IMPROVED SYNTHESIS AND STABILITY OF 8-SELENOQUINOLINE AND ITS SODIUM SALT AS ORGANIC REAGENTS

EIICHI SEKIDO and ISAMU FUJIWARA
Department of Chemistry, Faculty of Science, Kobe University, Nada, Kobe, Japan

(*Received* 18 *June* 1971. *Accepted* 14 *July* 1971)

Summary—The synthesis of 8-selenoquinoline and its sodium salt has been improved by optimization of each process. The stability of the reagents in air and nitrogen has been examined and correlated with the drying method. Both 8-selenoquinoline and its sodium salt can exist as the monohydrate. It was found that the sodium salt of 8-selenoquinoline monohydrate is best as the weighing form of the reagent and that it can be kept stable under nitrogen in a vessel containing silica gel.

8-SELENOQUINOLINE (8-quinolineselenol), so-called selenoxine, was synthesized by Sekido, Fernando and Freiser,[1] and the properties of this reagent and some of its metal chelates were studied.[2–4] Because of the poor yield and its instability in air, however, further studies appeared necessary.

Hitherto, 8-selenoquinoline has been synthesized according to scheme I. The diazotization of 8-aminoquinoline proceeds successfully in mineral acid but the resulting diazonium salt solution does not necessarily react smoothly with potassium selenocyanate; consequently the yield of 8-selenoquinoline or 8,8′-diquinolyldiselenide is usually poor. 8-Selenoquinoline is so unstable in air that it is necessary to take care in storing it, and on the other hand 8,8′-diquinolyldiselenide must be reduced just before use.

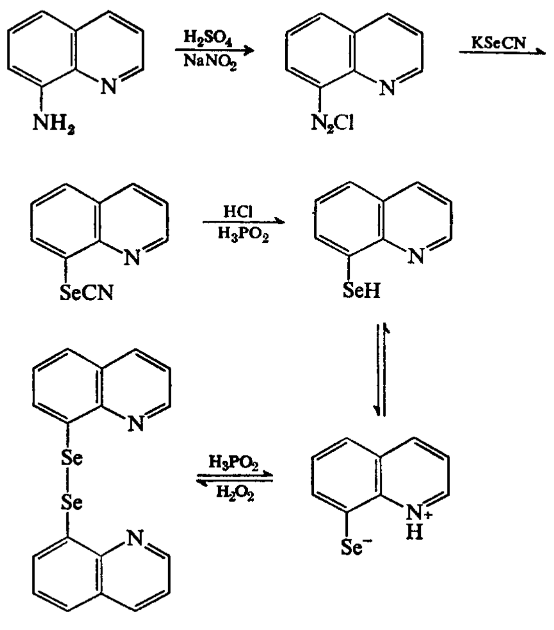
This paper deals with the improved synthesis of 8-selenoquinoline and the stability of 8-selenoquinoline and its sodium salt as a function of the drying method used.

EXPERIMENTAL

Synthesis of 8-selenoquinoline and its sodium salt

8-Selenocyanatoquinoline. Pure 8-aminoquinoline (15 g, 0·105 mole) prepared from 8-hydroxyquinoline,[3] is dissolved in 48% hydrobromic acid (78 ml, 0·50 mole) and water (200 ml). Into the solution cooled to 0°, 10% sodium nitrite solution is dropped with stirring. A colour change from red to yellow-green indicates the end of the diazotization. The excess of nitrite is destroyed by addition of 2*M* sulphamic acid until evolution of nitrogen ceases. The diazonium solution is neutralized with solid sodium acetate to pH 1·5–2·0, in an ice-bath. Then 15% potassium selenocyanate solution (100 ml, 0·104 mole) is added slowly during one hour, at below 5°. The bulky yellow-brown product is formed as a suspension and nitrogen is evolved. To complete the reaction, the solution is stirred for 30 min at below 5° and then for several hours at room temperature (in a fume-cupboard). The solution is adjusted to pH 8·0 with 12*M* sodium hydroxide and the precipitate filtered off. If 1% hydrogen peroxide solution is added to the filtrate, a little yellow-brown precipitate may be formed. This precipitate, probably impure 8,8′-diquinolyldiselenide, is added to the 8-selenocyanatoquinoline in the following procedure. 8-Selenocyanatoquinoline can be recrystallized from 50% v/v aqueous methanol (to give yellow-brown needles, m.p. 74–75°), but as it is an evil-smelling compound and the recrystallization is difficult, the crude compound is used in the following procedure.

8,8′-Diquinolyldiselenide. The crude 8-selenocyanatoquinoline (10 g, 0·043 mole) is dissolved in 6*M* hydrochloric acid (50 ml) and 50% hypophosphorous acid (10 ml) and the resulting solution is warmed for about 15 min on a water-bath. The colour changes gradually from yellow to red, which indicates the formation of 8-selenoquinoline by hydrolysis of 8-selenocyanatoquinoline. After cooling in an ice-bath, the impurity is filtered off (in a fume-cupboard, because hydrogen cyanide gas may



Scheme I

be produced). The 8-selenoquinoline in acid solution is neutralized with 5*M* sodium hydroxide in an ice-bath while nitrogen is bubbled through the solution. The colour changes to red-violet in weakly acidic or neutral solution and then to yellow in alkaline solution. The alkaline solution of 8-selenoquinoline is rapidly filtered under nitrogen to remove the impurities. When 1% hydrogen peroxide solution is added to the filtrate, a white precipitate of 8,8′-diquinolyldiselenide forms rapidly. The precipitate is filtered off, washed with water and dried *in vacuo* at room temperature. It is purified by dissolving it in hydrochloric and hypophosphorous acids and repeating the above-mentioned procedure. Yield, 40% (from 8-aminoquinoline); fine white crystals, m.p. 205° (lit.,[1] 205–206°). Calculated for $C_{18}H_{12}N_2Se_2$: C, 52·19%; H, 2·92%; N, 6·76%. Found: C, 52·6%; H, 3·0%; N, 7·3%.

8-Selenoquinoline. Purified 8,8′-diquinolyldiselenide (15 g) is dissolved in as little 6*M* hydrochloric acid as possible and 50% hypophosphorous acid (5 ml). The colour changes from yellow to red, which indicates the formation of 8-selenoquinoline. To complete the reduction the solution is warmed on a water-bath for about 10 min. It is not favourable to heat at high temperature and for a long time. After cooling, the solution is filtered if necessary, put in an ice-bath, and kept under nitrogen while 12*M* sodium hydroxide is added dropwise. The red solution becomes deep violet-red and then a precipitate forms, which redissolves on further addition of sodium hydroxide, to give a yellow solution, which is rapidly filtered if necessary. Then 2*M* hydrochloric acid is carefully added until the pH reaches 4, and dark red-brown needles precipitate. The precipitate is rapidly filtered off under nitrogen and washed with oxygen-free cold water. The 8-selenoquinoline is dried and kept in a desiccator containing silica gel and filled with nitrogen. More product can be obtained by repeating the procedure with the filtrate and washings. Yield, 52%; red-brown needles, m.p. not measurable (oxidation to 8,8′-diquinolyldiselenide). Calculated for C_9H_7NSe: C, 51·94%; H, 3·39%. Found: C, 51·7%; H, 3·6%.

Sodium salt of 8-selenoquinoline. When 12*M* sodium hydroxide is added to an acidic solution of 8-selenoquinoline, in an ice-bath under nitrogen, the yellow sodium salt of 8-selenoquinoline is precipitated. After filtration, the sodium salt is dried and recrystallized from 95% ethanol at least thrice. The amount of water of crystallization depends on the method of drying. Drying and storage in a desiccator containing silica gel and filled with nitrogen yields the monohydrate. Yield, 21·0% (from 8,8′-diquinolyldiselenide); yellow crystals, Calculated for $C_9H_8NOSeNa$: C, 43·57%; H, 3·25%. Found: C, 43·3%; H, 3·6%.

When the salt is dried *in vacuo* at 120°, the anhydride is obtained. Yellow crystals; Calculated for C_9H_6NSeNa: C, 46·98%; H, 2·63%; N, 6·09%. Found: C, 46·7%; H, 2·9%; N, 5·9%.

Other reagents

8-Mercaptoquinoline was prepared by the method of Kealey and Freiser[5] and its sodium salt by the method of Nakamura and Sekido.[4]

Apparatus

Drying. Vacuum desiccators containing silica gel or calcium chloride as desiccant were used for drying at room temperature and an electric oven under reduced pressure for drying by heating.

RESULTS AND DISCUSSION

Synthesis of 8-selenoquinoline

The improvements in the synthesis of 8-selenoquinoline are summarized in Table I.

TABLE I.—IMPROVEMENTS OF THE SYNTHESIS OF 8-SELENOQUINOLINE COMPARED WITH THE CONVENTIONAL METHOD

Reaction parameter	This method	Conventional method[1]
Acidity of diazotization	Mineral acids (HCl, HBr or H_2SO_4) 0·25M	H_2SO_4, 0·1M
Neutralization of diazonium salt solution	Addition of solid sodium acetate	Addition of 5M sodium hydroxide
Acidity of diazonium salt solution and KSeCN solution	pH 1·5–2·5	pH 7·0
Order of addition	Addition of KSeCN to diazonium salt solution	Addition of diazonium salt solution to KSeCN solution
Temperature and time of the reaction	30 min in an ice-bath and then 60 min at room temperature	30 min in an ice-bath
Yield of 8,8′-diquinolyldiselenide from 8-aminoquinoline	40%	12% (Maximum)

Effect of acidity on the diazotization of 8-aminoquinoline. It was found that the diazotization proceeds in hydrochloric or hydrobromic acid as well as in sulphuric acid and that at least 5 equivalents of acid per equivalent of 8-aminoquinoline are needed for smooth diazotization.

Neutralization of diazonium salt of 8-aminoquinoline. When 5M sodium hydroxide is used for neutralization to pH 1·5–2·5, higher pH values may be attained locally. In addition, heating by the exothermic reaction might accelerate decomposition of the diazonium salt. Use of more dilute sodium hydroxide solution makes the volume too large, and causes difficulty later. Addition of solid sodium acetate eliminates these disadvantages.

Acidity of the diazonium salt solution and the potassium selenocyanate solution. Potassium selenocyanate decomposes in acid solution to yield colloidal red selenium.

The rate of decomposition as a function of pH is as follows:

pH	below 1	1·0	2·0	4·0	5·0	7·0
Decomposition time, *min*	instantly	2	5–6	5–6	10	no change

The decomposition is accelerated by increase in temperature.

Although the diazonium salt of 8-aminoquinoline is stable in strongly acidic solution, it decomposes at higher pH. The yield of 8,8′-diquinolyldisulphide by reaction of the diazonium salt with thiourea was used to monitor the effect of pH on decomposition of the diazonium salt (the rate of reaction of the urea increases with pH, so an inverse relationship of yield to pH indicates faster decomposition as the pH is increased):

pH	−0·4	1·0	2·0	4·0	5·0	7·0
Yield, %	50	40	32	19	7	9

The best compromise between decomposition of the diazonium salt and of potassium selenocyanate was to use a pH of 1·5–2·5.

Order of addition of the diazonium salt and selenocyanate. If the neutralized diazonium salt solution is added to the selenocyanate solution,[1] the product becomes very tarry and difficult to remove. The reverse order of addition was found to give a readily filterable yellow-brown precipitate.

Drying conditions. The effect of varying the drying conditions is shown in Table II.

TABLE II.—WATER CONTENT AND COLOUR OF 8-SELENOQUINOLINE AND ITS SODIUM SALT WHEN THESE ARE DRIED UNDER VARIOUS CONDITIONS

		Drying condition					
No.	Substance	Desiccant	Atmosphere	Temp., °*C*	Time, *hr*	Water content,* %	Colour
1	8-SQ†	silica gel	nitrogen	20–25	24	8·2	red
2	8-SQ†	silica gel	nitrogen	20–25	48	0	red-brown
3	8-SQ†	silica gel	vacuum (0·1 μbar)	20–25	24	0	red-brown
4	8-SQ†	$CaCl_2$	nitrogen	20–25	48	0	red-brown
5	8-SQ-Na‡	silica gel	vacuum (0·1 μbar)	20–25	24	6·7	yellow
6	8-SQ-Na‡	silica gel	(0·1 μbar)	20–25	48	7·6	yellow
7	8-SQ-Na‡	silica gel	(0·1 μbar)	20–25	7 days	7·2	yellow
8	8-SQ-Na‡	silica gel	25–40 mbar	20–25	48	7·8	yellow
9	8-SQ-Na‡	no	vacuum (0·1 μbar)	120	1–6	0	orange

* Average value of at least 5 results. Range ±0·5%. One molecule of water of crystallization corresponds to 8·0% H_2O for 8-SQ and 7·3% for 8-SQ-Na.

† 8-SQ: 8-selenoquinoline.

‡ 8-SQ-Na: sodium salt of 8-selenoquinoline.

Experiments 1–4 show that 8-selenoquinoline easily loses its water of crystallization. In contrast, the sodium salt exists as the monohydrate over a fairly wide range of drying conditions. The anhydrous salt is so hygroscopic that it must be kept in a desiccator containing phosphorus pentoxide.

Thermal stability of 8-selenoquinoline and its sodium salt

8-Selenoquinoline, especially its monohydrate, is easily oxidized in air to 8,8′-diquinolyldiselenide. Therefore, its thermal stability was examined in nitrogen as well as in air. Thermogravimetry of 8-selenoquinoline monohydrate in air (curve *A* in Fig. 1) shows loss of the water at a temperature of 51° or lower, accompanied by a colour change to red-brown at 50–51°. These facts may support the hypothesis that the water is not adsorbed by 8-selenoquinoline but weakly bound to it as shown in structure **I**. Bankovskii, Chera and Ievin'sh[6] proposed structure **II** for 8-mercaptoquinoline dihydrate. Considering the difference in the acid dissociation constants[1] of —SH in 8-mercaptoquinoline and —SeH for 8-selenoquinoline (in other words, the difference of electronegativities for sulphur and selenium) the S· · ·H bond in **II** may be stronger than the Se· · ·H bond in **I**.

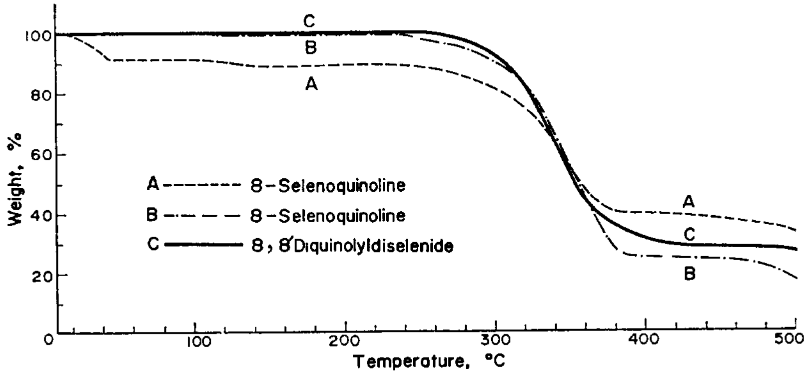


FIG. 1.—Thermogravimetric curves of 8-selenoquinoline and 8,8′-diquinolyldiselenide in air.

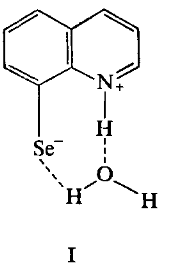
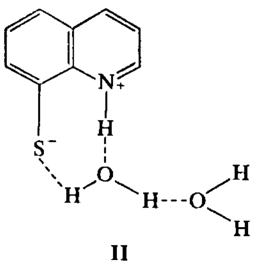


I



II

Therefore, the temperature of dehydration for 8-mercaptoquinoline (58–59°) should be higher than that for 8-selenoquinoline (51°). In the case of 8-mercaptoquinoline, the second water molecule may be weakly connected *via* a hydrogen bond to the cyclically bound water molecule.

The anhydride (curve *A* above 50° and curve *B* in Fig. 1) changes to 8,8′-diquinolyldiselenide by 140° (*cf.* curve *C* in Fig. 1). The oxidation of 8-selenoquinoline is also confirmed by the identity or the infrared spectra of the product from 8-selenoquinoline heated to 180–190° and of 8,8′-diquinolyldiselenide. The differential thermal analysis (DTA) and thermogravimetric curves of 8-selenoquinoline under nitrogen (curves *A* and *A'* in Fig. 2) are different from those of 8,8'-diquinolyldiselenide (curves *C* and *C'*). The peak at 204° on curve *C* corresponds to melting of 8,8'-diquinolyldiselenide and that at 360° to decomposition of the quinoline nucleus.

8-Selenoquinoline is completely oxidized to 8,8'-diquinolyldiselenide after 3 hr in air. This oxidation is confirmed by the disappearance of the infrared absorption band at 2925 cm^{-1} (N–H stretching vibration) and by the agreement with the infrared spectrum of 8,8'-diquinolyldiselenide. Anhydrous 8-selenoquinoline is stable for at least three weeks when stored under nitrogen in a vessel containing silica gel.

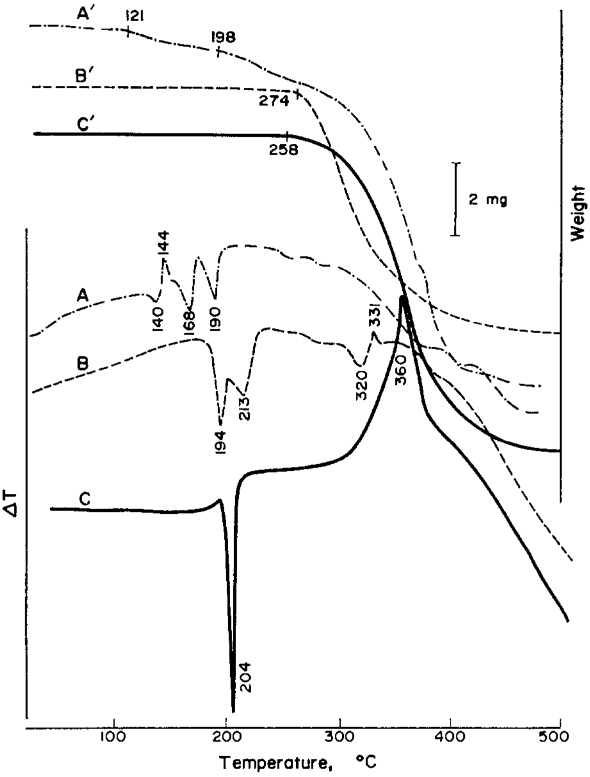


FIG. 2.—Differential thermal curves (A, B and C) and thermogravimetric curves (A', B' and C') of the reagents in nitrogen gas. A and A': 8-selenoquinoline; B and B': 8,8'-diquinolyldisulphide; C and C': 8,8'-diquinolyldiselenide.

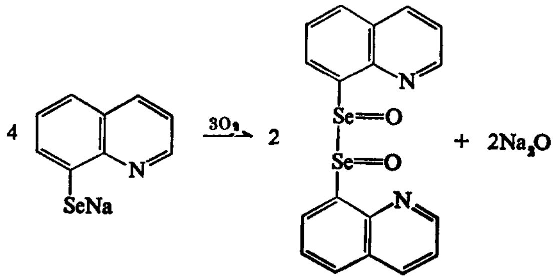
Thermogravimetric curves for the sodium salt of 8-selenoquinoline in nitrogen and in air are shown in Fig. 3. The water is all lost between 78 and 106° (curve *A*). The anhydride increases in weight by 10% over the temperature range 160–190° if heated in air (curves *A* and *B*) but not if heated in nitrogen or carbon dioxide (curve *C*). A similar phenomenon occurs with the sodium salt of 8-mercaptoquinoline,[7] and not for 8-selenoquinoline or 8,8'-diquinolyldiselenide. It is assumed that the sodium salt of 8-selenoquinoline is oxidized by air. Oxidation according to the reaction below gives a theoretical weight increase of 10·4% (experimental value, 10·0%).



The DTA curves for the sodium salts of 8-selenoquinoline monohydrate and 8-mercaptoquinoline dihydrate are shown in Fig. 4; for both there is a large endothermic peak at about 120°, which corresponds to loss of the water. The rest of the decomposition is rather complex. The bond strength between the water and the organic molecule is presumably almost the same for both compounds. The O–H stretching vibration in the infrared spectra for both compounds exists at almost the same position, 3277 cm^{-1} for the 8-selenoquinoline salt and 3200–3300 cm^{-1} for that of 8-mercaptoquinoline, the first being relatively sharp and the other broad (Fig. 5). These facts suggest that the structures may be III and IV respectively.

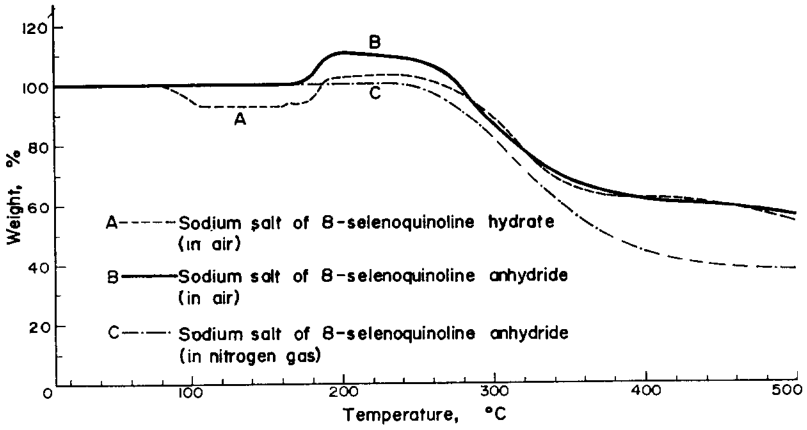


FIG. 3.—Thermogravimetric curves of the sodium salt of 8-selenoquinoline in air and nitrogen.

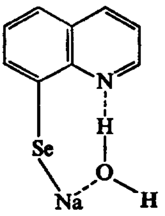
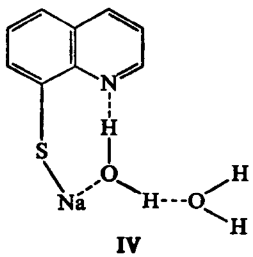


III



IV

That the dehydration temperature of the sodium salts is higher than that of the 8-seleno- or 8-mercaptoquinoline may be attributed to the bond between the sodium

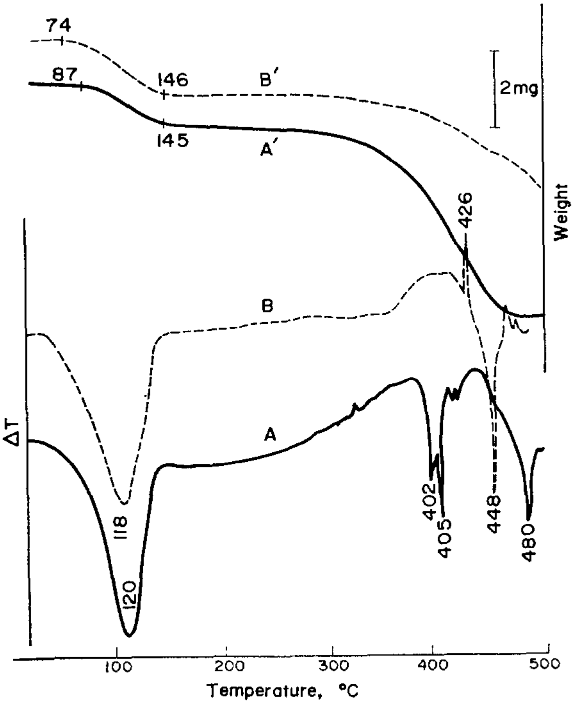


FIG. 4.—Differential thermal curves (A and B) and thermogravimetric curves (A' and B') of the reagents in nitrogen gas. A and A': sodium salt of 8-selenoquinoline; B and B': sodium salt of 8-mercaptoquinoline.

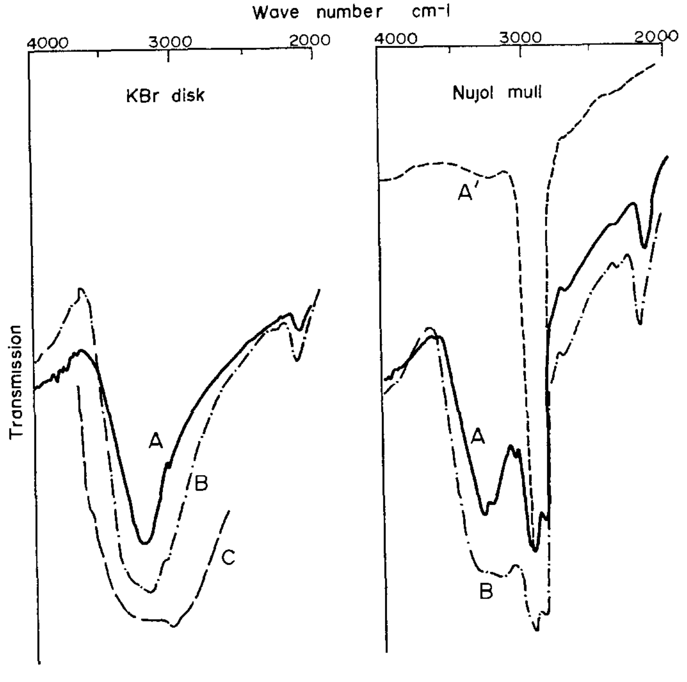

FIG. 5.—Infrared spectra of sodium salt of the reagents in the region of 4000–2000 cm^{-1}. A: 8-selenoquinoline monohydrate; *A'*: its anhydride; B: 8-mercaptoquinoline dihydrate; C: 8-hydroxyquinoline hydrate.

atom and the oxygen atom of water being stronger than that between the oxygen atom and the selenium or the sulphur atom. Furthermore, the similar dehydration temperatures for the sodium salts suggest that one water molecule exists between the sodium atom and the nitrogen atom of the quinoline nucleus in both. The second water molecule of the dihydrate, being bound to the cyclically bound water molecule by a hydrogen bond, will broaden the O—H stretching vibration band.

The temperature of incipient decomposition of the sodium salt of 8-selenoquinoline is lower than that for 8-mercaptoquinoline salt; the S—Na bond may be stronger than the Se—Na bond.

The anhydrous sodium salt of 8-selenoquinoline is so hygroscopic that it abstracts water from silica gel in a desiccator. It is stable if kept in a nitrogen atmosphere over phosphorus pentoxide in a desiccator, but over P_2O_5 in a vacuum it changes gradually into a red-brown compound. The sodium salt monohydrate is the best storage form, being stable for at least 2½ months in a nitrogen atmosphere in a desiccator containing silica gel.

Zusammenfassung—Die Synthese von 8-Selenochinolin und seines Natriumsalzes wurde durch Optimierung jeder Stufe verbessert. Die Stabilität der Reagentien an Luft und Stickstoff wurde geprüft und mit der Trocknungsmethode in Zusammenhand gebracht. Sowohl 8-Selenochinolin als auch sein Natriumsalz können als Monohydrat existieren. Es wurde gefunden, daß das Natriumsalz von 8-Selenochinolin-Monohydrat die beste Wägeform des Reagens darstellt und daß es unter Stickstoff in einem Silicagel enthaltenden Gefäß stabilisiert werden kann.

Résumé—On a amélioré la synthèse de la 8-sélénoquinoléine et de son sel de sodium en optimalisant chaque opération. On a examiné la stabilité des réactifs à l'air et sous azote et on l'a rattachée à la méthode de séchage. La 8-sélénoquinoléine et son sel de sodium peuvent exister à l'état de monohydrate. On a trouvé que le monohydrate du sel de sodium de la 8-sélénoquinoléine est la meilleure forme du réactif pour la pesée et qu'il peut être conservé de manière stable sous azote dans un récipient contenant du gel de silice.

(*Received* 12 *November* 1970. *Revised* 25 *April* 1971. *Accepted* 28 *June* 1971)

Summary—A two-step flow-coulometry method has been developed for rapid determination of elements (plutonium, iron, *etc*) which exist in various oxidation states in solution, and applied to the determination of plutonium in 0·5*M* sulphuric acid medium. The first-step column electrode potential is fixed at between +0·10 and +0·35 V *vs.* Ag–AgCl, and all plutonium ions are reduced to Pu(III). The second-step column electrode potential is fixed at +0·75 V *vs.* Ag–AgCl, and Pu(III) which flows from the first column electrode is oxidized to Pu(IV). The quantity of plutonium is determined from the number of coulombs used in the oxidation. It is possible to eliminate interference by diverse ions by electroanalysis at the first column electrode. About a 10-μl sample is necessary and the electrolysis for determination is finished in 1 min.

IT IS WELL KNOWN that plutonium has several oxidation states such as PuO_2^{2+}, PuO_2^{+}, Pu^{4+} and Pu^{3+} in aqueous solution (Pu^{4+} and Pu^{3+} are more stable than the others), and it is difficult to convert them into a single oxidation state by simple chemical procedures. Since plutonium is strongly poisonous, care must be taken in its handling (*e.g.* glove-box operation) and complex procedures are not practical in plutonium analyses.

In this work, the flow-coulometric method[1] has been applied to the determination of plutonium, and a two-step flow-coulometry method has been developed. Micro-amounts of plutonium can be determined precisely by this simple procedure. Plutonium solution (5–50 μl) is passed through the first-step column electrode, which is controlled at a proper potential in order to convert all plutonium into Pu^{3+} ions. The Pu^{3+} ions are passed through the second-step column electrode immediately; here, the working electrode potential is controlled so as to complete the electrode reaction:

$$\mathrm{Pu(III)} - e = \mathrm{Pu(IV)}.$$

The amount of plutonium is then obtained from the integration of the electrolytic current (number of coulombs) at the second-step column electrode:

$$\mathrm{Pu\ (mole)} = \frac{1}{96500}\int_0^\infty i\,\mathrm{d}t$$

where i denotes the oxidation current (A) at time t (sec). The procedure is rapid, and only one minute is required for the whole procedure, including sample injection, valency control at the first-step column electrode and the recording of an electrolytic current at the second-step column electrode. Furthermore, diverse ions which interfere with the determination of plutonium are eliminated at the first-step column electrode by reduction or oxidation.

In the determination of plutonium by electrochemical methods such as potentiometry,[2] coulometry,[3] polarography[4] and amperometry,[5] the oxidation states must be controlled just before the determination. In general, this behaviour of plutonium is a serious source of error in the micro-determination of plutonium. Two-step flow-coulometry, however, will easily be applicable to automatic determination of plutonium in remotely-controlled processes.

EXPERIMENTAL

Reagents

Plutonium. Plutonium metal from Nuclear Materials and Equipment Corporation, U.S.A. (isotopic composition; ^{239}Pu 91·3, ^{240}Pu 7·81, ^{241}Pu 0·85, ^{242}Pu 0·04 atom %) was dissolved in 0·5*M* sulphuric acid after electro-refining and weighing. Plutonium in this solution was expected to be present as a mixture of Pu^{3+}, Pu^{4+} and a small amount of PuO_2^{2+}.

Uranium. Uranium oxide (U_3O_8; Johnson Matthey Co., Ltd.) was dissolved in 6*M* nitric acid and the solution evaporated nearly to dryness. Then the residue was dissolved with small amounts of 0·5*M* sulphuric acid and evaporated almost to dryness. This procedure was repeated three times. The final sulphate solution was prepared by dissolving the residue in 0·5*M* sulphuric acid solution. Uranium in this solution was expected to be present as UO_2^{2+}.

All other reagents used were of extra-pure grade.

Apparatus

The electrolytic cell for two-step flow-coulometry is shown in Fig. 1 and is essentially the same as that described previously[6] except that two column electrodes are used, the distance between them being minimized, and the dispersion of a sample within the carrier solution being kept as small as possible. The glassy carbon counter electrode lasts longer than the silver one used in the previous work.[1] The glassy carbon counter electrodes, however, are not practical in the potential range where electrolysis of the counter electrode solution (saturated potassium chloride solution) takes place markedly. Saturated potassium chloride solution is more suitable for the counter electrode solution than is 0·5*M* sulphuric acid because the solubility of chlorine generated by anodic reaction in saturated potassium chloride solution is greater than that of oxygen generated by anodic reaction in 0·5*M* sulphuric acid.

The glassy carbon working electrode is pretreated as already described. The reference electrode is a saturated KCl–AgCl/Ag electrode (SSE).

Recommended procedure for the determination of plutonium

Pure nitrogen gas is passed through the supporting electrolyte (0·5*M* sulphuric acid) and plutonium sample solution. The supporting electrolyte is passed through the flow-coulometric column electrode at a flow-rate of 5 ± 0·5 ml/min, regulated by varying the height of the solution reservoir. The working potential of the first-column electrode (E_1) is adjusted to +0·35 V *vs.* SSE and that of the second-column electrode (E_2) to +0·75 V *vs.* SSE. Then 10–50 μl of plutonium solution are injected into the supporting electrolyte stream. Plutonium is reduced to Pu(III) at E_1 and Pu(III) is oxidized to Pu(IV) at E_2. The current–time curve for oxidation at E_2 is recorded. The amount of plutonium is determined by integrating the current–time curve and converting the quantity of electricity into weight or concentration.

A blank correction is not needed for the determination of more than 1 μg of plutonium. The total time required for the determination of plutonium (sample injection to recording of current–time curve) is 10–40 sec, depending on the plutonium concentration.

RESULTS AND DISCUSSION

Preliminary studies using the Fe(II)/Fe(III) *couple*

Preliminary studies were made with the Fe(II)/Fe(III) couple as a simple system which has only two oxidation states in aqueous solution. The oxidation-reduction

potential of this couple is near that of the Pu(III)/Pu(IV) couple; the formal oxidation-reduction potentials of Fe(II)/Fe(III) and Pu(III)/Pu(IV) are +0·47 and +0·54 V *vs.* SSE, respectively, in 0·5M sulphuric acid at 25°.

The voltage *vs.* quantity of electricity curves (*E–Q* curves), for the Fe(II)/Fe(III) system in 0·5*M* sulphuric acid, are shown in Fig. 2. Ten μl of 0·02*M* Fe(III) in 0·5*M* sulphuric acid were injected into the carrier solution, *i.e.*, the supporting electrolyte of 0·5*M* sulphuric acid, with the potential at the first-step column electrode (E_1) not applied (open circuit). Curve 1 in Fig. 2 shows the reduction reaction from Fe(III) to Fe(II), on changing the working electrode potential at the second-step column electrode (E_2) from +0·70 to 0·00 V *vs.* SSE.

$$\text{Fe(III)} + e \rightarrow \text{Fe(II)} \quad \text{(Curve 1)}$$

Similarly, curve 2 shows the *E–Q* curve for the oxidation reaction:

$$\text{Fe(II)} - e \rightarrow \text{Fe(III)} \quad \text{(Curve 2)}$$

Curve 3 shows the *E–Q* curve for a mixed sample of 0·0094*M* Fe(III) and 0·0106*M* Fe(II) in 0·5*M* sulphuric acid solution.

From these three curves it is found that if E_1 is +0·10 V *vs.* SSE, Fe(III) ions in the sample solution are all reduced to Fe(II), and the quantity of electricity used in this

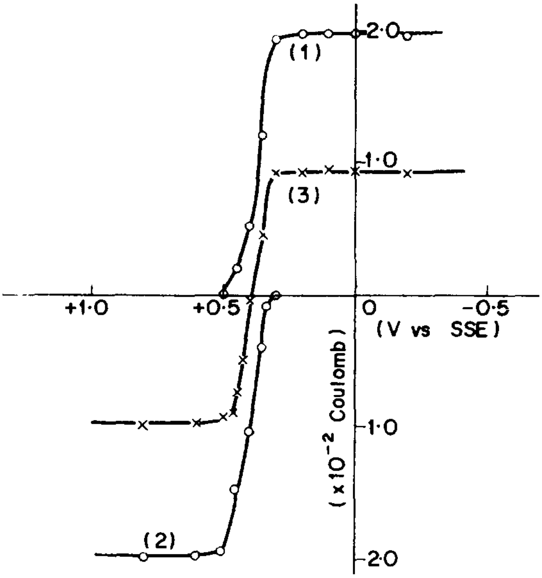

FIG. 2.—Coulomb-potential curves of iron.
Sample: (1) 2×10^{-7} mole Fe^{3+}, (2) 2×10^{-7} mole Fe^{2+}, (3) $0·94 \times 10^{-7}$ mole Fe^{3+}, $1·06 \times 10^{-7}$ mole Fe^{2+}.
Electrolyte: 0·5*M* H_2SO_4.
Flow-rate: 5 ml/min.

reaction is proportional to the amount of Fe(III) ions in the solution, and if E_1 is controlled to +0·65 V *vs.* SSE, Fe(II) ions in the sample solution are all oxidized to Fe(III), and the quantity of electricity for this reaction is proportional to the amount of Fe(II) ions in the solutions.

With the two column electrodes, E_1 is controlled to +0·10 V *vs.* SSE and E_2 to +0·65 V *vs.* SSE. The quantity of electricity used in the second step shows the total amount of iron in the sample solution. The reaction is then Fe(II) — $e \rightarrow$ Fe(III). Similarly, when E_1 is controlled to +0·65 and E_2 to +0·10 V *vs.* SSE, the electrolytic current at the second-step column electrode shows the total amount of iron at the sample solution but the reaction is Fe(III) + $e \rightarrow$ Fe(II). Since both of these reactions correspond to one-electron transfers, the absolute values of these two quantities of electricity are 0·0193 C for the 0·200 μ mole of iron taken.

Figures 3*a* and 3*b* show typical coulometry records. The electrolysis begins at the first-step column electrode 3 sec after sample injection, and after 6 sec it occurs at the second-step column electrode (the arrow shows the time of sample injection). About 50 sec are required to complete the electrolysis. Figure 3*a* shows the case where 10 μl of 0·02*M* Fe(III) are reduced at the first-step column electrode (curve 1) and that in which the Fe(II) reduced is oxidized to Fe(III) again at the second-step column electrode (curve 2). The quantities of electricity for these two electrochemical reactions are similar, and are equal to the theoretical value of 0·0193 C. Figure 3*b* shows 10 μl of sample solution, 0·0106*M* Fe(III) and 0·0094*M* Fe(II), reduced at the first-step electrode (E_1 = +0·10 V *vs.* SSE, curve 3) and then oxidized at the second-step electrode (E_2 = +0·65 V *vs.* SSE, curve 5). Curve 4 corresponds to the oxidation of

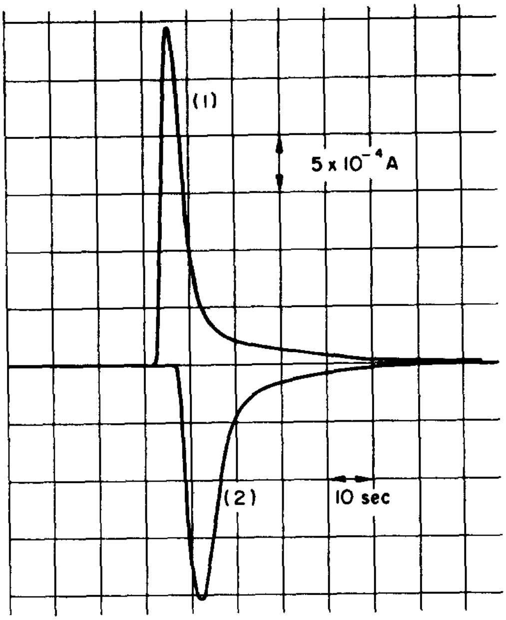

FIG. 3a.—Current-time curve recorded with 10 μl of 2·0 × $10^{-2}M$ Fe(III).

(Broken lines show oxidation or reduction precedes that of samples.)

the solution at the first-step electrode ($E_1 = +0{\cdot}65$ V *vs.* SSE). The sum of the integrated values of curves 3 and 4 is equal to that of curve 5.

E–Q curves of various ions

The *E–Q* curves for the Cu(II)/Cu, U(VI)/U(IV), $\frac{1}{2}Cl_2/Cl^-$, Ce(IV)/Ce(III), Cr(VI)/Cr(III), Ni(II)/Ni, $\frac{1}{2}O_2/H_2O_2$ and $\frac{1}{2}O_2/OH^-$ reactions are shown in Fig. 4. Ten μl of $10^{-3}M$ solutions of various metal ions, chloride ion and hydrogen peroxide and 10 μl of air-saturated 0·5*M* sulphuric acid, were injected into the carrier solution (0·5*M* sulphuric acid), with E_1 not applied (open circuit) and *E–Q* curves were obtained by changing E_2. The broken lines show estimated *E–Q* curves because the reduction or oxidation reaction of the elements is preceded by that of the solvent. The oxidation states of iron and plutonium samples were adjusted previously by controlled potential electrolysis.

The *E–Q* curve of Cu(II)/Cu in 0·5*M* sulphuric acid is about 0·4 V more negative than that of the Fe(III)/Fe(II) couple, as shown in Fig. 4. Therefore copper ions do not interfere with the determinations of iron mentioned above. If E_1 is controlled to +0·65 V *vs.* SSE and E_2 to —0·25 V *vs.* SSE, the total amount of iron plus copper ions can be obtained. The difference of these two results (at $E_2 = +0{\cdot}10$ V and $E_2 =$ —0·25 V) gives the amount of copper ions. The amounts of iron and copper ions could be determined without mutual interference.

Coulometry of plutonium

Figure 4 shows that the cathodic and anodic reactions of the Pu(III)/Pu(IV) couple are both about 0·1 V more positive than those for the Fe(II)/Fe(III) couple. The *E–Q* curves for plutonium are shown in Fig. 5. Ten μl of $4{\cdot}18 \times 10^{-3}M$ plutonium [Pu(III) and Pu(IV) present] solution were used as the sample. Curve 1 shows the reduction reaction of Pu(IV) to Pu(III) on varying E_2 from +0·80 to —0·20 V *vs.*

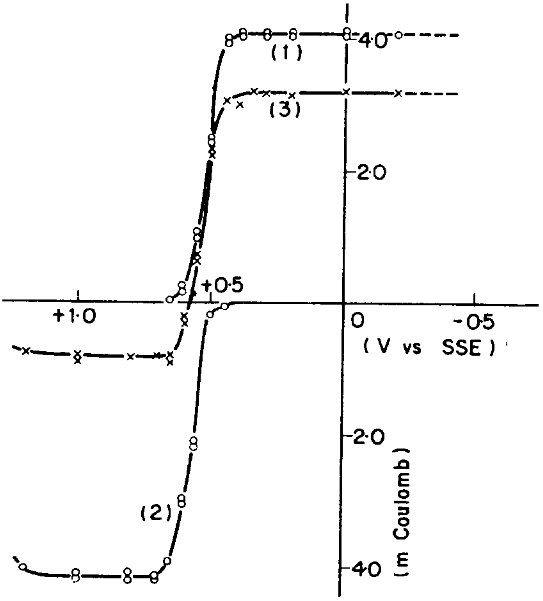

FIG. 5.—Coulomb-potential curves of plutonium.
Sample: 4·18 × 10^{-8} mole Pu.
Electrolyte: 0·5*M* H_2SO_4.
(1) Pu(IV) + *e* = Pu(III).
(2) Pu(III) − *e* = Pu(IV).
(3) Mixture of Pu(III) and Pu(IV).
(The solution was left for five months after dissolution of the plutonium metal.)

SSE. Pu(IV) was produced at the first-step column electrode when potential E_1 was controlled to +0·75 V *vs.* SSE.

$$\mathrm{Pu(IV)} + e \rightarrow \mathrm{Pu(III)} \quad \text{(Curve 1)}$$

Similarly, curve 2 shows the oxidation of Pu(III) to Pu(IV).

$$\mathrm{Pu(III)} - e \rightarrow \mathrm{Pu(IV)} \quad \text{(Curve 2)}$$

Pu(III) was produced at the first-step column electrode, the potential of which was controlled to +0·10 V *vs.* SSE. Curve 3 shows the oxidation and reduction reactions for the mixed solution of Pu(III) and Pu(IV) (a solution which had been left for five months after dissolution of the plutonium metal in 0·5*M* sulphuric acid) when E_1 is not applied (open circuit). It is found from curve 3 that the ratio of Pu(IV) to Pu(III) in this solution is nearly 3:1. In this connection, it is confirmed by comparing curve 3 with curve 2 in Fig. 5, that the presence of Pu(VI) is negligibly small in 0·5*M* sulphuric acid. The sum of the quantity of electricity (Q_3) for reduction at +0·35 V and oxidation at +0·75 V, in curve 3, is nearly equal to the quantity of electricity (Q_2) at +0·75 V in curve 2. If Pu(VI) is present, Q_3 should be larger than Q_2 because, at +0·35 V, Pu(VI) should be reduced to Pu(III) and hence a three-electron change should be involved. After controlled potential electrolysis at +0·75 V at a glassy carbon working electrode, the quantity of electricity used at +0·35 V is nearly equal to Q_2. Therefore, it is considered that the oxidation state of plutonium is Pu(IV) after

electrolysis at +0·75 V. The reason why Pu(VI) generated by the disproportionation reaction of Pu(IV) disappears is not clear, but it can be considered that the reduction of Pu(VI) by hydrogen peroxide[7] or α-ray direct reduction[8] and the enhanced complex-forming power of Pu(IV) with sulphate make Pu(VI) unstable. Hydrogen peroxide is generated by radiolysis of water[7] or reduction of dissolved oxygen by Pu(III).[9]

The results of the determination of plutonium by a method based on the information presented in Fig. 5 are summarized in Table I. It is seen that 0·1 μg (0·42 *p* mole) and above of plutonium can be determined within ±3%. This error may be due to an error in sampling and to the current integration procedure.

Elimination of interference by other ions in the determination of plutonium

From Fig. 4, when reducible substances co-exist in a potential range higher than +0·75 V *vs.* SSE, it is seen that plutonium can be determined by the second-step column electrode if $E_1 = +0·75$ and $E_2 = +0·35$ V *vs.* SSE. Similarly, when oxidizable substances co-exist in a potential range lower than +0·35 V *vs.* SSE, plutonium can be determined by the second-step column electrode if $E_1 = +0·35$ and $E_2 = +0·75$ V *vs.* SSE. The results of determination of diverse ions alone, and of plutonium in co-existence with these ions, are summarized in Table II, which shows that plutonium can be determined without interference by these elements.

Coulometric determination of plutonium in the presence of iron

As seen in Fig. 4, the oxidation-reduction potential of the Pu(III)/Pu(IV) couple is similar to that of the Fe(II)/Fe(III) couple, and it is difficult to determine plutonium in the presence of iron by ordinary electrolysis.

The E–Q curves of plutonium (curves 1, 1′) and iron (curves 2, 2′) are shown in Fig. 6. Curves 1 and 2 show the reduction reactions of Pu(IV) and Fe(III), respectively, at $E_1 = +0{\cdot}75$ V *vs.* SSE and varying E_2. Curves 1′ and 2′ show the oxidation reactions of Pu(III) and Fe(II), respectively, at $E_1 = +0{\cdot}10$ V *vs.* SSE and varying E_2. The determination of plutonium in the presence of iron was attempted by varying E_2 with E_1 controlled at +0·75 V *vs.* SSE. The results are shown in Table III. The error in determination is minimum at $E_2 = +0{\cdot}45$ V *vs.* SSE. For $E_2 = +0{\cdot}45$ V and $E_1 = +0{\cdot}75$ V *vs.* SSE, the effect of iron on the determination of plutonium is shown in Table IV. Plutonium in the presence of 6% of its weight of iron can be determined with an error of ±3%.

Differential determination of plutonium and uranium by coulometry

The determination of plutonium and uranium in mixtures is often important, especially when mixed oxides or carbides of plutonium and uranium are used as

nuclear fuels. After preliminary studies with plutonium and uranium as described above, a determination procedure for mixed plutonium and uranium oxides has been established. The procedure is as follows.

Determination of the Pu/(Pu + U) *ratio.* The mixed oxide sample (100 mg) is dissolved in 5 ml of 10*M* nitric acid plus 3 drops of 1*M* hydrofluoric acid in 10*M* nitric acid. The nitrate solution is evaporated to near dryness. To the residue are added 10 ml of 0·5*M* sulphuric acid, and the solution is evaporated almost to dryness, and the procedure is repeated three times. The final sample solution is prepared by dissolving the residue in 25 ml of 0·5*M* sulphuric acid, and deaerated by passage of pure nitrogen gas. Ten μl of this solution are taken, and plutonium and uranium determined by two-step flow-coulometry as follows.

Determination of plutonium. Plutonium in the solution is reduced to Pu(III) and uranium is

TABLE V.—DETERMINATION OF Pu/(Pu + U) RATIO

Sample nominal ratio, %	Pu found, *mg*	U found, *mg*	Pu/(Pu + U), %
25	21·8	65·5	25·0
	30·4	90·7	25·1
	22·1	66·2	25·1
30	33·3	82·2	28·8
	32·8	84·0	28·1
	32·8	80·1	29·0
33	24·3	49·8	32·8
	23·0	47·0	32·9

oxidized to U(VI) at the first-step column electrode (E_1 = +0·10 V). Pu(III) is then oxidized to Pu(IV) at the second-step column electrode (E_2 = +0·75 V). The amount of plutonium is determined from the quantity of electricity used at E_2. Uranium does not interfere in the determination of plutonium, as U(VI) is not oxidized at E_2.

Determination of uranium. Uranium in the solution is oxidized to U(VI) and plutonium is reduced to Pu(III) at E_1 = +0·10 V. U(VI) is then reduced to U(IV) at E_2 = −0·60 V. The amount of uranium is determined from the quantity of electricity used at E_2. Plutonium does not interfere with the determination of uranium as Pu(III) is not reduced at E_2.

In this procedure, +0·10 V is used for E_1 but a range from +0·35 to +0·10 V *vs.* SSE is permissible for E_1.

The quantity of electricity used at the second-step column electrode is calculated in terms of weight, and the Pu/(Pu + U) ratio is determined. The results of the determination by this procedure are summarized in Table V.

Determinations are reproducible to within ±3% and blank corrections are not needed for more than 1 μg of plutonium and more than 10 μg of uranium. The sampling by micro-syringe (10 μl) is done with a reproducibility of ±0·1 μl and the current–time curve is integrated with a reproducibility of ±1% for more than 500 mm^2.

CONCLUSION

Two-step flow-coulometry is effective for determination of not only plutonium but also other ionic species which have various oxidation states and are not stable in solution. The method is also applicable to metal ions giving metal as reduction product, *e.g.*, copper. Therefore the method is useful in the differential analysis of mixed samples containing couples with oxidation-reduction potentials close to each other. The size of sample required is small and the method is easily used in remote-control operations. It is expected that successive determination of several elements can be achieved by increasing the number of steps (*i.e.*, columns) used.

Acknowledgement—The authors wish to thank Mr. T. Honda of Japan Atomic Energy Research Institute for his suggestions and the supply of glassy carbon, and Dr. H. Onishi for his helpful advice. The samples of mixed oxides were prepared at the Plutonium Fuel Laboratory in the Japan Atomic Energy Research Institute.

Zusammenfassung—Ein zweistufiges durchflußcoulometrisches Verfahren wurde entwickelt, das zur schnellen Bestimmung von Elementen (Plutonium, Eisen usw.) dient, die in Lösung in verschiedenen Oxidationsstufen vorliegen. Das Verfahren wurde auf die Bestimmung von Plutonium in $0.5M$ Schwefelsäure angewandt. Das Elektrodenpotential in der Säule der ersten Stufe wird zwischen +0·10 und +0·35 V gegen Ag–AgCl festgelegt; hier werden alle Plutoniumionen zu Pu(III) reduziert. Das Elektrodenpotential in der Säule der zweiten Stufe wird bei +0·75 V gegen Ag–AgCl fixiert; hier wird das Pu(III), das von der Elektrode der ersten Säule kommt, zu Pu(IV) oxidiert. Die Plutoniummenge wird aus der bei der Oxidation verbrauchten Anzahl Coulomb bestimmt. Störungen durch verschiedene Ionen können durch Elektroanalyse an der Elektrode der ersten Säule beseitigt werden. Man braucht eine Probe von etwa 10 μl; die Elektrolyse für eine Bestimmung ist in 1 min beendet.

Résumé—On a élaboré une méthode de coulométrie par écoulement à deux temps pour le dosage rapide d'éléments (plutonium, fer, etc.) qui existent à divers stades d'oxydation en solution, et on l'a appliquée au dosage du plutonium en milieu acide sulfurique $0{,}5M$. Le potentiel d'électrode de colonne du premier temps est fixé entre +0,10 et +0,35 V par rapport à Ag–AgCl, et tous les ions plutonium sont réduits à l'état Pu(III). Le potentiel d'électrode de colonne du second temps est fixé à +0,75 V par rapport à Ag–AgCl, et le Pu(III) qui s'écoule de la première électrode de colonne est oxydé en Pu(IV). La quantité de plutonium est déterminée à partir du nombre de coulombs consommés dans l'oxydation. Il est possible d'éliminer l'interférence de divers ions par électroanalyse à la première électrode de colonne. La prise d'essai nécessaire est d'environ 10 μl et l'électroanalyse pour le dosage est terminée en 1 mn.

(*Received* 12 *November* 1970. *Revised* 25 *April* 1971. *Accepted* 28 *June* 1971)

Summary—A two-step flow-coulometry method has been developed for rapid determination of elements (plutonium, iron, *etc*) which exist in various oxidation states in solution, and applied to the determination of plutonium in 0·5*M* sulphuric acid medium. The first-step column electrode potential is fixed at between +0·10 and +0·35 V *vs.* Ag–AgCl, and all plutonium ions are reduced to Pu(III). The second-step column electrode potential is fixed at +0·75 V *vs.* Ag–AgCl, and Pu(III) which flows from the first column electrode is oxidized to Pu(IV). The quantity of plutonium is determined from the number of coulombs used in the oxidation. It is possible to eliminate interference by diverse ions by electroanalysis at the first column electrode. About a 10-μl sample is necessary and the electrolysis for determination is finished in 1 min.

IT IS WELL KNOWN that plutonium has several oxidation states such as PuO_2^{2+}, PuO_2^{+}, Pu^{4+} and Pu^{3+} in aqueous solution (Pu^{4+} and Pu^{3+} are more stable than the others), and it is difficult to convert them into a single oxidation state by simple chemical procedures. Since plutonium is strongly poisonous, care must be taken in its handling (*e.g.* glove-box operation) and complex procedures are not practical in plutonium analyses.

In this work, the flow-coulometric method[1] has been applied to the determination of plutonium, and a two-step flow-coulometry method has been developed. Micro-amounts of plutonium can be determined precisely by this simple procedure. Plutonium solution (5–50 μl) is passed through the first-step column electrode, which is controlled at a proper potential in order to convert all plutonium into Pu^{3+} ions. The Pu^{3+} ions are passed through the second-step column electrode immediately; here, the working electrode potential is controlled so as to complete the electrode reaction:

$$\mathrm{Pu(III)} - e = \mathrm{Pu(IV)}.$$

The amount of plutonium is then obtained from the integration of the electrolytic current (number of coulombs) at the second-step column electrode:

$$\mathrm{Pu\ (mole)} = \frac{1}{96500}\int_0^\infty i\,\mathrm{d}t$$

where i denotes the oxidation current (A) at time t (sec). The procedure is rapid, and only one minute is required for the whole procedure, including sample injection, valency control at the first-step column electrode and the recording of an electrolytic current at the second-step column electrode. Furthermore, diverse ions which interfere with the determination of plutonium are eliminated at the first-step column electrode by reduction or oxidation.

In the determination of plutonium by electrochemical methods such as potentiometry,[2] coulometry,[3] polarography[4] and amperometry,[5] the oxidation states must be controlled just before the determination. In general, this behaviour of plutonium is a serious source of error in the micro-determination of plutonium. Two-step flow-coulometry, however, will easily be applicable to automatic determination of plutonium in remotely-controlled processes.

EXPERIMENTAL

Reagents

Plutonium. Plutonium metal from Nuclear Materials and Equipment Corporation, U.S.A. (isotopic composition; ^{239}Pu 91·3, ^{240}Pu 7·81, ^{241}Pu 0·85, ^{242}Pu 0·04 atom %) was dissolved in 0·5*M* sulphuric acid after electro-refining and weighing. Plutonium in this solution was expected to be present as a mixture of Pu^{3+}, Pu^{4+} and a small amount of PuO_2^{2+}.

Uranium. Uranium oxide (U_3O_8; Johnson Matthey Co., Ltd.) was dissolved in 6*M* nitric acid and the solution evaporated nearly to dryness. Then the residue was dissolved with small amounts of 0·5*M* sulphuric acid and evaporated almost to dryness. This procedure was repeated three times. The final sulphate solution was prepared by dissolving the residue in 0·5*M* sulphuric acid solution. Uranium in this solution was expected to be present as UO_2^{2+}.

All other reagents used were of extra-pure grade.

Apparatus

The electrolytic cell for two-step flow-coulometry is shown in Fig. 1 and is essentially the same as that described previously[6] except that two column electrodes are used, the distance between them being minimized, and the dispersion of a sample within the carrier solution being kept as small as possible. The glassy carbon counter electrode lasts longer than the silver one used in the previous work.[1] The glassy carbon counter electrodes, however, are not practical in the potential range where electrolysis of the counter electrode solution (saturated potassium chloride solution) takes place markedly. Saturated potassium chloride solution is more suitable for the counter electrode solution than is 0·5*M* sulphuric acid because the solubility of chlorine generated by anodic reaction in saturated potassium chloride solution is greater than that of oxygen generated by anodic reaction in 0·5*M* sulphuric acid.

The glassy carbon working electrode is pretreated as already described. The reference electrode is a saturated KCl–AgCl/Ag electrode (SSE).

Recommended procedure for the determination of plutonium

Pure nitrogen gas is passed through the supporting electrolyte (0·5*M* sulphuric acid) and plutonium sample solution. The supporting electrolyte is passed through the flow-coulometric column electrode at a flow-rate of 5 ± 0·5 ml/min, regulated by varying the height of the solution reservoir. The working potential of the first-column electrode (E_1) is adjusted to +0·35 V *vs.* SSE and that of the second-column electrode (E_2) to +0·75 V *vs.* SSE. Then 10–50 μl of plutonium solution are injected into the supporting electrolyte stream. Plutonium is reduced to Pu(III) at E_1 and Pu(III) is oxidized to Pu(IV) at E_2. The current–time curve for oxidation at E_2 is recorded. The amount of plutonium is determined by integrating the current–time curve and converting the quantity of electricity into weight or concentration.

A blank correction is not needed for the determination of more than 1 μg of plutonium. The total time required for the determination of plutonium (sample injection to recording of current–time curve) is 10–40 sec, depending on the plutonium concentration.

RESULTS AND DISCUSSION

Preliminary studies using the Fe(II)/Fe(III) *couple*

Preliminary studies were made with the Fe(II)/Fe(III) couple as a simple system which has only two oxidation states in aqueous solution. The oxidation-reduction

potential of this couple is near that of the Pu(III)/Pu(IV) couple; the formal oxidation-reduction potentials of Fe(II)/Fe(III) and Pu(III)/Pu(IV) are +0·47 and +0·54 V *vs.* SSE, respectively, in 0·5M sulphuric acid at 25°.

The voltage *vs.* quantity of electricity curves (*E–Q* curves), for the Fe(II)/Fe(III) system in 0·5*M* sulphuric acid, are shown in Fig. 2. Ten μl of 0·02*M* Fe(III) in 0·5*M* sulphuric acid were injected into the carrier solution, *i.e.*, the supporting electrolyte of 0·5*M* sulphuric acid, with the potential at the first-step column electrode (E_1) not applied (open circuit). Curve 1 in Fig. 2 shows the reduction reaction from Fe(III) to Fe(II), on changing the working electrode potential at the second-step column electrode (E_2) from +0·70 to 0·00 V *vs.* SSE.

$$\mathrm{Fe(III)} + e \rightarrow \mathrm{Fe(II)} \quad \text{(Curve 1)}$$

Similarly, curve 2 shows the *E–Q* curve for the oxidation reaction:

$$\mathrm{Fe(II)} - e \rightarrow \mathrm{Fe(III)} \quad \text{(Curve 2)}$$

Curve 3 shows the *E–Q* curve for a mixed sample of 0·0094*M* Fe(III) and 0·0106*M* Fe(II) in 0·5*M* sulphuric acid solution.

From these three curves it is found that if E_1 is +0·10 V *vs.* SSE, Fe(III) ions in the sample solution are all reduced to Fe(II), and the quantity of electricity used in this

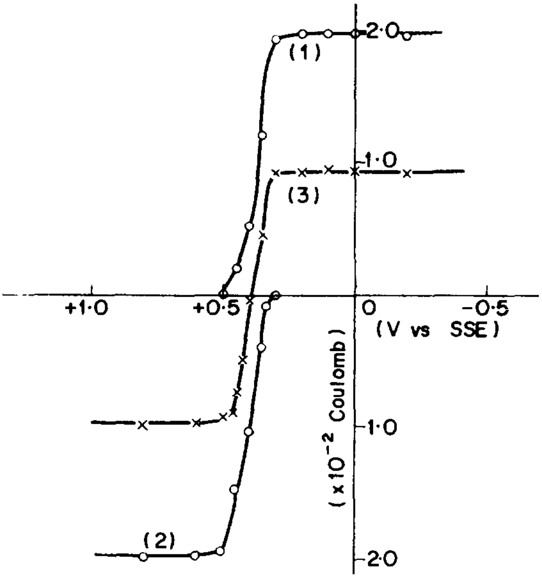

FIG. 2.—Coulomb-potential curves of iron.
Sample: (1) 2 × 10^{-7} mole Fe^{3+}, (2) 2 × 10^{-7} mole Fe^{2+}, (3) 0·94 × 10^{-7} mole Fe^{3+}, 1·06 × 10^{-7} mole Fe^{2+}.
Electrolyte: 0·5*M* H_2SO_4.
Flow-rate: 5 ml/min.

reaction is proportional to the amount of Fe(III) ions in the solution, and if E_1 is controlled to +0·65 V *vs*. SSE, Fe(II) ions in the sample solution are all oxidized to Fe(III), and the quantity of electricity for this reaction is proportional to the amount of Fe(II) ions in the solutions.

With the two column electrodes, E_1 is controlled to +0·10 V *vs*. SSE and E_2 to +0·65 V *vs*. SSE. The quantity of electricity used in the second step shows the total amount of iron in the sample solution. The reaction is then Fe(II) $- e \rightarrow$ Fe(III). Similarly, when E_1 is controlled to +0·65 and E_2 to +0·10 V *vs*. SSE, the electrolytic current at the second-step column electrode shows the total amount of iron at the sample solution but the reaction is Fe(III) $+ e \rightarrow$ Fe(II). Since both of these reactions correspond to one-electron transfers, the absolute values of these two quantities of electricity are 0·0193 C for the 0·200 μ mole of iron taken.

Figures 3*a* and 3*b* show typical coulometry records. The electrolysis begins at the first-step column electrode 3 sec after sample injection, and after 6 sec it occurs at the second-step column electrode (the arrow shows the time of sample injection). About 50 sec are required to complete the electrolysis. Figure 3*a* shows the case where 10 μl of 0·02*M* Fe(III) are reduced at the first-step column electrode (curve 1) and that in which the Fe(II) reduced is oxidized to Fe(III) again at the second-step column electrode (curve 2). The quantities of electricity for these two electrochemical reactions are similar, and are equal to the theoretical value of 0·0193 C. Figure 3*b* shows 10 μl of sample solution, 0·0106*M* Fe(III) and 0·0094*M* Fe(II), reduced at the first-step electrode (E_1 = +0·10 V *vs*. SSE, curve 3) and then oxidized at the second-step electrode (E_2 = +0·65 V *vs*. SSE, curve 5). Curve 4 corresponds to the oxidation of

the solution at the first-step electrode ($E_1 = +0{\cdot}65$ V *vs.* SSE). The sum of the integrated values of curves 3 and 4 is equal to that of curve 5.

E–Q curves of various ions

The *E–Q* curves for the Cu(II)/Cu, U(VI)/U(IV), $\frac{1}{2}Cl_2/Cl^-$, Ce(IV)/Ce(III), Cr(VI)/Cr(III), Ni(II)/Ni, $\frac{1}{2}O_2/H_2O_2$ and $\frac{1}{4}O_2/OH^-$ reactions are shown in Fig. 4. Ten μl of $10^{-3}M$ solutions of various metal ions, chloride ion and hydrogen peroxide and 10 μl of air-saturated 0·5M sulphuric acid, were injected into the carrier solution (0·5M sulphuric acid), with E_1 not applied (open circuit) and *E–Q* curves were obtained by changing E_2. The broken lines show estimated *E–Q* curves because the reduction or oxidation reaction of the elements is preceded by that of the solvent. The oxidation states of iron and plutonium samples were adjusted previously by controlled potential electrolysis.

The *E–Q* curve of Cu(II)/Cu in 0·5M sulphuric acid is about 0·4 V more negative than that of the Fe(III)/Fe(II) couple, as shown in Fig. 4. Therefore copper ions do not interfere with the determinations of iron mentioned above. If E_1 is controlled to $+0{\cdot}65$ V *vs.* SSE and E_2 to $-0{\cdot}25$ V *vs.* SSE, the total amount of iron plus copper ions can be obtained. The difference of these two results (at $E_2 = +0{\cdot}10$ V and $E_2 = -0{\cdot}25$ V) gives the amount of copper ions. The amounts of iron and copper ions could be determined without mutual interference.

Coulometry of plutonium

Figure 4 shows that the cathodic and anodic reactions of the Pu(III)/Pu(IV) couple are both about 0·1 V more positive than those for the Fe(II)/Fe(III) couple. The *E–Q* curves for plutonium are shown in Fig. 5. Ten μl of $4{\cdot}18 \times 10^{-3}M$ plutonium [Pu(III) and Pu(IV) present] solution were used as the sample. Curve 1 shows the reduction reaction of Pu(IV) to Pu(III) on varying E_2 from $+0{\cdot}80$ to $-0{\cdot}20$ V *vs.*

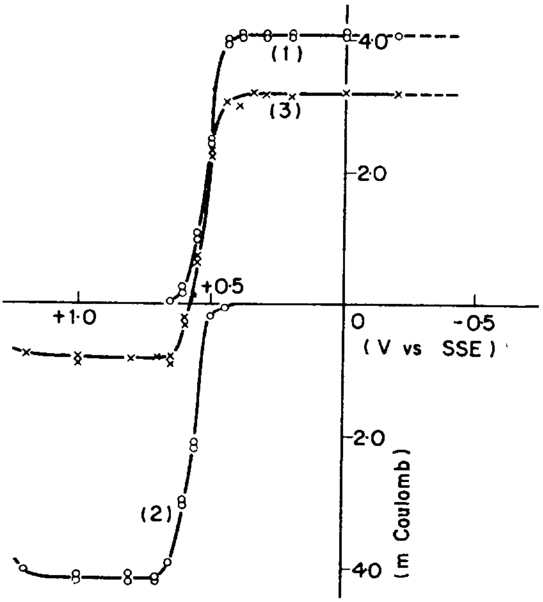

FIG. 5.—Coulomb-potential curves of plutonium.
Sample: 4·18 × 10^{-8} mole Pu.

(1) Pu(IV) + *e* = Pu(III).
(2) Pu(III) − *e* = Pu(IV).
(3) Mixture of Pu(III) and Pu(IV).
(The solution was left for five months after dissolution of the plutonium metal.)

SSE. Pu(IV) was produced at the first-step column electrode when potential E_1 was controlled to +0·75 V *vs.* SSE.

$$\text{Pu(IV)} + e \rightarrow \text{Pu(III)} \quad \text{(Curve 1)}$$

Similarly, curve 2 shows the oxidation of Pu(III) to Pu(IV).

$$\text{Pu(III)} - e \rightarrow \text{Pu(IV)} \quad \text{(Curve 2)}$$

Pu(III) was produced at the first-step column electrode, the potential of which was controlled to +0·10 V *vs.* SSE. Curve 3 shows the oxidation and reduction reactions for the mixed solution of Pu(III) and Pu(IV) (a solution which had been left for five months after dissolution of the plutonium metal in 0·5*M* sulphuric acid) when E_1 is not applied (open circuit). It is found from curve 3 that the ratio of Pu(IV) to Pu(III) in this solution is nearly 3:1. In this connection, it is confirmed by comparing curve 3 with curve 2 in Fig. 5, that the presence of Pu(VI) is negligibly small in 0·5*M* sulphuric acid. The sum of the quantity of electricity (Q_3) for reduction at +0·35 V and oxidation at +0·75 V, in curve 3, is nearly equal to the quantity of electricity (Q_2) at +0·75 V in curve 2. If Pu(VI) is present, Q_3 should be larger than Q_2 because, at +0·35 V, Pu(VI) should be reduced to Pu(III) and hence a three-electron change should be involved. After controlled potential electrolysis at +0·75 V at a glassy carbon working electrode, the quantity of electricity used at +0·35 V is nearly equal to Q_2. Therefore, it is considered that the oxidation state of plutonium is Pu(IV) after

electrolysis at +0·75 V. The reason why Pu(VI) generated by the disproportionation reaction of Pu(IV) disappears is not clear, but it can be considered that the reduction of Pu(VI) by hydrogen peroxide[7] or α-ray direct reduction[8] and the enhanced complex-forming power of Pu(IV) with sulphate make Pu(VI) unstable. Hydrogen peroxide is generated by radiolysis of water[7] or reduction of dissolved oxygen by Pu(III).[9]

The results of the determination of plutonium by a method based on the information presented in Fig. 5 are summarized in Table I. It is seen that 0·1 μg (0·42 *p* mole) and above of plutonium can be determined within ±3%. This error may be due to an error in sampling and to the current integration procedure.

Elimination of interference by other ions in the determination of plutonium

From Fig. 4, when reducible substances co-exist in a potential range higher than +0·75 V *vs.* SSE, it is seen that plutonium can be determined by the second-step column electrode if $E_1 = +0·75$ and $E_2 = +0·35$ V *vs.* SSE. Similarly, when oxidizable substances co-exist in a potential range lower than +0·35 V *vs.* SSE, plutonium can be determined by the second-step column electrode if $E_1 = +0·35$ and $E_2 = +0·75$ V *vs.* SSE. The results of determination of diverse ions alone, and of plutonium in co-existence with these ions, are summarized in Table II, which shows that plutonium can be determined without interference by these elements.

Coulometric determination of plutonium in the presence of iron

As seen in Fig. 4, the oxidation-reduction potential of the Pu(III)/Pu(IV) couple is similar to that of the Fe(II)/Fe(III) couple, and it is difficult to determine plutonium in the presence of iron by ordinary electrolysis.

The E–Q curves of plutonium (curves 1, 1′) and iron (curves 2, 2′) are shown in Fig. 6. Curves 1 and 2 show the reduction reactions of Pu(IV) and Fe(III), respectively, at $E_1 = +0{\cdot}75$ V *vs.* SSE and varying E_2. Curves 1′ and 2′ show the oxidation reactions of Pu(III) and Fe(II), respectively, at $E_1 = +0{\cdot}10$ V *vs.* SSE and varying E_2. The determination of plutonium in the presence of iron was attempted by varying E_2 with E_1 controlled at +0·75 V *vs.* SSE. The results are shown in Table III. The error in determination is minimum at $E_2 = +0{\cdot}45$ V *vs.* SSE. For $E_2 = +0{\cdot}45$ V and $E_1 = +0{\cdot}75$ V *vs.* SSE, the effect of iron on the determination of plutonium is shown in Table IV. Plutonium in the presence of 6% of its weight of iron can be determined with an error of ±3%.

Differential determination of plutonium and uranium by coulometry

The determination of plutonium and uranium in mixtures is often important, especially when mixed oxides or carbides of plutonium and uranium are used as

nuclear fuels. After preliminary studies with plutonium and uranium as described above, a determination procedure for mixed plutonium and uranium oxides has been established. The procedure is as follows.

Determination of the Pu/(Pu + U) *ratio.* The mixed oxide sample (100 mg) is dissolved in 5 ml of 10*M* nitric acid plus 3 drops of 1*M* hydrofluoric acid in 10*M* nitric acid. The nitrate solution is evaporated to near dryness. To the residue are added 10 ml of 0·5*M* sulphuric acid, and the solution is evaporated almost to dryness, and the procedure is repeated three times. The final sample solution is prepared by dissolving the residue in 25 ml of 0·5*M* sulphuric acid, and deaerated by passage of pure nitrogen gas. Ten μl of this solution are taken, and plutonium and uranium determined by two-step flow-coulometry as follows.

Determination of plutonium. Plutonium in the solution is reduced to Pu(III) and uranium is

TABLE V.—DETERMINATION OF Pu/(Pu + U) RATIO

Sample nominal ratio, %	Pu found, *mg*	U found, *mg*	Pu/(Pu + U), %
25	21·8	65·5	25·0
	30·4	90·7	25·1
	22·1	66·2	25·1
30	33·3	82·2	28·8
	32·8	84·0	28·1
	32·8	80·1	29·0
33	24·3	49·8	32·8
	23·0	47·0	32·9

oxidized to U(VI) at the first-step column electrode (E_1 = +0·10 V). Pu(III) is then oxidized to Pu(IV) at the second-step column electrode (E_2 = +0·75 V). The amount of plutonium is determined from the quantity of electricity used at E_2. Uranium does not interfere in the determination of plutonium, as U(VI) is not oxidized at E_2.

Determination of uranium. Uranium in the solution is oxidized to U(VI) and plutonium is reduced to Pu(III) at E_1 = +0·10 V. U(VI) is then reduced to U(IV) at E_2 = −0·60 V. The amount of uranium is determined from the quantity of electricity used at E_2. Plutonium does not interfere with the determination of uranium as Pu(III) is not reduced at E_2.

In this procedure, +0·10 V is used for E_1 but a range from +0·35 to +0·10 V *vs.* SSE is permissible for E_1.

The quantity of electricity used at the second-step column electrode is calculated in terms of weight, and the Pu/(Pu + U) ratio is determined. The results of the determination by this procedure are summarized in Table V.

Determinations are reproducible to within ±3% and blank corrections are not needed for more than 1 μg of plutonium and more than 10 μg of uranium. The sampling by micro-syringe (10 μl) is done with a reproducibility of ±0·1 μl and the current-time curve is integrated with a reproducibility of ±1% for more than 500 mm^2.

CONCLUSION

Two-step flow-coulometry is effective for determination of not only plutonium but also other ionic species which have various oxidation states and are not stable in solution. The method is also applicable to metal ions giving metal as reduction product, *e.g.*, copper. Therefore the method is useful in the differential analysis of mixed samples containing couples with oxidation-reduction potentials close to each other. The size of sample required is small and the method is easily used in remote-control operations. It is expected that successive determination of several elements can be achieved by increasing the number of steps (*i.e.*, columns) used.

Acknowledgement—The authors wish to thank Mr. T. Honda of Japan Atomic Energy Research Institute for his suggestions and the supply of glassy carbon, and Dr. H. Onishi for his helpful advice. The samples of mixed oxides were prepared at the Plutonium Fuel Laboratory in the Japan Atomic Energy Research Institute.

Zusammenfassung—Ein zweistufiges durchflußcoulometrisches Verfahren wurde entwickelt, das zur schnellen Bestimmung von Elementen (Plutonium, Eisen usw.) dient, die in Lösung in verschiedenen Oxidationsstufen vorliegen. Das Verfahren wurde auf die Bestimmung von Plutonium in 0.5*M* Schwefelsäure angewandt. Das Elektrodenpotential in der Säule der ersten Stufe wird zwischen +0·10 und +0·35 V gegen Ag–AgCl festgelegt; hier werden alle Plutoniumionen zu Pu(III) reduziert. Das Elektrodenpotential in der Säule der zweiten Stufe wird bei +0·75 V gegen Ag–AgCl fixiert; hier wird das Pu(III), das von der Elektrode der ersten Säule kommt, zu Pu(IV) oxidiert. Die Plutoniummenge wird aus der bei der Oxidation verbrauchten Anzahl Coulomb bestimmt. Störungen durch verschiedene Ionen können durch Elektroanalyse an der Elektrode der ersten Säule beseitigt werden. Man braucht eine Probe von etwa 10 μl; die Elektrolyse für eine Bestimmung ist in 1 min beendet.

Résumé—On a élaboré une méthode de coulométrie par écoulement à deux temps pour le dosage rapide d'éléments (plutonium, fer, etc.) qui existent à divers stades d'oxydation en solution, et on l'a appliquée au dosage du plutonium en milieu acide sulfurique 0,5*M*. Le potentiel d'électrode de colonne du premier temps est fixé entre +0,10 et +0,35 V par rapport à Ag–AgCl, et tous les ions plutonium sont réduits à l'état Pu(III). Le potentiel d'électrode de colonne du second temps est fixé à +0,75 V par rapport à Ag–AgCl, et le Pu(III) qui s'écoule de la première électrode de colonne est oxydé en Pu(IV). La quantité de plutonium est déterminée à partir du nombre de coulombs consommés dans l'oxydation. Il est possible d'éliminer l'interférence de divers ions par électroanalyse à la première électrode de colonne. La prise d'essai nécessaire est d'environ 10 μl et l'électroanalyse pour le dosage est terminée en 1 mn.

RAPID ANALYSIS OF FERTILIZERS BY THE DIRECT-READING THERMOMETRIC METHOD

ISTVÁN SAJÓ and B. SIPOS
Research Institute for Ferrous Metallurgy, Budapest, Hungary

(*Received* 4 *December* 1970. *Revised* 10 *September* 1971. *Accepted* 2 *November* 1971)

Summary—The authors have developed rapid methods for the determination of the main components of fertilizers, namely phosphate, potassium and nitrogen fixed in various forms. In the absence of magnesium ions phosphate is precipitated with magnesia mixture; in the presence of magnesium ions ammonium phosphomolybdate is precipitated and the excess of molybdate is reacted with hydrogen peroxide. Potassium is determined by precipitation with silicofluoride. For nitrogen fixed as ammonium salts the ammonium ions are condensed in a basic solution with formalin to hexamethylenetetramine; for nitrogen fixed as carbamide the latter is decomposed with sodium nitrite; for nitrogen fixed as nitrate the latter is reduced with titanium(III). In each case the temperature change of the test solution is measured. Practically all essential components of fertilizers may be determined by direct-reading thermometry; with this method and special apparatus the time of analysis is reduced to at most about 15 min for any determination.

IN DIRECT thermometric analysis a reagent is added to the test solution which reacts selectively with the component in question, and a substantial heat of reaction accompanies the reaction. The temperature variation of the test-solution due to the addition of the reagent is measured, after the reaction is completed. If the reagent is added in excess to the test-solution and the heat-capacity of the system is constant, the temperature variation of the test solution is directly proportional to the concentration of the component in question.[1,2,3] Therefore the concentration of that component can be determined from a single measured value: the temperature change in the sample solution. The results are evaluated either from calibration curves or by direct reading in percentage if the apparatus is built and calibrated for direct-reading thermometric analysis.[4]

The concentration of the dissolved substances may be determined by this method in general within a period of 4–10 min. This method may therefore be used to advantage in the analysis of substances which can be rapidly brought into solution, since if preparation of the test solution is lengthy there cannot be a substantial reduction of the total time of analysis, however rapid the determination itself. In the case of fertilizers the test solutions for the determination of the various components are easily and rapidly prepared and that is why the thermometric method may be used to advantage in the rapid analysis of fertilizers. The test solution does not permit any substantial reduction of the total time of analysis, however rapid the determination itself. In the case of fertilizers the test solutions for the determination of the various components are easily and rapidly prepared and that is why the thermometric method may be used to advantage in the rapid analysis of fertilizers.

EXPERIMENTAL

Equipment and working procedure

In this work we use the same equipment and working procedure described in connection with the analysis of plating baths.[2,4]

Determination of water-soluble P_2O_5 *content*

Principle. Phosphate is precipitated with magnesia mixture as the compound magnesium ammonium phosphate; the temperature change due to the heat of precipitation is measured.

Reagents. Hydrochloric acid, sp. gr. 1·12. Ammonium chloride, solid. Potassium oxalate solution, 30%. Ammonia solution, sp. gr. 0·91. Magnesia mixture. Dissolve 1000 g of $MgCl_2{\cdot}6H_2O$ in 3500 ml of water and add 1000 g of ammonium chloride and 200 ml of ammonia.

Procedure. Pulverize the sample in a porcelain mortar; weigh 10 g of the prepared sample into a 400-ml Stohmann flask, add 400 ml of distilled water and shake vigorously for 30 min on a shaker. Fill up to the mark and mix; filter the solution, discarding the first 20–30 ml of the filtrate, transfer by pipette 100 ml of the filtrate into a 400-ml beaker, add 3 ml of hydrochloric acid, 10 g of ammonium chloride and 5 ml of potassium oxalate solution, neutralize with ammonia, add 5 ml excess of ammonia and dilute to 200 ml with distilled water. Adjust the temperature of this test solution to 1° below the temperature of the measuring cell, place the solution in the measuring cell, add 15 ml of magnesia mixture as reagent and complete the analysis according to the general working procedure. Evaluate the results with the aid of a calibration curve prepared by use of samples of known P_2O_5 content.

If the analysis is carried out in a system without heat of dilution or with compensation of the heat of dilution by a suitable arrangement of the measuring device, the P_2O_5 content can be read directly in percentage on the sensing instrument fitted with a suitable shunt.

The method may be used to determine a water-soluble P_2O_5 content of 3–40% with an error of ±0·3% P_2O_5. One determination takes 10–12 min after preparation of the test solution.

The method may also be used for the determination of the P_2O_5 content of dicalcium phosphate. In this case, however, the sample is dissolved in 100 ml of 0·4*M* hydrochloric acid (for a 1-g sample) and 10 ml of potassium oxalate solution are added to it. The procedure is then the same.

Magnesium in the sample interferes, and in that case an indirect method is used.

Indirect rapid determination of the P_2O_5 *content*

Principle. Phosphate is precipitated with an exactly measured amount of ammonium molybdate solution as ammonium phosphomolybdate; the excess of molybdate is reacted with hydrogen peroxide and the temperature change measured. It is not necessary to filter off the precipitate since the molybdic acid bound in the ammonium phosphomolybdate does not react with hydrogen peroxide.[5]

Reagents. Nitric acid, sp. gr. 1·2. Hydrogen peroxide, 30%. Ammonium molybdate solution. Dissolve 1000 g of ammonium nitrate in 1000 ml of water and heat to 80°. Heat 3000 ml of nitric acid (sp.gr. 1·2) to 80°, pour the ammonium nitrate solution into the nitric acid, and add a solution of 220 g of ammonium molybdate in 1500 ml water which has also been heated previously to 80°. After mixing allow to cool slowly; after two days filter off any precipitate and use the filtrate for analysis.

Procedure. Prepare an aqueous solution of the fertilizer as for the P_2O_5 determination, transfer 10 ml by pipette into a 500-ml beaker, add 40 ml of nitric acid and heat to boiling. To the hot solution add from a burette or pipette an exactly measured 50 ml of molybdate solution. Heat the solution to 80° and stir vigorously at this temperature for 3 min. Cool the solution, transfer it to a 200-ml volumetric flask and dilute to the mark with distilled water. Adjust the initial temperature of the solution to 0·5° below the temperature of the measuring cell, place the solution in the measuring cell, add 5 ml of hydrogen peroxide as reagent and measure the temperature change. Evaluate the results with a calibration curve.

The method may be used to determine a P_2O_5 content of 1–20%; for higher P_2O_5 content the sample weight should be reduced.

The method may be used not only for the determination of the water-soluble P_2O_5 content but also for determining the phosphate content of crude ores used in the production of fertilizers; in this case the phosphate should be brought into solution previously by a treatment with sulphuric or nitric acid.

Determination of the potassium content

It is most convenient to precipitate the potassium as the hexafluorosilicate.[6]

Reagents. Hydrochloric acid, (1 + 1). Hydrofluoric acid, 40%. Precipitating agent. Weigh 100 g of finely powdered silica gel or voluminous precipitated silicic acid into a 2000-ml plastic flask. Slurry with 200 ml of distilled water and add 50 ml of hydrochloric acid (1 + 1). Cool the flask with cold water, add 650 ml of hydrofluoric acid in small portions and leave the mixture until the silica is dissolved.

Procedure. Weigh 20 g of finely powdered fertilizer into a 250-ml volumetric flask, add 200 ml of distilled water and shake the flask vigorously. After 10–15 min, when the potassium salts are dissolved, dilute to volume with distilled water. Mix, filter through a fluted filter, discard the first 10–20 ml of filtrate, transfer 50 ml of filtrate by pipette into a 200-ml polyethylene beaker, add 30 ml of hydrochloric acid and 2 ml of hydrofluoric acid, transfer to a plastic volumetric flask or measuring cylinder and dilute to 200 ml with distilled water. Adjust the initial temperature of the solution to 0·5° below the ambient temperature, place the solution in the measuring cell, add 15 ml of precipitating agent from a platinum or plastic immersion pipette and finish the analysis according to the general working procedure. Evaluate the results with a calibration curve prepared with fertilizers of known potassium oxide content. Direct reading is also possible, as for water-soluble P_2O_5.

The method may be used to determine a K_2O content of 2–40%, on a 20-g sample, with an error of ±0·3% K_2O. One determination takes 20–25 min.

Determination of nitrogen fixed as carbamide

Principle. When carbamide reacts in an acid solution with sodium nitrite it is decomposed with a substantial heat of reaction.

Reagents. Hydrochloric acid, sp.gr. 1·12. Potassium nitrite solution. Saturate a 20% potassium nitrite solution with ammonium sulphate, remove the undissolved ammonium sulphate by filtering and use the filtrate as reagent.

Procedure. Prepare the test solution as described for P_2O_5. Take 50 ml of filtrate by pipette, add 30 ml of hydrochloric acid, filter into a 200-ml volumetric flask and dilute to the mark. Adjust the initial temperature of this test solution to 0·5° below the temperature of the measuring cell. Place the solution in the measuring cell, add 15 ml of potassium nitrite reagent and complete the analysis according to the general working procedure. The reaction does not occur instantaneously, but is completed within about 3 min after addition of the reagent. Evaluate the results with a calibration curve prepared with fertilizer samples of known carbamide content or with model solutions.

A carbamide nitrogen content of 1–20% can be determined in 15 min with an error of ±0·1% N_2. When the nitrite reagent is added to the test solution nitrous gases are formed. Therefore the measuring cell should be placed in a fume cupboard.

Determination of nitrogen fixed as ammonium salts

Principle. Ammonium ions are condensed with formalin in basic solution to hexa-methylenetetramine, with a substantial heat of reaction.

Reagents. Sodium hydroxide solution, 10%. Formalin solution, 20%.

Procedure. Prepare the stock sample solution as before. Transfer 50 ml by pipette into a 200-ml volumetic flask and dilute to the mark with distilled water. Adjust the temperature of this test solution to 0·5° below that of the measuring dell, place the solution in the measuring cell, let the temperature differences equalize, add 10 ml of sodium hydroxide solution, wait for 1 min, then compensate the measuring bridge to adjust the galvanometer pointer to zero. Add 10 ml of formalin solution as reagent and measure the temperature change. Evaluate the results as usual.

The method may be used to determine 1–20% nitrogen fixed as ammonium salts, in 10–15 min, with an error of ±0·2% N_2.

Determination of nitrogen fixed as nitrate

Principle. Nitrate is reduced in acid solution with a mixture of titanium trichloride and stannous chloride and the temperature change is measured.

Reagents. Hydrochloric acid, sp.gr. 1·12. Reducing mixture. Mix 75 ml of 30% titanium trichloride solution with 25 ml of 50% stannous chloride solution.

Procedure. Transfer 50 ml of the stock sample solution by a pipette into a 200-ml volumetric flask, add 10 g of carbamide and 100 ml of hydrochloric acid and dilute to volume with distilled water. Adjust the temperature of this test solution to 0·5° below the temperature of the measuring cell, place the solution in the measuring cell, add 15 ml of the reducing mixture and complete the analysis according to the general working procedure.

A 1–30% nitrate nitrogen content can be determined in 15 min with an error of 0·2% N_2.

RESULTS

Typical results are shown in Tables I and II. The errors quoted above are based on over 100 comparison analyses.

RAPID ANALYSIS OF FERTILIZERS BY THE DIRECT-READING THERMOMETRIC METHOD

ISTVÁN SAJÓ and B. SIPOS
Research Institute for Ferrous Metallurgy, Budapest, Hungary

(*Received* 4 *December* 1970. *Revised* 10 *September* 1971. *Accepted* 2 *November* 1971)

Summary—The authors have developed rapid methods for the determination of the main components of fertilizers, namely phosphate, potassium and nitrogen fixed in various forms. In the absence of magnesium ions phosphate is precipitated with magnesia mixture; in the presence of magnesium ions ammonium phosphomolybdate is precipitated and the excess of molybdate is reacted with hydrogen peroxide. Potassium is determined by precipitation with silicofluoride. For nitrogen fixed as ammonium salts the ammonium ions are condensed in a basic solution with formalin to hexamethylenetetramine; for nitrogen fixed as carbamide the latter is decomposed with sodium nitrite; for nitrogen fixed as nitrate the latter is reduced with titanium(III). In each case the temperature change of the test solution is measured. Practically all essential components of fertilizers may be determined by direct-reading thermometry; with this method and special apparatus the time of analysis is reduced to at most about 15 min for any determination.

IN DIRECT thermometric analysis a reagent is added to the test solution which reacts selectively with the component in question, and a substantial heat of reaction accompanies the reaction. The temperature variation of the test-solution due to the addition of the reagent is measured, after the reaction is completed. If the reagent is added in excess to the test-solution and the heat-capacity of the system is constant, the temperature variation of the test solution is directly proportional to the concentration of the component in question.[1,2,3] Therefore the concentration of that component can be determined from a single measured value: the temperature change in the sample solution. The results are evaluated either from calibration curves or by direct reading in percentage if the apparatus is built and calibrated for direct-reading thermometric analysis.[4]

The concentration of the dissolved substances may be determined by this method in general within a period of 4–10 min. This method may therefore be used to advantage in the analysis of substances which can be rapidly brought into solution, since if preparation of the test solution is lengthy there cannot be a substantial reduction of the total time of analysis, however rapid the determination itself. In the case of fertilizers the test solutions for the determination of the various components are easily and rapidly prepared and that is why the thermometric method may be used to advantage in the rapid analysis of fertilizers. The test solution does not permit any substantial reduction of the total time of analysis, however rapid the determination itself. In the case of fertilizers the test solutions for the determination of the various components are easily and rapidly prepared and that is why the thermometric method may be used to advantage in the rapid analysis of fertilizers.

EXPERIMENTAL

Equipment and working procedure

In this work we use the same equipment and working procedure described in connection with the analysis of plating baths.[2,4]

Determination of water-soluble P_2O_5 *content*

Principle. Phosphate is precipitated with magnesia mixture as the compound magnesium ammonium phosphate; the temperature change due to the heat of precipitation is measured.

Reagents. Hydrochloric acid, sp. gr. 1·12. Ammonium chloride, solid. Potassium oxalate solution, 30%. Ammonia solution, sp. gr. 0·91. Magnesia mixture. Dissolve 1000 g of $MgCl_2 \cdot 6H_2O$ in 3500 ml of water and add 1000 g of ammonium chloride and 200 ml of ammonia.

Procedure. Pulverize the sample in a porcelain mortar; weigh 10 g of the prepared sample into a 400-ml Stohmann flask, add 400 ml of distilled water and shake vigorously for 30 min on a shaker. Fill up to the mark and mix; filter the solution, discarding the first 20–30 ml of the filtrate, transfer by pipette 100 ml of the filtrate into a 400-ml beaker, add 3 ml of hydrochloric acid, 10 g of ammonium chloride and 5 ml of potassium oxalate solution, neutralize with ammonia, add 5 ml excess of ammonia and dilute to 200 ml with distilled water. Adjust the temperature of this test solution to 1° below the temperature of the measuring cell, place the solution in the measuring cell, add 15 ml of magnesia mixture as reagent and complete the analysis according to the general working procedure. Evaluate the results with the aid of a calibration curve prepared by use of samples of known P_2O_5 content.

If the analysis is carried out in a system without heat of dilution or with compensation of the heat of dilution by a suitable arrangement of the measuring device, the P_2O_5 content can be read directly in percentage on the sensing instrument fitted with a suitable shunt.

The method may be used to determine a water-soluble P_2O_5 content of 3–40% with an error of $\pm 0{\cdot}3\%$ P_2O_5. One determination takes 10–12 min after preparation of the test solution.

The method may also be used for the determination of the P_2O_5 content of dicalcium phosphate. In this case, however, the sample is dissolved in 100 ml of 0·4*M* hydrochloric acid (for a 1-g sample) and 10 ml of potassium oxalate solution are added to it. The procedure is then the same.

Magnesium in the sample interferes, and in that case an indirect method is used.

Indirect rapid determination of the P_2O_5 *content*

Principle. Phosphate is precipitated with an exactly measured amount of ammonium molybdate solution as ammonium phosphomolybdate; the excess of molybdate is reacted with hydrogen peroxide and the temperature change measured. It is not necessary to filter off the precipitate since the molybdic acid bound in the ammonium phosphomolybdate does not react with hydrogen peroxide.[5]

Reagents. Nitric acid, sp. gr. 1·2. Hydrogen peroxide, 30%. Ammonium molybdate solution. Dissolve 1000 g of ammonium nitrate in 1000 ml of water and heat to 80°. Heat 3000 ml of nitric acid (sp.gr. 1·2) to 80°, pour the ammonium nitrate solution into the nitric acid, and add a solution of 220 g of ammonium molybdate in 1500 ml water which has also been heated previously to 80°. After mixing allow to cool slowly; after two days filter off any precipitate and use the filtrate for analysis.

Procedure. Prepare an aqueous solution of the fertilizer as for the P_2O_5 determination, transfer 10 ml by pipette into a 500-ml beaker, add 40 ml of nitric acid and heat to boiling. To the hot solution add from a burette or pipette an exactly measured 50 ml of molybdate solution. Heat the solution to 80° and stir vigorously at this temperature for 3 min. Cool the solution, transfer it to a 200-ml volumetric flask and dilute to the mark with distilled water. Adjust the initial temperature of the solution to 0·5° below the temperature of the measuring cell, place the solution in the measuring cell, add 5 ml of hydrogen peroxide as reagent and measure the temperature change. Evaluate the results with a calibration curve.

The method may be used to determine a P_2O_5 content of 1–20%; for higher P_2O_5 content the sample weight should be reduced.

The method may be used not only for the determination of the water-soluble P_2O_5 content but also for determining the phosphate content of crude ores used in the production of fertilizers; in this case the phosphate should be brought into solution previously by a treatment with sulphuric or nitric acid.

Determination of the potassium content

It is most convenient to precipitate the potassium as the hexafluorosilicate.[6]

Reagents. Hydrochloric acid, (1 + 1). Hydrofluoric acid, 40%. Precipitating agent. Weigh 100 g of finely powdered silica gel or voluminous precipitated silicic acid into a 2000-ml plastic flask. Slurry with 200 ml of distilled water and add 50 ml of hydrochloric acid (1 + 1). Cool the flask with cold water, add 650 ml of hydrofluoric acid in small portions and leave the mixture until the silica is dissolved.

Procedure. Weigh 20 g of finely powdered fertilizer into a 250-ml volumetric flask, add 200 ml of distilled water and shake the flask vigorously. After 10–15 min, when the potassium salts are dissolved, dilute to volume with distilled water. Mix, filter through a fluted filter, discard the first 10–20 ml of filtrate, transfer 50 ml of filtrate by pipette into a 200-ml polyethylene beaker, add 30 ml of hydrochloric acid and 2 ml of hydrofluoric acid, transfer to a plastic volumetric flask or measuring cylinder and dilute to 200 ml with distilled water. Adjust the initial temperature of the solution to 0·5° below the ambient temperature, place the solution in the measuring cell, add 15 ml of precipitating agent from a platinum or plastic immersion pipette and finish the analysis according to the general working procedure. Evaluate the results with a calibration curve prepared with fertilizers of known potassium oxide content. Direct reading is also possible, as for water-soluble P_2O_5.

The method may be used to determine a K_2O content of 2–40%, on a 20-g sample, with an error of ±0·3% K_2O. One determination takes 20–25 min.

Determination of nitrogen fixed as carbamide

Principle. When carbamide reacts in an acid solution with sodium nitrite it is decomposed with a substantial heat of reaction.

Reagents. Hydrochloric acid, sp.gr. 1·12. Potassium nitrite solution. Saturate a 20% potassium nitrite solution with ammonium sulphate, remove the undissolved ammonium sulphate by filtering and use the filtrate as reagent.

Procedure. Prepare the test solution as described for P_2O_5. Take 50 ml of filtrate by pipette, add 30 ml of hydrochloric acid, filter into a 200-ml volumetric flask and dilute to the mark. Adjust the initial temperature of this test solution to 0·5° below the temperature of the measuring cell. Place the solution in the measuring cell, add 15 ml of potassium nitrite reagent and complete the analysis according to the general working procedure. The reaction does not occur instantaneously, but is completed within about 3 min after addition of the reagent. Evaluate the results with a calibration curve prepared with fertilizer samples of known carbamide content or with model solutions.

A carbamide nitrogen content of 1–20% can be determined in 15 min with an error of ±0·1% N_2.

When the nitrite reagent is added to the test solution nitrous gases are formed. Therefore the measuring cell should be placed in a fume cupboard.

Determination of nitrogen fixed as ammonium salts

Principle. Ammonium ions are condensed with formalin in basic solution to hexa-methylenetetramine, with a substantial heat of reaction.

Reagents. Sodium hydroxide solution, 10%. Formalin solution, 20%.

Procedure. Prepare the stock sample solution as before. Transfer 50 ml by pipette into a 200-ml volumetic flask and dilute to the mark with distilled water. Adjust the temperature of this test solution to 0·5° below that of the measuring dell, place the solution in the measuring cell, let the temperature differences equalize, add 10 ml of sodium hydroxide solution, wait for 1 min, then compensate the measuring bridge to adjust the galvanometer pointer to zero. Add 10 ml of formalin solution as reagent and measure the temperature change. Evaluate the results as usual.

The method may be used to determine 1–20% nitrogen fixed as ammonium salts, in 10–15 min, with an error of ±0·2% N_2.

Determination of nitrogen fixed as nitrate

Principle. Nitrate is reduced in acid solution with a mixture of titanium trichloride and stannous chloride and the temperature change is measured.

Reagents. Hydrochloric acid, sp.gr. 1·12. Reducing mixture. Mix 75 ml of 30% titanium trichloride solution with 25 ml of 50% stannous chloride solution.

Procedure. Transfer 50 ml of the stock sample solution by a pipette into a 200-ml volumetric flask, add 10 g of carbamide and 100 ml of hydrochloric acid and dilute to volume with distilled water. Adjust the temperature of this test solution to 0·5° below the temperature of the measuring cell, place the solution in the measuring cell, add 15 ml of the reducing mixture and complete the analysis according to the general working procedure.

A 1–30% nitrate nitrogen content can be determined in 15 min with an error of 0·2% N_2.

RESULTS

Typical results are shown in Tables I and II. The errors quoted above are based on over 100 comparison analyses.

CATALYTIC REACTIONS—II†

ACTIVATION

P. R. BONTCHEV

(*Received* 19 *May* 1971. *Accepted* 24 *October* 1971)

Summary—The activation of the homogeneous catalytic reactions used in analysis is discussed. The use of activators in catalytic methods permits increase in their sensitivity by 2–4 orders of magnitude and improvement in their selectivity as well. Many different mechanisms of activation are discussed and used as illustrations of the principles for choice of an appropriate activator.

THE MAIN ADVANTAGES that catalytic analysis offers to the analyst are a very high sensitivity and a relative simplicity of the methods used, there being no need for any special apparatus or technique. In many cases, however, the sensitivity of the catalytic methods is too far from maximal and even from the average level in catalytic analysis.

Most catalytic methods of analysis used so far have a sensitivity of the order of 10^{-7}–10^{-9} g/ml. In many cases the sensitivity is even 10^{-10}–10^{-12} g/ml, while for cadmium and lead, for example, it is about 10^{-6} g/ml.

In some other cases, *e.g.*, in reactions catalysed by alkaline earth elements, the catalytic activity shown by the metal ions is very low. This is the reason why catalytic analysis plays a very restricted role in their analytical chemistry and it seems that this situation will remain unchanged unless some new possibilities appear for enhancement of their catalytic activity.

Hence, in spite of the fact that on the whole catalytic analysis has a high average sensitivity, further increase in sensitivity is still a serious and real problem.

The rate of the so-called indicator reaction

$$X + Y \rightarrow P \tag{1}$$

in the presence of the catalyst M^{n+} is given by

$$\text{Rate} = \frac{dP}{dt} = \kappa[X]^p[Y]^q[M^{n+}]^r + k[X]^{p'}[Y]^{q'} \tag{2}$$

where κ is the rate constant of the catalytic reaction ("the catalytic constant"), k is the rate constant of the uncatalysed reaction, and p, q, r, p' and q' are coefficients determined by the reaction equation.

If the reaction scarcely proceeds in the absence of M^{n+}, equation (2) reduces to

$$\text{Rate} = \kappa[X]^p[Y]^q[M^{n+}]^r \tag{3}$$

The possibilities for increase in the reaction sensitivity follow from equations (2) and (3).

The lowest concentration of M^{n+} which can be determined by the use of reaction (1) depends on the lowest amount of the product P that can be estimated for a given

---

† Part I: *Talanta*, 1970, **17**, 499.

interval of time. The sensitivity of the catalytic method is therefore closely related to the method used for monitoring the reaction kinetics. The application of more sensitive methods for determination of the "indicator" substance P increases the sensitivity of the catalytic method.[1]

Thus the determination of S^{2-} based on the iodine-azide reaction was first realized with a sensitivity of the order of $\mu g/ml$, a volumetric technique being used for determination of the reaction product nitrogen.[2] The application of a colorimetric method for monitoring the reaction kinetics increased the sensitivity to 10^{-2} $\mu g/ml$,[3] and by the use of amperometric techniques the determination of sulphide in concentrations as low as 10^{-13} $\mu g/ml$ became possible.[4]

When colorimetric methods are used to follow the reaction kinetics, which is the most frequent case in catalytic analysis, the molar absorptivity of the indicator substance is of prime importance for the sensitivity of the procedure. In this connection the use of quinoidal products or of some dyes as indicator substances might be recommended for highly sensitive catalytic reactions (see Part I).

Another way to increase the catalytic constant and thus the reaction sensitivity, is to carry out the reaction at elevated temperatures. This possibility, however, cannot be used when the uncatalysed reaction also proceeds at a considerable rate at higher temperatures. In such case the rate of the catalytic reaction only is determined as a difference between two large values and the error of the determination becomes too large. There are not many examples of analytical catalytic reactions with low values of the uncatalysed reaction rate and for that reason procedures carried out at temperatures higher than 20–30° are not too common in catalytic analysis.[1]

The possibility that at present seems the most promising for further increase in the catalytic constant and therefore of the sensitivity of catalytic methods is the application of activators.

A review of the literature for the last 6–8 years shows that the most sensitive catalytic methods proposed in this period are connected with the development of the theory and practice of activation of homogeneous catalytic reactions.

By definition, an activator for a homogeneous catalytic reaction is "a substance which does not catalyse this reaction but strongly increases its rate in the presence of certain catalysts."[5]

The mechanism of the activator's action in the process may differ considerably depending on the role of the catalyst in the reaction, the character of the catalyst-activator interaction and the stage of the reaction directly affected by the presence of the activator. Taking into account these factors, activators can be classified into three groups:

(*a*) activators that affect the catalyst–substrate interaction
(*b*) activators that participate in the regeneration of the catalyst
(*c*) activators which act in an indirect way in the catalytic process.

Each will be discussed in turn.

The activator affects the catalyst–substrate interaction

When the catalyst participates in the process through a direct interaction with the substrate (see Part I) the first stage of the catalytic reaction is usually the formation of an intermediate complex M–S.† In this complex further transformations with the substrate take place, having as a final result the formation of the reaction products. In some cases such intermediate complexes have been identified by direct physical methods (EPR, spectral methods), but in many others their formation is assumed on the grounds of kinetic data only (see Part I).

The influence of the activator on this stage of the reaction might affect the formation of the complex M–S and/or its subsequent reactions. In both cases, however, complex formation between the catalyst and the activator is a necessary condition for the activation of the catalytic reaction. In the complex M–A the activator might influence in different ways the reactivity of M towards the reaction substrate.

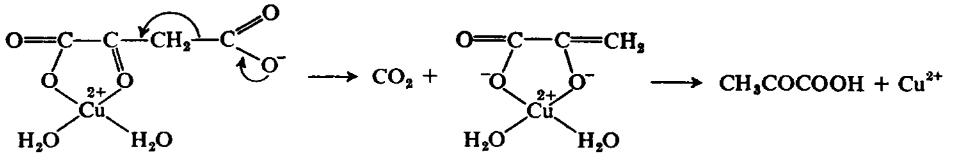
Thus if the activator in M–A can form hydrogen bonds with the substrate it might orient the catalyst and the substrate in a suitable position for the formation of the intermediate M–S. In such cases the activator must possess not only groups capable of keeping together the catalyst and the substrate but also an appropriate structure making possible the interaction of the bound reagents. It is considered, for example, that the activation effect of glycerol in oxidation reactions catalysed by vanadium(V) is of that type.[6] Ethylene glycol shows no effect on the reaction because there is no group in its molecule, co-ordinated to vanadium(V), capable for hydrogen bonding with the substrate, as is the case with the third hydroxyl group of glycerol.

Another example of that type of activation is the catalytic oxidation of aromatic compounds in the presence of Cu(II), activated by hydroxyl ions. According to Yatsimirskii[7] the activation effect is due to the covalent M—OH bond, leading to a more diffuse character of the catalyst's $d_{x^2-y^2}$ orbital and, therefore, to a greater overlap between this orbital and the corresponding filled π-orbitals of the substrate. At the same time the hydroxyl groups in $Cu(OH)_3^-$ and $Cu(OH)_4^{2-}$ can form hydrogen bonds with the aromatic substrate (usually an arylamine or phenol) and thus also can favour the catalyst–substrate complex formation.

Another reason for the activator's action in this stage of the process might be the increased polarization in the complex M–S when the activator is also included in the co-ordination sphere of the catalyst.

The catalytic activity of metal ions in hydrolytic and decarboxylation reactions is due to the polarization effect of the metal ion on the substrate molecule (see Part I).

For example, the decarboxylation of oxaloacetic acid proceeds in the presence of metal ion catalysts according to the scheme:



(4)

The metal ion catalyst weakens the bond HOOC—CH_2 as a result of the polarization. For this reason the catalytic effect is not a specific one and it might be expected that any increase of the effective charge of the catalyst should result in a higher catalytic activity.

† Here and later in the text M stands for the catalyst, S for the reaction substrate and A for the activator.

We have tried to increase the effective charge on the metal ion in this reaction and, therefore, its catalytic activity, by the use of suitable ligands as activators.[8] Two types of ligands were used for the purpose.

An activator with a lower basicity than the other species in the co-ordination sphere of the catalyst (the substrate and/or the solvent) will cause an increased effective charge on the metal ion. On the other hand, complex formation with such a ligand will take place only if its concentration is much higher than that of the substrate and any other ligands with a higher basicity present in the system.

We were able to demonstrate such an activation on the reaction of catalytic decarboxylation of oxalacetic acid in the presence of Cu^{2+} as a catalyst.[8] The catalytic reaction was carried out in the presence of relatively large amounts of organic oxygen containing solvents, soluble in water, such as ethanol, glycerol, butyric acid and dioxan. In these conditions water is partly displaced by the activator from the co-ordination sphere of Cu^{2+} and ternary complexes of the type catalyst–substrate–activator are formed as intermediates in the course of the catalytic reaction. The existence of copper(II) complexes with the activator in the reaction conditions was confirmed by the use of electronic and EPR spectra.[9]

The other type of ligands used to increase the effective charge of the metal ion catalyst were complexing agents, capable of forming $(M \rightarrow L)$ π-bonds with the catalyst. The formation of such bonds with the activator lowers the electron density on the metal ion catalyst and therefore might be expected to increase its effective charge.

Pyridine, having unoccupied π^* orbitals is a good π-acceptor and it was found[8] that in its presence the rate constant of the model catalytic reaction can be increased by a factor of nearly 8. An analogous effect was found by Rund and Plane[10] with 1,10-phenanthroline and tripyridyl in the decarboxylation of dimethyl oxaloacetate catalysed by Mn^{2+} and Ni^{2+}.

Some steric factors can also be taken into account for a further increase in the activation effect. A good example of this type is the use of 2-methylpyridine as activator in copper(II)-catalysed decarboxylation of oxaloacetic acid.[8] This activator not only increases the effective charge on the metal ion catalyst, but also favours the formation of catalyst–substrate complexes when substrate is being substituted for water and/or the activator in the catalyst co-ordination sphere.

The methyl group in the activator molecule causes steric hindrance in the plane of the square-planar catalyst complexes and thus lowers the energy barrier for the formation of the transition trigonal bipyramidal state. For that reason 2-methylpyridine shows a much higher activation effect than pyridine—it increases the rate constant of the model catalytic reaction by a factor of more than 26.

These investigations served as a basis for the use of decarboxylation reactions in catalytic analysis. Here the catalytic determination of metal ions with a filled outer electron shell must be mentioned first.

The ions of this type usually do not catalyse redox processes and their catalytic activity in hydrolytic and decarboxylation reactions is too low to be of any analytical interest. On the basis of the theoretical considerations above, it was possible to increase the catalytic activity of some of these ions sufficiently and to develop catalytic analytical methods for their determination. Thus in plant materials it was possible to determine catalytically total amounts as low as 5 μg of zinc,[11] 0·5 μg of aluminium,[12] and 50 μg of magnesium.[13]

The activator might also increase the rate of a catalytic reaction through another mechanism—affecting the rate of complex formation between the substrate and the catalyst.

This is, for example, the case with the activating effect of 8-hydroxyquinoline and its derivatives on the oxidation of arylamines by halates, catalysed by vanadium(V).[14] It was shown that in this reaction the activators strongly increase the rate of complex formation between the catalyst and the substrate—the first, rate-limiting step of the overall catalytic reaction. It is supposed that the reason for such action is the *trans*-effect they have on the co-ordination sphere of vanadium(V), in the *xy*-plane.

According to Chatt and Orgel[15] it might be expected that the stronger the electron-acceptor abilities of the ligand, the higher its *trans*-effect and hence its activation action. We have studied this correlation experimentally, varying the substituents in the activator molecule. Thus the presence of two electron-withdrawing groups ($-SO_3H$ and $-I$) in the molecule of 8-hydroxyquinoline strongly increases its electron-acceptor properties and the activation effect connected with them. The rate constant of the model catalytic reaction increases about 36 times when 5-sulpho-7-iodo-8-hydroxyquinoline is substituted for 8-hydroxyquinoline, as activator. The results of these investigations were used for development of a very sensitive method for determination of vanadium in plant materials (sensitivity 10^{-4} μg/ml).[16] Analogous effects were obtained when other electron-acceptors (1,10-phenanthroline, 2,2′-dipyridyl) were used as activators.[17]

Compounds with a system of conjugated π-bonds provide another possibility for activation of redox catalytic reactions. As was shown by Taube[18] such compounds can serve as a bridge between the reagents in electron-transfer reactions. The conjugated system provides a conductive path between the reagents, thus increasing the redox reaction rate. Such substances could be used, therefore, as activators for catalytic reactions where the rate-determining step is electron transfer in the catalyst–substrate interaction. The acceleration of vanadium(V)-catalysed redox reactions by phthalic acid could serve as an illustration of this type of activation.[6]

It must be pointed out that in all cases of activation discussed above, the dependence of the reaction rate on the activator concentration shows a maximum. This is due to the fact that at high activator concentrations the co-ordination sphere of the catalyst is fully occupied by the activator and any complexation with the substrate is prevented.

Nevertheless, in many cases such "blocking" of the co-ordination sphere does not result in a complete quenching of the catalytic activity. If the substitution process

$$MA_n + S \rightleftharpoons MA_{n-1}S + A \qquad (5)$$

proceeds with a measurable rate it will provide a certain concentration of catalyst–substrate complex and therefore some catalytic activity will be obtained. In such conditions the substitution of the activator by the substrate in the co-ordination sphere of the catalyst becomes the rate-limiting step of the overall catalytic reaction.

The existence of a maximum in the curve of reaction rate *vs.* activator concentration is a characteristic feature for all types of activated reactions when the activator action is connected with the formation of ternary complexes of the type A–M–S.

In some cases the activator's influence on the catalytic reaction might be due to a shift in an equilibrium with the participation of the catalyst. This is, for instance, the case with the activation effect of chloride ions on the catalytic decomposition of hydrogen peroxide in the presence of Cu^{2+}.[19]

According to Uri[20] the activation is due to a shift, to the right, of the equilibrium

$$Cu^{2+} + HO_2^- \rightleftharpoons Cu^+ + HO_2^\cdot \tag{6}$$

The overall reaction rate is determined by the position of the equilibrium process, the reactivity of $HO_2^\cdot$ being high enough. Chloride ions, forming more stable complexes with Cu^+ than with Cu^{2+} shift the equilibrium (6) to the right and hence accelerate the catalytic reaction.

A similar fact was found in the catalytic oxidation of arylamines, catalysed by vanadium(V).[21] Recently it was estimated that the highest catalytic activity amongst all ionic species of vanadium(V) is possessed by a form, stable in a very narrow pH-range, which is formed in the process of depolymerization of $H_2V_{10}O_{28}^{4-}$ to VO_2^+.[22] The presence of phosphates, which form complexes with vanadium, shifts the depolymerization equilibrium and thus an activation of the catalytic reaction is observed.[21]

An analogous fact was discovered by Kriss and Yatsimirskii who found that various phosphorus-containing ligands activate the vanadium(V)-catalysed oxidation of iodide by chlorates.[23]

The activator affects the regeneration of the catalyst

Most of the catalysts for homogeneous redox reactions are ions of transition elements that can exist in several oxidation states, *e.g.*, iron, manganese, vanadium, copper, silver. In many reactions of this type the catalyst participates in the process as a mediator for the redox interaction between the reagents, according to the following scheme

$$M^{(n+1)+} + S \rightarrow \text{Products} + M^{n+} \tag{7}$$

$$M^{n+} + Ox \rightarrow M^{(n+1)+} + \text{Red} \tag{8}$$

The catalyst acts by alternate oxidation-reduction steps, any of which can determine the overall reaction rate. Some reactions in which (7) is rate-limiting and which can be affected by activators were discussed in the previous paragraph. Here the cases where (8) determines the overall reaction rate, and therefore could be a means of activation, will be considered.

The theory of Marcus[24] can help to reveal the possibilities for activation of the metal ion–oxidant processes of type (8). According to the theory, for cases when in the transition state a small orbital overlap takes place between the reagents† the rate constant of a redox process is given by the equation

$$k = Z \,.\, \exp\left(-\frac{\Delta G^*}{RT}\right) \tag{9}$$

where Z is the collision number and ΔG^* is the free energy of activation. This last parameter is a function of the standard free energy change of the process, of the charges of the reacting particles, and of terms that account for the solvation of the

---

† It seems that for many cases of direct oxidation of metal ions by oxygen-containing anions this condition is fulfilled.[25]

reagents and the reaction products. Hence, the rate of a catalytic reaction might be increased with activators able to affect these three factors in an appropriate way.[25]

This possibility was demonstrated by the example of silver(I)-catalysed oxidation of sulphanilic acid by peroxydisulphate.[26] The investigations on the reaction mechanism have shown that the process proceeds in two stages, according to (7) and (8), the two oxidation states of the catalyst being Ag(I) and Ag(II) respectively.[27] The rate-determining step of the overall reaction is (8), *i.e.*, the oxidation of Ag(I) to Ag(II).

The application of the Marcus theory to this case has shown that if a neutral ligand capable of complexation with Ag(I) and Ag(II) is added, an acceleration of the process $\mathrm{Ag(I)} - e \rightarrow \mathrm{Ag(II)}$ might be expected. The main contribution to such an effect comes from the lowering of the high oxidation potential of the couple Ag(II)/Ag(I),† *i.e.*, of the free energy change of the process, the role of the other two factors being relatively smaller.

A complexant with nitrogen donors might be expected to cause such a lowering, *i.e.*, to form more stable complexes with Ag^{2+} than with Ag^+ because of the higher charge of Ag^{2+} and of the considerable crystal field stabilization energy (CFSE) for Ag^{2+}, while for Ag^+ CFSE = 0. Polydentate ligands are expected to exhibit a bigger effect, taking into account the difference between the structures of Ag^{2+} and Ag^+ complexes.[28,29]

In complexes with nitrogen-containing ligands Ag(I) has a co-ordination number of 2 and a linear structure of the complexes due to the small difference in energy between the 4*d* and 5*s* orbitals, while a co-ordination number of 4 and a square-planar structure is characteristic for the analogous Ag(II) complexes. The chelate effect can therefore also contribute to a further stabilization of the corresponding Ag(II) complexes. This effect can be still bigger if the polydentate ligand is a strong electron acceptor and can participate in $(M \rightarrow L)$ π-bond formation.

The validity of the theoretical considerations stated above is supported also by the data published in a series of experimental works by Yassinskene and co-workers, who proposed several analytical procedures for determination of silver with the use of nitrogen-containing ligands as activators.[30,31]

The lowering of the oxidation potential can play an important role in reactions where the free-energy change in the reoxidation of the catalyst is high enough to represent the main barrier in the reaction path.

Another mechanism of activation that can affect this stage of the catalytic reaction includes processes where the activator could serve as a matrix for an appropriate orientation of the reagents—the reduced form of the catalyst M^{n+} and the oxidant Ox.

Such a role of the activator could be of importance in cases where several structures of the activated complex $[M^{n+}\text{–}Ox]^*$ could be realized that differ in energy, and the thermodynamically preferred structure is not the most appropriate one for the oxidation process to proceed.[7]

Multidentate activators capable of complexation with M^{n+} and at the same time of forming hydrogen bonds with Ox, could facilitate the formation of the transition state necessary for the oxidation of M^{n+} and thus increase the overall reaction rate. A necessary condition for such an effect is that the structure of the activator must correspond to the inter-atomic distances in the activated complex.

---

† The standard oxidation potential of Ag^{2+}/Ag^+ is $\sim$2·0 V.

Examples of such activators are hydroxycarboxylic acids such as citric, tartaric, for vanadium(V)-catalysed oxidation reactions.[32,33]

Activation of this type is closely connected with the possibility of hydrogen-bonding between the activator and the oxidant. For that reason the activator is very sensitive to any change in its structure that can prevent the formation of such bonds. For example, esterification of the activator's hydroxy groups leads to complete quenching of the activation.[34]

The activator acts in an indirect way in the catalytic process

This group includes activators that participate in parallel processes which can affect the rate of the main catalytic reaction. A typical example of this type of activation is the effect shown by phenols on the catalytic oxidation of some arylamines.[35]

The catalytic oxidation of arylamines proceeds usually by a one-electron mechanism with the formation of free amino-radicals

$$M^{(n+1)+} + ArNH_2 \rightarrow M^{n+} + ArNH^{\cdot} + H^+ \tag{9}$$

which react further to form the final reaction products—quinone-imine compounds (see Part I).

In the presence of phenols an interaction takes place with the primarily formed imino-radicals[36,37]

$$ArOH + ArNH^{\cdot} \rightarrow ArO^{\cdot} + ArNH_2 \tag{10}$$

followed by recombination of $ArO^{\cdot}$ and $ArNH^{\cdot}$ with the formation of quinone-imines:

$$ArO^{\cdot} + ArNH^{\cdot} \rightarrow \text{quinone-imines} \tag{11}$$

Reactions (10) and (11) proceed very rapidly and the rate of quinone-imine formation increases as a result.

In some cases the product of the conjugated oxidation is identical with that of the non-activated reaction and then the term "activation" can be used for the observed increase of the reaction rate. However, as a rule, another quinone-imine compound is obtained in the presence of phenol. Because of the very small differences in the wavelengths of the absorption maxima of similar quinone-imines, the formation of a new reaction product in the presence of such "activators" is very often missed. In spite of the fact that the substrate is used up in the reaction at a higher rate, such cases could scarcely be considered as examples of activation, being in fact only an oxidative coupling.

Thus the oxidation of *p*-phenetidine with chlorate, catalysed by vanadium(V), gives *N*-(4-ethoxyphenyl)quinone-imine as a main oxidation product. The reaction can be activated by the addition of phenol, the product of the oxidative coupling being the same quinone-imine.[38] This activated reaction was used in a sensitive catalytic determination of vanadium.[35]

In the presence of other phenols (such as hydroquinone, catechol, resorcinol, naphthols) the rate of formation of the coloured product strongly increases and the solution seems to keep its red colour unchanged. In fact, chromatographic separation on aluminium oxide, combined with infrared spectral investigations, has shown that different quinone-imines are formed, which absorb in a relatively narrow region of the visible spectrum (500–530 nm).[39]

An analogous mechanism of activation was found[40] for the action of hydroxy- and polycarboxylic acids in arylamine oxidations catalysed by vanadium(V)[40] and chromium(VI).[41] These reactions proceed through a one-electron mechanism, the first, rate-limiting step of the process being the oxidation of the substrate by the catalyst with the formation of arylimino-radicals:

$$S + M^{(n+1)+} \xrightarrow{k_1} S^{\cdot} + M^{n+} \tag{12}$$

The radicals S· then react through recombination or further oxidation to the final reaction products (see Part I).

Hydroxy- and polycarboxylic acids are also oxidized easily by the catalysts to radicals, which then react with the substrate:

$$A + M^{(n+1)+} \xrightarrow{k_2} A^{\cdot} + M^{n+} \tag{13}$$

$$A^{\cdot} + S \xrightarrow{k_3} A \text{ (or } A') + S^{\cdot} \tag{14}$$

An activation effect could be obtained if $k_2 + k_3 > k_1$. Usually the oxidation of polydentate carboxylic acids, such as citric, tartaric, oxalic, proceeds faster than that of the substrates because of the stronger tendency of the catalysts vanadium and chromium for complexation with oxygen than with nitrogen.

The formation of the radicals A· was estimated experimentally.[40] The fact that they really react further with the substrate with the formation of the same reaction products was proved independently.[42] Radicals of type A· were obtained by a photochemical decomposition of trisoxalate iron(III) $Fe(Ox)_3^{3-}$ and their interaction with arylamine substrate studied. It was found that the reaction products thus formed are the same as those obtained when oxalic acid is used as activator.

The investigations on this type of activator served as a basis for development of highly sensitive analytical methods for determination of vanadium and chromium in different materials.[41,43]

In some cases the carboxylic acids used as activators can affect simultaneously several stages of the catalytic reaction through a different mechanism.

Thus the oxidation of *p*-phenetidine with halates, catalysed by vanadium(V), is activated by citric acid. The activator acts in two stages of the reaction: it accelerates the catalyst–substrate interaction through a radical mechanism[40] [according to (13) and (14)] and at the same time increases the rate of regeneration of the catalyst, serving as a matrix for the V(IV)–XO_3^- interaction.[42]

Oxalic acid is also used as an activator for the same reaction, but while a strong effect on the catalyst–substrate interaction is observed,[40] at the same time it acts as an inhibitor for the regeneration of the catalyst.[32] The influence on the first, rate-limiting, stage of the process results in the rates of both reaction stages becoming of the same order and hence the inhibition of the second stage is now of importance. For that reason the total effect of oxalic acid on the overall reaction rate is smaller than that of citric acid.[44]

Another attempt at explanation of the difference in the effect of citric and oxalic acids on the rate-limiting stage and on the overall reaction rate was made by means of molecular orbital theory and the electronic spectra of the catalyst–activator complex.[45] Here the influence of the activator on the second reaction stage was not taken into account at all, the discussion including only the rate-determining step. It was shown that the energy of the charge-transfer band of the complex $M^{(n+1)+}$–A could be used to predict qualitatively the possibility of activation and the order of the activating effect in cases where the activator is oxidized during the reaction, according to (13).

Higher sensitivity is not the only advantage that could be realized by the use of activators in catalytic analysis. Another possibility seems much more attractive—selection of an activator for a given catalytic reaction, that would increase the catalytic activity of the ion to be determined and at the same time quench the activity of other catalysts that can interfere. In such a case an improvement in sensitivity and selectivity could be accomplished simultaneously.

Such a possibility was first pointed out and experimentally realized in 1963 in a catalytic method for determination of vanadium in the presence of copper(II) and iron(III), which also catalyse the indicator reaction.[46] The addition of citric acid increases the sensitivity for vanadium(V) by about 15 times, the activity of both interfering ions being completely suppressed.

The catalytic determination of silver offers another example. Thus 25 μg of silver can be determined catalytically by the sulphanilic acid oxidation, copper(II) and iron(III) interfering in amounts $>0{\cdot}6$ μg and >10 μg respectively.[26] The use of 2,2′-dipyridyl permits the determination of 5×10^{-3} μg of silver (5000 times higher sensitivity) at the same time raising the levels at which copper(II) and iron(III) interfere to 10 and 100 μg respectively.[28] The presence of ethylenediamine increases the sensitivity for silver only 1000 times, but increases tolerance for copper(II) to 50 μg.[29]

It must be pointed out that so far only a few examples of simultaneous improvement of sensitivity and selectivity of catalytic reactions are known. In our opinion, however, this offers one of the most promising lines of research on application of activators in catalytic analysis.

The use of a combination of properly selected activators must also be mentioned as a prospective means of affecting a catalytic reaction. It was shown that sometimes the joint activating effect can be much higher than that of either activator alone.[47] Higher selectivity might also be expected, as shown by Kalinitchenko.[48] This work and other papers by the same author[49–51] are also interesting as examples of the use of activators in catalytic luminescence analysis. The simultaneous application of a system of activators is another promising field for research that could reveal new possibilities for further improvement of catalytic analytical methods.

CONCLUSION

The present paper does not pretend to cover all the data on activators and their application in catalytic analysis. Its aim is only to show the possibilities that the use of activators offers to the analyst, to discuss the mechanisms of their action and on that basis to show the way to select suitable activators for a given catalytic method. This, in our opinion, could help the further development and application of catalytic methods which are amongst the most sensitive modern analytical methods.

Zusammenfassung—Die Aktivierung der analytisch verwendeten homogenen katalytischen Reaktionen wird diskutiert. Die Verwendung von Aktivatoren bei katalytischen Methoden bringt einen Gewinn an Empfindlichkeit von 2–4 Größenordnungen und verbessert außerdem die Selektivität. Viele verschiedene Aktivierungsmechanismen werden diskutiert und als Beispiele für die Gesichtspunkte angeführt, nach denen man einen geeigneten Aktivator auswählt.

Résumé—On discute de l'activation de réactions catalytiques homogènes utilisées en analyse. L'emploi d'activeurs dans les méthodes catalytiques permet d'accroître leur sensibilité d'ordres de grandeur 2–4 et d'améliorer aussi bien leur sélectivité. On discute de nombreux mécanismes différents d'activation et les utilise comme illustration des principes pour le choix d'un activeur approprié.

CATALYTIC REACTIONS—II†

ACTIVATION

P. R. BONTCHEV

Department of Analytical Chemistry, University of Sofia,
1 Anton Ivanov Str., Sofia 26, Bulgaria

(*Received* 19 *May* 1971. *Accepted* 24 *October* 1971)

Summary—The activation of the homogeneous catalytic reactions used in analysis is discussed. The use of activators in catalytic methods permits increase in their sensitivity by 2–4 orders of magnitude and improvement in their selectivity as well. Many different mechanisms of activation are discussed and used as illustrations of the principles for choice of an appropriate activator.

THE MAIN ADVANTAGES that catalytic analysis offers to the analyst are a very high sensitivity and a relative simplicity of the methods used, there being no need for any special apparatus or technique. In many cases, however, the sensitivity of the catalytic methods is too far from maximal and even from the average level in catalytic analysis.

Most catalytic methods of analysis used so far have a sensitivity of the order of 10^{-7}–10^{-9} g/ml. In many cases the sensitivity is even 10^{-10}–10^{-12} g/ml, while for cadmium and lead, for example, it is about 10^{-6} g/ml.

In some other cases, *e.g.*, in reactions catalysed by alkaline earth elements, the catalytic activity shown by the metal ions is very low. This is the reason why catalytic analysis plays a very restricted role in their analytical chemistry and it seems that this situation will remain unchanged unless some new possibilities appear for enhancement of their catalytic activity.

Hence, in spite of the fact that on the whole catalytic analysis has a high average sensitivity, further increase in sensitivity is still a serious and real problem.

The rate of the so-called indicator reaction

$$X + Y \rightarrow P \tag{1}$$

in the presence of the catalyst M^{n+} is given by

$$\text{Rate} = \frac{dP}{dt} = \kappa[X]^p[Y]^q[M^{n+}]^r + k[X]^{p'}[Y]^{q'} \tag{2}$$

where κ is the rate constant of the catalytic reaction ("the catalytic constant"), k is the rate constant of the uncatalysed reaction, and p, q, r, p' and q' are coefficients determined by the reaction equation.

If the reaction scarcely proceeds in the absence of M^{n+}, equation (2) reduces to

$$\text{Rate} = \kappa[X]^p[Y]^q[M^{n+}]^r \tag{3}$$

The possibilities for increase in the reaction sensitivity follow from equations (2) and (3).

The lowest concentration of M^{n+} which can be determined by the use of reaction (1) depends on the lowest amount of the product P that can be estimated for a given

---

† Part I: *Talanta*, 1970, **17**, 499.

interval of time. The sensitivity of the catalytic method is therefore closely related to the method used for monitoring the reaction kinetics. The application of more sensitive methods for determination of the "indicator" substance P increases the sensitivity of the catalytic method.[1]

Thus the determination of S^{2-} based on the iodine-azide reaction was first realized with a sensitivity of the order of μg/ml, a volumetric technique being used for determination of the reaction product nitrogen.[2] The application of a colorimetric method for monitoring the reaction kinetics increased the sensitivity to 10^{-2} μg/ml,[3] and by the use of amperometric techniques the determination of sulphide in concentrations as low as 10^{-13} μg/ml became possible.[4]

When colorimetric methods are used to follow the reaction kinetics, which is the most frequent case in catalytic analysis, the molar absorptivity of the indicator substance is of prime importance for the sensitivity of the procedure. In this connection the use of quinoidal products or of some dyes as indicator substances might be recommended for highly sensitive catalytic reactions (see Part I).

Another way to increase the catalytic constant and thus the reaction sensitivity, is to carry out the reaction at elevated temperatures. This possibility, however, cannot be used when the uncatalysed reaction also proceeds at a considerable rate at higher temperatures. In such case the rate of the catalytic reaction only is determined as a difference between two large values and the error of the determination becomes too large. There are not many examples of analytical catalytic reactions with low values of the uncatalysed reaction rate and for that reason procedures carried out at temperatures higher than 20–30° are not too common in catalytic analysis.[1]

The possibility that at present seems the most promising for further increase in the catalytic constant and therefore of the sensitivity of catalytic methods is the application of activators.

A review of the literature for the last 6–8 years shows that the most sensitive catalytic methods proposed in this period are connected with the development of the theory and practice of activation of homogeneous catalytic reactions.

By definition, an activator for a homogeneous catalytic reaction is "a substance which does not catalyse this reaction but strongly increases its rate in the presence of certain catalysts."[5]

The mechanism of the activator's action in the process may differ considerably depending on the role of the catalyst in the reaction, the character of the catalyst-activator interaction and the stage of the reaction directly affected by the presence of the activator. Taking into account these factors, activators can be classified into three groups:

(*a*) activators that affect the catalyst–substrate interaction
(*b*) activators that participate in the regeneration of the catalyst
(*c*) activators which act in an indirect way in the catalytic process.

Each will be discussed in turn.

The activator affects the catalyst–substrate interaction

When the catalyst participates in the process through a direct interaction with the substrate (see Part I) the first stage of the catalytic reaction is usually the formation of an intermediate complex M–S.† In this complex further transformations with the substrate take place, having as a final result the formation of the reaction products. In some cases such intermediate complexes have been identified by direct physical methods (EPR, spectral methods), but in many others their formation is assumed on the grounds of kinetic data only (see Part I).

The influence of the activator on this stage of the reaction might affect the formation of the complex M–S and/or its subsequent reactions. In both cases, however, complex formation between the catalyst and the activator is a necessary condition for the activation of the catalytic reaction. In the complex M–A the activator might influence in different ways the reactivity of M towards the reaction substrate.

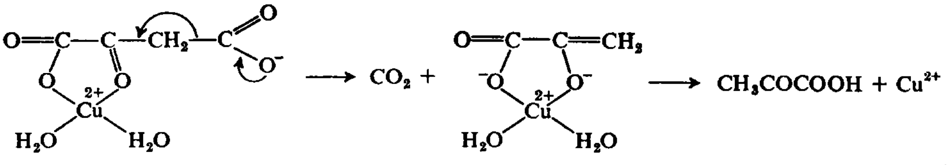
Thus if the activator in M–A can form hydrogen bonds with the substrate it might orient the catalyst and the substrate in a suitable position for the formation of the intermediate M–S. In such cases the activator must possess not only groups capable of keeping together the catalyst and the substrate but also an appropriate structure making possible the interaction of the bound reagents. It is considered, for example, that the activation effect of glycerol in oxidation reactions catalysed by vanadium(V) is of that type.[6] Ethylene glycol shows no effect on the reaction because there is no group in its molecule, co-ordinated to vanadium(V), capable for hydrogen bonding with the substrate, as is the case with the third hydroxyl group of glycerol.

Another example of that type of activation is the catalytic oxidation of aromatic compounds in the presence of Cu(II), activated by hydroxyl ions. According to Yatsimirskii[7] the activation effect is due to the covalent M—OH bond, leading to a more diffuse character of the catalyst's $d_{x^2-y^2}$ orbital and, therefore, to a greater overlap between this orbital and the corresponding filled π-orbitals of the substrate. At the same time the hydroxyl groups in $Cu(OH)_3^-$ and $Cu(OH)_4^{2-}$ can form hydrogen bonds with the aromatic substrate (usually an arylamine or phenol) and thus also can favour the catalyst–substrate complex formation.

Another reason for the activator's action in this stage of the process might be the increased polarization in the complex M–S when the activator is also included in the co-ordination sphere of the catalyst.

The catalytic activity of metal ions in hydrolytic and decarboxylation reactions is due to the polarization effect of the metal ion on the substrate molecule (see Part I).

For example, the decarboxylation of oxaloacetic acid proceeds in the presence of metal ion catalysts according to the scheme:



(4)

The metal ion catalyst weakens the bond HOOC—CH_2 as a result of the polarization. For this reason the catalytic effect is not a specific one and it might be expected that any increase of the effective charge of the catalyst should result in a higher catalytic activity.

---

† Here and later in the text M stands for the catalyst, S for the reaction substrate and A for the activator.

We have tried to increase the effective charge on the metal ion in this reaction and, therefore, its catalytic activity, by the use of suitable ligands as activators.[8] Two types of ligands were used for the purpose.

An activator with a lower basicity than the other species in the co-ordination sphere of the catalyst (the substrate and/or the solvent) will cause an increased effective charge on the metal ion. On the other hand, complex formation with such a ligand will take place only if its concentration is much higher than that of the substrate and any other ligands with a higher basicity present in the system.

We were able to demonstrate such an activation on the reaction of catalytic decarboxylation of oxalacetic acid in the presence of Cu^{2+} as a catalyst.[8] The catalytic reaction was carried out in the presence of relatively large amounts of organic oxygen containing solvents, soluble in water, such as ethanol, glycerol, butyric acid and dioxan. In these conditions water is partly displaced by the activator from the co-ordination sphere of Cu^{2+} and ternary complexes of the type catalyst–substrate–activator are formed as intermediates in the course of the catalytic reaction. The existence of copper(II) complexes with the activator in the reaction conditions was confirmed by the use of electronic and EPR spectra.[9]

The other type of ligands used to increase the effective charge of the metal ion catalyst were complexing agents, capable of forming $(M \rightarrow L)$ π-bonds with the catalyst. The formation of such bonds with the activator lowers the electron density on the metal ion catalyst and therefore might be expected to increase its effective charge.

Pyridine, having unoccupied π^* orbitals is a good π-acceptor and it was found[8] that in its presence the rate constant of the model catalytic reaction can be increased by a factor of nearly 8. An analogous effect was found by Rund and Plane[10] with 1,10-phenanthroline and tripyridyl in the decarboxylation of dimethyl oxaloacetate catalysed by Mn^{2+} and Ni^{2+}.

Some steric factors can also be taken into account for a further increase in the activation effect. A good example of this type is the use of 2-methylpyridine as activator in copper(II)-catalysed decarboxylation of oxaloacetic acid.[8] This activator not only increases the effective charge on the metal ion catalyst, but also favours the formation of catalyst–substrate complexes when substrate is being substituted for water and/or the activator in the catalyst co-ordination sphere.

The methyl group in the activator molecule causes steric hindrance in the plane of the square-planar catalyst complexes and thus lowers the energy barrier for the formation of the transition trigonal bipyramidal state. For that reason 2-methylpyridine shows a much higher activation effect than pyridine—it increases the rate constant of the model catalytic reaction by a factor of more than 26.

These investigations served as a basis for the use of decarboxylation reactions in catalytic analysis. Here the catalytic determination of metal ions with a filled outer electron shell must be mentioned first.

The ions of this type usually do not catalyse redox processes and their catalytic activity in hydrolytic and decarboxylation reactions is too low to be of any analytical interest. On the basis of the theoretical considerations above, it was possible to increase the catalytic activity of some of these ions sufficiently and to develop catalytic analytical methods for their determination. Thus in plant materials it was possible to determine catalytically total amounts as low as 5 μg of zinc,[11] 0·5 μg of aluminium,[12] and 50 μg of magnesium.[13]

The activator might also increase the rate of a catalytic reaction through another mechanism—affecting the rate of complex formation between the substrate and the catalyst.

This is, for example, the case with the activating effect of 8-hydroxyquinoline and its derivatives on the oxidation of arylamines by halates, catalysed by vanadium(V).[14] It was shown that in this reaction the activators strongly increase the rate of complex formation between the catalyst and the substrate—the first, rate-limiting step of the overall catalytic reaction. It is supposed that the reason for such action is the *trans*-effect they have on the co-ordination sphere of vanadium(V), in the xy-plane.

According to Chatt and Orgel[15] it might be expected that the stronger the electron-acceptor abilities of the ligand, the higher its *trans*-effect and hence its activation action. We have studied this correlation experimentally, varying the substituents in the activator molecule. Thus the presence of two electron-withdrawing groups ($-SO_3H$ and $-I$) in the molecule of 8-hydroxyquinoline strongly increases its electron-acceptor properties and the activation effect connected with them. The rate constant of the model catalytic reaction increases about 36 times when 5-sulpho-7-iodo-8-hydroxyquinoline is substituted for 8-hydroxyquinoline, as activator. The results of these investigations were used for development of a very sensitive method for determination of vanadium in plant materials (sensitivity 10^{-4} μg/ml).[16] Analogous effects were obtained when other electron-acceptors (1,10-phenanthroline, 2,2′-dipyridyl) were used as activators.[17]

Compounds with a system of conjugated π-bonds provide another possibility for activation of redox catalytic reactions. As was shown by Taube[18] such compounds can serve as a bridge between the reagents in electron-transfer reactions. The conjugated system provides a conductive path between the reagents, thus increasing the redox reaction rate. Such substances could be used, therefore, as activators for catalytic reactions where the rate-determining step is electron transfer in the catalyst–substrate interaction. The acceleration of vanadium(V)-catalysed redox reactions by phthalic acid could serve as an illustration of this type of activation.[6]

It must be pointed out that in all cases of activation discussed above, the dependence of the reaction rate on the activator concentration shows a maximum. This is due to the fact that at high activator concentrations the co-ordination sphere of the catalyst is fully occupied by the activator and any complexation with the substrate is prevented.

Nevertheless, in many cases such "blocking" of the co-ordination sphere does not result in a complete quenching of the catalytic activity. If the substitution process

$$MA_n + S \rightleftharpoons MA_{n-1}S + A \tag{5}$$

proceeds with a measurable rate it will provide a certain concentration of catalyst–substrate complex and therefore some catalytic activity will be obtained. In such conditions the substitution of the activator by the substrate in the co-ordination sphere of the catalyst becomes the rate-limiting step of the overall catalytic reaction.

The existence of a maximum in the curve of reaction rate *vs.* activator concentration is a characteristic feature for all types of activated reactions when the activator action is connected with the formation of ternary complexes of the type A–M–S.

In some cases the activator's influence on the catalytic reaction might be due to a shift in an equilibrium with the participation of the catalyst. This is, for instance, the case with the activation effect of chloride ions on the catalytic decomposition of hydrogen peroxide in the presence of Cu^{2+}.[19]

According to Uri[20] the activation is due to a shift, to the right, of the equilibrium

$$Cu^{2+} + HO_2^- \rightleftharpoons Cu^+ + HO_2^\cdot \qquad (6)$$

The overall reaction rate is determined by the position of the equilibrium process, the reactivity of $HO_2^\cdot$ being high enough. Chloride ions, forming more stable complexes with Cu^+ than with Cu^{2+} shift the equilibrium (6) to the right and hence accelerate the catalytic reaction.

A similar fact was found in the catalytic oxidation of arylamines, catalysed by vanadium(V).[21] Recently it was estimated that the highest catalytic activity amongst all ionic species of vanadium(V) is possessed by a form, stable in a very narrow pH-range, which is formed in the process of depolymerization of $H_2V_{10}O_{28}^{4-}$ to VO_2^+.[22] The presence of phosphates, which form complexes with vanadium, shifts the depolymerization equilibrium and thus an activation of the catalytic reaction is observed.[21]

An analogous fact was discovered by Kriss and Yatsimirskii who found that various phosphorus-containing ligands activate the vanadium(V)-catalysed oxidation of iodide by chlorates.[23]

The activator affects the regeneration of the catalyst

Most of the catalysts for homogeneous redox reactions are ions of transition elements that can exist in several oxidation states, *e.g.*, iron, manganese, vanadium, copper, silver. In many reactions of this type the catalyst participates in the process as a mediator for the redox interaction between the reagents, according to the following scheme

$$M^{(n+1)+} + S \rightarrow \text{Products} + M^{n+} \qquad (7)$$

$$M^{n+} + Ox \rightarrow M^{(n+1)+} + \text{Red} \qquad (8)$$

The catalyst acts by alternate oxidation-reduction steps, any of which can determine the overall reaction rate. Some reactions in which (7) is rate-limiting and which can be affected by activators were discussed in the previous paragraph. Here the cases where (8) determines the overall reaction rate, and therefore could be a means of activation, will be considered.

The theory of Marcus[24] can help to reveal the possibilities for activation of the metal ion–oxidant processes of type (8). According to the theory, for cases when in the transition state a small orbital overlap takes place between the reagents† the rate constant of a redox process is given by the equation

$$k = Z \,.\, \exp\left(-\frac{\Delta G^*}{RT}\right) \qquad (9)$$

where Z is the collision number and ΔG^* is the free energy of activation. This last parameter is a function of the standard free energy change of the process, of the charges of the reacting particles, and of terms that account for the solvation of the

---

† It seems that for many cases of direct oxidation of metal ions by oxygen-containing anions this condition is fulfilled.[25]

reagents and the reaction products. Hence, the rate of a catalytic reaction might be increased with activators able to affect these three factors in an appropriate way.[25]

This possibility was demonstrated by the example of silver(I)-catalysed oxidation of sulphanilic acid by peroxydisulphate.[26] The investigations on the reaction mechanism have shown that the process proceeds in two stages, according to (7) and (8), the two oxidation states of the catalyst being Ag(I) and Ag(II) respectively.[27] The rate-determining step of the overall reaction is (8), *i.e.*, the oxidation of Ag(I) to Ag(II).

The application of the Marcus theory to this case has shown that if a neutral ligand capable of complexation with Ag(I) and Ag(II) is added, an acceleration of the process Ag(I) $-$ *e* → Ag(II) might be expected. The main contribution to such an effect comes from the lowering of the high oxidation potential of the couple Ag(II)/Ag(I),† *i.e.*, of the free energy change of the process, the role of the other two factors being relatively smaller.

A complexant with nitrogen donors might be expected to cause such a lowering, *i.e.*, to form more stable complexes with Ag^{2+} than with Ag^+ because of the higher charge of Ag^{2+} and of the considerable crystal field stabilization energy (CFSE) for Ag^{2+}, while for Ag^+ CFSE = 0. Polydentate ligands are expected to exhibit a bigger effect, taking into account the difference between the structures of Ag^{2+} and Ag^+ complexes.[28,29]

In complexes with nitrogen-containing ligands Ag(I) has a co-ordination number of 2 and a linear structure of the complexes due to the small difference in energy between the 4*d* and 5*s* orbitals, while a co-ordination number of 4 and a square-planar structure is characteristic for the analogous Ag(II) complexes. The chelate effect can therefore also contribute to a further stabilization of the corresponding Ag(II) complexes. This effect can be still bigger if the polydentate ligand is a strong electron acceptor and can participate in (M → L) π-bond formation.

The validity of the theoretical considerations stated above is supported also by the data published in a series of experimental works by Yassinskene and co-workers, who proposed several analytical procedures for determination of silver with the use of nitrogen-containing ligands as activators.[30,31]

The lowering of the oxidation potential can play an important role in reactions where the free-energy change in the reoxidation of the catalyst is high enough to represent the main barrier in the reaction path.

Another mechanism of activation that can affect this stage of the catalytic reaction includes processes where the activator could serve as a matrix for an appropriate orientation of the reagents—the reduced form of the catalyst M^{n+} and the oxidant Ox.

Such a role of the activator could be of importance in cases where several structures of the activated complex $[M^{n+}\text{–}Ox]^*$ could be realized that differ in energy, and the thermodynamically preferred structure is not the most appropriate one for the oxidation process to proceed.[7]

Multidentate activators capable of complexation with M^{n+} and at the same time of forming hydrogen bonds with Ox, could facilitate the formation of the transition state necessary for the oxidation of M^{n+} and thus increase the overall reaction rate. A necessary condition for such an effect is that the structure of the activator must correspond to the inter-atomic distances in the activated complex.

† The standard oxidation potential of Ag^{2+}/Ag^+ is ~2·0 V.

Examples of such activators are hydroxycarboxylic acids such as citric, tartaric, for vanadium(V)-catalysed oxidation reactions.[32,33]

Activation of this type is closely connected with the possibility of hydrogen-bonding between the activator and the oxidant. For that reason the activator is very sensitive to any change in its structure that can prevent the formation of such bonds. For example, esterification of the activator's hydroxy groups leads to complete quenching of the activation.[34]

The activator acts in an indirect way in the catalytic process

This group includes activators that participate in parallel processes which can affect the rate of the main catalytic reaction. A typical example of this type of activation is the effect shown by phenols on the catalytic oxidation of some arylamines.[35]

The catalytic oxidation of arylamines proceeds usually by a one-electron mechanism with the formation of free amino-radicals

$$M^{(n+1)+} + ArNH_2 \rightarrow M^{n+} + ArNH^{\cdot} + H^+ \qquad (9)$$

which react further to form the final reaction products—quinone-imine compounds (see Part I).

In the presence of phenols an interaction takes place with the primarily formed imino-radicals[36,37]

$$ArOH + ArNH^{\cdot} \rightarrow ArO^{\cdot} + ArNH_2 \qquad (10)$$

followed by recombination of $ArO^{\cdot}$ and $ArNH^{\cdot}$ with the formation of quinone-imines:

$$ArO^{\cdot} + ArNH^{\cdot} \rightarrow \text{quinone-imines} \qquad (11)$$

Reactions (10) and (11) proceed very rapidly and the rate of quinone-imine formation increases as a result.

In some cases the product of the conjugated oxidation is identical with that of the non-activated reaction and then the term "activation" can be used for the observed increase of the reaction rate. However, as a rule, another quinone-imine compound is obtained in the presence of phenol. Because of the very small differences in the wavelengths of the absorption maxima of similar quinone-imines, the formation of a new reaction product in the presence of such "activators" is very often missed. In spite of the fact that the substrate is used up in the reaction at a higher rate, such cases could scarcely be considered as examples of activation, being in fact only an oxidative coupling.

Thus the oxidation of *p*-phenetidine with chlorate, catalysed by vanadium(V), gives *N*-(4-ethoxyphenyl)quinone-imine as a main oxidation product. The reaction can be activated by the addition of phenol, the product of the oxidative coupling being the same quinone-imine.[38] This activated reaction was used in a sensitive catalytic determination of vanadium.[35]

In the presence of other phenols (such as hydroquinone, catechol, resorcinol, naphthols) the rate of formation of the coloured product strongly increases and the solution seems to keep its red colour unchanged. In fact, chromatographic separation on aluminium oxide, combined with infrared spectral investigations, has shown that different quinone-imines are formed, which absorb in a relatively narrow region of the visible spectrum (500–530 nm).[39]

An analogous mechanism of activation was found[40] for the action of hydroxy- and polycarboxylic acids in arylamine oxidations catalysed by vanadium(V)[40] and chromium(VI).[41] These reactions proceed through a one-electron mechanism, the first, rate-limiting step of the process being the oxidation of the substrate by the catalyst with the formation of arylimino-radicals:

$$\mathrm{S} + \mathrm{M}^{(n+1)+} \xrightarrow{k_1} \mathrm{S}^{\cdot} + \mathrm{M}^{n+} \qquad (12)$$

The radicals $\mathrm{S}^{\cdot}$ then react through recombination or further oxidation to the final reaction products (see Part I).

Hydroxy- and polycarboxylic acids are also oxidized easily by the catalysts to radicals, which then react with the substrate:

$$\mathrm{A} + \mathrm{M}^{(n+1)+} \xrightarrow{k_2} \mathrm{A}^{\cdot} + \mathrm{M}^{n+} \qquad (13)$$

$$\mathrm{A}^{\cdot} + \mathrm{S} \xrightarrow{k_3} \mathrm{A}\ (\text{or } \mathrm{A}') + \mathrm{S}^{\cdot} \qquad (14)$$

An activation effect could be obtained if $k_2 + k_3 > k_1$. Usually the oxidation of polydentate carboxylic acids, such as citric, tartaric, oxalic, proceeds faster than that of the substrates because of the stronger tendency of the catalysts vanadium and chromium for complexation with oxygen than with nitrogen.

The formation of the radicals $\mathrm{A}^{\cdot}$ was estimated experimentally.[40] The fact that they really react further with the substrate with the formation of the same reaction products was proved independently.[42] Radicals of type $\mathrm{A}^{\cdot}$ were obtained by a photochemical decomposition of trisoxalate iron(III) $\mathrm{Fe(Ox)_3^{3-}}$ and their interaction with arylamine substrate studied. It was found that the reaction products thus formed are the same as those obtained when oxalic acid is used as activator.

The investigations on this type of activator served as a basis for development of highly sensitive analytical methods for determination of vanadium and chromium in different materials.[41,43]

In some cases the carboxylic acids used as activators can affect simultaneously several stages of the catalytic reaction through a different mechanism.

Thus the oxidation of *p*-phenetidine with halates, catalysed by vanadium(V), is activated by citric acid. The activator acts in two stages of the reaction: it accelerates the catalyst–substrate interaction through a radical mechanism[40] [according to (13) and (14)] and at the same time increases the rate of regeneration of the catalyst, serving as a matrix for the $\mathrm{V(IV)–XO_3^-}$ interaction.[42]

Oxalic acid is also used as an activator for the same reaction, but while a strong effect on the catalyst–substrate interaction is observed,[40] at the same time it acts as an inhibitor for the regeneration of the catalyst.[32] The influence on the first, rate-limiting, stage of the process results in the rates of both reaction stages becoming of the same order and hence the inhibition of the second stage is now of importance. For that reason the total effect of oxalic acid on the overall reaction rate is smaller than that of citric acid.[44]

Another attempt at explanation of the difference in the effect of citric and oxalic acids on the rate-limiting stage and on the overall reaction rate was made by means of molecular orbital theory and the electronic spectra of the catalyst–activator complex.[45] Here the influence of the activator on the second reaction stage was not taken into account at all, the discussion including only the rate-determining step. It was shown that the energy of the charge-transfer band of the complex $M^{(n+1)+}$–A could be used to predict qualitatively the possibility of activation and the order of the activating effect in cases where the activator is oxidized during the reaction, according to (13).

Higher sensitivity is not the only advantage that could be realized by the use of activators in catalytic analysis. Another possibility seems much more attractive—selection of an activator for a given catalytic reaction, that would increase the catalytic activity of the ion to be determined and at the same time quench the activity of other catalysts that can interfere. In such a case an improvement in sensitivity and selectivity could be accomplished simultaneously.

Such a possibility was first pointed out and experimentally realized in 1963 in a catalytic method for determination of vanadium in the presence of copper(II) and iron(III), which also catalyse the indicator reaction.[46] The addition of citric acid increases the sensitivity for vanadium(V) by about 15 times, the activity of both interfering ions being completely suppressed.

The catalytic determination of silver offers another example. Thus 25 μg of silver can be determined catalytically by the sulphanilic acid oxidation, copper(II) and iron(III) interfering in amounts >0·6 μg and >10 μg respectively.[26] The use of 2,2′-dipyridyl permits the determination of 5×10^{-3} μg of silver (5000 times higher sensitivity) at the same time raising the levels at which copper(II) and iron(III) interfere to 10 and 100 μg respectively.[28] The presence of ethylenediamine increases the sensitivity for silver only 1000 times, but increases tolerance for copper(II) to 50 μg.[29]

It must be pointed out that so far only a few examples of simultaneous improvement of sensitivity and selectivity of catalytic reactions are known. In our opinion, however, this offers one of the most promising lines of research on application of activators in catalytic analysis.

The use of a combination of properly selected activators must also be mentioned as a prospective means of affecting a catalytic reaction. It was shown that sometimes the joint activating effect can be much higher than that of either activator alone.[47] Higher selectivity might also be expected, as shown by Kalinitchenko.[48] This work and other papers by the same author[49–51] are also interesting as examples of the use of activators in catalytic luminescence analysis. The simultaneous application of a system of activators is another promising field for research that could reveal new possibilities for further improvement of catalytic analytical methods.

CONCLUSION

The present paper does not pretend to cover all the data on activators and their application in catalytic analysis. Its aim is only to show the possibilities that the use of activators offers to the analyst, to discuss the mechanisms of their action and on that basis to show the way to select suitable activators for a given catalytic method. This, in our opinion, could help the further development and application of catalytic methods which are amongst the most sensitive modern analytical methods.

Zusammenfassung—Die Aktivierung der analytisch verwendeten homogenen katalytischen Reaktionen wird diskutiert. Die Verwendung von Aktivatoren bei katalytischen Methoden bringt einen Gewinn an Empfindlichkeit von 2–4 Größenordnungen und verbessert außerdem die Selektivität. Viele verschiedene Aktivierungsmechanismen werden diskutiert und als Beispiele für die Gesichtspunkte angeführt, nach denen man einen geeigneten Aktivator auswählt.

Résumé—On discute de l'activation de réactions catalytiques homogènes utilisées en analyse. L'emploi d'activeurs dans les méthodes catalytiques permet d'accroître leur sensibilité d'ordres de grandeur 2–4 et d'améliorer aussi bien leur sélectivité. On discute de nombreux mécanismes différents d'activation et les utilise comme illustration des principes pour le choix d'un activeur approprié.

N-Acetylacetone–anthranilic acid as a gravimetric reagent for copper(II)

(*Received* 25 *June* 1971. *Accepted* 18 *November* 1971)

METAL CHELATES of the Schiff bases have been recently reviewed by Holm *et al.*[1] Several metal chelates of the Schiff bases are solids and have therefore found application in gravimetry. No systematic study seems to have been made of the Schiff base *N*-acetylacetone–anthranilic acid (H_2AA). It is a diprotic tridentate ligand containing a carboxylic group, an enolic hydroxyl group and a donor nitrogen atom, which forms solid metal chelates with Fe(II), Co(II), Ni, Cu(II), Zn, Cd and UO_2(II).[2] The copper(II) chelate is insoluble in water, and can thus form the basis of a quantitative separation procedure.

EXPERIMENTAL

Reagents

N-Acetylacetone–anthranilic acid. The reagent was prepared by adding anthranilic acid (2·6 g) to freshly distilled acetylacetone (2·0 ml) and stirring thoroughly. Piperidine (2 or 3 drops) was used as a condensing agent. The mixture was refluxed on a water-bath for nearly an hour, till a transparent yellow solution was obtained. It was allowed to cool and then methanol was added and the solution was left overnight in a refrigerator for crystallization. Fine shining yellow crystals of the Schiff base were obtained which were separated, recrystallized from methanol and preserved in a vacuum desiccator. Yield 2·0 g. Found: C, 65·6%; H, 5·8%; N, 6·3%; calc. for $C_{12}H_{13}NO_3$: C, 65·75%, H, 5 93%; N, 6·36%.

Procedure

Gravimetric determination of copper(II). A 10% solution of the reagent was prepared in aqueous ethanol. Copper sulphate, 24·97 g, was dissolved in a litre of distilled water to give a copper(II) solution which was then standardized iodometrically.

An aliquot of the copper(II) solution was placed in a 250-ml Pyrex beaker and its pH was adjusted to between 3·9 and 4·6 with acetic acid–sodium acetate buffer. To this solution the reagent was added gradually with constant stirring till no further formation of the dark green precipitate took place. The contents of the flask were heated to 100° for 20 min, cooled and filtered (sintered glass crucible). The precipitate was wahed with warm aqueous alcohol till it was free from the reagent as well as sulphate. It was dried at 100°. Analyses gave: found, Cu, 22·6%; N, 4·0%; calc. for $Cu(C_{12}H_{11}NO_3)$, Cu, 22·64%; N, 4·99%. It has been found that nitrate, cobalt(II) and nickel(II) do not interfere in the estimation of copper(II) in the pH range 3·9–4·6.

The analysis of this chelate showed the metal–ligand ratio to be 1:1 and water to be absent. The molecular weight of the chelate in dioxan was found by ebulliometry to be 551 ± 15.

RESULTS AND DISCUSSION

The results of the gravimetric estimation of copper(II) by the procedure given earlier are summarized in Table I.

TABLE I.—RESULTS OF GRAVIMETRIC ESTIMATION OF COPPER(II)

Weight of chelate, *mg*	Copper, *mg* Found	Copper, *mg* Taken	Error, %
261·21	59·02	59·12	0·2
231·82	52·39	52·51	0·2
192·72	43·56	43·65	0·2
155·89	35·23	35·31	0·2
145·62	32·93	32·98	0·2

The copper(II) chelate exists as an unsolvated dimer, which is evident from its molecular weight. Infrared spectroscopy shows the absence of the characteristic frequencies of the —OH group in free or chelated form. Elemental analysis of the chelate reveals 1:1 metal–ligand ratio and also suggests the absence of water molecules. The magnetic moment was found to be 1·88 B.M. at 298 K. The electronic absorption spectra in dioxan and pyridine consist of two bands with peaks at 24000 and 14200 cm^{-1}, the first being the stronger. The band at 14200 cm^{-1} may be due to the electronic transition $2E \rightarrow 2T_2$ of the copper(II). The other band at 24600 cm^{-1} is an intraligand charge-transfer band. These results suggest a non-planar dimeric tetrahedral structure (I) for the copper(II) chelate. In this structure the four co-ordination positions of the cupric ions are fully satisfied and these ions are situated at the opposite ends of an eight-membered ring so that direct copper–copper bonding does not take place. Consequently superexchange is prevented and the chelate would exhibit a normal magnetic moment. Thus structure (I) explains satisfactorily all the experimental data. This structure is in agreement with that of the copper(II) complex of *N*-salicylidene–anthranilic acid investigated by Kubo *et al.*[3]

Analysis of metals by solid–liquid separation after liquid–liquid extraction
Spectrophotometric determination of palladium(II) by extraction of palladium dimethylglyoxime with melted naphthalene

(*Received* 9 *August* 1971. *Accepted* 15 *November* 1971)

RECENTLY many new reagents have been employed for the solvent extraction and spectrophotometric determination of small amounts of metal ions. We have been studying a new method "analysis by solid–liquid separation after liquid–liquid extraction," and this method has been successfully applied for the spectrophotometric determination of micro amounts of copper,[1,2] zinc,[3] magnesium[4] and nickel[5] by using a molten organic compound with appropriate melting point as the organic phase, *e.g.*, naphthalene (m.p. 80·1°), diphenyl (m.p. 70·5°) and a suitable organic reagent *e.g.*, 8 hydroxyquinoline or dimethyl glyoxime. Generally, the stable water-insoluble complexes are rapidly and quantitatively extracted into molten naphthalene, and micro amounts of metals can thus be determined with the same degree of accuracy as by chloroform extraction. The separation and drying of the naphthalene mixture after extraction takes longer than the comparable step in a simple chloroform extraction, but it is convenient for the determination of zinc, magnesium, cadmium, beryllium, *etc*, because the complexes of these metals are difficult to dissolve in chloroform or benzene. It is a characteristic of this method that the equilibrium distribution in the two phases is attained rapidly and the complexes are dissolved merely by contact with molten naphthalene.

In the present work, the extraction of palladium(II) with dimethylglyoxime into molten naphthalene is reported.

EXPERIMENTAL

Reagents

Standard palladium solution, $5 \times 10^{-3}M$. Prepared by dissolving 0·4433 g of palladium chloride in 10 ml of concentrated hydrochloric acid and diluting to 500 ml with water. More dilute palladium solutions were prepared as required by diluting the standard solution.

Dimethylglyoxime solution, 0·5% in ethanol.

Buffer solution. Appropriate mixtures of $1M$ acetic acid and $1M$ sodium acetate or, $0{\cdot}5M$ disodium hydrogen phosphate and $0{\cdot}5M$ potassium dihydrogen phosphate or $1M$ ammonia and $1M$ ammonium chloride.

Alkali metal salt solutions. Prepared by dissolving 1·000 g of each salt in water and diluting to 100 ml.

Solutions of metal salts. Made to contain 0·100 g of each salt per 100 ml of solution.

Naphthalene, chloroform and all other reagents were of analytical-reagent grade, and were used without further purification.

The water used was redistilled demineralized water.

Procedure

To 30 ml of the sample solution containing 1–9 ml of $5 \times 10^{-4}M$ palladium chloride, in a 50 or 100-ml tightly stoppered Erlenmeyer flask, add 2 ml of acetic acid–sodium acetate buffer solution and 1 ml of 0·5% dimethylglyoxime solution, and adjust the pH to about 4. Mix the solution well, and warm it on a water-bath at around 60°. Add 2·0 g of naphthalene and warm the mixture in the water-bath at 90° to melt the naphthalene layer completely. Shake it vigorously till the naphthalene layer solidifies. Once more melt and shake the mixture till the naphthalene layer solidifies, forming many very fine crystals, and allow to cool to room temperature. Again warm and melt the fine crystals slowly, and let them grow to give a coarser crystalline deposit. Cool to room temperature, collect the solidified deposit on a filter paper, wash with water, and blot the surplus water with a dry filter paper. Spread the crystals on a filter paper and allow to dry. Then dissolve them with chloroform by vigorous shaking and dilute to 10 ml. Dry the solution by addition of about 2 g of anhydrous sodium sulphate, transfer a portion into a 10-mm cell and measure its absorbance at 370 nm against a reagent blank prepared similarly. Calculate the amount of palladium from the calibration curve.

RESULTS AND DISCUSSION

Absorption spectra

The absorption spectra of dimethylglyoxime and palladium dimethylglyoximate in naphthalene–chloroform solution, measured against water, are shown in Fig. 1. Consideration of this led to 370 nm being adopted as the optimum wavelength.

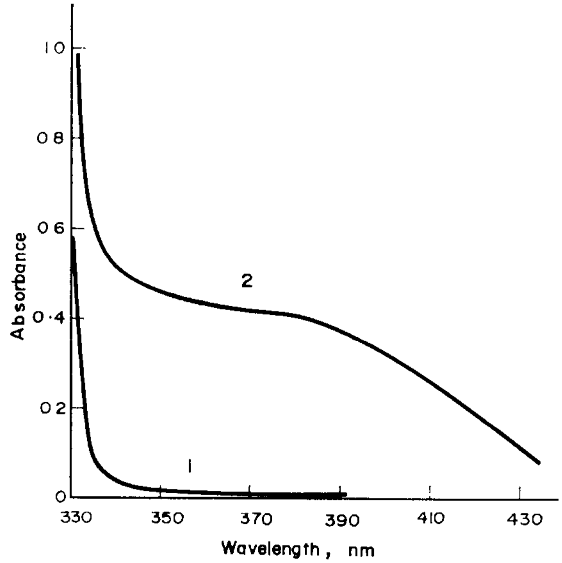

FIG. 1.—Absorption spectra of dimethylglyoxime and palladium dimethylglyoximate in naphthalene-chloroform.
Palladium: 266 μg; naphthalene: 2·0 g; pH: 4·0; 0·5% dimethylglyoxime: 1·0 ml; Reference: water; ① dimethylglyoxime; ② palladium dimethylglyoximate.

Effect of pH

The relationship between the absorbance and the pH of the aqueous solution after extraction was studied, and the results obtained are shown in Fig. 2. From these it is clear that the pH range 1·1–7·8 is suitable for quantitative extraction of palladium.

Effect of reagent concentration

The effect of dimethylglyoxime concentration on the absorbance was studied by varying the amount of dimethylglyoxime in solutions containing 266 μg of palladium at pH 4. The absorbance is maximal if 1·0 ml of 0·5% dimethylglyoxime solution is used, but varies by less than 1% over the range 0·5–3·0 ml.

Effect of amount of naphthalene

The amounts of naphthalene were varied from 0·5 to 2·8 g and the extraction was carried out by the recommended procedure. Only a slight increase in the absorbance was caused by increasing amounts of naphthalene. Large amounts of naphthalene made the experimental operations difficult owing to the sublimation of naphthalene, which was followed by the volatilization of chloroform. The volume of chloroform required to dissolve 1 g of naphthalene was 2 ml. Therefore, 2·0 g of naphthalene were used for further study.

Effect of concentration of buffer solution and shaking time

Sample solutions containing 266 μg of palladium, 1·0 ml of 0·5% dimethylglyoxime solution and various amounts of the acetate buffer solution in a total volume of about 33 ml were prepared according to the recommended procedure, and extracted with 2·0 g of naphthalene. The absorbance of the mixture of palladium complex and naphthalene in the chloroform solution was measured at 370 nm against the reagent blank. The amounts of the acetate buffer solution (pH 4) were varied from 0·5 to 4·5 ml at intervals of 0·5 ml. A negative error of 2% was found when 4·5 ml of the buffer

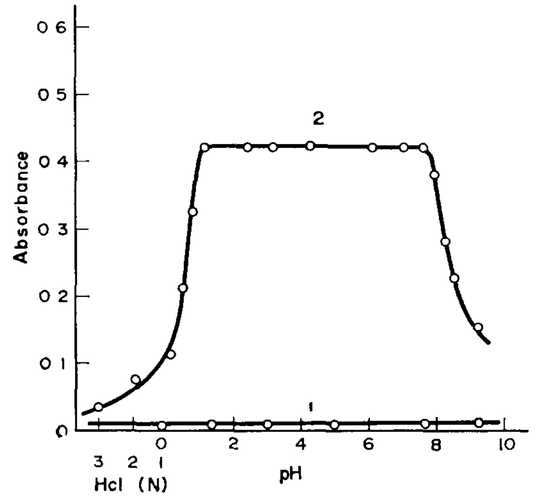

FIG. 2.—Effect of pH on absorbance.
Palladium: 266 μg; naphthalene: 2·0 g; wavelength: 370 nm; 0·5% dimethylglyoxime: 1·0 ml; Reference: water; ① dimethylglyoxime; ② palladium dimethylglyoximate.

solution were added. The extraction of the palladium complex into molten naphthalene was very fast owing to the high temperature; a constant degree of extraction was obtained when the vigorous shaking operation was repeated twice. Then the mixture of palladium complex and naphthalene had to be dissolved in chloroform by vigorous shaking because the solubility of the palladium complex in chloroform is rather low. The colour of the palladium complex in naphthalene–chloroform solution was quite stable for a long time.

Calibration curve

With the optimum conditions described above, the calibration curve for palladium determination was established at the wavelength of 370 nm against the reagent blank. It was linear over the range of 30–530 μg of palladium(II) in 10 ml of chloroform. The molar absorptivity was calculated to be $1{\cdot}72 \times 10^4$ l.mole.$^{-1}$mm^{-1}, and the sensitivity 0·0626 μg of palladium per cm^2 for an absorbance of 0·001.

Sample solutions containing 266 μg of palladium, prepared by the recommended procedure, gave a mean absorbance of 0·425, with a standard deviation of 0·0027.

Effect of diverse ions

Various ions (100 mg of alkali metal salts or 1 mg of other salts) were added individually to solutions containing 266 μg of palladium, and their effects on the absorbance examined. The test solution was extracted with 2·0 g of naphthalene at a temperature above 81°. The following alkali metal salts and metal salts did not interfere: KSCN, $Na_2C_2O_4$, KH_2PO_4, Na_2HPO_4, Na_2CO_3, Na_2SO_3, NaF, KCl, KBr, KI, sodium tartrate, sodium citrate, EDTA, $MgCl_2{\cdot}6H_2O$, $CaCl_2{\cdot}2H_2O$, $Sr(NO_3)_2$, $BaCl_2$, $CdCl_2{\cdot}2\frac{1}{2}H_2O$, $Na_2WO_4{\cdot}2H_2O$, $CuSO_4{\cdot}5H_2O$, $ZnCl_2$, $Co(NO_3)_2{\cdot}6H_2O$, $Pb(NO_3)_2$, potassium alum, Mohr's salt. Nickel and iron(III) interfered seriously. Nickel did not interfere in the pH region 1·5–2·5. The interference of iron(III) was masked by addition of 10 ml of 1% EDTA or by reduction to iron(II) with 5 ml of 5% hydroxylamine sulphate solution.

Summary—A method of liquid–liquid extraction of palladium dimethylglyoximate with molten naphthalene followed by solid–liquid separation is successfully applied to palladium. The complex between palladium and dimethylglyoxime is easily extracted into molten naphthalene. After extraction, the very fine solidified naphthalene crystals are dissolved in chloroform, and the absorbance of the resultant solution is measured at 370 nm against a reagent blank. Beer's law is obeyed for 30–370 μg of palladium in 10 ml of chloroform, and the molar absorptivity is calculated to be $1{\cdot}72 \times 10^4$ l.mole.$^{-1}$mm^{-1}. Various alkali metal salts and metal ions do not interfere. The interference of nickel(II) is overcome by the extraction at pH 2, and that of iron(III) by masking with EDTA or by reduction to iron(II). The method is rapid and accurate.

Zusammenfassung—Zur Bestimmung von Palladium wird Palladiumdimethylglyoximat mit geschmolzenem Naphthalin extrahiert und dann Festkörper und Flüssigkeit getrennt. Der Komplex aus Palladium und Dimethylglyoxim wird leicht in geschmolzenes Naphthalin extrahiert. Nach der Extraktion werden die sehr feinen Kristalle von wieder fest gewordenem Naphthalin in Chloroform gelöst und die Extinktion der Lösung bei 370 nm gegen eine Reagens-Blindprobe gemessen. Das Beersche Gesetz gilt bei 30–370 μg Palladium in 10 ml Chloroform, der molare Extinktionskoeffizient wird zu $1{,}72 \cdot 10^4$ 1 mol^{-1}mm^{-1} berechnet. Eine Reihe von Alkalimetallsalzen und Metallionen stören nicht. Die Störung durch Nickel(II) wird beseitigt, wenn bei pH 2 extrahiert wird, die durch Eisen(III) durch Maskierung mit EDTA oder durch Reduktion zu Eisen(II). Die Methode ist schnell und genau.

Résumé—On a appliqué avec succès au palladium une méthode d'extraction liquide-liquide du diméthylglyoximate de palladium avec du naphtalène fondu, suivie d'une séparation solide-liquide. Le complexe entre le palladium et la diméthylglyoxime est aisément extrait en naphtalène fondu. Après extraction, les cristaux très fins de naphtalène solidifié sont dissous en chloroforme, et l'on mesure l'absorption de la solution résultante à 370 nm par rapport à un témoin des réactifs. La loi de Beer est suivie pour 30–370 μg de palladium dans 10 ml de chloroforme, et l'on a calculé que le coefficient d'absorption moléculaire est de $1{,}72 \times 10^4$ mm^{-1} l.mole^{-1}. Divers sels alcalins et ions métalliques ne gênent pas. On évite l'interférence du nickel(II) par l'extraction à pH 2, et celle du fer(III) en le dissimulant par l'EDTA ou par réduction en fer(II). La méthode est rapide et précise.

Analysis of metals by solid–liquid separation after liquid–liquid extraction
Spectrophotometric determination of palladium(II) by extraction of palladium dimethylglyoximate with melted naphthalene

(*Received* 9 *August* 1971. *Accepted* 15 *November* 1971)

RECENTLY many new reagents have been employed for the solvent extraction and spectrophotometric determination of small amounts of metal ions. We have been studying a new method "analysis by solid–liquid separation after liquid–liquid extraction," and this method has been successfully applied for the spectrophotometric determination of micro amounts of copper,[1,2] zinc,[3] magnesium[4] and nickel[5] by using a molten organic compound with appropriate melting point as the organic phase, *e.g.*, naphthalene (m.p. 80·1°), diphenyl (m.p. 70·5°) and a suitable organic reagent *e.g.*, 8 hydroxyquinoline or dimethyl glyoxime. Generally, the stable water-insoluble complexes are rapidly and quantitatively extracted into molten naphthalene, and micro amounts of metals can thus be determined with the same degree of accuracy as by chloroform extraction. The separation and drying of the naphthalene mixture after extraction takes longer than the comparable step in a simple chloroform extraction, but it is convenient for the determination of zinc, magnesium, cadmium, beryllium, *etc*, because the complexes of these metals are difficult to dissolve in chloroform or benzene. It is a characteristic of this method that the equilibrium distribution in the two phases is attained rapidly and the complexes are dissolved merely by contact with molten naphthalene.

In the present work, the extraction of palladium(II) with dimethylglyoxime into molten naphthalene is reported.

EXPERIMENTAL

Reagents

Standard palladium solution, $5 \times 10^{-3}M$. Prepared by dissolving 0·4433 g of palladium chloride in 10 ml of concentrated hydrochloric acid and diluting to 500 ml with water. More dilute palladium solutions were prepared as required by diluting the standard solution.

Dimethylglyoxime solution, 0·5% in ethanol.

Buffer solution. Appropriate mixtures of $1M$ acetic acid and $1M$ sodium acetate or, $0{\cdot}5M$ disodium hydrogen phosphate and $0{\cdot}5M$ potassium dihydrogen phosphate or $1M$ ammonia and $1M$ ammonium chloride.

Alkali metal salt solutions. Prepared by dissolving 1·000 g of each salt in water and diluting to 100 ml.

Solutions of metal salts. Made to contain 0·100 g of each salt per 100 ml of solution.

Naphthalene, chloroform and all other reagents were of analytical-reagent grade, and were used without further purification.

The water used was redistilled demineralized water.

Procedure

To 30 ml of the sample solution containing 1–9 ml of $5 \times 10^{-4}M$ palladium chloride, in a 50 or 100-ml tightly stoppered Erlenmeyer flask, add 2 ml of acetic acid–sodium acetate buffer solution and 1 ml of 0·5% dimethylglyoxime solution, and adjust the pH to about 4. Mix the solution well, and warm it on a water-bath at around 60°. Add 2·0 g of naphthalene and warm the mixture in the water-bath at 90° to melt the naphthalene layer completely. Shake it vigorously till the naphthalene layer solidifies. Once more melt and shake the mixture till the naphthalene layer solidifies, forming many very fine crystals, and allow to cool to room temperature. Again warm and melt the fine crystals slowly, and let them grow to give a coarser crystalline deposit. Cool to room temperature, collect the solidified deposit on a filter paper, wash with water, and blot the surplus water with a dry filter paper. Spread the crystals on a filter paper and allow to dry. Then dissolve them with chloroform by vigorous shaking and dilute to 10 ml. Dry the solution by addition of about 2 g of anhydrous sodium sulphate, transfer a portion into a 10-mm cell and measure its absorbance at 370 nm against a reagent blank prepared similarly. Calculate the amount of palladium from the calibration curve.

RESULTS AND DISCUSSION

Absorption spectra

The absorption spectra of dimethylglyoxime and palladium dimethylglyoximate in naphthalene–chloroform solution, measured against water, are shown in Fig. 1. Consideration of this led to 370 nm being adopted as the optimum wavelength.

Détermination gravimétrique de l'iode sous forme de Nt(ICl$_2$)*

(*Reçu le* 28 *avril* 1971. *Accepté le* 28 *novembre* 1971)

On connaît deux méthodes de détermination gravimétrique de l'iode. Elles sont basées sur sa précipitation sous forme d'AgI[1] et d'iodure de palladium(II).[2] Une méthode gravimétrique de détermination de l'iode sous forme d'un autre composé, utilisant un agent organique, n'a pas été proposée jusqu'ici. C'est une telle méthode que nous préconisons dans le présent mémoire. L'iode y est déterminé et pesé sous forme de dichloriodure de nitron.

* L'abréviation Nt désigne le cation de la base (nitron).

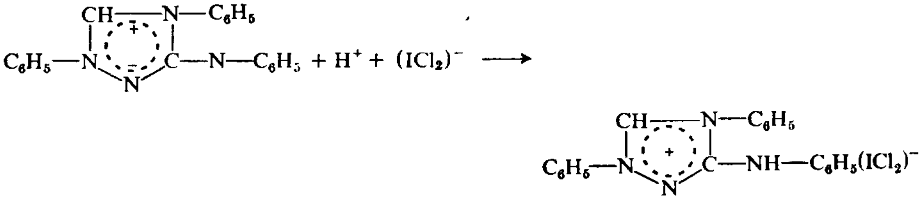
Des essais[3] portant sur le système eau–acide chlorhydrique–iode–chlore, ont montré que lors de son oxydation au moyen du chlore en milieu chlorhydrique saturé de chlore, l'iode se transforme quantitativement en complex $(ICl_2)^-$. On sait que les anions de même type $(ICl_4)^-$ et $(AuCl_4)^-$ réagissant avec certaines bases organique, fournissent des composés peu solubles et que les méthodes de détermination quantitative de la nicotine[4] et de l'or[5] sont basées sur ces propriétés. Ayant en vue ces faits, nous nous sommes proposés pour but d'élaborer une nouvelle méthode gravimétrique de détermination de l'iode, où seraient mises à profit les propriétés du composé que forme le complexe $(ICl_2)^-$ avec le nitron.

PARTIE EXPERIMENTALE

Si l'on additionne une solution contenant le complexe (ICl_2) d'une solution de sulphate de nitron, on obtient un précipité faiblement coloré en jaune qui, après agitation, acquiert une forme nettement cristalline.

Le composé s'obtient en milieu chlorhydrique fortement saturé (d'acide chlorhydrique) offre une solubilité extrêmement faible.

La réaction entre le nitron et le complexe $(ICl_2)^-$ se déroule probablement selon l'équation suivante:



La basicité élevée du nitron provoque la production de protons et l'association du nitron et du complexe iodochlorure. Ce mécanisme se trouve confirmé par les spectres IR du composé obtenu et du nitron. Le spectre du composé, contrairement à celui du nitron, présente un pic de liaison N–H nettement visible.

On a procédé à l'analyse du composé pour en déterminer les teneurs en C, H, N, et la somme de l'iode et du chlore. Les résultats figurent dans le tableau No. I. On y inclu aussi les résultats théoriques, calculés selon les formules: $Nt(ICl_2)$, $Nt(ICl_4)$. Les données du tableau attestent que le composé obtenu est $Nt(ICl_2)$.

Tableau I.—Données sur la constitution du composé

	C%	H%	N%	Cl + I%
Théorie pour $Nt(ICl_2)$	47,06	3,34	10,98	38,82
Trouvé	47,4	3,5	10,2	38,6
Théorie pour $Nt(ICl_4)$	43,08	2,95	9,66	46,38

$Nt(ICl_2)$ fond sans se décomposer à 160°C. Il se dissout au mieux dans l'acétone, moins bien dans l'alcool éthylique (0,74%), le dichloréthane (0,40%), le chloroforme (0,06%) et l'éther (0,04%). Il est insoluble dans les solvants non-polaires: benzène, tétrachloromethane. Dans l'eau le composé acquiert une coloration orangée qui, en fin d'opération, vire au noire. Sa solubilité a été déterminée en HCl à 5%, où il ne manifeste pas de modification.

À la température de 20°C, en HCl à 5%, la solubilité est de $6,3 \times 10^{-5}M$ en HCl à 5% et en présence de sulfate de nitron que nous avons basé notre nouvelle méthode gravimétrique de détermination de l'iode.

Analyse

Dans un ballon Kjeldahl de 50 ml on introduit environ 20 ml de solution d'ions iodiques contenant de 5 à 40 mg d'iode. On ajoute 20 ml de HCl concentré, saturé en Cl_2, agite, et, aussitôt, on fait barboter de l'air durant 5 minutes à travers cette solution. On transvase le mélange dans une fiole et le dilue à 100 ml, puis on ajoute lentement, et en agitant toujours, 25 ml de solution de sulfate de nitron à 1%. On obtient d'abord un précipité jaune à peine perceptible qui, après agitation énergique, acquiert peu à peu une coloration jaune et une structure cristalline très nette. On laisse reposer pendant une heure, puis on filtre sur un filtre de verre G_3 ou G_4.

Le contenu de la fiole est versé sur le filtre, puis la fiole est rincée par de l'acide chlorhydrique à 4% contenant un peu de sulfate de nitron où, mieux encore, par le filtrat lui-même. Le précipité est ensuite lavé à deux où trois reprises par un peu d'acide chlorhydrique à 4%, sêché pendant 1 hr à 100°–105° et pesé.

Pour illustrer la précision de la méthode, nous avons établi le tableau No. II, qui rend compte des résultats relatifs aux quantités de 4,5 à 40 mg.

Le coefficient de variation pour 15 à 40 mg dans 10 déterminations, evalué pour une sûreté statistique de 95% est respectivement de ±1,70 et ±0,75%.

Les ions bromate ne gênent pas la détermination. Si leur quantité est de l'ordre de celle de l'iode, il n'est pas indispensable de changer de mode opératoire. En l'occurence, lors du barbotage, le brome obtenu est éliminé en même temps que l'excédent de chlore, ce qui modifie pas les conditions du travail ultérieur. Si la teneur en Br est élevée, par example si le rapport Br/I = 5–10 et même davantage, la technique doit être modifiée en début d'opération. Dans le ballon de Kjeldahl on doit introduire d'abord de l'acide chlorhydrique concentré et saturé en chlore, puis remplir le ballon de chlore et, alors seulement ajouter à l'aide d'une pipette la solution à analyser. Par la suite, la détermination se déroule selon le schéma décrit plus haut. Dans ces conditions la présence du Br n'a pas d'effet sur les résultats. Ainsi, dans deux déterminations de 40 mg d'I, en présence de la même quantité de Br, on a détecté 40,10 et 40,15 mg d'iode.

La méthode préconisée a été confrontée avec la méthode la plus sûre, pratiquée le plus souvent la détermination gravimétrique de l'iode, sous forme d'AgI. Les résultats de 10 essais de détermination de 15 et de 40 mg d'iode, effectués avec précipitation par l'argent, figurement dans le tableau No. III. La confrontation des données des tableaux II et III, met en évidence d'une façon catégorique la meilleure précision de la nouvelle méthode. Elle présente encore les avantages suivants.

1. Elle se déroule en présence de Cl et de Br.
2. Elle exclu l'erreur due à l'oxydation de I^- en I_2.
3. La décomposition d'AgI, sous l'effet de la lumière n'entrâine pas d'erreurs.
4. Contrairement au précipité d'AgI, celui de $Nt(ICl_2)$ ne retient pas de solvant ni d'autres substances contenues dans la solution.

TABLEAU III.—DETERMINATION DE L'IODE AVEC L'ARGENT

Prélevé, *mg*	Trouvé, *mg*	Erreur relat., %	Prélevé, *mg*	Trouvé, *mg*	Erreur relat., %
15,0	$15,1_6$	+1,1	40,0	40,6	+1,5
15,0	$15,1_6$	+1,1	40,0	40,7	+1,8
15,0	$15,7_1$	+4,7	40,0	40,2	+0,5
15,0	$15,4_3$	+2,8	40,0	39,9	−0,3
15,0	$15,4_8$	+3,2			
15,0	$15,4_8$	+3,0			
Erreur relative moyenne		+2,6%			+0,9%

5. En raison du poids moléculaire élevé et de la faible solubilité de Nt(ICl$_2$), la méthode permet de déterminer des quantités d'iode 2–3 fois plus petites.

6. Pour la même raison, le facteur de transformation du poids du précipité en iode est aussi deux fois plus petit.

7. On utilise le sulfate et non pas l'acétate de nitron, car le nitron, comme reactif, contient beaucoup d'impurités qui, au cours de sa dissolution dans l'acide acétique, restent dans la solution et empêchent la détermination. Au contraire, le sulphate peut être facilement obtenu du nitron.[6]

Résumé—On a obtenu le composé dichloriodure de nitron—Nt(ICl$_2$)—et l'on a etudié les propriétés. En se basant sur les résultats obtenus, on a elaboré une méthode gravimétrique de détermination de l'iode sous forme de Nt(ICl$_2$). Elle permet de determiner par voie gravimétrique de 4 à 40 mg d'iode, l'erreur étant moindre que lors de détermination de l'iode sous forme d'AgI. Les ions bromate et chlorate ne gênent pas la détermination.

Summary—Nitron dichloroiodide—Nt(ICl$_2$)—has been prepared and studied, and a gravimetric determination of iodine as Nt(ICl)$_2$ has been based on the result. For 4–40 mg of iodine the error is less than that of the determination as AgI. Bromate and chlorate do not interfere.

Zusammenfassung—Nitrondichlorojodid—Nt(JCl$_2$)—wurde hergestellt und untersucht; auf den Ergebnissen wurde eine gravimetrische Bestimmung von Jod als Nt(JCl$_2$) aufgebaut. Für 4–40 mg Jod ist der Fehler kleiner als bei der Bestimmung als AgJ. Bromat und Chlorat stören nicht.

Trennung anorganischer Phosphate an Anionenaustauscher-Fertigplatten

(*Eingegangen am* 19. *Juli* 1971. *Angenommen am* 18. *Oktober* 1971)

Die analytische Chemie der Phosphate gewinnt auf Grund der vielfältigen Formen und des häufigen Auftretens dieser Verbindungen in Natur- und Syntheseprodukten zunehmend an Bedeutung. Bisherige papierchromatographische[1,2] und dünnschicht-chromatographische Trennungen (an Celluloseschichten)[3] zeigen zwar gute Ergebnisse, sind aber nur schwer reproduzierbar. Im Gegensatz dazu liefert die Gradientenelution an Anionenaustauscher-Säulen[4,5] sehr gute Ergebnisse, jedoch ist dieses Verfahren sehr zeitaufwendig. Um die Vorteile der Dünnschichtchromatographie mit denen des Ionenaustausches zu verbinden, wendeten wir die Ionenaustauscher-Dünnschichtchromatographie an.[6,7] Wir verwendeten selbst gefertigte Anionenaustauscher-Fertigplatten (200 × 200 mm) vom Typ Dowex 2-X8, die sowohl in der Chlorid-, als auch in der Acetat-Form vorlagen. Zum Vergleich wurden auch einige "Ionex 25" Anionenaustauscher-Fertigplatten des gleichen Typs der Firma Macherey-Nagel (Düren, BRD) in der Acetat-Form herangezogen.

naphthalene. After extraction, the very fine solidified naphthalene crystals are dissolved in chloroform, and the absorbance of the resultant solution is measured at 370 nm against a reagent blank. Beer's law is obeyed for 30–370 μg of palladium in 10 ml of chloroform, and the molar absorptivity is calculated to be $1{\cdot}72 \times 10^4$ l.mole.$^{-1}$mm^{-1}. Various alkali metal salts and metal ions do not interfere. The interference of nickel(II) is overcome by the extraction at pH 2, and that of iron(III) by masking with EDTA or by reduction to iron(II). The method is rapid and accurate.

Zusammenfassung—Zur Bestimmung von Palladium wird Palladiumdimethylglyoximat mit geschmolzenem Naphthalin extrahiert und dann Festkörper und Flüssigkeit getrennt. Der Komplex aus Palladium und Dimethylglyoxim wird leicht in geschmolzenes Naphthalin extrahiert. Nach der Extraktion werden die sehr feinen Kristalle von wieder fest gewordenem Naphthalin in Chloroform gelöst und die Extinktion der Lösung bei 370 nm gegen eine Reagens-Blindprobe gemessen. Das Beersche Gesetz gilt bei 30–370 μg Palladium in 10 ml Chloroform, der molare Extinktionskoeffizient wird zu $1{,}72 \cdot 10^4$ l mol^{-1}mm^{-1} berechnet. Eine Reihe von Alkalimetallsalzen und Metallionen stören nicht. Die Störung durch Nickel(II) wird beseitigt, wenn bei pH 2 extrahiert wird, die durch Eisen(III) durch Maskierung mit EDTA oder durch Reduktion zu Eisen(II). Die Methode ist schnell und genau.

Résumé—On a appliqué avec succès au palladium une méthode d'extraction liquide-liquide du diméthylglyoximate de palladium avec du naphtalène fondu, suivie d'une séparation solide-liquide. Le complexe entre le palladium et la diméthylglyoxime est aisément extrait en naphtalène fondu. Après extraction, les cristaux très fins de naphtalène solidifié sont dissous en chloroforme, et l'on mesure l'absorption de la solution résultante à 370 nm par rapport à un témoin des réactifs. La loi de Beer est suivie pour 30–370 μg de palladium dans 10 ml de chloroforme, et l'on a calculé que le coefficient d'absorption moléculaire est de $1{,}72 \times 10^4$ mm^{-1} l.mole^{-1}. Divers sels alcalins et ions métalliques ne gênent pas. On évite l'interférence du nickel(II) par l'extraction à pH 2, et celle du fer(III) en le dissimulant par l'EDTA ou par réduction en fer(II). La méthode est rapide et précise.

Détermination gravimétrique de l'iode sous forme de $Nt(ICl_2)$*

(*Reçu le* 28 *avril* 1971. *Accepté le* 28 *novembre* 1971)

ON CONNAÎT deux méthodes de détermination gravimétrique de l'iode. Elles sont basées sur sa précipitation sous forme d'AgI[1] et d'iodure de palladium(II).[2] Une méthode gravimétrique de détermination de l'iode sous forme d'un autre composé, utilisant un agent organique, n'a pas été proposée jusqu'ici. C'est une telle méthode que nous préconisons dans le présent mémoire. L'iode y est déterminé et pesé sous forme de dichloriodure de nitron.

