The ion-exchange isotherms for univalent ion exchange in the Na^+–Y zeolite terminate at ~70% exchange for Rb^+, Cs^+, Tl^+ and NH_4^+ ions[139,274] indicating that these ions are too large to penetrate the sodalite cages. The non-sigmoidal shape of the isotherms (up to 68% exchange) indicates no site heterogeneity in the supercages and the selectivity thus decreases in the order $Tl^+ > Ag^+ > Cs^+ > Rb^+ > NH_4^+ > K^+ > Na^+ > Li^+$. The sites in the network of small cavities exhibit a selectivity pattern typical of a surface which binds ions tightly: $Ag^+ > Na^+ > K^+ > Li^+$;[139] $Ag^+ > K^+ > Na^+ > Li^+$.[274] In contradistinction to the Na^+–X zeolite, Tl^+ ions do not replace the 16 Na^+ cations in the sodalite cages of Na^+–Y. This difference in behaviour of Tl^+ in the more siliceous form (Na^+–Y) of synthetic faujasite is attributed to the lattice contraction which occurs when SiO_2 replaces $NaAlO_2$.[139] The values of the standard thermodynamic functions for ion-exchange in the zeolite Na^+–Y are summarized in Table V.

The exchange of organic cations, such as $MeNH_3^+$, $EtNH_3^+$, $PrNH_3^+$, $BuNH_3^+$, $C_5H_{11}N^+$, $C_6H_{14}N^+$, $PhNH_3^+$, p-$C_7H_{10}N^+$, $C_5N_5N^+$ and $PhCH_2NH_3^+$ is limited by available cavity volume and steric effects. Selectivity due to affinity of zeolite lattice for protons dominates over the steric factors.[279] The maximum extent of exchange decreased with increasing molecular weight and polarizability of these cations.[280]

The hydrogen forms of zeolites X and Y show irreversible changes of the crystal lattice when H^+ is exchanged for Na^+.[281]

The bivalent ion exchange equilibria in the zeolites X and Y have been studied for the Ca^{2+}–Na^+, Sr^{2+}–Na^+, Ba^{2+}–Na^+,[274,275,282–286] Cd^{2+}–Na^+ and Zn^{2+}–Na^+[287] systems. The ion-exchange isotherms for zeolite Na^+–X show 100% exchange of Ca^{2+} and Sr^{2+} at 25 and 50°, and of Ba^{2+} at 50°.[282] The Ba^{2+}–Na^+ isotherms at 25° terminate at 82% exchange for Na^+–X,[283] at 68% exchange for Na^+–Y.[282] The same value has been obtained also in the Ca^{2+}–Na^+ and Sr^{2+}–Na^+ systems on Na^+–Y[274,282] at 25°. Some examples of the exchange isotherms are shown in Fig. 5. The sigmoidal shape of the isotherms in the case of zeolite X is interpreted in terms of two different equilibrium constants (>1 and <1) for the exchange of supercage Na^+ ions and sodalite-cage Na^+ ions respectively. These two constants have been evaluated for the Ba^{2+}–Na^+–X system[282] and are presented (as $\Delta G°$ values) in Table IV. In the case of the Sr^{2+}–Na^+ system an unusual shape of the exchange isotherms has been found, which arises from limited miscibility of the end-members Na^+–X and Sr^{2+}–X. At a fixed aqueous solution composition, two solid phases co-exist.[288] Even if 100% exchange has been reached in the zeolite Na^+–X, the replacement of the 16 Na^+ ions in the small cages is very slow[273,282] and the hydrated water of the ingoing cations should be at least partially stripped before these cations enter the small cages.[273,282] The values of the standard thermodynamic functions for bivalent ion exchange in the Na^+–X and Na^+–Y zeolites are summarized in Tables IV and V. It has been concluded from the thermodynamic data that in the case of Ca^{2+}–Na^+ and Sr^{2+}–Na^+ exchange in Na^+–X the reactions are entropy-directed and controlled by water-ion interactions in the aqueous solution phase.[282] A small enthalpy change in the Ba^{2+}–Na^+–X system indicates that there is no strong interaction between the Ba^{2+} ions and the framework.[283] Further, a net transfer of water from the zeolite phase to the solution takes place during the Ba^{2+}–Na^+ exchange.[282] In the zeolite Na^+–Y there is no

ion-siting in the large cages, so hydrated alkaline earth metal cations exchange for hydrated Na^+ cations.[282]

Reversible isotherms have been obtained by Sherry[289] and Ames[290] for the exchange of La^{3+} in Na^+–X and Na^+–Y as well as of Ce^{3+} and Y^{3+} in Na^+–X at 25°. The 16 Na^+ cations per unit cell in the network of small cages could not be replaced by these ions at 25°. However, at higher temperatures ($>80°$) a complete replacement occurred and the rate-controlling step in the replacement of the small-cage Na^+ ions was stripping of hydration water from the tervalent ions in the large cages.[289]

Equilibria in the Linde A zeolites. For the zeolite Linde A, the exchange isotherms and thermodynamic functions have been measured in many systems of uni- and bivalent cations.[154,284,291–295] The ion-exchange in the systems Li^+–Na^+, Cs^+–Na^+ and Ca^{2+}–Na^+ shows very marked energetic heterogeneity which is explained in the case of the Li^+–Na^+ system in terms of two sets of available sites. The first set accounts for 35–45% of all available ions (an average of 4–5 from the total 13 Na^+ ions per unit cell), while the remaining ions are associated with the second group of sites. However, larger ions such as Cs^+ are excluded for steric reasons from certain sites, at any rate from the sites located in or adjacent to the 6-membered rings.[291] Very often an excess of ion-exchange capacity of Linde A occurs owing to trapping of the AlO_2^- anion of the $NaAlO_2$ "molecule" occluded in the sodalite cage[112,292] during crystallization of the zeolite. This anion is too large to diffuse through the

2·6 Å window between the sodalite cage and the supercage. It has been found that there is one occluded $NaAlO_2$ "molecule" per sodalite cage which, together with the 12 AlO_2^- anions needed for the formation of the Linde A unit cell, is consistent with the unit cell formula of $Na_{12}[12AlO_2 \cdot 12SiO_2] \cdot NaAlO_2 \cdot 29H_2O$.[2] Larger cations such as Tl^+ and Ba^{2+} are unable to replace Na^+ ions from the sodalite cages and thus their isotherms terminate at 92 and 97% exchange.[112,154,296]

The following affinity series have been found for univalent cations: $Na^+ > K^+ > Rb^+ > Li^+ > Cs^+$,[291] $K^+ > Na^+ > NH_4^+ > Rb^+ > Cs^+ > Li^+ > (CH_3)_2NH_2^+$.[277] However, it is difficult to compare the affinity series found by various authors on various materials. The cation selectivity is a function of the anion charge-density[112] and thus a function of the anionic site separation distances.[297] As only the AlO_4 tetrahedra bear the negative charge of the framework an increasing SiO_2 content will enlarge the anionic site separation distances and decrease the anion charge-density.[112,297] Generally, the Na^+–A zeolite prefers cations of higher valency, atomic weight, polarizability, tendency to form ionic pairs, and ability to form more strongly dissociated complexes, but of lower tendency to hydrate in comparison with other cations of equal charge.[298,299]

The thermodynamic data for ion-exchange in the zeolite Linde A are summarized in Table VI. From the thermodynamic data it has been concluded that there is much ion-pair formation between cations and the fixed anionic sites in Ag^+–A and Ca^{2+}–A, less in Sr^{2+}–A, and almost none in Ba^{2+}–A.[154] No structural collapse has been found for the hydrated Ba^{2+} form of this zeolite[154,300] contrary to other observations,[296] and no structural changes have been found after the exchange of Co^{2+} for Na^+ ions.[301]

Ion exchange kinetics. The study of kinetics of processes on synthetic zeolites is very important from a practical as well as a theoretical point of view, because zeolites are amongst the few solids which show high ion mobility in a rigid and well defined crystal lattice. The diffusion kinetics of various cations in these materials show greater variety and complexity than they usually do for organic resins and thus attempt to correlate the kinetic and thermodynamic data with the nature of the cation, the restricting dimensions of the zeolitic framework, and the properties of solvent molecules, which is very useful for the deeper understanding of the ion-exchange processes on synthetic zeolites.

The alkali metal ions diffuse very quickly in the X-zeolite, and substantially faster than the bivalent cations. The values of the diffusion coefficients increase with increasing atomic weight for the elements of the same group.[302] The values of self-diffusion coefficients in the Linde A and X-zeolites for Na^+, Cs^+ and Sr^{2+} range from 1×10^{-9} to 5×10^{-7} cm²/sec in aqueous systems at 50°.[303] Sodium ions are, according to Dyer *et al.*,[304] freely mobile between the various sites even at low temperatures in the X- and Y-zeolites, but in the case of zeolite A, two unequal structural positions for Na^+, K^+, Rb^+ and Cs^+ were proved to exist by Hoinkis *et al.* from the self-diffusion data, even if the diffusion process of Na^+ and K^+ was extremely fast.[305,306] In the latter case, the distribution of Na^+, Cs^+ and Rb^+ over the different lattice types was found to be temperature-dependent.[128]

The self-diffusion coefficients of H_2O occluded in Na^+–X, Ca^{2+}–X and Ca^{2+}–Y zeolites were determined by pulsed field-gradient spin-echo NMR and corresponded to values of 1·34, 1·65 and $1{\cdot}88 \times 10^{-5}$ cm²/sec at 30°. The corresponding activation energies for self-diffusion were 6·9, 6·8 and 5·6 kcal/mole, respectively, and 5·04 kcal/mole for pure water. Thus there appears to be little difference between free water and water occluded in the zeolites.[307]

The self-diffusion and ion-exchange data for the systems Na^+–alkaline earth metal cations in X-, Y-, A- and ZK-4-type zeolites show considerable differences, which may be explained by the significant solvent-cation association in the case of bivalent ions.[306] The coulombic forces make the major contribution to the activation energies of these self-diffusion processes and thus the enhancement in the framework charge increases the self-diffusion energy.[284] The progress of a Ca^{2+}, Sr^{2+} or Ba^{2+}–water "complex" through the layer lattice window of the X-zeolite seems to be the rate-determining step.[166,308] For the Ba^{2+} ion, the diffusion energy barrier arises from the large bare ion moving from site I, through successive hexagonal windows out into the supercage. A much higher barrier exists for Sr^{2+}, which occupies site I′, in the zeolite X. Thus to gain a position in the large cavities, Sr^{2+} ions first have to lose their hydration sheaths before the ion passes through the hexagonal window of the sodalite unit.[309] Thus the increased values of activation energy would be explained by these high-energy barriers[166] increasing for the series $Ba^{2+} < Ca^{2+} < Sr^{2+}$.[308] On the other hand no ion-size effect has been noted for Sr^{2+}, Ca^{2+} and Ba^{2+} in this zeolite.[166,308] Also the values of entropy of activation can be indications of the differences in the diffusion path followed by Sr^{2+} and Ba^{2+}. The positive value associated with Sr^{2+} migration in zeolite X (137 J/mole/deg) would thus be a reflection of its restricted diffusion path and a large ion–water orientation. Conversely the negative value measured for Ba^{2+} migration (−66 J/mole/deg) is indicative of a comparatively higher degree of mobility and the lack of orientational effect which the ion has upon its water environment. The overall activation free-energy changes are nearly identical for both ion-diffusion processes (84 and 83 kJ/mole) which would seem to preclude structural changes as a contributory factor to Sr^{2+} self-diffusion in the zeolite X.[309] Bivalent cations such as Ca^{2+}, Sr^{2+} and Ba^{2+} experience difficulty in replacing a proportion of Na^+ ions, especially those in site I. However, if the temperature is raised to ~200°, the effect is to depopulate site I with respect to univalent ions in favour of bivalent ions. In these cases Sr^{2+} and Ba^{2+} occupy only one-half of the available site I positions.[304] The degree of conversion of X-zeolite into the bivalent form seems therefore to be the decisive factor for the diffusion phenomena. It has been shown that 80% of the exchangeable barium ions and 65% of the strontium ions have very high diffusion velocities in X zeolites, but the remainder diffuse only slowly, the diffusion coefficients differing by 4–5 orders of magnitude. The enthalpy of activation of the slower process is about twice that of the fast one. This is explained in terms of location of the ions in two types of channels, which are supposed to be separated from each other, each of them accommodating a certain proportion of the bivalent ions.[306,310]

Similar studies on bivalent cations were made with the A-type zeolites. In contrast to Cs^+ ions, the Sr^{2+} and Ba^{2+} distribution in A-zeolite is practically uniform.[306] For example, all six Sr^{2+} ions present per unit cell in zeolite A occupy structurally similar positions and the activation energy for self-diffusion was calculated as ~13 cal/mole/deg.[311] The self-diffusion measurements for Ca^{2+}, Sr^{2+} and Ba^{2+} illustrate the effect of increase in size of bivalent cations on the energy barriers for self-diffusion through type-A zeolites.[296] These cations are not completely surrounded by water molecules and some coulombic contribution to the energy barrier is of importance.[166] The rate-determining step for movement of the large Ba^{2+} ion through zeolites A, ZK-4 and chabazite is a sterically hindered process. The movement of Ca^{2+} and Sr^{2+} ions in chabazite and zeolite ZK-4 could be one in which the ion moves from a completely hydrated state through a restricting ring, losing part of its hydration envelope, and returns to its hydrated state on the other side of the ring.[308] Above 100°, the barium ion diffusion became an ideal diffusion process. At sufficiently high temperature all exchangeable cations leave their well-defined positions in the framework and are statistically distributed in the supercage.[312]

The use of non-aqueous solvents with lower dielectric constants and larger solvent molecules than water, has apparently little effect on the rate of Na^+ ion migration, the rate being extremely rapid even in zeolite A which has relatively small pore openings. The use of non-aqueous solvents has a considerable effect on the kinetics and thermodynamics of alkaline earth metal cation self-exchange processes.[284] The rate becomes immeasurably slow in zeolite A, and in zeolite X and Y there is a marked reduction in the self-diffusion rate and an increase in the activation energy with increasing size and decreasing dielectric constant of the solvent molecules. The effect of increasing size in an ion-solvent aggregate is the main cause of increasing energy barriers for self-diffusion.[284,313,314]

Mordenite-like zeolites

Natural mordenite $[(Ca,K_2,Na_2)O{\cdot}Al_2O_3{\cdot}10SiO_2{\cdot}6\text{–}7H_2O]$ has a well-known synthetic counterpart with a nearly rigid framework in all three dimensions, which is thermally stable and has a structure with various degrees of porosity (Zeolite AW-300, Zeolon[278]). Alkaline-earth varieties of this high-silica synthetic mordenite were prepared hydrothermally[315–317] by heating a mixture of SiO_2 and sodium aluminate with aqueous solutions of Na_2SiO_3 at 75–175°. The following formulae have been determined: $(Na,Ca/2)_2{\cdot}Al_2Si_9O_{22}{\cdot}2{\cdot}8H_2O$[315] and $(Na_2,K_2,Ca)Al_2Si_{10}{\cdot}O_{24}{\cdot}7H_2O$.[316] Mordenite crystals were prepared by prolonged autoclaving of the solutions with sodium silicate at 90–120°. The crystals contained a lower amount of Ca (<1% of

CaO) than that of natural mordenites (2–4 % of CaO).[318] The SiO_2/Al_2O_3 and Na^+/H^+ ratios in the mordenites can be changed without destroying their zeolitic structure. The Na^+- and H^+-forms of mordenites were prepared and their composition corresponded to $1{\cdot}04Na_2O{\cdot}Al_2O_3{\cdot}12{\cdot}2SiO_2$ and $2{\cdot}47H_2O{\cdot}0{\cdot}5Al_2O_3{\cdot}12{\cdot}2SiO_2$, respectively. Treatment of the Na^+-form with acids leads to ion-exchange and de-alumination processes. By the de-alumination the zeolite capacity is decreased and non-equivalent H^+ groups are formed. Heating of mordenite to ~400° causes deprotonation and de-alumination.[319]

Sorption phenomena on mordenites are closely related to the structural arrangement. The volume of two large channels (length ~7·52 Å) in the elementary unit cell of the synthetic mordenite was found to be 477 Å^3. The ions adsorbed are predominantly situated in the 12-membered oxygen windows. From these windows smaller channels formed by 8-membered windows branch out. The volumes of the large and small channels in the sodium (hydrogen) form of mordenite were found to be 0·0935(0·0980) and 0·0565 cm^3/g, respectively.[320] It was reasoned that if the zeolites were synthesized with a given ion in place, the structure should conform slightly to the spatial needs of the ion in question. If these ions are removed by ion-exchange, the zeolite should still retain a "frozen-in" structural preference for the original ions and thus an element of selectivity for this ion is built-in.[316] A strontium-selective mordenite can be prepared by this method.[321] PMR and infrared studies on synthetic mordenite have been performed.[322]

Heulandite-like zeolites

Naturally-occurring zeolites of the heulandite group are characterized by frameworks that tend to be lamellar. The minerals heulandite ($CaO{\cdot}Al_2O_3{\cdot}6SiO_2{\cdot}5H_2O$), clinoptilotite [$(Ca,Na_2,K_2)O{\cdot}Al_2O_3{\cdot}10SiO_2{\cdot}8H_2O$], stilbite [$(Na_2Ca)O{\cdot}Al_2O_3{\cdot}6SiO_2{\cdot}6H_2O$], and ferrierite [$(Na_2,Mg)O{\cdot}Al_2O_3{\cdot}10SiO_2{\cdot}6H_2O$] have well-known synthetic analogues.[316,317,321,323–329]

Synthetic heulandite of the formula $(Na_2,Ca)O{\cdot}Al_2O_3{\cdot}7SiO_2{\cdot}H_2O$ gives the same X-ray data as the natural mineral. The basic volume of the zeolite is ~900 Å^3.[323] From NMR studies it is obvious that hydrogen enters the structure in the form of OH groups.[326] The high-silica zeolites of this group have been the most studied.

A synthetic heulandite–clinoptilotite zeolite was prepared hydrothermally by autoclaving at ~300° a mixture of LiOH, $Al(OH)_3$ and silica gel in the ratio of 1:1:12. A zeolite with the composition $11{\cdot}5SiO_2{\cdot}Al_2O_3{\cdot}0{\cdot}99Li_2O{\cdot}18{\cdot}9H_2O$ has been prepared, with capacities for Sr_2^+ and Ce^{3+} of 0·46 and 1·16 meq/g, respectively.[317,324] Alkaline earth varieties of high-silica clinoptilolite, *e.g.*, $Ca(Na,K)_4Al_6Si_{30}O_{72}{\cdot}24H_2O$,[316] can also be prepared hydrothermally and a Ba-clinoptilolite-like phase has been prepared reproducibly in this way.[316] Low alkalinity of the solutions favours the formation of high-silica compounds. Na^+-alkylammonium clinoptilolites were prepared by the ion-exchange conversion of Na^+-clinoptilolite. The ion-sieve effects and the groups of ions which can displace all or only some of the total Na^+ can be reconciled with the free dimensions of the windows giving access to the two kinds of channels in clinoptilolite, if this is assumed to have an aluminosilicate framework isostructural with that of heulandite. The kinetics proved fully compatible with intraparticle diffusion, but not with intracrystalline or film diffusion.[325] As in the case of mordenite, selectivity of clinoptilolite for Sr^{2+} can be incorporated by the localized perturbations of the Al–Si network due to the conformation of this network, during formation, to the spatial needs of the exchangeable cation. For the gross composition $SrO{\cdot}Al_2O_3{\cdot}7SiO_2$, the separation factor for Sr^{2+} decreases in the order clinoptilotite > mordenite > ferrierite > yugawaralite. The higher separation factors for Sr may be explained by their relation to the larger channels of ~6·6 Å in the case of mordenite and perhaps clinoptilolite.[321] Very low values of ion-exchange enthalpies were found for the systems Na^+–Sr^{2+}, Na^+–Ca^{2+} and Sr^{2+}–Ca^{2+}.[327]

Alkaline-earth high-silica ferrierite-like zeolite was prepared hydrothermally, with the composition $(Na,K)_4Mg_2Al_6Si_{30}O_{72}{\cdot}18H_2O$.[316] Synthetic products containing strontium, usually designated as Sr–D, have X-ray characteristics very similar to those of natural ferrierite.[329] The corresponding H^+, Na^+, K^+ and Ca^{2+} forms were prepared by the ion-exchange conversion of the Sr^{2+} form.[328] Similarly to mordenite and clinoptilolite, the "frozen-in" structures can be incorporated for the Sr^{2+}-selective ferrierite preparation.[321]

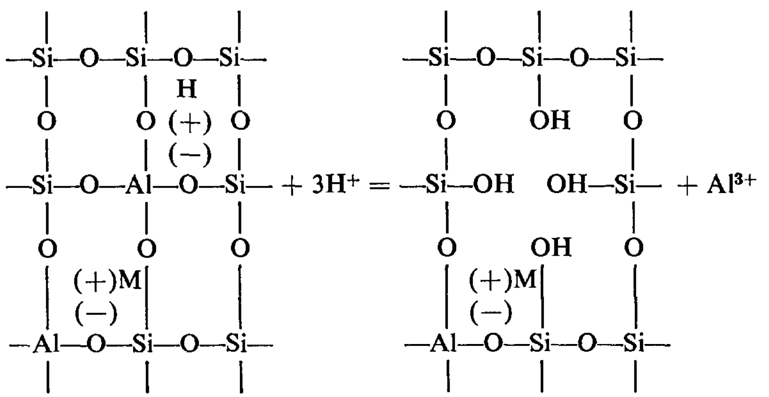
Chabazite-like zeolites

Chabazite-group minerals possess a rigid three-dimensional framework. Their structure may be represented by layer stacking, and the hexagonal prism units can be considered as the building blocks. Each zeolite of this group can be regarded as a sequence of layers of hexagonal prisms, the layers being firmly bonded to one another to give strong frameworks. Synthetic counterparts of natural chabazite $[(Ca,Na_2)O{\cdot}Al_2O_3{\cdot}4SiO_2{\cdot}6H_2O]$, levynite $(CaO{\cdot}Al_2O_3{\cdot}3SiO_2{\cdot}5H_2O)$, and especially of erionite $[(Ca,Mg,Na_2,K_2)O{\cdot}Al_2O_3{\cdot}6SiO_2{\cdot}6H_2O]$ have been described[278,322,327,330–340] From the X-ray studies of hydrated Ca-chabazite at +20 and −150°, three possible ordered arrangements of Si and Al atoms have been proposed.[330]

The chabazite-like synthetic zeolite AW-500 contains in its structure ellipsoidal cavities ~10 Å in free length and 6–7 Å in free diameter. Entry of either ionic or molecular species into these cavities occurs through one of the 6 eight-membered rings which form some of the polyhedral faces of each cavity. These rings are elliptical with maximum and minimum free diameters of 4·1 and 3·7 Å, respectively.[339] Free energies and enthalpies for the Na^+–Cs^+, K^+–Na^+ and K^+–Cs^+ ion-exchange reactions on chabazite-like synthetic zeolite AW-500 are very low and ΔH values diminish as the difference in the sizes of the exchanging cations decreases. The same conclusions were reached for the mordenite- and erionite-type synthetic zeolites AW-300 and AW-400.[278]

ZK-20 zeolite is isostructural with levynite. The composition corresponds to the formula $R_2O{\cdot}Na_2O{\cdot}Al_2O_3{\cdot}SiO_2{\cdot}yH_2O$ with the components in ratios of 0·1–0·2:0·8–0·9:1·0:4·0–5·0, where $y = 1$–5 and R is the cation derived from 1-methyl-1 azonia-4-azobicyclo[2, 2, 2]octane silicate. The synthesis was carried out in the presence of sodium aluminate and at 80–120°.[331]

The erionite-like zeolite, designated usually as zeolite T, zeolite AW-400, or Linde T, has a hexagonal structure with $a = 13{\cdot}25$ Å, $c = 15{\cdot}12$ Å and density 2·07 g/cm³. The dimensions of the 8-membered windows are 3·5 × 4·7 Å and the cavity diameter corresponds to 6·3 Å. The number of these cavities is about $\frac{2}{3}$ that in chabazite.[335] From the electron-density map it has been concluded that the Na^+ and Ca^{2+} cations are placed in the large cavities.[338] Attempts to replace all K^+ ions from the pure potassium form of this zeolite indicate that 25% of the total cations, or one of the 4 cations per unit cell, are not exchangeable below 300°. Structural conditions make it likely that the non-exchangeable K^+ ion in each unit cell is placed in the small cancrinite cage.[333] The synthetic erionite of composition $0{\cdot}5K_2O{\cdot}5Na_2O{\cdot}Al_2O_3{\cdot}6{\cdot}6SiO_2{\cdot}5{\cdot}5H_2O$ does not lose its structure after replacement of the Na^+ and K^+ ions by H^+.[334,336] Univalent ions are preferred, sorption decreasing in the order $Cs^+ > Rb^+ > Ag^+ > K^+ \geqslant NH_4^+ > Na^+ > Li^+$, with large separation factors between adjacent alkali metal ions. It has been concluded that synthetic erionites prefer K^+ to Ba^{2+} and Ca^{2+} ions.[332,333] An inverse relation was noted between SiO_2/Al_2O_3 ratios and bivalent cation selectivities for the Na^+–Sr^{2+}, Na^+–Ca^{2+} and Sr^{2+}–Ca^{2+} ion-exchange equilibria.[327] Separation of heavy metals is also possible on these materials.[332] Synthetic erionites are stable up to 800°, which may be explained by the relatively high Si:Al ratio.[336] The prolonged treatment of erionite with an excess of dilute acids involves de-alumination; the Al lost thus may reach 40%. The process is expressed by the equation:



Over the temperature ranges 200–400° and 450–550°, these de-aluminated erionites release more water than exists in the starting materials. This is a direct verification of the existence of SiOH groups created by de-alumination.[336] Covalently bonded OH groups were found in the acid centres of decationized erionite. It is interesting, that compared with the original phase, an enhanced H_2O content in the H-centres was detected by PMR.[337]

Analcite-like and phillipsite-like zeolites

The analcite group contains two main minerals: analcite ($Na_2O{\cdot}Al_2O_3{\cdot}4SiO_2{\cdot}2H_2O$) and wairakite ($CaO{\cdot}Al_2O_3{\cdot}4SiO_2{\cdot}2H_2O$). These possess a three-dimensional rigid framework and, like phillipsite [$(K_2,Ca)O{\cdot}Al_2O_3{\cdot}4SiO_2{\cdot}4\text{-}5H_2O$], they are characterized by the SiO_2/Al_2O_3 ratio usually ranging from 3·18 to 5·26. All these minerals have corresponding synthetic analogues.[316,327,341–346] Synthetic analcite[316] has an extremely slow rate of water self-diffusion and very high values of the corresponding activation energies[341] as compared with other zeolites. The extent of replacement of Na^+ ions by small bivalent or univalent cations exceeding a certain size is quite limited.[342] Synthetic wairakites[316] in the Sr^{2+}- and Ca^{2+}- forms prefer the univalent Na^+ cations to the bivalent Ca^{2+} and Sr^{2+} ions.[343] A phillipsite-like zeolite was prepared under precise hydrothermal conditions (to prevent the formation of faujasite).[344] Phillipsite is a zeolite closely related to zeolite B, which has the same composition as zeolite X.[345] Three different structures of sodium-phillipsite (NaP) synthetic zeolites may exist: (1) with primitive cell, where $a \geqslant c$, and the Li^+- and Na^+-forms are tetragonal and the Mg^{2+}-, Co^{2+}-, Ni^{2+} and Cu^{2+}-forms are cubic; (2) with body-centred cell, where $a > c$ and the K^+-, Rb^+-, Cs^+- and Ag^+-forms are tetragonal; (3) with body-centered cell, where $c \geqslant a$, and the Ca^{2+}-, Sr^{2+}- and Ba^{2+}-(Pb^{2+})-forms are tetragonal and the Cd^{2+}-form is cubic. The NaP-type zeolite containing $(K_2, Ca)^+$ and H^+ has a structure identical with that of natural phillipsite.[346] Very low ion-exchange enthalpies were found for the Na^+–Sr^{2+}, Na^+–Ca^{2+} and Sr^{2+}–Ca^{2+} ion-exchange reactions on synthetic phillipsite.[327]

Other zeolites

In this group there are included the remaining zeolites with counterparts in natural minerals, modified types of zeolites, and purely synthetic aluminosilicates without natural analogues.

The synthetic yugawaralite ($4CaAl_2Si_5O_{14}\cdot 4H_2O$)[316] and the synthetic zeolite Sr–Q[329] have X-ray characteristics very similar to those of the natural mineral. Potassium analogues of the sodium forms of synthetic sodalite-like zeolite Zh, with composition $Na_2O\cdot Al_2O_3\cdot 2\cdot 1SiO_2\cdot xH_2O$[347] cannot be prepared by direct synthesis. In the systems Na_2O–Al_2O_3–SiO_2–H_2O with Si/Al ratio 5, the zeolite Zh crystallizes at lowest SiO_2 contents.[122] From the electron-density map it was concluded that Na^+ ions in the zeolite Zh are placed in the centres of cubo-octahedral cavities. No ions were detected inside the 6-membered oxygen windows.[347] Hydrothermal syntheses were undertaken with the systems SiO_2–$Al(OH)_3$–NaOH–H_2O—anions for preparing synthetic zeolites which behave as anion-exchangers. Anions were formed when the NaOH/SiO_2 ratio was 0·5–3·0, for orthorhombic nepheline hydrate I in the presence of OH^- or F^-, or with cubic sodalite or one of its derivatives in the presence of Cl^-, Br^- or I^-, or with hexagonal derivatives of cancrinite in the presence of SO_4^{2-}, CrO_4^{2-}, MoO_4^{2-}, WO_4^{2-}, NO_3^-, PO_4^{3-} or CO_3^{2-}. Much higher values of the NaOH/SiO_2 ratio caused formation of pure basic sodalite and hydroxyparacancrinite. These zeolites exchange OH^- groups with Cl^- anions at $>150°$.[348] Synthetic boehmite and pseudo-boemmite gels have been hydrothermally aged under acidic and neutral conditions.[349] Hydrothermal synthesis in the Li_2O–Al_2O_3–SiO_2 system leads to the formation of new zeolites. MCP II is an acid-resistant zeolite having a characteristic X-ray pattern, while MCP III is a layer-type mineral of the montmorillonite type, with possible composition $Li_2O\cdot(2Li_2O\cdot Al_2O_3)\cdot 8SiO_2\cdot xH_2O$, where the Li^+ ion appears as the exchangeable ion.[350] Zeolite L possesses a unique framework structure which has not been observed in any minerals. The structure has been tentatively ascribed to hexagonal β-tridymite. This zeolite has exceptional thermal stability and ability to exchange tervalent ions.[121] The zeolite of type Z-14HS was prepared by the paste method. This product retains a large percentage of its surface after steaming at 480–650°.[349] Modified zeolites have been prepared by treatment with multivalent elements, *e.g.*, zeolites with the general formula $(D_{2/n}O)_x$: MO_2:$(SiO_2)_y$ where D = univalent or bivalent metal, NH_4^+ or H^+, n = oxidation number of D, $x = 0\cdot 5$–$4\cdot 0$, M = Ti, Zr or Hf, and $y = 2$–10.[351] The zeolites with a high degree of Na^+-substitution were prepared by multiple treatment with saturated solutions of cations of group VI and VIII metals or the lanthanides and by subsequent heating at 140–550°.[352]

Practical ion-exchange applications of synthetic aluminosilicates

If the field of catalysis is excluded, relatively few interesting applications of the synthetic aluminosilicates have been suggested during the last five years. Most of these have been concerned with the removal of ions from waste solutions. ^{137}Cs may be recovered from fission-product wastes by zeolite ion-exchangers.[353] Mordenite- and erionite-like zeolites have been successful in the column separation of Cs^+ from the alkaline supernatant solutions in the Purex-process, desorption being effected by $3M\ (NH_4)_2CO_3$.[340] Two MCi of ^{137}Cs were recovered from Hanford wastes by an aluminosilicate ion-exchanger "Decalso".[354] Natural and synthetic aluminosilicate zeolites have been used for the removal of NH_4^+ in the presence of Ca^{2+}, Mg^{2+} and Na^+ ions from agricultural run-off and municipal waste-water.[355] Ag^+ can be separated from aqueous solutions by natural or synthetic aluminosilicates in the Na^+, K^+, or Na^+–K^+ forms. Ag^+ elution by concentrated NaCl or KCl solutions is possible without deterioration of the sorbent's ion-exchange properties.[356] The possibility of ^{137}Cs, ^{90}Sr and ^{91}Y removal from solutions containing variable amounts of humic acids has been studied on the Na^+–X type zeolite.[357] The zeolite 4–A was examined for adsorption of ^{137}Cs, ^{89}Sr, ^{60}Co and ^{106}Ru from NaCl solutions at $pH > 7$.[358] Separation of ^{106}Ru from ^{137}Cs, ^{152}Fe, ^{144}Ce and ^{60}Co on molecular sieve 4-A was successfully performed at pH 5.[359] The application of synthetic zeolites for removal of ruthenium from radioactive effluents has also been described.[360] Synthetic aluminosilicates MCPl, 2 and 3 were found to be effective adsorbents for radioactive waste disposal.[350]

Other practical applications are very limited. The cells of a solid-state battery, which perform satisfactorily even at 500°, utilize ion-exchanged crystalline zeolites as basic materials.[361] Papers containing crystalline zeolite particles[362] and ion-exchange membranes from natural or synthetic zeolites,[363] which were used for hyperfiltration and electrodialysis, have also been prepared. Zeolite applications in dissolution[364] and column chromatography[365] techniques are of secondary importance.

MISCELLANEOUS EXCHANGERS

Synthetic apatites

Various apatitic compounds have been studied with respect to their ion-exchange properties. Some of the anionic and cationic components of the apatitic structure $M_{10}(XO_4)_6Y$ are exchangeable, *e.g.*, where M = Ca, Sr, Ba, Cd and Pb, X = P, As, V, Cr(V), Mn(V), Si, Ge and Y = F_2, Cl_2, Br_2, $(OH)_2$, O and CO_3^{2-}. Hydroxyapatites containing Ca^{2+} ions and zeolitic water are the materials studied most.[370] Different methods of hydroxyapatite preparation are well known from the literature[371,372] and single crystals at least 1·4 mm in diameter can be prepared from single crystals of chloroapatite.[371] The structure, physicochemical properties, thermal stability, infrared spectra and ion-exchange properties of Ca^{2+}, Sr^{2+} and Ba^{2+} salts have been reported.[370] The adsorption of ^{45}Ca tracer on calcium hydroxyapatites, has been shown to proceed by a reversible iso-ionic exchange process at laboratory temperatures.[373] However, the ion-exchange of Ca^{2+} for univalent cations such as Li^+, Na^+, K^+ and Cs^+ was verified though the $(CH_3)_4N^+$ cation was found to be unexchangeable.[374]

Many authors have shown interest in OH–Cl exchange in these compounds. At lower temperatures, such an ion-exchange is impossible,[370,375–377] but at 250° and high pressure the exchange process occurs with limited reversibility and is dependent on the crystallographic parameter *a* of the sorbent,[375,376] on the chloride concentration in the system,[375] and on the Sr/(Pb + Sr) and Sr/(Ba + Sr) mole fraction.[376] The mixed Ca^{2+}–Ba^{2+} hydroxyapatite adsorbs chloride ions negligibly at higher temperatures. However, the process was found to be reversible.[377]

The presence of Na^+ and Pb^{2+} ions increases the exchange capacity for Cl^-. Na^+ ions favour the diffusion into the lattice channels by introducing vacancies at anionic sites. Pb^{2+} ions favour the diffusion into tunnels in the lattice as a result of the higher polarizability of Pb^{2+} relative to that of Sr^{2+} and Ba^{2+} ions.[376] On the other hand the presence of Na^+ ions gives rise to a shortening of lattice parameters as well as enhancing the exchange reversibility.[378] The compound $Sr_xPb_y($ [illegible] $_4)_6(OH)_2$ $(x + y = 10)$ sorbed Cl^- at room temperature and good reversibility of exchange was given by $Sr_3Pb_7(PO_4)_6(OH)_2$.[375] The exchange capacity for Na^+ was considerably increased by introducing Pb^{2+} ions into the alkaline earth hydroxyapatite lattice.[378]

OH–F exchange on synthetic and natural hydroxyapatites is facilitated by increase of the fluoride concentration and decrease in pH[370,379–381] and is strongly dependent upon the surface.[381] Non-stoichiometric compounds, *e.g.*, $Ca_{10}(PO_4)_6(OH,F)$, are formed,[379] and the exchange process is partially reversible.[377] Sodium monofluorophosphate is a less efficient agent than NaF for fluorinating the hydroxyapatites.[381] The first rapid stage of exchange is surface-dependent and the second slow stage may be diffusion-controlled.[380]

Two kinds of structural effects must be considered when trying to account for adsorption processes of the hydroxyapatites: those which are due to channels around the screw axis and those which are connected with the whole lattice. Occurrence of channels is connected with anisotropy of ionic conductivity, high diffusion rates along the channels, ion-exchange properties, and the ability of the apatitic lattice to fix some salts in the channel sites. The whole lattice arrangement enables CO_3^{2-} ions to be placed in sites out of the channels.[372]

The ion-exchange properties of strontium hydroxyapatites in the systems containing Na^+, Ca^{2+}, Ba^{2+} and Pb^{2+} ions have been described.[378] The OH^- content in these compounds is lower than the theoretical content and increases with decreasing content of Na^+ in the systems.

All problems connected with the synthesis, structure, structural properties and single-crystal preparation of fluoro, chloro and hydroxyapatites have been critically reviewed by Montel.[372]

Insoluble sulphides

The ion-exchange properties of a wide range of insoluble sulphides, *e.g.*, Ag_2S, FeS, CuS, ZnS, PbS, CdS, NiS, As_2S_3 and Sb_2S_3 have been studied in recent years.[382–386] These materials are usually prepared by precipitation from metal salt solutions with H_2S or Na_2S. Precipitation at low temperatures (70·5–253 K) leads to formation of granular materials with particle size increasing with decreasing temperature.[384,386,387]

The sulphides are selective towards cations forming insoluble sulphides. The exchange reaction proceeds primarily through metathetical reactions in which the metal of the sulphide is displaced by appropriate ions in the solution.[388] The exchange reactions are usually fast and can be carried out in small columns.[386,388,389] Quantitative adsorption of Pb^{2+}, Cu^{2+}, Mn^{2+}, Co^{2+}, Ni^{2+} and Tl^{+} has been reported on ZnS, CdS and PbS,[389] of Pb^{2+}, Cd^{2+} and Cu^{2+} on NiS,[387] and of Cu^{2+} on ZnS and CdS. An equivalent exchange of the metal ion from the solution for the metal of the sulphides has been found.[387] The selectivity series for bivalent cations corresponded to the solubilities of freshly prepared amorphous sulphides.[389] On the other hand, no correspondence has been found with the solubilities of sulphide minerals.[383,389] The adsorption of Cu^{2+} on ZnS has been shown by X-ray measurements to proceed *via* formation of CuS. The limiting precipitate composition expressed by the formula NiS·2CuS has been found for the adsorption of Cu^{2+} on granular NiS.[390]

The rate and extent of conversion of the insoluble sulphides are determined by rates of diffusion of the pertinent ionic species in the solids. For example, the high reaction rates of Ag^{+} with most sulphides are connected with the large self-diffusion coefficient of Ag^{+} in Ag_2S.[388] However, some other processes such as physical adsorption[389] and oxidation-reduction processes[384] may accompany the ion-exchange reactions in these materials.

Alkaline earth sulphates

Special attention has been paid to materials based on the barium sulphate lattice. Two main applications of these materials have been studied. The first is the use of barium sulphate as a co-precipitation agent, where generally all positive ions of a charge >2 and an ionic radius larger than $\sim 1 \cdot 1$ Å are co-precipitated and can thus be isolated from solutions with 99% completeness or better. Although the exact adsorption mechanism is not clear, the strict dependence of efficiency on the ionic size and charge suggests isomorphous replacement in the $BaSO_4$ lattice.[391] However, the field of co-precipitation is well outside the scope of this Review. The second is based on the adsorption properties of barium sulphates with artificially introduced crystal-lattice defects.

Thus $BaSO_4$ preparations possessing enhanced sorption activity especially for Sr^{2+} have been prepared either by the partial metasomatic transformation of $CaSO_4$ into $BaSO_4$ by contacting the former with solutions of soluble barium salts, or by the heat treatment of the mixture of $BaSO_4$ and $CaSO_4$ above the $\beta \rightarrow \alpha$ transformation temperature (above 1000°), where both sulphates are miscible, with subsequent rapid chilling of the glowing mass in water.[392,393] These materials can also be prepared by the simultaneous precipitation of the insoluble sulphates from solutions of soluble barium salts containing salts of other metals, especially of calcium.[394] By the procedure involving the heat treatment, the metastable product is obtained with calcium sulphate fixed in the $BaSO_4$ lattice.[392,393] When placed in water, the weakly bound $CaSO_4$ component is eluted with consequent rapid recrystallization in the whole mass. During this process, ions, the sulphates of which are isomorphous with $BaSO_4$, are rapidly incorporated and thus may be removed from the solution. By the recrystallization and by the incorporation of these ions, the existing lattice stress is abolished, mixed crystals being formed.[392–395] The heat-treated and rapidly chilled product exhibits X-ray diffraction patterns and infrared absorption spectra characteristic of $BaSO_4$ only. No $CaSO_4$ features were detected.[392,396,397] At least a part of the $CaSO_4$ adopts the space group of the low-temperature (β) modification of $BaSO_4$.[396,397] The unit-cell parameters of the heat-treated sorbents (obtained by repeated recycling) are $a = 8{\cdot}480$, $b = 5{\cdot}397$, and $c = 6{\cdot}956$ Å, which are practically identical with the parameters of anglesite.[398] This coincidence of lattice parameters was suggested as a possible factor in promoting the selectivity for Sr^{2+}.[398] A nearly eutectoid mixture of $BaSO_4/CaSO_4 = 60/40$ mole % was found most convenient for preparation of the sorbents,[393,394,397,399] with the optimum cooling time 30 sec.[400] Different cooling media were examined, and thermal cycling facilitated formation of larger crystals.[400,401] Specific surface measurements of different preparations have been correlated with the adsorption abilities.[401] The radiation stability of these materials was found to be satisfactory but doses up to 5×10^9 rad caused a gradual decomposition into the original components.[402,403] Great attention has been paid to the sorption of Sr^{2+} on these materials in the presence of large amounts of Ca^{2+} ions.[393–395,399,401] The first stage of Sr^{2+} adsorption is a reversible ion-exchange process obeying the law of mass-action. The values of the diffusion coefficients and activation energies showed the existence of steric hindrance. The final stage of Sr^{2+} adsorption is an irreversible process.[392] Trace levels of Sr^{2+} were successfully separated from a large excess of Ca^{2+} ions under different conditions,[392,394,395] and practical applications in medicine and in waste-water decontamination on a pilot-plant scale were realized.[23]

CONCLUSION

In Parts I[1] and II of this Review we have attempted to cover as completely as possible the published papers in the field for the period 1965–70, both from the Western and Eastern countries, and especially those which are not easily available.

The number of materials which may be understood as inorganic ion-exchanging substances has grown enormously during the period reviewed. However, because the ion-exchange processes in many substances are accompanied by other phenomena such as physical adsorption, surface adsorption, precipitation and co-precipitation processes, lattice defects, *etc*, it has been difficult to find an exactly limited scope for the term "inorganic ion-exchanger." We have therefore included all the cases where at least some features of the ion-exchange process could be distinguished.

There appears to have been a marked trend towards providing a more exact explanation of ion-exchange reactions rather than studying purely practical separation applications. The basic studies of ion-exchange mechanisms have been carried out on defined crystalline materials, the detailed structures of which, along with the location of the exchanging ions in the crystal lattice, are of great interest. This knowledge, accompanied by the determination of the main thermodynamic functions, has permitted a full explanation of the ion exchange process. These studies have till now been carried out on synthetic zeolites and some acidic salts of multivalent metals. This tendency will probably also be extended to the other materials.

It is interesting that the ion-exchange process in many substances is connected with formation of defined insoluble compounds of the ingoing ion with the "matrix," and that the formation of two distinct solid phases has been detected in some cases. These facts together with the other observed phenomena mentioned above suggest that the ion-exchange processes in the case of inorganic ion-exchangers are of complex character and that the traditional treatment of these processes in terms of pure ion-exchange do not fully describe all aspects of the process.

Zusammenfassung—Ein Überblick über die Entwicklungen während der Jahre 1965–70 im Gebrauch von Salzen der Heteropolysäure, von Cyaneisenverbindungen und synthetischen Zeolithen als Ionenaustauscher.

Résumé—Une revue des développements durant la période 1965–1970 dans l'emploi des sels d'hétéropoly acides, de ferrocyanures et de zéolites synthétiques comme échangeurs d'ions.

A CONTRIBUTION TO THE PROBLEM OF INCREASING THE SENSITIVITY OF ANODIC-STRIPPING VOLTAMMETRY

LUDMILA HUDEROVÁ and KAREL ŠTULÍK®
Research Institute for Pharmacy and Biochemistry, and
Department of Analytical Chemistry, Charles University, Prague, Czechoslovakia

(*Received* 18 *January* 1972. *Accepted* 3 *March* 1972)

Summary—A brief discussion of problems connected with increasing the sensitivity of anodic-stripping determinations is presented. A new microcell for anodic-stripping voltammetry in solution volumes down to about 0.01 ml was constructed. The effect of the solution volume, the mercury-drop electrode size, and of the pre-electrolysis time and potential on the sensitivity of determinations was studied and the reproducibility of results for determinations of lead in mineral acids is given. It was found that nanogram amounts of heavy metals can easily be determined in this way. In determination of 2 ng of Pb^{2+} in 0.02 ml of solution the results were 2.00 ± 0.13 ng (95% confidence limits), the mean relative deviation being 6.3%. For determination of copper in KNO_3, stripping microanalysis was compared with atomic-absorption spectrophotometry. Advantages and disadvantages of stripping voltammetry on the macro- and micro-scales are discussed.

TWO OF THE MOST IMPORTANT ASPECTS of anodic-stripping voltammetry, as with any other analytical technique, are its selectivity and sensitivity. The former was dealt with in our previous paper.[1] The problem of increasing the sensitivity is chiefly that of increasing the electrolytic current due to dissolution of the species monitored, compared to the background current value. In d.c. voltammetry, the detection limit is represented by electrolytic currents of the order of tenths of nanoamperes; at lower values, the signal-to-noise ratio is already too low for obtaining unambiguous results.

One way of improving the signal-to-noise ratio is utilization of a more sensitive measuring method (*e.g.*, a.c. voltammetry or square-wave polarography, see for example ref. 2). These methods are subject to two serious drawbacks, namely, the necessity of employing much more involved apparatus and the fact that with slow charge-transfer reactions the gain in sensitivity is very small and frequently non-existent.[3,4] Another way is to carry out the stripping process under conditions of convective diffusion (stirring, rotating or vibrating electrodes *etc*, see for example ref. 5). The disadvantage of this approach is poorer accuracy and precision, especially if solid electrodes are used. Nonetheless, the application of rotating disk electrodes, either solid or mercury thin-layer electrodes, seems to be very promising.[6] The sensitivity may also be improved by using mercury thin-layer electrodes, because of a more favourable ratio of the active surface to the volume of mercury (see for example ref. 7). There is an additional advantage in increased selectivity, owing to the very narrow peaks obtained.

If the conventional type of apparatus is employed for anodic-stripping voltammetry, there is still the possibility of varying the sensitivity of measurement by means of variations in the solution volume, mercury-drop electrode size, and the pre-electrolysis time, the pre-electrolysis potential being usually determined by the selectivity requirements. The dependence of the anodic peak current, I_a, on the experimental conditions is a complex function and according to Stromberg and Zakharov[8] it may be written in the following form:

$$I_a = a(1 - e^{-b})$$

where

$$a = 3K_1 c_M{}^{\circ} V \frac{1}{r} \quad ; \quad b = 4\pi K_e r^2 \frac{t}{V}$$

K_1 being a proportionality constant, K_e an electrolytic constant depending upon the pre-electrolysis potential and hydrodynamic conditions, $c_M{}^{\circ}$ the initial metal concentration in the solution, V the solution volume, r the mercury-drop radius, and t the pre-electrolysis time.

From analysis of these equations it follows[8] that, for small values of $b (< 0{\cdot}1)$, when V is sufficiently large and t and r are sufficiently small, the peak height is independent of V and is directly proportional to r and t. The concentration in the solution is practically unchanged after pre-electrolysis. For $0{\cdot}1 < b < 3$ the peak height increases with increasing t and V up to a certain limiting value, while the dependence of I_a on r exhibits a maximum at $b = 1{\cdot}26$. For $b > 3$, when V is sufficiently small and t and r sufficiently large, the peak height is independent of t (the metal is practically completely removed from the solution during pre-electrolysis), directly proportional to V and indirectly to r.

In the present paper we have attempted to show that the conditions in the last case ($b > 3$) are advantageous not only for increasing the sensitivity of the method but generally for any stripping determination.

For work with very small volumes, a special microelectrolytic cell had to be constructed, since no convenient microcell has been described in the literature so far. Several microcells have been constructed for polarography,[9–12] amperometric titrations,[10,13–15] coulometry,[16] and chronopotentiometry.[17] The two microcells which have been constructed for stripping analysis, one for volumes of 0·3–0·5 ml[18] and the other for 1–2 ml,[19] still employ volumes that are too large for our purposes, and are actually only miniatures of normal polarographic cells.

EXPERIMENTAL

Reagents

The mercury used was of *pro analysi* purity, further purified by distillation. Water was redistilled in a quartz apparatus.

The mineral acids (H_2SO_4, $HClO_4$) were of *pro analysi* purity.

Stock solutions of $Cu(NO_3)_2$ and $Pb(NO_3)_2$ ($10^{-2}M$) were prepared by dissolving the metals ("extrapur", Soyuzkhimeksport, Moscow) in dilute nitric acid, evaporating to dryness, and dissolving the residue in water. From these stock solutions freshly diluted solutions were prepared daily.

Apparatus

The PO-4 polarograph (Radiometer, Copenhagen) was used for voltammetric measurements. The nitrogen used for deaerating and stirring the electrolysed solutions was freed from oxygen by passage through a column containing zinc amalgam and a 0·2% w/v solution of sodium anthraquinone-2-sulphonate in 1*M* sodium hydroxide, and its flow-rate was measured with a bubble flow-meter. Mercury drops were produced from a 1-ml syringe burette (Manostat, USA), readable to 0·1 μl. In some cases the size of the drops was checked by weighing. The depolarizer solutions were measured with the Agla 0·5-ml syringe burette, readable to 0·2 μl.

The determination of copper in potassium nitrate by atomic-absorption spectrophotometry (AAS) was performed with a Unicam SP 90 spectrophotometer with an air–acetylene flame.

Design of the microelectrolytic cell

The types of microcells proposed by Majer for polarography,[8] which basically consist of a large mercury surface, onto which a drop of solution is placed, are unsuitable because of the instability of the drop and the impossibility of maintaining an inert atmosphere. The best results were obtained with the cell shown in Fig. 1.

The cell consists of a glass U-tube with one arm widened to form an electrolytic space. In the bottom of this space is sealed a platinum contact. The other arm is filled with mercury to provide electrical contact with the platinum wire. The electrolytic space is closed with a stopper with three openings, for the capillary of the salt bridge of the reference electrode, the capillary of the nitrogen inlet, and for nitrogen outlet. The cell itself is placed in a larger glass container and fixed in place with plastic foam. Under normal conditions, the air mantle thus formed around the vessel itself keeps the temperature sufficiently constant. However, if desired, it is very easy to provide the vessel with a constant-temperature mantle.

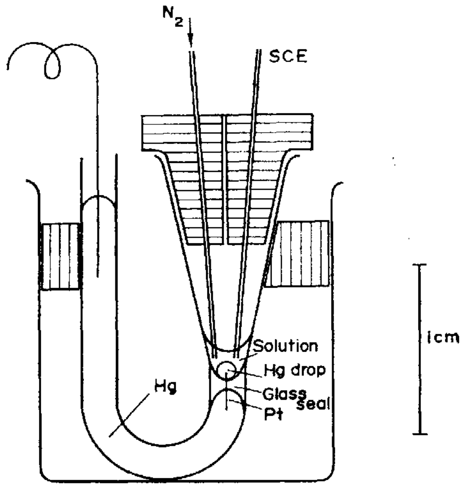

FIG. 1.—The microelectrolytic cell.

The vessel makes possible the stripping analysis of as little as 10 μl of solution, using mercury drops of various sizes as electrodes. Nitrogen serves both for deaerating the solution and for stirring during pre-electrolysis.

Procedure

A mercury drop of the desired size is measured and put on the platinum contact in the bottom of the electrolytic space. Instead of measuring the drops with a syringe burette as in the present paper, it is advantageous to use an ordinary polarographic capillary, which produces drops of fairly reproducible size. Then the solution is measured into the cell, passage of nitrogen is begun, and the solution is electrolysed at a preset potential for a predetermined time. The passage of nitrogen is stopped, electrolysis is continued for a certain time in the quiet solution, and then the dissolution peaks are recorded. Owing to the very small volume of the solution, the deaeration is accomplished in a very short time interval and thus can be performed simultaneously with the pre-electrolysis. Nitrogen is passed above the level of the solution during the electrolysis in the quiet solution and during the potential scan.

In the present paper, the following conditions were utilized, unless stated otherwise: a mercury-drop size of 5 μl, a pre-electrolysis time of 5 min, 30 sec of electrolysis in a quiet solution, a saturated calomel reference electrode (SCE) connected with the cell by a capillary bridge filled with a saturated solution of potassium nitrate and closed with an agar plug (the bridge was connected to the electrode by a ground-glass joint), a nitrogen flow-rate of 20 ml/min, a potential-scan rate of 800 mV/min, a chart speed of 80 mm/min.

All potentials are referred to the SCE. The measurements were performed at 22 ± 0·5°.

Notes for work with the microcell

The capillary for introducing nitrogen should be very fine to prevent splashing of the solution. Care should be taken to prevent contact of the solution with the platinum wire and formation of gas bubbles between the platinum wire and the mercury drop (which can happen during passage of nitrogen at too high a flow-rate). To prevent formation of air bubbles in the orifice of the capillary bridge of the SCE it is advantageous to cover it with a piece of sealed polyethylene tubing when not working. It is advantageous to work with several cells so that new samples can be prepared during the analysis of those already prepared.

RESULTS

The reproducibility of the mercury-drop size was checked by weighing. It was found, from ten measurements with 8-μl drops (0·10872 g), that the maximum relative deviation was 1·33%, mean relative deviation 0·67%, and the standard deviation $8{\cdot}9 \times 10^{-4}$g.

Dilute mineral acids (perchloric, sulphuric) were found to be the best base electrolytes, since they contain relatively the smallest amounts of metallic impurities. The most suitable concentration of the base electrolyte was found to be about 0·1*M*.

Dependence of the peak current on the pre-electrolysis time, potential, and the drop size

It was found that amounts of depolarizer of the order of tens of nanograms in tens of microlitres of solution are completely transferred into the mercury drop (5 μl) in about 4 min of pre-electrolysis at the potential of the depolarizer limiting current. A typical dependence of the peak current on the pre-electrolysis time is shown in Fig. 2.

On the basis of this result, a 5-min pre-electrolysis with a 30-sec electrolysis in the quiet solution was used in all succeeding experiments. It is obvious that in practical applications this value must always be determined for the particular measuring conditions utilized. Experiment showed that the precision improved with increasing pre-electrolysis time, the optimum time being about 4–5 min.

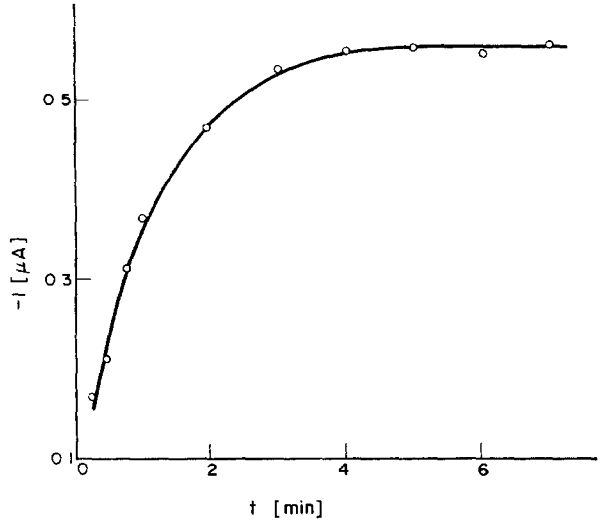

FIG. 2.—The dependence of the lead peak-current on the time of pre-electrolysis. 40 ng of Pb^{2+} in 40 μl of 0·1*M* $HClO_4$, pre-electrolysis potential, −1·5 V. (The pre-electrolysis time given in the graph corresponds to the pre-electrolysis in the nitrogen-stirred solution; this was followed by a 30-sec electrolysis in quiet solution).

The dependences of the copper and lead peak-currents on the pre-electrolysis potential are shown in Fig. 3. This dependence has the shape usually found in stripping analysis, the only difference from that for analysis in larger amounts of solutions being that there is no peak-current increase due to the stirring of the solution by hydrogen evolving at very negative potentials (*cf.* curve *c* in Fig. 3, which has been taken from Fig. 1 of our previous paper[1]). Evolution of hydrogen at higher potentials does not increase the peak current since the depolarizer is already completely electrolysed into the mercury drop under given conditions so that nothing can be gained by increasing the rate of stirring of the solution. In practice the pre-electrolysis potential may, therefore, be set at any value corresponding to complete removal of the depolarizer from the solution under the given working conditions.

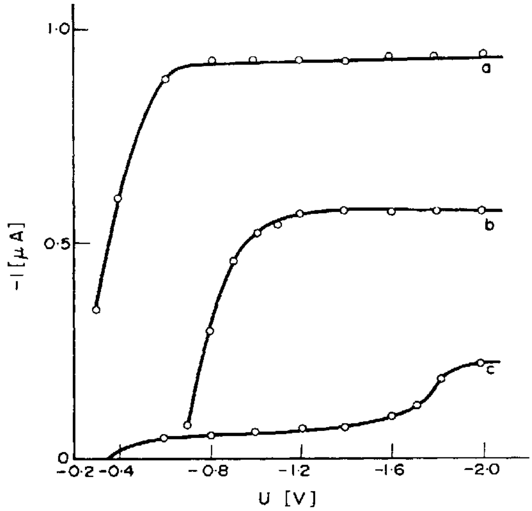

FIG. 3.—The dependence of the copper and lead peak-currents on the pre-electrolysis potential.
(*a*) 40 ng of Cu^{2+} in 0·1*M* H_2SO_4; (*b*) 40 ng of Pb^{2+} in 0·1*M* $HClO_4$; solution volume, 40 μl; 5 min pre-electrolysis. (*c*) 10^{-6}*M* Pb^{2+} in an acetate buffer, 15 ml of solution, 2 min pre-electrolysis, Kemula electrode.[1]

The dependence of the lead peak-current on the mercury-drop size is given in Fig. 4, and is in agreement with the conclusions reached by Stromberg and Zakharov.[8] Unfortunately, the active area or the radius of the mercury drop could not be found since the shape of the drop is determined by the geometry of the bottom of the microcell and only a part of the mercury surface is actually in contact with the solution. In any case, it is evident from the dependence that the sensitivity of determinations increases with decreasing size of the mercury-drop electrode, but that the variations in the drop size will have a progressively greater effect on the reproducibility of determinations as the drop is made smaller.

For large volumes of solution (of the order of tens of millilitres) the dependence of the peak currents on the mercury-drop size is reversed: the current increases with the drop size.[20–23] On further increase of the drop size, a dependence exhibiting a maximum would probably eventually be obtained. Some workers[20,23] actually

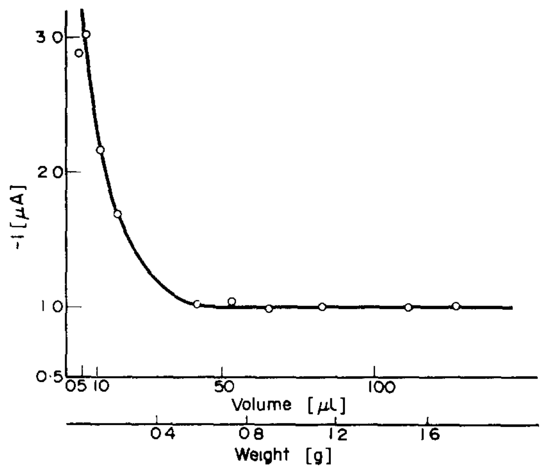

FIG. 4.—The dependence of the lead peak-current on the size of the mercury-drop electrode.

150 ng of Pb^{2+} in 0·03 ml of 0·1*M* $HClO_4$. 10 min pre-electrolysis at a potential of −1·5 V.

found that the peak-current–drop-size dependence reaches a certain limiting value.

In contrast to the conclusions reached by Stromberg and Zakharov,[8] direct proportionality between the solution volume and the peak current has not been found over the volume range 0·01–0·1 ml. There is no change in the sensitivity due to variations of the solution volume within this interval. Apparently, the drop size and consequently the concentration of the depolarizer in the amalgam is the decisive factor, and in comparison the effect of the solution volume is negligible in this interval of very small volumes where all the depolarizer is transferred into the drop during pre-electrolysis.

Reproducibility of results and calibration curves

The reproducibility with the microcell was studied by using small amounts of lead in 0·1*M* perchloric acid. The results are summarized in Table I. It follows that

TABLE I.—THE REPRODUCIBILITY OF DETERMINATIONS OF LEAD IN 0·1*M* $HClO_4$. [2 ng OF Pb^{2+} IN 20 μl OF SOLUTION; MERCURY DROP 5 μl; 5 min PRE-ELECTROLYSIS AT −1·5 V; 1 mm CORRESPONDS TO 4 nA (1 μA FULL SCALE DEFLECTION)].

Peak height *h, mm*	$\bar{h}$, *mm*	Absolute deviation Δ*h, mm*	$\Delta\bar{h}$, *mm*	Relative deviation ε, %	$\bar{\varepsilon}$, %	Standard deviation, *s, mm*
8·0	8·0	0·0	0·5	0·0	6·25	0·74
8·5		0·5		6·25		
6·5		1·5		18 75		
8·0		0·0		0·0		
7·0		1·0		12·5		
9·0		1·0		12·5		
8·0		0·0		0·0		
8·0		0·0		0·0		
8·5		0·5		6·25		
8·5		0·5		6·25		

the reproducibility is good. The lead concentration determined is $4{\cdot}83 \times 10^{-7}M$. If the same amount of lead were to be determined in 10 ml of solution it would correspond to $9{\cdot}6 \times 10^{-10}M$ which is already below the detection limit of the classical stripping determination of lead. There is still the possibility of decreasing by almost one order the amount determined by using the microcell, if a higher polarographic sensitivity is employed.

Calibration curves were determined for copper in $0{\cdot}1M$ sulphuric acid and for lead in $0{\cdot}1M$ perchloric acid in 20 μl of solution, from 1 to 40 ng and 1 to 150 ng, respectively, corresponding to the concentration ranges $7{\cdot}9 \times 10^{-7} - 3{\cdot}1 \times 10^{-5}M$ and $2{\cdot}4 \times 10^{-7} - 3{\cdot}6 \times 10^{-5}M$, respectively. The calibration curves were perfectly linear and passed through the origin. The peaks corresponding to these concentrations are very well developed.

Determination of copper in pro-analysi *potassium nitrate*

As an example of a practical application, copper was determined in pure potassium nitrate. The following conditions were used: a 12% KNO_3 solution in $0{\cdot}1M$ H_2SO_4 was analysed; the analysis was performed in 20 μl of solution, with a drop size of 5 μl, pre-electrolysis time of 5 min and potential of $-1{\cdot}0$ V. The method of standard addition was employed, using 0·02 ml of a standard solution containing 0·5 μg of Cu^{2+}/ml. From four measurements the value found was $3{\cdot}30 \pm 0{\cdot}12 \times 10^{-4}\%$ copper (95% confidence limits).

A parallel determination in a 6% KNO_3 solution by AAS, using an air–acetylene flame and standard solutions containing 0·5–0·2 μg of Cu^{2+}/ml, gave a value of $4{\cdot}8 \times 10^{-4}\%$.

The determination by AAS is just at the detection limit under the given conditions: peaks about 5 mm high were obtained at the maximum sensitivity of the instrument. Moreover, the concentration of potassium nitrate cannot be increased above 6% (the producer of the instrument does not recommend analyses of more concentrated solutions than about 6%, because of difficulties involved in atomizing the entire sample and clogging of capillaries). On the other hand, the stripping determination provided peaks 40–80 mm high at a sensitivity of 1 μA full-scale deflection. The sensitivity of determination can be further increased by using sample solutions more concentrated than 12% and by increasing the sensitivity of the current measurement.

DISCUSSION

As follows from the results above, stripping analysis in very small volumes of solution makes possible determinations of substantially smaller amounts of metals than conventional stripping voltammetry. Of course, the *concentration* determinable is approximately the same. The dependences of the peak current on the working conditions correspond basically to the conclusions arrived at by Stromberg and Zakharov.[8]

Besides the obvious advantages of the stripping microanalysis, which are the possibility of carrying out an analysis even if a very small amount of sample is available, and very low consumption of chemicals, there are several general advantages over conventional stripping voltammetry. The apparatus is very simple and there is no need for any special parts (stationary-drop electrodes, stirrers) in addition to the usual type of polarograph. The deaeration of the solution is very fast and effective.

The mercury drops for the electrodes can be produced by an ordinary polarographic capillary. For this reason, the troubles which frequently occur with the Kemula type of stationary-drop electrode, *e.g.*, air bubbles in the reservoir and the capillary, drop instability, solution penetration into the capillary *etc*, are avoided.

The chief advantage of the microanalysis is that all the depolarizer is transferred into the mercury drop during the pre-electrolysis. In this way all sources of error stemming from variations in the pre-electrolysis time, potential, stirring rate, and temperature are eliminated. The only thing necessary is to find a time sufficient for complete electrolysis and to use a safety margin to provide for variations in the working conditions. These times are relatively short in analyses of very small amounts. Possible defects in the microcell (gas bubbles between the platinum contact and the mercury drop) are easily detectable and removable. The time required for an analysis is shorter with the microcell.

During tests with the microcell it was also found that it is very convenient for cyclic voltammetry; very narrow, sharp, and reproducible peaks were obtained.

Work with the microcell, however, places greater demands on clean and careful work. For measurements at very low concentrations it is desirable to use shielded leads from the electrodes. A disadvantage also lies in the fact that greater accuracy and precision of measuring solution volumes is necessary (as with all micro-techniques). If all these conditions are fulfilled, the accuracy and precision are very good and under optimum conditions even sub-nanogram amounts of certain elements can be determined.

If the method is compared with AAS it is found that stripping microanalysis is more sensitive and precise for certain metals, *e.g.* Cu, Pb, Cd, and that the apparatus is substantially simpler and cheaper. On the other hand, routine determinations by AAS are faster and the method has a broader application. In many cases work with AAS entails fewer difficulties with interferences but, on the other hand, stripping analysis more frequently makes possible simultaneous determinations of several elements and such determinations can be performed more easily. In many cases, stripping analysis makes possible determinations in very concentrated matrix solutions while in AAS very concentrated salt solutions cannot be used. As can be seen from the discussion, stripping analysis and AAS can often complement each other in the broad spectrum of routine determinations.

Zusammenfassung—Es wird eine kurze Besprechung von Problemen gebracht, die mit Steigerung der Empfindlichkeit anodischer Abscheidungsbestimmungen verbunden sind. Es wurde eine neue Mikrozelle für anodische Abscheidungsvoltampèremessung in Lösungsvolumen bis hinunter auf etwa 0,01 ml konstruiert. Es wurde die Wirkung des Lösungsvolumens, der Quecksilbertropfengrösse der Elektrode und der Zeit und des Potentials vor Elektrolyse auf die Empfindlichkeit der Bestimmungen untersucht, und es wird die Reproduzierbarkeit der Ergebnisse für Bestimmungen von Blei in Mineralsäuren wiedergegeben. Es wurde gefunden, dass Nanogrammengen schwerer Metalle leicht auf diese Weise bestimmt werden können. In Bestimmungen von 2 ng Pb^{2+} in 0,02 ml Lösung waren die Ergebnisse 2,00 ± 0,13 ng (95% Vertrauensgrenzen), die mittlere relative Abweichung war 6,3%. Mikroanalyse für Abscheidung zur Bestimmung von Kupfer in KNO_3 wurde mit atomischer Absorptionsspektralphotometrie verglichen. Es werden Vorteile und Nachteile der Abscheidungsvoltampèremessung auf die Grösst- und Kleinstabscheidungen besprochen.

Résumé—On présente une brève discussion des problèmes liés à l'accroissement de la sensibilité des dosages par dissolution anodique. On a construit une nouvelle microcuve pour la voltammétrie de dissolution anodique dans des volumes de solutions descendant jusqu'à 0,01 ml environ. On a étudié l'influence du volume de solution, de la dimension de l'électrode à goutte de mercure, et du temps et du potentiel de pré-électrolyse sur la sensibilité des dosages et l'on donne la reproductibilité des résultats pour les dosages du plomb dans les acides minéraux. On a trouvé que des quantités de l'ordre du nanogramme de métaux lourds peuvent être aisément déterminées de cette manière. Dans le dosage de 2 ng de Pb^{2+} dans 0,02 ml de solution, les résultats ont été de 2,00 ± 0,13 ng (limite de confiance 95%), la déviation relative moyenne étant 6,3%. Pour le dosage du cuivre dans KNO_3, la microanalyse par dissolution a été comparée à la spectrophotométrie d'absorption atomique. On discute des avantages et des désavantages de la voltammétrie de dissolution aux échelles macro et micro.

DETERMINATION OF AND DIFFERENTIATION BETWEEN CASSITERITE AND SILICATE-BOUND TIN IN SILICATE ROCKS CONTAINING TRACES OF TIN

J. AGTERDENBOS and J. VLOGTMAN
Laboratory for Analytical Chemistry, State University, Croesestraat 77A, Utrecht, Holland

(*Received* 5 *December* 1971. *Accepted* 10 *March* 1972)

Summary—A simple, sensitive and reproducible method is described for the determination of tin in silicate rocks at the ppm level. By applying a selective decomposition it seems possible to differentiate between tin present in the silicate lattice, in readily-accessible cassiterite (SnO_2) and in cassiterite enclosed in the silicate. The final determination is made by extraction and photometry with phenylfluorone. Results for total tin agree well with those obtained by X-ray fluorescence.

TIN OCCURS in many silicate rocks, often in concentrations far below 100 ppm. Part of this tin may be a constituent of the silicate lattice ("lattice-bound tin") and another part may be present in the form of cassiterite, tin(IV) oxide, and knowledge of their proportions is useful to geochemists, both for prospecting and for scientific studies.

Some of the methods for the determination of tin in ores have been described and compared by Jeffery.[1] With methods such as emission spectrography and X-ray fluorescence the total amount of tin is determined without risk of loss due to incomplete destruction, but the results do not differentiate between different types of tin. These techniques are not sensitive enough at the lower levels of tin concentration to be studied here.

Other techniques require a decomposition step. For the final determination several spectrophotometric procedures have been described. After preliminary experiments with Wood's[2] galleïne procedure, which did not give satisfactory results in our hands, we successfully used the method described by Gilbert and Sandell.[3] It consists of a separation of tin from other elements (especially germanium) by extraction of tin(IV) iodide into benzene, stripping into water and final determination with phenylfluorone. Atomic absorption may also be used,[4,5] but was not investigated in our study.

The ignition of sample with ammonium iodide at 400–500° (Caley and Burford[6]) quantitatively converts cassiterite into tin(IV) iodide, but lattice-bound tin is not attacked. The silicate lattice may be decomposed by treatment with a mixture of hydrofluoric and sulphuric acids, or perchloric and nitric acids. Cassiterite does not react with these mixtures. In this way "fresh" tin(IV) oxide is formed, and this may then be similarly treated with ammonium iodide to give tin(IV) iodide. "Fresh" tin(IV) oxide is also converted into tin(IV) iodide by hydriodic acid solution; cassiterite is not attacked by this reagent. These differentiations form the basis of the proposed method, which allows tin down to 3 ppm to be determined.

Other decomposition procedures include fusion with sodium peroxide, with potassium pyrosulphate and with a sodium carbonate–sulphur mixture.[1] None of these procedures enables tin present as cassiterite and tin present in the silicate lattice to be differentiated, and they do not seem useful at tin levels below 20 ppm. Total tin may be found by attacking the sample with hydrofluoric–nitric acid mixture, and then heating it with ammonium iodide.

EXPERIMENTAL

Apparatus

Destruction unit. Pyrex-tube 2 cm wide and 25 cm long fitted with a 40-cm Liebig condenser.

Platinum crucibles. About 20 ml capacity.

Reagents. All reagents were of analytical-reagent grade.

Destruction mixture. Mix two volumes of 40% hydrofluoric acid with one volume of 65% nitric acid.

Sulphuric acid, concentrated and 0·25M.

Ammonium iodide.

Twice-distilled demineralized water.

Hydriodic acid, 57% and 2·5M.

Wash liquid. Ammonium iodide (15 g) dissolved in 20 ml of 2·5*M* hydriodic acid.

Benzene.

Potassium hydrogen phthalate–hydrochloric acid buffer, pH 2·6.

Gum arabic solution, 1%. Discard the solution when it becomes turbid.

Phenylfluorone solution, 0·01%. Dissolve 10 mg of reagent in 1 ml of 1·2*M* hydrochloric acid and 100 ml of ethanol. The solution is stable for two months.

Sodium sulphite solution, 0·3M.

Standard solution of tin(IV) 0·1%, in 3M sulphuric acid. Dissolve 0·50 g of tin in 20 ml of concentrated sulphuric acid, cool, add 5 ml of 30% hydrogen peroxide, heat to fumes of sulphur trioxide, cool, and dilute to 500 ml, with addition of 65 ml of 18*M* sulphuric acid.

Procedures

Destruction with hydrofluoric–nitric acid mixture. Weigh 1 g of sample in a weighed platinum crucible and place in a heating-block. Add 1 ml of the destruction mixture, and wait until the violent reaction is finished. Heat gently on an electric hot-plate, and add 1 ml of the destruction mixture. Repeat this until the silicate is dissolved (generally two or three additions are necessary). Heat to dryness and fume the residue three times with 2-ml portions of sulphuric acid. Cool and weigh the platinum crucible. Transfer the residue into a mortar and grind to a fine powder.

Decomposition with ammonium iodide. Transfer to the destruction unit an exactly weighed amount (as much as possible) of the powder resulting from the procedure above and mix it thoroughly with 10 g of ammonium iodide. Place the lower part of the tube (about 6 cm) in an electric oven heated at about 480°. Heat for 1 hr, and cool.

Extraction. Transfer 20 ml of 2·5*M* hydriodic acid and 5 g of ammonium iodide into the destruction unit. After dissolution is complete add 7 ml of benzene and extract for 3 min. After both layers have separated, transfer 5 ml of the benzene layer into a 100-ml separating-funnel, add 5 ml of wash liquid and shake for 30 sec. After separation, discard the water layer and add 5 ml of 0·25*M* sulphuric acid to the funnel. Shake for 2 min to transfer the tin into the water layer.

Spectrophotometric determination. Transfer the water layer into a 25-ml volumetric flask, using 3 ml of water to rinse the separating-funnel. Heat in a water-bath to evaporate any benzene not completely removed by the separation. Cool, add some drops of sodium sulphite solution to reduce iodine (formed during the destruction). Add successively 10 ml of buffer, 1 ml of gum arabic solution, and 5 ml of reagent solution. Dilute to the mark, mix, and after 15 min measure in a 1-cm cuvette at 510 nm against water as reference. Subtract the absorbance of a blank run on the same day. Prepare a calibration curve in the usual way.

Destruction of "fresh" tin(IV) oxide with hydriodic acid, extraction and determination. Transfer an exactly weighed amount (as much as possible) of the powder from the HF/HNO_3 treatment into a reagent tube with ground-glass stopper. Add 6 ml of concentrated hydriodic acid and heat in a water-bath for 5 min at 100°. Cool, add 7 ml of benzene, and continue with the extraction and spectophotometric determination.

Note. The procedures given are applicable to samples containing about 3–15 ppm of tin. If more tin is present, smaller samples may be used or a smaller part of the benzene layer may be transferred into the separating-funnel, or a combination of both modifications may be used. The amount of ammonium iodide should be at least ten times the amount of sample and at least 2 g. If less than 10 g of ammonium iodide are used in the destruction, a correspondingly larger amount of ammonium iodide should be used in the extraction in order to reach the required concentration of this reagent.

RESULTS

Tin has been determined in some types of geological sample, such as granite, biotite and muscovite by the proposed method. The results are given in Table I, and compared with those obtained with X-ray fluorescence by van der Weyden.[7] The precision of the latter results is reported to decrease from about 5 or 10 ppm at the lower tin levels, to about 5 or 10% at the higher tin-levels.

TABLE I.—RESULTS OF EXPERIMENTS

	Amount of tin, *ppm*

The results obtained by treatment with hydrofluoric–nitric acid and subsequent ignition with ammonium iodide are given in column 2. Results obtained after treatment with hydrofluoric–nitric acid with subsequent reaction with hydriodic acid are given in column 3 and the results obtained by treating the sample with ammonium iodide only are given in column 5.

DISCUSSION

Extraction and spectrophotometric determination

The extraction is promoted by a high concentration of hydrogen ions and iodide ions and by a high electrolyte concentration. The different decomposition procedures led to different concentrations of those species, but with each of the resulting solutions practically the same calibration curves were obtained. The absorbance of the blank increased with time (by *ca.* 0·10–0·15 in two months) and varied from day to day by up to 0·01.

Iodine formed from the hydriodic acid and ammonium iodide used for decomposition did not interfere, nor did fluoride up to 0·01*M*, though higher concentrations did. It is important to ensure removal of the bulk of the fluoride if hydrofluoric acid is used.

Decomposition with ammonium iodide

Caley and Burford[6] observed that heating of cassiterite with a 10- or 15-fold excess of ammonium iodide resulted in complete removal of both compounds. They suggested that a determination of tin based on this reaction was possible.

Wood[2] and some others used the method for the determination of cassiterite in soils and sediments. Wood used a twofold excess of ammonium iodide, but neither he nor later investigators reported recovery figures. Little attention has been given to the possibility that the tin(IV) iodide may be lost because of its volatility. An exception is Kerr (quoted by Jeffery[1]), who designed a special apparatus to prevent evaporation losses. We performed 25 recovery experiments under various conditions with about 20 μg of cassiterite or an equivalent amount of tin(IV) solution, added to granite. The results gave bad recoveries (50–80% in most cases) if heating was performed in reagent tubes cooled with moistened cotton-wool and in most cases with an ammonium iodide–sample ratio 2:1.

Results, given in Table II, were obtained with the procedure described above. In these experiments the cassiterite used was supposed to have a tin(IV) oxide content between 90 and 95%. It was therefore concluded that the recovery was practically quantitative.

TABLE II.—RECOVERY EXPERIMENTS WITH DIFFERENT AMMONIUM IODIDE–SAMPLE RATIOS.

Amount of granite, *g*	Amount of ammonium iodide, *g*	Ratio, ammonium iodide–sample	Recovery*, %
0·200	2·0	10:1	90
0·130	first 1·3 then 0·7	first 10:1 then 5:1	91
0·130	2·0	15:1	90
0·100	2·0	20:1	89

* The cassiterite was assumed to contain about 90–95% tin(IV) oxide. About 20 μg of cassiterite were added in each experiment.

Reaction of tin(IV) oxide with hydriodic acid

It was also found by Caley and Burford[8] that tin(IV) oxide reacts with concentrated hydriodic acid at 90–100° as follows:

$$SnO_2 + 4HI \rightarrow SnI_4 + 2H_2O$$

Other insoluble oxides do not show any characteristic reactions with this acid. When we treated "fresh" tin(IV) oxide with warm concentrated hydriodic acid, no reaction seemed to occur, but the solid became voluminous. This phenomenon could be explained only by the formation of tin(IV) iodide. Indeed, on shaking the reaction product with benzene the solid disappeared instantaneously and tin was detected in the benzene layer. With cassiterite no reaction took place. This difference in behaviour suggested the possibility of differentiation between cassiterite and lattice-bound tin, because as we saw before, lattice-bound tin may be converted into "fresh" tin(IV) oxide by hydrofluoric–nitric acid mixture.

The time of warming the solution was found to be very important. We performed therefore a number of recovery experiments with different amounts of tin(IV) oxide or tin(IV) solution. They only gave good recoveries when the solution was warmed for not much more than 5 min. Some of the results are given in Table III. The reason for the incomplete recovery was not investigated but it is suggested that a partial reduction to tin(II) takes place.

TABLE III.—INFLUENCE OF THE TIME OF WARMING WITH HYDRIODIC ACID ON THE RECOVERY.

Tin added as	Amount of added tin, *μg*	Amount of hydriodic acid, *ml*	Time of warming, *min*	Recovery, %
Tin(IV) oxide	40·5	2	60	68
Tin(IV) oxide	21·9	2	30	86
Tin(IV) oxide	17·7	2	15	89
Tin(IV) oxide	18·4	3	5	98
Tin(IV) oxide	18·4	5	5	103
Tin(IV) oxide	565·2	5	5	99
Tin(IV) solution	19·3	2	0	99
Tin(IV) solution	9·6	2	2	105
Tin(IV) solution	14·3	2	5	96
Tin(IV) solution	7·2	6	5	104
Tin(IV) solution	14·3	2	15	90
Tin(IV) solution	19·3	2	30	71
Tin(IV) solution*	5·9	6	5	102
Tin(IV) solution*	5·9	6	5	91
Tin(IV) solution*	5·9	6	5	95

* The tin solution was added to about 1 g of a granite with known content of lattice-tin. Destruction with hydrofluoric–nitric acid was followed by the treatment with hydriodic acid.

After the treatment with hydrofluoric–nitric acid some hydrofluoric acid is left in the reaction product and too large amounts of it may interfere. Fuming the residue with sulphuric acid is generally applied to remove hydrofluoric acid but it is a well-known fact that the resistance to dissolution of many products is greatly increased if they are exposed to high temperatures. Therefore it seemed possible that the fuming might influence the reactivity of the "fresh" tin(IV) oxide. Consequently some experiments were performed with known amounts of tin added to granite, with fuming repeated various numbers of times. The results showed that fuming between one and five times did not significantly change the recovery, which was close to 100%.

Interpretation of the results

The replicate experiments for the total tin determination (Table I) show a standard deviation of about 1·3 ppm at the 3·5 ppm level (3 variates) 2 ppm at the 20–40-ppm level ($n = 10$) and 3 ppm at the 75-ppm level ($n = 3$). For the lattice-bound tin standard deviations of about 1 ppm at the 8-ppm level ($n = 5$) and 3 ppm at the 60-ppm level ($n = 3$) were found. The contribution to the total error by the extraction and spectrophotometric procedure depends on the final concentration of the sample solution. It varies from about 20% for 3 ppm to 4% for 15 ppm and more. The absolute values for the total tin should agree with the X-ray fluorescence results. Within the limits of error expected the agreement is satisfactory, except for sample 18. No explanation for the deviation found here can be given, except for an untraced error in one of the measurements.

The figures in columns 4 and 5 would be expected to be equal. In many cases rather large deviations have been found, however. To explain this, it should be realized that part of the cassiterite may be occluded in the silicate lattice and therefore may be inaccessible to the ammonium iodide if the sample is ignited with this reagent. It is suggested therefore that the differences between the figures given in columns 4 and 5 give the amount of cassiterite which is more or less enclosed in the silicate lattice.

We conclude that for the determination of the total tin, the destruction described here gives good results and that it may be used at much lower concentrations than X-ray fluorescence can. Moreover it may also allow differentiation between the various types of tin present in the rock: tin bound in the silicate lattice, tin present as cassiterite and readily accessible to reaction with NH_4I, and tin present as cassiterite enclosed in the silicate lattice.

For the determination of cassiterite in silicate rocks the procedures using only ammonium iodide probably often give low results, because they do not take account of the fact that part of the cassiterite is enclosed within the silicate lattice.

Acknowledgement—We express our thanks to Drs. C. H. van der Weyden of the Vening Meinesz Laboratorium voor geochemie en mineralogie of this University. He suggested that we do some work on the analysis of tin with a purely chemical method, put at our disposition his results of the X-ray fluorescence measurements and had valuable talks with us on the geochemical problems we encountered.

Zusammenfassung—Ein einfaches, empfindliches und reproduzierbares Verfahren zur Bestimmung von Zinn im ppm-Bereich in Silikatgesteinen wird angegeben. Durch Verwendung eines selektiven Aufschlusses scheint es möglich, zwischen im Silikatgitter eingebautem Zinn, zwischen gut angreifbarem Cassiterit (SnO_2) und im Silikat eingeschlossenem Cassiterit zu unterscheiden. Die endgültige Bestimmung wird mittels Extraktion und Photometrie mit Phenylfluoron ausgeführt. Die Ergebnisse für das Gesamtzinn stimmen gut mit denen der Röntgenfluoreszenz überein.

Résumé—On décrit une méthode simple, sensible et reproductible pour le dosage de l'étain dans des roches aux silicates au niveau de la p.p.m. En appliquant une décomposition sélective, il semble possible de différencier l'étain présent dans le réseau de silicate, dans la cassitérite aisément accessible (SnO_2) et dans la cassitérite enrobée dans le silicate. On effectue le dosage final par extraction et photométrie à la phénylfluorone. Les résultats pour l'étain total sont en bon accord avec ceux obtenus par fluorescence de rayons X.

(*Received* 4 *February* 1972. *Accepted* 3 *March* 1972)

Summary—The atomic-fluorescence characteristics of manganese heated on a carbon-filament atom-reservoir (CFAR) are described and compared with (*a*) the atomic-absorption behaviour of the element on the same filament apparatus, and (*b*) its fluorescence behaviour in a separated air–acetylene flame. By fluorescence at 279·5 nm, using 1-μl samples, manganese may be determined down to 0·6 pg (6×10^{-4} ppm) by use of an electrodeless discharge lamp source (3 pg or 3×10^{-3} ppm by absorption, and 20 ng or 1×10^{-2} ppm by flame emission at 403 nm). The effects of fourteen representative cations and anions examined showed no interference at 10-fold and 100-fold levels and serious interference only from magnesium at the 1000-fold level, with *ca.* 10% suppression from Cr, V, Na and K. No fluorescence signals were observed at any wavelength other than 279·5 nm when the CFAR device was used.

PREVIOUS REPORTS from this laboratory have demonstrated the advantages of atomic-fluorescence spectroscopy (AFS) as a sensitive and selective analytical technique, and some applications and advantages of the carbon-filament atom-reservoir (CFAR) have been reported both in AFS and atomic-absorption spectroscopy (AAS).[1] We have recently reported the analytical behaviour of manganese in AFS using an air-acetylene flame[2] and by AAS using a carbon-filament atom-reservoir.[3] The study of the atomic-fluorescence characteristics of manganese in the flame when a high-intensity source was used indicated that manganese may be determined with sensitivity *ca.* one order of magnitude higher than that attainable by flame emission or AAS, and with good selectivity; only magnesium was found to interfere chemically, and scattering interference was observed in the presence of high concentrations of several refractory elements. Although the limits of detection obtained when using AAS with the carbon-filament atom-reservoir or AFS with the air–acetylene flame corresponded to the same solution concentration of manganese, only 5 μl of sample were required for the CFAR and thus a gain of several orders of magnitude in the absolute limit of detection was attainable. A study of interferences when the carbon-filament device was used, indicated six ions which interfered at the 100-fold excess level and with two exceptions, vanadium and magnesium, the interfering ions differed from those reported for the flame cell. In this communication the determination of manganese by using AFS and a CFAR is reported, and the results are compared with our earlier reports of the determination of manganese to illustrate the advantages of both atomic fluorescence and the carbon filament technique.

EXPERIMENTAL

Apparatus

The carbon-filament atom-reservoir, Unicam SP 900A and Telequipment storage oscilloscope described previously were used.[3] The a.c. amplification system of the SP 900A was replaced by a fast response d.c. detection system employing an independent EHT supply and taking the photomultiplier output direct to the oscilloscope amplifier as recently reported.[4] Both a manganese hollow-cathode lamp (Atomic Spectral Lamps Pty, Ltd.) as used in the AAS work with the CFAR,[3] and an electrodeless discharge lamp, similar to that used in the previous AFS work,[2] were employed as spectral sources. The optical system used for the atomic-absorption studies[3] was used, with the sole modification that the source and lens were moved to be at 90° to the CFAR–monochromator optical axis. This was achieved by placing the source and lens above the filament and focussing the light from the source down on to the filament.[5] This arrangement, although not ideal, as the lens has to be periodically cleaned to remove deposited carbon, was the most suitable for limited-field viewing. Limited-field viewing has been shown, both in this study and previously,[5] to decrease interferences greatly in the carbon-filament technique.

Reagents and procedure

All reagents were of analytical-reagent grade and the water used was glass-distilled and then demineralized. The water used to prepare the solutions, and the reagents used in the interference studies, were periodically checked for contamination by manganese.

The sample pipette and all glassware were treated with "Repelcote" as described previously.[6]

The procedure followed in routine determination was the same as that described previously,[3] but additionally the EHT was set to a previously determined optimum voltage.

RESULTS AND DISCUSSION

Use of a hollow-cathode lamp as excitation source

Usually hollow-cathode lamps operated at typical powers suitable for AAS would not be regarded as sufficiently intense for atomic-fluorescence studies with flame cells. However, because of the low background emission of the carbon-filament atom-reservoir at the time of measurement of the manganese fluorescence signal, appreciable manganese atomic fluorescence was observed when a conventional manganese hollow-cathode lamp was used as source.

The optimum parameters for the determination of manganese by AFS at 279·5 nm were established. The variation of fluorescence signal with filament voltage, for 2 ng of manganese, is shown in Fig. 1. The optimum filament voltage used was *ca.* 11 V. The variation of signal (for 2 ng of manganese) with argon (shielding-gas) flow-rate is shown in Fig. 2. The optimum argon flow-rate was shown to be 3·8 l./min. As expected, the fluorescence signal at 279·5 nm increased as the hollow-cathode lamp current was increased, and the maximum recommended current (30 mA) was used. The fluorescence signal also showed a marked increase as the monochromator slit was opened. The continuum intensity from the glowing filament increased as the slit was opened and therefore the slit-width employed, 0·35 mm, was chosen to give the most favourable ratio of AFS signal to continuum background intensity. This slit-width corresponded to a spectral band-pass of *ca.* 2·4 nm. The optimum value of the EHT was found to be 900 V, and the time-base used on the oscilloscope was 100 msec/cm.

Under these optimum conditions, the detection limits for manganese (signal-to-noise ratio 2:1) at 279·5 nm were 0·001 μg/ml with 5 μl of sample and 0·003 μg/ml for 1-μl samples, *i.e.*, an absolute limit of detection of 3 pg. This limit is of the same order as that previously reported (5 pg) for manganese atomic fluorescence, using a hollow-cathode lamp and the carbon-filament atom-reservoir, but different instrumentation.[7]

Linear calibration graphs were obtained in the region from 5 to 300 pg of manganese.

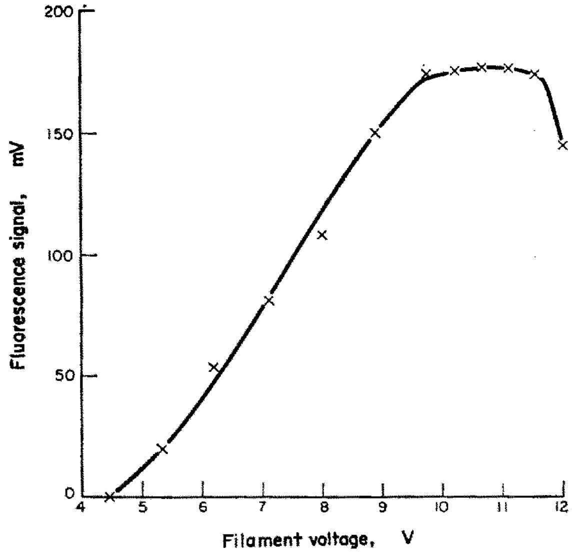

FIG. 1. –Effect of filament voltage on manganese atomic-fluorescence signal at 279·5 nm, using a hollow-cathode lamp source.

The growth curve for manganese atomic fluorescence under these conditions is shown in Fig. 3. The growth curve shows that scatter of the source radiation occurs when more than ca. 0·25 μg of manganese is present. By using the radiation at 283·3 nm from a lead lamp it was shown that with below 0·25 μg of manganese, scatter was not the cause of the signals noted above and no signal was observed from even 5×10^{-8} g of manganese at the 283·3 nm lead line.

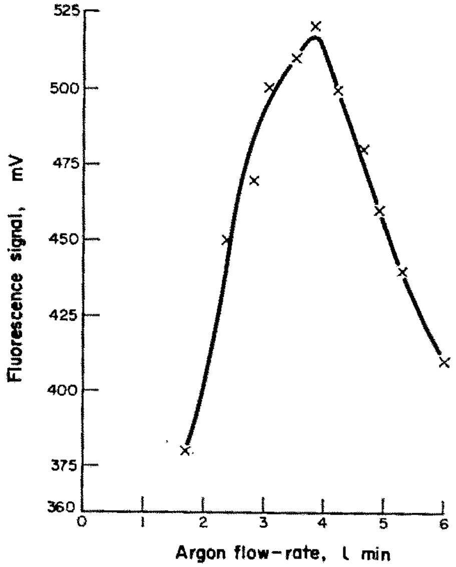

FIG. 2.– Effect of argon flow-rate on manganese fluorescence signal at 279·5 nm, using a hollow-cathode lamp source.

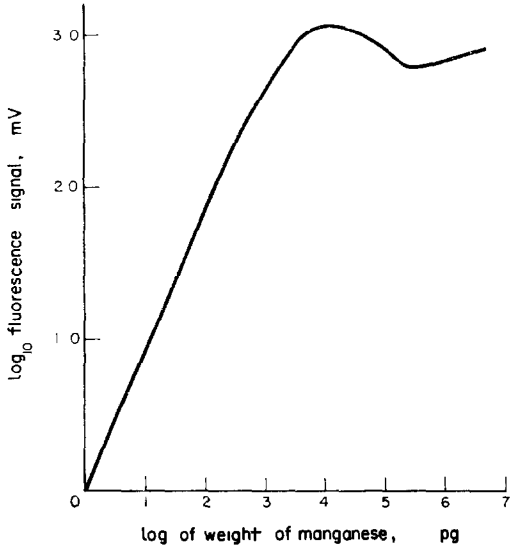

Fig. 3.—Growth curve for manganese atomic-fluorescence at 279·5 nm, using a hollow-cathode lamp source.

Use of an electrodeless discharge lamp (EDL) as source

The preparation, operation and characteristics of manganese electrodeless discharge lamps have previously been described.[2] The optimum argon shielding-gas flow-rate, filament voltage and monochromator slit-width were found to be the same as those reported above for the hollow-cathode lamp source. The optimum EHT for best signal-to-noise ratio was found to be 950 V. The optimum EDL lamp power was 50 W, as previously. The limit of detection (signal-to-noise ratio 2:1) for a 5-μl sample was found to be 0·2 ng/ml, *i.e.*, an absolute limit of detection of 1 pg of manganese. When a 1-μl sample was used an 6 ng/ml solution corresponded to the limit of detection *i.e.*, an absolute limit of detection of 0·6 pg.

The reproducibility of the signals obtained was poorer than that for manganese atomic-absorption with use of the filament. It appears that the short-term noise from the source contributes an additional factor. The reproducibility (95% confidence level) of the signal obtained from any single solution was $\pm 5\%$.

Fluorescence signals at other wavelengths

Attempts to observe manganese atomic fluorescence at wavelengths other than 279·5 nm were unsuccessful with both sources. Particular attention was paid to examination at all the lines at which atomic fluorescence was observed when a flame cell was used).[2] It was not unexpected that fluorescence from the two Mn(II) triplets was not observed. Although the ion line-emission from the electrodeless discharge lamp source was present, as shown by our previous observation of ionic fluorescence of manganese at 257·6 nm in flames,[2] no such emission was observed here because the CFAR does not cause ionization of manganese (the first Mn ionization potential is 7·4 eV). It was not possible to observe atomic fluorescence at 403 nm because of the high continuum intensity from the glowing filament at this longer wavelength; any

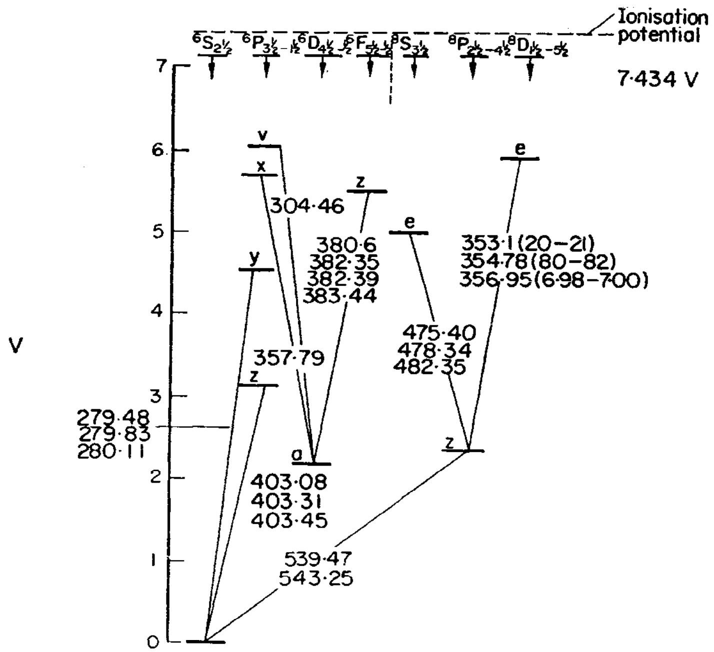

FIG. 4.—Simplified Grotrian diagram for manganese.

fluorescence signal could not, with the d.c. instrumentation employed, be distinguished from the continuum. Study of the simplified Grotrian diagram for manganese (Fig. 4) shows that the fluorescence observed in the flame cell[2] at 304·5, 357·8 and 383·4 nm probably arises from thermally assisted resonance fluorescence. In the air–acetylene flame sufficient energy exists to provide a small population in the lower energy state ($a^6D_{2\frac{1}{2}}$). It is obvious, however, that the carbon filament does not produce sufficient energy (greater than 2 eV is required) to populate this level significantly. This conclusion is in agreement with the estimated temperature above the filament[8] and results obtained for atomic-absorption studies on iron.[4]

Use of nitrogen as shielding gas

The use of nitrogen as shielding gas was investigated and the signals were compared with those obtained with argon. The intensity of atomic-fluorescence signal at 279·5 nm when nitrogen was used was found to be *ca.* 1/16 that obtained with argon as shielding gas. This is to be expected from the much larger quenching cross-section of nitrogen. When a carbon rod is used in the determination of lead in matrices prone to scatter, the fluorescence intensity ratio is 13:1 between argon and nitrogen-shielded rods, and it has been suggested[9] that to a good approximation the scatter signal could be nullified by subtracting the signal obtained with nitrogen-shielding from that obtained with argon-shielding. The results obtained with such matrices in this study would strongly support use of such an approach for manganese determinations.

Effects of foreign ions on AFS of manganese at 279·5 *nm*

The effects of 14 foreign ions on the atomic fluorescence of 5-μl aliquots of 0·04 μg/ml manganese solutions (200 pg) at 1000, 100 and 10-fold weight-ratio levels were studied. An electrodeless discharge lamp was used as the spectral source. Only the fluorescence signal occurring in the range 0–0·7 mm above the rod was viewed, by using a slit fitted in the manner previously described.[3] The effects of these ions are listed in Table I as suppressions or enhancements of the manganese fluorescence signal at 279·5 nm. Only interferences which result in a change of signal of 5% or more were taken to be significant.

It should be noted that at the 10 and 100-fold levels no interference was obtained from any of the ions studied. This would agree with the conclusion reported earlier,[7] that the absolute amount of sample is important, rather than the weight-ratio. The 100-fold level in this study corresponds to a 10-fold amount by weight at the 2-ng level used for absorption studies, at which level no interference with the manganese absorption was reported. At the 1000-fold level interference was observed here for five cations, but only that of magnesium (the most serious interference in flame atomic-fluorescence and non-flame atomic-absorption) was serious. That the other cations studied give less interference in atomic-fluorescence than in atomic-absorption determinations probably results from the higher filament voltage used in the fluorescence measurements and the faster response of the measuring system employed. It was noted that certain oscilloscope traces indicated that effects from elements less volatile than manganese were observed after the manganese signal peak had been passed. Thus with the fast-response system such interferences can be minimized. Advantage might also therefore be expected from the use of this fast-response system to minimize interference in the absorption technique.

§ Ref. 3.

From this interference study it would appear feasible to improve upon the carbon filament determination of manganese in the presence of elements which interfere in the atomic-absorption technique, by diluting the solution tenfold and then determinating the manganese by atomic-fluorescence spectrometry, provided that a slightly higher coefficient of variation can be tolerated.

CONCLUSION

This study further emphasises the usefulness of the carbon-filament atom-reservoir for the determination of trace metals when only small amounts of sample are available. Table II shows a comparison of the detection limits obtainable in the determination of manganese, when our apparatus is used with an air–acetylene flame and with a carbon-filament atom-reservoir. Either the carbon filament or the flame cell can be used to analyse solutions of the same manganese concentration, but the former requires only 1 or 5 μl of solution whereas the flame cell needs 2 ml of solution. Table I shows that both techniques have good selectivity as well as high sensitivity, and that with the exception of magnesium even at 1000-fold amounts by weight of other ions interfere only slightly when the carbon filament is used in the fluorescence mode.

Acknowledgement—We are grateful to the Procurement Executive, Ministry of Defence, for support of this work.

Zusammenfassung—Es werden die atomischen Fluoreszenzeigenschaften von Mangan, das auf einem KohlenfadenAtomspeicher (CFAR) erhitzt wird, beschrieben, und sie werden mit (a) dem atomischen Absorptionsverhalten des Elements auf dem gleichen Heizfadenapparat, und (b) ihrem Fluoreszenzverhalten in einer getrennten Luft-Acetylenflamme verglichen. Mit Fluoreszenz bei

279,5 nm und 1-μl Mustern kann Mangan mittels einer Lichtquelle elektrodenloser Entladung (3 pg oder 3×10^{-3} ppm durch Absorption und 20 ng oder 1×10^{-2} ppm durch Flammenemission bei 403 pm) bis hinunter auf 0,6 pg (6×10^{-4} ppm) bestimmt werden. Die Wirkungen von vierzehn kennzeichnenden Kationen und Anionen, die untersucht wurden, ergab bei 10-fachen und 100-fachen Stufen keinen störenden Einfluss und ernste Störungseinflüsse von Mangan bei 1000-facher Stufe, mit etwa zehn prozentiger Unterdrückung von Cr, V, Na und K. Es wurden keine Fluoreszenzzeichen ausser bei der Wellenlänge 279,5 nm während Benutzung der CFAR Vorrichtung beobachtet.

Résumé—On décrit les caractéristiques de fluorescence atomique du manganèse chauffé sur un réservoir d'atomes à filament de carbone (CFAR) et les compare avec (a) le comportement d'absorption atomique de l'élément sur le même appareil à filament, et (b) son comportement de fluorescence dans une flamme séparée air-acétylène. Par fluorescence à 279,5 nm, utilisant des échantillons de 1 μl, on peut déterminer le manganèse jusqu'à 0,6 pg (6×10^{-4} p.p.m.) en utilisant comme source une lampe à décharge sans électrode (3 pg ou 3×10^{-3} p.p.m. par absorption, et 20 ng ou 1×10^{-2} p.p.m. par émission de flamme à 403 nm). Les influences de quatorze cations et anions représentatifs examinés ne montrent pas d'interférence à des teneurs 10 et 100 fois supérieures et seul le magnésium apporte une interférence sérieuse à une teneur 1000 fois supérieure, avec une suppression d'environ 10% provenant de Cr, V, Na et K. On n'a observé de signaux de fluorescence à aucune longueur d'onde autre que 279,5 nm lorsque le dispositif CFAR est utilisé.

SOME CONSIDERATIONS ON SPECTRAL LINE PROFILES OF MICROWAVE-EXCITED ELECTRODELESS DISCHARGE LAMPS

D. O. COOKE, R. M. DAGNALL and T. S. WEST
Department of Chemistry, Imperial College of Science and Technology, London, SW7

(*Received* 1 *November* 1971. *Accepted* 24 *February* 1972)

Summary—The problems of line broadening in microwave-excited electrodeless discharge lamps for the more volatile elements, P, S, I, Se, Zn, Cd and Hg are discussed in relation to their use in atomic-absorption and fluorescence spectrometry. Both theoretical and practical implications are considered.

THE MICROWAVE-EXCITED electrodeless discharge lamp (EDL) has recently received considerable attention in the literature and it is not surprising that much of this has been concerned with the more volatile elements (As, Se, Hg, Zn and Cd).[1–5] These elements have their main resonance lines in the ultraviolet and generally provide short-lived or less satisfactory hollow-cathode lamps. Furthermore, the detection limits by atomic-fluorescence spectrometry (AFS) for these elements are often a considerable improvement on those obtained for atomic-absorption spectrometry (AAS) provided a suitable high-intensity source (*eg*, an EDL) is used. Recent trends in AAS towards non-dispersive systems, using both interference filters and resonance monochromators[6,7] have also highlighted the importance of the high-intensity source. The resonance monochromator is particularly attractive for routine single element determination when expensive apparatus cannot be justified. Again, this system is particularly well suited to the more volatile elements although with more elaborate apparatus it may be applied to a wider range of elements. Figure 1 shows a spectral scan in the region 200–300 nm, obtained by using such a device for cadmium (simple quartz reservoir with optical flats, maintained at *ca.* 500° in a furnace, with a side-arm to regulate the cadmium vapour pressure at *ca.* 150°). A typical calibration graph obtained by using the device for AAS in conjunction with an EDL and an air–propane flame (circular Méker type burner of path-length *ca.* 2 cm) is included.

The recent interest in non-flame atom reservoirs has enabled very impressive detection limits to be obtained for many of these elements.[8–11] In addition, the advent of such devices has aroused some interest in the direct determination by AAS or AFS of iodine, sulphur and phosphorus.[12] Hitherto the direct determination of these has received little attention. Manning and Slavin,[13] and Kahn *et al.*[14] have examined the determination of phosphorus at non-resonance lines (213·55/213·62 nm and 214·91 nm) and obtained a sensitivity of *ca.* 290 ppm at the 213·55/213·62 lines when using a nitrous oxide–acetylene flame. Although these workers used a hollow-cathode lamp as source, Manning and Slavin mention problems encountered because of the very low intensity and high background associated with the source. In contrast the EDL provides a very high line:background ratio at these wavelengths (Fig. 2) and may prove useful in further improving this type of determination. Thompson[15] has examined the AAS and AFS of iodine at the 206·1 nm non-resonance line, and concluded this to be impracticable; a detection limit of 1·6 mg/ml was obtained by AFS. Using non-flame cells, however, L'vov[12] has obtained sensitivities (for 1 % absorption) in the

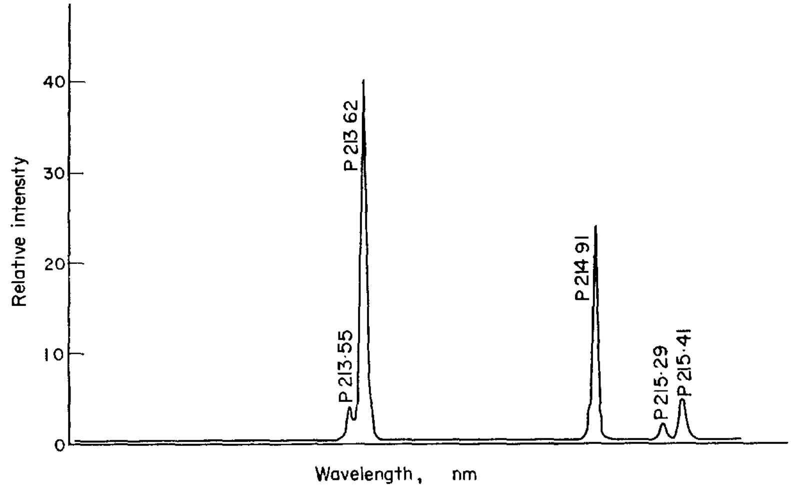

FIG. 2.—Partial emission spectrum of phosphorus EDL; $\frac{3}{4}\lambda$ cavity with microwave power 30 W.

region of 10^{-10}–10^{-12} g for sulphur, phosphorus and iodine, using the main resonance lines in the vacuum ultraviolet region. L'vov used a radiofrequency EDL as source and indeed it would seem that the EDL (radiofrequency or microwave-excited) would be the first choice as spectral source for the resonance lines of such elements. As with the other more volatile elements the main problem in using these EDL's is the critical nature of both preparative and operating conditions. Some idea of the magnitude of the problems involved may be gained from theoretical considerations.

In addition to the natural line width and the Doppler broadening, emission lines from EDL's will be subject to some extent to Lorentz (foreign gas), Holtsmark (resonance) and Stark (electric field) broadening. It seems generally accepted, however that the contribution from Stark broadening, as with Zeeman (magnetic field) broadening, is of little or no significance,[16,17] at least at low total pressures <20 mmHg. Furthermore, the contribution from Doppler broadening is not excessive, because the lamps operate at a relatively low temperature (probably between 400 and 1100°, depending on the microwave power used).

Expressions for the half-intensity line widths (nm) have been given as follows,[10*]

$$\Delta\lambda_N = \frac{\lambda_0^2}{2\pi C} A_{tu} \tag{1}$$

$$= 5{\cdot}32 \times 10^{-19} \lambda_0^2 A_{tu}$$

$$\Delta\lambda_D = \frac{2(2R \ln 2)^{1/2}}{C} \lambda_0 \left(\frac{T}{M_a}\right)^{1/2} \tag{2}$$

$$= 7{\cdot}16 \times 10^{-7} \lambda_0 \left(\frac{T}{M_a}\right)^{1/2}$$

$$\Delta\lambda_L = \frac{2\lambda_0 \sigma_L^2 P_f}{\pi C k T}\left[2\pi R T\left(\frac{1}{M_a} + \frac{1}{M_f}\right)\right]^{1/2} \tag{3}$$

$$= 4{\cdot}67\, \lambda_0^2 \sigma_L^2 P_f 10^{-9} \frac{1}{T}\left(\frac{1}{M_a} + \frac{1}{M_f}\right)^{1/2}$$

$$\Delta\lambda_{\text{Total}} = \{(\Delta\lambda_D)^2 + (\Delta\lambda_L + \Delta\lambda_H + \Delta\lambda_N)^2\}^{1/2} \tag{4}$$

where subscripts N, D and L refer to the natural, Doppler and Lorentz widths respectively, R is the gas constant in erg/mol/K, C is the speed of light in m/sec, T is the absolute temperature, P_f is the pressure of foreign gases in mmHg, M_a is the atomic weight of the absorbing or emitting species in atomic mass units, M_f is the effective (average values for gases) molecular weight of foreign gas molecules in atomic mass units, λ_0 is the wavelength of the line centre in nm, σ_L is the effective cross-section for collisional broadening, A_{tu} is the spontaneous probability between the upper and lower states and k is the Boltzmann constant in erg/K. The value of $\Delta\lambda_H$, the half-intensity width for Holtsmark broadening is obtained from equation (3) by replacing σ_L with σ_H and P_f with P_a, the pressure of absorbing or emitting species, and by replacing M_f with M_a. Ideal gas behaviour is assumed in the derivation of the expressions for $\Delta\lambda_L$ and $\Delta\lambda_H$.[20,21] Table I shows the theoretical half-intensity widths for the resonance lines of certain elements due to natural, Doppler, Lorentz and Holtsmark broadening, together with the total half-intensity widths which have been calculated from equations (1)–(4). The collisional cross-sections are not accurately known and indeed very little information exists regarding optical cross-sections. Winefordner *et al.*[18] have used quenching cross-sections to calculate the half-widths of various absorption lines in flames. The present authors, however, feel that these may lead to somewhat low values. The quenching cross-section for argon is generally assumed to be zero, whilst the optical cross-section for argon at the Na 589·0-nm line has been quoted[22] as 1·12 nm^2 and at the Hg 253·7-nm line as 0·7–0·9 nm^2. Cross-sections for

* Pressures in mmHg.

† Vapour pressure taken as that of Hg at 25° *i.e.*, the situation prevailing in an Hg lamp with reservoir outside the microwave field.

Holtsmark broadening are generally accepted as considerably greater than those for foreign gas species, often as great as 5 nm^2.[22] In view of this uncertainty the line widths have been calculated for maximum and minimum values of the optical cross-sections, *viz* σ_L max 1·5 nm^2, σ_L min 0·5 nm^2, σ_H max 5 nm^2, σ_H min 1 nm.^{2} The lamp parameters assumed are a pressure of argon of 3 mmHg at 20°, and that excess of element is always present, that is, the pressure of the species concerned is given by the vapour pressure at the given temperature (except where stated).

Obviously at the higher pressures, and indeed at all pressures (of emitting species) for which an EDL is likely to be used, there is considerable self-absorption. Very little information exists regarding interferometric measurements of resonance lines emitted by EDL's, although some qualitative results has been reported by Kirkbright and Sargent[23] for calcium and thallium sources (prepared from chlorides). Even with these less volatile species severe self-absorption and self-reversal were observed. L'vov[11] has reported some results for radiofrequency lamps, but they are rather scanty. Typically, he found the line width from a cadmium radiofrequency lamp at 120 mA was equal to that of a hollow-cathode lamp at 10 mA, but the intensity was 1000 times as great. The vapour pressures quoted appear at first sight somewhat high, but although an EDL cannot normally be initiated at a pressure much above 10 mmHg, it is relatively easy to maintain such a discharge up to a pressure of 1 atmosphere. However, even at relatively low pressures the discharge may no longer be homogeneous and self-reversal or quenching of the discharge becomes a problem. The discharge shows a steady transition from the so-called "skin effect" through a homogeneous discharge to that of an arc, under which conditions the resonance lines are severely self-reversed (Fig. 3). A further contribution which has to be taken into account is the shift in wavelength, due to pressure broadening, of both the absorption profile of the analyte atoms and the emission profile of the source ($\Delta\lambda_s$). Theory[24,25] predicts that

$$\frac{\Delta\lambda_S}{\Delta\lambda_C} = -0{\cdot}36 \qquad (5)^*$$

This result yields a red shift which is in agreement with reported results[26,27] for the perturbing species N_2 and Ar, though the values are somewhat lower and 0·25 would appear a more realistic figure. In the case of light perturbing molecules such as H_2, He and Ne, however, the shift can be to the violet. This has recently been explained in terms of the Lindholm theory.[28] It is apparent that a shift of unequal magnitude or in opposing directions, between the emission profile of the source and the absorption profile of the analyte atoms within the atom reservoir, will lead to inferior results in both AAS and AFS. The magnitude of this effect has been evaluated by graphical integration for Gaussian distributions of both emission and absorption profiles and for various emission line widths and wavelength shifts. The results for the case of an absorption line half-width of 2 pm are shown in Fig. 4. The results indicate that for an absorption profile of 2 pm and a shift of *ca* 0·5–0·6 pm and a source line width of 0·45 pm and a shift of *ca.* 0·05–0·2 pm (see Table I, *e.g.* Cd EDL at 500°), the separation $\Delta\lambda_{sp}$ (of peak wavelengths of the absorption and emission profiles) would be *ca.* 0·3–0·55 pm and the absorption signal would be depressed by *ca.* 2–4%. The situation is more pronounced at larger emission line widths, but in these instances it should be remembered that the signal is already degraded because the ratio of emission line width to absorption line width (α) is no longer $\ll 1$. For example, in the case of an

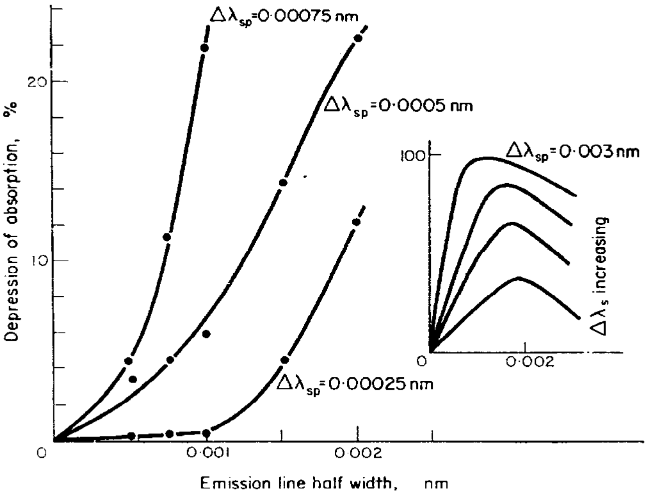

FIG. 4.—Depression in absorption for various wavelength shifts and emission line widths; absorption line width assumed to be 0·002 nm.

---

* Although the ratio $\Delta\lambda_S/\Delta\lambda_C$ is zero for the C_3/r^3 term of Lindholm's expression the van der Waals term C_6/r^6 is dependent on the total pressure of all uncharged species.

absorption profile of 2 pm width and a shift of *ca.* 0·5–0·6 pm and a source broadened to a line width of 2 pm, (as might be the case for a Cd EDL at 500°), whilst the shift remains *ca.* 0·05–0·2 pm the already degraded absorption would be further depressed by *ca.* 20–30% relative to that which would result from a zero shift in the absorption profile.

Hyperfine structure (*hfs*)[30]

The presence of hfs in a spectral line (a result of the radiating atoms consisting of a mixture of isotopes or of possessing a non-zero nuclear spin) also contributes to an increase in line width and to a decrease in analytical signal (in AAS) in addition to that predicted from theoretical considerations.[21] The presence of hfs in a spectral line is analogous to the situation arising when more than one transition falls within the spectral bandpass of the monochromator.[29,34] The deviation from the theoretical growth curve for peak absorption due to the presence of hfs is somewhat complex and varies with the element (and isotope ratios) concerned. Evidence at present suggests its effect to be significant. Model calculations[29] in the case of copper have indicated a decrease of 16% in sensitivity due to the presence of hfs, whilst decreases considerably in excess of this could well be expected. However, the presence of hfs has been neglected in the line-width calculations concerned in this study.

Such is the magnitude of line broadening, self-absorption and the shift in wavelength when an EDL is used under adverse circumstances, that they may be qualitatively observed by using a conventional (prism) monochromator when operating in the far ultraviolet. Figure 5 shows a series of spectral scans of the selenium 196·026 nm line at various microwave power levels and illustrates clearly the effects of self-absorption. It is not expected that any self-reversal present would be resolved. Unlike EDL's for many elements, the selenium lamp shows little tendency towards arc formation even at very high pressures. Figure 6 shows spectral scans of the selenium 196·026 nm line with and without *ca.* 50,000 ppm of selenium nebulized into the flame (the high concentration was necessary because of gross broadening present in the source). The shift in wavelength between the absorption profile and the source emission profile may just be observed. The bismuth 195·948 nm emission line was

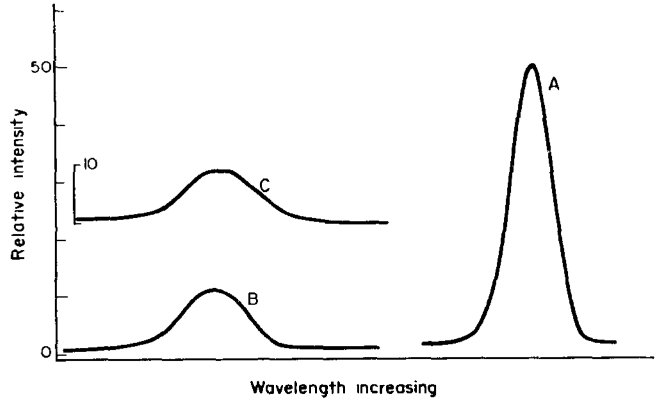

FIG. 5.—Spectral scans of Se 196·026 line at various microwave powers; scan-rate 0·8 nm/min, spectral slit <0·005 nm, lamp (Se metal/argon) operated in $\frac{3}{4}\lambda$ cavity. (A) 50 W; (B) 150 W; (C) 180 W

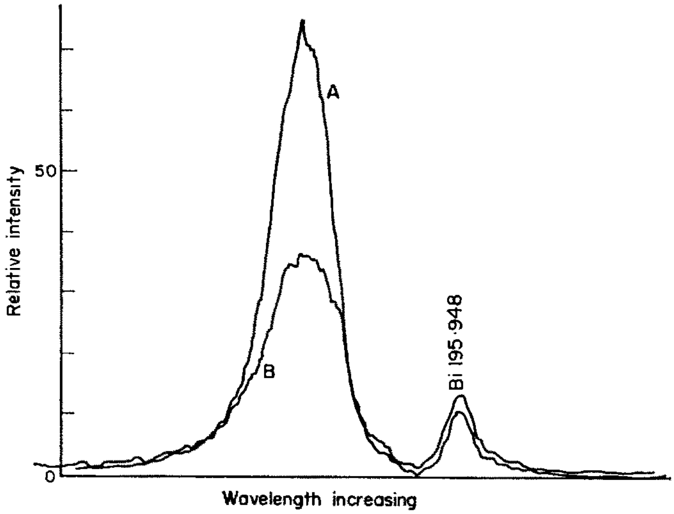

FIG. 6.—Spectral scans of Se 196·026 nm line at 150 W, other conditions as for Fig. 5. (A) after passage through flame; (B) on nebulizing *ca.* 50,000 ppm Se.

obtained by using a separate EDL as a wavelength guide to facilitate alignment of the individually recorded spectra. It is of interest, however, that the absorption profile appears to be shifted to a longer wavelength than that of the source. The shift of absorption profile in the flame, from equation (5) would be expected to be *ca.* 0·85–0·5 pm and any shift to a longer wavelength in the source would reduce the separation. The observation of this separation may well suggest that the source line profile has shifted towards the violet. Attempts to observe a shift in wavelength for the bismuth line were unsuccessful, though in this instance the emission line would not be as readily broadened as the selenium emission.

Practical implications

The practical consequences of the ease with which emission lines from EDL's may be broadened or reversed may be considered in two distinct aspects.

Those applications for which line broadening is advantageous. Into this class falls the technique of line overlap which has received particular attention in AFS and more recently in AAS. Such occurrences have been recognized for some time as a source of spectral interference in AAS.[19] The importance of line broadening in this technique is readily appreciated, owing to the separation which already exists between the absorption and emission profiles. There are three reasons for the use of line overlap methods. First, under certain circumstances they permit improved sensitivities in AFS as a result of an effective higher line intensity from the line overlap source as opposed to the more normal source. Such occurrences are, however, rare and so far as the authors are aware increased sensitivity has so far only been obtained in the case of the determination of bismuth at 206·170 nm, using the iodine 206·163 nm emission line.[31] Secondly, to provide an increased range for a given source. Several workers have reported examples,[32,33,34] although sensitivities in AAS (or absolute signal in AFS) are invariably lower than those which are obtained when using the more conventional source. Frank *et al.*[35] have determined Mg, Mn, Ni and Cu, using an iron hollow-cathode lamp. Fulton *et al.*[36] have examined the AFS of cadmium (228·802 nm), using the arsenic (228·812 nm) non-resonance line and obtained a detection limit of 0·0017 ppm, a factor of only 3 below that more normally obtained by using the same premixed flame (air–acetylene) and a cadmium EDL.[37] The line separation in this instance is (+) 0·01 nm which would be further removed from the absorption line profile by any shift in wavelength of the arsenic 228·812 nm line. The third reason for the use of line overlap procedures, perhaps at first sight rather surprising, is to enable a reduction in sensitivity to be obtained when the more normal methods, such as burner rotation, sample dilution or the use of a less sensitive line are not possible. As yet this has only been reported for calcium.[38]

Those applications for which line broadening is detrimental. The requirement of a narrow emission line width in AAS (ratio of emission line width to absorption line $\alpha \ll 1$) is well known.[12,21] Deviation from this requirement will result in decreased absorbance values and departure from linearity of the calibration curve.* In AFS, however, line width is of less importance because the presence of unwanted radiation outside the absorption profile has little or no effect on the analytical signal. Gross broadening such that the emission line is effectively a continuum over the absorption line profile will of course result in a change in shape of the growth curve[39,40] at high concentration. However, this effect is difficult to observe before severe self-absorption or self-reversal of the emission line (which leads to a decrease in intensity at the line centre or over the whole absorption profile) results in a decreased analytical signal. The importance of the EDL line widths as regards the analytical situation may be seen from Table II which shows the theoretical line widths for various elements under various analytical conditions. Calculations in this instance have excluded any contribution due to resonance broadening because in an analytical useful situation this is negligible in comparison with other causes of line broadening. Comparison of Tables I and II indicates that α is by no means always $\ll 1$. The situation appears particularly critical when the sources are used in conjunction with low temperature operation of a non-flame cell, under which circumstances non-linearity in AAS would be expected. The use of a high-pressure device appears at first sight to rectify this, but the shift of the absorption profile would lead to a decrease in sensitivity relative to that which could be obtained by improving the source conditions.

Obviously then, to ensure optimal results for an EDL prepared from volatile elements, it must be ensured that the pressure within the EDL is maintained as low as possible. A particularly attractive, though often difficult, means of ensuring these conditions, is to use the quantity of material within the lamp as the vapour pressure regulator.[41] Provided sufficiently small amounts of material are introduced into the lamp, the sensitivity in AAS, and under certain circumstances the AFS signal, may be increased. Table III shows some sensitivities obtained when using various zinc EDL's.

---

* It should be noted that even when the so-called ideal source is used there is some decrease in atomic absorbance from the theoretical peak absorption (apart from considerations relating to hyperfine structure) due to the shift in absorption profile of the analyte atoms in the flame or other atom reservoir. A truly ideal source would therefore have an emission line shifted in wavelength by the same amount as that of the absorption profile whilst still maintaining the condition $\alpha \ll 1$. Clearly from equation (5), this is not likely to be a practical occurrence.

The reader is reminded of the other causes of curvature of calibration curves, namely chemical interferences (ionization, compound formation) and the non-linear relation between flame gas concentration and solution concentration, due to variation in nebulization efficiency.

* Air–propane flame (*ca* 10 cm). Lamps prepared with 3 mmHg argon pressure and operated in a three-quarter wave cavity.

Zinc chloride lamps have been included because in this instance the effect is somewhat more pronounced (presumably due to the presence of free chlorine) and may be more readily examined. Much of the discussion here is of course applicable to EDL's prepared from volatile compounds, with the additional problems that the secondary constituent (normally a halogen) affords an increase in total pressure within the lamp. This may be an important problem if the constituents do not recombine readily on cooling. Furthermore, the collisional cross-sections for the halogens are appreciably greater than that for argon[22] and thus additional broadening can result from halogen present within the lamp. For very volatile elements with sufficient vapour pressure for operation at room temperature, long lamps, having a reservoir of the element (or compound) well outside the microwave field (which can be maintained at room temperature or cooled if necessary) can prove useful. The authors have operated such lamps some 20–25 cm long for mercury and iodine. The discharge does not fill the lamp, but it is normally advantageous to enable the discharge to come into contact with the top of the lamp as this tends to improve stability. A carrier-gas pressure of *ca.* 1–3 mmHg is normally required to ensure initiation of such a discharge and is essential in the case of iodine. Small diameter (2 mm bore instead of the more normal 8 mm) lamps used under these conditions can sometimes be useful, owing to a further reduction in self-absorption.

When the vapour pressure at room temperature is insufficient to provide a high intensity in long lamps, *e.g*, sulphur, zinc, then slightly larger lamp dimensions than normal (*i.e.*, >3 cm length) can provide a useful improvement in signal, although only at the expense of stability and warm-up time. It is best to ensure that the discharge fills the lamp, or migration of material to the much cooler portion will result in a considerably reduced radiation output. Cooling of the lamp may also be an advantage, but unless the air flow is accurately regulated, poor stability will result. Cooling of a lamp can seldom result in greater improvement than that which may be readily obtained by other means (reduction of microwave power or modification of preparative conditions).[46] The carrier gas normally chosen is argon, although the other inert gases have all been examined.[12,42,43] In addition to the problem of short lifetime when helium is used, the somewhat higher temperature of operation associated with helium lamps renders its choice undesirable for volatile species. The use of helium or neon could possibly be expected to induce shift in emission profile opposing that of the absorption profile in the atom reservoir. However, in view of the low pressure of carrier gas involved it is considered that this is likely to be of little consequence. Sensitivities obtained in AAS when using helium and argon-filled lamps are generally similar, provided both can be optimized with respect to microwave power (Table IV).

TABLE IV.—SENSITIVITIES* (ppm for 1% absorption) AT 213·8 nm USING VARIOUS ZINC EDL'S

† Lamps prepared using excess zinc metal and operated in a three-quarter wave cavity.

Because of the comparatively insignificant contribution to line broadening afforded by the carrier gas (Table I), variation of this parameter can also provide a useful means of improving the analytical signal. This would appear to be a result of the decreased operating temperature of lamps containing higher pressures of argon. Figure 7 shows the effect of argon pressure on the AAS of zinc. As can be seen the rate of decrease in absorbance at high microwave powers increases as the pressure is decreased. The highest absorbance is obtained at *ca.* 5 mmHg. Lamps prepared with argon pressures of ≤1 mmHg were comparatively short-lived (10–50 hr), although they could be initiated on heating the lamp. Line: background ratios were high in all

instances, ranging between 100:1 and 2000:1, depending on the lamp and its operating conditions. Optimum AAS performance was normally obtained at line:background ratios of 100:1–300:1. The effect of argon pressure on the AFS signal is more markedly dependent on the properties of the element or compound concerned than for AAS. For example, a decrease in argon pressure (down to 0·5 mmHg) results in an increase in AFS signal for zinc lamps (made with zinc metal); this was the lowest pressure at which the discharge could be initiated readily. However, some improvement at higher pressures may be obtained for very highly volatile elements when self-absorption/self-reversal is particularly pronounced; in certain instances higher pressure may provide a higher line intensity and an increased sensitivity in AFS for less volatile species such as Tl[44] and Mn.[43]

Acknowledgements—We thank Beckman-RIIC Ltd. for the provision of a research grant to one of us (DOC) and for the loan of some of the apparatus used in this study.

Zusammenfassung—Die Probleme der Verbreiterung der Linien in elektrodenlosen, Mikrowellen erregten Entladungslampen werden für die flüchtigeren Elemente P, S, I, Se, Zn, Cd und Hg in Bezug auf ihre Verwendung in Atomabsorption und Fluoreszenzspektrometrie besprochen. Es werden sowohl theoretische wie praktische Begleiterscheinungen in Betracht gezogen.

Résumé—On discute du problème de l'élargissement des raies dans les lampes à décharge sans électrode excitées par micro-ondes pour les éléments les plus volatils, P, S, I, Se, Zn, Cd et Hg, en relation avec leur emploi en spectrométrie d'absorption atomique et de fluorescence. On considère les conséquences tant théoriques que pratiques.

(*Received* 6 *September* 1971. *Accepted* 6 *March* 1972)

Summary—A method is described for the simultaneous determination of plutonium and uranium in mixed oxides by controlled potential coulometry at a gold working electrode in two stages: first a coulometric oxidation, at 0·73 V *vs.* a silver/silver chloride electrode, of Pu(III) and U(IV) to Pu(IV) and U(VI) by a combination of a direct electrode reaction and a secondary chemical reaction proceeding concurrently, and secondly, a coulometric reduction at 0·33 V of Pu(IV) to Pu(III), leaving uranium as U(VI). The determination is carried out in a mixture of sulphuric and nitric acids, and Ti(III) is used to reduce plutonium and uranium to Pu(III) and U(IV) before electrolysis. The precision (3σ) of Pu:U ratio results obtained from mixtures containing about 30% and 2% plutonium was 0·5% and 1·5% respectively. The effect of experimental variables on the time taken to complete the coulometric determination is discussed.

THE FABRICATION of mixed oxide fuel for both thermal and fast reactors has led to a substantial analytical requirement for the determination of plutonium and uranium in oxides containing approximately 2–30% plutonium. In order to extend the range of techniques available for this purpose, it was decided to attempt the development of a coulometric method.

There are well-established methods for the individual determination of these elements by controlled potential coulometry, *e.g.*, plutonium by electrolysis at a platinum or gold electrode,[1] and uranium at a mercury pool electrode.[2] A difficulty in the way of a method suitable for the determination of both elements is the large difference in the potentials of the redox couples involved. Electrolytic reduction of uranium(VI) to uranium(IV) in dilute mineral acid requires a more negative potential than can normally be obtained at a platinum or gold electrode without simultaneous reduction of hydrogen ion. Advantage is therefore taken of the high hydrogen overvoltage on mercury. However, the more positive potentials required for plutonium coulometry in mineral acid media would oxidize mercury, and a noble metal must be chosen in this case.

Thus the determination of plutonium and uranium by coulometry normally involves two entirely distinct measurements in separate cells equipped with the appropriate working electrodes. It would obviously be beneficial, in terms of convenience and economy, to be able to carry out both determinations in a single procedure.

The formal potential of the plutonium(IV)/(III) couple may be lowered by working with a citrate medium so that a mercury electrode may be used for the determination[3] but in this medium the formal potentials of the uranium and plutonium couples are not sufficiently different to allow both elements to be determined separately. Uranium has been determined by reduction at a silver electrode[4] without the concurrent liberation of hydrogen, but this electrode is unlikely to be suitable for use at the potentials required for the plutonium electrolysis. The evolution of hydrogen at a platinum electrode has been overcome by using constant-current potential limit coulometry[5] with addition of bismuth(III) to the electrolyte and periodically anodizing the electrode. Under these conditions plutonium and uranium were determined successively at a platinum electrode with a relative standard deviation of ±0·2% for each element.

In developing the new method described in this paper, consideration was first given to the redox process that might be employed. A conventional coulometric procedure for the determination of plutonium[6] in which a redox cycle between the tervalent and quadrivalent states is carried out by electrolysis at a noble metal electrode in a sulphuric acid medium was chosen as the basis for development. The attractive features of the method are as follows.

(*a*) Plutonium can be determined without interference from uranium(VI).

(*b*) The presence of nitric acid in the electrolyte can be tolerated, thus nitric acid used to dissolve mixed oxide would not have to be removed from the solution.

(*c*) It has been demonstrated[1] that the time required for electrolysis can be shortened considerably by using a gold electrode with a large surface area.

It was estimated that it would be possible to determine the sum of plutonium and uranium by coulometric oxidation provided that these elements were initially present as plutonium(III) and uranium(IV). Despite the much lower formal potential of the uranium(IV)/(VI) couple, uranium(IV) is not electroactive at the potential required for quantitative oxidation of plutonium(III). However, the mechanism envisaged was electrolytic production of plutonium(IV), which would oxidize uranium(IV) to give uranium(VI), and the regenerated plutonium(III) would again undergo electrolytic oxidation until eventually both plutonium and uranium were fully oxidized to the quadrivalent and sexivalent states, respectively.

This proposal requires that the two elements should initially be present as plutonium(III) and uranium(IV). An all-electrolytic process would present the basic problem of conflicting requirements for electrode materials. It appeared that this problem could be circumvented by the use of a chemical reduction treatment to avoid the need for mercury cathode electrolysis. However, it would be essential to have a sure method for destruction of the excess of reductant without oxidizing any of the uranium(IV) or plutonium(III). Titanium(III) in a mixture of sulphuric and nitric acids was chosen as the reductant on the ground that the solution medium would be compatible with the coulometric oxidation stage proposed for the determination of the sum of plutonium and uranium.

The new method was designed on the basis of these concepts, which are amplified in the next section. Since the method depends on the secondary reaction between uranium(IV) and plutonium(IV), information on the factors which govern the rate of this reaction is included, together with a brief review of the published uses of secondary reactions in coulometry. This paper covers experimental work carried out to develop a satisfactory procedure for mixtures containing more than 2% plutonium, and to determine its performance characteristics.

SECONDARY REACTIONS IN CONTROLLED POTENTIAL COULOMETRY

Various authors have referred to secondary reactions occurring during controlled-potential coulometric analysis. Meites and Moros[8] in a review of factors which contribute to the magnitude of background-current corrections in coulometry have defined a kinetic quantity of electricity which results from cyclic processes involving the oxidation and reduction of products of the primary electrode reaction. The effect is illustrated by the reduction of vanadium(IV) inducing the reduction of hydrogen ions. Geske and Bard[9] have presented a mathematical treatment of various hypothetical reaction schemes in which secondary chemical reactions occur which generate or consume the electroactive material, and methods of calculating the *n*-value of complex secondary reactions are described. Coulometric measurements have been used to calculate the kinetics of secondary reactions. For example Rechnitz and McLure[10] have studied the kinetics of the iridium(III)/chlorate reaction, using steady-state controlled-potential coulometry in the presence of excess of chlorate, and McCullough and Meites[11] have described the disproportionation of the product, and the chemical interaction between reactant and product during the coulometric reduction of niobium(V). An example of an analytical application is provided by the work of Shults[12] on a secondary coulometric method for the determination of plutonium by reducing plutonium(VI) with electrogenerated iron(II). This method was designed to overcome the interfering effect of iron on the normal procedure for the determination of plutonium.

No method appears to have been published in which a secondary reaction is used to determine two species quantitatively, one species being electroactive and the other not. For the determination of plutonium and uranium the following procedure was envisaged.

(*a*) Chemical treatment of the sample to convert it quantitatively into plutonium (III) and uranium(IV).

(*b*) Coulometric oxidation of plutonium(III) to (IV) concurrently with which the chemical reaction between plutonium(IV) and uranium(IV) would occur, forming uranium(VI) and regenerating plutonium(III).

(*c*) Continuing step (*b*) until the final products of the coulometric oxidation are uranium(VI) and plutonium(IV). The integrated current measured would correspond to the two-electron oxidation of uranium and the one-electron oxidation of plutonium.

(*d*) Coulometric reduction of plutonium(IV) to (III) under conditions where uranium(VI) remains stable. The integrated current for this step would correspond to plutonium alone.

i.e.,

$$\begin{array}{lll}
\mathrm{Pu(III)} & \rightarrow \mathrm{Pu(IV)} & \text{Electro-oxidation} \\
\mathrm{Pu(IV)} + \mathrm{U(IV)} & \rightarrow \mathrm{Pu(III)} + \mathrm{U(VI)} & \text{Chemical reaction} \\
\mathrm{Pu(III)} + \mathrm{U(IV)} & \rightarrow \mathrm{Pu(IV)} + \mathrm{U(VI)} & \text{Complete electro-oxidation} \\
\mathrm{Pu(IV)} & \rightarrow \mathrm{Pu(III)} & \text{Electro-reduction}
\end{array}$$

Information has been published on the conditions suitable for the chemical reduction [step (*a*)]. In the redox titration method described by Corpel and Regnaud[13] plutonium and uranium are reduced to the ter- and quadrivalent states respectively by titanium(III) in a mixture of nitric, sulphuric and sulphamic acids. This medium would be suitable for the coulometric procedure, and the reduction system has the additional advantage that a pre-electrolysis step could be carried out before the plutonium is electrolysed to ensure that all of the titanium is in the quadrivalent state.

It was expected that the efficiency of steps (*b*) and (*c*) would be influenced by the rate of the chemical reaction between uranium(IV) and plutonium(IV). The kinetics of this reaction in perchlorate solution have been studied by Newton[14] who showed that the rate was first-order with respect to uranium(IV) and plutonium (IV) and inversely proportional to the square of the hydrogen-ion concentration. The presence of traces of sulphuric acid accelerated the reaction. More recent work on perchloric acid solutions[15] has shown rates 3–5 times faster than those reported by Newton, and rates in nitric acid about half those in perchloric acid. The reaction rate has been considered during assessment of the suitability of uranium(IV) as an alternative reductant to iron(II) in nuclear-fuel reprocessing plants,[16] and it was concluded that the reaction was sufficiently fast in the aqueous phase to allow complete reduction of plutonium(IV) in solvent extraction equipment giving mixing times of 1–2 min. Although the conditions existing in a reprocessing plant, namely the provision of a concentration of uranium(IV) greater than that stoichiometrically equivalent to the plutonium(IV), would be different from those expected for the present application, it was felt that the reaction between uranium(IV) and plutonium(IV) during the coulometric oxidation would not be inconveniently slow, particularly since as the oxidation approaches completion the plutonium(IV) concentration would approach its maximum value.

EXPERIMENTAL

Apparatus

The controlled-potential coulometer used in this work was similar to that described by Goode *et al.*[2] The integrated current readings were made with a digital voltmeter, Dynamco type DM 2001 Mk. 2. The coulometer was calibrated electrically by substituting precision resistors for the electrolysis cell, following standard practice. The electrical calibration in coulombs per volt was converted into weight of plutonium or uranium per volt by using Faraday's laws.

The electrolysis cell comprised a flat-bottomed glass vessel 35 mm in diameter and 70 mm high, fitted with a polythene stopper (Fig. 1). Through the stopper were inserted two Corning 7930 Vycor unfired glass tubes of ¼ in. diameter, one containing a silver/silver chloride, saturated potassium chloride reference electrode, and the other containing a platinum wire spiral, both in $0{\cdot}5M$ sulphuric acid. The reference electrode sheath was made by plugging a length of polythene tubing, 3 mm bore and 1 mm wall thickness, with a short length of Vycor rod. The cell also contained a glass stirrer, having a paddle in the form of a disc with corrugations, driven by a 24-V d.c. motor capable of approximately 6000 rpm, and a tube to provide an argon purge. The gold working electrode comprised two pieces of 48-mesh expanded sheet, each 2 × 72 cm, spot-welded to a length of 16 S.W.G.

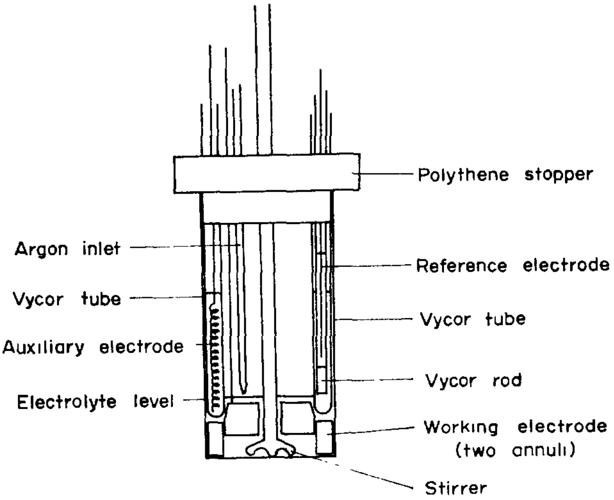

FIG. 1.—Coulometer cell.

gold wire to provide an electrical connection. Each was coiled so as to provide two ring electrodes, one of which would fit partly inside the other.

Reagents

Solutions were prepared by dissolving plutonium–uranium mixed oxides in $8M$ nitric acid/$0{\cdot}05M$ hydrofluoric acid, evaporating to remove the excess of fluoride and then diluting with $1M$ nitric acid to give a total metal concentration of 20–30 mg/ml.

Titanium(III) sulphate solution was prepared by refluxing a mixture of 50 ml of water, 10 ml of concentrated sulphuric acid and 5 g of titanium sponge, until the metal had dissolved. The solution was stored over a piece of cadmium metal in an atmosphere of argon.

Procedure

Transfer the sample solution containing 15–20 mg of plutonium plus uranium to the titration cell, together with 5 ml of a $0{\cdot}25M$ sulphuric–$1M$ nitric acid mixture and 1 ml of saturated sulphamic acid solution. Set the stirrer at approximately 500 rpm and direct the argon flow over the surface of the electrolyte. Add titanium(III) solution dropwise until present in excess, as judged by a darkening in colour of the electrolyte. Allow the chemical treatment to proceed for 10 min. Increase the stirrer speed to approximately 5000 rpm and pre-electrolyse the solution at a potential of 0·33 V *vs.* silver/silver chloride until the electrolysis current falls to 20 μA or less. Apply a potential of 0·73 V *vs.* silver/silver chloride to the working electrode and electrolyse until the current falls to a low and constant value of 25 μA or less. The integrated current for this process corresponds to the oxidation of the plutonium(III) to (IV) and the uranium(IV) to (VI). Determine the plutonium by applying a voltage of 0·33 V to the working electrode and electrolysing until the current falls to a low and constant value of about 10 μA or less. Correct the integrated current at both analytical voltages for integrator drift and residual current by the standard procedure.

Carry out a blank determination using the same quantity of reagents but with the plutonium–uranium solution omitted.

Subtract the corrected integrated current readings for the blank from the corresponding readings for the sample at the two voltages, and calculate the weights of uranium and plutonium in the sample from the electrical calibration of the coulometer.

RESULTS

Preliminary investigation

The selection of the working electrode potentials required did not present any difficulty since those normally used for the determination of plutonium in a sulphuric acid medium would apply. The method chosen for the chemical treatment of the sample to produce uranium(IV) and plutonium(III) did not require any change to be made to the electrode potentials. In the chemical treatment the titanium(III) reduces the uranium and plutonium and the excess of titanium(III) is oxidized by the nitric acid present[13] in the electrolyte. A pre-electrolysis at 0·33 V *vs.* silver/silver chloride, which would normally be carried out for a plutonium determination, was also found to be suitable to oxidize any remaining titanium(III). After the 10-min reaction time allowed in the procedure, pre-electrolysis normally required only 2–3 min and the integrated current was usually very small. It did, however, ensure that a reproducible starting point was achieved before each run.

The procedure was tested on a pure plutonium standard. The results obtained did not differ significantly from those obtained when the plutonium was determined in sulphuric acid electrolyte containing neither nitric acid nor titanium. A precision (3σ) of $\pm 0{\cdot}4\%$ with no detectable bias was obtained on 6-mg quantities of plutonium. Solutions containing both plutonium and uranium were analysed and the results were compared with those obtained by amperometric redox titration methods in which the plutonium was determined by reduction from plutonium(VI) to (IV) in sulphuric acid by iron,[17] and uranium by the oxidation of uranium(IV) to (VI) in phosphoric–sulphuric acids by dichromate.[18] Results are shown in Table I.

TABLE I.—RESULTS FOR PLUTONIUM AND URANIUM BY COULOMETRY AND REDOX TITRATION.

Method	Plutonium, *mg/ml*	Uranium, *mg/ml*	Ratio, 100 × Pu/(Pu + U)
Coulometry	$2{\cdot}86_3$, $2{\cdot}85_7$	15·55, 15·54	$15{\cdot}5_5$, $15{\cdot}6_1$
Redox titration	$2{\cdot}86_3$	15·54	$15{\cdot}5_8$
Coulometry	$4{\cdot}98_1$, $4{\cdot}99_4$	12·44, 12·46	$28{\cdot}5_9$, $28{\cdot}6_1$
Redox titration	$5{\cdot}00_1$	12·44	$28{\cdot}6_6$

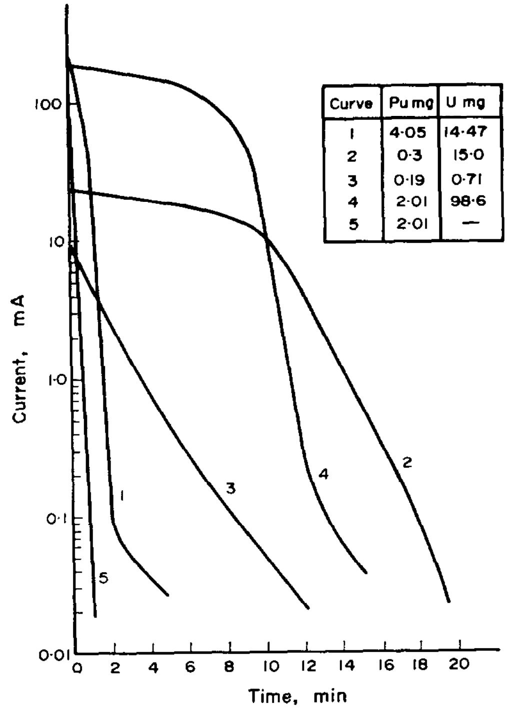
With the large surface-area gold electrode the coulometric oxidation of plutonium (III) and uranium(IV) [which includes the secondary reaction between plutonium(IV) and uranium(IV)] at 0·73 V *vs.* silver/silver chloride was complete in 5–6 min and the coulometric reduction of plutonium alone required 2 min. However, when solutions of low plutonium–uranium ratio were analysed, the time for the oxidation was increased to about 20 min for samples containing 15–20 mg of plutonium and uranium. It became apparent that with solutions of low plutonium–uranium ratio (about 5%) the rate of oxidation was controlled by a rate-limiting process, presumably either the rate of generation of plutonium(IV) at the working electrode or the rate of the chemical reaction between plutonium(IV) and uranium(IV). The rate of the electrode reaction is influenced primarily by the cell parameters, that is by the size of the working electrode, the volume of electrolyte and efficiency of stirring, whilst the rate of the chemical reaction is enhanced by increase in the concentration of plutonium(IV) and uranium (IV), and by decrease in the concentration of acid.

In controlled-potential coulometry where a single electrode reaction occurs under limiting current conditions the overall effective constant k is given in the expression $i_t = i_0\, e^{-kt}$ where i_0 and i_t are the current at time zero and t. Figure 2 shows current–time curves for plutonium and plutonium–uranium mixtures. Curve 5 corresponds to the electrolysis of 2 mg of plutonium, and from this curve a value for k of 0·07 sec^{-1} was calculated. This value is in good agreement with others reported for high-speed coulometry.[1,7] When plutonium–uranium solutions were analysed, the shape of the current–time curves depended on the plutonium–uranium ratio of the sample and the total quality of plutonium and uranium in the cell. Examples are discussed below.

Emphasis was placed on obtaining optimum conditions for a rapid coulometric oxidation step for two reasons, first to reduce the overall time for the determination of plutonium and uranium to a minimum in the interests of analytical convenience and economy, and secondly, because the corrections (due to residual current and integrator drift) to be applied to the integrated current reading for the electrolysis are smaller the shorter the electrolysis time.

The determination of plutonium and uranium

High plutonium–uranium ratio. For analysis of solutions of high plutonium–uranium ratio (greater than about 15%), the time required for the electrolytic oxidation was approximately the same as that for solutions of pure plutonium in quantities that gave an equivalent total integrated current. Curve 1 in Fig. 2 shows the current–time characteristics of a mixture containing 4·05 mg of plutonium and 14·47 mg of uranium, [Pu/(Pu + U) = 21·9%)]. The rate of the reaction was found to be unaffected by a small variation in the acidity of the electrolyte or plutonium and uranium concentration. When the concentrations of uranium and plutonium were decreased



Curve	Pu mg	U mg
1	4·05	14·47
2	0·3	15·0
3	0·19	0·71
4	2·01	98·6
5	2·01	—

FIG. 2.—Current-time curves for plutonium and plutonium–uranium mixtures.

markedly but the same plutonium–uranium ratio was maintained, the electrolysis time was increased and a negative bias appeared in the result. This effect is illustrated by curve 3 in Fig. 2, where 0·19 mg of plutonium and 0·71 mg of uranium were electrolysed [Pu/(Pu + U) = 21·9 %]. The electrolysis of less than 1 mg of plutonium would be expected to be complete within 1 min (*cf.* curve 5). The plutonium–uranium ratios calculated from the determinations corresponding to curves 1 and 3 were 21·9 % and 21·4 % respectively.

Solutions prepared from sintered plutonium–uranium mixed oxides were analysed by the coulometric procedure, and the results were compared with those obtained by redox titration and by X-ray spectrometry. These results are shown in Table II. For coulometry, samples containing 15–20 mg of plutonium plus uranium were used.

The agreement between these results is good, especially in view of fundamental differences in the character of the methods. The X-ray method, for example, is wholly dependent upon the integrity of the plutonium–uranium standards used for its calibration, whereas the coulometry results were calculated from the electrical calibration of the coulometer and were independent of plutonium–uranium standards.

TABLE II.—PLUTONIUM–URANIUM RATIO RESULTS ON MIXED OXIDES.

Coulometry			Redox titration	X-Ray spectrometry
100 × Pu/(Pu + U) Mean	Precision (3σ) %	Number of determinations	100 × Pu/(Pu + U)	100 × Pu/(Pu + U)
$15{\cdot}5_6$	0·8	11	$15{\cdot}5_6$	—
$23{\cdot}9_4$	0·7	10	$23{\cdot}9_8$	$23{\cdot}9_5$
$28{\cdot}6_2$	0·5	10	$28{\cdot}6_6$	$28{\cdot}5_9$

Low plutonium–uranium ratio. Current-time curves for samples of low plutonium–uranium ratio are illustrated for a 2% mixture in Fig. 2, curves 2 and 4. A comparison of curves 1 and 2 which represent samples of similar plutonium plus uranium content, and hence similar integrated currents for the oxidation process, shows the effect of plutonium–uranium ratio on the electrolysis time. When a series of solutions containing about 2% plutonium was analysed by the procedure described, that is with a sample of about 15 mg of plutonium plus uranium, the results showed a poor precision ($3\sigma = 4{\cdot}7\%$) and also a negative bias of about 2% when compared with results from the redox titration and X-ray spectrometry methods. The negative bias was shown to be related to the effect already noted on high plutonium–uranium ratio samples, by varying the quantity of plutonium plus uranium in the cell. It was found that as the size of the sample was increased from 15 to 100 mg the bias disappeared and also the time for the electrolysis to be completed was reduced (*cf.* curves 2 and 4 in Fig. 2). Accurate results were obtained when the sample contained more than about 1 mg of plutonium. With low plutonium–uranium ratio samples this resulted in relatively large quantities of uranium in the cell, but as shown by curve 4, Fig. 2, the overall coulometric oxidation was completed within a convenient time. An improvement in precision for low plutonium–uranium ratio results was obtained by modifying the basic procedure. It follows that since uranium(VI) does not interfere with the normal coulometric method for the determination of plutonium by reduction and oxidation of the plutonium(IV)–(III) couple, the plutonium may be determined first before titanium(III) is added to reduce the sample to plutonium(III) and uranium(IV). The recommended modification to the basic procedure is as follows.

Transfer a portion of the sample solution containing 1–2 mg of plutonium to the titration cell together with 5 ml of a 0·25*M* sulphuric–1*M* nitric acid mixture and 1 ml of saturated sulphamic acid solution.

Set the stirrer at approximately 5000 rpm and purge with argon for 5 min. Pre-electrolyse the solution at 0·33 V *vs.* silver/silver chloride until the current falls to about 10 μA. Zero the integrator then apply a potential of 0·73 V and electrolyse until the current falls to about 10 μA. The integrated current for this step corresponds to the oxidation of plutonium(III) to (IV).

Proceed with the addition of titanium(III) and carry out the basic procedure.

More precise results for plutonium were obtained by using this modification, and so the precision of the plutonium–uranium ratio was improved. The improvement was brought about primarily by the effect of the modification on the size and precision of the titration blank. When the modified procedure was used, the blank correction amounted to 2·0% of the integrated current for the electrolysis of 2 mg of plutonium, and the precision (3σ) of the blank calculated from results accumulated over several weeks was 22·2%. The lower limit imposed by the blank on the precision attainable for the plutonium determination was thus 0·45%. When the determination was carried out as described in the experimental section, that is on less than 0·5 mg of plutonium for a 2% plutonium sample, and plutonium was determined after the coulometric oxidation step, the precision of the blank limited the precision attainable for the plutonium determination to about 3% (3σ).

In the modified procedure developed specifically for the analysis of low plutonium–uranium ratio samples, the time required for the coulometric oxidation step was not affected by small changes in the plutonium or uranium concentration or in the acidity of the medium. The results obtained on four different solutions prepared from plutonium–uranium mixed oxides are shown in Table III.

TABLE III.—PLUTONIUM–URANIUM RATIO RESULTS ON MIXED OXIDES.

Sample	Coulometry 100 × Pu/(Pu + U)	X-Ray spectrometry 100 × Pu/(Pu + U)
1	$1\cdot99_7$	$1\cdot99_6$
2	$1\cdot55_9$	$1\cdot55_9$
3	$1\cdot80_6$, $1\cdot82_5$, $1\cdot82_4$ $1\cdot80_2$, $1\cdot82_3$	$1\cdot81_3$
4	$1\cdot80_4$, $1\cdot80_6$, $1\cdot79_6$ $1\cdot79_7$, $1\cdot79_8$	$1\cdot80_5$

The precision of the coulometric method is 1·5% (3σ) at this level, and the bias between the coulometric and X-ray spectrometry results is insignificant. The time taken for the coulometric oxidation step in these samples was about 15 min, and the plutonium determination required less than 2 min.

Maintenance of the working electrode

For the determination of plutonium and uranium a large surface-area gold electrode was chosen to ensure a high rate of electrolysis and thus a short analysis time. For analysis of pure plutonium solutions an occasional cleaning by immersion in chromic acid sufficed to keep the working electrode in good condition. With plutonium–uranium solutions it was more important that the electrode should be treated with chromic acid daily to maintain high initial electrolysis currents and short titration times. This effect is presumably related to the strong reducing treatment which the electrode is subjected to during the chemical reduction of the sample with titanium(III). Although it would be possible to reduce the sample and then introduce the electrodes after the excess of titanium(III) had been oxidized by the nitric acid, it was considered more convenient to carry out all steps in the procedure directly in the titration cell. The first run carried out each day was usually found to be anomalous in either the result obtained or the titration time, probably because of adsorption of chromic acid, and for this reason two or three blanks were normally run first to ensure reproducibility of the cell conditions. This type of behaviour is frequently encountered in coulometric work and in electrometric titration end-point detection systems. When not in use the electrode was stored in chromic acid.

Interferences

At an early stage in this work a coulometer cell was used in which the reference electrode comprised a silver/silver chloride electrode in saturated potassium chloride in a Vycor tube, which was immersed directly in the electrolyte. It was found that chloride diffusing through the Vycor tube adversely affected the precision of the results, particularly with low plutonium–uranium ratio samples. The diffusion of chloride into the electrolyte was greatly reduced with a reference electrode having the design shown in Fig. 1. The tip of the reference electrode is plugged with a short length of Vycor rod, which has a much lower leakage rate than Vycor tube, and the electrode is enclosed in a Vycor tube containing $0\cdot5M$ sulphuric acid. It is likely that the chloride affected the reproducibility of behaviour of the gold working electrode. Fluoride on the other hand did not interfere in the quantities present from the dissolution of samples of mixed oxides in $8M$ nitric acid–$0\cdot05M$ hydrofluoric acid. Some of this fluoride would be lost during dissolution, but when the sample taken comprised 0·5 ml of the acid mixture, the result for the plutonium–uranium ratio agreed with that obtained from a second portion of the sample which had been treated with a few drops of sulphuric acid and evaporated to fumes of sulphur trioxide to remove fluoride. Iron was found to interfere quantitatively with the result for plutonium, but not with uranium. Iron is likely to be the major metal impurity in mixed oxides, and the effect of other impurities at much lower concentrations would not be significant.

DISCUSSION

Throughout this work emphasis was placed on establishing conditions such that the coulometric/chemical oxidation of plutonium(III) and uranium(IV) should proceed rapidly and quantitatively so that the overall time for the determination might be reduced to a minimum. This involved optimizing both the rate of electrolysis and the rate of the chemical reaction. The former was shown to compare favourably with other reported high-speed coulometric studies. Rechnitz[10] has reviewed the conditions which must be fulfilled in order to determine the rate of a secondary chemical reaction proceeding in opposition to a primary electrode reaction. This author has determined the rate constant for the second-order reaction between iridium(III), electrogenerated from iridium(IV), and chlorate, having established conditions where a steady state existed, *i.e.*, the rates of the electrode reaction and the chemical reaction were the same. This condition was manifested by the appearance of a constant electrolysis current following the initial exponential decay which is expected in controlled-potential coulometry. Because of the slowness of the iridium–chlorate reaction[10] ($k = 1{\cdot}92 \times 10^{-2}$ l.mole^{-1}min^{-1} the electrolysis current had decayed appreciably before the onset of a constant current, and furthermore the concentration of chlorate did not change appreciably as a result of the chemical reaction. In the present work the secondary reaction between plutonium(IV) and uranium(IV) obviously proceeded very rapidly. Although some of the current-time curves exhibited a plateau, no evidence was found for a decay in current occurring before the plateau was established, as would be expected if the rate of regeneration of plutonium(III) by chemical reaction were rate-limiting. In addition, the oxidation of uranium(IV) was obviously proceeding rapidly in the plateau region. Newton[14] has reported that the second-order rate constant for the uranium(IV)–plutonium(IV) reaction is $5{\cdot}3 \times 10^2$ l.mole^{-1}.min^{-1} in $2M$ perchloric acid at 20°. The addition of a trace of sulphuric acid ($2 \times 10^{-3}M$) increased the rate of reaction by a factor of about 50.

Some rate measurements on the reaction between plutonium(IV) and uranium(IV) were made in the present work. The conditions were by no means rigorously controlled, and the observations served only to establish approximately the rate under the experimental conditions used for the coulometric analysis. The reaction was carried out in the titration cell by adding known amounts of plutonium(IV) to a solution of uranium(IV) which had been formed by the titanium(III) reduction procedure. After varying intervals of reaction time, the residual plutonium(IV) was determined by coulometric reduction to plutonium(III). Errors would be introduced by this measurement technique because of the finite time required for the reduction of the plutonium (IV), but by choosing conditions where the residual plutonium(IV) concentration was small, the majority of it was reduced within the first few seconds of electrolysis. The measurements were carried out in a mixture of $0{\cdot}5M$ sulphuric–$1M$ nitric acids, with

4 mg of plutonium and 2–6 mg of uranium, and a second-order rate constant of about 2×10^5 l.mole^{-1}.min^{-1} was obtained. This reaction rate is approaching the theoretical maximum value measurable for secondary chemical reactions by steady-state coulometry with a high-speed titration cell.[10] It was concluded therefore that any limitation in the rate of coulometric oxidation of plutonium(III) and uranium(IV) in the present application resulted from the electrode reaction generating plutonium(IV). This observation is supported by two further factors.

(*a*) A short appraisal had been made of the suitability of a coulometric cell having a small-area platinum working electrode to be used in conjunction with a potentiostat having a limited current-handling capacity. The platinum electrode cell produced initial electrolysis currents of about 50 mA in comparison with 250 mA or greater from the gold cell when used for the coulometric oxidation of plutonium and uranium. Table IV shows results obtained, using both of these cells, for the time taken to attain a residual current of 25 μA or less when analysing samples of high and low plutonium–uranium ratio.

TABLE IV.—COMPARISON OF PLATINUM AND GOLD WORKING ELECTRODE CELLS.

Working electrode	Time to reach a residual current of <25 μA, *min*		100 × Pu/(Pu + U)
	Coulometric oxidation of plutonium + uranium	Coulometric reduction of plutonium	
Large gold	5	2	$21{\cdot}9_0$
	5	2	$21{\cdot}8_7$
Small platinum	14	5	$21{\cdot}8_6$
	13	6	$21{\cdot}7_7$
Large gold	15	1	$2{\cdot}0_7$
Small platinum	Only 65 % complete after 25 min		

These results confirm that the time for the overall oxidation of plutonium(III) and uranium(IV) is very dependent upon the electrolysis cell parameters and consequently upon the rate of electrogeneration of plutonium(IV). The design of stirrer and speed of rotation used in the present work are not usual in controlled-potential coulometry, but the arrangement was found to give smoother and more efficient stirring than a conventional paddle at slower speeds in the present application.

(*b*) The importance of apparatus and equipment design was exemplified further by primary coulometric reactions carried out on large quantities of sample. In Fig. 2, curve 4 represents the oxidation of about 100 mg of plutonium plus uranium. The integrated current for this oxidation is equivalent to that from the oxidation of about 200 mg of plutonium. Because of experimental difficulties associated with handling 200 mg of plutonium in the cell, the measurement of a current–time curve for this quantity of sample was not possible, but iron may be oxidized and reduced under similar conditions to plutonium in a sulphuric acid electrolyte and was used as a convenient alternative. The current–time curve obtained for 48 mg of iron, which is equivalent in integrated current to about 206 mg of plutonium, is shown in Fig. 3. Its characteristics are very similar to those of curve 4, Fig. 2, confirming that the exponential decay of electrolysis current obtained with small samples does not hold when determining large samples with the same cell design.

