunate that this process is surprisingly variable: sometimes the resulting mass spectrum can be matched very well with that of a standard, at other times the solvent may extract from the paper not only the sample material but also a great deal of contamination from the paper itself. The amount and nature of this contamination are dependent not only on the nature of the paper but also on its previous history, *i.e.*, which solvents it has already been exposed to during the chromatographic separation. Some improvements are observed when paper chromatography is replaced by thin-layer chromatography, on silica gel, cellulose *etc.* It has been possible, for example, to separate drugs from whole blood by a single separation upon cellulose and to identify the drug by removing a small area of the thin layer with a spatula and extracting with the appropriate eluent, filtering the slurry, evaporating the solvent and transferring the residue to the ion source in the manner described in the experimental section. Further, in the case of some compounds it has been possible to show that this process may be quantitative, so that submicrogram quantities of the components of complex mixtures may be separately identified and determined.[1]

When the sample components are sufficiently volatile they may be separated by gas chromatography. The very high efficiencies of separation obtainable with these methods, which greatly exceed those possible with fractionating columns, and their ability to deal with very small sample sizes, have encouraged experimenters to combine them with mass spectrometry. The separation of a pair of compounds by gas–liquid chromatography depends not only upon differences in the volatility of the two components but also upon differences in their interaction with the involatile liquid into which they are partitioned from the gas phase. As a result it is possible to take advantage not only of simple solution forces but of specific chemical interactions. It is thus possible, for example, to separate the *cis* and *trans* isomers of many simple hydrocarbons by using an involatile liquid containing a silver salt with which the unsaturated compounds form transient complexes. In a similar fashion the isomers of aromatic hydrocarbons may be separated by including in the involatile liquid some polynitro compound capable of forming molecular complexes with the aromatic. In each case some small difference in the stability of these complexes is exploited and quite small quantities of the involatile liquid are required. On the other hand, separations involving conventional solution forces may be made possible by having a very much larger quantity of the involatile liquid, maintained as a very thin film, and considerably multiplying the number of equilibrations of the sample mixture with the liquid. The limit to this is set only by purely experimental considerations of size and carrier gas inlet pressure. However, by an appropriate choice of column length and involatile liquid composition, it is possible to separate the components of complex mixtures of chemically very similar compounds. As an example, with the most efficient columns (either glass capillaries lined with squalane, or narrow packed columns with the same material dispersed upon small mesh size inert support) it is possible to separate deuterated hydrocarbons from their protonated counterparts. Dodecadeuterocyclohexane may be separated from normal cyclohexane with a relatively inefficient column of about 2000 theoretical plates, hexadeuterobenzene is separated from benzene, and trideuterotoluene from toluene[2] with packed or capillary columns with an efficiency of 10,000–15,000 plates, and with the highest efficiency columns of above 100,000 plates, monodeuterobenzene can be separated from benzene. The success of separations has in the past been limited by the inability of the gas chromatographic technique to provide an unequivocal means of identifying the separated species. The idea of specific retention volumes as a unique physical property which could be used for identification purposes has not been enthusiastically accepted by gas chromatographers. The determination of this constant, which is independent of temperature, gas flow-rate, involatile liquid concentration and sample size, required such precisely defined operating conditions that it was seldom used. A more successful compromise was the relative retention volume in which the retention volume of the unknown was expressed as a fraction of that of some similar known substance. Some variations in the experimental parameters were rendered less important but the uncertainties remained. Uncertainty could be removed by segregating the components of the mixture as they emerged from the chromatographic column, by adsorption on silica gel or alumina or by the passage of the effluent through a trap cooled in liquid air. A separate adsorbent tube or liquid-air trap was required for each component of the mixture requiring identification. The sample components recovered in this way were then identified by a second technique. Such a two-stage separation and identification does, however, involve difficulties, mainly resulting from the problem of manipulating small amounts of volatile material. This has resulted in the development of a direct coupling of the effluent from the gas chromatograph to the inlet system of the mass spectrometer, so that there is no handling process after the injection of the sample mixture into the inlet of the gas chromatograph. The manner in which this has been achieved is discussed in the section dealing with instrumentation and it is only necessary to point out that the problem of matching unknown and standard spectra is considerably simplified when the purity of the specimen is so assured. Further, although the retention volume is not normally determined with sufficient precision to make it a primary means of identification, it provides a useful additional piece of evidence to back up the mass spectra identification.

In all the foregoing it has been assumed that there exists a library spectrum of the unknown, and the only problem is that of matching. While this may be the case for some experimentalists, even in a routine analytical laboratory there will be times when the analyst will be faced with the identification of a completely new compound from its mass spectrum.

As outlined earlier, the mass spectrum presents a record of the unimolecular decomposition of an assembly of highly excited molecular ions. The chemistry of the decomposition is unique, and no great reward is obtained by comparisons with ground state chemistry or with radiolysis. And yet the only structural information available from a mass spectrum is that which can be gleaned from an understanding of the way in which the molecule ion breaks down. There are three distinct approaches to the problem of extracting this information. The analyst may attempt to understand this novel type of chemistry so that he may deduce the structure of the molecule ion from recognized decomposition processes. This approach is analogous to that by which many natural products were identified by classical organic chemical degradations, *e.g.*, pyrolysis or dehydrogenation. The second approach is to change the ionization process so that a different dissociation route is traversed. The third approach, which will commend itself most readily to the analytical chemist since he may make use of much of his armoury of chemical identification methods, is to modify the sample itself by means of a known chemical reaction and to infer the structure from a comparison of the mass spectrum before and after the chemical process. This method is analogous to the preparation of a derivative with a known physical property such as a melting point, absorption spectrum, R_f value or cryoscopic molecular weight. Our present understanding of the chemistry of the decomposition of ions has in fact been largely accumulated by studies involving the second and third approaches, and Beynon[3] in this country and McLafferty[4] in the United States have been particularly successful in expanding our understanding of the mechanisms involved. While it has been stressed that the chemistry of ion decomposition cannot be interpreted with the aid of an understanding of ground state mechanisms alone, there are certain features or underlying principles of chemical theory which must apply with equal force to these very fast reactions. It would be expected that the effect of neighbouring groups upon each other would be reflected in the rates of decomposition. An extreme example of this would be the so-called "*ortho* effect" where much stronger interactions would be expected between groups when they are adjacent to each other as substituents on a benzene ring than when they are more remote. Such an effect is observed and the spectra of isomers such as those of the nitrophenols or the hydroxybenzaldehydes are appreciably different (Fig. 1).

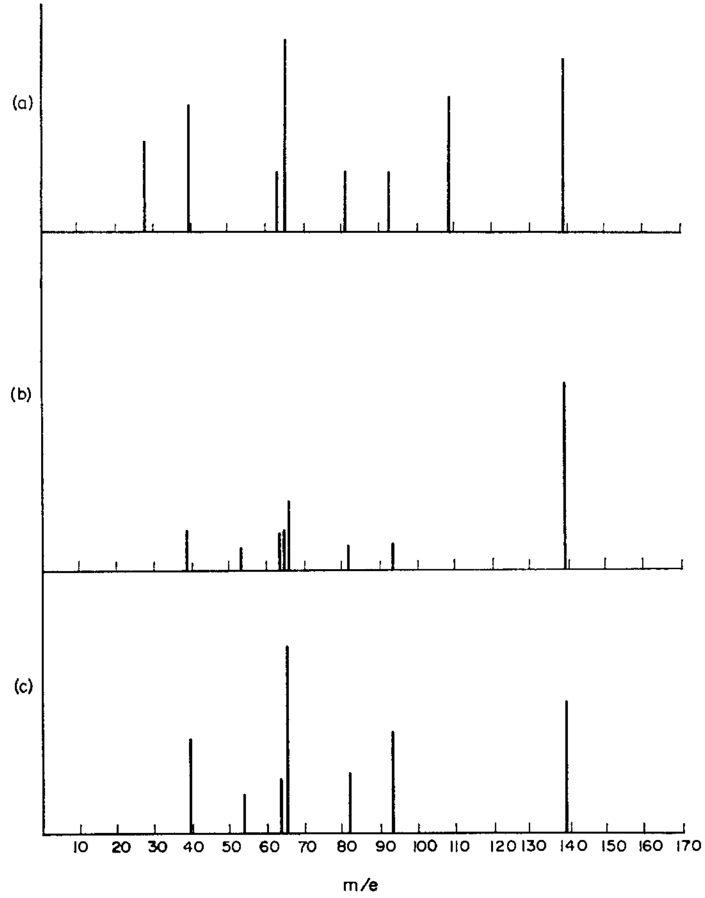

FIG. 1.—Mass spectra of nitrophenols: *a*, *p*-nitrophenol; *b*, *o*-nitrophenol; *c*, *m*-nitrophenol.

Since the energy is lost from the excited ion by breaking chemical bonds the strength of these bonds must have an effect upon the rate. As a result the rate of production of an ion from the molecule ion by the fission of a carbon–bromine bond would be expected to be much faster than if the same ion were being produced by the fission of a carbon–hydrogen bond, which has twice the bond dissociation energy. There are many examples in which this may be clearly demonstrated. The nature of the second species must also play a part in determining the rate of decomposition. Where the un-ionized fragment is a stable radical such as benzyl or allyl, then this dissociation is favoured. A very common example of the effect of the second species is when that species has a high electron affinity and so may readily form a negative ion with the release of up to 3 eV of energy. The most commonly observed example is the production of ion-pairs when compounds containing fluorine atoms are ionized. The high electron affinity of the fluorine atom results in the rapid dissociation of the molecule ion, and the mass spectra of most saturated fluorocarbons have negligibly small molecule ion peaks.[5] The most valuable information from a fundamental point of view would be the thermodynamic heats of formation of the ions, but although many values are available the thermochemical relationships have only been constructed for the simplest cases, and the main obstacle to their use in more complex systems is the lack of information about the excited states of the ions involved. If the mass spectrum represented only the results of the bond-breaking processes then the interpretation of most spectra would be greatly simplified. However, there are in addition a number of other processes occurring, leading to the formation of ions which could not arise by simple bond-breaking. The peaks in the mass spectra corresponding to ions produced in these processes were originally considered as noise, but recent improvements in instrumentation have provided more information about them and their recognition may actually aid structural analysis. These processes, which are normally called rearrangements, usually occur at low energies and result in the formation of an even-electron neutral species and an odd-electron ion, (*cf.* the bond-breaking process leads to the formation of an even-electron radical ion and an odd-electron atom or radical). An exception to this is when hydrogen atoms are involved. Hydrogen atoms appear to be quite mobile in the excited ion molecule and substantial rearrangements occur. Thus in the spectrum of 1,1,1-trideuterodimethyl sulphide[2] there are substantial peaks corresponding to the ions CD_2H^+ and CDH_2^+.[6] Another example of the mobility of atoms is the transfer to metal observed in the mass spectra of metal chelates. The spectrum of the titanium derivative of the diketone benzoyltrifluoroacetone exhibits peaks corresponding to ions in which one or two fluorine atoms have been transferred to the metal atom (Fig. 2). The elimination reactions referred to previously however may be more useful once they are understood. Certainly the most widely known of these rearrangement processes is the McLafferty rearrangement[7] in which the hydrogen atom gamma to a carbonyl or other electronegative group is transferred to the heteroatom with beta-cleavage of the molecular

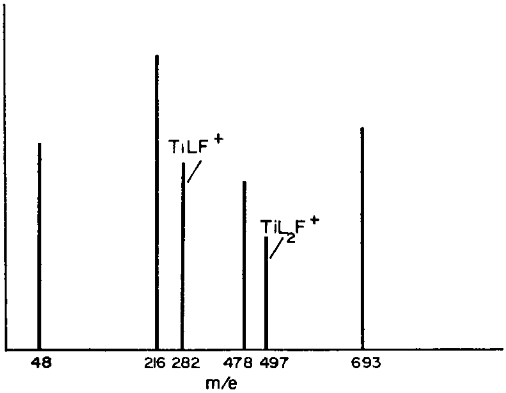

FIG. 2.—Mass spectrum of titanium benzoylacetonate, illustrating fluorine transfer to metal.

ion and the elimination of an unsaturated compound or a diradical (Fig. 3). Other examples include the elimination of CF_2 from atomatic compounds containing a CF_3 group, such as benzotrifluoride,[8] or the elimination of CO from aromatic ketones such as anthraquinone.[9]

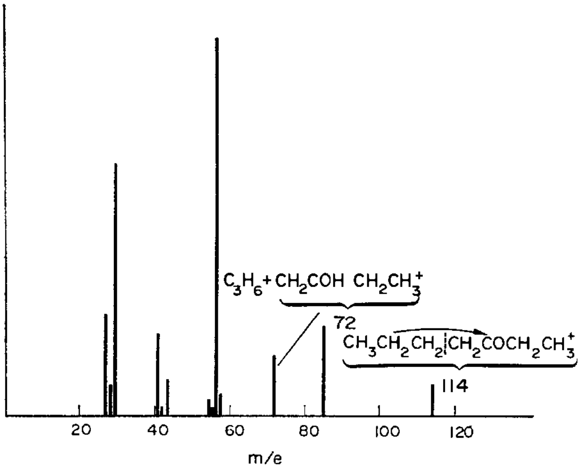

FIG. 3.—Mass spectrum of heptanone-3, illustrating the McLafferty rearrangement.

All these rearrangements lead to the formation of ions having an even mass (provided they do not contain an odd number of nitrogen atoms) and even-mass peaks other than molecule ion peaks are comparatively rare, so that it is easy to pick out the peaks due to rearrangement processes and to infer the structures from which they are formed.

In carrying out identification of unknown species by their mass spectrum alone, there are two techniques now available as a result of modern instrumentation, which are of the greatest assistance. The first of these is precise mass analysis which has been made possible by the development of high resolution instruments. The presently accepted mass scale uses carbon 12 as its standard, assigning it a mass of 12.000000. On this scale the mass of the hydrogen atom is 1.007825 while that of the oxygen atom is 15.994914. It follows that there is an appreciable difference in mass between ions having the same integral mass. Thus both carbon dioxide and propane ions have an integral mass of 44 but their precise masses of 43.989828 and 44.062600 differ by about 1 in 600. As a result a mass spectrometer with a resolution of 1000 can resolve the beams of carbon dioxide and propane ions when they are produced simultaneously and from the mass scale it is possible to say which is which. A higher resolution is required to resolve the mass doublet due to carbon monoxide and nitrogen molecule ions. It can be seen that an assembly of carbon, hydrogen and oxygen atoms gives a unique precise mass and this is true for any other atomic assembly. At the time of writing commerical mass spectrometers are available which have a mass resolution of 100,000 and masses of ions can be measured with a precision of 1 ppm. As a result it is possible to determine the atomic constitution of ions with a high degree of certainty. Taking, for example, the molecule ion of adrenaline, its precise mass is 183.089541 and the nearest precise mass to this which can be envisaged is 183.088195 which differs by one part in 180,000, which is considerably greater than the uncertainty of measurement. The atomic constitution is thus unequivocally determined as $C_9H_{13}O_3N$. The identification of the atomic composition from the precise mass can be carried out by the use of tables of the precise masses of atomic assemblies or may be done automatically with quite a simple computer programme. The atomic constitution of all ions represented in a mass spectrum can be identified provided that either the time or the instrumentation is available. It should be stressed, however, that despite the very great advance in understanding that such information provides, there is still at this stage no direct evidence as to the manner in which the atoms are linked together in the ions. It would be considered a reasonable assumption, on finding that peaks of mass 91 and 77 in the spectra of aromatic compounds were due to the atomic species $C_7H_7^+$ and $C_6H_5^+$, that these were in fact the benzyl and phenyl ions. There is evidence to the contrary, mainly arising from labelling studies, that these are seven membered ring and open-chain structures, respectively. Quantitative evidence about the structure of ions is scanty but there is good reason for believing that the doubly-charged ion of benzene no longer retains its cyclic structure.

The second technique which has been found useful in the study of ionic decomposition is that of metastable defocusing. It was pointed out in the earlier paragraphs that the reactions of ionic decomposition were extremely rapid and that the result of this was the consistency of the cracking pattern. In fact most of the chemistry is complete before the ion has left the source region of the instrument and proceeded to the analysis region, this journey taking a time of the order of a μsec. Some molecules in the ion source have relatively inefficient encounters with the ionizing electrons and as a result have lower amounts of excitation energy in the ions produced. The rate of dissociation of such ions is slower and weakly excited ions may escape from the source region of the instrument before undergoing reaction. The experimental result of this situation is that the ion, having acquired a velocity appropriate to its mass from the accelerating voltage gradient in the instrument, now changes its mass by the loss of a neutral fragment before being subjected to mass analysis. The magnetic field therefore brings this ion to a focus on the mass scale at a position which is neither the focus of the parent or the daughter ion but lower than either. In many cases the masses of the ions are related by the simple equation.

$$m^* = m_2^2/m_1$$

where m_1 is the parent mass, m_2 the daughter mass and m^* the apparent or metastable mass. The ions so produced have been erroneously named metastable ions and the peaks metastable peaks. These peaks may easily be identified in a mass spectrum by their appearance. They are most commonly very much wider than the normal peaks. This is due to the fact that the ionic decomposition is usually associated with the release of kinetic energy, which effectively increases the energy spread of the ion beam for that species only, and hence decreases the resolution, giving wider peaks. In fact there is a quantitative relationship between peak width and kinetic energy release and there have been a number of studies on this relationship, but of more general use is the facility of identifying the parent and daughter ion responsible for the metastable peak. Since the mass of each of these ions must be greater than that of the metastable peak position on the mass scale, and because there is normally a large ion current due to the parent ion, it is a fairly simple matter to find values of m_1 and m_2 which satisfy the equation. As an example, the mass spectra of most saturated hydrocarbons exhibit a peak at $m/e = 39{\cdot}1$ and the appropriate values of m_1 and m_2 for this metastable mass are 43 and 41 respectively. This means that the mode of decomposition can be identified, and on combining this technique with precise mass measurement it can be shown that the decomposition pathway is

$$C_3H_7^+ \rightarrow C_3H_5^+ + H_2$$

This of course does not imply that the $C_3H_7^+$ ion is either a propyl or an isopropyl ion; in fact, what evidence there is, arising from labelling studies, suggests a cyclic structure. In general, metastable peaks are less intense than those produced conventionally and the technique of metastable defocusing allows the operator to overcome this sensitivity problem and eliminate the difficulty of disentangling the normal and metastable spectra. The instrument is so adjusted that only those ions which have suffered a change in velocity as a result of a dissociation process taking place outside the ion source are able to pass a diaphragm situated after the energy selector of a double focusing instrument. The ion current due to ions formed within the ion source is not detected and the spectrum consists only of a series of metastable peaks, the intensity of which can be increased by increasing the amplification of the instrument, without at the same time increasing the signal due to the normal ion processes.[10] It is also possible to scan the spectrum in such a way as to identify all those decompositions associated with one particular ion.

The second approach in the identification of unknown compounds from their mass spectra is to gain additional information by varying the ionization process. The simplest way in which this may be achieved is to vary the energy in the ionizing electron beam. Many of the processes which are possible at energies of 70 eV cannot take place if the electron voltage is reduced to say 10 eV (see *e.g.*, Fig. 4). In some cases it may be possible to eliminate all the dissociation processes and obtain a spectrum which represents only the molecule ions of the sample components. This is however, easiest to achieve if the normal mass spectrum reveals a large molecule ion peak. Reducing the electron energy does not increase the total molecule ion current and may substantially reduce it, but it does increase the relative importance of the parent peak. An alternative to the reduction of electron energy is the substitution of the electron impact source by what has been called the field ionization source. If a molecule is exposed to a potential gradient which is similar to that existing at the outer electronic shells of the molecule then the outer low-energy electrons can escape and the molecule becomes ionized without the transfer of large amounts of excitation energy to the ion. A value of 10^8 V/cm is sufficient for this purpose and this can be created experimentally by a voltage of 10^5 V applied upon a sharp edge with a radius of a few hundred Å, such as a razor blade. The ions accelerated away from this edge are not highly excited and it is possible to create ions from molecules having weak chemical bonds, such as hydrates. Such species would not survive ionization by an electron impact source. Thus the spectrum produced by a field ionization source is very much simpler than that obtained with a conventional electron impact source and it is very much easier to identify the molecule ion.[11]

A further way in which ionization can take place has been studied by Field and relies upon ion–molecule interactions.[12] A conventional ion source is normally

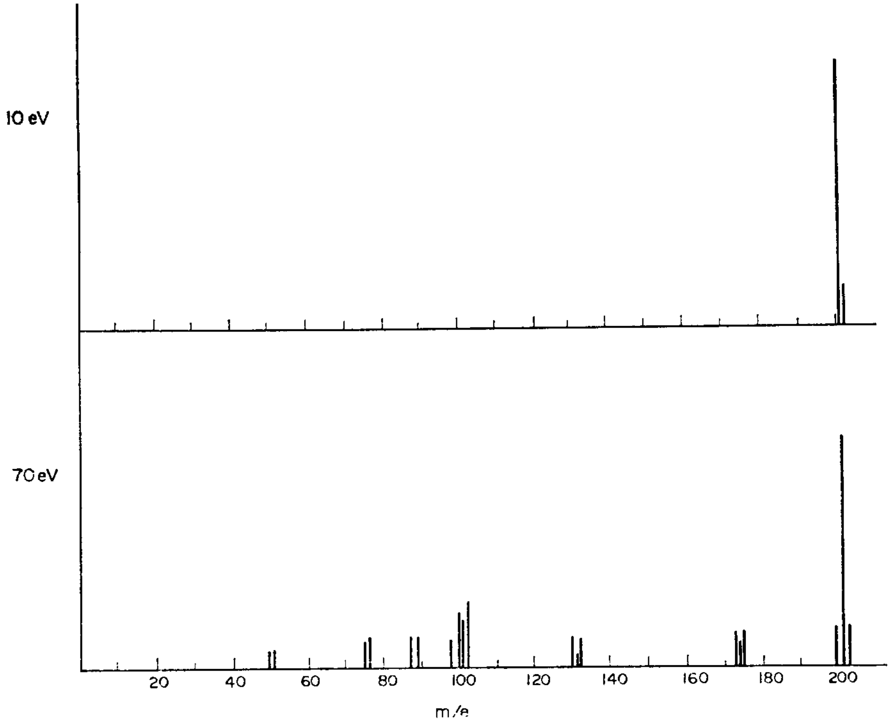

FIG. 4.—Mass spectrum of fluoranthene at 70 and 10 eV.

operated at a very low pressure so that the molecules have a long mean free path and secondary reactions are rendered insignificant. If, however, the pressure is allowed to rise above about 10^{-5} mm Hg the ion may interact with un-ionized gas molecules before it leaves the ion source. It has now become possible to eliminate the danger of producing gas discharges caused by the earthing of ion-accelerating voltages through a high pressure gas and to operate ion sources safely at pressures up to 1 mm Hg. If methane is ionized in such a source, then the methane ion, which is the initial result of the electron impact, abstracts a hydrogen atom from the methane gas to form CH_5^+.

$$CH_4 + CH_4^+ \rightarrow CH_5^+ + CH_3$$

If now a trace of a substance having a higher proton affinity is added to the methane, the proton is transferred to this molecule. The protonated molecule then decomposes in such a way that the charge remains with the fragment radicals. In this way an assembly of molecules gives rise to a mass spectrum with a different cracking pattern from that obtained by normal electron impact.

Finally, there is the purely chemical approach in which the sample substance is subjected to known reactions, the results of which are assessed by running additional mass spectra. The reactions chosen should be those which occur at room temperature (if possible) and lead to the formation of a derivative having a higher molecular weight than the original sample substance. There are a number of such reactions described in the literature, for the quantitative analysis of small amounts of compounds containing functional groups. The simplest possible reaction is that of deuteration. The sample is merely mixed with heavy water and allowed to equilibrate. Any labile hydrogen atoms such as those attached to oxygen atoms in hydroxyl or carboxyl groups will be replaced by deuterium. The result is that the mass spectrum, while retaining its overall pattern, will move to higher *m/e* values for those peaks which correspond to ions which have suffered deuteration. It is thus an easy matter to determine the number of hydrogen atoms replaced and which therefore were attached to oxygen. A second specific reaction which may be used with advantage is the conversion of aldehydes into aldoximes with hydroxylamine hydrochloride solution. For each aldehyde group converted the spectrum moves 15 mass units. The simplicity of this approach is that these reactions may be carried out on the microgram scale on the probe of the mass spectrometer, and the reaction products analysed without any pretreatment. As an example, the following three spectra (Fig. 5) show the spectrum of an alkaloid precursor[13] and its reaction products with heavy water and hydroxylamine hydrochloride. The presence of one hydroxyl and one aldehyde group is clearly indicated and the structure of the compound has been shown to be

INSTRUMENTATION

Mass spectrometry shares with the technique of molecular beams the distinction of being the physical method slowest to receive widespread acceptance and exploitation by the chemist. Both were being used by the physicist before the last war and it is only recently that the mass spectrometer has taken its place beside optical spectrometers in the laboratory for routine sampling and analysis. In no other technique has there been such widespread proliferation of instrumentation or so wide an application to diverse analytical problems. In this section the main types of instrument will be discussed and examples given. A more complete review has been made by Beynon and Fontaine.[14]

At the present time, because of the very diverse nature of the instruments which may be classed as mass spectrometers, it is necessary to define the instrument in the most general terms. The one feature which all instruments have in common is that ionization and mass analysis take place in a high vacuum system. Briefly then, a mass spectrometer is a device which is capable of introducing a sample into a high vacuum and converting a proportion of the molecules in the resulting vapour into ions. The ions so produced are classified according to their mass to charge ratio (m/e) and the abundances of each ionic species is measured and recorded. As will be discussed in a later section, because such measurement and recording takes an appreciable interval of time, ion abundances must be detected as ion currents n_1/t. In order to give any significance to such ion currents, it is necessary to maintain a constant partial pressure n_{M} of the sample in the source and to keep a constant rate of ionization n_X/t. These considerations are unimportant in the design of a mass spectrograph, where only the masses of the individual ions are to be measured. These instruments, however, are comparatively rare.