---

* L'abréviation Nt désigne le cation de la base (nitron).

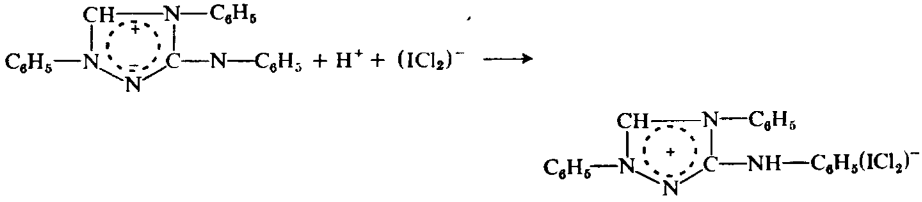
Des essais[3] portant sur le système eau–acide chlorhydrique–iode–chlore, ont montré que lors de son oxydation au moyen du chlore en milieu chlorhydrique saturé de chlore, l'iode se transforme quantitativement en complex $(ICl_2)^-$. On sait que les anions de même type $(ICl_4)^-$ et $(AuCl_4)^-$ réagissant avec certaines bases organique, fournissent des composés peu solubles et que les méthodes de détermination quantitative de la nicotine[4] et de l'or[5] sont basées sur ces propriétés. Ayant en vue ces faits, nous nous sommes proposés pour but d'élaborer une nouvelle méthode gravimétrique de détermination de l'iode, où seraient mises à profit les propriétés du composé que forme le complexe $(ICl_2)^-$ avec le nitron.

PARTIE EXPERIMENTALE

Si l'on additionne une solution contenant le complexe (ICl_2) d'une solution de sulphate de nitron, on obtient un précipité faiblement coloré en jaune qui, après agitation, acquiert une forme nettement cristalline.

Le composé s'obtient en milieu chlorhydrique fortement saturé (d'acide chlorhydrique) offre une solubilité extrêmement faible.

La réaction entre le nitron et le complexe $(ICl_2)^-$ se déroule probablement selon l'équation suivante:



La basicité élevée du nitron provoque la production de protons et l'association du nitron et du complexe iodochlorure. Ce mécanisme se trouve confirmé par les spectres IR du composé obtenu et du nitron. Le spectre du composé, contrairement à celui du nitron, présente un pic de liaison N–H nettement visible.

On a procédé à l'analyse du composé pour en déterminer les teneurs en C, H, N, et la somme de l'iode et du chlore. Les résultats figurent dans le tableau No. I. On y inclu aussi les résultats théoriques, calculés selon les formules: $Nt(ICl_2)$, $Nt(ICl_4)$. Les données du tableau attestent que le composé obtenu est $Nt(ICl_2)$.

TABLEAU I.—DONNÉES SUR LA CONSTITUTION DU COMPOSÉ

	C%	H%	N%	Cl + I%
Théorie pour $Nt(ICl_2)$	47,06	3,34	10,98	38,82
Trouvé	47,4	3,5	10,2	38,6
Théorie pour $Nt(ICl_4)$	43,08	2,95	9,66	46,38

$Nt(ICl_2)$ fond sans se décomposer à 160°C. Il se dissout au mieux dans l'acétone, moins bien dans l'alcool éthylique (0,74%), le dichloréthane (0,40%), le chloroforme (0,06%) et l'éther (0,04%). Il est insoluble dans les solvants non-polaires: benzène, tétrachloromethane. Dans l'eau le composé acquiert une coloration orangée qui, en fin d'opération, vire au noire. Sa solubilité a été déterminée en HCl à 5%, où il ne manifeste pas de modification.

À la température de 20°C, en HCl à 5%, la solubilité est de $6{,}3 \times 10^{-5}M$ en HCl à 5% et en présence de sulfate de nitron que nous avons basé notre nouvelle méthode gravimétrique de détermination de l'iode.

Analyse

Dans un ballon Kjeldahl de 50 ml on introduit environ 20 ml de solution d'ions iodiques contenant de 5 à 40 mg d'iode. On ajoute 20 ml de HCl concentré, saturé en Cl_2, agite, et, aussitôt, on fait barboter de l'air durant 5 minutes à travers cette solution. On transvase le mélange dans une fiole et le dilue à 100 ml, puis on ajoute lentement, et en agitant toujours, 25 ml de solution de sulfate de nitron à 1%. On obtient d'abord un précipité jaune à peine perceptible qui, après agitation énergique, acquiert peu à peu une coloration jaune et une structure cristalline très nette. On laisse reposer pendant une heure, puis on filtre sur un filtre de verre G_3 ou G_4.

Le contenu de la fiole est versé sur le filtre, puis la fiole est rincée par de l'acide chlorhydrique à 4% contenant un peu de sulfate de nitron où, mieux encore, par le filtrat lui-même. Le précipité est ensuite lavé à deux où trois reprises par un peu d'acide chlorhydrique à 4%, sêché pendant 1 hr à 100°–105° et pesé.

Pour illustrer la précision de la méthode, nous avons établi le tableau No. II, qui rend compte des résultats relatifs aux quantités de 4,5 à 40 mg.

Le coefficient de variation pour 15 à 40 mg dans 10 déterminations, evalué pour une sûreté statistique de 95% est respectivement de ±1,70 et ±0,75%.

TABLEAU II.—DETERMINATION DE L'IODE AVEC NITRON

Les ions bromate ne gênent pas la détermination. Si leur quantité est de l'ordre de celle de l'iode, il n'est pas indispensable de changer de mode opératoire. En l'occurence, lors du barbotage, le brome obtenu est éliminé en même temps que l'excédent de chlore, ce qui modifie pas les conditions du travail ultérieur. Si la teneur en Br est élevée, par example si le rapport Br/I = 5–10 et même davantage, la technique doit être modifiée en début d'opération. Dans le ballon de Kjeldahl on doit introduire d'abord de l'acide chlorhydrique concentré et saturé en chlore, puis remplir le ballon de chlore et, alors seulement ajouter à l'aide d'une pipette la solution à analyser. Par la suite, la détermination se déroule selon le schéma décrit plus haut. Dans ces conditions la présence du Br n'a pas d'effet sur les résultats. Ainsi, dans deux déterminations de 40 mg d'I, en présence de la même quantité de Br, on a détecté 40,10 et 40,15 mg d'iode.

La méthode préconisée a été confrontée avec la méthode la plus sûre, pratiquée le plus souvent la détermination gravimétrique de l'iode, sous forme d'AgI. Les résultats de 10 essais de détermination de 15 et de 40 mg d'iode, effectués avec précipitation par l'argent, figurement dans le tableau No. III. La confrontation des données des tableaux II et III, met en évidence d'une façon catégorique la meilleure précision de la nouvelle méthode. Elle présente encore les avantages suivants.

1. Elle se déroule en présence de Cl et de Br.
2. Elle exclu l'erreur due à l'oxydation de I^- en I_2.
3. La décomposition d'AgI, sous l'effet de la lumière n'entraîne pas d'erreurs.
4. Contrairement au précipité d'AgI, celui de $Nt(ICl_2)$ ne retient pas de solvant ni d'autres substances contenues dans la solution.

TABLEAU III.—DETERMINATION DE L'IODE AVEC L'ARGENT

Prélevé, *mg*	Trouvé, *mg*	Erreur relat., %	Prélevé, *mg*	Trouvé, *mg*	Erreur relat., %

Trennung anorganischer Phosphate an Anionenaustauscher-Fertigplatten

(*Eingegangen am* 19. *Juli* 1971. *Angenommen am* 18. *Oktober* 1971)

Die analytische Chemie der Phosphate gewinnt auf Grund der vielfältigen Formen und des häufigen Auftretens dieser Verbindungen in Natur- und Syntheseprodukten zunehmend an Bedeutung. Bisherige papierchromatographische[1,2] und dünnschicht-chromatographische Trennungen (an Celluloseschichten)[3] zeigen zwar gute Ergebnisse, sind aber nur schwer reproduzierbar. Im Gegensatz dazu liefert die Gradientenelution an Anionenaustauscher-Säulen[4,5] sehr gute Ergebnisse, jedoch ist dieses Verfahren sehr zeitaufwendig. Um die Vorteile der Dünnschichtchromatographie mit denen des Ionenaustausches zu verbinden, wendeten wir die Ionenaustauscher-Dünnschichtchromatographie an.[6,7] Wir verwendeten selbst gefertigte Anionenaustauscher-Fertigplatten (200 × 200 mm) vom Typ Dowex 2-X8, die sowohl in der Chlorid-, als auch in der Acetat-Form vorlagen. Zum Vergleich wurden auch einige "Ionex 25" Anionenaustauscher-Fertigplatten des gleichen Typs der Firma Macherey-Nagel (Düren, BRD) in der Acetat-Form herangezogen.

EXPERIMENTELLER TEIL

Pufferlösung: pH = 5,0. Die Lösung enthält pro Liter 20 ml Pyridin und 13,4 ml Eisessig. Zur Trennung der Oligophosphate werden zu dieser Stamm-Pufferlösung noch 0,25 Mol Natrium chlorid zugesetzt.

Bedingungen. Es wurden ungefähr 1 μg P von jeder Phosphor(v)-Verbindung auf die Platte aufgetragen. Zur Trennung der Oligophosphate äquilibrierten wir die Schicht mit $1M$ Salzsäure durch durchlaufende Chromatographie mit Papierzunge. Nach einem kurzen Zwischentrocknen wuschen wir die Platten mit ionenfreiem Wasser säurefrei. Zur Trennung der Amidophosphate erfolgte die Äquilibrierung nach der gleichen Methode jedoch ohne Nachwaschen mit $0{,}01M$ Essigsäure. Die Trennung der Oligophosphate geschah bei Zimmertemperatur, die der Amidophosphate bei etwa 5° im Kühlschrank. Bei beiden wurde die aufsteigende Technik angewendet. Die Laufzeit betrug in beiden Fällen ungefähr 70 Minuten.

Sprühreagenzien

(*a*) $1M$ Perchlorsäure, in Wasser–Aceton 1:1. Zur Hydrolyse von Di- und Triphosphat zu Monophosphat wird diese Lösung zweimal auf die warme Platte 60° aufgesprüht. Nach dem zweiten Besprühen wird die Platte langsam bei 50° getrocknet. Bei den Amidophosphaten erübrigt sich dieser Aufschluß.

(*b*) $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$(5 g) wird in einer Mischung aus 35 ml halbkonzentrierter Salpetersäure und 65 ml Wasser aufgelöst. Mit dieser Lösung wird die noch warme Platte befeuchtet.

(*c*) $SnCl_2\cdot 2H_2O$(0,5 g) wird in 100 ml $0{,}5M$ Salzsäure gelöst. Die Lösung wird auf die noch feuchte Platte gesprüht. Die Phosphate treten als blaue bis blau-grüne Flecke hervor.

Mono-, Di- und Triphosphat werden an einer Fertigplatte in der Chlorid-Form einwandfrei getrennt. Wie nicht anders zu erwarten, befindet sich das Triphosphat auf Grund seiner großen Ladung nur kurz oberhalb des Startpunktes. Diphosphat und Monophosphat wandern wegen der abnehmenden Ladungszahl entsprechend weiter.

Zur Trennung von Phosphorsäuretriamid, $PO(NH_2)_3$, Diamidophosphat, $NaPO_2(NH_2)_2$, Monoamidophosphat, $Na_2PO_3(NH_2)$ und Monophosphat, Na_2HPO_4, empfiehlt sich die Anwendung eines schwächeren Gegenions am Anionenaustauscher. Da erfahrungsgemäß die Amidophosphate auf den Chromatogrammen vor dem Monophosphat liegen, würden sie auf einer Anionenaustauscher-Fertigplatte in der Chlorid-Form nur kurz unterhalb der Front liegen und sich gegenseitig stören. Um eine Zersetzung der Amidophosphate so weit wie möglich zu verhindern, wurde die Entwicklung bei der angegebenen niedrigen Temperatur durchgeführt.

Die von uns vorgeschlagen Methode besitzt neben dem geringen Zeitaufwand und der großen Reproduzierbarkeit der Ergebnisse noch folgende Vorteile: die Trennung der Oligophosphate und der Amidophosphate kann im Prinzip mit nur einer Stamm-Pufferlösung vorgenommen werden. Bei der Trennung der Oligophosphate stören die Amidophosphate nicht, da sie vor dem Monophosphat liegen. Im umgekehrten Fall verbleiben die Oligophosphate am Start. Ein Vergleich mit den Ionenaustauscher-Fertigplatten "Ionex 25" ergab, daß keine bedeutenden Unterschiede in den Trennungen auftreten.

Anmerkung—An dieser Stelle möchte einer der Verfasser, H. K., Herrn Dr. T. Dévényi für die Überlassung der Anionenaustauscher Fertigplatten und für seine anregenden Diskussionen herzlich danken.

Zusammenfassung—Es wird ein Verfahren zur Trennung von Monophosphat, Diphosphat und Triphosphat bzw. Phosphorsäuretriamid, $PO(NH_2)_3$, Diamidophosphat, $NaPO_2(NH_2)_2$, Monoamidophosphat, $Na_2PO_3NH_2$ und Monophosphat an Anionenaustauscher-Fertigplatten des Typs Dowex 2-X8 beschrieben. Das Verfahren verbindet die Vorteile der Dünnschichtchromatographie mit denen des Ionenaustausches. Durch die Auswahl geeigneter Gegenionen am Harz (Chlorid bzw.

Acetat) ist im Prinzip nur eine Stamm-Pufferlösung zur Trennung erforderlich. Bei der Chromatographie tritt keine Störung beider Verbindungsklassen auf.

Summary—A procedure is described for the separation of mono-, di- and triphosphate, and of monophosphate and mono, di- and triamidophosphate on ready-made thin-layer plates of anion-exchange resin Dowex 2-X8. The procedure couples the advantages of thin-layer chromatography with those of ion-exchange techniques. By suitable choice of anion for the resin (*i.e.* chloride or acetate) only one stock buffer solution is needed for the separation. The two classes of compounds do not interfere with each other during the separations.

Résumé—On décrit une technique pour la séparation de mono-, di- et triphosphate, et de monophosphate et mono-, di- et triamidophosphate sur des plaques de couche mince de résine échangeuse d'anions Dowex 2-X8 toutes prêtes. La méthode réunit les avantages de la chromatographie sur couche mince avec ceux des techniques d'échange d'ions. Par un choix convenable de l'anion pour la résine (c'est-à-dire chlorure ou acétate), une seule solution tampon de réserve est nécessaire pour la séparation. Les deux classes de composés n'interfèrent pas l'une avec l'autre durant les séparations.

5. En raison du poids moléculaire élevé et de la faible solubilité de Nt(ICl$_2$), la méthode permet de déterminer des quantités d'iode 2–3 fois plus petites.

6. Pour la même raison, le facteur de transformation du poids du précipité en iode est aussi deux fois plus petit.

7. On utilise le sulfate et non pas l'acétate de nitron, car le nitron, comme reactif, contient beaucoup d'impurités qui, au cours de sa dissolution dans l'acide acétique, restent dans la solution et empêchent la détermination. Au contraire, le sulphate peut être facilement obtenu du nitron.[6]

Résumé—On a obtenu le composé dichloriodure de nitron—Nt(ICl$_2$)—et l'on a etudié les propriétés. En se basant sur les résultats obtenus, on a elaboré une méthode gravimétrique de détermination de l'iode sous forme de Nt(ICl$_2$). Elle permet de determiner par voie gravimétrique de 4 à 40 mg d'iode, l'erreur étant moindre que lors de détermination de l'iode sous forme d'AgI. Les ions bromate et chlorate ne gênent pas la détermination.

Summary—Nitron dichloroiodide—Nt(ICl$_2$)—has been prepared and studied, and a gravimetric determination of iodine as Nt(ICl)$_2$ has been based on the result. For 4–40 mg of iodine the error is less than that of the determination as AgI. Bromate and chlorate do not interfere.

Zusammenfassung—Nitrondichlorojodid—Nt(JCl$_2$)—wurde hergestellt und untersucht; auf den Ergebnissen wurde eine gravimetrische Bestimmung von Jod als Nt(JCl$_2$) aufgebaut. Für 4–40 mg Jod ist der Fehler kleiner als bei der Bestimmung als AgJ. Bromat und Chlorat stören nicht.

ANALYTICAL DATA

Potentiometric determination of stepwise stability constants of zirconium and thorium chelates formed with aspartic and glutamic acids

(*Received* 29 *September* 1971. *Accepted* 18 *October* 1971)

ASPARTIC and glutamic acids are known to form chelate complexes with various metal ions,[1–7] in which they act as bidentate or tridentate ligands. In previous communications[8,9] from this laboratory we reported stepwise stability constants of aspartate and glutamate chelates of Hg(II), Be(II), Al(III), Pd(II), Pt(IV), Au(III) and Bi(III). Their formation was studied potentiometrically by Calvin-Bjerrum's pH titration technique[10] as modified by Irving and Rossotti.[11] This paper gives the results of a similar study with zirconium(IV) and thorium(IV) ions.

RESULTS AND DISCUSSION

The protonation constants are log K_1^{H} 9·48, log K_2^{H} 3·75 for aspartic acid, and log K_1^{H} 9·45 and og K_2^{H} 4·23 for glutamic acid.[8,9]

The formation curves ($\bar{n}$ *vs.* pL) for the aspartate and glutamate chelates show that for Zr(IV) $\bar{n}$ approaches a value of 3, whereas for Th(IV) $\bar{n}$ approaches a maximum value of 4 (pH range 3-9).

Analysis of the formation curves for the Zr(IV) chelates shows that K_1, K_2, K_3 are well apart, with $K_1/K_2 \sim 10^3$ K_2/K_3 ratio $\sim 10^3$. The stability constants were computed by interpolation at half-$\bar{n}$ values[11] and also by successive approximation method.

For Th(IV) chelates, however, $K_1/K_2 \sim 10^{0.8}$ $K_2/K_3 \sim 10^4$ and $K_3/K_4 \sim 10^{0.8}$, so the formation curves can be divided into two separate regions, and each treated separately.[12] In the range $\bar{n} = 0$–2 approximate constants were obtained by interpolation at half-$\bar{n}$ values, and then refined by successive approximation. The results are further confirmed by the correction term method. In the second range ($\bar{n} = 2$–4) also, K_3 and K_4 were computed by the half-$\bar{n}$ and the correction term methods. The constants were further refined by successive approximation.

TABLE I.—STABILITY CONSTANTS OF ZIRCONIUM(IV) AND THORIUM(IV) CHELATES WITH ASPARTIC AND GLUTAMIC ACIDS.
(Temp. 25°C, $\mu = 0{\cdot}1M$ NaClO$_4$)

Metal ion	Method	Aspartic acid				Glutamic acid			
		log K_1	log K_2	log K_3	log β_3	log K_1	log K_2	log K_3	log β_3
Zr(IV)	Half $\bar{n}$ method	9·70	6·85	3·50	20·05	9·60	6·40	3·32	19·32
	Successive approximation method	9·70	6·85	3·50	20·05	9·60	6·40	3·32	19·32

Metal ion	Method	log K_1	log K_2	log K_3	log K_4	log β_4	log K_1	log K_2	log K_3	log K_4	log β_4
Th(IV)	Interpolation at half $\bar{n}$ values	9·38	8·55	4·70	3·87	—	9·25	8·50	4·27	3·60	—

Summary—The metal chelates of Zr(IV) and Th(IV) with aspartic and glutamic acids have been studied potentiometrically. Stepwise stability constants in 0·1*M* sodium perchlorate at 25° are reported as: aspartate chelates—log K_1 9·70, log K_2 6·85, and log K_3 3·50 for Zr, and log K_1 9·23, log K_2 8·57, log K_3 4·55 and log K_4 3·87 for Th; glutamate chelates—log K_1 9·60, log K_2 6·40 and log K_3 3·32 for Zr and log K_1 9·11, log K_2 8·52, log K_3 4·18 and log K_4 3·62 for Th.

Zusammenfassung—Die Metallchelate von Zr(IV) und Th(IV) mit Asparaginsäure und Glutaminsäure wurden potentiometrisch untersucht. Die Bildungskonstanten der einzelnen Stufen in 0,1*M* Natriumperchlorat bei 25° werden mitgeteilt: Asparaginsäure-Chelate—log K_1 9,70, log K_2 6,85, log K_3 3,50 für Zr und log K_1 9,23, log K_2 8,57, log K_3 4,55, log K_4 3,87 für Th; Glutaminsäure-Chelate—log K_1 9,60, log K_2 6,40, log K_3 3,32 für Zr und log K_1 9,11, log K_2 8,52, log K_3 4,18, log K_4 3,62 für Th.

Résumé—Les chèlates mètalliques de Zr(IV) et Th(IV) avec les acides aspartique et glutamique ont ètè ètudiès potentiomètriquement. Les constantes de stabilitè par palier en perchlorate de sodium 0,1 *M* à 25° sont: chèlates aspartiques—log K_1 9,70; log K_2 6,85; et log K_3 3,50 pour Zr et log K_1 9,23; log K$_2$ 8,57, log K_3 4,55 et log K_4 3,87 pour Th; chèlates glutamiques—log K_1 9,60, log K_2 6,40 et log K_3 3,32 pour Zr et log K_1 9,11; log K$_2$ 8,52; log K$_3$ 4,18 et log K_4 3,62 pour Th.

The protonation constants are log K_1^H 9·48, log K_2^H 3·75 for aspartic acid, and log K_1^H 9·45 and og K_2^H 4·23 for glutamic acid.[8,9]

The formation curves ($\bar{n}$ *vs.* pL) for the aspartate and glutamate chelates show that for Zr(IV) $\bar{n}$ approaches a value of 3, whereas for Th(IV) $\bar{n}$ approaches a maximum value of 4 (pH range 3-9).

Analysis of the formation curves for the Zr(IV) chelates shows that K_1, K_2, K_3 are well apart, with $K_1/K_2 \sim 10^3$ K_2/K_3 ratio $\sim 10^3$. The stability constants were computed by interpolation at half-$\bar{n}$ values[11] and also by successive approximation method.

For Th(IV) chelates, however, $K_1/K_2 \sim 10^{0 \cdot 8}$ $K_2/K_3 \sim 10^4$ and $K_3/K_4 \sim 10^{0 \cdot 8}$, so the formation curves can be divided into two separate regions, and each treated separately.[12] In the range $\bar{n} = 0$–2 approximate constants were obtained by interpolation at half-$\bar{n}$ values, and then refined by successive approximation. The results are further confirmed by the correction term method. In the second range ($\bar{n} = 2$–4) also, K_3 and K_4 were computed by the half-$\bar{n}$ and the correction term methods. The constants were further refined by successive approximation.

TABLE I.—STABILITY CONSTANTS OF ZIRCONIUM(IV) AND THORIUM(IV) CHELATES WITH ASPARTIC AND GLUTAMIC ACIDS.
(Temp. 25°C, $\mu = 0 \cdot 1 M$ NaClO$_4$)

Summary—The metal chelates of Zr(IV) and Th(IV) with aspartic and glutamic acids have been studied potentiometrically. Stepwise stability constants in 0·1*M* sodium perchlorate at 25° are reported as: aspartate chelates—log K_1 9·70, log K_2 6·85, and log K_3 3·50 for Zr, and log K_1 9·23, log K_2 8·57, log K_3 4·55 and log K_4 3·87 for Th; glutamate chelates—log K_1 9·60, log K_2 6·40 and log K_3 3·32 for Zr and log K_1 9·11, log K_2 8·52, log K_3 4·18 and log K_4 3·62 for Th.

Zusammenfassung—Die Metallchelate von Zr(IV) und Th(IV) mit Asparaginsäure und Glutaminsäure wurden potentiometrisch untersucht. Die Bildungskonstanten der einzelnen Stufen in 0,1*M* Natriumperchlorat bei 25° werden mitgeteilt: Asparaginsäure-Chelate—log K_1 9,70, log K_2 6,85, log K_3 3,50 für Zr und log K_1 9,23, log K_2 8,57, log K_3 4,55, log K_4 3,87 für Th; Glutaminsäure-Chelate—log K_1 9,60, log K_2 6,40, log K_3 3,32 für Zr und log K_1 9,11, log K_2 8,52, log K_3 4,18, log K_4 3,62 für Th.

Résumé—Les chèlates mètalliques de Zr(IV) et Th(IV) avec les acides aspartique et glutamique ont ètè ètudiès potentiomètriquement. Les constantes de stabilitè par palier en perchlorate de sodium 0,1 *M* à 25° sont: chèlates aspartiques—log K_1 9,70; log K_2 6,85; et log K_3 3,50 pour Zr et log K_1 9,23; log K_2 8,57, log K_3 4,55 et log K_4 3,87 pour Th; chèlates glutamiques—log K_1 9,60, log K_2 6,40 et log K_3 3,32 pour Zr et log K_1 9,11; log K_2 8,52; log K_3 4,18 et log K_4 3,62 pour Th.

Thermodynamic dissociation constants of *N*-phenylbenzohydroxamic acids and benzohydroxamic acid

(*Received* 23 *June* 1971. *Accepted* 17 *November* 1971)

THE p*K* VALUES of benzohydroxamic acid and substituted phenylbenzohydroxamic acids have been determined in 10–50% v/v dioxan–water media at 25° and 30°. The van Uitert and Haas relation[1] was used to obtain the hydrogen ion concentration from the values read on the pH-meter:

$$-\log [\mathrm{H}^+] = \mathrm{pH} + \log U_{\mathrm{H}}{}^0 - \log \frac{1}{\gamma_{\pm}}$$

Summary—The metal chelates of Zr(IV) and Th(IV) with aspartic and glutamic acids have been studied potentiometrically. Stepwise stability constants in $0{\cdot}1M$ sodium perchlorate at 25° are reported as: aspartate chelates—log K_1 9·70, log K_2 6·85, and log K_3 3·50 for Zr, and log K_1 9·23, log K_2 8·57, log K_3 4·55 and log K_4 3·87 for Th; glutamate chelates—log K_1 9·60, log K_2 6·40 and log K_3 3·32 for Zr and log K_1 9·11, log K_2 8·52, log K_3 4·18 and log K_4 3·62 for Th.

Zusammenfassung—Die Metallchelate von Zr(IV) und Th(IV) mit Asparaginsäure und Glutaminsäure wurden potentiometrisch untersucht. Die Bildungskonstanten der einzelnen Stufen in $0{,}1M$ Natriumperchlorat bei 25° werden mitgeteilt: Asparaginsäure-Chelate—log K_1 9,70, log K_2 6,85, log K_3 3,50 für Zr und log K_1 9,23, log K_2 8,57, log K_3 4,55, log K_4 3,87 für Th; Glutaminsäure-Chelate—log K_1 9,60, log K_2 6,40, log K_3 3,32 für Zr und log K_1 9,11, log K_2 8,52, log K_3 4,18, log K_4 3,62 für Th.

Thermodynamic dissociation constants of *N*-phenylbenzohydroxamic acids and benzohydroxamic acid

(*Received* 23 *June* 1971. *Accepted* 17 *November* 1971)

THE pK VALUES of benzohydroxamic acid and substituted phenylbenzohydroxamic acids have been determined in 10–50% v/v dioxan-water media at 25° and 30°. The van Uitert and Haas relation[1] was used to obtain the hydrogen ion concentration from the values read on the pH-meter:

$$-\log\,[\mathrm{H}^+] = \mathrm{pH} + \log U_{\mathrm{H}}{}^0 - \log \frac{1}{\gamma_\pm}$$

The mean activity coefficients were obtained from Harned and Owen[2] and U_H^0 was measured experimentally. It was assumed that the mean activity coefficients were the same on both the molal and molar scales. For aqueous organic media the dissociation constant K is given by

$$pK = pH + \log U_H^0 + \log \frac{[HA]}{[A]} + \log \frac{1}{\gamma_\pm}$$

Hydrolysis of the salt in aqueous medium was taken into consideration[3] *via* the equation

$$pK_{(aq)} = -\log [H^+] + \log \frac{[HA] + [OH^-]}{[A^-] - [OH^-]} + 2 \log \frac{1}{\gamma_\pm}$$

and for mixed aqueous-organic media by

$$pK = pH + \log U_H^0 + \log \frac{[HA] + [OH]}{[A^-] - [OH^-]} + \log \frac{1}{\gamma_\pm}$$

The standard free energy change was calculated in the usual way from pK, and the standard enthalpy change was obtained by integration of the van't Hoff equation at two temperatures. The results are approximate because the heats of ionization vary with temperature, but for the small temperature interval used (10°) $\Delta H°$ may be considered constant.[4] The standard entropy change was obtained from $\Delta G°$ and $\Delta H°$.

EXPERIMENTAL

All the chemicals used were of general or analytical-reagent grade unless otherwise stated. Benzohydroxamic acid was prepared by the method of Hauser and Renfrow[5] and the other hydroxamic acids by the method of Priyadarshini and Tandon.[6] The purity of the acids was established by m.p., elemental analysis and ultraviolet and infrared spectroscopy. Dioxan was purified according to Weissberger.[7] Carbonate-free potassium hydroxide solution was prepared by Vogel's electrolytic method[8] and standardized against potassium hydrogen phthalate and diluted to 0·1M with the solvent medium. The glass-distilled water used was tested for carbonate by Kolthoff's method.[9] The Radiometer pH-meter pHM-4c was calibrated (±0·01 pH unit) with aqueous standard buffer.[10]

The tritation procedure was essentially that recommended by Albert and Serjeant.[11] Generally, 0·01M hydroxamic acid was titrated without addition of inert salts (unadjusted ionic strength). To find the effect of dilution, a few titrations were performed on 0·008–0·012M hydroxamic acid. In the titration vessel (controlled to ±0·1°) 0·5 mmole of hydroxamic acid in 47·5 ml of solvent was titrated with 0·5-ml increments of alkali, after being deaerated by passage of nitrogen (presaturated with solvent) for 15 min, the highest steady pH value being noted after each increment.

RESULTS

Titration of perchloric acid in the presence and absence of the hydroxamic acids showed that the protonation of these acids is very low, as found by others.[12,13] The pK values in various media are shown in Table I. The average error in pK is generally 0·02 but does not exceed 0·03. The pK values were plotted against n, the mole fraction of dioxan, and the empirical relationships derived are shown in Table II. The thermodynamic functions are summarized in Table III.

DISCUSSION

The acidity of the hydroxamic acids may be attributed essentially to the —OH group, and the basic character of the nitrogen atom is suppressed as it is in amides. Hydroxamic acids are very weak, though several times stronger than phenol. The suppression of acidic character may be attributed to intramolecular hydrogen-bonding, as shown by infrared studies.[14–16]

Effect of the medium

A solvent of low dielectric constant increases the electrostatic forces between the ions and facilitates formation of molecular species, and should increase pK, as borne out for hydroxamic acids by Tables I and II. Gurney[17] and others[18,19] have pointed out that the standard free energy change of proton transfer may be considered in two parts—electrostatic and non-electrostatic ($\Delta G_{el}°$ and ΔG°_{non}).

ΔG° and ΔH° in kcal/mole; ΔS° in cal/mole/K; first value at 25°C, second at 35°C.
Values in brackets were obtained by extrapolation.
* From Shukla.[12]

The electrostatic contribution is often estimated from the Born equation[20]

$$\Delta G_{\mathrm{el}}^\circ = \frac{Ne^2}{2D}\left(\frac{1}{r_+} + \frac{1}{r_-}\right)$$

where r_+ and r_- are the radii of the ions and for dilute solutions D is taken as the dielectric constant of the solvent.[21,22] Hence

$$\mathrm{p}K = \frac{\Delta G^\circ_{\mathrm{non}}}{2{\cdot}303RT} + \frac{Ne^2}{2D}\left(\frac{1}{r_+} + \frac{1}{r_-}\right)$$

Conventionally, p*K* is plotted *vs.* $1/D$, with $\Delta G^\circ_{\mathrm{non}}$ assumed independent of the solvent. Nearly linear relationships have been reported,[23–26] especially for water-rich media, but so has non-linearity.[27] The plots for the hydroxamic acids are distinctly curved and evidently non-electrostatic factors exert a considerable influence on the dissociation.

HO_2	2·17	8·11

The change in p*K* with mole fraction of dioxan is considerable for all the hydroxamic acids, the difference being >2 for water media containing 0 and 50% dioxan.

Thermodynamic functions

The p*K* values were determined with a precision between 0·02 and 0·03, and hence the error in $\Delta G°$ is estimated to be between 0·03 and 0·04 kcal/mole. The method used to compute $\Delta H°$ is subject to large error because the enthalpy change is small and p*K* was not determined at a series of temperatures, which would have allowed use of a more precise method.[28] In our case, an error of 0·01 in ΔpK causes an error of 0·42 kcal/mole in $\Delta H°$, and the magnitude of error in ΔpK depends on the cancellation or addition of errors in the individual p*K* values determined at the two temperatures. However, the positive value of $\Delta H°$ found for all solvent media and acids studies here indicates that the ionization process at temperatures up to 25° is endothermic. Further, the change in $\Delta H°$ with change in medium is relatively small and within experimental error. For this reason the plots of p*K* *vs*. *n* give practically the same slopes at both temperatures (except for *N*-phenyl-*o*-methylbenzohydroxamic acid, for which the results were obtained by others).

It is therefore justifiable to assume that $\Delta H°$ is independent of solvent composition over the range studied. On this basis fresh $\Delta H°$ values were computed from 42 times the difference in the intercepts on the p*K* axis for the p*K*/*n* plots, and it is these values that are given in Table III. The $\Delta S°$ values were also assumed to be independent of solvent composition.

If an acid ionizes in two media, the free energy change for the transfer reaction from one medium to the other is given by 2·303*RT* Δp*K*. For example, with benzohydroxamic acid, $\Delta G°$ is 12·15 and 14·58 kcal/mole for water and 50% aqueous dioxan respectively, and $\Delta G°$ changes by 2·43 kcal/mole in the transfer reaction

$$HA_{(diox)} + H^+_{(ag)} + A^-_{(ag)} \rightleftharpoons HA_{(aq)} + H^+_{(diox)} + A^-_{(diox)}$$

and this is essentially due to a change of $-8{\cdot}2$ cal.mole^{-1} . K^{-1} in $\Delta S°$.

Substituent effects

In the benzoic acid series, regardless of electronic type, nearly all the substituents are acid-strengthening in the *ortho*-position[29] but may be either acid-weakening or strengthening when they are in the *meta*- or *para*-positions, depending on their character. In the *ortho*-substituted phenylbenzohydroxamic acids the acid-strengthening effect is also observed in all cases except methoxy substitution, but it is less than for the corresponding carboxylic acids (Table IV). Like the parent benzoic acid, these *o*-substituted hydroxamic acids do not obey the Hammett equation.[30]

Summary—Thermodynamic association constants of benzohydroxamic acid and several *ortho*-substituted *N*-phenylbenzohydroxamic acids have been determined by pH titration in aqueous dioxan media at 25° and 35°. Empirical pH corrections for mixed aqueous media have been applied. The pK_a values do not vary linearly with the reciprocal of dielectric constant of the medium, but a plot of pK_a *vs.* the mole fraction of dioxan is linear at a given temperature. Values of $\Delta G°$, $\Delta H°$ and $\Delta S°$ are tabulated.

Zusammenfassung—Die thermodynamischen Assoziationskonstanten von Benzhydroxamsäure und mehreren *ortho*-substituierten *N*-Phenylbenzhydroxamsäuren wurden durch pH-Titration in wäßrigen Dioxanmedien bei 25° und 35° ermittelt. Empirische Korrekturen für gemischte wäßrige Medien wurden angebracht. Die pK_a Werte ändern sich nicht linear mit der reziproken Dielektrizitätskonstante des Mediums, aber pK_a gegen den Molenbruch von Dioxan aufgetragen ergibt bei einer gegebenen Temperatur eine Gerade. Die Werte von $\Delta G°$, $\Delta H°$ und $\Delta S°$ sind tabelliert.

Résumé—On a déterminé les constantes d'association thermodynamique de l'acide benzhydroxamique et de plusieurs acides N-phénylbenzhydroxamiques *ortho*-substitués par titrage pH en milieux dioxane aqueux à 25° et 35°. On a appliqué des corrections empiriques de pH pour les milieux aqueux mixtes. Les valeurs de pK_a ne varient pas linéairement avec l'inverse de la constante diélectrique du milieu, mais une courbe du pK_a en fonction de la fraction molaire de dioxane est linéaire à une température donnée. On indique dans une table les valeurs de $\Delta G°$, $\Delta H°$ et $\Delta S°$.

Behaviour of the thiodipropionic complex of In(III) and U(VI) at the DME in aqueous and aqueous methanolic solutions

(*Received* 21 *October* 1971. *Accepted* 14 *December* 1971)

THE COMPLEXATION of thiodipropionic acid (TDPA) with indium(III) and uranium(VI) has been studied by the methods used earlier.[1,2] Polarographic waves were recorded with a manual polarograph at 30 ± 0.1° using an H-cell with a saturated calomel electrode as reference electrode. The DME had the characteristics $m = 2.74$ mg/sec, $t = 3.20$ sec.

Experiments were performed with 0.25m*M* indium or uranium and 0.025–0.30*M* TDPA at an ionic strength of 1.2*M* (potassium chloride) for In and in 0.01*M* hydrochloric acid/0.1*M* potassium chloride for uranium (to obtain diffusion-controlled, reversible one-electron reduction of U(VI) at the DME).

The results were interpreted by means of the Deford and Hume[3] and the Irving[4] methods.

RESULTS AND DISCUSSION

Indium–TDPA

The reduction of indium–TDPA complex at the DME gives a well-defined diffusion controlled reversible 3-electron wave in aqueous and in aqueous methanol solutions. The half-wave potential increases slightly at pH values from 1.5 to 3, then more sharply till the pH reaches 5.0, above which precipitation takes place.

The presence of 10%, 30% and 50% methanol yields a well-defined wave with $E_{1/2} = -0.600$, -0.614 and -0.614 V *vs.* SCE respectively, $E_{1/2}$ is -0.6025 V for indium(III) in aqueous solution. This rules out complexation between the metal ions and methanol. A negative shift in $E_{1/2}$ on addition of increasing amounts of TDPA indicates complex formation.

The overall stability constants are summarized in Table I. Increasing the methanol concentration considerably increases the stability constants.

TABLE I.—STABILITY CONSTANTS FOR In(III)-TDPA SYSTEM

Methanol conc. of the media %	β_1	β_2	β_3	β_4
0	20	80	2.4×10^2	2.6×10^3
10	31	80	2.6×10^2	2.8×10^3
30	44	2.1×10^2	4.3×10^2	3.4×10^3
50	120	3.0×10^2	12.0×10^2	17.8×10^3

Summary—The metal chelates of Zr(IV) and Th(IV) with aspartic and glutamic acids have been studied potentiometrically. Stepwise stability constants in 0·1*M* sodium perchlorate at 25° are reported as: aspartate chelates—log K_1 9·70, log K_2 6·85, and log K_3 3·50 for Zr, and log K_1 9·23, log K_2 8·57, log K_3 4·55 and log K_4 3·87 for Th; glutamate chelates—log K_1 9·60, log K_2 6·40 and log K_3 3·32 for Zr and log K_1 9·11, log K_2 8·52, log K_3 4·18 and log K_4 3·62 for Th.

Zusammenfassung—Die Metallchelate von Zr(IV) und Th(IV) mit Asparaginsäure und Glutaminsäure wurden potentiometrisch untersucht. Die Bildungskonstanten der einzelnen Stufen in 0,1*M* Natriumperchlorat bei 25° werden mitgeteilt: Asparaginsäure-Chelate—log K_1 9,70, log K_2 6,85, log K_3 3,50 für Zr und log K_1 9,23, log K_2 8,57, log K_3 4,55, log K_4 3,87 für Th; Glutaminsäure-Chelate—log K_1 9,60, log K_2 6,40, log K_3 3,32 für Zr und log K_1 9,11, log K_2 8,52, log K_3 4,18, log K_4 3,62 für Th.

Résumé—Les chèlates mètalliques de Zr(IV) et Th(IV) avec les acides aspartique et glutamique ont ètè ètudiès potentiomètriquement. Les constantes de stabilitè par palier en perchlorate de sodium 0,1 *M* à 25° sont: chèlates aspartiques—log K_1 9,70; log K_2 6,85; et log K_3 3,50 pour Zr et log K_1 9,23; log K_2 8,57, log K_3 4,55 et log K_4 3,87 pour Th; chèlates glutamiques—log K_1 9,60, log K_2 6,40 et log K_3 3,32 pour Zr et log K_1 9,11; log K_2 8,52; log K_3 4,18 et log K_4 3,62 pour Th.

Thermodynamic dissociation constants of *N*-phenylbenzohydroxamic acids and benzohydroxamic acid

(*Received* 23 *June* 1971. *Accepted* 17 *November* 1971)

THE p*K* VALUES of benzohydroxamic acid and substituted phenylbenzohydroxamic acids have been determined in 10–50% v/v dioxan-water media at 25° and 30°. The van Uitert and Haas relation[1] was used to obtain the hydrogen ion concentration from the values read on the pH-meter:

$$-\log\,[\mathrm{H}^+] = \mathrm{pH} + \log U_{\mathrm{H}}{}^0 - \log\frac{1}{\gamma_\pm}$$

The mean activity coefficients were obtained from Harned and Owen[2] and U_H^0 was measured experimentally. It was assumed that the mean activity coefficients were the same on both the molal and molar scales. For aqueous organic media the dissociation constant K is given by

$$pK = pH + \log U_H^0 + \log \frac{[HA]}{[A]} + \log \frac{1}{\gamma_\pm}$$

Hydrolysis of the salt in aqueous medium was taken into consideration[3] *via* the equation

$$pK_{(aq)} = -\log [H^+] + \log \frac{[HA] + [OH^-]}{[A^-] - [OH^-]} + 2 \log \frac{1}{\gamma_\pm}$$

and for mixed aqueous-organic media by

$$pK = pH + \log U_H^0 + \log \frac{[HA] + [OH]}{[A^-] - [OH^-]} + \log \frac{1}{\gamma_\pm}$$

The standard free energy change was calculated in the usual way from pK, and the standard enthalpy change was obtained by integration of the van't Hoff equation at two temperatures. The results are approximate because the heats of ionization vary with temperature, but for the small temperature interval used (10°) $\Delta H°$ may be considered constant.[4] The standard entropy change was obtained from $\Delta G°$ and $\Delta H°$.

EXPERIMENTAL

All the chemicals used were of general or analytical-reagent grade unless otherwise stated. Benzohydroxamic acid was prepared by the method of Hauser and Renfrow[5] and the other hydroxamic acids by the method of Priyadarshini and Tandon.[6] The purity of the acids was established by m.p., elemental analysis and ultraviolet and infrared spectroscopy. Dioxan was purified according to Weissberger.[7] Carbonate-free potassium hydroxide solution was prepared by Vogel's electrolytic method[8] and standardized against potassium hydrogen phthalate and diluted to 0·1M with the solvent medium. The glass-distilled water used was tested for carbonate by Kolthoff's method.[9] The Radiometer pH-meter pHM-4c was calibrated (±0·01 pH unit) with aqueous standard buffer.[10]

The tritation procedure was essentially that recommended by Albert and Serjeant.[11] Generally, 0·01M hydroxamic acid was titrated without addition of inert salts (unadjusted ionic strength). To find the effect of dilution, a few titrations were performed on 0·008–0·012M hydroxamic acid. In the titration vessel (controlled to ±0·1°) 0·5 mmole of hydroxamic acid in 47·5 ml of solvent was titrated with 0·5-ml increments of alkali, after being deaerated by passage of nitrogen (presaturated with solvent) for 15 min, the highest steady pH value being noted after each increment.

RESULTS

Titration of perchloric acid in the presence and absence of the hydroxamic acids showed that the protonation of these acids is very low, as found by others.[12,13] The pK values in various media are shown in Table I. The average error in pK is generally 0·02 but does not exceed 0·03. The pK values were plotted against n, the mole fraction of dioxan, and the empirical relationships derived are shown in Table II. The thermodynamic functions are summarized in Table III.

DISCUSSION

The acidity of the hydroxamic acids may be attributed essentially to the —OH group, and the basic character of the nitrogen atom is suppressed as it is in amides. Hydroxamic acids are very weak, though several times stronger than phenol. The suppression of acidic character may be attributed to intramolecular hydrogen-bonding, as shown by infrared studies.[14–16]

Effect of the medium

A solvent of low dielectric constant increases the electrostatic forces between the ions and facilitates formation of molecular species, and should increase pK, as borne out for hydroxamic acids by Tables I and II. Gurney[17] and others[18,19] have pointed out that the standard free energy change of proton transfer may be considered in two parts—electrostatic and non-electrostatic ($\Delta G_{el}°$ and $\Delta G°_{non}$).

ΔG° and ΔH° in kcal/mole; ΔS° in cal/mole/K; first value at 25°C, second at 35°C.
Values in brackets were obtained by extrapolation.
* From Shukla.[12]

The electrostatic contribution is often estimated from the Born equation[20]

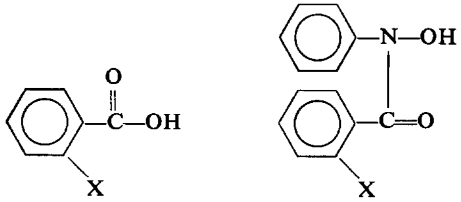
$$\Delta G_{\text{el}}^\circ = \frac{Ne^2}{2D}\left(\frac{1}{r_+} + \frac{1}{r_-}\right)$$

where r_+ and r_- are the radii of the ions and for dilute solutions D is taken as the dielectric constant of the solvent.[21,22] Hence

$$\mathrm{p}K = \frac{\Delta G^\circ_{\text{non}}}{2{\cdot}303RT} + \frac{Ne^2}{2D}\left(\frac{1}{r_+} + \frac{1}{r_-}\right)$$

Conventionally, pK is plotted *vs.* $1/D$, with $\Delta G^\circ_{\text{non}}$ assumed independent of the solvent. Nearly linear relationships have been reported,[23–26] especially for water-rich media, but so has non-linearity.[27] The plots for the hydroxamic acids are distinctly curved and evidently non-electrostatic factors exert a considerable influence on the dissociation.

TABLE IV.—THERMODYNAMIC IONIZATION CONSTANTS IN AQUEOUS MEDIUM AT 25°C



X	pK	
	Benzoic acids[31]	Hydroxamic acids
H	4·20	8·46
CH_3O	4·09	8·52
CH_3	3·91	8·44
F	3·27	8·18
Cl	2·94	8·12
Br	2·85	8·12
I	2·86	8·17
HO_2	2·17	8·11

The change in p*K* with mole fraction of dioxan is considerable for all the hydroxamic acids, the difference being >2 for water media containing 0 and 50% dioxan.

Thermodynamic functions

The p*K* values were determined with a precision between 0·02 and 0·03, and hence the error in $\Delta G°$ is estimated to be between 0·03 and 0·04 kcal/mole. The method used to compute $\Delta H°$ is subject to large error because the enthalpy change is small and p*K* was not determined at a series of temperatures, which would have allowed use of a more precise method.[28] In our case, an error of 0·01 in Δp*K* causes an error of 0·42 kcal/mole in $\Delta H°$, and the magnitude of error in Δp*K* depends on the cancellation or addition of errors in the individual p*K* values determined at the two temperatures. However, the positive value of $\Delta H°$ found for all solvent media and acids studies here indicates that the ionization process at temperatures up to 25° is endothermic. Further, the change in $\Delta H°$ with change in medium is relatively small and within experimental error. For this reason the plots of p*K* *vs.* *n* give practically the same slopes at both temperatures (except for *N*-phenyl-*o*-methylbenzohydroxamic acid, for which the results were obtained by others).

It is therefore justifiable to assume that $\Delta H°$ is independent of solvent composition over the range studied. On this basis fresh $\Delta H°$ values were computed from 42 times the difference in the intercepts on the p*K* axis for the p*K*/*n* plots, and it is these values that are given in Table III. The $\Delta S°$ values were also assumed to be independent of solvent composition.

If an acid ionizes in two media, the free energy change for the transfer reaction from one medium to the other is given by 2·303*RT* Δp*K*. For example, with benzohydroxamic acid, $\Delta G°$ is 12·15 and 14·58 kcal/mole for water and 50% aqueous dioxan respectively, and $\Delta G°$ changes by 2·43 kcal/mole in the transfer reaction

$$HA_{(diox)} + H^+_{(ag)} + A^-_{(ag)} \rightleftharpoons HA_{(aq)} + H^+_{(diox)} + A^-_{(diox)}$$

and this is essentially due to a change of $-8{\cdot}2$ cal.mole^{-1} . K^{-1} in $\Delta S°$.

Substituent effects

In the benzoic acid series, regardless of electronic type, nearly all the substituents are acid-strengthening in the *ortho*-position[29] but may be either acid-weakening or strengthening when they are in the *meta*- or *para*-positions, depending on their character. In the *ortho*-substituted phenylbenzohydroxamic acids the acid-strengthening effect is also observed in all cases except methoxy substitution, but it is less than for the corresponding carboxylic acids (Table IV). Like the parent benzoic acid, these *o*-substituted hydroxamic acids do not obey the Hammett equation.[30]

Summary—Thermodynamic association constants of benzohydroxamic acid and several *ortho*-substituted *N*-phenylbenzohydroxamic acids have been determined by pH titration in aqueous dioxan media at 25° and 35°. Empirical pH corrections for mixed aqueous media have been applied. The pK_a values do not vary linearly with the reciprocal of dielectric constant of the medium, but a plot of pK_a *vs.* the mole fraction of dioxan is linear at a given temperature. Values of $\Delta G°$, $\Delta H°$ and $\Delta S°$ are tabulated.

Zusammenfassung—Die thermodynamischen Assoziationskonstanten von Benzhydroxamsäure und mehreren *ortho*-substituierten *N*-Phenylbenzhydroxamsäuren wurden durch pH-Titration in wäßrigen Dioxanmedien bei 25° und 35° ermittelt. Empirische Korrekturen für gemischte wäßrige Medien wurden angebracht. Die pK_a Werte ändern sich nicht linear mit der reziproken Dielektrizitätskonstante des Mediums, aber pK_a gegen den Molenbruch von Dioxan aufgetragen ergibt bei einer gegebenen Temperatur eine Gerade. Die Werte von $\Delta G°$, $\Delta H°$ und $\Delta S°$ sind tabelliert.

Résumé—On a déterminé les constantes d'association thermodynamique de l'acide benzhydroxamique et de plusieurs acides N-phénylbenzhydroxamiques *ortho*-substitués par titrage pH en milieux dioxane aqueux à 25° et 35°. On a appliqué des corrections empiriques de pH pour les milieux aqueux mixtes. Les valeurs de pK_a ne varient pas linéairement avec l'inverse de la constante diélectrique du milieu, mais une courbe du pK_a en fonction de la fraction molaire de dioxane est linéaire à une température donnée. On indique dans une table les valeurs de $\Delta G°$, $\Delta H°$ et $\Delta S°$.

Behaviour of the thiodipropionic complex of In(III) and U(VI) at the DME in aqueous and aqueous methanolic solutions

(*Received* 21 *October* 1971. *Accepted* 14 *December* 1971)

THE COMPLEXATION of thiodipropionic acid (TDPA) with indium(III) and uranium(VI) has been studied by the methods used earlier.[1,2] Polarographic waves were recorded with a manual polarograph at 30 ± 0.1° using an H-cell with a saturated calomel electrode as reference electrode. The DME had the characteristics $m = 2.74$ mg/sec, $t = 3.20$ sec.

Experiments were performed with 0.25mM indium or uranium and 0.025–0.30M TDPA at an ionic strength of 1.2M (potassium chloride) for In and in 0.01M hydrochloric acid/0.1M potassium chloride for uranium (to obtain diffusion-controlled, reversible one-electron reduction of U(VI) at the DME).

The results were interpreted by means of the Deford and Hume[3] and the Irving[4] methods.

RESULTS AND DISCUSSION

Indium–TDPA

The reduction of indium–TDPA complex at the DME gives a well-defined diffusion controlled reversible 3-electron wave in aqueous and in aqueous methanol solutions. The half-wave potential increases slightly at pH values from 1.5 to 3, then more sharply till the pH reaches 5.0, above which precipitation takes place.

The presence of 10%, 30% and 50% methanol yields a well-defined wave with $E_{1/2} = -0.600$, -0.614 and -0.614 V *vs.* SCE respectively, $E_{1/2}$ is -0.6025 V for indium(III) in aqueous solution. This rules out complexation between the metal ions and methanol. A negative shift in $E_{1/2}$ on addition of increasing amounts of TDPA indicates complex formation.

The overall stability constants are summarized in Table I. Increasing the methanol concentration considerably increases the stability constants.

TABLE I.—STABILITY CONSTANTS FOR In(III)-TDPA SYSTEM

Methanol conc. of the media %	β_1	β_2	β_3	β_4
0	20	80	2.4×10^2	2.6×10^3
10	31	80	2.6×10^2	2.8×10^3
30	44	2.1×10^2	4.3×10^2	3.4×10^3

Summary—The complexation of In(III) and U(VI) with thiodipropionic acid has been investigated polarographically in water and water–methanol solutions at 30 ± 0·1°. All the chelates belong to polarographically reversible systems. With indium(III), complexes with metal to ligand ratios of 1:1, 1:2, 1:3 and 1:4 are found at pH 4.8. Uranium(VI) is found to form three successive complexes with metal to ligand ratios of 1:1, 1:2 and 1:3 in 0·1*M* HCl, with 0·1*M* KCl as supporting electrolyte.

Zusammenfassung—Die Komplexbildung von In(III) und U(VI) mit Thiodipropionsäure wurde polarographisch in Wasser und Wasser-Methanol bei 30 ± 0,1° untersucht. Alle Chelate gehören zu polarographisch reversiblen Systemen. Mit Indium(III) werden bei pH 4,8 Komplexe mit den Metall:Ligand-Verhältnissen 1:1, 1:2, 1:3 und 1:4 gefunden. Uran(VI) bildet in 0,01 M HCl mit 0,1 M KCl als Leitelektrolyt nacheinander drei Komplexe mit den Metall:Ligand-Verhältnissen 1:1, 1:2 und 1:3.

Résumé—On a étudié polarographiquement la complexation de In(III) et U(VI) avec l'acide thiodipropionique en solution dans l'eau et l'eauméthanol à 30 ± 0,1°. Tous les chélates appartiennent à des systèmes réversibles polarographiquement. Avec l'indium(III), on trouve des complexes avec des rapports métal:ligand de 1:1, 1:2, 1:3 et 1:4 à pH 4,8. On trouve que l'uranium(VI) forme trois complexes successifs avec des rapports métal:ligand de 1:1, 1:2 et 1:3 en HCl 0,01*M* avec KCl 0,1*M* comme électrolyte support.

Summary—The complexation of In(III) and U(VI) with thiodipropionic acid has been investigated polarographically in water and water–methanol solutions at 30 ± 0·1°. All the chelates belong to polarographically reversible systems. With indium(III), complexes with metal to ligand ratios of 1:1, 1:2, 1:3 and 1:4 are found at pH 4.8. Uranium(VI) is found to form three successive complexes with metal to ligand ratios of 1:1, 1:2 and 1:3 in 0·1*M* HCl, with 0·1*M* KCl as supporting electrolyte.

Zusammenfassung—Die Komplexbildung von In(III) und U(VI) mit Thiodipropionsäure wurde polarographisch in Wasser und Wasser-Methanol bei 30 ± 0,1° untersucht. Alle Chelate gehören zu polarographisch reversiblen Systemen. Mit Indium(III) werden bei pH 4,8 Komplexe mit den Metall:Ligand-Verhältnissen 1:1, 1:2, 1:3 und 1:4 gefunden. Uran(VI) bildet in 0,01 M HCl mit 0,1 M KCl als Leitelektrolyt nacheinander drei Komplexe mit den Metall:Ligand-Verhältnissen 1:1, 1:2 und 1:3.

Résumé—On a étudié polarographiquement la complexation de In(III) et U(VI) avec l'acide thiodipropionique en solution dans l'eau et l'eauméthanol à 30 ± 0,1°. Tous les chélates appartiennent à des systèmes réversibles polarographiquement. Avec l'indium(III), on trouve des complexes avec des rapports métal:ligand de 1:1, 1:2, 1:3 et 1:4 à pH 4,8. On trouve que l'uranium(VI) forme trois complexes successifs avec des rapports métal:ligand de 1:1, 1:2 et 1:3 en HCl 0,01*M* avec KCl 0,1*M* comme électrolyte support.

Uranyl-TDPA System

Uranyl ion in TDPA gives a diffusion-controlled reversible one-electron reduction at the DME in aqueous and 30% methanol media.

A negative shift in $E_{1/2}$ coupled with a decrease in diffusion current with increasing concentration of TDPA indicates complexation. The values for β_1, β_2 and β_3 are 3.3, 1.2 and 8.5 in aqueous media; in 30% methanolic media the corresponding values are 5.5, 1.2 and 34. Again addition of methanol increases the stability.

Determination of pK_a of acetic and benzoic acids in pyridine

(*Received* 23 *June* 1971. *Accepted* 2 *October* 1971)

FROM AN ANALYSIS of half-neutralization potentials (HNP) in pyridine referred to that of benzoic acid, Streuli and Miron[1] were able to classify a number of organic acids, including certain aliphatic

and aromatic mono- and dicarboxylic acids and phenols. The characteristic linear dependence of ΔHNP *vs*. $\mathrm{p}K_a^{aq}$ was broadly used in comparing the relative acidities of different groups of acids and in formulating criteria for their resolution. Although it is possible to obtain some estimates of *relative* $\mathrm{p}K_a$ values from these generalizations, unfortunately no information on the absolute $\mathrm{p}K_a$ of any of the acids can be derived. Subsequently, Elving and co-workers[2] noticed that nitric acid ($\mathrm{p}K_a^{aq} = -1{\cdot}3$) falls on the same smooth curve obtained on plotting the polarographic half-wave potentials ($E_{1/2}$) of hydrogen ion reduction in pyridine solutions of several monocarboxylic acids (using tetraethylammonium perchlorate as the supporting electrolyte) as a function of their $\mathrm{p}K_a^{aq}$ values. If it is assumed that acids of the same charge type maintain the same relative relationship in both water and pyridine, 10·09 and 9·56 are obtained as the estimated $\mathrm{p}K_a$ values for acetic and benzoic acid on the basis of the known value (4·06)[3] of the $\mathrm{p}K_a$ of nitric acid in pyridine. These estimates do indeed seem to agree with the earlier notion[4,5] that the carboxylic acids, in general, are extremely weakly dissociated in pyridine. The purpose of the present work was to determine the overall dissociation constant of acetic and benzoic acid in pyridine by conventional methods. Our preliminary attempts,[6] in this connection, involving the use of the $\mathrm{Pt/H_2}$ electrode in solutions of relatively large concentrations of the organic acid in the presence of nitric acid are considered unsatisfactory. In this investigation we chose to use "buffer" solutions composed of tetrabutylammonium salts and the acids in question. The work consisted of differential vapour pressure (DVP) studies of solutions of the acids and the salts, and of the acid/salt mixtures, as well as measurement of hydrogen ion activities of the latter (with a glass electrode).

Although the DVP measurements on tetrabutylammonium acetate and benzoate are considered helpful in providing independent estimates of the dissociation constants of these electrolytes, their precision is relatively low; furthermore, the temperature (37°) at which they had to be made prevents direct correlation of the results with those generally obtained at 25°. Because of these limitations, it was considered expedient to use the conductometric values of the salt dissociation constants obtained at 25° in the final calculations. The dissociation constant of tetrabutylammonium acetate in pyridine is already available[7]; however, since no such estimate for tetrabutylammonium benzoate has yet been reported, additional studies on this system have also been undertaken.

The experimental techniques and treatment of data are essentially the same as those described in our earlier work.[3,8,9,10] A Beckman glass electrode (#39099E-3) was used against an $\mathrm{Hg/HgCl_{2(s)}}$, $\mathrm{LiCl_{(s)}}$ reference; the electrode was calibrated with solutions of nitric acid in pyridine, of known $\mathrm{H^+}$-activity. For the DVP results, the Marshall-Grunwald equation[11] was used to evaluate the ionic activity coefficients.

RESULTS AND DISCUSSION

Differential vapour pressure measurements at 37° showed that solutions of the two acids closely resemble solutions of the standard monomer 1,3-diphenylguanidine in their behaviour, indicating that these two acids exist primarily as monomers in pyridine. On the other hand, the salts tetrabutylammonium acetate and benzoate are evidently slightly dissociated; the average dissociation constants are calculated[3] to be $2{\cdot}04 \times 10^{-4}$ and $1{\cdot}99 \times 10^{-4}$ respectively. The tetrabutylammonium acetate value is close to that ($1{\cdot}7 \times 10^{-4}$) reported[7] from conductance measurements at 25°.

* Average of 4 or 5 readings

† Sum of individual values for the acid and the salt.

The results for acid-salt mixtures are presented in Table I. The additivity of the individual ΔT values suggests that the acid molecules are extremely weakly dissociated and exist virtually as monomers. It also indicates the absence of any other interaction(s) that would cause change in the overall molarity.

From the conductance measurements at 25° on tetrabutylammonium benzoate, presented as a plot

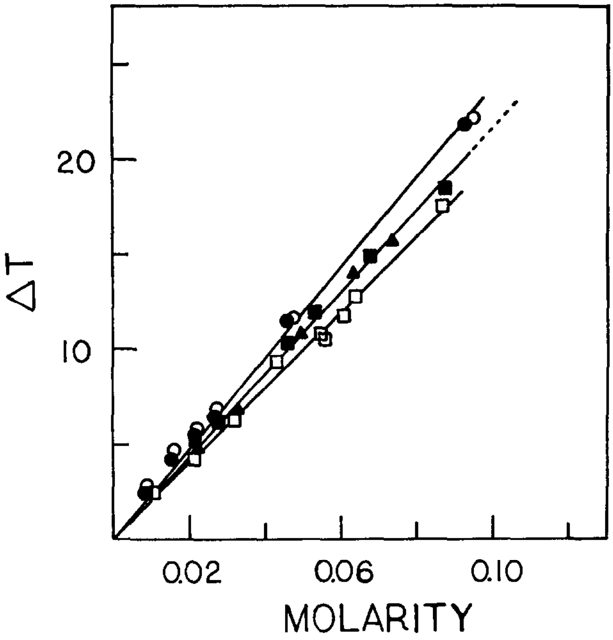

FIG. 1.—Differential vapour pressure measurements at 37°C. ▲-1,3-diphenylguanidine ☐-Acetic acid ■-Benzoic acid ○-Tetrabutylammonium acetate ●-Tetrabutylammonium benzoate. Average lines shown in the figure.

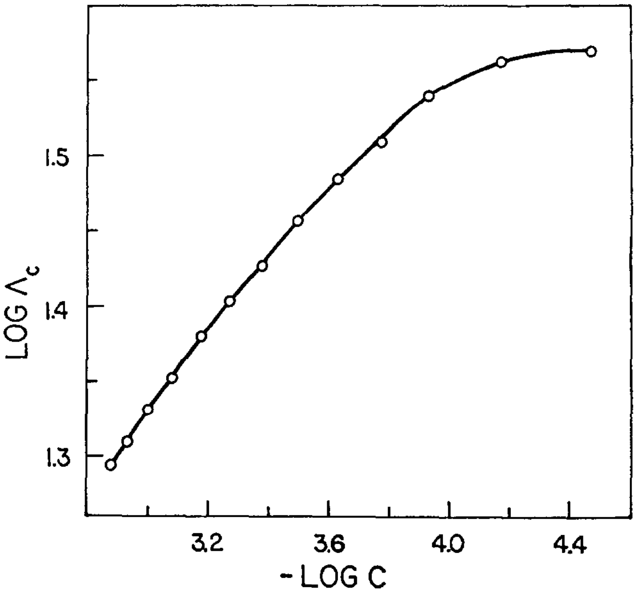

FIG. 2.—Conductance measurements on tetrabutylammonium benzoate at 25°.

of log Λ_0 *vs.* $-\log C$, a value of 2·00 × 10^{-4} was obtained for the dissociation constant of this salt (Fig. 2). (The close agreement with the DVP value at 37° suggests that the dissociation constant is practically independent of temperature.) The limiting conductance is found to be 44·6 $\text{ohm}^{-1}.\text{cm}^{-1}.\text{equiv}^{-1}$. Since the λ° of $(\text{n-C}_4\text{H}_9)_4\text{N}^+$ is 24·0,[7] the limiting conductance of benzoate ion is calculated to be 20.6—a value comparable to the limiting conductance of $\text{FB(C}_6\text{H}_5)_3^-$ in this solvent (24·0)[7].

* Calculated from $K_a = a_{\text{H}^+}\sqrt{K_{\text{MX}}\,C_{\text{MX}}}/C_{\text{HX}}$ where $K_{\text{MX}} = a_{\text{M}^+}a_{\text{X}^-}/[\text{MX}]$; C_{HX} and C_{MX} are the analytical concentrations of HX and MX.

The results of experiments with the glass electrode are presented in Table II. Calculations yield 10·1 and 9·8 for the average values of pK_a for acetic and benzoic acid, respectively, as compared to the values 4·73 and 4·20 in water, indicating that both acids are indeed very weakly dissociated in pyridine. Also it is interesting to note that the two acids do maintain almost the same relative pK_a relationship[1] (ΔpK_a = 0·3 in pyridine *vs.* 0·53 in water) in pyridine and water.

Summary—The pK_a's of acetic acid and benzoic acid in pyridine as solvent are found to be 10·1 and 9·8, respectively, at 25°. These results are based on measurements of hydrogen ion activities in mixtures of the acids and their tetrabutylammonium salts. Supplementary studies of differential vapour pressure characteristics of solutions of the acids and the acid–salt mixtures, and conductance of tetrabutylammonium benzoate solutions are also incorporated.

Zusammenfassung—Die pK_a-Werte von Eissigsäure und Benzoesäure in Pyridin als Lösungsmittel betragen bei 25° 10,1 bzw. 9,8. Diese Ergebnisse stützen sich auf Messungen von Wasserstoffionenaktivitäten in Gemischen der Säuren mit ihren Tetrabutylammoniumsalzen. Darüber hinaus werden die Differential-Dampfdruckeigenschaften von Lösungen der Säuren und der Säure-Salz-Gemische sowie die Leitfähigkeit von Tetrabutylammoniumbenzoat-Lösungen mitgeteilt.

Résumé—On a trouvé que les valeurs des pK_a de l'acide acétique et de l'acide benzoïque en pyridine sont respectivement de 10,1 et 9,8 à 25°. Ces résultats sont basés sur des mesures d'activités d'ion hydrogène dans des mélanges des acides et de leurs sels de tétrabutylammonium. On a aussi incorporé des études complémentaires de caractéristiques de pression de vapeur différentielle de solutions des acides et des mélanges acide-sel, et de conductance de solutions de benzoate de tétrabutylammonium.

Stability constants of complexes of *N*-arylhydroxamic acids with some bivalent metal ions

(*Received* 13 *August* 1971. *Accepted* 17 *November* 1971)

THIS COMMUNICATION gives the results of the determination of the stability constants of the Mn(II), Ni, Zn and Cu(II) chelates of five closely related *N*-arylhydroxamic acids by pH titration.[1]

EXPERIMENTAL

Hydroxamic acids (*Table I*). Synthesized by the method of Priyadarshini and Tandon,[1] recrystallized from a mixture of benzene and petroleum ether, and dried in vacuum over phosphorus pentoxide. Purity was confirmed by elemental analyses, m.p., and spectroscopy.

Procedure. As described earlier.[2]

RESULTS

The results were calculated as in previous work,[2] and are given in Table II. The chelates of Mn(II), Ni, and Zn with *m*-TBHA and *p*-TBHA were so insoluble that they separated out immediately on

TABLE I.—DETAILS OF HYDROXAMIC ACIDS

Uranyl–TDPA System

Uranyl ion in TDPA gives a diffusion-controlled reversible one-electron reduction at the DME in aqueous and 30% methanol media.

A negative shift in $E_{1/2}$ coupled with a decrease in diffusion current with increasing concentration of TDPA indicates complexation. The values for β_1, β_2 and β_3 are 3.3, 1.2 and 8.5 in aqueous media; in 30% methanolic media the corresponding values are 5.5, 1.2 and 34. Again addition of methanol increases the stability.

Determination of pK_a of acetic and benzoic acids in pyridine

(*Received* 23 *June* 1971. *Accepted* 2 *October* 1971)

FROM AN ANALYSIS of half-neutralization potentials (HNP) in pyridine referred to that of benzoic acid, Streuli and Miron[1] were able to classify a number of organic acids, including certain aliphatic

and aromatic mono- and dicarboxylic acids and phenols. The characteristic linear dependence of ΔHNP *vs.* pK_a^{aq} was broadly used in comparing the relative acidities of different groups of acids and in formulating criteria for their resolution. Although it is possible to obtain some estimates of *relative* pK_a values from these generalizations, unfortunately no information on the absolute pK_a of any of the acids can be derived. Subsequently, Elving and co-workers[2] noticed that nitric acid ($pK_a^{aq} = -1{\cdot}3$) falls on the same smooth curve obtained on plotting the polarographic half-wave potentials ($E_{1/2}$) of hydrogen ion reduction in pyridine solutions of several monocarboxylic acids (using tetraethylammonium perchlorate as the supporting electrolyte) as a function of their pK_a^{aq} values. If it is assumed that acids of the same charge type maintain the same relative relationship in both water and pyridine, 10·09 and 9·56 are obtained as the estimated pK_a values for acetic and benzoic acid on the basis of the known value (4·06)[3] of the pK_a of nitric acid in pyridine. These estimates do indeed seem to agree with the earlier notion[4,5] that the carboxylic acids, in general, are extremely weakly dissociated in pyridine. The purpose of the present work was to determine the overall dissociation constant of acetic and benzoic acid in pyridine by conventional methods. Our preliminary attempts,[6] in this connection, involving the use of the Pt/H_2 electrode in solutions of relatively large concentrations of the organic acid in the presence of nitric acid are considered unsatisfactory. In this investigation we chose to use "buffer" solutions composed of tetrabutylammonium salts and the acids in question. The work consisted of differential vapour pressure (DVP) studies of solutions of the acids and the salts, and of the acid/salt mixtures, as well as measurement of hydrogen ion activities of the latter (with a glass electrode).

Although the DVP measurements on tetrabutylammonium acetate and benzoate are considered helpful in providing independent estimates of the dissociation constants of these electrolytes, their precision is relatively low; furthermore, the temperature (37°) at which they had to be made prevents direct correlation of the results with those generally obtained at 25°. Because of these limitations, it was considered expedient to use the conductometric values of the salt dissociation constants obtained at 25° in the final calculations. The dissociation constant of tetrabutylammonium acetate in pyridine is already available[7]; however, since no such estimate for tetrabutylammonium benzoate has yet been reported, additional studies on this system have also been undertaken.

The experimental techniques and treatment of data are essentially the same as those described in our earlier work.[3,8,9,10] A Beckman glass electrode (#39099E-3) was used against an $Hg/HgCl_{2(s)}$, $LiCl_{(s)}$ reference; the electrode was calibrated with solutions of nitric acid in pyridine, of known H^+-activity. For the DVP results, the Marshall-Grunwald equation[11] was used to evaluate the ionic activity coefficients.

RESULTS AND DISCUSSION

Differential vapour pressure measurements at 37° showed that solutions of the two acids closely resemble solutions of the standard monomer 1,3-diphenylguanidine in their behaviour, indicating that these two acids exist primarily as monomers in pyridine. On the other hand, the salts tetrabutylammonium acetate and benzoate are evidently slightly dissociated; the average dissociation constants are calculated[3] to be $2{\cdot}04 \times 10^{-4}$ and $1{\cdot}99 \times 10^{-4}$ respectively. The tetrabutylammonium acetate value is close to that ($1{\cdot}7 \times 10^{-4}$) reported[7] from conductance measurements at 25°.

* Average of 4 or 5 readings

† Sum of individual values for the acid and the salt.

The results for acid-salt mixtures are presented in Table I. The additivity of the individual ΔT values suggests that the acid molecules are extremely weakly dissociated and exist virtually as monomers. It also indicates the absence of any other interaction(s) that would cause change in the overall molarity.

From the conductance measurements at 25° on tetrabutylammonium benzoate, presented as a plot

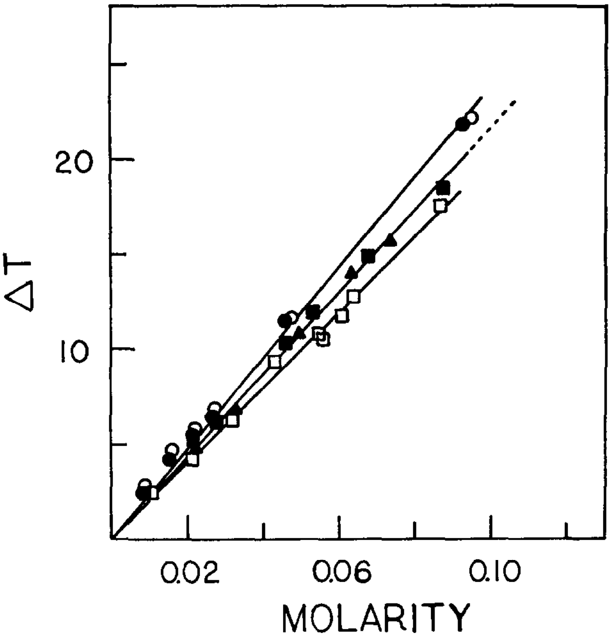

FIG. 1.—Differential vapour pressure measurements at 37°C. ▲-1,3-diphenylguanidine □-Acetic acid ■-Benzoic acid ○-Tetrabutylammonium acetate ●-Tetrabutylammonium benzoate. Average lines shown in the figure.

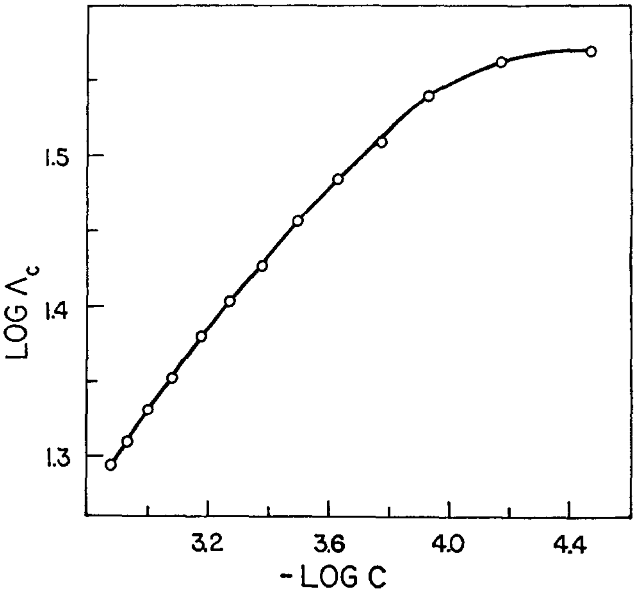

FIG. 2.—Conductance measurements on tetrabutylammonium benzoate at 25°.

of log Λ_0 *vs.* $-\log C$, a value of $2{\cdot}00 \times 10^{-4}$ was obtained for the dissociation constant of this salt (Fig. 2). (The close agreement with the DVP value at 37° suggests that the dissociation constant is practically independent of temperature.) The limiting conductance is found to be 44·6 ohm^{-1}.cm^{-1}.equiv^{-1}. Since the λ° of $(n\text{-}C_4H_9)_4N^+$ is 24·0,[7] the limiting conductance of benzoate ion is calculated to be 20.6—a value comparable to the limiting conductance of $FB(C_6H_5)_3^-$ in this solvent (24·0)[7].

				0·2316		8·433	9·62
				0·2441		9·440	9·59
							Av. $9{\cdot}8_0$

* Calculated from $K_a = a_{H^+}\sqrt{K_{MX}\,C_{MX}}/C_{HX}$ where $K_{MX} = a_{M^+}a_{X^-}/[MX]$; C_{HX} and C_{MX} are the analytical concentrations of HX and MX.

The results of experiments with the glass electrode are presented in Table II. Calculations yield 10·1 and 9·8 for the average values of pK_a for acetic and benzoic acid, respectively, as compared to the values 4·73 and 4·20 in water, indicating that both acids are indeed very weakly dissociated in pyridine. Also it is interesting to note that the two acids do maintain almost the same relative pK_a relationship[1] (ΔpK_a = 0·3 in pyridine *vs.* 0·53 in water) in pyridine and water.

Summary—The pK_a's of acetic acid and benzoic acid in pyridine as solvent are found to be 10·1 and 9·8, respectively, at 25°. These results are based on measurements of hydrogen ion activities in mixtures of the acids and their tetrabutylammonium salts. Supplementary studies of differential vapour pressure characteristics of solutions of the acids and the acid–salt mixtures, and conductance of tetrabutylammonium benzoate solutions are also incorporated.

Zusammenfassung—Die pK_a-Werte von Eissigsäure und Benzoesäure in Pyridin als Lösungsmittel betragen bei 25° 10,1 bzw. 9,8. Diese Ergebnisse stützen sich auf Messungen von Wasserstoffionenaktivitäten in Gemischen der Säuren mit ihren Tetrabutylammoniumsalzen. Darüber hinaus werden die Differential-Dampfdruckeigenschaften von Lösungen der Säuren und der Säure-Salz-Gemische sowie die Leitfähigkeit von Tetrabutylammoniumbenzoat-Lösungen mitgeteilt.

Résumé—On a trouvé que les valeurs des pK_a de l'acide acétique et de l'acide benzoïque en pyridine sont respectivement de 10,1 et 9,8 à 25°. Ces résultats sont basés sur des mesures d'activités d'ion hydrogène dans des mélanges des acides et de leurs sels de tétrabutylammonium. On a aussi incorporé des études complémentaires de caractéristiques de pression de vapeur différentielle de solutions des acides et des mélanges acide-sel, et de conductance de solutions de benzoate de tétrabutylammonium.

Stability constants of complexes of *N*-arylhydroxamic acids with some bivalent metal ions

(*Received* 13 *August* 1971. *Accepted* 17 *November* 1971)

THIS COMMUNICATION gives the results of the determination of the stability constants of the Mn(II), Ni, Zn and Cu(II) chelates of five closely related *N*-arylhydroxamic acids by pH titration.[1]

EXPERIMENTAL

Hydroxamic acids (*Table I*). Synthesized by the method of Priyadarshini and Tandon,[1] recrystallized from a mixture of benzene and petroleum ether, and dried in vacuum over phosphorus pentoxide. Purity was confirmed by elemental analyses, m.p., and spectroscopy.

Procedure. As described earlier.[2]

RESULTS

The results were calculated as in previous work,[2] and are given in Table II. The chelates of Mn(II), Ni, and Zn with *m*-TBHA and *p*-TBHA were so insoluble that they separated out immediately on

mixing the reagents or after addition of alkali. Attempts to determine their constants by decreasing the concentration of the metal ions to $5 \times 10^{-4}M$ did not succeed. In the acid range, Mn, Ni, and Zn complexes of PBHA gave maximum $\bar{n}$ values of 0·9. For such low values of $\bar{n}$, Goldberg's method[3] of calculation could not be applied and so the Bjerrum and Calvin graphical method was used. From the $\bar{n}$ values it appeared that precipitation started before formation of the 1:2 complex was complete. The stability constants were reproducible to 0·05 log units in replicate determinations, and variation of starting concentration of metal and ligand gave results varying by ±0·10 log units or less.

DISCUSSION

There was no evidence of metal ion hydrolysis, polynuclear complexes, protonated complexes, or influence of nitrate, chloride, perchlorate and alkali metal cations.

The Irving-Williams order of stabilities[4] was found to hold for all the systems with $K_1 > K_2$. The values of $\log K_1/K_2$ are consistently high for all copper complexes with a single exception. The $\Delta \log K$ value of 1·6–1·7 suggests that in these systems the electrostatic effect[5] has to be considered as well as the statistical effect (which gives $\log K = 0·6$).

Values of $\log K$ for copper are considerably higher than for the other metals and the values for Zn are greater than those for Ni. The higher value for the copper chelate may be due to a square planar structure. The order Zn > Ni has been observed earlier[6] and attributed to steric hindrance preventing the formation of a square planar Ni complex. Also the hydrolysis constant of Zn is greater than that of Ni, indicating greater affinity of Zn^{2+} for hydroxide ions; the NOH group of the hydroxamic acid resembles the OH group. These factors seem to account for the order Zn > Ni.

Since all the metal ions are bivalent and of much the same size, the electrostatic contribution to the metal–ligand bond in the first complexes formed with the same ligand is assumed to be very nearly the same. The $\log K_1$ values for the P(n)BHA, PBHA and *o*-TBHA complexes were a linear function of the overall ionization potentials of Mn(II), Zn(II) and Ni(II) but the points for the Cu(II) complexes were always above the line, confirming the higher stability of the copper complexes. The values of $\log K_1/K_2$ imply that there is little or no steric hindrance to the addition of the second chelate group. A plot of the stability constants for Cu(II) *vs.* the ligand protonation constants is linear, the equation being $\log K = 0·73\ pK_a + \text{constant}$. According to Jones and co-workers,[7] ligands with orbitals which can interact with suitable orbitals of the metal ion, give slopes greater than unity in such plots if the central ion has π-acceptor properties. They have further stated that Cu(II) and Ni(II) act as π-donors. The Cu(II) ion therefore seems to be acting as a π-donor.

The complexes of P(n)BHA with Zn, Ni and Mn(II) are less stable than the corresponding *o*-TBHA complexes, though P(n)BHA is more basic than *o*-TBHA. In contrast, the Cu(II) complexes follow the order of pK_a. Different geometries of the Cu and Zn, Ni and Mn complexes may be responsible for this unexpected behaviour in the stability order.

Summary—Thermodynamic stability constants of complexes of Mn(II), Ni(II), Zn(II) and Cu(II) with five closely related *N*-arylhydroxamic acids have been determined at 25 ± 0·1° in 50% v/v aqueous dioxan medium. The stabilities of the complexes mostly follow the order of the basicity of the ligands and the electron affinities of the metal ions as measured by their second ionization potential.

Zusammenfassung—Die thermodynamischen Stabilitätskonstanten der Komplexe von Mn(II), Ni(II), Zn(II) und Cu(II) mit fünf nahe verwandte *N*-Arylhydroxamsäuren wurden bei 25 ± 0,1° in 50%(v/v) wäßrigem Dioxan gemessen. Die Stabilität der Komplexe schließt sich meistens an die Basizitätsreihenfolge der Liganden und an die Elektronenaffinitäten der Metallionen an, wie sie sich im zweiten Ionisierungspotential zeigen.

Résumé—On a déterminé les constantes de stabilité thermodynamique de complexes de Mn(II), Ni(II), Zn(II) et Cu(II) avec cinq acides *N*-arylhydroxamiques etroitement apparentés, à 25 ± 0,1° en milieu dioxane aqueux 50% v/v. Les stabilités des complexes suivent essentiellement l'ordre de basicité des ligands et les affinités électroniques des ions métalliques telles qu'elles sont mesurées par leur second potentiel d'ionisation.

S. G. TANDON

Summary—Thermodynamic stability constants of complexes of Mn(II), Ni(II), Zn(II) and Cu(II) with five closely related *N*-arylhydroxamic acids have been determined at 25 ± 0·1° in 50% v/v aqueous dioxan medium. The stabilities of the complexes mostly follow the order of the basicity of the ligands and the electron affinities of the metal ions as measured by their second ionization potential.

Zusammenfassung—Die thermodynamischen Stabilitätskonstanten der Komplexe von Mn(II), Ni(II), Zn(II) und Cu(II) mit fünf nahe verwandte *N*-Arylhydroxamsäuren wurden bei 25 ± 0,1° in 50%(v/v) wäßrigem Dioxan gemessen. Die Stabilität der Komplexe schließt sich meistens an die Basizitätsreihenfolge der Liganden und an die Elektronenaffinitäten der Metallionen an, wie sie sich im zweiten Ionisierungspotential zeigen.

Résumé—On a déterminé les constantes de stabilité thermodynamique de complexes de Mn(II), Ni(II), Zn(II) et Cu(II) avec cinq acides *N*-arylhydroxamiques etroitement apparentés, à 25 ± 0,1° en milieu dioxane aqueux 50% v/v. Les stabilités des complexes suivent essentiellement l'ordre de basicité des ligands et les affinités électroniques des ions métalliques telles qu'elles sont mesurées par leur second potentiel d'ionisation.

Salicylaldehyde and β-resorcylaldehyde as indicators for DCTA titration of iron(III)

SIR,

Resorcylic acids have been used as indicators for the direct EDTA titration of ferric ions.[1] Salicylaldehyde and β-resorcylaldehyde have now been found suitable as indicators for the direct titration of iron(III) with DCTA. There is a sharp colour change from purple to deep yellow at the end-point. The optimum pH is 1·0–2·0, and 2 drops of 1% indicator solution give satisfactory results even in titration of 1 ml of 0·001*M* ferric nitrate with 0·001*M* DCTA. At pH 1·0, for 1·4 mg of iron, the following amounts of other ions could be tolerated: 140 mg of Na^+, K^+, NH_4^+, Cl^-, Br^-, ClO_4^-, NO_3^-, and SO_4^{2-}; 14 mg of Ag^+, Pb^{2+}, Al^{3+}, Ni^{2+} and Co^{2+}; 28 mg of Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Be^{2+} and Pd^{2+}; 7 mg of UO_2^{2+}, Zn^{2+} and Cd^{2+}; 1·4 mg of Cu^{2+}. Mn^{2+}, Zr^{4+}, Th^{4+} and anions forming stable complexes with iron(III), such as phosphates, vanadates, molybdates and tungstates, interfered at all levels. The process has been satisfactorily applied to the determination of ferric ions in ternary mixtures, iron ore and a drug. The suggested indicators are superior to Chrome Azurol S[2] with which aluminium interferes and thiocyanate[2] which can be used only under restricted conditions. With sulphosalicylic acid and tiron,[3] results are high by up to 4%.

Potentiometric titration of sodium pentacyanonitrosylferrate(III)

SIR,

Sodium pentacyanonitrosylferrate(III) (sodium nitroprusside) is often used to detect acetaldehyde, hydrogen, sulphur and aliphatic amines in organic analysis as well as in end-point indication of mercurimetric titrations.[1] It is usually analysed argentometrically by the Mohr method.[2] We have investigated the possibility of potentiometric titration of sodium pentacyanonitrosylferrate(III) with mercury(II) or silver.

A Radelkis precision pH-meter type OP-205 (input resistance >1GΩ) was used. Indicator electrodes were silicone-rubber based halide-selective electrodes (OP-Cl-711, OP-Br-711, OP-I-711, OP-S-711), platinum needles (15 mm² surface area) and silver. The reference was a 0·1*M* calomel electrode. An agar-agar potassium nitrate salt bridge was used.

Mercuric nitrate solution, 0·05*M*, was made by warming 10·03 g of mercury of analytical purity with 50 ml of nitric acid (1 + 1) in a 500-ml flask on a water-bath until the appearance of nitrous fumes, setting the flask aside until the mercury had completely dissolved, then warming it on the water-bath until the nitrous fumes were completely expelled, and finally cooling and diluting to 1 litre.

In the procedure about 1·5 g of the material to be investigated is dissolved in water and diluted accurately to 100 ml. A 10-ml aliquot is diluted with 90 ml of water in a 150-ml beaker and titrated (magnetic stirring) with 0·05*M* mercuric nitrate or 0·1*M* silver nitrate.

TALANTA REVIEW*

REACTION RATE METHODS IN ANALYSIS

HARRY B. MARK, JR.
Department of Chemistry, University of Cincinnati, Cincinnati, Ohio 45221, U.S.A.

(*Received* 22 *June* 1971. *Accepted* 30 *October* 1971)

Summary—A review is given of the principles and application of catalytic and reaction rate methods of analysis.

AS INSTRUMENTATION technology, measurement techniques, electronic circuitry, and analytical procedures have advanced in recent years to a very high degree of development, the accuracy and precision necessary to make dynamic reaction systems applicable to both routine and special analytical problems have become available. Thus, there has been considerable research by a fairly large number of analytical chemists on the development of instrumentation, methods, and applications of kinetic (dynamic) based analyses for both new and old analytical problems. In fact, some analytical chemists, the author included, have been heard to say that these advances in instrumentation and electronic circuitry have "opened up a completely *new* area of research in analytical chemistry." Such a statement is not really accurate, of course, as kinetic based methods of analysis have been used for many years by clinical chemists for enzyme assay and other biological and medical tests. It would be more correct to say that analytical chemists have recently realized the tremendous potential in the application of kinetic methods and are now opening up new areas and applications for these methods. Also they are actively engaged in improving the sensitivity as well as the accuracy and precision of such methods. This realization of the potential of kinetics in analysis came about when it was recognized that kinetic based procedures have several inherent properties which can be used advantageously in analysis.

First, analytical chemists have long realized that in a real analytical problem, the species to be determined is rarely found unaccompanied by one or more substances that are closely related chemically and/or physically, and generally separation techniques must be used, which are often laborious and lead to considerable error in the analysis. There are also cases, such as the analysis of the ratio of different functional groups in the same polymer molecules, where non-destructive separation is impossible. Thus, it is clear that the analysis should (or must) be performed without prior separation.

Methods for *in situ* analysis of a mixture of species having similar properties can be classified as either thermodynamic (equilibrium) or kinetic (dynamic) depending on the method used to eliminate or reduce the interference of the other components of the mixture. A thermodynamic masking involves the alteration of the equilibrium conditions of the solution in such a way as to render all reactions, except the one(s) of analytical interest, thermodynamically unfavoured. The kinetic approach involves

---

* For reprints of this Review, see Publisher's announcement near the end of the issue.

utilizing differences in the reaction rates (or adjusting them if necessary) to isolate the reactions(s) of analytical interest. The thermodynamic differences in reactions of closely related compounds, such as homologues or isomers, with a common reagent are often much too small to be used for analysis of mixtures. However, the kinetic differences are usually quite large and permit either individual or simultaneous *in situ* analysis of the components of the mixture. This arises from the fact that the free energy of activation and hence the rate constant for any reaction is very dependent on the effect of structure of the reactants on formation of the activated complex, *etc.* Thus, reactions of closely related species which differ slightly in structure will often have essentially the same net change in free energy for the overall reaction but will reach equilibrium at widely varying rates. Also, changes in temperature, solvent characteristics, activity changes, *etc.*, have much larger effects on the relative rate constants of similar species than they do on the relative values of the equilibrium constants.

Secondly, a large number of inorganic and organic reactions can now be used in analysis. Many chemical reactions are not sufficiently uniform in behaviour to be used in equilibrium-based methods as they attain equilibrium slowly, have side-reactions, or are not sufficiently quantitative (the formation constants are too small) to be applicable. However, the same reactions can be used easily under initial reaction-rate conditions (explained below in the text). Also catalytic kinetic methods are considerably more sensitive than equilibrium methods, and kinetic-based enzymatic reactions are often extremely selective for a particular substrate.

On the other hand, kinetic techniques have one obvious and serious disadvantage. Any dynamic measurement includes time as an experimental variable, which is not the case in equilibrium measurement. It is probably this consideration that has made analytical chemists in the past somewhat afraid of using kinetics as an analytical tool. However, recent developments in instrumentation, especially in computer-based data analysis, signal-averaging and automation have overcome this fear of lower measurement accuracy.

As a result of this increase in interest, several books have been recently published on various aspects of the subject.[1–5] Mark, Rechnitz and Greinke[1] published a comprehensive text on kinetic analytical techniques and mechanistic studies related to analysis problems, Yatsimirskii[2] has given an extensive compilation and discussion of the application of catalytic reactions in trace analysis, and Guilbault,[3] Bergmeyer,[4] and Ruyssen and Vandenriesche[5] have written texts covering the area of enzymatic reactions in analysis. There have also been monograph chapters by Blaedel and Hicks,[6] Mark, Papa and Reilley,[7] Janata,[8] Pardue[9] and Crouch[10] on various aspects of kinetic analysis. The last two are especially significant as they deal with the principles and advances in instrumentation designed *specifically* for kinetic analysis, There have also been the extensive review articles by Rechnitz,[11–13] Guilbault,[14–17] Bergmeyer,[18] Devlin[19] and Roth[20] on various aspects of kinetic analysis in chemistry and clinical chemistry.

Because the early literature on reaction rate techniques applied to chemical analysis is very well reviewed in the publications cited, this review will generally cover only the literature contributions of the past 2–5 years, though particularly important earlier work will be cited.

The topics reviewed individually are recent advances in methods of kinetic analysis, new procedures and approaches to chemical analysis, and reports of kinetic studies of systems which are of specific interest and/or application to analysis. (The huge literature concerned with fundamental kinetic studies of reaction kinetics and mechanisms will not be reviewed.)

MATHEMATICAL BASIS OF KINETIC METHODS OF ANALYSES

A very large number of methods for the calculation of the initial concentration(s) of the species of interest from reaction rate data have been developed over the past few years. These methods involve, in general, simple mathematical manipulation and rearrangement of the usual differential or integral forms of the classical reaction rate equations. With few exceptions most have been reported within the past 5—10 years. They can be classified in two main categories: methods for a single species and methods for the simultaneous *in situ* analysis of mixtures. Within each category, the methods can be subdivided according to the kinetic order of the reactions: pseudo zero-order or initial rate methods, first-order and pseudo first-order methods, and second-order techniques. The principles, mathematical treatments, applicability and limitations of these methods have been discussed in some of the works already cited.[1,6,7,9,10] Recent papers are reviewed below.

Methods for determination of a single species

Pseudo zero-order methods. This approach is the most commonly used in routine and special applications, partly owing to the simplicity of the calculations and the fact that essentially all catalytic methods, both chemical and enzymatic, use pseudo zero-order conditions during the rate measurement. The principle of the initial-rate methods is simple as they are based on taking measurements only during the initial 1–3% or so of total reaction. Under these conditions the amount of reactant consumed and product formed is negligible (*i.e.*, the concentration of the reactants does not change appreciably during the period of the rate measurement) and hence the rate curve is essentially linear, its slope being proportional to the concentration of the reactant being determined.[1,6,7,9,10] There are other advantages besides simplicity of calculation. First , the reverse reaction can be ignored, and secondly, complications such as side-reactions are minimal. Three initial-rate methods are described in the literature. The direct approach is the derivative slope method where the rate of the reaction is measured by electronic derivative circuitry.[9,10,21,22] Margerum and co-workers[23–25] have described a stopped-flow derivative method for determination of a single species. This technique uses repetitive slope measurement during each run, and signal-averaging by a built-in computer to improve the analytical results. In the second approach, essentially a two-point method called the fixed-time method,[1,6,7,9,10] the change in concentration of product (output signal) is measured over a fixed time-interval, giving $(\Delta C/\Delta t)$ which is, of course, the slope of the rate curve. The third approach is also a two-point method, the variable-time method.[1,6,7,9,10] In this method the time interval, Δt, required for the output signal to vary between two fixed values (ΔC) is measured. These three initial reaction rate methods have been used for both catalysed and uncatalysed reactions.[1,6,9] The concentrations of the catalyst (including enzymes) as well as of catalyst activators and inhibitors have been determined.[1,3,9,17]

First-order and pseudo first-order methods. Crouch has discussed the principles and parameters of importance for a non-linear response variable-time procedure for first-order and pseudo first-order reactions.[10] Mark, Rechnitz and Greinke[1] have also discussed the criteria for neglecting the contributions of either faster or slower-reacting components in the kinetic determination of a single species in a mixture. Janata and Mark[25a] have suggested analogue simulation techniques for the analysis of such rate curves.

Second-order methods. Very little work has been reported on the analytical applications of second-order conditions for determination of a single species. Weichselbaum *et al.*[21] have described derivative methods in which the maximum rate observed during an autocatalysed reaction run under second-order conditions was applicable for the determination of ammonia and blood-urea nitrogen. Janata and Mark[25a] have also discussed analogue simulation of second-order rate curves for determination of initial concentrations.

Methods for the simultaneous in situ *analysis of mixtures*

The development of methods for the *in situ* simultaneous determination of closely related components of mixtures has received considerable attention. As discussed in the instrumentation section, the tremendous advances in the accuracy and precision of rate measurements makes these methods practical.

Pseudo zero-order methods. Mark has reported an initial reaction rate method for the simultaneous assay of two alcohols, using enzyme-catalysed reactions.[26] Guilbault and co-workers[17,27,28] have reported a very effective method for the *in situ* analysis of multicomponent mixtures of a large variety of different and closely related substrates by taking advantage of enzyme catalysis selectivity.

First-order and pseudo first-order methods. Though each of the methods developed for reactions of this type is applicable to true first-order reactions, all the applications reported, with the exception of radionuclide decay reactions, are to second-order reactions run under pseudo first-order conditions (where either the reactants or the reagents are in very large excess and, hence, do not change appreciably in concentration during the course of the reaction).[1] A graphical method (called the logarithmic extrapolation method) based on the extrapolation of a typical first-order log response *vs.* time plot of the total rate curve has been described for binary mixtures where the reagent is in large excess with respect to the total concentration of the unknown in the mixture.[1] Lee and Kolthoff have described a mathematical single-point method based on a single measurement made at a fixed time during the reaction, for the same pseudo first-order conditions.[29] Garmon and Reilley have described a very simple and successful method of proportional equations based on the principle of constant fractional life.[1,7,30] This method is applicable to both simple and complex first-order reaction sequences. Margerum and co-workers[23-25,31] have described a continuous measurement approach to the method of proportional equations which is more accurate than the finite point approach of Garmon and Reilley[1,30] and have extended the method successfully to three-component mixtures. Roberts and Regan[32] have devised a mathematical single-point rate measurement procedure and Greinke and Mark[33] have devised a method of proportional equations for the reaction condition which is pseudo first-order with respect to the reagent concentration ($[\text{reagent}] \ll [\text{mixture}]$).

Second-order methods. Siggia and Hanna[34] have devised a second-order graphical (logarithmic) extrapolation procedure for the complete analysis of binary mixtures, the reagent and reactant concentrations being of the same order of magnitude. Reilley and Papa developed a second-order linear extrapolation method for the special case where [mixture] = [reagent].[35] For both of these second-order systems Reilley and Papa[35] and Papa, Mark and Reilley[36] have developed mathematical single-point and double-point methods which eliminate the need for a graphical plot. Lee and Kolthoff[29] have developed a different mathematical single-point method for the special case [mixture] = [reagent]. Schmalz and Geiseler[37–40] have reported a graphical differential method and graphical integral method for second-order reactions. They have presented several different modifications of each method.

Applicability and limitations of the various methods for the analysis of mixtures. As can be seen above, many different methods have been reported in recent years. These methods not only employ different reaction order conditions, but also use different mathematical and/or graphical methods of data manipulation and display and some make certain experimental and mathematical assumptions. The choice of the best method and conditions for a specific problem is not intuitively obvious,[1] and considerable work on this problem has recently been reported. Ingle and Crouch have examined the relative merits and limitations of the fixed-time and variable-time methods of data treatment for catalytic and pseudo first-order reaction procedures.[41] They have shown that the fixed-time method is preferable for first- or pseudo first-order reactions and substrate determinations in catalytic reactions. However, their error analysis shows that the variable-time approach is best for enzyme and catalyst determinations and also for non-linear response-rate curves. Reilley and Papa[35] and Papa, Mark and Reilley[36] have discussed the optimum conditions for the second-order linear and graphical extrapolation methods. Mark, Greinke and co-workers[1,36,42,43] have developed a very detailed error analysis for all the first-order and pseudo first-order methods discussed above. They have shown that for binary mixtures the choice of the best method for a particular mixture and of the optimum analysis conditions and experimental parameters of the chosen method was strongly dependent on the ratio of the rate constants as well as on the ratio of the initial concentrations of the species of interest in the mixture. They also gave a set of rules of thumb[1,42] for use as rapid guide lines for the choice of method and optimum conditions. There have also been a few experimental comparisons of the results obtained by using some of the pseudo first-order methods,[1,44–46] which are in general agreement with the theoretical predictions of the error analysis treatments. Siggia and Hanna[47] and Greinke and Mark[48] have also discussed the relative influence of synergistic effects on the accuracy of the various first-order and pseudo first-order methods. Such effects can often be ignored in graphical extrapolation methods, but can lead to huge errors in any of the non-graphical methods. Greinke and Mark[48] point out that when a non-graphical method is used it is absolutely necessary to have a very complete understanding of all the chemistry of the reactions employed.

Recently there has been a very important series of papers by Margerum and co-workers on the parameters affecting the accuracy of the simultaneous analysis of mixtures by pseudo first-order reaction methods.[23–25,31] Their conclusions are that their approach to the problem is the superior method in several examples of the use of reaction rate methods for analysis. In the early development of differential reaction rate methods for the simultaneous *in situ* analysis of mixtures of closely related substances, the chemical reactions used were not suitable for continuous automatic measurement of the entire rate response curves,[1,7] and calculations were generally done by hand. Hence, the emphasis at that time in the development of the reaction rate methods was on minimizing the number of experimental points taken and on predetermining the optimum times, *etc.*, for taking the readings.[1,7] However, in recent years the advances in electronic circuitry and computer technology have had a tremendous influence on the design of instrumentation for kinetic analysis. These instrumental advances have also had a strong influence on the principles and approaches to differential rate methods. Margerum and co-workers[23–25,31] (and also Weichselbaum and co-workers[21,49]) have shown conclusively that the use of built-in computation systems allows continuous analysis of the entire reaction rate curve. The results are thus immediately processed with both ensemble averaging and smoothing routines. Experimental results and detailed error analysis have shown that this approach to data acquisition, reduction and display leads to a much greater accuracy and precision of the analytical results.[23–25,31] In fact, good results can be obtained for fast reaction differential rate analyses where the usual finite or minimal data point methods fail completely.[23,31] Obviously, this approach will be that used in most future developments in kinetic-based methods of analysis.

INSTRUMENTATION

As mentioned above, the major reason for the considerable increase in practical applications of kinetic-based methods is the tremendous advance that has been made in quantitative chemical instrumentation and electronics in the past few years, especially the efforts of instrument manufacturers and certain research groups to design instruments which apply these technological advances to meet the special features and demands of kinetic measurements on dynamic systems. Perhaps the most important of these advances is a consequence of the fantastic developments in both analogue and digital computer technology, as a result of which low-cost linear and digital integrated circuits have been made readily available to people interested in designing chemical instrumentation for ultrasensitive measurement. To quote a statement in a recent publication by Crouch,[10] the availability of integrated circuits "is revolutionizing instrumentation in science."

The instrumental advances can be classified in three separate but overlapping categories. First there are the improvements in the accuracy and precision of the reaction monitoring system electronics such as the excitation and transducer response circuits which create and measure the signal which is proportional to some time-dependent parameter in the chemical reaction (*e.g.*, improved stabilization of spectrophotometer light sources and increases in the sensitivity of photoelectric transducer circuitry). Secondly, the availability of low-cost computing elements has made it possible to build into the instruments either limited or elaborate self-contained computing capability. The extent and elaboration of the computation capability is, of course, reflected in the price of the instrument. These built-in computers can vary from a simple device to convert an initial-rate slope into a digital display of the concentration of the species to be determined, to a full-scale computing device which not only handles data reduction but also controls the operation and timing of the sequencial operations in the experiment. In the extreme case, the computing device operates in a feed-back mode and can sample and analyse results during the course of an experiment and then alter the experimental control parameters in such a way as to optimize the sensitivity and/or selectivity of the determination. The third area of advance is in automation design. This includes advances in the mechanical design and accuracy of sampling units, reagent addition and mixing procedures, *etc*, as well as the application of computing devices to start, control and time the automated procedures and devices (which illustrates the overlap of the three categories).

In the area of new developments in instrumentation of kinetic methods of analysis, there have been two excellent monograph chapters published recently which discuss the basic principles and applications of analogue–digital circuitry employed in considerable detail data reduction and automation design.[9,10] The chapter by Crouch[10] is especially comprehensive and clear in its discussion of computer-based kinetic method instrumentation.

Reaction monitoring

System electronic circuitry. The first problem in improving the accuracy and precision of kinetic-based analytical results is improving the quantitative nature of the total reaction monitoring system (spectrophotometric, potentiostatic, conductometric, *etc.*) and modifying it specifically for time-dependent measurements in following reaction rates. It is convenient to discuss the advances according to the type of measurement system.

Spectrophotometric systems. One of the major problems in adapting spectrophotometric instrumentation to kinetic measurement is that of light-source variation. This problem is inherent in any spectrophotometric system and even though this technique is relatively simple and generally applicable, it has caused kineticists in the past to shy away from spectrophotometric systems for accurate measurement, because such light-fluctuations are often of the same or similar time period as the reaction being followed.[21,49] Most commercial spectrophotometers which are designed for time-independent spectral measurements minimize such light-source variations by the use of double-beam optical systems which partially cancel fluctuations by periodic comparison of reference and sample beam intensities. Such double-beam systems have not generally been considered suitable for spectrophotometric instruments specifically designed for reaction rate measurement. Such systems seriously limit the response-time of the instrument, tend to introduce significant noise, and also add to the cost and complexity of the instrument,[10,21,49] so most designs for kinetics instrumentation employ a single-beam (non-wavelength-scanning) system and concentrate on lamp stabilization.

Weichselbaum and co-workers[21,49] have described a simple stabilization system which regulates the lamp voltage. This circuit compensates for variations in the lamp filament resistance and is thus more efficient than the more common techniques which regulate only the applied voltage or the applied current. Further stabilization is achieved by having a thermal convection baffle in the lamp housing. This source system was reported to give a drift of less than 0·003 absorbance units per hour.

As the stabilization method of Weichselbaum *et al.*[21,49] controls the lamp electrical input and does not directly control the actual lamp output intensity, an uncertainty is introduced into the measurement. Loach and Loyd,[50] and Pardue and co-workers[51,52] have reported several different circuits which use an optical feed-back system for lamp stabilization. The lamp output beam is split and one beam is monitored by means of a photomultiplier tube, the signal from which is fed back to the lamp power supply as an error signal which modifies the power supply voltage to maintain a constant intensity output. Fluctuation of less than 0·03% transmission per hour has been attained.[50]

The elimination of detector noise and drift is also a critical problem in the application of a spectrophotometric system to kinetic analysis, especially if the derivative of the rate curve is being determined by a built-in computation module or unit[21,49] as discussed in a later section. Weichselbaum and co-workers[21,49] discussed the relative signal-to-noise ratios for photodiode tubes and photomultiplier tubes in some detail. They found that when both types of phototransducer are operated at the same anode current, the photodiode tube has a higher signal-to-noise ratio than the photomultiplier. They concluded that the photodiode tube was thus more applicable in non-wavelength-scanning spectrometers designed for kinetic measurement, where light source intensity is not a limiting factor. Crouch and co-workers[10,53] have pointed out correctly that this evaluation of comparative applicability from signal-to-noise ratios at constant anode current is not valid for all spectrophotometric uses. They demonstrated that for systems where the light level is low and/or cannot be controlled, a photomultiplier gives better results. Weichselbaum and co-workers[21,49] have also reported that vacuum phototubes have more favourable signal-to-noise ratios than similar gas-filled tubes. A recent paper by Franklin, Horlick and Malmstadt[54] discusses the optimum criteria for stability of the power supply to the detector.

Recently, fluorimetric methods for kinetic analysis of a variety of materials, mainly of a biological nature, have also been developed.[10,55,56] This technique, although less general in application, has inherent advantages over normal absorbance spectrophotometry in that it is considerably more sensitive for certain high-efficiency fluorescent systems, and in dilute solution the fluorescence intensity is directly proportional to chemical concentration, which reduces signal processing (linearization) significantly. Though so far no papers have been published specifically describing special electronic circuit design and modification of standard fluorimeters for kinetic measurement, it can be stated that similar criteria and/or requirements for detector noise and drift and excitation light-source reproducibility are the same as discussed above for spectrophotometric measurements.

Electrometric systems. Because of the simplicity and ease of making highly accurate current or voltage measurements (made possible by analogue operational amplifier circuitry[57]) considerable work has recently been done on adaptation of potentiometric, constant-current coulometric, and amperometric monitoring of reaction rates for analytical determinations. Some of the early work on potentiometric measurement used a concentration cell technique.[58] Rechnitz and co-workers[59–64] have described the applications of various ion-selective electrodes in potentiometric measurement of reaction rates and kinetic analysis. They have also reported the application of a fast-response, high input-impedance, differential amplifier circuit for kinetic measurement, using two different ion-selective electrodes as the potentiometric cell.[59] Janata and Mark have suggested the application of constant-current coulometric techniques for simultaneous differential reaction rate analysis.[25a] Pardue has described the application of a polarized rotating platinum electrode system using amperometric detection for kinetic-based determinations.[65]

Conductometric instrumentation based on operational amplifier circuitry has also been described for use in kinetic methods of analysis.[66–69] Recently a bipolar-pulse modification of conductometric measurement has been described by Johnson and Enke.[70] This technique seems to be very promising for rate measurement because of its great sensitivity to small changes in conductance.

Reaction temperature control apparatus. As essentially all chemical reaction rates are very strongly dependent on temperature, considerable effort has been made to design simple but highly reliable thermostatic reaction cells and convenient but accurate temperature control systems (generally water-baths). A very comprehensive discussion of the design and construction of temperature control systems has been given by Van Swaay.[71,72]

Pardue and Rodriguez[51] designed a spectrophotometer cell which was sealed into a Lucite outer jacket which allowed water from a thermostatic bath to be in direct contact with the spectrophotometer cell walls. This permitted rapid temperature equilibration of the reactant solutions mixed by stirring in the cell. Weichselbaum and co-workers[21,49] described a spectrophotometer cell which had a separate mixing chamber above the cell itself. Both compartments were thermostatically controlled and the mixing chamber was fitted with an effective magnetic induction stirrer. Very rapid temperature equilibration on mixing of reagents was reported. Feil *et al.*[73] have reported a rapid temperature equilibration cell specifically designed for use with the Beckman DU spectrophotometer. Excellent temperature regulation ($\pm 0{\cdot}005°$ at 25°) was attained.

Weichselbaum, Smith and Mark[74] described a proportional dual thermistor bridge temperature-control system using analogue–digital control circuitry. With use of the jacketed cell described above,[21,49] better than $\pm 0{\cdot}01°$ regulation in the cell was attained at various temperatures. The system was designed so that four different controlled temperatures (15°, 25°, 30°, and 37°) could be attained automatically in a few minutes by simply pushing a selector switch.

Data reduction and display systems

In the application of kinetic methods to routine analysis the detector signal response being used to follow the course of the chemical reaction must be converted into some convenient form, ideally directly into the concentration of the species being determined. Consequently a large volume of research on this has been reported. Systems described vary from the very simple to virtually a built-in digital computer unit.

Computation systems for initial reaction rate methods. Most practical reaction rate based procedures (enzymatic and other clinical assay methods in particular) measure only the initial 1–3% of the overall reaction rate curve, primarily because the mechanism and hence the kinetics are well-behaved in the early stages and the initial rate is essentially constant (pseudo zero-order) with time over this period and is directly proportional to the concentration of the species to be determined. (Detailed discussions of the theory and principles of initial reaction rate methods can be found in references 1, 6 and 9.)

The simplest initial reaction rate calculation involves the measurement of the extent of the reaction at a fixed time after initiation of the reaction.[1,6,9] This value is effectively equal to the slope of the linear initial rate curve. It is a popular method because it is conveniently used with flowing streams. Cordos, Crouch and Malmstadt described one of the first computation circuits for the fixed-time method.[75] It consisted of an analogue integration and subtraction network controlled with respect to timing and sequence by a digital logic circuit. This approach yields a very favourable signal-to-noise ratio in the output. Hicks and co-workers[76–78] have also described a similar analogue integration technique but developed a hardware interface system to free their time-shared computer system for control of other automation operations. A completely digital computation system for the fixed-time method has been proposed by Ingle and Crouch[79] which is similar to the analogue operations but employs digital integration. Ingle and Crouch[79] state that the digital method of computation has advantages over the analogue method because there are no drifts and circuit non-linearities, no mechanical and/or analogue switches are necessary, and shorter integration times (faster rates measured) can be employed.

Another commonly used initial reaction rate method is the variable-time (or fixed-concentration) technique[1,6,9,10] in which the time required for the reaction to proceed to a preselected fraction of completion (again, less than 3%) is the measured parameter, which is inversely proportional to the initial reaction rate and concentration of the species being determined. The computation is somewhat more complex than in the fixed-time method. The first completely automated variable-time computation system was based on analogue logic and was developed by Pardue and co-workers.[80,81] Stehl, Margerum and Latterell[82] designed a similar but improved analogue system which eliminated all but one mechanical switch from the circuit. James and Pardue recently reported an analogue variable-time system utilizing tunnel diodes and electronic silicon-controlled diode switches which totally eliminated mechanical switches.[83] This circuit significantly reduced the measurement time intervals that could be determined. Crouch[84] reported the circuit design of a hybrid analogue-digital computation circuit for variable-time systems which eliminated the temperature-sensitive logarithmic analogue operations of the James and Pardue circuit.[83] As analogue systems tend to have significant drift, especially in the integration operation, Pardue, Parker and Willis[85] designed a completely digital computation unit for the variable-time approach. This unit virtually eliminated drift as a source of error in the computation operation and also included a system for noise-averaging, which had not been done in any previous variable-time system.

Some designers have felt that it is more accurate and less susceptible to random error to make a continuous measurement of the total initial-rate curve.[21,23–25,49] As the slope of the initial-rate curve is the parameter that is directly proportional to the concentration of the species of interest, these groups have used analogue (continuous) derivative operations on the initial-rate curves. Weichselbaum and co-workers[21,49] designed a spectrophotometer unit which employed a direct analogue differentiation circuit with filter capacitors to reduce the noise enhancement inherent in direct differentiation of a signal. They also avoided the limited accuracy of analogue logarithmic circuits by using the rate of change of transmittance and the instantaneous value of the transmittance to obtain the derivative of the absorbance (A) with respect to time $[\mathrm{d}(-\log T)/\mathrm{d}t = (-\log e)[(1/T)(\mathrm{d}T/\mathrm{d}t] = \mathrm{d}A/\mathrm{d}t]$. Pardue *et al.* have developed several different systems for the derivative computation technique.[86–88] Instead of direct analogue differentiation, they employed an indirect method for obtaining the slope of the rate curve. Both a servo system[86,87] and an operational amplifier system[88] were used to compare the slope of the initial rate curve with a ramp generated by an operational amplifier integrator. Recently Malmstadt and Crouch[89] critically discussed circuits using manual, mechanical-servo and operational-amplifier slope-matching systems for derivative measurement. In most of these computation units recorders were used to present the response read-out, usually as concentrations. However, Weichselbaum and co-workers[21,49] and Crouch and Malmstadt[90] have shown that the use of digital read-out systems considerably improves the accuracy and precision of rate determinations. Crouch has also discussed the relative merits of direct differentiation and the fixed-time and variable-time methods.[10]

Computation by analogue simulation. Mark, Papa and Reilley[7] and Janata and Mark[25a] have suggested the uses of an analogue simulation approach to the determination of the initial concentration of a reactant. In this approach, the entire reaction rate response curve is simulated with an analogue computer. The initial input voltages to the computer are the electrical analogue of the initial concentrations in the chemical reaction. When the simulated curve exactly matches the experimental reaction rate response curve, the initial unknown concentrations are evaluated from the analogue voltages which yielded the match of the curves. It should be pointed out here that the success of this simulation method rests on an exact knowledge of the reaction mechanisms and rate constants of the reaction being followed.

Computation circuits for simultaneous analysis of mixtures. In recent years considerable research in kinetic methods has been devoted to the simultaneous *in situ* analysis of mixtures.[1,7] As the data reduction of the rate response curves in these differential rate methods is quite complex, built-in computer systems are necessary in order to make these methods practical for routine analytical procedures. Pinkel and Mark,[91] Toren and Davis,[92] and Toren and Gnuse,[93] have reported automatic analogue computer circuits for the solution of the simultaneous equations of the method of proportional equations.[1] Mark, Papa and Reilley,[7] and Janata and Mark[25a] have suggested analogue simulation for solving for initial concentrations in differential rate methods.

Automatic sample handling systems. In spite of the fact that automation of the entire sample handling procedure is an obvious means of eliminating much of the experimental error in sampling, reagent addition, mixing, and timing, and has received considerable attention by the manufacturers of clinical rate-based instrumentation, very little research in this area has been published directly related to kinetic methods of analysis. The most popular automated sampling and mixing systems are based on continuous flow. Various applications and the principles of continuous flow techniques have been discussed in great detail by Blaedel and Hicks,[6] Pardue,[9] Schwartz and Bodansky,[94] in Technicon Instrument Company literature[95] and in the recent reviews by Rechnitz.[14,15] The most recent research publications on automated techniques have generally utilized discrete discontinuous sampling systems, however.[10] Automated injection and refill pipets have been designed by Malmstadt and co-workers.[96,97] Javier, Crouch and Malmstadt have published the design of a completely automated stopped-flow instrument for kinetic analysis,[98] and Deming and Pardue have recently published the design of a computer-controlled electromechanical system for automated reagent addition.[99] Mueller and Burke[100] have reported a real-time computer control system for a reagent-addition unit which would be applicable to kinetic based measurement instrumentation. Fasce and Rej[101] have recently reported an automatic enzyme assay system. Further automated systems which are incorporated in *totally* computer-controlled kinetic analysis instrumentation are also mentioned in the following section. As indicated above, the advertisements and operation manuals of the clinical instrument companies are an excellent source of information on recent advances in automation techniques and hardware. The reader is recommended to contact the sales representatives of the following instrument companies in this regard: Analytical Instrument Division of American Optical Corporation, Richmond, California; Bausch and Lomb Corporation Analytical Systems Division, Rochester, New York; Technicon Company, Incorporated, Tarrytown, New York; Beckman Instrument Corporation, Fullerton, California, and Sherwood Medical Industries, Incorporated, St. Louis, Missouri. A radically new and very effective automated system (ACA) for clinical screening tests has been developed by the Instrument Products Division, E. I. DuPont Company, Wilmington, Delaware. This system employs a separate plastic pack in which each individual test, including the spectrophotometric measurement, is carried out. A computer built into the instrument controls the entire operation.

Sorokin, Gromov, and Chernyskii[102] have described an automated thermochemical apparatus for studying kinetic processes.

Applications of on-line computer systems to kinetic methods of analysis

As the expense of high-speed small digital computer systems goes down, the applications of these small computers as built-in (on-line) units in chemical instrumentation for data reduction, system control, data acquisition, and experimental optimization and design in "real time" have increased sharply. As discussed in an earlier section, the computer was originally used in kinetic methods for on-line fast data acquisition and data reduction to give final display as the concentration of the species in the sample being analysed. The computer was also used in some control applications. However, such limited applications do not efficiently use the full capabilities of the small on-line computer. Recently several research groups have been investigating and developing the small on-line computer for *total* control and operation of the instrumentation in kinetic methods of analysis. Systems have been described in which the computer not only handles the data acquisition and sample-manipulation, but actively takes part in all parts of the experiment by immediate examination of the data in real time and then makes various decisions which optimize the experimental parameters and variables during the actual experiment.[10] It is felt that this is the most important single improvement in kinetic-based analysis, which will greatly expand the routine and specialized applications of the technique.

James and Pardue[103] described an on-line computer system which utilized software to provide the calculations for either fixed-time or variable-time measurements. The signal–time profile is stored in the memory of the computer and the time scale is optimized on the basis of a preliminary rate measurement. This preliminary rate measurement is also used to optimize the time constant of the digital filter system. The basic block diagram of the programme for this system is shown in Fig. 1.

Hicks and co-workers[76–78] used a hybrid analogue-digital approach to on-line computer control. They employed a hardware interface to compute the reaction rate outside the computer, as discussed in an earlier part of this section. The computer was free to monitor and control the electromechanical equipment for the sampling,

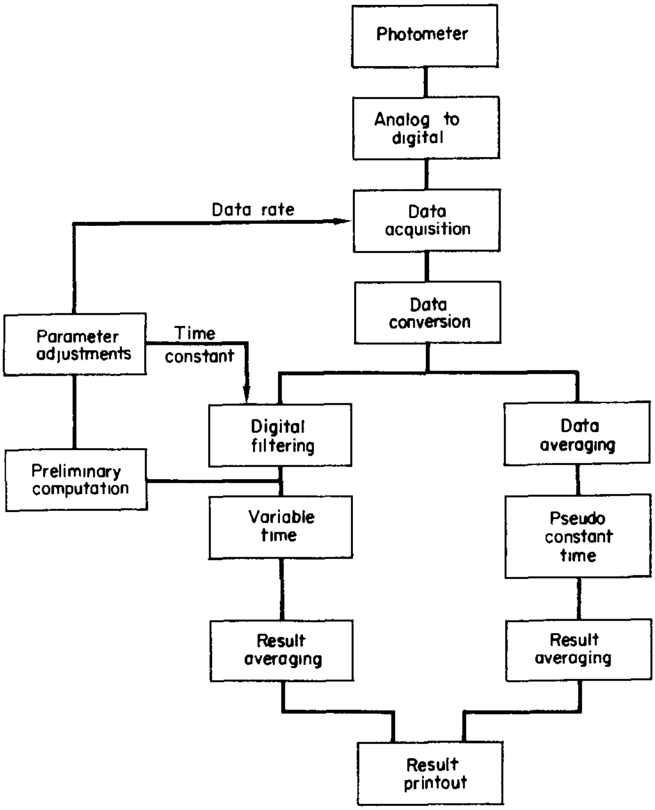

FIG. 1.—Flow diagram of a computer programme for an on-line computerized reaction-rate instrument.[103] Reprinted by permission of the American Chemical Society.

reagent addition, *etc*, for automatic scale selection, calibration, for timing and sequence application, and for output display. A block diagram of this computer system is shown in Fig. 2. Eggert, Hicks and Davis[78] have also discussed use of this hybrid system in experimental control operations.

Recently Willis *et al.*[25] have described the design and characteristics of an on-line computer-controlled stopped-flow system for kinetic analysis. The main feature of this system is its ability to carry out repetitive runs on the same sample and/or do multiple slope measurements on a single reaction for signal-averaging purposes. Such ensemble-averaging results in a very high precision. The programme also provides for display of a variety of kinetic and concentration parameters. Janata and Mark have[104] recently published an extensive discussion of the applications of analogue computer simulation to a wide variety of kinetic, mechanistic and analytical problems.

An excellent discussion of the principles, objectives and general design philosophy of computer-controlled instrumentation for study and characterization of chemical reactions has recently been published by Deming and Pardue.[99] This paper is certainly very important for any researcher interested in computer-based instrument design as it points out clearly the objectives in future design of kinetic analysis instrumentation. In this instrument, routine procedures as well as the decision-making procedures in

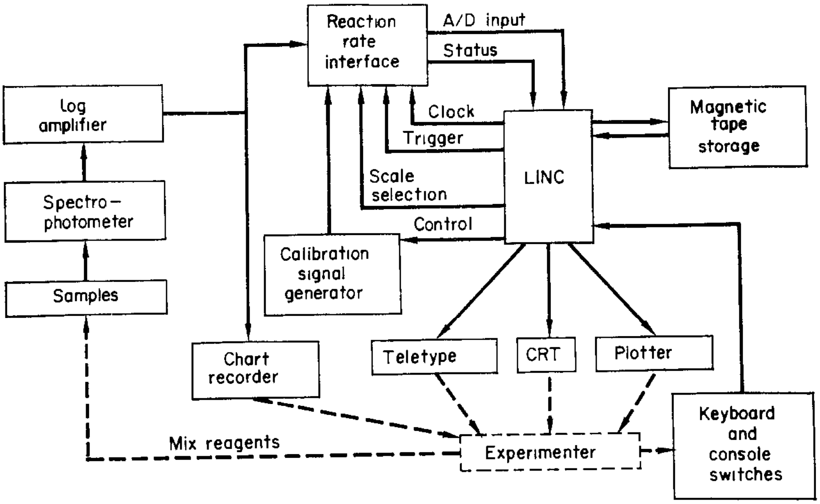

FIG. 2.—Block diagram of a hybrid (interactive) computer system for kinetic analysis.[76] Reprinted by permission of the American Chemical Society.

data interpretation and experimental design have been automated. In this paper, Deming and Pardue presented two very picturesque block diagrams which point out very dramatically the differences in fundamental operational concepts between the procedures conventionally used for the instrumental characterization of a chemical reaction and what these authors conceive as the general future trend of automated reaction characterization.[99] These diagrams are reproduced here as Fig. 3 and 4. This paper also gives the details of the design of such an automated and computerized instrument and the results of test applications are very impressive. There is another

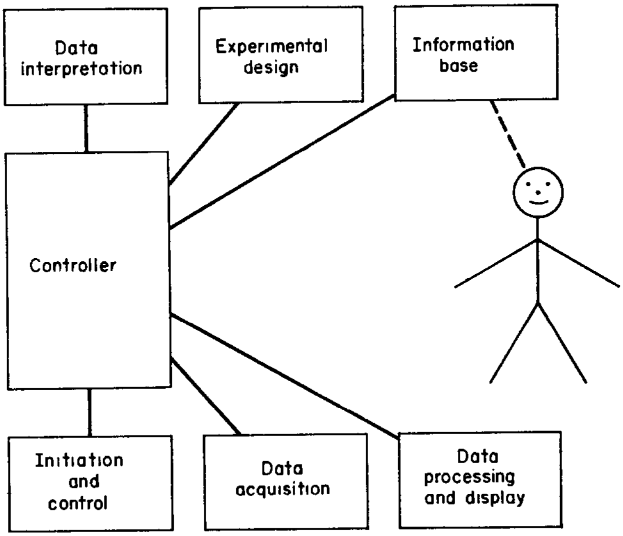

FIG. 4.—Procedures proposed for on-line computerized automated characterization of a chemical reaction.[99] Reprinted by permission of the American Chemical Society.

recent paper on the design and operation of a totally automated chemical instrument system that should be mentioned here, although it does not involve kinetic analysis methods. Perone, Jones and Gutknecht[105] have reported an electroanalytical system which also uses an on-line computer to analyse and interpret the results obtained during a repetitive electrochemical experiment and then control the various experimental parameters of the experiment to optimize the sensitivity and resolution of the response and the analytical results. Perone[106] has also recently published a detailed monograph chapter on the subject of real-time computer applications and optimization of experiments.

BIOLOGICAL AND CLINICAL APPLICATIONS (ENZYME METHODS)

Certainly the greatest amount of both use and research in the field of kinetic-based methods of analysis is in the general area of clinical analysis and other biological applications. Most of this work is oriented towards enzyme assay and the use of enzymes as specific reagents for a variety of different types or classes of reactants, such as the substrate in the enzyme-catalysed conversion reaction, inhibitors, activators, *etc.* As the enzyme is a biological catalyst which acts to lower the activation barrier and hence accelerate the rate of certain specific reactions, without being consumed in the overall conversion reaction and generally without changing the net free energy difference (equilibrium constant) between reactants and products, it is not only logical, but also for the most part necessary, to employ kinetic methods in the complex systems of chemical and biological analysis. As mentioned in the introduction, these types of analysis are of great importance in medical diagnosis and hence so is fundamental research on these analytical techniques, to broaden the scope of application and improve the speed, accuracy and precision of the methods.

Guilbault has recently written a very comprehensive and well-documented book on enzyme methods of analysis.[3] He has also written extensive reviews of recent publications in this field.[14–17] Other recent books by Purdy,[107] Udenfriend,[108] and

Ruyssen and Vandenriesche[109] have extensive discussions of kinetic-based clinical techniques, procedures, and methods. Also, there have been several monograph chapters on the various aspects of the subject by Blaedel and Hicks,[6] Guilbault,[110] Phillips and Elevitch[111] and Pardue.[9] There have also been other review articles by Bergmeyer,[18] Devlin,[19] Roth,[20] Danev[112] and Zuman.[113] It should also be pointed out that the literature of the various enzyme nanufacturers and supply houses as well as that of the various clinical instrumentation manufacturers is a wealth of information on methods and procedures of analysis. The literature will be reviewed here first according to the analytical species being determined and second according to the method used. As the literature is extensive, this review will attempt to cover only reports which represent significant improvements in procedures or inovations and new applications reported in the past few years.

Determination of enzymes

Since the enzyme is a biological catalyst and in most of the enzymatic catalysis reactions is not consumed, the rates of the reactions of the substrate (reactant) are strongly influenced by even small amounts of enzyme present. Thus the rates of enzyme-catalysed reactions are very sensitive to low enzyme concentration. A wide variety of experimental and instrumental procedures and techniques has been employed in enzyme assay.

Spectrophotometric and fluorimetric methods. The instrumental improvements in optical kinetic-based systems have already been discussed in the instrumentation section above. Much of this instrumentation was developed with enzymatic problems in mind.

Using fluorimetric rate-measurements, Guilbault *et al.* have studied the effects of various fluorogenic esters on the determination of cholinesterase.[114] They reported that *N*-methylindoxyl esters were the optimum substrates in terms of both sensitivity and reagent stability. Guilbault and Zimmerman[115] have also reported a technique for the determination of cholinesterase directly on a solid surface. Similarly, Guilbault and Heyn[116] tested several fluorogenic substrates for the determination of cellulase and suggest resorufin butyrate as the best substrate for a *rapid* initial-rate determination. Guilbault and co-workers[117] have developed a considerably more accurate and rapid analysis for hyaluronidase by taking advantage of the high fluorescence efficiency of indigo white. The optimum analytical conditions and fluorogenic substrates for a variety of lipase enzymes have been reported by Guilbault and Sadar[118] and Guilbault and Hieserman.[119] A comparative study of the use of umbelliferone as a fluorogenic substrate for acid and alkaline phosphatase with other commonly used substrates, showed that this substrate increased the sensitivity of the assay by 2–4 orders of magnitude.[120] The applicability of a variety of naphthol derivatives as substrates for the phosphatase enzymes has also been reported.[121–123] A systematic study of several new fluorometric substrates for sulphatase has been made and the fluorimetric method described appears to be superior to the usual colorimetric methods.[119] Fluorometric initial reaction rate methods for amino-acid oxidase,[124] peroxidase,[125] glucose oxidase,[125,126] xanthine oxidase[125] and galactose oxidase[126] have been reported. Guilbault and Kramer[127,128] have described a simple, rapid fluorometric method for the enzymes dehydrogenase, glucose-6-phosphate dehydrogenase, 1,α-glycerophosphate dehydrogenase and glycerol dehydrogenase. Also, an automated procedure for dehydrogenase has been reported which uses the reaction with the substrate resazurin to form the intensely fluorescent resorufin.[17]

A variety of spectrophotometric initial-rate methods for enzyme assay have also been described recently. Most of the methods cited below represent only minor modifications of the established procedures. However, the results reported have been used to show how the accuracy and precision of such determinations can be significantly improved by using modern instrument designs.[10] Weichselbaum and co-workers have reported a very reproducible method for the determination of lactic dehydrogenase.[21,74] These authors[21] and Pardue, Parker and Willis[85] also investigated kinetic methods for alkaline phosphatase. Pardue, Frings and Delaney[80] have reported results for the determination of glucose oxidase and galactose oxidase by a variable-time method. James and Pardue have also studied the analytical results for the determination of alkaline phosphatase by a variable-time procedure[129] and on-line computer system.[103] Toren *et al.*[77] have reported computer-based rate methods for acetic dehydrogenase and alkaline phosphatase.

Electroanalytical methods. The application of electroanalytical techniques to enzyme assay by rate-based methods was introduced less than ten years ago.[17,107] As these techniques are very simple and capable of a high degree of accuracy, electroanalytical methods are quite promising. One of the first methods described was a $\Delta E/\Delta t$ rate method introduced by Guilbault, Kramer and Cannon.[130] This technique has been employed in the determination of cholinesterase,[130] glucose oxidase,[131] xanthine oxidase[132] and peroxide catalase.[133] Potentiometric[58,134,135] and amperometric techniques[65,136,137] have been reported for glucose oxidase and for galactose oxidase.[138] Purdy[139] has reported amperometric and coulometric methods for urinase and urease. Katz[140] has also described a potentiometric method for the determination of urease, using a cation-sensitive electrode system as the detector. Guilbault, Smith and Montalvo[141] have also reported the use of an NH_4^+-selective glass electrode for the determination of deaminase. There have also been polarographic techniques reported for the determination of cholinesterase,[142,143] 3-hydroxyanthranilic oxidase[144] and catalase.[145] Curtin[146] has reported a potentiometric method using a silver–thiol electrode method for cholinesterase. Lipner and co-workers[147] have reported the use of an oxygen galvanic cell system for the analysis of a variety of oxygen-consuming enzymes, and Malmstadt and Piepmeier designed a pH-stat system for a variety of enzyme rate determinations.[148]

Determination of substrates

By far the greatest volume of recent research effort in enzymatic methods of analysis has been in the development of determinations of various substrates of enzyme-catalysed systems. A large variety of both organic and inorganic substrates has been studied. As Guilbault[3,14–16,19] and Bergmeyer[149] have presented extensive compilations of enzymatic methods for substrate analysis, only recent applications will be given here.

Spectrophotometric and fluorometric methods. Several enzymatic methods have recently been reported for the analysis of carbohydrate substrates. Spectrophotometric methods for glucose,[75,80,89] using modifications of the usual glucose oxidase catalysised technique, and galactose[80] by using galactose oxidase have been described by several research groups. Guilbault and co-workers have developed a very useful technique for the fluorimetric analysis of various sugar mixtures.[27,28] They reported the successful determination of lactose, maltose, fructose and glycogen mixtures by first reacting each sugar in separate aliquots with the specific enzyme which converts it into glucose, and using an initial-rate fluorimetric method which follows the formation of resorufin in a coupled reaction to determine the glucose produced. The analysis of several other carbohydrate mixtures, glucose and sorbitol mixtures, and methanol, sorbitol, and xylose mixtures have also been reported.[27,28] Guilbault, Sadar and McQueen[150] have used a similar procedure for the fluorimetric determination of a great variety of organic acids, both for single components of a mixture or for the simultaneous analyses of several acid components of a mixture.

Weichselbaum *et al.*[21] have reported a spectrophotometric maximum rate method for the determination of ammonia and blood urea nitrogen in biological systems. Faway and Dahl,[151] Mondzac, Ehrlich and Seegmiller,[152] Reichelt, Kuamme and Iveit,[153] and Kirsten, Gerz and Kirsten[154] have also described initial rate spectrophotometric methods for ammonia in various biological media. Roch-Ramel[155] and Rubin and Knott[156] have reported fluorimetric methods for the determination of ammonia.

Schulz, Passonneau and Lowry[157] have described a fluorometric method, and Faway, Roth and Faway[158] a spectrophotometric method for inorganic phosphate. Two unique rate methods employing the enzyme catalyst immobilized[17] in a solid matrix have been reported (considerable research is now being carried out on methods of immobilizing enzyme systems without loss of their catalytic activity.)[3,17,59] Hicks and Updike[160] have used lactate dehydrogenase immobilized in a gel for the assay of glucose and lactic acid. They have also coupled an immobilized glucose oxidase system with an electrochemical sensor for the determination of glucose in blood.[161]

Determination of activators

In many enzymatic catalysed reactions a substance called an activator is required before the enzyme itself becomes an active catalyst.[3,17] As the initial reaction rates of such enzymatic systems are proportional to the concentration of the activator (until all the catalyst is activated) rate measurement can be employed to determine the concentration of activator species in the same manner that is used for direct enzyme assay as discussed in another section of this review. Although this application has been shown to have considerable potential[3,6,17] and can under special conditions determine very small amounts [down to 10^{-15} mole (162)], very little research on the analytical applications has been published recently. Only the method for the determination of Mn^{2+} and Mg^{2+} which are activators for isocitric dehydrogenase reactions[6] and the determination of Ca^{2+} and Zn^{2+} activators for alkaline phosphatase[163] have been reported in the last few years.

Determination of inhibitors

There are many substances, called inhibitors, which cause a decrease in the rate of an enzyme-catalysed reaction.[3,6,17] In general, the decrease in the initial rate of an enzymatic reaction is directly proportional to the inhibitor concentration until total inhibition is reached (reaction rate reaches zero). Numerous examples have been reported recently of the determination of most common inorganic anions and cations. Guilbault has compiled a very complete list of the procedures for Ag^+, Al^{3+}, Be^{2+},

Bi^{3+}, Ce^{3+}, Cd^{2+}, Co^{2+}, Cu^{2+}, Fe^{2+}, Hg^{2+}, In^{3+}, Mn^{2+}, Ni^{2+}, Pb^{2+}, Zn^{2+}, CN^-, $Cr_2O_7^{2-}$, F^- and S^{2-}.[3] Very recently, Townshend and Vaughan have reported the determination of Hg^{2+} and Ag^+ (inhibitors of alcohol dehydrogenase)[164] and Be^{2+} and Zn^{2+} (inhibitors of alkaline phosphatase).[165] With growing concern for the effect of pesticides on the environment and the ecology, there has been considerable research on the application of the selective inhibition of enzyme activity by these substances. Kitz[166] has recently published an extensive review of the inhibition effects on cholinesterase activity, as used for the determination of various organophosphorus compounds. More recently several methods have been reported for a large variety of organophosphorus insecticides, *etc.*[167–174] Methods have been reported for a variety of chlorinated insecticides and herbicides,[171,172,175,176] and carbamate insecticides.[171,172,186–190]

There is a wide variety of factors such as choice of enzyme source and type, substrate, and other reaction conditions, which have considerable effect on the sensitivity and/or selectivity of a reaction for a particular pesticide inhibitor. There have been a large number of studies in this aspect.[180–173,186,189,191,192]

CHEMICAL APPLICATIONS OF RATE METHODS

Comprehensive compilations of the various general chemical applications of kinetic determinations reported before 1969 have been given in two recent books[1,2] and a series of review papers.[11–13,16,183] Druzhinin[184] has reviewed the kinetic-based methods for organic substances, in air-pollution studies. Heil[185] has reviewed kinetic methods applied to water analysis. Thus, this review will list only methods reported during the last two years, except in cases of special importance. These recent publications are listed below in two groups, first the methods for determination of a single species, and second the methods for determination of two or more species by differential reaction rate methods.

Determination of a single component

Inorganic species. The majority of chemical applications of reaction rate methods of analysis have used catalysed reactions and have, in general, employed initial reaction rate procedures. Yatsimirskii has described in detail the techniques and application of catalysed reactions in a recent book.[2]

Klockow, Ludwig and Giraudo[186] have reported the use of a zirconium catalysed reaction between perborate and iodide which can be used for the determination of fluoride. The fluoride acts as an inhibitor in the parts per milliard (ppM) range. Bruton has devised an ion-selective electrode rate method for the determination of both fluoride and chloride.[187] Thompson and Svehla[188] have used the perborate/iodide system for the same type of catalytic determination of iron and molybdenum, and Weisz, Klockow and Ludwig[189] have developed a new electrometric monitoring system for the determination of molybdenum. Cabello-Tomas and West[190] have described a "kineto-chromic" method for trace fluoride determination. Worthington and Pardue have reported a catalytic reaction procedure for the determination of trace ruthenium, using the Ce^{4+} and As^{3+} oxidation-reduction reaction.[191] Janjic, Milovanovic and Celap[192] described a method for the ultramicro determination of manganese by its catalytic action on the oxidation of alizarin by hydrogen peroxide. Analytical applications of the iodine and osmium catalysed reaction between Ce^{4+} and As^{3+} have been discussed by Rodriguez and Pardue.[193] James and Pardue have shown that built-in computer instrumentation is capable of determining levels of 10^{-9}–$10^{-11}M$ osmium, using this reaction system.[103] Kreingol'd and co-workers[194] have described a kinetic method for Cr^{6+} based on the catalysis of oxidation of the herbicide Methurin by potassium bromate. Dolmanova *et al.*[195] also reported a method for Cr^{6+} based on the catalytic oxidation of *o*-dianisidine with hydrogen peroxide. The concentrations of Cu^{2+} solutions have been determined by measuring the effect on the oxidation of furfuraldehyde.[196] Ruthenium has been determined by Ottaway, Fuller and Allan,[197] using the catalysis of the periodate oxidation of the tris[1,10-phenanthroline-iron(II)] complex. Trace determination methods for Ag^+, Hg^{2+} and I^- have been reported by Bognar and Sarosi,[198] based on the catalytic Ag^+–I^- and Hg^{2+}–I^- titrations and the IO_3^-–AsO_3^{3-} Landolt-type indicating system. Lazarev and Lazareva[199,200] have devised two different kinetic methods for V^{5+}. They made use of the catalytic action of V^{5+} on the bromate/5-amino-*N*-phenylanthranilic acid system[199] or the bromate/primary aromatic amine system.[200] Yatsimirskii and Kalinina[201] have also devised a trace vanadium method (0·01–100 ppM) based on the catalytic effect on the iodide oxidation by bromate. Hems, Kirkbright and West[202] have employed the catalytic effect of SO_4^{2-} on the zirconium/Methylthymol Blue reaction, for the determination of sulphate ion. A stopped-flow method for the kinetic determination of Fe^{3+} reacting with thiocyanate ion[23] and Sr^{2+} by a DCTA ligand-exchange reaction have been reported recently.[31]

A method for the determination of trace Cu^{2+} by means of the catalytic effect on the oxidation of amidol by hydrogen peroxide has been reported by Kreingol'd *et al.*[203] Trace methods for the determination of Mn^{2+} by the catalytic effect on the oxidation of Indigo Carmine has been developed by Slychev and Tiginyanu.[204] The Mn^{2+} catalysis of the oxidation of *p*-phenetidine by potassium perchlorate has also been employed in a trace analysis method.[205] A kinetic method for Mn^{2+} has been reported[205] which follows the complexation reaction rate with a sodium carminate–ethylenediamine system, using an integral variant technique. The catalytic effect of iridium on the oxidation of diphenylamines by cerium(IV) has been used in an analytical application by Tikhonova and Yatsimirskii.[207] Yatsimirskii *et al.* have also reported a kinetic method for the determination of iridium, which has been applied to paper chromatographic separation of noble metals.[208] A kinetic method for the determination of cobalt in vitamin B12 uses the catalysis of oxidation of the dye Bordeaux S by hydrogen peroxide.[209] Another catalytic method for Co^{2+} has been reported by Costache and Popa[210] which uses the Bromopyrogallol Red oxidation by peroxide. Filippou, Zyatkovskii and Yatsimirskii have employed the catalysis of the *p*-phenetidine/bromate reaction by Os^{8+} for trace analysis.[211] Segeda[212] has used the Ti^{3+} reaction with hydroxylamine as the basis of a rate method. Bilidiene, Cepelionyte and Jesinskiene[213] have reported a trace Cr^{6+} method based on the catalysis of the Methyl Orange oxidation by hydrogen peroxide. Trace Ag^+ has been determined by means of the catalytic effect on the oxidation of azo dyes by $K_2S_2O_5$.[214] A novel technique for the determination of either Rh^{3+} or Pd^{2+} by catalysis of the reduction of AgBr to Ag in a photographic emulsion by metol–hydroquinone developer has been reported by Pilipenko, Markova and Kaplan.[215]

Several reaction-rate modifications of the classic molybdenum blue method for the determination of inorganic phosphate have been reported.[79,84,98,216,217] These techniques employ either fixed-time or variable-time initial reaction rate measurement.

Similar methods employing the measurement of the initial rates of formation of heteropolymolybdate have been devised by Hargis for the determination of bismuth.[218]

Toropova and co-workers[219] have used an electroanalytical method of measuring the catalytic hydrogen wave of the cobalt–5-sulpho-8-mercaptoquinolinate complex to determine trace amounts of Sb^{3+}. Lukaweiwicz and Fitzgerald[220] have devised a fast photokinetic method for the determination of Fe^{3+}.

Organic species. Gilbert[221] has reported a pulse polarographic method which uses the Co^{2+} catalytic hydrogen wave for determining trace amounts of cystine. Rodziewicz *et al.*[222] have proposed a kinetic method for the determination of various phenolic compounds. A very sensitive method for the estimation of RNA by the Cu^{2+} catalysed orcinol reduction reaction has been reported.[223] Tutt and Schwartz[224] have devised a spectrophotometric assay of Ampicillin (α-aminobenzyl penicillin) involving a maximum rate method. The catalytic polarographic prewave of Ni^{2+} organic diamine systems has been proposed as a means of measuring the pK values of certain sparingly soluble organic amines.[225] A kinetic method for the determination of the stability constants of various metal complexes has been reported by Cohen and Connors.[226] Pillai, Lakshmenon, and Saryanarayana[227] have described a "redoxokinetic" titration method for organic acids. Szepesi and Gorog have reported a method for the determination of organic amines, which follows the rate of the acetylation or formylation reactions.[228]

Simultaneous analysis of mixtures

Inorganic systems. Margerum *et al.*[31] have reported a differential reaction rate method for the analysis of binary and ternary mixtures of lanthanides, transition metals, group II and group III metals, as DCTA complexes reacted with H^+ and/or an exchanging metal ion. Pausch and Margerum[23] have also reported the use of a stopped-flow spectrophotometric method for the simultaneous analysis of binary mixtures of Mg^{2+}, Ca^{2+}, Sr^{2+} and Ba^{2+}, using the exchange reactions of Pb^{2+} with alkaline earth metals complexes. Willis *et al.*[24] have improved this method by employing computer control and data reduction. Rodriguez and Pardue[229] have used the iodide and osmium catalysis of the Ce^{4+}–As^{3+} reaction for the simultaneous determination of I^- and Os^{8+}. Ingle and Crouch have reported a simultaneous differential rate procedure for silicate and phosphate in mixtures.[230]

Organic systems. Lohman and Mulligan have analysed mixtures of ethanolamides by a differential saponification rate method.[231] A kinetic method for the analysis of mixtures of glycols, using the cleavage reaction with lead(IV) has been reported by Benson and Fletcher.[232] Binary ketone mixtures have been determined by Toren and Gnuse[93] by taking advantage of the differences in the reaction rates with hydroxyamine hydrochloride. Greinke and Mark[48] have used the same reagent in the determination of various carbonyl mixtures. Zaia, Peruzzo and Plazzogna have reported a differential reaction rate method for mixtures of various hexa-alkyl-ditin compounds.[233] Shresta and Das have reported a second-order graphical extrapolation method for the simultaneous analysis of various organic amine mixtures.[234]

FUNDAMENTAL KINETIC STUDIES RELATED TO ANALYTICAL PROBLEMS

There have been numerous papers in the recent literature concerned with basic or fundamental kinetic studies on chemical systems which are either directly or indirectly related to analytical methods and procedures. Some of the basic work is intended to develop new methods and reactions for kinetic-based analytical techniques and some is intended to determine the mechanism of reactions involved in the more common equilibrium (or thermodynamic) methods. Once the details of such reaction mechanisms are known, it is possible to systematically improve a method. Recent papers in these two catagories are listed below. It should be pointed out that there is a huge volume of literature devoted to both inorganic and organic chemistry which involves the measurement of kinetic characteristics. It has been pointed out previously that this literature is a wealth of potentially analytically useful systems.[1,7] While this review will not attempt to list the publications in this area of research, the reader should be aware of its existence when faced with devising an analytical procedure for a new problem. There are a number of recent reviews of kinetic studies of the reactions of both organic[235–254] and inorganic species.[255–261]

Perhaps one of the major advances in sensors for rapid and selective *in situ* analysis has been the breakthrough in the theory and design of ion-selective electrodes. These have already been employed in a huge number of equilibrium (potentiometric) analytical methods. Recently Rechnitz and co-workers have also demonstrated that ion-selective electrodes are applicable as sensors in kinetic measurements.[60,61,63,64,262–269] They have studied metal complex reactions,[63,64,262,265,266] instrumentation considerations,[61,267] fast reaction applications[268] and biological systems.[60] Friedman, Palaty and Nakashima[270] have used ion-selective glass electrodes in the study of alkali metal ion-exchange processes. Honaker and Freiser[271] and McClellan and Freiser[272] have shown that solvent extraction methods can be employed, under certain conditions, to study the kinetics of fast chelation reactions. Subbaraman, Cordes and Freiser[273] have also studied the affect of auxiliary complexing agents on the rate of Zn^{2+} and Ni^{2+} extraction with diphenythiocarbazone. McClellan and Menis[19] have studied the kinetics and the mechanism of Fe^{2+} extraction with β-isopropyltropolone. Although there have been no direct applications taking advantage of the differential kinetics of extraction processes reported in the recent literature, it is obvious that there is a potential for future development. Hans has published a theoretical paper on electrolyte extraction kinetics.[275]

As the various organic and inorganic forms of phosphate are now recognized as a very large pollution hazard with respect to the ecological balance in natural water systems, the problem of trace determination of phosphates has received considerable attention in the recent literature. The standard colorimetric and/or spectrophotometric method for inorganic phosphate is the reaction with molybdate to form the 12-molybdophosphoric heteropoly acid species. There have been kinetic mechanism studies of these reactions by Javier, Crouch and Malmstadt.[276] In similar kinetic studies which have analytical significance, Hargis and co-workers have studied the reactions for the formation of silicon and bismuth heteropolymolybdates.[218,277–279] Solkovikov and Prinachek have reported the study of the mechanism and kinetics of the reaction of Al^{3+} with hafnium–molybdenum heteropoly acids.[280] Also in the area of environmental problems, Weber and co-workers have reported on studies of the rates of adsorption of organic pollutants,[284] pesticides,[281] and alkylbenzenesulphonates[282,283] on various activated carbons. These studies have potential for the improvement of activated carbon through a better understanding of the adsorption mechanism, and also for the determination and separation of various pesticides and pollutants.[285]

It is important to point out here that another group[286,287] has reported a kinetic-based pollution treatment system based on the *misinterpretation* of the results of Weber and Morris.[282,283]

In the past few years there have been a number of kinetic analytical methods reported that employ ligand-exchange reactions of metal ion complexes. These initial efforts in this area indicate that these types of metal ion complex reaction have considerable promise for broad analytical application, as discussed in a previous section of this review. Because of this potential certain recent papers describing fundamental kinetic and mechanism studies of metal ion complex systems are listed here. Funashashi and Tanaka[288–290] have studied the ligand-exchange reactions of various Co^{2+}, Cu^{2+} and Ni^{2+} complexes with 4-(2-pyridylazo)resorcinol. Frost and Hart have studied the ligand transfer kinetics of reactions of Eu^{3+}–(2,2,6,6-terpyridine) complexes with Tb^{3+}.[291] The kinetics and mechanism of other ligand transfer reactions have also been reported.[292] Ligand-exchange reactions of cobalt complexes have been reported.[293] Carr and Reilley[294] have reported a study on the kinetics of the ligand-exchange reaction of ethylenediaminetetra-acetate ion with ethylenediaminetetra-acetatonickel(II). Pausch and Margerum,[31] and Willis *et al.*[25] have studied the ligand-exchange kinetics of strontium complexes of *trans*-DCTA and hydrogen ion, using Pb^{2+} as a scavenger.

Recently there have been several reports on kinetic studies using thermogravimetric methods. Sharp and Wentworth,[295] Carroll and Manche,[296] and Wentworth and Sharp[297] have had an exchange of correspondence on this subject. Taylor and Watson[298] have reported a method of determining relative reaction rates by a differential thermal analysis method. Cerceo[299] has used an evaporation-rate method to determine the degree of "cure" of polymeric materials. Dorko and co-workers have developed a differential scanning calorimetric method for studying the kinetics of solid state reactions.[300] The application of scanning calorimetry to thermal kinetic studies has been reported by Rogers and Smith.[301] Thermogravimetric studies of decomposition reaction rates have been reported by Savin[302] and reviewed by Sestak[303] and by Skvara and Satava.[304]

Hammer and Craig[305] have studied the kinetics of the β-chloroamine reaction and Joris, Aspila and Chakrabarti[306] have reported the results of the decomposition reactions of monoalkyldithiocarbamates. Sand and Huber have developed a differential constant-current potentiometric method for application to kinetic-based analysis.[307] Frankel[308] has devised a nuclear magnetic resonance technique for following the rates of ion-exchange reactions.

Froede and co-workers[309] have reported the development of a rapid-sampling system for use in studying intermediate-speed reactions. A rapid method for the determination of first-order reaction rate constants has been described by Viale[310] and Roy and Al-Jallo[311] have reported a spectrophotometric study of the kinetics of saponification reactions of alkyl ester compounds. Patton and Langer[312] have reported an interesting reaction kinetic method for the detection of void zones in gas chromatographic columns. Rodriguez and Pardue[230] have made an extensive study of the iodine-catalysed reaction between Ce^{4+} and As^{3+} in sulphuric acid. Other studies of the kinetics of catalysed reactions of potential analytical interest have also been reported. The catalytic effect of Cu^{2+} and Fe^{3+} ions on the reaction of Pu^{3+} with chlorine in chloride solutions has been reported by Mazumdar *et al.*[313]

Habig, Pardue and Worthington[314] have found that the catalysis of the reaction between Ce^{4+} and As^{3+} by Os^{7+} is first-order with respect to Os^{7+} over a wide concentration range. With another osmium-catalysed system, Domka and Marciniec[315] have shown that OsO_4 catalyses the decomposition of hydrogen peroxide and the oxidation of Indigo Carmine with peroxide. Yoshiro and co-workers[316] have reported on the Cu^{+}-catalysed oxidation of Mo^{5+} solutions. The activity of Ag^{+} as a catalyst in the oxidation of Tl^{+} by Ce^{4+} has been studied by Zeltmann.[317] Bhat and Khan[318] have studied the catalytic effects of F^{-} and Cl^{-} on the oxidation reactions of various metal ions.

In other kinetic studies of analytical interest, Burkhart and Newton[319] studied the redox kinetics of V^{2+} and Np^{4+} reactions, Flechon and Chavane[320] studied the reduction of silver salts by EDTA, and Matyakha and co-workers[321] have reported kinetic studies of reduction of Ce^{4+} oxalate complexes by hydrogen peroxide. In other redox reaction studies, Krishna and Singh[322] have reported results on the oxidation of I^{-} by ferricyanide in acid media, Davies and co-workers[323] have reported on the Mn^{2+}–H_2O_2 reaction, and Goldberg and Obukhova[324] have studied Mn^{2+} reduction by caproic acid. Everett and Skoog have made a kinetic study of the As^{3+} and Ce^{4+} redox reaction.[325]

Tockstein and Tocksteinova[326] have developed a unique oxidation-reduction titration which they called a *kinetic titration*. They employed the measurement of the rate of change of potential with time, using a zero faradaic current condition as titrant is continuously added. They report that they were able to determine two substances with exactly the same formal potentials provided the reaction rate constants were different by about two orders of magnitude. Sinfelt has reviewed the applied applications of reaction kinetics and catalytic reactions.[327] Samandi and Jaky have studied the mechanism of the oxidation of various organic carboxylic acids with permanganate.[328] Masood, Shastri and Krishna[329] have studied the effects of the nature and concentration of electrolytes on the kinetics of the alkaline fading of phenolphthalein. Smith[330] has recently published a second edition of the book, *Chemical Engineering Kinetics*, which contains extensive information on applied uses of reaction kinetics and other information of potential analytical interest.

Zusammenfassung—Es wird eine Übersicht über Prinzipien und Anwendung katalytischer und kinetischer Analysenmethoden gegeben.

Résumé—On présente une revue des principes et applications des méthodes d'analyse par catalyse et vitesse de réaction.

TALANTA REVIEW*

REACTION RATE METHODS IN ANALYSIS

HARRY B. MARK, JR.
Department of Chemistry, University of Cincinnati, Cincinnati, Ohio 45221, U.S.A.

(*Received* 22 *June* 1971. *Accepted* 30 *October* 1971)

Summary—A review is given of the principles and application of catalytic and reaction rate methods of analysis.

AS INSTRUMENTATION technology, measurement techniques, electronic circuitry, and analytical procedures have advanced in recent years to a very high degree of development, the accuracy and precision necessary to make dynamic reaction systems applicable to both routine and special analytical problems have become available. Thus, there has been considerable research by a fairly large number of analytical chemists on the development of instrumentation, methods, and applications of kinetic (dynamic) based analyses for both new and old analytical problems. In fact, some analytical chemists, the author included, have been heard to say that these advances in instrumentation and electronic circuitry have "opened up a completely *new* area of research in analytical chemistry." Such a statement is not really accurate, of course, as kinetic based methods of analysis have been used for many years by clinical chemists for enzyme assay and other biological and medical tests. It would be more correct to say that analytical chemists have recently realized the tremendous potential in the application of kinetic methods and are now opening up new areas and applications for these methods. Also they are actively engaged in improving the sensitivity as well as the accuracy and precision of such methods. This realization of the potential of kinetics in analysis came about when it was recognized that kinetic based procedures have several inherent properties which can be used advantageously in analysis.

First, analytical chemists have long realized that in a real analytical problem, the species to be determined is rarely found unaccompanied by one or more substances that are closely related chemically and/or physically, and generally separation techniques must be used, which are often laborious and lead to considerable error in the analysis. There are also cases, such as the analysis of the ratio of different functional groups in the same polymer molecules, where non-destructive separation is impossible. Thus, it is clear that the analysis should (or must) be performed without prior separation.

Methods for *in situ* analysis of a mixture of species having similar properties can be classified as either thermodynamic (equilibrium) or kinetic (dynamic) depending on the method used to eliminate or reduce the interference of the other components of the mixture. A thermodynamic masking involves the alteration of the equilibrium conditions of the solution in such a way as to render all reactions, except the one(s) of analytical interest, thermodynamically unfavoured. The kinetic approach involves

---

* For reprints of this Review, see Publisher's announcement near the end of the issue.

utilizing differences in the reaction rates (or adjusting them if necessary) to isolate the reactions(s) of analytical interest. The thermodynamic differences in reactions of closely related compounds, such as homologues or isomers, with a common reagent are often much too small to be used for analysis of mixtures. However, the kinetic differences are usually quite large and permit either individual or simultaneous *in situ* analysis of the components of the mixture. This arises from the fact that the free energy of activation and hence the rate constant for any reaction is very dependent on the effect of structure of the reactants on formation of the activated complex, *etc.* Thus, reactions of closely related species which differ slightly in structure will often have essentially the same net change in free energy for the overall reaction but will reach equilibrium at widely varying rates. Also, changes in temperature, solvent characteristics, activity changes, *etc.*, have much larger effects on the relative rate constants of similar species than they do on the relative values of the equilibrium constants.

Secondly, a large number of inorganic and organic reactions can now be used in analysis. Many chemical reactions are not sufficiently uniform in behaviour to be used in equilibrium-based methods as they attain equilibrium slowly, have side-reactions, or are not sufficiently quantitative (the formation constants are too small) to be applicable. However, the same reactions can be used easily under initial reaction-rate conditions (explained below in the text). Also catalytic kinetic methods are considerably more sensitive than equilibrium methods, and kinetic-based enzymatic reactions are often extremely selective for a particular substrate.

On the other hand, kinetic techniques have one obvious and serious disadvantage. Any dynamic measurement includes time as an experimental variable, which is not the case in equilibrium measurement. It is probably this consideration that has made analytical chemists in the past somewhat afraid of using kinetics as an analytical tool. However, recent developments in instrumentation, especially in computer-based data analysis, signal-averaging and automation have overcome this fear of lower measurement accuracy.

As a result of this increase in interest, several books have been recently published on various aspects of the subject.[1–5] Mark, Rechnitz and Greinke[1] published a comprehensive text on kinetic analytical techniques and mechanistic studies related to analysis problems, Yatsimirskii[2] has given an extensive compilation and discussion of the application of catalytic reactions in trace analysis, and Guilbault,[3] Bergmeyer,[4] and Ruyssen and Vandenriesche[5] have written texts covering the area of enzymatic reactions in analysis. There have also been monograph chapters by Blaedel and Hicks,[6] Mark, Papa and Reilley,[7] Janata,[8] Pardue[9] and Crouch[10] on various aspects of kinetic analysis. The last two are especially significant as they deal with the principles and advances in instrumentation designed *specifically* for kinetic analysis, There have also been the extensive review articles by Rechnitz,[11–13] Guilbault,[14–17] Bergmeyer,[18] Devlin[19] and Roth[20] on various aspects of kinetic analysis in chemistry and clinical chemistry.

Because the early literature on reaction rate techniques applied to chemical analysis is very well reviewed in the publications cited, this review will generally cover only the literature contributions of the past 2–5 years, though particularly important earlier work will be cited.

The topics reviewed individually are recent advances in methods of kinetic analysis, new procedures and approaches to chemical analysis, and reports of kinetic studies of systems which are of specific interest and/or application to analysis. (The huge literature concerned with fundamental kinetic studies of reaction kinetics and mechanisms will not be reviewed.)

MATHEMATICAL BASIS OF KINETIC METHODS OF ANALYSES

A very large number of methods for the calculation of the initial concentration(s) of the species of interest from reaction rate data have been developed over the past few years. These methods involve, in general, simple mathematical manipulation and rearrangement of the usual differential or integral forms of the classical reaction rate equations. With few exceptions most have been reported within the past 5—10 years. They can be classified in two main categories: methods for a single species and methods for the simultaneous *in situ* analysis of mixtures. Within each category, the methods can be subdivided according to the kinetic order of the reactions: pseudo zero-order or initial rate methods, first-order and pseudo first-order methods, and second-order techniques. The principles, mathematical treatments, applicability and limitations of these methods have been discussed in some of the works already cited.[1,6,7,9,10] Recent papers are reviewed below.

Methods for determination of a single species

Pseudo zero-order methods. This approach is the most commonly used in routine and special applications, partly owing to the simplicity of the calculations and the fact that essentially all catalytic methods, both chemical and enzymatic, use pseudo zero-order conditions during the rate measurement. The principle of the initial-rate methods is simple as they are based on taking measurements only during the initial 1–3% or so of total reaction. Under these conditions the amount of reactant consumed and product formed is negligible (*i.e.*, the concentration of the reactants does not change appreciably during the period of the rate measurement) and hence the rate curve is essentially linear, its slope being proportional to the concentration of the reactant being determined.[1,6,7,9,10] There are other advantages besides simplicity of calculation. First , the reverse reaction can be ignored, and secondly, complications such as side-reactions are minimal. Three initial-rate methods are described in the literature. The direct approach is the derivative slope method where the rate of the reaction is measured by electronic derivative circuitry.[9,10,21,22] Margerum and co-workers[23–25] have described a stopped-flow derivative method for determination of a single species. This technique uses repetitive slope measurement during each run, and signal-averaging by a built-in computer to improve the analytical results. In the second approach, essentially a two-point method called the fixed-time method,[1,6,7,9,10] the change in concentration of product (output signal) is measured over a fixed time-interval, giving ($\Delta C/\Delta t$) which is, of course, the slope of the rate curve. The third approach is also a two-point method, the variable-time method.[1,6,7,9,10] In this method the time interval, Δt, required for the output signal to vary between two fixed values (ΔC) is measured. These three initial reaction rate methods have been used for both catalysed and uncatalysed reactions.[1,6,9] The concentrations of the catalyst (including enzymes) as well as of catalyst activators and inhibitors have been determined.[1,3,9,17]

First-order and pseudo first-order methods. Crouch has discussed the principles and parameters of importance for a non-linear response variable-time procedure for first-order and pseudo first-order reactions.[10] Mark, Rechnitz and Greinke[1] have also discussed the criteria for neglecting the contributions of either faster or slower-reacting components in the kinetic determination of a single species in a mixture. Janata and Mark[25a] have suggested analogue simulation techniques for the analysis of such rate curves.

Second-order methods. Very little work has been reported on the analytical applications of second-order conditions for determination of a single species. Weichselbaum *et al.*[21] have described derivative methods in which the maximum rate observed during an autocatalysed reaction run under second-order conditions was applicable for the determination of ammonia and blood-urea nitrogen. Janata and Mark[25a] have also discussed analogue simulation of second-order rate curves for determination of initial concentrations.

Methods for the simultaneous in situ *analysis of mixtures*

The development of methods for the *in situ* simultaneous determination of closely related components of mixtures has received considerable attention. As discussed in the instrumentation section, the tremendous advances in the accuracy and precision of rate measurements makes these methods practical.

Pseudo zero-order methods. Mark has reported an initial reaction rate method for the simultaneous assay of two alcohols, using enzyme-catalysed reactions.[26] Guilbault and co-workers[17,27,28] have reported a very effective method for the *in situ* analysis of multicomponent mixtures of a large variety of different and closely related substrates by taking advantage of enzyme catalysis selectivity.

First-order and pseudo first-order methods. Though each of the methods developed for reactions of this type is applicable to true first-order reactions, all the applications reported, with the exception of radionuclide decay reactions, are to second-order reactions run under pseudo first-order conditions (where either the reactants or the reagents are in very large excess and, hence, do not change appreciably in concentration during the course of the reaction).[1] A graphical method (called the logarithmic extrapolation method) based on the extrapolation of a typical first-order log response *vs.* time plot of the total rate curve has been described for binary mixtures where the reagent is in large excess with respect to the total concentration of the unknown in the mixture.[1] Lee and Kolthoff have described a mathematical single-point method based on a single measurement made at a fixed time during the reaction, for the same pseudo first-order conditions.[29] Garmon and Reilley have described a very simple and successful method of proportional equations based on the principle of constant fractional life.[1,7,30] This method is applicable to both simple and complex first-order reaction sequences. Margerum and co-workers[23–25,31] have described a continuous measurement approach to the method of proportional equations which is more accurate than the finite point approach of Garmon and Reilley[1,30] and have extended the method successfully to three-component mixtures. Roberts and Regan[32] have devised a mathematical single-point rate measurement procedure and Greinke and Mark[33] have devised a method of proportional equations for the reaction condition which is pseudo first-order with respect to the reagent concentration ($[\text{reagent}] \ll [\text{mixture}]$).

Second-order methods. Siggia and Hanna[34] have devised a second-order graphical (logarithmic) extrapolation procedure for the complete analysis of binary mixtures, the reagent and reactant concentrations being of the same order of magnitude. Reilley and Papa developed a second-order linear extrapolation method for the special case where [mixture] = [reagent].[35] For both of these second-order systems Reilley and Papa[35] and Papa, Mark and Reilley[36] have developed mathematical single-point and double-point methods which eliminate the need for a graphical plot. Lee and Kolthoff[29] have developed a different mathematical single-point method for the special case [mixture] = [reagent]. Schmalz and Geiseler[37–40] have reported a graphical differential method and graphical integral method for second-order reactions. They have presented several different modifications of each method.

Applicability and limitations of the various methods for the analysis of mixtures. As can be seen above, many different methods have been reported in recent years. These methods not only employ different reaction order conditions, but also use different mathematical and/or graphical methods of data manipulation and display and some make certain experimental and mathematical assumptions. The choice of the best method and conditions for a specific problem is not intuitively obvious,[1] and considerable work on this problem has recently been reported. Ingle and Crouch have examined the relative merits and limitations of the fixed-time and variable-time methods of data treatment for catalytic and pseudo first-order reaction procedures.[41] They have shown that the fixed-time method is preferable for first- or pseudo first-order reactions and substrate determinations in catalytic reactions. However, their error analysis shows that the variable-time approach is best for enzyme and catalyst determinations and also for non-linear response-rate curves. Reilley and Papa[35] and Papa, Mark and Reilley[36] have discussed the optimum conditions for the second-order linear and graphical extrapolation methods. Mark, Greinke and co-workers[1,36,42,43] have developed a very detailed error analysis for all the first-order and pseudo first-order methods discussed above. They have shown that for binary mixtures the choice of the best method for a particular mixture and of the optimum analysis conditions and experimental parameters of the chosen method was strongly dependent on the ratio of the rate constants as well as on the ratio of the initial concentrations of the species of interest in the mixture. They also gave a set of rules of thumb[1,42] for use as rapid guide lines for the choice of method and optimum conditions. There have also been a few experimental comparisons of the results obtained by using some of the pseudo first-order methods,[1,44–46] which are in general agreement with the theoretical predictions of the error analysis treatments. Siggia and Hanna[47] and Greinke and Mark[48] have also discussed the relative influence of synergistic effects on the accuracy of the various first-order and pseudo first-order methods. Such effects can often be ignored in graphical extrapolation methods, but can lead to huge errors in any of the non-graphical methods. Greinke and Mark[48] point out that when a non-graphical method is used it is absolutely necessary to have a very complete understanding of all the chemistry of the reactions employed.

Recently there has been a very important series of papers by Margerum and co-workers on the parameters affecting the accuracy of the simultaneous analysis of mixtures by pseudo first-order reaction methods.[23–25,31] Their conclusions are that their approach to the problem is the superior method in several examples of the use of reaction rate methods for analysis. In the early development of differential reaction rate methods for the simultaneous *in situ* analysis of mixtures of closely related substances, the chemical reactions used were not suitable for continuous automatic measurement of the entire rate response curves,[1,7] and calculations were generally done by hand. Hence, the emphasis at that time in the development of the reaction rate methods was on minimizing the number of experimental points taken and on predetermining the optimum times, *etc.*, for taking the readings.[1,7] However, in recent years the advances in electronic circuitry and computer technology have had a tremendous influence on the design of instrumentation for kinetic analysis. These instrumental advances have also had a strong influence on the principles and approaches to differential rate methods. Margerum and co-workers[23–25,31] (and also Weichselbaum and co-workers[21,49]) have shown conclusively that the use of built-in computation systems allows continuous analysis of the entire reaction rate curve. The results are thus immediately processed with both ensemble averaging and smoothing routines. Experimental results and detailed error analysis have shown that this approach to data acquisition, reduction and display leads to a much greater accuracy and precision of the analytical results.[23–25,31] In fact, good results can be obtained for fast reaction differential rate analyses where the usual finite or minimal data point methods fail completely.[23,31] Obviously, this approach will be that used in most future developments in kinetic-based methods of analysis.

INSTRUMENTATION

As mentioned above, the major reason for the considerable increase in practical applications of kinetic-based methods is the tremendous advance that has been made in quantitative chemical instrumentation and electronics in the past few years, especially the efforts of instrument manufacturers and certain research groups to design instruments which apply these technological advances to meet the special features and demands of kinetic measurements on dynamic systems. Perhaps the most important of these advances is a consequence of the fantastic developments in both analogue and digital computer technology, as a result of which low-cost linear and digital integrated circuits have been made readily available to people interested in designing chemical instrumentation for ultrasensitive measurement. To quote a statement in a recent publication by Crouch,[10] the availability of integrated circuits "is revolutionizing instrumentation in science."

The instrumental advances can be classified in three separate but overlapping categories. First there are the improvements in the accuracy and precision of the reaction monitoring system electronics such as the excitation and transducer response circuits which create and measure the signal which is proportional to some time-dependent parameter in the chemical reaction (*e.g.*, improved stabilization of spectrophotometer light sources and increases in the sensitivity of photoelectric transducer circuitry). Secondly, the availability of low-cost computing elements has made it possible to build into the instruments either limited or elaborate self-contained computing capability. The extent and elaboration of the computation capability is, of course, reflected in the price of the instrument. These built-in computers can vary from a simple device to convert an initial-rate slope into a digital display of the concentration of the species to be determined, to a full-scale computing device which not only handles data reduction but also controls the operation and timing of the sequencial operations in the experiment. In the extreme case, the computing device operates in a feed-back mode and can sample and analyse results during the course of an experiment and then alter the experimental control parameters in such a way as to optimize the sensitivity and/or selectivity of the determination. The third area of advance is in automation design. This includes advances in the mechanical design and accuracy of sampling units, reagent addition and mixing procedures, *etc*, as well as the application of computing devices to start, control and time the automated procedures and devices (which illustrates the overlap of the three categories).

In the area of new developments in instrumentation of kinetic methods of analysis, there have been two excellent monograph chapters published recently which discuss the basic principles and applications of analogue–digital circuitry employed in considerable detail data reduction and automation design.[9,10] The chapter by Crouch[10] is especially comprehensive and clear in its discussion of computer-based kinetic method instrumentation.

Reaction monitoring

System electronic circuitry. The first problem in improving the accuracy and precision of kinetic-based analytical results is improving the quantitative nature of the total reaction monitoring system (spectrophotometric, potentiostatic, conductometric, *etc.*) and modifying it specifically for time-dependent measurements in following reaction rates. It is convenient to discuss the advances according to the type of measurement system.

Spectrophotometric systems. One of the major problems in adapting spectrophotometric instrumentation to kinetic measurement is that of light-source variation. This problem is inherent in any spectrophotometric system and even though this technique is relatively simple and generally applicable, it has caused kineticists in the past to shy away from spectrophotometric systems for accurate measurement, because such light-fluctuations are often of the same or similar time period as the reaction being followed.[21,49] Most commercial spectrophotometers which are designed for time-independent spectral measurements minimize such light-source variations by the use of double-beam optical systems which partially cancel fluctuations by periodic comparison of reference and sample beam intensities. Such double-beam systems have not generally been considered suitable for spectrophotometric instruments specifically designed for reaction rate measurement. Such systems seriously limit the response-time of the instrument, tend to introduce significant noise, and also add to the cost and complexity of the instrument,[10,21,49] so most designs for kinetics instrumentation employ a single-beam (non-wavelength-scanning) system and concentrate on lamp stabilization.

Weichselbaum and co-workers[21,49] have described a simple stabilization system which regulates the lamp voltage. This circuit compensates for variations in the lamp filament resistance and is thus more efficient than the more common techniques which regulate only the applied voltage or the applied current. Further stabilization is achieved by having a thermal convection baffle in the lamp housing. This source system was reported to give a drift of less than 0·003 absorbance units per hour.

As the stabilization method of Weichselbaum *et al.*[21,49] controls the lamp electrical input and does not directly control the actual lamp output intensity, an uncertainty is introduced into the measurement. Loach and Loyd,[50] and Pardue and co-workers[51,52] have reported several different circuits which use an optical feed-back system for lamp stabilization. The lamp output beam is split and one beam is monitored by means of a photomultiplier tube, the signal from which is fed back to the lamp power supply as an error signal which modifies the power supply voltage to maintain a constant intensity output. Fluctuation of less than 0·03% transmission per hour has been attained.[50]

The elimination of detector noise and drift is also a critical problem in the application of a spectrophotometric system to kinetic analysis, especially if the derivative of the rate curve is being determined by a built-in computation module or unit[21,49] as discussed in a later section. Weichselbaum and co-workers[21,49] discussed the relative signal-to-noise ratios for photodiode tubes and photomultiplier tubes in some detail. They found that when both types of phototransducer are operated at the same anode current, the photodiode tube has a higher signal-to-noise ratio than the photomultiplier. They concluded that the photodiode tube was thus more applicable in non-wavelength-scanning spectrometers designed for kinetic measurement, where light source intensity is not a limiting factor. Crouch and co-workers[10,53] have pointed out correctly that this evaluation of comparative applicability from signal-to-noise ratios at constant anode current is not valid for all spectrophotometric uses. They demonstrated that for systems where the light level is low and/or cannot be controlled, a photomultiplier gives better results. Weichselbaum and co-workers[21,49] have also reported that vacuum phototubes have more favourable signal-to-noise ratios than similar gas-filled tubes. A recent paper by Franklin, Horlick and Malmstadt[54] discusses the optimum criteria for stability of the power supply to the detector.

Recently, fluorimetric methods for kinetic analysis of a variety of materials, mainly of a biological nature, have also been developed.[10,55,56] This technique, although less general in application, has inherent advantages over normal absorbance spectrophotometry in that it is considerably more sensitive for certain high-efficiency fluorescent systems, and in dilute solution the fluorescence intensity is directly proportional to chemical concentration, which reduces signal processing (linearization) significantly. Though so far no papers have been published specifically describing special electronic circuit design and modification of standard fluorimeters for kinetic measurement, it can be stated that similar criteria and/or requirements for detector noise and drift and excitation light-source reproducibility are the same as discussed above for spectrophotometric measurements.

Electrometric systems. Because of the simplicity and ease of making highly accurate current or voltage measurements (made possible by analogue operational amplifier circuitry[57]) considerable work has recently been done on adaptation of potentiometric, constant-current coulometric, and amperometric monitoring of reaction rates for analytical determinations. Some of the early work on potentiometric measurement used a concentration cell technique.[58] Rechnitz and co-workers[59–64] have described the applications of various ion-selective electrodes in potentiometric measurement of reaction rates and kinetic analysis. They have also reported the application of a fast-response, high input-impedance, differential amplifier circuit for kinetic measurement, using two different ion-selective electrodes as the potentiometric cell.[59] Janata and Mark have suggested the application of constant-current coulometric techniques for simultaneous differential reaction rate analysis.[25a] Pardue has described the application of a polarized rotating platinum electrode system using amperometric detection for kinetic-based determinations.[65]

Conductometric instrumentation based on operational amplifier circuitry has also been described for use in kinetic methods of analysis.[66–69] Recently a bipolar-pulse modification of conductometric measurement has been described by Johnson and Enke.[70] This technique seems to be very promising for rate measurement because of its great sensitivity to small changes in conductance.

Reaction temperature control apparatus. As essentially all chemical reaction rates are very strongly dependent on temperature, considerable effort has been made to design simple but highly reliable thermostatic reaction cells and convenient but accurate temperature control systems (generally water-baths). A very comprehensive discussion of the design and construction of temperature control systems has been given by Van Swaay.[71,72]

Pardue and Rodriguez[51] designed a spectrophotometer cell which was sealed into a Lucite outer jacket which allowed water from a thermostatic bath to be in direct contact with the spectrophotometer cell walls. This permitted rapid temperature equilibration of the reactant solutions mixed by stirring in the cell. Weichselbaum and co-workers[21,49] described a spectrophotometer cell which had a separate mixing chamber above the cell itself. Both compartments were thermostatically controlled and the mixing chamber was fitted with an effective magnetic induction stirrer. Very rapid temperature equilibration on mixing of reagents was reported. Feil *et al.*[73] have reported a rapid temperature equilibration cell specifically designed for use with the Beckman DU spectrophotometer. Excellent temperature regulation (±0·005° at 25°) was attained.

Weichselbaum, Smith and Mark[74] described a proportional dual thermistor bridge temperature-control system using analogue–digital control circuitry. With use of the jacketed cell described above,[21,49] better than ±0·01° regulation in the cell was attained at various temperatures. The system was designed so that four different controlled temperatures (15°, 25°, 30°, and 37°) could be attained automatically in a few minutes by simply pushing a selector switch.

Data reduction and display systems

In the application of kinetic methods to routine analysis the detector signal response being used to follow the course of the chemical reaction must be converted into some convenient form, ideally directly into the concentration of the species being determined. Consequently a large volume of research on this has been reported. Systems described vary from the very simple to virtually a built-in digital computer unit.

Computation systems for initial reaction rate methods. Most practical reaction rate based procedures (enzymatic and other clinical assay methods in particular) measure only the initial 1–3% of the overall reaction rate curve, primarily because the mechanism and hence the kinetics are well-behaved in the early stages and the initial rate is essentially constant (pseudo zero-order) with time over this period and is directly proportional to the concentration of the species to be determined. (Detailed discussions of the theory and principles of initial reaction rate methods can be found in references 1, 6 and 9.)

The simplest initial reaction rate calculation involves the measurement of the extent of the reaction at a fixed time after initiation of the reaction.[1,6,9] This value is effectively equal to the slope of the linear initial rate curve. It is a popular method because it is conveniently used with flowing streams. Cordos, Crouch and Malmstadt described one of the first computation circuits for the fixed-time method.[75] It consisted of an analogue integration and subtraction network controlled with respect to timing and sequence by a digital logic circuit. This approach yields a very favourable signal-to-noise ratio in the output. Hicks and co-workers[76–78] have also described a similar analogue integration technique but developed a hardware interface system to free their time-shared computer system for control of other automation operations. A completely digital computation system for the fixed-time method has been proposed by Ingle and Crouch[79] which is similar to the analogue operations but employs digital integration. Ingle and Crouch[79] state that the digital method of computation has advantages over the analogue method because there are no drifts and circuit non-linearities, no mechanical and/or analogue switches are necessary, and shorter integration times (faster rates measured) can be employed.

Another commonly used initial reaction rate method is the variable-time (or fixed-concentration) technique[1,6,9,10] in which the time required for the reaction to proceed to a preselected fraction of completion (again, less than 3%) is the measured parameter, which is inversely proportional to the initial reaction rate and concentration of the species being determined. The computation is somewhat more complex than in the fixed-time method. The first completely automated variable-time computation system was based on analogue logic and was developed by Pardue and co-workers.[80,81] Stehl, Margerum and Latterell[82] designed a similar but improved analogue system which eliminated all but one mechanical switch from the circuit. James and Pardue recently reported an analogue variable-time system utilizing tunnel diodes and electronic silicon-controlled diode switches which totally eliminated mechanical switches.[83] This circuit significantly reduced the measurement time intervals that could be determined. Crouch[84] reported the circuit design of a hybrid analogue-digital computation circuit for variable-time systems which eliminated the temperature-sensitive logarithmic analogue operations of the James and Pardue circuit.[83] As analogue systems tend to have significant drift, especially in the integration operation, Pardue, Parker and Willis[85] designed a completely digital computation unit for the variable-time approach. This unit virtually eliminated drift as a source of error in the computation operation and also included a system for noise-averaging, which had not been done in any previous variable-time system.

Some designers have felt that it is more accurate and less susceptible to random error to make a continuous measurement of the total initial-rate curve.[21,23–25,49] As the slope of the initial-rate curve is the parameter that is directly proportional to the concentration of the species of interest, these groups have used analogue (continuous) derivative operations on the initial-rate curves. Weichselbaum and co-workers[21,49] designed a spectrophotometer unit which employed a direct analogue differentiation circuit with filter capacitors to reduce the noise enhancement inherent in direct differentiation of a signal. They also avoided the limited accuracy of analogue logarithmic circuits by using the rate of change of transmittance and the instantaneous value of the transmittance to obtain the derivative of the absorbance (A) with respect to time $[\mathrm{d}(-\log T)/\mathrm{d}t = (-\log e)[(1/T)(\mathrm{d}T/\mathrm{d}t] = \mathrm{d}A/\mathrm{d}t]$. Pardue *et al.* have developed several different systems for the derivative computation technique.[86–88] Instead of direct analogue differentiation, they employed an indirect method for obtaining the slope of the rate curve. Both a servo system[86,87] and an operational amplifier system[88] were used to compare the slope of the initial rate curve with a ramp generated by an operational amplifier integrator. Recently Malmstadt and Crouch[89] critically discussed circuits using manual, mechanical-servo and operational-amplifier slope-matching systems for derivative measurement. In most of these computation units recorders were used to present the response read-out, usually as concentrations. However, Weichselbaum and co-workers[21,49] and Crouch and Malmstadt[90] have shown that the use of digital read-out systems considerably improves the accuracy and precision of rate determinations. Crouch has also discussed the relative merits of direct differentiation and the fixed-time and variable-time methods.[10]

Computation by analogue simulation. Mark, Papa and Reilley[7] and Janata and Mark[25a] have suggested the uses of an analogue simulation approach to the determination of the initial concentration of a reactant. In this approach, the entire reaction rate response curve is simulated with an analogue computer. The initial input voltages to the computer are the electrical analogue of the initial concentrations in the chemical reaction. When the simulated curve exactly matches the experimental reaction rate response curve, the initial unknown concentrations are evaluated from the analogue voltages which yielded the match of the curves. It should be pointed out here that the success of this simulation method rests on an exact knowledge of the reaction mechanisms and rate constants of the reaction being followed.

Computation circuits for simultaneous analysis of mixtures. In recent years considerable research in kinetic methods has been devoted to the simultaneous *in situ* analysis of mixtures.[1,7] As the data reduction of the rate response curves in these differential rate methods is quite complex, built-in computer systems are necessary in order to make these methods practical for routine analytical procedures. Pinkel and Mark,[91] Toren and Davis,[92] and Toren and Gnuse,[93] have reported automatic analogue computer circuits for the solution of the simultaneous equations of the method of proportional equations.[1] Mark, Papa and Reilley,[7] and Janata and Mark[25a] have suggested analogue simulation for solving for initial concentrations in differential rate methods.

Automatic sample handling systems. In spite of the fact that automation of the entire sample handling procedure is an obvious means of eliminating much of the experimental error in sampling, reagent addition, mixing, and timing, and has received considerable attention by the manufacturers of clinical rate-based instrumentation, very little research in this area has been published directly related to kinetic methods of analysis. The most popular automated sampling and mixing systems are based on continuous flow. Various applications and the principles of continuous flow techniques have been discussed in great detail by Blaedel and Hicks,[6] Pardue,[9] Schwartz and Bodansky,[94] in Technicon Instrument Company literature[95] and in the recent reviews by Rechnitz.[14,15] The most recent research publications on automated techniques have generally utilized discrete discontinuous sampling systems, however.[10] Automated injection and refill pipets have been designed by Malmstadt and co-workers.[96,97] Javier, Crouch and Malmstadt have published the design of a completely automated stopped-flow instrument for kinetic analysis,[98] and Deming and Pardue have recently published the design of a computer-controlled electromechanical system for automated reagent addition.[99] Mueller and Burke[100] have reported a real-time computer control system for a reagent-addition unit which would be applicable to kinetic based measurement instrumentation. Fasce and Rej[101] have recently reported an automatic enzyme assay system. Further automated systems which are incorporated in *totally* computer-controlled kinetic analysis instrumentation are also mentioned in the following section. As indicated above, the advertisements and operation manuals of the clinical instrument companies are an excellent source of information on recent advances in automation techniques and hardware. The reader is recommended to contact the sales representatives of the following instrument companies in this regard: Analytical Instrument Division of American Optical Corporation, Richmond, California; Bausch and Lomb Corporation Analytical Systems Division, Rochester, New York; Technicon Company, Incorporated, Tarrytown, New York; Beckman Instrument Corporation, Fullerton, California, and Sherwood Medical Industries, Incorporated, St. Louis, Missouri. A radically new and very effective automated system (ACA) for clinical screening tests has been developed by the Instrument Products Division, E. I. DuPont Company, Wilmington, Delaware. This system employs a separate plastic pack in which each individual test, including the spectrophotometric measurement, is carried out. A computer built into the instrument controls the entire operation.

Sorokin, Gromov, and Chernyskii[102] have described an automated thermochemical apparatus for studying kinetic processes.

Applications of on-line computer systems to kinetic methods of analysis

As the expense of high-speed small digital computer systems goes down, the applications of these small computers as built-in (on-line) units in chemical instrumentation for data reduction, system control, data acquisition, and experimental optimization and design in "real time" have increased sharply. As discussed in an earlier section, the computer was originally used in kinetic methods for on-line fast data acquisition and data reduction to give final display as the concentration of the species in the sample being analysed. The computer was also used in some control applications. However, such limited applications do not efficiently use the full capabilities of the small on-line computer. Recently several research groups have been investigating and developing the small on-line computer for *total* control and operation of the instrumentation in kinetic methods of analysis. Systems have been described in which the computer not only handles the data acquisition and sample-manipulation, but actively takes part in all parts of the experiment by immediate examination of the data in real time and then makes various decisions which optimize the experimental parameters and variables during the actual experiment.[10] It is felt that this is the most important single improvement in kinetic-based analysis, which will greatly expand the routine and specialized applications of the technique.

James and Pardue[103] described an on-line computer system which utilized software to provide the calculations for either fixed-time or variable-time measurements. The signal–time profile is stored in the memory of the computer and the time scale is optimized on the basis of a preliminary rate measurement. This preliminary rate measurement is also used to optimize the time constant of the digital filter system. The basic block diagram of the programme for this system is shown in Fig. 1.

Hicks and co-workers[76–78] used a hybrid analogue-digital approach to on-line computer control. They employed a hardware interface to compute the reaction rate outside the computer, as discussed in an earlier part of this section. The computer was free to monitor and control the electromechanical equipment for the sampling,

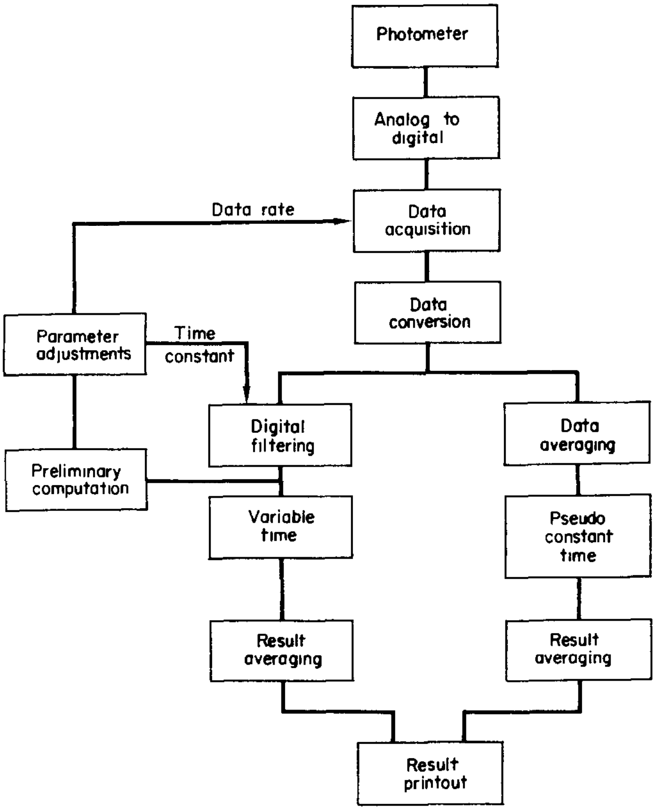

FIG. 1.—Flow diagram of a computer programme for an on-line computerized reaction-rate instrument.[103] Reprinted by permission of the American Chemical Society.

reagent addition, *etc*, for automatic scale selection, calibration, for timing and sequence application, and for output display. A block diagram of this computer system is shown in Fig. 2. Eggert, Hicks and Davis[78] have also discussed use of this hybrid system in experimental control operations.

Recently Willis *et al.*[25] have described the design and characteristics of an on-line computer-controlled stopped-flow system for kinetic analysis. The main feature of this system is its ability to carry out repetitive runs on the same sample and/or do multiple slope measurements on a single reaction for signal-averaging purposes. Such ensemble-averaging results in a very high precision. The programme also provides for display of a variety of kinetic and concentration parameters. Janata and Mark have[104] recently published an extensive discussion of the applications of analogue computer simulation to a wide variety of kinetic, mechanistic and analytical problems.