It was concluded that the chosen electrolyte was a suitable medium for a rapid chemical reaction during the coulometric oxidation of mixtures of plutonium(III) and

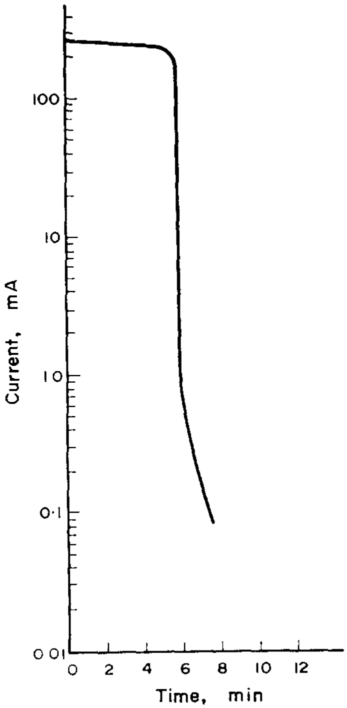


FIG. 3.—Current-time curve for iron (48 mg).

uranium(IV). It was advisable on principle to limit the amount of acid added in the sample to be analysed, but no differences were found in the plutonium–uranium ratio results or the titration time when the acidity of the sample was equivalent to 1 ml of 4*M* or 1 ml of 1*M* nitric acid. As an alternative to the use of titanium(III) as reductant for the chemical pretreatment of the plutonium–uranium sample, the use of electrolysis at a mercury pool was considered. This procedure would have the advantages that the addition of extraneous metal ions would be avoided, it could be carried out directly in sulphuric–nitric acid mixtures, and it would be possible to electro-deposit iron, the major interference in the plutonium determination. It would have the disadvantage, however, of greater complexity of apparatus and manipulations involved, and there would be uncertainty associated with quantitative transfer of sample to the coulometer cell and ensuring that no oxidation of the plutonium(III)–uranium(IV) mixture occurred during transfer.

A general advantage of the ability to determine both plutonium and uranium by one analysis in a single sample is that when only the plutonium–uranium ratio is required, no elaborate sample handling is needed. An accurate weight of plutonium–uranium mixed oxide need not be taken for analysis, nor need the sample be transferred quantitatively to the titration cell. For the coulometric method it is necessary to ensure only that the sample contains about 15 mg of plutonium plus uranium for high plutonium–uranium ratios, and about 100 mg for low ratios, the significant point being that the sample should contain at least 1 mg of plutonium.

The controlled potential coulometric procedure for the determination of plutonium and uranium is to the authors' knowledge the first reported procedure in which two major components in a mixture are determined quantitatively by a sequence of the type $A \rightarrow B$, $B + C \rightarrow D + A$ where A and B are electroactive and C and D are not at the potentials used. Reported work which is similar in principle has not been designed to achieve quantitative reaction of both components. The application is not restricted to plutonium and uranium. Iron may be used instead of plutonium so that the determination of uranium may be carried out conveniently in sulphuric/nitric acids at a solid electrode. This procedure may have advantages over the conventional determination at a mercury pool in some circumstances, *e.g.*, with a large solid electrode it is likely to be faster if a favourable iron–plutonium ratio is used, even though the method would be a two-stage procedure. In addition the determination would be more tolerant to nitric acid than the mercury pool method, and might be less prone to error from interferences, *e.g.*, ruthenium, which lowers the overvoltage for hydrogen evolution at mercury.

Zusammenfassung—Es wird ein Verfahren zur gleichzeitigen Bestimmung von Plutonium und Uranium in Mischoxyden durch geregelte Potentialcoulombmessung an einer goldenen Betriebselektrode in zwei Stufen beschrieben: erstens eine coulombmetrische Oxydierung bei 0,73 V versus einer Silber/Silberchloridelektrode von Pu(III) und U(IV) auf Pu(IV) und U(VI) durch eine Kombinierung einer direkten Elektrodenreaktion und einer gleichzeitig erfolgenden, sekundären chemischen Reaktion, und zweitens, eine coulombmetrische Reduktion von Pu(IV) auf Pu(III) bei 0,33 V, die Uranium als U(VI) hinterlässt. Die Bestimmung wird in einer Mischung von Schwefel- und Stickstoffsalzen durchgeführt und Ti(III) wird zur Reduktion von Plutonium und Uranium auf Pu(III) und U(IV) vor Elektrolyse benutzt. Die Genauigkeit (3σ) der Ergebnisses des Pu:U Verhältnisses, das sich aus Mischungen mit 30% und 2% Plutonium ergab, war 0,5% bzw. 1,5%. Die Wirkung experimenteller Veränderlichen auf die beanspruchte Zeit zur Beendigung der coulombmetrischen Bestimmung wird besprochen.

Résumé—On décrit une méthode pour le dosage simultané du plutonium et de l'uranium dans des oxydes mixtes par coulométrie à potentiel contrôlé en deux stades sur une électrode de travail en or: d'abord une oxydation coulométrique, à 0,73 V par rapport à une électrode argent/chlorure d'argent, de Pu(III) et U(IV) en Pu(IV) et U(VI) par une combinaison d'une réaction directe à l'électrode et d'une réaction chimique secondaire se développant concuremment, puis une réduction coulométrique à 0,33 V de Pu(IV) en Pu(III), laissant l'uranium à l'état U(VI). Le dosage est mené dans un mélange d'acides sulfurique et nitrique, et Ti(III) est utilisé pour réduire le plutonium et l'uranium en Pu(III) et U(IV) avant électrolyse. La précision (3σ) des résultats des rapports Pu:U obtenue à partir de mélanges contenant environ 30% et 2% de plutonium a été de 0,5% et 1,5% respectivement. On discute de l'influence de variables expérimentales sur le temps nécessaire pour réaliser le dosage coulométrique.

DETERMINATION OF PLUTONIUM AND URANIUM IN MIXED OXIDE FUELS BY SEQUENTIAL REDOX TITRATION

P. H. CHADWICK and I. R. MCGOWAN
British Nuclear Fuels Limited, Windscale and Calder Works, Sellafield, Seascale, Cumberland, U.K.

(*Received* 6 *September* 1971. *Accepted* 6 *March* 1972)

Summary—The use of a sequential determination of uranium and plutonium in a single sample solution results in a saving in analysis time and apparatus requirements. The method starts with U(IV) and Pu(III) in a mixture of sulphuric and nitric acids. Titration with dichromate, using amperometry at a pair of polarizable electrodes, produces two well-defined end-points corresponding to the sequential oxidation of U(IV) to U(VI) and Pu(III) to Pu(IV). The quantitative oxidation of U(IV) to U(VI) is achieved *via* the action of Pu(IV) as intermediate, and is dependent upon establishing conditions which favour rapid reaction between U(IV) and Pu(IV). The method is precise and accurate. With Pu-U mixtures containing between 15 and 30% plutonium the precision (3σ) of the Pu:U ratio results is ±0·6% on samples containing 100–120 mg of plutonium plus uranium. Iron and vanadium interfere quantitatively with plutonium, copper interferes non-quantitatively with uranium, and gross amounts of molybdenum mask the uranium end-point.

REDOX TITRATION methods are widely used for the determination of plutonium and uranium in plutonium–uranium mixed oxides. The methods in use for this purpose fall into two categories.

(*a*) Methods for the determination of plutonium where uranium does not interfere, and for uranium where plutonium does not interfere. The results from two separate determinations thus give the required information on the mixed oxide. Such methods are typified by those developed at D.E.R.E.; plutonium was determined, by Drummond and Grant,[1] by potentiometric titration of plutonium(VI) with iron(II) in a mixture of sulphuric and nitric acids, and uranium, by Davies and Gray,[2] by the oxidation of uranium(IV) to (VI) in phosphoric acid with dichromate to an end-point indicated by a redox indicator. Variations on these methods, in which amperometric end-point detection is used,[3,4] are in regular routine use at Windscale.

(*b*) Methods in which one of the variations in (*a*) is used in conjunction with a method which determines total plutonium plus uranium. An example is that described by Waterbury *et al.*[5] in which plutonium alone is determined by reduction of plutonium(VI) without interference from uranium, and the plutonium plus uranium, by cerimetric oxidation of plutonium(III) and uranium(IV) in a mixture of hydrochloric and sulphuric acids. A similar approach has been described by von Baeckmann *et al.*[6] Again the results of two separate determinations give the information required.

A saving in time and effort and a reduction in the number of facilities required would result from a method capable of determining plutonium and uranium sequentially in one sample. In principle the formal potentials of the plutonium(IV)–(III) and uranium(VI)–(IV) couples are sufficiently different for a sequential determination of the two elements by oxidation or reduction titrations to be considered. The difficulty in obtaining a reliable sequential determination by oxidation is probably associated with slowness in attainment of equilibrium during the oxidative titration of uranium(IV) to uranium(VI), since the analysis of pure uranium solutions is frequently carried out by adding an excess of dichromate to oxidize the uranium(IV) and back-titrating the remaining excess with a reductant after a waiting period,[7] or by adding an excess of iron(III) and titrating the iron(II) formed, with an oxidant.[9] It is significant, however, that uranium(IV) may be titrated directly with standard iron(III) solution, and good titration curves are obtained provided that favourable solution conditions and end-point detection methods are selected. Thus Florence and Shirvington[10] titrated uranium(IV) in 0·2*M* sulphuric acid at room temperature and recommended the use of amperometry with a dropping mercury electrode. The low-acid medium was chosen because it enhanced the rate of the uranium(IV)–iron(III) reaction, the rate being inversely proportional to the square of the acid concentration.[10,11] Since the formal potentials of the iron(III)–(II) and plutonium(IV)–(III) couples are very similar in sulphuric acid solution it was thought that acidity would be an important factor in the sequential oxidation of uranium(IV) and plutonium(III). This paper shows that plutonium(IV) behaves as an oxidizing intermediate during the titration of uranium(IV) and plutonium(III) with dichromate, and that the quantitative determination of uranium is strongly influenced by the acidity of the titration medium. Dichromate was used as oxidant because it is a reliable widely used standard; it is stable in water and therefore suitable for maintaining low-acid titration conditions. The chemical conversion of samples into the uranium(IV) and plutonium(III) oxidation states was achieved by the titanium(III) reduction method in sulphuric–nitric acids[8] for its convenience, reliability and tolerance to nitric acid, the latter point being a desirable feature because this acid is commonly used for dissolving mixed oxides. Both potentiometric and amperometric indication of equivalence points were investigated.

Under the conditions described, two equivalence points, corresponding to the quantitative oxidation of uranium(IV) to (VI) and plutonium(III) to (IV), are detected with high sensitivity. The method is suitable for the determination of plutonium and uranium in mixed oxides having compositions encountered in fast-reactor fuels, and the results produced are free from bias as judged by the analysis of plutonium–uranium standards.

EXPERIMENTAL

Apparatus

Titrations were carried out in a 100-ml beaker equipped with a glass stirrer driven by a 6-V d.c. motor. Dichromate solutions were delivered from either a glass burette (10-ml, A grade), or a polythene weight burette. The weight burettes were made from 2-oz polythene bottles by sealing a polythene tube with a fine tip to the neck of each bottle. An Agla micrometer syringe (0·5 ml capacity) was used for the precise location of end-points.

Potentiometric measurements were made with a calomel electrode and a platinum foil electrode (Type EPT 23, Electronic Instruments Ltd.) approximately 1 cm square. The potential was measured with a Pye Dynacap pH meter. For constant-current potentiometry, two EPT 23 electrodes were used, polarized by current supplied by a 90-V battery connected through a suitable megohm resistor (Fig. 1).

The amperometric indicator circuit employed the same two platinum electrodes connected to a 1·5-V battery through a 1000-ohm potentiometer and 2200-ohm fixed resistor. The potential applied

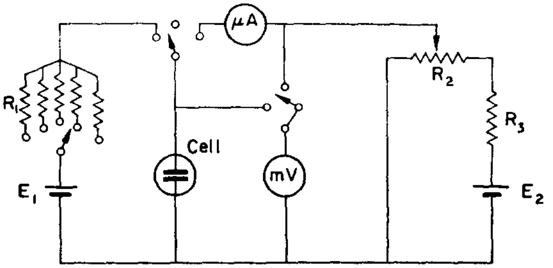

FIG. 1.—Polarizing circuit.

$E_1 = 90$ V $E_2 = 1{\cdot}5$ V
R_1 = various fixed resistances, 3·6–45 MΩ
$R_2 = 1{,}000\ \Omega$ $R_3 = 2{,}200\ \Omega$

across the electrodes was varied by adjusting the potentiometer, and measured with the pH meter. The indicator current was measured with a Cambridge spot galvanometer having a sensitivity of 12 scale divisions per μA (Fig. 1).

The electrodes were cleaned before use by immersion in chromic acid.

Materials

Uranium(VI) nitrate standard solution. Reactor-grade uranium dioxide with known total impurities was heated in air to U_3O_8. A known weight of the U_3O_8 was dissolved in 8*M* nitric acid, and the solution was diluted to 2*N* acidity to provide a weight standard (about 150 mg/g, 200 mg/ml).

Plutonium(IV) nitrate standard solution. A purified plutonium nitrate solution was assayed by igniting weighed aliquots in air at 1250° and weighing as stoichiometric plutonium dioxide. The solution was prepared as a weight standard (about 180 mg/g, 300 mg/ml) in 12*M* nitric acid, and the concentration was corrected for weight changes (due principally to radiolysis) on storage.

Plutonium–uranium standards. These were prepared by mixing the standard uranium and plutonium solutions in the required quantities. They were stored as weight standards (about 120 mg/g, 150 mg/ml) in 2*M* nitric acid solution and weight-change corrections were applied to these solutions.

Potassium dichromate standard solutions. Two solutions were prepared from P.V.S. grade potassium dichromate (Hopkin and Williams Ltd.) They were adjusted so that for the first, 1 g of solution was equivalent to 20·00 mg of uranium (about 0·17*N*, solution A) and for the second, 1 g was equivalent to 10·00 mg of plutonium (about 0·04*N*, solution B).

Titanium(III) sulphate solution. Titanium sponge (5 g) was warmed with a mixture of concentrated sulphuric acid (10 ml) and water (50 ml) until it had dissolved. The solution was stored in a 2-oz polythene bottle fitted with a dropper.

Sulphamic acid solution, 10% w/v.

Sample preparation

A weighed portion, about 0·5 g, of the mixed plutonium–uranium oxide sample was dissolved in 20 ml of 8*M* nitric acid/0·05*M* hydrofluoric acid mixture. The volume of solution was reduced to about 3 ml, then it was transferred to a tared flask, diluted to about 10 ml with 2*M* nitric acid and weighed. Weighed portions of the solution were taken for analysis.

Procedure

To provide a basis for development trials the procedure described by Corpel and Regnaud[8] was followed. The sample was transferred to the titration beaker and diluted to 40 ml with an acid mixture comprising 1*M* nitric–0·5*M* sulphuric–0·25*M* sulphamic acids. An excess of titanium(III) solution was added and the mixture was allowed to stand for 10 min to allow oxidation of surplus reductant to occur. The sample was then titrated with dichromate solution, potentiometry or amperometry being used to locate end-points for uranium and plutonium. In the preliminary study of the sequential oxidation, the dichromate solution was added from ordinary burettes; as titration conditions became established and data on precision and accuracy were needed, weight burettes were used. The weight burettes were used during the approach to the end-points, which were located precisely by further titration with dichromate delivered from the Agla Syringe.

RESULTS

Preliminary evaluation of end-point detection systems

Potentiometry. A brief study of the oxidation of uranium(IV) and plutonium(III) mixtures, using potentiometry with platinum and calomel electrodes and volumetric burettes, showed that only a single end-point was obtained. Variation in the acidity of the titration medium produced an ill-defined separation into two end-points at low acidity, but the titration was unsuitable for quantitative analysis. These results agree with other work.[8]

The titration of uranium(IV) and plutonium(III) separately, using constant-current potentiometry, gave good end-points for both species, and the titration curves were very different in character. It was found that a polarizing current of about 5 μA produced a well-defined titration curve for plutonium while one of 15 μA was needed for the uranium titration. Figure 2 shows curves for the separate titrations of plutonium(III) and uranium(IV) in a 0·5*M* sulphuric–1*M* nitric acid mixture. When mixtures of uranium and plutonium were titrated, two separate end-points were obtained, with the general shape expected from a knowledge of the individual uranium and plutonium titrations, but the uranium curve was markedly shifted on the voltage scale. A low-acid titration medium improved the quality of the two end-points, and

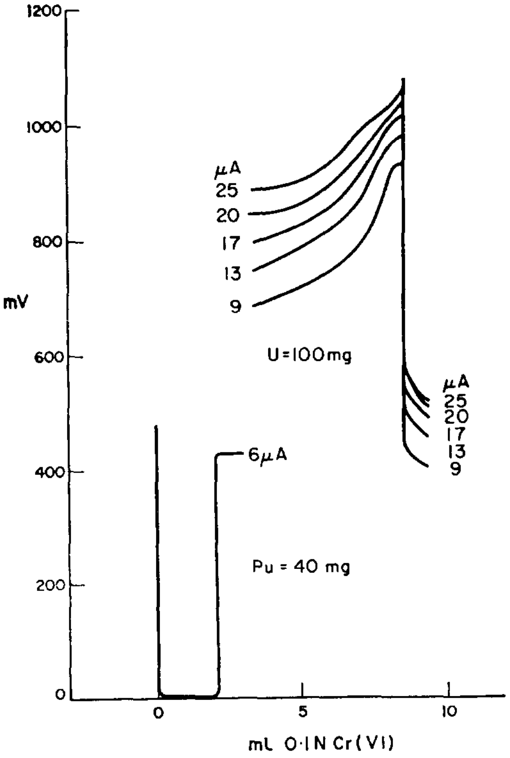

Fig. 2.—Constant-current potentiometry of separate uranium and plutonium samples in 1*M* HNO_3–0·5*M* H_2SO_4.

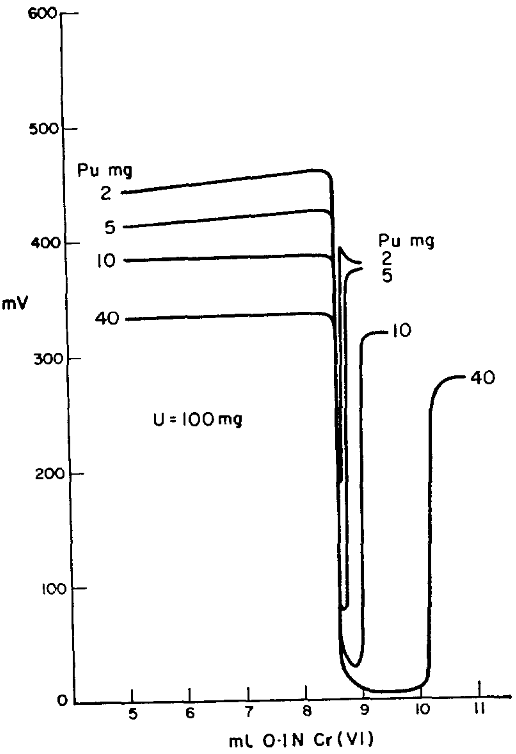

Fig. 3.—Constant-current potentiometry of uranium–plutonium mixtures in 0·2*M* HNO_3–0·2*M* H_2SO_4–0·2*M* NH_2SO_3H.

Fig. 3 shows the titration of uranium(IV) and varying amounts of plutonium(III) in $0{\cdot}2M$ sulphuric–$0{\cdot}2M$ nitric acids. A polarizing current of 15 μA was used. Although two separate end-points were obtained, the reproducibility of the determination of uranium and plutonium in mixtures was poor. A series of determinations on standards containing 15% plutonium showed a variation of several percent in the plutonium–uranium ratio results.

Amperometry. Solutions of uranium, plutonium and of mixtures of plutonium with uranium were titrated with dichromate solution, using a pair of electrodes polarized with a potential of about 200 mV. The titration of uranium(IV) produced no response in the indicator circuit at the titration equivalence point, as might be expected during the reaction of the two irreversible couples. The titration of plutonium(III) gave rise to an indicator current which increased to a maximum value, fell towards zero at the equivalence point and remained at a low constant value as further additions of dichromate were made. This behaviour is conventional for the titration of a reversible couple with an irreversible titrant, exemplified by plutonium(IV)–(III) and chromium(VI)–(III). When mixtures of uranium(IV) and plutonium(III) were titrated, a sharp rise in indicator current followed by a fall towards zero was observed for each addition of dichromate, at a stage well before the uranium equivalence point had been reached. The fall towards zero current was sluggish for titrations carried out in $0{\cdot}5M$ sulphuric–$1M$ nitric acids, but became more rapid when the acidity of the medium was lowered. Since it had been shown that an indicator current flowed only when both plutonium(IV) and plutonium(III) were present in the titration mixture, it was concluded that plutonium(IV) was formed during the titration before all of the uranium(IV) had been oxidized by the dichromate. The fall in current on standing presumably resulted from disappearance of the plutonium(IV) by interaction with uranium(IV), so that plutonium(IV) behaved as an important intermediate during the oxidation of uranium(IV) to (VI). It followed that the success of the sequential determination of uranium and plutonium would depend upon establishing conditions where the uranium(IV)–plutonium(IV) reaction was rapid and quantitative, to ensure precise location of the uranium end-point. The kinetics of this reaction have been studied,[12,13] and the most important feature of the reaction rate for the present application is its inverse dependence upon the square of the hydrogen ion concentration. The importance of the acidity of the titration medium in controlling the definition of the uranium end-point was thus established by the amperometric indicator system. After the uranium end-point had been passed and plutonium(IV) persisted during the titration with dichromate, stable indicator currents were produced and these current readings were used to locate the uranium end-point. After all the uranium had been oxidized, the plutonium(IV) concentration progressively increased and hence the current increased. The uranium end-point was given by the point of intersection of the (extrapolated) horizontal and rising lines of the titration curve.

The role of plutonium(IV) was demonstrated by using a standard solution of plutonium(IV) as titrant for a mixture of uranium(IV) and plutonium(III). Figure 4 shows the uranium end-point, which was within about 1% of that expected. After the uranium end-point had been passed, the total plutonium(III), *i.e.*, that present in the sample plus that formed by reaction of uranium(IV) with plutonium(IV), was

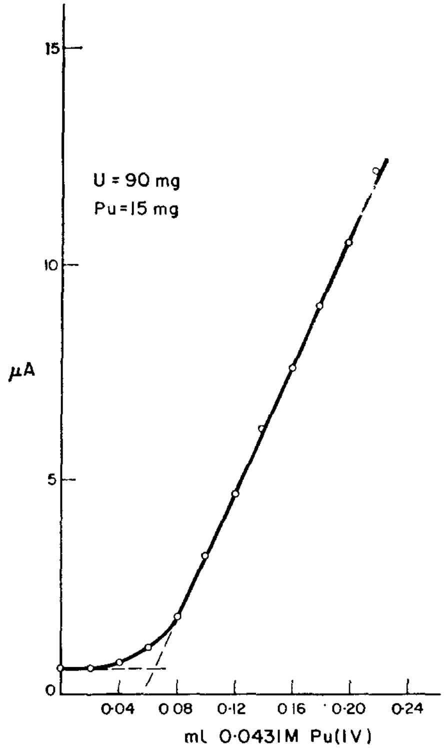

FIG. 4.—Amperometric titration of uranium(IV) with plutonium(IV).

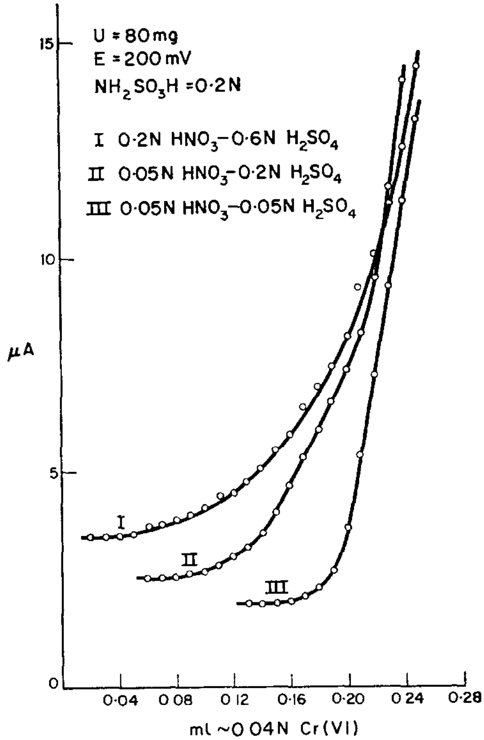

FIG. 5.—Effect of [H+] on the uranium end-point.

titrated with dichromate. The plutonium–uranium ratio result which was calculated for the sample was again within about 1% of that expected.

In view of the suitable response of amperometry to the plutonium(IV)–(III) couple, this technique was studied further.

Examination of amperometric titration variables

Effect of acidity. The effect of acidity on the uranium titration suggested that as low an acidity as possible would be an advantage. The acidity of the medium was found to be important for two other reasons.

(*a*) The reduction of the sample to the uranium(IV) and plutonium(III) oxidation states by titanium(III) requires a solution which is about 1*N* in both sulphuric and nitric acids.[8] The sulphuric acid controls the rate of oxidation of the excess of titanium(III) by nitric acid to ensure that quantitative reduction of the uranium and plutonium occurs. It was found that the chemical reduction could not be performed satisfactorily in a low-acid medium, and that it was necessary to reduce the sample in a small volume of 0·5*M* sulphuric–1*M* nitric acid, and then dilute the mixture to lower the acidity before titration.

(*b*) The extent to which the acidity of the medium could be lowered was limited by the quality of the plutonium end-point. Experiments in which the titration medium was less than 0·1*N* in both nitric and sulphamic acids and free from sulphuric acid showed that the plutonium end-point became impossible to locate, presumably because of disproportionation of the plutonium(IV). The addition of a small amount of sulphuric acid gave a much improved plutonium end-point. A medium comprising 0·05*M* nitric–0·025*M* sulphuric–0·2*M* sulphamic acids was found to be satisfactory for both uranium and plutonium end-point definition, and variation in the range 0·2–0·4*N* total acidity had little effect. The effect of acidity on the uranium titration curve is shown in Fig. 5, and typical uranium and plutonium titration curves are shown in Fig. 6. Under these conditions stable indicator currents were obtained 1–2 min after a dichromate addition had been made in the vicinity of the uranium end-point, but after this had been passed and plutonium(IV) persisted in the solution, current readings were stable within 30 sec.

Effect of applied voltage. During the development trials an arbitrarily chosen 200 mV had been applied across the electrodes. This value was confirmed as being most suitable by following titrations with different applied potentials. Figure 7 shows the effect of applied potential on the uranium end-point during the titration of mixtures having a plutonium–uranium ratio of about 15%. The plutonium end-point was also well-defined under these conditions.

Titration of plutonium and uranium standards. The titration of plutonium standards alone gave results showing a precision (3σ) of ±0·4% with 40–50 mg of plutonium. It

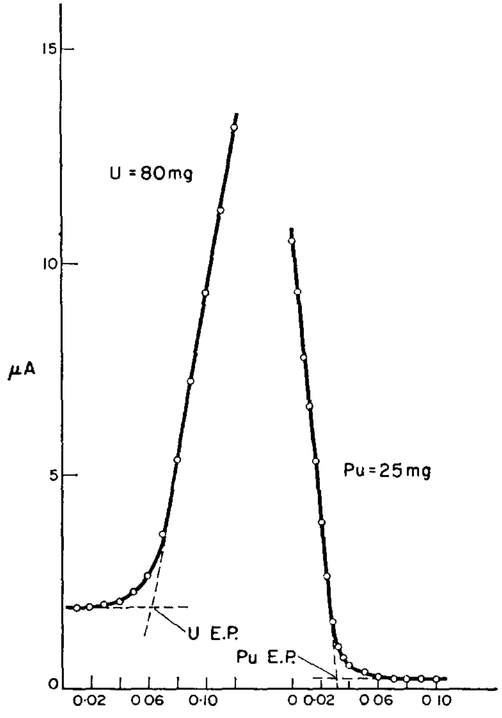

FIG. 6.—Typical end-points for uranium and plutonium.

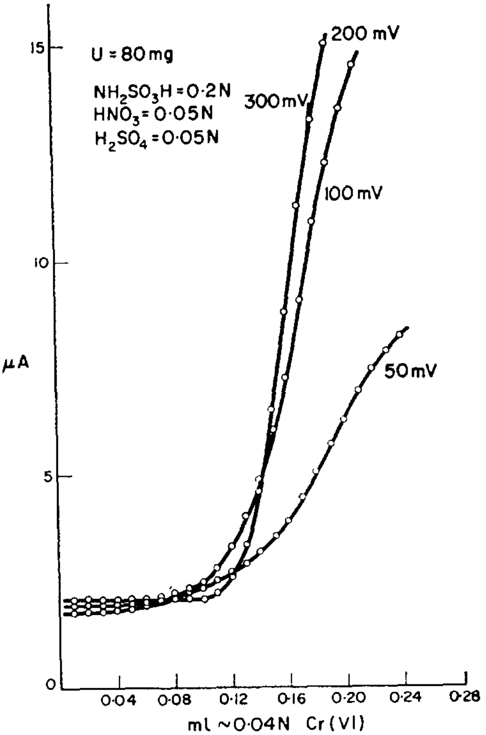

FIG. 7.—Effect of applied voltage on the shape of the uranium titration curve.

was not possible to obtain comparative data on uranium standards because of the inability of the amperometric end-point method to respond in the absence of an electrode depolarizer. Accordingly a plutonium–uranium standard containing about 15% plutonium was used to assess precision and accuracy. When the titration was carried out after the reduced sample had been diluted to lower the total acidity of the medium it was found that the uranium results obtained were lower than those expected for the standard by about 1%. Experiments in which the solutions were purged with inert gas to remove air gave results which were also low, and it was thought that atmospheric oxidation of the uranium(IV) was not the cause of the negative bias. A more likely explanation, although it was not proved, was that some disproportionation of the uranium(IV) occurred in the dilute acid. Whatever the cause of the bias, it was possible to minimize it by titrating part of the uranium(IV) with dichromate before the solution was diluted. Bias-free results were obtained when sufficient dichromate was added to oxidize about 90% of the uranium, the titration then being completed after dilution. To oxidize about 90% of the uranium presupposes knowledge of the uranium content of the sample. In the present application this did not create any special difficulties because plutonium–uranium mixed oxides are normally close to the specified plutonium–uranium ratio.

The procedure for the determination of uranium and plutonium would thus involve the sequence: reduction of the sample in 0·5M sulphuric–1M nitric acids, partial oxidation of the uranium(IV) with dichromate, dilution to reduce acidity, completion of the uranium titration, then titration of the plutonium. The full procedure is as follows

Recommended procedure for the determination of plutonium and uranium

If only the plutonium–uranium ratio of the sample is required then the oxide weight, solution weight and aliquot weight need not be measured accurately, but the same size of sample should be taken.

Weigh accurately into a 10-ml beaker an aliquot containing 100–150 mg of plutonium plus uranium. Add concentrated sulphuric acid (3 drops), evaporate just to fumes and dissolve the residue in warm 1M nitric acid (2 ml). Allow to cool, add 1M sulphamic acid (2 ml), followed by titanium(III) sulphate solution dropwise until the solution darkens in colour. This is usually accompanied by the evolution of nitrogen. Allow to stand for 10 min, during which time weigh the weight burette containing dichromate solution A to ±0·1 mg. Add sufficient of this solution to oxidize about 90% of the uranium estimated to be present, then transfer the sample solution to a 100-ml beaker with a solution of 1M sulphamic acid (8 ml) and water (30 ml). Start the stirrer, insert the electrodes and apply a potential of 200 mV across them. Stir for 5 min, after which time the initial high current will have fallen to a low value approaching zero. Continue dropwise addition of solution A until the indicator current shows a sharp rise followed by a slow fall to the original value; reweigh the weight burette.

Fill the Agla syringe with dichromate solution B and adjust the reading to zero. Mount it so that the tip just dips into the solution in the beaker. Add 0·01-ml increments and record the galvanometer and Agla readings after each addition. Allow 2 min between additions until the uranium end-point is passed, when the current begins to rise and stabilizes within 30 sec. Plot a graph of galvanometer deflection *vs.* volume added from the Agla and estimate the reading corresponding to the equivalence point, which is taken as the intersection of the horizontal and rising portions of the graph. Leave the Agla syringe in position with the tip immersed in the solution, fill a second weight burette with dichromate solution B and weigh to ±0·1 mg. Add this solution dropwise, when the current rises to a maximum and then begins to fall sharply. When the galvanometer deflection has fallen to 100–120 record the reading and reweigh the burette. Continue the titration with the Agla syringe, recording the Agla and galvanometer readings after each addition until the current falls to a constant value close to zero. Allow 30 sec between additions. Plot a graph of galvanometer deflection *vs.* volume added from the Agla and note the reading corresponding to the equivalence point. Calculate the weights of uranium and plutonium in the sample as follows:—

$$U = (20\,W_A + A_1 \times 4{\cdot}98)\ \text{mg}$$
$$Pu = 10[W_B + (A_2 - A_1)] - x\ \text{mg}$$

where W_A = weight of dichromate solution A

W_B = weight of dichromate solution B

A_1 = Agla reading (ml) at uranium equivalence point

A_2 = Agla reading (ml) at plutonium equivalence point

x = mg of Pu equivalent to the iron content of the titanium used

The uranium and plutonium content of the solid sample is obtained by multiplying each result by

$$\frac{\text{weight of sample solution in 10 ml flask}}{\text{weight of oxide specimen taken} \times \text{weight of solution analysed}}$$

These calculations are made on the assumption that 1 g of solution A is equivalent to 20·00 mg of uranium and that 1 g of solution B is equivalent to 4·98 mg of uranium and 10·00 mg of plutonium In practice, the appropriate factor must be used.

Performance of the method

Results on plutonium–uranium mixtures. Plutonium–uranium standards were analysed by the recommended procedure and the results obtained are shown in Table I.

The experimental results are calculated on the basis of dichromate as a primary standard. The agreement with the theoretical results shows that the method is free from bias at the plutonium–uranium ratios for which the method was designed, namely greater than about 15% plutonium. No results were obtained on mixtures intermediate between the 15% and 7% standards, hence the plutonium–uranium ratio at which the bias becomes significant is not known. The bias on the 7% mixture is most likely due to a combination of the plutonium–uranium ratio of the sample and the low concentration of plutonium present during the titration. It is possible that the use of a larger sample size would improve the results obtained at low plutonium–uranium ratios, but in a number of experiments where this was tried, difficulty was found in keeping the total acidity below the limit recommended. It was concluded that the optimum sample size under the conditions used was about 100 mg of plutonium plus uranium.

Two samples which were prepared from plutonium–uranium mixed oxides were analysed and the results compared with those from other methods in use in the Department. These results are shown in Table II.

The agreement between these results is good, particularly in view of the different physical bases of the methods.

Effect of impurities. From a knowledge of the plutonium assay method based on reduction by titanium(III)[8] it was expected that interference would be caused by iron, molybdenum, vanadium, arsenic and antimony. The most serious interference in the present method would thus be from iron, since this is likely to be the major impurity in plutonium–uranium oxides. Trials showed that iron interfered quantitatively with the plutonium but not with the uranium result. The effect of other elements is shown in Table III. High proportions of added element were employed to obtain an easily measurable effect. They were added at the sulphuric acid fuming stage of the method.

Molybdenum in the quantity added made the uranium end-point impossible to locate, and the total quantity of dichromate added to the plutonium end-point was

equivalent to the oxidation of the uranium and plutonium plus a one-electron oxidation of molybdenum.

Titration blank. It was found difficult to determine a true titration blank for the whole method. This was largely associated with the destruction of titanium(III) by the small amount of sulphuric–nitric acids used in the method when the amount of titanium(III) added in the blank was the same as that used for a plutonium–uranium sample. It was found however that titanium made a much greater contribution to the blank than any of the other reagents, and this contribution arose from iron as an impurity. Results from the chemical analysis of the titanium solution showed that the quantity of titanium(III) normally added during a determination would contain 32 μg of iron. The plutonium results quoted in Table I have been corrected for this quantity of iron. It was found necessary to determine iron in each batch of titanium(III) sulphate solution prepared.

TABLE III.—EFFECT OF IMPURITIES

Element	Amount, *mg*	Effect
Manganese	5	None
Tin	10	None
Tungsten	25	Precipitate, which dissolved on dilution. No interference
Copper	5	Precipitate, which dissolved on dilution. Low uranium result
Molybdenum	10	Masked uranium end-point
Vanadium	10	Quantitative interference with plutonium
Simulated mixed fission products	*	None

* The amount of inactive simulated mixed fission product added was equivalent to the quantities expected to be associated with 100 mg of plutonium plus uranium irradiated to 5 % burn-up and cooled for 6 months.

Behaviour of the indicator electrodes. Recommended procedures vary widely for the pretreatment of electrodes in polarized indicator circuits to ensure reproducibility and sensitivity. Some authors recommend electrolytic treatments (*e.g.*, ref. 10) while others prefer chemical procedures (*e.g.*, ref. 14). The choice of the most suitable pretreatment method appears to be largely associated with the particular system being studied, and a procedure which is suitable for electrodes which are exposed to strongly reducing conditions during a titration may not be suitable for those which experience strongly oxidizing conditions. In the present application the electrodes were treated initially by cleaning with hot chromic acid. Before use they were immersed for 5 min in a solution of 0·25*M* sulphamic acid containing a few drops of saturated iron(II) ammonium sulphate solution. After each titration they were again immersed in this iron(II) solution then rinsed with water before the next titration. The electrodes were stored overnight in sample solution which had been titrated beyond the plutonium end-point. When their performance began to deteriorate the procedure was repeated. The behaviour of the electrodes during a series of 20 runs is illustrated by the uranium titration end-points shown in Fig. 8. The results of the first two runs were normally discarded.

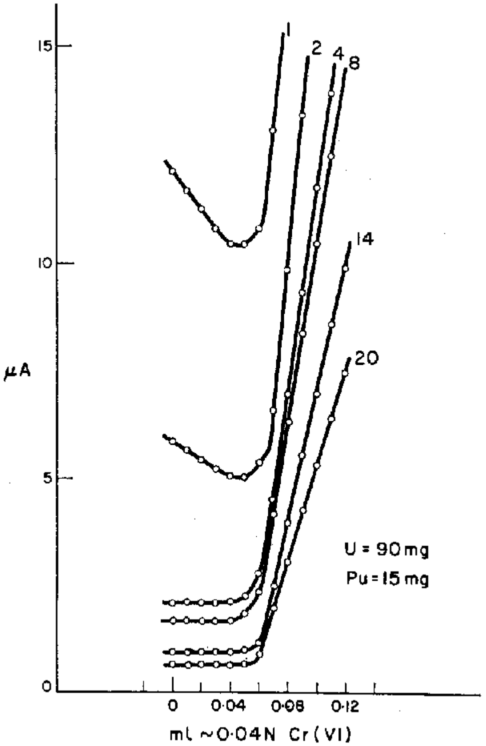

FIG. 8.—Performance of the electrodes in a series of titrations after thorough cleaning.

DISCUSSION

The method, which was developed for the sequential determination of plutonium and uranium, was found to be rapid and convenient to perform. Starting at the solution stage it may be completed within about 1 hr, which represents an appreciable saving in analysis time compared with separate redox titration methods for plutonium and for uranium in mixed oxides. The sequential procedure has the added advantage that when only a plutonium–uranium ratio result is required on the mixed oxide, the complete assay procedure is not needed. The precise weighing of the solid sample and quantitative preparation of solution may be eliminated, and the sampling arranged so that the portion of solution taken for analysis contains 100–120 mg of plutonium plus uranium.

An important feature of the sequential method, namely its reliance on the reaction between plutonium(IV) and uranium(IV), is common to the controlled potential coulometric method developed in this Department.[15] A difference between the two methods however is the smaller dependence upon acidity of the reaction medium in the coulometric method. This is related to other factors influencing the rate of the uranium(IV)–plutonium(IV) reaction in coulometry, primarily the concentration of plutonium(IV). In the coulometric method plutonium(IV) is continuously generated at the working electrode so that the final products of electrolysis are uranium(VI) and plutonium(IV). At no time do the concentrations of both uranium(IV) and plutonium(IV) tend towards zero, as they do during the redox titration method. Presumably at the uranium equivalence point in the redox method the rate of reaction between uranium(IV) and plutonium(IV) becomes very small as the concentrations of these species attain the low values defined by the equilibrium constant. The degree of rounding of the amperometric end-point for uranium is typical of many other redox systems. A better redox-titration analogy of the coulometric method would be the oxidation titration of uranium(IV) and plutonium(III) to uranium(VI) and plutonium(IV) followed by the reduction titration of plutonium(IV) to (III).

The amperometric indicator circuit was found to be useful in gaining information on the oxidation of uranium and plutonium mixtures and it provided sensitive and reproducible indication of the end-points. The constant-current potentiometric procedure was examined only briefly but it would be unlikely to be as satisfactory as amperometry. The electrode reactions giving rise to the observed potential changes were clearly complex, and the modification to the uranium titration curves caused by plutonium suggests that the latter was being oxidized or reduced at the electrodes. It is conceivable that in a complex system of reversible and irreversible couples, biased results may be obtained. In the worst case, for example, where the oxidation of plutonium(III) at one electrode is not accompanied by an equivalent reduction of plutonium(IV) at the other, the electrolysis resulting from the passage of a 20 μA current during a titration lasting 40 min would cause a bias of about 0·7% on 15-mg quantities of plutonium.

Zusammenfassung—Die Benutzung einer Folgebestimmung von Uranium und Plutonium in einer einzigen Musterlösung bringt Ersparnis in der Analysezeit und Apparatebeanspruchung. Das Verfahren beginnt mit U(IV) und Pu(III) in einer Mischung von Schwefel- und Stickstoffsalzen. Titrierung mit Bichromat mit Ampèremessung an einem Paar polarisierbarer Elektroden ergiebt entsprechend der Folgeoxydierung von U(IV) auf U(VI) und Pu(III) auf Pu(IV) zwei gut erkennbare Endpunkte. Die mengenmässige Oxydierung von U(IV) auf U(VI) wird über die Wirkung von Pu(IV) als Zwischenprodukt erreicht und hängt von der Gründung von Bedingungen ab, welche schnelle Reaktion zwischen U(IV) und Pu(IV) begünstigen. Das Verfahren ist präzise und genau. Bei Pu-U Mischungen mit einem Gehalt zwischen 15 und 30% Plutonium ist die Präzision (3σ) der Verhältnisergebnisse Pu:U ± 0,6% für Muster mit 100–120 mg Plutonium plus Uranium. Eisen und Vanadium wirken mengenmässig störend auf Plutonium ein, Kupfer wirkt, nicht mengenmässig, störend auf Uranium ein, und grosse Mengen von Molybdän verhüllen den Uranium Endpunkt.

Résumé—L'emploi d'un dosage séquentiel de l'uranium et du plutonium dans une seule solution d'échantillon a pour résultat une économie dans le temps d'analyse et les exigences instrumentales. La méthode part de U(IV) et Pu(III) dans un mélange d'acides sulfurique et nitrique. Le titrage au bichromate, utilisant l'ampérométrie sur une paire d'électrodes polarisables, produit deux points de fin de dosage bien définis correspondant à l'oxydation séquentielle de U(IV) en U(VI) et de Pu(III) en Pu(IV). L'oxydation quantitative de U(IV) en U(VI) est réalisée *via* l'action de Pu(IV) comme intermédiaire, et dépend de l'établissement de conditions qui favorisent la réaction rapide entre U(IV) et Pu(IV). La méthode est juste et précise. Avec des mélanges Pu–U contenant entre 15 et 30% de plutonium, la précision (3σ) des résultats des rapports Pu:U est de ±0,6% pour les échantillons contenant 100–120 mg de plutonium plus uranium. Le fer et le vanadium interfèrent quantitativement avec le plutonium, le cuivre interfère de manière non-quantitative avec l'uranium, et de grandes quantités de molybdène masquent le point de fin de dosage de l'uranium.

FLUORIDE DETERMINATION WITH A MICRO FLOW-CALORIMETER

CARL E. JOHANSSON
Department of Analytical Chemistry, Chemical Center, University of Lund,
Lund, Sweden*

(*Received* 15 *February* 1972. *Accepted* 18 *March* 1972)

Summary—Fluoride is determined by an integration technique with a flow calorimeter. All samples are absorbed on an anion-exchange resin before being brought into the calorimetric system. The reaction between hydrofluoric acid and sodium hydroxide is used in the determinations. The method is applied to samples with between 7 μg and 5 mg of fluoride. The confidence limit is $\pm 2{\cdot}5\ \mu g$ for small samples and $\pm 25\ \mu g$ for large samples. The enthalpy of the reaction $H^+ + F^- \rightarrow HF_{(aq)}$ was found to be $13{\cdot}77 \pm 0{\cdot}08$ kJ/mole.

THE ENTHALPIMETRIC determination of fluoride has been described in a previous article.[1] Samples of 6–8 mg of sodium fluoride could be determined with an injection technique and 40–400 μg with a flow calorimetric technique. With the method presented here the amounts are not so restricted and the range is 15 μg–10 mg of sodium fluoride.

In an enthalpimetric titration with a flow calorimeter of the heat leakage type, two calorimetric liquids are brought together in a mixing cell where heat effect is produced. If the temperatures of the solutions before the reaction are equal and constant, and the flow rate is kept constant, the heat effect is also constant during the experiment. The electrical output from the thermocouples is proportional to the heat effect,[2] which is caused by various factors including friction, dilution and reaction. When one of the solutions is in stoichiometric excess, the heat of reaction between them is proportional to the concentration of the other solution.

Zero adjustment of the output is done with a blank solution. When this is exchanged with a sample solution, the temperature in the cell rises until a steady state is reached.[3] This means that the heat leakage from the cell is equal to the heat entering the cell. When the sample is delivered into the blank solution as a normally distributed concentration gradient, the output signal will not refer to a steady state. However, the output signal will often closely resemble the real concentration curve. The integral of the output signal is then proportional to the amount of the sample. If the molar heat of reaction depends on the concentration, the integrated voltage *vs.* sample curve can still approximate to a straight line for narrow concentration ranges.

A problem in enthalpimetric measurements is to achieve good selectivity. With the usual technique a contaminant can give an error in the signal without being discovered. However, if the sample is separated from disturbing contaminants by a chromatographic process, it is possible to measure the amount of substance by integrating the output voltage. The slope of the signal on the recorder will indicate if there are any contaminants in the reacting substance.

As fluoride ions are easily separated from many other anions by anion-exchange, they may be determined conveniently by the integration technique. When the eluent is hydroxide solution, the alkaline fluoride solution is best converted into a dilute

hydrofluoric acid solution with a cation-exchange resin in H$^+$-form. The reaction measured in the flow cell is then a simple acid–base reaction.

When thermodynamic properties are to be measured, the integration technique is not very suitable since the values depend on the sample concentration. The ΔH of dissociation of hydrofluoric acid was therefore measured by the usual steady-state technique.

EXPERIMENTAL

Quantitative determination of fluoride

Reagents. The sample solutions were prepared from sodium fluoride of Suprapur quality (Merck), and sodium carbonate, chloride, phosphate, sulphate and sulphide all of *pro analysi* quality. In the oxygen-flask combustion samples of 2–5 mg of *p*-fluorobenzoic acid of *pro analysi* quality were used. The eluent in the anion-exchange was sodium hydroxide solution prepared from a concentrated, carbon dioxide-free solution. The anion-exchange resins were regenerated with $4M$ sodium hydroxide and the cation-exchange resins with $3M$ hydrochloric acid. The reagent solution in the enthalpimetric measurements was $0{\cdot}1M$ sodium hydroxide.

Oxygen combustion. The *p*-fluorobenzoic acid samples were wrapped in a paper sample carrier. Two drops of dodecyl alcohol and 2 mg of potassium chlorate were added as combustion aid and the carrier was enclosed in a platinum basket attached to a platinum wire on a rubber stopper. The paper was ignited and put into a 500-ml Nalgene polycarbonate flask[4] which had been flushed with oxygen. The flask also contained 5 ml of $0{\cdot}05M$ sodium hydroxide. The resulting sodium fluoride solution was adjusted to pH 5·2 with $0{\cdot}003M$ nitric acid and purged with carbon dioxide-free nitrogen for 15 min. The solution was then handled according to ion-exchange procedure II.

Ion-exchange procedure I. Fluoride was separated from other anions by anion exchange in a similar manner to that previously described.[1] Samples containing 1·000 mg of sodium fluoride and an 80-fold excess of carbonate, chloride, phosphate, sulphate and sulphide were put on a glass column with 2·5 g of Dowex 1 × 8, 200–400 mesh in OH-form. The flow-rate in the absorption step was 1 ml/min. After a wash with distilled water, the fluoride was eluted with $0{\cdot}2M$ sodium hydroxide at 1 ml/min. The first 20 ml of effluent did not contain any fluoride and were rejected. The following 50 ml contained all the fluoride and were passed through a Teflon column with 5 g (dry weight) of Dowex 50 W × 8, 20–50 mesh in H$^+$-form, and after that through 1 g of the resin in Na$^+$-form. The resulting sodium fluoride solution was adjusted to a pH of 5·2 with $0{\cdot}003M$ nitric acid and purged with carbon dioxide-free nitrogen for 15 min. Samples containing carbonate were also adjusted to pH 5·2 and purged with nitrogen before the ion-exchange procedure. The ion-exchange resins were regenerated and washed with distilled water before the next sample was introduced.

When the amounts of other anions are in the range <0·05 mmole, procedure I is not necessary and the determination can be done directly through procedure II. If any of the contaminants does pass through during the integration time it is easily detected on the recorder signal.

Procedure I was not used in direct connecton with the calorimetric step for the following reasons: (*a*) the flow-rate of the eluent, which was controlled by the pressure from a nitrogen cylinder, could not be reproduced with good precision, (*b*) the fluoride concentration peak was too broad, (c) the concentration of carbonate ions was relatively high in spite of the precautions taken.

Ion-exchange procedure II. The fluoride–nitrate solution from procedure I was absorbed on 0·5 g of an anion-exchange resin, Dowex 1 × 8, 200–400 mesh in OH$^-$-form. The resin was then connected with a 5-mm diameter PVC tube filled with 3 g of Dowex 50 W × 8 resin, 20–50 mesh in H$^+$-form. Sodium hydroxide ($0{\cdot}1M$) was pumped through the anion-exchange resin to elute the fluoride. The nitrate ions remained in the resin. The solution passed through the cation-exchange resin and the sodium ions were exchanged for hydrogen ions. The resulting hydrofluoric acid passed on to the calorimeter. Calibration samples with 15 μg–10 mg of sodium fluoride were also treated as in procedure II.

The anion-exchange resins were regenerated with $4M$ sodium hydroxide and washed with distilled water. The cation-exchange resins were regenerated with $3M$ hydrochloric acid and washed with distilled water after every third sample.

Calorimeter. A commercial instrument, the LKB 10700-1 was used[2] (Fig. 1). This calorimeter is a twin heat-leakage calorimeter utilizing semiconducting thermocouple plates for measurements of the heat flow. The mixing cell was made of a gold spiral and had an internal volume of 0·6 ml. An LKB 10200 and an LKB 12000 Perspex Pump were used to pump the reagent and the sample solutions through the reaction cell. The signal from the thermocouples was fed to a Keithley 150 B Amplifier with the input signal measured in the 3-mV range.

The time-voltage curve was followed on a Servogor RE 511-recorder. The integration unit consisted of an electronic integrator. The integrated signal was measured on a Dynamco DM 2006 Digital Voltmeter in the ranges 100 mV, 1 V and 10 V, depending on the amount of fluoride in the sample.

Calorimetric procedure. The reagent solution of 0·1*M* sodium hydroxide in the calorimetric step was pumped into the calorimeter at a rate of 32·2 ml/hr. The blank solution was 0·1*M* sodium hydroxide. It was first passed through an anion-exchange resin in the OH^--form which absorbed the carbonate ions and then through a cation-exchange resin in the H^+-form at a rate of 33·5 ml/hr. When a steady state was reached, the output signal from the amplifier was adjusted to zero. Then the anion-exchange resin was exchanged with the sample resin and procedure II was followed. About 15 min after the anion-exchange resin with the sample was connected, the hydrofluoric acid reached the calorimetric cell and reacted with the sodium hydroxide solution. The output signal increased and reached a maximum about 5 min later, and after 20 min the signal had returned to the zero level. The temperature in the calorimeter was 25°.

Determination of the enthalpy change for the acid-base reaction

The enthalpy change of the reaction between sodium fluoride and 0·2*M* hydrochloric acid was measured for different concentrations of the salt. As a comparison, the enthalpy change of the reaction between hydrochloric acid and sodium hydroxide was also measured.

Reagents. Hydrochloric acid solutions with concentrations between 0·005 and 0·01*M* were made from concentrated acid, and the reagent solution 0·1*M* sodium hydroxide made from a concentrated carbon dioxide-free solution.

Calorimeter. The same equipment was used as in the quantitative determinations. The heater in the reaction cell had a resistance of 49·816 Ω. The Keithley 150 B Amplifier was used on the 300-μV range and the output measured with the Dynamco DM 2006 Digital Voltmeter on the 100-mV range. The temperature of the calorimeter was 25°.

Calorimetric procedure. An electrical calibration was performed with the heater in the reaction cell. The liquids were $0{\cdot}1M$ sodium hydroxide and distilled water. The output voltage was measured for calibration currents between 3 and 10 mA. The flow-rates were the same as in the quantitative measurements, 33·5 ml/hr for the distilled water and 32·2 ml/hr for the sodium hydroxide. The distilled water was then replaced with hydrochloric acid. The output voltage was measured for different acid concentrations. The hydroxide was then exchanged for distilled water and the heat of dilution was measured for different concentrations of the acid solutions. Then the output voltage was measured for different concentrations of fluoride reacting with $0{\cdot}2M$ hydrochloric acid.

RESULTS AND DISCUSSION

The reaction between hydrogen fluoride and hydroxide consists of two steps: the dissociation of hydrogen fluoride and the reaction between hydrogen ions and hydroxide ions. The dissociation of hydrogen fluoride decreases with increasing concentration. Because the heat of dissociation, as shown later, is relatively high, the molar heat of reaction between hydrofluoric acid and hydroxide increases with increasing concentration of the acid. It is obvious that the voltage-time curve on the recorder must be the same for different determinations of the same amount of fluoride if reproducible results are to be obtained. This was achieved in the procedure described. Since the molar heat of reaction is different for different concentrations of fluoride, the plot of integrated voltage *vs.* amount of sample is not a straight line, but over short intervals, approximates to one, and the precision of the method in different concentration ranges could be calculated by regression analysis. For an unknown sample in duplicate the amount of fluorine could be determined within the ranges shown in Table I (95% confidence limits).

TABLE I.—PRECISION OF FLUORIDE DETERMINATION.

Fluoride taken, *mg*	Precision at a confidence limit of 95% *mg*	Number of determinations
0·007–0·02	±0·0025	7
0·02–0·3	±0·0065	7
0·3–2	±0·0065	13
2–5	±0·025	14

The best relative precision is given in the concentration range 0·3–2 mg of fluoride. For larger amounts the reproducibility is not so good. The reason could be that the samples are absorbed on a larger area of the ion-exchange resin and therefore give less reproducible time–concentration curves in the elution step. Since the molar heat of reaction is dependent on the concentration, the integrated voltage can then differ for the same amount of fluoride.

In Table II results from the oxygen-flask combustion experiment are shown. The value of the integrated signal from the calorimetric procedure is used to calculate the amount of the fluorine, from the calibration curve in the 0·3–2 mg range.

The source of the recorder signal is easily identified through a spot test.[5] It is also possible to absorb the fluoride on an anion-exchange resin after it has passed through the reaction cell and then let it go through the calorimetric procedure once more.

The microcalorimeter can possibly also be used as a detector in other chromatographic processes, *e.g.*, liquid partition chromatography.

Enthalpy change determination

The output voltages for calibration currents used here (3–10 mA) were directly proportional to the heat energy RI^2. A straight calibration line was established for output voltage *vs.* energy.

The heats of the actual reactions could be calculated from the calibration line. In the hydrochloric acid–sodium hydroxide reaction, the enthalpies at concentrations of the acid between 0·005*M* and 0·01*M* and ionic strength 0·1*M* were measured. The values for infinite dilution were then calculated.[6,7] The enthalpy of the ionization of water at infinite dilution was 56·03 ± 0·26 *kJ*/mole. This is in fairly good agreement with values in the literature.[6,8]

Table IV shows the molar enthalpies measured at ionic strength 0·1*M* for the reaction between sodium fluoride (at different concentrations) and hydrochloric acid, including the heat of dilution of the fluoride solution. The concentration of HF_2^- formed is $<3 \times 10^{-4}$. [HF].[7] The heat of formation of HF_2^- was calculated

0·0100	13·28	13·70
0·0233	13·26	13·85

from Hepler *et al.*[9] to be ~16 *kJ*/mole. The influence of this on the results was therefore neglected.

The enthalpy of the reaction $H^+ + F^- \rightarrow HF_{(aq)}$ at infinite dilution and 25° is then 13·77 ± 0·08 *kJ*/mole, which is rather different from the value given by Hepler *et al.*[9] of 13·31 ± 0·06 *kJ*/mole.

Acknowledgement—I wish to thank Dr. K. J. Karrman for valuable help during this work and Miss Birgitta Rees for performing the oxygen-flask combustions. I am also thankful to the Swedish National Research Council for defraying the cost of the calorimeter.

Zusammenfassung—Fluorid wird in einem Durchflußkalorimeter mit Hilfe eines Integrationsverfahrens bestimmt. Ebe die Proben ins Kalorimetersystem gebracht werden, werden sie an einem Anionenaustauschharz adsorbiert. Bei den Bestimmungen wird die Reaktion zwischen Flußsäure und Natriumhydroxid ausgenutzt. Das Verfahren wird auf Proben mit 7 μg bis 5 mg Fluorid angewandt. Die Vertrauensgrenze beträgt ± 2,5 μg bei kleinen und ±2,5 μg bei großen Proben. Für die Enthalpie der Reaktion $H^+ + F^- \rightarrow HF(aq)$ wurde der Wert 13,77 ± 0,08 kJ/Mol gefunden.

Résumé—On dose le fluorure par une technique d'intégration avec un calorimètre à écoulement. Tous les échantillons sont absorbés sur une résine échangeuse d'anions avant d'être introduits dans le système calorimétrique. On utilise la réaction entre l'acide fluorhydrique et la soude dans les dosages. La méthode est appliquée à des échantillons contenant entre 7 μg et 5 mg de fluorure. La limite de confiance est de ±2,5 μg pour les petits échantillons et ±25 μg poru les gros échantillons. On a trouvé que l'enthalpie de la réaction $H^+ + F^- \rightarrow HF$ (aq) est de 13,77 ± 0,08 kJ/mole.

SYNTHESIS AND ION-EXCHANGE PROPERTIES OF CERIC ANTIMONATE

SEPARATION OF Hg^{2+} FROM Zn^{2+}, Cd^{2+}, Pb^{2+} AND Tl^{+}; Cu^{2+} FROM Mn^{2+}; Fe^{3+} FROM Al^{3+}; AND Zr^{4+} FROM Th^{4+}

J. S. GILL and S. N. TANDON

(*Received* 25 *February* 1972. *Accepted* 5 *April* 1972)

Summary—Ceric antimonate has been prepared under varying conditions of precipitation. Its properties and ion-exchange behaviour have been studied. Separations of Hg^{2+} from Zn^{2+}, Cd^{2+}, Pb^{2+} and Tl^{+}; Cu^{2+} from Mn^{2+}; Fe^{3+} from Al^{3+}; and Zr^{4+} from Th^{4+} have been achieved with this material.

IN THE LAST DECADE a good deal of interest has grown in synthetic inorganic ion-exchangers.[1] This is mainly because of their greater power to withstand higher radiation doses and temperatures than the commonly-used organic-based resins. In addition to this they sometimes exhibit highly specific properties which might permit improved separations under ordinary conditions. A large number of insoluble salts formed from multivalent metals and polybasic acids have been investigated as inorganic ion-exchangers. Although most of the work deals with studies on zirconium phosphate, other phosphates, arsenates, antimonates, tungstates, molybdates and hydrous oxides have also been studied as potential ion-exchangers. Amongst the antimonates of quadrivalent elements which form an equally promising series, zirconium[2,3] and tin(IV)[4] antimonates have already been investigated by earlier workers. In continuation of our systematic studies on some new inorganic ion-exchangers[5,6] ceric antimonate was explored for its ion-exchange properties.

The present report summarizes our findings on the preparation, properties and ion-exchange behaviour of ceric antimonate. The conventional method of precipitating ceric antimonate with potassium pyroantimonate gives a product unsuitable for column operation. But the samples prepared with antimonic acid can be conveniently used in columns. Not only this, they also exhibit higher exchange capacity. The distribution ratios for 21 different metal ions have revealed that the exchanger is more or less specific for Hg^{2+}, which has been separated from closely associated elements such as Zn^{2+}, Cd^{2+}, Pb^{2+} and from Tl^{+} which is of interest in nuclear reaction studies. Besides this, other separations of analytical importance such as Cu^{2+} from Mn^{2+}; Fe^{3+} from Al^{3+}; Zr^{4+} from Th^{4+} have also been achieved on this material.

EXPERIMENTAL

Reagents

Ceric ammonium sulphate and potassium pyroantimonate were used without further purification.

Amberlite IR-120 ion-exchange resin (H^{+} form) was used for preparing antimonic acid.

^{203}Hg, ^{65}Zn, ^{115m}Cd, ^{58}Co, ^{204}Tl, $^{55+59}Fe$ and ^{51}Cr radioisotopes were used for the determination of distribution ratios.

All other reagents used were of analytical grade.

Preparation of ceric antimonate

All the samples of ceric antimonate were prepared by methathesis of Ce^{4+} and $[Sb(OH)_6]^-$ ($K[Sb(OH)_6]$ or $H[Sb(OH)_6]$) at room temperature (14 ± 3°). Details of precipitation are summarized in Table I. The precipitate was allowed to settle at room temperature for 4 hr. It was filtered off, washed thoroughly with demineralized water and dried in air at room temperature. The samples obtained with potassium pyroantimonate were sieved to 100–200 mesh. The precipitation with antimonic acid yielded gels which were broken to smaller particles by immersion in water. In cases where the gel did not break down to the desired particle size it was ground in a porcelain mortar and sieved to 100–200 mesh size for batch operation and 50–100 mesh size for column operation. To convert the ion-exchanger into the hydrogen form, it was immersed in 1–2*M* mineral acid for 2–3 days with intermittent shaking and renewal of acid. It was then washed several times with demineralized water and dried in air.

* Samples prepared by precipitating with antimonic acid.
A—Antimonate solution added to ceric solution.
B—Ceric solution added to antimonate solution.

Composition of ceric antimonate

Known amounts of ceric antimonate samples were dissolved in hot concentrated hydrochloric acid. In one portion cerium was estimated[7] as Ce(III) spectrophotometrically at 254 nm and in another portion Sb(V) was determined gravimetrically[8] by precipitation as Sb_2S_5. Ce(IV) and Sb(V) ratios are reported in Table I. To test the accuracy of the method of determining cerium:antimony ratios, control experiments and blanks were run.

Properties

All samples were yellow in colour. The samples obtained from potassium pyroantimonate were powdery, those from antimonic acid were in the form of a gel and could be sieved to the desired mesh size. The thermogravimetric curve of a typical sample (5A) recorded at an average heating rate of 5°/min shows a continuous loss in weight up to about 400°.

The chemical stability of sample 5A in various solutions was examined with the following results.

(*a*) All mineral acids up to 4*M* have no effect in the cold, but on heating the ion-exchanger starts dissolving.

(*b*) Alkalis of all concentrations have no effect.

(*c*) The ion-exchanger was stable in water, alcohol, benzene, acetic acid, 0·1*N* oxalic acid and in solutions of NaCl, KCl, LiCl, NH_4Cl, $BaCl_2$, $CaCl_2$ and $MgCl_2$.

Determination of exchange capacity

The exchange capacity, which is generally taken as a measure of the hydrogen ion liberated by a neutral salt, is found to depend upon the concentration and volume of the eluent for column operation. Therefore, to determine the most suitable concentration and volume, the elution curves of the hydrogen ion were found for various concentrations of eluent. The hydrogen ion eluted from the column was titrimetrically determined, with Methyl Orange as indicator. The results obtained with 0·1 and 1·0*M* sodium chloride are shown in Fig. 1. Although the hydrogen ions were still liberated even after

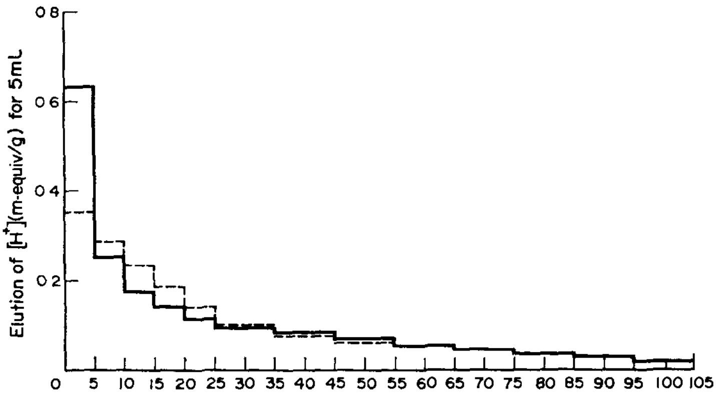

FIG. 1.—Elution curve of hydrogen ion. Continuous line—eluent 1·0*M* NaCl; dotted line—eluent 0·1*M* NaCl.

passage of 100 ml of the eluent, the exchange capacity was calculated from the amount of hydrogen ions liberated by 100 ml. The effect of concentration of neutral salt and time of equilibration on exchange capacity in batch operation, determined by the standard method,[9] is shown in Figs. 2 and 3, respectively. These studies were done on the typical sample 5A.

A constant value was obtained for concentrations of sodium chloride solution greater than 1*M* and it required practically 48 hr for complete equilibration. The capacity of different samples (H^+ form) is tabulated in (Table I), as is the value of hydrogen absorption capacity of different samples in Na^+ form. For checking the reproducibility of the method, the capacity of different samples from the same batch was determined for Na^+ ion. It shows a standard deviation of ±0.02. The batch reproducibility was checked by measuring the capacity of samples from different batches. It shows a standard deviation of ±0·038. The exchange capacity for Na^+ ion varies very little with initial pH (~ ±10%).

Since the sample 5A has the highest exchange capacity, the effect of the size and charge of the exchanging ion was studied with this sample only (Table II), as was the effect of drying temperature on exchange capacity (Table III).

The change of hydrogen liberation capacity in the course of regeneration cycles (Table IV) was studied for up to 6 cycles with different concentration of hydrochloric acid as regenerant.

Distribution coefficient

Distribution coefficients of metal ions were determined by batch operation, by radiometric, spectrophotometric and complexometric titration methods. About 100 mg of the exchanger (sample 5A) was loaded with 20 ml of 0·005*M* metal ion solution. The initial pH of the metal solution was adjusted to 2–3 with perchloric acid. The results are reported in Table V.

Separation of Hg^{2+} from Cd^{2+}, Zn^{2+}, Pb^{2+} and Tl^{+} was carried out in a column (5·0 cm × 0·19 cm^2) containing 50–100 mesh ceric antimonate. The column was loaded with 20% of the breakthrough capacity for each metal ion and the elution was started after 20 min at a flow-rate of ~0·15 ml/min. Cd^{2+}, Zn^{2+}, Pb^{2+} and Tl^{+} were separately eluted with water; Hg^{2+}, which remained on the exchanger, was then eluted with 0·5*M* NH_4Cl + 0·1*M* HCl (Fig. 4). Separations of Cu^{2+} from Mn^{2+}, Fe^{3+} from Al^{3+} and Zr^{4+} from Th^{4+} were carried out in a column 8·6 cm × 0·19 cm^2 (Fig. 5).

RESULTS AND DISCUSSION

The initial pH of the ceric solution is observed to have an effect on the exchange capacity of the products. With decreasing pH values higher exchange capacity is obtained. The pH of investigation was limited to between 0·75 and 2, since it is not possible to obtain a good product below pH 0·75 and above pH 2 cerium(IV) starts hydrolysing. The samples obtained with potassium pyroantimonate are not suitable for column operation, whereas those obtained with antimonic acid can be conveniently used in columns. The latter not only have better particle size but also a higher exchange capacity. The ratio and concentration of the mixing reagents seem to have negligible effect on the composition of the exchanger and its ion-exchange capacity.

The exchanger is apparently stable in water, alcohol, benzene, acetic acid, alkali solutions, different electrolyte solutions and mineral acids. Therefore, it can be used in these media without suffering deterioration in ion-exchange properties or break down of the particles.

As regards the effect of concentration of the neutral salt and the time of equilibration on capacity determination by batch operation, a constant value of the capacity for Na^+ ion was obtained at 1*M* or higher concentration, after 48 hr of equilibration.

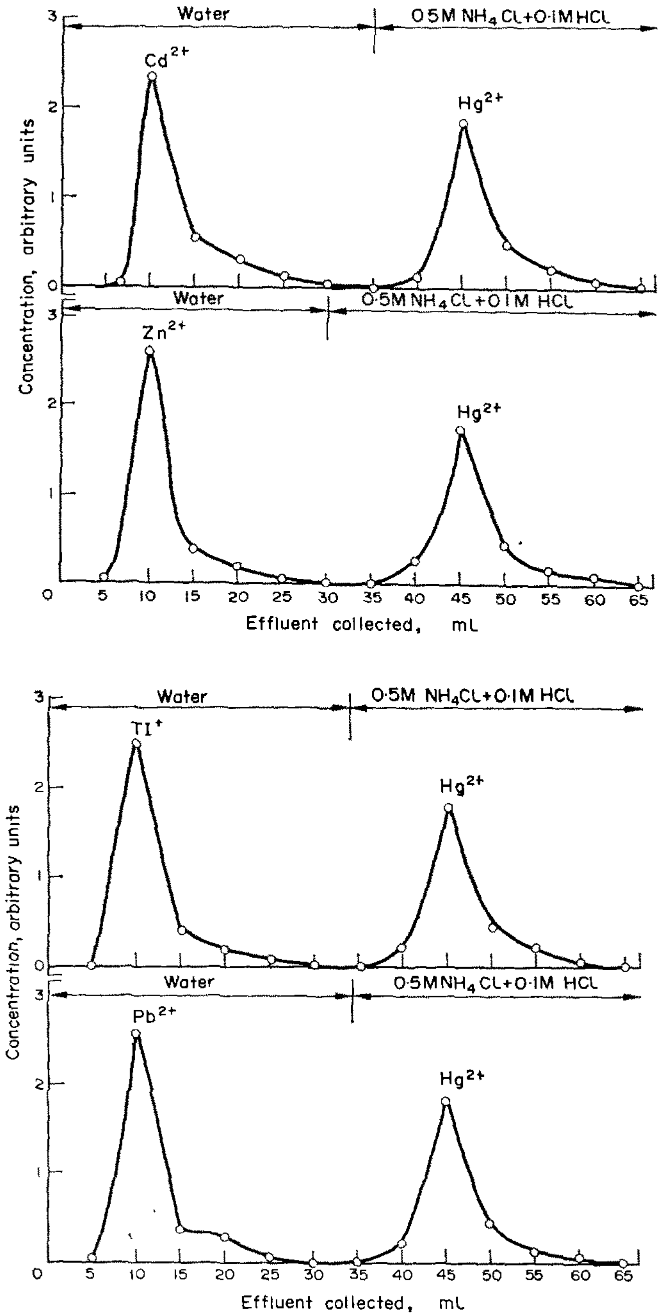

FIG. 4.—Separations on ceric antimonate column 5·0 cm × 0·19 cm^2, flow-rate ~0·15 ml/min.

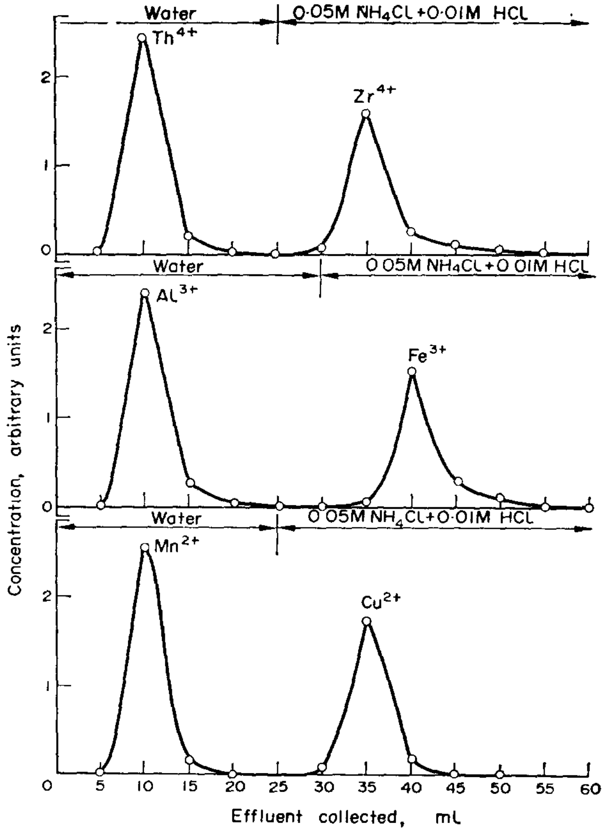

FIG. 5.—Separations on ceric antimonate column 8·6 cm × 0·19 cm², flow-rate ~0·15 ml/min.

Elution curves also reveal that at least 100 ml of 1*M* effluent is required for experimentally complete elution. The release of H^+ ions in the beginning is fast, then sharply decreases, and finally becomes insignificant after 100 ml of effluent. After 100 ml, it is not practical to continue the elution. The effect of pH on exchange capacity is practically negligible. Ceric antimonate in the acid form gives a buffer system of pH 2–3 and its exchange capacity remains unaltered at temperatures up to 100°. This suggests its possible use for buffering aqueous systems at higher temperatures. The exchange capacity seems to be negligibly affected by the size and charge of the exchanging ion, except for Li^+ and Ba^{2+} which show comparatively lower exchange capacity. The exchanger has a fairly good regeneration power.

The K_d values suggest the exchanger to be partly specific for Hg^{2+} ions and to provide a good method for its separation from other closely associated metal ions. Other separations of analytical importance have also been found possible.

Summary—A simple, rapid and accurate method for water analysis is proposed. The analytical procedure for the determination of Fe, Mn, Zn, Cu, Cd, As, Pb and Se in water in concentrations as low as a few ppM involves precipitation with a carrier of the metals by diethyldithiocarbamate (DDTC) or 1-(2-pyridylazo)-2-naphthol (PAN) and filtration through a Millipore filter. The precipitates collected on the filter disc are examined by X-ray fluorescence analysis. PAN is excellent for the determination of several metal ions at the ppM level, and DDTC can be used with tartrate as a masking agent if water samples contain large amounts of iron(III).

A LABORATORY engaged in making a large number of determinations of trace elements has a particular need for a rapid, simple and accurate method of analysis, especially in the field of quality control of natural waters. In this field, many spectrophotometric and atomic-absorption spectrometric methods are currently used. They are excellent for the determination of specific elements but they usually do not permit the simultaneous determination of several elements in water and they also lack sensitivity in the determination of trace metals below the 0·1 ppm level. Very few analytical methods allow the determination of several elements in microgram amounts in a single concentrate from water samples.

Neutron-activation, optical-emission and mass-spectrographic analysis have been successfully employed for the simultaneous determination of trace elements but these are time-consuming methods and their precision is rather poor. The X-ray fluorescence spectrometric method is excellent for the simultaneous determination of metals if a simple preparation of samples for X-ray measurement is established. Although this method has seldom been applied to water analysis, owing to its apparently low sensitivity, several workers have attempted to improve this sensitivity by developing a suitable method in which the trace elements are isolated before the X-ray analysis, using some physical or chemical method of separation,[1–7] including evaporation, precipitation, ion-exchange and solvent extraction.

Luke[8] and Püschel[9,10] have already reported that the precipitation of trace elements with some organic chelating reagents from water and the subsequent quick filtration of the precipitates with a Millipore filter were excellent for the determination of trace elements. Luke[8] has established the conditions for the determination of many trace metal ions with sodium diethyldithiocarbamate (DDTC), and Püschel[9] has recommended 1-(2-pyridylazo)-2-naphthol (PAN) as a precipitant. Such a chelating reagent, which forms insoluble metal chelates, can be used to recover the trace elements from water by isolating the trace elements as a thin uniformly dispersed precipitate in a low atomic-number matrix of relatively large area. The matrix absorption and enhancement are virtually negligible and hence the accuracy and the sensitivity of the

analysis is high. A single paper disc could permit the determination of several trace elements simultaneously.

In the present study (based on the works of Luke and Püschel) an attempt was made to establish a practical method for the simultaneous determination of several elements such as Fe, Mn, Cu, Zn, Cd, Pb, As and Se, which are always encountered in water analysis. The results clearly show that the X-ray method can be successfully applied to the determination of metal ions at ppM levels in water. The method is simple, rapid and sensitive.

EXPERIMENTAL

Apparatus

A Philips Universal Vacuum Spectrograph Model PW-1540/05 was employed. A chromium-target, thin-window X-ray tube operated at 50 kV and 28 mA was used in the determination of cadmium. A tungsten-target tube operated at 50 kV and 50 mA was used for all other elements tested. An EDDT analysing crystal was employed for cadmium and an LiF(220) crystal was used for the other metals. The diffracted radiation at each characteristic angle was measured with a gas-flow proportional counter, operated at about 2100 V in conjunction with pulse amplitude discrimination (Philips Pulse Height Amplifier, Model PW 4280) optimized for each element.

The filter equipment was the same as described by Luke.[8] It consists of a Pyrex filter holder supplied by the Millipore Corporation of Bedford, Mass. and includes a reservoir, a 17-mm circular fritted glass support and a metal clamp. The filter paper discs used were white 25-mm Millipore paper discs of 1·2 μm pore size. After insertion of the disc and clamping on of the reservoir, the solution was filtered under suction. The paper disc was held between two aluminium rings to prevent curling up on drying in an oven at 100°, and was then mounted in an aluminium sample holder that had a Mylar-film base through which the primary X-ray beam irradiated the precipitates on the paper disc. A pressed disc of pure cellulose, which had a diameter slightly smaller than the inside diameter of the aluminium holder and had a thickness of 5 mm, was inserted into the holder to keep the disc flat.

Reagents

Metal ion solutions were prepared from high purity metals or metal oxides ($<0{\cdot}001\%$ impurity). They were dissolved in an appropriate acid solution and then diluted with doubly distilled water to the desired concentration. The final acidity of the solutions was about $0{\cdot}11N$. Other reagents used were of analytical grade. Several buffer solutions were prepared[11] and purified by the following precipitation method: 100–200 μg of copper and 50 mg of DDTC were added to the buffer solution, and the precipitates formed were removed by filtering through a Millipore filter. Both the citrate and the tartrate solutions were purified in the same manner. The buffer solution of pH 10 prepared from ammonia and ammonium chloride was purified with a chloroform solution of PAN. PAN itself was purified by dissolving in chloroform and washing the solution with $0{\cdot}01M$ EDTA solution at pH 10 and with doubly distilled water. The chloroform was then evaporated.

All glassware, beakers and pipettes were immersed in nitric acid (1 + 1) and washed with doubly distilled water before use.

Procedure

In most experiments 50 ml of sample solution were transferred to a beaker and 5 ml of 2% DDTC solution (freshly prepared and filtered) were added. The acidity of the solution was adjusted with a buffer solution, and if necessary with suitable amounts of hydrochloric acid or sodium hydroxide solution. The precipitate was allowed to stand for 5 min and filtered off on the Millipore filter. When PAN was used as a precipitant the sample solution was gently boiled for about 20 min on a hot-plate after the addition of 0·1% methanol solution of PAN and of pH 10 buffer solution. PAN chelates tend to float on the surface of the solutions and climb up the wall of the beaker, so several drops of surfactant solution (1% sodium lauryl sulphate) were added.

The intensity of each characteristic line was measured for 1 min except for cadmium, lead, arsenic(III) and selenium, which were counted for 2 min. Both sample and spectrometer chambers were evacuated to a pressure of less than 0·5 mmHg. The analytical lines used for X-ray measurement are summarized in Table I.

TABLE I.—LINES USED IN X-RAY MEASUREMENTS.*

Element	2θ angle	
	Peak	Background
Mn	K_α 95·19°	97·00°
Fe	K_α 85·71°	87·00°
Cu	K_α 65·54°	65·54°
Zn	K_α 60·56°	60·56°

Se	K_α 45·70°	45·70°

* LiF analysing crystal, tungsten target (w), except for Cd, where an EDDT crystal and a chromium target were used.

RESULTS

DDTC as precipitant

In water analysis the following metal ions are most often determined: Fe, Mn, Cu, Zn, Cd, Pb, As and Se. For the precipitation of these elements in one step a rather non-specific organic reagent must be used. Among the precipitants that have been investigated DDTC would appear to be a good choice. The results obtained by Luke were confirmed for the precipitation of the elements Fe, Cu, Zn, Cd, Ni, Pb and Mn, atomic-absorption spectrometry being used to examine the filtrates. Nickel and copper were precipitated completely between pH 1 and 11. Zinc, cadmium, lead and iron(III) began to precipitate at pH 1–2 and precipitation was complete at pH above 4. Thus the pH of the solution should be kept above 4, and in the present work pH 5 was chosen. However, unsatisfactory results were obtained with manganese, over the whole pH range examined, because of incomplete precipitation. The recovery of manganese was improved by the addition of 50 μg of copper as a co-precipitant but recovery was never complete. Therefore the use of DDTC is unsuitable for the determination of manganese. Luke has recommended the use of 50 μg of copper or 100 μg of iron(III) as the co-precipitants at pH 9 for the recovery of manganese; however, both iron and copper are always primary elements to be determined in water analysis, which precludes their use.

The recovery of arsenic(III) was examined by using X-ray fluorescence. The results are shown in Fig. 1, where the ordinate is the ratio of the counts obtained at various pH values to those obtained at pH 5·0. Luke[8] reported that the recovery of arsenic(III) as the diethyldithiocarbamate was quantitative only at pH 4. However, these results indicate that the pH for arsenic(III) must be in the range 5·0–5.5. Therefore, in this experiment pH 5·1 was chosen for the precipitation of arsenic(III).

Calibration curves. On the basis of the results described above calibration curves were made by precipitating and determining from 0 to 50 μg of each of the elements.

Over the range examined, a linear relationship was obtained between the amount of element taken and the ratio obtained by dividing the net count of each sample by that of a reference sample. The reference chosen was the median of eleven samples

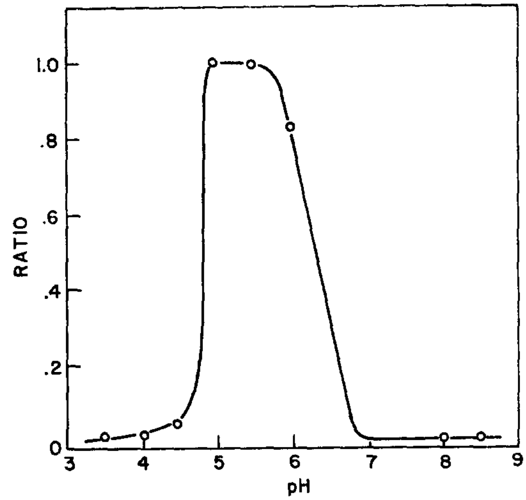

FIG. 1.—Influence of pH on the recovery of 5 μg of As(III) with DDTC, expressed as the ratio of the intensity determined at various pH values to that determined at pH 5·0.

examined over the concentration range. This linearity suggests the complete precipitation of each element. On the basis of these calibration curves the 95% confidence limit was calculated by the least-squares method, for the sample with concentration C yielding a ratio $R = 1$. The results are shown in Table II. The limit of detection at the 95% confidence level, D, was calculated from the relationship $D \sim 3C\sqrt{B}/M$, where M is the slope of the calibration curve and B the background intensity based on a 2-min counting period.[12] The backgrounds for zinc and selenium were determined by making measurements on blank samples at the appropriate line peak. From this table it is seen that the precision of this method is quite good. Five μg of Fe, Zn, Cd and Cu can be determined with a precision of ±0·3 μg. If 50 ml of solution contains 5 μg of an element it is then possible to determine 0·1 ppm of the element to within ±0·006 ppm.

TABLE II.—SENSITIVITY AND PRECISION USING DDTC.

Element	Carrier	Sensitivity, *counts/sec/ μg*	Background, *counts/sec*	Limit of detection, *μg*	95% confidence limit of C for $R^* = 1·0$, *μg*
Fe	Cu	98	129	0·03	5·15 ± 0·25
Zn	Cu	72	182	0·05	5·47 ± 0·30

Se	Ni	19	72	0·12	25·05 ± 0·60

* $R = a + bC$; R represents the ratio of determined intensity to that of the reference standard, and C the concentration.

Two calibration curves for zinc were established, for two sample sizes, 50 ml and 250 ml. In both cases a linear relationship and the same slope were obtained.

The precision can be expressed in concentration terms for the samples containing 5 μg of zinc as follows: 50 ml sample—0·1 ± 0·006 ppm, 250 ml sample—0·02 ± 0·0015 ppm. It is apparent from Table II that cadmium can be determined with the greatest accuracy. This is probably due to the low background in the vicinity of the cadmium $L_{\alpha 1}$ line.

As shown in Table II, satisfactory results were also obtained for the determination of arsenic(III), selenium(IV) and lead. Unfortunately their sensitivities are inferior to those of the the other elements.

Copper or nickel was used as the carrier metal ion in these experiments. There seems to be a slight difference in their efficiencies. Since copper is an important element in water analysis, nickel is recommended as the carrier element.

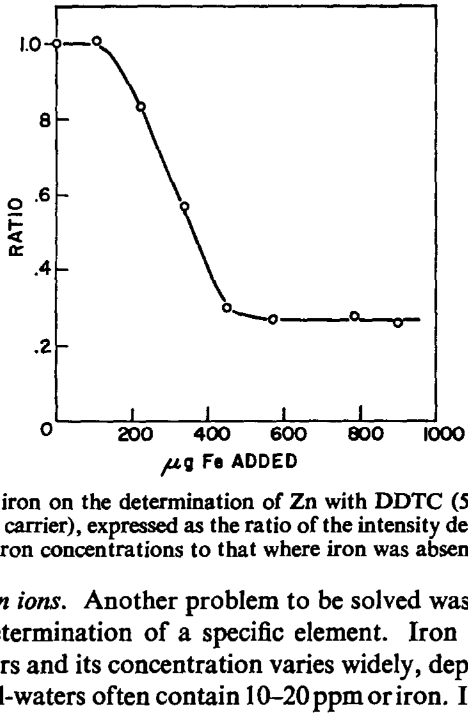

FIG. 2.—Effect of iron on the determination of Zn with DDTC (5 μg of Zn, pH 5·0, 50 μg of copper as carrier), expressed as the ratio of the intensity determined at various iron concentrations to that where iron was absent.

Influence of foreign ions. Another problem to be solved was the influence of other metal ions on the determination of a specific element. Iron is a common element found in natural waters and its concentration varies widely, depending on the geological locality. Some well-waters often contain 10–20 ppm or iron. If the method described here is used directly for the analysis of such waters the result will be erroneous because the precipitate will be too thick. This was tested on solutions containing 5 μg of zinc, 50 μg of copper and various amounts of iron(III). In Fig. 2, the ordinate shows the ratio between the net count of samples containing various amounts of iron(III) and that of the reference which contains no iron. Iron clearly interferes if large amounts of iron co-exist, but quantities up to 100 μg can be tolerated without appreciable error in the determination of zinc. Assuming 50 ml of sample solution, the concentration of iron should be below 2 ppm.

The determination of arsenic (III) is influenced by the presence of lead, and *vice versa*. The K_α line of arsenic(III) appears at the same 2θ angle as the $L_{\alpha 1}$ line of lead, as shown in Table I, making it impossible to identify and determine both elements simultaneously. However the separation of both elements is feasible, as discussed later.

Masking of iron(III). The concentration of iron in most river waters is usually below 2 ppm. For higher iron concentrations this method cannot be applied without some modifications. Iron could be separated before the analysis, but it was considered impractical to do so because the analytical procedure would lose its simplicity and rapidity. Thus, the only remaining approach was to mask the iron, thereby avoiding the addition of other analytical steps.

When copper is determined with DDTC, it is well-known that EDTA has strong complexing abilities with respect to iron(III), manganese, zinc and cadmium,[13] making it possible to separate these elements from copper. Therefore EDTA cannot be used for the determination of zinc and cadmium in the presence of iron. In the next experiment it was confirmed that iron(III) is masked with tartrate or citrate,[13] while zinc and cadmium are precipitated in the presence of these reagents. The influence of tartrate and citrate on the precipitation of zinc, cadmium and iron(III) is shown in Figs. 3 and 4 (atomic-absorption spectroscopy was used to determine the metal ions in a filtrate). This effect was confirmed by the examination of the precipitated metals by X-ray fluorescence. The recovery of zinc was also examined in the presence of 0·05*M* tartrate and various amounts of iron(III) (Fig. 5). Tartrate increases the tolerance for iron tenfold. Under the same conditions cadmium is also quantitatively precipitated although it is not shown here. Thus, if 50 ml of sample are taken, 20 ppm of iron(III) could be tolerated in the determination of zinc and cadmium. A borate buffer solution must be used for adjusting the pH of the solution to 9·5 or higher. Experiments showed that up to 275 μg of copper, 250 μg of manganese and 40 mg of calcium could be tolerated without any appreciable effect on the recovery of zinc.

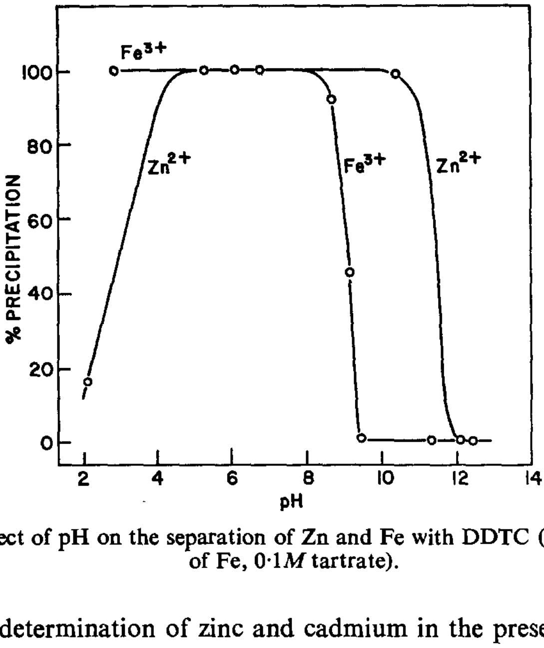

FIG. 3.—Effect of pH on the separation of Zn and Fe with DDTC (5 μg of Zn, 5 μg of Fe, 0·1*M* tartrate).

In Table III the influence of nickel on the recovery of Cd, Zn and Cu is also shown. Quantities of nickel below 100 μg have no effect on the determination of these elements

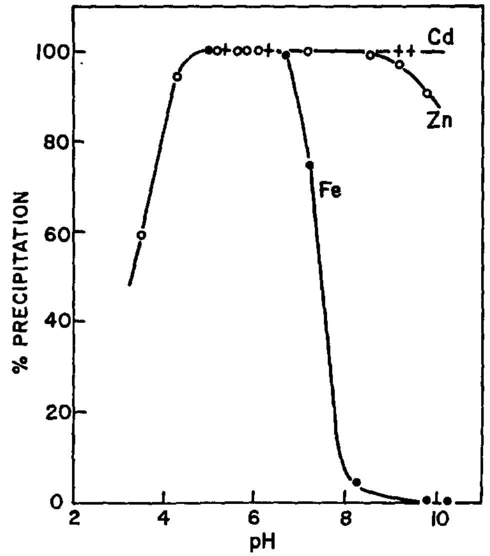

Fig. 4.—Effect of pH on the separation of Fe from Zn and Cd with DDTC (5 µg of Zn, 5 µg of Fe, 5 µg of Cd, 0·1*M* citrate).

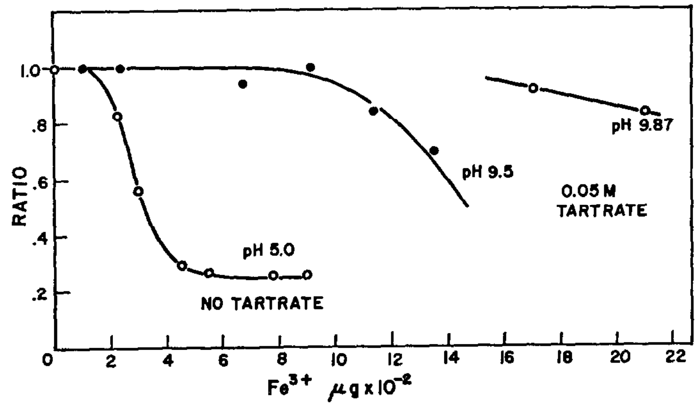

Fig. 5.—Recovery of Zn with DDTC in tartrate solutions (5 µg of Zn, 50 µg of copper as carrier).

Table III.—Influence of Ni on the determination of 5 µg of Cd, Zn and Cu with DDTC (in 50 ml).

Element	Ratio		
	Ni added, µg		
	50	100	200
Cd	1·00	1·01	0·66
Zn	1·00	1·02	1·04
Cu	1·00	0·98	0·94

and hence the amounts of copper or nickel to be added as a carrier do not have to be precise. Sodium, calcium and magnesium are always found in natural water but as they do not react with DDTC no interference would be expected.

When the concentration of iron is very high the simultaneous determination of iron and other trace elements is impossible and the sample must be divided into two portions. Large amounts of iron can be determined by using a smaller sample.

It is generally accepted that citrate is a more powerful masking reagent for iron(III) than tartrate.[14] Zinc can be separated from iron(III) by using citrate, as shown in Fig. 4. The pH of the solution should be kept within the range 8–8·5. Under these conditions cadmium also can be completely isolated from iron(III). Therefore citrate could well be used as a masking reagent for iron as well as tartrate, but no further experiments were carried out.

Influence of sample volume. Table IV shows the influence of sample volume on the determination of cadmium and arsenic(III). It is apparent that the recovery of cadmium and arsenic decreases with increasing sample size and hence DDTC cannot be used with the nickel carrier for samples larger than 50 ml for Cd and 100 ml for As(III). However when copper is used as a carrier the cadmium can be recovered quantitatively from volumes up to 300 ml. Other experiments indicated that cadmium could be completely recovered from volumes up to 200 ml by using the nickel carrier if the time of precipitation was extended to 30 min before filtration. As shown in Table II, zinc was determined with good precision from a 250-ml sample. Although no further experiments were carried out on the recovery of lead and selenium, these form very stable complexes with DDTC.[1,13] The metal ions which form the most stable complexes with the precipitant are easily and completely recovered.

TABLE IV.—EFFECT OF SAMPLE VOLUME ON THE DETERMINATION OF CADMIUM AND ARSENIC(III) WITH DDTC.

	Sample size *ml*	Ni added, *μg*	Ratio

* Nickel replaced with 50 *μg* of copper as carrier.

PAN as a precipitant

As a non-specific organic reagent, PAN was proposed by Püschel[9] for the determination of trace metals by X-ray fluorescence. DDTC is an ineffective reagent for the determination of manganese and in this respect PAN is superior. The most suitable pH for the determination of Fe, Mn, Cu, Zn and Cd was 10. In the procedure of Püschel metal ions were precipitated as the metal–PAN complexes from about 20–60 ml of solution to which 3 ml of pH 10 buffer solution and 5 ml of 0·1%

methanolic PAN solution had been added. For the precipitation of less than 10 μg of metal ions in the presence of 50 μg of nickel, 1 ml of 0·1 % PAN solution was more than adequate.

However PAN has some undesirable properties. The first of these is that PAN itself is only slightly soluble in water and hence the excess of reagent is also recovered on filtration. This causes an increase in the volume of the precipitates and results in the cracking and peeling of the precipitates from the Millipore filter on drying. The second drawback is due to the properties of the precipitates formed. They often float on the surface of the solution and tend to adhere to the walls of the beaker, necessitating the addition of several drops of surfactant solution.

Calibration curves. To establish the calibration curves for each element, 1 ml of 0·1 % PAN solution was added to 50 ml of the sample solution, which contained 50 μg of nickel and 0–10 μg of one of the elements to be determined. The solution was adjusted to pH 10 with 3 ml of ammonia buffer and several ml of 1*M* sodium hydroxide. The solution was heated gently to boiling on a hot-plate for about 20 min to complete the reaction. The slower reaction of metal ions with PAN than with DDTC makes the analysis time longer.

In Table V the results of the calibration curves for the elements are summarized.

TABLE V.—SENSITIVITY AND PRECISION USING PAN WITH NICKEL CARRIER.

Element	Sensitivity, *counts/sec/ μg*	Background *counts/sec*	Limit of detection, *μg*	95 % confidence limit of *C* for $R^* = 1·0$, *μg*
Mn	69	42	0·03	5·15 ± 0 20
Cu	104	392	0 05	6·30 ± 0·16
Cd	32	34	0·05	5·05 ± 0·13
Fe	78	19	0·02	5·07 ± 0·26
Zn	30	25	0·05	5·11 ± 0·23

* $R = a + bC$; *R* represents the ratio of determined intensity to that of the reference standard, and *C* the concentration.

It is apparent that each element can be determined with PAN with a better precision than with DDTC.

Influence of foreign ions. At the 5-μg level, cadmium, zinc, copper and manganese were quantitatively recovered without a carrier. However only 95 % of the iron was recovered. When nickel was used as a co-precipitant all the metals were completely recovered although quantities larger than 100 μg of nickel reduced the net count for cadmium. Thus the nickel carrier should be below 100 μg. In fact the addition of less than 50 μg of nickel is recommended to improve the ease of filtration of precipitates.

The influence of other elements is shown in Table VI. It is evident that 100 μg of Fe, Mn or Cu, when present individually, do not cause interference but the total amount of these metals in an aliquot should be below 100 μg when PAN is used as the precipitant. At least 24 mg of calcium could be tolerated without interference.

Influence of masking reagents. The effect of some masking reagents is summarized in Table VII. It has already been reported[15] that PAN can be used as an extractive spectrophotometric reagent for the simultaneous determination of cobalt, nickel and iron in a slightly acid solution without any interference from other elements if EDTA is used as a masking reagent. However, in basic solution EDTA is not selective and

† Nitrilotriacetic acid.

consequently cannot be used. Table VII shows that none of the reagents tested was effective in masking iron(III) since zinc and cadmium were also masked. In this respect PAN is inferior to DDTC.

Influence of sample size. A series of experiments was performed to determine the efficiency of the recovery from larger sample volumes, using 50 μg of nickel as carrier. It is interesting that copper, zinc and cadmium are completely recovered even from 1000 ml of solution. This means that less than one ppM of these metals can be determined if large aliquots are taken. In this respect PAN is superior to DDTC.

When the sample size is increased to 500 or 1000 ml the carrier must always be used, contrary to Püschel's recommendation that no carrier be used. Without a carrier, only 84% of the manganese and 89% of the iron was recovered from samples of 500 ml. This may be attributed to the low stability constants of the iron and manganese complexes with PAN.

Application of the method to water analysis

As a test of the method, a series of 25–200 ml portions of river water (Ottawa River) was analysed. The comparison of results obtained by using X-ray fluorescence, atomic-absorption and absorption spectrophotometry is given in Table VIII. The iron was determined colorimetrically with 1,10-phenanthroline, and the other metals were determined by atomic absorption after extraction with DDTC into methyl isobutyl ketone.[16] These results indicate that the proposed analytical method is satisfactory. All the water samples taken were acidified with 6*M* hydrochloric acid and gently boiled for 30 min before analysis.

DISCUSSION

The X-ray method proposed here has certain advantages. Many current methods of water analysis do not permit the simultaneous determination of several metal ions and the sensitivity is comparatively low. Thus, for the determination of heavy metal ions at the ppM level some preconcentration must be carried out and solvent extraction has often been used for this purpose. In this respect, the same situation arises in the X-ray method, but the precipitation makes the procedure relatively so simple that the method established in this study has a wider applicability than others, especially in the determination of trace metals below 50 or 100 ppM in water.

Some workers have recommended ion-exchange[6,16] and solvent extraction[1,2] for preparing the X-ray sample, but these methods are not simple and are time-consuming because of the complexity of the preparation of films in which trace metals are isolated and concentrated.

In the present method some problems remain. One is in the X-ray working conditions for the determination of cadmium. For the measurement of the L_{α_1} line of cadmium, the chromium target and EDDT analysing crystal must be used, instead of the tungsten target and LiF(220) crystal, which are used for other elements. Since two different counting conditions must be utilized for cadmium and other elements, there is no possibility of determining cadmium simultaneously with other elements by a scanning technique. Another problem is the precipitant. Neither DDTC nor PAN can be used for the analysis of all kinds of waters. DDTC does not recover the trace elements from large samples and low ppM levels of metals cannot be determined. On the other hand, PAN cannot be applied to the samples containing large amounts of iron because there are no suitable reagents to mask iron and to permit the precipitation of zinc and cadmium.

There is a problem in the determination of arsenic(III) and lead because the K_α line of arsenic appears at the same 2θ angle as the L_{α_1} line of lead. To avoid the mutual line interference, both elements must be separated. The first method is based on the fact that PAN does not react with As(III). The lead–PAN complex can be recovered with other elements, except for selenium(IV), under the conditions indicated in the procedure. On the other hand, As(III) is not precipitated by DDTC in basic solution. As shown in Fig. 1, arsenic(III) precipitates only in the pH range 5·0–5·5 and it does not precipitate at above pH 7. Therefore, DDTC permits the recovery of lead at pH 9·5 as well as zinc and cadmium. Hence both elements could be isolated and determined independently if their concentration was at least 10 μg/l. Although DDTC can precipitate the seven elements, except manganese, at pH 5, two separate precipitations must be carried out in order to avoid the mutual line interference between lead and arsenic. If PAN is used as a precipitant, six elements (except arsenic and selenium) can be recovered at pH 10 and subsequently arsenic and selenium are precipitated from the filtrate with DDTC at 5·1. In both cases two precipitation steps are needed, especially when arsenic and lead must be determined.

It has already been reported by some workers[13] that the stabilities of the chelates of each element with DDTC increase in the order $\mathrm{Mn} < \mathrm{As(III)}$, $\mathrm{Zn} < \mathrm{Fe(III)} < \mathrm{Cd} < \mathrm{Pb} < \mathrm{Ni}$, $\mathrm{Co} < \mathrm{Cu}$. Hence, the reason for the incomplete recovery of manganese with DDTC must be attributed to the low stability of its chelate. The arsenic chelate with DDTC also exhibits low stability, thus arsenic(III) is also difficult to precipitate quantitatively, if the pH of the solution is not controlled precisely between pH 5·0 and 5·5. On the other hand, the precipitation of selenium(IV) is complete at pH 5. Although the influence of pH on the precipitation of selenium(IV) with DDTC was not examined in this experiment, Bode[17] has already reported that selenium(IV) could be extracted with DDTC into carbon tetrachloride at a pH between 4 and 6·2. The selenium complex with DDTC seems to have greater stability than that of arsenic(III).

Finally, it is concluded that the advantages of the method lie in its rapidity, simplicity, relatively good precision and general sensitivity, since the preparation of sample for X-ray measurement is simple and reproducible.

Zusammenfassung—Eine einfache, rasche und genaue Methode zur Wasseranalyse wird vorgeschlagen. Das analytische Verfahren zur Bestimmung von Fe, Mn, Zn, Cu, Cd, As, Pb und Se in Wasser bei Konzentrationen von einigen ppM besteht in einer Trägerfällung der Metalle mit Diäthyldithiocarbamat (DDTC) oder 1-(2-Pyridylazo)-2-naphthol (PAN) und Filtration durch ein Millipore-Filter. Der auf der Filterscheibe gesammelte Niederschlag wird mittels Röntgenfluoreszenz untersucht. PAN ist ausgezeichnet zur Bestimmung mehrerer Metallionen im ppM-Bereich geeignet und DDTC kann mit Tartrat als Maskierungsmittel benutzt werden, wenn das Wasser große Mengen Eisen(III) enthält.

Résumé—On propose une méthode simple, rapide et précise pour l'analyse de l'eau. La technique analytique pour le dosage de Fe, Mn, Zn, Cu, Cd, As, Pb et Se dans l'eau à des concentrations aussi faibles que quelques p.p.m. comprend la précipitation des métaux avec un entraîneur par le diéthyldithiocarbamate (DDTC) ou le 1-(2-pyridylazo) 2-naphtol (PAN) et la filtration sur un filtre Millipore. Les précipités recueillis sur le disque de filtre sont examinés par analyse de fluorescence aux rayons X. Le PAN est excellent pour le dosage de plusieurs ions métalliques au niveau de la p.p.m., et l'on peut utiliser le DDTC avec le tartrate comme agent dissimulant si les échantillons d'eau contiennent de grandes quantités de fer(III).

STUDIES ON CHROMIUM(III) HYDROXIDE, ARSENATE, ANTIMONATE, MOLYBDATE AND TUNGSTATE

MOHSIN QURESHI, RAJENDRA KUMAR and H. S. RATHORE
Chemical Laboratories, Aligarh Muslim University, Aligarh, U.P., India

(*Received* 5 *November* 1971. *Accepted* 5 *April* 1972)

Summary—Five water-insoluble compounds of chromium(III) have been synthesized by mixing 0·10*M* solutions of chromic chloride and the appropriate sodium salts in the volume ratio of 1:2, at pH 6–7. Their ion-exchange characteristics have been compared. The tungstate has the highest chemical stability and the arsenate has the highest ion-exchange capacity. Chromium(III) molybdate columns have been used to separate Pb^{2+} from numerous metal ions.

NUMEROUS ion-exchangers have been synthesized and the mechanism[1,2] of separation has been studied for some of them. The ion-exchange properties of a material are considerably influenced by the chemical composition of the ion-exchanger.[3] They also depend on the method and the conditions of preparation. It is therefore not always possible to compare the ion-exchange properties of the same materials synthesized in different laboratories and it would be interesting and instructive to prepare inorganic ion-exchangers with the same cation but with different anions and to compare different preparations. Szirtes *et al.*[4] made a comparative study of zirconium, titanium and chromium phosphates. While our work on stannic arsenate was in progress we noticed that chromium(III) is irreversibly adsorbed on stannic arsenate.[5] We therefore decided to synthesize chromium(III) arsenate and to compare its ion-exchange properties with other insoluble compounds of chromium(III). The present paper summarizes the results of such a study.

EXPERIMENTAL

Reagents

Chromic chloride hexahydrate, sodium molybdate, sodium tungstate and sodium arsenate heptahydrate were used. Antimony pentachloride solution (s.g. 2·30) was diluted with 4*M* hydrochloric acid to obtain solutions of the required concentration. All other reagents were of analytical grade.

Apparatus

A Philips conductivity bridge PR 9500, Sargent Oscillometer type (V) and Aminco thermoanalyser were used for conductimetry, high frequency titrations, DTA and TG respectively. All other instruments were those used in our earlier studies.[6,7]

Preparation

The chromium(III) compounds have been synthesized under similar conditions to facilitate comparison (Table I). The reagents given in column 2 were mixed in the volume ratios given in column 3. The pH of the reaction mixture was found to be 6–7 in the case of arsenate, molybdate and tungstate, and was adjusted to 6·80 in the case of antimonate by adding ammonia solution dropwise with constant shaking. Chromium hydroxide has also been prepared by adding ammonia solution to aqueous 0·10*M* chromic chloride. The gelatinous precipitates obtained were washed by decantation, filtered off, washed again with distilled water and then dried at 40°. Aging always affects the properties of this type of inorganic ion exchanger.[8] Therefore all the precipitates were kept for 24 hr with reaction mixture at room temperature. The dried product was immersed in 1*M* nitric acid (approximately 40 g of the exchanger in 100 ml of 1*M* nitric acid) to remove the foreign ions adsorbed during the preparation. Some dissolution of the compound was observed during this process. Finally the exchangers were washed with demineralized water to remove the excess of acid and again dried at 40°.

Ion-exchange studies

Saturation ion-exchange capacity and the pH-titration curves were obtained by the method described earlier.[6,7] The K_d values for inorganic ions have been determined on the hydroxide, antimonate, molybdate and tungstate of chromium(III), and on chromium arsenate without shaking,[7] at pH 3–4. The loading of cations[9] for the system was less than 3% of the experimental ion-exchange capacity. The equation used was

$$K_d = \frac{I - F}{F} \times \frac{50}{0 \cdot 5} \text{ ml/g}$$

where I is the volume of $0 \cdot 002M$ EDTA needed to titrate the original cation solution and F is the volume of $0 \cdot 002M$ EDTA needed for titration after equilibration. The total volume of the equilibrating solution was 50 ml (concentration of each cation solution was $\sim 7 \times 10^{-5}M$) and the amount of the exchanger taken was 0·50 g.

Column preparation

For separation studies a 30 × 0·39 cm bore glass column was used and 1·50 g of chromium molybdate was put in the column with a glass-wool support. The column was washed with demineralized water and the amount of cation added to the column was less than 3% of the experimental ion-exchange capacity of the exchanger. The flow-rate of the effluent was 8–9 drops/min. All the cations other than lead were eluted with $0 \cdot 2M$ ammonium chloride and finally lead was eluted with $1M$ ammonium chloride in $0 \cdot 1M$ nitric acid. The amount of chromium and molybdenum dissolved in $0 \cdot 1M$ nitric acid was found to be 0·00 and $15 \cdot 2 \times 10^{-4}$ g/l. respectively. The cations were determined by EDTA titration and no interference due to the dissolved molybdenum was observed. All other details were similar to those reported earlier.[5–7]

Physical measurements

X-Ray photographs were taken with nickel-filtered Cu$K\alpha$ radiation by the powder method. For infrared studies the KBr disc method was used. For thermoanalytical studies 0·20 g of the exchanger in the hydrogen form was heated at 6°/min. High-frequency and conductimetric titrations of chromium(III) with arsenate, molybdate and tungstate were performed under conditions similar to those used for the synthesis of the respective compounds, *i.e.*, for high-frequency titrations 2 ml of the $0 \cdot 10M$ solution of sodium arsenate, molybdate or tungstate were taken in the cell and a $0 \cdot 10M$ solution of chromic chloride was added from the burette. For the conductimetric titrations 5 ml of the solution were taken in the cell. The reverse titrations were not possible, owing to continuous change in the conductivity of the chromic chloride solution.

Analytical procedure

A 0·20-g portion of the exchanger was oxidized in a porcelain crucible with sodium peroxide and the chromium(III) was titrated volumetrically with ferrous ammonium sulphate.[10] Another 0·20-g portion was dissolved in hydrochloric acid, and arsenic was precipitated as sulphide and determined by Volhard's thiocyanate method.[7] Antimony was also precipitated as the sulphide and determined with potassium iodide.[8] Tungsten and molybdenum were determined as lead tungstate[11] and molybdate[12] after removal of chromium(III) as the hydroxide.

To determine the solubility of the chromium(III) compounds, 0·50 g of the exchanger was shaken for 8 hr with 100 ml of the solution concerned, in a temperature-controlled shaker. The undissolved exchanger was filtered off and in the filtrate chromium was determined spectrophotometrically as dichromate.[13] Arsenic, antimony, molybdenum and tungsten were also determined spectrophotometrically by the molybdenum-blue,[7] Rhodamine B,[8] potassium thiocyanate[12] and sodium thiocyanate[11] methods respectively.

RESULTS

Physical properties

Some of the properties of chromium(III) compounds are recorded in Table I. All the compounds remain as stable gels in water, except chromium arsenate which disperses on shaking. The equilibrium pH of the system consisting of water and the hydroxide, arsenate, antimonate, molybdate and tungstate gels was found to be 3·5, 3·6, 4·6, 3·5 and 3·2 respectively. The gels crack on immersion in water, with slight evolution of heat.

TABLE II.—SOLUBILITY OF HYDROXIDE, ARSENATE, ANTIMONATE, MOLYBDATE AND TUNGSTATE OF CHROMIUM(III), mg/l AT 30 ± 1°C.

	Water		4*M* HCl		4*M* HNO_3

CrW	3·00	0·40	23·0	5·50	11·3	5·0

dc = dissolves completely, X = arsenic, antimony, molybdenum or tungsten.

Chemical properties

The saturation ion-exchange capacity and the change in colour of the exchangers dried at 40, 200 and 500° are recorded in Table I. The ion-exchange capacity of chromium hydroxide at pH 0·75, 7·00 and 12·00 is 1·32 (anion-exchange capacity), 0·00 and 1·64 meq/g (cation-exchange capacity).

Separation studies

The K_d values obtained are recorded in Table III. The ionic radii are those tabulated by Cotton and Wilkinson[14] and reported by Templeton and Dauken.[15] On the

Physical studies

X-Ray powder photographs show that all five compounds in the hydrogen form and dried at 40° are amorphous.

Infrared spectra of the five compounds dried at different temperatures are similar and resemble those reported for antimonic acid and sodium antimonate.[1] Therefore a similar band assignment may be given as follows. The bands with maxima at about 3300, 1380 and 1610 cm^{-1} are characteristic of the stretching vibration of interstitial water and OH groups [$\nu_1(H_2O \text{ or } OH)$], the M—OH deformation vibration [$\delta_2(OH)$] and the deformation vibration of interstitial water [$\delta_1(H_2O)$] respectively. The band with maxima at about 600–480 cm^{-1} is due to the stretching vibration of M—O [$\nu_2(Cr—O)$] and the deformation vibrations of anions [$\delta_3(AsO_4)$].

The thermoanalysis results are shown in Figs. 1 and 2.

DISCUSSION

All the five salts of chromium(III), reported here, were first prepared under varying conditions. The conditions of preparation finally chosen were those which appeared to give reproducible and fairly stable products. These conditions were adhered to in all preparations to facilitate comparison. The results of chemical composition of arsenate, molybdate and tungstate of chromium(III) obtained by electrometric titrations are in good agreement with those obtained by chemical analysis (Table I). Chromium

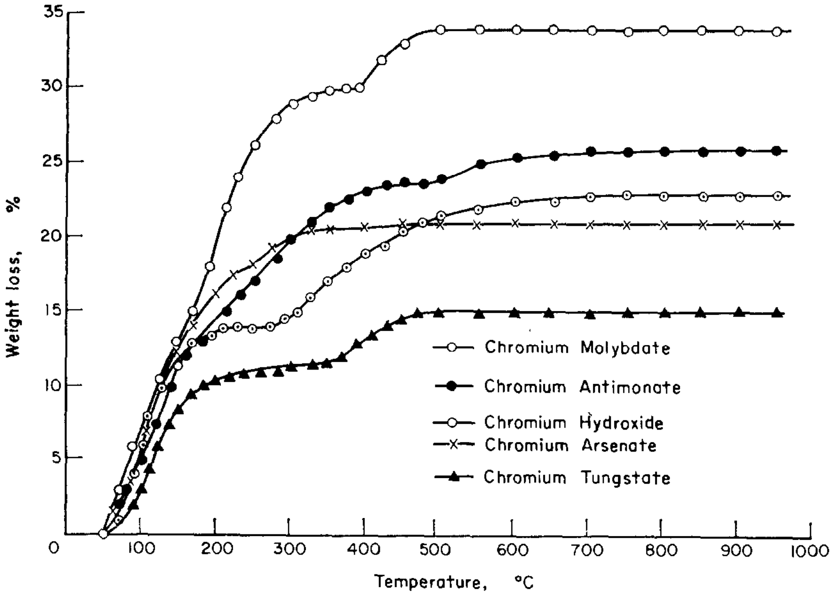

FIG. 1.—TGA graphs of chromium(III) compounds.

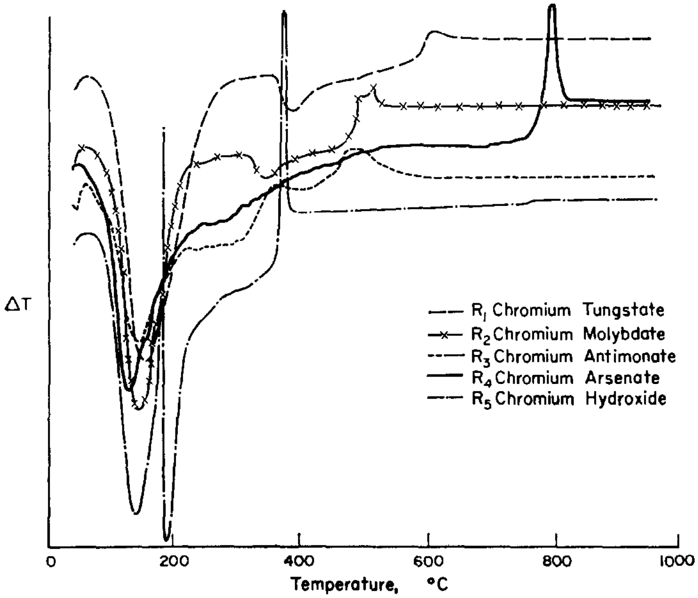

FIG. 2.—DTA graphs of chromium(III) compounds.

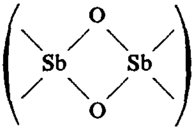
antimonate has a composition different from that of the other compounds studied. The great tendency of antimony pentachloride to hydrolyse even in dilute mineral acids, as distinct from arsenate, molybdate and tungstate, is responsible for this deviation. Nitrogen was not detected in the hydroxide and antimonate of chromium(III), and there is therefore no possibility of either NH_3 or NH_4^+ being present in these compounds.

The infrared spectra show that the band at 1610 cm^{-1} is absent in the compounds dried at 200° except in the case of chromium antimonate in which it is absent if the compound is heated to 500°. The intensity of the bands located at 3300 and 1380 cm^{-1} is also diminished as the drying temperature increases. At 500° the bands observed correspond to the respective oxides. The sequence for the thermal stability of the exchangers on the basis of infrared studies is CrSb > CrAs > CrOH > CrMO > CrW. It is also clear from the infrared spectra that all the compounds under study contain free water molecules as well as OH groups. The hydrogen ions attached in the form of OH groups are responsible for the ion-exchange capacity. These chromium(III) compounds are probably formed as a result of condensation of chromium hydroxide with the hydrated oxides of arsenic, antimony, molybdenum and tungsten. The monofunctional behaviour and cation-exchange capacity data (Table I) support these conclusions. Thermoanalytical results (Figs. 1 and 2) show that the weight loss % is in the order CrOH > CrSb > CrMo > CrAs > CrW, but because the formula weights differ so much, this is not a guide to the degree of hydration, which is in the order CrSb > CrW > CrMo > CrAs > CrOH. The TGA and DTA curves are similar to those reported for zirconium phosphate.[16] The exothermic peak at 380° in the DTA curve of chromium hydroxide, not found for other compounds, may be due to the conversion of chromium hydroxide into the oxide. At above 500° the weight of all the compounds is almost constant. Therefore the endothermic peaks at 170–190° seem to be due to the loss of either free water or water formed by the condensation of OH groups, and the exothermic peaks at higher temperatures are due to the formation of the corresponding oxides. The gradual change in the colour and the ion-exchange capacity of the compounds with increase in drying temperature (Table I) confirm these conclusions.

On the basis of these observations and the reported[17] species



the following tentative structure, similar to that of titanium antimonate[3] and hydrated chromium sulphate,[18] may be postulated for the chromium(III) compounds. Consider the case of chromium antimonate.

The Cr: Sb ratio by chemical analysis is 1:2·95. On heating, the oxides are produced, which should be in the same mole ratio. Allowing for experimental error, this may be rounded off to a 1:3 ratio. Therefore the empirical formula weight for $Cr_2O_3 \cdot 3Sb_2O_5$ is approximately 1122. The total weight loss on heating is 26%, so if n is the number of moles of water per mole of "mixed oxide",

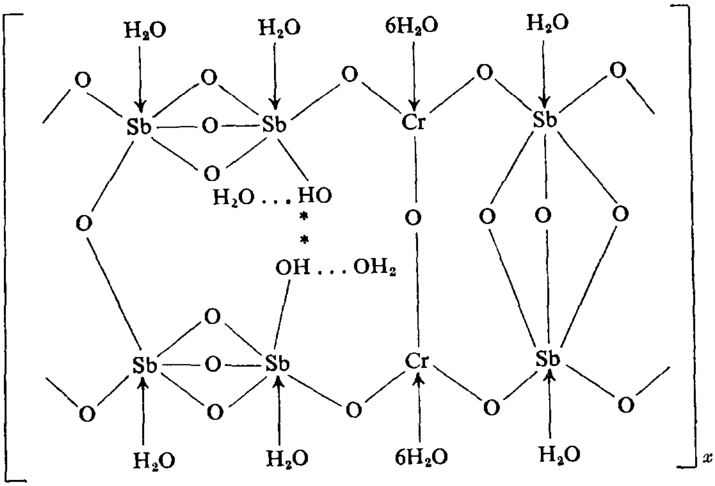
$$1800n/(1122 + 18n) = 26 \text{ and } n = 21{\cdot}9.$$

Again allowing for error in the TG work, we can write the formula as

$$Cr_2O_3{\cdot}3Sb_2O_5{\cdot}22H_2O,$$

formula weight 1442. The cation-exchange capacity on the basis of two protons per formula weight is 2000/1442 = 1·39 meq/g.

Therefore the structure of chromium antimonate may be written as:



where the protons marked with an asterisk are those considered responsible for the ion-exchange.

For the other compounds we have $Cr_2O_3{\cdot}4H_2O$, $Cr_2O_3{\cdot}2As_2O_5{\cdot}9H_2O$, $Cr_2O_3{\cdot}4MoO_3{\cdot}12H_2O$ and $Cr_2O_3{\cdot}4WO_3{\cdot}15H_2O$, which may be written as $Cr(OH)_3{\cdot}H_2O$, $Cr_2O_3(\overset{**}{H}_3AsO_4)_4{\cdot}3H_2O$, $Cr_2O_3(\overset{*}{H}_2MoO_4)_4{\cdot}8H_2O$ and $Cr_2O_3(\overset{*}{H}_2WO_4)_4{\cdot}11H_2O$. The hydroxide groups attached to chromium do not appear to have exchangeable protons whereas those attached to arsenic, antimony, molybdenum or tungsten do. The ion-exchange capacity calculated as above is always greater than the experimental ion-exchange capacity given in Table I. The amorphous nature of the compounds, *i.e.*, non-availability of all the exchange sites at neutral pH, may be responsible for this deviation.

The important sequences for the various chromium(III), tin(IV) and titanium(IV) compounds are given in Table VI. It is obvious from Table VI that the properties of the exchangers depend upon the composition of the material, *i.e.*, the tungstate is the most stable in nitric acid, the antimonate has the highest thermal stability and ion uptake, while the arsenate shows the greatest ion-exchange capacity. These facts support our earlier work on exchangers containing tin or titanium instead of chromium(III) (Table VI).

Like other hydroxides,[21,22] chromium hydroxide strongly adsorbs those cations which are prone to hydrolysis, *e.g.*, VO^{2+}, Al^{3+}, Ga^{3+}, In^{3+}, Fe^{3+}, Th^{4+}, ZrO^{2+}, HfO^{2+} and Sc^{3+} and it shows a lower uptake for bivalent cations at neutral pH (Table III). The molybdate and tungstate of chromium(III) are selective as they have high K_d values for certain metal ions only. The corresponding arsenate and antimonate show high uptake for all cations (Table III). Therefore the insoluble chromium compounds may be used to achieve separations and to soften water, though

TABLE VI.—COMPARISON OF Cr(III), Sn(IV) AND Ti(IV) ION-EXCHANGERS.

Property	Sequence of chromium(III) exchangers	Sequence of tin(IV) exchangers	Sequence of titanium(IV) exchangers
Stability in water	CrMo > CrW > CrOH > CrAs > CrSb	SnSb > SnW > SnAs > SnMo	TiW ~ TiSb > TiAs > TiMo
Stability in HNO_3	CrW > CrSb > CrAs ~ CrMo ~ CrOH	SnW > SnSb > SnAs > SnMo	TiW > TiSb > TiMo > TiAs
Ion uptake	CrSb > CrOH > CrAs > CrMo > CrW	SnSb > SnMo > SnW > SnAs	TiSb > TiW > TiAs > TiMo
Thermal stability on the basis of ion-exchange capacity	CrSb > CrAs > CrW > CrMo > CrOH	SnAs > SnSb > SnW > SnMo	TiAs > TiW > TiMo
Cation-exchange capacity at neutral pH	CrAs > CrSb ~ CrW > CrMo > CrOH	SnAs > SnMo > SnSb > SnW	TiAs > TiMo > TiW > TiSb

SnSb = stannic antimonate (unpublished work), SnAs = stannic arsenate,[6,7] SnW = stannic tungstate,[19] SnMo = stannic molybdate,[8] TiSb = titanium antimonate,[8] TiAs = titanium arsenate,[20] TiW = titanium tungstate,[11] and TiMo = titanium molybdate.[12]

toxicity studies would be necessary for the latter application. Their chief advantage is that they are inexpensive and are easily prepared. Their disadvantage is that they are not very stable in acids. It is unfortunate that Szirtes *et al.*[4] did not report the chemical stability of their chromium(III) phosphate. Our results suggest that it should not be very stable.

Acknowledgement—We thank Dr. S. M. F. Rahman for research facilities and Dr. B. Rama Rao for X-ray facilities. Financial assistance (to R. K.) and to (H. S. R.) by the UGC (India) and CSIR (India) is gratefully acknowledged.

Zusammenfassung—Fünf wasserunlösliche Chrom(III)-Verbindungen wurden durch Mischen von 0,10*M* Chrom(III)-chloridlösungen und Lösungen der entsprechenden Natriumsalze im Volumenverhältnis 1:2 bei pH 6-7 hergestellt. Ihre Ionenaustausch-Eigenschaften wurden verglichen. Das Wolframat besitzt die größte chemische Stabilität, das Arsenat die höchste Ionenaustauschkapazität. Chrom(III)-molybdat Säulen wurden zur Abtrennung von Pb^{2+} von zahlreichen Metallionen verwendet.

Résumé—On a synthétisé cinq composés insolubles dans l'eau du chrome(III) en mélangeant des solutions 0·10*M* de chlorure chromique et des sels de sodium appropriés dans le rapport de volumes 1:2, à pH 6–7. On a comparé leurs caractéristiques d'échange d'ions. Le tungstate a la stabilité chimique la plus élevée et l'arséniate à la plus forte capacité d'échange d'ions. On a utilisé des colonnes de molybdate de chrome(III) pour séparer Pb^{2+} de nombreux ions métalliques.

INVESTIGATIONS OF DIOXIMES AND THEIR METAL COMPLEXES

A SURVEY OF THE LITERATURE SINCE 1963

BIRGITTA EGNEUS
Department of Analytical Chemistry, University of Gothenburg,
Fack S-402 20 Göteborg, Sweden

(*Received* 28 *February* 1972. *Accepted* 26 *March* 1972)

Summary—A review is given of the chemistry and analytical applications of dioxime complexes from metals.

VICINAL α-dioximes have been used as analytical reagents for transition metals, especially nickel and palladium, since Tschugaeff[1] in the beginning of the 20th century discovered and outlined the selective properties of the dioximes. The most studied and used dioxime is dimethylglyoxime, which with nickel forms a characteristic scarlet precipitate, slightly soluble in water. Other widely used dioximes are α-furildioxime, where $R = R' = C_4H_3O$ (see Fig. 1), and the ring-stabilized 1,2-cyclohexanedionedioxime and 1,2-cycloheptanedionedioxime (nioxime and heptoxime respectively), where RCCR′ (Fig. 1) is cyclohexane and cycloheptane respectively. These reagents are as selective as dimethylglyoxime and have the advantage of being more soluble in water.[2]

Many investigations have been carried out to study the complexation properties of dioximes. Most transition metals form some kind of stable complex with these compounds. Usually the metal ion is co-ordinated to the functional group C(NOH)—C(NOH) of two dioxime molecules, as shown in Fig. 1, because the formation of four chelate rings will increase the stability of the complex.

With the aim of finding useful analytical reagents, the effect on the precipitation of several transition metals when the substituents in a dioxime are changed has been studied.[3,4] Dioximes prepared from large-ring diketones have thus been reported which precipitate bismuth, nickel and palladium.[5] For some dioximes used as analytical reagents, an attempt has been made to find a correlation between the electronic structure parameters (net π-electron charge on the oxygen atoms) and some thermodynamic quantities.[6] The results are, however, too meagre to allow a theoretical selection of dioximes for the determination of a certain metal.

Extensive reviews have previously been written by Babko,[7] Banks,[8–10] Dyrssen,[11] and Burger.[12] The present review deals mainly with the investigations related to the solution chemistry of the most common dioximes and their metal complexes that have been published and recorded in abstracts from January 1963 up to October 1971. It therefore constitutes a supplement to the review by Dyrssen.[11] Analytical procedures are summarized in condensed form only.

SEPARATION AND IDENTIFICATION OF DIOXIME ISOMERS

Orientation of the hydroxyl groups

Besides *cis* and *trans* configurations (see next section) the hydroxyl groups can be oriented in three ways relative to each other, Fig. 2*a*, *c*, *d*. The anti isomer (α-form)

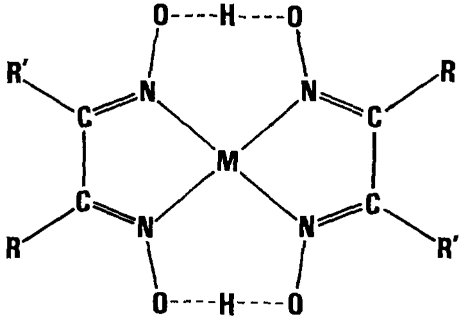

Fig. 1.—The structure of metal dioxides, $M(HA)_2$. R and R′ denote H, aliphatic or aromatic radicals.

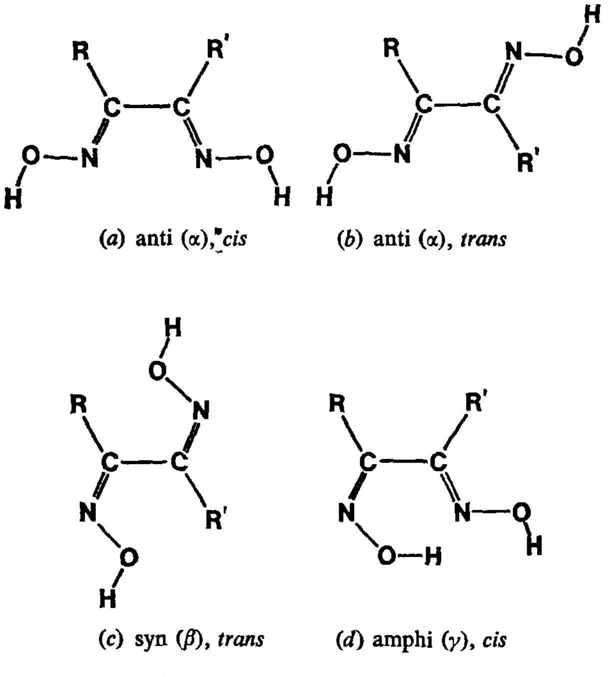


(a) anti (α), cis (b) anti (α), trans

(c) syn (β), trans (d) amphi (γ), cis

Fig. 2.—The isomers of dioximes, H_2A.

is known to form complexes with metal to ligand ratio 1:2, whereas the amphi isomer (γ-form) forms 1:1 complexes. The syn isomer (β-form), for steric reasons forms no complexes. The synthesis of an aromatic α-dioxime usually yields β- and γ-isomers as by-products, but there is little evidence of the formation of β- and γ-isomers in the preparation of aliphatic and alicyclic dioximes.[13] The mixed aliphatic-aromatic dioximes and the chlorodioximes are, however, known to exist as both anti and amphi isomers, see, *e.g.*, Toul *et al.*[14] and Ungnade *et al.*[15] The isomers are usually identified by chromatographic or spectroscopic methods, which have replaced such chemical methods as colour of solid metal derivates and isomerization with acids and bases. Thin-layer chromatography (TLC) has successfully been used by Toul *et al.*[14] to separate and identify benzilmonoxime, benzildioxime, furilmonoxime, furildioxime and their isomers, and dimethylmonoxime in dimethylglyoxime. Fractional recrystallization has been utilized by Burakevich *et al.*[16] to isolate three isomers of phenylglyoxime. The anti-, amphi- or syn-structures were identified by TLC and reactions with nickel(II) ions. Isomers have also been identified by using the ultraviolet and infrared spectra of the dioximes[15] or the ultraviolet and visible spectra of metal derivatives in solution.[17–19]

Nuclear magnetic resonance (nmr) spectroscopy seems to be a useful tool for identifying the isomers of a dioxime. Different chemical shifts, depending on the orientation of the oxime groups, are obtained for the protons in substituents adjacent to the oxime groups and for the hydroxyl protons. As the chemical shift of the hydroxyl proton is concentration-dependent, the chemical shifts of the protons in the substituents have been used in developing criteria for the different isomers in carbon tetrachloride and deuterated chloroform media. A shift independent of the concentration is, however, obtained in dimethylsulphoxide (DMSO), if the solution contains less than 5 mole $\%_0$ of the dioxime.[20] Guetté *et al.*[21] have calculated theoretically the chemical shifts of the hydroxyl protons of some dioximes and ketone oximes in DMSO in relation to the polarities and the configurations of the substituents of the rest of the molecule. The calculations are in fairly good agreement with experimentally obtained data. Tanaka *et al.*[22] have reported an analytical application of nmr, using the chemical shifts assumed to be due to the different isomers of benzil- and furildioxime. It was also shown that commercially available furildioxime may be a mixture of α- and γ-furildioximes.

Cis *and* trans *isomerism of the α-oxime groups*

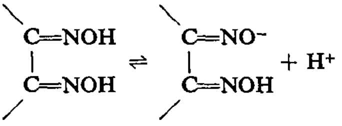
The oxime groups can be *cis* or *trans* to each other, Fig. 2*a*, *b*. Crystalline glyoxime[23] and dimethylglyoxime[24,25] have been shown to have the *trans* configuration. The configuration in the metal chelate must, however, be *cis*. It has been discussed whether the configuration of aliphatic anti-dioximes is *cis* or *trans* in solution.[26] From an infrared investigation of glyoxime it has been concluded that this compound must have a *trans* configuration in solution.[27] Theoretical calculations on the π-electron systems of the *cis* and *trans* configurations of dimethylglyoxime have been made by Roos,[28] and Bossa and Morpurgo.[29] The absorption bands in the ultraviolet region and the oscillator strengths have been calculated for each configuration and compared with experimental data. The investigators have used different parameters for their calculations. The results by Roos[28] indicate that dimethylglyoxime has a *cis* configuration, whereas Bossa and Morpurgo[29] claim that the configuration must be *trans*. The *trans* configuration is supported by an extensive study of dipole measurements of dimethylglyoxime and other dioximes in dioxan.[26] The ultraviolet spectra of ethylmethylglyoxime, and its singly and doubly charged anions have been determined by Egneus.[30] These results fit with the molecular calculation on the *cis* configuration by Roos.[28] The solvent effect may, however, be important.

Cyclic dioximes cannot have a *trans* configuration, as the oxime groups are fixed by the aliphatic ring in the *cis* position. Measurements of the maximum molar absorptivity in the ultraviolet region have shown that cyclic dioximes have a lower value than other, non-cyclic, dioximes.[31] The maximum molar absorptivities of the complexes between a metal and various dioximes are, however, nearly the same,[11] irrespective of the configuration of the dioxime in its uncomplexed form.

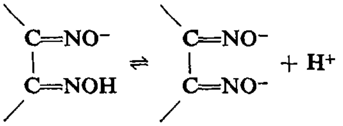
ACID AND BASIC BEHAVIOUR OF DIOXIMES; DECOMPOSITION IN ACID MEDIUM

Spectrophotometric investigations

In alkaline solution the dioxime splits off one or two protons according to equations (1) and (2).



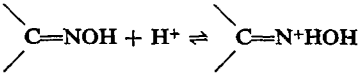
(1)



(2)

The dissociation constant for equation (1) is generally about $10^{-10.5}$ and for equation (2) about 10^{-12} (see ref. 2 and Table II).

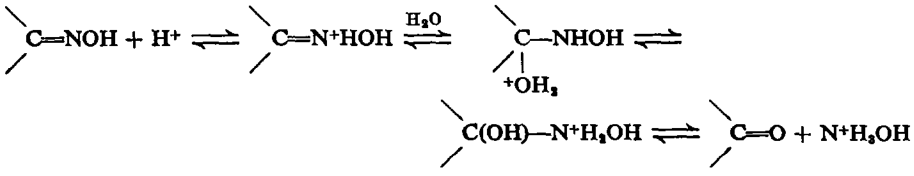
The nitrogen atom of the oxime group has weak basic properties, and a protonation according to equation (3) takes place in acid medium.



(3)

The protonation causes a bathochromic shift of about 20–30 nm from the maximum absorption wavelength of the neutral dioxime, with little or no change of the molar absorptivity.[31] The protonation constant can thus be determined spectrophotometrically. The protonation constant for dimethylglyoxime was found by Ellefsen and Gordon[32] to be 0·115 in hydrochloric acid at 25°. Shlenskaya *et al.*[31] obtained a value of 0·172 in perchloric acid at 25°. The decomposition that takes place in acid solution was considered in both works. The investigation by Shlenskaya *et al.*[31] indicates that alicyclic dioximes, *e.g.*, nioxime, have higher protonation constants than aromatic dioximes, *e.g.*, α-benzildioxime.

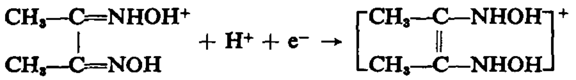
Alybina and Peshkova[33] have spectrophotometrically investigated the decomposition of dioximes in acid media with respect to time and concentration of hydrogen ions. The stability decreases in the following order: α-benzildioxime > dimethylglyoxime > heptoxime > nioxime. It seems as if a dioxime with lower protonation constant is less readily decomposed than a dioxime with a higher protonation constant. This implies that the first step of the decomposition is a protonation. The ultraviolet spectrum of nioxime in 5*M* hydrochloric acid measured after 5 hr shows the same features as the spectrum of the corresponding diketone. The decomposition may thus be a hydrolysis of the dioxime according to the reactions in equation (4).



(4)

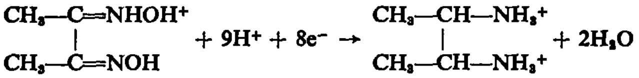
Polarographic investigations

The polarographic behaviour of dimethylglyoxime in acid solution has been studied by Spritzer and Meites.[34] A single well-defined wave is obtained at pH values below 3·5. A new wave appears at a more negative potential at pH values between 3·5 and 5·5. At pH values above 7 only an ill-defined wave at a very negative potential is obtained. The reduction product at pH values below 3·5 has been identified as 2,3-diaminobutane. The decomposition involves two protonation steps, but only one of the protonated intermediates is reduced. The rate-determining step is supposed to be



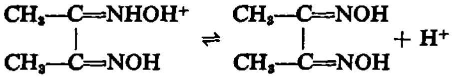
$$\begin{array}{l}CH_3—C{=}NHOH^+\\ \quad|\\ CH_3—C{=}NOH\end{array} + H^+ + e^- \rightarrow \left[\begin{array}{l}CH_3—C—NHOH\\ \quad\;\|\\ CH_3—C—NHOH\end{array}\right]^+ \tag{5}$$

The overall reduction is suggested to proceed according to

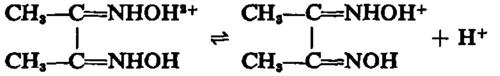


$$\begin{array}{l}CH_3—C{=}NHOH^+\\ \quad|\\ CH_3—C{=}NOH\end{array} + 9H^+ + 8e^- \rightarrow \begin{array}{l}CH_3—CH—NH_3^+\\ \quad|\\ CH_3—CH—NH_3^+\end{array} + 2H_2O \tag{6}$$

Burger *et al.*[35] have determined the dissociation constants for the two protonated species, equations (7) and (8).



$$\begin{array}{l}CH_3—C{=}NHOH^+\\ \quad|\\ CH_3—C{=}NOH\end{array} \rightleftharpoons \begin{array}{l}CH_3—C{=}NOH\\ \quad|\\ CH_3—C{=}NOH\end{array} + H^+ \tag{7}$$



$$\begin{array}{l}CH_3—C{=}NHOH^{2+}\\ \quad|\\ CH_3—C{=}NHOH\end{array} \rightleftharpoons \begin{array}{l}CH_3—C{=}NHOH^+\\ \quad|\\ CH_3—C{=}NOH\end{array} + H^+ \tag{8}$$

The overall reaction in equation (6) was found to take place. However, the polarographic data obtained can only be explained by assuming that both the protonated species are reduced. The values of the dissociation constants are $10^{-3\cdot00}$ and $10^{-3\cdot27}$ respectively. The value obtained for equation (7) is much lower than that determined spectrophotometrically.[31,32]

The reduction of dimethylglyoxime with stannous chloride in acid medium with molybdate as catalyst, has been proposed as proceeding through the formation of diacetyl.[36] The final reduction products have been identified as ammonia and acetoin [$CH_3CH(OH)COCH_3$].

The decomposition of dimethylglyoxime in hydrochloric acid has been studied by polarographic measurements.[34,36] The decrease of the concentration of dimethylglyoxime is proportional to the concentrations of unreacted dioxime and hydrogen ions.[34] The value of the decomposition rate constant is $1\cdot13 \times 10^{-3}$ l.mole^{-1}.sec^{-1} in $0\cdot1M$ sodium chloride–hydrochloric acid medium containing 15% ethanol. Different decomposition products have been proposed; 2,3-dinitrobutane was identified from its infrared spectrum,[34] and polarographic data indicated hydroxylamine and diacetylmonoxime.[36] No diacetyl was found in the reaction mixture.[34,36]

It should be observed that usually the protonation and the decomposition of dioximes need not be considered in the formation of metal complexes, unless the hydrogen ion concentration is high and the equilibrium time is long. Practically, it is only the formation of palladium complexes that can be affected.

The polarographic behaviour of dimethylglyoxime in alkaline medium has been suggested to be due to a four-electron process.[37] A dihydroxylamine might be the reduction product.

The polarographic behaviour of α-furildioxime has been studied in detail by Gelb and Meites.[38] The reduction proceeds in two distinct steps, both consisting of several stages. The first step involves six electrons. The product obtained will undergo transformation at a rate that depends on the hydrogen ion concentration. Further electrons may then be accepted. The final reaction product will depend on the hydrogen ion concentration at the different stages of the reaction. Under most conditions eight electrons are consumed and the reaction product has been identified as 1,2-bis-(2-furil)ethylenediamine (*cf.* dimethylglyoxime).

STRUCTURE OF METAL COMPLEXES

X-ray analysis of simple complexes

Many 1:2 complexes of bivalent transition metals with α-dioximes have been isolated. The crystal structure has been determined by X-ray spectrometry for a number of them. A collection of crystal data is given in the review by Dyrssen.[11] The characteristic feature of a 1:2 dioxime complex is the co-ordination of the four nitrogen atoms to the metal atom (central atom), Fig. 1. The nitrogen–metal bonds are usually in nearly the same plane and are almost of the same length (1·85–1·96 Å). The distances between the neighbouring oxygen atoms (hydrogen bonds) in a molecule are short; the measured values[11] are between 2·33 and 3·03 Å. The intramolecular hydrogen bonds between these oxygen atoms give an increased stability to the complex through the ring formation (see Fig. 1). The positions of the hydrogen atoms have not been definitely located, and it is still unknown whether the hydrogen bonds in dioxime complexes are linear or not. The long hydrogen bond in platinum(II) dimethylglyoximate (3·03 Å) has been queried by Schlemper,[39] who has found shorter oxygen–oxygen distances in similar nickel and platinum compounds.

A refinement of the structure of copper bisdimethylglyoximate has been made by Vaciago and Zambonelli,[40] using three-dimensional data obtained at room temperature. The crystal data differ little from those obtained earlier by Frasson *et al.*[41] who used low temperature and two-dimensional data. It could be argued[40] that cyclic delocalization of the electrons in the carbon–nitrogen bond might take place. Several resonance forms would then contribute to the stability. From the lengths of the copper–nitrogen bond it has, however, been concluded that no delocalization is likely to occur.

The crystal structure of copper dimethylglyoximate dichloride has been determined by Svedung.[42] The copper atom is co-ordinated by two nitrogen atoms within a molecule and the fifth co-ordination is offered by a chlorine atom of an adjacent molecule. The dimers thus formed are held together by two copper–chlorine–copper bridges. The triclinic structure is built up by chains of dimers, which are held together by intermolecular hydrogen bonds between pairs of oxygen atoms.

Many of the most studied nickel and palladium complexes[43] are isomorphous with nickel dimethylglyoximate. In these complexes the metal atoms are stacked above each other. Metal–metal chains, which were first proposed for nickel dimethylglyoximate,[44] have been proposed as a common property of these nickel and palladium dioximates. However, X-ray investigations show that nickel,[45,46] palladium[47] and platinum[48] glyoximates are not isomorphous with nickel dimethylglyoximate. None of these complexes has any appreciable metal–metal bonding. Nickel ethylmethylglyoximate, which exists in the two modifications α- and β- (according to the nomenclature of Anex and Krist[49]), in its β-form is isomorphous with nickel dimethylglyoximate. The α-form is isomorphous with nickel glyoximate. The nickel–nickel distances are 4·74 and 4·196 Å respectively[45,50] compared to 3·4 and 3·25 Å for β-nickel ethylmethylglyoximate[51] and nickel dimethylglyoximate.[44] No metal–metal interaction is thus possible in α-nickel ethylmethylglyoximate. A method of calculating the densest molecular arrangements of layers in crystals has been developed by Zorkii *et al.*[52] The predicted packing for nickel dimethylglyoximate is very close to that found experimentally, though it does not attain the highest possible density.

X-ray analysis of binary complexes

The structures of binary (mixed) dimethylglyoxime complexes containing two of the metals nickel, palladium and platinum, have been determined by X-ray diffraction by Lindoy *et al.*[53] The difference between the cell constants of the simple nickel, palladium and platinum dimethylglyoximates is small.[53] The binary complexes are isomorphous with the simple ones and have the metal–metal distances 3·23–3·25 ± 0·02 Å. The X-ray data have shown that, *e.g.*, two nickel and two palladium atoms in the unit cell occupy four equivalent crystallographic positions. The mixed complexes can therefore be supposed to built up in such a way that the metal atoms alternate in the metal chain extending through the crystal lattice. A disordered stacking sequence is, however, necessary to get a structure isomorphous with the simple complexes.[53] The close relationship between the structures of different bivalent transition metals explains the possibility of interfering co-precipitation of nickel, palladium and platinum dimethylglyoximates with each other in analysis.[54,55]

Spectrophotometric investigations of crystals in the ultraviolet–visible wavelength region

Several spectral investigations have been made of single crystals of some metal dioximates, particularly nickel dimethylglyoximate. Both polarized and unpolarized light have been used to make clear the interaction between the central atoms in the crystals. It was first reported by Yamada and Tsuchida[56] that crystals of nickel and palladium dimethylglyoximate have an anomalous dichroism and show characteristic absorption bands around 500 nm that are not present in the spectra of the corresponding solutions. These facts have been taken as support for the weak metal–metal interaction first proposed by Godycki and Rundle.[44] Banks and Barnum[57] have supported the metal–metal bond theory from their investigation of the absorption spectra of several solid nickel and palladium dioximates supposed to have metal–metal interactions. The characteristic absorption band for a metal complex in colloidal solution will shift to a longer wavelength when the metal–metal distance increases.[57] The position of the band will also depend on the central metal ion and the crystal structure. The absorption band of single crystals of nickel dioximates, in plane polarized light at about 500 nm, shows "abnormal" dichroism when the nickel–nickel distance is short. Normal dichroism occurs when the nickel–nickel distance is long.[57]

A possibility of verifying or disproving the intermetallic bonding theory is offered by studying the two modifications of solid nickel ethylmethylglyoximate (*cf.* above). Anex and Krist[49] have made an extensive investigation on the spectra of single crystals, solid films and solutions of α- and β-nickel ethylmethylglyoximate, nickel dimethylglyoximate and nickel heptoximate. From their results they have concluded that the characteristic band is of an intramolecular nature.

Another explanation, given by Ohashi *et al.*[58] is that the odd absorption band of the solid phase is due to a transition within the nickel ion. The intensity of the band is probably increased by an interatomic charge-transfer excitation in the crystal. Ohashi *et al.*[58] calculated the ground state stabilization energy to be 5 kcal/mole for nickel dimethylglyoximate. This is considerably less than the value of 10 kcal/mole for the strength of the nickel–nickel bond calculated from solubility data by Banks and Anderson.[59] A molecular orbital study by Ingraham[60] on nickel dimethylglyoximate has shown no strong nickel-nickel interaction. However, in general, the molecular orbital calculations suffer from the disadvantage of dependence on the parameters used. Thus the quantitative aspects of these calculations are somewhat uncertain.

Basu *et al.*[54] have investigated the temperature dependence of the absorption spectra of the solid, mixed, binary complexes of copper, nickel, palladium, and platinum with dimethylglyoxime. The absolute intensity is measured. No evidence for metal–metal bonds is obtained. On the basis of these experiments it is suggested that dioxime-complexes with the metal atoms stacked on top of each other (dimethylglyoximates of nickel, palladium and platinum) owe their crystal structure more to a favourable packing than to intermolecular bonds.

From a molecular orbital treatment of the absorption bands of copper bisdimethylglyoximate Roos[61] has given a theoretical explanation of the dimerization of the complex in the solid state. A covalent bond can be formed between a filled metal orbital of a molecule and an empty orbital of another molecule. The dimer should be further stabilized through the electrostatic interaction between a negatively charged oxygen atom and a positively charged copper atom.

Spectrophotometric investigations of metal complexes in solution in the ultraviolet–visible wavelength region

Much information about the bonds and the co-ordinations within a complex dissolved in various solvents is given by the ultraviolet and visible absorption spectra. Satisfactory assignments of the bands require, however, theoretical calculations combined with experimental data. Copper(II), cobalt(II) and iron(II) dioximates, which have preferably octahedral or distorted octahedral or square pyramidal configuration, have been investigated to study the effects on the ultraviolet–visible absorption spectrum by adduct formation, replacement of ligands, substitutions in the ligands, solvent interactions and changes in the bond strength, *etc.* Nickel(II), palladium(II) and platinum(II) dioximates have a square planar symmetry and a small tendency to be co-ordinated with axial unidentate ligands, in contrast to the cobalt(II), copper(II) and iron(II) complexes.

The ultraviolet–visible absorption spectra of copper- and nickel dimethylglyoximates and nickel ethylmethylglyoximate have been recorded by Caton and Banks.[62] Copper dimethylglyoximate exhibits significant solvent shifts, which have been assigned to changes in the nature of the copper–nitrogen bonds, due to an interaction between the complex and the solvents. No shift is observed for the nickel complexes. This partly reflects the inability of nickel dioximates to form adducts. A theoretical investigation of the normal (isolated molecule) and the excited states of copper dimethylglyoximate and its adducts with water and amines has been made by Roos.[61] The experimental data obtained by Dyrssen and Petković[63] were used. The results[61] show that a configuration interaction takes place between the ligand field and the charge-transfer transitions in copper dimethylglyoximate. This fact should be considered when interpreting spectral data from metal complexes with strong π-bondings. From the best agreement between theoretical data, calculated for a five- or six-co-ordinated copper ion, and experimental data,[63] the adducts with amines (B) and water are found to be $Cu(HA)_2B$ and $Cu(HA)_2(H_2O)_2$ respectively.

Iron(II) dioximates with the composition $Fe(HA)_2(pyridine)_2$ have a strong absorption band between 510 and 570 nm, which has been assigned to the metal → dioxime charge-transfer.[64–66] The position of this absorption band is correlated[64] to the C=N stretching band at 1500 cm^{-1} and the vibration band for Fe–N in the region 650–500 cm^{-1}. The charge-transfer band and the C=N stretching band of these complexes shift towards longer wavelengths in the order dimethylglyoxime < nioxime < α-benzildioxime < α-furildioxime, while the Fe–N vibration band will shift towards shorter wavelengths.[64] It is thus seen that in this type of iron(II) complex the absorption wavelength shifts are related to the increasing effect of the donor π-bond. The ultraviolet–visible spectra of bisdimethylglyoxime(pyridine)copper(II) resembles those of the corresponding iron(II) compound, and the same absorption ranges have been found.[63]

The influence of substituted pyridines on the ultraviolet–visible spectra of iron(II)–nioxime-pyridine complexes has been studied by Sanders and Day.[67] The solvent effect for the bisnioxime(bispyridine)iron(II) complex has also been investigated. The charge-transfer absorption bands are iron(II) → dioxime (~525 nm) and iron(II) → pyridine (~400 nm, ~295 nm). Electron-donating and electron-withdrawing substituents in the pyridine ring shift the 400-nm band to shorter and longer wavelengths respectively, relative to methyl substituents in the same position. The metal → dioxime band (525 nm) is, however, displaced in the opposite direction, thus showing an influence by the donor π-bond. The iron → pyridine absorption bands show a marked solvent effect. The iron → dioxime absorption band is only slightly affected by the solvent. The solvent effects are due to both the dielectric constant and the hydrogen-bonding power of the solvent. However, the large solvent shift for the 400-nm band may also be caused by the rotation of the pyridine rings around the z-axis, as no dissociation of the complex has been observed. Solvents more basic than pyridine have not been used.

Co(III) compounds with the composition $Co(HA)_2B_2^+$, where H_2A = α-dioxime and B = substituted anilines, have been investigated by Matsumoto *et al.*[68,69] The characteristic absorption bands are found between 300 and 375 nm, and 340 and 400 nm. The latter band is assigned to aniline → metal charge-transfer, because a linear correlation is found between the absorption frequencies and the ionization potential of the substituted aniline. The position of the band will shift when different substituted anilines are used. No effect is observed when the structure of the dioxime molecule is changed. The band between 300 and 375 nm is assigned to the metal → oxime charge-transfer and moves towards longer wavelengths in the order dimethylglyoxime < nioxime < α-benzildioxime < α-furildioxime (*cf.* the system iron(II)–dioxime–pyridine[64–66]).

The absorption spectra of palladium complexes with dimethylglyoxime, nioxime, heptoxime and α-furildioxime have been recorded in various solvents by Alimarin *et al.*[70] The spectra have been resolved into their bands and the oscillator strength of the different resolved absorption bands has been determined. For analytical purposes it may be interesting to note that the molar absorptivity of palladium α-furildioxime is considerably higher than that of the other complexes investigated.

In acid solution a neutral dimethylglyoxime molecule may be co-ordinated to a copper ion. Babko *et al.*[71] have recorded the absorption spectra of acid solutions containing dimethylglyoxime and $Cu(I)Cl$ or $Cu(II)Cl_2$. The spectra differ from those of the corresponding acid copper chloride solutions without dioxime. The complexes, proposed to be $Cu(I)H_2ACl$ and $Cu(II)H_2ACl_2$, are only formed in acid solutions. Corresponding complexes of copper(I) with other anions than chloride do not seem to be formed. Some of the lanthanides have been claimed to form similar complexes,[72] *e.g.*, $Ln(III)H_2ACl_2(H_2O)_nCl$. From the ultraviolet–visible spectral data it can be observed that the interaction between the metal and the dioxime is very weak. The difference between the spectra of the uncomplexed and the complexed species is very small both with respect to the absorption wavelengths and the intensities.

Infrared investigations of metal dioximes in solid phase and solution

Most infrared investigations have been focused on the stretching frequencies of the hydroxyl groups and the hydrogen bonds that are present in all known bivalent transition metal dioximates with the ligand to metal ratio 1:2, see *e.g.*, Blinc and Hadži,[73] Burger *et al.*,[74] Caton and Banks.[75]

A more complete assignment of the chelate ring vibrations has been made by Bigotto *et al.*[76,77] The spectra for the solid glyoxime and dimethylglyoxime complexes with some transition metals have been investigated between 4000 and 200 cm^{-1}. The assignments of the bands are done on the basis of the potential energy distribution. By this method it is found that the bands in the 2200–2700 cm^{-1} region originate from pure O—H—O stretchings and that the bands near 1700 cm^{-1} are due to almost pure O—H—O bendings. The asymmetric C═N stretching band is found between 1500 and 1600 cm^{-1} and the symmetric C═N stretching band between 1300 and 1400 cm^{-1}. These bands show, however, coupling with other vibrations, *e.g.*, C—C. Several of the vibration bands below 800 cm^{-1} are associated with the metal–nitrogen stretching mode. This is especially marked for the bands near to 500 cm^{-1}. An approximation of the force constants has been done so that good agreements are finally obtained between the observed and the calculated frequencies for all the investigated complexes. The force constants of the metal–nitrogen bonds decrease in the order Pt(II) > Pd(II) > Cu(II) > Ni(II). A comparison between the stability constants[2] of copper, nickel and palladium dimethylglyoximates shows a decrease in the same order (*cf.* Table II).

Caton and Banks[75] have made an extensive infrared study of the hydrogen bonds in copper and nickel dimethylglyoximates, nickel ethylmethylglyoximate and their deuterated analogues. The infrared spectra of the crystalline compounds and their chloroform solutions were recorded. The crystalline copper bisdimethylglyoximate has two different oxygen–oxygen distances,[40] 2·526 and 2·694 Å, and two absorption bands, 2382 and 2650 cm^{-1} respectively, have been assigned to the O—H—O stretchings. The hydrogen atom is symmetrically located between the two close oxygen atoms, but the deuterium atom is not, according to the "abnormal isotope effect".[78] A very small wavelength shift is obtained upon deuteration, because the increased bond strength will counteract the increased mass. Between the farther apart oxygen atoms both the deuterium and the hydrogen atoms are expected to be located unsymmetrically. The frequency shift in this case (from 2650 cm^{-1} to 1977 cm^{-1}) is in accordance with the increased mass. The oxygen–oxygen distances of the nickel complexes investigated are so short[44,50] (2·40 and 2·33 Å respectively) that both the deuterium and hydrogen atoms are supposed to be symmetrically located between oxygen atoms. The infrared spectrum of copper bisdimethylglyoximate in solution exhibits only one OH stretching band, which is in the same region as that for the nickel complexes. It is thus concluded that the oxygen atoms rearrange in solution and yield equal lengths for the oxygen–oxygen bonds.[75]

The infrared spectrum of crystalline copper dimethylglyoximate dichloride[42] shows two absorption bands at above 3000 cm^{-1} that can be assigned to hydroxyl stretchings of associated hydroxyl groups. The crystal structure indicates that one intermolecular hydrogen bond exists between two oxygen atoms close to each other. The other bond is an intramolecular interaction between the chlorine atom, bound to *one* copper ion, and the nearest oxygen atom that is involved in the intermolecular hydrogen bonding. The absence of a distinct C═N stretching band is puzzling and has not received a proper explanation. Mikhel'son and Evtushenko[79] have obtained the same spectrum of crystalline copper dimethylglyoximate dichloride but have given a different interpretation. They have suggested that a tautomeric transformation takes place. The hydrogen atoms should thus be attached to the nitrogen atoms and the copper ion should be co-ordinated through the oxygen atoms. The bands appearing at above 3000 cm^{-1} have, however, the same position as in dimethylglyoxime, showing the presence of associated hydroxyl groups.

Burger *et al.*[74] have recorded the infrared spectra of several metal dioximates. The nature of the hydrogen bonds and the existence of a metal → C═N donor π-bond are discussed on the basis of the data obtained for C═N and O—H—O stretchings.

Electron paramagnetic resonance investigations

Electron paramagnetic resonance (epr) can be used to determine the co-ordination in a metal complex. The epr data also give information about the covalent or the ionic character of the bonds. The method is especially advantageous when applied to copper complexes with ligands containing nitrogen atoms, because epr signals are obtained from both the copper and the nitrogen atoms. Schübel and Lutze[80] have calculated the epr parameters for copper methyl-, dimethyl- and ethylmethylglyoximate dichloride and copper bisethylmethylglyoximate, assuming the complexes to be planar. The experimental data were obtained from spectra measured at 77 K and 300 K in ethanol and pyridine. The influence of the ligand exchange can be observed in the spectra of complexes with one co-ordinated neutral dioxime molecule. The influence of the solvent can also be studied.[80] The low-temperature and room-temperature epr signals of copper bisdimethylglyoximate in different solvents have been studied by Falk *et al.*[71] The epr parameters calculated from experimental data are compared to the theoretically calculated epr parameters. Dyrssen and Hennichs[82] had earlier proposed that in a neutral aqueous solution of copper bisdimethylglyoximate two water molecules are co-ordinated to the complex and that in the pH range around 10 one proton will be removed from $Cu(HA)_2(H_2O)_2$. The epr data[71] confirm that at pH $\sim$10·5 a new species will appear, probably $Cu(HA)_2(H_2O)OH^-$ (H_2A = dimethylglyoxime). However, when the pH is increased to about 11·6, the epr data show that the chelate structure is broken and that the copper ion becomes co-ordinated to only two nitrogen atoms. The structure is probably $CuA(H_2O)_x(OH)_y^{y-}$ with $x + y \leq 4$. Above pH 14 the epr spectrum has the same characteristics as that of copper sulphate dissolved in sodium hydroxide. The signals are probably caused by $Cu(OH)_4^{2-}$. In the epr spectra of 0·1M pyridine and copper bisdimethylglyoximate in chloroform and benzene solutions where the adduct $Cu(HA)_2C_5H_5N$ is formed,[63] four equivalent couplings of dioxime nitrogen atoms to copper are discernible. The epr data show no appreciable coupling to any axial nitrogen. In order to calculate the adduct formation constant of copper bisdimethylglyoximate with pyridine in benzene,[83] the shift in the epr spectra (g-values at constant field strength) with increasing concentration of pyridine has been measured. The complex formation between molybdenum(V), obtained by reduction with tin(II), and nioxime and heptoxime was investigated by Marov *et al.*[84] They have concluded that an $MoO(HA)_2^+$ complex is formed.

Nuclear magnetic resonance investigations

The use of nmr spectroscopy to study metal dioximates has been restricted to cobalt(III) complexes. The cobalt(III) complexes of the type Co(III)$(HA)_2LX$, where H_2A = dimethylglyoxime, L = pyridine or triphenylphosphine and X = Cl^-, Br^-, I^-, CN^-, NO_2^-, Me, Et, *n*-Pr or CH_2CF_3, have been thoroughly investigated by Hill and Moralle.[85] The effect of the ligand (L) on the *cis* or *trans* position of the different anions or groups (X) was studied. The protons of dimethylglyoxime and the ligand (L) give chemical shifts that could be attributed to ground state *cis* and *trans* effects depending on the nature of the ligand X. A correlation has been found between the chemical shifts of the methyl protons and the Hammett σ_{para}-function of the ligand X, which may be related to a ground state *cis* effect due to the changes in the electron density of the *cis*-ligands in these complexes. It has been noticed by Naumberg *et al.*[86] that cobalt(III) complexes of the type Co(III)$(HA)_2RB$, where R = an alkyl group and B = a base, show a magnetic non-equivalence between the dioxime methyl groups, confirming the presence of an asymmetrical nitrogen atom.

Mössbauer investigations

Mössbauer spectroscopy has been used by Burger *et al.*[87,88] to study the structure and bonding relations of iron(II) and iron(III) complexes. The spectrum of solid iron(II) dimethylglyoximate shows that the complex must be polynuclear, as iron(II) has two bonding states. The crystals are thus built up[87] by molecules of $NaFe(HA)_2OH$ and $Fe(HA)_2$ in the ratio 2:1. The isomeric shifts of iron(II) and iron(III) dimethylglyoximate are nearly identical, showing that the *s*-electron density for both iron nuclei must be the same. The isomeric shift for the iron(II) α-furildioxime complex is smaller than for other investigated dioximes,[88] indicating that the *s*-electron density is relatively high compared with the other complexes. It has been pointed out[89] that an iron(II) spectrum must be measured under anaerobic conditions. A composite spectrum of signals from both iron(II) and iron(III) is otherwise easily obtained, like the one reported for iron(II)-salicylaldoxime.[87] The strength of the π-bond has been studied in the complexes Fe(II)$(HA)_2B_2$, where H_2A = dimethylglyoxime and B = a substituted pyridine.[90] Methyl groups in α- and γ-positions of the pyridine molecule strengthen the π-bonds by attracting the charge from the iron(II) atom. A methyl group in the β-position weakens these bonds. A greater effect is thus obtained in the spectra of the complexes with B = α- and γ-substituted pyridines than in the spectrum of the complex with B = β-substituted pyridines.