The story of the development of the modern mass spectrometer is an account of continued efforts to improve the sensitivity of the machine, to increase its ability to distinguish between ions of closely similar mass, *i.e.*, its mass resolution ($m/\Delta m$) and to decrease the time taken to record the magnitude of the ion currents, *i.e.*, the mass spectrum. At the same time there have been attempts to increase the range of the instrument both in the production of ions of higher m/e values and in the classification and recording of such ion currents.

180°-*Focusing instruments*

An ion moving with uniform velocity in a magnetic field at right angles to the plane of its motion describes a circular path provided that the magnetic field is constant and uniform. This principle was exploited in the earliest form of mass spectrometer described by Dempster[15] in 1918, and it is of considerable interest that an instrument of this type is still in an active stage of development today. Positive ions are accelerated in a potential gradient V and enter a uniform magnetic field H which is perpendicular to the direction of their motion. The ions of mass m aquire a velocity v and so have an energy given by $\frac{1}{2}mv^2 = \mathrm{e}\mathrm{V}$, where e is the electronic charge. The radius R of the circular path which the ions describe is then given by the equation

$$Hev = \frac{mv^2}{R}$$

On combination of these two equations the field and potential gradient requirements for an ion with mass to charge ratio m/e travelling in an orbit of radius R are given by

$$m/e = \frac{H^2R^2}{2V}$$

The uniform magnetic field has a focusing action equivalent to that of a cylindrical lens so that beams of ions issuing from a slit are brought to a focus after suffering a deflection of 180° to form a first-order image of the slit with ions of the appropriate m/e values for the given field strength and potential gradient. This system is thus direction-focusing so that it is not necessary to inject a parallel beam of ions into the magnetic field. On the other hand, it requires that all ions having the same m/e value should have the same velocity v, that is to say this is not an energy-focusing system. The resolution of this type of instrument depends upon the homogeneity of the magnetic field over the whole of the ion path, the stability of the ion-accelerating potential difference and the width of the entrance and exit slits. The optimum values for slitwidths are those in which a successful compromise is achieved between the increase in resolution obtained by reducing slitwidth and the accompanying reduction in sensitivity.

Before giving any actual values of mass resolution achieved by various instruments, it is necessary to make a satisfactory definition of the term $m/\Delta m$. The original definition used by Dempster is expressed in the formula

$$m/\Delta m = R/(S_1 + S_2)$$

where S_1 and S_2 are the entrance and exit slitwidths. This makes the assumption that a perfect image of the entrance slits is formed in the plane of the exit slit and that the adjacent beams of ions are resolved when one image occupies the exit slit while none of the ion current due to the adjacent image enters the exit slit. Owing to imperfections of the experimentally attainable ion optics system, this simple equation cannot be retained as an adequate definition of mass resolution. The image will be distorted, having chromatic aberration due to variations in the kinetic energy of ions of the same mass and would have "wings" on either side due to the gas scattering in the ion path. These aberrations are taken into account by assuming a constant β such that the effect of the aberrations is shown to be proportional to the radius of curvature of the ion path as in

$$m/\Delta m = R/(S_1 + S_2 + \beta R)$$

Despite the obvious value of this equation it is more common to apply an empirical definition of mass resolution in which unit resolution is said to be achieved when there is a valley between adjacent peaks in a mass spectrum record. The peaks should be of equal height and the depth of the valley is chosen arbitrarily; the height of the valley above the base-line is expressed as a fraction of the peak height. When comparing the advertised performance of commercial instruments or the published figures for mass resolution of experimental instruments, it is important to identify the criterion which has been applied for unit mass resolution, as this can range over two orders of magnitude. Alternative criteria for resolution which have been suggested are based on peak width or contribution to a mass peak from an adjacent peak of the same height. The effect of slitwidth on mass resolution in a modern 180°-focusing mass spectrometer is illustrated in Fig. 6 which shows a mass spectrum for krypton recorded with slitwidths of 0·25 and 0·50 mm.

The stability and simplicity of this method of mass selection has led to its adoption and development in a range of low-resolution instruments. In particular, Associated Electrical Industries have produced a number of commercial instruments under the generic name of M.S. 10 and 20, based on a design with a radius (*R*) of 5 cm. These instruments are still in a state of active development and improvement. The original design used a large permanent magnet with a field strength (*H*) of 1840 gauss. Scanning of a mass range of 1–200 was achieved by varying the accelerating voltage (*V*) either continuously or in steps. The resolution which could be achieved with a slitwidth of 0·50 mm was 40 with a 2% peak valley between adjacent peaks of equal height. This type of instrument is suitable for use as a sophisticated ionization gauge, when it may be bolted directly to the vacuum system being monitored. Alternatively, it may be used for leak testing, by using a gas with a characteristic mass spectrum as the test gas for tracing the leak in a vacuum system. The resolution is adequate for the identification of most of the residual gases found in high-vacuum systems.

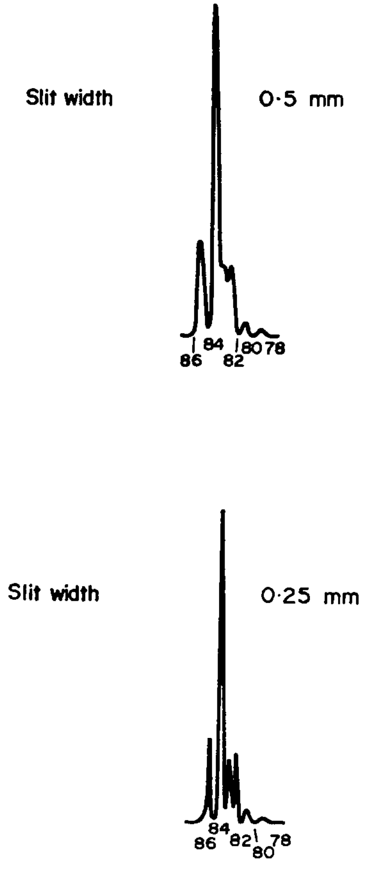

Fig. 6.—Effect of slitwidth on resolution: mass spectrum of krypton.

Recently, this design has been modified so as to convert the instrument into a versatile mass spectrometer for low-resolution general analytical studies. The mass range has been extended to 1000 by replacing the permanent magnet with a large electromagnet capable of providing fields up to 11,000 gauss. The resolution has been increased to approximately 550 by reducing the slitwidths to 0·025 mm and increasing the detector sensitivity. This design is particularly flexible since it permits the magnetic field to be swept at a number of alternative accelerating potentials.

The same company also produced a greatly simplified design in the Minimass Partial Pressure Gauge. The radius has been reduced to 1 cm and a small permanent magnet with a field strength of 4000 gauss is employed. Voltage scanning up to mass 240 permits the identification of each mass on a linear scale and the mass resolution is approximately 28 with 50% peak valley between adjacent peaks. This inexpensive compact model is intended for monitoring vacuum systems.

Similar models to the M.S. 10 range have been produced by the Atlas Co.* of Germany ($R = 28$ mm, $H = 2750$–4000 gauss, $m/\Delta m$ 18–44) and the Consolidated Electrodynamics Corporation of the U.S.A. ($H = 800$–6000 gauss, $m/\Delta m$ up to 600 with an electrostatic slit).

The chief advantage of the 180°-focusing system has been its comparative simplicity and consequent low price. The chief disadvantage in the past has been the necessity to scan the mass range by adjusting the ion-accelerating potential (V) so that ions are collected with varying efficiencies, the heavier ions requiring low potentials. Thus the sensitivity is lowest for ions with the highest m/e value and since in general such ion currents will give the most information from an analytical point of view, this reduction in sensitivity is a disadvantage. The recent substitution of large pole-face area electromagnets for the conventional permanent magnet has eliminated this disadvantage, permitting magnetic scanning. Although there is a corresponding rise in cost, the resulting flexibility has made this type of instrument the most important of the low-resolution magnetic series. The limiting factors in any further improvement of performance with this type of machine are the mechanical difficulties associated with providing source slitwidths of less than 0·025 mm and the resulting problem of providing additional detector sensitivity.

Sector field instruments

It was shown in 1940 that the phenomenon of the focusing of ion beams by causing deflection through 180° in a homogeneous magnetic field was in fact a special case of focusing by means of an inhomogenous field.[16] The ion beam should leave and enter the magnetic field at right angles to the field boundary and inside the field the ion describes a path which is a sector of a circle. The angle subtended by this sector may be 60°, 90° or in the limiting case above, 180°. The separation of ions of different mass to charge ratios takes place in an exactly analogous manner and beams of ions from the source situated some distance from the field boundary are brought to a focus at a collector symmetrically disposed on the other side of the sector magnetic field. The disadvantages of this type of geometry are the long path with consequent greater probability of collisional scattering, and the difficulties associated with the precise alignment of the sector magnetic field to obtain satisfactory focusing. On the other hand, there are considerable advantages in having both source and collector in

---

* Now Varian Mat.

field-free regions. The source is more readily accessible so that a variety of modifications may be carried out and the collector may be fitted without difficulty with an electron multiplier to increase detector sensitivity.

The most successful machine of this type was first introduced by the Metropolitan-Vickers Company (now G.E.C./A.E.I.) just before 1950. The M.S. 2 was a 90°-sector 15-cm radius instrument issued originally with a mechanically adjustable collector slit providing a maximum resolution of about 300. This resolution was later doubled by the use of a collector slit having an effective width which could be altered by giving it a high positive potential. For quantitative studies the collector slit was set at 0·62 mm to give a lower resolution but increased reproducibility, the record being in the form of a series of flat-topped rather than pointed mass peaks. A greatly improved version using the same basic geometry with a 90° sector of radius 15 cm was the M.S. 2H. The addition of an electron multiplier at the collector provided increased sensitivity, permitting a further increase in resolution to above 650. The mass range with the normal accelerating voltage of 2 kV was extended to 650 by increasing the magnetic field.

There have been a number of variations on this type of instrument, the most notable being the Atlas CH_4 with a resolution in excess of 1000.

A further stage in the improvement of the performance of the 90°-sector field instrument was provided by the A.E.I. M.S. 12 design in which the radius of curvature had been increased to 30 cm. A further decrease in slitwidth to 0·0125 mm was made possible by increasing the ion accelerating potential to 8 kV and with an electron multiplier detector a mass resolution of 7500 was achieved. In this design, which is now obsolete, both magnetic and voltage scanning facilities were provided, the latter permitting a mass spectrum to be displayed in less than 1/5 sec.

Double-focusing instruments

A beam of positive ions may also be analysed according to the velocity which the ions have attained. This velocity is proportional to the square root of the mass, provided that all the ions have suffered the same acceleration in a potential gradient, and velocity analysis is normally achieved by passage through transverse electrostatic fields. The principle of combining velocity and mass analysis to provide instruments having both direction and velocity focusing of beams of ions was discussed by a number of mass spectrometrists but little progress was made until Mattauch and Herzog[17] formulated their theory of double focusing, employing a radial electrostatic field for which $R\,dV/dR =$ constant where R is the radius and V the potential, and there is a homogeneous sector magnetic field. The improvements in the definition of the ion optic image made possible by the application of this principle stimulated the construction of a number of double-focusing instruments, culminating in the commercial development of two different types.

The first of these commercial double-focusing mass spectrometers was described in 1958 by Craig and Errock.[18] It was based upon the geometry suggested by Nier and Johnson[19] and was marketed as the first instrument specifically designed for the qualitative analysis of organic compounds. The commercial version became the A.E.I. M.S. 9 mass spectrometer.* It combined a magnetic sector of 90° with a radius

---

* Similar instruments have been developed by the Hitachi Organization in Japan and marketed by Perkin–Elmer.

of 15 cm, with an electrostatic analyser of radius 18·25 cm. A source slitwidth of 6·25 μm was used to give a resolution of 10,000. The instrument had the novel features of oscilloscope peak-matching, by which the precise masses of known and unknown ions were compared, with an accuracy sufficient to permit the identification of the atomic constitution of the unknown ion provided it had a mass of about 200. A further feature was the ability to record the spectra of compounds of low volatility by direct sample insertion into the ion source. There has been a steady improvement in the performance of the double-focusing instrument over the past ten years and the most recent models have a magnetic sector of 30 cm radius and an electrostatic sector of 38 cm radius with a source slit that can be reduced to 0·1 μm to give a resolving power of 100,000. At lower resolving powers the scan duration can be reduced to 2 sec. Additional features have included combined electron bombardment, field emission and water-cooled sources to permit the study of labile organic compounds. With a spectrometer having these characteristics it is possible to determine the atomic constitution of almost all the ions normally responsible for the peaks in a mass spectrum. However, making a number of precise mass determinations by the peak comparison technique is time-consuming and the most recent development is to carry out these determinations automatically by the aid of a small computer. The output from the spectrometer is digitized and the centroid of each mass peak determined from a score of ion current measurements or by differentiation. The centroids of known and unknown peaks are then compared not in terms of accelerating voltage as in the manual technique, but in terms of time with the aid of a megacycle clock. The spectra may be stored on magnetic tape to be played back in analogue form or they may be printed out in the form of a table of atomic constitution and ion abundance.

Double-beam mass spectrometer

The most recent development in instrument design has been the production of a double-beam instrument by the A.E.I. organization (M.S. 30). The beams from two ion sources are bent so as to pass through a single mass-analyser system and then allowed to diverge to two separate detectors. With such an arrangement it is possible to compare the spectra of two compounds recorded at the same time on a single chart recorder. The spectra may be of known and unknown compounds, permitting direct chemical mass marking or matching of spectra. The two spectra may equally well be those of a single compound ionized and analysed under different conditions, e.g., high and low resolution or electron voltage. The operation of this instrument has been simplified so as to make it appeal to the routine analyst. The multiplicity of controls on older models has been replaced by a few interlocked push buttons.

Spark-source mass spectrography

In the double-focusing high-resolution mass spectrometers described above, the deflection due to the electrostatic and magnetic sectors is in the same sense. In an alternative geometry, ion optic image corrections and double focusing may also be achieved if the two deflections have opposite senses.[20] In addition to providing high resolution, this geometry has the further advantage that all ions are brought to a focus in one plane. The result is that a complete mass spectrum may be recorded simultaneously by placing a photographic plate in this plane. These features were exploited successfully in instruments produced by the A.E.I. company in this country and the Atlas Co. in Germany. The ability of the double focusing system to accommodate ions with a large spread of kinetic energy made it possible to use an instrument for elemental analysis in which the ionization was carried out with a high-frequency spark. In the A.E.I. M.S. 7 the substances to be submitted to elemental analysis were incorporated into carbon electrodes if they were themselves non-conducting and submitted to the action of a high-frequency spark in the ion source region. The resulting vapour was then ionized and the ions submitted to mass analysis. Detection was by means of a photographic plate which not only permitted the simultaneous recording of ion currents at all masses but also compensated for variations in spark intensity by integrating ion current with time. The final measurement of ion abundance was made by developing the plate and measuring the density of the appropriate line. Comparisons with standards permitted quantitation of the technique and made it a competitor to emission spectrography. The great advantage of spark-source mass spectrometry is its ability to give a quantitative analysis of a large number of trace elements at the same time with only a few exposures. The limit of detection is very much lower than that of any other technique except activation analysis. Limits of detection of 1 in 10^9 are frequently quoted and the sample size may be as small as 50 mg.

While this type of instrument is eminently suitable for photoplate detection, the plate can be replaced by a slit and the ion current detected electrically. The spectrum may be scanned past the slit as in other instruments. This versatility has been made use of in designs developed by the Atlas company, who have marketed models which can be used with either electron bombardment or spark sources and with either photographic or electrical detection.

Mass filters

There are three types of non-magnetic mass analysers which can be classed as mass filters, that is devices in which radiofrequency fields are used to selectively exclude ions from a detector; they are classed according to their electrode systems and have been given the names of the quadrupole, the monopole and the three-electrode mass filters.

The quadrupole system consists of four rods which are mounted along the direction of the ion path between the ion source and the collector. The ions enter the space between the rods where they experience a radiofrequency field. Paul was the first to describe such an arrangement and in his design the rods were collinear and symmetrically disposed around the ion path, with opposite pairs being interconnected.[21] The potentials applied to the rods are as follows

$$V_x = U + V \cos \omega t$$

and

$$V_x = -V_y$$

where V is the amplitude of an RF sinewave of frequency ω, U is a superimposed d.c. voltage and x and y are planes at right angles to the ion path. Theoretically the rods should have a hyperbolic cross-section; in practice, with the exception of the instrument marketed by Industrial and Technical Equipment Co. Ltd., the cross-section is circular, and it is usual to make the distance between opposite pairs of rods smaller than the rod diameter by a factor of 1·16.

Under the conditions that $U/V < \frac{1}{6}$ for a given value of the RF amplitude V, only ions within a very small mass range can execute stable trajectories along the length of the rods and escape to the detector. All other ions have unstable trajectories which end in a collision with the rods. In order to scan a mass spectrum either the frequency or the RF amplitude V may be swept and for wide scans a combination has been preferred. Rods are about 20 cm long and 0·6 cm in diameter, so the assembly provides a very compact mass analyser. The upper frequency range is determined by power requirements and is about 5 MHz. The great advantage of this type of analyser is that it is insensitive to variations in ion energy, so quite crude sources can be used. On the other hand, it has the disadvantage of requiring very precise rod alignment and stability, of the order of a few thousandths of a centimeter. The power supplies must also be very stable and for the highest resolution the U/V ratio must be kept constant within at least 1 in 20,000. The first commercial mass filter was produced by the Atlas Co. in Germany in 1963. It has a resolution of 100 and a mass range of 2–100. More elaborate instruments have been produced by the E.A.I. Co. and most recently by the Finnegan Instrument Corporation. The latter organization has produced the mass filter with the highest performance, it being capable of scanning up to a mass of 750 with a resolution of 1000. Other instruments with more modest performances have been introduced by GEC/AEI, Vacuum Generators, Baltzers, 20th Century Electronics and Varian. The ability of the mass filter to scan a wide mass-range in a very short time interval has been exploited in the mass spectrometer/gas chromatograph combination described later. While in theory very high resolutions are accessible with the mass filter, at present it is in the stage of being an inexpensive low- and medium-resolution device having the virtue of rapid scan and small size.

The monopole

It was first pointed out by von Zahn that one quarter of the geometry of the quadrupole could be replaced by a single rod and a grounded electrode with a right angle cross-section.[22] The operation is the same, both RF and d.c. voltages being applied to the rod and scanning achieved by sweeping either the RF frequency or amplitude. As in the case of the quadrupole, the monopole suffers from the disadvantage of giving spiked peaks rather than the flat-topped peaks produced by magnetic sector instruments. On the other hand the monopole has the advantages of providing spatial separation of ions so that it is feasible to record several ion currents at the same time. In addition, the stability requirement of the U/V ratio is greatly reduced so that simple power supplies can be used while good resolution can be achieved without the same mechanical requirements. The chief disadvantage of the design is the sensitivity to contamination by particulate matter, which causes peak splitting, while small changes in the operating conditions may introduce large variations in the relative intensities of the ion currents. Nevertheless, a successful monopole partial pressure gauge *i.e.*, a low-resolution monopole, has been marketed by Veeco Instruments Ltd. It has a mass scan of 1–200, a resolution of 50 and a minimum detectable total pressure of 5×10^{-9} mm Hg.

The three-electrode analyser

This was first described by Fischer.[23] It is a very compact arrangement, each electrode being part of a hyperboloid of rotation. In practice this amounts to a ball-bearing being placed above and below a ring of the same cross-section. It will be at once realized that the quadrupole and three-electrode assemblies have the same cross-section geometries but the latter is in fact a three-dimensional device so that ions cannot escape from a field between the electrodes once they have entered it. The ions circulate continuously around the axis of the field, unstable ions being lost as before by collision with the electrodes. The stable ion current is detected by means of the inductive load which it presents to an external oscillator. High sensitivity has been obtained for the three-electrode system in experimental models, which have detected as few as 10,000 ions. There is also the possibility of storing ions for relatively long periods and hence integrating weak ion currents.

Time-of-flight mass spectrometers

In the time-of-flight mass spectrometer first described by Stevens[24] the ionizing electron beam was intermittent rather than continuous. The electron pulse lasted about 0·1 μsec and the time of a complete cycle was about 100 μsec. The ions formed during the pulse were accelerated into a drift tube which they traversed on their way to a detector. The rate of travel was inversely proportional to the square root of the mass to charge ratio, and with sufficiently good time resolution of the signal obtained from the detector it was possible to isolate the individual pulses produced by the separated bunches of ions. An oscilloscope was the most suitable means of displaying such a spectrum, provided that the time-base was coupled to the pulsing circuits. The original designs were rather insensitive but later instruments stored ions in the source for a few μsec before initiating the analysis, and commercial instruments such as that manufactured by the Bendix Co. have sensitivities which are comparable with those of other instruments. While repetition rates as high as 100,000 per sec at resolutions approaching 1000 are possible, it is important to stress the fact that the dynamic range under such conditions is low and good analytical operation is only possible by integration over some hundreds of cycles.

The great advantage of this type of mass analyser is the simplicity of the source and non-critical nature of the source and flight-tube geometry. Apart from the ability of the detector circuits to resolve smaller and smaller time intervals the only way of increasing the resolution of time-of-flight instruments is to increase the length of the path between source and collector. In order to prevent the size of the drift tube becoming unmanageably long the ions may be constrained by magnetic fields to move in a helix. A device of this type was recently described under the name of the Spiratron.[25] It is interesting that under these flight conditions the more energetic ions move in longer paths and arrive at the detector later, thus providing the possibility of a two-stage instrument. In this a helical path is coupled with a straight path in which the more energetic ions arrive first, thus eliminating the reduction in resolution caused by energy spread of the ion beam.

APPLICATIONS

Coupling with the gas chromatograph

The advantages of the direct coupling of the effluent of a gas chromatographic apparatus with the inlet system of a mass spectrometer were outlined in the introduction. The methods of carrying out the combination are discussed briefly here; for a more detailed discussion the reader is directed to earlier reviews.[26,27] There are two problems associated with such a combination, the first being the necessity of recording the mass spectrum during the period in which the sample is emerging from the base of the chromatographic column. This time may vary from about 10 sec to above 1 min, but during this time, in which the signal is rising and falling on the chromatograph detector, the concentration of the sample in the effluent carrier gas stream is rising and falling also. It is advantageous to record the mass spectrum with a constant sample pressure since otherwise the relative intensities of the ion currents will not be constant and the matching procedure referred to earlier will not be possible. For these reasons it is important to record the spectrum in a fraction of the time required for the whole of the sample to emerge and to make this record when the concentration is at its maximum. (Or alternatively to use a normalizing procedure based on a total ion-current measurement.) It is easier to change the accelerating voltage rapidly than to alter the magnetic field, and in many simple combination instruments the mass decade can be scanned in a second or less. Recent advances in instrumentation of magnetic instruments have made it possible to scan a mass decade magnetically in about 2 sec. This eliminates the disadvantage (associated with voltage scanning) of the lower efficiency of collection of the heavier ions. Much faster times of scanning are available with non-magnetic instruments and no problems are encountered with their use, for these reasons. A rapid scan allows the experimenter to examine partially resolved chromatographic peaks by recording the mass spectrum at the beginning and end of the chromatographic peak. In these spectra the role of the two sample components in the two spectra will be revealed.

The second problem associated with the direct coupling of the two instruments is the carrier gas. Even when the sample is at its highest concentration in the carrier gas effluent from the column, it is still present as only a small fraction of the carrier gas concentration. The direct admission of the carrier gas stream to the ion source would therefore result in the production of a high source pressure and in the recording of a mass spectrum which was largely that of the carrier gas itself. In order to overcome this problem it is necessary to achieve a segregation of the sample and to admit only it to the ion source, preferably without any loss of the sample. This ideal case has never been achieved in practice but there have been three successful compromises.

The first of these was developed by Ryhage and relied upon the effusion of the gas mixture from a narrow orifice for its separation.[28] The carrier gas used was helium and together with the sample the effluent passed through such a jet into a chamber at a reduced pressure. Immediately opposite to the jet was a small aperture leading to a second jet. The helium, because of its low gas density, had a high component of velocity at right angles to the line of flow and so collided with the chamber walls and was pumped away. The heavier sample molecules entered the aperture and issued together with a reduced amount of helium to the second jet where the process was repeated, the final aperture leading directly to the ion source and the second chamber being held at a pressure lower than that in the first chamber. Recoveries of the order of 50% of the original sample were achieved and the carrier gas concentration was reduced to 2%.

The second method also depended for its success on the exploitation of the low density of helium. The Watson-Biemann separator[29] allowed the effluent to pass into a tube made of glass frit or sinter. An outer jacket surrounded the frit and the annular space was continuously pumped out. The helium diffused through while the sample passed along the tube to the ion source. Recoveries of about 15% were achieved and the carrier gas concentration was reduced to a few per cent.

The third separator, which is now promising to oust all the others (although at present the majority use a glass frit separator) because of its cheapness and simplicity, was originally suggested by several investigators and is called the membrane separator. It uses a thin film of a polymer, usually silicone rubber, to divide the effluent stream from the ion source. The sample components are soluble in the membrane and diffuse through it into the ion source while the carrier gas is excluded. To eliminate memory effects and to increase the rate of diffusion and hence the response time, the film must be made as thin as possible. The recovery can be as high as 25% and the residual carrier gas concentration as low as 5%. All three separators are usually heated in order to increase the rate of the separation process and to reduce adsorption. There are a number of commercial instruments sold as a gas chromatograph–mass spectrometer package. The first successful design was the LKB 9000 which used the Ryhage separator, had a resolution of about 1000 and required a total sample size of only 0·1 μg. The GEC/AEI Co. used the glass frit separator in their M.S. 12 which in its final stages of development had a resolution of 7500 and required a sample size of only 2 μg. The M.S. 12 has now been replaced by the M.S. 30 double-beam instrument described previously, which uses a membrane separator. Lower resolution magnetic sector combinations have been developed by Edwards High Vacuum Ltd., and Vacuum Generators Ltd. The GEC/AEI Co. have combined their 180°-focusing instrument (the M.S. 20) with a gas chromatograph. The rapid-scan facility and low cost of the quadrupole mass filter have made it an attractive gas chromatograph detector and the EAI Co. and the Finnegan Instrument Co. in the U.S.A. have manufactured competitors to the magnetic instruments, using both frit and membrane separators. The resolution is in the 500–1000 range and the sensitivity is 3×10^{-11} g/sec. They have a very high scan-rate and indeed the scan-rate of all the instruments described is sufficiently fast to permit oscilloscope presentation of spectra. This is a useful facility because whether chromatographic peak detection is made by an external detector or by the ionization facilities of the instrument operating at an electron voltage below that of the ionization potential of the carrier gas, no peak identification is possible until the spectrum is run. The use of the oscilloscope obviates the need for the recording of unrequired mass spectra merely for peak identification purposes. In an analysis of a complex sample mixture this could be a costly undertaking.