An excellent discussion of the principles, objectives and general design philosophy of computer-controlled instrumentation for study and characterization of chemical reactions has recently been published by Deming and Pardue.[99] This paper is certainly very important for any researcher interested in computer-based instrument design as it points out clearly the objectives in future design of kinetic analysis instrumentation. In this instrument, routine procedures as well as the decision-making procedures in

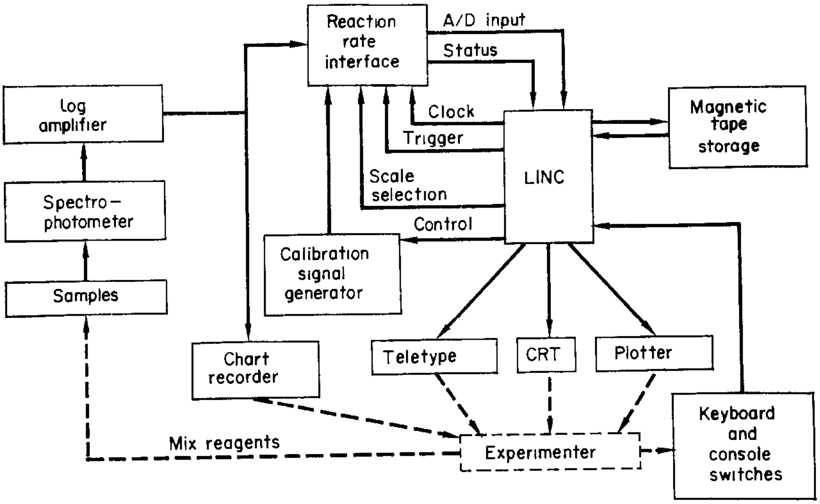

FIG. 2.—Block diagram of a hybrid (interactive) computer system for kinetic analysis.[76] Reprinted by permission of the American Chemical Society.

data interpretation and experimental design have been automated. In this paper, Deming and Pardue presented two very picturesque block diagrams which point out very dramatically the differences in fundamental operational concepts between the procedures conventionally used for the instrumental characterization of a chemical reaction and what these authors conceive as the general future trend of automated reaction characterization.[99] These diagrams are reproduced here as Fig. 3 and 4. This paper also gives the details of the design of such an automated and computerized instrument and the results of test applications are very impressive. There is another

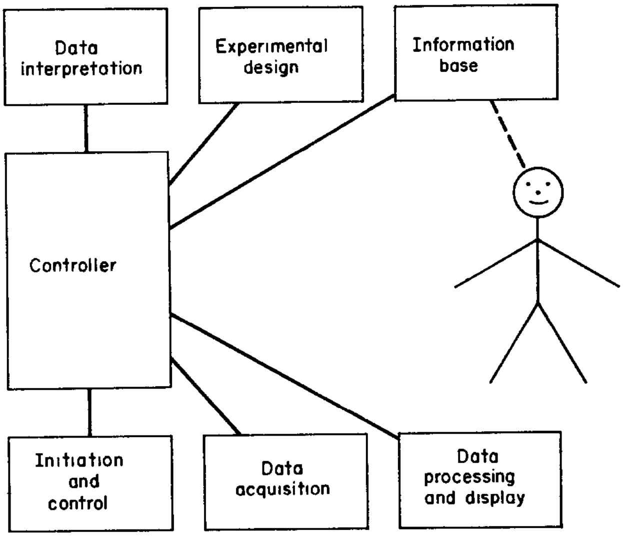

FIG. 4.—Procedures proposed for on-line computerized automated characterization of a chemical reaction.[99] Reprinted by permission of the American Chemical Society.

recent paper on the design and operation of a totally automated chemical instrument system that should be mentioned here, although it does not involve kinetic analysis methods. Perone, Jones and Gutknecht[105] have reported an electroanalytical system which also uses an on-line computer to analyse and interpret the results obtained during a repetitive electrochemical experiment and then control the various experimental parameters of the experiment to optimize the sensitivity and resolution of the response and the analytical results. Perone[106] has also recently published a detailed monograph chapter on the subject of real-time computer applications and optimization of experiments.

BIOLOGICAL AND CLINICAL APPLICATIONS (ENZYME METHODS)

Certainly the greatest amount of both use and research in the field of kinetic-based methods of analysis is in the general area of clinical analysis and other biological applications. Most of this work is oriented towards enzyme assay and the use of enzymes as specific reagents for a variety of different types or classes of reactants, such as the substrate in the enzyme-catalysed conversion reaction, inhibitors, activators, *etc.* As the enzyme is a biological catalyst which acts to lower the activation barrier and hence accelerate the rate of certain specific reactions, without being consumed in the overall conversion reaction and generally without changing the net free energy difference (equilibrium constant) between reactants and products, it is not only logical, but also for the most part necessary, to employ kinetic methods in the complex systems of chemical and biological analysis. As mentioned in the introduction, these types of analysis are of great importance in medical diagnosis and hence so is fundamental research on these analytical techniques, to broaden the scope of application and improve the speed, accuracy and precision of the methods.

Guilbault has recently written a very comprehensive and well-documented book on enzyme methods of analysis.[3] He has also written extensive reviews of recent publications in this field.[14–17] Other recent books by Purdy,[107] Udenfriend,[108] and

Ruyssen and Vandenriesche[109] have extensive discussions of kinetic-based clinical techniques, procedures, and methods. Also, there have been several monograph chapters on the various aspects of the subject by Blaedel and Hicks,[6] Guilbault,[110] Phillips and Elevitch[111] and Pardue.[9] There have also been other review articles by Bergmeyer,[18] Devlin,[19] Roth,[20] Danev[112] and Zuman.[113] It should also be pointed out that the literature of the various enzyme nanufacturers and supply houses as well as that of the various clinical instrumentation manufacturers is a wealth of information on methods and procedures of analysis. The literature will be reviewed here first according to the analytical species being determined and second according to the method used. As the literature is extensive, this review will attempt to cover only reports which represent significant improvements in procedures or inovations and new applications reported in the past few years.

Determination of enzymes

Since the enzyme is a biological catalyst and in most of the enzymatic catalysis reactions is not consumed, the rates of the reactions of the substrate (reactant) are strongly influenced by even small amounts of enzyme present. Thus the rates of enzyme-catalysed reactions are very sensitive to low enzyme concentration. A wide variety of experimental and instrumental procedures and techniques has been employed in enzyme assay.

Spectrophotometric and fluorimetric methods. The instrumental improvements in optical kinetic-based systems have already been discussed in the instrumentation section above. Much of this instrumentation was developed with enzymatic problems in mind.

Using fluorimetric rate-measurements, Guilbault *et al.* have studied the effects of various fluorogenic esters on the determination of cholinesterase.[114] They reported that *N*-methylindoxyl esters were the optimum substrates in terms of both sensitivity and reagent stability. Guilbault and Zimmerman[115] have also reported a technique for the determination of cholinesterase directly on a solid surface. Similarly, Guilbault and Heyn[116] tested several fluorogenic substrates for the determination of cellulase and suggest resorufin butyrate as the best substrate for a *rapid* initial-rate determination. Guilbault and co-workers[117] have developed a considerably more accurate and rapid analysis for hyaluronidase by taking advantage of the high fluorescence efficiency of indigo white. The optimum analytical conditions and fluorogenic substrates for a variety of lipase enzymes have been reported by Guilbault and Sadar[118] and Guilbault and Hieserman.[119] A comparative study of the use of umbelliferone as a fluorogenic substrate for acid and alkaline phosphatase with other commonly used substrates, showed that this substrate increased the sensitivity of the assay by 2–4 orders of magnitude.[120] The applicability of a variety of naphthol derivatives as substrates for the phosphatase enzymes has also been reported.[121–123] A systematic study of several new fluorometric substrates for sulphatase has been made and the fluorimetric method described appears to be superior to the usual colorimetric methods.[119] Fluorometric initial reaction rate methods for amino-acid oxidase,[124] peroxidase,[125] glucose oxidase,[125,126] xanthine oxidase[125] and galactose oxidase[126] have been reported. Guilbault and Kramer[127,128] have described a simple, rapid fluorometric method for the enzymes dehydrogenase, glucose-6-phosphate dehydrogenase, 1,α-glycerophosphate dehydrogenase and glycerol dehydrogenase. Also, an automated procedure for dehydrogenase has been reported which uses the reaction with the substrate resazurin to form the intensely fluorescent resorufin.[17]

A variety of spectrophotometric initial-rate methods for enzyme assay have also been described recently. Most of the methods cited below represent only minor modifications of the established procedures. However, the results reported have been used to show how the accuracy and precision of such determinations can be significantly improved by using modern instrument designs.[10] Weichselbaum and co-workers have reported a very reproducible method for the determination of lactic dehydrogenase.[21,74] These authors[21] and Pardue, Parker and Willis[85] also investigated kinetic methods for alkaline phosphatase. Pardue, Frings and Delaney[80] have reported results for the determination of glucose oxidase and galactose oxidase by a variable-time method. James and Pardue have also studied the analytical results for the determination of alkaline phosphatase by a variable-time procedure[129] and on-line computer system.[103] Toren *et al.*[77] have reported computer-based rate methods for acetic dehydrogenase and alkaline phosphatase.

Electroanalytical methods. The application of electroanalytical techniques to enzyme assay by rate-based methods was introduced less than ten years ago.[17,107] As these techniques are very simple and capable of a high degree of accuracy, electroanalytical methods are quite promising. One of the first methods described was a $\Delta E/\Delta t$ rate method introduced by Guilbault, Kramer and Cannon.[130] This technique has been employed in the determination of cholinesterase,[130] glucose oxidase,[131] xanthine oxidase[132] and peroxide catalase.[133] Potentiometric[58,134,135] and amperometric techniques[65,136,137] have been reported for glucose oxidase and for galactose oxidase.[138] Purdy[139] has reported amperometric and coulometric methods for urinase and urease. Katz[140] has also described a potentiometric method for the determination of urease, using a cation-sensitive electrode system as the detector. Guilbault, Smith and Montalvo[141] have also reported the use of an $NH_4{}^+$-selective glass electrode for the determination of deaminase. There have also been polarographic techniques reported for the determination of cholinesterase,[142,143] 3-hydroxyanthranilic oxidase[144] and catalase.[145] Curtin[146] has reported a potentiometric method using a silver–thiol electrode method for cholinesterase. Lipner and co-workers[147] have reported the use of an oxygen galvanic cell system for the analysis of a variety of oxygen-consuming enzymes, and Malmstadt and Piepmeier designed a pH-stat system for a variety of enzyme rate determinations.[148]

Determination of substrates

By far the greatest volume of recent research effort in enzymatic methods of analysis has been in the development of determinations of various substrates of enzyme-catalysed systems. A large variety of both organic and inorganic substrates has been studied. As Guilbault[3,14–16,19] and Bergmeyer[149] have presented extensive compilations of enzymatic methods for substrate analysis, only recent applications will be given here.

Spectrophotometric and fluorometric methods. Several enzymatic methods have recently been reported for the analysis of carbohydrate substrates. Spectrophotometric methods for glucose,[75,80,89] using modifications of the usual glucose oxidase catalysised technique, and galactose[80] by using galactose oxidase have been described by several research groups. Guilbault and co-workers have developed a very useful technique for the fluorimetric analysis of various sugar mixtures.[27,28] They reported the successful determination of lactose, maltose, fructose and glycogen mixtures by first reacting each sugar in separate aliquots with the specific enzyme which converts it into glucose, and using an initial-rate fluorimetric method which follows the formation of resorufin in a coupled reaction to determine the glucose produced. The analysis of several other carbohydrate mixtures, glucose and sorbitol mixtures, and methanol, sorbitol, and xylose mixtures have also been reported.[27,28] Guilbault, Sadar and McQueen[150] have used a similar procedure for the fluorimetric determination of a great variety of organic acids, both for single components of a mixture or for the simultaneous analyses of several acid components of a mixture.

Weichselbaum *et al.*[21] have reported a spectrophotometric maximum rate method for the determination of ammonia and blood urea nitrogen in biological systems. Faway and Dahl,[151] Mondzac, Ehrlich and Seegmiller,[152] Reichelt, Kuamme and Iveit,[153] and Kirsten, Gerz and Kirsten[154] have also described initial rate spectrophotometric methods for ammonia in various biological media. Roch-Ramel[155] and Rubin and Knott[156] have reported fluorimetric methods for the determination of ammonia.

Schulz, Passonneau and Lowry[157] have described a fluorometric method, and Faway, Roth and Faway[158] a spectrophotometric method for inorganic phosphate. Two unique rate methods employing the enzyme catalyst immobilized[17] in a solid matrix have been reported (considerable research is now being carried out on methods of immobilizing enzyme systems without loss of their catalytic activity.)[3,17,59] Hicks and Updike[160] have used lactate dehydrogenase immobilized in a gel for the assay of glucose and lactic acid. They have also coupled an immobilized glucose oxidase system with an electrochemical sensor for the determination of glucose in blood.[161]

Determination of activators

In many enzymatic catalysed reactions a substance called an activator is required before the enzyme itself becomes an active catalyst.[3,17] As the initial reaction rates of such enzymatic systems are proportional to the concentration of the activator (until all the catalyst is activated) rate measurement can be employed to determine the concentration of activator species in the same manner that is used for direct enzyme assay as discussed in another section of this review. Although this application has been shown to have considerable potential[3,6,17] and can under special conditions determine very small amounts [down to 10^{-15} mole (162)], very little research on the analytical applications has been published recently. Only the method for the determination of Mn^{2+} and Mg^{2+} which are activators for isocitric dehydrogenase reactions[6] and the determination of Ca^{2+} and Zn^{2+} activators for alkaline phosphatase[163] have been reported in the last few years.

Determination of inhibitors

There are many substances, called inhibitors, which cause a decrease in the rate of an enzyme-catalysed reaction.[3,6,17] In general, the decrease in the initial rate of an enzymatic reaction is directly proportional to the inhibitor concentration until total inhibition is reached (reaction rate reaches zero). Numerous examples have been reported recently of the determination of most common inorganic anions and cations. Guilbault has compiled a very complete list of the procedures for Ag^+, Al^{3+}, Be^{2+},

Bi^{3+}, Ce^{3+}, Cd^{2+}, Co^{2+}, Cu^{2+}, Fe^{2+}, Hg^{2+}, In^{3+}, Mn^{2+}, Ni^{2+}, Pb^{2+}, Zn^{2+}, CN^-, $Cr_2O_7^{2-}$, F^- and S^{2-}.[3] Very recently, Townshend and Vaughan have reported the determination of Hg^{2+} and Ag^+ (inhibitors of alcohol dehydrogenase)[164] and Be^{2+} and Zn^{2+} (inhibitors of alkaline phosphatase).[165] With growing concern for the effect of pesticides on the environment and the ecology, there has been considerable research on the application of the selective inhibition of enzyme activity by these substances. Kitz[166] has recently published an extensive review of the inhibition effects on cholinesterase activity, as used for the determination of various organophosphorus compounds. More recently several methods have been reported for a large variety of organophosphorus insecticides, *etc.*[167–174] Methods have been reported for a variety of chlorinated insecticides and herbicides,[171,172,175,176] and carbamate insecticides.[171,172,186–190]

There is a wide variety of factors such as choice of enzyme source and type, substrate, and other reaction conditions, which have considerable effect on the sensitivity and/or selectivity of a reaction for a particular pesticide inhibitor. There have been a large number of studies in this aspect.[180–173,186,189,191,192]

CHEMICAL APPLICATIONS OF RATE METHODS

Comprehensive compilations of the various general chemical applications of kinetic determinations reported before 1969 have been given in two recent books[1,2] and a series of review papers.[11–13,16,183] Druzhinin[184] has reviewed the kinetic-based methods for organic substances, in air-pollution studies. Heil[185] has reviewed kinetic methods applied to water analysis. Thus, this review will list only methods reported during the last two years, except in cases of special importance. These recent publications are listed below in two groups, first the methods for determination of a single species, and second the methods for determination of two or more species by differential reaction rate methods.

Determination of a single component

Inorganic species. The majority of chemical applications of reaction rate methods of analysis have used catalysed reactions and have, in general, employed initial reaction rate procedures. Yatsimirskii has described in detail the techniques and application of catalysed reactions in a recent book.[2]

Klockow, Ludwig and Giraudo[186] have reported the use of a zirconium catalysed reaction between perborate and iodide which can be used for the determination of fluoride. The fluoride acts as an inhibitor in the parts per milliard (ppM) range. Bruton has devised an ion-selective electrode rate method for the determination of both fluoride and chloride.[187] Thompson and Svehla[188] have used the perborate/iodide system for the same type of catalytic determination of iron and molybdenum, and Weisz, Klockow and Ludwig[189] have developed a new electrometric monitoring system for the determination of molybdenum. Cabello-Tomas and West[190] have described a "kineto-chromic" method for trace fluoride determination. Worthington and Pardue have reported a catalytic reaction procedure for the determination of trace ruthenium, using the Ce^{4+} and As^{3+} oxidation-reduction reaction.[191] Janjic, Milovanovic and Celap[192] described a method for the ultramicro determination of manganese by its catalytic action on the oxidation of alizarin by hydrogen peroxide. Analytical applications of the iodine and osmium catalysed reaction between Ce^{4+} and As^{3+} have been discussed by Rodriguez and Pardue.[193] James and Pardue have shown that built-in computer instrumentation is capable of determining levels of 10^{-9}–$10^{-11}M$ osmium, using this reaction system.[103] Kreingol'd and co-workers[194] have described a kinetic method for Cr^{6+} based on the catalysis of oxidation of the herbicide Methurin by potassium bromate. Dolmanova *et al.*[195] also reported a method for Cr^{6+} based on the catalytic oxidation of *o*-dianisidine with hydrogen peroxide. The concentrations of Cu^{2+} solutions have been determined by measuring the effect on the oxidation of furfuraldehyde.[196] Ruthenium has been determined by Ottaway, Fuller and Allan,[197] using the catalysis of the periodate oxidation of the tris[1,10-phenanthroline-iron(II)] complex. Trace determination methods for Ag^+, Hg^{2+} and I^- have been reported by Bognar and Sarosi,[198] based on the catalytic Ag^+–I^- and Hg^{2+}–I^- titrations and the IO_3^-–AsO_3^{3-} Landolt-type indicating system. Lazarev and Lazareva[199,200] have devised two different kinetic methods for V^{5+}. They made use of the catalytic action of V^{5+} on the bromate/5-amino-*N*-phenylanthranilic acid system[199] or the bromate/primary aromatic amine system.[200] Yatsimirskii and Kalinina[201] have also devised a trace vanadium method (0·01–100 ppM) based on the catalytic effect on the iodide oxidation by bromate. Hems, Kirkbright and West[202] have employed the catalytic effect of SO_4^{2-} on the zirconium/Methylthymol Blue reaction, for the determination of sulphate ion. A stopped-flow method for the kinetic determination of Fe^{3+} reacting with thiocyanate ion[23] and Sr^{2+} by a DCTA ligand-exchange reaction have been reported recently.[31]

A method for the determination of trace Cu^{2+} by means of the catalytic effect on the oxidation of amidol by hydrogen peroxide has been reported by Kreingol'd *et al.*[203] Trace methods for the determination of Mn^{2+} by the catalytic effect on the oxidation of Indigo Carmine has been developed by Slychev and Tiginyanu.[204] The Mn^{2+} catalysis of the oxidation of *p*-phenetidine by potassium perchlorate has also been employed in a trace analysis method.[205] A kinetic method for Mn^{2+} has been reported[205] which follows the complexation reaction rate with a sodium carminate–ethylenediamine system, using an integral variant technique. The catalytic effect of iridium on the oxidation of diphenylamines by cerium(IV) has been used in an analytical application by Tikhonova and Yatsimirskii.[207] Yatsimirskii *et al.* have also reported a kinetic method for the determination of iridium, which has been applied to paper chromatographic separation of noble metals.[208] A kinetic method for the determination of cobalt in vitamin B12 uses the catalysis of oxidation of the dye Bordeaux S by hydrogen peroxide.[209] Another catalytic method for Co^{2+} has been reported by Costache and Popa[210] which uses the Bromopyrogallol Red oxidation by peroxide. Filippou, Zyatkovskii and Yatsimirskii have employed the catalysis of the *p*-phenetidine/bromate reaction by Os^{8+} for trace analysis.[211] Segeda[212] has used the Ti^{3+} reaction with hydroxylamine as the basis of a rate method. Bilidiene, Cepelionyte and Jesinskiene[213] have reported a trace Cr^{6+} method based on the catalysis of the Methyl Orange oxidation by hydrogen peroxide. Trace Ag^+ has been determined by means of the catalytic effect on the oxidation of azo dyes by $K_2S_2O_5$.[214] A novel technique for the determination of either Rh^{3+} or Pd^{2+} by catalysis of the reduction of AgBr to Ag in a photographic emulsion by metol–hydroquinone developer has been reported by Pilipenko, Markova and Kaplan.[215]

Several reaction-rate modifications of the classic molybdenum blue method for the determination of inorganic phosphate have been reported.[79,84,98,216,217] These techniques employ either fixed-time or variable-time initial reaction rate measurement.

Similar methods employing the measurement of the initial rates of formation of heteropolymolybdate have been devised by Hargis for the determination of bismuth.[218]

Toropova and co-workers[219] have used an electroanalytical method of measuring the catalytic hydrogen wave of the cobalt–5-sulpho-8-mercaptoquinolinate complex to determine trace amounts of Sb^{3+}. Lukaweiwicz and Fitzgerald[220] have devised a fast photokinetic method for the determination of Fe^{3+}.

Organic species. Gilbert[221] has reported a pulse polarographic method which uses the Co^{2+} catalytic hydrogen wave for determining trace amounts of cystine. Rodziewicz *et al.*[222] have proposed a kinetic method for the determination of various phenolic compounds. A very sensitive method for the estimation of RNA by the Cu^{2+} catalysed orcinol reduction reaction has been reported.[223] Tutt and Schwartz[224] have devised a spectrophotometric assay of Ampicillin (α-aminobenzyl penicillin) involving a maximum rate method. The catalytic polarographic prewave of Ni^{2+} organic diamine systems has been proposed as a means of measuring the pK values of certain sparingly soluble organic amines.[225] A kinetic method for the determination of the stability constants of various metal complexes has been reported by Cohen and Connors.[226] Pillai, Lakshmenon, and Saryanarayana[227] have described a "redoxokinetic" titration method for organic acids. Szepesi and Gorog have reported a method for the determination of organic amines, which follows the rate of the acetylation or formylation reactions.[228]

Simultaneous analysis of mixtures

Inorganic systems. Margerum *et al.*[31] have reported a differential reaction rate method for the analysis of binary and ternary mixtures of lanthanides, transition metals, group II and group III metals, as DCTA complexes reacted with H^+ and/or an exchanging metal ion. Pausch and Margerum[23] have also reported the use of a stopped-flow spectrophotometric method for the simultaneous analysis of binary mixtures of Mg^{2+}, Ca^{2+}, Sr^{2+} and Ba^{2+}, using the exchange reactions of Pb^{2+} with alkaline earth metals complexes. Willis *et al.*[24] have improved this method by employing computer control and data reduction. Rodriguez and Pardue[229] have used the iodide and osmium catalysis of the Ce^{4+}–As^{3+} reaction for the simultaneous determination of I^- and Os^{8+}. Ingle and Crouch have reported a simultaneous differential rate procedure for silicate and phosphate in mixtures.[230]

Organic systems. Lohman and Mulligan have analysed mixtures of ethanolamides by a differential saponification rate method.[231] A kinetic method for the analysis of mixtures of glycols, using the cleavage reaction with lead(IV) has been reported by Benson and Fletcher.[232] Binary ketone mixtures have been determined by Toren and Gnuse[93] by taking advantage of the differences in the reaction rates with hydroxyamine hydrochloride. Greinke and Mark[48] have used the same reagent in the determination of various carbonyl mixtures. Zaia, Peruzzo and Plazzogna have reported a differential reaction rate method for mixtures of various hexa-alkyl-ditin compounds.[233] Shresta and Das have reported a second-order graphical extrapolation method for the simultaneous analysis of various organic amine mixtures.[234]

FUNDAMENTAL KINETIC STUDIES RELATED TO ANALYTICAL PROBLEMS

There have been numerous papers in the recent literature concerned with basic or fundamental kinetic studies on chemical systems which are either directly or indirectly related to analytical methods and procedures. Some of the basic work is intended to develop new methods and reactions for kinetic-based analytical techniques and some is intended to determine the mechanism of reactions involved in the more common equilibrium (or thermodynamic) methods. Once the details of such reaction mechanisms are known, it is possible to systematically improve a method. Recent papers in these two catagories are listed below. It should be pointed out that there is a huge volume of literature devoted to both inorganic and organic chemistry which involves the measurement of kinetic characteristics. It has been pointed out previously that this literature is a wealth of potentially analytically useful systems.[1,7] While this review will not attempt to list the publications in this area of research, the reader should be aware of its existence when faced with devising an analytical procedure for a new problem. There are a number of recent reviews of kinetic studies of the reactions of both organic[235–254] and inorganic species.[255–261]

Perhaps one of the major advances in sensors for rapid and selective *in situ* analysis has been the breakthrough in the theory and design of ion-selective electrodes. These have already been employed in a huge number of equilibrium (potentiometric) analytical methods. Recently Rechnitz and co-workers have also demonstrated that ion-selective electrodes are applicable as sensors in kinetic measurements.[60,61,63,64,262–269] They have studied metal complex reactions,[63,64,262,265,266] instrumentation considerations,[61,267] fast reaction applications[268] and biological systems.[60] Friedman, Palaty and Nakashima[270] have used ion-selective glass electrodes in the study of alkali metal ion-exchange processes. Honaker and Freiser[271] and McClellan and Freiser[272] have shown that solvent extraction methods can be employed, under certain conditions, to study the kinetics of fast chelation reactions. Subbaraman, Cordes and Freiser[273] have also studied the affect of auxiliary complexing agents on the rate of Zn^{2+} and Ni^{2+} extraction with diphenythiocarbazone. McClellan and Menis[19] have studied the kinetics and the mechanism of Fe^{2+} extraction with β-isopropyltropolone. Although there have been no direct applications taking advantage of the differential kinetics of extraction processes reported in the recent literature, it is obvious that there is a potential for future development. Hans has published a theoretical paper on electrolyte extraction kinetics.[275]

As the various organic and inorganic forms of phosphate are now recognized as a very large pollution hazard with respect to the ecological balance in natural water systems, the problem of trace determination of phosphates has received considerable attention in the recent literature. The standard colorimetric and/or spectrophotometric method for inorganic phosphate is the reaction with molybdate to form the 12-molybdophosphoric heteropoly acid species. There have been kinetic mechanism studies of these reactions by Javier, Crouch and Malmstadt.[276] In similar kinetic studies which have analytical significance, Hargis and co-workers have studied the reactions for the formation of silicon and bismuth heteropolymolybdates.[218,277–279] Solkovikov and Prinachek have reported the study of the mechanism and kinetics of the reaction of Al^{3+} with hafnium–molybdenum heteropoly acids.[280] Also in the area of environmental problems, Weber and co-workers have reported on studies of the rates of adsorption of organic pollutants,[284] pesticides,[281] and alkylbenzenesulphonates[282,283] on various activated carbons. These studies have potential for the improvement of activated carbon through a better understanding of the adsorption mechanism, and also for the determination and separation of various pesticides and pollutants.[285]

It is important to point out here that another group[286,287] has reported a kinetic-based pollution treatment system based on the *misinterpretation* of the results of Weber and Morris.[282,283]

In the past few years there have been a number of kinetic analytical methods reported that employ ligand-exchange reactions of metal ion complexes. These initial efforts in this area indicate that these types of metal ion complex reaction have considerable promise for broad analytical application, as discussed in a previous section of this review. Because of this potential certain recent papers describing fundamental kinetic and mechanism studies of metal ion complex systems are listed here. Funashashi and Tanaka[288–290] have studied the ligand-exchange reactions of various Co^{2+}, Cu^{2+} and Ni^{2+} complexes with 4-(2-pyridylazo)resorcinol. Frost and Hart have studied the ligand transfer kinetics of reactions of Eu^{3+}–(2,2,6,6-terpyridine) complexes with Tb^{3+}.[291] The kinetics and mechanism of other ligand transfer reactions have also been reported.[292] Ligand-exchange reactions of cobalt complexes have been reported.[293] Carr and Reilley[294] have reported a study on the kinetics of the ligand-exchange reaction of ethylenediaminetetra-acetate ion with ethylenediamine-tetra-acetatonickel(II). Pausch and Margerum,[31] and Willis *et al.*[25] have studied the ligand-exchange kinetics of strontium complexes of *trans*-DCTA and hydrogen ion, using Pb^{2+} as a scavenger.

Recently there have been several reports on kinetic studies using thermogravimetric methods. Sharp and Wentworth,[295] Carroll and Manche,[296] and Wentworth and Sharp[297] have had an exchange of correspondence on this subject. Taylor and Watson[298] have reported a method of determining relative reaction rates by a differential thermal analysis method. Cerceo[299] has used an evaporation-rate method to determine the degree of "cure" of polymeric materials. Dorko and co-workers have developed a differential scanning calorimetric method for studying the kinetics of solid state reactions.[300] The application of scanning calorimetry to thermal kinetic studies has been reported by Rogers and Smith.[301] Thermogravimetric studies of decomposition reaction rates have been reported by Savin[302] and reviewed by Sestak[303] and by Skvara and Satava.[304]

Hammer and Craig[305] have studied the kinetics of the β-chloroamine reaction and Joris, Aspila and Chakrabarti[306] have reported the results of the decomposition reactions of monoalkyldithiocarbamates. Sand and Huber have developed a differential constant-current potentiometric method for application to kinetic-based analysis.[307] Frankel[308] has devised a nuclear magnetic resonance technique for following the rates of ion-exchange reactions.

Froede and co-workers[309] have reported the development of a rapid-sampling system for use in studying intermediate-speed reactions. A rapid method for the determination of first-order reaction rate constants has been described by Viale[310] and Roy and Al-Jallo[311] have reported a spectrophotometric study of the kinetics of saponification reactions of alkyl ester compounds. Patton and Langer[312] have reported an interesting reaction kinetic method for the detection of void zones in gas chromatographic columns. Rodriguez and Pardue[230] have made an extensive study of the iodine-catalysed reaction between Ce^{4+} and As^{3+} in sulphuric acid. Other studies of the kinetics of catalysed reactions of potential analytical interest have also been reported. The catalytic effect of Cu^{2+} and Fe^{3+} ions on the reaction of Pu^{3+} with chlorine in chloride solutions has been reported by Mazumdar *et al.*[313]

Habig, Pardue and Worthington[314] have found that the catalysis of the reaction between Ce^{4+} and As^{3+} by Os^{7+} is first-order with respect to Os^{7+} over a wide concentration range. With another osmium-catalysed system, Domka and Marciniec[315] have shown that OsO_4 catalyses the decomposition of hydrogen peroxide and the oxidation of Indigo Carmine with peroxide. Yoshiro and co-workers[316] have reported on the Cu^{+}-catalysed oxidation of Mo^{5+} solutions. The activity of Ag^{+} as a catalyst in the oxidation of Tl^{+} by Ce^{4+} has been studied by Zeltmann.[317] Bhat and Khan[318] have studied the catalytic effects of F^{-} and Cl^{-} on the oxidation reactions of various metal ions.

In other kinetic studies of analytical interest, Burkhart and Newton[319] studied the redox kinetics of V^{2+} and Np^{4+} reactions, Flechon and Chavane[320] studied the reduction of silver salts by EDTA, and Matyakha and co-workers[321] have reported kinetic studies of reduction of Ce^{4+} oxalate complexes by hydrogen peroxide. In other redox reaction studies, Krishna and Singh[322] have reported results on the oxidation of I^{-} by ferricyanide in acid media, Davies and co-workers[323] have reported on the Mn^{2+}–H_2O_2 reaction, and Goldberg and Obukhova[324] have studied Mn^{2+} reduction by caproic acid. Everett and Skoog have made a kinetic study of the As^{3+} and Ce^{4+} redox reaction.[325]

Tockstein and Tocksteinova[326] have developed a unique oxidation-reduction titration which they called a *kinetic titration.* They employed the measurement of the rate of change of potential with time, using a zero faradaic current condition as titrant is continuously added. They report that they were able to determine two substances with exactly the same formal potentials provided the reaction rate constants were different by about two orders of magnitude. Sinfelt has reviewed the applied applications of reaction kinetics and catalytic reactions.[327] Samandi and Jaky have studied the mechanism of the oxidation of various organic carboxylic acids with permanganate.[328] Masood, Shastri and Krishna[329] have studied the effects of the nature and concentration of electrolytes on the kinetics of the alkaline fading of phenolphthalein. Smith[330] has recently published a second edition of the book, *Chemical Engineering Kinetics*, which contains extensive information on applied uses of reaction kinetics and other information of potential analytical interest.

Zusammenfassung—Es wird eine Übersicht über Prinzipien und Anwendung katalytischer und kinetischer Analysenmethoden gegeben.

Résumé—On présente une revue des principes et applications des méthodes d'analyse par catalyse et vitesse de réaction.

Summary—Requirements are laid down for the development of titrimetric methods and for writing up the work for publication. The general principles of various types of titration reaction are discussed, and special attention is paid to the parameters which influence chemical reactions.

ALTHOUGH about 200 years have elapsed since the publication of the first papers dealing with titrimetric analysis,[1] the technique is still as widely used as ever, especially since the development of physicochemical methods of measurement, which permit not only objective detection of the end-point of a titration but also monitoring of the course of the reaction and hence a better understanding of its chemistry. Better understanding in turn leads to improvements in speed, precision, accuracy, sensitivity and/or selectivity of the procedures. In spite of all this, however, many methods are published which leave much to be desired both in their usefulness and in validation of the conditions used. It may be argued that that is the fault of the editors and referees concerned, but it is not really part of their duties to give private tuition in research methods. This paper has therefore been added to those already published on how to develop and write up methods,[2,3] with the intention of fulfilling the need for such instruction.

GENERAL REQUIREMENTS OF A TITRIMETRIC METHOD

In general, as with other analytical methods, titrimetric procedures should be accurate and precise, simple to use, work under a wide range of conditions, fulfil a definite need and have practical applications (otherwise they are merely academic exercises and of little value) and should be rapid (if they are slow they offer no advantage over gravimetric methods). Some of these criteria are worth further comment. By "accurate and precise" we mean that the results should be correct and reproducible within the limits set by the random errors in measurement, and in the research work on a new method it is imperative that the errors be kept as small as possible. If it is known that a method is capable of giving results correct to within 1 part per thousand (1 ppt) then if a larger error is acceptable for some particular application, the method can be used with confidence even if less care is taken. On the other hand, if the best that can be done with a method gives an error of 1%, application of that method is limited to those situations in which a larger error than this can be tolerated. All too often there seems to be a failure to realise that in titrimetry the need to standardize the titrant introduces an additional source of error, since any mistake made in determining the titre will cause a bias in all the results obtained with the titrant. Consider, for example, the standardization of ceric sulphate with arsenious oxide, with osmium tetroxide as catalyst and ferroin as indicator. To give a reasonable titration volume of $0.1M$ ceric sulphate (*i.e.*, about 30 ml, which can be measured with a reading error of about 0.03 ml or less if care is taken), a weight of about 150 mg of arsenious oxide is required. Suppose this is weighed on a normal fourth-place balance with a standard deviation of 0.05 mg at the weight loading used, and that the balance weights have not been calibrated. The random error in weighing by difference will be about 0.15 mg (95% confidence limits) and in addition there may be a biased error from the unknown errors in the weights. The manufacturer's tolerance on weights up to 500 mg is 0·05 mg, and since there must be an exchange of at least two fractional weights it would be possible for this bias to amount to at least 0·1 mg. If this reinforces the random error, we have already an error of nearly 2 ppt in the weight of primary standard taken, plus an expected reading error of 1 ppt. In addition there is the end-point error arising from the fact that we do not know how much of the last increment added was actually required to reach the end-point and how much was excess. "Splitting" drops is tedious, and this error can be minimized by assuming that the end-point was reached on addition of half the last drop. The error is then only half the drop-size. If a varying amount of indicator is added to replicate samples, there will be a variation in the amount of titrant needed to oxidize the indicator, and if the indicator is too concentrated or too large an amount is added (or both!) another biased error can occur. Obviously care and thought are needed to measure the titre to within 1 ppt, and if the standardization is not done accurately, the results of use of the titrant will not be as meaningful as they should be. How often we see in a paper the statement that a solution was standardized by some method or other, usually described only by a reference, and no information is given as to the precision of the results obtained. Similar remarks apply to calibration of apparatus, for which the results are scarcely ever given.

By "simple to use" and "work under a wide range of conditions" we mean that there should be as few procedural steps as possible, since each can lead to a mistake being made, and that tolerances on such factors as pH range, ionic strength, amounts of particular compounds permitted to be present, should be as wide as possible, so that undue care need not be taken over adjustment of conditions. A procedure that requires very close control of pH is not nearly as satisfactory to use as one that operates over a pH range of several units.

By "rapid" we mean that reaction should proceed more rapidly than titrant can be added to the system, or at least very nearly so. A procedure in which a wait of several minutes is necessary between additions of titrant is going to be a very irksome one to use, and not at all suitable for routine analysis. Many potentiometric systems suffer from this drawback, when the electrode system used takes some time to reach a stable potential as the titration proceeds. Sometimes, of course, a slow reaction can be combined with a back-titration that is rapid, by adding an excess of reactant, leaving it for a sufficient time, and then titrating the excess. Again, an interfering reaction may be made to occur so slowly that it does not affect the main reaction, or the kinetics may already be sufficiently different for no interference to occur.

By "fulfilling a need and having practical application" we mean that a reaction that is suitable only for analysis of a pure solution of the substance to be determined is of such limited usefulness as to be practically worthless unless it is so very much better than any other available method that it is necessarily the method of choice for standardizing solutions of that substance. This was stated very clearly over 30 years ago by Lundell in his paper "Analysis of Things as They Are",[4] a paper that should be compulsory reading for all analytical chemists. The literature is full of "new and improved" methods that are in fact poorer in performance than the ones they seek to replace, and that are often based on standardizations performed by means of methods that they criticize and claim to supplant. Many methods have been published for the titrimetric determination of iron, but very few of them are better than the earliest methods of all—oxidation of iron(II) with dichromate[5] or permanganate.[6]

Unless the method being developed promises to fulfill these criteria, it seems scarcely worth while pursuing it. If it *does* show promise, however, there must be a proper investigation of the conditions under which it should be used, and a proper assessment of its scope of application and of its reliability. The remainder of this paper will deal with these aspects. Each type of reaction will be dealt with separately, as will standardization and end-point detection.

BASIC CONDITIONS OF TITRIMETRIC DETERMINATIONS

Only those reactions which proceed in stoichiometric ratio in a chosen solvent, without side-reactions and consecutive reactions, can serve as a basis for titrimetric determinations. The end-point of the reaction must be detectable by chemical or physical means.

Special demands are made of the substance used as titrant. It must be of well defined composition, easily soluble in the chosen solvent so that solutions covering a wide range of concentration can be prepared, and its solutions should either be stable or easily standardized. Some titrants which are unstable because of reactions with the solvent or the atmosphere, or because of volatility or light-sensitivity, can still be used if the active species is generated *in situ* electrolytically. It is desirable that the substance should be readily available.

Although a detailed study of the kinetics is not essential for development of a titrimetric method, it stands to reason that a method that is kinetically slow is not a very useful one, especially for routine work. However, slow reactions may be used in indirect methods if the back-titration reaction is fast. On the other hand, a competing reaction may be suppressed by proper adjustment of the conditions if its rate of reaction is much slower than that of the main reaction. Similarly it is not essential that the mechanism of the reaction be known, though again, knowledge of it may be useful in certain circumstances. The stoichiometry can be expressed in terms of equivalents or of the ratio of molar concentrations, which should be a ratio between small integers. It is worth stating at this point that in titrimetry it is essential to retain both the mole-concept and the concept of normality. Each has its own special field of application, together with an enormous overlap of applicability, where either can be used. For example, in dealing with polymers and many biochemical systems, it is not known (or cannot be known) what the molecular weight is, although it is perfectly easy to determine the number of equivalents of some reactive group in a given weight of sample. In contrast, normality is meaningless in complexation reactions. For the rest, the objection to the use of equivalents, *viz.* that a different equivalent weight must be used for different reactions of the same substance, is just as much an objection to the use of moles, because the equation must be written down in both cases, and the only real difference is in the point at which the stoichiometric coefficients are introduced into the calculation. If the equivalent is defined as that weight of material which will react with one mole of hydrogen ions or of electrons or with one equivalent of any other substance, both conventions are referred unambiguously to the mole concept, and there should be no difficulty in understanding and applying both.

Assumptions about stoichiometry are best verified by using equimolar solutions of the titrant and titrand and seeing whether the volumes needed to complete the reaction are in some simple whole-number ratio. If they are not, then either the reaction is non-quantitative for kinetic or thermodynamic reasons, or the main reaction is accompanied by side-reactions or consecutive reactions. Because these latter reactions can proceed at a considerably lower velocity than the main reaction, it is convenient to add an excess of titrant and to determine the amount unreacted after a sufficient time, to verify that there is no consecutive reaction. The stoichiometry can also be checked by quantitative determination of the reaction products. In direct titrations (see below), a titration error can be falsely attributed to non-quantitative reaction if the stoichiometry is not checked. It is often difficult, however, to decide whether non-quantitative results are due to the kinetics or the thermodynamics.[7]

Precipitation reactions

The main criterion is the value of the solubility product for the substance being precipitated. If C_M is the initial concentration of the metal to be precipitated by the titrant, then for 1 ppt error (which we will take as the working error to be aimed at) the final concentration must be $10^{-3}\,C_M$, and for a precipitate ML the apparent solubility product must be $10^{-6}\,C_M^2$. The apparent solubility product is related to the thermodynamic solubility product by the equations governing the amount of L that may be protonated at the pH of titration and hence unavailable for precipitation, and the amount of M that may be masked by hydrolysis or complexation by other anions present. As pointed out elsewhere,[8] it is easier to use the inverse of the solubility product, which may be called the insolubility constant and treated as a stability constant for the precipitate. Ringbom's α-coefficient methods[9] are then easily applied for calculation of the minimum pH *etc* permissible, as illustrated in Fig. 1, which should be self-explanatory. Similar diagrams can be prepared to take into account masking agents.

Once the permissible pH range has been calculated from the known values of stability constants, it should be checked experimentally—stability constants are often determined under highly specialized conditions, and the values obtained may be some orders of magnitude different from those for the conditions of the titration. If the constants are not known, they must either be determined or the pH range *etc* determined empirically.

Errors are most likely to arise from co-precipitation, especially from occlusion, because digestion and other means of reducing co-precipitation are not possible in this case. A typical example is the occlusion of AgCl in the determination of iodide by argentometric titration.[10] Normally there should be an exchange reaction between AgCl and I^- to give AgI and Cl^-, but if the AgCl is occluded within AgI particles the

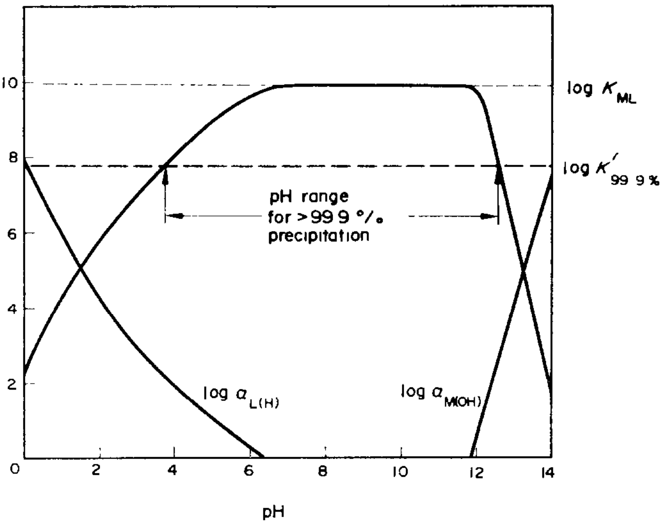

FIG. 1.—Precipitation titration of $10^{-2}M$ metal ion M with ligand H_2L, to form ML, where M forms soluble hydroxo-complexes. K_1 and K_2 for H_2L are 10^8 and 10^6 respectively, K_{sp} for ML is 10^{-10} (*i.e.*, $K_{ins} = 10^{10}$). K_3 and K_4 for $M(OH)_3^-$ and $M(OH)_4^{2-}$ are 10^6 and 10^2 respectively. $K'_{99.9\%}$ = conditional constant for at least 99.9% precipitation at the end-point.

exchange cannot take place, and there is an overconsumption of silver nitrate. The error can be eliminated by adding some ammonium carbonate to make diamminosilver(I) the effective titrant, in which case AgCl cannot precipitate. The effect of all other ions likely to be present in practical applications must therefore be checked experimentally. Precipitation reactions may sometimes be made more selective by judicious use of pH control, auxiliary masking agents, *etc*, but in general the utility of this type of reaction is severely limited by the lack of selectivity.

Further problems arise in the detection of the end-point. If a coloured precipitate is produced at the end of the main reaction, as in the Mohr method for halides, conditions must be carefully adjusted so that the overconsumption of titrant in production of a visible amount of coloured product is just compensated for by the underconsumption of titrant caused by the fact that the coloured product begins to be formed before the main reaction is entirely complete.[11] The situation may be further aggravated by the presence of ions (such as NH_4^+) which are normally thought of as harmless.[12,13] Adsorption indicators are usually fairly good, but often experience is required to recognize the end-point. Amperometric titration is often used, but the errors are seldom less than 1%, which is not surprising in view of the 1–2% error usually associated with polarographic methods. If say 10 points are used to construct the titration graph and there is an error of 2% associated with each, the overall error in assessing the end-point is likely to be about $2/\sqrt{10}\%$ or about 0.6%. In addition, it is customary to use small volumes of fairly concentrated titrant (in order to avoid excessive dilution and the need to apply a dilution correction) and the reading errors will be rather large. Potentiometric detection of the end-point is likely to prove the most satisfactory, provided that the electrodes reach potential equilibrium rapidly—otherwise the method will be too slow to be useful except for special or occasional use.

Conductimetric methods are satisfactory if the conductance can be measured sufficiently precisely (for reasons similar to those discussed for amperometric titrations) and the results are properly interpreted.

Redox reactions

The primary requirements are a means of converting the determinand into essentially the completely oxidized or reduced form, and a titrant capable of completely reducing or oxidizing the product. Obviously an excess of an auxiliary oxidant or reductant will be required in the first step, and this excess must be easily destroyed without the determinand being affected. The formal potentials for the titrant and determinand couples must be sufficiently far apart for the reaction to be at least 99·9% complete at the end-point; that means a difference of at least 0·36 V for two one-electron reactants, but only 0·09 V for a pair of two-electron reactants.

It is important to remember that the products may depend on whether a one-electron couple is matched with a one- or a two-electron couple. Hydrazine is oxidized to nitrogen by a two-electron oxidant, but to a mixture of ammonia and nitrogen by a one-electron reagent.

Examination of the Nernst equation shows that the redox potentials may be profoundly affected by changes in acidity, by complexation, and by precipitation or formation of undissociated compounds.

Effect of acidity. The most noticeable effect is on the potentials of couples involving oxy-anions that are oxidized or reduced. Typical examples are the fact that manganate is unstable in acid solution because of disproportionation, but stable in extremely alkaline solutions, and the fact that the interference of vanadium(IV) in the oxidimetric determination of iron(II) can be eliminated by making the solution $5M$ in sulphuric acid, and so raising the potential of the V(V)/V(IV) couple to a value comparable to that of the usual oxidants. Another effect is preferential protonation of one half of a couple, as for example the ferrocyanide/ferricyanide couple, or the effect of acidity on the potential of ferroin.

A further effect of changes of acidity may be on the kinetics of the reaction. As has recently been shown,[14] potassium chlorate can be used successfully as an oxidative titrant if the acidity is made high enough, though even then a catalyst is sometimes desirable as well.

Effect of complexation. It is well known that the potential of the iron couple can be shifted in either direction by use of complexing agents, the potential being increased if the iron(II) complex is more stable than the iron(III) complex (as with 1,10′-phenanthroline) and lowered if the order of stabilities is reversed (as with phosphate, fluoride, EDTA).

Effect of precipitation etc. The potential of the silver couple is decreased by introduction of an anion that forms an insoluble silver salt, the decrease being the greater the more insoluble the compound. Similarly, formation of an undissociated species such as mercuric chloride or cyanide will remove the ions of one form of the couple and hence shift the potential.

Importance of the Nernst equation. The Nernst equation not only permits calculation of the equilibrium constant (and hence the feasibility of the reaction) from the potentials of the couples involved, but also permits us to calculate the form of the potentiometric titration curve and so choose suitable indicators and decide whether other species may interfere or not by being co-titrated. It also reminds us that we cannot have an *absolutely* pure oxidant or reductant solution if the solvent is capable of redox action. It is for this reason that certain species are unstable in aqueous medium, even if protected from aerial oxidation. It further reveals that lack of thought has led to an incorrect ascription of chemical properties to certain oxidants. Many textbooks state that dichromate and ceric sulphate can be used for titrations in hydrochloric acid medium but permanganate can not. This statement is only partly true: permanganate can certainly be used, *e.g.*, for titration of antimony(III), in chloride medium. It is only unsuitable for use when the oxidation of chloride is induced by another reaction in the system, such as the oxidation of iron(II). The reason for this is that the kinetics of chloride oxidation are so slow at moderate acidities that the end-point can be detected without interference from the slow side-reaction. Unfortunately, however, many chemists read more into the statement than is there, and assume that dichromate and ceric sulphate are incapable of oxidizing chloride—an assumption that is completely false, as a practical test will readily verify.

Importance of kinetics. From what has just been said about permanganate it will be realized that the reaction kinetics may play a decisive part and override the thermodynamics. A good example is the determination of total iron in silicate rock by removal of silica by the Berzelius method, fusion of the metal oxides with pyrosulphate, dissolution in hydrochloric acid, reduction with the silver reductor, and titration with ceric sulphate, with ferroin as indicator.[15] Two difficulties arise: there is a variable blank, and the end-point "returns", that is, there is a sharp colour change followed by slow return of the reduced form of the indicator, and this behaviour is repeated on further addition of small increments of titrant. Both effects are kinetic in origin. The first arises from reduction of aerial oxygen to hydrogen peroxide in the silver reductor. The peroxide should be further reduced to water, but because the first reduction step is much faster than the second there is a build-up of peroxide, a steady state being reached because of the diffusion controlled supply of further oxygen from the air. The peroxide then reacts with iron(II) in the initiation and termination steps of the Haber-Weiss[16] mechanism for catalytic decomposition of peroxide:

$$\begin{array}{ll} Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + \cdot OH & \text{(initiation)} \\ Fe^{2+} + \cdot OH \rightarrow Fe^{3+} + OH^- & \text{(termination)} \\ \left.\begin{array}{l} H_2O_2 + \cdot OH \rightarrow HO_2\cdot + H_2O \\ HO_2\cdot + H_2O_2 \rightarrow H_2O + O_2 + \cdot OH \end{array}\right\} & \text{propagation} \end{array}$$

The chain propagation steps are unlikely to have a chance to occur, since the iron is greatly in excess of the peroxide. Similar effects occur with amalgams when they are used in the presence of air.[17] The returning end-point arises because the decomposition reaction takes place in a platinum crucible and some platinum is extracted as Pt(IV) in the fusion process. According to the thermodynamics the Pt(IV) should be reduced to the metal on the silver reductor, but if the reduction is slow and occurs in two stages, *via* Pt(II), and if the residence time in the reductor column is too short (short column and/or fast flow-rate) some Pt(II) passes into the effluent and is oxidized (slowly, of course) after the preferential oxidation of the iron is complete. Fortunately the kinetics are so slow that the first sharp end-point corresponds exactly to the iron titration.[15]

Induced reactions. The Haber-Weiss mechanism just quoted is an example of an induced catalytic reaction. When such reactions can occur, they constitute a hidden source of error, which may be extremely large. In the oxidation of tin(II) with dichromate, for example, induced aerial oxidation accounts for oxidation of no less than 98% of the tin.[18] On the other hand, induced coupled reactions, in which a definite stoichiometry exists between the inductor and the acceptor systems, may be used quantitatively.

End-point detection. Indicators and potentiometry are the means usually chosen for end-point detection. Naturally the indicator potential must be matched to the equivalence point potential of the system, either by choice of indicator or by shift of a potential (*e.g.*, addition of phosphoric acid when diphenylamine is used as indicator for iron(II) oxidation). Potentiometry is satisfactory subject to the usual proviso about the speed of electrode equilibration. Spectrophotometric titration is possible if one component of the titration system has suitable absorption characteristics differing from those of the others, but if the end-point section of the curve is too rounded, dilution corrections may be necessary and are rather tedious to apply.

Complexation and acid-base reactions

The basis of these reactions is formation of a highly stable (*i.e.*, little dissociated) species such as a metal complex or water. The main criterion for successful application to titrimetry is therefore the apparent equilibrium constant for the reaction under the conditions used. In complexation reactions, if the initial metal ion concentration is C_M then for the error to be 1 ppt or less, the concentration of free metal at the end-point must be $\leqslant 10^{-3} C_M$, and this must also be the total concentration of uncomplexed titrant in the titration solution. It follows that the minimum value for the apparent stability constant of the complex is $C_M/10^{-6} C_M^2$ or $10^6/C_M$. It is therefore advisable to use fairly concentrated solutions for titration of metals that form only weak complexes. The Ringbom[9] conditional constant method can again be used to predict the minimum pH required for complete titration. It is not always recognized, however, that it is really the indicator reaction which sets the lower boundary of the permissible pH range. In the case of a weak metal-indicator complex it would be possible to find a pH at which the metal-titrant complex could be formed quantitatively while the metal-indicator complex was formed scarcely or not at all. The upper boundary of the pH range is set either by the hydrolysis characteristics of the metal ion or by the nature of the indicator. Almost all metallochromic indicators are also acid-base indicators, the colours of their metal complexes being essentially those of the species obtained on removal of one proton (sometimes more) from the indicator. For a colour change to occur at the end-point, from the colour of the metal-indicator complex to that of the free indicator, the pH must be below that at which the indicator would be deprotonated anyway. The whole system is illustrated in Fig. 2.

It is possible to achieve selectivity of complexation by pH control if the metal ions present form complexes with the titrant, with sufficiently different stability constants (Fig. 2). For ions giving complexes with similar stabilities, auxiliary masking agents are used to achieve selectivity. When the pH is adjusted it is important to remember that the buffer system must not contain ions that can act as competing ligands.[19] It is also important to remember that the buffer must have sufficient capacity to absorb the protons released during the complexation reaction.

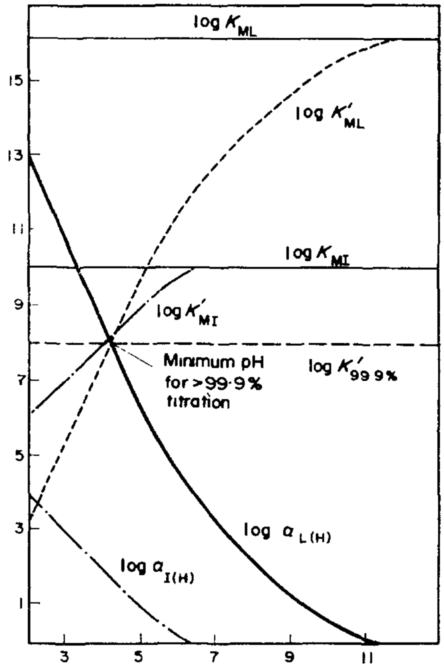

FIG. 2.—Complexation titration of $10^{-2}M$ metal ion M with ligand HL to form ML, with indicator HI. $K_{ML} = 10^{16}$; $K_{MI} = 10^{10}$; $K_{HI} = 10^{6}$; HL is EDTA. $K'_{99.9\%}$ = conditional constant for at least 99.9% completion of complexation at the end-point.

Acid-base reactions can be treated as a special case of complexation, in the simpler cases there being competition between two anions to form an undissociated species with protons. The decisive factor is the equilibrium constant for the reaction

$$HA + OH^- \rightleftharpoons A^- + H_2O$$

$$K_{eq} = \frac{[H_2O][A^-]}{[HA][OH^-]} = \frac{K_w}{K_{HA}}$$

where

$$K_w = [H_2O]/[H^+][OH^-]; \quad K_{HA} = [HA]/[H^+][A^-]$$

If the initial concentration of acid is C_{HA}, then for 99·9% neutralization the final concentration is $10^{-3}\,C_{HA}$, and since at equilibrium [HA] = [OH$^-$], it follows that K_{eq} must be greater than $10^6/C_{HA}$ for quantitative titration ([A$^-$] will be approximately equal to C_{HA} at equivalence). If we approximate a little and use "mixed" stability constants, we can call the activity of water unity and take K_w as 10^{14}. In that case K_{HA} must be less than $K_w \cdot C_{HA}/10^6$, *i.e.*, less than $10^8\,C_{HA}$, for quantitative titration.

If the acid is weaker than this, either a larger error must be accepted or the conditions must be changed to make the acid appear to be stronger. One way of doing this is to introduce a metal ion that will form a complex with A$^-$, thus releasing protons from HA; care must be taken, however, to choose a metal ion that will not itself interfere by a hydrolysis reaction. The more common method is to change the value of K_{eq} by changing the solvent system. The use of and choice of non-aqueous solvents have been adequately discussed in various monographs[20–22] and need not be dwelt on here.

End-point detection. The most common methods for end-point detection are by means of indicators, potentiometry, spectrophotometry, conductimetry and thermometry or enthalpimetry.

In complexation reactions the indicator must of necessity form with the determinand ion a complex that is less stable than the complex formed by the determinand and titrant. If the two complexes are of comparable stability there will be an end-point error that is a function of the amount of indicator added. An example is the use of Xylenol Orange for titration of lead with EDTA. It is also essential that the indicator should not be "blocked" by the presence of other metal ions that form with it complexes more stable than the determinand-indicator complex. Adequate buffering is also necessary to prevent appearance of a false end-point by virtue of decomposition of the indicator complex by reaction with the protons released as the main reaction proceeds. It is also most important that the transition interval should be as sharp as possible. If an appreciable volume of titrant is required to traverse the end-point colour change, and two elements are being determined in the same sample by titration of the sum followed by masking of one and titration of the complexant released, there will be an error if the "sum" titration end-point is taken as appearance of the free indicator colour but the back-titration end-point is the colour of metal-indicator complex. It is essential to use the same end-point colour in both cases. The general theory of these indicators has been well covered by Ringbom.[9] The theory of acid-base indicators is well known, and it need only be stressed that the pK value of the indicator must match the pH at the equivalence point, and that adequate precautions must be taken to avoid interference by carbon dioxide in the atmosphere.

Potentiometry has already been discussed, and fortunately the glass electrode has a very rapid response and equilibration, so is ideal for potentiometric acid-base titration. The limitations of conductimetry (and amperometry) have been dealt with above and will apply here also. Spectrophotometry has been dealt with in a monograph,[23] and the theory of spectrophotometric complexation titrations adequately covered.[24,25] Thermometric and enthalpimetric methods are relatively new, but are really useful only if relatively large errors (1% or more) are acceptable. Perusal of some of the literature on these methods shows that when comparisons are made between thermometric and classical indicator methods, the errors reported for the latter are very often greatly in excess of the values that are obtainable by careful work.

Interferences. In complexation reactions, interfering ions may be dealt with by pH control or selective masking, as pointed out above. A subtle form of interference may arise, however, from the use of masking agents. It sometimes happens that a masking agent added to sequester an interfering element can act as a bridging ligand to form a mixed-metal binuclear complex with the determinand ion. If this complex happens to be inert (*i.e.*, kinetically stabilized) then the determinand ion will not react with the titrant. Such is the case with aluminium in the presence of uranyl ions and citrate.[26] Similar cases are those of copper in the presence of chromium and citrate,[27] and copper in presence of aluminium and tartrate.[28]

In acid-base reactions, the interferences are those caused by the presence of other acids or bases besides the determinand. If the strengths of the various species differ sufficiently it may be possible to titrate them consecutively, provided means of detecting the end-points are available. If the strengths are comparable, selective complexation or a change of solvent may give sufficient differentiation.

GENERAL FACTORS INFLUENCING TITRIMETRIC METHODS

Ionic strength and variations in concentration

The ionic strength can affect both the velocity and the quantitativeness of a chemical reaction, the effect being largely a function of the charges on the reacting species.[29,30] In a titration there must inevitably be a change in ionic strength in the course of the reaction, but fortunately most analytical procedures require the use of concentrations at which activity coefficients change relatively little with variation in ionic strength,[31] so it is unlikely that the ionic strength will be a serious factor. If it is, the effect can usually be "swamped" by addition of a large and constant amount of an indifferent electrolyte.

Changes in the concentration of the reactants cause a change in the reaction velocity. This is seen in the decrease in the reaction velocity near the equivalence point, a feature of practical utility (the entering stream of titrant reacts immediately in the early part of a titration, but disperses sluggishly near the end-point, so that at the point of entry the indicator has changed colour). It is therefore convenient to keep the reactant concentrations fairly constant during the preliminary investigations. Later the concentrations can be varied, especially with a view to finding the lowest concentrations that can be used satisfactorily.

Temperature

A change in temperature influences the reaction velocity and the equilibrium constant, and sometimes even the stoichiometry. Sometimes a higher temperature is used deliberately to make a slow reaction more practicable, and sometimes a very low temperature is used to make an interfering reaction so slow that its effect is nullified (so-called "kinetic masking").

Ideally, room temperature should be the optimum, but it is necessary to investigate the effect of changing the temperature because "room" temperature may vary from a few degrees in winter in Scotland to 30° or more in summer in India. High temperatures are undesirable because they may cause unfavourable effects such as decrease in stability of reactants, thermal decomposition, reaction with solvent, increasing probability of side-reactions occurring. If higher temperatures are unavoidable, a "safe" range must be found in which these undesirable effects do not occur.

Catalysis

Catalysts are sometimes added to change the reaction velocity or the mechanism of reaction, especially in redox systems. Catalysts are associated with particular reactions, and there is no general theory for prediction of which catalyst will prove convenient. Catalysts are usually found by trial and error, with the initial choice based on experience. Sometimes autocatalysis occurs, in which a reaction product itself catalyses the reaction. Induced reactions are sometimes used, but as pointed out above, unwanted ones can be a source of error.

Stability of reagents

It sometimes happens that though a titrant may be stable in aqueous solution when it is being stored, it may become less stable under the conditions used for the titration, especially if these are particularly drastic in terms of acidity or alkalinity. The effect is most likely to be observed in an indirect procedure, in which an excess of reagent must be added and the mixture left for some time for the reaction to reach completion, followed by back-titration of the excess. In such cases it is necessary to check the stability of the reagent by running a number of blank determinations with different amounts of reagent present.

Indicator solutions may not be stable on storage, especially in the case of complexometric indicators. Xylenol Orange, for example, oxidizes slowly in aqueous solution, and the oxidation product will give a coloured complex only with copper(II). The storage life of all reagents should be checked and appropriate recommendations made for their preparation.

End-point sharpness

The accuracy of a titration will be partly determined by the volume of titrant required to traverse the end-point, and on how accurately the end-point can be located within that volume. As discussed in specialist texts and articles,[32] the equivalence point may not exactly correspond to the end-point, and a correction may be necessary. The correction may be calculated or empirical. The "sharpness index" or "relative precision"[33] may be used as a means of indicating the size of the end-point error. It is essential that *some* numerical value be given for the sharpness. If indicators are used, the volume of titrant needed to give the complete colour change must be determined and reported, and if possible the colours should be described in terms of the C.I.E. indices.[34]

Other influences

Electromagnetic radiation, usually in the form of visible or ultraviolet light, can not only affect the stability of the reactants but may also participate in the reaction or accelerate or introduce side-reactions. It is therefore sometimes necessary to perform titrations under special lighting conditions, and in indirect determinations it is often necessary to keep the reaction mixture in the dark during the reaction period before the back-titration.

Ultrasonic waves have occasionally been used to affect the course of a reaction. Pressure changes, though often used in technology, are not used in titrations, because of the experimental complications introduced.

RESULTS AND APPLICATIONS

Once the method has been worked out, it is necessary to validate it by standardization, and by application to standard samples containing the species of interest. The standardization is customarily done by preparing a standard solution of known concentration and titrating equal portions of it. In our opinion this is not a sound practice. First, all measurements are made by volume, and as discussed by Conway,[35] it is then necessary to calibrate all apparatus used, so that the personal error may be assessed. Secondly, once the first titration has been done, the tendency is to add rapidly almost the required volume of titrant to the second sample and only the last few drops are added slowly. The result is a variable drainage error, if a normal gravity-feed burette is used.[35] Furthermore, if fractions of a division are estimated in reading the burette, there is an unconscious urge to make the readings agree as closely as possible. It is much more reliable to make up the standard solution by weight and to take different weight fractions of it. Each titration must then be done more or less individually without reference to the others (unless the operator is unable to resist doing mental arithmetic), and the error in the amount of sample taken will be virtually eliminated. If a sufficiently wide range of sample weights is taken, a plot of "taken" against "found" will reveal any bias in the results, and the existence of any "blank" correction. Repetition of the procedure in the presence of the other elements expected to occur in any applications will reveal the extent of any interference by these species. The concentration ratios used must be realistic.[3]

Finally, the method must be applied to standard samples of the materials for which it is suitable, and the results compared statistically with those obtained by the best previously existing methods. It is essential to have enough replicate determinations to make the statistics meaningful, and the Snedecor *F*-test or "Student's" *t* should be applied as a criterion of significant improvement.[36]

PUBLICATION OF RESULTS

If the work has been successful, then in the preparation of a paper for publication it is necessary to report on all the features dealt with above. In particular, attention must be paid to the following points.

1. Stability of reagents, and special precautions to be taken in their preparation and storage.
2. Standardization of reagents and calibration of apparatus, with details given of the errors actually obtained.
3. Proof of the stoichiometry, and establishment of the tolerance ranges[37] for concentrations of reactants, interferents, and other species necessarily present.
4. The speed of the reaction, especially with regard to end-point detection and to the standing time in the case of indirect determinations.
5. The nature of the end-point detection, with specification of sharpness of any colour changes, details of indicator corrections or other end-point corrections. In cases of "dead-stop" methods *etc*, the response time of the indicating system should be expressed in terms of amount of titrant added, if the titrant is being added automatically or generated electrolytically. In coulometric work the current efficiency must be determined, and the timing error should be established and reported.
6. In description of the procedure, all tolerances on amounts of reagents should be clearly stated, and any special precautions stated.[37]
7. There must be adequate validation of results, supported by statistical analysis.
8. Applications of the method must be proposed and at least some of them validated experimentally. There must be a proper comparison with existing methods.
9. If possible, the method should be tested by someone who has not used it before, and *those* results quoted as well.

Résumé—On a établi les conditions nécessaires pour le développement de méthodes titrimétriques et pour la rédaction du travail pour publication. On discute des principes généraux de divers types de réaction de titrage, et l'on prête particulièrement attention aux paramètres qui influent sur les réactions chimiques.

Zusammenfassung—Die Anforderungen an die Ausarbeitung titrimetrischer Methoden und an zu publizierende Manuskripte mit solchen Themen werden aufgeführt. Die allgemeinen Grundlagen für verschiedene Typen von Titrationsreaktionen werden erörtert und dabei besonderes Gewicht auf die Parameter gelegt, die chemische Reaktionen beeinflussen.

Summary—Requirements are laid down for the development of titrimetric methods and for writing up the work for publication. The general principles of various types of titration reaction are discussed, and special attention is paid to the parameters which influence chemical reactions.

ALTHOUGH about 200 years have elapsed since the publication of the first papers dealing with titrimetric analysis,[1] the technique is still as widely used as ever, especially since the development of physicochemical methods of measurement, which permit not only objective detection of the end-point of a titration but also monitoring of the course of the reaction and hence a better understanding of its chemistry. Better understanding in turn leads to improvements in speed, precision, accuracy, sensitivity and/or selectivity of the procedures. In spite of all this, however, many methods are published which leave much to be desired both in their usefulness and in validation of the conditions used. It may be argued that that is the fault of the editors and referees concerned, but it is not really part of their duties to give private tuition in research methods. This paper has therefore been added to those already published on how to develop and write up methods,[2,3] with the intention of fulfilling the need for such instruction.

GENERAL REQUIREMENTS OF A TITRIMETRIC METHOD

In general, as with other analytical methods, titrimetric procedures should be accurate and precise, simple to use, work under a wide range of conditions, fulfil a definite need and have practical applications (otherwise they are merely academic exercises and of little value) and should be rapid (if they are slow they offer no advantage over gravimetric methods). Some of these criteria are worth further comment. By "accurate and precise" we mean that the results should be correct and reproducible within the limits set by the random errors in measurement, and in the research work on a new method it is imperative that the errors be kept as small as possible. If it is known that a method is capable of giving results correct to within 1 part per thousand (1 ppt) then if a larger error is acceptable for some particular application, the method can be used with confidence even if less care is taken. On the other hand, if the best that can be done with a method gives an error of 1%, application of that method is limited to those situations in which a larger error than this can be tolerated. All too often there seems to be a failure to realise that in titrimetry the need to standardize the titrant introduces an additional source of error, since any mistake made in determining the titre will cause a bias in all the results obtained with the titrant. Consider, for example, the standardization of ceric sulphate with arsenious oxide, with osmium tetroxide as catalyst and ferroin as indicator. To give a reasonable titration volume of $0.1M$ ceric sulphate (*i.e.*, about 30 ml, which can be measured with a reading error of about 0.03 ml or less if care is taken), a weight of about 150 mg of arsenious oxide is required. Suppose this is weighed on a normal fourth-place balance with a standard deviation of 0.05 mg at the weight loading used, and that the balance weights have not been calibrated. The random error in weighing by difference will be about 0.15 mg (95% confidence limits) and in addition there may be a biased error from the unknown errors in the weights. The manufacturer's tolerance on weights up to 500 mg is 0·05 mg, and since there must be an exchange of at least two fractional weights it would be possible for this bias to amount to at least 0·1 mg. If this reinforces the random error, we have already an error of nearly 2 ppt in the weight of primary standard taken, plus an expected reading error of 1 ppt. In addition there is the end-point error arising from the fact that we do not know how much of the last increment added was actually required to reach the end-point and how much was excess. "Splitting" drops is tedious, and this error can be minimized by assuming that the end-point was reached on addition of half the last drop. The error is then only half the drop-size. If a varying amount of indicator is added to replicate samples, there will be a variation in the amount of titrant needed to oxidize the indicator, and if the indicator is too concentrated or too large an amount is added (or both!) another biased error can occur. Obviously care and thought are needed to measure the titre to within 1 ppt, and if the standardization is not done accurately, the results of use of the titrant will not be as meaningful as they should be. How often we see in a paper the statement that a solution was standardized by some method or other, usually described only by a reference, and no information is given as to the precision of the results obtained. Similar remarks apply to calibration of apparatus, for which the results are scarcely ever given.

By "simple to use" and "work under a wide range of conditions" we mean that there should be as few procedural steps as possible, since each can lead to a mistake being made, and that tolerances on such factors as pH range, ionic strength, amounts of particular compounds permitted to be present, should be as wide as possible, so that undue care need not be taken over adjustment of conditions. A procedure that requires very close control of pH is not nearly as satisfactory to use as one that operates over a pH range of several units.

By "rapid" we mean that reaction should proceed more rapidly than titrant can be added to the system, or at least very nearly so. A procedure in which a wait of several minutes is necessary between additions of titrant is going to be a very irksome one to use, and not at all suitable for routine analysis. Many potentiometric systems suffer from this drawback, when the electrode system used takes some time to reach a stable potential as the titration proceeds. Sometimes, of course, a slow reaction can be combined with a back-titration that is rapid, by adding an excess of reactant, leaving it for a sufficient time, and then titrating the excess. Again, an interfering reaction may be made to occur so slowly that it does not affect the main reaction, or the kinetics may already be sufficiently different for no interference to occur.

By "fulfilling a need and having practical application" we mean that a reaction that is suitable only for analysis of a pure solution of the substance to be determined is of such limited usefulness as to be practically worthless unless it is so very much better than any other available method that it is necessarily the method of choice for standardizing solutions of that substance. This was stated very clearly over 30 years ago by Lundell in his paper "Analysis of Things as They Are",[4] a paper that should be compulsory reading for all analytical chemists. The literature is full of "new and improved" methods that are in fact poorer in performance than the ones they seek to replace, and that are often based on standardizations performed by means of methods that they criticize and claim to supplant. Many methods have been published for the titrimetric determination of iron, but very few of them are better than the earliest methods of all—oxidation of iron(II) with dichromate[5] or permanganate.[6]

Unless the method being developed promises to fulfill these criteria, it seems scarcely worth while pursuing it. If it *does* show promise, however, there must be a proper investigation of the conditions under which it should be used, and a proper assessment of its scope of application and of its reliability. The remainder of this paper will deal with these aspects. Each type of reaction will be dealt with separately, as will standardization and end-point detection.

BASIC CONDITIONS OF TITRIMETRIC DETERMINATIONS

Only those reactions which proceed in stoichiometric ratio in a chosen solvent, without side-reactions and consecutive reactions, can serve as a basis for titrimetric determinations. The end-point of the reaction must be detectable by chemical or physical means.

Special demands are made of the substance used as titrant. It must be of well defined composition, easily soluble in the chosen solvent so that solutions covering a wide range of concentration can be prepared, and its solutions should either be stable or easily standardized. Some titrants which are unstable because of reactions with the solvent or the atmosphere, or because of volatility or light-sensitivity, can still be used if the active species is generated *in situ* electrolytically. It is desirable that the substance should be readily available.

Although a detailed study of the kinetics is not essential for development of a titrimetric method, it stands to reason that a method that is kinetically slow is not a very useful one, especially for routine work. However, slow reactions may be used in indirect methods if the back-titration reaction is fast. On the other hand, a competing reaction may be suppressed by proper adjustment of the conditions if its rate of reaction is much slower than that of the main reaction. Similarly it is not essential that the mechanism of the reaction be known, though again, knowledge of it may be useful in certain circumstances. The stoichiometry can be expressed in terms of equivalents or of the ratio of molar concentrations, which should be a ratio between small integers. It is worth stating at this point that in titrimetry it is essential to retain both the mole-concept and the concept of normality. Each has its own special field of application, together with an enormous overlap of applicability, where either can be used. For example, in dealing with polymers and many biochemical systems, it is not known (or cannot be known) what the molecular weight is, although it is perfectly easy to determine the number of equivalents of some reactive group in a given weight of sample. In contrast, normality is meaningless in complexation reactions. For the rest, the objection to the use of equivalents, *viz.* that a different equivalent weight must be used for different reactions of the same substance, is just as much an objection to the use of moles, because the equation must be written down in both cases, and the only real difference is in the point at which the stoichiometric coefficients are introduced into the calculation. If the equivalent is defined as that weight of material which will react with one mole of hydrogen ions or of electrons or with one equivalent of any other substance, both conventions are referred unambiguously to the mole concept, and there should be no difficulty in understanding and applying both.

Assumptions about stoichiometry are best verified by using equimolar solutions of the titrant and titrand and seeing whether the volumes needed to complete the reaction are in some simple whole-number ratio. If they are not, then either the reaction is non-quantitative for kinetic or thermodynamic reasons, or the main reaction is accompanied by side-reactions or consecutive reactions. Because these latter reactions can proceed at a considerably lower velocity than the main reaction, it is convenient to add an excess of titrant and to determine the amount unreacted after a sufficient time, to verify that there is no consecutive reaction. The stoichiometry can also be checked by quantitative determination of the reaction products. In direct titrations (see below), a titration error can be falsely attributed to non-quantitative reaction if the stoichiometry is not checked. It is often difficult, however, to decide whether non-quantitative results are due to the kinetics or the thermodynamics.[7]

Precipitation reactions

The main criterion is the value of the solubility product for the substance being precipitated. If C_M is the initial concentration of the metal to be precipitated by the titrant, then for 1 ppt error (which we will take as the working error to be aimed at) the final concentration must be $10^{-3}\ C_M$, and for a precipitate ML the apparent solubility product must be $10^{-6}\ C_M^2$. The apparent solubility product is related to the thermodynamic solubility product by the equations governing the amount of L that may be protonated at the pH of titration and hence unavailable for precipitation, and the amount of M that may be masked by hydrolysis or complexation by other anions present. As pointed out elsewhere,[8] it is easier to use the inverse of the solubility product, which may be called the insolubility constant and treated as a stability constant for the precipitate. Ringbom's α-coefficient methods[9] are then easily applied for calculation of the minimum pH *etc* permissible, as illustrated in Fig. 1, which should be self-explanatory. Similar diagrams can be prepared to take into account masking agents.

Once the permissible pH range has been calculated from the known values of stability constants, it should be checked experimentally—stability constants are often determined under highly specialized conditions, and the values obtained may be some orders of magnitude different from those for the conditions of the titration. If the constants are not known, they must either be determined or the pH range *etc* determined empirically.

Errors are most likely to arise from co-precipitation, especially from occlusion, because digestion and other means of reducing co-precipitation are not possible in this case. A typical example is the occlusion of AgCl in the determination of iodide by argentometric titration.[10] Normally there should be an exchange reaction between AgCl and I^- to give AgI and Cl^-, but if the AgCl is occluded within AgI particles the

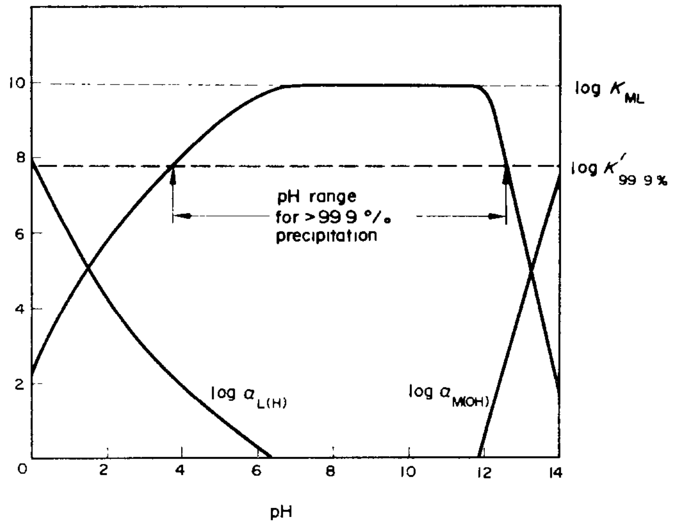

FIG. 1.—Precipitation titration of $10^{-2}M$ metal ion M with ligand H_2L, to form ML, where M forms soluble hydroxo-complexes. K_1 and K_2 for H_2L are 10^2 and 10^6 respectively, K_{sp} for ML is 10^{-10} (*i.e.*, $K_{ins} = 10^{10}$). K_3 and K_4 for $M(OH)_3^-$ and $M(OH)_4^{2-}$ are 10^6 and 10^2 respectively. $K'_{99.9\%}$ = conditional constant for at least 99.9% precipitation at the end-point.

exchange cannot take place, and there is an overconsumption of silver nitrate. The error can be eliminated by adding some ammonium carbonate to make diamminosilver(I) the effective titrant, in which case AgCl cannot precipitate. The effect of all other ions likely to be present in practical applications must therefore be checked experimentally. Precipitation reactions may sometimes be made more selective by judicious use of pH control, auxiliary masking agents, *etc*, but in general the utility of this type of reaction is severely limited by the lack of selectivity.

Further problems arise in the detection of the end-point. If a coloured precipitate is produced at the end of the main reaction, as in the Mohr method for halides, conditions must be carefully adjusted so that the overconsumption of titrant in production of a visible amount of coloured product is just compensated for by the underconsumption of titrant caused by the fact that the coloured product begins to be formed before the main reaction is entirely complete.[11] The situation may be further aggravated by the presence of ions (such as NH_4^+) which are normally thought of as harmless.[12,13] Adsorption indicators are usually fairly good, but often experience is required to recognize the end-point. Amperometric titration is often used, but the errors are seldom less than 1%, which is not surprising in view of the 1–2% error usually associated with polarographic methods. If say 10 points are used to construct the titration graph and there is an error of 2% associated with each, the overall error in assessing the end-point is likely to be about $2/\sqrt{10}\%$ or about 0.6%. In addition, it is customary to use small volumes of fairly concentrated titrant (in order to avoid excessive dilution and the need to apply a dilution correction) and the reading errors will be rather large. Potentiometric detection of the end-point is likely to prove the most satisfactory, provided that the electrodes reach potential equilibrium rapidly—otherwise the method will be too slow to be useful except for special or occasional use.

Conductimetric methods are satisfactory if the conductance can be measured sufficiently precisely (for reasons similar to those discussed for amperometric titrations) and the results are properly interpreted.

Redox reactions

The primary requirements are a means of converting the determinand into essentially the completely oxidized or reduced form, and a titrant capable of completely reducing or oxidizing the product. Obviously an excess of an auxiliary oxidant or reductant will be required in the first step, and this excess must be easily destroyed without the determinand being affected. The formal potentials for the titrant and determinand couples must be sufficiently far apart for the reaction to be at least 99·9% complete at the end-point; that means a difference of at least 0·36 V for two one-electron reactants, but only 0·09 V for a pair of two-electron reactants.

It is important to remember that the products may depend on whether a one-electron couple is matched with a one- or a two-electron couple. Hydrazine is oxidized to nitrogen by a two-electron oxidant, but to a mixture of ammonia and nitrogen by a one-electron reagent.

Examination of the Nernst equation shows that the redox potentials may be profoundly affected by changes in acidity, by complexation, and by precipitation or formation of undissociated compounds.

Effect of acidity. The most noticeable effect is on the potentials of couples involving oxy-anions that are oxidized or reduced. Typical examples are the fact that manganate is unstable in acid solution because of disproportionation, but stable in extremely alkaline solutions, and the fact that the interference of vanadium(IV) in the oxidimetric determination of iron(II) can be eliminated by making the solution 5*M* in sulphuric acid, and so raising the potential of the V(V)/V(IV) couple to a value comparable to that of the usual oxidants. Another effect is preferential protonation of one half of a couple, as for example the ferrocyanide/ferricyanide couple, or the effect of acidity on the potential of ferroin.

A further effect of changes of acidity may be on the kinetics of the reaction. As has recently been shown,[14] potassium chlorate can be used successfully as an oxidative titrant if the acidity is made high enough, though even then a catalyst is sometimes desirable as well.

Effect of complexation. It is well known that the potential of the iron couple can be shifted in either direction by use of complexing agents, the potential being increased if the iron(II) complex is more stable than the iron(III) complex (as with 1,10′-phenanthroline) and lowered if the order of stabilities is reversed (as with phosphate, fluoride, EDTA).

Effect of precipitation etc. The potential of the silver couple is decreased by introduction of an anion that forms an insoluble silver salt, the decrease being the greater the more insoluble the compound. Similarly, formation of an undissociated species such as mercuric chloride or cyanide will remove the ions of one form of the couple and hence shift the potential.

Importance of the Nernst equation. The Nernst equation not only permits calculation of the equilibrium constant (and hence the feasibility of the reaction) from the potentials of the couples involved, but also permits us to calculate the form of the potentiometric titration curve and so choose suitable indicators and decide whether other species may interfere or not by being co-titrated. It also reminds us that we cannot have an *absolutely* pure oxidant or reductant solution if the solvent is capable of redox action. It is for this reason that certain species are unstable in aqueous medium, even if protected from aerial oxidation. It further reveals that lack of thought has led to an incorrect ascription of chemical properties to certain oxidants. Many textbooks state that dichromate and ceric sulphate can be used for titrations in hydrochloric acid medium but permanganate can not. This statement is only partly true: permanganate can certainly be used, *e.g.*, for titration of antimony(III), in chloride medium. It is only unsuitable for use when the oxidation of chloride is induced by another reaction in the system, such as the oxidation of iron(II). The reason for this is that the kinetics of chloride oxidation are so slow at moderate acidities that the end-point can be detected without interference from the slow side-reaction. Unfortunately, however, many chemists read more into the statement than is there, and assume that dichromate and ceric sulphate are incapable of oxidizing chloride—an assumption that is completely false, as a practical test will readily verify.

Importance of kinetics. From what has just been said about permanganate it will be realized that the reaction kinetics may play a decisive part and override the thermodynamics. A good example is the determination of total iron in silicate rock by removal of silica by the Berzelius method, fusion of the metal oxides with pyrosulphate, dissolution in hydrochloric acid, reduction with the silver reductor, and titration with ceric sulphate, with ferroin as indicator.[15] Two difficulties arise: there is a variable blank, and the end-point "returns", that is, there is a sharp colour change followed by slow return of the reduced form of the indicator, and this behaviour is repeated on further addition of small increments of titrant. Both effects are kinetic in origin. The first arises from reduction of aerial oxygen to hydrogen peroxide in the silver reductor. The peroxide should be further reduced to water, but because the first reduction step is much faster than the second there is a build-up of peroxide, a steady state being reached because of the diffusion controlled supply of further oxygen from the air. The peroxide then reacts with iron(II) in the initiation and termination steps of the Haber-Weiss[16] mechanism for catalytic decomposition of peroxide:

$$\begin{aligned}
&Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + \cdot OH \quad \text{(initiation)}\\
&Fe^{2+} + \cdot OH \rightarrow Fe^{3+} + OH^- \quad \text{(termination)}\\
&\left.\begin{aligned}&H_2O_2 + \cdot OH \rightarrow HO_2\cdot + H_2O\\ &HO_2\cdot + H_2O_2 \rightarrow H_2O + O_2 + \cdot OH\end{aligned}\right\}\text{propagation}
\end{aligned}$$

The chain propagation steps are unlikely to have a chance to occur, since the iron is greatly in excess of the peroxide. Similar effects occur with amalgams when they are used in the presence of air.[17] The returning end-point arises because the decomposition reaction takes place in a platinum crucible and some platinum is extracted as Pt(IV) in the fusion process. According to the thermodynamics the Pt(IV) should be reduced to the metal on the silver reductor, but if the reduction is slow and occurs in two stages, *via* Pt(II), and if the residence time in the reductor column is too short (short column and/or fast flow-rate) some Pt(II) passes into the effluent and is oxidized (slowly, of course) after the preferential oxidation of the iron is complete. Fortunately the kinetics are so slow that the first sharp end-point corresponds exactly to the iron titration.[15]

Induced reactions. The Haber-Weiss mechanism just quoted is an example of an induced catalytic reaction. When such reactions can occur, they constitute a hidden source of error, which may be extremely large. In the oxidation of tin(II) with dichromate, for example, induced aerial oxidation accounts for oxidation of no less than 98% of the tin.[18] On the other hand, induced coupled reactions, in which a definite stoichiometry exists between the inductor and the acceptor systems, may be used quantitatively.

End-point detection. Indicators and potentiometry are the means usually chosen for end-point detection. Naturally the indicator potential must be matched to the equivalence point potential of the system, either by choice of indicator or by shift of a potential (*e.g.*, addition of phosphoric acid when diphenylamine is used as indicator for iron(II) oxidation). Potentiometry is satisfactory subject to the usual proviso about the speed of electrode equilibration. Spectrophotometric titration is possible if one component of the titration system has suitable absorption characteristics differing from those of the others, but if the end-point section of the curve is too rounded, dilution corrections may be necessary and are rather tedious to apply.

Complexation and acid-base reactions

The basis of these reactions is formation of a highly stable (*i.e.*, little dissociated) species such as a metal complex or water. The main criterion for successful application to titrimetry is therefore the apparent equilibrium constant for the reaction under the conditions used. In complexation reactions, if the initial metal ion concentration is C_M then for the error to be 1 ppt or less, the concentration of free metal at the end-point must be $\leqslant 10^{-3}\, C_M$, and this must also be the total concentration of uncomplexed titrant in the titration solution. It follows that the minimum value for the apparent stability constant of the complex is $C_M/10^{-6}\, C_M^2$ or $10^6/C_M$. It is therefore advisable to use fairly concentrated solutions for titration of metals that form only weak complexes. The Ringbom[9] conditional constant method can again be used to predict the minimum pH required for complete titration. It is not always recognized, however, that it is really the indicator reaction which sets the lower boundary of the permissible pH range. In the case of a weak metal-indicator complex it would be possible to find a pH at which the metal-titrant complex could be formed quantitatively while the metal-indicator complex was formed scarcely or not at all. The upper boundary of the pH range is set either by the hydrolysis characteristics of the metal ion or by the nature of the indicator. Almost all metallochromic indicators are also acid-base indicators, the colours of their metal complexes being essentially those of the species obtained on removal of one proton (sometimes more) from the indicator. For a colour change to occur at the end-point, from the colour of the metal-indicator complex to that of the free indicator, the pH must be below that at which the indicator would be deprotonated anyway. The whole system is illustrated in Fig. 2.

It is possible to achieve selectivity of complexation by pH control if the metal ions present form complexes with the titrant, with sufficiently different stability constants (Fig. 2). For ions giving complexes with similar stabilities, auxiliary masking agents are used to achieve selectivity. When the pH is adjusted it is important to remember that the buffer system must not contain ions that can act as competing ligands.[19] It is also important to remember that the buffer must have sufficient capacity to absorb the protons released during the complexation reaction.

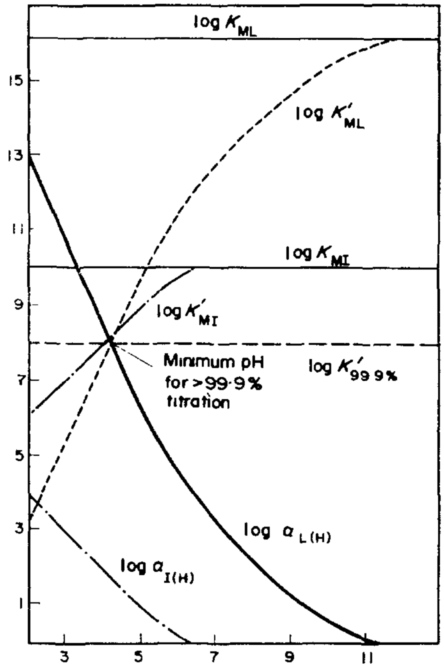

FIG. 2.—Complexation titration of $10^{-2}M$ metal ion M with ligand HL to form ML, with indicator HI. $K_{ML} = 10^{16}$; $K_{MI} = 10^{10}$; $K_{HI} = 10^{6}$; HL is EDTA. $K'_{99.9\%}$ = conditional constant for at least 99.9% completion of complexation at the end-point.

Acid-base reactions can be treated as a special case of complexation, in the simpler cases there being competition between two anions to form an undissociated species with protons. The decisive factor is the equilibrium constant for the reaction

$$HA + OH^- \rightleftharpoons A^- + H_2O$$

$$K_{eq} = \frac{[H_2O][A^-]}{[HA][OH^-]} = \frac{K_w}{K_{HA}}$$

where

$$K_w = [H_2O]/[H^+][OH^-]; \quad K_{HA} = [HA]/[H^+][A^-]$$

If the initial concentration of acid is C_{HA}, then for 99·9% neutralization the final concentration is $10^{-3}\,C_{HA}$, and since at equilibrium [HA] = [OH⁻], it follows that K_{eq} must be greater than $10^6/C_{HA}$ for quantitative titration ($[A^-]$ will be approximately equal to C_{HA} at equivalence). If we approximate a little and use "mixed" stability constants, we can call the activity of water unity and take K_w as 10^{14}. In that case K_{HA} must be less than $K_w \cdot C_{HA}/10^6$, *i.e.*, less than $10^8\,C_{HA}$, for quantitative titration.

If the acid is weaker than this, either a larger error must be accepted or the conditions must be changed to make the acid appear to be stronger. One way of doing this is to introduce a metal ion that will form a complex with A^-, thus releasing protons from HA; care must be taken, however, to choose a metal ion that will not itself interfere by a hydrolysis reaction. The more common method is to change the value of K_{eq} by changing the solvent system. The use of and choice of non-aqueous solvents have been adequately discussed in various monographs[20–22] and need not be dwelt on here.

End-point detection. The most common methods for end-point detection are by means of indicators, potentiometry, spectrophotometry, conductimetry and thermometry or enthalpimetry.

In complexation reactions the indicator must of necessity form with the determinand ion a complex that is less stable than the complex formed by the determinand and titrant. If the two complexes are of comparable stability there will be an end-point error that is a function of the amount of indicator added. An example is the use of Xylenol Orange for titration of lead with EDTA. It is also essential that the indicator should not be "blocked" by the presence of other metal ions that form with it complexes more stable than the determinand-indicator complex. Adequate buffering is also necessary to prevent appearance of a false end-point by virtue of decomposition of the indicator complex by reaction with the protons released as the main reaction proceeds. It is also most important that the transition interval should be as sharp as possible. If an appreciable volume of titrant is required to traverse the end-point colour change, and two elements are being determined in the same sample by titration of the sum followed by masking of one and titration of the complexant released, there will be an error if the "sum" titration end-point is taken as appearance of the free indicator colour but the back-titration end-point is the colour of metal-indicator complex. It is essential to use the same end-point colour in both cases. The general theory of these indicators has been well covered by Ringbom.[9] The theory of acid-base indicators is well known, and it need only be stressed that the pK value of the indicator must match the pH at the equivalence point, and that adequate precautions must be taken to avoid interference by carbon dioxide in the atmosphere.

Potentiometry has already been discussed, and fortunately the glass electrode has a very rapid response and equilibration, so is ideal for potentiometric acid-base titration. The limitations of conductimetry (and amperometry) have been dealt with above and will apply here also. Spectrophotometry has been dealt with in a monograph,[23] and the theory of spectrophotometric complexation titrations adequately covered.[24,25] Thermometric and enthalpimetric methods are relatively new, but are really useful only if relatively large errors (1% or more) are acceptable. Perusal of some of the literature on these methods shows that when comparisons are made between thermometric and classical indicator methods, the errors reported for the latter are very often greatly in excess of the values that are obtainable by careful work.

Interferences. In complexation reactions, interfering ions may be dealt with by pH control or selective masking, as pointed out above. A subtle form of interference may arise, however, from the use of masking agents. It sometimes happens that a masking agent added to sequester an interfering element can act as a bridging ligand to form a mixed-metal binuclear complex with the determinand ion. If this complex happens to be inert (*i.e.*, kinetically stabilized) then the determinand ion will not react with the titrant. Such is the case with aluminium in the presence of uranyl ions and citrate.[26] Similar cases are those of copper in the presence of chromium and citrate,[27] and copper in presence of aluminium and tartrate.[28]

In acid-base reactions, the interferences are those caused by the presence of other acids or bases besides the determinand. If the strengths of the various species differ sufficiently it may be possible to titrate them consecutively, provided means of detecting the end-points are available. If the strengths are comparable, selective complexation or a change of solvent may give sufficient differentiation.

GENERAL FACTORS INFLUENCING TITRIMETRIC METHODS

Ionic strength and variations in concentration

The ionic strength can affect both the velocity and the quantitativeness of a chemical reaction, the effect being largely a function of the charges on the reacting species.[29,30] In a titration there must inevitably be a change in ionic strength in the course of the reaction, but fortunately most analytical procedures require the use of concentrations at which activity coefficients change relatively little with variation in ionic strength,[31] so it is unlikely that the ionic strength will be a serious factor. If it is, the effect can usually be "swamped" by addition of a large and constant amount of an indifferent electrolyte.

Changes in the concentration of the reactants cause a change in the reaction velocity. This is seen in the decrease in the reaction velocity near the equivalence point, a feature of practical utility (the entering stream of titrant reacts immediately in the early part of a titration, but disperses sluggishly near the end-point, so that at the point of entry the indicator has changed colour). It is therefore convenient to keep the reactant concentrations fairly constant during the preliminary investigations. Later the concentrations can be varied, especially with a view to finding the lowest concentrations that can be used satisfactorily.

Temperature

A change in temperature influences the reaction velocity and the equilibrium constant, and sometimes even the stoichiometry. Sometimes a higher temperature is used deliberately to make a slow reaction more practicable, and sometimes a very low temperature is used to make an interfering reaction so slow that its effect is nullified (so-called "kinetic masking").

Ideally, room temperature should be the optimum, but it is necessary to investigate the effect of changing the temperature because "room" temperature may vary from a few degrees in winter in Scotland to 30° or more in summer in India. High temperatures are undesirable because they may cause unfavourable effects such as decrease in stability of reactants, thermal decomposition, reaction with solvent, increasing probability of side-reactions occurring. If higher temperatures are unavoidable, a "safe" range must be found in which these undesirable effects do not occur.

Catalysis

Catalysts are sometimes added to change the reaction velocity or the mechanism of reaction, especially in redox systems. Catalysts are associated with particular reactions, and there is no general theory for prediction of which catalyst will prove convenient. Catalysts are usually found by trial and error, with the initial choice based on experience. Sometimes autocatalysis occurs, in which a reaction product itself catalyses the reaction. Induced reactions are sometimes used, but as pointed out above, unwanted ones can be a source of error.

Stability of reagents

It sometimes happens that though a titrant may be stable in aqueous solution when it is being stored, it may become less stable under the conditions used for the titration, especially if these are particularly drastic in terms of acidity or alkalinity. The effect is most likely to be observed in an indirect procedure, in which an excess of reagent must be added and the mixture left for some time for the reaction to reach completion, followed by back-titration of the excess. In such cases it is necessary to check the stability of the reagent by running a number of blank determinations with different amounts of reagent present.

Indicator solutions may not be stable on storage, especially in the case of complexometric indicators. Xylenol Orange, for example, oxidizes slowly in aqueous solution, and the oxidation product will give a coloured complex only with copper(II). The storage life of all reagents should be checked and appropriate recommendations made for their preparation.

End-point sharpness

The accuracy of a titration will be partly determined by the volume of titrant required to traverse the end-point, and on how accurately the end-point can be located within that volume. As discussed in specialist texts and articles,[32] the equivalence point may not exactly correspond to the end-point, and a correction may be necessary. The correction may be calculated or empirical. The "sharpness index" or "relative precision"[33] may be used as a means of indicating the size of the end-point error. It is essential that *some* numerical value be given for the sharpness. If indicators are used, the volume of titrant needed to give the complete colour change must be determined and reported, and if possible the colours should be described in terms of the C.I.E. indices.[34]

Other influences

Electromagnetic radiation, usually in the form of visible or ultraviolet light, can not only affect the stability of the reactants but may also participate in the reaction or accelerate or introduce side-reactions. It is therefore sometimes necessary to perform titrations under special lighting conditions, and in indirect determinations it is often necessary to keep the reaction mixture in the dark during the reaction period before the back-titration.

Ultrasonic waves have occasionally been used to affect the course of a reaction. Pressure changes, though often used in technology, are not used in titrations, because of the experimental complications introduced.

RESULTS AND APPLICATIONS

Once the method has been worked out, it is necessary to validate it by standardization, and by application to standard samples containing the species of interest. The standardization is customarily done by preparing a standard solution of known concentration and titrating equal portions of it. In our opinion this is not a sound practice. First, all measurements are made by volume, and as discussed by Conway,[35] it is then necessary to calibrate all apparatus used, so that the personal error may be assessed. Secondly, once the first titration has been done, the tendency is to add rapidly almost the required volume of titrant to the second sample and only the last few drops are added slowly. The result is a variable drainage error, if a normal gravity-feed burette is used.[35] Furthermore, if fractions of a division are estimated in reading the burette, there is an unconscious urge to make the readings agree as closely as possible. It is much more reliable to make up the standard solution by weight and to take different weight fractions of it. Each titration must then be done more or less individually without reference to the others (unless the operator is unable to resist doing mental arithmetic), and the error in the amount of sample taken will be virtually eliminated. If a sufficiently wide range of sample weights is taken, a plot of "taken" against "found" will reveal any bias in the results, and the existence of any "blank" correction. Repetition of the procedure in the presence of the other elements expected to occur in any applications will reveal the extent of any interference by these species. The concentration ratios used must be realistic.[3]

Finally, the method must be applied to standard samples of the materials for which it is suitable, and the results compared statistically with those obtained by the best previously existing methods. It is essential to have enough replicate determinations to make the statistics meaningful, and the Snedecor F-test or "Student's" t should be applied as a criterion of significant improvement.[36]

PUBLICATION OF RESULTS

If the work has been successful, then in the preparation of a paper for publication it is necessary to report on all the features dealt with above. In particular, attention must be paid to the following points.

1. Stability of reagents, and special precautions to be taken in their preparation and storage.
2. Standardization of reagents and calibration of apparatus, with details given of the errors actually obtained.
3. Proof of the stoichiometry, and establishment of the tolerance ranges[37] for concentrations of reactants, interferents, and other species necessarily present.
4. The speed of the reaction, especially with regard to end-point detection and to the standing time in the case of indirect determinations.
5. The nature of the end-point detection, with specification of sharpness of any colour changes, details of indicator corrections or other end-point corrections. In cases of "dead-stop" methods *etc*, the response time of the indicating system should be expressed in terms of amount of titrant added, if the titrant is being added automatically or generated electrolytically. In coulometric work the current efficiency must be determined, and the timing error should be established and reported.
6. In description of the procedure, all tolerances on amounts of reagents should be clearly stated, and any special precautions stated.[37]
7. There must be adequate validation of results, supported by statistical analysis.
8. Applications of the method must be proposed and at least some of them validated experimentally. There must be a proper comparison with existing methods.
9. If possible, the method should be tested by someone who has not used it before, and *those* results quoted as well.

Résumé—On a établi les conditions nécessaires pour le développement de méthodes titrimétriques et pour la rédaction du travail pour publication. On discute des principes généraux de divers types de réaction de titrage, et l'on prête particulièrement attention aux paramètres qui influent sur les réactions chimiques.

Zusammenfassung—Die Anforderungen an die Ausarbeitung titrimetrischer Methoden und an zu publizierende Manuskripte mit solchen Themen werden aufgeführt. Die allgemeinen Grundlagen für verschiedene Typen von Titrationsreaktionen werden erörtert und dabei besonderes Gewicht auf die Parameter gelegt, die chemische Reaktionen beeinflussen.

ON THE ELECTROLYTIC ACCUMULATION OF HALIDE IONS AT HANGING MERCURY DROP ELECTRODES

A. BARAŃSKI and Z. GALUS
Institute of Fundamental Problems of Chemistry, University of Warsaw, Warsaw, Poland

(*Received* 27 *June* 1971. *Accepted* 7 *November* 1971)

Summary—The process of electrolytic accumulation of halide ions as Hg_2X_2 at the hanging mercury drop electrode is considered theoretically. The efficiency of this process is explained by considering various chemical reactions of mercury ions with halogens, and the adsorption of Hg_2X_2. The agreement of these considerations with experimental results obtained by other authors is found to be satisfactory.

ANODIC-STRIPPING VOLTAMMETRY has gained wide application[1] as a sensitive method for determination of trace metal ion impurities. The anodic stripping is preceded by electrolytic accumulation in the hanging mercury drop electrode (HMDE), of the metal to be determined. This method may also be applied with considerable success to the determination of anions[2,3] by the formation (in the accumulation step) of sparingly soluble salts of the anions with mercurous ions. However, some aspects of the anion determination are not yet clear. For instance the complex character of the dependence of electrolytic accumulation on potential, and the relatively low sensitivity in comparison to metal ion determination, have not been fully explained. These problems will be discussed in the present paper.

The anomalous dependence of the efficiency of accumulation on potential, observed in the determination of halide ions, has been explained[2] in terms of crystallization of mercurous halide at some distance from the electrode if electrolytic accumulation was achieved at very positive potentials. These microcrystals should not be adsorbed at the solution–mercury interface. The occurrence of such crystallization in very dilute solutions (10^{-5}–$10^{-6}M$) does not seem very probable. The anomalous effects may also be explained by taking into account the formation of complexes of the anions with mercury ions, and later diffusion of the complexes away from the surface of the electrode. Kemula and Taraszewska[4] have attempted to explain the sensitivity limits of the determination of halides, based on precipitate complex equilibria, but satisfactory results were obtained only for chloride.

THEORETICAL

During electrolytic accumulation of halide ions on the mercury electrode the following reactions take place:

$$2Hg + 2X^- \rightleftharpoons Hg_2X_2 + 2e \quad (1)$$

$$2Hg \rightleftharpoons Hg_2^{2+} + 2e \quad (2)$$

$$Hg + nX^- \rightleftharpoons HgX_n^{2-n} + 2e \quad (3)$$

where $n = 0, 1, 2, 3, \ldots$

Hg_2X_2 is adsorbed on the electrode, the other products of reactions (2) and (3) diffuse away. Since the activity of the halide ions increases with distance from the electrode the following interactions may occur

$$HgX_n^{2-n} + X^- \rightleftharpoons HgX_{n+1}^{1-n} \qquad (4)$$

$$Hg_2^{2+} + 2X^- \rightleftharpoons Hg_2X_2 \qquad (5)$$

$$Hg_2^{2+} \rightleftharpoons Hg^{2+} + Hg(aq) \qquad (6)$$

We have to assume that the products of these reactions are in a state of molecular distribution. This assumption is indisputable in respect to the products of (4) and (6), and should also be fulfilled in respect to reaction (5) since the concentrations of the reactants are low. Also, if $[Hg_2^{2+}] < [X^-]$ the role of reaction (5) should be small.

The equations describing the concentrations of various species existing in the solution may be obtained from Fick's second law of diffusion with the addition of kinetic terms. By taking the sum of these equations we obtain

$$\frac{\partial C_X^*(x,t)}{\partial t} = D\frac{\partial^2 C_X^*(x,t)}{\partial x^2} \qquad (7)$$

where D is the diffusion coefficient (equal for all species), and $C_X^*(x,t)$, the analytical concentration of halide, is given by

$$C_X^*(x,t) = C_X(x,t) + 2C_{Hg_2X_2}(x,t) + \sum_{n=1}^{N} nC_{HgX_n}(x,t) \qquad (8)$$

By consideration of mass balance we obtain

$$\frac{d\Gamma_{Hg_2X_2}}{dt} = \frac{1}{2}D\left(\frac{\partial C_X^*}{\partial x}\right)_{x=0} \qquad (9)$$

where $\Gamma_{Hg_2X_2}$ denotes the surface concentration of the accumulated species. Using the solutions to equation (7) we may write (*a*) for a plane electrode in quiet solutions

$$\frac{d\Gamma_{Hg_2X_2}}{dt} = \frac{1}{2}\frac{D^{1/2}}{(\pi t)^{1/2}}[C_X^0 - C_X^*(x=0)] \qquad (10)$$

and (*b*) for accumulation with uniform mixing of the solution

$$\frac{d\Gamma_{Hg_2X_2}}{dt} = \frac{1}{2}\frac{D}{\delta}[C_X^0 - C_X^*(x=0)] \qquad (11)$$

where C_X^0 and C_X^* $(x = 0)$ denote the analytical concentrations of X^- in the bulk of the solution and at the surface of the electrode respectively, and δ is the thickness of the diffusion layer.

The function $\varphi = [C_X^0 - C_X^*(x=0)]/C_X^0$ (the coefficient of efficiency of electrolytic accumulation) is also introduced. This function may be calculated on the assumption that all processes occurring at the surface of the electrode are reversible. Then the concentrations of all species at the electrode surface may be calculated from the following equilibria

$$[Hg_2^{2+}] = \exp\frac{2F}{RT}(E - E^0) \qquad (12)$$

$$[Hg^{2+}] = K[Hg_2^{2+}] \qquad (13)$$

$$[Hg_2^{2+}][X^-]^2 = K_{s0}f(\theta) \qquad (14)$$

$$[HgX_n^{2-n}] = \beta n[Hg^{2+}][X^-]^n \qquad (15)$$

$$[Hg_2X_2]_b \sim 0 \qquad (16)$$

where E^0 is the standard potential of the Hg_2^{2+}/Hg couple, K_{s0} the solubility product of Hg_2X_2, β_n the stability constants of the halide complexes, and $[Hg_2X_2]_b$ the bulk concentration of Hg_2X_2.

From these arguments we obtain

$$\varphi = 1 - \frac{1}{C_X^0}\left\{\sqrt{K_{s0}f(\theta)}\exp\left[\frac{-F(E-E^0)}{RT}\right] + \sum_{n=1}^{N} n\beta_n K\,[K_{s0}f(\theta)]^{n/2}\exp\left[\frac{(2-n)F(E-E^0)}{RT}\right]\right\} \qquad (17)$$

In these equations $f(\theta)$ denotes the activity of Hg_2X_2 on the surface of the electrode, as a function of the degree of coverage θ ($\theta = \Gamma/\Gamma_m$). Alternatively, $f(\theta)$ may be formulated in terms of the dependence of the equilibrium adsorption $\Gamma_{Hg_2X_2}$ on $[Hg_2X_2]_b$ where

$$[Hg_2X_2]_b = \beta_2{}^*[Hg_2^{2+}][X^-]^2 \qquad (18)$$

If for $\theta < 1$ we assume that the Langmuir isotherm is obeyed, then

$$[Hg_2X_2]_b = \frac{\beta\theta}{1-\theta} \qquad (19)$$

and

$$[Hg_2^{2+}][X^-]^2 = \frac{\beta\theta}{\beta_2{}^*(1-\theta)} \qquad (20)$$

From (14) and (20) we obtain

$$f(\theta) = \frac{\beta\theta}{K_{s2}(1-\theta)} \qquad (21)$$

where β is the equilibrium adsorption constant and $K_{s2} = \beta_2{}^*K_{s0}$. When $[Hg_2X_2]$ reaches the K_{s2} value, crystallization begins, $\theta > 1$ and multilayers form on the surface of the electrode.

Then

$$[Hg_2^{2+}][X^-]^2 = \frac{K_{s2}}{\beta_2{}^*} = K_{s0}$$

and

$$f(\theta) = 1$$

It is not useful to apply equation (21) together with (17) in these considerations, because the value of $\beta_2{}^*$ is not known. Furthermore, additional experiments should be carried out to find whether the Langmuir adsorption is obeyed. The potential dependence of the adsorption constant should also be determined. It will not be possible then, to calculate precisely the efficiency of the electrolytic accumulation; however, some other interesting parameters of the accumulation process may be predicted. The value of $f(\theta)$ may be determined only by experimentation; its determination will be difficult, however, even if it is possible.

Since in systems with halide concentrations lower then $10^{-4}M$ only the complexes HgX and HgX_2 are present, equation (17) may be simplified to

$$\varphi = 1 - \frac{2}{C_X^0}\left\{\beta_2KK_{s0}f(\theta) + \sqrt{\beta_1KK_{s0}f(\theta)}\cosh\left[\frac{F(E-E_{max})}{RT}\right]\right\} \qquad (22)$$

where

$$E_{\max} = E^0 - \frac{RT}{2F} \ln \beta_1 K$$

If $f(\theta)$ and the constants in (22) are assumed to be independent of the potential then $E_{\max}$ determines the potential of the maximum efficiency of electrolytic accumulation. In Fig. 1 the dependence of φ on E for Cl^-, Br^- and I^- is given, calculated with the use of equation (22), assuming $f(\theta) = 1$ and $C_X{}^0 = 10^{-5}M$.

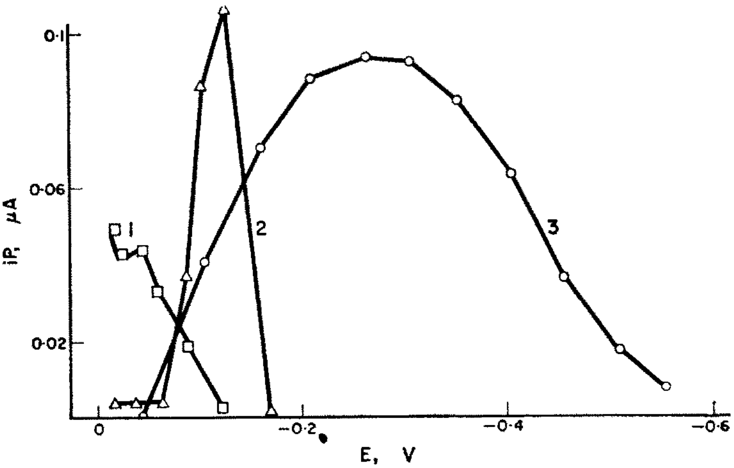

FIG. 1.—The dependence of the coefficient of efficiency of electrolytic accumulation on the accumulation potential, calculated according to equation (22) for Cl^- (curve 1), Br^- (2), and I^- (3).

The following values were used in the calculation:

$f(\theta) = 1$, $C_X{}^0 = 10^{-5}M$, $\log K = -1{\cdot}94$[5];
$\log \beta_1 = 6{\cdot}74$, $\log \beta_2 = 13{\cdot}22$, $\log K_{s0} = -16{\cdot}88$ for Cl^- [5];
$\log \beta_1 = 9{\cdot}02$, $\log \beta_2 = 17{\cdot}30$, $\log K_{s0} = -21{\cdot}28$ for Br^- [6];
$\log \beta_1 = 12{\cdot}87$, $\log \beta_2 = 23{\cdot}79$, $\log K_{s0} = -27{\cdot}46$ for I^-.[7]
Potentials are given with respect to the $Hg/Hg_2SO_4/1M\ H_2SO_4$ electrode.

An important relationship, from the analytical point of view, between time of electrolytic accumulation and $\Gamma_{Hg_2X_2}$ may be formulated on the basis of equations (10), (11) and (22). It is scarcely possible to give a strict time dependence if the function $f(\theta)$ is not precisely defined; however, the asymptotic solutions may be obtained for times that are short or long in comparison to the time needed to obtain full coverage of the electrode by a monolayer.

1. Short accumulation times.

When $t \to 0$ then $\theta \to 0$, $f(\theta) \to 0$ and $\varphi \to 1$.

If the accumulation is carried out in quiet solutions then

$$\Gamma_{Hg_2X_2} = \sqrt{\frac{Dt}{\pi}}\, C_X{}^0 \tag{23}$$

and for stirred solutions,

$$\Gamma_{Hg_2X_2} = \frac{D}{2\delta}\, C_X{}^0 t \tag{24}$$

2. Long accumulation times.

Two cases may be distinguished, in dependence on $C_X{}^0$.

When

$$C_X{}^0 > L_1(E)$$

where

$$L_1(E) = 2\left\{\beta_2 KK_{s0} + \sqrt{\beta_1 KK_{s0}}\cosh\left[\frac{F(E - E_{\max})}{RT}\right]\right\}$$

and $t \rightarrow \infty$, then $f(\theta) = 1$, $\varphi = \text{const.}$

For solutions not stirred during electrolytic accumulation we have

$$\Gamma_{Hg_2X_2} = C_1 + \sqrt{\frac{Dt}{\pi}}\,\varphi C_X{}^0 \tag{25}$$

For stirred solutions

$$\Gamma_{Hg_2X_2} = C_2 + \frac{DC_X{}^0}{2\delta}\,\varphi t \tag{26}$$

where C_1 and C_2 are constants equal to or larger then 0.

Equations (25) and (26) are valid as long as the transport of ions from the bulk of the solution is slower then the rate of the transport through the layer covering the electrode surface.

In the second case

$$C_X{}^0 < L_1(E)$$

and the coefficient of efficiency of electrolytic accumulation will assume positive values only for $f(\theta) < 1$. This means that θ cannot be larger then $\theta_{\max}$, which itself is independent of the mode of electrolytic accumulation. The function $f(\theta_{\max})$ may be defined from equation (22).

When $t \rightarrow \infty$, then $\varphi \rightarrow 0$ and

$$f(\theta_{\max}) = \frac{C_X{}^0}{2\beta_2 KK_{s0}}\left[\sqrt{\frac{L_2(E)}{C_X{}^0}} + 1 - \sqrt{\frac{L_2(E)}{C_X{}^0}}\right]^2 \tag{27}$$

where

$$L_2(E) = \frac{\beta_1}{2\beta_2}\cosh^2\left[\frac{F(E - E_{\max})}{RT}\right] \tag{28}$$

In Fig. 2a the dependence of $f(\theta_{\max})$ on E, calculated with the use of equation (27), is given for $10^{-6}M$ Cl^-, Br^-, I^-. In Fig. 3 the dependence of $\Gamma_{Hg_2X_2}$ on t is shown for various concentration ranges and electrolytic accumulation with uniform stirring of the solution.

Comparison of theory with experiment

The experimental dependence of peak current (i_p) of accumulated Hg_2X_2 on the deposition potential, found by Kemula, Kublik and Taraszewska[2] in their chronovoltammetric determination of halide ions with the use of the HMDE is given in Fig. 2b. A similar dependence was found by Perchard, Buvet and Molina.[3] The equations (22) and (27) explain these experiments semi-quantitatively. A strict quantitative correlation between φ or $f(\theta_{\max})$ and i_p calls for experimental determination of $f(\theta)$ and $i_p(\theta)$. One may suppose that for low coverages both dependences are linear; this may, however, be confirmed only by experiment.

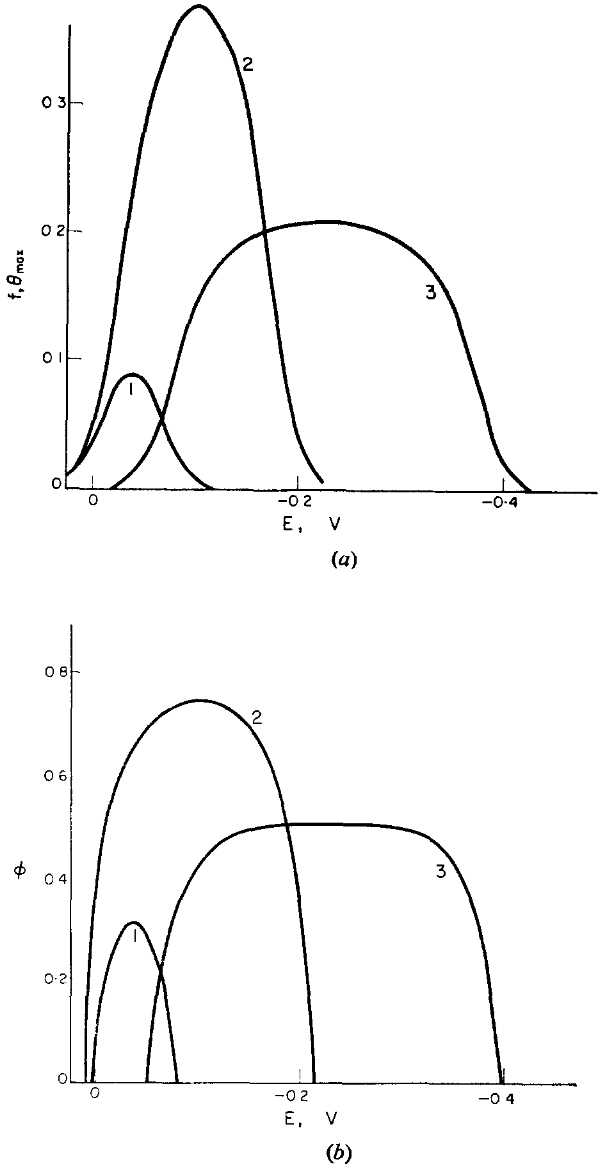

FIG. 2.—(*a*) The dependence of $f(\theta_{max})$ on the accumulation potential, calculated according to equation (27) for Cl^- (curve 1), Br^-(2) and I^-(3).

The values of equilibrium constants were taken from the literature[5–8] and $C_X{}^0$ was assumed to be $10^{-6}M$. The potential is given with respect to the $Hg/Hg_2SO_4/1M$ H_2SO_4 electrode

(*b*) Experimental dependence of peak current on the accumulation potential[2] for determination of $10^{-5}M$ Cl^- (curve 1), $10^{-6}M$ Br^-(2); $10^{-6}M$ I^-(3). In experiments with the HMDE, 0·01*N* H_2SO_4 served as background electrolyte, and the accumulation time was 120 sec.

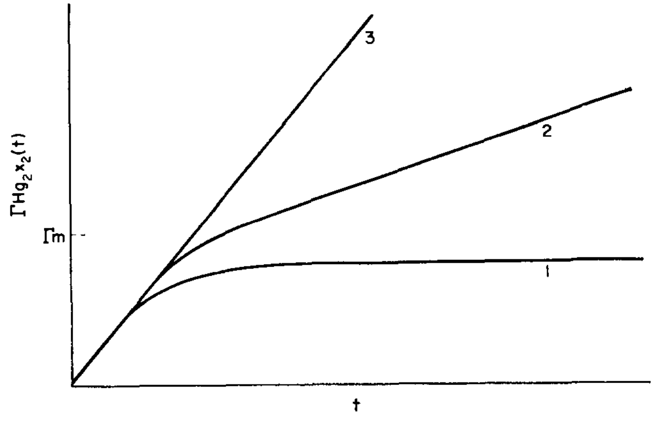

FIG 3.—Dependence of $\Gamma_{Hg_2X_2}$ on t, obtained with use of equations (24), (26) and (27). Curve 1 for $C_X{}^0 < L_1(E)$, curve 2 for $C_X{}^0 > L_1(E)$ and curve 3 for $C_X{}^0 \gg L_1(E)$.

A satisfactory agreement was found between the theoretical and experimental potentials for maximum efficiency of the electrolytic accumulation (Table I). Experimental values of E_{max} were taken from figures given in both the cited papers.

The small differences in E_{max} may be due to different concentrations of background electrolytes and their influence on the adsorption equilibrium constant. The specific adsorption of $SO_4{}^{2-}$ and $ClO_4{}^-$ ions and their interaction with Hg_2X_2 in the adsorbed state may also be responsible for these differences.

TABLE I.—EXPERIMENTAL AND THEORETICAL POTENTIAL E_{max}

Ion	E_{max} theoretical, mV	E_{max} experimental, mV	
		Ref. 2*	Ref. 3†
Cl^-	−37	−45	−87
Br^-	−105	−127	−82
I^-	−222	−258	−232

* Composition of the solutions: Cl^- $10^{-5}M$; Br^- $10^{-6}M$; I^- $10^{-6}M$; all in $0{\cdot}01N$ H_2SO_4

† Composition of the solutions: Cl^- $5 \times 10^{-4}M$; Br^- $5 \times 10^{-5}M$; I^- $5 \times 10^{-6}M$; all in $0{\cdot}1M$ $HClO_4$.

The theoretical dependence of $\Gamma_{Hg_2X_2}$ on t may be compared with experiments carried out to establish the dependence of i_p on the time of electrolytic accumulation. The assumption that the peak current is linearly dependent on $\Gamma_{Hg_2X_2}$ has to be made. Such a linear dependence was found by Perchard *et al.*[3] in their study of deposition of chlorides from $5 \times 10^{-5}M$ solution. This dependence corresponds to curve 3 in Fig. 3. The magnitude of the measured peak currents indicates multilayer coverage.

The same authors, in their determination of Cl^-, Br^- and I^- at concentrations not exceeding $10^{-5}M$ found a linear i_p–t relationship only for short accumulation times. With longer times the peak current was independent of the time of deposition, as is illustrated by curve 1 in Fig. 3. In this case the peak current shows that the electrode coverage at its maximum is a monolayer. Such a dependence was found also by Kemula, Kublik and Taraszewska.[2]

The limiting experimental value of concentration, $10^{-5}M$, agrees with the theoretical value of $L_1(E_{\max})$ which is $7 \cdot 3 \times 10^{-6}$, $1 \cdot 3 \times 10^{-6}$ and $4 \cdot 4 \times 10^{-6}M$ for Cl^-, Br^- and I^- respectively.

The considerations presented do not give a complete and precise picture of the process of electrolytic accumulation of halogen ions at mercury electrodes, since they are limited to dealing with the transport phenomena. The full knowledge of this process, especially at low coverages, calls for the determination of the mode of adsorption. We intend to study this problem in the near future.

The arguments given refer to halide ions, but similar reasoning may be applied to other systems.

Zusammenfassung—Die elektrolytische Anreicherung von Halogenidionen als Hg_2X_2 am hängenden Quecksilbertropfen wird theoretisch erörtert. Zur Erklärung werden verschiedene chemische Reaktionen von Quecksilberionen mit Halogenen in Betracht gezogen sowie die Adsorption von Hg_2X_2. Die Übereinstimmung mit den Versuchsergebnissen anderer Autoren ist zufriedenstellend.

Résumé—On considére thèoriquement le processus d'accumulation èlectrolytique d'ions halogènures à l'ètat Hg_2X_2 sur l'èlectrode à goutte de mercure pendante. L'efficacité de ce processus est expliquée en considérant diverses réactions chimiques d'ions mercure avec les halogènes, et l'adsorption de Hg_2X_2. On a trouvé satisfaisant l'accord de ces considérations avec les résultats expérimentaux obtenus par d'autres auteurs.

ON THE ELECTROLYTIC ACCUMULATION OF HALIDE IONS AT HANGING MERCURY DROP ELECTRODES

A. Barański and Z. Galus
Institute of Fundamental Problems of Chemistry, University of Warsaw, Warsaw, Poland

(*Received* 27 *June* 1971. *Accepted* 7 *November* 1971)

Summary—The process of electrolytic accumulation of halide ions as Hg_2X_2 at the hanging mercury drop electrode is considered theoretically. The efficiency of this process is explained by considering various chemical reactions of mercury ions with halogens, and the adsorption of Hg_2X_2. The agreement of these considerations with experimental results obtained by other authors is found to be satisfactory.

Anodic-stripping voltammetry has gained wide application[1] as a sensitive method for determination of trace metal ion impurities. The anodic stripping is preceded by electrolytic accumulation in the hanging mercury drop electrode (HMDE), of the metal to be determined. This method may also be applied with considerable success to the determination of anions[2,3] by the formation (in the accumulation step) of sparingly soluble salts of the anions with mercurous ions. However, some aspects of the anion determination are not yet clear. For instance the complex character of the dependence of electrolytic accumulation on potential, and the relatively low sensitivity in comparison to metal ion determination, have not been fully explained. These problems will be discussed in the present paper.

The anomalous dependence of the efficiency of accumulation on potential, observed in the determination of halide ions, has been explained[2] in terms of crystallization of mercurous halide at some distance from the electrode if electrolytic accumulation was achieved at very positive potentials. These microcrystals should not be adsorbed at the solution–mercury interface. The occurrence of such crystallization in very dilute solutions (10^{-5}–$10^{-6}M$) does not seem very probable. The anomalous effects may also be explained by taking into account the formation of complexes of the anions with mercury ions, and later diffusion of the complexes away from the surface of the electrode. Kemula and Taraszewska[4] have attempted to explain the sensitivity limits of the determination of halides, based on precipitate complex equilibria, but satisfactory results were obtained only for chloride.

THEORETICAL

During electrolytic accumulation of halide ions on the mercury electrode the following reactions take place:

$$2Hg + 2X^- \rightleftharpoons Hg_2X_2 + 2e \tag{1}$$

$$2Hg \rightleftharpoons Hg_2^{2+} + 2e \tag{2}$$

$$Hg + nX^- \rightleftharpoons HgX_n^{2-n} + 2e \tag{3}$$

where $n = 0, 1, 2, 3, \ldots$

Hg_2X_2 is adsorbed on the electrode, the other products of reactions (2) and (3) diffuse away. Since the activity of the halide ions increases with distance from the electrode the following interactions may occur

$$HgX_n^{2-n} + X^- \rightleftharpoons HgX_{n+1}^{1-n} \tag{4}$$

$$Hg_2^{2+} + 2X^- \rightleftharpoons Hg_2X_2 \tag{5}$$

$$Hg_2^{2+} \rightleftharpoons Hg^{2+} + Hg(aq) \tag{6}$$

We have to assume that the products of these reactions are in a state of molecular distribution. This assumption is indisputable in respect to the products of (4) and (6), and should also be fulfilled in respect to reaction (5) since the concentrations of the reactants are low. Also, if $[Hg_2^{2+}] < [X^-]$ the role of reaction (5) should be small.

The equations describing the concentrations of various species existing in the solution may be obtained from Fick's second law of diffusion with the addition of kinetic terms. By taking the sum of these equations we obtain

$$\frac{\partial C_X^*(x, t)}{\partial t} = D\frac{\partial^2 C_X^*(x, t)}{\partial x^2} \tag{7}$$

where D is the diffusion coefficient (equal for all species), and $C_X^*(x, t)$, the analytical concentration of halide, is given by

$$C_X^*(x, t) = C_X(x, t) + 2C_{Hg_2X_2}(x, t) + \sum_{n=1}^{N} nC_{HgX_n}(x, t) \tag{8}$$

By consideration of mass balance we obtain

$$\frac{d\Gamma_{Hg_2X_2}}{dt} = \frac{1}{2}D\left(\frac{\partial C_X^*}{\partial x}\right)_{x=0} \tag{9}$$

where $\Gamma_{Hg_2X_2}$ denotes the surface concentration of the accumulated species. Using the solutions to equation (7) we may write (*a*) for a plane electrode in quiet solutions

$$\frac{d\Gamma_{Hg_2X_2}}{dt} = \frac{1}{2}\frac{D^{1/2}}{(\pi t)^{1/2}}[C_X^0 - C_X^* (x = 0)] \tag{10}$$

and (*b*) for accumulation with uniform mixing of the solution

$$\frac{d\Gamma_{Hg_2X_2}}{dt} = \frac{1}{2}\frac{D}{\delta}[C_X^0 - C_X^* (x = 0)] \tag{11}$$

where C_X^0 and C_X^* $(x = 0)$ denote the analytical concentrations of X^- in the bulk of the solution and at the surface of the electrode respectively, and δ is the thickness of the diffusion layer.

The function $\varphi = [C_X^0 - C_X^* (x = 0)]/C_X^0$ (the coefficient of efficiency of electrolytic accumulation) is also introduced. This function may be calculated on the assumption that all processes occurring at the surface of the electrode are reversible. Then the concentrations of all species at the electrode surface may be calculated from the following equilibria

$$[Hg_2^{2+}] = \exp\frac{2F}{RT}(E - E^0) \tag{12}$$

$$[Hg^{2+}] = K[Hg_2^{2+}] \tag{13}$$

$$[Hg_2^{2+}][X^-]^2 = K_{s0}f(\theta) \tag{14}$$

$$[HgX_n^{2-n}] = \beta n[Hg^{2+}][X^-]^n \tag{15}$$

$$[Hg_2X_2]_b \sim 0 \tag{16}$$

where E^0 is the standard potential of the Hg_2^{2+}/Hg couple, K_{s0} the solubility product of Hg_2X_2, β_n the stability constants of the halide complexes, and $[Hg_2X_2]_b$ the bulk concentration of Hg_2X_2.

From these arguments we obtain

$$\varphi = 1 - \frac{1}{C_X{}^0}\left\{\sqrt{K_{s0}f(\theta)}\exp\left[\frac{-F(E-E^0)}{RT}\right] + \sum_{n=1}^{N} n\beta_n K\,[K_{s0}f(\theta)]^{n/2}\exp\left[\frac{(2-n)F(E-E^0)}{RT}\right]\right\} \qquad (17)$$

In these equations $f(\theta)$ denotes the activity of Hg_2X_2 on the surface of the electrode, as a function of the degree of coverage θ ($\theta = \Gamma/\Gamma_m$). Alternatively, $f(\theta)$ may be formulated in terms of the dependence of the equilibrium adsorption $\Gamma_{Hg_2X_2}$ on $[Hg_2X_2]_b$ where

$$[Hg_2X_2]_b = \beta_2{}^*[Hg_2{}^{2+}][X^-]^2 \qquad (18)$$

If for $\theta < 1$ we assume that the Langmuir isotherm is obeyed, then

$$[Hg_2X_2]_b = \frac{\beta\theta}{1-\theta} \qquad (19)$$

and

$$[Hg_2{}^{2+}][X^-]^2 = \frac{\beta\theta}{\beta_2{}^*(1-\theta)} \qquad (20)$$

From (14) and (20) we obtain

$$f(\theta) = \frac{\beta\theta}{K_{s2}(1-\theta)} \qquad (21)$$

where β is the equilibrium adsorption constant and $K_{s2} = \beta_2{}^*K_{s0}$. When $[Hg_2X_2]$ reaches the K_{s2} value, crystallization begins, $\theta > 1$ and multilayers form on the surface of the electrode.

Then

$$[Hg_2{}^{2+}][X^-]^2 = \frac{K_{s2}}{\beta_2{}^*} = K_{s0}$$

and

$$f(\theta) = 1$$

It is not useful to apply equation (21) together with (17) in these considerations, because the value of $\beta_2{}^*$ is not known. Furthermore, additional experiments should be carried out to find whether the Langmuir adsorption is obeyed. The potential dependence of the adsorption constant should also be determined. It will not be possible then, to calculate precisely the efficiency of the electrolytic accumulation; however, some other interesting parameters of the accumulation process may be predicted. The value of $f(\theta)$ may be determined only by experimentation; its determination will be difficult, however, even if it is possible.

Since in systems with halide concentrations lower then $10^{-4}M$ only the complexes HgX and HgX_2 are present, equation (17) may be simplified to

$$\varphi = 1 - \frac{2}{C_X{}^0}\left\{\beta_2KK_{s0}f(\theta) + \sqrt{\beta_1KK_{s0}f(\theta)}\cosh\left[\frac{F(E-E_{max})}{RT}\right]\right\} \qquad (22)$$

where

$$E_{\max} = E^0 - \frac{RT}{2F} \ln \beta_1 K$$

If $f(\theta)$ and the constants in (22) are assumed to be independent of the potential then $E_{\max}$ determines the potential of the maximum efficiency of electrolytic accumulation. In Fig. 1 the dependence of φ on E for Cl^-, Br^- and I^- is given, calculated with the use of equation (22), assuming $f(\theta) = 1$ and $C_X{}^0 = 10^{-5}M$.

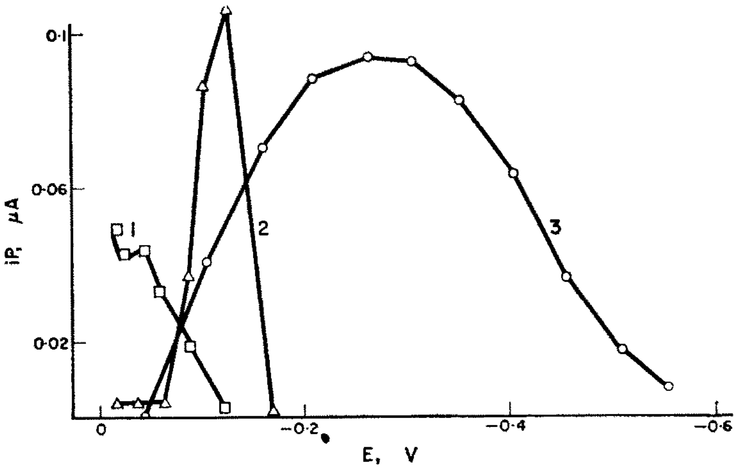

Fig. 1.—The dependence of the coefficient of efficiency of electrolytic accumulation on the accumulation potential, calculated according to equation (22) for Cl^- (curve 1), Br^- (2), and I^- (3).

The following values were used in the calculation:

$f(\theta) = 1$, $C_X{}^0 = 10^{-5}M$, $\log K = -1{\cdot}94$[5];
$\log \beta_1 = 6{\cdot}74$, $\log \beta_2 = 13{\cdot}22$, $\log K_{s0} = -16{\cdot}88$ for Cl^- [5];
$\log \beta_1 = 9{\cdot}02$, $\log \beta_2 = 17{\cdot}30$, $\log K_{s0} = -21{\cdot}28$ for Br^- [6];
$\log \beta_1 = 12{\cdot}87$, $\log \beta_2 = 23{\cdot}79$, $\log K_{s0} = -27{\cdot}46$ for I^-.[7]
Potentials are given with respect to the $Hg/Hg_2SO_4/1M\ H_2SO_4$ electrode.

An important relationship, from the analytical point of view, between time of electrolytic accumulation and $\Gamma_{Hg_2X_2}$ may be formulated on the basis of equations (10), (11) and (22). It is scarcely possible to give a strict time dependence if the function $f(\theta)$ is not precisely defined; however, the asymptotic solutions may be obtained for times that are short or long in comparison to the time needed to obtain full coverage of the electrode by a monolayer.

1. Short accumulation times.

When $t \rightarrow 0$ then $\theta \rightarrow 0$, $f(\theta) \rightarrow 0$ and $\varphi \rightarrow 1$.

If the accumulation is carried out in quiet solutions then

$$\Gamma_{Hg_2X_2} = \sqrt{\frac{Dt}{\pi}}\, C_X{}^0 \tag{23}$$

and for stirred solutions,

$$\Gamma_{Hg_2X_2} = \frac{D}{2\delta}\, C_X{}^0 t \tag{24}$$

2. Long accumulation times.

Two cases may be distinguished, in dependence on $C_X{}^0$.

When

$$C_X{}^0 > L_1(E)$$

where

$$L_1(E) = 2\left\{\beta_2 KK_{s0} + \sqrt{\beta_1 KK_{s0}}\cosh\left[\frac{F(E - E_{\max})}{RT}\right]\right\}$$

and $t \to \infty$, then $f(\theta) = 1$, $\varphi = \text{const.}$

For solutions not stirred during electrolytic accumulation we have

$$\Gamma_{Hg_2X_2} = C_1 + \sqrt{\frac{Dt}{\pi}}\,\varphi C_X{}^0 \tag{25}$$

For stirred solutions

$$\Gamma_{Hg_2X_2} = C_2 + \frac{DC_X{}^0}{2\delta}\,\varphi t \tag{26}$$

where C_1 and C_2 are constants equal to or larger then 0.

Equations (25) and (26) are valid as long as the transport of ions from the bulk of the solution is slower then the rate of the transport through the layer covering the electrode surface.

In the second case

$$C_X{}^0 < L_1(E)$$

and the coefficient of efficiency of electrolytic accumulation will assume positive values only for $f(\theta) < 1$. This means that θ cannot be larger then $\theta_{\max}$, which itself is independent of the mode of electrolytic accumulation. The function $f(\theta_{\max})$ may be defined from equation (22).

When $t \to \infty$, then $\varphi \to 0$ and

$$f(\theta_{\max}) = \frac{C_X{}^0}{2\beta_2 KK_{s0}}\left[\sqrt{\frac{L_2(E)}{C_X{}^0}} + 1 - \sqrt{\frac{L_2(E)}{C_X{}^0}}\right]^2 \tag{27}$$

where

$$L_2(E) = \frac{\beta_1}{2\beta_2}\cosh^2\left[\frac{F(E - E_{\max})}{RT}\right] \tag{28}$$

In Fig. 2a the dependence of $f(\theta_{\max})$ on E, calculated with the use of equation (27), is given for $10^{-6}M$ Cl^-, Br^-, I^-. In Fig. 3 the dependence of $\Gamma_{Hg_2X_2}$ on t is shown for various concentration ranges and electrolytic accumulation with uniform stirring of the solution.

Comparison of theory with experiment

The experimental dependence of peak current (i_p) of accumulated Hg_2X_2 on the deposition potential, found by Kemula, Kublik and Taraszewska[2] in their chronovoltammetric determination of halide ions with the use of the HMDE is given in Fig. 2b. A similar dependence was found by Perchard, Buvet and Molina.[3] The equations (22) and (27) explain these experiments semi-quantitatively. A strict quantitative correlation between φ or $f(\theta_{\max})$ and i_p calls for experimental determination of $f(\theta)$ and $i_p(\theta)$. One may suppose that for low coverages both dependences are linear; this may, however, be confirmed only by experiment.

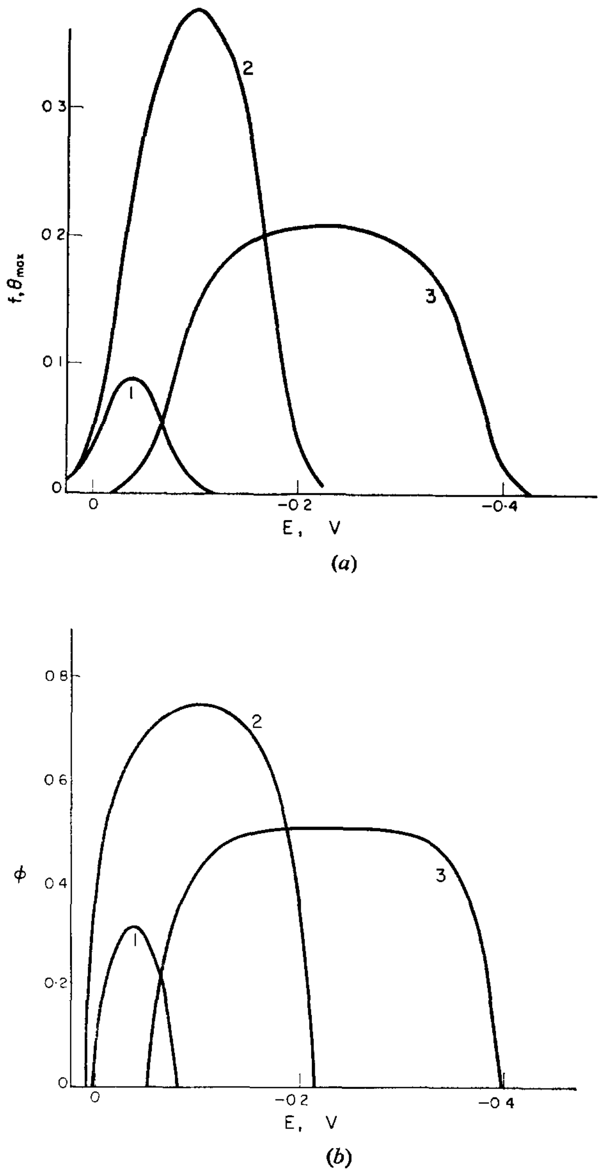

FIG. 2.—(*a*) The dependence of $f(\theta_{max})$ on the accumulation potential, calculated according to equation (27) for Cl^- (curve 1), Br^-(2) and I^-(3).

The values of equilibrium constants were taken from the literature[5–8] and $C_X{}^0$ was assumed to be $10^{-6}M$. The potential is given with respect to the $Hg/Hg_2SO_4/1M$ H_2SO_4 electrode

(*b*) Experimental dependence of peak current on the accumulation potential[2] for determination of $10^{-5}M$ Cl^- (curve 1), $10^{-6}M$ Br^-(2); $10^{-6}M$ I^-(3). In experiments with the HMDE, 0·01N H_2SO_4 served as background electrolyte, and the accumulation time was 120 sec.

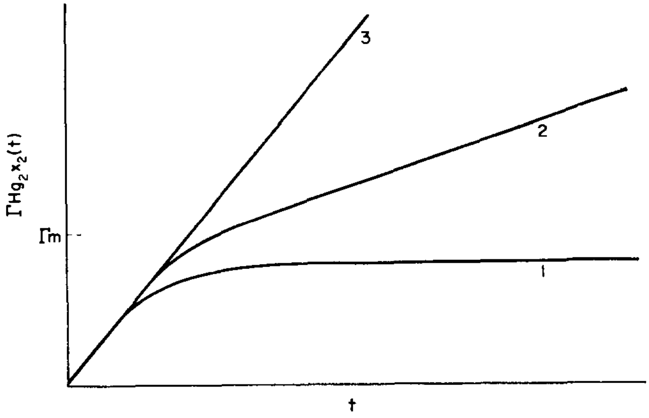

FIG 3.—Dependence of $\Gamma_{Hg_2X_2}$ on t, obtained with use of equations (24), (26) and (27). Curve 1 for $C_X{}^0 < L_1(E)$, curve 2 for $C_X{}^0 > L_1(E)$ and curve 3 for $C_X{}^0 \gg L_1(E)$.

A satisfactory agreement was found between the theoretical and experimental potentials for maximum efficiency of the electrolytic accumulation (Table I). Experimental values of E_{max} were taken from figures given in both the cited papers.

The small differences in E_{max} may be due to different concentrations of background electrolytes and their influence on the adsorption equilibrium constant. The specific adsorption of $SO_4{}^{2-}$ and $ClO_4{}^-$ ions and their interaction with Hg_2X_2 in the adsorbed state may also be responsible for these differences.

TABLE I.—EXPERIMENTAL AND THEORETICAL POTENTIAL E_{max}

Ion	E_{max} theoretical, mV	E_{max} experimental, mV	
		Ref. 2*	Ref. 3†
Cl^-	−37	−45	−87
Br^-	−105	−127	−82
I^-	−222	−258	−232

* Composition of the solutions: Cl^- $10^{-5}M$; Br^- $10^{-6}M$; I^- $10^{-6}M$; all in $0{\cdot}01N$ H_2SO_4

† Composition of the solutions: Cl^- $5 \times 10^{-4}M$; Br^- $5 \times 10^{-5}M$; I^- $5 \times 10^{-5}M$; all in $0{\cdot}1M$ $HClO_4$.

The theoretical dependence of $\Gamma_{Hg_2X_2}$ on t may be compared with experiments carried out to establish the dependence of i_p on the time of electrolytic accumulation. The assumption that the peak current is linearly dependent on $\Gamma_{Hg_2X_2}$ has to be made. Such a linear dependence was found by Perchard *et al.*[3] in their study of deposition of chlorides from $5 \times 10^{-5}M$ solution. This dependence corresponds to curve 3 in Fig. 3. The magnitude of the measured peak currents indicates multilayer coverage.

The same authors, in their determination of Cl^-, Br^- and I^- at concentrations not exceeding $10^{-5}M$ found a linear i_p–t relationship only for short accumulation times. With longer times the peak current was independent of the time of deposition, as is illustrated by curve 1 in Fig. 3. In this case the peak current shows that the electrode coverage at its maximum is a monolayer. Such a dependence was found also by Kemula, Kublik and Taraszewska.[2]

The limiting experimental value of concentration, $10^{-5}M$, agrees with the theoretical value of $L_1(E_{max})$ which is $7{\cdot}3 \times 10^{-6}$, $1{\cdot}3 \times 10^{-6}$ and $4{\cdot}4 \times 10^{-6}M$ for Cl^-, Br^- and I^- respectively.

The considerations presented do not give a complete and precise picture of the process of electrolytic accumulation of halogen ions at mercury electrodes, since they are limited to dealing with the transport phenomena. The full knowledge of this process, especially at low coverages, calls for the determination of the mode of adsorption. We intend to study this problem in the near future.

The arguments given refer to halide ions, but similar reasoning may be applied to other systems.

Zusammenfassung—Die elektrolytische Anreicherung von Halogenidionen als Hg_2X_2 am hängenden Quecksilbertropfen wird theoretisch erörtert. Zur Erklärung werden verschiedene chemische Reaktionen von Quecksilberionen mit Halogenen in Betracht gezogen sowie die Adsorption von Hg_2X_2. Die Übereinstimmung mit den Versuchsergebnissen anderer Autoren ist zufriedenstellend.

Résumé—On considère thèoriquement le processus d'accumulation èlectrolytique d'ions halogènures à l'ètat Hg_2X_2 sur l'èlectrode à goutte de mercure pendante. L'efficacité de ce processus est expliquée en considérant diverses réactions chimiques d'ions mercure avec les halogènes, et l'adsorption de Hg_2X_2. On a trouvé satisfaisant l'accord de ces considérations avec les résultats expérimentaux obtenus par d'autres auteurs.

ELECTROCHEMICAL DETERMINATION OF ADENINE AND ADENOSINE

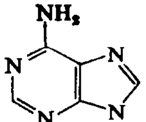
ADSORPTION OF ADENINE AND ADENOSINE AT THE PYROLYTIC GRAPHITE ELECTRODE

GLENN DRYHURST
Department of Chemistry, University of Oklahoma, Norman, Oklahoma, 73069, U.S.A.

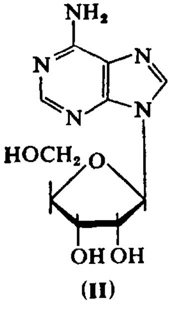
(*Received* 12 *July* 1971. *Accepted* 30 *October* 1971)

Summary—Adenine and adenosine are polarographically reducible from aqueous solution at pH 4·7 at the DME at the same $E_{1/2}$, and are also voltammetrically oxidizable at the PGE, but at different potentials, adenosine at higher potentials. Competitive adsorption of both compounds at the PGE results in a decrease in the scanning voltammetric oxidation peak of adenine in the presence of adenosine, reaching a constant value when the concentration of the latter is above 6 m*M*. In mixtures, the sum of the two is obtained by polarography at the DME. Solid adenosine is then added to the solution and the adenine is determined by voltammetry at the PGE.

THE POLAROGRAPHIC reduction of adenine (I) and its application to the determination of this compound have been described by Smith and Elving.[1,2] Adenosine (II) appears to be polarographically reduced by the same mechanism as is adenine,[3] but as the half-wave potentials are very close, the analysis of mixtures of the two compounds is not possible.



(I)



(II)

Adenine[4] and adenosine[5] can also be oxidized electrochemically at the pyrolytic graphite electrode (PGE). The mechanism[4] and a brief examination of the analytical utility of the oxidation peak of adenine at the PGE have been reported.[6]

In some recent work in this laboratory we found it necessary to be able to determine small quantities of adenine in the presence of fairly large amounts of adenosine, and also on occasion to be able to determine both adenine and adenosine in mixtures of the two compounds.

Methods have been described for the determination of adenine and adenosine in mixtures. Johnstone and Briner[7] and Cerletti and Siliprandi[8] developed methods based on separation of adenine and adenosine by paper chromatography. However, these methods are very slow and were not applicable to the concentration levels of adenine and adenosine in which we were interested.

As the ultraviolet absorption spectra of adenine and adenosine are very similar, their simultaneous spectrophotometric determination is difficult. In addition, it is impossible to determine adenine in the presence of very large amounts of adenosine (*i.e.*, 100-fold) by ultraviolet spectrophotometry.

This paper describes techniques whereby adenine and adenosine can be determined by utilizing the polarographic reduction waves of both compounds at the dropping mercury electrode (DME), and the voltammetric oxidation peak of adenine at the PGE. In order to develop a satisfactory analytical method it was found necessary to investigate in some detail the adsorpion of adenine and adenosine at the PGE, and the effect of adenosine on the extent of adsorption of adenine.

EXPERIMENTAL

Chemicals

Adenine and adenosine were obtained from Nutritional Biochemicals Corp. The acetate buffer pH 4·7 used throughout this work was prepared from reagent grade chemicals and had an ionic strength of 0·5. Water-saturated argon (Linde) was used for deaeration.

Apparatus

Polarograms (DME) were recorded on a Sargent Model XVI Polarograph at a scan-rate of 3·3 mV/sec. Direct current voltammograms at the PGE were recorded with the apparatus described by Dryhurst *et al.*,[9] incorporating a Hewlett-Packard Model 7001A X–Y recorder at a scan rate of 5 mV/sec. Alternating current voltammograms at the PGE were also obtained with the same operational amplifier instrument combined with a Princeton Applied Research Model 121 Lock-in Amplifier/Phase Detector. For a.c. voltammetry a d.c. ramp of 5 mV/sec and a sinusoidal signal of 100 Hz and 10 mV peak-to-peak was used for all experiments. A three-compartment cell maintained at 25 ± 0·1° was used for all experiments and contained a saturated calomel reference electrode (SCE) and a platinum gauze counter-electrode. All potentials are referred to the SCE at 25°C.

The PGE's were machined from small rods of pyrolytic graphite (Super-Temp Company, Santa Fe Springs, Calif.) to a diameter of 4 mm and length *ca.* 10 mm, and were sealed into lengths of 4-mm bore glass tube with Hysol Epoxi-Patch (Hysol Corp., Olean, New York). The electrodes were ground flush with the end of the glass tube.

A conventional dropping mercury electrode was used which had normal *m* and *t* values.

Polarographic procedure

Suitable solutions of adenine, adenosine or mixtures of the two compounds were prepared by diluting appropriate volumes of stock solutions of adenine and adenosine in acetate buffer pH 4·7 with the same buffer solution. Polarograms were run from −1·0 to −1·6 V. The polarogram of pure buffer solution was also recorded, and the limiting currents for the reduction waves were obtained by difference.

Voltammetric procedure

For d.c. voltammetry the PGE was resurfaced before each voltammogram was run, by polishing on a 600-grade silicon carbide paper mounted on a rotating metallographic polishing disc (Buehler Inc., Evanston, Ill.). The surface of the PGE was then washed for 10–15 sec with a fine spray of water. The shaft of the electrode was dried thoroughly and any excess of water remaining on the electrode surface was removed by touching the surface very gently with a soft absorbent paper tissue.

Test solutions were not deaerated. The PGE was inserted into the test solution and after 10 sec at the initial potential (0·4 V for d.c. voltammetry) the voltage scan was started. At least three replicate voltammograms were recorded for each test solution. Voltammograms on background solution were recorded in the same way. The adenine or adenosine peak current was obtained by arithmetically subtracting the observed background current at the peak potential from the test solution peak current.

For a.c. voltammetry it was found that even for pure background solution supporting electrolyte the alternating base current was not very reproducible after each resurfacing of the PGE, no doubt because of variations in the surface roughness and hence in the electrode double-layer capacity.

Accordingly, after resurfacing of the electrode, one set of results was obtained by immersing the electrode in supporting electrolyte, applying the initial potential (0·00 V) for 10 sec and then commencing the scan. The final potential was normally 1·4 or 1·5 V. The first voltammogram was not normally recorded since in general it did not agree with subsequent voltammograms. This is possibly due to the fact that the first trace reflects certain specific surface effects (*e.g.*, surface oxide reduction) which are not observed on the subsequent traces. At the end of the scan the electrode was removed from the cell and the shaft carefully dried but the electrode surface itself was not touched. After 30 sec the electrode was replaced in the cell and the background trace recorded at least three times. Under these conditions the background voltammograms always agreed very closely. The electrode was then removed and treated as just described, except that the background solution in the cell was replaced by the appropriate test solution. After 30 sec the electrode was replaced and the sample trace was recorded at least twice.

Polarographic calibration curves

Calibration curves for the polarographic reduction of adenine and adenosine at the DME in an acetate buffer at pH 4·7 were prepared for concentrations of each compound ranging from *ca.* 0·1 to 1·5 m*M*. Both compounds give straight-line i_1 *vs.* C plots over this concentration range, adenosine giving slightly lower currents.

Voltammetric calibration curve

Concentrations of adenine ranging from *ca.* 0·1 to 1·5 m*M* in acetate buffer at pH 4·7 were made *ca.* 6–6·5 m*M* in adenosine by adding the appropriate amount of solid adenosine to each solution (*i.e.*, for a 25-ml aliquot of an adenine solution 0·045–0·046 g of solid adenosine was added). Voltammetric traces were recorded between 0·4 and 1·25 V. Adenine gives a well-formed peak at 1·10–1·16 V (the peak potential shifts to more positive values with increasing concentration of adenine), and in the presence of 6–6·5 m*M* adenosine a linear relationship between the peak current i_1 and adenine concentration was obtained.

Determination of adenine and adenosine in mixtures

For solutions containing mixtures of up to *ca.* 1·5 m*M* adenine and *ca.* 1·5 m*M* adenosine where both compounds are to be determined, the solution is adjusted to pH 4·7 and ionic strength of about 0·5 with an acetate buffer. An aliquot of the resulting solution is placed in a polarographic cell, thoroughly deaerated with argon and a polarogram at the DME recorded between −1·0 and −1·6 V. The current observed for this polarogram is proportional to the total concentration of adenine plus adenosine.

A second aliquot is then taken and sufficient solid adenosine is weighed into the solution to increase its concentration to 6–6·5 m*M*. After dissolution of the adenosine the solution is placed in a polarographic cell and a voltammogram is run at the stationary PGE between 0·4 and 1·25 V. The height of the peak observed at 1·10–1·16 V is proportional to the adenine concentration.

Thus, the concentration of adenine in the mixture is determined from the height of the voltammetric oxidation peak of adenine in the presence of a large excess of adenosine. The current expected for the polarographic reduction of this amount of adenine is determined from the calibration curve for polarographic reduction of adenine. This current is subtracted from the total polarographic current observed for the adenine–adenosine mixture and hence the current due to adenosine is calculated. The concentration of adenosine is then readily obtained from the adenosine polarographic calibration curve.

RESULTS AND DISCUSSION

Polarography

The pH-dependent half-wave potential for polarographic reduction of adenine at the DME is described by the equation,[3] $E_{1/2} = -0{\cdot}975 - 0{\cdot}084\,\text{pH}$ between pH 1·0 and 6·5. The $E_{1/2}$ for the single, well-formed polarographic wave of adenosine is also pH dependent. Between pH 0 and 4·5, $E_{1/2} = -1{\cdot}040 - 0{\cdot}070\,\text{pH}$ and between pH 4·5 and 6·0, $E_{1/2} = -1{\cdot}180 - 0{\cdot}041\,\text{pH}$.[3] The waves for both compounds are relatively constant in height up to about pH 5, when they begin to decrease sharply with increasing pH and disappear by pH 6–7, since both compounds are only reducible in the protonated form (pK_a of adenine 4·20, pK_a adenosine 3·60). Comparison of the equations for adenine and adenosine reveals that at all pH values where the polarographic waves are observed both compounds have essentially identical $E_{1/2}$ values, *i.e.*, at pH 4·7 both compounds have an $E_{1/2}$ value of −1·37 V.

Adenine and adenosine both gave limiting currents that were linearly proportional to concentration, and which were additive for mixtures.

Voltammetry

Over the normal pH range (0–14) adenine and adenosine give a single pH-dependent voltammetric oxidation peak at the PGE. The adenine peak always occurs at more negative potentials than that of adenosine (Fig. 1). The shift of peak potential with pH is described by the equation $E_p = 1·338 - 0·063$ pH for adenine and $E_p = 1·778 - 0·087$ pH for adenosine at concentrations of *ca.* 0·25 m*M*. However, the peak potentials for both adenine and adenosine are concentration-dependent and shift to more positive values with increasing concentration. Over the approximate concentration range of 0·1–1 m*M* this shift was about 80 mV for both compounds. At below pH 4–5 in buffer solutions containing chloride ion the oxidation peaks of both adenine and adenosine are masked by the facile oxidation of chloride ion in the background electrolyte.

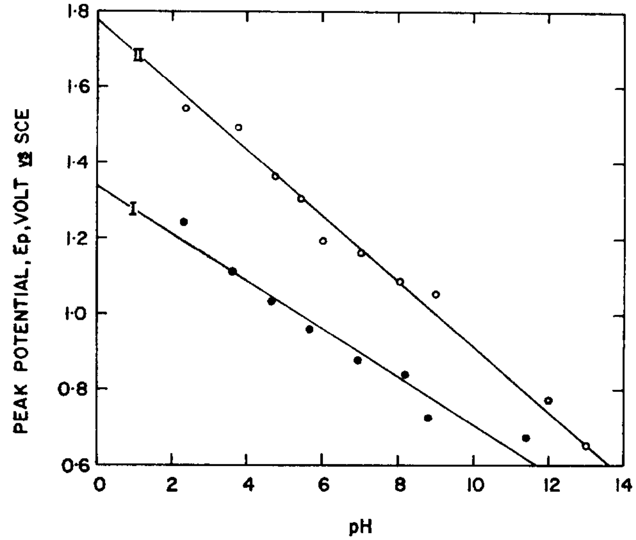


FIG. 1.—Variation of peak potential with pH for the voltammetric oxidation of adenine (I) and adenosine (II) at the PGE at the 0·25 m*M* concentration level.

Both compounds exhibit a rather non-linear relationship between peak current and concentration (Fig. 2), the non-linearity being more pronounced in the case of adenine.

A preliminary examination of the determination of adenine in the presence of adenosine on the basis of the adenine peak current and a calibration curve of the type shown in Fig. 2-I revealed that the adenine concentrations so determined were always very low. Further investigation revealed that addition of adenosine to an adenine solution caused a pronounced decrease in the height of the adenine peak, reaching a constant value of about 55% for a molar ratio of greater than 5:1.

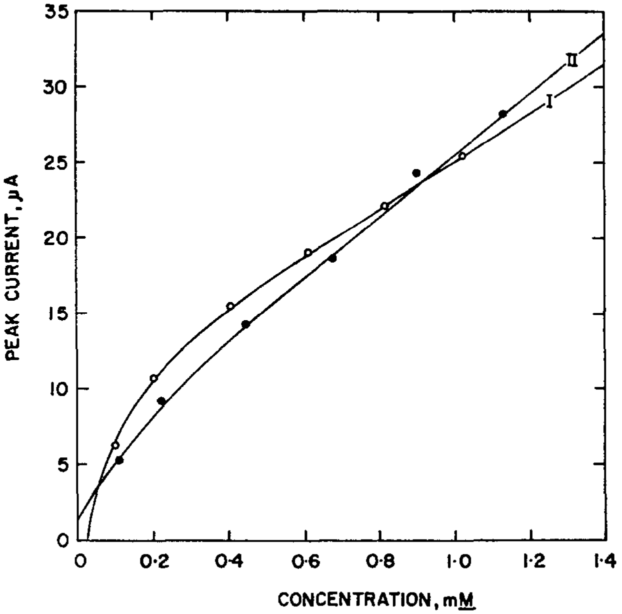

FIG. 2.—Peak current versus concentration relation for the voltammetric oxidation of adenine (I) and adenosine (II) at the PGE.

The non-linear i_p *vs.* C curves for adenine and adenosine suggested that both compounds were adsorbed on the PGE. The fact that the presence of adenosine caused the peak current for adenine to decrease suggested that a competitive adsorption of the two compounds occurred, and that adenosine was displacing part of the adenine from the electrode surface.

In order to investigate further the adsorption of adenine a scan-rate study of the voltammetric oxidation peak of adenine was carried out. This could not be done for adenosine since its oxidation peak occurs so close to background discharge potentials that at scan-rates above *ca.* 20 mV/sec it gives only an inflection on the rise of the background current and accurate measurement of the peak current is impossible.

Earlier studies[4,10] and a.c. voltammetry (*vide infra*) of adenine had revealed that the electrochemical oxidation of adenine is an irreversible process. The theoretical equation for the peak current, i_p (μA) for a linear diffusion-controlled irreversible peak voltammogram at a plane electrode is shown in equation (1).[11,16,13]

$$(i_p)_{\text{irrev}} = 2{\cdot}98 \times 10^5 n\,(\alpha n_a)^{1/2} A D^{1/2} V^{1/2} C \qquad (1)$$

where n is the number of electrons involved in the overall reaction, α the electron transfer coefficient, n_a the number of electrons involved in the rate-controlling electron-transfer process, A the electrode area (cm^2), D the diffusion coefficient of the electroactive species (cm^2/sec), V the voltage scan-rate (V/sec) and C the bulk concentration of the electroactive species (mM). According to this equation, $i_p/ACV^{1/2}$, the peak current function, should be a constant, and a plot of this function *vs.* $V^{1/2}$ (or V) should be a straight line parallel to the $V^{1/2}$ axis. In the case of adenine however the peak-current function shows a pronounced increase with increasing scan-rate (Fig. 3A), typical of an electrode process where the reactant is adsorbed at the electrode surface. In such a

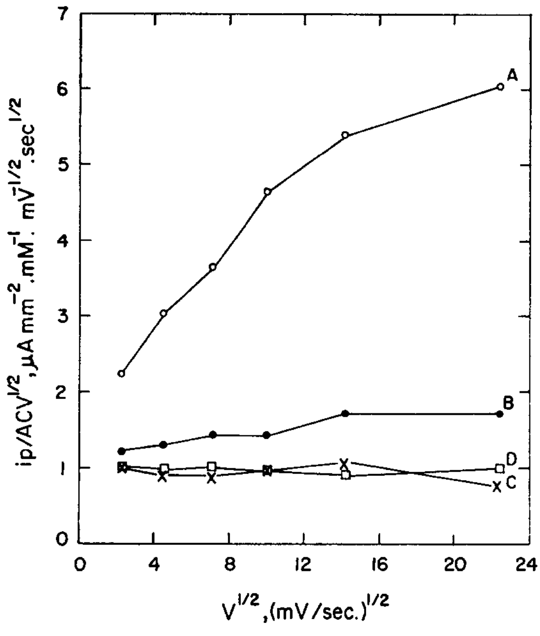

FIG. 3.—Variation of the peak current function, $i_p/ACV^{1/2}$, with the square root of the voltage scan-rate for (A) 0·1025 m*M* adenine, (B) 0·1025 m*M* adenine with 1·00 m*M* adenosine, (C) 0·1025 m*M* adenine with 2·77 m*M* adenosine and (D) 0·2228 m*M* adenine with 6·27 m*M* adenosine. Acetate buffer pH 4·7. PGE geometric area: 12·5 mm².

case the amount of adsorbed material and hence of charge flow (at least in the case of a perfectly reproducible electrode surface) is constant, and the amount of material diffusing to the electrode surface is time dependent with the result that as the scan-rate increases, the contribution from diffusing material decreases with respect to the amount of adsorbed material reacting at the electrode surface, and the peak-current function increases.[14]

On addition of adenosine to adenine in 10:1 molar ratio the peak-current function decreased markedly (Fig. 3B) and the variation of the peak-current function became more in line with that expected for a diffusion-controlled reaction. Addition of a 30:1 molar ratio of adenosine resulted in a further slight decrease in the peak-current function, particularly at higher scan-rates (Fig. 3CD), but the effect was very small at the lowest scan rates studied (5 mV/sec). It was not possible to study the peak current for adenine in the presence of large amounts of adenosine at scan-rates much above 500 mV/sec because the peak potential for adenine shifts to more positive values with increasing scan-rate and the peak merges with the background discharge (from oxidation of the adenosine).

Values of the diffusion coefficient as calculated from relevant polarographic data ($1{\cdot}87 \times 10^{-3}$ mm²/sec) and of αn_a calculated according to

$$E_p - E_{p/2} = 0{\cdot}048/\alpha n_a \qquad (2)$$

were inserted into (1) to obtain theoretical peak currents of 1·55 and 2·32 $\mu A \cdot mm^{-2} \cdot mM^{-1} \cdot mV^{-1/2} \cdot sec^{1/2}$ assuming a four- or a six-electron oxidation respectively. Coulometric evidence suggests that six electrons are involved per molecule of adenine, but in the presence of a large amount of adenosine as is here the case, the experimental value of around unity for the peak current (Fig. 3) would be more in agreement with a four-electron reaction. It should be stressed that the αn_a value cannot be determined accurately since the adenine peak lies so close to the background discharge, and a close agreement between the theoretical and experimental values is not to be expected.

Alternating current voltammetry

A qualitative technique for observing the regions of potential where adsorption of organic molecules takes place at a dropping mercury electrode is a.c. polarography. In the potential regions where adsorption occurs, pronounced depressions of the alternating base current occur owing to a decrease of the double-layer capacity of the electrode.[15] A few reports of a.c. techniques at solid or stationary electrodes have appeared[16-20] but only that of Delahay and Trachtenberg[21] at stationary mercury electrodes has dealt specifically with adsorption effects. Alternating current voltammograms of adenine and adenosine and mixtures of the two are presented in Fig. 4. It is clear from the voltammograms shown in Figs. 4A and 4B that both adenine and adenosine markedly depress the alternating base current over the whole potential range examined. Since the base current for both compounds is depressed at potentials more negative than the DC peak it is obvious that both adenine and adenosine are adsorbed at the PGE. Both compounds also exhibit a rather pronounced pit, or well potentials corresponding to the rising portion of the d.c. peak. The depression of the base current at potentials more positive than the d.c. peak appears to be more pronounced than at more negative ones, indicating that one of the products of the oxidation of these compounds is quite strongly adsorbed at the PGE. The a.c. voltammetric results are clearly in agreement with the results of the scan-rate and sweep-rate studies on adenine, *i.e.*, that adenine is adsorbed at the PGE. The absence of any faradaic a.c. peaks at potentials in the vicinity of the d.c. peaks for both adenine and adenosine confirms the irreversible nature of these electrode processes.[4,5]

Figure 4C shows that making a 6·3m*M* solution of adenosine in acetate buffer at pH 4·7 1m*M* in adenine still causes an appreciable base current depression at potentials more negative and more positive than the adenine d.c. peak, especially at the more positive potentials. However this depression is not as pronounced as it is in the absence of adenosine and indeed for 20:1 or 30:1 molar ratios of adenosine to adenine, it is not observed by a.c. techniques.

The conclusion that can be drawn from the qualitative a.c., sweep-rate and concentration studies is that both adenine and adenosine and at least one of their oxidation products are adsorbed at the PGE. In the presence of large amounts of adenosine, adsorbed adenine is largely displaced from the electrode surface and the voltammetric oxidation of adenine becomes effectively diffusion-controlled.

Development of analytical methods

The DME studies on adenine, adenosine and mixtures of the two show that the polarographic limiting current is directly proportional to the sum of the concentrations of the two bases. In contrast, at the PGE adenine and adenosine are both adsorbed and as a result of competitive adsorption the peak current for adenine is dependent on the concentration of adenosine present, though at sufficiently large concentrations of adenosine, adenine is to a considerable extent displaced from the electrode surface

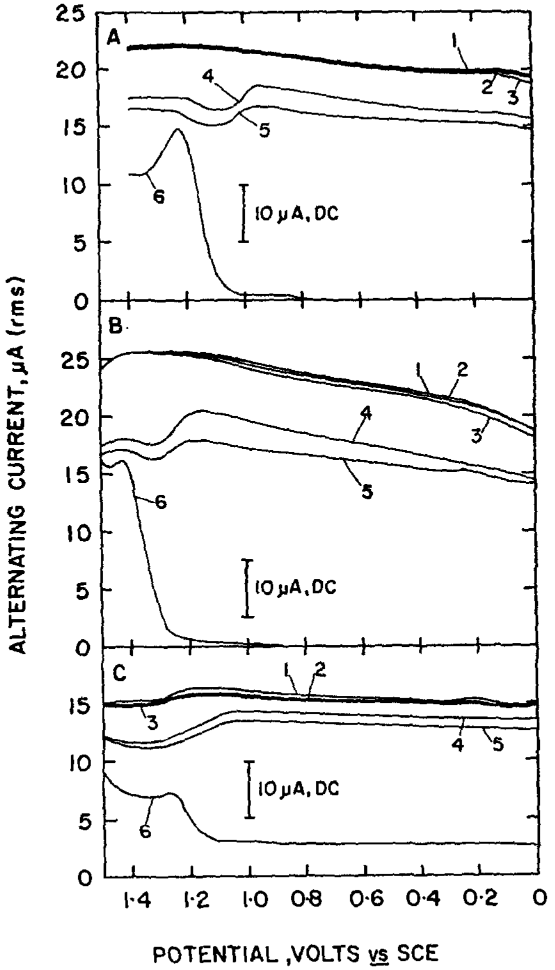

FIG. 4.—Alternating current voltammograms at the PGE in acetate buffer at pH 4·7 of A, 1 m*M* adenine; B, 1 m*M* adenosine. Scans 1, 2, 3 are a.c. background traces, scans 4 and 5 are a.c. traces in the presence of adenine or adenosine, scan 6 is a d.c. voltammogram. C: Scans 1, 2, 3 are of 6·27 m*M* adenosine in acetate buffer pH 4·7, scans 4 and 5 are 6·27 m*M* adenosine plus 1 m*M* adenine, scan 6 is a d.c. voltammogram. Scan rate: 5 mV/sec; alternating voltage 10 mV peak-to-peak, 100 Hz. PGE geometric area: 12·5 mm^2.

and its oxidation becomes a diffusion-controlled process. For a quantitative determination of adenine by voltammetric oxidation large concentration ratios should be used, with a maximum adenine concentration around 1m*M* (approaching its limit of solubility).

Typical i_p *vs*. *C* curves for adenine in the presence of approximately 3m*M* and 6m*M* adenosine are clearly linear but a slightly lower current is observed in the presence of the higher adenosine concentration. In view of the linearity of the latter i_p *vs*. *C* plot over a wide range of molar ratios from 8 to 156 it was felt that accurate determinations of adenine could be performed simply by adding sufficient solid adenosine to adenine–adenosine mixtures to ensure at least a 6–7 fold molar excess of it was present.

In order to test the methods developed, some mixtures of adenine and adenosine in acetate buffer at pH 4·7 were examined. The samples were first analysed polarographically, then solid adenosine was added to the test solutions sufficient to make them *ca.* 6–7m*M* in adenosine. The concentration of adenine was then determined from the height of the resulting voltammetric oxidation peak of adenine at the PGE. Typical analytical results are presented in Table I. Once the calibration curves have been obtained a total analysis of the adenine and adenosine present in a sample can be completed in at most 15 min.

TABLE I.—TYPICAL RESULTS FOR THE ELECTROCHEMICAL DETERMINATION OF MIXTURES OF ADENINE AND ADENOSINE.

0·37	0·24	0·37	0·26

CONCLUSION

By a combination of polarography at the DME and voltammetry at the PGE a rapid and reasonably accurate analysis for adenine and adenosine in mixtures is possible. No previously reported method is capable of determining adenine in the pressure of such large amounts of adenosine.

The studies reported in this paper have utilized an acetate buffer at pH 4·7 as the background electrolyte system. A very brief examination of the adenine–adenosine system at lower pH values in acetate buffers or with sulphuric acid-potassium sulphate supporting electrolyte systems revealed that similar results may be obtained. Above pH 6 the polarographic waves of adenine and adenosine become small and kinetically controlled, and utimately disappear at about pH 7, with the result that the polarographic procedure for the determination of the total adenine plus adenosine can no longer be used.

However, the voltammetric oxidation peaks of adenine and of adenosine at the PGE persist to a very high pH, and hence the adenine concentration could still be determined. If it were necessary to determine the adenosine and adenine concentration at above pH 6 it should be possible to determine the total base concentrations by ultraviolet absorption spectrophotometry and the adenine concentration from its voltammetric oxidation peak at the PGE in the presence of a large excess of adenosine.

Zusammenfassung—Adenin und Adenosin lassen sich aus wäßriger Lösung bei pH 4·7 polarographisch an der Quecksilbertropfelektrode (DME) beim selben Halbstufenpotential reduzieren. An einer Elektrode aus Pyrolysegraphit (PGE) sind beide voltammetrisch oxidierbar, Adenosin jedoch bei höherem Potential. Die konkurrierende Adsorption beider Verbindungen an der PGE führt dazu, daß der Adeninpeak beim Registrieren der voltammetrischen Oxidation in Gegenwart von Adenosin kleiner wird und bei einer Adenosinkonzentration über 6 m*M* einen konstanten Wert erreicht. In Gemischen wird die Summe beider Verbindungen durch Polarographie an der DME erhalten. Dann wird festes Adenosin zur Lösung gegeben und Adenin durch Voltammetrie an der PGE bestimmt.

Résumé—L'adénine et l'adénosine sont réductibles polarographiquement en solution aqueuse à pH 4,7 à l'électrode à goutte de mercure au même $E_{1/2}$, et sont également oxydables voltammétriquement à l'élec trode de toile de platine, mais à des potentiels différents, l'adénosine aux potentiels plus élevés. L'adsorption compétitive des deux composés sur l'électrode de toile de platine a pour conséquence un abaissement dans le pic d'oxydation voltammétrique de l'adénine en la présence d'adénosine, atteignant une valeur constante lorsque la concentration de cette dernière est supérieure à 6 m*M*. Dans les mélanges, la somme des deux est obtenue par polarographie à l'électrode à goutte de mercure. On ajoute alors de l'adénosine solide à la solution et l'on dose l'adénine par voltammétrie a l'électrode de toile de platine.

ELECTROCHEMICAL DETERMINATION OF ADENINE AND ADENOSINE

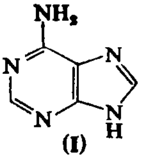
ADSORPTION OF ADENINE AND ADENOSINE AT THE PYROLYTIC GRAPHITE ELECTRODE

GLENN DRYHURST
Department of Chemistry, University of Oklahoma, Norman, Oklahoma, 73069, U.S.A.

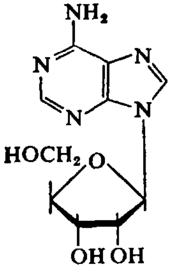
(*Received* 12 *July* 1971. *Accepted* 30 *October* 1971)

Summary—Adenine and adenosine are polarographically reducible from aqueous solution at pH 4·7 at the DME at the same $E_{1/2}$, and are also voltammetrically oxidizable at the PGE, but at different potentials, adenosine at higher potentials. Competitive adsorption of both compounds at the PGE results in a decrease in the scanning voltammetric oxidation peak of adenine in the presence of adenosine, reaching a constant value when the concentration of the latter is above 6 m*M*. In mixtures, the sum of the two is obtained by polarography at the DME. Solid adenosine is then added to the solution and the adenine is determined by voltammetry at the PGE.

THE POLAROGRAPHIC reduction of adenine (I) and its application to the determination of this compound have been described by Smith and Elving.[1,2] Adenosine (II) appears to be polarographically reduced by the same mechanism as is adenine,[3] but as the half-wave potentials are very close, the analysis of mixtures of the two compounds is not possible.



(I)



(II)

Adenine[4] and adenosine[5] can also be oxidized electrochemically at the pyrolytic graphite electrode (PGE). The mechanism[4] and a brief examination of the analytical utility of the oxidation peak of adenine at the PGE have been reported.[6]

In some recent work in this laboratory we found it necessary to be able to determine small quantities of adenine in the presence of fairly large amounts of adenosine, and also on occasion to be able to determine both adenine and adenosine in mixtures of the two compounds.

Methods have been described for the determination of adenine and adenosine in mixtures. Johnstone and Briner[7] and Cerletti and Siliprandi[8] developed methods based on separation of adenine and adenosine by paper chromatography. However, these methods are very slow and were not applicable to the concentration levels of adenine and adenosine in which we were interested.

As the ultraviolet absorption spectra of adenine and adenosine are very similar, their simultaneous spectrophotometric determination is difficult. In addition, it is impossible to determine adenine in the presence of very large amounts of adenosine (*i.e.*, 100-fold) by ultraviolet spectrophotometry.

This paper describes techniques whereby adenine and adenosine can be determined by utilizing the polarographic reduction waves of both compounds at the dropping mercury electrode (DME), and the voltammetric oxidation peak of adenine at the PGE. In order to develop a satisfactory analytical method it was found necessary to investigate in some detail the adsorpion of adenine and adenosine at the PGE, and the effect of adenosine on the extent of adsorption of adenine.

EXPERIMENTAL

Chemicals

Adenine and adenosine were obtained from Nutritional Biochemicals Corp. The acetate buffer pH 4·7 used throughout this work was prepared from reagent grade chemicals and had an ionic strength of 0·5. Water-saturated argon (Linde) was used for deaeration.

Apparatus

Polarograms (DME) were recorded on a Sargent Model XVI Polarograph at a scan-rate of 3·3 mV/sec. Direct current voltammograms at the PGE were recorded with the apparatus described by Dryhurst *et al.*,[9] incorporating a Hewlett-Packard Model 7001A X–Y recorder at a scan rate of 5 mV/sec. Alternating current voltammograms at the PGE were also obtained with the same operational amplifier instrument combined with a Princeton Applied Research Model 121 Lock-in Amplifier/Phase Detector. For a.c. voltammetry a d.c. ramp of 5 mV/sec and a sinusoidal signal of 100 Hz and 10 mV peak-to-peak was used for all experiments. A three-compartment cell maintained at 25 ± 0·1° was used for all experiments and contained a saturated calomel reference electrode (SCE) and a platinum gauze counter-electrode. All potentials are referred to the SCE at 25°C.

The PGE's were machined from small rods of pyrolytic graphite (Super-Temp Company, Santa Fe Springs, Calif.) to a diameter of 4 mm and length *ca.* 10 mm, and were sealed into lengths of 4-mm bore glass tube with Hysol Epoxi-Patch (Hysol Corp., Olean, New York). The electrodes were ground flush with the end of the glass tube.

A conventional dropping mercury electrode was used which had normal *m* and *t* values.

Polarographic procedure

Suitable solutions of adenine, adenosine or mixtures of the two compounds were prepared by diluting appropriate volumes of stock solutions of adenine and adenosine in acetate buffer pH 4·7 with the same buffer solution. Polarograms were run from −1·0 to −1·6 V. The polarogram of pure buffer solution was also recorded, and the limiting currents for the reduction waves were obtained by difference.

Voltammetric procedure

For d.c. voltammetry the PGE was resurfaced before each voltammogram was run, by polishing on a 600-grade silicon carbide paper mounted on a rotating metallographic polishing disc (Buehler Inc., Evanston, Ill.). The surface of the PGE was then washed for 10–15 sec with a fine spray of water. The shaft of the electrode was dried thoroughly and any excess of water remaining on the electrode surface was removed by touching the surface very gently with a soft absorbent paper tissue.

Test solutions were not deaerated. The PGE was inserted into the test solution and after 10 sec at the initial potential (0·4 V for d.c. voltammetry) the voltage scan was started. At least three replicate voltammograms were recorded for each test solution. Voltammograms on background solution were recorded in the same way. The adenine or adenosine peak current was obtained by arithmetically subtracting the observed background current at the peak potential from the test solution peak current.

For a.c. voltammetry it was found that even for pure background solution supporting electrolyte the alternating base current was not very reproducible after each resurfacing of the PGE, no doubt because of variations in the surface roughness and hence in the electrode double-layer capacity.

Accordingly, after resurfacing of the electrode, one set of results was obtained by immersing the electrode in supporting electrolyte, applying the initial potential (0·00 V) for 10 sec and then commencing the scan. The final potential was normally 1·4 or 1·5 V. The first voltammogram was not normally recorded since in general it did not agree with subsequent voltammograms. This is possibly due to the fact that the first trace reflects certain specific surface effects (*e.g.*, surface oxide reduction) which are not observed on the subsequent traces. At the end of the scan the electrode was removed from the cell and the shaft carefully dried but the electrode surface itself was not touched. After 30 sec the electrode was replaced in the cell and the background trace recorded at least three times. Under these conditions the background voltammograms always agreed very closely. The electrode was then removed and treated as just described, except that the background solution in the cell was replaced by the appropriate test solution. After 30 sec the electrode was replaced and the sample trace was recorded at least twice.

Polarographic calibration curves

Calibration curves for the polarographic reduction of adenine and adenosine at the DME in an acetate buffer at pH 4·7 were prepared for concentrations of each compound ranging from *ca.* 0·1 to 1·5 m*M*. Both compounds give straight-line i_l *vs.* C plots over this concentration range, adenosine giving slightly lower currents.

Voltammetric calibration curve

Concentrations of adenine ranging from *ca.* 0·1 to 1·5 m*M* in acetate buffer at pH 4·7 were made *ca.* 6–6·5 m*M* in adenosine by adding the appropriate amount of solid adenosine to each solution (*i.e.*, for a 25-ml aliquot of an adenine solution 0 045–0 046 g of solid adenosine was added). Voltammetric traces were recorded between 0·4 and 1·25 V. Adenine gives a well-formed peak at 1·10–1·16 V (the peak potential shifts to more positive values with increasing concentration of adenine), and in the presence of 6–6·5 m*M* adenosine a linear relationship between the peak current i_l and adenine concentration was obtained.

Determination of adenine and adenosine in mixtures

For solutions containing mixtures of up to *ca.* 1·5 m*M* adenine and *ca.* 1·5 m*M* adenosine where both compounds are to be determined, the solution is adjusted to pH 4·7 and ionic strength of about 0·5 with an acetate buffer. An aliquot of the resulting solution is placed in a polarographic cell, thoroughly deaerated with argon and a polarogram at the DME recorded between −1·0 and −1·6 V. The current observed for this polarogram is proportional to the total concentration of adenine plus adenosine.

A second aliquot is then taken and sufficient solid adenosine is weighed into the solution to increase its concentration to 6–6·5 m*M*. After dissolution of the adenosine the solution is placed in a polarographic cell and a voltammogram is run at the stationary PGE between 0·4 and 1·25 V. The height of the peak observed at 1·10–1·16 V is proportional to the adenine concentration.

Thus, the concentration of adenine in the mixture is determined from the height of the voltammetric oxidation peak of adenine in the presence of a large excess of adenosine. The current expected for the polarographic reduction of this amount of adenine is determined from the calibration curve for polarographic reduction of adenine. This current is subtracted from the total polarographic current observed for the adenine–adenosine mixture and hence the current due to adenosine is calculated. The concentration of adenosine is then readily obtained from the adenosine polarographic calibration curve.

RESULTS AND DISCUSSION

Polarography

The pH-dependent half-wave potential for polarographic reduction of adenine at the DME is described by the equation,[3] $E_{1/2} = -0{\cdot}975 - 0{\cdot}084\,\mathrm{pH}$ between pH 1·0 and 6·5. The $E_{1/2}$ for the single, well-formed polarographic wave of adenosine is also pH dependent. Between pH 0 and 4·5, $E_{1/2} = -1{\cdot}040 - 0{\cdot}070\,\mathrm{pH}$ and between pH 4·5 and 6·0, $E_{1/2} = -1{\cdot}180 - 0{\cdot}041\,\mathrm{pH}$.[3] The waves for both compounds are relatively constant in height up to about pH 5, when they begin to decrease sharply with increasing pH and disappear by pH 6–7, since both compounds are only reducible in the protonated form (pK_a of adenine 4·20, pK_a adenosine 3·60). Comparison of the equations for adenine and adenosine reveals that at all pH values where the polarographic waves are observed both compounds have essentially identical $E_{1/2}$ values, *i.e.*, at pH 4·7 both compounds have an $E_{1/2}$ value of −1·37 V.

Adenine and adenosine both gave limiting currents that were linearly proportional to concentration, and which were additive for mixtures.

Voltammetry

Over the normal pH range (0–14) adenine and adenosine give a single pH-dependent voltammetric oxidation peak at the PGE. The adenine peak always occurs at more negative potentials than that of adenosine (Fig. 1). The shift of peak potential with pH is described by the equation $E_p = 1{\cdot}338 - 0{\cdot}063$ pH for adenine and $E_p = 1{\cdot}778 - 0{\cdot}087$ pH for adenosine at concentrations of *ca.* 0·25 m*M*. However, the peak potentials for both adenine and adenosine are concentration-dependent and shift to more positive values with increasing concentration. Over the approximate concentration range of 0·1–1 m*M* this shift was about 80 mV for both compounds. At below pH 4–5 in buffer solutions containing chloride ion the oxidation peaks of both adenine and adenosine are masked by the facile oxidation of chloride ion in the background electrolyte.

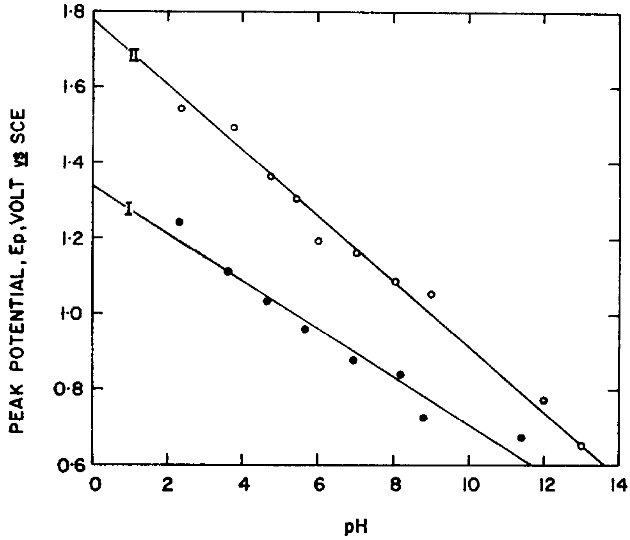


FIG. 1.—Variation of peak potential with pH for the voltammetric oxidation of adenine (I) and adenosine (II) at the PGE at the 0·25 m*M* concentration level.

Both compounds exhibit a rather non-linear relationship between peak current and concentration (Fig. 2), the non-linearity being more pronounced in the case of adenine.

A preliminary examination of the determination of adenine in the presence of adenosine on the basis of the adenine peak current and a calibration curve of the type shown in Fig. 2-I revealed that the adenine concentrations so determined were always very low. Further investigation revealed that addition of adenosine to an adenine solution caused a pronounced decrease in the height of the adenine peak, reaching a constant value of about 55% for a molar ratio of greater than 5:1.

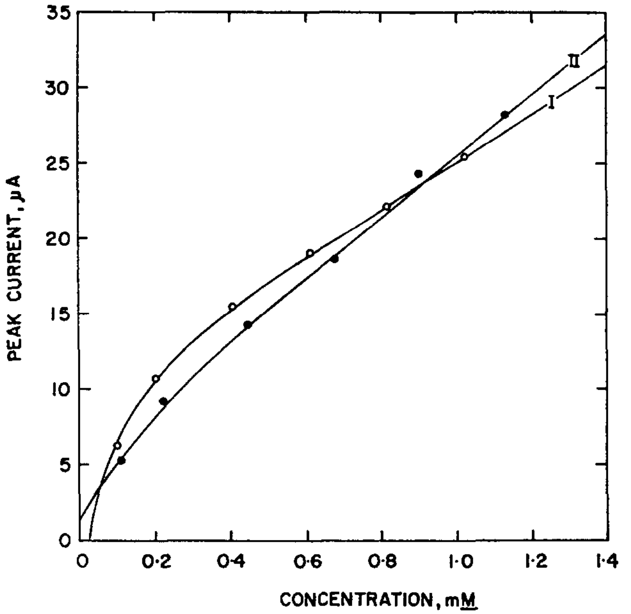

FIG. 2.—Peak current versus concentration relation for the voltammetric oxidation of adenine (I) and adenosine (II) at the PGE.

The non-linear i_p *vs.* C curves for adenine and adenosine suggested that both compounds were adsorbed on the PGE. The fact that the presence of adenosine caused the peak current for adenine to decrease suggested that a competitive adsorption of the two compounds occurred, and that adenosine was displacing part of the adenine from the electrode surface.

In order to investigate further the adsorption of adenine a scan-rate study of the voltammetric oxidation peak of adenine was carried out. This could not be done for adenosine since its oxidation peak occurs so close to background discharge potentials that at scan-rates above *ca.* 20 mV/sec it gives only an inflection on the rise of the background current and accurate measurement of the peak current is impossible.