Miscellaneous investigations

A great number of composite complexes, especially of cobalt(III), have been prepared and analysed. In Table I references are given to some papers containing information on the preparation and characterization of Co(HA)XY compounds. As the aim of the investigations has often been to study the mechanism of substitution reactions, *e.g.*, the exchange of the ligands X and Y in $Co(HA)_2XY$, the determination of the structure of the compounds by the methods mentioned above is in most cases of secondary importance. With few exceptions composite complexes have not been utilized for analytical purposes. Adduct formation has, however, been used in the determination of iron(II) and cobalt(II) with dimethylglyoxime (see Table III), and Zolotov and Vlasova[91] have studied the ion-pair extraction of the Co(III)$(HA)_2$ $(pyridine)_2^+$ ion with different anions. Bearing in mind the possible analytical use of the composite cobalt(III) complexes in the future, it seems worthwhile to give a short summary of some investigations.

The associated water molecule in cobalt(III) complexes of the type $CoX(HA)_2H_2O$ with X and H_2O in *trans* positions (H_2A = dimethylglyoxime, X = Cl^-, Br^-, OH^-, NO_2^-, H_2O, NH_3 and amines) can dissociate[124,125] according to

$$CoX(HA)_2H_2O \rightleftharpoons CoXOH(HA)_2^- + H^+ \tag{9}$$

Palade *et al.*[125] have shown that the degree of dissociation is dependent on the influence of the ligand X in the *trans* position. The more *trans*-active X is, the lower the dissociation constant. The *trans* effect was found to diminish in the order $OH^- > NO_2^- > Br^- > Cl^-$. The proton may also be dissociated from the dioxime according to

$$CoXY(HA)_2^- \rightleftharpoons CoXY(HA)(A)^{2-} + H^+ \tag{10}$$

with Br^-, CN^- and NO_2^- as X and Y ligands. The dissociation constant has been determined spectrophotometrically by Birk *et al.*[126] Additional X and Y ligands (*e.g.* NH_3 and aromatic amines) have been investigated by others.[127,128] The replacement of iodine with water has been determined for dimethylglyoxime complexes with the composition $CoXI(HA)_2$, where X = Cl^-, Br^-, I^-, NO_2^-, SCN^-, N_2O. The values of the equilibrium constants for the reaction

$$CoXI(HA)_2 + H_2O \rightleftharpoons CoX(HA)_2(H_2O) + I^- \tag{11}$$

have been determined by Dubinskii.[129] The value will increase with the increasing *trans*-activity of the ligand X in the order $I^- < H_2O < Cl^- < Br^- < NO_2^- < SCN^-$.

In a recent work Burger *et al.*[130] have used $Co(HA)_2(solvent)_2^+$ as a reference acceptor for studying the donor strengths of different solvents. The iodide ion was

found to be the most advantageous ligand for the displacement of the solvent molecules. The substitution of the first solvent molecule, according to

$$Co(HA)_2S_2^+ + I^- \rightleftharpoons CoI(HA)_2S + S \tag{12}$$

where S denotes the solvent molecule, is promoted by the electrostatic interaction between the iodide ion and the complex cation. The equilibrium constant for equation (12) can be correlated with the donor strength of the solvent. The displacement of the second solvent molecule according to

$$CoI(HA)_2S + I^- \rightleftharpoons CoI_2(HA)_2^- + S \tag{13}$$

can be related to the dielectric constant of the solvent. The dissociation of $CoI_2(HA)_2^-$ will increase with increasing dielectric constant, mainly on the basis of the easier solvation of the iodide ion. Several dioximato compounds of rhodium(III) have been prepared in analogy with the corresponding cobalt(III) complexes.[131–133] The similarity in the X-ray diffraction patterns of $[M(HA)_2(NH_3)_2]Cl{\cdot}5H_2O$ where H_2A = dimethylglyoxime and M = Co, Rh, indicates that the compounds are isostructural.[132] The dissociation constant in aqueous solution for the reaction

$$[Rh(HA)_2(NH_3)_2]^+ \rightleftharpoons Rh(HA)(A)(NH_3)_2 + H^+ \tag{14}$$

has been determined.[131] The value is $\log K = -7{\cdot}10$, which is considerably higher than the value for the corresponding cobalt(III) compound ($-10{\cdot}5$ according to Yamano *et al.*[127]).

When the mixed complex between Co(II), dimethylglyoxime and the anions Cl^-, Br^-, I^- and SCN^- is formed, only one proton is removed.[134,135] The composition is $CoX_2(HA)(H_2A)^-$, whereas it is[135] $CoX_2(HA)_2^-$ for X = $SeCN^-$. In a similar study of Fe(II) only the complexes with the composition $FeX_2(HA)_2^-$ have been found. The stability constants for both Co(II)-and Fe(II)-dimethylglyoxime-X complexes increase in the order $Cl^- < Br^- < I^- < SCN^- < SeCN^-$. The co-ordination of SCN^- and $SeCN^-$ is believed to take place through the sulphur and selenium atoms,[135] because in the infrared spectra of the complexes the C≡N stretching band appears at increased frequencies in the order $SCN^- < Co(SCN)^+ < CoSCN(HA)_2^-$. A co-ordination through the nitrogen atom should cause a decrease of the C≡N frequency. The same behaviour has been found for the corresponding complexes with $SeCN^-$. When $Co(II)(HA)_2$ is oxidized in aqueous solution, a cobalt(III) complex with Co:HA^- ratio 1:3 is formed.[136] Spectrophotometric data have shown that $Co(HA)_3$ does not co-ordinate SCN^- and hence the oxidation of $Co(HA)_2$ to a Co(III) complex can be inhibited by the addition of SCN^-. It is believed that the oxidation takes place through the complex $CoOH(HA)_2^-$, which is less readily formed than the compound.

$Co(SCN)_2(HA)_2^{2-}$.

The stability constants for the following reactions between cobalt(II) and dimethylglyoxime or nioxime have been determined for different ionic strengths.[137]

$$Co(HA)(H_2A)^+ + I^- \rightleftharpoons CoI(HA)(H_2A) \tag{15}$$

$$CoI(HA)(H_2A) + I^- \rightleftharpoons CoI_2(HA)(H_2A)^- \tag{16}$$

As the iodide ions replace co-ordinated water molecules, the stability constants can be correlated to the water activity (ionic strength). The values of $\log K_1$ for equation (15) increase with increasing ionic strength, *i.e.*, the water molecule is more easily substituted at low water activity.[137] The formation of a neutral complex probably also promotes the co-ordination of the first iodide ion. The ratio between the stability constants K_1 [equation (15)] and K_2 [equation (16)] increases with increasing ionic strength. The co-ordination of the second iodide ion to form the negatively charged complex $CoI_2(HA)_2^-$ may be hindered by the increasing concentration of anions.

THE SOLUTION CHEMISTRY OF METAL DIOXIMES

Formation constants

The selectivity of a dioxime can be interpreted in terms of the stability constants for the metal complexes. The following reactions may be considered in addition to the H_2A equilibria:

$$M^{2+} + HA^- \rightleftharpoons MHA^+ \tag{17}$$

$$MHA^+ + HA^- \rightleftharpoons M(HA)_2 \tag{18}$$

$$M(HA)_2(s) \rightleftharpoons M(HA)_2 \tag{19}$$

$$M(HA)_2(aq) \rightleftharpoons M(HA)_2(org) \tag{20}$$

The equilibrium constants are K_1 $(= \beta_1)$, K_2, K_{s2} and K_{D2} respectively. The techniques used for the determination of the constants are, *e.g.*, potentiometric titration, spectrophotometric determination, solubility and distribution experiments. Sometimes competing equilibria with other ligands are used.

Dyrssen[2] has made a compilation of the stability constants for dioximes and their metal complexes up to 1964. In Table II the values of the stability constants determined since 1964 are given for the most common *vic*-dioxime complexes.

Table II shows that the values of K_1, K_2 and β_2 $(= K_1K_2)$ for the metal complexes change with the dioxime. Generally it can be said that the value of K_2 is higher than statistically expected, owing to the stabilization brought about by the formation of the hydrogen bonds (Fig. 1). The relative distribution of the metal species in solution with various concentrations of dioxime anions is shown in Fig. 3. It is evident that in the case when $K_1 < K_2$ the range for $M(HA)^+$ is rather small compared to the ranges

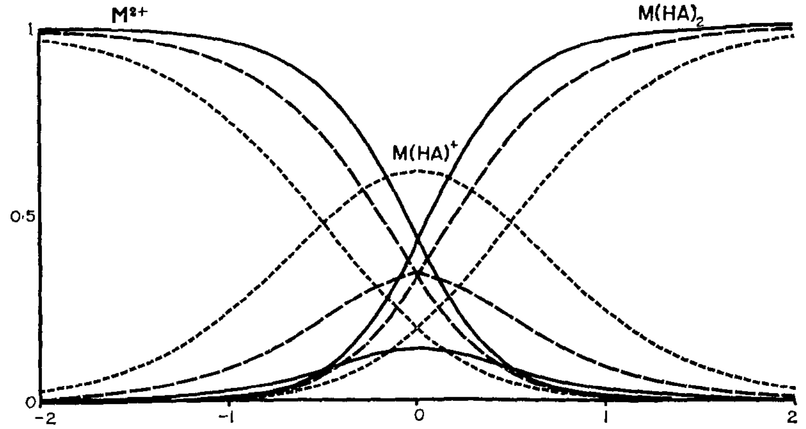

FIG. 3.—The distribution of the species M^{2+}, $M(HA)^+$ and $M(HA)_2$ as a function of $\log v = \log [HA^-] + \frac{1}{2} \log \beta_2$.

———— $\beta_1^2/\beta_2 = K_1/K_2 = 0{\cdot}1$

— — — $\beta_1^2/\beta_2 = K_1/K_2 = 1$

-·-·-· $\beta_1^2/\beta_2 = K_1/K_2 = 10$

for M^{2+} and $M(HA)_2$. This means that the separate determination of K_1 and K_2 is difficult to carry out accurately, and that the dominating reaction, with excess of dioxime anion, can be expressed as

$$M^{2+} + 2HA^- \rightleftharpoons M(HA)_2 \qquad (21)$$

with the equilibrium constant β_2. This will simplify the treatment of dioxime equilibria in analytical chemistry, since only one complex needs to be considered.

The thermal stability of some metal dioximes has been investigated by Burger *et al.*[156] The results show that the stronger the co-ordinate bond is, the lower is the initial decomposition temperature. This shows that the metal–nitrogen bonds in the chelate ring do not rupture first, but some other bond weakened by the co-ordinate bond. A comparison between the thermal stability and the value of log β_2 is, however, only possible for metal complexes with the same dioxime.

Solubility

The marked difference in the solubilities of metal dioximes in aqueous solution, especially nickel and palladium *vs.* copper dimethylglyoximate, has met with much interest. The low solubilities and solubility products of the nickel and the palladium complexes in water have often been related to metal–metal bonds in the crystals.[43,44,51,57,62] A determination of the solubilities in water of α- and β-nickel ethylmethylglyoximates has shown that α-nickel ethylmethylglyoximate, in spite of its longer nickel–nickel distance, has a lower solubility than β-nickel ethylmethylglyoximate.[144] This supports the view that the solubility is more dependent on the crystal packing[54] than the proposed intermolecular metal–metal bonds.[44,51] The distance between two successive molecular planes decreases in the order β-nickel ethylmethylglyoximate, α-nickel ethylmethylglyoximate and nickel dimethylglyoximate. The aqueous solubility of the complexes diminishes in the same order. On the basis of these data an attempt has been made to express the aqueous solubility of nickel dialkyldioximates (R and R′ being alkyl groups in Fig. 1) as a function of the distance between the molecular planes and the number of CH_2 groups in the complex.[144] It is suggested that the forces between the molecular planes can be neglected when the interplanar distance is more than 4 Å. The solubility would then depend mainly on the number of CH_2 groups.

The effect on the solubility of metal dioximates due to the ligand, the metal and the solvation power of the solvent has been discussed for the copper and nickel complexes of dimethylglyoxime and ethylmethylglyoxime.[145] The decrease in solubility noted for copper bisethylmethylglyoximate in water compared to copper bisdimethylglyoximate may be explained by the increased hydrophobic character of the ligand, which should diminish the adduct formation with water that has been shown to occur for copper bisdimethylglyoximate.[81,82] The "loosening" effect in the solid phase caused by the increased number of CH_2 groups is discernible in the nickel complexes, because nickel dimethylglyoximate has a lower solubility than nickel ethylmethylglyoximate in all solvents studied.[62] Further increase in the number of CH_2 groups will, however, probably decrease the aqueous solubility, in spite of the "loosening" effect.[144]

It can be noted that palladium complexes can be precipitated from acid solutions owing to the very high formation constants and the low solubility constants. A gradual rise in pH will, however, increase the solubility, as the hydroxy-complex

$Pd(HA)_2OH^-$ is formed.[157]

$$Pd(HA)_2 + OH^- \rightleftharpoons Pd(HA)_2OH^- \qquad (22)$$

A similar reaction occurs with the copper complexes[82] but not with the nickel complexes.

Distribution

The distribution constant can be estimated from the ratio of the solubilities in organic solvents and water. Chloroform is usually chosen as organic solvent for the extraction of metal dioximates, owing to its ability to form hydrogen bonds with the oxygen and nitrogen atoms of the oxime groups. The extraction of nickel is easily carried out from neutral or slightly alkaline solutions with the dioximes mentioned in Table II. No water molecules are associated with the nickel complexes with dimethylglyoxime and α-benzildioxime in the chloroform phase.[158] Palladium is best extracted from acid solutions,[142,157] thus avoiding the formation of $Pd(HA)_2OH^-$ and any interference from copper and nickel. The distribution constant is lower for palladium dimethylglyoximate than for nickel dimethylglyoximate, which may be due to a slight tendency of $Pd(HA)_2$ to co-ordinate water molecules.

The distribution constants determined for copper dioximates are rather low, owing to the solvation of $Cu(HA)_2$ in the aqueous phase (adduct formation with H_2O). For copper the distribution constant for the ethylmethylglyoxime complex is higher than would be expected from the constant for the dimethylglyoxime complex. The introduction of two CH_2 groups[11] should increase $\log K_{D2}$ by 1·2, but the observed difference is 1·47. This may be attributed to the lower solvation of copper bisethylmethylglyoximate in the aqueous phase. When the total concentration of copper exceeds 0·33mM, the extraction is markedly increased by the dimerization of the copper complex in the organic phase.[145]

The solvent extraction of Cu(II) with α-benzildioxime into benzene has been investigated by Einaga and Ishii.[155] Two neutral extractable complexes have been found with metal to ligand ratios 1:1 and 1:2. The 1:1 complex is formed with excess of copper and can only be extracted in the presence of ammonium nitrate. The extracted species might thus be the ion-pair $Cu(HA)^+NO_3^-$. The 1:2 complex is formed with an excess of dioxime and the extraction constant K_{ex} ($= K_{D2}\beta_2K_{a1}{}^2K_{D2}{}^{-2}$) has been determined for the reaction

$$Cu^{2+} + 2H_2A(org) \rightleftharpoons Cu(HA)_2(org) + 2H^+ \qquad (23)$$

The iron(III) complex with nioxime can be extracted with chloroform or n-pentanol, but the overall reaction is very slow.[149,150] The extraction curves for the two solvents are quite different, but in both cases the extracted compound is supposed to be Fe(III)$(HA)_3$. The possibilities that iron is reduced and extracted as $Fe(HA)_2$ by chloroform or is extracted as an ion-pair $Fe(HA)_2{}^+ClO_4{}^-$ with n-pentanol have, however, not been considered.

Adduct formation

The ability of copper complexes to form adducts in the organic phase can be used to increase the distribution of copper. Hitherto only the adduct formation with copper bisdimethylglyoximate has been investigated.[63,82] Chloroform and benzene have been used as organic solvents. The difference in the formation of adducts with pyridine, aniline and aliphatic amines is minor.[63] The formation seems, however, to be sterically hindered for tertiary amines.

It is well known that complex formation between iron(II) and dioximes takes place. The simple compound iron(II) dimethylglyoximate has, however, not been isolated. On the other hand, if an organic base is added to a solution containing iron(II) and a dioxime, isolation of the resulting compound can readily be achieved. The complex formation and extraction in the iron(II)–dioxime–amine (ammonia) system have been studied by Babko and co-workers.[65,66] The iron(II) complexes with dimethylglyoxime and nioxime can be extracted from pyridine solution with chloroform, but not from ammoniacal solution.[65,66] Spectrophotometric measurements indicate that the equilibrium in aqueous solution containing dimethylglyoxime, ammonia, pyridine (py) and iron(II) is

$$\mathrm{Fe(HA)_2(H_2O)py + NH_3 \rightleftharpoons Fe(HA)_2(H_2O)NH_3 + py} \qquad (24)$$

The extracted complex is probably $\mathrm{Fe(HA)_2(py)_2}$. The iron(II) complexes with α-benzildioxime[66] and α-furildioxime[159] are best extracted from ammoniacal solutions. The addition of pyridine will in this case lower the extraction, in contrast to the extraction of iron(II) dimethylglyoximate. Bases other than ammonia and pyridine do not give extractable compounds. The results thus indicate that only ammonia and pyridine can enter the co-ordination sphere of the complex,[66] probably for steric reasons.

Some reactions of metal dioximes in solution

In the gravimetric determination of, *e.g.*, nickel as nickel dimethylglyoximate the use of precipitation from homogeneous solution (PFHS) gives more perfect and larger crystals than those prepared by conventional methods.[160,161] In the reaction sequence[162] diacetyl + hydroxylamine → diacetyl monoxime $\xrightarrow{+\text{hydroxylamine}}$ dimethylglyoxime $\xrightarrow{+\mathrm{Ni}^{2+}}$ [yellow soluble complex] ⟶ red nickel dimethylglyoximate precipitate, a yellow colour appears, which is normally not obtained in conventional precipitation. The yellow species can be extracted with chloroform. The ultraviolet–visible absorption spectrum of the yellow chloroform solution is the same as that of the conventionally formed nickel dimethylglyoximate dissolved in chloroform. The yellow colour is assumed to be caused by undissociated nickel dimethylglyoximate, a "monomeric" species which can be present in concentrations several hundreds times the equilibrium concentration just before the formation of the red precipitate.[163] Boiling of the red precipitate in ammoniacal solution gives the yellow colour, *i.e.*, separated molecules are supposed to exist. An explanation of this behaviour based on the ligand field theory is given by Magee and Gordon[162] and the statements have been verified experimentally.

Yellow soluble nickel complexes with glyoxime, dipyridyl- and dihydroxyglyoxime can be formed in ammoniacal solution.[164] An anionic form of nickel dihydroxyglyoximate, $\mathrm{Ni(HA)_3^-}$, is suggested on the basis of data obtained by the method of continuous variation. Though an octahedral configuration is unlikely for a nickel–dioxime complex, this has been suggested for $\mathrm{Ni(HA)_3^-}$. As dihydroxyglyoxime is a considerably stronger dibasic acid[164] ($pK_{a1} = 6{\cdot}81$ and $pK_{a2} = 8{\cdot}66$) than dimethylglyoxime[139] ($pK_{a1} = 10{\cdot}57$ and $pK_{a2} = 12{\cdot}05$), alternative explanations to $\mathrm{Ni(HA)_3^-}$, *e.g.*, $\mathrm{Ni(HA)A^-}$, should be tested.

When an oxidant is added to nickel dimethylglyoxime in alkaline solution an intense red colour will appear.[1,165] The reaction is complicated to explain, as both the dioxime and the nickel ion can be oxidized. Polarographic investigations have shown that a reversible two-electron reaction[164,166–168] takes place. The nickel ion is supposed to be in a quadrivalent state in the oxidized nickel dimethylglyoxime complex. The highest ligand to metal ratio found (3:1) was determined spectrophotometrically.[164,166]

Ion-exchange studies indicate that in alkaline solution with the total concentration of $H_2A >$ the total concentration of Ni^{2+}, both neutral and doubly charged anionic complexes are present, as NiA_2 and $NiA_3{}^{2-}$ respectively. The formation constant for the reaction

$$NiA_2 + A^{2-} \rightleftharpoons NiA_3{}^{2-} \tag{25}$$

has been determined[169] to be $\log K_3 = 3{\cdot}02$.

In the preparation of red oxidized nickel dimethylglyoximate in 0·1–1M potassium hydroxide, a yellow colour appears before the oxidation starts. If no oxidant is added and the reaction solutions are kept free from air, the yellow colour persists, and nickel remains in oxidation state two. The solution is supposed to contain 1:1, 1:2 and 1:3 species of $Ni^{2+}:A^{2-}$ in equilibrium.[170] The yellow solution can be oxidized by air,[170] PbO_2[166] and iodine.[168] When iodine is used, the red solution is formed only when iodine is present in the minimum molar ratio $Ni:H_2A:I_2 = 2:6:5$. Polarographic studies have shown that dimethylglyoxime reacts with iodine in the ratio 2:1, and that a compound that can be isolated appears before the reaction with nickel will take place. The iodine is, however, not likely to be a part of the red oxidized complex.[168]

In a recent work Ksenzhek *et al.*[171] have studied the absorption of oxygen by alkaline solutions of nickel dimethylglyoximate. An absorption of oxygen, which can be removed by physical methods, takes place first, and is followed by an irreversible oxidation when the original complex decomposes. The results do not show any oxidation of the nickel ion.

The hydroxyl protons in copper and nickel dimethylglyoximates have been reported to be very unreactive towards methylmagnesium iodide.[172,173] This has been claimed to be due to the formation of strong hydrogen bonds. A recent investigation by Uhlig and Dorn[174] shows that methylmagnesium bromide does react with the hydroxyl groups in metal dioximates. Methane is evolved quantitatively if the metal complex is dissolved in xylene or pyridine. No reaction occurs if the metal dioxime is in the solid state (or suspended in a liquid).

ANALYTICAL PROCEDURES BASED ON DIOXIME REAGENTS

In Table III the determinations of some metals have been listed together with condensed information on the type of dioxime, method, range of metal concentration and precision, interferences, applications, *etc.*

The analytical problems that have been solved and the techniques that have been used can briefly be summarized as follows. Dioximes have mostly been used for the determination of nickel and rhenium in for example metals, minerals, ores, rocks, soils and biological materials. The nickel complex is usually determined after prior separation either by precipitation or chloroform extraction, *i.e.*, the low solubility of the nickel complex in aqueous solution is utilized. It has been noted that when nickel is precipitated in the presence of cobalt and iron,[191] precaution must be taken against the oxidation of nickel(II) to nickel(IV). The dioxime should thus be added to an acidified solution at $\mathrm{pH} < 4$, which is then made slightly ammoniacal. The precipitate can be dissolved in acid and analysed by, *e.g.*, Rollet's method,[211] extraction or titration procedures. The determination of nickel by extraction can be made rather specific by the use of masking reagents and a carefully chosen pH. The final determination is preferably carried out spectrophotometrically because of the higher sensitivity obtained. Either the organic phase is used directly or Rollet's method[211] applied, after a back-extraction from the organic phase. Rhenium is determined spectrophotometrically by the sensitive reaction in acid solution between perrhenate, reduced with stannous chloride, and an added dioxime. The serious interferences caused by molybdenum and platinum seem to be best avoided by extraction with pyridine followed by ion-exchange.[177] These comments show that no really new method has appeared in the determination of metals with dioximes.

Several of the procedures quoted in Table III do not deal with any special analytical problems, but are included because the reactions investigated can be used for different analytical purposes, as often suggested by the authors. Some of these works will be mentioned in the following. Precipitation from homogeneous solution (PFHS) makes it possible to handle up to 200 mg of metal in the sample compared with 30 mg usually recommended in the conventional precipitation of nickel and palladium.[189] Small amounts of nickel and palladium dioximates can be separated by co-precipitation with various compounds, *e.g.*, metal dioximates,[55,186,204,205] magnesium hydroxide[193] and 2,4-dinitroaniline.[202] Studies of the precipitation of nickel have shown that, owing to supersaturation,[163] the procedure is not quantitative for nickel unless amounts of more than 0·5 mg are used. Trace amounts of nickel as nickel dimethylglyoximate[196] can be detected by mass spectrometry. However, the quantitative determination may be a problem, owing to difficulties in the standardization. Several spectrophotometric methods have been devised for cobalt, iron and manganese, using different dioximes,[175,182,183] though the applications have not been fully outlined.

Dioximes have also been used in the analysis of other compounds than those containing transition metals. The reaction between rhenium and α-furildioxime has been applied to an indirect spectrophotometric determination of 3–5 ppm of nitrate.[212] Perrhenate and nitrate form a complex that is not reducible by stannous chloride in acid medium. Excess of rhenium is reduced and complexed with α-furildioxime. Urea in small amounts can be determined in blood[213,214] and urine[213] by the colour reaction with dimethylglyoxime in strongly acid solution. The advantage is that only small volumes are required for the quantitative determinations.[214]

Some reactions not used for analytical determinations are, *e.g.*, the increased extraction of copper and iron(II) bisdimethylglyoximates when an adduct-former is added to the organic phase, and the extraction of anions as ion-pairs with cobalt(III) and iron(III) bisdimethylglyoximate cations or *vice versa.* An ion-exchange resin has been prepared by condensation of α-furildioxime with formaldehyde and phenol.[215] The following transition metals can be sorbed from different media, $\mathrm{Pd^{2+}}$ (0·1*M* hydrochloric acid), $\mathrm{Co^{2+}}$, $\mathrm{Ni^{2+}}$, $\mathrm{Zn^{2+}(NH_3)}$ and $\mathrm{Cu^{2+}}$ (acetate buffer, pH 5·2).

Subjects not much studied are the development of suitable indicators for the complexometric titrations of transition metals, *e.g.*, by introducing chromophoric and hydrophilic groups into the dioxime molecule, and the preparation of ion-specific electrodes, especially for the nickel ion. It does not seem possible to prepare a good electrode from nickel dimethylglyoximate.[216]

A somewhat unusual dioxime, biacetyloximeazine [C(NOH)—C=N—N=C—C(NOH)] has been synthesized because of its structural relationship with dimethylglyoxime.[217] The complex formed with nickel is slightly soluble in water. The complex molecule in the solid state is a dimer consisting of two nickel atoms and two oximeazine molecules. No hydrogen bonds are formed between the oxime groups of the two ligands. The nickel ions may be more exchangeable than in nickel dimethylglyoximate and the complex may be useful for the preparation of a nickel-selective electrode. Many unusual dioximes have been prepared as model substances for the study of biochemical (enzymatic) processes. This is only one aspect of the co-ordination chemistry of dioximes; the analytical application of such investigations will, however, probably be of minor importance.

Acknowledgement—Very grateful acknowledgement is due to Professor David Dyrssen for helpful discussions of this review and the material presented in it.

Zusammenfassung—Es wird eine Übersicht über die Chemie und analytische Anwendungen von Metall-Dioximkomplexen gegeben.

Résumé—On présente une revue sur la chimie et les applications analytiques des complexes de dioxime avec les métaux.

NEW MASKING PROCEDURE FOR SELECTIVE COMPLEXOMETRIC DETERMINATION OF COPPER(II)

RAJINDER PAL SINGH
Department of Chemistry, Panjabi University, Patiala, India

(*Received* 22 *March* 1971. *Revised* 14 *April* 1972. *Accepted* 23 *April* 1972)

Summary—A study has been made of a new masking procedure for highly selective complexometric determination of copper(II), based on decomposition of the copper–EDTA complex at pH 5–6. Among the various combinations of masking agents tried, ternary masking mixtures comprising a main complexing agent (thiourea), a reducing agent (ascorbic acid) and an auxiliary complexing agent (thiosemicarbazide or a small amount of 1,10-phenanthroline or 2,2′-dipyridyl) have been found most suitable. An excess of EDTA is added and the surplus EDTA is back-titrated with lead (or zinc) nitrate with Xylenol Orange as indicator (pH 5–6). A masking mixture is then added to decompose the copper–EDTA complex and the liberated EDTA is again back-titrated with lead (or zinc) nitrate. The following cations do not interfere: Ag^+, Hg^{2+}, Pb^{2+}, Ni^{2+}, Bi^{3+}, As^{3+}, Al^{3+}, Sb^{3+}, Sn^{4+}, Cd^{2+}, Co^{2+}, Cr^{3+} and moderate amounts of Fe^{3+} and Mn^{2+}. The notable feature is that consecutive determination of Hg^{2+} and Cu^{2+} can be conveniently carried out in the presence of other cations.

As the direct complexometric methods for the determination of copper are not selective it is usually determined in the presence of some other cations by performing two separate titrations. The sum of all the cations including copper is first determined by back-titration of a known excess of EDTA with lead nitrate, with Xylenol Orange as indicator (pH 5–6), then in the second aliquot copper is masked by thiourea and the sum of the remaining cations is determined by a similar titration. The difference in the two titration results corresponds to copper.

A convenient method of determining copper selectively however, is to decompose the copper–EDTA complex (I) with a suitable masking agent and determine the liberated EDTA by back-titration. Only a few masking agents have been proposed for this purpose, which decompose I by displacement. 1,10-Phenanthroline[1] in acidic medium and thioglycollic acid[2] in alkaline medium have been used but both lack selectivity. Cystein[3] has also been proposed as the masking agent but cadmium, bismuth and mercury interfere. Budevsky and Simova[4] have recommended the use of thiourea in strongly acidified solution for masking but as the EDTA complexes of other bivalent metals also decompose at this low pH, the method suffers from the serious interference of cadmium, mercury, manganese and cobalt. The method is also time-consuming and inconvenient.

The present study was undertaken to develop a convenient masking procedure for fast and selective decomposition of I at the pH (5–6) at which the back-titration with lead (or zinc) nitrate is carried out with Xylenol Orange as indicator. Obviously more selective masking would be obtained by reduction of I to yield copper(I) and complexation of that with a masking agent such as thiourea or sodium thiosulphate. This, however, presents a difficult problem as these masking agents have little effect on I at pH 5–6, first because of the lowering of the redox potential[5] of the Cu^{2+}/Cu^+

system and secondly, and more importantly, because the copper(II) is surrounded by a large saturated ligand and electron transfer is sluggish. A detailed study was therefore undertaken, in which common masking agents were tried in various combinations to decompose **I** (Table I). It was found that although certain binary mixtures give quite satisfactory results, fast and smooth decomposition is best brought about by ternary mixtures. Each mixture, in general, comprises an auxiliary complexing agent (a small amount of 1,10-phenanthroline or 2,2′-dipyridyl and thiosemicarbazide), a reducing agent (ascorbic acid) and the main complexing agent (thiourea, sodium thiosulphate or thiosemicarbazide).

TABLE I.—EFFECT OF VARIOUS MASKING AGENTS ON THE DECOMPOSITION OF COPPER-EDTA COMPLEX (at pH 5–5·5).

Masking agent(s)*	Decomposition
TU, hypo	Almost nil
AA	Slight
TU, hypo + AA	Slight
TSC	Incomplete
TSC + AA	Incomplete
TSC + AA + phen (dipy)	Incomplete
TU + TSC	Complete†
TU + TSC + phen (dipy)	Complete†
TU + AA + TSC	Complete, fast
Hypo + TSC	Complete, slow
Hypo + TSC + phen (dipy)	Complete, slow
Hypo + AA + TSC	Complete, fast
Hypo + AA + phen (dipy)	Incomplete
TU + AA + phen (dipy)	Complete, fast

* TU = thiourea; hypo = sodium thiosulphate; AA = ascorbic acid; TSC = thiosemicarbazide; phen = 1,10-phenanthroline (small amount); dipy = 2,2′-dipyridyl (small amount).

† Slightly slow near the end-point.

On the basis of experimental findings and the stability constants[6] of the various complexes involved, the catalytic effect of a small amount of 2,2′-dipyridyl or (1,10-phenanthroline) on the masking of **I** in the presence of a mixture of thiourea and ascorbic acid can be explained as follows.

A small amount of copper(II) is withdrawn from **I** by the auxiliary masking agents as these form stronger complexes with it.

$$CuY^{2-} + 3\ dipy = Cu(dipy)_3^{2+} + Y^{4-} \qquad (1)$$

$$(\log K = 12{\cdot}2) \qquad (\log K = 17{\cdot}85)$$

As the copper ion is now surrounded by a large unsaturated ligand instead of the saturated EDTA ligand the exchange of electrons can be much faster.[7] The new complex is, therefore, readily reduced by ascorbic acid to the corresponding copper(I) complex.

$$Cu(dipy)_3^{2+} + e = Cu(dipy)_2^{+} + dipy \qquad (2)$$

As thiourea forms a more stable complex with copper(I) the auxiliary complexing agent is finally liberated from its copper(I) complex by the excess of thiourea

$$Cu(dipy)_2^{+} + 4\ tu = Cu(tu)_4^{+} + 2\ dipy \qquad (3)$$

$$(\log K = 14{\cdot}2) \qquad (\log K = 15{\cdot}4)$$

and is thus made available for further decomposition of **I**. In this three-stage process each stage is brought about by an individual constituent of the masking mixture, the cumulative effect of which leads to the fast and complete decomposition of **I**. When sodium thiosulphate and thiosemicarbazide are used in the masking mixture in place of thiourea, the addition of the auxiliary masking agents (1,10-phenanthroline or 2,2′-dipyridyl) does not enhance the speed of decomposition of **I**, because the thiosulphate and thiosemicarbazide complexes of copper(I) are too weak ($\log K = 13{\cdot}8$ and $11{\cdot}2$ respectively) to liberate the auxiliary masking agent by the displacement reaction (3). The presence of ascorbic acid in the masking mixture is essential as the redox potential of the Cu^{2+}/Cu^{+} system, although favourably affected by the presence of auxiliary complexing agent,[8] is nevertheless apparently not sufficiently high to enable thiourea alone to bring about the reduction [equation (2)].

As thiosemicarbazide is an important constituent of some masking mixtures, it was considered necessary to study its role in the masking of free copper(II). In the literature[9] thiosemicarbazide has been recommended for the masking of mercury and mercury–EDTA complex only, and copper(II) has been found to interfere seriously by forming an intense blue colour. In the course of the present study it was noted that the blue complex $Cu(TSC)_2^{2+}$ which is formed at low pH undergoes partial self-reduction slowly as the pH is raised to 5–6. This reduction to colourless $Cu(TSC)_2^{+}$ is made instantaneous by the addition of ascorbic acid. Thus this mixture can be conveniently used for masking of free copper(II) at pH 5–6. The masking of **I** by ternary masking mixtures with thiosemicarbazide as a constituent is thus also a three-stage process as described above. Here thiosemicarbazide behaves similarly to 2,2′-dipyridyl or 1,10-phenanthroline, the only difference being that the amount required is comparatively larger, although much smaller than required in binary mixtures for masking free copper(II). Unlike the ternary mixture with 1,10-phenanthroline or 2,2′-dipyridyl the presence of ascorbic acid in this masking mixture is not necessary, because reduction is facilitated by thiourea itself. In the binary mixtures of thiosemicarbazide and ascorbic acid the former has a dual function in the first and the third stage of the masking.

EXPERIMENTAL

Reagents

EDTA, 0·05M. Standardized against pure zinc, with Eriochrome Black T as indicator.

Copper nitrate 0·05M. Prepared from analytical grade copper metal.

Lead nitrate and zinc nitrate, 0·05M. Prepared from reagent grade salts and standardized with 0·05*M* EDTA, Xylenol Orange being used as indicator.

Xylenol Orange. Aqueous solution, 0·1%.

Thiourea and sodium thiosulphate. Aqueous solution, 1%.

Ascorbic acid. Aqueous solution, 5%.

1,10-*Phenanthroline and 2,2′-dipyridyl,* 0·1%. Prepared by dissolving the compounds in a little ethanol followed by dilution with demineralized water.

Potassium fluoride. Aqueous solution, 20%.

Hexamine. Reagent grade nitrates of the cations were used for studying interferences.

Determination of copper in the presence of other cations

To an acidic aliquot of the sample solution containing not more than 30 mg of copper, add excess of 0·05*M* EDTA, dilute the solution to about 50–100 ml with demineralized water and adjust the solution to pH 5–5·5 with solid hexamine. Add sufficient Xylenol Orange indicator and back-titrate the excess of EDTA with 0·05*M* lead (or zinc) nitrate to a sharp colour change from green-yellow to violet-blue or red-violet. Add 10 ml of 10% thiourea, about 5 ml of 5% ascorbic acid and 5 ml of 10% thiosemicarbazide for each 12 mg of copper, or 4–5 drops of 0·1% 1,0-phenanthroline (or 2,2′-dipyridyl) irrespective of the amount of copper. Shake till the solution becomes yellow and back-titrate the liberated EDTA with 0·05*M* lead (or zinc) nitrate to a sharp colour change from yellow to red-violet. Adjust the pH to 5–6 near the end-point, if necessary.

RESULTS AND DISCUSSION

Determinations of copper(II) were made with use of five different masking mixtures comprising thiourea, ascorbic acid and thiosemicarbazide; thiourea, ascorbic acid and 1,10-phenanthroline; thiourea, ascorbic acid and 2,2′-dipyridyl; sodium thiosulphate, ascorbic acid and thiosemicarbazide; and a mixture of thiourea and thiosemicarbazide. On the basis of detailed study the minimum amounts of the various constituents of these masking mixtures for the determination of 12 mg of copper were found to be 4–5 ml of 1% thiosemicarbazide solution, 8–10 ml of 10% thiourea solution, 10 ml of 10% sodium thiosulphate solution and 4–5 ml of 5% ascorbic acid solution, whereas 4–5 drops of 0·1% 1,10-phenanthroline or 2,2′-dipyridyl solution were found sufficient to catalyse the masking irrespective of the amount of copper determined. These amounts of a constituent may be varied slightly if larger amounts of the other constituents of the mixture are taken. When the binary mixture of thiourea and thiosemicarbazide is used, the amount of thiourea should be larger than normally required in the ternary mixture. Larger amounts of the masking agents do not affect the accuracy of the results. Although the order of addition of the masking agents does not appear to effect the speed of the masking process, in general thiourea was added first followed by ascorbic acid and 1,10-phenanthroline (or 2,2′-dipyridyl or thiosemicarbazide). As the constituents of the masking mixtures reinforce each other's effect on the decomposition of I they should be added at the beginning of the titration; their addition in lots during the course of the titration slightly slows down the masking.

Both lead and zinc nitrate can be used as back-titrants when thiosemicarbazide is used as one of the constituents of the masking mixture. In the masking catalysed by 1,10-phenanthroline or 2,2′-dipyridyl lead nitrate is somewhat more suitable as back-titrant; with zinc nitrate the results are slightly higher and the end-point is sharp only at pH 5·5–6. With the masking mixture containing sodium thiosulphate, only zinc nitrate should be used as the back-titrant and the pH at the end-point should preferably be between 5·5 and 6·0 for a sharp end-point.

The rate of masking is affected by the pH of the solution; lower pH makes the masking process faster. It is, therefore, preferable to carry out the masking at about pH 5 and adjust the solution to pH 5–6, if necessary, near the end-point. At the upper limit of the pH range the masking is somewhat slow but it is completed in the normal course of the titration (about 2 min). Accurate results are obtained with all the masking mixtures, and therefore the results are not given in separate tables.

Temperature has no appreciable effect on the rate of masking, and the titrations can be done at 15–35°. Too high a temperature makes the solution slightly turbid.

Interferences

Although Ag^+ is readily reduced to the metal by ascorbic acid and forms interfering precipitates with thiosemicarbazide, no interference is encountered if thiourea is added before the other consitiuents of the masking mixtures; transitory white precipitates are formed which dissolve on the addition of excess of thiourea to form a stable, soluble and colourless complex. Even large quantities of silver have no effect on the titration.

Zn^{2+}, Pb^{2+}, Ni^{2+}, As^{3+}, Sb^{3+} and Bi^{3+} do not interfere. Al^{3+} does not interfere at room temperature. Cd^{2+} and moderate amounts of Co^{2+} can be tolerated, but large amounts affect the quality of the end-point in the second back-titration. Zn^{2+} is a better back-titrant with larger amounts of Cd^{2+}. Large amounts of Cr^{3+} can also be tolerated. A small excess of EDTA should be added before the first back-titration otherwise the results are slightly high. As Mn^{2+} is only partially complexed at the pH used it tends to affect badly the sharpness of the end-point. Up to 10 mg of Mn^{2+} can easily be tolerated by maintaining the pH at the end-point at about 6 in both back-titrations. Tin, when present, can easily be removed as tin(IV) oxide by boiling with nitric acid.

As mercury(II) and mercury-EDTA complex are also masked readily by the masking agents used for masking copper(II) or **I**, they provide main interference in the determination of copper. A notable feature of the present method is that not only

can the interference of mercury(II) be avoided but it is also possible to carry out the consecutive determination of mercury and copper in the presence of other cations by successive masking with thiourea[10] and the present masking mixtures.

Typical results for the determination of copper in the presence of the cations mentioned, by using a masking mixture of thiourea, thiosemicarbazide and ascorbic acid with Pb^{2+} as the back-titrant, are recorded in Table II. As identical results were obtained with masking catalysed by 1,10-phenanthroline no separate table is considered necessary for those results. The determination is, however, not selective with the masking mixture containing sodium thiosulphate, where Cd^{2+} and Pb^{2+} give a drawn-out end-point and Ag^{+} causes serious interference owing to its reduction.

Small amounts of Fe^{3+} (up to 10 mg) can be tolerated by using the minimum amounts of ascorbic acid in the masking mixtures. Larger quantities of ascorbic acid impair the quality of the end-point. The ternary masking mixture with thiosemicarbazide as a constituent gives a better performance than the one with 1,10-phenanthroline (or 2,2′-dipyridyl). With preliminary masking of Fe^{3+} with potassium fluoride, either of these masking mixtures can be used. The binary masking mixture of thiourea and thiosemicarbazide is especially suitable for tolerating moderate amounts (up to 20 mg) of Fe^{3+} without any preliminary masking, with accurate results, but the titration is a bit slow near the end-point (Table III).

Acknowledgement—Professor Nazar Singh, Head of Chemistry Department, is thanked for providing research facilities.

Zusammenfassung—Eine neue Maskierungsmethode zur hochselektiven komplexometrischen Bestimmung von Kupfer(II) wurde untersucht. Sie beruht auf der Zersetzung des Kupfer-EDTA-Komplexes bei pH 5–6. Unter den verschiedenen ausprobierten Kombinationen von Maskierungsmitteln bewährten sich ternäre Maskierungsgemische mit einem Haupt-Komplexbildner (Thioharnstoff), einem Reduktionsmittel (Ascorbinsäure) und einem Hilfs-Komplexbildner (Thiosemicarbazid oder eine kleine Menge 1,10-Phenanthrolin oder 2, 2′-Dipyridyl) am besten. Ein Überschuß von EDTA wird zugegeben und die überschüssige EDTA mit Blei- (oder Zink-) nitrat und Xylenolorange als Indikator (pH 5–6) zurücktitriert. Dann wird Maskierungsgemisch zugegeben, um den Kupfer-EDTA-Komplex zu zerlegen; die freigesetzte EDTA wird wiederum mit Blei- (oder Zink-) nitrat zurücktitriert. Folgende Kationen stören nicht: Ag^+, Hg^{2+}, Pb^{2+}, Ni^{2+}, Bi^{3+}, As^{3+}, Al^{3+}, Sb^{3+}, Sn^{4+}, Cd^{2+}, Co^{2+}, Cr^{3+} sowie nicht zu große Mengen von Fe^{3+} und Mn^{2+}. Beachtlich ist, daß Hg^{2+} und Cu^{2+} in Gegenwart anderer Kationen bequem nacheinander bestimmt werden können.

Résumé—On a effectué une étude d'une nouvelle technique de dissimulation pour le dosage complexométrique hautement sélectif du cuivre(II), basée sur la décomposition du complexe cuivre-EDTA à pH 5–6. Parmi les diverses combinaisons d'agents dissimulants essayés, les mélanges de dissimulation ternaires comprenant un agent complexant principal (thiourée), un agent réducteur (acide ascorbique) et un agent complexant auxiliaire (thiosemicarbazide ou une petite quantité de 1,10-phénanthroline ou de 2,2′-dipyridyle) ont été trouvés être les plus convenables. On ajoute un excès d'EDTA et le surplus d'EDTA est dosé en retour par le nitrate de plomb (ou de zinc) avec l'Orangé Xylénol comme indicateur (pH 5–6). Un mélange dissimulant est alors ajouté pour décomposer le complexe cuivre-EDTA et l'EDTA libéré est de nouveau dosé en retour avec le nitrate de plomb (ou de zinc). Les cations suivants n'interfèrent pas: Ag^+, Hg^{2+}, Pb^{2+}, Ni^{2+}, Bi^{3+}, As^{3+}, Al^{3+}, Sb^{3+}, Sn^{4+}, Cd^{2+}, Co^{2+}, Cr^{3+}, ainsi que des quantités modérées de Fe^{3+} et Mn^{2+}. Le caractère remarquable est que le dosage consécutif de Hg^{2+} et Cu^{2+} peut être commodément mené en la présence d'autres cations.

VOLUMETRIC DETERMINATION OF PRIMARY ARYLAMINES AND NITRITES, USING AN INTERNAL INDICATOR SYSTEM

EUGEN SZEKELY, AMALIA BANDEL and MIRIAM FLITMAN

Summary—A new nitrite titration method is presented. The titration is performed in the presence of a standard solution of 4,4′-sulphonyldianiline and diphenylamine, which is used as an internal indicator. An intense red colour develops during the titration as a result of a simultaneous diazotization and coupling process. A very sharp end-point is given by a colour change to yellow. The titration is performed at a temperature of about 45° in the presence of large amounts of nitrate. The method is specific and precise. It is suitable for the direct volumetric determination of various easily diazotized primary arylamines, sulphonamides and other amino-compounds which can be determined by nitrite titration. It is suitable also for the indirect determination of nitrites. The method is applicable on the semimicro and macro scales.

MOST OF THE early work on arylamine determination was done in the dyestuff industry. Diazotization by direct nitrite titration is also the method of assay for most of the pharmaceutical drugs which have a free primary arylamine group and for those drugs which yield a free amino-group by hydrolysis or reduction.

In the standard methods the end-point is detected either visually with starch-iodide as an external indicator[1] or electrochemically (the dead-stop technique).[2] Different external indicators are recommended by various investigators. Some of these are tolusafranine,[3] rivanol,[4] leuco Methylene Blue,[5] and a mixture of brucine, benzidine and phosphoric acid.[6]

Attempts have been made to find suitable internal indicators for the visual detection of the end-point. Acriflavine was used by Frost,[7] diphenylbenzidine disulphonic acid by Ågren,[8] Orange IV by Vasiliev,[9] ferrocyphen by Schilt,[10] and by Banick and Valentine.[11] The potentiometric titration method was proposed by Singh andAhmed.[12] La Rocha and Waters,[13] McNaughton *et al.*[14] have reported that the method seems to give better results than those obtained when using indicators, but it is time-consuming.

Sholten and Stone[15] used an amperometric method and their results indicate that the method has some advantage over both visual and potentiometric methods. They state, however, that the end-point is somewhat sluggish and cannot be easily detected. This method (dead-stop end-point) has been introduced recently into standard methods.

The object of this investigation was to find a simple, specific, rapid and precise method, which eliminates the disadvantages and difficulties of other methods. The experiments were started with "dapsone" (4,4′-sulphonyldianiline) and diphenylamine, reagents proposed for the colorimetric determination of nitrites.[16] It was observed that a yellow colour develops when a small amount of sodium nitrite is added to an acidified solution of dapsone and that on further nitrite addition the colour fades almost completely. It was observed also that the diazotization and coupling is a simultaneous process, when a very acid solution of dapsone and diphenylamine is used at various temperatures. The resulting reddish-violet azo dye has an intense tinctorial power and is not photosensitive.[16]

EXPERIMENTAL

Solutions containing dapsone and diphenylamine were titrated in the presence of various amounts of nitric acid and the stability of nitrous acid was investigated, on the basis of the experiments of Jones and Lee.[17] The standard sodium nitrite solution was added slowly to the samples with continuous stirring. The variables were the amount of nitric acid and the temperature. When a large amount of nitric acid was present, no loss of nitrous acid was found even when the temperature of the sample solution was increased to 50°.

The addition of nitric acid alters the pH conditions. It was replaced with sodium nitrate which is preferable as it is available free from nitrite. The amount of hydrochloric acid and sodium nitrate necessary for optimal reaction conditions was established experimentally. About 45° was found to be the optimal temperature for colour development, speed of reaction and end-point detection; there is no risk of losing nitrous acid. The amount of dapsone and diphenylamine required to create an indicator solution which develops the best colour effect during the titration and at the end-point was also experimentally established.

Reagents

Standard dapsone solution 0·05*M*. Dissolve 12·5 g of reagent grade desiccated 4,4′-sulphonyldianiline in approximately 2*M* hydrochloric acid and make up to 1000 ml. The solution is stable indefinitely.

Diphenylamine solution. Dissolve 0·05 g of reagent grade diphenylamine in 100 ml of alcohol (95%).

Standard sodium nitrite solution 0·1*M*. Dissolve 7·1 g of reagent grade sodium nitrite in demineralized water, add a few drops of 0·1*M* sodium hydroxide, make up to 1000 ml, and standardize by dead-stop titration against sulphanilic acid.

Hydrochloric acid 6*M*. Mix equal volumes of reagent grade hydrochloric acid and demineralized water.

Dapsone–diphenylamine (indicator) solution. Mix 10 ml of diphenylamine solution with 100 ml of standard dapsone solution. The solution is stable for several weeks if kept in darkness.

Procedures

Amine determination. Take a sample weighed to ±0.1 mg which contains 0·2–2 meq of amine, and dissolve it in 20 ml of 6*M* hydrochloric acid in a 250-ml titration vessel. Alternatively, take an aliquot of sample solution containing 0·2–2 meq of amine, and make it about 6*M* in hydrochloric acid. Add 20 ml of sodium nitrate solution and dilute to about 100 ml. Add from a pipette 5 ml of dapsone–diphenylamine solution, heat the sample to 45° (±2°) and titrate it with 0·1*M* sodium nitrite. Use a burette with lengthened tip dipped well under the surface of the solution, and stir continuously with a magnetic stirrer. Continue the titration slowly, as the initially developed raspberry red colour turns violet. Just before the end-point, as the colour begins to fade, add the nitrite solution in 0·05-ml increments or less, at intervals of 10–20 sec. The end-point is detected by a colour change from orange-yellow to greenish-yellow. Make a blank titration using the same volumes of reagents, water and exactly the same volume of dapsone–diphenylamine solution. Subtract the volume of the standard nitrite solution used in the blank from the volume of the nitrite solution used in the titration of the sample. Calculate the content.

The method can also be applied on the semimicro scale. In this case the volume of the sample solution and of the reagents should be reduced to half of that described in the procedure. Only 2 ml of dapsone-diphenylamine solution are added and a microburette or micrometer syringe should be used.

Nitrite determination. Weigh an amount of sample containing 25-500 mg of sodium nitrite, and make up with water to 100 ml. Take a volume of 0–20 ml* of 0·05*M* dapsone solution in a 250-ml titration vessel, add 20 ml of 6*M* hydrochloric acid, 20 ml of sodium nitrate solution and 5 ml of dapsone-diphenylamine solution. Dilute to about 80 ml. Slowly add 25 ml of the sample solution from a pipette to the prepared solution, while stirring. Heat the reaction mixture to 45° (±2°). The red colour developed indicates the presence of an excess of the dapsone reagent. If the colour obtained is yellow, it is a sign of miscalculation (insufficient dapsone) and the determination should be repeated with a more dilute sample solution. Titrate the excess of dapsone with 0·1*M* sodium

---

* It is not necessary to add dapsone solution to determine less than 25 mg of sodum nitrite, since the amount of dapsone already present in the 5 ml of dapsone–diphenylamine solution is sufficient for the determination of these amounts.

nitrite as described for the amine determination. Make a blank titration with the same amount of dapsone and dapsone–diphenylamine solution, using 25 ml of water instead of the sample solution. The determination can be performed also on the semimicro scale.

Calculate the sodium nitrite content from the equation

$$\frac{(v_1 - v_2) \times f \times 4 \times 0{\cdot}069 \times 10}{W} = \frac{(v_1 - v_2) \times f \times 2{\cdot}76}{W} = A$$

where v_1 is the volume of the nitrite solution used in the blank titration (ml)
v_2 is the volume of the nitrite solution used in the sample titration (ml)
f is the factor of the standard nitrite solution
0·069 is the weight of 1 m mole of sodium nitrite (g)
W is the weight of the sample (g)
A is the amount of sodium nitrite found (%).

RESULTS

The reliability and accuracy of the method were verified on the macro and semimicro scales by titration of sulphanilic acid (purity ~ 99·9%).

A purity of 99·8–100·0% was found in 5 determinations when 1·2–1·8 meq were taken (macro method), the maximum error being 0·1%. For the semimicro method 0·04–0·05 meq was taken. The maximum error was 0·4% and the relative standard deviation 0·15% (5 determinations).

Tables I and II list the amine compounds which were determined by the procedure given.

TABLE I.—DYESTUFF INTERMEDIATES. (VALUES OBTAINED FROM AT LEAST 4 DETERMINATIONS).

	Rel. std. devn., %	Max. error, %
4-Aminoacetanilide	0·15	+0·6
8-Amino-1,3,6-naphthalene trisulphonic acid	1·2	+2
Di-(4-aminophenyl) ether	0·15	+0·5
m-Nitroaniline	0·08	+0·3
o-Nitroaniline	0·07	+0·25
p-Nitroaniline	0·08	+0·2
5-Nitro-*o*-toluidine	0·2	+0·4

TABLE II.—REAGENTS AND DRUGS. (VALUES OBTAINED FROM AT LEAST 4 DETERMINATIONS).

	Rel. std. devn. %	Max. error, %
N-Acetylsulphanilamide	0·10	+0·15
N-Amidinosulphanilamide (Sulphaguanidine)	0·05	+0·15
p-Aminobenzenesulphonamide (Sulphanilamide)	0·06	+0·2
o-Aminobenzoic acid	0·08	+0.2
p-Aminobenzoic acid	0·10	+0·25
p-Aminobenzoyldiethylaminoethanol	0·18	+0·5
hydrochloride (Procaine hydrochloride)	(semi micro determination)	
p-Aminosalicylic acid	0 10	+0.2
5-Amino-3-sulphosalicylic acid	0·08	+0·2
N-(3,4-Dimethyl-5-isoxazolyl) sulphanilamide (Sulphisoxazole)	0·15	+0.35
Ethyl aminobenzoate	0·08	+0·2
N-(6-Methoxy-3-pyridazinyl)sulphanilamide (Sulphamethoxypridazine)	0·18	+0.3
N-(4-Methyl-2-pyrimidyl)sulphanilamide (Sulphamerazine)	0·15	+0·3
N-2-Pyridylsulphanilamide (Sulphapyridine)	0·12	+0·2
2-Sulphanilamidopyrimidine (Sulphadiazine)	0·10	+0·15
N-2-Thiazolylsulphanilamide (Sulphathiazole)	0·12	+0·2

A very sharp end-point was detected in all these determinations, except in the titration of 8-amino-1,3,6-naphthalene trisulphonic acid, where the colour turns to orange-yellow at the end of the titration. In this case the error is about ±1%.

DISCUSSION

In Scheme 1 is shown the course of the reactions when dapsone–diphenylamine solution is titrated under the conditions given in the procedures.

Reactions

Phase 1. Dapsone is diazotized. The reaction process is accelerated by heating. The product is a yellow tetra-azonium salt.

Phase 2. Most of the tetra-azonium salt is hydrolysed in the course of the titration and 4,4′-dihydroxydiphenylsulphone forms (probably), which is colourless. A very small part of the yellow tetra-azonium salt is coupled at the same time with diphenylamine. The coupling process is faster than the hydrolysis and the intense raspberry red bis-diphenylamino-4,4′-azodiphenylsulphone forms.[16]

Phase 3. The dye product splits slowly into diphenyalmine and 4,4′-dihydroxydiphenylsulphone. The effect is that the colour fades towards the end of the titrations.

Phases 4–5. The liberated diphenylamine is oxidized by the nitrous acid to diphenylbenzidine (colourless) then to diphenylbenzidine violet near the end of the titration, consequently the colour of the sample solution turns to bluish-violet.

Phase 6. The diphenylbenzidine violet is nitrosated to the yellow dinitrosidiphenylbenzidine.[18] (End-point.)

These reactions take place also when a primary arylamine is titrated in the presence of the dapsone–diphenylamine solution. If the amine is easily diazotized, phase 1 is a simultaneous diazotization of both the amine product and of the dapsone. Phases 2–6 take place in similar stages and have the same velocity. The end point is also similar.

The amount of $0{\cdot}1M$ sodium nitrite required to produce a colour change from bluish-violet to yellow is 0·03 ml, if 5 ml of dapsone–diphenylamine solution are taken, and only 0·012 ml when 2 ml are taken (semimicro determination). It was found experimentally also that these calculated amounts of nitrite are necessary to produce the ultimate colour changes.

Effect of nitrate and of temperature. It was found that it is necessary to add nitrate in order to prevent loss of nitrous acid. It was observed that the presence of nitrate has a second and very important effect.

Dapsone–diphenylamine solutions, and also amine samples in the presence of dapsone–diphenylamine solution, were titrated in the absence of sodium nitrate. It was found that not only a loss of nitrite occurs, but the ultimate phases (see Scheme I) do not take place. The violet colour of the sample does not disappear and consequently a precise end-point cannot be detected. This phenomenon can be explained by the fact that under the conditions of the procedure the diphenylamine is easily oxidizable only in the presence of large amounts of nitrate ion. The diphenylbenzidine violet is not nitrosated to the yellow nitroso product in the absence of nitrate ion.

Experiments were made with diphenylamine solutions acidified with hydrochloric acid. When no nitrate ion was present in the solution, no colour developed after the addition of nitrite either at room temperature or at about 45°. In the presence of a sufficient amount of sodium nitrate a violet colour develops slowly, which intensifies in

a few minutes and turns grey, greenish-grey and than greenish-yellow (at room temperature). The colour development is faster at higher temperatures; in this case the violet colour appears instantaneously and begins to fade in a few seconds and turns greenish-grey and then to greenish-yellow in less than one minute. The same colour developments also take place when an amine is determined by the procedure described.

Effect of dapsone. Experiments were made to determine sulphanilic acid under the conditions described in the procedure, but omitting dapsone. No colour development occurs in phase 1. A pink colour develops in the course of the titration and the colour turns to bluish-violet and then to grey near the end of the titration, but it is not possible to detect a precise end-point.

APPLICATION OF METHODS, CONCLUSIONS

The determination of colourless or slightly coloured amino compounds is uncomplicated and rapid by this method. The sensitivity is high, so it is possible to determine with accuracy also small amounts of samples. The method is less suitable for the determination of naphthylamines, where an intense colour may be developed during the diazotization process. The method is not applicable for samples which are coloured owing to the presence of impurities or of decomposition products. Nitrites are easily determined by the procedure described. The determinations are not affected by the presence of reductants such as sulphurous acid, formic acid, hydroquinone, nor by alcohol or acetone.

Oxidizing agents must be absent. Bromide does not interfere even if present in large amounts, but the use of potassium bromide as catalyst is not necessary, since the velocity of the reactions is quite satisfactory.

Zusammenfassung—Es wird eine neue Nitrit-Titrierungsmethode gebracht. Die Titrierung wird mit einer normalen Lösung von 4,4′-Sulfonyl-Dianilin und Diphenylamin durchgeführt, welche als innerer Indikator benutzt wird. Während der Titrierung entwickelts sich eine kräftige rote Färbung infolge der gleichzeitigen Diazotierung und des Verbindungsprozesses. Durch Farbwechsel auf gelb ergiebt sich ein sehr scharf ausgesprochener Endpunkt. Die Titrierung erfolgt bei einer Temperatur von etwa 45° in Gegenwart von grossen Nitratmengen. Das Verfahren ist definitiv und genau. Es ist zur direkten Bestimmung von Volumen von verschiedenen, leicht diazotierten, primären Acrylaminen, Sulfoamiden und anderen Aminoverbindungen geeignet, welche durch Nitrittitrierung bestimmt werden können. Es ist auch zur indirekten Bestimmung von Nitriten geeignet. Das Verfahren kann in semi-mikro und Grösstniederschlägen verwandt werden.

Résumé—On présente une nouvelle méthode de dosage au nitrite. Le titrage est mené en la présence d'une solution titrée de 4,4′-sulfonyldianiline et diphénylamine, qui est utilisée comme indicateur interne. Une coloration rouge intense se développe durant le titrage comme résultat d'un processus simultané de diazotation et copulation. Un point de fin de dosage très net est fourni par un virage de coloration au jaune. Le titrage est réalisé à une température d'environ 45° en la présence de grandes quantités de nitrate. La méthode est spécifique et précise. Elle convient au dosage volumétrique direct de diverses arylamines primaires aisément diazotées, de sulfamides et d'autres composés aminés qui peuvent être déterminés par titrage au nitrite. Elle convient aussi au dosage indirect des nitrites. La méthode est applicable aux échelles semimicro et macro.

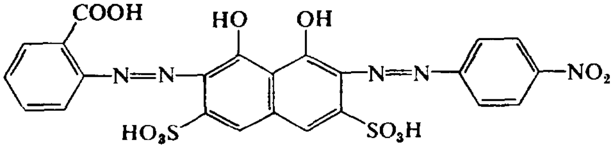
SHORT COMMUNICATIONS

Arsenazo III and its analogues—VII. Colour reactions of the rare earth elements with a new reagent—Carboxynitrazo

(*Received* 28 *November* 1969. *Revised* 26 *July* 1970. *Accepted* 21 *October* 1971)

SPECTROPHOTOMETRIC methods are widely used for the determination of the rare earth elements,[1] mono- and 2,7-bisazo-derivatives of chromotropic acid being extensively employed.[2-4] Almost all well-known reagents react with all the rare earths, but small differences, observed in some cases,[5] may enable one element to be determined in the presence of the others.

In this paper the new reagent carboxynitrazo—the 2,7-bisazo-derivative of chromotropic acid—is suggested for the determination of the rare earth elements.



This reagent has been recommended for the determination of strontium, barium and sulphate.[6,7] With it some rare earth elements give coloured reaction products with very different analytical characteristics. The difference is greatest for the elements of the cerium and yttrium subgroups.

EXPERIMENTAL

Reagents

Carboxynitrazo—2,7-bisazo-chromotropic acid. The synthesis, purification, checking of purity and properties of Carboxynitrazo have been reported earlier,[6,7] as have the acid dissociation constants.[8-10] In the present work $0{\cdot}5 \times 10^{-3}M$ and $0{\cdot}25 \times 10^{-3}M$ solutions of reagent were prepared and passed through a cation-exchange column, KY-2, in the H-form, to remove possible impurities such as calcium and other elements.

Rare earths. The solutions of the rare earth elements were prepared by dissolution of exactly weighed amounts of the metals (La, Pr, Nd and Y), or oxides (Sm, Eu, Gd, Tb, Dy, Ho, Er, Yb) in hydrochloric acid. The concentrations were checked spectrophotometrically and complexometrically.

RESULTS

Spectrophotometric investigation of the complexes of carboxynitrazo with the rare earth elements

The relevant absorption spectra, conditions for reactions and optical constants are given in Figs. 1–4 and Table I.

1, *2* and *4* recorded against water,
3 recorded against two parts of reagent.
$[M] = 0{\cdot}5 \times 10^{-5}M$; pH 3·0.

The influence of temperature, time and addition of some organic solvents

The absorbance of the complexes usually varies with time, especially for 20 min after preparation of the solutions. With Ce, La, Pr and Nd the absorbance reaches a constant value in ~30 min, with the other elements which form colours the reaction takes 1–2 hr. For the solutions containing Y, Yb, Er, Ho and Dy colour development is not observed even after 24 hr. Heating of the solution and addition of organic solvent (acetone, ethanol, propanol) results in a decrease of the absorbance of the solutions at 730 nm.

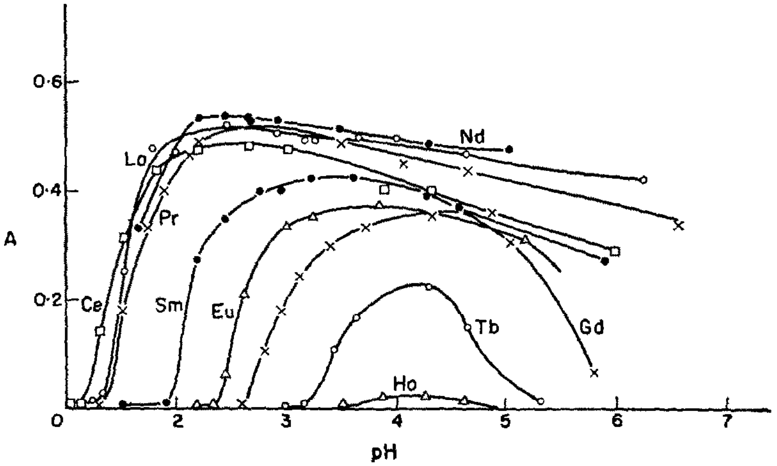

FIG. 3.—The effect of pH on the colour reaction between rare earth elements and Carboxynitrazo.
$[R] = 2 \times 10^{-5}M$, $[Me] = 0{\cdot}4 \times 10^{-5}M$, $\lambda = 730$ nm.

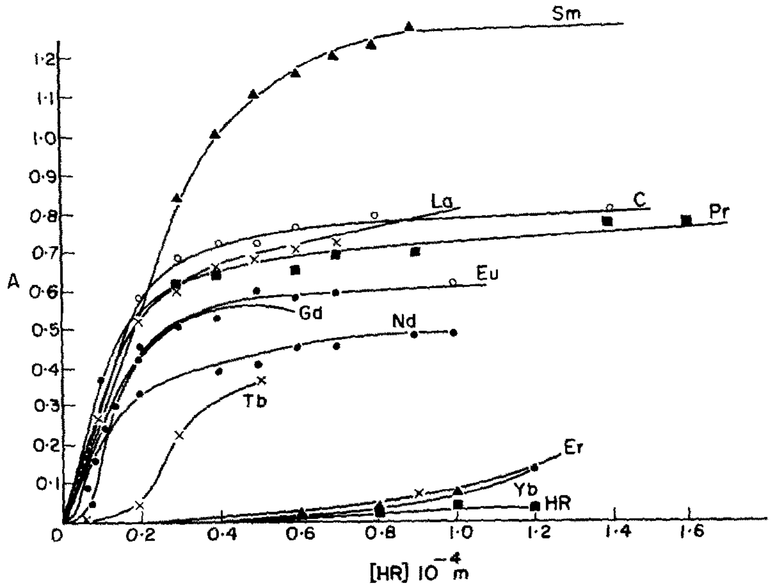

FIG. 4.—The effect of the concentration of Carboxynitrazo on the colour reaction with the rare earth elements.
$[Me] = 0{\cdot}5 \times 10^{-5}M$ ($[Sm] = 1 \times 10^{-5}M$), pH 2·8–3·0; $\lambda = 730$ nm.

5—Yb variable, 7·7 μg of La, pH 3·0
6—Yb variable, pH 3·0.

Mutual influence of elements of the Y- and Ce-groups

The curves for A *vs.* pH (Fig. 3) and A *vs.* [R] (at constant [Me]) (Fig. 4) show a possibility of the determination of the Ce-group elements in presence of the Y-group elements. We checked such a possibility by using a lanthanum–ytterbium mixture as an example. Measurements were made at pH 2·0 and 3·0, which is the range for the maximum colour reaction for lanthanum, whereas the absorbance of the ytterbium solutions is equal to that of the reagent itself.

However, at 730 nm the absorbance of the solutions containing both ytterbium and lanthanum is greater than that of the analogous solutions of ytterbium-free lanthanum. This effect is more pronounced at pH 3·0 than at pH 2·0. For example, at the ratio Yb:La $\sim$ 2:1 the increase in absorbance amounts to almost 50% at pH 3.0 but only 7–10% at pH 2·0. The absorbance at 730 nm increases with increasing ytterbium concentration only up the ratio Yb:La $\sim$ 2:1 (Fig. 5). The calibration curves at pH 3·0 in the presence and absence of ytterbium (Fig. 5, curves 1, 2) have different slopes. At pH 2·0 these curves almost coincide with each other and permit the determination of lanthanum in the presence of ytterbium. So a 25-fold excess of ytterbium does not interfere with the determination of 10 μg of lanthanum if water or reagent solution are used as reference solutions, and a 40-fold excess can also be dealt with if the reagent and Yb is used as a blank. The permissible concentration of the ytterbium can be increased provided that the pH is decreased, although in this case the sensitivity of the lanthanum determination is slightly decreased.

Probable mechanism of reactions

It has been noted that the colour reactions of alkaline earths and some other elements with 2,7-bisazo derivatives of chromotropic acid are of three basic types.[6,11] Each of these types can take place for the same pair of the components (metal and reagent) depending on conditions (pH, concentration of the components, with or without organic solvents, *etc*).

From consideration of the spectral characteristics, and also the influence of temperature and additions of organic solvents on the spectra, it can be noted that the reactions of rare earths with Carboxynitrazo described in this paper resemble reactions of the alkaline earths with analogous reagents, proceeding according to the third type of reaction.

On this basis the structures of the corresponding complexes are expected to be similar.

Summary—A new reagent, Carboxynitrazo, gives a colour reaction with some rare earth elements. For the individual rare earth elements the sensitivities of the reactions are very different. The difference is greatest for the elements of the Ce- and Y-subgroups. For the first subgroup the molar absorptivities are about 16×10^4 l. mole^{-1} cm^{-1}, whereas most of the elements of the Y-group do not give any colour reaction. A possible procedure for the determination of lanthanum in the presence of ytterbium is discussed.

Zusammenfassung—Ein neues Reagens, Carboxynitrazo, gibt eine Farbreaktion mit einigen seltenen Erden. Für die einzelnen seltenen Erden ist die Empfindlichkeit der Reaktion sehr verschieden. Am größten ist der Unterschied bei den Elementen der Cer- und Yttrium-Untergruppen. Bei der ersten Untergruppe liegen die molaren Extinktionskoeffizienten um $16 \cdot 10^4$ l. mol^{-1} cm^{-1}, wogegen die meisten Elemente der Y-Gruppe gar keine Farbreaktion geben. Ein mögliches Verfahren zur Bestimmung von Lanthan in Gegenwart von Ytterbium wird diskutiert.

Résumé—Un nouveau réactif, le Carboxynitrazo, donne une réaction colorée avec quelques éléments des terres rares. Pour les éléments individuels des terres rares, les sensibilités des réactions sont très différentes. La différence est la plus grande pour les éléments des sous-groupes Ce et Y. Pour le premier sous-groupe, les coefficients d'absorption moléculaire sont d'environ 16×10^4 l.mole.cm^{-1}, tandis que la plupart des éléments du groupe Y ne donne pas de réaction colorée. On discute d'une technique possible pour le dosage du lanthane en résence d'ytterbium.

Application of photon-counting in atomic-absorption spectrophotometry

(*Received* 14 *January* 1972. *Accepted* 16 *February* 1972)

PHOTON-COUNTING is usually employed for the detection and measurement of very weak radiation levels, where the stability and integral nature of the method make it superior to other techniques.[1] It can, however, be used in the presence of quite high radiation levels, provided that the pulse rate does not exceed the linear counting range. An excellent example of this is in atomic-absorption spectrometry where pulse pile-up[2] is not a problem because the number of photons striking the detector actually decreases during the signal period. Malmstadt *et al.*[3] demonstrated the application of photon-counting to solution absorption spectrophotometry and gave statistical equations relating the signal:noise ratios to the count-rates. These equations however, as this study shows, are not valid in their simplest form for atomic-absorption spectrometry where extra noise factors such as flame flicker and variations in nebulization are present.

EXPERIMENTAL

Apparatus

The photon-counting system used for this work has been described elsewhere[4] and incorporates a cooled (−40°) high-gain photomultiplier coupled directly to a frequency meter. This has advantages over the more conventional system consisting of a photomultiplier, amplifier, discriminator and frequency meter.[2,5] Cadmium was chosen for atomic-absorption measurements, as hollow-cathode lamps for this element are usually quite stable and have high line-to-background ratios. The dispersive system used was a Hilger and Watts D330 monochromator having a grating with 1200 lines/mm blazed at 330 nm. A hydrogen/argon/air diffusion flame stabilized on a 5-cm slot burner fitted to the nebulizer of a Perkin–Elmer 290 atomic-absorption spectrometer served as a free atom reservoir. The flow-rates and pressures were: hydrogen 8·0 l./min at 3 psig, argon 4·0 l./min at 30 psig. Radiation from the hollow cathode lamp was focussed at the centre of the flame *ca.* 4 cm above the burner slot. The image was refocussed on the entrance slit of the monochromator, which was set to transmit the 228·8-nm resonance line of cadmium.

Procedures

Direct current measurements. Direct measurements were made by connecting the output of the photomultiplier (all atomic-absorption measurements were made with the photomultiplier cooled) directly to a Servoscribe recorder having a 100 kΩ load resistor across its input.

An attempt to determine the optimal slit-width showed that the signal:noise ratio increased steadily as the slit-width was increased. Drawing large currents from a photomultiplier results in energy trapping in the photo-cathode (which causes increased dark-current and noise) and therefore the slit-width was set so that the output current did not exceed 10 μA. The cadmium hollow-cathode lamp was operated at 3 mA *via* the lamp supply of a Perkin–Elmer 290B atomic-absorption spectrophotometer. The power supply had a 50-Hz modulation which was monitored by the recorder and proved to be the limiting noise component of the d.c. signal. The recorder gain was set so that the chart represented 0–100% transmission. A working curve was constructed for concentrations of 0·05–10·0 ppm Cd; the linear range was 0·05–4·0 ppm Cd and the detection limit was 0·05 ppm Cd. The concentration range studied was limited by the difficulty of making precise readings on a simple d.c. system at high absorbances (10 ppm Cd ≡ 0·76 absorbance units).

Photon-counting measurements. The error in reciprocal transmission $1/T$ is given by the equation:

$$\left(\frac{S_{1/T}}{1/T}\right)^2 = \left(\frac{S_{N_0}}{N_0}\right)^2 + \left(\frac{S_{N_t}}{N_t}\right)^2 \qquad (1)$$

where S_i is the standard deviation of the i_{th} variable, N_0 is the reference-beam count-rate and N_t is the transmitted-beam count-rate.

The equation shows that the precision of $1/T$ can be increased either by increasing the count-period or the count-rate. Based on this criterion the slit-width was set so that with the longest counter gating-time of 10 sec the register would be nearly filled. The reference-beam count-rate in most of our experiments was *ca.* 89700/sec, which corresponded to a slit-width of 0·03 mm, compared with 0·05 mm used for the d.c. measurements.

First, an analytical working curve was constructed for concentrations of 0·05–100 ppm Cd, the linear range being 0·05–30·0 ppm Cd (36·0 ppm Cd ≡ 0·76 absorbance units) and the detection limit 0·02 ppm Cd. The lower detection limit obtained by photon-counting can be attributed to the integral nature of the method, which effectively removes the noise component derived from the 50-Hz lamp modulation. Thirty 10-sec readings of the reference-beam count were taken and analysis yielded the following results; average count 896317, standard deviation 2841, and relative standard deviation 0·32%, which shows that in terms of a 10-sec period the lamp was quite stable.

"Normal" statistical populations have the property that the standard deviation of the sample mean decreases as the square root of the number of samples taken increases. In counting experiments, the number of samples taken is equivalent to the count period so that the precision of measurement is inversely proportional to the square root of the count period. The signal-noise ratio will therefore be proportional to the square root of the count-period t:

$$\frac{\text{signal}}{\text{noise}} = \frac{N_S t^{1/2}}{(N_s + 2N_0)^{1/2}} \tag{2}$$

where $N_S = N_0 - N_t$.

An experiment was carried out to investigate whether in practice the signal:noise ratio increases in proportion to $t^{1/2}$. Repetitive spraying (30 times) of solutions containing 1·0 ppm Cd, for count periods of 0·1, 1·0 and 10·0 sec yielded the following results; for the 0·1-sec count signal:noise ratio was 420·6, for the 1·0-sec count 2199 and for the 10·0-sec count 2243. The large increase in signal:noise ratio which occurred between the 0·1 and 1·0-sec count-periods can be attributed to the increasing noise contribution of the lamp modulation at short count-periods. Once the count-period had reached 50 times the modulation period (*i.e.* 1 sec) the results showed an increase in the signal: noise ratio somewhat less than that predicted by theory. This has also been our experience[4] when studying atomic-fluorescence signals, with unmodulated sources. The reason for this is the difficulty of maintaining experimental conditions constant during the longer count-periods, and during the whole sampling time which amounted to 30 min for the 10·0-sec count-periods. Drift in the source and monochromator, *etc*, is a serious limitation in obtaining precise results from integral measurements, because the error is cumulative. Random interference, *e.g.*, electrical and cosmic radiation, is also a problem, because although it may prove to obey Poisson statistics, the time-scale is so different from that of photon arrival that a particular interference may be a unique event in terms of a sampling period.

The unorthodox use of a modulated reference beam for d.c. and integral measurement was deliberate, since it clearly demonstrated the ability of photon-counting (and other integration techniques) to improve significantly measurements made on signals having poor short-term stability, particularly if the instability is periodic in nature.

RESULTS AND DISCUSSION

Error analysis for atomic absorption

Atomic-absorption measurements by photon-counting can be made in two ways; at low absorbances (less than about 0·07) the concentration is directly proportional to the number of absorbed photons, whilst at higher absorbances it is necessary to plot absorbance *vs*, concentration to obtain good linearity. In the first instance the analysis of the results is the same as that for atomic-fluorescence and emission spectrometry, the signal:noise ratio being given by equation (2).

When the noise is somewhat worse than that predicted by counting statistics, it is necessary to measure the standard deviation of N_s experimentally. For values of absorbance Malmstadt *et al.*[3] defined the error in absorbance (% EA) as:

$$\%\,\text{EA} = \frac{\log\,(1/T + S_{1/T}) - \log\,(1/T)}{\log\,(1/T)} \times 100 \tag{3}$$

where $S_{1/T}$ can be derived from equation (1) which is quite general and not specific to counting statistics. The value of EA has a shallow minimum at about 1·0 absorbance units and high precision can be obtained in this region. Table I shows the error, calculated by the various methods described, for the 1·0-ppm Cd solution, using 1·0 and 0·1-sec count-periods. It is clear that certain conclusions can be drawn from this table.

1. As expected, the error predicted by counting statistics is apt to be low, especially for systems exhibiting a large experimental error (*e.g.*, 0·1-sec count-period with 50-Hz lamp modulation).

2. The experimental values show good correlations between the various methods, but some comment can be made with regard to the method of derivation. Values for absorbance errors depend

on the ratio I_0/I_t, whereas errors in N_s depend on the difference $I_0 - I_t$. Over the experimentally useful ranges of I_0 and absorbance calculations show that I_0/I_t is less sensitive than $I_0 - I_t$ to changes in I_0 and therefore greater precision can be expected from absorbance measurements (on single-beam instruments).

TABLE I.—COMPARISON OF RELATIVE STANDARD DEVIATIONS.

	Relative standard deviation of N_s, %		Relative standard deviation of absorbance, %	
	1-sec	0·1-sec	1·0-sec	0·1-sec
Counting statistics	4·91	14·2	3·95	14·0
Experimental	4·55	23·8	4·74	19·9
From equations (1) and (3) and the experimental values S_{N_0} and S_{N_t}	—	—	6·53	18·6

In conclusion, great care must be exercised when predicting errors from photon-counting in atomic spectrometric experiments. Equations calculated on the basis of simple Poisson statistics are usually inadequate because they relate to only one noise component, which is not normally the dominant one in these experiments. Previous work in this laboratory[4] has shown that noise contributions from sources such as flame flicker, variations in the solution sampling (either by nebulizers or one-shot devices such as a platinum filament) and apparatus drift, can be several times greater than Poisson or shot noise. Under these conditions it is necessary to measure the precision experimentally, at least initially, in order to determine what the noise contributions are, and whether the simple and convenient equations of counting statistics are applicable.

Summary—An analysis is given of the statistics of photon-counting as a means of making measurements in atomic-absorption spectrometry. It is concluded that the simple application of Poisson counting statistics may give an over-optimistic estimate of the error, since other sources of error, such as flame flicker and variable nebulization rate, may be more significant.

Zusammenfassung—Es wird eine Analyse der Statistik über Photonzählung als ein Mittel zur Durchführung von Messungen in Atomabsorption Spektrometrie gebracht. Man kommt zu dem Schluss, dass die einfache Anwendung von Zählstatistiken nach Poisson eine überoptimistische Schätzung des Fehlers ergeben könnte, da andere Ursachen für Fehler, wie Flickern der Flamme und veränderlicher Zerstäubungsgrad bezeichnender sein können.

Résumé—On donne une analyse des statistiques de comptage de photons comme moyen de faire des mesures en spectrométrie d'absorption atomique. On en conclut que la simple application des statistiques de comptage de Poisson peut donner une estimation par trop optimiste de l'erreur, car d'autres sources d'erreur, telles que le vacillement de la flame et la vitesse de nébulisation variable peuvent être plus importantes.

Some new applications of ferroin as redox indicator in titrations with dichromate

(*Received* 11 *February* 1972. *Accepted* 22 *February* 1972)

DESPITE the advantage of being a primary standard, potassium dichromate has found limited application as an oxidizing titrant. This has hitherto been attributed to the low oxidation potential of the system under normal conditions,[1] but recently it has been shown[2] that some reactions with dichromate may fail for kinetic rather than for thermodynamic reasons; further the reported conditional potential[3] of the Cr(VI)/Cr(III) system is shown to be useless for calculations of equilibrium constants of dichromate reactions. Ferroin is close to an ideal reversible indicator with excellent indicator properties; unfortunately its slow reaction with dichromate has prohibited its use as an indicator in dichromate titration of reducing agents other than iron(II). A critical study of the behaviour of ferroin in the iron(II)–dichromate titration[4] has revealed some interesting points. The catalytic effect of iron(III) on the indicator oxidation is utilized in a procedure for the dichromate determination of arsenic(III), and it is also possible to use ferroin as redox indicator in the dichromate titration of hydroquinone, ferrocyanide, uranium(IV) and molybdenum(V) by suitable choice of conditions.

Arsenic(III) reacts rather sluggishly with cerium(IV) or permanganate; and hence either osmium tetroxide[5] or iodine monochloride[6] is used as catalyst in titrimetric procedures based on these reactions. The reaction between arsenic(III) and chromium(VI) seems to proceed through the following intermediate steps:

$$\mathrm{Cr(VI)} + \mathrm{As(III)} \rightarrow \mathrm{Cr(IV)} + \mathrm{As(V)} \tag{1}$$

$$2\mathrm{Cr(IV)} + \mathrm{As(III)} \rightarrow 2\mathrm{Cr(III)} + \mathrm{As(V)} \tag{2}$$

Step (2) is slow and probably more complex. However this reaction is used to induce the rapid and complete oxidation of manganese(II) and cerium(III) under suitable experimental conditions;[7] these reactions are believed to proceed through reaction steps (1) and (3), the latter being faster than step (2).

$$\left.\begin{array}{l}\mathrm{Cr(IV)} + \mathrm{Mn(II)} \rightarrow \mathrm{Cr(III)} + \mathrm{Mn(III)}\\ \mathrm{Cr(IV)} + \mathrm{Ce(III)} \rightarrow \mathrm{Cr(III)} + \mathrm{Ce(IV)}\end{array}\right. \tag{3}$$

In view of the sluggishness of the reactions involved, arsenic(III) is usually determined by oxidation with excess of dichromate and titration of the excess with iron(II).[8]

Spitalsky[9] first described the determination of chromate with arsenite solution, but the method has been little used because so many other simple methods exist. Later, Kolthoff and Sandell[10] applied the method to the rapid analysis of chromium-vanadium steels, but permanganate was used to determine the unreacted arsenic(III) and it is believed that in acid solution chromium(VI) is selectively reduced by arsenic(III) added to a mixture of chromium(VI) and vanadium(V). Szabó and Csányi[11] have made a determination of chromium(VI) by titrating directly with arsenic(III), using a catalyst mixture containing potassium iodide and manganese(II) sulphate, and diphenylamine as indicator; however the colour change towards the end of the titration seems to be slow, requiring a 5-min wait at the end-point to make sure that it has been reached. Swift[12] used an immiscible solvent as indicator for detecting the end-point in the titration of arsenic(III) with potassium dichromate, adding a small amount of iodine monochloride to the titration mixture before the start of the titration; this extended Andrews procedure requires the hydrochloric acid concentration not to fall below $8M$ near the end-point. The present communication describes experimental conditions for arsenic(III)-chromium(VI) titration with a sharp and reversible colour change at the end-point.

EXPERIMENTAL

Reagents

Arsenic(III) solution, approx. $0{\cdot}1N$. Prepared from analytical-reagent grade arsenious oxide, according to Vogel.[13]

Potassium dichromate, $0{\cdot}1N$.

Ferroin, 0·025 and $0{\cdot}01M$.

Hydroquinone, $0{\cdot}05N$. Prepared in $0{\cdot}5M$ sulphuric acid and standardized with ceric sulphate.[14]

Potassium ferrocyanide, $0{\cdot}05N$.

Uranium(IV), $0{\cdot}05N$. Prepared and standardized according to Kolthoff and Lingane.[15]

Molybdenum(V), 0·05M. Prepared by reduction in a mercury reductor and standardized according to Furman and Murray.[16]

Iodine monochloride. Add 25 ml of 0·04M potassium iodide and 40 ml of 12M hydrochloric acid to 20 ml of 0·025M potassium iodate. Add a few ml of chloroform and titrate with iodate or iodide, as needed, until a barely perceptible iodine colour remains in the organic solvent after shaking and settling. The aqueous phase is ~0·017M in iodine monochloride.

Iron(III) alum solution, approx. 10%, in 1M sulphuric acid. All other chemicals used in this investigation were of analytical-reagent grade.

Recommended procedures

Arsenic. To 4–10 ml of ~0·05N arsenic(III) solution, add 20 ml of iron(III) alum solution (~10%) and enough hydrochloric acid to make the titration solution 2·0–3·0M in hydrochloric acid near the equivalence point. Dilute to ~45 ml and add a drop or two of (~0·017M) iodine monochloride. Titrate with potassium dichromate, using a drop of 0·025M ferroin as indicator. The colour change at the end-point is from orange-red to intense greenish-yellow. An indicator correction of 0·02 ml of 0·05N dichromate is applied.

Hydroquinone (HQ). To 5–10 ml of ~0·05N HQ add 20 ml of ferric alum solution and make the mixture 1·5–3M in sulphuric acid or 1–2M in hydrochloric acid when diluted to ~45 ml. Add a drop of 0·01M ferroin and titrate with dichromate.

Ferrocyanide. The final ferricyanide concentration must be at least 0·005M. Titrate the ferrocyanide in the presence of 3N sulphuric or hydrochloric acid. The end-point is ~1·0% short of the equivalence point, so that it is essential to standardize the dichromate against ferrocyanide under the same conditions.

Uranium(IV) and molybdenum(V). Use the same conditions as for hydroquinone.

RESULTS AND DISCUSSION

Iodine monochloride is known to speed up the reduction of ferriin by arsenic(III) in dilute hydrochloric acid solution, but this catalytic effect diminishes with increasing concentration of hydrochloric acid. On the other hand, oxidation of ferroin by chromium(VI) is slow under similar experimental conditions but becomes rapid with increasing concentration of hydrochloric acid. With these opposing experimental conditions for rapid oxidation and reduction of the indicator, it has not proved possible to prescribe a working optimum condition for ferroin to serve as a satisfactory indicator, over the entire range of hydrochloric acid concentration studied (0·5–8·0M). At lower hydrochloric acid concentrations the equivalence point is overstepped and at higher concentrations the slow colour change of the indicator necessitates dropwise addition of titrant even at the beginning of the titration.

Iron(III) is reported to increase the speed of oxidation of ferroin by chromium(VI).[4] In ~0·08M iron(III) media this indicator reaction is fast enough, even in a solution which is only 2·0M in hydrochloric acid; the reduction of ferriin by arsenic(III) in the presence of a drop or two of iodine monochloride solution also being fast under the same experimental conditions, it is observed that the indicator works satisfactorily under such conditions. The behaviour of ferroin is completely satisfactory if the titration solution is 2·0–3·0M in hydrochloric acid, and can tolerate a further variation of 0·5M in the acid concentration (i.e., 1·5–3·5M), provided the titrant is added dropwise with a 30-sec wait between additions towards the close of titration. The titration is continued until the red colour of ferroin in the yellow of iron(III) chloride is completely discharged.

The reverse titration of chromium(VI) with arsenic(III) under similar experimental conditions is found to be equally satisfactory. The titration is continued until a permanent bright orange-red colour is obtained in the titration solution; the indicator correction is negligible. Typical results for both titrations are given in Table I.

Amounts of 250 mg of iron(III), 9 mg of chromium(III) and 295 mg of manganese(II) have been found not to interfere. Vanadium(IV), vanadium(V) and antimony(III) interfere in the titrations.

Kolthoff[17] prescribed an elevated temperature for dichromate titration of hydroquinone, presumably because of the sluggishness of the indicator reaction. The ferriin–HQ reaction is fast over a wide range of sulphuric acid concentration and the ferroin–Cr(VI) reaction becomes fast in 5M sulphuric acid. The titration is satisfactory in the latter medium if the temperature is not allowed to rise as a result of dilution of the acid, and the final quinone concentration is less than 0·002M. Use of iron(III) to catalyse the indicator reaction obviates the need to cool during the titration and permits the final quinone concentration to be up to 0·005M.

Ferricyanide catalyses the oxidation of the indicator, but ferrocyanide does not induce the oxidation as iron(II) does. It is not necessary to add iron(III) as catalyst.

TABLE 1

Amount of arsenic(III), *mmole*		Amount of chromium(VI), *mmole*	
taken	found	taken	found
0·1050	0·1052	0·06426	0·06436
0·1313	0·1316	0·07230	0·07240
0·1575	0·1574	0·08033	0·08028
0·1838	0·1835	0·08836	0·08845

0·2363	0·2368		
0·2625	0·2631		

Uranium(IV) and molybdenum(V) can both be titrated in 3–3·5*M* sulphuric acid. At lower acidities the indicator oxidation is slow, and at higher acidities (above 4*M* sulphuric acid for Mo) the ferroin colour is either prematurely discharged (in uranium titrations) or the reduction of ferriin is slow (molybdenum titrations). Molybdenum can be titrated in 4–5*M* hydrochloric acid, but the indicator reactions are too slow at other acidities. Uranium can be titrated in 3–4*M* hydrochloric acid. Chromium(VI) induces reduction of ferriin by uranium(IV) but the uranium does not induce oxidation of ferroin by chromium(VI). Iron(III) as catalyst permits use of a wider range of working conditions, *i.e.*, 1·5–3·5*M* sulphuric acid or 1–3*M* hydrochloric acid.

K. SRIRAMAM

Summary—Working conditions for the titration of arsenic(III), hydroquinone, ferrocyanide, uranium(IV) and molybdenum(V) with dichromate in sulphuric acid and hydrochloric acid media have been established, with ferroin as the redox indicator.

Zusammenfassung—Es sind Arbeitsbedingungen für die Titrierung, mit Ferroin als Redoxanzeiger, von Arsen(III), Hydrochinon, Cyaneisen, Uranium(IV) und Molybdän(V) mit Bichromat in Schwefel- und Salzsäure Medium festgelegt worden.

Résumé—On a établi les conditions de travail pour le dosage des arsenic(III), hydroquinone, ferrocyanure, uranium(IV) et molybdène(V) avec le bichromate en milieux acide sulfurique et acide chlorhydrique, avec la ferroïne comme indicateur redox.

A note on successive complexometric determination of thorium and rare earths

(*Received* 2 *March* 1972. *Accepted* 25 *March* 1972)

IT IS WELL KNOWN[1] that in spite of a sufficient difference between the stability constants of the thorium–EDTA complex and the rare-earth complexes ($\log K_{\mathrm{ThY}} = 23{\cdot}2$, $\log K_{\mathrm{LaY}} = 15{\cdot}50$, $\log K_{\mathrm{DyY}} = 17{\cdot}9$), the rare earths (RE) cannot be titrated at pH 5–5·5 after thorium, when Xylenol Orange (XO), Pyrocatechol Violet, Methylthymol Blue *etc.* are used as indicators, because of the formation of coloured ternary complexes such as Th–EDTA–XO, at pH 4. EDTA does not saturate all the co-ordination sites of thorium. A few years ago we proposed[1] as titrants diethylenetriaminepenta-acetic acid (DTPA) and triethylenetetraminehexaacetic acid (TTHA) for these successive titrations. DTPA and TTHA complexes of thorium do not react with Xylenol Orange (the best indicator for this purpose) at higher pH. Because of shortage of material at that time we studied only the first lanthanides, from lanthanum to neodymium. Later this procedure was extended to all RE by Mukherji.[2] Gupta and Powell[3] confirmed the original procedure and in addition for the titration of RE replaced DTPA by *N*-Hydroxyethylethylenediaminetriacetic acid (HEDTA). In all these procedures Xylenol Orange was used as indicator.

Because these volumetric reagents, especially TTHA and HEDTA, might not always be available, we have tried to improve the EDTA method. In principle the formation of the coloured Th–EDTA–XO complex has to be prevented by addition of another complex-forming compound. We have found that acetylacetone (acac) is very suitable for this reaction. We assume that the colourless ternary complex TH–EDTA–acac is formed instead of Th–EDTA–XO. This makes possible a reliable determination of RE after thorium titration. The whole procedure is very simple, as described below.

EXPERIMENTAL

Reagents

EDTA, 0·05*M*. Standardized with 0·05*M* lead nitrate, with Xylenol Orange as indicator. A 0·02*M* solution was made by appropriate dilution.

Rare earth solutions, 0·05*M*. Prepared by dissolving the nitrates in water or the oxides in nitric acid, and standardized by EDTA titration at pH 5–5·5, with Xylenol Orange as indicator.

Acetylacetone–acetone mixture (1:1).

Saturated hexamine solution.

Xylenol Orange solution, 0·5%.

Procedure

Dilute the sample solution, containing not more than 35 mg of thorium and 40–50 mg of RE, to 250–300 ml. Adjust the pH carefully to 2 ± 0·1, with sodium hydroxide or nitric acid. (Chloroacetic acid buffer is not suitable for thorium titration.) Add a few drops of Xylenol Orange indicator and titrate slowly with 0·02–0·05*M* EDTA to the colour change from the intense red colour to lemon yellow. Then warm the solution to 35–40°, add 20 ml of acetylacetone–acetone mixture and mix thoroughly (magnetic stirrer). Add saturated hexamine solution dropwise till an intensely red-violet colour appears and add a few drops of hexamine in excess. Titrate slowly with EDTA to a pure yellow or slightly orange-yellow. The amounts of EDTA used correspond to the thorium and the total RE respectively. Typical results are summarized in Table I.

11·90	37·35 Yb	23§‡	—	+11·10	—	3·70
35·71	3·74 Yb	37·01‡	2·88	+1·30	−0·86	

* After the titration, acac was added and pH adjusted with hexamine: no colour appeared.
† On addition of acac and adjustment of pH, slight formation of Th–EDTA–XO complex.
§ End-point from violet to pink not sharp. Insufficient amount of acac (see *Remarks*).
‡ Co-titration of RE, end-point sluggish and not sharp.

Remarks

The amount of thorium is limited to 35–40 mg in the volume stated. Higher concentrations of Th–EDTA complex need larger amounts of acac for suppressing the Th–EDTA–XO complex formation and this interferes with the subsequent titration of RE. Use of a higher temperature (40°) accelerates the dissolution of the acac–acetone mixture and makes the indicator colour change sharper.

Methylthymol Blue or Pyrocatechol Violet are not suitable for this procedure because of indistinct and sluggish end-points.

DISCUSSION

The proposed method is suitable for the determination of thorium and those rare earths having a sufficiently lower stability constant for their EDTA-complexes [lathanum up to erbium ($\log K_{ErY} = 18{\cdot}85$)]. Thulium ($\log K_{TmY} = 19{\cdot}51$) and lutetium ($\log K_{LuY} = 19{\cdot}83$) were not available, but we can assume that both will be partly co-titrated with thorium.

As an auxiliary complex-forming compound for RE titration, and masking of aluminium, iron, *etc*, Chernikhov *et al.*[4] proposed sulphosalicylic acid and titrated thorium with EDTA at pH 1·5 and then RE at pH 4·5, using Xylenol Orange as indicator. The method is limited to smaller amounts of thorium (up to 15 mg) and smaller amounts of RE. The colour change of Xylenol Orange is much less sharp than in the method described above.

RUDOLF PŘIBIL
VLADIMÍR VESELÝ

Summary—An improved method for successive determination of thorium and rare earths is described. It is based on the EDTA titration of thorium at pH 2 (Xylenol Orange as indicator) followed by addition of acetylacetone–acetone mixture, adjustment of the pH to 5–5·5 with hexamine, and by further EDTA titration of rare earths with the same indicator.

Zusammenfassung—Ein verbessertes Verfahren zur Bestimmung von Thorium und seltenen Erden nacheinander wird beschrieben. Es beruht auf der EDTA-Titration von Thorium bei pH 2 (Indikator Xylenolorange), anschließender Zugabe eines Acetylaceton-Aceton-Gemisches, Einstellung des pH auf 5–5,5 mit Hexamethylentetramin und Weitertitration der seltenen Erden mit EDTA und dem selben Indikator.

Résumé—On décrit une méthode améliorée pour le dosage successif du thorium et des terres rares. Elle est basée sur le titrage à l'EDTA du thorium à pH 2 (Orangé Xylénol comme indicateur), suivi de l'addition d'un mélange acétylacétone-acétone, ajustement du pH à 5–5,5 par l'hexamine, et nouveau titrage à l'EDTA des terres rares avec le même indicateur.

Spectrophotometric study of the reaction of bismuth(III) with Xylenol Orange

(*Received* 16 *July* 1971. *Accepted* 16 *February* 1972)

Xylenol Orange forms complexes with bismuth(III), which can be used for spectrophotometric determination of bismuth.[1–8] It is generally believed that only the 1:1 Bi:XO complex is formed, but the system has not been fully studied. Our study shows that several complexes are formed.

EXPERIMENTAL

Reagents

Xylenol Orange solution $1{\cdot}00 \times 10^{-3}M$. The purity of the reagent was checked by elemental analysis.

Bismuth perchlorate solution $1{\cdot}00 \times 10^{-3}M$. Dissolve spectrally-pure metal in nitric acid, add perchloric acid and evaporate the solution. Dilute to volume (the pH should be ~1·3).

The pH of solutions was controlled with perchloric acid and sodium hydroxide. All investigations were carried out at a constant ionic strength of 1·0 maintained by the addition of the required amount of sodium perchlorate. The reagents used were *pro analysi* grade.

RESULTS AND DISCUSSION

The absorption spectra of bismuth(III) and Xylenol Orange (XO) solutions of various concentrations and pH are shown in Fig. 1. In acidic medium XO has an absorption maximum at 440 nm (curve 8). The addition of bismuth(III) gives rise to an absorption maximum at about 550 nm (curve 7). When XO is in excess in slightly acidic medium this maximum decreases and a new one appears at 500 nm (curves 1 and 6). These changes are associated with the formation of different complexes, the composition of which was established by the isomolar series and mole-ratio methods. The complex formed over the pH interval from −0·2 to 1·0 has a 1:1 composition, but the one formed at pH >1·0 has a 1:2 composition.

Summary—An improved method for successive determination of thorium and rare earths is described. It is based on the EDTA titration of thorium at pH 2 (Xylenol Orange as indicator) followed by addition of acetylacetone–acetone mixture, adjustment of the pH to 5–5·5 with hexamine, and by further EDTA titration of rare earths with the same indicator.

Zusammenfassung—Ein verbessertes Verfahren zur Bestimmung von Thorium und seltenen Erden nacheinander wird beschrieben. Es beruht auf der EDTA-Titration von Thorium bei pH 2 (Indikator Xylenolorange), anschließender Zugabe eines Acetylaceton-Aceton-Gemisches, Einstellung des pH auf 5–5,5 mit Hexamethylentetramin und Weitertitration der seltenen Erden mit EDTA und dem selben Indikator.

Spectrophotometric study of the reaction of bismuth(III) with Xylenol Orange

(*Received* 16 *July* 1971. *Accepted* 16 *February* 1972)

XYLENOL ORANGE forms complexes with bismuth(III), which can be used for spectrophotometric determination of bismuth.[1–8] It is generally believed that only the 1:1 Bi:XO complex is formed, but the system has not been fully studied. Our study shows that several complexes are formed.

EXPERIMENTAL

Reagents

Xylenol Orange solution $1{\cdot}00 \times 10^{-3}M$. The purity of the reagent was checked by elemental analysis.

Bismuth perchlorate solution $1{\cdot}00 \times 10^{-3}M$. Dissolve spectrally-pure metal in nitric acid, add perchloric acid and evaporate the solution. Dilute to volume (the pH should be ~1·3).

The pH of solutions was controlled with perchloric acid and sodium hydroxide. All investigations were carried out at a constant ionic strength of 1·0 maintained by the addition of the required amount of sodium perchlorate. The reagents used were *pro analysi* grade.

RESULTS AND DISCUSSION

The absorption spectra of bismuth(III) and Xylenol Orange (XO) solutions of various concentrations and pH are shown in Fig. 1. In acidic medium XO has an absorption maximum at 440 nm (curve 8). The addition of bismuth(III) gives rise to an absorption maximum at about 550 nm (curve 7). When XO is in excess in slightly acidic medium this maximum decreases and a new one appears at 500 nm (curves 1 and 6). These changes are associated with the formation of different complexes, the composition of which was established by the isomolar series and mole-ratio methods. The complex formed over the pH interval from −0·2 to 1·0 has a 1:1 composition, but the one formed at pH >1·0 has a 1:2 composition.

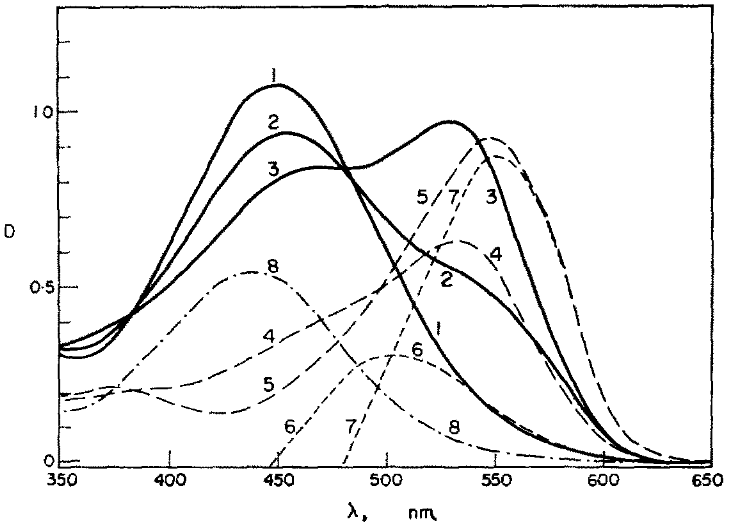

FIG. 1.—Absorption spectra
1–3, $C_{Bi} = 4{\cdot}00 \times 10^{-5}M$, $C_{XO} = 8{\cdot}00 \times 10^{-5}M$; *1*, pH = 4·0; *2*, pH = 2·0; *3*, pH = 0·8.
4–5, $C_{Bi} = 2{\cdot}00 \times 10^{-4}M$, $C_{XO} = 4{\cdot}00 \times 10^{-5}M$; *4*, pH = 0·4; *5*, pH = 1·0.
6, $C_{Bi} = 4{\cdot}00 \times 10^{-5}M$; $C_{XO} = 2{\cdot}00 \times 10^{-4}M$, pH = 3·0.
7, $C_{Bi} = 2{\cdot}00 \times 10^{-4}M$; $C_{XO} = 4{\cdot}00 \times 10^{-5}M$, pH = 1·0.
8, $C_{XO} = 4{\cdot}00 \times 10^{-5}M$, pH = 1·8.
1–5 and *8*, water blank; *6* and *7*, XO blank.

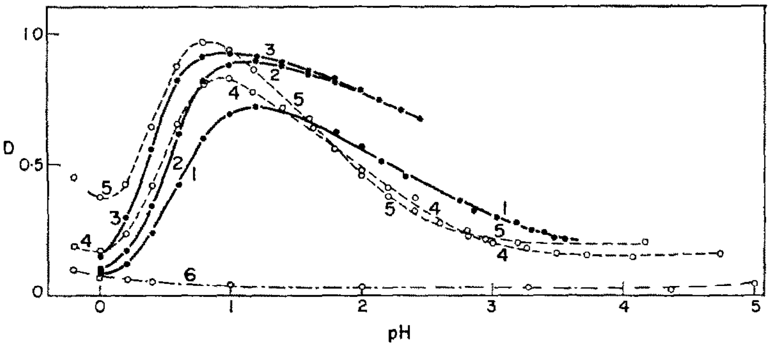

FIG. 2.—Absorbance as a function of pH, at 550 nm
C_{Bi}: *1*, $4{\cdot}00 \times 10^{-5}M$; *2*, $8{\cdot}00 \times 10^{-5}M$; *3*, $2{\cdot}00 \times 10^{-4}M$; *4* and *5*, $4{\cdot}00 \times 10^{-5}M$.
C_{XO}: *1*, *2* and *3*, $4{\cdot}00 \times 10^{-5}M$; *4*, $8{\cdot}00 \times 10^{-5}M$; *5*, $2{\cdot}00 \times 10^{-4}M$; *6*, $4{\cdot}00 \times 10^{-5}M$. XO blank.

pH–absorbance curves of various mixtures of bismuth(III) and XO (Fig. 2) have been used to determine the composition and dissociation constants of the complexes.

The dissociation constants of Xylenol Orange[10] and those of the hydroxo-complexes of Bi(III),[11] suggest that the formation of the complex in the pH range from −0·2 to 1 can be expressed by

$$\mathrm{Bi(OH)}_{3-i}^{i+} + \mathrm{H}_m\mathrm{R}^{(m-6)+} \rightleftharpoons [\mathrm{Bi(OH)}_{3-i}\mathrm{H}_{m-n}\mathrm{R}]^{(i+m-6-n)+} + n\mathrm{H}^+ \qquad (1)$$

The number of hydrogen ions (n) involved was determined by using the dependence of $-\log A$ on pH:

$$A = \frac{[\mathrm{Bi(OH)}_{3-i}][\mathrm{H}_m\mathrm{R}]}{[\mathrm{Bi(OH)}_{3-i}\mathrm{H}_{m-n}\mathrm{R}]} = \frac{C_{\mathrm{Bi}}(D_{\max} - D') \cdot (aD_{\max} - D')}{D_{\max} \cdot D' \cdot f_{\mathrm{Bi(OH)}_{3-i}} \cdot f_{\mathrm{H_6R}}} \qquad (2)$$

where D_{max} is the maximum absorbance at pH 0·8–1·0 when the concentration of XO is constant ($C_{XO} = 4{\cdot}00 \times 10^{-5}M$) and the ratio [Bi]/[XO] is greater than 2, C_{Bi} and C_{XO} are the total analytical concentrations of Bi and XO, $a = C_{Bi}/C_{XO}$ when Bi(III) is in excess and C_{XO}/C_{Bi} when XO is in excess, $f_{H_6R} = C_{XO}/[H_6R]$, $f_{Bi(OH)_{3-i}} = C_{Bi}/[Bi(OH)_{3-i}]$. The absorbance D' of the mixture at 550 nm has a contribution from XO which must be allowed for.

The plot of $-\log A$ against pH is a straight line with slope $n = 3$. Consequently, the complex has the composition $[Bi(H_3R)]$. It is possible to calculate its dissociation constant from the values of A by using the equation:

$$K_{Bi(H_3R)} = \frac{[Bi^{3+}][H_3R^{3-}]}{[Bi(H_3R)]} = \frac{A \cdot f_{H_6R}}{f_{H_3R}} \tag{3}$$

The values of this constant have been calculated from curves 1–5 in Fig. 2. After a statistical treatment of the results the value of $pK_{Bi(H_3R)}$ is found to be 9·80 ± 0·03.

The formation of the 1:2 complex can be expressed by

$$Bi(H_3R) + H_mR^{(m-6)+} \rightleftharpoons [Bi(H_{m+3-n}R_2)]^{(m-6-n)+} + nH^+ \tag{4}$$

In the interval from pH 1·0 to 3·0, where the 1:1 complex is changed into the 1:2 complex H_5R^- begins to predominate.

The dependence of log B against pH has been used to determine the number of hydrogen ions involved in reaction (4):

$$B = \frac{[Bi(H_{8-n}R_2)]}{[Bi(H_3R)]} \cdot f_{H_5R} = \left(\frac{D_{max} - D'}{D' - D_{min}}\right) f_{H_5R} \tag{5}$$

where D_{min} is the minimum absorbance at pH > 3·0 when the concentration of Bi(III) is constant ($C_{Bi} = 4{\cdot}00 \times 10^{-5}M$) and $C_{XO}/C_{Bi} > 2$.

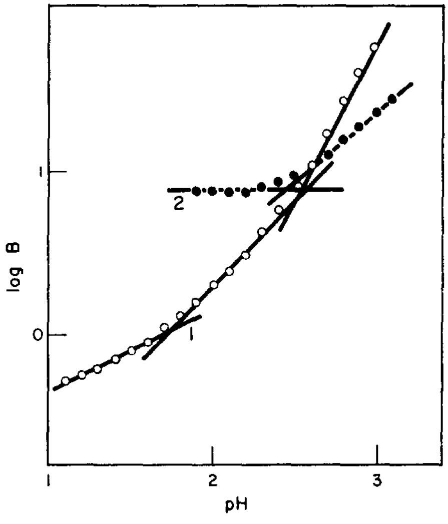

FIG. 3.—Dependence of log B on pH at 550 nm, $D_{min} = 0{\cdot}133$.
1, $C_{Bi} = 4{\cdot}00 \times 10^{-5}M$; $C_{XO} = 8{\cdot}00 \times 10^{-5}M$.
2, $C_{Bi} = 4{\cdot}00 \times 10^{-5}M$; $C_{XO} = 2{\cdot}00 \times 10^{-4}M$.

The number of protons released varies with pH (Fig. 3, curve 1). It is evident that with the increase of pH, bismuth(III) forms complexes with various ionic groups on XO.

pH 1·0–1·7 $n = 0{\cdot}5$

$$2Bi(H_3R) + 2H_5R^- \rightleftharpoons [Bi(H_4R)_2]^- + [Bi(H_4R)(H_3R)]^{2-} + H^+ \tag{6}$$

pH 1·7–2·4 $n = 1$

$$Bi(H_3R) + H_5R^- \rightleftharpoons [Bi(H_4R)(H_3R)]^{2-} + H^+ \tag{7}$$

pH > 2·4 $n = 2$

$$Bi(H_3R) + H_5R^- \rightleftharpoons [Bi(H_3R)_2]^{3-} + 2H^+ \tag{8}$$

As H_5R^- and H_4R^{2-} co-exist, the number of hydrogen ions involved can be determined if H_4R^{2-} takes part in the reaction between bismuth(III) and XO (Fig. 3, curve 2). The result for n also confirms the conclusion about the composition of the complex compounds.

$pH < 2{\cdot}4 \quad n = 0$

$$Bi(H_3R) + H_4R^{2-} \rightleftharpoons [Bi(H_4R)(H_3R)]^{2-} \tag{9}$$

$pH > 2{\cdot}4 \quad n = 1$

$$Bi(H_3R) + H_4R^{2-} \rightleftharpoons [Bi(H_3R)_2]^{3-} + H^+ \tag{10}$$

It is seen that from curves 4 and 5 in Fig. 2 that at pH > 3·0 bismuth(III) is completely bound as $[Bi(H_3R)_2]^{3-}$. This enables its dissociation constant to be calculated from the equation

$$K_{Bi(H_3R)_2} = \frac{[Bi^{3+}][H_3R^{3-}]^2}{[Bi(H_3R)_2]^{3-}} = \frac{K_{Bi(H_3R)} \cdot C_{XO} \cdot f_{H_5R}}{B \cdot f_{H_3R}} \tag{11}$$

The value of $pK_{Bi(H_3R)_2}$ is 15·53 ± 0·03.

Summary—The reaction between bismuth(III) and Xylenol Orange (XO) has been investigated by spectrophotometry. It has been established that bismuth(III) and Xylenol Orange form complex compounds with compositions Bi(III):XO = 1:1 (up to pH 1) and Bi(III):XO = 1:2 (above pH 1) which have absorption maxima at 550 and 500 nm respectively. The formula of the 1:1 complex is $[Bi(H_3R)]$ whereas the 1:2 complex can take one of the following forms: $[Bi(H_4R)_2]^{1-}$, $[Bi(H_4R)(H_3R)]^{2-}$ and $[Bi(H_3R)_2]^{3-}$.
If

$$K_{Bi(H_3R)} = \frac{[Bi^{3+}][H_3R^{3-}]}{[Bi(H_3R)]} \quad \text{and} \quad K_{Bi(H_3R)_2} = \frac{[Bi^{3+}][H_3R^{3-}]^2}{[Bi(H_3R)_2]^{3-}}$$

the values for $pK_{Bi(H_3R)}$ and $pK_{Bi(H_3R)_2}$ respectively are 9·80 ± 0·03 and 15·53 ± 0·03 at a constant ionic strength of 1·0.

Zusammenfassung—Die Reaktion zwischen Wismuth(III) und Xylenol Orange (XO) ist mit Spektralphotometrie untersucht worden. Es ist festgestellt worden, dass Wismuth(III) und Xylenol Orange Komplexverbindungen mit Bi(III):XO = 1:1 (bis zu pHl) Verbindungen und Bi(III):XO = 1:2 (über pHl) bilden, welche Absorptionsmaximums von 550 bzw. 500 nm haben. Die Formel der 1:1 Komplexverbindung ist $[Bi(H_3R)]$, während die 1:2 Komplexverbindung eine der folgenden Formen annehmen kann: $[Bi(H_4R)_2]$, $[Bi(H_4R)(H_3R)^{2-}$ und $[Bi(H_3R)]^{3-}$.
Wenn

$$K_{Bi(H_3R)} = \frac{[Bi^{3+}][H_3R^{3-}]}{[Bi(H_3R)]} \quad \text{und} \quad K_{Bi(H_3R)_2} = \frac{[Bi^{3+}][H_3R^{3-}]^2}{[Bi(H_3R)_2]^{3-}}$$

sind die Werte für $pK_{Bi(H_3R)}$ bzw. $pK_{Bi(H_3R)_2}$ 9,80 ± 0,03 und 15,53 ± 0,03 bei konstanter Ionenstärke von 1,0.

Résumé—On a étudié par spectrophotométrie la réaction entre le bismuth(III) et l'Orangé Xylénol (XO). On a établi que le bismuth(III) et l'Orangé Xylénol forment des composés complexes de compositions Bi(III):XO = 1:1 (jusqu'à pH 1) et Bi(III):XO = 1:2 (au-dessus de pH 1), qui ont des maximums d'absorption à 550 et 500 nm respectivement. La formule du complexe 1:1 est $[Bi(H_3R)]$, tandis que le complexe 1:2 peut prendre l'une des formes suivantes: $[Bi(H_4R)_2]$, $[Bi(H_4R)(H_3R)]^{2-}$ et $[Bi(H_3R)_2]^{3-}$.

Si

$$K_{\mathrm{Bi(H_3R)}} = \frac{[\mathrm{Bi^{3+}}][\mathrm{H_3R^{3-}}]}{[\mathrm{Bi(H_3R)}]} \quad \text{et} \quad K_{\mathrm{Bi(H_3R)_2}} = \frac{[\mathrm{Bi^{3+}}][\mathrm{H_3R^{3-}}]^2}{[\mathrm{Bi(H_3R)_2}]^{3-}}$$

les valeurs pour $\mathrm{p}K_{\mathrm{Bi(H_3R)}}$ et $\mathrm{p}K_{\mathrm{Bi(H_3R)_2}}$ sont respectivement 9,80 ± 0,03 et 15,53 ± 0,03 à une force ionique constante de 1,0.

Radiochemical separation of zirconium and hafnium from other radionuclides

(*Received* 17 *February* 1972. *Accepted* 3 *March* 1972)

NEUTRON-ACTIVATION techniques have been used for the determination of zirconium and/or hafnium in a variety of materials.[1,2] Most methods employ thermal neutrons and relatively long radiation periods to form ^{181}Hf ($t_{1/2}$ = 42·5 d) and ^{95}Zr ($t_{1/2}$ = 65·5 d). After a suitable cooling period for the decay of short-lived activities, zirconium and hafnium are separated from other activities and gamma-counted (usually the 0·482-MeV gamma-ray for Hf and the 0·722 + 0·754 MeV gamma-rays for Zr). The method is quite sensitive for hafnium owing to its relatively high cross-section but is less sensitive for zirconium. Koch[2] gives sensitivities of 40 pg for hafnium and 6 ng for zirconium. Because of interferences from other gamma-emitters, a radio-chemical separation is usually necessary before counting.

Many methods have been recommended for the separation of zirconium and hafnium from other radionuclides.[3] Most of them are lenthy and tedious. A recent method devised by Brooks[4] utilizes precipitation with mandelic acid, a highly selective reagent for zirconium and hafnium[5,6] for separation from all activities except those of ^{46}Sc and ^{233}Pa. Solvent extraction with cupferron in chloroform separated zirconium and hafnium from scandium, and the protactinium was removed by scavenging with niobium pentoxide in acid solution. The mandelic acid precipitate was ignited to the oxide for weighing and counting.

The method proposed in this paper represents an improvement over Brook's method since it eliminates the solvent extraction step and removes both protactinium and scandium simultaneously in a single, simple scavenging operation in which the precipitate is dissolved in sodium carbonate solution[7] and barium carbonate subsequently precipitated. Ignition to the oxide is also eliminated since zirconium and hafnium tetramandelate may be weighed directly.[8]

EXPERIMENTAL

Reagents

Zirconium standard (1·00 mg/ml). A known weight of "Specpure" $ZrOCl_2 \cdot 8H_2O$ (Johnson, Matthey and Co.) was dissolved in a known volume of 1*N* sulphuric acid prepared with distilled demineralized water, and the solution standardized gravimetrically by the mandelic acid and cupferron methods. Standard solutions could be made with an error of ±3·0% by direct weighing of the $ZrOCl_2 \cdot 8H_2O$ (3·533 mg of $ZrOCl_2 \cdot 8H_2O$ is equivalent to 1·000 mg of Zr).

Hafnium standard (1·00 mg/ml). Similarly prepared (from "Specpure" $HfOCl_2 \cdot 8H_2O$) and standardized. Preparation by direct weighing (2·294 mg of $HfOCl_2 \cdot 8H_2O$ is equivalent to 1·000 mg of Hf) again gave ±3·0% error.

Si

$$K_{Bi(H_3R)} = \frac{[Bi^{3+}][H_3R^{3-}]}{[Bi(H_3R)]} \quad \text{et} \quad K_{Bi(H_3R)_2} = \frac{[Bi^{3+}][H_3R^{3-}]^2}{[Bi(H_3R)_2]^{3-}}$$

les valeurs pour $pK_{Bi(H_3R)}$ et $pK_{Bi(H_3R)_2}$ sont respectivement 9,80 ± 0,03 et 15,53 ± 0,03 à une force ionique constante de 1,0.

Ignition to the oxide is also eliminated since zirconium and hafnium tetramandelate may be weighed directly.[8]

EXPERIMENTAL

Reagents

Zirconium standard (1·00 mg/ml). A known weight of "Specpure" $ZrOCl_2 \cdot 8H_2O$ (Johnson, Matthey and Co.) was dissolved in a known volume of 1*N* sulphuric acid prepared with distilled demineralized water, and the solution standardized gravimetrically by the mandelic acid and cupferron methods. Standard solutions could be made with an error of ±3·0% by direct weighing of the $ZrOCl_2 \cdot 8H_2O$ (3·533 mg of $ZrOCl_2 \cdot 8H_2O$ is equivalent to 1·000 mg of Zr).

Hafnium standard (1·00 mg/ml). Similarly prepared (from "Specpure" $HfOCl_2 \cdot 8H_2O$) and standardized. Preparation by direct weighing (2·294 mg of $HfOCl_2 \cdot 8H_2O$ is equivalent to 1·000 mg of Hf) again gave ±3·0% error.

Zirconium carrier (*approx.* 10 mg/ml). Prepared by dissolving commercial zirconyl chloride in $1M$ hydrochloric acid, heating and filtering. Standardized by precipitating zirconium mandelate as in steps 1–4 of the procedure, collecting on a sintered-glass filter with the aid of 95% ethyl alcohol or acetone, drying at 110–120° for 1 hr, cooling and weighing.

Mandelic acid solution, 15% w/v.

Barium nitrate solution, 2% w/v.

Procedure

(1) Place 1 ml of zirconyl chloride carrier in a 40-ml centrifuge tube, then add a measured amount of the sample to be analysed. The sample should be in hydrochloric acid solution. Fluorides, phosphates, oxalates, nitrates, and strong oxidizing agents should be absent since they interfere in the precipitation of zirconium tetramandelate. Adjust the volume to approximately 15–20 ml and the concentration of hydrochloric acid to $5–10M$.

(2) Heat to at least 90° in a boiling water-bath, then add 10 ml of mandelic acid solution. Stir thoroughly, continue heating with occasional stirring until the precipitate has completely settled (approx. 30 min), then remove the tube and let stand until cool (about 30 min).

(3) Centrifuge, discard the supernatant liquid, stir the precipitate with 5 ml of 2% mandelic acid solution in $4M$ hydrochloric acid, centrifuge, and discard the washings.

(4) Stir the precipitate with 10 ml of distilled water, wash the stirring rod and sides of the tube with about 1 ml of 95% ethyl alcohol to wet any floating hydrophobic precipitate. Centrifuge and discard the washings.

(5) Add 3 ml of $1M$ sodium carbonate solution and stir to dissolve the precipitate. Do not heat the mixture to hasten dissolution, as this will decompose the soluble carbonato-complexes of zirconium and hafnium.

(6) Wash down the sides of the tube with about 2 ml of distilled water, then add 1 ml of barium nitrate solution *dropwise and with vigorous stirring* (otherwise scavenging is less effective). Centrifuge, and decant the supernatant solution into a clean tube.

(7) Cautiously add six 1-ml portions of conc. hydrochloric acid, allowing effervescence to subside between additions. Cautiously stir to expel carbon dioxide, then place the tubes in a boiling water-bath for 5–10 min, stirring vigorously from time to time to eliminate all carbon dioxide.

(8) Repeat steps 2–7, then proceed to step 9.

(9) Add 10 ml of distilled water to the precipitate, stir vigorously, then wash down the stirring rod and the sides of the tube with about 1 ml of 95% ethyl alcohol. Centrifuge and discard the washings.

(10) Add 10 ml of 95% ethyl alcohol and stir vigorously. Centrifuge and discard the washings.

(11) Transfer the precipitate to a tared planchet with about 1 ml of 95% ethyl alcohol. Dry for 15–30 min under an infrared lamp or in an oven at 110–120°. Let cool, weigh, and count. If the gamma spectrum indicates contamination, the dried sample may be dissolved in sodium carbonate and the procedure repeated, starting with step 5.

DISCUSSION

Choice of carrier

Tracer experiments with ^{95}Zr and ^{181}Hf and with pure hafnyl and zirconyl chlorides as carrier demonstrated quantitative recoveries of both radionuclides. Commercial zirconyl chloride was chosen as carrier since it also contains hafnium (about 2%) and trace impurities such as rare earths, *etc*, which would function as holdback carriers. With two scavenging steps, excellent carrier recoveries were obtained, ranging from 80 to 90%

Separations

Studies with various tracers confirmed Brook's observations that precipitation of zirconium mandelate separates zirconium and hafnium activities from all radionuclides except protactinium and scandium. Without scavenging, approximately 10–20% of the two latter activities were carried down with the zirconium. After scavenging, no detectable protactinium activity remained, but about 10^{-3}% of the original scandium activity remained.

Testing the method

The method was checked by analysing a dilute solution of commercial zirconyl chloride for both zirconium and hafnium, and by analysing the standard rock samples G-1 and W-1. Samples and standards were weighed into silica ampoules, sealed, then irradiated in a reactor with a thermal neutron flux of 5 × 10^{12} n/cm^2/sec for a period of either one or two weeks. After a cooling period of about two weeks the samples were dissolved and analysed.

Measurements were made with a 30-cm^3 co-axial Ge(Li) detector coupled to a 2000-channel PDB-8/gamma-spectrometer system. Excellent resolution was attained and both photopeaks of zirconium, at 0·722 and 0·754 MeV were clearly resolved. The 0·722-MeV peak was used for zirconium and the 0·482-MeV peak for hafnium. Results are compiled in Tables I and II.

TABLE I.—ANALYSIS OF COMMERICAL ZIRCONYL CHLORIDE.

Sample	Zr found, *µg*	Hf found, *µg*	Hafnium, %	Total Zr + Hf taken, *µg*	Total Zr + Hf found, *µg*
1	10·9	0·22	2·0	11·9	11·1
2	20·1	0·40	2·0	20·2	20·5

(Irradiation for 1 week)

Discussion of results

No analyses were available for the commercial zirconyl chloride. The results must be judged from the precision of the hafnium determinations and from the total zirconium plus hafnium recovered, compared with that taken.

TABLE II.—DETERMINATION OF ZIRCONIUM AND HAFNIUM IN STANDARD ROCK SAMPLES.

Sample*		Zr, *ppm* Found	Zr, *ppm* Recommended value	Hf, *ppm* Found	Hf, *ppm* Recommended value
G-1	(*a*)	231	210	6·0	6
	(*b*)	201	210	5·8	6
W-1	(*a*)	103	100	2·6	2
	(*b*)	107	100	2·3	2

* Irradiated for (*a*) 1 week, (*b*) 2 weeks.

About 100 mg of standard rock were fused with a mixture of sodium hydroxide and sodium peroxide in nickel crucibles, by the procedure recommended by Brooks.[4] Carrier was added before fusion by adding 1·0 ml of zirconyl chloride carrier to an excess of 6*M* ammonia solution in the crucible, and evaporating to dryness. After fusion the cake was treated with water and digested at 90° for about 30 min to ensure complete removal from the crucible. The residue was centrifuged down and the alkaline supernatant liquid discarded. The residue was washed once with hot water, then dissolved by heating with 15 ml of conc. hydrochloric acid. This solution was used for the zirconium and hafnium determinations.

Duplicate analyses given in Tables I and II are results from separate irradiations using new, different standards, to eliminate systematic errors arising from the preparation of standard and from the irradiation.

Summary—Radiozirconium and radiohafnium may be separated from all other radionuclides except scandium and protactinium by precipitation with mandelic acid from 5–10*M* hydrochloric acid, using commercial zirconyl chloride as carrier. Scandium and protactinium are removed by dissolving the precipitate in sodium carbonate, then adding barium nitrate to precipitate barium carbonate which acts as a scavenger. Zirconium mandelate is finally reprecipitated and the sample weighed and counted in this form. The method was checked by analysing commercial zirconyl chloride and standard rock samples for zirconium and hafnium by neutron-activation analysis.

Zusammenfassung—Radiozirkonium und Radiohafnium kann von allen anderen Radionukliden ausser Scandium und Protaktinium durch Niederschlag mit Mandelsäure aus 5–10*M* Salzsäure mittels handelsüblichem Zirkoniumchlorid als Träger getrennt werden. Scandium und Protaktinium werden durch Auflösen des Niederschlags in Natriumkarbonat und dann Zufügung von Bariumnitrat zum Niederschlagen von Bariumkarbonat entfernt, welch letzteres als Spülmittel fungiert. Zirkoniummandelat wird schliesslich wieder niedergeschlagen, und das Muster wird gewogen und in dieser Form berechnet. Das Verfahren wurde durch Analysieren von gewerblichem Zirkoniumchlorid und normalen Gesteinmustern von Zirkonium und Hafnium mittels Neutronaktivierungsanalyse geprüft.

Résumé—On peut séparer le radiozirconium et le radiohafnium de tous les autres radionuclides à l'exception du scandium et du protactinium par précipitation avec l'acide mandélique à partir d'acide chlorhydrique 5–10*M*, en utilisant le chlorure de zirconyle commercial comme entraîneur. On élimine le scandium et le protactinium en dissolvant le précipité dans du carbonate de sodium, puis en ajoutant du nitrate de baryum pour précipiter le carbonate de baryum qui agit comme un fixateur. Le mandélate de zirconium est finalement reprécipité et l'échantillon est pesé et compté sous cette forme. On a contrôlé la méthode en analysant le chlorure de zirconyle commercial et des échantillons de roche étalon pour le zirconium et le hafnium par analyse par activation de neutrons.

Determination of phosphorus in phosphazenes and phosphines*

(*Received* 24 *April* 1972. *Accepted* 1 *May* 1972)

IN RECENT YEARS organic polymers have grown in importance, owing to their many uses and diverse properties. Among the newer polymers are the polyphosphazenes and polyphosphine oxides which are unique because of their high phosphorus content and chemical resistance. The chemical and physical properties of these polymers preclude the use of ordinary methods of elemental analysis. This is especially true in the initial step of decomposition and dissolution. However, accurate analysis can be accomplished by using the techniques described in this paper.

In the past, phosphorus has generally been determined in organic compounds by decomposing the sample, converting the phosphorus into orthophosphate, and measuring the orthophosphate in one of several ways. Decomposition of the organic material has been done by an acid digestion with nitric and perchloric acids,[1] nitric and sulphuric acids,[2-4] fuming nitric acid[5] and a mixture of nitric, sulphuric and perchloric acids.[6] None of these acid mixtures was adequate when used on phosphazenes

and phoshines. The method of Boos and Conn,[7] consisting of a sodium carbonate fusion, did not give a complete recovery of phosphorus. The same result was obtained when sodium peroxide was used in a Parr bomb as described by Burton and Riley.[8] Oxidation in an oxygen flask (Schöniger technique) has been used by several,[9-12] but the method did not work on these polymer samples. Very poor combustion was obtained, even on very small samples.

Measurements of the orthophosphate resulting from the decomposition of a sample has been done in several ways. The classical Lorenz[13] procedure based on the precipitation of phosphorus as ammonium phosphomolybdate has been used extensively. A drawback of this method is that an empirical factor is used in calculating the weight of phosphorus in the amount of precipitate collected; therefore, carefully defined conditions for precipitation must be followed. A colorimetric method based on the reduction of phosphomolybdic acid to molybdenum blue has been described.[14] Quinoline has also been used as a precipitating agent.[15,16] Precipitation of the orthophosphate as magnesium ammonium phosphate[17] provided the best results in this investigation.

EXPERIMENTAL

Procedure

Place a sample containing about 10 mg of phosphorus in a 10-ml Kjeldahl flask. Add 1 ml of conc. sulphuric acid and 0·5 ml of red fuming nitric acid, and heat gently with a micro-burner until foaming ceases. Increase the heat and boil the solution until it turns black. Continue adding fuming nitric acid, a few drops at a time, and heating until all of the black colour is gone and an amber solution remains. Heating must be strong enough to break down the organic material, but not severe enough to produce sulphur trioxide fumes. Add 4 drops of perchloric acid and heat the flask until the green colour is gone—but no longer. As the flask cools, acid condensed in the neck will drain into the solution and a colour, either green or brown, may reappear but will do no harm.

When the contents of the flask are cool, transfer them into a beaker, add 4 ml of concentrated nitric acid, and carefully dilute the solution to 80 ml with distilled water. Cover the beaker with a watch-glass and heat gently for 1 hr on a hot-plate. Neutralize the solution by adding ammonia solution. While the sample is still warm, add 10 ml of freshly filtered magnesia solution (55 g of magnesium chloride hexahydrate, 140 g of ammonium chloride, 350 ml of conc. ammonia solution, diluted with water to 1 litre) with stirring. After precipitation has started, add 20 ml of conc. ammonia solution. Allow to age for a minimum of 2 hr, filter off on an ignited and weighed 1A2 Berlin crucible, and wash with 100 ml of 20% v/v ammonia solution. Dry the precipitate at 105° for 1 hr, ignite in a muffle at 1000° for 1 hr, cool, and weigh. The gravimetric factor is 0·2783.

DISCUSSION

Since no standard polymers containing phosphorus were available, compounds of known composition and with similar phosphorus linkage were substituted. Triphenylphosphine was used extensively.

Decomposition of the sample and conversion of the phosphorus into orthophosphate was the most difficult part of the analysis. Of the many decomposition procedures tried, acid digestion was the only one which appeared promising. Refluxing in perchloric acid for 24 hr did not give quantitative recovery of phosphorus. Fuming nitric acid used alone did not completely decompose the samples. A mixture of sulphuric, nitric and perchloric acids was tried on triphenylphosphine, but results were about 5% (relative) low. The ignited $Mg_2P_2O_7$ obtained was often discoloured. Higher digestion temperatures were tried but resulted in losses by volatilization.

Substitution of red fuming nitric acid for conc. nitric acid gave good results; however, the amount of acid and the sequence of addition became significant. Most published methods require a small sample size, but a larger amount of polymeric material provided both a more representative sample and better accuracy. A sample size large enough to provide 30 mg of $Mg_2P_2O_7$ gave sufficient accuracy and was representative of the material tested. About 100 mg of triphenylphosphine were used and the amount of sulphuric acid varied from 0·5 to 5·0 ml. Best results were obtained with 1 ml; decomposition was difficult with more, and phosphorus was lost with less.

The addition of red fuming nitric acid was made as soon as the sample was mixed with the sulphuric acid: 0·5 ml worked best for the initial digestion; more than that slowed the reaction. When the straw colour was reached, the perchloric acid was added and the sample heated until the greenish colour disappeared. Earlier addition of perchloric acid causes foaming and does not accelerate the reaction. With this digestion technique, complete decomposition was always obtained regardless of sample composition. Also, the ignited product was always snow-white.

Precipitation with magnesia solution was slower when done hot, but a more easily filterable precipitate was obtained. The precipitate was aged for a minimum of 2 but not more than 24 hr, since the glass container was apparently attacked on prolonged aging and high results were obtained. Filtration was conveniently done with 1A2 Berlin crucibles.

Results

BDH standard triphenylphosphine was used to evaluate the procedure. Results obtained from eight determinations are shown in Table I.

TABLE I.—ANALYSIS OF TRIPHENYLPHOSPHINE (BDH).

Run	Phosphorus, %
1	11·71
2	11·86
3	11·77
4	11·97
5	11·88
6	11·94
7	11·91
8	11·86
Average	11·86 ± 0·09%

The average value of 11·86% compares well with the theoretical value of 11·81% for triphenylphosphine, thereby establishing the accuracy of the method. Precision, as shown by a standard deviation of 0·09%, was acceptable. Several Eastman chemicals similar to phosphines and phosphazenes were analysed by this procedure and the results shown in Table II illustrate the precision and accuracy of the method.

TABLE II.—P CONTENT OF VARIOUS EASTMAN CHEMICALS.

Compound	% P (theory)	% P (found)	No. of runs	Std. devn. % P
Carbomethoxymethylene-triphenylphosphorane	9·26	9·42	7	±0·06
Tri-*m*-tolyphosphine	10·18	10·14	4	±0·07
Benzyltriphenylphosphonium chloride	7·96	8·02	4	±0·08
Triphenylphosphine oxide	11·13	11·27	4	±0·10

A polyphosphazene, synthesized by J. Holovka, Sandia Laboratories, was analysed by the procedure and the results are shown in Table III. The precision, as shown in Table III, was excellent.

TABLE III.—PHOSPHORUS CONTENT OF PHOSPHAZENE POLYMER.

Run	P, %
1	26·76
2	27·10
3	26·96
4	26·95
Average	26·94 ± 0·14

Although no direct test for accuracy could be made in this case, it could be shown indirectly. A phosphazene has one nitrogen atom bound to each phosphorus atom; therefore an estimation of the accuracy of the phosphorus method can be based on analysis of the polymer for nitrogen. Nitrogen values obtained by the Kjeldahl technique yielded 12·1 ± 0·1%.[18] The 1:1 correspondence of nitrogen to phosphorus demands that the phosphorus content be 26·8 ± 0·2%. Comparison of this value with the 26·94 ± 0·14% phosphorus shown in Table III provides a strong argument for the accuracy of the method.

Summary—An improved technique for the determination of phosphorus in organic phosphazenes and phosphines is described. An acid digestion using a mixture of fuming nitric, sulphuric and perchloric acids converts the organically bound phosphorus into orthophosphate. The orthophosphate is precipitated as magnesium ammonium phosphate, which is ignited to magnesium pyrophosphate. With this technique phosphorus was determined in several compounds. The results establish both good accuracy and precision for the method.

Zusammenfassung—Es wird ein verbessertes Verfahren zur Bestimmung von Phosphor in organischen Phosphazenen und Phosphinen beschrieben. Eine Säuredigestion mittels einer Mischung von rauchenden Stickstoff, Schwefelund Perchlorsäuren verwandelt den organisch gebundenen Phosphor in Orthophosphat. Das Orthophosphat wird als Magnesium–Ammonium–Phosphat niedergeschlagen, was zur Verbrennung in Magnesiumpyrophosphat erhitzt wird. Mit diesem Verfahren wurde Phosphor in mehreren Verbindungen bestimmt. Die Ergebnisse bezeugen günstige Genauigkeit und Präzision mit diesem Verfahren.

Résumé—On décrit une technique améliorée pour le dosage du phosphore dans les phosphazènes et phosphines organiques. Une digestion acide utilisant un mélange d'acides nitrique fumant, sulfurique et perchlorique convertit le phosphore lié organiquement en orthophosphate. L'orthophosphate est précipité à l'état de phosphate ammoniaco-magnésien, qui est calciné en pyrophosphate d'ammonium. Avec cette technique, on a dosé le phosphore dans plusieurs composés. Ces résultats établissent tant la bonne précision que la bonne fidélité de la méthode.

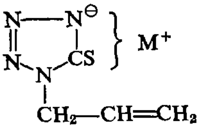
New tests for the detection of azide

(*Received* 10 *January* 1972. *Accepted* 17 *February* 1972)

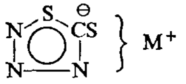
FEW TESTS are available for the analysis and identification of azides.[1-7] The classical Werner test,[1] modified by Sommer and Pincus,[2] and by Feigl[3] is based on the complete destruction of nitrate by azide in the presence of dilute acid ($HN_3 + HNO_2 \rightarrow H_2O + N_2O + N_2$); the reaction, however, invariably requires a blank test. The ferric chloride test[4] for azides, giving the red colour of soluble ferric azide, $Fe(N_3)_3$, is subject to interference by thiocyanate. The detection of azide ion by precipitation with nitron, followed by infrared spectroscopy on the precipitate[5] is only possible for high azide concentrations and even then has not always been found feasible. The test for azide with silver chromate-impregnated paper[6] lacks rapidity and suffers from interferences. The uranyl nitrate–ascorbic acid test for nitrite[7] is also useful, but to a limited extent, for the detection of azide and its differentiation from nitrite.

The present communication describes two simple, rapid, and reliable colour tests for the detection of azide; neither is subject to interference by thiocyanate. The first is based on the interaction of azide with allyl isothiocyanate in aqueous medium, forming a novel heterocyclic compound 1-allyl-2-tetrazoline-5-thione (I), which forms a deep yellow precipitate with bismuth. Addition of pyridine enhances the colour intensity, or turns the precipitate yellowish-orange. This test can be done in a test-tube, on a spot-plate, or on filter paper. A modification of the test starts with allylamine, which is converted into allyl isothiocyanate by treatment with carbon disulphide and hydrogen peroxide in presence of a little diethylamine.[8]

The second test is based on the reaction of azide with carbon disulphide in aqueous acetone to form 1,2,3,4-thiatriazoline-5-thionate (II); the latter gives a yellow precipitate with copper(II) or bismuth. The colour intensity of the copper precipitate is slightly increased on addition of pyridine; the bismuth precipitate turns yellowish-orange or deep orange on treatment with pyridine.



I



(M = a univalent cation, *e.g.*, Na^+, K^+, NH_4^+)

II

Both tests are highly specific for azide, as no other anion gives these tests. Milligram quantities of azide can be detected by these tests. The tests are, however, applicable only to water-soluble azides; heavy metal azides which are practically insoluble in water fail to give a positive response.

EXPERIMENTAL

Reagents

Hydrogen peroxide, 20-vol.
Bismuth nitrate solution, 1% w/v in dilute nitric acid.
Copper sulphate solution, 0·5% w/v.

Procedures

Allyl isothiocyanate test. Take 3 ml of water in a test-tube, add 2 drops of allyl isothiocyanate and ~20 mg of test solid or 1 ml of aqueous test solution (the azide content in either test material should be 5–10 mg). Heat the tube in boiling water for 2–3 min. A clear colourless solution is obtained. Remove the tube and proceed in any of the following ways.

(*a*) To 1 ml of bismuth nitrate solution in a separate test-tube, add ~0·5 ml of the test solution. Azide is indicated by formation of a fine canary yellow precipitate. On addition of 1 or 2 drops of pyridine the precipitate turns very deep yellow, and becomes coarser and may adhere to the walls of the tube. Sometimes a transient precipitate is obtained but becomes permanent on addition of more test solution.

(*b*) Place a drop of bismuth nitrate solution in a depression on a spot-plate and add two drops of test solution. If azide is present, a canary yellow precipitate appears.

(*c*) Place a drop of bismuth nitrate solution on a filter paper, and add one drop of the test solution. A yellow spot indicates azide.

Allylamine test via the formation of allyl isothiocyanate. Take 3 drops of allylamine, 2 drops of carbon disulphide, and 1 drop of diethylamine in a test-tube, and carefully add 4 or 5 drops of 20-vol hydrogen peroxide. A brisk exothermic reaction ensues which soon subsides. This reaction forms allyl isothiocyanate, which has the sharp characterictic smell of mustard oil. Add a little of the solid or aqueous test sample (containing 5–10 mg of azide) and 2 ml of water, and then proceed further as described above. (In this test, the sample may be added even at the start.)

Carbon disulphide test. Take 3 ml of water in a test-tube, add 3 drops of carbon disulphide, ~20 mg of test solid and 1·5 ml of acetone. Heat the tube in boiling water for 1–2 min until a clear colourless solution is obtained. Prolonged heating must be avoided. Remove the tube and proceed in any of the following ways.

(*a*) To 1 ml of copper sulphate solution in a separate tube, add several drops of the test solution. A yellow precipitate which turns fairly deep yellow on addition of a drop of pyridine indicates azide.

(*b*) To 1 ml of bismuth nitrate solution add 0·5–1·0 ml of test solution. A yellow precipitate which turns yellowish-orange or deep orange on addition of 1 or 2 drops of pyridine indicates azide.

(*c*) Place a drop of bismuth nitrate solution on a filter paper and add a drop of test solution. A deep yellow spot indicates azide.

RESULTS AND DISCUSSION

Effect of pH

Both the allyl isothiocyanate and carbon disulphide tests are to be conducted at pH $\geqslant 7{\cdot}0$. At lower pH, the azide is likely to be decomposed and completely expelled (even at fairly low temperature, *ca.* 37°) in the form of hydrazoic acid, HN_3.

Interferences

None of the tests described suffers from interference by Cl^-, Br^-, I^-, F^-, SO_3^{2-}, SO_4^{2-}, NO_3^-, PO_4^{3-}, CN^-, and SCN^- ions. Nitrite does cause some interference in the carbon disulphide test, but only when present in larger amounts. Sulphides cause serious interference as the product is masked by the simultaneous formation of black copper sulphide in the carbon disulphide test and black bismuth sulphide in both the allyl isothiocyanate and carbon disulphide tests. This interference can be avoided by preliminary oxidation of the neutral or alkaline test solution with several drops of hydrogen peroxide.[8] Hydrogen peroxide treatment also removes thiosulphates.

Negative results

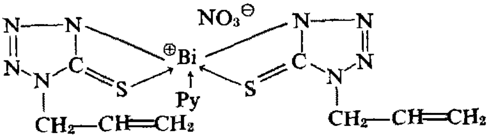
Heavy metal azides, being practically insoluble in water, yield a negligible quantity of azide ions in solution, and so fail to give any of the tests reported here.

Nature of the product in the allyl isothiocyanate test

The interaction of azide with organic isothiocyanates in solution is known to give 1-substituted 2-tetrazoline-5-thiones.[9–13] Generally a heating period of 4–8 hr is required for complete reaction. The reaction rate of a large number of isothiocyanates (aromatic and aliphatic) with azide has been studied, but only with allyl isothiocyanate is the reaction rapid. For qualitative purposes the reaction goes sufficiently within 2 min, giving 1-allyl-2-tetrazoline-5-thione (I). This compound has been described earlier[11,14] as 1-allyl-5-mercaptotetrazole.

A quantitative study of a different tetrazolinethione compound (1-phenyl-2-tetrazoline-5-thione) with bismuth has been reported by Stevancevic.[15–17] We have studied the reaction of a number of 1-substituted 2-tetrazoline-5-thiones with bismuth,[18] and established that an internal bismuth complex is formed in all cases. The complex is invariably yellow. The allyl isothiocyanate test for azide is based on these facts. We have found that when reacted with a solution of bismuth nitrate 1-allyl-2-tetrazoline-5-thione gives a complex having the formula $Bi(L)_2NO_3$, which on treatment with pyridine gives $Bi(L)_2NO_3.Py$. The metal and sulphur analysis confirms a 1:2 (metal:ligand) ratio in these complexes. Found: Bi, 37·2%, S, 11·8%; required for $Bi(C_8H_{10}N_9O_3S_2)$: Bi, 37·7%, S, 11·5%. Found: Bi, 32·4%, S, 10·7%; required for $Bi(C_{13}H_{15}N_{10}O_3S_2)$ or $Bi(L)_2NO_3.Py$: Bi 33·0%, S, 10·1%.

A study of the infrared absorption spectra (Perkin-Elmer Model 521, KBr discs) of the yellow complexes of bismuth, made on the pattern reported earlier,[19–26] showed that the metal ion is co-ordinated through both the thiocarbonyl sulphur atom and a nitrogen atom of the ligand. In consistence with these findings, III is proposed as the most probable structure for the bismuth 1-allyl-2-tetrazoline-5-thione complex pyridine adduct, *i.e.*, bis(1-allyl-2-tetrazoline-5-thionato)pyridinonitratobismuth(III).



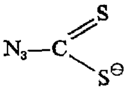
III

Nature of the product in the carbon disulphide test

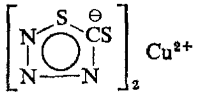
Sommer[27] was the first to observe that the interaction of azide with carbon disulphide results in the formation of azidodithiocarbonate ions (IV). This view was accepted by some other workers,[28,29] but later Lieber *et al.*[30–32] rejected the previous view, and confirmed that the product is undoubtedly 1,2,3,4-thiatriazoline-5-thionate(II). Our findings on the elemental and infrared spectroscopic analysis of pure 1,2,3,4-thiatriazoline-5-thione, prepared by the method described in the literature,[32] confirm this view. The negative charge on the thiatriazolinethionate ions is considered to be delocalized over the entire heterocyclic ring.[32]

The yellow product obtained in the carbon disulphide test has been found to be a co-ordination complex of copper(II) with 1,2,3,4-thiatriazoline-5-thionate. The elemental analysis confirms a 1:2 (metal:ligand) ratio. Found: C, 7·9%, H, 0·0%, S, 42·3%, Cu, 20·8%; required for $Cu(C_2N_6S_4)$: C, 8·0%, H, 0·0%, S, 42·6%, Cu, 21·1%. The infrared absorption bands of the copper complex nearly matched those reported by Beck and Fehlhammer[33] for the palladium(II) complex of 1,2,3,4-thiatriazoline-5-thione (triphenylphosphine adduct).

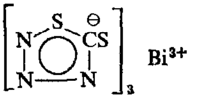
From these findings, V is proposed as the likely structure for the copper complex, *i.e.*, bis(1,2,3,4-thiatriazoline-5-thionate)copper(II). This substance slowly decomposes on storage.



IV



V



VI

It was not possible to analyse the yellow product obtained by the action of bismuth nitrate solution on 1,2,3,4-thiatriazoline-5-thionate formed in the carbon disulphide test, because the product always underwent decomposition with dangerous detonation, during attempts to dry it. However, it seems probable that it will be the bismuth analogue of the copper complex just described, and VI is tentatively proposed as its formula.

Summary—Two new, simple, reliable, and specific colour tests are described for the detection of azide. In one, the azide is heated with allyl isothiocyanate and water to form 1-allyl-2-tetrazoline-5-thione in solution; the latter gives a yellow precipitate on treatment with bismuth nitrate solution. Pyridine enhances the intensity of the colour. The allyl isothiocyanate can be produced *in situ* by treating allylamine with carbon disulphide, diethylamine and hydrogen peroxide. In the other test the azide is heated with carbon disulphide, water and acetone, resulting in the formation of 1,2,3,4-thiatriazoline-5-thione which gives a yellow precipitate with Cu(II) or Bi(III). Pyridine again enhances the colour. The method is applicable to 5–10 mg of soluble azides, but insoluble azides cannot be tested. CN^-, SCN^-, and other common anions do not interfere. Only S^{2-} interferes by masking the colour (black CuS or Bi_2S_3 is precipitated). NO_2^- in larger amounts interferes in the second test.

Zusammenfassung—Es werden zwei neue, einfache, zuverlässige und bestimmte Farbenteste zur Feststellung von Azid beschrieben. In einem wird das Azid mit Allyl-Isothiocyanat und Wasser erhitzt, um 1-Allyl-2-Tetrazolin-5-Thion in Lösung zu bilden. Letzteres gibt bei Behandlung mit Wismuthnitratlösung einen gelben Niederschlag. Pyridin verstärkt die Intensität der Farbe. Das Allyl Isothiocyanat kann in ursprünglicher Lage durch Behandlung des Allylamins mit Karbonbisulfid, Diäthylamin und Wasserstoffsuperoxyd produziert werden. In dem anderen Test wird das Azid mit Karbonbisulfid, Wasser und Aceton erhitzt, wodurch sich 1,2,3,4-Thiatriazolin-5-Thion bildet, was einen gelben Niederschlag mit Cu(II) oder Bi(III) gibt. Wieder verstärkt Pyridin die Farbe. Das Verfahren kann bis zu 5–10 mg löslicher Azide verwandt werden, unlösliche Azide können jedoch nicht geprüft werden. CN^-, SCN^- und andere übliche Anionen haben keinen störenden Einfluss. Nur S^{2-} hat durch Tarnung der Farbe (schwarzes CuS oder Bi_2S_3 wird niedergeschlagen) störenden Einfluss. NO_2^- hat in grösseren Mengen einen störenden Einfluss in dem zweiten Test.

Résumé—On décrit deux nouveaux essais colorés simples, sûrs et spécifiques pour la détection de l'azide. Dans l'un, l'azide est chauffé avec l'isothiocyanate d'allyle et l'eau pour former la 1-allyl 2-tétrazoline 5-thione en solution; cette dernière donne un précipité jaune par traitement avec une solution de nitrate de bismuth. La pyridine exalte l'intensité de la coloration. L'isothiocyanate d'allyle peut être produit *in situ* en traitant l'allylamine par le sulfure de carbone, la diéthylamine et l'eau oxygénée. Dans l'autre essai, l'azide est chauffé avec du sulfure de carbone, de l'eau et de l'acétone, avec pour conséquence la formation de 1,2,3,4-thiatriazoline 5-thione qui donne un précipité jaune avec Cu(II) ou Bi(III). La pyridine exalte de nouveau la coloration. La méthode est applicable à 5–10 mg d'azides solubles, mais les azides insolubles ne peuvent être essayés. CN^-, SCN^- et autres anions communs ne gênent pas. Seul S^{2-} gêne en dissimulant la coloration (il précipite CuS ou Bi_2S_3 noirs). NO_2^- en quantités plus importantes gêne dans le second essai.

Potentiometric titration of heterocyclic nitrogen bases in non-aqueous media

(*Received* 15 *February* 1972. *Accepted* 24 *May* 1972)

PERCHLORIC ACID has been widely used for potentiometric titration of heterocyclic nitrogen bases in acetic acid and other non-aqueous media, with various electrodes.[1-8] We have now examined the use of chlorosulphonic acid as titrant in methyl ethyl ketone–acetic acid medium, for the same purpose, in continuation of our work with this titrant.[9,10]

EXPERIMENTAL

Reagents

Methyl ethyl ketone.
Acetic acid. Purified by refluxing with acetic anhydride for 8 hr and then distilling.
Chlorosulphonic acid.
Quinoline. Dried over anhydrous magnesium sulphate and then distilled.
Isoquinoline. Distilled at reduced pressure.
Picolines. Purified by the method recommended by Vogel.[11]
2,6-*Lutidine.* Distilled.
Acridine.
Sodium acetate trihydrate.
The purity of the liquid bases was checked from precision density values and boiling points.

Procedures

Preparation of titrant. Approximately $1M$ chlorosulphonic acid in acetic acid was prepared by adding about 250 ml of acetic acid to about 7 ml of cooled chlorosulphonic acid. This solution was then diluted with methyl ethyl ketone to obtain a solution of the desired concentration, which was standardized by titration with sodium acetate in methyl ethyl ketone–acetic acid (1:1) medium either potentiometrically (glass and calomel electrodes) or with Methyl Orange indicator. Earlier work[9] had shown that up to 1% of water does not affect the potential change at the end point. The amount of hydrated sodium acetate used introduces only about 0·1% of water into the system, so there is no interference.

Preparation of base solutions. Solutions of the bases ($0{\cdot}5M$) in acetic acid were prepared. Aliquots of these were successively diluted with methyl ethyl ketone to yield a series of concentrations.

Potentiometric titrations. Titrations of $0{\cdot}5M$ acridine with $0{\cdot}1M$ chlorosulphonic acid were done (glass and calomel electrodes) in a mixed solvent of methyl ethyl ketone and acetic acid in 1:1, 5:1, 10:1 and 20:1 v/v ratio. The slope of the potentiometric curves in the vicinity of the end-point increased with increase in the proportion of methyl ethyl ketone, but with high concentrations of the ketone the potential during the initial stages of titration did not conform to regular Nernstian behaviour. The 1:1 medium was therefore preferred. The glass electrode gave a steeper slope at the end-point (30 mV/0·1 ml) than the chloranil or quinhydrone electrodes (both 18 mV/0·1 ml).

RESULTS AND DISCUSSION

The end-point was determined by the calculation method.[12] The results are given in Table I, and show that semimicro quantities of heterocyclic nitrogen bases can be determined in this way with an

Rapid determination of selenium and tellurium by atomic-absorption spectrophotometry

(*Received* 13 *March* 1972. *Accepted* 7 *May* 1972)

FOR THE PAST few decades, the literature of applied geochemistry has described the possibility of volatile elements forming "halos" around precious and base-metal mineralization.[1] The elements commonly considered in this context are mercury, arsenic, selenium and tellurium and it is assumed that such "halo" or "pathfinding" elements would present an indirect but larger target for geochemical exploration using either soil or vegetation sampling techniques.

A suitable analytical method for these elements, except mercury, should allow for the determination of concentrations as low as 0·1 ppm and at a rate of at least fifty samples per day.

Because scattering problems are particularly serious at the short wavelengths of the most sensitive resonance lines of selenium and tellurium (*ca.* 200 nm), it is seldom possible to determine these elements directly by atomic-absorption spectrophotometry and therefore a separation step[2] is essential. Such a separation step should remove all possible interfering species, thereby allowing the use of the low-temperature nitrogen–hydrogen flame. This flame affords greater sensitivity for selenium and tellurium than the conventional air–acetylene flame.

A rapid method[3] has recently been developed for determining selenium in geological materials. This method involved co-precipitation of selenium with an arsenic carrier. Further work was carried out with a view to determining arsenic, selenium and tellurium in the same solution by a co-precipitation technique followed by atomic-absorption analysis of the redissolved precipitate. Although it was not possible to obtain quantitative recoveries of all three elements, good results were obtained for selenium and tellurium when arsenic was employed as a carrier. The method so developed is reported in this paper.

EXPERIMENTAL

Apparatus

The atomic-absorption measurements were done with a Techtron AA5 unit using the following conditions:

Source: standard ASL hollow cathode lamps
Lamp currents: Se—5 mA, Te—7 mA
Wavelengths: Se—196·0 nm, Te—214·2 nm
Slit width: 0·2 mm
Burner: standard 10-cm laminar burner
Photomultiplier: R106 (Hamamatsu TV. Co.)
Gas mixture: nitrogen, flow-rate 7·5 scale units (15 psig)
hydrogen, flow-rate 3·5 scale units (2 psig)
Scale expansion: up to ×8. Damping was not used.

Reagents

Analytical grade perchloric acid (60%).

Analytical grade nitric acid (s.g 1·42).

Hydrochloric acid, 6M.

Hypophosphorous acid, 30% w/v aqueous solution.

Arsenic solution. Dissolve 250 mg of arsenic trioxide and 2 g of sodium hydroxide in water and dilute to 200 ml.

Standard selenium solution. Dissolve 50 mg of selenium in hot conc. nitric acid and dilute to 500 ml with water (100 ppm Se).

Standard tellurium solution. Dissolve 0.0625 g of tellurium dioxide with 2 g of sodium hydroxide in about 100 ml of water and make up to 500 ml (100 ppm Te).

Digestion of geological samples

One-g samples of soil, rock, gossan or sulphide ore were digested with 15 ml of a 1:1 mixture of nitric and hydrofluoric acids in polypropylene beakers, at 80° over a water-bath, and then evaporated to dryness (in about 4 hr).

Digestion of biological samples

One-g samples of dried vegetation (leaves, twigs, bark or wood) were digested with 10 ml of a 4:1 mixture of nitric and perchloric acids in test-tubes (20 × 150 mm). These tubes were placed in close-fitting recesses in a thermostatically-controlled aluminium heating block. One glass bead and one drop of kerosene were added to each tube and digestion was begun at 70°. After 8 hr, the temperature was increased to 130°, whereby all the nitric acid was boiled off overnight. The solutions were then allowed to cool. The bead and kerosene were used to prevent bumping and frothing of the digestion mixture.

Separation of selenium and tellurium

The residues were leached with 20 ml of hot 6*M* hydrochloric acid for 15 min and the mixtures were then transferred to 50-ml centrifuge tubes. The solutions were centrifuged for 3 min, and decanted into clean test-tubes, thus discarding the siliceous residues. Two ml of arsenic solution were added to each tube, and after mixing, were followed by 8 ml of 30% hypophosphorous acid. The tubes were placed for 15 min in a hot water-bath (80°) and were then allowed to cool and stand for at least 8 hr to allow complete flocculation of the brown-black arsenic precipitate.

The next stage of the procedure was complete removal of the supernatant liquid by means of suction through a glass tube drawn out to a capillary. The precipitate was washed with 10 ml of 6*M* hydrochloric acid, centrifuged, and the supernatant phase removed as before. This residue was dissolved in 2 ml of 1·6*M* nitric acid, which was most easily accomplished by adding 0·2 ml of conc. (16*M*) nitric acid to dissolve the precipitate, then adding 1·8 ml of water. For larger quantities of selenium and tellurium (>100 μg) 20 ml of 1·6*M* acid are added to ensure complete dissolution.

Atomic-absorption determination of selenium and tellurium

For routine samples, standards comprised 1·5 and 10 ppm selenium and tellurium in 1·6*M* nitric acid. For higher concentrations of these elements, standards containing 10, 20, 40, 60 and 100 ppm were used. Beer's law was obeyed up to 10 ppm. Under the routine instrumental conditions, sensitivity for both selenium and tellurium is better than 0·7 ppm.

RESULTS AND DISCUSSION

Digestion of plant material

It is certain that significant losses of selenium, at least, would occur on dry-ashing vegetation. Hence wet-ashing with a nitric-perchloric acid mixture is essential for determination of total selenium and/or tellurium concentrations.

During the digestion stage for plant material, 10 ml of a 4:1 nitric-perchloric acid mixture are adequate to digest most vegetation samples (12 ml of nitric acid may be necessary in some cases) provided the nitric acid is not boiled off too quickly, as charring and loss of volatile elements may then result. All nitric acid must be removed before the addition of the hypophosphorous acid in the reduction step and hence a two-stage digestion process is used, the second stage being at temperatures above the boiling point of nitric acid (121°) though lower than the temperature of the constant-boiling mixture of perchloric acid and water.

Recoveries of selenium and tellurium

Experiments were carried out to determine the relationship between the amount of arsenic added and the recovery of added selenium and tellurium. Recovery of added selenium and tellurium ranging from 1 to 100 μg was complete when 2 ml of arsenic solution (~1800 μg of As) were used for the separation procedure. However, recoveries were only about 75% when settling times shorter than 8 hr were used. Recovery tests were carried out by adding known amounts of both elements (0–200 μg) to a number of soil samples of known composition and with non-detectable amounts of selenium and tellurium. Full recovery of both elements was achieved even when iron was present in high concentrations.

Reproducibility and accuracy of the method

Table I summarizes analytical data for selenium and tellurium in a standard sulphide ore,[4] and for replicates of five other selected samples chosen for their variable range of selenium and tellurium concentrations. The results show that the reproducibility is more than adequate for geochemical prospecting. The agreement with values obtained by other workers using different methods indicates that the accuracy of this method is also satisfactory. The results appear to be the first for selenium and tellurium in the C.A.A.S. standard sulphide ore.

TABLE I.—RESULTS OF REPLICATE DETERMINATIONS OF SELENIUM AND TELLURIUM IN GEOLOGICAL AND PLANT SAMPLES.

Sample	No. of determinations	Selenium, ppm		Tellurium, ppm	
		Mean	Range	Mean	Range
Acacia leaves (Aust.)	4	130	121–146	< 0·1	–
Acacia twigs (Aust.)	4	34	32–38	< 0·1	–
Argentiferous quartz (N.Z.)	4	9·3	8·8–9·8	1850	1800–1950
Auriferous pyrite (Aust.)	3	5·6	5·5–5·7	2·5*	2·4–2·6
C.A.A.S. sulphide ore[4] (Canada)	12	20·6†	18–22	2·0*	1·9–2·1
Uranium ore (U.S.A.)	12	4700	4000–4900	< 0·1	–

* A colleague (Mr. K. Arundale) employed a distillation method[5] for the determination of tellurium, and obtained a mean of 1·8 ppm for the auriferous pyrite and 1·86 ppm for the C.A.A.S. sulphide ore.

† Dr J. H. Watkinson, Ruakura Research Centre, using his colorimetric method,[6] obtained an average of 23·8 ppm Se for the C.A.A.S. sulphide ore.

Limits of detection

If *limit of detection* is defined as a signal equal to twice the noise level, the method appears to have a detection limit of about 0·1 ppm for selenium and tellurium, with a conventional burner. This should be improved considerably by using the *flame-in-tube* method.[7]

Conclusions

It is concluded that the method has the required rapidity, reproducibility, and sensitivity for geochemical prospecting. For vegetation samples containing background selenium levels[8] (*i.e.*, 0·05 ppm on the dry weight), the *flame-in-tube* method would have to be used for the atomic-absorption part of this procedure.

Summary—A rapid method has been developed for the determination of selenium and tellurium in geological and biological samples. It involves acid digestion of the sample with mineral acids, addition of arsenic as a carrier, reduction of arsenic to co-precipitate selenium and tellurium, dissolution of the precipitate in dilute nitric acid and subsequent determination of selenium and tellurium by conventional atomic-absorption spectrophotometry. Selenium and tellurium have been measured on a routine basis, down to 0.1 ppm.

Zusammenfassung—Es ist eine Schnellmethode zur Bestimmung von Selen und Tellur aus geologischen und biologischen Mustern entwickelt worden. Sie umfasst Säuredigestion des Musters mit Mineralsäuren, Zusatz von Arsen als ein Träger, Reduktion von Arsen auf zusammen fällbares Selen und Tellur, Auflösung des Niederschlags in verdünnter Salpetersäure und darauffolgende Bestimmung von Selen und Tellur durch übliche atomische Absorptionspektralphotometrie. Selen und Tellur sind auf üblicher Grundlage bis auf 0,1 ppm hinunter gemessen worden.

Résumé—On a élaboré une méthode rapide pour le dosage du sélénium et du tellurium dans des échantillons géologiques et biologiques. Elle comprend la digestion acide de l'échantillon avec des acides minéraux, l'addition d'arsenic comme entraîneur, la réduction de l'arsenic pour coprécipiter le sélénium et le tellurium, la dissolution du précipité en acide nitrique dilué et la détermination subséquente du sélénium et du tellurium par spectrophotométrie d'absorption atomique classique. On a mesuré le sélénium et le tellurium de manière courante jusqu'à 0,1 p.p.m.