The determination of isotopic constitution

The examination of any mass spectrum of an organic compound immediately reveals the polyisotopic nature of naturally occurring carbon, sulphur, chlorine, bromine and boron. The small proportions of the heavier stable isotopes of hydrogen, nitrogen and oxygen are less obvious. All these isotopes are stable and should not be confused with artificially produced radioactive isotopes such as carbon-14. The very great success of labelling techniques based on radioactive isotopes may be shared to some extent by the use of artificially enriched stable isotopes. The ability of the mass spectrometer to detect stable isotopes can never be as great as the ability of the counter to detect radioactive isotopes, but the great advantage is that the stable isotopes may be handled with none of the precautions inherent in the handling of radioactive compounds. The principles involved in tracing with stable isotopes are, however, exactly the same, the change in the isotopic constitution of samples (drawn from a dynamic or reacting system) being assayed by the mass spectrometer, and the signal at the abnormal isotope peak being analogous to the signal derived from the counter.

There is, however, a further advantage in the mass spectrometer method, because the ionization is followed by a dissociation process in which the labelling atoms are combined with fewer and fewer of the other atoms in the molecule. Thus an examination of the spectrum can give information not only on the extent of labelling but also on the position of labelling within the structure. In order to do this of course it may be necessary to use all the techniques which have already been outlined in previous paragraphs, such as precise mass determination.

If now the spectra of the labelled and unlabelled molecules are compared and the atomic constitution of the fragment ions is determined, it will be seen that the labelled atom is concentrated in one part of the molecule. This of course can only be achieved when the label atom is part of the backbone of the molecule. As has been observed earlier, hydrogen and deuterium atoms are notoriously labile in the ions and it is difficult to draw any but statistical conclusions from such labelling. This determination of the site of introduction of the label atom depends upon the ionization of a compound sufficiently volatile to permit evaporation into the source of the mass spectrometer. In some cases, because of the complexity of the reaction mixture or the intractable nature of the products, it may not be possible to make such a determination. It may still be feasible to get tracing information by conversion of the reaction mixture or some part of it into a volatile product which contains the stable isotope. In the case of carbon-14, radioactive tracing of the labelled compound is achieved by conversion into carbon dioxide or even methane. A similar conversion may be carried out with compounds containing carbon-13 and the ion current at $m/e = 45$ used as a measure of the total carbon-13 content. In a similar way the nitrogen-15 content of, for example, excreted urea, may be determined by Kjeldahl digestion followed by a hypobromite treatment to release molecular nitrogen. The ion current at $m/e = 29$ is a measure of the enrichment of the sample. Oxygen-18 may be assayed by pyrolysis followed by the oxidation of the carbon monoxide to carbon dioxide. The ^{18}O concentration is measured at $m/e = 46$. The precision of these measurements can be quite high and is improved by integrating the results of a number of measurements. The sensitivity depends upon the dynamic range of the instrument and can have a value of 0·01 atom %. When determinations of the isotopic concentration of both carbon and nitrogen are required the mass spectrometer may be connected directly to a conventional C, H, N analyser.

The very great advantage of the stable isotope method of tracing is that quite highly labelled material may be fed to experimental animals or patients without fear of the side-effects arising from the administration of similar doses of radioactive material. With the increasing availability of compounds labelled with ^{13}C, ^{15}N and ^{18}O and the wide distribution of moderately priced instruments capable of analysing them, a large increase may be expected in the use of stable isotope tracing in the biochemical and medical fields.

Quantitative analysis

With an ion source with a constant ionizing electron beam current and with a constant source pressure of the sample gas it is possible to determine the sensitivity of an instrument for any particular substance. Since in general any substance will produce ion currents at a number of different m/e values the sensitivity at any one of these values may be chosen. In the absence of any reason to the contrary the value chosen will be that at which the most intense ion current is produced, that is to say the m/e value corresponding to the highest peak in the mass spectrum. It is however difficult to record the pressure of the sample vapour in the ion source by any other than some form of ionization gauge, because of the very low pressures involved. It is therefore common practice to establish a constant flow of sample vapour through a capillary or sinter into the ion source from a reservoir of the sample gas maintained at a higher pressure. The sample pressure in the reservoir and hence the pressure in the ion source remain substantially constant during the time in which measurements are made. Once the instrument has been calibrated by measuring the sensitivities on selected m/e values for pure sample vapours the analyst is in a position to deal with any mixture of those compounds for which he has recorded sensitivities. For every component in the mixture the analyst must measure the intensity of one ion current or peak height in the mixture spectrum. While it is sometimes possible to calculate the mixture composition by a spectrum-stripping technique, a more general method is to express the values of the ion currents or peak heights as sums of the products of sensitivities and partial pressures, obtaining a series of linear simultaneous equations and to invert the matrices. For complex mixtures this is best carried out by computer. It is sometimes impossible to carry out this routine because the resolution of the instrument is not sufficient to enable separation of ion currents at closely similar m/e values. If this is the case then a solution to the problem is to record two spectra of the mixture, one before and one after the quantitative conversion of one of the components of the mixture into a second substance. As an example the masses of carbon monoxide and nitrogen differ only by 1 part in 2800 and if the instrument available cannot achieve this resolution then a low-resolution spectrum is recorded and then the sample vapour in the inlet system is exposed to iodine pentoxide which converts the carbon monoxide into carbon dioxide quantitatively. A second spectrum is then recorded and in this spectrum the ion current at mass 28 is due only to nitrogen. From a comparison of the two spectra the concentration of carbon monoxide can be deduced.[30]

Analyses such as those described can only be carried out if a few milligrams of the sample are available and if the sample is sufficiently volatile to permit the achievement of suitable reservoir pressures. Much modern mass spectrometry is carried out, however, with solid samples of low volatility and these are normally analysed by introducing them directly into the ion source on the end of a ceramic or glass probe which is inserted into the instrument through a vacuum lock and within a few mm of the ionizing electron beam. In the most recent developments the probe may be heated or cooled to control evaporation. The resulting vapour molecules move only a short distance before they become ionized and so substances with extremely low vapour pressures may be analysed. Under these circumstances the sample pressure within the source is controlled only by the rate of evaporation and can only be adjusted crudely by altering the temperature or the position of the sample. It is thus not easy to calibrate the instrument or to analyse quantitatively. Further, since sample sizes have tended to diminish, the sample pressure may vary widely during evaporation, owing to the exhaustion of the solid on the probe. For this reason an alternative system has been devised in which the ion current due to the sample is integrated while the whole of a known amount of the sample is being evaporated. It is then possible to relate the integrated ion current to the amount of sample evaporated and to determine a sensitivity for the instrument with that sample.[31] One method of doing this would be to scan the whole mass spectrum repetitively at as rapid a rate as possible, while evaporating the sample, and to measure the corresponding peak height on each scan and plot peak height against time for each significant *m/e* value. This is possible experimentally and Fig. 7 shows the results of such a determination, using 60 ng of *p*-tyramine as the sample. The total evaporation time is about 100 sec. However, the recording of a large number of spectra is an expensive process and measurement of the spectra is tedious. The system only becomes practical if the mass spectrometer output is digitized and stored either on tape or in a core for processing by computer.

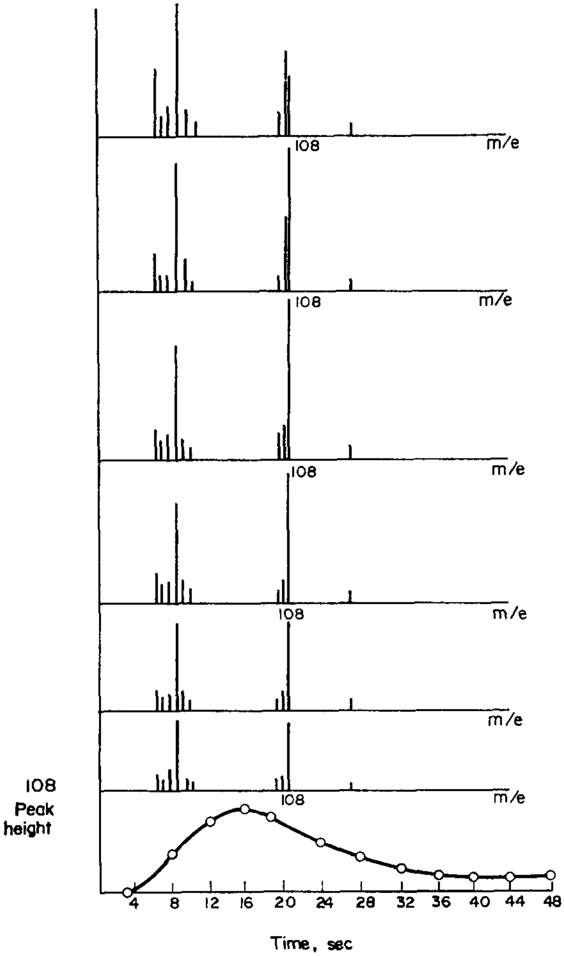

FIG. 7.—Mass spectrum scanned at 8-sec intervals during the evaporation of 60 ng of *p*-tyramine.

However, a compromise may be made in which not all of the spectrum but only a small part of it is repetitively scanned during the course of evaporation. The simplest possible situation is when only one ion current is recorded, for example the molecule ion-current since that will give most information about the molecule, although the argument would apply with equal force to a characteristic fragmentation peak in the mass spectrum. If the instrument is tuned to the selected *m/e* value before the evaporation begins and the ion current is recorded during the whole course of the evaporation of a small sample, then the record of the ion current at the selected *m/e* value is a measure of the rise and fall of the sample vapour concentration in the ion source, and the area under the curve so obtained is directly proportional to the integrated ion current and hence to the weight of sample evaporated. Thus an inexpensive and greatly simplified record is obtained and computer analysis is unnecessary. The problem of tuning in to a specific *m/e* value before an ion current is established at this value, *i.e.*, before evaporation has begun, is not always a simple matter. If voltage scanning, time-of-flight or radiofrequency instruments are being used, it is not too difficult, but with magnetic sector instruments without a very accurate mass-marking system it may not be possible to achieve. Further, it is often the case that an instrument of the latter type will go off tune during the course of an evaporation. For these reasons a system has been developed in which the single mass is repetitively scanned by means of peak switching facilities. Since this may be carried out in about 1 sec, only a short inexpensive recording is required and this consists of a series of peaks, the heights of which are proportional to the instantaneous ion current at the selected *m/e* value. These peaks rise and fall as the evaporation proceeds and it is the envelope of these peaks which constitutes the integrated ion current curve. Further, it is the area under this envelope which is proportional to the amount of sample evaporated. The problem of tuning to the *m/e* value with sector instruments may be solved by using a second calibrating substance in a second inlet system of the instrument, usually a reservoir of the type described above. The compound used is most commonly heptacosafluoro-tri-n-butylamine, which is allowed to flow into the source, and a peak in its spectrum is selected which is close to the *m/e* value which is being used for integration. This peak is then tuned in on the instrument by adjusting the magnet scan and the accelerating voltage is then altered so as to tune in the desired *m/e* value. The reference supply may then be cut off and evaporation initiated. If it is suspected that the sensitivity of the instrument is varying during the course of the evaporation then the ion currents due to the reference sample peaks may be recorded alternately with the sample peak currents. Any change in the height of the reference peaks would be due to a change in instrument sensitivity alone, since the sample source pressure of the reference compound is constant. In quantitative analysis by this technique the machine is first calibrated with known weights of pure samples of the compound. Comparison of the sample integrated ion-current curve area with the calibration graph gives a direct determination of the amount of unknown evaporated. Figure 8 shows such a calibration graph and it can be seen that there is linearity of response over several orders of magnitude. The limits of detection are very low indeed and detection of as little as 10^{-14} g has been achieved in favourable cases.[31] The effect of the matrix from which the sample is evaporated has been studied by making mixtures of two compounds, the major component being present in up to a million times the concentration of the minor component. It was found that provided the total sample size did not

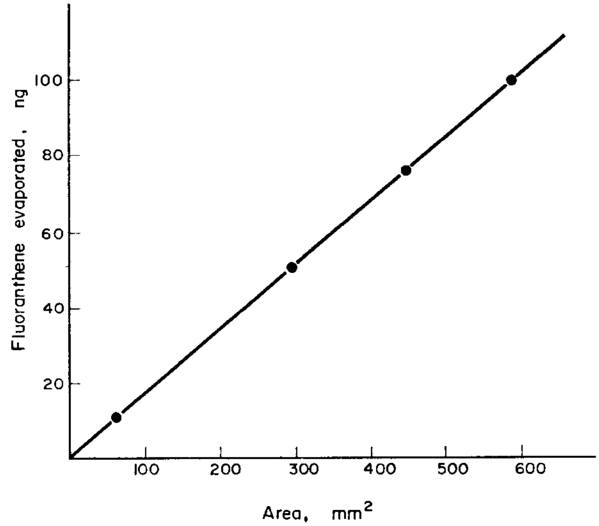

FIG. 8.—Calibration graph for fluoranthene.

exceed 5 μg, thus ensuring that the ion source pressure did not rise above 10^{-5} mm Hg, a plot of the integrated ion-current curve area for a characteristic *m/e* value of the minor component was linear down to the detection limit. The sensitivity of this technique varies with the compound and also with the characteristic *m/e* value selected. While it may be felt that the molecule ion peak is the most characteristic in the spectrum this sometimes carries only a very tiny fraction of the total ion current and thus can only give a low sensitivity. In such cases a characteristic fragment ion peak may provide a suitable *m/e* value for integration.

The analysis of metals

The most efficient method of analysing for trace metals is by the use of the spark-source double-focusing mass spectrometer such as the A.E.I. M.S. 7. Although the accuracy is limited by photoplate detection the ion currents due to all the ionized species are recorded at the same time and a limit of detection of one part in 10^9 has been claimed. Where the analytical requirements are less stringent it is sometimes possible to use the integrated ion current method with a general purpose mass spectrometer. Some metal salts such as mercuric chloride are themselves sufficiently volatile to permit their evaporation into the ion source directly. Figure 9 shows a portion of the mass spectrum for mercuric chloride, including the molecule ion region. It can be seen that the isotopic complexity has resulted in the distribution of the ion current over a number of isotopic ions and the sensitivity is thus much lower than that which can be achieved for a monoisotopic substance. However, amounts of mercuric chloride down to 1 ng can be determined with an error of 5%.[32]

Where no simple salt can be prepared it is necessary to convert the metal into a volatile form by making a chelate such as the acetylacetonate. The volatile nature of such chelates was first demonstrated by Morgan[33] over 40 years ago and more recently their properties have been exploited in an elegant and extensive study by Sievers,[34] using gas chromatography. The volatility of many metal chelates is improved by

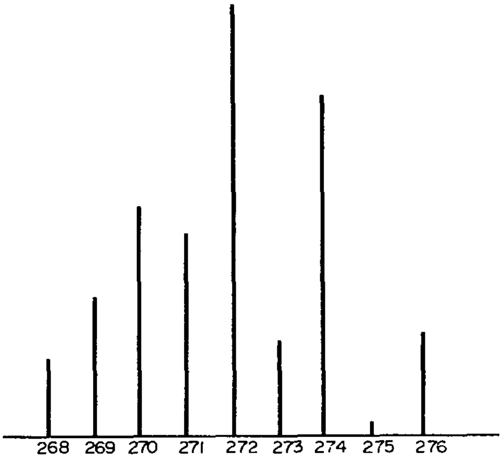

Fig. 9.—Mass spectrum of mercuric chloride.[32]

the substitution of fluorine and sulphur atoms in the diketone molecule. Although it is debatable whether alkali metal derivatives of diketones and keto esters can be classified as chelates, they may be evaporated from a probe into the ion source at temperatures below 200°.[35] Although it is possible to detect very small quantities of these compounds by the integrated ion current method the procedure is complicated by the fact that alkali metal chelates undergo two types of reaction upon evaporation—association and exchange.[36] Thus the mass spectra exhibit ions of the form $M_xL_y{}^+$ and the introduction of a large amount of a sodium chelate followed by, for example, a potassium derivative of a second diketone may result in the production of a spectrum revealing ions in which the two alkali metals have exchanged diketones. More complex association reactions are revealed if the chelates of alkali and alkaline earth metals are evaporated together.[37] Double chelates of the form $MM'L_3$ have been shown to exist. In the absence of the alkali metals however it is possible to estimate as little as 10^{-9} g of alkaline earth metals as their chelates with trifluoro-5,5-dimethylhexan-2,4-dione even though the mass spectrum exhibits polymeric peaks. Similar association reactions have been shown to occur between the chelates of alkali and rare-earth metals with the formation of binary chelates having the general formula $MM'L_4$.[35] In the absence of the alkali metals, however, very small quantities of rare-earth metals may be estimated as their chelates with heptafluoro-7,7-dimethyloctan-4,6-dione by the integrated ion current method.

1,3-Diketones or keto-esters have been used to make volatile derivatives of a number of other metals, the most volatile of these being the transition metal chelates, and detection limits for these species in the subnanogram range have been claimed. The power of the integrated ion current technique is, however, best demonstrated by the determination of mixtures of zirconium, hafnium and titanium as their trifluoroacetylbenzoylmethane chelates at the nanogram level–a formidable task by any other method.[39] There are many other chelating agents which form metal derivatives sufficiently volatile for their ready evaporation into the ion source and among these are 8-hydroxyquinoline, dipyridyl, dimethyl- and phenylglyoxime and the thio and amino derivatives of acetylacetone. A notable exception to this list is benzoylphenylhydroxylamine which forms derivatives which are not sufficiently stable to survive evaporation.

The integrated ion current method has been applied to the determination of a variety of organic compounds. It is perhaps very well suited to the analysis of polycyclic hydrocarbons obtained as air pollutants from automobile exhausts or the soot of smoky flames. The limit of detection for compounds such as the benzpyrenes is several orders of magnitude lower than that of any other technique. Further the spectrum of a complex mixture may be reduced to a number of molecule ion peaks by reducing the ionizing electron voltage to about 10 eV. Drugs have been assayed in blood and urine, and the distribution of non-catecholic amines in the human brain has been plotted.

A final feature of the integrated ion current technique is provided fortuitously by the differential rates of evaporation of closely similar compounds from the surface of a mass spectrometer probe. If the sample consists of a pair of isomers such as for example *o*- and *p*-nitrophenol, and if the curve is plotted for the molecule ion, then instead of the gaussian curve obtained for most sample evaporations a curve with two distinct maxima is obtained. This is because one isomer is being evaporated before the other. In all cases where isomerism can occur the integrated ion current curves have been shown to have fine structure. In the case of the chlorinated hydrocarbon "Chloran" no less than five maxima are visible. Structure has been demonstrated in curves obtained for *cis-trans* isomers, dioximes, polycyclic hydrocarbons, and very convincingly for metal chelates. By this means, the existence of *cis-trans* isomerism in the 8-hydroxyquinoline derivatives of bivalent metals has been demonstrated and complete separation of the isomers has been achieved in the 8-hydroxyquinoline derivatives of tervalent metals.[40]

An interesting application of the integrated ion current technique is in the assessment of the efficiency of decontamination agents and the cleaning of surfaces. For this application the probe is replaced by a small cylinder made of the material on which decontamination studies are to be made. The surface is then coated with a substance which is sufficiently volatile to be evaporated into the ion source at a high temperature. The amount adhering is determined in the normal way. The probe is then recontaminated and before assay is washed in the appropriate decontamination agent. The amount remaining is then assayed as before.

In the original study it was found that washing in cold solutions of efficient decontamination agent removed the contamination down to the level where it existed as a monolayer on the surface. This monolayer was only removed by treatment with the agent at elevated temperatures. More recently a phosphate-free decontamination agent, Decon 90, has been shown to break through the monolayer even in the cold and to leave no detectable film of contamination on the mass spectrometer probe after treatment at 50°.

Zusammenfassung—Es wird ein Überblick über die elementare Theorie, die Technik und die Anwendung der Massenspektrometrie gegeben. Besonders wird auf apparative Entwicklungen und dadurch bedingte neue Anwendungsmöglichkeiten hingewiesen.

Résumé—On a effectué une revue de la théorie fondamentale, de l'instrumentation et de l'application de la spectrométrie de masse, spécialement en ce qui concerne le développement de l'équipement et sa répercussion sur le cadre l'application.

DEVELOPMENT AND PUBLICATION OF WORK WITH SELECTIVE ION-SENSITIVE ELECTRODES

G. J. MOODY and J. D. R. THOMAS
University of Wales Institute of Science and Technology, Cardiff, Wales

(*Received* 7 *July* 1971)

Summary—Features concerning development, response, selectivity and applications of selective ion-sensitive electrodes are reviewed. Recommendations are made concerning investigations involving the development and applications of electrodes and attention given to the manner of presenting data for publication.

OVER SIXTY YEARS have elapsed since the initial discovery[1] and characterization[2] of the electrical potential arising at a thin glass membrane interposed between aqueous solutions of different acidity, but it is only within the last five or six years that there has been widespread development and interest in sensor membrane electrodes based upon a more general application of ion-exchanging materials. This might seem surprising when viewed against the prediction by Lengyel and Blum[3] in 1934 of a cation-sensitive glass electrode and of reports by Tendeloo[4] in 1935 and Kolthoff and Sanders[5] in 1937 detailing potentiometric response to certain ions by electrodes composed of solid-state membranes of barium sulphate and calcium fluoride slices[4] or discs of silver halides.[5]

Glass electrodes selective to hydrogen ions have been standard items of laboratory equipment for over thirty years, but it was just over ten years ago that glasses of modified composition were adapted for selective response to cations other than hydrogen ions. As the advantages of a wider range of selectively sensitive electrodes were materializing, Pungor and Holós-Rokosinyi[6] described in 1961 the selective working of precipitate-based ion-sensitive electrodes. However, it was the commercial availability of the fluoride solid-state electrode[7] in 1966, which coincided with the tremendous interest in the determination of trace fluoride following water fluoridation and dental health programmes, that initiated the recent vast interest in selective ion-sensitive electrodes. Symposia such as those held in January 1969 at the National Bureau of Standards, Gaithersburg, Maryland, U.S.A., and in February 1969 at the University of Wales Institute of Science and Technology, Cardiff, U.K., have boosted their general acceptance. The subsequent publication of the N.B.S. Symposium proceedings has provided a very useful source book[8] which has been well-supplemented by the Orion Research Incorporated Data Sheets and *Newsletter*.

The full benefit of selective ion-sensitive electrodes can only be realized by thorough familiarity with their properties and mode of operation. With this in view, this paper is intended to suggest a set of requirements in outlining the development, assessment and application of these electrodes. This is felt to be necessary in view of the existing ambiguities concerning the relation of potential to the logarithm of the activity of active ion and presentation of selectivity ratios or coefficients. Further reasons involve lifetimes and response time under various operating conditions. While it is recognized that different opinions and individual preferences will still flourish, it is nevertheless hoped that a format can be developed for the convenient presentation of results that will permit ease of assimilation and realistic appraisal by other workers.

DEVELOPMENT OF NEW ELECTRODES

Potential response

In general, the potentiometric cell assembly incorporating a selective ion-sensitive electrode takes the form shown in Fig. 1 where the e.m.f., E, of the cell is the sum of various junction potentials:

$$E = E_M + E_{M'} + E_R + E_{R'} + E_j \tag{1}$$

Except for E_M, which depends on the nature of the test or standardizing solution, the remaining contributory potentials may be taken as constant, although some of the junction potentials, particularly those of the reference electrode, can be troublesome. The reference electrode used in any investigation should be specified in published reports, along with the model and impedance of the e.m.f.-measuring instrument.

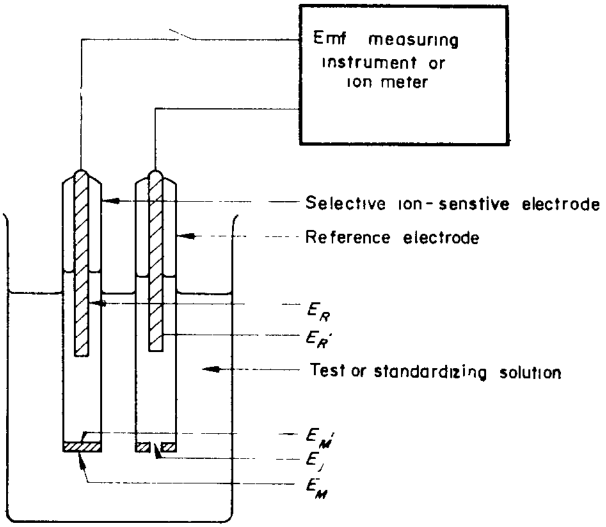

FIG. 1.—Experimental circuit for using selective ion-sensitive electrodes.

For an electrode responding selectively to an ion, i, of activity a_i and charge z, in the presence of an interfering ion, j, of activity a_j and charge y, E, for Nernstian response, is given by

$$E = \text{constant} \pm \frac{2{\cdot}303RT}{zF} \log \left[a_i + K_{ij}(a_j)^{z/y}\right] \tag{2}$$

where K_{ij} is the selectivity coefficient. The constant term incorporates the various junction potentials and the standard potential characteristic of E_M. The second term on the right-hand side of equation (2) takes the positive sign for cations and the negative for anions.