Earlier studies[4,10] and a.c. voltammetry (*vide infra*) of adenine had revealed that the electrochemical oxidation of adenine is an irreversible process. The theoretical equation for the peak current, i_p (μA) for a linear diffusion-controlled irreversible peak voltammogram at a plane electrode is shown in equation (1).[11,16,13]

$$(i_p)_{\text{irrev}} = 2{\cdot}98 \times 10^5 n\,(\alpha n_a)^{1/2} A D^{1/2} V^{1/2} C \qquad (1)$$

where n is the number of electrons involved in the overall reaction, α the electron transfer coefficient, n_a the number of electrons involved in the rate-controlling electron-transfer process, A the electrode area (cm^2), D the diffusion coefficient of the electroactive species (cm^2/sec), V the voltage scan-rate (V/sec) and C the bulk concentration of the electroactive species (mM). According to this equation, $i_p/ACV^{1/2}$, the peak current function, should be a constant, and a plot of this function *vs.* $V^{1/2}$ (or V) should be a straight line parallel to the $V^{1/2}$ axis. In the case of adenine however the peak-current function shows a pronounced increase with increasing scan-rate (Fig. 3A), typical of an electrode process where the reactant is adsorbed at the electrode surface. In such a

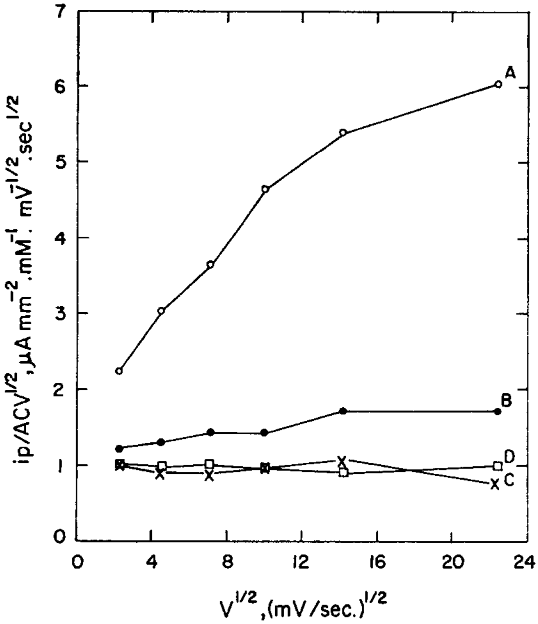

FIG. 3.—Variation of the peak current function, $i_p/ACV^{1/2}$, with the square root of the voltage scan-rate for (A) 0·1025 m*M* adenine, (B) 0·1025 m*M* adenine with 1·00 m*M* adenosine, (C) 0·1025 m*M* adenine with 2·77 m*M* adenosine and (D) 0·2228 m*M* adenine with 6·27 m*M* adenosine. Acetate buffer pH 4·7. PGE geometric area: 12·5 mm².

case the amount of adsorbed material and hence of charge flow (at least in the case of a perfectly reproducible electrode surface) is constant, and the amount of material diffusing to the electrode surface is time dependent with the result that as the scan-rate increases, the contribution from diffusing material decreases with respect to the amount of adsorbed material reacting at the electrode surface, and the peak-current function increases.[14]

On addition of adenosine to adenine in 10:1 molar ratio the peak-current function decreased markedly (Fig. 3B) and the variation of the peak-current function became more in line with that expected for a diffusion-controlled reaction. Addition of a 30:1 molar ratio of adenosine resulted in a further slight decrease in the peak-current function, particularly at higher scan-rates (Fig. 3CD), but the effect was very small at the lowest scan rates studied (5 mV/sec). It was not possible to study the peak current for adenine in the presence of large amounts of adenosine at scan-rates much above 500 mV/sec because the peak potential for adenine shifts to more positive values with increasing scan-rate and the peak merges with the background discharge (from oxidation of the adenosine).

Values of the diffusion coefficient as calculated from relevant polarographic data ($1{\cdot}87 \times 10^{-3}$ mm²/sec) and of αn_a calculated according to

$$E_p - E_{p/2} = 0{\cdot}048/\alpha n_a \qquad (2)$$

were inserted into (1) to obtain theoretical peak currents of 1·55 and 2·32 $\mu A \cdot mm^{-2} \cdot mM^{-1} \cdot mV^{-1/2} \cdot sec^{1/2}$ assuming a four- or a six-electron oxidation respectively. Coulometric evidence suggests that six electrons are involved per molecule of adenine, but in the presence of a large amount of adenosine as is here the case, the experimental value of around unity for the peak current (Fig. 3) would be more in agreement with a four-electron reaction. It should be stressed that the αn_a value cannot be determined accurately since the adenine peak lies so close to the background discharge, and a close agreement between the theoretical and experimental values is not to be expected.

Alternating current voltammetry

A qualitative technique for observing the regions of potential where adsorption of organic molecules takes place at a dropping mercury electrode is a.c. polarography. In the potential regions where adsorption occurs, pronounced depressions of the alternating base current occur owing to a decrease of the double-layer capacity of the electrode.[15] A few reports of a.c. techniques at solid or stationary electrodes have appeared[16–20] but only that of Delahay and Trachtenberg[21] at stationary mercury electrodes has dealt specifically with adsorption effects. Alternating current voltammograms of adenine and adenosine and mixtures of the two are presented in Fig. 4. It is clear from the voltammograms shown in Figs. 4A and 4B that both adenine and adenosine markedly depress the alternating base current over the whole potential range examined. Since the base current for both compounds is depressed at potentials more negative than the DC peak it is obvious that both adenine and adenosine are adsorbed at the PGE. Both compounds also exhibit a rather pronounced pit, or well potentials corresponding to the rising portion of the d.c. peak. The depression of the base current at potentials more positive than the d.c. peak appears to be more pronounced than at more negative ones, indicating that one of the products of the oxidation of these compounds is quite strongly adsorbed at the PGE. The a.c. voltammetric results are clearly in agreement with the results of the scan-rate and sweep-rate studies on adenine, *i.e.*, that adenine is adsorbed at the PGE. The absence of any faradaic a.c. peaks at potentials in the vicinity of the d.c. peaks for both adenine and adenosine confirms the irreversible nature of these electrode processes.[4,5]

Figure 4C shows that making a 6·3m*M* solution of adenosine in acetate buffer at pH 4·7 1m*M* in adenine still causes an appreciable base current depression at potentials more negative and more positive than the adenine d.c. peak, especially at the more positive potentials. However this depression is not as pronounced as it is in the absence of adenosine and indeed for 20:1 or 30:1 molar ratios of adenosine to adenine, it is not observed by a.c. techniques.

The conclusion that can be drawn from the qualitative a.c., sweep-rate and concentration studies is that both adenine and adenosine and at least one of their oxidation products are adsorbed at the PGE. In the presence of large amounts of adenosine, adsorbed adenine is largely displaced from the electrode surface and the voltammetric oxidation of adenine becomes effectively diffusion-controlled.

Development of analytical methods

The DME studies on adenine, adenosine and mixtures of the two show that the polarographic limiting current is directly proportional to the sum of the concentrations of the two bases. In contrast, at the PGE adenine and adenosine are both adsorbed and as a result of competitive adsorption the peak current for adenine is dependent on the concentration of adenosine present, though at sufficiently large concentrations of adenosine, adenine is to a considerable extent displaced from the electrode surface

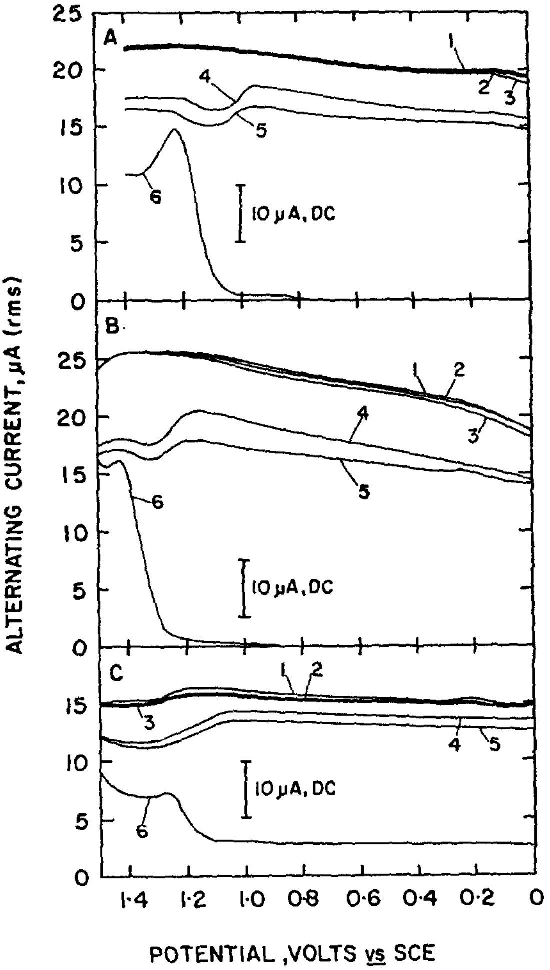

FIG. 4.—Alternating current voltammograms at the PGE in acetate buffer at pH 4·7 of A, 1 m*M* adenine; B, 1 m*M* adenosine. Scans 1, 2, 3 are a.c. background traces, scans 4 and 5 are a.c. traces in the presence of adenine or adenosine, scan 6 is a d.c. voltammogram. C: Scans 1, 2, 3 are of 6·27 m*M* adenosine in acetate buffer pH 4·7, scans 4 and 5 are 6·27 m*M* adenosine plus 1 m*M* adenine, scan 6 is a d.c. voltammogram. Scan rate: 5 mV/sec; alternating voltage 10 mV peak-to-peak, 100 Hz. PGE geometric area: 12·5 mm².

and its oxidation becomes a diffusion-controlled process. For a quantitative determination of adenine by voltammetric oxidation large concentration ratios should be used, with a maximum adenine concentration around 1m*M* (approaching its limit of solubility).

Typical i_p *vs*. *C* curves for adenine in the presence of approximately 3m*M* and 6m*M* adenosine are clearly linear but a slightly lower current is observed in the presence of the higher adenosine concentration. In view of the linearity of the latter i_p *vs*. *C* plot over a wide range of molar ratios from 8 to 156 it was felt that accurate determinations of adenine could be performed simply by adding sufficient solid adenosine to adenine–adenosine mixtures to ensure at least a 6–7 fold molar excess of it was present.

In order to test the methods developed, some mixtures of adenine and adenosine in acetate buffer at pH 4·7 were examined. The samples were first analysed polarographically, then solid adenosine was added to the test solutions sufficient to make them *ca.* 6–7m*M* in adenosine. The concentration of adenine was then determined from the height of the resulting voltammetric oxidation peak of adenine at the PGE. Typical analytical results are presented in Table I. Once the calibration curves have been obtained a total analysis of the adenine and adenosine present in a sample can be completed in at most 15 min.

TABLE I.—TYPICAL RESULTS FOR THE ELECTROCHEMICAL DETERMINATION OF MIXTURES OF ADENINE AND ADENOSINE.

Taken, m*M*		Found, m*M*	
Adenine	Adenosine	Adenine	Adenosine
0·098	1·12	0·08	1·14
0·29	0·92	0·30	0·85
0·49	0·73	0·52	0·67
0·93	0·29	0·90	0·29
0·37	0·24	0·37	0·26

CONCLUSION

By a combination of polarography at the DME and voltammetry at the PGE a rapid and reasonably accurate analysis for adenine and adenosine in mixtures is possible. No previously reported method is capable of determining adenine in the pressure of such large amounts of adenosine.

The studies reported in this paper have utilized an acetate buffer at pH 4·7 as the background electrolyte system. A very brief examination of the adenine–adenosine system at lower pH values in acetate buffers or with sulphuric acid-potassium sulphate supporting electrolyte systems revealed that similar results may be obtained. Above pH 6 the polarographic waves of adenine and adenosine become small and kinetically controlled, and utimately disappear at about pH 7, with the result that the polarographic procedure for the determination of the total adenine plus adenosine can no longer be used.

However, the voltammetric oxidation peaks of adenine and of adenosine at the PGE persist to a very high pH, and hence the adenine concentration could still be determined. If it were necessary to determine the adenosine and adenine concentration at above pH 6 it should be possible to determine the total base concentrations by ultraviolet absorption spectrophotometry and the adenine concentration from its voltammetric oxidation peak at the PGE in the presence of a large excess of adenosine.

Acknowledgement—The author would like to express his thanks to the National Science Foundation for financial support of the work.

Zusammenfassung—Adenin und Adenosin lassen sich aus wäßriger Lösung bei pH 4·7 polarographisch an der Quecksilbertropfelektrode (DME) beim selben Halbstufenpotential reduzieren. An einer Elektrode aus Pyrolysegraphit (PGE) sind beide voltammetrisch oxidierbar, Adenosin jedoch bei höherem Potential. Die konkurrierende Adsorption beider Verbindungen an der PGE führt dazu, daß der Adeninpeak beim Registrieren der voltammetrischen Oxidation in Gegenwart von Adenosin kleiner wird und bei einer Adenosinkonzentration über 6 m*M* einen konstanten Wert erreicht. In Gemischen wird die Summe beider Verbindungen durch Polarographie an der DME erhalten. Dann wird festes Adenosin zur Lösung gegeben und Adenin durch Voltammetrie an der PGE bestimmt.

Résumé—L'adénine et l'adénosine sont réductibles polarographiquement en solution aqueuse à pH 4,7 à l'électrode à goutte de mercure au même $E_{1/2}$, et sont également oxydables voltammétriquement à l'électrode de toile de platine, mais à des potentiels différents, l'adénosine aux potentiels plus élevés. L'adsorption compétitive des deux composés sur l'électrode de toile de platine a pour conséquence un abaissement dans le pic d'oxydation voltammétrique de l'adénine en la présence d'adénosine, atteignant une valeur constante lorsque la concentration de cette dernière est supérieure à 6 m*M*. Dans les mélanges, la somme des deux est obtenue par polarographie à l'électrode à goutte de mercure. On ajoute alors de l'adénosine solide à la solution et l'on dose l'adénine par voltammétrie a l'électrode de toile de platine.

SIMULTANEOUS DETERMINATION OF OXYGEN AND NITROGEN IN IRON AND STEEL BY SPARK-SOURCE MASS SPECTROGRAPHY

SHOHEI ODA, ZENJI OHASHI, KEIICHI FURUYA and HITOSHI KAMADA
Department of Industrial Chemistry, Faculty of Engineering,

(*Received* 19 *May* 1971. *Revised* 14 *October* 1971. *Accepted* 2 *November* 1971)

Summary—A conventional technique has been developed for the simultaneous determination of oxygen and nitrogen in iron and steel by spark-source mass spectrography in the range of 2–400 ppm with a precision of 20%. The instrumental background can be reduced by cryosorption pumping and sample cooling. The adsorbed oxygen on the surface of the sample is easily eliminated by presparking to exhaust the surface concerned. A difference in matrix effect in oxygen determination was observed between iron and steel.

IT IS WELL KNOWN that nitrogen and oxygen in metallic materials seriously affect the mechanical properties. These elements have been determined by vacuum fusion, inert gas fusion, isotope dilution, emission spectrometry and chemical methods.

The use of spark-source mass spectrography for low-level impurity analysis of metals has several advantages over other methods, as has been already established.[1,2] The analysis for non-metallic impurities such as nitrogen and oxygen is, however, still difficult on account of the high instrumental background, and surface contamination of the sample.

Vidal *et al.*[3] tested three different methods for the elimination of adsorbed gases on the surface of iron samples and concluded that the oxygen adsorbed should be removed by eight hours' baking at 150°, but they did not report any oxygen determinations.

Harrington *et al.*[4] discuss the simultaneous determination of carbon, nitrogen and oxygen in metals, with a reduction in the blank by use of a strong cryosorption pump in the source chamber. They concluded that baking the surface surrounding the sparking area did not reduce the intensities of these elements.

Leipziger *et al.*[5] reduced the blank levels for hydrogen, nitrogen and oxygen by baking, presparking, and the judicious choice of etching reagents, to determine levels of 0·1 ppm in gold and platinum. From our experience these samples are not so active towards these elements. With iron samples these authors got only scattered oxygen values, at the 100-ppm level.

A cryosorption pump designed by us gave low instrumental background for nitrogen, but not for oxygen. This effect may be due to contamination on the surface of the sample for sparking.

The method reported here allows the simultaneous determination of nitrogen and oxygen in iron and steel, in the range of 2–400 ppm, with a precision of 20%, using a cryosorption pump in the source chamber and presparking for the elimination of surface contamination of sample.

EXPERIMENTAL

Apparatus and emulsion

A Mattach-Herzog type double-focusing mass spectrograph (Type JMS-01BM, JEOLCO) was used. The chambers of the electrostatic and magnetic analysers were evacuated to a pressure of less than 10^{-8} mmHg. The objective slitwidth was 25 μm to resolve the close proximities of $^{56}Fe^{4+}$ to $^{14}N^{+}$, and $^{32}S^{2+}$ to $^{16}O^{+}$.

Ilford Q2 photographic plates were used. The spectrum line intensity was recorded with a microphotometer (Type JA-2310, Jarrell-Ash Co.).

Quantitative calculation

Although Owens[6] proposed a rapid calibration method, a simplified method was applied. From the spectra of a series of standard samples in which the nitrogen and oxygen contents were already known by other methods, the arbitrary concentration of these elements was calculated with the conventional method on the assumption that their sensitivity and spectrum areas were unity. The ratios of relative sensitivity to spectrum area (S/A) for each elements were determined from the ratios of calculated values *vs.* standard analytical values. The analytical values of unknown samples were calculated from the arbitrary mass spectrographic content and the S/A value thus determined.

Reference analysis

The procedures of the other methods used for the standard samples are reported elsewhere.

Oxygen, vacuum fusion analysis. The conventional analysis at 1650° was used for the determination of oxygen in electrolytic iron and steel. Pure electrolytic iron (15 g) was used as bath metal. For the determination of oxygen in zone-melted iron, the oxygen contamination on the surface of samples was removed by electrolytic polishing and reduction with hydrogen on the surface before analysis.[7]

Nitrogen, isotope dilution analysis. Synthesized ^{15}N-enriched silicon nitride was used as master alloy. A sample (10 g) was sealed into an degassed graphite capsule with a known quantity of the labelled silicon nitride and dropped into a crucible at 1650°. The extracted gas was circulated in the furnace to establish equilibrium. The content of nitrogen-15 was measured by mass spectrometer.[8,9]

Nitrogen, chemical analysis. The conventional Japanese Industrial Standard method (Kjeldahl method) was used.

Reduction of instrumental background and sample preparation

The largest difficulty in mass spectrographic determination of nitrogen and oxgyen in metals is the high instrumental background, and contamination of the sample surface. It was already known by us that it is possible to determine nitrogen as low as several ppm without any special treatment. For oxygen, however, these interferences are intrinsic.

After several trials, presparking of sample electrodes was found to reduce substantially and minimize the effect of adsorbed oxygen on the surface of samples.

A sample was machined into a pair of 15 × 1 × 1 mm electrodes, which were rinsed in dichloroethane and in ethanol with aid of an ultrasonic cleaner. After drying, the sample was set in the electrode holders in the source chamber, and baked for 30 min at 100–150° with an electric heater under a pressure of less than 10^{-6} mmHg. Then the top 2-mm portion of the electrodes was manipulated so as to be exhausted to about 0·1 mm depth, with sparking to clean the surface.

In order to reduce the instrumental background, cryosorption pumping was used as the most convenient method.[4,10] A pumping unit with a 150 × 35 × 1 mm copper support bound with activated charcoal was mounted between the accelerating slit and the earth slit in the source chamber. The unit was kept cool by copper cooling tubes of 12 mm bore which were connected to a liquid nitrogen reservoir. Sample holders were also kept cool by heat conduction through beryllia insulators in contact with other copper cooling tubes.

Figure 1 shows the effects of cryosorption pumping and sample cooling to reduce the instrumental background effect in nitrogen and oxygen determination. The vertical axis in Fig. 1 shows the ratios of ion intensity of nitrogen or oxygen to that of iron. The sample used here was zone-melted iron which contained 6·0 ppm nitrogen and 3·5 ppm oxygen. Figure 1 shows that not only cryosorption pumping but also sample cooling can effectively reduce the oxygen background. It is assumed that the effect of sample cooling is due to a cryosorptive effect rather than to the sample itself. Nitrogen intensities were not changed; no special treatment is required for the determination of nitrogen at the ppm level.

Sparking conditions

The effect of sparking conditions on the intensities of spectrum lines of nitrogen, oxygen and iron was investigated. Figures 2–5 show the results. The sample used was electrolytic iron which contained 200 ppm nitrogen and 300 ppm oxygen. Exposure was 3 × 10^{-11} coulomb. Each point in these figures shows the mean of three determinations. In Fig. 3, min, med, and max show the minimum, mean, and maximum gaps at which the sparks can be struck. As the spectrum intensities of both elements reduce when the gap becomes narrow, the gap was always kept wider than the medium

position. Pulse duration, sparking voltage, and electrode gap have large influences on the intensities of spectra. These factors, especially the electrode gap which cannot be controlled instrumentally, should be kept constant throughout the experiment. The adjustment of exposure time was accomplished by change of the repetition frequency, which has the least effect on the line intensity.

The fixed experimental conditions are shown in Table I.

RESULTS

A calibration curve of *S*/*A* for nitrogen and oxygen is shown in Fig. 6. The standard samples consisted of a series of carbon steels (C 0·1–0·8%) and a series of

irons. The iron series consisted of four samples of electrolytic iron treated to avoid segmentation effects, and one sample of sintered iron manufactured by Sumitomo Tokushu Kinzoku Co. (Osaka, Japan), from pure iron and alumina powder as a standard sample for gas analysis in vacuum fusion, activation, and other methods.

It is very interesting that there is a remarkable difference in the values of S/A for oxygen in Fig. 6: 4·60 for iron, and 2·35 for steel. It shows there is a difference in the relative sensitivities for oxygen in iron and steel, as the relative area of a spectrum of an element is always constant. On the other hand, in the case of nitrogen no difference can be observed between iron and steel. The relative intensity of the nitrogen spectrum is 1·37.

The necessity of using standard samples in spark-source mass spectrographic determination is often underestimated, and it is recommended for accurate determination that the relative sensitivities of samples are measured by using a series of standards having similar composition to the samples.

The effect of sample cooling was to give a slight reduction of S/A in the nitrogen analysis. The value of S/A without cooling was 1·67, and with cooling it was 1·37.

Table II shows the results of simultaneous determination of nitrogen and oxygen for two types of iron and one type of steel, using values of S/A obtained from Fig. 6.

The precision of the analytical values is about 20% relative standard deviation, and the results were in good agreement with those obtained by other methods. This

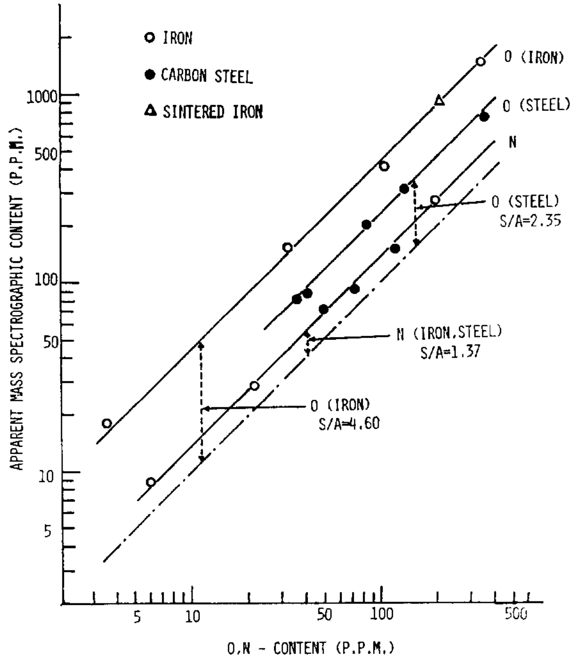

FIG. 6.—Analytical curves.

TABLE II.—ANALYTICAL RESULTS

Sample	Element	Content, *ppm*	Relative standard deviation, %	No. of tests	Values by other methods
Zone-melted iron	O	3·9 ± 0·6	15·4	3	3·5 (V)

procedure can be applied to practical samples in the range of 2–400 ppm oxygen or nitrogen. Although the detection limits of this method have not been discussed, because of the lack of standard samples which contain less nitrogen and oxygen than those used in this experiment, it may be considered as 1 ppm from the results of other experiments in which the instrumental background was found to be less than 1 ppm when high-purity silicon electrodes were used.

DISCUSSION

It is commonly assumed that almost all elements have nearly equal sensitivities and that the sensitivity of an element is not influenced by the other elements present. It is, however, very interesting that a large difference in relative sensitivities was observed for oxygen in iron and steel. This phenomenon has never been reported, and it will be discussed here briefly.

As the sparking mechanism in the mass spectrographic analysis is very complex and might be a combination of several ionization mechanisms, it is still very hard to discuss the mechanism on the basis of the limited results obtained. More experimental data on the mechanism are needed, obtained by using time-resolving and other techniques. Possible reasons for the difference in sensitivity of oxygen are as follows. (1) Difference of the state of oxygen in iron and steel. Oxygen in iron exists in the form of FeO or dissolved oxygen, whereas in steel most oxygen exists as more stable oxides, *e.g.*, Al_2O_3, SiO_2. A difference in vaporization and dissociation energies between these oxides may bring about the difference of ionization efficiency of oxygen. (2) Other elements existing in steel may reduce the relative sensitivity of oxygen. Some elements which have low ionization potential may reduce the ionization yield of oxygen which has relatively high ionization potential, and the other elements may recombine with oxygen extracted from sample electrodes, and so reduce the yield. (3) Sample cooling may promote selective distillation and so reduce the ionization yield of oxygen.

Of these reasons, (1) should be discarded, as the oxygen sensitivity of the sintered iron in which the oxygen exists as alumina, has the same value as that of the electrolytic iron; (3) is considered to be unlikely on present knowledge. The second reason is assumed to be most likely, because steel contains so many alloying elements.

The dependence of the spectrum intensity on the electrode gap may be explained on the assumption that the local spark-breaking voltage is dependent on the length of gap. This is supported by the curves in Fig. 2; the higher the sparking voltage, the stronger the intensities of both elements. As a possible improvement for analytical precision, it is recommended that a voltage control element be built in the spark source circuit, thus achieving independence between the spark-breaking voltage and the electrode gap.

The dependence of spectrum intensities on other conditions such as sparking voltage and pulse duration will also cause significant analytical errors.

From these considerations, it can be said that the relative sensitivity of an element not only depends on the kind of element, but also on the experimental conditions, matrix elements, and other constituents. For an accurate mass spectrographic measurement, it is best to obtain the relative sensitivities by using a series of standards which have similar composition to the sample.

Zusammenfassung—Ein schon bekanntes Verfahren wurde für die gleichzeitige Bestimmung von Sauerstoff und Stickstoff in Eisen und Stahl weiterentwickelt. Man verwendet ein Massenspektrometer mit Funkenquelle und kann damit im Bereich 2–400 ppm eine Genauigkeit von 20% erzielen. Der Untergrund des Instruments kann durch Kryosorptionspumpen und Kühlung der Probe reduziert werden. Der an der Probenoberfläche adsorbierte Sauerstoff kann leicht durch vorheriges Abfunken beseitigt werden; dadurch wird die betreffende Oberfläche gereinigt. Bei der Sauerstoffbestimmung wurde zwischen Eisen und Stahl ein Unterschied im Matrixeffekt gefunden.

Résumé—On a élaboré une technique ordinaire pour le dosage simultané de l'oxygène et de l'azote dans le fer et l'acier par spectrographie de masse à source d'étincelle, dans le domaine de 2–400 ppm, avec une précision de 20%. On peut réduire le fond instrumental par pompage

en cryosorption et refroidissement de l'échantillon. On élimine aisément l'oxygène adsorbé sur la surface de l'échantillon par jaillissement préalable d'étincelle pour épuiser la surface concernèe. On a observé une différence d'effet de matrice dans la détermination de l'oxygène entre le fer et l'acier.

Summary—A conventional technique has been developed for the simultaneous determination of oxygen and nitrogen in iron and steel by spark-source mass spectrography in the range of 2–400 ppm with a precision of 20%. The instrumental background can be reduced by cryosorption pumping and sample cooling. The adsorbed oxygen on the surface of the sample is easily eliminated by presparking to exhaust the surface concerned. A difference in matrix effect in oxygen determination was observed between iron and steel.

IT IS WELL KNOWN that nitrogen and oxygen in metallic materials seriously affect the mechanical properties. These elements have been determined by vacuum fusion, inert gas fusion, isotope dilution, emission spectrometry and chemical methods.

The use of spark-source mass spectrography for low-level impurity analysis of metals has several advantages over other methods, as has been already established.[1,2] The analysis for non-metallic impurities such as nitrogen and oxygen is, however, still difficult on account of the high instrumental background, and surface contamination of the sample.

Vidal *et al.*[3] tested three different methods for the elimination of adsorbed gases on the surface of iron samples and concluded that the oxygen adsorbed should be removed by eight hours' baking at 150°, but they did not report any oxygen determinations.

Harrington *et al.*[4] discuss the simultaneous determination of carbon, nitrogen and oxygen in metals, with a reduction in the blank by use of a strong cryosorption pump in the source chamber. They concluded that baking the surface surrounding the sparking area did not reduce the intensities of these elements.

Leipziger *et al.*[5] reduced the blank levels for hydrogen, nitrogen and oxygen by baking, presparking, and the judicious choice of etching reagents, to determine levels of 0·1 ppm in gold and platinum. From our experience these samples are not so active towards these elements. With iron samples these authors got only scattered oxygen values, at the 100-ppm level.

A cryosorption pump designed by us gave low instrumental background for nitrogen, but not for oxygen. This effect may be due to contamination on the surface of the sample for sparking.

The method reported here allows the simultaneous determination of nitrogen and oxygen in iron and steel, in the range of 2–400 ppm, with a precision of 20%, using a cryosorption pump in the source chamber and presparking for the elimination of surface contamination of sample.

EXPERIMENTAL

Apparatus and emulsion

A Mattach-Herzog type double-focusing mass spectrograph (Type JMS-01BM, JEOLCO) was used. The chambers of the electrostatic and magnetic analysers were evacuated to a pressure of less than 10^{-8} mmHg. The objective slitwidth was 25 μm to resolve the close proximities of $^{56}Fe^{4+}$ to $^{14}N^{+}$, and $^{32}S^{2+}$ to $^{16}O^{+}$.

Ilford Q2 photographic plates were used. The spectrum line intensity was recorded with a microphotometer (Type JA-2310, Jarrell-Ash Co.).

Quantitative calculation

Although Owens[6] proposed a rapid calibration method, a simplified method was applied. From the spectra of a series of standard samples in which the nitrogen and oxygen contents were already known by other methods, the arbitrary concentration of these elements was calculated with the conventional method on the assumption that their sensitivity and spectrum areas were unity. The ratios of relative sensitivity to spectrum area (S/A) for each elements were determined from the ratios of calculated values *vs.* standard analytical values. The analytical values of unknown samples were calculated from the arbitrary mass spectrographic content and the S/A value thus determined.

Reference analysis

The procedures of the other methods used for the standard samples are reported elsewhere.

Oxygen, vacuum fusion analysis. The conventional analysis at 1650° was used for the determination of oxygen in electrolytic iron and steel. Pure electrolytic iron (15 g) was used as bath metal. For the determination of oxygen in zone-melted iron, the oxygen contamination on the surface of samples was removed by electrolytic polishing and reduction with hydrogen on the surface before analysis.[7]

Nitrogen, isotope dilution analysis. Synthesized ^{15}N-enriched silicon nitride was used as master alloy. A sample (10 g) was sealed into an degassed graphite capsule with a known quantity of the labelled silicon nitride and dropped into a crucible at 1650°. The extracted gas was circulated in the furnace to establish equilibrium. The content of nitrogen-15 was measured by mass spectrometer.[8,9]

Nitrogen, chemical analysis. The conventional Japanese Industrial Standard method (Kjeldahl method) was used.

Reduction of instrumental background and sample preparation

The largest difficulty in mass spectrographic determination of nitrogen and oxgyen in metals is the high instrumental background, and contamination of the sample surface. It was already known by us that it is possible to determine nitrogen as low as several ppm without any special treatment. For oxygen, however, these interferences are intrinsic.

After several trials, presparking of sample electrodes was found to reduce substantially and minimize the effect of adsorbed oxygen on the surface of samples.

A sample was machined into a pair of 15 × 1 × 1 mm electrodes, which were rinsed in dichloroethane and in ethanol with aid of an ultrasonic cleaner. After drying, the sample was set in the electrode holders in the source chamber, and baked for 30 min at 100–150° with an electric heater under a pressure of less than 10^{-6} mmHg. Then the top 2-mm portion of the electrodes was manipulated so as to be exhausted to about 0·1 mm depth, with sparking to clean the surface.

In order to reduce the instrumental background, cryosorption pumping was used as the most convenient method.[4,10] A pumping unit with a 150 × 35 × 1 mm copper support bound with activated charcoal was mounted between the accelerating slit and the earth slit in the source chamber. The unit was kept cool by copper cooling tubes of 12 mm bore which were connected to a liquid nitrogen reservoir. Sample holders were also kept cool by heat conduction through beryllia insulators in contact with other copper cooling tubes.

Figure 1 shows the effects of cryosorption pumping and sample cooling to reduce the instrumental background effect in nitrogen and oxygen determination. The vertical axis in Fig. 1 shows the ratios of ion intensity of nitrogen or oxygen to that of iron. The sample used here was zone-melted iron which contained 6·0 ppm nitrogen and 3·5 ppm oxygen. Figure 1 shows that not only cryosorption pumping but also sample cooling can effectively reduce the oxygen background. It is assumed that the effect of sample cooling is due to a cryosorptive effect rather than to the sample itself. Nitrogen intensities were not changed; no special treatment is required for the determination of nitrogen at the ppm level.

Sparking conditions

The effect of sparking conditions on the intensities of spectrum lines of nitrogen, oxygen and iron was investigated. Figures 2–5 show the results. The sample used was electrolytic iron which contained 200 ppm nitrogen and 300 ppm oxygen. Exposure was 3 × 10^{-11} coulomb. Each point in these figures shows the mean of three determinations. In Fig. 3, min, med, and max show the minimum, mean, and maximum gaps at which the sparks can be struck. As the spectrum intensities of both elements reduce when the gap becomes narrow, the gap was always kept wider than the medium

position. Pulse duration, sparking voltage, and electrode gap have large influences on the intensities of spectra. These factors, especially the electrode gap which cannot be controlled instrumentally, should be kept constant throughout the experiment. The adjustment of exposure time was accomplished by change of the repetition frequency, which has the least effect on the line intensity.

The fixed experimental conditions are shown in Table I.

RESULTS

A calibration curve of S/A for nitrogen and oxygen is shown in Fig. 6. The standard samples consisted of a series of carbon steels (C 0·1–0·8 %) and a series of

TABLE I.—EXPERIMENTAL CONDITIONS

irons. The iron series consisted of four samples of electrolytic iron treated to avoid segmentation effects, and one sample of sintered iron manufactured by Sumitomo Tokushu Kinzoku Co. (Osaka, Japan), from pure iron and alumina powder as a standard sample for gas analysis in vacuum fusion, activation, and other methods.

It is very interesting that there is a remarkable difference in the values of *S*/*A* for oxygen in Fig. 6: 4·60 for iron, and 2·35 for steel. It shows there is a difference in the relative sensitivities for oxygen in iron and steel, as the relative area of a spectrum of an element is always constant. On the other hand, in the case of nitrogen no difference can be observed between iron and steel. The relative intensity of the nitrogen spectrum is 1·37.

The necessity of using standard samples in spark-source mass spectrographic determination is often underestimated, and it is recommended for accurate determination that the relative sensitivities of samples are measured by using a series of standards having similar composition to the samples.

The effect of sample cooling was to give a slight reduction of *S*/*A* in the nitrogen analysis. The value of *S*/*A* without cooling was 1·67, and with cooling it was 1·37.

Table II shows the results of simultaneous determination of nitrogen and oxygen for two types of iron and one type of steel, using values of *S*/*A* obtained from Fig. 6.

The precision of the analytical values is about 20% relative standard deviation, and the results were in good agreement with those obtained by other methods. This

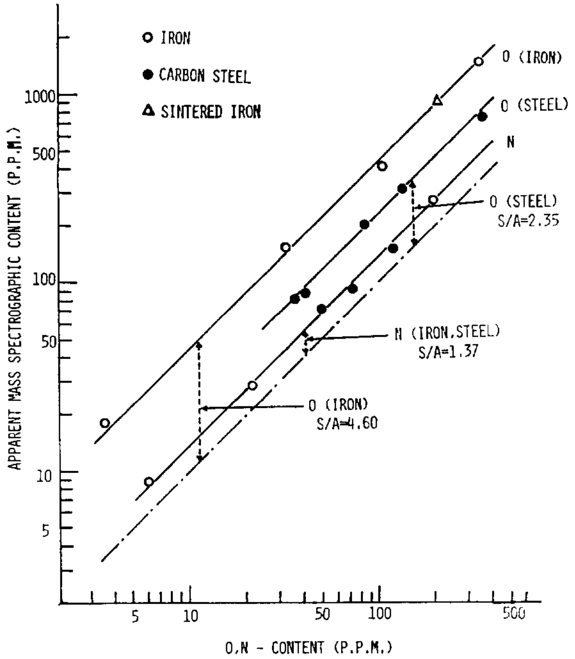

FIG. 6.—Analytical curves.

TABLE II.—ANALYTICAL RESULTS

Sample	Element	Content, *ppm*	Relative standard deviation, %	No. of tests	Values by other methods
Zone-melted iron	O	3·9 ± 0·6	15·4	3	3·5 (V)
	N	6·5 ± 1·6	24·6	3	6·0 (I)
Electrolytic iron	O	320 ± 39	12·2	5	335 (V)
	N	20·7 ± 2·5	12·1	5	21 (I)

procedure can be applied to practical samples in the range of 2–400 ppm oxygen or nitrogen. Although the detection limits of this method have not been discussed, because of the lack of standard samples which contain less nitrogen and oxygen than those used in this experiment, it may be considered as 1 ppm from the results of other experiments in which the instrumental background was found to be less than 1 ppm when high-purity silicon electrodes were used.

DISCUSSION

It is commonly assumed that almost all elements have nearly equal sensitivities and that the sensitivity of an element is not influenced by the other elements present. It is, however, very interesting that a large difference in relative sensitivities was observed for oxygen in iron and steel. This phenomenon has never been reported, and it will be discussed here briefly.

As the sparking mechanism in the mass spectrographic analysis is very complex and might be a combination of several ionization mechanisms, it is still very hard to discuss the mechanism on the basis of the limited results obtained. More experimental data on the mechanism are needed, obtained by using time-resolving and other techniques. Possible reasons for the difference in sensitivity of oxygen are as follows. (1) Difference of the state of oxygen in iron and steel. Oxygen in iron exists in the form of FeO or dissolved oxygen, whereas in steel most oxygen exists as more stable oxides, *e.g.*, Al_2O_3, SiO_2. A difference in vaporization and dissociation energies between these oxides may bring about the difference of ionization efficiency of oxygen. (2) Other elements existing in steel may reduce the relative sensitivity of oxygen. Some elements which have low ionization potential may reduce the ionization yield of oxygen which has relatively high ionization potential, and the other elements may recombine with oxygen extracted from sample electrodes, and so reduce the yield. (3) Sample cooling may promote selective distillation and so reduce the ionization yield of oxygen.

Of these reasons, (1) should be discarded, as the oxygen sensitivity of the sintered iron in which the oxygen exists as alumina, has the same value as that of the electrolytic iron; (3) is considered to be unlikely on present knowledge. The second reason is assumed to be most likely, because steel contains so many alloying elements.

The dependence of the spectrum intensity on the electrode gap may be explained on the assumption that the local spark-breaking voltage is dependent on the length of gap. This is supported by the curves in Fig. 2; the higher the sparking voltage, the stronger the intensities of both elements. As a possible improvement for analytical precision, it is recommended that a voltage control element be built in the spark source circuit, thus achieving independence between the spark-breaking voltage and the electrode gap.

The dependence of spectrum intensities on other conditions such as sparking voltage and pulse duration will also cause significant analytical errors.

From these considerations, it can be said that the relative sensitivity of an element not only depends on the kind of element, but also on the experimental conditions, matrix elements, and other constituents. For an accurate mass spectrographic measurement, it is best to obtain the relative sensitivities by using a series of standards which have similar composition to the sample.

Zusammenfassung—Ein schon bekanntes Verfahren wurde für die gleichzeitige Bestimmung von Sauerstoff und Stickstoff in Eisen und Stahl weiterentwickelt. Man verwendet ein Massenspektrometer mit Funkenquelle und kann damit im Bereich 2–400 ppm eine Genauigkeit von 20% erzielen. Der Untergrund des Instruments kann durch Kryosorptionspumpen und Kühlung der Probe reduziert werden. Der an der Probenoberfläche adsorbierte Sauerstoff kann leicht durch vorheriges Abfunken beseitigt werden; dadurch wird die betreffende Oberfläche gereinigt. Bei der Sauerstoffbestimmung wurde zwischen Eisen und Stahl ein Unterschied im Matrixeffekt gefunden.

Résumé—On a élaboré une technique ordinaire pour le dosage simultané de l'oxygène et de l'azote dans le fer et l'acier par spectrographie de masse à source d'étincelle, dans le domaine de 2–400 ppm, avec une précision de 20%. On peut réduire le fond instrumental par pompage

en cryosorption et refroidissement de l'échantillon. On élimine aisément l'oxygène adsorbé sur la surface de l'échantillon par jaillissement préalable d'étincelle pour épuiser la surface concernèe. On a observé une différence d'effet de matrice dans la détermination de l'oxygène entre le fer et l'acier.

Indirect method for the determination of aluminium by atomic-absorption spectrometry using an air–acetylene flame

(*Received* 9 *November* 1971. *Accepted* 13 *December* 1971)

It has been reported that serious interelement interferences are observed in the atomic-absorption determination of iron under certain operating conditions using an air–acetylene flame.[1,2] When flame conditions are optimized for maximum iron absorbance to be obtained for solutions prepared in sulphate or nitrate media, cobalt, nickel and copper cause depressive interferences.[2] Maximum absorption by iron occurs in a slightly fuel-lean air–acetylene flame, but in the stoichiometric or fuel-rich flame the iron absorption falls sharply when a purely sulphate or nitrate medium is used. Under these conditions many metals cause enhancement of the iron absorbance,[3] and of these, titanium, aluminium, calcium and zirconium are notable for the very low concentrations at which they interfere. A similar interference pattern has also been observed for nickel, cobalt and chromium[3,4] and may be explained on the basis of overexcitation phenomena.[3,5]

The enhancement effect has been used to provide a sensitive indirect method for the determination of titanium in the concentration range 0·01–10 ppm.[6] This paper reports a similar method for aluminium and includes a more detailed discussion of the choice of matrix element and the interference effects in this type of procedure. Aluminium cannot normally be determined directly by using an air–acetylene flame[7] as the monoxide AlO is not sufficiently dissociated in this flame,[8] but a working range of 50–500 ppm aluminium has recently been attained in a direct procedure in the presence of ammonium fluoride.[9] Normally either a nitrous oxide–acetylene flame or an oxy-acetylene flame must be used and a detection limit of about 1 ppm may be readily obtained.[7,10,11] Unfortunately, this is not sufficiently sensitive for many routine industrial applications and the method proposed here, which has a limit approximately two orders of magnitude lower than this, may be suitable in some cases.

EXPERIMENTAL

A Perkin–Elmer 290 Atomic Absorption Spectrometer and hollow-cathode lamps were used and operated at the manufacturer's recommended settings. The standard 50-mm slot tubular burner head and the 50-mm slot high-temperature head were used for air–acetylene and nitrous oxide–acetylene flames respectively. Gas flow-rates were measured with Fischer and Porter ¼-in. bore flowmeters and corrected to atmospheric pressure. The air flow-rate was maintained at 46 l./min (equivalent to a flowmeter reading of 14·0 at a feed pressure of 35 psig) and the acetylene flow-rate varied between 2·0 and 4·8 l./min (equivalent to a flowmeter reading of 13·7 at a feed pressure of 8 psig). The optimum height of the optical beam above the burner for maximum enhancement was found to be 15 mm, and absorbance readings were recorded on a Honeywell Electronik 19 chart recorder.

Stock solutions of all the metals in sulphate medium were prepared as described previously.[6] A 1000-ppm aluminium solution was prepared from 1 g of aluminium powder dissolved in sulphuric acid and diluted to 1 litre so that the final concentration of sulphuric acid was $10^{-3}M$. Distilled water from an all-quartz still[12] was used throughout. The purity of water from other types of still was not adequate, presumably because of the effect of very small amounts of calcium on the phenomena to be described. Care must be taken to avoid the addition of chloride ions.

RESULTS AND DISCUSSION

The sharp drop in absorbance by iron (as sulphate or nitrate) which occurs in a fuel-rich air–acetylene flame has been described previously.[3,5] The enhancement effect of small amounts of aluminium on this depression of the iron signal in the fuel-rich flame is shown in Fig. 1. The enhancement for a 25-ppm iron solution gives a linear relationship between 0·25 and 1·2 ppm of aluminium. The signal became more or less constant from 2 up to at least 500 ppm aluminium. The shape and characteristics of this calibration curve and the enhancement effect itself are dependent on the geometry of the burner and optical systems and their orientation relative to one another. This would be

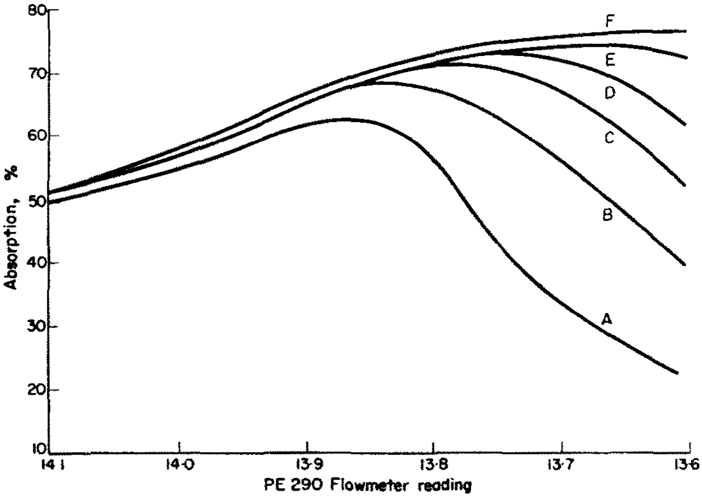

FIG. 1.—Absorption of 25 ppm iron(III) in sulphate medium as a function of acetylene flow-rate. Concentration of aluminium added: (*A*) none; (*B*) 0·5 ppm; (*C*) 1 ppm; (*D*) 2 ppm; (*E*) 10 ppm; (*F*) 500 ppm.

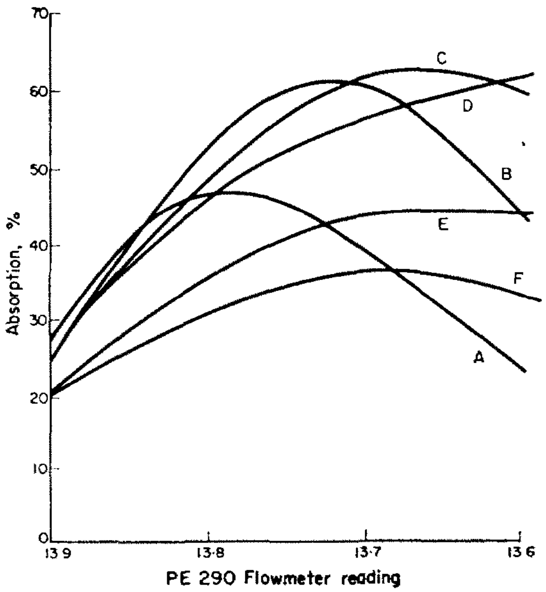

FIG. 2.—Absorption of 10 ppm chromium in sulphate medium as a function of acetylene flow-rate. Concentration of aluminium added: (*A*) none; (*B*) 0·5 ppm; (*C*) 2 ppm; (*D*) 20 ppm; (*E*) 100 ppm; (*F*) 500 ppm.

expected to depend on the particular instrument used but with the PE 290 fitted with a standard air-acetylene burner the optimum conditions for maximum sensitivity are those given above. The working range for the determination of aluminium may be varied by using different concentrations of iron. Thus, for example, the most sensitive conditions with our apparatus required use of 10 ppm of iron when the working range was 0·01–0·09 ppm of aluminium. At higher concentrations of iron, higher levels of aluminium may be detected but concentrations above 25 ppm would mean working in the range in which the direct atomic-absorption determination of aluminium is possible and the method would therefore not be particularly advantageous.

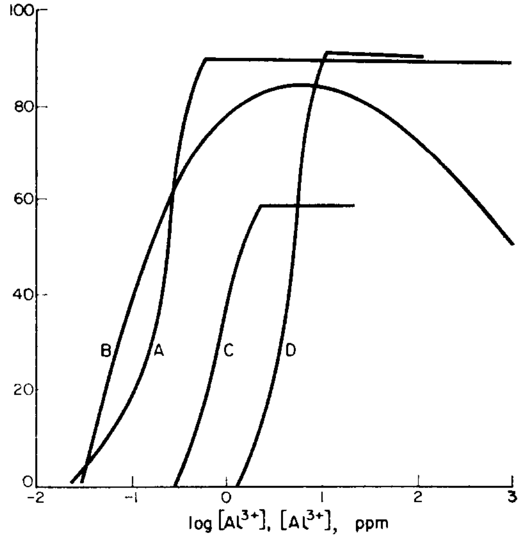

FIG. 3.—Effect of aluminium at a fuel-flow of 13·7 (meter reading) and burner height of 15 mm, on (*A*) 10 ppm of iron; (*B*) 10 ppm of chromium; (*C*) 25 ppm of cobalt; (*D*) 25 ppm of nickel; all in sulphate medium.

Aluminium gives a similar enhancement of the signals of cobalt, nickel and chromium and any of these may be used as the matrix element. The effect for chromium is shown in Fig. 2 and occurs only in the fuel-rich air–acetylene flame. At high aluminium concentrations the chromium signal does not reach a constant level but begins to fall again (Fig. 2), the maximum in the calibration curve depending on the chromium concentration, being at 5 ppm of aluminium for 10 ppm of chromium. The effect of aluminium on the atomic-absorption signals of cobalt and nickel was very similar to that for iron, although the detection of aluminium was far less sensitive with nickel. The effects of increasing aluminium concentration are shown in Fig. 3 for all four elements, which suggests that iron is the most suitable matrix element.

The operating conditions will vary from one instrument to another but they may be summarized as follows. (*i*) Slightly fuel-rich air-acetylene flame such that yellow carbon incandescence is just visible. (*ii*) Light-beam centred at 15–20 mm above the burner head. (*iii*) Matrix element iron(III) sulphate in $10^{-3}M$ sulphuric acid at an iron concentration appropriate to the working range required. (*iv*) Aluminium standards and samples prepared as sulphate and/or nitrate solutions.

We have investigated some interference effects on this procedure and these are largely as expected from the known effects of the elements on the atomic-absorption signal of iron.[8] Elements that behave in a similar manner to aluminium, *e.g.*, calcium and titanium, interfere at an equivalent concentration to the aluminium, whereas others that give an enhancement or depression of the iron signal at concentrations equivalent to the iron concentration, *e.g.*, nickel and chromium, interfere at a similar level. Thus, this method is only suitable for relatively pure aluminium solutions or for analyses in which a separation process is also included. It does, however, offer a substantial improvement in detection limit over that normally obtainable by direct atomic-absorption spectrometry, using either a nitrous oxide–acetylene or oxy-acetylene flame.

Precipitation of barium chromate in the presence of strontium and lead by complexation followed by volatilization of ammonia

(*Received* 9 *November* 1971. *Accepted* 14 *December* 1971)

A NEW PROCEDURE has been developed to separate barium from equal molar concentrations of strontium and lead. The multivalent cations are complexed with MEDTA (1,2-diaminopropane-tetra-acetic acid) or DCTA (1,2-diaminocyclohexane-*N,N,N',N'*-tetra-acetic acid) at a pH of 10·3 or higher in ammoniacal solution. The addition of chromate does not bring about precipitation. The solution is then heated and agitated. Ammonia volatilizes from solution, causing a gradual increase in hydrogen ion concentration. Hydrogen ions compete for the chelating agent which results in a gradual increase in the free barium ion concentration. This causes a slow precipitation of barium chromate from homogeneous solution.

Both the strontium and lead chelates are more stable than the barium chelate. Therefore, the concentration of free strontium ions and free lead ions remains low throughout the precipitation of the barium chromate. Atomic-absorption measurements show that less than 0·05% of the strontium and less than 0·06% of the lead co-precipitate when MEDTA is used. About 0·15% of the strontium and about 0·03% of the lead co-precipitate when DCTA is used.

Precipitation of barium chromate has been the classical method[1] of separating barium fom strontium. The use of precipitation from homogeneous solution[2] as well as complexation[3] has improved the classical method. Complexation has also made a separation of barium from lead possible, with chromate as the precipitant.

Additional modifications based on these fundamental ideas have resulted in further improvements in the separation of barium from both strontium and lead. The method described co-precipitates only about a twelfth of the strontium co-precipitated by the earlier method,[3] and should be applicable to many other systems where cation release is required. Lower pH values can be attained by addition of acid by volatilization in a closed system.

Precipitation of barium chromate in the presence of strontium and lead by complexation followed by volatilization of ammonia

(*Received* 9 *November* 1971. *Accepted* 14 *December* 1971)

A NEW PROCEDURE has been developed to separate barium from equal molar concentrations of strontium and lead. The multivalent cations are complexed with MEDTA (1,2-diaminopropane-tetra-acetic acid) or DCTA (1,2-diaminocyclohexane-*N*,*N*,*N'*,*N'*-tetra-acetic acid) at a pH of 10·3 or higher in ammoniacal solution. The addition of chromate does not bring about precipitation. The solution is then heated and agitated. Ammonia volatilizes from solution, causing a gradual increase in hydrogen ion concentration. Hydrogen ions compete for the chelating agent which results in a gradual increase in the free barium ion concentration. This causes a slow precipitation of barium chromate from homogeneous solution.

Both the strontium and lead chelates are more stable than the barium chelate. Therefore, the concentration of free strontium ions and free lead ions remains low throughout the precipitation of the barium chromate. Atomic-absorption measurements show that less than 0·05% of the strontium and less than 0·06% of the lead co-precipitate when MEDTA is used. About 0·15% of the strontium and about 0·03% of the lead co-precipitate when DCTA is used.

Precipitation of barium chromate has been the classical method[1] of separating barium fom strontium. The use of precipitation from homogeneous solution[2] as well as complexation[3] has improved the classical method. Complexation has also made a separation of barium from lead possible, with chromate as the precipitant.

Additional modifications based on these fundamental ideas have resulted in further improvements in the separation of barium from both strontium and lead. The method described co-precipitates only about a twelfth of the strontium co-precipitated by the earlier method,[3] and should be applicable to many other systems where cation release is required. Lower pH values can be attained by addition of acid by volatilization in a closed system.

Zusammenfassung—Die Verstärkung der Atomabsorptions-Signale von Eisen, Kobalt, Nickel und Chrom in einer fetten Luft-Acetylen-Flamme durch kleine Mengen Aluminium ermöglicht die indirekte Bestimmung von Aluminium im Konzentrationsbereich 0,01–10 ppm. Es wird über die Optimierung der Arbeitsbedingungen und das Auftreten von Störungen berichtet.

Résumé—Le renforcement des signaux d'absorption atomique des fer, cobalt, nickel et chrome dans une flamme air–acétylène riche en combustible par de petites quantités d'aluminium rend possible le dosage indirect de l'aluminium dans le domaine de concentration 0,01–10 ppm. On décrit l'optimalisation des conditions de travail et la présence d'interférences.

Precipitation of barium chromate in the presence of strontium and lead by complexation followed by volatilization of ammonia

(*Received* 9 *November* 1971. *Accepted* 14 *December* 1971)

A NEW PROCEDURE has been developed to separate barium from equal molar concentrations of strontium and lead. The multivalent cations are complexed with MEDTA (1,2-diaminopropane-tetra-acetic acid) or DCTA (1,2-diaminocyclohexane-*N,N,N′,N′*-tetra-acetic acid) at a pH of 10·3 or higher in ammoniacal solution. The addition of chromate does not bring about precipitation. The solution is then heated and agitated. Ammonia volatilizes from solution, causing a gradual increase in hydrogen ion concentration. Hydrogen ions compete for the chelating agent which results in a gradual increase in the free barium ion concentration. This causes a slow precipitation of barium chromate from homogeneous solution.

Both the strontium and lead chelates are more stable than the barium chelate. Therefore, the concentration of free strontium ions and free lead ions remains low throughout the precipitation of the barium chromate. Atomic-absorption measurements show that less than 0·05% of the strontium and less than 0·06% of the lead co-precipitate when MEDTA is used. About 0·15% of the strontium and about 0·03% of the lead co-precipitate when DCTA is used.

Precipitation of barium chromate has been the classical method[1] of separating barium fom strontium. The use of precipitation from homogeneous solution[2] as well as complexation[3] has improved the classical method. Complexation has also made a separation of barium from lead possible, with chromate as the precipitant.

Additional modifications based on these fundamental ideas have resulted in further improvements in the separation of barium from both strontium and lead. The method described co-precipitates only about a twelfth of the strontium co-precipitated by the earlier method,[3] and should be applicable to many other systems where cation release is required. Lower pH values can be attained by addition of acid by volatilization in a closed system.

EXPERIMENTAL

Procedure

Add a sample containing about 0·5 mmole of barium (about 70 mg) to a 400-ml beaker.* Add about 50 ml of demineralized water and an excess of chelating agent.† Bring the pH of the solution to 10·3 or slightly higher by the addition of 3*M* ammonia. Add 50 ml of 0·02*M* potassium dichromate adjusted to pH 10·3 or higher.§ Dilute to about 125 ml.

Place the beaker on an oscillating hot-plate. Maintain the temperature within the range 45–60°. Keep the volume of solution reasonably constant by occasional additions of demineralized water. Within about 6–8 hr the pH of the solution will fall to 6–7, usually to 6·7–6·8. Remove the beaker from the hot-plate, stir and let stand overnight.

Filter off on a medium porosity crucible, wash with 0·001*M* potassium dichromate adjusted to pH 7·0, finally rinse with a small portion of demineralized water, and dry the precipitate at 110–120° for 2 hr.

RESULTS AND DISCUSSION

Table I gives the results obtained for the pH range of 6·7–6·8 for the final solution. In this range the ammonia is essentially removed from solution. The precipitation is also maximal in this pH range. The results show that more than 99·3% of the barium is precipitated.

TABLE I.—PRECIPITATION OF BARIUM CHROMATE

Ba found, *mg* (gravimetric)	Ba in filtrate, *mg* (atomic absorption)
71·2	0·45
71·8	0·54
71·3	0·20
71·4	0·35
71·0	0·30

Barium taken 71·7 mg (0·5 mmole); 1·0 mmole of potassium dichromate and 0·6 mmole of MEDTA added to each solution. Final pH 6·7–6·8.

Additional investigation showed that precipitation was not nearly quantitative above pH 7·0 or below pH 5·5, but within this range precipitation was at least 99% complete, being maximal over the pH range 6·0–6·8 (average 99·5–99·6%). Atomic-absorption measurements showed that up to 0·7% of the barium appeared in the filtrate (average about 0·4%).

To study the effect of pH at values lower than 6·7, a method of homogeneously increasing the hydrogen ion concentration was needed. To do this with a minimum of disturbance to the solution, either acetic or hydrochloric acid was allowed to volatilize into the solution. A polyethylene bag was placed on an oscillating plate. The beaker containing both barium and chromate was placed inside this bag. A second beaker containing either acetic or hydrochloric acid was also placed inside the bag. The bag was then closed, and the oscillating cycle started. Acid volatilized into the barium solution, causing a slow increase in hydrogen ion concentration. Even though the acid could only enter at the surface of the solution, the agitation tended to distribute it throughout the solution.

Table II gives the results obtained when strontium and lead are also present in the solution. These results show that less than 0.05% of the strontium is co-precipitated when MEDTA is used as the chelating agent. With DCTA as chelating agent, the strontium co-precipitated is about 0.16%. Less than 0·06% of the lead is co-precipitated when MEDTA is used. When DCTA is used the amount of lead co-precipitated is about 0·03% or less.

---

* For easy removal of the precipitate, spray a thin film of silicone on a new, unscratched beaker. Dry the beaker at 125° for about 1 hr.

† Enough chelating agent must be added to complex all the barium and all the cations in solution that form a more stable complex with the chelating agent than barium. An excess of about 20% is sufficient. MEDTA and DCTA give similar results. MEDTA is superior for strontium separation, DCTA for lead separation.

§ If the pH of either solution is below 10·3, a precipitation from heterogeneous solution will occur on mixing. This destroys most of the advantages of the proposed method.

TABLE II.—SEPARATION OF BARIUM CHROMATE FROM STRONTIUM AND LEAD

Ba found, *mg* (gravimetric)	Chelating agent	Other ion present	Ba in filtrate, *mg* (atomic absorption)	Sr or Pb in precipitate, *mg* (atomic absorption)
71·4	MEDTA	Sr	0·28	0·01
71·4	MEDTA	Sr	0·28	0·01
71·2	MEDTA	Sr	0·19	0·01
71·5*	MEDTA	Sr	0·40	0·02
72·1	MEDTA	Sr	0·26	0·02
71·7	MEDTA	Pb	0·03	0·06
71·4	MEDTA	Pb	0·25	0·05
72·3	DCTA	Sr	0·04	0·07
71·4	DCTA	Pb	0·23	0·03
72·2	DCTA	Pb	0·22	0·00

Barium taken 71·7 mg (0·5 mmole); 0·5 mmole of strontium or lead and 1·2 mmole of MEDTA or DCTA added to each solution. Final pH 6·7–6·8.

* pH 7·2.

The barium ion is released slowly and uniformly. Even though ammonia escapes only at the surface of the solution, the agitation used results in an essentially homogeneous solution of barium and chromate ions.

The experimental results support the conclusions drawn from a calculation involving the formation constants and solubility products. MEDTA provides the better separation from strontium, DCTA is better for lead separation.

This method has several distinct advantages over the earlier method.[8] Only about a twelfth as much strontium is co-precipitated. Furthermore, dropwise addition of a magnesium chloride solution from a burette is not required, so there is no magnesium contamination of the filtrate.

Acknowledgement—The authors wish to thank Joseph B. Johnson for the preliminary work that indicated this separation would be successful.

Summary—Cation-release is used to precipitate barium chromate from homogeneous solution in the presence of lead and strontium. MEDTA or DCTA is added to complex the metal ions at pH $\geqslant$ 10·3 (adjusted with ammonia). On heating, the ammonia slowly volatilizes and the consequent increases in acidity releases the metal ion bound in the least stable chelate (barium). Precipitation is about 99·3–99·7% complete at pH 6·7–6·8, with less than 0·1% co-precipitation of lead or strontium. Lower pH values can be attained by volatilizing acetic or hydrochloric acid into the solution in a closed system.

Zusammenfassung—Zur Fällung von Bariumchromat aus homogener Lösung in Gegenwart von Blei und Strontium wurde die Kationen-Freisetzung verwendet. Zur komplexen Bindung der Metallionen wird bei pH $\geqslant$ 10,3 (mit Ammoniak eingestellt) MEDTA oder DCTA zugegeben. Beim Erhitzen geht Ammoniak langsam flüchtig und das Anwachsen der Acidität gibt das im am wenigsten stabilen Chelat gebundene Metall (Barium) frei. Die Fällung ist bei pH 6,7–8,6, zu etwa 99,3–99,7% vollständig. Mitfällung von Blei oder Strontium findet zu weniger als 0,1% statt. Niedrigere pH-Werte kann man erreichen, wenn man in einem geschlossenen System Essigsäure oder Salzsaure in die Lösung eindestillieren läßt.

Résumé—On utilise la libération de cations pour précipiter le chromate de baryum d'une solution homogène en la présence de plomb et de strontium. On ajoute MEDTA ou DCTA pour complexer les ions métalliques à pH $>$ 10,3 (ajusté par l'ammoniaque). Par chauffage, l'ammoniaque se volatilise lentement et l'accroissement conséquent de l'acidité libère l'ion métallique lié dans le chélate le moins stable (baryum). La précipitation est complète à 99,3–99,7% à pH 6,7–6,8, avec moins de 0,1% de coprécipitation du plomb ou du strontium. On peut atteindre des valeurs de pH plus basses en volatilisant de l'acide acétique ou chlorhydrique dans la solution dans un système clos.

Catalysis of the arsenic(III)–potassium bromate reaction—I. Titrimetric determination of arsenic(III) in the presence of osmium tetroxide

(*Received* 9 *November* 1971. *Accepted* 13 *December* 1971)

Many studies of the titrimetric determination of arsenic(III) and antimony(III) with potassium bromate have been reported and these have been reviewed on several occasions.[1,2] In the course of a careful investigation[2] of the limiting conditions under which the titration of arsenic(III) with potassium bromate is stoichiometric, it was shown that positive errors are obtained at hydrochloric acid concentrations below 0·55*M* in the absence of added bromide and below 0·3*M* in the presence of 0·1*M* bromide (see Fig. 1). The reaction becomes extremely slow in the absence of both chloride and bromide, and gross positive errors result in, for example, sulphuric acid solution. Chloride and bromide may be considered to act as catalysts in the system through the intermediate formation of halogens, *e.g.*, for bromide,

$$BrO_3^- + 5Br^- + 6H^+ \rightarrow 3Br_2 + 3H_2O \quad (1)$$

$$As(III) + Br_2 \rightarrow As(V) + 2Br^- \quad (2)$$

Chloride is less effective than bromide as a catalyst since its reaction with bromate is slower and this explains the limiting hydrochloric acid concentration being slightly higher in a bromide-free medium than in one that is 0·1*M* in bromide.

The possibility of using other species to catalyse the antimony(III) or arsenic(III) reactions with bromate seemed worth investigating with a view to extending the range of acid concentrations over which the titration is analytically feasible. This was successful only in the case of arsenic(III), the reaction of which with bromate was found to be catalysed by osmic acid. Although osmic acid has been used to catalyse a number of reactions it does not seem to have been applied previously for this one. This paper therefore reports the application of this catalyst to the titrimetric determination of arsenic(III); subsequent papers will describe methods for the catalytic determination of chloride, bromide and osmium by the arsenic(III)–bromate reaction.

EXPERIMENTAL

Reagents

A stock solution of osmium tetroxide was prepared by breaking a phial containing 1 g of osmium tetroxide under 40 ml of 0·5*M* sulphuric acid and diluting to approximately 400 ml. It was standardized iodometrically.[3]

Other solutions and reagents were prepared and standardized as described previously.[2,4] Analytical-grade reagents were used wherever possible and glass-distilled water was used throughout.

Precipitation of barium chromate in the presence of strontium and lead by complexation followed by volatilization of ammonia

(*Received* 9 *November* 1971. *Accepted* 14 *December* 1971)

A NEW PROCEDURE has been developed to separate barium from equal molar concentrations of strontium and lead. The multivalent cations are complexed with MEDTA (1,2-diaminopropane-tetra-acetic acid) or DCTA (1,2-diaminocyclohexane-*N,N,N',N'*-tetra-acetic acid) at a pH of 10·3 or higher in ammoniacal solution. The addition of chromate does not bring about precipitation. The solution is then heated and agitated. Ammonia volatilizes from solution, causing a gradual increase in hydrogen ion concentration. Hydrogen ions compete for the chelating agent which results in a gradual increase in the free barium ion concentration. This causes a slow precipitation of barium chromate from homogeneous solution.

Both the strontium and lead chelates are more stable than the barium chelate. Therefore, the concentration of free strontium ions and free lead ions remains low throughout the precipitation of the barium chromate. Atomic-absorption measurements show that less than 0·05% of the strontium and less than 0·06% of the lead co-precipitate when MEDTA is used. About 0·15% of the strontium and about 0·03% of the lead co-precipitate when DCTA is used.

Precipitation of barium chromate has been the classical method[1] of separating barium fom strontium. The use of precipitation from homogeneous solution[2] as well as complexation[3] has improved the classical method. Complexation has also made a separation of barium from lead possible, with chromate as the precipitant.

Additional modifications based on these fundamental ideas have resulted in further improvements in the separation of barium from both strontium and lead. The method described co-precipitates only about a twelfth of the strontium co-precipitated by the earlier method,[3] and should be applicable to many other systems where cation release is required. Lower pH values can be attained by addition of acid by volatilization in a closed system.

EXPERIMENTAL

Procedure

Add a sample containing about 0·5 mmole of barium (about 70 mg) to a 400-ml beaker.* Add about 50 ml of demineralized water and an excess of chelating agent.† Bring the pH of the solution to 10·3 or slightly higher by the addition of 3*M* ammonia. Add 50 ml of 0·02*M* potassium dichromate adjusted to pH 10·3 or higher.§ Dilute to about 125 ml.

Place the beaker on an oscillating hot-plate. Maintain the temperature within the range 45–60°. Keep the volume of solution reasonably constant by occasional additions of demineralized water. Within about 6–8 hr the pH of the solution will fall to 6–7, usually to 6·7–6·8. Remove the beaker from the hot-plate, stir and let stand overnight.

Filter off on a medium porosity crucible, wash with 0·001*M* potassium dichromate adjusted to pH 7·0, finally rinse with a small portion of demineralized water, and dry the precipitate at 110–120° for 2 hr.

Catalysis of the arsenic(III)–potassium bromate reaction—I. Titrimetric determination of arsenic(III) in the presence of osmium tetroxide

(*Received* 9 *November* 1971. *Accepted* 13 *December* 1971)

MANY STUDIES of the titrimetric determination of arsenic(III) and antimony(III) with potassium bromate have been reported and these have been reviewed on several occasions.[1,2] In the course of a careful investigation[2] of the limiting conditions under which the titration of arsenic(III) with potassium bromate is stoichiometric, it was shown that positive errors are obtained at hydrochloric acid concentrations below 0·55*M* in the absence of added bromide and below 0·3*M* in the presence of 0·1*M* bromide (see Fig. 1). The reaction becomes extremely slow in the absence of both chloride and bromide, and gross positive errors result in, for example, sulphuric acid solution. Chloride and bromide may be considered to act as catalysts in the system through the intermediate formation of halogens, *e.g.*, for bromide,

$$BrO_3^- + 5Br^- + 6H^+ \rightarrow 3Br_2 + 3H_2O \quad (1)$$

$$As(III) + Br_2 \rightarrow As(V) + 2Br^- \quad (2)$$

Chloride is less effective than bromide as a catalyst since its reaction with bromate is slower and this explains the limiting hydrochloric acid concentration being slightly higher in a bromide-free medium than in one that is 0·1*M* in bromide.

The possibility of using other species to catalyse the antimony(III) or arsenic(III) reactions with bromate seemed worth investigating with a view to extending the range of acid concentrations over which the titration is analytically feasible. This was successful only in the case of arsenic(III), the reaction of which with bromate was found to be catalysed by osmic acid. Although osmic acid has been used to catalyse a number of reactions it does not seem to have been applied previously for this one. This paper therefore reports the application of this catalyst to the titrimetric determination of arsenic(III); subsequent papers will describe methods for the catalytic determination of chloride, bromide and osmium by the arsenic(III)–bromate reaction.

EXPERIMENTAL

Reagents

A stock solution of osmium tetroxide was prepared by breaking a phial containing 1 g of osmium tetroxide under 40 ml of 0·5*M* sulphuric acid and diluting to approximately 400 ml. It was standardized iodometrically.[3]

Other solutions and reagents were prepared and standardized as described previously.[2,4] Analytical-grade reagents were used wherever possible and glass-distilled water was used throughout.

Catalysis of the arsenic(III)–potassium bromate reaction—I. Titrimetric determination of arsenic(III) in the presence of osmium tetroxide

(*Received* 9 *November* 1971. *Accepted* 13 *December* 1971)

Many studies of the titrimetric determination of arsenic(III) and antimony(III) with potassium bromate have been reported and these have been reviewed on several occasions.[1,2] In the course of a careful investigation[2] of the limiting conditions under which the titration of arsenic(III) with potassium bromate is stoichiometric, it was shown that positive errors are obtained at hydrochloric acid concentrations below $0{\cdot}55M$ in the absence of added bromide and below $0{\cdot}3M$ in the presence of $0{\cdot}1M$ bromide (see Fig. 1). The reaction becomes extremely slow in the absence of both chloride and bromide, and gross positive errors result in, for example, sulphuric acid solution. Chloride and bromide may be considered to act as catalysts in the system through the intermediate formation of halogens, *e.g.*, for bromide,

$$BrO_3^- + 5Br^- + 6H^+ \rightarrow 3Br_2 + 3H_2O \qquad (1)$$

$$As(III) + Br_2 \rightarrow As(V) + 2Br^- \qquad (2)$$

Chloride is less effective than bromide as a catalyst since its reaction with bromate is slower and this explains the limiting hydrochloric acid concentration being slightly higher in a bromide-free medium than in one that is $0{\cdot}1M$ in bromide.

The possibility of using other species to catalyse the antimony(III) or arsenic(III) reactions with bromate seemed worth investigating with a view to extending the range of acid concentrations over which the titration is analytically feasible. This was successful only in the case of arsenic(III), the reaction of which with bromate was found to be catalysed by osmic acid. Although osmic acid has been used to catalyse a number of reactions it does not seem to have been applied previously for this one. This paper therefore reports the application of this catalyst to the titrimetric determination of arsenic(III); subsequent papers will describe methods for the catalytic determination of chloride, bromide and osmium by the arsenic(III)–bromate reaction.

EXPERIMENTAL

Reagents

A stock solution of osmium tetroxide was prepared by breaking a phial containing 1 g of osmium tetroxide under 40 ml of $0{\cdot}5M$ sulphuric acid and diluting to approximately 400 ml. It was standardized iodometrically.[3]

Other solutions and reagents were prepared and standardized as described previously.[2,4] Analytical-grade reagents were used wherever possible and glass-distilled water was used throughout.

Procedures

The visual titration procedure has been described previously.[2] Potentiometric titrations were performed in a 250-ml beaker, using a bright platinum wire (1 in., 22 swg) indicator electrode with a saturated calomel reference electrode. The equivalence-point volume of titration solution was arranged to be as near 150 ml as possible and in titrations for which the end-point concentration of acid is quoted, the volume of the titration solution at the end-point was measured and the concentration calculated for this volume. For titrations conducted in the absence of air, all reagents and titrand solution were deaerated with "White-spot" nitrogen for 15 min before titration and during titration nitrogen was passed over the surface of the titrand.

RESULTS AND DISCUSSION

A number of compounds were investigated as possible catalysts, amongst them being osmium(VIII), ruthenium(III), rhenium(VII), gold(III), thallium(III), molybdenum(VI), tungsten(VI), vanadium(V) and iridium(IV). Some of these are well known to catalyse other reactions involving arsenic(III), for example, ruthenium[5] and osmium[6-8] catalyse the cerium(IV)-arsenic(III) reaction and vanadium and molybdenum are known[9,10] to catalyse a number of other bromate reactions. The only compound which was found to be effective in either of the reactions under investigation was osmium tetroxide which catalysed the arsenic(III)-bromate reaction. Reaction in the presence of osmium(VIII) is stoichiometric under a wide range of acid conditions and the error curves obtained in the presence of varying concentrations of sulphuric acid (curve *d*) and hydrochloric acid (curve *c*) are shown in Fig. 1 together with the error curves previously reported[2] for titrations in hydrochloric acid media in the absence of osmium. Results on the straight line are accurate to within 0·01 ml in a 25-ml titration and are in agreement with the dry weights of arsenious oxide and potassium bromate used to prepare the standard solutions. The amount of osmic acid stock solution added to each titration does not appear critical since the smallest drop is sufficient to allow the reaction to proceed at a satisfactory rate. Since the indicator mechanism of all known bromatometric and bromometric indicators is by reaction with bromine,[11] none is suitable for the titration in the presence of osmium(VIII), as bromine is not generated rapidly enough at the equivalence point at acid concentrations below 0·1*M*. It is possible to use such indicators at high acid concentrations, above 1*M*, when reaction of the first excess of bromate with the bromide generated by the reduction of bromate up to the equivalence point to form bromine, is fast.[2] To cover the whole range with one method of indication, potentiometry was used. At lower acid concentrations, the electrode takes a considerable time to attain a steady potential in the region of the equivalence point, but at 0·1*M* acid and above the maximum time was 30 sec, and the potential break is sufficiently large (400 mV) for even

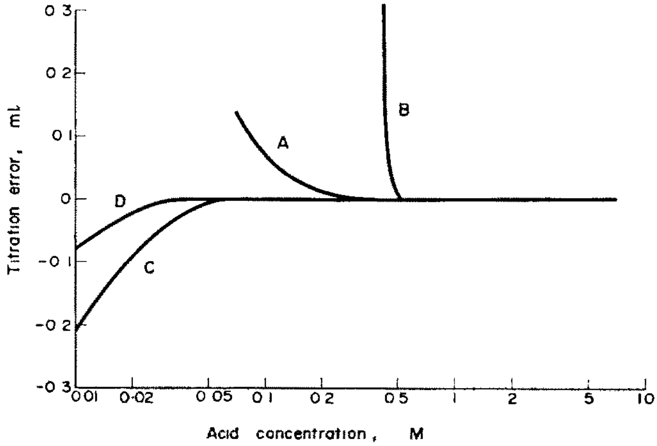

FIG. 1.—Errors in the potentiometric titration of 25 ml of 0·05*M* arsenic(III) with 0·01667*M* potassium bromate in various media.
(A) Initial bromide concentration 0·1*M*, hydrochloric acid.[2]

continuous titration to be possible under these conditions. In acid concentrations below $0{\cdot}05M$, negative titration errors were obtained, which increased in size with a decrease in hydrogen ion concentration. That this was caused by a slow reaction seemed unlikely since in that case positive errors would have been expected. The errors were not related to the presence of bromide, generated from bromate, since addition of mercuric nitrate to complex the bromide was without effect on the error. However when the titrations were performed in a closed titration vessel under an inert atmosphere, the negative errors disappeared. This suggests that oxygen is involved in a secondary oxidation process which may be an induced reaction, similar to that found for antimony(III).[4] Although the titration reaction of antimony(III) with potassium bromate was not catalysed by osmium(VIII), the negative errors obtained at concentrations of hydrochloric acid between $0{\cdot}3$ and $1{\cdot}0M$ were found to be considerably increased in the presence of osmium(VIII). Thus the extent of induced air oxidation of antimony(III) is apparently increased by osmium and a similar reaction may be the cause of the negative errors shown in Fig. 1 for the titration of arsenic(III) at low acid concentrations. This hypothesis is also supported by the fact that the negative error was found to increase with a decrease in the rate of titration.[12] However this aspect has not been pursued.

The use of osmic acid as a catalyst in the titration of arsenic(III) thus offers the advantage of a wider acid concentration range than is available in the presence of chloride or bromide and also avoids the intermediate formation of halogens with the possibility of loss of titrant by volatilization. In addition it appears to offer the possibility of determining arsenic(III) in the presence of antimony(III) by selective catalysis of the arsenic(III) reaction. We have attempted to realize this possibility, using both potentiometric and thermometric determination of the end-point. Fairly low acid concentration is required, *i.e.*, $0{\cdot}1M$, as otherwise the bromide produced from the reaction of arsenic(III) with bromate, reacts with bromate after the end-point, producing bromine which initiates the oxidation of the antimony(III). We have so far been unable to find suitable conditions for this selective determination of arsenic(III), as the arsenic(V) produced reacts at least partially with antimony(III) under those conditions suitable for the selective catalysis. For the titration of arsenic(III) alone, the recommended conditions are a solution of the arsenic(III) sample in $0{\cdot}1M$ acid (either sulphuric or hydrochloric) with one or two drops of $0{\cdot}01M$ osmic acid catalyst added. The arsenic(III) may then by titrated directly with potassium bromate potentiometrically.

Summary—The range of acid concentration available for the titration of arsenic(III) with bromate is considerably extended by the use of osmium tetroxide as catalyst in preference to the use of hydrochloric acid or hydrochloric acid–potassium bromide media. The acid concentration range over which reaction is stoichiometric has been established by potentiometric titration.

Zusammenfassung—Der Bereich an Säurekonzentrationen für die Titration von Arsen(III) mit Bromat läßt sich durch die Verwendung von Osmiumtetroxid als Katalysator beträchtlich ausdehnen, verglichen mit salzsauren oder salzsauren, Kalium-bromid enthaltenden Medien. Durch potentiometrische Titration wurde der Säurekonzentrationsbereich ermittelt, in dem die Reaktion stöchiometrisch abläuft.

Résumé—On étend considérablement le domaine de concentration d'acide convenable pour le dosage de l'arsenic(III) par le bromate en utilisant le tétroxyde d'osmium comme catalyseur de préférence à des milieux acide chlorhydrique ou acide chlorhydrique–bromure de potassium. On a établi le domaine de concentration d'acide dans lequel la réaction est stoechiométrique par titrage potentiométrique.

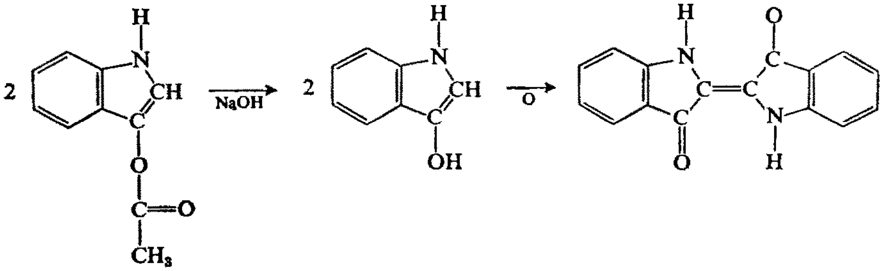
Rapid colorimetric determination of indoxyl acetate

(*Received* 31 *October* 1971. *Accepted* 3 *December* 1971)

AN ESTIMATION of cholinesterase activity can be made by following the colour or fluorescence changes produced in indoxyl acetate or other substrates.[1,2] When used to detect anticholinesterase agents, the proper colorimetric response per unit quantity of indoxyl acetate is vital, and thus a rapid method to assess the quality of each batch of recrystallized indoxyl acetate is useful. A simple colorimetric method devised for this purpose is presented here.

The determination of indoxyl (3-hydroxyindole) compounds has been widely studied as indoxyl compounds are formed by metabolic processes in the body, and certain intestinal and renal conditions are characterized by abnormally high concentrations of indoxyl and related compounds in the blood and/or urine of persons so afflicted. Several analytical methods[3-7] are routinely employed for indoxyl determination in blood or urine. These methods were generally considered too complicated for our use.

In the detection test reaction, a wetted mixture of indoxyl acetate and potassium ferricyanide reacts with acetycholinesterase to produce a blue colour when no anticholinesterase agents are present. Feigl[8] describes the similar reaction of indican, an indoxyl glucoside occurring in plants, with the enzyme emulsin. The reaction involves hydrolysis of the indican to indoxyl, which in turn is oxidized to indigo. As has been shown,[9] indoxyl compounds in urinary extracts undergo similar colour changes when treated with alkali and a mild oxidizing agent. These reactions, summarized below for indoxyl acetate, are the basis of our rapid colorimetric method.



Indoxyl acetate Indoxyl Indigo

EXPERIMENTAL

Reagents

Indoxyl acetate calibration solution. Dissolve 25 mg of recrystallized indoxyl acetate (m.p. 128° or above) in 50 ml of methanol. The solution should be freshly prepared and protected from light.

Sodium hydroxide solution, 0.1*M in methanol.*

Procedure

Prepare a solution to contain 25 mg of the indoxyl acetate to be tested, per 50 ml of methanol. Transfer 0·5 ml of this solution by Mohr pipette into a 10-ml volumetric flask, and dilute with water to approximately 9 ml. Add (Mohr pipette) 0.3 ml of methanolic 0.1*M* sodium hydroxide, mix, let

Catalysis of the arsenic(III)–potassium bromate reaction—I. Titrimetric determination of arsenic(III) in the presence of osmium tetroxide

(*Received* 9 *November* 1971. *Accepted* 13 *December* 1971)

Many studies of the titrimetric determination of arsenic(III) and antimony(III) with potassium bromate have been reported and these have been reviewed on several occasions.[1,2] In the course of a careful investigation[2] of the limiting conditions under which the titration of arsenic(III) with potassium bromate is stoichiometric, it was shown that positive errors are obtained at hydrochloric acid concentrations below 0·55*M* in the absence of added bromide and below 0·3*M* in the presence of 0·1*M* bromide (see Fig. 1). The reaction becomes extremely slow in the absence of both chloride and bromide, and gross positive errors result in, for example, sulphuric acid solution. Chloride and bromide may be considered to act as catalysts in the system through the intermediate formation of halogens, *e.g.*, for bromide,

$$BrO_3^- + 5Br^- + 6H^+ \rightarrow 3Br_2 + 3H_2O \qquad (1)$$

$$As(III) + Br_2 \rightarrow As(V) + 2Br^- \qquad (2)$$

Chloride is less effective than bromide as a catalyst since its reaction with bromate is slower and this explains the limiting hydrochloric acid concentration being slightly higher in a bromide-free medium than in one that is 0·1*M* in bromide.

The possibility of using other species to catalyse the antimony(III) or arsenic(III) reactions with bromate seemed worth investigating with a view to extending the range of acid concentrations over which the titration is analytically feasible. This was successful only in the case of arsenic(III), the reaction of which with bromate was found to be catalysed by osmic acid. Although osmic acid has been used to catalyse a number of reactions it does not seem to have been applied previously for this one. This paper therefore reports the application of this catalyst to the titrimetric determination of arsenic(III); subsequent papers will describe methods for the catalytic determination of chloride, bromide and osmium by the arsenic(III)–bromate reaction.

EXPERIMENTAL

Reagents

A stock solution of osmium tetroxide was prepared by breaking a phial containing 1 g of osmium tetroxide under 40 ml of 0·5*M* sulphuric acid and diluting to approximately 400 ml. It was standardized iodometrically.[3]

Other solutions and reagents were prepared and standardized as described previously.[2,4] Analytical-grade reagents were used wherever possible and glass-distilled water was used throughout.

Procedures

The visual titration procedure has been described previously.[2] Potentiometric titrations were performed in a 250-ml beaker, using a bright platinum wire (1 in., 22 swg) indicator electrode with a saturated calomel reference electrode. The equivalence-point volume of titration solution was arranged to be as near 150 ml as possible and in titrations for which the end-point concentration of acid is quoted, the volume of the titration solution at the end-point was measured and the concentration calculated for this volume. For titrations conducted in the absence of air, all reagents and titrand solution were deaerated with "White-spot" nitrogen for 15 min before titration and during titration nitrogen was passed over the surface of the titrand.

RESULTS AND DISCUSSION

A number of compounds were investigated as possible catalysts, amongst them being osmium(VIII), ruthenium(III), rhenium(VII), gold(III), thallium(III), molybdenum(VI), tungsten(VI), vanadium(V) and iridium(IV). Some of these are well known to catalyse other reactions involving arsenic(III), for example, ruthenium[5] and osmium[6–8] catalyse the cerium(IV)–arsenic(III) reaction and vanadium and molybdenum are known[9,10] to catalyse a number of other bromate reactions. The only compound which was found to be effective in either of the reactions under investigation was osmium tetroxide which catalysed the arsenic(III)–bromate reaction. Reaction in the presence of osmium(VIII) is stoichiometric under a wide range of acid conditions and the error curves obtained in the presence of varying concentrations of sulphuric acid (curve *d*) and hydrochloric acid (curve *c*) are shown in Fig. 1 together with the error curves previously reported[8] for titrations in hydrochloric acid media in the absence of osmium. Results on the straight line are accurate to within 0·01 ml in a 25-ml titration and are in agreement with the dry weights of arsenious oxide and potassium bromate used to prepare the standard solutions. The amount of osmic acid stock solution added to each titration does not appear critical since the smallest drop is sufficient to allow the reaction to proceed at a satisfactory rate. Since the indicator mechanism of all known bromatometric and bromometric indicators is by reaction with bromine,[11] none is suitable for the titration in the presence of osmium(VIII), as bromine is not generated rapidly enough at the equivalence point at acid concentrations below 0·1*M*. Rapid colorimetric determination of indoxyl acetate

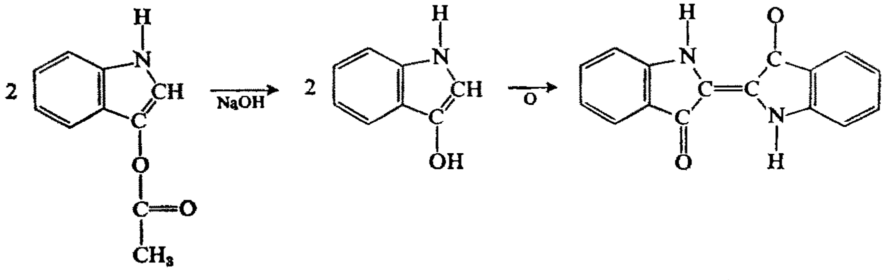
(*Received* 31 *October* 1971. *Accepted* 3 *December* 1971)

AN ESTIMATION of cholinesterase activity can be made by following the colour or fluorescence changes produced in indoxyl acetate or other substrates.[1,2] When used to detect anticholinesterase agents, the proper colorimetric response per unit quantity of indoxyl acetate is vital, and thus a rapid method to assess the quality of each batch of recrystallized indoxyl acetate is useful. A simple colorimetric method devised for this purpose is presented here.

The determination of indoxyl (3-hydroxyindole) compounds has been widely studied as indoxyl compounds are formed by metabolic processes in the body, and certain intestinal and renal conditions are characterized by abnormally high concentrations of indoxyl and related compounds in the blood and/or urine of persons so afflicted. Several analytical methods[3-7] are routinely employed for indoxyl determination in blood or urine. These methods were generally considered too complicated for our use.

In the detection test reaction, a wetted mixture of indoxyl acetate and potassium ferricyanide reacts with acetycholinesterase to produce a blue colour when no anticholinesterase agents are present. Feigl[8] describes the similar reaction of indican, an indoxyl glucoside occurring in plants, with the enzyme emulsin. The reaction involves hydrolysis of the indican to indoxyl, which in turn is oxidized to indigo. As has been shown,[9] indoxyl compounds in urinary extracts undergo similar colour changes when treated with alkali and a mild oxidizing agent. These reactions, summarized below for indoxyl acetate, are the basis of our rapid colorimetric method.



Indoxyl acetate Indoxyl Indigo

EXPERIMENTAL

Reagents

Indoxyl acetate calibration solution. Dissolve 25 mg of recrystallized indoxyl acetate (m.p. 128° or above) in 50 ml of methanol. The solution should be freshly prepared and protected from light.

Sodium hydroxide solution, 0.1M *in methanol.*

Procedure

Prepare a solution to contain 25 mg of the indoxyl acetate to be tested, per 50 ml of methanol. Transfer 0·5 ml of this solution by Mohr pipette into a 10-ml volumetric flask, and dilute with water to approximately 9 ml. Add (Mohr pipette) 0.3 ml of methanolic 0.1M sodium hydroxide, mix, let

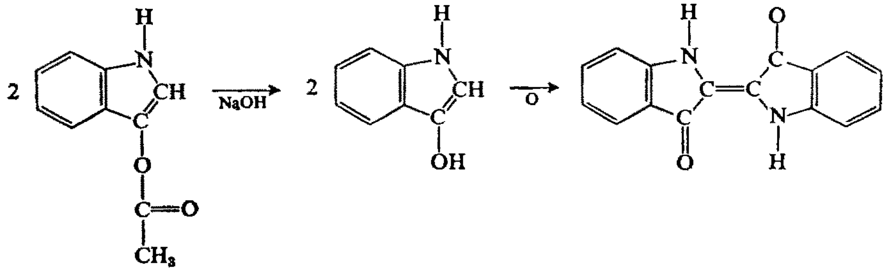
Rapid colorimetric determination of indoxyl acetate

(*Received* 31 *October* 1971. *Accepted* 3 *December* 1971)

AN ESTIMATION of cholinesterase activity can be made by following the colour or fluorescence changes produced in indoxyl acetate or other substrates.[1,2] When used to detect anticholinesterase agents, the proper colorimetric response per unit quantity of indoxyl acetate is vital, and thus a rapid method to assess the quality of each batch of recrystallized indoxyl acetate is useful. A simple colorimetric method devised for this purpose is presented here.

The determination of indoxyl (3-hydroxyindole) compounds has been widely studied as indoxyl compounds are formed by metabolic processes in the body, and certain intestinal and renal conditions are characterized by abnormally high concentrations of indoxyl and related compounds in the blood and/or urine of persons so afflicted. Several analytical methods[3–7] are routinely employed for indoxyl determination in blood or urine. These methods were generally considered too complicated for our use.

In the detection test reaction, a wetted mixture of indoxyl acetate and potassium ferricyanide reacts with acetycholinesterase to produce a blue colour when no anticholinesterase agents are present. Feigl[8] describes the similar reaction of indican, an indoxyl glucoside occurring in plants, with the enzyme emulsin. The reaction involves hydrolysis of the indican to indoxyl, which in turn is oxidized to indigo. As has been shown,[9] indoxyl compounds in urinary extracts undergo similar colour changes when treated with alkali and a mild oxidizing agent. These reactions, summarized below for indoxyl acetate, are the basis of our rapid colorimetric method.



Indoxyl acetate Indoxyl Indigo

EXPERIMENTAL

Reagents

Indoxyl acetate calibration solution. Dissolve 25 mg of recrystallized indoxyl acetate (m.p. 128° or above) in 50 ml of methanol. The solution should be freshly prepared and protected from light.

Sodium hydroxide solution, $0.1M$ in methanol.

Procedure

Prepare a solution to contain 25 mg of the indoxyl acetate to be tested, per 50 ml of methanol. Transfer 0·5 ml of this solution by Mohr pipette into a 10-ml volumetric flask, and dilute with water to approximately 9 ml. Add (Mohr pipette) 0.3 ml of methanolic $0.1M$ sodium hydroxide, mix, let stand at room temperature for 4 min and dilute to the mark with water. Read the absorbance of the blue solution *vs.* that of a reagent blank at 615 nm, in 1-cm matched cells. Find the amount of indoxyl acetate by reference to a calibration curve, or from equation (1). The indoxyl acetate batch is considered acceptable if the 0.5-ml sample taken contains 0.25 ± 0.02 mg of indoxyl acetate.

Calibration curve. Develop and measure the colour of standard solutions containing 0.2–0.6 ml of indoxyl acetate calibration solution.

RESULTS AND DISCUSSION

This procedure was developed on the basis of the results obtained during preliminary experiments described below. The addition of sodium hydroxide and an oxidant solution (potassium ferricyanide and potassium ferrocyanide) to small quantities of indoxyl acetate solution, followed by dilution, produced green rather than blue solutions. The colour was slow in forming, not intense, and unstable owing to the slow formation of a coloured precipitate. On varying the ratio of reactants, it was found that more suitable colours resulted from using less oxidant solution. This agrees with the results of staining studies(10) made with ferricyanide ions to locate indoxyl *in situ* in tissue. Elimination of the oxidant solution entirely resulted in blue reaction products, the oxidation apparently being accomplished by air. The visible absorption spectrum of the blue reaction product showed it had a broad absorption maximum in the range 600–625 nm. This range matches literature values[11] for the absorption maximum for indigo, of between 590 and 630 nm in various organic solvents.

The problem of sensitivity remained, as the colours were too light to be useful for a dependable colorimetric method. In addition, the colour development appeared to be erratic and non-reproducible. Improved results were realized when the amount of $0.1M$ sodium hydroxide added in a final reaction volume of 10 ml was limited to 0.3 ml. Other experimental variations, such as heating the test solution to 50°, using acetone or methanol as the diluent, or waiting for extended periods for full colour development, proved to be ineffective. Improved colour development, however, was later achieved by dilution of the methanolic indoxyl acetate solution with water to almost the desired volume *before* rather than *after* the addition of the 0.3 ml of sodium hydroxide solution. In this way intense and reproducible colours were fully developed after a 4-min development time at room temperature.

A calibration curve was then established for various amounts of indoxyl acetate up to 0.5 mg. The colour system obeys Beer's law in the range of 0.1–0.3 mg, and can be expressed by the relationship:

$$\text{Absorbance} = 1.94 \times \text{mg of indoxyl acetate} \tag{1}$$

The molar absorptivity at 615 nm, based on the molecular weight of indoxyl acetate, is 3720 $\text{l.mole}^{-1}.\text{cm}^{-1}$. The blue colour was found to be due to a colloidally dispersed solid, which is in agreement with the known low water-solubility of indigo. The colour, however, is stable for over 1 hr after formation. The reproducibility of the absorbance values for the colour developed for 0.25 mg of indoxyl acetate was 0.485 ± 0.005 (standard deviation) based on 8 trials. The postulated reaction of indoxyl acetate to form indigo is probably neither complete nor the only one occurring, but under the defined experimental conditions the amount of indoxyl acetate converted into indigo is apparently constant and reproducible. Because of the known composition of the samples, no study of interferences or the applicability to the determination of other indoxyl-related compounds was made. Consequently this procedure is recommended solely for the analysis of solutions containing only indoxyl acetate, although other alkali-hydrolysable indoxyl esters could probably be determined in a similar way.

Precision of fragmentation patterns in high-resolution mass spectrometry

(*Received* 12 *October* 1971. *Accepted* 19 *November* 1971)

THE OBJECT of this work was to investigate the effect of ion-source temperature on the analytical results for high-resolution mass-spectrometric procedures. Three parameters had major effects on both absolute and relative ion intensities. These were the repeller voltage, the scan-rate and, in the case of saturated molecules, the temperature of the ion source. The work described here is concerned essentially with temperature control of the ion source and its effects on the precision of pattern coefficients and pattern summations of saturated hydrocarbon molecules.

The quantitative analysis of petroleum hydrocarbons is not widely practised at high resolution although there are many advantages in this approach. Basically, a high-resolution mass spectrometer is neither designed nor built for quantitative work. The main limitations are, of course, the effect of fast scanning (10 sec/decade) and of double-focusing the ions, both of which introduce statistical errors in measuring accurately the intensities of ions at the collector. In low-resolution work such limitations are not analytically important at slow scan-speeds (~20 min/decade).

An important criterion for the analysis of petroleum saturates has been that the ratio of the intensities of masses 127 and 226 in normal hexadecane be arbitrarily selected, along with other summations, to have certain values.[1] These values change with the source temperature—the higher the temperature the greater the fragmentation arising from the instability of the parent ions of n-hexadecane. It is necessary to know the magnitude of the effects of temperature control on both cracking patterns and summations in order to carry out quantitative high-resolution analyses of petroleum distillates.

EXPERIMENTAL

A high-resolution mass spectrometer (A.E.I. Ltd. model MS 902) was used. The associated data system MSDS-20 (and later -30), which included a DEC PDP 8i computer, automatically digitized all the ion intensities and calculated their atomic compositions. This data system was supplied with the mass spectrometer. All the results reported here were obtained with either static or dynamic resolving powers of 10,000 (~5% valley definition). High-boiling perfluorokerosene was used as an internal calibrant for the mass scale in the latter mode of operation. A standard precalibrated mass range from $m/e = 617$ to $m/e = 60$ was used in all dynamic runs.

Two different ion sources were used in the comparative studies. One was the conventional ion source with temperature not controlled; the second was a specially designed source the temperature of which was controlled (quoted as within 0.1°). Both sources and the temperature controller were supplied by A.E.I. Ltd.

The temperature in the ion source was measured with a conventional thermocouple located near the ion box. However, this recorded value, which varied with and was relative to the ambient room

Two different ion sources were used in the comparative studies. One was the conventional ion source with temperature not controlled; the second was a specially designed source the temperature of which was controlled (quoted as within 0.1°). Both sources and the temperature controller were supplied by A.E.I. Ltd.

The temperature in the ion source was measured with a conventional thermocouple located near the ion box. However, this recorded value, which varied with and was relative to the ambient room

temperature, gave no indication of the degree of stability afforded by the controller, which worked on an absolute basis. All the temperatures recorded in the results are therefore only approximations of the ion-source temperature.

The repeller voltage, which also affected the ion intensities, was adjusted to that value at which all peak intensities were maximized. This occurred at the first maximum of the ion repeller voltage/ion intensity curve.[3]

RESULTS

In order to isolate any effects of scan speed on the repeatability of cracking patterns, a set of data for normal hexadecane was obtained at a static resolving power of 10,000. A first set of data was recorded manually both for an uncontrolled source temperature and a controlled source temperature. A sample of normal hexadecane was vaporized in the heated inlet system (300°) and the intensities at $m/e = 226$, the parent ion, and at $m/e = 127$, a major fragment ion, were recorded over a period of 6 hr. Standard deviations for the ratio of masses 127 and 226 were computed for the mean value of the ratio for the series. Nominal temperatures of the ion source were also recorded. The results are presented in Table I. The standard deviation for the mean is considerably reduced with control of the ion-source temperature.

It is common practice to use summations of peak intensities in the analysis of petroleum, so Table II shows the stability of $\sum 71/\mathrm{TI}$ for both ion sources. Inaccuracies in $\sum 71/\mathrm{TI}$ will be ultimately reflected in any analytical results. $\sum 71$ is the sum of the C_nH_{2n+1} series *i.e.*, 71, 85, 99, 113, and TI is the sum of all the ion intensities in the spectrum. The values of $\sum 71/\mathrm{TI}$ were obtained under dynamic conditions at a scan speed of 4·6 min/decade.

The decrease in deviation is much smaller than under static conditions and the reduced deviation for the uncontrolled source is probably the result of compensating errors. Poorer ion statistics and peak clipping under dynamic conditions may partly compensate for random fluctuations of the ratio with temperature.

We found that n-$C_{16}H_{34}$ was not an ideal compound for monitoring source temperatures. We accumulated results (Table I) showing source-conditioning effects which introduced a bias into the results. To overcome this we made up a blend of paraffins (C_{10}–C_{24}) with an isomer ratio, iso/normal, of 0·5. The ion-source temperature was set to give approximately the value of the ratios suggested for performing ASTM analyses.[1] The calibration blend was run for statistical analysis and selected values of $\sum_{71}^{113} 71/\mathrm{TI}$ and 71/TI were chosen as criteria for routine operation. $\sum_{71}^{113} 71/\mathrm{TI}$ was selected

to be 0·56 ± 0·02 and 71/TI to be 0·30 ± 0·02. Table III shows typical results for the values of these ratios over a two-month period. The last three ratios in Table III were recorded a few days before the filament failed. The usual practice was to record the key ratios for the calibration blend and, if necessary, to adjust the source temperature to maintain the values within the stated limits. When this failed to re-establish the ratios suggested as criteria for analysis, the ion source was removed and cleaned.

DISCUSSION

The purpose of this work has been to establish the conditions for quantitative analyses at high resolution. The analysis of petroleum saturates requires constant source temperatures before meaningful analytical results are possible. The temperature stability of aromatic ions is relatively high in contrast to paraffinic ions. Since instability of paraffin ions is experimentally reflected as changes in fragmentation pattern, the overall ion stability will be related both to the ionic enthalpy

and to the value of the dissociation energy in the ion $(R_1–R_2)^+$. The ion energies are directly related to the temperature of the ion source, all other factors, such as electron energy and repeller voltage being constant. Since it is common practice to establish calibration matrices by using summations of intensities of characteristic ions, $\sum 71/TI$ for paraffins for instance, it is vital that criteria be established so that calibration and subsequent analytical results are recorded under identical conditions A calibration blend is used to check analytical results.

The effect of scan speed is also important. Scan speeds faster than 4.6 min/decade at 10,000 resolving power gave large deviations for characteristic aromatic as well as saturate summations. Under these conditions controlling the ion-source temperature to maintain precise patterns is useless, for only by increasing the number of ions collected (by larger sample size, decreased resolution and slower scan speeds) may poor ion statistics be counteracted.

Quantitative high-resolution mass spectrometry is still in its infancy and no satisfactory methods for analysing both saturates and aromatics together, by using genuine high-resolution matrices, have been published. We have found, in practice, that an adequate check on paraffin fragmentation may be maintained by running the calibration blend intermittently and recording the key intensity ratios. Small temperature variations are indicated by changes in the value of the ratios, which may be kept within the selected deviations by adjusting the source temperature. In this way it has been possible to develop methods for analysing both saturates and aromatics together and with repeatable and realistic saturate:aromatic ratios.

Precision of fragmentation patterns in high-resolution mass spectrometry

(*Received* 12 *October* 1971. *Accepted* 19 *November* 1971)

THE OBJECT of this work was to investigate the effect of ion-source temperature on the analytical results for high-resolution mass-spectrometric procedures. Three parameters had major effects on both absolute and relative ion intensities. These were the repeller voltage, the scan-rate and, in the case of saturated molecules, the temperature of the ion source. The work described here is concerned essentially with temperature control of the ion source and its effects on the precision of pattern coefficients and pattern summations of saturated hydrocarbon molecules.

The quantitative analysis of petroleum hydrocarbons is not widely practised at high resolution although there are many advantages in this approach. Basically, a high-resolution mass spectrometer is neither designed nor built for quantitative work. The main limitations are, of course, the effect of fast scanning (10 sec/decade) and of double-focusing the ions, both of which introduce statistical errors in measuring accurately the intensities of ions at the collector. In low-resolution work such limitations are not analytically important at slow scan-speeds (~20 min/decade).

An important criterion for the analysis of petroleum saturates has been that the ratio of the intensities of masses 127 and 226 in normal hexadecane be arbitrarily selected, along with other summations, to have certain values.[1] These values change with the source temperature—the higher the temperature the greater the fragmentation arising from the instability of the parent ions of n-hexadecane. It is necessary to know the magnitude of the effects of temperature control on both cracking patterns and summations in order to carry out quantitative high-resolution analyses of petroleum distillates.

EXPERIMENTAL

A high-resolution mass spectrometer (A.E.I. Ltd. model MS 902) was used. The associated data system MSDS-20 (and later -30), which included a DEC PDP 8i computer, automatically digitized all the ion intensities and calculated their atomic compositions. This data system was supplied with the mass spectrometer. All the results reported here were obtained with either static or dynamic resolving powers of 10,000 (~5% valley definition). High-boiling perfluorokerosene was used as an internal calibrant for the mass scale in the latter mode of operation. A standard precalibrated mass range from $m/e = 617$ to $m/e = 60$ was used in all dynamic runs.

Two different ion sources were used in the comparative studies. One was the conventional ion source with temperature not controlled; the second was a specially designed source the temperature of which was controlled (quoted as within 0.1°). Both sources and the temperature controller were supplied by A.E.I. Ltd.

The temperature in the ion source was measured with a conventional thermocouple located near the ion box. However, this recorded value, which varied with and was relative to the ambient room

temperature, gave no indication of the degree of stability afforded by the controller, which worked on an absolute basis. All the temperatures recorded in the results are therefore only approximations of the ion-source temperature.

The repeller voltage, which also affected the ion intensities, was adjusted to that value at which all peak intensities were maximized. This occurred at the first maximum of the ion repeller voltage/ion intensity curve.[3]

RESULTS

In order to isolate any effects of scan speed on the repeatability of cracking patterns, a set of data for normal hexadecane was obtained at a static resolving power of 10,000. A first set of data was recorded manually both for an uncontrolled source temperature and a controlled source temperature. A sample of normal hexadecane was vaporized in the heated inlet system (300°) and the intensities at $m/e = 226$, the parent ion, and at $m/e = 127$, a major fragment ion, were recorded over a period of 6 hr. Standard deviations for the ratio of masses 127 and 226 were computed for the mean value of the ratio for the series. Nominal temperatures of the ion source were also recorded. The results are presented in Table I. The standard deviation for the mean is considerably reduced with control of the ion-source temperature.

Semi-automated determination of aluminium with Xylenol Orange

(*Received* 29 *September* 1971. *Accepted* 15 *December* 1971)

Xylenol Orange has been recommended for the spectrophotometric determination of aluminium.[1–4] High sensitivity is reported. One disadvantage is the slow rate of reaction, which necessitates a

heating step in the colour development. The reagent is not specific, and many elements may cause interference.[5] In most cases the interference can be eliminated by pH control, masking or extraction.

The reagent cannot be purchased in the pure state. Possible impurities include Cresol Red used in the synthesis, and another material related to Xylenol Orange and called Semi-Xylenol Orange.[6] This also forms complexes with many metals, which are indistinguishable from those of Xylenol Orange.

This report outlines the modification of the photometric method to give a semi-automated procedure using commercially available reagent in alcohol solution.

EXPERIMENTAL

Reagents

Stock solutions of Xylenol Orange ($10^{-3}M$) were prepared by dissolving the sodium salt in the minimum volume of distilled water, converting into the free acid by eluting through Zeocarb 325 (H) resin and diluting with sufficient methylated spirit to give the required concentration. The solution was standardized by photometric titration with zinc solution at pH 5·7 (hexamine buffer). The absorbance of the standardized solution was measured and allowed subsequent direct standardization by absorbance measurement.

Potassium aluminium sulphate solutions were used as calibration standards.

Equipment

A Technicon sample changer and proportioning pump were used. Colour intensity was measured by a Watson Marlow AJC automatic colorimeter with green filter number 625 (transmission maximum 25% at 531 nm). The linear output was recorded by a Heathkit servo recorder EUW 204, with 250 mV fsd.

Procedure

Two arrangements were tested, using aluminium solution in $0.1M$ acetate buffer at pH 3·8 and in $0{\cdot}05M$ sulphuric acid respectively. Pumping rates are shown in Table I.

TABLE I.—PUMPING RATE OF REAGENTS IN COLOUR DEVELOPMENT (*ml/min*)

	System *a*	System *b*
Sample	2·0	2·0
Air	0·8	0·8
$4M$ sodium acetate	—	0·1
Alcohol	1·69(s)	—
Xylenol Orange	1·69(s)	1·69(s)

(s) "Solvaflex" tubes.

System a. Reagents were mixed in a 20 × 80 × 2·5 mm coil, followed by alcohol dilution in a delay coil to increase the flow-rate in the cell. A water wash was used between samples, resulting in a small peak for the buffered solution which had zero aluminium concentration, owing to the slight colour change in the Xylenol Orange on contacting the buffer.

System b. Samples were buffered with sodium acetate in the first coil, and mixed with reagent in the second coil. A sulphuric acid wash between samples was used to avoid a colour change in the solution stream caused by the high pH of the sodium acetate.

RESULTS AND DISCUSSION

The Semi-Xylenol Orange impurity can only be removed completely with difficulty, for example by column chromatography on cellulose or multistage solvent extraction. No practical difficulties due to its presence are reported by previous authors, but there are marked differences in composition between different samples of the reagent. In the present work, no attempt was made to purify the reagent. The preparation of the solutions however confirmed the reported observation[6] that part of the Xylenol Orange is strongly adsorbed onto the cation resin, and there is an indication that the Semi-Xylenol Orange is partially removed by this process. Xylenol Orange in acid form has a single broad absorption peak, maximum 434 nm. The molar absorptivity at 434 nm, based on the standardization with zinc solution, was $1{\cdot}51 \times 10^4$ l.mole^{-1}.cm^{-1}.

The two complexes formed on reaction with aluminium and reported by previous authors are confirmed. With excess of metal ion there is a red complex, maximum absorption 555 nm, molar absorptivity $3{\cdot}16 \times 10^4$ l.mole^{-1}.cm^{-1}. With excess of reagent, a more orange complex forms, maximum absorbance about 510 nm. There is an isosbestic point at 536 nm. The molar absorptivity of the mixture at this wavelength is $1{\cdot}91 \times 10^4$ l.mole^{-1}.cm^{-4}. Measurement at this wavelength results in an indeterminate reagent blank error, but this is sufficiently small to allow linear calibration under the conditions reported.

One application of the reaction is the determination of aluminium extracted from soil samples.[3] Interference from other complexing anions is removed in the destruction of organic matter with concentrated sulphuric acid. The principal interference is from iron(III), which can be removed by preliminary extraction with cupferron from the diluted acid solution. This was found to be more satisfactory than the kinetic method previously reported. Titanium is also extracted if present, but can be stripped from the extract with ammonia solution if direct measurement of the iron cupferronate is also required. Copper and zinc form Xylenol Orange complexes of lower stability and will only interfere if present in very large excess.

Xylenol Orange has been reported to be decomposed by both ethanol and methanol.[6] In the present work, no decomposition was observed over short periods of time. Solutions were renewed if necessary after three weeks, during which time no alteration took place. After three months, notable fading of the solution had occurred, and this could be accelerated by the presence of oxidizing agents such as hydrogen peroxide or even iron(III).

In aqueous solutions Xylenol Orange reacts very slowly with aluminium at room temperature. Addition of the reagent in alcohol solution greatly increases the rate of reaction. For aluminium determination in the method under test, about equal volumes of reagent and sample were mixed. Under these conditions reaction is almost complete in 5 min, and over 70% complete in less than 1 min. This is sufficiently far advanced to permit automated colour development. A change in the total alcohol concentration has only a slight effect on the rate. Addition of alcohol to the buffered solution gave an apparent pH in the reaction mixture of 5·4–5·5, measured at the colorimeter outlet.

Each system gave a linear calibration (10 points plus zero) with aluminium concentrations from 10^{-5} to $10^{-4}M$(0–2·7μg/ml) presented at 70 samples per hour, using $1{\cdot}5 \times 10^{-4}M$ Xylenol Orange. For aluminium concentrations of less than $10^{-5}M$, the recorder scale was expanded to give 50 mV fsd and the same Xylenol Orange solution was used. More dilute Xylenol Orange solutions gave slower reaction and less reproducible results.

The repeatability of the complete process was tested with $10^{-4}M$ aluminium. The relative standard deviation on 63 results was 4·5%.

Conclusion

Xylenol Orange in alcoholic solution reacts quickly with aluminium, and is recommended for the semi-automated determination of this metal in acid solution.

and to the value of the dissociation energy in the ion $(R_1-R_2)^+$. The ion energies are directly related to the temperature of the ion source, all other factors, such as electron energy and repeller voltage being constant. Since it is common practice to establish calibration matrices by using summations of intensities of characteristic ions, $\sum 71/TI$ for paraffins for instance, it is vital that criteria be established so that calibration and subsequent analytical results are recorded under identical conditions A calibration blend is used to check analytical results.

The effect of scan speed is also important. Scan speeds faster than 4.6 min/decade at 10,000 resolving power gave large deviations for characteristic aromatic as well as saturate summations. Under these conditions controlling the ion-source temperature to maintain precise patterns is useless, for only by increasing the number of ions collected (by larger sample size, decreased resolution and slower scan speeds) may poor ion statistics be counteracted.

Quantitative high-resolution mass spectrometry is still in its infancy and no satisfactory methods for analysing both saturates and aromatics together, by using genuine high-resolution matrices, have been published. We have found, in practice, that an adequate check on paraffin fragmentation may be maintained by running the calibration blend intermittently and recording the key intensity ratios. Small temperature variations are indicated by changes in the value of the ratios, which may be kept within the selected deviations by adjusting the source temperature. In this way it has been possible to develop methods for analysing both saturates and aromatics together and with repeatable and realistic saturate:aromatic ratios.

Summary—The effect of controlling the temperature of the ion source of a high-resolution mass spectrometer is to increase the confidence in mass spectral pattern coefficients of saturated molecules. Results are presented for both controlled and uncontrolled ion-source temperatures. Standard deviations have been calculated for selected summations of ion intensities and criteria have been suggested for maintaining meaningful analytical results in the study of petroleum distillates.

Zusammenfassung—Die Wirkung einer Temperaturregelung an der Ionenquelle eines hochauflösenden Massenspektrometers besteht in der Erhöhung der Zuverlässigkeit in den Parametern der Massenspektren gesättigter Moleküle. Ergebnisse für geregelte und nicht geregelte Temperaturen an der Ionenquelle werden mitgeteilt. Für ausgewählte Summierungen von Ionenintensitäten werden die Standardabweichungen berechnet und Kriterien vorgeschlagen, mit Hilfe derer sinnvolle analytische Ergebnisse bei der Untersuchung von Erdöldestillaten erhalten werden können.

Résumé—L'effet du contrôle de la température de la source ionique d'un spectromètre de masse à haute résolution est l'accroissement de la confiance dans les coefficients des diagrammes des spectres de masse de molécules saturées. On présente les résultats pour les températures de source ionique contrôlées et non contrôlées. On a calculé les écarts types pour des sommations choisies d'intensités d'ions et l'on suggère des critères pour conserver les résultats analytiques significatifs dans l'étude de distillats de pétrole.

Semi-automated determination of aluminium with Xylenol Orange

(*Received* 29 *September* 1971. *Accepted* 15 *December* 1971)

Xylenol Orange has been recommended for the spectrophotometric determination of aluminium.[1-4] High sensitivity is reported. One disadvantage is the slow rate of reaction, which necessitates a heating step in the colour development. The reagent is not specific, and many elements may cause interference.[5] In most cases the interference can be eliminated by pH control, masking or extraction.

The reagent cannot be purchased in the pure state. Possible impurities include Cresol Red used in the synthesis, and another material related to Xylenol Orange and called Semi-Xylenol Orange.[6] This also forms complexes with many metals, which are indistinguishable from those of Xylenol Orange.

This report outlines the modification of the photometric method to give a semi-automated procedure using commercially available reagent in alcohol solution.

EXPERIMENTAL

Reagents

Stock solutions of Xylenol Orange ($10^{-3}M$) were prepared by dissolving the sodium salt in the minimum volume of distilled water, converting into the free acid by eluting through Zeocarb 325 (H) resin and diluting with sufficient methylated spirit to give the required concentration. The solution was standardized by photometric titration with zinc solution at pH 5·7 (hexamine buffer). The absorbance of the standardized solution was measured and allowed subsequent direct standardization by absorbance measurement.

Potassium aluminium sulphate solutions were used as calibration standards.

Equipment

A Technicon sample changer and proportioning pump were used. Colour intensity was measured by a Watson Marlow AJC automatic colorimeter with green filter number 625 (transmission maximum 25% at 531 nm). The linear output was recorded by a Heathkit servo recorder EUW 204, with 250 mV fsd.

Procedure

Two arrangements were tested, using aluminium solution in 0.1*M* acetate buffer at pH 3·8 and in 0·05*M* sulphuric acid respectively. Pumping rates are shown in Table I.

Analysis by phase-titration of three-component systems containing two mutually immiscible or partially miscible components

(*Received* 30 *August* 1971. *Accepted* 1 *November* 1971)

THE PRINCIPLE of phase-titrations has been used to determine the composition of a large number of binary solutions of organic liquids.[1-5] Suri[6] has developed a phase titration procedure for the analysis of ternary mixtures containing two mutually immiscible or partially miscible components. The method is useful for systems where chemical determination of any of the components is difficult.

In the present communication, another phase-titration method is described, which can be used to analyse one-phase ternary mixtures containing two mutually immiscible or partially miscible components, without separate determination of any component. The method involves titrating a measured amount of the ternary mixture at constant temperature with one of the immiscible components until a second phase just appears. The refractive index (a physical property which can be quickly measured) of the resultant solution on the binodal curve is then measured, and the complete composition of the ternary mixture is calculated.

THEORY

A ternary phase-diagram for a system containing A, B and C where B and C are mutually immiscible and A is miscible with both B and C in all proportions is shown in Fig. 1. Solutions represented by a point on or below the binodal curve are heterogeneous and turbid. At constant temperature, the position of the binodal line is fixed for a given ternary mixture, and serves as a reference line in the procedure described below.

A set of binary solutions of A and B, richer in B and of known composition is prepared by weight and titrated with C until a permanent turbidity appears. The resultant ternary solution is then weighed to determine the weight of the titrant added. The turbid solution is clarified by adding a drop of two of A and the refractive index is measured. Two calibration curves are then drawn indicating (*a*) the weight of C required to produce turbidity in 1 g of the binary solution, and (*b*) the refractive index as a function of original binary composition. The procedure is repeated for binary solutions of A and C, richer in C, and another pair of calibration curves is drawn for B as the titrant.

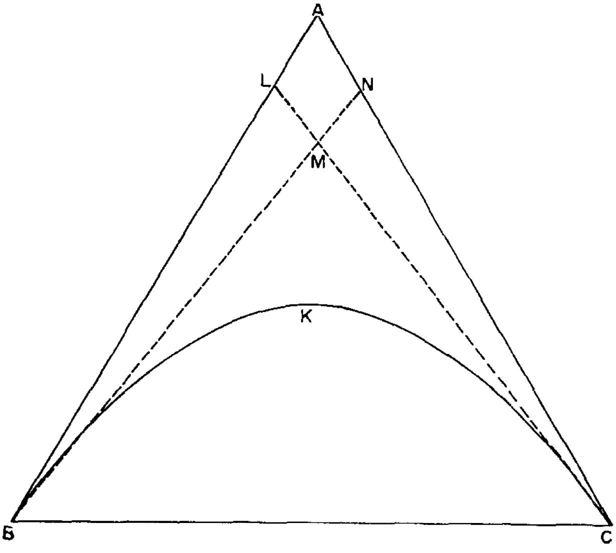

FIG. 1.—Ternary miscibility diagram showing regions suitable for phase-titration analysis.

The dual set of calibrations is necessary because sometimes only one of the two titrants will give a satisfactory end-point (see below).

To analyse a homogeneous mixture of A, B and C, two samples of known weight are titrated, one with B and the other with C to bring the composition on to the binodal curve.* The solution is weighed, clarified by adding a drop of A, and its refractive index measured.

With C used as the titrant, a refractive index value corresponding to $y\%$ B signifies the ratio of A:B in the original ternary mixture to be $(100 - y):y$ (during titration with C, the ratio remains unchanged). From the calibration curve, the weight of C required to titrate 1 g of a binary mixture of A and B in the same ratio as in the sample is found (z g). This means that $(1 + z)$ g of the turbid solution (obtained by titration with C) contains $(100 - y)/100$, $y/100$ and z g of A, B and C respectively. If x g is the weight C required to titrate 1 g of the original ternary mixture to this point on the binodal curve, the composition of the sample is given by $A = (100 - y)(1 + x)/(1 + z)\%$; $B = y(1 + x)/(1 + z)\%$, and $C = 100(z - x)/(1 + z)\%$. The calculation is similar when B is used as the titrant.

In some cases, the refractive index calibration plot show a maximum or minimum, so two composition values can correspond to a single refractive index value. To find which one refers to the actual composition, a small amount of B or C is added, the solution is clarified with A, and the direction of shift of refractive index is observed.

Ternary solutions with composition represented by a point anywhere in areas BKCL or BKCN will yield a turbidimetric end-point on titration with B and C respectively. If the composition of the ternary lies outside BKCNML, the area defined by the tangents and the binodal curve, it will not yield any turbidimetric end-point on titration with either B or C. In such cases, a sufficient and known weight of B or C is added to a known weight of the ternary, to bring its composition into one of the titratable regions BKCL or BKCN.[6]

The method is illustrated for the ternary system benzene, cyclohexane and nitromethane, the system used to illustrate the method described earlier.[6]

EXPERIMENTAL

The solvents were purified according to established procedures.[6,7] Densities and refractive index values for the liquids used are recorded in Table I along with the literature values for comparison.[8] The experimental details of the titration and the apparatus have been described earlier.[6]

Calibration curves were prepared, as outlined under *Theory*, for benzene–nitromethane mixtures titrated with cyclohexane, and for benzene–cyclohexane mixtures titrated with nitromethane. The experimental values are given in Table II.

TABLE 1.—SOME PHYSICAL PROPERTIES OF SOLVENTS USED AT 30°C

	Density, *g/ml*		Refractive index	
	Present work	Literature value[7,8]	Present work	Literature value[7,8]
Benzene	0·8685	0·8685	1·4945	1·4948
Cyclohexane	0·7694	0·7690	1·4205	1·4208*
Nitromethane	1·1239	1·1245	1·3770	1·3771*

* Values extrapolated to 30°C.

To illustrate the method, over the entire one-phase region of the system, seven synthetic ternary mixtures were prepared and analysed. The results obtained are compared with the actual composition values in Table III.

Samples 1 and 2 gave turbidimetric end-points with nitromethane, 5 and 6 with cyclohexane, 3 with both, and 4 and 7 with neither. Two sets of each of samples 4 and 7 were diluted with about the same weight of nitromethane or cyclohexane (*vide* ref. 7) and the resulting solutions titrated with cyclohexane or nitromethane respectively. The refractive indices of all the titrated solutions were measured and the weight ratios benzene:nitromethane in samples 3, 5, 6 and the solutions obtained by diluting samples 4 and 7 with nitromethane were computed from the calibration curves. The weight ratios benzene:cyclohexane in samples 1, 2, 3 and the solutions obtained by diluting samples 4 and 7 with cyclohexane were similarly calculated.

* The selection of the titrant depends on the composition of the ternary to be titrated.[5] Some samples yield turbidity with B, some with C, some with both and some with neither.[6]

TABLE II.—EXPERIMENTAL DATA FOR CALIBRATION CURVES FOR THE SYSTEM C_6H_6–C_6H_{12}–CH_3NO_2 AT 30°C.

Solutions of benzene + nitromethane titrated with cyclohexane

Weight % CH_3NO_2 in original binary	Weight of C_6H_{12} required to titrate 1 g of binary	Refractive index of the resultant solution
91·31	0·0886	1·3888
82·04	0·1336	1·4000
72·93	0·2257	1·4096
62·33	0·4200	1·4191
49·73	0·7767	1·4260

Solutions of benzene + cyclohexane titrated with nitromethane

Weight % C_6H_{12} in original binary	Weight of CH_3NO_2 required to titrate 1 g of binary	Refractive index of the resultant solution
94·18	0·0451	1·4235
83·56	0·0764	1·4293
67·69	0·2186	1·4322
59·33	0·4367	1·4308
54·06	0·6844	1·4283

TABLE III.—COMPARISON OF THE ACTUAL AND ESTIMATED COMPOSITION OF THE TERNARY MIXTURE $C_6H_6 + C_6H_{12} + CH_3NO_2$.

Sample	Cyclohexane % w/w		Nitromethene % w/w		Titrant
	Present	Estimated	Present	Estimated	
1	63·2	62·7	12·3	12·4	Nitromethane
2	52·6	52·9	13·8	13·8	Nitromethane
3	39·3	39·1	32·4	31·8	Nitromethane
		39·3		32·2	Cyclohexane
4	29·8	30·4	16·0	16·1	Nitromethane
		30·0		16·0	Cyclohexane
5	13·7	13·4	62·2	61·8	Cyclohexane
6	10·7	10·4	43·7	44·1	Cyclohexane
7	9·2	9·6	14·8	14·2	Nitromethane
		9·3		14·6	Cyclohexane

DISCUSSION

On the whole, the agreement between the actual and determined composition values (Table III) is good. The maximum difference is ~ 1% when cyclohexane is used and ~ 3% when nitromethane is used as the titrant. The agreement between the actual value and the two sets of determined values for samples 3, 4 and 7 are reasonably good.

The method of analysis is more precise and less time-consuming than the one described earlier.[6] This can be attributed to (*i*) the calibration curves being drawn directly from the experimental results and not needing any graphical treatment, and (*ii*) only one phase-titration being needed instead of the two required in the other procedure.

The procedure does not involve a separate determination of any of the components by an independent method. It is extremely useful for ternary systems where chemical analysis of any of the components is difficult. The method has, however, the same limitations and errors as other phase-titrations.[6]

Summary—A method, based on phase titration, for the analysis of ternary mixtures containing two mutually immiscible or partially miscible components is described. The method involves titrating a measured amount of the sample at constant temperature with one of the immiscible components to a turbidimetric end-point. The refractive index of the resultant solution (clarified by addition of the mutually miscible component) is determined and from the results the composition of the ternary mixture is estimated. The method is illustrated for the system consisting of benzene, cyclohexane and nitromethane.

Zusammenfassung—Beschrieben wird ein auf einer Phasentitration beruhendes Verfahren zur Analyse ternärer Gemische, die zwei gegenseitig nicht mischbare oder teilweise mischbare Komponenten enthalten. Dabei wird eine abgemessene Menge der Probe bei konstanter Temperatur mit einer der nicht mischbaren Komponenten zum turbidimetrischen Endpunkt titriert. Der Brechungsindex der entstehenden Lösung (geklärt durch Zugabe der mischbaren Komponente) wird bestimmt und aus dem Ergebnis die Zusammensetzung des ternären Gemisches ermittelt. Das Verfahren wird an dem System Benzol–Cyclohexan–Nitromethan beispielhaft erläutert.

Résumé—On décrit une méthode basée sur le titrage de phase pour l'analyse de mélanges ternaires contenant deux composants non miscibles ou partiellement miscibles l'un dans l'autre. La méthode comprend le titrage à température constante d'une quantité mesurée de l'échantillon avec l'un des constituants non miscibles jusqu'à point de fin de dosage turbidimétrique. On détermine l'indice de réfraction de la solution résultante (clarifiée par addition du constituant mutuellement miscible) et l'on estime la composition du mélange ternaire à partir des résultats. La méthode est illustrée par le système constitué de benzène, cyclohexane et nitrométhane.

Simple spectrophotometric method for determination of zirconium or hafnium in selected molybdenum-base alloys

(*Received* 13 *September* 1971. *Accepted* 2 *November* 1971)

ARSANAZO III (1,8-dihydroxynaphthalene-3,6-disulpho-2,7-bis(azo-2)-phenylarsonic acid) gives marked colour reactions with a number of elements. The high stability of the metal complexes permits the elements to be photometrically determined in strongly acidic media, which eliminates partial hydrolysis of certain elements. A high degree of selectivity is attained when determining the quadrivalent elements, zirconium and hafnium, in strongly acidic media, $9M$ hydrochloric acid.

It has been reported that no colour reactions with Arsenazo III are observed for elements having cations of radius less than 0·7–0·8 Å. The ionic radii, in Å, for those elements that might be components of molybdenum-base alloys are Cr 0·52, Fe 0·64, Mo 0·62, Ni 0·69, Re 0·56, Ta 0·68, Ti 0·68,

Analysis by phase-titration of three-component systems containing two mutually immiscible or partially miscible components

(*Received* 30 *August* 1971. *Accepted* 1 *November* 1971)

THE PRINCIPLE of phase-titrations has been used to determine the composition of a large number of binary solutions of organic liquids.[1-5] Suri[6] has developed a phase titration procedure for the analysis of ternary mixtures containing two mutually immiscible or partially miscible components. The method is useful for systems where chemical determination of any of the components is difficult.

In the present communication, another phase-titration method is described, which can be used to analyse one-phase ternary mixtures containing two mutually immiscible or partially miscible components, without separate determination of any component. The method involves titrating a measured amount of the ternary mixture at constant temperature with one of the immiscible components until a second phase just appears. The refractive index (a physical property which can be quickly measured) of the resultant solution on the binodal curve is then measured, and the complete composition of the ternary mixture is calculated.

THEORY

A ternary phase-diagram for a system containing A, B and C where B and C are mutually immiscible and A is miscible with both B and C in all proportions is shown in Fig. 1. Solutions represented by a point on or below the binodal curve are heterogeneous and turbid. At constant temperature, the position of the binodal line is fixed for a given ternary mixture, and serves as a reference line in the procedure described below.

A set of binary solutions of A and B, richer in B and of known composition is prepared by weight and titrated with C until a permanent turbidity appears. The resultant ternary solution is then weighed to determine the weight of the titrant added. The turbid solution is clarified by adding a drop of two of A and the refractive index is measured. Two calibration curves are then drawn indicating (*a*) the weight of C required to produce turbidity in 1 g of the binary solution, and (*b*) the refractive index as a function of original binary composition. The procedure is repeated for binary solutions of A and C, richer in C, and another pair of calibration curves is drawn for B as the titrant.

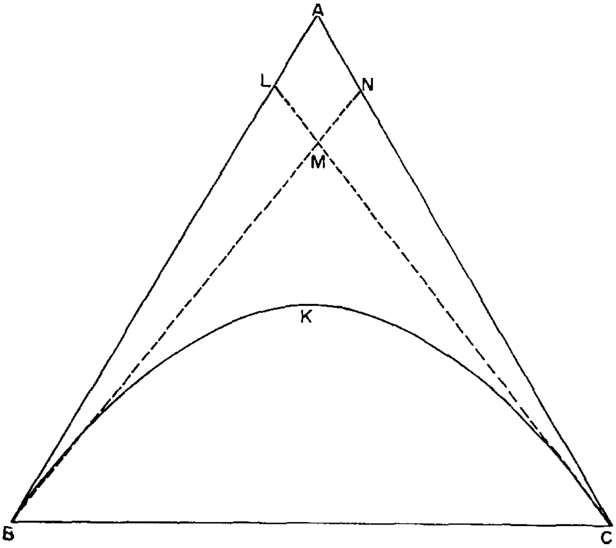

FIG. 1.—Ternary miscibility diagram showing regions suitable for phase-titration analysis.

The dual set of calibrations is necessary because sometimes only one of the two titrants will give a satisfactory end-point (see below).

To analyse a homogeneous mixture of A, B and C, two samples of known weight are titrated, one with B and the other with C to bring the composition on to the binodal curve.* The solution is weighed, clarified by adding a drop of A, and its refractive index measured.

With C used as the titrant, a refractive index value corresponding to y% B signifies the ratio of A:B in the original ternary mixture to be $(100 - y):y$ (during titration with C, the ratio remains unchanged). From the calibration curve, the weight of C required to titrate 1 g of a binary mixture of A and B in the same ratio as in the sample is found (z g). This means that $(1 + z)$ g of the turbid solution (obtained by titration with C) contains $(100 - y)/100$, $y/100$ and z g of A, B and C respectively. If x g is the weight C required to titrate 1 g of the original ternary mixture to this point on the binodal curve, the composition of the sample is given by $A = (100 - y)(1 + x)/(1 + z)\%$; $B = y(1 + x)/(1 + z)\%$, and $C = 100(z - x)/(1 + z)\%$. The calculation is similar when B is used as the titrant.

In some cases, the refractive index calibration plot show a maximum or minimum, so two composition values can correspond to a single refractive index value. To find which one refers to the actual composition, a small amount of B or C is added, the solution is clarified with A, and the direction of shift of refractive index is observed.

Ternary solutions with composition represented by a point anywhere in areas BKCL or BKCN will yield a turbidimetric end-point on titration with B and C respectively. If the composition of the ternary lies outside BKCNML, the area defined by the tangents and the binodal curve, it will not yield any turbidimetric end-point on titration with either B or C. In such cases, a sufficient and known weight of B or C is added to a known weight of the ternary, to bring its composition into one of the titratable regions BKCL or BKCN.[6]

The method is illustrated for the ternary system benzene, cyclohexane and nitromethane, the system used to illustrate the method described earlier.[6]

EXPERIMENTAL

The solvents were purified according to established procedures.[6,7] Densities and refractive index values for the liquids used are recorded in Table I along with the literature values for comparison.[8] The experimental details of the titration and the apparatus have been described earlier.[6]

Calibration curves were prepared, as outlined under *Theory*, for benzene–nitromethane mixtures titrated with cyclohexane, and for benzene–cyclohexane mixtures titrated with nitromethane. The experimental values are given in Table II.

TABLE 1.—SOME PHYSICAL PROPERTIES OF SOLVENTS USED AT 30°C

	Density, *g/ml*		Refractive index	
	Present work	Literature value[7,8]	Present work	Literature value[7,8]
Benzene	0·8685	0·8685	1·4945	1·4948
Cyclohexane	0·7694	0·7690	1·4205	1·4208*
Nitromethane	1·1239	1·1245	1·3770	1·3771*

* Values extrapolated to 30°C.

To illustrate the method, over the entire one-phase region of the system, seven synthetic ternary mixtures were prepared and analysed. The results obtained are compared with the actual composition values in Table III.

Samples 1 and 2 gave turbidimetric end-points with nitromethane, 5 and 6 with cyclohexane, 3 with both, and 4 and 7 with neither. Two sets of each of samples 4 and 7 were diluted with about the same weight of nitromethane or cyclohexane (*vide* ref. 7) and the resulting solutions titrated with cyclohexane or nitromethane respectively. The refractive indices of all the titrated solutions were measured and the weight ratios benzene:nitromethane in samples 3, 5, 6 and the solutions obtained by diluting samples 4 and 7 with nitromethane were computed from the calibration curves. The weight ratios benzene:cyclohexane in samples 1, 2, 3 and the solutions obtained by diluting samples 4 and 7 with cyclohexane were similarly calculated.

* The selection of the titrant depends on the composition of the ternary to be titrated.[5] Some samples yield turbidity with B, some with C, some with both and some with neither.[6]

TABLE II.—EXPERIMENTAL DATA FOR CALIBRATION CURVES FOR THE SYSTEM C_6H_6–C_6H_{12}–CH_3NO_2 AT 30°C.

Solutions of benzene + nitromethane titrated with cyclohexane

Weight % CH_3NO_2 in original binary	Weight of C_6H_{12} required to titrate 1 g of binary	Refractive index of the resultant solution

54·06	0·6844	1·4283

TABLE III.—COMPARISON OF THE ACTUAL AND ESTIMATED COMPOSITION OF THE TERNARY MIXTURE $C_6H_6 + C_6H_{12} + CH_3NO_2$.

Sample	Cyclohexane % w/w		Nitromethene % w/w		Titrant
	Present	Estimated	Present	Estimated	
1	63·2	62·7	12·3	12·4	Nitromethane
2	52·6	52·9	13·8	13·8	Nitromethane
3	39·3	39·1	32·4	31·8	Nitromethane
		39·3		32·2	Cyclohexane
4	29·8	30·4	16·0	16·1	Nitromethane
		30·0		16·0	Cyclohexane
5	13·7	13·4	62·2	61·8	Cyclohexane
6	10·7	10·4	43·7	44·1	Cyclohexane
7	9·2	9·6	14·8	14·2	Nitromethane
		9·3		14·6	Cyclohexane

DISCUSSION

On the whole, the agreement between the actual and determined composition values (Table III) is good. The maximum difference is ~ 1% when cyclohexane is used and ~ 3% when nitromethane is used as the titrant. The agreement between the actual value and the two sets of determined values for samples 3, 4 and 7 are reasonably good.

The method of analysis is more precise and less time-consuming than the one described earlier.[6] This can be attributed to (*i*) the calibration curves being drawn directly from the experimental results and not needing any graphical treatment, and (*ii*) only one phase-titration being needed instead of the two required in the other procedure.

The procedure does not involve a separate determination of any of the components by an independent method. It is extremely useful for ternary systems where chemical analysis of any of the components is difficult. The method has, however, the same limitations and errors as other phase-titrations.[6]

Summary—A method, based on phase titration, for the analysis of ternary mixtures containing two mutually immiscible or partially miscible components is described. The method involves titrating a measured amount of the sample at constant temperature with one of the immiscible components to a turbidimetric end-point. The refractive index of the resultant solution (clarified by addition of the mutually miscible component) is determined and from the results the composition of the ternary mixture is estimated. The method is illustrated for the system consisting of benzene, cyclohexane and nitromethane.

Zusammenfassung—Beschrieben wird ein auf einer Phasentitration beruhendes Verfahren zur Analyse ternärer Gemische, die zwei gegenseitig nicht mischbare oder teilweise mischbare Komponenten enthalten. Dabei wird eine abgemessene Menge der Probe bei konstanter Temperatur mit einer der nicht mischbaren Komponenten zum turbidimetrischen Endpunkt titriert. Der Brechungsindex der entstehenden Lösung (geklärt durch Zugabe der mischbaren Komponente) wird bestimmt und aus dem Ergebnis die Zusammensetzung des ternären Gemisches ermittelt. Das Verfahren wird an dem System Benzol–Cyclohexan–Nitromethan beispielhaft erläutert.

Résumé—On décrit une méthode basée sur le titrage de phase pour l'analyse de mélanges ternaires contenant deux composants non miscibles ou partiellement miscibles l'un dans l'autre. La méthode comprend le titrage à température constante d'une quantité mesurée de l'échantillon avec l'un des constituants non miscibles jusqu'à point de fin de dosage turbidimétrique. On détermine l'indice de réfraction de la solution résultante (clarifiée par addition du constituant mutuellement miscible) et l'on estime la composition du mélange ternaire à partir des résultats. La méthode est illustrée par le système constitué de benzène, cyclohexane et nitrométhane.

Simple spectrophotometric method for determination of zirconium or hafnium in selected molybdenum-base alloys

(*Received* 13 *September* 1971. *Accepted* 2 *November* 1971)

ARSANAZO III (1,8-dihydroxynaphthalene-3,6-disulpho-2,7-bis(azo-2)-phenylarsonic acid) gives marked colour reactions with a number of elements. The high stability of the metal complexes permits the elements to be photometrically determined in strongly acidic media, which eliminates partial hydrolysis of certain elements. A high degree of selectivity is attained when determining the quadrivalent elements, zirconium and hafnium, in strongly acidic media, $9M$ hydrochloric acid.

It has been reported that no colour reactions with Arsenazo III are observed for elements having cations of radius less than 0·7–0·8 Å. The ionic radii, in Å, for those elements that might be components of molybdenum-base alloys are Cr 0·52, Fe 0·64, Mo 0·62, Ni 0·69, Re 0·56, Ta 0·68, Ti 0·68,

V 0·59. Zirconium has been photometrically determined in uranium with Arsenazo III. The zirconium was removed by solvent extraction before formation of the Zr–Arsenazo III complex in 6*M* hydrochloric acid. Molybdenum does not form a coloured complex with Arsenazo III, so direct photometric measurement of the Zr or Hf complex, without prior separation, was thought to be feasible.

EXPERIMENTAL

Reagents

Hydrochloric acid, conc. and 9*M*.

Nitric acid, conc.

Arsenazo III solution, 0·10%. Dissolve 100 mg of reagent in 100 ml of water containing 0·5 ml of 5% sodium carbonate solution.

Zirconium, standard solution. Dissolve 1·021 g of reactor-grade zirconium in 6*M* hydrochloric acid, with dropwise addition of the minimum of hydrofluoric acid necessary. Evaporate to dryness, then add hydrochloric acid. Repeat this twice more and finally dissolve the residue in 9*M* hydrochloric acid and dilute to 500 ml in a standard flask with that acid. Standardize by the mandelic acid method, igniting to ZrO_2. Prepare working standards by dilution with 9*M* hydrochloric acid.

Hafnium, standard solution. Oxidize 0·498 g of hafnium (99·8% pure, low zirconium content) to HfO_2 at 800°. Fuse the oxide with 2 g of sodium carbonate/sodium borate flux (1:1). Dissolve in 9*M* hydrochloric acid, transfer to a 500 ml volumetric flask and dilute to volume with 9*M* hydrochloric acid. Standardize by precipitation with mandelic acid and ignition to HfO_2. Prepare working solutions by dilution with 9*M* hydrochloric acid.

Molybdenum solution. Prepared by dissolving 2 g of molybdenum in nitric acid, and evaporating repeatedly with hydrochloric acid a minimum of three times to remove nitrate. Take up the

residue with 9*M* hydrochloric acid, transfer to a 200 ml volumetric flask and make up to volume with 9*M* hydrochloric acid.

Rhenium solution. Prepared by fusing 2 g of rhenium with 5 g of potassium carbonate. Dissolve the clear melt in hydrochloric acid, transfer to a 200 ml volumetric flask and make up to volume with 9*M* hydrochloric acid.

Absorption spectra The absorption spectra of Arsenazo III and its Zr and Hf complexes showed a well-defined peak at 670 nm for the complexes. The reagent had a low absorption at this wavelength (Fig. 1).

Solutions of Zr and Hf, at concentrations up to 1 µg/ml, were reacted with Arsenazo III at three hydrochloric acid concentrations, 2·76, 5·52, and 8·28*M*. The absorbances showed that sensitivity increased with hydrochloric acid concentration, and a concentration of 8.3*M* hydrochloric acid was chosen for high sensitivity.

A calibration curve was prepared, standard Zr solution being added to a 50-ml volumetric flask containing 25 ml of 9*M* hydrochloric acid, followed by addition of 4 ml of Arsenazo III solution and dilution to 50 ml with the acid. The absorbance was measured at 670 nm in a 1-cm cell and corrected for the blank. Beer's law was obeyed up to 20 µg of zirconium. Addition of 10 mg of molybdenum, 10 mg of rhenium, or 1 mg of titanium did not affect the calibration curve.

Calibration curves for 10 µg of zirconium in 50 ml of final solution, similarly prepared, were equally satisfactory, either 2-cm or 5-cm cells being used.

Similar results were obtained for hafnium by the same procedure, for the 0–50 and 0–10 µg ranges.

Procedure

Weigh a sample of a size based on the expected homogeneity of the alloy, place it in a 250-ml beaker, dissolve it in *aqua regia*, then remove the cover glass and evaporate to dryness under infrared drying lamps. Cool, add 20 ml of conc. hydrochloric acid, rinse down the sides of the beaker and again evaporate to dryness under the lamps. Repeat this operation at least twice more for the complete removal of nitrate. Cool, add 20–30 ml of $9M$ hydrochloric acid to dissolve the metal salts, transfer the sample solution to a suitable volumetric flask, dilute to volume with $9M$ hydrochloric acid and mix thoroughly. Transfer a suitable aliquot containing not more than 20 μg of zirconium or 50 μg of hafnium to a 50 ml volumetric flask containing 25 ml of $9M$ hydrochloric acid. Prepare a similar reagent blank. Add 4 ml of Arsenazo III solution to each flask, dilute to volume with $9M$ hydrochloric acid, mix, measure the absorbance for samples and the blank. Apply the blank correction.

RESULTS

The procedure was applied to four molybdenum alloys, with the results shown in Tables I and II. The results show good agreement with accepted values, and are reproducible. The method is simple and no prior separation is necessary. The relative standard deviation ranges from 1·3 to 2·7%.

Summary—A simple analytical procedure is described for determining zirconium or hafnium in molybdenum-base alloys by formation of the Arsenazo III complex of zirconium or hafnium in $9M$ hydrochloric acid medium. The absorbance is measured at 670 nm. Molybdenum (10 mg), titanium (1 mg), and rhenium (10 mg) have no adverse effect. No prior separation is needed. The relative standard deviation is 1·3–2·7%.

Zusammenfassung—Ein einfaches analytisches Verfahren zur Bestimmung von Zirkonium oder Hafnium in Legierungen auf Molybdängrundlage wird beschrieben. Es beruht auf der Bildung des Komplexes von Zirkonium oder Hafnium mit Arsenazo III in 9 M Salzsäure. Die Extinktion wird bei 670 nm gemessen. 10 mg Molybdän, 1 mg Titan und 10 mg Rhenium stören nicht. Es ist keine vorhergehende Abtrennung notwendig. Die relative Standardabweichung betragt 1,3–2,7%.

Résumé—On décrit une technique analytique simple pour le dosage du zirconium ou du hafnium dans les alliages à base de molybdène par formation du complexe Arsenazo III du zirconium ou du hafnium en milieu acide chlorhydrique $9M$. On mesure l'absorption à 670 nm. Le molybdène (10 mg), le titane (1 mg) et le rhénium (10 mg) n'ont pas d'effet défavorable. Une séparation préalable n'est pas nécessaire. L'écart type relatif est 1,3–2,7%.

Das Verfahren wird an dem System Benzol–Cyclohexan–Nitromethan beispielhaft erläutert.

Résumé—On décrit une méthode basée sur le titrage de phase pour l'analyse de mélanges ternaires contenant deux composants non miscibles ou partiellement miscibles l'un dans l'autre. La méthode comprend le titrage à température constante d'une quantité mesurée de l'échantillon avec l'un des constituants non miscibles jusqu'à point de fin de dosage turbidimétrique. On détermine l'indice de réfraction de la solution résultante (clarifiée par addition du constituant mutuellement miscible) et l'on estime la composition du mélange ternaire à partir des résultats. La méthode est illustrée par le système constitué de benzène, cyclohexane et nitrométhane.

Simple spectrophotometric method for determination of zirconium or hafnium in selected molybdenum-base alloys

(*Received* 13 *September* 1971. *Accepted* 2 *November* 1971)

ARSANAZO III (1,8-dihydroxynaphthalene-3,6-disulpho-2,7-bis(azo-2)-phenylarsonic acid) gives marked colour reactions with a number of elements. The high stability of the metal complexes permits the elements to be photometrically determined in strongly acidic media, which eliminates partial hydrolysis of certain elements. A high degree of selectivity is attained when determining the quadrivalent elements, zirconium and hafnium, in strongly acidic media, $9M$ hydrochloric acid.

It has been reported that no colour reactions with Arsenazo III are observed for elements having cations of radius less than 0·7–0·8 Å. The ionic radii, in Å, for those elements that might be components of molybdenum-base alloys are Cr 0·52, Fe 0·64, Mo 0·62, Ni 0·69, Re 0·56, Ta 0·68, Ti 0·68,

V 0·59. Zirconium has been photometrically determined in uranium with Arsenazo III. The zirconium was removed by solvent extraction before formation of the Zr–Arsenazo III complex in 6*M* hydrochloric acid. Molybdenum does not form a coloured complex with Arsenazo III, so direct photometric measurement of the Zr or Hf complex, without prior separation, was thought to be feasible.

EXPERIMENTAL

Reagents

Hydrochloric acid, conc. and 9*M*.

Nitric acid, conc.

Arsenazo III solution, 0·10%. Dissolve 100 mg of reagent in 100 ml of water containing 0·5 ml of 5% sodium carbonate solution.

Zirconium, standard solution. Dissolve 1·021 g of reactor-grade zirconium in 6*M* hydrochloric acid, with dropwise addition of the minimum of hydrofluoric acid necessary. Evaporate to dryness, then add hydrochloric acid. Repeat this twice more and finally dissolve the residue in 9*M* hydrochloric acid and dilute to 500 ml in a standard flask with that acid. Standardize by the mandelic acid method, igniting to ZrO_2. Prepare working standards by dilution with 9*M* hydrochloric acid.

Hafnium, standard solution. Oxidize 0·498 g of hafnium (99·8% pure, low zirconium content) to HfO_2 at 800°. Fuse the oxide with 2 g of sodium carbonate/sodium borate flux (1 :1). Dissolve in 9*M* hydrochloric acid, transfer to a 500 ml volumetric flask and dilute to volume with 9*M* hydrochloric acid. Standardize by precipitation with mandelic acid and ignition to HfO_2. Prepare working solutions by dilution with 9*M* hydrochloric acid.

Molybdenum solution. Prepared by dissolving 2 g of molybdenum in nitric acid, and evaporating repeatedly with hydrochloric acid a minimum of three times to remove nitrate. Take up the

residue with 9*M* hydrochloric acid, transfer to a 200 ml volumetric flask and make up to volume with 9*M* hydrochloric acid.

Rhenium solution. Prepared by fusing 2 g of rhenium with 5 g of potassium carbonate. Dissolve the clear melt in hydrochloric acid, transfer to a 200 ml volumetric flask and make up to volume with 9*M* hydrochloric acid.

Absorption spectra The absorption spectra of Arsenazo III and its Zr and Hf complexes showed a well-defined peak at 670 nm for the complexes. The reagent had a low absorption at this wavelength (Fig. 1).

Solutions of Zr and Hf, at concentrations up to 1 μg/ml, were reacted with Arsenazo III at three hydrochloric acid concentrations, 2·76, 5·52, and 8·28*M*. The absorbances showed that sensitivity increased with hydrochloric acid concentration, and a concentration of 8.3*M* hydrochloric acid was chosen for high sensitivity.

A calibration curve was prepared, standard Zr solution being added to a 50-ml volumetric flask containing 25 ml of 9*M* hydrochloric acid, followed by addition of 4 ml of Arsenazo III solution and dilution to 50 ml with the acid. The absorbance was measured at 670 nm in a 1-cm cell and corrected for the blank. Beer's law was obeyed up to 20 μg of zirconium. Addition of 10 mg of molybdenum, 10 mg of rhenium, or 1 mg of titanium did not affect the calibration curve.

Calibration curves for 10 μg of zirconium in 50 ml of final solution, similarly prepared, were equally satisfactory, either 2-cm or 5-cm cells being used.

Similar results were obtained for hafnium by the same procedure, for the 0–50 and 0–10 μg ranges.

Procedure

Weigh a sample of a size based on the expected homogeneity of the alloy, place it in a 250-ml beaker, dissolve it in *aqua regia*, then remove the cover glass and evaporate to dryness under infrared drying lamps. Cool, add 20 ml of conc. hydrochloric acid, rinse down the sides of the beaker and again evaporate to dryness under the lamps. Repeat this operation at least twice more for the complete removal of nitrate. Cool, add 20–30 ml of $9M$ hydrochloric acid to dissolve the metal salts, transfer the sample solution to a suitable volumetric flask, dilute to volume with $9M$ hydrochloric acid and mix thoroughly. Transfer a suitable aliquot containing not more than 20 μg of zirconium or 50 μg of hafnium to a 50 ml volumetric flask containing 25 ml of $9M$ hydrochloric acid. Prepare a similar reagent blank. Add 4 ml of Arsenazo III solution to each flask, dilute to volume with $9M$ hydrochloric acid, mix, measure the absorbance for samples and the blank. Apply the blank correction.

RESULTS

The procedure was applied to four molybdenum alloys, with the results shown in Tables I and II. The results show good agreement with accepted values, and are reproducible. The method is simple and no prior separation is necessary. The relative standard deviation ranges from 1·3 to 2·7%.

Summary—A simple analytical procedure is described for determining zirconium or hafnium in molybdenum-base alloys by formation of the Arsenazo III complex of zirconium or hafnium in $9M$ hydrochloric acid medium. The absorbance is measured at 670 nm. Molybdenum (10 mg), titanium (1 mg), and rhenium (10 mg) have no adverse effect. No prior separation is needed. The relative standard deviation is 1·3–2·7%.

Zusammenfassung—Ein einfaches analytisches Verfahren zur Bestimmung von Zirkonium oder Hafnium in Legierungen auf Molybdängrundlage wird beschrieben. Es beruht auf der Bildung des Komplexes von Zirkonium oder Hafnium mit Arsenazo III in 9 M Salzsäure. Die Extinktion wird bei 670 nm gemessen. 10 mg Molybdän, 1 mg Titan und 10 mg Rhenium stören nicht. Es ist keine vorhergehende Abtrennung notwendig. Die relative Standardabweichung betragt 1,3–2,7%.

Résumé—On décrit une technique analytique simple pour le dosage du zirconium ou du hafnium dans les alliages à base de molybdène par formation du complexe Arsenazo III du zirconium ou du hafnium en milieu acide chlorhydrique $9M$. On mesure l'absorption à 670 nm. Le molybdène (10 mg), le titane (1 mg) et le rhénium (10 mg) n'ont pas d'effet défavorable. Une séparation préalable n'est pas nécessaire. L'écart type relatif est 1,3–2,7%.

analysis involves inherent difficulties, one of the main problems being differences in matrix effects when samples and standards are not identical in chemical and physical characteristics. However, there are means whereby these problems may be minimized.[1–5] The literature contains numerous papers[6–12] on the technique, the application to quantitative analyses, and descriptions of radioisotope source assemblies. Therefore, the theory of the method and the varied applications will not be presented here.

The application of EDXS to qualitative analysis is relatively rapid and generally straightforward. The $K\alpha$ and $K\beta$ or $L\alpha$, $L\beta$, and $L\gamma$ peaks obtained experimentally can be compared with the corresponding peaks obtained from standards or with tabulated values, to obtain qualitative identification. By use of a source which emits photons with a definite maximum energy, either in the form of X-rays, gamma-rays or bremsstrahlung, the range of elements which can be excited and caused to emit characteristic X-rays can be controlled. There are a number of commercially available radioisotopic sources and required sources that are not available can be prepared. The sensitivity, which is dependent on a number of parameters such as matrix, atomic number and excitation source, is in the range from parts per thousand to parts per million for most elements. For $18 > Z > 10$, the use of helium or vacuum, rather than air, in the apparatus is necessary. Elements with $Z < 10$ are not directly detectable by this technique.

In an analytical laboratory, the use of EDXS for qualitative analysis can relieve the sample load on other methods such as emission spectroscopy. Since these other techniques are capable of identifying specific alloys, full utilization of EDXS should include qualitative identification of alloys.

Although Sellers and Brinkerhoff[12] have suggested a technique for alloy sorting which uses energy filters and multiple counts, the method described in this paper requires only one sample counting and no filters are needed. The experimental results are incorporated with specification data in a graph which permits unique identification of a specific alloy within an alloy type.

EXPERIMENTAL

Instrumentation

A Nuclear Diodes EDXS system, Model XS-25-240-DSS, was used in this work. The Si(Li) detector was 25 mm^2 × 3 mm and had a 2-mil beryllium window. The signals were passed through an amplifier into a TMC 404C analyser. The system resolution was <300 eV FWHM (full peak width at half the maximum peak height) for the 6·4 keV $K\alpha$ X-rays of iron.

Samples were supported on a Mylar film stretched across a Nuclear Diodes Model XFS-1 source-holder. The sources were mounted in the holder such that line of sight between the source and sample was at 45° to the axis defined by the sample and detector. The holder shielded the detector from direct bombardment by the source and also served to collimate the X-rays generated in the sample.

Excitation

Samples were placed by hand in the centre of the Mylar film as reproducibly as possible. ^{241}Am and ^{109}Cd sources were used individually for excitation of the characteristic X-ray lines of the samples. Accumulation of the spectra was for either 1 or 4 min, depending on the size of the samples and the intensity of the X-rays produced. The areas under the individual peaks of interest were obtained by integration with a TMC Resolver/Integrator unit.

Samples

The samples used in this work were NBS SRM brass standards (standards C1103–C1119), lead–tin solder spectrochemical standards obtained from Morris P. Kirk Co. (standard numbers 527–585), analysed stainless steel (austenitic) from Armco Steel Co., Rustless Division and a gold–silver alloy series prepared in this laboratory and analysed by standard wet chemical procedures.

RESULTS AND DISCUSSION

In the case of the brass samples, the areas under the $K\alpha$ peaks of copper and zinc were obtained for each sample. The logarithm of the ratio of these two numbers was defined as log(Cu/Zn), measured. From the standard specification sheet, the logarithm of the percentage ratio of copper to zinc was found and defined as log(Cu/Zn), specification. Figure 1 illustrates a plot of log(Cu/Zn), specification *vs.* log(Cu/Zn), measured for several common brasses. In the case of the lead–tin solders, the areas under the $L\beta$ peak of lead and the $K\alpha$ peak of tin were obtained, and the logarithms of the measured and specification ratios of lead/tin were plotted and are also shown in Fig. 1. The $K\alpha$ peak of silver and the $L\beta$ peak of gold were used to obtain a similar plot for the gold–silver alloy.

Each set of points exhibits a definite trend which can be approximated by a smooth curve. The scatter about the line can perhaps be explained by different counting efficiencies for different X-ray

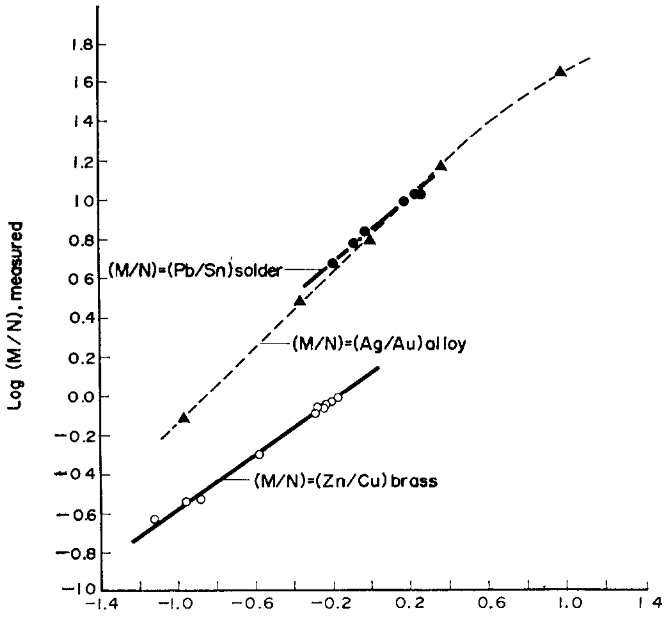

FIG. 1.—A plot of log(M/N), measured, *vs.* log(M/N), specification, for series of brass alloys, solders alloys and Ag–Au alloys illustrating that individual alloys can be identified by energy-dispersive X-ray spectroscopy.

fluxes, by differential absorption of X-rays in the sample as a function of X-ray energy, by fluorescence or absorption by trace elements, or by inhomogeneity in the sample. Since there is no requirement that the points fit a particular type of curve, this scatter does not invalidate the technique. The important fact is that each point represents a specific alloy and is a function only of the composition of the sample.

The reason for plotting ratios of elements is that this minimizes differences due to any physical discrepancies between one sample and another, *e.g.*, comparison of a small sample to a large sample, a smooth to a rough sample; also, it normalizes experimental irregularities such as differences in, counting times between samples.[4–5] This emphasises the fact that each point is a function, primarily of the composition of the sample and not of its physical features.

There are cases where two alloys may have almost identical major element composition and in the plot their points may be so close together that it is difficult to distinguish between them. Two examples of this are shown in the brass plot in the log(M/N), measured, region from −0·05 to −0·09 and in the log(M/N), specification, region from −0·2 to −0·3. However, in both cases one of the brasses is free-machining and has a lead content that is 20–30 times higher than that in the non-free-machining brass, represented by the adjoining point. The *L* series lines of lead in the case of the high lead-content alloys (free-machining) can easily be seen and thereby it is easy to distinguish between them and the adjoining low lead-content alloys. A somewhat similar occurrence is apparent at the top of the solder alloy points—two alloys are very close to one another. In this case, one of the alloys has 10 times the amounts of Cu, Sb, Ag and Bi that the other alloy has. Thus, characteristic X-ray lines of one or more of these elements are apparent for one alloy, but not for the other; therefore, the two alloys can be distinguished.

Although the applicability of this technique to a variety of alloy systems can be visualized, caution must be exercised in some cases. For example, a variation of the method can be used superficially for stainless steels. In ternary or more complex alloys, some measure must be made of all major elements to ensure that they are within specification. However, it would be preferred if the advantage could be retained of a data point representing the chemical composition of a sample, independent of physical characteristics such as size or surface finish. For ternary systems such as stainless steel (Fe, Cr, Ni), this can be accomplished by plotting ratios of two of the elements to the

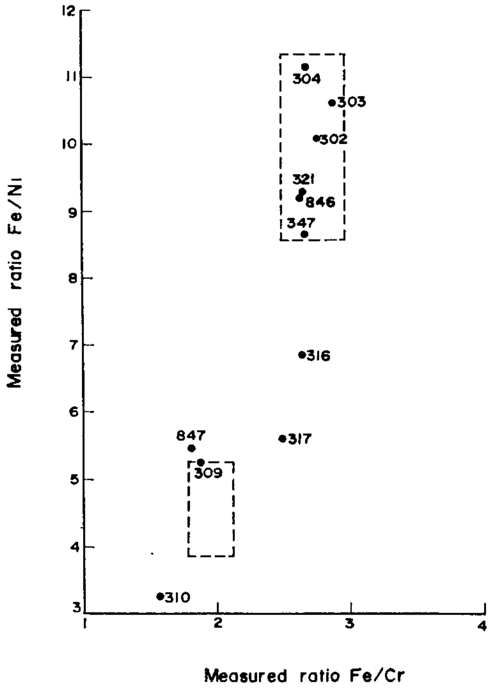

FIG. 2.—A plot of Fe/Ni *vs.* Fe/Cr ratios for stainless steels as determined by energy-dispersive X-ray spectroscopy illustrating that analysed steel alloys can be identified. The rectangles represent the variation in Cr and Ni contents that can be present in actual steel samples, Types 302 and 309 stainless steels, in this case.

third used as a normalizing factor. Figure 2 illustrates such a plot where the areas under the characteristic $K\alpha$ peaks for iron, chromium and nickel were obtained, the ratios Fe/Ni and Fe/Cr were determined and then plotted *vs.* each other. The point of this discussion is that, whereas analysed standards provide point plots, complex alloys such as stainless-steel samples yield area plots because the specifications for stainless steels do not specify a single percentage for iron, chromium or nickel. Rather, the specifications define ranges; *e.g.*, for an AISI Type 302 stainless steel, the chromium content must be between 17·00 and 19·00%, the nickel between 8·00 and 10·00%, there are maxima of 1·00% Si, 2·00% Mn and 0·15% C and the remainder is iron. Because of this, the Fe/Cr and Fe/Ni ratios can vary over an appreciable range—this range is designated for the Type 302 and 309 stainless steels by the rectangles in Fig. 2. Obviously, there is a great deal of overlapping than can occur among the various steels. Therefore, although it is possible to distinguish between a Type 304 steel and a Type 309, caution must be exercised in distinguishing between Types 304 and 347 (the presence of niobium would identify the Type 347). Other analytical techniques suffer from these overlapping compositions and experience difficulty in qualitatively characterizing a steel. Certainly, EDXS can distinguish between the various series of stainless steels since the chromium and nickel contents are quite different; this frequently is all the distinction necessary in production control.

The possible applications of this technique are numerous and include verification of composition on production lines, in stock control to ensure no mix-up in the inventory and in general laboratory work to identify the type of alloy in question. The last two uses have frequently been used in the authors' laboratory. Two of the outstanding advantages of this technique are the speed of identification and the ease with which the equipment can be operated.

Summary—Energy dispersive X-ray spectroscopy can be used to identify alloy types quickly and, in many cases, to distinguish between alloy systems within a certain alloy type. Characteristic X-rays of major components in an alloy are produced through excitation by an isotopic source. Ratios of the X-ray intensities of a pair of elements are plotted *vs.* ratios of the theoretical weight fractions of these elements. This provides a unique data point which is a function of the composition of the particular alloy system. In some cases, characteristic X-rays of minor constituents are used for total identification.

Zusammenfassung—Die Röntgenspektroskopie mit Energiedispersion kann zur raschen Identifizierung von Legierungstypen und in vielen Fällen zur Unterscheidung zwischen Legierungssystemen innerhalb eines bestimmten Legierungstyps dienen. Die charakteristische Röntgenstrahlung der Hauptbestandteile einer Legierung wird mit Hilfe einer Isotopenquelle angeregt. Die Verhältnisse der Röntgenintensitäten eines Elementpaars werden gegen die Verhältnisse der theoretischen Gewichtsbrüche dieser Elemente aufgetragen. Das ergibt einen kennzeichnenden Satz von Daten, der von der Zusammensetzung des jeweiligen speziellen Legierungssystems abhängt. In einigen Fällen werden die charakteristischen Röntgenstrahlen von Nebenbestandteilen für die Identifizierung im Ganzen herangezogen.

Résumé—On peut utiliser la spectroscopie de rayons X à dispersion d'énergie pour identifier rapidement des types d'alliages et, dans de nombreux cas, pour distinguer les systèmes d'alliages à l'intérieur d'un certain type d'alliage. Des rayons X caractéristiques des composants majeurs d'un alliage sont produits par excitation par une source isotopique. On porte les rapports des intensités des rayons X d'une paire d'éléments en fonction des rapports des fractions de poids théoriques de ces éléments. Ceci fournit un point de données particulières qui est une fonction de la composition du système d'alliage concerné. Dans quelques cas, on utilise les rayons X caractéristiques de constituants mineurs pour l'identification totale.

6-phenyl-2,3-dihydro-*asym*-triazine-3-thione and 5,6-diphenyl-2,3-dihydro-*asym*-triazine-3-thione as gravimetric reagents for the determination of thallium and palladium

(*Received* 27 *August* 1971. *Accepted* 18 *November* 1971)

SULPHUR-CONTAINING ligands show a marked selectivity for a relatively small number of transition metals. In this work the analytical applications of two sulphur-containing ligands, 6-phenyl-2,3-dihydro-*asym*-triazine-3-thione (PDTT) and 5,6-diphenyl-2,3-dihydro-*asym*-triazine-3-thione (DDTT) were investigated.

Procedure

Weigh a sample of a size based on the expected homogeneity of the alloy, place it in a 250-ml beaker, dissolve it in *aqua regia*, then remove the cover glass and evaporate to dryness under infrared drying lamps. Cool, add 20 ml of conc. hydrochloric acid, rinse down the sides of the beaker and again evaporate to dryness under the lamps. Repeat this operation at least twice more for the complete removal of nitrate. Cool, add 20–30 ml of $9M$ hydrochloric acid to dissolve the metal salts, transfer the sample solution to a suitable volumetric flask, dilute to volume with $9M$ hydrochloric acid and mix thoroughly. Transfer a suitable aliquot containing not more than 20 μg of zirconium or 50 μg of hafnium to a 50 ml volumetric flask containing 25 ml of $9M$ hydrochloric acid. Prepare a similar reagent blank. Add 4 ml of Arsenazo III solution to each flask, dilute to volume with $9M$ hydrochloric acid, mix, measure the absorbance for samples and the blank. Apply the blank correction.

RESULTS

The procedure was applied to four molybdenum alloys, with the results shown in Tables I and II. The results show good agreement with accepted values, and are reproducible. The method is simple and no prior separation is necessary. The relative standard deviation ranges from 1·3 to 2·7%.

WILLIAM A. DUPRAW

Summary—A simple analytical procedure is described for determining zirconium or hafnium in molybdenum-base alloys by formation of the Arsenazo III complex of zirconium or hafnium in $9M$ hydrochloric acid medium. The absorbance is measured at 670 nm. Molybdenum (10 mg), titanium (1 mg), and rhenium (10 mg) have no adverse effect. No prior separation is needed. The relative standard deviation is 1·3–2·7%.

Zusammenfassung—Ein einfaches analytisches Verfahren zur Bestimmung von Zirkonium oder Hafnium in Legierungen auf Molybdängrundlage wird beschrieben. Es beruht auf der Bildung des Komplexes von Zirkonium oder Hafnium mit Arsenazo III in 9 M Salzsäure. Die Extinktion wird bei 670 nm gemessen. 10 mg Molybdän, 1 mg Titan und 10 mg Rhenium stören nicht. Es ist keine vorhergehende Abtrennung notwendig. Die relative Standardabweichung betragt 1,3–2,7%.

Résumé—On décrit une technique analytique simple pour le dosage du zirconium ou du hafnium dans les alliages à base de molybdène par formation du complexe Arsenazo III du zirconium ou du hafnium en milieu acide chlorhydrique $9M$. On mesure l'absorption à 670 nm. Le molybdène (10 mg), le titane (1 mg) et le rhénium (10 mg) n'ont pas d'effet défavorable. Une séparation préalable n'est pas nécessaire. L'écart type relatif est 1,3–2,7%.

Qualitative identification of alloys by energy-dispersive X-ray spectroscopy*

(*Received* 23 *September* 1971. *Accepted* 14 *November* 1971)

ENERGY-DISPERSIVE X-RAY SPECTROSCOPY (EDXS) has been advancing rapidly in recent years, largely on account of the development of high-resolution semiconductor detectors and the increasing availability of radioisotopic sources suitable for use in excitation. The use of this technique for quantitative

* This work was supported by the United States Atomic Energy Commission.

analysis involves inherent difficulties, one of the main problems being differences in matrix effects when samples and standards are not identical in chemical and physical characteristics. However, there are means whereby these problems may be minimized.[1–5] The literature contains numerous papers[6–12] on the technique, the application to quantitative analyses, and descriptions of radioisotope source assemblies. Therefore, the theory of the method and the varied applications will not be presented here.

The application of EDXS to qualitative analysis is relatively rapid and generally straightforward. The $K\alpha$ and $K\beta$ or $L\alpha$, $L\beta$, and $L\gamma$ peaks obtained experimentally can be compared with the corresponding peaks obtained from standards or with tabulated values, to obtain qualitative identification. By use of a source which emits photons with a definite maximum energy, either in the form of X-rays, gamma-rays or bremsstrahlung, the range of elements which can be excited and caused to emit characteristic X-rays can be controlled. There are a number of commercially available radioisotopic sources and required sources that are not available can be prepared. The sensitivity, which is dependent on a number of parameters such as matrix, atomic number and excitation source, is in the range from parts per thousand to parts per million for most elements. For $18 > Z > 10$, the use of helium or vacuum, rather than air, in the apparatus is necessary. Elements with $Z < 10$ are not directly detectable by this technique.

In an analytical laboratory, the use of EDXS for qualitative analysis can relieve the sample load on other methods such as emission spectroscopy. Since these other techniques are capable of identifying specific alloys, full utilization of EDXS should include qualitative identification of alloys.

Although Sellers and Brinkerhoff[12] have suggested a technique for alloy sorting which uses energy filters and multiple counts, the method described in this paper requires only one sample counting and no filters are needed. The experimental results are incorporated with specification data in a graph which permits unique identification of a specific alloy within an alloy type.

EXPERIMENTAL

Instrumentation

A Nuclear Diodes EDXS system, Model XS-25-240-DSS, was used in this work. The Si(Li) detector was 25 mm^2 × 3 mm and had a 2-mil beryllium window. The signals were passed through an amplifier into a TMC 404C analyser. The system resolution was <300 eV FWHM (full peak width at half the maximum peak height) for the 6·4 keV $K\alpha$ X-rays of iron.

Samples were supported on a Mylar film stretched across a Nuclear Diodes Model XFS-1 source-holder. The sources were mounted in the holder such that line of sight between the source and sample was at 45° to the axis defined by the sample and detector. The holder shielded the detector from direct bombardment by the source and also served to collimate the X-rays generated in the sample.

Excitation

Samples were placed by hand in the centre of the Mylar film as reproducibly as possible. ^{241}Am and ^{109}Cd sources were used individually for excitation of the characteristic X-ray lines of the samples. Accumulation of the spectra was for either 1 or 4 min, depending on the size of the samples and the intensity of the X-rays produced. The areas under the individual peaks of interest were obtained by integration with a TMC Resolver/Integrator unit.

Samples

The samples used in this work were NBS SRM brass standards (standards C1103–C1119), lead–tin solder spectrochemical standards obtained from Morris P. Kirk Co. (standard numbers 527–585), analysed stainless steel (austenitic) from Armco Steel Co., Rustless Division and a gold–silver alloy series prepared in this laboratory and analysed by standard wet chemical procedures.

RESULTS AND DISCUSSION

In the case of the brass samples, the areas under the $K\alpha$ peaks of copper and zinc were obtained for each sample. The logarithm of the ratio of these two numbers was defined as log(Cu/Zn), measured. From the standard specification sheet, the logarithm of the percentage ratio of copper to zinc was found and defined as log(Cu/Zn), specification. Figure 1 illustrates a plot of log(Cu/Zn), specification *vs.* log(Cu/Zn), measured for several common brasses. In the case of the lead–tin solders, the areas under the $L\beta$ peak of lead and the $K\alpha$ peak of tin were obtained, and the logarithms of the measured and specification ratios of lead/tin were plotted and are also shown in Fig. 1. The $K\alpha$ peak of silver and the $L\beta$ peak of gold were used to obtain a similar plot for the gold–silver alloy.

Each set of points exhibits a definite trend which can be approximated by a smooth curve. The scatter about the line can perhaps be explained by different counting efficiencies for different X-ray

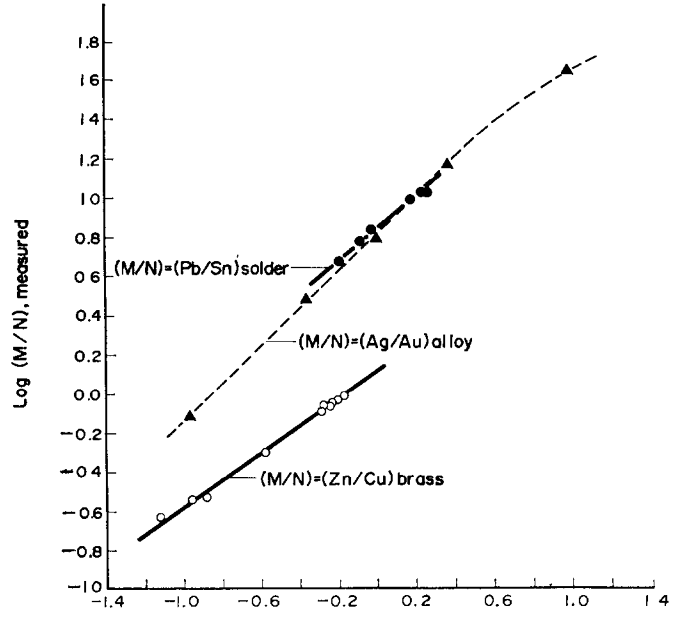

FIG. 1.—A plot of log(M/N), measured, *vs.* log(M/N), specification, for series of brass alloys, solders alloys and Ag–Au alloys illustrating that individual alloys can be identified by energy-dispersive X-ray spectroscopy.

fluxes, by differential absorption of X-rays in the sample as a function of X-ray energy, by fluorescence or absorption by trace elements, or by inhomogeneity in the sample. Since there is no requirement that the points fit a particular type of curve, this scatter does not invalidate the technique. The important fact is that each point represents a specific alloy and is a function only of the composition of the sample.

The reason for plotting ratios of elements is that this minimizes differences due to any physical discrepancies between one sample and another, *e.g.*, comparison of a small sample to a large sample, a smooth to a rough sample; also, it normalizes experimental irregularities such as differences in, counting times between samples.[4–6] This emphasises the fact that each point is a function, primarily of the composition of the sample and not of its physical features.

There are cases where two alloys may have almost identical major element composition and in the plot their points may be so close together that it is difficult to distinguish between them. Two examples of this are shown in the brass plot in the log(M/N), measured, region from —0·05 to —0·09 and in the log(M/N), specification, region from —0·2 to —0·3. However, in both cases one of the brasses is free-machining and has a lead content that is 20–30 times higher than that in the non-free-machining brass, represented by the adjoining point. The *L* series lines of lead in the case of the high lead-content alloys (free-machining) can easily be seen and thereby it is easy to distinguish between them and the adjoining low lead-content alloys. A somewhat similar occurrence is apparent at the top of the solder alloy points—two alloys are very close to one another. In this case, one of the alloys has 10 times the amounts of Cu, Sb, Ag and Bi that the other alloy has. Thus, characteristic X-ray lines of one or more of these elements are apparent for one alloy, but not for the other; therefore, the two alloys can be distinguished.

Although the applicability of this technique to a variety of alloy systems can be visualized, caution must be exercised in some cases. For example, a variation of the method can be used superficially for stainless steels. In ternary or more complex alloys, some measure must be made of all major elements to ensure that they are within specification. However, it would be preferred if the advantage could be retained of a data point representing the chemical composition of a sample, independent of physical characteristics such as size or surface finish. For ternary systems such as stainless steel (Fe, Cr, Ni), this can be accomplished by plotting ratios of two of the elements to the

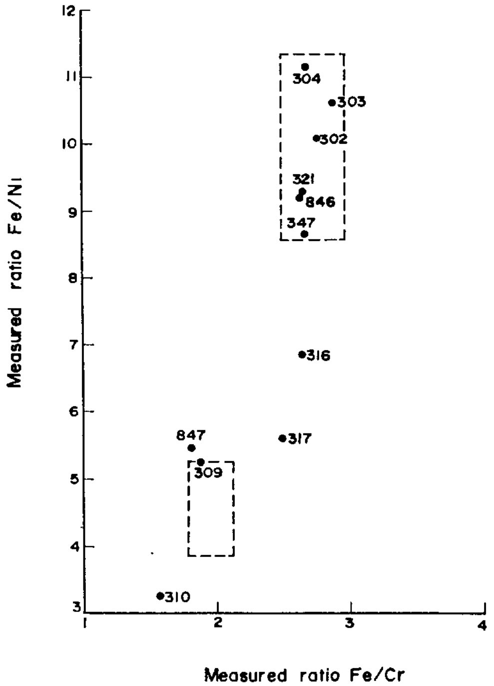

FIG. 2.—A plot of Fe/Ni *vs.* Fe/Cr ratios for stainless steels as determined by energy-dispersive X-ray spectroscopy illustrating that analysed steel alloys can be identified. The rectangles represent the variation in Cr and Ni contents that can be present in actual steel samples, Types 302 and 309 stainless steels, in this case.

third used as a normalizing factor. Figure 2 illustrates such a plot where the areas under the characteristic $K\alpha$ peaks for iron, chromium and nickel were obtained, the ratios Fe/Ni and Fe/Cr were determined and then plotted *vs.* each other. The point of this discussion is that, whereas analysed standards provide point plots, complex alloys such as stainless-steel samples yield area plots because the specifications for stainless steels do not specify a single percentage for iron, chromium or nickel. Rather, the specifications define ranges; *e.g.*, for an AISI Type 302 stainless steel, the chromium content must be between 17·00 and 19·00%, the nickel between 8·00 and 10·00%, there are maxima of 1·00% Si, 2·00% Mn and 0·15% C and the remainder is iron. Because of this, the Fe/Cr and Fe/Ni ratios can vary over an appreciable range—this range is designated for the Type 302 and 309 stainless steels by the rectangles in Fig. 2. Obviously, there is a great deal of overlapping than can occur among the various steels. Therefore, although it is possible to distinguish between a Type 304 steel and a Type 309, caution must be exercised in distinguishing between Types 304 and 347 (the presence of niobium would identify the Type 347). Other analytical techniques suffer from these overlapping compositions and experience difficulty in qualitatively characterizing a steel. Certainly, EDXS can distinguish between the various series of stainless steels since the chromium and nickel contents are quite different; this frequently is all the distinction necessary in production control.

The possible applications of this technique are numerous and include verification of composition on production lines, in stock control to ensure no mix-up in the inventory and in general laboratory work to identify the type of alloy in question. The last two uses have frequently been used in the authors' laboratory. Two of the outstanding advantages of this technique are the speed of identification and the ease with which the equipment can be operated.

Summary—Energy dispersive X-ray spectroscopy can be used to identify alloy types quickly and, in many cases, to distinguish between alloy systems within a certain alloy type. Characteristic X-rays of major components in an alloy are produced through excitation by an isotopic source. Ratios of the X-ray intensities of a pair of elements are plotted *vs.* ratios of the theoretical weight fractions of these elements. This provides a unique data point which is a function of the composition of the particular alloy system. In some cases, characteristic X-rays of minor constituents are used for total identification.

Zusammenfassung—Die Röntgenspektroskopie mit Energiedispersion kann zur raschen Identifizierung von Legierungstypen und in vielen Fällen zur Unterscheidung zwischen Legierungssystemen innerhalb eines bestimmten Legierungstyps dienen. Die charakteristische Röntgenstrahlung der Hauptbestandteile einer Legierung wird mit Hilfe einer Isotopenquelle angeregt. Die Verhältnisse der Röntgenintensitäten eines Elementpaars werden gegen die Verhältnisse der theoretischen Gewichtsbrüche dieser Elemente aufgetragen. Das ergibt einen kennzeichnenden Satz von Daten, der von der Zusammensetzung des jeweiligen speziellen Legierungssystems abhängt. In einigen Fällen werden die charakteristischen Röntgenstrahlen von Nebenbestandteilen für die Identifizierung im Ganzen herangezogen.

Résumé—On peut utiliser la spectroscopie de rayons X à dispersion d'énergie pour identifier rapidement des types d'alliages et, dans de nombreux cas, pour distinguer les systèmes d'alliages à l'intérieur d'un certain type d'alliage. Des rayons X caractéristiques des composants majeurs d'un alliage sont produits par excitation par une source isotopique. On porte les rapports des intensités des rayons X d'une paire d'éléments en fonction des rapports des fractions de poids théoriques de ces éléments. Ceci fournit un point de données particulières qui est une fonction de la composition du système d'alliage concerné. Dans quelques cas, on utilise les rayons X caractéristiques de constituants mineurs pour l'identification totale.

6-phenyl-2,3-dihydro-*asym*-triazine-3-thione and 5,6-diphenyl-2,3-dihydro-*asym*-triazine-3-thione as gravimetric reagents for the determination of thallium and palladium

(*Received* 27 *August* 1971. *Accepted* 18 *November* 1971)

SULPHUR-CONTAINING ligands show a marked selectivity for a relatively small number of transition metals. In this work the analytical applications of two sulphur-containing ligands, 6-phenyl-2,3-dihydro-*asym*-triazine-3-thione (PDTT) and 5,6-diphenyl-2,3-dihydro-*asym*-triazine-3-thione (DDTT) were investigated.

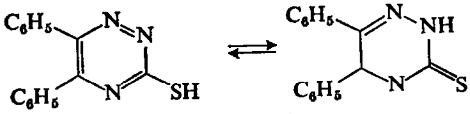
(PDTT)



(DDTT)

They are both yellow powders insoluble in water, soluble in ethanol, chloroform and aqueous alkaline solutions.

Preliminary investigations showed that of the 35 metal ions examined in tartrate media of pH 8·5–12·5 only Pd(II), Cu(II), Hg(II), Ag(I) and Tl(I) could be precipitated by PDTT and that on the addition of cyanide only thallium(I) gave a precipitate. The DDTT reagent is more selective as it only gives precipitates with Hg(II), Ag(I), Pd(II) and Tl(I), but no reaction with copper. It proved useful for the determination of palladium. All the precipitates are yellow except the Cu–PDTT complex which is orange-red.

EXPERIMENTAL

Reagents

PDTT. Prepared by the procedure of Lalezari and Golgolab[1] by one-step cyclization of phenylglyoxaldoxime and thiosemicarbazide in dilute hydrochloric acid and recrystallized from dimethylsulphoxide to give dark yellow crystals: m.p. 242–243°, yield 90%.

DDTT. Prepared by the method of Polonovski and Pesson[2] by interaction of benzil and thiosemicarbazide in boiling acetic acid and recrystallized from ethanol to give yellow crystals: m.p. 217–218°, yield 60%.

Reagent solutions (0·5%) are prepared by dissolving the reagents in 1*M* sodium hydroxide and filtering.

Standard solutions of thallium and palladium. Dissolve the pure metals in nitric acid and hydrochloric acid respectively.

Procedure

A solution containing 5–50 mg of palladium(II) or thallium(I) per 100 ml is prepared and to this 10 ml of 10% ammonium tartrate solution are added. The pH of this solution is adjusted to 10–12 with dilute sodium hydroxide solution and 1*M* tartaric acid. The solution is warmed and a 20% excess of the reagent is added with stirring. The precipitate is digested for 10 min on the water-bath and then filtered off on a sintered-glass crucible (porosity 4) and washed with about 100 ml of hot water. The precipitate is dried at 110° for 30 min. For the determination of palladium, DDTT reagent is used and the precipitate is weighed as $Pd(C_{15}H_{10}N_3S)_2$ which contains 16·75% of palladium. For the determination of thallium, PDTT reagent is used and the precipitate is weighed as $TlC_9H_6N_3S$ which contains 52·00% of thallium.

RESULTS AND DISCUSSION

Solutions of the reagents in sodium hydroxide are stable indefinitely. The solid sodium salts of the reagents, recovered from aqueous sodium hydroxide solutions, were orange powders stable up to 360° and moderately soluble in chloroform. Analysis of the precipitates of the palladium and thallium complexes prepared according to the recommended gravimetric procedures are given in Table I and results of gravimetric determination of palladium(II) and thallium(I) are given in Table II.

TABLE I.—ANALYTICAL DATA OF PALLADIUM AND THALLIUM COMPLEXES

	C, %	H, %	N, %	S, %	Decomposition temperature, °*C*
$Pd(C_{15}H_{10}N_3S)_2$					
required	56·75	3·15	13·24	10·12	
found	56·7	3·2	13·3	10·0	248–250
$Tl\ C_9H_6N_3S$					
required	27·35	1·58	10·65	8·25	
found	27·3	1·6	10·6	8·2	150–152

TABLE II.—RESULTS OF DETERMINATION OF PALLADIUM AND THALLIUM

Pd taken, *mg*	Pd found, *mg*	Relative error %	Tl taken, *mg*	Tl found, *mg*	Relative error %
5·0	5·1	2	6·2	6·1	−2
11·3	11·2	−1	12·5	12·5	0
25·4	25·5	+0·4	25·0	25·1	+0·4
33·9	34·0	+0·3	37·5	37·4	−0·3

When cyanide was used as a masking agent DDTT still gave a yellow precipitate with thallium(I) in alkaline solution. The precipitation is specific but unsuitable for gravimetry because the precipitate has a low decomposition temperature (110–112°).

The precipitation of thallium(I) by PDTT and palladium(II) by DDTT is quantitative over the pH range 9–13. Both precipitates are yellow, crystalline, and non-hygroscopic and can easily be dried at 110°. The thermograms of the two metal complexes have been recorded (Fig. 1). Tl–PDTT (curve *a*) decomposes at temperatures above 150° and Pd–DDTT (curve *b*) is stable up to at least 240°. Pd(II)–DDTT complex is soluble in chloroform ($\varepsilon = 2{\cdot}3 \times 10^4$ l. mole^{-1}.cm^{-1} at 250 nm). An attempt to extract this complex into chloroform and measure it spectrophotometrically failed because the excess of reagent ($\lambda_{max} = 315$ nm in chloroform) is also extracted and causes non-reproducible results.

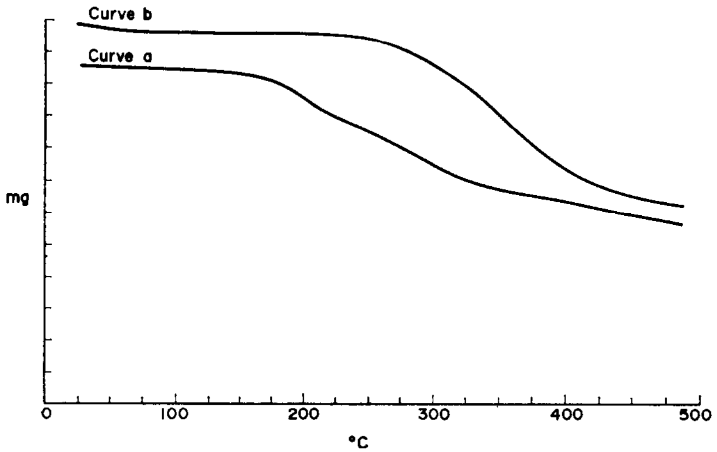


FIG. 1.—Thermograms of (*a*) Tl–PDTT; (*b*) Pd(II)–DDTT.

In the precipitation of palladium a 100-fold excess of Au(III), Bi, Cu(II), Fe(III), Pb, Co(II) and Ni give an error within ±2%. Sn(II) must be oxidized to Sn(IV) by addition of appropriate amounts of iron(III) chloride to prevent its hydrolysis in alkaline tartrate medium. Hg(II), Ag and Tl(I) will interfere in the gravimetric determination of palladium(II). The method is more sensitive than the dimethylglyoxime method. The precipitation of thallium as the PDTT complex is specific but less sensitive than the thionalide method.[3,4] In the presence of cyanide a 100-fold excess of Pd(II), Cu(II) or Ag did not cause significant error in the determination of thallium.

Summary—The analytical use of 6-phenyl-2,3-dihydro-*asym*-triazine-3-thione (PDTT) and 5,6-diphenyl-2,3-dihydro-*asym*-triazine-3-thione (DDTT) has been investigated. PDTT proved to be suitable for the

determination of thallium(I) in the presence of cyanide whereas DDTT is more selective than PDTT in alkaline tartrate solution and is applied for the selective gravimetric determination of palladium. The method is more sensitive than the dimethylglyoxime method. The only metal ions interfering are Hg(II), Ag and Tl(I).

