SIMULTANEOUS DETERMINATION OF ARSENIC, MANGANESE, AND SELENIUM IN BIOLOGICAL MATERIALS BY NEUTRON-ACTIVATION ANALYSIS

KAJ HEYDORN and ELSE DAMSGAARD
Isotope Division, Research Establishment Risø, Roskilde, Denmark

(*Received* 27 *March* 1972. *Accepted 8 May* 1972)

Summary—A new method was developed for the simultaneous determination of arsenic, manganese, and selenium in biological material by thermal-neutron activation analysis. The use of ^{81m}Se as indicator for selenium permitted a reduction of activation time to 1 hr for a 1 g sample, and the possibility of loss of volatile compounds during irradiation could be dismissed. No pretreatment of the sample is required, and the radiochemical separation scheme is based on simple chemical operations, completed in less than 3 hr. A systematic experimental investigation of the performance characteristics of the method was carried out, including studies of the accuracy of the results. The actual precision achieved in routine application of the method in the analytical laboratory was in good agreement with the calculated precision, and the results are therefore well suited for statistical evaluation of differences at the ppM level in samples of biological tissue.

The possible development of abnormal trace element concentrations in uraemic patients undergoing regular peritoneal dialysis has been suggested as a factor in the evolution of uraemic polyneuropathy.[1]

The observation by Brune *et al.*[2] that uraemic patients show elevated concentrations of arsenic in blood, focused attention on this element, and the unique metabolic antagonism between arsenic and selenium[3] made the simultaneous determination of both these elements desirable. Manganese was included because the concentrations of manganese appear to be regulated by a homeostatic mechanism which does not depend on excretion through the kidneys.[4]

Reliable measurement of possible deviations from normal levels of these elements in human tissue requires analytical techniques capable of determining concentrations at the ppM (parts per milliard) level with good precision and accuracy.

Manganese can be determined in small biological samples with sufficient sensitivity by the catalytic oxidation of leucomalachite green with periodate,[5] while selenium can be determined by fluorometry of the 2,3-diaminonaphthalene complex.[6] For arsenic, colorimetric measurement of the reaction of arsine with silver diethyldithiocarbamate[7] is satisfactory for larger samples only, while small samples require the use of neutron-activation analysis.[8]

Any of the three elements can be determined by neutron-activation analysis. Selenium may be determined instrumentally after intense irradiation and several weeks of decay, by the measurement of ^{75}Se with a Ge(Li)-detector,[9] or, in dialysed samples, by a very short irradiation followed by the measurement of ^{77m}Se with a scintillation detector;[10] comparable sensitivity is achieved by β-counting of ^{81}Se after rapid radiochemical separation,[11] while the highest sensitivity and precision are reached by combining radiochemical separation with the measurement of ^{75}Se.[12] Attempts to utilize ^{79m}Se[13] or ^{81m}Se[14] have so far been unsuccessful for achieving a satisfactory limit of detection. Neither arsenic nor manganese has been determined in biological samples with satisfactory precision by purely instrumental analysis, but only relatively simple radiochemical separations are needed before measurement of ^{76}As[15] or ^{56}Mn.[16]

A combined determination of all three elements is possible with the automatic group-separation system developed by Samsahl,[17] but it requires the use of special apparatus not available in most laboratories.

An analytical procedure employing standard laboratory equipment was therefore developed for the simultaneous determination of arsenic, manganese and selenium in biological material by neutron-activation analysis.

EXPERIMENTAL

Methods of analysis

The absence of reagent blanks characteristic of activation analysis is limited to the post-irradiation treatment of the sample, and operations before irradiation should be restricted to the bare minimum necessary for sampling; radiochemical separation thus becomes necessary for all three elements.

Irradiation. Intense reactor irradiation of biological samples leads to radiolysis of the sample material and is often accompanied by a temperature rise, both of which may result in volatilization of elements such as arsenic and selenium. Mild irradiation conditions are thus preferable together with irradiation times at the minimum needed for satisfactory sensitivity.

The pneumatic tube system of the Danish reactor DR 2 offers a thermal-neutron flux density of 7×10^{12} neutron/cm^2/sec, and the energy absorption in biological tissue from the accompanying fast neutrons and γ-irradiation is about 5 Mrad/hr, corresponding to a maximum decomposition loss of well below 0·5% per hr of irradiation.