On the basis of the response characteristics above, selective ion-sensitive membrane electrodes have been described for about twenty ions which are fairly evenly divided between cations and anions. There is, therefore, plenty of scope for fresh developments, both for electrodes selectively sensitive to an extended range of ions and for improvements and refinements to existing electrodes.

Unless the electrode is going to be available commercially, its description should carry exact details for its construction, and the design need not be any more intricate than the minimum necessary for the performance claimed.

The dependence of the e.m.f. response on the logarithm of the activity indicates [equation (2) in the absence of interferent] that E will alter by only 2·72 mV for a univalent ion and by 1·36 mV for a bivalent ion for a 10% decrease in the activity of the active species and by only 2·45 mV for a univalent ion and by 1·23 mV for a bivalent ion for a 10% increase in the activity of the active species. These figures mean that a sensitive voltmeter (with high impedance to cope with the high resistances involved) responding to 0·1 mV, or better, is recommended[9] for work of acceptable precision. Expanded scale facilities on commercial pH-meters do not normally meet this requirement.

Selectivity

Membrane electrodes have the advantage that they can be tailor-made for almost any ion, but the difficulty of distinguishing adequately between different ions, particularly of the same sign, is a serious limitation. Hence, considerable effort has been devoted to assessing the performance of the new range of electrodes in the presence of possibly interfering ions. This has been done in terms of the selectivity coefficients, K_{ij}, defined by equation (2), the methods employed[9,10] for evaluating K_{ij} being based on e.m.f. measurements either in separate, or more realistically in mixed, solutions of the primary ion, i, and interfering ion, j.

The two separate-solution methods with the solutions producing e.m.f.s E_1 and E_2, involve either equation (3) or (4) depending, respectively, on equality of the primary and interferent ion activities and of the e.m.f.s:

$$\pm\left(\frac{E_2 - E_1}{2{\cdot}303RT/zF}\right) = \log K_{ij} + \left(\frac{z}{y} - 1\right)\log a_i \tag{3}$$

$$a_i = K_{ij}(a_j)^{z/y} \tag{4}$$

For cations, the left-hand side of equation (3) takes the positive sign, and the negative sign for anions. The second term of the right-hand side disappears when the charges of the primary and interfering ions are equal.

Separate solutions are not typical of operating systems so a more common procedure for assessing selectivity ratings is measurement of the e.m.f. in solutions containing a fixed amount of interferent with varying activities of the primary ion for which the electrode is designed. Figure 2 illustrates the general idealized pattern and the calculation of K_{ij} from equation (4).

It is pertinent at this point to stress the benefits[11] of the universal and consistent adoption of K_{ij} as described above for listing selectivity data. The inconsistencies to date, particularly in some manufacturers' literature, can only cause bewilderment to readers and users alike. Such a system of presenting selectivity data consistently indicates that when $K_{ij} < 1$ the electrode preferentially responds to the primary ion, i. However, Fig. 3 stresses the care needed in any interpretation of any single published item of selectivity information, for selectivity varies with the relative primary ion/interferent activities. Thus, for the poly(vinylchloride) calcium-sensitive electrode[12] the value $K_{\mathrm{CaMg}} = 0{\cdot}024$ obtained at a high magnesium content ($a_{\mathrm{Mg}} = 5 \times 10^{-3}M$)

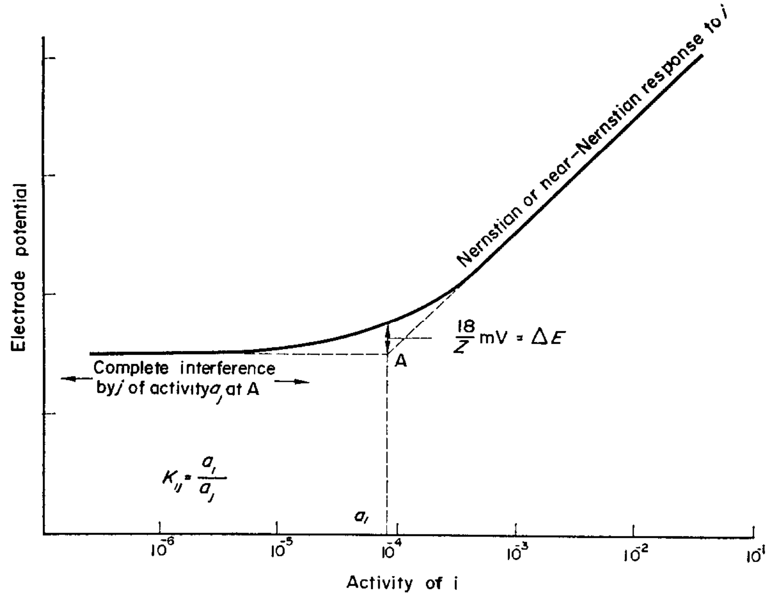

FIG. 2.—Illustration of selectivity coefficient evaluation, using fixed initial amount of interferent of same valence as *i*.

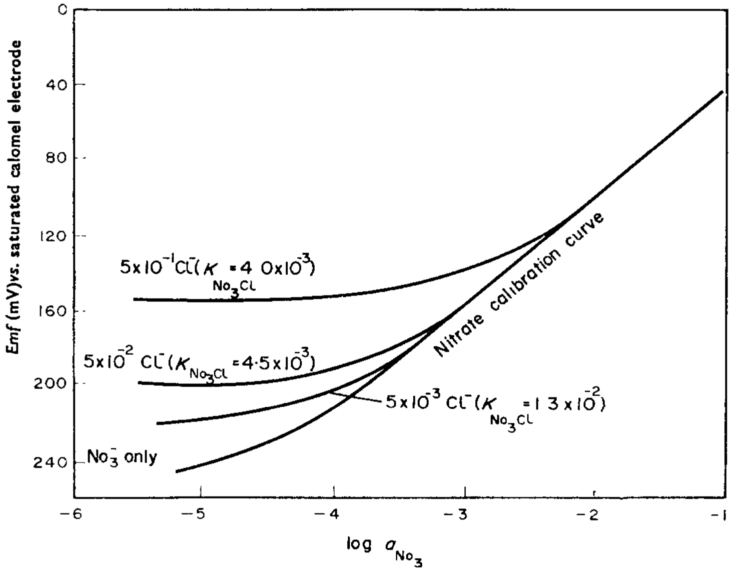

FIG. 3.—Influence of chloride on the response characteristics of a nitrate-sensitive (Orion 92-07-02 nitrate liquid ion exchanger) poly(vinylchloride) electrode.

suggests a better selectivity than $K_{CaMg} = 0{\cdot}222$ at a lower magnesium level ($a_{Mg} = 4{\cdot}3 \times 10^{-5}M$), while in fact the electrode gives the most extensively useful response at lower magnesium levels (*cf.* Fig. 3 for a nitrate-sensitive electrode affected by chloride interference).

The considerable variation of selectivity with interferent concentration is further illustrated by the work of Lal and Christian[13] on fifteen foreign cations, using the Orion 92–82 lead electrode. However, the apparent lack of critical assessment in this paper[13] emphasises the attention to detail essential for studies on electrode assessment. Thus, in commenting that the Orion lead electrode is much more responsive to univalent cations than is reported by the manufacturers, Lal and Christian[13] have not considered the modifying influence of the power term of equation (4). Yet this equation shows that the lead electrode has nearly the same useful range in the presence of $10^{-5}M$ sodium (down to $8{\cdot}9 \times 10^{-4}M$ lead) as it has in the presence of $10^{-5}M$ calcium (down to $2{\cdot}5 \times 10^{-4}M$ lead) even though the respective K_{ij} values differ by several orders of magnitude ($K_{\mathrm{PbNa}} = 8{\cdot}9 \times 10^6$ and $K_{\mathrm{PbCa}} = 25$). The extensive useful range permits the lead potentiometric titrations mentioned by these workers[13] but a high response to the sodium and potassium salt titrants used would hardly permit such an application. Moreover, potentiometric titrations of various univalent cations with sodium tetraphenylborate, with the lead electrode as sensor, warrant further investigation to determine the true mechanism.

The importance of the useful role of plots such as Fig. 3 for investigations involving interference parameters cannot be over-emphasized. Unfortunately, however, such plots take up journal space and where the mixed-solution method[9,10,13] has been employed, an alternative procedure[11] is to quote the activity, a_j, of the interfering ion corresponding to each K_{ij} value. Readers will then be realistically informed that should the level of j in the test situation exceed this value and the expected activity level of i be less than $K_{ij}(a_j)^{z/y}$, then the electrode will very likely be useless in such a test situation.

An alternative mixed-solution method of expressing selectivity involves variation of interferent activity at constant primary ion activity[9,10,14] and is generally used for assessing hydrogen ion and hydroxide ion interference. Several diagrams expressing constancy of e.m.f. response over a pH range have been published[12,15,16] and these confirm that unless there are unusual features it is adequate to quote a pH range for which there is unlikely to be interference with electrode behaviour, but again it is essential to quote the level of primary ion for that pH range.

Srinivasan and Rechnitz[10] considered neither of the foregoing mixed-solution methods in their treatment of potential data obtained for several different Orion liquid membrane ion-sensitive electrodes. Instead, two rather complicated equations were proposed, the general form of the one for high values of K_{ij} being

$$\left[\exp \pm\left(\frac{E_2 - E_1}{RT/zF}\right)\right]a_i - a_i' = K_{ij}(a_j')^{z/y} \tag{5}$$

and that for low values of K_{ij} being

$$a_i' - \left[\exp \pm\left(\frac{E_2 - E_1}{RT/zF}\right)\right]a_i = K_{ij}\left[\exp \pm\left(\frac{E_2 - E_1}{RT/zF}\right)(a_j)^{z/y} - (a_j')^{z/y}\right] \tag{6}$$

As before, the positive sign alternative is used for cation-sensitive electrodes and the negative for anion-sensitive electrodes. The a values refer to E_1, the a' values to E_2.

Equation (5) is used by plotting the left-hand side against interferent activities, a_j', and equation (6) is used by plotting the left-hand side against the square-bracketed function of the right-hand side. In each case, linear plots are obtained, of slope K_{ij}.

However, there is little to commend such complicated functions when the desired information concerning the potential applicability of electrodes can so conveniently be obtained from plots of the kind shown in Fig. 3.

Selectivities of solid-state electrodes have been variously expressed and emphasize the present chaos regarding selectivity quotations.[11,14] Except for the method involving equations (5) and (6), the practical methods employed for evaluating the selectivities are those already described above, although Light and Swartz[17] used equation (5) in a non-graphical procedure for determining anion interferences for the Orion 94-16 sulphide electrode.

The interference mechanism of solid-state electrodes differs from that of liquid ion-exchange and glass electrodes in the manner in which the primary ion and interfering ion(s) gain access to the all-important membrane.[14] This has led to criticism by Pungor and Tóth[18] concerning the application of the methods above for determining the selectivities of precipitate-based selective ion-sensitive electrodes. Even so, these workers used equation (4) in its appropriate form for obtaining "measured" selectivities of halide electrodes for comparison with those calculated from solubility product ratios.[18] This, of course, highlights a common form of interference of crystal membrane and precipitate-impregnated membrane electrodes, arising from the interfering ion actually reacting at the membrane surface to form a new insoluble compound.[19] For this kind of interference, a knowledge of solubility products of the membrane salt and of the insoluble compound formed is helpful in predicting the usefulness of an electrode. For example, for thiocyanate interference with the silver bromide electrode, the selectivity ratio, K_{BrSCN}, is given by the ratio of the solubility product of silver bromide to the solubility product of silver thiocyanate. This implies that for the electrode to be functional to bromide in the presence of thiocyanate, the ratio of the interfering thiocyanate to the primary bromide activity must not exceed the ratio (solubility product of AgSCN)/(solubility product of AgBr). Of course, the inverse relationship holds when the electrode is to be used for thiocyanate, with bromide interference, the form[11] of the selectivity ratio then being K_{SCNBr}.

Interference with solid-state electrodes also occurs when the membrane material reacts with interferent to give a soluble complex, a feature that has been exploited in adapting silver halide membranes for use as cyanide electrodes.[18,20,21] Dissolution of the membrane is also regarded as the basis of the "high" fluoride readings[14,22] obtained with the lanthanum fluoride electrode in the presence of citrate in dilute fluoride solutions.

Activity and ionic strength

The various equations for calculating selectivity coefficients depend upon a knowledge of activities and it follows that consistency and exact reporting of selectivity data ought also to include outline information on the calculation of the activity coefficient, f, which is used to calculate activity from concentration. Such information is especially desirable since the Debye-Hückel equation,

$$\log f = -Az^2\sqrt{\mu} \tag{7}$$

where A is a constant which for water is 0·511 at 25°, holds strictly only for zero ionic strength, μ, and its predictions differ from the behaviour of real electrolytes at ionic strengths greater than 10^{-3}–$10^{-2}M$. To meet this situation a variety of more or less empirical extensions to equation (7) have been proposed to fit the data (with varying success) at moderate values of ionic strength (Fig. 4).

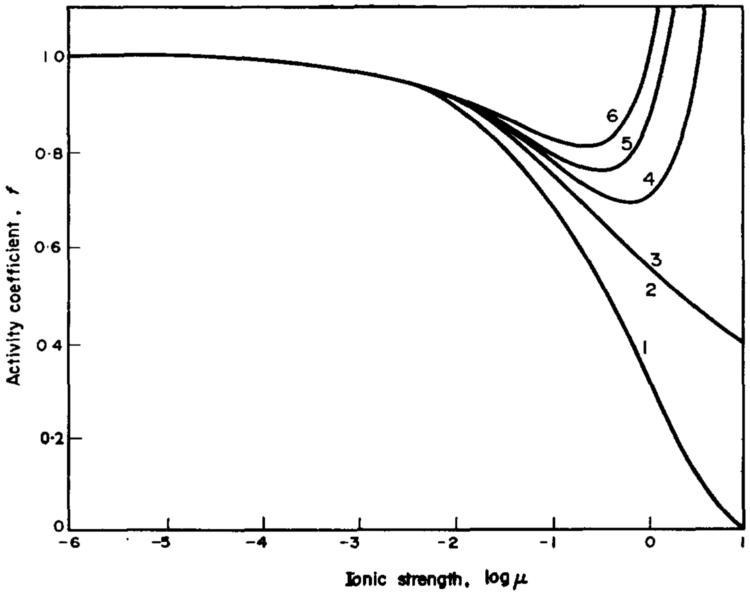

FIG. 4.—Computer simulations of various activity coefficient-ionic strength equations for univalent ions.

1. $\text{Log} f = -Az^2\sqrt{\mu}$

2. $\text{Log} f = \dfrac{-Az^2\sqrt{\mu}}{(1 + \sqrt{\mu})}$

3. $\text{Log} f = \dfrac{-Az^2\sqrt{\mu}}{(1 + 0{\cdot}329R\sqrt{\mu})}$ (*R* taken as 3 Å)

4. $\text{Log} f = -Az^2\left[\dfrac{\sqrt{\mu}}{1 + 1{\cdot}5\sqrt{\mu}} - 0{\cdot}2\,\mu\right]$

5. $\text{Log} f = -z^2\left[\dfrac{A\sqrt{\mu}}{1 + \sqrt{\mu}} - 0{\cdot}2\,\mu\right]$

6. $\text{Log} f = -z^2\left[\dfrac{A\sqrt{\mu}}{1 + 1{\cdot}5\sqrt{\mu}} - 0{\cdot}2\,\mu\right]$

The variation of the Debye-Hückel equation shown in equation (8) is extensively used in selective ion-sensitive electrode work for calculating the single ion activity:

$$\log f = -\frac{Az^2\sqrt{\mu}}{(1 + \sqrt{\mu})} \tag{8}$$

The ionic strength, μ, is given by

$$\mu = \tfrac{1}{2}\sum cz^2 \tag{9}$$

where c and z are the concentration and charge respectively of each ionic species present.

Stability of response

Closely related to selective response in the rating of ion-sensitive electrodes is drift and response time. Reports on steadiness and reproducibility of electrode response can provide useful guides to prospective users on frequency of recalibration and the suitability of the electrode for continuous process use.

Electrodes of different types are liable to different extents of drift, although wider drifts necessitating frequent recalibration can be tolerated when alternative methods of analysis are cumbersome or non-existent. Some electrodes have very low drift, *e.g.*, a potassium electrode with biological membrane (Beckman Catalogue No. 39622) for which daily checking during a continuous ten-day soaking period in $10^{-2}M$ potassium chloride "did not produce a noticeable drift."[16] However, an accompanying table does show differences in response of up to ± 2 mV after ten days, compared with the initial response.[16] No results are quoted for the intervening period, although the ten-day results cover the potassium concentration range 10^{-5}–$10^{-1}M$ ($9{\cdot}96 \times 10^{-6}$–$7{\cdot}7 \times 10^{-2}M$ activity).

Data[22–24] for the well-established and widely used lanthanum fluoride crystal membrane fluoride-responsive electrode indicate a similar ± 2 mV drift for the Orion 94-09 model, although Srinivasan and Rechnitz[25] report drifts of up to 7 mV depending on stirring and activity conditions, the response being steadier at high ionic strengths.

Miniaturization of electrodes is desirable for *in vivo* measurements or for *in situ* studies where solution volume is a limitation.[26] However, design demands can lead to specification change and for this reason reports should clearly specify electrode types used. Thus, for a fluoride microelectrode[26] the zero potential varied by about ± 20 mV from day to day but, on the other hand, depth of immersion had little effect on the potential, the e.m.f. shift being about -2 mV over the 1 mm length of the exposed lanthanum fluoride crystal.

While 2 mV drifts may seem insignificant, it must be emphasized that drifts of this magnitude can lead to errors of several per cent. Frequent recalibration of selective ion-sensitive membrane electrodes is therefore essential, especially for the liquid ion-exchanger membrane electrodes which are reported to have drifts of over 2 mV for a single day's use,[12,27,28] even extending to 70 mV for an Orion 92-07 nitrate electrode.[27] However, provided the calibration slope does not alter with time, recalibration is a simple matter and not a serious drawback, particularly when alternative analysis procedures are cumbersome or non-existent.

Calibration slopes

Equation (2) suggests that calibration slopes should be $59/z$ mV at 25°. For selective ion-sensitive electrodes this is far from universally true, although slopes are normally within 2–3 mV of the Nernstian value. This is no inconvenience so long as the particular calibration slope does not change with time, and unlike the overall drifts mentioned above, slopes have been found to be extremely steady during normal electrode life; if not, failure of the electrode is indicated.

A drastic change in slope can often be related to some malfunction of the reference electrode, whereas failure of a functional selective-ion sensitive electrode is more gradual, being manifested as a drop in calibration slope.

As with drifts, some very large deviations in calibration slope have been reported;

for example, slopes ranging from 64 to 50 mV per activity decade and attributed to defective assembly have been reported[27] for the liquid ion-exchanger Orion 92-07 nitrate electrode.

Deviations from Nernstian behaviour may be attributed to incomplete permselectivity of the membrane, a factor which Helfferich[29] covered by an integral term in the function for membrane potential to account for the co-ion flux. Such integrals may be evaluated graphically, but this is of no benefit in the present context and for general application here it is adequate to take a coefficient, S, instead of $2{\cdot}303RT/zF$ in equation (2), where S is the calibration slope.

Speed of response

Several studies have been made of the response times of selective ion-sensitive electrodes, principally by Rechnitz[30–34] and Pungor,[35] although descriptions of new electrodes frequently include details of response times.[12,16,28] In general, liquid exchanger ion-sensitive membrane electrodes respond less rapidly than the solid-state type.

It can be argued that rather too much emphasis has been placed on response times of electrodes; this is certainly the case for direct potentiometric determination of activity where response times of some minutes are quite tolerable. However, automatic analysers and continuous-measurement cells require sensors with more rapid response, and response times of minutes are too long for kinetic work and potentiometric titrations.

In attempts to determine very short response times, the relatively high time-constants of measuring instruments can be a limitation, but when electrodes with such ideal time responses have been achieved, there is no reason for obsession with this characteristic until the measuring instruments and the slow equilibration of junction potentials within the measuring-cell have been improved.

Response times are usually measured either by immersing the electrode in the solution and finding the time needed to reach equilibrium, or by injecting a solution of appropriate concentration into the system in which the electrode is already immersed. The equilibration can be monitored by chart-recorder, but Pungor[35] used an oscilloscope for times in the millisecond range. Response time data should be given for change from dilute to concentrated solution and for change in the opposite direction, and in addition, for reading within 1 mV of the equilibrium value. The latter times are usually a mere fraction of the full equilibration times and can provide guides for continuous monitoring and potentiometric applications. Indeed, where full equilibration times are long, the "1-mV times" can be short enough for rapid potentiometric titration rather than the intermittent start and stop of the burette system in automatic systems that is sometimes necessary[36] in order to allow equilibration near the equivalence point. However, there are few reports on response times in mixed solutions.

It is interesting that electrode response is very steady during stirring[12,16,25,33,34] and that base-line noise levels of recorders are only important at low activities.[16] However, there can be differences in potential response between stirred and unstirred solutions[25] and for different rates of stirring.[33,34] Differences of 0·4 and 6 mV have been observed[25] in the potential response of the Orion 94-09 fluoride electrode for

10^{-1} and $10^{-3}M$ fluoride solutions respectively, although at high ionic strengths, for example in $1M$ sodium nitrate, no such differences are evident.[25]

Conditioning and storage of electrodes

As with glass electrodes, the selective ion-sensitive electrodes often need conditioning before use. The description of any new electrode should specify any conditioning needed, particularly when there are unusual features such as the need to age the Corning Model No. 476132 potassium electrode in a solution having a composition simulating that of the test solution in order to avoid long response times and hysteresis effects.[37] Similarly, information should be given on the conditioning necessary to recover from detrimental circumstances; for example, liquid ion-exchanger calcium electrodes take an hour to regain proper response potentials to pure calcium chloride solutions after exposure to zinc chloride[12] and, after exposure to perchlorate, nitrate electrodes take almost as long to return to normal behaviour.[28] Silver thiocyanate should be removed from the membrane (by wiping or with a toothbrush and toothpaste) of silver bromide electrodes after exposure to interfering levels of thiocyanate.[38]

Storage conditions for electrodes when not in use should also be stated.

APPLICATION OF SELECTIVE ION-SENSITIVE ELECTRODES

The recent interest in selective ion-sensitive electrodes has resulted in about 400 papers devoted to development and uses. A large proportion concern the specification and appraisal of electrodes, but as the rate of appearance of new electrodes might be expected to diminish, it can be expected that an increasing proportion of future publications will be devoted to application and mechanism.

It is therefore necessary to specify which factors must be examined in development of an application, and what information must be given in any paper published on the work done.

The applications are generally to direct determination of activity (or concentration), or to titration procedures.

With adequate attention to calibration, particularly at low concentration levels and low ionic strength, selective ion-sensitive electrodes may be used for direct concentration measurements.

In using membrane electrodes, precautions must therefore be taken against complications at high concentrations and due to other ionic species with respect to variation of activity with ionic strength. Interference effects must also be tested at realistic levels. For example, bearing in mind equation (4), there is *no* point in attempting to use a nitrate electrode with selectivity coefficient $K_{\mathrm{NO_3Cl}} = 4 \times 10^{-3}$ determined for a chloride level of $0{\cdot}5M$, when assessing soil nitrate in concentrations of about $10^{-4}M$, when $2M$ potassium chloride is the extracting agent. This is evident from Fig. 3, which confirms that the response would be constant regardless of the nitrate activity. However, $0{\cdot}01M$ copper sulphate or water could be used as extractant,[40] although saline soils high in chloride might require supplementary treatment.

Both the Øien[40] and Milham[41] papers on soil nitrate determination are thorough in their enquiry and can serve as models for this kind of publication, although the former tends to include ambiguous statements. Both give due attention to comparisons with established methods, recovery, a wide variety of samples, and the limitations of published selectivity coefficients and of making corrections by equations, which for complicated systems of this kind would demand selectivity terms additional to the single one given in equation (2). Hence, Milham *et al.*[41] used rather an involved buffer system to cope with some interferents: a low pH kept the equilibrium bicarbonate low and the water-extractable organic acids undissociated; aluminium was added to complex anions of organic acids, and sulphamic acid was used to destroy nitrite quantitatively.

Both papers also pay attention to possible effects of ionic strength, and give information on electrode conditioning and mixing times before measurement. The inclusion of the correlation coefficient and regression equation is also valuable.

Concentration measurements of uncomplexed ions

Exhaustive examination of the effect of ionic strength is necessary for appraisal of the application of selective ion-sensitive electrodes. Conductance monitoring may not give satisfactory guidance—possibly because of the power term in z in equation (9). Though direct measurement on the sample can give acceptable results, it is only when a sample consists largely of one salt that an activity–e.m.f. calibration plot can be used accurately. However, such a plot may be acceptable for mixed solutions if the ratio of the primary ion to that of the other ions is constant. For example, to estimate potassium in sea-water, calibration standards are made by diluting synthetic potassium sea-water samples with demineralized water.[14]

The constant ionic-background method is frequently used when the analytical sample contains a high but essentially constant level of ions besides the one of interest. Calibration standards of similar composition are then employed, but ions at interfering levels must be absent, of course.