Zusammenfassung—Die analytische Verwendbarkeit von 6-Phenyl-2,3-dihydro-*asym*-triazin-3-thion (PDTT) und 5,6-Diphenyl-2,3-dihydro-*asym*-triazin-3-thion (DDTT) wurde untersucht. PDTT ist zur Bestimmung von Thallium(I) in Gegenwart von Cyanid geeignet, DDTT ist in alkalischer Tartratlösung selektiver als PDTT und wird zur selektiven gravimetrischen Bestimmung von Palladium verwendet. Das Verfahren ist empfindlicher als das mit Dimethylglyoxim. An Metallionen stören nur Hg(II), Ag und Tl(I).

Résumé—On a étudié l'usage analytique de la 6-phényl 2,3-dihydro-*asym*-triazine 3-thione (PDTT) et de la 5,6-diphényl 2,3-dihydro-*asym*-triazine 3-thione (DDTT). La PDTT s'est avérée convenable pour le dosage du thallium(I) en la présence de cyanure, tandis que la DDTT est plus sélective que la PDTT en solution de tartrate alcalin et est appliquée au dosage gravimétrique sélectif du palladium. La méthode est plus sensible que la méthode à la diméthylglyoxime. Les seuls ions métalliques gênants sont Hg(II), Ag et Tl(I).

Darstellung einer neuen Organoselenverbindung $(C_6H_5COCH_2)_4Se$, und ihre Anwendung zur Extraction von Selen. Bestimmung von Tellurspuren in reinem Selen

(*Eingegangen am* 5. *Juli* 1971. *Angenommen am* 2. *Dezember* 1971)

Es WERDEN organische Verbindungen des Selens mit gesättigten Monoketonen dargestellt—$(RCOCHR')_2SeCl_2$ (R und R′ sind Alkyl- und Arylradikale)[1–8] die sich weder in Chloroform noch in Tetrachlorkohlenstoff oder Benzol leicht lösen, bedingt durch ihre polaren Charakter da sie leicht löslich sind in polaren Lösungsmitteln. Unser Ziel ist es, um die analytische Anwendung selenorganischen Verbindungen zu erweitern, polare Verbindungen darzustellen, die in Chloroform oder Tetrachlorkohlenstoff gut löslich sind, und die Extraktionsabtrennungen von großen Mengen Selens gewährleisten. Wir wählten also die vollständig organosubstituierte Verbindung des Typs $(RCOCHR')_4Se$ und verwendet Acetophenon als Ligand, da $(C_6H_5COCH_2)_2SeCl_2$ in festem Zustand mühelos erhalten wird und von uns besser erforscht ist.[7]

DARSTELLUNG UND EIGENSCHAFTEN VON $(C_6H_5COCH_2)_4Se$

Es werden 0,5 g Selen (in Form von SeO_2 oder H_2SeO_3) in 20–25 ml 8,5*M* Salzsäure aufgelöst und 3 ml Acetophenon zugesetzt, entsprechend dem molaren Verhältnis Selen:Acetophenon = 1:4. Nach 1,5–2 Std. tritt das Selen in Verbindung quantitativ auf, als weißer Niederschlag der Zusammensetzung $(C_6H_5COCH_2)_2SeCl_2$.[6,7] Nach 350–400 stündigem Stehen wandelt sich der Niederschlag in ein gelb-grünes ölartiges Produkt um. Bei einem größeren Überschuß an Acetophenon steigt die Reaktionsgeschwindigkeit. Da unsere Versuche, mußte die Zusammensetzung des Produktes indirekt bestimmt werden. Als Kennzeichnungsmerkmal des Systems Selen–Acetophenon–Salzsäure wählten wir die Extrahierbarkeit der entstehenden Produkte durch Chloroform. Die Verteilung des Selens in den beiden Phasen ist in Abb. 1 angegeben.

Summary—Energy dispersive X-ray spectroscopy can be used to identify alloy types quickly and, in many cases, to distinguish between alloy systems within a certain alloy type. Characteristic X-rays of major components in an alloy are produced through excitation by an isotopic source. Ratios of the X-ray intensities of a pair of elements are plotted *vs.* ratios of the theoretical weight fractions of these elements. This provides a unique data point which is a function of the composition of the particular alloy system. In some cases, characteristic X-rays of minor constituents are used for total identification.

Zusammenfassung—Die Röntgenspektroskopie mit Energiedispersion kann zur raschen Identifizierung von Legierungstypen und in vielen Fällen zur Unterscheidung zwischen Legierungssystemen innerhalb eines bestimmten Legierungstyps dienen. Die charakteristische Röntgenstrahlung der Hauptbestandteile einer Legierung wird mit Hilfe einer Isotopenquelle angeregt. Die Verhältnisse der Röntgenintensitäten eines Elementpaars werden gegen die Verhältnisse der theoretischen Gewichtsbrüche dieser Elemente aufgetragen. Das ergibt einen kennzeichnenden Satz von Daten, der von der Zusammensetzung des jeweiligen speziellen Legierungssystems abhängt. In einigen Fällen werden die charakteristischen Röntgenstrahlen von Nebenbestandteilen für die Identifizierung im Ganzen herangezogen.

Résumé—On peut utiliser la spectroscopie de rayons X à dispersion d'énergie pour identifier rapidement des types d'alliages et, dans de nombreux cas, pour distinguer les systèmes d'alliages à l'intérieur d'un certain type d'alliage. Des rayons X caractéristiques des composants majeurs d'un alliage sont produits par excitation par une source isotopique. On porte les rapports des intensités des rayons X d'une paire d'éléments en fonction des rapports des fractions de poids théoriques de ces éléments. Ceci fournit un point de données particulières qui est une fonction de la composition du système d'alliage concerné. Dans quelques cas, on utilise les rayons X caractéristiques de constituants mineurs pour l'identification totale.

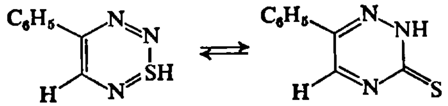
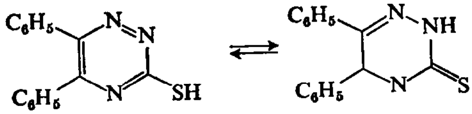
6-phenyl-2,3-dihydro-*asym*-triazine-3-thione and 5,6-diphenyl-2,3-dihydro-*asym*-triazine-3-thione as gravimetric reagents for the determination of thallium and palladium

(*Received* 27 *August* 1971. *Accepted* 18 *November* 1971)

SULPHUR-CONTAINING ligands show a marked selectivity for a relatively small number of transition metals. In this work the analytical applications of two sulphur-containing ligands, 6-phenyl-2,3-dihydro-*asym*-triazine-3-thione (PDTT) and 5,6-diphenyl-2,3-dihydro-*asym*-triazine-3-thione (DDTT) were investigated.



(PDTT)



(DDTT)

They are both yellow powders insoluble in water, soluble in ethanol, chloroform and aqueous alkaline solutions.

Preliminary investigations showed that of the 35 metal ions examined in tartrate media of pH 8·5–12·5 only Pd(II), Cu(II), Hg(II), Ag(I) and Tl(I) could be precipitated by PDTT and that on the addition of cyanide only thallium(I) gave a precipitate. The DDTT reagent is more selective as it only gives precipitates with Hg(II), Ag(I), Pd(II) and Tl(I), but no reaction with copper. It proved useful for the determination of palladium. All the precipitates are yellow except the Cu–PDTT complex which is orange-red.

EXPERIMENTAL

Reagents

PDTT. Prepared by the procedure of Lalezari and Golgolab[1] by one-step cyclization of phenylglyoxaldoxime and thiosemicarbazide in dilute hydrochloric acid and recrystallized from dimethylsulphoxide to give dark yellow crystals: m.p. 242–243°, yield 90%.

DDTT. Prepared by the method of Polonovski and Pesson[2] by interaction of benzil and thiosemicarbazide in boiling acetic acid and recrystallized from ethanol to give yellow crystals: m.p. 217–218°, yield 60%.

Reagent solutions (0·5%) are prepared by dissolving the reagents in 1*M* sodium hydroxide and filtering.

Standard solutions of thallium and palladium. Dissolve the pure metals in nitric acid and hydrochloric acid respectively.

Procedure

A solution containing 5–50 mg of palladium(II) or thallium(I) per 100 ml is prepared and to this 10 ml of 10% ammonium tartrate solution are added. The pH of this solution is adjusted to 10–12 with dilute sodium hydroxide solution and 1*M* tartaric acid. The solution is warmed and a 20% excess of the reagent is added with stirring. The precipitate is digested for 10 min on the water-bath and then filtered off on a sintered-glass crucible (porosity 4) and washed with about 100 ml of hot water. The precipitate is dried at 110° for 30 min. For the determination of palladium, DDTT reagent is used and the precipitate is weighed as Pd $(C_{15}H_{10}N_3S)_2$ which contains 16·75% of palladium. For the determination of thallium, PDTT reagent is used and the precipitate is weighed as $TlC_9H_6N_3S$ which contains 52·00% of thallium.

RESULTS AND DISCUSSION

Solutions of the reagents in sodium hydroxide are stable indefinitely. The solid sodium salts of the reagents, recovered from aqueous sodium hydroxide solutions, were orange powders stable up to 360° and moderately soluble in chloroform. Analysis of the precipitates of the palladium and thallium complexes prepared according to the recommended gravimetric procedures are given in Table I and results of gravimetric determination of palladium(II) and thallium(I) are given in Table II.

TABLE I.—ANALYTICAL DATA OF PALLADIUM AND THALLIUM COMPLEXES

	C, %	H, %	N, %	S, %	Decomposition temperature, °*C*
Pd $(C_{15}H_{10}N_3S)_2$					
required	56·75	3·15	13·24	10·12	
found	56·7	3·2	13·3	10·0	248–250
Tl $C_9H_6N_3S$					
required	27·35	1·58	10·65	8·25	
found	27·3	1·6	10·6	8·2	150–152

TABLE II.—RESULTS OF DETERMINATION OF PALLADIUM AND THALLIUM

Pd taken, *mg*	Pd found, *mg*	Relative error %	Tl taken, *mg*	Tl found, *mg*	Relative error %
5·0	5·1	2	6·2	6·1	−2
11·3	11·2	−1	12·5	12·5	0
25·4	25·5	+0·4	25·0	25·1	+0·4
33·9	34·0	+0·3	37·5	37·4	−0·3

When cyanide was used as a masking agent DDTT still gave a yellow precipitate with thallium(I) in alkaline solution. The precipitation is specific but unsuitable for gravimetry because the precipitate has a low decomposition temperature (110–112°).

The precipitation of thallium(I) by PDTT and palladium(II) by DDTT is quantitative over the pH range 9–13. Both precipitates are yellow, crystalline, and non-hygroscopic and can easily be dried at 110°. The thermograms of the two metal complexes have been recorded (Fig. 1). Tl–PDTT (curve *a*) decomposes at temperatures above 150° and Pd–DDTT (curve *b*) is stable up to at least 240°. Pd(II)–DDTT complex is soluble in chloroform ($\varepsilon = 2{\cdot}3 \times 10^4$ l. mole^{-1}.cm^{-1} at 250 nm). An attempt to extract this complex into chloroform and measure it spectrophotometrically failed because the excess of reagent (λ_{max} = 315 nm in chloroform) is also extracted and causes non-reproducible results.

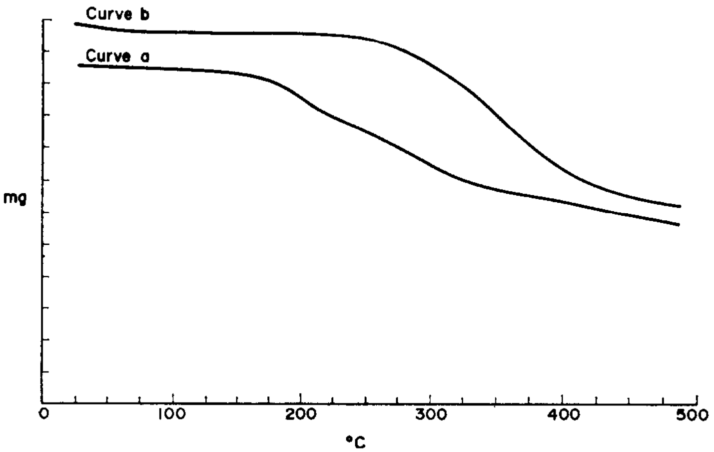


FIG. 1.—Thermograms of (*a*) Tl–PDTT; (*b*) Pd(II)–DDTT.

In the precipitation of palladium a 100-fold excess of Au(III), Bi, Cu(II), Fe(III), Pb, Co(II) and Ni give an error within ±2%. Sn(II) must be oxidized to Sn(IV) by addition of appropriate amounts of iron(III) chloride to prevent its hydrolysis in alkaline tartrate medium. Hg(II), Ag and Tl(I) will interfere in the gravimetric determination of palladium(II). The method is more sensitive than the dimethylglyoxime method. The precipitation of thallium as the PDTT complex is specific but less sensitive than the thionalide method.[3,4] In the presence of cyanide a 100-fold excess of Pd(II), Cu(II) or Ag did not cause significant error in the determination of thallium.

Summary—The analytical use of 6-phenyl-2,3-dihydro-*asym*-triazine-3-thione (PDTT) and 5,6-diphenyl-2,3-dihydro-*asym*-triazine-3-thione (DDTT) has been investigated. PDTT proved to be suitable for the

determination of thallium(I) in the presence of cyanide whereas DDTT is more selective than PDTT in alkaline tartrate solution and is applied for the selective gravimetric determination of palladium. The method is more sensitive than the dimethylglyoxime method. The only metal ions interfering are Hg(II), Ag and Tl(I).

Zusammenfassung—Die analytische Verwendbarkeit von 6-Phenyl-2,3-dihydro-*asym*-triazin-3-thion (PDTT) und 5,6-Diphenyl-2,3-dihydro-*asym*-triazin-3-thion (DDTT) wurde untersucht. PDTT ist zur Bestimmung von Thallium(I) in Gegenwart von Cyanid geeignet, DDTT ist in alkalischer Tartratlösung selektiver als PDTT und wird zur selektiven gravimetrischen Bestimmung von Palladium verwendet. Das Verfahren ist empfindlicher als das mit Dimethylglyoxim. An Metallionen stören nur Hg(II), Ag und Tl(I).

Résumé—On a étudié l'usage analytique de la 6-phényl 2,3-dihydro-*asym*-triazine 3-thione (PDTT) et de la 5,6-diphényl 2,3-dihydro-*asym*-triazine 3-thione (DDTT). La PDTT s'est avérée convenable pour le dosage du thallium(I) en la présence de cyanure, tandis que la DDTT est plus sélective que la PDTT en solution de tartrate alcalin et est appliquée au dosage gravimétrique sélectif du palladium. La méthode est plus sensible que la méthode à la diméthylglyoxime. Les seuls ions métalliques gênants sont Hg(II), Ag et Tl(I).

Darstellung einer neuen Organoselenverbindung $(C_6H_5COCH_2)_4Se$, und ihre Anwendung zur Extraction von Selen. Bestimmung von Tellurspuren in reinem Selen

(*Eingegangen am* 5. *Juli* 1971. *Angenommen am* 2. *Dezember* 1971)

Es WERDEN organische Verbindungen des Selens mit gesättigten Monoketonen dargestellt—$(RCOCHR')_2SeCl_2$ (R und R' sind Alkyl- und Arylradikale)$^{1-8}$ die sich weder in Chloroform noch in Tetrachlorkohlenstoff oder Benzol leicht lösen, bedingt durch ihre polaren Charakter da sie leicht löslich sind in polaren Lösungsmitteln. Unser Ziel ist es, um die analytische Anwendung selenorganischen Verbindungen zu erweitern, polare Verbindungen darzustellen, die in Chloroform oder Tetrachlorkohlenstoff gut löslich sind, und die Extraktionsabtrennungen von großen Mengen Selens gewährleisten. Wir wählten also die vollständig organosubstituierte Verbindung des Typs $(RCOCHR')_4Se$ und verwendet Acetophenon als Ligand, da $(C_6H_5COCH_2)_2SeCl_2$ in festem Zustand mühelos erhalten wird und von uns besser erforscht ist.^{7}

DARSTELLUNG UND EIGENSCHAFTEN VON $(C_6H_5COCH_2)_4Se$

Es werden 0,5 g Selen (in Form von SeO_2 oder H_2SeO_3) in 20–25 ml 8,5*M* Salzsäure aufgelöst und 3 ml Acetophenon zugesetzt, entsprechend dem molaren Verhältnis Selen:Acetophenon = 1:4. Nach 1,5–2 Std. tritt das Selen in Verbindung quantitativ auf, als weißer Niederschlag der Zusammensetzung $(C_6H_5COCH_2)_2SeCl_2$.^{6,7} Nach 350–400 stündigem Stehen wandelt sich der Niederschlag in ein gelb-grünes ölartiges Produkt um. Bei einem größeren Überschuß an Acetophenon steigt die Reaktionsgeschwindigkeit. Da unsere Versuche, mußte die Zusammensetzung des Produktes indirekt bestimmt werden. Als Kennzeichnungsmerkmal des Systems Selen–Acetophenon–Salzsäure wählten wir die Extrahierbarkeit der entstehenden Produkte durch Chloroform. Die Verteilung des Selens in den beiden Phasen ist in Abb. 1 angegeben.

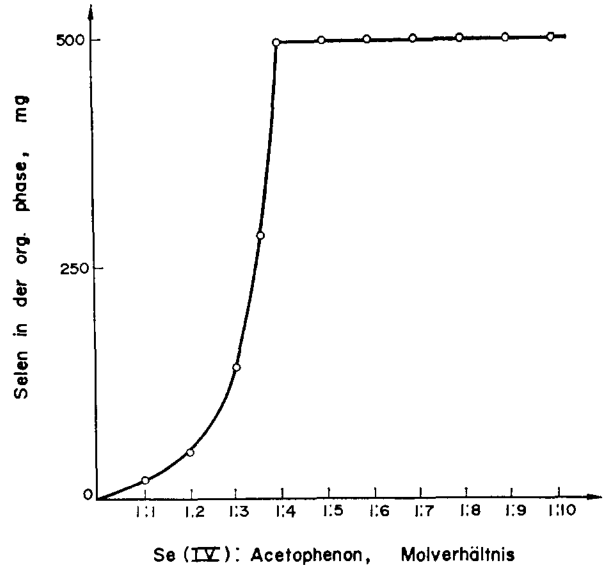

ABB. 1.—[HCl] = $9M$, ^{75}Se(IV)-Einwaage = 500 mg.

Es wurden versuche durchgeführt, wobei verschiedene Mengen an Acetophenon zu 25 ml $8{,}5M$ Salzsäure, die 500 mg Selen enthielten zugesetzt wurden. Nach 350 stündigem Stehen wurde das Selen in 10 ml Chloroform nach dreiminutigem Schütteln extrahiert. Der Gehalt an Selen wurde auch in den beiden Phasen bestimmt. Diese und alle folgenden Versuche wurden mit radioaktiven Selen-75 durchgeführt.

Um die molaren Verhältnisse, in denen die Komponenten reagieren, bestimmen zu können, muß man die Kinetik der Zusammenwirkung zwischen Selen und Acetophenon in salzsaurem Medium kennen. Die Ergebnisse von derartigen Versuchen sind in Abb. 2 dargestellt. Diese Versuche wurden bei denselben Bedingungen durchgeführt, wobei nur die Zeit des Stehens variiert wurde.

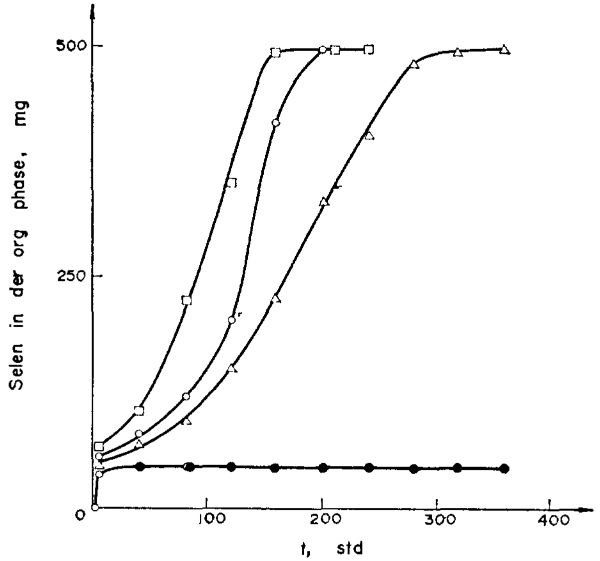

ABB. 2.—[HCl] = $9M$, ^{75}Se(IV)-Einwaage = 500 mg, molare Verhältnisse—● Selen:Acetophenon(I) = 1:2, △—Se:I = 1:4, ○—Se:I = 1:6, □—Se:I = 1:8.

Es wurde versucht Chloridionen in dem bei molarem Verhältnis Selen:Acetophenon größer als 1:4 erhaltenen ölartigen Produkt zu bestimmen. Zu diesem Zweck wurde das Produkt mehrmals mit Wasser gewaschen aber Chloridionen fand man nicht. Unter denselben Bedingungen wird das Chlor aus der Verbindung, die bei Verhältnis 1:2 erhalten wird und in großen Mengen Chloroform aufgelöst ist, mit Wasser quantitativ herausgewaschen. Die IR-Spektren, registriert aus flüssiger Schicht, zeigen, daß die Carbonylgruppe und der Benzolring in der erhaltenen Verbindung auf keine Weise beeinflußt sind. Bei 552 cm^{-1} wird eine für die C–Se Bindung charakteristische Absorption beobachtet. Die Ergebnisse von der Elementaranalyse sind: gefunden C 68,9%; H 5,4%; Se 14,1%, Cl 0,0%; gerechnet $[(C_6H_5COCH_2)_4Se]$ C 69,43%; H 5,07%; Se 14,21%, Cl 0,0%.

Das bis hier dargelegte läßt uns vermuten, daß $(C_6H_5COCH_2)_4Se$ die wahrscheinlichste Formel der erhaltenen Verbindung ist.

ANALYTISCHE ANWENDUNG VON $(C_6H_5COCH_2)_4Se$ ZUR ABTRENNUNG VON SELEN ALS MATRIXELEMENT

Das Extrahieren von großen Mengen an Selen gibt eine Möglichkeit für die analytische Bestimmung der Beimischungen, die das reine Selen begleiten und unter den beschriebenen Bedingungen in der wässrigen Phase zurückbleiben. Zu diesen Zweck war es notwendig, die Zeit zur Entstehung der selenorganischen Verbindung zu verkürzen.

Die Untersuchungen führten wir unter Erwärmung im Wasserbad in Gegenwart von Salzsäure oder einem Gemisch aus Salz- und Schwefelsäure durch. Der Einfluß der Schwefelsäure mußte untersucht werden, weil sie beim Auflösen reines Selens in Salpetersäure als Denitrierungsmittel verwendet wird und in der Lösung immer anwesend ist. Die Versuche zur Darstellung der Verbindung führten wir durch, indem wir zu 0,5 g Selen (in Form von SeO_2 oder H_2SeO_3), aufgelöst in 25 ml Salzsäure verschiedener Konzentration, unter Schütteln Acetophenon zusetzten. Die Menge an Acetophenon entsprach dem molaren Verhältnis Selen:Acetophenon = 1:2. Nach ungefähr 1,5 Std bindet sich das Selen quantitativ und fällt in Form eines weißen Niederschlages aus. Die Lösung über dem Niederschlag muß klar sein. Man gibt noch zwei molare Teile Acetophenon unter periodischem Schütteln hinzu und erwärmt im Wasserbad. Die Zeit zur Entstehung der bei verschiedenen Temperaturen und Konzentrationen der Salzsäure dargestellten Verbindung ist in Tabelle I angegeben. Ein Maß für die Entstehung der Verbindung war ihre völlige Extraktion aus der wässrigen Phase in das Chloroform.

Analoge Versuche führten wir auch in Anwesenheit von $3N$ Schwefelsäure durch. Die Ergebnisse sind in Tabelle II angegeben.

TABELLE I.—REAKTIONSGESCHWINDIGKEIT IN SALZSAURE

[HCl], *M*	Zeit zur Entstehung der Verbindung, *Std*, bei Reaktionstemperatur 60–65°C	80–85°C	siedendes Wasserbad
5,0	2,5–3	1–1,5	0,85–1
5,5	2–2,5	1–1,5	0,85–1
6	1,5–2	0,7–1	0,5–0,75
7	1–1,5	0,45–0,5	0,25–0,40
8	0,75–1	zersetzt sich	zersetzt sich
9	0,75–1	zersetzt sich	zersetzt sich
10	0,75–1	zersetzt sich	zersetzt sich

TABELLE II.—REAKTIONSGESCHWINDIGKEIT IN GEMISCHTEN SÄUREN

Gesamtkonzentration von HCl + H_2SO_4 *N*	Zeit zur Entstehung der Verbindung, *Std*, bei Reaktionstemperatur 60–65°C	siedendes Wasserbad
4	8–9	5–6
6	3,5–4	4–5
7	0,75–1	1,5–2
8	0,75–1	0,5–0,70
9	1	zersetzt sich
10	1	zersetzt sich
11	1	zersetzt sich

Festgestellt wurde, daß die Verbindung bei 5*M* Salzsäure und 3*N* Schwefelsäure und Erwärmung im Wasserbad im Laufe einer Stunde bei 60–65° entsteht. Danach wird mit 5 ml Chloroform oder Tetrachlorkohlenstoff extrahiert. Das Selen geht in die organische Phase quantitativ über. Unter den beschriebenen Bedingungen geht neben Selen auch Gold(III) in die organische Phase über. Das letztere wird durch verdünnte Salzsäure nicht zurückextrahiert. In der wässrigen Phase bleiben folgende Metallionen zurück: Ru(IV), Rh(IV), Os(IV), Ir(IV), Pt(IV), Pd(II), Te(IV), Cu(II). Das Verhalten von Gold(III) wird Gegenstand weiterer Untersuchungen sein. Die erhaltenen Ergebnisse wurden zur Bestimmung von Tellur in reinem Selen benutzt.

ANWENDUNG DER METHODE ZUR BESTIMMUNG VON TELLUR IN REINEM SELEN

Zur Bestimmung von Tellur, das nach der Abtrennung von Selen in der wässrigen Phase zurückbleibt, beschlossen wir die bekannte photometrische Methode anzuwenden, die auf der Messung der Extinktion von Kolloidlösungen von elementarem Tellur, erhalten durch Reduktion mit Zinn(II)-chlorid, beruht.[9–11] Die Ergebnisse zeigten, daß folgende Elemente in den angegebenen Mengen (in 50 ml) die Photometrische Bestimmung von Tellur nicht stören: Pd(II)—5 μg, Au(III)—15 μg, Os(IV)—19 μg, Ru(IV)—13 μg, Ir(IV)—19 μg, Pt(IV)—6 μg.

Reagenzien

Konz. HCl, H_2SO_4 und HNO_3 *p.a.*
Lösung von $SnCl_2$, 25%-ige.
Lösung von Gelatine, 0,5%-ige.
Acetophenon *p.a.*

Es werden 0,2–3 g Selen in 5–15 ml konz. Salpetersäure aufgelöst. Die Probe die 20–200 μg Tellur enthalten soll wird im Wasserbad erwärmt, bis sich das Volumen auf 2–3 ml verringert. Man setzt 2,5 ml konz. Schwefelsäure und 2–3 ml Wasser hinzu und erwärmt weiter auf 250–300° im Sandbad bis zur Entstehung von SO_3. Man setzt noch Wasser und Salzsäure so zu, daß das Gesamtvolumen 25 ml und die Konzentration an Salzsäure 5*M* wird. Dann werden pro molaren Teil Selen vier molaren Teile Acetophenon zugesetzt. Zuerst gibt man unter heftigem Schütteln die Hälfte von der berechneten Menge an Acetophenon zu. Nach 1,5 Std wird die andere Hälfte zugegeben. Es wird im Wasserbad bei 60–65° eine Stunde lang erwärmt, wobei man in Zeitabständen schüttelt. Die Lösung muß völlig klar sein. Die Probe wird in einem Schütteltrichter gegeben und mit 8 ml Chloroform oder Tetrachlorkohlenstoff 2 min lang extrahiert. Die wässrige Phase wird filtriert und in einen 50 ml Meßkolben versetzt. Die organische Phase wird mit 5 ml 2*M* Salzsäure 20–30 sec lang gewaschen und die salzsaure Lösung der wässrigen Phase zugesetzt. Die Gesamtmenge in dem Meßkolben wird auf 40 ml gebrucht. Man kühlt auf 20° ab und setzt 0,5 ml $SnCl_2$-Lösung zu. Es wird geschüttelt und 5 min stehengelassen; man gibt noch 3 ml Gelatine-Lösung hinzu, verdünnt nach 10 min auf 50 ml und mißt die Extinktion bei 434 nm in einer 50-mm Küvette. Die Standartgraphik wird für Mengen von 20–200 μg pro 50 ml aufgezeichnet.

Um uns zu überzeugen, daß keine Verlußte an Tellur beim Auflösen und Abtrennen des Selens entstehen, setzten wir verschiedenen Mengen reinen Selens (0,5, 1, 2, 3 g) 50 μg Te zu. Die Proben wurden nach der Analysenvorschrift bearbeitet. Die Ergebnisse sind statistisch bearbeitet worden.

$$N = 10 \qquad \bar{x} = 50{,}0\,\mu\text{g} \qquad s = 1{,}19\,\mu\text{g} \qquad V = \frac{s}{\bar{x}} \cdot t \cdot 100 = 5{,}4\%$$
$$\text{bei } P = 95 \qquad t = 2{,}26$$

Wir geben auch die statistischen Ergebnisse von der Bestimmung von 50 μg Te unter reinen Bedingungen an.

$$N = 10 \qquad \bar{x} = 49{,}8\,\mu\text{g} \qquad s = 1{,}22\,\mu\text{g} \qquad V = \frac{s}{\bar{x}} \cdot t \cdot 100 = 5{,}3\%$$
$$\text{bei } P = 95 \qquad t = 2{,}26$$

DISKUSSION

Eine frühere Arbeit[6] befaßte sich mit der Extraktion von 5–25 μg Selen. Während in jenem Falle die begrenzte Löslichkeit von $(C_6H_5COCH_2)_2SeCl_2$ keine Schwierigkeiten bot, wird die Extraktion von großen Mengen Selen nur möglich sein, wenn die Selenverbindung in Chloroform praktisch unbegrenzt löslich ist, das bei $(C_6H_5COCH_2)_4Se$ der Fall ist. Da andere Elemente wie Te(IV), Au(III) nur als Ionenassoziate extrahiert werden, sind sie auch leight zurückzuextrahieren und daher von Selen abzutrennen, wie in vorliegender Arbeit am Beispiel von Tellurbestimmung aufgezeigt wird.

Zusammenfassung—Erhalten wurde eine neue Verbindung von Se(IV) mit Acetophenon in salzsaurem Medium, $(C_6H_5COCH_2)_4Se$. Der Prozeß der Entstehung der Verbindung dauert beim Überschuß an Acetophenon (Selen:Acetophenon $<$ 1:4) ungefähr 300–400 Std, aber bei 60–70° nur 1,5–2 Std. Die erhaltene Verbindung löst sich sehr gut in Chloroform und Tetrachlorkohlenstoff. Diese Eigenschaft wird zur Extraktionsabtrennung von großen Mengen an Selen benutzt. Auf diese Weise wird eine gute Möglichkeit zur Bestimmung von Beimischungen in reinem Selen gegeben. Die Methode ist zur Bestimmung von Tellur in Selen angewandt worden.

Summary—A new compound has been prepared from Se(IV) and acetophenone in hydrochloric acid solution. At 60–70° conversion into $(C_6H_5COCH_2)_4Se$ is complete in 1·5–2 hr. The product is very soluble in chloroform and in carbon tetrachloride and thus offers a possibility for the separation of large quantities of selenium before determination of impurities in it. The method has been applied to the separation and determination of traces of tellurium in selenium.

Résumé—On a préparé un nouveau composé à partir de Se(IV) et d'acétophénone en solution dans l'acide chlorhydrique. A 60–70°, la conversion en $(C_6H_5COCH_2)_4Se$ est complète en 1,5–2 h. Le produit est très soluble en chloroforme et en tétrachlorure de carbone et offre ainsi une possibilité de séparation de grandes quantités de sélénium avant détermination des impuretés qu'il contient. On a appliqué la méthode à la séparation et au dosage de traces de tellurium dans le sélénium.

Détermination de l'or par réaction d'échange de complexes triples à association ionique

(*Reçu le* 31 *Mars* 1971. *Accepté le* 2 *Octobre* 1971)

De nombreux anions du type [ML_4], réagissant avec certains agents organiques de nature basique, fournissent des composés ordinairement peu solubles dans l'eau, mais extractibles dans des solvants organiques appropriés.

Lorsque l'agent organique—base —est un colorant, on est en présence de réactions à sensibilité élevée, mais généralement à faible sélectivité. D'autre part, les réactions de ces mêmes anions [ML_4^-] avec certains agents à basicité plus prononcée, mais incolores, se distinguent par leur haute sélectivité et leur faible sensibilité.

L'usage combiné de ces deux espèces de réactions permet de créer des méthodes sensibles et en même temps suffisamment sélectives.

determination of thallium(I) in the presence of cyanide whereas DDTT is more selective than PDTT in alkaline tartrate solution and is applied for the selective gravimetric determination of palladium. The method is more sensitive than the dimethylglyoxime method. The only metal ions interfering are Hg(II), Ag and Tl(I).

Zusammenfassung—Die analytische Verwendbarkeit von 6-Phenyl-2,3-dihydro-*asym*-triazin-3-thion (PDTT) und 5,6-Diphenyl-2,3-dihydro-*asym*-triazin-3-thion (DDTT) wurde untersucht. PDTT ist zur Bestimmung von Thallium(I) in Gegenwart von Cyanid geeignet, DDTT ist in alkalischer Tartratlösung selektiver als PDTT und wird zur selektiven gravimetrischen Bestimmung von Palladium verwendet. Das Verfahren ist empfindlicher als das mit Dimethylglyoxim. An Metallionen stören nur Hg(II), Ag und Tl(I).

Résumé—On a étudié l'usage analytique de la 6-phényl 2,3-dihydro-*asym*-triazine 3-thione (PDTT) et de la 5,6-diphényl 2,3-dihydro-*asym*-triazine 3-thione (DDTT). La PDTT s'est avérée convenable pour le dosage du thallium(I) en la présence de cyanure, tandis que la DDTT est plus sélective que la PDTT en solution de tartrate alcalin et est appliquée au dosage gravimétrique sélectif du palladium. La méthode est plus sensible que la méthode à la diméthylglyoxime. Les seuls ions métalliques gênants sont Hg(II), Ag et Tl(I).

Darstellung einer neuen Organoselenverbindung $(C_6H_5COCH_2)_4Se$, und ihre Anwendung zur Extraction von Selen. Bestimmung von Tellurspuren in reinem Selen

(*Eingegangen am* 5. *Juli* 1971. *Angenommen am* 2. *Dezember* 1971)

Es WERDEN organische Verbindungen des Selens mit gesättigten Monoketonen dargestellt—$(RCOCHR')_2SeCl_2$ (R und R′ sind Alkyl- und Arylradikale)$^{1-8}$ die sich weder in Chloroform noch in Tetrachlorkohlenstoff oder Benzol leicht lösen, bedingt durch ihre polaren Charakter da sie leicht löslich sind in polaren Lösungsmitteln. Unser Ziel ist es, um die analytische Anwendung selenorganischen Verbindungen zu erweitern, polare Verbindungen darzustellen, die in Chloroform oder Tetrachlorkohlenstoff gut löslich sind, und die Extraktionsabtrennungen von großen Mengen Selens gewährleisten. Wir wählten also die vollständig organosubstituierte Verbindung des Typs $(RCOCHR')_4Se$ und verwendet Acetophenon als Ligand, da $(C_6H_5COCH_2)_2SeCl_2$ in festem Zustand mühelos erhalten wird und von uns besser erforscht ist.^{7}

DARSTELLUNG UND EIGENSCHAFTEN VON $(C_6H_5COCH_2)_4Se$

Es werden 0,5 g Selen (in Form von SeO_2 oder H_2SeO_3) in 20–25 ml 8,5*M* Salzsäure aufgelöst und 3 ml Acetophenon zugesetzt, entsprechend dem molaren Verhältnis Selen:Acetophenon = 1:4. Nach 1,5–2 Std. tritt das Selen in Verbindung quantitativ auf, als weißer Niederschlag der Zusammensetzung $(C_6H_5COCH_2)_2SeCl_2$.^{6,7} Nach 350–400 stündigem Stehen wandelt sich der Niederschlag in ein gelb-grünes ölartiges Produkt um. Bei einem größeren Überschuß an Acetophenon steigt die Reaktionsgeschwindigkeit. Da unsere Versuche, mußte die Zusammensetzung des Produktes indirekt bestimmt werden. Als Kennzeichnungsmerkmal des Systems Selen–Acetophenon–Salzsäure wählten wir die Extrahierbarkeit der entstehenden Produkte durch Chloroform. Die Verteilung des Selens in den beiden Phasen ist in Abb. 1 angegeben.

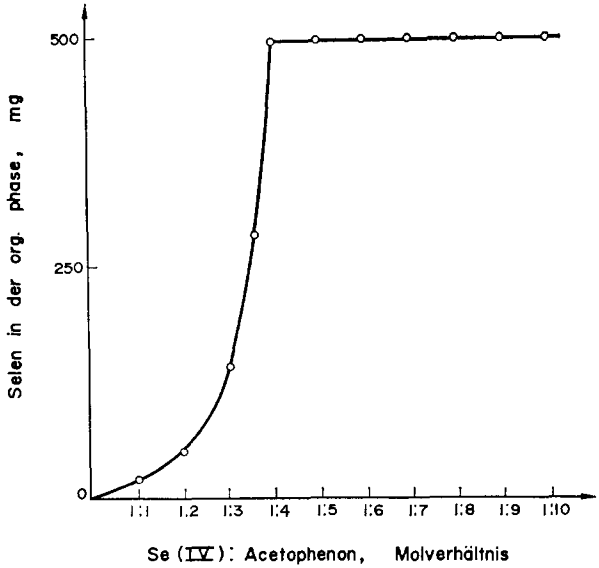

Abb. 1.—[HCl] = $9M$, ^{75}Se(IV)-Einwaage = 500 mg.

Es wurden versuche durchgeführt, wobei verschiedene Mengen an Acetophenon zu 25 ml $8,5M$ Salzsäure, die 500 mg Selen enthielten zugesetzt wurden. Nach 350 stündigem Stehen wurde das Selen in 10 ml Chloroform nach dreiminutigem Schütteln extrahiert. Der Gehalt an Selen wurde auch in den beiden Phasen bestimmt. Diese und alle folgenden Versuche wurden mit radioaktiven Selen-75 durchgeführt.

Um die molaren Verhältnisse, in denen die Komponenten reagieren, bestimmen zu können, muß man die Kinetik der Zusammenwirkung zwischen Selen und Acetophenon in salzsaurem Medium kennen. Die Ergebnisse von derartigen Versuchen sind in Abb. 2 dargestellt. Diese Versuche wurden bei denselben Bedingungen durchgeführt, wobei nur die Zeit des Stehens variiert wurde.

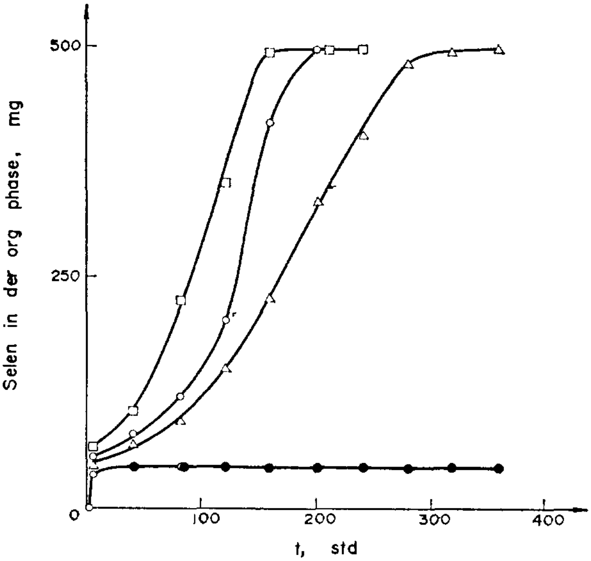

Abb. 2.—[HCl] = $9M$, ^{75}Se(IV)-Einwaage = 500 mg, molare Verhältnisse—● Selen:Acetophenon(I) = 1:2, △—Se:I = 1:4, ○—Se:I = 1:6, □—Se:I = 1:8.

Es wurde versucht Chloridionen in dem bei molarem Verhältnis Selen:Acetophenon größer als 1:4 erhaltenen ölartigen Produkt zu bestimmen. Zu diesem Zweck wurde das Produkt mehrmals mit Wasser gewaschen aber Chloridionen fand man nicht. Unter denselben Bedingungen wird das Chlor aus der Verbindung, die bei Verhältnis 1:2 erhalten wird und in großen Mengen Chloroform aufgelöst ist, mit Wasser quantitativ herausgewaschen. Die IR-Spektren, registriert aus flüssiger Schicht, zeigen, daß die Carbonylgruppe und der Benzolring in der erhaltenen Verbindung auf keine Weise beeinflußt sind. Bei 552 cm^{-1} wird eine für die C–Se Bindung charakteristische Absorption beobachtet. Die Ergebnisse von der Elementaranalyse sind: gefunden C 68,9%; H 5,4%; Se 14,1%, Cl 0,0%; gerechnet $[(C_6H_5COCH_2)_4Se]$ C 69,43%; H 5,07%; Se 14,21%, Cl 0,0%.

Das bis hier dargelegte läßt uns vermuten, daß $(C_6H_5COCH_2)_4Se$ die wahrscheinlichste Formel der erhaltenen Verbindung ist.

ANALYTISCHE ANWENDUNG VON $(C_6H_5COCH_2)_4Se$ ZUR ABTRENNUNG VON SELEN ALS MATRIXELEMENT

Das Extrahieren von großen Mengen an Selen gibt eine Möglichkeit für die analytische Bestimmung der Beimischungen, die das reine Selen begleiten und unter den beschriebenen Bedingungen in der wässrigen Phase zurückbleiben. Zu diesen Zweck war es notwendig, die Zeit zur Entstehung der selenorganischen Verbindung zu verkürzen.

Die Untersuchungen führten wir unter Erwärmung im Wasserbad in Gegenwart von Salzsäure oder einem Gemisch aus Salz- und Schwefelsäure durch. Der Einfluß der Schwefelsäure mußte untersucht werden, weil sie beim Auflösen reines Selens in Salpetersäure als Denitrierungsmittel verwendet wird und in der Lösung immer anwesend ist. Die Versuche zur Darstellung der Verbindung führten wir durch, indem wir zu 0,5 g Selen (in Form von SeO_2 oder H_2SeO_3), aufgelöst in 25 ml Salzsäure verschiedener Konzentration, unter Schütteln Acetophenon zusetzten. Die Menge an Acetophenon entsprach dem molaren Verhältnis Selen:Acetophenon = 1:2. Nach ungefähr 1,5 Std bindet sich das Selen quantitativ und fällt in Form eines weißen Niederschlages aus. Die Lösung über dem Niederschlag muß klar sein. Man gibt noch zwei molare Teile Acetophenon unter periodischem Schütteln hinzu und erwärmt im Wasserbad. Die Zeit zur Entstehung der bei verschiedenen Temperaturen und Konzentrationen der Salzsäure dargestellten Verbindung ist in Tabelle I angegeben. Ein Maß für die Entstehung der Verbindung war ihre völlige Extraktion aus der wässrigen Phase in das Chloroform.

Analoge Versuche führten wir auch in Anwesenheit von 3*N* Schwefelsäure durch. Die Ergebnisse sind in Tabelle II angegeben.

TABELLE I.—REAKTIONSGESCHWINDIGKEIT IN SALZSAURE

	Zeit zur Entstehung der Verbindung, *Std*, bei Reaktionstemperatur		
[HCl], *M*	60–65°C	80–85°C	siedendes Wasserbad
5,0	2,5–3	1–1,5	0,85–1
5,5	2–2,5	1–1,5	0,85–1
6	1,5–2	0,7–1	0,5–0,75
7	1–1,5	0,45–0,5	0,25–0,40
8	0,75–1	zersetzt sich	zersetzt sich
9	0,75–1	zersetzt sich	zersetzt sich
10	0,75–1	zersetzt sich	zersetzt sich

TABELLE II.—REAKTIONSGESCHWINDIGKEIT IN GEMISCHTEN SÄUREN

Gesamtkonzentration von HCl + H_2SO_4	Zeit zur Entstehung der Verbindung, *Std*, bei Reaktionstemperatur	
N	60–65°C	siedendes Wasserbad
4	8–9	5–6
6	3,5–4	4–5
7	0,75–1	1,5–2
8	0,75–1	0,5–0,70
9	1	zersetzt sich
10	1	zersetzt sich
11	1	zersetzt sich

Festgestellt wurde, daß die Verbindung bei $5M$ Salzsäure und $3N$ Schwefelsäure und Erwärmung im Wasserbad im Laufe einer Stunde bei 60–65° entsteht. Danach wird mit 5 ml Chloroform oder Tetrachlorkohlenstoff extrahiert. Das Selen geht in die organische Phase quantitativ über. Unter den beschriebenen Bedingungen geht neben Selen auch Gold(III) in die organische Phase über. Das letztere wird durch verdünnte Salzsäure nicht zurückextrahiert. In der wässrigen Phase bleiben folgende Metallionen zurück: Ru(IV), Rh(IV), Os(IV), Ir(IV), Pt(IV), Pd(II), Te(IV), Cu(II). Das Verhalten von Gold(III) wird Gegenstand weiterer Untersuchungen sein. Die erhaltenen Ergebnisse wurden zur Bestimmung von Tellur in reinem Selen benutzt.

ANWENDUNG DER METHODE ZUR BESTIMMUNG VON TELLUR IN REINEM SELEN

Zur Bestimmung von Tellur, das nach der Abtrennung von Selen in der wässrigen Phase zurückbleibt, beschlossen wir die bekannte photometrische Methode anzuwenden, die auf der Messung der Extinktion von Kolloidlösungen von elementarem Tellur, erhalten durch Reduktion mit Zinn(II)-chlorid, beruht.[9–11] Die Ergebnisse zeigten, daß folgende Elemente in den angegebenen Mengen (in 50 ml) die Photometrische Bestimmung von Tellur nicht stören: Pd(II)—5 μg, Au(III)—15 μg, Os(IV)—19 μg, Ru(IV)—13 μg, Ir(IV)—19 μg, Pt(IV)—6 μg.

Reagenzien

Konz. HCl, H_2SO_4 und HNO_3 *p.a.*
Lösung von $SnCl_2$, 25 %-ige.
Lösung von Gelatine, 0,5 %-ige.
Acetophenon *p.a.*

Es werden 0,2–3 g Selen in 5–15 ml konz. Salpetersäure aufgelöst. Die Probe die 20–200 μg Tellur enthalten soll wird im Wasserbad erwärmt, bis sich das Volumen auf 2–3 ml verringert. Man setzt 2,5 ml konz. Schwefelsäure und 2–3 ml Wasser hinzu und erwärmt weiter auf 250–300° im Sandbad bis zur Entstehung von SO_3. Man setzt noch Wasser und Salzsäure so zu, daß das Gesamtvolumen 25 ml und die Konzentration an Salzsäure $5M$ wird. Dann werden pro molaren Teil Selen vier molaren Teile Acetophenon zugesetzt. Zuerst gibt man unter heftigem Schütteln die Hälfte von der berechneten Menge an Acetophenon zu. Nach 1,5 Std wird die andere Hälfte zugegeben. Es wird im Wasserbad bei 60–65° eine Stunde lang erwärmt, wobei man in Zeitabständen schüttelt. Die Lösung muß völlig klar sein. Die Probe wird in einem Schütteltrichter gegeben und mit 8 ml Chloroform oder Tetrachlorkohlenstoff 2 min lang extrahiert. Die wässrige Phase wird filtriert und in einen 50 ml Meßkolben versetzt. Die organische Phase wird mit 5 ml $2M$ Salzsäure 20–30 sec lang gewaschen und die salzsaure Lösung der wässrigen Phase zugesetzt. Die Gesamtmenge in dem Meßkolben wird auf 40 ml gebrucht. Man kühlt auf 20° ab und setzt 0,5 ml $SnCl_2$-Lösung zu. Es wird geschüttelt und 5 min stehengelassen; man gibt noch 3 ml Gelatine-Lösung hinzu, verdünnt nach 10 min auf 50 ml und mißt die Extinktion bei 434 nm in einer 50-mm Küvette. Die Standartgraphik wird für Mengen von 20–200 μg pro 50 ml aufgezeichnet.

Um uns zu überzeugen, daß keine Verlußte an Tellur beim Auflösen und Abtrennen des Selens entstehen, setzten wir verschiedenen Mengen reinen Selens (0,5, 1, 2, 3 g) 50 μg Te zu. Die Proben wurden nach der Analysenvorschrift bearbeitet. Die Ergebnisse sind statistisch bearbeitet worden.

$$N = 10 \quad \bar{x} = 50{,}0\,\mu g \quad s = 1{,}19\,\mu g \quad V = \frac{s}{\bar{x}} \cdot t \cdot 100 = 5{,}4\%$$
$$\text{bei } P = 95 \quad t = 2{,}26$$

Wir geben auch die statistischen Ergebnisse von der Bestimmung von 50 μg Te unter reinen Bedingungen an.

$$N = 10 \quad \bar{x} = 49{,}8\,\mu g \quad s = 1{,}22\,\mu g \quad V = \frac{s}{\bar{x}} \cdot t \cdot 100 = 5{,}3\,\%$$
$$\text{bei } P = 95 \quad t = 2{,}26$$

DISKUSSION

Eine frühere Arbeit[6] befaßte sich mit der Extraktion von 5–25 μg Selen. Während in jenem Falle die begrenzte Löslichkeit von $(C_6H_5COCH_2)_2SeCl_2$ keine Schwierigkeiten bot, wird die Extraktion von großen Mengen Selen nur möglich sein, wenn die Selenverbindung in Chloroform praktisch unbegrenzt löslich ist, das bei $(C_6H_5COCH_2)_4Se$ der Fall ist. Da andere Elemente wie Te(IV), Au(III) nur als Ionenassoziate extrahiert werden, sind sie auch leight zurückzuextrahieren und daher von Selen abzutrennen, wie in vorliegender Arbeit am Beispiel von Tellurbestimmung aufgezeigt wird.

Détermination de l'or par réaction d'échange de complexes triples à association ionique

(*Reçu le* 31 *Mars* 1971. *Accepté le* 2 *Octobre* 1971)

De nombreux anions du type $[ML_4]$, réagissant avec certains agents organiques de nature basique, fournissent des composés ordinairement peu solubles dans l'eau, mais extractibles dans des solvants organiques appropriés.

Lorsque l'agent organique—base —est un colorant, on est en présence de réactions à sensibilité élevée, mais généralement à faible sélectivité. D'autre part, les réactions de ces mêmes anions $[ML_4^-]$ avec certains agents à basicité plus prononcée, mais incolores, se distinguent par leur haute sélectivité et leur faible sensibilité.

L'usage combiné de ces deux espèces de réactions permet de créer des méthodes sensibles et en même temps suffisamment sélectives.

Le principe d'un pareil usage combiné des deux espèces de réactions peut être illustré par l'exemple suivant. L'élément à déterminer (M) est extrait sous forme de complexe $K^+[ML_x^-]$, où K^+ est un cation organique incolore. La phase organique, contenant le complexe, est traitée par une solution aqueuse, contenant un autre cation $[K_1^+]$, coloré et apte, dans des conditions données, à se substituer au premier. Le complexe coloré $K_1^+[ML_x^-]$ ainsi obtenu, passe dans la phase organique qui est ensuite soumise à la photométrie. Des données sur des réactions d'échange de chélates, ayant lieu directement dans la phase organique, existent depuis quelques années.[1-3] Dernièrement un tel échange a été utilisé pour des complexes triples, à association ionique.[4]

Dans le présent mémoire, nous avons mis à profit le principe d'echange énoncé plus haut, pour obtenir une méthode colorimétrique de détermination de l'or, sélective et sensible à la fois.

Nos essais ont prouve que l'aurichlorure de nitrone extrait avec un solvant organique peut être déterminé par voie photométrique après échange avec du bleu de méthylène.

PARTIE EXPÉRIMENTALE

Réactifs utilisés

Solution étalon d'or. Pour la préparer, on fait dissoudre 0,1000 g d'or dans quelques ml d'eau régale, et évapore la solution á sec. Le résidu est traité à trois reprises par HCl avec evaporation presque totale, puis dilué à 1000 ml avec HCl 1*M*. Avant emploi, cette solution est diluée au dixiéme par l'eau.

Solution de sulfate de nitrone—1,000 μg/ml
Solution de bleu de méthylène—0,001*M*
Solution de complexone III—0,05*M*
Chloroforme p.a.

Mode opératoire

Pendant 5 mn on extrait, par 5 ml de chloroforme, 25 ml de solution aqueuse à pH 1, contenant 3–8 μg d'or III et 1 ml de solution de sulfate de nitrone. Après séparation des phases, on transvase la couche organique dans une ampoule à décanter, on y ajoute 20 ml d'acide chlorhydrique 0,1*M*, contenant 0,4 ml de solution de bleu de méthylène, et on agite pendant 5 mn. La couche organique séparée est soumise à la centrifugation et mesurée photométriquement (filtre rouge).

DISCUSSION DES RÉSULTATS

On a étudié la formation et l'extraction de l'aurichlorure de nitrone et on les a mises à profit pour la séparation par extraction de microquantités d'or[5,6] dans des melanges complexes. Les extraits que l'on obtient contiennent ordinairement de l'or de l'ordre de 10^{-6} g/ml. En raison de cette faible teneur en or, ils sont incolores et ne peuvent être soumis directement à la photométrie. Pour cette raison et afin de pourvoir déterminer l'or, on a évaporé à sec l'extrait organique contenant l'aurichlorure de nitrone, calciné le résidu et après dissolution de l'or dans de l'eau de chlore, on l'a déterminé selon la méthode connue, à l'aide de bleu de méthylène.[7]

Dans l'extraction de l'or(III) à l'aide de nitrone, on peut extraire aussi les complexes de Tl,Pl et Pd. Les deux derniers éléments accompagnent trés rarement l'or dans les concentrés de minerai. Nos essais ont prouvé que le platine et le palladium ne gênent pas la détermination de l'or selon la méthode énoncée, les rapports respectifs étant: Au : Pt : Pd = 1 : 6 : 12.

Si, dans la détermination de l'or, on procède à la combustion du résidu (contenant de l'aurichlorure de nitrone et du thallichlorure de nitrone), le thallium ne gêne pas le dosage sous forme d'aurichlorure de bleu de méthylène. Cependant, si l'on procède par échange, le thallium interfére en donnant les résultats par excés.

Pour réaliser le dosage de l'or(III) par échange en présence de Tl(III), on a étudié les aptitudes à l'extraction de l'aurichlorure de nitrone et du thallichlorure de nitrone en fonction du pH, entre pH 1 et pH 4(Fig. 1).

Cette figure montre que l'or(III) s'extrait à l'aide de nitrone, à pH 1,82 et le thallium á pH 1,12. Pour des valeurs de pH allant de 1,12 à 1,81,l'effet gênant du Tl(III) diminue. Pour eliminer complétement son influence lors de la séparation par extraction de l'or(III) sous forme d'aurichlorure de nitrone, nous avons eu recours à la dissimulation à l'aide de complexone III et de thiocarbamide.

Dans ce but, nous avons effectué des essais en vue de déterminer séparément l'or(III) et le Tl(III) en présence de complexone III et de thiocarbamide, en modifiant leurs quantités respectives et le pH de la solution.

L'usage de complexone III nous a permis d'obtenir de tres bons resultats. Ils montrent que la concentration la plus élevée du complexone III dans la phase aqueuse, lorsque l'or(III) est extrait quantitativement, est de l'ordre de $2\cdot10^{-3}M$, le pH allant de 0,76 à 0,98. Si les valeurs de pH sont

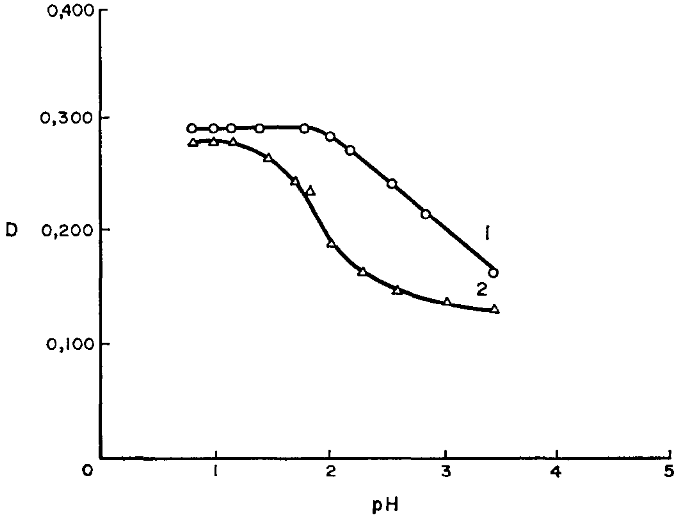

FIG. 1 —Correlation entre l'extraction de Au(III) (1) et (2) a l'aide du nitrone et en fonction du pH du milieu.

$[Au^{3+}] = [Tl^{3+}] = 50 \cdot 2$ mg/ml

supérieures à 0,98 l'extraction de l'or(III) n'est pas quantitative. On n'a pas étudié en vue de sa séparation sélective l'effet dissimulant du complexone III pour des valeurs du pH inferieures à 0,76.

Dans les conditions énoncées, Tl(III) se trouve être totalement dissimulé.

Nous avons aussi effectué des essais en vue de déterminer les quantités de Tl(III) pouvant être dissimuleés lors de la détermination d'une quantité donnée d'or (Tableau I). Ce tableau montre que, dans les conditions mentionneés, l'or(III) peut ètre déterminé par échange du nitrone dans l'aurichlorure de nitrone au moyen du bleu de méthylène en présence de 60 g Tl(III).

TABLEAU I

Prélevé		Rapport Au : Tl	Trouvé, or μg
Or, μg	Thallium, μg		
5,0	10	1 : 2	5,0
5,0	20	1 : 4	5,0
5,0	30	1 : 6	5,0
5,0	40	1 : 8	5,0
5,0	50	1 : 10	5,0
5,0	60	1 : 12	5,0
5,0	70	1 : 14	5,3

On a aussi étudié l'effet gênant des ions qui accompagnent ordinairement l'or dans les concentrés de minerai. Nos essais ont porté sur des quantités de l'ordre de 5 . 10^{-3} g des éléments cités. Il a été établi qu'ils ne peuvent pas être extraits au moyen du nitrone dans les mêmes conditions où l'on extrait l'or, et, que par conséquent, ils ne participent pas à l'échange.

Les essais effectués attestent que le principe d'echange préconisé peut être mis en pratique avec beaucoup de succèss dans la détermination photométrique de l'or en présence de thallium, de platine, de palladium et tous les autres éléments que l'accompagnent ordinairement dans les minerais et les concentrés de minerai.

Résumé—On a mis à profit le principe d'échange de complexes triples à association ionique pour déterminer l'or par photométrie. On a éthidié les effets de Pt, Pd, Tl et d'autres éléments sur la détermination de l'or(III). On a établé les conditions de détermination de l'or(III) en leur présence.

Summary—The principle of exchange of ion-association triple complexes has been used for photometric determination of gold. The effects of Pt, Pd, Tl and other elements have been examined, and conditions established for determination of gold(III) in their presence.

Zusammenfassung—Das Prinzip des Austausches von Ionenassoziations-Tripelkomplexen wurde auf die photometrische Bestimmung von Gold angewandt. Der Einfluß von Pt, Pd, Tl und anderen Elementen wurde untersucht und Bedingungen ermittelt, unter denen Gold(III) in ihrer Gegenwart bestimmt werden kann.

Zusammenfassung—Erhalten wurde eine neue Verbindung von Se(IV) mit Acetophenon in salzsaurem Medium, $(C_6H_5COCH_2)_4Se$. Der Prozeß der Entstehung der Verbindung dauert beim Überschuß an Acetophenon (Selen:Acetophenon < 1:4) ungefähr 300–400 Std, aber bei 60–70° nur 1,5–2 Std. Die erhaltene Verbindung löst sich sehr gut in Chloroform und Tetrachlorkohlenstoff. Diese Eigenschaft wird zur Extraktionsabtrennung von großen Mengen an Selen benutzt. Auf diese Weise wird eine gute Möglichkeit zur Bestimmung von Beimischungen in reinem Selen gegeben. Die Methode ist zur Bestimmung von Tellur in Selen angewandt worden.

Summary—A new compound has been prepared from Se(IV) and acetophenone in hydrochloric acid solution. At 60–70° conversion into $(C_6H_5COCH_2)_4Se$ is complete in 1·5–2 hr. The product is very soluble in chloroform and in carbon tetrachloride and thus offers a possibility for the separation of large quantities of selenium before determination of impurities in it. The method has been applied to the separation and determination of traces of tellurium in selenium.

Résumé—On a préparé un nouveau composé à partir de Se(IV) et d'acétophénone en solution dans l'acide chlorhydrique. A 60–70°, la conversion en $(C_6H_5COCH_2)_4Se$ est complète en 1,5–2 h. Le produit est très soluble en chloroforme et en tétrachlorure de carbone et offre ainsi une possibilité de séparation de grandes quantités de sélénium avant détermination des impuretés qu'il contient. On a appliqué la méthode à la séparation et au dosage de traces de tellurium dans le sélénium.

Détermination de l'or par réaction d'échange de complexes triples à association ionique

(*Reçu le* 31 *Mars* 1971. *Accepté le* 2 *Octobre* 1971)

De nombreux anions du type [ML_4], réagissant avec certains agents organiques de nature basique, fournissent des composés ordinairement peu solubles dans l'eau, mais extractibles dans des solvants organiques appropriés.

Lorsque l'agent organique—base —est un colorant, on est en présence de réactions à sensibilité élevée, mais généralement à faible sélectivité. D'autre part, les réactions de ces mêmes anions [ML_4^-] avec certains agents à basicité plus prononcée, mais incolores, se distinguent par leur haute sélectivité et leur faible sensibilité.

L'usage combiné de ces deux espèces de réactions permet de créer des méthodes sensibles et en même temps suffisamment sélectives.

Le principe d'un pareil usage combiné des deux espèces de réactions peut être illustré par l'exemple suivant. L'élément à déterminer (M) est extrait sous forme de complexe $K^+[ML_x^-]$, où K^+ est un cation organique incolore. La phase organique, contenant le complexe, est traitée par une solution aqueuse, contenant un autre cation $[K_1^+]$, coloré et apte, dans des conditions données, à se substituer au premier. Le complexe coloré $K_1^+[ML_x^-]$ ainsi obtenu, passe dans la phase organique qui est ensuite soumise à la photométrie. Des données sur des réactions d'échange de chélates, ayant lieu directement dans la phase organique, existent depuis quelques années.[1-3] Dernièrement un tel échange a été utilisé pour des complexes triples, à association ionique.[4]

Dans le présent mémoire, nous avons mis à profit le principe d'echange énoncé plus haut, pour obtenir une méthode colorimétrique de détermination de l'or, sélective et sensible à la fois.

Nos essais ont prouve que l'aurichlorure de nitrone extrait avec un solvant organique peut être déterminé par voie photométrique après échange avec du bleu de méthylène.

PARTIE EXPÉRIMENTALE

Réactifs utilisés

Solution étalon d'or. Pour la préparer, on fait dissoudre 0,1000 g d'or dans quelques ml d'eau régale, et évapore la solution á sec. Le résidu est traité à trois reprises par HCl avec evaporation presque totale, puis dilué à 1000 ml avec HCl 1*M*. Avant emploi, cette solution est diluée au dixiéme par l'eau.

Solution de sulfate de nitrone—1,000 µg/ml
Solution de bleu de méthylène—0,001*M*
Solution de complexone III—0,05*M*
Chloroforme p.a.

Mode opératoire

Pendant 5 mn on extrait, par 5 ml de chloroforme, 25 ml de solution aqueuse à pH 1, contenant 3–8 µg d'or III et 1 ml de solution de sulfate de nitrone. Après séparation des phases, on transvase la couche organique dans une ampoule à décanter, on y ajoute 20 ml d'acide chlorhydrique 0,1*M*, contenant 0,4 ml de solution de bleu de méthylène, et on agite pendant 5 mn. La couche organique séparée est soumise à la centrifugation et mesurée photométriquement (filtre rouge).

DISCUSSION DES RÉSULTATS

On a étudié la formation et l'extraction de l'aurichlorure de nitrone et on les a mises à profit pour la séparation par extraction de microquantités d'or[5,6] dans des melanges complexes. Les extraits que l'on obtient contiennent ordinairement de l'or de l'ordre de 10^{-6} g/ml. En raison de cette faible teneur en or, ils sont incolores et ne peuvent être soumis directement à la photométrie. Pour cette raison et afin de pourvoir déterminer l'or, on a évaporé à sec l'extrait organique contenant l'aurichlorure de nitrone, calciné le résidu et après dissolution de l'or dans de l'eau de chlore, on l'a déterminé selon la méthode connue, à l'aide de bleu de méthylène.[7]

Dans l'extraction de l'or(III) à l'aide de nitrone, on peut extraire aussi les complexes de Tl,Pl et Pd. Les deux derniers éléments accompagnent trés rarement l'or dans les concentrés de minerai. Nos essais ont prouvé que le platine et le palladium ne gênent pas la détermination de l'or selon la méthode énoncée, les rapports respectifs étant: Au : Pt : Pd = 1 : 6 : 12.

Si, dans la détermination de l'or, on procède à la combustion du résidu (contenant de l'aurichlorure de nitrone et du thallichlorure de nitrone), le thallium ne gêne pas le dosage sous forme d'aurichlorure de bleu de méthylène. Cependant, si l'on procède par échange, le thallium interfére en donnant les résultats par excés.

Pour réaliser le dosage de l'or(III) par échange en présence de Tl(III), on a étudié les aptitudes à l'extraction de l'aurichlorure de nitrone et du thallichlorure de nitrone en fonction du pH, entre pH 1 et pH 4(Fig. 1).

Cette figure montre que l'or(III) s'extrait à l'aide de nitrone, à pH 1,82 et le thallium á pH 1,12. Pour des valeurs de pH allant de 1,12 à 1,81,l'effet gênant du Tl(III) diminue. Pour eliminer complétement son influence lors de la séparation par extraction de l'or(III) sous forme d'aurichlorure de nitrone, nous avons eu recours à la dissimulation à l'aide de complexone III et de thiocarbamide.

Dans ce but, nous avons effectué des essais en vue de déterminer séparément l'or(III) et le Tl(III) en présence de complexone III et de thiocarbamide, en modifiant leurs quantités respectives et le pH de la solution.

L'usage de complexone III nous a permis d'obtenir de tres bons resultats. Ils montrent que la concentration la plus élevée du complexone III dans la phase aqueuse, lorsque l'or(III) est extrait quantitativement, est de l'ordre de $2\cdot10^{-3}M$, le pH allant de 0,76 à 0,98. Si les valeurs de pH sont

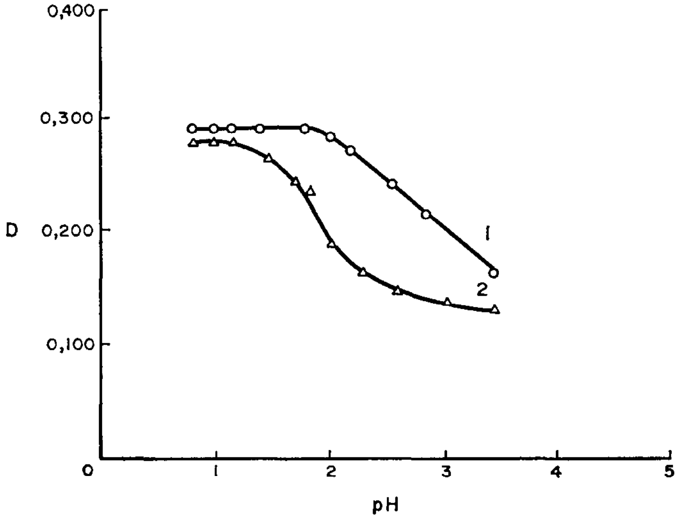

FIG. 1 —Correlation entre l'extraction de Au(III) (1) et (2) a l'aide du nitrone et en fonction du pH du milieu.

$[Au^{3+}] = [Tl^{3+}] = 50{\cdot}2$ mg/ml

supérieures à 0,98 l'extraction de l'or(III) n'est pas quantitative. On n'a pas étudié en vue de sa séparation sélective l'effet dissimulant du complexone III pour des valeurs du pH inferieures à 0,76.

Dans les conditions énoncées, Tl(III) se trouve être totalement dissimulé.

Nous avons aussi effectué des essais en vue de déterminer les quantités de Tl(III) pouvant être dissimuleés lors de la détermination d'une quantité donnée d'or (Tableau I). Ce tableau montre que, dans les conditions mentionneés, l'or(III) peut ètre déterminé par échange du nitrone dans l'aurichlorure de nitrone au moyen du bleu de méthylène en présence de 60 g Tl(III).

PRELIMINARY COMMUNICATIONS

Extraction of some metal phenylacetates into chloroform

(*Received* 4 *October* 1971. *Accepted* 25 *November* 1971)

During the investigation of new compounds for highly selective extraction of metals we have paid attention to phenylacetic acid—$C_6H_5CH_2COOH$ (PAA). An aqueous solution of this acid will precipitate iron(III), copper(II), uranyl ion *etc* from slightly acidic or nearly neutral solutions (pH 6). The precipitate dissolves easily in chloroform and other organic solvents.

With further experimentation we have found that phenylacetic acid offers more selective reactions than does, for example, oxine. From slightly acidic dilute solutions large amounts of nickel, cobalt, manganese, alkaline earth metals, molybdate, vanadate are not precipitated or extracted. The extraction capacity for iron, copper and uranium is very large, exceeding the extractibility of most other metal chelates. It is possible to extract smoothly 200 mg and more of iron in the presence of micro amounts of nickel, cobalt or manganese.

There are some possibilities for using such separations on the micro-scale for colorimetric determination of particular elements as well on the macro-scale for complexometric determinations. Phenylacetic acid is slightly soluble in water (1·26 g/100 ml) but very soluble in chloroform. Its chloroform solution was therefore used as extractant. We can expect that other substituted acetic acids will behave similarly. Extractable precipitates are formed, for example, by 1-hydroxynaphthylacetic acid.

In this work the dependence of the extraction on pH and metal ion concentration was studied, because it has been observed that the extractability of individual metals varies very much.

EXPERIMENTAL

Reagents

*Phenylacetic acid solution, 1*M *in chloroform.* Prepared by dissolution of 34·0 g of PAA in 250 ml of chloroform.

*Metal solutions, 0·05*M. Prepared from the salts (sulphate, chloride, nitrate) and checked complexometrically.

*EDTA solution 0·05*M. Standardized with 0·05*M* lead nitrate, with Xylenol Orange as indicator.

Other reagents include saturated solutions of hexamethylenetetramine (hexamine), borax and ammonium acetate.

Influence of pH on the extraction

Because the extraction of the metals is primarily dependent on quantitative precipitation, it was obvious that the solution before extraction should not be acid. Tervalent iron is only partly extracted at pH 3–4 but quantitatively at pH 6. The same holds for other elements. Iron gives an orange to deep red extract, copper gives an intense blue from borax medium or a green extract from hexamine solutions. Easily hydrolysed metals—zirconium, hafnium, thorium, bismuth, aluminium, titanium—are not extracted, forming precipitates at the chloroform interface which are partly suspended in the chloroform.

The first experiments were carried out as follows. To the acidic metal solution solid PAA was added and the solution was extracted with chloroform. Usually all the PAA was dissolved. Then the pH was adjusted to about 6 by addition of saturated solutions of hexamine, borax or ammonium acetate, and the solution was shaken again. In later experiments a 1*M* solution of PAA in chloroform was used.

Effect of dilution on the extraction

As already said, the extraction can be carried out only after precipitation of particular metals. Some metal phenylacetates are soluble and precipitate only from relatively concentrated solutions. The results in Table I for bivalent metals, iron(III) and uranyl ion were obtained by the following procedure. To 2 ml of 0·05*M* metal solution in a 150-ml separatory funnel, water was added (0, 5, 10 ml) followed by 5 ml of buffer solution. The mixture was extracted for 1 min with 5 ml of 1*M*

UO_2^{2+}	100	100	100	100	98

(*a*) pH 5–5·5 (*b*) pH 6 (*c*) pH 4–6 in final solutions.

PAA in chloroform. The phases were separated and the aqueous phase was extracted once more with 5 ml of pure chloroform. The metal left in the aqueous phase after dilution with water was determined by a suitable complexometric method. The degree of extraction is summarized in Table I.

From Table I we can see that in the case of bivalent metals, with the exception of copper, the degree of extraction is very dependent on the metal concentration. It can be expected that at high dilution (about 0·01*M*) these metals are not extracted at all. The second series of extractions of bivalent metals and some others was carried out as follows. A 5-ml portion of 0·05*M* metal solution in a 150–250-ml separatory funnel was diluted to 50, 100 or 150 ml. After addition of 20 ml of saturated hexamine solution and 10 ml of 1*M* PAA in chloroform, the mixture was shaken for 1 min. After separation of the phases, the aqueous phase was extracted twice with 10-ml portions of pure chloroform. The metal remaining in the aqueous phase was determined complexometrically. The consumption of 0·05 ml or less of 0·05*M* EDTA in the titration of the aqueous phase was considered as zero for the calculation of the degree of extraction. Some results are summarized in Table II.

TABLE II.—DEGREE OF EXTRACTION (%) OF METAL PHENYLACETATES FROM LARGE VOLUMES
(For 5 ml of 0·05*M* metal solutions; hexamine buffer pH 5·5–6)

Final volume, *ml*	70	120	170
Final molarity of metal before extraction	$3{\cdot}5 \times 10^{-3}$	2×10^{-3}	$1{\cdot}47 \times 10^{-3}$
Co(II)	0	0	0

Pr	96	74	0
Dy	75	50	3
Y	56	4	1
Sc	92	92	100

The extraction of some metals by the described procedure was followed only qualitatively. These observations are given in Table III.

TABLE III.—EXTRACTION OF LESS COMMON METALS
(qualitative tests)

Metal ion	Extraction	Aqueous phase
Vanadium(IV)	Violet extract	Negative test with H_2O_2
Vanadium(V)	Not extracted	Intense yellow
Molybdenum(VI)	Not extracted	Oxine precipitation
Tungsten(VI)	Not extracted	Oxine precipitation
Gold(III)	Yellow extract	Colourless
Platinum(IV)	Yellow extract	Colourless
Palladium(II)	Yellow-brown	Colourless
Germanium(IV)	Not extracted	Positive test with phenylfluorone

Influence of masking

Complex-forming compounds will compete with the formation of the phenylacetate precipitate. For example, copper is extracted incompletely in the presence of ammonium acetate, and lead not at all (see Table I). EDTA prevents all precipitations. Ammonium fluoride masks iron and uranium, making extraction of copper highly selective. On the other hand copper can be masked with thiourea, uranium with hydrogen peroxide or ammonium carbonate *etc.*

Table II offers some possibilities for the separation of metals. From the practical point of view this type of extraction is suitable for removal of larger amounts of iron, copper and uranium from complex material. Further experiments have shown that it is possible to determine minute traces of manganese in iron or steels (with formaldoxime) or cobalt (less than 0·05%) in the same material with nitroso-R-salt, or to determine complexometrically zinc and manganese in copper alloys, nickel or cobalt in various iron alloys *etc.* The results will be published elsewhere.

Summary—Phenylacetic acid has been found to be very useful as a reagent in the extraction of large quantities of certain ions, notable iron(III), cobalt(II), copper(II), lead, zinc, cadmium and uranyl. A 1*M* solution of the reagent in chloroform is used to extract up to 200 mg of certain ions from small volumes of aqueous phase. Selectivity is increased by pH control and masking.

Zusammenfassung—Phenylessigsäure ist sehr nützlich als Reagens zur Extraktion großer Mengen bestimmter Ionen, besonders Eisen(III), Kobalt(II), Kupfer(II), Blei, Zink, Cadmium und Uranyl. Eine 1*M* Lösung des Reagens in Chloroform dient zur Extraktion von bis zu 200 mg dieser Ionen aus kleinen Volumina wäßriger Phase. Die Selektivität wird durch pH-Kontrolle und Maskierung verbessert.

Résumé—On a trouvé que l'acide phénylacétique est très utile en tant que réactif pour l'extraction de grandes quantités de certains ions, notamment les fer(III), cobalt(II), cuivre(II), plomb, zinc, cadium et uranyle. On utilise une solution 1*M* du réactif en chloroforme pour extraire jusqu'à 200 mg de certains ions de petits volumes de phase aqueuse. La sélectivité est accrue par contrôle de pH et dissimulation.

PRELIMINARY COMMUNICATIONS

Extraction of some metal phenylacetates into chloroform

(*Received* 4 *October* 1971. *Accepted* 25 *November* 1971)

DURING the investigation of new compounds for highly selective extraction of metals we have paid attention to phenylacetic acid—$C_6H_5CH_2COOH$ (PAA). An aqueous solution of this acid will precipitate iron(III), copper(II), uranyl ion *etc* from slightly acidic or nearly neutral solutions (pH 6). The precipitate dissolves easily in chloroform and other organic solvents.

With further experimentation we have found that phenylacetic acid offers more selective reactions than does, for example, oxine. From slightly acidic dilute solutions large amounts of nickel, cobalt, manganese, alkaline earth metals, molybdate, vanadate are not precipitated or extracted. The extraction capacity for iron, copper and uranium is very large, exceeding the extractibility of most other metal chelates. It is possible to extract smoothly 200 mg and more of iron in the presence of micro amounts of nickel, cobalt or manganese.

There are some possibilities for using such separations on the micro-scale for colorimetric determination of particular elements as well on the macro-scale for complexometric determinations. Phenylacetic acid is slightly soluble in water (1·26 g/100 ml) but very soluble in chloroform. Its chloroform solution was therefore used as extractant. We can expect that other substituted acetic acids will behave similarly. Extractable precipitates are formed, for example, by 1-hydroxynaphthylacetic acid.

In this work the dependence of the extraction on pH and metal ion concentration was studied, because it has been observed that the extractability of individual metals varies very much.

EXPERIMENTAL

Reagents

*Phenylacetic acid solution, 1*M *in chloroform.* Prepared by dissolution of 34·0 g of PAA in 250 ml of chloroform.

*Metal solutions, 0·05*M. Prepared from the salts (sulphate, chloride, nitrate) and checked complexometrically.

*EDTA solution 0·05*M. Standardized with 0·05*M* lead nitrate, with Xylenol Orange as indicator.

Other reagents include saturated solutions of hexamethylenetetramine (hexamine), borax and ammonium acetate.

Influence of pH on the extraction

Because the extraction of the metals is primarily dependent on quantitative precipitation, it was obvious that the solution before extraction should not be acid. Tervalent iron is only partly extracted at pH 3–4 but quantitatively at pH 6. The same holds for other elements. Iron gives an orange to deep red extract, copper gives an intense blue from borax medium or a green extract from hexamine solutions. Easily hydrolysed metals—zirconium, hafnium, thorium, bismuth, aluminium, titanium—are not extracted, forming precipitates at the chloroform interface which are partly suspended in the chloroform.

The first experiments were carried out as follows. To the acidic metal solution solid PAA was added and the solution was extracted with chloroform. Usually all the PAA was dissolved. Then the pH was adjusted to about 6 by addition of saturated solutions of hexamine, borax or ammonium acetate, and the solution was shaken again. In later experiments a 1*M* solution of PAA in chloroform was used.

Effect of dilution on the extraction

As already said, the extraction can be carried out only after precipitation of particular metals. Some metal phenylacetates are soluble and precipitate only from relatively concentrated solutions. The results in Table I for bivalent metals, iron(III) and uranyl ion were obtained by the following procedure. To 2 ml of 0·05*M* metal solution in a 150-ml separatory funnel, water was added (0, 5, 10 ml) followed by 5 ml of buffer solution. The mixture was extracted for 1 min with 5 ml of 1*M*

TABLE I.—DEGREE OF EXTRACTION (%) OF METAL PHENYLACETATES
(For 2 ml of 0·05*M* metal solutions)

Final volume, *ml*	7	12	17	7	7
Buffer	Hexamine (a)	Hexamine (a)	Hexamine (a)	Borax (b)	$NH_4O_2C{\cdot}CH_3$ (c)
Final molarity of the metal solution	$1{\cdot}4 \times 10^{-2}$	$8{\cdot}3 \times 10^{-3}$	$5{\cdot}8 \times 10^{-3}$	$1{\cdot}4 \times 10^{-2}$	
Co(II)	60	25	13	5	1
Ni	49	18	8	0	0

Zn	98	96	90	0	0·9
Cd	91	83	30	0	0
Mn(II)	0	0	0	0	0
Cu(II)	99	99	99	99	20
Fe(III)	100	100	100	100	100
UO_2^{2+}	100	100	100	100	98

(*a*) pH 5–5·5 (*b*) pH 6 (*c*) pH 4–6 in final solutions.

PAA in chloroform. The phases were separated and the aqueous phase was extracted once more with 5 ml of pure chloroform. The metal left in the aqueous phase after dilution with water was determined by a suitable complexometric method. The degree of extraction is summarized in Table I.

From Table I we can see that in the case of bivalent metals, with the exception of copper, the degree of extraction is very dependent on the metal concentration. It can be expected that at high dilution (about 0·01*M*) these metals are not extracted at all. The second series of extractions of bivalent metals and some others was carried out as follows. A 5-ml portion of 0·05*M* metal solution in a 150–250-ml separatory funnel was diluted to 50, 100 or 150 ml. After addition of 20 ml of saturated hexamine solution and 10 ml of 1*M* PAA in chloroform, the mixture was shaken for 1 min. After separation of the phases, the aqueous phase was extracted twice with 10-ml portions of pure chloroform. The metal remaining in the aqueous phase was determined complexometrically. The consumption of 0·05 ml or less of 0·05*M* EDTA in the titration of the aqueous phase was considered as zero for the calculation of the degree of extraction. Some results are summarized in Table II.

TABLE II.—DEGREE OF EXTRACTION (%) OF METAL PHENYLACETATES FROM LARGE VOLUMES
(For 5 ml of 0·05*M* metal solutions; hexamine buffer pH 5·5–6)

Final volume, *ml*	70	120	170
Final molarity of metal before extraction	$3{\cdot}5 \times 10^{-3}$	2×10^{-3}	$1{\cdot}47 \times 10^{-3}$
Co(II)	0	0	0
Ni	0	0	0
Pb	88	56	28

Ce(III)	36	1	0
Pr	96	74	0
Dy	75	50	3
Y	56	4	1
Sc	92	92	100

The extraction of some metals by the described procedure was followed only qualitatively. These observations are given in Table III.

TABLE III.—EXTRACTION OF LESS COMMON METALS
(qualitative tests)

Metal ion	Extraction	Aqueous phase
Vanadium(IV)	Violet extract	Negative test with H_2O_2
Vanadium(V)	Not extracted	Intense yellow
Molybdenum(VI)	Not extracted	Oxine precipitation
Tungsten(VI)	Not extracted	Oxine precipitation
Gold(III)	Yellow extract	Colourless
Platinum(IV)	Yellow extract	Colourless
Palladium(II)	Yellow-brown	Colourless
Germanium(IV)	Not extracted	Positive test with phenylfluorone

Influence of masking

Complex-forming compounds will compete with the formation of the phenylacetate precipitate. For example, copper is extracted incompletely in the presence of ammonium acetate, and lead not at all (see Table I). EDTA prevents all precipitations. Ammonium fluoride masks iron and uranium, making extraction of copper highly selective. On the other hand copper can be masked with thiourea, uranium with hydrogen peroxide or ammonium carbonate *etc.*

Table II offers some possibilities for the separation of metals. From the practical point of view this type of extraction is suitable for removal of larger amounts of iron, copper and uranium from complex material. Further experiments have shown that it is possible to determine minute traces of manganese in iron or steels (with formaldoxime) or cobalt (less than 0·05%) in the same material with nitroso-R-salt, or to determine complexometrically zinc and manganese in copper alloys, nickel or cobalt in various iron alloys *etc.* The results will be published elsewhere.

Foam chromatography

Solid foams as supports in column chromatography

(*Received* 25 *October* 1971. *Accepted* 4 *December* 1971)

THIS PRELIMINARY NOTE deals with a new possibility in reversed-phase partition (extraction) chromatography. The concept may also be extended to ion-exchange and analogous techniques. Our investigations in these fields are in progress. In the last decades extraction chromatography has undergone considerable progress[1-4] and numerous separations have become possible which could only be achieved with difficulty, or not at all, by static extraction. General use of this method was limited by two major problems: the lack of inert supports with suitable chemical and physical properties, and the relatively low capacity of the extraction chromatographic columns.

A solution of the first problem has been given by the application of organic polymeric (plastic) inert supports. Thus the introduction, for use in column chromatography, of polytrifluoroethylene (Kel-F),[5-7] polytetrafluoroethylene (Teflon, Haloport-F, Fluoroplast),[8,9] the copolymer of polyvinyl acetate and polyvinyl chloride (Corvic),[10] the copolymer of styrene and divinylbenzene,[11] polyethylene (Mipor)[12] and polyfluorocarbon[13] represents marked progress. These supports are applied in granular form, and the adsorption and elution of the components to be separated take place in a thin film of the stationary phase coated on the polymer surface. The considerable advantages of the application of such plastic supports are lessened by the necessity of using them as finely granulated particles, with large specific surface, in order to increase the capacity; this adversely affects the flow-rate through the column, and therefore pressurized columns have to be employed. Even in this case, the capacity is less than that of ion-exchange resins.

For a solution of the problems mentioned above, the idea occurred that chromatographic adsorption, exchange and partition processes could be favourably influenced by giving the adsorbent a hollow spherical (cellular) form, and effecting the adsorption on the internal surface of the cells. This can be done by using solid, flexible, foamed synthetic polymers as inert supports in columns. Open-cell plastic foams may be regarded as a relatively regular stack of hollow spheres (cells).

The hydrodynamic properties of chromatographic columns packed with a foamed polymer are extremely favourable, and high flow-rates may be attained. The large specific surface of the foams ensures a large capacity compared with granular supports. In ion-exchange chromatography it may also be expected that the rate of the exchange processes will increase when the thin membranes forming the inner surface of the cells provide the site of exchange.

With the highly developed technology for making foamed plastics and synthetic polymers today,[14] probably many or all organic supports, applied hitherto in granular form, may be produced as a foam.

To our knowledge, results have not been published so far on the application of plastic foams as supports in chromatographic columns, though Bowen[15] recently suggested polyurethane foams as adsorbents in batch adsorption separations.

Our investigations were initiated with plastic foams available on the market. The first experiments concerned mainly the flow characteristics and chemical resistance of the foams applied.

Of the different foams examined (PVC, viscose, rubber and polyurethane), polyurethane foam proved to be the most appropriate, hence only this was subjected to a more thorough examination. Attempts at the preparation of other foamed inert synthetic and ion-exchange polymers are in progress.

As a model, the extraction chromatographic separation of palladium, in the form of palladium-thiourea complex in perchloric acid medium, was examined, with tri-n-butyl phosphate[16] on polyurethane foam as the stationary phase.

EXPERIMENTAL

Reagents and material

All reagents used were of analytical grade unless otherwise mentioned. Tri-n-butyl phosphate (TBP) used as the stationary phase was purified according to the procedure described by Hamlin *et al.*[7] Polyurethane foam, polyether of open cell-type, was used as the supporting material. It was a flexible polymer with 60 cells/cm on the average. This material was supplied by the North Hungarian Chemical Works, Sajóbábony, Hungary.

Column packing

A column of 1·5 cm bore and 15 cm length (with inlet and outlet taps at both ends) was used. The polyurethane packing material was washed 3 times with acetone. The dried material either in the form of small cubes or cylinders was equilibrated with purified TBP (3 ml per g of foam) with efficient stirring, then left overnight. The loaded foam was dried between two sheets of filter paper to remove excess of TBP. The cylindrical foam was cut such that each rod had a little larger diameter than that of the column. Either form of the loaded foam was evenly packed in the column by gentle pressure with a glass rod. This procedure reduced the volume of the compressed foam to one third of its original value. The packed column was evacuated by means of an oil-pump. Distilled water saturated with TBP was gradually allowed to fill the column through the outlet tap. This allows any residual air bubbles to escape from the foam inner surface to the top of the column and results in a homogeneous bed.

Procedure

Separation of Pd *and* Ni. The feed solution contained 1 ml of $PdCl_2$ solution (Pd 1 mg/ml), 1 ml of $NiCl_2$ solution (Ni 1 mg/ml) and 10 ml of 0·1*M* perchloric acid containing 3% thiourea and 1% sodium perchlorate. Different experiments were made in which the concentration of Pd was kept constant while that of Ni was varied by a factor of up to 100.

Sorption of this mixture took place at a flow-rate of 1 ml/min. The mixture was chromatographed at flow-rates of 1–4 ml/min.

Water saturated with TBP was used as eluting solution. Ni was eluted with 0·1*M* perchloric acid containing 3% thiourea and 1% sodium perchlorate, and Pd with water. In both cases the eluent was saturated with TBP, which served to keep the concentration of TBP on the foam material constant. Pd and Ni were determined spectrophotometrically as the Pd–thiourea and Ni–dimethylglyoxime complexes, at 292 and 366 nm respectively.

RESULTS AND DISCUSSION

Under the experimental conditions used Ni does not form a complex with thiourea,[17] and comes off the column in the first free column volumes without any measurable retention. On the other hand, Pd, which forms a complex with thiourea, was completely taken up by the loaded foam even in presence of 100 times its weight of Ni.

In comparison with published work[18] in which TBP was used as stationary phase loaded on different inert supports in granular form, it was found that polyurethane foam column support takes up TBP much more efficiently. For example, Kel-F takes up 1 ml of TBP per g, whereas polyurethane foam takes up 2 ml/g. This high uptake of stationary phase results in a high relative break-through capacity of the column, *i.e.*, ~30 mg of Pd^{2+} per g of coated foam.

Sharp and symmetrical peaks were obtained for both Ni and Pd. For Pd the height equivalent to one theoretical plate (HETP) was calculated to be ~1·4 mm.

The flow-rates were considerably higher than for granular supports,[15,18] without pressure applied at the top of the columns.

Summary—Foamed polymer is loaded with tributyl phosphate as stationary phase and compressed into a chromatographic column which will give flow rates of 1–4 ml/min, has a high break-through capacity and gives sharp and symmetrical peaks in elution chromatography. It has been applied to separation of nickel and palladium.

Zusammenfassung—Ein Polymerenschaum wird mit Tributylphosphat als stationärer Phase getränkt und in eine Chromatographiesäule gepreßt. Man erreicht Durchflußgeschwindigkeiten von 1–4 ml/min, eine hohe Durchbruchskapazität und bei der Elutionschromatographie scharfe und symmetrische Peaks. Das Verfahren wurde auf die Trennung von Nickel und Palladium angewandt.

Résumé—Un polymère-mousse chargé de phosphate de tributyle comme phase stationnaire et comprimé dans une colonne chromatographique qui donnera des vitesses d'écoulement de 1–4 ml/mn donne des pics accentués et symétriques en chromatographie d'élution. On l'a appliqué à la séparation du nickel et du palladium.

LETTER TO THE EDITOR

Computer calculation of equilibrium constants using programme SCOGS. A further modification

SIR,

Further work by one of us (VSS) has shown that the correction recently published for programme SCOGS,[1] while mathematically more correct than that used in the original programme,[2] still requires a minor modification to one card of the programme. Statement No. 150, the derivation of calculated titre CTITR from known initial quantities and the measured pH, at present reads[1]

```
150 CTITR = (VOX1(K)*TURM(K) + V(K)*AC(K) − VOX1(K)*HO)/BA(K)
```

The quantity VOX1(K) (*i.e.*, current total volume at point K, equal to original volume plus added titrant) is correctly used in the term VOX1(K)*TURM(K) as the latter quantity, having earlier been corrected for volume change, must now be reduced to refer to original volume. No volume change appears in the term V(K)*AC(K). However the term VOX1(K)*HO contains the change in volume and this quantity should more correctly be assumed to be unknown and equal to CTITR. Thus the expression above ought to be written

```
CTITR = (VOX1(K)*TURM(K) + V(K)*AC(K) − V(K)*HO − CTITR*HO)/BA(K)
```

Rearranging gives the expression below and this should be substituted for Statement No. 150,

```
150 CTITR = (VOX1(K)*TURM(K) + V(K)*AC(K) − V(K)*HO)/(BA(K) + HO)
```

This modification, while advisable, has not made significant difference to the constants calculated to date.

DETERMINATION OF TRACE ELEMENTS IN METALS AND ALLOYS BY ATOMIC-ABSORPTION SPECTROSCOPY USING AN INDUCTION-HEATED GRAPHITE WELL FURNACE AS ATOM SOURCE

J. B. HEADRIDGE and DAVID RISSON SMITH
Chemistry Department, Sheffield University, Sheffield, U.K.

(*Received* 19 *August* 1971. *Accepted* 29 *October* 1971)

Summary—An induction-heated graphite furnace, coupled to a Unicam SP 90 atomic-absorption spectrometer, is described for the direct determination of trace elements in metals and alloys. The furnace is capable of operation at temperatures up to 2400°, and has been used to obtain calibration graphs for the determination of ppm quantities of bismuth in lead-base alloys, cast irons and stainless steels, and for the determination of cadmium at the ppm level in zinc-base alloys. Milligram samples of the alloys were atomized directly. Calibration graphs for the determination of the elements in solutions were obtained for comparison. The accuracy and precision of the determination are presented and discussed.

IN RECENT years much interest has been shown in the development of non-flame methods of atomization for atomic-absorption spectroscopy.[1] Many such atomization methods have been reported but few have dealt with systems suitable for direct analysis of solid samples. The authors have previously reported on an induction furnace for the direct determination of trace elements by atomic-absorption spectroscopy using the solid sample directly.[2] The results obtained were very encouraging and it was decided that further investigations on a similar atomizer should be continued. The major disadvantage of the system described previously was that, since alumina sheathing was used, the operating temperature was limited to approximately 1900°. A furnace, based on a system commonly used for vacuum fusion, and capable of operation up to 2400°, was thus constructed, and the application of this furnace to atomic-absorption spectroscopic determination of trace elements is reported.

EXPERIMENTAL

Apparatus

A diagram of the furnace is shown in Fig. 1. The carbon core consisted of a cylinder of graphite, 120 mm long and 38 mm in diameter, with a 13 mm hole bored centrally along its length to within 10 mm of one end. Light-guides, consisting of graphite tubes 75 mm long, 15 mm outside diameter and with a 6 mm bore, were positioned at each side of the core, centred on a point 50 mm from the base (closed end). Acheson e.g.w. grade graphite was used in this construction.

The core was held in a quartz tube, 130 mm long and 47 mm internal diameter, with side-arms, 50 mm long and 18 mm internal diameter to cover the light-guides. The side-arms were tapered at their ends to give a tight fit on the light-guides. The space between the graphite core and quartz sheathing was packed with insulating graphite, 300 mesh.

The core was heated by a six-turn induction coil wound round the quartz sheathing as shown in the diagram, the power to the coil being supplied by a 6 kW Radyne Induction Generator.

The whole of this was seated on an asbestos work-table and enclosed by an asbestos box which was sealed to the table with refractory cement. The box had gas inlet and outlet points so that the system could be flushed out and operated in an inert gas atmosphere. Argon was used in these experiments. "Spectrosil" windows, 40 mm in diameter, were fitted in two sides of the asbestos box, in line with the light-guides to allow the passage of light through the cell.

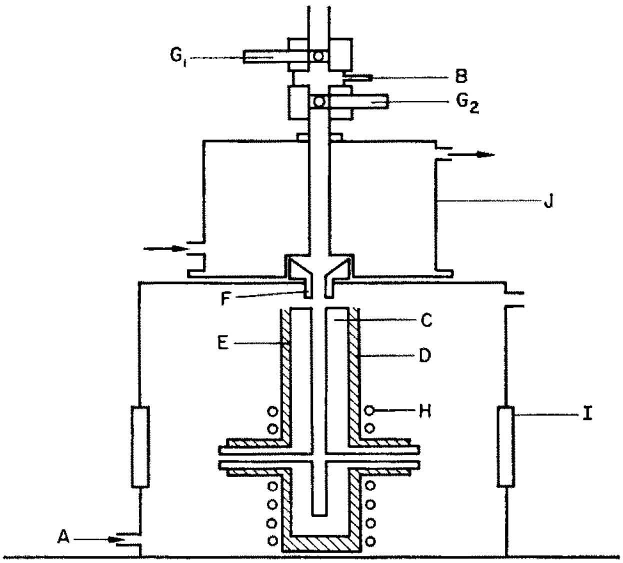

FIG. 1.—Induction-heated graphite furnace for atomic-absorption spectroscopy. *A*, Argon inlet; *B*, argon inlet; *C*, graphite core; *D*, quartz sheath; *E*, graphite insulation; *F*, graphite funnel; G_1 and G_2, Econ-O-Miser ball valves type 44/46/T (Worcester Valve Co. Ltd.) of 13-mm nominal bore; *H*, induction coil; *I*, "Spectrosil" windows; *J*, aluminium cooling jacket with cold water circulating through it.

Samples were introduced into the furnace from above *via* a double valve arrangement which prevented the introduction of air along with the sample. A graphite funnel was positioned in the top of the asbestos box, directly above the bore in the graphite core, to guide the samples into the hot core. A hollow aluminium cooling unit was designed to fit under the valves and over the graphite funnel, and was secured to the lid of the asbestos box. This was necessary to prevent heat from the furnace destroying the Teflon valve seats and seals.

Radiation was provided by electrodeless discharge tubes. These were powered by a Microtron 200 microwave generator, fitted with a voltage stabilizing unit and frequency modulator unit operating at 50 Hz. A Unicam SP 90 atomic-absorption spectrophotometer was used as detector and amplification unit, the output signal being obtained on a Honeywell 10 mV recorder, fast-response type.

Preliminary investigations

To obtain maximum sensitivity of the atomic-absorption determination when using a system such as that described above, it is necessary, particularly when a peak-height method of absorbance measurement is used, that all the atoms of the element of interest appear in the light-path in a short period of time. Thus when solid samples were used, sensitivity was expected to be dependent upon the furnace temperature, and preliminary experiments were carried out to investigate this point. These indicated that the optimum temperature is one just above the boiling point of the matrix element, provided the element of interest is also volatile at this temperature.

Should the element to be determined be less volatile than the matrix element, a temperature just above the boiling point of the trace element should be used. When the matrix element is not in the gaseous phase at the maximum temperature of the furnace, suitable calibration graphs can still be obtained provided that the matrix element is molten and the element of interest is volatile.

A similar series of experiments was carried out to investigate the effect of varying the argon gas flow. Maximum sensitivity was obtained when the argon flow was stopped just before introduction of the sample into the furnace, the flow being restored after the peak, to flush metal vapour from the cell.

General procedure

The argon flow through inlet *A* was adjusted to 10 l./min to flush out the system. The Radyne generator was adjusted to bring the furnace to a suitable temperature and the argon flow was adjusted to 7 l. min. Valve G_1 was opened and a sample was introduced into the sample tube (see Note).

Argon inlet *B* was opened and a flow of 2 l. min was used to flush out air from the sample tube. Valve G_1 and argon inlet *B* were then closed.

The controls of the SP 90 were adjusted to give a transmission setting of 100% on the recorder. The argon supply was stopped by closing argon inlet *A*, and valve G_2 was opened and closed quickly to allow the sample to fall into the "well" furnace. After recording of a minimum transmission reading, argon inlet *A* was opened and an argon flow of 7 l. min was used to flush out the system.

Once the base-line for 100% transmission had again been achieved, the procedure was repeated for the next sample.

Note. In analysis for trace elements directly on solid samples, small pieces of the materials under study (mg samples) were introduced into the furnace. These materials were alloys which contained traces of elements of which the concentrations had been determined by well-established analytical methods. For solution analysis, small volumes were dispensed by micrometer syringe and were collected on carbon pellets 6 mm in diameter and 3 mm in depth. After evaporation of the solvent, to produce a solid deposit of the salt, the carbon pellets were added to the furnace as described above. Standard solutions of the metals were prepared by dissolving the metals in nitric acid.

RESULTS

Calibration graphs for the determination of cadmium in zinc-base alloys (curve *A*) and solutions (curve *B*), using the 228·8-nm line and furnace temperatures of 1050° and 2300° respectively are shown in Fig. 2. A temperature of 2300° was used to ensure dissociation of any molecular species of cadmium formed from cadmium nitrate. The sensitivities (1% absorption values) calculated from these graphs were 0·40 ng for cadmium from zinc-base alloys and 0·62 ng for cadmium from solution. As 5-mg samples of zinc-base alloys were used, the 1% absorption value for cadmium in zinc-base alloys corresponds to a concentration of 0·08 μg/g.

Calibration graphs for the determination of bismuth in lead-base alloys, stainless steels, cast irons and solutions are shown in Figs. 3 and 4 respectively. The resonance

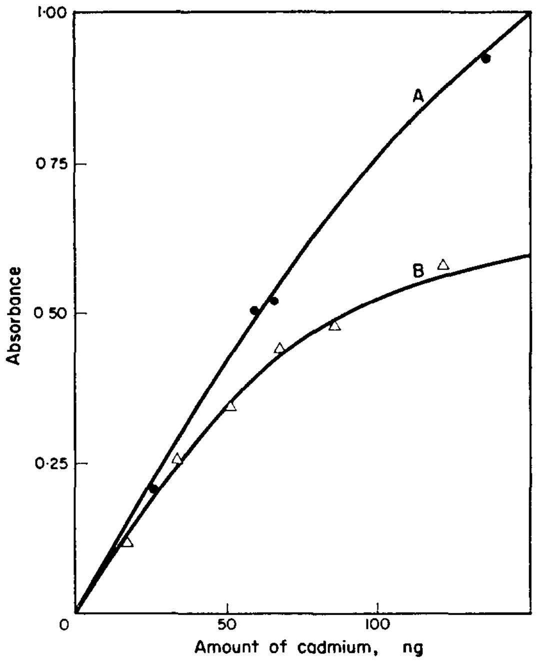

Fig. 2.—Calibration graphs for the determination of cadmium in (*A*) zinc-base alloys and (*B*) solutions.

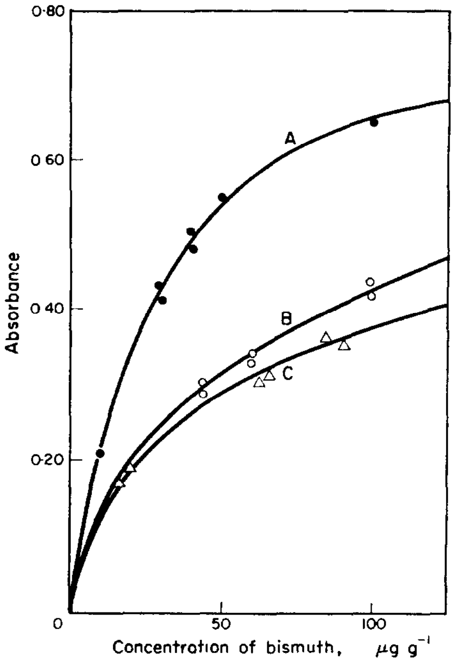

FIG. 3.—Calibration graphs for the determination of bismuth in (*A*) lead-base alloys; (*B*) stainless steels and (*C*) cast irons.

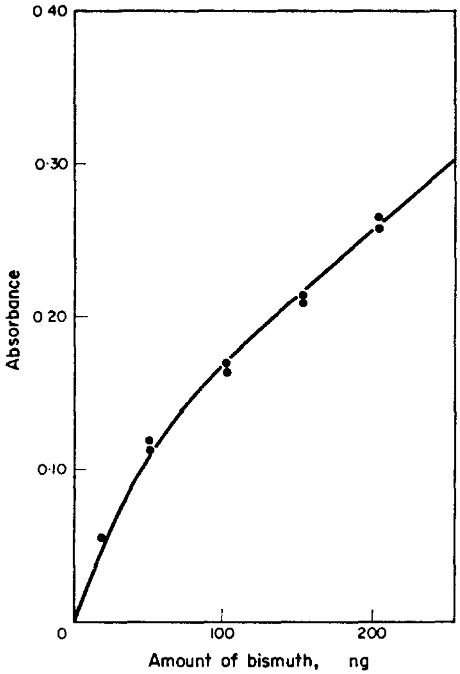

FIG. 4.—Calibration graph for the determination of bismuth in solution.

line at 306·8 nm was used in all cases. A furnace temperature of 1775° was employed for the lead-base alloys, all other determinations being carried out at 2400°. All the graphs in Fig. 3 have been obtained for solid samples and the abscissa conveniently shows the concentration of bismuth (μg/g) in the 6-mg samples used. The 1% absorption values calculated from the calibration graphs were 0·24 μg/g for bismuth from lead-base alloys, 0·30 μg/g for bismuth from stainless steels and 0·33 μg/g for bismuth from cast irons. Since the weights of sample used were 6 mg, these 1% absorption values correspond to amounts of bismuth of 1·4 ng for lead-base alloys, 1·8 ng for stainless steels and 2·0 ng for cast irons. By comparison the 1% absorption value for bismuth from solution, calculated from Fig. 4, was 1·4 ng.

Accuracy and precision data obtained for the determination of bismuth in lead-base alloys and cast irons, together with corresponding figures for the determination of cadmium in zinc-base alloys are summarized in Table I. In order to obtain these results, a sample of the appropriate alloy, not used in the preparation of the calibration graph, was analysed a number of times by the procedure given, the concentrations being read off the calibration graph.

TABLE I.—ACCURACY AND PRECISION OF ANALYSES USING GRAPHITE INDUCTION FURNACE

Determination	No. of samples analysed	Concentration of trace element determined μg/g		Relative standard deviation %
		This method	Independent method	
Bi in lead-base alloy	10	43	40	8·1
Bi in cast iron	10	66	63	8·1
Cd in zinc-base alloy	6	12·7	13·0	3·6*

* These samples were weighed on a semimicro 5-place balance; other samples were weighed on a 4-place laboratory balance.

DISCUSSION

The results obtained for the determination of bismuth and cadmium in various matrices were considered to be satisfactory, the accuracy and precision of the determinations using the graphite "well" furnace being quite comparable with those obtained by other workers on furnace systems. As indicated in Table I, weighing errors can account for a considerable proportion of the error and, if more sensitive balances are used, the precision can be improved.

All the calibration graphs are curved, and this is thought to be due mainly to a sluggish response of the amplification system to a rapidly changing signal. This becomes particularly noticeable when a peak-height method of absorbance measurement is used. Since distortion of the peak height will increase as the height of the peak increases, curved calibration graphs result.

The decrease in sensitivity of bismuth determination from lead-base alloys to cast irons and stainless steels is due to the use of a peak-height method of absorbance measurement. Since the maximum temperature available was not above the boiling point of the base element in the last two types of sample, vaporization of the trace element of interest was not so rapid. The absorption peaks were shallower and broader than those obtained with the more volatile base materials. Use of an integration method of absorbance measurement would probably overcome this lack of sensitivity.

Although the sensitivities obtained by using the graphite "well" furnace are not so good as those obtained with the horizontal furnace described previously,[2] it is felt that this furnace does have a future. It appears particularly useful for the determination of trace elements at the ppm level, using the solid sample directly.

Initial determinations of tin at the ppm level in lead-base alloys and aluminium-base alloys have also been carried out successfully. The furnace appears suitable for the determination of many elements, including Ag, As, Ca, Hg, Mg, Mn, Pb, Sb and Zn, in a wide range of matrices. Whilst the accuracy and precision values so far obtained by this technique may not be acceptable for the most exacting determinations at the ppm level, the technique could prove very useful as an analytical tool for rapid semi-quantitative analysis.

Acknowledgements—One of the authors (D. R. S.) thanks the Science Research Council for a Studentship to undertake this work. The authors are indebted to B.I.S.R.A. and B.C.I.R.A. for provision of samples and to Mr. W. R. Nall of Bragg Laboratory, Sheffield for discussion in connection with certain samples.

Zusammenfassung—Ein an ein Unicam SP 90-Atomabsorptionsspektrometer gekoppelter Graphit-Induktionsofen wird beschrieben, der zur direkten Bestimmung von Spurenelementen in Metallen und Legierungen dient. Der Ofen kann bei Temperaturen bis 2400° betrieben werden und wurde verwendet zur Aufstellung von Eichkurven zur Bestimmung von ppm-Mengen Wismut in Legierungen mit Blei als Grundmetall und zur Bestimmung von Cadmium im ppm-Bereich in Legierungen auf Zinkbasis. Milligramm-Proben der Legierungen wurden direkt in den atomaren Zustand überführt. Zum Vergleich wurden Eichkurven zur Bestimmung der Elemente in Lösung aufgenommen. Genauigkeit und Richtigkeit der Bestimmung werden angegeben un diskutiert.

Résumé—On décrit un four de graphite chauffé par induction et couplé à un spectromètre d'absorption atomique Unicam SP 90 pour le dosage direct de traces d'éléments dans les métaux et alliages. Le four est capable d'opérer à des températures allant jusau'á 2400°, et a été utilisé pour obtenir des courbes d'étalonnage pour le dosage de quantités de l'ordre du ppm de bismuth dans des alliages à base de plomb, des fontes et des aciers inoxydables, et pour le dosage du cadmium au niveau de la ppm dans des alliages à base de zinc. Des échantillons des alliages, de l'ordre du milligramme, ont été atomisés directement. Les courbes d'étalonnage pour le dosage des éléments en solutions ont été obtenues pour comparaison. On présente la précision et la fidélité du dosage et en discute.

SEPARATION OF THE NON-VOLATILE NOBLE METALS BY REVERSED-PHASE EXTRACTION CHROMATOGRAPHY

CHRISTEL POHLANDT and T. W. STEELE
National Institute for Metallurgy, Private Bag 6, Johannesburg, South Africa

(*Received* 15 *July* 1971. *Accepted* 4 *November* 1971)

Summary—The procedure involves the use of tri-n-butyl phosphate (TBP) adsorbed by Porasil C and stepwise elution with sulphuric acid and hydrochloric acid. The distribution coefficients for the two systems (TBP and hydrochloric acid and TBP and sulphuric acid) and the elution characteristics were studied. A description is given of a procedure applicable to the analysis of prills obtained from the fire assay of platinum-bearing ores.

ION-EXCHANGE[1–4] and chromatographic techniques[5,6] have been applied in the search for better and faster separation methods for multicomponent mixtures of the noble metals. A useful contribution in this field has been the work of Kember and Wells,[7] who describe the separation of microgram amounts of platinum, palladium, rhodium and iridium by chromatographic procedures on paper strips. James[8] examined their procedure for the separation of platinum and palladium, and, after making modifications to the apparatus, applied the method to the separation of platinum and palladium in silver prills obtained from ore samples by the conventional fire-assay technique.

This procedure and a modified procedure of Kember and Wells for rhodium and iridium[9] were applied at the National Institute for Metallurgy to the analysis of prills obtained from the fire assay of samples of ore from the Merensky Reef. Although the results obtained for platinum and palladium compared favourably with the results obtained by atomic-absorption methods, the procedure was found to be tedious and time-consuming. Moreover, the very small amount of sample solution that could be applied to a paper strip often made the determination of rhodium and iridium in low concentrations very difficult.

Because of these disadvantages, it was decided to explore the related technique of reversed-phase extraction chromatography (RPEC). This technique combines the selectivity of many organic extractants with the multistage character of chromatography, and should be applicable to the separation of noble metals from one another and from base metals. Columns permit the use of much larger volumes of sample solution, thus facilitating the determination of the separated noble metals.

From reviews published by Eschrich and Drent[10] and by Cerrai and Ghersini,[11] it is apparent that a number of papers on the separation of the noble metals have been published. It was decided that the use of tri-n-butyl phosphate (TBP) as a stationary phase should be investigated. Contradictory statements had been made, particularly about R_f values for the noble metals in the system TBP and hydrochloric acid.[12–15] The distribution coefficients for noble metals and for several base metals commonly associated with noble metals in ores and concentrates were therefore determined under conditions appropriate to RPEC on columns by use of the TBP and hydrochloric acid system. The distribution coefficients for the system TBP and sulphuric acid were also determined. These determinations were followed by extensive elution studies in an attempt to achieve a separation of platinum, palladium, rhodium, iridium and gold, and to develop a working procedure applicable to cupellation prills obtained from the fire assay of ores, to hydrochloric acid solutions of the noble metals obtained from the dissolution of tin and nickel sulphide buttons, and to acid extracts and concentrates of samples from the Merensky Reef.

EXPERIMENTAL

Standard solutions of noble metals

Standard solutions of platinum (10·0 mg/ml) *and palladium* (1·0 mg/ml). Prepared by dissolution of the metals in *aqua regia*. After evaporation and repeated treatment with hydrochloric acid, the residues were dissolved in 50% v/v hydrochloric acid.

Standard gold solution, 1·0 *mg/ml.* Prepared by dissolving gold in *aqua regia.*

Standard solutions of rhodium, iridium, ruthenium, and osmium were prepared by dissolution of an amount of their "Specpure" ammonium salts representing 0·1000 g of the metal, in a mixture of hydrochloric acid and nitric acid. After removal of the nitric acid by repeated treatment with concentrated hydrochloric acid, the salts were dissolved in 50% v/v hydrochloric acid to give solutions containing 1·0 mg of metal/ml. The composition of the ammonium salts of rhodium, iridium and ruthenium is not strictly stoichiometric, and the percentage of the metal in the salt was determined after reduction of a known amount of salt to the metal with burning hydrogen. From the weight of metal obtained, its content in the salt was calculated.

Determination of the noble metals

It was found convenient to monitor the elution during chromatographic separations by continuous photometric measurement of the eluate. A Zeiss spectrophotometer (model PMQII) and a "Rikadenki" recorder were used for this purpose, and the absorbance was measured at 300 nm. Although the sensitivity for iridium was poor, rhodium, platinum and palladium were readily detectable.

This detection method is not selective for the platinum-group metals, but it served as a useful indication of changes in the concentration of an individual metal in the eluate, thereby considerably reducing the time required for the subsequent analysis.

Platinum in individual eluate fractions was determined by measurement of its tin(II) chloride complex[7] at 403 nm. Palladium was determined photometrically with thioglycollic acid,[7] and gold in inorganic and organic solutions was measured by atomic-absorption spectrometry. Rhodium in sulphuric acid solutions was determined by a modified method of Khattak and Magee,[16] based on the formation of the yellow rhodium(III)–tin(II) chloride complex in concentrated hydrochloric acid, followed by the extraction of this complex into an amine solution and the measurement of the organic phase at 415 nm. This extraction method effectively eliminates interference by base metals, 1-mg amounts of the following ions having been tested and found not to interfere: iron(III), lead, nickel, copper(II), and cobalt(II). Sulphate, chloride and nitrate do not interfere.

The method used for the photometric determination of iridium in hydrochloric acid solutions is a modification of that developed by Ayres and Bolleter,[17] in which leuco-Crystal Violet is oxidized to its coloured form by iridium(IV).

Distribution coefficients

Kel-F powder was used as the inert support for TBP for the determination of the distribution coefficients. However, because Kel-F powder was found to vary in absorption properties and appearance from batch to batch, it was replaced by Porasil C for the subsequent elution studies.

The solvent capacity of the different supports was determined by a standard method proposed by Pietrzyk.[18] Different batches of Porasil C absorbed 43·6–44·0% of the TBP, compared with the 1·6–35·0% absorbed by Kel-F powder. In later experiments Porasil C having a TBP content of 25% by weight was used on the assumption that the E_{a}° values would not be altered by the change of support. The mixture had the properties of a dry, free-flowing powder, whereas Kel-F powder containing the same amount of TBP was a sticky mass. The TBP-treated Kel-F powder was mixed with the extractant dissolved in chloroform and the chloroform was allowed to evaporate.

Aliquot portions (10 ml each) of standard solutions containing 100–500 ppm of metal and varying concentrations of hydrochloric and sulphuric acids were shaken with 1 g of TBP-treated Kel-F powder in a stoppered glass bottle for 3 hr. After equilibration the aqueous phase was analysed, and the distribution coefficients were calculated according to the equation:

$$E_a^\circ = \frac{\text{concentration of metal in organic phase} \times \text{vol. of solution}}{\text{TBP-treated Kel-F powder (g)} \times \text{concentration of metal in aqueous phase}}.$$

To determine the time needed for equilibrium to be reached, 10 ml portions of 6*M* hydrochloric acid, containing 100 ppm of platinum, were shaken with treated Kel-F for 0·5–8 hr. Constant results were obtained after 2 hr.

The concentration of metals in the aqueous phase was determined by atomic-absorption spectrometry, spectrophotometry (iridium) and isotopic measurements (osmium, ruthenium and silver). The distribution coefficients for the noble metals for the system TBP and sulphuric acid were determined, where necessary, in the presence of trace amounts of hydrochloric acid to prevent losses by precipitation. For osmium and ruthenium, the respective chloride tracer was added to the sulphuric acid solutions. In an attempt to ensure that the noble metals were in their oxidized state, solutions were used that had previously been oxidized with sodium chlorate. The results are given in Table I.

Platinum(IV) and osmium have almost identical distribution coefficients and are thus not separable. However, it should be possible for these metals together to be separated from the other four platinum-group metals when hydrochloric acid (3–6*M*) is used as eluent. Rhodium and palladium cannot be separated, but both metals could perhaps be separated from iridium with hydrochloric acid ranging from 3 to 5*M* if the column were long enough. As aluminium, chromium, cobalt, nickel, copper and manganese are only very slightly retained, they can be separated from iron, gold, osmium, platinum and iridium. The platinum-group metals can be separated from gold by elution with 1–11*M* hydrochloric acid.

Distribution coefficients for the platinum-group metals in sulphuric acid (Table II) are distinctly higher than in hydrochloric acid solutions, and separation factors between the individual noble metals differ sufficiently for separation to be made. Gold has distribution coefficients higher than 10^4 and can therefore easily be separated from all the other noble metals. The base metals, including iron and tin, are not significantly retained and can be separated from all the noble metals with the possible exception of rhodium and ruthenium.

Although R_f values are not strictly comparable with E_a° values, it is noted that the values in Table I do not agree with the R_f values obtained by Bark *et al.*[12] for osmium, molybdenum, silver and to a lesser extent, palladium. The values in this table also do not correspond with the R_f values quoted by Volynets *et al.*,[15] who give values of 0·07 and 0·06 for platinum and iridium with 4*M* hydrochloric acid as the mobile phase. Similarly our values show that rhodium and palladium could not be separated on a column with 4–5*M* hydrochloric acid, which is contrary to Bark *et al.*[13] and Volynets *et al.*[15] The low E_a° value for platinum in 9*M* hydrochloric acid in Table I does not agree with the zero R_f value given by O'Laughlin[14] for platinum on TBP-treated paper with 9*M* hydrochloric acid as the mobile phase.

However, the results presented in Tables I and II are in good agreement with the liquid-liquid-extraction results published by Ishimori *et al.*[19] for both hydrochloric acid and sulphuric acid solutions. The few exceptions—mainly for the noble metals—may be due to different oxidation states of the noble metals.

Elution studies

To verify the conclusions drawn from the distribution coefficients, elution studies with mixed noble-metal solutions on columns 10 cm in length were carried out. Since one of the objectives of the project was to develop a separation technique applicable to prills obtained by fire assay, ruthenium and osmium were omitted from all further experiments; they would be volatilised during dissolution and evaporation of samples with *aqua regia* in the presence of an oxidizing agent. As can be seen from Fig. 1, when 5*M* hydrochloric acid was used as the eluent, palladium and rhodium were readily eluted together, and were thus separated from platinum and iridium, which move much more slowly. Although an oxidizing agent (sodium chlorate) had been added to the hydrochloric acid solution and the platinum(IV) was expected to be eluted after the iridium, the platinum was eluted first. The platinum behaved as if it were in the reduced state and moved in accordance with the distribution coefficients for platinum(II). It appears that, in the absence of an oxidizing environment and possibly because of reducing impurities in the TBP-treated Porasil C, the platinum(IV) can be reduced after it has been transferred to the column. This hypothesis is supported by the observation that platinum(II) in hydrochloric acid solution moves at the same rate as platinum(IV) under the conditions described. When 4*M* sulphuric acid was used as the eluent, rhodium was clearly separated from the other metals, and platinum and iridium both showed extensive tailing (Fig. 2). All attempts to achieve better resolution of the peaks and less tailing were unsuccessful. These attempts included variations in

TABLE I.—E_a° VALUES OF METAL CHLORIDES FOR THE SYSTEM TBP AND HYDROCHLORIC ACID

Metal	Acid concentration, *M*

the flow-rate, the acid concentration of the eluent, the length of the column, and the amount of oxidizing agent (sodium chlorate) both in the sample solution and in the eluent.

From the two systems studied it became clear that the non-volatile noble metals could not be separated by the use of a single acid system. However, a combination of two systems, *i.e.*, the introduction of stepwise elution on a column bed 30 cm in length, produced the elution curves shown in Fig. 3. Rhodium (and base metals) were sharply separated from palladium by elution with 4*M* sulphuric acid, and palladium was completely separated from platinum by elution with 5*M* hydrochloric

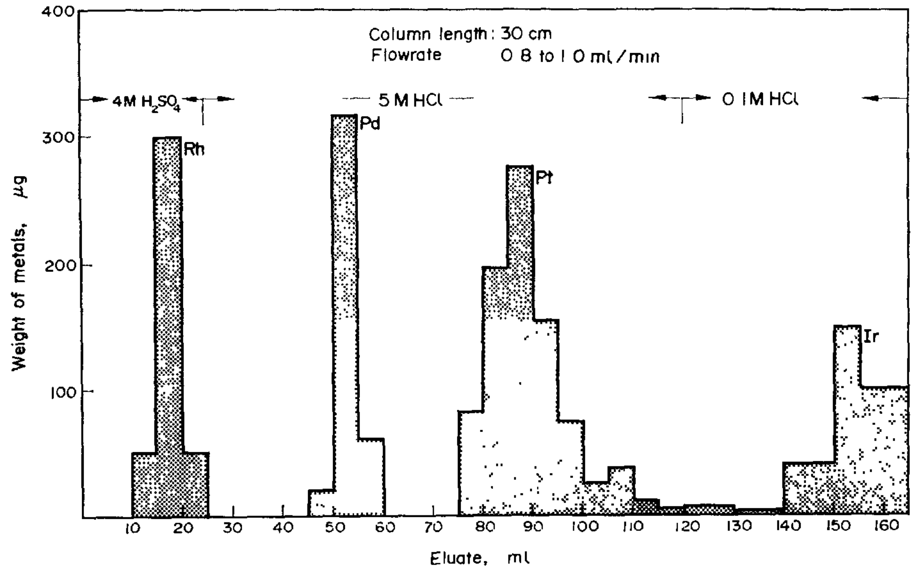

FIG. 3.—Reversed-phase chromatographic separation of the platinum group metals.

acid. After elution of the platinum with 5*M* hydrochloric acid, the iridium was eluted with 0·1*M* hydrochloric acid to increase its elution rate. Gold was completely separated from all the other metals and remained on the column.

Because the elution peaks of platinum and iridium were clearly separated when 5*M* hydrochloric acid was used as eluent, it was thought that a complete separation could be achieved by the variations previously attempted to achieve better resolution of the peaks. However, platinum invariably formed two bands (Fig. 4); the first—probably platinum(II)—representing 90–95% of the platinum present, moved considerably faster than the iridium, the second—probably platinum(IV)—moved at a slower rate than the iridium. Iridium, in the absence of platinum, formed two bands that moved at a much slower rate than platinum and could conveniently be eluted together with 0·1*M* hydrochloric acid. In the presence of platinum, it formed a third band, which was eluted in the fraction containing the bulk of the platinum. The amount of iridium in this fraction represented between 5 and 20% of the total iridium, depending on the amount of platinum present. It was thus concluded that the presence of the one metal affected the behavior of the other.

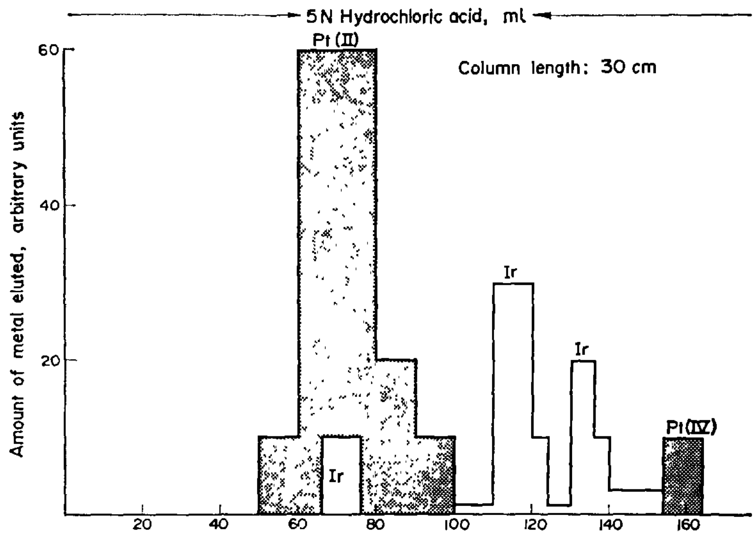

FIG. 4.—Elution of platinum and iridium under oxidizing conditions.

In an attempt to inhibit the formation of overlapping bands, varying amounts of oxidizing agents were added to the sample solution and to the eluent. Only sodium nitrate, added in milligram amounts, eliminated these effects for platinum, possibly because the platinum(IV) was reduced to platinum(II) by traces of nitrite impurities. The addition of nitrate had no effect in the presence of iridium, but it suggested that the presence of reducing agents might be beneficial.

Separation of platinum and iridium under reducing conditions

Platinum and iridium in a mixed solution of hydrochloric and sulphuric acids (2·5*M* and 4*M* respectively) were reduced with either sodium nitrite or sodium sulphite before the chromatographic separations, 5*M* hydrochloric acid being used as the eluting agent. Iridium under reducing conditions moved considerably faster than platinum, which apparently was not affected. However, the recovery of iridium in the eluate, when nitrite was used as reducing agent, was found to be poor and not reproducible. The addition of sodium sulphite to the sample solution gave a quantitative separation of iridium from platinum (Fig. 5).

After elution of the iridium with 5*M* hydrochloric acid, the platinum can be eluted with water to increase its elution rate. The effect of varying amounts of sulphite is shown in Table III. To ensure an excess of sulphite, it was decided that 20 mg of sodium sulphite should be added to the solution.

Separation of gold

After separation of the base metals and platinum-group metals from gold by separate elutions with 4*M* sulphuric acid, 5*M* hydrochloric acid, and 0·1*M* hydrochloric acid, the gold can be eluted from the column with 14*M* nitric acid.[20] Since this approach is unpleasant and time-consuming and

reduces the life of the column because of losses of TBP, it was considered advisable to conduct the separation of gold on a separate small column. That the recovery of gold is quantitative under these conditions is shown in Table IV.

Amounts of metals that can be separated

Varying ratios of non-volatile noble metals in a mixed acid solution were tested. The minimum amount of an individual metal required for separation depended on the sensitivity of the subsequent detection method, *i.e.*, 5 *μg* for platinum, rhodium, iridium, and gold, and 3 *μg* for palladium. The maximum amount that can be separated depends first, on the solubility of the individual metal in a given amount of sample solution, and secondly on the width of the band occupied by that metal on the column.

Up to 3 mg of rhodium can be separated on a column 30 cm in length from milligram amounts of palladium, platinum, iridium and gold. The amount of palladium that can be separated from platinum depends on the band width of the latter. With increasing amounts of platinum, the retention time decreases, *i.e.*, the elution peak shifts towards that of the palladium. However, 1 mg of palladium can be separated from 5 mg of platinum. The amounts of iridium and platinum that have

100	95(±1·5)		

been tested under reducing conditions in the presence of 20 mg of sodium sulphite are shown in Table V. The recoveries are generally satisfactory when considered in relation to the errors associated with the methods of determination.

Relatively large amounts of gold (up to 20 mg/g of TBP-treated Porasil C) can be separated from all the other metals tested when these are eluted with 0·1*M* hydrochloric acid.

The effect of other variables

When the total amount of noble metals does not exceed 1500 μg, the amount of solution that can be applied to the column is not critical. However, in the separation of unknown amounts of noble metals, a volume not larger than 2 ml was maintained so that the peak-width for the metals to be separated would not be affected.

The presence of hydrochloric acid in the original solution was found to be necessary to ensure the dissolution of the combined noble-metal salts in 4*M* sulphuric acid. However, hydrochloric acid concentrations from 1 to 5*M* in the total amount of solution did not affect the course of separation, and the concentration was conveniently maintained at 2·5*M* in all experiments.

An initial flow-rate of 1 ml/min was maintained, but, since the flow-rate of the eluate was found not to be critical in stepwise elution, separations were done at the maximum speed for the column (approximately 2·5 ml/min).

Although the life span of a column used for the separation of noble metals under oxidizing conditions has not been thoroughly tested, columns have been used for fifteen successive separations without any deterioration. Columns for the separation of iridium from platinum under reducing conditions have been used ten times in succession.

Recommended procedure

The method[21] derived from this experimental work is summarized in Fig. 6. It should be observed that the sample solution is free from nitric acid and that the columns are preconditioned with the first acid solution to be used. Gold present on the column used for the separation of rhodium and palladium does not interfere with subsequent separations unless it accumulates to such an extent that the capacity of the column bed is considerably reduced. On a 3-cm column, to avoid incomplete recovery of the gold, owing to reduction, the gold must be extracted as quickly as possible with methyl isobutyl ketone (MIBK).

Approximately 12 hr are needed for all the procedures, including the quantitative determination of the individual noble metals. Exhausted columns can be reconditioned by removal of the organic phase with carbon tetrachloride and fresh treatment with TBP.

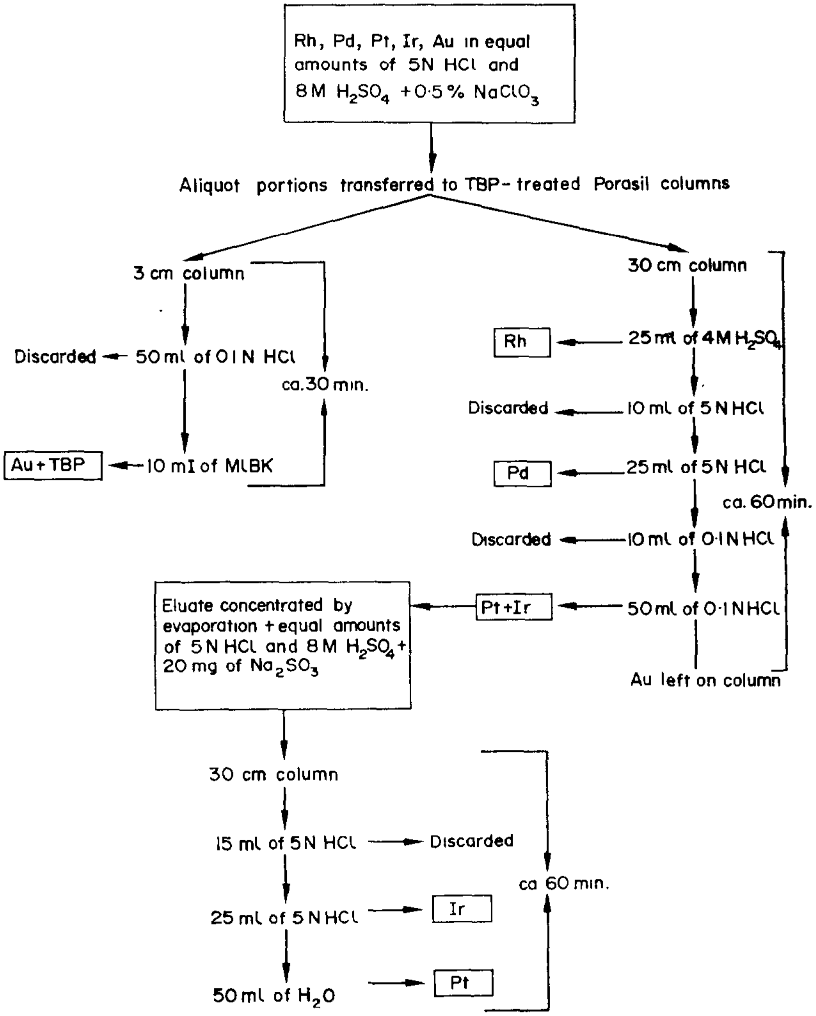

FIG. 6.—Separation of non-volatile noble metals by reversed-phase extraction chromatography.

Application of the method to ore samples

Since the results on synthetic solutions were satisfactory, the separation procedure was applied to the analysis of ore samples. Prills obtained from the fire assay of ores by the lead-collection procedure were dissolved in *aqua regia* or by chlorination in a sealed tube.[21]

Prills that were dissolved in *aqua regia* under atmospheric pressure were gently heated on a hot-plate. The solutions were then evaporated and the residues repeatedly treated with concentrated hydrochloric acid, being evaporated to a moist state after each addition of acid. After final evaporation to a moist state and the addition of 0·5 ml of 5*M* hydrochloric acid, 0·1 ml of a 5% solution of sodium chlorate, and 0·5 ml of 8*M* sulphuric acid, the solutions were ready for chromatographic separation.

Prills that were not readily dissolved under atmospheric pressure were transferred to glass tubes and, after the addition of 2 ml of concentrated hydrochloric acid and 6 drops of fuming nitric acid, the sealed tubes in a steel jacket were heated in an oven to 275° and were kept at this temperature overnight. After being cooled, the solutions were evaporated and from then on treated as described for the dissolution of prills with *aqua regia*. The total amount of sample solution or, when gold was determined in addition to the platinum-group metals, an aliquot portion of the suitably diluted sample solution, was transferred to the column, and the noble metals were separated and determined as described.

The results obtained for different sets of prills of a typical sample of Merensky Reef ore are shown in Table VI, together with comparative results from atomic-absorption spectroscopy. It should be borne in mind that the collection technique used for obtaining the prills is subject to errors and that the RPEC results are therefore not strictly comparable with the atomic-absorption results. Nevertheless, the agreement for platinum, rhodium and gold and, to a lesser extent, for palladium, is very satisfactory.

CONCLUSIONS

Rhodium and palladium can be separated from each other and from the other non-volatile noble metals on a TBP-treated Porasil C column by stepwise elution with $4M$ sulphuric acid and $5N$ hydrochloric acid. Platinum and iridium are eluted together with $0.1M$ hydrochloric acid and separated on a second column under reducing conditions. Gold is collected on a third column, from which it is extracted with MIBK.

Noble metals in widely varying ratios have been separated. The analyses of a sample of ore from the Merensky Reef gave results that compare favourably with those obtained by atomic-absorption spectrometry.

Because of the success of the separation for non-volatile noble metals and because the column can be regenerated, the process could be considered for industrial use.

Acknowledgement—The authors wish to thank Mrs. M. Ewen and Mrs. A. Gereghty for competent technical assistance and the Director of the National Institute for Metallurgy for permission to publish this paper.

Zusammenfassung—Das Verfahren beruht auf der Verwendung von an Porasil C adsorbiertem Tri-n-butylphosphat (TBP) und die stufenweise Elution mit Schwefelsäure und Salzsäure. Die Verteilungskoeffizienten der beiden Systeme (TBP und Salzsäure sowie TBP und Schwefelsäure) und ihre Elutionseigenschaften wurden untersucht. Ein Verfahren wird beschrieben, das man zur Analyse von Reguli aus der Schmelzaufbereitung platinführender Erze verwenden kann.

Résumé—La technique comprend l'emploi de tri-*n*-butyl phosphate (TBP) adsorbé sur Porasil C et l'élution graduelle à l'acide sulfurique et à l'acide chlorhydrique. On a étudié les coefficients de partage pour les deux systèmes (TBP et acide chlorhydrique et TBP et acide sulfurique) et les caractéristiques d'élution. On décrit une technique applicable à l'analyse des boutons obtenus dans l'essai par voie sèche de minerais contenant du platine.

DETERMINATION OF TRACE AMOUNTS OF URANIUM IN SILICATE MINERALS BY THE FISSION TRACK TECHNIQUE

HIDEKI MATSUDA, YUTAKA TSUTSUI, SHIGENORI NAKANO and SHUNJI UMEMOTO
Department of Chemistry, Faculty of Science, Kyushu University,
Hakozaki, Fukuoka, Japan

(*Received* 30 *August* 1971. *Accepted* 14 *October* 1971)

Summary—The fission track technique has been applied to the determination of uranium on Dowex 1 × 8 after chemical separation from silicates. Standard rock and several stone meteorite samples were treated by this method and satisfactory results were obtained. The procedure is applicable to natural waters.

IN RECENT YEARS, application of the fission track technique has been developed in the field of nuclear physics, neutron dosimetry, cosmochemical studies and geochronology.[1] Fission tracks are produced in several insulating solid materials such as micas, glasses and plastics. So far, the application of this technique to uranium determination has been carried out by few investigators. Hashimoto[2] examined the sensitivities of detection for the actinide elements with neutron-induced fission tracks, and found that ^{235}U is the most sensitive of the nuclides examined and $6{\cdot}24 \times 10^{10}$ fission events are available from 1 μg of this isotope by thermal neutron irradiation of $4{\cdot}21 \times 10^{14}$ n/mm^2. However, ^{238}U and ^{232}Th also gave $3{\cdot}2 \times 10^7$ and $1{\cdot}75 \times 10^6$ fission events per μg. Fleischer[3] observed the uranium distribution in the silicate minerals of several stony meteorites by the fission track method and found a tremendous variation of uranium content within a small area. The uranium contents were determined by the mapping procedure and were found to be different from the previous values in a few cases. On the other hand, by neutron-activation analysis,[4] the present authors found a different distribution pattern, from chondrite to chondrite, of uranium in the silicate minerals of several stony meteorites. The uranium distribution of the Richardton chondrite showed an unexpected pattern, that is, only 20–30% of the uranium was found in the hydrochloric acid soluble fraction. As about 70% was found in the same fraction of the other meteorites, a cross-check by the alternative method is desirable.

Hashimoto *et al.*[5] determined concentrations of a few ppm of uranium by a fission track method. In their experiment, a mica detector was attached to the powdered standard rock and the result showed relatively good agreement with the previous data. Bertine *et al.*[6] also determined the uranium content of homogenized powdered samples of sedimentary rocks, utilizing a digital discharge counter instead of visual counting.

All determinations of uranium by the fission track method were carried out without chemical separation of thorium and were performed on samples containing a few ppm of uranium (with the exception of Fleischer's[3]). However, since these fission track methods have relatively high back-grounds and low sensitivities for less than 1 ppm of uranium and errors arise from fission tracks produced from ^{238}U and ^{232}Th, these methods are not suitable for the determination of trace amounts (of the order of ppb) of uranium in silicate minerals or in samples of unknown thorium content.

The present authors avoided these difficulties by a simple chemical treatment followed by anion-exchange separation applied to the several standard rocks and stony meteorites.

EXPERIMENTAL

On the assumption that the fission tracks produced in micas attached to the fine grains of resin absorbing uranium are homogeneously distributed, the irradiation samples were prepared and bombarded with thermal neutrons.

The distribution coefficient of the uranyl ion between strong-base anion-exchange resins and 8*M* hydrochloric acid is about 10^3 and that for iron(III) is also fairly large, but thorium(IV) is not adsorbed on the resin under the same conditions.[7] Since iron is one of the main constituents of silicate minerals, a relatively large amount of iron will be adsorbed on the resin along with uranium unless iron is removed in advance.

Silicate samples were dissolved with hydrofluoric acid and perchloric acid in a platinum dish. The solution was made 8*M* in hydrochloric acid, and most of the iron was removed by extraction with di-isopropyl ether. Thorium was removed by anion-exchange. The uranium adsorbed on the resin column was eluted and purified. The procedure is given in Fig. 1. The purified uranium was dissolved in 2 ml of 8*M* hydrochloric acid, then 100 mg of pulverized anion-exchange resin (Dowex 1 × 8) were added to this solution, and the mixture was allowed to stand for 12 hr with occasional stirring. The resin was filtered off, and transferred into the sample holder (Fig. 2).

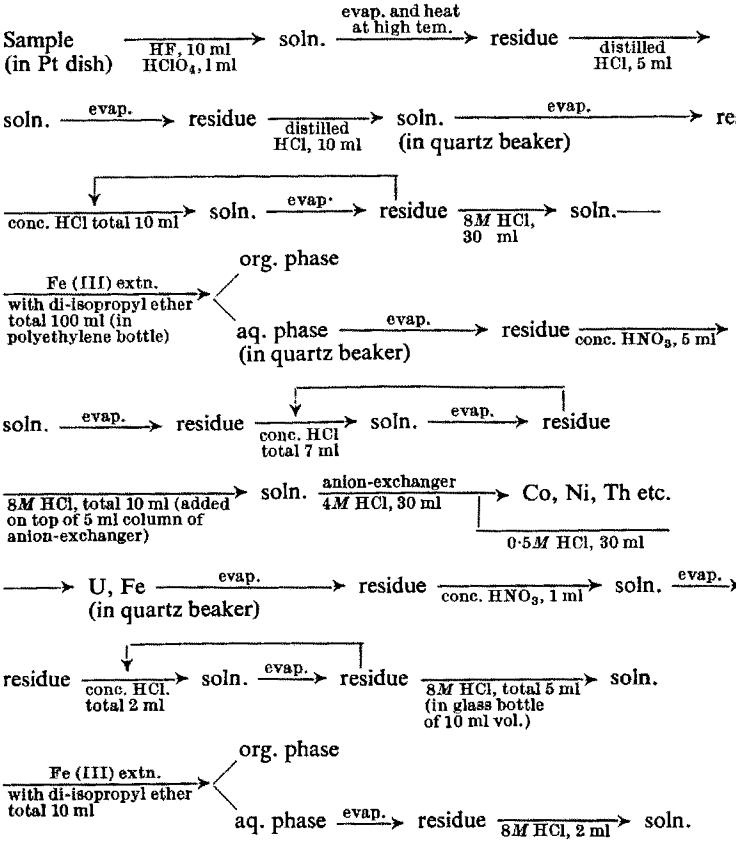

FIG. 1.—Flow-sheet of the chemical procedure used for silicate minerals and for blank test.

The sample holder and its support are square sheets of Perspex 1 mm and 5 mm in thickness having 4 mm diameter holes. A mica detector is attached to the bottom of the holder, and the support is fixed to the top of the holder, and the assembly taped together.

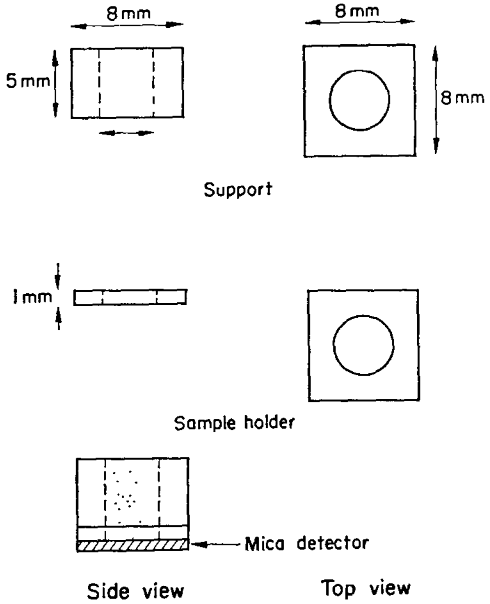

FIG. 2.—Side and top views of sample holder and support.

The resin is placed in the hole, and compacted by centrifugation. The support and excess of resin are removed and the top of the holder and the mica detector are covered with thin Perspex sheets and taped together.

An aliquot of a standard uranium solution was evaporated to dryness in a quartz beaker, and 2 ml of 8*M* hydrochloric acid were added and the solution was treated in the same way as the samples.

In order to determine the uranium content of the reagents, aliquots of demineralized water, distilled water, hydrochloric acid, distilled hydrochloric acid, nitric acid, hydrofluoric acid and di-isopropyl ether were weighed out on a Perspex plate and evaporated to dryness under an infrared lamp. A mica detector was taped to the plate.

The samples (except W-1), the reference standards(II) and the blank were placed together in a capsule and irradiated with thermal neutrons in a pneumatic tube of the KUR reactor of the Research Reactor Institute at Kyoto University. The total neutron flux was $8\cdot4 \times 10^{14}$ n/mm^2. The sample W-1, the reference standards(I), and the reagent blanks were irradiated in a different run in the same tube and the total neutron flux was $3\cdot36 \times 10^{14}$ n/mm^2.

A few days after the irradiation, all mica detectors were etched with 46% hydrofluoric acid at 20° for 30 min. The etch pits developed in each detector were counted under an optical microscope.

In each detector the density of the etch pits was measured in five different arbitrarily chosen areas and the density value was taken as the average together with the 95% confidence limits. In the reagent detectors all the etch pits were counted.

RESULTS AND DISCUSSION

The reference standards gave fairly linear working curves. The limit of detection is about 1 ng of uranium in the original sample, and the determination limit 2–3 ng.

The uranium contents of the various silicate samples were determined by using the working curves, and the results are shown in Table I. The result was obtained after subtraction of the blank including that due to the mica detectors. The Richardton meteorite samples were supplied by Honda,[20] who separated this meteorite into two fractions, white powder and black grains, the amounts in both fractions being similar. Each of these two fractions was further divided into a hydrochloric acid soluble and a hydrochloric acid insoluble fraction (5*M* hydrochloric acid). The former is designated as HCl and the latter as HF in Table I. The overall uranium

§ The blank was not measured.

content of the Richardton sample was calculated as the weighted mean of its content in each fraction.

Most of the uranium contents shown in Table I are in between the various values previously reported, but Allende and PCC-1 are slightly lower than the lowest. The blank value shown in Table I is thought to originate from the reagents and contamination.

The uranium contents of the reagents used are tabulated in Table II. The amount of uranium in the reagent samples is obtained by using the equation

RAPID MASS-SPECTROMETRIC DETERMINATION OF BORON ISOTOPIC DISTRIBUTION IN BORON CARBIDE

JAMES E. REIN and ROBERT M. ABERNATHEY
University of California, Los Alamos Scientific Laboratory, Los Alamos,
New Mexico 87544, U.S.A.

(*Received* 24 *August* 1971. *Accepted* 24 *October* 1971)

Summary—Boron isotopic ratios are measured in boron carbide by thermionic ionization mass spectrometry with no prior chemical separation. A powder blend of boron carbide and sodium hydroxide is prepared, a small portion is transferred to a tantalum filament, the filament is heated to produce sodium borate, and the filament is transferred to the mass spectrometer where the $^{11}B/^{10}B$ ratio is measured, using the $Na_2BO_2^+$ ion. Variables investigated for their effect on preferential volatilization of ^{10}B include the sodium hydroxide–boron carbide ratio and the temperature and duration of filament heating. A series of boron carbide pellets containing natural boron, of the type proposed for the control rods of the Fast Flux Test Facility reactor, were analysed with an apparently unbiased result of 4·0560 for the $^{11}B/^{10}B$ ratio (standard deviation 0·0087). The pellets contained over 3% metal impurities typically found in this material. Time of analysis is 45 min per sample, with one analyst.

BORON CARBIDE is a commonly used material as a burnable poison in nuclear fuels and as a neutron absorber in nuclear reactor control rods. The ^{10}B isotope with a natural abundance of 19·8 atom % provides this property because of its thermal neutron cross-section of 3840 barn. The proposed material form for the control rods of the Fast Flux Test Facility under construction at Richland, Washington for the AEC's Fast Breeder Reactor programme is compressed 1·2-g pellets of boron carbide. The analytical method described in this paper for the determination of boron isotope ratios in this material should also be applicable to all boron carbide materials with ^{10}B isotopic abundances ranging from natural to high enrichment.

As discussed in the excellent monograph by Lerner,[1] most boron materials are analysed isotopically for boron isotope ratios with thermionic ionization mass spectrometers. The ion usually measured is $Na_2BO_2^+$ from a charge material of sodium tetraborate.[2] The general scheme used to obtain sodium tetraborate is to dissolve samples either by sodium carbonate fusion or acid reflux, separate the boron as boric acid by such techniques as distillation of the methyl ester or by cation-exchange removal of metal impurities, and neutralize the separated boric acid with sodium hydroxide to pH $9·2 \pm 0·2$. All these schemes are time-consuming, especially the dissolution of boron carbide samples, and involve many reagents and operations that are potential sources of boron contamination. The mass spectrometric technique of Spitzer and Sites[3] offers the means to analyse boron carbide directly with virtually no chemical operations. In their technique, a sample of boron metal or of a boron compound is added to a tantalum filament containing a small amount of sodium hydroxide, the filament is heated to approximately 750° to produce sodium borate

---

(presumed to be sodium tetraborate), which is mass spectrometrically analysed as the $Na_2BO_2^+$ ion spectrum.

Preliminary experimentation with the Spitzer and Sites technique confirmed production of the $Na_2BO_2^+$ spectrum; however, ion production was erratic and the scans were unstable. This inconsistency was presumed to be caused by the physical difficulty of obtaining reproducible ratios of sodium hydroxide and boron carbide on the filament. Reproducible ratios are considered necessary to obtain effective fusions and conversions into sodium borate. Their technique has been made the basis of an improved method of analysis that is based on first blending weighed amounts of pulverized boron carbide and pulverized sodium hydroxide, then fusing a small portion of the blend on a tantalum filament, followed by the mass spectrometric analysis. Shields and co-workers[4] found that preferential volatilization of ^{10}B from sodium tetraborate may occur, depending on the Na/B ratio and the temperature and duration of filament heating. These three variables were studied for the development of the method described in this report.

EXPERIMENTAL

Reagents

Boron carbide. Two batches of boron carbide were used in this study. Both contained natural boron. The first, a fine powder, was used for all experiments to evaluate effects of variables. The second, a batch of well-characterized pellets prepared by the Hanford Engineering Development Laboratory (Richland, Washington), was used to establish the precision of the method and the tolerance of the method for impurities.

Sodium hydroxide, pellets, analytical-reagent grade. Powder was prepared by a 1-min pulverization with a Mixer/Mill, using stainless-steel containers and balls. The powder was stored in a desiccator. Although the laboratory atmosphere had a relative humidity of 50%, no coalescence of the powder was experienced.

Apparatus

Mixer/Mill, No. 5100: Spex Industries, P.O. Box 798, Metuchen, N.J. 08840.

Plastic mixing containers and balls. Containers were 13-mm o.d. and 25 mm long, polystyrene, with polyethylene slip-on caps (Spex No. 3111). The balls were 9-mm diam, methacrylate (Spex No. 3112).

Mass spectrometer, thermionic ionization. AVCO Model No. 90001, 0·35 m radius, 90° sector.

Filaments. Tantalum and rhenium, 30-mil wide, 1·2-mil thick.

Filament heating apparatus. Capable of preheating filaments to about 800°.

General procedure

A quantity of pulverized sodium hydroxide (fresh from the desiccator) is weighed to ±1 mg into a plastic mixing container and 25 mg of B_4C are transferred to the container with minimum exposure of the contents to air moisture. (The amount of sodium hydroxide is dictated by the desired ratio of Na/B.) A plastic ball is added, the cap is placed on the container, and the contents are blended for 1 min on the Mixer/Mill. With a stainless-steel microspatula, a portion of the blend containing about 10 μg of boron is transferred to a V-grooved tantalum filament. The filament is gradually heated just to the point where the exothermic reaction of the sodium hydroxide with the filament occurs. (This reaction is characterized by a sudden brightening of the filament.) The filament with fused sample is transferred to the mass spectrometer and the spectrum is measured for the mass range 88–89 ($Na_2BO_2^+$). A Faraday cup detector is used and 9 spectra recorded after a stabilized ion-current is attained. The $^{11}B/^{10}B$ ratio is measured and converted into atom % abundances if desired. The ^{17}O correction to the $^{11}B/^{10}B$ ratio is 0·00075.

RESULTS AND DISCUSSIONS

In the comprehensive study by Shields and co-workers,[4] who used samples of boric acid reacted both with sodium hydroxide and sodium carbonate, the measured $^{11}B/^{10}B$ ratio was shown to depend on the Na/B ratio, the filament temperature and the residence time in the mass spectrometer. In all experiments, the $Na_2BO_2^+$ ion-beam intensity was maintained at 1–2 pA, and where possible the filament current was maintained within a narrow range to yield constant filament temperatures. With sodium hydroxide reacted samples, the greatest variation in $^{11}B/^{10}B$ ratio was caused by a varying Na/B ratio. At Na/B ratios of 1/2 and 1/1, the observed $^{11}B/^{10}B$ ratios were not significantly different nor did the ratios change much with filament heating time. At a higher ratio of 2/1, the $^{11}B/^{10}B$ ratio increased by as much as 1% as well as increasing further with filament heating time and temperature. At an Na/B ratio of 4/1, the $Na_2BO_2^+$ ion-current was suppressed so much that the filament current had to be increased considerably to obtain the $Na_2BO_2^+$ ion intensity of 1–2 pA. The consequent increased temperature caused isotopic fractionation and hence the observed increase in the $^{11}B/^{10}B$ ratio. Another significant finding was an aging phenomenon with sodium hydroxide-reacted boric acid samples. When these samples were stored for two weeks before mass analysis, the solutions with an Na/B ratio of 4/1 gave the desired 1–2 pA $Na_2BO_2^+$ ion-current at a filament current almost as low as that used for the 1/2 and 1/1 Na/B ratio samples, instead of at the higher filament current noted above.

In the method proposed in this paper, the sample preparation conditions are very different from those used by Shields *et al.* The most striking difference is that the sodium hydroxide fusion reaction with boron carbide is done on the filament. As the filament temperature is raised, the sodium hydroxide forms a melt, the mixture spreads over the filament, and then fuses when the temperature rises to the point where the tantalum reacts with the sodium hydroxide. At this point, the reaction becomes highly exothermic, the filament glows brightly and a very adherent deposit forms on the filament. Preliminary experiments showed that such filament preparations gave quickly attained and stable $Na_2BO_2^+$ ion intensities. With this very different method of sample preparation, blends of boron carbide and sodium hydroxide were prepared (as described under *General procedure*) with Na/B ratios varing from 1/4 to 4/1 and were analysed for the $^{11}B/^{10}B$ ratio, using the $Na_2BO_2^+$ ion. A scan was taken as soon as stable emission was attained at an ion intensity of 1–2 pA and a second scan was taken 15–30 min later at the same ion-intensity level with the filament current left on between scans. Filament temperatures were estimated for each scan from the filament currents, based on an optical pyrometer calibration.

The results (Table I) show complete randomness with no trend of an increasing $^{11}B/^{10}B$ ratio with either an increasing Na/B ratio or filament heating time. Also, there is no trend of an increasing $^{11}B/^{10}B$ ratio with increasing filament current. It appears that the boron carbide is mainly converted into sodium borate at the time of the exothermic reaction of the sodium hydroxide with the tantalum filament. Because of these simultaneous reactions and the formation of a tightly adherent deposit, the amount of sodium hydroxide in excess of that used to form borate is reduced and decreases the Na/B ratio effect on the $^{11}B/^{10}B$ ratio. It seems unlikely that boron isotope fractionation would occur in the short time that the high-temperature reaction occurs. Indirect evidence to substantiate this belief is that the grand average $^{11}B/^{10}B$ result of 4·0465 (Table I) corresponds to 19·81% ^{10}B, which is only slightly greater than the generally accepted value of 19·78% for natural boron.

As a further test of the effect of filament heating time on the measured $^{11}B/^{10}B$ ratio, filament with a 1/1 Na/B ratio was scanned for a continuous period of 5·5 hr.

‡ Ion emission too unsteady to permit data collection.

The filament temperature was essentially constant at 700° for most of the time, increasing to about 750° at the end of the period. The results summarized in Table II show no significant trend of an increase in the ^{11}B/^{10}B ratio with time.

TABLE II.—STABILITY OF ^{11}B/^{10}B RATIO WITH FILAMENT HEATING TIME WITH A SAMPLE LOADING OF FUSED BORON CARBIDE IN SODIUM HYDROXIDE WITH A 1/1 Na/B RATIO

Time of scan, after sample insertion	Measured ^{11}B/^{10}B ratio
15 min	4·041
30 min	4·051
1·5 hr	4·043
2·5 hr	4·046
3·5 hr	4·049
4·5 hr	4·055
5·5 hr	4·052

Based on observations made in the previous experiments, the use of a 1/1 Na/B ratio is recommended for routine use. Steady $Na_2BO_2^+$ ion emission is obtained within a few minutes after pump-down (10^{-7} mbar in the source) and remains so for hours. With Na/B ratios of 1/2 and 2/1, however, the time needed to attain steady ion emission can be as long as 30 min. At 1/4 and 4/1 ratios, the obtaining of steady ion emission requires undue patience. Also at a 4/1 ratio, filament burn-outs are common, and undoubtedly caused by corrosive degradation of the filament. With a 1/1 Na/B ratio, the weight of sodium hydroxide to use in the procedure is 72 mg for the recommended 25-mg boron carbide sample.

Upon first consideration, the substitution of rhenium for tantalum filaments seemed logical. Because of the low reactivity of rhenium with sodium hydroxide, the likelihood of filament burn-out diminishes. Also with little reaction taking place, the Na/B ratio of the mixture placed on the filament is not affected. A series of six filament loadings of boron carbide–sodium hydroxide blends was prepared at a Na/B ratio of 1/1. In all cases, the instrument residence time to reach stable ion emission was greater than 30 min compared to less than 10 min for tantalum filaments. In two cases, the ion emission was still erratic after 60 min. This finding is indirect evidence that the exothermic reaction of sodium hydroxide with tantalum gives a sodium borate deposit that uniquely produces stable $Na_2BO_2^+$ ion intensities. Shields *et al.*[4] reported that tantalum filaments gave more stable ion intensities than rhenium. Also in agreement with Shields, we find that tantalum filaments do not require prebaking and that at the low temperature used for ionization of sodium borate, no strontium impurity is volatilized from the filament to cause high bias in the 88 mass peak.

The only potentially significant source of boron contamination in the proposed method is the sodium hydroxide, the only reagent used. The plastic mixing containers and balls are sufficiently inexpensive to be thrown away. Natural boron contamination in the sodium hydroxide is effectively measured by using the NBS ^{10}B-enriched boric acid (SRM952). The sodium hydroxide used in this investigation (see *Reagents*) was tested by preparing a solution in distilled water in a plastic container, mixing this solution with a solution of the NBS 952 boric acid to form a Na/B ratio of 1/1, and applying mass spectrometric analysis. The level of boron found was less than 70 μg of boron per gram of sodium hydroxide. In the proposed procedure using a 25-mg boron carbide sample and 72 mg of sodium hydroxide (Na/B ratio of 1/1), this level is equivalent to less than 1 atom of natural boron contamination per 4000 atoms of sample boron.

The method was used to analyse a series of 12 boron carbide samples selected randomly from one batch of pellets. The pellets were pulverized by hammer blows in a stainless-steel mortar and the powder fractions passing through a 100-mesh sieve were used as the samples. The general procedure was used with 25 mg of boron carbide and 72 mg of sodium hydroxide (Na/B ratio of 1/1) and V-grooved tantalum filaments. The average result for the $^{11}B/^{10}B$ ratio, corrected for ^{17}O, for the 12 samples was 4·0506 with a standard deviation of 0·0087 for a single sample analysis. The ^{10}B isotopic abundance corresponding to the average $^{11}B/^{10}B$ ratio result of 4·0506 is 19·80%.

The impurity contents of the pellets are given in Table III. There is no apparent adverse effect from these impurities, which in this method are not separated from the boron, on the $Na_2BO_2^+$ ionization process.

The 12 samples were analysed in a total elapsed time of 9 hr by one analyst, exclusive of the initial pellet pulverization.

Future studies being considered are the substitution of caesium hydroxide for

sodium hydroxide and the applicability of the method to other boron materials. The higher mass of $Cs_2BO_2^+$ should decrease any preferential volatilization effect and would also have the advantage of a smaller mass discrimination correction for those laboratories that prefer to use electron multiplier detectors. Other boron materials include the metal, the oxide, and boric acid.

Zusammenfassung—Bor-Isotopenverhältnisse in Borcarbid werden durch Massenspektrometrie mit thermischer Ionisierung ohne vorausgehende chemische Abtrennung gemessen. Ein Pulvergemisch von Borcarbid und Natriumhydroxid wird hergestellt und eine kleine Portion davon auf einen Tantalfaden gebracht. Der Faden wird geheizt, wobei sich Natriumborat bildet, und dann ins Massenspektrometer gebracht, wobei am $Na_2BO_2^+$-Ion das Verhältnis $^{11}B/^{10}B$ gemessen wird. Auf ihren Einfluß auf die bevorzugte Verflüchtigung von ^{10}B wurden folgende Variable geprüft: das Verhältnis Natriumhydroxid zu Borcarbid und Temperatur und Dauer der Erhitzung des Fadens. Eine Reihe von natürliches Bor enthaltenden Borcarbidpreßlingen vom für die Kontrollstäbe des Fast Flux Test Facility-Reaktors vorgeschlagenen Typ wurden analysiert; das offenbar von systematischen Fehlern freie Ergebnis betrug 4,0560 für das $^{11}B/^{10}B$-Verhältnis (Standardabweichung 0,0087). Die Preßlinge enthielten über 3% metallische Verunreinigungen, wir sie üblicherweise in diesem Material gefunden werden. Die Analysenzeit beträgt für einen Analytiker 45 min je Probe.

Résumé—On mesure les rapports isotopiques du bore dans le carbure de bore par spectrométrie de masse à ionisation thermoionique sans séparation chimique préalable. On prépare un mélange en poudre de carbure de bore et de soude, en transfère une petite portion sur un filament de tantale, le filament est chauffé pour produire du borate de sodium, et le filament est transféré dans le spectromètre de masse où l'on mesure le rapport $^{11}B/^{10}B$ en utilisant l'ion $Na_2BO_2^+$. Les variables étudiées quant à leur influence sur la volotalisation préférentielle de ^{10}B comprennent le rapport soudecarbure de bore et la température et la durée de chauffage du filament. On a analysé une série de pastilles de carbure de bore contenant du bore naturel, du type proposé pour les baguettes de contrôle du réacteur Fast Flux Test Facility, avec un résultat apparemment impartial de 4,0560 pour le rapport $^{11}B/^{10}B$ (écart type 0,0087). Les pastilles contenaient plus de 3% d'impuretés métalliques typiquement trouvés dans cette matière. Le temps d'analyse est de 45 mn par échantillon, avec un analyste.

DETERMINATION OF NIOBIUM IN ROCKS, ORES AND ALLOYS BY ATOMIC-ABSORPTION SPECTROPHOTOMETRY

JOHN HUSLER
Department of Geology, University of New Mexico, Albuquerque, New Mexico 87106, U.S.A.

(*Received* 7 *October* 1971. *Accepted* 14 *November* 1971)

Summary—Niobium, in concentrations as low as 0·02% Nb_2O_5, is determined in a variety of materials without separation or enrichment. Chemical and ionization interferences are controlled, and sensitivity is increased, by maintaining the iron, aluminium, hydrofluoric acid and potassium content within certain broad concentration limits. There is close agreement with the results of analyses by emission spectrographic, electron microprobe and X-ray fluorescence methods.

THE DETERMINATION of niobium by classical wet methods is involved and time-consuming because of the invariable need for separations or extractions. Nearly all the commonly used colorimetric methods require the prior separation of tungsten, molybdenum and titanium.[1] Atomic absorption has not been widely used for the determination of niobium because of the low inherent sensitivity, *e.g.*, Schiller advocated the use of as much as a 60-g sample to analyse steels containing 0·01% niobium.[2] Fortunately, however, there are several chemical species which, over a wide concentration range, enhance the absorption of niobium. This property can be used to advantage to lower the niobium detection limit, because these species provide an "enhancement buffer" over reasonably broad concentration limits. They include aluminium, iron, hydrofluoric acid and the easily ionized alkali metals.

Initially, attempts were made to analyse pandaite ores from Brazil and pyrochlore ores from Canada by the often recommended method of fusion with potassium bisulphate followed by leaching of the melt with hot 4% ammonium oxalate solution or hot 20–30% tartaric acid solution. Most of the Brazilian ores contained pandaite, approximate formula $Ba_{1-x}Nb_2O_{6-x}(H_2O)_{1+x}$, with large amounts of titanium in the form of ilmenite, $FeTiO_3$; also present were aluminium phosphate, the rare earths, quartz, and apatite, along with small amounts of titania.[3,4] Most of the Canadian ores carried very fine-grained uranium-bearing pyrochlore in a silicate-rich matrix such as acmite and potash feldspar. Many other minerals were present, such as calcite, pyrite, pyrrhotite, fluorite, apatite, biotite and magnetite.[5]

The bisulphate fusion of these types of ore proved to be unreliable, presumably owing to the presence of rare earths in the Brazilian ores[1] and uranium in the pyrochlore. Faye reported that uranium in pyrochlore, betafite, euxenite and other niobium-bearing ores led to low niobium results with associated low precision.[6] Faye further found by thorough study of the hydrofluoric acid dissolution method that a mixture of that acid with hydrochloric acid readily dissolved the niobium along with the associated minerals such as ilmenite and magnetite, and that sulphides such as pyrite and molybdenite remained unattacked. The hydrofluoric acid, which interfered with the subsequent ether–thiocyanate spectrophotometric estimation as prescribed by Ward and Marranzino,[7] was removed by evaporation (to a paste) in the presence of phosphoric acid. Faye's hydrofluoric–hydrochloric–phosphoric acid approach was used successfully for the atomic-absorption method in this laboratory, but since hydrofluoric acid greatly enhances the niobium absorption, it was decided to use this to advantage and to eliminate the volatilization of hydrofluoric acid in the presence of phosphoric acid, if possible. This proved to be feasible because the effect of hydrofluoric acid is constant when between 10 and 20% of concentrated hydrofluoric acid are present, the resulting increase in absorption being about 30% (Table I). Teflon beakers eliminate the need for platinum ware, and loss of hydrofluoric acid by its reaction with glassware is circumvented by utilizing polypropylene volumetric flasks. Silica, in the amounts which might remain from incomplete volatilization of silicon tetrafluoride, does not interfere.

In a thorough investigation of other potential interfering ions in the atomic-absorption determination, it was found that aluminium, iron and the alkali metals also produce enhancement effects, but that these effects can also be controlled (Table I). Aluminium also negates potential interference from titanium, which otherwise would produce low results (if the titanium is not eliminated in the acid attack).

The enhancement from the alkali metals is attributed mainly to the ionization effects of the nitrous oxide–acetylene flame. Manning observed that the best sensitivity for niobium, about 20 μg/ml for 1% absorption, was obtained at 3343·7 Å, and that when 0·1% of potassium was added, a detection limit of 5 μg/ml was achieved.[8] This sensitivity was not attainable on the instrument in this laboratory, but by addition of aluminium, iron, hydrofluoric acid and potassium, a sensitivity of 15 μg/ml could be achieved.

In this laboratory the effect of potassium was not observed to be as great as that reported by Manning, but this is probably because of different burner conditions and because Manning used niobium as the chloride, whereas in this work studies were made with stock solutions of niobium pentoxide which had been dissolved in hydrofluoric and hydrochloric acids.

The effects of other ions were studied, with solutions containing 500 μg of aluminium, 1000 μg of iron and 500 μg of potassium per ml and 5% v/v concentrated hydrofluoric acid. These quantities of additives cause nearly a threefold enhancement of the niobium absorption, and are not critical, since at least twice these amounts can be present without significant change in the enhancement. The absorption of a niobium solution containing between 500 and 3000 μg of aluminium per ml appears to be only 3–5% less than that of a similar solution plus hydrofluoric acid, iron and potassium. The concentrations chosen for these reagents in the enhancement buffer are near the middle of the tolerance ranges, so their presence in samples is without further influence. Table I indicates that large amounts of potassium in the sample begin to reduce the enhancing effect of the combined additives. In the presence of 20 ml of enhancement buffer per 100 ml of sample solution, there was no significant interference with 125 μg of niobium per ml from the following concentrations of other species: TiO_2 or $Na_2HPO_4 \cdot 12H_2O$, 3·0 mg/ml; Mg, 2·5 mg/ml; $Na_2SiO_3 \cdot 9H_2O$, $CaCO_3$, $SrCO_3$, $BaCO_3$, 1·0 mg/ml; Co, Cr, Cu, Mn, Mo, Ni, Ta, U, V, W, or Zn, 200 μg/ml. These were added as solutions of the species named, in hydrochloric, nitric or hydrofluoric acid, or mixtures of these acids.

No interference was observed from a mixture of yttrium plus the rare earths La, Ce, Pr, Nd, Sm and Gd totalling 800 μg/ml. The composition of the mixture was based on the ratio of the abundances of these elements in the earth's crust.[9]

No interference was noted from 5% v/v nitric or sulphuric acid, or from as much as 15% v/v hydrochloric or phosphoric acid, except for the slight reduction in absorbance expected as a result of the change in viscosity.

EXPERIMENTAL

Instrument parameters

The conditions used to achieve optimum sensitivity are listed in Table II. One of the most important factors is the use of wide diameter (0·023 in. bore) tubing to allow a sample uptake rate of 10–12 ml/min. It is felt that many of the conflicting reports of sensitivities, chemical and ionization interferences, *etc*, could be explained if contributors would report aspiration rates, burner heights and flame characteristics. For example, the best niobium sensitivity is obtained with a large uptake rate and the burner head 1–1·5 cm below the light-path. The acetylene and nitrous oxide flow-rates should be set to yield a 1–2 cm high blue flame just above the burner, with an 8–9 cm high "red feather." There is a large reduction in sensitivity for niobium (and tungsten) when the acetylene pressure drops below 50–100 psig. Similar effects, causing erratic results, and attributed to acetone in the acetylene cylinder, have been reported by the Perkin–Elmer Corporation, as for example in the determination of gold with an acetylene–air flame.[10] Niobium sensitivities obtained with other burner and flame types are given by Slavin.[11]

Solutions

Niobium pentoxide, 2000 µg/ml stock solution. Dissolve 1·000 g of pure Nb_2O_5 by warming with 30 ml of 48–50% hydrofluoric acid and 20 ml of concentrated hydrochloric acid in a Teflon beaker.

TABLE II.—INSTRUMENT PARAMETERS

Instrument	Perkin–Elmer, Model 303 with Model 165 recorder
Wavelength	3343·7 Å
Slit	3 (2 Å)
Cathode current	38 mA (40 max)
Scale	10× (for less than 1% Nb_2O_5)
Fuel	Acetylene (9 psig)
Oxidant	Nitrous oxide (40 psig)
Sample uptake rate	10–12 ml/min
Burner height	1–1·5 cm below light-path

After dissolution is complete, dilute to 500 ml with water. Transfer immediately to a polyethylene bottle. This solution is stable for at least 6 months.

Iron solution, 20 *g/l*. Dissolve 20·0 g of pure iron powder in 200 ml of hydrochloric acid (1 + 1) and dilute to 1 litre with water.

Aluminium solution, 10 *g/l*. Dissolve 10·0 g of aluminium powder or fine wire in 200 ml of hydrochloric acid (1 + 1) plus a few drops of 30% hydrogen peroxide and dilute to 1 litre with water.

Potassium solution, 10 *g/l*. Dissolve 19·1 g of reagent-grade potassium chloride in water and dilute to 1 litre.

Enhancement buffer solution. Mix 500 ml each of the iron, aluminium and potassium solutions with 500 ml of 48–50% v/v hydrofluoric acid. Store in a 2-litre polyethylene bottle. This is enough solution for 100 samples and standards.

Standard solutions of Nb_2O_5, 50, 100, 150 and 200 *μg/ml*. Using a polyethylene pipette, transfer 2·5, 5·0, 7·5 and 10 ml of the 2000-μg/ml Nb_2O_5 stock solution into 100-ml polypropylene volumetric flasks. Add 20 ml of enhancement buffer solution and dilute to 100 ml with water. Prepare a blank containing 20 ml of the buffer solution. These solutions are stable for at least 6 months.

Dissolution of sample

Place an accurately weighed 1–2 g sample in a 100-ml Teflon beaker. Rinse the walls with 5–10 ml of water. Add 10 ml of concentrated hydrochloric acid and 10 ml of concentrated hydrofluoric acid and heat the solution for 2 hr on a hot-plate at a temperature low enough to prevent the beaker from sticking to the hot-plate. The solution should not evaporate to dryness, but if it does, repeat the addition of acid and heat to redissolve the niobium. Add 20 ml of the enhancement buffer solution and filter through a Whatman No. 1 paper in a polyethylene funnel into a 100-ml polypropylene volumetric flask. Rinse the beaker and paper with 2–3% v/v hydrochloric acid and dilute to 100 ml with water. Analyse for niobium, using the parameters listed in Table II. Samples containing more than 1% niobium pentoxide can be analysed by preparing more concentrated standards with a corresponding attenuation of the instrument scale.

CONCLUSIONS

The comparison between the atomic-absorption (AA) and two independent X-ray analyses of Canadian niobium-bearing ores is presented in Table III. The two sets of samples, those analysed by AA and laboratory A and those analysed by laboratories A and B are from different drill holes but from the same deposit. The AA results of samples containing less than 0·8% niobium pentoxide agree with the X-ray results from laboratory A within about 4%, but at higher concentrations there is a difference of up to −14%. Results from laboratory B for >0·8% Nb_2 are lower than those from laboratory A by about 6%. This implies that the AA results would agree with those from laboratory B to within 3%.

The results in Table IV show that there is also excellent agreement between the AA and spectrographic analyses for low-grade Brazilian ores. Tables V and VI, respectively, show the comparative results of microprobe analyses and replicate AA analyses of other ores. The results for duplicate analyses of BCS Steel Standard No. 365 were 0·56 and 0·58%. Nb (certificate value 0·57%). The only procedural difference in

analysing alloys is the addition of 5 ml of concentrated nitric acid per gram of sample to aid in the dissolution. In an attempt to determine the niobium content of an Inconel nickel sample, it was found that concentrations of nickel much greater than 2500 μg/ml begin to reduce drastically the absorption of niobium (Table VII). In such analyses, when the niobium content is low enough to require a dissolved sample with a nickel concentration greater than 0·25 g/100 ml, a prior chemical separation is recommended.

Acknowledgements—The author wishes to thank Paul-Emile Hamelin of the St. Lawrence Columbium and Metals Corporation for the analysed Canadian ore sample, and the University of New Mexico Department of Chemistry for the steel standard. Thanks, also, to Klaus Keil for information on the microprobe and microscopic studies, E. F. Cruft and F. Dubuc for additional information on the ore samples, and R. A. Nash for providing a copy of the spectrographic results.

Zusammenfassung—Niob wird in Konzentrationen bis herunter zu 0,02% Nb_2O_5 in einer Reihe von Materialien ohne Abtrennung oder Anreicherung bestimmt. Man behält chemische und Ionisierungsstörungen im Griff und erhöht die Empfindlichkeit, wenn mann die Gehalte an Eisen, Aluminium, Flußsäure und Kalium innerhalb bestimmter breiter Konzentrationsgrenzen hält. Die Analysenergebnisse stimmen gut überein mit solchen der Emissionsspektrographie, der Elektronen-Mikrosonde und der Röntgenfluoreszenz.

Résumé—On détermine le niobium à des concentrations aussi faibles que 0,02% de Nb_2O_5 dans diverses substances sans séparation ou enrichissement. On contrôle les interférences chimiques et d'ionisation, et la sensibilité est accrue, en maintenant les teneurs en fer, aluminium, acide fluorhydrique et potassium à l'intérieur de certaines larges limites de concentration. Il y a un accord étroit entre les résultats d'analyses par les méthodes de spectrographie d'émission, de microessai électronique et de fluorescence de rayons *X*.

CONSTITUTION AND STABILITY OF ACIDIC PERIODATE SOLUTIONS

D. J. B. GALLIFORD*, R. H. NUTTALL and J. M. OTTAWAY®
Chemistry Department, University of Strathclyde, Cathedral Street, Glasgow C.1, Scotland

(*Received* 30 *August* 1971. *Accepted* 14 *November* 1971)

Summary—Acidic periodate solutions are shown to contain two species, tetrahedral IO_4^- and octahedral H_5IO_6. Equilibrium between the two is attained rapidly and the solutions are stable for long periods of time if stored in amber glass bottles.

PERIODATE is a well-established reagent of considerable application in analytical chemistry.[1] It has recently been shown[2] that it is more suitable for the oxidimetric determination of vanadium(IV) than many of the usually preferred oxidants such as permanganate, cerium(IV) or bromate. Many periodate oxidations are also susceptible to trace metal catalysis and these are useful for the determination of very small amounts of catalysts such as ruthenium[3] and chromium.[4] During some recent kinetic and analytical studies of periodate solutions in this laboratory,[2,3] difficulties were encountered from lack of reproducibility in the kinetic results (found to be caused by traces of chromium—as little as 0·01 ppm—adsorbed on the walls of the reaction vessels from chromic acid cleaning mixture) and it became necessary to establish (*a*) the nature of the species present in acidic periodate solutions and (*b*) the stability of the solutions in terms of the total oxidizing power and also in changes in the proportions of the ions with time.

Studies of the nature of periodate solutions have been reported by many authors but rarely do the results obtained relate to the solutions of relatively high ionic strength or high acid concentrations normally used in analytical applications, and many reports are contradictory. Crouthamel *et al.*[5] have shown that spectrophotometric data for solutions of periodic acid and potassium metaperiodate are adequately described by the equilibria

$$H_5IO_6 \rightleftharpoons H^+ + H_4IO_6^- \qquad K_1 = 5{\cdot}1 \times 10^{-4}$$
$$H_4IO_6^- \rightleftharpoons IO_4^- + 2H_2O \qquad K_D = 40$$
$$H_4IO_6^- \rightleftharpoons H^+ + H_3IO_6^{2-} \qquad K_2 = 2 \times 10^{-7}$$

in the pH range 0–7 and temperature range 0–70°. The important species in acid solutions at pH < 2 are therefore H_5IO_6 and IO_4^-. However, the data are dependent on the assumption that the absorbance at 222·5 nm and pH 5·8 is due to the IO_4^- species only, an assumption which is open to question following the observation that the diffuse reflectance spectrum of solid KIO_4 shows no band at 222·5 nm.[6] The data are also only really satisfactory for solutions of low ionic strength, since anomalous effects, in solutions of higher ionic strength which would significantly alter the values of the equilibrium constants, are ignored. Mishra and Symons[7] have

---

* Present address: May and Baker Ltd., Dagenham, Essex.

also postulated that in strong acid solutions at negative pH, the H_5IO_6 species is further protonated to form $H_6IO_6^+$ or $I(OH)_6^+$ and have reported a pK of $-0{\cdot}8$, in reasonable agreement with a predicted value.

Raman spectroscopy is clearly an advantageous technique for studying the proportions of these species present in solution, since spectra of aqueous solutions can be measured directly, and the observed bands can be assigned on symmetry grounds, and several papers on the Raman spectra of periodate solutions have been reported. Spectra of an 8% aqueous solution of sodium metaperiodate and a 40% solution of paraperiodic acid led Siebert[8] to assign bands at 256, 325, 791 and 853 cm^{-1} to the ν_2, ν_4, ν_1 and ν_3 modes of tetrahedral IO_4^- and bands at 632, 594 and 387 cm^{-1} to ν_1, ν_2 and ν_3 bands of octahedral H_5IO_6. He also concluded that both species were present in equilibrium in both solutions. Chantry and Plane[9] also report that a band at 797 cm^{-1} due to IO_4^- decreases with decrease in pH and, at the same time, a band at 640 cm^{-1} due to H_5IO_6 increases, but no information is given with respect to media or the precise pH used. Infrared spectra of the solid paraperiodic acid and its salts reported by Siebert[10] also lead to the conclusion that these compounds are not hydrates but octahedral species correctly represented by the formulae H_5IO_6, $Na_2H_3IO_6$, *etc.* Keen and Symons[11] have also reported infrared spectra of periodate solutions but suggest that the similarity of spectra to those of $Na_2H_3IO_6$ and $Na_3H_2IO_6$ can only be explained if the major constituent of metaperiodate solutions is not IO_4^- but ions such as $H_4IO_6^-$ or $H_2IO_5^-$.

In this paper we report some investigations of the Raman spectra and stability of periodate solutions, particularly in strongly acid media, in an attempt to provide information for the development of potassium periodate as an analytical reagent.

EXPERIMENTAL

Analytical-reagent grade chemicals were used throughout and water distilled from an all-quartz still was used in the preparation of all solutions.

Preparation of periodate solutions

Using a Stanton automatic recording thermobalance at a heating rate of 6–8°/min, it was found that decomposition of analytical-reagent grade potassium metaperiodate to potassium iodate started in the region of 250°. A temperature of 110° was therefore selected for drying the material and it was found that 0·01% weight loss occurred after one hour at this temperature and that no further loss was recorded after a further four hours' heating. After drying for one hour at 110°, the appropriate weight of KIO_4 was dissolved in distilled water or other media as required. Analytical reagent grade sodium metaperiodate was treated in a similar manner.

Standardization of periodate solutions

Solutions were standardized with reference to sodium arsenite solutions prepared from arsenious oxide.[1,12] An aliquot of the periodate solution was neutralized with sodium bicarbonate and a 3-g excess of bicarbonate were added. Then 3 g of potassium iodide were added and the liberated iodine was titrated with standard 0·025N arsenite.

Raman spectroscopy

Raman spectra were measured on a Cary Model 81 Spectrophotometer equipped with a Spectro-Physics 125 Helium-Neon Laser emitting radiation at 6328 Å. Solid samples were measured in glass vials and solutions in capillary tubes. Solutions for Raman studies were prepared by direct weighing immediately before use, unless otherwise stated.

RESULTS AND DISCUSSION

Stability of periodate solutions

The photodecomposition of periodate to iodate and ozone has been reported[13,14] and has been used for the homogeneous precipitation of thorium iodate.[15] Under more favourable storage conditions, however, periodate solutions are said to be stable for indefinite periods of time.[13,16] To test the effect of various acid media on the long-term stability of periodate solutions, solutions of 0·0125*M* KIO_4 were prepared in distilled water, 0·01*N*, 0·1*N* and 1*N* sulphuric acid, and a 0·4*M* $NaIO_4$ solution was prepared in 5*M* perchloric acid. Half of the solution in distilled water was stored in a screw-cap clear glass bottle and the remaining solutions were stored in screw-cap amber glass bottles, and the bottles were placed on a laboratory shelf in direct natural light. Each solution was standardized at intervals against standard arsenite, as described above, and the results are given in Table I. With the exception of the solution stored in clear glass, no detectable change in potassium periodate concentration was observed over a period of six months. The solution stored in the clear glass bottle deteriorated rapidly over the same period. The sodium periodate solution in 5*M* perchloric acid was stable for only 11–12 days and showed definite signs of decomposition after this, and for kinetic work described elsewhere[2,4] it was necessary to prepare fresh solutions at fortnightly intervals.

TABLE I.—STABILITY OF PERIODATE SOLUTIONS

Titration values (*ml*) for standardization with sodium arsenite. For 0·0125*M* solutions, 50-ml aliquots were titrated with 0·02578*N* sodium arsenite and for the 0·4*M* solution, 6·2-ml portions were titrated with 0·1027*N* arsenite. Storage was in amber glass bottles, except where indicated.

It is therefore established that in a range of neutral and acid media, the total oxidizing power of periodate solutions remains constant for up to six months. It is not clear, however, whether the species present in these solutions remain unchanged during this time.

Raman spectra of periodate solutions

Preliminary studies were carried out with 0·4*M* solutions of sodium periodate in concentrations of perchloric acid from 0·1 to 5*M*. Unfortunately, perchlorate ion exhibits a strong band at 640 cm^{-1} which interfered with an important periodate band and further work was carried out in nitric acid solutions. Careful comparison of the Raman spectra of the periodate species in both acid media indicated that they were essentially identical and that the Raman-active nitrate modes of vibration did not interfere with any periodate bands.

Raman spectra were obtained for solutions of 0·4*M* sodium periodate in distilled water, 0·1, 0·5, 1·0, 3·0 and 5·0*M* nitric acid. Initially, routine spectra were obtained but, following satisfactory interpretation of the observed bands, the solutions were re-examined under the conditions of maximum sensitivity available with the instrument. All solutions were examined immediately after preparation and at intervals over a 3-day period while being stored under air- and light-free conditions and, in addition, stock periodate solutions in perchloric acid were similarly examined. In no case was any change in peak height or peak position observed with time.

The bands observed and their relative intensities are given in Table II and a typical spectrum, *i.e.*, that in distilled water, is shown in Fig. 1A. Four of the five bands observed in neutral aqueous solution correspond closely to those assigned to IO_4^- by Siebert[8] and also correspond to the IO_4^- modes observed in solid KIO_4 and $NaIO_4$, and there seems little doubt as to the validity of this assignment. As the acid concentration is increased, the four bands due to IO_4^- decrease in intensity and the fifth band in distilled water medium at 615 cm^{-1} increases in intensity and shifts to 643 cm^{-1}. In addition, a new band appears at 386 cm^{-1} and also increases in intensity. In 5*M* acid, the bands at 643 and 386 cm^{-1} are the predominant features of the spectrum and only a very weak peak due to IO_4^- remains at 795 cm^{-1}. Operation at the highest available sensitivity shows no additional spectral features in any of the solutions and no new bands are observed on storing the solutions. The spectrum of the commercially available 50% paraperiodic acid solution (Fig. 1B) shows a band at 795 cm^{-1} which must be due to IO_4^- but also shows very strong bands at 386 and 643 cm^{-1} which suggests that the fifth band (615/643 cm^{-1}) in sodium metaperiodate solutions is also due to an octahedral species, in agreement with the observations of Siebert.[8] We were, however, unable to observe the third band required by theory for octahedral symmetry, which Siebert reported at 597 cm^{-1}.

TABLE II.—RELATIVE INTENSITIES OF THE LINES IN THE RAMAN SPECTRUM OF 0·4*M* SODIUM PERIODATE AT VARIOUS NITRIC ACID CONCENTRATIONS

$[HNO_3]$	Relative intensities						
M	860 cm^{-1}	795 cm^{-1}	643 cm^{-1}	615 cm^{-1}	386 cm^{-1}	313 cm^{-1}	270 cm^{-1}
none	19	100	—	2	—	6	9
0·1	6	85	4	—	—	3	5
0·5	3	23	17	—	2	—	—

5·0	—	3	45	—	8	—	—

The Raman spectra, therefore, indicate that two species are present in significant concentrations in acidic periodate solutions. No long-term changes could be observed which might suggest the formation of, for example, peroxides as a precursor of ozone, and use of an oxygen atmosphere had no effect on the spectra. The species are tetrahedral IO_4^- ions in equilibrium with an octahedral species. If the results of Crouthamel *et al.*[5] are even approximately valid for the present media, then at low

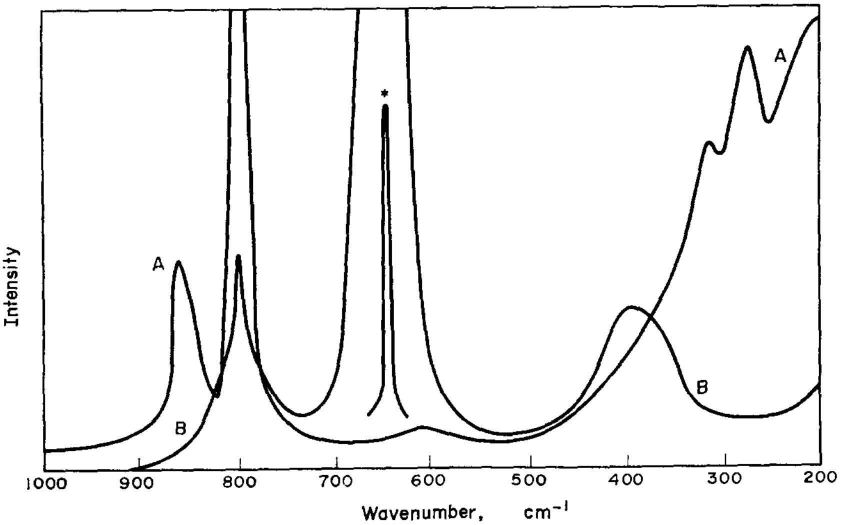

FIG. 1.—Raman spectra of (*A*) 0·4*M* aqueous sodium metaperiodate and (*B*) 50% aqueous paraperiodic acid (H_5IO_6). *(*B*) at reduced sensitivity.

acid concentrations the equilibrium

$$IO_4^- + 2H_2O \rightleftharpoons H_4IO_6^-$$

satisfies the Raman data provided it is assumed that the octahedral species is further hydrated in such a way that either all the oxygen atoms are equivalent or that exchange occurs very rapidly within the vibrational time scale so that the oxygen atoms appear equivalent. As the pH decreases, protonation occurs

$$H_4IO_6^- + H^+ \rightleftharpoons H_5IO_6$$

and the band at 615 cm^{-1} shifts to 643 cm^{-1} and increases in intensity, the equivalence of the oxygen atoms being maintained. As the pH decreases still further, from 1*M* to 5*M* nitric acid, the overall equilibrium,

$$IO_4^- + H^+ + 2H_2O \rightleftharpoons H_5IO_6$$

is pushed even further to the right and the concentration of metaperiodate ions decreases significantly. No evidence was found for the further protonation to $H_6IO_6^+$ but it is possible that this would not be detectable as a separate entity from the other octahedral species, although some further shift of the 643 cm^{-1} band might have been expected.

It is clear that acidic periodate solutions contain a mixture of two species, the proportion of which is dependent on the pH of the solution. From this and other evidence,[18] it is also clear that equilibrium is attained rapidly and that the oxidizing power of such solutions is not altered over at least a six months period. Kinetic evidence[2] suggests that in at least one application the IO_4^- ion is the active oxidizing species and control of pH will be an important factor in this and possibly many other analytical applications of periodate.

Zusammenfassung—Es wird gezeigt, daß saure Perjodatlösungen zwei Spezies enthalten: tetraedrisches JO_4^- und oktaedrisches H_5JO_6. Das Gleichgewicht zwischen beiden stellt sich rasch ein und die Lösungen sind über lange Zeit stabil, wenn sie in braunen Glasflaschen aufbewahrt werden.