Developments in indicators

(*Received* 30 *September* 1971. *Revised* 11 *February* 1972. *Accepted* 18 *March* 1972)

IN RECENT years narrow-range pH indicators have been introduced.[1,2,3] In addition, a pH indicator changing through three distinct colours has been recommended.[4] α-Aminonaphthaleneazoantipyrine changes from a light colour to a dark one, and then to a light one again.[5] Complementary tristimulus colorimetry has been used for calculating the ratios of the individual components of mixed indicators, necessary for the formation of a transition colour.[6]

Very weak acids which cannot be titrated successfully with alkali in aqueous solution, may be titrated in basic non-aqueous solvents. This approach offers many new possibilities but is also not without some difficulties. Methods are known based on the principle that if the stability constant of a complex is too low, it may be possible to add some substance that will increase the conditional constant.[7] In this way boric acid, which is too weak to be titrated directly, can be transformed into a stronger acid by adding mannitol, and glycine can be titrated after addition of copper sulphate, with Methyl Red as indicator.

Metal–metallochromic indicator complexes can be employed as acid–base indicators, when the formation of a complex is accompanied by the release of more than one proton per indicator molecule. Such an indicator can provide a whole range of pH indicators by variation of the metal ion used.[8]

This paper describes the application of such indicator systems to the titration of weak acids. When an alkali is used as titrant, and a metal indicator together with a metal salt as the acid-base indicator, the colour change occurs at a definite pH, the acid form of the indicator turning not into the alkaline form but into a complex. Some of the possible applications of this principle are illustrated.

1-(2′,4′-Dinitrobenzene)-2-acetyl hydrazine (DBAH) forms green complex with Cu^{2+}, Cu^{+} and to a slight extent with Ni^{2+}. Copper forms a 1:1 complex in aqueous medium; the stability constant was determined spectrophotometrically at pH 8·5 as $\log \beta = 8{\cdot}5$ ($I = 0{\cdot}1$.) The complex is stable at pH 7·8–9·0.[9]

In a conventional acid–base indicator the transition interval is about 2 pH units. In the case of a metal–metallochromic indicator having iminodiacetic acid groups where n protons could be released at the same time, the pH interval for the complete colour change would be $2/n$.[8] In the copper–DBAH indicator system the colour change does not occur over a pH range because the complex

Résumé—On a élaboré une méthode rapide pour le dosage du sélénium et du tellurium dans des échantillons géologiques et biologiques. Elle comprend la digestion acide de l'échantillon avec des acides minéraux, l'addition d'arsenic comme entraîneur, la réduction de l'arsenic pour coprécipiter le sélénium et le tellurium, la dissolution du précipité en acide nitrique dilué et la détermination subséquente du sélénium et du tellurium par spectrophotométrie d'absorption atomique classique. On a mesuré le sélénium et le tellurium de manière courante jusqu'à 0,1 p.p.m.

Developments in indicators

(*Received* 30 *September* 1971. *Revised* 11 *February* 1972. *Accepted* 18 *March* 1972)

IN RECENT years narrow-range pH indicators have been introduced.[1,2,3] In addition, a pH indicator changing through three distinct colours has been recommended.[4] α-Aminonaphthaleneazoantipyrine changes from a light colour to a dark one, and then to a light one again.[5] Complementary tristimulus colorimetry has been used for calculating the ratios of the individual components of mixed indicators, necessary for the formation of a transition colour.[6]

Very weak acids which cannot be titrated successfully with alkali in aqueous solution, may be titrated in basic non-aqueous solvents. This approach offers many new possibilities but is also not without some difficulties. Methods are known based on the principle that if the stability constant of a complex is too low, it may be possible to add some substance that will increase the conditional constant.[7] In this way boric acid, which is too weak to be titrated directly, can be transformed into a stronger acid by adding mannitol, and glycine can be titrated after addition of copper sulphate, with Methyl Red as indicator.

Metal–metallochromic indicator complexes can be employed as acid–base indicators, when the formation of a complex is accompanied by the release of more than one proton per indicator molecule. Such an indicator can provide a whole range of pH indicators by variation of the metal ion used.[8]

This paper describes the application of such indicator systems to the titration of weak acids. When an alkali is used as titrant, and a metal indicator together with a metal salt as the acid-base indicator, the colour change occurs at a definite pH, the acid form of the indicator turning not into the alkaline form but into a complex. Some of the possible applications of this principle are illustrated.

1-(2′,4′-Dinitrobenzene)-2-acetyl hydrazine (DBAH) forms green complex with Cu^{2+}, Cu^{+} and to a slight extent with Ni^{2+}. Copper forms a 1:1 complex in aqueous medium; the stability constant was determined spectrophotometrically at pH 8·5 as $\log \beta = 8{\cdot}5$ ($I = 0{\cdot}1$.) The complex is stable at pH 7·8–9·0.[9]

In a conventional acid–base indicator the transition interval is about 2 pH units. In the case of a metal–metallochromic indicator having iminodiacetic acid groups where *n* protons could be released at the same time, the pH interval for the complete colour change would be $2/n$.[8] In the copper–DBAH indicator system the colour change does not occur over a pH range because the complex forms sharply at a definite pH, *e.g.*, at pH 7·62 the colour of the indicator is pale yellow (the complex being not yet formed) but at pH 7·80 the colour is green, being that of the complex.

Figure 1 shows the pH-absorbance curve for the DBAH complex of Cu^{2+}. On the basis of Fig. 1 the p*K* value of DBAH–Cu indicator in the case of $r = 1$ is 7·7. The p*K* value changes relatively only to a slight extent with change in the concentration of the free metal ion present.

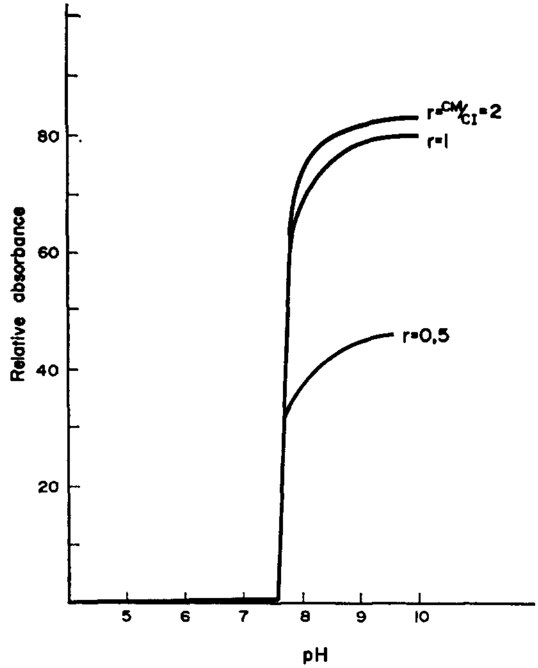

FIG. 1.—The pH-absorbance curve for the DBAH–Cu complex.

Titration of weak acids, using Cu–DBAH *complex as indicator*

Dissolve about 1 mequiv. of benzoic acid in 5 ml of ethanol, add 30 ml of water, 0·2 ml of 0·01*M* (0·024%) ethanolic DBAH, 0·2 ml of 0·01*M* copper sulphate and titrate with 0·1*M* aqueous sodium hydroxide. The acid colour of DBAH is pale yellow, the alkaline one is orange and the copper complex is green. Cu–DBAH complex indicator is not suitable for the titration of weak acids forming complexes with Cu^{2+}, *e.g.*, hydroxycarboxylic acids.

For the titration of weak acids giving a complex with Cu^{2+} as well as having a high p*K* value the magnesium complexes of nitronic acids can be utilized. Azo Violet is a well-known nitronic acid giving a green or blue lake with Mg^{2+} in alkaline medium. The apparent stability constant of the Azo Violet–magnesium complex is $K_{s0}' = 10^{7 \cdot 9}$ and the logarithmic stability constant is $\log K_{s0} = 18{\cdot}26$ at pH 12·10 in sodium hydroxide–glycine buffer.[9]

The magnesium complex of Azo Violet can be used for titrimetric purposes. The precipitation of the complex depends on the alkali and magnesium concentrations. In Fig. 2 the formation of complex is plotted as a function of pH. The formation of the Azo Violet–magnesium complex is not complete, because of the formation of a magnesium hydroxo-complex and magnesium hydroxide.

The colour change occurs here also within a very small pH range, *e.g.*, at pH 11·31 the colour of the indicator is yellow, at pH 11·44 the colour is green (a mixture of the yellow indicator and the blue complex), at pH 11·57 it is blue (the colour of the complex in solution) and at pH 11·8 the blue complex precipitates.

Figure 3 shows the pH transition range for the titration of glycine, as a function of magnesium concentration. The p*K* value of the Azo Violet–magnesium complex indicator corresponds to the pH value for 50% complex formation, $pK_{\mathrm{complex}} = 11{\cdot}45$, which increases with decrease in magnesium concentration.

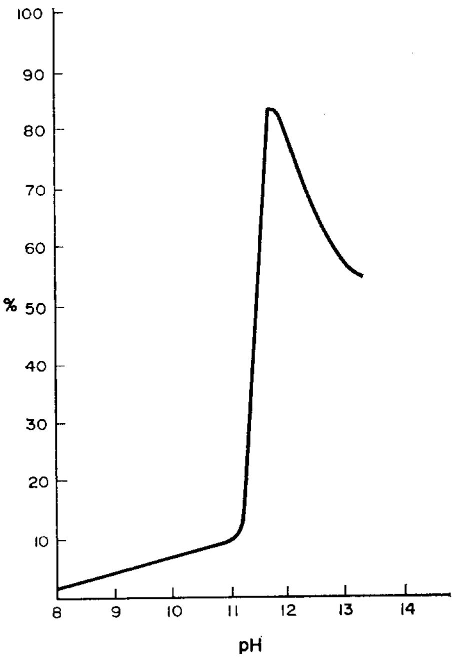

FIG. 2.—Formation of the Mg-Azo Violet complex as a function of pH.

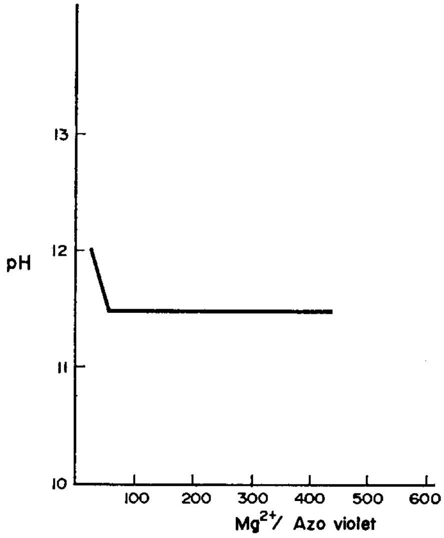

FIG. 3.—Transition pH of titration of glycine, as a function of magnesium concentration.

Titration of weak acids using Azo Violet–magnesium complex as indicator

Dissolve 0·1–0·2 g of glycine in 50 ml of water, add 6 drops of 0·1% acetone solution of Azo Violet, 2 ml of 0·1*M* magnesium sulphate and titrate with 0·1*M* aqueous sodium hydroxide. At the equivalence point the indicator changes its colour from yellow to green. With this indicator system 0·1 g of phenol or of *o*-cresol can be titrated (when 1·5 ml or 0·4 ml of 0·1*M* $MgSO_4$ respectively is added to the Azo Violet). Table I illustrates results obtained with the indicators Cu–DBAH and

Mg–Azo Violet used in titrations with 0·1M sodium hydroxide. For comparison the Cu-DBAH titration was repeated with phenolphthalein as indicator. The absolute error is generally less than 1%. The relative error in the titration of benzoic acid or of glycine is 0·2%. (The volume of 0·1M sodium hydroxide required to raise the pH from 11·31 to 11·44 is 0·5 ml for 70 ml of solution, equivalent to titration of 2 mequiv. of glycine in 50 ml.)

TABLE I.—TITRATION OF WEAK ACIDS (100% PURE).

Acid	Medium	Indicator	Recovery in titration,	
			%	average

L. LÉGRÁDI

Summary—The use of metal ion–metallochromic indicator complexes as narrow-range pH indicators is shown to be advantageous for the titration of weak acids in aqueous media. The Cu–DBAH and the Mg–Azo Violet complexes with apparent pK values of 7·7 and 11·5 have been used for the titrations of benzoic acid and of glycine and phenol, respectively, with good precision.

Zusammenfassung—Es wird gezeigt, daß zur Titration schwacher Säuren in wäßrigen Medien die Verwendung von Komplexen aus Metallionen und Metallfarbindikatoren als Indikatoren für enge pH-Bereiche Vorteile bietet. Die Komplexe Cu-DBAH und Mg-Azoviolett mit scheinbaren pK-Werten von 7,7 und 11,5 wurden für Titrationen von Benzoesäure bzw. von Glycin und Phenol mit guter Genauigkeit verwendet.

Résumé—On montre que l'emploi de complexes ion métallique-indicateur métallochrome comme indicateurs de pH à zone étroite est avantageux pour le titrage d'acides faibles en milieux aqueux. On a utilisé les complexes Cu-DBAH et Mg–Azo Violet avec des valeurs de pK apparentes de 7,7 et 11,5 pour les titrages de l'acide benzoïque, et du glycocolle et du phénol, respectivement, avec une bonne précision.

Nouvelle microcolorimétrie des nitrites

(*Reçu le* 23 *novembre* 1971. *Accepté le* 5 *avril* 1972)

La littérature scientifique fait état, pour le dosage de faibles quantités d'ion nitrite, de colorimétries obtenues à l'aide de divers réactifs organiques. La plus utilisée, connue sous le nom de Griess,[1–6] est fondée sur la diazotation de l'acide sulfanilique et la copulation du sel de diazonium formé avec la 1-naphthylamine. La sensibilité de la réaction est de l'ordre de 0,01 μg NO_2^-/ml. L'acide sulfanilique diazoté peut, suivant des méthodes voisines, être condensé sur la N-(1-naphthyléthylène diamine)[7] ou le 1-naphthol.[8] D'autres couples de réactifs ont été retenus: *p*-diaminodiphénylsulfone et diphénylamine,[9] acide *p*-sulfanilique et 1-naphthylamine,[10] *p*-nitraniline et guaiazulène,[11] ou azulène,[12] sulfanilamide et N-(1-naphthyléthylène diamine).[13,14] D'autres réactions colorées ont été mises à profit, l'ion nitrite étant révélé entre autres par l'un des réactifs suivants: 2,3-diméthyl 1-phényl pyrazolone,[15] chlorpromazine,[16] Rouge neutre,[17] brucine,[18] strychnine,[19] salipyrine,[20] benzidine.[5]

Nos recherches ont conduit à la mise au point d'une microcolorimétrie fondée sur l'action de l'ion NO_2^- sur l'*o*-tolidine en milieu acétique avec formation d'une coloration jaune à orange. Le tracé et l'étude du spectra d'absorption dans l'ultraviolet et dans le visible (Fig. 1) du colorant formé montrent des maximums vers 206, 280 et 437 nm caractéristiques du groupe azo, suivant les données de la littérature.[21]

PARTIE EXPERIMENTALE

Réactifs

Solution mère de NO_2Na contenant 0,3728 g de nitrite de sodium pour 250 ml (1 ml $\equiv$ 1 mg NO_2^-). La solution, conservée en verre jaune, est stable plusieurs mois.

Solutions diluées de NO_2Na obtenues par dilution extemporanée de la solution mère pour obtenir 0,25–10 μg NO_2^-/ml. La stabilité n'excède pas quelques jours.

Solution d'o-tolidine obtenue en dissolvant 1 g d'*o*-tolidine purifiée dans 10 ml d'acide acétique pur et diluant à 100 ml avec de l'eau. Conservée en verre jaune, la solution est stable pendant deux mois.

Solution de fluorure d'ammonium; solution aqueuse à 10%.

Gamme d'étalonnage

A 1 ml des solutions diluées de NO_2Na soit 0,25–10 μg NO_2^-, on ajoute 1 ml de solution de fluorure d'ammonium, 1 ml de solution d'*o*-tolidine et complète à 5 ml avec de l'eau. Lecture à 437 nm en cuve de 1 cm après 10 minutes (la coloration est stable jusqu'à 40 minutes après réaction).

Dosage des nitrites dans les eaux potables et les eaux minérales

L'eau à analyser (10–50 ml) est placé dans une capsule de verre, neutralisé et évaporé à sec au bain-marie. Le résidu est repris par 3 ml d'eau puis on ajoute 1 ml de solution de fluorure d'ammonium, 1 ml de solution d'*o*-tolidine. Lecture après 10 minutes à 437 nm après centrifugation éventuelle et report à la courbe d'étalonnage. Plusieurs résultats sont consignés dans le Tableau II, montrant que l'erreur relative moyenne est ±1% ainsi que la comparaison avec la méthode par diazocopulation solon Greiss.

Résumé—On propose, pour la détermination des nitrites, une microméthode fondée sur une réaction avec l'*o*-tolidine, avec formation d'un composé azoïque coloré en jaune-orange, permettant la spectrophotométrie. La sensibilité de la réaction est de 0,05 *μg* NO_2^-/ml. La méthode est applicable à la détermination des nitrites dans les eaux potables et les eaux minérales, avec une erreur relative moyenne de ±1%.

Summary—A micromethod for determination of nitrite is based on a reaction with *o*-tolidine, forming a yellow-orange product suitable for spectrophotometry. The sensitivity is 0·05 *μg* of nitrite/ml. The method is suitable for analysis of potable and mineral waters, and has a mean relative error of 1%.

Zusammenfassung—Eine Mikromethode zur Bestimmung von Nitrit beruht auf der Reaktion mit o-Tolidin, wobei sich ein für die Spektralphotometrie geeignetes gelb-orangefarbiges Produkt bildet. Die Empfindlichkeit beträgt 0,05 *μg* Nitrit/ml. Die Methode ist zur Analyse von Trink- und Mineralwasser geeignet und weist einen mittleren relativen Fehler von 1% auf.

Analytical application of the urease method for determination of urea in the presence of biuret

(*Received* 25 *August* 1970. *Revised* 8 *March* 1972. *Accepted* 1 *May* 1972)

It is well known that urease acts on urea to catalyse the reaction

$$CO(NH)_2 + 2H_2O = (NH_4)_2CO_3$$

and a method for determination of urea has been developed on the basis of this reaction.

Many opinions have been published regarding the specificity of the reaction. According to some authors the urease also acts on biuret,[1] according to others the activity of urease towards biuret is only apparent and is due to small amounts of urea in the biuret.[2]

Our preliminary investigations showed that the pH of a solution of pure biuret does not change during more than an hour in the presence of crystal urease or an alcoholic extract of the enzyme. It was therefore decided that mixtures of urea and biuret could be analysed according to the procedure described in the literature.[3]

EXPERIMENTAL

An alcoholic extract of urease was prepared from soya beans.[3] A mixture of urea and phosphorus pentoxide was heated at about 90°. The products of the reaction[4] contain nitrogen in various forms, which can be determined by appropriate methods: total nitrogen—according to Kjeldahl;[3] ammonia nitrogen—according to ref. 5; urea nitrogen—according to the procedure given in ref. 3; biuret nitrogen—by the colorimetric method.[6]

All reagents were of analytical grade.

RESULTS AND DISCUSSION

A series of solutions was prepared containing different ratios of urea and biuret (Table I). It was found that the alcoholic extract of urease catalyses the hydrolysis reaction of the urea and not that of the biuret.

Analytical application of the urease method for determination of urea in the presence of biuret

(*Received* 25 *August* 1970. *Revised* 8 *March* 1972. *Accepted* 1 *May* 1972)

IT IS WELL KNOWN that urease acts on urea to catalyse the reaction

$$CO(NH)_2 + 2H_2O = (NH_4)_2CO_3$$

and a method for determination of urea has been developed on the basis of this reaction.

Many opinions have been published regarding the specificity of the reaction. According to some authors the urease also acts on biuret,[1] according to others the activity of urease towards biuret is only apparent and is due to small amounts of urea in the biuret.[2]

Our preliminary investigations showed that the pH of a solution of pure biuret does not change during more than an hour in the presence of crystal urease or an alcoholic extract of the enzyme. It was therefore decided that mixtures of urea and biuret could be analysed according to the procedure described in the literature.[3]

EXPERIMENTAL

An alcoholic extract of urease was prepared from soya beans.[3] A mixture of urea and phosphorus pentoxide was heated at about 90°. The products of the reaction[4] contain nitrogen in various forms, which can be determined by appropriate methods: total nitrogen—according to Kjeldahl;[3] ammonia nitrogen—according to ref. 5; urea nitrogen—according to the procedure given in ref. 3; biuret nitrogen—by the colorimetric method.[6]

All reagents were of analytical grade.

RESULTS AND DISCUSSION

A series of solutions was prepared containing different ratios of urea and biuret (Table I). It was found that the alcoholic extract of urease catalyses the hydrolysis reaction of the urea and not that of the biuret.

TABLE I.—EFFECT OF BIURET ON THE DETERMINATION OF UREA BY THE UREASE METHOD.

Urea, %	Biuret, %	Urea nitrogen, %	
		calculated	found
0	100	0·0	0·0
25	75	11·6	11·6
50	50	23·2	23·2
75	25	34·9	34·7
100	0	46·5	46·5

The analytical application of the urease method was verified by analysis of the products of the reaction of the mixture of phosphorus pentoxide and urea heated at about 90° (Table II). The results for the biuret nitrogen found by the colorimetric method compare favourably with those calculated.

Determination of gallium in an iron-aluminium matrix by solvent extraction and flame emission spectroscopy

(*Received* 7 *March* 1972. *Accepted* 15 *May* 1972)

GALLIUM is readily determined by flame emission spectroscopy (FES) in a variety of flames, and under optimized conditions this technique has been shown to give detection limits superior to those obtainable by atomic-absorption spectroscopy.[1] The application of FES to the determination of gallium in matrices such as soil or rock fusion fluxes, which may contain very substantial excesses of iron and aluminium, is limited[1,2] by the increase in background emission attributable to the concomitant elements, even when a spectral band-pass as low as 0·04 nm is employed.[2] For aqueous solutions, extraction of the 8-quinolinolate[3,4] or pyrollidinedithiocarbamate[5] has been recommended as a preconcentration technique before flame spectroscopic analysis, and the addition of organic solvents has been suggested[6] as a method of enhancing the sensitivity of the determination. Methods commonly used[7] for the extraction of gallium are susceptible to co-extraction of iron(III), however. Sandell overcame[8] this problem by reduction of iron(III) to iron(II) by filtration through silver powder, The analytical application of the urease method was verified by analysis of the products of the reaction of the mixture of phosphorus pentoxide and urea heated at about 90° (Table II). The results for the biuret nitrogen found by the colorimetric method compare favourably with those calculated.

Determination of gallium in an iron–aluminium matrix by solvent extraction and flame emission spectroscopy

(*Received* 7 *March* 1972. *Accepted* 15 *May* 1972)

GALLIUM is readily determined by flame emission spectroscopy (FES) in a variety of flames, and under optimized conditions this technique has been shown to give detection limits superior to those obtainable by atomic-absorption spectroscopy.[1] The application of FES to the determination of gallium in matrices such as soil or rock fusion fluxes, which may contain very substantial excesses of iron and aluminium, is limited[1,2] by the increase in background emission attributable to the concomitant elements, even when a spectral band-pass as low as 0·04 nm is employed.[2] For aqueous solutions, extraction of the 8-quinolinolate[3,4] or pyrollidinedithiocarbamate[5] has been recommended as a preconcentration technique before flame spectroscopic analysis, and the addition of organic solvents has been suggested[6] as a method of enhancing the sensitivity of the determination. Methods commonly used[7] for the extraction of gallium are susceptible to co-extraction of iron(III), however. Sandell overcame[8] this problem by reduction of iron(III) to iron(II) by filtration through silver powder, followed by the immediate extraction of the gallium chloro-complex into diethyl ether from hydrochloric acid solution. The method described here involves the use of titanous sulphate as a reductant, which obviates the need for filtration and, by maintaining a reducing environment, for immediate extraction. Methyl isobutyl ketone,[9] which is a particularly suitable solvent[4] for the flame spectroscopic determination of gallium, is employed as an extractant.

EXPERIMENTAL

Reagents

Gallium(III) *solution*, 1·00 mg/ml Dissolve 1·00 g of gallium metal in the minimum necessary volume of reagent-grade constant-boiling hydrochloric acid; dilute to 1 litre.

Diverse ions. Stock solutions were prepared for a range of elements from the metals as above, or from suitable metal salts.

Titanium(III) *sulphate solution, 15% w/v.*

Apparatus

Flame emission/atomic absorption spectrometer. A Unicam model SP900A with 5-cm air–acetylene slot-burner was used in the emission mode.

Procedure

Evaluation of the effect of hydrochloric acid concentration on extraction efficiency. Twenty-ml aliquots of 50 μg/ml gallium solutions in hydrochloric acid (0–6*M w.r.t.* HCl in final solution) were extracted with 5 ml of methyl isobutyl ketone. The organic phases were nebulized into a fuel-lean air–acetylene flame, and the intensity of the gallium emission at 417·2 nm was measured.

Procedure in the presence of large excesses of Fe(III) and Al(III). To suitable aliquots of neutral or near neutral test solutions and standards, were added 10 ml of concentrated hydrochloric acid and 2 ml of titanium(III) sulphate solution. The solutions were diluted to 20 ml, shaken, and extracted with 5 ml of methyl isobutyl ketone. The emission intensity was measured for the organic phase, methyl isobutyl ketone previously saturated with hydrochloric acid being used to set the instrumental zero. Linear calibration curves could be prepared over the range 0–1 and 0–12 μg/ml (gallium concentration in aqueous phase). The variation in standard deviation and related parameters with gallium concentration (based on ten determinations) is shown in Table I.

RESULTS AND DISCUSSION

Figure 1 illustrates the effect of acid concentration on the gallium emission intensity. Acid digestions of 5-ml aliquots of organic phase, and evaporation of 10-ml aliquots of aqueous phase to dryness followed by dissolution of any residue in 10 ml of 1*M* hydrochloric acid, indicated quantitative extraction of gallium over the acid concentration range 4·3–7·2*M*, within the limits of experimental error (i.e. >98% extraction). Over this acid concentration range, atomic-absorption spectroscopic analysis indicated that iron(III) was virtually quantitatively co-extracted, whereas aluminium was not extracted to any measurable extent. The interference of iron(III) was found to be eliminated by reduction to iron(II) with titanous sulphate. This procedure was found to be effective in dealing with 5000-fold excesses (the largest investigated) of iron in the determination of gallium concentration

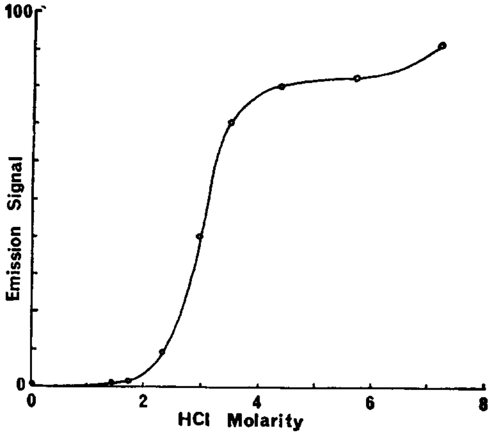

Fig. 1.—The influence of hydrochloric acid concentration on the emission signal from 50-μg/ml gallium solutions after extraction into methyl isobutyl ketone.

TABLE I.—PRECISION OF RESULTS.

Gallium concentration, *μg/ml*	Signal range	Mean signal	Standard deviation	Relative standard deviation, %
1·0	72–80	77·7	0·9	1
0·2	10–20·5	16·0	1·0	6
0·05	−1–8·5	4·0	1·0	25

of 2 μg/ml in aqueous solution, *i.e.*, 0·5 μg/ml in the aqueous phase when using a 5-ml aliquot for analysis. Thousand-fold excesses of the following elements caused no measurable interference in the determination of the same concentration of gallium; Al, Ba, Ca, Cd, Co, Cr, K, La, Li, Mg, Mn, Mo, Na, Ni, Pb, Sr, Ti, Tl, V and Zn; copper, which is partially co-extracted under these conditions, was found to give rise to appreciable spectral interference. At the level mentioned, which is at least an order of magnitude greater than that likely to be encountered in soil samples, this caused a 50% enhancement in the gallium signal.

To obtain some indication of the influence of other acids likely to be encountered after digestion procedures, on the determination of gallium at the 50 μg/ml level, solutions were prepared which were 5·7*M* with respect to hydrochloric acid, and also 2·0*N* with respect to sulphuric, nitric and perchloric acid: At this level sulphuric acid gave an enhancement of 3%, whereas nitric and perchloric acids caused suppressions of 62% and 77% respectively. Although the interference of nitric and perchloric acids may be ignored provided samples and standards are carefully matched with respect to acid concentration, both acids were found to impede the quantitative reduction of iron(III) to iron(II) with titanium(III) sulphate. The result obtained for sulphuric acid indicates that the sulphuric acid content of the titanium(III) sulphate solution is not critical.

Summary—Solvent extraction of gallium(III) into methyl isobutyl ketone from hydrochloric acid solutions containing titanium(III) sulphate provides a rapid method for separation of gallium from an iron/aluminium matrix and may be employed to eliminate the interference of these elements in the flame emission spectrometric determination of gallium.

Zusammenfassung—Lösende Ausscheidung von Gallium(III) in Methylisobutylketon aus Salzsäurelösungen mit Titanium(III) Sulphatgehalt stellt eine schnelle Methode zur Trennung von Gallium aus einer Eisen/Aluminium-Grundmasse dar und kann benutzt werden, die Interferenz dieser Elemente bei der Flammenausstrahlung spektrometrischer Ermittlung von Gallium zu eliminieren.

Résumé—L'extraction par solvant du gallium(III) en méthylisobutylcétone à partir de solutions en acide chlorhydrique contenant du sulfate de titane(III) fournit une méthode rapide pour la séparation du gallium d'une matrice fer/aluminium et peut être employée pour éliminer l'interference de ces éléments dans le dosage spectrométrique du gallium par émission de flamme.

ANALYTICAL DATA

Complexes of some rare earth metals with 1-amino-4-hydroxyanthraquinone

(*Received* 7 *February* 1972. *Accepted* 5 *March* 1972)

THE FLUORESCENCE SPECTRA of beryllium and thorium-1-amino-4-hydroxy-anthraquinone complexes were studied by White *et al.*,[1] but no systematic study has been made of the complexes of 1-amino-4-hydroxyanthraquinone with metal ions. The present paper deals with the lanthanum, cerium, praseodymium, neodymium and samarium complexes.

EXPERIMENTAL

Reagents

1-*Amino*-4-*hydroxyanthraquinone* (*AHA*). The reagent was prepared by the direct condensation of phthalic anhydride and triacetyl *p*-aminophenol in the presence of an anhydrous aluminium chloride–sodium chloride melt.[2] The product was purified by thin-layer and column chromatography, and used as a solution in methanol.

Lanthanide chloride solutions. Prepared as methanol solutions.

Nature of the complex

AHA immediately gives a reddish-violet colour with La^{3+}, Ce^{3+}, Pr^{3+}, Nd^{3+} and Sm^{3+}. The colour remains unchanged for 3 or 4 days.

Vosburgh and Cooper's method[3] showed that only one type of complex was formed. The absorption maximum was at 530 nm for AHA and at 605 nm for La, Pr and Sm and 610 nm for Ce and Nd.

The method of continuous variations,[4] mole-ratio,[5] and slope ratio[6] methods all showed the complexes to be 1:1.

Evaluation of stability constants

The stability constants were determined from the absorbances measured in the Job's method by using Banerji and Dey's formula[7]

$$K = \frac{x}{(a_1 - x)(b_1 - x)} = \frac{x}{(a_2 - x)(b_2 - x)}$$

where a_1 and a_2 are the total concentrations of metal, b_1 and b_2 the total concentrations of AHA and x the concentration of the complex at equilibrium.

TABLE I.—STABILITY CONSTANTS AND FREE ENERGY OF FORMATION OF VARIOUS METAL–AHA COMPLEXES AT 30°C.

Complex	λ_{max} nm	$\log K$	Method	ΔG^0, *kcal/mole*
La(III)–AHA	605	5·16 ± 0·08	(a)	—
		5·26 ± 0·02	(b)	7·34 ± 0·03
Ce(III)–AHA	610	5·25 ± 0·10	(a)	—
		5·33 ± 0·03	(b)	7·40 ± 0·02
Pr(III)–AHA	605	5·36 ± 0·08	(a)	—
		5·42 ± 0·04	(b)	7·57 ± 0·05
Nd(III)–AHA	610	5·40 ± 0·14	(a)	—
		5·45 ± 0·03	(b)	7·60 ± 0·04
Sm(III)–AHA	605	5·25 ± 0·06	(a)	—
		5·46 ± 0·04	(b)	7·62 ± 0·06

(a) Banerji and Dey method.[7]
(b) Mole-ratio method.

The mole-ratio method was also used by means of the equation

$$K = \frac{1 - \alpha}{\alpha^2 C}$$

where C is the concentration of the complex and α is the degree of dissociation, given by

$$\alpha = \frac{A_m - A_s}{A_m}$$

where A_m is the absorbance of the complex when excess of AHA is present and A_s is the absorbance of the complex at the equivalence point.

The free energy of formation was calculated from K. The results are summarized in Table I. The stability constants are very similar, increasing as the size of the cation decreases.

ANNOTATIONS

A study of the evaporation of gold solutions

(*Received* 2 *March* 1972. *Accepted* 26 *March* 1972)

There have been several reports in the literature, referring to losses of gold by volatilization on heating of gold solutions. Mizuike and Takata[1] reported the loss of the trace elements ^{51}Cr, ^{60}Co, ^{65}Zn, ^{110}Ag, ^{198}Au and ^{203}Hg when solutions were evaporated to dryness at 100°. Gilchrist[2] found as much as 2% loss of gold as gold chloride upon heating to dryness, presumably through volatilization. On the other hand, some authors have not considered the possibility of gold losses. Plaskin and Kayukhova[3] did not consider gold losses in their determination of gold by hydrazine hydrochloride, which involved repeated evaporation with hydrochloric acid at temperatures not over 60–70°. In co-crystallization experiments with 2-mercaptobenzimidazole, Weiss and Lai[4] did not consider the possibility of gold volatilization occurring during the several hours of boiling required. A colorimetric method by Brodigan[5] ignored any loss of gold during an evaporation to a volume of 1–2 ml. The colorimetric method by Gachev[6] required the boiling of a gold solution to dryness but gave no consideration to any possible gold loss. Novikova[7] showed that the process of dissolving gold is temperature-dependent but did not discuss possible gold losses.

Chapman, Marvin and Tyree[8] reported specifically on the volatilization of elements in solutions of mixed hydrofluoric and perchloric acids heated to dryness by an overhead heating unit kept at 200°. They concluded that under these conditions there was no loss of gold.

Owing to the seemingly contradictory information available an investigation was undertaken of the losses of gold during evaporation of various aqueous gold solutions.

EXPERIMENTAL

Gold-195 ($t_{1/2}$ 180 days) was produced by cyclotron irradiation of a 1-cm^2 platinum foil with 25 MeV protons for approximately 2 hr. The foil was dissolved in *aqua regia* and the nitrogen oxides were expelled by heating to dryness several times in the presence of small amounts of concentrated hydrochloric acid. The residue was dissolved in 3*M* hydrochloric acid containing 2 drops of phosphoric

* Chimney separated from beaker by 2 mm, as a capillary action check.

† Cooling coil used directly above beaker but not in contact.

acid and the solution was extracted several times with equal volumes of ethyl acetate. The combined extracts were evaporated to dryness, decomposed with nitric acid and hydrogen peroxide, and then evaporated to dryness several times in the presence of concentrated hydrochloric acid. The auric chloride thus obtained was dissolved and made up to 10 ml with $2M$ hydrochloric acid. The radiopurity of the stock solution was confirmed by γ-spectrometry.

Special beakers were made from 34/35 ground-glass joints (Fig. 1) for the experiment.

Samples were prepared containing 1 ml of ^{195}Au solution. The conditions were varied by adding various volumes and strengths of acids, salts, inhibitors, desurfactants and non-radioactive gold, as shown in Table I. The beaker and chimney were assembled and put on a steam-bath, and the temperature noted. In some cases a water-bath or a hot-plate was used. After evaporation to dryness, the activity at the base of the chimney and the activity at different heights in the chimney were recorded as in Table I. Counting errors amount to approximately 2 cps. Any activity on the chimney was washed down into the beaker with the acid required for the next experiment and the chimney checked for residual activity.

As a check for capillary action, some experiments were run with the chimney separated from the beaker by 2 mm, and the solutions were evaporated to dryness. Several solutions were also evaporated to dryness with a cooling coil placed just above but not in contact with the beaker. As shown by the results in Table I, there was no appreciable activity on the cooling coil or chimney.

Some of the experiments which showed a significant migration of gold were repeated with various concentrations of inhibitors such as agar agar or salts or substances such as "Triton-X" or ethanol.

DISCUSSION

The results indicate that gold does not volatilize appreciably from aqueous solutions but that it does have a significant ability to creep. The use of salts, non-radioactive gold and agar agar significantly suppresses the creeping of gold solutions, whereas the use of more volatile solvents does not seem to have any significant effect. When concentrated acids are used the degree of creeping seems directly related to the viscosity of the acid. The absence of significant activity on the separated chimney and the absence of gold on the cooling coil show that gold is not volatile under the various conditions used. The results also indicate that while losses as high as 2 or 3% may occur *via* creeping when submicrogram amounts of gold are used, the presence of even microgram amounts of gold is sufficient to suppress the loss significantly.

Thus because of creeping, it is necessary to use particular care in washing the beaker walls to ensure that a quantitative recovery of gold is obtained after any procedure involving the evaporation of a solution containing gold. The losses formerly attributed by some authors to volatilization were probably due to difficulties caused by creeping.

Acknowledgement—The authors wish to thank the National Research Council of Canada for its financial support and Johnson Matthey and Mallory Ltd. (Toronto, Canada) for providing the gold used.

Summary—The study indicates that despite several reports to the contrary, gold does not volatilize appreciably during the evaporation of aqueous solutions. Gold solutions were shown to have a tendency to creep significantly in solutions of various metal concentrations, acid content and salt content, and that careful washing must be carried out to obtain quantitative recovery.

Zusammenfassung—Die Untersuchung zeigt, daß entgegen mehreren Angaben Gold während des Eindampfens wäßriger Lösungen nicht merklich flüchtig geht. Es wird gezeigt, daß Goldlösungen in verschiedenen Metallkonzentrationen, Säure- und Salzgehalten beträchtlich zum Kriechen neigen und daß daher sorgfältig gewaschen werden muß, um quantitative Ergebnisse zu erhalten.

Résumé—L'étude indique que, malgré plusieurs indications contraires, l'or ne se volatilise pas de manière appréciable durant l'évaporation de solutions aqueuses. On a montré que les solutions d'or ont une tendance à "grimper" de manière importante dans des solutions de concentrations en métal, teneur en acide et teneur en sel diverses, et qu'il convient de procéder à un lavage soigné pour obtenir une récupération quantitative.

Modifications of the computer programme SCOGS

(*Received* 13 *December* 1971. *Accepted* 20 *January* 1972)

THE COMPUTER PROGRAMME SCOGS[1,2] was developed to extract "best-fit" equilibrium constants for acid dissociation or metal-complex formation from pH-titration data. On the basis of some experience in the use of this programme we offer the following comments and modifications.

The programme is designed to generate or utilize "mixed" acidity constants of the type $K_a = H[A]/[HA]$, where $H = 10^{-pH}$. Similarly, expressions for formation constants of protonated metal complexes contain H, and those of deprotonated species, including products of hydrolysis of metallic ions, contain $OH = 10^{pH-pK_w}$. Many workers, including the authors, prefer to express these quantities as concentration quotients, and we have accordingly modified the computer programme for this purpose. To do so we required some rationale for converting pH value into hydrogen-ion concentrations. In the original description of SCOGS this was accomplished by means of an appropriate value for the activity coefficient of hydrogen ion; this appears to have been a suitable mean activity coefficient $f_{\pm}$. Subsequent users of the programme[3] introduced the notion that, since this conversion factor ($F = H/[H]$) could not strictly be evaluated on theoretical grounds, it be treated as an adjustable parameter within the computer programme. The most suitable value of F was that leading to minimum standard deviation in titre (SDT). Alternatively, F can be directly evaluated with solutions of known hydrogen-ion concentration,[4-6] and this is the authors' practice.

It is also advantageous to express K_w as a concentration quotient, K_{cw}. Where appropriate data are available the value of K_{cw} can be estimated from values of K_w and the factor $\gamma_H\gamma_{OH}/a_{H_2O}$.[7] Where such data are lacking, K_{cw} can be found by suitably combining the results of pH measurements in acid and alkaline solutions of known composition.[6]

The changes required in the original SCOGS programme then become:

(1) Main programme, card 0094
  —use value of ionic concentration product
  —use value of F appropriate to the solvent medium
(2) Main programme, card 0105
  —from 129 UXS (K) = 10**U(K)
  —to 129 UXS(K) = 10**U(K)*F
(3) Subroutine COGSNR, card 0039
  —from HO = HO/F
  —to DELETE THIS CARD

The extensive capabilities of SCOGS are achieved at the expense of a fair amount of computer time. The authors have found that savings in central processing-unit time of about 30–40% can be achieved by the use of the FORTRAN H compiler (rather than FORTRAN G). Further saving in compiling time is achieved by having the programme produced as an object deck, or alternatively by storing the object module on a direct access tape or drum. The authors would be pleased to supply a listing of the modified programme on request.

The original description of the programme fails to make clear that formation constants for any deprotonated species are incorporated or produced in the form appropriate to a proton-releasing

Modifications of the computer programme SCOGS

(*Received* 13 *December* 1971. *Accepted* 20 *January* 1972)

THE COMPUTER PROGRAMME SCOGS[1,2] was developed to extract "best-fit" equilibrium constants for acid dissociation or metal-complex formation from pH-titration data. On the basis of some experience in the use of this programme we offer the following comments and modifications.

The programme is designed to generate or utilize "mixed" acidity constants of the type $K_a = \mathrm{H[A]/[HA]}$, where $\mathrm{H} = 10^{-\mathrm{pH}}$. Similarly, expressions for formation constants of protonated metal complexes contain H, and those of deprotonated species, including products of hydrolysis of metallic ions, contain $\mathrm{OH} = 10^{\mathrm{pH}-\mathrm{p}K_w}$. Many workers, including the authors, prefer to express these quantities as concentration quotients, and we have accordingly modified the computer programme for this purpose. To do so we required some rationale for converting pH value into hydrogen-ion concentrations. In the original description of SCOGS this was accomplished by means of an appropriate value for the activity coefficient of hydrogen ion; this appears to have been a suitable mean activity coefficient $f_{\pm}$. Subsequent users of the programme[3] introduced the notion that, since this conversion factor (F = H/[H]) could not strictly be evaluated on theoretical grounds, it be treated as an adjustable parameter within the computer programme. The most suitable value of F was that leading to minimum standard deviation in titre (SDT). Alternatively, F can be directly evaluated with solutions of known hydrogen-ion concentration,[4-6] and this is the authors' practice.

It is also advantageous to express K_w as a concentration quotient, K_{cw}. Where appropriate data are available the value of K_{cw} can be estimated from values of K_w and the factor $\gamma_H\gamma_{OH}/a_{H_2O}$.[7] Where such data are lacking, K_{cw} can be found by suitably combining the results of pH measurements in acid and alkaline solutions of known composition.[6]

The changes required in the original SCOGS programme then become:

(1) Main programme, card 0094
 —use value of ionic concentration product
 —use value of F appropriate to the solvent medium
(2) Main programme, card 0105
 —from 129 UXS (K) = 10**U(K)
 —to 129 UXS(K) = 10**U(K)*F
(3) Subroutine COGSNR, card 0039
 —from HO = HO/F
 —to DELETE THIS CARD

The extensive capabilities of SCOGS are achieved at the expense of a fair amount of computer time. The authors have found that savings in central processing-unit time of about 30–40% can be achieved by the use of the FORTRAN H compiler (rather than FORTRAN G). Further saving in compiling time is achieved by having the programme produced as an object deck, or alternatively by storing the object module on a direct access tape or drum. The authors would be pleased to supply a listing of the modified programme on request.

The original description of the programme fails to make clear that formation constants for any deprotonated species are incorporated or produced in the form appropriate to a proton-releasing reaction, *e.g.*,

$$M + H_2O = MOH + H$$
$$M + L + H_2O = MOHL + H, \textit{etc.}$$

There is also a contradiction in the published account[1] concerning the significance of the residual R_i. The statement on p. 1398 is at variance with the instruction on card 0161 of the main programme; the residual is, in fact, the calculated titre minus the actual titre. Since modification or introduction of new trial equilibrium constants as input data is often based on interpretation of the significance of individual residuals, it is important that the sign of each residual be correctly understood.

Summary—The computer programme SCOGS has been modified to accept and yield all equilibrium constants involving proton transfer, as concentration quotients. Significant savings in operating time are achieved through use of the FORTRAN H compiler.

Zusammenfassung—Das Rechnerprogramm SCOGS wurde abgeändert, um alle Gleichgewichtskonstanten aufzunehmen oder zu liefern, die mit Protonenübergängen zu tun haben, und zwar in der Form von Konzentrationsverhältnissen. Beträchtliche Einsparungen an Bedienungszeit werden durch Verwendung des FORTRAN H-Kompilierers erzielt.

Résumé—On a modifié le programme de calculatrice SCOGS pour accepter et rendre toutes les constantes d'équilibre impliquées dans le transfert de proton, comme les quotients de concentration. Des économies importantes dans le temps d'opération peuvent être réalisées par l'emploi du compilateur FORTRAN H.

TALANTA REVIEW*

EXTREME TRACE ANALYSIS OF THE ELEMENTS—I

METHODS AND PROBLEMS OF SAMPLE TREATMENT, SEPARATION AND ENRICHMENT

GÜNTHER TÖLG
Max-Planck-Institut für Metallforschung, Laboratorium für Reinststoffe,

(*Received* 5 *May* 1971. *Accepted* 17 *March* 1972)

Summary—In the determination of elements in the ppM range in inorganic and organic matrices, solution techniques are useful because they simplify calibration problems and improve the limit of detection. The author reviews, in the light of his own experience, some 350 publications concerned with methods for the preparation and dissolution of samples and for the isolation of trace elements before their determination. The errors in these methods, made more difficult to reduce because of the additional operations required, are compared with those associated with the more direct methods.

WHILE micro- and ultramicro elemental analysis[1,2] is concerned with the determination of major and minor constituents ($10^{-2}\%$) in small samples (<10 mg), the aim of trace analysis[3–19] is to detect the elements in an amount of matrix material at least 10^4 times as great, *i.e.* at the ppm or ppM level. Thus in microanalysis the small amount to be determined is dictated by the small amount of sample available, but in trace analysis by its very low concentration in the matrix.

Confusion has arisen through the unfortunately frequent inconsistent usage of the terms "micro-" and "trace-", particularly in connection with literature documentation. For this reason one ought to characterize the techniques of trace analysis according to the concentrations which can be handled, in the same way that those of microanalysis are classified according to size of sample.[21–22] Thus instead of "trace analytical techniques" we should say ppm-techniques (1 ppm $= 10^{-4}\%$), and instead of "ultra- or micro-trace techniques" ppM-techniques (1 ppM $= 10^{-7}\%$). The former are nowadays in routine use; this review is to deal with the ppM-techniques and also ppm-techniques applied to samples of limited size—so-called ppm-microtechniques. The absolute amounts of the elements which can be determined by methods presently at our disposal lie in both cases in the ng and upper pg ranges, and in a few cases even lower.

The extremely low limits of detection required for methods that are to cope with such small amounts (Table I) are often raised by several orders of magnitude, depending on the matrix and the trace element, by the high concentration of the matrix element. For this reason one can rarely avoid the necessity of separating or at least concentrating the trace elements sought in cases of extreme trace analysis. In addition to the specialized vaporization procedures involving direct excitation of the sample

---

* Favourable limit of detection for a particularly easily determined element. These can only be very approximate estimates for reasonably favourable conditions, and may be very readily influenced by many experimental factors.

† For neutron flux of 10^{14} neutrons/cm^2/sec.

in spectroscopic analysis, there are procedures with good limits of detection (10^{-9}–10^{-14} g) which can be applied to the analysis of small volumes of more concentrated solutions. Some techniques well suited to this approach include solution spectroscopy,[23–30] inverse voltammetry,[31,32] and gas chromatography.[33,345] Traces, enriched on the surface of a very small target, can also be excited by laser-, electron-, or ion-beam irradiation for spectrographic analysis.

The increased expense and the propagation of errors occasioned by the additional manipulation and handling steps in the preconcentration procedures have to be accepted. The separation problems are frequently very difficult, being made even more so by the variety of matrices which may be encountered.

The matrix is sometimes a single element, as in the analysis of high-purity materials such as metals,[16,18,34] semiconductors,[7,13,16,35] and reactor materials,[36–38] but more often is a combination of elements (compounds, mixtures, alloys, *etc*) as in the case of geological[39] and lunar[41] samples and organic and biological materials.[17,20,39] Foodstuffs,[40] water,[41–43] and air[44–48] are increasing in importance as matrices with the mounting concern about the environment.

We regrettably know little about the causes of the numerous predominant systematic errors in extreme trace analysis. The literature gives only rough generalized rules for reducing them, and it cannot be too strongly emphasized that these rules must not be used uncritically, since chemically similar species can show marked differences of behaviour under similar conditions. For this reason, each individual step of a procedure under development for extreme trace analysis—the preparation, weighing, dissolution, separation or concentration of the trace element—must be carefully investigated for sources of error and their causes.

This, the first of two parts of a review article, will go into the problems met with in extreme trace analysis in the processes of dissolution, separation and preconcentration.

RELIABILITY, DETECTION CRITERIA AND CALIBRATION

The reliability of a trace analytical method is characterized by its "reproducibility", depending on statistical errors and precision, and its accuracy, depending on systematic errors. Both terms have been clearly defined in the literature.[49–51] In the case of microanalytical techniques for the determination of major or minor components in small samples, reproducibility is of great importance; systematic errors can be relatively easily avoided when working with concentrations $>10^{-3}M$. In trace analysis good reproducibility is of course desirable, but a lower accuracy of determination of lower concentrations must be accepted. Thus for example trace element concentrations in biological and geological materials are in any case subject to enormous variation,[52] or again, the quantity to be determined may be only just above the limit of detection for the particular method (see next section). Great attention must be given to avoiding systematic errors in trace analysis methods which involve dissolution and separation. The problem of calibration must be considered carefully, in particular when dealing with ppM techniques.

Statistical errors, limits of detection and determination

With all instrumental techniques, even in the supposed absence of the element to be determined there is a statistical variation of the analytical signal—the so-called noise-level, or blank value. This can be caused by variations in operating conditions of sources or detectors (*e.g.*, noise in the electronics, voltage fluctuations) or by impurities being carried into the excitation cell. When various procedures are combined in a method—weighing, dissolution, preconcentration, and determination—the individual blank values are combined according to the law of propagation of errors.[53] The amount of an element to be determined must therefore be greater than the total blank value and its variation.

Kaiser suggested[53–55] that a signal (X) could be considered with reasonable confidence to be different from the blank value when it is at least as great as the mean blank value $\bar{X}_{\mathrm{b}(N)}$ plus three standard deviations of the blank value ($s_{\bar{X}_{\mathrm{b}(N)}}$):

$$X = \bar{X}_{\mathrm{b}(N)} + 3s_{\bar{X}_{\mathrm{b}(N)}}$$

The limit of detection thus determined can be given with greater confidence if a larger number (N) of determinations of the blank value $\bar{X}_{\mathrm{b}(N)}$ is made. At least 20 measurements of the blank value should be used.[54]

According to this criterion the smallest amount of the element which might be detected, is done so with a probability of only 0·5. Feigl[56] preferred to define a limit of determination—which has been discussed at some length[18]—which implies, for homogeneous samples, Kaiser's "limits for the guarantee of purity":[54]

$$X = \bar{X}_{\mathrm{b}(N)} + 6s_{\bar{X}_{\mathrm{b}(N)}}$$

Ehrlich has indicated the difference between the two concepts when applied to inhomogeneous samples.[18]

The relative standard deviation for an analytical procedure in the vicinity of the limit of determination is $\geqslant 33\%$.[53] Mathematically speaking, the sensitivity of a method can even better be applied as a guarantee of the highest possible purity.[18] Püschel describes a linear relationship between the concentration of the determinand

and the reproducibility over the range 10^{-4}–100%. This proportionality remains to be tested for lower concentrations.

Systematic errors[58]

Even if reproducible blank values and small statistical errors are inherent in a method, the analytical results may deviate in either direction from the true values. This may be the case, for example, when the standardization and the analysis are not carried out in exactly the same manner. It is, however, very difficult to work out such comprehensive instructions for a trace analysis procedure, since the sources of error vary from one sample to the next and cannot always be anticipated. The relevance of systematic errors is best illustrated by an example.

In the spectrophotometric determination of selenium in effluents (selenium concentration $\leqslant 0{\cdot}02$ ppm) traces of selenium can be lost by irreversible adsorption on the surface of the container even during very short storage periods. The degree of adsorption is dependent on the nature of the surface material, its pretreatment, the pH of the solution, the contact time, and a number of other parameters. Another portion of the selenium can be lost by evaporation during boiling down of the aqueous sample or mineralization of the residue, or can again be lost by adsorption. Loss of selenium can also occur during separation from interfering elements, or the chromophoric reagent may have undergone some change during the time between the calibration and the analysis. Values that are too high can be encountered when glassware contaminated with selenium is used, or when the selenium content of a reagent has increased.

Püschel's relationship between concentration and reproducibility for levels above 1 ppm does not hold with any certainty for lower concentrations. The difficulty of eliminating systematic errors becomes increasingly greater with decreasing levels in the ppM region, and eventually the principal problem.

In extreme trace analysis, standard samples are simply not available, and for this reason it is no longer possible to compensate for systematic errors by calibration. Other ways must be found, as follows.

(1) A carefully chosen sample is investigated by at least two or three different methods involving different sources of systematic error. However, even if enough different procedures are available, and each has good reproducibility, no agreement may be found between the results.

(2) Varying amounts of the same sample are analysed or varying amounts of standard solution of the determinand are added to a constant amount of sample before analysis. The results are plotted against sample weight or concentration added, and only when the curve can be extrapolated through the origin, is systematic error absent. Even so, for the extrapolated region itself, nothing can be said about the systematic errors. It is also possible that the added element is present in a different oxidation state or in a more reactive compound than it is in the sample, and thus behaves differently.

(3) If the element to be determined has a radioactive isotope with convenient half-life and decay pattern, then the systematic errors can be reduced by using isotope dilution analysis.[59–66] A small amount of the radioactive isotope is added to the sample before the analysis, and the activity is followed till the end of the procedure. The result is then corrected according to the radiochemically determined yield.

(4) By far the best solution lies in optimizing the procedure so that the systematic errors are reduced to a minimum. Comprehensive statistically significant yield determinations are rather laborious, but always worthwhile. Whenever possible, radiochemical tracer methods[59,61–63,65] should be used. In applied extreme trace analysis the goal is generally reached by a combination of routes.

Calibration problems

The majority of direct instrumental methods of trace analysis are matrix-dependent, and rely on comparison with analysed standards. But if the concentration levels are very low, reliably analysed samples of similar composition to that of the unknown are generally not available. Only in a few cases can high-purity materials such as water, gases, mercury, aluminium, germanium and arsenic be doped to make suitable standards and even then the homogeneity of the product is always open to doubt. Standard addition procedures and the use of internal standards have their limitations, as already mentioned. A further possibility is to calibrate by using very small samples, weighed on an ultramicrobalance, of accurately analysed standards with relatively high contents of the element sought. By using such a procedure it is possible to calibrate a method for the determination of carbon in high-purity iron, with ordinary steel samples as standards.

In contrast, methods of determination combined with separation techniques are much easier to calibrate. Standard solutions around 10^{-3}–$10^{-4}M$ and prepared from high-purity materials, may be handled with ultramicro pipettes or burettes[1] readable to 0·01 μl, allowing most solution techniques such as emission spectrography, atomic-absorption spectroscopy and inverse voltammetry to be calibrated for many elements even in the picogram range, in some cases with statistical errors $<2\%$. In this way separation and determination methods can compete in many cases with direct determination methods of high sensitivity such as neutron activation analysis and solid-source mass spectrometry.

SOURCES OF ERROR AND MINIMIZATION OF ERRORS

As a general rule the blank value (impurities introduced by reagents, apparatus and laboratory air) primarily affects the reproducibility and limit of detection of an analysis while adsorption and volatilization tend to affect the accuracy. The order of magnitude of the individual errors varies greatly from element to element, and from one dissolution and separation procedure to another, so that the following considerations can only be considered as generalizations.

The laboratory

Special standards of cleanliness must be adhered to in laboratories where extreme trace analysis is to be carried out.[10–12,14,16,18,19,67] In addition to the particularly common elements in air, such as Si, Al, Fe, Ca, Na, K, Mg, C, Ti, Cl, P and S, the atmosphere in densely populated areas also contains less common elements including Pb, V, Zn, Ni, Cr, Cu, Br and F at concentrations above 0·1 μg/m^3.[68,69] In laboratory air these and other elements such as mercury may be present at much higher levels. The dust in laboratories contains many unusual elements at low levels, depending on the type of work normally being carried out. Thus Ag, Au, Ga, In, Tl, Bi, As, Sb have all been found in relatively high concentrations.[14] The sources of all these impurities, which should be sought both outside and inside the laboratory, include building and industrial dust, rust, exhaust fumes and gases from motor vehicles and factories, as well as natural materials such as pollens. Thus microparticles of the most diverse compositions may be derived from wear on floors, walls and ceilings, from clothing and from the skin of persons working in the laboratory. Air-dried healthy skin has been shown to contain typically about 6 ppm Zn, 0·7 ppm Cu, 0·03 ppm Ag, 0·77 ppm As and 0·002 ppm Au.[70] Traces of silver and gold may be derived from articles of jewellery, and traces of zinc from cosmetics.

Corroding constructional materials considerably increase the levels of Fe, Cr, Ni, and Mo, and increased levels of Cu and Zn may be traced in many cases to heating equipment such as water-heaters, steam-baths, sand-baths and gas burners. The evaporation of solvents from floor polishes can add to the C and P levels of the atmosphere, and also cause periodic variations in these levels. Gas flames contaminate the air heavily with S; detergents and cleaning materials introduce Na, Mg, B, P, C, S *etc.*[1]

The use of plastic glove-boxes which can be flushed with purified air or an inert gas, helps to reduce all sources of contamination very considerably.[14,16,18,71] Special arrangements have also been described[71] for working with a dry atmosphere. Instead of work in the open laboratory for the dissolution of samples or evaporation of solutions, completely sealed vessels are used,[1,6,72,73] or the whole analytical procedure takes place in a closed, programmed system in which the sample is protected from contamination from the air at all stages except the first one of transfer to the system.

Nowadays, however, even more stringent purity conditions can be achieved. The development of high-capacity air filters has progressed so far in recent years that whole rooms may now be maintained substantially free from dust and suspended particles.[74,75] Such "clean rooms" are flushed with a laminar flow of clean air, either horizontally or vertically, and may only be entered through air-locks, with specially dust-free protective clothing being worn. There are three standards of cleanliness.[75] In class I rooms—those with the highest standard—there should be, per cubic metre, fewer than $3{\cdot}5 \times 10^3$ particles with size above 0·5 μm, and none greater than 5 μm. When planning our own laboratories for the analysis of high-purity materials, we adopted a slightly less stringent but nevertheless very effective approach. In clean rooms of class III (non-laminar flow; $3{\cdot}5 \times 10^6/\text{m}^3$ and $25 \times 10^3/\text{m}^3$ for 0·5–5 μm and 5 μm particles respectively) "clean benches"[76] have been set up. They have the dimensions of normal fume-cupboards in chemical laboratories, and are flushed with filtered air according to the laminar-flow principle (Fig. 1) in such a way that chemical vapours can be sucked outside the clean area altogether. This concept permits all chemical stages of sample preparation, up to introduction of the sample into the instrument, to be done on the "clean benches", and also the instruments such as spectrographs, gas chromatographs, *etc*, to be kept in a state of highest cleanliness, and with full air-conditioning. For work in a metal-free environment the inside of the "clean bench" should be completely lined with polypropylene.

The residual dust-particle count in a clean-room, and the particle-size distribution must be continuously monitored by light-scattering measurements in order to detect leaks or sources of turbulence in good time. The rooms should be laid out and equipped so that at least 25 m^2 are allowed per person working there. The sole source of heat in these rooms should be electrical elements sealed into quartz.

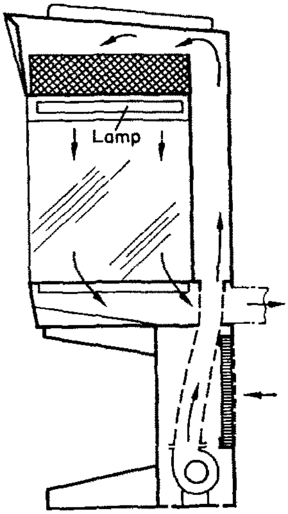

FIG. 1.—Cross-section of a "clean bench" working on the principle of laminar flow downwards displacement. (South London Electrical Equipment Co. Ltd., London, S.E. 13)

By working with a "clean bench" instead of a glove-box in the determination of silicon in high-purity materials, it has been possible to reduce by a factor of more than ten, the blank value due to contamination from laboratory air.[77]

Exchange processes between solutions and vessels

Even highly polished glass and quartz surfaces possess a much higher active surface area than their apparent geometrical surface area would suggest, since they still possess quite a marked surface structure, in terms of irregularities of the order of 0·1 μm depth or less. This results in pronounced adsorption and desorption exchange reactions taking place between the surface and the solution. As a rule, such effects first become noticeable at concentrations below $10^{-3}M$, as slow time-dependent changes in concentration. In very dilute solutions, however, the decrease in concentration can be quite rapid. On the other hand high purity acids, alkalis, and solutions of complexing agents tend to dissolve impurities out of the surface (see below) and both effects could be operative.

Adsorption. Very few measurements on adsorption of ions from aqueous solutions on to surfaces in common use for trace analysis can be usefully compared, since a multitude of parameters such as container material, nature of the ions, concentrations, pH values, other ions present, contact time, and, not least, the manufacture and pretreatment of the surface all complicate the investigations. In addition, the processes of ion-exchange must be considered.[78] The losses would seem to amount to something of the order of 10^{-9}–10^{-12} mole/cm^2. In many cases the effects decrease for the sequence of materials borosilicate glass, soda glass, platinum, silica, polythene, polypropylene, Teflon.[79–83] But there are many exceptions. For example, Ce^{3+}, Be^{2+} and La^{3+} are more weakly adsorbed onto glass than onto polypropylene from aqueous solutions,[84] and the same has been shown to hold for phosphate.[85] For aqueous $^{60}Co(II)$ solutions ($2 \times 10^{-5}M$) increasing adsorption was found, in the sequence silica, Teflon, polythene, glass, at pH 9, but at pH 1·5 silica adsorbed more strongly

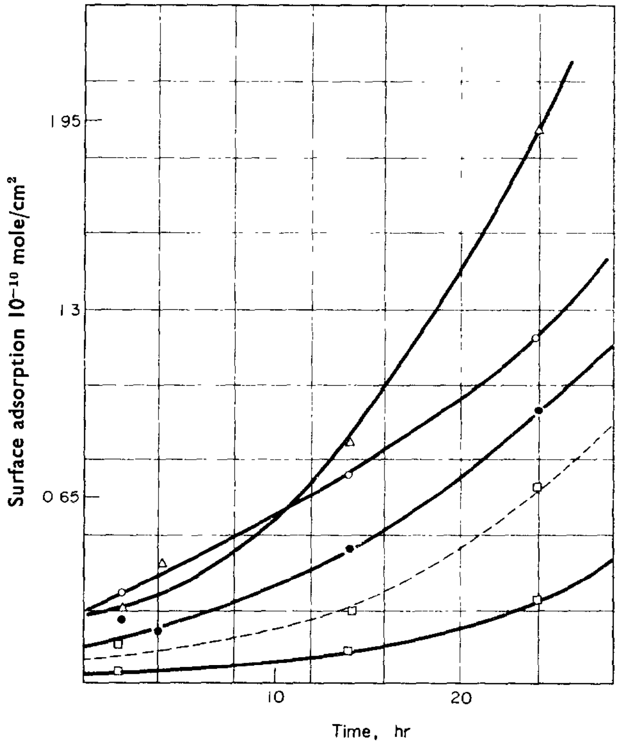

FIG. 2.—Adsorption of ^{60}Co(II) ions on different materials at pH 9 as a function of time.

—△— Glass G20, polished

—○— polythene
- -□- - fused silica, grinded
—●— Teflon

than Teflon (Figs. 2 and 3). Studies with ^{65}Zn(II) at the same concentration and under the same conditions showed adsorption increasing in the sequence Teflon, polythene, silica, glass at pH 9, whereas at pH 1·5 silica adsorbed more weakly than polythene.[86]

The dependence of the adsorption on the nature of the ion may be gathered from the following examples: Pb^{2+} and H^+ are more strongly adsorbed on glass than are Cu^{2+}, Ba^{2+} and K^+.[87] Silver ions show a pronounced tendency to be adsorbed from aqueous solutions onto glass,[79] as do Th^{4+} ions from uranyl nitrate solution.[78] Zinc is adsorbed much less strongly than cobalt.[86] Long-term studies with the ions of Sc, Fe, Zn, Co, Pb, Ag, In, Sb, Cs, U and Sr in aqueous solutions have shown differences in their behaviour towards polythene and Pyrex glass.[88] A change in oxidation state of an ion also affects the adsorption properties.[89]

The adsorption of one ionic species can be strongly affected by the presence of another in the same solution; for example, the adsorption of aluminium on silica is strongly reduced in the presence of sodium chloride.[90] Generally speaking, metal ions are less strongly adsorbed from acid solutions than from alkaline or neutral ones. In the case of ^{60}Co(II) and ^{65}Zn(II) ions, adsorption increased markedly above pH 8 on Teflon and polythene, and even more so on glass. Depending on the contact time, the adsorption is 10–20 times as great at pH 9 as at pH 5.[86] Naturally the dependence

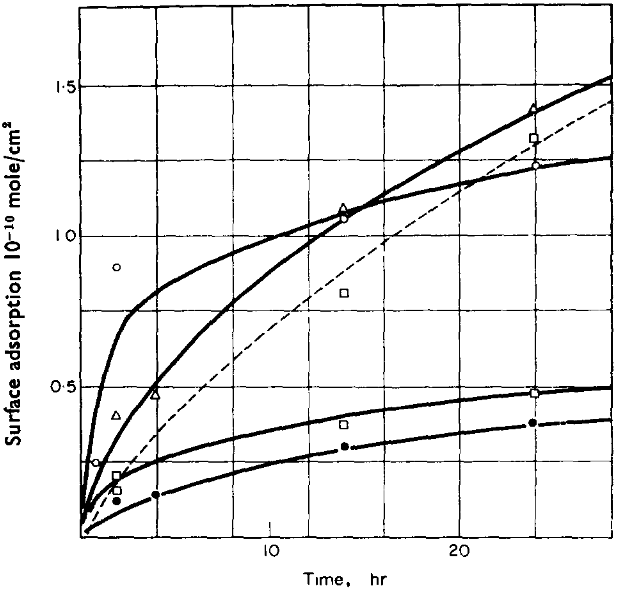

FIG. 3.—Adsorption of ^{60}Co(II) ions on different materials at pH 1·5, as a function of time.[86]
(same symbols as in Fig. 2.)

on pH is much greater in the case of glass or silica, and not only are there small variations, but completely different dependences, as exemplified by thorium adsorption glass and polythene.[89] Cations which tend to form colloids (*e.g.*, Tl^{3+}, UO_2^{2+}, Y^{3+}, Ru^{3+}) exhibit a maximum adsorption at a pH dependent on the isoelectric point.[19,20]

Reproducible adsorption of an ionic species presupposes that the surface remains the same, and hence the processing and pretreatment of the surface of the apparatus play an important role. Chromium is very strongly adsorbed onto glass surfaces from chromic acid: glassware to be used for trace analysis must therefore not be cleaned with this reagent. Treatment of glass surfaces with silicones brings about little improvement; the films are not resistant to alkali, and in any case tend to introduce other impurities into the system.[84]

For most purposes it is recommended that apparatus be degreased with acetone, and left standing for some time in acid. The particular effectiveness of the acid treatment is attributable to the strong bonding of hydrogen ions to glass surfaces.[87]

Comparative experiments using ^{60}Co(II) solutions and glass or silica surfaces showed that adsorption was reduced much more by soaking for one hour at room temperature in 2% hydrofluoric acid, or boiling out with 6*M* hydrochloric acid, or soaking for five hours in hot 2*M* sodium hydroxide, than by simple steam treatment. Minimum adsorption was found to occur after boiling with 6*M* hydrochloric acid.[86]

Most ionic species are retained by filter paper in amounts depending on the nature and concentration of the ion, the paper, and the pH, but varying between 10^{-4} and 10^{-7} g/cm². Adsorption on to pure asbestos, glass-wool, and cotton-wool is of the same magnitude.[19] Because of this, if at all possible filtration should be avoided in cases when the ions sought are those remaining in solution after a precipitation; An exception is the separation of elements by co-precipitation; here the important factor is interference from foreign ions introduced by the material of the filter (see below).

As our present knowledge of the adsorption behaviour of ionic solutions is so limited when compared to what we know about the materials used in trace analysis, the results just presented should in no case be generalized; in the investigation of any new separation procedure for trace quantities, studies on adsorption must be included. The adsorption of water and gases depends on more than just the humidity or the partial pressure, as the case may be, and the temperature; it is also strongly dependent on the nature of the material and the previous treatment of the surface. The amount of water adsorbed on glass[1]—depending on the type of glass—varies at room temperature between 0·3 and 20 $\mu g/cm^2$. Simple soda glasses,[91] silica and platinum show rather little adsorption, but in contrast, agate[92] can adsorb up to 160 $\mu g/cm^2$. Silicate-rich soda-lime glasses adsorb less than high-alkali ones. Artificial aging by steam treatment is said to diminish the adsorption of water.[92] This is an important source of error in the determination of trace amounts of water and oxygen in high-purity materials, and one which controls the limit of detection in all conventional methods for the determination of oxygen, if the oxygen content of the adsorbed water or the oxide film on the sample is of the same order of magnitude as that of the sample itself. In such cases it is only possible to obtain an accurate value by using the temperature gradient method[93] or activation analysis.[94,95]

Desorption. Since neither completely pure nor completely inert materials are known, great difficulties are encountered in the preparation, storage, and usage of not only corrosive acids, alkalis, and solutions of complexing agents but also high-purity water, without the introduction of contaminating residues from the materials of the containers. Errors in trace analysis, from these sources, are increased by long storage and use of high temperatures. Here only the question of storage of high-purity reagents will be discussed. Yet again our experience is severely limited, as the procedures used depend on the particular reagent being investigated, and the methods are very tedious.

For long-term storage of reagents only vessels of quartz, Teflon, and in some cases polythene or polypropylene[96] should be used. Results are available from long-term studies on these materials exposed to hydrofluoric, hydrochloric and nitric acids, and also to pure water.[16,97] Twenty-two elements were sought spectrographically. The levels of twelve were below the limits of detection (Bi, W, Ga, In, Au, Ag, Mo, Sn, Sb, Tl, Ta and Zn). The amounts of Al, Fe, Ca and Mg in the acids stored in Teflon and polythene vessels changed very little during the thirty days storage. Nitric and hydrochloric acids took only a very small amount of magnesium from silica. When high-purity water with Ca, Mg, Ti and Cu contents in the range 10^{7}–10^{-10}% was stored in Teflon or polythene for thirty days, these levels increased by factors between five and ten, and in addition small amounts of Al, Fe and Cr were found. After prolonged storage only the concentrations of Cr and Cu showed any further increase. It follows, then, that water remains pure only when stored for short periods. The advantageous adsorption and desorption properties of high-pressure polythene (low-pressure polythene is entirely unsuitable) and of Teflon towards inorganic ions should not be allowed to obscure the fact that other types of interferences may be introduced. Polythene especially, even after suitable treatment, releases organic reducing substances with the result that ions in higher oxidation states (e.g., CrO_4^{2-}, MnO_4^-, Ce^{4+}, BrO^-) are rapidly reduced. It is also known that solutions of ammonia stored in polythene become more dilute with time. Impurities found in solutions that have been kept in polythene sometimes cause interferences in ultraviolet spectrophotometry,[98] and in many electrochemical methods of analysis.[14] High phosphorus blank values have been recorded when silicomolybdic and phosphomolybdic acids are shaken with butanol in polythene vessels.[99]

More than twenty elements have been found to occur as impurities when low-ash filter papers are used, being either desorbed from the filter paper or introduced by dissolution of the ash during analysis. The major contaminants are Si, Ca, Mn, Pb and Zn.[19]

Reagents

In extreme trace analysis of solutions, the greatest care and attention must be paid to the reagents used, as the degree of purity obtainable varies very much from one reagent to another, and from element to element. The levels of the commonly encountered contaminants Si, Mg, Al, Ca, Mn, Fe, Ni, Cu and Pb[19] may, by appropriate procedures, be reduced to around 10^{-7}–10^{-9}%, and for less common elements even lower levels may be achieved. The preparation of reagents in a dust-free atmosphere may reduce the contamination by more than an order of magnitude. The commercially available "Suprapur" reagents as a rule do not satisfy the standards required by extreme trace analysis, since the control of impurities is usually restricted to only a few elements, and also since introduction of impurities from the storage vessel will proceed uncontrolled. The only way to be sure of the purity of a reagent is by regularly checking it, and therefore it is best whenever possible, to use only a few easily purified reagents such as, in addition to water, hydrochloric, hydrofluoric and nitric acids, aqueous ammonia, ammonium chloride, and some organic solvents.[1,3,6,12,17,18,67] Often it is sufficient to remove only the interfering impurity; special purification procedures may be devised based on combination of distillation, co-precipitation, liquid-liquid extraction, adsorption, *etc.* see *Separation of the matrix*, below.

One can reach particularly high purities with gases[100]—such as oxygen or hydrogen—which are particularly suitable for destruction of organic material (see *Decomposition methods*) or—such as helium, nitrogen and argon—are used as carrier gases.

One major problem is the storage and stability of very dilute standard solutions. The best storage conditions should be determined beforehand (see above). In addition to the phenomena of adsorption and desorption, the effect of exposure to light and to heat should be considered.[101] It is advisable to keep such standard solutions as relatively concentrated stock solutions, and to dilute them by using calibrated pipettes and standard flasks (of silica) immediately before use, or, better, to use solutions with concentrations $>10^{-4}M$ in microburettes with attached storage compartments.[1] The surfaces of all the apparatus should be equilibrated with the solution by shaking for some hours with a portion of the solution, discarding that portion, and filling up with a second portion for storage and use. It is good practice to keep the same apparatus always for the same concentrations of the same solutions, as they are then permanently equilibrated.

The purest reagents may be kept for long periods deep-frozen at $-25°$ without undergoing any change.[102] What has been said about attainable purity of reagents and solutions applies equally to electrode materials, *e.g.*, mercury and graphite for use in electrochemical separation procedures and inverse voltammetry, or to graphite and high-purity metals (Al, Cu, Au) to be used as electrodes for solution spectrography. It may be assumed that graphite used for electrodes contains, apart from some silicon and boron traces, no impurities in its core. Surface contamination is best removed by heating for a short time in an inert atmosphere in an induction furnace at 2500–2700°.[103]

Loss and volatilization

Even at room temperature, solutions of mercury(II) containing reducing agents lose mercury to the atmosphere. This loss can be prevented by adding a small excess of some oxidizing agent such as permanganate.[104]

Volatile chlorides of, for example, Hg^{2+}, Sb^{3+}, As^{3+} and Se^{4+} tend to be lost from hydrochloric acid solutions, and in contrast, Cr^{3+} tends to be lost from perchloric acid solutions at temperatures above 150° through formation of chromyl chloride. Slight differences in volatility of chlorides are found when samples are fumed with perchloric or sulphuric acid, for example with As^{3+}, Sn^{2+}, Ru and Os.[19] In some cases the fluorides and bromides behave differently. When metals are dissolved in non-oxidizing acids, some elements, including Si, P, As, Sb and S, may escape as hydrides. Traces of boric acid volatilize even evaporation of aqueous solutions, but the loss can be reduced by addition of mannitol or glucose.[19] Of course the problem of loss by volatilization is one which becomes much more serious when methods of dissolution and attack at high temperature have to be employed and in such cases must be given due consideration.

PREPARATION OF SAMPLE

In principle all stages in the preparation of the sample, including sample-taking, transport, storage and processing, should be considered in an assessment of the sources of error. The following example will illustrate the problem of storage. The carbon content of metal powders can be increased markedly when they have been stored for a length of time in plastic foil; the carbon in the plastic migrates on to the very large surface area of the metal powder.[105] The same applies to the chlorine, sulphur and antimony contents after storage in plastic foils containing these elements, or in rubber.[106]

Mortars and grinding vessels made of porcelain, agate and sintered corundum *etc*, contaminate samples as a result of wear;[16,19] only vessels made of crystalline corundum or boron carbide are effectively resistant to wear.[67] Solid samples should therefore at most be broken into coarse pieces, and never pulverized, even if this results in a much longer digestion being needed to dissolve the sample. Larger metal samples are best broken up in a spark-erosion machine, with electrodes made out of the sample to be analysed, or by irradiation with a laser beam[107] or, if they are very hard, by cutting with a diamond saw. Brittle materials should be wrapped in polythene film and crushed with a few hammer blows. The coarse pieces must then be etched with purest hydrochloric, hydrofluoric or nitric acid (or their mixtures), depending on the sample, in order to loosen and remove impurities trapped on the surface during the crushing.[102] Care must be taken during the final rinsing with high-purity water, and drying, that no contamination is introduced from impurities in the air. Surfaces can also be cleaned by bombarding them with noble gas ions, usually argon.

Organic samples such as biological material or food should not be ground up, but if this is unavoidable, the sample should be deep-frozen, and ground in a silica mortar cooled by liquid air. Liquid samples such as blood, vaccine and urine may be concentrated by freeze-drying.[108–110]

OPENING-OUT PROCEDURES

Before enrichment or separation of the trace elements sought, the sample must be brought into solution, and decomposition methods are usually used. The optimum conditions for decomposition are a favourable ratio of the sample amount to surface area of crucible, only a small excess of reagents which can be easily purified, and work in a clean atmosphere. Volatilization of elements must be prevented, or allowed to proceed quantitatively so as to provide a means of separating these elements. Exchange reactions between the melt or the solution and the vessel surfaces should be minimized. Volatilization of many elements, whether as such or as halides, oxides or hydrides, is conveniently studied by use of radioactive isotopes.[111,112]

The dissolution or fusion of inorganic matrices is naturally associated with more problems than for organic materials, which is evident from the sometimes completely different procedures used.

Inorganic matrices

When dealing with the opening out of inorganic matrices account must be taken of the numerous matrix elements and their possible combinations, with the result that a great variety of methods has to be used.[16,111,348] Most pure substances will dissolve in acids or mixtures of acids (Table II) though some will volatilize in the process, allowing determination of trace elements in the residue.[67] In some cases a metal matrix may be separated very elegantly by volatilization as an organometallic compound as for example aluminium[113] in determination of traces of the alkali metals in pure aluminium. Conversely, volatile trace elements may be separated from a non-volatile matrix by distillation in a quartz or Teflon apparatus and transferred with or without the aid of a carrier gas to a receiver, as for example, Si,[36,114] Cl,[115,116] Re,[117] Os, Ru,[118–120] As,[16,36] or Se.[121] Gas evolution methods have proved themselves suitable also in determinations of sulphur[16] and of arsenic.[16,122,123]

Much more difficult is the opening out of acid-insoluble materials such as quartz, silicates, many minerals and ores, which can only be brought into solution by fusion or sintering methods (Table III). Very high blank values are often introduced by the solid fusion mixture, which can only be purified with difficulty, and which attacks the crucibles at the high temperatures used. The crucible material must also be carefully chosen as it may sometimes react with the trace elements. Losses as spray or from spitting can be avoided by taking special precautions.[1]

Fusion and sintering procedures have very limited usefulness in extreme trace analysis, and decomposition in the gas phase (Table IV) is much more important. Gases can be prepared in a very high state of purity, and the very pure silica used for the reaction vessels (Fig. 4) shows little tendency to react with the volatile reaction products. Only in a few cases—mainly at very high temperatures—do products diffuse into the silica surface.

Special decomposition procedures are used in the conventional determinations of gases, carbon, sulphur, *etc* in high-purity metals. Samples are melted or burned in

TABLE II.—ACID DECOMPOSITION METHODS FOR HIGH-PURITY INORGANIC MATERIALS

Acid used for decomposition	Matrix		Crucible material	Volatile trace elements*	Remarks
	non-volatile	volatile

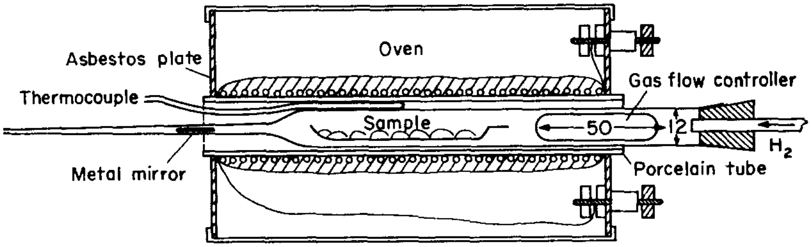

FIG. 4.—Arrangement for gas-phase distillation.[310] The volatile element or a volatile compound of the element is driven off from the sample by heating in a suitable atmosphere.

an atmosphere of pure carrier gas in tubes made of silica or "Pythagorasmasse" (a high-temperature porcelain), sometimes with flux added. As container materials and fluxes can raise blank values substantially, it is preferable, in order to achieve very low limits of detection, to use high frequency (3–6 MHz) induction heating[95] or to fuse the sample without a container by suspending it free in a specially shaped high-frequency field.[124]

Organic matrices

The majority of organic materials, being composed of only a few elements, are readily ashed dry, or according to procedures outlined in Table V.[112,125–127,348] About half of the procedures in the literature use liquid reagents and relatively low temperatures to achieve decomposition, so that losses through volatilization, adsorption and reaction with vessel materials are limited to only a few elements. For this reason, substances particularly difficult to decompose are occasionally not completely mineralized, or require such a large amount of reagent that the blank value exceeds the permissible limit.

Of the reagents under consideration nitric acid and hydrogen peroxide are available in highest purity. Detailed instructions have been published which effectively ensure that easily volatile elements are retained, and that a minimum amount of reagent is required.[128,339,348]

The oldest and simplest method of dry ashing by heating in a muffle furnace at 400–800° in the presence of air can lead to more or less loss of many elements, including Hg, B, Pb, Zn, Cd, Ga, In, Tl, As, Sb, Fe, Cr and Cu. The addition of fluxes such as sulphur, phosphates, or sulphuric acid, reduces the losses in many cases,[6] but magnifies the risk of raising the blank value. Interaction between the flux and the vessel—such as formation of insoluble silicates from silica and porcelain—and the formation of difficultly insoluble oxides, cause losses which, together with the other disadvantages, render these procedures unsuitable for extreme trace analysis.

Combustion in the oxygen-flask[129–132] offers advantages when readily volatilized elements such as halogens, S, Se, P, B, Hg, As and Sb are to be determined. But for complete combustion of 1 g of material a flask of about 10 l. is required, and hence there is a serious increase in the magnitude of the adsorption errors. A modification of the so-called static combustion procedure, well-tried in micro-elemental analysis, permits the determination of many elements, both volatile and non-volatile, in the nanogram region in samples weighing less than 0·3 g.[133]

Up to 2 g of organic matter may be burned in a 200-ml calorimeter bomb filled

TABLE V.—WET-ASHING PROCEDURES FOR ORGANIC MATRICES

Reagents	Matrix	Remarks
$H_2SO_4 + HNO_3$	plants	The most common procedure; danger of loss of As, Se, Hg and others by volatilization.[6]
$H_2SO_4 + H_2O_2$	plants	Pb is lost by co-precipitation with $CaSO_4$.[331] Ge, As, Ru and Se are also lost.[332]
HNO_3	biological samples	HNO_3 is easily purified; decomposition temperature of 350°.[6] Short reaction time, metal nitrates are soluble.[6,125,333–335] In a PTFE-bomb[338,339]
$HNO_3 + H_2O_2$	biological samples	A rapid decomposition method for small samples at low temperature.[335]
$HClO_4$	biological samples	Catalysts such as $(NH_4)_2MoO_4$ may be added.[6,112]
$H_2SO_4 + HClO_4$	biological samples	Only suitable for small samples.[6,112,348] Explosion danger!
$HNO_3 + HClO_4$	protein and carbohydrate (no fats)	Less danger of explosion; no loss of Pb.[6,112]
$H_2SO_4 + HNO_3 + HClO_4$	universally applicable, even fats and soot	No danger if the temperature is carefully controlled. As, Sb, Hg, Au, Fe and some other elements are volatile; ashing should be done under reflux.[6,112,335,336]
$HCl + KClO_3$	biological samples	Not suitable for trace analysis as too many elements may be lost by volatilization.[6]
$H_2O_2 + Fe^{2+}$	widely used (except fats, oils, dense plastics and carbon)	Ashing occurs through formation of OH radicals, and at about 100°, so there is minimum danger of loss through volatilization. Particularly useful for large samples, and in control of environmental radioactivity.[337]

with oxygen to a pressure of 30 atmospheres. With this apparatus, 1 μg of selenium has been recovered quantitatively by releasing the pressure very slowly after the combustion and passing the gaseous products through a suitable absorption train.[121]

Combustion in a stream of oxygen, so widely employed for determinations of elements forming volatile oxides and other products, requires that a slow, controlled combustion be achieved in order to minimize problems associated with the absorption of the products. Significant improvements on the simple arrangement of silica or Supremax combustion tubes[134,135] are offered by the principle of controlled combustion rate developed by Rademacher and Hoverath.[136]

Special apparatus has been described for handling the combustion of inflammable liquids such as petrol and paraffin.[137,138]

Far and away the best conditions for extreme trace analysis are offered by "low-temperature ashing".[139–142] The sample is slowly burned in a stream of oxygen at a pressure of 2–5 mmHg, excited by a high-frequency field of 300 W at 13·56 MHz, with the temperature between 100 and 200°. Elements still volatile at these low temperatures, such as Ag, Au, Hg, Se and I, may be trapped in a suitable receiver.

This principle has been further adapted by the author and his co-workers[143] to the peculiar requirements of extreme trace analysis: the combustion is carried out in a special, small silica reagent tube fitted with a cold finger (Fig. 5). Excitation of the oxygen is achieved in a microwave resonant cavity operated at 2450 MHz with variable

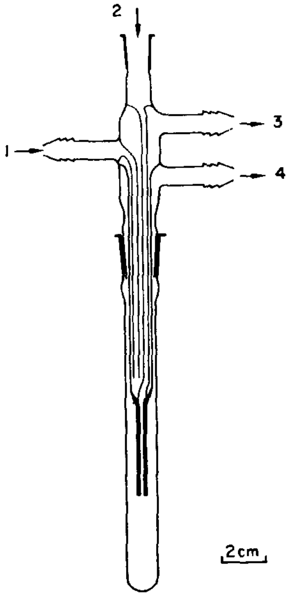

FIG. 5.—Decomposition vessel for cold-ashing of organic matrices before the determination of extremely small amounts of trace elements.[148]

power up to 200 W (Fig. 6). With this source, practically all organic matrices, including plastics, slimes, soot and so on, in amounts up to 1 g, can be completely decomposed, and nanogram amounts of volatile elements may be recovered with yields >98%, With a slightly different apparatus it has proved possible to obtain recoveries of mercury above 91%, also at the nanogram level. This procedure is thus an ideal decomposition technique which, in combination with very sensitive methods of

TABLE VI.—EXAMPLES OF SEPARATION BY CO-PRECIPITATION

Trace element	Matrix	Collector precipitate	Remarks
Se, Te		$Fe(OH)_3$, $Al(OH)_3$, $MnO(OH)_2$	pH 5, strongly time-dependent[121,340]
Te		As	$6M$ HCl + H_3PO_2[340]
Tl		$MnO(OH)_2$	NH_3 in presence of Mn^{2+} and H_2O_2[309]
Cr		Eriochrome Black T + Fuchsin	pH 5·5[282]
Mo	W	Sb_2S_5	Precipitation from tartrate solution with thioacetamide[341]
Pb	Bi, In, Tl	$SrSO_4$	4–$8M$ HNO_3[174]
Ag	Cu	TlBr	$4M$ HNO_3[174]
Hg	Ag	AgI	In presence of EDTA[165]
Se	Ag, Ni, Cu, Co	$Bi(OH)_3$	pH 10–11[174]
Sb, Bi, Pb, Sn	Ni	$MnO(OH)_2$	pH 2–3, Mn^{2+} + MnO_4^- at 70°[342]
Zr, Nb, Ta and others	Mo, W	$Fe(OH)_3$	pH 12[343]
K	Na	Ammonium tetraphenylborate	pH 5, NH_4^+ + $NaB(C_6H_5)_4$[344]

determination, should find wide application in the field of extreme trace analysis applied to forensic and medical science.

Combustion in an oxy-hydrogen flame[144–146] is widely employed in determination of traces of halogens, sulphur, selenium and nitrogen. Pyrolytic decomposition in hydrogen is also becoming more widely used, for example, before determination of traces of carbon, nitrogen, phosphorus and sulphur.[147–149]

SEPARATION OF THE MATRIX OR THE TRACE ELEMENTS

From what has so far been said it can be seen that there is only some point in carrying out a separation of the matrix material, or of the trace elements, when the method of physical measurement does not itself offer adequate selectivity, when calibration problems arise through non-availability of suitable standards, or when the determination of a large number of trace elements in one sample—particularly in ppm microanalysis—is called for. In the last case separation schemes which isolate each individual element are necessary. Separation procedures are also indispensible when traces of elements are to be determined by rather unselective chemical techniques such as kinetic methods, or when the limit of detection can be significantly lowered through the use of multiplication techniques[150,151] as in the determination of titanium,[152] silicon,[153] or phosphorus[154] in terms of the molybdenum in the corresponding heteropolymolybdate.

The ideal separation method should offer a large distribution coefficient, rapid equilibration, minimal interferences at the phase boundary, and low blank values. Only a few typical examples can be given here, from the many possible combinations of decomposition and separation methods which are now in use.

Volatilization methods

These methods are particularly attractive because of the very low associated danger of contamination from reagents. Usually separation occurs simultaneously with the decomposition step.

The matrix element can be separated by evaporation (organic solvents, water, sulphur, iodine, mercury, *etc*) by formation of volatile organometallic compounds (*e.g.*, aluminium,[113] gallium,[155] beryllium[156]) or oxides (B, C, Se, Re, Os, Ru) or by distillation of chlorides (Si, Ge, Se, Te, P, As, Sb, Sn, *etc*).[67,157] Traces can be separated as the element (Hg,[158,159,160] In, Cd,[158]), as volatile compounds ($GeCl_4$, $AsCl_3$, SeO_2, CrO_2Cl_2, As_2O_3,[1,157,161] as bromides of Sn, As, Sb, Se and Re,[162]) as oxides (OsO_4, RuO_4,[119] Mn_2O_7,[163]) or as gaseous compounds (BF_3, SiF_4, H_2S, SO_2, H_2Se, CO_2, AsH_3, PH_3, NH_3, *etc*)[1,161] The determination of nitrogen in high-purity niobium will serve as an example of how experimental conditions may be optimized.[159]

With the normal Kjeldahl method a limit of detection somewhat over 1 ppm may be achieved,[101] mainly because of high blanks from reagents and the laboratory air, and the rather large volume of solution resulting from the steam distillation of the ammonia. The limit of detection may be reduced by almost two orders of magnitude when the sample is attacked in a nitrogen-free argon atmosphere with a mixture of hydrofluoric acid (purified by distillation in a Teflon apparatus) and hydrogen peroxide. A closed-circuit distillation apparatus (Fig. 7) was developed for the final separation of the ammonia. The steam for the distillation is produced in the absorption vessel. Specially purified absorption solution and sodium hydroxide solution

are taken through magnetically-operated valves direct from storage vessels protected from the atmosphere, so that the very low blank value may also be kept constant. The volume of the absorption solution is kept constant at about 2 ml during and after the distillation by balancing the heating of the two flasks. The ammonia is determined directly in the distillation apparatus by coulometric titration with bromine generated *in situ*, with biamperometric end-point detection. As the standard deviation is less than 10 ng, nitrogen at the 1 ppm level may be determined with reasonable accuracy in 100-mg samples.

Precipitation methods

Few successful applications of precipitation as a means of separating a matrix without at least partial co-precipitation of trace elements have been described.[67] A systematic investigation has been made of silver as a matrix.[164] The ions of other metals which normally tend to be absorbed on silver halide precipitates—such as Bi^{3+}, Cd^{2+}, Hg^{2+}, Pt^{2+}, Pd^{2+}, Tl^{+} and Tl^{3+}—will not be co-precipitated if they can be masked as sufficiently stable undissociated molecules or complexes, and quantitative separation of traces of Cd, Pd and Hg from Ag is in this way made possible. The separation of traces of mercury succeeds only under carefully controlled conditions.[165]

One of the exceptions concerns the electrolytic deposition of a number of matrix materials (*e.g.*, Cu, Pb, Zn, Cd, Ni, Co and Fe) at controlled potential on a mercury cathode.[67,166–168] Trace elements, including Be, Al, Ti, Zr, Hf, U, Nb, Ta, W, B, S and P, remain quantitatively in the solution. Conversely, of course, trace elements may be separated from matrix elements of the second group, by electro-deposition on platinum,[67,169] graphite[170] or mercury cathodes,[67] before their subsequent determination.

Radiochemical yield determinations have shown that over 90% of nanogram amounts of Zn, Co and Fe in Nb, Ta and W matrices (in amounts over 100 mg) can be deposited on a mercury cathode and recovered by vacuum distillation of the mercury.[171] Noble metals, either as traces or as matrices, can be deposited on mercury or other less noble metals without the application of any external potential.[67,172,173]

Co-precipitation of traces of elements on suitable collectors has been well studied.[14,67,157,161,174] Co-precipitation may usually be attributed to co-crystallization adsorption, colloid-interactions, or occlusion.[161,174] The collector material—generally a metal sulphide or hydroxide, or an organic reagent—should co-precipitate the trace ion quantitatively but not interfere in the subsequent determination, and should itself be selectively precipitated, in the presence of complexing agents if need be. Organic collectors composed, for example, of a large dyestuff cation (Methylene Blue or Rhodamine B) and a large dyestuff anion (Methyl Orange) offer a number of advantages. The salts are only sparingly soluble in water, they co-precipitate many heavy metals quantitatively and, as they are purely organic, they are readily destroyed and completely removed by mineralization.[175,176] The separation factor (again readily determined by radiochemical tracer methods) depends on the type of collector and the amount used, the presence of foreign ions and complexing ligands, the order of addition of reagents, the acidity, the time of standing of the precipitate, and the temperature. All of these factors should be optimized for a given problem. The well-established theory of precipitation processes allows suitable choice of collector and precipitation conditions.

Liquid-liquid extraction procedures

Solvent extraction methods[6,67,157,161,177–189,190] rank among the most important and most widely used separation methods, partly because the Nernst distribution law is obeyed by most systems down to very low concentrations,[191] and also because nearly every ionic species can form at least one extractable entity such as an undissociated compound, solvated species, ion-pair, chelate, and so on. Synergic effects[178,192,193] which have been shown to occur in some combinations of solvents, add to the number of possibilities.

Matrix elements[194] or traces can be separated, either in groups or individually, and in extremely low concentrations.[6,67,195,347] In contrast to precipitation methods, adsorption at phase boundaries presents no problem in extraction methods and furthermore, equilibrium is usually attained very rapidly. When the distribution coefficient is sufficiently large, large volumes of aqueous solution may be extracted with very small volumes of organic solvent, thus effecting a considerable gain in concentration.

The extracted elements can be submitted to quantitative determination after evaporation of the organic solvent, or following a back-extraction into an aqueous solution. Occasionally small amounts of organic solvent remaining can cause interferences in electrochemical determinations, and in such cases they must be destroyed by fuming with nitric and perchloric acids.

The selectivity of certain reagents together with the possibilities offered by variation of oxidation state, pH, solvent, and addition of masking reagents allow the creation of numerous separation schemes[196–202] by means of which up to forty components can be completely separated from a single mixture, so as to permit their subsequent determination. Such procedures are indeed valuable in ppm-microanalysis when many elements must be determined in just one 100- mg sample.[203]

Solvent extraction methods can of course be combined with other separation procedures, particularly co-precipitation[67,204–209] and ion-exchange.[210–211]

If the extractable ion is also coloured a direct spectrophotometric determination becomes an obvious choice.[179] Sometimes it is possible to determine ions directly in the organic phase polarographically after addition of a suitable electrolyte. Substoichiometric extraction methods[64] are finding increasing application in activation and isotope-dilution analysis.

Ion-exchange procedures

These procedures[67,212–223] are universally applicable to the separation of ions of opposite charge (cation–anion separations) and of like-charge ions (ion-exchange chromatography) both for matrix–trace separations and for handling mixtures of trace ions. Cation- and anion-exchangers based on organic polymers are to be preferred, used either in columns or as impregnated papers[224,225] and with aqueous or organic solvents.[222] Anion-exchanger resins make possible good separations of transition elements as anionic complexes.[226] Combined ion-exchange–extraction procedures in which some species out of a group of ions are selectively held on a resin and then eluted into an organic phase have proved useful in certain problems.[223] Liquid ion-exchangers offer further possibilities.[178,227]

Small beads of ion-exchange resin of reproducible size and loaded with one particular ionic species are useful as a means of standardizing trace analytical procedures.[228] Redox exchangers[228] have been used for the preparation of oxygen-free water, and for the removal of peroxides and metal ions from organic solvents.

Chelating ion-exchange resins[229] have many applications in trace analysis, though only a few extensions to extreme trace analysis have been described, such as for example, the enrichment of gold in natural waters.[230] The same can be said for ion-exchange resin membranes,[231] which have been used for the separation of traces of boron in silicon,[232] or of trace elements in biological samples.[233]

When ion-exchange resins are used to extract only the trace ions, a large volume of sample solution can be poured through a relatively small column with low exchange capacity, or just filtered through a paper impregnated with ion-exchange resin. In addition to separation, enrichment is achieved by eluting with a small volume of solution. In such cases it should be remembered that the distribution coefficients of the trace ions between solution and resin are appreciably smaller in the presence of large amounts of other ions than for pure, dilute solutions.

In the case of retention of the matrix ions by the resin the trace ions will remain in a rather large volume of solution and will have to be concentrated by boiling down the solution, which in turn adds to the sources of error. In addition, when large amounts of matrix material are held on the resin, the capacity is rapidly exhausted and the distribution coefficient falls. The answer to this problem lies simply in the use of sufficiently large columns of adequate capacity.

The use of ion-exchange resin in extreme trace analysis is limited by two sources of error: irreversible adsorption of small quantities of material, and contamination of the eluate by the resin (traces of iron, for example, or organic material such as the resin itself). Organic impurities particularly affect electrochemical methods. Sometimes the interferences can be reduced by pretreatment of the column with suitable acids or bases, by a change of elution conditions, by use of radio-active isotopes[234] (dilution analysis), by ashing the resin and determining the trace ions in the ash (*e.g.*, by use of oxygen gas excited by a microwave discharge[235]) or by direct excitation of the absorbed elements on the resin, *e.g.*, with X-ray fluorescence analysis.[236–239]

Specialized separation procedures

While those techniques already discussed are as applicable to separations of macro- from micro-components as to further separations of groups of trace elements, thin-layer, paper, and gas chromatography and related techniques are certainly microchemical in scope.

Practically all ions can be separated on a sub-micro scale by thin-layer chromatography.[240–242] Extremely thin films of metal oxides (less than 20 μm thick) deposited by evaporation *in vacuo* (*e.g.*, of In_2O_3[243]) or by anodic oxidation of metal plates such as aluminium, have been used for thin-layer chromatographic separations of sub-microgram amounts of many ions.[240–242] Metal chelates such as dithizonates and dithiocarbamates have been separated and determined in picogram amounts on 6-μm thick alumina films.[244] The limit of detection can be lowered even further by procedures such as the following: metal chelates with polychlorinated xanthates (*e.g.*, hexachlorobicycloheptene derivatives) may be separated by conventional thin-layer chromatography, and the metals determined indirectly after thermal decomposition of the chelates, as the polychlorinated alcohol is detected by GLC with an electron-capture detector, with sufficient accuracy even at levels of less than 1 ng.[245]

The possibilities of paper chromatographic and electrophoretic separations of elements in microgram amounts will not be discussed in this review. Usually the limit of detection for these techniques is no lower than 100 ng. The ring-oven technique[246] and others developed from it are well suited to rapid separations of trace elements[247,248] when the matrix has already been removed by some other method. Under certain circumstances the technique may be coupled with the use of isotope exchange reactions to permit determination of elements in nanogram amounts.[249–251] A paper chromatographic separation employing a specialized technique[252] permits the separation of trace elements from a matrix with an enrichment factor of 10^4.

Though gas chromatographic separations of metal chelates[33,253–256] and of non-metals in the form of compounds formed from anions[257,258] are possible, separations at the nanogram level are beset by many problems. On the other hand isolated determinations such as those of beryllium[259–261] and chromium[262] with trifluoroacetyl-acetone,[259–261] nickel, zinc and others with polychlorinated xanthates,[245] selenium as selenate esters formed from SeO_2 and certain polychlorinated alcohols[263] or as 5-chloropiaselenol,[264] can be achieved either directly or indirectly by use of special detectors after separation by gas chromatography.[345]

In choosing the type of column precautions should be taken to avoid any irreversible exchange reactions with the stationary phase. Special techniques are necessary for concentrating, evaporating, and injecting μl volumes of solutions on to the column.[245]

Gas chromatographic methods are of great importance in the determination of very low levels of impurities in gases[265] and of gases and non-metals (H, C, O, N, S, P and others) in solids such as metals and semiconductors. Gases (*e.g.*, H_2, N_2) isolated from the matrix or gaseous reaction products such as CO_2 CO, SO_2, H_2O, NH_3, H_2S, *etc*[95,266–268,346] may be separated by gas chromatography and determined in amounts less than a nanogram with suitable detectors.[269–271]

A number of separation procedures based on selective freezing out, absorption or diffusion (*e.g.*, of hydrogen through palladium[100] or of helium through silica or certain glasses[272]) complete the range of techniques available for gaseous samples.

Zone-refining[273] has been shown in recent years to offer interesting possibilities for the enrichment of trace impurities in high-purity materials without the use of additional reagents,[283,274] and also, in contrast, for the separation of "impurity" metal chelates from large excesses of the pure reagent,[275,276] for example, from 8-hydroxyquinoline.

Acknowledgement—I should like to thank Dr. I. L. Marr, Aberdeen, for his kindness in translating this paper into English, my colleagues Dr. E. Grallath, Dr. V. Krivan, and Dr. P. Tschöpel for their helpful criticism, and Miss I. Lorenz and Miss U. Nagorny for their assistance in preparing the manuscript.

Zusammenfassung—Bei der Bestimmung von Elementgehalten im ppM-Bereich in anorganischen und organischen Matrices helfen Lösungsverfahren, Eichprobleme zu vereinfachen und Nachweisgrenzen zu senken. Der erste Teil des Übersichtsreferates behandelt unter Berücksichtigung von ca. 350 Literaturstellen und Erfahrungen des Autors auf diesem Gebiet die vielfältigen Methoden zur Probenvorbereitung, zum Lösen der Proben und zur Isolierung von Spurenelementen vor ihrer Bestimmung und die Problematik der Fehlerreduzierung bei diesen gegenüber direkten Bestimmungsverfahren zusätzlichen Operationen.

Résumé—Dans le dosage d'éléments au niveau de la ppM dans les matrices minérales et organiques, les techniques en solution sont utiles parce qu'elles simplifient les problémes d'étalonnage et améliorent la limite de détection. L'auteur passe en revue, à la lumière de sa propre expérience, quelques 350 publications traitant de méthodes de préparation et de dissolution d'échantillons et de l'isolement d'éléments à l'état de traces avant leur dosage. Les erreurs dans ces méthodes, rendues plus difficiles à réduire à cause des opérations supplémentaires exigées, sont comparées à celles associées aux méthodes plus directes.

TALANTA REVIEW*

DETERMINATION OF WATER

CLIFFORD HARRIS†
88 Charlton Road, Keynsham, Nr. Bristol, U.K.

(*Received* 15 *October* 1971. *Accepted* 7 *May* 1972)

Summary—The complexity of the subject and the problems involved in the estimation of water in the many materials required to be tested are explained. The various methods available are classified, their techniques summarized, and their applications and limitations indicated. In many materials the determination of absolute moisture is impossible and a compromise must be accepted. Trade and industry require rapid results for many processes and products, and optical or electronic methods are increasingly used in conjunction with reference methods. For official purposes the method of determination must be agreed and stated in detail. More progress in international standardization is very desirable.

A KNOWLEDGE of the water or moisture content of a substance is a matter of universal importance because it is required not only by research workers but by various authorities and firms processing chemicals, foods and other materials. The water content will often determine the nature, consistency and keeping quality or storage properties of a material and will play a large part in the economics of a process, water being the cheapest raw material other than air.

The estimation of water is usually required as part of a general analysis and the water may vary from a trace amount to a quantity approaching 100%; the substance to be tested may be solid, liquid or gas. The method used will depend on the following factors.

1. Availability of the sample and its physical state.
2. Stability of the sample to heat.
3. Presence of volatile material other than water.
4. Retention of water by sample.
5. Amount of water present.
6. Time available and frequency of testing.
7. Cost of estimation.
8. Accuracy required.

It is impossible to determine the absolute water content of the majority of composite materials. Many foods and other organic materials begin to decompose towards the end of a heat-drying process and there may be a slow continuous loss of weight due to substances other than water. Quantity, time and temperature have to be fixed to give a result close to the true water content. Such a result is empirical but usually adequate for the purpose required. The difficulty lies in obtaining agreement between different laboratories, and authorities, and because of this there are many "official

---

† Formerly Chief Analyst, J. S. Fry & Sons, Bristol (Cadbury Bros. Ltd.)

methods" for specified materials (see section on Reference Methods). These methods and associated apparatus are published in detail and if closely followed will give reproducible results. There is a very extensive literature dealing with water or moisture determination. A symposium was held by the American Chemical Society in 1951,[1] and an International Symposium on humidity and moisture was held in Washington D.C. in 1963.[2] Geary (British Scientific Instrument Research Association) reviewed methods for determining moisture in solids in 1956 and again in 1970.[3] Many other reviews deal only with particular materials, *e.g.*, honey.[4]

The present review places emphasis on the practical rather than the theoretical side. References to instruments illustrate principles or indicate types available and imply no special recommendations, being indicative only of the author's experience.

SAMPLING

Results are meaningless if samples are not uniform and representative. Recognized methods of mixing and bulking may be followed but moisture may be lost by evaporation, or gained if the material is hygroscopic. Official tests will give some guidance. Problems occur when solid materials have to be milled or pulverized. Precautions can be taken or a correction made for moisture gain or loss, as the result of trials. Enclosed mixers for blending and grinding are used which utilize high-speed multi-bladed stainless-steel rotary cutters. The general capacity is about 1 litre but much larger ball mills are available. Micro hammer-mills will deal effectively with small samples.[5] Other apparatus can combine grinding with extraction with a solvent such as methanol (see section on titrimetric methods).

Closed containers are required to hold the samples before testing. Liquids are easier to deal with but in sampling them care must be taken to distribute and include sediment or crystals if it is desired to know the water content of the whole. This may be troublesome, for example, with bulk containers of partly crystallized honey or highly concentrated syrups.

The water content of a substance is usually given as a direct percentage of the material as sampled and tested but in some trades the water may be required for practical considerations as a percentage relative to the weight of the dry substance, for example, textiles and wood.

Water retention

Water in solid materials may be held in various ways. It may be present as water of crystallization, *e.g.*, lactose hydrate in milk products. Many pure chemicals exist as hydrates. Water can be held chemically bound in association with protein as in plant cells or organic matter, or absorbed as in fibres; it can exist in pores or as "free" or surface moisture. These are some factors which will influence the choice of method of estimation. In rocks and minerals, water may be loosely bound "interstitial" water, removable at temperatures little above 100°, or chemically bound "constitutional" water, which may be retained in part even at temperatures up to 1000°. Rock analysis is dealt with in the *Appendix*.

CLASSIFICATION OF METHODS

The diversity and overlapping of parts of methods make scientific classification difficult. Some are more or less direct methods; others are indirect. Some require other procedures for calibration.

Classification may be based on physical, chemical, electrical and radioisotope methods, but the following is used in this survey of the more usual methods.

- Drying methods (range of estimation approx. 0–100%)
  - By desiccant
  - By freeze drying
  - By heat at atmospheric pressure
  - By heat under reduced pressure
- Distillation with immiscible liquid—Dean and Stark (range of estimation 0–100% approx. but lower accuracy for water > 20%)
- Titrimetric—Karl Fischer (range of estimation usually 0–15% but can be extended to 100%)
- Optical
  - Refractometric (range of estimation approx. 15–100% for specified solutions)
  - Infrared absorption (range of estimation approx. 0–100%)
- Vapour pressure
  - Equilibrium relative humidity (E.R.H.) and relative humidity (R.H.) (limited ranges of estimation for specified materials)
- Electronic
  - Conductance and capacitance (limited ranges of estimation)
  - Microwave attenuation (range of estimation approx. 0–100%, more usually 5–35%)
  - Nuclear magnetic resonance (NMR) (range of estimation approx. 0–100%)
  - Nuclear radiation (range of estimation approx. 0–100%)
- Miscellaneous
  - Apparatus and methods for specified purposes (various ranges of estimation)

Drying methods

These depend on recording the loss of weight of a solid or liquid after drying or on the gain in weight of a desiccant (gases).

By desiccants. These are among the oldest methods. Drying is carried out, at room temperature for heat-sensitive materials, in a desiccator over concentrated sulphuric acid, sometimes with a supported upper layer of sodium hydroxide flakes, and with or without the application of vacuum. Anhydrous phosphorus pentoxide, calcium sulphate or calcium oxide may also be used, as applicable. Drying is very slow with some materials and the method is not of general use except for isolated investigations of heat-sensitive material.

Techniques are also used whereby dry air or nitrogen is passed over the sample and through a desiccant in a weighed U-tube and the gain in weight is related to water. Heat is used where possible. This procedure may be useful for large samples holding but little water as the U-tube can be weighed very accurately. Gases are tested in like manner if they themselves have no reaction with the desiccant.

Freeze-drying. Drying from the frozen state is often the only safe method of removing water from heat-labile biological substances without producing undesirable chemical changes. Tappel has described a laboratory freeze-drying apparatus.[6] Water is removed under high vacuum from the frozen test substance by sublimation, the receiver being cooled by "dry ice"/acetone or liquid nitrogen (lyophilization). Cell walls are broken down and the water released. The final traces can often be removed by other methods of drying without decomposing the material.

By heat at atmospheric pressure. These methods have the widest application for many solids and liquids, and require relatively cheap apparatus. The results are often recorded as "loss at 100°." Willits[1] reviewed the basic problems of oven-drying, in 1951. The suitably prepared sample is spread over the bottom of a "moisture bottle"—a flat-bottomed shallow dish with ground-glass cover which is used to close the dish before and after the drying process to avoid moisture change during weighing. It is essential that the bottom surface be flat for a drying procedure dependent on heat, so that the heat gain is uniform when a number of vessels are used.

For many purposes flat-bottomed seamless dishes with close-fitting slip-on lids made of nickel, stainless steel or aluminium may be used. The diameter is usually between 4 and 8 cm. Official methods always quote dimensions. Modern aperiodic balances reduce weighing time and minimize moisture pick-up after drying. For batch-testing the lids and dishes are numbered. Some workers stand the moisture dish inside its inverted lid in the oven and if the bottom of the dish and the lid give a flush fit with each other and the shelf there is usually no influence on the result, but official procedure is to partly remove the lid or lean it adjacent to the dish in the oven. A British Standard Method[7] for liquid milk is exceptional in requiring the bottom of the dish to be insulated from the shelf. After drying, the dish is closed with its lid and allowed to cool to room temperature in an anhydrous calcium chloride (or calcium oxide or sulphate or silica gel) desiccator before reweighing. Half-an-hour of cooling may be required, depending on the number of dishes, but the minimum time should be allowed.

About 5 g is taken for a test as this amount gives the required accuracy when using a "milligram" balance. Limitations on weight may be set by bulkiness, or water-retention properties. Official tests will always state the weight, which may be 1–10 g or even much more.

Reproducibility is better than 0·1 % for many materials, which is satisfactory for most purposes, but refined sugar for example will have a water content as low as 0·02 % and results are required to the second decimal place. Weighing then must be more accurate.

The traditional oven had a jacket of boiling water but this type has largely been displaced by insulated ovens with thermostatically controlled electric elements in the base and sometimes the sides, with a fan for circulating the air so that the temperature anywhere on the shelves remains practically constant. A British Standard[8] sets out conditions for laboratory drying ovens and pays particular attention to temperature variation and ventilation.

Drying time may vary from 2 hr to overnight or longer—this being subject to a knowledge of the properties of the test materials. Many official tests require redrying to "constant weight"—often defined as further loss not exceeding 5 mg. Some stipulate a further loss not exceeding 2 mg (0·5 mg for milk products). This provides a check on the ventilation and possible overloading of the oven and is always necessary when testing new substances.

Drying at 100° at atmospheric pressure is not suitable for many substances with a glue-like or syrupy nature, where water-retention properties are strong and where a skin or crust can form. The difficulty can be overcome in some cases by dispersal as a solution on weighed, dried and purified pumice granules or sand in the moisture vessel. The British Standard Method for liquid milk stipulates predrying for 30 min on a steam-bath before final drying in an oven at 100°; evaporated and sweetened condensed milk (weighed) is mixed first with water by means of a glass rod and then with dry sand (both weighed) in a moisture dish, the mixture being predried with stirring on a steam-bath before final drying at 98—100°.[9] The object is to produce an aerated mixture for the final drying and not a hard cake.

Temperatures above 100° are also used. The British Standard (B.S.) for milk powder requires 102–103°.[10] The B.S. for gelatine is 105° for 18 hr after a predrying process to produce a uniform film, by dissolving 1 g in water in the moisture dish and drying on a steam-bath.[11]

There may be shelf-to-shelf variations with individual ovens and it is advisable to make preliminary multiple tests with a uniform sample, placing the moisture vessels in various parts of the oven. Even when an oven with a fan is used, it is possible for results to differ by as much as 0·6% in testing milk powder at a nominal 102°. Temperatures tend to be higher at the sides of the ovens and lower near the doors.

There are several variations of the simple oven. *The Imperial Tobacco Co. Oven*[12] was designed to handle very large numbers of tobacco samples. The steam-jacketed oven is suitable for any material to be tested for "loss at 100°." The steam is condensed and the condensate returned to the electric boiler in the base of the apparatus. Air is aspirated through the central support in the circular chamber and across each shelf before leaving the exit tube. The test-samples are carried on a 10-tier circular rack within the heated jacket and can be removed from the top by lifting back the hinged head of the oven. Heat-gain is constant as all vessels are exposed to the same degree of conduction and radiation and the oven meets the requirements of a uniform temperature of 100° with adequate removal of moist air. For many substances 4 hr drying is sufficient and 80 test-samples can be accommodated.

Moisture in tobacco is legally defined as the loss in weight when tobacco is dried at 212°F and the standard is fixed by the U.K. 1952 Customs and Excise Act as 14% for calculating refund of duty. The Laboratory of the Government Chemist makes 150,000 tests per annum, using *Air Flow Ovens*[13] based closely on the principles of the original I.T.C. oven. The test-samples are dried for 17 hr with an air-flow of 12·5 l./min. Tobacco is bulky and for this reason perforated lids are used which are left on the moisture vessels, even throughout the drying period, to avoid spillage. On removal from the ovens the vessels are not placed in desiccators to cool but are stacked one above the other in special racks so that the holes are covered, the top vessel being empty.

The *Brabender Oven*[14] is a combined oven and balance. Each dish must be exactly the same in weight but there is the advantage that no time is lost in waiting for the dishes to cool in the desiccator. The oven is provided with forced hot-air circulation. A circular support carries 10 aluminium dishes for simultaneous drying and by turning a central knob each dish can be brought over the balance in turn for weighing *in situ* without interrupting the drying, which may be prolonged for a further period if desired. Some workers use the oven at 105° for 1 hr, finding that this gives reasonable agreement with reference methods for many common commodities. Bauer[15] determined the optimum temperature and time for various pharmaceutical products for comparison of results with those given by vacuum drying and the Karl Fischer technique.

The *Mytron Oven*[16] is similar in principle to the Brabender oven but the apparatus is of more recent development. The volume of predried air blown into the drying chamber can be regulated and during the drying process the disc holding the 10 moisture vessels is rotated to give uniform conditions. A switch coupled to the balance controls this rotation and a safety device ensures there is no movement of the disc during weighing. Ten-gram samples are normally tested and the results for loss on drying are projected onto a screen. Thermostatic control is obtained over the range 50–150°. A reproducibility of ±0·1 % is claimed.

The *Carter Simon Oven*[17] is relatively simple and useful for some products which have to be tested regularly throughout the day for process control. It holds three test vessels in line and a freshly weighed one is pushed in through a flap at 5-min intervals. As one goes in it ejects another through the opposite flap so that each spends 15 min within the oven, which is ventilated with preheated air. Such rapid drying demands a high temperature and results are merely empirical. The thermostat must be set for each material, to obtain results as close as possible to those given by a suitable reference method (examples from the author's laboratory are: starch 5 g at 155°, wafer biscuit 2 g at 120°). After the initial delay for cooling, results follow at 5-min intervals—time enough for weighing and calculating results.

Radiant Lamp (*Infrared*) *Moisture Testers* are usually based on a sample being on a balance pan and heated from above by means of an infrared lamp. They usually have the advantage possessed by the Brabender oven, of following the weight loss without interrupting the drying process, which enables time and heat to be standardized to give "moistures" values before loss by decomposition increases unduly. They are useful for routine testing of materials which give up their moisture readily, but the heat of the lamp can be affected by aging and voltage variation and there is no thermostat to correct for this.

Some testers incorporate a voltage controller and this is used to adjust the lamp intensity, thus avoiding adjustment of the lamp height. Analysis in random order of samples with widely-differing water content introduces errors, as low-moisture samples will be heated for longer than it takes to drive the water off, whereas high-moisture samples may not lose all their water in the fixed time interval, and so the calibration for a fixed lamp-height (or voltage) and time holds only for a particular range of moisture contents.

Results obtained by infrared drying are also affected by the thermal history of the apparatus and may become progressively higher as determinations progress throughout the day. Thermal equilibrium is not reached immediately the lamp is switched off, thus starting temperatures are variable unless a fixed sequence is adopted. Nevertheless if due regard is given to these factors when calibrating, moisture testers using infrared lamps can serve a very useful industrial purpose.

Recording Balances are designed so that the sample can be hung from the rear pan of a precision balance of the aperiodic type and be heated in any suitable oven, the weight-loss *vs.* time curve being recorded on a chart for up to several days if required. Rate of loss of free water can be followed and steps on the chart will show the existence of hydrates and transition points—useful for preliminary investigation. Double pen recorders for both weight and temperature are available.[18]

Some tests on hydrates with recording differential thermogravimetric balances have been described by Waters.[19]

By heat under vacuum. As indicated above, many substances will not yield up all their water under the simple application of heat, owing to their strong water-retention properties. During the drying process at atmospheric pressure the vapour pressure of the material decreases and the rate of drying is greatly retarded. Complications are introduced by crust formation producing low results, with decomposition working in the opposite direction to give high results. Fructose (laevulose) will decompose at 100° to give high moisture results for materials containing it, such as honey and invert sugar. Drying under vacuum at a lower temperature can overcome some of the problems if significant amounts of volatiles are not present, and the method is usually quicker. Vacuum drying is now included with officially recognized tests for some materials. Commercial laboratories use vacuum ovens because of their wide general application and the speed with which results can be obtained with otherwise slow-drying samples. Ovens can be obtained either with heated shelves or heated jackets.[20]

It is not easy to obtain an accurate knowledge of the temperature under vacuum as there is a drop in the observed reading, due to slight expansion of the thermometer bulb. A sleeve overcomes this but the temperature indicated is lower than that of the test material. As part of the preliminary testing the thermometer bulb should be placed in the test material in the dish in contact with the heated shelf. Electrical thermistors are best for checking. Under the shelf is a sliding tray which may contain silica gel desiccant. Vacuum is applied by means of an external pump. An oven may hold 10–15 dishes, depending on their size. One pump can exhaust and maintain several ovens under vacuum.[21] Most mechanical ones are fitted with oil traps and non-return valves and some with phosphorus pentoxide moisture-traps. Generally the water evolved by samples under test is not sufficient to cause trouble with modern rotary pumps and the degree of vacuum need not be high. It is best to standardize on a degree of vacuum—some workers prefer 20 mmHg, others obtain more consistent results with pressures of 5 mmHg. A Cartesian-type manostat is used for this purpose in the vacuum line between the pump and the oven(s). Once preset it will allow the pump to exhaust down to the desired pressure and not lower. An accurate barometrically-compensated dial manometer reading directly 0–100 mmHg is required.

The door of the oven is clamped, and made air-tight by a rubber gasket which must be maintained in good condition. Some leak will nearly always be present and this is not a matter for concern provided the pump can cope, as an air-bleed is desirable and some workers introduce one to make sure that there is some flow through the oven. Some official tests require a "bleed" of dry air.

The drying temperature chosen is usually between 60° and 80°; 70° is preferred by some as giving consistent results in a reasonable time without decomposition. Two hr drying may be satisfactory but 4 hr is often used in a standardized procedure with a mixed lot of test-materials. Also for convenience, overnight drying may be used without results being materially different. When the vacuum is first applied, care must be taken that materials do not spatter or foam, and when air is finally admitted it is usual to proceed slowly to prevent powders being blown about. Once started, the vacuum must not be "broken "or aerated materials may collapse and lose the open texture so necessary for the free evaporation of water.

Some materials need pretreatment for successful results to be obtained. Viscous materials such as jams, honey, caramel, nougatine, boiled sweets, require dispersion as a solution on dried, purified sand or 4–8 mesh pumice for results consistent to the first decimal place to be obtained. There are various techniques employed, based on weighing the sample into a moisture dish containing a short glass stirring rod and previously dried (ignited) sand or pumice. Hot water is added and the weighed test substance slowly dissolved for dispersion on the sand or pumice, the stirrer being left in the dish. The mixture is partially predried on a steam-bath with occasional stirring, before final drying under vacuum. A hard skin must not be allowed to form, neither should the mixture be so moist as to spatter under vacuum. Results of multiple tests on the same sample will show if the correct technique is being used.

The *Infrared Vacuum Oven*[22] is useful where single results are required quickly under factory conditions, provided vibration is not excessive, as a test can be completed in about 10 min. The apparatus uses a variable-temperature infrared lamp and a single-pan torsion balance, both enclosed in a chamber which can be evacuated. A 5-g sample is spread on a foil disc and placed on the pan after removal of a counter weight. Very viscous materials may require spreading with a polytetrafluoroethylene roller, followed by re-adjustment of weight. The cover of the apparatus, usually preheated, is closed and clamped and the vacuum applied. The balance beam is restored to its original null position as indicated by an index pointer, by rotating a drum or wheel calibrated directly in percentage moisture. This can be done at the end of an agreed standard time or while drying continues and so its progress followed. The test is an empirical one as with all infrared drying methods, but conditions can be chosen to give results close to "standard" ones.

As practical examples, carbon black heated on heat scale No. 5 attains 140° in 8 min, and drying is complete; application of 80 V for 20 min at 10 mmHg will give a satisfactory result with nougatine. Caramel spatters, however, and this method is unsuitable. For uniform testing it is best to use a constant-voltage transformer if there are mains variations.

Distillation methods—entrainment or azeotropic distillation

The procedure is to heat the sample in a flask with a liquid immiscible with water so that water vapour is carried into a reflux condenser with vapour from the boiling solvent. The condensate is collected in a graduated tube where the water separates and the volume can be read. The Dean and Stark apparatus[23] is much used with immiscible liquids lighter than water, such as heptane, toluene or xylene (b.p. 98°, 111°, and 140° respectively). The entrainment liquid overflows from the water trap and returns to the original flask while boiling continues. Usually less than 1 hr is sufficient to transfer all the water from the test-sample to the graduated receiver.

With 100-g samples results can be read to a satisfactory degree of accuracy, depending on the water content and correct selection of receiver, but 50 g and often less may taken for test. Some types of apparatus have a draw-off tap for the moisture trap and this extends the range for testing materials with high water-content; emptying and cleaning the apparatus at the end of each test is then not necessary.

The method is suitable for butter, petroleum, oils and fatty materials in general, but not for those which do not disperse in the boiling liquid. Syrups and sugary materials which settle and stick on the bottom of the flask will burn. Fetzer[1] recommended that such materials should first be dispersed on dry diatomaceous earth. Anti-bumping aids, *e.g.*, dry asbestos, can also be used.

The distillation method has the advantage that the water can be seen and the separation observed throughout the test. Volatiles soluble in the water-immiscible solvent do not interfere. The condenser and receiver must be kept very clean to avoid droplets of water adhering to the glass surfaces. It is possible to detach droplets from the condenser and make them join with the water in the graduated part of the receiver with a glass rod or by spray tube at the end of the test. Barr and Yarwood[24] recommend baking silicone oil on the apparatus before use. A B.S.[25] gives details of the Dean and Stark apparatus. Immiscible liquids heavier than water, such as carbon tetrachloride, perchloroethylene and tetrachloroethane, may also be used, the upper part of the receiver being graduated. Excess of entrainment liquid flows from the bottom part back to the original flask. These solvents have the advantage of being non-inflammable. The most suitable liquid will depend on the material to be tested. Fetzer[1] preferred toluene, but benzene (b.p. 80°) if the material was heat-sensitive. Meredith *et al.*[26] compared the distillation method with the Karl Fischer and vacuum methods for cereal grains and by-products and found toluene very satisfactory. Harel and Talmi[27] reported that xylene removed free water and water of crystallization from gypsum, but benzene did not, and thus suggested a means for examining hydrates.

The determination of water down to 0·01 ml in some plastic materials by use of xylene and downward condensation of the vapours was described by Alsop and Wadsworth.[28] The method avoids droplets of water remaining in the condenser.

Titrimetric methods—Karl Fischer titration

The titration method published by Fischer[29] in 1935 has been widely adopted and is in use in many laboratories. It is convenient and rapid for the accurate estimation of small amounts of water (up to 100 mg) where there is no interference with the reagent by other chemical compounds. The Karl Fischer (K.F.) reagent consists of iodine and sulphur dioxide in pyridine–methanol solution and it reacts with water according to the equations:[30]

$$SO_2 + I_2 + H_2O + 3\,C_5H_5N \rightarrow 2\,C_5H_5N{\cdot}HI + C_5H_5NSO_3 \qquad (1)$$

$$C_5H_5NSO_3 + CH_3OH \rightarrow C_5H_5NH{\cdot}SO_4{\cdot}CH_3 \qquad (2)$$

Only reaction (1) involves water; (2) completes reaction of the intermediate pyridine–sulphur trioxide complex. One molecule of iodine is theoretically equivalent to one molecule of water but in practice the K.F. reagent must be standardized against a known amount of water. Excess of iodine is shown by the colour but the end-point is nearly always obtained electrometrically by the "dead-stop" technique using a microammeter which indicates a sudden increase in current when the platinum electrodes are depolarized. Various types of apparatus have been designed to do this and to make the titration semi-automatic.[31]

The K.F. reagent is hygroscopic and very sensitive to moisture, and the reagents, solvents, burettes, titration vessel *etc.*, must be guarded by silica gel tubes (containing a water-sensitive indicator to show when their desiccant capacity is exhausted). Other ancillary glass apparatus is dried at 100° before use.

Anhydrous methanol is used as a sample solvent but a 4:1 mixture of methanol and pyridine is better for many materials. Some workers use other mixtures such as 7:3 methanol–formamide, or 3:2:1 formamide–chloroform–methanol which are preferred for dissolving or dispersing sugar products, but formamide tends to give high blanks (author's laboratory). The K.F. reagent has a titre equivalent to approx. 5 mg of water per ml and a methanol solution of water with this concentration is used as a means of back-titrating to give a sharper end-point. A typical apparatus has 2 burettes connected to an enclosed titration vessel fitted with a magnetic stirrer. The solvent mixture added to this vessel is titrated to the null-point for each series of tests. The powdered sample is added through a side tube and titrated after allowing time for dispersion or dissolution to take place. This may take 5 min, but generally a titration is completed in less than 10 min, and the method is a rapid one providing all is ready, but it is essentially a laboratory method and not suitable for use under factory or field conditions.

The K.F. reagent must be standardized daily, usually with distilled water added to the titration vessel from an "Agla" or other micrometer-syringe. Hydrates such as disodium tartrate dihydrate and sodium acetate trihydrate are also employed for standardization, 0·2–0·6 g being added to the solvent in the titration vessel and titrated with the K.F. reagent. The theoretical water content of these hydrates must be checked by drying at an appropriate temperature (*e.g.*, 150° for the tartrate, 130° for the corresponding acetate).

The methanol can be purchased specially dried. A B.S. for the Karl Fischer method of water estimation gives details of apparatus and reagents.[32]

Some materials cannot be dispersed to give up all their water in the titration vessel and it is best to give a preliminary treatment with a solvent mixture in a flask with heating, or boiling under reflux if necessary, and then transfer the mixture or an aliquot to the titration vessel. To give an example, taking caramel as a "difficult" substance, 0·5 g is refluxed with 8 ml of 4:1 methanol–pyridine mixture, cooled, and added to the K.F. vessel, followed by 2 ml of rinsings, all (including the condenser) being guarded by silica gel.

The cost of the reagent and solvent can be appreciable for a long series of tests and some workers use the K.F. titration as a reference method or for special investigations, using other procedures for multiple routine testing. Some object to the smell—it is not desirable to breathe the vapours of methanol and pyridine for long periods. Mitchell[1] examined substances which interfere with the K.F. reaction and suggested means of prevention. Vitamin C interferes, being oxidized to dehydroascorbic acid. The K.F. titration estimates total water, including water of hydration. It is valuable for testing explosives.

Peters and Jungnickel[33] found that methylcellosolve in place of methanol in the K.F. reagent gave greater stability and that direct titration of water in ketones and some aldehydes was possible if a mixture of ethylene glycol and pyridine was used as solvent.

Modified reagents are available for interfering compounds, and a catalyst, *N*-ethylpiperidine, speeds up the estimation and improves the accuracy.[34]

Duncan and Brabson[35] determined free and total water in fertilizers. Free water was obtained by extracting with 1,4-dioxan and titrating the extract with K.F. reagent. Total water was found by azeotropic distillation with n-pentanol and titration of the distillate, the difference being "hydrate water."

Heslop *et al.*[36] described how fertilizers and materials insoluble in methanol may be ground in a closed vessel with a high-speed cutter, followed by direct K.F. titration in the same vessel. Moisture estimation by oven-drying is not suitable when ammonium nitrate is present.

A semi-automatic timed end-point K.F. titrator for liquids and gases is described by Cope, and uses a relay in place of a microammeter.[37] A coulometric microdetermination of water in the range 0·1–2 mg has been described.[38] Archer *et al.*[39] recommended voltage measurement as being more sensitive than current measurement. They also described a totally enclosed titration cell to prevent pick-up of water and avoid end-point drift. A sensitive double electrode system is the subject of a British Patent.[40]

Optical methods—refractometric and infrared

Refractometric methods. The refractive index of a solution can indicate its water content, and refractometers of various types are in regular daily use in industries dealing with syrups, such as the sugar, glucose, jam and confectionary trades. The refractive index of water at 20° is 1·3330 and that of an aqueous solution will be increased according to the amount and nature of the dissolved solids. Tables are available, the most often used being those for sugar, to show the "concentration," *i.e.*, percentage dissolved solids corresponding to a particular refractive index. The water content of clear solutions is given by the difference from 100%. Undissolved material does not affect the refractive index, the refractometer giving only the concentration of the syrup phase. When crystallized sugar or other undissolved material is present the water content found by difference will be too high. For clear syrups the refractometer is extremely useful as it requires only a few drops of sample and a reading is obtained at once with only a minimum of preparation and cleaning. Slightly different values are given by dextrose, fructose, honey and invert sugar. The Corn Refiners' Association Inc.[41] has published corrections for corn syrup, which contains dextrins, according to its dextrose equivalent and mineral matter content.

Tables for sucrose and other sugars are published internationally[42] and various reference books include tables for many other aqueous mixtures.[43]

Readings are usually taken at 20°, which means that hot syrups have to be cooled down to this temperature; alternatively a correction based on temperature can be applied. The Abbe refractometer is a general-purpose instrument incorporating a water-jacket and thermometer to make temperature correction easy. It may have a sugar scale calibrated 0–95%, capable of estimation to 0·1%, but in practice high-boiled solutions approaching the highest concentrations will set hard very rapidly unless kept at a high temperature. Sugar alone at 20° will begin to crystallize at concentrations above 65%. A more practical range for confectionary syrups of mixed sugars is up to 85% concentration, corresponding to a refractive index of approx. 1·503 at 20°.

To correct for the temperature of the refractometer prisms, at 15° 0·4% is added to the per cent of water, and at 25° 0·4% is subtracted. Refractometric tables are based on the mean sodium D lines but instruments have an adjustable white-light compensator so that they can be used under ordinary conditions of illumination. The Abbe instrument can be checked for correct calibration by using pure water at 20° in conjunction with a test-piece of glass of known refractive index. The instrument can have a flow-through cell which is very useful for fast repetition testing of low-concentration solutions in an industrial process.

Simple pocket instruments are available without stand or temperature control, which will give results to about 0·5 % for soft drinks, cordials, wines and malt extracts. Various scales are offered to suit the products to be tested.

The *Projection Refractometer*[44] was designed for on-the-spot testing of products regardless of colour and the presence of solid pip-like material, the sample being merely spread onto the horizontal surface of the glass prism set in a robust rectangular instrument using the principle of internal reflection. The critical angle borderline, observed through a glass window, intercepts the scale reading directly in terms of sugar concentration or "soluble solids." Scales can be read to 0·2 % but dark opaque products (*e.g.*, containing cocoa) cannot be read accurately.

Temperature control, with the instrument in a room at 20° or at constant temperature, is not usually required, because of the weight and bulk of the instrument in relation to the small amount of sample.

Pipeline Refractometers employ the same principles as the projection refractometer but are designed for direct installation in pipelines to give continuous readings. They must withstand considerable pressure and are hydraulically tested to ensure prisms cannot be blown out. Allowance is made for temperature which may be very high in in-line process control.

Immersion Refractometers differ from the Abbe in that the prism is dipped in the test liquid, which is convenient for larger samples. The accuracy is high and the range is correspondingly restricted, but full application may be covered by using interchangeable prisms. A small cylindrical chamber which holds the solution to be tested fits over the prism at the bottom of the instrument. The critical angle borderline due to the difference in refractive index between the prism and the liquid sample is observed on a scale through the eyepiece.

The same instrument can be obtained with a water-jacketed prism box for temperature control, which requires only a few drops of sample. Another option is a small auxiliary prism which can be attached to the main prism to enable liquids of high optical density to be tested, only one drop being required. Another alternative is a flow-cell attachment to provide continual monitoring or rapid measurement of separate samples.

Differential Refractometers are now available with split cells. One half holds a reference solution while the other is used for the test-liquid. The difference in refractive index is measured and this provides greater sensitivity and overcomes the necessity for temperature corrections, if reference and test solutions are at the same temperature.

Infrared absorption. Infrared or near-infrared spectroscopy may be used for water estimation with transmitted or reflected radiation. Making use of reflectance is a fairly recent development and instruments are expensive at present, but there is no physical contact with the test material and continuous monitoring is possible for solids, liquids and gases.

A standard form of instrument will measure up to 30 % water but by use of different filters measurements to almost 100 % are feasible, a flow-through cell being used for liquids.

The principle is that of absorption by water of infrared radiation of specific wavelength, principally 1·93 μm, the extent of absorption on reflectance being compared by photo-cell with a reference beam at a different wavelength (1·7 μm) to compensate to some extent for other factors such as fat. A twin-beam infrared spectrophotometer is used with an attenuator which can control a digital voltmeter to read water content. It is an empirical method, but under best conditions with a fine light-coloured powder, sensitivity can be good (0·05%). The apparatus is in use for paper manufacture. Results are not affected greatly by temperature variations within ±5°, but particle size and chemical composition affect results. Swift[45] and Slight[46] have reported on such an instrument.[47] Keyworth[48] found a wavelength of 1·9 μm most suitable for the measurement of water in methanol, isopropanol, dioxan, glycols and polyols by direct spectrophotometry. He used a differential spectrophotometer with ethylene glycol of known water content to test anti-freeze mixtures. Goulden and Manning[49] determined water in methanol extracts at 1·93 μm and found a coefficient of variation of 0·4% and detectability down to 0·01%. These limitations could be further reduced, if required, by modifications in instrumental technique. Calibration was done by adding known amounts of water to methanol. They proposed the method for dairy products. Uses are very diverse; infrared radiation can be used to measure the water present in steam at high temperature and pressure.[2]

Vapour pressure methods

Indirect and non-destructive methods based on vapour pressure or determination of equilibrium relative humidity (E.R.H.) are in use. Absolute humidity is the mass of water per unit mass of dry air; relative humidity (R.H.) is the ratio of the water vapour pressure in the air to the saturated water vapour pressure, expressed as a percentage. The vapour pressure of the air over a substance in an enclosed space will come into equilibrium with that of the vapour pressure of the substance, as a result of moisture transfer to or from the substance. The change in water content of the substance is negligible, as the mass is usually large in relation to that of the air. In practice the relative humidity of the air in the head space is measured after time has been allowed for equilibrium to be reached. Paper, boards and textiles are often examined in this way. A dial hygrometer can be used over a test-sample in a container and observed through glass. The sample can be large, which is an advantage with paper and similar materials where water distribution is not uniform and very small samples may be unrepresentative. The equilibrium point is easily observed but it may take 30 min to reach for paper and very much longer for other materials. Each type of material will have its own E.R.H./water relationship and this must be determined by a reference method. The E.R.H. method in terms of water content is not very accurate and is useless at the extremes of the range as there is only a small change in vapour pressure for a comparatively large change in moisture. Also it is only the free moisture and not that chemically bound which can be measured. Chipboard with E.R.H. about 65% will have 6–8% water while strawboard at the same E.R.H. will possess 8–12%. A manufacturer or user of paper and board is usually more concerned with E.R.H. and does not necessarily want to know the water content. It is important that paper and board are "normalized" to the ambient humidity around 65% to avoid curling or warping. A sword-type hygroscope—a stainless-steel sheath with hair element and a dial—is available for testing stacks. The "sword" is simply inserted between layers of material and the E.R.H. noted when it reaches a steady value. This will give the water content after suitable calibration and allowance for temperature.

Wet and dry temperature elements (psychrometer) will determine relative humidity and are much used in air-conditioning plants and for testing atmospheres but are not of general application.

Much research has been directed to E.R.H., water activity, and vapour pressure measurements, for food materials for comparison with other methods. The manometric, volumetric, sorption isotherm, sorption rate, and dew-point method have all been tried for special cases, taking advantage of their non-destructive nature, but are slow and require laboratory apparatus and technique. Smith[50] has reviewed the literature. Hickman[51] has also reviewed the subject of humidity measurement.

A 1969 directory lists 62 suppliers of hygrometrical instruments, the types including Assmann, dew-point, diffusion, electrolytic, capacitance, frost-point, hair-type, microwave, and wet and dry.[52] One of the problems associated with relating water to E.R.H. measurements is the hysteresis effect shown by some materials whereby for a given water content the E.R.H. may differ according to whether the sample approaches this water content by taking up or giving off moisture.

Dial hygrometers using hair or parchment elements require frequent calibration. A far more accurate measurement can be obtained by employing an electrical hygrometer.

Electrical Hygrometers were reviewed by Weaver[1] in 1951 and Smith[50] in 1971. The earlier instruments measured the conductivity of a hygroscopic salt solution, lithium chloride. Some time is required for this to attain equilibrium with the head-space to be tested and developments were directed towards reducing the amount of salt solution and obtaining maximum exposure at the sensitive end of the moisture probe. One type uses glass-fibre yarn impregnated with lithium chloride but response is non-linear and limited to a range of 25–90% R.H. The temperature coefficient is large but can be compensated. Aging is also a factor. Anodized aluminium sensors and ferric oxide/chromic oxide films have now been produced for instruments which are more robust, quicker to respond, and possess a smaller temperature coefficient. A thin porous oxide layer on an aluminium rod responds to changes in humidity and can be used with conductance or capacitance instruments. Stability is improved by impregnating the oxide layer with sodium tungstate. Details of the construction, properties, theory, and application of the anodized aluminium hygrometer were given by Jason.[2]

The oxide layer is only a few μm thick and dynamic equilibrium is achieved between the liquid water in the pores and the external water vapour pressure. The sensitivity depends on the thickness of the oxide film and can be very high, but limited to a top range of 90% R.H. Pore size and structure are also important.[53]

The electrical hygrometer will give rapid indication of the R.H. in a gas and hence the water vapour pressure and dew-point when the temperature is known. Published tables will show the amount of water per unit volume.[54] Electrical hygrometers are widely used in air-conditioning installations.

Modern aluminium oxide types are less affected by temperature, dust, and age, but like lithium chloride hygrometers, must be checked in atmospheres of known R.H. This is conveniently done by using the head-space over various saturated salt solutions. Tables are available covering the range 12–98% R.H. over a temperature range of 5–40°.[55] Alternatively, sulphuric acid solutions of known concentration are used.

Where a number of hygrometric moisture meters are in use in an industrial concern it is common practice to check these quickly with a master meter which is laboratory-calibrated.

When testing solids, the measurement of R.H. is delayed by the time required to obtain correct E.R.H. in the head-space over the sample. This may vary from 15 min to more than a day, depending on such factors as weight and size of sample, diffusion rate within the sample, surface area.

The E.R.H. and R.H. can be obtained with a high degree of accuracy, but when related to solids and liquids the accuracy in terms of water percentage is poor for most materials and the range is limited although often suitable for some kind of process or storage control.

Electronic methods

A large and growing number of instruments is now available, designed either for general use or for more specific purposes to meet the demand of industry and commerce for rapid results for process and storage control. Such instruments are called moisture-meters rather than water-meters—the latter meaning flow-recorders. Electrical hygrometers were discussed in the preceding section. Electronics can produce a continuous read-out and sound-alarm or provide servo action if required. The cost varies a great deal—from less than £100 to several thousand pounds, depending on the degree of sophistication, flexibility, and accuracy required. None determines the absolute water content, all have to be calibrated by some reference method for the material to be tested, and zero, scale and other instrument adjustments made. Claims may be made that the accuracy is ±0·1 % when what is meant is that this is the extent of repeatability.

Development of the earlier types based on conductance or capacitance has slowed, but it is still early days for microwave, N.M.R., and radioisotope techniques. Future development lies mainly with the electronics engineer and not the chemist. The latter can state the problem and give help, while industry will indicate the demand on efficiency and economic grounds.

Conductance or capacitance methods. Moisture meters of this class are relatively simple and cheap. They can be mains-operated but many use batteries to make them completely portable, as speed and portability are among their main advantages.

Conductance-type instruments are based on the fact that electrical resistance in the presence of an electrolyte decreases as the water content of non-conducting solids increases. The first electrical instruments were based on this, using Wheatstone bridge circuits for measuring the resistance. A limit is reached when sufficient free water is present to conduct current along a path between the electrodes. The resistance decreases at higher frequencies and an optimum is chosen for the material and range of water content. Temperature correction is necessary. The measurement of resistance or conductance is employed where electrodes have to be clamped or make close contact with materials in bulk such as sheets, planks, timber, *i.e.*, materials in a form difficult to sample on a representative basis, or that at best involve procedures which are very time-consuming. The electrodes are designed for specific purposes and may be needle, hammer or probe types. Roller or profile electrodes are used on conveyor bands, or moving webs of materials.

Calibration may be of an arbitrary scale or in terms of moisture as found by some other method. Repeatability may be only to within ±1 % but the large number of results which can be obtained in a short time, or continuously over a bulk of materials, will average to give a good practical result. Certainly, variations are correctly indicated provided the effective range of the instrument is not exceeded.

A range of special electrodes has been produced for batch or continuous testing of tobacco at various stages of processing; many other commodities may also be tested. Resistance is measured by a milliammeter in a special circuit using a cathode-coupled tube voltmeter with a current amplifier and automatic temperature compensation. It is claimed that this circuit is very stable and that the instruments do not require recalibration even after years of use.

Extracts from soil can be tested for electrical resistance. Soil is shaken with pure isopropanol and the fall in specific resistance of the filtered extract (saturated with dry sodium chloride) measured to give water content. Accuracy to within 1 % absolute is claimed over a wide range, and with a variety of soils. Calibration is carried out by adding water to oven-dried soil.[56] Industrial applications of resistance measurement for continuous moisture determination have been patented recently for wood veneer, paper web, board,[57] and cotton, silk and man-made fibres.[58]

With *capacitance-type* instruments the estimation of moisture in a sample is not so limited as is the case with conductance, and utilizing the electrical property of capacitance widens the scope of the instruments. Capacitance is less affected by variations in salt content and enables a greater range of water contents to be covered for many materials. Water has a very high dielectric constant (81) and when dry matter absorbs moisture its dielectric constant is considerably increased. Plastic ("Perspex") cells between plates act as condensers to which a high frequency current is applied. The cells are removable and may be in various sizes. Two balanced oscillating circuits are used, one fixed at say 18 MHz while the other, which includes the test cell, can be adjusted to balance with the fixed oscillator by use of a variable condenser, the balance being indicated by the brightness of a neon lamp or by a milliameter.

Replacing the air in the cell by the test-sample changes the capacitance, thus requiring adjustment of the variable condenser. Each manufacturer has his own favoured circuits for particular products. General-purpose instruments may have various fixed condensers in the circuits, operated by push-buttons to provide several ranges of readings. The dielectric constant for a given frequency will vary according to the water present only within limits and each manufacturer will recommend suitable ranges up to about 60 %, based on water calibrations, for various types of materials. Outside these ranges the results may be useless, but otherwise repeatability can be good, to within 0·1–0·2 %. The error, as shown by comparing results with standard gravimetric methods, may be 0·5 %, however, for a range of samples even of the same type. Precautions must be taken even to obtain this. Texture, and degree of packing of the material in the cell, are important factors, and so is temperature. It is normal to weigh the sample, although the weight may not be very critical, and use a compression device or plunger for the cell for granular materials or powders such as starch and dried milk. Repeatability and accuracy are reduced in the higher ranges.

Cells commonly hold about 100–400 g. The instruments may record directly in terms of moisture but as the relationship of electrical properties to water-content is different for various types of material, interchangeable plastic moisture scales are used—sometimes multiple ones for convenience on the same instrument. The moisture for a given electrical reading may differ by as much as 3 % for different cereals. Closer agreement can be obtained by coarse-grinding the sample as a preliminary.

Variations in density are more important than temperature. Compensation for specific materials (*e.g.*, flour) can be made by using a radioactive probe designed to measure density, thus circuit correction for particle size and packing makes possible in-line process control, at extra cost.

New apparatus has been designed to measure conductance and capacitance at three separate frequencies simultaneously. One or more of the electrical parameters is related to water, the others compensate for variables such as fat.[59]

Microwave attenuation methods. Development of these methods followed that of the conductance and capacitance instruments and research is still active to improve response specifically for water and to produce satisfactory designs for industry for sample-testing or continuous recording.[60]

The microwave principle is based on the absorption by water of high-frequency radio energy generated by a klystron oscillator. Electromagnetic microwaves of frequency 10^3–10^5 MHz (wavelengths 30 cm–3 mm) can be absorbed and reflected like light. The distance of the receiver from the transmitter is an obvious variable to standardize.

One instrument consists of a transmitter with a frequency of 10,680 MHz operating through waveguides ending in a 3-in. square horn and an attenuator with crystal detector. Microwave absorption is much greater with "free" moisture than with dry substances and so the degree of attenuation can be related on a linear basis to moisture as determined by reference methods, due correction being made for temperature. In actual use for sample-testing, a "Perspex" cell is placed between the transmitter and the receiver, these two parts being fixed on a stand at a predetermined distance. Following the usual adjustments for zero, scale deflection, *etc.*, the degree of attenuation produced by the sample is obtained within seconds in terms of decibels. Slide-rule calculators covering the ranges of temperature (found by thermistor), weight of sample and degree of attenuation, are calibrated for water for the type of material undergoing test. The error is of the order of 0·5% absolute for baked goods (cakes) and Ince and Turner[61] found that texture and density were more important than recipe change. Closer results were obtained for nougat (author's laboratory) by using a 2½-in. deep cell, 5½-in. diameter, taking due note of the weight to compensate for air inclusion. It should be noted that these are rather difficult materials to sample representatively for more orthodox testing, and the microwave apparatus has an important industrial future as more applications are found. The instrument can be calibrated directly in terms of moisture for fixed installations and the product (*e.g.*, milk powder, cereals, and foods in general) can be continuously monitored without contact, damage or loss if passed through "Perspex" pipes between the transmitting and receiving horns.

Temperature and salt content influence microwave attenuation but compensation can be made for both, by using thermistors and conductivity circuits, and research on this is proceeding.[45] Maximum accuracy for water measurement lies within the signal range 7–40 decibels and wavelengths can be selected to bring the attenuations within these limits.

Microwaves have been employed to measure water variations in concrete and brick walls, by using portable battery-operated instruments.[2] Air can be used to fluidize a controlled feed of powder or granular material to maintain a constant density for continuous testing.[62]

NMR methods. Nuclear magnetic resonance is a later development of non-destructive electronic testing (since about 1950). The apparatus produces two magnetic fields simultaneously—a strong field very slowly oscillating about a mean value and a weak constant radiofrequency field perpendicular to the other. Hydrogen nuclei in the liquid phase of a sample absorb energy from the radiofrequency field and at a certain value of the strong field strength the rate of absorption is at a maximum in relation to the particular frequency and the nuclei are said to be in a state of resonance. Nuclei in solids are immobile and cannot resonate. The field strength and frequency of the apparatus can be arranged so that only hydrogen nuclei resonate.

Hydrogen nuclei in foods and similar materials are primarily in the oil, fat, or water present but those in carbohydrates and protein will respond if these substances are in the liquid phase. High-resolution instruments are required to distinguish between hydrogen in fat and water. NMR is proving very useful for the direct monitoring of fat in food manufacturing processes (*e.g.*, chocolate) but in the case of water alternative cheaper methods are available. Research continues and there may be worthwhile applications for high-moisture materials where other electronic methods are not suitable, also where the oil content is low, or known and constant. The NMR signal is calibrated against results obtained by reference methods. The use of NMR apparatus is quick and simple but the equipment and theory are complex.[2]

A portable high-resolution broad-line NMR spectrometer has recently been introduced.[63] The test-material is weighed into a sample tube and the NMR signal calculated per gram for reference to moisture tables. NMR apparatus has been used with static and moving beds of coal and coke for water measurement with an error of about 1%.[64] NMR may be used to distinguish between free and bound water, if the temperature is reduced to below freezing point.

Electrolytes may affect NMR readings and when soils are tested the leaching out of electrolytes over a period can introduce errors.

Nuclear radiation methods. Fast neutrons emitted from a radioactive source in a probe are slowed down by elastic collisions with the hydrogen nuclei of water in a moist material, which results in the formation of a cloud of slow neutrons, the density of which (as measured in counts/sec) can be related to the water content. This is known as neutron moderation or scattering. The atomic nuclei of matter in general will cause scattering but to a much lesser extent. Water indication is by proportion by volume of the moist substance and to determine proportion by weight it is necessary to correct for density, usually with a gamma-radiation source and detector. A dual neutron–gamma instrument will combine the output signals from both detectors to give water percentage by weight. The inclusion of such a compensating probe can reduce errors to about 1%.

Although nuclear-radiation gauging can be used for testing many materials the greatest application has been in the examination of soil. It offers greater precision than standard gravimetric methods because of the large test sample (a cubic yard—about 1 ton) which can be tested *in situ* without disturbance.

The effect of soil composition is significant, as the detector is for hydrogen nuclei and is not specific for water; nevertheless, for known areas the instrument can be valuable and it is simple to make tests at varying depths.

The difficulties of calibration (laboratory, field, and by simulation) for soil were discussed at the U.S.A. 1963 Symposium.[2] When composition and density remain constant, either a neutron or gamma gauge can be used for monitoring water content. Soane[65] reported results of tests using dual (high and low) energy gamma-ray transmissions for simultaneous measurement of water content and dry bulk-density of soil.

The Institute of Hydrology has developed with the Atomic Weapons Research Establishment, Aldermaston, an instrument using the neutron-scattering technique for soil-moisture measurement. Besides the probe there are a shielded transport carrier and a ratemeter. The standard aluminium alloy access tube immersed in water shows about 850 counts/sec, while in air it is about 5 counts/sec. The effect of temperature variation between −10 and +40° is claimed to be insignificant (less than 2 counts/sec).

The probe carries 50 mCi of americium/beryllium and a slow-neutron detector, E.H.T. generator and pulse-shaping circuits, powered by a battery so that the instrument is easily portable.[66] The use of radiation gauging for water monitoring is being extended where there are special industrial problems with such materials as coal, coke, iron ore, sinter mix, concrete.

Instruments have also been designed for food testing.[67]

Miscellaneous methods

The foregoing shows the main groups of methods and techniques employed for water measurement but for every type of material for which a knowledge of the water content is required there will be found a specific method devised with a view to obtaining a quick result under non-laboratory conditions. All are empirical and rely on reference methods carried out under closely controlled laboratory conditions. Unfortunately, this is not always understood by semi-skilled workers using the instruments, who tend to have implicit faith in the dial readings and neglect the apparatus or delay too long the recalibration made necessary by wear and the deterioration produced by time.

Much literature has been published on various methods of testing soil, sand, gravel, coal, and similar materials because of their commercial importance and the problem of reducing such bulky and variable materials to the small representative samples which are normally required by the conventional reference methods. Loss of weight after heating in a non-volatile oil and after evaporating the water with burning alcohol have been used. Water present will influence to some extent a material's physical, chemical, or electrical properties and each type of substance will have one or more parameters suitable for relating to water to give a result satisfactory for commerce.

Density or specific gravity methods are much used for solutions of simple substances such as sucrose, salt, and soluble chemicals in general, and tables relating to aqueous mixtures are published together with temperature corrections. As an alternative to hydrometers or pycnometers a "moisture balance" will accurately determine density or specific gravity by the buoyancy principle, using a plummet suspended in the test-solution. If the test-substance is in the solid state, it may be weighed in a liquid of known specific gravity (Archimedes' principle). Success with the latter method presupposes no pores or voids in the solid substance, and insolubility in the liquid.

For general testing of insoluble composite material the water can often be extracted with ethanol or methanol and a result calculated from a change in density or boiling point, or the extract may be used for a Karl Fischer titration. Acetone, isopropanol, dioxan, dimethylformamide and glycerol are other extractants which have been used and the possibilities are numerous as the extracts can be tested by many of the methods previously mentioned and the result calculated back to give the water-content of the original solid.

Gases can be simply tested in the laboratory by passage through weighed U-tubes containing phosphorus pentoxide, calcium sulphate or calcium oxide desiccant, alternatively by the Karl Fischer method, or by G.L.C. using a thermal conductivity detector. Dew-point can also be determined accurately and is used to standardize other techniques, but industrially, wet and dry bulb hygrometers or hair-type hygrometers are used for immediate measurement and continuous recording. Electrical hygrometers have become very important because of their versatility.

Miscellaneous methods include application of rise in temperature due to chemical reaction with sulphuric acid, thermal conductivity, specific heat, surface tension or suction and the use of absorbent blocks. The last two are made use of for measurements of water in soil. The reading produced by a buried porous pot filled with water and connected to a vacuum gauge will indicate water-content, although influenced by soil particle-size and degree of packing.[68] Saturated soil will show a reading of 30–60 mmHg; drought conditions are indicated by over 300 mmHg. Watson[69] has described a modern field tensiometer.

Absorbent blocks can be buried in soil and the weight at equilibrium made to give the water content, but more conveniently the blocks may be tested *in situ* for electrical resistance.

One well-known method based on chemical reaction is that using calcium carbide. It is popular for "field testing" because of its cheapness, speed and convenience. The sample is weighed and shaken with calcium carbide in a sealed pressure vessel fitted with a dial pressure gauge, the maximum pressure produced by the acetylene generated being related to water by suitable calibration.[70] There are variations using this chemical method, *e.g.*, the volume of the gas may be measured, or the loss in weight determined.

Various workers have sought an alternative to the K.F. titration. When dissolved in ethylenediamine, water acts as an acid and can be titrated under a nitrogen atmosphere.[71]

The use of G.L.C. is proposed for low amounts of water in gases and liquids. Columns with 80–100 mesh Porapak at 140° with hydrogen as carrier-gas are claimed to give optimum results, but sensitivity can change and fresh calibration is required.[72]

Water in air and natural gas can be estimated down to 50 ppm by using polytetrafluoroethylene column packed with Porapak Q and employing a thermal conductivity detector.[73]

The cloud-point or critical solution temperature of a two-component system such as dry methanol in n-hexane is dependent on traces of water, and thus common solvents such as methanol, ethanol, acetone, ethyl methyl ketone and dioxan may be tested for water content by using this technique with controls. Test samples may be 10–50 μl in volume but the number, amounts and identity of the components must be known for calibration to be applicable.[74]

Pande[75] has described a new micro-determination based on hygrophotography.

REFERENCE METHODS

Standardized reference methods are published by various official bodies (see list below) only for specified materials—there can be no one all-embracing method, as this review will have made clear. Where there is no official reference method for a product of commercial importance, firms or their Research Associations will often have agreed upon one. The most favoured, as being of widest application, is a drying method with or without vacuum, subject to limitations as described in the appropriate section above. At one time there was reluctance to include vacuum procedures with reference methods, as this meant stipulating some particular manufacturer's vacuum oven, with obvious objections, but this has now been overcome by setting out the precise conditions required. Drying has the advantage that in most cases it can be investigated so that conditions can be set to yield a result close to the "true" water content, and the apparatus is simple and cheap, apart from the balance, which is part of the general laboratory equipment anyway. Also any range of water can be measured and almost any amount of sample taken.

The Karl Fischer method comes closest to measuring absolute water content, and will cover any range, although accuracy is reduced at high levels because aliquots have to be taken to keep the amount of water within the best range for titration. There is not wide adoption of the Karl Fischer test as an official one, but there is a present-day trend toward this, or it is given as an alternative method. Earlier policy with official tests has always been to keep them simple for the widest possible use by all concerned. The K.F. test serves a very useful purpose in deciding the conditions necessary for the more simple drying methods.

Distillation by the Dean and Stark method has been taken as an official method for some materials and it has obvious claims in this respect.

Refractometric methods are taken as "standard" in some trades but their use is obviously restricted.

Various physical properties, when accurately measured under laboratory conditions, can estimate absolute water but under conditions so restricted that these methods are never adopted as official although of course, like the K.F. test, they can serve an important function in checking the accuracy of other accepted methods.

None of the electrical methods can be used as official tests as they are dependent on calibration by other procedures.

The following publish official methods in either the U.K. or U.S.A.

British Standards Institution, Park Street, London, W.1.
British Pharmacopoeia, General Medical Council, Pharmaceutical Press, London.
The Society for Analytical Chemistry, Savile Row, London, W.1.[76]
Association of Official Analytical Chemists, Washington, D.C.[77]
Pharmacopoeia of the U.S.A., Mack Publishing Co., Easton Pa.
National Formulary, American Pharmaceutical Association, Washington.
National Bureau of Standards, U.S.A. Government Printing Office.
American Society for Testing and Materials (A.S.T.M. Standards), Philadelphia.

In addition there is a large number of Trade Research Associations which publish recommended methods for water or moisture measurement. Some of these methods are more or less identical but not all. Usually the official tests are the result of collaboration by interested parties and, although without legal authority, they provide a common ground between vendor and purchaser where water content is stipulated and it would be clear in arbitration what is meant and intended when, for example, a British Standard is quoted. The various Trade Research Associations give details of recommended methods and also from time to time investigate and critically examine the performance of various instruments. Their publications are sometimes only available to member companies but Research Reports can be purchased.

Apart from the U.K. and the United States there are, of course, many other countries interested in standardization. International organizations in Brussels, Geneva, and Zurich become increasingly important.

Close international standardization will not be easy. A B.S.[78] for coal and coke gives nine procedures for water estimation, if all variations of sample weight, temperature and time are included, depending on type of coal and mesh size. Two use Dean and Stark apparatus, one uses a drying process with nitrogen, another uses vacuum, the others use simple drying to constant weight.

The International Standards Office, with regard to starch, states moisture content equals loss in mass undergone by the material under the specified conditions of the test but a B.S.[79] prefers the term "loss in mass on drying" in place of "moisture content" in this statement. Three methods are given, drying at 130° for $1\frac{1}{2}$ hours and finally to constant weight (further loss <5 mg), drying at 100° for 4 hr and finally to constant weight, and drying at 73° at 10–20 mmHg for 24 hr to constant weight (further loss <1 mg).

To review all reference methods in all major countries and to bring them on to an internationally agreed basis will be a great task but will become increasingly important as more and more materials become subject to standard methods of testing. Deviations should be as few as possible and agreement should not be hindered by trade practices and traditions.

International symposia will continue to review methods and techniques. In the U.K. there is the annual Physics Exhibition organized by the Institute of Physics and the Physical Society, also the parallel exhibition of the Scientific Instrument Manufacturers' Association.

As regards the future there is little likelihood of any great change in drying methods, and these and the Karl Fischer and distillation techniques are the basic reference methods. No new fundamental principle has been widely established for water measurement since NMR and nuclear radiation techniques were introduced over 20 years ago, except that of infrared absorption by reflectance.

APPENDIX

The determination of water in rocks and minerals is rather different from the determination of moisture in general, in that the water present may be either loosely or firmly held, and different methods are required for determination of the two kinds. The loosely held or interstitial water is usually defined as the amount of water evolved on heating the sample at some defined temperature such as 105° or 110°. For this purpose the oven-drying methods may be used, or the Dean and Stark method. The drying methods are not suitable, however, if other volatile substances are also present in the rock, or if the rock contains large proportions of easily oxidized species such as ferrous iron, but such difficulties may be overcome by absorbing the evolved water, in a closed system such as that described by Jeffery and Wilson.[80] Similar apparatus, modified to allow for heating the sample to the higher temperatures necessary, may be used for determining the total water, *i.e.*, the interstitial and the "constitutional water".[80–82] In determining the total water it is necessary to avoid errors due to evolution of carbon dioxide, hydrogen fluoride, sulphur compounds *etc.*, and for this purpose various additives or absorbents can be used to retain or collect these species. The simplest method for total water determination is the Penfield method[83] or one of its modifications,[84–87] used with or without a flux such as litharge or sodium tungstate. In this method the sample is heated to high temperature in a hard glass tube and the water evolved is condensed or absorbed, and then weighed either by difference or directly. Care must be taken in preparation of the sample when water is to be determined in rocks: if the grinding is too fierce, water may be lost, but on the other hand the great increase in surface area on comminution of the sample may increase the amount of hygroscopic moisture taken up.[88] With the closed systems, a blank correction must be made for residual water in the gas used as carrier-gas for the water vapour evolved, and the sample size must be large enough for variations in the blank to be insignificant as a source of error.

Acknowledgement—Grateful acknowledgement is made to colleagues of J. S. Fry & Sons and Cadbury Bros. Ltd., for assistance with this Review and to the University of Bristol for facilities provided.

Zusammenfassung—Die komplizierte Natur des Themas und die bei der Bestimmung von Wasser in den vielen zu prüfenden Materialien auftretenden Probleme werden erklärt. Die verschiedenen vorhandenen Methoden werden klassifiziert, Übersichten über die Arbeitstechniken gegeben und ihre Anwendungsmöglichkeiten und -grenzen gezeigt. In vielen Materialien ist die Bestimmung der absoluten Feuchte nicht möglich und es muß ein Kompromiß geschlossen werden. Gewerbe und Industrie brauchen für viele Prozesse und Produkte rasche Ergebnisse; daher werden in immer größerem Ausmaß optische oder elektronische Verfahren in Verbindung mit Vergleichsmethoden verwendet. Für amtliche Zwecke muß Einigkeit über die Bestimmungsmethode erzielt und diese im einzelnen festgelegt werden. Weitergehende Fortschritte bei der internationalen Standardisierung sind sehr wünschenswert.