If samples exhibit considerable overall variation in composition, adding an "ionic strength adjuster" to the sample and calibration solutions tends to bring all the solutions to a common ionic strength. It is assumed that the ultimate ionic strength arises almost exclusively from the ionic strength adjuster and not the sample itself. This is the basis of the involved buffer system[41] described above for nitrate determination in various materials, although the buffer was also a judicious recipe to meet the selectivity parameters of the electrode. Though virtually any substance may serve as an ionic strength adjuster, it must not complex with the primary ion, and the selectivity coefficient, K_{ij}, where j is the ionic strength adjuster, must be negligible. Tetramethylammonium nitrate was chosen for this reason for an investigation[42] of calcium complexes with tri- and tetrametaphosphate, using a calcium-selective liquid ion-exchange membrane electrode. Certain variations may sometimes be necessary in addition to ionic strength adjustment, for example, pH adjustment will release anions of weak acids. Thus, at pH 10·5 the cyanide ion is present and not undissociated hydrocyanic acid.[35]

Measurements of total concentration

The methods just discussed give the concentrations (or activities) of free (that is, uncomplexed) ions. These may be quite different from the total concentrations (that is, free + complexed species). Two elegant methods are now available for total concentration measurements.[43,44,45] Electrode calibration is not usually necessary and only two potentials need be taken.

Both methods require a change in the concentration of the primary ion, *i*. For *known addition* (otherwise known as the *spiking* or *known-increment method*) more *i* is introduced, whereas in *known subtraction* the level of *i* is lowered by adding a complexing agent. There are no complications from ionic strengths as in the previous cases.

In the known-addition method, the potential, E_1, is measured for the sample solution of volume V_0 and total molar concentration C_0 of species sought,

$$E_1 = \text{constant} \pm S \log x_1 f_1 C_0 \tag{10}$$

where S is the electrode calibration slope, f_1 is the activity coefficient and x_1 the mole fraction of uncomplexed ions. A new potential, E_2, is then measured after addition of a small volume, V_A, of a standard solution (concentration C_s) of ions of the species sought where $C_s \sim 100C_0$:

$$E_2 = \text{constant} \pm S \log (x_2 f_2 C_0 + x_2 f_2 C_\Delta) \tag{11}$$

where f_2 and x_2 correspond to the new activity coefficient and mole fraction of free ions, respectively, and C_Δ is the change in concentration, given by $V_A C_s / V_0$. An essential assumption is that $x_1 \sim x_2$ and $f_1 \sim f_2$. Hence the difference between equations (10) and (11) simplifies to

$$E_2 - E_1 = \Delta E = \pm S \log \left(\frac{C_0 + C_\Delta}{C_0}\right) \tag{12}$$

and C_0 can be calculated.

A variation of the known addition method has recently been recommended[46,47] and is based on a modification of the method described by Gran[48] for presenting potentiometric titration data in linear form by using a semi-antilog plot. The method[47] involves plotting the appropriate potential response on the vertical antilog axis against volume (ml) of "known addition" with the intercept yielding the concentration of ion present. The Orion Gran's Plot Paper now available[47] is a semi-antilog paper corrected for limited volume changes. Further reports on total concentration measurement are expected, particularly since Gran plots facilitate measurement on samples in which the level of the ion being determined is close to the electrode's limit of detection.[47] For the known-addition Gran plots, the top of the vertical (antilog) axis is equated to the potential of the electrode immersed in a solution containing 10 ml of known-addition solution plus 100 ml of test solution.

An early suggestion[46] for the application of Gran's method to the known-addition procedure is rather more cumbersome, for it involves calculation of

$$(V_0 + V)10^{-EF/2\cdot 303RT}$$

where E is the electrode response and V_0 and V are the volumes of the sample and known-addition solutions respectively.

Orion Gran's Plot Paper can also be used for the known-subtraction methods,[46] when the approach corresponds to a titration procedure. The known-subtraction method depends on a lowering of the activity of the uncomplexed ions by addition of a complexing agent, and the additional assumption that the complexing (or precipitating) agent is much stronger in its effect than any other present in the original sample. Calculations along similar lines to the known-addition method give the expression

$$E_2 - E_1 = \Delta E = \pm S \log \left(\frac{C_0 - C_\Delta}{C_0}\right) \tag{13}$$

Extensive computer tables of appropriate C_Δ and ΔE values are available to overcome the tedious arithmetic of the known-addition and known-subtraction calculations.[44]

Methods of coping with problems of wide variation of ionic strengths, interferents and complexing agents are not restricted to those above; further developments for dealing with special situations have been suggested and more can be expected. The use of a 1:1 dilution of both samples and standards with Total Ionic Strength Adjuster Buffer (TISAB) is an elegant example of a rapid method in fluoride determination for overcoming variations in ionic strength and possible presence of complexing cations such as iron(III) and aluminium(III).[49] The essential point is that the methods proposed should be as simple as possible and there should be adequate testing of the precision, reproducibility and recoveries under optimum conditions, including calculation of standard deviations and confidence limits.

Of course, subsequent experimentation can lead to suspicions of defectiveness, as has happened with TISAB interference[50,51] in the potentiometric titration of fluoride with lanthanum nitrate. Such interference has been attributed[50] to the carboxylate ion content of TISAB, and although the acetate is retained, citrate has now been replaced by DCTA (1,2-diaminocyclohexane,*N*,*N*,*N*′,*N*′-tetra-acetic acid) when analytical samples contain aluminium or iron.[52] However, for the direct determination of fluoride, the lanthanum fluoride electrode is only minimally affected by these carboxylate ions.[22]

Selective ion-sensitive electrodes in process control

Process control imposes additional demands and restrictions on the application of selective ion-sensitive electrodes. Direct monitoring of the process stream without supplementary chemistry is the simplest, but even here there must be adequate assessment of recalibration demands and of the severe limitations often imposed by leaching effects on the membrane. The latter is particularly marked for liquid ion-exchanger electrodes, where owing to leaching of the solvent, the solute becomes concentrated on the surface of the membrane with resultant sharp increase in potential.[53]

A watch must be kept for the creation of open circuits by the trapping of air bubbles at electrode tips and for static charges resulting from fast-moving process streams rubbing against the plastic walling of electrodes. Since the electrode will probably have been assessed for its suitability for analysis of the process solution under static conditions, publications on continuous monitoring applications must pay attention to these matters as well as to constancy of flow-rate of the process sample stream and the reagent streams. The results ought to be confirmed by information derived from intermittent sampling.

Compensation can be made for temperature fluctuation, but where the process sample stream contains a steady level of primary ion the need for compensation can be avoided by filling the electrode with a solution of the same concentration of primary ion as in the sample stream.

Titration procedures with selective ion-sensitive electrodes

Potentiometric procedures are of limited accuracy for direct concentration determination. However, for sufficiently high concentrations potentiometric titration gives good accuracy, for the potentiometry no longer depends on the exact interpretation of small changes in voltage and is not restricted by the accuracy of the electrode response to changes in solution concentration. However, development of suitable potentiometric titration procedures has a whole variety of possible pitfalls. Thus, in addition to the often severe limitations imposed by interferences, restricted concentration/activity range and response times of the electrodes, there are also the chemical factors of suitability of reagents, relative rates of reactions and the effects of pH and various side-reactions.

The variety of titration procedures with selective ion-sensitive electrodes indicates that problems associated with response times are surmountable, for example, Hadjiioannou and Papastathopoulos[54] claim that the time needed for the EDTA titration of calcium and magnesium with a calcium electrode varies from a few seconds to a few minutes. Even so, the point of maximum rate of potential change does not coincide with the equivalence point, and the over-titration must be at least partly due to sluggish response. Clearly a detailed investigation is necessary for the successful application of selective ion-sensitive electrodes for potentiometric titration. Thus, the slope of the titration curve, the overall voltage change, the blank, all depend on sample composition, buffer used and such experimental conditions as titrant delivery rate and concentration, stirring rate, size of beaker, position of delivery tip and depth of electrode immersion.[54]

There is much to commend the approach of Whitfield and Leyendekkers[55] which makes an initial theoretical assessment and examines possible problems of locating the equivalence point on practical titration curves from the standpoint of both chemical and potentiometric considerations. In this way possible effects of factors such as interferences, ionic strength and limitations imposed by restrictions in electrode response after the end-point can be anticipated. The electrode response can restrict[56] the simple application of $\Delta E/\Delta V$ *vs.* V relationships for end-point location.

There are other ways besides derivative methods for selecting the end-point.[56,57,58] The obvious one is to take the mid-point of the "potential jump" section of the normal E vs. V titration curve. Independent estimates by several observers help to avoid bias in the location of this point, or a computer programme based on least squares may be used. Alternatively, especially for unsymmetrical titration curves, a Gran plot[48] can be used, *e.g.*, on Orion Gran's Plot Paper.[47]

The final procedure should be tested on a wide range of solution compositions and rigorously tested statistically. In general it is fundamental that the end-point and equivalence point be as close as possible. Ambiguities in locating the end-point are intolerable and corrections through blanks, particularly if these are variable, are also not recommended.

Many useful hints on theoretical and practical aspects of titration procedures, including precision and accuracy of potentiometric end-point determination, are contained in two recent publications.[58,59]

Differential potentiometry

Membrane electrode potentials are normally measured with respect to a reversible reference electrode, *e.g.*, a calomel or silver–silver chloride electrode. Measurements may equally well be made with reference to another membrane electrode and in order to overcome the limitations imposed by the excessively high impedance of two membrane electrodes, Brand and Rechnitz[60] have described a new instrument. This can be used with, say, two glass electrodes making up the electrochemical cell and it has been assessed for sodium ion determinations, using a cell composed of a pH (reference) electrode and a sodium glass (indicator) electrode. Differential potentiometric titrations using glass reference and appropriate indicator electrodes are also discussed for calcium and copper determination by EDTA titration, but the assessment can only be described as incomplete because in view of the comments above on the coincidence of end-points with equivalence points of titration curves, the conclusion that the "shape of the titration curve was entirely adequate for analytical purposes" is insufficient. However, the paper[60] does show the prospective scope for widescale use of membrane electrodes as references for both direct potentiometry and potentiometric titration. Certain of the low impedance membrane electrodes, such as the fluoride electrodes have already been used[61,62] for these purposes.

CONCLUSIONS

The possible number of combinations of available selective ion-sensitive membrane electrodes and solution systems is already large and likely to increase considerably. Hence, because of the limitations due to interferences, complex formation and a whole variety of operating conditions, it is imperative that prospective users should be well-guided to make intelligent decisions regarding the advantages and limitations of a new electrode or application in the context of their own particular problem.

The following summary specifies a number of vital points to be included in reports on new electrodes and their applications. Emphasis is placed on realistic assessment in terms of speed, accuracy, cost, selectivity, simplicity, and comparison with other methods.

1. *A new or modified electrode.* In addition to constructional details and cell assembly, the report on the electrode must show assessments of useful activity/concentration range, response times and selectivity for the primary ion over other ions likely to be present in possible applications. Information on operational lifetime, freedom from drift and effective pH range at various activity levels should also be given.

2. *Applications for direct concentration/activity measurement.* Details must be given of the cell assembly, particularly of the reference electrode used with the selective ion-sensitive electrode. After information has been given on selectivity factors and means of overcoming interferences, the experimental procedure should be detailed, and this must avoid the addition of interferents. The activity/concentration values obtained must, whenever possible, be carefully compared with those given by traditional and established methods (if they exist). It is desirable that statistical tests of comparison be made and attention given to recoveries.

3. *On-line process applications.* The utility of any analytical system depends on accuracy and an on-line continuous pH monitoring system is considered good if it measures to ±0·02 pH unit representing a deviation of about ±1·2 mV at 25° or an error of about ±5% in the hydrogen activity measurement. Selective ion-sensitive electrodes have similar capabilities, but reports of applications to on-line continuous monitoring systems should clearly define the electrode behaviour as in 2 above and ought to include an assessment for intermittent samples as well as for continuous monitoring. This will help to characterize possible errors due to the additional parameters imposed by the flowing system.

4. *Titration applications.* Reports must attend to points concerning electrode behaviour and comparisons with established procedures as in 2. Special attention must be given to correct end-point location, to possible interferences, and to damage to electrodes by titration solutions.

Zusammenfassung—Es wird eine Übersicht über Entwicklung, Ansprechverhalten, Selektivität und Anwendungen selektiv ionenfindlicher Elektroden gegeben. Bezüglich der Entwicklung und Anwendung von Elektroden werden Empfehlungen ausgesprochen; auch die Art und Weise, wie Ergebnisse publiziert werden sollten, wird angesprochen.

Résumé—On passe en revue les caractères concernant le développement, la réponse, la sélectivité et les applications des électrodes sélectives sensibles aux ions. On fait des recommandations concernant les recherches impliquant le développement et les applications d'électrodes et l'on porte attention sur la manière de présenter les données pour publication.

DEVELOPMENT AND PUBLICATION OF WORK WITH SELECTIVE ION-SENSITIVE ELECTRODES

G. J. MOODY and J. D. R. THOMAS
University of Wales Institute of Science and Technology, Cardiff, Wales

(*Received* 7 *July* 1971)

Summary—Features concerning development, response, selectivity and applications of selective ion-sensitive electrodes are reviewed. Recommendations are made concerning investigations involving the development and applications of electrodes and attention given to the manner of presenting data for publication.

OVER SIXTY YEARS have elapsed since the initial discovery[1] and characterization[2] of the electrical potential arising at a thin glass membrane interposed between aqueous solutions of different acidity, but it is only within the last five or six years that there has been widespread development and interest in sensor membrane electrodes based upon a more general application of ion-exchanging materials. This might seem surprising when viewed against the prediction by Lengyel and Blum[3] in 1934 of a cation-sensitive glass electrode and of reports by Tendeloo[4] in 1935 and Kolthoff and Sanders[5] in 1937 detailing potentiometric response to certain ions by electrodes composed of solid-state membranes of barium sulphate and calcium fluoride slices[4] or discs of silver halides.[5]

Glass electrodes selective to hydrogen ions have been standard items of laboratory equipment for over thirty years, but it was just over ten years ago that glasses of modified composition were adapted for selective response to cations other than hydrogen ions. As the advantages of a wider range of selectively sensitive electrodes were materializing, Pungor and Holós-Rokosinyi[6] described in 1961 the selective working of precipitate-based ion-sensitive electrodes. However, it was the commercial availability of the fluoride solid-state electrode[7] in 1966, which coincided with the tremendous interest in the determination of trace fluoride following water fluoridation and dental health programmes, that initiated the recent vast interest in selective ion-sensitive electrodes. Symposia such as those held in January 1969 at the National Bureau of Standards, Gaithersburg, Maryland, U.S.A., and in February 1969 at the University of Wales Institute of Science and Technology, Cardiff, U.K., have boosted their general acceptance. The subsequent publication of the N.B.S. Symposium proceedings has provided a very useful source book[8] which has been well-supplemented by the Orion Research Incorporated Data Sheets and *Newsletter*.

The full benefit of selective ion-sensitive electrodes can only be realized by thorough familiarity with their properties and mode of operation. With this in view, this paper is intended to suggest a set of requirements in outlining the development, assessment and application of these electrodes. This is felt to be necessary in view of the existing ambiguities concerning the relation of potential to the logarithm of the activity of active ion and presentation of selectivity ratios or coefficients. Further reasons involve lifetimes and response time under various operating conditions. While it is recognized that different opinions and individual preferences will still flourish, it is nevertheless hoped that a format can be developed for the convenient presentation of results that will permit ease of assimilation and realistic appraisal by other workers.

DEVELOPMENT OF NEW ELECTRODES

Potential response

In general, the potentiometric cell assembly incorporating a selective ion-sensitive electrode takes the form shown in Fig. 1 where the e.m.f., E, of the cell is the sum of various junction potentials:

$$E = E_M + E_{M'} + E_R + E_{R'} + E_j \tag{1}$$

Except for E_M, which depends on the nature of the test or standardizing solution, the remaining contributory potentials may be taken as constant, although some of the junction potentials, particularly those of the reference electrode, can be troublesome. The reference electrode used in any investigation should be specified in published reports, along with the model and impedance of the e.m.f.-measuring instrument.

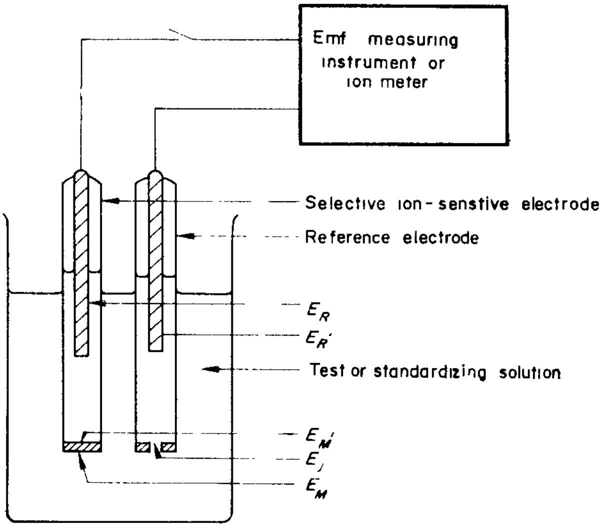

FIG. 1.—Experimental circuit for using selective ion-sensitive electrodes.

For an electrode responding selectively to an ion, i, of activity a_i and charge z, in the presence of an interfering ion, j, of activity a_j and charge y, E, for Nernstian response, is given by

$$E = \text{constant} \pm \frac{2{\cdot}303RT}{zF} \log [a_i + K_{ij}(a_j)^{z/y}] \tag{2}$$

where K_{ij} is the selectivity coefficient. The constant term incorporates the various junction potentials and the standard potential characteristic of E_M. The second term on the right-hand side of equation (2) takes the positive sign for cations and the negative for anions.

On the basis of the response characteristics above, selective ion-sensitive membrane electrodes have been described for about twenty ions which are fairly evenly divided between cations and anions. There is, therefore, plenty of scope for fresh developments, both for electrodes selectively sensitive to an extended range of ions and for improvements and refinements to existing electrodes.

Unless the electrode is going to be available commercially, its description should carry exact details for its construction, and the design need not be any more intricate than the minimum necessary for the performance claimed.

The dependence of the e.m.f. response on the logarithm of the activity indicates [equation (2) in the absence of interferent] that E will alter by only 2·72 mV for a univalent ion and by 1·36 mV for a bivalent ion for a 10% decrease in the activity of the active species and by only 2·45 mV for a univalent ion and by 1·23 mV for a bivalent ion for a 10% increase in the activity of the active species. These figures mean that a sensitive voltmeter (with high impedance to cope with the high resistances involved) responding to 0·1 mV, or better, is recommended[9] for work of acceptable precision. Expanded scale facilities on commercial pH-meters do not normally meet this requirement.

Selectivity

Membrane electrodes have the advantage that they can be tailor-made for almost any ion, but the difficulty of distinguishing adequately between different ions, particularly of the same sign, is a serious limitation. Hence, considerable effort has been devoted to assessing the performance of the new range of electrodes in the presence of possibly interfering ions. This has been done in terms of the selectivity coefficients, K_{ij}, defined by equation (2), the methods employed[9,10] for evaluating K_{ij} being based on e.m.f. measurements either in separate, or more realistically in mixed, solutions of the primary ion, i, and interfering ion, j.

The two separate-solution methods with the solutions producing e.m.f.s E_1 and E_2, involve either equation (3) or (4) depending, respectively, on equality of the primary and interferent ion activities and of the e.m.f.s:

$$\pm\left(\frac{E_2 - E_1}{2{\cdot}303RT/zF}\right) = \log K_{ij} + \left(\frac{z}{y} - 1\right)\log a_i \tag{3}$$

$$a_i = K_{ij}(a_j)^{z/y} \tag{4}$$

For cations, the left-hand side of equation (3) takes the positive sign, and the negative sign for anions. The second term of the right-hand side disappears when the charges of the primary and interfering ions are equal.

Separate solutions are not typical of operating systems so a more common procedure for assessing selectivity ratings is measurement of the e.m.f. in solutions containing a fixed amount of interferent with varying activities of the primary ion for which the electrode is designed. Figure 2 illustrates the general idealized pattern and the calculation of K_{ij} from equation (4).

It is pertinent at this point to stress the benefits[11] of the universal and consistent adoption of K_{ij} as described above for listing selectivity data. The inconsistencies to date, particularly in some manufacturers' literature, can only cause bewilderment to readers and users alike. Such a system of presenting selectivity data consistently indicates that when $K_{ij} < 1$ the electrode preferentially responds to the primary ion, i. However, Fig. 3 stresses the care needed in any interpretation of any single published item of selectivity information, for selectivity varies with the relative primary ion/interferent activities. Thus, for the poly(vinylchloride) calcium-sensitive electrode[12] the value $K_{\mathrm{CaMg}} = 0{\cdot}024$ obtained at a high magnesium content ($a_{\mathrm{Mg}} = 5 \times 10^{-3}M$)

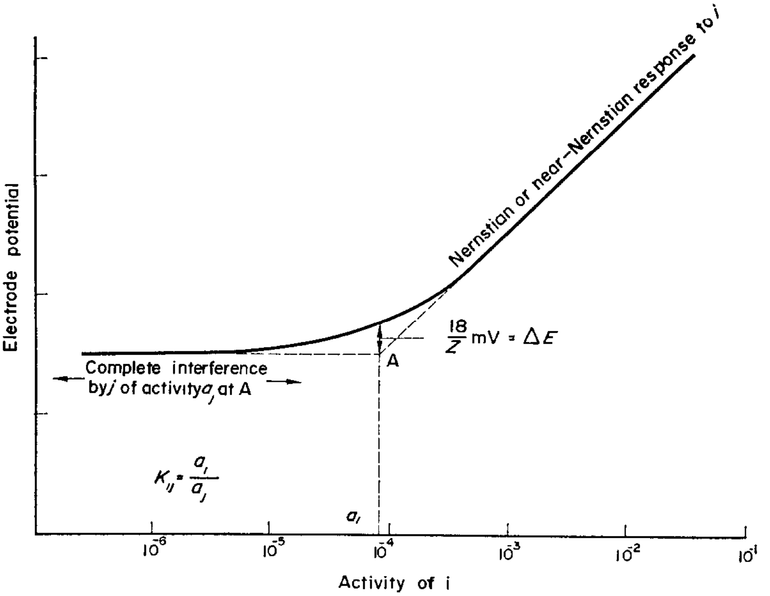

FIG. 2.—Illustration of selectivity coefficient evaluation, using fixed initial amount of interferent of same valence as *i*.

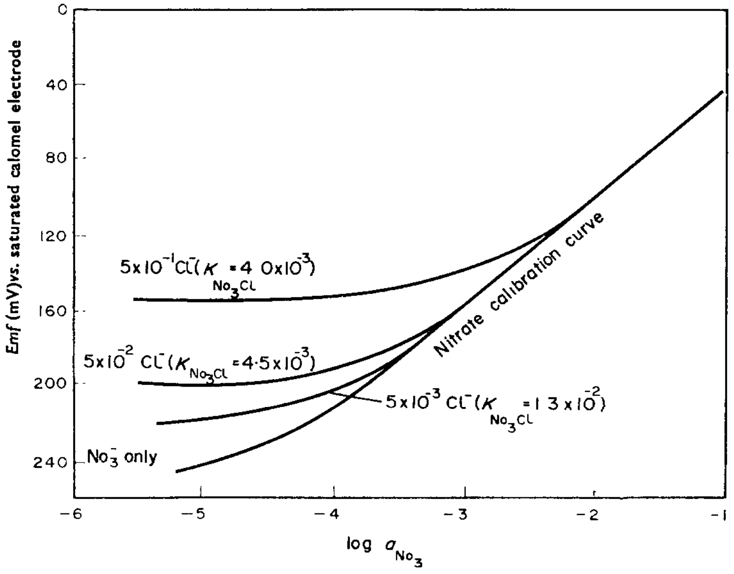

FIG. 3.—Influence of chloride on the response characteristics of a nitrate-sensitive (Orion 92-07-02 nitrate liquid ion exchanger) poly(vinylchloride) electrode.

suggests a better selectivity than $K_{CaMg} = 0{\cdot}222$ at a lower magnesium level ($a_{Mg} = 4{\cdot}3 \times 10^{-5}M$), while in fact the electrode gives the most extensively useful response at lower magnesium levels (*cf.* Fig. 3 for a nitrate-sensitive electrode affected by chloride interference).

The considerable variation of selectivity with interferent concentration is further illustrated by the work of Lal and Christian[13] on fifteen foreign cations, using the Orion 92–82 lead electrode. However, the apparent lack of critical assessment in this paper[13] emphasises the attention to detail essential for studies on electrode assessment. Thus, in commenting that the Orion lead electrode is much more responsive to univalent cations than is reported by the manufacturers, Lal and Christian[13] have not considered the modifying influence of the power term of equation (4). Yet this equation shows that the lead electrode has nearly the same useful range in the presence of $10^{-5}M$ sodium (down to $8{\cdot}9 \times 10^{-4}M$ lead) as it has in the presence of $10^{-5}M$ calcium (down to $2{\cdot}5 \times 10^{-4}M$ lead) even though the respective K_{ij} values differ by several orders of magnitude ($K_{\text{PbNa}} = 8{\cdot}9 \times 10^6$ and $K_{\text{PbCa}} = 25$). The extensive useful range permits the lead potentiometric titrations mentioned by these workers[13] but a high response to the sodium and potassium salt titrants used would hardly permit such an application. Moreover, potentiometric titrations of various univalent cations with sodium tetraphenylborate, with the lead electrode as sensor, warrant further investigation to determine the true mechanism.

The importance of the useful role of plots such as Fig. 3 for investigations involving interference parameters cannot be over-emphasized. Unfortunately, however, such plots take up journal space and where the mixed-solution method[9,10,13] has been employed, an alternative procedure[11] is to quote the activity, a_j, of the interfering ion corresponding to each K_{ij} value. Readers will then be realistically informed that should the level of j in the test situation exceed this value and the expected activity level of i be less than $K_{ij}(a_j)^{z/v}$, then the electrode will very likely be useless in such a test situation.

An alternative mixed-solution method of expressing selectivity involves variation of interferent activity at constant primary ion activity[9,10,14] and is generally used for assessing hydrogen ion and hydroxide ion interference. Several diagrams expressing constancy of e.m.f. response over a pH range have been published[12,15,16] and these confirm that unless there are unusual features it is adequate to quote a pH range for which there is unlikely to be interference with electrode behaviour, but again it is essential to quote the level of primary ion for that pH range.