Résumé—On montre que les solutions acides de periodate contiennent deux espèces, IO_4^- tetraédrique et H_5IO_6 octaédrique. L'équilibre entre les deux est atteint rapidement et les solutions sont stables pendant de longues périodes de temps si elles sont conservées en flacons de verre teinté.

COMPLEXATION OF POLYVINYL ALCOHOL WITH IODINE

ANALYTICAL PRECISION AND MECHANISM*

J. G. PRITCHARD and D. A. AKINTOLA
North East London Polytechnic, London, E.15, U.K.

(*Received* 16 *July* 1971. *Accepted* 3 *November* 1971)

Summary—Polyvinyl alcohol (PVA), boric acid and tri-iodide form a characteristic blue complex. For a number of PVA samples, prescribed conditions were used to examine the precision of the formation and spectrophotometry of the complex. The precision of calibration curves was 1–2% over the range 0–4 mg of PVA per 50 ml of final solution, over which Beer's law holds. Greater deviations can be caused by faulty preparation and aging of individual PVA solutions. The absorbance is independent of the content of residual acetate groups in the PVA for the range 0–15%. The limit of detection is about 0.01 mg of PVA in 25 ml of sample. A pink colour in the system is due to association of iodine with acetate groups in the PVA. A blue or green colour is due to helical envelopment of iodine molecules by PVA chains stiffened by scattered cyclic groups. The mechanisms of these effects are discussed.

SPECTROPHOTOMETRY of the polyvinyl alcohol(PVA)–borate–iodine complex in aqueous solution is in limited current use for the determination of PVA in paper[1] and biological materials.[2] The blue PVA–iodine complex, first observed in 1927,[3,4] finds use in solid or gel form as the antiseptic "Iodinol" in human and veterinary medicine,[5] and the polarizing[6] and potential superconducting[7] properties of the complex have attracted some attention. In the present work the sensitivity and precision of the spectrophotometric method of analysis are examined over an extended range, and some clarification of the general features of the complex formation is given.

The main conditions chosen for study are those used by Finley,[8] who found that at 690 nm Beer's law was obeyed for the PVA range 0–1 mg/50 ml. This was confirmed with the implication that linearity did not extend beyond the range stated.[9] In our study, the range is extended to 4 mg/50 ml by use of the Hilger and Watts Uvispek spectrophotometer, which accurately covers the wide absorbance range 0–3·2, and the precision of the method is examined in some detail. Also, the effects of residual acetate groups in the PVA are examined quantitatively.

EXPERIMENTAL

Materials

The PVA resins were "Gelvatol" grades 0-60-G, 1-60, 1-90, and 20-90, which have the following weight-average molecular weights and degrees of hydrolysis: 86000, 98·8–100%; 86000, 99–100%; 115000, 99–100%; 125000, 87–89%. Other reagents were of analytical grades.

Calibration-curve solutions

Gelvatol 0-60-G (1 g) was dissolved at 70–80° in *ca.* 100 ml of distilled water, and the solution diluted to 1000 ml in a calibrated flask at room temperature. This stock solution was diluted to give four solutions containing exactly 0·1, 0·15, 0·2, and 0·4 g of PVA per litre. The first two dilutions

were from fresh stock solution, the second two from the same stock solution allowed to stand for about four weeks. The composition of the final colorimetric solution is given in Table I. Four sets of solutions were made up to give the ranges of PVA concentration shown in Table II, the PVA being diluted to about 25 ml, then mixed with the boric acid before any iodine was added.

Alternatively, Gelvatol 1-60 and Gelvatol 20-90 solutions containing 0·0100, 0·0150, 0·0200 and 0·0400 g of PVA were made up successively in one particular 100-ml flask, and aliquots were used to make a set of standards as before. Nine standard solutions were prepared from each 100-ml solution in order to determine the scatter due to the complexing reaction and the dilution procedure used in the first approach.

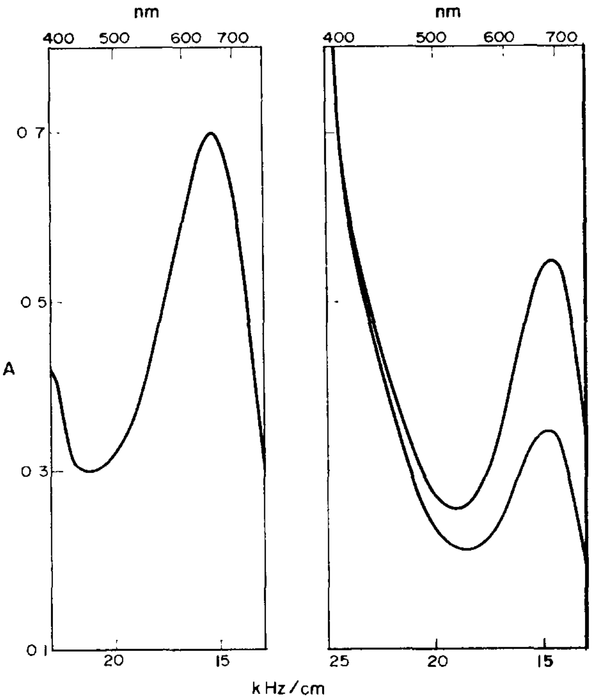

FIG. 1.—Left; spectrum of the complex formed from 1 mg of Gelvatol 1-90/50 ml under the conditions of the analytical method (Tables I and V). The spectrum of Gelvatol 20-90 is the same. Right: spectra given by 1 mg/50 ml, of Gelvatol 1-90 (upper line) and Gelvatol 20-90 (lower line), with 0·194*M* boric acid and 0·0003*M* iodine in aqueous potassium iodide (Table V), *vs.* water.

Spectrophotometry and statistics

Absorbances were measured on the Uvispek at 690 nm *vs.* an appropriate reagent blank, with 1-cm matched cells and suitable slitwidths in the range 0·1–1 mm. The mean of three estimates was taken for each solution, and the instrument was adjusted between each estimate. For each set, the best straight line passing through the origin for absorbance (A) *vs.* concentration of PVA (c) was calculated by the least-squares method. Limits for the true mean values were calculated as $\bar{A}_t \pm ts/3$, where $\bar{A}_i$ is the mean of nine results, s is their standard deviation, and t the value of Gossett's t for 99% confidence.

The spectra of several PVA–iodine combinations with and without boric acid were scanned on a Unicam SP 700 spectrophotometer for Gelvatol 1-90 and Gelvatol 20-90 (*cf.* Figs. 1–3 and Table V). The solutions were made up as for the analytical standards (Table I) except that either 1% or 0·1% Gelvatol and 0·05 or 0·005*M* iodine were used, as appropriate.

RESULTS

The analytical method

Table II gives the results for the successive dilution of the 1 g/l. stock solution of PVA. The best straight lines for the first two ranges give $A = 0{\cdot}69c$. The deviations of the points are random and average about 1%. The results for the other ranges give $A = 0{\cdot}77c$, which is somewhat higher and no doubt reflects the aging of the PVA stock solution. The deviations for these two sets are nearer on average to 2% than 1%, but this average is biased by the first two results in the last range. The deviations are nevertheless quite random. We conclude that Beer's law holds over the complete

range. The observed 1–2 % random error arises from a combination of random errors in the dilutions, spectrophotometry and degree of reaction.

Table III summarizes the statistics for Gelvatol 1-60 and Gelvatol 20–90. The deviations are random and average 1 %, which confirms the conclusion that random errors in the dilution, complexing and spectrophotometry do not together greatly exceed 1 %. More critically, Table III shows that the calculated limits of the true mean absorbance for each solution do not exceed ± 1·4 % (99 % confidence) and are random.

The best straight lines passing through the origin, for these results, are given in Table IV. The slopes for the two polymers differ by only about 2 % and agree reasonably with those for the first two sets of results in Table II. The deviations of the individual points are reasonably random. There appears to be no correlation between the deviation and transmittance (I). The possibility of slight curvature in the graphs plotted from Table III is not supported by the good linearity of the results in Table I. However, the deviations of the individual points average 4–5 % owing to combination

of random general error (1–2%, as above), weighing error of the small samples, and any inhomogeneity of the PVA.

General spectrophotometry

Figure 1 shows a scan of the well-defined spectral peak of the PVA–borate–iodine complex measured *vs.* the reagent blank. At the concentrations of iodine and iodide used, the reference solution absorbs so strongly ($A_{520} \sim 1{\cdot}0$; $A_{645} \sim 0{\cdot}1$), that a scan *vs.* water instead of the reagent blank does not distinguish the absorption band due to

the complex. Only a small fraction of the iodine reacts to form the complex. The yellow-green colour of the colorimetric solution is due to absorption of almost all of the blue incident light by unreacted iodine and of the red by complex, which leaves a window around 480 nm. The scans for Gelvatol 1-90 and Gelvatol 20-90 under the conditions chosen for the analysis are almost identical and reveal no dependence on the different acetate-group contents. However, this is not true for other conditions.

Table V contrasts the colour effects observable with Gelvatols 1-90 and 20-90 for various concentrations of the PVA and iodine, both in the presence and absence of boric acid. When the iodine concentration is reduced by a factor of 10 the amount of complex formed by the two polymers is markedly different (Fig. 1), that for Gelvatol 20-90 being reduced the more. Some most interesting effects are revealed when the iodine concentration is reduced further by a factor of six and the PVA concentration is increased to a large excess over the iodine. The polymer with 12% residual acetate groups shows an absorption band with $\lambda_{max} = 482$ nm associated with a reddish colour, whether boric acid is present or not, provided that the iodine concentration is low enough (Figs. 2 and 3). However, at higher iodine concentrations and in the presence of boric acid, the absorption band with $\lambda_{max} \sim 680$ nm associated with the blue complex also appears prominently and becomes very intense for iodine concentrations much in excess of $10^{-4}M$. In contrast (Fig. 2), the polymer with only 0–1% residual acetate groups shows in the presence of boric acid a prominent blue colour even for the lowest final iodine concentrations, provided that the iodine solution has a concentration not less than about 0·005*M when it is added.* When 0·0005*M* iodine solution is used, no colour reaction is observed: also, the amount of colour developed

when the $0{\cdot}005M$ iodine solution is used appears to depend on its rate of dilution when added to the PVA–borate solution. There is, therefore, a kinetic effect which appears to dictate the final colour of the homogeneous solution. A small amount of absorption at 500 nm is also shown by the almost fully hydrolysed polymer (Fig. 2).

When there is no boric acid, the polymer with 12% of acetate groups shows only the broad 482-nm absorption band for low iodine concentration, whereas the almost fully hydrolysed polymer does not react at low iodine concentration. Only when treated with $0{\cdot}01M$ iodine would the latter polymer *slowly* develop a deep green colour, again clearly indicating a kinetic effect in which the "blue" complex is slowly formed. The green colour is, of course, due to a combination of the absorption of violet and blue light by unreacted iodine and the absorption of red and yellow light by the "blue" complex; when the PVA concentration is high, most of the iodine reacts to form complex and the colour of the solution is deep blue. The 12% of acetate groups inhibits formation of the blue complex when boric acid is absent.

DISCUSSION

The colorimetric method

We can accept the equation $A = 0{\cdot}70c$ as representing the absorbance of fresh PVA solutions at 690 nm to within about 2% (c in mg/50 ml). The equation is independent of the amount of residual non-hydrolysed acetate groups in the PVA, up to at least about 15%. This is important because the majority of commercial PVA's are not completely hydrolysed, but only substantially so. The equation applies to molecular weights near 10^5. If the minimum detectable absorbance is taken as 0·007, this establishes the limit of detection as 0·01 mg of PVA in 25 ml of sample solution (50 ml of colorimetric solution).

Some limitations of the method are evident. To achieve the 1–2% operator–instrument precision, solutions of unknowns and standards should be fresh and uniformly prepared from samples weighing at least 0·1 g. Several solutions of an unknown sample should be prepared and analysed to check that reproducibility is indeed within 2%. We have noted that a small amount of insoluble, fibrous dark-blue complex can sometimes precipitate during the analysis, especially in the case of polymers with high molecular weights. This causes a low result, and such analyses should be discarded. The accuracy is likely to be limited from this cause in the case of unknown samples of PVA which contain a substantial fraction of high-molecular-weight "tail", which can be relatively easily precipitated in aqueous solution by boric acid.

The degree of intramolecular cyclic borate formation for PVA in aqueous solution can generally approach 20% before intermolecular borate formation gels the polymer.[10] Under the conditions of the present method, approximately this semi-saturation level of intramolecular borate formation should be achieved, and it is plausible that 10–15% of acetate groups should not interfere. If the iodine level is high enough, ~ 12% of acetate groups does not interfere, but if the iodine level is low or borate is absent, notable effects of acetate groups are observed (Table V). As the PVA : borate ratio is increased, the degree of cyclic borate formation possibly decreases, the more so with increase in acetate-group content, but the main effect at low iodine concentration is the preferential formation of the red type of complex which robs the system of iodine that would otherwise be available for formation of the blue complex. These effects are not important under the conditions of the analytical method which, within limits, is independent of the preparative history of the PVA sample. However, it appears likely that eventually, at perhaps 30–40% of acetate groups, the freedom of the analytical method from dependence on the acetate content of the polymer must break down. We might also note that in the case of relatively small amounts of borate, order-of-mixing effects apparently preclude an accurate method for the determination of borate via the PVA–borate–iodine complex.[11]

General characteristics of PVA–iodine complex formation

In the absence of boric acid, complex formation at room temperature, for sufficiently high concentrations of aqueous iodine, potassium iodide, and well-hydrolysed PVA, involves the slow development of a blue or green colour characterized by $\lambda_{max} \sim 620$ nm. Under some conditions, the maximum absorbance and a state of apparent equilibrium are not achieved for some days, and the kinetics and a number of other characteristics of this reaction continue to attract interest.[12–15] The degree of blue colour at equilibrium has been shown to depend very much on structural features of the PVA such as (it would appear at first sight) its tacticity.[12,16,17] The addition of sufficient boric acid to the PVA–I_2–KI system removes the dependence of the absorbance on time and tacticity.[12] In the absence of boric acid, PVA deliberately substituted with cyclic acetal or formal groups produces the usual blue complex, which is strikingly more intensely coloured as the degree of acetal or formal substitution increases.[18]

Our main results show that random substitution of one acetate group for one hydroxyl group in eight along the PVA chain has essentially no effect on the formation of the blue PVA–borate–iodine complex provided that a large excess of both iodine and boric acid is present. However, this fraction of acetate groups is sufficient to attenuate seriously the formation of the blue complex for iodine: PVA ratios of about 1 or more even in the presence of boric acid (Fig. 2). Furthermore, we have shown that the presence of acetate groups leads to *preferential* formation of a "red" complex characterised by $\lambda_{max} \sim 500$ nm, whether boric acid is present or not (Fig. 3). The formation of such red colours has been observed previously,[19,20] and even in the case of some specimens of so-called "fully" hydrolysed PVA, when its concentration is relatively high, *e.g.*, for 1% PVA (0·23*M*) with 0·001*M* iodine and 0·002*M* iodide, a red colour is reported to be produced with $\lambda_{max} \sim 500$ nm.[15] These red complexes formed in aqueous solution are almost certainly closely related to the red-violet complex formed when a methanolic solution of polyvinyl acetate and iodine is added to an aqueous solution of potassium iodide.[21,22]

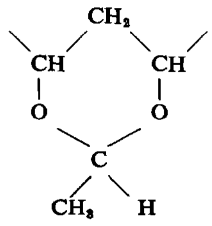
The red acetate complex

Clearly the red complex is associated with the acetic ester function in PVA. As it is extremely difficult to remove the last traces of acetate groups from PVA, this polymer may show the red reaction in solution whenever the acetate: iodine ratio is sufficiently high and other conditions are suitable. Before the borate reaction was known, the formation of this red colour was proposed as the basis of an analytical method for PVA.[23] It cannot be reliable, because the intensity of colour depends on both the concentration of the PVA and the fraction of acetate groups it contains.

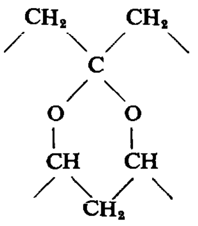
In seeking a model for the red complex, we must remember that the orange-brown colour of aqueous solutions of iodine is due to a complex of the "ether" type in which an iodine molecule is loosely bonded to the unshared electrons of bivalent oxygen.[24,25] Thus, a solution of pure iodine in water shows a broad absorption band with λ_{max} = 459 nm in the visible region, associated with $H_2O{\cdot}I_2$, and two less intense bands in the ultraviolet region with λ_{max} = 288 and 352 nm associated with the formation of I_3^- and IO^- ions (see below). In the presence of an excess of potassium iodide, the intensities of the latter two bands are very strongly enhanced, leaving the 459-nm $H_2O{\cdot}I_2$ band merely as a "tail" at the side of the 352-nm band, so that the solution appears yellow when dilute (Fig. 2) and orange-red when concentrated. Unperturbed iodine in carbon tetrachloride solution has a single band with λ_{max} = 516 nm, which gives a pink-violet colour. Models of the rather convoluted polyvinyl acetate and partially acetylated PVA molecules show that they possess cells in which an iodine molecule can fit in association with one set of ether-oxygen orbitals. Bonding of the "acetone" type[24] to the π-bonding orbitals of the carboxyl oxygen also appears possible. We conclude that the type of absorption in the 460-nm region due to $H_2O{\cdot}I_2$ is enhanced and its wavelength slightly increased when iodine is chemisorbed at the ester-oxygen functions in PVA polymers (Fig. 3).

The blue complex

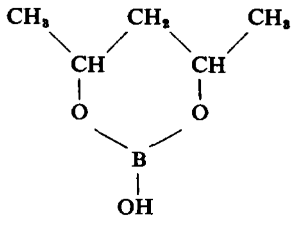
This complex is circumstantially connected with the formation of cyclic acetal and cyclic borate groups in PVA. Small proportions of acetal groups are always present in PVA prepared from vinyl acetate, because partial hydrolysis of this monomer is difficult to avoid and yields acetaldehyde which acetalates the PVA ultimately prepared. It is also difficult to prepare PVA in the entire absence of oxygen, which introduces keto groups along the chain and aldehyde end groups, and these can yield cyclic ketal and acetal links between PVA chains by a slow acid-catalysed reaction.[6] Thus, the observed source-dependence of the absorbance intensity of the PVA–iodine complex in the absence of boric acid most probably arises from different numbers and types of cyclic acetal (**1**) and ketal (**2**) structures. The kinetics of complex formation may also be affected by these structures, as discussed later.



(1)



(2)



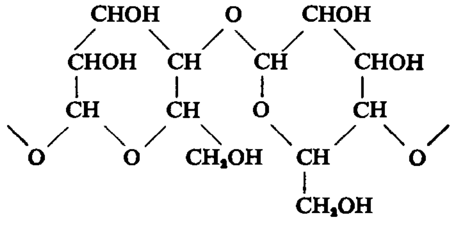
(3)

Mechanism of formation of the blue complexes

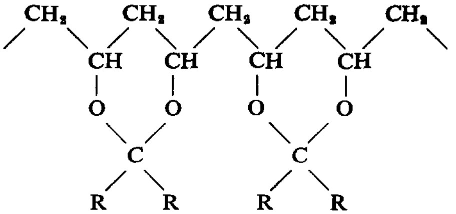
The PVA–iodine complex probably has a similar structure to the better understood amylose–iodine complex, *i.e.*, long straight chains of associated iodine molecules are crystallized down the centres of helical amylose chains.[7,26] We have shown that 2,4-dihydroxypentane cyclic borate ester[27] (3) does not react with our iodine–iodide stock solution. The formation of the PVA–borate–iodine complex therefore requires the concerted effect of many segments of the borated PVA chain. It can be argued that the amylose molecule can crystallize easily in helical form, enveloping a string of iodine molecules, because the backbone of this polymer (4) lacks complete flexibility. We take the view that any microcrystallization of pure PVA in aqueous solution should occur in the stacked planar zig-zag form, as observed for aqueous gels of PVA.[28] Helical crystallization should only be possible if the flexibility of the PVA chain is reduced, through formation of cyclic groups, to give a structure somewhat analogous (5) to that of amylose. This would, of course, prevent zig-zag crystallization for these substituted segments and several adjacent ones. Thus, partial acetalation or boration of the PVA chain may remove degrees of freedom of movement sufficiently to permit formation of the first turn of the helix in conjunction with iodine.

Recent kinetic studies of the very rapid formation of the blue amylose–iodine complex ($\lambda_{\max} \sim 630$ nm) show reaction orders of one with respect to amylose and four with respect to iodine and tri-iodide ions considered together.[29] This suggests that I_8 may be complexed, no doubt in stages. The observation of threshold concentrations of iodine required for complex formation with PVA is consistent with a high-order dependence of this reaction on iodine concentration. No reaction can be detected with $10^{-4}M$ iodine in the presence of boric acid, and in its absence about $10^{-2}M$ iodine is needed for a slow reaction to ensue at such cyclic sites as there are. The latter reaction is inhibited by 12 % of acetate groups in the case of Gelvatol 20-90.

The tri-iodide ion appears necessary for the successful production of the blue complex, although the latter can be formed without deliberately added iodide ions,

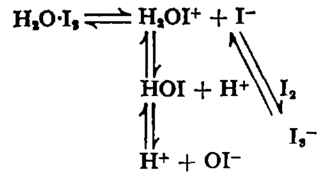


(4)



(5)

especially in the presence of plenty of boric acid.[30] Iodine in aqueous solution generates a small quantity of its own I_3^- ions:



The I_3^- ion is linear, stable, and abundant in aqueous iodine–iodide solutions and may well provide the matrix on which the first turns of the PVA helix can wind. A likely mechanism for the formation of the helical complex would be:

$$\begin{aligned} &\text{Helix-}I_3^- + I_2 \rightarrow \text{Helix-}I_4 + I^- \\ &\text{Helix-}I_4 \;+ I_3^- \rightarrow \text{Helix-}I_7^- \\ &\text{Helix-}I_7^- + I_2 \rightarrow \text{Helix-}I_8 + I^-. \end{aligned}$$

It appears unlikely that ions such as I_5^-, I_7^-, or I_9^- occur in the final complex. Such ions do exist, for example, in the tetramethylammonium salts (which are no doubt ion-paired in solution), but they absorb strongly over the complete visible range, and more so in the range 400–600 nm, so that they are very deep red in colour when viewed by transmitted light.[31,32]

The shift from $\lambda_{max} = 516$ nm in the unperturbed iodine molecule to 459 nm in the iodine–water complex represents an increase of 7 kcal/mole in the energy of the electronic transition. This is associated with a slight extension of the I–I bond when co-ordinated to oxygen.[24] The formation of the blue complexes between iodine and amylose, starch, and PVA represents a change from iodine–solvent complexation to $(I_2)_n$ chemisorption in which the iodine is protected from complexing oxygen groups by a helix of hydrocarbon groups. This change is associated with a decrease of 9–14 kcal/mole in the energy of the transition compared to unperturbed iodine, and this may be related to a corresponding compression of the I–I bonds within the helix.

Zusammenfassung—Polyvinylalkohol (PVA), Borsäure und Trijodid bilden einen charakteristischen blauen Komplex. Bei einer Anzahl von PVA-Proben wurden konstante Bedingungen angewandt, um die Reproduzierbarkeit der Bildung und des spektrophotometrischen Verhaltens des Komplexes zu prüfen. Die Reproduzierbarkeit der Eichkurven betrug 1–2% im Bereich 0–4 mg PVA pro 50 ml endgültig zubereiteter Lösung; in diesem Bereich gilt auch das Beersche Gesetz. Größere Abweichungen können durch fehlerhafte Präparation und Alterung einzelner PVA-Lösungen vorkommen. Im Bereich 0–15% ist die Extinktion unabhängig vom Gehalt des PVA an restlichen Acetatgruppen. Die Nachweisgrenze liegt bei etwa 0,01 mg PVA in 25 ml Probe. Eine Rosafärbung des Systems beruht auf Anlagerung des Jods an Acetatgruppen im PVA. Blau- oder Grünfärbung kommt durch schraubenförmige Einschließung von Jodmolekülen durch PVA-Ketten zustande, die durch cyclische Gruppen hier und da versteift werden. Die Mechanismen dieser Effekte werden diskutiert.

Résumé—L'alcool polyvinylique (PVA), l'acide borique et le triiodure forment un complexe bleu caractéristique. Pour un certain nombre d'échantillons de PVA, on a utilisé les conditions prescrites pour examiner la précision de formation et de spectrophotométrie du complexe. La précision des courbes d'étalonnage est de 1–2% dans le domaine 0–4 mg de PVA pour 50 ml de solution finale, domaine dans lepuel la loi de Beer est suivie. Des écarts plus grands peuvent être causés par une préparation et un vieillissement défectueux de solutions particulières de PVA. L'absorption est indépendante de la teneur en groupes acétate résiduels du PVA pour le domaine 0–15%. La limite de détection est d'environ 0,01 mg de PVA dans 25 ml d'échantillon. Une coloration rose du système est dûe à l'association de l'iode avec les groupes acétate dans le PVA. Une coloration bleue ou verte est dûe à l'enveloppement hélicoïdal de molécules d'iode par des chaînes de PVA rigidifiées par des groupements cycliques dispersés. On discute des mécanismes de ces influences.

SHORT COMMUNICATIONS

Liquid–liquid interfaces as potentiometric ion-sensors—I
The n-butanol–water interface as indicating sensor for the potentiometric titration of some acids and bases

(*Received* 20 *May* 1971. *Accepted* 5 *January* 1972)

The interface between two immiscible liquids must function as an indicating electrode because the concentration of a particular ion will be different on the two sides of the interface. The literature mentions only an attempt at potentiometric titration of some acids and bases[1] by use of benzene, toluene, chloroform and nitrobenzene interfaces with water.

Here we present the results of titrations of some acids and bases, with the n-butanol–water interface as indicating electrode. The titrations were performed in a cell with a base area of ~ 20 cm^2, the solution to be titrated being covered with a layer of water-saturated n-butanol about 5 mm thick.

The potential on both sides of the interface was monitored by two calomel electrodes, to give the e.m.f. of the following cell (Fig. 1):

(+) S.C.E.—n-butanol | aqueous solution—S.C.E. (−)

The electrode functions obtained by titrating 0·1*N* hydrochloric, nitric, perchloric and sulphuric acids with 1*M* potassium hydroxide are given in Fig. 2. The corresponding pH values were simultaneously measured with a glass electrode. For the first three acids similar electrode functions were obtained. For sulphuric acid a different shape was observed, perhaps because of the influence of the anion.

Figure 3 gives the titration curves of these four acids and 0·1*N* phosphoric acid. They do not have the shape of classical potentiometric titration curves—their slope for sulphuric acid differs from the

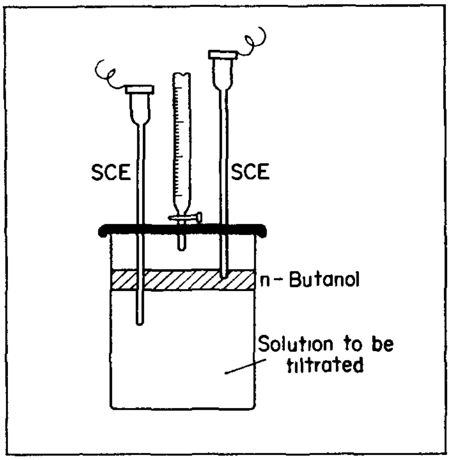

Fig. 1.—Titration cell.

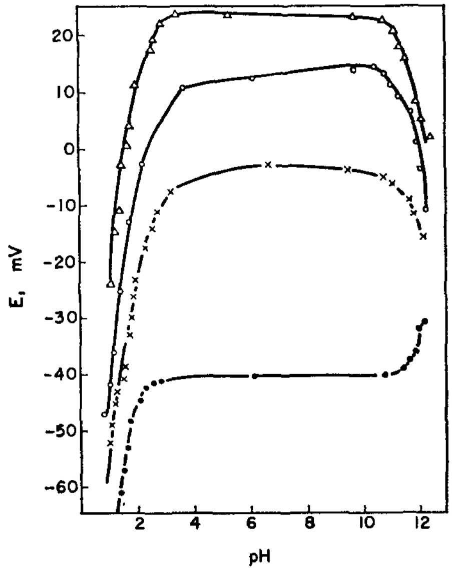

Fig. 2.—Electrode function.
—×— HCl —Δ— HClO$_4$
—○— HNO$_3$ —●— H$_2$SO$_4$

others in shape and in potential change. Table I gives comparative results for titration of acids by this potentiometric method and with a pH-meter.

Figure 4 shows titration curves for hydrochloric acid of different concentrations. The equivalence point can easily be located for concentrations down to $10^{-3}M$. Increasing the electrolyte concentration decreases the slopes of the two branches of the titration curve, but the equivalence point can still be located even for $5M$ potassium chloride media (Fig. 5).

TABLE I.—Titration of $0{\cdot}1N$ acids with $0{\cdot}1M$ KOH

Acid	Titration, *ml*	
	Glass-electrode*	n-Butanol–water interface
HCl	3·95	3·93
H_2SO_4	5·90	5·75
HNO_3	4·06	4·06
$HClO_4$	4·22	4·15
H_3PO_4	5·32	5·25†

* Hahn-Weiler location of end-point.

† Only the first step of neutralization was observed.

The influence of surface-active substances on the titration of $0{\cdot}05M$ hydrochloric acid with $0{\cdot}5M$ potassium hydroxide was also investigated (Fig. 6). In the presence of surfactant anions the position

of the equivalence point remains practically the same but the shape of the curve changes, there being a pronounced minimum. In the presence of surfactant cations (*e.g.*, alkyl pyridinium ions) both the shape of the curve and the position of the equivalence point are affected, most probably because of consumption of hydroxide by the surface-active substance. Neutral surface-active substances (*e.g.*, polyvinyl alcohol) have no influence.

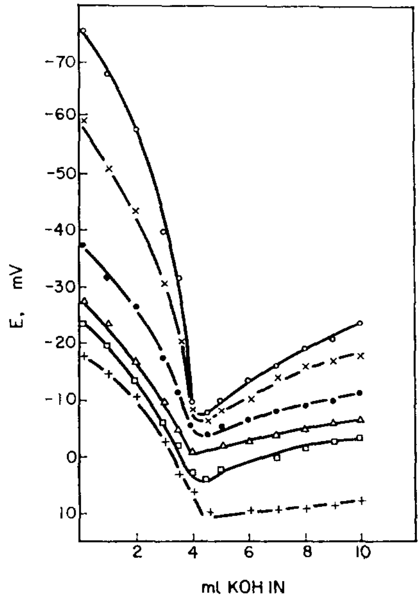

FIG. 5.—Influence of electrolyte concentration on $10^{-1}M$ HCl titration.
—○— without electrolyte —△— $1M$ KCl
—×— $0{\cdot}1M$ KCl —□— $2M$ KCl
—●— $0{\cdot}5M$ KCl —+— $5M$ KCl

The titration curves of sodium, barium and ammonium hydroxides ($0{\cdot}1M$) with $1M$ hydrochloric acid all have much the same shape (Fig. 7), the equivalence point being indicated by a sudden potential jump. The titration curve of $0{\cdot}1M$ potassium hydroxide with $0{\cdot}1N$ sulphuric acid has the normal shape of a potentiometric curve, emphasizing again the influence of the anion.

Table II gives the results of titration of bases, compared with indicator titrations. Potassium hydroxide (down to $10^{-3}M$) can be satisfactorily titrated with hydrochloric acid.

Establishment of the potential

The interface may be considered as a liquid membrane existing between the two phases. The thickness *a* (Fig. 8) of the membrane is determined by layers of molecules of the two liquids fixed

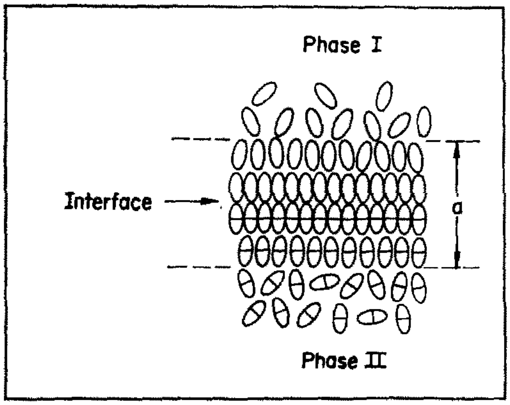

FIG. 8.—Schematic representation of liquid–liquid interface.

mutually by surface tension forces.[2] That is why these molecules cannot move turbulently but only through laminar flow. The potential differences appear owing to differences in activities of the ions on both sides of this membrane. At a proton-sensitive membrane (S) in contact with an electrolyte HX, owing to the distribution of H$^+$ between the solution and the membrane the following equilibrium is established, characterized by the partition coefficient K_{H^+}:

$$H^+_{sol} + S_m \overset{K_{H^+}}{\rightleftharpoons} HS_m^+ \qquad (1)$$

For the interface of the membrane with phase I we can write the expression for the membrane potential:

$$E_{\mathrm{I}} = E_{\mathrm{I}}^{0} + \frac{RT}{F} \ln \frac{(a_{\mathrm{H}^+})_{\mathrm{I}}}{(a_{\mathrm{HS}^+})_{\mathrm{m_I}}} \tag{2}$$

and similarly for the interface with phase II:

$$E_{\mathrm{II}} = E_{\mathrm{II}}^{0} + \frac{RT}{F} \ln \frac{(a_{\mathrm{H}^+})_{\mathrm{II}}}{(a_{\mathrm{HS}^+})_{\mathrm{m_{II}}}} \tag{3}$$

The membrane potential of the system is given by:

$$E_m = E_{\mathrm{I}} - E_{\mathrm{II}} = E_{\mathrm{I}}^{0} - E_{\mathrm{II}}^{0} + \frac{RT}{F} \ln \frac{(a_{\mathrm{H}^+})_{\mathrm{I}}}{(a_{\mathrm{H}^+})_{\mathrm{II}}} - \frac{RT}{F} \ln \frac{(a_{\mathrm{HS}^+})_{\mathrm{m_I}}}{(a_{\mathrm{HS}^+})_{\mathrm{m_{II}}}} \tag{4}$$

Putting $E_{\mathrm{I}}^{0} - E_{\mathrm{II}}^{0} = E^{0'}$ and the diffusion potential

$$E_{\mathrm{d}} = \frac{RT}{F} \ln \frac{(a_{\mathrm{HS}^+})_{\mathrm{m_I}}}{(a_{\mathrm{HS}^+})_{\mathrm{m_{II}}}}$$

we obtain for the membrane potential

$$E_{\mathrm{m}} = E^{0'} - E_{\mathrm{d}} + \frac{RT}{F} \ln \frac{(a_{\mathrm{H}^+})_{\mathrm{I}}}{(a_{\mathrm{H}^+})_{\mathrm{II}}} \tag{5}$$

We observe that the membrane potential will be subject to changes arising from the diffusion potential term E_{d}, as a result of the transfer of ions through the very narrow membrane layer. In other words the hydrogen-ion activity changes in the liquid phase, which can be considered as the internal solution. That is why a linear relationship between E and a_{H^+} holds only in a narrow range of a_{H^+}, which can be observed from the electrode function. With the increase in pH, the shape of the electrode function becomes unusual. This behaviour is reflected in the unusual shape of the titration curves obtained.

At the same time, from equation (5), increase of hydrogen-ion concentration in the n-butanol phase will lower the value of the membrane potential, in accordance with our experimental results. Indeed, previously saturating the n-butanol with $1M$ hydrochloric acid causes a smaller change of potential during the titration of hydrochloric acid with potassium hydroxide. The equivalence point, though distinguishable, is then less certain.

The greater extractibility of sulphuric acid into n-butanol, compared with the other acids titrated,[3] explains the unusual shape of both the electrode function and titration curves for this acid.

Because of the many combinations possible for forming liquid–liquid interface membranes, this type of electrode represents a general form, offering new possibilities for analytical sensors.

Summary—The property that liquid–liquid interfaces modify their electrical charge as a function of the composition of the two phases in contact has been used to detect the end-points in a series of acid–base titrations in the aqueous phase. Although the titration curves are not classical in shape, the equivalence points can be located if the solutions are not too dilute. Good results for concentrations down to $10^{-3}N$ have been obtained. The electrode has a fast response. The influence of surface-active substances on the titration has also been investigated.

Zusammenfassung—Grenzflächen zwischen zwei Flüssigkeiten ändern ihre Ladung in Abhängigkeit von der Zusammensetzung der sich berührenden Phasen. Dieser Effekt wurde zum Nachweis des Endpunktes bei einer Reihe von Säure-Basen-Titrationen in der wäßrigen Phase verwendet. Obwohl die Titrationskurven nicht die klassische Form haben, können die Äquivalenzpunkte bestimmt werden, wenn die Lösungen nicht zu verdünnt sind. Bei Konzentrationen über 10^{-3} N wurden gute Ergebnisse erhalten. Die Elektrode spricht schnell an. Auch der Einfluß oberflächenaktiver Substanzen auf die Titration wurde untersucht.

Résumé—La propriété qu'ont les interfaces liquide–liquide de modifier leur charge électrique en fonction de la composition des deux phases en contact a été utilisée pour déceler les points de fin de dosage dans une série de titrages acide-base en phase aqueuse. Quoique les courbes de titrage ne soient pas classiques dans leur forme, les points d'équivalence peuvent être localisés si les solutions ne sont pas trop diluées. On a obtenu de bons résultats pour les concentrations descendant jusqu'à $10^{-3}N$. L'électrode a une réponse rapide. On a aussi examiné l'influence de substances tensioactives sur le titrage.

Studies on nucleation from solution of some analytically important metal chelates—II. Nickel dimethylglyoximate

(*Received* 30 *September* 1971. *Accepted* 26 *November* 1971)

THE LITERATURE on nucleation from solution is filled with experimental results that are inconsistent and confusing. In addition, serious questions are being asked about the validity of the model normally used to interpret experimental data. It seems, then, that progress in the understanding of nucleation from solution is dependent upon improved or entirely new experimental techniques. The aim of this series of investigations is to study the kinetics of crystal nucleation from solution of some analytically important metal chelates, by a diversity of experimental approaches.

In a previous communication[1] a combination of precipitation from homogeneous solution and Vonnegut's droplet technique[2] was used as the experimental method to investigate bis(1,2-cyclohexanedionedioximato) and bis(1,2-cycloheptanedionedioximato)nickel(II) and the corresponding palladium(II) chelates. The present paper describes a direct-mixing and rapid particle-counting technique developed as a second experimental technique for nucleation studies and reports the results found during studies on nickel dimethylglyoximate.

EXPERIMENTAL

Aqueous solutions, one containing dimethylglyoxime and the other nickel(II) were rapidly mixed. Then the number and size distribution of crystals formed during the nucleation and growth periods were determined as a function of time after mixing.

Apparatus

Direct mixing system. Two 10-ml syringes were interlocked so that their plungers operated simultaneously and each was connected to an input port of a Roughton cell. A third syringe was connected to the outlet port of the cell.

Particle-counting system. The rapid particle-counting system was made up of a "Coulter Counter" (Industrial Model B, Coulter Electronics. Industrial Division), a multichannel analyser (Model ND 161F, Nuclear Data Inc.) and a magnetic tape recording unit (Model MT36, Potter Instrument Co. Inc.). The results collected on the magnetic tapes were processed and recovered by computer.

Reagents and solutions

Calibration dispersions for the particle-counting system were prepared in aqueous 1% w/v ammonium chloride solution from polystyrene spheres (Dow Chemical Co.) or ragweed pollen (Coulter Electronic, Industrial Division). Stock solutions of $0.1M$ nickel chloride and $3{\cdot}0 \times 10M^{-3}$ dimethylglyoxime were each prepared in aqueous 1% w/v ammonium chloride solution. Less

It seems, then, that progress in the understanding of nucleation from solution is dependent upon improved or entirely new experimental techniques. The aim of this series of investigations is to study the kinetics of crystal nucleation from solution of some analytically important metal chelates, by a diversity of experimental approaches.

In a previous communication[1] a combination of precipitation from homogeneous solution and Vonnegut's droplet technique[2] was used as the experimental method to investigate bis(1,2-cyclohexanedionedioximato) and bis(1,2-cycloheptanedionedioximato)nickel(II) and the corresponding palladium(II) chelates. The present paper describes a direct-mixing and rapid particle-counting technique developed as a second experimental technique for nucleation studies and reports the results found during studies on nickel dimethylglyoximate.

EXPERIMENTAL

Aqueous solutions, one containing dimethylglyoxime and the other nickel(II) were rapidly mixed. Then the number and size distribution of crystals formed during the nucleation and growth periods were determined as a function of time after mixing.

Apparatus

Direct mixing system. Two 10-ml syringes were interlocked so that their plungers operated simultaneously and each was connected to an input port of a Roughton cell. A third syringe was connected to the outlet port of the cell.

Particle-counting system. The rapid particle-counting system was made up of a "Coulter Counter" (Industrial Model B, Coulter Electronics. Industrial Division), a multichannel analyser (Model ND 161F, Nuclear Data Inc.) and a magnetic tape recording unit (Model MT36, Potter Instrument Co. Inc.). The results collected on the magnetic tapes were processed and recovered by computer.

Reagents and solutions

Calibration dispersions for the particle-counting system were prepared in aqueous 1% w/v ammonium chloride solution from polystyrene spheres (Dow Chemical Co.) or ragweed pollen (Coulter Electronic, Industrial Division). Stock solutions of $0.1M$ nickel chloride and $3{\cdot}0 \times 10M^{-3}$ dimethylglyoxime were each prepared in aqueous 1% w/v ammonium chloride solution. Less concentrated solutions of each were prepared by dilution with aqueous 1% w/v ammonium chloride solution. All solutions were filtered through 0·1-μm PVC membrane filters until each solution gave a negligible background particle-count.

Procedures

Calibrations. For each calibration dispersion and also for mixtures of them the particle counter probe (30-μm aperture) was inserted into 200 ml of the dispersion and the number and size distribution of particles were determined with each of the ten amplification settings of the particle counter; 0·5 ml of the dispersion was used for each measurement. The results from each setting were recorded and stored on magnetic tape.

Nucleation studies. The appropriate nickel solution was placed in one of the 10-ml syringes connected to the Roughton cell and the dimethylglyoxime solution was placed in the second. The solutions were mixed and transferred to the third syringe connected to the cell. After a certain time, a fraction of the contents of the third syringe was transferred to a beaker containing enough 1% w/v ammonium chloride solution to yield 200·0 ml of a dispersion containing about 10^5 countable particles/ml. The number of particles and the size distribution of the particles were determined by the procedure described in the previous paragraph. The reaction conditions for each set of experiments are shown in Table I.

	$1{\cdot}18 \times 10^2$		$2{\cdot}22 \times 10^2$	$11{\cdot}3 \times 10^6$
	$6{\cdot}91 \times 10^2$		$2{\cdot}00 \times 10^1$	$5{\cdot}40 \times 10^4$

RESULTS AND DISCUSSION

Particle-counting system

Preliminary results with both spherical particles and an actual precipitating system showed that the voltage pulses appearing on the line between the main amplifier and the oscilloscope of the particle counter had those characteristics recommended for best resolution and linearity of the analyser. Also, standard deviations found for equally sized particles compared well with those quoted by the manufacturer. From these results it was concluded that the rapid particle-counting system could be used not only to count the total number of particles above 1 μm in size formed during a nucleation and growth experiment but also to determine the particle-size distribution and its variation. Typical size-distribution curves for nickel dimethylglyoximate are shown in Fig. 1.

Nucleation studies

The total number of particles with a diameter d greater than $2r^*$ at any particular time t after mixing the reagents can be calculated from equation (1).

$$N(2r^*, t) = \int_{2r^*}^{\infty} \left(\frac{\partial N(d, t)}{\partial d}\right)_t \mathrm{d}d \qquad (1)$$

where r^* = the critical radius of the nucleus.

Further, the rate of nucleation J is defined as $\partial N(2r^*, t)/\partial t$. Therefore, the slope of a plot of $N(2r^*, t)$ *vs* time is the rate of nucleation for any given set of reation conditions. Because the particle counter had a sensitivity limit of about 1 μm the lower limit of integration in equation (1) was changed from $2r^*$ to 1 μm and $N(2r^*, t)$ was replaced by $N(1, t)$ in all of the data analyses. Typical plot of $N(1, t)$ *vs.* time constructed from the data from Fig. 1, are shown in Fig. 2. The rate of nucleation was found to be proportional to $(\log s)^{-2}$.

That the rates of nucleation reported here are rates of homogeneous nucleation was indicated by the following general characteristics noted during comparative study of about 150 size distribution curves. In all but the very early size-distributions at any one initial supersaturation a large maximum with a small shoulder on the large-particle side was observed. With increased initial supersaturation there was a marked increase in the total number and a decrease in the average size of the particles formed. In addition, the experimental values of J and S conformed to the correlation drawn from

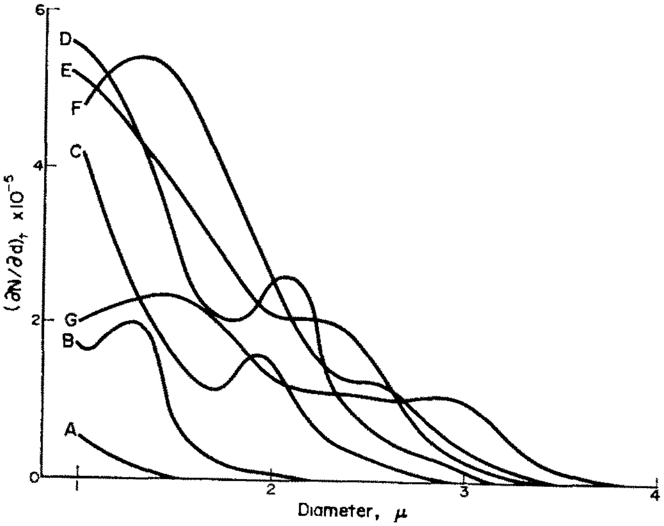

FIG. 1—Nickel dimethylglyoxinate size distributions ($C_0 = 2{\cdot}5 \times 10^{-4}M$). Size distributions A, B, C, D, E, F and G taken after 10, 30, 38, 60, 90, 120 and 230 sec. respectively

the Volmer-Weber, Becker-Döring model of homogeneous nucleation of crystals from solution. Recent criticism of the model, however, does cast doubt on the validity of the predicted correlation.[3,4,5]

Various parameters in the model calculated from the slope and intercept of the correlation of nucleation rate with supersaturation are shown in Table II. Although their actual significance is unclear, we find that these parameters do provide an adequate means of comparing experimental results. Experimental values of the kinetic constant A many orders of magnitude smaller than the

Summary—A new direct-mixing and rapid particle-counting system useful for studies on crystal nucleation solution is described. The methods used to calibrate and evaluate the system are reported together with the results obtained during studies on nucleation from solution of nickel dimethylglyoximate. The Volmer-Weber, Becker-Döring model of the nucleation process is used to correlate the results.

Zusammenfassung—Ein neues schnelles Teilchenzählsystem mit direkter Mischung wird beschrieben, das für Untersuchungen über die Kristallkeimbildung aus Lösungen von Nutzen ist. Es wird über die Methoden berichtet, mit denen das System geeicht und überprüft wurde, sowie über die Ergebnisse von Keimbildungsuntersuchungen aus Lösungen von Nickeldimethylglyoximat. Das Keimbildungsmodell von Volmer-Weber und Bekker-Doring wird verwendet, um die Ergebnisse zu ordnen.

Résumé—On décrit un nouveau système de mélange direct et de comptage de particules rapide, utile pour les études sur la production de germes cristallins en solution. On rapporte les méthodes utilisées pour étalonner et évaluer le système, en même temps que les résultats obtenus pendant les études sur la nucléation d'une solution de diméthylglyoximate de nickel. On utilise le modèle Volmer–Weber, Becker–Doring du processus de nucléation pour coordonner les résultats.

ANNOTATION

Losses of iridium during heating in various atmospheres

(*Received* 31 *August* 1971. *Accepted* 24 *October* 1971)

THE LOSS of iridium on heating may present a serious difficulty in analysis. Although it has been reported[1] that there are significant losses of iridium when the finely divided metal is heated in air at 800–950°, there has been no extensive, systematic investigation of this problem.

The reaction of iridium metal with oxygen[2–5] and with chlorine[1,6] has been investigated by several authors, most of whom studied the rates of reaction at relatively high temperatures, and used large quantities of material. The oxidation of the platinum metals was surveyed by Chaston[3] and indicates the surface formation of the oxide but no appreciable loss in weight of iridium up to 900°. Other authors[2,4] using mg or g amounts of iridium found weight losses in air of about 1–30 μg/mm^2/hr for the temperature range 650–1400°. Iridium losses during fire assay and cupellation were reported[7] to be as high as 63% after cupellation for 90 min at 1300°; radioactive iridium was used as a tracer. Beamish[1] reports losses of 1–3% on heating mg amounts of iridium in air at 800–950° and also notes complete chlorination of the metal and some volatilization when chlorine and sodium chloride are used at 700° for 8 hr. Some authors[6,8] have studied the chlorination as a preparative method for the various halides but these again deal with mg amounts and temperatures above 600°. Other reports concern the conversion of iridium compounds when various gases are used.[8–12] Delépine[10,11] reported on the use of sodium chloride and caesium chloride in aiding the action of chlorine on g amounts of iridium metal at 600°. Krauss and Gerlach investigated the products of the reaction of iridium metal with chlorine and with a mixture of chlorine and carbon monoxide at 600–620°. Merinis and Bouissières[13] used chlorination to volatilize submicrogram amounts of radioactive iridium at 700–1000° and used this technique as a means of separating different elements. The products were condensed in a tube possessing a large fixed temperature gradient; iridium moved 0·10–0·24 m and condensed in an area at about 575° in temperature.

The present report describes the effect of various atmospheres on iridium, both mg and μg amounts of metal and a wide range of temperatures being used.

EXPERIMENTAL

Apparatus

Lindberg Hevi-Duty Tube furnace.
Baird-Atomic Spectrometer Model 530.
Ultra Violet Products U.V. lamp, Model PCQX1.
Vycor combustion tubes 25 mm × 0·75 m and boats 10 × 40 mm.
Iridium-192 from Amersham/Searle.

Procedure

The volatility of iridium metal in various atmospheres was studied by using ^{192}Ir as a radioactive tracer because of its convenient 74·4 day half-life. The iridium samples were prepared by evaporating aliquots of the tracer in a Vycor combustion boat with or without the addition of various amounts of inactive iridium. The residue was then reduced to metal by heating the boat in a hydrogen atmosphere at 600–700° for 4 hr and then allowing it to cool in hydrogen.

Various sources were used to provide the different atmospheres tested. Commercial gas cylinders were used for hydrogen, nitrogen, oxygen, hydrogen sulphide, hydrogen chloride and chlorine. Air was obtained from an air-compressor. Bromine was obtained by gentle heating of a flask containing bromine, which was directly connected to the combustion tube. Hydrochloric and hydrobromic acids were obtained by boiling the acids. Hydrobromic acid, hydrochloric acid, acetic acid and perchloric acid atmospheres were obtained by bubbling air or oxygen or chlorine through a 500-ml flask half-filled with the particular acid and leading *via* Tygon tubing to the combustion tube. The gas flow for the system was controlled at between 2–5 ml/min in all cases.

The physical arrangement was as shown in Fig. 1 with both the combustion boat and tube offset in the furnace. The boat was situated closer to the gas inlet end and the tube had a longer outlet than inlet to aid in condensing any volatile compounds. The outlet from the combustion tube was led through a water trap to collect any volatiles and then to the fume exhaust. When perchloric acid was used, an all-glass system was employed with dry ground-glass joints fitted to a Vycor combustion tube.

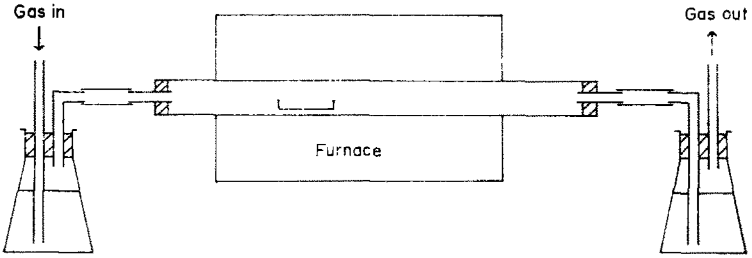

FIG. 1.—Apparatus used.

The distribution of ^{192}Ir radioactivity was observed by spectrometer with a 75-mm NaI(Tl) crystal with an additional lead shield fitted so that only an area 30 × 60 mm was counted. The change in ^{192}Ir distribution was observed by counting the tube before and after every run at a given temperature in a particular atmosphere. The same iridium sample was used until the change in distribution became significant. A count was taken at positions along the tube of 5, 15, 20, 25, 30, 35, 40, 50, 60, 70 cm, measured from the inlet end. The combustion boat was centred at 25 cm with the ends of the furnace at about 15 and 49 cm. In one case a low-pressure mercury lamp was used to irradiate the chlorine gas before it passed over the sample.

RESULTS AND DISCUSSION

The results from several trials using various amounts of iridium, various atmospheres and various temperatures are reported in Table 1. It should be noted that in no case was any radioactivity observed in the water trap for the effluent gases. When a volatile compound was produced, iridium

activity moved in both directions in the combustion tube, condensing just outside the furnace area, although the majority of the activity was found at the down-stream position. No attempt was made to identify the volatile species because of the difficulty of analysis of the vapour and the probability of a difference in either the condensed product or the dissolved product.

The results indicate that only in nitrogen or hydrogen may iridium be heated to much above 700° without some loss. In other atmospheres iridium losses occurred to a varying extent, depending on the amount of material present and probably on its surface area. In most experiments where air or oxygen was bubbled through acid, the acid did not have a significant effect on the temperature at which volatilization occurred although the species formed may well be different. In these cases, significant movement of iridium activity was observed at about 400°, which is similar to the experiments using oxygen alone. In chlorine, iridium was volatilized at temperatures as low as 220° and this was not affected by the presence of sodium chloride or by the chlorine being passed through perchloric acid. Microamounts seem to be more affected at the lower temperatures in chlorine and while this may not be of importance in many analyses, it may be useful for the separation of micro- and submicro-amounts of radioisotopes, *etc.*

The results obtained indicate that iridium should not be treated as an inert metal in analysis but that due concern should be paid to losses that may occur during heating, especially in chlorine or oxygen atmospheres.

Acknowledgement—The author wishes to thank the National Research Council of Canada for its financial support and Johnson Matthey and Mallory Ltd. (Toronto Canada) for providing the iridium used.

Summary—The volatility of iridium metal in different atmospheres was studied, using various weights, times and temperatures. Significant volatility was observed in oxygen and oxygen plus acid at temperatures above 400° and in chlorine above 220°

Zusammenfassung—Die Flüchtigkeit von metallischem Iridium in verschiedenen Atmosphären wurde bei verschiedenen Gewichten, Zeiten und Temperaturen untersucht. Merkliche Flüchtigkeit wurde in Sauerstoff und in Sauerstoff plus Säure bei Temperaturen über 400° beobachtet, in Chlor über 220°.

Résumé—On a étudié la volatilité de l'iridium métallique dans différentes atmosphères, en utilisant des poids, des temps et des températures divers. On a observé une volatilité importante en oxygène et oxygène plus acide aux températures supérieures à 400° et en chlore au-dessus de 200°.

Zusammenfassung—Eine neue, säulenchromatographische Methode der Molybdän-Matrixabtrennung bei der Alkali- und Erdalkali-Spurenbestimmung wird beschrieben. Die Molybdän-Sorption gelingt auf Sephadex G-10 Säulen bei pH 2,5 in ammoniumchloridhaltiger Lösung durch Ausbildung eines Molybdän-Ammoniak-Glucose-komplexes. Die quantitativ im Eluat verbleibenden Alkalispuren werden mittels Flammenemissionsphotometrie, die Erdalkalispuren mittels Atomabsorption erfaßt. Bei einer Trenndauer von 2 Stunden und entsprechender Automatisierung ist das Verfahren für die routinemäßige Alkali- und Erdalkali-Spurenanalyse in metallischem Molybdän, MoS_2, MoO_3, MoO_2 etc. geeignet. Die relative Standardabweichung liegt bis 60 ppm bei ±10%, darüber bei ±5%.

ALKALI- und Erdalkali-Verunreinigungen bzw. Beimengungen spielen bei der Molybdänherstellung eine Rolle, da sie die Eigenschaften des Endproduktes beeinflussen können. Diesbezügliche systematische Untersuchungen existieren jedoch noch nicht, was nicht zuletzt darauf zurückzuführen sein dürfte, daß die bekannten Methoden der exakten Bestimmung von Alkali- and Erdalkalispuren in Molybdän sehr mühsam, kontaminationsanfällig und aufwendig sind. Sublimationsverfahren zur Matrixbeseitigung[1] sind bei Molybdän schlecht reproduzierbar. Ionenaustauschverfahren,[2,3] insbesondere zur Alkaliabtrennung ergeben auf Grund schwer zu reinigender Reagenzien hohe Blindwerte oder machen langwierige Reinigungsoperationen derselben nötig. Über die direkte Bestimmung von Alkali- und Erdalkalispuren in Molybdän mittels physikalisch-chemischer Analysenverfahren wie Festkörpermassenspektrometrie, Emissionsspektralanalyse, Aktivierungsanalyse oder Atomabsorption ist wenig bekannt.[4,5] Durchwegs beeinträchtigen ausgeprägte Matrixeffekte die Reproduzierbarkeit und Nachweisempfindlichkeit der Messung. Insbesondere bei der Analyse von Molybdänoxiden führt die überaus stark ausgeprägte Inhomogenität dieser Materialien beim Einsatz kleiner Probenmengen (Massenspektrometrie, Emissionsspektralanalyse) zu stark streuenden Werten.

Die ausgeprägte Tendenz des Molybdäns zur Komplexbildung mit aliphatischen Polyhydroxoverbindungen ist schon seit längerem bekannt. Es war daher zu erwarten, daß Molybdän auch von Dextrangelen stark sorbiert wird. Ferner ist bekannt, daß Alkali- und Erdalkaliionen sowie eine Vielzahl anderer Anionen und Kationen bei Ionenstärken über 0,01 Sephadexsäulen ungehindert passieren. Somit schien die Abtrennung des Molybdäns als Matrix von einer unter Umständen beträchtlichen Anzahl von Spurenenlementen gegeben. Auf Grund dieser Überlegungen wurde zunächst das Verhalten von Molybdän an Dextrangelen prinzipiell untersucht.

Hierauf gelang auf Sephadex G-10 die Ausarbeitung einer raschen und sicheren Abtrennung von Alkali- und Erdalkalispuren von Molybdän. Dieses säulenchromatographische Verfahren bedient sich lediglich der durch Isothermdiffusion in beinahe beliebiger Reinheit leicht zu erhaltenden Reagenzien Ammoniak und Salzsäure. Bei einer Trenndauer von 2 Stunden und entsprechender Automatisierung ist das Verfahren für die routinemäßige Alkali- und Erdalkalispurenanalyse in Molybdän bestens geeignet.

AUSARBEITUNG DER METHODE

Geräte

Radioaktivitätsmessungen erfolgten mit einem Zählgerät der Firma Frieseke & Hoepfner, FH 49A, Grundsonde FH 421 AS, NaJ-Bohrlochszintillationskristall Z 11, in Verbindung mit einem 100-Kanal Gammaspektrometer TMC-Gammascope II[*] in Einkanalschaltung.

Flammenemissionsspektrophotometrische und atomabsorptionsphotometrische Messungen wurden an folgenden Geräten durchgeführt: Zeiss-Spektralphotometer PMQ II mit den Flammenzusätzen FA1 und FA2; Eppendorf Flammenphotometer[†]; Perkin–Elmer Atomabsorptionsspektrophotometer 290B[†]; Beckmann DU[‡]; Jarrel Ash Atomsorb, Serie 82–250.[‡]

Säulenchromatographie: Es kamen sowohl käufliche Säulen (Pharmacia, Uppsala, Schweden: Typen K9/15 und K15/30) als auch selbst gefertigte Säulen zum Einsatz. Letztere wurden aus Plexiglasrohren (30 mm Durchmesser), gestanzten Filterplatten aus Hochdruckpolyäthylen (Plastibrand-Labpor, Dicke 1,6 mm, Porosität 70 μm) und Auslauftrichtern aus Vinidur hergestellt. Proben- und Elutionsmittelaufgabe erfolgte mit einer Mikropumpe der Firma Bühler & Co., Tübingen, BRD Typ mp 1. Es wurden ausschließlich Silikonschläuche verwendet. Ein automatischer Fraktionssammler "Fraktomat", Buchler Instruments, Fort Lee, USA, wurde bei Bedarf eingesetzt. Es wurde durchwegs in PVC-, Polyäthylen- bzw. Teflongefäßen gearbeitet.

Materialien

Sephadex G-10 fine, G-15 fine und LH-20 fine von Pharmacia, Uppsala.

Natriumchlorid, Kaliumchlorid, Cäsiumchlorid, Ammoniumchlorid, Calciumchlorid-4-hydrat, Ammoniaklösung (min. 25 %), Salzsäure (min. 37 %), Salpetersäure (min. 65 %), alle Reinheitsgrad "suprapur", sowie Magnesiumchlorid, Zinn(II)chlorid, Kaliumthiocyanat p.a. und Äthylendiamintetraessigsäure (Titriplex II), von Merck, Darmstadt.

MoO$_3$, zweifach sublimiert, von Metallwerk Plansee AG. & Co. KG.

^{22}Na und ^{47}Ca von The Radiochemical Centre, Amersham, England.

^{99}Mo und ^{42}K wurden durch Bestrahlung von MoO$_3$ bzw. KCl im ASTRA-Reaktor der Österreichischen Studiengesellschaft für Atomenergie in Seibersdorf selbst hergestellt.[§]

Bidestilliertes Wasser aus einer Quarzapparatur.

Die Sorption von Molybdän(VI) *an Dextrangelen*

Erste Versuche wurden unter dynamischen Bedingungen, d.h. auf Säulen durchgeführt, Tab. I. Das am engsten vernetzte Gel Sephadex G-10 weist die größte Sorptionskapazität für Molybdän auf. Daher wurden sämtliche weiteren Versuche mit diesem Gel durchgeführt.

In einer Reihe von Batch-Versuchen, Tab. II, wurde das Verhalten von Mo(VI)-Lösungen auf Sephadex G-10 einer näheren Untersuchung unterzogen. Es wurde 0,5 g trockenes Sephadex G-10 in ein Zentrifugenglas eingewogen und 3 ml Wasser

zugesetzt. Das Gel wurde über Nacht quellen gelassen. Hierauf wurden jeweils 3 ml der zu untersuchenden Lösung zugesetzt und auf einer Schüttelmaschine kräftig geschüttelt. Die Lösungen waren durchwegs mit ^{99}Mo* dotiert. Drei ml der überstehenden Lösung wurden nach Zentrifugieren vorsichtig abpipettiert und die Impulsrate im Bohrlochszintillationszähler gemessen. Anschließend wurde nochmals der pH-Wert gemessen. Sämtliche Batch-Versuche wurden bei Zimmertemperatur

---

* ^{99}Mo wurde ab 0,30 MeV integral gemessen.

ausgeführt (*ca.* 22°C). Die Berechnung der Gewichtsverteilungskoeffizienten erfolgte nach folgender Gleichung:

$$D_g = \frac{\text{mmol sorbiertes Mo/g trockenes Gel}}{\text{mmol Mo/ml Lösung}}$$

Bei den Batch-Versuchen konnte folgendes festgestellt werden.

(*a*) *Kinetik.* Die Ausbildung des Molybdän-Sephadexkomplexes verläuft bei Zimmertemperatur relativ langsam. Daher muß bei Säulenexperimenten mit ziemlich niedrigen Durchflußgeschwindigkeiten gearbeitet werden.

(*b*) *pH-Abhängigkeit.* Die Molybdän-Sorption ist sehr pH-abhängig und weist in Lösungen mit geringer Fremdsalzkonzentration ein ausgeprägtes Optimum bei pH 1,4–1,7 auf. Der pH-Wert nach dem Batch-Versuch liegt durchwegs höher als vorher.

(*c*) *Abhängigkeit von der Molybdän-Konzentration.* Überraschenderweise nahmen die Verteilungskoeffizienten mit abnehmender Mo(VI)-Konzentration ab. Die zweite Variable dieser Versuchsreihe war die ebenfalls sinkende NH_4Cl-Konzentration. Es lag daher nahe, das Experiment bei konstanter NH_4Cl-Konzentration zu wiederholen.

(*d*) *Abhängigkeit von der Ammoniumchloridkonzentration.* Tatsächlich ist die Molybdän-Sorption nicht nur eine Funktion des pH-Wertes, sondern auch der NH_4Cl-Konzentration. Bei konstanter Ammoniumchloridkonzentration erreicht die Molybdän-Sorption bei mittleren Molybdän-Konzentrationen ein Maximum. Die sinkende Sorption bei niedriger Molybdän-Konzentration läßt auf eine gewisse Löslichkeit des anzunehmenden Mo–NH_3-Glucosekomplexes schließen. Dies steht auch in Einklang mit den unter (*c*) beschriebenen Resultaten.

(*e*) *pH-Optimum bei Molybdän-Sorption in Gegenwart von* NH_4Cl. Der pH-Variation sind bei hoher Molybdän- *und* NH_4Cl-Konzentration Grenzen gesetzt. Zu niedrige pH-Werte verursachen vor allem bei längerem Stehen der Lösung eine (ziemlich temperaturabhängige) Ausfällung von Ammoniummolybdat. pH-Werte unter 2,5 können daher nicht verifiziert werden. Wieder zeigt sich ein deutliches Absinken der Sorption mit steigendem pH-Wert.

(*f*) *Endgültige Optimierung.* Schließlich wurde bei pH 2,5 nochmals der Einfluß steigender Ammoniumchloridmengen bei höchstmöglicher Molybdän-Konzentration untersucht. Die eingesetzte Molybdänlösung (0,174*M*) entspricht der für spätere Säulenexperimente verwendeten Einwaage von 2,5 g Mo/100 ml.

Säulenchromatographie

Weitere Versuche wurden wieder unter dynamischen Bedingungen in einer Reihe von Säulenexperimenten unternommen. Die Füllung der Säulen wurde nach der in der Gelchromatographie üblichen Art vorgenommen. Wichtig ist eine Einlaufzeit von mindestens 12 Stunden bei *ca.* 100 ml/h nach erfolgter Neufüllung einer Säule. Zur Feststellung der Molybdändurchbruchskapazität wurde die Tüpfelreaktion mit $SnCl_2$ und KSCN angewandt.[6]

Abbildung 1 zeigt ein überaus stark ausgeprägtes pH-Optimum für die Molybdändurchbruchskapazität bei pH 2,5. Dies steht in Einklang mit den Batch-Versuchen. Abbildung 2 zeigt pH-Profile von Eluaten bei Säulen experimenten, welche unter sonst gleichen Bedingungen mit verschiedener NH_4Cl-Konzentration der

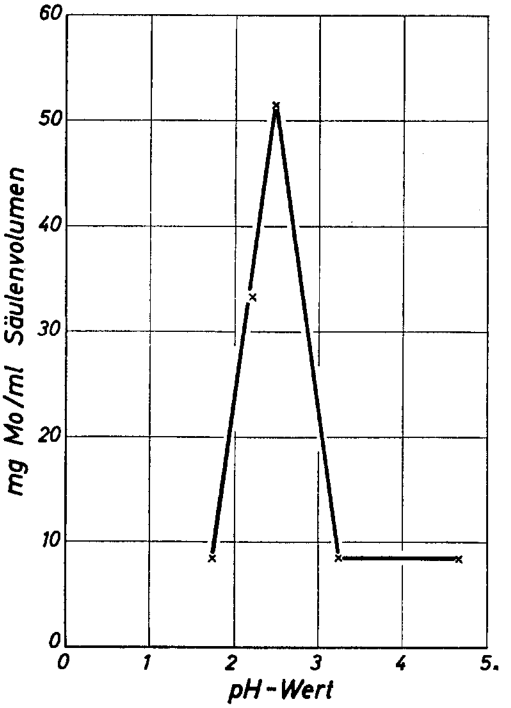

ABB. 1.—Bestimmung der Mo-Durchbruchskapazität auf Sephadex G-10 Säulen als Funktion des pH-Wertes.

Säulendimensionen: 125 × 9 mm; Zimmertemperatur; Durchflußgeschwindigkeit: 0,47 ml/h^{-1} mm^{-2} (= 30 ml/h); Aufgabelösung: 0,14*M* Mo; 0,05*M* NH$_4$Cl. pH-Einstellung jeweils mit HCl.

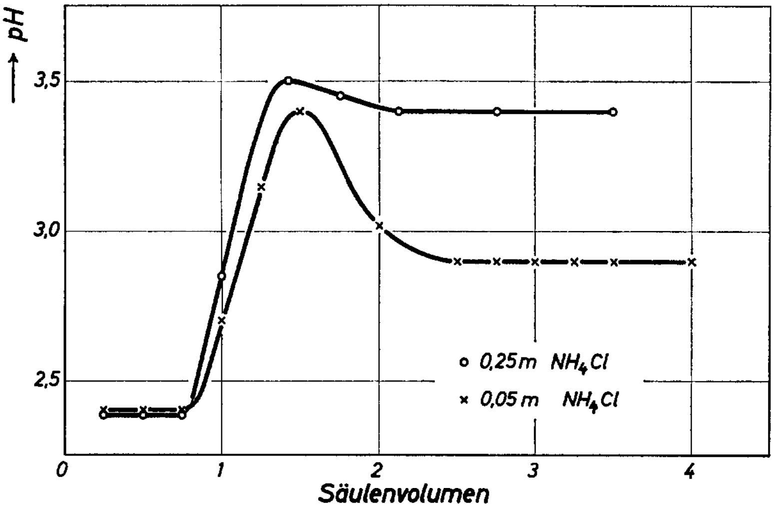

ABB. 2.—pH-Elutionsprofile bei Molybdänsorption auf Sephadex G-10 Säulen. Einfluß steigender Ammonchloridmengen.

Säulendimensionen: 100 × 30 mm; Zimmertemperatur; Durchflußgeschwindigkeit: 0,14 ml/h^{-1} mm^{-2}; Aufgabelösung: 0,174*M* Mo; pH-Wert 2,5.

Aufgabelösung durchgeführt wurden. Bei Komplexbildung des Molybdäns mit den Glucoseeinheiten des Dextrangels werden OH-Ionen frei. Bei höherer NH_4Cl-Konzentration ist diese OH-Ionenbildung offensichtlich verstärkt; dies deutet wohl auf ausgeprägtere Komplexbildung bei Anwesenheit von NH_4Cl hin. Auch bei den Batch-Experimenten läßt sich diese Tendenz feststellen. Da durch die auftretende pH-Änderung ein Abweichen von dem zur Komplexbildung optimalen pH-Wert eintritt, wurde versucht, letzteren durch Anwendung eines geeigneten Puffergemisches konstant zu halten. Sämtliche in Frage kommenden Puffergemische enthalten jedoch organische Säureanionen, die mit Molybdän Komplexe bilden. Es kommt dadurch immer zu einer Verminderung der Durchbruchskapazität. Daher wurde auf eine Pufferung der Aufgabelösung verzichtet.

Wie schon die Batch-Experimente zeigten, muß mit ziemlich niedrigen Durchflußgeschwindigkeiten gearbeitet werden. Bis zu 20 $ml.h^{-1}.cm^{-2}$ erreicht man jedoch Säulenkapazitäten, die mit denen von Ionenaustauschern durchaus vergleichbar sind (0,86 mmol Mo/ml Säulenvolumen). Als Säulendimensionen wurden daher für die Sorption von maximal 5 g MoO_3 und im Hinblick auf eine möglichst rasche Trennung 100 × 30 mm gewählt.

Elutionsverhalten von Alkali- und Erdalkalispuren bei der Molybdän-Matrixabtrennung auf Sephadex G-10

Untersuchungen über das Elutionsverhalten von Alkalispuren ergaben, daß bei geringer NH_4Cl-Konzentration der Aufgabelösung Kalium über den gesamten untersuchten Konzentrationsbereich mit gleichbleibend schlechter Ausbeute von etwa 50 % eluiert wird, während die Ausbeuten für Natrium erst ab etwa 300 ppm als quantitativ zu betrachten sind (Abb. 3). Immerhin ist bei Natrium eine Sorptionsisotherme erkennbar, während sich Kalium durchwegs statistisch auf stationäre innere

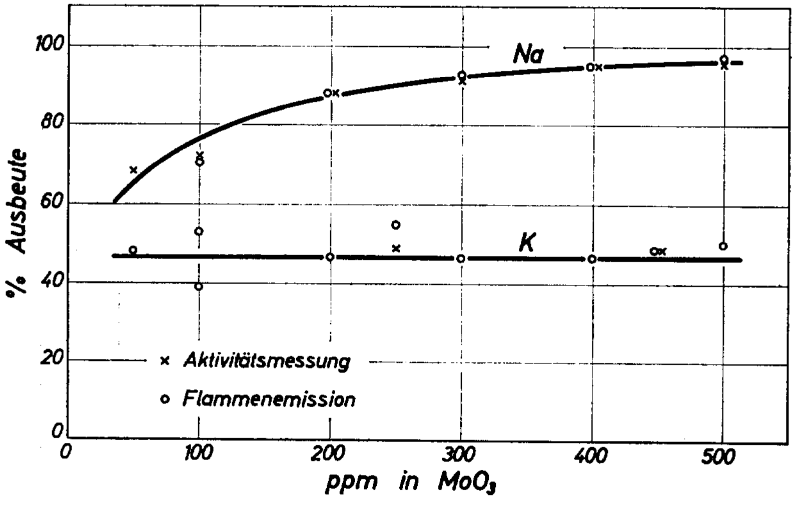

ABB. 3.—Alkalispurenverhalten bei der Mo-Matrixabtrennung bei niedriger NH_4Cl-Konzentration der Aufgabelösung.

Säulendimensionen: 120 × 30 mm; Zimmertemperatur; Tropfgeschwindigkeit: 100 ml/h. Aufgabelösung: jeweils 250 ml; 0,14*M* Mo (= 5 g MoO_3); pH-Wert 2,5; 0,05*M* NH_4Cl; Nachelution mit 100 ml 0,2*M* NH_4Cl. Gesamtelutionsvolumen 350 ml. Mo ist erst ab 350 ml im Eluat nachweisbar.

und mobile äußere Phase zu verteilen scheint. Ferner wurde das Elutionsverhalten von NaCl-Spuren auf reinen und mit Molybdän beladenen Sephadex G-10 Säulen untersucht: An reinen G-10 Säulen wurde NaCl mit einem Peakelutionsvolumen eluiert, das der Summe aus Zwischenkornvolumen und innerem Gelvolumen ($v_0 + v_i$) entspricht. An mit Molybdän beladenen Säulen erscheinen die ersten Natriumspuren beim *ca.* 2,5-fachen Peakelutionsvolumen des ersten Versuches. Die Ursache dieser Erscheinungen dürfte folgende sein.

Durch Bildung des Mo–NH_3-Glucosekomplexes wird die Sephadexsäule in eine Art "anorganischen Ionenaustauscher" verwandelt. Bekanntlich weist z.B. mikrokristallines Ammoniumphosphomolybdat hohe Selektivität für Kalium, Rubidium und Cäsium in sauren Lösungen auf.[7] Damit ist aber auch der Weg zur Überwindung dieser Schwierigkeit aufgezeigt: Bei Anwendung einer höheren NH_4Cl-Konzentration der Aufgabelösung verhindern die im riesigen Überschuß vorhandenen, praktisch gleich großen NH_4^+-Ionen die Kalium-Sorption und bedingen gleichzeitig eine bessere Komplexbildung des Molybdäns mit dem Sephadex.

Tabelle III gibt eine Übersicht über Ausbeuteuntersuchungen bei endgültig optimierten Bedingungen. Um Fehler durch Kontamination zu vermeiden und die Messungen mit konstanter hoher Präzision durchführen zu können, wurden radioaktiv markierte Lösungen und Gamma-Spektrometrie zur Endbestimmung herangezogen. Die Ausbeuten für Kobalt zeigen, daß die Methode auch zur Abtrennung anderer Metallspuren geeignet ist.

Tabelle III.—Ausbeuteuntersuchung bei endgültig optimierten Bedingungen

Element*	Aufgegeben, *ppm*	Ausbeute, %
$Na(+{}^{22}Na)$	trägerfrei	98, 99, 98
$K(+{}^{42}K)$	34	98,0
	50	96,0
	168	99,5
$Ca(+{}^{47}Ca)$	5	96,0
	7	98,0
$Co(+{}^{60}Co)$	100	97,0

* ${}^{22}Na$, ${}^{42}K$ und ${}^{47}Ca$ wurden in den Bereichen der Peaks bei 0,51, 1,52 bzw. 1,31 MeV gemessen.

Säulendimensionen: 100 × 30 mm; Zimmertemperatur; Tropfgeschwindigkeit: 100 ml/h.

Aufgabelösungen: jeweils 200 ml; 0,174*M* an Mo (= 5 g MoO_3); pH-Wert 2,5; *ca.* 2 g NH_4Cl/200 ml; Nachelution mit 100 ml 1*M* NH_4Cl (pH 2,5).

Zur spektroskopischen Endbestimmung

Die flammenphotometrische Alkali- und Erdalkalibestimmung erfolgte ohne Einengung des Säuleneluates nach Zugabe von 1000 ppm Cäsium als Strahlungspuffer. Interelementbeeinflussungen (besonders die des Natrium auf Kalium) werden dadurch hintangehalten. Eine Einengung der Säuleneluate zur Erhöhung der Nachweisempfindlichkeit ist zwar möglich, aber mühsam und bei Konzentrationen über 10 ppm unzweckmäßig (Die Vertreibung der Ammonsalze gelingt nach Einengung bis zur Krustenbildung durch portionsweise Zugabe (3–4 mal) von je 5 ml konz. HNO_3. Ein Verlust an Alkali- und Erdalkalispuren tritt dabei nicht auf).

Für die Erfassung von Natrium und Kalium wurde die Flammenemissionsspektralanalyse (Propan-Luft) verwendet, für Calcium und Magnesium die Atomabsorption (Preßluft-Acetylen).

Eichkurven

Molybdänprobelösungen wurden mit variierenden Mengen an Alkali- und Erdalkalispuren versetzt und zur Matrixabtrennung über die Säule geschickt. Für die Endauswertung wurden auf 2 verschiedenen Wegen Eichkurven erstellt:

(*a*) Die Eichlösungen enthielten neben dem zu bestimmenden Element 3% Ammoniumchlorid.

(*b*) Zur Erstellung von Eichlösungen wurde mit entsprechenden Zugaben an Alkali- und Erdalkalichloriden aufgestocktes Säuleneluat von reinem MoO_3 verwendet. Nach erfolgter Chromatographie wurden die Alkali- und Erdalkaligehalte der dotierten Proben gegen die aufgestockten Eluate als Eichlösungen vermessen und mit der tatsächlich zugesetzten Menge verglichen.

Im folgenden ist die Arbeitsvorschrift für MoO_3-Einwaagen von 2,5 g pro Säulentrennung wiedergegeben. Die Säulenkapazität reicht jedoch für Einwaagen bis zu 5,0 g MoO_3 (= 200 ml Aufgabelösung) pro Säulentrennung aus.

ARBEITSVORSCHRIFT

Probenvorbereitung

Molybdänmetallpulver oder -späne werden in möglichst wenig konzentrierter HNO_3 und konzentrierter HCl (1:1) gelöst (Teflonbecher) und zur Trockene eingedampft. Anschließend glüht man das entstehende MoO_3 drei Stunden bei 450° (Platinschale). MoO_2 wird mit konzentrierter HNO_3 durch leichtes Erhitzen in MoO_3 überführt und ebenfalls 3 Stunden bei 450° geglüht. Bei MoS_2 und Ammoniummolybdaten genügt dreistündiges Glühen bei 450°.

Es wird 6,25 g MoO_3 hierauf in einem Teflonbecher in *ca.* 50 ml H_2O suspendiert, auf 70–80° erwärmt und unter Rühren mit 8 ml Ammoniak (25 Gew.-%) versetzt. Die Auflösung erfolgt sofort. Dann wird auf *ca.* 200 ml verdünnt und 6 ml konzentrierte HCl (37 Gew.-%) zugegeben. Bei sehr unreinen Produkten bleibt vorhandenes SiO_2 ungelöst und muß abfiltriert werden. Die Lösung wird nun in einen Plastikmeßkolben überführt und auf 250 ml aufgefüllt; 2–3 ml werden zur pH-Messung entnommen. Der pH-Wert liegt meist bei 3,0–2,8. Nach Zugabe einiger Tropfen konz. HCl und Umschütteln wird der pH-Wert nochmals gemessen. Dies wird fortgesetzt, bis der pH-Wert von 2,5 erreicht ist. Auf diese Weise vermeidet man eine eventuelle Kaliumkontamination der Probelösung durch die Glaselektrode. Die angegebene Menge Ammoniak entspricht nach dem Ansäuern dem nötigen Ammoniumchloridüberschuß von *ca.* 1 g/100 ml Aufgabelösung. Dadurch wird die Zugabe von NH_4Cl überflüssig. Je 100 ml der so hergestellten Lösung (entsprechend einer Einwaage von je 2,5 g MoO_3) werden zu zwei parallelen Alkali- und Erdalkalibestimmungen verwendet. Nur frisch bereitete Lösungen führen unter strenger Einhaltung der angeführten Bedingungen zu reproduzierbaren Resultaten. Besonders bei Zimmertemperaturen unter 20° tritt bei längerem Stehen Ausfällung von Ammoniummolybdat ein.

Auch Ammoniummolybdate müssen vor der Auflösung mit Ammoniak in MoO_3 übergeführt werden, da sonst keine quantitative Sorption auf der Säule stattfindet. Vermutlich ergeben deren Lösungen bei der Ansäuerung andere, schlechter sorbierbare Aggregate als dies bei MoO_3 als Ausgangsmaterial der Fall ist.

Säulenchromatographie

Säulenbett: 100 × 30 mm Sephadex G-10 fine. Durchflußgeschwindigkeit: 0·14 ml/h.mm^2 (= 100 ml/h). Zimmertemperatur. Aufgabevolumen: 100 ml; Nachelution mit 100 ml 1*M* Ammoniumchlorid (pH 2,5).

Die ersten 30 ml Eluat werden verworfen, dann werden 150 ml Eluat in einem Plastikmeßzylinder gesammelt. Die Säulen werden durch Aufgabe von 200 ml 0,1*M* Ammonium-ÄDTE (pH 6, 100 ml/h), gefolgt von 150 ml 1*M* Ammoniumchlorid (pH 2,5) regeneriert. Die Säulen sind vor Licht durch Alu-Folie oder Kohlepapier zu schützen, da sonst intensive Blaufärbung des Säulenbettes eintritt und die Regenerierung erschwert ist. Eine leichte Blaufärbung des Säulenbettes ist unbedenklich. Die Säulen sind nach unserer Erfahrung praktisch unbegrenzt verwendbar.

Endbestimmung

Die flammenphotometrische Alkali- und Erdalkalianalyse erfolgt ohne Einengung im Eluat. Zu 150 ml Eluat wird jeweils 1 ml einer CsCl-Lösung zugesetzt, die 19 g CsCl/100 ml enthält. Dies entspricht einer Dotierung mit 1000 ppm Cs.

ANWENDUNG DER ENTWICKELTEN METHODE AUF KALIUM-ANALYSEN IN VERSCHIEDENEN MOLYBDÄNVERBINDUNGEN

Ein Beispiel der praktischen Anwendung der entwickelten Methode ist die Bestimmung des Kaliumgehaltes einer Reihe von MoO_3-, MoS_2- und Ammoniummolybdat-Rohstoffproben (Tab. IV). Zum Vergleich wurden einige Proben auch von einem Schiedslabor nach dort üblichen Methoden untersucht. Die Übereinstimmung kann, abgesehen von den Werten für MoS_2, als sehr gut bezeichnet werden. Ferner ist in Tab. V die Veränderung des Kaliumgehaltes in Molybdänvorprodukten und Sintermolybdän während des Erzeugungsganges zusammengestellt.

TABELLE IV.—KALIUM-ANALYSEN IN MOLYBDÄN-ROHSTOFFEN

DISKUSSION

Zur Komplexbildung des Molybdäns mit Dextrangelen

Über die Komplexbildung des Molybdän(VI) mit aliphatischen Polyhydroxoverbindungen liegen zahlreiche Untersuchungen mit einander oft widersprechenden Ergebnissen vor.[8–14] So behaupten Bourne *et al.*,[10] daß nur diejenigen Monosaccharide mit Molybdän Komplexe bilden, welche ein *cis–cis* 1,2,3-triol System aufweisen.

Rimbach und Ley[11] finden jedoch Molybdän–Glucose Komplexe. Dieser Befund wird durch die vorliegende Untersuchung erhärtet. Das Gel mit der höchsten Gelkonzentration pro Volumeneinheit weist auch die höchste Sorptionskapazität für Molybdän auf. Im Sephadexgel LH-20 ist die Anzahl der 1,2,3-triolgruppen gegenüber den anderen eingesetzten Geltypen stark vermindert. Es tritt jedoch nur eine geringfügige Kapazitätsverminderung gegenüber G-15 ein, was auf den etwas geringeren Vernetzungsgrad von LH-20 zurückzuführen ist. Somit genügen zur Chelatkomplexbildung des Molydäns mit den Glucoseeinheiten der Dextrangele zwei benachbarte OH-Gruppen.

Übereinstimmend wird berichtet, daß die Molybdän-Polyhydroxoverbindungen nur in saurer Lösung stabil sind[12] (Optimum bei pH-Wert 2 und durch Alkalien zerstört werden. Eine Zunahme des pH-Wertes der Lösung bei Komplexbildung wurde beobachtet.[9,13] Dies wird nach dem von Püschel und Lassner[14] angegebenen Reaktionschema verständlich, das hier in etwas modifizierter Form wiedergegeben

$$[Mo(OH)_8]^{2-} + R(OH)_n \rightarrow [Mo(OH)_{8-x}R(OH)_n]^{-2+x} + xOH^-$$

wird. Der Übersichlichkeit halber wurde ein Molybdation zur Reaktion gebracht, obwohl es sich bei pH-Wert 2,5 und der relativ hohen Konzentration an Molybdän natürlich um Isopolysäuremoleküle handelt. Am Prinzip der Reaktion ändert diese Vereinfachung nichts. In Analogie zu Überlegungen betreffend die Chemie des Niobs und Tantals in wäßrigen Lösungen[15] wurde auch im vorliegenden Fall das Molybdation als vollkommen hydratisiert formuliert. Es ist anzunehmen, daß der Polymerisationsgrad des sorbierten Molybdäns nicht einheitlich ist.[16] Die Erniedrigung des Polymerisationsgrades bei sinkender Molybdän-Konzentration könnte zu schlechterer Sorbierbarkeit des Molybdäns bei niedriger Konzentration beitragen (vgl. Batch-Experimente). Daß jedoch die Löslichkeit des Mo–NH_3–Glucosekomplexes eine wohl dominierende Rolle spielt, geht daraus hervor, daß die Molybdän-Durchbruchskapazität auf Sephadex G-10 Säulen sehr abhängig von der NH_4^+-Konzentration der Probe und auch der Nachelutionslösung ist. Schon Frey[17] und Soubarew-Chatelain[18] isolierten salzartige Molybdän–Zuckerkomplexe, die NH_3 komplex im Anion gebunden hatten. Die hier vorgeschlagene Konstitutionsformel führt zu Mo–NH_3–Glucosekomplexen chelatartigen Charakters, was die Bildung des Molybdäns an die Glucoseeinheiten des Gels sowie die Bindung der einzelnen Molybdänatome untereinander betrifft. Die entstehenden Komplexe sind ungeladen. Die offensichtlich hohe Affinität dieser Komplexe für K^+ und NH_4^+ dürfte in Analogie zu Salzen verschiedener Heteropolysäuren des Molybdäns und Wolframs[7] auf sterische Effekte zurückzuführen sein, wie sie auch für die Austauscheigenschaften der Zeolithe bekannt sind. Die stabilere Komplexbildung bei Anwesenheit von NH_4Cl dürfte

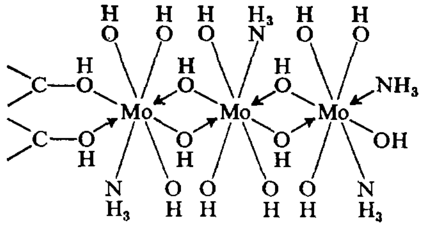

Abb. 4.—Vereinfachtes Reaktionsschema von Molybdän mit aliphatischen Polyhydroxoverbindungen—Mögliche Konstitutionsformel des Mo-NH_3-Glucosekomplexes.

durch eine Erniedrigung der Gitterenergie des entstehenden Komplexes bei Einbau von NH_3-Gruppen verusacht sein. Die Komplexbildung deutet sich durch leichte Gelbfärbung des Säulenbettes in der Sorptionszone an. Bei Lichteinwirkung verfärbt sich das Säulenbett blau, offenbar durch Bildung von Mischoxidhydraten infolge schwacher Reduktion durch die UV-Strahlung.

Zur flammenphotometrischen Alkali- und Erdalkalibestimmung

Direktzerstäuberbrenner vom Ringspalttyp (Zeiss-Flammenansatz FA1, Beckman DU) sind wegen der relativ hohen Ammoniumchloridkonzentration in den Säuleneluaten nicht anwendbar. Es tritt sehr bald Verstopfung der Ansaugkanüle ein. Die Hohlkathodenlampen des zur Verfügung stehenden Zeiß-Atomabsorptionszusatzes FA2 waren bei keinem Lampenstrom auf annähernd konstante Strahlungsintensität zu bringen. Die Bestimmung von Natrium und Kalium in Emission auf dem Eppendorf-Gerät sowie die Erfassung von Calcium und Magnesium in Absorption mit den Geräten Perkin–Elmer 290B und Jarrel Ash Atomsorb verliefen komplikationslos.

Wie bei allen Verfahren der direkten flammenphotometrischen Erfassung von Metallspuren ist auch hier ein Verdünnungsfaktor gegeben, d.h. die ursprünglich in 2,5 g Einwaage vorhandenen Spuren werden nach erfolgter Matrixabtrennung in einem Volumen von 150 ml erfaßt (Faktor 60). Bei niedrigen Spurengehalten arbeitet man somit (vor allem bei Calcium) an der Grenze der exakt quantitativen Erfaßbarkeit.

Durch den Ammoniumchloridgehalt von etwa 3% in den Säuleneluaten tritt insbesondere bei Flammenemission eine beträchtliche Depression der Strahlungsintensität gegenüber rein wäßrigen Lösungen ein.

Die genaue Überprüfung des Analysenverfahrens erfolgte unter Anwendung von aufgestockten Säuleneluaten als Eichlösung. Reine Molybdänlösungen wurden vor Aufgabe auf die Säule mit bekannten Mengen an Natrium, Kalium, Calcium und Magnesium versetzt, chromatographiert und die Alkali- und Erdalkaligehalte gegen die aufgestockten Eluate (als Eichlösungen) vermessen. Die Übereinstimmung mit der tatsächlich zugesetzten Menge war zufriedenstellend. Dieses Verfahren erfaßt sämtliche Analysenparameter. Die so erhaltenen Werte stimmten jedoch auch mit Resultaten überein, die man erhält, wenn dieselben Eluate mit entsprechend dotierten Ammoniumchloridlösungen als Eichlösungen verglichen wurden. Auch die nach beiden Verfahren ermittelten Blindwerte für das eingesetzte reine MoO_3 waren praktisch identisch. Die Reproduzierbarkeit ist für beide Methoden gleich. Bis etwa 60 ppm liegt der Variationskoeffizient bei ±10%, darüber bei ±5%. Zur Aufstellung der Eichkurven kann daher eine 3%ige Ammoniumchloridlösung verwendet werden, die mit Salzsäure auf pH 2,5 gebracht wurde.

Summary—A new column chromatographic method for the separation of molybdenum as matrix element from traces of alkali and alkaline earth metals is introduced. The molybdenum(VI) sorption is achieved on Sephadex G-10 columns at pH 2·5 in ammonium chloride solutions, by the formation of an Mo–NH_3–glucose complex. Alkali and alkaline earth metal traces remain quantitatively in the effluent and are determined by flame-emission and atomic-absorption spectrophotometry respectively. Separation time is slightly less than 2 hr. With some automation the procedure is well suited for routine trace analysis of sodium, potassium, calcium and magnesium in metallic molybdenum, MoO_3, MoO_2, MoS_2, *etc.* The coefficient of variation is ±10% up to 60 ppm, and ±5% at above 60 ppm.

Résumé—On présente une nouvelle méthode de chromatographie sur colonne pour la séparation du molybdène en tant qu'élément de matrice de traces de métaux alcalins et alcalino-terreux. La sorption du molybdène(VI) est réalisée sur des colonnes de Sephadex G-10 à pH 2,5 dans des solutions de chlorure d'ammonium, par la formation d'un complexe Mo-NH_3-glucose. Les traces de métaux alcalins et alcalino-terreux restent quantitativement dans l'effluent et sont dosées par spectrophotométrie d'émission de flamme et spectrophotométrie d'absorption atomique respectivement. Le temps de séparation est légèrement inférieur à 2 h. Avec une certaine automatisation, la technique convient bien à l'analyse de routine de traces de sodium, potassium, calcium et magnésium dans le molybdène métallique, MoO_3, MoO_2, MoS_2, etc. Le coefficient de variation est de ±10% jusqu'à 60 ppm, et de ±5% au-delà de 60 ppm.

COMPUTER CALCULATION OF ACTIVATION ENERGIES OF IRREVERSIBLE ELECTRODE PROCESSES AT A DROPPING MERCURY ELECTRODE

D. R. CROW and S. L. LING
Thames Polytechnic, London S.E.18, U.K.

(*Received* 26 *August* 1971. *Accepted* 29 *November* 1971)

Summary—A computer program has been written for calculation of the activation energies of irreversible electrode processes at a dropping mercury electrode, based on the variation of current and half-wave potential with temperature. The program calculates the half-wave potential, the transfer coefficient, and the activation energies of the diffusion process and the irreversible electrode process. It has been written in both ALGOL and FORTRAN.

POLAROGRAPHIC methods for obtaining thermodynamic parameters relating to coordination compounds have already been established. Knowledge of the activation energy and the frequency factor for a reduction process can be of importance to inorganic chemists. These two parameters can yield important information regarding the mechanism of the electrode reaction. The first is a measure of structural changes within the depolarizer during the acceptance of electrons, and the second indicates the orientation of the depolarizer at the electrode surface.

Experimentally, the absolute value of the activation energy cannot be determined; it is possible, however, to determine a relative value. Values of the activation energy have usually been determined from the temperature-dependence of current–voltage curves without concentration polarization. A simple polarographic method based on that proposed by Vlček,[1] provides two means for determining activation energy. The first requires measurement of the change in current, $i_{\text{irrev.}}$, with temperature, from which the activation energy is determined from the dependence of log $i_{\text{irrev.}}/(i_d - i_{\text{irrev.}})$ on $1/T$ where i_d is the diffusion current. The second depends on the measurement of the change of half-wave potential with temperature. Both approaches involve a large number of experimental results and graphical plots, especially logarithmic plots. Therefore, extremely laborious and time-consuming numerical computation, although simple, is necessary. It is therefore not surprising that not very many values of such parameters have been obtained this way. In this field one may take advantage of the capacity of high-speed digital computers.

A computer program has been published for analysis of polarograms,[2] which does not include activation energy calculations. We have here a general ALGOL program—POLENACT—for calculating the half-wave potential ($E_{1/2}$), transfer coefficient (α), the activation energy of the diffusion process (Q_D) and the activation energy of the irreversible electrode process (Q), using the two approaches outlined above. We publish this program in the hope that it may be of some help to others.

METHOD

For an irreversible diffusion-controlled system, the half-wave potential and the transfer coefficient can be determined from the so-called logarithmic analysis of the current–voltage curve. The equation of the irreversible polarographic curve for a cathodic reduction may be expressed as

$$E = E_{1/2} - \frac{2{\cdot}303RT}{\alpha nF}\log\frac{i}{i_d - i} \tag{1}$$

where n is the number of electrons exchanged in the electrode reaction, ($R = 8{\cdot}314$ V.C.K^{-1}, $F = 96486{\cdot}82$ C), T is the temperature in K and i denotes the current in μA at a given potential E. It follows from equation (1) that a plot of $\log i/(i_d - i)$ *vs.* E is a straight line with intercept $E_{1/2}$ and a slope from which α is directly determinable.

The two equations proposed by Vlček for computing the activation energy of the electrode processes are based on the equation for an irreversible polarographic wave and also on the assumption that the rate-constant of the electrode process satisfies the Arrhenius equations. The first of the two equations is expressed as

$$\log\frac{i}{i_d - i} = \log A' - \frac{Q - Q_D/2}{2{\cdot}303RT} \tag{2}$$

where A' is the "apparent frequency factor."

By means of equation (2), the value of $(Q - Q_D/2)$ can be directly evaluated graphically from the dependence of $\log i/(i_d - i)$ on $1/T$.

Alternatively, we can determine an arbitrary activation energy Q', referred to some arbitrary constant potential E'. Here, the observation of the change of half-wave potential with the temperature gives the corresponding form of equation (2) as

$$\frac{\alpha nF(E_{1/2} - E')}{2{\cdot}303RT} = \log A - \frac{Q' - Q_D/2}{2{\cdot}303RT} \tag{3}$$

Once again, the value of $(Q' - Q_D/2)$ can be evaluated graphically from the plot of $\alpha nF(E_{1/2} - E')/2{\cdot}303RT$ *vs.* $1/T$.

However, in calculating the value of Q (or Q'), the value of Q_D must be known independently. This value can be determined from the dependence of the diffusion current on temperature, the slope of the $\log i_d$ *vs.* $1/T$ plots being $\frac{1}{2}(Q_D/2{\cdot}303R)$.[3]

Using the program described in the Appendix, the computer reads in from the cards the arbitrary potential at which the activation energy is to be determined, the number of temperature sets of polarograms, the relevant potentials, the temperature, the diffusion current and the relevant current-values for each polarogram of the system. Applying equation (1), the computer then calculates, using the least-squares method,[4] the half-wave potentials, the transfer coefficient, and the slope and intercept of the $\log i/(i_d - i)$ *vs.* $1/T$ plot, for each polarogram of a system at different temperatures. With the results obtained above, the machine proceeds to compute the activation energy of diffusion, and then follows with activation energies of the electrode process, from equations (2) and (3). The results are finally printed out in tabular form.

DISCUSSION

The program has been tested for the hexa-aquonickel(II) ion. The solution was $5 \times 10^{-4}M$ nickel in $0{\cdot}1M$ potassium nitrate plus 0·0004% of Triton-X. The temperature range used was from 20° to 50° and the reference electrode was a saturated

calomel electrode (SCE). An ICL 1902A digital computer took 54 sec to calculate all the required parameters for the system. Table I gives the data obtained from the experimental polarograms. The computer-calculated parameters are given in Tables II, III and IV.

Zusammenfassung—Zur Berechnung der Aktivierungsenergien irreversibler Elektrodenprozesse an einer Quecksilbertropfelektrode wurde ein Computerprogramm geschrieben, das auf der Temperaturabhängigkeit des Stroms und des Halbwellenpotentials beruht. Das Programm berechnet das Halbwellenpotential, den Durchtrittsfaktor und die Aktivierungsenergien des Diffusionsvorgangs sowie des irreversiblen Elektrodenprozesses. Es ist in ALGOL und FORTRAN geschrieben.

Résumé—On a écrit un programme pour calculatrice pour le calcul des énergies d'activation de processus d'électrode irréversibles à l'électrode à goutte de mercure, basé sur la variation du courant et du potentiel de demi-vague avec la température. Le programme calcule le potentiel de demi-vague, le coefficient de transfert et les énergies d'activation du processus de diffusion et du processus d'électrode irréversible. Il a été écrit en ALGOL et FORTRAN.

APPENDIX

The computer program POLENACT in ALGOL 60 is divided into two sections. The first section is used to read the data from the cards and perform the logarithmic analysis on the polarograms. It

TABLE V.—EXPLANATION OF SYMBOLS IN POLENACT

real

E2 = arbitrary potential; int = intercept of log $i/(i_d - i)$ *vs.* E plot; slope = slope of that plot; b, d, f, g, h, bq, dq, fq, gq, hq, ba, da, fa, ga, ha = numerical values in general; qe = diffusion activation energy in calories; qd = diffusion activation energy in kJ/mole; arbq = activation energy of electrode process at an arbitrary potential in kJ/mole; arbqca = as arbq but in cal/mole; refq = activation energy of electrode process extrapolated to the arbitrary potential from Q *vs.* E plot; intt and slop = intercept and slope of log i_d *vs.* $1/T$ plot respectively; inter and grad = intercept and slope of log $i/(i_d - i)$ *vs.* $1/T$ plot respectively; cut and incline = intercept and slope of $\alpha nF(E - E')/2{\cdot}303\,RT$ *vs.* $1/T$ plot respectively; intcept and gradt = intercept and slope of Q *vs.* E plot respectively.

integer (nr. = number)

set = nr. of sets of polarograms in the system; sys = nr. of systems; c, ca, cq, y, j, p = integers in general; n = nr. of electrons involved in the transfer process; r = upper bound nr. of the potential for the polarogram; x = lower bound nr. of the potential for the polarogram; total = total nr. of potential used; check = the section of program to be run.

real array

p can have values from 1 to set; j can have values from 1 to total; id[p] = diffusion current of the polarogram at t[p]; t[p] = temperature at which polarogram is measured; logid[p] = $\log_{10}$ id[p]; alpha[p] = transfer coefficient of the polarogram at t[p]; E1[p] = half-wave potential of the polarogram at t[p]; ecal[p] = potential of SCE at temperature t[p]; enh[p] = E1[p] − ecal[p]; alpe[p] = product of alpha[p] and E1[p]; alpenh[p] = product of enh[p] and alpha[p]; i[p, j] = current measured at t[p] and E[j]; log [p, j] = $\log_{10}$(i[p, j]/id[p] − i[p, j]); E[j] = potential applied; E12[p] = E1[p] − E1 at t[p]; AET[p] = (alpha[p] × n × F × E12[p])/2·303R × t[p]; s[p] = 1/t[p]; QEQ[j] = activation energy at E[j] in cal/mole; Q[j] = as QEQ[j] but in kJ/mole.

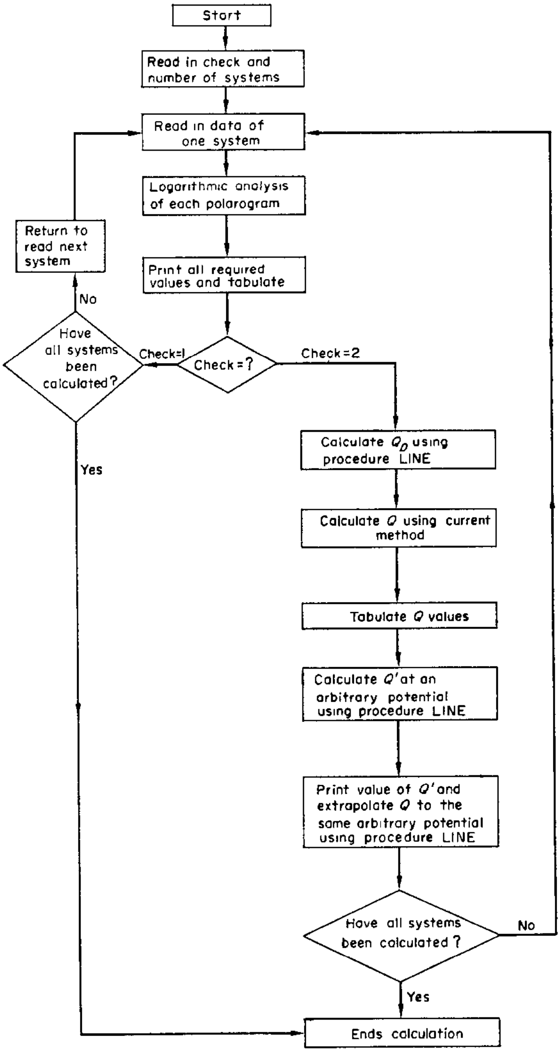

FIG. 1.—Flow-chart for computer program POLENACT.

TABLE VI.—INPUT DATA

1. Section of POLENACT to be run (either 1 or 2; see flow-chart).
2. Number of system to be run.
3. Title of the system to be run. (SYSTEM is the copy-text procedure).
4. Arbitrary potential.
5. Number of polarograms in the system.
6. Total number of potential used in the system (see Table I).
7. Number of electrons involved in the transfer process.
8. Complete series of the potential values used in the system.
9. Temperature of the polarogram.
10. Diffusion current for that temperature.
11. Upper bound number of the potential value (see Table I).
12. Lower bound number of the potential value (see Table I).
13. Current values for the above temperature.