Experimental sensitivities reported by Yule[18] show that, for an irradiation time of 1 hr, ^{81m}Se is the most sensitive indicator for selenium, apart from ^{77m}Se which leaves no time for chemical separation. Counting yields observed for ^{76}As and ^{56}Mn produce satisfactory sensitivities for arsenic and manganese as compared with selenium.

It was found that satisfactory precision for all three elements in biological material could be achieved with a 1-hr irradiation in the pneumatic tube system and a sample size of about 1 g. The surface temperature of the sample during irradiation did not exceed 42°, and the total activity at the end of irradiation was less than 2 mCi. No special precautions were therefore called for in the transfer and handling of the irradiated sample.

Radiochemical separation. Incorporation of separation procedures for manganese and selenium into an existing method for the separation of arsenic[15] led to a simple method for the combined separation of all three elements.

Selenium was precipitated with ascorbic acid immediately after decomposition of the sample and before the cupferron scavenging. Manganese can be determined after the precipitation of arsenic with thioacetamide and the removal of sodium with hydrated antimony pentoxide.[16]

Further purification of selenium by dissolution and extraction into methyl isobutyl ketone[19] proved necessary, whereas no separation of manganese was required.

The separation procedure is shown schematically in Fig. 1; it is completed within 3 hr after the end of irradiation.

Detection and measurement. Satisfactory sensitivity required counting in well-type NaI(Tl) scintillation detectors for up to 80 min, and for ^{81m}Se an additional counting period of the same length some hours later was needed to eliminate the influence of ^{75}Se and other long-lived activities.

Counting times were small compared with the half-lives of ^{56}Mn and ^{76}As, but for ^{81m}Se the counting time exceeded one half-life, and a correction was necessary for decay during the counting period.

Counting data from the multi-channel analysers were produced on punched paper tape and processed *via* a teletype terminal in a GE 265 time-sharing computer system.

Peak areas were calculated from a smoothed spectrum generated by a five-point polynomial convolution of the counting data with the technique described by Savitzky and Golay.[20] Peak boundaries for both sample and comparator were decided by the method of Yule,[21] except that the sign changes of the first derivative were determined from a third degree polynomial convolution of the smoothed sample spectrum.

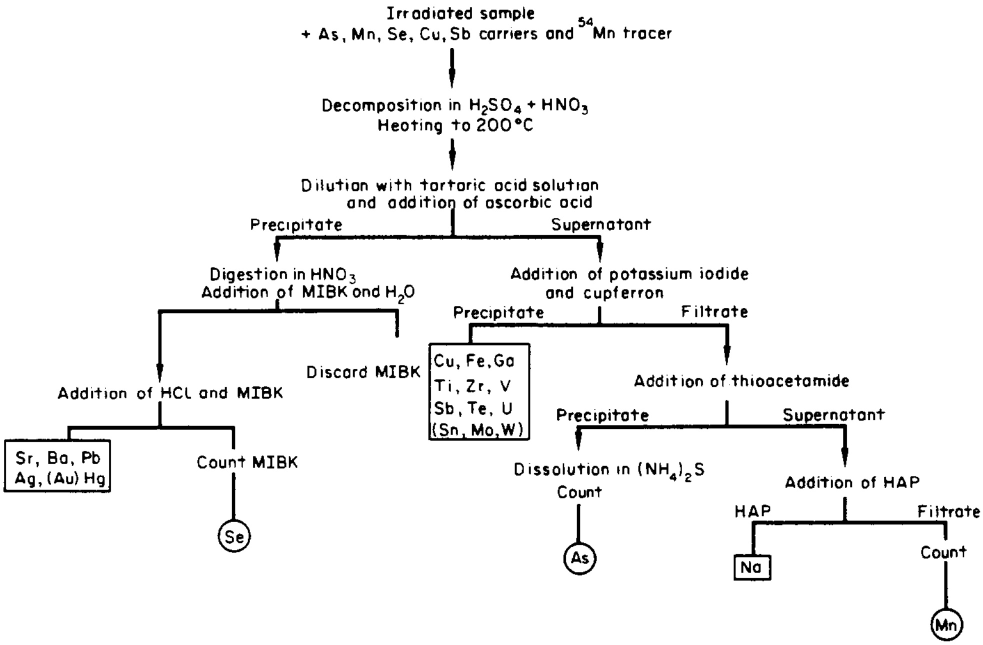

Fig. 1. Radiochemical separation scheme for arsenic, manganese, and selenium.

All samples and standards were counted for 1·0 ml of solutions in half-dram* polethylene vials, so as to eliminate differences in counting geometry.