Srinivasan and Rechnitz[10] considered neither of the foregoing mixed-solution methods in their treatment of potential data obtained for several different Orion liquid membrane ion-sensitive electrodes. Instead, two rather complicated equations were proposed, the general form of the one for high values of K_{ij} being

$$\left[\exp \pm \left(\frac{E_2 - E_1}{RT/zF}\right)\right] a_i - a_i' = K_{ij}(a_j')^{z/v} \tag{5}$$

and that for low values of K_{ij} being

$$a_i' - \left[\exp \pm \left(\frac{E_2 - E_1}{RT/zF}\right)\right] a_i = K_{ij}\left[\exp \pm \left(\frac{E_2 - E_1}{RT/zF}\right)(a_j)^{z/v} - (a_j')^{z/v}\right] \tag{6}$$

As before, the positive sign alternative is used for cation-sensitive electrodes and the negative for anion-sensitive electrodes. The a values refer to E_1, the a' values to E_2.

Equation (5) is used by plotting the left-hand side against interferent activities, a_j', and equation (6) is used by plotting the left-hand side against the square-bracketed function of the right-hand side. In each case, linear plots are obtained, of slope K_{ij}.

However, there is little to commend such complicated functions when the desired information concerning the potential applicability of electrodes can so conveniently be obtained from plots of the kind shown in Fig. 3.

Selectivities of solid-state electrodes have been variously expressed and emphasize the present chaos regarding selectivity quotations.[11,14] Except for the method involving equations (5) and (6), the practical methods employed for evaluating the selectivities are those already described above, although Light and Swartz[17] used equation (5) in a non-graphical procedure for determining anion interferences for the Orion 94-16 sulphide electrode.

The interference mechanism of solid-state electrodes differs from that of liquid ion-exchange and glass electrodes in the manner in which the primary ion and interfering ion(s) gain access to the all-important membrane.[14] This has led to criticism by Pungor and Tóth[18] concerning the application of the methods above for determining the selectivities of precipitate-based selective ion-sensitive electrodes. Even so, these workers used equation (4) in its appropriate form for obtaining "measured" selectivities of halide electrodes for comparison with those calculated from solubility product ratios.[18] This, of course, highlights a common form of interference of crystal membrane and precipitate-impregnated membrane electrodes, arising from the interfering ion actually reacting at the membrane surface to form a new insoluble compound.[19] For this kind of interference, a knowledge of solubility products of the membrane salt and of the insoluble compound formed is helpful in predicting the usefulness of an electrode. For example, for thiocyanate interference with the silver bromide electrode, the selectivity ratio, K_{BrSCN}, is given by the ratio of the solubility product of silver bromide to the solubility product of silver thiocyanate. This implies that for the electrode to be functional to bromide in the presence of thiocyanate, the ratio of the interfering thiocyanate to the primary bromide activity must not exceed the ratio (solubility product of AgSCN)/(solubility product of AgBr). Of course, the inverse relationship holds when the electrode is to be used for thiocyanate, with bromide interference, the form[11] of the selectivity ratio then being K_{SCNBr}.

Interference with solid-state electrodes also occurs when the membrane material reacts with interferent to give a soluble complex, a feature that has been exploited in adapting silver halide membranes for use as cyanide electrodes.[18,20,21] Dissolution of the membrane is also regarded as the basis of the "high" fluoride readings[14,22] obtained with the lanthanum fluoride electrode in the presence of citrate in dilute fluoride solutions.

Activity and ionic strength

The various equations for calculating selectivity coefficients depend upon a knowledge of activities and it follows that consistency and exact reporting of selectivity data ought also to include outline information on the calculation of the activity coefficient, f, which is used to calculate activity from concentration. Such information is especially desirable since the Debye-Hückel equation,

$$\log f = -Az^2\sqrt{\mu} \tag{7}$$

where A is a constant which for water is 0·511 at 25°, holds strictly only for zero ionic strength, μ, and its predictions differ from the behaviour of real electrolytes at ionic strengths greater than 10^{-3}–$10^{-2}M$. To meet this situation a variety of more or less empirical extensions to equation (7) have been proposed to fit the data (with varying success) at moderate values of ionic strength (Fig. 4).

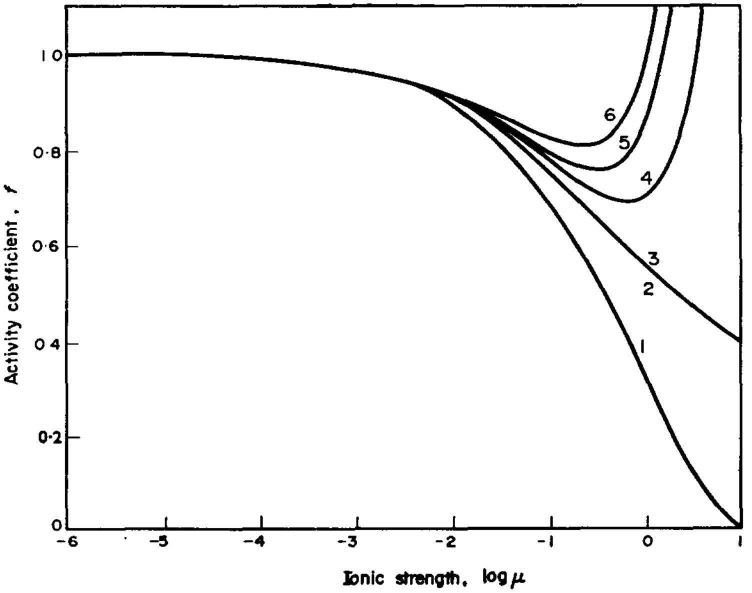

FIG. 4.—Computer simulations of various activity coefficient-ionic strength equations for univalent ions.

1. $\text{Log} f = -Az^2\sqrt{\mu}$
2. $\text{Log} f = \dfrac{-Az^2\sqrt{\mu}}{(1 + \sqrt{\mu})}$
3. $\text{Log} f = \dfrac{-Az^2\sqrt{\mu}}{(1 + 0{\cdot}329R\sqrt{\mu})}$ (R taken as 3 Å)
4. $\text{Log} f = -Az^2\left[\dfrac{\sqrt{\mu}}{1 + 1{\cdot}5\sqrt{\mu}} - 0{\cdot}2\,\mu\right]$
5. $\text{Log} f = -z^2\left[\dfrac{A\sqrt{\mu}}{1 + \sqrt{\mu}} - 0{\cdot}2\,\mu\right]$
6. $\text{Log} f = -z^2\left[\dfrac{A\sqrt{\mu}}{1 + 1{\cdot}5\sqrt{\mu}} - 0{\cdot}2\,\mu\right]$

The variation of the Debye-Hückel equation shown in equation (8) is extensively used in selective ion-sensitive electrode work for calculating the single ion activity:

$$\log f = -\frac{Az^2\sqrt{\mu}}{(1 + \sqrt{\mu})} \tag{8}$$

The ionic strength, μ, is given by

$$\mu = \tfrac{1}{2}\sum cz^2 \tag{9}$$

where c and z are the concentration and charge respectively of each ionic species present.

Stability of response

Closely related to selective response in the rating of ion-sensitive electrodes is drift and response time. Reports on steadiness and reproducibility of electrode response can provide useful guides to prospective users on frequency of recalibration and the suitability of the electrode for continuous process use.

Electrodes of different types are liable to different extents of drift, although wider drifts necessitating frequent recalibration can be tolerated when alternative methods of analysis are cumbersome or non-existent. Some electrodes have very low drift, *e.g.*, a potassium electrode with biological membrane (Beckman Catalogue No. 39622) for which daily checking during a continuous ten-day soaking period in $10^{-2}M$ potassium chloride "did not produce a noticeable drift."[16] However, an accompanying table does show differences in response of up to ±2 mV after ten days, compared with the initial response.[16] No results are quoted for the intervening period, although the ten-day results cover the potassium concentration range 10^{-5}–$10^{-1}M$ ($9{\cdot}96 \times 10^{-6}$–$7{\cdot}7 \times 10^{-2}M$ activity).

Data[22–24] for the well-established and widely used lanthanum fluoride crystal membrane fluoride-responsive electrode indicate a similar ±2 mV drift for the Orion 94-09 model, although Srinivasan and Rechnitz[25] report drifts of up to 7 mV depending on stirring and activity conditions, the response being steadier at high ionic strengths.

Miniaturization of electrodes is desirable for *in vivo* measurements or for *in situ* studies where solution volume is a limitation.[26] However, design demands can lead to specification change and for this reason reports should clearly specify electrode types used. Thus, for a fluoride microelectrode[26] the zero potential varied by about ±20 mV from day to day but, on the other hand, depth of immersion had little effect on the potential, the e.m.f. shift being about −2 mV over the 1 mm length of the exposed lanthanum fluoride crystal.

While 2 mV drifts may seem insignificant, it must be emphasized that drifts of this magnitude can lead to errors of several per cent. Frequent recalibration of selective ion-sensitive membrane electrodes is therefore essential, especially for the liquid ion-exchanger membrane electrodes which are reported to have drifts of over 2 mV for a single day's use,[12,27,28] even extending to 70 mV for an Orion 92-07 nitrate electrode.[27] However, provided the calibration slope does not alter with time, recalibration is a simple matter and not a serious drawback, particularly when alternative analysis procedures are cumbersome or non-existent.

Calibration slopes

Equation (2) suggests that calibration slopes should be $59/z$ mV at 25°. For selective ion-sensitive electrodes this is far from universally true, although slopes are normally within 2–3 mV of the Nernstian value. This is no inconvenience so long as the particular calibration slope does not change with time, and unlike the overall drifts mentioned above, slopes have been found to be extremely steady during normal electrode life; if not, failure of the electrode is indicated.

A drastic change in slope can often be related to some malfunction of the reference electrode, whereas failure of a functional selective-ion sensitive electrode is more gradual, being manifested as a drop in calibration slope.

As with drifts, some very large deviations in calibration slope have been reported;

for example, slopes ranging from 64 to 50 mV per activity decade and attributed to defective assembly have been reported[27] for the liquid ion-exchanger Orion 92-07 nitrate electrode.

Deviations from Nernstian behaviour may be attributed to incomplete permselectivity of the membrane, a factor which Helfferich[29] covered by an integral term in the function for membrane potential to account for the co-ion flux. Such integrals may be evaluated graphically, but this is of no benefit in the present context and for general application here it is adequate to take a coefficient, S, instead of $2{\cdot}303RT/zF$ in equation (2), where S is the calibration slope.

Speed of response

Several studies have been made of the response times of selective ion-sensitive electrodes, principally by Rechnitz[30–34] and Pungor,[35] although descriptions of new electrodes frequently include details of response times.[12,16,28] In general, liquid exchanger ion-sensitive membrane electrodes respond less rapidly than the solid-state type.

It can be argued that rather too much emphasis has been placed on response times of electrodes; this is certainly the case for direct potentiometric determination of activity where response times of some minutes are quite tolerable. However, automatic analysers and continuous-measurement cells require sensors with more rapid response, and response times of minutes are too long for kinetic work and potentiometric titrations.

In attempts to determine very short response times, the relatively high time-constants of measuring instruments can be a limitation, but when electrodes with such ideal time responses have been achieved, there is no reason for obsession with this characteristic until the measuring instruments and the slow equilibration of junction potentials within the measuring-cell have been improved.

Response times are usually measured either by immersing the electrode in the solution and finding the time needed to reach equilibrium, or by injecting a solution of appropriate concentration into the system in which the electrode is already immersed. The equilibration can be monitored by chart-recorder, but Pungor[35] used an oscilloscope for times in the millisecond range. Response time data should be given for change from dilute to concentrated solution and for change in the opposite direction, and in addition, for reading within 1 mV of the equilibrium value. The latter times are usually a mere fraction of the full equilibration times and can provide guides for continuous monitoring and potentiometric applications. Indeed, where full equilibration times are long, the "1-mV times" can be short enough for rapid potentiometric titration rather than the intermittent start and stop of the burette system in automatic systems that is sometimes necessary[36] in order to allow equilibration near the equivalence point. However, there are few reports on response times in mixed solutions.

It is interesting that electrode response is very steady during stirring[12,16,25,33,34] and that base-line noise levels of recorders are only important at low activities.[16] However, there can be differences in potential response between stirred and unstirred solutions[25] and for different rates of stirring.[33,34] Differences of 0·4 and 6 mV have been observed[25] in the potential response of the Orion 94-09 fluoride electrode for

10^{-1} and $10^{-3}M$ fluoride solutions respectively, although at high ionic strengths, for example in $1M$ sodium nitrate, no such differences are evident.[25]

Conditioning and storage of electrodes

As with glass electrodes, the selective ion-sensitive electrodes often need conditioning before use. The description of any new electrode should specify any conditioning needed, particularly when there are unusual features such as the need to age the Corning Model No. 476132 potassium electrode in a solution having a composition simulating that of the test solution in order to avoid long response times and hysteresis effects.[37] Similarly, information should be given on the conditioning necessary to recover from detrimental circumstances; for example, liquid ion-exchanger calcium electrodes take an hour to regain proper response potentials to pure calcium chloride solutions after exposure to zinc chloride[12] and, after exposure to perchlorate, nitrate electrodes take almost as long to return to normal behaviour.[28] Silver thiocyanate should be removed from the membrane (by wiping or with a toothbrush and toothpaste) of silver bromide electrodes after exposure to interfering levels of thiocyanate.[38]

Storage conditions for electrodes when not in use should also be stated.

APPLICATION OF SELECTIVE ION-SENSITIVE ELECTRODES

The recent interest in selective ion-sensitive electrodes has resulted in about 400 papers devoted to development and uses. A large proportion concern the specification and appraisal of electrodes, but as the rate of appearance of new electrodes might be expected to diminish, it can be expected that an increasing proportion of future publications will be devoted to application and mechanism.

It is therefore necessary to specify which factors must be examined in development of an application, and what information must be given in any paper published on the work done.

The applications are generally to direct determination of activity (or concentration), or to titration procedures.

With adequate attention to calibration, particularly at low concentration levels and low ionic strength, selective ion-sensitive electrodes may be used for direct concentration measurements.

In using membrane electrodes, precautions must therefore be taken against complications at high concentrations and due to other ionic species with respect to variation of activity with ionic strength. Interference effects must also be tested at realistic levels. For example, bearing in mind equation (4), there is *no* point in attempting to use a nitrate electrode with selectivity coefficient $K_{NO_3Cl} = 4 \times 10^{-3}$ determined for a chloride level of $0{\cdot}5M$, when assessing soil nitrate in concentrations of about $10^{-4}M$, when $2M$ potassium chloride is the extracting agent. This is evident from Fig. 3, which confirms that the response would be constant regardless of the nitrate activity. However, $0{\cdot}01M$ copper sulphate or water could be used as extractant,[40] although saline soils high in chloride might require supplementary treatment.

Both the Øien[40] and Milham[41] papers on soil nitrate determination are thorough in their enquiry and can serve as models for this kind of publication, although the former tends to include ambiguous statements. Both give due attention to comparisons with established methods, recovery, a wide variety of samples, and the limitations of published selectivity coefficients and of making corrections by equations, which for complicated systems of this kind would demand selectivity terms additional to the single one given in equation (2). Hence, Milham *et al.*[41] used rather an involved buffer system to cope with some interferents: a low pH kept the equilibrium bicarbonate low and the water-extractable organic acids undissociated; aluminium was added to complex anions of organic acids, and sulphamic acid was used to destroy nitrite quantitatively.

Both papers also pay attention to possible effects of ionic strength, and give information on electrode conditioning and mixing times before measurement. The inclusion of the correlation coefficient and regression equation is also valuable.

Concentration measurements of uncomplexed ions

Exhaustive examination of the effect of ionic strength is necessary for appraisal of the application of selective ion-sensitive electrodes. Conductance monitoring may not give satisfactory guidance—possibly because of the power term in z in equation (9). Though direct measurement on the sample can give acceptable results, it is only when a sample consists largely of one salt that an activity–e.m.f. calibration plot can be used accurately. However, such a plot may be acceptable for mixed solutions if the ratio of the primary ion to that of the other ions is constant. For example, to estimate potassium in sea-water, calibration standards are made by diluting synthetic potassium sea-water samples with demineralized water.[14]

The constant ionic-background method is frequently used when the analytical sample contains a high but essentially constant level of ions besides the one of interest. Calibration standards of similar composition are then employed, but ions at interfering levels must be absent, of course.

If samples exhibit considerable overall variation in composition, adding an "ionic strength adjuster" to the sample and calibration solutions tends to bring all the solutions to a common ionic strength. It is assumed that the ultimate ionic strength arises almost exclusively from the ionic strength adjuster and not the sample itself. This is the basis of the involved buffer system[41] described above for nitrate determination in various materials, although the buffer was also a judicious recipe to meet the selectivity parameters of the electrode. Though virtually any substance may serve as an ionic strength adjuster, it must not complex with the primary ion, and the selectivity coefficient, K_{ij}, where j is the ionic strength adjuster, must be negligible. Tetramethylammonium nitrate was chosen for this reason for an investigation[42] of calcium complexes with tri- and tetrametaphosphate, using a calcium-selective liquid ion-exchange membrane electrode. Certain variations may sometimes be necessary in addition to ionic strength adjustment, for example, pH adjustment will release anions of weak acids. Thus, at pH 10·5 the cyanide ion is present and not undissociated hydrocyanic acid.[35]

Measurements of total concentration

The methods just discussed give the concentrations (or activities) of free (that is, uncomplexed) ions. These may be quite different from the total concentrations (that is, free + complexed species). Two elegant methods are now available for total concentration measurements.[43,44,45] Electrode calibration is not usually necessary and only two potentials need be taken.

Both methods require a change in the concentration of the primary ion, *i*. For *known addition* (otherwise known as the *spiking* or *known-increment method*) more *i* is introduced, whereas in *known subtraction* the level of *i* is lowered by adding a complexing agent. There are no complications from ionic strengths as in the previous cases.

In the known-addition method, the potential, E_1, is measured for the sample solution of volume V_0 and total molar concentration C_0 of species sought,

$$E_1 = \text{constant} \pm S \log x_1 f_1 C_0 \tag{10}$$

where S is the electrode calibration slope, f_1 is the activity coefficient and x_1 the mole fraction of uncomplexed ions. A new potential, E_2, is then measured after addition of a small volume, V_A, of a standard solution (concentration C_s) of ions of the species sought where $C_s \sim 100C_0$:

$$E_2 = \text{constant} \pm S \log (x_2 f_2 C_0 + x_2 f_2 C_\Delta) \tag{11}$$

where f_2 and x_2 correspond to the new activity coefficient and mole fraction of free ions, respectively, and C_Δ is the change in concentration, given by $V_A C_s / V_0$. An essential assumption is that $x_1 \sim x_2$ and $f_1 \sim f_2$. Hence the difference between equations (10) and (11) simplifies to

$$E_2 - E_1 = \Delta E = \pm S \log \left(\frac{C_0 + C_\Delta}{C_0} \right) \tag{12}$$

and C_0 can be calculated.

A variation of the known addition method has recently been recommended[46,47] and is based on a modification of the method described by Gran[48] for presenting potentiometric titration data in linear form by using a semi-antilog plot. The method[47] involves plotting the appropriate potential response on the vertical antilog axis against volume (ml) of "known addition" with the intercept yielding the concentration of ion present. The Orion Gran's Plot Paper now available[47] is a semi-antilog paper corrected for limited volume changes. Further reports on total concentration measurement are expected, particularly since Gran plots facilitate measurement on samples in which the level of the ion being determined is close to the electrode's limit of detection.[47] For the known-addition Gran plots, the top of the vertical (antilog) axis is equated to the potential of the electrode immersed in a solution containing 10 ml of known-addition solution plus 100 ml of test solution.

An early suggestion[46] for the application of Gran's method to the known-addition procedure is rather more cumbersome, for it involves calculation of

$$(V_0 + V)10^{-EF/2\cdot 303RT}$$

where E is the electrode response and V_0 and V are the volumes of the sample and known-addition solutions respectively.

Orion Gran's Plot Paper can also be used for the known-subtraction methods,[46] when the approach corresponds to a titration procedure. The known-subtraction method depends on a lowering of the activity of the uncomplexed ions by addition of a complexing agent, and the additional assumption that the complexing (or precipitating) agent is much stronger in its effect than any other present in the original sample. Calculations along similar lines to the known-addition method give the expression

$$E_2 - E_1 = \Delta E = \pm S \log \left(\frac{C_0 - C_\Delta}{C_0} \right) \tag{13}$$

Extensive computer tables of appropriate C_Δ and ΔE values are available to overcome the tedious arithmetic of the known-addition and known-subtraction calculations.[44]

Methods of coping with problems of wide variation of ionic strengths, interferents and complexing agents are not restricted to those above; further developments for dealing with special situations have been suggested and more can be expected. The use of a 1 :1 dilution of both samples and standards with Total Ionic Strength Adjuster Buffer (TISAB) is an elegant example of a rapid method in fluoride determination for overcoming variations in ionic strength and possible presence of complexing cations such as iron(III) and aluminium(III).[49] The essential point is that the methods proposed should be as simple as possible and there should be adequate testing of the precision, reproducibility and recoveries under optimum conditions, including calculation of standard deviations and confidence limits.

Of course, subsequent experimentation can lead to suspicions of defectiveness, as has happened with TISAB interference[50,51] in the potentiometric titration of fluoride with lanthanum nitrate. Such interference has been attributed[50] to the carboxylate ion content of TISAB, and although the acetate is retained, citrate has now been replaced by DCTA (1,2-diaminocyclohexane,*N*,*N*,*N'*,*N'*-tetra-acetic acid) when analytical samples contain aluminium or iron.[52] However, for the direct determination of fluoride, the lanthanum fluoride electrode is only minimally affected by these carboxylate ions.[22]

Selective ion-sensitive electrodes in process control

Process control imposes additional demands and restrictions on the application of selective ion-sensitive electrodes. Direct monitoring of the process stream without supplementary chemistry is the simplest, but even here there must be adequate assessment of recalibration demands and of the severe limitations often imposed by leaching effects on the membrane. The latter is particularly marked for liquid ion-exchanger electrodes, where owing to leaching of the solvent, the solute becomes concentrated on the surface of the membrane with resultant sharp increase in potential.[53]

A watch must be kept for the creation of open circuits by the trapping of air bubbles at electrode tips and for static charges resulting from fast-moving process streams rubbing against the plastic walling of electrodes. Since the electrode will probably have been assessed for its suitability for analysis of the process solution under static conditions, publications on continuous monitoring applications must pay attention to these matters as well as to constancy of flow-rate of the process sample stream and the reagent streams. The results ought to be confirmed by information derived from intermittent sampling.

Compensation can be made for temperature fluctuation, but where the process sample stream contains a steady level of primary ion the need for compensation can be avoided by filling the electrode with a solution of the same concentration of primary ion as in the sample stream.

Titration procedures with selective ion-sensitive electrodes

Potentiometric procedures are of limited accuracy for direct concentration determination. However, for sufficiently high concentrations potentiometric titration gives good accuracy, for the potentiometry no longer depends on the exact interpretation of small changes in voltage and is not restricted by the accuracy of the electrode response to changes in solution concentration. However, development of suitable potentiometric titration procedures has a whole variety of possible pitfalls. Thus, in addition to the often severe limitations imposed by interferences, restricted concentration/activity range and response times of the electrodes, there are also the chemical factors of suitability of reagents, relative rates of reactions and the effects of pH and various side-reactions.

The variety of titration procedures with selective ion-sensitive electrodes indicates that problems associated with response times are surmountable, for example, Hadjiioannou and Papastathopoulos[54] claim that the time needed for the EDTA titration of calcium and magnesium with a calcium electrode varies from a few seconds to a few minutes. Even so, the point of maximum rate of potential change does not coincide with the equivalence point, and the over-titration must be at least partly due to sluggish response. Clearly a detailed investigation is necessary for the successful application of selective ion-sensitive electrodes for potentiometric titration. Thus, the slope of the titration curve, the overall voltage change, the blank, all depend on sample composition, buffer used and such experimental conditions as titrant delivery rate and concentration, stirring rate, size of beaker, position of delivery tip and depth of electrode immersion.[54]

There is much to commend the approach of Whitfield and Leyendekkers[55] which makes an initial theoretical assessment and examines possible problems of locating the equivalence point on practical titration curves from the standpoint of both chemical and potentiometric considerations. In this way possible effects of factors such as interferences, ionic strength and limitations imposed by restrictions in electrode response after the end-point can be anticipated. The electrode response can restrict[56] the simple application of $\Delta E/\Delta V$ *vs.* V relationships for end-point location.

There are other ways besides derivative methods for selecting the end-point.[56,57,58] The obvious one is to take the mid-point of the "potential jump" section of the normal E vs. V titration curve. Independent estimates by several observers help to avoid bias in the location of this point, or a computer programme based on least squares may be used. Alternatively, especially for unsymmetrical titration curves, a Gran plot[48] can be used, *e.g.*, on Orion Gran's Plot Paper.[47]

The final procedure should be tested on a wide range of solution compositions and rigorously tested statistically. In general it is fundamental that the end-point and equivalence point be as close as possible. Ambiguities in locating the end-point are intolerable and corrections through blanks, particularly if these are variable, are also not recommended.

Many useful hints on theoretical and practical aspects of titration procedures, including precision and accuracy of potentiometric end-point determination, are contained in two recent publications.[58,59]

Differential potentiometry

Membrane electrode potentials are normally measured with respect to a reversible reference electrode, *e.g.*, a calomel or silver–silver chloride electrode. Measurements may equally well be made with reference to another membrane electrode and in order to overcome the limitations imposed by the excessively high impedance of two membrane electrodes, Brand and Rechnitz[60] have described a new instrument. This can be used with, say, two glass electrodes making up the electrochemical cell and it has been assessed for sodium ion determinations, using a cell composed of a pH (reference) electrode and a sodium glass (indicator) electrode. Differential potentiometric titrations using glass reference and appropriate indicator electrodes are also discussed for calcium and copper determination by EDTA titration, but the assessment can only be described as incomplete because in view of the comments above on the coincidence of end-points with equivalence points of titration curves, the conclusion that the "shape of the titration curve was entirely adequate for analytical purposes" is insufficient. However, the paper[60] does show the prospective scope for widescale use of membrane electrodes as references for both direct potentiometry and potentiometric titration. Certain of the low impedance membrane electrodes, such as the fluoride electrodes have already been used[61,62] for these purposes.