Résumé—La complexité du sujet, et les problèmes impliqués dans le dosage de l'eau dans les nombreux produits qui doivent être essayés sont expliqués. Les diverses méthodes disponibles sont classées, leurs techniques résumées, et leurs applications et limitations indiquées. Dans de nombreux produits, le dosage de l'humidité absolue est impossible et un compromis doit être accepté. Le commerce et l'industrie requièrent des résultats rapides pour de nombreux procédés et produits, et des méthodes optiques ou électroniques sont utilisées de manière croissante conjointement aux méthodes de référence. Pour les usages officiels la méthode de dosage doit être agréée et exposée en détail. Il est trés désirable que davantage de progrés soit fait dans la standardisation internationale.

NUCLEAR MAGNETIC RESONANCE ANALYSIS OF PHARMACEUTICALS*—VII

DETERMINATION OF AMINOPHYLLINE IN TABLETS

JOHN W. TURCZAN, BRUCE A. GOLDWITZ and JAMES J. NELSON
Food and Drug Administration, U.S. Department of Health, Education and Welfare, 850 Third Avenue, Brooklyn, New York 11232, U.S.A.

(*Received* 17 *March* 1972. *Accepted* 28 *April* 1972)

Summary—An NMR procedure is described by which theophylline and ethylenediamine are simultaneously determined in aminophylline tablets. t-Butyl alcohol was chosen as the internal standard and 4% ammonia–0.3% potassium cyanide in deuterium oxide was the solvent. The solvent system was selected to deal with the problems of solubility of the theophylline, overlapping of the components' resonance signals, and potential interference from metal impurities. Known standard and commercial preparations were determined and the results compared with those obtained by alternative procedures. The technique, when applied to the determination of aminophylline in tablets, is rapid, simple and specific and has an error of 1–2%.

THE DETERMINATION of aminophylline, a mixture of theophylline and ethylenediamine in the ratio 2:1, has been widely discussed. The theophylline content is usually determined and expressed as aminophylline. The analysis of this drug involves a variety of analytical techniques. Aminophylline has been assayed gravimetrically[1] by extraction of theophylline with a chloroform–isopropyl alcohol mixture, and subsequent weighing of the residue. Other methods include both colorimetry[2] and ultraviolet spectrophotometry.[3–8] A potentiometric titration approach to the determination of theophylline alone, and in combination with other drugs, has been investigated by Bartilucci and Discher[9] and others.[10–12] Sarsunova and Tölgyessy[13] have determined aminophylline and theophylline by means of a radiometric titration of the purines, using $^{110}AgNO_3$ to form the insoluble silver salts. The activity of the ^{110}Ag in the solution is then plotted *vs.* the volume of titrant used.

Theophylline has been determined electrochemically by Dušinský and Čavaňák,[14] Yashino[15] and Kalinowska.[16] Methods of complexation of theophylline with copper with subsequent gravimetric or titrimetric determination of the complex have been studied by Runti,[17] Plumel[18] and Blagojević.[19] A non-aqueous titration procedure for the analysis of aminophylline, developed by Medwick and Schiesswohl,[20] involves the differential titration of theophylline and ethylenediamine as a mixture of bases. Non-aqueous titration methods for aminophylline[21–23] and theophylline[20] in combination with other drugs have also been examined.

Other techniques used in the determination of aminophylline and theophylline are aqueous titration as a weak acid in the presence of Thymol Blue[25] and an aqueous

thermometric titration of aminophylline with silver nitrate.[26] An NMR method for the determination of theophylline in the presence of other xanthines was reported by Rehse.[27]

The official method (USP XVIII[28]) for aminophylline in tablet form involves the precipitation of theophylline as a silver complex and subsequent back-titration of the excess of silver nitrate with ammonium thiocyanate. In a separate USP procedure, ethylenediamine is determined by titrating an amount of aminophylline with hydrochloric acid to a Methyl Orange end-point. It has been reported [29,30] that the USP assay has a source of error attributable to the solubility of the silver theophylline complex in the ammonia solution used. The cooling step in the official procedure thus becomes a critical factor during the filtration and washing of the complex before the titration.

An alternative procedure presented here uses NMR spectroscopy. By addition of an internal standard and solvent extraction, we have quantitatively analysed many high-dosage pharmaceuticals. The NMR spectrum identifies the active ingredients, contributing to the specificity of the method.

The components of aminophylline in tablet form were assayed by this technique. Many of the results were compared with those obtained by the official procedure and by an ultraviolet spectrophotometric method for theophylline. The NMR procedure is simple, specific, accurate and precise.

EXPERIMENTAL

Apparatus

A Varian A-60 NMR spectrometer equipped with a V-6031 variable-temperature probe having a six-turn insert was used. All spectra were scanned at a probe temperature of 42°.

Reagents

Standard. Aminophylline working standard (USP assay values: moisture 4·06%, theophylline 86·3% on anhydrous basis, ethylenediamine 14·4% on anhydrous basis).

Internal standard. t-Butyl alcohol, 99%.

Solvent. Deuterium oxide, 99·8% isotopic purity, Mallinckrodt Chemical Works, St. Louis, Missouri.

Ammonia solution, sp. gr. 0·880.

Potassium cyanide

Samples. Aminophylline tablets, 1·5 and 3 grains, from various commercial sources.

Procedure

Weigh and finely powder not less than 20 tablets. Weigh accurately a portion of the powder equivalent to about 200 mg of aminophylline into a glass-stoppered centrifuge tube. Add about 9 mg of reagent-grade potassium cyanide and about 50 mg (accurately weighed) of the t-butyl alcohol internal standard. Fill the tube to approximately the 3-ml mark with deuterium oxide. Add about 10 drops of ammonia solution, stopper the tube and shake for 2 min. The tube may be warmed to aid dissolution. Centrifuge to separate the solution from the excipients. Transfer about 0·4 ml of the solution to an analytical NMR tube. Place in an NMR spectrometer and obtain the spectrum, adjusting the spin-rate so that no spinning side-bands occur between 1·1 and 1·5 ppm and between 2·6 and 3·8 ppm on the delta scale. All peak field positions are referred to sodium 2,2-dimethyl-2-silapentane sulphonate (DSS) as 0 ppm. Integrate each of the peaks of interest at least five times.

The amounts of theophylline and ethylenediamine may then be calculated individually as follows:

$$\frac{\text{mg theophylline}}{\text{tablet}} = \frac{A_{\text{th}}}{A_{\text{tba}}} \times \frac{\text{E.W.}_{\text{th}}}{\text{E.W.}_{\text{tba}}} \times \frac{\text{mg t-butyl alcohol}}{\text{mg sample}} \times \text{A.T.W.}$$

$$\frac{\text{mg ethylenediamine}}{\text{tablet}} = \frac{A_{\text{ed}}}{A_{\text{tba}}} \times \frac{\text{E.W.}_{\text{ed}}}{\text{E.W.}_{\text{tba}}} \times \frac{\text{mg t-butyl alcohol}}{\text{mg sample}} \times \text{A.T.W.}$$

where A_{th} = integral value of the signal representing theophylline
A_{ed} = integral value of the signal representing ethylenediamine
A_{tba} = integral value of the signal representing t-butyl alcohol
E.W.$_{th}$ = formula weight of theophylline/6 = 30·03
E.W.$_{ed}$ = formula weight of ethylenediamine/4 = 15·02
E.W.$_{tba}$ = formula weight of t-butyl alcohol/9 = 8·236
A.T.W. = average tablet weight

The amount of aminophylline can be calculated from the theophylline content by multiplying the weight of theophylline (mg) by 1·267, representing the formula weight of aminophylline containing two molecules of water of hydration and divided by twice the formula weight of theophylline.

RESULTS AND DISCUSSION

The choice of a solvent is more complex than in the usual NMR procedure. The solubility of theophylline in deuterium oxide is fairly good, but some theophylline precipitates from solution as soon as carbon dioxide from the atmosphere is absorbed. Furthermore, the absorption peak due to ethylenediamine partially overlaps one of the two sharp singlet peaks due to the two methyl groups on theophylline (Fig. 1*a*). In order to maintain the solution at an alkaline pH to prevent the precipitation of theophylline and to separate the spectrum resonance signals due to theophylline and ethylenediamine, deuterium oxide containing 4% ammonia was used as a solvent. This solvent proved satisfactory for analysis of aminophylline powder, but not for the tablet samples (Fig. 1*b*) where the ethylenediamine peak was too broad for integration. This behaviour was attributed to complex formation between ethylenediamine and a heavy metal impurity present in the tablets. The presence of iron was shown by the formation of a pink colour with thiocyanate. The same broadening was noted when iron(III) was added to ethylenediamine in the same solvent. Competitive complexation was used in order to prevent the undesirable complexation. Cyanide (as the potassium salt) was added to complex iron(III) (or other heavy metals) thereby displacing ethylenediamine and sharpening the absorption line (Fig. 1*c*). The solvent used was 4% ammonia in deuterium oxide containing about 3 mg of potassium cyanide per ml.

A single internal standard, t-butyl alcohol, was satisfactory for all analyses. This alcohol was easily soluble in the solvent and provided a strong signal at a convenient upfield position, thereby resulting in unambiguous identification and interference-free quantitative analysis.

Figure 1*c* shows a spectrum of aminophylline obtained under the recommended analytical conditions. The amounts of each component are calculated from the integration of the singlets (at approximately 3·30 and 3·45 ppm) due to the two methyl groups of theophylline bonded to the nitrogen ring at positions 3 and 1 respectively, the singlet at approximately 2·90 ppm attributed to the four methylene protons of ethylenediamine, and the singlet at approximately 1·30 ppm due to the nine methyl protons of t-butyl alcohol. The other absorption bands at about 4·7 ppm and about 7·50 ppm are ascribable to the HDO in the solvent mixture and the theophylline proton at position 8 on the ring.

A group of known aminophylline mixtures was analysed and the results are summarized in Table I. The NMR results were compared with those obtained by the USP method as well as by a non-aqueous titration procedure.[20] The procedure is both

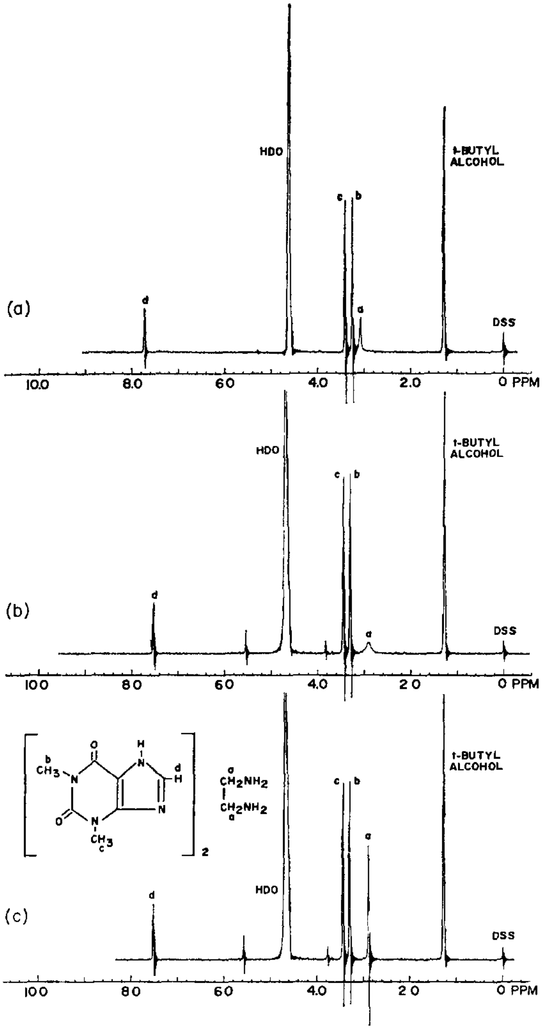

Fig. 1

accurate and precise with relative standard deviation of 0·5% for the theophylline and 0·2% for the ethylenediamine. The relative proportion of aminophylline to t-butyl alcohol has no significant bearing on the accuracy of the determination for the range shown in Table I. The lower results obtained by the USP assay can be attributed to the slight solubility of the silver–theophylline precipitate in ammonia solution. When compared with the USP procedure, the NMR method is simpler, faster, and more specific. An analysis of the two components can be performed in one operation, thus avoiding the two titrations required to achieve the same result.

Some 15 commercial tablet preparations were analysed by NMR. Six of these preparations were also analysed by ultraviolet spectrophotometry for theophylline and titrimetry (using Bromocresol Green as an indicator) for ethylenediamine.[20] The results presented in Table II are in good agreement.

Acknowledgement—The authors are grateful to Dr. Thomas Medwick, Science Advisor, FDA, New York District and Professor of Pharmaceutical Chemistry, College of Pharmacy, Rutgers University, New Brunswick, New Jersey, for many valuable discussions and encouragement in the preparation of this manuscript.

Zusammenfassung—Es wird ein NMR-Verfahren beschrieben, mit dem Theophyllin und Äthylendiamin gleichzeitig in Aminophyllintabletten bestimmt werden können. Als innerer Standard wurde t-Butylalkohol gewählt, 4% Ammoniak-0,3% Kaliumcyanid in Deuteriumoxid als Lösungsmittel. Das Lösungsmittelsystem wurde so ausgewählt, um mit den Problemen der Löslichkeit von Theophyllin, Überlappung der Resonanzsignale der Komponenten und möglichen Störungen von metallischen Verunreinigungen fertig zu werden. Bekannte Standard- und handelsübliche Präparationen wurden analysiert und die Ergebnisse mit denen anderer Verfahren verglichen. Bei der Anwendung auf die Bestimmung von Aminophyllin in Tabletten geht das Verfahren rasch und einfach; es ist spezifisch und zeigt einen Fehler von 1–2%.

Résumé—On décrit une technique de RMN selon laquelle on dose simultanément la théophylline et l'éthylènediamine dans des comprimés d'aminophylline. On a choisi l'alcool t-butylique comme étalon interne, le solvant étant une solution à 4% d'ammoniaque—0,3% de cyanure de potassium dans l'oxyde de deutérium. Le système de solvant a été sélectionné en envisageant les problèmes de solubilité de la théophylline, le recouvrement des signaux de résonance des composants, et l'interférence potentialle d'impuretés métalliques. On a dosé des étalons connus et des préparations commerciales et les résultats ont été comparés à ceux obtenus par d'autres techniques. La technique, lorsqu'elle est appliquée au dosage de l'aminophylline dans des comprimés, est rapide, simple et spécifique et a une erreur de 1-2%.

THE DECOMPOSITION OF HYPOBROMITE SOLUTIONS

N. VELGHE and A. CLAEYS
Laboratory of Analytical Chemistry, Faculty of Pharmacy, University of Ghent,
Ghent, Belgium

(*Received* 26 *January* 1972. *Accepted* 30 *March* 1972)

Summary—The stability of 10^{-1}–$10^{-3}N$ hypobromite solutions, stored in brown or colourless bottles at room temperature, has been investigated. A reaction mechanism of decomposition has been proposed and some practical conclusions have been drawn concerning the optimal method of preparation and the required frequency of control of hypobromite solutions used as an analytical reagent.

SEVERAL authors[1–5] have studied the stability of hypobromite solutions during a period of several weeks or months, but most of them did not take account of the formation of BrO_2^- during the decomposition: only the BrO^- concentration and/or the total oxidizing capacity of the solutions are given so the internal composition (content of BrO^-, BrO_2^- and BrO_3^-) remains partially or completely unknown. Only in the study by Hashmi[1] are the concentration-changes of the three oxidizing components followed, but the decomposition curves given by this author show a rather unexpected irregular course.

During a study with hypobromite solutions we worked out an accurate titration method of analysis for the three oxidizing components. In this paper we report use of this procedure to investigate the stability of hypobromite solutions over the concentration range 10^{-1}–$10^{-3}N$.

EXPERIMENTAL

Apparatus

The amperometric titrations were performed with the Metrohm E 261 R polarograph, using a rotating microplatinum-indictor electrode and an Ag/AgCl/satd KCl reference electrode.

Reagents

All reagents were of analytical grade and the water was purified by ion-exchange. Buffer solution with pH 8·3 was obtained by the addition of hydrochloric acid to a borax solution. Standard 0·1*N* arsenite was prepared by dissolving an exactly weighed quantity of arsenious oxide; 0·01 and 0·001*N* arsenite solutions were obtained by dilution.

Solutions of hypobromite. Solutions of about $10^{-1}N$ (indicated as S_1, S_2, S_3) were prepared by addition of 40 ml of 6*N* sulphuric acid to a solution containing 6 g of potassium bromate and 32 g of potassium bromide in 800 ml of water. After a reaction time of one hour 48 ml of 10*M* sodium hydroxide were added quickly (solutions S_1 and S_3) or slowly (solution S_2) and the hypobromite solution obtained was diluted to 2 l. with water.

Solutions, $10^{-2}N$, (indicated as S_4, S_5, S_6) were obtained by tenfold dilution with water of the solutions S_1, S_2 and S_3 respectively.

Solutions, $10^{-3}N$ (indicated as S_7, S_8, S_9) were obtained by hundredfold dilution with 0·01*M* sodium hydroxide of the solutions S_1, S_2, and S_3 respectively.

The pH, measured immediately after preparation, was 12·8 for the $10^{-1}N$ hypobromite solutions and 11·9 for the dilute solutions.

Storage. All the solutions were kept at room temperature (23 ± 1°); the solutions S_1, S_2, S_4, S_5, S_7 and S_8 were stored in brown bottles, the solutions S_3, S_6 and S_9 in colourless bottles. To eliminate the influence of the quality of the glass on stability, identical bottles from the same firm (Scott and Jena) were used after 1 week's pretreatment with $10^{-1}N$ hypobromite.

Determination of the BrO^-, BrO_2^- *and* BrO_3^- *concentration.* A new procedure was used for the determination of the three oxidizing components in the hypobromite solutions. It is based on their reaction with arsenite or iodide at different pH.

Determination of BrO^-. For $10^{-1}N$ solutions, to 25·00 ml of hypobromite solution, 0·1*N* arsenite is added until 1 ml before the equivalence point; after the addition of 25 ml of pH 8·3 buffer and 0·5 ml of 0·05% Bromothymol Blue as indicator, the titration is continued until a colour change from yellow-green to blue-green is obtained.

For 10^{-2}–$10^{-3}N$ solutions, 25·00 ml of hypobromite solution and 10 ml of pH 8·3 buffer are titrated with an equinormal arsenite solution and the equivalence point is detected amperometrically.

Determination of BrO_2^-. For $10^{-1}N$ solutions, 5 ml of 20% potassium iodide solution are added very quickly (addition time <1 sec) to the BrO_2^- solution obtained after the determination of BrO^-; the I_3^- formed is titrated with 0·1*N* arsenite, with starch as indicator. A colour change from mauve to blue-green indicates the equivalence-point.

For 10^{-2}–$10^{-3}N$ solutions, the same procedure is followed as for $10^{-1}N$ solutions but the I_3^- formed is titrated amperometrically with a 0·01 or 0·001*N* arsenite solution.

Determination of total $BrO^- + BrO_2^- + BrO_3^-$. For 10^{-1} *N* solutions, 12 ml of 6*M* hydrochloric acid and 0·5 ml of 0·05% Quinoline Yellow solution are added to 25·00 ml of 0·1*N* arsenite and the solution is titrated with hypobromite until a colour change from yellow to colourless is obtained.

For 10^{-2}–$10^{-3}N$ solutions, 12 ml of 6*M* hydrochloric acid are added to 25·00 ml of 0·01 or 0·001*N* arsenite and the solution is titrated amperometrically with 10^{-2} or $10^{-3}N$ hypobromite.

Calculation of BrO_3^- *concentration.* The concentration of BrO_3^- is obtained by subtracting the sum of the $[BrO^-] + [BrO_2^-]$ from the total oxidizing capacity of $[BrO^-] + [BrO_2^-] + [BrO_3^-]$.

RESULTS AND DISCUSSION

Procedure

The hypobromite solutions (S_1–S_9) were analysed as soon as possible (10–20 min after their preparation) and then after standing during 1, 3 and 6 hr. The analyses were repeated after 24 hr and then at intervals of 3 or 4 days during a period of 29 days; the results of some analyses are summarized in Table I; (*a*), (*b*), (*c*) and (*d*) refer respectively to $[BrO^-]$, $[BrO_2^-]$, $[BrO_3^-]$ and the total $[BrO^-] + [BrO_2^-] + [BrO_3^-]$; the results are expressed in $N \times 10^2$ for the solutions S_1–S_3, $N \times 10^3$ for the solutions S_4–S_6 and $N \times 10^4$ for the solutions S_7–S_9. The $10^{-1}N$ solutions (S_1, S_2, S_3) were further investigated during a total period of 238 days and the results were set out in Figs. 2, 3 and 4.

Initial composition

The analysis during the first hours after preparation demonstrated that after 20 min the internal composition of all hypobromite solutions has already reached an equilibrium and the solutions are ready for use.

The data obtained in the analysis after 1 day (Table I) indicate that the initial internal composition of the hypobromite solutions is dependent on the rate of addition of sodium hydroxide to the acid bromine solution during the preparation: slow addition (S_2) gives a low BrO^- content and a high yield of BrO_2^- and BrO_3^-, while a fast addition (S_1 and S_3) causes a higher BrO^- content, the absence of BrO_2^- and a smaller yield of BrO_3^-. The total oxidizing capacity, however, is not influenced by the rate of addition of alkali.

The effect of varying rate of addition of alkali during the preparation of hypobromite, which was studied in a separate series of experiments, is illustrated in Fig. 1: with slower addition a continuous decrease of BrO^- concentration and increase of BrO_3^- concentration occurs while the BrO_2^- content reaches a plateau with addition times >300 secs. This influence must be attributed to the instability of BrO^-, BrO_2^-, HBrO and $HBrO_2$ in weakly acid and alkaline medium, which

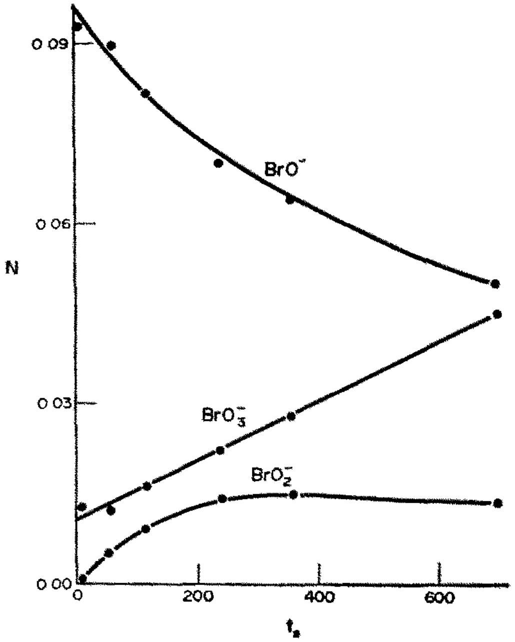

FIG. 1.—Influence of the addition time of NaOH (t_g) on the composition of the hypobromite solution.

results in the partial transformation of these components into the stable BrO_3^- during slow addition of alkali.

Stability of hypobromite solutions

The variation of normality as a function of storage time (Table I) reveals a marked difference between analogous solutions kept in colourless and brown bottles. The variations in concentration of the hypobromite solutions stored in brown bottles (S_1, S_2, S_4, S_5, S_7, S_8) can be explained qualitatively by a decomposition mechanism with two second-order reactions,[6-9] which is supported by the further stability investigation during 238 days:

$$BrO^- + BrO^- \xrightarrow{k_1} BrO_2^- + Br^- \quad \frac{-d[BrO^-]}{dt} = 2k_1[BrO^-]^2 + k_2[BrO^-][BrO_2^-] \tag{1}$$

$$BrO^- + BrO_2^- \xrightarrow{k_2} BrO_3^- + Br^- \quad \frac{d[BrO_2^-]}{dt} = k_1[BrO^-]^2 - k_2[BrO^-][BrO_2^-]$$

$$\times \frac{d[BrO_3^-]}{dt} = k_2[BrO^-][BrO_2^-] \tag{2}$$

In accordance with these reactions the internal composition (concentration of BrO^-, BrO_2^- and BrO_3^-) is more stable for the dilute solutions and the BrO_2^- concentration varies with mode of preparation (S_1 increase; S_2 decrease). The total

oxidizing capacity is not influenced by the occurrence of these decomposition reactions; its very slow decrease for the 10^{-1}–$10^{-2}N$ solutions and somewhat more pronounced decrease for the $10^{-3}N$ solutions must be attributed to catalytic reduction[10] or reaction with impurities.

The hypobromite solutions stored in colourless bottles are much less stable than the other solutions: the decomposition rate of BrO^- by transformation into BrO_3^-, and the reduction rate of BrO^-, resulting in a loss of total oxidizing capacity, are both increased by exposure to the light. In contrast to solutions stored in the dark,

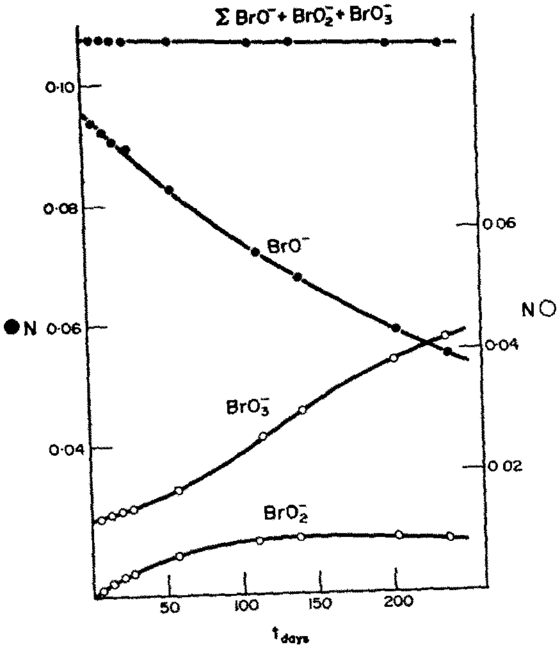

FIG. 2.—Decomposition curves of a BrO_3^--free $10^{-1}N$ hypobromite solution (S_1) stored in a brown bottle.

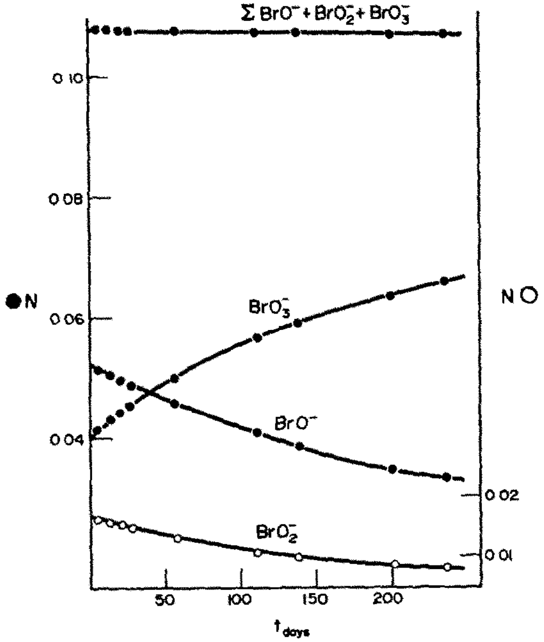

FIG. 3.—Decomposition curves of a BrO_3^--containing $10^{-1}N$ hypobromite solution (S_2) stored in a brown bottle.

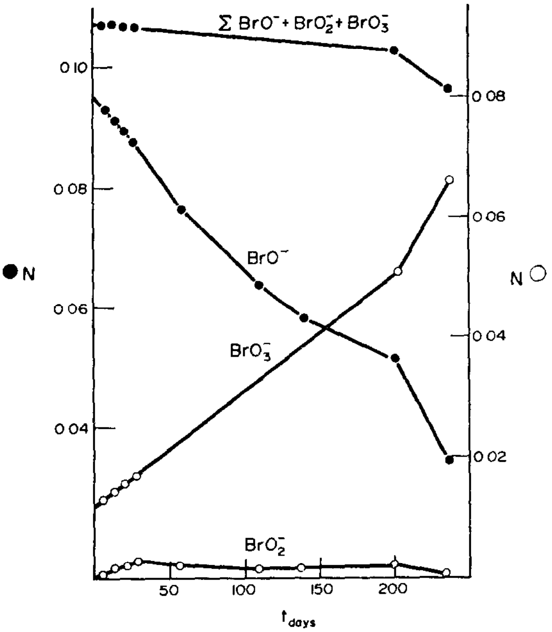

FIG. 4.—Decomposition curves of a BrO_2^--free $10^{-1}N$ hypobromite solution (S_3) stored in a colourless bottle.

in solutions stored in light the total relative variation of BrO^- concentration becomes more pronounced with increasing dilution of the hypobromite solutions.

Stability of $10^{-1}N$ *solutions over a long period*

From the curves of $[BrO^-]$, $[BrO_2^-]$ and $[BrO_3^-]$ as a function of time for the solutions S_1 and S_2 (Figs. 2 and 3) approximate reaction rate constants k_1 and k_2 ($l.mole^{-1}.day^{-1}$) were determined: for solution S_1, $k_1 = 2{\cdot}25 \times 10^{-2}$ and $k_2 = 31{\cdot}1 \times 10^{-2}$, for solution S_2, $k_1 = 2{\cdot}28 \times 10^{-2}$ and $k_2 = 30{\cdot}9 \times 10^{-2}$.

The curves for solution S_3 (Fig. 4) show an irregular pattern which is due to the varying light intensity during the period of storage.

CONCLUSIONS

With the proposed method of preparation, the 10^{-1}–$10^{-3}N$ hypobromite solutions can be used practically immediately after dilution to the required concentration; a maximum yield of BrO^- is obtained by a fast addition of alkali to an acid bromine solution, whereas the total oxidizing capacity $(\Sigma[BrO^-] + [BrO_2^-] + [BrO_3^-])$ is independent of the rate of addition of alkali.

The study of the decomposition of hypobromite solutions demonstrates that storage in the dark is always recommended and becomes an absolute requirement for obtaining sufficient stability of dilute solutions ($<10^{-2}N$). The decomposition of solutions protected from light is caused partly by two second-order reactions which result in a change of the internal composition by the formation of BrO_2^- and BrO_3^- and partly by a reaction with impurities whereby Br^- is formed and the total oxidizing capacity is decreased.

For volumetric applications where $[BrO^-]$ and $\Sigma[BrO^-] + [BrO_2^-] + [BrO_3^-]$ are involved a daily check of the $[BrO^-]$ in $10^{-1}N$ hypobromite is required; a weekly check of this component in 10^{-2}–$10^{-3}N$ hypobromite and of $\Sigma[BrO^-] + [BrO_2^-] + [BrO_3^-]$ in 10^{-1}–$10^{-3}N$ hypobromite is sufficient.

Zusammenfassung—Die Stabilität von Hypobromitlösungen 10^{-1}–$10^{-3}N$, aufbewahrt in braune odere farblose Flaschen, war kontrolliert. Diese Untersuchung erlaubte uns das Reaktionsmechanismus der Zersetzung zu bestimmen und einige praktische Schlüsse zu ziehen hinsichtlich die Optimale Bereitungsmethode und die erforderliche Kontrollefrekwentie von Hypobromitlösungen angewendet als analytisches Reagens.

Résumé—La stabilité de solutions d'hypobromite 10^{-1}–$10^{-3}N$ conservées dans des bouteilles brunes ou incolores a été contrôlée à la température ambiante. Cette étude nous a permis de déterminer les réactions de décomposition, et de tirer quelques conclusions pratiques concernant la méthode optimale de préparation et la fréquence nécessaire de contrôler des solutions d'hypobromite employées comme réactif analytique.

QUANTITATIVE REFLECTOMETRY—I

PRINCIPLES AND SCOPE

DAVID KEALEY
School of Chemical Science and Technology, Kingston Polytechnic,
Kingston-upon-Thames, Surrey, U.K.

(*Received* 24 *March* 1972. *Accepted* 25 *April* 1972)

Summary—The technique of quantitative reflectometry is critically investigated, the model being the quantitative determination of nickel in aqueous media. Direct reflectance measurements can be made on commercially available nickel test-strips which develop a pink or red colour in the presence of nickel ions. Relative precisions at the 10 and 50 ppm levels are 2.3-3.6%.

THE DETERMINATION of materials in the form of spots on an absorbent paper or other inert support has been the subject of study for many years. Visual qualitative spot-tests of the type developed by Feigl[1] and his co-workers have provided the basis for many such studies, whilst quantitative aspects of both paper and thin-layer chromatography have been explored in detail. Tananaeff[2] used the term "spot colorimetry" to describe methods of direct measurement, but "reflectometry" is considered more appropriate for the technique described in this paper.

Early attempts to obtain quantitative data directly from spot-tests by reflectance or transmittance measurements yielded relative precisions of 10–20%.[3–8] In some cases, the poor precision can be attributed to variation in spot size, but results were little better when the spots were confined within a pre-determined area.[3,4,6] Malissa[9] considers that poor precision is due primarily to the variable physical properties of absorbent paper and that results achieved by eye are more reliable than those from instrumental measurements. In particular, the ring-oven technique of Weisz[10] has achieved much success, owing to its simplicity, and can give relative precisions of 6–20%. Investigations by other workers[11,12] have shown that large variations occur in detection limits for a number of spot-tests when different sources of filter-paper are used. Ayers[13] has studied spotting techniques and the effect of using different types of filter-paper on the determination of a variety of organic and inorganic species. Although an error of 2–5% was claimed, no details of precision were given. It is apparent that quantitative results obtained by use of conventional spot-test procedures are often unreliable.

Reflectance measurements on spots separated by thin-layer chromatography have yielded relative precisions of 2·2–20%. A bibliography of applications to organic and inorganic systems is given by Frei.[14] However, the overall time for an analysis is usually at least 1–2 hr, and the manipulations involved increase the risk of incurring determinate errors. Vaeck[15] has used a chromatographic technique for the determination of nickel in alloys whereby interfering elements move with the developing solvent, leaving the nickel spot almost at the origin. Uniformity of distribution of nickel over the initial spot area was achieved by applying the spot in 3*M* hydrochloric acid solution. After spraying with rubeanic acid or dimethylglyoxime solution, the reflectance of the dried nickel complex was measured spectrophotometrically. Relative precisions of 1·5–3% were achieved but the complete procedure took 5–6 hr.

The advantages of direct reflectance measurements are speed and simplicity, and the recent commercial availability of reagent-treated test-strips has prompted a fresh examination of this approach. The determination of nickel has been chosen to illustrate the capabilities of the proposed technique as test-strips are available which show a high selectivity for nickel ions. Each strip consists of a white plastic backing (0·55 × 6·0 cm) to which is attached a rectangular piece of white, reagent-impregnated absorbent paper (0·65 × 0·60 cm) close to one end. On immersion in a solution containing nickel ions, the paper becomes coloured from pink to red depending on the concentration of nickel. For semi-quantitative work, a colour-matching chart is provided covering the range 10–500 ppm.

THEORY OF REFLECTANCE MEASUREMENTS

Kubelka-Munk equation

The most widely accepted theory of diffuse reflectance is that developed by Kubelka and Munk.[16] A full account of this theory and the derivation of the basic equation relating reflectance, absorption, scattering and concentration is given by Kortüm.[17] The Kubelka-Munk equation may be written in the form:

$$F(R_\infty) = \frac{(1 - R_\infty)^2}{2R_\infty} = \frac{K}{S} \tag{1}$$

where R_∞ is the absolute diffuse reflectance of an infinitely thick opaque layer (in practice 0·1–100 mm depending on particle size), K the absorption coefficient and S the scattering coefficient.

K and S have differing wavelength dependence, hence the equation holds only for monochromatic radiation. For low concentrations of absorbing species on an inert support (diluent) the value of S is determined solely by the diluent and can be assumed to be constant over a limited concentration range. Under such conditions, K is proportional to the concentration of the adsorbed species (*cf.* Beer-Lambert law for solutions) and the equation may be rewritten:

$$F(R_\infty) = \frac{(1 - R_\infty)^2}{2R_\infty} = \frac{2{\cdot}303\varepsilon \,.\, C}{S} \tag{2}$$

or

$$F(R_\infty) = \frac{(1 - R_\infty)^2}{2R_\infty} = \text{constant} \times C \tag{3}$$

where ε is the decadic molar absorptivity and C the molar concentration of the adsorbed species.

As in a solution system which obeys the Beer-Lambert law, adherence to this form of the Kubelka-Munk equation is indicated by linearity of a calibration curve. Curvature towards the concentration axis occurs at high concentrations and is attributable to an increasing proportion of regular reflectance.[17] Such reflectance increases with absorption coefficient, K, and particle size, which therefore determine the extent of the linear portion of the curve and the degree of curvature. Other effects may cause curvature at low R_∞ values, and it has been suggested[17] that caution be exercised in using values below 0·6.

The precision of measurements is normally limited to 2–3 % by variations in humidity, but it may well exceed this level, owing to instrumental fluctuations. The variation of relative error with reflectance, assuming a constant instrumental reading error, is similar to that observed for the Beer-Lambert law, *i.e.*

$$\frac{dC}{C} = \frac{(R_\infty + 1)\, dR_\infty}{(R_\infty - 1)R_\infty}$$

When dC/C is plotted as a function of R_∞ (Fig. 1), a minimum occurs at $R_\infty = 0{\cdot}414$. Reflectance measurements outside the range 0·2–0·7 are thus subject to increasingly large instrumental reading errors.

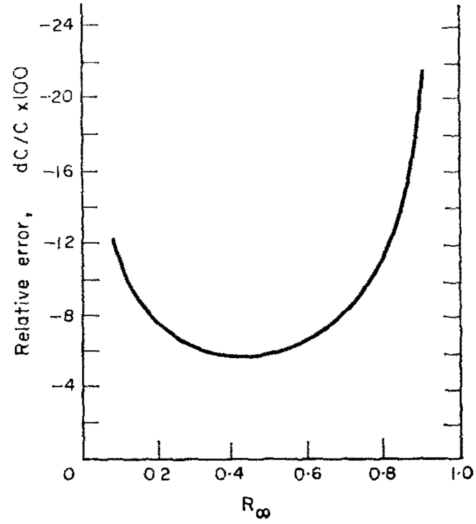

FIG. 1.—Relative error as a function of reflectance, $dR_\infty = 0{\cdot}01$.

It should be emphasized that, like the Beer-Lambert law, the Kubelka-Munk equation represents a limiting case assuming low concentration, monochromatic radiation and a negligible degree of regular reflectance. Strictly, it applies only to absolute reflectance measurements (R_∞) obtained by measuring both samples and blank against an accepted standard of known high reflectance, *e.g.*, freshly prepared magnesium oxide. Only if the diluent or adsorbed species shows very low absorption will a linear curve be obtained by plotting $F(R'_\infty)$ against concentration (R'_∞ represents reflectance measured relative to a blank of the pure diluent). Increasing curvature at low concentrations of adsorbed species will occur, the larger the absorbance of the diluent. For diluents with R_∞ values greater than 0·95 the effect is insignificant.

As an aid to the choice of an optimum concentration range for reflectance measurements, the reflectance values for standards may be plotted as a logarithmic function of concentration (Fig. 2). The curve is similar to a Ringbom plot for solution measurements.[18,19] The linear portion indicates the optimum concentration range and the slope is related to sensitivity and precision. The precision can be calculated for a given instrumental reading error, *e.g.*, for a reading error of 0·01, i.e.; $dR_\infty = 0{\cdot}01$,

$$\frac{dC}{C} . 100 = 2{\cdot}303 \frac{d\,(\log C)}{dR_\infty}$$

or

$$\frac{dC}{C} \cdot 100 = \frac{2{\cdot}303}{\text{slope}}$$

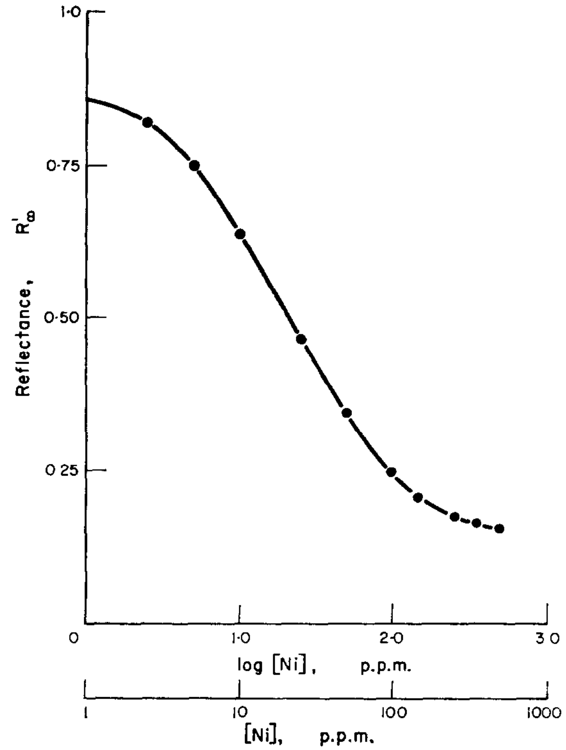

FIG. 2.—Ringbom plot for nickel complex at 547 ± 1 nm. Two-minute immersion time; reference standard MgO.

EXPERIMENTAL

Reagents and apparatus

Standard nickel solution, 500 ppm. Nickel chloride hexahydrate (2·024 g) dissolved in distilled water and diluted to 1 litre. Other standards were prepared by dilution as required.

Nickel test-strips, "Merckoquant," E. Merck.

Magnesium ribbon.

Unicam SP800 recording spectrophotometer.

Unicam SP890 diffuse reflectance attachment.

Joyce-Loebl "Chromoscan" recording densitometer.

Visible reflectance spectrum of the nickel complex

Six test-strips were immersed consecutively in a 10-ppm nickel solution for 2 min (±1 sec), rinsed with distilled water and allowed to dry in air for about 1 hr. The six strips were trimmed to facilitate mounting on a 2½ × 3 in. white card to form a continuous coloured area approximately ¾ × ½ in. The visible reflectance spectrum of the complex was recorded on the SP800 spectrophotometer, with freshly prepared magnesium oxide as a reference standard. Additional sets of six test-strips were prepared and mounted on cards, covering a wide range of nickel concentrations—0, 1, 2·5, 5, 25, 50, 100, 150, 250, 350 and 500 ppm. The period of immersion (2 min), washing and drying procedures were carefully standardized. The reflectance spectrum of each set was recorded as before (Fig. 3).

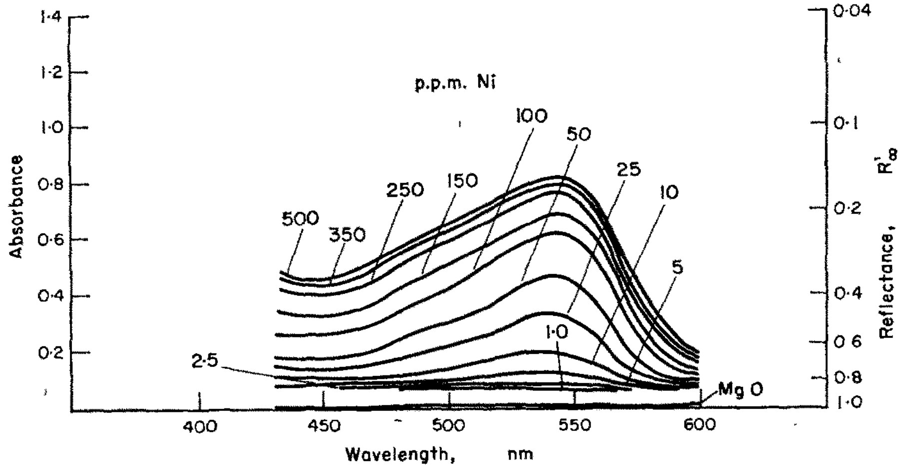

Fig. 3.—Reflectance spectra of nickel test-strips (reference MgO).

Optimization of conditions for quantitative measurements

Reflectance measurements were made on the Joyce-Loebl "Chromoscan," using a green filter (λ_{max} 550 nm), rectangular slit 0510, cams C or D, and neutral density wedge 0-2D. The plastic backing of each strip was trimmed to facilitate mounting at right angles to the direction of scan, and held in position with the white plastic backing plate and elastic sample-retaining strap supplied with the sample holder.

Immersion time. Single test-strips were immersed in 0–100 ppm nickel solutions for times of 0·5, 1·0, 1·5 and 2·0 min (±1 sec), rinsed with distilled water and dried in air for about 1 hr. During immersion, the solutions were gently agitated by hand. Reflectance measurements are given in Table I.

Table I.—Effect of immersion time on reflectance of Ni test-strips

[Ni], *ppm*	Reflectance (cm.)			
	0·5 min*	1·0 min*	1·5 min*	2·0 min*
0	0	0	0	0
10	1·4	1·7	1·85	1·9
25	3·5	4·25	5·4	5·95
50	6·4	7·85	8·15	9·0
75	8·2	10·95	12·6	13·35
100	10·25	12·2	14·2	15·1

Notes 1. Reflectance measured to nearest 0·05 cm.
2. Maximum pen travel is 15·5 cm.
3. 0-ppm (blank) set to zero.
* Immersion time.

Agitation of solutions. Two sets of five test-strips each were immersed consecutively in a 10-ppm nickel solution for 2 min, rinsed with distilled water and dried in air for about 1 hr. For the first set, the solution was agitated gently with a magnetic stirrer; for the second set the solution was not stirred. The procedure was repeated for a 50-ppm solution and reflectance measurements made as before (Table II).

Drying of test-strips. Five test-strips were immersed consecutively in a 10-ppm nickel solution for 2 min, rinsed with distilled water and dried for 3 min with a hot-air blower. The procedure was repeated for a 50-ppm solution and reflectance measurements recorded as before (Table II).

Long-term stability of developed test-strips. Reflectance measurements on a number of test-strips covering the concentration range 0–100 ppm were repeated at intervals over a period of three months (Table III).

RESULTS AND DISCUSSION

The visible spectrum of the nickel complex shows a broad maximum at 546 nm which shifts to 548 nm at higher concentrations (Fig. 3), an effect which could be due to an increase in particle size. The system obeys the Kubelka–Munk equation up to 100 ppm of nickel but above this level there is curvature towards the concentration axis (Fig. 4). The onset of curvature would be affected by the quality of the paper and conditions of formation of the complex, both of which affect particle size, which in turn affects the proportion of regular reflectance. Thus, for example, linear response could be extended to higher concentrations by decreasing the immersion time. However, the difficulty in timing short immersion periods accurately would result in poorer precision; one minute is considered to represent a practical lower limit. A Ringbom plot (Fig. 2) confirms that the optimum concentration range, for the conditions used, has an upper limit of around 100 ppm and that the lower limit is around 5 ppm. The relative precision, calculated from the slope of the curve, is 2·8 %, assuming an instrumental reading error of 0·5 %, and 5·6 % for a reading error of 1 %. Measurements need not be restricted to the linear portions of the Kubelka–Munk or Ringbom curves, but results will be less reliable and precision poorer outside these limits. In addition, Fig. 1 demonstrates the importance of restricting reflectance measurements to within the range 0·2–0·7 to minimize instrumental error. The linear portion of the Ringbom curve falls within these limits.

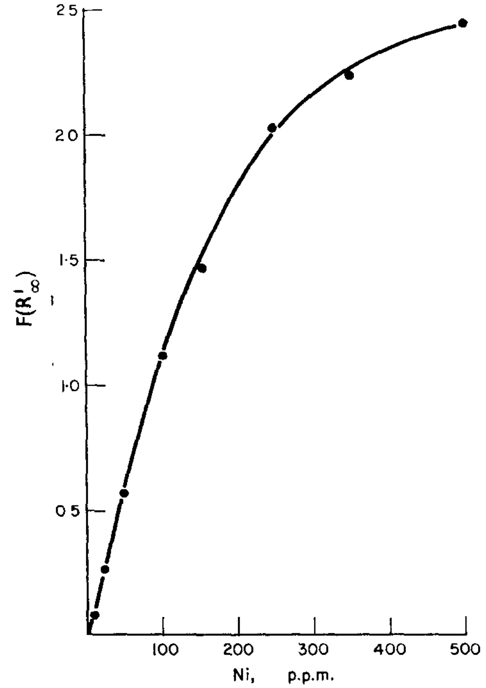

FIG. 4.—Kubelka–Munk plot for nickel complex at 547 ± 1 nm. Two-minute immersion time; reference standard MgO.

Optimum conditions for the preparation of strips for quantitative measurement were established, using the Joyce–Loebl "Chromoscan", a double-beam instrument giving a repeatability of better than 1 %. Measurements can be made on single test-strips, whereas six strips were required to give adequate response on the SP800 spectrophotometer. The spots were scanned across the width of a strip, with a rectangular slit having an area (0·05 cm^2) about 1/7 that of the test area. The recorder trace thus represents the average reflectance from areas equivalent to that of the slit.

Typical traces are shown in Fig. 5. A pronounced edge effect can be observed, owing to a higher concentration of the nickel complex around the edges of the test-strips. Uneven distribution of the adsorbed species is inherent in this type of system because of enhanced capillary flow near the exposed edges of the paper. The average reflectance over the centre two-thirds of the recorder trace is assessed subjectively as shown by the broken lines in Fig. 5. Readings are in arbitrary units, as the design of the instrument does not permit a calibrated response in reflectance. However, scale expansion facilities using cams enable linear calibration curves to be prepared even when the Kubelka–Munk equation is not valid.

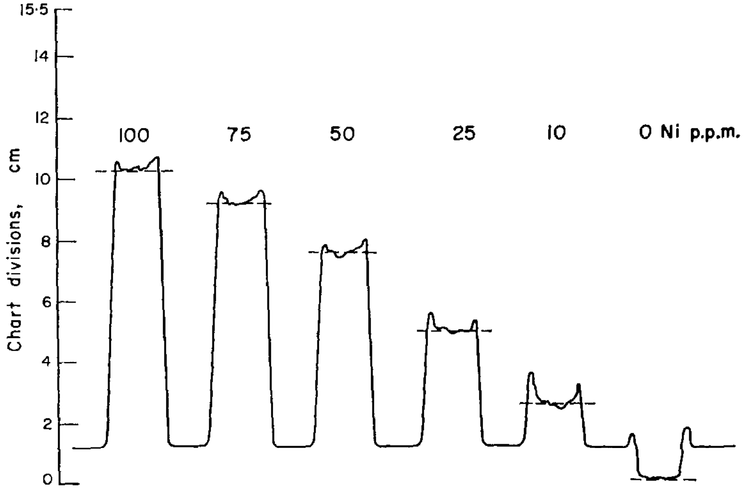

FIG. 5.—Scanning densitometer traces of reflectance of nickel test-strips, at 550 nm.

A 2-min immersion time was selected so as to produce reflectance readings within the optimum range and without incurring significant timing errors. Immersion of the strips in unstirred solutions gave a more even distribution of the complex than did use of continuous stirring. This was particularly noticeable at the 10-ppm level and resulted in poorer precision (Table II). At the 50-ppm level, uneven distribution was again noticeable and the good precision is considered to be fortuitous. No significant differences were observed between those strips which were dried in air for 1 hr and others which were dried with a hot-air blower for 3 min (Table II). Relative precision for unstirred solutions is between 2·3 and 3·6%, which agrees well with the value of 2·8% calculated from the Ringbom curve, for a 0·5% reading error.

The stability of strips covering the concentration range 10–100 ppm, with respect to changes in reflectance over a period of several months, is good (Table II). Relative precision is comparable to that for sets of freshly prepared standards. The variation observed is thought to be due primarily to changes in humidity. Further checks will be made on these particular strips from time to time to assess stability over a longer period.

CONCLUSIONS

It has been shown that quantitative information can be obtained by direct reflectometry using commercially available test-strips for nickel. Relative precision for sets of five standards at the 10- and 50-ppm levels is between 2·3 and 3·6%.

The overall time for the procedure is under 10 min and the long-term stability of prepared standards allows instrument calibration checks to be made very rapidly.

As test-strips for other species in solution become available, it should be possible to develop similar quantitative procedures. Direct reflectometry as described in this paper should be capable of further refinement and it is hoped that it may eventually become a satisfactory alternative to some of the well-established methods of quantitative trace analysis.

Acknowledgement—I should like to express my gratitude to Professor E. J. Shellard of Chelsea College of Science and Technology for the use of the Joyce-Loebl "Chromoscan."

Zusammenfassung—Das Verfahren der quantitativen Reflektometrie wird kritisch untersucht; als Modell wird die quantitative Bestimmung von Nickel in wäßrigen Medien verwendet. An käuflichen Nickel-Teststreifen können direkte Reflexionsmessungen ausgeführt werden: sie zeigen in Gegenwart von Nickelionen eine rosa oder rote Farbe. Die relativen Genauigkeiten bei 10 und 50 ppm sind 2,3-3,6%.

Résumé—On a étudié de manière critique la technique de réflectométrie quantitative, le modèle étant la détermination quantitative du nickel en milieux aqueux. Des mesures de réflectance directes peuvent être faites sur des lamelles réactives de nickel commercialement disponibles, qui développent une coloration rose ou rouge en la présence d'ions nickel. Les précisions relatives aux niveaux de 10 et 50 p.p.m. sont 2,3-3,6%.

Summary—Chromium(III) is oxidized to chromium(VI) at room temperature or by conventional persulphate oxidation. The chromium(VI) is separated from other metal ions by retention on a small anion-exchange column, and then eluted with a perchlorate solution and measured spectrophotometrically with a flow-through cell. The method is rapid, selective and amenable to automation.

ADAM AND PŘIBIL[1] have pointed out that direct colorimetric determination of chromate or dichromate, though less sensitive than with the diphenylcarbazide reaction, is more free from interference by other metal ions. These authors used a solvent extraction technique to avoid certain interferences and to achieve concentration of the chromate.

Present anion-exchange separations of chromium(III) are not easily adapted to an instrumental cycle since the resin is not maintained in a single form or the chromium is not retained completely.[2] Chromium(VI) separations[3] require solution conditions for sorption which are difficult to attain after sample dissolution and oxidation.

Recently a forced-flow liquid chromatograph was used for the rapid separation and determination of small amounts of iron.[4] With the aid of a calibration curve, the amount of iron was determined simply by measuring the height of the peak eluted.

This apparatus and principle have now been applied to the determination of chromium. The method described uses strong-base anion-exchange resin in only the perchlorate form to achieve separation from most other metal ions in a short (10-min) analysis cycle for chromium(VI). Solution conditions for sorption and concentration permit use of standard persulphate, periodate or cerium(IV) oxidation procedures. Selectivity of the method for chromium is shown by analysis of National Bureau of Standards samples containing many other metal ions. The detection system uses the absorbance of chromium(VI) at 360 nm to achieve sensitivity in the 1–10 μg range for sample volumes from 40 μl to 5 ml, without amplification of the spectrophotometer signal. A commercial detector with photomultiplier at 254 nm is sensitive to 25 ng of chromium(VI) in the absence of large amounts of nitrate or sulphate.

EXPERIMENTAL

Apparatus

The liquid chromatograph described earlier[4] was used. For a limited number of studies, a Chromatronix Model 200 UV detector was used. This has a 253·7-mm mercury-line source and a 1-cm light-path, 8-μl dead-volume flow-through cell. It is a double-beam differential photometer with a photomultiplier which can be attenuated from 0·01 to 0·12 absorbance units full scale, with a linear dynamic range from 0·0001 to 3·0 absorbance units.

Reagents

Rohm and Haas Amberlyst A-26 strong-base anion-exchange resin was ground wet and sieved while moist, to yield a 140–160 mesh fraction. Approximately 0·5 g of this was slurried with 25 ml of

the acidic 0·4*M* sodium perchlorate described below. After 3-min settling the fines were decanted. The decantation procedure was repeated until the supernatant liquid was clear.

A pH-3·75 eluent was prepared by adding perchloric acid to distilled water until the solution reached the required pH, as measured by pH-meter.

The 0·4*M* sodium perchlorate eluent was prepared by acidifying the sodium perchlorate solution to pH 3·75 with perchloric acid.

Ceric ammonium nitrate was dissolved and diluted to volume with 1*M* nitric acid to give a 0·018*M* cerium(IV) solution.

Standard reference materials

The treatment of each sample is described below.

Acid Open-Hearth Steel 20*F*. The sample was dissolved according to a standard procedure,[5] with the minimum necessary amounts of acid. A 20-ml portion of sulphuric–phosphoric acid mixture, (160 ml H_2SO_4 + 80 ml H_3PO_4 per litre) was added and heated. After dissolution, 5 ml of nitric acid were added cautiously and the solution was boiled to remove most of the excess of water and nitric acid. The salts were taken up in 50 ml of 1*M* nitric acid. Silver nitrate solution (2 ml, 1·0% w/v) and 20 ml of freshly prepared ammonium persulphate solution (15% w/v) were added, then the solution was boiled for 20 min, the volume being maintained constant with water. The solution was cooled, diluted to volume with 1*M* nitric acid and analysed within 20 min.

Aluminium Alloy 85*A*. The sample was dissolved according to a standard procedure for non-ferrous alloys,[5] with 10 ml of nitric acid and 2 drops of hydrofluoric acid. Dissolution was slow, so 1 ml of 30% hydrogen peroxide was added dropwise. After complete dissolution, 3 ml of sulphuric acid were added and the solution was evaporated till fuming. Then 25 ml of 1*M* nitric acid, 2 ml of 1% silver nitrate solution and 4 g of ammonium persulphate were added. The solution was boiled for 20 min, the volume being kept constant with water, then was cooled, diluted to volume with 1*M* nitric acid and analysed within 20 min.

Waspaloy (*Ni, Cr, Co*) 349. Dissolution followed the same procedure as for alloy 85A above. The cooled solution was transferred to a volumetric flask, 50 ml of 0·017*M* cerium(IV) in 1*M* nitric acid were added, and the solution was diluted to volume. Oxidation was done 15–20 min before the main analysis.

Standard chromium solution. A 0·05298*M* standard chromium(III) stock solution was prepared by dissolving Baker Analytical Reagent $CrCl_3.6H_2O$ (assay 99·0%) in water and 10 ml of nitric acid. The solution was evaporated to dryness, the residue dissolved in nitric acid and taken to dryness again to remove chloride, the evaporation treatment being repeated a third time. The salts were redissolved and the solution diluted to volume with 1*M* nitric acid. The solution was standardized by the persulphate oxidation method with use of a primary standard potassium dichromate solution and diphenylamine sulphonate indicator instead of permanganate.

Procedure

The 6·3-mm bore analytical column was filled with 0·25 g (weighed dry after use) of 140–160 mesh perchlorate-form Amberlyst A-26 slurried in 0·4*M* sodium perchlorate, pH 3·75. This gave a column bed 1·8 cm long, having a total capacity of approximately 1·5 meq. A typical chromium sample would contain 1×10^{-4} meq of chromium(VI).

The detector was set at 360 nm, with a stray-light filter and a tungsten source. The pressure was set to give a flow-rate of 3·0 ml/min for the acidic 0·4*M* sodium perchlorate eluent used to strip chromium (VI) from the column. The sorbing medium (perchloric acid, pH 3·75) was allowed to pre-equilibrate the column for 2 min before injection of a 0·514-ml sample in approximately 0·5–1*M* nitric acid. After 5·5 min the sample injection valve was returned to the by-pass loop mode to gather another aliquot in the sample loop. At minute 6 the acidic 0·4*M* sodium perchlorate flow was started and chromium was eluted; the peak was obtained within 7 min from the beginning of the chromatography At minute 10 equilibration was started for the next sample.

By means of the peak height obtained, the amount of chromium in the sample was read from a calibration curve prepared with standard solutions by the same procedure.

RESULTS

Oxidation

Cerium(IV) oxidizes[5] chromium(III) to chromium(VI) at room temperature.[6] The chromium(VI) anion is separated from the excess of cerium(IV) on the anion-exchange column. The oxidation of chromium(III) is rapid in dilute perchloric acid, or nitric acid, but slower in sulphuric acid.[7] Nitric acid was chosen for sample dissolution and the oxidation step because chromium(VI) is not retained on the resin from a solution containing enough perchloric acid for the oxidation.

The chromium can be oxidized with in-stream addition of cerium by means of a mixing chamber,[8] provided a delay loop is used to allow sufficient time for the oxidation. Figure 1 shows that 2 min is required for in-stream oxidation of chromium (III) under these conditions.

In the presence of fairly large amounts of manganese(II), cerium(IV) oxidation produces a precipitate of manganese dioxide. For this case and for oxidation of chromium in general, oxidation with persulphate is satisfactory, although it requires heating.

Conditions for separation

Resin. Initially a weak-base anion-exchange resin (Rohm and Haas A-21) was used to permit rapid elution of the chromium(VI) anion with dilute base. However, part of the chromium(VI) was reduced by the resin under the conditions employed. Sussman *et al.*[9] encountered similar difficulty with chromium(VI) on a weak-base anion-exchanger. A macroreticular, strong-base anion-exchanger, Rohm and Haas A-26, was found satisfactory.

Acidity. Chromium(VI) is retained by the A-26 resin in a tight band from 1*M* nitric acid (used in the oxidation step) or from more dilute acid. The ultraviolet spectrum of chromium(VI) changes appreciably with changes in acidity, indicating that a variety of chromium(VI) species is present. In perchlorate media between pH 2 and 4 the spectrum is due solely to $HCrO_4^-$.[10] For this reason, perchloric acid at pH 3·75 was used to equilibrate the column before injection of the sample and to wash ions other than the chromium(VI) anion from the column.

Eluent. Selectivity of the anion-exchange resin in the perchlorate form for chromium(VI) is an important consideration. Except in large concentrations where mass action becomes important, chemical interference is limited to anions of acids, which are stronger than H_2CrO_4 (pK 0·75).[11]

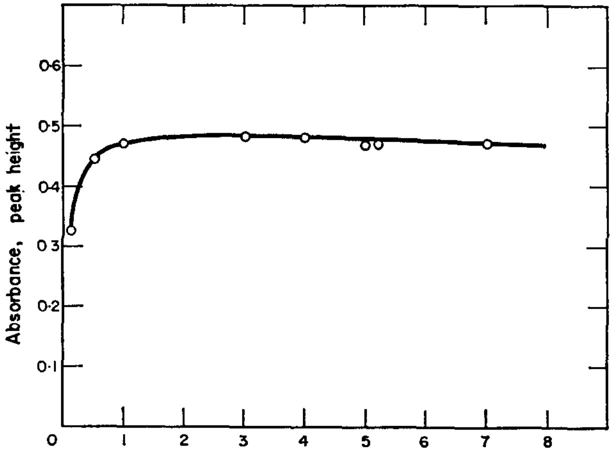

FIG. 1.—Time required for oxidation of chromium(III) by cerium(IV.)
Conditions: 2·08 × $10^{-3}M$ cerium(III) and (IV); 2·97 × $10^{-4}M$ chromium(III) and (VI) in 0·75*M* nitric acid.

The only common mineral acid anion which will rapidly displace chromium(VI) from a strong-base anion-exchange resin at low acidity is perchlorate. Reasons for this extremely high selectivity coefficient of perchlorate have been discussed.[11] A 0·4*M* sodium perchlorate solution adjusted to pH 3·75 with perchloric acid was selected as the lowest concentration able to strip chromium(VI) rapidly from the resin and produce a single coloured species for detection.

Analysis cycle time. The effect of the analysis cycle time on peak height was studied to determine a minimum cycle time. Each phase, pre-equilibration, injection and stripping, was varied in turn while the remaining two were held constant.

Changing the time from sample injection to stripping shows the greatest effect. Peak height decreases as the band spreads by diffusion. An initial change in peak height reflects slow conversion of various chromium(VI) species into a single one.

Detection wavelength. A fixed-wavelength detector at 254 nm with a photomultiplier provides a sensitive method for detecting chromium(VI) in the eluent. In the absence of significant concentrations of nitrate and sulphate, the detection limit, where signal:noise is 2·0, was reached at 25 ng of chromium(VI) in a 5-ml sample, with scale expansion to 0·01 absorbance unit for full-scale deflection.

Because nitrate (0·5–1·0*M* nitric acid) interferes at 254 nm, a wavelength of 360 nm, where it does not, was used. A calibration curve for 360 nm prepared by oxidizing standard chromium(III) solution with cerium(IV) in 5-fold stoichiometric excess is shown in Fig. 2. The deviation of the curve from a straight line at higher concentrations may be the result of the monomer–dimer equibrium of chromium(VI).[12] Curvature at lower concentrations is caused by using peak height rather than area, since the peak base-width remains nearly constant.

Separations

A typical chromatogram is shown in Fig. 3. This figure illustrates the 10-min cycle used for separation of chromium(VI) from a sample. The column equilibrated with perchloric acid (pH 3·75) for 2 min, then the sample is injected. The peaks at about 2·5 min are due to copper(II) and iron(III) in this sample. At minute 6, the

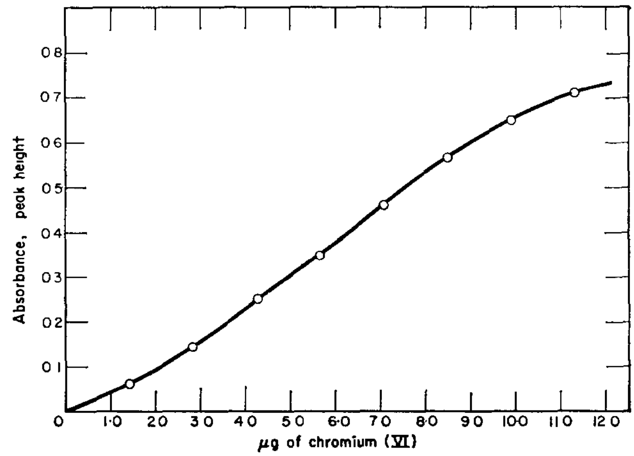

FIG. 2.—Calibration curve for chromium(VI) at 360 nm.

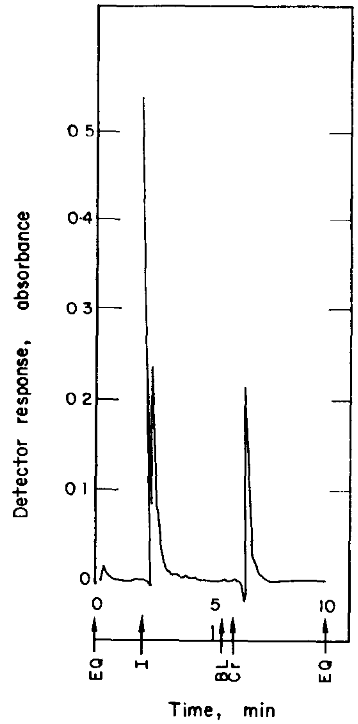

FIG. 3.—Typical chromatogram of chromium analysis.
Conditions: sample NBS 85A, 157·0 mg/50 ml;
0·514-ml loop; detection at 360 nm.

elution of the chromium(VI) is started with acidic 0·4*M* sodium perchlorate; the chromium peak occurs at minute 7. By minute 10 the absorbance has returned to the baseline and the next sample cycle can begin.

Results for analysis of three National Bureau of Standards samples containing chromium are summarized in Table I. In each case the weight of sample taken for analysis was varied so that a 0·514-ml loop containing the appropriate amount of chromium could be used for the calibration curve. Three replicates of each were analysed.

For Alumimium Alloy 85A and Acid Open-Hearth Steel 20F the precision is comparable to that shown on the Certificate of Analysis. Precision for Waspaloy 349 was not indicated by the Provisional Certificate of Analysis with the sample. For steel analysis the result was 4% relative higher than that of the Certificate or 2% relative higher than that of the NBS analyst. Interference studies indicate that this is due

to the excess of permanganate over chromium(VI). No attempt was made to reduce this selectively with hydrochloric acid as in the titrimetric procedure.

Oxidation of chromium(III) with cerium(IV) in standard sample preparation was used only with Waspaloy 349. For the other samples containing manganese in much larger amounts than chromium, a precipitate of manganese dioxide formed. Although the solution was filtered, chromium results were low. Oxidation with ammonium persulphate proved satisfactory.

Specificity of this procedure for chromium(VI) is indicated by the elemental analysis of the NBS samples shown in Table II. In a nitric acid sample, elements forming strong nitrate complexes show chemical (column overloading) interference. In nitric acid $<1M$ these are limited to molybdenum(VI), palladium(II), rhenium(VII), gold(III), mercury(II), thallium(I), bismuth(III), neptunium(IV) and plutonium(IV).[13] Another anion interfering chemically is permanganate. Permanganate was retained in a highly coloured band by the column in standard sample analysis and was desorbed only by repeated injections of perchloric acid (1 + 1) into the stripping eluent. No detrimental effect on the resin was apparent.

Zusammenfassung—Chrom(III) wird bei Raumtemperatur oder mit der üblichen Persulfatmethode zu Chrom(VI) oxidiert. Das Chrom(VI) wird durch Adsorption an einer kleinen Anionenaustausch-Säule von anderen Metallionen getrennt, mit einer Perchloratlösung eluiert und spektrophotometrisch in einer. Durchflußzelle gemessen. Das Verfahren ist rasch, selektiv und für die Automatisierung geeignet.

Résumé—Le chrome(III) est oxydé en chrome(VI) à température ambiante ou par oxydation habituelle au persulfate. Le chrome(VI) est séparé des autres ions métalliques par rétention sur une petite

colonne échangeuse d'anions, puis élué avec une solution de perchlorate et mesuré spectrophotométriquement avec une cellule à écoulement continu. La méthode est rapide, sélective, et peut être rendue automatique.

REVIEW OF THE ANALYTICAL CHEMISTRY OF MELATONIN

E. R. COLE and G. CRANK
Department of Applied Organic Chemistry, The University of New South Wales,
Kensington, 2033, N.S.W., Australia

(*Received* 23 *February* 1972. *Accepted* 28 *April* 1972)

Summary—A survey has been made of procedures, chemical and biochemical, for the separation and estimation of melatonin, the active constituent of the pineal gland. In view of the extremely small amounts of material generally present, discussion is built around chromatographic and spectroscopic techniques leading to a comparison with assays based on the skin-blanching effect of the hormone.

THE INDOLE DERIVATIVE melatonin (*N*-acetyl-5-methoxytryptamine, II in Fig. 1) has been characterized as the active constituent (hormone) of the pineal gland, a small conelike structure situated between the cerebral hemispheres of the mammalian brain. Until recently actions attributable to the pineal gland have been little understood, but a considerable volume of information on its function is now being accrued, including discussions on the relationships between age and weight of the gland and malignancy,[1] as well as on the use of melatonin as an adjunct in the treatment of rhabdomyo- and of osteogenic sarcomas,[2] thus lending interest to the establishment of adequate methods of analysis.

It has been known for over fifty years that mammalian pineal tissue contains a substance extremely potent in effecting blanching of amphibian and fish melanocyte tissue.[3,4,5] An aqueous extract of (50,000) lyophilized beef pineal glands, when submitted to selective extraction by ethyl acetate followed by countercurrent treatment of a concentrate, gave 40 μg of a pure active constituent, the structure of which (II) was suggested by a combination of spectroscopic evidence, chromatographic behaviour and reasoned deduction from comparisons of biological activity with that of other derivatives.[6] The structure was later confirmed by comparison with synthetic material.[7,8]

In considering the problems of its determination it is important to recognize that melatonin is only one of a series of indole derivatives present, which include serotonin (5-hydroxytryptamine, I)[9,10] 5- hydroxy- and 5-methoxyindole-3-acetic acids (III and IV respectively)[11,12] together with 5-methoxytryptophol (V).[13] The inter-relation of these materials is shown by the schematic representation in Fig. 1, in which the sequences leading to the formation of melatonin should be observed.

It was noted that the extract of pineal glands, in preventing the darkening of frog skin by the melanocyte-stimulating hormone, was at least 60 times as active as adrenaline or noradrenaline, 200 times as active as tri-iodothyronine and 5000 times as active as serotonin, thus reinforcing the need for specific characterization and methods of estimation. The scale of the analytical problem in this field is shown by the fact that based on the hydroxyindole-*O*-methyl transferase (HIOMT) activity of pineal tissue, it has been calculated that the output of the metabolite, 6-hydroxymelatonin, would be less than 7 μg per day.[14]

Melatonin is only very slightly soluble in water but is readily soluble in most

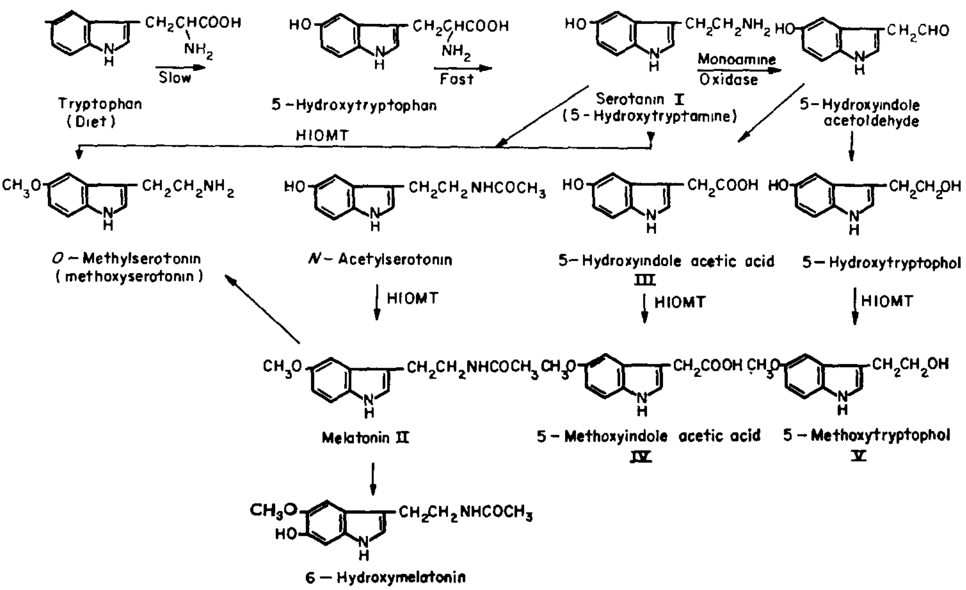

FIG. 1.—Inter-relation of pineal indoleamines and derivatives.

organic solvents and consequently may be extracted from biological materials by ethanol, acetone, chloroform or ethyl acetate. It has recently been found[15] that recoveries of more than 80% may be achieved from serum, either by direct extraction with ether or by continuous extraction with ethyl acetate. Such procedures will remove other indoles plus a great variety of materials normally present in serum. Thus it has been claimed that melatonin, which is chemically neutral, may be separated from acidic and basic substances by suitable treatment with dilute alkali and acid respectively.[16] However, these procedures must be treated with care if melatonin at the microgram level is not to be lost.

CHROMATOGRAPHIC PROCEDURES

In view of the small quantities to be determined it has been inevitable that chromatographic techniques have been well investigated as final steps in separation and estimation procedures.

Paper and thin-layer chromatography

Structural solute/solvent relationships are illustrated in the design of systems for these techniques. Thus in accordance with the polar properties of the solute, higher R_F values are obtained with polar organic solvents, alcohols, chloroform or ether, than with non-polar hydrocarbons (Table I).

It will be seen that addition of water to alcoholic solvents, acidic or basic, is necessary to reduce R_F values to a useful range. Sensitivity of detection on paper chromatograms is about 0·5 μg.

A comparison has been made of the R_F values of melatonin and serotonin with those of other indoleamines of biological origin.[19]

Some attention has recently been given[15] to reversed-phase chromatography in attempts to provide a system with a greater spread of R_F values over the series of

TABLE I.—PAPER CHROMATOGRAPHY OF MELATONIN

derivatives. With Whatman No. 1 paper impregnated with liquid paraffin the influence of various mixtures of methyl alcohol and water on R_F values was determined. It became apparent that although the R_F value of melatonin is related to the strength of the methyl alcohol–water mixture, falling as the alcohol content is reduced, nevertheless the system does not lead to good separation from other tryptamine derivatives. The influence of the stationary phase itself, apart from slightly lowering the R_F values with comparable solvents, is somewhat negligible and the control of the system is dominated by the solvent mixture.

Use of isotopes has been applied to the study of tissue metabolites following intravenous injection of (*a*) acetyl-^{3}H, (*b*) 2-^{14}C or (*c*) methoxy-^{14}C labelling of melatonin. With 3-MM paper and isopropanol–5% ammonia, (2:1), as developing solvent, two peaks, R_F values 0·22 and 0·55, were identified as the glucuronate and sulphate conjugates respectively of 6-hydroxymelatonin, accounting for 5% and 70–80% of administered radioactivity.[21] In this experiment an appreciable fraction (12%) of the radioactivity was attributed to an oxidation product (R_F 0·8), later characterized as 6-hydroxymelatonin itself.[23] In addition, 5-methoxyindole-3-acetic acid, accounting for 0·5% of the activity, has been identified by using the n-butanol–acetic acid–water, (4:1:1) system on 1-MM paper.*

---

* This result leads to the alternative that 5-methoxyindole-3-acetic acid found in pineal body arises either by deacetylation of melatonin followed by deamination or by *O*-methylation of 5-hydroxyindole-3-acetic acid, possibly by HIOMT.

It should be noted that the characteristic R_F values of melatonin may be modified on both paper and thin-layer chromatograms when the material is recovered from samples containing lipid material. If the latter is present as in direct solvent extraction, melatonin is held back, leading to formation of streaks rather than spots.[15]

The problem of tracing melatonin administered in animal experiments is enhanced by the fast rate of metabolism as illustrated by the rate of disappearance in the mouse.[21] Thus there will probably be a need for methods for endogenous rather than exogenous melatonin, and a key to the development of these are methods for 6-hydroxymelatonin and its conjugates in human urine.[14]

Silica gel and polyamide have been used in thin-layer chromatography (Table II). The use of silica gel follows normal practice and the application of polyamide is logical in view of the structural features of the substrate. With this technique a variety of organic solvent mixtures has been used but it has been claimed that two-dimensional chromatography is necessary to achieve a specific separation of melatonin. Moreover prior spraying of the thin-layer with 0·5% methanolic ascorbic acid solution is considered to enhance the stability of melatonin during chromatography.[27]

A summary of the chromatography of melatonin relative to a series of (*N*- methylated) tryptamines with one basic and one acidic solvent, has been presented.[20] Lower R_F values were given by the unacetylated amines with the acidic solvent.

Ion-exchange and gel chromatography

These procedures (Table III) have been mainly used as part of clean-up procedures.

The efficiency of Sephadex-25 in separating melatonin from other components of aqueous extracts of pineal glands has been measured against a synthetic mixture consisting of a macromolecule, "blue dextran" (molecular weight about 2×10^6) sodium chloride (representative of a small molecule) and melatonin. Fractions eluted with distilled water were tested for activity in the blanching reaction.[29] Distribution coefficients for the blue dextran and sodium chloride were 0 and 1 respectively, but K_d for melatonin was 2·8 following adsorption due to the indole nucleus. The correspondence of elution volumes in the control with those of the biological samples provides an inferential method of detection of melatonin (Fig. 2).

TABLE II.—THIN-LAYER CHROMATOGRAPHY OF MELATONIN

Adsorbent	Solvent system	Proportions	R_F for melatonin	Remarks	Refs.
Silica gel G	1. Acidic solvents n-butanol–acetic acid–water	12:3:5	0.90	Serotonin R_F 0.70	20, 21
	2. Basic solvents isopropanol–ammonia–water	8:1:1	0.92	Serotonin R_F 0.68	
Silica gel F254	isopropanol–ammonia–ethyl acetate	2:1:7			17
Silica gel G	3. Two-dimensional (*i*) methyl acetate–isopropanol–25% ammonia	9:7:4		Used for separation from sulphate and glucuronate of hydroxymelatonin	14
	chloroform–methanol	7:3			

TABLE II (*Continued*)

	or				
	(*i*) benzene–acetone (*ii*) ethyl acetate	1:1			
	4. Simple organic solvents				
	chloroform–methanol	9:1	0.34	Used in preparation of β-^{14}C melatonin	14
	chloroform–methanol	85:15		Detected decomposition products as additional spots, higher R_F value than melatonin	
Silica gel two-dimensional	(*i*) methyl acetate–isopropanol–25% ammonia	45:35:20	0.85	Used as two-directional system, claimed nearly specific for melatonin, with quantitative recovery; separates from 5-methoxytryptamine, 5-hydroxyindole-3-acetic acid, *N*-acetylserotonin, serotonin	24
	(*ii*) chloroform–methyl alcohol–acetic acid (two rises)	93:7:1	Separation good	Residual acid from the first solvent improves separation of melatonin following use of second solvent. Ascorbic acid included in loading solvent. Detection by spraying with ethanol–hydrochloric acid, followed by oxidation and colour formation on exposure to air	25

TABLE III.—ION-EXCHANGE AND GEL CHROMATOGRAPHY

System	Solvent	Remarks	Refs.
Dowex 50 WX 2 (hydrogen form)	Eluted by 0.1*M* ammonia in 65% ethanol	Elutes all indoleamines for later paper or thin-layer separation	20
Sephadex G25	Water	Elution volume 70–100 ml in various samples	28, 29
G15	Loaded from aqueous solution, eluted with 0.01*M* sodium chloride adjusted to pH 4 with hydrochloric acid	Elution volumes: tryptamine 115 ml, melatonin 130 ml, 5-methoxytryptamine 148 ml, serotonin 157 ml	30
G10	Elution pattern for metabolites: 0.1*M* hydrochloric acid and 0.02*M* ammonia, separated by small volume of water, are used in that order	Shows differential action from G-25	31
G10 (short column, 17 cm)	Elution with 0.01*M* sodium hydroxide after equilibration with same solvent	Melatonin appears as separate peak for pineal extracts as follows. Peak 1, mixture of 5-hydroxyindole acetic acid, tryptophan, indole acetic acid, 5-methoxyindole acetic acid Peak 2 melatonin Peak 3 5-methoxytryptophol, tryptamine	32
G10 (long column 143 cm)	Pretreated with 0.2*M* pyridine–0.05*M* acetic acid. Equilibrated and eluted with 0.01*M* sodium hydroxide	Position of melatonin confirmed	

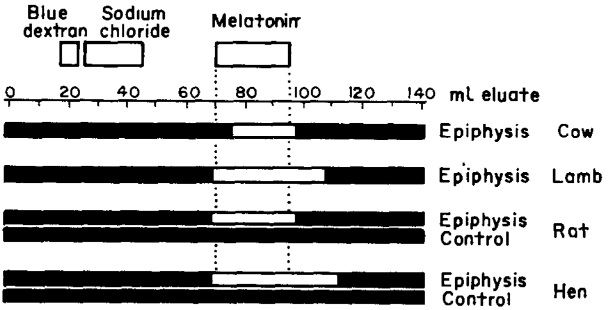

FIG. 2.—Gel chromatography of melatonin. The lower part of the diagram shows the blanching reaction on *Xenopus* larvae (adapted to a black background) after 20 min swimming in the eluate fractions from a Sephadex column. ■ Larvae remain dark: □ Larvae become lighter. The upper part of the diagram shows the elution pattern for the column. (From *Nature*, 1965, **208**, 1324, by permission of the copyright holders.)

Other melanin-concentrating agents which may occur in pineal tissue do not interfere[33,34] and other materials with amine groups—adrenaline, noradrenaline and serotonin—are retarded more on the Sephadex gel owing to its small content of carboxylic acid groups. In effect the gel functions in distilled water as a weak ion-exchange resin.

Gas–liquid chromatography

It is clear that this technique must contend with the polarity and relative involatility of melatonin, leading to the need for high column temperatures (above 200°) and rather long retention times.[35,36] Attention has also been given to control of temperatures (200–250°) at the injection port area, with the observation that for polar compounds subject to strong hydrogen bonding, such as *N*-acetyltryptamine and melatonin, it is necessary to maintain a flash-heater temperature 50–75° above that of the column,[36] otherwise curves assume broad tops suggestive of slow volatilization of the sample.

A balance must be struck between the operating temperature and the level of impregnation with stationary phase. Thus use of SE-30, silicone polymer, at the 0·75% level on silaned Gas Chrom P, was less satisfactory with melatonin than with alkaloids and steroids, despite the lower volatility of these compounds. Better results were obtained with melatonin following column loading at the 4% level but higher column temperatures were then needed.[36] The use of silaned support follows from the need to reduce to a minimum any adsorptive reactions between the compound and support.

It has been claimed that a two-component mixed stationary phase of moderate polar character gives, with a series of catecholamines, tryptamines and other biological amines, symmetrical peaks suitable for quantitative work. The process is aided by the stability of acetyl derivatives, differences in retention times of which are further induced by substitution at the 5-position by methoxyl or acetoxyl. Well-defined separation of *N*-acetyltryptamine, melatonin and diacetylserotonin may thus be attained at 216° on a silicone oil F-60/EGGS column as indicated in Table IV.[34,35]

An extensive study of the silyl and trifluoroacetyl derivatives of melatonin and a series of related indoles has shown that relative retention times may be reduced even at considerably lower column temperatures[37] (Fig. 3). Thus clear separation of indoles was achieved in programmed chromatography starting with column temperatures as low as 160°. Conversion into trifluoroacetyl derivatives permits the mildest conditions with longer isothermal periods at lower temperatures. However, the method suffers at present from the fact that several small interfering peaks are obtained from each original indole. The possibility thus exists of interference if the melatonin is present in mixtures although this is not likely to be a common situation.

Limitations are imposed on the use of gas–liquid chromatography in dealing with the ultramicro quantities of melatonin found in body tissues, by the fact that generally only a fraction of a final solution is used for a single determination. Thus the method, even though the most sensitive of the chromatographic methods, is not as sensitive as the fluorometric or bioassay methods.

Where more concentrated solutions of melatonin are used, as in studies of the effect of γ-radiation, gas–liquid chromatography has been useful in showing that four decomposition products are obtained.[38]

TABLE IV.—GAS-LIQUID CHROMATOGRAPHY OF MELATONIN

System	Operating conditions	Retention times	Remarks	Refs.
Silicone oil F-60, 7% with polymer EGGS-2, 1%, on Gas Chrom P support acid-washed and heated with dichlorodimethylsilane	Column temperature 216°	Melatonin approx. 36 min *N*-acetyltryptamine 15 min Diacetylserotonin 85 min	Study incidental to general work on catecholamines and tryptamines, two-component mixed stationary phases	35
Silicone oil DC-W98 10% on Gas Chrom P	Column temperature 265° with injection temperature 250°	Melatonin 3 min	Injection temperature 250°	22
Silicone SE-30, 0.75–4% on acid-washed Gas Chrom P	Support treated with dichlorodimethylsilane, column temperatures varied	Melatonin 28 min at 160°, 24 min at 205°	Used with flash heater zone at 200–250°	35

COLORIMETRY AND FLUORIMETRY

Colour tests

Colour-developing reagents for the detection of melatonin on paper and thin-layer chromatograms have been related to the presence of the indole nucleus in the molecule.

Ehrlich reagent. The active constituent of this reagent is *p*-dimethylaminobenzaldehyde in mixtures of hydrochloric acid and acetone or ethanol. The reagent gives a blue colour with melatonin, but as a general test for indoles is non-specific for the pineal hormone. The colour with indoles is often purplish at first, turning blue on standing. Colour development is said to be faster after exposure of sprayed thin-layer plates to long-wavelength ultraviolet light. Provided excessive exposure is avoided, improved sensitivity also results.[22] Alternatively brief exposure to vapours from *aqua regia* gives a blue colour almost immediately.[24]

Different formulations are given for Ehrlich's reagent, probably related to variations in shade and rate of colour development. Thus it seems not improbable that modification of the reagent consisting of a simple solution of *p*-dimethylaminobenzaldehyde in ethanol by inclusion of hydrochloric acid was intended to hasten colour development.[39] Similarly replacement of ethanol with the lower-boiling acetone would lead to a faster concentration of reactants on chromatograms. Indeed following upon consideration of earlier reagents,[40] reduction in hydrochloric acid content and consequent water content, has been suggested to overcome slow colour development.[41]

Substitution effects also impose control on the shade of colour. Tryptophan, tryptamine and *N*-mono- and *N,N*-dialkylamines give red-purple colours, but more strongly blue colours are given by the hydroxy and methoxy derivatives—5-hydroxytryptophan, 5-methoxytryptamine and 5-methoxy-*N,N*-dimethyltryptamine.

p-Dimethylaminocinnamaldehyde. This reagent, which gives colours with indole derivatives similar to those given by the Ehrlich reagent, was introduced as a vinyl analogue of the latter, with the expectation that condensation products would be more intensely coloured owing to the greater conjugation.[42] Colours are similar to those given with the Ehrlich reagent but sensitivity is much greater (× 10). However the penalty paid for this greater sensitivity is loss of selectivity.

Ferric chloride–potassium ferricyanide. Depending on reaction with oxidizable substrates to yield blue spots from the products of the reagent, this test, though useful for detection, could not be regarded as specific for indole derivatives. Nevertheless it is useful in locating different members of a known series of compounds.[26] For instance tryptophan is oxidized by ferric chloride to indole-3-aldehyde with concurrent reduction of the iron salt. The reaction of the ferrous iron with ferricyanide, giving Turnbull's Blue, is the basis of the test.

α-Nitroso-β-naphthol. Consequent to the observation that coloured derivatives result from reaction with phenols, this reagent has been applied to the detection[43] and estimation[44] of tyrosine and more pertinently of serotonin as a hydroxytryptamine.[45] Emphasis has been placed on the phenolic group requirement, noting also that both *ortho*- and at least one of the *meta*- positions must be free.[46]

However, the chemistry of the test earlier considered to require concentrated nitric acid, leading to formation of a nitronaphthol, is vague. Modifications of the original conditions propose the use of dilute acids, hydrochloric or sulphuric, in the presence of a small amount of added nitrite, to give a violet chromophore.[47,48] None of the stated structural requirements is provided by melatonin, hence reaction must then depend on other principles, most likely involving the nitroso groups and the heterocyclic ring.

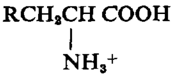
The reagent gives a purple colour with melatonin, deepening over a period of 30 min. Serotonin and its *N*-acetyl derivative give a grey-pink colour changing to grey-violet.[47]

Diazotized sulphanilic acid. This reagent, which may be formed *in situ* by spraying first with a solution of sulphanilic acid in dilute hydrochloric acid, then with sodium nitrite solution, may be used to distinguish 5-hydroxy- from 6-hydroxyindoles. No colour is obtained with serotonin or its *N*-acetyl derivative, contrasting with the brownish red given by 6-hydroxy-*N*-acetyltryptamine. The same colour is given by melatonin despite the absence of a hydroxyl group.[47] The reagent is probably more sensitive than the α-nitroso-β-naphthol reagent.

Fluorimetry

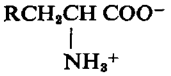
Direct. The ultraviolet absorption curve of melatonin has a peak at 272·5 nm with inflections at 295 and 308 nm. Excitation at about each of these wavelengths has been used as a basis of fluorometric detection and estimation for members of this and related indoles. Emission spectra, subject to control by pH, also contain several peaks. Thus qualitative use has been made of the technique for the identification of serotonin in brain tissue.[49]

With tryptophan as the parent substance, the fluorescence spectrum is determined mainly by the indole ring since various derivatives, indole-3-acetic acid, indole-3-propionic acid, tryptamine and serotonin have practically the same fluorescence as the parent system. Furthermore changes in the pH of solutions of tryptophan, resulting in ionization of the amino or carboxyl groups, have only a weak influence on the position of the band. Thus the three forms **VI**, **VII** and **VIII** have maxima at 347, 353 and 360 nm respectively.[50]



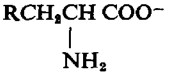
$\mathrm{RCH_2}\underset{\mathrm{NH_3^+}}{\underset{|}{\mathrm{CH}}}\,\mathrm{COOH}$

(VI)



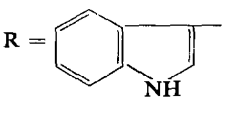
$\mathrm{RCH_2}\underset{\mathrm{NH_3^+}}{\underset{|}{\mathrm{CH}}}\,\mathrm{COO^-}$

(VII)



$\mathrm{RCH_2}\underset{\mathrm{NH_2}}{\underset{|}{\mathrm{CH}}}\,\mathrm{COO^-}$

(VIII)



The simplicity and lack of structure in the fluorescence spectra of indole and tryptophan have been attributed to interaction of the excited state with the surrounding medium.

It is important to note that changes in the fluorescence spectrum occur at very high and very low pH levels. In more strongly alkaline solutions, *e.g.*, 4 % sodium hydroxide solution, the fluorescence curve of tryptophan has a peak in the visible region at 420 nm attributed to ionization of the imino group in the excited state.[50] Quenching effects occur at higher pH levels so that in 4 % sodium hydroxide solution indole and tryptophan exhibit fluorescence with a quantum yield about 1·5 orders of magnitude lower than in neutral solvent. The spectra are often measured in the presence of formaldehyde because in the pH range 11–13 formaldehyde exerts an effective blocking action on the imino group.

These principles have been extended to the tryptamines, including serotonin and melatonin[51] (Table V). Following excitation at 307 nm melatonin gives a fluorescence spectrum with a peak at 430 nm, having an intensity exceeded only by that of 5-methoxytryptamine. Inclusion of formaldehyde gives at 360 nm a peak intensified nearly ten times. Other tryptamines show similar changes under these conditions. It will be seen, however, that the most significant change is produced under the third set of conditions, which leads to peaks in the visible region (545–560 nm) with much lower intensity, and serves to distinguish the 5-hydroxy- and 5-methoxy- derivatives from the other types. Indoles without this substitution in the 5-position show only low fluorescence between 340 and 440 nm. Thus a degree of specificity is introduced with the technique.

Over the pH range 2–11 unsubstituted indoles on excitation at 275 nm give a peak in the fluorescence spectrum at 360 nm. In contrast, excitation of 5-hydroxyindoles at 295 nm leads to a peak at 330 nm. With $3M$ hydrochloric acid as medium, activation at 295 nm and measurement of a peak in the visible region at 540–550 nm provides a specific test for 5-hydroxy- and 5-methoxyindoles. The degree of specificity is indicated by the fact that a series of closely related compounds, tryptophan, 5-methyltryptophan, tryptamine, 3- and 5-methylindole, indole-3-acetic acid, 4-hydroxytryptophan, 4- and 6-hydroxytryptamine, 4-hydroxy-*N*, *N*-dimethyltryptamine-*O*-phosphoryl ester and 6-methoxyindole do not show this characteristic.[52] Thus it is not surprising that with the need for methods for the estimation of ultramicro quantities of 5-hydroxytryptamine and in view of the suggestion that the fluorescence measurement shows more discrimination than the colorimetric and spectrophotometric assays,[45] considerable effort has been applied to putting this technique on a sound basis.[49]

It is important to emphasize the fact that the change in the fluorescence spectrum of these derivatives with change in pH of the medium has itself been used for selective measurements. The shift to 540–550 nm has been particularly useful, illustrated by change in technique applied to serotonin previously measured at 295 nm excitation and 350 nm fluorescence.[49] Limitations remain since 5-methoxy derivatives still have only weak fluorescence and require chromatographic or selective solvent separation for specificity.[53]

Conditions affecting the fluorescence of melatonin in relation to other tryptamines have been examined as a basis of method of assay,[17] with the conclusion that the spectrum, although very similar to those of 5-hydroxyindoles and 5-methoxytryptamines, nevertheless is sufficiently distinctive to be used selectively. Conforming to the general pattern, the spectrum is sensitive to change in pH of the medium. In neutral or weakly acid medium (pH 4) maximum excitation is achieved at about 300 nm, giving a fluorescence peak at 355 nm. These values contrast with those for serotonin (302 nm excitation, 338 nm peak) and for 5-methoxytryptamine (300 and 345 nm) (Fig. 4).

Differences in the spectra of serotonin and melatonin in more strongly acid media are shown in Fig. 5 in which should be noted the appearance of the band at 540 nm for serotonin and at 550 nm for melatonin. The intensity of this band increases with increase in acidity and varies inversely as the band at 355 nm, which is therefore correspondingly lowered as the pH of the solution is lowered.

The intensity of the 355 nm band for melatonin is at its maximum over the pH

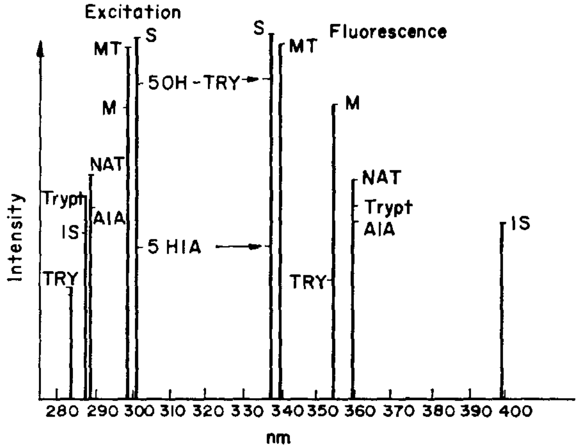


FIG. 4.—Excitation and emission maxima of various indoles at the same concentration and pH (4). M–melatonin; S–serotonin; MT–methoxytryptophan; NAT–*N*-acetyltryptophan; IS–indoxyl sulphate; AIA–indole acetic acid; 5HIA–5-hydroxyindole acetic acid; TRY–trytophan; TRYPT–tryptamine. (From *Clin. FIG. 5.—Excitation and emission spectra of serotonin and melatonin in 0.1*M* hydrochloric acid. ——— excitation – – – emission S–serotonin; M–melatonin (From *Clin. Chim. Acta*, 1970, **30**, 519, by permission of the copyright holders.)

range 6–10. Differences in degree of response of other tryptamines with change in pH have been observed, leading to various intersections of the curves.

Derivatives—the o-phthalaldehyde reaction. 5-Hydroxy- and 5-methoxytryptamines, with a side-chain of even one carbon at the 3- position, when heated with *o*-phthalaldehyde in acid solution give intensely fluorescent products.[54] The fluorescence given by the various derivatives is similar, with activation maximum at 360 nm and emission maximum at 470 nm. The relative intensity however varies considerably. It will be seen that indole itself does not lead to fluorescence nor does substitution singly with hydroxyl or methoxyl at the 5-position (R_1) or with a side-chain at the 3-position (R_2) lead to a marked increase. By contrast the doubly substituted derivatives (at R_1 and R_2) are much more strongly fluorescent. The necessity for hydroxyl or methoxyl at the 5-position must be emphasized since fluorescence does not follow substitution by methyl despite the presence of a side-chain at the 3-position. Further discussion of structural requirements has appeared.[55,56]

Application of the reaction to the detection of serotonin on thin-layer chromatograms has been tested with a reagent that includes cysteine.[57] Inclusion of the cysteine leads to fluorescence maxima at wavelengths 10 nm longer than those obtained in its absence.[54] Thus although the fluorescence reaction itself is not specific for indolealkylamines substituted at the 5-position, nevertheless the maxima at 470–480 nm appear to make the test specific for this group of compounds.[57] In the present context melatonin gives the greatest response, approached only by the related unacetylated 5-methoxytryptamine (Table V).

The test evolved from a survey of products from the reaction of amino-acids with aromatic aldehydes, earlier considered to involve, partly at least, a Strecker degradation.[58] An equivalent survey of various carbonyl compounds using 5-hydroxytryptamine as reference material, emphasized the specificity given by aromatic 1,2-dialdehydes in the fluorescence reaction. In the acid medium the reaction is specific for tryptamines and interference from a variety of amino-acids such as glycine, histidine, phenylalanine and di-*o*-hydroxyphenylalanine, is removed.

Comparison of the relative intensity of the fluorescence of the 5-hydroxytryptamine–phthalaldehyde product with the native fluorescence of the amine in aqueous solution is shown in Table VI.

BIOASSAY TECHNIQUES

Historically, bioassays of pineal substance preceded the isolation of melatonin as the active constituent, with the demonstration that injections of extracts of pineal bodies into toads (*Xenopus laevis*) led to contraction of melanophores in a specific manner.[59] From such results it was possible to predict that the active component would be relatively stable, since it survived boiling, and of low molecular weight by dialysis for 24 hr in distilled water.

It has been pointed out that although the technique has been used as a screening test to determine presence or absence of melatonin[28,29,60], or as a quantitative assay for relative values in serum,[61] the applications of melatonin bioassay have never been fully exploited.[62] However, the establishment of bioassay procedures may represent a major commitment in terms of laboratory time and facilities, to be justified by the extent of involvement in study of the pineal function and related problems.

The method is highly specific and, as indicated above, more sensitive than the fluorimetric method, since melatonin is more potent by several orders of magnitude than any other known agent in the blanching reaction. Within the frog melanophore, concentrations as low as 1 pg/l. are sufficient to cause aggregation.

Relative potencies in these effects may be alternatively expressed. Based on the use of frog melanocytes, 0·45 μg of melatonin has the same effect as 20 μg of epinephrine or of norepinephrine. Specific structural requirements are illustrated by the fact that serotonin, the melatonin precursor, has no skin-lightening effect in doses up to 4000 μg.[63]

It may also be observed that the skin-lightening action of melatonin, as the active principle of the pineal gland, is opposed to the melanocyte-stimulating hormone of the pituitary gland. Indeed the pineal and pituitary glands have been discussed as functional mirror images of each other.[64]

TABLE V.—RELATIVE FLUORESCENCE INTENSITIES OF 3- AND 5-SUBSTITUTED INDOLES IN THREE SOLVENT SYSTEMS: I, M NaOH; II, 40% FORMALDEHYDE-1M NaOH (1:1); III, 1M NaOH–ACETIC ANHYDRIDE (1:1). CONCENTRATION OF ALL COMPOUNDS $5 \times 10^{-5}M$

Bioassay procedures have been reviewed[65] and fall mainly into two groups, as follows.

Methods dependent on changes in transmission or reflectance of incident light by isolated frog skin

In the absence of earlier knowledge of the active constituent of the pineal gland considerable attention was given to improvement of assay techniques by measuring light transmitted through frog's skin,[66,68] leading to some simple arrangements of apparatus,[68,69] (*e.g.*, that[69] shown in Fig. 6). Results are expressed as a "unit" of melatonin, which is that quantity producing minimum increase in light transmission. Thus if a solution must be diluted 100,000 times to produce the minimum effect, the sample contains 100,000 units.

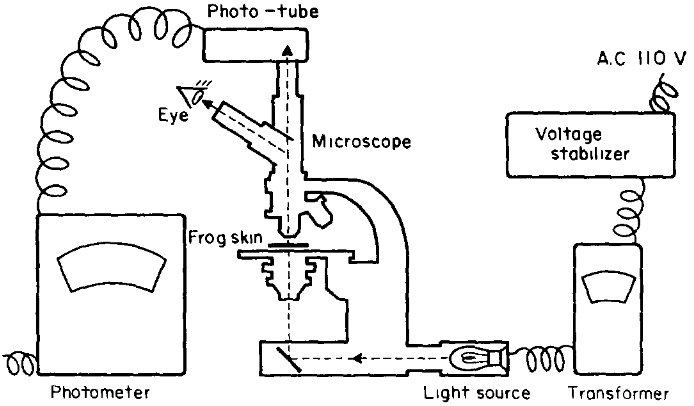

FIG. 6.—A simple arrangement for measuring transmission of light through frog skin. (From *Endocrinol.*, 1960, 67, 443, by permission of the copyright holders.)

With a 10X objective lens 50 melanocytes at a time may be observed but changes in a single cell may be observed with a 75X objective. The technique requires that the population density of melanophores be relatively large and fully dispersed—about fifty cells per field. Few cells other than melanocytes must be present and the skin section must be relatively thin. Best response is given by skin from the median dorsal portion of the thigh. Application to homogenates of rat and hen pineal glands following fractionation on Sephadex G25, has been discussed previously,[29] while detection of melatonin on paper chromatograms has followed transfer of cut sections of the paper to the liquid bathing *Xenopus* larvae.

The method follows development of the concept of a "melanocyte index", employing a microscope for measurement.[70]

Tests on a variety of compounds have confirmed the specificity of this method. A metabolic product, 6-hydroxymelatonin, is about the only other compound to produce an effect at low dose, but its minimum effective dose (MED)—0·1 μg ml—is still considerably higher than that observed for melatonin. Thus the addition of the hydroxyl group in the 6-position raises the MED by a factor of 10^3, clearly demonstrating that essential structural requirements for highest activity are the tryptamine nucleus with 5-methoxyl and *N*-acetyl groups.[71]

Microscopic measurement of degree of melanin dispersion within melanophores—Hogben Index

The Hogben Index has been developed as a measure of the body-lightening reaction as in *Xenopus* larvae.[27]

The dermal melanophore response of larval *Rana pipiens* has been developed as a quantitative method, in which the critical element is rigid attention to details of the test procedure. This is based on a constant supply of perfectly uniform test animals emanating from a tadpole-culturing programme.

The responsiveness of the dermal melanophores to melatonin varies with an endogenous 24-hr rhythm, with light-adapted animals maintained under a specified light regimen appearing optimally responsive at a set period.

Melanophores in a triangular area between the eye and mouth on the left side are "read" in the killed (with formalin) and fixed animal. Measurements are made on a group of ten tadpoles after their immersion for 30 min in the test sample. Reading, on the basis of an estimate of the average state of the melanophores in a field, consists in assigning an appropriate stage number according to the Hogben Index.[72] The mean melanophore stage shown by each group after collation is used to construct a calibration curve plotted on two cycle semi-log paper with melanophore stages represented on the linear axis and melatonin concentrations on the log scale.[62] Between zero and 1 μg/ml a linear relationship is shown but sensitivity lessens at higher concentrations.

This technique has been applied to studies of diurnal variations in pineal melatonin of rats, quail and chickens, including the effect of surgical procedures.

Acknowledgements—The support of this work by the New South Wales State Cancer Council is gratefully acknowledged.

Zusammenfassung—Es wird eine Übersicht über chemische und biochemische Verfahren zur Abtrennung und Bestimmung von Melatonin, dem aktiven Bestandteil der Epiphyse, gegeben. In Anbetracht der normalerweise vorliegenden extrem kleinen Stoffmengen wird die Diskussion auf chromatographischen und spektroskopischen Verfahren aufgebaut; diese werden schließlich mit Analysenmethoden verglichen, die auf der hautbleichenden Wirkung des Hormons beruhen.

Résumé—On a effectué une étude des techniques, chimiques et biochimiques, pour la séparation et le dosage de la mélatione, le constituant actif de la glande pinéale. Eu égard aux quantités extrêmement faibles de produit généralement présentes, la discussion est établie autour des techniques chromatographiques et spectroscopiques menant à une comparaison avec les essais basés sur l'effet de blanchiment de peau de l'hormone.

(*Received* 23 *February* 1972. *Accepted* 23 *March* 1972)

Summary—Mixed hydroxides of iron and aluminium have been precipitated from solutions containing iron and aluminium salts. The ratio of iron and aluminium was changed from 1:1 to 1:9. The mixed oxides produced by heating the hydroxides have been investigated by the Mössbauer effect. The Mössbauer spectra were composed of two systems of lines: one is due to magnetic splitting produced by α-Fe_2O_3, the other is due to quadrupole splitting (0·45 mm/s) which can be assigned to iron atoms in the lattice of α-Al_2O_3. The role of the anion of the solvated salts has also been investigated.

THE MÖSSBAUER isomer-shift is proportional to the change of electron density at the resonant nucleus. From the magnitude of the quadrupole splitting conclusions may be drawn regarding the symmetry of the surroundings (the electron shell) of the nucleus. Accordingly, changes in the chemical environment will change these parameters. The Mössbauer effect can be used to elucidate incorporation processes and to determine the proportion of Mössbauer atoms in different surroundings.

Metal hydroxides were precipitated from solutions containing different concentrations of iron(III) and aluminium(III) chlorides. The concentration ratio of iron to aluminium in the solution was varied from 1:1 to 1:9. The stock solution concentration was 0·1*M* for both aluminium and iron and the precipitation was carried out with 50% sodium hydroxide solution. The precipitates were dried and ignited at 1100° for 8 hr to give aluminium and iron oxides (M_2O_3). The aim of the present work was the examination of these mixed oxides.

The Mössbauer spectrum of hematite (α-Fe_2O_3) and of iron incorporated in corundum (α-Al_2O_3) has been examined many times.[1-7] These investigations were concerned with the magnetic behaviour of α-Fe_2O_3 and the phenomena of magnetic relaxation. Compounds of the composition $Al_{2-x}Fe_xO_3$ corresponding to the concentration range studied by us, have also been investigated. Dayal and co-workers[8] have prepared samples in a similar way and other authors have prepared compounds of this type by fusing Al_2O_3 with Fe_2O_3.[9]

EXPERIMENTAL

The investigations were carried out with a spectrograph (applying modulation with constant acceleration) constructed in the Department of Atomic Physics at the Eötvös University. The source was a stainless steel plate containing ^{57}Co (Radiochemical Centre, Amersham, England).

Samples were prepared from the substances to be investigated by pressing them between two thin aluminium foils into an even layer containing 30 mg/cm^2.

The measurements were carried out as described previously[10] with both source and sample at ambient temperature. The more important samples were also studied at liquid-nitrogen temperatures.

RESULTS AND DISCUSSION

The Mössbauer spectra obtained are complex and can be resolved into two superimposed line systems. One contains six magnetically split lines which can be shown to be due to α-Fe_2O_3. The other contains a quadrupole-split line with a splitting of 0·45 mm/s and a 0·27 mm/s isomer shift (compared to iron). These figures characterize an iron(III) atom bound by a relatively covalent bond. On the basis of data published by Bhide and co-workers[7] it can be assumed that this line is due to the iron incorporated into the corundum lattice.

Whereas at a 1:1 ratio of iron to aluminium the magnetically split spectrum is predominant at a 1:2 ratio, the appearance of an intense central quadrupole-split line indicates the changed environment of part of the iron. The intensity of the magnetically split lines (characteristic of α-Fe_2O_3) decreased with increase in the ratio of aluminium to iron, while the relative intensity of the quadrupole-split line increased. At iron to aluminium ratios of 1:7 and 1:8 only the central quadrupole-split line is obtained (Figs. 1 and 2). On separation of the two line systems the changes in the areas under the Mössbauer lines clearly show the variation in the ratio of the two different kinds of iron (Table I).*

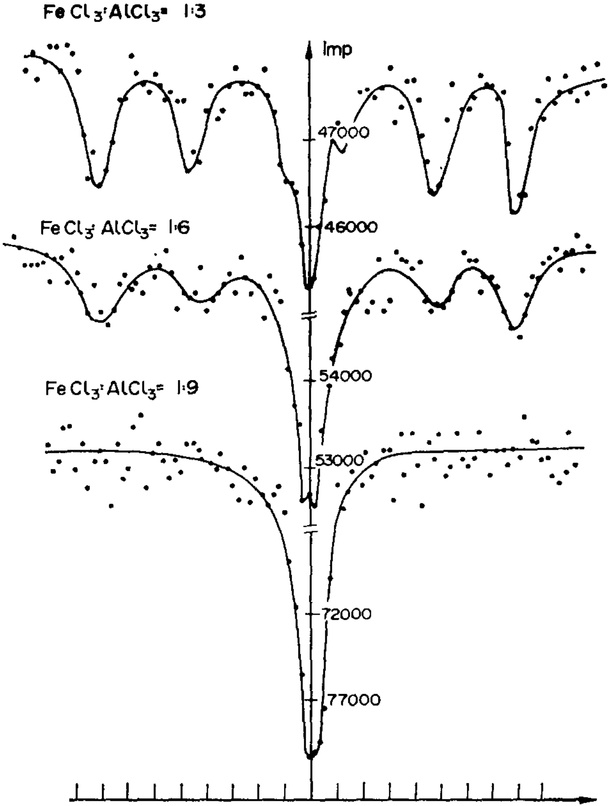

FIG. 1.—Mössbauer spectra of mixed oxides containing iron and aluminium in the ratios 1:3, 1:6 and 1:9.

* The probability of the Mössbauer effect, calculated on the basis of the areas under the absorption lines, for the magnetic line system (Fe:Al = 1:1) is $f = 0{\cdot}34 \pm 0{\cdot}05$, while for the central quadrupole-split line (Fe:Al = 1:9) it is $f = 0{\cdot}47 \pm 0{\cdot}05$.

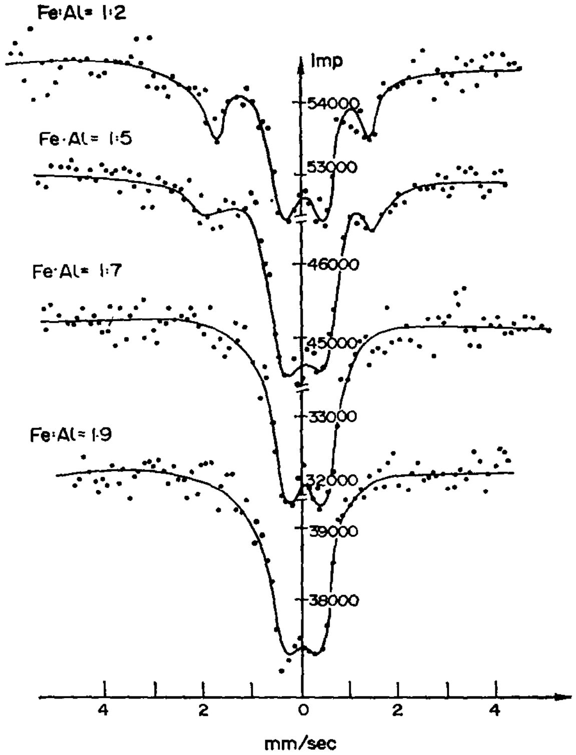

FIG. 2.—Central portions of the spectra of mixed oxides at higher resolution. The samples contained iron and aluminium in the ratios 1:2, 1:5, 1:7, and 1:9.

TABLE I.—AREAS OF MAGNETICALLY AND QUADRUPOLE-SPLIT LINES IN THE MÖSSBAUER SPECTRA OF SAMPLES HAVING VARYING INITIAL IRON AND ALUMINIUM CONCENTRATIONS

Fe:Al	Total area (normalized)	Area of the magnetically split line (normalized)	Area of the quadrupole-split line (normalized)
1:1	0·49	0·49	0
1:2	0·45	0·34	0·11
1:3	0·37	0·25	0·12
1:4	0·33	0·18	0·15
1:5	0·31	0·13	0·18
1:6	0·30	0·13	0·17
1:7	0·18	0·05	0·13
1:8	0·13	0·00	0·13
1:9	0·11	0·00	0·11

For those samples in which iron chloride and aluminium chloride were the starting materials, the area under the quadrupole-split line reached a maximum at a 1:5 iron:aluminium ratio, and decreased at lower Fe:Al ratios. At this maximum about 15–20% of the aluminium atoms are replaced by iron in the corundum lattice. At higher aluminium concentrations the decrease can be explained by the decrease of the total iron content of the sample.

The experimental results show that the relative amount of α-Fe_2O_3 diminishes with decreasing iron concentration and at the 1:9 iron:aluminium ratio only the mixed oxide is formed. Only a few aluminium atoms are incorporated into the iron oxide lattice since the magnetically split spectrum does not show significant changes, although this would appear possible from the similar size of the ionic radii (aluminium 0·05 nm, iron 0·06 nm).

The interpretation of our experimental results is supported by X-ray measurements. Some of our roentgenograms (Fig. 3) show that the samples consist of two components α-Fe_2O_3 and α-Al_2O_3. The intensity of the two line systems changes with increasing aluminium content, that due to corundum increasing and that due to hematite decreasing. At a 1:9 ratio only the lines characteristic of corundum can be detected. The increase in the lattice parameters for this sample compared with those of pure corundum indicates the incorporation of iron. The position of the iron oxide lines reveals a minute decrease in the lattice constant which may be due to the incorporation of aluminium ions.

Relaxation effects may also cause spectra[4] similar to the Mössbauer spectra obtained by us. However, our X-ray investigations and the fact that our Mössbauer

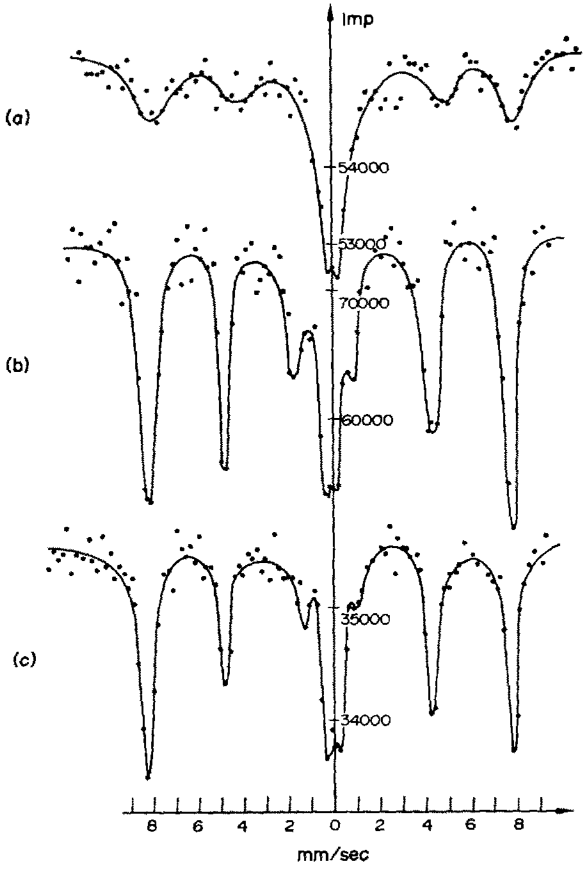

FIG. 4.—Mössbauer spectra of mixed oxides of iron and aluminium: (*a*) precipitated and ignited together (*b*) precipitated and ignited separately, then after mixing ignited once more (*c*) precipitated separately and ignited together. The initial Fe:Al ratio was 1:6.

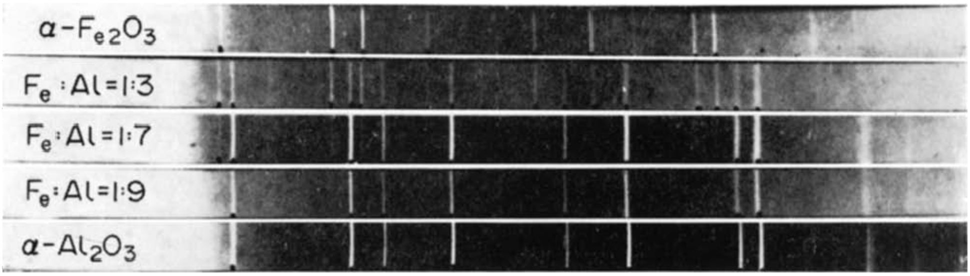

FIG. 3.—X-ray photographs of mixed oxides containing iron and aluminium in the ratios 1:3, 1:7 and 1:9 and of pure α-Fe_2O_3 and α-Al_2O_3.

spectra obtained at the temperature of liquid nitrogen were basically the same as the spectra recorded at room temperature, eliminate this possibility.

In order to decide whether the iron was incorporated during precipitation or upon ignition, measurements were made on samples where the possibility of incorporation in solution was excluded. The iron and aluminium hydroxides were precipitated and ignited separately and mixed in the form of their oxides. This mixture yielded only the Mössbauer spectrum of α-Fe_2O_3. Upon ignition the Mössbauer spectrum showed some incorporation effects (Fig. 4b) but less than that shown by samples prepared by co-precipitation. In some experiments the hydroxides were precipitated separately, dried at 130° and ignited together (Fig. 4c). In these samples the ratio of iron to aluminium was also 1:6 and a quadrupole-split line appeared in the Mössbauer spectrum. The intensity was the same as that in Fig. 4b, but smaller than that obtained with the sample prepared by co-precipitation (Fig. 4a).

Comparison of the area under the quadrupole-split lines with the total area shows a smaller incorporation effect in the case of a 6:1 aluminium:iron ratio, if the iron and aluminium samples are precipitated separately, than with a 2:1 aluminium:iron ratio if the samples are precipitated and ignited together. Accordingly, the incorporation must take place in the solution. Any incorporation during ignition has not been investigated in detail.

Experiments were carried out to study the effect of the nature of the anion upon the incorporation process. Samples were precipitated in the presence of sulphate and perchlorate ions. The behaviour of samples precipitated from solutions containing

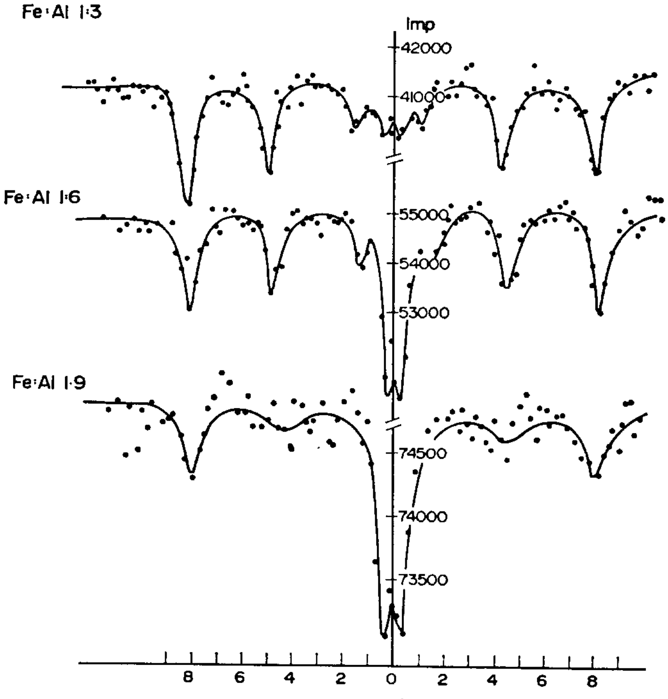

FIG. 5.—Mössbauer spectra of samples precipitated from sulphate solutions containing iron and aluminium in the ratios 1:3, 1:6 and 1:9.

chloride and perchlorate ions was similar, but those from solutions containing sulphate showed a smaller incorporation of iron. The magnetically split spectrum disappears at a greater aluminium:iron ratio and the increase of the central quadrupole doublet is slower. With iron and aluminium in a 1:3 ratio the quadrupole-split line is more intense for samples precipitated from chloride solution than for those from sulphate solution with a 1:6 iron:aluminium ratio. This phenomenon may be explained by assuming that the anions are co-ordinated to the iron and aluminium in the solution and that the strength of the metal–ligand bond influences the formation of the oxygen bridge in the hydroxides. It has been shown that sulphate ions are co-ordinated to aluminium and iron more strongly than are chloride ions.

Our results are in good agreement with the data of the oscillometric equilibrium measurements carried out by Pungor and Zapp[11] in an examination of aluminium hydrolysis and the effect of the anion on the composition of the polymer formed.

Zusammenfassung—Aus Lösungen, die Eisen- und Aluminiumsalze enthielten, wurden gemischte Hydroxide von Eisen und Aluminium ausgefällt. Das Verhältnis von Eisen und Aluminium wurde von 1:1 bis 1:9 variiert. Die durch Erhitzen der Hydroxide hergestellten gemischten Oxide wurden mit Hilfe des Mößbauereffekts untersucht. Die Mößbauerspektren setzten sich aus zwei Liniensystemen zusammen: eines beruht auf der durch γ-Fe_2O_3 hervorgerufenen magnetischen Aufspaltung, das andere auf Quadrupolaufspaltung (0,45 mm/s), die Eisenatomen im α-Al_2O_3-Gitter zugeschrieben werden kann. Auch die Rolle des Anions der solvatisierten Salze wurde untersucht.

Résumé—On a précipité des hydroxydes mixtes de fer et d'aluminium de solutions contenant des sels de fer et d'aluminium. Le rapport du fer à l'aluminium a été changé de 1:1 à 1:9. Les oxydes mixtes produits par chauffage des hydroxydes ont été étudiés par effet Mössbauer. Les spectres de Mössbauer sont composés de deux systèmes de raies: l'un est dû au dédoublement magnétique produit par α-Fe_2O_3, l'autre est dû au dédoublement quadrupole (0,45 mm/s) qui peut être attribué aux atomes de fer dans le réseau de α-Al_2O_3. On a aussi étudié le rôle de l'anion des sels solvatés.

COULOMETRIC TITRATION OF ACIDS IN ISOPROPANOL—I

A RAPID DIRECT METHOD FOR THE DETERMINATION OF CARBON IN STEEL

B. METTERS, B. G. COOKSEY and J. M. OTTAWAY
Department of Pure and Applied Chemistry, University of Strathclyde,
Cathedral Street, Glasgow. C.1

(*Received* 9 *February* 1972. *Accepted* 7 *May* 1972)

Summary—A new procedure is described for the direct coulometric titration of the carbon dioxide liberated in the high-temperature combustion of steel. The carbon dioxide is absorbed in isopropanol containing 3% of ethanolamine and titrated with 100% titration efficiency with a constant current of 50 mA and spectrophotometric detection of the end-point. The accuracy and precision of the method have been established by the analysis of a wide range of standard steel samples.

THE DETERMINATION of carbon in steel by the non-aqueous titration of the carbon dioxide resulting from the high-temperature combustion of the sample in a stream of pure oxygen is now a well-established analytical technique. The titration procedure suggested by Blom *et al.*[1,2] in which the carbon dioxide is absorbed in pyridine and titrated with a solution of sodium methoxide dissolved in a mixture of methanol and pyridine has been modified by several workers[3–7]. Grant *et al.*[3] replaced the pyridine with dimethylformamide and used potassium methoxide in a benzene/methanol mixture as titrant. Jones *et al.*[4,6] added small amounts of ethanolamine to the same absorbent to give more efficient absorption of carbon dioxide and used tetra-n-butylammonium hydroxide in benzene/methanol or toluene/methanol as titrant. More recently, Ottaway *et al.*[8] suggested the replacement of the non-aqueous titrant with an aqueous solution of potassium hydroxide. All of these procedures were rapid, applicable to a wide range of steels and of sufficiently high accuracy. End-points have been detected visually with Thymol Blue or thymolphthalein as indicator.

The method of Ottaway *et al.*[8] was developed as a result of a wider investigation[9] into the feasibility of determining small amounts of carbon dioxide by a direct coulometric titration procedure in non-aqueous media. Back-titration methods have been reported in which the carbon dioxide is absorbed in aqueous barium hydroxide and the solution back-titrated coulometrically but the direct titration of carbon dioxide with electrogenerated base had not been described previously. Whymark[9] found that 100% coulometric titration efficiency could not be attained in the solvents necessary for carbon dioxide absorption, without the addition of large amounts of water. These additions of water, however, reduced the efficiency of carbon dioxide absorption in all solvents investigated and hydrolysed dimethylformamide to formic acid which was also titrated. Contrary to these results, Boniface and Jenkins[10] have recently described a method using a solution of ethanolamine in dimethylformamide containing 4% of water, in which no hydrolysis was observed. This method, although accurate and precise, is not as rapid as earlier methods since it requires approximately 8 min for a single determination.

In this paper a solution to the problems encountered by Whymark is suggested and 100% coulometric titration efficiency in non-aqueous solvents has been achieved without the addition of water. Based on these results a method is described for the coulometric determination of carbon in steel, using a solution of ethanolamine in isopropanol as absorbent.

EXPERIMENTAL

Reagents

The purest available chemicals were used. Tetraethylammonium bromide was purified by recrystallization.

Absorbent solutions

Dissolve 105·0 g of recrystallized tetraethylammonium bromide in isopropanol and dilute to 1 litre (solution A).

Dilute 11·5 ml of distilled water together with 6·0 ml of 0·1% w/v methanolic solution of thymolphthalein and 50 ml of ethanolamine to 500 ml with pyridine (solution B).

Dilute 200 ml of solution A together with 30 ml of ethanolamine and 10 ml of 0·1% w/v thymolphthalein solution in isopropanol to 1 litre with isopropanol (solution C).

Dilute 20 ml of solution A together with the required amount of ethanolamine (0, 1·0, 1·5, 2·0, 2·5, 3·0, 5·0, or 10·0 ml) to 100 ml with isopropanol (solution D).

Procedures

Recrystallization of tetraethylammonium bromide. Dissolve the crude tetraethylammonium bromide in the minimum amount of hot isopropanol. Cool slightly, then add acetone to precipitate the solid. Filter off, using a sintered-glass funnel, wash with acetone and dry immediately in an oven at 70°. Store in a desiccator to prevent absorption of water.

Measurement of absorption efficiency. A standard steel sample was combusted at 1250° in a stream of pure oxygen with pure tin as flux. Sulphur and nitrogen compounds were removed from the gas stream with manganese dioxide and magnesium perchlorate. The gas stream was passed though 50 ml of solution D and subsequently into 50 ml of previously neutralized pyridine solution B contained in a cylindrical absorption cell. The cell was fitted with a stopper through which the tip of a 10-ml burette was inserted. The pyridine solution was titrated with 0·05*M* potassium hydroxide and the amount of carbon dioxide not absorbed in the isopropanol solution was calculated.[8]

Determination of carbon in steel. The apparatus is outlined in Fig. 1. The constant-current generator has been described in detail by McMillan[11] and is similar to the valve circuit described by Glass and Moore.[12] This circuit gives currents of 50 mA at an output voltage of up to 200 V, which is necessary to avoid changes in the current during electrolysis in a purely non-aqueous medium. Before combustion of each steel sample the apparatus was flushed out with oxygen at 400 ml/min for 1 min. The absorption solution contained in the titration vessel, Fig. 2, was then titrated coulometrically to the end-point which was indicated by a suitable absorbance reading on an EEL spectrotitrator. The accurately weighed steel sample contained in a combustion boat with tin flux was pushed into the hot zone of the furnace. After 4 min the oxygen flow was switched off, the current (50 mA) was switched on simultaneously with a timing mechanism and the absorption solution retitrated to the marked end-point. During the titration the current was measured accurately with a standard resistance and a three-dial Tinsley potentiometer. Following subtraction of a blank value for the combustion boat and tin flux,

$$\%\mathrm{C} = \frac{12{\cdot}011}{96{,}486} \times \frac{i \times t}{W \times 10}$$

where i = current (mA), t = time (sec), W = weight of sample (g).

RESULTS AND DISCUSSION

Choice of supporting electrolyte

The main problem in a coulometric titration procedure is one of maintaining 100% coulometric titration efficiency. Whymark[9] showed that this efficiency could not be achieved in certain organic media when lithium chloride was used as supporting electrolyte unless substantial amounts of water were added, which then caused hydrolysis or a reduction in efficiency of carbon dioxide absorption. A more fundamental

investigation into this problem[13] revealed that in isopropanol with lithium chloride as the supporting electrolyte, insoluble lithium hydroxide was formed on the electrode. The lithium hydroxide did not react with the acid being titrated and therefore the coulometric efficiency was reduced. When tetraethylammonium bromide was substituted as supporting electrolyte in the same solvent, no insoluble product formed on the cathode and 100% coulometric titration efficiency was obtained. When this same solution was electrolysed for several hours, and the products of electrolysis were precipitated with lithium bromide, analysis showed that the precipitate was lithium isopropoxide, suggesting that the solvent had been reduced to basic isopropoxide ions which in turn reacted completely with the acid being titrated.

Choice of ethanolamine concentration

The minimum amount of ethanolamine for efficient absorption of carbon dioxide was determined by passing the carbon dioxide through two absorption solutions. Any carbon dioxide not absorbed in the test solution was trapped in the second solution, which was known to absorb carbon dioxide efficiently, and then titrated manually (see procedure B). The results given in Table I show that only 3% of ethanolamine was necessary for quantitative absorption of carbon dioxide. The ethanolamine content was kept at a minimum since it was observed that the sharpness of the end-point decreased as the ethanolamine concentration increased, probably because of a buffer effect.

Reaction sequence

The following reactions are thought to occur, and supporting evidence is described elsewhere.[13,14]

$$CO_2 + 2HO(CH_2)_2NH_2 \rightarrow (HO(CH_2)_2NHCOO)^-(HO(CH_2)_2NH_3)^+ \quad (1)$$

$$(C_2H_5)_4NBr \rightleftharpoons (C_2H_5)_4N^+Br^- \rightleftharpoons (C_2H_5)_4N^+ + Br^- \quad (2)$$

$$(CH_3)_2CHOH + e^- \rightarrow (CH_3)_2CHO^- + \tfrac{1}{2}H_2 \quad (3)$$

$$(CH_3)_2CH\,.\,O^- + (C_2H_5)_4N^+ \rightarrow (C_2H_5)_4N^+OCH(CH_3)_2^- \quad (4)$$

$$\begin{aligned}&(HO(CH_2)_2NHCOO)^-(HO(CH_2)_2NH_3)^+ + (C_2H_5)_4N^+OCH(CH_3)_2^- \\ &\rightarrow (HO(CH_2)_2NH_3)^+(OCH(CH_3)_2)^- + (C_2H_5)_4N^+\ HO(CH_2)_2NHCOO^- \quad (5)\end{aligned}$$

In reaction (1) carbon dioxide reacts with ethanolamine to form the ethanolamine salt of 2-hydroxyethylcarbamic acid.[14] In reaction (3), isopropanol is reduced with 100% coulometric efficiency to form basic isopropoxide ions[13] which are then available for the titration of the previously formed acid. It should also be mentioned that the reactions above do not necessarily predict the existence of free ions in isopropanol. In fact, it is probable that in reaction (2), for example, at equilibrium, ion-pairs predominate.

Carbon determinations

The determination of carbon in a wide range of steels was carried out by the procedure described above, and the results are given in Tables II and III. The method is accurate and fairly rapid, a single determination taking 5 min, of which 4 min are allowed for combustion of the sample with the apparatus available. The furnace available in our laboratory was unsuitable for the fast oxygen flow-rates necessary to

reduce the combustion time to under 2 min, which is the normal practice in the analogous volumetric procedures[4,6,8]. However, with such a furnace coupled to the present coulometric procedure, the time of determination may be reduced to between 2 and 3 min as the coulometric titration takes only 1 min to complete. The method therefore compares favourably in speed with the volumetric method which is commonly used in routine analysis for the control of the steelmaking process.

The main advantage of the method, as of any coulometric procedure, is that standardization is by direct reference to Faraday's law and no standardization of solutions or of the method itself is necessary. At least ten determinations are possible with each portion of absorbent solution. Although we have not attempted to do so, the method could easily be automated and could be made more rapid as described above and also by the use of higher generating currents. To our knowledge, only one other direct coulometric titration procedure has been reported for this determination[10] and this involves titration in a medium containing dimethylformamide with 3·5% of ethanolamine and 3·5% of water with potassium iodide as supporting electrolyte, a single determination taking about 8 min. Both coulometric methods obviously possess advantages from the point of view of automation and removal of the need for a separate titrant solution. The present method possesses a number of minor advantages in the use of a purely organic medium which would be expected to remove possible sources of error such as those due to hydrolysis of dimethylformamide,[9] or possible precipitation of inorganic compounds during titration. However, the main advantage of the present method would appear to be speed, which will possibly render it suitable for routine analysis and satisfactory as a replacement for the existing volumetric titration procedures.

Acknowledgement—We wish to thank W. Grierson and D. Mather of the Dalzell Steel Works, British Steel Corporation, Motherwell, for the gift of a tube furnace. We also wish to thank W. A. Alexander, our ex-colleague, who built the coulometer used in this work.

Zusammenfassung—Eine neue Arbeitsvorschrift für die direkte coulometrische Bestimmung des bei der Hochtemperaturverbrennung von Stahl freigesetzten Kohlendioxids wird angegeben. Das Kohlendioxid wird in Isopropanol absorbiert, das 3% Äthanolamin enthält, und mit 100-prozentiger Titrationsausbeute mit einem konstanten Strom von 50 mA und spektrophotometrischer Endpunktsanzeige titriert. Die Genauigkeit und Richtigkeit der Methode wurden durch Analyse einer großen Anzahl von Standard-Stahlproben ermittelt.

Résumé—On décrit une nouvelle technique pour le titrage coulométrique direct du gaz carbonique libéré dans la combustion à haute température de l'acier. Le gaz carbonique est absorbé dans de l'isopropanol contenant 3% d'éthanolamine et titré avec une efficacité de titrage de 100% avec un courant constant de 50 mA et une détection spectrophotométrque du point final. La précision et la fidélite de la méthode ont été établies par l'analyse d'une large gamme d'échantillons étalons d'aciers.

Zusammenfassung—Die Methode der logarithmischen Transformation von photometrischen Titrationskurven zur Bestimmung der Komplexzusammensetzung wurde entwickelt und diskutiert. Sie eignet sich vor allem für eine sichere Unterscheidung von ein- und mehrkernigen Komplexen. Es wurde theoretisch abgeleitet und auf praktischen Beispielen gezeigt, daß die logarithmische Analyse zu eindeutigen Resultaten führt. Die Methode ist begrenzt durch zwei Bedingungen: (*a*) Bildung eines einzigen Komplexes in einem großen Konzentrationsgebiet; (*b*) es muß sich um relativ schwache Komplexe handeln.

In unseren früheren Mitteilungen beschäftigten wir uns mit einigen Gesetzmäßigkeiten, die vor allem bei der Bildung von schwachen Komplexen und bei Verwendung solcher Reaktionen bei den spektralphotometrischen Bestimmungen in Vordergrund treten.[1–4] Es wurden Beziehungen abgeleitet und in der Praxis benutzt,[1–3] die auf dem Massenwirkungsgesetz gegründet und für die Festlegung des Komplextypus und seiner Beständigkeitskonstante geeignet sind. Mit ähnlichen Transformationen beschäftigten sich bisher am meisten Newman[5,6] und Hume,[5–7] vor allem mit Rücksicht auf die Bestimmung von Beständigkeitskonstanten mit Hilfe spektralphotometrischer Messungen bei sukzessiver Bildung von einkernigen Komplexen. In seiner Arbeit, die dem Studium der Bildung von schwachen Komplexen eines Typus in der Lösung gewidmet ist, geht Klausen[8] von Werten aus, die mit Hilfe der Methode der kontinuierlichen Variationen (Job) erhalten werden. Die Methode wurde zur Unterscheidung von ein- und zweikernigen Komplexen angewandt und sie stützt sich auf eine Beziehung zwischen der Beständigkeitskonstante und den maximalen Extinktionswerten der Jobschen Kurven.

In dieser Arbeit wollen wir das Problem beurteilen, in wie weit man die Parameter der erhaltenen Funktion nach der logarithmischen Transformation einiger Titrationskurven für die eindeutige Festlegung des angenommenen Komplextypus und für die eindeutige Festlegung des angenommenen Komplextypus und für die Bestimmung seiner Beständigkeitskonstante eindeutig ausnutzen kann. Aus diesem Grund beschäftigten wir uns näher mit der Diskussion der allgemeinen Funktion bei den logarithmischen Analysen, und zwar besonders für die Fälle, bei welchen die stöchiometrischen Koeffizienten *a* und *b* des Komplexes M_aL_b nicht richtig vorausgesetzt wurden. Die Ergebnisse der allgemeinen Untersuchung führen dann zu Forderungen auf die experimentelle Ausführung der Titrationen. Die weiteren Erwägungen und Resultate gelten außer für die im Vordergrund stehenden photometrischen Titrationen auch für die weiteren "linearen Titrationskurven".[4]

Verwendete Symbole und Grundbeziehungen

A	Extinktion, gemessen gegen Blindansatz (Absorption des Kations vernachläßigbar)
A_0	Maximaler Wert von A. Allgemein wird A_0 bei genügend großem Titrantüberschuß direkt gemessen
K	Beständigkeitskonstante (scheinbare Konstante) nach Gl. (1)

$$K = \frac{[\mathrm{M}_a\mathrm{L}_b]}{(c_\mathrm{M} - a[\mathrm{M}_a\mathrm{L}_b])^a \cdot (c_\mathrm{L} - b[\mathrm{M}_a\mathrm{L}_b])^b} \tag{1}$$

$[\mathrm{M}_a\mathrm{L}_b]$	Gleichgewichtskonzentration des Komplexes $\mathrm{M}_a\mathrm{L}_b$, molar
a, b	Stöchiometrische Koeffizienten des gebildeten Komplexes
$c_\mathrm{L}, c_\mathrm{M}$	Totale Ligand- bzw. Metall-Konzentration, molar
k	Steigung der transformierten Titrationskurve im Punkt (ξ, η)
k_0	Steigung der transformierten Titrationskurve für $A \rightarrow 0$
k_{A_0}	Steigung der transformierten Titrationskurve für $A \rightarrow A_0$
α, β	Stöchiometrische Koeffizienten eines angenommenen Komplexes $\mathrm{M}_\alpha\mathrm{L}_\beta$; bei richtiger Voraussetzung gilt gleichzeitig $\alpha = a$ und $\beta = b$
Δ	Entfernung eines Punktes (ξ, η) der transformierten Titrationskurve von der Gerade der richtigen Transformation
Δ_0	Wert von Δ für $A \rightarrow 0$
Δ_{A_0}	Wert von Δ für $A \rightarrow A_0$
χ	Hilfskonstante

$$\chi = \frac{\varepsilon_{ab}^{a+b-1}}{K \cdot b^b}$$

ε_{ab}	Differentieller molarer Extinktionskoeffizient des Komplexes $\mathrm{M}_a\mathrm{L}_b$
ξ	Transformierte Titrationskurven—Abscissenachse
η	Transformierte Titrationskurven—Ordinatenachse

Logarithmische Transformation photometrischer Titrationskurven

Aus Gl. (1) folgt nach einfacher Umformung:[1,3]

$$-\log\left(b\frac{c_\mathrm{M}}{c_\mathrm{L}}A_0 - aA\right) = -\frac{1}{a}\log\frac{A}{(A_0 - A)^b} - \frac{1}{a}\log\frac{\varepsilon_{ab}^{a+b-1}}{K \cdot b^b} \tag{2}$$

In dieser Form gilt Gl. (2) für die Titration eines Ligandes L durch ein Kation M, d.h. für $A = A(c_\mathrm{M})_{c_\mathrm{L}=\mathrm{konst}}$. Für die Titration eines Kations durch ein Ligand, d.h. für $A = A(c_\mathrm{L})_{c_\mathrm{M}=\mathrm{konst}}$, gilt eine ganz analoge Beziehung, die man durch Austausch von M gegen L und a gegen b aus G. (2) erhalten kann. Die weiter abgeleiteten Beziehungen gelten deshalb nach dem Tausch der Symbole auch für die umgekehrten Titrationen. Für $a = 1$ ist die Beziehung (2) mit einer von Newman und Hume[5] abgeleiteten Gleichung praktisch identisch.

In der Praxis werden die gemessenen Titrationskurven nach Gl. (2) transformiert, indem man die Extinktionswerte A in das kartesische Koordinatensystem als Punkte (ξ, η) einträgt, wobei

$$\eta = -\log\left(\beta\frac{c_\mathrm{M}}{c_\mathrm{L}}A_0 - \alpha A\right) \text{ (Ordinatenachse)} \tag{3}$$

und

$$\xi = \log \frac{A}{(A_0 - A)^\beta} \text{ (Abscissenachse).} \tag{4}$$

Bei richtig gewählten α, β (d.h. $\alpha = a$ und gleichzeitig $\beta = b$) liegen die Punkte (ξ, η), die durch Transformation auch mehrerer Titrationskurven (bei verschiedenen Konzentrationen c_L) erhalten werden, an einer einzigen Gerade mit der geforderten Steigung $-1/a$. Dabei muß allerdings die Grundbedingung erfüllt werden, daß in der Lösung ein einziger genügend dissoziierter Komplex entsteht, und daß die gemessenen Extinktionswerte seiner Gleichgewichtskonzentration proportional sind. Auch die Kenntnis von A_0-Werten ist für die Transformation erforderlich.

Um die Eindeutigkeit und Richtigkeit dieser Aussage beurteilen zu können, ist es nötig den allgemeinen Verlauf der Beziehung (2) bei nicht richtig gewählten Koeffizienten α, β zu untersuchen.

In der Lösung entsteht in einem breiten Konzentrationsverhaltnis nur ein einziger Komplex

In diesem Fall sind die benötigten A_0-Werte durch die horizontalen Äste der Titrationskurven gegeben. Dabei gilt in guter Näherung: $[M_aL_b] = 1/b \cdot c_L$ und $A_0' : A_0'' : \ldots = c_L' : c_L'' : \ldots$, wobei A_0', A_0'' ... die Extinktionswerte an den horizontalen Ästen und c_L', c_L'' ... die entsprechenden totalen Ligandkonzentrationen bedeuten. Werden für die Transformation nach Gl. (3) und (4) die geschätzten Werte α, β benutzt, resultiert im Allgemeinen eine Kurve, und darüber hinaus sind die einzelnen transformierten Titrationskurven in Abhängigkeit von den verschiedenen c_L-Werten voneinander verschoben. Dieser Umstand ist für die richtige Beurteilung oft maßgebend, wie es bereits bei dem Studium der Komplexbildung von Arsenazo III mit Uranyl und Thorium empirisch gezeigt werden konnte.[3]

Den allgemeinen Verlauf der transformierten Titrationskurven kann man mathematisch optimal mit Hilfe einer Veränderlichen Δ untersuchen, die wir als die Entfernung der Punkte (ξ, η) von der hypothetischen Gerade definieren die bei richtig gewählten Werten $\alpha = a$ und $\beta = b$ gewonnen wäre.

Die Normalenform der Gl. (2) lautet:

$$\frac{a}{\sqrt{1 + a^2}} \log \left(\frac{c_M}{c_L} A_0 b - aA\right) + \frac{1}{\sqrt{1 + a^2}} \log \frac{(A_0 - A)^b}{A} - \frac{1}{\sqrt{1 + a^2}} \log \chi = 0 \tag{5}$$

Für die Entfernung Δ eines Punktes (ξ, η) von der Gerade (5) gilt:

$$\Delta = \frac{a}{\sqrt{1 + a^2}} \log \left(\frac{c_M}{c_L} A_0 \beta - \alpha A\right) + \frac{1}{\sqrt{1 + a^2}} \log \frac{(A_0 - A)^b}{A} - \frac{1}{\sqrt{1 + a^2}} \log \chi \tag{6}$$

Aus Gl. (2) berechnet man

$$\frac{c_M}{c_L} = \frac{1}{bA_0} \left[\frac{a\chi}{(A_0 - A)^b}\right]^{1/a} + \frac{a}{bA_0} A \tag{7}$$

Nach Einsetzen in (6) und Umformung resultiert für den gesuchten Wert von Δ:

$$\Delta = \frac{1}{\sqrt{1 + a^2}} \log \frac{(A_0 - A)^\beta}{a\chi} \left[\frac{\beta}{b} A^{1/a} \cdot \chi^{1/a} \cdot (A_0 - A)^{-b/a} + \frac{\beta}{b} aA - \alpha A\right]^a \tag{8}$$

Nach dieser Gleichung kann man die Entfernungen Δ der Punkte (ξ, η), die bei der Transformation bei falsch gewählten α, β gewonnen werden, von der Gerade der richtigen Transformation ($\alpha = a$ und $\beta = b$) berechnen.

Um einen anschaulicheren Überblick über den Verlauf der Funktion Δ zu bekommen, untersuchen wir erstens ihre Werte für die beiden extreme Zustände, d.h. den Anfang der Titration ($A \rightarrow 0$) und das Ende der Titration bei sehr großen Titrantüberschüssen ($A \rightarrow A_0$).

Für den Anfang der Titration ($A \rightarrow 0$) gilt:

$$\Delta_0 \equiv \lim_{A \to 0} \Delta = \frac{1}{\sqrt{2}} \log \left(\frac{\beta}{b} A_0^{-b} + \frac{\beta}{b\chi} - \frac{\alpha}{\chi} \right) A_0^{\beta} \tag{9}$$

für $a = 1$, und

$$\Delta_0 \equiv \lim_{A \to 0} \Delta = \frac{a}{\sqrt{1 + a^2}} \log \frac{\beta}{b} A_0^{(\beta - b)/a} \tag{10}$$

für $a > 1$.

Für das Ende der Titration ($A \rightarrow A_0$) gilt:

$$\Delta_{A_0} \equiv \lim_{A \to A_0} \Delta = 0 \tag{11}$$

für $\beta = b$,

$$\Delta_{A_0} \equiv \lim_{A \to A_0} \Delta = +\infty \tag{12}$$

für $\beta < b$, und

$$\Delta_{A_0} = \lim_{A \to A_0} \Delta = -\infty \tag{13}$$

für $\beta > b$.

Bei der Transformation von n Titrationskurven (n verschiedene c_L-Werte) resultiert in den Koordinaten ξ, η bei $a, b \neq \alpha, \beta$, die gleiche Anzahl von Kurven analoger Form. Die Verschiebung dieser transformierten Kurven voneinander folgt aus der allgemeinen Beziehung (8) für Δ, anschaulicher wird sie jedoch in einigen Fällen aus den Δ_0-Werten, die nach Gl. (9) und (10) berechnet werden. So z.B. folgt aus Gl. (10) bei $a > 1$ für zwei Werte A_0' und A_0'':

$$\begin{aligned} \Delta_0' - \Delta_0'' &= \frac{a}{\sqrt{1 + a^2}} \log \frac{\beta}{b} A_0'^{(\beta - b)/a} - \frac{a}{\sqrt{1 + a^2}} \log \frac{\beta}{b} A_0''^{(\beta - b)/a} \\ &= \frac{\beta - b}{\sqrt{1 + a^2}} \log \frac{A_0'}{A_0''} = \frac{\beta - b}{\sqrt{1 + a^2}} \log \frac{c_L'}{c_L''} . \end{aligned} \tag{14}$$

Falls $a = b = 2$ und $\alpha = \beta = 1$, wird die Entfernung von zwei transformierten Anfängen der Titrationskurven bei c_L' und c_L'' durch Gl. (15) gegeben:

$$\Delta_0' - \Delta_0'' = -\frac{1}{\sqrt{5}} \log \frac{c_L'}{c_L''} \tag{15}$$

Analog kann man aus Gl. (9) die Entfernung von zwei transformierten Anfängen der Titrationskurven für den Fall berechnen, in dem bei der Existenz eines Komplexes ML die Transformation irrtümlich für $\alpha, \beta = 2$ vorgenommen wurde:

$$\Delta_0' - \Delta_0'' = \frac{1}{\sqrt{2}} \log \frac{c_L'}{c_L''} \tag{16}$$

Nur in dem Fall, daß die stöchiometrischen Koeffizienten richtig vorausgesetzt wurden, bekommt man also bei der Transformation von mehreren Titrationskurven bei verschiedenen Ausgangskonzentrationen eine einzige resultierende Gerade mit der geforderten Steigung.

Neben den extremen Werten von Δ ist es für die Beschreibung der Funktion Δ sinnvoll, den Wert der Steigung ihrer Tangente in einem beliebigen Punkt zu berechnen. Falls man an der unter einer falschen Voraussetzung transformierten Titrationskurve einen pseudolinearen Abschnitt mit genügend von $-1/\alpha$ abweichender Steigung findet, wäre es dann für die Eliminierung der falschen Annahme ausreichend, nur eine einzige Titrationskurve zu transformieren.

Die Steigung der transformierten Titrationskurve in ihrem beliebigen Punkt (ξ, η)

$$k = \frac{\mathrm{d}\eta}{\mathrm{d}A} \Big/ \frac{\mathrm{d}\xi}{\mathrm{d}A} \tag{17}$$

kann man aus den Beziehungen (7), (3) und (4) berechnen. Nach der Ableitung resultiert für k:

$$k = \tag{18}$$
$$-\frac{(A - A_0)\left[a - \alpha\frac{b}{\beta} + \frac{1}{a}\chi^{1/a}A^{(1/a-1)}(A_0 - A)^{-b/a} + \frac{b}{a}\chi^{1/a}A^{1/a}(A_0 - A)^{(-b/a-1)}\right]}{(A_0 - A + \beta A)\left[a - \alpha\frac{b}{\beta} + (A_0 - A)^{-b/a}\chi^{1/a}A^{(1/a-1)}\right]}$$

Für die beiden oben diskutierten extremen Fälle ($A \rightarrow 0$, $A \rightarrow A_0$) gilt dann:

$$k_{A_0} \equiv \lim_{A \rightarrow A_0} k = -\frac{b}{a\beta} \tag{19}$$

$$k_0 \equiv \lim_{A \rightarrow 0} k = -\frac{1}{a} \tag{20}$$

Bei der Berechnung der Beziehungen (19) und (20) kann man entweder nach der l'Hopital'schen Regel, oder auch einfacher nach Multiplizieren des Zählers und des Nenners durch $(A_0 - A)^{b/a}$ [Gl. (19)] oder durch $A^{(1-1/a)}$ [Gl. (20)]. Aus Gl. (19) und (20) folgt, daß man mit Hilfe einer einzigen transformierten Titrationskurve die Existenz eines angenommenen Komplexes $M_\alpha L_\beta$ ausschließen kann, falls bei $A \rightarrow 0$, $\alpha \neq a$ und bei $A \rightarrow A_0$, $b/a\beta \neq 1/\alpha$.

Auf Grund der oben abgeleiteten Beziehungen kann man die Kurventypen darstellen, die bei der Transfromierung einer Titrationskurve unter nicht richtiger Annahme eines Komplexes $M_\alpha L_\beta$ bei der wirklichen Bildung eines Komplexes $M_a L_b$ resultieren. Diese Kurven sind in Abb. 1 und 2 für alle Kombinationen $a, b, \alpha, \beta = 1,2$ schematisch dargestellt. Die Grenzwerte Δ_0, Δ_{A_0}, k_0, k_{A_0} bzw. $\Delta_{\max}$ sind in Tab. I zusammengestellt (in den Klammern sind die Kurvenbezeichnungen aus Abb. 1 und 2 angeführt). Für alle diese Kurven gilt, daß $\mathrm{d}\xi/\mathrm{d}A > 0$ und $\mathrm{d}\eta/\mathrm{d}A < 0$, die einzelnen Punkte (ξ, η) liegen somit bei höheren A Werten an den Kurven rechts unten, bei sinkenden Extinktionen links oben. Die Grenzwerte k_{A_0} sind bei den einzelnen Kurven angegeben. Für alle Kurven in Abb. 1 gilt im Einklang mit Gl. (20) $k_0 = -1$, in Abb. 2 $k_0 = -0{,}5$.

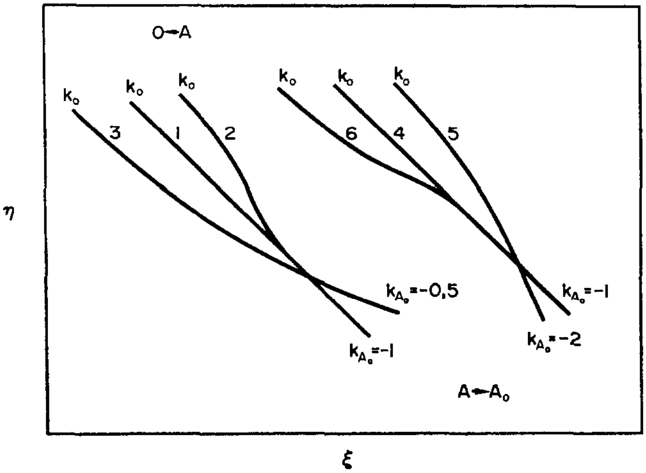

ABB. 1.—Typischer Verlauf transformierter Titrationskurven.
Kurven *1–3*—Es entsteht ein Komplex ML; Kurven *4–6*—Es entsteht ein Komplex ML_2
1—ML richtig vorausgesetzt; *2*—M_2L vorausgesetzt; *3*—M_2L_2 oder ML_2 vorausgesetzt;
4—ML_2 richtig vorausgesetzt; *5*—ML oder M_2L vorausgesetzt; *6*—M_2L_2 vorausgesetzt.

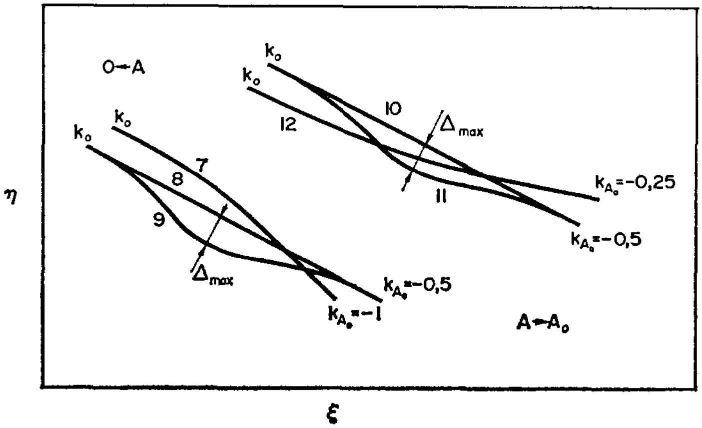

ABB. 2.—Typischer Verlauf transformierter Titrationskurven.
Kurven *7–9*—Es entsteht ein Komplex M_2L_2; Kurven *10–12*—Es entsteht ein Komplex M_2L *7*—ML oder M_2L vorausgesetzt; *8*—M_2L_2 richtig vorausgesetzt; *9*—ML_2 vorausgesetzt; *10*—M_2L richtig vorausgesetzt; *11*—ML vorausgesetzt; *12*—ML_2 oder M_2L_2 vorausgesetzt.

In Abb. 1 und 2 schneiden sich die Kurven *3*, *5*, *7* und *12* mit den Geraden der richtigen Transformation *1*, *4*, *8* und *10*. Ein Schnittpunkt entsteht nur dann, falls die Grenzwerte Δ_0 und Δ_{A_0} ein entgegengesetztes Vorzeichen haben. So z.B. für $\alpha = \beta = 2$ und $a = b = 1$ schneiden sich die Kurven nur, falls $A_0 > 0,5$ (bei $A = A_0 - 0,5$), wie es auch aus Gl. (8) für $\Delta = 0$ ersichtlich ist. Bei niedrigeren c_L-Konzentrationen ($A_0 < 0,5$) werden die transformierten Kurven in Richtung zu höheren ξ, η verschoben und sie bilden keinen Schnittpunkt mit der Gerade der richtigen Transformation.

TABELLE 1.—ENTFERNUNGEN DER PUNKTE (ξ, η) VON DEN GERADEN DER RICHTIGEN TRANSFORMATION UND STEIGUNGEN DER TRANSFORMIERTEN KURVEN IN GRENZGEBIETEN FÜR $A \to 0$ und $A \to A_0$

a,b \ α,β	$\alpha = \beta = 1$ (ML)	$\alpha = 1 \quad \beta = 2$ (ML_2)	$\alpha = 2 \quad \beta = 1$ (M_2L)	$\alpha = \beta = 2$ (M_2L_2)
$a = b = 1$ (ML)	(1) $\Delta = 0$ für $0 = A = A_0$ $k_0 = k = k_{A_0} = -1$	(3) $\Delta_{A_0} = -\infty$ $\Delta_0 = \frac{\sqrt{2}}{2} \log A_0\left(2 + \frac{A_0}{\chi}\right)$ $k_0 = -1 \quad k_{A_0} = -0{,}5$	(2) $\Delta_{A_0} = 0$ $\Delta_0 = \frac{\sqrt{2}}{2} \log\left(1 - \frac{A_0}{\chi}\right)$ $k_0 = -1 \quad k_{A_0} = -1$	(3) $\Delta_{A_0} = -\infty$ $\Delta_0 = \frac{\sqrt{2}}{2} \log 2A_0$ $k_0 = -1 \quad k_{A_0} = -0{,}5$
$a = 1$ $b = 2$ (ML_2)	(5) $\Delta_{A_0} = +\infty$ $\Delta_0 = \frac{\sqrt{2}}{2} \log \frac{1}{2}\left(\frac{1}{A_0} - \frac{A_0}{\chi}\right)$ $k_0 = -1 \quad k_{A_0} = -2$	(4) $\Delta = 0$ für $0 \leq A \leq A_0$ $k_0 = k = k_{A_0} = -1$	(5) $\Delta_{A_0} = +\infty$ $\Delta_0 = \frac{\sqrt{2}}{2} \log\left(\frac{1}{2A_0} - \frac{3A_0}{2\chi}\right)$ $k_0 = -1 \quad k_{A_0} = -2$	(6) $\Delta_{A_0} = 0$ $\Delta_0 = \frac{\sqrt{2}}{2} \log\left(1 - \frac{A_0}{\chi}\right)$ $k_0 = -1 \quad k_{A_0} = -1$
$a = 2$ $b = 1$ (M_2L)	(11) $\Delta_{A_0} = 0$ $\Delta_0 = 0$; $\Delta_{\max}$ für $A = \frac{1}{2}A_0$ $k_0 = -0{,}5 \quad k_{A_0} = -0{,}5$	(12) $\Delta_{A_0} = -\infty$ $\Delta_0 = \frac{\sqrt{5}}{5} \log 4A_0$ $k_0 = -0{,}5 \quad k_{A_0} = -0{,}25$	(10) $\Delta = 0$ für $0 \leq A \leq A_0$ $k_0 = k = k_{A_0} = -0{,}5$	(12) $\Delta_{A_0} = -\infty$ $\Delta_0 = \frac{\sqrt{5}}{5} \log 4A_0$ $k_0 = -0{,}5 \quad k_{A_0} = -0{,}25$
$a = b = 2$ (M_2L_2)	(7) $\Delta_{A_0} = +\infty$ $\Delta_0 = \frac{\sqrt{5}}{5} \log \frac{1}{4A_0}$ $k_0 = -0{,}5 \quad k_{A_0} = -1$	(9) $\Delta_{A_0} = 0$ $\Delta_0 = 0$; $\Delta_{\max}$ für $A = \frac{1}{3}A_0$ $k_0 = -0{,}5 \quad k_{A_0} = -0{,}5$	(7) $\Delta_{A_0} = +\infty$ $\Delta_0 = \frac{\sqrt{5}}{5} \log \frac{1}{4A_0}$ $k_0 = -0{,}5 \quad k_{A_0} = -1$	(8) $\Delta = 0$ für $0 \leq A \leq A_0$ $k_0 = k = k_{A_0} = -0{,}5$

In einigen Fällen geht Δ durch ein Maximum bei $0 < A < A_0$ (vgl. Kurven *9*, *11*). Die Extinktionswerte A, bei denen $\Delta = \Delta_{\max}$, wurden nach Einsetzen von a, b, α, β in Gl. (8) und der Bestimmung des Extrems mit Hilfe der ersten Ableitung berechnet. Wie es aus Kurven *9* und *11* und aus den Angaben für Δ_0 und Δ_{A_0} in Tab. I folgt, werden die Anfangs- und Endteile der transformierten Titrationskurven bei verschiedenen c_L in diesem Fall voneinander nicht verschoben. In dem Gebiet $0 < A < A_0$ wird jedoch die Verschiebung der einzelnen unter falschen Annahme transformierten Titrationskurven sichtbar, worüber man sich nach Einsetzen der konkreten Werten a, b, α, β in Gl. (8) und nach Auswertung des allgemeinen Ausdruckes für die Differenz $(\Delta' - \Delta'')$ für A_0' und A_0'' überzeugen kann.

Möglichkeiten der Anwendung logarithmischer Transformationen bei der stufenweisen Bildung mehrerer Komplexe

In einigen Fällen der stufenweisen Bildung mehrerer Komplexe wird die Bedingung, daß in der untersuchten Lösung nur ein Komplex entsteht, bei geeigneten experimentellen Bedingungen in guter Näherung erfüllt, nämlich bei einem genügenden Überschuß einer der reagierenden Komponenten. Zur Transformation eignen sich dabei die Anfangsteile der Titrationskurven. Den Grenzwert A_0 muß man mit Hilfe des unabhängig bestimmten molaren Extinktionskoeffizienten bestimmen, vgl. z.B. ref. 1–3, 9–11. Die Anwendung der Methode der logarithmischen Transformationen setzt in diesem Fall voraus, daß es sich um genügend dissoziierte Komplexe handelt (Transformation des Anfangsteiles der Titrationskurve). Kaum geeignet ist diese Methode für das Studium eines Systems, in welchem mehr als zwei verschiedene Komplexe nacheinander entstehen.

Anwendungsbeispiele

Die Anwendbarkeit der Methode der logarithmischen Transformationen photometrischer Titrationskurven und die Gültigkeit oben abgeleiteter Beziehungen wurden in der Praxis beim Studium der Komplexbildung von Arsenazo III mit Uranylionen und Thorium(IV) bewiesen.[3] Im Falle der Uranylkomplexen wurde die Existenz von zwei verschiedenen ML Komplexen mit $K_{ML} = 3 \cdot 10^3 – 1 \cdot 10^5$ in Abhängigkeit von den Versuchsbedingungen (pH) entdeckt. Die Möglichkeit einer eventuellen Bildung von M_2L_2 Komplexen wurde ausgeschlossen. Thorium(IV) bildet bei geeigneten Bedingungen vorwiegend Komplexe M_2L, ML_2 und zwei verschiedene ML Komplexe. Es wurden überall die Beständigkeitskonstanten bestimmt.

In Abb. 3 sind die transformierten photometrischen Titrationskurven von Sulfonazo III durch Ba^{2+}-Ionen gezeichnet. Gerade *1* wurde bei richtiger Voraussetzung ($a = b = 1$) für drei verschiedene Ligandkonzentrationen erhalten. Kurven *2*, *3* und *4* resultierten nach Transformation derselben Titrationskurven bei der falschen Voraussetzung $\alpha = \beta = 2$. Die an der Gerade *1* gezeichneten Punkte wurden aus Kurven *2–4* mit Hilfe der Gl. (8) errechnet. Die logarithmische Transformation bewies in diesem Fall eindeutig die Bildung eines ML-Komplexes.