Note: 1 and 2 are used only once, at the beginning of the input; 3–8 are used only once for each system and 9–13 are repeated for the whole of the system to be worked out. Example (only part of data input extracted from Table I).

```

This is repeated until all seven sets are completed as shown in Table I.

will then summarize the parameters of the polarograms—the half-wave potentials (first referred to SCE and, after making the necessary temperature correction, the normal hydrogen electrode, NHE). At the same time the values of $\alpha E_{1/2}$ will also be computed. Finally, it rearranges all the log $i/(i_d - i)$ values and temperatures at constant potential.

The second half of POLENACT calculates the activation energy of diffusion, in calories or kilojoules per mole. Having done this, it then works out the activation energy of the electrode process from the current at different applied potentials (when four or more sets of data are available). Then it will tabulate Q values at different potentials. Using the $E_{1/2}$ shifts and α, it proceeds to calculate the value of Q' at the required arbitrary potential. Finally, the values of Q are extrapolated to this arbitrary potential for comparison purpose.

Table V explains the symbols used. A simplified flow-chart showing the calculation is shown in Fig. 1. The procedure called LINE has been used to calculate the best fit for the straight line, by the least-squares method. The program translated into FORTRAN will be supplied on request. Since FORTRAN is much closer to the machine code, computing time is reduced. With the translated program, the time taken to do the same calculations was 40 sec. The input data for POLENACT are shown in Table VI.

SOME OPTICAL STUDIES WITH THE AIR-ACETYLENE FLAME

K. M. ALDOUS*, R. F. BROWNER†, D. CLARK, R. M. DAGNALL
and T. S. WEST
Chemistry Department, Imperial College, London S.W.7 2AY, U.K.

(*Received* 25 *October* 1971. *Accepted* 2 *December* 1971)

Summary—The application of Schlieren and shadow techniques for the study of flame processes is discussed in relation to analytically useful premixed flames. The information obtained, particularly with shadowgraphs, may be correlated with the measured signals and signal noise in atomic-absorption and flame-emission spectrometry.

OPTICAL methods employing Schlieren and shadowgraph techniques have been used extensively in combustion research for examining refractive-index fields,[1] particularly when information on such fundamental parameters as burning velocities or energy-release profiles has been required. However, there appears to have been no attempt to correlate the photographic records obtained by these methods with quantitative observations on the behaviour of metal atoms when nebulized into flames.

It is known that turbulent *diffusion* flames, such as those produced with Beckman burners, have a higher emissive background than the corresponding laminar flames[2] and it has also been observed that atomic species introduced into them are subject to more severe interelement interference[3] than in laminar flames. Though, as an adjunct to these observations, it is generally agreed that turbulence in *pre-mixed* flames is also undesirable, and various workers have published Schlieren[3,4,5] and shadow[6] records of several flames, the studies were purely qualitative and no conclusions were drawn indicating just how turbulence in pre-mixed flames influences analytical measurements.

The purposes of this study were therefore to examine Schlieren and shadow techniques as a means of observing flame processes (particularly the effect of flame separation) in some analytically useful flames, and to correlate this information with signals obtained from atomic-absorption and flame-emission measurements. In this context, changes in signal magnitude and signal noise are of particular interest as they are likely to be influenced directly by the flame processes.

The work described in this communication indicates that net changes in free atom fractions due to variations in the temperature or chemical composition of the flame gases can be a direct consequence of flame turbulence in premixed flames, as can the signal noise due to fluctuations of the atomic concentration in the flame.

INFORMATION PROVIDED BY OPTICAL TECHNIQUES

General theory

The theory and applications of Schlieren, shadow and interferometric techniques have been reviewed most thoroughly by Weinberg[1] and here we summarize only the salient features which are of direct relevance to the present study. The optical

---

* Present address: Division of Laboratories and Research, N.Y. State Health Department, Albany, N.Y. 12201, U.S.A.

† Present address: Department of Chemistry, University of Florida, Gainesville 32601, U.S.A.

methods mentioned provide means of measuring refractive index gradients in gases by photographic techniques and hence of defining regions over which the processes which produce such changes are occurring.

In the shadow method, light from a point source of illumination is passed through the test zone onto a screen. Any optical disturbance which takes place within the zone and which produces a refractive index gradient normal to the direction of the light-beam results in a local change of illumination on the screen. Refractive index gradients parallel to the light-beam cause no change in screen illumination.

In Schlieren photography, a parallel beam of light, after passing through the test zone, is brought to a focus at a "marking aperture" (which may take the form of a knife-edge, a pin-hole or a neutral optical wedge) by another lens. The aperture removes from the image (which in the absence of the marking aperture would be a normal image of the flame) the rays undeflected by the flame, whilst allowing some of the deflected rays to pass. An optical arrangement which may be used for shadow work and converted for use in Schlieren photography by the incorporation of only one further component (the marking aperture) is shown in Figs. 1 and 2. With these arrangements, the positioning of the flame with respect to the lens (*F*) is varied, depending on whether shadowgraph or Schlieren records are required.

Both optical methods provide the following information. They indicate the positions and dimensions of the primary and secondary reaction zones, as these are regions over which rapid refractive index changes are occurring. By the shapes of the zones they indicate the contours of the refractive index gradients in the burning or burned gases. A wrinkled appearance of a zone shows turbulence. They indicate the rate of refractive index change by the sharpness and degree of darkening of the zone (*e.g.*, primary reaction zones of laminar flames give much sharper images than do the zones of secondary diffusion flames).

Time variable processes

The optical observation of rapid fluctuations in the flame is important even though the higher frequency fluctuations may not register as noise on the recorder read-out (owing to its limited frequency bandpass) when the radiative emission from the flame is observed. Nevertheless, these fluctuations will give rise to overall changes in the

composition of the burned gases, because of the different combustion processes induced. Changes in gas composition, which will also be associated with changes in gas temperature, may alter the free atom fraction and the magnitude of thermal emission signals from solutions nebulized into the flame.

Influence of measurement time on photographic record

All turbulent phenomena exhibit fluctuating refractive index fields. In this study exposure times of 1·5 msec were found effectively to "freeze" the turbulent phenomena occurring within the flames examined.

Signal measurements

In atomic-absorption spectrometry, when all the obvious variables which effect the total concentration of the element (free and combined) in the flame (such as nebulization rate, flame path-length, *etc*) are fixed, then the signal is a direct comparative measure of the free atom fraction, β. In flame-emission spectrometry, the signal magnitude is again dependent on β, but is also further influenced by the flame temperature, because of the nature of the radiative process.

Noise measurements

The noise in any measured signal, whether from atomic absorption or flame emission, is a combination of many components. Those noise components which are unrelated to flame processes are of no relevance to this work and can be eliminated from measurements of the total signal noise by the subtraction of quadratic components.

For a spectrometric system with a fixed electronic (noise) bandpass (Δf), the total root mean square noise voltage, N_T, may be related to the independent root mean square noise components, N_i, by the relationship:[7]

$$N_T = [\sum(N_i)^2]^{1/2} \tag{1}$$

This summation includes all the independent root mean square noise components which contribute to N_T.* In this particular instance only one noise component is of interest, the noise (from atoms in the flame) induced by flame processes, and this may be represented as N_F. As a direct corollary of the signal magnitude in atomic absorption and atomic emission, the signal noise, N_F, will measure fluctuations in the free atom concentration, β. In atomic emission it will also measure fluctuations in the flame temperature. Experimentally, N_T is measured as the total root mean square noise in the analytical signal and N_F is obtained by subtracting from this the remaining noise components as measured by the root mean square noise of the baseline, thus:

$$N_F = [N_T^2 - (N_i - N_F)^2]^{1/2} \tag{2}$$

This eliminates from the noise the components which are a consequence of electronic circuitry, stray room-light or hollow-cathode lamp instability in atomic-absorption measurements. As only noise which originates in the flame itself can be related to

* Winefordner *et al.* have used relationships of this kind in order to determine the magnitude of noise signals in atomic-emission,[8,9] atomic-absorption[10,9] and atomic-fluorescence spectrometry.[11] Reference should be made to these publications for a more detailed discussion of all the factors which may give rise to noise in atomic flame spectrometry.

optical observations of the flame gases, in all subsequent discussion this noise alone will be considered and will be referred to as "signal noise".

The apparent frequency of this noise as it registers on a recorder will be limited by the effective bandpass of the whole read-out system. However, the root mean square value of this waveform is a valid and convenient *comparative* measure of noise resulting from fluctuating processes in the flame.

For the purpose of this discussion, it is convenient to consider signal noise as originating from two separate sources. First there is nebulization noise. This noise should remain a constant proportion of the signal magnitude and is not amenable to measurement by Schlieren or shadow records of the flame gases although the spray supply itself can be studied by these means. Secondly there are fluctuations in the burned gases themselves. In a stable laminar flame this will be reduced to a minimum and will be of much smaller magnitude than in a turbulent flame. However stable and laminar a flame may appear to be, there will exist within it local variations in temperature and gas composition which will produce noise both in the background emission from the flame (flame flicker noise) and in any signal which is dependent on atomic concentrations in the flame. When the signal noise is *not* a constant proportion of the signal magnitude, even though the same solution is being nebulized, then it may be assumed that the deviation from proportionality is a measure of the flame fluctuations.

EXPERIMENTAL

Optics

There are numerous possible experimental arrangements for Schlieren and shadow photography. The optical systems employed in this work were shown in Figs. 1 and 2. Lenses were used throughout.

In the shadow system the flame position (*E*) is not critical, provided that it is not optically conjugate with the film plane, *i.e.*, a focused image of (*E*) is not formed at (*H*) by the lens (*F*).

For Schlieren photography, the flame *must* be optically conjugate with the film plane. In addition, a pinhole matched to (*C*) is placed at (*G*) and this acts as the marking aperture. Exposure times of 1/1000 sec nominal (1·5 msec actual, electronically measured) were used for all the photographic records and this effectively "froze" most flame fluctuations. Photographs were taken on Ilford F.P.4 120 Professional Roll Film.

Flames

Circular flames of *ca.* 10 mm diameter provided adequate photographic contrast and were also easier to align than long-path flames. Nevertheless conclusions drawn from their behaviour can be related to the behaviour of such flames. The influence of shielding gases on the stability of long-path flames should be more pronounced than with the cylindrical flame, as the area of contact and mixing of gases will occupy a greater proportion of the whole flame. However, the reduction in the background emission signal will be less, as the outer mantle corresponds to a smaller proportion of the total optical path through such a flame. The flames were produced on both capillary burners[13] and burners of the Méker type (manufactured by Beckman Research and Industrial Instrument Corporation Limited, Worsley Bridge Road, London S.E.26). Both types of burner had provision for gas sheathing.

Records were obtained for both air–acetylene and nitrous oxide–acetylene flames on burners of this type, with varying degrees of nitrogen separation. However, the information provided by the nitrous oxide–acetylene flame was no different in nature from that obtained with the air–acetylene flame. For all further work, including atomic-absorption and flame-emission signal measurements, the air–acetylene flame alone was used.

RESULTS

Comparison of results obtained by shadow and Schlieren photography

All optical records of flame disturbances were made alternately with both the shadow and Schlieren methods. As shadowgrams were especially sensitive to rapid changes in the refractive index field normal to the optical path, gradual changes across the flame ends do not register strongly and a flat, seemingly two-dimensional, picture is obtained (Plates 1–4 and 6–8). The Schlieren records have a three-dimensional appearance (Plate 5), which is a result of the greater responsiveness of the technique to the small components of refractive index change, normal to the light path, which occur at the flame ends.

The one instance where Schlieren photography has a clear advantage in the quality of the record produced is when flames of very high emissive background (such as nitrous oxide–acetylene) are to be studied. Here the marking aperture considerably reduces the light intensity from the flame, which would in its absence (as in shadow work) pass directly to the film and reduce the image contrast.

In view of the simplicity of the shadow method it is to be recommended for visual studies of laminar flames of low emissive background, and only shadowgrams will be discussed further.

Information obtained from shadowgrams of air–acetylene flames

General. The unseparated fuel-rich air–acetylene flame maintained on a capillary burner is exceptionally stable and laminar (Plate 1)*, up to the height of *ca* 57 mm. The leaner flame (not shown) is more nearly cylindrical in shape, with less expansion at all levels.

The same fuel-rich flame on a Beckman RIIC burner (Plate 6) has a larger initial diameter, showing greater expansion at the flame base, but reaches approximately the same diameter as the flame maintained on the capillary burner, at 30 mm above the primary zones. The initial expansion of gases, being more rapid, is less laminar. The more diffuse secondary reaction zone also indicates that the secondary combustion process is less sharply defined. The unevenness of the top of the flame illustrates what may also be visually observed, that this flame is more susceptible to draughts.

Flame background. Progressive separation of the air–acetylene flame on the capillary burner with an outer sheath of nitrogen, produces changes both in flame shape and laminarity. Plates 2, 3 and 4 show the effects of nitrogen flow-rates of 2, 6 and 10 l./min. From these representative photographs (selected from a set covering also all intermediate flows), the best compromise between efficient separation and induced turbulence, at a height of measurement 15 mm above the primary cones, would seem to occur at 6 l./min. Reference to Fig. 3(*i*) shows that the most efficient removal of OH emission does indeed occur at 6 l./min nitrogen flow.

At a position of measurement 30 mm above the primary reaction zones, separation with flow-rates above 6 l./min might be expected to lead to increased turbulence. Figure 3(*i*)(*c*) does show a slight increase in signal at flow-rates above 6 l./min, indicating that the induced turbulence is producing some air entrainment. This leads to increased combustion, with a consequent increase in OH emission.

From the noise curves (Fig. 3(*ii*)), the signal:noise ratio at 15 mm height in the flame passes through a minimum at a nitrogen flow of 6 l./min. In other words, a nitrogen flow of 6 l./min stabilizes the hot flame gases by diminishing their fluctuations.

---

* This may be contrasted with results of Rann[4] whose air–acetylene flame maintained on a Méker type burner showed extreme turbulence right from the base of the flame. This could only be reduced by flame shielding. The unshielded capillary burner flame appears as laminar as Rann's shielded flame. This shows how an unsatisfactory burner design may produce unstable flames.

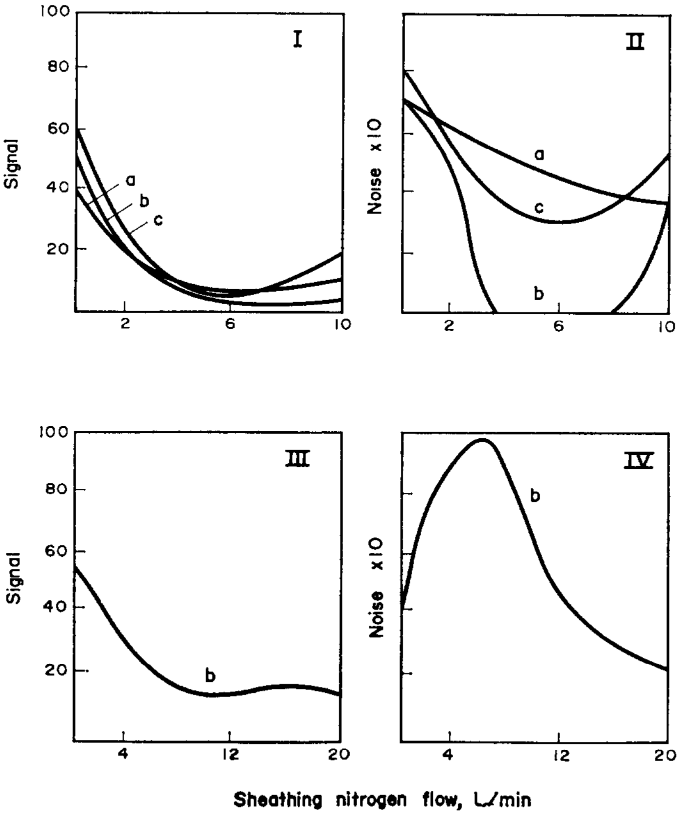

Fig. 3.—Emission and noise from fuel-rich air-C_2H_2 flames. (*i*) OH emission with capillary burner, (*ii*) OH emission noise with capillary burner, (*iii*) OH emission with Beckmann RIIC burner, (*iv*) OH emission noise with Beckmann RIIC burner. Height of observation above primary reaction zones: *a*—3 mm; *b*—15 mm; *c*—30 mm.

However, this increase in stability of the flame zones is not clearly seen on the shadowgrams because the *un*separated flame is so stable and only regions of greater turbulence than this show clearly on the photographs. Increasing the flow-rate to 10 l./min causes optical inhomogeneities in the gases, appearing as increased noise, and these are compatible with an examination of the flow patterns as shown by the shadowgrams.

The noise curves also show that noise levels measured high in the flame (*c*) are greater than those measured in the central regions (*b*) *at all nitrogen flow-rates*. This again accords with the photographs (Plates 2–4). Here the higher regions of the flame are seen to be more turbulent than the central regions at all separation flows.

The information provided by the shadowgrams can also be correlated with the variation of OH emission signals with height (Fig. 4). With no shielding [Fig. 4(*i*)(*a*) and 4(*ii*)(*a*)] the signal:noise ratio is approximately constant with height. The shadowgram (Plate 1) also shows no visible variation of optical inhomogeneities or turbulence with height. With a 6 l./min flow of shielding gas the signal:noise ratio passes through a pronounced minimum at a measurement height of 15 mm. The relevant shadowgram (Plate 3) shows some inhomogeneity low in the flame, where the gases are close to the primary zones, and also slight turbulence in the outer flame

regions at heights above 20 mm. The central flame regions appear to be relatively laminar.

The leaner air–acetylene flame is physically smaller and "stiffer" than the fuel-rich flame. Whatever turbulence is present, as indicated by the shadowgrams (not illustrated here), it varies little with height, whether the flame is unseparated or separated. Figures 4(*iii*) and (*iv*) confirm this behaviour in terms of the signals and their associated noise.

The effect of separation on the air–acetylene flame maintained on the Beckman RIIC burner is different from the effect when the flame is stabilized on a capillary burner. At a height of observation of 15 mm [Figs. 3(*iii*) and (*iv*)], the noise level actually increases at first as the nitrogen separation reduces the signal. The peak noise occurs at a flow-rate of 4 l./min. Plate 7 shows that at this flow there is a sharp delineation between the lower part of the flame, which is separated, and the part above it, which is unseparated, and where gases are burning. This transitional region occurs at a height of about 15 mm in the flame and of course leads to a noisy signal. The behaviour of the Beckman RIIC burner and separator should be contrasted with that of the capillary burner and separator. With this capillary arrangement, all flow-rates of nitrogen give progressive separation up the flame without any sharp boundaries between separated and unseparated regions.

Atomic-absorption signals. Copper is nearly completely atomized in the air–acetylene flame.[13] Therefore, the atomic-absorption signal from a copper solution nebulized into such a flame is a measure of the steady-state atomic concentration which lies in the radiative path between the atomic line source and the detector. Any fluctuations in the signal must then only reflect fluctuations in the local steady-state atomic concentration plus nebulizer noise, which will remain a constant proportion of the signal.

Figure 5(*iii*) shows the variation in copper atomic absorption with increasing nitrogen separation. As expected, the signal is negligibly altered. On separation at a flow-rate of 6 l./min of nitrogen the noise drops by a factor of 2. This confirms the previous deduction that separation at this flow rate not only reduces fluctuations in the outer flame mantle, but actually stabilizes the whole body of the flame. Again, separation at a flow-rate of 10 l./min causes turbulence, and the noise returns almost to its unseparated level, as with the OH emission.

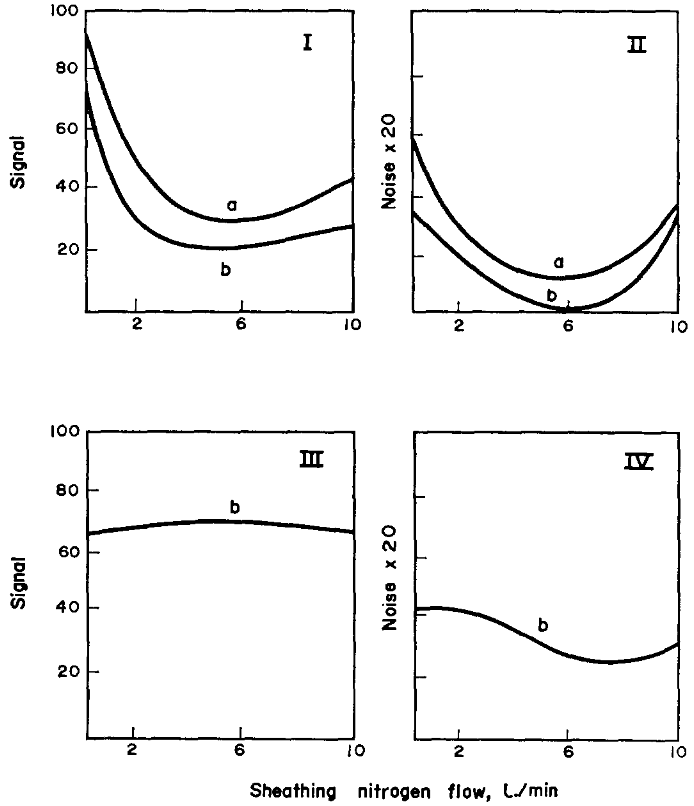

Fig. 5.—Copper atomic-absorption and emission at 324·1 nm.
(*i*) Cu emission signal. Lean flame
(*ii*) Cu emission noise. Lean flame
(*iii*) Cu atomic-absorption signal. Fuel-rich flame
(*iv*) Cu atomic-absorption noise. Fuel-rich flame.

Atomic-emission signals. The copper flame-emission signals in a lean air–acetylene flame are shown in Figs. 5(*i*) and (*ii*) in comparison with the OH emission in the same flame (the signals are scaled). Copper is assumed to have a β value of unity in this flame, so the copper emission magnitude is a measure of the temperature of the flame. With increased nitrogen flow the signal drops in almost exactly the same way as the OH emission. The drop in signal is equivalent to about a 10° drop in temperature of the whole flame. The noise observed, however, drops by a greater degree than does the OH noise.

Influence of other sources of turbulence. So far only turbulent phenomena in laminar flames with nitrogen sheaths have been considered. Although these have considerable application to atomic-fluorescence spectroscopy,[14] in other applications, *i.e.*, long-path atomic-absorption spectroscopy, separation may not be considered so advantageous. In these instances the laminarity of the *un*separated flame is of prime importance. In order to relate this to the analytical signal, atomic-absorption and flame-emission signals from copper in laminar flames were compared with the signals from the same flames when made turbulent by doubling the total gas supply to the burner. The acetylene:air ratio was maintained constant. The drop in signal in both atomic-absorption and flame-emission was slight, 2% and 7% respectively. However, the noise in both cases approximately doubled. Turbulence therefore gives rise to noise in unseparated flames in much the same way that it does in separated flames.

CONCLUSIONS

It has been shown by this study that optical methods provide valuable records of the combustion processes in premixed laminar flames. The optical disturbances which these photographs reveal may be interpreted in terms of the laminarity or turbulence of the flame gases, provided that the information is used on a well-defined comparative basis. From an analytical standpoint, the records are of value because they give insight into the processes which lead to variations in the magnitudes and noise levels of atomic-absorption (and hence atomic-fluorescence) and flame emission signals. The beneficial effect on signal noise of the correct level of nitrogen separation has been shown.

Of the two optical techniques examined, both of which require relatively inexpensive equipment, the shadow method has been shown to provide as much information as Schlieren photography whilst involving a simpler experimental arrangement, and so is to be preferred.

Zusammenfassung—Die Anwendung von Schlieren- und Schattenverfahren auf die Untersuchung von Vorgängen in Flammen wird im Hinblick auf die analytisch nützlichen vorgemischten Flammen diskutiert. Die besonders aus Schattenphotographien erhaltene Information kann zu den bei der Atomabsorptions- und Flammenemissionspektrometrie gemessenen Signalen und deren Rauschen in Beziehung gesetzt werden.

Résumé—On discute de l'application des techniques "Schlieren" et d'ombre pour l'étude des processus de flamme en relation avec les flammes prémélangées analytiquement utiles. Les informations obtenues, particulièrement avec les sciogrammes, peuvent être rattachées aux signaux mesurés et au bruit remarquable en spectrométrie d'absorption atomique et d'émission de flamme.

SELECTIVE EXTRACTION OF ZINC DITHIZONATE IN THE PRESENCE OF DITHIOCARBAMINOACETIC ACID AS MASKING AGENT

QUANTITATIVE TREATMENT OF AN EXTRACTION EQUILIBRIUM

O. BUDEVSKY, E. RUSSEVA and R. STOYTCHEVA

(*Received* 15 *October* 1971 *Accepted* 17 *November* 1971)

Summary—Dithiocarbaminoacetic acid (TCA) is proposed as an effective masking agent in the dithizone extraction determination of zinc in the presence of lead, cadmium and cobalt(II). The extraction equilibrium is treated quantitatively by means of two approaches: the "conditional distribution coefficient" and the computer program HALTAFALL. Both methods give similar results and enable the most suitable conditions for the separation and determination of zinc in the presence of the other ions to be determined. A successful attempt is made to predict the maximum permissible quantity of interfering elements. The experimental check, performed under various conditions, is in satisfactory agreement with the theory.

THE DETERMINATION of trace amounts of zinc in the presence of other elements and especially in the presence of cadmium and lead is a comparatively difficult analytical problem. The dithizone extraction method is useful for the isolation and determination of small amounts of metal ions, and the selectivity of the extraction equilibrium can be favourably shifted by means of suitable masking agents, such as dithiocarbamates. Margerum and Santacana[1] in a comparative study of the methods for determination of trace amounts of zinc, recommended the dithizone extraction method in the presence of bis (2-hydroxyethyl) dithiocarbamate, the latter having also been used by Galík.[2] Hulanicki[3,4] proposed bis(carboxymethyl) dithiocarbamate for similar purposes. Other investigations showed that dithiocarbaminoacetic acid (TCA) can be successfully used as a masking agent in the complexometric determination of zinc in the presence of lead, cadmium, nickel and cobalt(II).[5] There is a difference of 3–4 logarithmic units between the stability constants of zinc–TCA complexes and the TCA complexes of other metal ions (see Table I).[6–10] The extraction constant of zinc dithizonate is the highest for any dithizonate. These factors together suggest that it should be possible to find conditions for the selective extraction of zinc dithizonate in the presence of TCA as a masking agent and this was the first aim of the present investigation. The behaviour of other metal ions in this extraction cannot be predicted by general considerations, since their extraction constants are generally 5–6 logarithmic units higher than the stability constants of the corresponding TCA complexes, but it should be possible to compute the most favourable conditions for this determination from a quantitative treatment of the appropriate equilibria. The second aim of the present investigation was to compute the optimum conditions and the third aim was to test the validity of the calculations against experimental evidence.

METHODS OF CALCULATION

The solvent extraction problem, like many others, can be reduced to the calculation of the distribution coefficients of the different ions as a function of several factors. Many authors, from Irving, Rossotti and Williams onward,[11-15] have treated extraction equilibria quantitatively, but it seems at the present moment that two approaches are most convenient. One of them, developed by Ringbom and Still,[16] is based on the concept of the "conditional equilibrium constant" and uses several approximations in the course of the calculations. The second one, proposed by Sillén and co-workers,[17] gives an exact solution of the problem by using the multipurpose computer program HALTAFALL.

Both methods were examined in this study and therefore some specific details of the application of these methods will be briefly discussed.

Method of calculation based on the concept of conditional distribution coefficient

The fundamental principles of the concept will not be stated here, because they are comprehensively dealt with in Ringbom's book[18] but because the equation for the conditional distribution coefficient used in the present paper is not derived in that book, its derivation will be shortly discussed.

The conditional distribution coefficient, the most important in a particular analysis, is defined as a ratio between the total concentration of the metal, whatever its form, in the organic and aqueous phases (symbols used are the same as those in ref 18)

$$D' = \frac{\text{Total concentration of the metal in the organic phase}}{\text{Total concentration of the metal in the aqueous phase}} = \frac{[\mathrm{M}']_0}{[\mathrm{M}']} \qquad (1)$$

Simplifications in (1) can be made when some chelates (*e.g.* dithizonates) are extracted, if it is assumed that the only form of the metal ions present in the organic phase is the uncharged chelate MR_n. Then

$$D' = \frac{[\mathrm{MR}_n]_0}{[\mathrm{M}']} \qquad (1')$$

On the other hand, extraction equilibria of chelates are quantitatively described by the extraction constant

$$E_{\mathrm{MR}_n} = \frac{[\mathrm{MR}_n]_0}{[\mathrm{M}][\mathrm{R}]^n} \qquad (2)$$

but when interferences are present (e.g. acidity of the solution, the presence of masking agents *etc*) a convenient way to take into consideration the side-reactions that can occur in the system is to introduce the overall α-coefficients and the conditional extraction constant

$$E'_{\mathrm{MR}_n} = \frac{[\mathrm{MR}_n]_0}{[\mathrm{M}'][\mathrm{R}']^n} = \frac{E_{\mathrm{MR}_n}}{\alpha_{\mathrm{M}}\alpha_{\mathrm{R}}^{\,n}} \qquad (3)$$

A substitution of (1′) in (3) gives the equation of the conditional distribution coefficient

$$D' = \frac{E_{\mathrm{MR}_n}[\mathrm{R}']^n}{\alpha_{\mathrm{M}}\alpha_{\mathrm{R}}^{\,n}} \qquad (4)$$

or in its logarithmic form

$$\log D' = \log E_{\mathrm{MR}_n} + n \log \mathrm{R}' - \log \alpha_{\mathrm{M}} - n \log \alpha_{\mathrm{R}} \qquad (4')$$

The overall α-coefficients introduced in (3) and (4) will be discussed more closely.

α_{R} is calculated on the basis of considerations that have been thoroughly discussed by Ringbom.[18] Further it is assumed that microgram amounts of zinc will be extracted, so a sufficient excess of dithizone would be provided by a $10^{-4}M$ solution. The volumes of the organic and aqueous phase are taken as equal (10 ml).

α_{M} is the overall α-coefficient taking into consideration the side-reactions of the metal ions in the aqueous phase. Two side-reactions can be considered: (*i*) the reaction of the metal ion with TCA and (*ii*) the formation of hydroxo-complexes, hence

$$\alpha_{\mathrm{M}} = \alpha_{\mathrm{M(TCA)}} + \alpha_{\mathrm{M(OH)}} - 1 \qquad (5)$$

At pH 9 the value of $\alpha_{\mathrm{M(OH)}}$ for zinc, lead, cadmium, cobalt(II) and nickel can be neglected (see ref. 18, Table A.5, p. 353) and α_{M} is given by (*cf.* ref. 19)

$$\alpha_{\mathrm{M}} \sim \alpha_{\mathrm{M(TCA)}} = \sum \beta_n \frac{[\mathrm{TCA}']^n}{\alpha^n_{\mathrm{TCA(H)}}} \qquad (6)$$

where the β_n values are the corresponding stability constants of zinc and the other metal ions with TCA; [TCA′] is the total concentration of dithiocarbaminoacetic acid not bound to the main metal ion and $\alpha_{\mathrm{TCA(H)}}$ is the α-coefficient of TCA taking into consideration the protonation of the ligand. $\alpha_{\mathrm{TCA(H)}}$ is calculated as a function of pH according to

$$\alpha_{\mathrm{TCA(H)}} = 1 + \beta_1{}^{\mathrm{H}}[\mathrm{H}] + \beta_2{}^{\mathrm{H}}[\mathrm{H}]^2 \qquad (7)$$

where $\beta_1{}^{\mathrm{H}}$ and $\beta_2{}^{\mathrm{H}}$ are the overall proton stability constants of TCA.

TABLE I.—EQUILIBRIUM CONSTANTS USED IN THE PRESENT PAPER

Dithizone extraction constants in CCl_4[18]		Constants for dithizone[18]	
$\log E_{\mathrm{ZnR_2}} = 19{\cdot}3$		$\mathrm{p}K_{\mathrm{H}} = 4{\cdot}5$	
$\log E_{\mathrm{CdR_2}} = 18{\cdot}8$		$\log D_{\mathrm{HR}} = 4{\cdot}0$ (CCl_4)	
$\log E_{\mathrm{PbR_2}} = 17{\cdot}7$		$\mathrm{pH}_{1/2} = 8{\cdot}5$	
$\log E_{\mathrm{CoR_2}} = 18{\cdot}6$			
$\log E_{\mathrm{NiR_2}} = 16{\cdot}2$			
Constants for TCA[6-10]			
H^+	$\log \beta_1{}^{\mathrm{H}} = 3{\cdot}7$	$\log \beta_2{}^{\mathrm{H}} = 6{\cdot}7$	
Zn^{2+}	$\log \beta_1 = 3{\cdot}4$	$\log \beta_2 = 6{\cdot}5$	$\log \beta_3 = 9{\cdot}1$
Cd^{2+}	$\log \beta_1 = 5{\cdot}4$	$\log \beta_2 = 9{\cdot}3$	$\log \beta_3 = 13{\cdot}6$
Pd^{2+}	$\log \beta_1 = 7{\cdot}3$	$\log \beta_2 = 13{\cdot}1$	
Co^{2+}	$\log \beta_1 = 3{\cdot}3$	$\log \beta_2 = 7{\cdot}8$	$\log \beta_3 = 13.3$
Ni^{2+}		$\log \beta_2 = 8{\cdot}5$	

The calculations of the α-coefficients and the conditional distribution coefficients were performed with the set of stability constants shown in Table I. In Table II are shown the calculated values of the α-coefficients and the conditional distribution coefficients according to (4′) for zinc, cadmium and lead dithizonates. The values of $\log D'_{\mathrm{MR}_2}$ from Table II are drawn in Fig. 1 with a full line and will be discussed later.

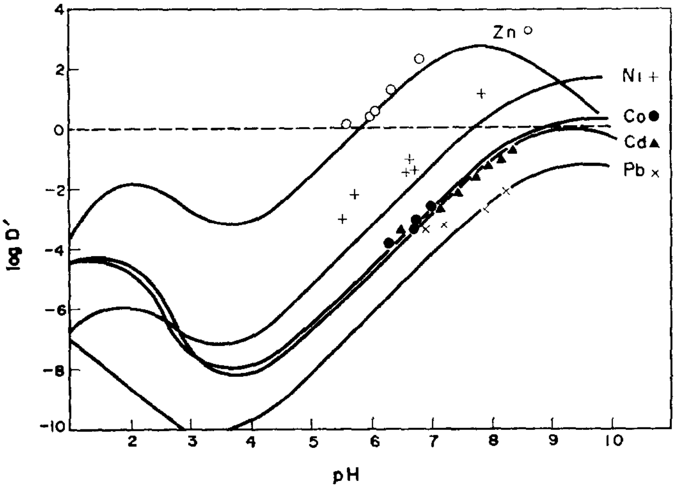

Fig. 1.—pH-dependence of logarithm of distribution coefficient of dithizonates in the presence of TCA.

Analogous calculations with 0·01M and 0·05M TCA solutions were performed but no advantage was found: the family of curves shown in Fig. 1 is shifted towards lower pH values without change in their mutual position. Therefore it is considered that 0·1M TCA solution is more suitable for a masking procedure as it is easier for preparation in analytical work; moreover such a solution is less sensitive to unexpected influences.

Computer method of calculation

The method of Sillén uses high-speed computers and the program HALTAFALL to resolve a system of mass-balance equations of the components, provided that the equilibrium constants of the complexes and the total concentrations of the components are known. The HALTAFALL program is flexible and can be used in many fields of chemistry dealing with homogenous and heterogenous equilibria, including extraction. The input for the program was made for the same conditions as these used in the foregoing calculations. As an illustration Table III gives the input and output from the calculations for cadmium dithizonate in the presence of TCA, as performed on the Danish GIER computer. More details of writing the input for HALTAFALL can be found in the original paper[17] or in the monograph by Dyrssen *et al.*[20]

Choice of conditions for the selective extraction of zinc dithizonate

The starting point in the choice of conditions for the selective extraction of zinc dithizonate must be the analysis of the distribution coefficient of zinc and the other ions as a function of pH as well as of other variables. From Fig. 2, where the calculated degree of extraction of the dithizonates is plotted it can be seen that in the absence of TCA no separation of zinc from the other ions is possible. In the presence of TCA, however, the same figure shows that at pH 6·5–7·0 zinc can be selectively extracted.

Furthermore, it is found that the calculations can be used for the quantitative evaluation of the maximum permissible amount of interfering ions. From the curves plotted in Fig. 1, the lowest pH value can be found for satisfactory extraction of zinc, viz. pH = 6·8. At this pH value the distribution coefficient is $\log D'_{\mathrm{ZnR_2}} = 1{\cdot}7$, corresponding to a *ca.* 98% extraction of zinc. At the same pH value the extraction of the other ions is given by $\log D'_{\mathrm{NiR_2}} = -1{\cdot}8$, $\log D'_{\mathrm{CoR_2}} = -3{\cdot}2$ $\log D'_{\mathrm{CdR_2}} = -3{\cdot}3$ and $\log D'_{\mathrm{PbR_2}} = -4{\cdot}7$. Using the molar absorptivities of the dithizonates at 530 nm and the distribution coefficients mentioned, the quantity of foreign ions can be calculated (as shown in Table IV), that will produce interference in the organic phase equal to +0·1 μg of zinc.

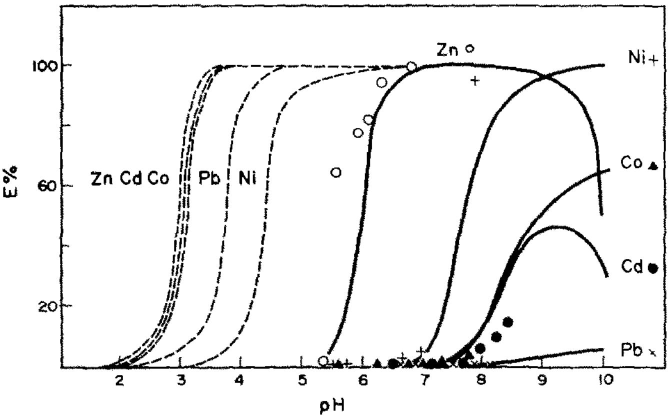

FIG 2.—pH-dependance of degree of extraction of dithizonates in the presence (———) and in the absence (— — —) of TCA.

TABLE IV.—CALCULATIONS OF MAXIMUM PERMISSIBLE QUANTITY OF INTERFERING IONS WITH THE DITHIZONE EXTRACTION OF 1 μg OF ZINC

Metal ion	ε, Molar absorptivity of dithizonates at 530 nm*	Ratio $\varepsilon_{Zn/Me}$	Ratio of atomic weights Me/Zn	Interference of unit weight of metal per weight unit of Zn	Amount of interfering metal equivalent to 0·1 μg of Zn	$D'_{pH=6\cdot8}$ of metal dithizonates	Permissible maximum quantity of interfering ion μg

† Recalculated from Iwantschew,[21] Fig. 36, p. 279.

EXPERIMENTAL

Reagents

Dithizone solution, $10^{-3}M$. Reagent grade dithizone (0·0256 g) was dissolved in 100 ml of carbon tetrachloride. After tenfold dilution the dithizone concentration was checked by extraction titration with standard silver nitrate solution.[21]

Diammonium dithiocarbaminoacetate monohydrate, ($NH_4SCSNHCH_2COONH_4 \cdot H_2O$). Prepared and kept according to ref. 5.

Carbon tetrachloride. Purified and distilled.[21]

Stock solutions of zinc, lead, cadmium, cobalt(II) and nickel were standardized complexometrically and then diluted.

Water. Twice distilled from a quartz still and kept in Teflon vessels.

In the light of the chosen conditions, the experiments were performed with two objectives: (*i*) estimation of distribution coefficients of the dithizonates as a function of pH at constant TCA concentration and (*ii*) evaluation of maximum permissible amount of interfering element in the determination of zinc.

The distribution coefficients of the dithizonates was determined spectrophotometrically from the difference of the metal ion content in the organic phase and the total amount. With zinc the total was 4 μg, while with the other ions the total was increased (cadmium up to 900 μg, lead up to 5000 μg etc). For higher metal ion concentrations, a corresponding correction in the total of TCA was made, ensuring 0·1M free TCA concentration.

TABLE V.—DETERMINATION OF 1·00 μg OF ZINC IN THE PRESENCE OF DIFFERENT AMOUNTS OF INTERFERING ELEMENTS (pH = 6·8, 0·1M TCA)

Procedure

Aqueous phase (10 ml), containing a definite quantity of metal ion, 0·2 g of TCA (0·1M), adjusted to pH 6·8 before extraction and checked afterwards, was extracted with 10 ml of $10^{-4}M$ dithizone solution in carbon tetrachloride. After separation, the organic phase was washed twice with 10 ml of 0·01M ammonia. The absorbance of the washed extract was measured at 530 nm in a 2-cm cell against a blank. The quantity of metal ion was obtained from a calibration curve.

For the determination of the maximum permissible amount of interfering element, the extraction was performed in the same manner, except that a (phosphate) buffer was added and a constant amount of zinc was used.

The experimental results are plotted in Figs. 1 and 2 and given in Table V, and coincide satisfactorily with the theory.

DISCUSSION

Dithiocarbaminoacetic acid serves as an effective masking agent for the dithizone extraction and determination of zinc in the presence of lead, cadmium and cobalt (II). As lead and cadmium normally cause grave interferences, TCA could serve as an useful masking agent in the development of methods for the determination of trace amounts of zinc.

It is shown that by calculation the most suitable conditions can be predicted for an extractive analytical procedure for the separation and determination of one component in the presence of others. This is illustrated in Fig. 2, where at pH 6·5–7·0 a separation and determination of zinc in the presence of lead, cadmium, cobalt(II) and nickel is seen to be possible. The experimental check performed in the presence of TCA is in good agreement with the theory. It is obvious also that in the absence of TCA no separation can be realized.

A successful attempt was made to predict the maximum permissible quantity of interfering elements in the dithizone determination of zinc in the presence of TCA, *e.g.*, for cadmium the predicted ratio Zn:Cd is 1:360 and the experimental ratio is 1:200. Some discrepancies found for lead and nickel can be explained by the low value of the distribution coefficient of the former, and insufficient accuracy of some of the equilibrium constants used for the latter.

Both methods of calculation used give similar results and are in good agreement with experiment but it seems that the HALTAFALL method is less time-consuming and is more exact.

Zusammenfassung—Dithiocarbaminoessigsäure (TCA) wird als wirksams Maskierungsmittel bei der Bestimmung von Zink in Gegenwart von Blei, Cadmium und Kobalt(II) durch Extraktion mit Dithizon vorgeschlagen. Das Extraktions-Gleichgewicht wird auf zwei Arten quantitativ behandelt: unter Verwendung des "konzentrationsbedingten Verteilungskoeffizienten" und mit dem Rechnerprogramm HALTAFALL. Beide Methoden geben ähnliche Ergebnisse und geben die Möglichkeit, die für die Abtrennung und Bestimmung von Zink in Gegenwart der anderen Ionen am besten geeigneten Bedingungen zu ermitteln. Es wird ein erfolgreicher Versuch unternommen, die höchste zulässige Menge an störenden Elementen vorauszusagen. Die Überprüfung durch das Experiment stimmt unter verschiedenen Bedingungen zufriedenstelland mit der Theorie überein.

Résumé—On propose l'acide dithiocarbaminoacétique (TCA) comme agent de dissimulation efficace dans le dosage par extraction à la dithizone du zinc en la présence de plomb, cadmium et cobalt(II). L'équilibre à l'extraction est traité quantitativement par deux voies: le "coefficient de partage conditionnel" et le programme de calculatrice HALTAFALL. Les deux méthodes donnent des résultats similaires et rendent possible la détermination des conditions les plus convenables pour la séparation et le dosage du zinc en la présence des autres ions. On a fait un essai réussi de prédiction de la quantité maximale admissible d'éléments gênants. Le contrôle expérimental, réalisé dans diverses conditions, est en accord satisfaisant avec la théorie.

NIEDERSCHLAGSBILDUNG—III

KRISTALLWACHSTUM UND EINFLUSS DER FREMDIONENKONZENTRATION IN DER BARIUMSULFATFÄLLUNG

CANDIN LITEANU und HARALD LINGNER
Lehrstuhl für Analytische Chemie der Universität von Cluj-Rumänien

(*Eingegangen am* 20. *April* 1971. *Angenommen am* 4. *Dezember* 1971)

Zusammenfassung—Es wurde sedimentometrisch der Einfluß von Fremdionen auf die Korngrösse der Bariumsulfatniederschläge bestimmt und festgestellt, daß bei großen Konzentrationen von NaCl, $NaNO_3$, KBr, KNO_3 u.a. auch bei großen Übersättigungsgraden das Wachstum der Kristalle stark gehemmt ist. Die lineare Wachstumsgeschwindigkeit wurde in Abhängigkeit von der $BaSO_4$-Konzentration, der Fremdionenkonzentration und des Verhältnisses $[BaCl_2]/[K_2SO_4]$ untersucht. Da schon bei fünffacher Übersättigung das Wachstum diffusionsbestimmt ist, können Bariumsulfatniederschläge keine Ostwaldreifung aufweisen. Für die Wachstumsbestimmungen wurde eine entsprechende Versuchseinrichtung gebaut.

IN ZWEI vorherigen Arbeiten[1,2] wurde der Einfluß verschiedener Faktoren auf die Bariumsulfatfällung mit Hilfe der Sedimentationsanalyse untersucht. Dieselbe Methode wurde benutzt, um den Einfluß einiger Salze wie NaCl, KCl, KNO_3, KBr, KJ, CH_3COONa u.a. auf die Korngröße des Bariumsulfatnierschlages zu bestimmen. La Mer und Dinegar[3] haben gezeigt, daß besonders die Nitrationen stark an der Oberfläche adsorbiert werden und daß in Gegenwart von Fremdionen der Übersättingungsgrad stark fällt. Die Adsorbtion einiger Ionen wie Diphosphat[4] oder Farbstoffen[5,6] können das Kristallwachstum völlig verhindern. Es wurde festgestellt, daß der mittlere Kornradius $\bar{r}$ (Stokesscher Radius) stark von der Konzentration der Fremdionen abhängt, wie Abb. 1 zeigt.

Ähnliche Resultate erhält man auch mit allen anderen oben angeführten Salzen. Eine Erklärung dafür wäre der geringere Übersättingungsgrad in diesem Falle. Da für einen Niederschlag C_mA_n das Löslichkeitsprodukt gegeben ist durch

$$K_S = c_A{}^n \cdot c_C{}^m = \frac{K_a}{\gamma_A{}^n \cdot \gamma_C{}^m} = \frac{K_a}{\gamma_\pm^{m+n}}$$

wo c_C und c_A die Konzentration der Ionen, γ_A und γ_C die entsprechenden Aktivitätskoeffizienten und $\gamma_\pm$ der mittlere Aktivitätskoeffizient bedeuten, K_a konstant bleibt und $\gamma_\pm$ mit steigender Ionenkonzentration fällt, so ist das Löslichkeitsprodukt in Gegenwart von Fremdionen größer als in Abwesenheit. Für den Aktivitätskoeffizienten gilt, wie bekannt, nach Hückel[7]:

$$-\log \gamma_\pm = \frac{z_A \cdot z_C A\sqrt{\mu}}{1 + Ba\sqrt{\mu}} + C\mu,$$

A, B, C, Konstanten sind, a der mittlere Ionenradius, μ die Ionenstärke und z_A, z_C die Ionenladung bedeuten.

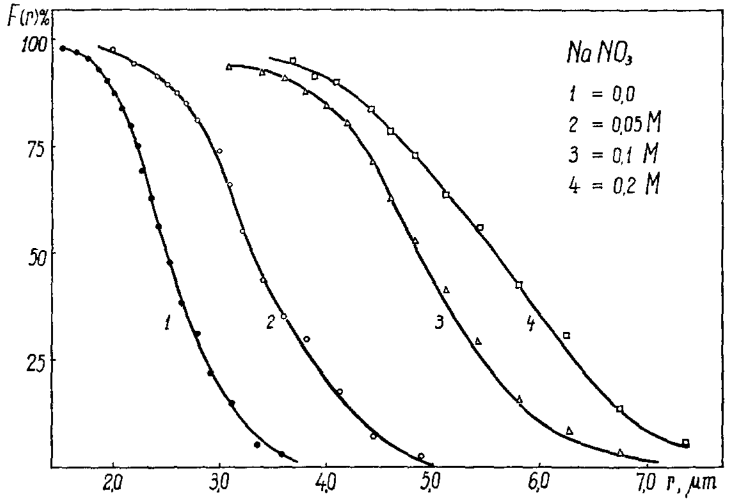

ABB. 1.—Einfluß der Natriumnitratkonzentration auf die Korngrößeverteilung bei Bariumsulfat.

Der Stokessche Radius wächst aber nicht gleichförmig mit wachsender Fremdionenkonzentration, da die Kristalle ihre Form nicht beibehalten. Trotz kleineren Abmessungen haben die in konzentrierten Lösungen erhaltenen Kristalle einen größeren Stokesschen Radius, da sie regelmäßigere Formen haben und ihre Fallgeschwindigkeit deshalb groß ist. Bei großen Fremdionenkonzentrationen wird die Niederschlagsbildung gehemmt; bei Konzentrationen größer als 0,1–0,2*M* bilden sich die meisten Kristalle an den Gefäßwänden. Scheinbar können sich in diesen Bedingungen in der Lösung keine Keime bilden, oder werden sie aufgelöst. Ähnliche Resultate wurden auch im Falle des Magnesiumammoniumphosphates erhalten.[8] In sehr konzentrierten Lösungen, zum Beispiel in gesättigten Natriumnitrat-oder Kaliumnitratlösungen, ist die Bildung des Niederschlages sogar bei Übersättigungsgraden über 100 auch nach Stunden nicht nachweisbar (in ungerührten Lösungen). Die Form der Bariumsulfatkristalle ändert sich in Gegenwart von Fremdionen bei allen untersuchten Übersättigungsgraden. Um zu bestimmen, ob die Adsorbtion oder eine Änderung des Wachstumsmechanismus die Formveränderung hervorruft, wurden die linearen Wachstumsgeschwindigkeiten unter verschiedenen Bedingungen gemessen. Im gegebenen Falle konnten natürlich keine Leitfähigkeitsmessungen durchgeführt werden und so wurde die Verschiebung einer Kristallfläche mikroskopisch verfolgt. Um während der Dauer der Bestimmung bei konstanter Konzentration zu arbeiten, wurde der in Abb. 2 wiedergegebene Apparat benutzt.

Auf eine farblose, durchsichtige Kunstoffplatte wurde eine kleine Schnellmischkammer *4* mit dem Einflußröhrchen *1,2* und dem Austrittsröhrchen *3* aufgekittet. Die im Verhältnis 1 :1 gemischten Bariumchlorid- und Kaliumsulfatlösungen strömen durch den mit einem Mikroskopdeckgläschen *6* abgedeckten Raum *5*. Werden die auf der Innenseite des Deckgläschens gebildeten Kristalle nach bestimmten Zeitintervallen fotografiert, so kann die lineare Wachstumsgeschwindigkeit leicht berechnet werden. Die Vorteile dieser Methode bestehen darin, daß dieselben Kristalle während

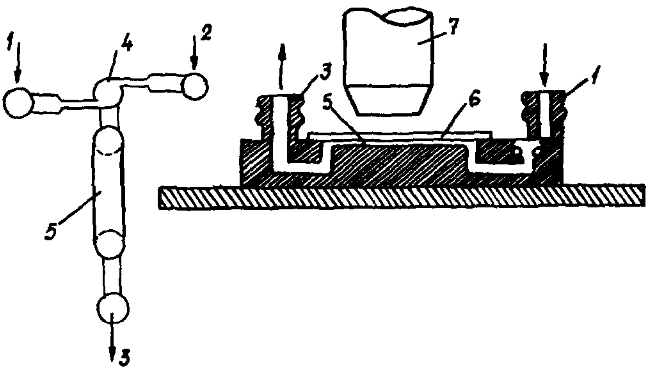

Abb. 2.—Apparat zur Bestimmung der linearen Wachstumsgeschwindigkeit. Es bedeuten:
1, 2 Einflußrohre für $BaCl_2$—und K_2SO_4—Lösung; 3 Abflußrohr; 4 Durchmischungskammer; 5 Meßraum; 6 Deckglas; 7 Mikroskop.

der ganzen Wachstumsperiode verfolgt werden und daß die Bariumsulfatkonzentration konstant gehalten wird. Die Durchflußgeschwindigkeit muß natürlich konstant gehalten werden, um vergleichbare Resultate zu erhalten.

Bei kleinen Übersättigungsgraden, ungefähr 10, ist die Wachstumsgeschwindigkeit sehr klein, es bilden sich stundenlang keine Kristalle auf dem Deckglas. Deshalb werden Kristalle durch Eintrocknen einer Suspension auf das Deckglas gebracht und es wird das Wachstum dieser Kristalle verfolgt. Am besten eignen sich dazu Kristalle, die durch Vermischen einer $4{,}10^{-4}M$ Bariumchloridlösung mit einer Kaliumsulfatlösung derselben Konzentration erhalten wurden, da sie regelmäßige Formen haben. Das Deckglas wird mit einer Mischung von Wachs und Kolophonium auf die Kunststoffplatte geklebt.

Ist die Diffusion wachstumsbestimmend, so wächst der Radius eines kugelförmigen Kristalles nach Neumann's[9] Gleichung;

$$r(t) = [2DV(c - c_s)t]^{1/2}$$

Ist die Grenzflächenreaktion Wachstumsbestimmend, so gilt

$$r(t) = kV(c - c_s)t$$

Hier bedeuten V das Molvolumen, D der Diffusionskoeffizient, c und c_s die Konzentration der Lösung bzw. die Sättigungskonzentration und t die Zeit.

Im Falle des Bariumsulfates erhält man Geraden, wenn man $r(t) = f(t^{1/2})$ graphisch darstellt, und zwar bei Konzentrationen über $5{,}10^{-5}M$. Bei kleineren Konzentrationen konnte auch nach 8 Stunden kein Wachstum festgestellt werden. Die Diffusion kann also schon bei einer fünffachen Übersättigung hemmend wirken. Dieser Wert ist fast um eine Größenordnung kleiner als der von Nielsen[10,11] gefundene. Kahlweit[12] hat festgestellt, daß TlJ äußerst langsam wächst, wenn die Konzentration nahe der Sättingungskonzentration liegt.

Stellt man die Länge der Bariumsulfatkristalle in Abhängigkeit von der Quadratwurzel der Zeit $\sqrt{t}$ graphisch dar, so erhält man für verschiedene Ausgangskonzentrationen wie in Abb. 3 dargestellte Geraden. Es wurden für jede Konzentration wenigstens 10 Kristalle gemessen. Unter denselben Versuchsbedingungen erhält man für jeden Kristall eine Gerade; diese sind parallel, aber gegeneinander verschoben, da für jeden Kristall eine bestimmte Induktionsperiode nötig ist. Diese Unterschiede sind jedoch nicht groß.

Da unter gegebenen Bedingungen $(c - c_s)$ konstant bleibt, kann Neumann's Gleichung geschrieben werden:

$$r(t) = K \cdot t^{1/2}$$

wo

$$K = [2DV(c - c_s)]^{1/2}$$

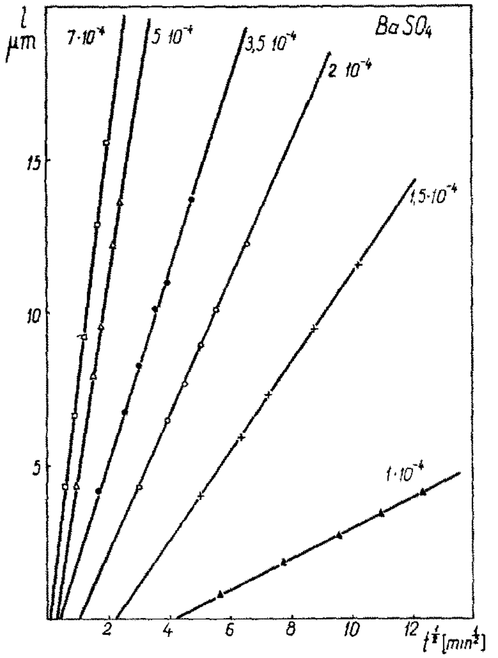

Abb. 3.—Einfluß der Bariumsulfatkonzentration auf die lineare Wachstumsgeschwindigkeit.

Aus der Neigung der Geraden kann also der Diffusionskoeffizient berechnet werden. Da aber die Kristalle stark von der Kugelform abweichen, müß ein Korrektionsfaktor bestimmt werden. So erhält man für die in Abb. 3 dargestellten Fälle Werte zwischen $2{,}4 \cdot 10^{-6}$ und $7{,}5 \cdot 10^{-6}$ cm² sec⁻¹, Werte die mit denen von Nielsen[11] aus Leitfähigkeitsmessungen erhaltenen ziehmlich gut übereinstimmen. Die für Konzentrationen unter $1 \cdot 10^{-4}M$ erhaltenen Werte sind jedoch kleiner, da in diesem Falle wahrscheinlich ein Zusammenspiel der Grenzflächenreaktion und der Diffusion vorliegt.

Aus diesen graphischen Darstellungen kann man für $l = 0$, wo l die Kristalllänge bedeutet, auch die Induktionsperiode bestimmen. Es wurde festgestellt, daß bei gleicher Konzentration für verschiedene Deckgläser verschiedene Werte für die Induktionsperiode erhalten werden, da ihre Oberfläche verschieden "aktiv" in der Keimbildung ist. Da Bariumsulfatkristalle unter $c = 5 \cdot 10^{-5}M$ sozusagen kein Wachstum aufweisen, können diese Niederschläge durch Umlösen auch nicht altern.

Dieses wurde experimentell sowohl sedimentometrisch als auch fotografisch nachgewiesen. Kleine Kristalle wurden in Gegenwart von großen Kristallen in einer gesättigten Bariumsulfatlösung 3 Monate bei Zimmertemperatur aufbewahrt, ohne daß sich die kleinen Kristalle lösten.

Dieses zeigt klar, daß bei Sättigungskonzentration die Grenzflächenreaktion wachstumsbestimmend ist.

Die Gegenwart von Fremdionen beeinflußt stark die lineare Wachstumsgeschwindigkeit, wie aus Abb. 4, 5 und 6 hervorgeht, und zwar fällt sie mit wachsender Ionenkonzentration. Gleichzeitig haben erhaltenen Kristalle regelmässigere geometrische Formen.

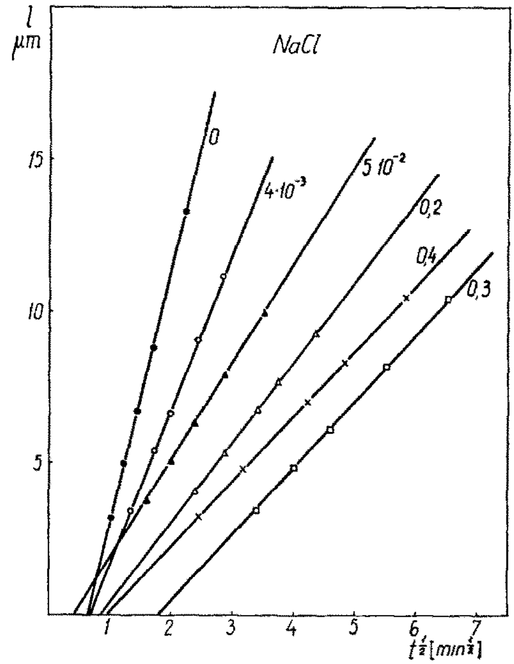

Abb. 4.—Einfluß der Natriumchloridkonzentration auf das Wachstum der Bariumsulfatkristalle; $[BaSO_4] = 5 \cdot 10^{-4}$.

Berechnet man auch in diesen Fällen die Diffusionskoeffizienten bei verschiedenen Konzentrationen, unter Berücksichtigung der Aktivitäten der Barium- und Sulfationen sowie der Löslichkeit des Bariumsulfates in Gegenwart von Fremdionen, so erhält man Werte, die von den Obengenannten wenig abweichen. Das heißt, daß der Wachstumsmechanismus auch in Gegenwart von Fremdionen diffusionsbestimmt ist und daß die Adsorbtion der Ionen die Eingliederung in das Kristallgitter nicht beeinflussen, aber einen Einfluß auf die Kristallform durch die Veränderung der Oberflächenspannung haben.

Wie aus Abb. 7 hervorgeht, hat auch das Verhältnis $[BaCl_2]/[K_2SO_4]$ einen Einfluß auf die Wachstumsgeschwindigkeit.

Grosse Bariumchlorid- und Kaliumsulfatüberschüsse haben einen großen Einluß auf die Kristallform. und zwar führen sie zu dünnen, unregelmässigen Plättchen.

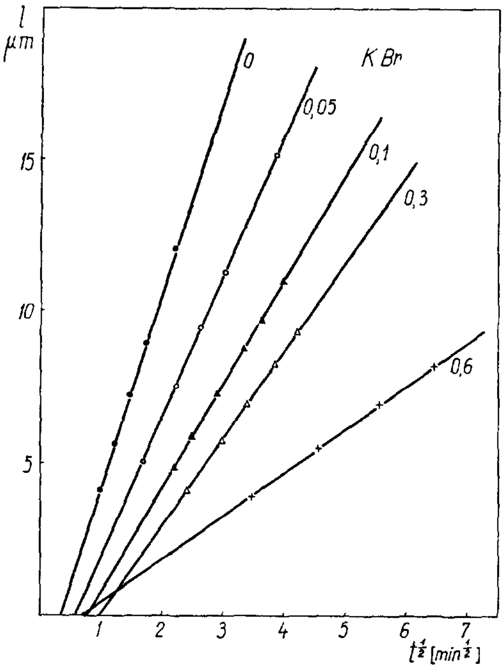

Abb. 5.—Einfluß der Kaliumbromidkonzentration auf das Wachstum der Bariumsulfatkristalle; [$BaSO_4$] = $5 \cdot 10^{-4}$.

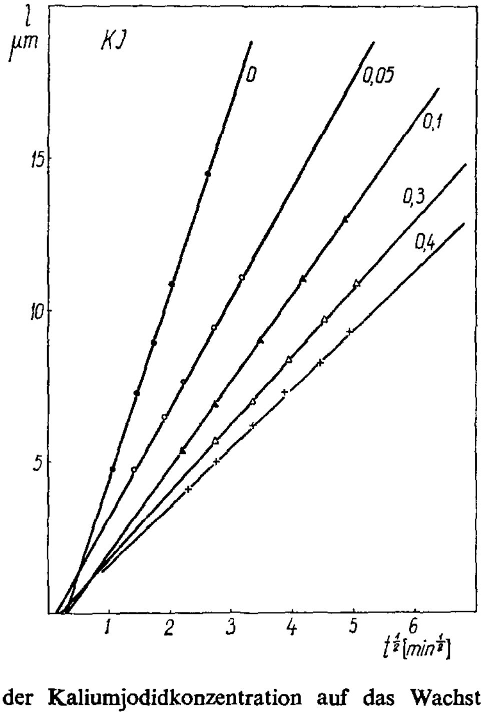

Abb. 6.—Einfluß der Kaliumjodidkonzentration auf das Wachstum der Bariumsulfatkristalle; [$BaSO_4$] = $5 \cdot 10^{-4}$.

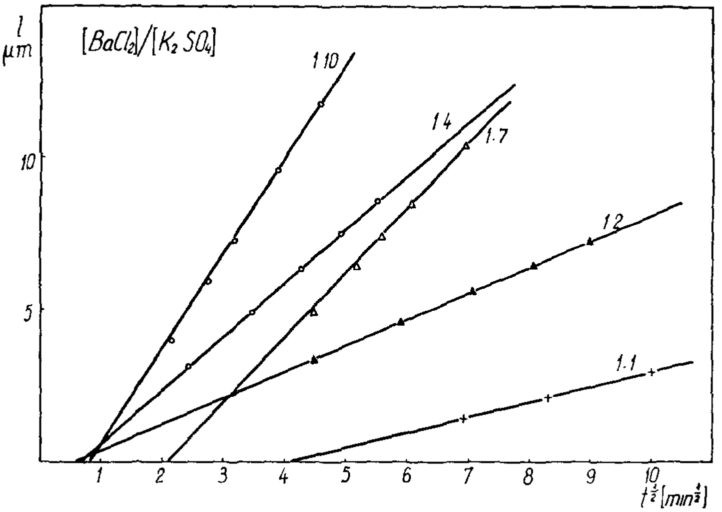

Abb. 7.—Einfluß des Verhältnisses $[BaCl_2]/[K_2SO_4]$ auf das Wachstum der Bariumsulfatkristalle; $[BaSO_4] = 10^{-4}M$.

Diese Methode der Wachstumsbestimmung kann jedoch nur bis zu Konzentrationen von höchstens $1 \cdot 10^{-3}M$ angewendet werden, weil sonst die Kristalle zu nahe aneinander liegen und sich ihre Diffusionshöfe überlappen.

Summary—The influence of foreign ions on the particle size of barium sulphate precipitates has been investigated by sedimentation experiments, establishing that NaCl, $NaNO_3$, KBr, KNO_3 and other salts at high concentrations powerfully hinder the growth of the crystals even at high supersaturation. The linear growth rate has been measured as a function of $BaSO_4$ concentration, foreign ion concentration and $[BaCl_2]/[K_2SO_4]$ ratio. Because the growth is already diffusion controlled at a fivefold supersaturation, the $BaSO_4$ precipitates will not undergo Ostwald ripening. A suitable apparatus has been devised for the investigations.

Résumé—On a étudié l'influence d'ions étrangers sur la dimension de particules de précipités de sulfate de baryum par des expériences de sédimentation, établissant que NaCl, $NaNO_3$, KBr, KNO_3 et d'autres sels à haute concentration gênent puissamment la croissance des cristaux, même à haute sursaturation. On a mesuré la vitesse de croissance linéaire des cristaux en fonction de la concentration en $BaSO_4$, de la concentration en ion étranger et du rapport $[BaCl_2]/[K_2SO_4]$. Etant donné que la croissance est déjà contrôlée par diffusion à une sursaturation de cinq fois, les précipités de $BaSO_4$ ne subiront pas la maturation d'Ostwald. On a conçu un appareil convenable pour les recherches.

EFFECT OF SOLVENT EXTRACTION ON THE ATOMIC-ABSORPTION SPECTROPHOTOMETRY IN DETERMINATION OF ppM LEVELS OF CADMIUM WITH DITHIZONE

Y. YAMAMOTO, T. KUMAMARU, Y. HAYASHI and M. KANKE
Department of Chemistry, Faculty of Science, Hiroshima University,
Higashisenda, Hiroshima, Japan

(*Received 9 September* 1971. *Accepted 7 November* 1971)

Summary—Various organic solvents for cadmium dithizonate extraction have been examined for their suitability for subsequent absorption spectrophotometry. The solvents are discussed on the basis of their physical properties. Much enhanced sensitivity is achieved by use of a large aqueous phase/solvent volume ratio. Conditions for the determination of ppM levels of cadmium are described for nitrobenzene and n-butyl acetate as solvents. Dithizone and cadmium dithizonate are very stable in nitrobenzene. The extraction is completely quantitative over the pH range 3·5–10·0. Interference by diverse ions was studied, and their tolerance levels are given.

THE DETERMINATION of traces of several metal ions such as cadmium, lead, copper and zinc, has received increasing attention in connection with water pollution. Atomic-absorption spectrophotometry currently offers the best means for the reliable determination of these metal ions in trace concentrations. However, the determination of parts per milliard (ppM) levels of these elements in water is virtually impossible by direct aspiration of the sample, because the detection limits are usually 0·01 ppm or higher. When these elements exist in waters at concentrations below the detection limits, they can readily be concentrated by solvent extraction, with a consequent increase in sensitivity, caused not only by the favourable phase-volume ratio but also by the effect of the solvent on the atomic-absorption spectrophotometry. The ammonium pyrrolidinedithiocarbamate(APDC)–methyl isobutyl ketone(MIBK) and diethyldithiocarbamate(DDTC)–MIBK systems have been recommended for solvent extraction and atomic-absorption spectrophotometry by several authors,[1-3] because APDC and DDTC give a number of transition element complexes with high extractability over a wide pH range and MIBK has been shown to enhance the atomic absorption considerably. Moreover, the solubility of MIBK in water increases the phase-volume (water:MIBK) ratio[4] further increasing the sensitivity.

It is well known that diphenylthiocarbazone (dithizone) is a strong complexing agent, forming red or orange complexes with a variety of metal ions. Chloroform or carbon tetrachloride have generally been used as the solvents for extraction of dithizonates, but these chlorinated solvents are not suitable in atomic-absorption spectrophotometry because of their incomplete combustion in the flame and the toxity of the decomposition products such as phosgene. Except for the work of Sachdev and West,[5] who used ethyl propionate as solvent, no attempt seems to have been made to utilize metal dithizonate extraction systems for atomic-absorption spectrophotometry(AAS).

In this paper, the utility of various organic solvents for dithizonate extraction and subsequent AAS is studied, using cadmium as a typical element. It appears that the so-called "solvent effect" is primarily related to the aspiration rate which is governed by the physical properties of the solvent. With nitrobenzene and n-butyl acetate, the effect of their partial miscibility with water was investigated by varying the phase-volume ratio.

EXPERIMENTAL

Apparatus

Atomic-absorption measurements were made with a Nippon Jarrell–Ash Model AA-1 EW atomic-absorption spectrophotometer fitted with a Hitachi Model HLA-3 hollow-cathode lamp and equipped with a Yanagimoto Model YR-101 recorder. Radio-activity measurements were made with a Nihonmusen Model R-1360 low-background counter. Viscosity measurements on MIBK were made with an Ubbelohde-type viscometer.

Reagents

All reagents are analytical grade unless otherwise stated and the aqueous solutions are stored in polyethylene bottles. Demineralized water is used.

Cadmium solution, 1000 *ppm*. Dissolve 1·00 g of cadium metal (99·99%) in 10 ml of 3*M* hydrochloric acid and add 2 ml of concentrated sulphuric acid. Evaporate the solution nearly to dryness and ditute to 1000 ml with water.

Cadmium-115*m solution.* Dilute 1 mCi ^{115m}Cd solution (in 0·5*M* hydrochloric acid) to 100 ml with water. This solution contains 20·8 μg of cadmium per ml and is diluted to tracer scale when it is used in the experiment.

Dithizone solutions, 0·03%. Dissolve 75 mg of refined dithizone in 250 ml of a solvent. The solvents used were MIBK, ethyl propionate, n-butyl acetate, nitroethane and nitrobenzene.

Buffer solution, pH 4–6. Prepare acetate buffers by mixing 2*M* acetic acid and 2*M* sodium acetate in suitable ratio.

Procedure

Transfer an aliquot of cadmium solution by pipette into a 50–1000 ml standard flask. Add 5 ml of the buffer solution to adjust the pH of the final solution to 4–6 and dilute to the mark with water. Then transfer the solution into a suitable separatory funnel. Add 10–50 ml of the dithizone solution and shake the funnel for 10 min on a mechanical shaker. Let stand for 15 min, then separate the organic phase. Measure the atomic absorption of cadmium (2288 Å) in the extract against a reference consisting of the solvent saturated with water, under the optimum operating conditions.

RESULTS AND DISCUSSION

Effect of pH and solvent

Effect of pH on the extraction of cadmium dithizonate into various solvents was studied radiochemically with ^{115m}Cd. Five solvents were tested: MIBK, ethyl propionate (EP), n-butyl acetate (BA), nitroethane (NE) and nitrobenzene (NB). Each extraction was done with equal volumes of the two phases, which had previously been mutually saturated. As shown in Fig. 1, all the solvents tested gave complete extraction of cadmium dithizonate over the pH range 3·5–10·0. For practical convenience, pH 5·3 was selected in this experiment.

The effect of the solvent on the atomic absorption of cadmium is shown in Fig. 2. The volume of both phases (which were previously saturated with each other) was 50 ml. In atomic-absorption spectrophotometry the addition of a water-soluble organic solvent in the aqueous phase or use of an extract made with a water-immiscible organic solvent usually affects the sensitivity. This effect may be attributed to two factors: the effect on the aspiration rate, and the effect on atomization efficiency. As shown in Fig. 2, the order of decreasing sensitivity is MIBK $>$ EP $>$ BA $>$ NE $>$ (water) $>$ NB. Table I shows some physical properties of the solvents together with the aspiration rate of the extracts measured here. It is observed that the aspiration rate increases as the viscosity, density and surface tension decrease. It may be said that the sensitivity order is primarily due to the aspiration rate, which is governed by these physical properties. The similar sensitivities of the aqueous solution and NB extract

suggest that an increased atomization efficiency in the flame with NB compensates the decrease in sensitivity caused by the low aspiration rate of this solvent.

Effect of phase-volume ratio on sensitivity

To obtain higher sensitivity for the determination of ppM levels of cadmium, use of a large initial aqueous phase/solvent volume ratio (V_w/V_o) is required. In subsequent experiments, NB and BA were chosen as typical solvents. The former is a solvent with extremely small solubility in water, and the latter is appreciably soluble. The volume changes of the NB and BA phases after extraction are shown in Fig. 3. The volume after extraction was measured by pipette after centrifugation 15 min after extraction was complete. With increasing V_w/V_o, the volume of the extract with BA appreciably decreases, while that with NB remains almost unchanged. As is shown in Fig. 4, the degree of extraction determined by using cadmium tracer (^{115m}Cd) shows that NB extracts cadmium completely over the whole range of V_w/V_o used, but in the case of BA appreciable loss of the element occurs owing to the partial miscibility of solvent with water. An increasing *relative* absorption with increase in the volume

ratio (V_w/V_0) is shown in Fig. 5. A much enhanced sensitivity is achieved in BA extraction by use of a larger volume ratio, mainly because of the greater degree of concentraton of the dithizonate in the diminished organic phase. Calibration curves are shown in Fig. 6.

The precision was estimated from 10 samples in each of two series of extractions with $V_w/V_0 = 500/10$. One series (Cd, 20 μg) with NB as solvent gave a standard deviation of 2%, and the other series (Cd 5 μg) with BA gave 5%.

Interferences

Atomic-absorption spectroscopy is relatively free from interferences. However, large amounts of various cations may suppress the extraction of cadmium because of

their consumption of dithizone. Permissible concentrations causing errors less than 2% in the NB extraction method are shown in Table II.

No interference by alkali and alkaline earth metal ions and by several anions was observed, but large amounts of transition metal ions that react with dithizone markedly lowered the extraction of cadmium. Interference by these ions could be reduced by use of a higher concentration of dithizone.

This extraction system should be suitable for other elements which form stable dithizonates, such as copper, zinc, lead and silver.

Zusammenfassung—Verschiedene organische Lösungsmittel zur Extraktion von Cadmiumdithizonat wurden auf ihre Eignung zur nachfolgenden Absorptions-Spektrophotometrie geprüft. Die Lösungsmittel werden an Hand ihrer physikalischen Eigenschaften diskutiert. Stark verbesserte Empfindlichkeit erhält man durch Anwendung eines großen Volumenverhältnisses von wäßriger Phase zu Lösungsmittel. Die Arbeitsbedingungen zur Bestimmung von ppM-Mengen Cadmium werden mit Nitrobenzol und n-Butylacetat als Lösungsmittel angegeben. Dithizon und Cadmiumdithizonat sind in Nitrobenzol sehr stabil. Die Extraktion ist im pH-Bereich 3,5–10,0 vollständig quantitativ. Die Störung durch verschiedene Ionen wurde untersucht und die Toleranzmengen werden angegeben.

Résumé—On a examiné divers solvants organiques pour l'extraction du dithizonate de cadmium quant à leur convenance pour la spectrophotométrie d'absorption subséquente. On discute des solvants sur la base de leurs propriétés physiques. On obtient une sensibilité de beaucoup accrue par l'emploi d'un grand rapport de volume phase aqueuse/solvant. On décrit les conditions de dosage du cadmium à l'échelle du ppM avec le nitrobenzène et l'acétate de *n*-butyle comme solvants. La dithizone et le dithizonate de cadmium sont très stables en nitrobenzène. L'extraction est totalement quantitative dans le domaine de pH 3,5–10,0. On a étudié la gêne apportée par divers ions, et l'on donne leurs niveaux de tolérance.

UNIVALENT CATION-EXCHANGE IN ORGANIC SOLVENT WATER AND ORGANIC SOLVENT–WATER–PHENOL MIXTURES

J. G. JONES and J. D. R. THOMAS
Department of Chemistry, University of Wales Institute of Science and Technology, Cardiff, Wales

(*Received* 4 *August* 1971. *Accepted* 12 *November* 1971)

Summary—Selectivity coefficients, K_H^M, for the exchange of alkali metal ions and ammonium ions with the hydrogen form of ZeoKarb 225 cation-exchange resin have been determined in various organic solvent–water and organic solvent–water–phenol mixtures. There is an increase in K_H^M in passing from purely aqueous conditions to media of increasing organic solvent content, frequently with the effect of producing magnified differences and selectivity reversals between one ion and another. The results are discussed in terms of the relationship between K_H^M and the reciprocal of the dielectric constant of the medium and also in the light of free energies of transfer of cations between methanol–water systems. The effect of phenol giving a lowering of K_H^{Cs} in methanol–water, of K_H^K and K_H^{Na} in ethanol–water and of K_H^{Na} and K_H^{Li} in acetone–water systems cannot be fully reconciled with the mechanism involving  $M^+ \ldots O\begin{smallmatrix}H\\R\end{smallmatrix}$ bonding proposed by earlier workers.

USEFUL information is available on cation-exchange processes in non-aqueous and mixed solvent systems.[1] The frequent increase in selectivity coefficients for the exchange of given pairs of ions as the dielectric constant of the solvent medium decreases is interesting, and the linear relation between log selectivity coefficient and the reciprocal of the dielectric constant of the medium[2-11] has initiated several explanations. These range from the hypothetical desolvation energy involved in ion-exchange[4,5] to ion-pair formation[7,8] and to changes in the solution and resin-phase activity coefficients.[9,10] Variations in trends can lead to changes of order in selectivities, for example, on Dowex 50 × 8 the aqueous selectivity order of $Cs^+ > K^+ > CH_3NH_3^+ > NH_4^+ > Na^+ > Li^+$ is twice reversed in methanol, where $K^+ > Cs^+$ and $Na^+ > CH_3NH_3^+ > NH_4^+$.[9]

This paper extends existing knowledge[9] for univalent cation exchange in methanol–water and ethanol–water to a larger range of univalent cations and to acetone–water systems. Additionally, phenol was incorporated in the media in order to supplement available information on the greater selectivity of bifunctional sulphonated phenol-formaldehyde exchangers for the heavier alkali metal ions, compared with sulphonated polystyrene–divinyl benzene exchangers,[11,12,13] and also to gain further knowledge of the lowering of the affinity of monofunctional sulphonic acid resins for Cs^+ ions when the solvent medium contains phenol.[11]

EXPERIMENTAL

Materials

Solvents. Analytical-reagent grade methanol and acetone. BPC grade absolute ethanol.

Salts. Analytical-reagent grade chlorides of sodium, potassium, caesium and ammonium, and Koch-Light (purity > 99·9%) rubidium chloride. Lithium chloride was prepared from analytical-reagent grade lithium carbonate assayed acidimetrically.

Phenol. Analytical-reagent grade.

Ion-exchange resin. ZeoKarb 225 resin (8% DVB; 52–100 mesh) supplied in the sodium form was converted into the hydrogen form by a column technique using five bed-volumes of 10% hydrochloric acid. The resin was washed free from acid with demineralized water and then repeatedly washed with the solvent (for example, with methanol for studies involving methanol) until the refractive index of the eluate was that of the pure solvent. To avoid possible adverse thermal effects, the resin was dried for 24 hr at 30°.

In order to equate more precisely the results from different resin batches, the loss of weight on drying at 105° was determined for each batch before use. The exchange capacity of the hydrogen-form resin was determined by conversion into the sodium form and estimation of the displaced hydrogen ions by potentiometric titration to pH 7·0 with standard sodium hydroxide.

Equilibration procedure

Equilibrium studies were made with glass-stoppered Quickfit tubes (54 ml capacity) containing ion-exchange resin and liquid phase of initial concentration 0·1*M* with respect to the cation. To prepare the mixture for equilibration, 1·00(±0·01) g of air-dried resin was weighed into the tube, and in the case of systems involving phenol, 2·50(±0·01) g phenol were added. According to the liquid phase composition required, 0·0, 5·0, 15·0, 25·0, 35·0 or 45·0 ml of pure solvent were measured into the tubes and demineralized water was added to give a total volume of 45·0 ml. The cation was then added as 5·0 ml of 1·0*M* alkali metal/ammonium chloride, thus making the initial composition of the liquid phase of each series of six tubes 0, 10, 30, 50, 70 and 90% organic solvent, respectively.

The exchange equilibria were allowed to establish at 30 ± 1° in an air thermostat by allowing the resin to cascade through the solution. This was achieved by placing the tubes containing the resin-solvent system on a rotating wheel within the thermostat. The run was allowed to proceed for 16 hr, although preliminary experiments showed that equilibrium was reached in 4 hr and that runs of 24 hr did not alter the equilibrium.

Analysis of equilibrium solutions

After equilibration the resin and liquid phase were separated by transfer of the liquid to a Buchner flask under gentle suction through a sintered-glass disc interposed between two Quickfit cones connecting the Buchner flask and equilibration tube. A 25-ml portion of the liquid phase was titrated potentiometrically with 0·1*M* sodium hydroxide to pH 7·00, a glass and calomel electrode pair being used. The titre corresponds to the hydrogen ions liberated from the resin during equilibration; it also corresponds to the metal/ammonium ion associated with the resin phase at equilibrium. The selectivity coefficients, $K_H{}^M$, for the resin phase were calculated by computer, using a Fortran program.

In the case of systems involving potassium, rubidium and caesium, a check was made on the total cation content of the liquid phase by determining its metal ion concentration gravimetrically as the tetraphenylborate salt. Table I is representative of the results obtained and confirms that the hydrogen ion content of the liquid phase corresponds to the metal/ammonium ion content of the resin phase.

RESULTS

Figure 1 gives plots of log selectivity coefficients (log $K_H{}^M$) *vs.* volume fraction of water for the univalent cation exchanges in the various organic solvent–water and organic solvent–water–phenol mixtures. Difficulties were encountered with solubility problems for acetone–water systems with a high content of acetone, for potassium, rubidium, caesium and ammonium chlorides, and the results for these show trends different from those that might otherwise have been obtained.

The order of resin affinities for cations in the various systems studied is given in Tables II, III and VI, while Table IV and V show the enhancement and alterations in $K_H{}^M$ between water and organic solvent–water (0·1 volume fraction water) mixtures in the absence (Table IV) and in the presence (Table V) of phenol.

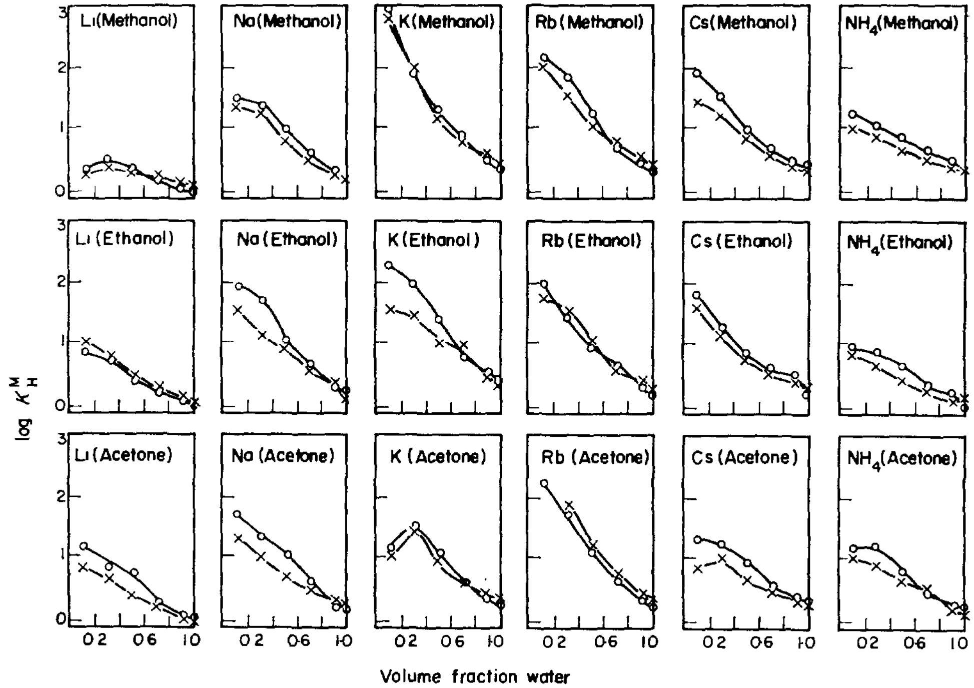

FIG. 1.—Selectivity coefficients of alkali metal ions and ammonium ions between ZeoKarb 225 and various organic solvent–water (○) and organic solvent–water–phenol mixtures (×).

DISCUSSION

Organic solvent–water systems

The results for methanol–water media in the absence of phenol are in broad agreement with those of Fessler and Strobel[9] except that the selectivity maxima noted by them and other workers[6,14] using resins other than ZeoKarb 225, were not so much in evidence. However, because of solubility considerations, the present studies were not extended to media containing less than 0·1 volume fraction water. Nevertheless, the maximum noted by Fessler and Strobel[9] for potassium in methanol–water (at 0·2 mole fraction water in methanol) should have been evident. Instead, the selectivity coefficient for potassium rises steadily to a phenomenally high level of 978 at 0·1 volume fraction (0·19 mole fraction) water in methanol compared with just 2·34 in water. In this respect it is perhaps significant that log $K_H{}^M$ is a linear function of $1/D$ (Fig. 2) where D is the macroscopic dielectric constant of the external solution, as used by Fessler and Strobel.[9] Indeed, while Fessler and Strobel confirm the linear relation

between log K_H^M and $1/D$ for water-rich methanol noted by other workers[5,15,16,17] they stress the shortness of the linear region, in general from 0·7 or 0·8 to 1·0 mole fraction (0·5 or 0·6–1·0 volume fraction) water. In this work, the linear range is often longer and particularly so for potassium (Fig. 2).

The tendency for selectivity maxima clearly leads to a breakdown of the linear relation between log K_H^M and $1/D$ (Figs. 1 and 2), and while the interpretation of Fessler and Strobel,[9] based on the effect of the medium on ionic activity coefficients, may be valid, other considerations may hold. These may include the inability of large solvated ions, such as those of lithium and sodium, to penetrate the shrunken resin and hence upset activity and energy considerations.

The methanol–water trends are also evident for the ethanol–water systems, but the tendency for K_H^M to maximize is not so evident and neither does potassium show such a phenomenal increase of affinity for the resin with diminishing water content of the medium. This may be due to the more shrunken state of the resin in media of lower dielectric constant. In this respect, it may be relevant that sodium and lithium now show an enhancement of selectivity for the resin (Fig. 1) which might be attributed to the hydration shell being phased out, thus permitting penetration of even the smaller pores of the resin in ethanol media. Indeed, the pattern for sodium and lithium is

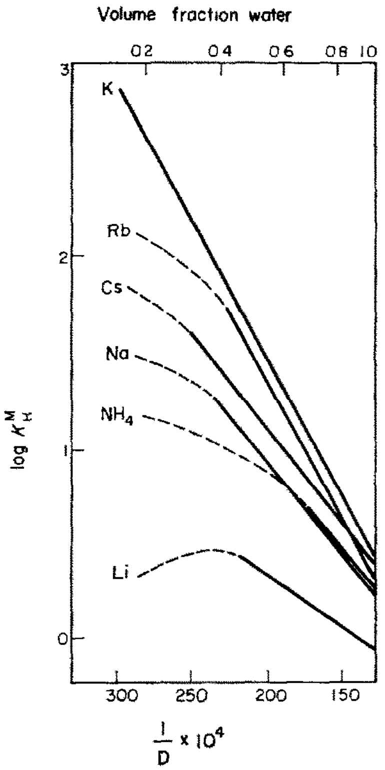

FIG. 2.—Plot of log selectivity coefficient *vs.* reciprocal of the dielectric constant (D) for methanol-water system.

similar in acetone–water media. In these latter media, however, maxima become prominent for potassium, caesium and ammonium ions, but this may be due to the poor solubility of the salts used in acetone-rich media and the affinity for the resin (due to its shrunken state) may be inadequate to overcome this. Poor solubility is, however, not very plausible as an explanation (the solid salt noted on first making up the batch disappears during equilibration), for gravimetric studies on the equilibrium liquid phase together with its hydrogen ion content gave a full mass-balance for the cation.

The phenomenal increase in K_H^M, in passing from purely aqueous conditions to media of increasing organic solvent content. (Fig. 1), frequently with the effect of producing magnified differences between one ion and another, is remarkable and merits consideration in the light of standard molar free energies of transfer for single cations between various media.[18] Such free energies of transfer between water and water–methanol media are shown in Table VI, from which it can be seen that the cations are in an increasingly lower free-energy state with increasing methanol content of the medium.

The relevance of the values is to be seen in the context of the observation of Davies and Thomas[19] in that the medium associated with the resin phase is predominantly aqueous. Thus, the fact that the alkali metal ions, Li^+, Na^+ and K^+ are sequentially in a higher (more positive) free energy state than hydrogen (Table VI)

TABLE VI.—STANDARD FREE ENERGY OF TRANSFER (*J/mole*) AT 25°C OF SINGLE CATIONS FROM WATER TO WATER–METHANOL MEDIA[18]

K^+	−800	±5000
	(±250 J/mole)	(±2500 J/mole)

suggests that hydrogen ions prefer the more organic liquid medium, thus leading to an increase in $K_H{}^M$ as the organic solvent content of the medium is increased and to increasingly higher values of $K_H{}^M$ in the series Li^+, Na^+, K^+ as the free energy of the ion relative to hydrogen becomes more positive. In this last respect, it would be interesting to learn how free energy transfer data for rubidium and caesium fit into the ion-exchange pattern.

No amount of theoretical explanation will alter the feature of potential analytical interest and that is the extent to which mixed organic solvent–water media are capable of creating large differences in selectivity coefficients (Table IV). The several selectivity order reversals noted in these systems (Table II) offer a basis for variety in separation schemes. Fessler and Strobel[9] have already remarked on this feature and the present results are also consistent with those of Gorshkov, Korolev and Shabanov[11] who found that the effect of added methanol on $K_H{}^M$ for alkali metal cations increases on going from Li^+ to K^+ and decreases on going from K^+ to Cs^+. This study was confined to methanol–water media of more than 0·4 mole fraction (0·23 volume fraction) water and therefore does not extend so much into the region where maxima in selectivity coefficient data might be observed.

Organic solvent–phenol–water systems

An important objective of the study by Gorshkov, Korolev and Shabanov[11] was the effect of 57·5–72% phenol on selectivity, for the monofunctional sulphonic acid cation-exchangers KU-1 and Dowex 50 × 2. It was found that phenol appreciably lowers $K_H{}^M$, particularly for the caesium exchange. Hence it is interesting to note that the milder conditions of the present investigation (using 5% phenol) sufficiently lower $K_H{}^{Cs}$ to cause a pronounced difference between it and the greater $K_H{}^{Rb}$ (Fig. 1 and Tables IV and V).

Added phenol gives different patterns for the ethanol and acetone systems (Fig. 1) in that the more pronounced lowering of $K_H{}^M$ at high organic solvent content occurs for sodium and potassium in the ethanol systems and for lithium, sodium and caesium in the acetone systems. However, $K_H^{NH_4}$ is almost always lower in the presence of phenol for all three systems studied.

The interesting aspect of the trend in $K_H{}^M$ lowering is that, with the exception of caesium in acetone, the trend is towards the lower atomic number alkali metal ions as the dielectric constant of the organic solvent decreases ($D = 80, 33, 25, 21$ for water, methanol, ethanol, acetone respectively). Such a trend is not consistent with an explanation[11] which rules out ion-dipole interactions. Such interactions should weaken as the ionic radius increases and as the dipole moment falls (that is, on going from Rb^+ to Cs^+ and also from water to methanol to ethanol to acetone and to phenol). However, because of the lowering of K_H^{Cs} in methanol–water media containing phenol, Gorshkov, Korolev and Shabanov[11] proposed the mechanism of Esafov[20] involving an  $M^{+}\ldots O{<}^{H}_{R}$ complex where the metal–oxygen bond will be stronger, the weaker the hydration of the cations, and the more complex the hydrocarbon radical of R in ROH, that is, it will be stronger for Cs^+ than Rb^+ and stronger for phenol than methanol.

The present results suggest that ion-dipole interaction cannot be entirely ruled out, for, as noted above, the K_H^M lowering associated with phenol moves towards the lighter alkali metal ions. This is consistent with the ions becoming less hydrated as the dielectric constant of the organic solvent decreases, while the anomalous position of caesium in acetone arises from solubility considerations. The real explanation is clearly complex, demanding further study, and must await the results of a continuing programme. For example, acidity considerations may have their part to play, for both alcohols and phenols have different acidity effects from water.[18,21]

Zusammenfassung—In verschiedenen Gemischen aus organischem Lösungsmittel und Wasser oder organischem Lösungsmittel, Wasser und Phenol wurden die Selektivitätskoeffizienten K_H^M für den Austausch von Alkalimetall- und Ammoniumionen mit der protonierten Form des Kationenaustauschharzes ZeoKarb 225 bestimmt. K_H^M steigt an, wenn man von rein wäßriger Lösung zu Medien mit steigendem Gehalt an organischem Lösungsmittel übergeht; oft sind damit größere Differenzen und Umkehrungen der Selektivität zwischen zwei Ionen verbunden. Die Ergebnisse werden im Hinblick auf die Beziehung zwischen K_H^M und der reziproken Dielektrizitätskonstanten des Mediums sowie auf die freien Überführungsenergien von Kationen zwischen Methanol-Wasser-Systemen diskutiert. Der Einfluß von Phenol, das K_H^{Cs} in Methanol-Wasser, K_H^K und K_H^{Na} in Äthanol-Wasser sowie K_H^{Na} und K_H^{Li} in Aceton-Wasser erniedrigt, kann mit dem von früheren Autoren vorgeschlagenen Mechanismus, der eine  $M^{+}\ldots O{<}^{H}_{R}$ -Bindung enthält, nicht voll in Einklang gebracht werden.

Résumé—On a déterminé les coefficients de sélectivité K_H^M pour l'échange d'ions metalliques alcalins et d'ions ammonium avec la forme hydrogène de la résine échangeuse de cations ZeoKarb 225 dans divers mélanges solvant organique-eau et solvant organique-eau-phénol. Il y a un accroissement de K_H^M lorsqu'on passe de conditions purement aqueuses à des milieux à teneur croissante en solvant organique, avec fréquemment pour effet la production de différences amplifiées et d'inversions de sélectivité entre ions. On discute des résultats en fonction de la relation entre K_H^M et l'inverse de la constante diélectrique du milieu et aussi à la lumière des énergies libres de transfert de cations entre les systèmes méthanol-eau. L'influence du phénol donnant un abaissement de K_H^{Cs} en méthanol-eau, de K_H^K et de K_H^{Na} en systèmes ethanol-eau et de K_H^{Na} et K_H^{Li} en systèmes acétone-eau ne peut être pleinement conciliée avec le mécanisme mettant en jeu la liaison  $M^{+}\ldots O{<}^{H}_{R}$ proposé par des auteurs antérieurs.

Studies on the polymer + plasticizer membrane-electrode—VIII* Use of the PVC + tricresyl phosphate membrane as indicating electrode in potentiometric precipitation titration

(*Received* 17 *June* 1971. *Accepted* 27 *November* 1971)

THE MEMBRANE-ELECTRODE obtained[1] by plasticizing PVC with tricresyl phosphate has been successfully used in potentiometric titration of strong acids and bases,[2,3] weak acids and bases,[4] salts that give alkaline hydrolysis,[5] mixtures of acids and bases,[4] organic acids and bases,[6] and in automatic acid–base potentiometric titrations.[7] The membrane-electrode is sensitive to certain cations such as Ag^+, Tl^+, Hg_2^{2+}, Na^+ and K^+.[8] This permits the electrode to be used as transducer in potentiometric titration of certain halides and pseudohalides, if solutions of these cations are used as titrants.

EXPERIMENTAL

The electrolytic cell used is represented by:

SCE | satd. KNO_3 | internal soln. | membrane | external soln. | satd. KNO_3 | SCE

A saturated potassium nitrate bridge was used in order to avoid contact of the calomel electrodes with the Ag^+, Tl^+, or Hg_2^{2+} solutions. Measurements were made at room temperature while the solution was being stirred.

To show the sensitivity of the membrane-electrode to Ag^+, Tl^+ and Hg_2^{2+} the electrode functions are given in Fig. 1. It is obvious that when these cations are used as titrants, the membrane-electrode potential will change very sharply simultaneously with the appearance of an excess of the titrant.

Titration of halides and pseudohalides with $AgNO_3$

Titration curves for halides and pseudohalides (50-ml 0·02*M* samples, 0·1*M* silver nitrate) have the typical *S*-shape of potentiometric titration curves, and the potential break is about 100 mV. The equivalence volumes, calculated according to the Hahn-Weiler method,[9] have been compared with those obtained by use of indicators (chromate for chloride, eosin for bromide and iodide, and ferric alum for thiocyanate), in order to characterize the accuracy of the titrations. The results are given in Table I.

TABLE I.—ACCURACY AND PRECISION OF HALIDE AND PSEUDOHALIDE TITRATIONS WITH SILVER NITRATE

Anion	ΔE*, *mV*	$V_{H\text{-}W}$,† *ml*	V_{ind},‡ *ml*	Error, %
Cl^-	75	7·63	7·65	−0·3
Br^-	115	8·37	8·40	0·4
I^-	125	9·87	9·85	−0.2
SCN^-	90	8·63	8·60	0·4

* For titrant interval from $V_e - 1\%$ to $V_e + 1\%$, where V_e is the equivalence-point volume.
† Equivalence-point volume calculated by the Hahn–Weiler method.
‡ Volume of titration with indicator end-point.

When 0·02*M* potassium iodide is titrated with 0·1*M* silver nitrate at different pH values the potential break decreases with increasing acidity, being 120 mV at pH 4, 105 mV at pH 3, 80 mV at pH 2 and 40 mV at pH 1. In fact, under the conditions used, H^+ and Ag^+ ions are competitive in determining the membrane potential, especially after the equivalence point. The potentials of the initial

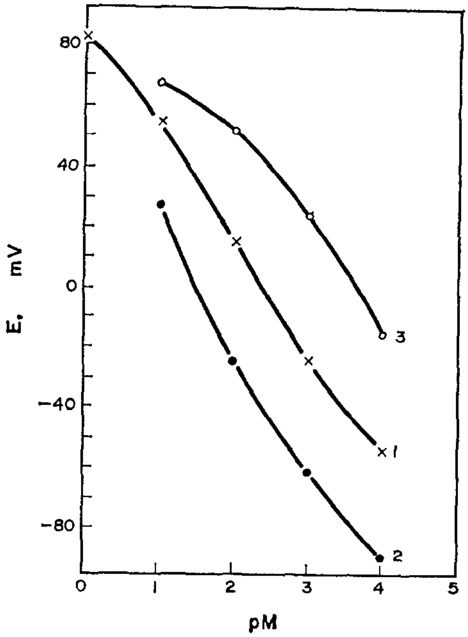

FIG. 1.—pM electrode functions.
1—Ag^+; *2*—Tl^+; *3*—Hg_2^{2+}.

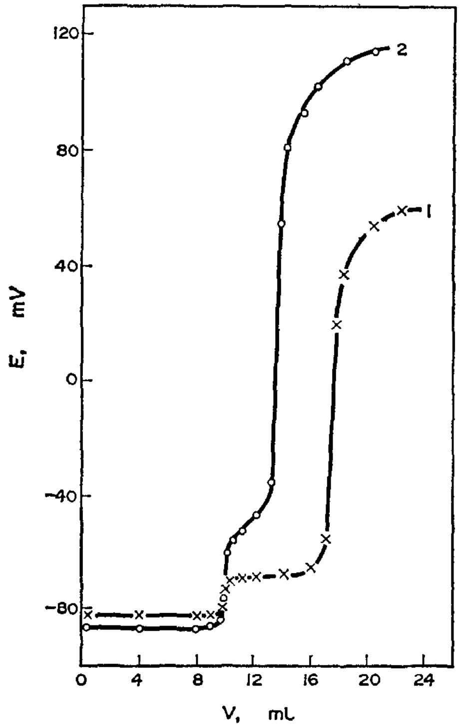

FIG. 2.—Titration of $Cl^- + I^-$ mixture with $0{\cdot}1M$ $AgNO_3$.
1—$0{\cdot}02M$ KI + $0{\cdot}02M$ KCl
2—$0{\cdot}02M$ KI + $0{\cdot}01M$ KCl

solutions are different because of the different acidities used, since the concentration of iodide is the same in all.

The influence of the concentrations of the titrand and titrant has been studied for the iodide-silver titration. The potential break is 100–120 mV for iodide in the range 0·001–0·1M titrated with silver solution ten times as concentrated. The equivalence point can still be easily located even if $10^{-4}M$ iodide is titrated with $10^{-3}M$ silver (60-mV break).

Titration of halide mixtures is satisfactory for $Cl^- + I^-$ but not for $Cl^- + Br^-$ or $Br^- + I^-$. For $Cl^- + I^-$ mixtures the first equivalence point corresponds to the iodide. The potential break is a function of the chloride concentration. The lower the concentration of chloride the larger the potential jump at the first equivalence point (Fig. 2).

Determination of halides with Tl^+ *and* Hg_2^{2+}

Thallous acetate is suitable as titrant for iodide but not for bromide and chloride, the solubility of thallium bromide and chloride being too high to ensure the accuracy needed for the potentiometric titration. The potential break for iodide is only 20–40 mV.

Titration of chloride with mercurous nitrate is similar to that for chloride with thallous acetate, the potential jump being much smaller (10–15 mV) than that obtained in titration with silver nitrate.

Automatic potentiometric titration of iodide

The fast response of the membrane-electrode permits its use in automatic potentiometric determinations. The speed of response was determined by automatically recording the potential of the electrode (on a Radelkis OH 102 polarograph) when it was suddenly introduced into the solution studied: 0·1M silver nitrate, 0·01M thallous acetate or 0·01M mercurous nitrate (Fig. 3). The membrane-electrode shows a practically constant potential in about 4 sec. On the basis of this fast response, the membrane-electrode was used in automatic titration of iodide with silver nitrate, by either direct or derivative potentiometry.

Summary—Results obtained by use of the PVC + tricresyl phosphate membrane-electrode in potentiometric precipitation titration of some halides and pseudohalides are given. Solutions of Ag^+, Tl^+ and Hg_2^{2+} were used as titrants, to which the membrane is responsive. The fast response to Ag^+ ions allowed the determination of iodide by automatic recording of the potentiometric curve (or its derivative).

Zusammenfassung—Mit der Membranelektrode aus PVC + Trikresylphosphat erhaltene Ergebnisse potentiometrischer Fällungstitrationen einiger Halogenide und Pseudohalogenide werden mitgeteilt. Lösungen von Ag^+, Tl^+ und Hg_2^{2+} wurden als Titranten verwendet; auf diese spricht die Membran an. Das schnelle Ansprechen auf Ag^+-Ionen erlaubte die Bestimmung von Jodid durch automatische Aufzeichnung der potentiometrischen Kurve (oder ihrer Ableitung).

Résumé—On donne les résultats obtenus par l'emploi de l'électrode membrane PVC + phosphate de tricrésyle dans le titrage potentiométrique par précipitation de quelques halogénures et pseudo-halogénures. Des solutions de Ag^+, Tl^+ et Hg_2^{2+} auxquelles la membrane répond ont été utilisées comme agents de titrage. La réponse rapide aux ions Ag^+ a permis le dosage de l'iodure par enregistrement automatique de la courbe potentiométrique (ou de sa dérivée).

Use of membranes for equivalence point indication—VIII*
Electrochemical characterization of $BaSO_4$-parchment membrane-electrode

(*Received* 24 *June* 1971. *Accepted* 27 *November*)

THE ELECTROCHEMICAL characterization of ion-selective membrane-electrodes presumes the establishment of the factors which affect the electrode function, the selectivity, and the speed of response of the electrode.[1]

We have measured the electrode potential, speed of response, and impedance, under different experimental conditions, in order to obtain more thorough knowledge of the H^+-selective $BaSO_4$-parchment membrane-electrode.[2-4]

EXPERIMENTAL

The electrode function

The apparatus is shown in Fig. 1. The cell (with transport) can be represented by

(+) SCE	satd. KCl bridge	internal soln. 0·05*N* $Ba(OH)_2$	membrane	external soln. H_2SO_4, *xN*	satd. KCl bridge	SCE (−)	(1)

The pH-dependence of the membrane-electrode potential at 25 ± 0·1° was established by measuring the e.m.f. of cell (1) by means of an electronic potentiometer while the solution was being stirred. The results obtained, each the mean of 4 measurements with each of two electrodes, are represented in Fig. 2 (curve 1) for 10^{-6}–4*N* sulphuric acid. Membrane potentials were also measured at constant ionic strength ($I = 0{\cdot}075$; Fig. 2, curve 2).

Use of membranes for equivalence point indication—VIII[*] Electrochemical characterization of $BaSO_4$-parchment membrane-electrode

(*Received* 24 *June* 1971. *Accepted* 27 *November*)

THE ELECTROCHEMICAL characterization of ion-selective membrane-electrodes presumes the establishment of the factors which affect the electrode function, the selectivity, and the speed of response of the electrode.[1]

We have measured the electrode potential, speed of response, and impedance, under different experimental conditions, in order to obtain more thorough knowledge of the H^+-selective $BaSO_4$-parchment membrane-electrode.[2-4]

EXPERIMENTAL

The electrode function

The apparatus is shown in Fig. 1. The cell (with transport) can be represented by

(+) SCE	satd. KCl bridge	internal soln. 0·05*N* $Ba(OH)_2$	membrane	external soln. H_2SO_4, xN	satd. KCl bridge	SCE (−)	(1)

The pH-dependence of the membrane-electrode potential at 25 ± 0·1° was established by measuring the e.m.f. of cell (1) by means of an electronic potentiometer while the solution was being stirred. The results obtained, each the mean of 4 measurements with each of two electrodes, are represented in Fig. 2 (curve 1) for 10^{-6}–4*N* sulphuric acid. Membrane potentials were also measured at constant ionic strength ($I = 0{\cdot}075$; Fig. 2, curve 2).

---

3—external solution; 4—membrane; 5—magnetic stirrer.

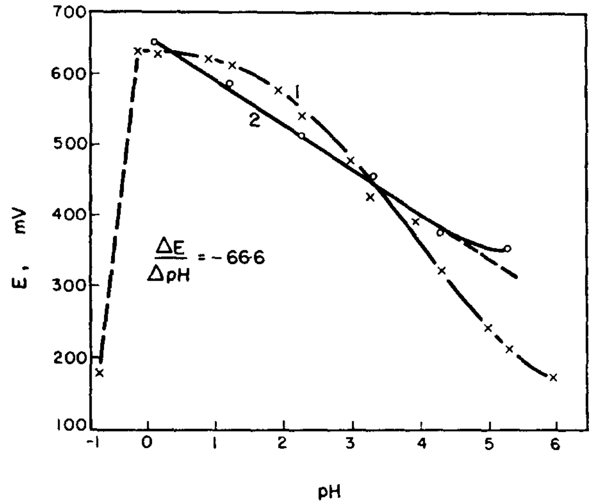

FIG. 2.—The electrode function E vs. pH.
1—Variable ionic strength.
2—Constant ionic strength (0·1).

Selectivity of the electrode

The ionic strength of the external solution was adjusted with sodium sulphate. It was therefore necessary to determine the influence of sodium ions on the electrode, by measuring the e.m.f. of the following cell (with transport):

(+) SCE	satd. KCl bridge	internal soln. 0·05N $Ba(OH)_2$	membrane	external soln. 0·05N H_2SO_4 xN Na_2SO_4	satd. KCl bridge	SCE (−)	(2)

Sodium sulphate solution (10^{-6}–$10^{-1}N$) had no effect on the electrode potential at 25°.

The temperature coefficient

The electrode functions best if the concentrations of the external and internal solutions are equal.[2-4] Therefore measurements of electrode potential as a function of temperature were made with 0·05*N* sulphuric acid as external solution and 0·05*N* barium hydroxide as internal solution. Results (mean values as above) are presented in Fig. 3.

Speed of response

A recording electronic potentiometer with small response inertia (Radelkis OH-102) was used to record the potential change when the electrode was immersed in a stirred 0·05*N* sulphuric acid solution at 25 ± 0·1°. The electrode (internal solution: 0·05*N* barium hydroxide) was equilibrated beforehand in sulphuric acid of concentrations 10^{-3}, 5×10^{-4}, 10^{-4}, 5×10^{-5}, 10^{-5}, 5×10^{-6} and $10^{-6}N$. In Fig. 4 a typical *E vs. t* curve is presented (curve 1), together with its linearization in co-ordinates $\log(E_\infty - E_t)$ *vs.* $\sqrt{t}$ (curve 2).

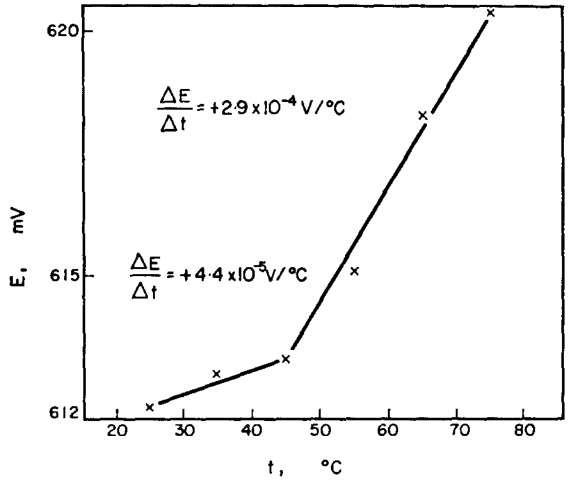

FIG. 3.—The temperature-dependence of the electrode potential.

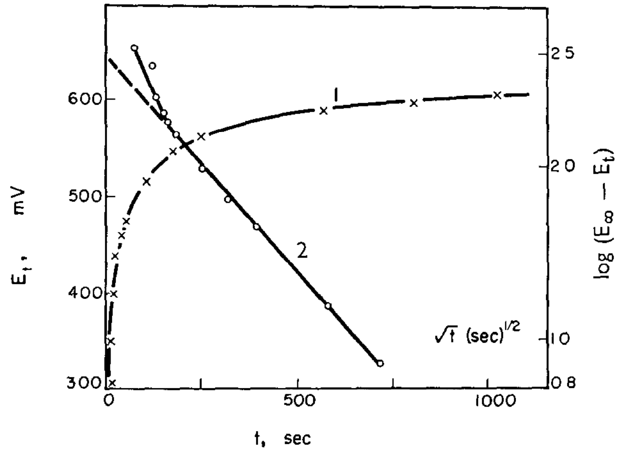

FIG. 4.—The time-dependence of the electrode potential.
1—*E vs. t.*
2—Linearization of the *E vs. t* function.

TABLE I.—MEAN SLOPE (k) OF LINEARIZED POTENTIAL *vs.* TIME CURVES.

	$(k \pm ts_k) \times 100$,*			
Concentration step $[H_2SO_4]$, N	25°C	45°C	65°C	$Ba(OH)_2$ 0·1N
$10^{-3} \rightarrow 5 \times 10^{-2}$	4·9 ± 0·9	5·8 ± 0·8	11·9 ± 0·2	6·9 ± 0·1
$5 \times 10^{-4} \rightarrow 5 \times 10^{-2}$	5·5 ± 0·3			
$10^{-4} \rightarrow 5 \times 10^{-2}$	4·7 ± 0·5			
$5 \times 10^{-5} \rightarrow 5 \times 10^{-2}$	5·6 ± 0·2			
$10^{-5} \rightarrow 5 \times 10^{-2}$	6·5 ± 1·3			
$5 \times 10^{-6} \rightarrow 5 \times 10^{-2}$	6·7 ± 0·2			
$10^{-6} \rightarrow 5 \times 10^{-2}$	6·9 ± 0·6			

* Three degrees of freedom confidence limit $\alpha = 0{\cdot}95$ (Student's $t = 3{\cdot}18$); s_k = standard deviation.

Table I gives the mean of 4 measurements, (2 with each of 2 electrodes) of speed of response of the electrode, in terms of the slope of the linearized E *vs.* t curves ($t > 30$ sec). The speed of response was also measured with the sulphuric acid heated to 45° and 65°, and for 0·1N barium hydroxide as the internal solution.

Impedance of the electrode

The membrane-electrode was connected in the assembly shown in Fig. 5. The signal generator (Tesla BM 314) gave a sinusoidal signal with amplitude 1·5 V. By means of the ellipse method with an oscillograph (Orion EMG Type/15380), the impedance and the phase-displacement angle were determined as a function of frequency. Figure 6 shows the results for impedance (curve 1) and for phase-displacement angle (curve 2).

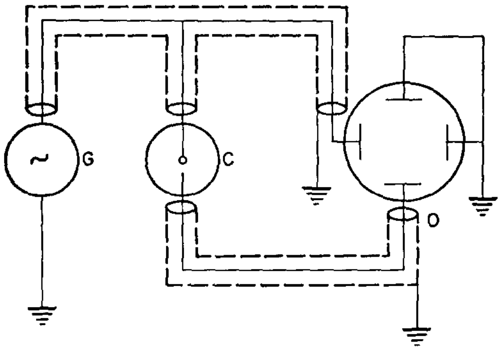

FIG. 5.—The experimental device for impedance measurements.
G, signal generator (TESLA BM-344).
C, measuring cell.
O, oscillograph (ORION EMG-1538/C).

The impedance of the electrode has been resolved into the capacitive (Z_c) and the reactive (Z_R) components.[5-7] Reciprocal variation of these components is shown in Fig. 7.

DISCUSSION

Electrode function

The parchment membrane-electrode, impregnated with barium sulphate, is well known to be a proton-selective electrode.[2,3] The slope of the E *vs.* pH plot has been evaluated as 65 mV at 25°, by titration of sulphuric acid with sodium hydroxide. This meant recording the electrode function at constant ionic strength. This explains the behaviour of the electrode as shown in Fig. 2. In curve 2, the slope reaches 66·6 mV per pH unit, in good agreement with the earlier result.

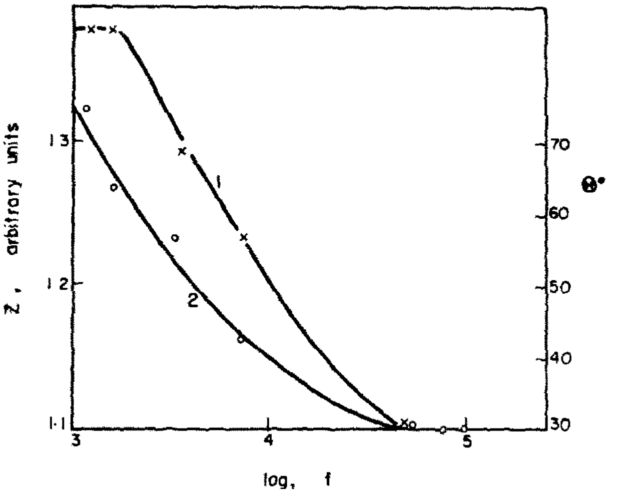

Fig. 6.—The dependence on log f, of (1) the impedance Z, (2) the phase-displacement angle θ.

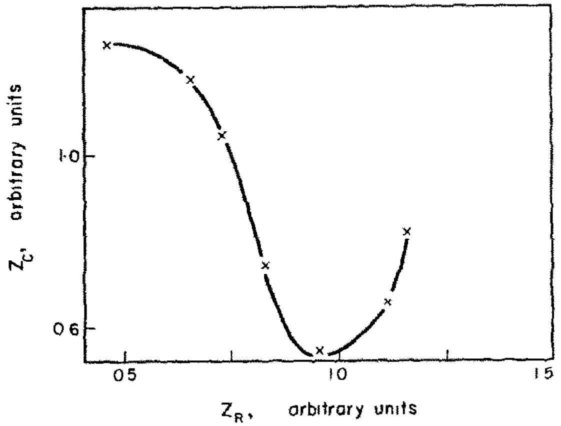

Fig. 7.—Relationship between Z_c and Z_R.

Selectivity of the electrode

It was found that the improvement in the behaviour of the electrode when it is operated at constant ionic strength is not the result of interference by sodium ions, so the electrode works on the basis of selective diffusion. The more dense the ion layer adsorbed on the barium sulphate surface, the more selective the electrode. This is the explanation for the increasing slope ($\Delta E/\Delta pH$) observed in curve 1 of Fig. 2.

The behaviour of the electrode at high temperatures offers further evidence in support of this hypothesis. Thus, at not too high temperatures the electrode has a temperature coefficient (88 $\mu V/K$) that is lower than the Nernstian value. Above a certain temperature (45°) diffusion ceases to be selective, and the temperature coefficient changes its value.

Speed of response

The process of reaching the equilibrium potential is generally slow. It proceeds in two stages: the first, electrical in nature, is rapid, and the second is slower and diffusional in nature, which is proved by the shape of the equation describing the E *vs.* t curve:

$$E_\infty - E_t = \text{const.}\, e^{-k\sqrt{t}} \qquad (3)$$

The facts that k is independent of the concentration of the pre-equilibrating solution, and that it increases in value with increasing temperature of the external solution and with increasing concentration of the internal solution support this explanation.

Impedance of the electrode

Though the experimental results are incomplete (the sensitivity of the apparatus is too low to allow exploration of the whole frequency range), it can be deduced, by analogy with glass electrodes, that presumably there is a layer on the surface of the parchment electrode that is different from the inside of the membrane. This is probably formed of barium sulphate on which sulphate ions are adsorbed. The existence of this layer is consistent with results on investigations on the formation of the electrode,[8–10] as well as with silver ions.[11]

It can be stated with certainty that the H^+-selective membrane-electrode made of parchment impregnated with barium sulphate works on the basis of a selective diffusion process.

CANDIN LITEANU
IONEL CATALIN POPESCU

Summary—Some new aspects of the electrochemical characterization of the $BaSO_4$-parchment membrane-electrode are discussed. The electrode function E *vs.* pH is strongly affected by the ionic strength of the external solution. The electrode is mainly selective for hydrogen, and without interference from sodium ions. The basis of operation of the electrode is selective diffusion. This conclusion is supported by the temperature coefficient, the response rate, and the impedance measurements.

Zusammenfassung—Einige neue Aspekte der elektrochemischen Charakterisierung der Membranelektrode aus $BaSO_4$ und Pergament werden diskutiert. Die Elektrodenfunktion E(pH) wird durch die Ionenstärke der Außenlösung stark beeinflußt. Die Elektrode ist im wesentlichen selektiv für Wasserstoff und wird durch Natriumionen nicht gestört. Die Wirksamkeit der Elektrode beruht auf selektiver Diffusion. Dieser Schluß wird durch den Temperaturkoeffizienten, die Ansprechgeschwindigkeit und durch Impedanzmessungen gestützt.

Résumé—On discute de quelques nouveaux aspects de la caractérisation électrochimique de l'électrode-membrane $BaSO_4$-parchemin. La fonction d'électrode E par rapport au pH est fortement affectée par la force ionique de la solution externe. L'électrode est principalement sélective pour l'hydrogène, et sans interférence des ions sodium. La base de fonctionnement de l'électrode est la diffusion sélective. Cette conclusion est étayée par les mesures de coefficient de température, de la vitesse de réponse et de l'impédance.

Conductometric titration with indicating resistance—III* Mechanism of the PVC + Alassion CS (Cationite R-H) + dioctyl phthalate (plasticizer) membrane as indicating resistance

(*Received* 14 *June* 1971. *Accepted* 5 *January* 1972)

THE END-POINT of conductometric acid–base titrations can be detected even when a highly conducting medium is used, if they are done in the presence of an indicating membrane.[1,2] In the presence of an ion-exchange membrane, the equivalence point is marked by a sudden decrease in the conductivity of the solution.

A previous paper[1] discussed the titration of hydrochloric acid in the presence of the membrane obtained by the plasticization of a mixture of PVC + Alassion CS + dioctyl phthalate at 140°. The present paper discusses the mechanism by which a similar membrane (PVC + Alassion CS + dioctyl phthalate, 2:1:4, plasticized at 175°) functions.

EXPERIMENTAL

The preparation of the membrane and the conductivity cell were described earlier.[2] Conductivities were measured with a Radelkis instrument with 300 and 80 Hz alternating current.

Hydrochloric acid (10^{-1}, 10^{-2}, 10^{-3} and $10^{-4}M$) in sodium chloride $5M$ was titrated with sodium hydroxide solutions ten times as concentrated as the acid, under equilibrium conditions (Fig. 1).

Recording the results under equilibrium conditions allows detection of the conductivity drop when a small excess of alkali is added. The time needed for the conductivity to become steady in the vicinity of the equivalence point and on first contact of the membrane with the acid solution to be analysed, varies between 30 min and 2 hr. The reversible exchange reaction

$$\text{R-H} + \text{Na}^+ \rightleftharpoons \text{RNa} + \text{H}^+ \qquad (1)$$

is shifted to the right at the equivalence point, and to the left initially. At other stages of the titration, the time necessary to establish equilibrium is 3–10 min. Before and after the equivalence point, the conductivity varies little. The general appearance of the curve is that of potentiometric curves, in contrast with the curves obtained in non-equilibrium conditions.[1]

Very low concentrations of acid may de determined, down to $10^{-4}N$. This concentration reduces the shift of the exchange equilibrium to the R-H form, giving a resistance change of only 50 Ω at the equivalence point. This change cannot be recorded in the case of a membrane with high resistance (2130 Ω, Fig. 1, curve *a*) but it can be if the membrane has a sufficiently low resistance, between 400 and 1300 Ω (1290 Ω, curve *b*, and 430 Ω, curve *c*). For acid concentrations higher than $10^{-3}N$ at the beginning of the titration, the exchange equilibrium is shifted further to the left, and thus the effect of the shift to the R-Na form is a change of about 600 Ω in resistance at the equivalence point and this variation can easily be measured whatever the resistance of the membrane (1140 Ω, curve *d*; 780 Ω, curve *e*; 578 Ω, curve *f*).

The conductivity of the membrane increases with the number of determinations (Fig. 2), the value also increasing inversely with the pH of the solutions. Solutions with initial pH between 3 and 4 give a membrane conductivity close of that obtained in neutral solutions. For acid solutions with initial pH below 3, the jump registered at the equivalence point of the titration represents a combination of two jumps, one occurring at pH 5–7 and the other at pH 9–11. The presence of the two jumps explains the non-superposition of curves *b* and *c* in Fig. 2.

The conductivity of $0{\cdot}01M$ hydrochloric acid in $5M$ sodium chloride is 21·45 $\Omega^{-1}.\text{m}^{-1}$. Introduction of a membrane between the electrodes decreases the conductivity. The decrease is not very large if the membrane is made without plasticizer, (*i.e.* only of PVC + Alassion CS, and obtained by dissolution of the polymer in tetrachlorethane), the conductivity then being 17·4 $\Omega^{-1}.\text{m}^{-1}$. For the same membrane thermally treated at 175°, the conductivity decreases to 13·1 $\Omega^{-1}.\text{m}^{-1}$. These conductivities

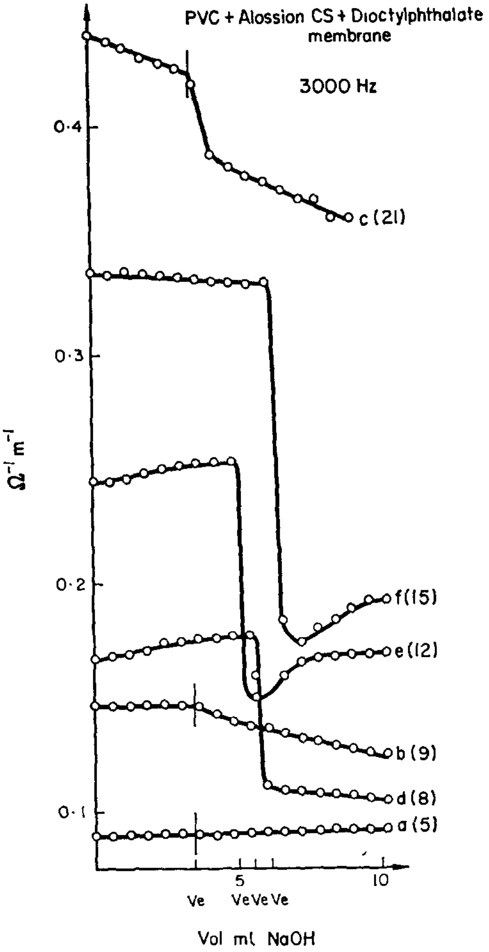

Fig. 1.—Curves *a*, *b*, *c*—titration of $10^{-4}M$ HCl + $5M$ NaCl with $10^{-3}N$ NaOH; *d*—titration of $10^{-3}M$ HCl + $5M$ NaCl with $10^{-2}M$ NaOH; *e*—titration of $10^{-2}M$ HCl + $5M$ NaCl with $10^{-1}M$ NaOH; *f*—titration of $10^{-1}M$ HCl + $5M$ NaCl with $1M$ NaOH. The figure in brackets gives the serial number of the determination in a set with the same membrane.

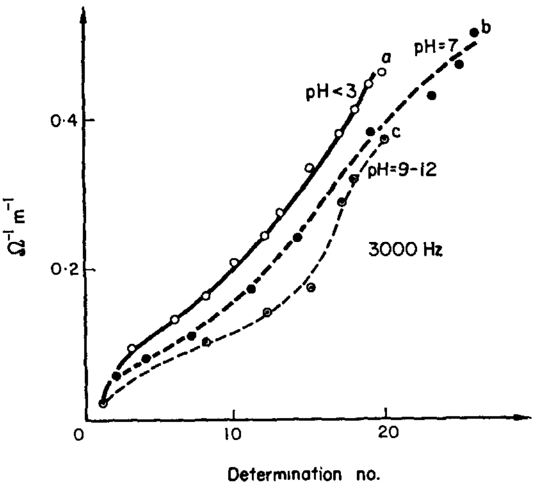

Fig. 2.—Variation of the conductivity of PVC + Alassion CS + dioctyl phthalate membrane with the number of determinations.

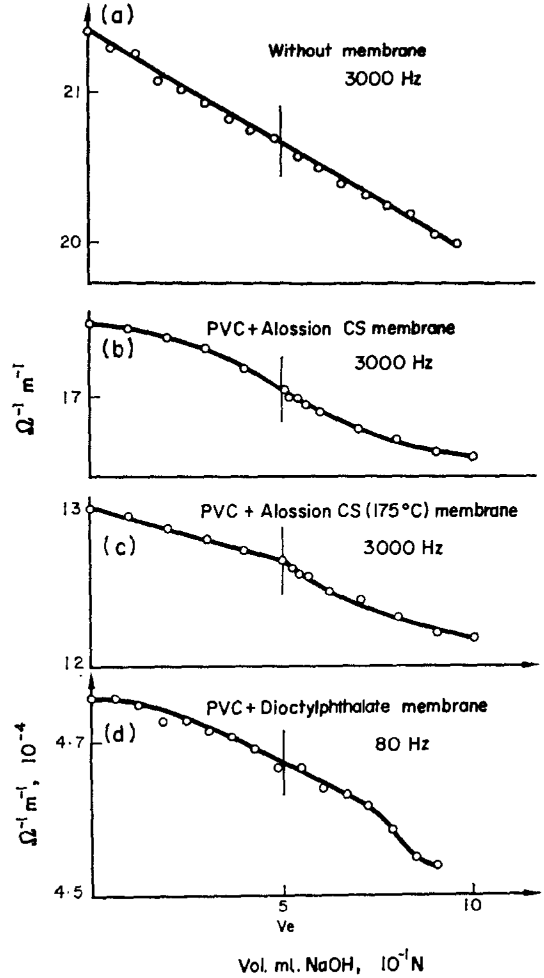

FIG. 3.—Conductometric titration curves of $10^{-2}M$ HCl + $5M$ NaCl with $10^{-1}M$ NaOH. Curve *a* without membrane; *b*, *c*, *d* with various membranes.

were measured under equilibrium conditions and do not vary with the number of determinations. A membrane without cation-exchanger, obtained from PVC + dioctyl phthalate, plasticized at 175°, diminishes the conductivity of the system by a factor of 10^4. The membrane PVC + Alassion CS + dioctyl phthalate decreases the conductivity a great deal (0·023 $\Omega^{-1}.m^{-1}$ in the first determination) and, as mentioned above, the conductivity increases with the number of determinations. When the conductivity of the membrane has increased to the optimum (determinations 5–20), it is about 1/100 that of the solution.

The transport of electricity in the membrane is performed by the exchange ions, which are held back to an extent determined by the exchange group, leading to a larger or smaller conductivity. Alassion CS is a strongly acidic cation-exchanger with sulphonic acid groups. In the case of a membrane formed only of PVC + Alassion CS, the exchange R-H + $Na^+ \rightleftharpoons$ R-Na + H^+ occurs also in the acid pH range. In such a membrane, after repeated treatment with $5M$ sodium chloride, the amount of H^+ unexchanged leads to an increase of the resistance by only 0·2 Ω when the membrane is in contact with alkali, whereas in the case of a solution with a 1 : 50 ratio of $[H^+]:[Na]$, the increase is 1·5–2 Ω. This change in conductivity at the equivalence point in the presence of alkali is insufficient for the membrane to be used as an indicating device, as shown by the appearance of a simple inflexion on the titration curve (Fig. 3, curves *b* and *c*). The PVC + dioctyl phthalate membrane has a particularly large resistance and an exchange of H^+ ions for Na^+ (decrease in conductivity) is observed only

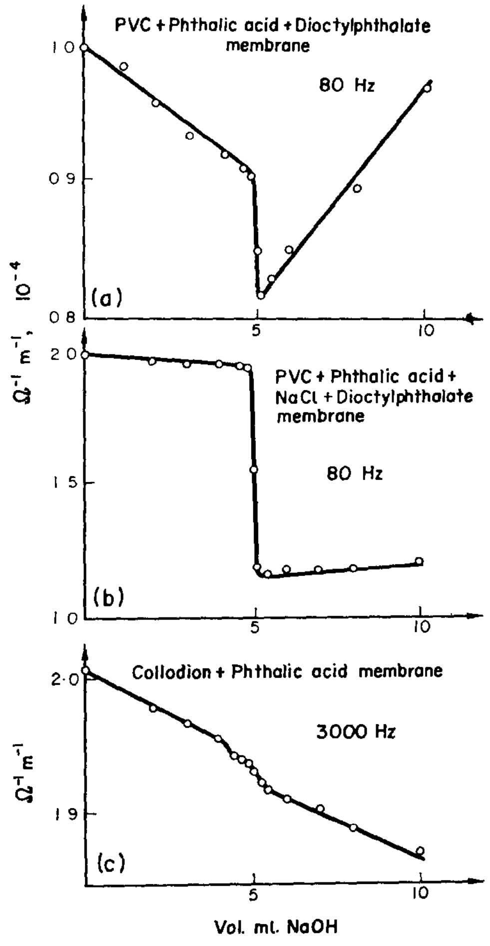

FIG. 4.—Conductometric titration curves of $10^{-2}M$ HCl + $5M$ NaCl with $10^{-1}M$ NaOH with different membranes containing phthalic acid.

at a very alkaline pH (Fig. 3, curve *d*). For these reasons the membrane formed only of PVC + plasticizer cannot be used as an indicator in acid-base titrations.

The indicator properties of the PVC + Alassion CS + dioctyl phthalate membrane (plasticized at 175°) can be explained by the existence of two types of protonated species in the membrane, with different dissociation constants, which give exchange of H^+ for Na^+ in two pH regions (5–7 and 9–11). These species arise as follows: at the membrane formation temperature (175°), dioctyl phthalate reacts with the sulphonic acid group of the ion-exchanger, forming octyl sulphonate and phthalic acid. The latter has two carboxylic groups with dissociation constants $K_1 = 1{\cdot}3 \times 10^{-3}$ and $K_2 = 3{\cdot}9 \times 10^{-6}$. The presence of phthalic acid in the membrane was proved on the basis of its optical properties, and the reaction of Alassion CS with dioctyl phthalate at the same temperature. A newly prepared membrane contains non-crystalline phthalic acid, since crystallization takes some time. The presence of phthalic acid right from the preparation of the membrane means that a conductivity jump will occur at the equivalence point, even in the first titrations. Esterification of the sulphonic acid grouping explains the low conductivity of the membrane immediately after its preparation. Slow hydrolysis of the sulphonate ester (*i.e.*, with repeated determinations) increases the number of ionogenic groups and hence the conductivity of the membrane. At the equivalence point both carboxylic groups of the phthalic acid can give ion-exchange, the first at pH 5–7, the second at pH 9–11, thus increasing the effect as the pH rises. As the number of determinations increases, some phthalic acid is dissolved out and the conductivity jump at the equivalence point decreases considerably. That is why, although the resistance of the membrane falls below 500 Ω, it cannot be used further for this purpose.

The role of the phthalic acid was deduced from experiments in which a homogeneous PVC + phthalic acid + dioctyl phthalate (3:1:4) membrane (plasticized at 175°) was used in the titration of 0·01*M* hydrochloric acid in 5*M* sodium chloride with 0·1*M* sodium hydroxide (Fig. 4, curve *a*). This membrane has a particularly high resistance. Introduction of sodium chloride (PVC + NaCl + phthalic acid + dioctyl phthalate: 4:1:1:8) diminishes its resistance a little, but the titration curve obtained is identical with that of the Alassion CS membrane (Fig. 4, curve *b*).

A membrane made of phthalic acid in collodion has a high conductivity, but is a poor indicator because of its heterogeneity. In such a membrane only a small part of the phthalic acid takes part in an exchange reaction, *viz.* that part dissolved by the ether of the collodion solution and recrystallized. The undissolved phthalic acid granules react only on the surface. The titration curve with a collodion + phthalic acid membrane indicates both the exchange steps of phthalic acid, though only by small conductivity changes (Fig. 4, curve *c*).

Summary—The problem of conductometric acid–base titration in a highly-conducting medium (5*M* sodium chloride) has been solved by introducing a PVC + Alassion CS + dioctyl phthalate membrane between the two electrodes. The equivalence point is marked by a sudden decrease in conductivity. The membrane (obtained by plasticization at 175°) functions through the phthalic acid dissolved in the PVC membrane, this acid being formed by decomposition of the dioctyl phthalate by the sulphonic acid groups of the cation-exchanger. In this process the sulphonic acid groups are esterified, but hydrolyse on being treated for 2–3 hr with NaOH, and then increase the conductivity in the membrane.

Zusammenfassung—Das Problem der konduktometrischen Säure-Basen-Titration in einem gut leitenden Medium (5 M Natriumchlorid) wurde dadurch gelöst, daß eine Membran aus PVC + Alassion CS + Dioctylphthalat zwischen die Elektroden gesetzt wird. Der Äquivalenzpunkt macht sich durch einen plötzlichen Abfall in der Leitfähigkeit bemerkbar. Die durch Verpressen bei 175° hergestellte Membran ermöglicht diesen Effekt durch die im PVC gelöste Phthalsäure, die durch die Zersetzung des Dioctylphthalats an den Sulfonsäuregruppen des Kationenaustauschers entsteht. Bei diesem Prozeß werden die Sulfonsäuregruppen verestert; sie hydrolysieren jedoch bei 2–3-stündiger Behandlung mit NaOH. Dann erhöhen sie die Leitfähigkeit in der Membran.

Résumé—Le problème du titrage conductimétrique acide-base dans un milieu hautement conducteur (chlorure de sodium 5*M*) a été résolu en introduisant une membrane PVC + Alassion CS + phtalate de dioctyle entre les deux électrodes. Le point d'équivalence est marqué par un décroissement brusque en conductivité. La membrane (obtenue par plastification à 175°) fonctionne par l'intermédiaire de l'acide phtalique dissous dans la membrane en PVC, cet acide étant formé par la décomposition du phtalate de dioctyle par les groupes acide sulfonique de l'échangeur de cations. Dans ce processus les groupes acide sulfonique sont estérifiés, mais s'hydrolysent par traitement de 2–3 h par NaOH, accroissant la conductivité dans la membrane.

Characterization of ceramic ion-selective membrane-electrodes—I
The Ag_2S electrode

(*Received* 9 *June* 1971. *Accepted* 27 *November* 1971)

SILVER SULPHIDE has been used for making homogeneous or heterogeneous silver-selective membrane-electrodes, the former by heating a mixture of silver halides and silver sulphide[1] or from single crystals of the sulphide[2–5] and the latter by using an inert material to bind the silver sulphide.[6–7]

The performance of heterogenous ion-selective membrane-electrodes (ISME) has been shown to be inferior to that of homogeneous ISME if silver sulphide is used as the electrochemically active material.[8] We have therefore tried to produce an easily fabricated homogeneous Ag^+-selective membrane-electrode.[9] In this paper the behaviour of a ceramic silver sulphide membrane as an Ag^+-selective electrode is described.

EXPERIMENTAL

Electrode

To one end of a "plexiglass" tube a ceramic Ag_2S disc was attached (Fig. 1). As inner solution, $0{\cdot}1M$ silver nitrate was used. The electrode potential was evaluated by means of the cell

(−) S.C.E.	$0{\cdot}1M$ KNO_3 agar-agar bridge	Internal solution $0{\cdot}1M$ $AgNO_3$	Membrane	External solution (test)	$0{\cdot}1M$ KNO_3 agar-agar bridge	S.C.E. (+)	(1)

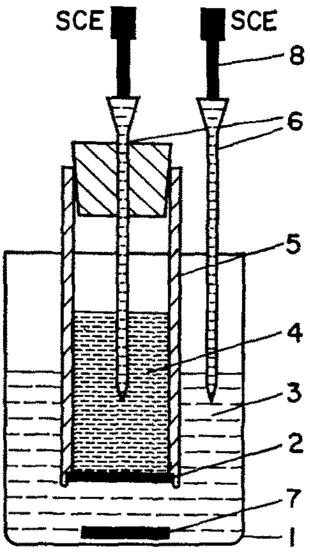

FIG. 1.—Schematic diagram of the working cell. 1—cell; 2—membrane; 3—external solution; 4—internal solution; 5—electrode body; 6—KNO_3 agar-agar bridge; 7—magnetic stirrer; 8—saturated calomel electrode.

Electrode response

Silver ions. With the ISME immersed in aqueous solutions (10^{-6}–$2M$) of silver nitrate, the electrode response was recorded with and without stirring. The electrode response is linear, but the slope is lower than the Nernstian value (64·6 mV with stirring, 50 mV without). These experiments were repeated at constant ionic strength (0·1*M*) maintained by addition of potassium nitrate. The slope is then within 2% of being Nernstian (58·2 mV). The activity response curve is parallel, but shifted on account of the activity coefficient of silver ions (the value[10] used was 0·61).

Mercury(II) ions. Since it is known that mercury(II) interferes seriously when this electrode is used, the ISME was tested for response to mercury(II), by similar methods. The response curve (for an ionic strength of 0·1*M*) is linear with Nernstian slope (30 mV). The activity response is parallel, the shift depending on the activity coefficient of mercury(II) (the value[10] 0·14 was used).

Selectivity

Mercury(II). To determine the selectivity constant of the electrode for Hg^{2+}, a variant of Rechnitz's method[11] was used. From the equations:

$$E_1 = E^\circ + 0{\cdot}0582 \log a_{Ag^+} \tag{2}$$

$$E' = E^\circ + 0{\cdot}0582 \log (a_{Ag^+} + K_{Ag^+,Hg^{2+}} . a^{1/2}_{Hg^{2+}}) \tag{3}$$

where $K_{Ag^+,Hg^{2+}}$ is the selectivity coefficient, we obtain

$$10^{(E'-E_1)/0{\cdot}0582} = 1 + K_{Ag^+,Hg^{2+}} . \frac{a^{1/2}_{Hg^{2+}}}{a_{Ag^+}} \tag{4}$$

When a_{Ag^+} and the ionic strength are kept constant, from a plot of $10^{(E'-E_1)/0{\cdot}0582}$ *vs.* $c^{1/2}_{Hg^{2+}}$ the selectivity coefficient can be obtained, if the individual activity coefficients of Hg^{2+} and Ag^+ are known. Results for a $5 \times 10^{-5}M$ Ag^+ solution titrates with a $10^{-2}M$ solution of Hg^{2+} which contains $5 \times 10^{-5}M$ Ag^+, at $I = 0{\cdot}1M$, are presented in Fig. 2.

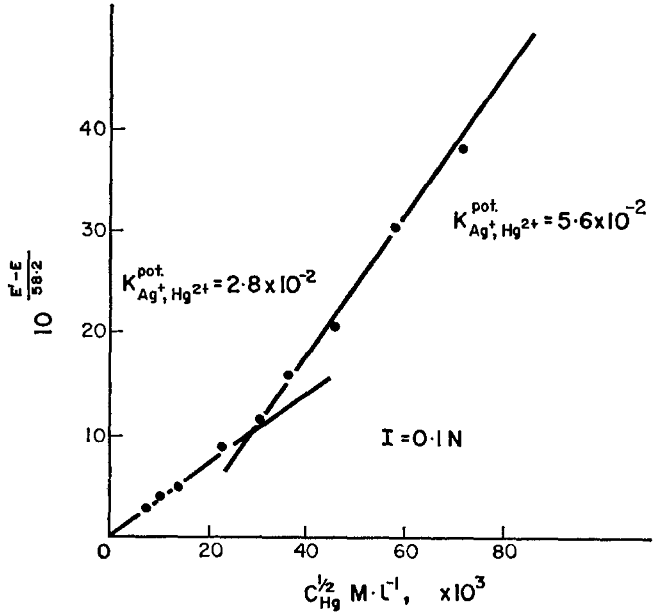

FIG. 2.—Plot of $10^{(E'-E_1)/58{\cdot}2}$ *vs.* $c^{1/2}_{Hg^{2+}}$ for $5 \times 10^{-5}M$ $AgNO_3$ with various additions of $10^{-2}M$ $Hg(NO_3)_2$ + $5 \times 10^{-5}M$ $AgNO_3$.

Copper(II). A faster but less accurate method[12] consists of electrode potential measurements in two solutions, of Ag^+ and of Cu^2, respectively, of the same activity. It follows from equation (3) that for $a_{Ag^+} = 0$,

$$E_2 = E^\circ + 0{\cdot}0582 \log K_{Ag^+;Cu^{2+}} . a^{1/2}_{Cu^{2+}} \tag{5}$$

By combining equations (2) and (5), we obtain

$$\log K_{\mathrm{Ag^+,Cu^{2+}}} = \frac{E_2 - E_1}{0{\cdot}0582} \tag{6}$$

Results of determinations for $c_{\mathrm{Ag^+}} = 0{\cdot}1M \equiv c_{\mathrm{Cu^{2+}}}$ gave $K_{\mathrm{Ag^+,Cu^{2+}}} = 10^{-5}$.

Hydrogen ions. Hydrogen ions must affect the electrode potential through acid-base equilibria in which the sulphide ion is involved. The electrode could indeed be used as an indicating electrode in acid-base titrations. Determination of the selectivity coefficient by the Rechnitz method[11] gave $K_{\mathrm{Ag^+,H^+}} = 10^{-5}$.

Reproducibility

Reproducibility of potential measurements was tested for 10^{-1}, 10^{-3} and $10^{-5}M$ silver (ionic strength $0{\cdot}1M$). The results were practically identical for 20 measurements in each case. The variation of the electrode potential does not exceed 1–2 mV over a period of 24 hr.

Applications

The electrode may be used with good results in the titration of silver with $\mathrm{Cl^-}$, $\mathrm{SCN^-}$, $\mathrm{Br^-}$ and $\mathrm{I^-}$ The potential jump at the equivalence point exceeds 200 mV for $\mathrm{Cl^-}$ and reaches 600 mV for $\mathrm{I^-}$. Titrations of mercury(II) with $\mathrm{Cl^-}$, $\mathrm{SCN^-}$, $\mathrm{Br^-}$ and $\mathrm{I^-}$ also give good results. The potential jump is particularly large (700–800 mV) in the titration of $\mathrm{Hg^{2+}}$ or $\mathrm{Ag^+}$ with $\mathrm{SH^-}$.

DISCUSSION

The membrane gives an electrode response closer to the theoretical for $\mathrm{Ag^+}$ and $\mathrm{Hg^{2+}}$, if the ionic strength is kept constant at a value equal to that of the salt bridges used, and this shows that the non-Nernstian response at variable ionic strength is due to the contribution of the diffusion potential, at the interfaces, to the e.m.f. of the cell. The influence of stirring also supports this view. The electrode is primarly $\mathrm{Ag^+}$-selective, with strong interference by $\mathrm{Hg^{2+}}$. Interference by other cations may be due either to precipitation of a sulphide more sparingly soluble than $\mathrm{Ag_2S}$, on the surface of the electrode, or to decomposition of the $\mathrm{Ag_2S}$ by sequestration of $\mathrm{Ag^+}$ or of $\mathrm{S^{2-}}$. Interference by precipitation has been detected in the case of $\mathrm{Hg^{2+}}$ and $\mathrm{Cu^{2+}}$. The response to hydrogen ions can be considered as the second type of interference. If the potential *vs.* pH relationship for this electrode in an acid–base titration is considered, the slope is about 25 mV per pH unit, confirming the assumption[4] that hydrogen ions interfere by protonating the sulphide ion.

Summary—The behaviour of a new type of electrode, made from ceramic $\mathrm{Ag_2S}$, has been investigated. The electrode response is Nernstian for $\mathrm{Ag^+}$ over the range 10^{-6}–$2M$ and for $\mathrm{Hg^{2+}}$ in the concentration range 10^{-6}–$10^{-2}M$, both at constant ionic strength (0.1M). The electrode is $\mathrm{Ag^+}$-selective, with maximum interference from $\mathrm{Hg^{2+}}$. It can be used for acid–base potentiometric titration and for potentiometric $\mathrm{Ag^+}$ and $\mathrm{Hg^{2+}}$ precipitation titrations.

Zusammenfassung—Das Verhalten eines neuen Elektrodentyps aus keramischem $\mathrm{Ag_2S}$ wurde untersucht. Das Verhalten der Elektrode entspricht mit $\mathrm{Ag^+}$ im Bereich 10^{-6}–$2M$ der Nernstschen Gleichung und mit $\mathrm{Hg^{2+}}$ bei 10^{-6}–$10^{-2}M$, jeweils bei konstanter Ionenstärke (0,1M). Die Elektrode ist selektive für $\mathrm{Ag^+}$ und wird am stärksten durch $\mathrm{Hg^{2+}}$ gestört. Sie kann zur potentiometrischen Säure-Basen-Titration und zu potentiometrischen Fällungstitrationen von $\mathrm{Ag^+}$ und $\mathrm{Hg^{2+}}$ verwendet werden.

Résumé—On a étudié le comportement d'un nouveau type d'électrode, fait de $\mathrm{Ag_2S}$ céramique. La réponse de l'électrode est Nernstienne pour $\mathrm{Ag^+}$ dans le domaine 10^{-6}–$2M$ et pour $\mathrm{Hg^{2+}}$ dans le domaine de concentration 10^{-6}–10^{-2} M, tous deux à force ionique constante (0,1M). L'électrode est sélective pour $\mathrm{Ag^+}$, avec interférence maximale de $\mathrm{Hg^{2+}}$. Elle peut être utilisée pour le titrage potentiométrique acide-base et pour les titrages par précipitation de $\mathrm{Ag^+}$ et $\mathrm{Hg^{2+}}$.

VOLTAMMETRY IN DIMETHYLSULPHOXIDE—A REVIEW

THOMAS R. KOCH* and WILLIAM C. PURDY
Department of Chemistry, University of Maryland, College Park, Md. 20742, U.S.A.

(*Received* 15 *November* 1971. *Accepted* 27 *December* 1971)

Summary—A review is given of voltammetric studies using dimethylsulphoxide as supporting electrolyte, and includes details of inorganic and organic systems studied and of the reference electrodes developed for use in this medium.

IN RECENT YEARS the scope of voltammetry has been expanded by an increase in the number of non-aqueous solvents employed. Dimethylsulphoxide (DMSO) has been of great value in these voltammetric studies owing to its high dielectric constant and absence of ionizable protons. Many investigators have found purification of the solvent to be a necessity, owing to a cathodic wave caused by an impurity. This impurity can be removed by distillation; in addition, distillation over a drying agent helps to ensure a constant, low water level (usually about 0·03–0·05%). Tetra-alkylammonium salts are generally employed as supporting electrolytes to take full advantage of the extended cathodic range of DMSO as compared to water. While a variety of reference electrodes have been used, the most common is an aqueous saturated calomel electrode (SCE), separated from the sample compartment by a salt bridge. Several reference electrodes employing DMSO as a solvent have been described and they will be discussed later.

EARLIER WORK

The first voltammetric studies in DMSO were conducted in 1959 by Gutmann and Schöber.[1] With tetraethylammonium nitrate as supporting electrolyte, they reported a usable voltage range from −0·2 to −2·74 *vs.* SCE. These workers described the frequent occurrence of maxima which, in some cases, were at least partially eliminated by varying the drop-rate. Conventional and derivative polarographic methods were used. Single, well-defined waves were found for the alkali metal ions and for the ammonium ion. The alkaline-earth metal ions were reported to give single, well-defined waves. Silicon tetrachloride exhibited two waves, well-formed and of equal height. Zirconium(IV) and hafnium(IV) gave well-developed waves, each exhibiting a small first-order maximum. Titanium(IV) gave a wave which was ideal in shape; derivative polarography showed three indistinct steps in this reduction, corresponding to

$$\mathrm{Ti(IV)} \rightarrow \mathrm{Ti(III)} \rightarrow \mathrm{Ti(II)} \rightarrow \mathrm{Ti(0)}.$$

Antimony(III) exhibited three waves and niobium(V) one. The half-wave potential values reported by Gutmann and Schöber are included in Table I. These authors carried out no concentration studies. However, by use of a variety of reference

Key to Table I

n = number of electrons transferred in the half-cell
D = diffusion coefficient in 10^6 cm²/sec.
m = slope of a plot of $E_{d,c}$ *vs.* $\log \dfrac{i}{i_d - i}$

I = diffusion-current constant = $i_d/Cm^{2/3}t^{1/6}$
s = i_d/concentration
$x = E_{3/4} - E_{1/4}$.

TEAP = tetraethylammonium perchlorate
Ag/DMSO = Ag/$AgCl_2^-$ reference in DMSO
$TEANO_3$ = tetraethylammonium nitrate

TBAP = tetrabutylammonium perchlorate
SCE = saturated calomel electrode (aqueous)
Hg Pool = mercury pool reference electrode

The figures in brackets after the $E_{1/2}$ values indicate the number of the wave.

ions they determined the diffusion potential between an aqueous SCE and a DMSO test solution.[2]

Iwamoto[3] investigated the electro-oxidation of iodide. Chronopotentiometric studies at a platinum-foil electrode indicated a two-step oxidation.

$$6I^- \rightarrow 2I_3^- + 4e^-$$

$$2I_3^- \rightarrow 3I_2 + 2e^-$$

This is in contrast to the oxidation of iodide ion in water, which proceeds by a single step.

Gutmann *et al.*[4] extended their previous studies to several silicon compounds, including $SiCl_4$, SiF_4, and compounds of the type RCl_3Si. The polarographic waves for the RCl_3Si species in DMSO occurred at approximately the same potential, permitting polarographic analysis for organic silicon.

Kolthoff and Reddy[5] studied the polarographic behavior of several acids and of cobalt and nickel in DMSO. They reported the polarization limits with sodium perchlorate and tetraethylammonium perchlorate supporting electrolytes, using the rotating platinum electrode (RPE), the rotating mercury pool electrode (RMPE), and the dropping mercury electrode (DME). These polarization limits are presented in Table II.

The polarographic characteristics of perchloric acid, sulphuric acid, hydrochloric acid, acetic acid, sodium bisulphate and tetraethylammonium bisulphate are included in Table I. Well-defined and identical current–voltage curves were observed for solutions of perchloric, hydrochloric, and sulphuric acids in $0{\cdot}1M$ sodium perchlorate; the half-wave potential was $-0{\cdot}67 \pm 0{\cdot}02$ V. The basic strength of DMSO is reported to be about the same as that of water. Because these acids gave the same polarographic wave, Kolthoff and Reddy concluded that sulphuric (K_1), perchloric, and hydrochloric acids are completely dissociated in DMSO. Amperometric titrations of dilute strong acid solutions can be carried out in DMSO; the current is measured at an applied potential of $-1{\cdot}00$ V.

Kolthoff and Reddy calculated from polarographic data the diffusion coefficient of the hydrogen ion in DMSO solutions of strong acids and found it to be $4{\cdot}4 \times 10^{-6}$ cm^2/sec at 30°. On the basis of the specific conductance calculated from these data, the proton-diffusion mechanism in DMSO was shown to be different from that in water.

Cobalt(II) and nickel(II) in $0{\cdot}1M$ sodium perchlorate gave sharp maxima, even in very dilute solution; no surface-active substance could be found which would entirely eliminate these maxima. Studies at the RMPE (120 rpm) gave well-defined waves without maxima. A dilute solution of sodium perchlorate in $0{\cdot}1M$ tetraethylammonium perchlorate (TEAP) gave a well-defined, nearly reversible wave for sodium with a half-wave potential of $-2{\cdot}07$ V.

In $0{\cdot}1M$ TEAP, quinhydrone and benzoquinone showed two cathodic waves of unequal height. The first wave was a one-electron reversible reduction, and the second wave was irreversible. When $0{\cdot}01M$ hydrochloric acid, acetic acid, or water was added, the second wave was shifted to more positive potentials until only one wave with a maximum was observed. This wave had a height equal to the sum of the heights of the original waves. Duroquinone gave two waves, the first reversible, the second irreversible. Tetrachloroquinone gave two irreversible waves of equal height. The authors

SCE = saturated calomel electrode (aqueous)
Hg Pool = mercury pool reference electrode

RMPE = rotating mercury pool electrode.
Ag/DMSO = $Ag/AgCl_2^-$ electrode in DMSO
TBA = tetrabutylammonium salt
TEA = tetraethylammonium salt
TMA = tetramethylammonium salt

concluded that the polarographic behavior of quinones in DMSO provided evidence that DMSO is a much weaker acid than water. In relatively acidic solvents such as water or acetic acid, the general reduction mechanism for the two-electron reduction of organic compounds at the DME was reported to be:

$$R + e^- \rightarrow R\cdot^-$$

$$R\cdot^- + HS \rightarrow RH\cdot + S^-$$

$$RH\cdot + e^- \rightarrow RH^-$$

$$RH^- + HS \rightarrow RH_2 + S^-$$

Since the electron affinity of RH· has been shown always to be greater than that of R, the two are reduced at the same potential in a single two-electron reduction wave, such as is observed for quinones in water. In DMSO, as well as in dimethylformamide and acetonitrile (all weakly acidic), the reduction mechanism for quinones was reported to be:

$$R + e^- \rightarrow R\cdot^- \text{ (first wave)}$$

$$R\cdot^- + e^- \rightarrow R^{2-} \text{ (second wave)}$$

R^{2-} diffuses into solution, where:

$$R^{2-} + HS \rightarrow RH^- + S^- \text{ (slow)}$$

$$RH^- + HS \rightarrow RH_2 + S^- \text{ (slow)}$$

A double wave results since $R\cdot^-$ is reduced at a more negative potential than R. The second wave is somewhat smaller, probably because of limited protonation of $R\cdot^-$ or repulsion of $R\cdot^-$ by the negatively-charged mercury drop. When a proton donor is added, it reacts with R^{2-} but not with $R\cdot^-$, and the rate of the reaction

$$R^{2-} + HA \rightarrow RH^- + A^-$$

becomes potential-determining. The second wave, therefore, shifts toward the first, and eventually merges with it.

Oxygen gave two waves in DMSO, although only one drawn-out wave with a maximum was observed in concentrated solutions. Also, only one wave was observed in 0·1*M* sulphuric acid and in a 0·1*M* ammonium acetate and 0·1*M* acetic acid buffer. The polarography of oxygen showed qualitatively the same effects observed with quinones, but more detailed studies were considered necessary. Peover and White[6,7] studied the reduction of oxygen to superoxide ion by a.c. and d.c. polarography. Their results, included in Table I, showed that the reduction is diffusion-controlled, and that the superoxide ion has considerable stability in DMSO. The reduction is reversible. On addition of a strong acid, the process reverts to the normal two-electron reduction.

The preparative-scale reduction of oxygen to superoxide ion was studied by Maricle and Hodgson.[8] Their polarographic work was similar to that of Peover and White. Preparative-scale reductions produced both tetrabutylammonium superoxide and potassium superoxide. The polarographic reduction of oxygen in DMSO that was 0·1*M* in TEAP was studied by Johnson *et al.*[9] As shown in Table I, two waves were obtained; in agreement with other workers, the authors found that the first wave was due to the reduction of oxygen to superoxide ion. The second wave, studied as a function of various cations at varying concentrations, was attributed to the combination of superoxide with one electron plus a cation to give a peroxide product.

Jones and Fritsche[10] used potential-sweep chronoamperometry at a hanging mercury drop electrode to study DMSO as an electrochemical solvent, and reported working ranges for various supporting electrolytes. The behaviour of oxygen differs from that reported by Johnson *et al.*,[9] indicating, as the latter authors mentioned, that the reduction of oxygen in DMSO is very dependent on the nature and concentration of the supporting electrolyte. Cadmium and magnesium were also studied.

In 1962, Burras[11] carried out an extensive study into the polarographic behaviour of a number of common cations in DMSO. The effects of various parameters were also investigated. Burras employed both aqueous saturated calomel and mercury-pool reference electrodes, and used a variety of supporting electrolytes. The potentials of the electrocapillary maxima, and the usable potential ranges, are reported in Table II. The effects of variation of temperature and of supporting electrolyte concentration were studied. Also, the influence of a maximum suppressor and of water on the polarogram of cadmium, and of added chloride on the cadmium and lead polarograms, was investigated. The polarographic data for the various ions studied by Burras are included in Table I.

Gutmann and Schöber[12] studied the polarographic behaviour of various chromium(III)–anion systems. The equilibria of various co-ordination forms of chromium(III) with chloride ion and DMSO were investigated. The co-ordination forms $[Cr(DMSO)_6]^{3+}$, $[CrCl_2(DMSO)_4]^+$, $[CrCl_3(DMSO)_3]$, $[CrCl_4]^-$, $[CrCl_5]^{2-}$, and $[CrCl_6]^{3-}$ were observed. Schöber and Rahak[13] discussed the application, to non-aqueous solutions, of methods used to establish reversibility in aqueous solution. The Cr(III)–Cr(II) redox system in DMSO was investigated for reversibility. Within the limits of error of the experiment, both chromic nitrate and $CrCl_4^-$ were found to be entirely reversibly reduced in this solvent.

Dehn *et al.*[14] studied the polarographic behaviour of aluminium chloride and aluminium acetylacetonate in DMSO. One wave was reported for the former, two for the latter; half-wave potentials are shown in Table I. The authors suggested that since aluminium can be extracted as the acetylacetonate, the polarographic method would be useful as an analytical tool for aluminium.

The lanthanides (as chlorides) were investigated polarographically by Gritzner *et al.*[15] Lanthanum, cerium, praseodymium, neodymium, gadolinium, terbium, dysprosium, holmium, and erbium gave one wave; samarium, europium, and ytterbium gave two waves. All waves were diffusion-controlled and had no maxima.

The polarographic behaviour of uranium compounds in DMSO was studied by Michlmayr *et al.*[16] Uranium tetrachloride shows two waves, the first involving one electron, the other three electrons. Both waves are quite irreversible and the second wave exhibits a maximum. However, both waves were found to be diffusion-controlled. Uranyl compounds exhibit one diffusion-controlled, well-defined wave involving the one-electron reduction to UO_2^+. The effect of added water on the waves was also reported.

Gritzner *et al.*[17] investigated the polarography of thorium salts in DMSO. Thorium tetrachloride gives three waves at a concentrations below millimolar; at higher concentrations, the third wave merges with the most cathodic wave. Thorium tetraperchlorate monohydrate and trihydrate give two waves, whereas thorium tetranitrate pentahydrate and thorium tetranitrate solvated with four DMSO molecules give only one wave.

DMSO solutions of sodium chloride and sodium iodide were subjected to electrolysis at platinum electrodes.[18] The cathode reaction involved initial discharge of sodium ions, after which the sodium metal reacted with the solvent. An anodic reaction was also reported that involved reactions of the iodide and tri-iodide ions.

Gritzner *et al.*[19] found that nitrogen monoxide, dioxide and trioxide, and nitrous oxide could be determined polarographically in DMSO. Lindbeck and Young[20] investigated the polarographic and controlled-potential coulometric determination of the nitric acid oxidation products of soil humic acid. Reduction waves were found which compared closely with the polarographic reduction waves of the nitrobenzoic acids. Although the authors discussed the advantages of the extended potential range of DMSO, their choice of a $0{\cdot}1M$ sodium hydroxide supporting electrolyte precluded the possibility of using it, by limiting the range to about that of water. Lindbeck and Freund[21] studied substituted nitrobenzene compounds in DMSO by polarography and controlled-potential coulometry. The main purpose of their paper was to report n values for the nitrobenzene compounds. Polarography was used only to determine the proper potentials for use in constant-potential coulometry.

Di Giacomo *et al.*[22] reported that phenylfluorone in DMSO gives two waves, as opposed to one in water. The second wave is higher than the first, and can be resolved by linear-sweep polarography into two steps; the more cathodic step shows kinetic characteristics. In the presence of benzoic acid, the two reduction waves are of equal height. A reduction mechanism is proposed.

A number of sulphydryl, disulphide, amine compounds, and sulphur-amino acids were studied polarographically in DMSO by Giang *et al.*[23] The half-wave potentials, n values, and i_d/C values given are shown in Table I. The authors reported that all of the waves were diffusion controlled and irreversible. An excellent review of electrochemistry in DMSO was published in 1967 by Butler.[24] Both polarographic data and reference electrodes were discussed.

REFERENCE ELECTRODES

A reference electrode employing the silver–silver chloride couple in DMSO was constructed by Courtot-Coupez and Le Demezet.[25] The range of electroactivity in DMSO was tested, using a polished platinum electrode in the presence of sodium, potassium, lithium and quaternary ammonium perchlorates. Ranges varied from 4·18 to 4·80 V.

Smyrl[26] determined the standard cell potential of $Pt_{(s)}/Li_{(s)}/LiCl_{(soln)}/TlCl_{(s)}/Tl_{(Hg)},_{(l)}/Pt_{(s)}$ in DMSO. The standard potential for the analogous calcium amalgam electrode was estimated. McMaster and co-workers[27] developed and tested a reference electrode consisting of a saturated solution of $Zn(ClO_4)_2{\cdot}4DMSO$ in contact with a saturated zinc amalgam. By comparing their half-wave potentials with those reported by other workers, the potential of this reference electrode was found to be $-1{\cdot}10$ V *vs.* aqueous SCE. Relative reduction–potential scales for several solvents were established.

A reference electrode employing the Ag/$AgCl_2^-$ couple in DMSO was developed and tested by Courtot-Coupez and Le Demezet.[28] The regions of electroactivity of the platinized platinum, mercury, graphite and silver electrodes were determined, and are listed in Table II. A reference electrode of Ag/AgCl/LiCl in methanol was developed for potentiometric titrations in DMSO.[29] Rallo and Ceccaroni[30] described a reference electrode consisting of cadmium metal in contact with saturated DMSO solutions of $CdCl_2$, $CdCl_2 \cdot H_2O$, or NaCl. The electrode was considered suitable for use in electrochemical studies.

Synnott and Butler[31] developed and tested four chloride reference electrodes in DMSO. The half-cell Tl(Hg)/TlCl in DMSO appeared to be a good reference electrode for use in this solvent.

RECENT STUDIES

Polarographic investigations on DMSO solutions of zirconium and hafnium compounds were carried out by Michlmayr and Gutmann.[32] The half-wave potentials, the nature of the limiting currents, the temperature coefficients of half-wave potentials and wave heights, the reversibility or irreversibility of the electrode processes, and the influence of water were determined. Schmid and Gutmann[33] reported the half-wave potentials in DMSO (*vs.* aqueous SCE) of thallium(I), rubidium, potassium, sodium, barium, zinc, cadmium, manganese(II), cobalt(II), and nickel perchlorates. These potentials were referred to that of bis(biphenyl)chromium(I) iodide. Reduction mechanisms, various analytical aspects of the system, and the effects of water were discussed.

Pyatnitskii and Ruzhanskaya[34] reported half-wave potentials for the 8-hydroxyquinolinates of copper(II), lead, iron(III), cadmium, and bismuth in mixtures of methanol and DMSO, and with eleven other solvents. Lithium chloride was used as the supporting electrolyte. No correlation was found between the half-wave potential and the dielectric constant of the solvent. Kumar and Pantony[35] investigated the polarographic behaviour of a number of anhydrous inorganic perchlorates in DMSO. Gritzner *et al.*[36] applied oscillographic polarography to the study of DMSO solutions of the lanthanides. These results were compared with those of classical polarography. The peak potentials are shown in Table III.

Haynes and Sawyer[37] have employed chronopotentiometry, controlled-potential coulometry, gas chromatography, and pH titrations to investigate the electrochemical reduction of carbon dioxide in DMSO solutions at gold and mercury electrodes. At a gold electrode, irreversible but well-defined chronopotentiograms were observed; the reduction is a one-electron process and is diffusion-controlled. The diffusion-controlled reduction at a mercury electrode, complicated by equilibria involving water has $\alpha n = 0{\cdot}64$. Controlled-potential coulometry at a mercury electrode indicates an overall one-electron process. In anhydrous medium, the reduction products at both electrodes are carbon monoxide and carbonate ion; some bicarbonate and formate ions are formed in the presence of water.

Johnson *et al.*[38] observed a unique reduction wave, at potentials less cathodic than the reduction wave of either reducible species alone, in DMSO solutions containing both oxygen and one of the metal ions, cadmium, zinc, strontium, thallium(I), or yttrium. The variation of the height of this wave was studied as a function of concentration of oxygen and the various metal ions. Studies of this type revealed

TABLE III.—OSCILLOGRAPHIC PEAK POTENTIALS IN DMSO[36]

the stoichiometry of the materials which caused the reduction wave. Controlled-potential coulometry was employed to determine values of n. Massive preparation of reduction products by controlled-potential electrolysis, along with the above information, revealed the probable reduction mechanism. In the cases of zinc, strontium, and thallium(I), the reduction was of metal ion plus oxygen to the superoxide; cadmium and yttrium with oxygen were reduced to the peroxides.

Fujinaga *et al.*[39] found that in DMSO containing between 10 and 30% water, the first oxygen wave (reduction to superoxide ion) becomes a two-electron wave, because of protonation by water. The polarographic diffusion coefficients of oxygen in the mixed solvent were calculated.

Pasadas *et al.*[40] studied the kinetics of hydrogen evolution on an iron electrode as a function of hydrochloric acid concentration; excess of potassium perchlorate was employed. Temperatures were varied from 20° to 45°. A two-step mechanism was proposed in which the simple discharge of solvated hydrogen ions was rate-determining.

The function of a hydrogen electrode in DMSO was studied by Courtot-Coupez and Le Demezet.[41] The authors determined the pK values of a number of acids, and reported the ion product of the solvent to be $pK_s = 33{\cdot}3 \pm 0{\cdot}05$. This differs greatly from the value reported by Reddy[42] ($pK_s = 17{\cdot}3$), but is in virtual agreement with the value determined spectrophotometrically by Steiner[43,44] ($pK_s = 32$).

Rallo *et al.*[45] studied the polarographic reduction of nitric oxide in 0·1*M* TEAP. Solutions with varying NO/N_2 content were investigated. One wave appeared when there was less than 10% NO in the gas mixture; with more than 10% NO, a second, more anodic wave appeared, which was not diffusion-controlled and was thought to be due to the reduction of a dimer. The rate-determining dimerization which preceded reduction was thought to control the wave height.

Michlmayr and Sawyer[46] investigated the electrochemical behaviour of the hydrogen halides at platinum electrodes in DMSO by chronopotentiometry, controlled-potential coulometry, and cyclic voltammetry. The results indicated that the oxidation products of the hydrogen halides reacted with the solvent. In the cases of HCl and

HBr, a catalytic process occurred which enhanced the value of $i\tau^{1/2}$ by a factor of 5–10.

The electrochemical oxidation of formate has been studied at gold and platinum electrodes, by chronopotentiometry, controlled-potential coulometry and cyclic voltammetry.[47] Well-defined chronopotentiograms were obtained, with quarter-wave potentials of 0·33 and —0·07 V *vs.* SCE at a gold and a platinum electrode respectively. The process is diffusion-controlled. The oxidation products were carbon dioxide and hydrogen ions, which react with formate ion. Thus, the overall reaction is a one-electron oxidation in which half a mole of carbon dioxide and half a mole of formic acid are formed for each mole of formate ion electrolysed.

Jacobson and Sawyer[48] studied the electrochemical oxidation of oxalate at a gold electrode. The chronopotentiometric quarter-wave potential was 1·25 V *vs.* SCE. The final oxidation product was carbon dioxide, but an unstable intermediate was formed during the oxidation process. In the absence of excess of hydroxide ion, oxalate ion is partially hydrolysed to the hydrogen oxalate ion, which is oxidized to carbon dioxide and hydrogen ions.

Buchta and Evans[49] examined the electrochemical behaviour of 1,3-diphenyl-1,3-propanedione, as well as a number of other β-diketones. Controlled-potential coulometry at the potential for the first wave gave an *n*-value of 0·55. The products were found to be the enolate of 1,3-diphenyl-1,3-propanedione and the pinacole 1,4-dibenzoyl-2,3-diphenyl-2,3-butanediol. Further electrolysis resulted in an increase in current, followed by a decrease to the residual value. This was caused by an electrolytic autocatalytic decomposition of the pinacol in a base-catalysed reverse aldol condensation to benzil and acetophenone. The presence of the benzil radical anion was confirmed by ESR spectroscopy. Other β-diketones behaved in an analogous fashion.

Goolsby and Sawyer[50] studied the electrochemistry of hydroxylamine at gold and platinum electrodes in 0·2*M* lithium perchlorate in DMSO. The electroactive species, NH_2OH, is oxidized irreversibly in a diffusion-controlled, two-electron process. The chronopotentiometric $E_{1/4}$ values were —0·84 V *vs.* SCE at a platinum electrode and —1·18 V at a gold electrode. The major products are water, hydrogen ion and nitrous oxide. The rate-controlling step is a one-electron process which follows a preceding chemical reaction of a hydroxide ion with hydroxylamine.

The electrochemical oxidation, at platinum electrodes, of hydrazine, 1,1-dimethylhydrazine, and 1,2-dimethylhydrazine in DMSO was studied by Michlmayr and Sawyer.[51] In each case the oxidation involved one electron. Chronopotentiometric quarter-wave potentials were reported as 0·00, 0·02, and 0·03 V *vs.* SCE, for the three compounds in the order listed above. The oxidation products were identified and mechanisms proposed.

Koch and Purdy [52] studied the polarographic behaviour of amino-acids in DMSO. Nine amino-acids, asparagine, hydroxyproline, isoleucine, methionine, phenylalanine, proline, threonine, tryptophan, and tyrosine, gave single waves involving the one-electron reduction of the proton of the carboxyl group. Five amino-acids, dihydroxyphenylalanine, glutamic acid, aspartic acid, glutamine, and cysteine gave multiple waves.

The electrical double-layer in DMSO solutions was studied by Payne.[53] He noted a strong resemblance in electrocapillary curves and double-layer capacities of DMSO and aqueous solutions. Anions are specifically adsorbed from DMSO solutions in the order $I^- > Br^- > Cl^- > NO_3^- > ClO_4^- > PF_6^-$; cations are not significantly adsorbed. The electrocapillary maximum is shifted in the positive direction in DMSO as compared to water, and a large hump appears close to the limit of anodic polarization in solutions where the anion is not strongly adsorbed. The influence of diffusion-layer capacity is more marked in DMSO. The interfacial tension at the electrocapillary maximum is about 60 dyn/cm lower (370·5 dyn/cm) than in water.

Payne[54] reported the occurrence of capacity humps on the electrocapillary curve for 0·1*M* KPF_6 solutions in DMSO. The hump appears on the anodic side of the electrocapillary maximum.

Synnott and Butler[55] studied the equilibria of silver chloride in DMSO–water mixtures containing excess of chloride. They used potentiometric results to determine equilibrium constants for the system.

Gutmann[56] reviewed the effect of the donor properties of various solvents, including DMSO. Also discussed were the effects of the acceptor properties of metal ions, solvation of metal ions and complex formation on half-wave potentials and the thermodynamics of reduction processes.

Zusammenfassung—Es wird eine Übersicht über voltametrische Untersuchungen mit Dimethylsulfoxid als Trägerelektrolyt gegeben. Sie umfaßt Einzelheiten über die untersuchten anorganischen und organischen Systeme sowie über die für dieses Medium entwickelten Bezugselektroden.

Résumé—On présente une revue des études voltammétriques utilisant le diméthylsulfoxyde comme électrolyte-support, et celle comprend des détails de systèmes minéraux et organiques étudiés et des électrodes de référence élaborées pour l'emploi dans ce milieu.

PRETREATED BRIGHT PALLADIUM ELECTRODE IN POTENTIOMETRIC REDOX TITRATIONS

TITRATION OF $Cr_2O_7^{2-}$ AND Ce^{4+} WITH Fe^{2+}

CANDIN LITEANU and IOVANCA HAIDUC
University of Cluj, Department of Analytical Chemistry, Cluj, Romania

(*Received* 2 *June* 1971. *Accepted* 5 *January* 1972)

Summary—The behaviour of the bright palladium electrode toward the redox systems $Cr_2O_7^{2-}/Fe^{2+}$ and Ce^{4+}/Fe^{2+} (in potentiometric titration) has been investigated as a function of pretreatment of the electrode. Anodization of the electrode at potentials higher than 800 mV increases ΔE at the equivalence point by 300–400 mV for the dichromate titration. The sharp change in potential is due to the reaction between PdO_2 and Fe^{2+}. The equivalence point corresponds to the beginning of the potential drop, rather than the inflexion point, especially for dilute solutions. If the electrode is ignited before use the surface oxide PdO is oxidized to PdO_2 by Cr(V), the potential increases during the titration and ΔE is 200 mV bigger than when an untreated electrode is used. In the titration of Ce^{4+} with Fe^{2+} the ΔE is largest with untreated electrodes, and if the anodized electrode is used, the titration curves clearly show the reaction between PdO_2 and Fe^{2+}.

NOBLE METAL electrodes (Pt, Pd, Au, Ir, Rh, Ru, Os), by subjection to various treatments (chemical and electrochemical oxidations and reductions, heating in a flame, *etc*), can be brought into different states, which influence the electrode processes on the metal surface. The bright palladium electrode is much used in various electrochemical procedures. Several techniques have been used to obtain information about the state of the surface of pretreated palladium electrodes, including charging curves[1–6]; potential sweep curves;[7] steady-state galvanostatic oxygen overvoltage curves in acid[8,9] and alkaline[9–12] solutions; steady-state potentiostatic polarization,[8] and rest-potential measurements.[13–16]

The surface composition of the anodized palladium electrode has been investigated in some detail. The anodic pretreatment may result in the formation of PdO and PdO_2 on the electrode surface, depending on the anodization potential used. The rest-potential has been established for the systems PdO_2/Pd (1·47 V) and PdO/Pd (0·87 V) in sulphuric acid; these values are characteristic for the systems named. The simultaneous presence of both palladium oxides (PdO_2 and PdO) on the surface results in the occurrence of a mixed potential, the value of which depends on the relative amounts of the two oxides on the surface, and lies between 1·10 and 1·40 V.[13]

We are interested in the response time of differently pretreated palladium electrodes, when they are dipped into dichromate, ceric sulphate and ferrous sulphate solutions,[17–18] and the possibility of their use as indicating electrodes in automatic potentiometric titration.

EXPERIMENTAL

A palladium wire (length 1 cm, diameter 0·5 mm) and a palladium plate (0·5 cm^2 surface area) sealed in a glass tube, were used as electrodes. The $FeSO_4$, $K_2Cr_2O_7$ and $Ce(SO_4)_2$ solutions were prepared from analytical grade reagents with doubly distilled water.

The electrodes were subjected to potentiostatic (anodic and cathodic) pretreatment, by using the Radelkis-R OH-102 polarograph as a source of constant potential. Other pretreatments used were the chemical reduction and flame ignition of the electrode (in the oxidizing part of a methane flame).

All the measurements were made at a temperature of 22 ± 1°. The saturated calomel electrode (SCE) was used as reference electrode, but the potential values were recalculated and are given with respect to the normal hydrogen electrode (NHE) in the same solution. The behaviour of the electrode was characterized by the potential as a function of time, the pretreated electrode being dipped into 0·1 and 0·001*N* solutions of the three reagents, and the potential recorded with the same polarograph. For comparison, similar curves were recorded for an untreated palladium electrode.

The treated electrodes were used as indicating electrodes in redox titrations. Direct or derivative potentiometric curves were recorded, by using an automatic burette with a flow-rate of 3 ml/min. The titration curves were characterized by dE/dV or the volume V_i of titrant added, at the inflexion point.

RESULTS AND DISCUSSION

Response times in $K_2Cr_2O_7$ *solution*

Untreated electrodes. The initial potential of the palladium electrode in contact with a dichromate solution depends on the state of its surface. The untreated electrode, introduced into 0·1*N* dichromate, shows after a few seconds a constant Nernstian potential for the $Cr_2O_7^{2-}/Cr^{3+}$ couple (1080–1090 mV). For somewhat more dilute solutions the potential is 1090 mV, but for 0·001*N* solution it is only 920 mV.

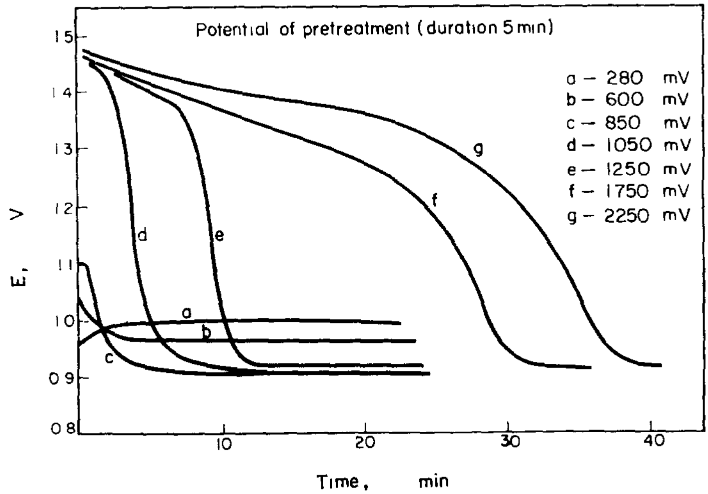

FIG. 1.—The potential–time variation of a preanodized electrode introduced into 0·1*N* $K_2Cr_2O_7$.

Chemically reduced electrode. After chemical reduction (by standing in ferrous sulphate solution) a palladium electrode shows a potential–time behaviour, in 0·1*N* dichromate, similar to that of an untreated electrode, the rest-potential showing a slight increase during the first 10–20 sec (presumably owing to oxidation of ferrous ions adsorbed on the palladium surface) and then remains constant at 1090 mV.

Preanodized electrode. The electrode was preanodized in either 1*N* sulphuric acid or 0·1*N* dichromate in 1*N* sulphuric acid. The $E = f(t)$ curves for electrodes anodized for 5 min at potentials between 0·2 and 2·25 V are shown in Fig. 1. It can be seen that if the pretreatment potential was under 0·80 V, the electrode behaves almost as an untreated electrode. Only at higher potentials are palladium oxides formed on the electrode surface[6] and these are responsible for the potential variations described by curves *d*–*g*.

The potential-time behaviour of an electrode preanodized at 2·25 V in 0·1N dichromate for various time intervals is shown in Fig. 2. The curves show that the longer the pretreatment the longer the rest-potential of the electrode remains high; this can be explained by the dependence between the amount of surface oxide formed and the duration of pretreatment.

When severe pretreatment conditions are used (2·25 V for 60 min) the rest potential remains at 1470–1500 mV for a longer time (Fig. 2, curve *f*) and then decreases rather abruptly, as expected[6] for a PdO_2/Pd system. It can be assumed that under these conditions the electrode behaviour is determined practically only by the PdO_2/Pd system. Intermediate pretreatment conditions (0·80–1·75 V) result in smoothly decreasing rest-potentials (Fig. 1, curves *c* and *d*) which can be interpreted in terms of mixed potentials due to the simultaneous presence of both PdO_2 and PdO (present in variable proportions) on the electrode surface.

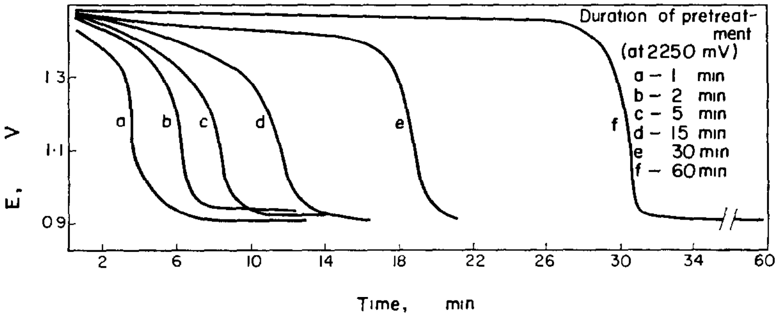

FIG. 2.—The potential–time variation of a preanodized electrode introduced into 0·1N $K_2Cr_2O_7$.

Thermally treated electrode. The electrode was heated for 1–5 min in the oxidizing part of a methane flame having a temperature of *ca.* 900°. The electrode potential is 1150–1200 mV, which suggests that some palladium oxides are present on the surface, but decreases (Fig. 3) to about 900 mV, presumably because of gradual decomposition of PdO_2 in the acidic medium.

Electrochemically reduced electrode. The potential of an electrode placed in dichromate solution after reduction by cathodic treatment in 1N sulphuric acid, depends upon the duration of the pretreatment and the current density used. If the cathodic pretreatment is stopped after the surface oxide has been reduced, the electrode obtained behaves like an untreated one. If the treatment is continued, however, a palladium–hydrogen electrode[18] is obtained, owing to the sorption of hydrogen by the metal. The rest-potential of such an electrode is negative with respect to the SCE, but increases as the hydrogen is lost from the metal by diffusion.

Response times in $Ce(SO_4)_2$ *solution*

Regardless of the type of pretreatment (no treatment at all, potentiostatic polarization at potentials between 0·20 and 2·00 V, ignition, or chemical reduction) the potential of the electrode in 0·1N ceric sulphate is 1470–1500 mV, is not influenced by stirring, and reaches this value in about 4 min. Thus, the palladium electrode shows essentially the potential of the Ce^{4+}/Ce^{3+} system in 1N sulphuric acid. A similar situation occurs for 0·001N ceric sulphate but the potential is about 1·4 V, owing to the dilution effect.

Response time in $FeSO_4$ *solution*

The behaviour of the pretreated electrode is the most interesting in this case, since the surface palladium oxides formed during the anodic pretreatment are reduced by the ferrous sulphate. The reduction rate of the surface oxide layer by iron(II) can readily be followed by recording the potential–time curves. Results for 0·1*N* and 0·01*N* ferrous sulphate are shown in Figs. 4 and 5. The potential decreases from 1470 mV (characteristic for the PdO_2/Pd system) to 700 mV (characteristic for the Fe^{3+}/Fe^{2+} system), at a rate dependent on the intensity of pretreatment and on the concentration of ferrous sulphate. For 0·1*M* iron(II) the potential of the Fe^{3+}/Fe^{2+} system is achieved in 10 sec, but in more dilute solutions (0·001*M*) it takes *ca.* 90 sec.

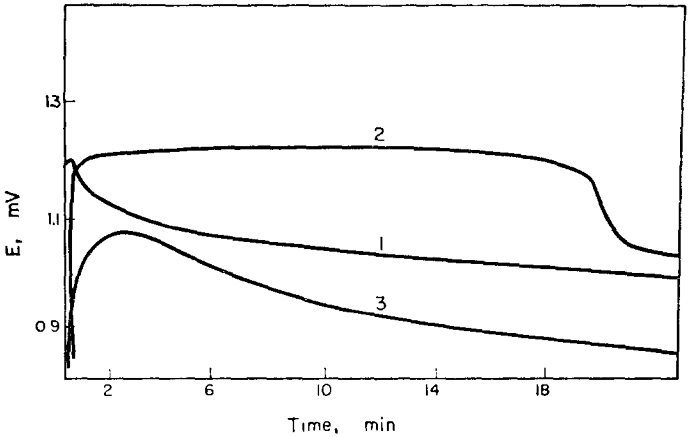

FIG. 3.—The potential–time variation of an ignited electrode introduced into $K_2Cr_2O_7$
1. Ignited for 30 sec; 0·1*N* $K_2Cr_2O_7$.
2. Ignited for 5 min; 0·1*N* $K_2Cr_2O_7$.
3. Ignited for 1 min; 0·001*N* $K_2Cr_2O_7$.

In effect the $E = f(t)$ curves can be considered as describing a "titration" of the surface palladium oxide with ferrous sulphate. No quantitative determinations were made, but these curves could, in principle, be used to determine the amount of surface palladium oxide formed during the pretreatment.

Palladium as an indicator electrode

The results presented above were used in some titration experiments in which the palladium electrode served as an indicating electrode. Since the surface palladium dioxide is unstable,[2,6] automatic potentiometric titrations were made, which are rather rapid (*ca.* 90 sec) and thus permit investigation of the influence of the state of the metal surface on its behaviour as an indicating electrode.

Titration of dichromate with iron(II). The curves for 0·1*N* dichromate titrated with 0·1*M* iron(II) are shown in Fig. 6. With an untreated electrode (curve 2) the potential change follows almost the normal course, with a break of about 400 mV. The cathodically treated electrode (curve 1) also gives a "classical" curve with a much smaller potential break.

If the electrode is preanodized at potentials higher than 800 mV, the electrode potential before the equivalence point is determined by the PdO_2/Pd and/or PdO/Pd systems and is 1·40–1·50 V, much higher than the 1·10 V of the untreated electrode.

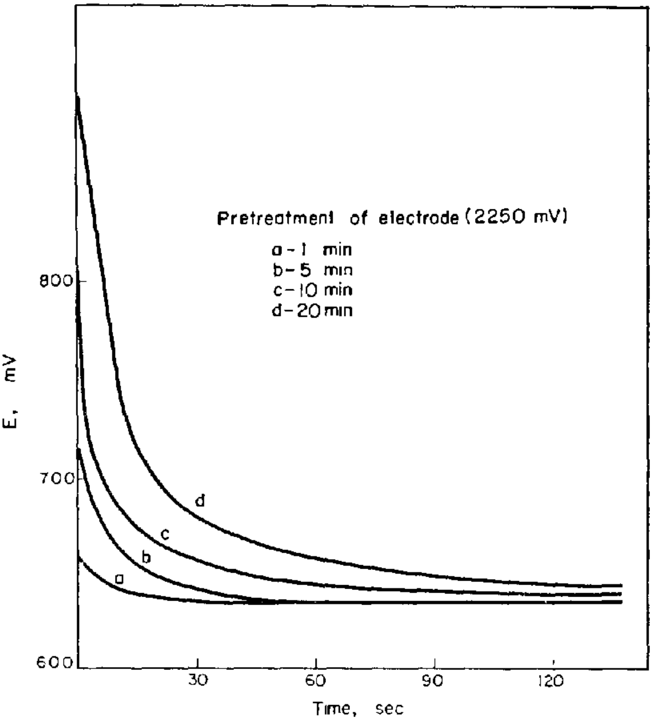

FIG. 4.—The potential-time variation of a preanodized electrode introduced into $0{\cdot}1N$ $FeSO_4$.

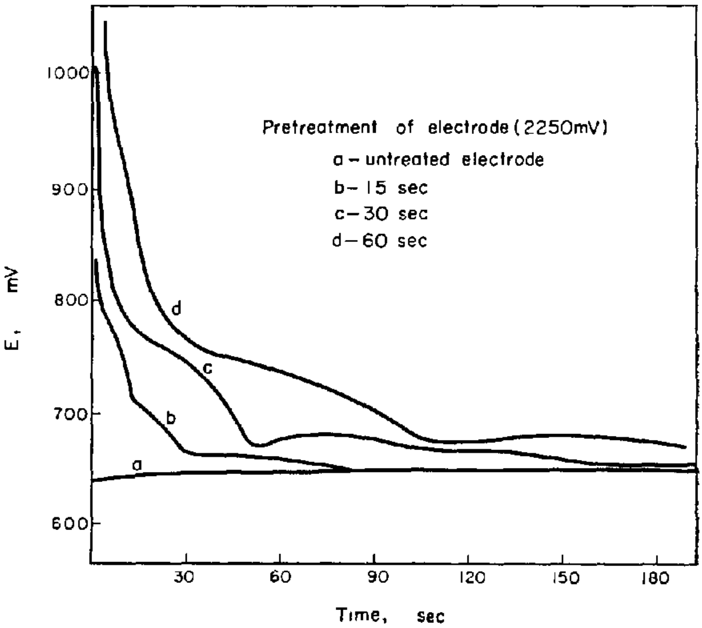

FIG. 5.—The potential-time variation of a preanodized electrode in $0{\cdot}01M$ $FeSO_4$.

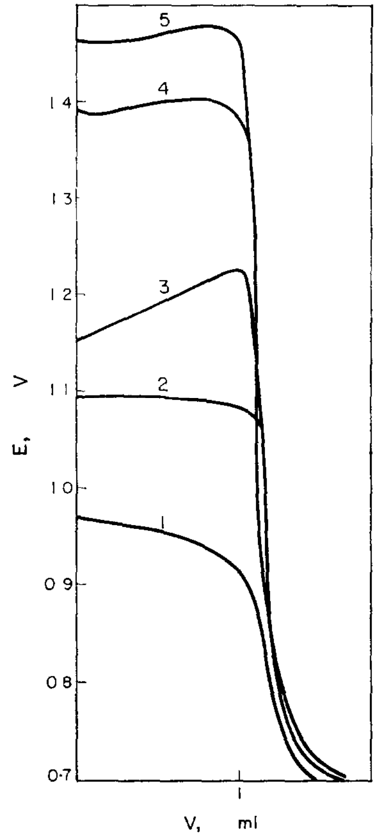

FIG. 6.—Potentiometric titration of 0·1N $Cr_2O_7^{2-}$ with 0·1M Fe^{2+}.

1. Pd cathodically reduced for 10 min at 10 μA.
2. Pd untreated.
3. Pd ignited for 30 sec at ~900°C.
4. Pd anodized for 1 min at 2·25 V.
5. Pd anodized for 5 min at 2·25 V.

The ferrous sulphate reduces the dichromate, but the electrode potential does not follow the change of composition of the titrated solution. Only *after* the equivalence point will the ferrous ions, now in excess, react with PdO_2 (which is still present on the electrode surface, as demonstrated by the high value of the potential at the equivalence point (curves 4 and 5) according to

$$PdO_2 + 4Fe^{2+} + 4H^+ = Pd + 4Fe^{3+} + 2H_2O$$

and the electrode show the potential of the Fe^{3+}/Fe^{2+} system. The potential after the equivalence point decreases from about 1·45 V to about 0·75 V, giving a ΔE of about 700 mV, almost twice that with the untreated electrode. It follows from this mechanism that the equivalence point should be taken as the point at which a sudden decrease of potential occurs, rather than the inflexion point of the titration curve. This is more evident for dilute solutions, as discussed below.

The thermally ignited electrode shows more unusual behaviour (curve 3), the potential first increasing by about 200 mV. This increase is more pronounced with

0·1*N* dichromate and is lower for more dilute dichromate solutions. Since the effect is not observed in the titration of ceric sulphate, the $Cr_2O_7^{2-}/Cr^{3+}$ system must be responsible for this initial increase, presumably because of an increase in the PdO_2/PdO ratio on the electrode surface. Probably PdO_2 is formed by oxidation of the surface PdO (formed during the thermal ignition) by some chemical species, more oxidizing than $Cr_2O_7^{2-}$, which is formed during the reduction of Cr(VI). In a kinetic study of the reduction of dichromate with iron(II), Espenson and King[19] suggested a multi-step mechanism, in which the oxidation states Cr(V) and Cr(IV) occur, the rate-determining step being the Cr(V) → Cr(IV) stage. Since Cr(V) is a stronger oxidizing species than Cr(VI), it seems reasonable to assume that Cr(V) oxidizes the surface PdO to PdO_2, thus causing the initial increase of the electrode potential. After the equivalence point, owing to the reduction of PdO_2 by iron(II), the potential decreases abruptly, as for the anodized electrode. The value of ΔE at the equivalence point is 200–250 mV larger for the ignited electrode than for the untreated electrode.

When 0·01*N* solutions were titrated, similar titration curves were obtained but because ΔE near the equivalence point is determined by the reaction between PdO_2 and iron(II), the end-point indicated by the inflexion point (maximum dE/dV) is shifted from the equivalence point if a preanodized or ignited electrode is used. This effect becomes more pronounced with increasing dilution of the solutions (Tables I and II).

Titration of ceric sulphate with iron(II). The titration curves for this system are classical in shape, irrespective of electrode pretreatment, except that the cathodically reduced electrode gives a variation in the shape of the curve before the equivalence point. The starting potential in titrations with this electrode depends on the time

		80	4·20

* Volume of titrant added at inflexion point.

interval between stopping the cathodic pretreatment and beginning the titration. If the electrode is used immediately after pretreatment, the inflexion point appears earlier than with the untreated electrode. The preanodized electrode gives an inflexion point later than that with the untreated electrode, and the break is not as steep. A similar effect was observed in the titration of dichromate with an intensively anodized electrode (30 min at 2·25 V in 0·1*N* dichromate).

Titration of 0·001*N* solutions, with an electrode preanodized in 1*N* sulphuric acid, gives two end-points on the derivative curve, indicating two superimposed electrode processes (Fig. 7). The first corresponds to the titration of cerium(IV) with iron(II) and the second to reduction of surface PdO_2 after the equivalence point.

CONCLUSIONS

Dichromate titration

The preanodization of a bright palladium electrode at potentials higher than 800 mV dramatically increases the potential change around the equivalence point (300–400 mV more than with an untreated electrode) in the titration of 0·1*N* dichromate with ferrous sulphate solution. This dramatic increase of $(\Delta E)v_i$ is due to the reaction between iron(II) and palladium oxides deposited by preanodization of the indicating electrode. These oxides function at the titration as *auxilliary redox systems*. The equivalence point corresponds to the beginning of the potential drop, especially with more dilute solutions (0·001*N*).

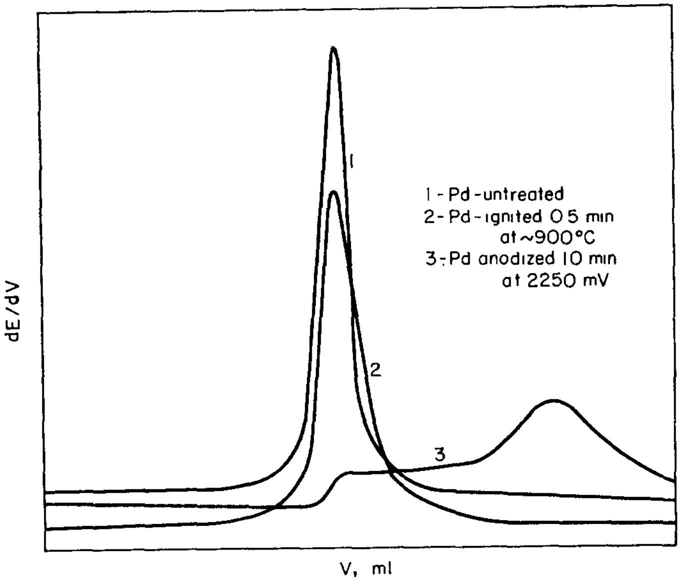

FIG. 7.—Derivative potentiometric titration of 0·001*M* Ce^{4+} with 0·001*M* Fe^{2+}.

The use of a chemically reduced palladium electrode offers no advantage over the untreated electrode. A cathodically reduced electrode behaves like a palladium-hydrogen electrode and gives negative errors.

A thermally treated electrode behaves almost like a preanodized electrode, owing to the oxidation of the surface oxide PdO to PdO_2 by Cr(V) during the titration.

Cerium(IV) *titration*

The untreated electrode gives the largest potential change at the equivalence point. Preanodization results in a less steep curve at the inflexion point, and two processes are involved, one of which is the reduction of PdO_2 by iron(II) after the end-point.

Zusammenfassung—Das Verhalten der blanken Palladiumelektrode gegenüber den Redoxsystemen $Cr_2O_7^{2-}/Fe^{2+}$ und Ce^{4+}/Fe^{2+} (bei potentiometrischer Titration) wurde in Abhängigkeit von der Vorbehandlung der Elektrode untersucht. Anodische Belastung der Elektrode bei Potentialen über 800 mV erhöht den ΔE-Wert am Äquivalenzpunkt der Dichromat-Titration um 300–400 mV. Die scharfe Potentialänderung beruht auf der Reaktion von PdO_2 und Fe^{2+}. Der Äquivalenzpunkt entspricht eher dem Beginn des Potentialabfalls als dem Wendepunkt, besonders bei verdünnten Lösungen. Wird die Elektrode vor dem Gebrauch erwärmt, so wird das Oberflächenoxid PdO durch Cr(V) zu PdO_2 oxidiert, das Potential steigt während der Titration und ΔE ist 200 mV größer als bei Verwendung einer unbehandelten Elektrode. Bei der Titration von Ce^{4+} mit Fe^{2+} ist ΔE bei unbehandelten Elektroden am größten; bei Verwendung der anodisch belasteten Elektrode zeigen die Titrationskurven deutlich die Reaktion zwischen PdO_2 und Fe^{2+}.

Résumé—On a étudié le comportement de l'électrode de palladium poli vis-à-vis des systèmes redox $Cr_2O_7^{2-}/Fe^{2+}$ et Ce^{4+}/Fe^{2+} (en titrage potentiométrique) en fonction du prétraitement de l'électrode. L'anodisation de l'électrode à des potentiels supérieurs à 800 mV accroît ΔE au point d'équivalence de 300–400 mV pour le titrage du bichromate. Le changement net en potentiel est dû à la réaction entre PdO_2 et Fe^{2+}. Le point d'équivalence correspond au début de la chute de potentiel, plutôt qu'au point d'inflexion, particulièrement pour les solutions diluées. Si l'électrode est chauffée avant usage, l'oxyde de surface PdO est oxydé en PdO_2 par Cr(V), le potentiel croît durant le titrage et ΔE est de 200 mV plus grand que lorsqu'on utilise une électrode non traitée. Dans le titrage de Ce^{4+} avec Fe^{2+}, la valeur de ΔE est la plus grande avec des électrodes non traitées, et si l'on utilise l'électrode anodisée, les courbes de titrage montrent clairement la réaction entre PdO_2 et Fe^{2+}.

QUANTITATIVE SEPARATION OF Al, Ga, In, AND Tl BY CATION EXCHANGE CHROMATOGRAPHY IN HYDROCHLORIC ACID–ACETONE*

F. W. E. STRELOW and A. H. VICTOR
National Chemical Research Laboratory, P.O. Box 395, Pretoria, South Africa

(*Received* 30 *September* 1971. *Accepted* 12 *November* 1971)

Summary—Up to 4 mmole (1 mmole each) of tervalent Al, Ga, In and Tl are separated from each other on a 60-ml column of AG50W-X8 resin of 200–400 mesh particle size by cation-exchange chromatography in hydrochloric acid–acetone mixtures. Separations are very sharp and without tailing. Recoveries for amounts from 1–100 mg average 100·0 ± 0·1% for the analysis of synthetic mixtures. An anion-exchange method is described for the separation of gallium from the hydrochloric acid–acetone eluate. Relevant cation-exchange distribution coefficients, anion-exchange coefficients for gallium in hydrochloric acid–acetone, an elution curve for all four elements and results of quantitative separations of synthetic mixtures are presented.

THE ONLY ION-EXCHANGE method described in the literature which provides a complete separation of the group IIIA elements Al, Ga, In and Tl in a single column run seems to be that of Kraus *et al.*[1] which uses an anion-exchange resin in the chloride form and involves the elution of the elements with aqueous hydrochloric acid according to the stability of their chloride complexes. The method has the weakness that in 7*M* hydrochloric acid, the eluting agent used for aluminium, indium has a distribution coefficient of only about 20. This causes an early appearance of indium in the eluate and makes separation of large amounts of indium impossible unless comparatively large columns are used. In addition, indium shows appreciable tailing and thallium very strong tailing. Quantitative aspects of the separation have unfortunately not been investigated, but it seems probable that the tailing could lead to incomplete recoveries of thallium and indium unless very large elution volumes are used.

Some information is available on the separation of pairs of the elements mentioned above. Kocheva[2] has separated gallium and indium by eluting the gallium from Dowex 1-X8 resin with 0·5*M* potassium iodide while indium is retained, and Kocheva *et al.*[3] have separated gallium from aluminium by cation-exchange and by anion-exchange using potassium thiocyanate–hydrochloric acid mixtures. Klement *et al.*[4] have eluted indium from a Dowex 50 cation-exchanger with 0·4*M* hydrochloric acid while gallium is retained and Tsintsevich *et al.*[5] have used 3% oxalic acid solution at pH 4 to elute gallium from a Russian cation-exchange resin, aluminium being retained.

In hydrochloric acid containing an organic solvent, differences in chloride complex formation and hence in separation factors are often considerably enhanced. Fritz *et al.*[6] have determined cation-exchange distribution coefficients for 14 elements in hydrochloric acid–acetone and have shown that indium can be separated from aluminium by elution with 0·5*M* hydrochloric acid in 40% aqueous acetone with a separation factor considerably larger than in aqueous hydrochloric acid. Coefficients for gallium and

* This is part of a D.Sc. thesis by the second author at the department of Inorganic and Analytical Chemistry of the University of Pretoria.

indium in hydrochloric acid–organic solvent mixtures have been determined by Alimarin *et al.*[7] and Gorokhova *et al.*,[8,9] using Russian resins, and various conditions for separation ranging from 0·1*M* hydrochloric acid in 80% aqueous acetone to 0·75*M* hydrochloric acid in 20% acetone have been presented. Korkisch *et al.*[10] have separated indium, gallium and aluminium by anion-exchange chromatography in hydrochloric acid–acetone and hydrochloric acid-2-methoxyethanol mixtures. Since the distribution coefficients are not very high under the experimental conditions employed, long columns (75 cm) have to be used. Furthermore, results of recovery tests do not seem to be very accurate.

A recent systematic study of cation-exchange distribution coefficients[11] suggested that a separation of all four elements in a single run and with considerably larger distribution coefficients than those obtained by Kraus[1] or Korkisch[10] might be possible by using cation-exchange chromatography in hydrochloric acid–acetone. Favourable distribution coefficients do not always guarantee a good separation, because they cannot predict features of column behaviour such as tailing. The quantitative aspects of the separation of the group IIIA elements was therefore investigated in detail by preparing elution curves and carrying out column experiments with synthetic mixtures.

EXPERIMENTAL

Reagents

Chemicals of analytical-reagent grade purity were used throughout. The resins used were the AG50W-X8 cation-exchanger and AG1-X8 anion-exchanger (BioRad Laboratories, Richmond, California). Resin of 100–200 mesh was used for determination of distribution coefficients and of 200–400 mesh for column work. Borosilicate glass tubes of 20 mm bore with fused-in glass sinters of No. 2 porosity, a burette tap at the bottom and a B19 ground-glass joint at the top, were used as columns.

Distribution coefficients

The relevant cation-exchange distribution coefficients have been published previously,[11] but are included in Table I together with relevant intermediate coefficients obtained from plots of known coefficients[11] against acetone concentration.

TABLE I.—CATION-EXCHANGE DISTRIBUTION COEFFICIENTS IN HCl–ACETONE

Element	0·1*M* HCl + 50% acetone	0·5*M* HCl + 50% acetone	0·5*M* HCl + 90% acetone	2·0*M* HCl + 70% acetone
Tl(III)	0·5	0·5	<0·5	<0·5
In	240	2·0	<0·5	<0·5
Ga	$>10^4$	780	1·9	<0·5
Al	$>10^4$	910	1250	75

Because it was found that gallium is slightly volatile when solutions containing gallium, acetone and hydrochloric acid are evaporated on the water-bath, the possibility of separating gallium from acetone by anion-exchange was investigated. Table II shows relevant distribution coefficients for 1 mmole of gallium in 250 ml of hydrochloric acid containing various amounts of acetone after equilibration with 2·500 g of dry AGI-X8 resin.

TABLE II.—ANION-EXCHANGE DISTRIBUTION COEFFICIENTS FOR Ga IN HCl–ACETONE

	Acetone							
HCl, *M*	0%	20%	40%	60%	70%	75%	80%	90%
0·5	1·0	1·9	9·0	18·9	6·1	3·3	2·2	1·1
1·0	2·2	10·0	52·7	22·3	3·5	2·2	1·1	—
2·0	6·2	47	286	20·0	5·0	3·6	—	—

Elution curve

The conditions suggested by the distribution coefficients in Table I were selected for the quantitative separation. Hydrochloric acid (0·5*M*) in 90% acetone gives a larger separation factor for the Ga–Al pair than 2·0*M* hydrochloric acid in 70% acetone, but the latter eluent shows practically no tailing of gallium and was preferred for this reason. A mixture containing about 0·5 mmole of each element in 25 ml of 0·1*M* hydrochloric acid containing 50% acetone and a small amount of chlorine to keep thallium in the tervalent state was placed on a column of 60 ml of AG50W-X8 resin of 200–400 mesh particle size. The resin column was 19 cm in length, 2·0 cm in diameter and had been equilibrated with 0·1*M* hydrochloric acid in 50% acetone. The cations were washed onto the column with 0·1*M* hydrochloric acid in 50% acetone containing a small amount of chlorine, and thallium(III) was eluted with 200 ml of the same reagent. Indium was then eluted with 300 ml of 0·5*M* hydrochloric acid in 50% acetone, followed by gallium with 300 ml of 2·0*M* hydrochloric acid in 70% acetone, and finally aluminium with 300 ml of 3·0*M* aqueous hydrochloric acid. The flow-rates were about 2·0 ± 0·3 ml for Tl(III) and In and about 3·0 ± 0·3 ml for Ga and Al. Fractions of 25-ml volume were taken with an automatic fractionater and analysed. The experimental curve is shown in Fig. 1.

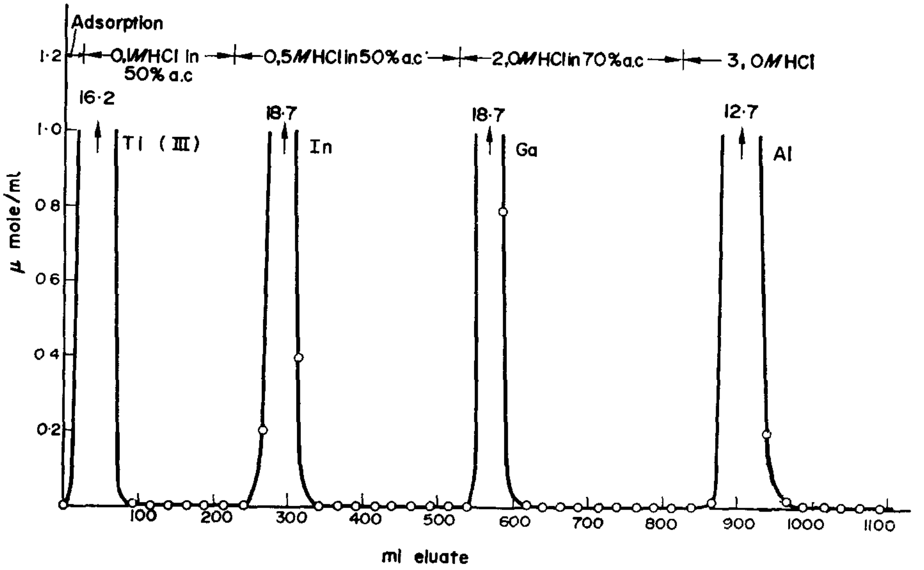

FIG. 1.—Elution of Al, Ga, In and Tl(III).

Quantitative separations

Volumes of standard solutions of two adjacent elements or of all four elements in 0·1*M* hydrochloric acid were measured out in triplicate and hydrochloric acid and acetone were added to give the desired concentrations. The solutions were adsorbed on a column containing 60 ml of AG50W-X8 resin of 200–400 mesh particle size in the hydrogen form which had previously been equilibrated with 0·1*M* hydrochloric acid in 50% acetone. The elements were then eluted with the same sequence of reagents as described above. The eluates were kept separately and the elements determined after the excess of solvent had been removed by evaporation. A special procedure had to be adopted in the case of gallium, because it was found that between 1 and 2% of the gallium present was lost by volatilization. No gallium was lost in control experiments in which aqueous hydrochloric acid solutions were evaporated on the water-bath. The gallium-containing eluate was therefore collected in a 500-ml separating funnel containing 180 ml of 2*M* hydrochloric acid. The solution was mixed and passed through a column containing 45 ml of AG1-X8 anion-exchange resin previously equilibrated with 2*M* hydrochloric acid in 40% acetone. From the mixture (2*M* hydrochloric acid in 44% acetone) gallium was adsorbed with a distribution coefficient of about 240 (Table II), and could then be eluted with 300 ml of 0·1*M* hydrochloric acid. Thallium was partly reduced during the evaporation of excess of eluting agent and had to be reoxidized to thallium(III) with chlorine or bromine. Small amounts of organic matter resulting from the polymerization of acetone were destroyed by evaporation with nitric acid plus 2 ml of perchloric acid. The analytical methods are summarized in Table III and the results are presented in Table IV.

TABLE III.—ANALYTICAL PROCEDURES

Element	Method
Tl(III)	Excess of DCTA, back-titration with Zn(II), Xylenol Orange as indicator. Small amounts spectrophotometrically with Alizarin Red S (elution curves).
Ga	Excess of EDTA, back-titration with Zn(II), Xylenol Orange as indicator. Small amounts spectrophotometrically with Xylenol Orange at pH 5·5 and 515 nm (elution curves).
In	Excess of EDTA, back-titration with Zn(II), Xylenol Orange as indicator. Small amounts by atomic-absorption spectrometry (elution curves).
Tl(III)	Titration with EDTA in the presence of tartrate at pH 10, Methylthymol Blue as indicator.

DISCUSSION

The method described provides a useful means for the quantitative separation of the group IIIA elements (from Al to Tl) in a single column run. The presence of acetone makes the separation factors considerably higher than those for aqueous hydrochloric acid media. That for the Al–Ga pair is enhanced to more than 150 in $2M$ hydrochloric acid containing 70% acetone as compared with about 1·6 in aqueous $2M$ hydrochloric acid. In $0{\cdot}5M$ hydrochloric acid containing 90% acetone the separation factor for the same pair is larger than 600, but more tailing occurs.

Separations are very sharp and quantitative and tailing is practically non-existent with a 200–400 mesh resin. This is demonstrated on the elution curve shown in Fig. 1, which has been enlarged in the vertical direction to show the sharpness of the tail ends. The method thus compares favourably with the anion-exchange procedures of Kraus *et al.*[1] and Korkisch *et al.*,[10] which show considerably more tailing. Recoveries in the analysis of synthetic mixtures (Table IV) are excellent and average 100·0 ± 0·1% for amounts from 1 to 100 mg. The accuracy of the analysis results for synthetic mixtures is mainly dependent on the accuracy of the method of determination because this introduces the major part of the error.

The additional anion adsorption step for the separation of gallium from solutions containing large amounts of acetone is necessary for accurate work, otherwise gallium recoveries will only be about 98–99%. When the method is applied to semiconductor alloys containing group IIIA elements as well as arsenic, the arsenic will accompany the thallium, and can be separated by an additional anion-exchange step when required. Even at room temperature As(III) is extremely volatile from hydrochloric acid containing more acetone and is partially lost even from drops falling from the tip of the column into a beaker. For complete recovery the tip should dip into a fair volume of water containing sulphide.

When large amounts of thallium are present, Tl(III) tends to be reduced and may precipitate as TlCl in the column, apparently because the chlorine or bromine added initially is slowly used up by reaction with the acetone. In such cases it is better to elute thallium with aqueous 0·1*M* hydrobromic acid containing a little free bromine. In, Ga and Al are also strongly retained under these conditions and the bromide complexes of Tl(III) are considerably more stable to reduction than the chloride complexes.

Zusammenfassung—Bis zu 4 mMol (je 1 mMol) dreiwertiges Al, Ga, In und Tl werden an einer 60 ml-Säule AG50W-X8-Harz der Teilchengröße 200–400 mesh durch Kationenaustauschchromatographie in Salzsäure-Aceton-Gemischen voneinander getrennt. Die Trennungen sind sehr scharf und verlaufen ohne Schwanzbildung. In Testmischungen werden durchschnittlich 100,0 ± 0,1 % bei Mengen von 1–100 mg wiedergefunden. Ein Anionenaustauschverfahren zur Abtrennung von Gallium aus dem Salzsäure-Aceton-Eluat wird beschrieben. Die wesentlichen Kationenaustausch Verteilungskoeffizienten, die Anionenaustauschkoeffizienten für Gallium in Aceton-Salzsäure und eine Elutionskurve für alle vier Elemente und die Ergebnisse quantitativer Trennungen von Testmischungen werden angegeben.

Résumé—On sépare l'un de l'autre jusqu'à 4 mmoles (1 mmole de chaque) d'Al, Ga, In et Tl trivalents sur une colonne de 60 ml de résine AG50W-X8 de dimensions de particule 200–400 mailles par chromatographie d'échange de cations en milieux acide chlorhydrique-acétone Les séparations sont très nettes et sans traînées. Les récupérations pour des quantités de 1–100 mg s'établissent en moyenne à 100,0 ± 0,1 % pour l'analyse de mélanges synthétiques. On décrit une méthode d'échange d'anions pour la séparation du gallium de l'éluat acide chlorhydrique-acétone. On présente les coefficients de partage échange de cations et les coefficients d'échange d'anions concernant le gallium en acide chlorhydrique-acétone, une courbe d'élution pour les quatre éléments, et les résultats de séparations quantitatives de mélanges synthétiques.

SPECTROPHOTOMETRIC DETERMINATION OF COPPER IN ALKALINE SOLUTIONS AND EVALUATION OF SOME HYDROXY-SUBSTITUTED 1,10-PHENANTHROLINES AS CHROMOGENIC REAGENTS

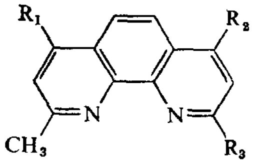
W. E. DUNBAR and A. A. SCHILT
Department of Chemistry, Michael Faraday Laboratories,
Northern Illinois University, DeKalb, Illinois 60115, U.S.A.

(*Received* 6 *December* 1971. *Accepted* 6 *January* 1972)

Summary—Seven new hydroxy-substituted 1,10-phenanthroline derivatives have been evaluated as chromogenic reagents for the determination of copper in strongly alkaline solution. The most sensitive of these, 2,9-dimethyl-4,7-dihydroxy-1,10-phenanthroline, has proven to be highly effective in a simple, rapid procedure for determining trace amounts of copper in sodium hydroxide, potassium carbonate, sodium phosphate or ammonium hydroxide.

DISCOVERY of the extraordinary ability of 4,7-dihydroxy-1,10-phenanthroline to form a stable iron(II) chelate in concentrated, even saturated, sodium hydroxide solutions led to its study and use as a chromogenic reagent for the determination of iron in strongly alkaline substances.[1] Moreover, it called attention to the desirability of incorporating hydroxy groups in substituted 1,10-phenanthrolines as a promising means of extending their usefulness as metal chelate ligands to higher pH regions. Contrary to the findings of an earlier study,[2] the presence of a hydroxy group in 1,10-phenanthroline enhances its co-ordination affinity towards iron(II), provided that solutions are strongly alkaline and that an effective reductant, such as sodium hydrosulphite, is employed to prevent atmospheric oxidation of the iron(II).[3]

One of the more promising possibilities, with regard to utilizing the effect of hydroxy substituents, was the modification of the highly selective copper reagents cuproine (2,2′-biquinoline) and neocuproine (2,9-dimethyl-1,10-phenanthroline). By introduction of hydroxy groups into the structures of these important analytical reagents their applicability should be extended to strongly alkaline solutions, thereby eliminating the disadvantages associated with the necessity for neutralization and pH adjustment. However, synthetic problems proved formidable, and progress has been slow. The first success was achieved by Case and Lesser in 1966, who prepared the dihydroxy derivative of cuproine (4,4′-dihydroxy-2,2′-biquinoline).[4] Fulfilling expectations, this compound proved to be a highly effective chelation reagent for copper in concentrated alkaline solutions.[5] More recently, Case succeeded in the difficult synthesis of a number of 4-hydroxy and 4,7-dihydroxy-1,10-phenanthrolines, including the long sought-for neocuproine derivative 2,9-dimethyl-4,7-dihydroxy-1,10-phenanthroline.[6] These phenanthrolines, and their characterization as analytical reagents, are the subject of this paper. Each of the seven identified below will be referred to hereafter by a Roman numeral.



Compound	R_1	R_2	R_3	*Name (prefix) of substituted* 1,10-*phenanthroline*
I	OH	OH	CH_3	2,9-dimethyl-4,7-dihydroxy-
II	OH	OH	C_6H_5	2-methyl-4,7-dihydroxy-9-phenyl-
III	OH	OCH_3	CH_3	2,9-dimethyl-4-hydroxy-7-methoxy-
IV	OCH_3	OH	C_6H_5	2-methyl-4-methoxy-7-hydroxy-9-phenyl-
V	OH	H	CH_3	2,9-dimethyl-4-hydroxy-
VI	H	OH	C_6H_5	2-methyl-7-hydroxy-9-phenyl-
VII	OH	CH_3	CH_3	2,7,9-trimethyl-4-hydroxy-

EXPERIMENTAL

Apparatus and reagents

A Cary Model 14 recording spectrophotometer and a Corning Model 7 pH meter with saturated calomel and glass electrodes were used for spectral and pH measurements respectively.

The substituted phenanthrolines were samples of the original analysed samples synthesized and reported by Case.[6] Solutions (0·01*M*) of these were prepared by dissolving weighed amounts in measured volumes of 95% ethanol.

Standard copper sulphate solution containing 0·1589 mg of Cu/g was prepared by dissolving pure copper in nitric acid, fuming with sulphuric acid, cooling and adding water to give a known concentration. The 10% hydroxylamine hydrochloride solution was prepared by dissolving 100 g of the salt in 900 g of water. All chemicals were reagent quality, except for the isopentanol, which was purified grade.

Absorption spectra

Solution conditions and pH for maximum colour development in the copper reaction of each new phenanthroline derivative were determined. These were reproduced in preparing solutions for spectral examination when determining the visible absorption characteristics of the copper complexes.

Solutions of the copper(I) complexes of the dihydroxy derivatives (compounds I and II) were prepared by delivering weighed amounts of the standard copper solution into 10-ml volumetric flasks, followed by 1 ml of 10% hydroxylamine hydrochloride solution, 5 ml of 8*M* sodium hydroxide, 2 ml of 0·01*M* phenanthroline derivative, and sufficient distilled water to dilute to volume. Copper(II) solutions were prepared similarly, but without hydroxylamine hydrochloride.

The copper(I) complexes of the monohydroxy derivatives (compounds III–VII) proved to be insoluble in aqueous solutions, so extraction into isopentanol was employed to prepare solutions for spectral examination. Weighed samples of the copper solution were delivered into 60-ml separatory funnels, followed by addition of 2 ml of 10% hydroxylamine hydrochloride solution, 20 ml of 5*M* sodium hydroxide, and 1 ml of the 0·01*M* phenanthroline derivative (in the order cited). After mixing, the contents were extracted first with a 5-ml and then a 1-ml portion of isopentanol. The extracts were combined in a 10-ml volumetric flask and diluted to volume with 95% ethyl alcohol.

Spectra of the prepared solutions and of appropriate blanks were recorded *vs.* air, using a 1·00-cm silica cell. Wavelengths of maximum absorbance, molar absorptivities, and conformity to Beer's law were determined.

Identity and stability of complexes

The method of continuous variations[7] and the mole-ratio method[8] were employed to determine the ligand to metal ratios of the copper(I) and (II) complexes of compounds I and II. For all four complexes, within experimental error, the results indicated two ligand molecules per copper ion. Lack of curvature in the plotted results precluded reliable calculation of formation constants but indicated very high stability for all four complexes.

Acid dissociation constants of compound I were determined from ultraviolet spectral measurements of solutions of various pH containing identical concentrations of I.

Recommended procedure for determination of copper

Transfer a sample (by weight or volume, and of sufficient size to provide a concentration of 1–6*M* hydroxide ion on final dilution) into a 25-ml volumetric flask. If the sample is a carbonate, phosphate, or only a moderately strong base (or does not have the requisite hydroxide ion content), add 5 ml of 5*M* sodium hydroxide to the flask. Add 2 ml of 10% hydroxylamine hydrochloride solution and 4 ml of $2 \times 10^{-3}M$ 2,9-dimethyl-4,7-dihydroxy-1,10-phenanthroline in 0·1*M* sodium hydroxide. Dilute to volume with distilled water, and measure the absorbance in either a 1·00- or 10·0-cm cell (depending on copper content) at 400 nm against a reagent blank.

RESULTS AND DISCUSSION

All seven of the investigated compounds readily form intense yellow or orange complexes with copper(I) in solutions of pH 11 and higher. The copper(I) complexes of the monohydroxy derivatives, compounds **III–VII**, are insoluble in aqueous solution, soluble in aqueous ethanol, and quantitatively extractable into isopentanol. Compounds **I** and **II**, the dihydroxy derivatives, yield water-soluble copper(I) complexes that are not extractable into isopentanol unless an appropriate cation, such as tetrabutylammonium, is present in relatively high concentration.

Less intensely coloured complexes are formed by the seven compounds in reactions with copper(II). The dihydroxy derivatives form blue, water-soluble complexes extractable into isopentanol, from solutions of pH 11 and higher. The monohydroxy compounds yield blue-green soluble copper(II) complexes from solutions of pH 6–9, and much less coloured but stable complexes in more alkaline solutions.

Spectra of the copper(I) and copper(II) complexes of compound **I**, the most sensitive chromogen of the group, are shown in Fig. 1. Wavelengths of maximum absorbance, and molar absorptivities, of the copper complexes of all seven chromogens are listed in Table I. Ranging from 8300 to 11,500 $\mathrm{l.mole^{-1}.cm^{-1}}$, the molar absorptivities are higher than the value of 7,000 found for the complex of 4,4′-dihydroxy-2,2′-biquinoline.[5] This is as expected, since copper(I)–phenanthroline complexes commonly exhibit greater absorptivities than their biquinoline analogues. On the basis of its superior chromogenic properties, as well as other interesting aspects, compound **I** was selected for more extensive investigation and analytical application.

The copper(I) and copper(II) complexes of **I** are both bis-chelates, as shown by the results of mole-ratio and continuous-variations measurements. For both complexes, the most reasonable structure would involve two bidentate ligands with their molecular planes at right angles and their nitrogen atoms co-ordinated in a tetrahedral configuration about copper. The high stability of the complexes, as shown by the completeness of reaction when small but stoichiometric amounts are mixed, even in concentrated sodium hydroxide, argues against other co-ordination modes or structures, all of which, as models show, would involve considerable steric hindrance or strain.

The ionic charge on either of the copper complexes of **I** depends on the extent of ionization of the hydroxy groups, which is governed by pH. In order to predict charge magnitudes, p*K* values for the dissociation of **I** were determined by ultraviolet spectrophotometry. Three sets of isosbestic points are consecutively produced on changing the pH of an aqueous solution of **I** from 0 to 14, demonstrating the existence of three dissociation steps and four acid–base species of **I**. From pH 0 to 5, isosbestic points at 255 and 277 nm are observed, representative of the dissociation of an acid of $pK = 2$, presumably the protonated phenanthroline species $(CH_3)_2(OH)_2phen \cdot H^+$.

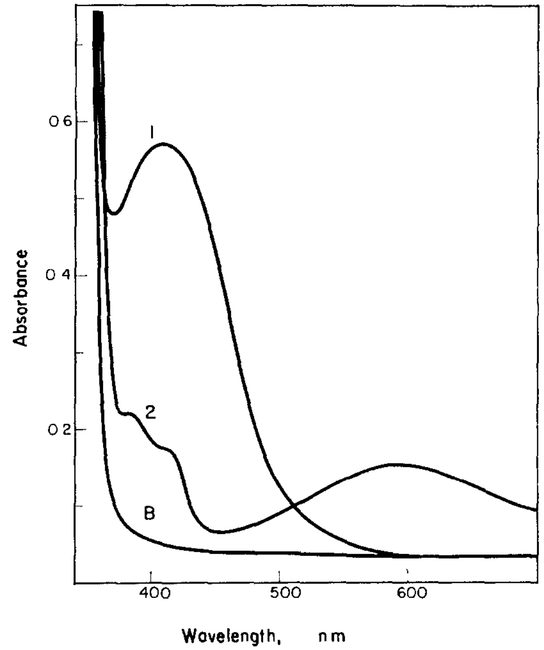


FIG. 1.—Visible absorption spectra of the copper(I) complex (curve 1), copper(II) complex (curve 2) of 2,9-dimethyl-4,7-dihydroxy-1,10-phenanthroline and reagent blank (curve B). Both copper complexes are $4{\cdot}34 \times 10^{-5}M$, measured in 1·00 cm cell *vs.* air.

Over the pH range 2–11, with isosbestic points at 244 and 265 nm, the results are indicative of the dissociation of an acid of $pK = 7{\cdot}5$, believed to be the un-ionized phenanthroline or its zwitterion $(CH_3)_2(OH)(O)^{-}phen \cdot H^+$. Above pH 11, an isosbestic point at 245 nm is displayed, presumed to be associated with the final ionization or deprotonation step:

$$(CH_3)_2(OH)(O)phen^- \rightleftharpoons (CH_3)_2(O)_2phen^{2-} + H^+$$

The p*K* value for this step could not be determined precisely, because of the high pH, and alkaline error of the glass electrode. An estimate, based on hydroxide concentration rather than pH, gives a p*K* value of the order of 13. It is, therefore, concluded that **I** exists predominantly as a doubly charged anion, with both hydroxy protons ionized, in solutions of hydroxide ion concentrations of 1*M* or greater. If the bound ligands ionize to the same degree as the free ligand, then the copper(I) complex exists as $[CuI_2]^{3-}$ and the copper(II) as $[CuI_2]^{2-}$.

Since pH determines the degree of ionization of the hydroxy groups of the bound ligands, and thus the ionic charge on the copper complexes of **I**, it should also affect the spectra and extractability of the complexes. The effect on spectra is especially evident over the pH range from 11 to 13. However, in sodium hydroxide solutions of concentration 1*M* or greater only minor changes in spectra occur, which supports the conclusion that ionization of the hydroxy groups is essentially complete above pH 13. The results are given in Table II. For analytical purposes it is fortunate that the

absorbance of the copper(I) complex of **I** is independent of hydroxide ion concentration over a broad range (1–7*M* NaOH). Precipitation of the copper(I) and (II) complexes of **I** from sodium hydroxide more concentrated than 8*M* is curious, and probably a salting-out effect, but not a serious problem for analytical purposes. The effect of pH or hydroxide ion concentration on extractabilities is also interesting. The copper(I) complex of **I** is not extractable at any pH, whereas the extractability of the copper(II) complex into isopentanol increases from essentially zero at pH 12 to quantitative extractability at 3*M* or higher concentration of sodium hydroxide. Such behaviour with increasing sodium hydroxide concentration is believed to be a consequence of increased ion association between sodium ions and the anionic copper(II) complex, leading to greater extractability, rather than a result of increasing ionization and ionic charge of the complex.

The recommended procedure was evaluated for effectiveness and reliability for the determination of copper in four different alkaline substances of commercial importance: sodium hydroxide, potassium carbonate, sodium phosphate, and concentrated ammonium hydroxide. Because of lack of a variety of different samples to test, synthetic samples were prepared by adding known amounts of standard copper solution to weighed samples of the pure alkaline substances. The analytical results are compiled in Table III. Beer's law is obeyed, and the molar absorptivity of the

copper(I) complex is $11{,}500 \pm 100$ l.mole^{-1}.cm^{-1}, the same for all four media, within experimental error. Colour development is rapid, and no change in absorbance occurs during a one hour period of exposure to the atmosphere. In stoppered flasks the colour is stable for several weeks, and indefinitely if protected against oxygen and carbon dioxide absorption.

Several commonly-encountered substances were tested as possible interferents in the determination of copper. Samples of a 4*M* solution of sodium hydroxide containing 1·90 ppm copper were treated with various amounts of substances added before analysis. None of the following ions, at a concentration of 100 ppm, gave rise to a relative error greater than 1%, and hence these ions do not interfere: acetate, borate, carbonate, halides, halates, oxalate, perchlorate, phosphate, silicate, tartrate, alkali metals, alkaline earth metals, aluminium, ammonium, antimony, arsenic, chromium(III), lead, manganese(II), nickel, and tin(II). Cyanide or sulphide ions cause serious interference, and only 0·01 and 0·1 ppm are tolerated, respectively. If present in excess of 10 ppm, cobalt and zinc interfere by reacting with the chromogenic reagent **I**, larger concentrations are tolerated if more reagent is employed. Iron interferes above 10 ppm and is not masked by addition of tartrate. Its interference can be avoided by modifying the recommended procedure to include an extraction step. If hydroxylamine hydrochloride is omitted, the copper(II) complex can be separated from the iron by extraction with isopentanol followed by back-extraction with 2*M* sodium hydroxide containing hydroxylamine to yield the copper(I) complex for subsequent measurement.

The major advantage of the use of **I** for the determination of copper is that it can be applied directly to alkaline samples without the necessity of neutralization and pH adjustment. This advantage is shared by the closely related copper chromogen 4,4-dihydroxy-2,2′-biquinoline. On comparison, compound **I** (2,9-dimethyl-4,7-dihydroxy-1,10-phenanthroline) is superior in sensitivity and simpler to employ. Unlike its cuproine analogue, the copper(I) complex of **I** is soluble in alkaline solutions, an extraction step or addition of alcohol is unnecessary, and its use in automated procedures is practicable. One disadvantage, common to both chromogens, is that their synthesis is involved and expensive. Fortunately, a small amount suffices for many determinations, so cost should not be a serious deterrent to use.

Zusammenfassung—7 neue Hydroxylderivate von 1,10-Phenanthrolin wurden als Farbreagentien für Kupfer in stark alkalischer Lösung getestet. Das empfindlichste davon, 2,9-Dimethyl-4,7-dihydroxy-1,10-phenanthrolin ist sehr nützlich bei einem einfachen Verfahren zur raschen Bestimmung von Kupferspuren in Natriumhydroxid, Kaliumcarbonat, Natriumphosphat oder Ammoniumhydroxid.

Résumé—On a évalué sept nouveaux dérivés hydroxy substitués de la 1,10-phenanthroline en tant qu'agents chromogènes pour le dosage du cuivre en solution fortement alcaline. Le plus sensible d'entre eux, la 2,9-diméthyl 4,7-dihydroxy 1,10-phénanthroline s'est montrée hautement efficace dans une technique simple et rapide de dosage de traces de cuivre dans la soude, le carbonate de potassium, le phosphate de sodium ou l'ammoniaque.

Aligarh Muslim University, Aligarh (U.P.), India

(*Received* 12 *August* 1971. *Accepted* 9 *December* 1971)

Summary—Stannic selenites have been synthesized under a variety of conditions. The most stable sample is prepared by mixing 0·05*M* solutions of stannic chloride and sodium selenite in the ratio of 1:1 at pH 1. It is a bifunctional amorphous material. A tentative structure has been proposed on the basis of chemical composition, pH titrations, infrared and thermogravimetric analyses. Its ion-exchange capacity is 0·75 and 0·73 meq/g after drying at 50° and 500° respectively. Its analytical importance has been established by the following quantitative separations: Cu^{2+} from Ni^{2+}, Co^{2+}, Fe^{3+}, Ga^{3+} and In^{3+}, Fe^{3+} from Pb^{2+} and Sc^{3+}, and Sc^{3+} from VO^{2+}.

THERE ARE two problems yet to be solved despite the large amount of work already carried out on synthetic inorganic ion-exchangers. They are to develop thermally stable ion-exchange materials and to prepare materials which are specific for certain cations. We have synthesized a number of inorganic substances and studied their properties with these ends in view. Cation separations have been achieved on paper impregnated with stannic selenite,[1] but no further studies were made. The present paper describes the synthesis, ion-exchange properties and analytical applications of stannic selenite.

EXPERIMENTAL

The instrumental studies were performed as described in our earlier paper.[2]

Synthesis

Stannic selenite was precipitated by mixing sodium selenite and stannic chloride solutions under the conditions given in Table I. The pH was adjusted by adding either hydrochloric acid or sodium hydroxide solution. On standing for 24 hr the precipitate settled. It was filtered off, washed first with water at the precipitation pH, then with demineralized water at pH 6, and dried in an oven at 50°. The material was converted into the H^+ form. To study the effect of drying temperatures on the ion-exchanger, different portions of one precipitate (Table I, sample 6) were dried at various temperatures.

Chemical stability

The chemical stability was determined as described earlier.[2] The solubilities are given in Tables I and III. Tin and selenium were determined by the phenylfluorone[5] and the diaminobenzidine[6] methods respectively.

Chemical composition

A 200-mg portion of the ion-exchanger was dissolved in 30 ml of hot concentrated hydrochloric acid. The solution was then cooled to room temperature and selenium was precipitated as red selenium metal[3] with sulphur dioxide solution. The precipitate was filtered off and dried at 105° to constant weight. Tin[4] was estimated by titration with potassium dichromate after prior reduction with lead metal.

Ion-exchange capacity

After elution of hydrogen ions with 0·1, 0·5, 1, 2, 3 and 4*M* potassium chloride it was found that optimum results are obtained with 1*M* potassium chloride. The ion-exchange capacity was determined with 1*M* salt solutions as eluents and the results are given in Table II. Topp and Pepper's method[7] was followed for pH titrations (Fig. 1).

Thermal treatment

Thermogravimetric analysis of various samples in the H^+ form was performed at a heating rate of 4°/min. Sample 6 was also analysed in the potassium form (Fig. 2). To examine the effect of drying temperature on the ion-exchange properties of the material, the orginal precipitates of sample 6 were also dried at various temperatures in a muffle furnace for 2 hr.

RESULTS

X-Ray diffraction analysis

X-Ray photographs of samples dried at 50°, nickel-filtered Cu-Kα radiation being used, show that they are amorphous.

Infrared spectra

Infrared spectra were measured by the standard KBr disc technique (Fig. 3).

Distribution coefficient

K_d values for 27 metal ions were determined on samples 1 and 6 in water (pH 6) and $10^{-2}M$ nitric acid as described earlier.[8] In order to explore the effect of drying on the behaviour of the ion-exchanger, distribution coefficients were also determined on

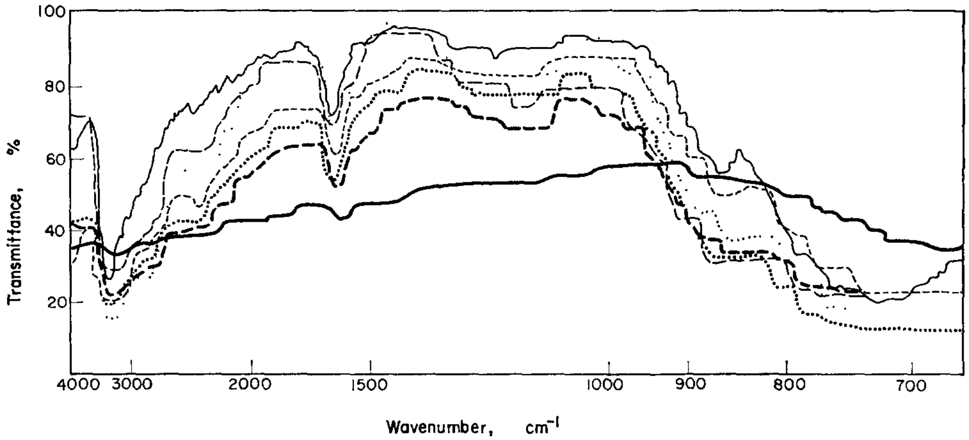

Fig. 3.—Infrared spectra of stannic selenite dried at different temperatures (KBr disc method).

materials dried at various temperatures. These results are summarized in Tables IV and V. The sorption of Ba^{2+} and Cu^{2+} was also tested at different pH values.

Quantitative separations of metal ions on stannic selenite columns:

Separations were achieved on columns of 0·6 cm diameter, using 1·5 g of ion-exchanger (100–150 mesh) in the hydrogen form. The flow-rate was 8–10 drops/min. The metal ions in 10-ml fractions of the effluent were estimated by titration with 0·002*M* EDTA. Quantitative separations of Cu(350 μg)–Ni(230 μg), Cu(350 μg)–Co(185 μg), Cu(350 μg)–In(250 μg), Cu(350 μg)–Ga(180 μg), Fe(175 μg)–Sc(162 μg), Fe(175 μg)–Pb(215 μg), Fe(175 μg–Cu(350 μg) and Sc(162 μg)–V(153·6 μg) were achieved and their elution curves are shown in Figs. 4 and 5.

DISCUSSION

Stannic selenite shows an unusual selectivity towards alkali metals. The ion-exchange capacity of sample 1 decreases from 0·9 to 0·6 meq/g on going from Li^+ to Cs^+. On the basis of the radii of the hydrated ions one would expect the reverse order. This reversal is probably due to the specific size of the cavities. A similar case was observed by Torracca and co-workers[9] who found that in zirconium arsenate the cavities play a more dominant role in the exchange process than any other factor. The exchange capacity of stannic selenite samples for K^+ ions varies from 0·6 to 0·77 meq/g at pH 6. The capacity is dependent on the selenite content as the replaceable hydrogen ions are attached to this group. Thus sample 2 has the maximum capacity. This behaviour is similar to that of other inorganic ion-exchangers of this class. Stannic selenite is unique in one respect: on drying the ion-exchanger at elevated temperatures from 50° to 500° there is an almost negligible loss in ion-exchange capacity (Fig. 6). Zirconium tungstate[10] and titanium tungstate[11] on the other hand are much more sensitive in this temperature range and their ion-exchange capacity is almost completely lost on heating them at 100° and 270° respectively. Stannic

tungstate[12] and stannic molybdate[13] behave in a similar manner. Stannic selenite is therefore superior to other inorganic ion-exchangers as it can be dried at high temperatures without appreciable loss in ion-exchange capacity.

The following conclusions can be drawn from the K_d values (Tables IV and V). Stannic selenite has a very high affinity for many metal ions, *e.g.*, Zr^{4+}, Hf^{4+}, Th^{4+}, UO_2^+, rare earths, Cu^{2+} and Pb^{2+}, even in acid media. The sequence of adsorption for various ions is found to be $Cu^{2+} > Zn^{2+} > Co^{2+} > Ni^{2+}:Al^{3+} > Ga^{3+} > In^{3+}:La^{3+} > Ce^{3+} > Y^{3+} > Al^{3+}$ as in the case of zirconium phosphate. The selectivity order for alkaline earth metals follows a pattern $Ba^{2+} > Sr^{2+} > Ca^{2+} > Mg^{2+}$ similar to that for sulphonic acid resins and also in accordance with the hydrated ion radii, which increase from Ba to Mg.

The effect of drying temperature on distribution coefficients (Table V) reveals many interesting results for alkaline earths and rare earth metals. It can be inferred from the table that the increase in drying temperature from 50° to 300° has very little effect on the K_d values of these metal ions. It is clear that the K_d values generally increase when the drying temperature is raised to 300° and upwards. This characteristic of stannic selenite is in agreement with the measurements of Alberti *et al.*[14] for zirconium phosphate. However, the decrease in K_d values for rare earth metals, especially in the case of Ce^{3+} and Nd^{3+} on exchanger dried at 300°, may be explained by the fact that in addition to condensation, steric and free energy factors sometimes play a significant role which may affect the equilibrium constant. The high uptake on stannic selenite dried at 800° agrees with the findings of Veselý,[15] where obviously no

ion-exchange mechanism is involved and ion-pair formation takes place owing to the conversion of the exchanger into the oxide, as is also evident from the thermogram and ion-exchange capacity data. The absorption sequence for alkaline earth metals on exchanger dried at 500° is $Ca^{2+} > Ba^{2+} > Sr^{2+} > Mg^{2+}$. This behaviour is difficult to explain at this stage as the ion-exchange material is amorphous, but the ions may be retained by a mechanism other than ion-exchange. The variation in K_d values with pH for Ba and Cu ions was also studied. A plot of log K_d *vs.* pH for these ions gave a straight line with a slope of 1 for Ba^{2+} and 1·5 for Cu^{2+}. In an ideal exchange reaction a slope of 2 would be expected for bivalent metal ions. This deviation from the actual value may be due to the simultaneous effect of ion-exchange and other processes, *e.g.*, adsorption. Elution studies showed that most of the hydrogen ions are released from the exchanger with the first 40 ml of the eluent.