CONCLUSIONS

The possible number of combinations of available selective ion-sensitive membrane electrodes and solution systems is already large and likely to increase considerably. Hence, because of the limitations due to interferences, complex formation and a whole variety of operating conditions, it is imperative that prospective users should be well-guided to make intelligent decisions regarding the advantages and limitations of a new electrode or application in the context of their own particular problem.

The following summary specifies a number of vital points to be included in reports on new electrodes and their applications. Emphasis is placed on realistic assessment in terms of speed, accuracy, cost, selectivity, simplicity, and comparison with other methods.

1. *A new or modified electrode.* In addition to constructional details and cell assembly, the report on the electrode must show assessments of useful activity/concentration range, response times and selectivity for the primary ion over other ions likely to be present in possible applications. Information on operational lifetime, freedom from drift and effective pH range at various activity levels should also be given.

2. *Applications for direct concentration/activity measurement.* Details must be given of the cell assembly, particularly of the reference electrode used with the selective ion-sensitive electrode. After information has been given on selectivity factors and means of overcoming interferences, the experimental procedure should be detailed, and this must avoid the addition of interferents. The activity/concentration values obtained must, whenever possible, be carefully compared with those given by traditional and established methods (if they exist). It is desirable that statistical tests of comparison be made and attention given to recoveries.

3. *On-line process applications.* The utility of any analytical system depends on accuracy and an on-line continuous pH monitoring system is considered good if it measures to ±0·02 pH unit representing a deviation of about ±1·2 mV at 25° or an error of about ±5% in the hydrogen activity measurement. Selective ion-sensitive electrodes have similar capabilities, but reports of applications to on-line continuous monitoring systems should clearly define the electrode behaviour as in 2 above and ought to include an assessment for intermittent samples as well as for continuous monitoring. This will help to characterize possible errors due to the additional parameters imposed by the flowing system.

4. *Titration applications.* Reports must attend to points concerning electrode behaviour and comparisons with established procedures as in 2. Special attention must be given to correct end-point location, to possible interferences, and to damage to electrodes by titration solutions.

Zusammenfassung—Es wird eine Übersicht über Entwicklung, Ansprechverhalten, Selektivität und Anwendungen selektiv ionenfindlicher Elektroden gegeben. Bezüglich der Entwicklung und Anwendung von Elektroden werden Empfehlungen ausgesprochen; auch die Art und Weise, wie Ergebnisse publiziert werden sollten, wird angesprochen.

Résumé—On passe en revue les caractères concernant le développement, la réponse, la sélectivité et les applications des électrodes sélectives sensibles aux ions. On fait des recommandations concernant les recherches impliquant le développement et les applications d'électrodes et l'on porte attention sur la manière de présenter les données pour publication.

IODOMETRIC MICRODETERMINATION OF SULPHUR IN ORGANIC COMPOUNDS BY AN AMPLIFICATION REACTION

Y. A. GAWARGIOUS* and A. B. FARAG
Microanalytical Research Laboratory, National Research Centre, Dokki, Cairo, U.A.R.

(*Received* 31 *March* 1971. *Accepted* 8 *July* 1971)

Summary—A new method is described for the iodometric microdetermination of sulphur in organic compounds, using a 12-fold amplification reaction after oxygen-flask combustion. The method is based on reaction of the resulting sulphuric acid with an excess of saturated barium bromate solution. The unreacted barium bromate is precipitated by addition of acetone, filtered off, redissolved in hot water and after addition of an excess of iodide and acid, the iodine liberated is titrated with thiosulphate. The method is simple, rapid, highly accurate, and of wide application in the microanalysis of organosulphur compounds containing other common acid-forming elements.

SEVERAL methods are available in the literature for the determination of sulphur in organic compounds *via* sulphate estimation.[1–5] Redox titration methods after precipitation as barium sulphate, with slightly soluble salts such as barium iodate or chromate, were suggested by Andrews[6] and Sojbelman[7] and described in greater detail by Erdey and Banyai.[8] In a recent publication, Jaselskis and Vas[9] revived the barium iodate method for the semimicro determination of the sulphate ion in synthetic inorganic mixtures. They determined sulphate iodometrically, using a 3-hr equilibration of the sulphate solution with solid barium iodate in 40% acetone–$0{\cdot}1M$ aqueous acetic acid mixture. The liberated iodate was determined iodometrically after separation of the mixed precipitates of barium sulphate and barium iodate. Although an amplified iodometric reaction is involved, the procedure is time-consuming, and is not suitable for the microdetermination of sulphur in organic compounds.

Recently, Prokopov[10] published a method for the iodometric microdetermination of sulphur in organic compounds containing C, H, O, and S. The method is based upon combustion in the oxygen flask, with use of aqueous hydrogen peroxide as absorbant to convert sulphur combustion products into sulphuric acid. Addition of an excess of potassium iodide and iodate to the solution liberates iodine which is then titrated with thiosulphate. Unfortunately, this method cannot be used when other acid-forming elements are present in the organic compound. Various attempts[11] have been made to eliminate such interferences but the procedures tend to be rather lengthy and complicated and were thus ignored.

In the present investigation a new amplification method is described for the iodometric microdetermination of sulphur in organic compounds containing other acid-forming elements. The method depends upon reaction of the sulphuric acid, produced from oxygen-flask combustion of organosulphur compounds, with a known and excessive amount of saturated barium bromate solution which on precipitating barium sulphate releases an equivalent amount of bromic acid. On addition of acetone to the solution the excess of barium bromate is then precipitated and, after filtration, is

redissolved in hot water and determined iodometrically in the presence of acid and an excess of iodide.

EXPERIMENTAL

Reagents

All the reagents were of analytical grade: saturated bromine water, hydrogen peroxide, sodium thiosulphate (0·02–0·04*N*), potassium iodide, starch, acetone and saturated solution of barium bromate monohydrate.

Barium bromate was prepared by adding a hot aqueous solution of potassium bromate slowly and with stirring to a hot aqueous solution containing sufficient barium chloride for stoichiometric reaction. The solution was stirred for 20 min, the precipitate washed by decantation with five or six 500-ml portions of distilled water, filtered off on a Büchner funnel, dried at room temperature and stored.

Apparatus

A 250-ml oxygen combustion flask and ordinary microanalytical equipment.

Procedure

Weigh exactly 3–6 mg of the organosulphur compound and wrap it as usual with the Schöniger technique. Place 10 ml of doubly distilled water in the 250-ml flask, fill the flask with oxygen and quickly add 1 ml of saturated bromine water or 3 or 4 drops of 100-volume hydrogen peroxide. Light the paper fuse, insert the stopper rapidly and invert the flask, holding it and stopper firmly together. When the combustion is complete shake for 5 min, after which the cloud of sulphur trioxide completely disappears. Open the flask and rinse down the stopper and gauze with about 10 ml of doubly distilled water. Place the flask on a hot-plate and boil gently until the volume of the solution has been reduced to 2–4 ml.

While the solution is still hot, add dropwise 2 ml of the saturated barium bromate solution with continuous swirling for 1 min and then cool the flask under running water. Add 50 ml of acetone and filter into a 250-ml conical flask by suction through a sintered glass filter (porosity 4). Wash the precipitate with 10 ml of acetone and remove the filtrate from the conical flask. Redissolve the unreacted excess of barium bromate on the disc, washing it into the conical flask with 50 ml of hot water. To the cold solution add 5 ml of 6*M* hydrochloric acid and an excess of potassium iodide. Titrate the liberated iodine with standardized sodium thiosulphate solution, using starch as indicator. Carry out a blank experiment, using an equal volume of the barium bromate solution.

Since the overall reaction sequence corresponds to

$$SO_4^{2-} \equiv 2BrO_3^- \equiv 12I^- \equiv 12S_2O_3^{2-},$$

the percentage of sulphur in the organic compound is easily calculated from the equation:

$$\%S = \frac{(Y - X).N.32{\cdot}07}{W.12} \times 100$$

where *Y* and *X* are the volumes of thiosulphate (ml) used in the blank and actual determinations respectively, *N* is the normality of the thiosulphate solution, and *W* is the weight (mg) of the organic compound.

RESULTS AND DISCUSSION

The iodometric determination of sulphur in organic compounds is based on complete conversion of the sulphur combustion products into sulphuric acid, which is allowed to undergo a precipitation reaction with a known excess of barium bromate solution. The unreacted barium bromate is precipitated by addition of a water-miscible organic solvent, filtered and redissolved in hot water.

Two possibilities exist for the estimation of sulphuric acid. In one, it can be determined directly with a 12-fold iodometric amplification reaction via estimation of the liberated bromic acid. In the other, the sulphuric acid can be indirectly determined, also with a 12-fold iodometric amplification reaction, but this time *via* estimation of the unreacted excess of barium bromate after its separation and dissolution in hot water.

Barium bromate was selected as the displacement reagent as it is sufficiently soluble in aqueous solutions (7·96 mg/ml at 20° and 56·7 mg/ml at 100°). This appreciable solubility of the salt has a number of advantages

(*i*) It assists the rapid and quantitative reaction with the sulphate ion so that 1 min was found to be quite long enough for completion of the precipitation.

(*ii*) It allows the use of very small volumes of barium bromate solution which helps to minimise the dilution difficulties usually encountered in the quantitative precipitation of the sulphate ion on the micro-scale. As little as 2 ml of the saturated barium bromate solution proved quite satisfactory throughout this work. As expected, this amount was found to greatly exceed that required for the quantitative reaction with the sulphuric acid arising from ignition of micro-amounts of the various organosuphur compounds analysed.

Preliminary experiments revealed that the acidity arising from combustion of organosulphur compounds, whether containing other acid-forming elements or not, was sufficient for quantitative precipitation of the sulphate, and that the addition of more strong acid was unnecessary.

The next step was quantitative precipitation of the remaining excess of unreacted barium bromate (essential before an iodometric finish can be used). One solution is addition of a water-miscible organic solvent which is not oxidized by bromic acid or barium bromate. Several such solvents, *e.g.*, alcohols, dioxan and acetone were tried, and acetone was found to be best, at concentrations above 80%, when the solubility of barium bromate drops to a minimum of 0·0076 mg/ml.

Attempts to estimate the liberated bromic acid directly, after the addition of acetone and without filtering off the precipitates of barium sulphate and bromate, did not succeed, mainly because the reaction with iodide was very slow in the presence of large amounts of acetone. In such media, the reaction goes to completion only after the addition of a few drops of ammonium molybdate catalyst and an excess of acid. The latter unfortunately causes the unreacted barium bromate precipitate to dissolve.

The indirect determination of sulphuric acid *via* iodometric estimation of the excess of unreacted barium bromate, which is easily and quantitatively separated from the aqueous medium by addition of acetone, was then tried. On filtering off the precipitate and redissolving it in hot water, a pure solution of the unreacted barium bromate is obtained. Addition of an excess of iodide and acid to this liberates a 12-fold amount of iodine which may be titrated with thiosulphate as usual. With this indirect method, no correction factor is required to account for the slight solubility of barium bromate because this is almost compensated for in the blank determination.

On applying the procedure for the analysis of compounds containing C, H, and S or C, H, O, and S, accurate results (*cf.* Table I) were obtained. *p*-Toluenesulphonic acid was used as test compound, for which representative figures are given in the Table. Duplicate analyses of dibenzylsulphide and *o*-mercaptobenzoic acid also gave very satisfactory values, indicating the efficiency of the procedure.

INTERFERENCES

Under the prevailing combustion and absorption conditions chlorine, bromine and nitrogen are converted to HCl, $HBr–Br_2$, and HNO_3–nitrogen oxides respectively. Of these, bromine is added in the procedure to oxidize the sulphur combustion products. Further, the excess of bromine, the HBr, CO_2 and oxides of nitrogen, are completely eliminated in the boiling step normally involved in the procedure to concentrate the absorption solution prior to addition of the barium bromate.

TABLE I.—THE IODOMETRIC MICRODETERMINATION OF SULPHUR IN ORGANOSULPHUR COMPOUNDS USING AN AMPLIFICATION REACTION

Compound	Weight, *mg*	Sulphur, % Calc.	Sulphur, % Found
p-Toluenesulphonic acid	2·640	16·86	17·0
	3·775		16·7

However, a series of determinations was carried out using solutions containing micro-amounts of sulphuric acid alone and in mixture with micro-amounts of hydrochloric, hydrobromic, and/or nitric acids. Running these solutions through the whole procedure showed that the presence of small amounts of these acids did not interfere.

Application of the procedure for the analysis of a variety of organosulphur compounds containing chlorine, nitrogen, or both, gave very satisfactory results (*cf.* Table I). The average absolute error for all the results included in Table I is $\pm 0{\cdot}1_3\%$ and the maximum deviation is $\pm 0{\cdot}2_5\%$.

Organosulphur compounds containing phosphorus or iodine were not available during this study. However, since phosphorus is converted under the present conditions into orthophosphoric acid,[12,13] mixtures containing micro-amounts of sulphuric and orthophosphoric acids were run through the normal procedure. These experiments showed that sulphate could be determined accurately in the presence of phosphate if the precipitation step is conducted within 1 min, followed by rapid addition of the 50 ml acetone to precipitate the excess of barium bromate. In this way, co-precipitation of barium phosphate is minimized.

Similarly, iodine is not expected to interfere in the procedure, mainly because with bromine–water as the absorbent, the iodine combustion products absorbed would be almost expelled from the aqueous sulphuric acid solution in the boiling step.

The procedure described extends the application of the attractive iodometric titration to elemental sulphur microanalysis. The clear advantages of the method are the high sensitivity due to the 12-fold amplification, and the sharp end-point which overcomes the difficulties encountered with the indicator Thorin sometimes used for the direct titration of sulphate with barium ion.[1] In series analysis one determination requires about 30 min.

Zusammenfassung—Eine neue Methode zur jodometrischen Mikrobestimmung von Schwefel in organischen Verbindungen wird beschrieben. Nach der Verbrennung im Sauerstoffkolben wird eine zwölffache Verstärkungsreaktion verwendet. Sie beruht auf der Reaktion der entstandenen Schwefelsäure mit einem Überschuß an gesättigter Bariumbromatlösung. Das nicht verbrauchte Bariumbromat wird durch Zugabe von Aceton ausgefällt, abfiltriert und in heißem Wasser wieder gelöst; nach Zugabe von überschüssigem Jodid und Säure wird das freigesetzte Jod mit Thiosulfat titriert. Die Methode ist einfach, schnell, sehr genau und hat umfangreiche Anwendungsmöglichkeiten bei der Mikroanalyse von schwefelhaltigen organischen Verbindungen, die andere säurebildende Elemente enthalten.

Résumé—On décrit une nouvelle méthode pour la microdétermination iodométrique du soufre dans les composés organiques, utilisant une réaction d'amplification de facteur 12 après combustion en fiole d'oxygène. La méthode est basée sur la réaction de l'acide sulfurique résultant avec un excès de solution saturée de bromate de baryum. Le bromate de baryum qui n'a pas réagi est précipité par addition d'acétone, filtré, redissous dans l'eau chaude et, après addition d'un excès d'iodure et d'acide, on titre l'iode libéré par le thiosulfate. La méthode est simple, rapide, hautement précise et d'une large application dans la microanalyse de composés organosulfurés contenant d'autres éléments communs formant des acides.

IODOMETRIC MICRODETERMINATION OF SULPHUR IN ORGANIC COMPOUNDS BY AN AMPLIFICATION REACTION

Y. A. GAWARGIOUS* and A. B. FARAG
Microanalytical Research Laboratory, National Research Centre, Dokki, Cairo, U.A.R.

(*Received* 31 *March* 1971. *Accepted* 8 *July* 1971)

Summary—A new method is described for the iodometric microdetermination of sulphur in organic compounds, using a 12-fold amplification reaction after oxygen-flask combustion. The method is based on reaction of the resulting sulphuric acid with an excess of saturated barium bromate solution. The unreacted barium bromate is precipitated by addition of acetone, filtered off, redissolved in hot water and after addition of an excess of iodide and acid, the iodine liberated is titrated with thiosulphate. The method is simple, rapid, highly accurate, and of wide application in the microanalysis of organosulphur compounds containing other common acid-forming elements.

SEVERAL methods are available in the literature for the determination of sulphur in organic compounds *via* sulphate estimation.[1–5] Redox titration methods after precipitation as barium sulphate, with slightly soluble salts such as barium iodate or chromate, were suggested by Andrews[6] and Sojbelman[7] and described in greater detail by Erdey and Banyai.[8] In a recent publication, Jaselskis and Vas[9] revived the barium iodate method for the semimicro determination of the sulphate ion in synthetic inorganic mixtures. They determined sulphate iodometrically, using a 3-hr equilibration of the sulphate solution with solid barium iodate in 40% acetone–0·1*M* aqueous acetic acid mixture. The liberated iodate was determined iodometrically after separation of the mixed precipitates of barium sulphate and barium iodate. Although an amplified iodometric reaction is involved, the procedure is time-consuming, and is not suitable for the microdetermination of sulphur in organic compounds.

Recently, Prokopov[10] published a method for the iodometric microdetermination of sulphur in organic compounds containing C, H, O, and S. The method is based upon combustion in the oxygen flask, with use of aqueous hydrogen peroxide as absorbant to convert sulphur combustion products into sulphuric acid. Addition of an excess of potassium iodide and iodate to the solution liberates iodine which is then titrated with thiosulphate. Unfortunately, this method cannot be used when other acid-forming elements are present in the organic compound. Various attempts[11] have been made to eliminate such interferences but the procedures tend to be rather lengthy and complicated and were thus ignored.

In the present investigation a new amplification method is described for the iodometric microdetermination of sulphur in organic compounds containing other acid-forming elements. The method depends upon reaction of the sulphuric acid, produced from oxygen-flask combustion of organosulphur compounds, with a known and excessive amount of saturated barium bromate solution which on precipitating barium sulphate releases an equivalent amount of bromic acid. On addition of acetone to the solution the excess of barium bromate is then precipitated and, after filtration, is

redissolved in hot water and determined iodometrically in the presence of acid and an excess of iodide.

EXPERIMENTAL

Reagents

All the reagents were of analytical grade: saturated bromine water, hydrogen peroxide, sodium thiosulphate (0·02–0·04*N*), potassium iodide, starch, acetone and saturated solution of barium bromate monohydrate.

Barium bromate was prepared by adding a hot aqueous solution of potassium bromate slowly and with stirring to a hot aqueous solution containing sufficient barium chloride for stoichiometric reaction. The solution was stirred for 20 min, the precipitate washed by decantation with five or six 500-ml portions of distilled water, filtered off on a Büchner funnel, dried at room temperature and stored.

Apparatus

A 250-ml oxygen combustion flask and ordinary microanalytical equipment.

Procedure

Weigh exactly 3–6 mg of the organosulphur compound and wrap it as usual with the Schöniger technique. Place 10 ml of doubly distilled water in the 250-ml flask, fill the flask with oxygen and quickly add 1 ml of saturated bromine water or 3 or 4 drops of 100-volume hydrogen peroxide. Light the paper fuse, insert the stopper rapidly and invert the flask, holding it and stopper firmly together. When the combustion is complete shake for 5 min, after which the cloud of sulphur trioxide completely disappears. Open the flask and rinse down the stopper and gauze with about 10 ml of doubly distilled water. Place the flask on a hot-plate and boil gently until the volume of the solution has been reduced to 2–4 ml.

While the solution is still hot, add dropwise 2 ml of the saturated barium bromate solution with continuous swirling for 1 min and then cool the flask under running water. Add 50 ml of acetone and filter into a 250-ml conical flask by suction through a sintered glass filter (porosity 4). Wash the precipitate with 10 ml of acetone and remove the filtrate from the conical flask. Redissolve the unreacted excess of barium bromate on the disc, washing it into the conical flask with 50 ml of hot water. To the cold solution add 5 ml of 6*M* hydrochloric acid and an excess of potassium iodide. Titrate the liberated iodine with standardized sodium thiosulphate solution, using starch as indicator. Carry out a blank experiment, using an equal volume of the barium bromate solution.

Since the overall reaction sequence corresponds to

$$SO_4^{2-} \equiv 2BrO_3^- \equiv 12I^- \equiv 12S_2O_3^{2-},$$

the percentage of sulphur in the organic compound is easily calculated from the equation:

$$\%S = \frac{(Y - X) . N . 32{\cdot}07}{W . 12} \times 100$$

where Y and X are the volumes of thiosulphate (ml) used in the blank and actual determinations respectively, N is the normality of the thiosulphate solution, and W is the weight (mg) of the organic compound.

RESULTS AND DISCUSSION

The iodometric determination of sulphur in organic compounds is based on complete conversion of the sulphur combustion products into sulphuric acid, which is allowed to undergo a precipitation reaction with a known excess of barium bromate solution. The unreacted barium bromate is precipitated by addition of a water-miscible organic solvent, filtered and redissolved in hot water.

Two possibilities exist for the estimation of sulphuric acid. In one, it can be determined directly with a 12-fold iodometric amplification reaction via estimation of the liberated bromic acid. In the other, the sulphuric acid can be indirectly determined, also with a 12-fold iodometric amplification reaction, but this time *via* estimation of the unreacted excess of barium bromate after its separation and dissolution in hot water.

Barium bromate was selected as the displacement reagent as it is sufficiently soluble in aqueous solutions (7·96 mg/ml at 20° and 56·7 mg/ml at 100°). This appreciable solubility of the salt has a number of advantages

(*i*) It assists the rapid and quantitative reaction with the sulphate ion so that 1 min was found to be quite long enough for completion of the precipitation.

(*ii*) It allows the use of very small volumes of barium bromate solution which helps to minimise the dilution difficulties usually encountered in the quantitative precipitation of the sulphate ion on the micro-scale. As little as 2 ml of the saturated barium bromate solution proved quite satisfactory throughout this work. As expected, this amount was found to greatly exceed that required for the quantitative reaction with the sulphuric acid arising from ignition of micro-amounts of the various organosuphur compounds analysed.

Preliminary experiments revealed that the acidity arising from combustion of organosulphur compounds, whether containing other acid-forming elements or not, was sufficient for quantitative precipitation of the sulphate, and that the addition of more strong acid was unnecessary.

The next step was quantitative precipitation of the remaining excess of unreacted barium bromate (essential before an iodometric finish can be used). One solution is addition of a water-miscible organic solvent which is not oxidized by bromic acid or barium bromate. Several such solvents, *e.g.*, alcohols, dioxan and acetone were tried, and acetone was found to be best, at concentrations above 80%, when the solubility of barium bromate drops to a minimum of 0·0076 mg/ml.

Attempts to estimate the liberated bromic acid directly, after the addition of acetone and without filtering off the precipitates of barium sulphate and bromate, did not succeed, mainly because the reaction with iodide was very slow in the presence of large amounts of acetone. In such media, the reaction goes to completion only after the addition of a few drops of ammonium molybdate catalyst and an excess of acid. The latter unfortunately causes the unreacted barium bromate precipitate to dissolve.

The indirect determination of sulphuric acid *via* iodometric estimation of the excess of unreacted barium bromate, which is easily and quantitatively separated from the aqueous medium by addition of acetone, was then tried. On filtering off the precipitate and redissolving it in hot water, a pure solution of the unreacted barium bromate is obtained. Addition of an excess of iodide and acid to this liberates a 12-fold amount of iodine which may be titrated with thiosulphate as usual. With this indirect method, no correction factor is required to account for the slight solubility of barium bromate because this is almost compensated for in the blank determination.

On applying the procedure for the analysis of compounds containing C, H, and S or C, H, O, and S, accurate results (*cf.* Table I) were obtained. *p*-Toluenesulphonic acid was used as test compound, for which representative figures are given in the Table. Duplicate analyses of dibenzylsulphide and *o*-mercaptobenzoic acid also gave very satisfactory values, indicating the efficiency of the procedure.

INTERFERENCES

Under the prevailing combustion and absorption conditions chlorine, bromine and nitrogen are converted to HCl, $HBr-Br_2$, and HNO_3–nitrogen oxides respectively. Of these, bromine is added in the procedure to oxidize the sulphur combustion products. Further, the excess of bromine, the HBr, CO_2 and oxides of nitrogen, are completely eliminated in the boiling step normally involved in the procedure to concentrate the absorption solution prior to addition of the barium bromate.

TABLE I.—THE IODOMETRIC MICRODETERMINATION OF SULPHUR IN ORGANOSULPHUR COMPOUNDS USING AN AMPLIFICATION REACTION

IMPROVED SYNTHESIS AND STABILITY OF 8-SELENOQUINOLINE AND ITS SODIUM SALT AS ORGANIC REAGENTS

EIICHI SEKIDO and ISAMU FUJIWARA
Department of Chemistry, Faculty of Science, Kobe University, Nada, Kobe, Japan

(*Received* 18 *June* 1971. *Accepted* 14 *July* 1971)

Summary—The synthesis of 8-selenoquinoline and its sodium salt has been improved by optimization of each process. The stability of the reagents in air and nitrogen has been examined and correlated with the drying method. Both 8-selenoquinoline and its sodium salt can exist as the monohydrate. It was found that the sodium salt of 8-selenoquinoline monohydrate is best as the weighing form of the reagent and that it can be kept stable under nitrogen in a vessel containing silica gel.

8-SELENOQUINOLINE (8-quinolineselenol), so-called selenoxine, was synthesized by Sekido, Fernando and Freiser,[1] and the properties of this reagent and some of its metal chelates were studied.[2–4] Because of the poor yield and its instability in air, however, further studies appeared necessary.