Svoboda und Chromý[12] benutzten erfolgreich die logarithmischen Transformationen bei der Untersuchung der Komplexbildung von Magnesium mit Xylidyl Blue II (Magon). Es wurde die Existenz eines einzigen ML_2-Komplexes mit einem K-Wert von $(6{,}1 \pm 0{,}3) \cdot 10^9$ bei den gegebenen Bedingungen bewiesen.

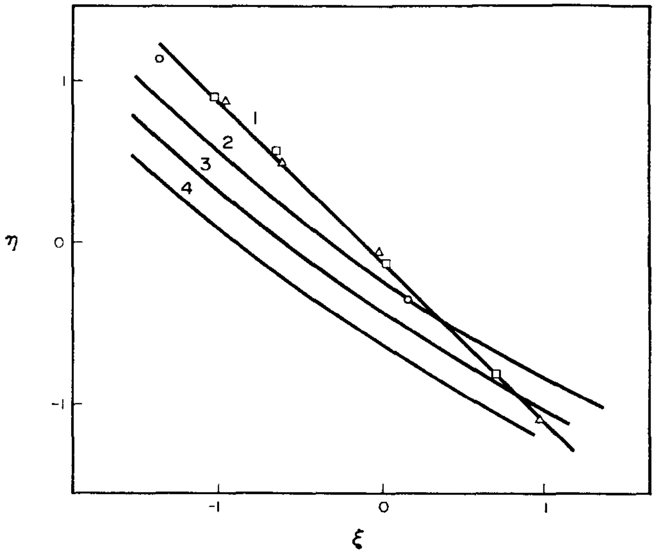

ABB. 3.—Logarithmische Transformation von drei photometrischen Titrationskurven von Sulfonazo III durch Bariumionen.

Kurven *2–4*—Transformation (ξ, η) für $\alpha = 2$, $\beta = 2$ (M_2L_2). *2*—$c_L = 2 \cdot 10^{-5}M$; *3*—$c_L = 5 \cdot 10^{-5}M$; *4*—$c_L = 1 \cdot 10^{-4}M$. Kurve *1*—richtige Transformation für $a = b = \alpha = \beta = 1$ (ML); die gezeichnete Kurve wurde von ref. 1, Abb. 8 übernommen, die markierten Punkte aus den falsch transformierten Kurven *2–4* als △ nach Gl. (8) berechnet (○ aus *2*; △ aus *3* und □ aus *4*).

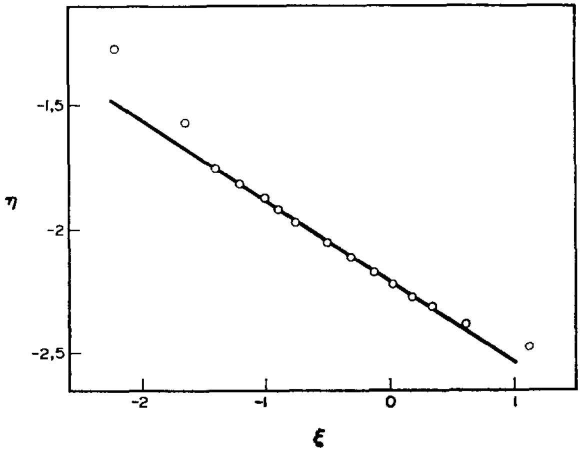

ABB. 4.—Logarithmische Transformation einer Titrationskurve von Azomethin durch Eisen(II).

Ein Komplex ML_3 richtig angenommen. Die experimentellen Angaben von Asmus[13] übernommen.

Asmus[13] widmete sich der Reaktion von Eisen(II) mit Azomethin (ein Kondensationsprodukt von Pyridin-2-aldehyd mit Sulfanilsäure) und stellte fest, daß ein einziger stark dissoziierter ML_3-Komplex gebildet wird. In der erwähnten Arbeit[13] (Seite 112) sind in einer Tabelle die gemessenen Werte der Extinktionen an einer Titrationskurve gegeben; wir haben uns erlaubt diese Titrationskurve logarithmisch zu transformieren. In Abb. 4 ist die resultierende transformierte Titrationskurve für

$\alpha = 1, \beta = 3$ gezeichnet. Die Steigung der Gerade beträgt $-0{,}326$ (daraus $b = 3{,}08$), der berechnete Wert von $1/K$ ist $4{,}26 \cdot 10^{-5}$ in ausgezeichneter Übereinstimmung mit der Angabe von Asmus $4{,}3 \cdot 10^{-5}$. Für die Transformation wurde $A_0 = 1{,}565$ aus dem angegebenen molaren Extinktionskoeffizienten ausgerechnet. In der Praxis könnte man in diesem Fall A_0 direkt bei einem genügenden c_L-Überschuß oder nach[1–3,9–11] bestimmen. Der gebildete Komplex ist stark dissoziiert, für die eindeutige Aussage genügt es, nur eine einzige ganze Titrationskurve zu transformieren. Die Abweichungen beider äußersten Teile der transformierten Titrationskurve von dem linearen Verlauf sind wahrscheinlich durch Meßfehler bei sehr kleinen Extinktionsmessungen, bzw. durch eine kleine Differenz in dem angenommenen Wert von A_0, bedingt.

SCHLUSSFOLGERUNGEN UND DISKUSSION

Es wurden allgemeine aus dem Massenwirkungsgesetz folgende Beziehungen abgeleitet, die eine eindeutige Interpretation der photometrischen Titrationskurven mit dem Ziel der Bestimmung der stöchiometrischen Koeffizienten des gebildeten Komplexes ermöglichen. Diese Beziehungen wurden an dem konkreten Beispiel aller Kombinationen a, b, α, $\beta = 1{,}2$ veranschaulicht. Auf ähnlicher Weise können analoge Gleichungen auch für andere Komplexe (z.B. 1:3) berechnet werden. Die Bildung vorwiegend eines einzigen Komplexes in einem weiten Konzentrationsgebiet wird vorausgesetzt.

Bei der richtigen Wahl des Komplextypus werden immer zwei Kriterien erfüllt.

1. Die transformierten Titrationskurven haben einen linearen Verlauf und den geforderten Wert der Steigung.
2. Die transformierten Punkte mehrerer bei verschiedenen Konzentrationen des zu titrierenden Stoffes erhaltenen Titrationskurven liegen an einer einzigen Gerade.

Falls die transformierte Titrationskurve keinen linearen Charakter aufweist, wird auch die zweite Forderung nicht erfüllt. In diesem Fall ist die Voraussetzung der stöchiometrischen Koeffizienten falsch, oder die Bedingung der überwiegenden Bildung eines einzigen Komplextypus blieb unerfüllt.

Aus den Achsenabschnitten kann man bei richtiger Transformation leicht den Wert von χ bestimmen, und daraus laut Definition die Stabilitätskonstante K berechnen:

$$\eta = -\frac{1}{a}\log\chi \qquad (\text{für } \xi = 0) \tag{21}$$

$$\xi = \log\chi \qquad (\text{für } \eta = 0) \tag{22}$$

Den dazu benötigten Wert des Extinktionskoeffizienten ε_{ab} erhält man mit Hilfe des Wertes A_0 aus der bekannten Grundbeziehung

$$A_0 = \frac{1}{b}\varepsilon_{ab}c_L \tag{23}$$

Aus Gl. (8) bzw. (21) und (22) folgt, daß bei den experimentellen Messungen der Titrationskurven alle Bedingungen äußerst konstant gehalten werden müssen, da auch eine relativ kleine Änderungen in K-Werten zwischen den einzelnen Versuchen (bedingt z.B. durch andere Ionenstärke, pH, Temperatur) eine Verschiebung der Geraden in Koordinaten ξ, η zur Folge hat. Wird also als Resultat der Transformation von mehreren Titrationskurven die Existenz von parallelen Geraden mit der geforderten

Steigung beobachtet, ist es wahrscheinlich, daß die Wahl des Komplextypus richtig war, die einzelnen Titrationskurven jedoch nicht bei vergleichbaren Bedingungen erhalten wurden.

Die beschriebene Methode eignet sich besonders für die Untersuchung bedeutend dissoziierter Komplexe [$K^{1/(a+b-1)} < 10^5$]. In diesem Fall ist es möglich den Typus und die Beständigkeitskonstante des gebildeten Komplexes durch die Transformation einer einzigen Titrationskurve zu bestimmen, da der starken Dissoziation wegen praktisch die ganze Kurve transformierbar ist und deshalb der lineare Verlauf der transformierter Kurve in einem großen Abschnitt nachweisbar ist.

Bei relativ festeren Komplexen ($K^{1/(a+b-1)} \sim 10^5$–10^6) kann man nur die gekrümmten Teile der Titrationskurven, oder sogar nur die einzelnen Punkte mehrerer Kurven bei $c_M/c_L = a/b$, wo der sich bildende Komplex am meisten dissoziiert, transformieren. Auch hier ist die Bedingung der alleinigen Bildung eines einzigen Komplexes wichtig (wegen der Bestimmung von A_0 aus den horizontalen Ästen der Titrationskurven). Bei festeren Komplexen steigern sich auch die Forderungen auf die Genauigkeit aller Extinktionsmessungen. Die Anwendung der Methode der logarithmischen Transformationen bietet sich auch für das Studium von festen Komplexen beim Ausnutzen von Konkurrenzreaktionen ein. Bei dieser Reaktion, die zur Erniedrigung des K-Wertes führt, dürfen jedoch keine ternäre Komplexe gebildet werden.

Soll die Methode der logarithmischen Transformation ihre Anwendung auch in Fällen finden, bei welchen die Bedingung der praktisch ausschließlichen Bildung eines einzigen Komplexes nur in einem begrenzten Gebiet der Werte von c_M/c_L (z.B. bei $c_L \gg c_M$) erfüllt wird, müssen immer mehrere Titrationskurven bei verschiedenen Konzentrationen des zu titrierenden Bestandteiles transformiert werden. Man beobachtet dann die Steigungen und die Verschiebung der erhaltenen transformierten Kurven. Werden die beiden oben formulierten Bedingungen gleichzeitig in einem bestimmten Konzentrationsgebiet erfüllt, bedeutet es, daß hier überwiegend der vorausgesetzte Komplex existiert.

Summary—A method is presented for the logarithmic transformation of photometric titration curves, with the aid of which it is possible to differentiate with certainty between mononuclear and polynuclear complexes. The mathematical expressions are derived, and applied to practical examples, leading to unequivocal conclusions. The method suffers from two limitations—over a wide range of concentrations only one complex should be formed, and it must be a relatively weak one.

Résumé—On présente une méthode pour la transformation logarithmique des courbes de titrage photométrique, à l'aide de laquelle il est possible de faire avec certitude la différence entre complexes mononucléaires et polynucléaires. On en déduit les expressions mathématiques et les applique à des exemples pratiques, menant à des conclusions sans équivoque. La méthode présente deux limitations: dans un large domaine de concentrations seulement un complexe doit être formé, et il doit être relativement faible.

STUDIES OF COPPER(II) SULPHIDE ION-SELECTIVE ELECTRODES

GILLIS JOHANSSON and KERSTIN EDSTRÖM
Department of Analytical Chemistry, University of Umeå, 901 87 Umeå, Sweden

(*Received* 1 *March* 1972. *Accepted* 7 *May* 1972)

Summary—Changes in liquid junction potentials in copper(II) solutions were measured when different reference electrodes were used. The slope and intercept of a calibration curve for a copper-selective electrode will depend on the selection of reference electrode. The condition of the electrode surface of an Orion copper-selective electrode was studied microscopically and the influence of redox potential on stability of the electrode against corrosion is discussed. Oxidizing solutions will produce pits at dislocations in the material and there will be a mixed electrode potential. The slope, stability, and speed of response are much lower when the surface contains pits. Diamond-polishing was shown to improve the electrode significantly.

IN RECENT years a number of papers on the behaviour of ion-selective electrodes have appeared in the literature. Most of these have given a simplified picture of the electrode behaviour and the manufacturers' literature has also tended to give an idealistic impression. When a need arose to test the ion radical electrodes described recently[1] and compare them with the sulphide electrodes, a more thorough investigation of the latter was necessary. This paper reports such an investigation of a copper(II) ion-electrode, namely the Orion copper sulphide electrode.[2]

An electrode is said to have a Nernstian or "theoretical" slope of the calibration curve if this equals $(RT \ln 10)/zF$, *i.e.*, 59·2 and 29·6 mV/decade at 25° for univalent and bivalent ions respectively. These values should be obtained only if a number of conditions are fulfilled. The most important prerequisites are that the variation in liquid-junction potential, the changes in activity coefficients and the changes in the activity of the reference ion in the solid electrode material are negligible. The activity of the reference ion in the surface layer of the electrode material is tactily assumed to be constant but usually no experiments have been made to test this assumption. Sato[3] has discussed the electrode behaviour for varying ion activity in the surface. Departures from the simple Nernst's law, due to cracks and pits in the surface, will be discussed in this paper.

EXPERIMENTAL

Electrodes

An Orion Cupric Ion Electrode 94-29 A and Orion Double Junction Reference Electrodes 90-02 were used. The bridge solution of the reference electrode was Orion 90-00-02 filling solution, 2*M*-potassium nitrate, 1*M* potassium nitrate, or 1*M* sodium nitrate. A Radiometer Calomel Electrode K 401 with saturated potassium chloride solution as bridge solution was also used.

Procedure

Potentiometric measurements were made in a Metrohm titration cell, EA 880-20. Solutions were prepared immediately before measurement, by dilution of a 0·1*M* stock solution. The dilution was made with an Oxford Sampler micropipete system. The cell was filled with 27 ml of solution and stirred with a magnetic follower. The measurements were then made at room temperature, 23°. Potential readings were made to the nearest 0·1 mV and in some cases to 0·01 mV. The electrodes were washed thoroughly with distilled water between the measurements. An electrode switch was used when several electrodes were studied simultaneously.

Surface studies

The electrode surface was studied with an inverted metal polarizing microscope, Zeiss UP 1, with a Polaroid camera attachment. The objectives were of the type Zeiss Epiplan, 4x, 8x, 16x, 40x, and 80x. The copper sulphide electrode was polished with a diamond paste of the smallest grain size, DP-paste type C (Struers, Copenhagen), in a polishing machine running at 125 rpm. A support held the electrode orthogonal to the turntable.

Calculations

For calculation of the liquid-junction potential the following constants were used: $\lambda^{\circ}_{Na^+} = 50{\cdot}1$, $\lambda_{K^+}{}^{\circ} = 73{\cdot}5$, $\lambda^{\circ}_{Cu^{2+}} = 53{\cdot}6$, $\lambda^{\circ}_{Cl^-} = 76{\cdot}35$, $\lambda^{\circ}_{NO_3^-} = 71{\cdot}46$ ohm^{-1}. cm^2. equiv.$^{-1}$. Figure 9 was constructed by using the following constants: $E^{\circ}_{Cu^{2+}/Cu} = 0.337$ V, $E^{\circ}_{Cu^{2+}/Cu^+} = 0{\cdot}153$ V, $E^{\circ}_{S^{2+}/S} = -0{\cdot}48$ V, $E^{\circ}_{Ag^+/Ag} = 0{\cdot}799$ V, and the solubility products: $K_{sp}(CuS) = 10^{-36.1}$ and $K_{sp}(Ag_2S) = 10^{-49{\cdot}4}$.

RESULTS AND DISCUSSION

Liquid-junction potentials

There are large differences in liquid-junction potentials between different bridge solutions used to connect the reference electrode to the sample solution. Figure 1 shows the difference in liquid-junction potentials between a reference electrode containing 2*M* potassium nitrate and other reference electrodes using different bridge solutions. The measurements were made in copper(II) nitrate solutions and in two salt solutions. Figure 2 shows the differences when the ionic strength was kept constant in the copper(II) nitrate solutions, $I = 0{\cdot}3$, by addition of potassium nitrate. It is seen that even when the ionic strength was kept constant there was a significant variation in the liquid-junction potential. This variation may cause a curved calibration graph which might be confused with deviations from Nernst's law. A calibration curve of an ideal ion-selective electrode will thus result in a curved calibration curve, the curvature being dependent on the selected reference electrode. If on the other hand a procedure is used in which the best straight line is drawn through the calibration points an analytical error of up to 20% may occur.

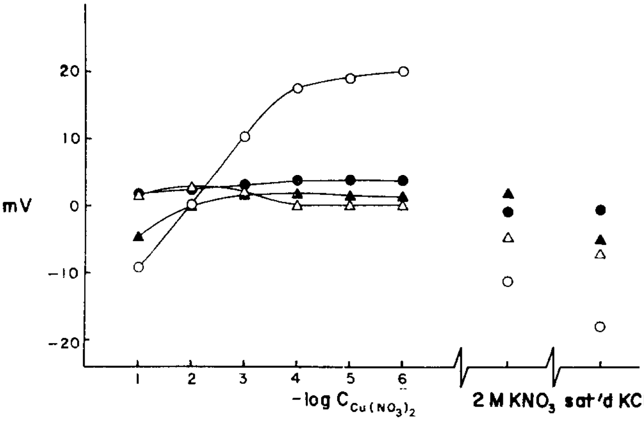

FIG. 1.—Difference in liquid-junction potential measured between a double-junction reference electrode containing 2*M* KNO_3 and a double-junction reference electrode containing

△ saturated KCl solution (Radiometer K 401)
immersed in solutions of $Cu(NO_3)_2$ with varying ionic strength and into two salt solutions.

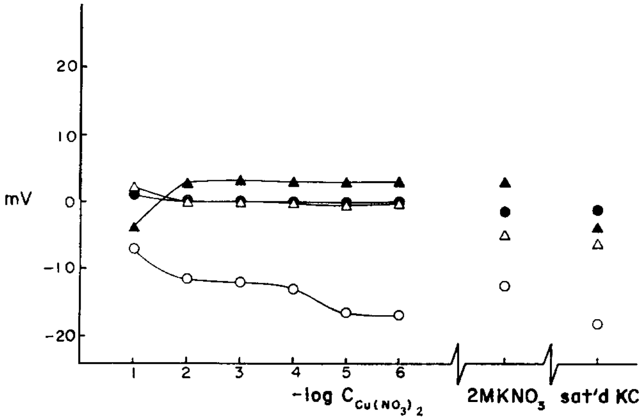

FIG. 2.—Difference in liquid-junction potential measured between a double-junction reference electrode containing $2M$ KNO_3 and a double-junction reference electrode containing
○ $1M$ $NaNO_3$
● Orion 90-00-02 filling solution
▲ $1M$ KNO_3
△ saturated KCl solution (Radiometer K 401)
immersed in solutions of $Cu(NO_3)_2$ with constant ionic strength, $I = 0{\cdot}3$, obtained by addition of KNO_3 and into two salt solutions. (100 mV was subtracted from all the readings with the $NaNO_3$ bridge solution.)

Figures 1 and 2 show only the difference between two liquid-junction potentials and it is not possible to measure the variation of a single liquid-junction potential independent of the determination of single ion activities. It is, however, possible to make approximate calculations of a single liquid-junction potential.

Henderson's equation gives the liquid-junction potentials for a "continuous mixture" junction

$$E_j = -\frac{RT}{F}\int_1^2 \sum \frac{T_i}{z_i}\,\mathrm{d}\ln c_i - \frac{RT}{F}\int_1^2 \sum \frac{T_i}{z_i}\,\mathrm{d}\ln \gamma_i = E_{jc} + E_{j\gamma}$$

where T_i is the transport number, z_i the charge, c_i the concentration and γ_i the activity coefficient. The first term, E_{jc}, can be evaluated if the transport number is assumed to be constant. The second term representing the non-ideal contributions cannot be evaluated directly. The first term was evaluated by using a computer programme. Figure 3 shows a plot of the differences in E_{jc} between a number of bridge solutions and $2M$ potassium nitrate, in copper(II) nitrate solutions and in two salt solutions. Figure 4 is a corresponding plot of a calculation made for copper(II) nitrate solutions in which the ionic strength was kept constant, $I = 0{\cdot}3$, by addition of potassium nitrate. If it had been possible to calculate correct liquid-junction potentials, Figs. 3 and 4 should have been identical to Figs. 1 and 2 respectively. As the agreement between calculated and measured differences was rather poor the calculation seems to be of limited value.

It is desirable to select a bridge solution which is likely to give a small variation in liquid-junction potential. The mobility of potassium ions is almost equal to the mobility of nitrate ions and therefore a salt bridge containing potassium nitrate

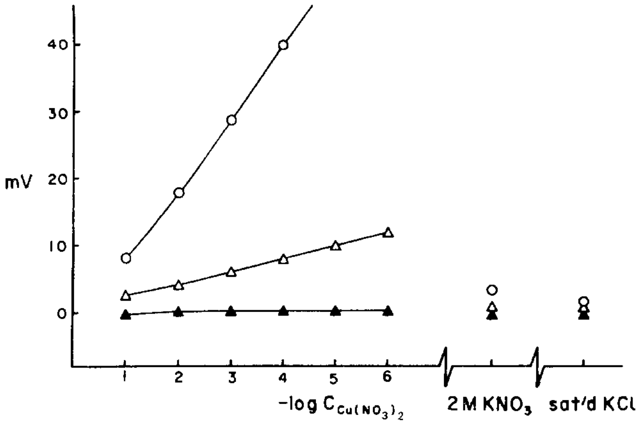

FIG. 3.—Calculated differences in liquid-junction potential between a bridge solution of $2M$ KNO_3 contacting copper and salt solutions and a bridge solution of

○ $1M$ $NaNO_3$
▲ $1M$ KNO_3
△ saturated KCl

contacting the same solutions. The ionic strengths of the copper solutions were varied.

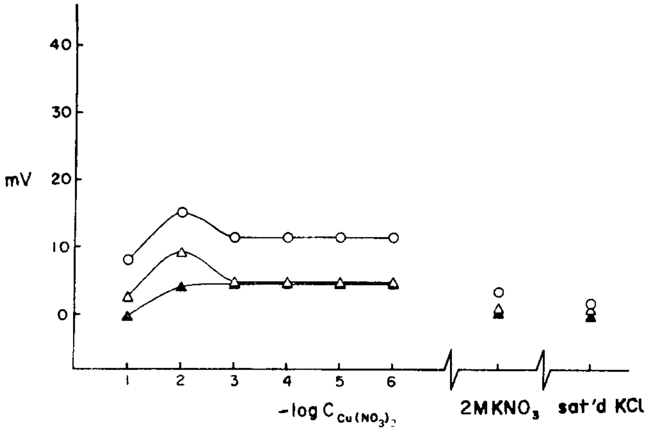

FIG. 4.—Calculated differences in liquid-junction potential between a bridge solution of $2M$ KNO_3 contacting copper and salt solutions and a bridge solution of

○ $1M$ $NaNO_3$
▲ $1M$ KNO_3
△ saturated KCl

contacting the same solutions. The ionic strength of the copper solutions was 0·3, obtained by addition of KNO_3.

should be a better choice than a bridge containing sodium nitrate. The Orion filling solution contains about $0{\cdot}7M$ potassium chloride, about $1{\cdot}5M$ potassium nitrate and small amounts of sodium and silver ions. Chloride ions form complexes with copper(II) ions and both the Orion filling solution and saturated potassium chloride are less suitable. The $2M$ potassium nitrate bridge solution has therefore been used throughout in the following and no calculated corrections for the liquid-junction potential have been applied.

The electrode surface

If the electrode surface contains cracks or pits the first sample solution will enter these. When the electrode is moved to a second sample solution the first will be displaced from the cracks only slowly. Different parts of the solid will be in contact with solutions of different concentrations. A mixed potential with a current path through the solid, the first sample solution, the main sample solution and back to the solid will be set up. The mixed potential will lie somewhere between what it should have been in the first and in the second solution. There will be a slow drift due to displacement of the first solution from the cracks. The Orion copper sulphide electrode has been studied with respect to influence from mixed potentials.

Figure 5 shows the electrode surface after two months use following delivery from the manufacturer, during which time the electrode had not been polished. Three types of spots can be recognized, linear pits, shallow diffuse pits with a rough bottom, and dark areas of various shapes with well-defined boundaries. Figure 6 shows the electrode surface after polishing with a diamond paste. The electrode was rinsed in distilled water before the picture was taken. Only spots of the third type can be seen on this picture. The spots were originally of light colour, but in the intense light of the microscope they turned black in a few minutes. A part of the surface shown in Fig. 6 was illuminated for some minutes with a small light cone covering only a part of the picture area. The aperture was then opened and the picture was taken. It can be seen that the illuminated spots of Fig. 6 are darker.

Electrode stability

Table I shows the stability of the potential readings when the electrode was subjected to different pretreatments. The results show that filling the pits with oil improves the stability and removing most of the pits by polishing improves the stability further. The last row but one shows measurements on a polished electrode treated with silicone oil. The surface condition of the electrode seemed to be of paramount importance for the stability of the potential and for obtaining a stable reading within reasonable time.

Copper(II) ion activity

Activity coefficients for the calculations made in this paper were obtained from a computer programme of the type given by Lee.[5] A positive deviation was always found at 0·1*M* copper(II) nitrate both in the medium with varying ionic strength and in the medium with constant ionic strength, $I = 0{\cdot}3$. The measurements were therefore repeated with constant nitrate concentration, $[NO_3^-] = 0{\cdot}3M$, in order to test for a weak nitrate complex. The deviation from linearity decreased but the result was inconclusive with regard to the existence of a nitrate complex. The deviation may be caused by a change in the liquid-junction potential or an erroneous value of the activity coefficient. It is not possible at present to arrive at better values of the activity coefficients but work along the lines described by Bates and Alfenaar,[7] and Leyendekkers,[7] seems promising for the future.

Calculation of the slope and the intercept

Calibration curves were obtained for the electrode after it had been subjected to various forms of pretreatment. The calibration was made with copper(II) nitrate solutions and a double-junction reference electrode filled with 2*M* potassium nitrate.

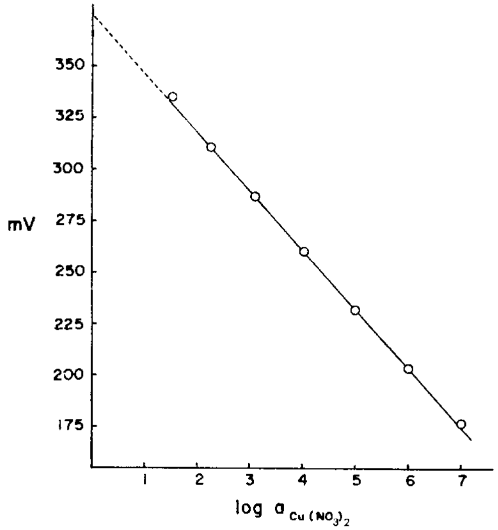

FIG. 7.—Calibration curve of a polished and silicone oil treated copper selective electrode in $Cu(NO_3)_2$ solutions with varying ionic strength. A double-junction reference electrode containing 2*M* KNO_3 was used.

The calibration curves were not strictly linear, as shown in Figs. 7 and 8. The measurement in 0·1*M* solution always resulted in a point above the line. Although this was the case a straight line was fitted to the points by using the least-squares method. This procedure will produce comparable values except for the EDTA-treated electrode. Evaluation was made over the range 10^{-1}–$10^{-6}M$ and the measurements were made in the order from lower to higher concentration. The temperature was always 23° which corresponds to a value of 29·38 mV/decade for $(RT \ln 10)/2F$.

The results of the measurements (Table II) confirm the conclusion drawn from the investigation of the drift. An electrode surface containing pits produces a line

* Slightly S-shaped calibration curve, probably due to residues of EDTA in the pits causing the points at $10^{-5}M$ and $10^{-6}M$ to fall below the line.

with a lower value of the slope than that of a polished electrode surface. The highest values of the slopes were obtained for a polished surface in which the remaining depressions were filled with silicone oil so that the penetration of solution into the material was reduced. This shows conclusively that surface irregularities produce a mixed electrode potential. The value of the slope of the EDTA-etched electrode is not comparable to the other values, because the calibration curve was S-shaped. A slope measured on the middle linear parts was lower (28·0 mV/decade) than that of a polished electrode. The measurements made on solutions with constant ionic strength were somewhat more reproducible than those for varying ionic strength.

The E' values depend on the long-term stability of the reference electrode. No checks were made to estimate this drift.

Electrode corrosion

Figures 9*a* and 9*b* show logarithmic plots of ionic activities at the copper electrode surface for solutions containing $10^{-1}M$ and $10^{-6}M$ Cu^{2+} respectively. The plots were made as described by Sillén.[4] Potentials are referred to the N.H.E. Below 0·31 V (Fig. 9*a*) or 0·15 V (Fig. 9*b*) respectively Cu^{2+} concentration decreases due to formation of Cu°. The concentration of S^{2-} due to dissolution of CuS is also shown. It is lower than that required for the reaction

$$S^{2-} \rightleftharpoons S + 2e^- \qquad E^\circ = -0{\cdot}48\ V$$

up to a redox potential of about 0·57 (Fig. 9*a*) or 0·42 V (Fig. 9*b*) respectively. At more oxidizing potentials CuS can be corroded if a suitable accelerating agent is present. Thermodynamically such an oxidation can be performed with nitrate ions but the reaction rate becomes appreciable only in strongly acid solutions. The same is true for perchloric acid and in this case the reaction rate in $0{\cdot}1M$ perchloric acid is so high that the response to Cu^{2+} is seriously impaired. Measurements in $1M$ sodium perchlorate could be carried out at pH 4–5, however. The corrosion was visible under the microscope. In nitrate solutions, $I = 0{\cdot}3$, an E–pH diagram could be obtained down to pH 2 and possibly lower.

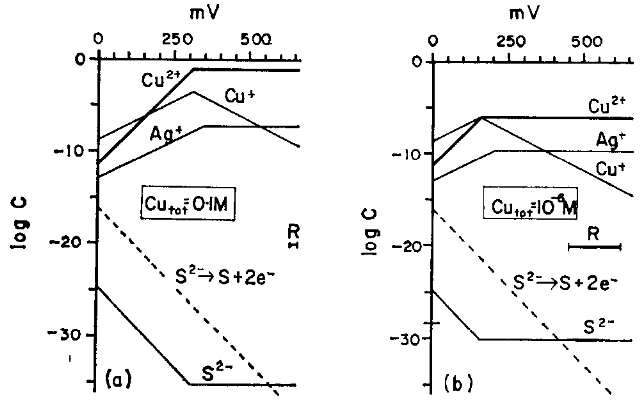

FIG. 9.—Logarithmic plots of some ion activities in equilibrium at the surface of a copper ion-selective electrode as a function of the redox potential *vs.* N.H.E. The equilibrium of oxidation of sulphide to sulphur is also shown. (*a*) Cu $0{\cdot}1M$; (*b*) Cu $10^{-6}M$.

The amount of Cu^+ can be neglected at a total copper concentration of the order of $0{\cdot}1M$ but this is not the case below a redox potential of 0·25 V in $10^{-6}M$ solutions. The redox potential of the copper(II) nitrate solutions used was determined by use of bright platinum electrodes. Two electrodes were used to check the reproducibility, which was rather poor. Two series were made, one at about pH 4 and the other at about pH 5·5. The ranges of redox potentials obtained are marked with R in the figure. The redox potential was so high that the presence of Cu^+ in the standard solutions could be neglected in all cases. The redox potentials of the calibration solutions were so high that oxidation of S^{2-} to S can take place readily, but the rate is probably very low or measurements in the most dilute solutions would have been impossible.

The electrode surface consists of a mixture of CuS and Ag_2S. If equilibrium is attained, the silver ion activity in the solution adjacent to the surface will be that shown in Fig. 9. When the solution is made more reducing, reduction of silver ions will occur before reduction of copper(II) ions to copper metal. Silver can also be formed under the influence of light. In order to study whether such a reaction interfered with the electrode function the surface of a polished dry electrode was illuminated with focused strong light for three hours. The slope and intercept were then determined and found to be identical to those for a newly polished electrode. Reduction of some of the silver ions to silver metal does not affect the electrode function.

Hansen, Lamm and Růžička[8] have shown that EDTA treatment of a sulphide-activated "Selectrode" improves the performance. They also reported that conditioning of commercial electrodes with EDTA, including the Orion electrode, did not produce significant effects. In order to study the conditioning effects on the electrode surface we have immersed the Orion electrode in stirred 0·1*M* EDTA at pH 4·5 for about 50 hr. A photomicrograph of the surface is shown in Fig. 10. The etching has produced diffuse pits with rounded contours. From the slope and intercept of this treated electrode (Table II) it is seen that this treatment is inferior to diamond polishing. The stability, as shown in Table I, is good but slightly less than that of a polished electrode treated with silicone oil.

Thomas and Williams[9] have shown that dislocations in solid surfaces possess enhanced reactivity and that etching is initiated at the dislocations. It is very likely that the attack on the copper electrode surface in corroding media also starts at dislocations. Spots of the first two types mentioned above, see Fig. 5, may be caused by this type of attack. As the etching was made under undefined conditions and mechanical scratches cannot be ruled out, no conclusions about the types of dislocations may be drawn. If this explanation is valid, a more perfect solid should make an electrode more resistant to chemical attack.

The etching rate in EDTA solutions is probably also greater at dislocations and will produce pits which cause mixed potentials. Preparation of the precipitate in the presence of EDTA according to Hansen, Lamm and Růžička will probably decrease the number of dislocations in the material. When the material is later pressed or rubbed into Teflon–graphite a compact solid more resistant to etching attacks will result. These authors also report a considerable improvement when the activated "Selectrode" was conditioned with EDTA. The surface of a Teflon–graphite electrode has probably quite different properties from those of the surface of a pressed pellet and these may arise from a lower formation of etch pits.

Some sulphide electrodes studied a year earlier had deep cracks around the edge where the electrode material was glued to the stem. These electrodes, of course, produced very erratic calibration curves with slopes between 10 and 20 mV/decade. The cracks were so large that inspection of an electrode with a magnifying glass revealed such defects in manufacture. Attempts to fill the cracks with paint or glue were unsuccessful.

Zusammenfassung—Beim Gebrauch verschiedener Referenzelektroden wurden in Kupfer(II)-Lösungen Änderungen der Diffusionspotentiale gemessen. Neigung und Achsenabschnitt einer Eichkurve für eine kupfer-selektive Elektrode werden von der Auswahl der Referenzelektrode abhängen. Der Zustand der Elektrodenoberfläche einer kupfer-selektiven Elektrode von Orion wurde mikroskopisch untersucht und der Einfluß des Redoxpotentials auf die Korrosionsbeständigkeit der Elektrode diskutiert. Oxidierende Lösungen bilden Ätzgruben an Versetzungen im Material und es stellt sich ein Mischpotential an der Elektrode ein. Wenn die Oberfläche Ätzgruben enthält, sind Neigung, Beständigkeit und Ansprechgeschwindigkeit viel geringer. Es wurde gezeigt, daß Polieren mit Diamant die Elektrode beträchtlich verbessert.

Résumé—On a mesuré les changements dans les potentiels de jonction liquide dans des solutions de cuivre(II) quand différentes électrodes de référence sont utilisées. La pente et l'allure entre deux points d'une courbe d'étalonnage pour une électrode sélective du cuivre dépendront du choix de l'électrode de référence. On a étudié microscopiquement la condition de la surface d'électrode d'une électrode Orion sélective du cuivre, et l'on discute de l'influence du potentiel redox sur la stabilité de l'électrode vis-á-vis de la corrosion. Les solutions oxydantes produiront des cavités aux dislocations de la matière et il y aura un potentiel d'électrode mixte. La pente, la stabilité et la vitesse de réponse sont beaucoup plus faibles lorsque la surface contient des cavités. On a montré que le polissage au diamant améliore grandement l'électrode.

INDIRECT ATOMIC-ABSORPTION DETERMINATION OF ppM LEVELS OF ARSENIC BY COMBUSTION OF AN MIBK EXTRACT OF ARSENOMOLYBDIC ACID

Y. YAMAMOTO, T. KUMAMARU, Y. HAYASHI, M. KANKE and A. MATSUI

(*Received* 13 *October* 1971. *Accepted* 24 *March* 1972)

Summary—An indirect atomic-absorption method for arsenic has been developed. Arsenic(III) is oxidized to arsenic(V) by iodine, then arsenomolybdic acid is formed and extracted into MIBK from 0·2–1·6*M* hydrochloric acid. Excess of molybdate is scrubbed from the organic phase, and then the molybdenum in the heteropoly acid is determined by its atomic absorption at 313·3 nm. Silicate and phosphate interfere. A procedure is described for determination of ppM levels of arsenic in water.

ALTHOUGH atomic-absorption spectrophotometry is commonly used for direct determination of metals, the method is not suitable for most non-metallic elements, because their resonance lines lie in the far ultraviolet, and various indirect methods are generally used, often coupled with a solvent extraction separation.

Several indirect methods based on heteropoly acid chemistry have been developed. Inorganic phosphate is determined by extracting phosphomolybdic acid into a suitable solvent and estimating the molybdenum content in the extract by means of atomic-absorption spectrophotometry.[1–4] Silicon,[3] vanadium[5] and niobium[6] are also determined indirectly by measuring the molybdenum content of the heteropoly acid.

Boltz *et al.*[7] have recently done the same for arsenic, extracting arsenomolybdic acid into methyl isobutyl ketone (MIBK), scrubbing with hydrochloric acid and water to remove excess of molybdate from the extract, then stripping the heteropoly acid into alkaline aqueous medium and determining the molybdenum.

We have found that direct nebulization of the MIBK extract into an air–acetylene or nitrous oxide–acetylene flame is satisfactory if the extract is properly scrubbed. The use of a larger aqueous/organic phase-volume ratio enhances the sensitivity by the enrichment effect, and MIBK is more efficiently nebulized than water. A determination of ppM levels of arsenic is described which has been successfully applied to various water samples.

EXPERIMENTAL

Reagents

All solutions were prepared from analytical-reagent grade chemicals and demineralized water, and stored in polyethylene bottles.

Standard arsenic(III) solution. Arsenious oxide (0·133 g) was dissolved in 10 ml of 0·1*M* sodium hydroxide, 5 ml of hydrochloric acid were added and the solution was diluted to 1000 ml to give a 100-ppm arsenic solution which was diluted to 5 ppm concentration before use.

Arsenic-76 solution. One mCi of arsenic ($HAsO_2$ in 1*M* hydrochloric acid) was diluted to a suitable concentration.

Iodine–potassium iodide solution. Potassium iodide (0·4 g) and iodine (0·25 g) were dissolved in 100 ml of water.

Potassium iodide solution, 15% w/v.

Sodium bicarbonate solution, 4·2% w/v.

Ammonium paramolybdate tetrahydrate solution, 10% w/v.

Stannous chloride dihydrate solution, 40% w/v, in hydrochloric acid. A small amount of metallic tin was added to prevent oxidation.

Metallic zinc. Granular zinc metal (1000–1410 μm) with arsenic content <0·01 ppm, washed with hydrochloric acid (1 + 10), then water, and dried before use.

Ferric chloride hexahydrate solution, 5% w/v in 0·6*M* hydrochloric acid.

Apparatus

A Nippon Jarrell-Ash Model AA-1 EW atomic-absorption spectrophotometer with a Westinghouse hollow-cathode molybdenum lamp. An Aloka Model PSM 801 γ-ray spectrometer equipped with a 1·5 × 1 in. NaI(Tl) crystal.

Procedure

Place 10 ml of solution, containing not more than 50 μg of arsenic(III), in a 125-ml separatory funnel and dilute to 50 ml. Add 1 ml of iodine solution, 4 ml of ammonium molybdate solution and 5 ml of conc. hydrochloric acid (final acidity ~1·2*N*). After 5 min, add 10 ml of MIBK and shake the funnel vigorously for 3 min with a mechanical shaker. Allow to stand for about 15 min, and discard the aqueous layer. Wash the MIBK layer with 10 ml of hydrochloric acid (1 + 10). Repeat the washing with 10 ml of hydrochloric acid (1 + 10) at least four times to remove excess of molybdate. Measure the absorption of the molybdenum at 313·3 nm against a reagent blank, under the optimum operating conditions of the instrument, using an air–acetylene flame.

Procedure for water analysis

Place the sample solution (containing up to 5 μg of arsenic) in a conical beaker, add 3 ml of sulphuric acid (1 + 9) and 1 ml of ferric chloride solution per litre of the sample solution. Heat on a water-bath at 70–80° and neutralize with ammonia solution (1 + 3) to pH 9–10 (*m*-Cresol Purple). Cool, filter (*e.g.*, Toyo Roshi paper No. 5A), and dissolve the precipitate in 2–10 ml of warm hydrochloric acid (1 + 1) into a 50 ml conical flask (Fig. 1), washing the filter paper with a small portion of water. Keep the total volume of the aqueous solution to <25 ml. Add 2 ml of potassium iodide solution and 1 ml of stannous chloride solution, let stand for 15–30 min, quickly add 2 g of granular zinc, immediately insert the stopper and let the gases bubble through a mixture of 1 ml of the iodine solution and 0·2 ml of the sodium bicarbonate solution, for one hour at room temperature. Transfer

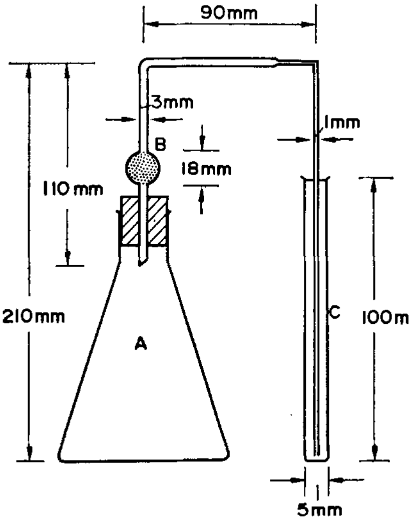

FIG. 1.—Apparatus for evolution of arsine. A Erlenmeyer flask (50 ml); B glass wool impregnated with lead acetate; C absorption tube.

the absorption solution to a 125-ml separatory funnel, dilute it to 50 ml with water, and continue according to the general procedure described above, using a nitrous oxide–acetylene flame to increase the sensitivity.

RESULTS AND DISCUSSION

Oxidation

Arsenic(III) does not form a heteropolymolybdate, and iodine was selected to oxidize it to arsenic(V). A pH between 0·5 and 6 was found necessary for quantitative formation of arsenomolybdic acid, and an acidity of 0·2–1·6*M* hydrochloric acid for quantitative extraction from 0·2–6*M* hydrochloric acid. The degree of extraction rapidly decreases with acid concentrations less than 0·2*N*, suggesting incomplete formation of arsenomolybdic acid. When the acidity is >1·6*N*, the reagent blank increases with acidity, presumably because of the extraction of the isopolymolybdate formed. The acidity was therefore set at approximately 1·2*M* with respect to hydrochloric acid.

Molybdate concentration

Addition of 0·2–0·5 g of ammonium molybdate was adequate for complete extraction of the heteropoly acid. Addition of more led to positive errors, because the 6-ml excess was then not completely removed by washing, unless further washing was done.

Acidity and number of washings

The effect of the number of washings is shown in Fig. 2. Ten-ml portions of hydrochloric acid (1 + 10) were shaken with 10-ml portions of the extract, and the molybdenum content in each phase was determined by atomic absorption. The results indicate that the excess of molybdenum was completely removed by washing at least three times.

In alkaline or neutral solutions arsenomolybdic acid may decompose, while from acidic solution the isopolymolybdate is appreciably extracted. The effect of

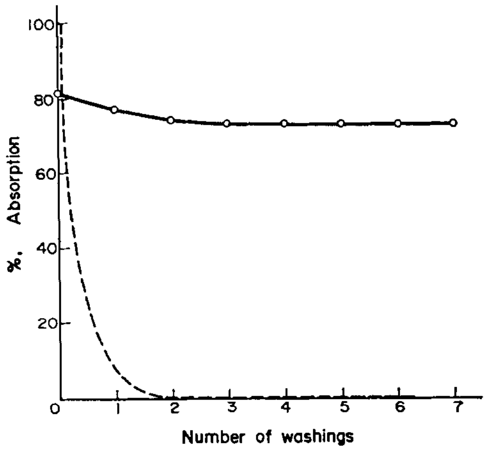

FIG. 2.—Effect of number of washings with hydrochloric acid (1 + 10) for 50 μg of arsenic: 1: Organic phase, 2. washing solution. Reference for 1, reagent blank; reference for 2, hydrochloric acid (1 + 10) saturated with MIBK.

acidity at two concentrations of arsenic is shown in Fig. 3. For a single washing with equal phase volumes, an acidity of 0·2–1·6*M* hydrochloric acid was found to give a plateau on the absorption *vs.* pH graph.

Recovery of arsenic

MIBK is more efficiently nebulized than water, so the sensitivity for molybdenum in the organic phase is higher than that for the aqueous phase. Therefore, it was not certain from the experiments described above whether appreciable loss of arsenic occurred. This point was tested by using ^{76}As as tracer, and as Table I shows, oxidation by iodine was complete and loss of arsenic in the extraction procedure was negligible.

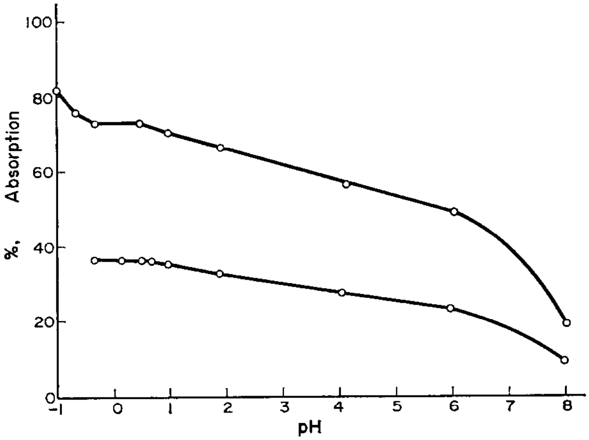

FIG. 3.—Effect of acidity on washing. 1 : 50 μg of arsenic, 2 : 25 μg of arsenic. 10 ml of MIBK, 10 ml of washing solution; reference, reagent blank.

TABLE I.—RECOVERY OF ARSENIC (1 ppm LABELLED WITH ^{76}As)

Number of washings	Degree of extraction of As, %
0	99·8 ± 0·1
1	99·8 ± 0·3
2	99·6 ± 0·4
3	99·5 ± 0·4
4	98·8 ± 0·4

The shaking time for the extraction was varied from 0·5 to 10 min. It was found that 2 min shaking sufficed for equilibration in the extraction. Shaking for 1 min was found to be sufficient for each washing.

Choice of solvent

Various ketones, alcohols and esters were tested as extractants. Arsenomolybdic acid was well extracted by ketones (MIBK, *etc*) and alcohols (*e.g.*, n-butanol and n-pentanol) but not by esters. MIBK was selected because of the enhancement of sensitivity by its more efficient nebulization.

It was found that the apparent sensitivity increased with increasing volume-ratio of aqueous to organic phase (Fig. 4), owing to the solubility of MIBK in water causing a decrease in volume of the organic phase.

Calibration curves and precision

Beer's law is obeyed up to 1 ppm of arsenic and the sensitivity for 1 % absorption was 0·01 ppm of arsenic. For 10 solutions, each containing 1 ppm of arsenic, the mean scale reading (% absorption) was 73, with a relative standard deviation of 3 %.

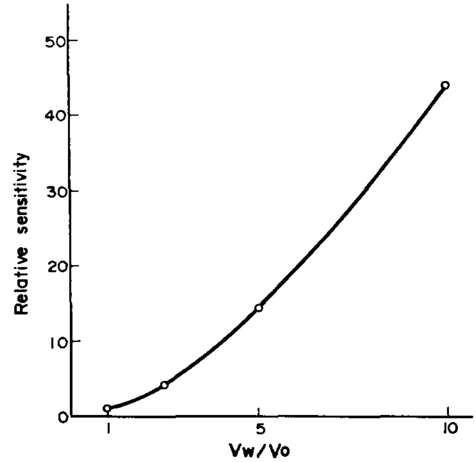

FIG. 4.—Effect of the volume ratio on sensitivity. 50 μg of arsenic; 10 ml of MIBK; reference, reagent blank.

Temperature fluctuations (15–25°) had no effect. A nitrous oxide–acetylene flame gave approximately ten times the sensitivity obtained with an air–acetylene flame. Thus, if a larger phase-volume ratio such as 20:1 is also used, 0·1 ppM of arsenic can be determined.

Selectivity

Large amounts of sodium, potassium, magnesium, calcium, aluminium, tin(II), lead, chromium(III), manganese(II), cobalt, zinc, cadmium, mercury(II), chloride, bromide, nitrate, sulphate, perchlorate and permanganate do not interfere. Antimony(III), silicate, phosphate, tungstate, vanadate and dichromate interfere (Table II). Phosphomolybdic and silicomolybdic acids are well extracted into MIBK and give positive errors. The others give large negative errors when present in similar amounts to arsenic, possibly by formation of mixed or competing heteropoly

acids which make the amount of molybdenum not equivalent to the amount of arsenic present.

Application to water analysis

Arsenic must be separated from phosphate and silicate, which can be done by co-precipitation with ferric hydroxide. The arsenic is then evolved as arsine and oxidized to arsenic(V). As a check, samples were also analysed by the silver–diethyldithiocarbamate–brucine–chloroform spectrophotometric method (a modification of the silver–diethyldithiocarbamate–pyridine method.)[8] The results are shown in Table III. It is seen that both sets of results are in satisfactory agreement.

Zusammenfassung—Eine indirekte Arsen-Bestimmungsmethode durch Atomabsorption wurde entwickelt. Arsen(III) wird durch Jod zu Arsen(V) oxidiert, dann Arsenomolybdänsäure gebildet und aus 0,2–1,6*M* Salzsäure in MIBK extrahiert. Der Überschuß von Molybdat wird aus der organischen Phase ausgewaschen und dann das Molybdän in der Heteropolysäure mit Hilfe seiner Atomabsorption bei 313,3 nm bestimmt. Silikat und Phosphat stören. Ein Verfahren zur Bestimmung von ppm-Mengen Arsen in Wasser wird beschrieben.

Résumé—On a élaboré une méthode indirecte d'absorption atomique pour l'arsenic. On oxyde l'arsenic(III) en arsenic(V) par l'iode, puis on forme l'acide arsénomolybdique et l'extrait en méthylisobutylcétone (MIBK) d'une solution 0,2–1,6*M* d'acide chlorhydrique. L'excès de molybdate est lavé de la phase organique, puis l'on dose le molybdène dans l'hétéropoly acide par son absorption atomique à 313,3 nm. Le silicate et le phosphate gênent. On décrit une méthode pour le dosage de ppm d'arsenic dans l'eau.

SHORT COMMUNICATIONS

Determination of small amounts of water with coulometrically generated Karl Fischer reagent

(*Received* 1 *May* 1972. *Accepted* 23 *May* 1972)

FOR THE DEVELOPMENT and improvement of many industrial processes, it is often necessary to be able to determine very small amounts of water in a variety of substances. A large number of methods have been reported including some based on infrared[1,2] and gas chromatographic[3-6] procedures. In general these methods apply only to the determination of water in solutions and only a few methods have been proposed for water in solids, of which different forms of titration with the Karl Fischer (KF) reagent[7,8] and electrolysis of water in cells of the Keidel type[9] are the most widely applicable. For the smaller amounts of water, these methods give errors of a few per cent. Besides, a large number of substances interfere and cause erroneous results.

In a previous paper,[10] we presented a method based on the coulometric generation of iodine at controlled potential. This method has now been improved. The electrolysis cell has been reconstructed and equipped with clay filters instead of glass frits. The electronic circuitry is fitted with a booster which makes it possible to draw considerably higher currents and the integrator is furnished with a digital read-out. These improvements have resulted in shorter analysis times, better accuracy and an increased range of determination (0·005–5 mg of water). A moveable oven system connected to the nitrogen inlet of the electrolysis cell has extended the field of applications to include the determination of water of absorption, adsorption and hydration, both in inorganic and organic solids. As the samples are not in direct contact with the solution, substances which otherwise could interfere with the KF reagent can also be analysed.

EXPERIMENTAL

Apparatus

Electrolysis cell. A cross-section of the redesigned electrolysis cell is shown in Fig. 1. The nitrogen inlet is through the Teflon B5 socket (A) and a Teflon tube with Swagelock connection (B). The working electrode (C) is a circular platinum-gauze, which is firmly fixed at the end of a shaft coated with Teflon and running in two 3 × 10 mm stainless-steel ball-bearings (F). Two Haldenvanger clay filters (D) (W. Haldenvanger, Berlin 20) separate the counter-electrode (E) from the working electrode. The pore size of these clay filters is about a fifth that of glass frits of porosity 4 and the electrical conductivity of the clay filters is also much smaller. Consequently, electrolysis with larger currents can be carried out. The clay filters are, however, rather fragile and difficult to fix to the glass walls. A special cement supplied by Haldenvanger must often be used to get sufficiently good sealing between glass and filter. Electrodes and solutions are as described earlier.[10]

Oven system. An outline of the oven system with electrolysis cell is shown in Fig. 2. The oven is made of aluminium, insulated with asbestos, and heated by two 100-mm long heaters. Temperatures up to 500° can be obtained and are measured with a platinum–platinum/rhodium thermocouple. The Pyrex glass tube has an inner diameter of 8 mm, a B10 joint and nitrogen inlet connections.

Electronic circuitry. Some improvements in the electronic circuitry described earlier have been made. The potentiostat has been fitted with a booster (see Fig. 3) capable of supplying larger electrolysis currents.

The integrating resistor of 1 MΩ is replaced by a series of eight changeable resistors ranging from 0·2 to 5 MΩ in order to cover the whole range of determinations more accurately. Each resistor is separately calibrated together with the capacitor by time and voltage measurements. The read-out device for the integrator, earlier a compensation bridge, is now a digital voltmeter (Model 404 Tyco Instrument Division) which gives a faster and more accurate presentation.

Determination of water in solids

A sample in an aluminium boat is placed in the glass tube and the oven is put into the forward position. During the sample heating, a calculated excess of iodine is generated. A nitrogen stream

R 25 = 180 ohm
R 26 = 560 ohm
R 27, 28 = 47 ohm
R 29 = 5 kohm
R 30, 31 = 82 kohm

D 5–D 10 = BA 127
T 17 = BC 107
T 18, 21 = RCA 40362
T 19, 20 = RCA 40348
T 22 = 2 N 3767
T 23 = 2 N 3741

at a rate of 5–25 ml/min (depending on heating temperature and kind of sample) carries the liberated water into the electrolysis cell. The reduction of the iodine excess is started after 3–7 min heating of the sample and, when the reduction is completed, the oven is moved to the rear and the glass tube is cooled with compressed air. To ensure completeness of analysis, a blank test is performed between every sample analysis. If the blank test gives too high a read-out, some more blank tests must be done until a stable result is reached. Accordingly, before the next analysis, the nitrogen stream and/or the heating temperature must be increased.

RESULTS AND DISCUSSION

Stock solutions were prepared from "dry" methanol by the addition of known amounts of water. All handling was under a dry nitrogen atmosphere. The water content in the "dry" methanol was, however, first determined both by the standard-addition technique and by direct analysis of 0·5-ml samples added to the electrolysis cell by Agla syringe. The results obtained by the two methods agreed very well. Series of samples were then prepared from the stock solutions and the results of such a series are shown in Table I. The most favourable range for the apparatus is 0·01–5 mg of water (rel. std. devn. $< 0{\cdot}3\,\%$). It is of course possible to determine larger amounts of water, but it will take rather a long time to generate the amount of iodine required and also to reduce the excess (15–25%), which will influence the accuracy. Besides, conventional KF methods work rather well for solutions containing more than 5 mg of water.

Smaller amounts of water than 0·01 mg have been determined in several organic liquids, but for the sake of simplicity, the presentation is restricted to water determined in methanolic solutions, as the technique is similar for other solutions.

TABLE I.—COULOMETRIC DETERMINATION OF WATER IN METHANOL

H_2O calculated, *μg*	H_2O found, *μg*	No. of determinations	Standard deviation, *μg*	Rel. standard deviation, %
0·56	0·60	4	0·07	11·6
1·41	1·43	4	0·05	3·5
2·82	2·75	4	0·04	1·5
4·50	4·48	4	0·04	0·8
5·63	5·62	4	0·04	0·7
10·11	10·09	4	0·03	0·3
50·56	50·61	4	0·10	0·2
101·1	101·0	3	0·14	0·1
500·4	499·9	3	0·31	0·06
1001	1002	3	0·6	0·06
5004	5007	3	4	0·08

The determination limit for a quantitative analysis is defined by Currie[11] as the amount for which a relative standard deviation of 10% is expected. This value is obtained in this case for about 0·75 μg. One limiting factor is the slow reaction between KF reagent and water at these low concentrations, and it is necessary to generate up to a tenfold excess of iodine to get complete reaction, which necessitates relatively long analysis times and accordingly large blank corrections. Experiments with *N*-ethylpiperidine used as a catalyst to increase the rate of reactions as proposed by Archer and Jeater[12] gave no observable improvement. Another limiting factor is the great difficulty in handling samples. It is very difficult to keep these low concentrations of water in the samples constant. Small drifts in the values, day to day, could not be avoided.

In many cases, when maximum accuracy is not required, the times of analysis can be shortened considerably. The principle for an accurate determination at controlled potential is that the reduction is allowed to proceed until the residual current results in only a small and reproducible integrator read-out (1–2 mV/min). As the last part of the reduction takes most of the time, some minutes can be saved if the reduction stops when the read-out is about 10 mV/min, but in this case the uncertainty of the determination will of course increase.

TABLE II.—DETERMINATION OF WATER IN SOME HYDRATES

Substance	Moles of H_2O	No. of determinations	Std. deviation, *mole*
(Weight 0·2–1 mg*)			
Oxalic acid ($2H_2O$)	1·994	6	0·004

† Mettler microbalance M5.

Water in solids has been determined by the oven method described earlier. Table II gives results for the determination of water of hydration in some salts. It can be seen that the barium chloride contains somewhat smaller amounts of water than expected from the formula. According to Duval,[13] this is due to the fact that the salt is a mixture of the mono- and dihydrate. Consequently, the salt should not be employed as a standard in aquametry. The oxygen content in the salt[14] was in very good agreement with the results obtained here.

The water content of the copper sulphate pentahydrate was also determined by preparing methanolic solutions of 15–40 mg of the salt in volumetric flasks and then adding samples (50–100 μl) directly to the cell with an Agla syringe. With normal composition of the KF reagent, the analysis of copper sulphate pentahydrate will result in only 4·5 moles of water as reported by Mitchell *et al.*,[15] because of the reaction:

$$Cu(II) + I^- \rightarrow Cu(I) + 1/2\,I_2$$

If a very low iodine concentration (below 0·01M) and rather high sulphur dioxide concentration (more than 0·1M) are used, a reagent is obtained which gives a very slow reaction with the copper(II), allowing the $5H_2O$ of crystallization to be determined without interference. Blanks must be taken between every analysis to indicate whether any interference from the copper(II)–iodide reaction will arise. We found, for the pentahydrates, 4·996 moles of water per mole of copper with a standard deviation of 0·005 mole (25 determinations); the analysis times were 250–300 sec.

Replacing the oven with a high-temperature furnace and a quartz tube enables substances with very firmly bound water to be analysed, e.g., metal alloys with water contents in the range 1–5 ppm w/w. Temperatures up to 1200° can be obtained if necessary and the accuracy of the determinations is very satisfactory.

Experiments with a more automated method, some kind of air-locks for the electrolysis cell and tests of modified KF reagents are just some of the more urgent improvements being prepared.

Summary—A coulometric method for the determination of small amounts of water described in a previous report has been further developed. Improved electronic circuitry and a redesigned electrolysis cell have extended the range of determination and decreased the time of analysis. By means of a movable oven specially adapted to the cell, water in solids has also been determined. The method presented is applicable with high accuracy in the range 0.005–5 mg of water in a large variety of substances.

Zusammenfassung—Ein in einer früheren Arbeit beschriebenes coulometrisches Verfahren zur Bestimmung kleiner Wassermengen wurde weiter entwickelt. Verbesserte elektronische Schaltungen und eine neu konstruierte Elektrolysezelle haben die Anwendungsmöglichkeiten des Verfahrens erweitert und die Analysenzeit vermindert. Mit Hilfe eines der Zelle besonders angepaßten beweglichen Ofens wurde auch Wasser in festen Stoffen bestimmt. Die angegebene Methode läßt sich mit hoher Genauigkeit im Bereich 0,005–5 mg Wasser in einer großen Anzahl verschiedener Stoffe anwenden.

Résumé—Une méthode coulométrique pour le dosage de petites quantités d'eau décrite dans un mémoire antérieur a été développée davantage. Un circuit électronique amélioré et une cellule d'électrolyse reconçue ont étendu le domaine de dosage et réduit le temps d'analyse. Au moyen d'un four mobile spécialement adapté à la cellule, on a également déterminé l'eau dans les solides. La méthode présentée est applicable avec une haute précision au domaine 0,005–5 mg d'eau dans une grande variété de substances.

Studies on the extraction and determination of metals—I

Extraction of hafnium into methyl isobutyl ketone and tributyl phosphate

(*Received* 30 *March* 1971. *Revised* 10 *December* 1971. *Accepted* 15 *January* 1972)

ALTHOUGH there are many reports[1–18] on the extraction of hafnium from nitric acid alone or mixed with other acids, by TBP with xylene, kerosine or heptane as a diluent, little information can be found in the literature on the extraction of hafnium from different acids with MIBK or from hydrochloric acid with TBP–benzene solutions. The effect of various factors on such extractions was examined in the present work.

EXPERIMENTAL

Reagents

Standard hafnium solution. Hafnium dioxide (>99% purity), about 1 g, was dissolved by heating in 40 ml of a mixture (40:1) of nitric and hydrofluoric acids. Ammonia solution was added to precipitate the hydroxide, which was filtered off on paper, washed thoroughly with distilled water, and dissolved at once in dilute hydrochloric acid. Precipitation and dissolution were repeated several times and the final precipitate was dissolved in 5*M* hydrochloric acid. The concentration of hafnium in this solution was determined by gravimetry.[19]

Radioactive hafnium solution. $^{175+181}$Hf solution of about 1 mCi activity was diluted to 100 ml with 5*M* hydrochloric acid.

Hafnium solution (<*1 mg/ml*). Radioactive hafnium solution of about 10 μCi activity was added to various volumes (Hf < 50 mg) of the standard hafnium solution and mixed thoroughly, then ammonia solution was added to precipitate the hydroxide. The precipitate was collected on paper, washed thoroughly with water, and dissolved in the desired acid. The precipitation and dissolution were repeated several times and the final precipitate was dissolved in 50 ml of 5*M* acid.

Other reagents used were all of analytical-reagent grade.

Extraction procedure

Ten ml of an acid solution containing a 1·00-ml aliquot of the hafnium solution were shaken vigorously for a desired time (240 shakes/min) with an equal volume of MIBK or TBP–benzene in a 50-ml separatory funnel. When the two phases had separated, equal aliquots of each were transferred into polyethylene tubes. The gamma-activity of the $^{175+181}$Hf in each aliquot was counted by means of a scintillation counter (1080 V, discrimination 42·5 V). No temperature control was exercised but the ambient temperature was fairly constant at 20 ± 3°.

RESULTS AND DISCUSSION

Effect of various factors on the distribution ratio

Shaking time. With MIBK, equilibrium was found to be reached within 30 sec, irrespective of the acid used. Therefore, shaking for 1 min was adopted. In extraction with TBP, at least 20 min were needed to reach equilibrium with 6*M* hydrochloric acid medium, though 10 min sufficed for 7*M* hydrochloric acid and 9*M* nitric acid, and shaking for 30 min was adopted.

Extraction of hafnium into methyl isobutyl ketone and tributyl phosphate

(*Received* 30 *March* 1971. *Revised* 10 *December* 1971. *Accepted* 15 *January* 1972)

ALTHOUGH there are many reports[1–18] on the extraction of hafnium from nitric acid alone or mixed with other acids, by TBP with xylene, kerosine or heptane as a diluent, little information can be found in the literature on the extraction of hafnium from different acids with MIBK or from hydrochloric acid with TBP–benzene solutions. The effect of various factors on such extractions was examined in the present work.

EXPERIMENTAL

Reagents

Standard hafnium solution. Hafnium dioxide (>99% purity), about 1 g, was dissolved by heating in 40 ml of a mixture (40:1) of nitric and hydrofluoric acids. Ammonia solution was added to precipitate the hydroxide, which was filtered off on paper, washed thoroughly with distilled water, and dissolved at once in dilute hydrochloric acid. Precipitation and dissolution were repeated several times and the final precipitate was dissolved in $5M$ hydrochloric acid. The concentration of hafnium in this solution was determined by gravimetry.[19]

Radioactive hafnium solution. $^{175+181}$Hf solution of about 1 mCi activity was diluted to 100 ml with $5M$ hydrochloric acid.

Hafnium solution ($<$*1 mg/ml*). Radioactive hafnium solution of about 10 μCi activity was added to various volumes (Hf < 50 mg) of the standard hafnium solution and mixed thoroughly, then ammonia solution was added to precipitate the hydroxide. The precipitate was collected on paper, washed thoroughly with water, and dissolved in the desired acid. The precipitation and dissolution were repeated several times and the final precipitate was dissolved in 50 ml of $5M$ acid.

Other reagents used were all of analytical-reagent grade.

Extraction procedure

Ten ml of an acid solution containing a 1·00-ml aliquot of the hafnium solution were shaken vigorously for a desired time (240 shakes/min) with an equal volume of MIBK or TBP–benzene in a 50-ml separatory funnel. When the two phases had separated, equal aliquots of each were transferred into polyethylene tubes. The gamma-activity of the $^{175+181}$Hf in each aliquot was counted by means of a scintillation counter (1080 V, discrimination 42·5 V). No temperature control was exercised but the ambient temperature was fairly constant at 20 ± 3°.

RESULTS AND DISCUSSION

Effect of various factors on the distribution ratio

Shaking time. With MIBK, equilibrium was found to be reached within 30 sec, irrespective of the acid used. Therefore, shaking for 1 min was adopted. In extraction with TBP, at least 20 min were needed to reach equilibrium with $6M$ hydrochloric acid medium, though 10 min sufficed for $7M$ hydrochloric acid and $9M$ nitric acid, and shaking for 30 min was adopted.

TBP concentration. Plots of log D *vs.* log C_{TBP} for hafnium extraction from 7 or 10M hydrochloric acid into TBP-benzene solution of various concentrations gave curves that had a slope of 2 for their linear portions. For 10M hydrochloric acid medium, log D was about 2 for TBP concentrations from 0·05 to 3·75M, indicating that quantitative extraction (>99%) of hafnium would be possible under these conditions. With TBP concentrations above 2M a longer time was needed for separation of the phases after shaking, so 1M TBP in benzene was used as the extractant in further work.

Acid concentration. The relationship between the distribution ratio and the acid concentration is shown in Fig. 1.

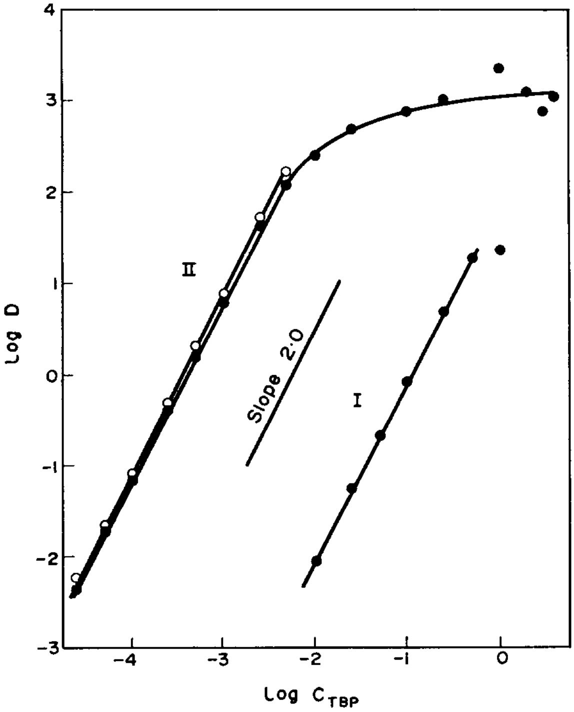

FIG. 1.—Distribution ratio of hafnium as a function of TBP concentration in benzene.
I. HCl 7.0M; Hf(IV) 5·60 × $10^{-5}M$, ● (slope 1·95)
II. HCl 10M; Hf(IV) trace, ○ (slope 2·05); 5·60 × $10^{-5}M$, ● (slope 2·0) C_{TBP} = initial TBP concentration in benzene (M)

The curves of log D *vs.* C_{acid} are similar for both MIBK and TBP with a given aqueous medium, but a much higher acidity is needed for extraction with MIBK. Hafnium is quantitatively extracted with TBP, from 7·5–11M hydrochloric acid. Hafnium was hardly extracted at all from sulphuric acid in the concentration range tested, both with MIBK and TBP, because it forms a stable anionic sulphato complex[20] and does not easily form an association compound.

A more detailed examination was made of the HCl–TBP system because of the good extraction of hafnium.

Hafnium concentration. Plots of log D *vs.* log C_{Hf} at different concentrations (5–8M) of hydrochloric acid gave straight lines with zero slope.

Chloride ion and hydrogen ion concentration. Plots of log D *vs.* log C_{Cl^-} for constant hydrogen ion concentration and constant ionic strength gave straight lines, with a slope of about 2.

Plots of log D *vs.* log C_{H^+} at constant chloride ion concentration and constant ionic strength were not linear (as shown in Fig. 2) which is the same tendency as in the case[21] of zirconium extraction from hydrochloric acid with TBP–benzene.

Stripping. After extraction of hafnium from 10M hydrochloric acid with 1M TBP in benzene, the organic phase was shaken with 10 ml of hydrochloric acid (of various concentrations) for 30 min. It was found that 1–3M hydrochloric acid quantitatively strips hafnium into the aqueous phase.

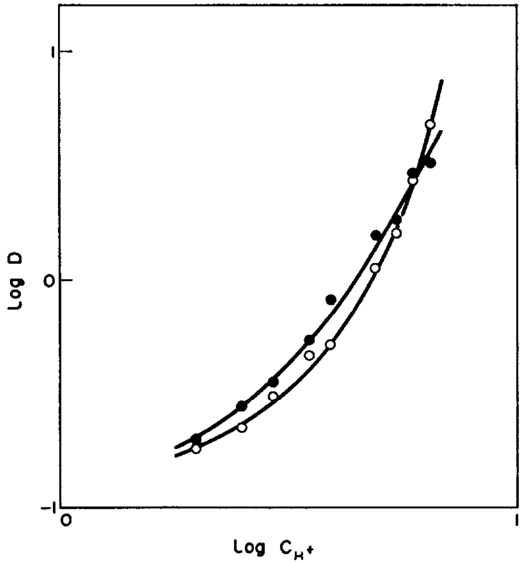

FIG. 2.—Distribution ratio of hafnium as a function of hydrogen ion concentration in the aqueous phase.

Chloride ion 6·5*M*; ionic strength 6·5; Hf(IV): trace ○, 5·60 × $10^{-5}M$ ●; TBP 1*M* in benzene; C_{H^+} = equilibrium aqueous hydrogen ion concentration (*M*).

Conclusion

When MIBK is used as the extraction solvent, good extraction of hafnium is not obtained from any kind of acid solution, but hafnium ($<5{\cdot}60 \times 10^{-4}M$) is extracted quantitatively from >7·5*M* hydrochloric acid with 1*M* TBP in benzene. Stripping with 1–3*M* hydrochloric acid gives a recovery of over 99%.

The slopes of the plots of log *D vs.* log C_{TBP} and of log *D vs.* log C_{Cl^-} are both about 2, and it may be concluded that this is the molar ratio of TBP or chlorine to hafnium in the extractable species, provided that there is no gross non-linearity of the activity of TBP or chloride ion over the concentration range examined. In contrast, the slope in the plots of log *D vs.* log C_{H^+} changes with increase in C_{H+} which can be interpreted as signifying the presence of different kinds of extractable species.

Summary—The effect of various factors on the distribution of hafnium ($<5{\cdot}60 \times 10^{-4}M$) between different acids and methyl isobutyl ketone (MIBK) or tributyl phosphate (TBP) was studied by using $^{175+181}$Hf as a tracer. When the extraction is made from 7·5–11*M* hydrochloric acid with an equal volume of 1*M* TBP in benzene, hafnium is extracted quantitatively (>99%). The hafnium can be stripped with 1–3*M* hydrochloric acid.

Zusammenfassung—Der Einfluß verschiedener Parameter auf die Verteilung von Hafnium ($<5{,}6 \cdot 10^{-4}$M) zwischen verschiedenen Säuren und Methylisobutylketon (MIBK) oder Tributylphosphat (TBP) wurde mit Hilfe von $^{175+181}$Hf als Tracer untersucht. Extrahiert man aus 7,5–11 M Salzsäure mit einem gleichen Volumen 1 M TBP in Benzol, so wird Hafnium quantitativ extrahiert (>99%). Das Hafnium kann mit 1–3 M Salzsäure rückextrahiert werden.

Résumé—On a étudié l'influence de divers facteurs sur le partage du hafnium ($\leqslant 5{,}60 \times 10^{-4}M$) entre différents acides et la méthylisobutylcétone (MIBK) ou le tributyl phosphate (TBP) en utilisant $^{175+181}$Hf comme traceur. Lorsque l'extraction est faite à partir d'acide chlorhydrique 7,5–11M avec un égal volume de TBP 1M en benzène, le hafnium est extrait quantitativement (>99%). Le hafnium peut être extrait à l'acide chlorhydrique 1–3M.

Non-destructive method for the analysis of gold(I) cyanide plating baths
Complexometric determination of nickel and indium

(*Received* 24 *June* 1971, *Accepted* 25 *March* 1972)

PURE GOLD, although chemically inactive, is not mechanically resistant in thin coatings and not suitable, for example, for printed circuits that are subject to high mechanical stress. Therefore various electrolytically plated gold alloys have been proposed for electronic purposes. The quality of the coatings is of course dependent on the composition of the gold baths. Besides the main component [potassium cyanoaurate(I)] other metals such as indium, nickel, cobalt are used, mostly as citrate complexes. Regular control of such baths is desirable. Gravimetric methods are tedious and require the total destruction of organic matter. Among volumetric methods only EDTA titrations

man aus 7,5–11 M Salzsäure mit einem gleichen Volumen 1 M TBP in Benzol, so wird Hafnium quantitativ extrahiert (>99%). Das Hafnium kann mit 1–3 M Salzsäure rückextrahiert werden.

Résumé—On a étudié l'influence de divers facteurs sur le partage du hafnium ($\leqslant 5,60 \times 10^{-4}M$) entre différents acides et la méthylisobutylcétone (MIBK) ou le tributyl phosphate (TBP) en utilisant $^{175+181}$Hf comme traceur. Lorsque l'extraction est faite à partir d'acide chlorhydrique 7,5–11*M* avec un égal volume de TBP 1*M* en benzène, le hafnium est extrait quantitativement (>99%). Le hafnium peut être extrait à l'acide chlorhydrique 1–3*M*.

Non-destructive method for the analysis of gold(I) cyanide plating baths
Complexometric determination of nickel and indium

(*Received* 24 *June* 1971, *Accepted* 25 *March* 1972)

Pure gold, although chemically inactive, is not mechanically resistant in thin coatings and not suitable, for example, for printed circuits that are subject to high mechanical stress. Therefore various electrolytically plated gold alloys have been proposed for electronic purposes. The quality of the coatings is of course dependent on the composition of the gold baths. Besides the main component [potassium cyanoaurate(I)] other metals such as indium, nickel, cobalt are used, mostly as citrate complexes. Regular control of such baths is desirable. Gravimetric methods are tedious and require the total destruction of organic matter. Among volumetric methods only EDTA titrations can be considered, but the presence of citrate and citric acid (up to 100 g/l.) makes complexometric determination impossible. In addition the baths contain incidental impurities such as iron and copper. Gold ions also interfere with the colour changes of indicators.

Complexometric determination of indium, nickel, zinc, and aluminium after decomposition of gold baths with sulphuric and nitric acids was described by the present authors some years ago.[1] No attempts have been made to determine the alloying metals without time-consuming destruction of the organic acid present in the baths. The method described below makes it possible to determine indium and nickel within 40 min. It is based on the following principle.

Gold(I) cyanide is extracted from the acidic solution with ethyl acetate. The extract can be used for recovery of the gold in the usual way. After the gold extraction a suitable aliquot is used for the separation of nickel. Indium is masked with thioglycollic acid and nickel precipitated with sodium diethyldithiocarbamate and extracted with chloroform. Nickel is then stripped from the organic phase with mercuric chloride and determined complexometrically. In another aliquot indium and nickel are precipitated with the same reagent (without addition of thioglycollic acid), extracted into chloroform, and stripped with mercuric chloride. Nickel is masked with 1,10-phenanthroline and indium titrated directly with EDTA.

EXPERIMENTAL

Reagents

EDTA solution, 0·02*M*. Standardized with 0·02*M* zinc chloride or lead nitrate (Xylenol Orange as indicator).

Indium chloride solution, 0·01*M*. Prepared by dissolution of 2·2964 g of metallic indium in 25 ml of hydrochloric acid (1 + 1) and dilution to 1 litre.

Nickel nitrate solution, 0·01*M*. Prepared by dissolution of 2·95 g of the hexahydrate in 1 litre of redistilled water.

1,10-*Phenanthroline solution*, 0·1*M*. Prepared by suspending 18·02 g of reagent in 50 ml of water and adding 1*M* hydrochloric acid dropwise till all is dissolved, then diluting to 100 ml.

Saturated mercuric chloride solution.

Buffer solution, pH 3. Monochloroacetic solution (0·2*M*) neutralized with 1*M* sodium hydroxide to the desired pH.

Thioglycollic acid solution. Prepared by diluting 20 ml of the 80% acid solution to 100 ml with water.

Other reagents include 0·5% aqueous Xylenol Orange solution, 10% potassium chloride solution, potassium iodide solution, solid hexamine, thiourea, and 0·15*M* sodium diethyldithiocarbamate (3·4 g of reagent in 100 ml of water, prepared fresh daily).

Procedure

Separation of gold. Transfer by pipette a sample of gold-bath solution containing not more than 25 mg of indium and 15 mg of nickel, into a 150–250 ml separatory funnel, adjust the acidity to 0·2–0·3*N* with 1*M* hydrochloric acid, add 5 ml of 10% potassium chloride solution and extract twice with 20-ml portions of ethyl acetate. Separate the phases, remove the organic layer and transfer the aqueous solution into a 25- or 50-ml standard flask.

Determination of nickel. To an aliquot of the gold-free solution containing up to 6 mg of nickel add 5 ml of 10% potassium chloride solution, 1–2 ml of thioglycollic acid solution and make alkaline by addition of 5 ml of 5% ammonia solution. (The solution must be alkaline before the precipitation of nickel, otherwise indium is not quantitatively masked.) Now add 3–4 ml of 0·15*M* sodium diethyldithiocarbamate to precipitate nickel. Adjust the volume to about 30 ml and extract twice with 20 ml of chloroform. Collect both extracts in another separatory funnel, add 10 ml of 0·2*M* hydrochloric acid, and 5 ml of potassium chloride solution. The solution must be acid (pH control). Then add 4–5 ml of saturated mercuric chloride solution and shake for 2 min. The quantitative stripping of nickel is indicated by disappearance of the green colour of the organic phase. Separate the aqueous layer into a 400-ml titration flask, wash the organic layer with water containing a little potassium chloride solution and add the washings to the titration flask. Add 5% potassium iodide solution until the yellow precipitate dissolves (masking of excess of mercuric chloride. Add 10 ml of 0·02*M* EDTA, dilute, and adjust the pH to 5–5·5 with 0·2*M* hydrochloric acid and solid hexamine. Add a few drops of Xylenol Orange indicator and titrate slowly with 0·02*M* zinc chloride to the end-point indicated by a colour change from lemon yellow to red-violet.

During the titration the solution usually become cloudy but this does not affect the end-point. Mercury together with copper can also be masked with thiourea.

(1 ml of 0·02*M* EDTA corresponds to 1·174 mg of Ni.)

Determination of indium. To an aliquot containing up to 10 mg of indium and 6 mg of nickel add 10 ml of 0·2*M* hydrochloric acid, 5 ml of 10% potassium chloride solution and 3–4 ml of 0·15*M* sodium diethyldithiocarbamate. Continue as described for nickel.

After stripping indium and nickel with mercuric chloride add 0·5 g of thiourea to mask excess of mercury, then 20 ml of monochloroacetic acid buffer and 3 ml of 0·1*M* 1,10-phenanthroline to mask nickel. At this stage the pH must be 3. Dilute to 100–120 ml, warm to 70–80°, add Xylenol Orange indicator and titrate slowly with 0·02*M* EDTA to the end-point indicated by a colour change from violet to lemon yellow.

(1 ml of 0·02*M* EDTA corresponds to 2·736 mg of In.)

Typical results are given in Table I.

TABLE I.—DETERMINATION OF NICKEL AND INDIUM IN THE PRESENCE OF 400–500 mg OF CITRIC ACID

Taken, *mg*		Found, *mg*	Taken, *mg*		Found, *mg*
In	Ni	Ni	In	Ni	In
5·70	3·03	2·80	1·14	0·60	1·07
2·27	1·51	1·53	1·14	4·55	1·18
11·41	0·76	0·76	2·27	4·55	2·25
1·14	6·06*	6·05	5·70	3·03	5·61
1·42	12·12†	12·24	5·70	4·55	5·61
9·12	4·85	4·84			
3·44	0·31	0·23			

* Small precipitate between the two phases.

† Poor separation. The organic layer had to be washed with potassium chloride solution.

Remarks

Copper does not interfere. It is precipitated and extracted together with nickel and indium and also stripped into the aqueous phase but it is masked before titration, either with thiourea or 1,10-phenanthroline.

The procedure can be modified as follows. In one aliquot indium and nickel are precipitated with sodium diethyldithiocarbamate and extracted. Their sum is determined by indirect titration with EDTA after stripping with mercuric chloride.

In another aliquot, nickel is determined as already described. This method has the advantage that the relatively expensive 1,10-phenanthroline is not needed.

Practical application

The procedure was tested by analysis of the gold-baths used at the Establishment for Industrial Automation in Nová Paka. The gravimetric results for indium and nickel after the destruction of organic matter gave on average 3·89 mg/ml for indium and 0·76 mg/ml for nickel. Our results by the extraction method were 3·61 and 3·73 mg/ml for indium and 0·71 and 0·69 mg/ml for nickel.

Acknowledgement—The authors are grateful to Dr. B. Rejha (Establishment for Industrial Automation) for providing the samples of gold-baths, and for his keen interest in their work.

Summary—A method is described for rapid determination of nickel and indium in gold(I) cyanide baths containing large amounts of citric acid and/or sodium citrate, without previous destruction of organic matter. Gold is removed by extraction with ethyl acetate. In one aliquot of the solution indium is masked with thioglycollic acid and nickel is precipitated with sodium diethyldithiocarbamate, extracted into chloroform, stripped into water and determined complexometrically.

In a second aliquot indium and nickel are precipitated together with the same reagent and stripped into water, then nickel is masked with 1,10-phenanthroline, and indium is determined by direct titration with EDTA.

Zusammenfassung—Zur raschen Bestimmung von Nickel und Indium in Gold(I)-cyanidbädern, die große Mengen Zitronensäure und/oder Natriumcitrat enthalten, wird ein Verfahren beschrieben, das ohne die vorhergehende Zerstörung des organischen Materials auskommt. Gold wird durch Extraktion mit Äthylacetat entfernt. In einem aliquoten Teil der Lösung wird Indium mit Thioglykolsäure maskiert und Nickel mit Natriumdiäthyldithiocarbamat gefällt, in Chloroform extrahiert, in Wasser rückextrahiert und komplexometrisch bestimmt. In einem zweiten aliquoten Teil werden Indium und Nickel zusammen mit dem selben Reagens gefällt, die Komplexe in Wasser wieder zerlegt, Nickel mit 1,10-Phenanthrolin maskiert und Indium durch direkte Titration mit EDTA bestimmt.

Résumé—On décrit une méthode pour le dosage rapide du nickel et de l'indium dans des bains de cyanure d'or(I) contenant de grandes quantités d'acide citrique et/ou de citrate de sodium, sans destruction préalable de la matière organique. On élimine l'or par extraction à l'acétate d'éthyle. Dans une partie aliquote de la solution, on dissimule l'indium par l'acide thioglycolique, et le nickel est précipité par le diéthyldithiocarbamate de sodium, extrait en chloroforme, réextrait dans l'eau et dosé complexométriquement. Dans une seconde partie aliquote, l'indium et le nickel sont précipités ensemble par le même réactif et redissous dans l'eau, puis le nickel est dissimulé par la 1,10-phénanthroline, et l'on dose l'indium par titrage direct à l'EDTA.

Potentiometric argentimetric method for the successive titration of sulphide and dissolved sulphur in polysulphide solutions

(*Received* 26 *July* 1971. *Accepted* 30 *March* 1972)

AS IS COMMONLY KNOWN, free sulphur dissolves in an alkaline solution of sulphide to form polysulphides.

$$S^{2-} + (x - 1)S = S_x^{2-}$$

We denote one sulphur atom in each polysulphide ion as sulphide sulphur (S^{2-}), and the rest of the ion (S_{x-1}) as dissolved sulphur.

Various methods to determine polysulphide have already been presented.[1-14] Most of these, however, are rather complicated and time-consuming. For the simultaneous determination of S^{2-} and S_{x-1}, Papp and Havas[13] have recently developed a potentiometric method using mercuric chloride as the titrant and a sulphide-ion selective electrode as the indicator. This method is useful, particularly for the routine analysis of kraft cooking and waste liquors, which contain reducing organic substances and others, in sulphate pulping processes. It seems, however, that argentimetry is also worth further study for the simple and accurate analysis of polysulphide solutions that contain no reducing substances, and this is one of the purposes of our present study.

Ikeda and Musha[8] previously reported that S_{x-1} in polysulphide solutions can be determined rapidly and accurately by means of a short-circuit amperometric titration with silver nitrate. The replacement of the amperometric means of end-point detection in this procedure by such potentiometric means as a sulphide-ion selective electrode permits successive determination of S^{2-} and S_{x-1}. The

In a second aliquot indium and nickel are precipitated together with the same reagent and stripped into water, then nickel is masked with 1,10-phenanthroline, and indium is determined by direct titration with EDTA.

Potentiometric argentimetric method for the successive titration of sulphide and dissolved sulphur in polysulphide solutions

(*Received* 26 *July* 1971. *Accepted* 30 *March* 1972)

As is commonly known, free sulphur dissolves in an alkaline solution of sulphide to form polysulphides.

$$S^{2-} + (x - 1)S = S_x^{2-}$$

We denote one sulphur atom in each polysulphide ion as sulphide sulphur (S^{2-}), and the rest of the ion (S_{x-1}) as dissolved sulphur.

Various methods to determine polysulphide have already been presented.[1-14] Most of these, however, are rather complicated and time-consuming. For the simultaneous determination of S^{2-} and S_{x-1}, Papp and Havas[13] have recently developed a potentiometric method using mercuric chloride as the titrant and a sulphide-ion selective electrode as the indicator. This method is useful, particularly for the routine analysis of kraft cooking and waste liquors, which contain reducing organic substances and others, in sulphate pulping processes. It seems, however, that argentimetry is also worth further study for the simple and accurate analysis of polysulphide solutions that contain no reducing substances, and this is one of the purposes of our present study.

Ikeda and Musha[8] previously reported that S_{x-1} in polysulphide solutions can be determined rapidly and accurately by means of a short-circuit amperometric titration with silver nitrate. The replacement of the amperometric means of end-point detection in this procedure by such potentiometric means as a sulphide-ion selective electrode permits successive determination of S^{2-} and S_{x-1}. The advantage of the proposed method is that the content of these two species can be calculated directly from the two titration steps for the same sample. In this method, polysulphide solutions are titrated by silver nitrate after the cyanolysis of polysulphide ions and the subsequent masking of the excess of cyanide ions with formaldehyde.

$$S_x^{2-} + (x - 1)CN^- = S^{2-} + (x - 1)SCN^-$$

EXPERIMENTAL

Materials and apparatus

All the chemicals used were of reagent grade.

Polysulphide stock solution. Dissolve about 12 g of crystalline sodium sulphide and about 1·6 g of powdered sulphur in 30 ml of oxygen-free water in a 100-ml flask with the aid of shaking for about 1 hr at room temperature. Dilute the solution to 100 ml to give a 0·05*M* sodium polysulphide stock solution, the colour of which is reddish brown. The surface of the solution is covered with liquid paraffin to prevent aerial oxidation. Working solutions are prepared by further dilution.

Automatic recording potentiometric titrator. A Hiranuma RAT-101 instrument with a sulphide ion selective electrode (Orion, Model 94-16) and a saturated calomel electrode was used.

Procedure

Place a definite amount of the stock solution in a titration cell under an atmosphere of nitrogen, and cover the surface of the solution with a 1-cm thick liquid paraffin layer. Add an excess of potassium cyanide solution, which should be gently poured against the wall of the cell so that air bubbles are not entrained. Heat the solution to 40–50° until its reddish brown (or yellow) colour disappears (10 min), and then allow it to stand for 2 min. Cool the solution to below 15°, and add 2 or 3 drops of phenolphthalein indicator. Add sufficient formaldehyde and adjust the pH of the solution to 3 with dilute sulphuric acid (in order to mask the residual cyanide ions) then, without delay, make the solution alkaline again (pale pink) with dilute ammonia water, and finally add oxygen-free water to make up to about 100 ml. Titrate this solution with a standardized silver nitrate solution until the titration curve shows a sudden change, which corresponds to the first end-point (Fig. 1). Then adjust the pH of the solution to below 3 with dilute sulphuric acid, and continue the titration until the second end-point is reached. The first is for sulphide ion (free sulphide plus the sulphide bound by polysulphide), and the second for thiocyanate ion (consequently, for dissolved sulphur originally present).

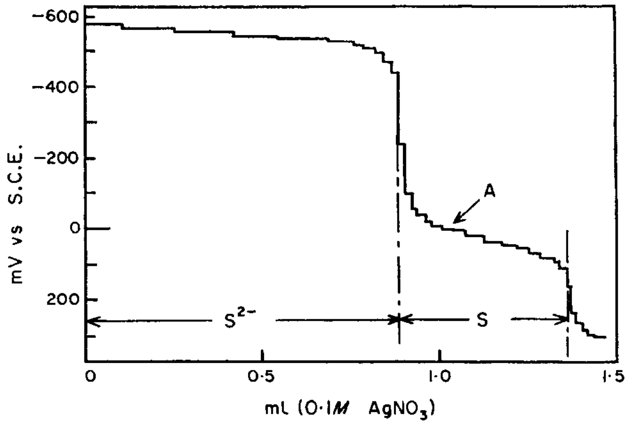

FIG. 1.—Titration curve for 100 ml of 5 × $10^{-4}M$ polysulphide solution containing 1·6 mg of S.
(A) Around here, 1*M* H_2SO_4 was added.

In the case of concentrated samples, if precipitates settle to the electrode they may reduce its response, so the cell must be occasionally shaken during titration.

RESULTS AND DISCUSSION

The present method was compared with two others, the iodometric method reported by Szekeres[4] and the amperometric method by Ikeda and Musha;[8] the results are listed in Tables I and II. Table I shows the analytical values obtained for each 100-ml volume of a $5 \times 10^{-3}M$ polysulphide solution, originally containing about 16 mg of dissolved sulphur. The values obtained by the proposed method are in good agreement with those obtained by the other two, which shows the proposed method is as good as the established methods. Table II shows the results for solutions of various concentrations and compositions. It indicates that the proposed method is capable of determining 5×10^{-5}–$5 \times 10^{-3}M$ S^{2-} and 0·16–20 mg of sulphur with good accuracy and reproducibility.

Further, the method was compared (for higher polysulphides) with the mercurimetric method of Papp and Havas.[13] The results are listed in Table III. Calculated values of x in S_x^{2-} indicate that S_4^{2-} as well as S_2^{2-} or S_3^{2-} can be determined by our method.

TABLE I.—COMPARISON OF ANALYTICAL VALUES BY THREE METHODS

Coefficient of variation, %	0·05	0·07	—	0·4	0·3	—

Each value is the average of 4 titrations.

TABLE II.—ACCURACY AND REPRODUCIBILITY AT VARIOUS CONCENTRATIONS AND COMPOSITIONS

Concentration		S^{2-}		S	
S^{2-}, M	S, *mg*/100 ml	Difference*, %	Coefficient of variation %	Difference,† %	Coefficient of variation, %
5×10^{-3}	5	+0·2	0·4	−1·3	0·5
5×10^{-3}	10	+0·1	0·2	+0·3	0·4
5×10^{-3}	16	+0·2	0·1	+0·4	0·3
5×10^{-3}	20	+0·4	0·5	+0·5	0·5
5×10^{-4}	1·6	+1·0	0·3	−1·1	0·6
5×10^{-5}	0·16	+0·1	0·6	−2·5	0·8

* Difference between the value found by the proposed method and the value expected for each specified concentration of S^{2-} from the value found by iodometry for 100 ml of $5 \times 10^{-3}M$ polysulphide solution containing 16 mg of S.

† The meaning is similar to that for S^{2-}, except that the reference value for S was obtained by the amperometric method.

Each value is the average of 4 titrations.

Though the values for sulphide sulphur by the two methods agreed well, the values for dissolved sulphur by argentimetry were about 5% smaller than those by mercurimetry. The potential change at the end-point for dissolved sulphur was sharper and more stable in argentimetry than in mercurimetry. The sulphide values by our method and by Papp's always give the sum of the amounts of free and bound sulphide in polysulphide solutions.

During the analysis, hydrogen sulphide and hydrogen cyanide were not evolved from the solutions, because the cyanolysis of polysulphide was carried out in alkaline solution and the subsequent acidification of the solution was quickly done, the surface being covered with liquid paraffin. Hydrogen cyanide was, of course, not evolved after the masking of cyanide ions by formation of formaldehyde cyanhydrin in the acidic solution.

The presence of sodium hydroxide, sodium carbonate, or sodium sulphate (the concentration of each being 0·05*N*) did not disturb the proposed method. Sodium thiosulphate caused a positive error in the values found for dissolved sulphur, as was to be expected because of its cyanolysis to form thiocyanate.

Each value is the average of 5 titrations (100 ml of 5 × $10^{-3}M$ S_x^{2-}).

Summary—Sulphide sulphur and dissolved sulphur in a polysulphide solution can be successively determined with satisfactory accuracy and reproducibility by potentiometric argentimetry in which a sulphide-selective indicator electrode is used. Before the titration, polysulphide ions need to be converted by an excess of potassium cyanide into thiocyanate and sulphide ions. The excess of cyanide ions is masked with formaldehyde and sulphuric acid, then the solution is made alkaline with ammonia and titrated with silver nitrate till the first end-point is reached (sulphide sulphur). After the acidification of the solution with sulphuric acid, the titration is continued till the second end-point is attained (dissolved sulphur).

Zusammenfassung—Sulfidschwefel und gelöster Schwefel in einer Polysulfidlösung können ausreichend genau und reproduzierbar durch potentiometrische Argentimetrie mit einer sulfidspezifischen Indikatorektrode bestimmt werden. Vor der Titration müssen Polysulfidionen mit einem Überschuß von Kaliumcyanid zu Thiocyanat- und Sulfidionen umgesetzt werden. Der Überschuß an Cyanidionen wird mit Formaldehyd und Schwefelsäure maskiert, dann wird die Lösung mit Ammoniak alkalisch gemacht und mit Silbernitrat bis zum ersten Endpunkt (Sulfidschwefel) titriert. Nach Ansäuern der Lösung mit Schwefelsäure wird die Titration fortgesetzt, bis man den zweiten Endpunkt erreicht (gelöster Schwefel).

Résumé—Le soufre à l'état de sulfure et le soufre dissous dans une solution de polysulfure peuvent être déterminés successivement avec une précision et une reproductibilité satisfaisantes par une argentimétrie potentiométrique dans laquelle on utilise une électrode indicatrice sélective des sulfures. Avant le titrage, les ions polysulfure doivent être convertis par un excès de cyanure de potassium en ions thiocyanate et sulfure. L'excès d'ions cyanure est dissimulé par le formaldéhyde et l'acide sulfurique, puis la solution est alcalinisée par l'ammoniaque et titrée par le nitrate d'argent jusqu'à ce que le premier point de fin de dosage soit atteint (soufre à l'état de sulfure). Après acidification de la solution par l'acide sulfurique, on poursuit le titrage jusqu'à ce que le second point de fin de dosage soit atteint (soufre dissous).

Cation-exchange of metal ions in organic solvent–cupferron media

(*Received* 13 *March* 1972. *Accepted* 1 *May* 1972)

RECENTLY, the use of common extractants, as employed in the liquid-liquid extraction of metal ions, has been studied with respect to their applicability to ion-exchange.[1–5] The strongly acidic cation-exchanger Dowex 50 has proved highly successful. On this exchanger several unique separations of

Summary—Sulphide sulphur and dissolved sulphur in a polysulphide solution can be successively determined with satisfactory accuracy and reproducibility by potentiometric argentimetry in which a sulphide-selective indicator electrode is used. Before the titration, polysulphide ions need to be converted by an excess of potassium cyanide into thiocyanate and sulphide ions. The excess of cyanide ions is masked with formaldehyde and sulphuric acid, then the solution is made alkaline with ammonia and titrated with silver nitrate till the first end-point is reached (sulphide sulphur). After the acidification of the solution with sulphuric acid, the titration is continued till the second end-point is attained (dissolved sulphur).

Zusammenfassung—Sulfidschwefel und gelöster Schwefel in einer Polysulfidlösung können ausreichend genau und reproduzierbar durch potentiometrische Argentimetrie mit einer sulfidspezifischen Indikatorektrode bestimmt werden. Vor der Titration müssen Polysulfidionen mit einem Überschuß von Kaliumcyanid zu Thiocyanat- und Sulfidionen umgesetzt werden. Der Überschuß an Cyanidionen wird mit Formaldehyd und Schwefelsäure maskiert, dann wird die Lösung mit Ammoniak alkalisch gemacht und mit Silbernitrat bis zum ersten Endpunkt (Sulfidschwefel) titriert. Nach Ansäuern der Lösung mit Schwefelsäure wird die Titration fortgesetzt, bis man den zweiten Endpunkt erreicht (gelöster Schwefel).

Cation-exchange of metal ions in organic solvent–cupferron media

(*Received* 13 *March* 1972. *Accepted* 1 *May* 1972)

Recently, the use of common extractants, as employed in the liquid-liquid extraction of metal ions, has been studied with respect to their applicability to ion-exchange.[1–5] The strongly acidic cation-exchanger Dowex 50 has proved highly successful. On this exchanger several unique separations of metal ions in organic solvent–mineral acid solutions containing certain extractants, have been found possible. The alkali metals can be selectively separated from practically all other elements on Dowex 50 by using 2-thenoyltrifluoroacetone in pyridine as eluent.[1] Another extractant that has proved to be suitable is trioctylphosphine oxide. With this extractant dissolved in tetrahydrofuran or methanol in the presence of hydrochloric or nitric acids, very effective cation-exchange separations of scandium from the rare earths,[2] of hafnium and zirconium,[3] thorium[4] or uranium[5] from a variety of elements can be achieved. With dithizone dissolved in tetrahydrofuran–nitric acid solution silver, copper, bismuth, and mercury can be separated effectively from numerous bi- and tervalent metal ions.[6]

Since cupferronates of iron, titanium, copper and other metals can be completely extracted into organic solvents such as chloroform[7,8] these systems are of potential interest for ion-exchange when making use of the principle of combined ion-exchange–solvent extraction (CIESE) described earlier.[9]

In the present paper the applicability of organic solvent–cupferron–hydrochloric acid systems for the separation of metal ions on Dowex 50 was investigated. As a result separations of several elements have found to be possible in these media.

EXPERIMENTAL

Reagents

Ion-exchange resin. Air-dried Dowex 50, X8 (100–200 mesh; hydrogen form) was used for the column and batch experiments. Before use the resin was purified as described earlier.[5]

Organic solvents. The following reagent-grade solvents were used: methanol, ethanol, diethyl ether, ethyl acetate and chloroform.

Cupferron.

Eluent solution. Freshly prepared solution of $0{\cdot}1M$ cupferron in chloroform–methanol–$1M$ hydrochloric acid (60:35:5 v/v).

Metal ions. Standard solutions of the following metal ions in $6M$ nitric acid were used: Fe(III), Cu(II), Ni(II), Zn(II), Hg(II), Co(II), Mn(II), Cd(II), Bi(III), Al(III), Ca(II), Ce(III), Ga(III), In(III), La(III), Mg(II), Sr(II), Ti(IV), Th(IV), and UO_2(II).

Determination of distribution coefficients

The batch distribution coefficients (K_d values) of the above-mentioned elements were determined as described earlier.[10] The quantitative determinations of the metal ions in the eluates and filtrates were performed by suitable methods based on EDTA titrations. Cerium was determined titrimetrically with potassium iodide and sodium thio-sulphate. Uranium was determined fluorimetrically.[11]

In the case of the solutions containing cupferron the organic matter was destroyed by successive evaporations with nitric acid (1 + 1) before the determination of the metal ion concentration.

Procedures

Pretreatment of the resin bed. Resin (1 g) is soaked for about 5 min in a few ml of the eluent solution and the slurry is transferred to the ion-exchange column (0·5 × 25 cm). The resulting resin bed is washed with 5–10 ml of the eluent solution.

Sorption and elution. Hydrochloric acid ($1M$, 0·5 ml) containing the metal ions (5 mg) to be separated, is mixed with 9·5 ml of methanol–chloroform mixture (3·5 ml of methanol and 6 ml of chloroform) containing 155 mg of cupferron. This mixture is passed through the pretreated resin bed at a flow-rate corresponding to the back-pressure of the resin column (about 0·35 ml/min). Under these conditions the ions having low K_d-values *i.e.*, Fe, Ti, Cu, Ce and Th, pass into the effluent. These elements are completely eluted by passage of about 40 ml of the eluent solution. If larger amounts of the metal ions are present, either the eluent volume or its cupferron concentration must be increased for quantitative elution.

Following the removal of cupferron and chloroform by washing the resin bed with 10–15 ml of a mixture consisting of 95% methanol and 5% $1M$ hydrochloric acid (v/v), the adsorbed elements can be eluted with 10 ml of $6M$ hydrochloric acid.

RESULTS AND DISCUSSION

Determinations of the distribution coefficients of iron, copper, zinc and nickel in organic solvent media containing 5% v/v $1M$ nitric or hydrochloric acid and which were $0{\cdot}05M$ or $0{\cdot}1M$ in cupferron gave the results listed in Tables I and II.

From these results it is seen that the presence of methanol and hydrochloric acid leads to lower K_d values of iron and copper. Also the presence of chloroform decreases the K_d values of the elements more than any other organic solvent. Further investigations were carried out with systems with higher chloroform concentrations. The most suitable system was found to be 60% chloroform–35% methanol–5% $1M$ hydrochloric acid. In this medium the K_d values of Fe, Cu and Ti are less than 10 (Table III).

Table I.—Distribution coefficients of Fe, Cu, Zn and Ni on dowex 50 in methanol and ethanol media (0·05 or 0·1M in cupferron)

System	Metal ion			
	Fe(III)	Cu(II)	Zn(II)	Ni(II)
I. 0·05M Cupferron				
95% ethanol–5% 1M HNO_3	102	670	$>3\times10^3$	$>10^3$
95% ethanol–5% 1M HCl	102	410	430	$>10^3$
95% ethanol–5% 1M HNO_3	41	410	$>10^3$	$>10^3$
95% methanol–5% 1M HCl	29	90	430	$>10^3$
II. 0·1M Cupferron				
95% ethanol–5% 1M HNO_3	83	410	$>10^3$	$>10^3$
95% ethanol–5% 1M HCl	83	240	180	$>10^3$
95% methanol–5% 1M HNO_3	41	410	$>10^3$	$>10^3$
95% methanol–5% 1M HCl	29	57	180	$>10^3$

Table II.—Distribution coefficients of Fe, Cu, Zn and Ni on dowex 50 in 50% organic solvent–45% alcohol–5% 1M HCl media (0·1M in cupferron)

System	Metal ion			
	Fe(III)	Cu(II)	Zn(II)	Ni(II)
Ethyl acetate + methanol + HCl	19	14	53	$>10^3$
Ethyl acetate + ethanol + HCl	29	38	180	$>10^3$
Diethyl ether + methanol + HCl	19	14	53	$>10^3$
Diethyl ether + ethanol + HCl	41	38	430	$>10^3$
Chloroform + methanol + HCl	3	8	40	$>10^3$

Table III.—Distribution coefficients of 20 metal ions on dowex 50 in 60% chloroform–35% methanol–5% 1M HCl in the presence and absence of 0.1M cupferron.

Metal Ion	Cupferron absent	Cupferron present
Fe(III)	5×10^2	2
Cu(II)	$>10^3$	6
Ti(IV)	4×10^2	2
Ce(III)	230	8
Th(IV)	2×10^3	9
Ga(III)	7×10^2	10
La(III)	$>10^3$	25
In(III)	$>10^4$	81
Bi(III)	230	13
Hg(II)	470	69
Ni(II)	$>10^3$	$>10^3$
Mn(II)	4×10^3	6×10^2
Cd(II)	125	8×10^3
Ca(II)	9×10^3	$>10^3$
Co(II)	4×10^3	$>10^3$
UO_2(II)	$>10^4$	9×10^3
Sr(II)	3×10^3	$>10^3$
Mg(II)	4×10^3	333
Al(III)	10^3	80
Zn(II)	10^3	40

An increase of the acidity in the mixture from 5% $1M$ to 5% 3 or $6M$ hydrochloric acid caused a decrease of the distribution coefficients of many metal ions. However, in these more acidic solutions cupferron was rapidly converted into a green compound which did not form cupferronates and hence was not effective for the elution of Fe, Cu and Ti.

To investigate the effect of cupferron on the adsorption of 20 elements on Dowex 50, their distribution coefficients were measured in the absence and presence of $0{\cdot}1M$ concentrations of the chelating agent. The results of these investigations are recorded in Table III and show that Fe, Ti, Cu, Ce and Th have low K_d-values (< 10) and hence can be readily separated from Ni, Mn, Cd, Co, Ca, U and Sr.

TABLE IV.—ELUTION CHARACTERISTICS OF Fe, Cu, Ti, Ce AND Th ON DOWEX 50

Metal ion	Breakthrough volume, *ml*	Volume of elution peak, *ml*	Elution volume, *ml*
Fe(III)	1	2	20
Cu(II)	2	6	30
Ti(IV)	1	2	30
Ce(III)	2	8	40
Th(IV)	2	9	35

In Table IV the volumes required for the complete elution of the slightly adsorbed elements are listed as well as the volumes of the eluent solution in which the concentration of the elements reaches a maximum.

Summary—Distribution coefficients of 20 metal ions were determined on the strongly acidic cation-exchanger Dowex 50 in a 30:7:1 mixture of chloroform-methanol-$1M$ hydrochloric acid which was $0{\cdot}1M$ in cupferron. In this system the distribution coefficients of Fe(III), Ti(IV), Cu(II), Ce(III) and Th are lower by several orders of magnitude than those of Ni, Mn(II), Cd, Co(II), Ca, U(VI), and Sr. It is possible to separate these two groups of elements on an ion-exchange column.

Zusammenfassung—Verteilungskoeffizienten von 20 Metallionen wurden an dem stark sauren Kationenaustauscher Dowex 50 in einem $0{,}1M$ Cupferron enthaltenden Gemisch 30:7:1 Chloroform-Methanol-$1M$ Salzsäure bestimmt. In diesem System sind die Verteilungskoeffizienten von Fe(III), Ti(IV), Cu(II), Ce(III) und Th um mehrere Größenordnungen-kleiner als die von Ni, Mn(II), Cd, Co(II), Ca, U(VI) und Sr. Man kann diese beiden Gruppen von Elementen an einer Ionenaustauschersäule trennen.

Résumé—On a déterminé les coefficients de partage de 20 ions métalliques sur l'échangeur de cations fortement acide Dowex 50 dans un mélange 30:7:1 de chloroforme-méthanol-acide chlorhydrique $1M$ qui est $0{,}1M$ en cupferron. Dans ce système, les coefficients de partage de Fe(III), Ti(IV), Cu(II), Ce(III) et Th sont plus faibles de plusieurs orders de grandeur que ceux de Ni, Mn(II), Cd, Co(II), Ca, U(VI) et Sr. Il est possible de séparer ces deux groupes d'éléments sur une colonne échangeuse d'ions.

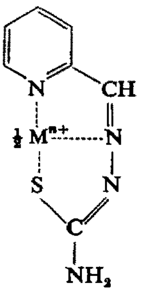
ANALYTICAL DATA

Comparative study of analytical properties and applications of picolinaldehyde thiosemicarbazone and selenosemicarbazone

(*Received* 8 *March* 1972. *Accepted* 24 *May* 1972)

Picolinaldehyde thiosemicarbazone (PAT) has been used in the photometric determination of Co(II),[1] Fe(II) and Fe(III),[2] Ni and Cu(II),[3] and their mixtures.[4] The complexes of Ni, Co(III) and Fe(II) have been isolated and studied.[5] With these cations, PAT acts as a terdentate chelating agent, and forms octahedral complexes of the type.



In certain conditions it may act as a bidentate chelating agent.

In this paper, a comparative study is made of the physical properties and chemical reactions of PAT and picolinaldehyde selenosemicarbazone (PASE), and the effect of increasing the separation of the thiosemicarbazide grouping from the pyridine ring has also been investigated, with nicotinaldehyde thiosemicarbazone (NAT). Benzaldehyde thiosemicarbazone (BAT) was also tested for comparison.

EXPERIMENTAL

Reagents

Standardized solutions of Fe(II) and Fe(III) (both 0·990 g/l.), Ni (0·986 g/l.), Co(II) (1·089 g/l.) and Cu(II) (1·995 g/l.) were used. More dilute solutions were prepared from these.

All solvents and reagents were of analytical grade.

Preparation of the compounds

PAT. A mixture of 200 ml of 0·5% aqueous thiosemicarbazide solution and 10 ml of 10% ethanolic picolinaldehyde solution was refluxed, then cooled to yield PAT, which was recrystallized from ethanol (m.p. 198–200°; found: C 46.7%; H 4.4%; N 30.9%; S 17.7%; calculated for $C_7H_8N_4S$: C 46·67%; H 4·44%; N 31·11%; S 17·72%).

BAT. Prepared similarly to PAT. White crystals, extremely bitter taste (m.p. 158–160°; found: C 53.7%; H 5.1%; N 23.7%; S 17.6%: calculated for $C_8H_9N_3S$: C 53.65%; H 5.04%; N 23.45%; S 17·88%).

PASE. Hydrazine hydrate (10·5 g) was added to 27 g of previously synthesized potassium selenocyanate dissolved in the minimum amount of water. The mixture was acidified with 3·8*M* hydrochloric acid to pH 5; 15 ml of acetone were then added, and the solution was refluxed for 90 min, cooled and filtered. The acetone selenosemicarbazone crystallized slowly in white crystals, which easily became red. This product was dissolved in water and refluxed with an ethanolic solution of the stoichiometric amount of picolinaldehyde. On cooling the mixture, the desired substance was obtained. The product was recrystallized from ethanol. It formed brown needles, stable in air (m.p. 212–4°; found: C 36.9%; H 3.5%; N 24.9%: calculated for $C_7H_8N_4Se$: C 36.85%; H 3.53%; N 24·56%).

NAT. Nicotinaldehyde thiosemicarbazone was obtained commercially.

Solubility

PAT and PASE are soluble in acetone and methanol, moderately soluble in ethanol, and sparingly soluble in water, chloroform, nitrobenzene and carbon tetrachloride.

Infrared spectra

Infrared spectra were obtained in nujol suspension, and the bands assigned to the stretching vibrations of -NH- (3500–3000 cm^{-1}), >C=N (1630–1515 cm^{-1}), >C=S (1130–1010 and 830–805 cm^{-1}) and >C=Se (1110–720 cm^{-1}) groups. The most characteristic bands of the last two groups were at 820 and 770 cm^{-1} for PAT and PASE, respectively.

Ultraviolet spectra

The ultraviolet absorption spectra for reagent in water and ethanol media showed similar maximum between 300 and 350 nm. Bathochromic shifts were produced on changing from water to ethanol as solvent (from 312 to 323 nm for PAT and from 320 to 335 nm for PASE). The solutions decomposed in time, PAT slowly and PASE faster. The effect of pH on the spectra is shown in Figs. 1 and 2.

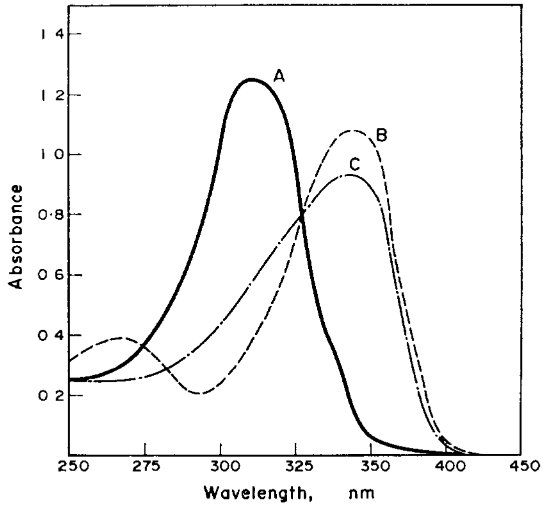


FIG. 1.—Absorption spectra of PAT (4 × 10^{-5} M in water) at pH 7·2 (*A*), 12·8 (*B*) and 1·3 (*C*).

NAT behaved similarly to PAT and PASE (bathochromic shifts at pH < 4 or > 10), but BAT gave a shift only in alkaline medium.

Determination of ionization constants

The Phillips and Merritt method[7] was used with 2 × 10^{-3}M ethanolic solutions. Table I gives the results.

Action of reducing and oxidizing agents

Reducing agents in moderate concentrations did not alter the absorption spectra of PAT and PASE, but oxidizing substances did. PAT was oxidized in different ways, depending on the pH; PASE always gave the same final form (also given on aerial oxidation of the solution for 7–8 days). The oxidation of PASE was reversible. Attempts to isolate the oxidation products were unsuccessful.

Reactions with cations

The reaction of PAT, PASE and NAT with 40 cations, up to concentrations of 1000 ppm, at various pH values, was investigated. As(III) or (V), Sn(II) or (IV), Pt(IV), Al, Cr(III), Be, UO$_2$(II)

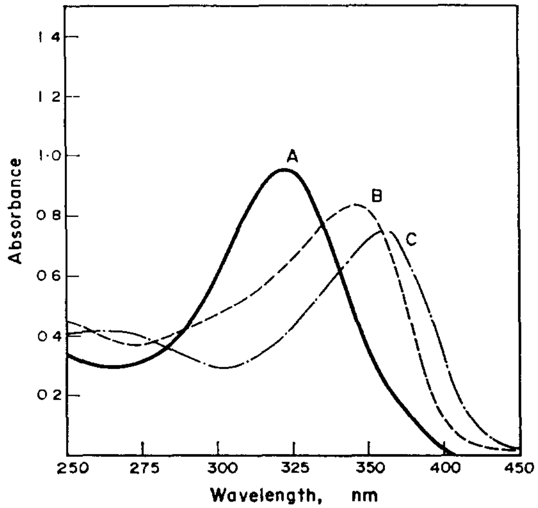

FIG. 2.—Absorption spectra of PASE ($4 \times 10^{-5}M$ in water) at pH 6·9 (*A*), 12·8 (*B*) and 1·2 (*C*).

TABLE I.—VALUES OF IONIZATION CONSTANTS

Substance	pK_b	pK_a
Picolinaldehyde thiosemicarbazone	9·40	9·75
Picolinaldehyde selenosemicarbazone	9·80	9·60
Nicotinaldehyde thiosemicarbazone	9·60	10·40
Benzaldehyde thiosemicarbazone	—	11·30

Th, La, Ce(III), W(VI), Mo(VI), alkaline and alkaline earth metals did not react. Zn and Mn(II) reacted with PAT and PASE in alkaline medium only.

The reactions of PAT and PASE were very similar, but the PASE complexes were more highly coloured and the sensitivity lower. In many cases, red precipitates of elementary selenium appeared soon after the solutions had been prepared. The most sensitive reactions (pD > 5) were those of Co(II), Fe(II) and (III), Ni and Cu(II). With Pd(II), Au(III) and V(V) an orange-yellow colour was produced (pD 5·4, 4·0 and 5·7 respectively). Bi and Sb(III) gave a weak yellow colour, as did Ag and Pb. Hg(I) and Hg(II) formed yellowish-white precipitates.

NAT reacts with Hg(I) and Hg(II) (yellowish precipitates), Cu(II) (green colour) and Pd(II) (yellow colour). The last was the most sensitive (pD 5·4 at pH 3–5).

The PASE complexes of Fe(II), Fe(III), Ce(II), Ni and Cu(II) were investigated in the same way as the PAT complexes. The results are given in Table II, with those for PAT for comparison.

The Cu(II) complex was very unstable, red precipitates of elementary selenium being formed a

TABLE II.—CHARACTERISTICS OF PAT AND PASE COMPLEXES IN SOLUTION

	Picolinaldehyde thiosemicarbazone				Picolinaldehyde selenosemicarbazone

Cu(II)	8·9–10·7	360	22×10^3	1:1		388		

few minutes after preparation of the samples. The Ni complex was stable for 1 hr and then decomposed slowly. The other three complexes were stable for at least 5 hr. The effect of pH on the oxidation rate of the green Fe(II) complex to the yellow Fe(III) complex was studied for both reagents. The results are shown in Table III.

TABLE III.—TIME NEEDED TO OXIDIZE THE FERROUS COMPLEXES

pH	Fe(II)-PAT *hr*	Fe(II)-PASE *hr*
4·5	0·3	0·1
5·0	1·5	0·2
6·2	3·5	0·2
6·5	4·0	0·3
8·5	21·0	0·4
10·0	40·0	
12·0	43·0	

The Fe(II)-PASE complex was extracted more easily into chloroform than the Fe(II)-PAT complex, although it was stable in this medium for only 1·5–2 hr. The PAT complex was stable for 5 hr. Ascorbic acid prevents the oxidation of these complexes in aqueous solution.

DISCUSSION

The infrared spectra agreee with those described by Gingras *et al.* for thiosemicarbazones[8–10] and selenosemicarbazones.[11] The band at 820 cm^{-1} in the picolinaldehyde thiosemicarbazone spectrum disappears when the complexes are formed,[3] showing that the sulphur atom is involved in the formation of these complexes.

The bathochromic shift in alkaline medium can be considered as due to the greater resonance[8] of the form $—N{=}\underset{\displaystyle S^-}{\underset{|}{C}}—NH_2$, which has the conjugated $—HC{=}N—N{=}C\lt$ group as chromophore. The bathochromic shift in acid medium may be due to protonation of the nitrogen atom in the pyridine ring, as it does not appear in benzaldehyde thiosemicarbazone, and has a very similar value to that of pyridine and its derivatives.[12] That pK_a for PAT is higher than that of PASE agrees with Volka and Holzbecher's results[13] for salicilaldehyde thiosemicarbazone and selenosemicarbazone.

The oxidation of selenosemicarbazone to a form with maximum absorption at 287 nm may be explained as due to formation of a diselenide, based on the tendency of compounds with $\gt C{=}Se$ or $\gt C{=}S$ groups to dimerize to the form $+—\overset{\diagdown}{\underset{\diagup}{C}}—Se—Se—\overset{\diagup}{\underset{\diagdown}{C}}+$;[14,15] unfortunately, the rapid decomposition of the product precludes its study.

An interesting difference between the behaviour of nicotinaldehyde and benzaldehyde thiosemicarbazone and of PAT and PASE is that the former two hydrolyse in acid medium, but the latter two do not. This again reveals the different character of positions 2 and 3 of the pyridine ring. Another important characteristic is that PAT is much more reactive than NAT with cations. NAT has important reactions only with Pd(II) and Cu(II), behaviour similar to that of other thiosemicarbazones in which the group attached to the thiosemicarbazide does not have a free electron pair (benzaldehyde, acetone, *etc*). Increased separation of the thiosemicarbazide group from the pyridine ring prevents the latter from participating in the formation of the complexes.

Summary—The analytical properties of picolinaldehyde thiosemicarbazone and selenosemicarbazone have been studied, in order to investigate the changes produced when the Se atom is substituted for the S atom. The ionization constants of both substances are very similar. The complexes of picolinaldehyde selenosemicarbazone with cations in aqueous solution are less stable, and the absorption spectra show bathochromic and hypochromic shifts. The introduction of the Se atom offers no advantages in the analytical application of these compounds.

Zusammenfassung—Die analytischen Eigenschaften des Thiosemicarbazons und des Selenosemicarbazons von Picolinaldehyd wurden untersucht, um die Änderungen bei Substitution des S-durch ein Se-Atom zu erfassen. Die Ionisationskonstanten beider Substanzen sind sehr ännlich. Die Komplexe von Picolinaldehyd-Selenosemicarbazon mit Kationen in wäßriger Lösung sind weniger stabil und ihre Absorptionsspektren zeigen bathochrome und hypochrome Verschiebungen. Die Einführung des Se-Atoms bietet bei der analytischen Verwendung dieser Verbindungen keine Vorteile.

Résumé—On a étudié les propriétés analytiques de la thiosemicarbazone et de la sélénosemicarbazone de l'aldéhyde picolinique, afin d'examiner les changements produits quand l'atome de Se est substitué à l'atome de S. Les constantes d'ionisation des deux substances sont très similaires. Les complexes de la sélénosemicarbazone de l'aldéhyde picolinique avec les cations en solution aqueuse sont moins stables, et les spectres d'absorption montrent des déplacements bathochromes et hypsochromes. L'introduction de l'atome de Se n'offre pas d'avantages dans l'application analytique de ces composés.

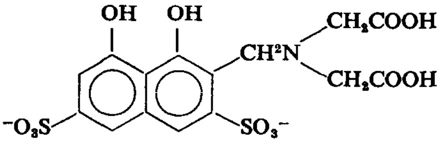
ANNOTATIONS

On the nature of so-called "Khimdu"

(*Received* 24 *April* 1972. *Accepted* 18 *May* 1972)

THE methyliminodiacetic acid derivative of chromotropic acid (disodium salt of 1,8-dihydroxynaphthalene-2*N*,*N*-dicarboxymethylaminomethyl-3,6-disulphonic acid, so-called "Khimdu") was first reported by Basargin *et al.* as a colorimetric reagent for titanium(IV).[1]

As we have been interested in this type of reagent, we tried to repeat their work carefully, but found some doubts about the nature of the reported compound. According to the result of our investigation, it is very likely that the reported reagent is a mixture of various reaction products, and not the pure compound having the proposed chemical structure(I).



(I)

EXPERIMENTAL

Reagents

Buffer solutions of hydrochloric acid/potassium chloride (pH 2), hexamethylenetetraamine/hydrochloric acid (pH 3) and potassium acetate/acetic acid (pH 5) were used.

Metal ion stock solutions (0·01*M*) were prepared from analytical grade ferric nitrate and metallic titanium, and their strengths were determined by EDTA titration. The stock solutions were diluted with distilled water before use.

Apparatus

A column 16 mm in diameter and 500 mm long was used for the gel chromatographic separation of the reaction mixture. The column was filled with a Sephadex LH-20 gel which had been swollen in the eluent (80% aqueous methanol) for 24 hr before use.

Electronic spectra were observed with a Hitachi 124 double-beam recording spectrophotometer.

Synthesis of Khimdu

Khimdu was synthesized according to the method of Basargin.[2] A mixture of 4·37 g (0·12 mole) of chromotropic acid (disodium salt) and 1·6 g (0·012 mole) of iminodiacetic acid was placed in a 100-ml reaction flask. After addition of 20 ml of water, the mixture was heated on a water-bath until dissolution was complete. The solution was cooled to about 50°, and the pH adjusted to 2·0–3·0 with 1*M* hydrochloric acid. Then 0·87 ml (0·012 mole) of 37% formaldehyde was added while stirring for several minutes. The reaction mixture was kept at room temperature for 3 hr, then transferred into a 300-ml beaker, and 120 ml of acetone were added to precipitate the product. The solution at first, gave a white suspension, from which a reddish-brown heavy oil separated. After collection, the oily product was treated with acetone to yield a brown powder.

The product was carefully pulverized under acetone, then filtered off, washed with acetone and ether successively, and finally dried over phosphorus pentoxide. The yield of the crude product was 5·25–5·88 g (86–96%) (product KA).

In an alternative procedure, the mole ratio of the reagents was altered to 1:2:3, and the reaction was carried out at 50° in an atmosphere of nitrogen for 14 hr. The reaction product was treated in a similar fashion to that described above, and a reddish brown powder (product KB) was obtained (yield: 73%).

Chromatographic fractionation of the reaction products

In order to purify the crude reaction products, samples of KA and KB were subjected to chromatographic fractionation on a Sephadex LH 20 gel column at an elution speed of 0·3 ml/min. The effluents were fractionated into three or four fractions according to their relative differences in ultraviolet absorption spectra. Each fraction was concentrated to a small volume under reduced pressure, and pure product precipitated with acetone. The isolated product was washed with acetone and ether, and vacuum-dried.

The yields of fractions obtained were as follows: 100 mg of KA gave 8·2 mg of KA-(1), 44·4 mg of KA-(2) and 9·1 mg of KA-(3), and 150 mg of KB gave 1·0 mg of KB-(1), 66·5 mg of KB-(2), 7·4 mg of KB-(3) and 10·5 mg of KB-(4).

The purified sample as well as the crude products were subjected to the absorption spectral analysis and elemental analysis.

RESULTS AND DISCUSSION

Our original purpose was to reproduce Basargin's results, and the samples obtained were found to have spectral characteristics identical with those of Khimdu. It is seen from Figs. 1, 2 and 3, that the crude product KA gave an absorption spectrum which is very close to that of Khimdu, and the visible absorption spectra of iron(III) and titanium(IV) complexes of the product KA also showed identical characteristics with those of Khimdu. A continuous variation study of the iron(III) complex was also made in order to obtain an additional proof of identity of our sample with Khimdu. The results, as shown in Figs. 4 and 5, again confirmed the identity of our crude product with the material called Khimdu by Basargin, and the different metal ligand ratios obtained in the studies at different wavelengths also imply that more than one complex-forming species is present.

However, as the result of elemental analysis on the crude sample showed discrepancies from the expected value for Khimdu, the sample was purified. The sample was rather unstable, becoming darker at elevated temperature, and was very slightly soluble in most common organic solvents, so that purification by recrystallization did not seem to be feasible.

Of the chromatographic separations investigated, gel chromatography on Sephadex LH-20 column with 80% methanol as an eluent was found to give best separation. However, contrary to expectation, the absorption spectra of the fractionated samples became more divergent from those

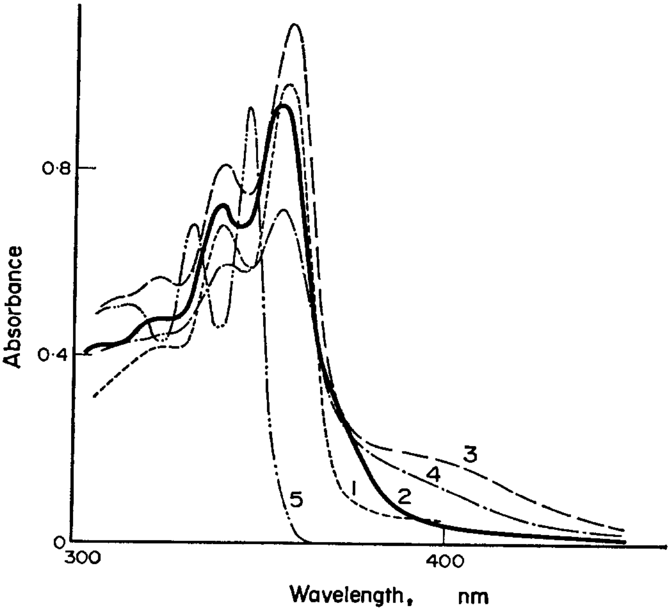


FIG. 1.—Visible absorption spectra of "Khimdu," the reaction products and chromotropic acid (reference water, 1-cm cells)

1, Khimdu 8 × $10^{-5}M$ (reproduced from ref. 1);
2, KA; *3*, KA-(2); *4*, KB-(2); *5*, chromotropic acid (all 1 × $10^{-4}M$).

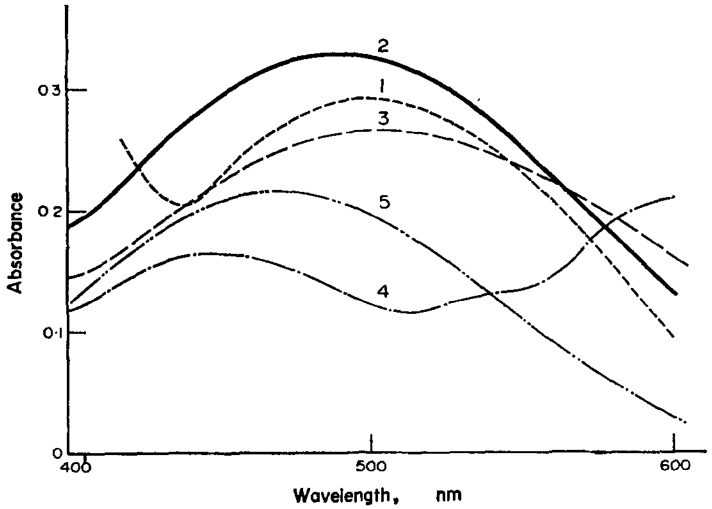

FIG. 2.—Visible absorption spectra of titanium(IV) complexes (reference reagent blank, 1-cm cells, pH 2)

1, Khimdu, 4 × $10^{-4}M$ and Ti 4 × $10^{-5}M$ (reproduced from ref. 1);
2, KA; *3*, KA-(2); *4*, KB-(2); *5*, chromotropic acid (all 1 × $10^{-4}M$ and Ti 4 × $10^{-5}M$).

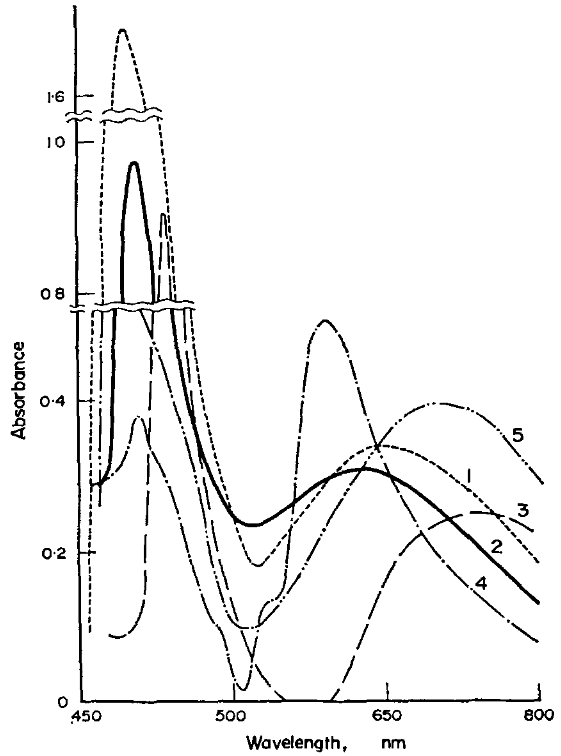

FIG. 3.—Visible absorption spectra of iron(III) complexes (reference reagent blank, 1-cm cells, pH 5).

1, Khimdu 2·5 × $10^{-3}M$ and Fe 2·5 × $10^{-4}M$ (reproduced from ref. 1);
2, KA; *3*, KA-(2); *4*, KB-(2); *5*, chromotropic acid (all 2·5 × $10^{-3}M$ and Fe(III) 2·5 × $10^{-4}M$).

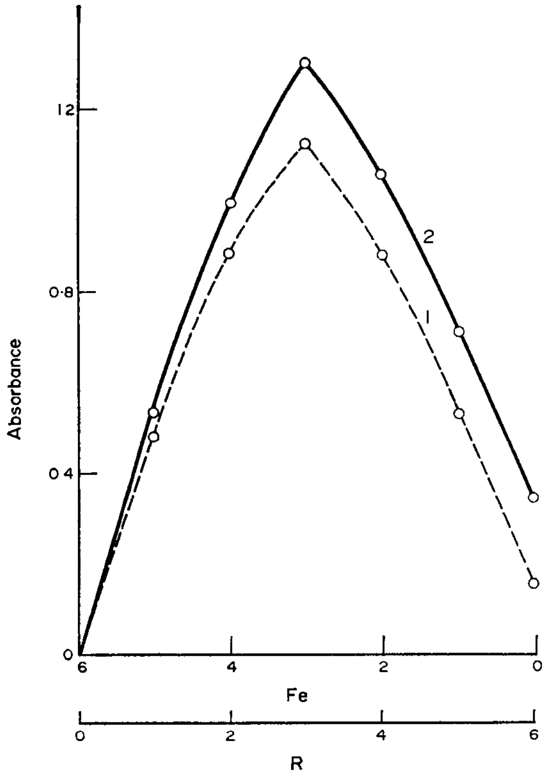

FIG. 4.—Continuous variation study on iron(III) complex at 400 nm. Total corcentration 1·0 × $10^{-4}M$; 1-cm cells; *1*, Khimdu, at 395 nm and pH 3·0 (reproduced from ref. 1); *2*, KA, at 403 nm and pH 2·0.

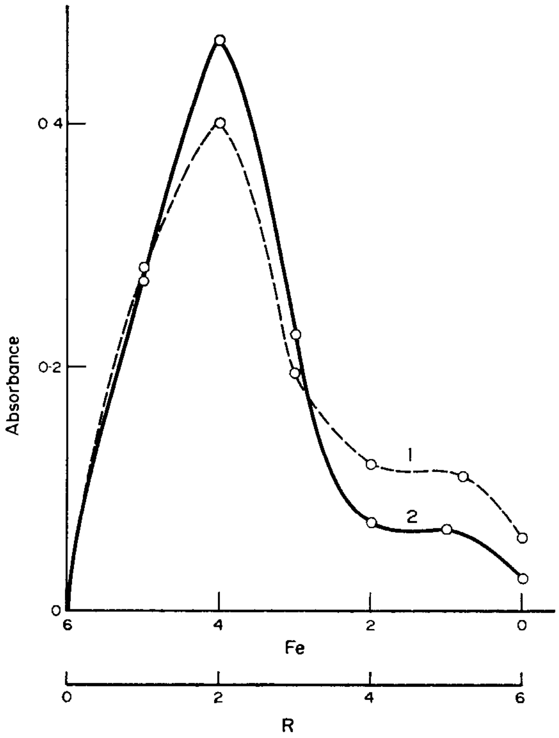

FIG. 5.—Continuous variation study on iron(III) complex at 650 nm Total concentration 2·0 × $10^{-4}M$, 5-cm cells; *1*, Khimdu, at 650 nm and pH 3·0 (reproduced from ref. 1); *2*, KA, at 630 nm and pH 2·0.

of Khimdu. Moreover, the results of elemental analyses on the fractionated samples deviated more and more from the calculated values for Khimdu, as shown in Table I. In the case of KB, where the mole-ratio of the reactants was 1:2:3, the nitrogen content in the product as well as in the chromatographed fractions was higher than for KA. However, none of the results for the fractions agree with the calculated value for Khimdu. Generally, as the fractionation goes on, the nitrogen content becomes lower. For example, the fraction KA-(2) does not contain nitrogen and the analytical value is rather close to that of the dimethylol derivative of chromotropic acid.

TABLE I.—ELEMENTAL ANALYSES OF THE CRUDE PRODUCTS AND THE CHROMATOGRAPHED FRACTIONS

Sample	C%	H%	N%	Na%
KA	36·0	3·2	2·0	8·2
KA-(1)	34·6	3·1	0·7	8·8
KA-(2)	34·7	2·6	0·0	9·5
KA-(3)	33·4	2·8	0·2	10·5
KB-(1)	37·8	3·6	3·1	6·0
KB-(2)	35·2	3·3	2·6	9·3
KB-(3)	—	—	1·6	—
KB-(4)	—	—	0·5	—
Calcd. value for Khimdu ($C_{15}H_{13}NO_{12}S_2Na_2$)	35·37	2·57	2·75	9·03
Chromotropic acid (sodium salt) ($C_{10}H_6O_8S_2Na_2$)	32·97	1·66	0·00	12·62
Dimethylol deriv. of chromotropic acid (sodium salt) ($C_{12}H_{10}O_{10}S_2Na_2$)	33·97	2·38	0·00	10·84

Although we do not want to give any decisive conclusion, as Basargin *et al.* did not show the analytical results for their sample, it is very likely that the product called "Khimdu" is not a compound with well-defined structure, but is a mixture of various reaction products.

Zur Frage des Verlustes von Molybdän während der Analyse von metallischem Wolfram auf Molybdänspuren

(*Eingegangen am* 9. *Dezember* 1971. *Angenommen am* 10. *Januar* 1972)

TECHNISCHES Wolfram-Metall enthält stets Spurenverunreinigungen an Molybdän, in der Größenordnung zwischen 1000 und 10 ppm. Spezielle Anwendungsgebiete in der Elektronik und der Glühlampenfertigung erfordern einen möglichst geringen Molybdängehalt; damit eng verknüpft ist daher die Notwendigkeit einer exakten Methode zur analytischen Bestimmung dieser kleinen Gehalte neben überwiegend Wolfram.

In Fachkreisen bestehen derzeit sehr unterschiedliche Meinungen darüber, inwieweit bei einem der Bestimmung vorgeschalteten Glüh- bzw. Erhitzungsprozeß Molybdän infolge von Sublimation des Oxids verloren gehen kann. Um das Wolfram-Metall in Lösung zu bringen gibt es grundsätzlich zwei Vorbehandlungs-Möglichkeiten.

(1) Man oxidiert das Wolfram-Metall durch Glühen an Luft zu WO_3 und löst anschließend in Natriumhydroxidlösung. Um diesen Oxidationsvorgang in annehmbaren Zeiten durchführen zu können, werden Temperaturen von 750–850° vorgeschlagen.

(2) Man löst in einem Gemisch von Flußsäure und Salpetersäure, setzt danach Schwefelsäure zu und erhitzt entweder bis zum Auftreten von SO_3-Nebeln; meist wird aber bis zur Trockene eingedampft.

Im ersten Fall ist man sich uneinig darüber inwieweit MoO_3 unter diesen Glühbedingungen durch Sublimation flüchtig ist, im zweiten Fall wird die Bildung flüchtiger Oxyfluoride vermutet.

Wir haben nun diese beiden Varianten einer genauen Überprüfung im Hinblick auf Molybdän-Verluste unterzogen und sind dabei zu folgenden Ergebnissen gekommen.

(*a*) Ein oxidierendes Glühen von Wolfram-Metall an Luft bei 750° verursacht einen beträchtlichen Verlust an Molybdän, z.B. wurde der Gehalt von 350 auf 30 ppm herabgesetzt.

(*b*) Nach dem Lösen mit Flußsäure–Salpetersäure-Gemisch führt ein Erhitzen bis zur Verflüchtigung von SO_3 und auch ein Rösten nach vollständigem Abdampfen der Schwefelsäure bei 400° zu keinerlei Molybdän-Verlusten.

Diese Ergebnisse führen zu dem Schluß, daß die erste Vorbehandlungsvariante der Wolframproben vollkommen ungeeignet ist. Die zweite Arbeitsweise ist sicher und es besteht keine Gefahr von Molybdän-Verlusten. Letzteres wurde darüber hinaus von uns bereits in zwei Arbeiten bewiesen.[1,2]

Ergänzend muß erwähnt werden, daß bei oxidierendem Glühen von Wolfram-Metall auf Grund der exothermen Reaktion intermediär und lokal höhere Temperaturen auftreten werden, als der Ofentemperatur entspricht. Darüber hinaus dürfte auch die Kinetik der Oxidation des W-Mo-Mischkristalles eine Rolle spielen. Es ist anzunehmen, daß primär freies MoO_3 und WO_3 entstehen, die erst im weiteren Verlauf der Reaktion Oxidmischkristalle bilden.

Freies MoO_3 ist bekanntlich schon bei Temperaturen über 450° flüchtig. Sind hingegen die kleinen MoO_3-Mengen in das WO_3-Gitter eingebaut, so kann man ohne weiteres auf 750° erhitzen ohne daß Molybdän-Verluste auftreten. Dies wurde durch Glühversuche an einer Reihe von WO_3 Mustern, die auf Molybdän analysiert wurden, überprüft.

Versuchsanstalt
Metallwerk Plansee A.G.
A-6600 Reutte, Austria

E. LASSNER
H. SCHEDLE

Zusammenfassung—Es wird gezeigt, daß ein oxidierendes Glühen von Wolfram-Metall zu Wolframtrioxid zu einer Abnahme des Molybdängehaltes führt. Im Hinblick auf eine nachfolgende Molybdänbestimmung ist daher eine solche Glühung zu unterlassen. Hingegen ist beim Lösen von Wolfram in Fluß-Salpetersäuregemisch und anschließendem Abdampfen mit Schwefelsäure (bis zur Trockene) keine Verringerung des Molybdängehaltes zu verzeichnen.

Summary—It is shown that oxidative ignition of metallic tungsten to tungsten trioxide causes a decrease in the molybdenum content. Thus the ignition cannot be used when the molybdenum content is to be determined. On the other hand, when the tungsten is dissolved in a

mixture of hydrofluoric and nitric acids with subsequent fuming with sulphuric acid, no such decrease in the molybdenum content takes place.

Résumé—On a montré que l'ignition par voie oxydante du tungstène métallique en trioxyde de tungstène cause un décroissement de la teneur en molybdène. Une telle ignition doit donc être évitée lorsqu'il faut déterminer la teneur en molybdène. D'autre part, lorsque le tungstène est dissous dans un mélange d'acides fluorhydrique et nitrique avec traitement subséquent à l'acide sulfurique jusqu'à production de fumées, un tel décroissement de la teneur en molybdène ne se produit pas.

Louis Gordon Memorial Award 1970

Professor and Mrs. L. MEITES were presented with the Louis Gordon Memorial Award by Dr. HOWARD FRANCIS JR. (on left), for their paper on "Theory of Titration Curves—VII: The Properties of Derivative Titration Curves for Strong Acid–Strong Base and other Isovalent Ion-Combination Titrations" (*Talanta*, 1970, **17**, 525), which was judged to be the best-written paper published in *Talanta* in 1970.

Talanta, 1972, Vol. 19, p. i. Pergamon Press. Printed in Northern Ireland

PUBLICATIONS RECEIVED

Recent Advances in Gas Chromatography: I. I. DOMSKY and J. A. PERRY (Eds.) Dekker, New York, 1971. pp. xi + 414. $19.50.

The book consists of the typescripts of 17 lectures presented at short courses on Gas Chromatography. The reproduction, which is in the modern style, serves to emphasise the origins of the book. Some authors quite clearly were more concerned with delivering a lecture whereas others were also concerned with publication (or providing those attending the lecture with a good paper whilst they spoke of something else). The book is inevitably a pot pourri of discussion and comment on various aspects of GLC such as columns, flow patterns, detectors, computer link-ups, silylation, and applications to the analysis of lipids, pesticides and metabolites. There are also two chapters on gel permeation chromatography.

Most of the chapters contain useful practical information and present it in a straightforward, well-illustrated manner, but overall the rigour demanded of formal papers or books is lacking. It provides a useful survey, and many workers may wish to consult specific chapters, but overall one is left with the impression that, whilst the lectures may have been informative and entertaining, on their translation into book form they should have been expanded and edited.

The Determination of Impurities in Nuclear Grade Sodium Metal: L. Silverman, Pergamon, Oxford, 1971. pp. ix + 143. £3.75, $10.00.

The book appears to be a collection of laboratory procedures for the determination of impurities in sodium metal and also sodium chloride, hydroxide and carbonate. Most emphasis is placed on carbon and oxygen but procedures for the determination of Al, Bi, B, Cd, Ca, Mg, Cs, Cl, Cr, Co, Cu, H, I, Fe, Pb, Li, Nn, Ni, P, K, Si, S and U are also given. There is little theory but the text abounds with practical wisdom, which may be appreciated by many analysts, since the procedures described have a general applicability. The descriptions of procedures are clear and likely pitfalls are pointed out.

Analytical Photochemistry and Photochemical Analysis: J. M. FITZGERALD (Ed.) Dekker, New York, 1971. pp. xiv + 360. $23.50.

The editors hope that the contributions in this volume will bring the developments of photochemistry with analytical implications to the attention of analytical chemists and provide photochemists with a critical survey of useful analytical methods. In view of the rapid growth of photochemistry the work is timely and stimulating. Several useful and unusual determinations are described in a series of reviews by various authors. These deal with lasers in analytical chemistry, actinometry, photochemical titrations and methods for studying the photolysis of polymers and co-ordination compounds, and other related topics.

Analytical Emission Spectroscopy, Vol. 1, Part 1; E. L. GROVE (Ed.), Dekker, New York, 1971. pp. xvi + 401. £12.60.

This is the first part of a projected three part work. Judgment of the whole will have to await the appearance of the whole, but in its own right the first part is most valuable. It contains long articles on the historical development of emission spectroscopy, the origins of atomic spectra, prisms, gratings, prism and grating instruments and spectroradiometric principles. There is little that is new in all this but the spacious accounts of fundamentals are welcome. If the other volumes match this the set will prove an invaluable tome of reference.

ANALYTICAL DATA

An essential but little acclaimed part of scientific research is the measurement of accurate values of the many constants used in the development and application of theory. Development work is usually thought of as interesting and exciting, and careful measurement by established methods as being dull and somehow less praiseworthy. The onlooker is sometimes left with the sneaking suspicion that this attitude sometimes arises because its holder lacks either the patience or the skill necessary for work of the highest accuracy. Be that as it may, it is quite certain that without the consolidation provided by the many careful workers who garner values for constants, theory would not progress very far and would not be nearly so useful as a guide to action. One of the problems of workers in this field is that of publication. Their results are usually of value in several fields of chemistry, but strictly speaking belong to none in particular. A consequence of this is that publication committees are often tempted to suggest submission to some other journal than their own, and authors experience difficulty in finding a medium for publication of their work. One of their difficulties is that journal space is already at a premium, and editors are naturally reluctant to occupy it with details of standard procedures applied to individual problems. We therefore propose to begin a new feature in *Talanta*, to be called "Analytical Data", which will serve for publication of such results with the minimum of background information. Once a pattern of experimentation has been established, a reference to it is all that is necessary to indicate how the work was done. Of course, if there is a new development discovered in the course of such work, that is a different matter, and it can be mentioned in more detail and itself become the reference point for future publications. In this issue we present the first papers in this feature. They are a little longer than we would normally expect, simply in order to set the pattern.

FOREWORD

ON THE occasion of the IUPAC International Congress on Analytical Chemistry and the 20th Anniversary of the founding of the Japan Society for Analytical Chemistry, it gives the Editorial Board and Publishers of *Talanta* great pleasure to mark the occasion and honour the work of Japanese analytical chemists by presenting this special issue containing invited contributions showing the wide range of interests and research in modern Japanese analytical chemistry.

The cover of this issue carries a transliteration of *Talanta* into Katakana characters.

Computer calculation of equilibrium constants by using program SCOGS; a further modification: I. G. SAYCE and V. S. SHARMA. (31 *December* 1971)

Méthode nouvelle de séparation des sulfates de strychnine et brucine: M. MARIAUD and D. HALOT. (31 *December* 1971)

Solvent extraction studies of indium(III): Separation from gallium(III): M. B. CHAVAN and V. M. SHINDE. (31 *December* 1971)

Acenaphthenequinone monoxime as a selective reagent for the spectrophotometric determination of platinum(IV) by solvent extraction: S. K. SINDHWANI and R. P. SINGH. (31 *December* 1971)

Microanalysis of sulphide, sulphite, sulphate and thiosulphate by thin-layer chromatography and ring-colorimetry: A. C. HANDA and K. N. JOHRI. (31 *December* 1971)

Bestimmung des Komplextypus von dissoziierten Komplexen mit Hilfe transformierter Titrationskurven: J. BORÁK, Z. SLOVÁK and J. FISCHER. (5 *January* 1972)

Applications involving the iodide ion—X. Determination of copper and analysis of its mixtures with some other cations: H. KHALIFA and E. A. EL-GAZZAR. (5 *January* 1972)

Selective detection of bismuth(III) and iron(II) with certain new reagents: G. S. JOHAR. (5 *January* 1972)

New tests for the detection of azide: G. S. JOHAR. (5 *January* 1972)

The application of photon counting in atomic-absorption spectrophotometry: R. M. DAGNALL, B. L. SHARP and T. S. WEST. (14 *January* 1972)

On the problem of increasing the sensitivity of anodic stripping voltammetry: LUDMILA HUDEROVÁ and KAREL ŠTULÍK. (18 *January* 1972)

Talanta, 1972, Vol. 19, p. i. Pergamon Press. Printed in Northern Ireland

PAPERS RECEIVED

Rapid colorimetric determination of indoxyl acetate: R. J. Nadalin. (31 *October* 1971)

Trennungsfreie Bestimmungen der Erdalkalimetalle—Calcium, Strontium, Barium—mit Hilfe der AAS: Gerhard M. Neumann. (5 *November* 1971)

Precipitation of barium chromate in the presence of strontium and lead by complexation followed by volatilization of ammonia: F. H. Firsching and Paul H. Werner. (9 *November* 1971)

Reversible electrode reactions: Reduction of Cd–malonate–oxalate complex at the D.M.E.: S. C. Khurana and C. M. Gupta. (18 *November* 1971)

Nouvelle microméthode colorimétrique pour le dosage des nitrites: Camelia Ghimicescu and Vasile Dorneanu. (23 *November* 1971)

Formation of nickel, cobalt(II), manganese(II) and cadmium ferrocyanides—II: Athos Bellomo, Domenico De Marco and Agatino Casale. (23 *November* 1971)

Gallacetophenone as an analytical reagent for tantalum: R. Raghava Naidu. (29 *November* 1971)

Extraction with long-chain amines—VI. Polarographic determination of uranium: Rudolf Přibil, Jr. and Jiří Adam. (30 *November* 1971)

Selective extraction and spectrophotometric determination of copper as phenylacetate: Jiří Adam and Rudolf Přibil. (30 *November* 1971)

Analytical chemistry in Japan: Taitiro Fujinaga. (1 *December* 1971)

A general multiparameter least-squares curve-fitting computer program and some of its applications: Thelma Meites and Louis Meites. (1 *December* 1971)

Study of chromium hydroxide precipitated from homogeneous solution: M. N. Sastri and J. Rajagopala Rao. (2 *December* 1971)

Determination of and differentiation between cassiterite and silicate-lattice-bound tin in silicate rocks containing traces of tin: J. Agterdenbos and J. Vlogtman. (5 *December* 1971)

Spectrophotometric determination of copper in alkaline solutions and evaluation of some hydroxy-substituted 1,10-phenanthrolines as chromogenic reagents: W. E. Dunbar and A. A. Schilt. (6 *December* 1971)

Cation-exchange separation of alkaline earths, using mixed solvent eluents: R. P. Bhatnagar and S. L. Garde. (6 *December* 1971)

Candoluminescence—a new flame technique for trace analysis—I. Determination of bismuth: R. Belcher, S. Bogdanski and A. Townshend. (6 *December* 1971)

Photometric complex-formation titrations of submicromole amounts of metals—III. Back-titrations: J. Kragten. (10 *December* 1971)

A simple non-selective detector for gas-phase chromatography, using the measurement of reflected microwave power: R. M. Dagnall, M. D. Silvester, T. S. West and P. Whitehead. (10 *December* 1971)

Indirect atomic-absorption spectrophotometry for determination of ppM levels of arsenic by combustion of MIBK extract of arsenomolybdic acid: Y. Yamamoto, T. Kumamaru, Y. Hayashi, M. Kanke and A. Matsui. (13 *December* 1971)

Modifications of the computer programme SCOGS: W. A. E. McBryde and J. L. McCourt. (13 *December* 1971)

ADVISORY BOARD OF TALANTA

The Editorial Board and Publishers of *Talanta* take pleasure in welcoming the following new members to the Advisory Board of the journal.

A. CORSINI J. JORDAN
F. BERMEJO-MARTINEZ
L. E. SMYTHE A. TOWNSHEND

They also wish to record their sincere thanks for the help given by

M. L. DIMBAT S. GREENFIELD
K. J. KARRMAN K. ISSLEIB
R. E. SIEVERS W. SIMON
E. STAHL

who retire from the Advisory Board.

PROFESSOR ALFIO CORSINI was born in Hamilton, Ontario in 1934, and graduated from McMaster University, B.Sc. in 1956 and Ph.D. in 1961. He worked as Research Associate with Professor Freiser in Arizona from 1961 to 1963 and has served on the staff of McMaster University since, first as Assistant Professor, and as Associate Professor since 1968. His research interests are the chemistry of analytically useful chelates, especially factors affecting selectivity, complexes of oxine and its derivatives, and trace analysis by fluorescence and atomic-absorption methods. He is married, with two children, and his hobbies are gardening, athletics and reading.

JOSEPH JORDAN, M.Sc., Ph.D., is a Professor of Chemistry at the Pennsylvania State University, where he has chaired the analytical area committee since 1960. He has authored and co-authored about a hundred research papers, and several authoritative reviews on electroanalytical chemistry, thermochemical titrimetry and enthalpimetric analysis. Professor Jordan's contributions include: development of hydrodynamic voltammetry, direct injection enthalpimetry, thermo-kinetic analysis and gas enthalpimetry; the use of mixed carrier gases in gas chromatography and quantitation based on considerations of kinetic theory; thermometric enthalpy titrations in molten salts; kinetics and mechanisms of electrode reactions and electron transfer; electrochemical models of haemoproteins; calorimetric titrations of antibodies and antigens and the thermochemistry of immunological processes; polarography, rotating disk electrode voltammetry and redox chemistry in fused salts at elevated temperatures.

Professor Jordan has served as chairman (1967–71) of the Commission on Electrochemistry of the International Union of Pure and Applied Chemistry (IUPAC) and is currently a titular member of IUPAC's Physical Chemistry Division Committee.

PROFESSOR F. BERMEJO-MARTINEZ was born in Corunna, Spain. He studied chemistry and pharmacy at the Santiago de Compostela University in Spain, where he got his diploma with *extraordinary prize* in 1943. A few years later he took his Doctor of Chemical Sciences degree, *cum laude* at the Madrid University in 1948. After completing his university studies he worked with Professor J. González-Carreró in the "Montequi Institute for Inorganic and Analytical Chemistry" of the Faculty of Pharmacy in Santiago de Compostela as Assistant Professor. In 1950 he became Professor of Analytical Chemistry at Oviedo University, and in 1951 in the Faculty of Sciences of Santiago de Compostela University. He is now Head of the Analytical Department in this University and Chief of the Analytical Chemistry Section of the High Conseil Scientific Research in Santiago de Compostela. His main scientific activities are in the field of analytical applications of EDTA and analogous reagents and in microanalysis. His book *Analytical Applications of EDTA and Analogues*, though published in Spanish, is well known to specialists throughout the world. He is a member of 16 scientific societies in Spain and abroad. His academic books *Handbook of Quantitative Analytical Chemistry* and *Numerical Calculations in Analytical Chemistry* are used by many students and professional analysts. His editorial activity comprises 8 books and translations from English, French and German, and he is the founder and editor of the *Acta Científica Compostelana*. His scientific publications number about 140, half on analytical applications of EDTA *etc*, and half in other fields of analytical chemistry. He is married and has nine children (4 boys and 5 girls) aged between 21 and 7 His hobbies are scientific documentation, gardening, and swimming.

DR. ALAN TOWNSHEND has been a lecturer in Analytical Chemistry at the University of Birmingham since 1966, where he had obtained the degrees of B.Sc. (1960) and Ph.D. (1963). After spending one year as a Research Fellow with Dr. Louis Gordon at Cleveland, he returned to Birmingham as an Assistant Lecturer in 1964. His research interests are in catalytic and enzymatic methods of trace analysis, gravimetry, solution and flame spectroscopy, polarography and many other aspects of analytical chemistry. Dr. Townshend is Hon. Treasurer of the Midlands Region of the Society for Analytical Chemistry and Recorder of the Midlands Association for Qualitative Analysis.

Professor Lloyd E. Smythe graduated in Australia and did research at Cambridge before joining the Analytical Group at Harwell. After working with A. A. Smales for several years he was appointed as Head of the Analytical Group of the Australian Atomic Energy Commission Establishment at Lucas Heights. He left that position in 1969 to become the first Professor of Analytical Chemistry in an Australian University, the University of New South Wales. There he has built up a flourishing research group working on trace analysis by flame spectroscopy and spectrofluorimetry, on analytical instrumentation, and on instrument design. He was elected Federal President of the Royal Australian Chemical Institute in 1970.

LOUIS GORDON MEMORIAL AWARD

Dr. Chalmers presenting the 1971 Louis Gordon Memorial Award to Dr. Sue Humphries and Dr. Gordon Briscoe

Talanta, 1972, Vol. 19, p. i. Pergamon Press. Printed in Northern Ireland

PAPERS RECEIVED

Stepwise formation of bivalent metal complexes with 4-hydroxy-3-oximinomethylazobenzene: P. N. Mohan Das, O. P. Sunar and C. P. Trivedi. (5 *June* 1972)

Acid-base equilibria in ethylene glycol—I. Definition of pH and determination of p*K*-values of acid-base indicators: P. Zikolov and O. Budevsky. (19 *June* 1972)

Separation of lithium from Dead Sea brines by gel-permeation chromatography: M. Rona and G. Schmuckler. (19 *June* 1972)

Amperometrische Bestimming der Metalle unter Anwendung von Thioacetamid—XI. Untersuchungen über Cu_2S-Bildungsgeschwindigkeit in Ammoniakalischen Cu^+-Ionen Lösungen mittels Thioacetamid: Maria Pryszczewska. (19 *June* 1972)

Atomic-absorption and emission spectrometry of mercury at 184·9 nm: R. M. Dagnall, J. M. Manfield, M. D. Silvester and T. S. West. (20 *June* 1972)

Potentiometric determination of stepwise stability constants of vanadium, molybdenum and tungsten chelates formed with asparagine and glutamine: R. C. Tewari and M. N. Srivastava. (20 *June* 1972)

Comparison of the ion-exchange behaviour of zirconium, thorium, vanadium, uranium, stannic and titanium tungstates: Mohsin Qureshi, Jai Prakash Gupta and Veenz Sharma. (20 *June* 1972)

Extraktion der Metallionen Cr(III), Fe(III), Co(II), Ni(II), Cu(II) and Zn(II) mit geschmolzenem Oxin und Bestimmung der extrakierten Metalle mit Hilfe von Röntgenfluoreszenz: B. Magyar and F. I. Lobanov. (20 *June* 1972)

Extractive spectrophotometry of the molybdenum(III) 1,10-phenanthroline thiocyanate and 2,2′-dipyridyl thiocyanate complexes: Amal Kanti Bhadra and Siddheswar Banerjee. (21 *June* 1972)

Indirect atomic-absorption determination of boron by solvent extraction as the tris(1,10-phenanthroline) cadmium–tetrafluoroborate ion-pair: Y. Hayashi, S. Matsushita, T. Kumamaru and Y. Yamamoto. (26 *June* 1972)

Talanta, 1972, Vol. 19, p. i. Pergamon Press. Printed in Northern Ireland

PAPERS RECEIVED

Logarithmic diagrams and Gran-curves as an aid in potentiometric titrations in complexometry: Axel Johansson. (18 *March* 1972)

Preparation and infrared spectra of palladium derivatives of some organophosphorus insecticides: T. F. Bidleman and R. W. Frei. (1 *May* 1972)

Atomabsorptionspektralphotometrische Bestimmung von Zink in Galliumarsenid und Galliumaluminiumarsenid: K. Dittrich and W. Zeppan. (3 *May* 1972)

Thermal, X-ray and neutron-activation investigation of compounds of niobium and tantalum: Fadhil Jasim. (17 *May* 1972)

Analysis of metals by solid–liquid separation after liquid–liquid extraction. Spectrophotometric determination of cadmium by extraction of cadmium oxinate with naphthalene: Masatada Satake. (22 *May* 1972)

Bestimmung ^{35}S-markierter Polythionate nach hochspannungsionophoretischer Trennung: E. Blasius and H. Wagner. (23 *May* 1972)

A proposed sampling constant for use in geochemical analysis: C. O. Ingamells and P. Switzer. (23 *May* 1972)

Potassium thiocarbonate (PTC) as a precipitant for osmium and iridium: K. N. Johri, N. K. Kaushik and Kiran Bakshi. (25 *May* 1972)

The acid stability constants of Alizarin Fluorine Blue: Folke Ingman. (27 *May* 1972)

The indirect polarographic determination of tripolyphosphate ions in the presence of other polyphosphates, with oxtyltin chloride: S. Shaw and A. Townshend. (29 *May* 1972)

A new titrimetric method: Thermoradiometric titration: J. Tölgyessy and J. Lesný. (30 *May* 1972)

Enthalpimetry of non-aromatic alkenes: D. W. Rogers and R. J. Sasiela. (30 *May* 1972)

Rapid chelometric determination of lead in lubricating oil *via* mercaptoacetate extraction: Samaresh Banerjee and R. K. Dutta. (7 *June* 1972)

Talanta 1972, Vol. 19, p. i. Pergamon Press. Printed in Northern Ireland

PAPERS RECEIVED

Determination of metals in organo-lanthanide compounds by the oxygen-flask method: P. Bonda, A. E. Crease and P. Legydins. (30 *March* 1972)

Raman spectrometric studies of aqueous borate complexes with ethylene glycol and mannitol: John Knoeck. (12 *April* 1972)

Metal complexation with 2-hydroxy-6-methylpyridine-3-carboxylic acid: Veena Kushwaha, R. P. Singh and Mohan Katyal. (21 *April* 1972)

Macro and semimicro infrared determination of nitrogen in raw nitrocellulose and nitrocellulose contained in propellants: George Norwitz and David E. Chasan. (21 *April* 1972)

Determination of phosphorus in phosphazenes and phosphines: Sanford L. Erickson. (24 *April* 1972)

Cadmium and silver sulphide-impregnated silicone rubber membranes as selective electrodes for cadmium ions: Hiroshi Hirata and Kenji Date. (24 *April* 1972)

On the nature of so-called "Khimdu": Yong Kuen Lee, Kyu Ja Whang and Keihei Ueno. (24 *April* 1972)

Limitations in Bishop's treatment and application of indicator parameters with reference to redox indicators: K. Sriramam. (26 *April* 1972)

Uses of liquid ion-exchangers in inorganic analysis: H. Green. (1 *May* 1972)

Determination of small amounts of water with coulometrically generated Karl Fischer reagent: Ronald Karlsson. (1 *May* 1972)

Pyrazine-2,3-dicarboxylic acid as an analytical reagent: Spectrophotometric determination of iron(II): G. S. Sanyal and S. Mookherjea. (3 *May* 1972)

Hydrogen peroxide formation upon oxidation of oxalic acid in presence and absence of oxygen and of manganese(II)—III. Iron(III) and copper(II) as retarders: I. M. Kolthoff, E. J. Meehan and Masaru Kimura. (5 *May* 1972)

Iron(II)—chloramine-T reaction: V. R. S. Rao and G. Aravamudan. (8 *May* 1972)

Nouvelle microméthode colorimétrique pour la détermination de l'ion I^-, comme microélement, dans des eaux et des produits organiques: Camelia Chimicescu, Maria Stan and Mujor Dragomir. (9 *May* 1972)

Electronic absorption and fluorescence of cinchophen, cinchoninic acid and their methyl esters: Biprotonic phototautomerism of the singly protonated species: B. Zalis, A. C. Capomacchia, D. Jackman and S. G. Schulman. (9 *May* 1972)

Locating the more acidic hydroxyl group on dihydroxy compounds. *o*, *o*′-Dihydroxyazo dye metal-ion indicators: Frederick Lindstrom and Ann Edwards Womble. (12 *May* 1972)

Direct polarography in the microdetermination of copper, lead, manganese and calcium in organometallic compounds after oxygen-flask combustion: S. W. Bishara and M. E. Attia. (16 *May* 1972)

Talanta, 1972, Vol. 19, p. i. Pergamon Press. Printed in Northern Ireland

PUBLICATIONS RECEIVED

Recent Advances in Gas Chromatography: I. I. DOMSKY and J. A. PERRY (Eds.) Dekker, New York, 1971. pp. xi + 414. $19.50.