Chemical analysis shows that stannic selenite has Sn:Se ratios which vary from 1:1 to 2·2:1. It can be inferred from Table I that the excess of sodium selenite solution in the reaction mixture decreases the tin content in the product (sample 2). Studies have been concentrated on samples 1 and 6 owing to their high ion-exchange capacity and good stability. The composition of sample 6 was found to be Sn:Se = 4:3 and the following formula is tentatively suggested:

$$(SnO)_4(OH)_2(SeO_3)_3 \cdot 6H_2O$$

Thermogravimetric results also provide evidence in support of this formula. The number of water molecules was calculated by the method of Alberti *et al.*[16] The thermogram (Fig. 2) shows two apparent breaks, one at 450° and the other at 775°. There is no change in weight observed on increasing the temperature above 775°. If the formula above is assumed to be correct, the theoretical weight loss due to the removal of 6 water molecules is 10%, in agreement with the experimental value. It may therefore be concluded that the weight loss which continues up to 450° is due to the removal of external water molecules. A sharp increase in weight loss is observed when the temperature is raised to 775°. Significant structural changes must occur over this temperature range and condensation may take place, resulting in the removal of water molecules. Above 775° the weight becomes almost constant owing to the formation of oxides. Infrared absorption spectra and the ion exchange capacity of stannic selenite dried at temperatures above 700° confirm this conclusion.

The infrared absorption spectra of stannic selenite (Fig. 3) dried at various temperatures show three absorption peaks. These spectra, when compared with those of thorium tungstate[2] and stannic arsenate, yield the following interpretation. A very strong peak in the 3800–2900 cm^{-1} region with a maximum at 3400 cm^{-1} represents the interstitial water, free water and OH groups. The strong peak in the region 1700–1500 cm^{-1} is characteristic of interstitial water molecules. The third strong peak in the region 900–700 cm^{-1} may be due to the selenite[17] group. It is interesting to note that infrared spectra of stannic selenite dried at 700° show no absorption peaks and thus confirm the removal of external water molecules and interstitial water from the ion-exchanger.

The pH titration curves give two inflexion points, showing the bifunctional behaviour of the exchanger, which differs from other inorganic ion-exchangers prepared in our laboratory. It can be easily inferred from the curve that the exchanger is not appreciably hydrolysed in acid media. It is also evident that the hydrolysis of sample 1 is more pronounced than that of sample 6 in the pH range 2·5–11, and the reverse holds at above pH 12. Similar types of titration curves are obtained for other samples, except sample 3 which shows only one inflexion point. The molecular weight of 1063 corresponds to a theoretical ion-exchange capacity of 1·8 meq/g and coincides with the practical value at pH 8·2 as obtained from the titration curve.

The exchanger is quite stable in nitric acid and water. Sample 2, in which the Sn:Se ratio is 1:1, seems to be less stable than other samples. It may therefore be inferred that decrease in the tin content decreases the stability. It can also be seen that the drying temperature has little effect on the stability of stannic selenite up to 500°. However, the material appears to be unstable and hydrolyses appreciably if heated above this temperature.

The great affinity and differential selectivity for many metal ions even on drying at high temperatures reveals that stannic selenite is a useful ion-exchanger and a number of separations of metal ions appear possible. Eight binary separations have been achieved quantitatively on a small column (Figs. 4,5).

Zusammenfassung—Zinn(IV)-selenite wurden unter verschiedenen Bedingungen dargestellt. Das stabilste Präparat erhält man durch Mischen von 0,05*M* Lösungen von Zinn(IV)-chlorid und Natriumselenit im Verhältnis 1:1 bei pH 1. Es ist ein bifunktioneller amorpher Stoff. Auf Grund der chemischen Zusammensetzung, von pH-Titrationen und Infrarot- sowie thermogravimetrischen Analysen wird ein Strukturvorschlag gemacht. Nach Trocknen bei 50° bzw. 500° beträgt die Ionenaustauschkapazität 0,75 bzw. 0,73 mÄq/g. Die analytische Bedeutsamkeit geht aus folgenden quantitativen Trennungen hervor: Cu^{2+} von Ni^{2+}, Co^{2+}, Fe^{3+}, Ga^{3+} und In^{3+}, Fe^{3+} von Pb^{2+} und Sc^{3+} sowie Sc^{3+} von VO^{2+}.

Résumé—On a synthétisé les sélénites stanniques sous diverses conditions. L'échantillon le plus stable est préparé en mélangeant des solutions 0,05*M* de chlorure stannique et de sélénite de sodium dans le rapport 1:1 à pH 1. C'est une substance amorphe bifonctionnelle. On a proposé une structure possible sur la base de la composition chimique, de titrages pH, et d'analyses infrarouge et thermogravimétrique. Sa capacité d'échange d'ions est de 0,75 et 0,73 Meq/g après séchage à 50° et 500° respectivement. On a établi son importance analytique par les séparations quantitatives suivantes: Cu^{2+} de Ni^{2+}, Co^{2+}, Fe^{3+}, Ga^{3+} et In^{3+}, Fe^{3+} de Pb^{2+} et Sc^{3+}, et Sc^{3+} de VO^{2+}.

ION-EXCHANGE BEHAVIOUR OF METALS ON DEAE-CELLULOSE IN METHANOL–THIOCYANATE–HYDROCHLORIC ACID MEDIA

ROKURO KURODA, TAKAAKI KONDO and KOICHI OGUMA
Laboratory for Analytical Chemistry, Faculty of Engineering,
University of Chiba, Yayoi-cho, Chiba, Japan

(*Received* 17 *September* 1971. *Accepted* 26 *December* 1971)

Summary—Only a few metals can be adsorbed on DEAE-cellulose from aqueous thiocyanate–chloride media. However, several metal ions, including Cu(II), Zn, Cd, In, Bi and U(VI), exhibit enhanced adsorption on DEAE-cellulose from methanol–thiocyanate–hydrochloric acid mixtures. The distribution coefficients for these metals are given as functions of methanol, ammonium thiocyanate and hydrochloric acid concentration. Differences in adsorption among metals permit many useful separations, including those of two-, three- and four-component mixtures, on short columns containing 1–1·5 g of DEAE-cellulose.

WE HAVE been exploring the possibilities of separating many metals on weakly basic anion-exchangers, particularly DEAE-cellulose(DEAE), both in aqueous media and in mixed aqueous–organic solvent media. Progress in this field has been reviewed in a previous paper[1] and also in a monograph.[2]

Although only a few metals can be adsorbed on DEAE from aqueous solution,[3,4] the addition of a protic solvent such as methanol to nitric[5] and hydrochloric acid[1] solutions improves the adsorption characteristics of nitrato and chloro complexes on DEAE.

We have investigated the adsorption behaviour of a number of metals on DEAE in methanol–thiocyanate–hydrochloric acid media. The number of metals which are adsorbed on DEAE sufficiently to permit their separation on columns is less than the number adsorbed on a strongly basic resin from aqueous thiocyanate–hydrochloric acid media.[6] This provides a basis for developing selective ion-exchange methods.

EXPERIMENTAL

Materials

DEAE(diethylaminoethylcellulose, Serva, 0·74 meq/g) was placed in a large column and treated with 1*M* ammonium thiocyanate adjusted to pH 1 with dilute thiocyanic acid. It was then washed with demineralized water by centrifugation, until the pH of the supernatant liquid was 2·5. After drying at 40° for 2–3 hr, the DEAE was stored in a desiccator over a saturated potassium bromide solution.

Stock solutions of metals were prepared by dissolving appropriate amounts of their salts in 0·5 or 3*M* hydrochloric acid, according to their ease of hydrolysis, to give *ca.* 10 mg of metal/ml.

Equilibrium study

The weight distribution coefficients of Cu(II), Zn, Cd, In, Bi and U(VI) were determined by a batch equilibrium method. The DEAE in the thiocyanate form (0·5 g) was weighed and placed in glass-stoppered conical flasks containing the equivalent of 1 mg each of Zn, Cd, In, Bi or U(VI) and 40 ml of appropriate methanol–ammonium thiocyanate–hydrochloric acid mixtures of various compositions. For Cu(II) 0·30 mg was used to avoid heavy loading. The mixtures were shaken mechanically for 20 hr at 25·0 ± 0·1°. The two phases were separated by filtration and the filtrates were analysed colorimetrically. The distribution coefficient was computed according to the equation:

$$K_d = \frac{\text{(amount of metal in DEAE phase/g of DEAE)}}{\text{(amount of metal in solution phase/ml of solution)}}.$$

Procedure for chromatographic separation

Two types of column (bore 13 mm) containing 1 g and 1·5 g of DEAE are used, the beds being 3 cm and 4·5 cm long, respectively. The columns are pretreated with a methanol–ammonium thiocyanate–hydrochloric acid mixture, the composition of which is the same as that used in the sample preparation. About 5 ml of a sample solution are loaded onto the top of the column, allowed to percolate and then eluted. The individual procedures are shown in Table III and Fig. 3. A flow-rate of 1 ml/min is used throughout.

Analytical methods used for the determination of distribution coefficients and for the effluent analyses are summarised in Table I.

TABLE I.—ANALYTICAL METHODS

Cation	Method
Al	Titration with EDTA, using Cu-PAN* as indicator.
Ni	Colorimetrically with 4-(2-pyridylazo) resorcinol.[7]
Cu(II), Bi	Colorimetrically with diethyldithiocarbamate.[8]
Zn	Colorimetrically with zincon.[9]
Ga	Titration with EDTA, using Cu-PAN as indicator.
Rare earths, U(VI)	Titration with EDTA, using Xylenol Orange as indicator. Traces of the rare earths[10] and U(VI)[11] determined colorimetrically with arsenazo III.
Cd	Titration with EDTA, using Xylenol Orange as indicator. Traces of Cd determined colorimetrically with dithizone.[12]
In	Colorimetrically with Xylenol Orange.[13]

* A mixture of 1-(2-pyridylazo)-2-naphthol and Cu-EDTA.

RESULTS AND DISCUSSION

Adsorption

The distribution coefficients of Cu(II), Zn, In, Bi and U(VI) on DEAE in methanol–ammonium thiocyanate–hydrochloric acid media are indicated in Fig. 1 as a function of methanol concentration, the concentrations of ammonium thiocyanate and hydrochloric acid being kept constant at 1·1*M* and 0·5*M*, respectively. The coefficient increases with increasing concentration of methanol for each metal, indicating the pronounced effect of methanol on the adsorption of thiocyanato complexes on DEAE.

Table II lists the coefficients for Cu(II), Zn, Cd, In, Bi and U(VI) on DEAE as functions of thiocyanate and hydrochloric acid concentrations. Zn, Cd and Bi have already been found to be adsorbed from mixed methanol–hydrochloric acid media.[1] For these metals the coefficient decreases with increasing concentration of thiocyanate, indicating that thiocyanate ions compete with thiocyanato complexes of these metals for the ion-exchange sites. However, the chloride-dependence of the coefficient in the presence of thiocyanate is different with different metals. For example, Zn is adsorbed strongly at lower concentrations of both thiocyanate (0·1*M*) and chloride (0·001–0·01*M*), while Cd is adsorbed weakly under the same conditions.

Pronounced adsorption of Cu(II), In and U(VI) on DEAE was observed when mixed solvent systems involving methanol, thiocyanate and hydrochloric acid were used. In contrast to Zn, Cd and Bi, their coefficients tend to increase with increasing concentration of thiocyanate.

DEAE adsorbs only a limited number of metals from aqueous thiocyanate–chloride media. It is certain that the addition of methanol to the aqueous thiocyanate–chloride media allows Cu(II), Zn, Cd, In, Bi and U(VI) to be adsorbed on DEAE,

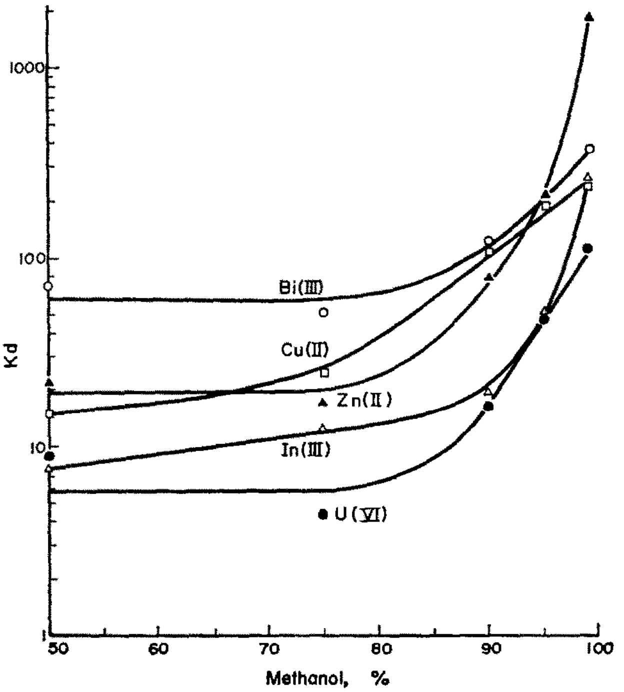

FIG. 1.—Distribution coefficients of metals on DEAE in methanol–1·1*M* NH_4SCN–0·52*M* HCl media as a function of methanol concentration.

TABLE II.—DISTRIBUTION COEFFICIENTS OF METALS ON DEAE IN METHANOL–NH_4SCN–HCl(19:1) MEDIA

	0·0011	55	76	104

but the number of cations adsorbed is still much less than that of metals adsorbed on Dowex 1 from aqueous thiocyanate media[6,14] and from mixed solvent thiocyanate media.[15] Thus, the number of thiocyanato complexes adsorbed by the various ion-exchange systems involved is in the order: strongly basic anion-exchange resin–aqueous thiocyanate and mixed solvent thiocyanate media > DEAE–methanolic thiocyanate media > DEAE–aqueous thiocyanate media.

Figure 2 indicates the effect of loading on the distribution coefficients of Cu(II), Zn, Cd, In, Bi and U(VI) in methanol–thiocyanate–hydrochloric acid media (19:1).

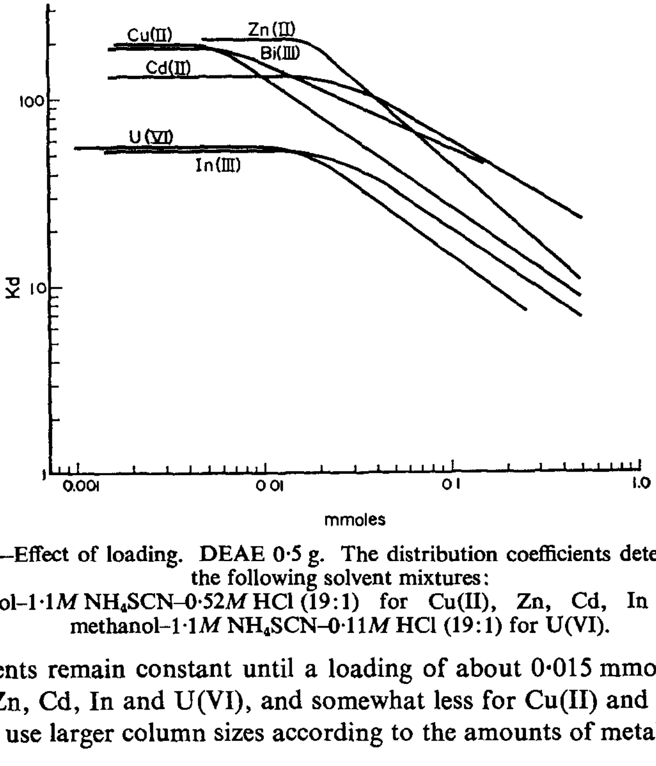

FIG. 2.—Effect of loading. DEAE 0·5 g. The distribution coefficients determined in the following solvent mixtures:
methanol–1·1M NH_4SCN–0·52M HCl (19:1) for Cu(II), Zn, Cd, In and Bi;
methanol–1·1M NH_4SCN–0·11M HCl (19:1) for U(VI).

The coefficients remain constant until a loading of about 0·015 mmole per 0·5 g of DEAE for Zn, Cd, In and U(VI), and somewhat less for Cu(II) and Bi. It may be necessary to use larger column sizes according to the amounts of metal to be loaded.

Separations

The adsorption of most other metals is sufficiently low to allow their separation on columns, and selectivity can still be achieved for the separation of the six metals (Table II) in this ion-exchange system.

Multicomponent separations were attempted and the results obtained are shown in Table III and Fig. 3. Each separation was repeated more than three times and averages and standard deviations are listed for the individual metals. Recoveries are satisfactory. In order to show the versatility of the present ion-exchange system, U(VI) and the mixed rare earths in proportions of 1:100 and 100:1 (runs 2 and 3) were separated from each other. A four-component chromatographic separation is illustrated in Fig. 3. The separation was quantitative and no marked tailing was found.

When cellulosic ion-exchangers are used in mixed solvents, they do not always exhibit their inherent ion-exchange function regardless of the nature of the organic solvent used. For solvent systems involving aprotic solvents a pronounced partition

mechanism appears to prevail, even though apparent adsorption takes place, as revealed in thin-layer chromatographic systems involving DEAE.[16,17] Therefore, a plain cellulosic support may retain metals in some cases.

In the present study it has been demonstrated that the addition of a protic solvent, methanol, to the thiocyanate-hydrochloric acid media permits more metals to be adsorbed on DEAE columns, thus extending the utility of DEAE in inorganic column chromatography.

Acknowledgement—The authors thank the Ministry of Education, Japan Government, for a grant-in-aid.

Zusammenfassung—Nur wenige Metalle können aus wäßrigen Thiocyanat-Chlorid-Medien an DEAE-Cellulose adsorbiert werden. Cu(II), Zn, Cd, In, Bi und U(VI) werden jedoch aus Gemischen von Methanol, Thiocyanat und Salzsäure verstärkt an DEAE-Cellulose adsorbiert. Die Verteilungskoeffizienten dieser Metalle werden in Abhängigkeit von den Konzentrationen an Methanol, Ammoniumthiocyanat und Salzsäure angegeben. Die Unterschiede in der Adsorption zwischen den Metallen ermöglichen viele nützliche Trennverfahren von Gemischen aus zwei, drei und vier Komponenten an kurzen Säulen mit 1–1,5 g DEAE-Cellulose.

Résumé—Seulement quelques métaux peuvent être adsorbés sur la DEAE-cellulose à partir de milieux aqueux thiocyanate-chlorure. Toutefois, plusieurs ions métalliques, comprenant Cu(II), Zn, Cd, In, Bi et U(VI), présentent une adsorption accrue sur la DEAE-cellulose à partir de mélanges méthanol-thiocyanate-acide chlorhydrique. Les coefficients de partage pour ces métaux sont donnés en fonction de la concentration en méthanol, thiocyanate d'ammonium et acide chlorhydrique. Des différences d'adsorption parmi les métaux permettent de nombreuses séparations utiles, comprenant celles de mélanges à deux, trois et quatre composants, sur des colonnes courtes contenant 1–1,5 g de DEAE-cellulose.

CANDOLUMINESCENCE—A NEW FLAME TECHNIQUE FOR TRACE ANALYSIS—I

DEVELOPMENT OF A METHOD FOR DETERMINATION OF BISMUTH

R. BELCHER, S. BOGDANSKI and A. TOWNSHEND
Chemistry Department, Birmingham University, P.O. Box 363, Birmingham B15 2TT, U.K.

(*Received* 6 *December* 1971. *Accepted* 11 *January* 1972)

Summary—Early work on candoluminescence is reviewed and the phenomenon is investigated experimentally for the elements Bi, Mn, Sb and the lanthanides. It is demonstrated that it is feasible to determine bismuth (5–1000 μg) by measuring its candoluminescent intensity at 399 nm, using a calcium hydroxide–calcium sulphate matrix and a hydrogen–helium–air flame.

CERTAIN metal oxides containing trace amounts of activating elements luminesce when placed at the outer edge of a hydrogen diffusion flame. The phenomenon was reported as early as 1842 by Balmain,[1] and was termed *candoluminescence* by Nichols[2] to distinguish it from thermal incandescence, cathodoluminescence and other types of luminescence. Donau[3] has used candoluminescence for qualitative analysis. He detected traces of bismuth and manganese by adding them to calcium carbonate and observing their respective characteristic blue and yellow emissions in the hydrogen flame. Von Neunhoeffer[4] extended this work to provide a qualitative test for a number of lanthanides in a calcium carbonate matrix.

Nichols and his co-workers[2] made a prolonged study of candoluminescence. They investigated numerous activators and matrices,[5] and showed that for many matrix–activator pairs there were particular flame-temperature limits within which luminescence was produced.[6] They also established that luminescence occurred only when the matrix was held at the outer edge of the hydrogen diffusion flame. Smith[7] published a review of developments in candoluminescence up to 1940 in which he clarified some of Nichols's work and presented spectrograms resulting from the presence of bismuth, manganese, lead and antimony in calcium oxide. The nature of candoluminescence remained obscure until Arthur and Townend[8] showed that it arose from a radical-recombination process. The high radical concentration in the outer layers of the hydrogen diffusion flame is thus the reason for the maximal candoluminescence of matrices placed in this region. Recent work by Sokolov and co-workers[9,10] on the mechanism of candoluminescence has confirmed the validity of the radical-recombination theory.

These previous investigations indicated that candoluminescence might provide a very sensitive means of quantitative inorganic analysis, especially for bismuth, lead, manganese and some lanthanides. Initial experiments were carried out by spraying a solution of a calcium salt, containing some bismuth, *via* a conventional flame photometric pneumatic nebulizer, into a hydrogen diffusion flame. No luminescence was observed, probably because the solid particles formed pass too quickly through the flame. All further experiments, therefore, were concerned with obtaining a reproducible luminescence from a solid calcium hydroxide matrix in a fixed position in the flame. Bismuth was chosen as the activator for these development studies because of its easily visible brilliant blue emission. Calcium hydroxide was preferred to calcium carbonate because luminescence was initiated more quickly.

It was found, in accord with the observations of earlier workers, that the most intense candoluminescence occurred when the calcium hydroxide surface was placed at the outer " edge" of the diffusion flame. However, the irregular motion of the flame in this region caused the luminescence to fluctuate greatly in intensity. Addition of nitrogen to the hydrogen made the flame more rigid, but restricted the most active, outer, zone of the flame to a very narrow region, so that it became impossible, with the apparatus used, to position the sample surface reproducibly in this zone. In a hydrogen or hydrogen–nitrogen diffusion flame, no luminescence was observed from a sample surface in the interior of the flame. Introduction of a small proportion of air into the hydrogen *via* the spray aperture of a conventional nebulizer operated by nitrogen, so that the flame temperature was well below 1000°, allowed candoluminescence to be produced in the flame interior. As the composition of the flame interior is less variable than that of the outer zone, accurate positioning of the calcium hydroxide surface became much less critical. However, the intensity of luminescence under these conditions was between 1/10 and 1/100 that produced at the edge of a pure hydrogen flame. This was thought to be due to the nitrogen reducing the incidence of radical recombination by collisional deactivation, and had been observed previously[8]. Replacement of nitrogen by helium, a much less effective quenching agent, gave appreciably enhanced luminescence emission, and was used in all subsequent experiments. No doubt argon would be as effective as helium.

EXPERIMENTAL

Apparatus

An Evans Electroselenium Ltd. (EEL) model 240 atomic-absorption spectrophotometer was operated in the emission mode (0·4 mm slit), with water-cooling device removed. The EEL emission burner with a circular 2·5 cm diameter head was used. Hydrogen was introduced *via* the fuel input system, helium *via* the support gas system, and additional oxygen was available from the secondary support gas system. All gases were mixed before entering the burner head. The spectrophotometer was modified to function, when required, as a scanning instrument, by coupling an electric motor to the wavelength fine-control drive.

The sample-holder assembly is shown in Fig. 1. The sample to be tested was inlayed onto a hexagonal aperture (max. diagonal 5 mm) in the head of a 3 cm long steel Allen screw (outside head diameter 8 mm). The screw was inserted into the accurately positioned bar, so that its head was reproducibly positioned in the flame in line with the optical system, 3·8 cm above the burner head. The screw head was tilted 5° to facilitate contact between the sample surface and the impinging flame.

Reagents

Calcium solution for matrix preparation. Analytical-reagent grade calcium carbonate dissolved in dilute nitric acid and diluted so that 1 g of calcium is contained in 4–10 ml of soln.

Activator solutions. A 10 mg/ml bismuth solution was prepared by dissolving $Bi(NO_3)_3 . 5H_2O$ in 1M nitric acid. A 250 ppm solution was prepared by appropriate dilution with water.

Praseodymium, dysprosium, samarium, neodymium, ytterbium and yttrium solutions were prepared from the acetates. Other lanthanide solutions were prepared by dissolution of the respective oxides, or in the case of erbium a metal ingot, in dilute nitric acid.

Preparation of sample, and measurement of candoluminescence

The calcium solution (containing 0·5 g of calcium) was added to a 30-ml test-tube, followed by the desired volume of activator solution (see below) and water to make up to 10 ml. Plaster of Paris ($CaSO_4 . \frac{1}{2}H_2O$, 1 g) was added, the test-tube was corked, and the mixture shaken well. An excess of 30% sodium hydroxide solution was added, the suspension was shaken for 5 min and filtered by suction on sintered glass until the precipitate had compacted to a dense cake. The solid was inlaid in a *clean* screw head so that the surface was flat and smooth, and the screw was placed in an oven at 105°

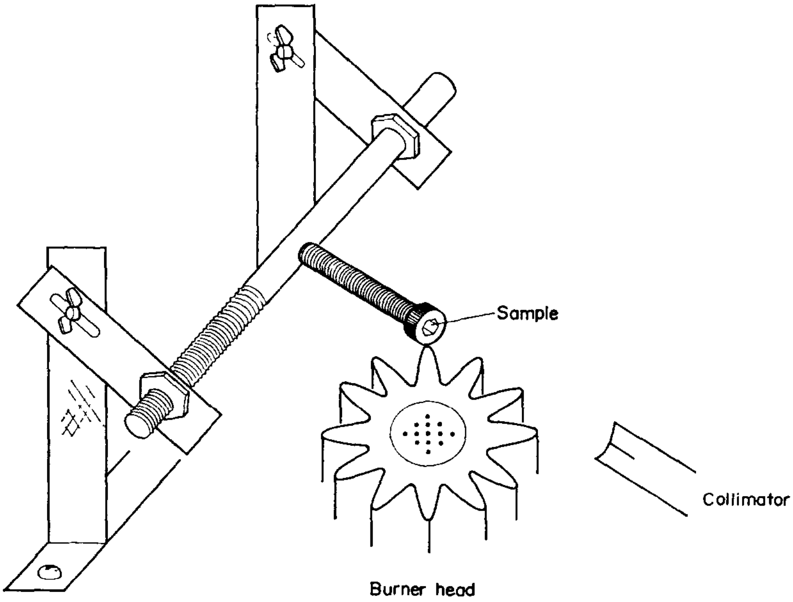

FIG. 1.—Burner and sample holder assembly.

for 15 min. Any excess of material around the inlay was removed, and the screw was inserted into its holder, in the desired position.

The helium was turned on (5·2 units on Brooks tube 4–65) followed by the hydrogen (3·1 units on Brooks tube 4–65) and the flame was ignited. The change in emission intensity with time was recorded on a chart-recorder. The screw was removed from the flame by rotating the bar and replaced by another screw which was then introduced into the flame by rotating the bar back again.

The bismuth-stimulated candoluminescence was measured at 399 nm. A calibration graph for bismuth was prepared by adding the following volumes of 250-ppm bismuth solution to the calcium solution: 20, 40, 60, 100, 300, 500, 700, 1000 and 2000 μl. The maximal intensity produced in each instance was used for the calibration.

The spectra from the various activators (Figs. 2–5) were recorded under the conditions outlined above, *except* that a 10-sec blast of air (4·65 units on Brooks tube 4–65) was introduced into the flame to activate the matrix (see later) before measurement of the candoluminescence.

RESULTS AND DISCUSSION

It quickly became apparent that there were several parameters that had to be recognized and controlled before reproducible luminescence could be achieved. Apart from the flame composition and position of the sample in the flame, which were readily optimized, it was the preparation and pretreatment of the sample that were the greatest problems. Although calcium hydroxide alone was a suitable matrix, inclusion of 50% of Plaster of Paris imparted more rigidity to the matrix and made it easier to produce a smooth surface. The amount of water retained in the matrix was also important. Too much water caused the matrix to shrink when heated in the oven, thus hindering the exposure of the surface to the flame. It was essential, also, to dry the matrix at the relatively low temperature of 105° to avoid forcing the matrix from the screw with a sudden pressure of water vapour. The drying time of 15 min was found to be optimal. Further drying often hampered the initiation of candoluminescence. The activator was introduced into the matrix by co-precipitation. Thus, it was necessary to standardize the conditions of precipitation of the matrix–activator mixture,

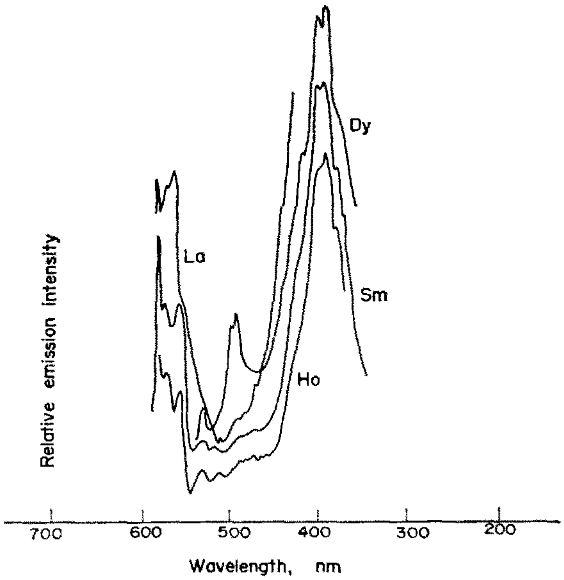

FIG. 3.—Candoluminescence spectra of lanthanum, dysprosium, samarium and holmium (background as spectrum B, Fig. 6).

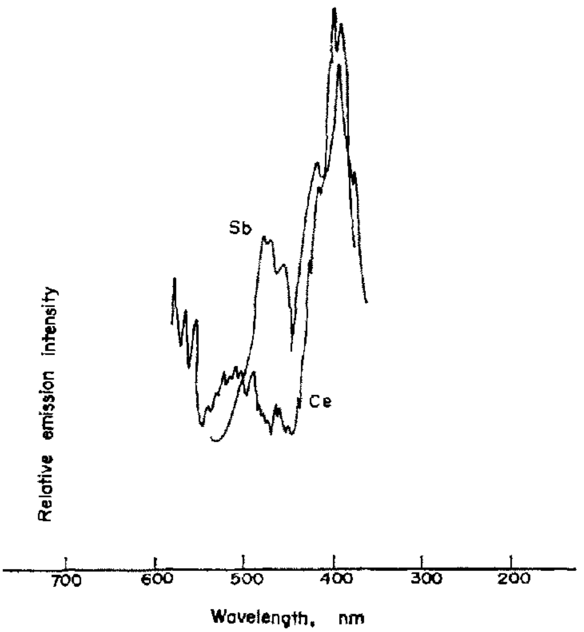

FIG. 4.—Candoluminescence spectra of cerium and antimony (background as spectrum B, Fig. 6).

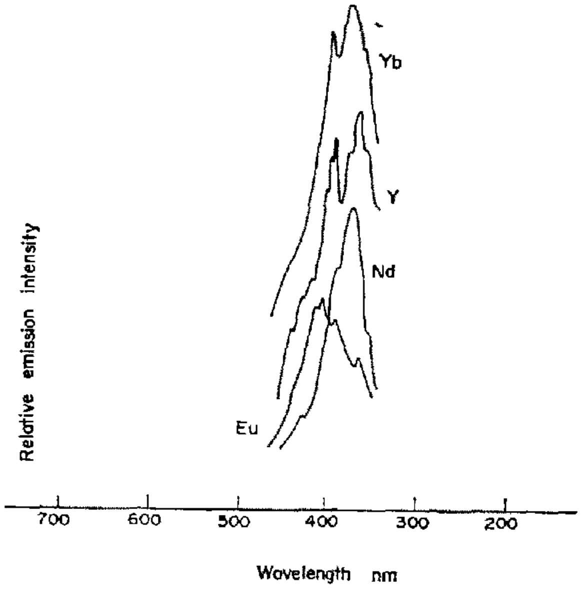

FIG. 5.—Candoluminescence peaks of europium, ytterbium, yttrium and neodymium (background as spectrum B, Fig. 6).

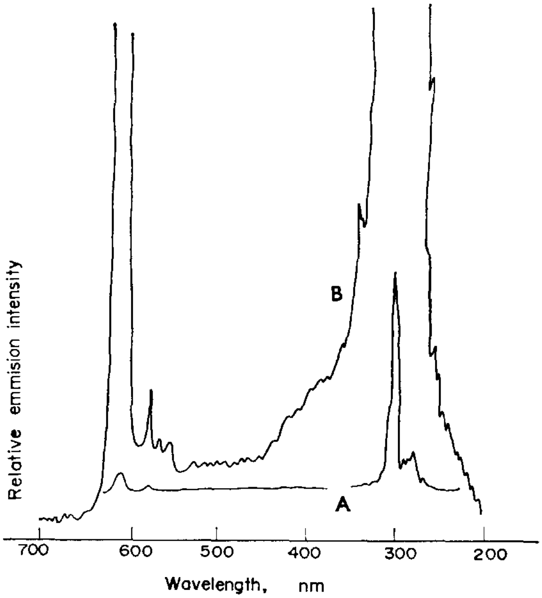

FIG. 6.—Background emission spectrum, with a helium-diluted flame. Spectrum A is recorded at 1/20 the sensitivity for spectrum B.

both to have reproducible activator inclusion in the matrix, and to produce a precipitate with reproducible water-retaining characteristics.

Purity of reagents and screw cleanliness were further sources of variable results. A commercial preparation of calcium hydroxide, laboratory-reagent grade calcium oxide, and calcium hydroxide prepared from laboratory-reagent grade calcium nitrate each gave a yellow luminescence in the absence of added activator, with a spectrum identical to that of manganese-activated candoluminescence (see Fig. 2). Thus it was necessary to prepare calcium hydroxide from analytical-reagent grade materials; such a matrix was free from the yellow luminescence, and gave a background as shown in Fig. 6. The screws required scrupulous cleaning to remove candoluminescent material. This involved scraping out most of the matrix, washing with dilute hydrochloric acid, followed by water and finally heating to red-heat in the hydrogen-added air flame.

Determination of bismuth

Figure 2 shows the candoluminescence spectrum of bismuth; the peak was at 399 nm. The change in intensity of the emission at this wavelength, measured under the recommended conditions, that occurs after ignition of the flame, is shown in Fig. 7. There was a constant time before light emission began which was independent of activator concentration. The shape of this emission–time curve could be changed, however, by altering the rate of air aspiration or by changing the position of the sample in the flame. Under constant flame conditions and with reproducible sample preparation technique, the maximal intensity of the emission at 399 nm was a function of the amount of bismuth added to the calcium solution. A log-log calibration graph was linear (Fig. 8). The vertical diameter of each spot represents the standard deviation calculated from 12 intensity measurements made on samples taken from one

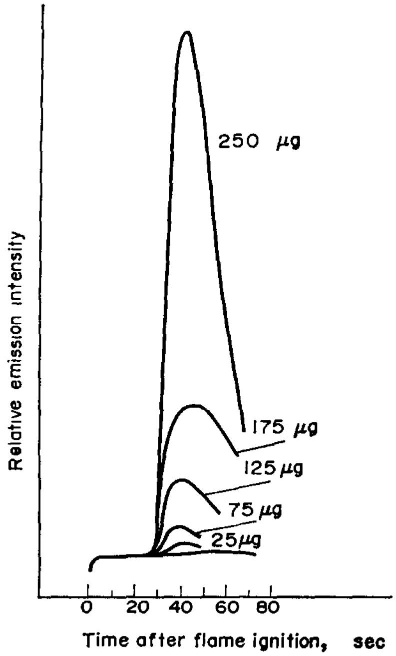

FIG. 7.—Variation in emission at 399 nm with time, for the amounts of bismuth shown.

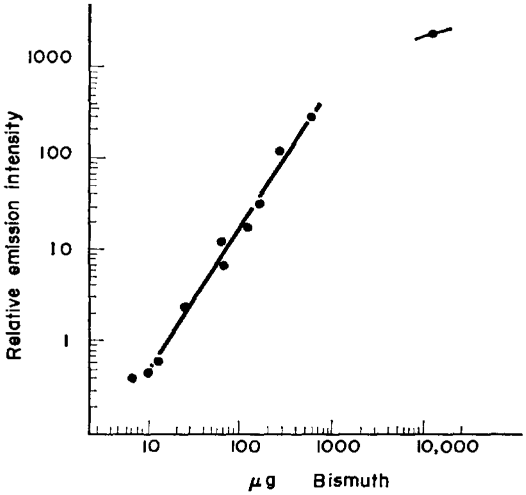

FIG. 8.—Variation of peak emission intensity at 399 nm with amount of bismuth.

calcium hydroxide precipitation. The coefficient of variation remains at *ca.* 10% over the whole range of bismuth concentrations studied. In order to achieve this precision with the apparatus used, it was necessary to work in diffuse light, to avoid variations in background illumination.

Figure 7 also shows the background spectrum in the absence of bismuth. The only emissions recorded, which were also present in the absence of the screw, were the OH band at 306 nm (and the second-order band at 612 nm) and a very faint emission at 589 nm, presumably arising from traces of sodium. The region between *ca.* 320 and 600 nm was thus free of significant background variation.

The present paper is intended to establish the feasibility of using candoluminescence as an analytical technique. It was possible, by using increased detector amplification, to detect as little as 0·5 μg of bismuth added to the original calcium solution. However, as only a small fraction of the calcium precipitate was used for one screw inlay, and as it is probably only the surface layers of the inlay that are involved in candoluminescence, the amount of bismuth actually being monitored is probably in the ng region. Investigations are continuing in order to achieve such increased sensitivity.

Effects of other activators

Previous workers have identified a number of activators, especially many of the lanthanides, that induce candoluminescence when present in a calcium hydroxide matrix. The candoluminescence of the following elements was measured by using the flame and sample preparation conditions optimized for bismuth: Mn, Fe, Ni, Pb, Y, Sb, La, Ce, Pr, Nd, Sm, Eu, Gd, Dy, Ho, Er and Yb. Of these, only iron, nickel, gadolinium and erbium gave no luminescence, although gadolinium gave a bright red luminescence when more air was added to the flame. The candoluminescence colours given by the other elements investigated are summarized in Table I, together with the wavelengths of the major candoluminescence peaks, and the colours observed by Donau,[3] Smith[7] and von Neunhoeffer.[4] Observations by Nichols are not included because many of his "pure" matrices were also observed to luminesce. Apart from the colours of lanthanum and samarium, the present observations agree with those of previous workers.

The candoluminescence spectra of the elements investigated are shown in Figs. 2–5. The spectrograms of lead, bismuth, manganese, antimony and praseodymium, as measured by Smith,[7] agree closely with the present spectra. Manganese, lead, bismuth and praseodymium each gave only one emission band, although praseodymium must have had another peak at a wavelength greater than that of the peak observed but not picked up by the photodetector system used, because the luminescence was red. The praseodymium spectrogram given by Smith[7] shows an additional peak at 600 nm, which would have been obscured in the present instance by the second-order diffraction of the 306 nm OH band. Samarium, lanthanum and holmium gave almost identical spectra, and that of dysprosium differed from these only in the presence of additional peaks at 490 and 530 nm (Fig. 3). Cerium and antimony (Fig. 4) gave intense, complex spectra, whereas neodymium, yttrium, ytterbium and europium all gave multiple peaks in the 400 nm region.

It is interesting that although individual elements gave rise to characteristic candoluminescence spectra, those spectra usually consisted of one or more peaks occurring in three spectral regions, *viz.* ~400, 500 and 570 nm. Only manganese was an exception, with a single emission peak at 600 nm. Thus, although a number of spectral bands may be resolved from each other, as in the case of manganese and bismuth, the grouping of emission peaks limits the possibilities of resolving the spectral peaks of different elements, and thus restricts the selectivity of the technique. However, other possibilities exist for improving selectivity. Although a detailed investigation of interference effects has not yet been made, it was apparent that appreciable differentiation

TABLE I.—CANDOLUMINESCENCE GIVEN BY VARIOUS ACTIVATORS

Activator	Peak maxima, *nm*	Emission colour (intensity)	Previously observed colour
Mn	568	yellow (v.s.)	yellow
Y	387,360	blue-violet (s)	blue-violet
Sb	390,480	green-blue (v.s.)	blue-green
La	400,395,568	white-yellow (s)	brick red
Ce	395,500,568	green (s)	yellow-green

between elements with similar candoluminescence spectra could be made by changing the flame conditions. The spectra in Figs. 2–5 were all measured *after* the sample had been pretreated in a hydrogen–helium flame into which a 10-sec blast of of air had been injected. Without this pretreatment, praseodymium and a number of other elements did not give rise to luminescence, whereas bismuth still gave an intense emission, as shown by the analytical procedure for bismuth, which does not involve pretreatment in the flame. An increase in the permanent amount of air introduced into the flame caused the 400-nm peaks of dysprosium and cerium to disappear, although the red emission from gadolinium now became apparent. Bismuth still responded well in the presence of extra air, although the time–luminescence response (Fig. 7) was markedly changed. These phenomena are a consequence of the different flame conditions (temperature, radical concentrations, *etc*) required to produce candoluminescence in the presence of different activators. Thus, judicious choice of flame conditions could lead to appreciable differentiation between activators, although precise control would be essential for quantitative analytical measurements.

Conclusion

Candoluminescence has been shown to be a sensitive and potentially useful technique for the determination of bismuth. It is expected that much greater sensitivity will be achieved as the technique is developed and refined. At present, the sample preparation involves co-precipitation of bismuth with the calcium hydroxide used in the matrix. This is time-consuming and wasteful of sample, and methods of direct introduction of bismuth into the inlaid matrix would be preferable and give much greater analytical sensitivity. Methods for achieving this are being investigated.

The technique also appears to provide a sensitive means of determining many of the lanthanides, as well as manganese, antimony and lead. A detailed examination of these elements is in progress.

Zusammenfassung—Es wird eine Übersicht über frühe Arbeiten auf dem Gebiet der Candolumineszenz (Lumineszenz über 1000°C erhitzter Stoffe) gegeben und das Phänomen an den Elementen Bi, Mn, Sb und den Lanthaniden experimentell untersucht. Es wird gezeigt, daß man Wismut (5–1000 μg) durch Messung seiner Candolumineszenz-Intensität bei 399 nm bestimmen kann. Man verwendet eine Calciumhydroxid-Calciumsulfat-Matrix und eine Wasserstoff–Helium–Luft-Flamme.

Résumé—On passe en revue les travaux anciens sur la candoluminescence et l'on étudie le phénomène expérimentalement pour les éléments Bi, Mn, Sb et les lanthanides. On démontre qu'il est possible de doser le bismuth (5–1000 μg) en mesurant son intensité candoluminescente à 399 nm, en utilisant une matrice hydroxyde de calcium–sulfate de calcium et une flamme hydrogène–hélium–air.

Summary—A carbon rod flameless atomizer is used for the determination of Cr in water, sea-water, sugar, glycine and blood. The reported analytical curves show that the quantitative determination of Cr in these matrices is feasible in the ppM–ppm range. The influence of the most common anionic and cationic interferents is reported.

SEVERAL methods for the determination of traces of chromium in different matrices have been investigated by a number of workers. In Table I some results from recent papers are gathered.[1–12] No attempt at a critical evaluation of these results has been made, but a rapid survey shows that ppM sensitivity can be reached with several techniques, sometimes with the help of a prior extraction.

Determinations of a number of elements at this impurity level are demanded by modern clinical analysis and by pollution control or environmental studies. The sensitivity is not the only demand made by these fields: further requirements are small size of sample (clinical analysis), freedom from interference by major constituents, and simplicity and rapidity (for possible automation or field application in environmental studies). In our opinion flameless atomic-absorption spectroscopy is a good candidate to fill these requirements, as is evident from the increasing literature in this field. Whereas for the L'vov furnace some conclusive results are reported,[9,13–27] there is a paucity of analytical data for the simpler West-type carbon rod, especially for the less volatile elements, in matrices other than water solutions.

In this study we have tried to assess the possibility of using the carbon rod atomizer for determination of subnanogram amounts of chromium, stressing more the aspect of interference effects in actual matrices than further improvement of the detection limit, on which other work is in progress in this laboratory.

EXPERIMENTAL

Reagents

All chemicals used were of analytical grade purity. Stock solutions were prepared with demineralized water and stored in polyethylene bottles. The chromium solutions were standardized by EDTA titration. The most dilute solutions were freshly prepared before use. In order to avoid erratic effects due to hydrolysis of Cr(III) followed by precipitation, the solutions were acidified to pH 1.

The argon used was certified to contain $<0{\cdot}1$ ppm *v*/*v* of oxygen and <5 ppm *v*/*v* of water. The hydrogen was certified to contain <5 ppm *v*/*v* of oxygen and <5 ppm *v*/*v* of water. At the beginning the gases were freed from oxygen and water by flowing them through two towers filled with pellets of a copper-based catalyst (BASF-Germany) kept at 150°. Since no improvement in the strength of the signal was found this purification was discontinued.

Apparatus

The instrumentation has already been described.[27] Some minor modifications were introduced into the flameless atomizer: (a) the rod supports were water-cooled; (*b*) the material chosen for the

TABLE I.—REPORTED RELATIVE AND ABSOLUTE DETECTION LIMITS FOR CHROMIUM WITH DIFFERENT ANALYTICAL TECHNIQUES

Technique	Relative detection limit	Absolute detection limit	Matrix	Experimental conditions	Remarks	Ref.
Neutron activation analysis	Sub ppM range		blood	8×10^{17} neutron/cm^2/sec; 5–6 weeks of cooling time after irradiation	high neutron flux	1

rod was vitreous carbon, since it gives less interference at the highest temperatures.* The rod had a small cavity 1 × 1 × 2 mm at the centre. Temperatures up to 1600° were determined with a Pt(Pt, Rh 10%) thermocouple. Higher temperatures were evaluated by melting different metals in the form of thin strips wrapped around the rod. The highest temperature used was about 3000°. A step-down transformer was used with maximum output 30 V and 100 A. At variance with the previous report,[27] in this work steeper impulse signals were realized (rise-time 50 msec as measured on the oscilloscope so that the rise-time of 0·5–0·6 sec as read at the recorder was practically the overall time-response of the detector–amplifier–recording system. The maximum absorbance was measured on the plot of absorbance *vs.* time.

The flow-meters were calibrated according to the gas used. The sample (usually 1 or 2·5 μl) was injected with a micrometer syringe fitted with a polyethylene needle.

RESULTS AND DISCUSSION

Experimental parameters

The experimental conditions used in order to obtain the maximum signal were as follows.

(*a*) The 357·87 nm line was used (the sensitivity of the 359·35 nm line was 30% lower, at variance with the results reported[28] for flame AAS).

(*b*) Slit-width of 0·05 mm, corresponding to a band pass of 0·25 nm.

(*c*) A carrier gas flow-rate of 1 1./min was found the most convenient.

(*d*) Argon gave the best result as carrier gas. Hydrogen had a depressant effect on the signal, when flowing in the cell during the thermal "flash". The effect of hydrogen apparently could not be ascribed to a cooling of the rod surface, since increase of the input power did not restore the signal found in presence of argon.

(*e*) Owing to the dynamic character of the process of atomization the maximum temperature reported above (3000°) does not represent an average temperature of vaporization of chromium atoms but only the final temperature of the rod at the end of the thermal "flash". In this connection it is not so important to define the highest temperature experienced by the rod as to produce at the surface of the rod a variation of temperature fast enough to yield as compact as possible a burst of atoms, keeping in mind that the strength of the signal is also limited by the overall response of the detector–amplifier–recorder system. Practically every time a new rod was used, other conditions being equal, the optimum value of the voltage for the thermal flash was checked. Because of the similar dimensions of the rods used, this operation was not particularly time-consuming.

Procedure

As previously found, a gentle heating at a temperature below 100° in order to dry the sample is important to the final result. For the simplest aqueous solutions of chromium, it does not matter if a thermal treatment precedes the thermal flash or not; in any case a signal of the same strength is obtained and the analytical curves are practically the same. In the case of matrices containing interferent species, however, we have found that it is useful for the suppression of these interferences, or at least for minimizing them, to ash the sample at a temperature of 800–850° with only hydrogen gas flowing (at a rate of about 0·2 1./min). After this step the flowing gas is switched from hydrogen to argon at 1 1./min and the sample is flash-heated.

---

* An evaluation of the different carbon materials used for the rod will be published elsewhere.

Analytical curves and detection limits

Chromium in water gives a calibration curve which in a log/log plot is linear from 10^{-11} to 10^{-9} g, and then tails off. The same curve is obtained with $Cr(NO_3)_3$, Na_2CrO_4 and $Cr(SO_4)_3$. All these salts decompose[29–31] to give Cr_2O_3, a fairly stable oxide which is practically not reduced by hydrogen at temperatures up to 1300°.[32] Carbon is able to convert Cr_2O_3 into carbide at 1100°,[33,34] but it is doubtful if this can be a convenient route to Cr atoms, since there is the possibility of losing atoms of the analyte by evaporation, as suggested by the lowering of the strength of the signal when ashing at such a high temperature. $CrCl_3$ also gives the same calibration curve, but some care must be exercised to control the temperature during the ashing step, because this compound is much more volatile[35] than Cr_2O_3.

Since this technique makes use of a discrete sample, the response depends on the amount of sample, and accordingly in the calibration curve amounts and not concentrations are used.

In Table II relative standard deviations are reported in terms of chromium concentration, the volumes used also being quoted. From the relative standard deviation of 18% for 10^{-11} g of chromium (signal to noise, S/N, ratio about 5) it is estimated that, assuming $S/N = 2$, the absolute detection limit is approximately 5×10^{-12} g. On the usual 1% absorption basis, the sensitivity was 10^{-11} g.

As far as the relative detection limit is concerned, increasingly lower concentrations could in principle be detected if increasing volumes of sample were used. From a practical point of view volumes in excess of 5–10 μl are not convenient with our rod, and this sets 1 ppM as the relative detection limit, if it is necessary or desired to vaporize a single injection of sample. If the process of injecting and drying the sample is repeated many times, larger equivalent volumes are used and the concentration limit will be lowered. With this technique, using up to 50-μl volumes, we found $0{\cdot}4 \pm 0{\cdot}1$ ppM of chromium in the drinking water of the town of Bari (June 1971). However in presence of a concentrated matrix this process is impractical, owing to the deleterious effect, on the signal, of the concomitant increase of the interfering species.

Anionic and cationic interferences

Figure 1 shows the effect of some sodium salts of different anions on the signal strength of 80 ppM of chromium, from Na_2CrO_4, the volume of the solutions being 2·5 μl. Two patterns are recognizable in this plot. In the first, no practical interference is noted provided the concentrations of the various salts are kept in the ranges indicated in the figure. NaCl, $NaClO_4$ and $NaNO_3$ have in common this behaviour, which should be related to the ability of these salts to decompose and/or to vaporize

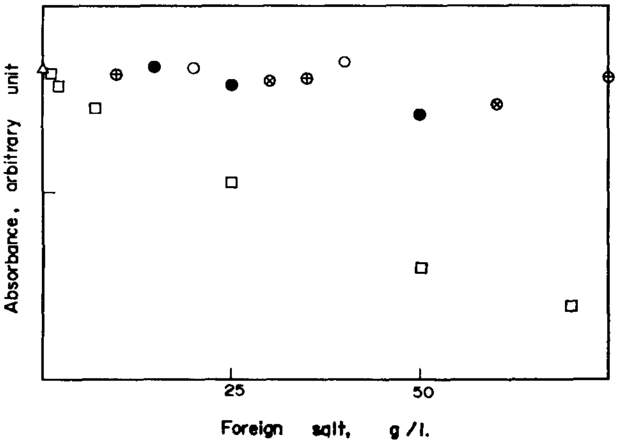

FIG. 1.—Optical response at 357·87 nm of 0·2 ng of Cr in water, as a function of the amounts of different Na salts added. △ Cr alone; □ Cr + Na_2HPO_4; ○ Cr + Na_2SO_4; ⊕ Cr + NaCl; ● Cr + $NaNO_3$; ⊗ Cr + $NaClO_4$.

at temperatures below the 800° used in the ashing step, leaving on the rod a sample with a much simpler matrix. (No hydrogen gas should be permitted to flow during the thermal decomposition of perchlorate matrices, since some chromium is observed to be locally vaporized in small plumes and the strength of the signal is accordingly lowered.) When $NaNO_3$ is present, the sample has a tendency to creep out of the notch during the decomposition process even when the temperature of the rod is carefully controlled. This has a negative effect on the signal, probably because the distribution of the sample over a larger area of the rod causes a less compact burst of atoms during the vaporization, owing to the thermal gradients along the rod. For a 2·5-μl sample this effect becomes evident at a sodium nitrate concentration of 50 g/l.

Sodium sulphate, thermally stable under the conditions of the ashing step, also gives no interference provided its concentration does not exceed 40 g/l. For concentrations of sodium sulphate greater than this, at the thermal flash the spray of material from the matrix becomes thick enough to give a scattering signal which simulates the presence of chromium. Disodium hydrogen phosphate at concentrations greater than about 5 g/l. lowers the chromium signal. We cannot say at the moment whether this effect is physical or chemical in nature and further study is necessary to elucidate the mechanism.

For investigation of cationic interferences, silver, nickel, cobalt and iron nitrates and potassium permanganate were used in 1000-fold ratio to chromium (as Na_2CrO_4). The chromium concentration was 80 ppM in a 2·5-μl sample. As mentioned above the presence of hydrogen during the ashing step at 800° is important when the matrix contains a large excess of these cations (except silver), since otherwise a smaller signal and sometimes no signal at all is obtained. As shown in Table III, Ag, Ni, Mn have practically no effect whereas, even with use of hydrogen, Co and Fe cause a loss of 30 % of the chromium signal.

More work is necessary to explain these results; all we can say is that the amount of oxygen in the sample after the ashing step appears an important parameter, possibly because it can increase the chance of recombination to chromium oxide after the flash.

TABLE III.—CATIONIC INTERFERENCES FOR CARBON ROD ATOMIZER

Ratio (interferent)/(Cr)	Signal strength %				
	$AgNO_3$	$Ni(NO_3)_2$	$KMnO_4$	$Co(NO_3)_3$	$Fe(NO_3)_3$
1000	101	98	102	70	70
200				80	83
100				101	90

Interferences from organic matrices

In order to investigate the effect of organic materials, chromium as Na_2CrO_4 was added to concentrated solutions of sugar and glycine. No interference was detected from concentrations of sugar or glycine up to 100 g/l., for 2·5 μl of 80-ppM chromium solution.

Calibration curve for chromium in sea-water

Some difficulties were experienced in the determination of chromium in sea-water since Cr(VI) is reduced in this matrix and the species then present, chromium chloride, is partially vaporized during the ashing step, unless extreme care is taken to control the temperature in order to vaporize NaCl, keeping at the minimum the loss of $CrCl_3$. In fact, even when this fractional vaporization was exploited, a large scatter of results was obtained. Attempts to transform $CrCl_3$ into a less volatile species and to simplify the matrix by displacing chloride with concentrated sulphuric acid were unsuccessful. In spite of the removal of excess of sulphuric acid during the ashing step large signals resulted which were more related to the modified matrix than to the amount of chromium in the sample. The formation of a chromium–EDTA complex and its thermal decomposition was the procedure finally used to obtain the analytical calibration curve.

The sea-water samples (taken from the shore near Monopoli, Bari, July 1971) with known amounts $CrCl_3$ added, were boiled with 0·1% EDTA solution for a few minutes, and then treated as already described. The means of results of five determinations on 2·5-μl samples fell on a straight line with the same slope as the curve obtained with standards prepared in pure water. From the plot a Cr concentration of 2 ± 1 ppM was obtained for the sample of sea-water.

Determination of chromium in blood

The blood was diluted 1:1 with water or with $Cr(NO)_3$ solutions in order to obtain blood samples with different chromium concentrations. Volumes of 1 μl of each sample were slowly preheated under hydrogen gas in order to remove the organic material without mechanical loss. The ashing step at 800° was retained and the gas flow switched from hydrogen to argon before the thermal flash*. The means of five determinations at each concentration gave a linear plot, from which a chromium concentration of 15 ppM was estimated for the pure blood sample. This value is slightly lower than that reported as normal by Metz[36](20–50 ppM) and was independently confirmed on a solution obtained by acid digestion of a 10-ml sample of the same blood at 200° for 1 hr.

---

* A carbon residue on the rod was removed mechanically after every ten runs.

Conclusions

The simplicity, speed in collecting analytical results, and the freedom—at least for the matrices investigated—from major interferences make this technique attractive for the determination of total content of chromium traces.

Acknowledgement—We thank Mr. V. Sacchetti and Mr. S. Giodice for co-operative help in the design and construction of the atomizer. Partial financial support from Consiglio Nazionale delle Ricerche is fully acknowledged.

Zusammenfassung—Zur Bestimmung von Cr in Wasser, Meerwasser, Zucker, Glycin und Blut wird ein Kohlestab als flammenloser Atomerzeuger verwendet. Die mitgeteilten analytischen Kurven zeigen, daß die quantitative Bestimmung von Cr in diesen Materialien im ppM–ppm-Bereich möglich ist. Der Einfluß der häufigsten anionischen und kationischen Störquellen wird mitgeteilt.

Résumé—On utilise un atomiseur sans flamme à tige de carbonne pour le dosage de Cr dans l'eau, l'eau de mer, le sucre, le glycocolle et le sang. Les courbes analytiques présentées montrent que le dosage quantitatif de Cr dans ces matrices est réalisable dans le domaine ppM–ppm. On rapporte l'influence des agents gênants anioniques et cationiques les plus communs.

THE DEPENDENCE OF THE DROPPING MERCURY ELECTRODE POTENTIAL AT CONSTANT CURRENT ON THE CONCENTRATION OF AN ELECTROACTIVE CONSTITUENT INVOLVED IN REVERSIBLE OR IRREVERSIBLE ELECTRODE REACTIONS

YECHESKEL ISRAEL
IMI Institute for Research and Development, P.O. Box 313, Haifa, Israel

(*Received* 3 *September* 1971 *Accepted* 7 *January* 1972)

Summary—A new method is described in which the potential of the d.m.e. is measured as a function of the concentration of an electroactive constituent when a constant current is maintained by adjusting the voltage applied to the polarographic cell. Equations are derived describing the expected potential change caused by changing the concentration of a constituent involved in a reversible or an irreversible electrode reaction. Graphical interpretations of the derived equation are made, indicating the most suitable conditions for performing potential measurements, yielding potential differences that greatly exceed those obtained by conventional potentiometry, especially when the method is applied to irreversible electrode reactions at the d.m.e. Experimental evidence is presented, which not only verifies all expectations, but also indicates that the method offers a new approach to the investigation of some fundamental problems.

THE POTENTIAL of the dropping mercury electrode, d.m.e., depends on the concentration of a pure electroactive constituent in solution, when a constant current, lower than the diffusion current, is maintained by imposing suitable values of the applied voltage to the polarographic cell. It was reported earlier that for mercury(II) solutions the applied voltage required to maintain a constant current, depended on the concentration of mercury(II), in the range 10^{-6}–10^{-5} M, but did not account for the theoretical background of such a correlation.[1]

Figure 1 illustrates this dependence. Each of the lines A–A and B–B is parallel to the slope of polarogram *a*, and gives a constant net current value at its intersection with polarograms *b* and *c*. Each line yields two values of the applied voltage, which are related to a defined current value in the lifetime of a mercury drop (*e.g.*, average, maximum or minimum current). The difference between each pair of values of applied voltage, related to a constant net current measured at the same instant in the mercury-drop cycle, is equal to the difference in potential between the two solutions used for depicting polarograms *b* and *c*, since the voltage drop is the same (ignoring variations of the residual current for each set of values of applied voltage). The measured potential differences, obtained for A–A and B–B in Fig. 1, related to average current values, are *ca.* 33 and 120 mV, respectively. This leads to the conclusion that the potential difference is a function of the current at which the measurement is made, and increases as the current approaches the value of the diffusion current in *b*. For the ratio of concentrations used, 1·5 : 1, the potential difference expected on the basis of direct potentiometry at zero current is only 10·4 mV at 25°, for a one-electron reaction. The present method of measurement seems to offer an advantage over conventional potentiometry, provided that a proper choice of the current value is made.

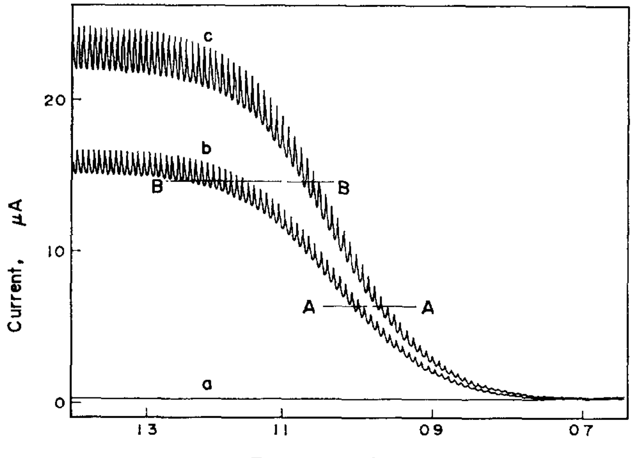

FIG. 1.—Polarograms of 0·1*M* NaOH supporting electrolyte, (a) alone; (*b*) 9·50 × $10^{-4}M$ in chromate; (*c*) 1·425 × $10^{-3}M$ in chromate. The polarograms were highly damped for illustrative purposes only.

This behaviour is unique to the d.m.e., which is a microelectrode with a periodically renewed surface at which electrolysis proceeds without stirring. Under these conditions, immediate polarization of the electrode results when the potential is set to a value corresponding to the rising part or the plateau of the current–potential curve, and is accompanied by a steady flow of current through the polarographic cell. Current reproducibility with time is achieved at a defined potential under conventional polarographic working conditions, as no measurable depletion in bulk concentration occurs during electrolysis, over a reasonable length of time, and a steady ratio of surface activities of the redox couple is established. If various concentrations of a pure compound are used, a constant current will cause various ratios of surface activities of the redox forms of the reactant to prevail, *i.e.*, various values of potential. However, potential is the independent variable whenever conventional polarography is used, suggesting that the present method of measurement is not potentiometry in the classical sense of the term, as opposed to potentiometry at a constant current applied to the d.m.e., in which case the potential is the dependent variable.[2] Other microelectrodes are usually not as suitable as the d.m.e. because they lack periodic surface renewal of the latter and therefore a steady potential is less likely to prevail when a constant current is maintained in the absence of stirring. With a macroelectrode, constant current and constant potential can under no circumstances be achieved simultaneously. Even potentiometry using the d.m.e. at constant applied current is less satisfactory than the present method, mainly on account of potential oscillations during the lifetime of the drops. This is shown by the potential–current relationships obtained with the constant-current polarographic method, developed by Ishibashi and Fujinaga.[3–5] Contrary to conventional polarographic behaviour (where only very slight oscillations in potential are obtained when the current oscillates at a given applied voltage), a constant current applied to the d.m.e. produces wide oscillations in potential which increase in magnitude as the applied current approaches the limiting current. The reason for these oscillations is the periodic variation in the surface area of the electrode. Consider the reduction of chromate ion in sodium hydroxide supporting electrolyte. Early in the drop life, when the diffusion current is small, a constant current, higher than the instantaneous diffusion current, drives the potential of the drop into the region of supporting-electrolyte discharge and simultaneous reduction of chromate and sodium ions occurs during this early stage. Then, as the drop grows, the potential returns (through a region over which the sodium will be stripped out of the drop) to more positive values, eventually reaching the rising part of the chromate reduction wave.[2]

In this paper, simple relationships between the potential change and concentration have been derived from current–potential relationships, both for reversible and irreversible electrode reactions at the d.m.e. These relationships permit the calculation of the potential difference expected for varying concentration ratios. Graphical interpretation and experimental verification of the derived equations are presented. A discussion of specific applications with a special reference to the irreversible reduction of chromate ion in alkali supporting electrolyte is also included.

THEORETICAL DISCUSSION

Reversible electrode processes

The theory of the current–potential relationship for reversible electrode processes has been the subject of discussion of numerous papers and books. The explicit treatment given by Meites,[6] for the various reversible half-reactions occurring at the d.m.e., served as a starting point for the present treatment.

If the diffusion current is proportional to concentration then the potential difference at a constant current i, maintained at the d.m.e., for two concentrations of a pure constituent involved in a reversible reaction is given by the equation

$$\Delta E_{\text{d.e.}} = (E_{\text{d.e.}})_2 - (E_{\text{d.e.}})_1 = \frac{RT}{nF} \ln \frac{i_{\text{d},2} - i}{i_{\text{d},1} - i} \tag{1}$$

The terms appearing in equation (1) have their usual meaning[6] and the numerical subscripts correspond to the solutions used for measurements. The potential refers to the average current value in the lifetime of a drop, for reversible reactions. Equation (1) applies to a variety of diffusion-controlled cases, such as the reduction of a simple metal ion, complexed metal ion, or cationic groups (*e.g.* NH_4^+ and RNH_3^+) forming the corresponding amalgams and also reductions involving only species in solution. In the case of the reversible oxidation of dropping mercury amalgams to form a simple metal ion, a complexed metal ion or a cationic group, and for oxidations involving only species in solution, equation (1) applies in essence, except that the anodic currents, denoted by subscript a, have the opposite sign. The equation for anodic reactions is

$$\Delta E_{\text{d.e.}} = (E_{\text{d.e.}})_2 - (E_{\text{d.e.}})_1 = \frac{RT}{nF} \ln \frac{(i_{\text{d}})_{\text{a},1} - i_{\text{a}}}{(i_{\text{d}})_{\text{a},2} - i_{\text{a}}} \tag{2}$$

For composite cathodic–anodic waves, each section can be treated independently, using either of the equations above. The only exception is the rare case of reversible processes involving a solid that is insoluble in mercury and formed by the reduction of metal ion. In this case the potential difference is given by:

$$\Delta E_{\text{d.e.}} = \frac{RT}{nF} \ln \frac{i_{\text{d},1}(i_{\text{d},2} - i)}{i_{\text{d},2}(i_{\text{d},1} - i)} \tag{3}$$

It is convenient to substitute new parameters x and y into equations 1, 2 and 3. When $i_{d,2} \geqslant i_{d,1}$, or $(i_d)_{a,2} \geqslant (i_d)_{a,1}$, then

$$y = \frac{i_{d,2}}{i_{d,1}} \text{ (cathodic)}$$

and

$$y = \frac{(i_d)_{a,2}}{(i_d)_{a,1}} \text{ (anodic)}$$

(y also corresponds to the ratio of concentrations of the solutions). The parameter x is defined as the ratio of the current at which the measurement of potential is made to the diffusion current of the solution of lower concentration, *i.e.*,

$$x = \frac{i}{i_{d,1}} \quad \text{(cathodic)}$$

or

$$x = \frac{i_a}{(i_d)_{a,1}} \quad \text{(anodic)}$$

Thus equation (1) can be rewritten for cathodic waves, as

$$\Delta E_{d.e.} = \frac{RT}{nF} \ln \frac{y - x}{1 - x} \tag{4}$$

and for anodic waves equation (2) may be rewritten as

$$\Delta E_{d.e.} = \frac{RT}{nF} \ln \frac{1 - x}{y - x} \tag{5}$$

and equation (3) becomes

$$\Delta E_{d.e.} = \frac{RT}{nF} \ln \frac{y - x}{y(1 - x)} \tag{6}$$

The present treatment will be limited to the case of cathodic waves described by equation (4) as, in essence, the same conclusions apply to anodic waves in equation (5), and the case of equation (6) is rare. At 25° and when the potential difference is expressed in mV, equation (4) may be rewritten as

$$\Delta E_{d.e.} = \frac{59{\cdot}15}{n} \log \frac{y - x}{1 - x} \tag{7}$$

It is seen from (7) that a plot of various measured values of $\Delta E_{d.e.}$ *vs.* $\log (y - x)/(1 - x)$, is a straight line with a positive slope of $59{\cdot}15/n$ mV and an intercept of zero. The same result is obtained with constant x and variable y as with variable x and constant y. Although such plots do not provide a simplification over the conventional technique of obtaining the same information from a single polarogram, they still offer a new alternative. Furthermore, as $x \rightarrow 0$, equation (7) reduces to

$$\Delta E_{d.e.} \sim \frac{59{\cdot}15}{n} \log y \tag{8}$$

In this limiting case, the equation approaches the form of the equation describing similar measurements with conventional potentiometry at zero current, provided the activity coefficient of the measured solutions remains constant, viz.

$$\Delta E = \frac{59 \cdot 15}{n} \log \frac{c_2}{c_1} \tag{9}$$

However, as $x \to 1$, for a constant y unusual amplification of the potential change with concentration results, depending on the value of x. A graphical interpretation of this concept is given in the family of curves of Fig. 2, in which $\Delta E_{\text{d.e.}}$ for a one-electron reduction is plotted *vs* x, for various values of y, taken to be constant in each case, on the basis of equation (7). From equation (9), the expected potential increment by conventional potentiometric methods for a one-electron reaction for *e.g.*, $y = 2$, may be calculated to be 17·8 mV. The potential differences by the present method of measurement are expected to be 61·6 mV for $x = 0{\cdot}90$ and 102 mV for $x = 0{\cdot}98$. Another interesting graphical interpretation of equation (7) is given in Fig. 3 where $\Delta E_{\text{d.e.}}$ is plotted *vs* y, for a constant value of x in each case. A family of curves is obtained for various values of x, indicating the advantages of the choice of conditions under which y is small for any constant value of x. From equation (9), for a one-electron reaction a change of 1 % in concentration (or $y = 1{\cdot}01$), causes an expected potential change of 0·26 mV, and from equation (7), under the same conditions, changes of 2·5 and 10·4 mV are expected for $x = 0{\cdot}90$ and 0·98 respectively.

Irreversible electrode processes

Meites and Israel[7] developed an equation describing the current–potential relationship at the d.m.e. for a totally irreversible process, the rate of which is governed by a single transfer step. The equation was derived from relationships that were previously presented for such an electrode reaction by Koutecký.[8] Smith, McCord

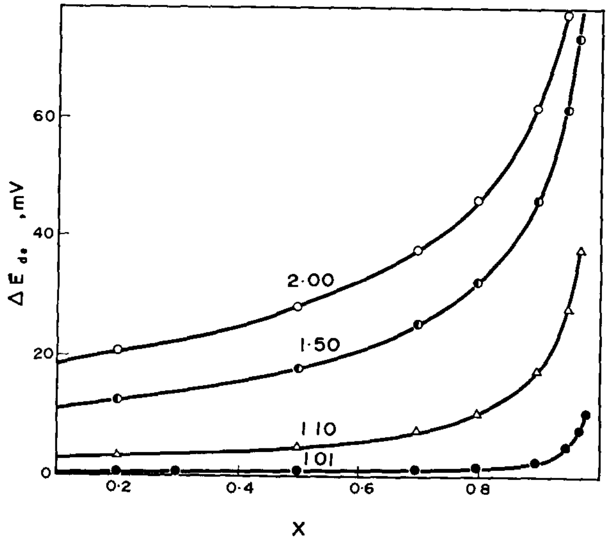

FIG. 2.—Plots of $\Delta E_{\text{d.e.}}$ *vs.* x for a given y; each curve represents equation (7), when $y = 1{\cdot}01$, $1{\cdot}10$, $1{\cdot}50$ and $2{\cdot}00$, respectively.

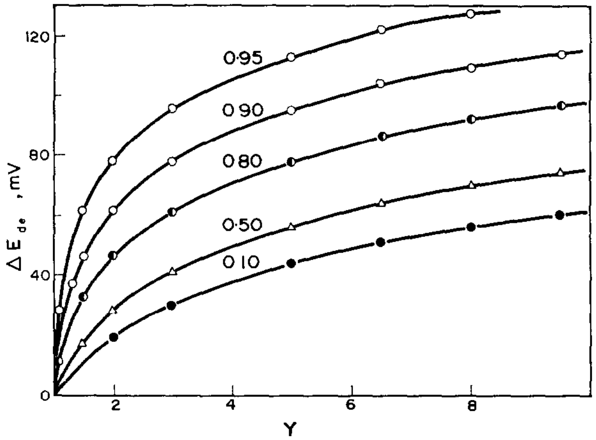

FIG. 3.—Plots of $\Delta E_{d.e.}$ *vs.* y for a given value of x; each curve represents equation (7), when $x = 0{\cdot}10$, $0{\cdot}50$, $0{\cdot}80$, $0{\cdot}90$ and $0{\cdot}95$, respectively.

and Hung[9] examined Meites and Israel's equation and found its accuracy to be sufficient to permit its use in most mechanistic and kinetic applications. This equation[7] can be expressed, in mV and for 25°, as follows:

$$E_{\mathrm{d.e.}} = \frac{59{\cdot}15}{\alpha n}\log\frac{1{\cdot}349k^{0}_{\mathrm{f,h}}}{D} - \frac{54{\cdot}2}{\alpha n}\left(\log\frac{i}{i_{\mathrm{d}}-i} - 0{\cdot}546\log t\right) \tag{10}$$

where D is the diffusion coefficient of the oxidant, α is the transfer coefficient, $k^{0}_{\mathrm{f,h}}$ is the potential-independent rate constant of the forward heterogeneous electrode reaction,[10] and i and i_{d} refer to maximum currents in the lifetime of a mercury drop. Equation (10) is conveniently separated into two terms; the second is dependent on potential and the first is not. This accounts for including the lifetime of the mercury drop, t, in the second term.[6]

From equation (10) and a similar treatment to that applied above for the case of reversible reactions, the potential difference (in mV and for 25°) at constant current at the d.m.e. used for a totally irreversible reduction, is described by the following equation:

$$\Delta E_{\mathrm{d.e.}} = \frac{54{\cdot}2}{\alpha n}\left(\log\frac{i_{\mathrm{d,2}}-i}{i_{\mathrm{d,1}}-i} + 0{\cdot}546\log\frac{t_2}{t_1}\right) \tag{11}$$

With the same definitions of y and x as before but noting that i and i_{d} refer now to the maximum current in the lifetime of the mercury drop, equation (11) becomes:

$$\Delta E_{\mathrm{d.e.}} = \frac{54{\cdot}2}{\alpha n}\left(\log\frac{y-x}{1-x} + 0{\cdot}546\log\frac{t_2}{t_1}\right) \tag{12}$$

Interpretation of equation (12) is analogous to that of equation (7) and suggests that a linear relationship intercepting the origin is expected, with a positive slope of $54{\cdot}2/\alpha n$ (in mV at 25°) when a plot of the measured values of $\Delta E_{\mathrm{d.e.}}$, for various values of x, is made at a constant y *vs.* $[\log(y-x)/(1-x) + 0{\cdot}546\log(t_2/t_1)]$. The same results are obtained for the relationship above, if the plot is made with variable y and constant x. Both plots provide an alternative method for the calculation of the transfer coefficient of the forward reaction. Furthermore, a family of curves is obtained, both when the plot is made for various values of x with constant y and *vice versa*. The general shape of all curves correspond to the curves in Figs. 2 and 3 for reversible reactions, except for the larger potential differences, obtained under identical conditions, in the case of a totally irreversible reaction. The differences are also dependent on the value of α, which is always less than 1. For $\alpha n = 0{\cdot}35$, a value reported for the reduction of chromate ion in $0{\cdot}1M$ sodium hydroxide supporting electrolyte,[7] and for $y = 2$, the expected potential differences are 161·3 and 264·5 mV for $x = 0{\cdot}90$ and 0·98 respectively. For the same transfer coefficient, the expected potential differences for $y = 1{\cdot}01$ and for $x = 0{\cdot}90$ and 0·98, are 6·4 and 27·3 mV respectively. It seems that the present method of measurement is especially advantageous when applied to totally irreversible electrode reactions.

EXPERIMENTAL

Analytical-grade reagents were used for the preparation of the standard solutions and the supporting electrolytes. Argon, after washing with a solution of chromium(II) in dilute sulphuric acid kept over amalgamated zinc, was used for the deaeration of the tested solutions. Mercury was cleaned by passing it through a pin-hole in a filter paper bubbling air through it for a few days after covering it with 8% nitric acid, then washing, degreasing, pin-hole filtering, drying[11] and double-distilling.

Polarograms were obtained with a Metrohm recording instrument, Polarecord E 261 R, after internal calibration of the potential and the current, but often the initial and span voltages were measured at the time of experiment with a Honeywell potentiometer model 2730. In some instances, the measurements of applied voltage were made by using Metrohm E 446 iR compensator. Experimental validity of equations (7) and (12) were usually verified by measurements of $E_{d.e.}$ and $\Delta E_{d.e.}$ from polarograms recorded at the slowest scan speed of *ca.* 1·4 mV/sec for the reversible reduction of thallous ion in $0{\cdot}1M$ potassium chloride supporting electrolyte and at a faster scan speed of *ca.* 2·8 mV/sec. for the irreversible reduction of chromate ion in 0·1 M sodium hydroxide supporting electrolyte. However, in the more detailed and accurate measurements made for the chromate system, either the recording 'polarograph or the manual polarograph previously described[12] was used both as a polarizing unit and as an indicator to maintain a constant maximum current, throughout a set of measurements. The minimum values of potential (which corresponded to maximum current values), were measured, under these conditions, with a Sargent model DR expanded-scale pH meter provided with mechanical digital readout corresponding to 0·2 mV/division. The polarographic cell used was supplied by Radiometer, and had a separate saturated calomel reference electrode, which was connected to the main cell compartment by an easily removable agar agar–saturated potassium chloride bridge, which was often replaced after prolonged use with alkaline solutions. The cell was immersed in a thermostat maintained at 25 ± 0·1°.

1. RESULTS AND CONCLUSIONS

Recorded polarograms for two concentrations of standard solution, corresponding to a defined value of y, were used for the measurement of $\Delta E_{d.e.}$ as a function x, adopting the approach used for Fig. 1.

The reduction of thallous ion in $0{\cdot}1M$ potassium chloride supporting electrolyte, containing 0·002% Triton X-100 as a maximum suppressor, was studied as a representative example of the reversible electrode reactions described by equation (7). For $y = 1{\cdot}36$ ($6{\cdot}43 \times 10^{-4}$ and $4{\cdot}73 \times 10^{-4}M$ solutions), and $x = 0{\cdot}12$–$0{\cdot}94$, the measured values of $\Delta E_{d.e.}$ gave a linear relationship with a positive slope of 59·6 mV when plotted against $\log (y - x)/(1 - x)$, with an intercept of less than 1 mV on the ΔE axis. Each of measured values of $\Delta E_{d.e.}$, for x ranging from 0·34 to 0·94, was used to calculate y, by applying equation (7) in the form

$$y = \left(\operatorname{antilog} \frac{\Delta E_{d.e.}}{59{\cdot}15}\right)(1 - x) + x \qquad (7a)$$

yielding values of y within $\pm 3\%$ of the ratio of concentrations used. Other ranges of concentrations of thallous ion were also tested, for values of y from 1·20 to 2·26, yielding a straight line passing through the origin in each case, and with slopes in the range 57–60 mV.

The validity of equation (12), describing totally irreversible reactions, was tested by using the reduction wave of chromate ion in 0·1M sodium hydroxide supporting electrolyte. For $y = 1{\cdot}50$ ($1{\cdot}425 \times 10^{-3}$ and $9{\cdot}50 \times 10^{-4}M$ solutions), and $x = 0{\cdot}12$–$0{\cdot}95$, the values of $\Delta E_{\mathrm{d.e.}}$, were plotted *vs.* $[\log (y - x)/(1 - x) + 0{\cdot}546 \log (t_2/t_1)]$ and gave a linear relationship with a positive slope of 147 mV (Fig. 4) corresponding to $\alpha n = 0{\cdot}37$, as compared with a value of 0·35 obtained previously by extremely careful experiment.[7] However, the intercept obtained by extrapolating curve *a* of Fig. 1 yielded a value of 12 mV for $\Delta E_{\mathrm{d.e.}}$. This discrepancy from the expected behaviour which is described by the dashed line *b* in Fig. 4 (calculated for $\alpha n = 0{\cdot}35$), was reproducible, and the calculation of y from the measured values of $\Delta E_{\mathrm{d.e.}}$, for a totally irreversible reaction, requires the introduction of experimentally determined values of the slope, s, and the intercept, a, into equation (12) as follows:

$$\Delta E_{\mathrm{d.e.}} = a + s\left[\log\frac{(y-x)}{(1-x)} + 0{\cdot}546 \log\frac{t_2}{t_1}\right] \tag{12a}$$

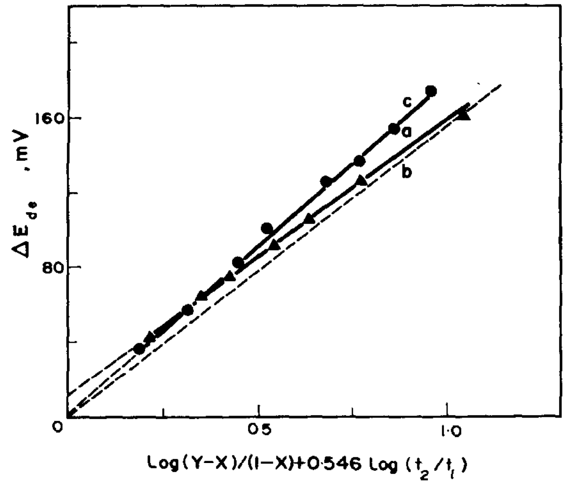

FIG. 4.—Log plots, corrected for variations of charging current, for the polarograms of $9{\cdot}50 \times 10^{-4}M$ and $1{\cdot}425 \times 10^{-3}M$ chromate in 0·10M sodium hydroxide: (*a*) no gelatin; (*b*) a theoretical plot representing equation (12) for $\alpha n = 0{\cdot}35$; (*c*) containing 0·005% gelatin.

The occurrence of the intercept, *a*, was puzzling, and it was suspected that a minor maximum might be responsible for the distortion of the current–potential relationship, especially since a maximum was developed if the polarographic system was left to stand. Evidence for this postulate is given by curve *c* in Fig. 4. Conditions identical to those for curve *a* in Fig. 4a, were used except that the ratio y was 2 and the solutions contained 0·005% gelatin as a maximum suppressor. A straight line passing through the origin was obtained, and had a slope of 185 mV, corresponding to $\alpha n = 0{\cdot}293$. Maximum suppressors and other surface-active agents are known to influence kinetic parameters in this fashion, usually decreasing the value of αn.[13] A more detailed study, with various concentrations of gelatin, was not performed in the present work, though such a study should provide information concerning the variation of αn with gelatin concentration, and the minimum concentration of gelatin required to obviate the maximum without affecting αn.

When an external expanded-scale potentiometer was used to measure $E_{\text{d.e.}}$ for various concentrations of chromate in $0{\cdot}1M$ sodium hydroxide supporting electrolyte, after adjustment of the applied voltage to maintain a constant current, the potential oscillated during the drop lifetime, yielding minimum potential at the maximum current and *vice versa*. The potential gradient (between minimum and maximum values of potential) is reported in Table I, which shows some of the experiments performed for various concentrations and currents, in the absence or presence of 0·005% gelatin as a maximum suppressor. From the results in Table I, it is seen that the potential gradient is due not only to the iR-drop variation resulting from current oscillations, but also to a potential gradient which diminishes upon the addition of a maximum suppressor (*cf.* the results obtained for $1{\cdot}90 \times 10^{-3}M$ chromate solutions, in columns 2 and 4). The latter potential gradient is not only dependent on the current magnitude but also on the ratio of i/i_d for each concentration (*cf.* columns 2 and 3), and is most likely linked with the existence of polarographic maxima. A detailed discussion of the implications of the difference in potential gradient in the presence and absence of gelatin is beyond the present paper. However, surface coverage of the mercury drop by the adsorption of maxima suppressors, has been reported by various authors to lower the surface tension and flatten the electrocapillary curves over a wide range of potential. The present study serves not only as an alternative for obtaining n or αn values but also serves as a new tool for the elucidation of fundamental problems.

TABLE I.—THE INFLUENCE OF A MAXIMUM SUPPRESSOR ON THE POTENTIAL GRADIENT* IN THE LIFETIME OF MERCURY DROPS

$i_{\max}$, μA	Potential gradient, mV*			
	—		0·005% gelatin	
	$1{\cdot}90 \times 10^{-3}M$	$1{\cdot}90 \times 10^{-4}M$	$1{\cdot}90 \times 10^{-3}M$	$1{\cdot}14 \times 10^{-3}M$
17·4	4·0		1·1	1·0
15·4	3·0		0·9	0·8
13·4	—		0·8	0·7
10·4	1·8		0·6	0·6
7·4	1·2		0·5	0·4
2·1	0·2	3·6	0·1	0·1
1·9	—	3·4	—	—

Measured for potassium chromate in $0{\cdot}1M$ NaOH, using an external expanded-scale potentiometer for various constant current values.

* See text.

To examine the dependence of $\Delta E_{\text{d.e.}}$ on y at a constant value of x, the minimum values of $E_{\text{d.e.}}$ were measured with an expanded-scale potentiometer for 0·95–2·5 mM chromate in $0{\cdot}1M$ sodium hydroxide containing 0·005% gelatin. Plots of $\Delta E_{\text{d.e.}}$ *vs.* $[\log (y - x)/(1 - x) + 0{\cdot}546 \log (t_2/t_1)]$ for each constant value of x were linear, and passed through the origin within experimental error. The calculated αn values for x varying from 0·12 to 0·90 varied from 0·286 to 0·300. These results show that application of the method described should prove useful for analytical purposes within limited concentration ranges.

A specific analytical application of the present method is accurate determination, especially when irreversible reactions with low αn values are involved. To give high accuracy, the method should display a detectable potential change for a slight change in concentration. This criterion was fulfilled for chromate ion in 0·1M sodium hydroxide, in the absence of gelatin, when the measurements were made at a high value of x, namely 0·9542. The results are given in Table II, y being calculated from $(\Delta E_{\text{d.e.}})_{\text{min}}$, according to the following equation, when variations in t are justifiably ignored:

$$y = \left[\text{antilog} \frac{(\Delta E_{\text{d.e.}})_{\text{min}}}{s}\right](1 - x) + x \qquad (12b)$$

where s equals 147 mV, the slope found in the absence of gelatin. The deviations calculated in Table II are very low, indicating the suitability of the method for accurate determinations. Determinations can be made after prior estimation of the concentration, by measuring the $\Delta E_{\text{d.e.}}$ of the solution against a standard solution having similar concentration. Although such an approach is not analogous to differential spectrophotometry, it strongly resembles it.

TABLE II.—DETERMINATION OF CHROMATE ION FROM POTENTIAL DIFFERENCES DUE TO LOW CONCENTRATION CHANGE

y, taken	$\Delta E_{\text{min}}, mV$	y, calc.*	Error, %
1·0020	3·6	1·0027	0·07
1·0040	6·0	1·0045	0·05
1·0070	9·5	1·0074	0·04
1·0100	14·0	1·0112	0·12

Measurements of minimum potential readings, $(E_{\text{d.e.}})_{\text{min}}$, were made for $x = 0{\cdot}9542$, using an expanded-scale potentiometer. ΔE_{min} is the difference in potential when the measured solutions were compared with a $9{\cdot}5 \times 10^{-4}$ solution of chromate in 0·1M NaOH.

* See text.

Davis and Shalgosky[14] and Davis and Seaborn[15] proposed the use of a differential cathode-ray polarograph with twin electrodes for accurate and precise determinations, using the method of comparative polarography. In the latter, a differential curve was recorded by using two cells, one containing the solution to be analysed and the other a similar solution of accurately known composition. Using twin electrodes and twin cells for direct measurement of $\Delta E_{\text{d.e.}}$ resembles the ideas involved in comparative polarography, and should prove advantageous for precise determinations.

The results of the present work agree well with equations (7) and (12), verifying the postulates in the theoretical discussion and demonstrating the use of this new method in fundamental studies as well as for analytical applications.

Acknowledgement—The permission of the management of IMI, Institute for Research and Development, to publish this work is gratefully acknowledged. My thanks are due to Miss Z. Shapira for performing part of the experimental work and I am indebted also to Professor Louis Meites, Chairman of the Department of Chemistry, Clarkson Institute of Technology, Potsdam, New York, for his helpful comments and discussions.

Zusammenfassung—Bei einem neuen Analysenverfahren wird das Potential einer Quicksilbertropfelektrode in Abhängigkeit von der Konzentration eines elektroaktiven Lösungsbestandteils gemessen, wobei durch Regelung der an die polarographische Zelle angelegten Spannung ein konstanter Strom aufrechterhalten wird. Es werden Gleichungen abgeleitet, die die Potentialänderung bei Änderung der Konzentration eines Bestandteils voraussagen, der an einer reversiblen oder irreversiblen Elektrodenreaktion teilnimmt. Die abgeleitete Gleichung wird graphisch interpretiert; dabei zeigen sich die besten Versuchsbedingungen für die Potentialmessungen. Es ergeben sich viel größere Potentialdifferenzen als bei der herkömmlichen Potentiometrie, insbesondere, wenn das Verfahren auf irreversible Elektrodenreaktionen an der Quecksilbertropfelektrode angewandt wird. Es werden Versuchsergebnisse mitgeteilt, die nicht nur alle Erwartungen erfüllen, sondern auch zeigen, daß das Verfahren einen neuen Weg zur Erforschung einiger grundlegender Probleme weist.

Résumé—On décrit une nouvelle méthode dans laquelle le potentiel de l'électrode à goutte de mercure tombante est mesuré en fonction de la concentration d'un constituant électroactif lorsqu'on maintient un courant constant en adjustant le voltage appliqué à la cellule polarographique. On en déduit des équations décrivant le changement de potentiel attendu causé en faisant varier la concentration d'un constituant impliqué dans une réaction d'électrode réversible ou irréversible. On effectue des interprétations graphiques de l'équation dérivée, indiquant les conditions les plus convenables pour effectuer les mesures de potentiel, donnant des différences de potentiel qui excèdent fortement celles obtenues par la potentiométrie classique, particulièrement lorsque la méthode est appliquée à des réactions d'électrode irréversibles à l'électrode à goutte de mercure tombante. On présente des arguments expérimentaux qui non seulement vérifient toutes les prévisions, mais qui indiquent aussi que la méthode offre un nouvel accès à l'étude de quelques problèmes fondamentaux.

NOTE

Nomenclature in thermal analysis—II

The recommendations in the First Report of the Nomenclature Committee of the International Confederation for Thermal Analysis (ICTA)[1] have been generally well received and are at present being considered for adoption by both the International Union of Pure and Applied Chemistry and the International Standards Organization. Considerable interest has also been shown by individual scientists.[2]

Since these proposals were promulgated, the Committee have drawn up a further report, the recommendations in which have been endorsed in Business Session at the Third International Conference on Thermal Analysis at Davos, Switzerland, in August, 1971. The Council of ICTA have therefore directed that this Second Report be also published as a definitive document of ICTA, with the recommendation that the conventions set out therein be adhered to in all publications in the English language. Background information on the reasons for adoption of certain conventions has already been published.[3]

The Sub-Committees dealing with the German, Japanese and Russian languages[1] have all been active and a nomenclature system in Japanese, based on the recommendations in the First Report, has now been published.[4]

I. AMPLIFICATION OF FIRST REPORT

Because of the variety of opinions expressed on, and the different interpretations of, the term *pyrolysis*, the Committee consider the time inopportune to promulgate on *thermal decomposition* and related terms—see First Report, Section I(*f*).

Some confusion appears to have arisen over the term *isobaric weight-change determination* as defined in the First Report, Section IIIB, Sub-section 1. The Committee consider that this confusion could be obviated by the following statement.

> In the context of the report published in *Talanta*, 1969, **16**, 1227, Section IIIB, Sub-sections 1 and 2 headed, respectively, *Static* and *Dynamic*, these terms refer to environmental temperature. It should be noted that the same terms are also used with reference to environmental atmosphere.

II. DTA AND TG APPARATUS AND TECHNIQUE

In considering the terms available, certain arbitrary choices have had to be made—*e.g.*, between *specimen* and *sample*—but the only term in fairly common use that is rejected is *inert material.*

A. DTA

The *sample* is the actual material investigated, whether diluted or undiluted.

The *reference material* is a known substance, usually inactive thermally over the temperature range of interest.

The *specimens* are the sample and reference material.

The *sample holder* is the container or support for the sample.

The *reference holder* is the container or support for the reference material.

The *specimen-holder assembly* is the complete assembly in which the specimens are housed. Where the heating or cooling source is incorporated in one unit with the containers or supports for the sample and reference material, this would be regarded as part of the specimen-holder assembly.

A *block* is a type of specimen-holder assembly in which a relatively large mass of material is in intimate contact with the specimens or specimen holders.

The *differential thermocouple** or ΔT *thermocouple** is the thermocouple* system used to measure temperature difference.

B. TG

A *thermobalance* is an apparatus for weighing a sample continuously while it is being heated or cooled.

* Should another thermosensing device be used, its name should replace *thermocouple* in these terms.

The *sample* is the actual material investigated, whether diluted or undiluted.†

The *sample holder* is the container or support for the sample.

C. DTA and TG

The *temperature thermocouple** or *T thermocouple** is the thermocouple* system used to measure temperature: its position with respect to the sample should always be stated.

The *heating rate* is the rate of temperature increase, which is customarily quoted in degrees per minute (on the Celsius or Kelvin scales). Correspondingly, the cooling rate is the rate of temperature decrease. The heating or cooling rate is said to be *constant* when the temperature/time curve is linear.

In simultaneous DTA–TG, definitions follow from those given for DTA and TG separately.

III. DTA AND TG CURVES

The Committee, in reaffirming their decision to use the terms *differential thermal curve* or *DTA curve*, *thermogravimetric curve* or *TG curve* and *derivative thermogravimetric curve* or *DTG curve*, recommend disuse of the other terms which have appeared in the literature, such as thermogravimetric analysis curve, thermolysis curve, thermoweighing curve, thermogravigram, thermoponderogram, thermogram, differential thermogravimetric curve, differential thermogram, derivative thermogram, polytherm, *etc.*

Certain conventions and reporting procedures for DTA and TG curves have already been specified in *Anal. Chem.*, 1967, **39**, 543, and in the First Report. The following definitions are to be read in conjunction with these recommendations.

A. DTA

In DTA **it must be remembered** that although the ordinate is conventionally labelled ΔT the output from the ΔT thermocouple will in most instances vary with temperature and the measurement recorded is normally the e.m.f. output, E, *i.e.*, the conversion factor, b, in the equation $\Delta T = bE$ is not constant since $b = f(T)$, and that a similar situation occurs with other sensor systems.

All definitions refer to a single peak such as that shown in Fig. 1: multiple peak systems, showing shoulders or more than one maximum or minimum, can be considered to result from superposition of single peaks.

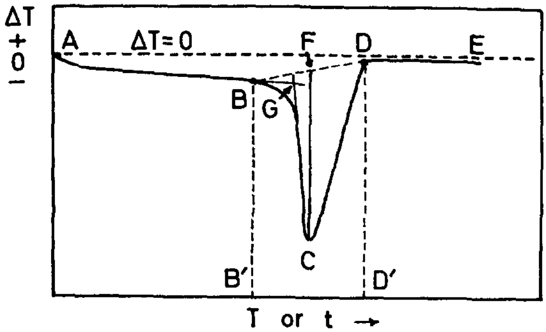

Fig. 1.—Formalized DTA curve.

The *base line* (AB and DE, Fig. 1) corresponds to the portion or portions of the DTA curve for which ΔT is approximately zero.

A *peak* (BCD, Fig. 1) is that portion of the DTA curve which departs from and subsequently returns to the base line.

An *endothermic peak* or *endotherm* is a peak where the temperature of the sample falls below that of the reference material; that is, ΔT is negative.

An exothermic peak or *exotherm* is a peak where the temperature of the sample rises above that of the reference material; that is, ΔT is positive.

---

* Should another thermosensing device be used, its name should replace *thermocouple* in these terms.

† Samples used in TG are normally not diluted, but in simultaneous TG and DTA diluted samples might well be used.

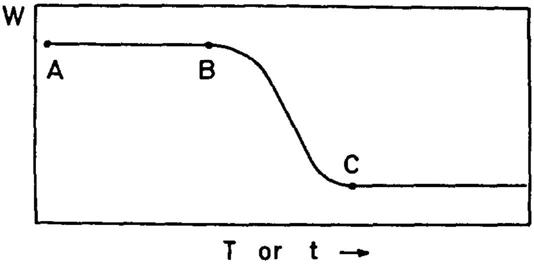

FIG. 2.—Formalized TG curve.

Peak width (B′D′, Fig. 1) is the time or temperature interval between the points of departure from and return to the base line.*

Peak height (CF, Fig. 1) is the distance, vertical to the time or temperature axis, between the interpolated base line* and the peak tip (C, Fig. 1).

Peak area (BCDB, Fig. 1) is the area enclosed between the peak and the interpolated base line.*

The *extrapolated onset* (G, Fig. 1) is the point of intersection of the tangent drawn at the point of greatest slope on the leading edge of the peak (BC, Fig. 1) with the extrapolated base line (BG, Fig. 1).

B. TG

All definitions refer to a single-stage process such as that shown in Fig. 2: multistage processes can be considered as resulting from a series of single-stage processes.

A *plateau* (AB, Fig. 2) is that part of the TG curve where the weight is essentially constant.

The *initial temperature*, T_i, (B, Fig. 2) is that temperature (on the Celsius or Kelvin scales) at which the cumulative weight change reaches a magnitude that the thermobalance can detect.

The *final temperature*, T_f, (C, Fig. 2) is that temperature (on the Celsius or Kelvin scales) at which the cumulative weight change reaches a maximum.

The *reaction interval* is the temperature difference between T_f and T_i as defined above.

LETTER TO THE EDITOR

Ammonium hexanitratocerate(IV) as an oxidizing agent—VII* Determination of some carboxylic acids

SIR,

Cerium(IV) sulphate has been widely used for determination of organic substances, especially acids.[1–9] The procedures generally involve heating the compound with excess of cerium(IV), cooling and back-titrating. The stoichiometry does not usually correspond to a definite oxidation path but but is fairly constant under carefully prescribed conditions. Formic acid is often an end-product, and resists further oxidation.

The earlier workers[1–8] used ceric sulphate in sulphuric acid, but Smith and Duke used the more powerful perchlorate oxidant.[9] We have found that ammonium hexanitratocerate(IV) in nitric acid medium has a reactivity between that of the sulphato and perchlorato reagents and that it gives a fixed stoichiometry for the oxidation of an organic acid over a wide range of temperature and time. The rate decreases with increasing nitrate and/or nitric acid concentration, and increases with temperature. The stoichiometry is highly favourable, ranging from 6 to 14 moles of cerium(IV) per mole of acid. Formic acid is not attacked and is usually an end-product. Results for malic, tartaric, citric and malonic acids were correct to within 1%. The main drawback is that the method cannot be applied to mixtures of acids, or to determination of the acids in the presence of other species oxidized by cerium(IV). As the method involves treatment with excess of oxidant, species such as chloride *etc* must be absent.

The procedure is as follows. $0\cdot1M$ solution of the reagent in $1M$ nitric acid is prepared and standardized with oxalate.[10] A known weight of sample is added to an excess of the oxidant, 5 ml of $10M$ nitric acid are added, and the whole is diluted to 100 ml and heated at 60° for 30 min. It is cooled, dilute sulphuric acid ($5N$ 20 ml) is added, and the excess of cerium(IV) is back-titrated with iron(II) solution in sulphuric acid, with ferroin as indicator.

The stoichiometry is 6 moles of cerium(IV) per mole of tartaric or malonic acid, 14 for citric acid, and 8 for malic acid, the products being formic acid and carbon dioxide.

Gatto and Stone[11] had previously used ammonium hexanitratocerate(IV) in acetic acid medium for oxidation of organic acids dissolved in glacial acetic acid and concluded that α-keto-acids and α-hydroxy-acids with an α-phenyl group are rapidly oxidized at room temperature and be determined accurately, that polycarboxylic hydroxy-acids are rapidly oxidized but not determinable, and that aliphatic α-hydroxy-acids are slowly oxidized and not determinable. No such difficulties seem to occur with the nitric acid system used by us.

Spectrophotometric determination of dimethyl sulphoxide

(*Received* 22 *March* 1971. *Revised* 9 *February* 1972. *Accepted* 17 *February* 1972)

Working with aqueous solutions of dimethyl sulphoxide (DMSO) has imposed the need for a quick and simple method for its quantitative determination. The existing methods are based either on the ability of the sulphoxide group to be oxidized to the sulphone, or on its ability to be reduced to the sulphide. Potassium permanganate[1,2] and, recently, chloramine-T[3] are used as oxidizing agents, titanium(III) chloride[4] and tin(II) chloride[5] as reducing agents.

Reduction with iodide in glacial acetic acid followed by the titration of liberated iodine[6] is suitable but cannot be applied to dilute aqueous solutions. The method of potentiometric titration used for the determination of the sulphoxide dissolved in acetic anhydride, when the titration is performed with an acetic anhydride[7] or dioxan[8] solution of perchloric acid, cannot be applied to such solutions either.

The oxidation methods fail in the presence of reducing agents, *e.g.*, dimethyl sulphide which is often present in the sulphoxide. The reduction methods, on the other hand, cannot be used in the presence of oxidizing agents such as dimethyl sulphone.

Our attempt to avoid these difficulties was based on the property that DMSO can cause changes in the visible absorption spectra of some metal compounds (especially compounds of the transition metals) in aqueous solution. In these solutions water and sulphoxide compete for places in the co-ordination sphere of the metal ions. Fratiello *et al.*[9] have established, from proton magnetic resonance studies, that DMSO contributes to the first co-ordination shell of aluminium ions even in the presence of a large excess of water. As a result, a change should be expected in the position of the absorption spectra, which are shifted to longer wavelengths (red shift). This medium effect has long been known.[10] We also established it by studying the absorption spectra of various metals salts in solutions containing various amounts of DMSO.[11] Though the shapes of the spectra are not essentially modified by the change of the medium, the intensities of the bands are increased and red shifts observed in the presence of DMSO. As the best result (the highest increase in intensity and the smallest shift of the band) was obtained with ammonium iron(III) sulphate the spectrophotometric determination of milligram quantities of DMSO in aqueous solutions was developed with this salt as the reagent.

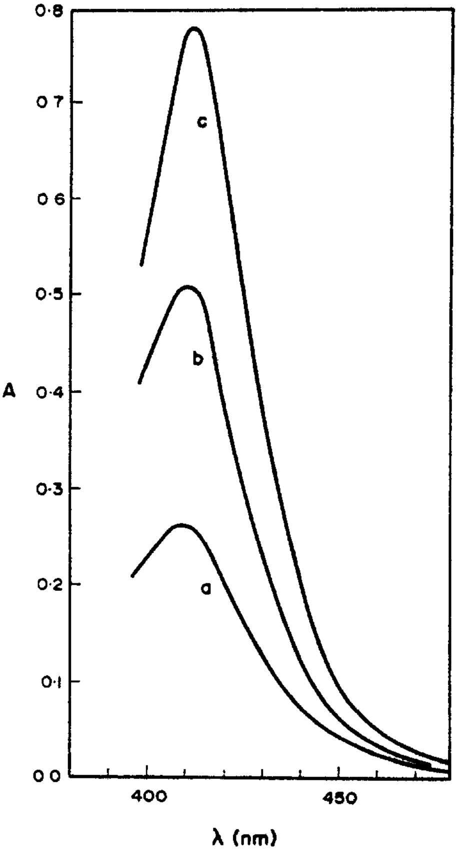

FIG. 1.—Spectra of 5·0 ml of 0·5M Fe(III) alum in 0·1M H_2SO_4, pH 1·4, diluted to 10 ml with water: (*a*) with 50·0 mg of DMSO; (*b*) with 100·0 mg of DMSO; (*c*) with 150·0 mg of DMSO, measured against the blank.

EXPERIMENTAL

Reagents

The DMSO was recrystallized three times (n_D^{20} 1·477) and stored over Linde 4A Molecular Sieve. In the visible region it showed no absorption. Other chemicals were of reagent grade quality, except for dimethyl sulphone, (Koch-Light pure grade). Doubly-distilled water was used throughout.

Procedure

The sample containing up to 200 mg of DMSO is placed in a 10-ml volumetric flask, being neutralized by addition of ammonia solution or dilute sulphuric acid if necessary, before addition of reagent. Then 5 ml of the reagent —0·5*M* iron(III) alum in 0·1*M* sulphuric acid—are added and the solution is diluted with water to the mark. After 30 min the absorbance is measured in 10-mm cells at 410 nm against a blank solution with identical concentration of the reagent. The temperature should be kept constant within ±1°. The amount of DMSO is read from the calibration curve obtained under the same conditions. Beer's law is obeyed over the DMSO concentration range up to 20 mg/ml.

RESULTS AND DISCUSSION

Spectra

The spectra are given in Fig. 1. The absorption maximum is at 410 nm, and the shift to longer wavelengths with the increase in DMSO concentration is negligible.

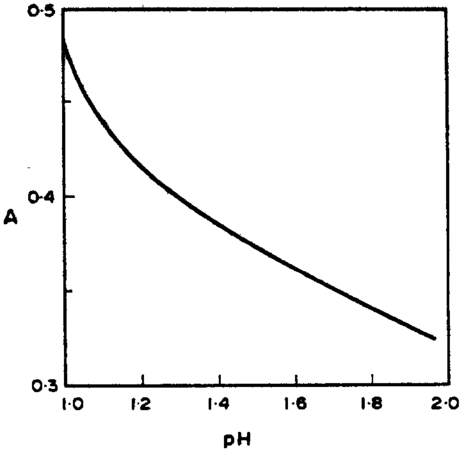

FIG. 2.—The effect of pH on the absorbance: 5 ml of 0·5*M* Fe(III) alum with 100.0 mg of DMSO, diluted to 10 ml.

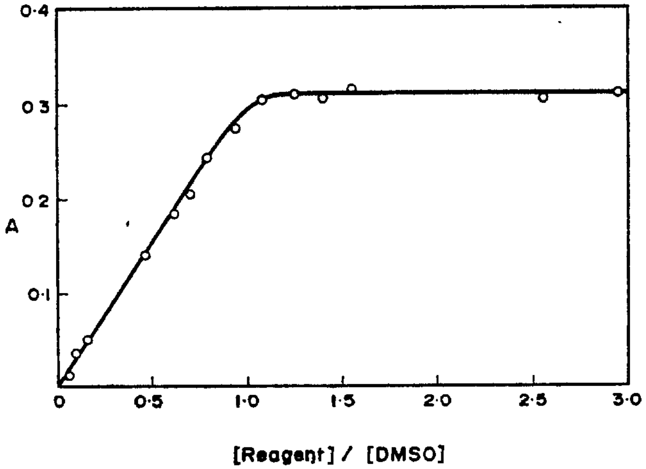

FIG. 3.—Mole-ratio plot at constant pH (1·4).

Effect of time, temperature and pH

The colour appears instantaneously on addition of the reagent, reaches full intensity in 30 min and remains stable for at least 24 hr.

With increase in temperature the absorption maximum shifts to longer wavelengths. This is due to the dependence of the nature of the solute (in the solvated form) on temperature.[12] Most frequently several solvates are involved which are in temperature-dependent mutual equilibrium.

With increase in pH, the absorbance decreases at first rapidly and then more slowly, as shown in Fig. 2. A glass electrode was used in the pH adjustment. This is quite permissible, owing to the low DMSO concentration. Kolthoff[13] showed that, under specific conditions, the glass electrode could be used even in concentrated DMSO solutions. In choosing the working value of pH 1·40, which is practically independent of the amount of DMSO, a compromise was made between sensitivity and dependence on acidity.

Effect of reagent concentration

Samples were treated as in the standard procedure except that the amount of reagent was varied to give a mole ratio of Fe(III) to DMSO ranging from 0·07 to 4. The pH was kept constant. The absorbance attained a constant value at a reagent:DMSO ratio of about 1 (Fig. 3).

Interferences

Dimethyl sulphide (pure) and dimethyl sulphone (concentrated aqueous solution) do not absorb in the visible region. In concentrations up to 25% that of the DMSO, dimethyl sulphide causes no interference. Dimethyl sulphone in amounts up to that of the DMSO content is without any effect (Table I).

TABLE I.—Effect of dimethyl sulphide (DMS) and dimethyl sulphone ($DMSO_2$) on DMSO determination.

DMSO taken, *mg*	DMS added *mg*	DMSO found, *mg*	$DMSO_2$ added *mg*	DMSO found, *mg*
100·0	0	100·0	0	100·0
100·0	5·0	100·0	5·0	100·0
100·0	25·0	100·0	25.0	100·0
100·0	50·0	103·5	50·0	100·0
100·0	75·0	106·0	75·0	100·0
100·0	100·0	110·0	100·0	100·0

Cations which interact with DMSO and especially those having spectra which are affected by DMSO, can interfere in the determination and therefore should be eliminated. This can be done by passing the sample through a small column of cation-exchanger before adding the ferric alum. We used Dowex 50-X8 [Na^+, 60-100 mesh] as the cation-exchanger. In one experiment the sample contained 200·0 mg of DMSO and 1·0 mg each of Ni, Co(II), Cr(III), U(VI) and Fe(III) sulphates in aqueous solution. The effluent as well as the water used for rinsing the column were collected in a 10-ml volumetric flask from which 5 ml were taken for the spectrophotometric determination. The experiment was repeated eight times and the mean value of 100·0 ± 1·1 mg obtained. It is evident that DMSO is quantitatively recovered from the resin, which is in agreement with an earlier finding,[8] and also proves the correctness of the method used for elimination of interfering cations.

Precision and accuracy

Solutions containing known amounts of DMSO were analysed ten times according to the recommended procedure. Averages and standard deviations were: 49·5 ± 0·5 mg (50·0 mg taken), 100·0 ± 0·5 mg (100·0 mg taken), 149·5 ± 0·5 mg (150·0 mg taken).

Sensitivity

The molar absorptivity is 3 l.mole^{-1}.cm^{-1} at 410 nm. The minimum amount detectable (Sandell sensitivity[14]) is 260 $\mu g/cm^2$.

Acknowledgement—The authors wish to thank Mrs. D. Nemoda for very valuable technical assistance, and the Laboratory of Physical Chemistry for use of its recording spectrophotometer.

Z. IDJAKOVIĆ

Summary—A spectrophotometric method for the determination of milligram quantities of dimethyl sulphoxide in aqueous solutions has been developed. The method is based on the medium effect on the visible absorption spectra of metal salt solutions. Out of several compounds investigated, iron(III) alum was chosen as most suitable for this purpose. Beer's law is obeyed for dimethyl sulphoxide concentrations up to 20 mg/ml at 410 nm. Dimethyl sulphone does not interfere and dimethyl sulphide can be tolerated in amounts up to 25% of the sulphoxide present. Possible interferences caused by metal cations can be avoided by passing the sample through a cation-exchanger before adding the reagent. The molar absorptivity is 3 l.mole^{-1}.cm^{-1} at 410 nm, and the average relative error ±0·5%.

Zusammenfassung—Ein spektrophotometrisches Verfahren zur Bestimmung von Milligrammengen Dimethylsulfoxid in wäßrigen Lösungen wurde entwickelt. Es beruht auf dem Mediumeffekt auf die sichtbaren Absorptionsspektren von Metallsalzlösungen. Unter verschiedenen untersuchten Verbindungen wurde Eisen(III)-alaun als für diesen Zweck am besten geeignet ausgewählt. Bei 410 nm gilt das Beersche Gesetz für Dimethylsulfoxid-Konzentrationen bis höchstens 20 mg/ml. Dimethylsulfon stört nicht und Dimethylsulfid kann in Mengen bis 25% des Sulfoxids vorhanden sein. Mögliche Störungen durch Metall-Kationen können vermieden werden, wenn man die Probe vor Zugabe des Reagens durch einen Kationenaustauscher laufen läßt. Der molare Extinktionskoeffizient beträgt 3 l mol^{-1} cm^{-1} bei 410 nm, der mittlere relative Fehler ±0,5%.

Résumé—On a élaboré une méthode spectrophotométrique pour le dosage de quantités de diméthylsulfoxyde de l'ordre du milligramme en solutions aqueuses. La méthode est basée sur l'effet du milieu sur les spectres d'absorption dans le visible de solutions de sels métalliques. Parmi plusieurs composés étudiés, on a choisi l'alun de fer(III) comme convenant le mieux à cet usage. La loi de Beer est suivie pour des concentrations en diméthylsulfoxyde allant jusqu'à 20 mg/ml à 410 nm. La diméthylsulfone ne gêne pas, et le sulfure de diméthyle peut être toléré en quantités allant jusqu'à 25% du sulfoxyde présent. On peut éviter les interférences possibles causées par des cations métalliques en passant l'échantillon sur un échangeur de cations avant addition du réactif. Le coefficient d'absorption moléculaire est de 3 l.mole^{-1}.cm^{-1} à 410 nm, et l'erreur relative moyenne est de ±0,5%.

Light-scattering, X-ray diffraction, elemental analysis and infrared spectrophotometry characterization of chitosan, a chelating polymer

(*Received* 30 *September* 1971. *Accepted* 16 *December* 1971)

THE CHELATING properties of chitosan have been described previously. The separation of transition metals from ammonium, thallium, alkali and alkaline-earth metals which cannot form co-ordination complexes with the polymer has been reported. It was pointed out that the collection rate of the first row transition metal ions follows the Irving and Williams series. Moreover, complexing agents were necessary to perform elutions from chitosan chromatographic columns. In several cases the adsorption of transition metal ions on chitosan is accompanied by the formation of intense colours, suggesting the occurrence of chemical bonding.[1–4]

The role of the free amino group $-NH_2$ in the interaction of cations with chitosan was confirmed when a study was made of solutions of chitosan in formic or acetic acids. Dissolution is made possible by the formation of $-NH_3^+$ groups: the $-NH_2$ groups are protonated, hindering the formation of a dative bond to a transition metal ion as shown by polarographic measurements.[4]

There is scarce information in the literature on the physical properties of chitosan and the present paper describes the correlation of the chromatographic behaviour of chitosan with physico-chemical data of particular interest in the technology of its preparation and use.

Data on chitin are more abundant, particularly X-ray diffraction studies.[9–11] The present work is limited to powders as at the present time there is no mean of isolating or obtaining a fibre or a crystal; artificial membranes are useful for infrared spectrophotometry only, as they are amorphous.[12]

EXPERIMENTAL

Cation-treated polymer

A 200-mg portion of chitosan was shaken for 30 min with 50 ml of a 0·044*M* solution of a metal sulphate or chloride. These concentrations are 100-fold higher than those currently used for chromatographic purposes and they were used to obtain clear X-ray and infrared records.

Instrumentation

Light-scattering measurements were carried out at 25° in pure benzene with a Model 42000 Sofica photometer equipped with cylindrical cells. The instrument was set to zero with dust-free benzene having a Rayleigh ratio $R_{90} = 16 \cdot 3 \times 10^{-6}$ at 546 nm. The refractive index increment d*n*/d*c* in 8·5% formic acid + 0·5*M* sodium formate at 25° was determined with a Brice–Phoenix Model BP-2000 V differential refractometer at 546 nm. All the glass equipment was cleaned by washing in a Thurmond apparatus,[13] and solutions were centrifuged at 15000 rpm for 2 hr. Infrared spectra were recorded with a Model 225 Perkin–Elmer spectrophotometer. X-Ray diffraction spectra were taken with a Nonius quadruple Guinier-De Wolff camera, with a quartz curved-crystal monochromator and a double cylinder camera of the Guinier-Jagodzinski type with a bent Johansson monochromator. Copper K_α radiation was used. Elemental analysis was carried out with an automatic F & M Hewlett–Packard analyser, with *N*-actylglucosamine as reference. Metals were measured with a Perkin–Elmer 305 atomic absorption spectrophotometer.

RESULTS AND DISCUSSION

Light-scattering

The refractive index increments were measured at four distinct concentrations of chitosan in 8·5% formic acid + 0·5*M* sodium formate and at the two wave-lengths 436 and 546 nm; from the results the value d*n*/d*c* = 0·174 ml/g was obtained. Where chitosan solutions in formic acid are concerned, $-NH_3^+$ groups are responsible for the polyelectrolyte behaviour of the polymer, the $HCOO^-$ counter-ions being free to move.

At high concentrations, the polyelectrolyte molecules are close together and the counter-ions do not leave the molecular domain. At lower concentrations counter-ions diffuse away from the polymer molecules. The effective charge increases and the structure becomes more extended: sodium formate was added to the solvent to reduce this polyelectrolyte effect.

For each chitosan concentration, the light scattering was measured and the value C/I *vs.* $\sin^2 \theta/2 + 500\,C$ was plotted (according to Zimm[14]), in Fig. 1. The form of the graph indicates a degree of polydispersion as reported previously.[4] The extrapolated average molecular weight value was $1 \cdot 2 \times 10^6$.

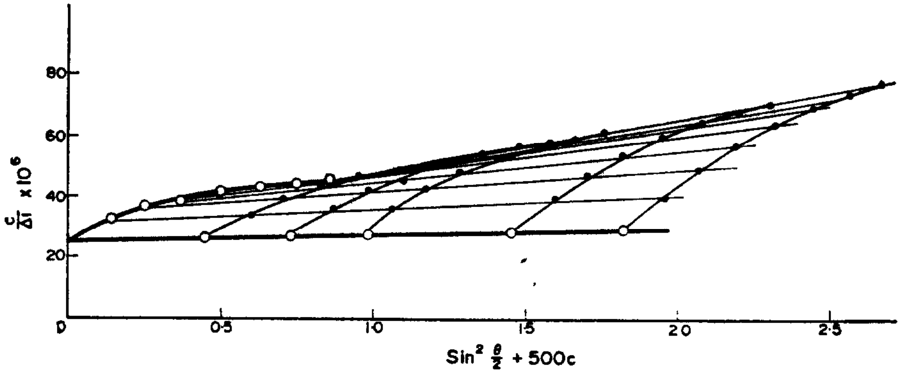

FIG. 1.—Light-scattering measurements on chitosan in formic acid (according to Zimm[14]).

Elemental analysis

In Table I results are reported for the nitrogen content of chitin and chitosan prepared under slightly different conditions (differing compositions of the deacetylation mixtures), derived from the method of Broussignac. Chitosan has the higher nitrogen content, which does not vary with the mode of preparation.

As shown in Table II there is a correlation between the nitrogen content and the capacity for

collecting transition metal ions, indicating that the nitrogen atom is the main site of attachment. Of course contributions of other atoms are also involved as well as steric configurations and surface areas. Chitosan is much faster than other polymers, for instance the percentages for Ni and Zn in Table II are already reached after 10 minutes, while DE Cellulose after 10 minutes collects 22% Ni and 10% Zn only, at pH 6.

X-Ray diffraction and infrared spectrophotometry

The diffraction patterns of chitin and chitosan show some structural resembalance between the two polymers. The patterns for chitosan treated with copper sulphate and copper chloride reveal new sharp bands indicating a new highly crystalline structure, as presented in Table III. It is a well-known fact that when a matrix substance crystallizes with a "solute" additive, one can observe either a matrix lattice parameter alteration, or the formation of a new crystalline phase which is characterized by new bands in the X-ray diffraction pattern, the latter case occurring when the "solute" atoms occupy well-defined positions in the matrix lattice.

Copper ions occupy definite and fixed positions in the chitosan lattice and a chemical bond is established between the chitosan nitrogen atoms and the copper ions. Of course there is also a contribution by the hydroxyl groups. An anionic component is not excluded, as it is known that chitosan sulphate is crystalline. Chitosan treated with copper chloride yields more diffuse X-ray diffraction patterns, but this is due to a partial collapse of the grains at the lower pH.

The same trend is not observed in the X-ray diffraction patterns recorded for chitosan treated with other metal ions, *e.g.*, cadmium. Although the cadmium ions are held by dative bonds, they are introduced into the chitosan without altering the crystal structure (Table III). Should a physical adsorption occur, a less ordered chitosan structure would be observed; on the contrary a faint new band appears.

The infrared spectra for chitosan treated with various metal ions confirm that copper interacts more strongly than other ions. The whole spectrum is altered, instead of only the region around

1600 cm^{-1} as observed with certain other ions. Complexation of copper by the monomer (glucosamine) has been reported[15] and adsorption of copper on chitosan has been observed in chemical oceanography studies.[16,17]

The crystallinity of chitosan powder is not lost during chromatography. X-Ray diffraction studies on samples taken from the tops of the columns which had been used for the adsorption of copper from 0·44 m*M* solutions and subsequent elution with 0·01*M* EDTA show that the crystallinity improves as the number of cycles increases. This is accompanied by an increase in the amount of EDTA solution necessary to elute the same amount of copper, as shown in Table IV.

* The variation in height is due to application of pressure by a peristaltic pump. Whatman precision columns were used.

CONCLUSIONS

It is clear that chitosan used so far for chromatography of inorganic compounds is a macromolecule of average molecular weight 1·2 × 10^5 and that selected deacetylation procedures on chitin from crab shells do not lead to extended degradation of the polymer.

It is also verified that chitosan adsorbs transition metal ions because of its high nitrogen content (higher that 7%). On the other hand the limitations of cellulosic exchangers in aqueous solutions are a recognized fact. The change in the infrared spectrum in the amino-group region supports the idea of a chemical bond between the macromolecule and the cation.

Chitosan also reacts with complex anions such as metavanadate, molybdate, tungstate and possibly hexachloroplatinate and tetrachloroaurate.[4]

On repeated use in a chromatographic column, the crystallinity of chitosan is not lost, and in the case of copper it improves.

These results encourage the use of chitosan in chromatography, especially for the isolation of trace metals. Moreover ligand-exchange chromatography is at present confined to the use of copper-treated iminodiacetic acid resin (Chelex 100 or Dowex A 1), that has the limitations of leakage of copper ions, considerable shrinking and retention of magnesium. Ligand-exchange chromatography has also been carried out on cation-treated celluloses in organic solvents.[18] Chitosan may be recommended for this type of chromatography, because the metal ions on the polymer are available for interaction with ligands.

Summary—Measurements on chitosan, which is used as a selective chromatographic support in inorganic chromatography, show that its molecular weight is 1·2 × 10^5, the nitrogen content is 7·4%, and its crystalline structure is not lost after adsorption of metal ions, which are co-ordinated with the nitrogen atoms of the —NH_2 groups of the polymer. Chitosan treated with copper sulphate exhibits a new crystal structure and a distinctive infrared spectrum, is quite stable and does not shrink, and is proposed as a chromatographic support for ligand-exchange chromatography.

Zusammenfassung—Messungen an Chitosan, das als selektiver chromatographischer Träger bei der anorganischen Chromatographie verwendet wird, ergaben ein Molekulargewicht von 1,2 · 10^5 und einen Stickstoffgehalt von 7,4%; seine Kristallstruktur geht nach Adsorption von Metallionen nicht verloren. Die Metallionen sind mit den Stickstoffatomen der —NH_2-Gruppen am Polymeren koordiniert. Mit Kupfersulfat behandeltes Chitosan zeigt eine neue Kristallstruktur und ein anderes Infrarotspektrum, ist recht stabil, schrumpft nicht und wird als chromatographischer Träger zur Ligandenaustauschchromatographie vorgeschlagen.

Résumé—Les mesures sur le chitosane, qui est utilisé comme support chromatographique sélectif en chromatographie minérale, montrent que son poids moléculaire est 1,2 × 10^5, la teneur en azote est 7,4%, et sa structure cristalline n'est pas perdue après adsorption d'ions métalliques, qui sont coordonnés avec les atomes d'azote des groupes —NH_2 du polymère. Le chitosane traité avec le sulfate de cuivre montre une nouvelle structure cristalline et un spectre infra-rouge particulier, il est tout à fait stable et ne se contracte pas, et on le propose comme support chromatographique pour la chromatographie d'échange de ligands.

A simple non-selective detector for gas-phase chromatography, using the measurement of reflected microwave power

(*Received* 10 *December* 1971. *Accepted* 8 *February* 1972)

THE CONSIDERABLE volume of work[1-9] on the use of microwave-excited discharges as detectors in gas-phase chromatography has been exclusively concerned with their capabilities as sources of selective spectral emission. The emission produced as the eluates are fragmented and excited in the discharge is usually detected with a monochromator, photomultiplier and electronic read-out system. Emission at particular wavelengths is found to be characteristic of certain atoms in the original compounds. One disadvantage of this type of system is the difficulty, even with very fast-scan monochromators or when using a polychromator, of detecting and determining all the species eluted from the column, with only one sample injection. A non-destructive, non-selective detector such as the katharometer, placed between the column and the discharge, would increase the amount of necessary apparatus and dead volume.

This communication describes a non-selective detector which can be used simultaneously with the emissive detector. The detector responds to nanogram quantities of all substances tested and requires

A simple non-selective detector for gas-phase chromatography, using the measurement of reflected microwave power

(*Received* 10 *December* 1971. *Accepted* 8 *February* 1972)

THE CONSIDERABLE volume of work[1-9] on the use of microwave-excited discharges as detectors in gas-phase chromatography has been exclusively concerned with their capabilities as sources of selective spectral emission. The emission produced as the eluates are fragmented and excited in the discharge is usually detected with a monochromator, photomultiplier and electronic read-out system. Emission at particular wavelengths is found to be characteristic of certain atoms in the original compounds. One disadvantage of this type of system is the difficulty, even with very fast-scan monochromators or when using a polychromator, of detecting and determining all the species eluted from the column, with only one sample injection. A non-destructive, non-selective detector such as the katharometer, placed between the column and the discharge, would increase the amount of necessary apparatus and dead volume.

This communication describes a non-selective detector which can be used simultaneously with the emissive detector. The detector responds to nanogram quantities of all substances tested and requires only a simple modification to the reflected-power meter associated with the usual microwave power supply.

EXPERIMENTAL

The system used is in principle the same as that described previously[6] except that a Beckman DU monochromator replaced the Hilger and Watts D292 monochromator.

An Evans Electroselenium Limited (EEL) model 245 microwave generator was used as the microwave power supply. The method of detection consisted of measuring the changes in the reflected microwave power produced by the chromatographic eluent entering the microwave discharge. The EEL 245 generator is ideally suited in this respect because it contains a built-in reflected-power meter and also the magnetron power supply is current-stabilized, which reduces the background noise. The output of the reflected-power meter was connected, *via* a coaxial cable and a backing-off system to a multirange Servo scribe recorder (see Fig. 1). A damping capacitor (40 μF) was connected across the recorder terminals to decrease the short-term noise on the background signal.

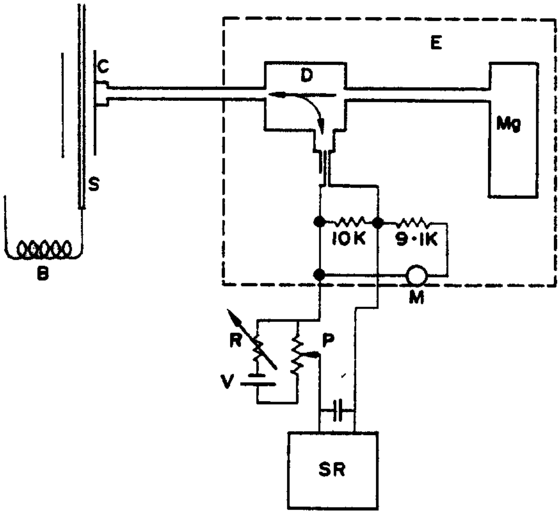

FIG. 1.—Experimental arrangement.
Mg—magnetron valve, D—directional coupler, C—cavity, B—column, S—silica tube, M—meter, E—EEL microwave generator, V—4·5-V battery, R—variable resistance (up to 1 MΩ), P—10 K potentiometer, SR—Servoscribe recorder.

With the discharge operating at 90 W of microwave power a background signal of *ca* 200 mV was produced by the reflected-power meter. When this voltage was backed-off so that it could be displayed on the 10-mV range of the recorder, a baseline with a drift of less than 3mV/hr and a low noise level was obtained. When an eluate passed through the discharge, the microwave power was coupled more efficiently, decreasing the reflected power and thus producing a signal peak.

The system conditions were optimized by using 5-μl injections of a mixture of 2.12% propene and 1·25% n-butene in nitrogen into a 1-m Porapak S column at 150°. The effect of microwave power variation when using an argon flow-rate of 3·5 l/hr is shown in Fig. 2, together with those for oxygen and nitrogen at the same flow-rate on a 3-m molecular sieve column at 25° (the maximum power obtainable from the microwave generator is limited to 90 W). The variation in the reflected-power background was also measured and found to be linear with respect to applied power. The variation of noise proved difficult to measure accurately, as signal detection was variable and limited by drift. However, no appreciable increase in noise was found at higher powers and 90 W was used throughout this work.

The effect of variations in flow-rate for the same substances is shown in Figs. 3 and 4. The effect of flow-rate changes is considerable and is *ca.* twice as great as for the emissive system alone (Fig. 4). However, the background drift was found to increase at slower flow-rates, probably as a result of increased instability in the flow-rate. Hence a non-optimum, but convenient, flow-rate of 3.5 l./hr was used for the sensitivity studies.

The reflected power detector could be used simultaneously with, and independently of, the emissive detector described in previous studies. Hence the method chosen to measure the ranges of linearity

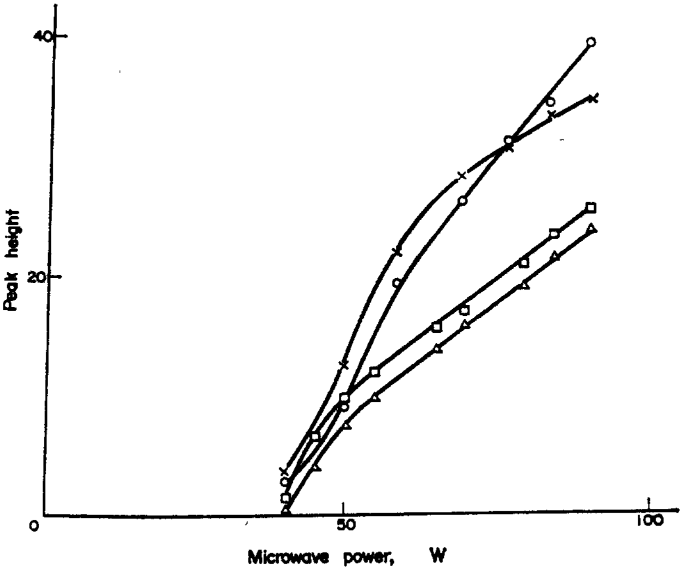

FIG. 2.—The effect of microwave power on detector response.
○—Oxygen; ×—nitrogen; □—propene; △—n-butene.

for a series of organic compounds was to compare the responses of these two systems; the emissive detector was set to record the atomic carbon emission at 247·9 nm. The response of the emissive detector at this wavelength had already been shown to be linear for the compounds used. A range of very small quantities ($\leqslant 1$ μl) of pure compounds were injected and the response of the two detector systems was recorded simultaneously. The linearity of response was established by plotting its response against that of the emissive detector.

From these results the approximate limits of detection were estimated and standard solutions of approximately these concentrations were made up and used to obtain more accurate figures. The

sensitivity to water was obtained in the same way by comparing it with the OH emission at 306.4 nm.

The response of the detector to a range of gases was measured directly, using 5-μl injections of the pure gases. For some gases, particularly nitrous oxide, oxygen and nitrogen impurities were observed and a correction was made, based on previously obtained sensitivities.

RESULTS AND DISCUSSION

A central position of the tube in the cavity was found to be optimum, and it was important to keep the tube position unchanged during operation, otherwise changes in reflected power occurred. Carbon deposition was generally not a problem at the sample levels used (less than 10 μg/sec) and the usable lifetime of the silica tubing was similar to that when used with the emissive detector.[8]

TABLE I.—DETECTOR RESPONSE TO SELECTED ORGANIC COMPOUNDS.

n-Butene	150	P	1·01	1.1

M = 3-m Molecular Sieve column.
P = 1-m Porapak column.

The limits of detection and ranges of linearity obtained for the organic compounds and gases are shown in Tables I and II. A comparison with the emissive detector is shown in Fig. 5. The range of linearity was greater than 500 for all the compounds investigated except ethyl iodide which was about 100. The limits of detection for all compounds and gases were quite similar, that is nanogram quantities, and the detector exhibited a particularly good response to hydrogen and to a lesser extent to hydrocarbons. No special sensitivity to N, S, O, I, Cl or Br compounds was found. The limits of detection for organic compounds were *ca.* 10–20 times poorer than those for carbon emission measurements with the emissive detector.[9] However, the limits of detection for helium, hydrogen, oxygen and water are superior to those obtained by emission measurement.[1,9]

Summary—A non-selective detector is described which can be used in conjunction with the microwave-excited emissive argon plasma detector. The mode of operation is based on the measurement of reflected power and its use is demonstrated with respect to a range of component vapours and permanent gases. The limit of detection for nearly all the species investigated is in the nanogram range and the detector responded to all compounds examined.

Zusammenfassung—Ein nichtselektiver Detektor wird beschrieben, der in Verbindung mit dem mikrowellen-erregten Argon-plasma-Emissionsdetektor verwendet werden kann. Die Arbeitsweise beruht auf der Messung der reflektierten Leistung; die Verwendung des Detektors wird an verschiedenen Dämpfen und permanenten Gasen demonstriert. Die Nachweisgrenze für fast alle untersuchten Spezies liegt im Nanogrammbereich; der Detektor sprach auf alle untersuchten Verbindungen an.

Résumé—On décrit un détecteur non sélectif qui peut être utilisé conjointement au détecteur à plasma d'argon émissif excité par microondes. Le mode d'action est basé sur la mesure de la puissance réfléchie et son usage est démontré par rapport à une gamme de vapeurs élémentaires et de gaz permanents. La limite de détection pour presque toutes les espèches étudiées est dans le domaine du nanogramme et le détecteur a répondu à tous les composés examinés.

Selective detection of bismuth(III) and iron(II) ions with certain new reagents

(*Received* 10 *January* 1972. *Accepted* 17 *February* 1972)

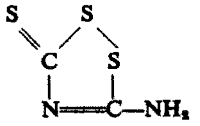
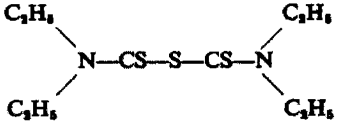
THIS COMMUNICATION describes the analytical applications of certain organic compounds proposed as reagents for the selective detection of bismuth(III): isoperthiocyanic acid (I), tetraethylthiuram monosulphide (II), eosin (III) and mercurochrome (IV). Eosin and mercurochrome also give useful fluorescent colour reactions with iron(II).

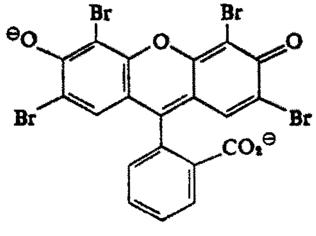


I

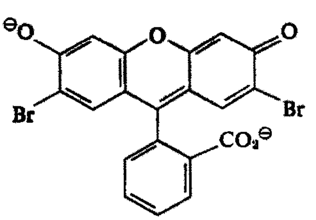


$$(C_2H_5)_2N{-}CS{-}S{-}CS{-}N(C_2H_5)_2$$

II



III



IV

Isoperthiocyanic acid, discovered by Wöhler,[1] has been a compound of controversial structure.[2] It has recently been shown to be 3-amino-5-thione-1,2,4-dithiazole (I).[3,4] No work has hitherto been reported on its analytical applications. It has now been observed that I dissolves in conc. sulphuric acid to give a stable yellow solution which reacts specifically with bismuth in presence of iodide, giving a deep red or intensely reddish-orange precipitate. With the exception of nitrite, no common anion or cation [including Sb(III) and As(III)] interferes. Nitrite, if present, should first be removed by treatment with sodium azide or sulphamic acid.[5] Like I, II reacts with bismuth in presence of iodide ions, giving a deep-orange precipitate. Only nitrite interferes. A 25% w/v alcohol solution of II is sold under the trade name of "Tetmosol".

Eosin and mercurochrome are important xanthene dyes. Both, when treated with bismuth and made alkaline with ammonia, give a bright and characteristic deep pink or reddish-pink precipitate. No other common anion or cation (except Pb) gives this result. Antimony(III) under identical conditions gives a light orange precipitate with a slightly pinkish tint, quite distinctive from that with bismuth. Because of their reaction with ammonia, Fe(II), Fe(III) and Cu(II) interfere.

Both III and IV, when treated with iron(II) and made alkaline with ammonia, give a highly fluorescent green precipitate. The reaction is specific for iron(II), and no interference is caused by iron(III) or by other common cations or anions.

EXPERIMENTAL

Reagents

Isoperthiocyanic acid solution (*A*). A 5% w/v solution in conc. sulphuric acid. I was obtained by the Seltzer and Considine method.[6]

Tetraethylthiuram monosulphide solution (*B*). A 5% w/v solution in acetone (prepared by diluting 20 ml of 25% w/v I.C.I. medicinal grade "Tetmosol" solution to 100 ml with acetone).

Eosin solution (*C*). A 0·5% w/v solution of the disodium salt in water.

Mercurochrome solution (*D*). A 0·3% w/v solution of the disodium salt in water.

Procedures

Bismuth with isoperthiocyanic acid. Place 2 drops of 2% potassium iodide solution on a spot plate, mix with it 1 drop of solution *A*, add 1 drop of test solution and again stir. Bismuth gives a deep red or intensely reddish-orange precipitate.

Limit of detection: 1 μg of bismuth: *limit of dilution*: 1:50,000.

Bismuth with tetraethylthiuram monosulphide. To 2 ml of 2% potassium iodide solution add 5 drops of solution *B*, followed by 1–2 ml of the test solution (containing 5–10 μg of bismuth). A deep reddish-orange precipitate indicates bismuth. Sometimes, generally in presence of large excess of potassium iodide, a transient blood-red precipitate forms which within seconds becomes intensely reddish-orange.

Bismuth with eosin or mercurochrome. To 2 ml of acidic test solution (containing >200 μg of bismuth) add 2–3 drops of solution *C* or *D*, and about 1 ml of conc. ammonia solution. A heavy, bright deep pink or reddish-pink precipitate indicates bismuth.

Iron(II) with eosin or mercurochrome. To 1–2 ml of the test solution, add 3–6 drops of solution

C or *D*, and 1–2 ml of conc. ammonia solution and shake the mixture thoroughly. In presence of iron(II) a brownish-orange or purple-orange precipitate with intense green fluorescence is formed. The fluorescence is so intense that a precipitate appears deep green with highly intense green fluorescence. Large quantities of copper(II) interfere.

Limit of detection: 3 μg/ml.

RESULTS AND DISCUSSION

The nature of products in the tests with I *and* II

I and II, like many other nitrogeneous organic bases, react with bismuth in presence of potassium iodide to form coloured products (double iodides) of general formula BiI_3. base. HI, which may be regarded as salts of the base with iodobismuthic acid, $H[BiI_4]$. The literature contains many examples of the "acid" character[7] of I, but only a few examples of its "basic" character are known.[6] The test for bismuth with I is an additional and unambiguous proof of its basic nature (*cf.* cinchonine, quinine, quinoline, *etc*[8]).

The bismuth tests with I and II are also specific for iodide. Nitrites, as usual, cause interference.

The nature of products in tests with III *and* IV

The characteristic coloured products in the bismuth test are likely to be "adsorption complexes" of the dyes with the bismuth hydroxide formed on addition of the ammonia. However, that ammonia may be involved in the constitution of the adsorption complexes is indicated by the fact that the test fails if sodium hydroxide is used in place of ammonia. The green fluorescent iron(II) precipitate is also presumed to be an "adsorption complex". This is confirmed by the fact that a similar product is obtained when a suspension of freshly prepared ferrous hydroxide [produced by treating an iron(II) solution with ammonia or sodium hydroxide] in water is mixed and shaken with a little eosin or mercurochrome solution.

Summary—Isoperthiocyanic acid (3-amino-5-thione-1,2,4-dithiazole) (I), tetraethylthiuram monosulphide ("Tetmosol") (II), eosin (III), and mercurochrome (IV) are used as new qualitative reagents for bismuth. III and IV are also used for detection of iron(II). A conc. sulphuric acid solution of I, or an acetone solution of II, when treated with bismuth in presence of potassium iodide, gives a deep red or reddish-orange precipitate, characteristic of bismuth. Bismuth in presence of III or IV gives a heavy and characteristically bright deep-pink precipitate on addition of ammonia. With I, 1 μg of bismuth may be detected with a dilution limit of 1:50,000. Sb(III) and As(III) do not interfere in any of these tests. Iodides interfere only when I and II are used as reagents. Pb, Cu(II), and Fe(III) interfere with III and IV. I and II are also proposed as reagents for iodide; nitrites would interfere. III and IV, with iron(II) on addition of ammonia, produce a precipitate with highly intense green fluorescence. No other common cation [including Fe(III)] or anion interferes. The limit of detection is 3 μg/ml.

Zusammenfassung—Isosuperthiocyansäure (3-Amino-5-Thion-1,2,4-Dithiazol) (I), Tetraäthylthiuram Monosulphid ("Tetmosol") (II), Eosin (III) und Mercurochrom (IV) werden als neue qualitative Reagenzien für Wismuth benutzt. III und IV werden auch zur Feststellung von Eisen(II) benutzt. Eine konz. Schwefelsäurelösung von I oder eine Acetonlösung von II ergibt einen tiefroten oder rötlich-orangenen, für Wismuth charakteristischen Niederschlag, wenn mit Wismuth in Gegenwart von Kaliumjodid behandelt. Wismuth gibt bei Vorhandensein von III oder IV einen schweren und bei Zugabe von Ammoniak charakteristischen glänzenden, tiefrosa Niederschlag. Bei I kann kann bei einem Verdünnungsgrenzwert von 1:50,00 1 μg von Wismuth entdeckt werden. Sb(III) und As(III) stören in keinem dieser

Teste. Jodide stören nur, wenn I und II als Reagens benutzt werden. Pb, Cu(II) und Fe(III) stören mit III und IV I. und II werden auch als Reagens für Jodid vorgeschlagen: Nitrate würden sich störend auswirken. III und IV, mit Eisen(II) und Zusatz von Ammonia produzieren einen Niederschlag mit sehr intensiver Fluoreszenz. Kein anderes gewöhnliches Kation (einschliesslich Fe(III)) oder Anion stört. Der Grenzwert für Feststellung ist 3 μg/ml.

Résumé—On utilise l'acide isoperthiocyanique (3-amino 5-thione 1,2,4-dithiazole) (I), le monosulfure de tétraéthylthiurame ("Tetmosol") (II), l'éosine (III), et le mercurochrome (IV) comme nouveaux réactifs qual-i tatifs du bismuth. III et IV sont aussi utilisés pour la détection du fer(II). Une solution de I dans l'acide sulfurique concentré, ou une solution de II dans l'acétone, lorsqu'elle est traitée par le bismuth en présence d'iodure de potassium, donne une précipité rouge foncé ou rouge-orangé, caractéristique du bismuth. Le bismuth en présence de III ou IV donne un précipité dense et spécifiquement rose foncé vif par addition d'ammoniaque. Avec I, on peut détecter 1 μg de bismuth avec une limite de dilution de 1:50 000. Sb(III) et As(III) ne gênent dans aucun de ces essais. Les iodures gênent seulement lorsque I et II sont utilisés comme réactifs. Pb, Cu(II) et Fe(III) gênent avec III et IV. I et II sont aussi proposés comme réactifs de l'iodure; les nitrites gêneraient. III et IV, avec le fer(II) en plus de l'ammoniaque produisent un précipité de fluorescence verte extrêmement intense. Aucun autre cation [y compris le fer(III)] ou anion communs n'interfèrent. La limite de détection est de 3 μg/ml.

ANALYTICAL DATA

Polarography of Cd–malonate–oxalate complex

(*Received* 18 *November* 1971. *Accepted* 26 *January* 1972)

Little attention has been paid to the polarographic study of mixed ligand complexes. Schaap and McMasters[1] were the first to provide a logical extension of the method of DeFord and Hume[2] for the study of such mixed species. We have applied their method to the study of malonate–oxalate complexes of cadmium.

Since Cd^{2+} forms hexaco-ordinate complexes with oxalate and malonate individually,[1,3] there can be at most three mixed complex species, $Cd(XY_2)$, $Cd(XY)$ and $Cd(X_2Y)$.

$$M + iX + jY \rightleftharpoons MX_iY_j$$

The DeFord and Hume expression for $F_0(X)$ may be extended to give a new function F_{00}:

$$F_{00}(X, Y) = \text{antilog}\left[\frac{0{\cdot}434nF}{RT}\Delta E_{1/2} + \log\frac{I_M}{I_0}\right]$$

where the symbols have their usual significance.

From Leden's approach[4]

$$\begin{aligned} F_0(X, Y) = {} & \{\beta_{00} + \beta_{01}[Y] + \beta_{02}[Y]^2 + \beta_{03}[Y]^3\}[X]^0 \\ & + \{\beta_{10} + \beta_{11}[Y] + \beta_{12}[Y]^2\}[X] \\ & + \{\beta_{20} + \beta_{21}[Y]\}[X]^2 + \{\beta_{30}\}[X]^3 \end{aligned}$$

or

$$F_{00}(X, Y) = A + B[X] + C[X]^2 + D[X]^3$$

The original graphical method may be applied to F_{00} if the activity of one of the ligands is held constant while that of the other is varied. The intercept on the F_0 axis in the plot of F_{00} *vs.* [X] gives A, and

$$F_{10} = \frac{F_{00} - A}{[X]} = B + C[X] + D[X]^2$$

By a similar plotting of F_{10} *vs.* [X], B is obtained, and then C and D by iteration.

From the knowledge of C, the mixed stability constant β_{21} may be calculated. In order to determine β_{11} and β_{12}, B must be evaluated at two concentrations of Y.

EXPERIMENTAL

All reagents were of analytical-reagent grade. Potassium oxalate and malonate at pH 7·0 were used as complexing agents. Potassium nitrate was the supporting electrolyte, used to keep the ionic strength constant at 2·1. A 0·004% gelatin solution was used to suppress maxima. All solutions were made up in conductivity water. The experimental technique was the same as described earlier.[5]

RESULTS AND DISCUSSION

Cd–oxalate system

The stability constants were determined by the DeFord and Hume method at pH 7·0 and 27 ± 1°. They were $\log\beta_1 = 2{\cdot}90$, $\log\beta_2 = 4{\cdot}00$, $\log\beta_3 = 5{\cdot}08$, which agree well with those obtained by Schaap and McMasters,[1] considering the difference in ionic strengths used.

Cd–malonate system

Under the same conditions the stability constants were found to be $\log\beta_1 = 1{\cdot}63$, $\log\beta_2 = 2{\cdot}36$, $\log\beta_3 = 3{\cdot}40$ which agree well with those obtained earlier.[3]

The mixed Cd–malonate–oxalate system

The concentration of oxalate was varied while that of the malonate was kept constant, two different values of [Mal] being used, intentionally chosen so that the simple Cd–malonate complex would contain predominantly one or two malonate ions.

Solutions containing $6 \times 10^{-4}M$ Cd^{2+}, $0{\cdot}1524M$ Mal^{2-} and enough potassium nitrate to make $\mu = 2{\cdot}1$ at pH 7·0 and 27°, were polarographed at various oxalate concentrations. In each case a single well-defined diffusion-controlled wave was obtained. The plots of E *vs.* log $i/(i_d - i)$ were linear with slope of 32 ± 1 mV, showing that the two-electron reduction is reversible. The half-wave potentials became more negative with increase in oxalate concentration, indicating mixed complex formation. The experiment was repeated with a malonate concentration of $0{\cdot}2286M$.

The plots of $E_{1/2}$ *vs.* log C_X may be interpreted as three straight lines, showing successive addition of oxalate ions, one in the oxalate concentration range $0{\cdot}00$–$0{\cdot}14M$, the second in the concentration range $0{\cdot}14$–$0{\cdot}28M$ and the third at concentrations $>0{\cdot}28M$.

The constants A, B, C and D were evaluated as described above, and from C, log β_{21} of the complex $Cd(Ox)_2(Mal)$ was found to be 4·96.

From the value of B at the two malonate concentrations log β_{11} and log β_{12} for complexes Cd(Ox)(Mal) and $Cd(Ox)(Mal)_2$ respectively were evaluated as 3·85 and 3·56.

Log β_{21} was also calculated from the second value of C and was found to be 5·02 in good agreement with the first.

Both values of log D (5·12, 5·10) agree with that of log β_2 (5·07) for the simple Cd–oxalate complex.

Summary—The composition and stability constants of mixed malonate oxalate complexes of cadmium have been determined polarographically. The logarithms of the stability constants of complexes $Cd(Ox)(Mal)_2$, Cd(Ox)(Mal), and $Cd(Ox)_2(Mal)$ were found to be 3·57, 3·86 ± 0·05 and 4·99 ± 0·10 respectively.

Zusammenfassung—Die Zusammensetzung und die Stabilitätskonstanten gemischter Malonat–Oxalat-Komplexe von Cadmium wurden polarographisch bestimmt. Die Logarithmen der Stabilitätskonstanten der Komplexe $Cd(Ox)(Mal)_2$, Cd(Ox)(Mal) und $Cd(Ox)_2(Mal)$ betragen 3,57, 3,86 ± 0,05 bzw. 4,99 ± 0,10.

Résumé—On a déterminé polarographiquement la composition et les constantes de stabilité de complexes mixtes malonate—oxalate du cadmium. On a trouvé que les logarithmes des constantes de stabilité des complexes $Cd(Ox)(Mal)_2$, Cd(Ox)(Mal), et $Cd(Ox)_2(Mal)$ sont respectivement de 3,57; 3,86 ± 0,05 et 4,99 ± 0,10.

Formation of nickel, cobalt, manganese and cadmium ferrocyanides

(*Received* 23 *November* 1971. *Accepted* 27 *December* 1971)

A systematic study has been made of hexacyanoferrates(II), in order to verify the relationship between the properties of the metal ion acting as precipitating agent (ionic dimensions, charge, *etc*) and the nature of the compounds formed on interaction with potassium ferrocyanide.[1,2] The interest arises because of the variety of stoichiometric behaviour which can been achieved by the reacting system, in dependence upon the actual reaction conditions.

The anion $Fe(CN)_6^{4-}$ forms a number of compounds with a variety of metals.[3] These species have specific colours, low solubility in water and sometimes a marked tendency to produce colloids. As a consequence ferrocyanide is often used in the identification of some cationic species[4] as well as in the enrichment of trace elements.[5,6] Some authors propose using this reagent quantitatively [7–10] but non-reproducible results are easily obtained because of the variety of factors involved in the reaction with a metal ion.[1,2] It is therefore necessary to know the nature of the products formed under the various experimental conditions.

The types of ferrocyanides formed in solution depend largely on the concentrations of the reagents; the existence of both "normal" and "mixed" ferrocyanides (the latter contain a univalent cation such as K^+, Rb^+, Cs^+, Tl^+, NH_4^+ in constant ratio to the other cation) is known from the literature.[1,2–14]

A systematic investigation[1] of the reaction of ferrocyanide with Cu^{2+}, Zn^{2+}, Pb^{2+} and Ag^+ has established the experimental conditions for formation of $M_2Fe(CN)_6$ and $K_2M_3[Fe(CN)_6]_2$ for Cu, Zn and Pb and of $Ag_4Fe(CN)_6$ and $KAg_3Fe(CN)_6$. The theory has also been given.

The present investigation studies similarly the systems formed by $K_4Fe(CN)_6$ with Ni^{2+}, Co^{2+}, Mn^{2+} and Cd^{2+}, which are known to form various ferrocyanides.[10,11,12–17]

EXPERIMENTAL

Procedure

The potentiometric methods described earlier[1] were used, and the precipitates were analysed for metal content by atomic-absorption spectrophotometry. The cation reagent solutions were standardized by EDTA titration (manganese was also checked spectrophotometrically as permanganate). The potassium ferrocyanide solution was standardized potentiometrically with zinc.

RESULTS

Results for the complexes are summarized in Table I. Table II gives results for the stoichiometry of the reactions and indicates the analytical possibilities.

* In 100 ml of solution.

Solubility products and thermodynamic formation functions

K_{sp} values were obtained by conductivity measurements on saturated solutions free from oxygen and carbon dioxide, except for $K_{12}Co_8[Fe(CN)_6]_7$ and $K_2CoFe(CN)_6$ (because of their easy alteration). Equivalent limiting conductivities at 20 and 25° were obtained from literature data; values at 30°, 35° and 45° were obtained by Walden's rule.[18]

Enthalpies for the Ni(II) and Co(II) complexes were calculated from

$$\Delta H = -T^2\left[\frac{\partial(\Delta G/T)}{\partial T}\right],$$

assuming that the incremental ratio $\left[\frac{\Delta(\Delta G/T)}{\Delta T}\right]$, between 20 and 30° may be identified with $\left[\frac{\partial(\Delta G/T)}{\partial T}\right]$, at 25°.

For the Mn(II) and Cd(II) complexes, for which the K_{sp} values are available at three temperatures, the following relationships were obtained by the least-squares method:[19]

$$\Delta G_T = -40{\cdot}28 - 2{\cdot}49 \times 10^{-1}\,(\Delta T) + 5{\cdot}7 \times 10^{-3}\,(\Delta T)^2 \text{ for } K_2Mn_3[Fe(CN)_6]_2$$
$$\Delta G_T = -88{\cdot}08 - 0{\cdot}086\,(\Delta T) - 6{\cdot}0 \times 10^{-3}\,(\Delta T)^2 \text{ for } K_8Mn_6[Fe(CN)_6]_5$$
$$\Delta G_T = -18{\cdot}34 + 0{\cdot}165\,(\Delta T) - 7{\cdot}3 \times 10^{-3}\,(\Delta T)^2 \text{ for } Cd_2Fe(CN)_6$$
$$\Delta G_T = -165{\cdot}1 + 3 \times 10^{-2}\,(\Delta T) \text{ for } K_{12}Cd_8[Fe(CN)_6]_7$$

Though the use of temperature coefficients is sometime advised[20] for evaluating heats and entropies of formation from the logarithm of the stability constants, in this case we have obtained an unlikely dependence of ΔH on temperature for the complexes $K_2Mn_3[Fe(CN)_6]_2$, $K_8Mn_6[Fe(CN)_6]_5$ and $Cd_2Fe(CN)_6$. This may be due to a limited validity of the expressions derived from only three points or the large multiplication of experimental error arising from the complexity of the compounds. We think that the best values for obtaining ΔH and ΔS are those at 35°, first because they are the ones least affected by limiting conditions and secondly because they are in agreement with the values obtained by two other methods. The results show that the $-\Delta H$ sequence of $d^6 < d^7 < d^8$ expected for stabilization due to the ligand field[20,21] is observed for every value of ΔH for $K_2M_3[Fe(CN)_6]_2$ obtained from the equations written above.

The results are summarized in Table III.

Conclusions

The stability (ΔG°) of these ferrocyanides in the sequence Zn > Cu > Ni > Mn ~ Co leads to the disappearance of simple forms such as $M_2Fe(CN)_6$, mixed species containing some K^+ appearing. The complex $K_2M_3[Fe(CN)_6]_2$ has probably some peculiarly stable structural properties, since its existence has been found in all the systems investigated.

Summary—Potentiometric and solubility studies have been made of the ferrocyanides of nickel, cobalt, manganese(II) and cadmium both in the presence and absence of potassium. The K_{sp}, ΔG°, ΔH° and ΔS° values are reported.

Zusammenfassung—Es wurden potentiometrische und Löslbarkeitsuntersuchungen an Cyaneisenverbindungen von Zink, Kuppfer(II), Nickel, Mangan II und Kobalt II sowohl mit und ohne Vorhandensein von Kalium vorgenommen. Es werden die K_{sp}, ΔG°, ΔH° und ΔS° Werte angegeben.

Résumé—On a effectué des études potentiométrique et de solubilité des ferrocyanures de nickel, cobalt, manganèse(II) et cadmium toutes deux en la présence et l'absence de potassium. On rapporte les valeurs de K_{sp}, $\Delta G°$, $\Delta H°$ et $\Delta S°$.

The acid dissociation constants of 2,3-quinoxalinedithiol

(*Received* 20 *January* 1972. *Accepted* 20 *February* 1972)

SINCE the preparation of 2,3-quinoxalinedithiol (H_2qdt) by Morrison and Furst in 1956,[1] many publications on its use as an analytical reagent have appeared.[2] Information on the properties of the reagent itself is scarce, however, and as yet there are no published data on the ionization constants. Stevančević and Dražić[3] attempted to obtain these constants by a spectrophotometric method but concluded erroneously that they were too close to be determined by such methods.

In order to rationalize the analytical procedures and to predict the optimum working conditions, the ionization constants of H_2qdt have been determined by potentiometric titration and solubility measurements.

EXPERIMENTAL

Reagents

2,3-*Quinoxalinedithiol.* Prepared as described previously[4] and purified by dissolving the crude product in sodium hydroxide, under a nitrogen atmosphere, reprecipitating it with acetic acid, and repeating the process. The product was dried at 100° under vacuum. Elemental analysis of the purified material gave C, 49·7%; H, 3·3%; N, 14·2%; S, 32·3% $C_8H_6N_2S_2$ requires C, 49·5%; H, 3·1%; N, 14·4%; S, 33·0%.

Sodium salts. Prepared by mixing H_2qdt with the calculated volume of 4*M* sodium hydroxide and evaporating under reduced pressure. The crude product was purified by dissolving it in the minimum volume of aqueous ethanol, filtering, and adding a large excess of diethyl ether. The bright yellow-orange material was filtered off, washed with ether and dried under vacuum. Elemental analysis of the

The acid dissociation constants of 2,3-quinoxalinedithiol

(*Received* 20 *January* 1972. *Accepted* 20 *February* 1972)

SINCE the preparation of 2,3-quinoxalinedithiol (H_2qdt) by Morrison and Furst in 1956,[1] many publications on its use as an analytical reagent have appeared.[2] Information on the properties of the reagent itself is scarce, however, and as yet there are no published data on the ionization constants. Stevančević and Dražić[3] attempted to obtain these constants by a spectrophotometric method but concluded erroneously that they were too close to be determined by such methods.

In order to rationalize the analytical procedures and to predict the optimum working conditions, the ionization constants of H_2qdt have been determined by potentiometric titration and solubility measurements.

EXPERIMENTAL

Reagents

2,3-*Quinoxalinedithiol.* Prepared as described previously[4] and purified by dissolving the crude product in sodium hydroxide, under a nitrogen atmosphere, reprecipitating it with acetic acid, and repeating the process. The product was dried at 100° under vacuum. Elemental analysis of the purified material gave C, 49·7%; H, 3·3%; N, 14·2%; S, 32·3% $C_8H_6N_2S_2$ requires C, 49·5%; H, 3·1%; N, 14·4%; S, 33·0%.

Sodium salts. Prepared by mixing H_2qdt with the calculated volume of 4*M* sodium hydroxide and evaporating under reduced pressure. The crude product was purified by dissolving it in the minimum volume of aqueous ethanol, filtering, and adding a large excess of diethyl ether. The bright yellow-orange material was filtered off, washed with ether and dried under vacuum. Elemental analysis of the disodium salt (dihydrate) gave C, 35·2%; H, 3·1%; N, 10·1%; S, 23·3%; Na, 16·8%. $C_8H_8N_2S_2O_2$-Na_2 requires C, 35·0; H, 2·9%; N, 10·2%; S, 23·4%; Na, 16·8%.

Perchloric acid. Prepared by dilution of the analytical grade acid and standardized with sodium carbonate.

Buffer solutions. For the pH range 3·0–10·5 buffer solutions recommended by Albert and Serjeant[5] were used, and Walpole buffers[6] for the pH range 0·7–3·0.

Procedure

Sodium salts of H_2qdt (100-ml portions of 0·001–0.01*M* solutions) were titrated potentiometrically at 20° under a nitrogen atmosphere with perchloric acid. The titrations were repeated at 25° and at ionic strength 0.1 (added sodium perchlorate) but no significant differences were observed.

Solubility measurements were carried out by preparing saturated solutions of H_2qdt in 0·1*M* sodium chloride and 0·005*M* buffer, equilibrating them by shaking for 3 hr at constant temperature, filtering, measuring the pH of the filtrate and determining the H_2qdt in the filtrate absorptiometrically as the $[Zn(qdt)_2]^{2-}$ complex, at pH 10 and 390 nm.

RESULTS AND DISCUSSION

The sodium salts are much more soluble than H_2qdt in water, *e.g.*, up to 2*M* solutions of the disodium salt can be prepared, and $Na_2qdt.2H_2O$ provides an excellent form of the analytical reagent because of its relative stability. Potentiometric titration of 0·01*M* Na_2qdt with perchloric acid clearly indicates the dibasic character of the reagent (see Fig. 1).

The region of the titration curve corresponding to addition of up to one equivalent of acid was used directly to obtain pK_2 by the method of Albert and Serjeant.[5] Typical results are shown in Table I. The mean value and spread found at 20° were 9·95 ± 0·03.

pK_1 could not be obtained directly because H_2qdt precipitated on addition of more than one equivalent of acid. For this region of the titration curve the method of Dyrssen and Hoek,[7] as described by King,[8] was therefore used. By applying the condition of electroneutrality to points on the curve corresponding to a saturated solution of H_2qdt (see Fig. 1), a series of values for the solubility product $K_s = [H^+][Hqdt^-]$ was obtained. Typical results are shown in Table II. The mean value

$Hqdt^-$ titrated, *mmole*	0·1928	0·2892	0·3856	0·4020	0·5784	0·6784
pK_s	10·88	10·89	10·95	10·89	10·94	10·88

and spread found for pK_s at 20° were 10·91 ± 0·04. The solubility of un-ionized H_2qdt (S_0), measured at 20°, was 7·2 × $10^{-5}M$. pK_1 was calculated by using the relationship

$$K_1 = \frac{[H^+][Hqdt^-]}{[H_2qdt]} = \frac{K_s}{S_0}$$

The value found for pK_1 was 6·80 ± 0·04. Similar results were obtained from potentiometric titration of the monosodium salt of H_2qdt.

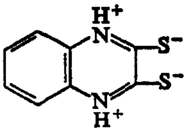
Measurements of solubilities in buffered solutions showed that the solubility of H_2qdt remains constant in the pH range 0·7–5·0 and is equal to S_0. Above pH 5 there is a marked increase in solubility. Solubilities in the pH range 5·0–8·5 were used to obtain pK_1 by the method of Krebs and Speakman,[8] also described by King.[9] The relevant equation is:

$$\log\left(\frac{S}{S_0} - 1\right) = \mathrm{pH} - \mathrm{p}K_1$$

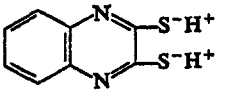
where S is the solubility of H_2qdt at a given pH. The pK_1 value obtained graphically by this method was 6·86 at 20°. Above pH 8·5 H_2qdt becomes extremely soluble and the solubility method cannot be used to determine pK_2.

The average values of the constants found in the present work are pK_1 = 6·84 and pK_2 = 9·95. They must be regarded essentially as the "mixed" acid ionization constants since activity corrections were not applied. However, as the determinations were carried out in solutions not stronger than 0.01M, the values of the thermodynamic constants may not be significantly different. The two pK values are sufficiently far apart to be determined sequentially with good precision.

It can be concluded that H_2qdt behaves as a dibasic acid and is not itself protonated at pH values not below 0·7. Lower pH values were not investigated. It would be of interest to know whether the acid protons are associated with sulphur or nitrogen atoms. The following extreme structures of H_2qdt are possible



(I)



(II)

as well as thiol-thione tautomeric forms.[10] The absence of any basic (proton-acceptor) properties in H_2qdt suggests structure (I) as the most probable. Other work carried out in these laboratories,[10] particularly infrared spectroscopic and preparative evidence, supports this view, which has bearing on the applications of H_2qdt as an analytical reagent.

Summary—Sodium salts of 2,3-quinoxalinedithiol have been prepared and used for determination of the acid ionization constants by potentiometric titration. The fully protonated form of the reagent was used in an alternative determination of the first ionization constant by a solubility method. The constants are $pK_1 = 6·84 \pm 0·04$ and $pK_2 = 9·95 \pm 0·03$.

Zusammenfassung—Es wurden Natrium Salze von 2,3-Chinoxalindithiol vorbereitet und zur Ermittlung der Säureionisationskonstanten durch potentiometrische Titrierung benutzt. Die völlig protonierte Form des Reagenz wurde mit einem Löslichkeitsverfahren in einer anderen Feststellung der ersten Ionisationskonstante verwandt. Die Konstanten sind $pK_1 = 6,84 \pm 0,04$ und $pK_2 = 9,95 \pm 0,03$.

Résumé—On a préparé les sels de sodium du 2,3-quinoxalinedithiol et les a utilisés pour la détermination des constantes d'ionisation acides par titrage potentiométrique. On a utilisé la forme totalement protonée du réactif dans une autre possibilité de détermination de la constante de première ionisation par une méthode de solubilité. Les constantes sont $pK_1 = 6,84 \pm 0,04$ et $pK_2 = 9,95 \pm 0,03$.

TALANTA REVIEW*

SYNTHETIC INORGANIC ION EXCHANGERS—II

SALTS OF HETEROPOLYACIDS, INSOLUBLE FERROCYANIDES, SYNTHETIC ALUMINOSILICATES AND MISCELLANEOUS EXCHANGERS

(*Received* 18 *June* 1971. *Accepted* 7 *February* 1972)

Summary—A review of the developments during the period 1965–70 in use of heteropoly acid salts, ferrocyanides and synthetic zeolites as ion-exchangers.

IN PART I[1] the ion-exchange properties of hydrous oxides and acidic salts of multivalent metals were described. In this part the progress made during the period 1965–1970 in studying the exchange properties of heteropoly acid salts, insoluble ferrocyanides, synthetic aluminosilicates and certain other substances will be reviewed.

SALTS OF HETEROPOLY ACIDS

The parent acids of the compounds considered in this section are the 12-heteropoly acids of the general formula $H_mXY_{12}O_{40}\cdot nH_2O$ ($m = 3, 4, 5$), where X may be phosphorus, arsenic, silicon, germanium, and boron, and Y different elements such as molybdenum, tungsten, and vanadium. The basic physicochemical and ion-exchange properties of these compounds have been widely described in many earlier papers and surveyed in the book by Amphlett.[2] The emphasis during the last five years has been on the applications of these compounds, especially the 12-molybdophosphates.

Molybdophosphates

12-Molybdophosphates (MP) of the alkali metals and NH_4^+, prepared by metathesis in acid solutions, are salts with base-equivalent ranging from 1·82 to 2·48 per mole. Nearly neutral salts with base-equivalents of 2·9 are prepared by neutralization. The salts of bivalent metals have base-equivalents varying from 2·68 to 3·10. All compounds examined, although non-stoichiometric, are true compounds with the water content generally lower for the alkali metal salts than for the bivalent metal salts and their thermal stability follows the order Rb > Cs > K > Na > Li.[3] Anhydrous salts of MP with pyridinium, lutidinium and collidinium cations have been described. These salts proved worse exchangers than the corresponding tungstophosphates.[4] Tungstophosphates retained $2H_2O$ of crystallization after drying at 150°, whereas MP and tungstosilicates became anhydrous.[5]

Like inorganic tungstophosphates all the MP form normal (X_3MP) and acidic

(X_2HMP) salts, but no diacidic (XH_2MP) salts. The main factor influencing the formation of normal or acid insoluble MP is the original X:Y ratio. The effect of hydrogen ions is of secondary importance, but is more decisive for tungstophosphate formation.[5] The following salts of MP were prepared:[5] Tl_3MP, Tl_2HMP, Cs_3MP, Cs_2HMP, Rb_3MP, Rb_2HMP, $(NH_4)_3MP$, $(NH_4)_2HMP$, K_3MP, K_2HMP, Hg_3MP, and Ag_3MP. The rate of Cs^+ and Rb^+ exchange in Tl_3MP is slower than with the NH_4^+ analogue,[6] and because thallium is bound more firmly than the proton the exchange is between the alkali metal and hydrogen ions. Caesium is adsorbed more easily than rubidium. Highest separation factors for caesium from rubidium were found on Tl_2HMP. The presence of thallium in the solution substantially depressed the caesium adsorption.[6] The preparation and properties of alkali metal salts of MP have been reviewed by Thistlethwaite.[7]

Ammonium molybdophosphate. Ammonium molybdophosphate (AMP) was the first MP salt to be used for practical separations and to be the subject of basic adsorption and physicochemical studies.

The preparation and properties of neutral and acid salts of $(NH_4)_3PMo_{12}O_{40}$ and $(NH_4)_2HPMo_{12}O_{40}$ have been described in detail by Healy[5] and Krtil.[6] Coarse AMP which allowed adequate flow-rates in large-scale columns without the need of carriers was prepared by Smit[8] by direct conversion of 12-molybdophosphoric acid into the ammonium salts. Rapid, irreversible, exchange of NH_4^+ for H^+ occurs in the solid and the conversion is accompanied by a phase transition. Each particle of the product consists of a stable agglomerate of microcrystals of about 1 μm diameter. The porosity permits a high rate of exchange.[8]

The capacity of AMP for caesium was found to be 1·0 meq/g and corresponds to the formation of Cs_2NH_4MP. Caesium is more easily adsorbed by the normal than the acidic ammonium salts. On the acidic salts caesium is exchanged only for protons at higher acidities.[6] The exchange of caesium for the first equivalent of ammonium ion is easier, than that for the second. Smaller alkali metal cations are exchanged as partially hydrated ions.[9] Coetzee[9] studied the sorption properties of AMP by the column chromatography method. However, the saturation capacities had no direct relation to the stoichiometric exchange of one or two equivalents of NH_4^+. Ammonium ions lowered strongly the sorption of Li^+, Na^+, K^+ and H_3O^+ but only a small effect on the Rb^+, Cs^+ and Tl^+ exchange was observed. The following affinity series was derived: $Cs^+ = Tl^+ > Rb^+ > Ag^+ > K^+ > H_3O^+ > Na^+ > Li^+$. The bonds between Tl^+, Ag^+ and the molybdophosphate anion are supposed to be partially covalent, because the adsorption of Ag^+ and Tl^+ was much higher than that of alkali metal ions of the same size.

The sorption behaviour of UO_2^{2+} on AMP was studied under static conditions as a function of the HNO_3, H_2SO_4, NH_4NO_3 and UO_2^{2+} concentration. The UO_2OH^+ cation was proved to be adsorbed at low acidities.[10] The thorium (IV) adsorption was examined in HNO_3 and H_2SO_4 solutions of various concentrations. Linear log K_d *vs.* log $[H^+]$ plots of different slopes were obtained, depending upon ammonium ion and proton concentration.[11] The Th^{4+}–NH_4^+ exchange is controlled by the law of mass action and the mechanism was proved to be ion-exchange except for the acidity range $<0{\cdot}01M$, where the adsorption process was complicated by hydrolysis. Partial irreversibility of Th^{4+} adsorption and relatively slow adsorption kinetics were ascribed to the probable formation of a Th^{4+}–heteropoly-anion complex.[11]

Practical AMP applications are of great interest. AMP has been applied for the concentration and purification of caesium-137 to give spectrally pure γ-sources[12] and for the determination of caesium in rain water[13] and fast-reactor coolants.[14]

Caesium-137 present in the nuclear reactor coolants was separated from ^{103}Ru on AMP. Ruthenium was only partially retained by this sorbent and therefore the contamination of caesium by ruthenium increased with increasing ruthenium content in the coolant.[15] Separation of Rb^+, Cs^+, K^+, Tl^+ and Ag^+ from acid solutions and from Na^+ or Li^+ has been successfully performed on AMP.[12,16] Rb^+, Tl^+ and Cs^+ were sorbed from 5*M* HNO_3, but Na^+ and K^+ were adsorbed negligibly by the exchanger supported on asbestos. Direct Tl^+–Cs^+ separation at tracer levels by using NH_4NO_3 as eluent was very difficult. Rb^+ was therefore eluted with 3*M* NH_4NO_3, thallium separated by oxidative elution with 0·05*M* Br_2 in 5% HBr and Cs^+ eluted with 12*M* NH_4NO_3.[17] Na^+–K^+–Rb^+–Cs^+ mixtures were completely separated on AMP with well-distinguished peaks, whereas an organic cation-exchanger (Dowex 50) required 250 times the bed depth to achieve such a resolution.[12] Up to 0·1 meq of K^+ can be separated quantitatively from amounts of up to 50 meq of Na^+ on a small column with 4 g of AMP supported by glass wool and an asbestos mat. Na^+ was eluted with 0·01*M* HNO_3 and K^+ with 0·25*M* NH_4NO_3.[18] Astatine was co-precipitated with Cs^+, NH_4^+ and K^+ salts of molybdophosphoric acid after oxidation with $Cr_2O_7^{2-}$ in HNO_3 solutions.[19] Sorption of Cs^+ and Rb^+ on $(NH_4)_3MP$ and $(NH_4)_2HMP$ from aqueous alcohol media was higher than from aqueous solutions, but the separation of these elements was not affected by this organic–aqueous mixture.[6]

Membrane electrodes made from AMP were prepared under a pressure of 150 atm with polystyrene, polyethylene and polymethacrylate as binders. The membrane potentials were measured for two-component systems of NH_4^+, Na^+, K^+, Li^+ and Cs^+ and the dependence on the concentration was found to be linear up to 3*M*.[20]

Tungstophosphates (WP)

The second most widely studied group of heteropolyacids are the tungstophosphates. The following mixed alkali metal salts of $H_3PW_{12}O_{40}$ have been prepared:[21] Cs_2NaWP, Cs_2KWP, Cs_2RbWP, Cs_2LiWP, $(NH_4)_2CsWP$, $(NH_4)_2RbWP$, and K_2CsWP. Pure sodium or potassium salts are soluble, and alkali metal salts have properties similar to the parent dialkali hydrogen heteropoly salts. Other salts such as $(NH_4)_3WP$, Tl_3WP and Tl_2HWP were described by Krtil.[6] Most of these preparations exhibit strong base-exchange properties. The mixed salts of $H_3PW_{12}O_{40}$ with bi- or tervalent cations were prepared and the following composition was proved for them: $BaHWP$, $Ba_3(WP)_2$, $Ce(Cs_2WP)_3$, $Al(K_2WP)_3$, $Al[(NH_4)_2WP]_3$ and $UO_2(Cs_2WP)_2$.[21] The salts with quaternary organic cations have interesting properties. Pyridinium WP, picolinium WP, lutidinium WP, and collidinium WP salts are anhydrous and the positions of the isotherms for a particular exchanging cation such as NH_4^+ suggest that the exchangeability decreases in the order pyridinium WP > picolinium WP > lutidinium WP > collidinium WP. The same order was proved for the MP salts. The exchangeability of picolinium WP for univalent cations decreases in the order $NH_4^+ > K^+ > Na^+ \approx Li^+$,[4] and for pyridinium WP in the order $Cs^+ > NH_4^+ > K^+ > Li^+ > Na^+$.[22] The crystal lattice in ammonium tungstophosphate is perhaps too compact to allow the entry of a large cation like collidinium, but loose enough to allow the pyridinium ion to exchange for NH_4^+. In collidinium WP the channels are no doubt large enough for the entry of NH_4^+, but the collidinium is too firmly bound to be replaced by NH_4^+.[4]

WP is a specific exchanger for Cs^+, with lower capacity than MP, *e.g.*, for ammonium WP it corresponds to 0·66 meq/g. Ammonium WP was therefore used for Rb^+, Cs^+, K^+, Tl^+ and Ag^+ separations.[12] Thallium salts are convenient for ^{137}Cs determination in solutions with high Na^+ and K^+ concentrations. Recoveries were 99% for extracting ^{137}Cs from solutions containing $\leqslant$ 128-fold excesses of Na^+ and $\leqslant$ 8-fold excesses of K^+ relative to the amount needed to replace Tl^+ completely from the sorbent.[24] Pyridinium WP is highly specific towards Cs^+. The slopes of the isotherms are widely different for NH_4^+, Cs^+ and K^+ as compared with Li^+ and Na^+ exchange, suggesting that the univalent ions can be separated with the help of this exchanger.[22] Cs^+, NH_4^+ and K^+ salts of tungstophosphoric acid were used for co-precipitating astatine.[19]

Other heteropoly acids

Tungstosilicates (WSi), derived from $H_4SiW_{12}O_{40}$, form M_4WSi, M_3HWSi, M_2H_2WSi, but no MH_3WSi salts,[5] where $M = Rb^+, Cs^+$. High resolution NMR spectra indicate the tetrabasic character of WSi (and similarly pentabasic character of tungstoboric acid).[25] The WS collidinium salt is insoluble, whereas the pyridinium, picolinium and lutidinium salts are soluble. Such cations as NH_4^+, K^+, Na^+, Li^+, Sr^{2+} and Al^{3+} replace collidinium negligibly. Ion-exchange occurs with $(CH_3)_4N^+$, $(CH_3)_3NH^+$ and $(CH_3)_2NH_2^+$ cations and the exchangeability decreases in the series $(CH_3)_4N^+ > (CH_3)_3NH^+ > (CH_3)_2NH_2^+$.[4] Whatman No. 4 paper impregnated with ammonium WSi was used for chromatographic separations of UO_2^{2+} from Bi^{3+}, La^{3+}, Cs^+, Eu^{3+} and Co^{2+}, and of Sr^{2+} from Y^{3+}. This method was designed for fission product and uranium ore analysis.[26]

Ammonium salts of molybdoarsenic and tungstoarsenic heteropoly acids as high-capacity cation-exchangers were applied to Rb^+, Cs^+, K^+, Tl^+ and Ag^+ separation.[12]

The quinine salt of molybdovanadophosphoric acid $H_3PMo_{10}V_2O_{39}$ was prepared as an electron exchanger. The total dynamic oxidation capacity with respect to Fe^{2+} and ascorbic acid was found to be 0·570 and 0·770 meq/g, respectively.[27] The molybdovanadosilicate of nitron(L) corresponding to the formula $(LH)_6SiMo_{10}V_2O_{40}\cdot H_2O$ also shows electron-exchange properties and was tested for its dynamic electron-exchange capacity with respect to $K_2Cr_2O_7$ and ascorbic acid.[28]

Oxine and pyridine salts of molybdogermanic acid were applied as thin-layers for the separation of uranium and fission products. Separations of Cs^+ from Zr/Nb, Ru, Sr/Y and Ce were performed in ammonium acetate–EDTA media.[29] A separation of Cs^+–Rb^+–K^+ and Na^+ by thin-layer electrophoresis on these materials was successful.[16]

Isopoly acids

The ion-exchange properties of isopoly acids, which can be considered as heteropoly acids of hydrogen,[30] have been of limited interest till now. For the univalent salts of isopolytungstic acid the NMR spectra suggest the formulae $M_{10}^I(OH)_2W_{12}O_{38}\cdot nH_2O$ and $M_6^I(OH)_2W_{12}O_{36}\cdot nH_2O$.[25] However, for transition metal salts an 11-heteropolytungstic structure has been proved by X-ray diffraction measurements.[31] The ion-exchange capacity of the K^+ and NH_4^+ salts of C-phase polymolybdic acid is dependent on the cationic polarizability of the ingoing cation.[32]

INSOLUBLE FERROCYANIDES

The ion-exchange properties of a large number of insoluble ferrocyanides of various metals, *e.g.*, of Ag, Zn, Cd, Cu(II), Ni, Co(II), Pb, Mn(II), Fe(III), Bi, Ti, Zr, V, Mo, W, U(VI), have been studied. Among them the ferrocyanides of bivalent metals, or cations like UO_2^{2+} and TiO^{2+}, have been the most extensively studied materials.

By mixing of metal salt solutions with $H_4Fe(CN)_6$, $Na_4Fe(CN)_6$ or $K_4Fe(CN)_6$ solutions, precipitates of various composition are formed, depending upon the initial ratio of reacting components, acidity, and the order of mixing. Pure compounds (or their mixtures) of limiting composition $M_2^{II}[Fe(CN)_6]$, $M_2^{I}M^{II}[Fe(CN)_6]$ and $M_2^{I}M_3^{II}[Fe(CN)_6]_2$ with various amount of water of crystallization (often not stated) are reported for ferrocyanides of bivalent metals. The composition and empirical formulae of individual ferrocyanides reported to be ion-exchangers are summarized in Table I.

TABLE I.—COMPOSITION AND EXCHANGE CAPACITIES OF VARIOUS FERROCYANIDE ION-EXCHANGERS

Ferrocyanide	Composition	Capacity for Cs^+, *meq/g*	Reference	Notes
Ag	$Ag_4Fe(CN)_6$	1·1	54	
Zn	$Zn_2Fe(CN)_6$	6·1	41, 56, 57, 58	
	$H_2Zn_3[Fe(CN)_6]_2$		97	
	$Na_2Zn_3[Fe(CN)_6]_2$		56	
	$K_2Zn_3[Fe(CN)_6]_2$		57	
	$Cs_2ZnFe(CN)_6$		56	
Cd	$Cd_2Fe(CN)_6{\cdot}7H_2O$		98	
	$5Cd_2Fe(CN)_6{\cdot}4K_4Fe(CN)_6$		98	
Cu	$Cu_2Fe(CN)_6{\cdot}6\text{–}8H_2O$		35	
	$Cu_2Fe(CN)_6$	4·5	41,42,44,99,100	
	$H_2CuFe(CN)_6$		99	
Co	$Co_2Fe(CN)_6$	4·6	34,41,101	
	$K_2CoFe(CN)_6$		34	
	$H_2Co_3[Fe(CN)_6]_2$		101	
	$AHCo_3[Fe(CN)_6]_2$		66	A = amine
	$A_2Co_3[Fe(CN)_6]_2$		66	A = amine
Ni	$Ni_2Fe(CN)_6$	5·8	33, 41	
	$K_2NiFe(CN)_6{\cdot}3H_2O$		36	
	$M_4Ni_4[Fe(CN)_6]_3$	1·0–1·2	47, 48	M = Rb^+, K^+
	$M_6Ni[NiFe(CN)_6]_4$	3·0–5·0	50, 102	M = Na^+, K^+, Rb^+, NH_4^+
Mn(II)	$Mn_2Fe(CN)_6$		99	
	$H_2MnFe(CN)_6$		99	
Fe(III)	$M^{I}Fe^{III}[Fe(CN)_6]{\cdot}nH_2O$	3·6	41, 103	M = alkali metal ion
	$Cs_{16}Fe_4^{III}[Fe(CN)_6]_7{\cdot}nH_2O$		103	
Ti(IV)	$[(TiO)_2(OH)(HFe(CN)_6){\cdot}4H_2O]_n$	2·3	37	
V(V)	V:Fe = 3·86:1		62	prepared from $NaVO_3$
	V:Fe = 1·1	2·3	62	prepared from $VOCl_2$
Mo(VI)	$[H_4Fe(CN)_6(MoO_3(H_2O)_x)_{2\cdot2-2\cdot5}]_i$	3·85	38	denoted by FeMo(II)
	$[H_4Fe(CN)_6(MoO_3(H_2O)_x)_{3\cdot8-4\cdot5}]_i$		38	denoted by FeMo(IV)
W(VI)	W:Fe = 1·32:1	1·02	67	
	W:Fe = 2:1–12:1		60	
U(VI)	U:Fe = 1·6:1	1·25	65	

For ferrocyanides of bivalent metals a general formula of $M^{2+}[N^{2+}Fe(CN)_6]$ has been reported by Doležal and Kouřím,[33] where M and N may be different metals. The N^{2+} and Fe^{2+} ions are bound together by CN^- groups and the M^{2+} ions are placed in the free space of the structural lattice. The M^{2+} ions are exchangeable. The composition of ferrocyanides containing alkali metals is formulated[33] as $A_{2x}M_{1-x}[NFe(CN)_6]$, where A is the alkali ion and x can lie between 0 and 1. Similar formulations have been proposed[34] also for the cobalt ferrocyanides, $Co[CoFe(CN)_6]$ and $K_2[CoFe(CN)_6]$.

Few data are available on the structure of ferrocyanide ion-exchangers. A cubic lattice has been reported for $Cu_2Fe(CN)_6$, with $a = 10{\cdot}013$ Å,[35] $K_2NiFe(CN)_6$ with $a = 10{\cdot}07$ Å,[36] and titanium ferrocyanide with $a = 10{\cdot}27$ Å,[37] and a tetragonal lattice has been reported for $K_2CuFe(CN)_6$ with $a = b = 9{\cdot}85$ Å and $c = 10{\cdot}50$ Å.[36] Infrared and NMR measurements on titanium ferrocyanide[37] indicate the presence of free H_2O and OH groups in the dried precipitates. No evidence was found of the presence of a large amount of free protons in this compound and the maximum ratio of exchangeable protons to $Fe(CN)_6$ groups reached the value of 1. The formula of basic salt, given in Table I, was the best representation to fit the infrared and NMR data.[37]

X-Ray structural data of molybdenyl ferrocyanides[38] with Mo:Fe ratio 2–4·5 indicate a body-centred tetragonal unit cell with a variable c-axis. The unit cell of the FeMo(II) compound (Table I) has a tetragonal structure with $c/a > 1$ which becomes perfectly cubic for the FeMo(IV) compound and again tetragonal at still higher Mo/Fe ratios, but now with $c/a < 1$. Continuity in the X-ray spectra and the evolution of the unit cell with increasing Mo/Fe ratio is an indication that molybdenyl ferrocyanides of different composition contain the same structural elements with different arrangements in the unit cell. Thus the unit cell of FeMo(II) contains 2 $[Mo_6O_{22}H_{16}]^{8+}$ groups, 5 $Fe(CN)_6^{4-}$ groups and 36 H^+ ions, which, in agreement with the titration curves,[39] corresponds to 12 meq/g. The unit cell of FeMo(IV) contains two $[Mo_6O_{22}H_{16}]^{8+}$, one $[Mo_4O_{17}H_{12}]^{2+}$ and four $Fe(CN)_6^{4-}$ groups, bringing the total amount of inbuilt H^+ ions to 44 [16 are associated with $Fe(CN)_6^{4-}$ groups] per unit cell, corresponding to 12·7 meq/g. The structure of both the forms is relatively open, which permits a high rate of exchange reaction and a very fast ionic transfer.[38] It is suggested that the structure is made up of parallel ferrocyanide–molybdenyl sheets 14 Å apart, separated by a layer of protonated ferrocyanide ions. Such a structure may swell on hydration and resembles to some extent the clay minerals.[40]

Ferrocyanide ion-exchangers are stable towards mineral acids; in HCl media the optimum stability range is 0·01–2M HCl.[37,38] In contact with HNO_3 a slight oxidation of Fe(II) to Fe(III) occurs, in alkaline media progressive hydrolysis has been observed. The most stable exchangers towards HNO_3 are the ferrocyanides of Co,[34] Ni and Fe(III).[41] Cu and Co ferrocyanides are reported to be resistant to hard γ-radiation.[34,42]

Ferrocyanide ion-exchangers act as cation-exchangers with a high affinity for heavy alkali metal ions, especially for Cs^+. However, copper ferrocyanide also exhibits anion-exchange behaviour.[42] The affinity series $Cs^+ > Rb^+ > NH_4^+ \geqslant K^+ > Na^+$ was found for Cu, Zn, Ni, Fe(III) and Zr ferrocyanides.[33,43] Similar affinity series were found for $Cu_2Fe(CN)_6$—$Cs^+ > Rb^+ > K^+ > Na^+ > Li^+$,[44] Ti ferrocyanide—$Cs^+ > Rb^+ > K^+ > NH_4^+ > Li^+$,[37] Mo ferrocyanide—$Cs^+ >$

$H^+ > Rb^+ > K^+ > Na^+$[40] and W ferrocyanide—$Cs^+ > Rb^+ > NH_4^+ > Na^+ > H^+$.[45,46] Affinity series for bivalent ions have been reported for $Cu_2Fe(CN)_6$—Ba > Ca > Cd > Zn > Mg[44] and Ti ferrocyanide—Ba > Sr > Ca > Mg > Be.[37] Although practically all ferrocyanides are described as highly selective towards Cs^+, higher selectivity towards Ag^+ has been reported for $Cu_2Fe(CN)_6$.[44] Similarly, compounds of the $K_4Ni_4[Fe(CN)_6]_3$ and $M_6Ni[NiFe(CN)_6]_4$ ($M = Na^+, K^+, NH^+_4$) types were found to be highly selective for Rb^+.[47–50] It is interesting that these compounds adsorb Rb^+ by molecular adsorption from SO_4^{2-},[51] NO_2^-,[52] and $C_2O_4^{2-}$,[51] solutions.

According to the M^+–M^{2+} exchange isotherms measured for different ferrocyanides,[33] the maximum uptake of alkali metal cations increases in the series Fe(III) < Cu < Zn < Ni < Co ferrocyanides. The same series is valid also for the uptake of alkaline earth metal cations. It is interesting that the affinity series for Co ferrocyanide (derived from the maximum amount adsorbed) is the reverse of that ($NH_4^+ = K^+ > Rb^+ > Cs^+ > Na^+$) for other ferrocyanides. It is assumed[33] that the property which is responsible for the affinity of various ferrocyanides towards alkali metal ions is the intensity of the electrostatic field on the surface of the cation in the ferrocyanide. The lower the value of this intensity, the higher the affinity for alkali metal ions. The lowest value of field intensity is in the case of cobalt ferrocyanide, where the inversion of the alkali metal affinity series occurs.[33] This behaviour is formally similar to that of some polystyrene resins with a high degree of cross-linking or to aluminosilicate glasses with a high aluminium content, and could be explained by an interaction of ionic size, field intensity and hydration energy effects.[33] However, the results of other authors conflict to some extent with these suggestions, showing Co ferrocyanide as highly selective towards Cs^+.[34,53] Also the high Rb^+/K^+ separation factor (390)[54] does not agree with the above-mentioned affinity series for Co ferrocyanide.[33]

Exchange capacities of individual ferrocyanide ion-exchangers for Cs^+ are summarized in Table I. They depend strongly upon the method of preparation of the exchanger and differ sometimes from batch to batch. Very often the maximum values corresponding to the stoichiometrical formulae are not reached.[40,41,55]

The ion-exchange mechanism in ferrocyanides seems to be rather complicated and not yet quite clear. Thus X-ray data on ferrocyanides of bivalent metals show differences between the compounds of the $M_2^IM^{II}Fe(CN)_6$ (or $M_2^IM_3^{II}[Fe(CN)_6]_2$) and $M_2^{II}Fe(CN)_6$ types. For the former compounds with different M^I, the same diffraction patterns were found. It has been established that during the Cs^+/M^+ exchange process[44,56] only one phase is present. On the other hand, in Cs^+ exchange on $Zn_2Fe(CN)_6$ the presence of two phases [a mixture of $Zn_2Fe(CN)_6$ and $Cs_2ZnFe(CN)_6$] was found.[55,56] The structural rearrangement in the latter case may also explain the rather slower kinetics of exchange reactions on $Zn_2Fe(CN)_6$ in comparison with those on $M_2^IZnFe(CN)_6$.[57,58] However, more data on exchange kinetics would be necessary for deeper understanding of the mechanism of the adsorption processes. The exchange-reaction rate on Mo ferrocyanide is governed by two processes,[59] film and particle diffusion. The apparent diffusion coefficients show a difference of 2–3 orders of magnitude between the diffusion in the film surrounding the particles and in the solid phase. A difference of about 2 orders of magnitude exists also between the reaction rates of 1–1, 2–1 and 3–1 exchange reactions.[59] A pure particle-diffusion mechanism has been observed for Cs^+ exchange on W ferrocyanide.[60]

More data have been reported on ion-exchange tracer equilibria and exchange thermodynamics. The plots of log K_d *vs.* log $[H^+]$ or log $[NH_4^+]$ give straight lines with the slopes corresponding to the valency of the exchanged cation for Na^+, K^+, Rb^+ and Cs^+ exchange on Zn ferrocyanide,[61] Rb^+ and Cs^+ exchange on V ferrocyanide,[62] Cs^+, Co^{2+}, Sr^{2+}, Fe^{3+} and Ce^{3+} exchange on Mo ferrocyanide[39,63] and Na^+, Rb^+, Cs^+, NH_4^+, Sr^{2+} and Ce^{3+} exchange on W ferrocyanide.[45,46] The exchange equivalence has been proved for the K^+–Cs^+, Zn^{2+}–Cs^+ and Cs^+–Na^+ systems on Zn ferrocyanide.[56,57] Thermodynamic equilibrium constants and the corresponding ΔG values have been determined for Na^+, Rb^+, Cs^+, Sr^{2+} and Ba^{2+} exchange on Mo ferrocyanide.[40] The only negative ΔG value was found for Cs^+/H^+ exchange (-560 cal/mole). All these findings indicate a true ion-exchange mechanism. However, very often some irregularities in these dependences have been observed, where the slopes of the plots did not correspond to the valency of the exchanged cation[62,64,75] or the plots were far from linear.[64] In the case of Ti ferrocyanide the log K_d values for Cs^+ decreased even with increasing pH.[64] Furthermore, non-equivalent exchange was observed in some systems,[34,56,64,66] which has been explained by simultaneous adsorption of anions.[56] The mechanism of the adsorption of bivalent transition metals and some ter[5] and quadrivalent metals (forming insoluble ferrocyanides) will be even more complicated and the formation of the corresponding ferrocyanide sheets in the sorbent should be considered as in the case of Ni^{2+} and Co^{2+} adsorption on Mo ferrocyanide.[40]

The selectivity coefficients and separation factors determined for a series of systems and various ferrocyanides[43,45,54,62,64,65,67] have enabled various separation procedures to be worked out. Thus Zn ferrocyanide is suitable for the Na^+–K^+ and Rb^+–Cs^+ separations[61] as well as for the separation of Cs^+ from mixtures[58,68] of fission products. A rapid thin-layer chromatographic separation of Na^+, K^+, Rb^+ and Cs^+ on Zn ferrocyanide plates has been described.[69] A wide range of separation applications has been reported for Co ferrocyanides, especially for large-scale column isolation and concentration of ^{137}Cs from fission-product waste solutions,[34,53] ^{137}Cs separation from radioactive wastes and sea-water,[70] adsorption of traces of Cs^+ from oceanic fall-out,[71] and for the isolation of ^{137}Cs and its subsequent γ-ray spectrometric determination.[72] Ni and Cu ferrocyanides have been used for the treatment of liquid radioactive effluents from the Italian nuclear centre at Cassaccia.[73] Fe(III) ferrocyanide has been successfully used as an isotope generator to separate ^{137m}Ba from ^{137}Cs.[74] The possibility of separating fission products (Cs, Sr, rare earths, Zr) from uranyl salt solutions as well as of Th from U has been mentioned for Ti ferrocyanide.[64] V ferrocyanides[75–77] are suitable for Rb^+ and Cs^+ isolation from acid solutions and in the presence of NH_4^+ salts. The ^{137}Cs separation from fission products yields radiochemically pure ^{137}Cs.[77] The possibility of Cs^+ co-precipitation with Cu and Fe ferrocyanides being suitable for the removal of radiocaesium from low and high activity-level waste water[78] or for the removal of Cs^+ contaminants from simple aqueous solutions[79] has been discussed. Manganese and vanadyl ferrocyanides may also be used as ion-exchanging membranes.[80,81]

In order to improve the mechanical properties of ferrocyanide ion-exchangers for use in column operations, the preparation of the exchangers has been carried out by precipitation on solid inert supports, *e.g.*, bentonite, silica gel *etc*,[82–85] by freezing and thawing the precipitated gels,[86] or by binding the precipitate particles with insoluble polymers such as polyvinyl acetate.[87] The exchangers prepared in such a way behave in general similarly to the mother ferrocyanides, although some differences have been also reported,[83] such as higher capacity, resulting from the larger overall surface area of coarsely-grained supports.

Ferrocyanide/ion-exchange resins have recently become the most intensively studied metal salt/ion-exchange materials. They are prepared by treatment of strongly basic anion-exchange resins with metal salt and $K_4Fe(CN)_6$ solutions. Thus V, Ce, Cu, Ni, Co, Fe, Cd, Zn ferrocyanides[88–94] in combination with anion-exchangers AV-17, AN-9, Amberlite IRA-410, IRA-904, IR-45, IRS-50, A-27 and Dowex 1 × 10 have been prepared. The exchangers behave both as cation- and anion-exchangers[88,89] and are very stable towards acids, alkalies and hard γ-radiation.[88] The cation-exchange capacity is usually high, which is explained by the presence of the negatively charged complexes with the anion-exchanger functional groups of the type $\{[R_4NFe(CN)_6]_2Cu\}^{4-}$.[90] The formation of the complexes has been proved by X-ray and infrared measurements.[89,95] The exchange ability of individual ferrocyanides decreases with decreasing charge on the ferrocyanide complex cation ($V > Ce > Cd > Zn > Co = Cu > Fe > Ni$) and according to the anion-exchange resins used, in the order IRA-410 > IR-45 > AN-9.[89]

The resins are specific for ^{137}Cs[91] and mutual separation of fission products ^{137}Cs, ^{90}Sr, ^{95}Zr, ^{95}Nb, ^{106}Ru and ^{144}Ce has been achieved on Cu ferrocyanide–Amberlite IRA-904 resin in HCl media. Similar results were obtained with Fe(III) ferrocyanide from HNO_3 solutions.[93] Removal of caesium from radioactive effluents,[96] and separation of ^{137}Cs from ^{137}Ba for the purpose of ^{137}Ba preparation,[92] have been described.

SYNTHETIC ALUMINOSILICATES

Synthetic aluminosilicates represent a great family of inorganic ion-exchangers which, depending upon their structure, may be divided into three main groups: amorphous, two-dimensional layered aluminosilicates (synthetic analogues of clay minerals), and aluminosilicates with rigid, three-dimensional structures (zeolites). Although the ion-exchange properties of the first two groups have been studied in recent years,[104–107] attention has been concentrated predominantly on the third group of synthetic aluminosilicates, the synthetic zeolites.

Synthetic zeolites

During the last 15–20 years, the synthetic zeolites have attracted increasing attention because of their molecular- and ion-sieving properties, and have been successfully applied in gas-adsorption and catalysis. Some of these synthetic zeolites are analogues of zeolite minerals, but many new varieties have been prepared. The ion-exchange and ion-sieving properties of both synthetic and natural zeolites have been described in many excellent books, reviews and surveys;[2,108–118] the fundamental structural and ion-exchange studies are presented in a great number of papers from the laboratories of Barrer and Sherry. The developments of the last five years will be reviewed in this section. The zeolites are crystalline, cross-linked, polymeric aluminosilicates. The basic units of the polymeric macromolecules are $Si(O/2)_4$ and $Al(O/2)_4^-$ tetrahedra, where O/2 represents the bridging oxygen atoms. Each tetrahedron containing aluminium formally bears one unit of negative charge which is compensated by metal cations, such as Na^+, K^+, Ca^{2+}, Mg^{2+}, Sr^{2+}, *etc*, present in the interstices of the aluminosilicate framework. These cations are usually mobile and are responsible for the ion-exchange properties of zeolites. The remaining space in the interstices of the framework is filled by water or solvent molecules.[112] Besides aluminosilicate zeolites, zeolitic structures containing Ga^{3+} and Cr^{3+} instead of Al^{3+}, and Ge^{4+}, Be^{2+} and Mn^{4+} instead of Si^{4+} have also been synthetized.[113,119,120]

The chemical composition of zeolites is usually expressed by the formula $M_{x/n}[(AlO_2)_x(SiO_2)_y]{\cdot}zH_2O$, where M = metal cation of valency n and y/x usually varies between 1 and 5. The portion in brackets discloses the framework composition.[113] Chemical composition and some properties of the main types of zeolite are given in Table II.

TABLE II.—SOME ZEOLITES AND THEIR PROPERTIES

Zeolite	Idealized unit cell contents	Free diameter of the largest channel, Å	Total ion-exchange capacity, *meq/g* (anhydrous)
Linde X	$Na_{85}[(AlO_2)_{85}(SiO_2)_{107}]{\cdot}256H_2O$	7·4	6·34
Linde Y	$Na_{52}[(AlO_2)_{52}(SiO_2)_{140}]{\cdot}256H_2O$	7·4	4·10
Linde A	$Na_{96}[(AlO_2)_{96}(SiO_2)_{96}]{\cdot}216H_2O$	4·1	7·04
ZK 4	$Na_9[(AlO_2)_9(SiO_2)_{15}]{\cdot}27H_2O$	4·1	5·50
ZK 5	$Na_{30}[(AlO_2)_{30}(SiO_2)_{66}]{\cdot}98H_2O$	3·8	4·57
Mordenite	$Na_8[(AlO_2)_8(SiO_2)_{40}]{\cdot}24H_2O$	6·7	2·62
Heulandite	$Ca_4[(AlO_2)_8(SiO_2)_{28}]{\cdot}24H_2O$	2·4–6·1	3·45
Clinoptilolite	$(Ca, Na_2, K_2)_3[(AlO_2)_6(SiO_2)_{30}]{\cdot}24H_2O$	4·1–6·2	2·64
Ferrierite	$(Na, K)_4Mg_2[(AlO_2)_6(SiO_2)_{30}(OH)_2]{\cdot}18H_2O$		3·39
Stilbite	$Na_2Ca_4[(AlO_2)_{10}(SiO_2)_{26}]{\cdot}28H_2O$		4·22
Chabazite	$Ca_2[(AlO_2)_4(SiO_2)_8]{\cdot}13H_2O$	3·7–4·2	4·95
Linde T(erionite)	$Na_8[(AlO_2)_8(SiO_2)_{28}]{\cdot}27H_2O$	3·5	3·43
Analcite	$Na_{16}[(AlO_2)_{16}(SiO_2)_{32}]{\cdot}16H_2O$	2·8	4·95
Wairakite	$Ca[(AlO_2)_2(SiO_2)_4]{\cdot}2H_2O$		5·02
Phillipsite	$(K, Na)_{10}[(AlO_2)_{10}(SiO_2)_{22}]{\cdot}20H_2O$	4·2–4·4	4·67
Yugawaralite	$Ca_4[(AlO_2)_8(SiO_2)_{20}]{\cdot}16H_2O$		3·57

The structure of the zeolite framework consists of a geometrical arrangement of linked (Si, AlO_4) tetrahedra forming secondary structural units, including 4-, 6-, 8-membered rings of tetrahedra, double rings of tetrahedra, several types of chain, sheets, and a variety of polyhedra. The larger polyhedra have substantial intrapolyhedral free volumes (called cages or cavities) in which guest molecules may reside, and where also the mobile exchangeable cations are usually sited. The faces of the polyhedral units include 4-, 6-, 8- and 12-membered rings (called windows) which themselves have free diameters allowing the ions (or guest molecules) to pass into or out of the polyhedra. Examples of cages encountered in zeolite structures are shown in Fig. 1. Most zeolites have cavities of more than one size and cations are often located in all kinds of cavities. The cavities may form one or two independent three-dimensional systems of cavities. However, there are some zeolites (*e.g.*, mordenite) that do not have three-dimensional cavity systems. In these zeolites the large cavities parallel to one axis are interconnected by smaller cavities which are not themselves interconnected.[112]

Synthetic aluminosilicates can be roughly divided into structurally defined groups, which can be related to their naturally-occurring analogues. For that reason we have classified all the material reviewed into the following groups: faujasite-, mordenite-, heulandite-, chabazite-, analcite- and phillipsite-like zeolites and other zeolites.

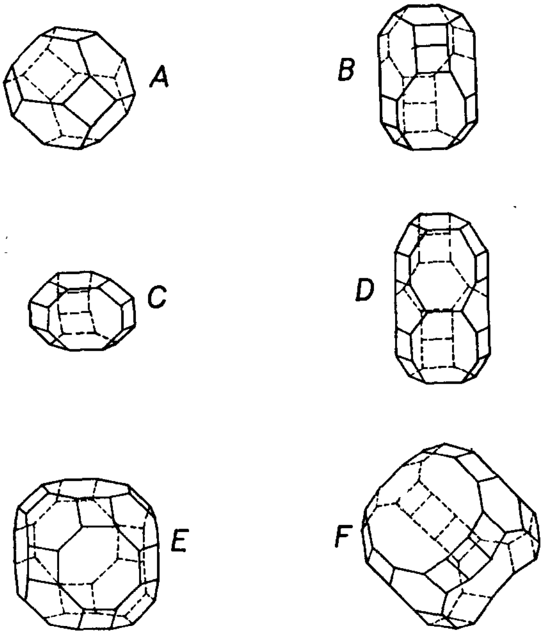

FIG. 1.—Diagrams of largest cavities in some zeolites.
A—sodalite, B—chabazite, C—gmelinite, D—erionite, E—Linde A, F—faujasite

The synthetic zeolites having no analogues in nature are mentioned either in the faujasite-like group (Linde A) or in the group of other zeolites.

Faujasite-like zeolites, zeolite Linde A

Of the wide range of synthetic zeolites, the zeolites of the faujasite group (Linde X, Linde Y) and zeolite Linde A have been the most extensively studied materials during the last five years.

Preparation, structure and chemical properties. These zeolites are usually prepared by hydrothermal treatment of sodium silicate, aluminate and hydroxide solutions[111,121–126] at temperatures of ~100°, or by mixing sodium silicate, aluminate and hydroxide solutions and evaporating till crystallization occurs.[127–133,366–368] Depending upon the ratio of reacting components, temperature, alkalinity and some other factors (the presence of binders, complexing agents, *etc.*[134–138]), products differing in chemical composition and properties (pore size, adsorption activity) are formed.

The faujasite-like zeolites Linde X and Linde Y (for chemical composition see Table II) have a common framework of the mineral faujasite and differ in the Si/Al ratio. The framework is formed[112] by stacking the cubo-octahedra (sodalite cages) by linking adjacent rings of 6 tetrahedra in a tetrahedral array similar to a diamond lattice. A part of the faujasite lattice is shown in Fig. 2. This arrangement forms two networks of cavities.[139,140] One network consists of large cavities, usually called supercages, with diameter ~12 Å. They are linked in a tetrahedral array by sharing rings of 12 tetrahedra. These rings (windows) have a face diameter of 8 Å. The other network is formed by linking smaller cages, called sodalite cages (diameter ~7 Å) in 2 tetrahedral array, through adjoining rings of 6 tetrahedra, thus forming secondary cavities which are hexagonal prisms, between sodalite cages. The rings of 6 tetrahedra form windows (free diameter $\sim$2·5 Å) between the sodalite cages and supercage. The faujasite lattice is a face-centered cubic lattice with octahedral symmetry, with a lattice parameter of 24·9 Å for Na–X.[112] However, the values of the lattice parameter are changed on changing the Si/Al ratio.[141] From the two breaks of the plot of lattice parameter against Si/Al ratio for a range of hydrated Na–X and Na–Y zeolites it has been concluded that in the Si/Al region between 1 and 1·4 the X-zeolite phase exists, the region between Si/Al $>$ 1·4:1 and Si/Al $<$ 2:1 represents transition between the X and Y phases, and at Si/Al = 2:1 the pure Y phase occurs.[141] The phase changes are due to changes in the Si–Al ordering in the 6-membered rings.[141] These phase-existence regions agree with the Si/Al ratios usually reported for the X (Si/Al = 1·1–1·5) and Y(Si/Al = 1·5–3·0) zeolites.[119,142] The Si/Al ratio in the zeolites, especially of the Y type, may be changed in different ways. The treatment of NaY zeolite with EDTA solutions leads to the removal of up to about 50% of the aluminium from the aluminosilicate. A highly crystalline product, with increased thermal stability and sorptive capacity, is thus prepared.[143,144] Also the extraction of Al_2O_3 by organic compounds leads to a material with an unchanged crystal lattice in which the acidity is characterized by a preponderance of sites corresponding to very strong acids. The aluminium sites removed by the extraction are those which give the zeolite a weak or intermediate acidity.[145] The aluminium component that is removable from the framework not only reduces the number of anionic sites when it is still present, but also occupies the cationic sites and thus decreases the ion-exchange capacity.[144]

The framework of the zeolite Linde A (Si/Al = 1·0) as well as of zeolite ZK-4 (1·0 $<$ Si/Al $<$ 1·7)[146] is formed by stacking the sodalite cages in a cubic array by linking a ring of 4 tetrahedra of the other cage. Double rings of 4 tetrahedra connect two sodalite cages, and the enclosed volume, the supercage, is the truncated cubo-octahedron (Fig. 1, E). The rings of 4 tetrahedra are too small to permit passage of ions or molecules. Thus the Linde A structure, a part of which is shown in Fig. 3, contains only one three-dimensional network of large cavities formed by connecting supercages through shared rings of 8 tetrahedra.[112] Isolated sodalite cages open out into supercages through shared rings of 6 tetrahedra.

If the truncated cubo-octahedra are linked in 8-fold co-ordination through their 8 × 6 rings the framework of the zeolite ZK-5 is formed. The bonds then form hexagonal prism units. By this arrangement additional 18-hedral cavities are created, having 12 × 4 ring and 6 × 8 ring faces.[109,147]

A lot of work has been carried out on investigating the position of various cations and water within the framework of these zeolites,[113,140,148] which is important for understanding the ion-exchange and ion-sieving properties of these materials. In the zeolite Na-X there are 38 Na^+ ions in large cavities and since they cannot be located by X-ray technique, they are presumed to be mobile completely hydrated counter-ions (Type III).[139,140] The MPR and NMR measurements suggest that these ions form with water a so-called "cationic solution".[149–151] The hydration number of cations in this solution is approximately equal to that in aqueous solutions. A further 32 Na^+ ions are located near the centre of the rings of 6 tetrahedra which interconnect the supercages and the sodalite cages, slightly displaced into the supercage (Type II). These ions are partially co-ordinated with water molecules. The remaining 16 Na^+ ions are located either in the hexagonal prism or in the sodalite cages (Type

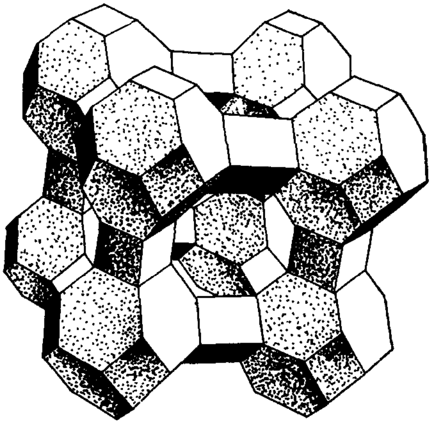

FIG. 3.—Arrangement of sodalite cages or cubo-octahedra to give Linde A. Reprinted from Ref. 112, p. 96, by courtesy of Marcel Dekker, Inc.

I).[139,140] A similar Na^+ distribution has been found for the Na–Y zeolite, but the majority of cations in the supercages are probably completely hydrated and non-sited.[139] However, a recent reinvestigation by X-ray diffraction of the Na–X zeolite structure[152] as well as the calculations of Madelung's potentials[153] led to a little different distribution of Na^+ ions (see Table III, Fig. 4.). The main difference is in dividing the type I Na^+ ions into two sites (I and I′), with 9 Na^+ ions occupying the centres of hexagonal prisms and 8 Na^+ ions lying on the inside of the sodalite cage opposite site I, near the 6-membered rings. In site II 24 Na^+ ions and 8 H_2O have been found. The number of Na^+ ions in this site agrees exactly with the number of site II 6-rings that contain three Al^{3+} ions. A rule that has been suggested,[152] is that three Al^{3+} ions per 6-ring are required to make partial dehydration and ion-siting

TABLE III.—LOCATION AND DISTRIBUTION OF Na^+ CATIONS AND H_2O IN NaX

Site	Reference 140	Reference 152
I	16 Na^+	9 Na^+
I′	0	8 Na^+ + 12 H_2O
II	32 Na^+	24 Na^+ + 8 H_2O
II′	0	26 H_2O
additional supercage sites	none located	127 H_2O (and Na^+)

Site I—centres of hexagonal prisms

Site I′—on the inside of sodalite cage opposite site I, near the six-membered ring

Site II—on six-ring faces of sodalite units, on the large cavity side

Site II′—within the sodalite cage opposite to site II

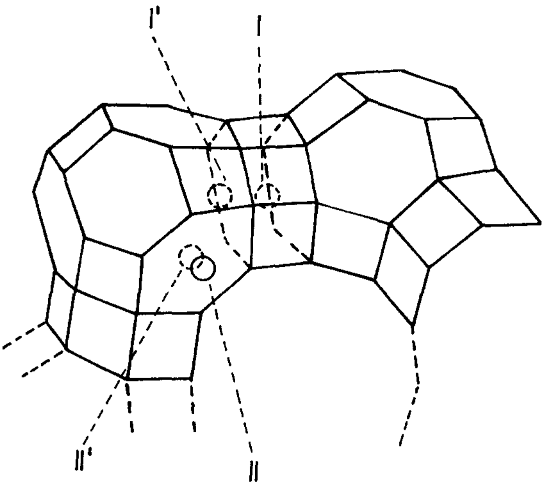

FIG. 4.—Schematic illustration of cation positions in Linde X. Designation of the sites is the same as in Table III.

energetically favourable. This rule will probably be valid for all zeolites that are sufficiently open to provide a choice between siting of partially dehydrated ions and non-localization of fully hydrated cations.[152]

Similar location of Na^+ ions has been found in the Na–A type zeolites. Eight Na^+ ions were located in the six-membered rings separating the large and small cavities (one in each of the 8 rings in a unit cell,)[140,154] the others were not been located and were presumed to be "dissolved" in the zeolitic water. However, their location has recently been found[155] in the plane of the 8-membered rings near the edge of the opening of the framework cavity.

Besides X-ray diffraction, ESR,[156–158] PMR[159] and Mössbauer spectra[160–163] measurements have been applied to the determination of siting of bi- and tervalent cations in these zeolites. Generally, the cation siting depends on the nature of the cations present, ionic charge and radius, degree of covalent character of the cation bonding, and on the water content.[164] The dependence of the various site occupancies upon the water content is evident for bivalent-cation faujasitic zeolites, where the occupancies of I′, II′ and I sites are a linear function of the site II′ water content.[165]

Dehydration of the zeolites causes changes in cation locations,[166–179] such as localization of non-located cations[180,181] and their concentration in sites within the sodalite cages.[164,182,183]

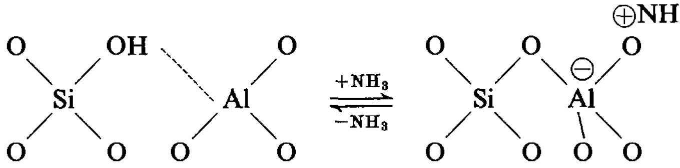
The dehydration of zeolites is thus highly dependent on their ionic forms. Generally, the thermal stability increases with enhancement of the Si content in the zeolites. For the same type of zeolite this increase depends also on the size of the cation present.[184] The tervalent rare-earth ions occupy, as partially dehydrated ions, the 6-membered ring sites in the large cavity of the X-zeolite;[183] in the natural faujasites all rare-earth ions are in the supercage, with partial occupancy of the site located in the centre of the 12-membered ring.[183] The Ce^{3+} ions are held in that position by hydrogen-bonding of the type  $Ce{-}O\langle^{H\cdots O}_{H}$.[185]

The water content is an important factor in determining the ion-exchange properties of the zeolites. The water and the cations in the most open zeolites of faujasite type and of Linde A possess many of the properties of an electrolyte solution.[112] This solution also contains imbibed neutral salt "molecules." The imbibement obeys the Donnan distribution law.[186] For the largest inclusions the average number of anions was between 3 and 4 chloride ions per large cavity of Li^+–X. The cations of the imbibed salt may occupy certain preferred sites within the zeolite framework and would then behave indistinguishably from similarly located lattice cations. The number of these preferred sites may be greater than the number of cations needed for electrical neutrality.[186] The majority (about $\frac{2}{3}$) of the water is present as a liquid phase of high mobility[187] filling the framework cavities. The electrical conductivity of the X- and Y-zeolites is comparable to that of aqueous electrolyte solutions and is attributed to the cations present in the supercages.[188] The remaining part of the water is bonded with freely-moving or located cations[187,189,190] or forms hydrogen-bonds with oxygen atoms of the cavity windows.[187] However, the presence of OH groups has also been identified by the infrared spectra measurements. These groups are sometimes resistant to high temperatures (~500°) and may be ascribed to surface OH groups,[189,191,192] cation-deficiency OH groups,[189,193] or defective-site OH groups.[189] The dehydrated zeolites contain also OH groups, as Al–OH and Si–OH groups.[189,191] The dehydration leads also to a positioning of the residual water.[133,194] The partially dehydrated bi-and tervalent ion forms of these zeolites contain also structural OH groups, forming the M^{II}–OH^+[195–200] or M^{III}–OH^{2+} groups.[196] The presence and positioning of the OH groups is an important factor determining the catalytic and adsorptive activity of these zeolites.

Various cationic forms of the X, Y and A type zeolites are prepared by an ion-exchange treatment of the basic Na^+ form,[112,201–203] by hydrothermal synthesis in the presence of components containing the desired cation,[204–206] or by contacting mother liquor slurries of the zeolite crystals with a cation-exchange resin in the desired cationic form.[207] Introduction of various cations into the basic Na^+ forms of these zeolites causes changes in their lattice parameters,[125,208–210] in window diameters,[211,212] in pore size,[213,214,369] and in electrostatic field strength.[215] Sometimes deformation and destruction of the crystal lattice occur.[199,209,211,216] Various cationic forms of the same structural type of the zeolite differ in their thermal, hydrolytic, and radiation stability,[217–224] as well as in the catalytic and adsorptive activity.[130,184,211,222,225–243] The details are outside the scope of this Review.

Decationized zeolites. The decationized forms of synthetic aluminosilicates have been widely applied in catalysis. However, the decationation process is rather complicated and the quality of the final products is highly dependent on the mode of preparation. The decationation by an ion-exchange process leads to partial zeolite decomposition if the conditions for the conversion are not carefully observed or the degree of conversion is overstepped.[244] Zeolites of high catalytic activity and of good stability have been prepared by selective replacement of the "cage" alkali metals by H^+, without replacing the "bridge" alkali metal cations.[226] In this way the hydroxyl groups are formed by replacement of the most readily exchangeable Na^+ ions located in the sites II and III (elsewhere in the supercage).[245] The destruction of NH_4^+-form zeolites, prepared usually by ion-exchange conversion,[246] has been proposed as one of the most convenient methods for the preparation of decationized zeolites[119] (besides the method of electrodialysis).

The NH_4^+-form of the A- and X-type zeolites exhibits maximum adsorption for H_2O vapour after thermal treatment at 100–150°. The NH_4^+-form of Y-type zeolite exhibits such a maximum on heating of the sorbent to 300°.[247] The thermal decationation of an NH_4^+–Y zeolite leads to the same products as the treatment of an Na^+–Y zeolite with HCl. Both products exist in the OH-forms. In the completely dehydroxylated form, 50% of the Al remains in 4-fold co-ordination, shown by a 50% retention of its initial ion-exchange capacity. The 3-fold co-ordinated Al is reconverted into the 4-fold co-ordinated form by the controlled addition of H_2O at elevated temperatures.[248] The maximum concentration of OH groups was obtained by heating the NH_4^+–Y zeolite at 350°. According to Kerr,[249] Ward,[250] and Uytterhoeven *et al.*[251] the hydroxyl groups are the Brønsted acid centres whereas the 3-co-ordinated Al atoms formed by a partial dehydroxylation of the zeolite are the Lewis centres. The formation of the Brønsted acid sites may be represented by the following reaction.[252]



By heating at 480° the Na^+–Y zeolite is converted into the Brønsted acid form. The concentration of these acidic sites increases linearly with decrease in the Na^+ content. After 60–70% of the Na^+ ions have been replaced, the concentration of these Brønsted acidity sites remains constant.[253]

The nature of the hydroxyl groups present in the decationized species was extensively studied by infrared spectra measurements.[248,252,254–262] Protons freed by zeolite decationation react with Si–O–Al bonds to form a trigonal  $\mathrm{O{-}Al}\genfrac{}{}{0pt}{}{\diagup O}{\diagdown O}$ and an adjacent  $\genfrac{}{}{0pt}{}{\mathrm{HO}\ \ \mathrm{O}}{}\!\!\mathrm{Si}\!\!\genfrac{}{}{0pt}{}{}{\mathrm{O}\ \ \mathrm{O}}$ group.[263] The location of these hydroxyl groups is not exactly known, but it is probable that they have different locations in the truncated octahedra sections of the structure.[264] Two or three types of surface hydroxyl groups were detected in the decationized Y-zeolite.[259,260] One type is located on oxygens forming the bridge between adjacent cubo-octahedra, the second is located on the 6-membered ring of oxygen ions in the cubo-octahedron.[265–268] The decationation process leads to the easier release of the molecular water of the X- and Y-type zeolites.[258] Half the protons present in the decationized Y-zeolite correspond to the adsorbed molecular water.[269] High thermal stabilities were found for the fully decationized hydrogen zeolites, probably as the result of a general structural rearrangement. Thus the hydrogen form of zeolite Y, when heated to 700–800°, contained only 175 Si + Al tetrahedra per unit cell as compared with the 192 in faujasite.[270] The same zeolite may undergo a reaction with ammonia at 500°, yielding a highly stable product.[271] The preparation of an ultrastable form of faujasite free from metal cations is described, stable even at temperatures $>1000°$.[272]

Ion-exchange equilibria in faujasite-like zeolites. The ion-exchange equilibria in the X- and Y-zeolites have been intensively studied, especially for univalent cations.[139,273–275] In the zeolite Na^+–X, first the 37 non-located hydrated Na^+ ions, then the 32 partially hydrated site II Na^+ ions, and finally the 16 Na^+ ions located in the hexagonal prisms or sodalite cages are stepwise exchanged.[139] The ion-exchange isotherms of the K^+–Na^+, Rb^+–Na^+, and Cs^+–Na^+ systems show a selectivity reversal which is explained as follows: the first 37 (*i.e.*, up to ~40% exchange) non-located sites, on the basis of the hydrated ionic radii and coulombic interactions, should prefer all of the alkali metal cations (except Li^+). The selectivity series is thus as follows: $Ag^+ \gg Tl^+ > Cs^+ > Rb^+ > K^+ > Na^+ > Li^+$. The selectivity of the other two sites for counter-ions (where no H_2O molecules are interposed between the fixed anionic sites and the counter-ions) should be the net result of the opposing effects of the free energy due to coulombic interactions between the partially dehydrated counter-ion and the negatively charged lattice, and the free energy of partial ion dehydration. The selectivity series for the 32-fold set of sites is then $Ag^+ \gg Tl^+ > Na^+ > K^+ > Rb^+ \geqslant Cs^+ > Li^+$.[139] The 16 Na^+ ions in the hexagonal prisms or sodalite cages could not be exchanged by Rb^+ and Cs^+ owing to opening for entry being too small for the Rb^+ and Cs^+ ions to enter the sodalite cage. The Rb^+–Na^+ and Cs^+–Na^+ isotherms thus terminate at 82% exchange[139] (or even at 65% exchange).[276] The selectivity series for this set of sites is $Ag^+ > Tl^+ > Na^+ > K^+ > Li^+$.[139] The high selectivity towards Ag^+ and Tl^+[139,273] is consistent with the high polarizability of these ions and indicates strong binding by all types of anionic sites. However, some different affinity series have been also reported: $Rb^+ > Cs^+ > K^+ > Na^+ > Li^+$,[276] $Cs^+ \approx Rb^+ > K^+ > Na^+ > Li^+$,[273] and $K^+ > Na^+ \geqslant Rb^+ > NH_4^+ > Cs^+ > Li^+ > (CH_3)_2NH_2^+$.[277] The standard thermodynamic functions for the ion-exchange in the zeolite Na^+–X are summarized in Table IV. For the $\Delta H°$ values a decrease has been found with decreasing difference in the sizes of the exchanging cations.[278] However, the interpretation of the thermodynamic data is difficult, owing to the incompleteness of exchange in some systems, and for that reason the $\Delta H°$ and $\Delta G°$ values are hardly obtainable. Further, the entropy changes given in the Table are composed values, containing terms for ionic hydration entropy, net transfer of water into or out the zeolite during the ion-exchange reaction, ion-pair formation, change of the ionic hydration and some other factors.[112,273,274] The

TABLE IV.—STANDARD THERMODYNAMIC FUNCTIONS FOR ION-EXCHANGE IN NaX AT 25°C

System	Max. exchange, %	$\Delta G°$, *kcal/eq*	$\Delta H°$, *kcal/eq*	$\Delta S°$, *cal/mole/deg*	Reference

* —50°C, refers to complete exchange of all the Na^+ ions in all the cavities

† —50°C, refers to replacement of only the Na^+ ions in the large cages

‡ —50°C, refers to replacement of only the Na^+ ions in the small cages

contribution of these factors to the total entropy change is mostly distinguishable only with difficulty.