Hitherto, 8-selenoquinoline has been synthesized according to scheme I. The diazotization of 8-aminoquinoline proceeds successfully in mineral acid but the resulting diazonium salt solution does not necessarily react smoothly with potassium selenocyanate; consequently the yield of 8-selenoquinoline or 8,8′-diquinolyldiselenide is usually poor. 8-Selenoquinoline is so unstable in air that it is necessary to take care in storing it, and on the other hand 8,8′-diquinolyldiselenide must be reduced just before use.

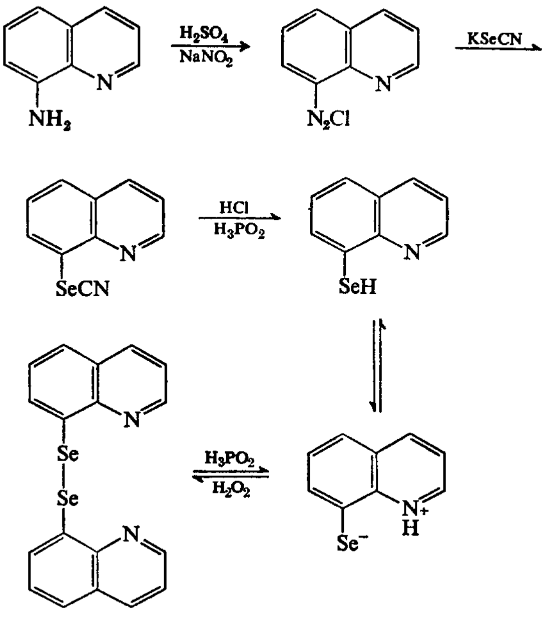
This paper deals with the improved synthesis of 8-selenoquinoline and the stability of 8-selenoquinoline and its sodium salt as a function of the drying method used.

EXPERIMENTAL

Synthesis of 8-selenoquinoline and its sodium salt

8-Selenocyanatoquinoline. Pure 8-aminoquinoline (15 g, 0·105 mole) prepared from 8-hydroxyquinoline,[3] is dissolved in 48% hydrobromic acid (78 ml, 0·50 mole) and water (200 ml). Into the solution cooled to 0°, 10% sodium nitrite solution is dropped with stirring. A colour change from red to yellow-green indicates the end of the diazotization. The excess of nitrite is destroyed by addition of 2*M* sulphamic acid until evolution of nitrogen ceases. The diazonium solution is neutralized with solid sodium acetate to pH 1·5–2·0, in an ice-bath. Then 15% potassium selenocyanate solution (100 ml, 0·104 mole) is added slowly during one hour, at below 5°. The bulky yellow-brown product is formed as a suspension and nitrogen is evolved. To complete the reaction, the solution is stirred for 30 min at below 5° and then for several hours at room temperature (in a fume-cupboard). The solution is adjusted to pH 8·0 with 12*M* sodium hydroxide and the precipitate filtered off. If 1% hydrogen peroxide solution is added to the filtrate, a little yellow-brown precipitate may be formed. This precipitate, probably impure 8,8′-diquinolyldiselenide, is added to the 8-selenocyanatoquinoline in the following procedure. 8-Selenocyanatoquinoline can be recrystallized from 50% v/v aqueous methanol (to give yellow-brown needles, m.p. 74–75°), but as it is an evil-smelling compound and the recrystallization is difficult, the crude compound is used in the following procedure.

8,8′-Diquinolyldiselenide. The crude 8-selenocyanatoquinoline (10 g, 0·043 mole) is dissolved in 6*M* hydrochloric acid (50 ml) and 50% hypophosphorous acid (10 ml) and the resulting solution is warmed for about 15 min on a water-bath. The colour changes gradually from yellow to red, which indicates the formation of 8-selenoquinoline by hydrolysis of 8-selenocyanatoquinoline. After cooling in an ice-bath, the impurity is filtered off (in a fume-cupboard, because hydrogen cyanide gas may



Scheme I

be produced). The 8-selenoquinoline in acid solution is neutralized with 5*M* sodium hydroxide in an ice-bath while nitrogen is bubbled through the solution. The colour changes to red-violet in weakly acidic or neutral solution and then to yellow in alkaline solution. The alkaline solution of 8-selenoquinoline is rapidly filtered under nitrogen to remove the impurities. When 1% hydrogen peroxide solution is added to the filtrate, a white precipitate of 8,8′-diquinolyldiselenide forms rapidly. The precipitate is filtered off, washed with water and dried *in vacuo* at room temperature. It is purified by dissolving it in hydrochloric and hypophosphorous acids and repeating the above-mentioned procedure. Yield, 40% (from 8-aminoquinoline); fine white crystals, m.p. 205° (lit.,[1] 205–206°). Calculated for $C_{18}H_{12}N_2Se_2$: C, 52·19%; H, 2·92%; N, 6·76%. Found: C, 52·6%; H, 3·0%; N, 7·3%.

8-Selenoquinoline. Purified 8,8′-diquinolyldiselenide (15 g) is dissolved in as little 6*M* hydrochloric acid as possible and 50% hypophosphorous acid (5 ml). The colour changes from yellow to red, which indicates the formation of 8-selenoquinoline. To complete the reduction the solution is warmed on a water-bath for about 10 min. It is not favourable to heat at high temperature and for a long time. After cooling, the solution is filtered if necessary, put in an ice-bath, and kept under nitrogen while 12*M* sodium hydroxide is added dropwise. The red solution becomes deep violet-red and then a precipitate forms, which redissolves on further addition of sodium hydroxide, to give a yellow solution, which is rapidly filtered if necessary. Then 2*M* hydrochloric acid is carefully added until the pH reaches 4, and dark red-brown needles precipitate. The precipitate is rapidly filtered off under nitrogen and washed with oxygen-free cold water. The 8-selenoquinoline is dried and kept in a desiccator containing silica gel and filled with nitrogen. More product can be obtained by repeating the procedure with the filtrate and washings. Yield, 52%; red-brown needles, m.p. not measurable (oxidation to 8,8′-diquinolyldiselenide). Calculated for C_9H_7NSe: C, 51·94%; H, 3·39%. Found: C, 51·7%; H, 3·6%.

Sodium salt of 8-selenoquinoline. When 12*M* sodium hydroxide is added to an acidic solution of 8-selenoquinoline, in an ice-bath under nitrogen, the yellow sodium salt of 8-selenoquinoline is precipitated. After filtration, the sodium salt is dried and recrystallized from 95% ethanol at least thrice. The amount of water of crystallization depends on the method of drying. Drying and storage in a desiccator containing silica gel and filled with nitrogen yields the monohydrate. Yield, 21·0% (from 8,8′-diquinolyldiselenide); yellow crystals, Calculated for $C_9H_8NOSeNa$: C, 43·57%; H, 3·25%. Found: C, 43·3%; H, 3·6%.

When the salt is dried *in vacuo* at 120°, the anhydride is obtained. Yellow crystals; Calculated for C_9H_6NSeNa: C, 46·98%; H, 2·63%; N, 6·09%. Found: C, 46·7%; H, 2·9%; N, 5·9%.

Other reagents

8-Mercaptoquinoline was prepared by the method of Kealey and Freiser[5] and its sodium salt by the method of Nakamura and Sekido.[4]

Apparatus

Drying. Vacuum desiccators containing silica gel or calcium chloride as desiccant were used for drying at room temperature and an electric oven under reduced pressure for drying by heating.

RESULTS AND DISCUSSION

Synthesis of 8-selenoquinoline

The improvements in the synthesis of 8-selenoquinoline are summarized in Table I.

TABLE I.—IMPROVEMENTS OF THE SYNTHESIS OF 8-SELENOQUINOLINE COMPARED WITH THE CONVENTIONAL METHOD

Reaction parameter	This method	Conventional method[1]
Acidity of diazotization	Mineral acids (HCl, HBr or H_2SO_4) 0·25*M*	H_2SO_4, 0·1*M*
Neutralization of diazonium salt solution	Addition of solid sodium acetate	Addition of 5*M* sodium hydroxide
Acidity of diazonium salt solution and KSeCN solution	pH 1·5–2·5	pH 7·0
Order of addition	Addition of KSeCN to diazonium salt solution	Addition of diazonium salt solution to KSeCN solution
Temperature and time of the reaction	30 min in an ice-bath and then 60 min at room temperature	30 min in an ice-bath
Yield of 8,8′-diquinolyldiselenide from 8-aminoquinoline	40%	12% (Maximum)

Effect of acidity on the diazotization of 8-aminoquinoline. It was found that the diazotization proceeds in hydrochloric or hydrobromic acid as well as in sulphuric acid and that at least 5 equivalents of acid per equivalent of 8-aminoquinoline are needed for smooth diazotization.

Neutralization of diazonium salt of 8-aminoquinoline. When 5*M* sodium hydroxide is used for neutralization to pH 1·5–2·5, higher pH values may be attained locally. In addition, heating by the exothermic reaction might accelerate decomposition of the diazonium salt. Use of more dilute sodium hydroxide solution makes the volume too large, and causes difficulty later. Addition of solid sodium acetate eliminates these disadvantages.

Acidity of the diazonium salt solution and the potassium selenocyanate solution. Potassium selenocyanate decomposes in acid solution to yield colloidal red selenium.

The rate of decomposition as a function of pH is as follows:

pH	below 1	1·0	2·0	4·0	5·0	7·0
Decomposition time, *min*	instantly	2	5–6	5–6	10	no change

The decomposition is accelerated by increase in temperature.

Although the diazonium salt of 8-aminoquinoline is stable in strongly acidic solution, it decomposes at higher pH. The yield of 8,8′-diquinolyldisulphide by reaction of the diazonium salt with thiourea was used to monitor the effect of pH on decomposition of the diazonium salt (the rate of reaction of the urea increases with pH, so an inverse relationship of yield to pH indicates faster decomposition as the pH is increased):

pH	−0·4	1·0	2·0	4·0	5·0	7·0
Yield, %	50	40	32	19	7	9

The best compromise between decomposition of the diazonium salt and of potassium selenocyanate was to use a pH of 1·5–2·5.

Order of addition of the diazonium salt and selenocyanate. If the neutralized diazonium salt solution is added to the selenocyanate solution,[1] the product becomes very tarry and difficult to remove. The reverse order of addition was found to give a readily filterable yellow-brown precipitate.

Drying conditions. The effect of varying the drying conditions is shown in Table II.

TABLE II.—WATER CONTENT AND COLOUR OF 8-SELENOQUINOLINE AND ITS SODIUM SALT WHEN THESE ARE DRIED UNDER VARIOUS CONDITIONS

		Drying condition					
No.	Substance	Desiccant	Atmosphere	Temp., *°C*	Time, *hr*	Water content,* %	Colour
1	8-SQ†	silica gel	nitrogen	20–25	24	8·2	red
2	8-SQ†	silica gel	nitrogen	20–25	48	0	red-brown
3	8-SQ†	silica gel	vacuum (0·1 μbar)	20–25	24	0	red-brown
4	8-SQ†	$CaCl_2$	nitrogen	20–25	48	0	red-brown
5	8-SQ-Na‡	silica gel	vacuum (0·1 μbar)	20–25	24	6·7	yellow
6	8-SQ-Na‡	silica gel	(0·1 μbar)	20–25	48	7·6	yellow
7	8-SQ-Na‡	silica gel	(0·1 μbar)	20–25	7 days	7·2	yellow
8	8-SQ-Na‡	silica gel	25–40 mbar	20–25	48	7·8	yellow
9	8-SQ-Na‡	no	vacuum (0·1 μbar)	120	1–6	0	orange

* Average value of at least 5 results. Range ±0·5%. One molecule of water of crystallization corresponds to 8·0% H_2O for 8-SQ and 7·3% for 8-SQ-Na.

† 8-SQ: 8-selenoquinoline.

‡ 8-SQ-Na: sodium salt of 8-selenoquinoline.

Experiments 1–4 show that 8-selenoquinoline easily loses its water of crystallization. In contrast, the sodium salt exists as the monohydrate over a fairly wide range of drying conditions. The anhydrous salt is so hygroscopic that it must be kept in a desiccator containing phosphorus pentoxide.

Thermal stability of 8-selenoquinoline and its sodium salt

8-Selenoquinoline, especially its monohydrate, is easily oxidized in air to 8,8′-diquinolyldiselenide. Therefore, its thermal stability was examined in nitrogen as well as in air. Thermogravimetry of 8-selenoquinoline monohydrate in air (curve *A* in Fig. 1) shows loss of the water at a temperature of 51° or lower, accompanied by a colour change to red-brown at 50–51°. These facts may support the hypothesis that the water is not adsorbed by 8-selenoquinoline but weakly bound to it as shown in structure **I**. Bankovskii, Chera and Ievin'sh[6] proposed structure **II** for 8-mercaptoquinoline dihydrate. Considering the difference in the acid dissociation constants[1] of —SH in 8-mercaptoquinoline and —SeH for 8-selenoquinoline (in other words, the difference of electronegativities for sulphur and selenium) the S· · ·H bond in **II** may be stronger than the Se· · ·H bond in **I**.

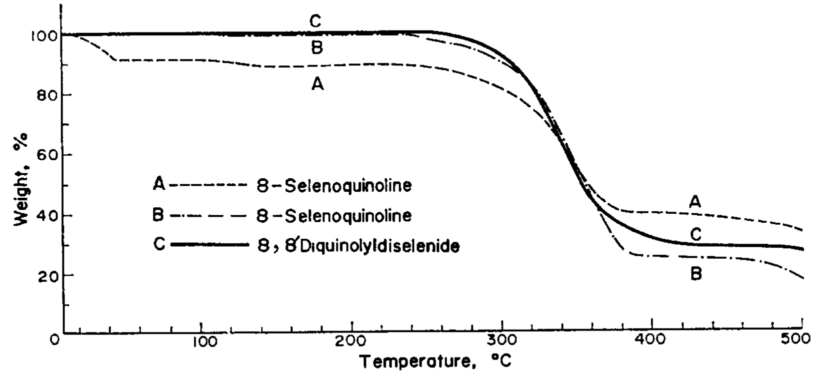


FIG. 1.—Thermogravimetric curves of 8-selenoquinoline and 8,8′-diquinolyldiselenide in air.

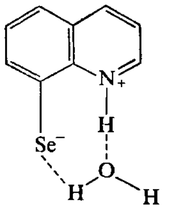
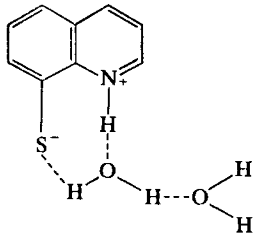


I



II

Therefore, the temperature of dehydration for 8-mercaptoquinoline (58–59°) should be higher than that for 8-selenoquinoline (51°). In the case of 8-mercaptoquinoline, the second water molecule may be weakly connected *via* a hydrogen bond to the cyclically bound water molecule.

The anhydride (curve *A* above 50° and curve *B* in Fig. 1) changes to 8,8′-diquinolyldiselenide by 140° (*cf.* curve *C* in Fig. 1). The oxidation of 8-selenoquinoline is also confirmed by the identity or the infrared spectra of the product from 8-selenoquinoline heated to 180–190° and of 8,8′-diquinolyldiselenide. The differential thermal analysis (DTA) and thermogravimetric curves of 8-selenoquinoline under nitrogen (curves *A* and A' in Fig. 2) are different from those of 8,8′-diquinolyldiselenide (curves C and C'). The peak at 204° on curve C corresponds to melting of 8,8′-diquinolyldiselenide and that at 360° to decomposition of the quinoline nucleus.

8-Selenoquinoline is completely oxidized to 8,8′-diquinolyldiselenide after 3 hr in air. This oxidation is confirmed by the disappearance of the infrared absorption band at 2925 cm^{-1} (N–H stretching vibration) and by the agreement with the infrared spectrum of 8,8′-diquinolyldiselenide. Anhydrous 8-selenoquinoline is stable for at least three weeks when stored under nitrogen in a vessel containing silica gel.

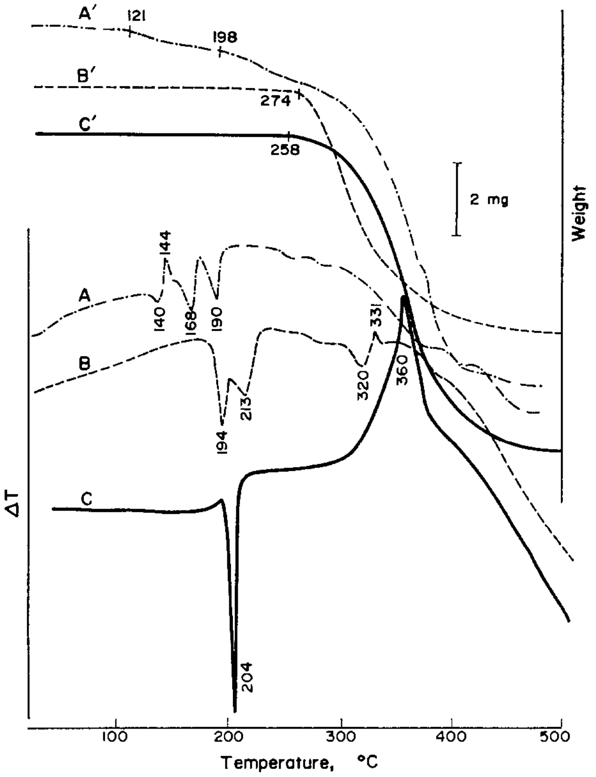


FIG. 2.—Differential thermal curves (A, B and C) and thermogravimetric curves (A′, B′ and C′) of the reagents in nitrogen gas. A and A′: 8-selenoquinoline; B and B′: 8,8′-diquinolyldisulphide; C and C′: 8,8′-diquinolyldiselenide.

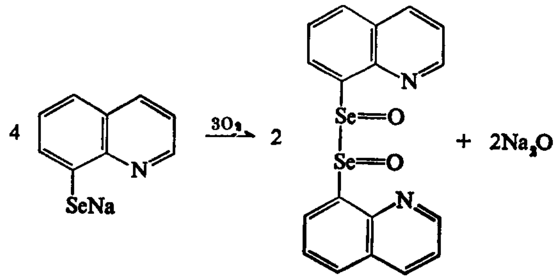
Thermogravimetric curves for the sodium salt of 8-selenoquinoline in nitrogen and in air are shown in Fig. 3. The water is all lost between 78 and 106° (curve A). The anhydride increases in weight by 10% over the temperature range 160–190° if heated in air (curves A and B) but not if heated in nitrogen or carbon dioxide (curve C). A similar phenomenon occurs with the sodium salt of 8-mercaptoquinoline,[7] and not for 8-selenoquinoline or 8,8′-diquinolyldiselenide. It is assumed that the sodium salt of 8-selenoquinoline is oxidized by air. Oxidation according to the reaction below gives a theoretical weight increase of 10·4% (experimental value, 10·0%).



The DTA curves for the sodium salts of 8-selenoquinoline monohydrate and 8-mercaptoquinoline dihydrate are shown in Fig. 4; for both there is a large endothermic peak at about 120°, which corresponds to loss of the water. The rest of the decomposition is rather complex. The bond strength between the water and the organic molecule is presumably almost the same for both compounds. The O–H stretching vibration in the infrared spectra for both compounds exists at almost the same position, 3277 cm^{-1} for the 8-selenoquinoline salt and 3200–3300 cm^{-1} for that of 8-mercaptoquinoline, the first being relatively sharp and the other broad (Fig. 5). These facts suggest that the structures may be III and IV respectively.

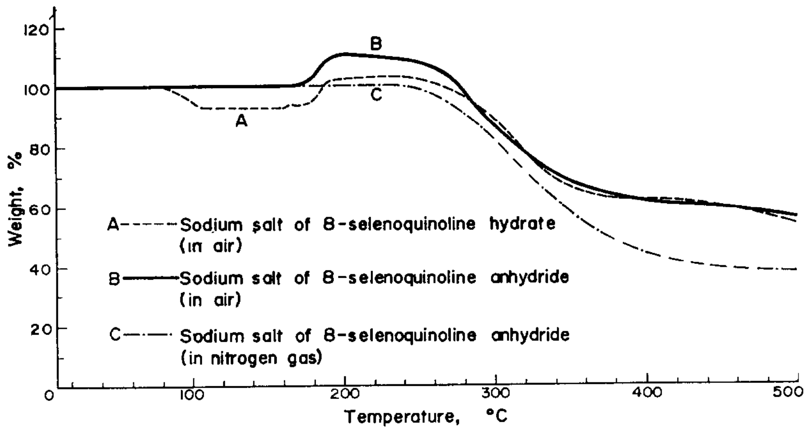


FIG. 3.—Thermogravimetric curves of the sodium salt of 8-selenoquinoline in air and nitrogen.

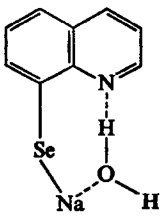
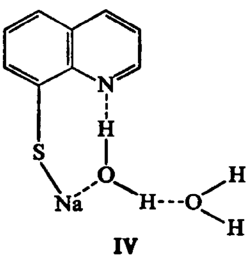


III



IV

That the dehydration temperature of the sodium salts is higher than that of the 8-seleno- or 8-mercaptoquinoline may be attributed to the bond between the sodium

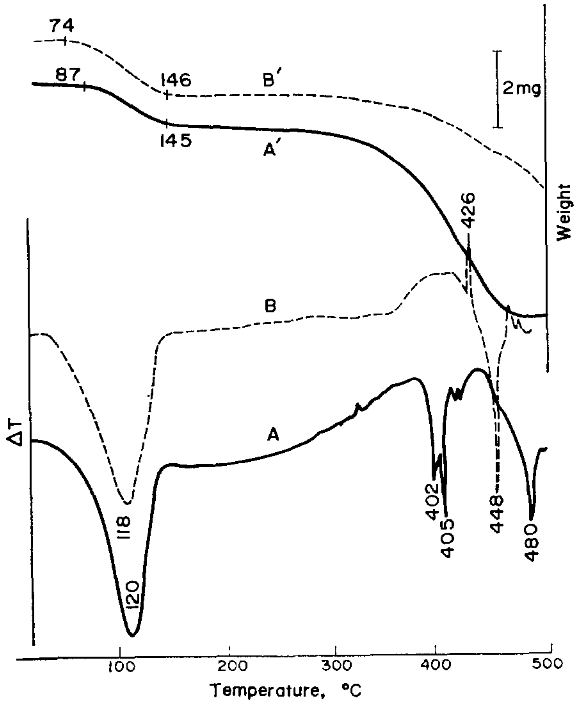


FIG. 4.—Differential thermal curves (A and B) and thermogravimetric curves (A′ and B′) of the reagents in nitrogen gas. A and A′: sodium salt of 8-selenoquinoline; B and B′: sodium salt of 8-mercaptoquinoline.

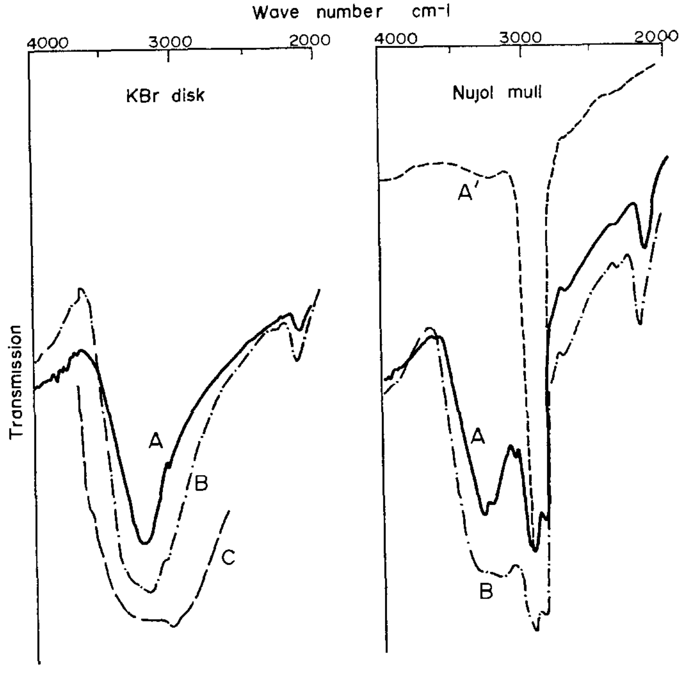

FIG. 5.—Infrared spectra of sodium salt of the reagents in the region of 4000–2000 cm^{-1}. A: 8-selenoquinoline monohydrate; *A′*: its anhydride; B: 8-mercaptoquinoline dihydrate; C: 8-hydroxyquinoline hydrate.

atom and the oxygen atom of water being stronger than that between the oxygen atom and the selenium or the sulphur atom. Furthermore, the similar dehydration temperatures for the sodium salts suggest that one water molecule exists between the sodium atom and the nitrogen atom of the quinoline nucleus in both. The second water molecule of the dihydrate, being bound to the cyclically bound water molecule by a hydrogen bond, will broaden the O—H stretching vibration band.

The temperature of incipient decomposition of the sodium salt of 8-selenoquinoline is lower than that for 8-mercaptoquinoline salt; the S—Na bond may be stronger than the Se—Na bond.

The anhydrous sodium salt of 8-selenoquinoline is so hygroscopic that it abstracts water from silica gel in a desiccator. It is stable if kept in a nitrogen atmosphere over phosphorus pentoxide in a desiccator, but over P_2O_5 in a vacuum it changes gradually into a red-brown compound. The sodium salt monohydrate is the best storage form, being stable for at least 2½ months in a nitrogen atmosphere in a desiccator containing silica gel.

Zusammenfassung—Die Synthese von 8-Selenochinolin und seines Natriumsalzes wurde durch Optimierung jeder Stufe verbessert. Die Stabilität der Reagentien an Luft und Stickstoff wurde geprüft und mit der Trocknungsmethode in Zusammenhand gebracht. Sowohl 8-Selenochinolin als auch sein Natriumsalz können als Monohydrat existieren. Es wurde gefunden, daß das Natriumsalz von 8-Selenochinolin-Monohydrat die beste Wägeform des Reagens darstellt und daß es unter Stickstoff in einem Silicagel enthaltenden Gefäß stabilisiert werden kann.