The book consists of the typescripts of 17 lectures presented at short courses on Gas Chromatography. The reproduction, which is in the modern style, serves to emphasise the origins of the book. Some authors quite clearly were more concerned with delivering a lecture whereas others were also concerned with publication (or providing those attending the lecture with a good paper whilst they spoke of something else). The book is inevitably a pot pourri of discussion and comment on various aspects of GLC such as columns, flow patterns, detectors, computer link-ups, silylation, and applications to the analysis of lipids, pesticides and metabolites. There are also two chapters on gel permeation chromatography.

Most of the chapters contain useful practical information and present it in a straightforward, well-illustrated manner, but overall the rigour demanded of formal papers or books is lacking. It provides a useful survey, and many workers may wish to consult specific chapters, but overall one is left with the impression that, whilst the lectures may have been informative and entertaining, on their translation into book form they should have been expanded and edited.

The Determination of Impurities in Nuclear Grade Sodium Metal: L. Silverman, Pergamon, Oxford, 1971. pp. ix + 143. £3.75, $10.00.

The book appears to be a collection of laboratory procedures for the determination of impurities in sodium metal and also sodium chloride, hydroxide and carbonate. Most emphasis is placed on carbon and oxygen but procedures for the determination of Al, Bi, B, Cd, Ca, Mg, Cs, Cl, Cr, Co, Cu, H, I, Fe, Pb, Li, Nn, Ni, P, K, Si, S and U are also given. There is little theory but the text abounds with practical wisdom, which may be appreciated by many analysts, since the procedures described have a general applicability. The descriptions of procedures are clear and likely pitfalls are pointed out.

Analytical Photochemistry and Photochemical Analysis: J. M. FITZGERALD (Ed.) Dekker, New York, 1971. pp. xiv + 360. $23.50.

The editors hope that the contributions in this volume will bring the developments of photochemistry with analytical implications to the attention of analytical chemists and provide photochemists with a critical survey of useful analytical methods. In view of the rapid growth of photochemistry the work is timely and stimulating. Several useful and unusual determinations are described in a series of reviews by various authors. These deal with lasers in analytical chemistry, actinometry, photochemical titrations and methods for studying the photolysis of polymers and co-ordination compounds, and other related topics.

Analytical Emission Spectroscopy, Vol. 1, Part 1; E. L. GROVE (Ed.), Dekker, New York, 1971. pp. xvi + 401. £12.60.

This is the first part of a projected three part work. Judgment of the whole will have to await the appearance of the whole, but in its own right the first part is most valuable. It contains long articles on the historical development of emission spectroscopy, the origins of atomic spectra, prisms, gratings, prism and grating instruments and spectroradiometric principles. There is little that is new in all this but the spacious accounts of fundamentals are welcome. If the other volumes match this the set will prove an invaluable tome of reference.

ANALYTICAL DATA

An essential but little acclaimed part of scientific research is the measurement of accurate values of the many constants used in the development and application of theory. Development work is usually thought of as interesting and exciting, and careful measurement by established methods as being dull and somehow less praiseworthy. The onlooker is sometimes left with the sneaking suspicion that this attitude sometimes arises because its holder lacks either the patience or the skill necessary for work of the highest accuracy. Be that as it may, it is quite certain that without the consolidation provided by the many careful workers who garner values for constants, theory would not progress very far and would not be nearly so useful as a guide to action. One of the problems of workers in this field is that of publication. Their results are usually of value in several fields of chemistry, but strictly speaking belong to none in particular. A consequence of this is that publication committees are often tempted to suggest submission to some other journal than their own, and authors experience difficulty in finding a medium for publication of their work. One of their difficulties is that journal space is already at a premium, and editors are naturally reluctant to occupy it with details of standard procedures applied to individual problems. We therefore propose to begin a new feature in *Talanta*, to be called "Analytical Data", which will serve for publication of such results with the minimum of background information. Once a pattern of experimentation has been established, a reference to it is all that is necessary to indicate how the work was done. Of course, if there is a new development discovered in the course of such work, that is a different matter, and it can be mentioned in more detail and itself become the reference point for future publications. In this issue we present the first papers in this feature. They are a little longer than we would normally expect, simply in order to set the pattern.

Talanta, 1972, Vol. 19, pp. i to ii. Pergamon Press. Printed in Northern Ireland

PAPERS RECEIVED

Applications of flow microcalorimetry to analytical problems—I. Determination of organophosphorus pesticides by inhibition of cholinesterase enzyme: A. E. Beezer and C. D. Stubbs. (12 *January* 1972)

The acid ionization constants of 2,3-quinoxalinedithiol: J. A. W. Dalziel and A. K. Slawinski. (20 *January* 1972)

The decomposition of hypobromite solutions: N. Velghe and A. Claeys. (26 *January* 1972)

The adsorption of silver on potassium cobalt(II) ferrocyanide: M. Wald, W. Soyka and B. Kaysser. (28 *January* 1972)

Spectrophotometric study of metal pyrogallol complexes: Osmar Nudelman and José A. Catoggio. (1 *February* 1972)

Effect of the addition of quaternary ammonium salts in the extraction of metal-pyrogallol complexes: Osmar Nudelman and José A. Catoggio. (1 *February* 1972)

Detection of nitroprusside by oxidation to nitrite: G. S. Johar. (4 *February* 1972)

The determination of manganese by atomic-fluorescence spectroscopy using a carbon-filament atom-reservoir: L. Ebdon, G. F. Kirkbright and T. S. West. (4 *February* 1972)

Spectrophotometric studies on complexes of some rare-earths with 1-amino-4-hydroxyanthraquinone: A. K. Jain, V. P. Aggarwala, Puran Chand and S. P. Garg. (7 *February* 1972)

Quantitative solvent extraction, spectrophotometric, and gravimetric determination of Cu(II) by metal-exchange in metal–acetylacetonate complexes: M. M. Aly. (7 *February* 1972)

Nomenclature in thermal analysis—II: R. C. Mackenzie, C. J. Keattch, D. Dollimore, J. A. Forrester, A. A. Hodgson and J. P. Redfern. (8 *February* 1972)

Coulometric titration of acids in isopropanol—I. A rapid, direct method for the determination of carbon in steel: B. Metters, B. G. Cooksey and J. M. Ottaway. (9 *February* 1972)

Arsenic(III)–chromium(VI) titration with visual end-point indication: K. Sriramam. (11 *February* 1972)

Fluoride determination with a micro flow-calorimeter: Carl E. Johansson. (15 *February* 1972)

Potentiometric titration of heterocyclic nitrogen bases in non-aqueous media: K. C. Mohan Rao and P. R. Naidu. (15 *February* 1972)

Radiochemical separation of zirconium and hafnium from other radionuclides: Richard B. Hahn. (17 *February* 1972)

Quick, successive determination, in the same sample, of Ca^{2+}, Mg^{2+}, Na^{+}, or other alkali metals, SO$_4^{2-}$ and Cl^{-}: D. Ceauşescu, Ana Sârbu and Maria Aşteleanu. (17 *February* 1972)

Identification de submicroquantités d'iode: N. Gantchev, D. Athanassova and V. Bogdanova. (17 *February* 1972)

Some observations on the redox behaviour of *N*-phenylanthranilic acid indicator in iron(II) titrations: K. Sriramam. (22 *February* 1972)

Application of back-titration of excess EDTA with mercury(II) to the analysis of ores: H. Khalifa and A. I. Atalla. (22 *February* 1972)

The analytical chemistry of melatonin: E. R. Cole and G. Crank. (23 *February* 1972)

Mössbauer investigation of iron-aluminium mixed oxides: L. Korecz, I. Kurucz, G. Menczel, E. Papp-Molnar, E. Pungor and K. Burger. (23 *February* 1972)

Analytical study of the Cu(II)–hydrazine-6-methylpicolinaldehyde system. A new "*in situ*" reaction type: M. Valcarcel and F. Pino. (23 *February* 1972)

Synthesis and ion-exchange properties of ceric antimonate. Separation of Hg^{2+} from Zn^{2+}, Cd^{2+}, **Pb^{2+} and Tl^{+}; Cu^{2+} from Mn^{2+}; Fe^{3+} from Al^{3+}; and Zr^{4+} from Th^{4+};** J. S. Gill and S. N. Tandon. (25 *February* 1972)

The determination of the optimum working range from an auto-analyser calibration curve for colorimetric analysis: D. Whitehead. (28 *February* 1972)

Investigations of dioximes and their metal complexes. A survey of the literature since 1963: Birgitta Egneus. (28 *February* 1972)

Studies on copper(II) sulphide ion-selective electrodes: Gillis Johansson and Kerstin Edström. (1 *March* 1972)

Spectrophotometry of the platinum metals in the ultraviolet region—I. The chloro-complexes of platinum, palladium, rhodium and iridium: Jan Vorlíček and Jan Doležal. (1 *March* 1972)

Talanta, 1972, Vol. 19, pp. i to ii. Pergamon Press. Printed in Northern Ireland

PAPERS RECEIVED

Microtitrimetric determination of uranium in tributylphosphate (30%)–n-dodecane–nitric acid medium in in the presence of excess of iron, magnesium and aluminium: V. Mareška and V. Šraier. (20 *July* 1972)

Spectrophotometric microdetermination of hydroxytriazenes: D. N. Purohit and Kusum C. Goswami. (1 *August* 1972)

2,2′-Dimercaprodiethylsulphide: A potential analytical reagent: A. Corsini and E. Nieboer. (12 *August* 1972)

A mass spectrometric study relating to aspects of the deterioration of polystyrene-based ion-exchangers: G. M. Armitage and S. J. Lyle. (22 *August* 1972)

Coulometric titration of acids in isopropyl alcohol—II. Electrode reactions with lithium chloride and tetraethylammonium bromide as supporting electrolytes: B. G. Cooksey, B. Metters, J. M. Ottaway and D. W. Whymark. (24 *August* 1972).

Calculation of chemical equilibrium concentrations of complexing ligands and metals: A flexible computer programme taking account of uncertainty of formation-constant values: G .A. Cumme. (6 *September*, 1972)

Application of n-(2-acyl-1,3-indandione-1-hydrazone)trialkylammonium iodides-a new group of reagents for the carbonyl group: M. K. Bachlaus and K. L. Menaria. (8 *September* 1972)

Emission-spectrometry detection of metal chelates separated by gas chromatography: Hiroshi Kawaguchi, Takeshi Sakamoto and Atsushi Mizuike. (11 *September* 1972)

Potentiometric determination of stepwise stability constants of zirconium, thorium, and uranium chelates formed with asparagine and glutamine: R. C. Tewari and M. N. Srivastava. (18 *September* 1972)

A study on the theory of action of reversible redox indicators: K. Sriramam. (21 *September* 1972)

Spectrophotometric study of complexes of Zr(IV), Th(IV) and U(VI) nitrates with 1-amino-4-hydroxyanthraquinone: A. K. Jain, V. P. Aggarwala, Puran Chand and S. P. Garg. (21 *September* 1972)

Dichloramine-T as a new oxidimetric titrant in non-aqueous and partially aqueous media: V. Rajasekharan Nair and C. G. Ramachandran Nair. (21 *September* 1972)

Electronic absorption and fluorescence of 9-anthraldehyde and its conjugate cation: John F. Young and Stephen G. Schulman. (28 *September* 1972)

Synthesis and ion-exchange properties of ceric tungstate. Separation of Hg^{2+} from Zn^{2+}, Cd^{2+} and Pb^{2+}; Co^{2+} from Mn^{2+} and Fe^{3+}(and Al^{3+} from Cr^{3+} and Fe^{3+}: J. S. Gill and S. N. Tandon. (3 *October* 1972)

Titrimetric microdetermination of 1,1–diphenyl-2-picryl hydrazal: B. N. Misra, S. K. Gupta and O. C. Saxena. (10 *October* 1972)

Suppression of interference by ammonium bifluoride in the AAS determination of chromium: A. Purushottam, P. P. Naidu and S. S. Lal. (10 *October* 1972)

Application of zone-melting to metal chelate systems—VI. Computer-assisted considerations on the solute distribution in zone melting: Shigeru Maeda, Hiroshi Kobayashi and Keihei Ueno. (11 *October* 1972)

Application of zone melting to metal chelate systems—VII. A new apparatus for zone-melting chromatography: Shigeru Maeda, Hiroshi Kobayashi and Keihei Ueno. (11 *October* 1972)

Reaction of Cu(II) and Cu(I) with 1-isonitroso-(1,2,3,4)-tetrahydrophenazine. Spectrophotometric investigation: Carla Bertoglio Riolo, Teresa Soldi and Giovanni Spini. (12 *October* 1972)

Thin-layer chromatographic method for the separation and determination of papaverine and its oxidation products: G. M. Habashy and Nagy A. Farid. (16 *October* 1972)

Stripping voltammetry with collection at a rotating ring–disc electrode: Dennis C. Johnson and Robert E. Allan. (11 *July* 1972)

Individual microdetermination of chlorine, bromine and iodine in halogenated organic compounds by the oxygen-flask method: Alfy B. Sakla, S. B. Awad and S. A. Abo-Taleb. (29 *August* 1972)

Evaluation of carbon-red atomizer for routine analysis of trace metals by atomic-absorption spectroscopy. Applications to analysis of lubricating oil and crude oil: Gwen Hall, M. P. Bratzel, Jr. and C. L. Chakrabarti. (29 *August* 1972)

Aromatic sulphonate ion-selective electrode membrane using Crystal Violet as ion-exchange site: Nobuhiko Ishibashi, Hitoshi Kohara and Kazuo Horinouchi. (1 *September* 1972)

Development and publication of new methods in kinetic analysis: Harry B. Mark, Jr. (4 *September* 1972)

Determination of uranium content of natural waters by the fission-track technique: Tsuyoshi Takebayashi, Hideki Matsuda and Shunji Umemoto. (4 *September* 1972)

New applications of certain common organic dyes (acriflavine, pyridium, eosin and mercurochrome) in inorganic qualitative analysis. Detection of bromide, bromate, nitrite, thallium(I), lead(II), cadmium(II), copper(II) and iron(III): G. S. Johar. (11 *September* 1972)

A comparative study of some titanium(IV)-based exchangers in a few aqueous and mixed solvent systems: Mohsin Qureshi, Nighat Zehra, Syed Ashfaq Nabi and Virendra Kumar. (12 *September* 1972)

The signal vs. concentration relationships in fluorimetry: R. van Slageren, G. den Boef and V. E. van der Linden. (12 *September* 1972)

Simultaneous determination of *N*-unsubstituted- and *N*-substituted nitroazoles and criteria for their identification—I. Nitroimidazoles and nitropyrazoles-Polarographic determination: Dragica Dumanović and Janka Čirić. (12 *September* 1972)

Chelometric determination of Zn^{2+} or Cd^{2+} in presence of Hg^{2+} by use of thiosalicylic acid as masking agent: M. K. Koul and K. P. Dubey (13 *September* 1972)

Selective extraction and photometric determination of molybdenum in alloy steels: K. Venugopala Rao, K. Ananthanarayana Rao and B. V. Shankar. (13 *September* 1972)

Catalytic hydrogen wave of pre-sodium type formed by selenocystine: V. Voicu and A. Călușaru. (18 *September* 1972)

A general method for the solution of polynomial equations in hydrogen-ion concentration calculations: M. J. D. Brand. (17 *September* 1972)

Gravimetric determination of uranium(VI) with pyridine-2,6-dicarboxylic acid: G. Marangoni S. Degetto and U. Croatto. (27 *September* 1972)

Trace analysis by microwave excitation of sealed samples—I. Preliminary investigations: A. van Sandwijk, P. F. E. van Montfort and J. Agterdenbos. (2 *October* 1972)

Separation of nitroanilines by gas–liquid chromatography: Sabri M. Farrouha, Albertine E. Habboush and Yana A. Barsoum. (17 *October* 1972)

Sulpholane as colour-enhancing and stabilizing agent for silicomolybdic acid: H. Flaschka and J. J. Tice IV. (18 *October* 1972)

The use of hydrazine sulphate as a primary standard for the titrimetric determination of vanadium(V) and chromium(VI): P. V. Krishna Rao and G. Gopala Rao. (19 *October* 1972)

SIXTH TALANTA MEDAL

In his capacity as Chairman of the Advisory Board, Professor R. **Belcher** (on right) presents the Sixth Talanta Medal to Dr. R. **Přibil** (Czechoslovakia). The award was made for Dr. **Přibil**'s outstanding contribution to analytical chemistry in his development of numerous practical applications of complexometric reagents (see *Talanta*, 1971 **18** *facing* 1175).

Professor A. A. VLČEK, Director of the Polarographic Institute of J. Heyrovský, examines the Medal. Much of Dr. PŘIBIL's work on complexometry has been carried out in the Laboratory of Analytical Chemistry of the Polarographic Institute, Czechoslovak Academy of Sciences.

The presentation was made in Prague during April 1972 at the Polarographic Institute. Amongst the guests were Mrs. Heyrovský (above), wife of the late Professor J. Heyrovský. An Honour Issue of *Talanta* (December 1968) was published to celebrate the seventy-fifth year of Professor Heyrovský.

SUBJECT INDEX

SUMMARIES FOR CARD INDEXES

Ion-selective chalcogenide electrodes for a number of cations: HIROSHI HIRATA, and KENJI HIGASHIYAMA, *Talanta*, 1972, **19**, 391. (Wireless Research Laboratory, Matsushita Electric Industrial Co., Ltd., Kadoma, Osaka, Japan.)

Summary—Ion-selective chalcogenide disc electrodes have been developed which are responsive to cations such as silver, lead, chromium(III), nickel, cobalt(II), cadmium, zinc, copper(II), and manganese(II) ions. Each was prepared by using the corresponding metal chalcogenide with silver sulphide. An electrode was assembled with both a compacted and a sintered disc. The sintered electrodes were more sensitive and stable than the compacted ones. Response to silver ion was 59·5 mV/pAg, to lead, nickel, cadmium, zinc and copper(II) 29·5 mV/pM and to chromium(III) 20 mV/pM. Cobalt(II) and manganese(II) electrodes had a non-Nernstian response of 25 mV/pM. Both selenides and tellurides can be used for potentiometric determination, but the manganese(II) electrode serves as an analytical tool only when the disc consists of manganese(II) telluride and silver sulphide.

Stalagmometric titrations: TOMIHITO KAMBARA and TOMOE KIBA, *Talanta*, 1972, **19**, 399. (Department of Chemistry, Faculty of Science, Hokkaido University, Saporo, Japan.)

Summary—End-point detection in some precipitation titrations is achieved by measurement of the surface tension between mercury and the solution ("stalagmometric" titration). The drop-time of a polarographic dropping mercury electrode in open circuit is plotted against volume of surface-active titrant added, and shows a break or a peak at the end-point. The stalagmometric titration of sodium tetraphenylborate with Zephiramine (tetradecyldimethylbenzylammonium chloride) was satisfactory and made possible the determination of potassium by back-titration. Potassium was also titrated directly with tetraphenylborate and with calcium dipicrylaminate. Sodium dodecylbenzenesulphonate was titrated directly with Zephiramine and the results were compared with those obtained by the *p*-toluidine method and Epton's method.

Investigation of manganese(III) fluoride for coulometric titration: M. KATOH and T. YOSHIMORI, *Talanta*, 1972, **19**, 407. (Faculty of Engineering, Science University of Tokyo, Shinjuku-ku, Tokyo, Japan.)

Summary—A study has been made of the use of electrogenerated manganese(III), in an electrolyte containing fluoride, for coulometric titration. The addition of fluoride prevented the deposition of manganese dioxide on the anode, and was responsible for increase of the current efficiency and for extension of the feasible range of current density, owing to complex formation between manganese(III) and fluoride. The bonding ratio, the apparent stability constant and the redox potential of the complex were also estimated from the Nernst equation and the current-potential curves.

ИОН-СЕЛЕКТИВНЫЕ ХАЛЬКОГЕНИДНЫЕ ЭЛЕКТРОДЫ ДЛЯ РЯДА КАТИОНОВ:

HIROSHI HIRATA and KENJI HIGASHIYAMA, *Talanta*, 1972, **19**, 391.

Резюме—Разработаны халькогенидные дисковые ион-селективные электроды, чувствительные к таким катионам, как серебро, свинец, хром(III), никель, кобальт(II), кадмий, цинк, медь(II) и марганец(II). Диск изготовлен из соответствующего металлического халькогенида с сернистым серебром. Один электрод собран из компактного и спекшегося дисков. Спекшиеся электроды более чувствительны и устойчивы, чем компактные. Чувствительность к иону серебра была 59,5 mV/pAg, к свинцу, никелю, кадмию, цинку и меди(II) 29,5 mV/pM, а к хрому(III) 20 mV/pM. Электроды из кобальта(II) и марганца(II) имели чувствительность 25 mV/pM (не по Нернсту). Как селениды, так и теллуриды могут применяться для потенциометрического определения, но марганцовый(II) электрод служит для анализа только тогда, когда диск состоит из марганцового(II) теллурида и серебряного сульфида.

СТАЛАГМОМЕТРИЧЕСКОЕ ТИТРОВАНИЕ:

TOMIHITO KAMBARA and TOMOE KIBA, *Talanta*, 1972, **19**, 399.

Резюме—Обнаружение концевой точки титрования некоторых осаждений получается измерением поверхностного натяжения между ртутью и раствором («сталагмометрическое» титрование). Вычерчивается кривая времени падения капель полярографического капельного ртутного электрода в открытой цепи и объема добавленного поверхностно-активного титрующего вещества; кривая показывает перерыв или пик у концевой точки. Сталагмометрическое титрование тетрафенибората с Зефирамином (тетрадецилдиметил-бензиламмоний хлорид) дает удовлетворительные результаты и далает возможным определение калия обратным титрованием. Калий тоже титровался непосредственно тетрафенилборатом и кальцием дипикриламинатом. Натрий додецилбензолсульфонат титровался непосредственно Зефирамином и результаты сравнивались с полученным методом р-толуидиновым и методом Эптона.

ИССЛЕДОВАНИЕ ПРИМЕНИМОСТИ ФТОРИДА МАРГАНЦА(III) В КУЛОНОМЕТРИЧЕСКИХ ТИТРАЦИЯХ:

M. KATOH and T. YOSHIMORI, *Talanta*, 1972, **19**, 407.

Резюме—Изучена применимость электрогенерированного марганца(III), в фторидсодержащем электролите, в кулонометрических титрациях. Присутствие фторида предупреждает осаждение двуокиси марганца на аноде и вызывает повышение выхода по току и расширение применимой области плотности тока, вследствие образования комплекса марганца(III) с фторидом. Отношение связей, кажущаяся константа устоичивости и окислительно-восстановительный потенциал определены с использованием уравнения Нернста и кривых ток-потенциал.

Solvent extraction of anions with metal chelate cations—XVIII. Spectrophotometric determination of maleic acid in the presence of fumaric acid by solvent extraction with tris(1,10-phenanthroline)iron(II) chelate cations: Y. Yamamoto, T. Kumamaru and M. Muranaka, *Talanta*, 1972, **19**, 415. (Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda, Hiroshima, Japan.)

Summary—A new colorimetric method is proposed for the determination of maleic acid. Among aliphatic dicarboxylic acids tested, maleic acid was found to be selectively extracted into nitrobenzene as the red ion-association complex (λ_{max} 516 nm) formed between the hydrogen maleate anion and the tris(1,10-phenanthroline)iron(II) cation. At least a 32-fold molar excess of tris(1,10-phenanthroline)iron(II) relative to maleic acid is needed and the optimal pH range is 3–5. A linear relationship is obtained over the concentration range 10^{-5}–10^{-4} M maleic acid. The relative standard deviation was 1·0%. The colour intensity of the extract remains constant at room temperature for at least 24 hr. A large amount of fumaric acid, the *trans*-isomer of maleic acid, is not extracted under the same conditions. This makes it possible to determine maleic acid in the presence of fumaric acid.

Studies on interfacial electrochemical phenomena in pigment-vehicle systems: Yoshiaki Ōyabu and Yoshikazu Yasumori, *Talanta*, 1972, **19**, 423. (Nippon Paint Co. Ltd., 246 Kyu-Iketanaka, oaza-Ikeda, Neyagawa, Osaka Japan and Yanagimoto Mfg. Co., Ltd., 28 Joshungamae-cho, Shimotoba, Fushimi-ku, Kyoto, Japan.)

Summary—Sedimentation potentials under a centrifugal field are studied with the disperse system titanium dioxide, alkyd resin and xylene. The relationships between the sedimentation potential and the rotation speed, the distance apart of the electrodes in the cell and the total weight of particles in the disperse system are examined. From the theoretical evaluation of the initial sedimentation potential, the zeta potential of the pigment in the disperse system is calculated. The calculated value was almost coincident with that obtained by the electrophoretic method. As the sedimentation potential is proportional to the total weight of pigment in the space between the electrodes in the cell, the particle-size distribution of pigment can be obtained from the sedimentation potential-time curve. The particle-size distribution in the above-mentioned disperse system was examined with respect to the effect of rotation speed and the pigment content. The modal diameter for the particle-size distribution obtained by this method had almost the same value as that obtained by the electron microscope method. By use of this method for particle-size analysis, the particle-size distribution for particles of diameter <1 μm can be obtained in a short time (*ca.* 10–30 min) and the zeta potential of the particles in the disperse system can be calculated.

СЕЛЕКТИВНАЯ ЭКСТРАКЦИЯ АНИОНОВ МЕТАЛЛИЧЕСКИМИ ХЕЛАТНЫМИ КАТИОНАМИ—XVIII. СПЕКТРОФОТОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ МАЛЕИНОВОЙ КИСЛОТЫ В ПРИСУТСТВИИ ФУМАРОВОЙ КИСЛОТЫ СЕЛЕКТИВНОЙ ЭКСТРАКЦИЕЙ ХЕЛАТНЫХ КАТИОНОВ ТРИ (1,10-ФЕНАНТРОЛИН) ЖЕЛЕЗА (II):

Y. YAMAMOTO, T. KUMAMARU and M. MURANAKA, *Talanta*, 1972, **19**, 415.

Резюме—Предлагается новый колорометрический метод для определения малеиновой кислоты. Среди исследованных алифатических дикарбоновых кислот оказалось, что малеиновая кислота селективно экстрагируется в нитробензол как красный ассоциированный ионный комплекс ($\lambda_{\text{макс}}$ 516 нм), образованный анионом малеинового водорода и катионом три (1,10-фенантролин) железа(II). Требуется молярный излишек три (1,10-фенантролин) железа(II) по крайней мере в 32 раза больше чем малеиновой кислоты, оптимальные пределы pH от 3 до 5. Получено линейное соотношение концентраций малеиновой кислоты 10^{-5}–10^{-4} M. Относительное стандартное отклонение было 1,0 %. Интенсивность цвета экстракта остается постоянной при комнатной температуре по крайней мере в течение 24 час. Большое количество фумаровой кислоты, транс-изомера малеиновой кислоты, не экстрагируется при тех же условиях. Это делает возможным определение малеиновой кислоты в присутствии фумаровой кислоты.

ИССЛЕДОВАНИЯ ЭЛЕКТРОХИМИЧЕСКИХ ЯВЛЕНИЙ НА ГРАНИЦЕ РАЗДЕЛА СИСТЕМ ПИГМЕНТ-НОСИТЕЛЬ:

YOSHIAKI ŌYABU and YOSHIKAZU YASUMORI, *Talanta*, 1972, **19**, 423.

Резюме—Изучались потенциалы осаждения в поле центробежных сил дисперсной системы двуокись титана, алкидная смола и ксилол. Исследовались взаимоотношения между потенциалом осаждения и скоростью вращения, расстоянием между электродами в ячейке и общим весом частичек в дисперсной системе. Zeta-потенциал пигмента в дисперсной системе высчитывался из теоретической оценки исходного потенциала осаждения. Высчитанная величина почти совпадала с величиной, полученной методом электрофореза. Так как потенциал осаждения пропорционален общему весу пигмента в расстоянии между электродами в ячейке, то можно было получить распределение частичек пигмента по размерам из кривой потенциал осаждения—время. Распределение частичек по размерам в вышеуказанной дисперсной системе исследовалось в отношении влияния скорости вращения и содержания пигмента. Модальный диаметр для распределения размеров частичек, полученный этим методом имел почти такую же величину, как и полученный при помощи электронного микроскопа. Использование этого метода анализа размеров частичек дает возможность получать распределение частичек по размерам для диаметров частичек <1 μм в течение короткого времени (около 10–30 мин) и высчитывать Zeta-потенциал частичек в дисперсной системе.

Mechanism and analytical aspects of the polarographic maximum wave of tellurium: MUTSUAKI SHINAGAWA, NOBUYUKI YANO and TAKEYUKI KUROSU, *Talanta*, 1972, **19**, 439. (Department of Nuclear Engineering, Faculty of Engineering, Osaka University, Yamadakami, Suita-shi, Osaka, Japan.)

Summary—The polarogram of tellurium(IV) in weakly basic solution has a sharp maximum on the diffusion current plateau. The electrode process causing this maximum has been examined by means of various techniques such as semiconductor catalysis, "block" polarography and ultraviolet irradiation of the dropping mercury electrode. The maximum was found to be caused by the catalytic wave of hydrogen produced by the tellurium deposited on the mercury surface. Part of the tellurium is reduced to hydrogen telluride by nascent hydrogen formed catalytically. The brown mist which usually appears in the vicinity of the surface of the dropping mercury cathode consists of elemental tellurium produced by the decomposition of the hydrogen telluride near the electrode. The sudden decrease in the current maximum at a potential more negative than the peak potential of the maximum is due to desorption of tellurium, caused by movement of mercury.

Separation and determination of ruthenium by evolution with chromium(VI)–condensed phosphoric acid reagent: TOSHIYASU KIBA, KIKUO TERADA, TOMOE KIBA and KAZUO SUZUKI, *Talanta*, 1972, **19**, 451. (Laboratory for analytical Chemistry, Department of Chemistry, Faculty of Science, Kanazawa University, Marunouchi-1, Kanazawa, Ishikawa Pref., Japan.)

Summary—Ruthenium in various chemical forms can be evolved as the tetroxide from insoluble matrix materials by heating the sample with chromium(VI)–condensed phosphoric acid reagent (abbreviated as Cr(VI)–CPA). Because of its excellent decomposing power for various solid samples, condensed phosphoric acid is very useful in the chemical analysis of various insoluble materials, and when an oxidizing agent such as potassium dichromate is added in the CPA medium, drastic oxidation proceeds on heating. This method is now extended to the separation of ruthenium from marine sediments. During the reaction with Cr(VI)–CPA ruthenium tetroxide is evolved and collected in an absorbent solution of $6M$ hydrochloric acid and ethanol (1:1), and the ruthenium is then determined spectrophotometrically with thiourea or radiometrically by counting the β- or γ-activity. Osmium, which can be evolved as the tetroxide by the same treatment, can be eliminated beforehand by heating the sample with Ce(IV)–CPA, which removes osmium but not ruthenium. The successive distillations by means of Ce(IV)–CPA and Cr(VI)–CPA give satisfactory results for the separation between osmium and ruthenium. This method might be useful for the separation of ruthenium in geochemical or neutron-activation analysis.

МЕХАНИЗМ И АНАЛИТИЧЕСКИЕ АСПЕКТЫ ПОЛЯРОГРАФИЧЕСКОЙ МАКСИМАЛЬНОЙ ВОЛНЫ ТЕЛЛУРИЯ:

MUTSUAKI SHINAGAWA, NOBUYUKI YANO and TAKEYUKI KUROSU, *Talanta*, 1972, **19**, 439.

Резюме—Полярограмма теллурия(IV) в слабо-основном растворе имеет крутой максимум на части кривой, параллельной оси абсцисс диффузионного потока. Вызывающий этот максимум электродный процесс исследовался различными способами, как напр. полупроводниковым катализом, «блок-полярографией» и ультрафиолетовым облучением капельного ртутного электрода. Найдено, что максимум причиняет каталитическая волна водорода, образующегося теллурием, осажденном на поверхности ртути. Образующийся каталитически водород в момент выделения восстанавливает часть теллурия в теллуристый водород. Коричневый туман, обычно наблюдаемый у поверхности капельного ртутного катода, состоит из элементального теллурия, образующегося вследствие разложения теллуристого водорода у электрода. Внезапное уменьшение максимума потока у потенциала более негативного, чем потенциал максимального пика, происходит благодаря десорбции теллурия, причиняемой движением ртути.

ОТДЕЛЕНИЕ И ОПРЕДЕЛЕНИЕ РУТЕНИЯ ПУТЕМ ВЫДЕЛЕНИЯ С РЕАКТИВОМ ХРОМ(VI)-КОНДЕНСИРОВАННАЯ ФОСФОРНАЯ КИСЛОТА:

TOSHIYASU KIBA, KIKUO TERADA, TOMOE KIBA and KAZUO SUZUKI, *Talanta*, **19**, 451.

Резюме—Рутений в различных химических формах может быть выделен как четырёхокись из нерастворимых матричных материлов путем нагрева образца с реактивом хром(VI)-конденсированная фосфорная кислота (сокращ. Cr(VI)-CPA). Благодаря своей превосходной способности разложения различных твердых образцов конденсированная фосфорная кислота очень полезна для химических анализов различных нерастворимых материалов; когда же к среде концентр. фосфр. кислоты добавляется окислитель, как напр. бихромат калия, то при нагревании наступает бурное окисление. Этот метод теперь распространеа на отделение рутения из Морских осаждений. Во время реакции с Cr(VI)-CPA выделяется четырёхокись рутения и собирается в растворе поглотителя—6*M* соляной кислоты и этанола (1:1), затем рутений определяется спектроскопически с тиомочевиной, или радиометрически счетом активности β или γ Осмий, который может выделиться как четырёхокись тем же способом, может быть удален заранее нагревом образца с Cr(IV)-CPA, удаляющем осмий, оставляя рутений. Последующая дистилляция с помощью Ce(IV)-CPA и Cr(VI)-CPA дает удовлетворительное разделение осмия и рутения. Этот метод может быть полезен для отделения рутения в анализах геохимических или активацией нейтронов.

Trace analysis by flameless atomic-absorption spectrometry: Tsugio Takeuchi, Masaaki Yanagisawa and Masami Suzuki, *Talanta*, 1972, **19**, 465. (Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya, Japan, and Department of Industrial Chemistry, Faculty of Engineering, Mie University, Kamihama-cho, Tsu-shi, Mie-ken, Japan.)

Summary—The operating conditions of an atomic-absorption system based on flameless atomization have been investigated for trace analysis for Al, Cr, Cu, Fe, Mg and Mn. The sample solution on a tantalum strip was atomized by electrical heating in an inert atmosphere within an absorption chamber. This technique allows the use of small sample sizes and results in a higher sensitivity than that with the conventional flame technique. Some interference effects and applications were investigated.

Spectrophotometric determination of zirconium, uranium, thorium, and rare earths with Arsenazo III after extractions with thenoyltrifluoroacetone and tri-n-octylamine: Hiroshi Onishi and Keiichi Sekine, *Talanta*, 1972, **19**, 473. (Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki-ken, Japan.)

Summary—A method is described for the spectrophotometric determination of microgram amounts of zirconium, uranium(VI), thorium and rare earths with Arsenazo III after systematic separation by extraction. First zirconium is extracted into a xylene solution of thenoyltrifluoroacetone (TTA) from about 4*M* hydrochloric acid. Uranium(VI) is then extracted into a xylene solution of tri-n-octylamine from about 4*M* hydrochloric acid. Thorium is next extracted into TTA solution at pH about 1·5, and finally rare earths are extracted into TTA solution at pH about 4·7. Each metal is back-extracted from the organic phase before determination.

Formation and composition of the precipitates of various metal 8-selenoquinoline complexes: Eiichi Sekido, Isamu Fujiwara and Yoshitaka Masuda, *Talanta*, 1972, **19**, 479. (Department of Chemistry, Faculty of Science, Kobe University, Nada, Kobe, Japan).

Summary—The effect of acidity on the precipitation of various bivalent metal 8-selenoquinoline and 8-mercaptoquinoline complexes has been systematically studied and compared. The metal ions were Zn^{2+}, Cd^{2+}, Pb^{2+}, Mn^{2+}, Ni^{2+}, Cu^{2+} and Co^{2+}. Most of the metal ions, except copper(II) and cobalt(II), precipitate as a 1:2 complex, metal:ligand. However, in hydrochloric acid solution cadmium precipitates as $CdR_2{\cdot}2HCl$ and lead as $PbR_2{\cdot}2HCl$ or $PbR{\cdot}Cl$. Copper(II) is reduced to copper(I) and precipitates as $CuR{\cdot}RH$ at pH above 2·0 and as CuR in strongly acidic solution. Cobalt(II) does not give a precipitate of composition but appears to precipitate as a mixture of $CoR_2{\cdot}RH$ and fixed CoR_2 or as other complexes. The reasons for the formation of the various types of precipitate are considered.

АНАЛИЗ ПРОСЛЕЖИВАНИЕМ ПРИ ПОМОЩИ БЕСПЛАМЕННОЙ СПЕКТРОМЕТРИИ ПОГЛОЩЕНИЯ АТОМОВ:

Tsugio Takeuchi, Masaaki Yanagisawa and Masami Suzuki, *Talanta*, 1972, **19**, 465.

Резюме—Исследовались условия работы с системой атомного поглощения, основанной на беспламенном распылении, для анализа прослеживания Al, Cr, Cu, Fe, Mg, Mn. Раствор образца на танталовой пластинке распылялся электрическим нагревом в инертной атмосфере в абсорбционной камере. Этот метод, давая возможность пользоваться образцами небольших размеров, отличается б’ольшой чувствительностью, чем обычный метод пламенной спектрометрии. Были исследованы применения и некоторые влияния интерференции.

СПЕКТРОФОТОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ ЦИРКОНИЯ, УРАНА, ТОРИЯ И РЕДКОЗЕМЕЛЬНЫХ ЭЛЕМЕНТОВ С ИСПОЛЬЗОВАНИЕМ АРСЕНАЗО III ПОСЛЕ ЭКСТРАГИРОВАНИЯ ТЕНОИЛТРИФТОРАЦЕТОНОМ И ТРИ-Н-ОКТИЛАМИНОМ:

Hiroshi Onishi and Keiichi Sekine, *Talanta*, 1972, **19**, 473.

Резюме—Описан метод спектрофотометрического определения микрограммовых количеств циркония, урана(VI), тория и редкоземельных элементов с использованием Арсеназо III после систематического отделения экстракцией. Сперва экстрагируют цирконий раствором теноилтрифторацетона в ксилоле из приблизительно 4*M* соляной кислоты. Затем экстрагируют уран(VI) ксилоловым раствором три-н-октиламина из приблизительно 4*M* раствора соляной кислоты. Затем экстрагируют торий раствором ТТА при pH 1,5 и конечно редкоземельные элементы раствором ТТА при pH 4,7. Каждый металл титрируют из органической фазы перед определением.

ОБРАЗОВАНИЕ И СОСТАВ ОСАДКОВ РАЗЛИЧНЫХ МЕТАЛЛИЧЕСКИХ 8-СЕЛЕНОХИНОЛИН КОМПЛЕКСОВ:

Eiichi Sekido, Isamu Fujiwara and Yoshitaka Masuda, *Talanta*, 1972, **19**, 479.

Резюме—Проводились систематические исследования и сравнения влияния кислотности на осаждение различных двухвалентных металлов 8-селенохинолинового и 8-меркаптохинолинового комплексов. Ионы металлов были следующие: Zn^{2+}, Cd^{2+}, Pb^{2+}, Mn^{2+}, Ni^{2+}, Cu^{2+} и Co^{2+}. Большая часть металлических ионов, за исключением меди(II) и кобальта(II) осаждаются в виде комплекса 1:2—металл: лиганд. Однако, в растворе соляной кислоты кадмий осаждается в виде $CdR_2 \cdot 2HCl$, а свинец в виде $PbR_2 \cdot 2HCl$ или $PbR \cdot Cl$. Медь(II) восстанавливается в медь(I) и осаждается в виде $CuR \cdot RH$ при pH выше 2,0 и в виде CuR в крепком кислотном растворе. Кобальт(II) не дает определенного осадка, но осаждается в виде смеси $CoR_2 \cdot RH$ и CoR_2, или в виде других комплексов. Рассматриваются причины образования осадков различных типов.

Determination of phosphorus in hypereutectic aluminium–silicon alloys: KOHICHI MUKAI, *Talanta*, 1972, **19**, 489. (Nippon Light Metal Research Laboratory, Ltd., Kambara, Shizuoka, Japan.)

Summary—A reproducible method is described for determination of small amounts of phosphorus (from 0·0005% to 0·02%) in hypereutectic aluminium–silicon complex alloys. The method permits the separate determination of phosphorus in acid-soluble and acid-insoluble fractions. Phosphomolybdate is extracted with n-butanol–chloroform solvent mixture and back-extracted with a stannous chloride reducing solution. The phosphorus content of a sample cut into small pieces decreases during storage; loss of phosphorus is negligible on acid dissolution under oxidizing conditions.

Enhancement of polarographic reduction currents by a static magnetic field: SHIZUO FUJIWARA and YOSHIO UMEZAWA, *Talanta*, 1972, **19**, 497. (Department of Chemistry, Faculty of Science, University of Tokyo, Hongo 113, Tokyo, Japan.)

Summary—The effect of a magnetic field on d.c. polarographic reduction currents was studied with a static magnetic field applied perpendicularly to the dropping mercury electrode. In the presence of the magnetic field, diffusion or migration currents show a slight but distinct increase. The factors which can influence this effect have been examined experimentally. The effect is interpreted in terms of suppression of transfer of concentration polarization from one drop to the next. It is shown that certain types of maxima are enhanced by application of a magnetic field.

Spectrophotometric determination of water in organic solvents with solvatochromic dyes—II: SADAKATSU KUMOI, HIROSHI KOBAYASHI and KEIHEI UENO, *Talanta*, 1972, **19**, 505. (Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812, Japan.)

Summary—The correlation between the absorbance of a merocyanine dye in an organic solvent and the water content of the solvent has been investigated. The merocyanine dyes investigated are 1-methyl-4-[(4-oxo*cyclo*hexa-2,5-dienylidene)-ethylidene]-1,4-dihydropyridine (I), 1-methyl-4-[(2-oxo*cyclo*hexa-3,5-dienylidene)-ethylidene]-1,4-dihydropyridine, 1-methyl-2-[(4-oxo*cyclo*hexa-2,5-dienylidene)-ethylidene]-1,2-dihydropyridine and 1-methyl-2-[(oxo*cyclo*hexa-3,5-dienylidene)-ethylidene]-1,2-dihydropyridine, and the organic solvents are isopropanol, acetone, acetonitrile and pyridine. The possibility of determining a trace amount of water in an organic solvent is demonstrated, and a procedure is proposed for the determination of trace water in pyridine. The sensitivity of the method depends on the solvent, being more sensitive in an aprotic solvent than in a protic one; for example, 0·05 or 0·27 mg of water in 1 ml of acetonitrile or of isopropanol respectively can be detected with **I**, by use of an ordinary spectrophotometer.

ОПРЕДЕЛЕНИЕ ФОСФОРА В ГИПЕРЭВТЕКТИЧЕКИХ СПЛАВАХ АЛЮМИНИЯ И КРЕМНИЯ:

KONICHI MUKAI, *Talanta*, 1972, **19**, 489.

Резюме—Приведен воспроизводимый метод определения небольших количеств фосфора (0,0005% до 0,02%) в сложных гиперэвтектических сплавах алюминия и кремния. Метод позволяет определять фосфор отдельно в растворимых и нерастворимых в кислотах фракциях. Фосфомолибдат экстрагируют смесью н-бутанола и хлороформа и реэкстрагируют с восстанавливающим раствором хлорида олова. Количество фосфора содержанное в пробе разрезанной на маленкие куски уменьшается в течение лежания на складе. Потеря фосфора незначительна после растворения в кислоте при окислительных условиях.

УСИЛЕНИЕ ПОЛЯРОГРАФИЧЕСКИХ ТОКОВ ВОССТАНОВЛЕНИЯ В СТАТИЧЕСКОМ МАГНИТНОМ ПОЛЕ:

SHIZUO FUJIWARA and YOSHIO UMEZAWA, *Talanta*, 1972, **19**, 497.

Резюме—Изучено влияние магнитного поля на постояннотоковые полярографические токи восстановления с использованием статического магнитного поля перпендикулярно к капельному ртутному электрду. В присутствии магнитного поля обнаружено небольшое но ясное усиление диффузионных и миграционных токов. Изучены экспериментально факторы влияющие на этот эффект. Эффект объясняется подавлением переноса концентрационной поляризации от одной капли на другую. Показано что известные типы максимумов усилены действием магнтного поля.

СПЕКТРОФОТОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ ВОДЫ В ОРГАНИЧЕСКИХ РАСТВОРИТЕЛЯХ С СОЛЬВАТОХРОМНЫМИ КРАСИТЕЛЯМИ—II:

SADAKATSU KUMOI, HIROSHI KOBAYASHI and KEIHEI UENO, *Talanta*, 1972, **19**, 505.

Резюме—Исследовалось соотношение между поглощением мероцианиновых красителей в органических растворителях и содержанием воды в последних. Рассматривались следующие мероцианиновые красители: 1-метил-4-[(4-оксоциклогекса-2,5-диенилиден)-этилиден]-1,4-дигидропиридин(I), 1-метил-4-[(2-оксоциклогекса-3,5-диенилиден)-этилиден]-1,4-дигидропиридин, 1-метил-2-[(4-оксоциклогекса-2,5-диенилиден)-этилиден]-1,2-дигидропиридин и 1-метил-2[(2-оксоциклогекса-3,5-диенилиден)-этилиден]-1,2-дигидропиридин; органические растворители были следующие: изопропанол, ацетон, ацетонитрил и пиридин. Демонстрировалась возможность определения следов воды в органическом растворителе и предлагается процедура для определения следов воды в пиридине. Чувствительность метода зависит от растворителя, причем она больше в апротонном растворителе, чем в протонном; напр. 0,05 или 0,27 мгр воды в 1 мл ацетонитрила или изопропанола соответственно могут быть обнаружены I при пользовании обычным спектрофотометром.

Yields of photonuclear reactions for photon-activation analysis with high-energy Bremsstrahlung: Toyoaki Kato and Yoshinaga Oka, *Talanta*, 1972, **19**, 515. (Department of Chemistry, Faculty of Science, Tohoku University, Sendai, Japan.)

Summary—Experimental reaction yields have been determined for various types of photonuclear reactions, induced in 52 elements by means of Bremsstrahlung irradiation with maximum energies ranging from 30 to 72 MeV, and of detection of the resultant activities with a lithium-drifted germanium detector. From the results obtained, sensitivities in photon-activation analysis were evaluated and the reactivity of high energy photons with nuclei in a wide range of atomic number is discussed. Some nuclear considerations in photon-activation analysis, involving the relative probability of forming each product as a result of the $(\gamma,xnyp)$ reactions are also given.

Solid-liquid extraction as a preconcentration technique in trace element analysis. Extraction of trace impurities from metal chlorides: Atsushi Mizuike, Katsuaki Fukuda and Yoji Ochiai, *Talanta*, 1972, **19**, 527. (Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya, Japan.)

Summary—Microgram quantities of iron, cobalt, copper, zinc and cadmium are extracted with various aqueous, organic and mixed solvents from chlorides of sodium, potassium, nickel, cadmium, barium and lead prepared by evaporation of aqueous sample solutions. An ultrasonic field accelerates the extraction, and satisfactory trace recoveries and separation factors are achieved in several systems within a reasonable time. The application to a polarographic determination and a two-stage separation technique are also described.

Selective gas-chromatographic detection using an ion-selective electrode-II. Selective detection of fluorine compounds: Tsugio Kojima, Mitsunojo Ichise and Yoshimitsu Seo, *Talanta*, 1972, **19**, 539. (Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Kyoto, Japan.)

Summary—Components in samples are separated on a gas chromatography column using hydrogen as carrier gas. The individual components from the column are passed through a platinum tube heated at 1000°, where they undergo hydrogenolysis, and fluorine compounds are converted into hydrogen fluoride. The hydrogen fluoride is dissolved in a slow stream of an absorption solution, and the fluoride ion concentration in the resulting solution is monitored in a flow-cell with a fluoride ion electrode. The potentiometric output of the cell is converted into a signal, which is proportional to the concentration of fluoride ion, by an antilogarithmic converter, and recorded. The response of the detector to fluorine compounds was about 10000 times that to an equal quantity of other organic compounds, and 5×10^{-11} mole of fluorobenzene could be detected.

РЕЗУЛЬТАТЫ ФОТОЯДЕРНЫХ РЕАКЦИЙ ДЛЯ АНАЛИЗА ФОТОННОЙ АКТИВАЦИИ С ТОРМОЗНЫМ ИЗЛУЧЕНИЕМ БОЛЬШОЙ ЭНЕРГИИ:

Toyoaki Kato and Yoshinaga Oka, *Talanta*, 1972, **19**, 515.

Резюме—Определялись результаты для различных типов экспериментальных фотоядерных реакций, проводимых в 52 элементах посредством тормозного облучения максимальной энергии в пределах от 30 до 72 мегаэлектронвольт, а также обнаружение вызванной активности посредством германиевого детектора с литиевым перемещением. По полученным результатам расценвалась степень чувствительности анализа активацией фотонов и обсуждалась реактивность фотонов большой энергии с ядрами широкого ряда атомных номеров. Приводятся также некоторые соображения по анализу фотонной активацией, связанные с относительной возможностью образования каждого продукта в результате реакций (γ, x, nyp).

ТВЕРДО- И ЖИДКОФАЗНАЯ ЭКСТРАКЦИЯ В КАЧЕСТВЕ МЕТОДА ПРЕДВАРИТЕЛЬНОГО НАКОПЛЕНИЯ ДЛЯ СЛЕДОВОГО ЭЛЕМЕНТАРНОГО АНАЛИЗА. ИЗВЛЕЧЕНИЕ СЛЕДОВЫХ ПРИМЕСЕЙ ИЗ ХЛОРИДОВ МЕТАЛЛОВ:

Atsushi Mizuike, Katsuaki Fukuda and Yoji Ochiai, *Talanta*, 1972, **19**, 527.

Резюме—Микрограммовые количества железа, кобальта, меди, цинка и кадмия извлекают различными водными, органическими и смешанными растворителями из хлоридов натрия, калия, никеля, кадмия, бария и свинца, приготовленных выпариванием водных растворов проб. Ультразвуковое поле поспешает экстракцию и получены удовлетворительные возвраты следов и факторы разделения в ряде систем в относительно коротком времени. Также описано применение метода в полярографическим определении и в двух-стадийном разделении.

СЕЛЕКТИВНОЕ ОБНАРУЖЕНИЕ ГАЗОВОЙ ХРОМАТОГРАФИЕЙ ПРИ ИСПОЛЬЗОВАНИИ ИОНО-СЕЛЕКТИВНОГО ЭЛЕКТРОДА—II. СЕЛЕКТИВНОЕ ОБНАРУЖЕНИЕ СОЕДИНЕНИЙ ФТОРА:

Tsugio Kojima, Mitsunojo Ichise and Yoshimitsu Seo, *Talanta*, 1972, **19**, 539.

Резюме—Компоненты в образцах отделялись в колонне газового хроматографа с водородом в качестве газа-носителя. Отдельные компоненты из колонны пропускались через платиновую трубку, нагретую до 1000°, где они подвергались гидрогенолизу, причем фторовые соединения превращались в фтороводород. Последний растворялся в медленном потоке абсорбирующего раствора; в получившемся растворе концентрация ионов фтора контролировалась в ячейке для потока электродом для ионов фтора. Потенциометрический выход из ячейки превращался посредством антилогарифмического преобразователя в сигнал, пропорциональный концентрации ионов фтора и регистрировался. Чувствительность дететора к соединениям фтора была примерно в 10000 раз больше, чем к такому же количеству других органических соединений; можно было обнаружить также 5×10^{-11} моля фторбензола.

Polarographic studies of cadmium, zinc and manganese(II) iodide complexes in acetonitrile: S. Misumi and M. Aihara, *Talanta*, 1972, **19**, 549. (Inorganic Chemistry Laboratory, Faculty of Science, Kyushu University, Fukuoka, Japan).

Summary—Cadmium, zinc and manganese(II) iodide complexes have been studied polarographically in acetonitrile and the electrode reactions for these complexes discussed. The overall stability constants of the iodide complexes of these metal ions were evaluated and corrected for the effect of the ion-pairing electrolyte. The values for log β_4 of CdI_4^{2-} and ZnI_4^{2-} are 26·2 and 18·4 respectively and the values found for the Mn(II) iodide complex are log $\beta_1 = 3·5$, log $\beta_2 = 5·6$, log $\beta_3 = 7·8$, log $\beta_4 = 10·0$, log $\beta_5 = 12·2$ and log $\beta_6 = 14·4$. Within certain limits, the wave-height for each complex is proportional to the metal concentration.

Use of ligand buffers for improved selectivity in the polarographic determination of metals. Polarographic determination of zinc in the presence of a large amount of cadmium: Genkichi Nakagawa and Motoharu Tanaka, *Talanta*, 1972, **19**, 559. (Laboratory of Analytical Chemistry, Nagoya Institute of Technology, Showa-ku, Nagoya, Japan, and Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya, Japan.)

Summary—The use of ligand buffers composed of a chelating agent and an excess of polarographically inert metal is recommended for the selective polarographic determination of a metal in the presence of a second metal, which has a polarographic wave at a less negative potential than the metal to be determined. Theoretical considerations on the optimum ligand concentration and the optimum composition of the ligand buffer are followed by the determination of zinc in cadmium as an example.

Flow method in high-resolution magnetic resonance: Yutaka Asahi and Eiji Mizuta, *Talanta*, 1972, **19**, 567. (Chemical Research Laboratories, Research and Development Division, Takeda Chemical Ind., Ltd., Oska, Japan.)

Summary—Flow-cells have been designed for following moderately rapid reactions by high-resolution NMR. Labile intermediates such as the yellow thiol form of thiamine and monoethyl carbonate in alkaline solutions were detected by using this device.

ПОЛЯРОГРАФИЧЕСКИЕ ИССЛЕДОВАНИЯ ИОДИСТОВОДОРОДНЫХ КОМПЛЕКСОВ КАДМИЯ, ЦИНКА И МАРГАНЦА(II) В АЦЕТОНИТРИЛЕ:

S. Misumi and M. Aihara, *Talanta*, 1972, **19**, 549.

Резюме—Исследовались полярографическим методом иодистоводородные комплексные соединения кадмия, цинка и марганца(II) в ацетонитриле и обсуждались электродные реакции для этих комплексов. Найдены величины констант общей стабильности иодистоводородных комплексов ионов этих металлов и введены поправки на спаривание ионов электролитом. Величины $\log \beta_4$ CdI_4^{2-} (кадмия) и ZnI_4^{2-} (цинка) равны 26,2 и 18,4 соответственно, а величины для иодистоводородного комплекса Mn(II) (марганца): $\log \beta_1 = 3{,}5$, $\log \beta_2 = 5{,}6$, $\log \beta_3$ 7,8, $\log \beta_4 = 10{,}0$, $\log \beta_5 = 12{,}2$, и $\log \beta_6 = 14{,}4$. В известных границах высота волны для каждого комплекса пропорциональна концентрации металла.

ИСПОЛЬЗОВАНИЕ ЛИГАНДОВЫХ БУФЕРОВ ДЛЯ УЛУЧШЕНИЯ СЕЛЕКТИВНОСТИ В ОПРЕДЕЛЕНИ МЕТАЛЛОВ ПОЛЯРОГРАФИЧЕСКИМ МЕТОДОМ. ПОЛЯРОГРАФИЧЕСКОЕ ОПРЕДЕЛЕНИЕ ЦИНКА В ПРИСУТСТВИИ БОЛЬШИХ КОЛИЧЕСТВ КАДМИЯ:

Genkichi Nakagawa and Motoharu Tanaka, *Talanta*, 1972, **19**, 559.

Резюме—Предложено использование лигандовых буферов представляющих собой хелатообразующий агент и избыток полярографически инертного металла для селективного полярографического определения металла в присутствии другого металла, который имеет полярографическую волну при менее отрицательном потенциале чем определяемый металл. Приведены теоретические обсуждения оптимальной концентрации лиганда и оптимального состава лигандового буфера и разработан метод определения цинка в кадмие в качестве примера.

ПОТОЧНЫЙ МЕТОД МАГНИТНОГО РЕЗОНАНСА ВЫСОКОЙ РАЗРЕШАЮЩЕЙ СПОСОБНОСТИ:

Yutaka Asahi and Eiji Mizuta, *Talanta*, 1972, **19**, 567.

Резюме—Были сконструированы ячейки потоков для прослеживания реакций средней скорости посредством ядерного магнитного резонанса высокой разрешающей способности. Посредством этого прибора были обнаружены неустойчивые промежуточные вещества, как напр. желтая тиоловая форма тиамина и моноэтил карбонат в щелочных растворах.

Application of urease to the precipitation of manganese(II) oxinate from homogeneous solution with urea in the presence of calcium: Seiichiro Hikime, Hitoshi Yoshida, Mitsuhiko Taga and Shigeru Taguchi, *Talanta*, 1972, **19**, 569. (Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo, Japan.)

Summary—The effect of calcium on precipitation of manganese(II) oxinate from homogeneous solution by means of decomposition of urea with urease was investigated. Manganese was determined satisfactorily in the presence of calcium.

Qualitative analysis of ultraviolet-absorbing substances by use of fluorescent materials: Zenzo Tamura, *Talanta*, 1972, **19**, 573. (Faculty of Pharmaceutical Sciences, University of Tokyo, Tokyo, Japan.)

Summary—Developments of detection techniques of ultraviolet absorbing substances with fluorescent materials are reviewed.

Automatic ion-exchange chromatograph for analysis of alkali and alkaline earth metal mixtures: Shun Araki, Shigetaka Suzuki and Masaaki Yamada, *Talanta*, 1972, **19**, 577. (Department of Industrial Analytical Chemistry, Faculty of Technology, Tokyo Metropolitan University, Setagaya-ku, Tokyo, Japan.)

Summary—A new automatic chromatograph for ultramicro determination of alkali and alkaline earth metals has been developed. It combines a high-sensitivity hydrogen flame-ionization detector with ion-exchange chromatography. Zirconium phosphate was chosen as ion-exchanger.

Spectrophotometric studies on 5,7-dibromo-8-aminoquinoline chelates of some bivalent transition metals: Katsumi Yamamoto and Hiroshi Tabata, *Talanta*, 1972, **19**, 582. (Department of Chemistry, Faculty of Science, Ibaraki University, Mito, Japan.)

Summary—The acid dissociation constant of 5,7-dibromo-8-aminoquinoline and the stability constants of 1:1 chelates of some bivalent transition metals were determined spectrophotometrically in 50% v/v dioxan–water medium at an ionic strength of 0·50 at 25·0 ± 0·1° and compared with those of 8-aminoquinoline. The dissociation constant was found to be $7{\cdot}54 \times 10^{-2}$ and the stability constants (log K_1) were 2·3 (copper), 1·8 (nickel), 1·8 (zinc), 2·2 (cobalt) and 1·6 (cadmium), respectively. The dissociation constants are greater and the stability constants smaller than the corresponding values for 8-aminoquinoline and 8-quinolinol.

ИСПОЛЬЗОВАНИЕ УРЕАЗЫ ДЛЯ ОСАЖДЕНИЯ ОКСИНАТА МАРГАНЦА (II) ИЗ ГОМОГЕННОГО РАСТВОРА МОЧЕВИНОЙ В ПРИСУТСТВИИ КАЛЬЦИЯ:

Seiichiro Hikime, Hitoshi Yoshida, Mitsukiko Taga and Shigeru Taguchi, *Talanta*, 1972, **19**, 569.

Резюме—Изучено влияние кальция на осаждение оксината марганца(II) из гомогенного раствора путем разложения мочевины уреазой. Разработан удовлетворительный метод определения марганца в присутствии кальция.

КАЧЕСТВЕННЫЙ АНАЛИЗ ПОГЛОЩАЮЩИХ В УЛЬТРАФИОЛЕТОВОЙ ОБЛАСТИ СПЕКТРА ВЕЩЕСТВ С ИСПОЛЬЗОВАНИЕМ ФЛУОРЕСЦИРУЮЩИХ МАТЕРИАЛОВ:

Zenzo Tamura, *Talanta*, 1972, **19**, 573.

Резюме—Приведен обзор методов обнаружения поглощающих в ультрафиолетовой области спектратвеществ с использованием флуоресцирующих материалов.

АВТОМАТИЧЕСКИЙ ИОНООБМЕННЫЙ ХРОМАТОГРАФ ДЛЯ АНАЛИЗА СМЕСЕЙ ЩЕЛОЧНЫХ И ЩЕЛОЧНОЗЕМЕЛЬНЫХ МЕТАЛЛОВ:

Shun Araki, Shigetaka Suzuki and Masaaki Yamada, *Talanta*, 1972, **19**, 578.

Резюме—Сконструирован новый автоматический хроматограф для ультрамикроопределения щелочных и щелочноземельных металлов. Прибор использует высокочувствительный пламенноионизационный детектор и ионообменную хроматографию. Фосфат циркония использован в качестве ионообменника.

СПЕКТРОФОТОМЕТРИЧЕСКОЕ ИЗУЧЕНИЕ ХЕЛАТОВ 5,7-ДИБРОМ-8-АМИНОХИНОЛИНА С НЕКОТОРЫМИ ДВУХВАЛЕНТНЫМИ ПЕРЕХОДНЫМИ МЕТАЛЛАМИ:

Katsumi Yamamoto and Hiroshi Tabata, *Talanta*, 1972, **19**, 582.

Резюме—Определены спектрофотометрическим методом константа кислотной диссоциации 5,7-дибром-8-аминохинолина и константы устойчивосчи 1:1 хелатов некоторых двухвалентных переходных металлов в 50 % по объему смеси диоксана и воды при ионной силы 0,50 при 25,0 ± 0,1° и сравнены с константами 8-аминохинолина. Определена константа диссоциации $7,54 \times 10^{-3}$ и константы устойчивости (ly K_I) 2,3 (медь), 1,8 (никель), 1,8 (цинк), 2,2 (кобальт) и 1,6 (кадмий). Константы диссоциации больше, а константы устойчивости меньше чем соответственные величины для 8-аминохинолина и 8-оксихинолина.

Talanta, 1972, Vol. 19, p. ii. Pergamon Press. Printed in Northern Ireland

NOTICES

31st CONGRESS OF THE GROUP FOR ADVANCEMENT OF PHYSICAL METHODS OF ANALYSIS (G.A.M.S.)

This Congress will be held in Paris on 5–9 June 1972 and will be devoted to spectrographic and chromatographic methods of analysis. On the 9th, the proceedings (under the aegis of the Analytical Chemistry Division of the Chemical Society of France) will deal with modern methods of analysis. The meeting will take place in the Salle d'Iéna, 10 Avenue d'Iéna, Paris-16°, and there will be an exhibition of apparatus. Offers of communications should be sent by 15 February 1972 (accompanied by a one-page summary) to

Secrétariat du G.A.M.S. (Congrès)
10 rue du Delta
75-Paris-9°.

Further information may be obtained from the same address.

DECISION, DESIGN AND THE COMPUTER

The Institution of Chemical Engineers is organising a symposium on this topic, in London on 12–14 September 1972. The meeting is the 117th Event of the European Federation and the 5th European Symposium of the Working Party on Routine Calculations and the Use of Computers in Chemical Engineering. The symposium is preceded by a symposium in Paris, on Chemical Engineering at the Service of Mankind, and followed (beginning 18 September) by the International Chemical and Petroleum Engineering Exhibition at Olympia, London. The symposium will deal with Project Evaluation, Computers and Management, Data Banks, Design, Process Models, Parameter Estimation and Data Collection, and On-Line Computers and Plant Operation. Further details may be obtained from

N. T. Shepherd
Institution of Chemical Engineers
16, Belgrave Square, London S.W.1.

TALANTA SCROLL

Professor R. Belcher presenting a special scroll in honour of **Professor C. L. Wilson**'s 60th birthday.

Talanta, 1972, Vol. 19, p. iii. Pergamon Press. Printed in Northern Ireland

PAPERS RECEIVED

A study of the evaporation of gold solutions: D. Buksak and A. Chow. (3 *February* 1972)

A note on successive complexometric determination of thorium and rare earths: Rudolf Přibil and Vladimír Veselý. (2 *March* 1972)

Spectrochemical determination of impurities in telluric acid: B. Zmbova and C. Teofilovski. (7 *March* 1972)

The determination of gallium in an iron-aluminium matrix by solvent extraction and flame-emission spectroscopy: M. S. Cresser and J. Torrent-Castellet. (7 *March* 1972)

Comparative study of analytical properties and applications of picolinaldehyde thiosemicarbazone and selenosemicarbazone: J. M. Cano Pavon and F. Pino. (7 *March* 1972)

The determination of iron, titanium and nickel in Apollo 14 samples by cathode-ray polarography: E. June Maienthal. (9 *March* 1972)

Cation-exchange of metal ions in inorganic solvent-cupferron media: J. Korkisch and M. M. Khater. (13 *March* 1972)

Rapid determination of selenium and tellurium by atomic-absorption spectrophotometry: B. C. Severne and R. R. Brooks. (13 *March* 1972)

Spectrophotometric determination of trace quantities of cobalt(II) with sodium 7-nitroso-8-hydroxyquinoline-5-sulphonate: M. M. Aly. (14 *March* 1972)

Rapid separation and determination of chromium: J. S. Fritz and J. P. Sickafoose. (16 *March* 1972)

Nuclear magnetic resonance analysis of pharmaceuticals—VII The determination of aminophylline in tablets by NMR: J. W. Turczan, R. A. Goldwitz and J. J. Nelson. (17 *March* 1972)

Stability constants of some metal dithizonates: B. W. Budesinsky and M. Sagat. (20 *March* 1972)

Quantitative reflectometry—Principles and scope: David Kealey. (24 *March* 1972)

Simultaneous determination of arsenic, manganese, and selenium in biological materials by neutron-activation analysis: Kaj Heydorn and Else Damsgaard. (27 *March* 1972)

Extraction with long-chain amines—VI Separation of manganese as the $Mn(CN)_6^{4-}$ complex and its complexometric determination in calcareous material: Rudolf Přibil and Jiří Adam. (5 *April* 1972)

Note on the complexation of iron(III) with quinizarin-2-sulphonic acid: B. W. Budesinsky. (5 *April* 1972)

Spectrophotometric determination of strychnine and methyl atropine by extraction with tetrabromophenolphthaleun ethyl ester: Masahiro Tsubouchi, Tadao Sakai, Toshikazu Watake, Kazuhito Kanazawa and Masaya Tanaka. (5 *April* 1972)

Spectrophotometric determination of vanadium with 1,10-phenanthroline: Amal Kanti Bhadra. (7 *April* 1972)

Talanta, 1972, Vol. 19, p. iii. Pergamon Press. Printed in Northern Ireland

NOTICES

ASSOCIATION OF OFFICIAL ANALYTICAL CHEMISTS, 86th ANNUAL MEETING

This meeting will be held on 9–12 October 1972 at Marriott Motor Hotel, Twin Bridges, Washington, D.C. 20001, U.S.A. The topics will be methods of analysis for materials and products important to health and agriculture, *i.e.*, drugs, pesticides, foods, beverages, additives, cosmetics, feeds, fertilisers, microbiological contamination of foods, *etc.* For further information write to L. G. Esminger, Executive Secretary, AOAC, Box 540, Benjamin Franklin Station, Washington, D.C. 20044, U.S.A.

SPECTROSCOPY SOCIETY OF CANADA 19th SPECTROSCOPY SYMPOSIUM AND EXHIBITION

This symposium will be held on 23–25 October 1972 at Le Chateau Champlain Hotel, Montreal, and will deal with optical-emission, atomic-absorption, molecular, X-ray and gamma-ray spectroscopy. The exhibition will cover the complete range of instrumentation in spectroscopy. For further information write to Prof. J. G. Dick, Department of Chemistry, Sir George Williams University, 1435 Drummond Street, Montreal, Quebec, Canada.

INTERNATIONAL SYMPOSIUM ON SELECTIVE ION-SENSITIVE ELECTRODES

A IUPAC symposium on selective ion-sensitive electrodes will be held at the University of Wales Institute of Science and Technology, Cardiff, Wales, on 9–12 April 1972. The programme will be devoted to all aspects of the topic, including development, operation, mechanism and applications. Anyone wishing to present a paper should obtain an application form from the Symposium Editor (Dr. G. J. Moody), Department of Chemistry, UWIST, Cardiff, Wales, U.K. and return it with an abstract of the paper not later than 1 September 1972. Further details and enrolment forms may be obtained from the Symposium Secretary, Mr. D. R. Hub, Organiser of Short Courses, UWIST, Cardiff, Wales, U.K.

SUMMARIES FOR CARD INDEXES

Removal of graphite by oxidation with perchloric acid plus periodic acid. Inapplicability to the spectrophotometric determination of manganese in steel: James A. Gaunt and Harvey Diehl, *Talanta*, 1972, **19**, 1. (Department of Chemistry, Iowa State University, Ames, Iowa, 50010 U.S.A.)

Summary—An attempt has been made to improve the Willard and Greathouse periodate method for the determination of manganese in high-carbon steel and cast iron by oxidizing the graphite with periodic acid in the presence of perchloric acid and phosphoric acid. Graphite is rapidly oxidized at 150° by this mixture but manganese is lost by volatilization as the heptoxide and decomposition of the latter on hot surfaces to manganese dioxide. No way was found for either the quantitative removal and recovery of manganese by volatilization or for quantitative return to the main solution. The spectrophotometric determination of manganese in the supernatant liquid after allowing graphite to settle yields imprecise but not wholly unacceptable results; for the highest accuracy, graphite should be removed along with silica following dehydration of the latter with perchloric acid.

Spectrophotometric determination of calcium in zirconium powder by use of murexide: Herman Gordon and George Norwitz, *Talanta*, 1972, **19**, 7. (Frankford Arsenal, Philadelphia, Pa. 19137, U.S.A.)

Summary—An accurate spectrophotometric method is proposed for the determination of calcium in zirconium powder by use of murexide. A 0·4-g sample is dissolved in hydrofluoric and sulphuric acids, the solution evaporated to fumes of sulphuric acid, and a mercury cathode electrolysis made if more than 0·05% copper or nickel is present. Ammoniacal precipitation in the presence of ammonium chloride separates zirconium and other elements and an aliquot of filtrate is collected, equivalent to 0·2 g of sample. The ammonium salts are destroyed with nitric and hydrochloric acids and the calcium is determined with murexide. The high reagent blank is shown to be due to the reagent grade nitric acid, hydrochloric acid, and ammonium hydroxide.

Microdosage du silicium dans les composés organiques: E. Debal, *Talanta*, 1972, **19**, 15. (Service Central de Microanalyse du Centre National de la Recherche Scientifique, 2, rue Henry Dunant, 94-Thiais, France.)

Summary—Organic silicon compounds are decomposed by sodium peroxide in a Würzschmitt nickel bomb. The silicate obtained is determined spectrophotometrically as silicomolybdate. The sample weight is 2-6 mg. The possible absolute error in the silicon content is 0·3–0·4%.

УДАЛЕНИЕ ГРАФИТА ОКИСЛЕНИЕМ ХЛОРНОЙ И ИОДНОЙ КИСЛОТАМИ. НЕПРИМЕНИМОСТЬ МЕТОДА В СПЕКТРОФОТОМЕТРИЧЕСКОМ ОПРЕДЕЛЕНИИ МАРГАНЦА В СТАЛЯХ:

James A. Gaunt and Harvey Diehl, *Talanta*, 1972, **19**, 1.

Резюме—Сделана попытка улучшать метод Вилларда и Грейтхауза для определения марганца в высокоуглеродных сталях и чугуне окислением графита иодной кислотой в присутствии хлорной и фосфорной кислот. Графит быстро окисляется этой смесью при 150° но марганец теряется улетучиванием в форме гептоксида и разлаганием этого до двуокиси марганца на горячих поверхностях. Не обнаружен метод количественного удаления и регенерации марганца улетучиванием или количественного возврата главному раствору. Спектрофотометрическое определение марганца в всплывающем слое после осаждения графита дает неточные но не весьма неприемлемые результаты. Для получения наилучшей точности надо удалять графит вместе с кремнием, после дегридатации двуокиси кремния хлорной кислотой.

СПЕКТРОФОТОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ КАЛЬЦИЯ В ПОРОШКОВИДНОМ ЦИРКОНИИ С ИСПОЛЬЗОВАНИЕМ МУРЕКСИДА:

Herman Gordon and George Norwitz, *Talanta*, 1972, 19, 7.

Резюме—Предложен точный спектрофотометрический метод определения кальция в порошковидном цирконии с использованием мурексида. 0,4 г пробы растворяют в фтороводородной и серной кислотах, раствор выпаривают до появления дымов серной кислоты и проводят электролиз с использованием ртутного катода если присутствуют больше чем 0,05 % меди или никеля. Цирконий отделяют от других элементов осаждением аммиаком в присутствии хлорида аммония и собирают аликвотную часть филътрата, соответствующую 0,2 г пробы. Соли аммония разрушают добавлением азотной и соляной кислот, а кальций определяют мурексидом. Показано что высокая слепая проба реагентов вызвана примесами присутствующими в азотной и соляной кислотах и хлориде аммония аналитической чистоты.

ОПРЕДЕЛЕНИЕ МИКРОКОЛИЧЕСТВ КРЕМНИЯ В ОРГАНИЧЕСКИХ СОЕДИНЕНИЯХ:

E. Debal, *Talanta*, 1972, **19**, 15.

Резюме—Органические соединения кремния разлагают перекисью натрия в никелевой бомбе Вирцшмитта. Полученный силикат определяют спектрофотометрическим методом в форме силикомолибдата. Для определения берут 2—6 мг пробы. Возможная абсолютная ошибка определения равна 0,3—0,4 % кремния.

Fluorimetric and phosphorimetric characteristics of several vitamins: JEAN-JACQUES AARON and J. D. WINEFORDNER, *Talanta*, 1972, **19**, 21. (Department of Chemistry, University of Florida, Gainesville, Florida 32601, U.S.A.)

Summary—The fluorescence and phosphorescence characteristics of 14 vitamins were evaluated. The existence or absence of fluorescence and phosphorescence was compared with predictions based upon molecular structure. Analytically useful fluorescence signals were obtained for *p*-aminobenzoic acid, folic acid, calciferol, pyridoxine hydrochloride, riboflavine, α-tocopherol and vitamin A, whereas analytically useful phosphorescence signals were obtained for *p*-aminobenzoic acid, folic acid, niacinamide, pyridoxine hydrochloride, and α-tocopherol. All other vitamins either did not fluoresce or phosphoresce or could not be measured, owing to experimental difficulties. The complementary nature of fluorimetry and phosphorimetry is evident in these studies.

Microdetermination of α-amino-acids by spectrophotometric and titrimetric methods: W. I. AWAD, S. NASHED, S. S. M. HASSAN and R. F. ZAKHARY, *Talanta*, 1972, **19**, 31. (Department of Chemistry, University College for Women, Ain Shams University, Cairo, U.A.R. and Department of Chemistry, Faculty of Science, Ain Shams University, Cairo, U.A.R.)

Summary—Micro-methods for spectrophotometric and oxidimetric determination of α-amino-acids are described. They are based on a reaction of the acids with *peri*-naphthindan-2,3,4-trione hydrate at pH 2.5 to give a red precipitate of dihydroxy-*peri*-naphthindenone. The red product is dissolved and measured either spectrophotometrically at 243 nm or titrimetrically by reaction with iodine or *N*-bromosuccinimide. The results obtained by the three methods are concordant, the average recovery being 98%.

Indirect near-infrared spectrophotometric determination of silicate by the 2-amino-4-chlorobenzenethiol method: LOUIS A. TRUDELL and D. F. BOLTZ, *Talanta*, 1972, **19**, 37. (Department of Chemistry, Wayne State University, Detroit, Michigan 48202, U.S.A.)

Summary—An indirect near-infrared spectrophotometric method for the determination of silicate, based on the absorbance of an equivalent amount of molybdenum-2-amino-4-chlorobenzenethiol complex in chloroform solution, has been developed. The green chloroform solution has an absorbance maximum at 715 nm. The development of the spectrophotometric method for the determination of silicate included a study of a buffer system for the purpose of maintaining the pH within a narrow optimum pH range, complex stability, effect of diverse ions, and conformity to Beer's law. The limit of detection is 0·034 μg of silicon per ml of aqueous heteropoly acid solution.

ФЛУОРИМЕТРИЧЕСКИЕ И ФОСФОРИМЕТРИЧЕСКИЕ ХАРАКТЕРИСТИКИ НЕКОТОРЫХ ВИТАМИНОВ:

JEAN-JACQUES AARON and J. D. WINEFORDNER, *Talanta*, 1972, **19**, 21.

Резюме—Изучены флуориметрические и фосфориметрические характеристики 14 витаминов. Присутствие или отсутствие флуоресценции и фосфоресценции сравнено с предсказаниями на основе молекулярного устройства. Испоьзуемые для анализа флуоресцентные сигналы получены для п-аминобензойной кислоты, фолевой кислоты, кальциферола, хлористоводородного пиридоксина, рибофлавина, α-токоферола и витамина A, а используемые для анализа фосфоресцентные сигналы—для п-аминобензойной кислоты, фолевой кислоты. ниацинамида, хлористоводородного пиридоксина и α-токоферола. В случае всех других витаминов флуоресценция или фосфоресценция не обнаружилась или не удалась измерять вследствие опытных трудностей. Комплементарная природа флуориметрии и фосфориметрии очевидна в этих изучениях.

МИКРООПРЕДЕЛЕНИЕ α-АМИНОКИСЛОТ СПЕКТРОФОТОМЕТРИЧЕСКИМИ И ТИТРОМЕТРИЧЕСКИМИ МЕТОДАМИ:

W. I. AWAD, S. NASHED, S. S. M. HASSAN and R. F. ZAKHARY, *Talanta*, 1972, **19**, 31.

Резюме—Описаны микрометоды спектрофотометрического и титрометрического определения α-аминокислот. Методы основаны на реакции кислот с пери-нафтиндан-2,3,4-трионгидратом при pH 2,5 с образованием красного осадка диокси-пери-нафтинденона. Красный продукт растворяют и измеряют спектрофотометрическим методом при 243 нм или титруют иодом или *N*-имидом бромянтарной кислоты. Эти три метода дают соглашающиеся результаты, средный возврат —98%.

КОСВЕННОЕ ОПРЕДЕЛЕНИЕ СИЛИКАТА СПЕКТРОФОТОМЕТРИЧЕСКИМ МЕТОДОМ В БЛИЗКОЙ ИНФРАКРАСНОЙ ОБЛАСТИ СПЕКТРА С ИСПОЛЬЗОВАНИЕМ 2-АМИНО-4-ХЛОРОТИОФЕНОЛА:

LOUIS A. TRUDELL and D. F. BOLTZ, *Talanta*, 1972, **19**, 37.

Резюме—Разработан косвенный метод определения силиката основывающийся на измерении светопоглощения в близкой инфракрасной области спектра эквивалентного количества комплекса молибдена с 2-амино-4-хлоротиофенолом в растворе хлороформа. Зеленый раствор в хлороформе показывает максимум светопоглощения при 715 нм. Разработка спектрофотометрического метода для определения силиката включила изучение буферной системи для поддержки pH в узких оптимальных пределах, исследование устойчивости комплекса, влияния различных ионов и соблюдения закону Бера. Чувствительность метода 0,034 мкг кремния/мл водного раствора гетерополикислоты.

Studies on potassium chlorate as a primary oxidimetric reagent: C. Radhakrishna Murty and G. Gopala Rao, *Talanta*, 1972, **19**, 45. (Department of Chemistry, Andhra University, Waltair, India.)

Summary—Conditions have been established for the use of potassium chlorate as a primary oxidizing agent in the direct titration of vanadium(III), tin(II) and titanium(III) with visual or potentiometric end-points.

A spectrophotometric method for the determination of copper ions and its application to the co-precipitation of copper in the crystallization of sodium chloride: A. Glasner, S. Sarig, D. Weiss and M. Zidon, *Talanta*, 1972, **19**, 51. (Department of Inorganic and Analytical Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel.)

Summary—The molar absorptivity of the cyanide complexes $[Cu(CN)_3]^{2-}$ and $[Cu(CN)_4]^{3-}$, at their isosbestic wavelength (235 nm) is $1{\cdot}13 \times 10^3$ $l.mole^{-1}.mm^{-1}$ and can be used for the quantitative determination of micro-amounts of copper in the ppm range. The determination of 1–10 μg of Cu^{2+} per g of NaCl, or 0·25–2·5 μg/ml, is described in detail. The co-precipitation of copper with NaCl crystallizing from aqueous solutions has been studied by this method.

Ammonium hexanitratocerate(IV) as an oxidizing agent—V. Titrimetric determination of arsenic(III) at room temperature: G. Gopala Rao, K. S. Murty and Muralikrishna Gandikota, *Talanta*, 1972, **19**, 59. (Department of Chemistry, Andhra University, Waltair, India.)

Summary—Conditions have been established for the accurate titration of arsenic(III) with ammonium hexanitratocerate(IV) at room temperature in sulphuric, nitric and hydrochloric acid media, using suitable catalysts, and ferroin as indicator.

ИЗУЧЕНИЕ ХЛОРАТА КАЛИЯ В КАЧЕСТВЕ ПЕРВИЧНОГО ОКСИДИМЕТРИЧЕСКОГО РЕАГЕНТА:

C. Radhakrishna Murty and G. Gopala Rao, *Talanta*, 1972, **19**, 45.

Резюме—Определены условия использования хлората калия в качестве первичного оксидиметрического реагента в непосредственном титровании ванадия(III), олова(II) и титана(III) с применением визуального и потенциометрического концев титрования.

СПЕКТРОФОТОМЕТРИЧЕСКИЙ МЕТОД ОПРЕДЕЛЕНИЯ МЕДИ И ЕГО ПРИМЕНЕНИЕ В КРИСТАЛЛИЗАЦИИ ХЛОРИДА НАТРИЯ ДЛЯ СООСАЖДЕНИЯ МЕДИ:

A. Glasner, S. Sarig, D. Weisz and M. Zidon, *Talanta*, 1971, **19**, 51.

Резюме—Молярное поглощение цианидных комплексов $(Cu(CN)_3)^{2-}$ и $(Cu(CN)_4)^{2-}$ при их изобестической длины волн (235 нм) составляет 1,13 . 10^3 л.моль$^{-1}$.мин$^{-1}$ и позволяет определять количественно микроколичества меди в области частей на миллион. Подробно описано определение 1–10 мкг Cu^{2+} (г NaCl или 0,25–2,5 мкг) мл. Соосаждение меди с кристаллизирующим из водных растворов хлоридом натрия изучено применяя этот метод.

ГЕКСАНИТРАТОЦЕРАТ(IV) АММОНИЯ В КАЧЕСТВЕ ОКИСЛИТЕЛЯ—V. ТИТРОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ МЫШЬЯКА(III) ПРИ КОМНАТНОЙ ТЕМПЕРАТУРЕ:

G. Gopala, Rao, K. S. Murty and Muralikrishna Gandikota, *Talanta*, 1972, **19**, 59.

Резюме—Определены условия точного титрометрического определения мышьяка(III) гексанитратоцератом(IV) аммония при комнатной температуре в серно-, азотно- и солянокислых средах, с использованием подходящих катализаторов и ферроина в качестве индикатора.

Ammonium hexanitratocerate(IV) as an oxidizing agent—VI. Determination of chromium(III) through oxidation to chromium(VI) at room temperature: G. GOPALA RAO, K. S. MURTY and MURALIKRISHNA GANDIKOTA, *Talanta*, 1972, **19**, 65. (Chemistry Department, Andhra University, Waltair, India.)

Summary—A new method has been developed for the determination of chromium(III), depending on its oxidation to chromium(VI) at room temperature by treatment with 50–100% excess of ammonium hexanitratocerate(IV) in 1·0*M* nitric acid medium. The reaction is complete within 15 min. The unreacted cerium(IV) is titrated potentiometrically with sodium oxalate.

A rapid automatic method for the determination of oxygen in organic substances, using coulometry at controlled potential: K. J. KARRMAN and RONALD KARLSSON, *Talanta*, 1972, **19**, 67. (Department of Analytical Chemistry, University of Lund, P.O.B. 740, S-220 07 Lund 7, Sweden.)

Summary—An Unterzaucher apparatus for the determination of oxygen in organic compounds is used. The iodine vapour formed in the anhydroiodic acid tube is led by a stream of nitrogen to the cathodic chamber of an electrolysis cell. Here the iodine is reduced at controlled potential at a rotating Pt-electrode. The amount of electricity used is determined by an electronic integrator and read from a digital voltmeter. For weights of samples in the range 0·5–6 mg the standard deviation is about 0·08% oxygen.

Successive complexometric determination of thorium and uranium in sulphuric acid media: M. M. L. KHOSLA and S. P. RAO, *Talanta*, 1972, **19**, 71. (Defence Laboratory, Jodhpur, India and Department of Chemistry, University of Jodhpur, Jodhpur, India.)

Summary—A selective analytical extraction method for rapid successive complexometric determination of thorium(IV) and uranium(VI) in sulphuric acid media is described. The method is based on the extraction of thorium and uranium from sulphuric acid media with *N*-butylaniline or *N*-benzylaniline in chloroform. Both thorium and uranium are selectively and quantitatively extracted in the presence of ascorbic acid and EDTA. Most cations and anions do not interfere. The reduction of uranium(VI) with sodium dithionite at room temperature is rapid and quantitative and superior to that with ascorbic acid, which reduces uranium(VI) in boiling solution. The method is simple, rapid and accurate, and the experimental conditions are not highly critical.

ГЕКСАНИТРАТОЦЕРАТ(IV) АММОНИЯ В КАЧЕСТВЕ ОКИСЛИТЕЛЯ—VI. ОПРЕДЕЛЕНИЕ ХРОМА(III) ПУТЕМ ОКИСЛЕНИЯ ДО ХРОМА(VI) ПРИ КОМНАТНОЙ ТЕМПЕРАТУРЕ:

G. Gopala Rao, K. S. Murty and Muralikrishna Gandikota, *Talanta*, 1972, **19**, 65.

Резюме—Разработан новый метод определения хрома(III), основчвающийся на окислении до хрома(VI) при комнатной температуре, обработкой с 50–100 % тным избытком гексанитратоцерата(IV) аммония в растворе 1,0*M* азотной кислоты. Реакция окончана в 15 мин. Нереагированный церий(IV) титруют потенциометрическим методом с использованием оксалата натрия.

БЫСТРЫЙ АВТОМАТИЧЕСКИЙ МЕТОД ОПРЕДЕЛЕНИЯ КИСЛОРОДА В ОРГАНИЧЕСКИХ ВЕЩЕСТВАХ С ПРИМЕНЕНИЕМ МЕТОДА ПОТЕНЦИОСТАТИЧЕСКОЙ КУЛОНОМЕТРИИ:

K. J. Karrman and Ronald Karlsson, *Talanta*, 1972, **19**, 67.

Резюме—Авторы пользуются прибором Унтерцаухера для определения кислорода в органических соедиенениях. Образующиеся в трубке иодистоводородной кислоты пары иода переносятся струей азота в катодный простор электролитической ячейки где иод восстанавливается при контроллированном напряжении на вращающемся платиновом электроде. Употребленное количество электричества определяют электронным интегратором и читают на цифровом вольтметре. Стандартная ошибка для проб 0,5–0,6 г равна около 0,08 % кислорода.

ПОСЛЕДОВАТЕЛЬНОЕ КОМПЛЕКСОНОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ ТОРИЯ И УРАНА В СЕРНОКИСЛЫХ СРЕДАХ:

M. M. L. Khosla and S. P. Rao, *Talanta*, 1972, **19**, 71.

Резюме—Описан селективный экстрактивный метод быстрого последовательного комплексонометрического определения тория(IV) и урана(VI) в сернокислых средах. Метод основывается на экстракции тория и урана из сернокислих средах *N*-бутиланилином или *N*-бензиланилином в хлороформе. Оба элемента селективно и количественно экстрагируются в присутствии аскорбиновой кислоты и ЭДТА. Большинство катионов и анионов не мешают определению. Восстановление урана(VI) дитионитом натрия при комнатной температуре является быстрым и количественным и лучшим восстановлению аскорбиновой кислотой, которая восстанавливает уран(VI) в кипящих растворах. Метод является несложным, быстрым и точным. а опытные условия не весьма критические.

Titrimetric determination of arsenic(III) with potassium dichromate, using redox indicators: G. Gopala Rao, B. Sarojini and Muralikrishna Gandikota, *Talanta*, 1972, **19**, 74. (Department of Chemistry, Andhra University, Waltair, India.)

Summary—Experimental conditions have been established for the accurate direct titrimetric determination of arsenic(III) with potassium dichromate, using ferroin and *N*-phenylanthranilic acid as redox indicators. Interferences have been considered.

The use of triethanolamine in a buffer for the determination of fluoride in calcium and transition metal orthophosphates, using a fluoride-selective electrode: Edward J. Duff and J. L. Stuart, *Talanta*, 1972, **19**, 76. (Department of Preventive Dentistry, Turner Dental School, The University, Manchester, U.K.)

Summary—A method is described for the determination of fluoride in inorganic orthophosphates. Interference by complex-forming metal ions is avoided by the use of a citric acid–triethanolamine buffer, $pH < 7{\cdot}5$.

Determination of phosphorus in coke by the oxygen-flask method: B. P. Kirk and H. C. Wilkinson, *Talanta*, 1972, **19**, 80. (British Coke Research Association, Coke Research Centre, Chesterfield, Derbyshire.)

Summary—Recent developments in the oxygen-flask technique for determination of phosphorus in coke are described. The existing method was modified by use of the recently proposed potassium antimonyl tartrate catalyst for the ascorbic acid reduction of phosphomolybdate.

ТИТРОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ МЫШЬЯКА(III) ДИХРОМАТОМ КАЛИЯ С ИСПОЛЬЗОВАНИЕМ ОКИСЛИТЕЛЬНО-ВОССТАНОВИТЕЛЬНЫХ ИНДИКАТОРОВ:

G. Gopala Rao, B. Sarojini and Muralikrishna Gandikota, *Talanta*, 1972, **19**, 74.

Резюме—Установлены опытные условия для точного непосредственного титрометрического определения мышьяка(III) дихроматом калия, с использованием ферроина и *N*-фенилантраниловой кислоты в качестве окислительно-восстановительных индикаторов. Изучено влияние мешающих веществ.

ИСПОЛЬЗОВАНИЕ БУФЕРА НА ОСНОВЕ ТРИЭТАНОЛАМИНА В ОПРЕДЕЛЕНИИ ФТОРИДИОНА В ОРТОФОСФАТАХ КАЛЬЦИЯ И ПЕРЕХОДНЫХ МЕТАЛЛОВ С ИСПОЛЬЗОВАНИЕМ ЭЛЕКТРОДА СЕЛЕКТИВНОГО ДЛЯ ФТОРИДИОНОВ:

Edward J. Duff and J. L. Stuart, *Talanta*, 1972, **19**, 76.

Резюме—Описан метод определения фторида в неорганических ортофосфатах. Влияние комплексообразующих ионов металлов избегнуто использованием буфера для $pH > 7.5$, состоящегося из лимонной кислоты и триэтеноламина.

ОПРЕДЕЛЕНИЕ ФОСФОРА В КОКСЕ МЕТОДОМ СОЖЖЕНИЯ В КОЛБЕ, НАПОЛНЕННОЙ КИСЛОРОДОМ:

B. P. Kirk and H. C. Wilkinson, *Talanta*, 1972, **19**, 80.

Резюме—Описаны успехи полученные в определении фосфора в коксе методом сожжения в колбе, наполненной кислородом. Обыкновенный метод изменен использованием недавно предложенного виннокислого антимонил-калия в качестве катализатора для восстановления фосфомолибдата аскорбиновой кислотой.

Spectrophotometric study of the determination of copper with ammonium 1-pyrrolidinecarbodithioate: R. W. LOOYENGA and D. F. BOLTZ, *Talanta*, 1972, **19**, 82. (Department of Chemistry, Wayne State University, Detroit, Michigan 48202, U.S.A.)

Summary—A new spectrophotometric method for the determination of traces of copper has been developed. The method is based on the formation of a stable 1:2 complex of copper(II) and 1-pyrrolidinecarbodithioate and the isolation of this complex by extraction into chloroform. The absorbance is measured at either 269 nm or 435 nm. The detection limit is 0.03 μg of copper per ml for absorbance measurements at 435 nm.

Stabilities of some cyclopentadienide metal complexes: B. W. BUDESINSKY and J. SVEC, *Talanta*, 1972, **19**, 87. (Department of Chemistry, University of Waterloo, Waterloo, Ontario, Canada.)

Summary—The composition and stabilities of hydrogen, manganese(II), iron(II), cobalt(II), nickel(II) and palladium(II) complexes with cyclopentadienide were investigated spectrophotometrically in aqueous and dimethylformamide solutions. Corresponding effective and overall stability constants were determined.

СПЕКТРОФОТОМЕТРИЧЕСКОЕ ИЗУЧЕНИЕ ОПРЕДЕЛЕНИЯ МЕДИ С ИСПОЛЬЗОВАНИЕМ I—ПИРРОЛИДИНКАРБОДИТИОАТА АММОНИЯ:

R. W. Looyenga and D. F. Boltz, *Talanta*, 1972, **19**, 82.

Резюме—Разработан новый спектрофотометрический метод определения следовых количеств меди. Метод основывается на образовании устойчивого комплекса 1:2 меди(II) с 1-пирролидинкарбодитиоатом аммония и выделении этого комплекса извлечением с хлороформом. Светопоглощение измеряют при 269 или 435 нм. Чувствительность метода 0,03 мкг меди/мл в случае измерения светопоглощения при 435 нм.

УСТОЙЧИВОСТЬ НЕКОТОРЫХ КОМПЛЕКСОВ МЕТАЛЛОВ С ЦИКЛОПЕНТАДИЕНОМ:

B. W. Budesinsky and J. Svec, *Talanta* 1972, **19**, 87.

Резюме—Исследованы спектрофотометрическим методом состав и устойчивость комплексов водорода, марганца(II), железа(II), кобальта(II), никеля(II) и палладия(II) с циклопентадиеном в водных растворах и растворах в диметилформамиде. Определены эффективные и общие константы устойчивости.

Talanta, 1972, Vol. 19, p. iii. Pergamon Press. Printed in Northern Ireland

PUBLICATIONS RECEIVED

Recent Advances in the Analytical Chemistry of the Noble Metals: F. E. BEAMISH and J. C. VAN LOON. Pergamon, Oxford, 1972. Pp. xvi + 511. £14.00.

Readers of this journal will be familiar with the scope, detail and critical standards of this book since several of the chapters are based on Talanta Reviews. The work updates the earlier *Analytical Chemistry of the Noble Metals* and provides testimony to the activity in this field. It deals with methods of separation and determinations based on AAS, neutron-activation, spectrochemical, XRF, electrometric, spectrophotometric, gravimetric, and titrimetric methods. With over 1600 references and lots of working procedures and summarizing tables it is destined to be a standard work.

***N*-Benzoylphenylhydroxylamine and its analogues:** A. K. MAJUMDAR. Pergamon, Oxford, 1972. Pp. x + 210. £7.00.

One of the virtues of the international series of Monographs in Analytical Chemistry, of which this is the 49th member, has been the introduction of books which provide an extended review of a novel or interesting aspect of the subject. Hitherto the volumes have been cheap enough to enable the interested analyst to acquire a shelf full of such volumes. This book is in the tradition of the series, but the price is going to limit its circulation. *N*-Benzoylphenylhydroxylamine (even if it doesn't rate as an "all-time great" alongside 1,10-phenanthroline, DMG and EDTA) and it is useful to have its scope clearly delineated by one who has been closely associated with its analytical application for over a decade.

Talanta, 1972, Vol. 19, p. iii. Pergamon Press. Printed in Northern Ireland

PAPERS RECEIVED

A study of the evaporation of gold solutions: D. BUKSAK and A. CHOW. (3 *February* 1972)

A note on successive complexometric determination of thorium and rare earths: RUDOLF PŘIBIL and VLADIMÍR VESELÝ. (2 *March* 1972)

Spectrochemical determination of impurities in telluric acid: B. ZMBOVA and C. TEOFILOVSKI. (7 *March* 1972)

The determination of gallium in an iron-aluminium matrix by solvent extraction and flame-emission spectroscopy: M. S. CRESSER and J. TORRENT-CASTELLET. (7 *March* 1972)

Comparative study of analytical properties and applications of picolinaldehyde thiosemicarbazone and selenosemicarbazone: J. M. CANO PAVON and F. PINO. (7 *March* 1972)

The determination of iron, titanium and nickel in Apollo 14 samples by cathode-ray polarography: E. JUNE MAIENTHAL. (9 *March* 1972)

Cation-exchange of metal ions in inorganic solvent-cupferron media: J. KORKISCH and M. M. KHATER. (13 *March* 1972)

Rapid determination of selenium and tellurium by atomic-absorption spectrophotometry: B. C. SEVERNE and R. R. BROOKS. (13 *March* 1972)

Spectrophotometric determination of trace quantities of cobalt(II) with sodium 7-nitroso-8-hydroxyquinoline-5-sulphonate: M. M. ALY. (14 *March* 1972)

Rapid separation and determination of chromium: J. S. FRITZ and J. P. SICKAFOOSE. (16 *March* 1972)

Nuclear magnetic resonance analysis of pharmaceuticals—VII The determination of aminophylline in tablets by NMR: J. W. TURCZAN, R. A. GOLDWITZ and J. J. NELSON. (17 *March* 1972)

Stability constants of some metal dithizonates: B. W. BUDESINSKY and M. SAGAT. (20 *March* 1972)

Quantitative reflectometry—Principles and scope: DAVID KEALEY. (24 *March* 1972)

Simultaneous determination of arsenic, manganese, and selenium in biological materials by neutron-activation analysis: KAJ HEYDORN and ELSE DAMSGAARD. (27 *March* 1972)

Extraction with long-chain amines—VI Separation of manganese as the $Mn(CN)_6^{4-}$ complex and its complexometric determination in calcareous material: RUDOLF PŘIBIL and JIŘÍ ADAM. (5 *April* 1972)

Note on the complexation of iron(III) with quinizarin-2-sulphonic acid: B. W. BUDESINSKY. (5 *April* 1972)

Spectrophotometric determination of strychnine and methyl atropine by extraction with tetrabromophenolphthaleun ethyl ester: MASAHIRO TSUBOUCHI, TADAO SAKAI, TOSHIKAZU WATAKE, KAZUHITO KANAZAWA and MASAYA TANAKA. (5 *April* 1972)

Spectrophotometric determination of vanadium with 1,10-phenanthroline: AMAL KANTI BHADRA. (7 *April* 1972)

Talanta, 1972, Vol. 19, p. iii. Pergamon Press. Printed in Northern Ireland

NOTICES

ASSOCIATION OF OFFICIAL ANALYTICAL CHEMISTS, 86th ANNUAL MEETING

This meeting will be held on 9–12 October 1972 at Marriott Motor Hotel, Twin Bridges, Washington, D.C. 20001, U.S.A. The topics will be methods of analysis for materials and products important to health and agriculture, *i.e.*, drugs, pesticides, foods, beverages, additives, cosmetics, feeds, fertilisers, microbiological contamination of foods, *etc.* For further information write to L. G. Esminger, Executive Secretary, AOAC, Box 540, Benjamin Franklin Station, Washington, D.C. 20044, U.S.A.

SPECTROSCOPY SOCIETY OF CANADA 19th SPECTROSCOPY SYMPOSIUM AND EXHIBITION

This symposium will be held on 23–25 October 1972 at Le Chateau Champlain Hotel, Montreal, and will deal with optical-emission, atomic-absorption, molecular, X-ray and gamma-ray spectroscopy. The exhibition will cover the complete range of instrumentation in spectroscopy. For further information write to Prof. J. G. Dick, Department of Chemistry, Sir George Williams University, 1435 Drummond Street, Montreal, Quebec, Canada.

INTERNATIONAL SYMPOSIUM ON SELECTIVE ION-SENSITIVE ELECTRODES

A IUPAC symposium on selective ion-sensitive electrodes will be held at the University of Wales Institute of Science and Technology, Cardiff, Wales, on 9–12 April 1972. The programme will be devoted to all aspects of the topic, including development, operation, mechanism and applications. Anyone wishing to present a paper should obtain an application form from the Symposium Editor (Dr. G. J. Moody), Department of Chemistry, UWIST, Cardiff, Wales, U.K. and return it with an abstract of the paper not later than 1 September 1972. Further details and enrolment forms may be obtained from the Symposium Secretary, Mr. D. R. Hub, Organiser of Short Courses, UWIST, Cardiff, Wales, U.K.

PROFESSOR C. L. WILSON

CECIL LEEBURN WILSON was born in Co. Londonderry on 11 May 1912. He attended Rainey Endowed School at Magherafelt and later studied chemistry at Queen's University, Belfast, where he graduated with a first class honours B.Sc. in 1932. The following year he took his M.Sc. at Queen's. A Musgrave research scholarship took him to the University of Glasgow in 1933 where he obtained a Ph.D. in 1936. In 1935 however, he was appointed to an Assistant Lectureship in Chemistry at the Sir John Cass College, London. During the war he was released from there to work with the Armaments Research Department, Ministry of Supply, where he stayed for the years 1940–1944. He then resumed work at the Cass College but in 1946 returned to his Alma Mater in Belfast and has stayed there ever since. Appointed originally as a Lecturer, he became a Reader in 1950. In 1953 he took his D.Sc. at Queen's and in 1958 was appointed to a personal chair in Analytical Chemistry, the first of these ever created in the United Kingdom. The personal chair was converted into an established chair in Inorganic and Analytical Chemistry, which in turn has been split into separate chairs, Cecil Wilson retaining the chair of Analytical Chemistry.

It was in Glasgow that Cecil Wilson's interests were first turned towards microchemistry, and as early as 1935 he designed and introduced an undergraduate course in this subject in Belfast. His first book, entitled "An Introduction to Microchemical Methods" was published in 1938. During the war he had to do mainly analytical—often microanalytical— work for the Ministry of Supply, and from this time his interest in analytical chemistry became dominating. In co-authorship with Professor R. Belcher he published a book on Inorganic Microanalysis in 1946, 2nd edition 1957, and a similar co-operation produced various editions of "New Methods of Analytical Chemistry". Although his interests in teaching and research in Analytical Chemistry were always predominant, he found time and energy to keep up with Inorganic and Physical Chemistry. At the request of his old Professor at Queen's, Dr Stewart, he collaborated on the 7th edition of "Recent Advances in Inorganic and Physical Chemistry", the 6th edition of which had been completely destroyed before publication, by fire during the London blitz. The book, published under the names of Stewart and Wilson, appeared in 1941. Later, with his colleague Barnett at Cass College, he produced the well-known textbook of Barnett and Wilson: Inorganic Chemistry.

As an Editor, Professor Wilson served the community of Analytical Chemists in many ways. He was elected to the editorial board of *Microchimica Acta* in 1949, and has served on it ever since; between 1955 and 1962 he also acted as regional editor for papers written in English. When *Talanta* was established in 1958 as a new journal for Analytical Chemistry, Cecil Wilson became its first Editor-in-Chief, acting as such up to 1964, and since then acting as consulting editor. In 1959, in collaboration with his brother, D. W. Wilson, he became editor of the series "Comprehensive Analytical Chemistry" and since its foundation in 1967 he has served on the editorial board of *Analytical Letters*.

The Society for Analytical Chemistry called upon Cecil Wilson's services on several occasions. He has served on the Council three times since 1951. He was a founding member of the Microchemical Group, and acted as Chairman for the same group in

1951–52. He is a Fellow of the Royal Institute of Chemistry and has acted for years as the Chairman of the Northern Ireland section. His growing international reputation led to Honorary Membership of the Austrian Microchemical Society in 1955, and he was elected to Membership of the Royal Irish Academy in 1966.

Although his duties as Professor and Head of Department leave little time for non-professional activities, he manages to find time to act as Document Examiner for the Ministry of Home Affairs of Northern Ireland, appearing frequently as expert witness in court proceedings. He has held this appointment since 1953. He also served for six years on the Northern Ireland regional Committee of the Independent Television Authority.

Cecil Wilson started to do research in microchemistry, microscopy, micro- and ultramicroanalysis, but his interests widened when he had the opportunity of building up his own Department and research school at Queen's. About 100 papers and more than 30 research students bear witness to these activities.

While congratulating him on his sixtieth birthday, we wish Cecil Wilson further successes in his wide range of activities.

GYULA SVEHLA

Talanta, 1972, Vol. 19, pp. iii to iv. Pergamon Press. Printed in Northern Ireland

PUBLICATIONS RECEIVED

Nuclear Analytical Chemistry I (Introduction to Nuclear Analytical Chemistry): J. Tölgyessy, Š. Varga, and V. Kriváň. University Park Press, Baltimore, and Publishing House of the Slovak Academy of Sciences, Bratislava (Czechoslovakia), 1971. Pp. 270.

With this book the authors start a five-volume series scheduled to appear in a relatively short period. The division of the rich and constantly developing material among the five books seems to be quite natural: I—Introduction; II—Radioactive indicators (isotope dilution, radioreagents, radiometric titration, radio-release); III—Radiochemical and activation analysis (environmental analysis); IV—Interaction of nuclear radiation with matter; V—Tables, Nomograms, Schemes. The first volume covers both the fundamentals of nucleonics (types of radiation, radioactivity laws, detection, safety, sample preparation) and some chapters interesting for the analyst (criteria for the choice of suitable radioisotopes in the tracer method, behaviour of radioactive substances in trace amounts, selection of an isotope indicator).

The authors are well qualified for their task because each of them had made several important contributions to the field of nuclear analytical chemistry (radiometric titration, radio-release method *etc*) and moreover Prof. Tölgyessy is author of several more specialized books dealing with certain aspects of nuclear analytical chemistry. The present introduction to the whole series is well balanced, quite readable and gives the newcomer to the practical use of nuclear phenomena in analytical chemistry all the information he would otherwise have to look for in several separate books.

The "seams" between separate chapters (written mostly by one, sometimes by two of the authors are almost invisible. Errors and shortcomings are relatively rare (the authors do not mention ways of resolving a decay curve of two independent radioisotopes by other means than graphically). As a whole the first volume of the series is a promise that the whole work will be a very useful systematic and comprehensive presentation of nuclear methods in analytical chemistry.

Mössbauer Spectroscopy: N. N. Greenwood and T. C. Gibb, Chapman & Hall, London, 1971. Pp. xii + 659. £12.00.

This is a standard work for chemists, on the most recent addition to the range of spectroscopic techniques now available to them. After a historical introduction to the Mössbauer Effect the book gives a concise account of the more recent experimental techniques which have been developed for the study of the iron and tin resonance absorption. The hyperfine structures in the spectra so obtained are detailed in the following chapter together with explanations of the physical effect and processes responsible for their observation. There follows a large section dealing with the absorptions due to ^{57}Fe in a variety of compounds. Of particular interest is the section devoted to compounds of biological origin such as the blood pigments. A similar detailed discussion is provided for the resonances due to ^{119}Sn and the book closes with a survey of the applications of the Mössbauer effect to other elements in the periodic table. Appendices listing the nuclear data for Mössbauer transitions and the relative intensities of hyperfine lines are provided.

Field Ionisation Mass Spectrometry: Hans-D. Beckey. Pergamon, Oxford, 1971. Pp. xvi + 344. £9.50.

Field ionization is one of the most recent techniques which have been added to the armoury of the mass spectrometrist for the qualitative analysis of organic compounds. The book gives an account of the theoretical implications of this technique and of the construction of field ionization sources. The application of the field ionization methods to physico-chemical problems is outlined and there is a full description of the use of field-ionization mass-spectrometry in the examination of organic structures. The newer technique of field desorption is also described together with other effects which are observed in high potential gradients. The book is written by the originator of the method.

Liquid Scintillation Counting, Vol. I: ed. A. Dyer. Heydon, London, 1971. Pp. vii + 133. £4.60.

This book is a record of an International Symposium on Liquid Scintillation Counting held at the University of Salford on 21–22 September 1970. The papers presented covered a wide field from the physics and physical chemistry of the scintillation process to biochemical studies using tracers and to the applications of computers to the processing of scintillation data.

Activation Analysis in Geochemistry and Cosmochemistry: ed. Arild O. Brunfelt and Eiliv Steinnes. Scandinavian University Books, Oslo, 1971, Pp. 468. Nkr 144.0

This is an account of the proceedings of a meeting of the Nato Advanced Study Institute held at Kjeller, Norway, 7–12 September 1970. There were ten sessions describing the applications of the many activation techniques to the study of rock and fossil specimens. Considerable emphasis was given in several contributions to the examination of samples of extra-terrestrial origin.

Chemical Analysis of Additives in Plastics: T. R. Crompton. Pergamon, Oxford, 1971. Pp. xi + 162. £7.00.

The term "plastics" in the title of this book is slightly misleading as the analysis of rubber additives is also included. The identification and determination of antioxidants, ultraviolet stabilizers, peroxides, plasticizers, some residual monomers and other additives are described. Column, paper, thin-layer and gas–liquid chromatography together with various forms of spectroscopy, form the backbone of the analytical techniques employed. The book is intended to fill a gap in the literature on the analytical chemistry of polymers and should be of particular value to chemists in the polymer manufacturing and fabrication industries. The half-tone diagrams are poor in quality and add very little to the substance of the text. There are 330 references.

Analytical Chemistry of Molybdenum and Tungsten: W. T. Elwell and D. F. Wood, Pergamon, Oxford, 1971. Pp. xi +277. £8.00.

This book, Volume 47 in the "International Series of Monographs in Analytical Chemistry", is a comprehensive treatment of the analytical chemistry of molybdenum and tungsten from a practical viewpoint. There is virtually no comparison or contrast made between the elements, and the discussions of their respective methods of determination run parallel throughout the book. Each analytical method is dealt with in a separate chapter, the methods comprising the so-called classical methods as well as electrical methods (polarography, amperometry, and coulometry), emission spectroscopy, atomic absorption, X-ray spectroscopy, radiochemistry and mass spectrometry. There are introductory chapters dealing with the physical and chemical properties, sampling, decomposition, qualitative detection, and separations, as well as a short chapter on miscellaneous methods and a final chapter on the determination of impurities and alloying elements. Each chapter comprises a short introductory critique of the method under consideration, followed by a discussion in depth of the particular method and the practical procedure for a variety of sample types, including iron, steel, ores and biological materials. The excellent presentation of the book, the succinct style and care over detail (*e.g.*, giving the systematic names of chromogens as well as the trivial names) make the book both easy to read and to understand.

Proceedings of the 2nd Conference on Applied Physical Chemistry, Veszprém, Hungary, 1971: edited by I. Buzás. Akadémiai Kiadó, Budapest, 1971. Two volumes, pp. 759 and 738. £12.00 the set.

The practice of requiring authors to submit the texts of their papers before a conference begins has led to the laudable result that the proceedings can be published soon enough to retain their value as a reflection of the current state of development of the topic. The editors who achieve this feat of rapid publication are always to be congratulated on their dedication and enthusiasm. These two volumes, which include the proceedings of the second Electroanalytical Symposium and the sixth Symposium on Oscillometry could well be required reading for chemistry students, to let them see the extraordinary breadth of application of chemical principles in technology today.

Ekstraktsiya neorganicheskikh soedinenii: V. V. Bagreev, Yu. A. Zolotov, N. A. Kurilina and G. F. Kalinina, Izdat. "Nauka", Moscow, 1971. Two Volumes, 1945–1962 and 1963–1967. Vol. 1, pp. 328, 2R.40Kop. Vol. 2, pp. 336, 2R.13Kop.

The two volumes represent an enormous amount of work on the part of the authors, who have compiled a bibliography of solvent extraction methods from 1945 to 1967, arranging the entries in alphabetical order of first author's name, and classifying the material by subject. A comprehensive index makes it easy to find an author or a subject in the main text. Each entry gives the authors' names, title of the paper, the reference, and a Russian translation of the title. The subject indexes alone come to over 100 pages.

Fundamental Chemical Equilibria: Nonionic—Ionic: Kelso B. Morris, Gordon and Breach, New York, 1971. Pp. x + 110. $12.50.

The cover says that this book is a modern treatment of chemical equilibria, and it is therefore rather a surprise to find no mention of Ringbom's development of conditional constants and their applications, nor of graphical methods of problem solving and information display. There are many existing texts on the topic that would appear to offer more value for money. It is a pity that "tautomerism" double arrows (⇄) and "equilibrium" signs (⇌) have been used more or less indiscriminately.

PROFESSOR C. L. WILSON

CECIL LEEBURN WILSON was born in Co. Londonderry on 11 May 1912. He attended Rainey Endowed School at Magherafelt and later studied chemistry at Queen's University, Belfast, where he graduated with a first class honours B.Sc. in 1932. The following year he took his M.Sc. at Queen's. A Musgrave research scholarship took him to the University of Glasgow in 1933 where he obtained a Ph.D. in 1936. In 1935 however, he was appointed to an Assistant Lectureship in Chemistry at the Sir John Cass College, London. During the war he was released from there to work with the Armaments Research Department, Ministry of Supply, where he stayed for the years 1940–1944. He then resumed work at the Cass College but in 1946 returned to his Alma Mater in Belfast and has stayed there ever since. Appointed originally as a Lecturer, he became a Reader in 1950. In 1953 he took his D.Sc. at Queen's and in 1958 was appointed to a personal chair in Analytical Chemistry, the first of these ever created in the United Kingdom. The personal chair was converted into an established chair in Inorganic and Analytical Chemistry, which in turn has been split into separate chairs, Cecil Wilson retaining the chair of Analytical Chemistry.

It was in Glasgow that Cecil Wilson's interests were first turned towards microchemistry, and as early as 1935 he designed and introduced an undergraduate course in this subject in Belfast. His first book, entitled "An Introduction to Microchemical Methods" was published in 1938. During the war he had to do mainly analytical—often microanalytical— work for the Ministry of Supply, and from this time his interest in analytical chemistry became dominating. In co-authorship with Professor R. Belcher he published a book on Inorganic Microanalysis in 1946, 2nd edition 1957, and a similar co-operation produced various editions of "New Methods of Analytical Chemistry". Although his interests in teaching and research in Analytical Chemistry were always predominant, he found time and energy to keep up with Inorganic and Physical Chemistry. At the request of his old Professor at Queen's, Dr Stewart, he collaborated on the 7th edition of "Recent Advances in Inorganic and Physical Chemistry", the 6th edition of which had been completely destroyed before publication, by fire during the London blitz. The book, published under the names of Stewart and Wilson, appeared in 1941. Later, with his colleague Barnett at Cass College, he produced the well-known textbook of Barnett and Wilson: Inorganic Chemistry.

As an Editor, Professor Wilson served the community of Analytical Chemists in many ways. He was elected to the editorial board of *Microchimica Acta* in 1949, and has served on it ever since; between 1955 and 1962 he also acted as regional editor for papers written in English. When *Talanta* was established in 1958 as a new journal for Analytical Chemistry, Cecil Wilson became its first Editor-in-Chief, acting as such up to 1964, and since then acting as consulting editor. In 1959, in collaboration with his brother, D. W. Wilson, he became editor of the series "Comprehensive Analytical Chemistry" and since its foundation in 1967 he has served on the editorial board of *Analytical Letters*.

The Society for Analytical Chemistry called upon Cecil Wilson's services on several occasions. He has served on the Council three times since 1951. He was a founding member of the Microchemical Group, and acted as Chairman for the same group in

1951–52. He is a Fellow of the Royal Institute of Chemistry and has acted for years as the Chairman of the Northern Ireland section. His growing international reputation led to Honorary Membership of the Austrian Microchemical Society in 1955, and he was elected to Membership of the Royal Irish Academy in 1966.

Although his duties as Professor and Head of Department leave little time for non-professional activities, he manages to find time to act as Document Examiner for the Ministry of Home Affairs of Northern Ireland, appearing frequently as expert witness in court proceedings. He has held this appointment since 1953. He also served for six years on the Northern Ireland regional Committee of the Independent Television Authority.

Cecil Wilson started to do research in microchemistry, microscopy, micro- and ultramicroanalysis, but his interests widened when he had the opportunity of building up his own Department and research school at Queen's. About 100 papers and more than 30 research students bear witness to these activities.

While congratulating him on his sixtieth birthday, we wish Cecil Wilson further successes in his wide range of activities.

Talanta, 1972, Vol. 19, pp. iii to v. Pergamon Press. Printed in Northern Ireland

PUBLICATIONS RECEIVED

Ultrapurity: Methods and Techniques. Ed. MORRIS ZIEF and ROBERT M. SPEIGHTS. Dekker, New York, 1972. Pp. 700. $37.50.

The subject matter of this book will be of interest to many analysts. Some of the articles are directly concerned with such associated problems as sources of contamination and choice of container materials for high-purity materials, but this should not be taken as an excuse for five additional chapters on commonly used analytical techniques. The exception is provided, however, by A. J. Barnard's stimulating survey "High-purity chemicals—a challenge to the practical analyst." The first eleven chapters are concerned with the preparation of a number of materials in high purity (alkali metal halides, sodium and potassium, solvents, P_2O_5, proteins, *p*-xylene, isopropylbenzene, cholesterol, and water) and with the use of some techniques for purification (GLC, fractional distillation, dry-column chromatography). There is much valuable information in this book, based on the personal experience of the authors, (the chapters on glass, silica and ceramics in particular).

Air Pollution. Part A: Analysis. JOE O. LEDBETTER. Dekker, New York, 1972. Pp. 424. $11.75.

The author makes a successful attempt to distinguish the real problems from the imaginary and to help the student appreciate the need for a clear understanding of what pollution is, and what kind of analytical data are likely to be useful to the controlling authorities. Topics covered include Sources of pollution, Atmospheric transport of pollutants, Statistical evaluation, Sampling, Properties of gaseous and particulate pollutants, and various aspects of the analytical methods used. This book can be recommended as interesting and worthwhile reading.

Electrochemistry: Calculations, Simulation and Instrumentation. (Computers in Chemistry and Instrumentation Series, Vol. 2) Ed. J. S. MATTSON, H. B. MARK, JR. and H. C. MACDONALD, JR. Dekker, New York, 1972. Pp. 466. $23.50.

The successful design and application of mathematical models has been a notable development in the study of electrochemical processes in recent years, being limited more by the complexity of the models than by their shortcomings. The contributors to this volume show how the use of computers can alleviate the problem of complexity and enable the chemist to design and test his mathematical models with ease. Thirteen chapters, contributed by sixteen authors, cover a wide variety of topics, some of rather specialized application, others, such as those on Numerical solution of integral equations, and Operational amplifier instruments for electrochemistry, may be commended as useful and readable introductions for the non-specialist. The offset-litho printing from the typescript—aimed at speeding up the publishing—suffers from a lack of variety in type faces which is particularly noticeable in chapters with a considerable mathematical content, and does not appear to effect any cost-saving.

Simplified Circuit Analysis: RICHARD B. SACKS and HARRY B. MARK, JR. Dekker, New York, 1972. Pp. 166. $6.50.

The two sections of this book, dealing with analogue and digital circuitry respectively, grew out of material presented in a course on basic electronics as applied to instrumentation and written for non-engineers. A special feature is the emphasis on circuit analysis by the Laplace Transform Method. There are many figures to illustrate the text, and examples are given of chemical applications—for example the solution of problems in kinetics by analogue computer.

Solvent Extraction Reviews Vol. 1: Ed. Y. MARCUS. Dekker, New York, 1972. $19.50.

The object of this new series of reviews is to provide authorative surveys and critical discussion of advances in the field of solvent extraction. Speedy publication is promised and future reviews will appear first in journal form and then in an annual hardback edition. The selection of items in this volume is diverse and covers discussion of extraction equilibrium and kinetics of organophosphorus acids, the extraction of protactinium and polonium, mixing equipment, mass transfer problems and the industrial extraction of phosphoric acid. The papers provide useful background reading for the analyst, although the bias is clearly towards the physico-chemical aspects of the technique. The emphasis on criticality however, is most welcome and future volumes may well have more contributions of direct analytical interest.

Etude analytique de dérivés fluorés: M. HANOCQ. Editions Arscia S.A., Brussels, and Librairie Maloine S.A. Paris, 1972. Pp. 241. 490 F.B.

This book contains a comprehensive account of the methods available for determination of fluoride (or fluorine) by spectrophotometry or potentiometry, with special reference to materials of biological or organic origin. In doing so it reports at some length original work from the author's laboratory, with statistical analysis of the results. In view of the author's undoubted interest in statistics, it seems curious to recommend optimum reaction conditions that apparently require very exact measurement of reagent volumes, and to state ratios of sensitivities to better than 1% relative. There is an English version of the summary of the book, and the publishers have done the author a disservice by not having the translation edited properly. Nevertheless the book as a whole is a useful summary of the present state of determination of fluorine in fluorinated compounds.

Luminescence Spectrometry in Analytical Chemistry. J. D. WINEFORDNER, S. G. SCHULMAN and T. C. O'HAVER. Wiley-Interscience, New York, 1972. Pp. xiii + 354. $19.95.

The senior author of this work is well known for his contributions to interpretations of errors in luminescence spectrometry and for his practical application of absorption and fluorescence, and this book amply reflects his interests, the first two thirds being devoted mainly to theory, whether of the basic phenomena or of the instrumentation, and the remainder to a review of the analytical applications. In view of the increasing interest in the technique it is a pity that the literature coverage appears to stop at 1969 except for a few references to work undertaken by the author(s) or described at meetings. The book will prove very useful to analysts working in this field.

Analytical Applications of EDTA and Related Compounds. R. PŘIBIL. Pergamon, Oxford, 1972. Pp. xxi + 368. £12·50.

The title of this book is slightly misleading, as the book does not deal at all with the direct application of EDTA and its analogues as titrants, but is concerned with their use as masking agents in gravimetric, titrimetric and colorimetric analysis, and with the use of metallochromic indicators as reagents in colorimetry. In addition there is mention of the solvent extraction of some metal complexes of these compounds. As might be expected from the author, there is a wealth of detail on practical application. The literature coverage stops at around 1967–8, largely because the author considers that practically all the important work had already been done by then. The book will prove a valuable reference work for all analysts concerned with inorganic analysis.

Marine Chemistry, Vol. 1, Analytical Methods. DEAN F. MARTIN, 2nd Ed. Dekker, New York, 1972. Pp. viii + 389. $9.50.

The fact that a second edition (expanded and revised) has been found necessary only four years after the appearance of the first doubtless reflects the interest taken in the chemistry of the ocean. The literature coverage has been brought up to date (up to late 1971).

Analytical Atomic Absorption Spectrometry: W. J. PRICE, Heyden, London, 1972. Pp. xii + 239 £5·80, $15.25.

Those familiar with the very extensive range of monographs on atomic-absorption spectrometry might well be excused for expressing dismay at the introduction of yet another work on this subject. It is therefore extremely gratifying to be able to report that this volume is undoubtedly one of the finest and most concise and readable expositions of atomic-absorption currently available. Selection of material and the level of treatment used clearly represent the results of a good deal of careful and painstaking thought and effort on the part of the author, who has produced a book which should serve for several years to come as an invaluable reference work for the analyst, regardless of his previous experience of the technique. The excellent résumé of sample dissolution methods for a wide range of sample types renders the book an asset not only in all branches of analytical flame spectrometry, but also in many other branches of analytical chemistry.

Annual Reports on Analytical Atomic Spectroscopy, Vol. 1: D. P. HUBBARD (Ed.), The Society for Analytical Chemistry, London, 1971. Pp. 204. £5·00, $13.00.

Much credit must go to the editor and editorial board of the first volume of this annual series for the promptness of publication which has resulted in a useful outline of the developments in all major branches of analytical atomic-spectroscopy during 1971, with few of the errors and omissions which are perhaps inevitable in a work of this kind. Particularly useful are the references to papers presented at conferences and to papers published in some of the less readily available journals. These, together with the frequent use of tabular presentation of data selected from a wide range of sources indicate that this inexpensive book should prove to be a valuable source of reference to spectroscopists engaged in both routine analysis and in academic and more applied research.

Bibliography of Paper and Thin Layer Chromatography 1966–1969, Journal of Chromatography, Supplementary Volume No. 2: edited by K. MACEK, I. M. HAIS, J. KOPECKÝ, J. GASPARIČ, V. RÁBEK and J. CHURÁČEK, Elsevier, Amsterdam, 1972. Pp. XVI + 991. Dfl. 200.00, $*ca.* 62.50.

The editors and those who collaborated in the production of this bibliography on paper and thin-layer chromatography have performed a daunting and arduous task. They have sifted the contents of countless papers, many of them in journals not readily available. This work lists papers deemed particularly significant. The titles, unless originally in English, German or French, have been translated and, in the case of the less readily available journals, references to *Chemical Abstracts* are commonly included. Over the past decade the *Journal of Chromatography* has published bibliographies on the fields covered by the present work. Now the collective labours for the years 1966–69 have been brought together in augmented, critically selected, rearranged and well-ordered form. There are 849 references to papers on general methods followed by 7846 references to compounds classified in about 500 groups. Such a book needs, and has, lengthy, comprehensive and reliable compound and author indices. There are also helpful cross-references at the end of each section to papers listed elsewhere in the book. Bibliographies are not for readers, but for the guidance of those lost or uncertain where to turn. This chromatographic gazetteer will save many travellers in the field much unnecessary toil and with, or without, a preceding volume covering the years 1961–65 will, it is to be hoped, justify the cost of placing it on the shelves of every library frequented by research workers using such chromatographic methods.

Neutron Activation Analysis: D. DE SOETE, R. GIJBELS and J. HOSTE. Wiley-Interscience, London, 1972. Pp. xx + 836. £14.

This comprehensive treatise upon the most important technique of trace analysis constitutes Volume 34 of the series of monographs edited by P. J. Elving and I. M. Kolthoff under the general title of Chemical Analysis. There is an introductory section describing the scope and application of the technique and this is followed by chapters dealing with the theoretical aspects of the interaction of neutrons with nuclei. Succeeding chapters outline the experimental methods and describe neutron sources, the growth and decay of induced radioactivity and the detection of the resulting radioelements. In addition, the preparation of samples and standards is described, together with procedures for chemical segregation of activities. The book closes with a survey of systematic errors and the statistical analysis of experimental results. There is an extensive bibliography classified in tabular form under author's name and element determined, and appendices containing lists of neutron cross-sections.

Photoelectron Spectroscopy: A. D. BAKER and D. BETTERIDGE. Pergamon, Oxford, 1972. Pp. x + 180. £3·50.

This is the first book dealing explicitly with the analytical applications of one of the most recent additions to spectroscopy. The theory of the photoelectric effect is outlined and there is a detailed discussion of instrumentation. The appearance and interpretation of photoelectron spectra are described with reference to the detailed fine structure. Although the book is mainly concerned with electron emission resulting from the absorption of X-ray and ultraviolet photons there is a section dealing with other techniques based upon the energy analysis of emitted electrons. There are appendices giving lists of ionization potentials and orbital energies.

EDITORIAL

SI UNITS

In 1968 the Royal Society Committee of Editors decided that as a matter of policy their journals would use SI units in future. The International Union of Pure and Applied Chemistry also gave its support to exclusive use of SI units. Because *Talanta* has always followed the recommendations of IUPAC, an editorial in the 1968 July issue informed readers that SI units would be used in this journal. Three years later, we have received a grand total of two papers actually written with use of SI units only, and it is clear that whatever the future may hold in the shape of papers written by scientists trained from childhood in the use of SI, the current generation of practising analysts will have no truck with the system. We shall therefore revert to allowing authors to use the units that are familiar to them and which are in everyday use on instrument dials *etc*, with some exceptions in the case of units that are unnecessary duplication of existing and more immediately understood units. Examples are "mil" (instead of 0.001 in.) and "torr" (instead of mmHg). We shall continue to use milliard (abbreviation M) for 10^9 to avoid the confusion between American and European billions, and mole for an Avogadro's number of units of the species named (the IUPAC abbreviation to "mol" seems singularly pointless). By a happy coincidence, the two papers that *were* written in terms of SI units also were the two best-written papers published in *Talanta* in 1971, and it is with pleasure that we announce the joint award of the Louis Gordon Memorial Award to Mrs. Elsie M. Donaldson, of Ottawa, Canada, for her paper on "Determination of aluminium in molybdenum and tungsten metals, iron, steel and ferrous and non-ferrous alloys with Pyrocatechol Violet" (*Talanta*, 1971, **18**, 905) and to Dr. G. B. Briscoe and Dr. S. Humphries, of Birmingham, England, for their paper on "Substoichiometric determination of traces of palladium by radioactive isotope-dilution analysis" (*Talanta*, 1971, **18**, 39).

SUMMARIES FOR CARD INDEXES

Determination of trace elements in metals and alloys by atomic-absorption spectroscopy using an induction-heated graphite well furnace as atom source: J. B. HEADRIDGE and DAVID RISSON SMITH, *Talanta*, 1972, **19**, 833 (Chemistry Department, Sheffield University, Sheffield, S3 7HF, U.K.)

Summary—An induction-heated graphite furnace, coupled to a Unicam SP 90 atomic-absorption spectrometer, is described for the direct determination of trace elements in metals and alloys. The furnace is capable of operation at temperatures up to 2400°, and has been used to obtain calibration graphs for the determination of ppm quantities of bismuth in lead-base alloys, cast irons and stainless steels, and for the determination of cadmium at the ppm level in zinc-base alloys. Milligram samples of the alloys were atomized directly. Calibration graphs for the determination of the elements in solutions were obtained for comparison. The accuracy and precision of the determination are presented and discussed.

Separation of the non-volatile noble metals by reversed-phase extraction chromatography: CHRISTEL POHLANDT and T. W. STEELE, *Talanta*, 1972, **19**, 839. (National Institute for Metallurgy, Private Bag 6, Johannesburg, South Africa.)

Summary—The procedure involves the use of tri-n-butyl phosphate (TBP) adsorbed by Porasil C and stepwise elution with sulphuric acid and hydrochloric acid. The distribution coefficients for the two systems (TBP and hydrochloric acid and TBP and sulphuric acid) and the elution characteristics were studied. A description is given of a procedure applicable to the analysis of prills obtained from the fire assay of platinum-bearing ores.

Determination of trace amounts of uranium in silicate minerals by the fission track technique: HIDEKI, MATSUDA, YUTAKA TSUTSUI, SHIGENORI NAKANO and SHUNJI UMEMOTO, *Talanta*, 1972, **19**, 851. (Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka, Japan.)

Summary—The fission track technique has been applied to the determination of uranium on Dowex 1 × 8 after chemical separation from silicates. Standard rock and several stone meteorite samples were treated by this method and satisfactory results were obtained. The procedure is applicable to natural waters.

ОПРЕДЕЛЕНИЕ СЛЕДОВ ЭЛЕМЕНТОВ В МЕТАЛЛАХ И СПЛАВАХ МЕТОДОМ АТОМНО-АБСОРБЦИОННОЙ СПЕКТРОСКОПИИ С ИСПОЛЬЗОВАНИЕМ ГРАФИТНОЙ ПЕЧИ С ИНДУКЦИОННЫМ НАГРЕВАНИЕМ В КАЧЕСТВЕ ИСТОЧНИКА АТОМОВ:

J. B. HEADRIDGE and DAVID RISSON SMITH, *Talanta*, 1972, **19**, 833.

Резюме—Описана графитная печь с индукционным нагреванием, комбинированная с атомно-абсорбционным спектрофотометром Юникам СП 90, для непосредственного определения следов элементов в металлах и сплавах. Печь позволяет нагревать пробы вплоть 2400° и использована для получения калибровочных кривых для определения микрограммовых количеств висмута в сплавах на основе свинца, в чугуне и нержавеющих сталях и для определения частей на миллион кадмия в сплавах на основе цинка. Метод позволяет распылять непосредственно миллиграмовые количества сплавов. Результаты сравнены с калибровочными кривыми полученными для растворах элементов. Приведены и обсуждены точность и воспроизводимость результатов.

РАЗДЕЛЕНИЕ НЕЛЕТУЧИХ БЛАГОРОДНЫХ МЕТАЛЛОВ МЕТОДОМ ЭКСТРАКЦИОННОЙ ХРОМАТОГРАФИИ С ОБРАТНОЙ ФАЗОЙ:

CHRISTEL POHLANDT and T. W. STEELE, *Talanta*, 1972, **19**, 839.

Резюме—Метод использует три-н-бутилфосфат (ТБФ) адсорбированный на Порасиле С и этапное элюирование серной и соляной кислотами. Изучены коэффициенты распределения для этих двух систем (ТБФ—соляная кислота и ТБФ—серная кислота) и характеристики элюирования. Описан метод применимый в анализе королков полученных при испытании сухим путём платинусодержащих руд.

ОПРЕДЕЛЕНИЕ СЛЕДОВЫХ КОЛИЧЕСТВ УРАНА В СИЛИКАТНЫХ МИНЕРАЛАХ МЕТОДОМ СЛЕДА ФИССИИ:

HIDEKI MATSUDA, YUTAKA TSUTSUI, SHIGENORI NAKANO and SHUNJI UMEMOTO, *Talanta*, 1972, **19**, 851.

Резюме—Метод следа фиссии применен в определении урана на смоле Дауекс 1 × 8 после химического отделения от силикатов. Эталонные горные породы и некоторые образци каменных метеоритов анализированы с помощью этого метода и получены удовлетворительные результаты. Методом можно пользоваться для анализа природных вод.

Rapid mass-spectrometric determination of boron isotopic distribution in boron carbide: James E. Rein and Robert M. Abernathey, *Talanta*, 1972, **19**, 857. (University of California, Los Alamos Scientific Laboratory, Los Alamos, New Mexico 87544, U.S.A.)

Summary—Boron isotopic ratios are measured in boron carbide by thermionic ionization mass spectrometry with no prior chemical separation. A powder blend of boron carbide and sodium hydroxide is prepared, a small portion is transferred to a tantalum filament, the filament is heated to produce sodium borate, and the filament is transferred to the mass spectrometer where the $^{11}B/^{10}B$ ratio is measured, using the $Na_2BO_2^+$ ion. Variables investigated for their effect on preferential volatilization of ^{10}B include the sodium hydroxide–boron carbide ratio and the temperature and duration of filament heating. A series of boron carbide pellets containing natural boron, of the type proposed for the control rods of the Fast Flux Test Facility reactor, were analysed with an apparently unbiased result of 4·0560 for the $^{11}B/^{10}B$ ratio (standard deviation 0·0087). The pellets contained over 3% metal impurities typically found in this material. Time of analysis is 45 min per sample, with one analyst.

Determination of niobium in rocks, ores and alloys by atomic-absorption spectrophotometry: John Husler, *Talanta*, 1972, **19**, 863. (Department of Geology, University of New Mexico, Albuquerque, New Mexico 87106, U.S.A.)

Summary—Niobium, in concentrations as low as 0·02% Nb_2O_5, is determined in a variety of materials without separation or enrichment. Chemical and ionization interferences are controlled, and sensitivity is increased, by maintaining the iron, aluminium, hydrofluoric acid and potassium content within certain broad concentration limits. There is close agreement with the results of analyses by emission spectrographic, electron microprobe and X-ray fluorescence methods.

Constitution and stability of acidic periodate solutions: D. J. B. Galliford, R. H. Nuttall and J. M. Ottaway, *Talanta*, 1972, **19**, 871. (Chemistry Department, University of Strathclyde, Cathedral Street, Glasgow C.1, Scotland.)

Summary—Acidic periodate solutions are shown to contain two species, tetrahedral IO_4^- and octahedral H_5IO_6. Equilibrium between the two is attained rapidly and the solutions are stable for long periods of time if stored in amber glass bottles.

БЫСТРОЕ ОПРЕДЕЛЕНИЕ РАСПРЕДЕЛЕНИЕ ИЗОТОПОВ БОРА В КАРБИДЕ БОРА МЕТОДОМ МАСС-СПЕКТРОМЕТРИИ:

JAMES E. REIN and ROBERT M. ABERNATHY, *Talanta*, 1972, **19**, 857.

Резюме—Отношения изотопов бора в карбиде бора измерены методом масс-спектрометрии с термоионной ионизацией без предварительного химического разделения. Приготовляют порошковидную смесь карбида бора и гидроокиси натрия, небольшую часть переносят на танталовую нить, нить нагревают для получения бората натрия и нить переносят в масс-спектрометр. Измеряют отношение $^{11}B/^{10}B$ с использованием иона $NaBO_2^+$. Изучены факторы влияющие на селективное улетучивание ^{10}B, так как отношение гидроокиси натрия и карбида бора, температура и продолжительность нагревания нити. Анализ ряда гранул карбида бора содержаших природный бор, типа предложенного для контрольных прутков реактора Fast Flux Test Facility дал очевидно беспристрастный результат 4,0560 для отношения $^{11}B/^{10}B$ (стандартная ошибка 0,0087). Гранулы содержали больше чем 3% примесей металлов, типических дла этого материала. Продолжительность анализа 45 на образец, с одним аналитиком.

ОПРЕДЕЛЕНИЕ НИОБИЯ В ГОРНЫХ ПОРОДАХ, РУДАХ И СПЛАВАХ МЕТОДОМ АТОМНО-АБСОРБДИОННОЙ СПЕКТРОФОТОМЕТРИИ:

JOHN HUSLER, *Talanta*, 1972, **19**, 863.

Резюме—Ниобий определяют в концентрациях вплоть до 0,02% Nb_2O_5 в разных материалах без предварительного выделения или обогащения. Химические и ионизационные действия предотвращаются а чувствительность повышается поддерживанием содержания железа, алюминия, фтористо-водородной кислоты и калия в известных широких диапазонах концентраций. Полученные результаты хорошо соглашаются с результатами полученными методами эмиссионной спектрографии, электронной микропробы и рентгеновской флуоресценции.

СТРОЕНИЕ И УСТОЙЧИВОСТЬ КИСЛЫХ РАСТВОРОВ ПЕРИОДАТА:

D. J. B. GALLIFORD, R. H. NUTTALL and J. M. OTTAWAY, *Talanta*, 1972, **19**, 871.

Резюме—Показано что кислые растворы периодата содержают две формы—тетраэдрическую IO_4^- и октаэдрическую H_5IO_6. Равновесие между этим двумя формами быстро устанавливается и растворы являются устойчивыми через долгие периоды времени если сохраняются в янтарных стеклянных склянках.

Complexation of polyvinyl alcohol with iodine. Analytical precision and mechanism: J. G. Pritchard and D. A. Akintola, *Talanta*, 1972, **19**, 877. (North East London Polytechnic, London, E. 15, U.K.)

Summary—Polyvinyl alcohol (PVA), boric acid and tri-iodide form a characteristic blue complex. For a number of PVA samples, prescribed conditions were used to examine the precision of the formation and spectrophotometry of the complex. The precision of calibration curves was 1–2% over the range 0–4 mg of PVA per 50 ml of final solution, over which Beer's law holds. Greater deviations can be caused by faulty preparation and aging of individual PVA solutions. The absorbance is independent of the content of residual acetate groups in the PVA for the range 0–15%. The limit of detection is about 0.01 mg of PVA in 25 ml of sample. A pink colour in the system is due to association of iodine with acetate groups in the PVA. A blue or green colour is due to helical envelopment of iodine molecules by PVA chains stiffened by scattered cyclic groups. The mechanisms of these effects are discussed.

Liquid-liquid interfaces as potentiometric ion-sensors—I. The n-butanol–water interface as indicating sensor for the potentiometric titration of some acids and bases: Candin Liteanu and Maria Mioşcu, *Talanta*, 1972, **19**, 889. (Department of Analytical Chemistry, University of Cluj, Romania.)

Summary—The property that liquid—liquid interfaces modify their electrical charge as a function of the composition of the two phases in contact has been used to detect the end-points in a series of acid–base titration in the aqueous phase. Although the titration curves are not classical in shape, the equivalence points can be located if the solutions are not too dilute. Good results for concentrations down to $10^{-3}N$ have been obtained. The electrode has a fast response. The influence of surface-active substances on the titration has also been investigated.

Studies on nucleation from solution of some analytically important metal chelates—II. Nickel dimethylglyoximate. J. D. Hanna and O. E. Hileman, Jr.®, *Talanta*, 1972, **19**, 894 (Department of Chemistry, McMaster University, Hamilton, Ontario, Canada.)

Summary—A new direct-mixing and rapid particle-counting system useful for studies on crystal nucleation from solution is described. The methods used to calibrate and evaluate the system are reported together with the results obtained during studies on nucleation from solution of nickel dimethylglyoximate. The Volmer-Weber, Becker-Döring model of the nucleation process is used to correlate the results.

Losses of iridium during heating in various atmospheres: A. Chow *Talanta*, 1972, **19**, 899. (Department of Chemistry, University of Manitoba, Winnipeg 19, Manitoba, Canada.)

Summary—The volatility of iridium metal in different atmospheres was studied, using various weights, times and temperatures. Significant volatility was observed in oxygen and oxygen plus acid at temperatures above 400° and in chlorine above 220°

ОБРАЗОВАНИЕ КОМПЛЕКСОВ ПОЛИВИНИЛОВОГО СПИРТА С ИОДОМ. ТОЧНОСТЬ ОПРЕДЕЛЕНИЯ И МЕХАНИЗМ:

J. G. Pritchard and D. A. Akintola, *Talanta*, 1972, **19**, 877.

Резюме—Поливиниловый спирт (ПВС), борная кислота и трииодид образуют характеристический голубой комплекс. Использованы определенные условия для испытания воспроизводимости образования комплекса и его спектрофотометрических характеристик на ряде образцов ПВС. Воспроизводимость калибровочных кривых была 1–2% в пределах 0–4 мг ПВС в 50 мл конечного раствора, в которых пределах почитается закон Бера. Большие ошибки могут быть вызваны неисправным приготовлением и старением растворов ПВС. Светопоглощение независимо от содержания остаточных ацетатных групп в ПВС в пределах 0–15%. Чувствительность равна 0,01 мг ПВС в 25 мл раствора пробы. Розовый цвет появляется в системе вследствие ассоциации иода с ацетатными группами в ПВС. Голубой или зелёный цвет появляется в результате спирального обёртывания молекул иода цепями ПВС, усиленными рассеянными циклическими группами. Рассмотрены механизмы этих эффектов.

ПОВЕРХНОСТЬ РАЗДЕЛА МЕЖДУ ЖИДКОСТЯМИ В КАЧЕСТВЕ ПОТЕНЦИОМЕТРИЧЕСКОГО ДАТЧИКА ДЛЯ ИОНОВ—I. ПОВЕРХНОСТЬ РАЗДЕЛА МЕЖДУ Н-БУТАНОЛОМ И ВОДОЙ В КАЧЕСТВЕ ИНДИКАТОРНОГО ДАТЧИКА ДЛЯ ПОТЕНЦИОМЕТРИЧЕСКОГО ТИТРОВАНИЯ НЕКОТОРЫХ КИСЛОТ И ОСНОВАНИЙ:

Candin Liteanu and Maria Mioscu, *Talanta*, 1972, **19**, 889.

Резюме—Свойство поверхности раздела между жидкостями изменять их электрический заряд в зависимости от состава этих двух фаз в контакте использовано для обнаружения конца титрования в ряде кислотно-щелочных титраций в водной фазе. Титрационные кривые не показывают классическую форму, однако возможно обнаружить конец титрования если растворы не слишком разбавлены. Получены хорошие результаты вплоть до концентрации 10^{-3} *N*. Электрод обладает быстрым ответом. Также изучено влияние поверхностно-активных веществ на титрование.

ИЗУЧЕНИЕ НУКЛЕАЦИИ ИЗ РАСТВОРА НЕКОТОРЫХ ПРИМЕНИМЫХ В АНАЛИЗЕ ХЕЛАТОВ МЕТАЛЛОВ—II. ДИМЕТИЛГЛИОКСИМАТ НИКЕЛЯ.

J. D. Hanna and O. E. Hileman, *Talanta*, 1972, **19**, 894.

Резюме—Новая система непосредственного смешивания и быстрого счёта частиц оказалась полезной в изучении нуклеации кристаллов из растворов. Рассмотрены методы калибровки и оценки системы, вместе с результатами полученными в изучении нуклеации из раствора диметилглиоксимата никеля. Модель Вольмера-Вебера, Бекера-Доринга процесса нуклеации использована для сравнения результатов.

ПОТЕРИ ИРИДИРЯ ПРИ НАГРЕВАНИИ В РАЗНЫХ АТМОСФЕРАХ:

A. Chow, *Talanta*, 1972, **19**, 899.

Резюме—Изучена летучесть металлического иридия в разных атмосферах, с использованием различных весов, продолжительностей и температур. Обнаружена значительная летучесть в кислороде и в кислороде в присутствии кислоты при температурах выще 400°, и в хлоре выше 220°.

NOTES FOR AUTHORS

1. General

Contributions may deal with any aspect of analytical chemistry, although papers exclusively concerned with limited fields already catered for by specialist journals should normally be directed to those journals, and should only be submitted to TALANTA if their analytical implications as a whole are such as to make their inclusion in a more general background desirable. Original papers, preliminary and short communications, annotations, reviews, and letters will be published.

Because TALANTA is an international journal, contributions are expected to be of a very high standard. They should make a definite contribution to the subject. Papers submitted for publication should be new publications. The submission of a paper is held to imply that it has not previously been published in **any language**, that it is not under consideration for publication elsewhere, and that, if accepted for publication, it will not be published elsewhere without the written consent of the Editor-in-Chief. Special importance will be attached to work dealing with the principles of analytical chemistry in which the experimental material is critically evaluated, and to similar fundamental studies. Reviews in rapidly expanding fields, and reviews of hitherto widely scattered material, will be considered for publication, **but should be critical.** The Editor-in-Chief will welcome correspondence on matters of interest to analytical chemists. Annotations should be critical commentaries on some aspects of analytical chemistry and may deal with topics such as sources of error, or the scope and limitations of methods and techniques.

Original papers, short communications annotations and reviews will be refereed (see *Talanta*, 1962, **9**, 89). Referees will be encouraged to present critical and unbiased reports which are designed to assist the author in presenting his material in the clearest and most unequivocal way possible. To assist in achieving this completely objective approach, referees will be asked to submit signed reports. At the discretion of the Editor-in-Chief, the names of referees may be disclosed if thereby agreement between author and referee is likely to result. Authors should appreciate that the comments of referees are presented in a constructive spirit, and that agreement between the views of author and referee must result in a higher standard of publication.

Preliminary communications will be refereed urgently and will be accorded priority in publication. Letters to the Editor will not be refereed, but will be published at the discretion of the Editor-in-Chief. If accepted, they will also be given priority.

Fifty free reprints will be provided (regardless of the number of authors) and additional copies can be supplied at reasonable cost if ordered when proofs are returned. A reprint order form will accompany the proofs.

2. Script Requirements

By following the Script Requirements carefully, authors will ensure more rapid publication of their papers.

General

Contributions should be submitted to the Editor-in-Chief or to a Regional Editor where appropriate (see editorial page for addresses). They may be written in English, French or German. All contributions in the French language should be submitted to Dr. M. Pesez, and those in the German language to Professor E. Blasius.

Preliminary communications should be limited to less than 1000 words in length and should not contain diagrams. If they do not fulfil these conditions they will be treated as short communications.

Scripts should be submitted in duplicate; they should be typewritten and the lines double-spaced. Where possible, papers should follow the pattern: *Introduction*, *Experimental*, *Results*, *Discussions*, *Conclusions* (or such of these headings as apply).

Because all material will be set directly in page proof, every attempt should be made to ensure that before being submitted, manuscripts are essentially in the final form desired by the authors, and that no alterations of moment will be required at the proof stage. Alterations suggested by the referee will be agreed with the authors at the manuscript stage. Authors writing in a foreign language are advised that in submitting papers they should endeavour to have the paper thoroughly corrected before submitting for publication. If the manuscript requires considerable editing, it may have to be returned to the authors for retyping, resulting in a serious delay in publication.

Summaries

The essential contents of each paper should be briefly recapitulated in a summary **placed at the beginning of a paper, or at the end of a preliminary or short communication.** This should be in the language of the paper, but for French or German papers an English version should also be provided wherever possible.

Illustrations

Illustrations should be separate from the typescript of the paper. Original line drawings should be supplied (about twice the final size required) together with one set of copies. **If the illustrations require redrawing, publication of the paper will be delayed.** The following standard symbols should be used on line drawings:

△ △ ⊡ □ ● ○ ◬ ⊙ ⊕ ⊖ ⌽ ⊗

Photographs should be restricted to the very minimum required.

Legends for illustrations should be typed on a separate sheet.

Straight-line calibration graphs are not generally permitted; the necessary information can usually be included in the text (*e.g.* in the form of an equation).

Tables should be so constructed as to be intelligible without reference to the text, every table and column being provided with a heading. Units of measure must always be clearly indicated. Unless it is essential to the argument, tables should not list the results of individual experiments, but should summarize results by an accepted method of expression (*e.g.* standard deviation). The same information should not be produced in both tables and figures.

The preferred positions for all figures and tables should be indicated in the manuscript by the authors.

References

References should be indicated in the text by consecutive superior numbers placed outside any punctuation marks; the full references should be given in a list at the end of the paper in the following form:

1. J. B. Austin and R. H. H. Pierce, *J. Am. Chem. Soc.*, 1955, **57**, 661.
2. S. T. Yoffe and A. N. Nesmeyanov, *Handbook of Magnesium-Organic Compounds*, 2nd Ed., Vol. 3, p. 214. Pergamon Press, Oxford, 1956.
3. R. J. Winterton in C. L. Wilson and D. W. Wilson, *Comprehensive Analytical Chemistry*, Vol. IB, p. 238. Elsevier, Amsterdam, 1960.
4. A. B. Smith, *The Effect of Radiation on Strength of Metals.* A.E.R.E., M/R 6329, 1962.
5. W. Jones, *Brit. Pat.* 654321, 1959.

Journal-name abbreviations should be those used in *Chemical Abstracts* (see *Chem. Abstr.*, 1961, *et seq.*).

Footnotes to pages and to tables, as distinct from literature references, should be indicated by the following symbols: *, †, ‡, ¶, beginning anew on each page.

Proofs

Proofs are not set in galley form and will be sent out to authors in page form for correction. **It is emphasized that at this stage alterations to the text or failure to return the corrected proofs promptly may result in serious delay in publication, and authors will be charged for changes other than printers' errors.**

Authors are particularly requested to check the correctness of their references, which should also, at some stage, be checked against the original papers.

Miscellaneous

Because of the international character of the journal, authors should follow the recommendations of the *International Union of Pure and Applied Chemistry* as regards nomenclature and symbols. In the editing of papers for publication, English spelling will be used for all matter in the English language. Authors who wish to retain American spelling, or to adhere to other generally accepted usages, should indicate this clearly at the time of submission of the manuscript. Attention is particularly drawn to the importance of correctness of grammar and clarity of expression.

Where several authors are involved in a paper, an indication of the author to whom requests for reprints should be addressed may be given by placing the symbol ® after the name of that author.

Des exemplaires en français des Notes aux Auteurs peuvent être obtenus auprès du Rédacteur en Chef

Reprints of Talanta Reviews

As the volume of scientific literature grows, reviews provide one of the best means of keeping abreast with recent developments. Talanta has commissioned a series of comprehensive and critical reviews of topics of current interest to analytical chemists; many of these reviews will also be of value to chemists in general and to other scientists. Talanta Reviews are intended primarily to introduce the non-specialist to a subject about which he previously knew little, but they may also help the specialist fill gaps in his knowledge of his own field or illuminate the subject from a new angle.

SUMMARIES FOR CARD INDEXES

Analytical mass spectrometry: J. R. MAJER, *Talanta*, 1972, **19**, 589. (Chemistry Department, University of Birmingham, P.O. Box 363, Birmingham 15, U.K.)

Summary—A review is made of the basic theory, instrumentation and application of mass spectrometry, with special reference to the development of the equipment and its impact on the scope of application.

Development and publication of work with selective ion-sensitive electrodes: G. J. MOODY and J. D. R. THOMAS, *Talanta*, 1972, **19**, 623. (University of Wales Institute of Science and Technology, Cardiff, Wales.)

Summary—Features concerning development, response, selectivity and applications of selective ion-sensitive electrodes are reviewed. Recommendations are made concerning investigations involving the development and applications of electrodes and attention given to the manner of presenting data for publication.

Iodometric microdetermination of sulphur in organic compounds by an amplification method: Y. A. GAWARGIOUS and A. B. FARAG, *Talanta*, 1972, **19**, 641. (Microanalytical Research Laboratory, National Research Centre, Dokki, Cairo, U.A.R.)

Summary—A new method is described for the iodometric microdetermination of sulphur in organic compounds, using a 12-fold amplification reaction after oxygen-flask combustion. The method is based on reaction of the resulting sulphuric acid with an excess of saturated barium bromate solution. The unreacted barium bromate is precipitated by addition of acetone, filtered off, redissolved in hot water and after addition of an excess of iodide and acid, the iodine liberated is titrated with thiosulphate. The method is simple, rapid, highly accurate, and of wide application in the microanalysis of organosulphur compounds containing other common acid-forming elements.

Improved synthesis and stability of 8-selenoquinoline and its sodium salt as organic reagents: EIICHI SEKIDO and ISAMU FUJIWARA, *Talanta*, 1972, **19**, 647. (Department of Chemistry, Faculty of Science, Kobe University, Nada, Kobe, Japan).

Summary—The synthesis of 8-selenoquinoline and its sodium salt has been improved by optimization of each process. The stability of the reagents in air and nitrogen has been examined and correlated with the drying method. Both 8-selenoquinoline and its sodium salt can exist as the monohydrate. It was found that the sodium salt of 8-selenoquinoline monohydrate is best as the weighing form of the reagent and that it can be kept stable under nitrogen in a vessel containing silica gel.

МАСС-СПЕКТРОМЕТРИЯ В АНАЛИЗЕ:

J. R. Majer, *Talanta*, 1972, **19**, 589.

Резюме—Приведен обзор основной теории, прибора и применения масс-спектрометрии, с особым учетом разработки аппаратуры и его эффекта на область применения метода.

РАЗРАБОТКА И ОПУБЛИКОВАНИЕ РАБОТ ПОЛЬЗУЮЩИСЯ ИОНОИЗБИРАТЕЛЬНЫМИ ЭЛЕКТРОДАМИ:

G. J. Moody and J. D. R. Thomas, *Talanta*, 1972, **19**, 623.

Резюме—Приведен обзор разработки, ответа, избирательности и применения ионоизбирательных электродов. Предложены исследования в области разработки и применения электродов и указаны пути приведения данных в статях.

МИКРОМЕТОД ИОДОМЕТРИЧЕСКОГО ОПРЕДЕЛЕНИЯ СЕРЫ В ОРГАНИЧЕСКИХ СОЕДИНЕНИЯХ С ИСПОЛЬЗОВАНИЕМ АМПЛИФИКАЦИИ:

Y. A. Gawargious and A. B. Farag, *Talanta*, 1972, **19**, 641.

Резюме—Описан новый микрометод для иодометрического определения серы в органических соединениях, пользующийся 12-кратной амплификационной реакцией после сожжения в кольбе, наполненной кислородом. Метод основан на реакции образующейся серной кислоты с избытком насыщенного раствора бромата бария. Нереагированный бромат бария осаждают добавлением ацетона, фильтрируют, осадок растворяют в кипящей воде и—после добавления избытка иодида и кислоты—выделенный иод титрируют раствором тиосульфата. Метод оказался несложным, быстрым и весьма точным; он широко применим в микроанализе органических соединений серы, содержащих другие обыкновенные образующие кислоты элементы.

УЛУЧШЕННЫЙ СИНТЕЗ И СТАБИЛЬНОСТЬ 8-СЕЛЕНОХИНОЛИНА И ЕГО НАТРИЕВОЙ СОЛИ В КАЧЕСТВЕ ОРГАНИЧЕСКИХ РЕАГЕНТОВ:

Eiichi Sekido and Isamu Fujiwara, *Talanta*, 1972, **19**, 647.

Резюме—Синтез 8-селенохинолина и его натриевой соли улучшен путем оптимизации каждого процесса. Испытана устоичивость реагентов в воздухе и азоте и сделана корреляция с методом осушки. Оба 8-селенохинолин и его натриева соль могут существовать в форме моногидрата. Обнаружено что натриева соль 8-селенохинолина представляет собой самую лучшую форму реагента для весового определения; она может храниться в устоичивой форме под азотом и в сосуде содержащем силикагель.

Determination of plutonium by two-step flow-coulometry at the column electrode: SORIN KIHARA, TADASHI YAMAMOTO, KENJI MOTOJIMA and TAITIRO FUJINAGA, *Talanta*, 1972, **19**, 657. (Japan Atomic Energy Research Institute, Tokai-mura, Naka-gun, Ibaraki-ken, Japan, and Department of Chemistry, Faculty of Science, Kyoto University, Kitashirakawa, Sakyo-ku, Kyoto, Japan.)

Summary—A two-step flow-coulometry method has been developed for rapid determination of elements (plutonium, iron, *etc*) which exist in various oxidation states in solution, and applied to the determination of plutonium in $0{\cdot}5M$ sulphuric acid medium. The first-step column electrode potential is fixed at between +0·10 and +0·35 V *vs.* Ag–AgCl, and all plutonium ions are reduced to Pu(III). The second-step column electrode potential is fixed at +0·75 V *vs.* Ag–AgCl, and Pu(III) which flows from the first column electrode is oxidized to Pu(IV). The quantity of plutonium is determined from the number of coulombs used in the oxidation. It is possible to eliminate interference by diverse ions by electroanalysis at the first column electrode. About a 10-μl sample is necessary and the electrolysis for determination is finished in 1 min.

Rapid analysis of fertilizers by the direct-reading thermometric method: ISTVÁN SAJÓ and B. SIPOS, *Talanta*, 1972, **19**, 669. (Research Institute for Ferrous Metallurgy, Budapest, Hungary.)

Summary—The authors have developed rapid methods for the determination of the main components of fertilizers, namely phosphate, potassium and nitrogen fixed in various forms. In the absence of magnesium ions phosphate is precipitated with magnesia mixture; in the presence of magnesium ions ammonium phosphomolybdate is precipitated and the excess of molybdate is reacted with hydrogen peroxide. Potassium is determined by precipitation with silicofluoride. For nitrogen fixed as ammonium salts the ammonium ions are condensed in a basic solution with formalin to hexamethylenetetramine; for nitrogen fixed as carbamide the latter is decomposed with sodium nitrite; for nitrogen fixed as nitrate the latter is reduced with titanium(III). In each case the temperature change of the test solution is measured. Practically all essential components of fertilizers may be determined by direct-reading thermometry; with this method and special apparatus the time of analysis is reduced to at most about 15 min for any determination.

Catalytic reactions—II. Activation: P. R. BONTCHEV, *Talanta*, 1972, **19**, 675. (Department of Analytical Chemistry, University of Sofia, 1 Anton Ivanov Str., Sofia 26, Bulgaria.)

Summary—The activation of the homogeneous catalytic reactions used in analysis is discussed. The use of activators in catalytic methods permits increase in their sensitivity by 2–4 orders of magnitude and improvement in their selectivity as well. Many different mechanisms of activation are discussed and used as illustrations of the principles for choice of an appropriate activator.

ОПРЕДЕЛЕНИЕ ПЛУТОНИЯ МЕТОДОМ ДВУСТУПЕНЧАТОЙ ПРОТОЧНОЙ КУЛОНОМЕТРИИ:

Sorin Kihara, Tadashi Yamamoto, Kenji Motojima and Taitiro Fujinaga, *Talanta*, 1972, **19**, 657.

Резюме—Разработан метод двуступенчатой проточной кулонометрии для быстрого определения элементов (плутония, железа и др.), существующих в различных степенях окисленния в растворе, и применен к определению плутония в растворе 0,5M серной кислоты. Потенциал электрода первой колонки установлен при +0,10 — +0,35 в в сравнении с Ag-AgCl электродом и все ионы плутония восстанавливаются до Pu(III). Потенциал электрода второй колонки установлен при +0,75 в в сравнении с Ag-AgCl электродом и вытекающие из электрода первой колонки ионы Pu(III) окисляются до Pu(IV). Концентрация плутония определена числом кулонов использованных для окисления. Метод позволяет устранять влияние разных ионов электроанализом при электроде первой колонки. Метод изыскует 10 мкл пробы а продолжительность электролиза—I мин.

БЫСТРЫЙ АНАЛИЗ УДОБРИТЕЛЕЙ МЕТОДОМ ТЕРМОМЕТРИЧЕСКОГО АНАЛИЗА С НЕПОСРЕДСТВЕННЫМ ОТСЧЁТОМ:

István Sajó and B. Sipos, *Talanta*, 1972, **19**, 669.

Резюме—Авторами разработаныбыстрые методы определения главных компонентов удобрителей, именно фосфата, калия и азота, связанных в разных соединениях. В отсутствии ионов магния фосфат осаждают магнезиальной смесью; в присутствии ионов магния осаждают фосфомолибдат аммония, а избыток молибдата реагируют перекисью водорода. Калий определяют осаждением солью кремнефтористо-водородной кислоты. Азот в форме солей аммония определяют конденсацией в основном растворе с формальдегидом в гексаметилентетрамин; для определения азота в форме карбамида, это соединение разлагают нитритом натрия; азот в форме нитрата определяют восстановлением титаном(III). В каждом определении измеряют перемены температуры исследуемого раствора. Метод термометрического анализа с непосредственным отсчетом позволяет определять почти все существенные компоненты удобрителей. Применением этого метода и специального прибора продолжительность анализа сокращается до 15 мин для каждого определения.

КАТАЛИТИЧЕСКИЕ РЕАКЦИИ—II. АКТИВАЦИЯ:

P. R. Bontchev, *Talanta*, 1972, **19**, 675.

Резюме—Рассмотрена активация гомогенных каталитических реакций, применимых в анализе. Использование активаторов в каталитических методах позволяет повышать в 2 — 4 раз их чувствительность а также улучшать их избирательность. Рассмотрены разные механизмы активации и на их основе объяснены принципы отбора подходящего активатора.

N-Acetylacetone–anthranilic acid as a gravimetric reagent for copper(II): R. K. MEHTA, R. K. GUPTA and S. L. PANIA, *Talanta*, 1972, **19**, 687. (Department of Chemistry, University of Jodhpur, Jodhpur, India.)

Summary—*N*-Acetylacetone–anthranilic acid has been employed as a reagent for the gravimetric determination of copper(II). The solid copper(II) chelate formed possesses 1:1 metal–ligand stoichiometry and is found to exist as an unsolvated dimer. The complex has a magnetic moment of 1·88 B.M. at 298 K. A non-planar dimeric structure is suggested to explain the observed facts.

Analysis of metals by solid–liquid separation after liquid–liquid extraction. Spectrophotometric determination of palladium(II) by extraction of palladium dimethylglyoximate with melted naphthalene: TAITIRO FUJINAGA, MASATADA SATAKE and TATSUO YONEKUBO, *Talanta*, 1972, **19**, 689. (Faculty of Science, Kyoto University, Sakyo-ku, Kyoto-shi, Japan, and Faculty of Engineering, Fukui University, Fukui-shi, Japan.)

Summary—A method of liquid–liquid extraction of palladium dimethylglyoximate with molten naphthalene followed by solid–liquid separation is successfully applied to palladium. The complex between palladium and dimethylglyoxime is easily extracted into molten naphthalene. After extraction, the very fine solidified naphthalene crystals are dissolved in chloroform, and the absorbance of the resultant solution is measured at 370 nm against a reagent blank. Beer's law is obeyed for 30–370 μg of palladium in 10 ml of chloroform, and the molar absorptivity is calculated to be $1 \cdot 72 \times 10^4$ l.mole.$^{-1}$mm^{-1}. Various alkali metal salts and metal ions do not interfere. The interference of nickel(II) is overcome by the extraction at pH 2, and that of iron(III) by masking with EDTA or by reduction to iron(II). The method is rapid and accurate.

Détermination gravimétrique de l'iode sous forme de Nt(ICl$_2$): N. GANTCHEV, V. KANAZIRSKA and D. ATHANASSOVA, *Talanta*, 1972, **19**, 692. (Chaire de chimie analytique, Ecole Normale Supérieure, 7 rue "V. Markov", Plovdiv, Bulgarie.)

Summary—Nitron dichloroiodide—Nt(ICl$_2$)—has been prepared and studied, and a gravimetric determination of iodine as Nt(ICl)$_2$ has been based on the result. For 4–40 mg of iodine the error is less than that of the determination as AgI. Bromate and chlorate do not interfere.

N-АЦЕТИЛАЦЕТОНАНТРАНИЛОВАЯ КИСЛОТА В КАЧЕСТВЕ ВЕСОВОГО РЕАГЕНТА ДЛЯ МЕДИ(II):

R. K. Mehta, R. K. Gupta and S. L. Pania, *Talanta*, 1972, **19**, 687.

Резюме—N-Ацетилацетонантраниловая кислота использована в качестве реагента для весового определения меди(II). Образующийся твёрдый хелат меди(II) представляет собой 1:1 металл-лиганд комплекс и существует в форме несольватизированного димера. Магнитный момент комплекса равен 1,88 Б.М. при 298°К. Обнаруженные свойства объясняются непланарной димерной структурой комплекса.

АНАЛИЗ МЕТАЛЛОВ МЕТОДОМ РАЗДЕЛЕНИЯ ТВЁРДОЙ И ЖИДКОЙ ФАЗ ПОСЛЕ ЖИДКОФАЗНОЙ ЭКСТРАКЦИИ:—СПЕКТРОФОТОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ ПАЛЛАДИЯ(II) ЭКСТРАГИРОВАНИЕМ ДИМЕТИЛГЛИОКСИМАТА ПАЛЛАДИЯ РАСПЛАВЛЕННЫМ НАФТАЛИНОМ:

Taitiro Fujinaga, Masatada Satake and Tatsuo Yonekubo, *Talanta*, 1972, **19**, 689.

Резюме—Метод жидкофазной экстракции диметилглиоксимата паллация расплавленным нафталином с последующим разделением твёрдой и жидкой фаз успешно применен в определении палладия. Комплекс диметилглиоксима с палладием легко экстрагируется расплавленным нафталином. После экстракции весьма мелкие кристаллы нафталина растворяют в хлороформе и измеряют светопоглощение полученного раствора при 370 нм в сравнении с слепой пробой реагента. Закон Бера почитается в области 30 – 370 мкг палладия в 10 мл хлороформа, а молярное поглощение $-1,72 \times 10^4$.л. моль$^{-1}$.мм$^{-1}$. Разные соли щелочных металлов не мешают определению. Влияние никеля(II) устраняется экстрагированием при pH 2, а влияние железа(III)—маскированием с ЭДТА или восстановлением до железа(II). Метод является быстрым и точным.

ГРАВИМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ ИОДА В ФОРМЕ $Nt(ICl_2)$:

N. Gantchev, V. Kanazirska and D. Athanassova, *Talanta*, 1972, **19**, 692.

Резюме—Приготовлен и изучен нитрон-дихлориодид $Nt(ICl_2)$ и использован в качестве реагента для гравиметрического определения иода. В области 4 – 40 мг иода ошибка меньше чем в определении в форме A I. Бромат и хлорат не мешают определению.

Trennung anorganischer Phosphate an Anionenaustauscher-Fertigplatten: H. Kroschwitz, E. Pungor and S. Ferenczi, *Talanta*, 1972, **19**, 695. (Institut für Allgemeine und Analytische Chemie, Technische Universität, Budapest XI, Gellért tér 4, Hungary, and Institut für Biochemie der Ungarischen Akademie der Wissenschaften Budapest XI, Karolina út 29–31.)

Summary—A procedure is described for the separation of mono-, di- and triphosphate, and of monophosphate and mono-, di- and triamidophosphate on ready-made thin-layer plates of anion-exchange resin Dowex 2-X8. The procedure couples the advantages of thin-layer chromatography with those of ion-exchange techniques. By suitable choice of anion for the resin (*i.e.*, chloride or acetate) only one stock buffer solution is needed for the separation. The two classes of compounds do not interfere with each other during the separations.

Potentiometric determination of stepwise stability constants of zirconium and thorium chelates formed with aspartic and glutamic acids: M. K. Singh and M. N. Srivastava, *Talanta*, 1972, **19**, 699. (Chemical Laboratories, University of Allahabad, Allahabad, India.)

Summary—The metal chelates of Zr(IV) and Th(IV) with aspartic and glutamic acids have been studied potentiometrically. Stepwise stability constants in $0.1M$ sodium perchlorate at 25° are reported as: aspartate chelates—log K_1 9·70, log K_2 6·85, and log K_3 3·50 for Zr, and log K_1 9·23, log K_2 8·57, log K_3 4·55 and log K_4 3·87 for Th; glutamate chelates—log K_1 9·60, log K_2 6·40 and log K_3 3·32 for Zr and log K_1 9·11, log K_2 8·52, log K_3 4·18 and log K_4 3·62 for Th.

Thermodynamic association constants of *N*-phenylbenzohydroxamic acids and benzohydroxamic acid: Y. K. Agrawal and S. G. Tandon, *Talanta*, 1972, **19**, 700. (Department of Chemistry, Govt. Science College, Raipur (M.P.), India.)

Summary—Thermodynamic association constants of benzohydroxamic acid and several *ortho*-substituted *N*-phenylbenzohydroxamic acids have been determined by pH titration in aqueous dioxan media at 25° and 35°. Empirical pH corrections for mixed aqueous media have been applied. The pK_a values do not vary linearly with the reciprocal of dielectric constant of the medium, but a plot of pK_a *vs.* the mole fraction of dioxan is linear at a given temperature. Values of $\Delta G°$, $\Delta H°$ and $\Delta S°$ are tabulated.

РАЗДЕЛЕНИЕ НЕОРГАНИЧЕСКИХ ФОСФАТОВ МЕТОДОМ ТОНКОСЛОЙНОЙ ХРОМАТОГРАФИИ НА КОММЕРЧЕСКИХ СЛОЯХ АНИОНООБМЕННИКОВ:

H. Kroschwitz, E. Pungor and S. Ferenczi, *Talanta*, 1972, **19**, 695.

Резюме—Описана методика разделения моно-, ди- и трифосфата, монофосфата и моно-, ди- и трамидофосфата на коммерческих пластинках для тонкослойной хроматографии на слоях анионообменной смолы Дауекс 2-X8. Метод объединяет преимущества тонкослойной хроматографии с преимуществами ионного обмена. Подходящии отбор аниона смолы (на пр. хлорида или ацетата) позволяет провести разделение только с одним буферным раствором. Два класса соединений не влияют один на другого в этих соединениях.

СТУПЕНЧАТОЕ ПОТЕНЦИОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ КОНСТАНТ УСТОИЧИВОСТИ ХЕЛАТОВ ЦИРКОНИЯ И ТОРИЯ С АСПАРАГИНОВОЙ И ГЛУТАМИНОВОЙ КИСЛОТАМИ:

M. K. Singh and M. N. Srivastava, *Talanta*, 1972, **19**, 699.

Резюме—Исследованы потенциометрическим методом хелаты Zr(IV) и Th(IV) с аспарагиновой и глутаминовой кислотами. Определены следующие константы устойчивости в 0,1*M* перхлорате натрия при 25°: хелаты аспарагиновой кислоты—$\lg K_1$ 9,70, $\lg K_2$ 6,85, $\lg K_3$ 3,50 для Zr и $\lg K_1$ 9,23, $\lg K_2$ 8,57, $\lg K_3$ 4,55, $\lg K_4$ 3,87 для Th; хелаты глутаминовой кислоты—$\lg K_1$ 9,60, $\lg K_2$ 6,40, $\lg K_3$ 3,32 для Zr и $\lg K_1$ 9,11, $\lg K_2$ 8,52, $\lg K_3$ 4,18, $\lg K_4$ 3,62 для Th.

ТЕРМОДИНАМИЧЕСКИЕ КОНСТАНТЫ АССОЦИАЦИИ *N*-ФЕНИЛБЕНЗГИДРОКСАМОВЫХ КИСЛОТ И БЕНЗГИДРОКСАМОВОЙ КИСЛОТЫ:

Y. K. Agrawal and S. G. Tandon, *Talanta*, 1972, **19**, 700.

Резюме—Определены методом титрования pH термодинамические константы ассоциации бензгидроксамовой кислоты и некоторых орто-замещенных *N*-фенилбензгидроксамовых кислот в водных растворах диоксана при 25° и 35°. Применены эмпирические поправки для смешанных водных сред. Величины pK_a не показывают линейную зависымость от обратной величины диэлектнрической постоянной среды, но pK_a в зависимости от мольной доли диоксана представляет собой прямолинейную функцию для данной температуры. Приведены таблицы величин $\Delta G°$, $\Delta H°$ и $\Delta S°$.

Behaviour of the thiodipropionic complex of In(III) and U(VI) at the DME in aqueous and aqueous methanolic solutions: P. C. RAWAT and C. M. GUPTA, *Talanta*, 1972, **19**, 706. (Department of Chemistry, M.R.E. College, Jaipur-4, India and Chemical Laboratories, University of Rajasthan, Jaipur-4, India.)

Summary—The complexation of In(III) and U(VI) with thiodipropionic acid has been investigated polarographically in water and water-methanol solutions at 30 ± 0.1°. All the chelates belong to polarographically reversible systems. With indium(III), complexes with metal to ligand ratios of 1:1, 1:2, 1:3 and 1:4 are found at pH 4.8. Uranium(VI) is found to form three successive complexes with metal to ligand ratios of 1:1, 1:2 and 1:3 in $0.01M$ HCl, with $0.1M$ KCl as supporting electrolyte.

Determination of pK_a of acetic and benzoic acids in pyridine: L. M. MUKHERJEE and RONALD S. SCHULTZ, *Talanta*, 1972, **19**, 708. (Chemistry Department, Illinois State University, Normal, Ill. 61761, U.S.A.)

Summary—The pK_a's of acetic acid and benzoic acid in pyridine as solvent are found to be 10·1 and 9·8, respectively, at 25°. These results are based on measurements of hydrogen ion activities in mixtures of the acids and their tetrabutylammonium salts. Supplementary studies of differential vapour pressure characteristics of solutions of the acids and the acid-salt mixtures, and conductance of tetrabutylammonium benzoate solutions are also incorporated.

Stability constants of complexes of *N*-arylhydroxamic acids with some bivalent metal ions: J. P. SHUKLA and S. G. TANDON, *Talanta*, 1972, **19**, 711. (Department of Chemistry, Government College of Science, Raipur, M.P., India.)

Summary—Thermodynamic stability constants of complexes of Mn(II), Ni(II), Zn(II) and Cu(II) with five closely related *N*-arylhydroxamic acids have been determined at 25 ± 0·1° in 50% v/v aqueous dioxan medium. The stabilities of the complexes mostly follow the order of the basicity of the ligands and the electron affinities of the metal ions as measured by their second ionization potential.

ХАРАКТЕРИСТИКИ КОМПЛЕКСОВ ИНДИЯ(III) И УРАНА(VI) С ТИОДИПРОПИОНОВОЙ КИСЛОТОЙ НА КАПЕЛЬНОМ РТУТНОМ ЭЛЕКТРОДЕ В ВОДНЫХ И ВОДНО-МЕТАНОЛОВЫХ РАСТВОРАХ:

P. C. Rawat and C. M. Gupta, *Talanta*, 1972, **19**, 706.

Резюме—Комплексообразование In(III) и U(VI) с тиодипропионовой кислотой изучено полярографическим методом в водных и водно-метаноловых растворах при 30 ± 0,1°. Все хелаты относятся к полярографически обратимыми системами. В случае индия(III) образуются при pH 4,8 комплексы имеющие отношения металля к лиганду 1:1, 1:2, 1:3 и 1:4. В случае урана(VI) образуются три последовательных комплекса имеющие отношения металла к лиганду 1:1, 1:2 и 1:3 в 0,01*M* HCl, с использованием 0,1*M* KCl в качестве фона.

ОПРЕДЕЛЕНИЕ pK_a УКСУСНОЙ И БЕНЗОЙНОЙ КИСЛОТ В ПИРИДИНЕ:

L. M. Mukherjee and Ronald S. Schultz, *Talanta*, 1972, **19**, 708.

Резюме—pK_a уксусной и бензойной кислот в пиридине в качестве растворителя равны 10,1 и 9,8, соответственно, при 25°. Эти результаты основаны на измерении активности ионов водорода в смесях кислот и их солей тетрабутиламмония. Также приведены результаты изучения дифференциальной упругости паров растворов этих кислот и их смесей с солями и проводимости растворов бензоата тетрабутиламмония.

КОНСТАНТЫ УСТОЙЧИВОСТИ КОМПЛЕКСОВ *N*-АРИЛГИДРОКСАМОВЫХ КИСЛОТ С НЕКОТОРЫМИ ДВУВАЛЕНТНЫМИ ИОНАМИ МЕТАЛЛОВ:

J. P. Shukla and S. G. Tandon, *Talanta*, 1972, **19**, 711.

Резюме—Определены термодинамические константы устойчивости комплексов Mn(II), Ni(II), Zn(II) и Cu(II) и пять узкосвязанных *N*-арилгидроксамовых кислот при 25 ± 0,1° в 50%-тном водном растворе диоксана. Устойчивость кмплексов в большинстве случаев следует порядок основности лигандов и электронное сродство ионов металлов, приказанное их вторим ионизационным напряжением.

SUMMARIES FOR CARD INDEXES

Analytical mass spectrometry: J. R. MAJER, *Talanta*, 1972, **19**, 589. (Chemistry Department, University of Birmingham, P.O. Box 363, Birmingham 15, U.K.)

Summary—A review is made of the basic theory, instrumentation and application of mass spectrometry, with special reference to the development of the equipment and its impact on the scope of application.

Development and publication of work with selective ion-sensitive electrodes: G. J. MOODY and J. D. R. THOMAS, *Talanta*, 1972, **19**, 623. (University of Wales Institute of Science and Technology, Cardiff, Wales.)

Summary—Features concerning development, response, selectivity and applications of selective ion-sensitive electrodes are reviewed. Recommendations are made concerning investigations involving the development and applications of electrodes and attention given to the manner of presenting data for publication.

Iodometric microdetermination of sulphur in organic compounds by an amplification method: Y. A. GAWARGIOUS and A. B. FARAG, *Talanta*, 1972, **19**, 641. (Microanalytical Research Laboratory, National Research Centre, Dokki, Cairo, U.A.R.)

Summary—A new method is described for the iodometric microdetermination of sulphur in organic compounds, using a 12-fold amplification reaction after oxygen-flask combustion. The method is based on reaction of the resulting sulphuric acid with an excess of saturated barium bromate solution. The unreacted barium bromate is precipitated by addition of acetone, filtered off, redissolved in hot water and after addition of an excess of iodide and acid, the iodine liberated is titrated with thiosulphate. The method is simple, rapid, highly accurate, and of wide application in the microanalysis of organosulphur compounds containing other common acid-forming elements.

Improved synthesis and stability of 8-selenoquinoline and its sodium salt as organic reagents: EIICHI SEKIDO and ISAMU FUJIWARA, *Talanta*, 1972, **19**, 647. (Department of Chemistry, Faculty of Science, Kobe University, Nada, Kobe, Japan).

Summary—The synthesis of 8-selenoquinoline and its sodium salt has been improved by optimization of each process. The stability of the reagents in air and nitrogen has been examined and correlated with the drying method. Both 8-selenoquinoline and its sodium salt can exist as the monohydrate. It was found that the sodium salt of 8-selenoquinoline monohydrate is best as the weighing form of the reagent and that it can be kept stable under nitrogen in a vessel containing silica gel.

МАСС-СПЕКТРОМЕТРИЯ В АНАЛИЗЕ:

J. R. Majer, *Talanta*, 1972, **19**, 589.

Резюме—Приведен обзор основной теории, прибора и применения масс-спектрометрии, с особым учетом разработки аппаратуры и его эффекта на область применения метода.

РАЗРАБОТКА И ОПУБЛИКОВАНИЕ РАБОТ ПОЛЬЗУЮЩИСЯ ИОНОИЗБИРАТЕЛЬНЫМИ ЭЛЕКТРОДАМИ:

G. J. Moody and J. D. R. Thomas, *Talanta*, 1972, **19**, 623.

Резюме—Приведен обзор разработки, ответа, избирательности и применения ионоизбирательных электродов. Предложены исследования в области разработки и применения электродов и указаны пути приведения данных в статях.

МИКРОМЕТОД ИОДОМЕТРИЧЕСКОГО ОПРЕДЕЛЕНИЯ СЕРЫ В ОРГАНИЧЕСКИХ СОЕДИНЕНИЯХ С ИСПОЛЬЗОВАНИЕМ АМПЛИФИКАЦИИ:

Y. A. Gawargious and A. B. Farag, *Talanta*, 1972, **19**, 641.

Резюме—Описан новый микрометод для иодометрического определения серы в органических соединениях, пользующийся 12-кратной амплификационной реакцией после сожжения в кольбе, наполненной кислородом. Метод основан на реакции образующейся серной кислоты с избытком насыщенного раствора бромата бария. Нереагированный бромат бария осаждают добавлением ацетона, фильтрируют, осадок растворяют в кипящей воде и—после добавления избытка иодида и кислоты—выделенный иод титрируют раствором тиосульфата. Метод оказался несложным, быстрым и весьма точным; он широко применим в микроанализе органических соединений серы, содержащих другие обыкновенные образующие кислоты элементы.

УЛУЧШЕННЫЙ СИНТЕЗ И СТАБИЛЬНОСТЬ 8-СЕЛЕНОХИНОЛИНА И ЕГО НАТРИЕВОЙ СОЛИ В КАЧЕСТВЕ ОРГАНИЧЕСКИХ РЕАГЕНТОВ:

Eiichi Sekido and Isamu Fujiwara, *Talanta*, 1972, **19**, 647.

Резюме—Синтез 8-селенохинолина и его натриевой соли улучшен путем оптимизации каждого процесса. Испытана устоичивость реагентов в воздухе и азоте и сделана корреляция с методом осушки. Оба 8-селенохинолин и его натриева соль могут существовать в форме моногидрата. Обнаружено что натриева соль 8-селенохинолина представляет собой самую лучшую форму реагента для весового определения; она может храниться в устоичивой форме под азотом и в сосуде содержащем силикагель.

Determination of plutonium by two-step flow-coulometry at the column electrode: SORIN KIHARA, TADASHI YAMAMOTO, KENJI MOTOJIMA and TAITIRO FUJINAGA, *Talanta*, 1972, **19**, 657. (Japan Atomic Energy Research Institute, Tokai-mura, Naka-gun, Ibaraki-ken, Japan, and Department of Chemistry, Faculty of Science, Kyoto University, Kitashirakawa, Sakyo-ku, Kyoto, Japan.)

Summary—A two-step flow-coulometry method has been developed for rapid determination of elements (plutonium, iron, *etc*) which exist in various oxidation states in solution, and applied to the determination of plutonium in $0{\cdot}5M$ sulphuric acid medium. The first-step column electrode potential is fixed at between $+0{\cdot}10$ and $+0{\cdot}35$ V *vs.* Ag–AgCl, and all plutonium ions are reduced to Pu(III). The second-step column electrode potential is fixed at $+0{\cdot}75$ V *vs.* Ag–AgCl, and Pu(III) which flows from the first column electrode is oxidized to Pu(IV). The quantity of plutonium is determined from the number of coulombs used in the oxidation. It is possible to eliminate interference by diverse ions by electroanalysis at the first column electrode. About a 10-μl sample is necessary and the electrolysis for determination is finished in 1 min.

Rapid analysis of fertilizers by the direct-reading thermometric method: ISTVÁN SAJÓ and B. SIPOS, *Talanta*, 1972, **19**, 669. (Research Institute for Ferrous Metallurgy, Budapest, Hungary.)

Summary—The authors have developed rapid methods for the determination of the main components of fertilizers, namely phosphate, potassium and nitrogen fixed in various forms. In the absence of magnesium ions phosphate is precipitated with magnesia mixture; in the presence of magnesium ions ammonium phosphomolybdate is precipitated and the excess of molybdate is reacted with hydrogen peroxide. Potassium is determined by precipitation with silicofluoride. For nitrogen fixed as ammonium salts the ammonium ions are condensed in a basic solution with formalin to hexamethylenetetramine; for nitrogen fixed as carbamide the latter is decomposed with sodium nitrite; for nitrogen fixed as nitrate the latter is reduced with titanium(III). In each case the temperature change of the test solution is measured. Practically all essential components of fertilizers may be determined by direct-reading thermometry; with this method and special apparatus the time of analysis is reduced to at most about 15 min for any determination.

Catalytic reactions—II. Activation: P. R. BONTCHEV, *Talanta*, 1972, **19**, 675. (Department of Analytical Chemistry, University of Sofia, 1 Anton Ivanov Str., Sofia 26, Bulgaria.)

Summary—The activation of the homogeneous catalytic reactions used in analysis is discussed. The use of activators in catalytic methods permits increase in their sensitivity by 2–4 orders of magnitude and improvement in their selectivity as well. Many different mechanisms of activation are discussed and used as illustrations of the principles for choice of an appropriate activator.

ОПРЕДЕЛЕНИЕ ПЛУТОНИЯ МЕТОДОМ ДВУСТУПЕНЧАТОЙ ПРОТОЧНОЙ КУЛОНОМЕТРИИ:

Sorin Kihara, Tadashi Yamamoto, Kenji Motojima and Taitiro Fujinaga, *Talanta*, 1972, **19**, 657.

Резюме—Разработан метод двуступенчатой проточной кулонометрии для быстрого определения элементов (плутония, железа и др.), существующих в различных степенях окисленния в растворе, и применен к определению плутония в растворе 0,5*M* серной кислоты. Потенциал электрода первой колонки установлен при +0,10 — +0,35 в в сравнении с Ag-AgCl электродом и все ионы плутония восстанавливаются до Pu(III). Потенциал электрода второй колонки установлен при +0,75 в в сравнении с Ag-AgCl электродом и вытекающие из электрода первой колонки ионы Pu(III) окисляются до Pu(IV). Концентрация плутония определена числом кулонов использованных для окисления. Метод позволяет устранять влияние разных ионов электроанализом при электроде первой колонки. Метод изыскует 10 мкл пробы а продолжительность электролиза—I мин.

БЫСТРЫЙ АНАЛИЗ УДОБРИТЕЛЕЙ МЕТОДОМ ТЕРМОМЕТРИЧЕСКОГО АНАЛИЗА С НЕПОСРЕДСТВЕННЫМ ОТСЧЁТОМ:

István Sajó and B. Sipos, *Talanta*, 1972, **19**, 669.

Резюме—Авторами разработаныбыстрые методы определения главных компонентов удобрителей, именно фосфата, калия и азота, связанных в разных соединениях. В отсутствии ионов магния фосфат осаждают магнезиальной смесью; в присутствии ионов магния осаждают фосфомолибдат аммония, а избыток молибдата реагируют перекисью водорода. Калий определяют осаждением солью кремнефтористо-водородной кислоты. Азот в форме солей аммония определяют конденсацией в основном растворе с формальдегидом в гексаметилентетрамин; для определения азота в форме карбамида, это соединение разлагают нитритом натрия; азот в форме нитрата определяют восстановлением титаном(III). В каждом определении измеряют перемены температуры исследуемого раствора. Метод термометрического анализа с непосредственным отсчетом позволяет определять почти все существенные компоненты удобрителей. Применением этого метода и специального прибора продолжительность анализа сокращается до 15 мин для каждого определения.

КАТАЛИТИЧЕСКИЕ РЕАКЦИИ—II. АКТИВАЦИЯ:

P. R. Bontchev, *Talanta*, 1972, **19**, 675.

Резюме—Рассмотрена активация гомогенных каталитических реакций, применимых в анализе. Использование активаторов в каталитических методах позволяет повышать в 2 — 4 раз их чувствительность а также улучшать их избирательность. Рассмотрены разные механизмы активации и на их основе объяснены принципы отбора подходящего активатора.

N-Acetylacetone–anthranilic acid as a gravimetric reagent for copper(II): R. K. Mehta, R. K. Gupta and S. L. Pania, *Talanta*, 1972, **19**, 687. (Department of Chemistry, University of Jodhpur, Jodhpur, India.)

Summary—*N*-Acetylacetone–anthranilic acid has been employed as a reagent for the gravimetric determination of copper(II). The solid copper(II) chelate formed possesses 1:1 metal–ligand stoichiometry and is found to exist as an unsolvated dimer. The complex has a magnetic moment of 1·88 B.M. at 298 K. A non-planar dimeric structure is suggested to explain the observed facts.

Analysis of metals by solid–liquid separation after liquid–liquid extraction. Spectrophotometric determination of palladium(II) by extraction of palladium dimethylglyoximate with melted naphthalene: Taitiro Fujinaga, Masatada Satake and Tatsuo Yonekubo, *Talanta*, 1972, **19**, 689. (Faculty of Science, Kyoto University, Sakyo-ku, Kyoto-shi, Japan, and Faculty of Engineering, Fukui University, Fukui-shi, Japan.)

Summary—A method of liquid–liquid extraction of palladium dimethylglyoximate with molten naphthalene followed by solid–liquid separation is successfully applied to palladium. The complex between palladium and dimethylglyoxime is easily extracted into molten naphthalene. After extraction, the very fine solidified naphthalene crystals are dissolved in chloroform, and the absorbance of the resultant solution is measured at 370 nm against a reagent blank. Beer's law is obeyed for 30–370 μg of palladium in 10 ml of chloroform, and the molar absorptivity is calculated to be $1 \cdot 72 \times 10^4$ $l.mole.^{-1}mm^{-1}$. Various alkali metal salts and metal ions do not interfere. The interference of nickel(II) is overcome by the extraction at pH 2, and that of iron(III) by masking with EDTA or by reduction to iron(II). The method is rapid and accurate.

Détermination gravimétrique de l'iode sous forme de Nt(ICl$_2$): N. Gantchev, V. Kanazirska and D. Athanassova, *Talanta*, 1972, **19**, 692. (Chaire de chimie analytique, Ecole Normale Supérieure, 7 rue "V. Markov", Plovdiv, Bulgarie.)

Summary—Nitron dichloroiodide—Nt(ICl$_2$)—has been prepared and studied, and a gravimetric determination of iodine as Nt(ICl)$_2$ has been based on the result. For 4–40 mg of iodine the error is less than that of the determination as AgI. Bromate and chlorate do not interfere.

N-АЦЕТИЛАЦЕТОНАНТРАНИЛОВАЯ КИСЛОТА В КАЧЕСТВЕ ВЕСОВОГО РЕАГЕНТА ДЛЯ МЕДИ(II):

R. K. Mehta, R. K. Gupta and S. L. Pania, *Talanta*, 1972, **19**, 687.

Резюме—*N*-Ацетилацетонантраниловая кислота использована в качестве реагента для весового определения меди(II). Образующийся твёрдый хелат меди(II) представляет собой 1:1 металл-лиганд комплекс и существует в форме несольватизированного димера. Магнитный момент комплекса равен 1,88 Б.М. при 298°К. Обнаруженные свойства объясняются непланарной димерной структурой комплекса.

АНАЛИЗ МЕТАЛЛОВ МЕТОДОМ РАЗДЕЛЕНИЯ ТВЁРДОЙ И ЖИДКОЙ ФАЗ ПОСЛЕ ЖИДКОФАЗНОЙ ЭКСТРАКЦИИ:—СПЕКТРОФОТОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ ПАЛЛАДИЯ(II) ЭКСТРАГИРОВАНИЕМ ДИМЕТИЛГЛИОКСИМАТА ПАЛЛАДИЯ РАСПЛАВЛЕННЫМ НАФТАЛИНОМ:

Taitiro Fujinaga, Masatada Satake and Tatsuo Yonekubo, *Talanta*, 1972, **19**, 689.

Резюме—Метод жидкофазной экстракции диметилглиоксимата паллация расплавленным нафталином с последующим разделением твёрдой и жидкой фаз успешно применен в определении палладия. Комплекс диметилглиоксима с палладием легко экстрагируется расплавленным нафталином. После экстракции весьма мелкие кристаллы нафталина растворяют в хлороформе и измеряют светопоглощение полученного раствора при 370 нм в сравнении с слепой пробой реагента. Закон Бера почитается в области 30 – 370 мкг палладия в 10 мл хлороформа, а молярное поглощение $-1{,}72 \times 10^4$.л. моль$^{-1}$.мм$^{-1}$. Разные соли щелочных металлов не мешают определению. Влияние никеля(II) устраняется экстрагированием при pH 2, а влияние железа(III)—маскированием с ЭДТА или восстановлением до железа(II). Метод является быстрым и точным.

ГРАВИМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ ИОДА В ФОРМЕ $Nt(ICl_2)$:

N. Gantchev, V. Kanazirska and D. Athanassova, *Talanta*, 1972, **19**, 692.

Резюме—Приготовлен и изучен нитрон-дихлориодид $Nt(ICl_2)$ и использован в качестве реагента для гравиметрического определения иода. В области 4 – 40 мг иода ошибка меньше чем в определении в форме A I. Бромат и хлорат не мешают определению.

Trennung anorganischer Phosphate an Anionenaustauscher-Fertigplatten: H. Kroschwitz, E. Pungor and S. Ferenczi, *Talanta*, 1972, **19**, 695. (Institut für Allgemeine und Analytische Chemie, Technische Universität, Budapest XI, Gellért tér 4, Hungary, and Institut für Biochemie der Ungarischen Akademie der Wissenschaften Budapest XI, Karolina út 29–31.)

Summary—A procedure is described for the separation of mono-, di- and triphosphate, and of monophosphate and mono-, di- and triamidophosphate on ready-made thin-layer plates of anion-exchange resin Dowex 2-X8. The procedure couples the advantages of thin-layer chromatography with those of ion-exchange techniques. By suitable choice of anion for the resin (*i.e.*, chloride or acetate) only one stock buffer solution is needed for the separation. The two classes of compounds do not interfere with each other during the separations.

Potentiometric determination of stepwise stability constants of zirconium and thorium chelates formed with aspartic and glutamic acids: M. K. Singh and M. N. Srivastava, *Talanta*, 1972, **19**, 699. (Chemical Laboratories, University of Allahabad, Allahabad, India.)

Summary—The metal chelates of Zr(IV) and Th(IV) with aspartic and glutamic acids have been studied potentiometrically. Stepwise stability constants in 0.1*M* sodium perchlorate at 25° are reported as: aspartate chelates—log K_1 9·70, log K_2 6·85, and log K_3 3·50 for Zr, and log K_1 9·23, log K_2 8·57, log K_3 4·55 and log K_4 3·87 for Th; glutamate chelates—log K_1 9·60, log K_2 6·40 and log K_3 3·32 for Zr and log K_1 9·11, log K_2 8·52, log K_3 4·18 and log K_4 3·62 for Th.

Thermodynamic association constants of *N*-phenylbenzohydroxamic acids and benzohydroxamic acid: Y. K. Agrawal and S. G. Tandon, *Talanta*, 1972, **19**, 700. (Department of Chemistry, Govt. Science College, Raipur (M.P.), India.)

Summary—Thermodynamic association constants of benzohydroxamic acid and several *ortho*-substituted *N*-phenylbenzohydroxamic acids have been determined by pH titration in aqueous dioxan media at 25° and 35°. Empirical pH corrections for mixed aqueous media have been applied. The pK_a values do not vary linearly with the reciprocal of dielectric constant of the medium, but a plot of pK_a *vs.* the mole fraction of dioxan is linear at a given temperature. Values of $\Delta G°$, $\Delta H°$ and $\Delta S°$ are tabulated.

РАЗДЕЛЕНИЕ НЕОРГАНИЧЕСКИХ ФОСФАТОВ МЕТОДОМ ТОНКОСЛОЙНОЙ ХРОМАТОГРАФИИ НА КОММЕРЧЕСКИХ СЛОЯХ АНИОНООБМЕННИКОВ:

H. Kroschwitz, E. Pungor and S. Ferenczi, *Talanta*, 1972, **19**, 695.

Резюме—Описана методика разделения моно-, ди- и трифосфата, монофосфата и моно-, ди- и трамидофосфата на коммерческих пластинках для тонкослойной хроматографии на слоях анионообменной смолы Дауекс 2-Х8. Метод объединяет преимущества тонкослойной хроматографии с преимуществами ионного обмена. Подходящии отбор аниона смолы (на пр. хлорида или ацетата) позволяет провести разделение только с одним буферным раствором. Два класса соединений не влияют один на другого в этих соединениях.

СТУПЕНЧАТОЕ ПОТЕНЦИОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ КОНСТАНТ УСТОИЧИВОСТИ ХЕЛАТОВ ЦИРКОНИЯ И ТОРИЯ С АСПАРАГИНОВОЙ И ГЛУТАМИНОВОЙ КИСЛОТАМИ:

M. K. Singh and M. N. Srivastava, *Talanta*, 1972, **19**, 699.

Резюме—Исследованы потенциометрическим методом хелаты Zr(IV) и Th(IV) с аспарагиновой и глутаминовой кислотами. Определены следующие константы устойчивости в 0,1*M* перхлорате натрия при 25°: хелаты аспарагиновой кислоты—lg K_1 9,70, lg K_2 6,85, lg K_3 3,50 для Zr и lg K_1 9,23, lg K_2 8,57, lg K_3 4,55, lg K_4 3,87 для Th; хелаты глутаминовой кислоты—lg K_1 9,60, lg K_2 6,40, lg K_3 3,32 для Zr и lg K_1 9,11, lg K_2 8,52, lg K_3 4,18, lg K_4 3,62 для Th.

ТЕРМОДИНАМИЧЕСКИЕ КОНСТАНТЫ АССОЦИАЦИИ *N*-ФЕНИЛБЕНЗГИДРОКСАМОВЫХ КИСЛОТ И БЕНЗГИДРОКСАМОВОЙ КИСЛОТЫ:

Y. K. Agrawal and S. G. Tandon, *Talanta*, 1972, **19**, 700.

Резюме—Определены методом титрования pH термодинамические константы ассоциации бензгидроксамовой кислоты и некоторых орто-замещенных *N*-фенилбензгидроксамовых кислот в водных растворах диоксана при 25° и 35°. Применены эмпирические поправки для смешанных водных сред. Величины pK_a не показывают линейную зависимость от обратной величины диэлектнрической постоянной среды, но pK_a в зависимости от мольной доли диоксана представляет собой прямолинейную функцию для данной температуры. Приведены таблицы величин $\Delta G°$, $\Delta H°$ и $\Delta S°$.

Behaviour of the thiodipropionic complex of In(III) and U(VI) at the DME in aqueous and aqueous methanolic solutions: P. C. Rawat and C. M. Gupta, *Talanta*, 1972, **19**, 706. (Department of Chemistry, M.R.E. College, Jaipur-4, India and Chemical Laboratories, University of Rajasthan, Jaipur-4, India.)

Summary—The complexation of In(III) and U(VI) with thiodipropionic acid has been investigated polarographically in water and water-methanol solutions at 30 ± 0.1°. All the chelates belong to polarographically reversible systems. With indium(III), complexes with metal to ligand ratios of 1:1, 1:2, 1:3 and 1:4 are found at pH 4.8. Uranium(VI) is found to form three successive complexes with metal to ligand ratios of 1:1, 1:2 and 1:3 in $0.01M$ HCl, with $0.1M$ KCl as supporting electrolyte.

Determination of pK_a of acetic and benzoic acids in pyridine: L. M. Mukherjee and Ronald S. Schultz, *Talanta*, 1972, **19**, 708. (Chemistry Department, Illinois State University, Normal, Ill. 61761, U.S.A.)

Summary—The pK_a's of acetic acid and benzoic acid in pyridine as solvent are found to be 10·1 and 9·8, respectively, at 25°. These results are based on measurements of hydrogen ion activities in mixtures of the acids and their tetrabutylammonium salts. Supplementary studies of differential vapour pressure characteristics of solutions of the acids and the acid-salt mixtures, and conductance of tetrabutylammonium benzoate solutions are also incorporated.

Stability constants of complexes of *N*-arylhydroxamic acids with some bivalent metal ions: J. P. Shukla and S. G. Tandon, *Talanta*, 1972, **19**, 711. (Department of Chemistry, Government College of Science, Raipur, M.P., India.)

Summary—Thermodynamic stability constants of complexes of Mn(II), Ni(II), Zn(II) and Cu(II) with five closely related *N*-arylhydroxamic acids have been determined at 25 ± 0·1° in 50% v/v aqueous dioxan medium. The stabilities of the complexes mostly follow the order of the basicity of the ligands and the electron affinities of the metal ions as measured by their second ionization potential.

ХАРАКТЕРИСТИКИ КОМПЛЕКСОВ ИНДИЯ(III) И УРАНА(VI) С ТИОДИПРОПИОНОВОЙ КИСЛОТОЙ НА КАПЕЛЬНОМ РТУТНОМ ЭЛЕКТРОДЕ В ВОДНЫХ И ВОДНО-МЕТАНОЛОВЫХ РАСТВОРАХ:

P. C. Rawat and C. M. Gupta, *Talanta*, 1972, **19**, 706.

Резюме—Комплексообразование In(III) и U(VI) с тиодипропионовой кислотой изучено полярографическим методом в водных и водно-метаноловых растворах при 30 ± 0,1°. Все хелаты относятся к полярографически обратимыми системами. В случае индия(III) образуются при pH 4,8 комплексы имеющие отношения металля к лиганду 1:1, 1:2, 1:3 и 1:4. В случае урана(VI) образуются три последовательных комплекса имеющие отношения металла к лиганду 1:1, 1:2 и 1:3 в 0,01*M* HCl, с использованием 0,1*M* KCl в качестве фона.

ОПРЕДЕЛЕНИЕ pK_a УКСУСНОЙ И БЕНЗОЙНОЙ КИСЛОТ В ПИРИДИНЕ:

L. M. Mukherjee and Ronald S. Schultz, *Talanta*, 1972, **19**, 708.

Резюме—pK_a уксусной и бензойной кислот в пиридине в качестве растворителя равны 10,1 и 9,8, соответственно, при 25°. Эти результаты основаны на измерении активности ионов водорода в смесях кислот и их солей тетрабутиламмония. Также приведены результаты изучения дифференциальной упругости паров растворов этих кислот и их смесей с солями и проводимости растворов бензоата тетрабутиламмония.

КОНСТАНТЫ УСТОЙЧИВОСТИ КОМПЛЕКСОВ *N*-АРИЛГИДРОКСАМОВЫХ КИСЛОТ С НЕКОТОРЫМИ ДВУВАЛЕНТНЫМИ ИОНАМИ МЕТАЛЛОВ:

J. P. Shukla and S. G. Tandon, *Talanta*, 1972, **19**, 711.

Резюме—Определены термодинамические константы устойчивости комплексов Mn(II), Ni(II), Zn(II) и Cu(II) и пять узкосвязанных *N*-арилгидроксамовых кислот при 25 ± 0,1° в 50%-тном водном растворе диоксана. Устойчивость кмплексов в большинстве случаев следует порядок основности лигандов и электронное сродство ионов металлов, приказанное их вторим ионизационным напряжением.

SUMMARIES FOR CARD INDEXES

Synthetic inorganic ion-exchangers—I. Hydrous oxides and acidic salts of multivalent metals: V. Veselý and V. Pekárek, *Talanta*, 1972, **19**, 219. (Nuclear Research Institute of the Czechoslovak Academy of Sciences, Řež near Prague, Czechoslovakia.)

Summary—An exhaustive literature survey is given of the hydrous oxides and acidic salts of multivalent metals that are used as ion-exchange materials, the survey covering the preparation, properties, uses and theory of these materials.

Le microdosage colorimétrique des phosphates dans des milieux divers (produits biologiques, pharmaceutiques et alimentaires): Gh. Ghimicescu and Vasile Dorneanu, *Talanta*, 1972, **19**, 263. (Institut de Médicine et de Pharmacie de Iassy, Roumanie.)

Summary—A colorimetric micromethod is proposed for determination of phosphates in various materials (biological substances, pharmaceuticals and food). It is based on precipitation of magnesium uranyl phosphate, which is then dissolved in dilute sulphuric acid, and the uranyl ion is determined spectrophotometrically *via* the dark red colour of uranyl ferrocyanide. The sensitivity is 0·01 mg of P, and the average error 1%. The method is very simple and applicable to many types of sample.

Determination of platinum group metals, gold and silver by the tin collection scheme: G. H. Faye and P. E. Moloughney, *Talanta*, 1972, **19**, 269. (Mineral Sciences Division, Mines Branch, Department of Energy, Mines and Resources, Ottawa, Canda.)

Summary—A comprehensive analytical scheme is presented for the determination of the six platinum-group metals, gold and silver. It is the result of the integration of separate procedures that have been described previously, in part, over the course of several years. The analytical scheme has been thoroughly tested in umpire and standards work on a wide variety of materials and, as a consequence, is of increasing interest to many laboratories. The precious metals are collected in molten tin when the sample is fused at 1200–1250° with a flux containing stannic oxide, sodium carbonate, silica, borax and flour. The resultant tin alloy is dissolved and the precious metals are isolated by ion-exchange, solvent extraction and/or distillation procedures. With the exception of the usual facilities required in the fusion step of fire assaying, standard equipment can be used in the wet-chemical operations for the isolation and determination of the individual precious metals.

ИСКУССТВЕННЫЕ НЕОРГАНИЧЕСКИЕ ИОНООБМЕНИКИ—I. ГИДРАТИРОВАННЫЕ ОКИСЛЫ И КИСЛЫЕ СОЛИ МНОГОВАЛЕНТНЫХ ЭЛЕМЕНТОВ:

V. Veselý и V. Pekárek, *Talanta*, 1972, **19**, 219. (Институт Ядерных Исследований, Чехословацкая Академия Наук, Ржеж у Праги, Уехословакия.)

Резюме—В статье дан исчерпывающий литературный обзор об исползовании гидратированных окислов и кислых солей многовалентных элементов в качестве ионообмеников. Обзор включает способы приготовления, свойства, назначение и теорию этих материалов.

КОЛОРИМЕТРИЧЕСКИЙ МЕТОД ОПРЕДЕЛЕНИЯ МИКРОДОЗ ФОСФАТОВ В РАЗЛИЧНЫХ СРЕДАХ (БИОЛОГИЧЕСКИХ, ФАРМАЦЕВТИЧЕСКИХ И ПИЩЕВЫХ ПРОДУКТОВ):

Gh. Ghimicescu and Vasile Dorneanu, *Talanta*, 1972, **19**, 263.

Резюме—Предлагается колориметрический метод для определения микроскопических доз фосфатов в различных материалах (биологических веществах, фармацевтических препаратах и в пищевых продуктах). Он основан на осаждении фосфата уранил-магния, который затем растворяется в разведённой серной кислоте, а ион уранила определяется спектрофотометрическим методом через темно-красный цвет уранил ферроцианида. Чувствительность метода = 0,01 мг P, ошибка в среднем 1 %. Метод отличается простотой и может применяться для многих видов образцов.

ОПРЕДЕЛЕНИЕ МЕТАЛЛОВ ПЛАТИНОВОЙ ГРУППЫ, ЗОЛОТА И СЕРЕБРА МЕТОДОМ СБОРА В ОЛОВЕ:

G. H. Faye and P. E. Moloughney, *Talanta*, 1972, **19**, 269.

Резюме—Предлагается исчерпывающая аналитическая схема для определения 6-ти металлов платиновой группы, золота и серебра. Она получена в результате суммирования отдельных процедур, которые частично описывались в течение нескольких лет. Эта аналитическая схема тщательно проверена при специальной испытательной и стандартной работе с широким рядом материалов и, вследствие этого, интерес в ней для многих лабораторий возрастает. Благородные металлы собираются в расплавленном олове, причем образец расплавляется при 1200–1250° температуре флюсом, содержащем окись олова, углекислый натрий, двуокись кремния, буру и муку. Полученный сплав олова растворяется, а благородные металлы изолируются путем ионнообмена, экстрагирования растворителя и/или дистилляцией. За исключением обычных средств расплавления для определения сухим путем при высоких температурах, можно применять стандартное оборудование в мокрых химических операциях для отделения и определения отдельных благородных металлов.

Kinetic method of analysis by analogue computer simulation: Masaki Nakanishi, *Talanta*, 1972, **19**, 285. (Department of Chemistry, Ochanomizu University, Bunkyo-ku, Tokyo, Japan.)

Summary—The simulation by an analogue computer of slow reactions used for the purpose of chemical analysis is described. Bromination of maleic and fumaric acids is used for illustration. The concentration of bromine is traced spectrophotometrically as a function of time and the trace simulated with an analogue computer by the trial and error method. The initial concentration of the substance in question and the rate constant of the reaction are determined from the values given to the computer variables to obtain the best fit. Only a single experiment is required for the analysis. The procedure can be followed easily without laborious mathematical or graphical treatment.

Möglichkeiten und Grenzen bei der Verwendung von Filterpapier als Träger bei der röntgenspektrometrischen Analyse: G. Ackermann, R.-K. Koch, H. Ehrhardt und G. Sanner, *Talanta*, 1972, **19**, 293. (Bergakademie Freiberg, Sektion Chemie—Lehrstuhl für Analytische Chemie und VEB Bergbau und Hüttenkombinat "Albert Funk"—Forschungsinstitut für NE-Metalle, Freiberg (Sachs), DDR.)

Summary—It has been shown that filter paper is a suitable support material for X-ray fluorescence analysis, but that the use of the Weisz ring-oven enables a higher sensitivity to be obtained with a sufficiently reproducible sample geometry. Linear calibration plots are obtained for Ag, Pd, Rh, Pt, Au, Cu, Fe and Ca in the range 0–100 μg. The relative standard deviations vary between 7 and 35, and the limits of detection range from 8 to 35 μg/ml (for iron and calcium respectively). Five samples may be analysed in 30 min. Use of the wax-ring technique enables the analysis time to be halved, but the sensitivity is then less.

Electrophoretic determination of pK-values of indicators and their relation to colour changes: I. Mori, M. Shinogi, E. Falk and Y. Kiso, *Talanta*, 1972, **19**, 299. (Kobe Pharmaceutical Women's College, Nakano 450, Motoyama-cho, Higashi-Nada-Ku, Kobe, Japan and Research Reactor Institute, Kyoto University, Kumatori-cho, Sennan-gun, Osakafu, Japan.)

Summary—The pK-values of Xylenol Orange, Pyrocatechol Violet, Thorin and Alizarin Complexone were determined electrophoretically on the basis of the Kiso equation. The colour changes of Xylenol Orange and Alizarin Complexone were found to take place at slightly higher pH values than the electrophoretically determined pK-values. The Kiso-equation for the determination of pK values by electrophoresis yielded reproducible results and the method is useful for complicated substances because the procedure is simple, the equipment inexpensive and only microamounts of the substances are needed.

КИНЕТИЧЕСКИЙ МЕТОД АНАЛИЗА АНАЛОГОВОЙ ВЫЧИСЛИТЕЛЬНОЙ МАШИНОЙ:

Masaki Nakanishi, *Talanta*, 1972, **19**, 285.

Резюме—Описывается воспроизведение медленных реакций при помощи аналоговой вычислительной машины в целях химических анализов. Для иллюстрирования проводилось бромирование малеиновой и фумаровой кислот Концентрация брома прослеживалась спектрофотометрически, как функция времени и моделировалась аналоговой вычислительной машиной методом проб и ошибок. Начальная концентрация данного вещества и константа скорости реакции определялись по величинам переменных, даваемых вычислительной машине, чтобы получать наиболее подходящее соответствие. Для анализа требуется только один эксперимент. Процедура проделывается легко, без трудоёмких математических или графических приемов.

ВОЗМОЖНОСТИ И ОГРАНИЧЕНИЯ ИСПОЛЬЗОВАНИЯ ФИЛЬТРОВАЛЬНОЙ БУМАГИ КАК НОСИТЕЛЯ ПРИ АНАЛИЗАХ РЕНТГЕНОВСКОЙ СПЕКТРОМЕТРИЕЙ:

G. Ackermann, R.-K. Koch, H. Ehrhardt and G. Sanner, *Talanta*, 1972, **19**, 293.

Резюме—Показано, что фильтровальная бумага является хорошим поддерживающим материалом для анализа рентгеновской флуоресценцией, но употребление кольцевой печи Вейша увеличивает получаемую чувствительность с достаточно воспроизводимой геометрией образца. Для Ag, Pd, Rh, Pt, Au, Cu, Fe и Ca получены линейные калибровочные графики в диапазоне 0–100 uг. Стандартные относительные отклонения колеблются между 7 и 35, а границы диапазона определения от 8 до 35 uг/мл (для железа и кальция соответственно). В течение 30-ти минут можно проанализировать 5 образцов. Применение техники воскового кольца укорачивает время анализа на половину, но тогда чувствительность уменьшается.

ОПРЕДЕЛЕНИЕ ЭЛЕКТРОФОРЕЗОМ ЗНАЧЕНИЙ pK ИНДИКАТОРОВ И И ИХ ОТНОШЕНИЕ К ИЗМЕНЕНИЮ ЦВЕТА:

I. Mori, M. Shinogi, E. Falk and Y. Kiso, *Talanta*, 1972, **19**, 299.

Резюме—Электрофорезом на основании уравнения Kiso были определены значения pK для красок: ксиленол-оранжевой, пирокатехин-фиолетовой, торин и ализарин комплексона. Изменения цвета ксиленол оранжевой и ализаринового комплексона имели место при более высоких значениях pH, чем определенные электрофорезом значения pK. Уравнение Kiso для определения значений pK электрофорезом дало воспроизводимые результаты; этот метод хорош для сложных веществ, так как процедура простая, оборудование недорогое и требуются только микроскопические количества веществ.

Application of displacement reactions in flame photometry–II. Emission flame photometric determination of alkaline earth metals in the presence of interfering anions: P. J. SLEVIN, E. GYÖRY-SZEBÉNYI and G. SVEHLA, *Talanta*, 1972, **19**, 307. (Department of Chemistry, Queen's University, Belfast, U.K.)

Summary—For the emission flame photometric determination of strontium and barium in the presence of interfering ions such as phosphate, sulphate, arsenate and oxalate, calibration or simple standard addition methods cannot be used. Greatly reduced errors can be achieved by dividing the sample solution into four equal parts and adding to each certain known amounts of two metal ions. One of these is identical to the determinand (*e.g.*, strontium or barium) the other has similar characteristics to it (*e.g.*, calcium). The amounts of these metals are chosen so that the total (molar) concentration of these should be identical in all solutions, but the ratio of the concentrations of the two metals should be different. The emission of the determinand metal must be measured, and a standard addition plot produced. The amount of determinand present in the sample can be obtained from the intersection of the emission *vs.* concentration line with the concentration axis.

A fully automated procedure for the determination of sodium hypochlorite and hydrogen peroxide, based on the use of a porous catalytic silver electrode: B. FLEET, A. Y. W. HO and J. TENYGL, *Talanta*, 1972, **19**, 317. (Department of Chemistry, Imperial College of Science and Technology, London, S.W.7, U.K. and Polarographic Institute, Czechoslovak Academy of Sciences, Prague 1, Czechoslovakia.)

Summary—A new approach to the automated determination of sodium hypochlorite and hydrogen peroxide is described, based on the use of a porous catalytic silver electrode. The principle of both methods involves the quantitative liberation of oxygen, which is measured coulometrically by the electrode. The procedures are suitable for the continuous monitoring of the contents of bleaching baths.

ПРИМЕНЕНИЕ РЕАКЦИЙ СМЕЩЕНИЯ В ПЛАМЕННОЙ ФОТОМЕТРИИ—ОПРЕДЕЛЕНИЕ ЩЕЛОЧНЫХ ЗЕМЕЛЬНЫХ МЕТАЛЛОВ ПОСРЕДСТВОМ ПЛАМЕННОЙ ФОТОМЕТРИИ ЭМИССИИ II В ПРИСУТСТВИИ ИНТЕРФЕРИРУЮЩИХ АНИОНОВ:

P. J. Slevin, E. Györy-Szebényi and G. Svehla, *Talanta*, 1972, **19**, 307.

Резюме—Калибровочный или простой стандартный метод добавления не могут применяться для определения пламенной фотометрией эмиссии стронция и бария в присутствии интерфериующих ионов, как напр. фосфатов, сульфатов, арсенатов и оксалатов. Можно значительно уменьшить ошибки, разделяя раствор образца на 4 равные части и добавляя к каждой известное количество ионов двух металлов. Один из них должен быть идентичен с детермтнантом (т.е. стронцием или барием), второй должен иметь подобные ему характеристики (напр. кальций). Количества этих металлов выбираются таким образом, чтобы общая (молярная) концентрация их была одинакова во всех растворах, но чтобы соотношение концентраций двух металлов было различно. Затем измеряется эмиссия металла-детерминанта и составляется стандартный график добавления. Количество детерминанта в образце получается на пересечении эмиссии против линии концентрации с осью концентрации.

ПОЛНОСТЬЮ АВТОМАТИЗИРОВАННАЯ ПРОЦЕДУРА ДЛЯ ОПРЕДЕЛЕНИЯ ГИПОХЛОРИТА НАТРИЯ И ПЕРЕКИСИ ВОДОРОДА, ОСНОВАННАЯ НА ИСПОЛЬЗОВАНИИ ПОРИСТОГО СЕРЕБРЯНОГО, КАТАЛИТИЧЕСКОГО, ЭЛЕКТРОДА:

B. Fleet, A. Y. W. Ho and J. Tenygl, *Talanta*, 1972, **19**, 317.

Резюме—Описывается основанный на использовании пористого каталитического серебряного электрода новый подход для определения гипохлорита натрия и перекиси водорода. Принцип обоих методов основан на выделении количеств кислорода, которые измеряются электродом кулонометрически. Эти процедуры могут применяться для непрерывного регулирования содержимого отбеливающих ванн.

Study of oxidation state of plutonium in solution, by flow-coulometric method: SORIN KIHARA, TADASHI YAMAMOTO, KENJI MOTOJIMA and TAITIRO FUJINAGA, *Talanta*, 1972, **19**, 329. (Japan Atomic Energy Research Institute, Tokai-mura, Naka-gun, Ibaraki-ken, Japan and Department of Chemistry, Faculty of Science, Kyoto University, Kitashirakawa, Sakyo-ku, Kyoto, Japan.)

Summary—Reduction rates of Pu(IV) and oxidation rates of Pu(III) have been studied in sulphuric acid and nitric acid media, as functions of acid concentration, plutonium concentration and kind of acid. A flow-coulometric method was used in this work. This procedure has many merits, namely, the sample size required is very small, special reagents are not used, fewer limitations are imposed by the type and concentration of acid, and the method is rapid.

Spectrophotometric determination of 0–50 ng of chromium in 1 ml of human serum: J. AGTERDENBOS, L. VAN BROEKHOVEN, B.A.H.G. JÜTTE and J. SCHURING, *Talanta*, 1972, **19**, 341. (Analytisch-Chemisch Laboratorium, Rijksuniversiteit, Croesestraat 77A, Utrecht, Holland.)

Summary—A method is described for the determination of chromium in 1 ml of human serum or plasma. It is based on a wet decomposition and a spectrophotometric determination with diphenylcarbazide after extraction with methyl isobutyl ketone. A 40-mm cuvette with less than 1 ml sample volume is described. Results are lower than expected from the literature, most samples from healthy persons containing less than 2 or 3 ng/ml. The reproducibility is about 1 ng/ml.

Dichloramine-T as a new oxidimetric titrant in non-aqueous and partially aqueous media: T. J. JACOB and C. G. R. NAIR, *Talanta*, 1972, **19**, 347. (University Department of Chemistry, Kerala University, Trivandrum-1, India.)

Summary—A new oxidimetric titrant, dichloramine-T, is proposed for redox titrations in glacial acetic acid medium. The general analytical conditions for using this oxidant and the procedures for potentiometric determination of ascorbic acid, iodide, arsenic(III) and iron(II) are described.

ИЗУЧЕНИЕ ОКИСЛЕНИЯ ПЛУТОНИЯ В РАСТВОРАХ ПРИ ПОМОЩИ СЧЕТЧИКА ПОТОКА (КУЛОНМЕТРА):

Sorin Kihara, Tadashi Yamamoto, Kenji Motojima and Taitiro Fujinaga, *Talanta*, 1972, **19**, 329.

Резюме—Изучались величины восстановления Pu(IV) и окисления Pu(III) в средах серной и азотной кислот, как функции концентрации и вида кислот и как функции концентрации плутония. Для этой работы пользовались кулометрическим методом. Эта процедура имеет много преимуществ, а именно: требуется очень небольшой образец, не требуется никаких специальных реактивов, вид и концентрация кислоты дают меньше ограничений и метод очень быстрый.

СПЕКТРОФОТОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ 0–50 НГ ХРОМА В 1 МЛ. ЧЕЛОВЕЧЕСКОЙ СЫВОРОТКИ:

J. Agterdenbos, L. van Broekhoven, B. A. H. G. Jüffe and J. Schuring, *Talanta*, 1972, **19**, 341.

Резюме—Описывается метод определения хрома в 1 мл. человеческой сыворотки или плазмы. Он основан на влажном разложении и спектрофотометрическом определении с дифенилкарбазидом после экстрагирования метилизобутилкетоном. Описывается кюветка на 40 мм с образцом меньше 1 мл объемом. Результаты оказались ниже, чем описываемые в литературе; большая часть образцов от здоровых людей содержала меньше, чем 2 или 3 нг/мл. Воспроизводимость около 1 нг/мл.

ДИХЛОРАМИН-Т В КАЧЕСТВЕ НОВОГО ОКИСНОМЕТРИЧЕСКОГО ТИТРУЮЩЕГО АГЕНТА В БЕЗВОДНЫХ И ЧАСТИЧНО ВОДНЫХ СРЕДАХ:

T. J. Jacob and C. G. R. Nair, *Talanta*, 1972, **19**, 347.

Резюме—Для восетиновительно-окислительного титрования в среде ледяной уксусной кислоты предлагается новый окисномотрический титрующий агент—дихлорамин-Т. Описываются общие аналитические условия при использовании этого окислителя, а также процедуры для потенциометрического определения аскорбиновой кислоты, иода, машьяка (III) и железа (II).

Purity of compounds by extraction-solubility: R. A. HUMMEL and W. B. CRUMMETT, *Talanta*, 1972, **19**, 353. (Analytical Laboratories, 574 Building, The Dow Chemical Company, Midland, Michigan, U.S.A.)

Summary—Thirty-three organic compounds prepared for use as analytical standards were examined for purity by the extraction-solubility method. Of these, twenty-one gave satisfactory results, seven behaved non-ideally, and five were not soluble in the useful range. Results on the twenty-one satisfactory samples compared favourably with those obtained by differential scanning calorimetry and other analytical methods. The method was found to be useful for following the improvement of compounds undergoing purification.

Determination of phosphorus in lubricating oils by cool-flame emission spectroscopy: W. N. ELLIOTT, C. HEATHCOTE and R. A. MOSTYN, *Talanta*, 1972, **19**, 359. (Quality Assurance Directorate (Materials), Royal Arsenal, London, S.E.18.)

Summary—The phosphorus content of lubricating oils is determined by measurement of the emission from the HPO molecular species at 528 nm in a cool hydrogen–nitrogen diffusion flame. The oil is ashed in the presence of potassium hydroxide and an aqueous extract of the melt is treated with ion-exchange resin to remove interferents, before aspiration into the flame. Analytical results are presented on samples containing phosphorus in the range 0.009–0.2%. The precision of the method is ±5% at the 0.04% phosphorus level.

Neutron-activation analysis for thorium in zircon: H. B. DESAI, R. PARTHASARATHY and M. SANKAR DAS, *Talanta*, 1972, **19**, 363. (Analytical Division, Bhabha Atomic Research Centre, Modular Laboratories, Trombay, Bombay-85 (AS), India.)

Summary—The thorium content of zircons and standard rock samples was determined by neutron-activation analysis. The 310-keV photopeak activity of ^{233}Pa was enhanced by a prior chemical separation which removed interfering induced activities.

ПРОВЕРКА ЧИСТОТЫ СОЕДИНЕНИЙ МЕТОДОМ ЭКСТРАГИРОВАНИЯ/РАСТВОРИМОСТИ:

R. A. HUMMEL and W. B. CRUMMETT, *Talanta*, 1972, **19**, 353.

Резюме—Приготовленные для использования в качестве аналитических стандартов тридцать три органические соединения проверялись на чистоту методом экстрагирования—растворимости. Из них двадцать одно соединение дало удовлетворительные результаты, семь—не очень хорошие, а пять не растворялись в требуемых пределах. Результаты двадцати одного удовлетворительного образца имели преимущества по сравнению с методом дифференциальной развертывающей калориметрии и с другими аналитическими методами. Метод оказался полезным для проверки улучшения соединений, подвергаемых очистке.

ОПРЕДЕЛЕНИЕ ФОСФОРА В СМАЗОЧНЫХ МАСЛАХ СПЕКТРОСКОПИЕЙ С ЭМИССИЕЙ ХОЛОДНОГО ПЛАМЕНИ:

W. N. ELLIOTT, C. HEATHCOTE and R. A. MOSTYN, *Talanta*, 1972, **19**, 359.

Резюме—Содержание фосфора в смазочных маслах определялось измерением эмиссии от видов молекул HPO при 528 нм в холодном диффузионном пламени водород-азот. В присутствии гидроокиси калия масло превращалось в золу и перед отсосом в пламя водный экстракт расплава обрабатывался ионообменной смолой для удаления интерферирующих веществ. Аналитические результаты представлены на образцах, содержащих фосфор в пределах 0,009–0,2 %. Точность метода ± 5 % при уровне фосфора = 0,04 %.

АНАЛИЗ НЕЙТРОННОЙ АКТИВАЦИИ ДЛЯ ОПРЕДЕЛЕНИЯ ТОРИЯ В ЦИРКОНИИ:

H. B. DESAI, R. PARTHASARATHY and M. SANKAR DAS, *Talanta*, 1972, **19**, 363.

Резюме—Содержание тория в циркониевых и стандартных образцах горных пород определялось анализом нейтронной активации. Максимальная фотоактивность ^{233}Pa в 310 кэв усиливалась предварительным химическим отделением, которое устраняло интерферирующую искусственную радиоактивность.

Spectrophotometric molybdenum determination with thiolactic acid: JAMES S. FRITZ and DONALD R. BEUERMAN, *Talanta*, 1972, **19**, 366. (Iowa State University, Ames, Iowa, U.S.A.)

Summary—A quick, selective method for molybdenum(VI) is based on the formation of a yellow thiolactic acid complex. The complex is formed at pH 1.0–1.6, and the absorbance is measured at 365 nm.

Determination of traces of iron(II) in the presence of iron(III) by the bathophenanthroline method: TAKAYUKI MIZUNO, *Talanta*, 1972, **19**, 369. (Technical Laboratory, Central Research Institute of Electrical Power Industry, Iwato, Komae, Tokyo, Japan.)

Summary—Traces of iron(II) (1–30 ppM) in the presence of iron(III) were determined (error <10%) by the bathophenanthroline method. Interference of iron(III) was eliminated by masking with sodium pyrophosphate (2·5–60 mg). The iron(II) complex was extracted with n-butanol, at pH 4·2–4·7.

СПЕКТРОФОТОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ МОЛИБДЕНА ПОСРЕДСТВОМ ТИОМОЛОЧНОЙ КИСЛОТЫ:

JAMES S. FRITZ and DONALD R. BEUERMAN, *Talanta*, 1972, **19**, 366.

Резюме—Быстрый селективный метод для молибдена(VI), основанный на образовании желтого комплексного соединения тиомолочной кислоты. Соединение это образуется при pH = 1,0–1,6, поглощаемость измеряется при 365 nm.

ОПРЕДЕЛЕНИЕ СЛЕДОВ ЖЕЛЕЗА (II) В ПРИСУТСТВИИ ЖЕЛЕЗА (III) БАТОФЕНАНТРОЛИНОВЫМ МЕТОДОМ:

TAKAYUKI MIZUNO, *Talanta*, 1972, **19**, 369.

Резюме—Следы железа (II) (1–30 ч/милл в присутствии железа (III) определялись батофенантролиновым методом (ошибка $<10\%$). Интерференция железа(III) исключалась маскировкой пирофосфатом натрия (2,5–60 мг). Комплекс железа(II) извлекался н-бутанолом при pH = 4,2–4,7.

Determination of inorganic impurities in vinyl chloride by activation analysis: FLORIN T. BUNUŞ and SANDA MURGALESCU, *Talanta*, 1972, **19**, 372. (Institute of Atomic Physics, Bucharest, Romania.)

Summary—Trace impurities in vinyl chloride have been determined by activation analysis in a reactor thermal neutron flux of $1{\cdot}2 \times 10^9$ $n/mm^2/sec$. Irradiations were carried out on liquid and solid samples at the same time as a standard. Gamma-spectrometry was used to reveal the presence of arsenic and bromine, the quantitative estimation being based on two calculus methods. The impurities determined were: arsenic $8{\cdot}0 \pm 0{\cdot}6 \times 10^{-4}\%$, bromine $3{\cdot}07 \pm 0{\cdot}2 \times 10^{-3}\%$ and phosphorus $2{\cdot}0 \pm 0{\cdot}15 \times 10^{-2}\%$.

Organic and inorganic ion-exchange beads as indicators in redox and precipitation titrations: MOHSIN QURESHI, SAIDUL ZAFAR QURESHI and NIGHAT ZEHRA, *Talanta*, 1972, **19**, 377. (Chemistry Department, Aligarh Muslim University, Aligarh (U.P.), India.)

Summary—Resin beads in the Fe(III) or *p*-dimethylaminobenzylidenerhodanine form are used as indicators in precipitation titrations with $K_3Fe(CN)_6$ and Ag^+. Resin beads with diphenylamine adsorbed on them can be used as indicators in cerimetric titrations. They have some advantages over conventional indicators.

On the analytical utility of quasi-linear molecular emission spectra: R. J. LUKASIEWICZ and J. D. WINEFORDNER, *Talanta*, 1972, **19**, 381. (Department of Chemistry, University of Florida, Gainesville, Florida 32601, U.S.A.)

Summary—The analytical utility of the Shpol'skii effect has been examined. It is concluded that the combined instrumental and theoretical restrictions limit the analytical usefulness of true quasi-line spectra for quantitative work.

ОПРЕДЕЛЕНИЕ НЕОРГАНИЧЕСКИХ ПРИМЕСЕЙ В ВИНИЛХЛОРИДЕ АКТИВАЦИОННЫМ АНАЛИЗОМ:

Florin T. Bunuş and Sandra Murgalescu, *Talanta*, 1972, **19**, 372.

Резюме—Следы примесей в винихлориде были определены активационным анализом в реакторе с тепловым нейтронным потоком в $1,2 \times 10^9$ н/мм^2/сек. Проводилось облучение жидкости и одновременно твердых образцов, как стандартов. Для обнаружения присутствия мышьяка и брома пользовались гамиа-спектрометрией, причем количественное определение основывалось на двух методах исчисления. Были определены следующие примеси: мышьяка $8,0 \pm 0,6 \times 10^{-4}\%$, брома $3,07 \pm 0,2 \times 10^{-4}\%$ и фосфора $2,0 \pm 0,15 \times 10^{-2}\%$.

ОРГАНИЧЕСКИЕ И НЕОРГАНИЧЕСКИЕ ИОНООБМЕННЫЕ ГРАНУЛЫ, КАК ИНДИКАТОРЫ ОКИСЛИТЕЛЬНО-ВОССТАНОВИТЕЛЬНОГО И ОСАДИТЕЛЬНОГО ТИТРОВАНИЯ:

Mohsin Qureshi, Saidul Zafar Qureshi and Nighat Zehra, *Talanta*, 1972, **19**, 377.

Резюме—Гранулы смолы в виде Fe(III) или в форме р-диметиламинобензилиденеροданина применялись как индикаторы при титровании с $K_3Fe(CN)_6$ и Ag^+. Смоляные гранулы с адсорбированным на них дифениламином могут служить индикаторами для цериметрических титрований. Они имеют некоторые преимущества перед обычными индикаторами.

ОБ АНАЛИТИЧЕСКОМ ИСПОЛЬЗОВАНИИ КВАЗИЛИНЕЙНОГО МОЛЕКУЛЯРНОГО СПЕКТРА ЭМИССИИ:

R. J. Lukasiewicz and J. D. Winefordner, *Talanta*, 1972, **19**, 381.

Резюме—Проверялось аналитическое использование эффекта Shpol'ского. Заключение: сочетание приборных и теоретических пределов ограничивает аналитическое использование настоящего квазилинейного спектра для количественного определения.

SUMMARIES FOR CARD INDEXES

Synthetic inorganic ion exchangers—II. Salts of heteropolyacids, insoluble ferrocyanides, synthetic aluminosilicates and miscellaneous exchangers: V. Pekárek and V. Veselý, *Talanta*, 1972, **19**, 1245. (Nuclear Research Institute of the Czechoslovak Academy of Sciences, Řež near Prague, Czechoslovakia.)

Summary—A review of the developments during the period 1965–70 in use of heteropoly acid salts, ferrocyanides and synthetic zeolites as ion-exchangers.

A contribution to the problem of increasing the sensitivity of anodic-stripping voltammetry: Ludmila Huderová and Karel Štulík, *Talanta*, 1972, **19**, 1285. (Research Institute for Pharmacy and Biochemistry, and Department of Analytical Chemistry, Charles University, Prague, Czechoslovakia.)

Summary—A brief discussion of problems connected with increasing the sensitivity of anodic-stripping determinations is presented. A new microcell for anodic-stripping voltammetry in solution volumes down to about 0.01 ml was constructed. The effect of the solution volume, the mercury-drop electrode size, and of the pre-electrolysis time and potential on the sensitivity of determinations was studied and the reproducibility of results for determinations of lead in mineral acids is given. It was found that nanogram amounts of heavy metals can easily be determined in this way. In determination of 2 ng of Pb^{2+} in 0.02 ml of solution the results were 2.00 ± 0.13 ng (95% confidence limits), the mean relative deviation being 6.3%. For determination of copper in KNO_3, stripping microanalysis was compared with atomic-absorption spectrophotometry. Advantages and disadvantages of stripping voltammetry on the macro- and micro-scales are discussed.

Determination of and differentiation between cassiterite and silicate-bound tin in silicate rocks containing traces of tin: J. Agterdenbos and J. Vlogtman, *Talanta*, 1972, **19**, 1295. (Laboratory for Analytical Chemistry, State University, Croesestraat 77A, Utrecht, Holland.)

Summary—A simple, sensitive and reproducible method is described for the determination of tin in silicate rocks at the ppm level. By applying a selective decomposition it seems possible to differentiate between tin present in the silicate lattice, in readily-accessible cassiterite (SnO_2) and in cassiterite enclosed in the silicate. The final determination is made by extraction and photometry with phenylfluorone. Results for total tin agree well with those obtained by X-ray fluorescence.

СИНТЕТИЧЕСКИЕ НЕОРГАНИЧЕСКИЕ ИОНООБМЕННИКИ—II. СОЛИ ГЕТЕРОПОЛИКИСЛОТ, НЕРАСТВОРИМЫЕ ФЕРРОЦИАНИДЫ, СИНТЕТИЧЕСКИЕ АЛЮМОСИЛИКАТЫ И РАЗНЫЕ ОБМЕННИКИ:

V. Pekárek and V. Veselý, *Talanta*, 1972, **19**, 1245.

Резюме—Приведен обзор успехов полученных в периоде 1965–70 при использовании гетерополикислот, ферроцианидов и синтетических зеолитов в качестве ионообменников.

ВКЛАД В ПРОБЛЕМУ ПОВЫШЕНИЯ ЧУВСТВИТЕЛЬНОСТИ МЕТОДА ВОЛЬТАМПЕРОМЕТРИИ С АНОДНЫМ СНИМАНИЕМ:

Ludmila Huderová and K. Štulík, *Talanta*, 1972, **19**, 1285.

Резюме—Кратко рассмотрены проблемы своязанные с повышением чувствительности вольтамперометрии с анодным сниманием. Сконструирована новая микроячейка лдя применения метода в растворах, использующая объемы вплоть до 0,01 мл. Изучено влияние объема раствора, размеров капельного ртутного электрода, продолжительности предварительного электролиза и потенциала на чувствительность определений и определена воспроизводимость результатов полученных в определении свинца в минеральных кислотах. Метод позволяет определять нанограммовые количества тяжёлых металлов. При определении 2 нг Pb^{2+} в 0,02 мл раствора получено 2,00 ± 0,13 нг (с пределем доверия 95 %), с относительной стандартной ошибкой 6,3 %. В случае определения меди в KNO_3 микроанализ обсужденным методом сравнен с методом атомно-абсорбционной спектрофотометрии. Обсуждены преимущества и недостатки вольтамперометрии с анодным сниманием на макро- и микромасштабе.

ОПРЕДЕЛЕНИЕ И РАЗЛИЧЕНИЕ МЕЖДУ КАССИТЕРИТОМ И СВЯЗАННЫМ С СИЛИКАТОМ ОЛОВОМ В СИЛИКАТНЫХ ГОРНЫХ ПОРОДАХ СОДЕРЖАЩИХ СЛЕДЫ ОЛОВА:

J. Agterdenbos and J. Vlogtman, *Talanta*, 1972, **19**, 1295.

Резюме—Описан несложный, чувствительный и воёпроизводимый метод определения олова в силикатных горных породах в области частей на миллион. Применение селективного разложения пробы позволяет различать между оловом присутствующим в силикатной решётке, в легкодоступном касситерите (SnO_2) и в касситерите, закрытом в силикате. Конечное определение состоит из экстрагирования и фотометрического определения с фенилфлуороном в качестве реагента. Результаты полученные для общего содержания олова хорошо соглашаются с результатами полученными методом рентгеновской флуоресценции.

Determination of manganese by atomic-fluorescence spectroscopy using a carbon-filament atom-reservoir: L. Ebdon, G. F. Kirkbright and T. S. West, *Talanta*, 1972, **19**, 1301. (Department of Chemistry, Imperial College of Science and Technology, London, SW7 2AY, U.K.).

Summary—The atomic-fluorescence characteristics of manganese heated on a carbon-filament atom-reservoir (CFAR) are described and compared with (*a*) the atomic-absorption behaviour of the element on the same filament apparatus, and (*b*) its fluorescence behaviour in a separated air–acetylene flame. By fluorescence at 279·5 nm, using 1-μl samples, manganese may be determined down to 0·6 pg (6×10^{-4} ppm) by use of an electrodeless discharge lamp source (3 pg or 3×10^{-3} ppm by absorption, and 20 ng or 1×10^{-2} ppm by flame emission at 403 nm). The effects of fourteen representative cations and anions examined showed no interference at 10-fold and 100-fold levels and serious interference only from magnesium at the 1000-fold level, with *ca.* 10% suppression from Cr, V, Na and K. No fluorescence signals were observed at any wavelength other than 279·5 nm when the CFAR device was used.

Some considerations on spectral line profiles of microwave-excited electrodeless discharge lamps: D. O. Cooke, R. M. Dagnall and T. S. West, *Talanta*, 1972, **19**, 1309. (Department of Chemistry, Imperial College of Science and Technology, London, SW7.)

Summary—The problems of line broadening in microwave-excited electrodeless discharge lamps for the more volatile elements, P, S, I, Se, Zn, Cd and Hg are discussed in relation to their use in atomic-absorption and fluorescence spectrometry. Both theoretical and practical implications are considered

---

Controlled potential coulometry: the application of a secondary reaction to the determination of plutonium and uranium at a solid electrode: J. B. Fardon and I. R. McGowan, *Talanta*, 1972, **19**, 1321. (British Nuclear Fuels Ltd., Windscale and Calder Works, Sellafield, Seascale, Cumberland, U.K.)

Summary—A method is described for the simultaneous determination of plutonium and uranium in mixed oxides by controlled potential coulometry at a gold working electrode in two stages: first a coulometric oxidation, at 0·73 V *vs.* a silver/silver chloride electrode, of Pu(III) and U(IV) to Pu(IV) and U(VI) by a combination of a direct electrode reaction and a secondary chemical reaction proceeding concurrently, and secondly, a coulometric reduction at 0·33 V of Pu(IV) to Pu(III), leaving uranium as U(VI). The determination is carried out in a mixture of sulphuric and nitric acids, and Ti(III) is used to reduce plutonium and uranium to Pu(III) and U(IV) before electrolysis. The precision (3σ) of Pu:U ratio results obtained from mixtures containing about 30% and 2% plutonium was 0·5% and 1·5% respectively. The effect of experimental variables on the time taken to complete the coulometric determination is discussed.

ОПРЕДЕЛЕНИЕ МАРГАНЦА МЕТОДОМ АТОМНО-ФЛУОРЕСЦЕНТНОЙ СПЕКТРОСКОПИИ С ИСПОЛЬЗОВАНИЕМ АТОМНОГО РЕЗЕРВУАРА В ФОРМЕ УГОЛЬНОЙ НИТИ:

L. Ebdon, G. F. Kirkbright and T. S. West, *Talanta*, 1972, **19**, 1301.

Резюме—Описаны атомно-флуоресцентные характеристики марганца, нагреванного на атомном резервуаре в форме угольной нити (CFAR) и сравнены с (а) атомно-абсорбционными характеристиками элемента на том же приборе, и (б) его флуоресцентными характеристиками в отделенной пламены воздуха-ацетилена. Флуоресценция при 279,5 нм, с использованием 1 мкл пробы, позволяет определять марганец вплоть до 0,6 пг ($6 \cdot 10^{-4}$ ч. на миллион), применяя безэлектродную разрядную лампу (3 пг или $3 \cdot 10^{-3}$ ч. на миллион с применением абсорбции и 20 нг или $1 \cdot 10^{-2}$ ч. на миллион методом пламенной эмиссии при 403 нм). Испытанных 14 типических катионов и анионов не показали мешающее влияние при 10-кратном и 100-кратном избытке, а только магный показал серьезное влияние при 1000-кратном избытке; Cr, V, Na и K дали 10%-тное подавление сигнала. Никакие флуоресцентные сигналы не обнаружены при длинах волн других чем 279,5 нм при использовании прибора CFAR.

РАССМОТРЕНИЕ ПРОФИЛЕЙ ЛИНИЙ СПЕКТРА ВОЗБУЖДЕННЫХ МИКРОВОЛНАМИ БЕЗЭЛЕКТРОДНЫХ РАЗРЯДНЫХ ЛАМП:

D. O. Cooke, R. M. Dagnall and T. S. West, *Talanta*, 1972, **19**, 1309.

Резюме—Рассмотрены проблемы расширения линий возбужденных микроволнами безэлектродных разрядных ламп для более летучих элементов P, S, I, Se, Zn, Cd и Hg в связи с их использованием в атомно-абсорбционной и атомно-флуоресцентной спектроскопии. Проблема обсуждена с теоретической и практической точки зрения.

КУЛОНОМЕТРИЯ С РЕГУЛИРОВАННЫМ ПОТЕНЦИАЛОМ: ПРИМЕНЕНИЕ ВТОРИЧНОЙ РЕАКЦИИ В ОПРЕДЕЛЕНИИ ПЛУТОНИЯ И УРАНА НА ТВЁРДОМ ЭЛЕКТРОДЕ:

J. B. Fardon and I. R. McGowan, *Talanta*, 1972, **19**, 1321.

Резюме—Описан метод одновременного определения плутония

ОПРЕДЕЛЕНИЕ ПЛУТОНИЯ И УРАНА В СМЕШАННЫХ ОКСИДНЫХ ТОПЛИВАХ МЕТОДОМ ПОСЛЕДОВАТЕЛЬНОГО ОКИСЛИТЕЛЬНО-ВОССТАНОВИТЕЛЬНОГО ТИТРОВАНИЯ:

P. H. Chadwick and I. R. McGowan, *Talanta*, 1972, **19**, 1335.

Резюме—Последовательное определение урана и плутония в том же растворе пробы позволяет экономить с временем анализа и затратой для прибора. Метод начинает с U(IV) и Pu(III) в смеси серной и азотной кислот. Титрование дихроматом, применяя амперометрический метод на пары поляризируемых электродов, дает два хорошо выраженных конца титрования, соответствующие последовательному окислению U(IV) в U(VI) и Pu(III) в Pu(IV). Количественное окисление U(IV) в U(VI) получено путем действия Pu(IV) как промежуточного продукта, и зависит от создания условий способству-

Determination of trace metals in water by x-ray fluorescence spectrometry: H. Watanabe, S. Berman and D. S. Russell, *Talanta*, 1972, **19**, 1363. (Division of Chemistry, National Research Council of Canada, Ottawa, Ontario, Canada.)

Summary—A simple, rapid and accurate method for water analysis is proposed. The analytical procedure for the determination of Fe, Mn, Zn, Cu, Cd, As, Pb and Se in water in concentrations as low as a few ppM involves precipitation with a carrier of the metals by diethyldithiocarbamate (DDTC) or 1-(2-pyridylazo)-2-naphthol (PAN) and filtration through a Millipore filter. The precipitates collected on the filter disc are examined by X-ray fluorescence analysis. PAN is excellent for the determination of several metal ions at the ppM level, and DDTC can be used with tartrate as a masking agent if water samples contain large amounts of iron(III).

Studies on chromium(III) hydroxide, arsenate, antimonate, molybdate and tungstate: Mohsin Qureshi, Rajendra Kumar and H. S. Rathore, *Talanta*, 1972, **19**, 1377. (Chemical Laboratories, Aligarh Muslim University, Aligarh, U.P., India.)

Summary—Five water-insoluble compounds of chromium(III) have been synthesized by mixing 0·10*M* solutions of chromic chloride and the appropriate sodium salts in the volume ratio of 1:2, at pH 6–7. Their ion-exchange characteristics have been compared. The tungstate has the highest chemical stability and the arsenate has the highest ion-exchange capacity. Chromium(III) molybdate columns have been used to separate Pb^{2+} from numerous metal ions.

Investigations of dioximes and their metal complexes. A survey of the literature since 1963: Birgitta Egneus, *Talanta*, 1972, **19**, 1387. (Department of Analytical Chemistry, University of Gothenburg, Fack, S-402 20 Göteborg, Sweden.)

Summary—A review is given of the chemistry and analytical applications of dioxime complexes from metals.

ОПРЕДЕЛЕНИЕ СЛЕДОВ МЕТАЛЛОВ В ВОДЕ МЕТОДОМ РЕНТГЕНОВСКОЙ ФЛУОРЕСЦЕНЦИИ:

H. WATANABE, S. BERMAN and D. S. RUSSELL, *Talanta*, 1972, **19**, 1363.

Резюме—Предложен несложный, быстрый и прецизионный метод анализа воды. Методика определения Fe, Mn, Zn, Cu, Cd, As, Pb и Se в воде при концентрациях вплоть несколько частей на миллион основана на осаждении металлов в присутствии носителя диэтилдитиокарбаминатом (ДДТК) или 1-(2-пиридилазо)-2-нафтолом (ПАН), и фильтровании через Миллипор фильтр. Удержанные на фильтре осадки исследуют методом рентгеновской флуоресценции. ПАНом получены отличные результаты в определении ряда ионов металлов если присутствуют в микрограммовых количествах, а ДДТК может использоваться вместе с тартратом в качестве маскирующего агента в случае присутствия больших количеств железа(III) в пробе.

ИЗУЧЕНИЕ ГИДРООКИСИ, АРСЕНАТА, АНТИМОНАТА, МОЛИБДАТА И ВОЛЬФРАМАТА ХРОМА(III):

MOHSIN QURESHI, RAJENDRA KUMAR and H. S. RATHORE, *Talanta*, 1972, **19**, 1377.

Резюме—Приготовлено пять нерастворимых в воде соединений хрома(III) смешиванием 0,10*M* растворов хлорида хрома(III) и соответственных солей натрия, в объемном отношении 1:2, при pH 6–7. Сравнены их ионообменные характеристики. Вольфрамат обладает самой лучшой химической устойчивостью, а арсенат—самой лучшой ионообменной емкостью. Колонки молибдата хрома(III) использованы для отделения Pb^{2+} от многочисленных ионов металлов.

ИССЛЕДОВАНИЕ ДИОКСИМОВ И ИХ КОМПЛЕКСОВ С МЕТАЛЛАМИ. ОБЗОР ЛИТЕРАТУРЫ С 1963 ГОДА:

BIRGITTA EGNEUS, *Talanta*, 1972, **19**, 1387.

Резюме—Приведен обзор химии и применений в анализе комплексов диоксимов с металлами.

New masking procedure for selective complexometric determination of copper(II): Rajinder Pal Singh, *Talanta*, 1792, **19**, 1421. (Department of Chemistry, Panjabi University, Patiala, India.)

Summary—A study has been made of a new masking procedure for highly selective complexometric determination of copper(II), based on decomposition of the copper–EDTA complex at pH 5–6. Among the various combinations of masking agents tried, ternary masking mixtures comprising a main complexing agent (thiourea), a reducing agent (ascorbic acid) and an auxiliary complexing agent (thiosemicarbazide or a small amount of 1,10-phenanthroline or 2,2′-dipyridyl) have been found most suitable. An excess of EDTA is added and the surplus EDTA is back-titrated with lead (or zinc) nitrate with Xylenol Orange as indicator (pH 5–6). A masking mixture is then added to decompose the copper–EDTA complex and the liberated EDTA is again back-titrated with lead (or zinc) nitrate. The following cations do not interfere: Ag^+, Hg^{2+}, Pb^{2+}, Ni^{2+}, Bi^{3+}, As^{3+}, Al^{3+}, Sb^{3+}, Sn^{4+}, Cd^{2+}, Co^{2+}, Cr^{3+} and moderate amounts of Fe^{3+} and Mn^{2+}. The notable feature is that consecutive determination of Hg^{2+} and Cu^{2+} can be conveniently carried out in the presence of other cations.

Volumetric determination of primary arylamines and nitrites, using an internal indicator system: Eugen Szekely, Amalia Bandel and Miriam Flitman, *Talanta*, 1972, **19**, 1429. (Department of Analytical Chemistry, Negev Institute for Arid Zone Research, Beer Sheva, Israel.)

Summary—A new nitrite titration method is presented. The titration is performed in the presence of a standard solution of 4,4′-sulphonyldianiline and diphenylamine, which is used as an internal indicator. An intense red colour develops during the titration as a result of a simultaneous diazotization and coupling process. A very sharp end-point is given by a colour change to yellow. The titration is performed at a temperature of about 45° in the presence of large amounts of nitrate. The method is specific and precise. It is suitable for the direct volumetric determination of various easily diazotized primary arylamines, sulphonamides and other amino-compounds which can be determined by nitrite titration. It is suitable also for the indirect determination of nitrites. The method is applicable on the semimicro and macro scales.

НОВЫЙ МЕТОД МАСКИРОВАНИЯ ДЛЯ СЕЛЕКТИВНОГО КОМПЛЕКСОНОМЕТРИЧЕСКОГО ОПРЕДЕЛЕНИЯ МЕДИ(II):

RAJINDER PAL SINGH, *Talanta*, 1972, **19**, 1421.

Резюме—Изучен новый метод маскирования для высокоизбирательного комплексонометрического определения меди(II), основанного на разложении комплекса меди с ЭДТА при pH 5–6. Среди испытанных комбинаций маскирующих агентов найлучшие результаты получены тройними маскирующими смесями, состоящимися из главного комплексообразующего агента (тиомочевины), восстанавливающего агента (аскорбиновой кислоты) и вспомогательного комплексообразующего агента (тиосемикарбазида или небольщего количества 1,10-фенантролина или 2,2′-дипиридила). Раствору добавляют избыток ЭДТА который оттитруют раствором нитрата свинца (или цинка), с использованием ксиленолового оранжевого в качестве индикатора (pH 5–6). Раствору затем добавляют маскирующую смесь для разложения комплекса меди с ЭДТА, а выделенный ЭДТА снова оттитруют нитратом свинца (или цинка). Следующие катионы не мешают определению: Ag^+, Hg^{2+}, Pb^{2+}, Ni^{2+}, Bi^{3+}, As^{3+}, Al^{3+}, Sb^{3+}, Sn^{4+}, Cd^{2+}, Co^{2+}, Cr^{3+}, и умеренные количества Fe^{3+} и Mn^{2+}. Значительное преимущество метода в том, что им можно последовательно определять Hg^{2+} и Cu^{2+} в присутствии других катионов.

ОБЪЕМНОЕ ОПРЕДЕЛЕНИЕ ПЕРВИЧНЫХ АРИЛАМИНОВ И НИТРИТОВ С ИСПОЛЬЗОВАНИЕМ ВНУТРЕННОЙ ИНДИКАТОРНОЙ СИСТЕМЫ:

EUGEN SZEKELY, AMALIA BANDEL and MIRIAM FLITMAN, *Talanta*, 1972, **19**, 1429.

Резюме—Предложен новый метод титрования нитритов. Титрование проводится в присутствии титрованного раствора 4,4′-сульфонилдианилина и дифениламина, который служит в качестве внутренного индикатора. В течении титрования проявляется яркая красная окраска в результате одновременного протекания процессов диазотирования и сочетания. Весма острый конец титрования обнаруживается при переходе окраски в желтую. Титрование проводится при температуре около 45° в присутствии больших количеств нитрата. Метод является специфическим и прецизионным; им можно пользоваться для непосредственного объемного определения разных легко диазотированных первичных ариламинов, сульфонамидов и других аминосоединений, которые могут быть определены нитритным титрованием. Метод также применимый для косвенного определения нитритов, и может быть использован на семимикро- и макрошкале.

Arsenazo III and its analogues—VII. Coloured reactions of the rare earth elements with a new reagent—Carboxynitrazo: S. B. Savvin, T. V. Petrova and P. N. Romanov, *Talanta*, 1972, **19**, 1437. (V. I. Vernadsky Institute of Geochemistry and Analytical Chemistry, U.S.S.R. Academy of Sciences, Moscow.)

Summary—A new reagent, Carboxynitrazo, gives a colour reaction with some rare earth elements. For the individual rare earth elements the sensitivities of the reactions are very different. The difference is greatest for the elements of the Ce- and Y-subgroups. For the first subgroup the molar absorptivities are about 16×10^4 l. mole^{-1} cm^{-1}, whereas most of the elements of the Y-group do not give any colour reaction. A possible procedure for the determination of lanthanum in the presence of ytterbium is discussed.

Application of photon-counting in atomic-absorption spectrophotometry: R. M. Dagnall, B. L. Sharp and T. S. West, *Talanta*, 1972, **19**, 1442 (Chemistry Department, Imperial College of Science and Technology, London S.W.7.)

Summary—An analysis is given of the statistics of photon-counting as a means of making measurements in atomic-absorption spectrometry. It is concluded that the simple application of Poisson counting statistics may give an over-optimistic estimate of the error, since other sources of error, such as flame flicker and variable nebulization rate, may be more significant.

Some new applications of ferroin as redox indicator in titrations with dichromate: K. Sriramam, *Talanta*, 1972, **19**, 1445. (Department of Chemistry, Andhra University Postgraduate Centre, Guntur-5, Andhra Pradesh, India.)

Summary—Working conditions for the titration of arsenic(III), hydroquinone, ferrocyanide, uranium(IV) and molybdenum(V) with dichromate in sulphuric acid and hydrochloric acid media have been established, with ferroin as the redox indicator.

A note on successive complexometric determination of thorium and rare earths: Rudolf Přibil and Vladimír Veselý, *Talanta*, 1972, **19**, 1448. (Analytical Laboratory, J. Heyrovský Polarographic Institute, Czechoslovak Academy of Sciences, Prague 1, Jilská 16, Czechoslovakia.)

Summary—An improved method for successive determination of thorium and rare earths is described. It is based on the EDTA titration of thorium at pH 2 (Xylenol Orange as indicator) followed by addition of acetylacetone–acetone mixture, adjustment of the pH to 5–5·5 with hexamine, and by further EDTA titration of rare earths with the same indicator.

АРСЕНАЗО III И ЕГО АНАЛОГИ—VII: ЦВЕТНЫЕ РЕАКЦИИ РЕДКОЗЕМЕЛЬНЫХ ЭЛЕМЕНТОВ С НОВЫМ РЕАГЕНТОМ—КАРБОКСИНИТРАЗО:

S. B. SAVVIN, T. V. PETROVA and P. N. ROMANOV, *Talanta*, 1972, **19**, 1437.

Резюме—Новый реагент—карбоксинитразо—дает цветную реакцию с некоторыми редкоземельными элементами. Чувствительность реакций индивидуальных редкоземельных элементов весьма различается. Самая большая разница наблюдается для элементов подгрупп Се и У. В случае первой подгруппы молярные поглощения в порядке 16×10^4 л. моль. см$^{-1}$; большинство элементов группы У не дают цветной реакции. Обсуждена предложенная процедура для определения лантана в присутствии иттербия.

ПРИМЕНЕНИЕ СЧИТАНИЯ ФОТОНОВ В АТОМНО-АБСОРБЦИОННОЙ СПЕКТРОФОТОМЕТРИИ:

R. M. DAGNALL, B. L. SHARP and T. S. WEST, *Talanta*, 1972, **19**, 1442.

Резюме—Приведен анализ статистики считания фотонов с целью применения в атомно-абсорбционной спектрофотометрии. Сделан вывод что простое применение статистики считания Пуассона может дать оптимистическую оценку ошибки, потому что другие источники ошибок, как на пример мерцание пламени и вариации в скорости распыления могут оказаться более значительными.

ТИТРОВАНИЕ МЫШЬЯКА(III) ХРОМОМ(VI) С ВИЗУАЛЬНЫМ ОБНАРУЖЕНИЕМ КОНЦА ТИТРОВАНИЯ:

K. SRIRAMAM, *Talanta*, 1972, **19**, 1445.

Резюме—Разработана методика для прямого и обратного титрования мышьяка(III) хромом(VI) до визуального конца титрования с использованием ферроина в качестве индикатора. Метод пользуется каталитическим эффектом однохлористого иода и железа(III) на индикаторные реакции в условиях титрования.

ПРИМЕЧАНИЯ К ПОСЛЕДОВАТЕЛЬНОМ ОПРЕДЕЛЕНИИ ТОРИЯ И РЕДКОЗЕМЕЛЬНЫХ ЭЛЕМЕНТОВ КОМПЛЕКСОНОМЕТРИЧЕСКИМ МЕТОДОМ:

RUDOLF PŘIBIL and VLADIMIR VESELÝ, *Talanta* 1972, **19**, 1448.

Резюме—Описан улучшенный метод последовательного определения тория и редкоземельных элементов. Метод основан на титровании тория с ЭДТА при pH 2 (с использованием ксиленолоранжевого в качестве индикатора), добавлении смеси ацетилацетона и ацетона, и дальнейшем титровании редкоземельных элементов с ЭДТА с использованием того же индикатора.

Spectrophotometric study of the reaction of bismuth(III) with Xylenol Orange: DONKA KANTCHEVA, PETRANA NENOVA and BORISLAV KARADAKOV, *Talanta*, 1972, **19**, 1450. (Department of Analytical Chemistry, Higher Institute of Chemical Technology and Metallurgy, Sofia-56, Bulgaria.)

Summary—The reaction between bismuth(III) and Xylenol Orange (XO) has been investigated by spectrophotometry. It has been established that bismuth(III) and Xylenol Orange form complex compounds with compositions Bi(III):XO = 1:1 (up to pH 1) and Bi(III):XO = 1:2 (above pH 1) which have absorption maxima at 550 and 500 nm respectively. The formula of the 1:1 complex is $[Bi(H_3R)]$ whereas the 1:2 complex can take one of the following forms: $[Bi(H_4R)_2]^{1-}$, $[Bi(H_4R)(H_3R)]^{2-}$ and $[Bi(H_3R)_2]^{3-}$.
If

$$K_{Bi(H_3R)} = \frac{[Bi^{3+}][H_3R^{3-}]}{[Bi(H_3R)]} \quad \text{and} \quad K_{Bi(H_3R)_2} = \frac{[Bi^{3+}][H_3R^{3-}]^2}{[Bi(H_3R)_2]^{3-}}$$

the values for $pK_{Bi(H_3R)}$ and $pK_{Bi(H_3R)_2}$ respectively are 9·80 ± 0·03 and 15·53 ± 0·03 at a constant ionic strength of 1·0.

Radiochemical separation of zirconium and hafnium from other radionuclides, RICHARD B. HAHN, *Talanta*, 1972, **19**, 1454. (Analytical Sciences Division, U.K. Atomic Energy Research Establishment, Harwell, Berks., U.K.)

Summary—Radiozirconium and radiohafnium may be separated from all other radionuclides except scandium and protactinium by precipitation with mandelic acid from 5–10*M* hydrochloric acid, using commercial zirconyl chloride as carrier. Scandium and protactinium are removed by dissolving the precipitate in sodium carbonate, then adding barium nitrate to precipitate barium carbonate which acts as a scavenger. Zirconium mandelate is finally reprecipitated and the sample weighed and counted in this form. The method was checked by analysing commercial zirconyl chloride and standard rock samples for zirconium and hafnium by neutron-activation analysis.

Determination of phosphorus in phosphazenes and phosphines: SANFORD L. ERICKSON, *Talanta*, 1972, **19**, 1457. (Sandia Laboratories, Albuquerque, New Mexico 87115, U.S.A.)

Summary—An improved technique for the determination of phosphorus in organic phosphazenes and phosphines is described. An acid digestion using a mixture of fuming nitric, sulphuric and perchloric acids converts the organically bound phosphorus into orthophosphate. The orthophosphate is precipitated as magnesium ammonium phosphate, which is ignited to magnesium pyrophosphate. With this technique phosphorus was determined in several compounds. The results establish both good accuracy and precision for the method.

ИЗУЧЕНИЕ СПЕКТРОФОТОМЕТРИЧЕСКИМ МЕТОДОМ РЕАКЦИИ ВИСМУТА(III) С КСИЛЕНОЛОВЫМ ОРАНЖЕВЫМ:

DONKA KANTCHEVA and B. KARADEKOV, *Talanta*, 1972, **19**, 1450.

Резюме—Изучена спектрофотометрическим методом реакция висмута(III) и ксиленолового оранжевого (КО). Установлено что висмут(III) и ксиленоловый оранжевый образуют комплексы состава Bi(III):КО = 1:1 (вплоть pH 1) и Bi(III):КО = 1:2 (выше pH 1), имеющие максимумы светопоглощения при 550 и 500 нм, соответственно. Формула комплекса 1:1 $[Bi(H_3R)]$, а комплекс 1:2 может имет одну из следующих форм: $[Bi(H_4R)_2]$, $[Bi(H_4R)(H_3R)]^{2-}$ и $[Bi(H_3R)_2]^{3-}$.
Если

$$K_{Bi(H_3R)} = \frac{[Bi^{3+}][H_3R^{3-}]}{[Bi(H_3R)]} \quad и \quad K_{Bi(H_3R)_2} = \frac{[Bi^{3+}][H_3R^{3-}]^2}{[Bi(H_3R)_2]^{3-}}$$

величины $pK_{Bi(H_3R)}$ и $pK_{Bi(H_3R)_2}$ равны 9,80 ± 0,03 и 15,53 ± 0,03, соответственно, при константной ионной силы 1,0.

РАДИОХИМИЧЕСКОЕ ОТДЕЛЕНИЕ ЦИРКОНИЯ И ГАФНИЯ ОТ ДРУГИХ РАДИОНУКЛИДОВ:

R. B. HAHN, *Talanta*, 1972, **19**, 1454.

Резюме—Радиоцирконий и радиогафний могуть быть отделены от всех других радионуклидов за исключением скандия и протактиния осаждением миндальной кислотой из раствора 5–10*M соляной кислоты*, с использованием коммерческого хлористого цирконила в качестве носителя. Скандий и протактиний устраняют растворением осадка в карбонате натрия и добавлением нитрата бария для осаждения карбоната бария который действует как собиратель. Затем переосаждают манделат циркония а пробу взвешивают и считают в этой форме. Метод испытан анализом коммерческого хлористого цирконила и стандартных образцев горных пород на цирконий и гафний методом нейтроноактивационного анализа.

ОПРЕДЕЛЕНИЕ ФОСФОРА В ФОСФАЗЕНАХ И ФОСФИНАХ:

SANFORD L. ERICKSON, *Talanta*, 1972, **19**, 1457.

Резюме—Описан улучшенный метод определения фосфора в органических фосфазенах и фосфинах. Фосфор в органической связи превращается в ортофосфат дигерированием с смесью дымящих азотной, серной и хлорной кислот. Ортофосфат затем осаждают в форме смешанного фосфата магния и аммония и сжигают до пирофосфата магния. Пользуясь этим методом фосфор определен в ряде соединений. Результаты показывают хорошую точность и воспроизводимость метода.

New tests for the detection of azide: G. S. JOHAR, *Talanta*, 1972, **19**, 1461. (Department of Chemistry, V.S.S.D. College, Kanpur-2, India.)

Summary—Two new, simple, reliable, and specific colour tests are described for the detection of azide. In one, the azide is heated with allyl isothiocyanate and water to form 1-allyl-2-tetrazoline-5-thione in solution; the latter gives a yellow precipitate on treatment with bismuth nitrate solution. Pyridine enhances the intensity of the colour. The allyl isothiocyanate can be produced *in situ* by treating allylamine with carbon disulphide, diethylamine and hydrogen peroxide. In the other test the azide is heated with carbon disulphide, water and acetone, resulting in the formation of 1,2,3,4-thiatriazoline-5-thione which gives a yellow precipitate with Cu(II) or Bi(III). Pyridine again enhances the colour. The method is applicable to 5–10 mg of soluble azides, but insoluble azides cannot be tested. CN^-, SCN^-, and other common anions do not interfere. Only S^{2-} interferes by masking the colour (black CuS or Bi_2S_3 is precipitated). NO_2^- in larger amounts interferes in the second test.

Potentiometric titration of heterocyclic nitrogen bases in non-aqueous media: K. C. MOHAN RAO and P. R. NAIDU, *Talanta*, 1972, **19**, 1465. (Physico-chemical Laboratories, Sri Venkateswara University, Tirupati (A.P.), India).

Summary—Pyridine, quinoline, isoquinoline, acridine, α-picoline, β-picoline, γ-picoline and 2,6-lutidine have been titrated potentiometrically (calomel and glass electrodes), with chlorosulphonic acid in methyl ethyl ketone–acetic acid (1:1) medium, with an error of less than 1%.

Rapid determination of selenium and tellurium by atomic-absorption spectrophotometry; B. C. SEVERNE and R. R. BROOKS, *Talanta*, 1972, **19**, 1467. (Department of Chemistry, Biochemistry, Biophysics, Massey University, Palmerston North, New Zealand.)

Summary—A rapid method has been developed for the determination of selenium and tellurium in geological and biological samples. It involves acid digestion of the sample with mineral acids, addition of arsenic as a carrier, reduction of arsenic to co-precipate selenium and tellurium, dissolution of the precipitate in dilute nitric acid and subsequent determination of selenium and tellurium by conventional atomic-absorption spectrophotometry. Selenium and tellurium have been measured on a routine basis, down to 0.1 ppm.

НОВЫЕ ПРОБЫ ДЛЯ ОТКРЫТИЯ АЗИДА:

G. S. Johar, *Talanta*, 1972, **19**, 1461.

Резюме—Описаны две новых, несложных, надёжных и специфических реакции для открытия азида. Для первой реакции азид нагревают с аллилизотиоцианатом и водой для образования 1-аллил-2-тетразолин-5-тиона в растворе. Это соединение дает желтый осадок с раствором нитрата висмута. Пиридин повышает интенсивность окраски. Аллилизотиоцианат может образоваться *in situ* обработкой аллиламина сероуглеродом, диэтиламином и перекисью водорода. В другой реакции азид нагревают с сероуглеродом, водой и ацетоном для образования 1,2,3,4-тиатриазолин-5-тиона, который дает желтый осадок с Cu(II) или Bi(III). Пиридин также повышает интенсивность окраски. Метод применим для 5–10 мг растворимых азидов, но методом не можно пользоватся в случае нерастворимых азидов. CN^-, SCN^- и другие обыкновенные анионы не мешают определению. Только S^{2-} маскирует цвет из-за осаждения черного CuS или Bi_2S_3. NO^{2-} в больших концентрациях мешает другой реакции.

ПОТЕНЦИОМЕТРИЧЕСКОЕ ТИТРОВАНИЕ ГЕТЕРОЦИКЛИЧЕСКИХ ОРГАНИЧЕСКИХ ОСНОВАНИЙ В НЕВОДНЫХ СРЕДАХ:

K. C. Mohan-Rao and P. R. Naidu, *Talanta*, 1972, **19**, 1465.

Резюме—Проведены потенциометрические титрации пиридина, хинолина, изохинолина, акридина, α-пиколина, β-пиколина, γ-пиколина и 2,6-лутидина (пользуясь каломелевым и стеклянным электродами) с хлорсульфоновой кислотой в растворе метилэтилкетона и уксусной кислоты (1:1), с ошибкой меньше чем 1%.

БЫСТРОЕ ОПРЕДЕЛЕНИЕ СЕЛЕНА И ТЕЛЛУРА МЕТОДОМ АТОМНОАБСОРБЦИОННОЙ СПЕКТРОФОТОМЕТРИИ:

B. C. Severne and R. R. Brooks, *Talanta*, 1972, **19**, 1467.

Резюме—Разработан быстрый метод определения селена и теллура в геологических и биологических образцах. Метод основан на дигерировании образца минеральными кислотами, добавлении мышьяка в качестве носителя, восстановлении мышьяка для соосаждения селена и теллура, растворении осадка в разбавленной азотной кислоте и последующем определении селена и теллура методом атомноабсорбционной спектрофотометрии. Этим образом определяли концентрации селена и теллура вплоть 0,1 частей на миллион, пользующися методом для рутинного анализа.

Developments in indicators: L. Légrádi, *Talanta*, 1972, **19**, 1470. (Nitrokémia Works, Füzfögyártelep, Hungary.)

Summary—The use of metal ion–metallochromic indicator complexes as narrow-range pH indicators is shown to be advantageous for the titration of weak acids in aqueous media. The Cu–DBAH and the Mg–Azo Violet complexes with apparent p*K* values of 7·7 and 11·5 have been used for the titrations of benzoic acid and of glycine and phenol, respectively, with good precision.

Nouvelle microcolorimétrie des nitrities: Camelia Ghimicescu and Vasile Dorneanu, *Talanta*, 1972, **19**, 1474. (Laboratoire de Chimie Analytique de la Faculté de Pharmacie de Iassy, Roumanie.)

Summary—A micromethod for determination of nitrite is based on a reaction with *o*-tolidine, forming a yellow-orange product suitable for spectrophotometry. The sensitivity is 0·05 μg of nitrite/ml. The method is suitable for analysis of potable and mineral waters, and has a mean relative error of 1%.

Analytical application of the urease method for determination of urea in the presence of biuret: P. Bozadziev, E. Balabanova and L. Ilcheva, *Talanta*, 1972, **19**, 1477. (Chemico-Technological Institute, Sofia 56, Bulgaria.)

Summary—Biuret does *not* interfere in the urease-catalysed hydrolysis of urea.

Determination of gallium in an iron–aluminium matrix by solvent extraction and flame emission spectroscopy: M. S. Cresser and J. Torrent-Castellet, *Talanta*, 1972, **19**, 1478. (Department of Soil Science, University of Aberdeen, Scotland.)

Summary—Solvent extraction of gallium(III) into methyl isobutyl ketone from hydrochloric acid solutions containing titanium(III) sulphate provides a rapid method for separation of gallium from an iron/aluminium matrix and may be employed to eliminate the interference of these elements in the flame emission spectrometric determination of gallium.

Complexes of some rare earth metals with 1-amino-4-hydroxyanthraquinone: A. K. Jain†, V. P. Aggarwala, Puran Chand and S. P. Garg, *Talanta*, 1972, **19**, 1481. (Chemical Laboratories, University of Jodhpur, Jodhpur, India).

Summary—La, Ce(III), Pr, Nd and Sm(III) form very stable reddish-violet 1:1 complexes with 1-amino-4-hydroxyanthraquinone in methanol. The stability constants are very similar.

УСПЕХИ В ОБЛАСТИ ИНДИКАТОРОВ:

L. Légrádi, *Talanta*, 1972, **19**, 1470.

Резюме—Показано что использование комплексов ионов металлов с металлохромными индикаторами в качестве индикаторов для узких областей pH имеет известные преимущества в титровании слабых кислот в водных средах. Комплексы Cu-DBAH и Mg-азофиолетовый, имеющие кажущиеся величины pK 7,7 и 11,5, соответственно, успешно использованы в титровании бензойной кислоты, глицина и фенола.

НОВЫЙ МИКРОКОЛОРИМЕТРИЧЕСКИЙ МЕТОД ОПРЕДЕЛЕНИЯ НИТРИТОВ:

Camelia Ghimicescu and Vasile Dorneanu, *Talanta*, 1972, **19**, 1474.

Резюме—Микрометод определения нитрита основан на реакции с *о*-толидином, при которой образуется желто-оранжевая окраска, прикладная для спектрофотометрии. Чувствительность определения составляет 0,05 мкг нитрита/мл. Метод применимый в анализе питьевой и минеральных вод, а средная относительная ошибка метода составляет 1 %.

ПРИМЕНЕНИЕ МЕТОДА ДЛЯ ОПРЕДЕЛЕНИЯ МОЧЕВИНЫ С ПОМОЩЬЮ УРЕАЗЫ В ПРИСУТСТВИИ БИУРЕТА:

P. Bozadziev, E. Balabanova and L. Ilcheva, *Talanta*, 1972, **19**, 1477.

Резюме—Биурет не влияет на катализированный уреазой гидролиз мочевины.

ОПРЕДЕЛЕНИЕ ГАЛЛИЯ В МАТРИЦЕ ЖЕЛЕЗА-АЛЮМИНИЯ ЭКСТРАКЦИЕЙ РАСТВОРИТЕЛЕМ И МЕТОДОМ ПЛАМЕННОЙ СПЕКТРОСКОПИИ:

M. S. Cresser and J. Torrent-Castellet, *Talanta*, 1972, **19**, 1478.

Резюме—Экстракция галлия(III) метилизобутилкетоном из растворов соляной кислоты, содержащих сульфат титана(III), представляет собой быстрый метод выделения галлия из матрици железа-алюминия, которым можно пользоваться для устранения мешающего действия этих элементов в определении галлия методом пламенной спектроскопии.

КОМПЛЕКСЫ НЕКОТОРЫХ РЕДКОЗЕМЕЛЬНЫХ ЭЛЕМЕНТОВ С 1-АМИНО-4-ОКСИАНТРАХИНОНОМ:

A. K. Jain, V. P. Aggarwala, Puran Chand and S. P. Garg, *Talanta*, 1972, **19**, 1481.

Резюме—La, Ce(III), Pr, Nd и Sm(III) образуют очень устойчивые комплексы 1:1 краснофиолетового цвета с 1-амино-4-оксиантрахиноном в метаноле. Константы устойчивости похожи.

A study of the evaporation of gold solutions: D. BUKSAK and A. CHOW, *Talanta*, 1972, **19**, 1483. (Department of Chemistry, University of Manitoba, Winnipeg, Canada.)

Summary—The study indicates that despite several reports to the contrary, gold does not volatilize appreciably during the evaporation of aqueous solutions. Gold solutions were shown to have a tendency to creep significantly in solutions of various metal concentrations, acid content and salt content, and that careful washing must be carried out to obtain quantitative recovery.

Modifications of the computer programme SCOGS: W. A. E. MCBRYDE and J. L. MCCOURT, *Talanta*, 1972, **19**, 1486. (Department of Chemistry, University of Waterloo, Waterloo, Ontario, Canada.)

Summary—The computer programme SCOGS has been modified to accept and yield all equilibrium constants involving proton transfer, as concentration quotients. Significant savings in operating time are achieved through use of the FORTRAN H compiler.

ИЗУЧЕНИЕ ВЫПАРИВАНИЯ РАСТВОРОВ ЗОЛОТА:

D. Buksak and A. Chow, *Talanta*, 1972, **19**, 1483.

Резюме—Результаты изучения показывают что, несмотря на некоторые противоречащие отчеты, золото улетучивается только в незначительной мере при выпаривании водных растворов. Указано что растворы золота показывают значительную тенденцию ползучести в растворах содержащих различные концентрации других металлов, кислот и солей. Надо провести тщательную промивку для получения количественных выходов.

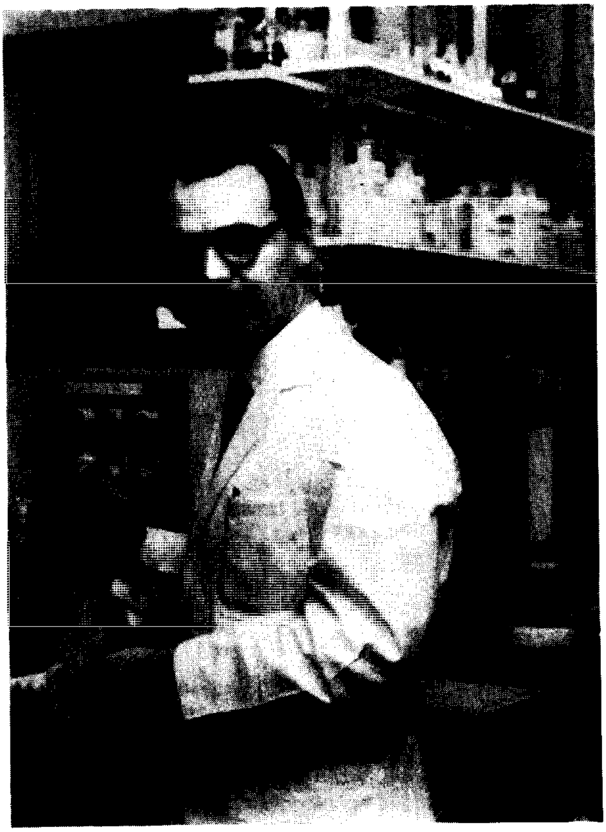
ИЗМЕНЕНИЯ ПРОГРАММЫ SCOGS ДЛЯ ЭЛЕКТРОНОВЫЧИСЛИТЕЛЬНОЙ МАШИНЫ:

W. A. E. McBryde and J. L. McCourt, *Talanta*, 1972, **19**, 1486.

Резюме—Программа SCOGS изменена с целью применения на все константы равновесия включающие перенос протонов, в форме частного концентрации. Получены значительные экономии времени при использовании компилятора FORTRAИ Н.

ADVISORY BOARD OF TALANTA

The Editorial Board and Publishers of *Talanta* take pleasure in welcoming Professor GILLIS JOHANSSON to the Advisory Board of the journal.



PROFESSOR JOHANSSON was born in 1931, and graduated Ph.D. at Lund in 1965. In 1967 he was appointed the first professor in analytical chemistry in Umeå University, where he is now also Dean of the Faculty of Science. He is also a member of the Swedish National Committee for Chemistry. His scientific interests include electrochemical methods of analysis, ion-selective electrodes and atomic-absorption spectroscopy by the graphite furnace technique. He has written 30 papers and a book (on operational amplifiers). Professor Johansson is married and has two children.

Reprints of Talanta Reviews

As the volume of scientific literature grows, reviews provide one of the best means of keeping abreast with recent developments. Talanta has commissioned a series of comprehensive and critical reviews of topics of current interest to analytical chemists; many of these reviews will also be of value to chemists in general and to other scientists. Talanta Reviews are intended primarily to introduce the non-specialist to a subject about which he previously knew little, but they may also help the specialist fill gaps in his knowledge of his own field or illuminate the subject from a new angle.

Reprints of Talanta Reviews

As the volume of scientific literature grows, reviews provide one of the best means of keeping abreast with recent developments. Talanta has commissioned a series of comprehensive and critical reviews of topics of current interest to analytical chemists; many of these reviews will also be of value to chemists in general and to other scientists. Talanta Reviews are intended primarily to introduce the non-specialist to a subject about which he previously knew little, but they may also help the specialist fill gaps in his knowledge of his own field or illuminate the subject from a new angle.

REMOVAL OF GRAPHITE BY OXIDATION WITH PERCHLORIC ACID PLUS PERIODIC ACID

INAPPLICABILITY TO THE SPECTROPHOTOMETRIC DETERMINATION OF MANGANESE IN STEEL

JAMES A. GAUNT and HARVEY DIEHL
Department of Chemistry, Iowa State University, Ames, Iowa, 50010, U.S.A.

(*Received* 2 *July* 1971. *Accepted* 4 *October* 1971)

Summary—An attempt has been made to improve the Willard and Greathouse periodate method for the determination of manganese in high-carbon steel and cast iron by oxidizing the graphite with periodic acid in the presence of perchloric acid and phosphoric acid. Graphite is rapidly oxidized at 150° by this mixture but manganese is lost by volatilization as the heptoxide and decomposition of the latter on hot surfaces to manganese dioxide. No way was found for either the quantitative removal and recovery of manganese by volatilization or for quantitative return to the main solution. The spectrophotometric determination of manganese in the supernatant liquid after allowing graphite to settle yields imprecise but not wholly unacceptable results; for the highest accuracy, graphite should be removed along with silica following dehydration of the latter with perchloric acid.

MANGANESE in steel is commonly determined spectrophotometrically as permanganate following oxidation of the manganese by periodic acid, a procedure devised by Willard and Greathouse[1] in 1917 and subsequently adopted by the ASTM[2] and other organizations publishing official methods of analysis. In the Willard and Greathouse procedure carbon is oxidized by boiling with persulphate after dissolution of the steel in sulphuric acid. This procedure works well for most steels but fails with high-carbon steels and cast irons in which an appreciable amount of the carbon is present as graphitic carbon. In the present work, a procedure has been devised for destroying graphitic carbon by oxidation with periodic acid in a perchloric acid–phosphoric acid medium. Curiously, the procedure fails as a method for the spectrophotometric determination of manganese owing to the volatility of manganese in the septavalent state.

The use of a mixture of perchloric acid and periodic acid for the wet oxidation of organic matter was described by Smith and Diehl.[3] The mixture was applied by Spielholtz *et al.*[4] to the wet oxidation of coal before the determination of minor constituents, and again by Spielholtz *et al.*,[4] with more careful control of the concentration of perchloric acid and thus of the boiling temperature, to the destruction of carbon in coal, leaving spores unchanged for isolation for studies in stratigraphy. Periodic acid is used for the cleavage of the bond joining two carbon atoms each of which carries a functional group, the attack presumably involving the temporary formation of a five-membered ring involving iodine. The flat, hexagonal arrangement of carbon in graphite provides for rapid attack by periodic acid, which is in fact the only agent which attacks it with speed.

The volatility of manganese in the septavalent state has been noted earlier. Willard and Filson[5] observed it when developing the determination of chromium in steel by volatilization of chromyl chloride by passing chlorine and hydrogen chloride into a perchloric acid solution of a steel. Again, the volatility was observed by Strickland

and Spicer[6] who attempted to develop a method for the separation of manganese based on this phenomenon.

In the present work, the optimum conditions for the oxidation of graphite with periodic acid have been established and attempts have been made to adapt the oxidation to the spectrophotometric determination of manganese in steel and cast iron. The latter effort failed owing to the volatility of manganese heptoxide and its decomposition in the vapour phase to manganese dioxide. In a supplemental study it has also been shown that suspended particles of graphite interfere seriously in the spectrophotometric determination of manganese and must be removed by filtration.

Oxidation of graphitic carbon

Most steels contain less than 2% carbon and this carbon, predominantly iron carbide, is readily oxidized by hot perchloric acid. Carbon obtained on dissolving high-carbon steel or cast iron—the graphite and presumably some of the interstitial carbon—is not destroyed by boiling with concentrated perchloric acid, that is, at 203°. Molybdenum, chromium, vanadium and cerium, materials which catalyse the oxidation of nylon, 8-hydroxyquinoline, 1,10-phenanthroline and other recalcitrant heterocyclic nitrogen compounds by perchloric acid, are not effective in the oxidation of graphite.

After dissolution of a steel in a mixture of nitric acid, perchloric acid and water (1:1:1), graphite present is oxidized rapidly by the addition of sodium periodate. However, during the oxidation there is formed a yellow precipitate which cannot be dissolved by heating or by increasing the concentration of the acids. This yellow precipitate is extremely insoluble and is formed whether the steel is dissolved in a mixture of nitric and perchloric acids or in perchloric acid alone. It is not formed if phosphoric acid is added to the mixture before the addition of sodium periodate, although once formed it takes a large amount of phosphoric acid and heating to dissolve it. In the final procedure, recommended below, the steel is dissolved in a mixture of the three acids. About 3 min are required for the dissolution of a 1-g sample at a temperature of about 120°. The oxidation is best effected by adding the sodium periodate in increments of 0·1 g and at a temperature of 150–160°. For the oxidation of the graphite in a steel containing 2–3% carbon, 1·5 g of sodium periodate and 20–30 min are required. Addition of the sodium periodate must be made in increments owing to the decomposition of periodic acid in hot perchloric acid.[3] If it is added in one portion oxidation is incomplete and more periodate is required.

Recommended procedure for the dissolution of steel and oxidation of carbon

To a sample of steel or cast iron in a 250-ml flask add 50 ml of a mixture of two volumes of 70% perchloric acid, one volume of 70% nitric acid and two volumes of 85% phosphoric acid. Heat to boiling and after the sample has dissolved except for carbonaceous material and silica, continue heating to expel nitric acid and oxides of nitrogen. When the temperature reaches 150–160° add 0·1-g portions (preferably in the form of pellets) of sodium periodate at intervals of 4–5 min, continuing until all of the graphite has been removed.

Formation of manganese heptoxide and dioxide

During the oxidation of graphite with periodic acid in a boiling perchloric acid solution, small droplets of pink liquid formed on the upper walls of the reaction vessel where reflux was occurring. The colour of this liquid was that of the permanganate ion. This pink liquid also formed on a microscope slide held about an inch above the mouth of the flask, indicating that it was being formed by condensation from the vapour and not by spray from the boiling solution. It was thus apparent also that a considerable amount of manganese was being carried from the flask. It was noted further that during the oxidation a brown solid was deposited on the upper walls of the reaction vessel. This deposit was not soluble in hot concentrated perchloric acid and remained on the glassware after the oxidation of graphite was complete; it was soluble in warm hydrochloric acid, and the resulting solution, when treated with periodate, yielded the characteristic colour of permanganate.

It thus became apparent that manganese is oxidized to the septavalent state by periodic acid in hot perchloric acid solution and is volatilized as the heptoxide which condenses in the refluxing liquid to form permanganic acid. It was apparent also that on contact with the hot, dry, upper walls of the reaction vessel manganese heptoxide was decomposed to manganese dioxide. The reactions are

$$5H_5IO_6 + 2Mn^{2+} = Mn_2O_7 + 5HIO_3 + 4H^+ + 8H_2O$$

$$2Mn_2O_7 = 4MnO_2 + 3O_2.$$

That the decomposition of manganese occurred on contact of vapour and the hot wall was further demonstrated by an experiment in which the upper part of the flask was cooled by a water jacket. Manganese was deposited in the border area between the cooled upper walls and the boiling perchloric acid solution and on the exposed part of a sealed-in thermometer well.

Attempts to retain and recover manganese heptoxide and dioxide

The escape of manganese heptoxide was easily prevented by the use of a reflux condenser attached by a ground-glass joint to the flask in which the dissolution and oxidation reactions were carried out. Preventing the formation of manganese dioxide or recovering it quantitatively, however, presented a more formidable problem and one which was not solved in satisfactory fashion.

The possibility of volatilizing all of the manganese from the sample and of collecting it for measurement is attractive. The Bethge apparatus,[7] [8] designed for the retention of volatile materials during the wet oxidation of organic matter by digestion with perchloric acid, appeared ideal for such an experiment. In the Bethge apparatus vapour from the reaction vessel travels up a by-pass into the condenser and reflux is returned to a sump, in the intermediate chamber, from which it can be either returned to the main reaction or withdrawn.

A series of experiments was made with manganese steels and perchloric acid–periodic acid mixtures, the temperature being raised slowly from 60° to 204°. Only small amounts of manganese were obtained in the condensate as judged by the appearance of permanganate colour. The permanganate colour disappeared quickly as it entered the condensate, undoubtedly because of reaction with hydrochloric acid always produced during the boiling of perchloric acid. More manganese was obtained when the temperature was raised rapidly but quantitative distillation was never obtained. Nor did experiments with simpler, conventional distillation apparatus give better results. Iron as well as manganese was found in the distillates in these experiments.

Dissolving the deposit of manganese dioxide from the walls of the flask proved easy with hydrochloric acid plus bisulphite, but the resulting solution was not satisfactory for the spectrophotometric determination of manganese; the hydrochloric acid caused the permanganate (formed by periodate oxidation as in the usual Willard and Greathouse procedure) to be unstable.

Somewhat better results were obtained when the main solution, containing the major part of the manganese was transferred to a volumetric flask after oxidation of the graphite and the deposit of manganese dioxide on the upper walls of the reaction vessel was dissolved by treatment with a mixture of equal volumes of sulphuric acid and phosphoric acid plus sodium bisulphite. In 5 min or so the manganese dioxide was dissolved and sulphur dioxide expelled. This solution was added to the main solution and the usual periodate oxidation of the manganese to permanganate and spectrophotometric measurement was then applied. The results were not good; on NBS 122D, Cast Iron, the results were consistently low and scattered: found, 0·453, 0·478, 0·476, 0·463%, NBS value: 0·504% manganese.

The cumbersome and time-consuming manipulations required to retain the manganese heptoxide and to recover the manganese dioxide make the periodic acid oxidation of graphite unacceptable for the spectrophotometric determination of manganese in steel or cast iron.

Interference of graphite in the spectrophotometric determination of manganese

Having failed to find a method of destroying graphite without loss of manganese, we assessed the effect of carrying out the spectrophotometric determination of manganese in the presence of the graphite. Basically, this study involved a comparison of two procedures, one in which the graphite was simply allowed to settle and the determination made on the clear supernatant liquid, and a second in which the graphite was removed by filtration and the determination made on the filtrate. The final procedures used are given in the next two paragraphs.

Graphite allowed to settle. A sample containing approximately 2–3 mg of manganese was dissolved in 50 ml of a mixture of concentrated perchloric, nitric, and phosphoric acids (2:1:2). The mixture was heated until the nitric acid fumes had been driven off. The solution was then cooled and then diluted with 100 ml of water. About 1 g of sodium periodate was added. The solution was heated almost to boiling to oxidize manganese(II) to permanganate. The solution was cooled, transferred to a volumetric flask, and diluted to exactly 250 ml with water. The particles of graphite were then allowed to settle and an aliquot of the supernatant liquid was carefully withdrawn for the spectrophotometric measurement. A calibration curve was made from measurements on dilutions of a stock solution of known concentrations of manganese(II) prepared from electrolytic manganese metal, 99·75% pure, treated in the same manner. The purity of the electrolytic manganese was established by comparison with primary-standard manganous oxalate dihydrate.[9]

Removal of graphite by filtration. A sample containing approximately 2–3 mg of manganese was dissolved in 50 ml of the acid mixture. The mixture was heated until nitric oxide fumes had been expelled and perchloric acid was refluxing smoothly on the lower half of the walls of the flask. The mixture was held at this temperature for 20 min to dehydrate silica. The solution was cooled and then diluted with 100 ml of water. The solution was filtered through a coarse filter paper (Whatman No. 41). To the filtrate was added 1 g of sodium periodate. The solution was heated almost to boiling to oxidize manganese(II) to permanganate. The solution was cooled, transferred to a volumetric flask, and diluted to exactly 250 ml. The absorbance was then measured. A calibration curve was made as before.

RESULTS AND DISCUSSION

The studies were made on two samples of cast iron of the National Bureau of Standards, NBS 342 and NBS 122D. The results are shown in Table I. The average of seven determinations of the manganese in NBS 342 by the settling procedure was slightly lower than the NBS value and the precision was poor. The average of seven determinations on NBS 122D was slightly higher than the NBS value and again the precision was poor.

TABLE I.—DETERMINATION OF MANGANESE IN CAST IRON AND STEEL: EFFECT OF REMOVAL OF GRAPHITE BY FILTRATION

Sample	NBS values		Procedure	Mn average %	Manganese found		Relative standard deviation *ppt*
	Carbon %	Manganese %			Number of determinations	Standard deviation %	
NBS 342 Nodular Cast Iron	2·45	0·369	Settling	0·361	9	0·017	47
			Filtration	0·379	6	0·004	11
NBS 122D Cast Iron	3·28	0·504	Settling	0·578	6	0·013	23
			Filtration	0·523	6	0·008	15
NBS 51 Electric Steel	1·29	0·271	Settling	0·282	6	0·002	7
NBS 16D Basic Open Hearth Steel	1·01	0·439	Settling	0·466	7	0·008	7
NBS 14D Basic Open Hearth Steel	0·841	0·399	Settling	0·401	8	0·003	7

On the other hand, accuracy and precision were much better when the graphite was removed by filtration. The precision was from two to five times better than that of the settling method.

Several samples of steel were analysed by the settling procedure. Although these samples contained up to 1·2% carbon, no graphite and very little silica remained after dissolution. Excellent precision was obtained and the values were close to those of the NBS.

For results of the highest accuracy in the determination of manganese, graphite should be removed before the spectrophotometric measurement is made.

Zusammenfassung—Es wurde versucht, die Perjodatmethode von Willard und Greathouse zur Bestimmung von Mangan in kohlenstoffreichem Stahl und Gußeisen durch Oxidation des Graphits mit Überjodsäure in Gegenwart von Überchlorsäure und Phosphorsäure zu verbessern. Graphit wird von diesem Gemisch bei 150° rasch oxidiert, aber Mangan geht als flüchtiges Heptoxid verloren; dieses zersetzt sich an heißen Oberflächen zu Mangandioxid. Es wurde kein Weg gefunden, das Mangan entweder quantitativ zu verflüchtigen und wieder aufzufangen oder es quantitativ in die Hauptlösung zurückzuführen. Die spektrophotometrische Bestimmung von Mangan in der Lösung nach Absitzen des Graphits gibt ungenaue, wenn auch nicht völig unbrauchbare Ergebnisse; um die höchste Genauigkeit zu erzielen, sollte Graphit zusammen mit der Kieselsäure entfernt werden, nachdem diese mit Überchlorsäure entwässert wurde.

Résumé—On a tenté d'améliorer la technique de Willard et Greathouse au periodate pour le dosage du manganèse dans l'acier à haute teneur en carbone et dans la fonte en oxydant le graphite par l'acide periodique en la présence d'acide perchlorique et d'acide phosphorique. Le graphite est oxydé rapidement à 150° par ce mélange, mais il y a perte de manganèse par volatilisation à l'état d'heptoxyde et décomposition de ce dernier sur les surfaces chaudes en bioxyde de manganèse. On n'a pas trouvé de voie, soit pour l'élimination et la récupération quantitatives du manganèse par volatilisation, soit pour le retour quantitatif dans la solution principale. Le dosage spectrophotométrique du manganèse dans le liquide surnageant après que le graphite se soit déposé donne des résultats imprécis mais non absolument inacceptables; pour avoir la meilleure précision, le graphite doit être séparé en même temps que la silice après la déshydratation de celle-ci par l'acide perchlorique.

NOTICES

SECOND AUSTRALIAN SYMPOSIUM ON ANALYTICAL CHEMISTRY

The Analytical Chemistry Division of the Royal Australian Chemical Institute will be holding its Second Symposium on Analytical Chemistry at the University of New South Wales, Kensington, on 14–18 May 1973.

Papers dealing with all aspects of analytical chemistry, including biochemical, clinical, mineral, metallurgical, environmental, modern instrumental, pharmaceutical, educational, and data handling and processing will be accepted.

Further information may be obtained from the Hon. Secretary:

Mr. L. S. Dale,
Australian Atomic Energy Commission,
Research Establishment
Private Mail Bag P.O. Sutherland,
N.S.W. 2232 Australia.

INTERNATIONAL SYMPOSIUM ON MICROCHEMICAL TECHNIQUES—1973

"Progress and Projections for Microchemistry," will be the general theme for The International Symposium on Microchemical Techniques—1973. The symposium will be held at The Pennsylvania State University, University Park, Pennsylvania, on 19–24 August 1973 and will be conducted by The American Microchemical Society, with the sponsorship of the International Union of Pure and Applied Chemistry.

The scientific programme will consist of sessions dedicated to topics of current interest, general papers, discussion groups, practical demonstrations, an equipment exhibit, and will also include a number of instructional workshop sessions. Special sessions will be included on such topics as:

Automated Elemental Analyzers—Ten years Later
Computers in Elemental Analysis
Organic Elemental Analysis: New Methods and Equipment
Environmental Microanalysis: New Sensors and Techniques
Microelectrodes
Forensic Analysis: Narcotics and Drugs of Abuse
Organic Functional Group Analysis: New Directions
Electroanalytical Advances, including Ion Selective Electrodes
Microscale Separations: Advances in Techniques and Methods
Standards and Standardization for Microchemistry and Microanalysis
Trace Analysis: Advances in Organic and Inorganic Analysis
New Techniques in Microchemistry

Persons interested in presenting a paper under any of the above topics, or a paper on the general topic of microchemistry, should submit their paper to:

Mr. Howard J. Francis, Jr.
Pennwalt Corporation
900 First Avenue
King of Prussia, Pennsylvania 19406

Included in the program of scientific presentations will be classroom workshops on the topics of:
Applications of Ion Selective Electrodes
Theory and Applications of thermal Methods of Analysis

1973 PITTSBURGH CONFERENCE

The twenty-fourth Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy will be held at the Cleveland Convention Center, Cleveland, Ohio, U.S.A., 5–9 March 1973. An estimated 350 papers on all phases of Analytical Chemistry and Spectroscopy will be presented. Symposia on the following subjects are now being arranged.

1. LIQUID CHROMATOGRAPHY—Analytical Bridge to Spectroscopy.
2. THREE DIMENSIONAL MICROCOMPOSITIONAL ANALYSIS: The Advent of Ion Probe Mass Spectrometry.
3. INDUSTRIAL APPLICATIONS OF ^{13}C NMR.
4. FORENSIC SCIENCE.
5. WOMEN IN MASS SPECTROMETRY.
6. INDUSTRIAL RESEARCH—Is it Worth It?
7. GUIDELINES FOR DEFINING AND IMPLEMENTING THE COMPUTERIZED LABORATORY SYSTEM (ASTM).
8. THE ANALYSIS OF SLAGS AND RELATED OXIDE-TYPE MATERIALS (ASTM).
9. COBLENTZ SOCIETY AWARD SYMPOSIUM.
10. SPECTROSCOPY SOCIETY OF PITTSBURGH AWARD SYMPOSIUM

In addition to the programme of technical papers, more than 250 companies, both foreign and domestic, will be represented at the exposition of Modern Laboratory Equipment, the largest exposition of analytical instrumentation and related materials in the world.

For further information apply to

H. L. Retcofsky
1973 Pittsburgh Conference
U.S. Bureau of Mines
4800 Forbes Avenue
Pittsburgh, Pa. 15213, U.S.A.

INTERNATIONAL SYMPOSIUM ON LIQUID SCINTILLATION COUNTING

Following last year's very successful venture the Radiochemical Methods Group of the Society for Analytical Chemistry/Analytical Division, Chemical Society propose holding a second International Symposium on Liquid Scintillation Counting. It will be held at the Hotel Metropole, Brighton, England, on 3–6 September 1973. An exhibition of scintillation counters, scintillators, and associated equipment will be held in conjunction with the scientific programme.

Persons wishing to present a contribution to this symposium and firms wishing to take part in the exhibition should write for further details to

Mr. M.A. Crook,
The Society for Analytical Chemistry,
9/10 Savile Row,
London W1X 1AF.

SUMMARIES FOR CARD INDEXES

Extreme trace analysis of the elements—I. Methods and problems of sample treatment, separation and enrichment: GÜNTHER TÖLG, *Talanta*, 1972, **19**, 1489. (Max-Planck-Institut für Metallforschung, Laboratorium für Reinstoffe, 7070-Schwäbisch Gmünd, Katherinenstraße 17, B.R.D.)

Summary—In the determination of elements in the ppM range in inorganic and organic matrices, solution techniques are useful because they simplify calibration problems and improve the limit of detection. The author reviews, in the light of his own experience, some 350 publications concerned with methods for the preparation and dissolution of samples and for the isolation of trace elements before their determination. The errors in these methods, made more difficult to reduce because of the additional operations required, are compared with those associated with the more direct methods.

Determination of water: CLIFFORD HARRIS, *Talanta*, 1972, **19**, 1523. (88 Charlton Road, Keynsham, Nr. Bristol, U.K.)

Summary—The complexity of the subject and the problems involved in the estimation of water in the many materials required to be tested are explained. The various methods available are classified, their techniques summarized, and their applications and limitations indicated. In many materials the determination of absolute moisture is impossible and a compromise must be accepted. Trade and industry require rapid results for many processes and products, and optical or electronic methods are increasingly used in conjunction with reference methods. For official purposes the method of determination must be agreed and stated in detail. More progress in international standardization is very desirable.

Nuclear magnetic resonance analysis of pharmaceuticals—VII. Determination of aminophylline in tablets: JOHN W. TURCZAN, BRUCE A. GOLDWITZ and JAMES J. NELSON, *Talanta*, 1972, **19**, 1549. (Food and Drug Administration, U.S. Department of Health, Education and Welfare, 850, Third Avenue, Brooklyn, New York 11232.)

Summary—An NMR procedure is described by which theophylline and ethylenediamine are simultaneously determined in aminophylline tablets. t-Butyl alcohol was chosen as the internal standard and 4% ammonia–0.3% potassium cyanide in deuterium oxide was the solvent. The solvent system was selected to deal with the problems of solubility of the theophylline, overlapping of the components' resonance signals, and potential interference from metal impurities. Known standard and commercial preparations were determined and the results compared with those obtained by alternative procedures. The technique, when applied to the determination of aminophylline in tablets, is rapid, simple and specific and has an error of 1–2%.

КРАЙНЫЙ СЛЕДОВЫЙ АНАЛИЗ ЭЛЕМЕНТОВ—I. МЕТОДЫ И ПРОБЛЕМЫ ОБРАБОТКИ, РАЗДЕЛЕНИЯ И ОБОГАЩЕНИЯ ПРОБЫ:

G. Tölg, *Talanta*, 1972, **19**, 1489.

Резюме—В определении элементов в области частей на миллион в неорганических и органических матрицах, методы пользующиеся растворами оказалися полезными потому что упрощают проблемы калибровки и улучшают предел чувствительности. Учитывая собственный опыт, автор приводит обзор 350 публикаций касающихся методов приготовления и растворения образцов и выделения следов элементов перед их определением. Ошибки этих методов, которые трудно избежать из-за надобности применения дополнительных операций, сравнены с ошибками более непосредственных методов.

ОПРЕДЕЛЕНИЕ ВОДЫ:

Clifford Harris, *Talanta*, 1972, **19**, 1523.

Резюме—Рассмотрена сложность вопроса и проблемы связанные с определением воды в многочисленных исследуемых веществах. Сделана классификация имеющихся методов, приведены тезисы их методики и указано их применение и недостатки. В ряде материалах невозможно определять абсолютную влагу и надо придти к компромиссу. В торговле и промышленности изыскуют быстрые результаты для многих процессов и продуктов, следоватольно применяют во всё возрастающем размере оптиуеские или электронные методы в связы с стандартными методами. Для официальных целей надо привести детальное описание методики и соглашаться с методом. Развить международную стандартизацию очень желательно.

АНАЛИЗ ФАРМАЦЕВТИЧЕСКИХ ПРЕПАРАТОВ МЕТОДОМ ЯДЕРНОГО МАГНИТНОГО РЕЗОНАНСА—VII. ОПРЕДЕЛЕНИЕ АМИНОФИЛЛИНА В ТАБЛЕТКАХ:

John W. Turczan, Bruce A. Goldwitz and James J. Nelson, *Talanta*, 1972, **19**, 1549.

Резюме—Описана методика ЯМР для одновременного определения теофиллина и этилендиамина в таблетках аминофиллина. В качестве внутренного стандарта отобран трет-бутиловый спирт, а смесь 4% аммиака и 0,3% цианида калия в окиси дейтерия в качестве растворителя. Состав растворителя отобран с целью решить проблемы растворения теофиллина, избежать перекрытие резонансных сигналов компонентов и устранять мешающее действие примесей металлов. Методика испытана на стандартных и коммерческих преларатах и результаты сравнены с результатами полученными другими методами. Применена в определении аминофиллина, методика является быстрой, несложной и специфической, а ошибка метода—1–2%.

The decomposition of hypobromite solutions: N. VELGHE and A. CLAEYS, *Talanta*, 1972, **19**, 1555. (Laboratory of Analytical Chemistry, Faculty of Pharmacy, University of Ghent, Ghent, Belgium.)

Summary—The stability of 10^{-1}–$10^{-3}N$ hypobromite solutions, stored in brown or colourless bottles at room temperature, has been investigated. A reaction mechanism of decomposition has been proposed and some practical conclusions have been drawn concerning the optimal method of preparation and the required frequency of control of hypobromite solutions used as an analytical reagent.

Quantitative reflectometry—I. Principles and scope: DAVID KEALEY, *Talanta*, 1972, **19**, 1563. (School of Chemical Science and Technology, Kingston Polytechnic, Kingston-upon-Thames, Surrey, U.K.).

Summary—The technique of quantitative reflectometry is critically investigated, the model being the quantitative determination of nickel in aqueous media. Direct reflectance measurements can be made on commercially available nickel test-strips which develop a pink or red colour in the presence of nickel ions. Relative precisions at the 10 and 50 ppm levels are 2.3-3.6%.

Rapid separation and determination of chromium: JAMES S. FRITZ and JOHN P. SICKAFOOSE, *Talanta*, 1972, **19**, 1573. (Ames Laboratory USAEC and Department of Chemistry, Iowa State University, Ames, Iowa 50010, U.S.A.)

Summary—Chromium(III) is oxidized to chromium(VI) at room temperature or by conventional persulphate oxidation. The chromium(VI) is separated from other metal ions by retention on a small anion-exchange column, and then eluted with a perchlorate solution and measured spectrophotometrically with a flow-through cell. The method is rapid, selective and amenable to automation.

Review of the analytical chemistry of melatonin: E. R. COLE and G. CRANK, *Talanta*, 1972, **19**. 1581. (Department of Applied Organic Chemistry, The University of New South Wales, Kensington, 2033, N.S.W., Australia).

Summary—A survey has been made of procedures, chemical and biochemical, for the separation and estimation of melatonin, the active constituent of the pineal gland. In view of the extremely small amounts of material generally present, discussion is built around chromatographic and spectroscopic techniques leading to a comparison with assays based on the skin-blanching effect of the hormone.

РАЗЛОЖЕНИЕ РАСТВОРОВ ГИПОБРОМИТА:

N. Velghe and A. Claeys, *Talanta*, 1972, **19**, 1555.

Резюме—Изучена устойчивость при комнатной температуре содержанных в бурых или неокрашенных склянках 10^{-1} до 10^{-3} N растворов гипобромита. Предложен реакционный механизм разложения и сделаны некоторые практические выводы касающиеся оптимального метода приготовления и нужной частоты контроля растворов гипобромита, использованных в качестве аналитического реагента.

КОЛИЧЕСТВЕННАЯ РЕФЛЕКТОМЕТРИЯ—I. ПРИНЦИПЫ И ОБЛАСТЬ ПРИМЕНЕНИЯ МЕТОДА:

David Kealy, *Talanta*, 1972, **19**, 1563.

Резюме—Критически исследован метод количественной рефлектометрии на примере количественного определения никеля в водных средах. Можно измерять непосредственно коэффициент отражения на коммерческих образцах никеля, на которых проявляется розовая или красная окраска в присутствии ионов никеля. Относительная точность при 10 и 50 ч. на миллион составляет 2,3 и 3,6 %, соответственно.

БЫСТРОЕ ВЫДЕЛЕНИЕ И ОПРЕДЕЛЕНИЕ ХРОМА:

James S. Fritz and John P. Sickafoose, *Talanta*, 1972, **19**, 1573.

Резюме—Хром(III) окисляют в хром(VI) при комнатной температуре или обыкновенным методом с помощью персульфата. Хром(VI) отделяют от других ионов металлов абсорбцией на небольшой колонке анионообменника, а его затем элюируют раствором перхлората и измеряют спектрофотометрическим методом, с использованием проточной кюветки. Метод быстрый и селективный и легко поддается автоматизации.

ОБЗОР АНАЛИТИЧЕСКОЙ ХИМИИ МЕЛАТОНИНА:

E. R. Cole and G. Crank, *Talanta*, 1972, **19**, 1581.

Резюме—Сцелан обзор химических и биохимических методик для выделения и определения мелатонина, активного компонента гэпифизы. Принимая во внимание имеющиеся очень небольшие количества материала, главный интерес посвящен хроматографическимии спектроскопическим методам, в сравнении с определением основывающемся на белении кожи этим гормоном.

Mössbauer investigation of iron-aluminium mixed oxides: L. KORECZ, I. KURUCZ, G. MENCZEL, E. PAPP-MOLNÁR, E. PUNGOR and K. BURGER, *Talanta*, 1972, **19**, 1599. (Department of Atomic Physics, Department of Experimental Physics and Institute of Inorganic and Analytical Chemistry, L. Eötvös University, Budapest, and Institute for General and Analytical Chemistry, Technical University, Budapest, Hungary.)

Summary—Mixed hydroxides of iron and aluminium have been precipitated from solutions containing iron and aluminium salts. The ratio of iron and aluminium was changed from 1:1 to 1:9. The mixed oxides produced by heating the hydroxides have been investigated by the Mössbauer effect. The Mössbauer spectra were composed of two systems of lines: one is due to magnetic splitting produced by α-Fe_2O_3, the other is due to quadrupole splitting (0·45 mm/s) which can be assigned to iron atoms in the lattice of α-Al_2O_3. The role of the anion of the solvated salts has also been investigated.

Coulometric titration of acids in isopropanol—I. A rapid direct method for the determination of carbon in steel: B. METTERS, B. G. COOKSEY and J. M. OTTAWAY, *Talanta*, 1972, **19**, 1605. (Department of Pure and Applied Chemistry, University of Strathclyde, Cathedral Street, Glasgow, C.1.)

Summary—A new procedure is described for the direct coulometric titration of the carbon dioxide liberated in the high-temperature combustion of steel. The carbon dioxide is absorbed in isopropanol containing 3% of ethanolamine and titrated with 100% titration efficiency with a constant current of 50 mA and spectrophotometric detection of the end-point. The accuracy and precision of the method have been established by the analysis of a wide range of standard steel samples.

Bestimmung des Komplextypus und der Beständigkeitskonstante von dissoziierten Komplexen mit Hilfe transformierter Titrationskurven: J. BORÁK, Z. SLOVÁK and J. FISCHER, *Talanta*, 1972, **19**, 1611. (Forschungsinstitut für reine Chemikalien, Lachema, Brno, Tschechoslowakei.)

Summary—A method is presented for the logarithmic transformation of photometric titration curves, with the aid of which it is possible to differentiate with certainty between mononuclear and polynuclear complexes. The mathematical expressions are derived, and applied to practical examples, leading to unequivocal conclusions. The method suffers from two limitations—over a wide range of concentrations only one complex should be formed, and it must be a relatively weak one.

ИЗУЧЕНИЕ СМЕШАННЫХ ОКИСЕЙ ЖЕЛЕЗА И АЛЮМИНИЯ С ПОМОЩЬЮ ЭФФЕКТА МЕССБАУЕРА:

L. Korecz, I. Kurucz, G. Menczel, E. Papp-Molnár, E. Pungor and K. Burger, *Talanta*, 1972, **19**, 1599.

Резюме—Смешанные гидроокиси железа и алюминия осаждены из растворов, содержащих соли железа и алюминия. Отношение железа и алюминия изменено от 1:1 до 1:9. Смешанные окиси произведенные нагреванием гидроокисей исследованы с помощью эффекта Мессбауера. Спектры Мессбауера составлены из двух систем линий: одна из них появляется в результате расщепления вызванного α-Fe_2O_3, друга—в результате квадрупольного расщепления (0,45 мм/сек) которое можно приписать действию атомов железа в решетке γ—Al_2O_3. Также изучен рольанион а сольватированных солей.

КУЛОНОМЕТРИЧЕСКОЕ ТИТРОВАНИЕ КИСЛОТ В ИЗОПРОПАНОЛЕ—I. БЫСТРЫЙ НЕПОСРЕДСТВЕННЫЙ МЕТОД ОПРЕДЕЛЕНИЯ УГЛЕРОДА В СТАЛИ:

B. Metters, B. G. Cookey, and J. M. Ottaway, *Talanta*, 1972, **19**, 1605.

Резюме—Описана новая методика непосредственного кулонометрического определения двуокиси углерода, выделенного при высокотемпературном сжигании стали. Двуокись углерода поглощают в изопропанол содержащий 3% этаноламина и титруют с 100%-тной эффективностью постоянным током 50 ма с использованием спектрофотометрического обнаружения конца титрования. Определены точность и воспроизводимость метода анализируя ряд эталонных образцов стали.

ОПРЕДЕЛЕНИЕ ТИПА И КОНСТАНТЫ УСТОЙЧИВОСТИ ДИССОЦИИРОВАННЫХ КОМПЛЕКСОВ С ПОМОЩЬЮ ТРАНСФОРМИРОВАННЫХ КРИВЫХ ТИТРОВАНИЯ:

J. Borák, Z. Slovák and J. Fischer, *Talanta*, 1972, **19**, 1611.

Резюме—Предложен метод логарифмической трансформации фотометрических кривых титрования, который позволяет различать одноядерные от многоядерных комплексов. Выведены математические выражения и применены на практические примеры, ведуши к недвусмысленным выводам. Недостатки метода—только один комплекс надо образоваться в широком диапазоне концентраций и этот комплекс должен быть относительно неустойчивый.

Studies of copper(II) sulphide ion-selective electrodes: GILLIS JOHANSSON and KERSTIN EDSTRÖM: *Talanta*, 1972, **19**, 1623. (Department of Analytical Chemistry, University of Umeå, 901 87 Umeå, Sweden.)

Summary—Changes in liquid junction potentials in copper(II) solutions were measured when different reference electrodes were used. The slope and intercept of a calibration curve for a copper-selective electrode will depend on the selection of reference electrode. The condition of the electrode surface of an Orion copper-selective electrode was studied microscopically and the influence of redox potential on stability of the electrode against corrosion is discussed. Oxidizing solutions will produce pits at dislocations in the material and there will be a mixed electrode potential. The slope, stability, and speed of response are much lower when the surface contains pits. Diamond-polishing was shown to improve the electrode significantly.

Indirect atomic-absorption determination of ppM levels of arsenic by combustion of an MIBK extract of arsenomolybdic acid: Y. YAMAMOTO, T. KUMAMARU, Y. HAYASHI, M. KANKE and A. MATSUI, *Talanta*, 1972, **19**, 1633. (Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda, Hiroshima, Japan.)

Summary—An indirect atomic-absorption method for arsenic has been developed. Arsenic(III) is oxidized to arsenic(V) by iodine, then arsenomolybdic acid is formed and extracted into MIBK from 0·2–1·6*M* hydrochloric acid. Excess of molybdate is scrubbed from the organic phase, and then the molybdenum in the heteropoly acid is determined by its atomic absorption at 313·3 nm. Silicate and phosphate interfere. A procedure is described for determination of ppM levels of arsenic in water.

Determination of small amounts of water with coulometrically generated Karl Fischer reagent: RONALD KARLSSON, *Talanta*, 1972, **19**, 1639. (Department of Analytical Chemistry, Chemical Center, University of Lund, S 220 07 Lund 7, Sweden.)

Summary—A coulometric method for the determination of small amounts of water described in a previous report has been further developed. Improved electronic circuity and a redesigned electrolysis cell have extended the range of determination and decreased the time of analysis. By means of a movable oven specially adapted to the cell, water in solids has also been determined. The method presented is applicable with high accuracy in the range 0·005–5 mg of water in a large variety of substances.

ИЗУЧЕНИЕ ИОНОИЗБИРАТЕЛЬНЫХ ЭЛЕКТРОДОВ НА ОСНОВЕ СУЛЬФИДА МЕДИ(II):

Gillis Johansson and Kerstin Edström, *Talanta*, 1972, **19**, 1623.

Резюме—Измерены изменения потенциала жидкостного спая при использовании различных электродов сравнения в растворах меди(II). Наклон и отрезок калибровочной кривой избирательного для меди электрода зависит от отбора электрода сравнения. Состояние поверхности избирательного для меди электрода марки Орион испытано микроскопическим путем и рассмотрено влияние окислительно-восстановительного потенциала на коррозионную устойчивость электрода. Окисляющие растворы вызывают оброзование язв при дислокациях в материале и появление смешанного напряжения электрода. Наклон, устойчивость и скорость ответа значительно ниже в случае присутствия язв на поверхности электрода. Показано что полирование алмазами в значительной мере улучшает характеристики электрода.

КОСВЕННОЕ ОПРЕДЕЛЕНИЕ МИКРОГРАММОВЫХ КОЛИЧЕСТВ МЫШЬЯКА МЕТОДОМ АТОМНО-АБСОРБЦИОННОЙ СПЕКТРСКОПИИ, ПУТЕМ СЖИГАНИЯ ЭКСТРАКТА МЫШЬЯКОВОМОЛИБДЕНОВОЙ КИСЛОТЫ В МИБК:

Y. Yamamoto, T. Kumamaru, Y. Hayashi, M. Kanke and A. Matsui, *Talanta*, 1972, **19**, 1633.

Резюе—Разработано косвенное определение мышьяка методом атомно-абсорбционной спектроскопии. Мышьяк(III) окисляют в мышьяк(V) иодом, затем образуют мышьяковомолибденовую кислоту и её экстрагируют метилизобутилкетоном (МИБК) из 0,2 — 1,6*M* раствора соляной кислоты. Избыток молибдата устраняют из органической фазы и молибден в форме гетерополикислоты определяют на основе его атомного поглощения при 313,3 нм. Силикат и фосфат мешают определению. Описана методика определения частей на миллион мышьяка в воде.

ОПРЕДЕЛЕНИЕ НЕБОЛЬШИХ КОЛИЧЕСТВ ВОДЫ С КУЛОНОМЕТРИЧЕСКИ ОБРАЗОВАННЫМ РЕАГЕНТОМ КАРЛА ФИШЕРА:

Ronald Karlsson, *Talanta*, 1972, **19**, 1639.

Резюме—Дальше разработана методика кулонометрического определения небольших количеств воды, описанная в предыдущей стате. Улучшенные электронные цепи и новая конструкция электролитической ячейки позволили протянуть область применимости метода и сокращать продолжительность анализа. Использование подвижной печи приспособленной к ячейке также позволяет определять воду в твердых веществах. Методом можно определять с высокой точностью 0,005–5 мг воды в множестве разных веществ.

Studies on the extraction and determination of metals—I. Extraction of hafnium into methyl isobutyl ketone and tributyl phosphate: Norio Ichinose, *Talanta*, 1972, **19**, 1644. (Department of Chemistry, Faculty of Liberal Arts, Yamaguchi University, Yamaguchi-City, Japan.)

Summary—The effect of various factors on the distribution of hafnium ($<5.60 \times 10^{-4}M$) between different acids and methyl isobutyl ketone (MIBK) or tributyl phosphate (TBP) was studied by using $^{175+181}$Hf as a tracer. When the extraction is made from 7·5–11*M* hydrochloric acid with an equal volume of 1*M* TBP in benzene, hafnium is extracted quantitatively (>99%). The hafnium can be stripped with 1–3*M* hydrochloric acid.

Non-destructive method for the analysis of gold(I) cyanide plating baths. Complexometric determination of nickel and indium: Rudolf Přibil and Vladimír Veselý, *Talanta*, 1972, **19**, 1647. (Laboratory of Analytical Chemistry, J. Heyrovský Polarographic Institute, Czechoslovak Academy of Sciences, Prague 1, Jilská 16, Czechoslovakia).

Summary—A method is described for rapid determination of nickel and indium in gold(I) cyanide baths containing large amounts of citric acid and/or sodium citrate, without previous destruction of organic matter. Gold is removed by extraction with ethyl acetate. In one aliquot of the solution indium is masked with thioglycollic acid and nickel is precipitated with sodium diethyldithiocarbamate, extracted into chloroform, stripped into water and determined complexometrically. In a second aliquot indium and nickel are precipitated together with the same reagent and stripped into water, then nickel is masked with 1,10-phenanthroline, and indium is determined by direct titration with EDTA.

Potentiometric argentimetric method for the successive titration of sulphide and dissolved sulphur in polysulphide solutions: Sanae Ikeda, Hiromu Satake, Takeo Hisano and Toshio Terazawa, *Talanta*, 1972, **19**, 1650. (Department of Applied Chemistry, Faculty of Engineering, Tokushima University, Tokushima, Japan.)

Summary—Sulphide sulphur and dissolved sulphur in a polysulphide solution can be successively determined with satisfactory accuracy and reproducibility by potentiometric argentimetry in which a sulphide-selective indicator electrode is used. Before the titration, polysulphide ions need to be converted by an excess of potassium cyanide into thiocyanate and sulphide ions. The excess of cyanide ions is masked with formaldehyde and sulphuric acid, then the solution is made alkaline with ammonia and titrated with silver nitrate till the first end-point is reached (sulphide sulphur). After the acidification of the solution with sulphuric acid, the titration is continued till the second end-point is attained (dissolved sulphur).

ИЗУЧЕНИЕ ЭКСТРАКЦИИ И ОПРЕДЕЛЕНИЯ МЕТАЛЛОВ—I. ЭКСТРАКЦИЯ ГАФНИЯ МЕТИЛИЗОБУТИЛКЕТОНОМ И ТРИБУТИЛФОСФАТОМ:

NORIO ICHINOSE, *Talanta*, 1972, **19**, 1644.

Резюме—Изучено влияние разных факторов на распределение гафния ($<5{,}60 \cdot 10^{-4}M$) между разными кислотами и метилизобутилкетоном (МИБК) или трибутилфосфатом (ТБФ), с использованием $^{175+181}$Hf в качестве индикатора. При экстрагировании из $7{,}5 - 11M$ раствора соляной кислоты с тем же объемом $1M$ ТБФ в бензоле, гафний экстрагируется количественно ($>99\%$). Гафний можно освободить 1–3*M* раствором соляной кислоты.

НЕДЕСТРУКТИВНЫЙ МЕТОД АНАЛИЗА ГАЛЬВАНИЧЕСКОЙ ВАННЫ СОДЕРЖАЩЕЙ ЦИАНИД ЗОЛОТА(I). КОМПЛЕКСОНОМЕТРИЧЕСКОЕ ОПРЕДЕЛЕНИЕ НИКЕЛЯ И ИНДИЯ:

R. PRIBIL and V. VESELY, *Talanta*, 1972, **19**, 1647.

Резюме—Описан метод быстрого определения никеля и индия в ваннах цианида золота(I), содержащих большие количества лимонной кислоты и (или цитрата натрия, без предварительного разложения органического вещества. Золото устраняют экстракцией с этилацетатом. В аликвотной части раствора маскируют индий тиогликолевой кислотой и осаждают никель диэтилдитиокарбаминатом натрия, экстрагируют хлороформом, переводят в водный раствор и определяют никель комплексонометрическим методом. В другой аликвотной части раствора индий и никель осаждают одновременно пользуясь тем же реагентом и переводять в водный раствор; никель затем маскируют 1,10-фенантролином а индий определяют непосредственным титрованием с ЭДТА.

ПОТЕНЦИОМЕТРИЧЕСКИЙ АРГЕНТОМЕТРИЧЕСКИЙ МЕТОД ПОСЛЕДОВАТЕЛЬНОГО ТИТРОВАНИЯ СУЛЬФИДА И РАСТВОРЕННОЙ СЕРЫ В РАСТВОРАХ ПОЛИСУЛЬФИДА:

SANAE IKEDA, HIROMU SATAKE, TAKEO HISANO and TOSHIO TERAZAWA, *Talanta*, 1972, **19**, 1650.

Резюме—Метод потенциометрической аргентометрии позволяет определять сульфидную серу и растворенную серу в растворе полисульфида с довольной точностью и воспроизводимостью, пользуясь селективным для сульфидиона индикаторным электродом. Перед титрованием полисульфидионы надо превратить в тиоцианат- и сульфидионы обработкой с избытком цианида калия. Избыток цианидионов маскируют формальдегидом и серной кислотой, раствор затем подщелачивают аммиаком и титруют нитратом серебра до первого конца титрования (сульфидная сера). После подкисления раствора серной кислотой титрование продолжают до второго конца титрования (растворенная сера).

Cation-exchange of metal ions in organic solvent-cupferron media: J. Korkisch and M. M. Khater, *Talanta*, 1972, **19**, 1654 (Analytical Institute, University of Vienna, IX Wahringerstrasse 38, Austria.)

Summary—Distribution coefficients of 20 metal ions were determined on the strongly acidic cation-exchanger Dowex 50 in a 30:7:1 mixture of chloroform–methanol–$1M$ hydrochloric acid which was $0{\cdot}1M$ in cupferron. In this system the distribution coefficients of Fe(III), Ti(IV), Cu(II), Ce(III) and Th are lower by several orders of magnitude than those of Ni, Mn(II), Cd, Co(II), Ca, U(VI), and Sr. It is possible to separate these two groups of elements on an ion-exchange column.

Comparative study of analytical properties and applications of picolinaldehyde thiosemicarbazone and selenosemicarbazone: J. M. Cano Pavon and F. Pino, *Talanta*, 1972, **19**, 1659. (Department of Analytical Chemistry, University of Seville, Seville, Spain.)

Summary—The analytical properties of picolinaldehyde thiosemicarbazone and selenosemicarbazone have been studied, in order to investigate the changes produced when the Se atom is substituted for the S atom. The ionization constants of both substances are very similar. The complexes of picolinaldehyde selenosemicarbazone with cations in aqueous solution are less stable, and the absorption spectra show bathochromic and hypochromic shifts. The introduction of the Se atom offers no advantages in the analytical application of these compounds.

On the nature of so-called "Khimdu": Yong Kuen Lee, Kyu Ja Whang and Keihei Ueno, *Talanta*, 1972, **19**, 1665. (Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812, Japan).

Summary—The reagent called "Khimdu" has been investigated and evidence found to show that it is not a pure compound but a mixture of several reaction products.

Zur Frage des Verlustes von Molybdän während der Analyse von metallischem Wolfram auf Molybdänspuren: E. Lassner and H. Schedle, *Talanta*, 1972, **19**, 1670. (Versuchsanstalt, Metallwerk Plansee A. G., A-6600 Reutte, Austria.)

Summary—It is shown that oxidative annealing of metallic tungsten to tungsten trioxide causes a decrease in the molybdenum content. Thus such annealing must be avoided when the molybdenum content is to be determined. On the other hand, when the tungsten is dissolved in a mixture of hydrofluoric and nitric acids with subsequent fuming with sulphuric acid, no such decrease in the molybdenum content takes place.

КАТИОННЫЙ ОБМЕН ИОНОВ МЕТАЛЛОВ В СРЕДАХ СОДЕРЖАЩИХ ОРГАНИЧЕСКИЕ РАСТВОРИТЕЛИ И КУПФЕРРОН:

J. Korkisch and M. M. Khater, *Talanta*, 1972, **19**, 1654.

Резюме—Определены коэффициенты распределения 20 ионов металлов на сильнокислом катионообменнике Дауекс 50 в смеси хлороформа, метанола и 1*M* соляной кислоты 30:7:I, в присутствии 0,1*M* купферрона. В этой системе коэффициенты распределения Fe(III), Ti(IV), Cu(II), Ce(III) и Th в несколько раз ниже чем коэффициенты распределения Ni, Mn(II), Cd, Co(II), Ca, U(VI) и Sr. Поэтому удается разделять эти две группы элементов на колонке ионообменника.

СРАВНЕНИЕ ПРИМЕНИМОСТИ В АНАЛИЗЕ ТИОСЕМИКАРБАЗОНА И СЕЛЕНОСЕМИКАРБАЗОНА ПИКОЛИНАЛЬДЕГИДА:

J. M. Cano Pavon and F. Pino, *Talanta*, 1972, **19**, 1659.

Резюме—Изучены аналитические характеристики тиосемикарбазона и селеносемикарбазона пиколинальдегида с целью определить эффект замещения атома серы атомом селена. Константы ионизации обоих веществ очень похожие. Комплексы селеносемикарбазона пиколинальдегида с катионами в водном растворе менее устойчивы, а спектры светопоглощения показывают батохромные и гипсохромные перемещения. Введением атома селена не получаются преимущества в применении этих соединений в анализе.

ПРИРОДА ТАК НАЗЫВАЕМОГО "КХИМДУ":

Yong Kuen Lee, Kyu Ja Whang and Keihei Ueno, *Talanta*, 1972, **19**, 1665.

Резюме—Результаты изучения так называемого "Кхимду" показывают что это вещество не представляет собой чистое соединение, но ряд продуктов реакции.

К ВОПРОСЕ ПОТЕР В МОЛИБДЕНЕ ПРИ ОПРЕДЕЛЕНИИ СЛЕДОВ МОЛИБДЕНА В МЕТАЛЛИЧЕСКОМ ВОЛЬФРАМЕ:

E. Lassner and H. Schedle, *Talanta*, 1972, **19**, 1670.

Разюме—Показано что окислительнный отжиг металлического вольфрама в трёхокись вольфрама вызывает снижение содержания молибдена. Таким образом надо избежать отжиг в случае определения молибдена. С другой стороны, потери в молибдене не обнаружены если вольфрам растворен в смеси фтористоводородной и азотной кислот с последующим дымлением серной кислотой.