Chemical yield. Determination of chemical yield by re-irradiation has several advantages over other methods of yield determination. No transfer from the counting vial takes place, and when identical indicators are used for both analysis and yield, differences in self-absorption between sample and standard are automatically compensated for.

In addition, positional differences in neutron flux during the simultaneous irradiation of sample and comparator may be neutralized, and the influence of interfering elements may be reduced.[15]

The yield of selenium was determined by re-irradiation for 10 sec and counting under exactly the same conditions as in the analytical determination of ^{81m}Se. The arsenic yield was measured after 10 min re-irradiation in a γ-ionization chamber for the determination of ^{76}As.[22]

The manganese yield was determined as the recovery of ^{54}Mn tracer added to the manganese carrier, by counting the sample after the decay of ^{56}Mn. The practically identical γ-energies of 0·84 MeV give the same compensation for differences in self-absorption as that achieved by re-irradiation.

Apparatus

Danish reactor DR 2 operating at 5 MW with pneumatic tube system extending into a thermal-neutron flux density of 7×10^{12} n/cm^2/sec.

Nuclear Data multi-channel pulse height analysers with Harshaw 3 × 3 in. and 2 × 1¾ in. well-type NaI(Tl) scintillation detectors.

Vibron Electrometer connected to Solartron Digital Voltmeter with National Physical Laboratory ionization chamber.

Reagents

Sulphuric acid 97–98%
Nitric acid 100%
Hydrochloric acid 37%
Methyl isobutyl ketone (MIBK)
Thioacetamide
Hydrated antimony pentoxide (HAP)
Ascorbic acid

---

* The U.S. dram, or 1/8 U.S. fluid ounce or about 3·7 ml. Not to be confused with the Scottish dram!

Ammonium sulphate solution, 50% w/v
Ammonium sulphide solution, 40%
Tartaric acid solution, 1% w/v
Potassium iodide solution, 15% w/v
Cupferron, 6% w/v solution, prepared weekly

Carriers

Se-carrier, 10 mg/ml as Se(IV) in aqueous solution
As-carrier, 10 mg/ml as As(III) in 0·15*M* ammonia solution
Mn-carrier, 10 mg/ml as Mn(II) in 4*M* nitric acid, plus ^{54}Mn activity of 2 μCi/ml
Cu-carrier, 10 mg/ml as Cu(II) in aqueous solution
Sb-carrier, 10 mg/ml as Sb(III) in 1*M* citric acid and 0·25*M* oxalic acid solution

The carrier solutions are stable systems that can be stored in rubber-stoppered glass bottles for long periods of time. Accurately prepared carrier solutions, with concentrations verified by chemical analysis, are used for the preparation of reference standards by dilution with redistilled water.

Reference standards

Se, 50 μg Se/ml
As, 0·5 μg As/ml
Mn, 0·2 μg Mn/ml

The reference solutions were stored in screw-cap polyethylene bottles, and the changes in concentration were found to be about 1% per month for Mn and significantly less for As and Se.

Procedures

Irradiation. Samples of about 1 g are weighed into half-dram polyvials* and stored in a deep freezer until activation. Reference standards of about 1·2 ml of Se, As, and Mn are transferred to half-dram polyvials. All polyvials are heat-sealed and placed in a polyethylene bag which is also heat-sealed, and subsequently transported in a polyethylene rabbit to the irradiation position, where neutron activation takes place for 1 hr.

Decomposition. In a 50-ml beaker 2 ml of Cu-carrier, 0·1 ml of Sb-carrier, and 100 μl of Mn-carrier are dried at 110°. After cooling, 500 μl of Se-carrier and 100 μl of As-carrier are added, followed by 2·5 ml of conc. sulphuric acid. Identical volumes of Se-, As-, and Mn-carrier are transferred to separate half-dram polyvials and diluted to 1·0 ml; the vials are heat-sealed and set aside for yield determination. The irradiated sample is transferred to the beaker, care being taken to moisten all sample material with the sulphuric acid carrier mixture. The beaker is placed on a hot-plate at 130°, and nitric acid is added dropwise to prevent charring while the plate temperature is slowly raised to 250°. After complete destruction of organic matter, heating is continued until fumes of sulphuric acid evolve.

Separation of selenium. After cooling, the solution is poured slowly into a 40-ml centrifuge tube containing 5 ml of tartaric acid solution, and 10 ml of water are added. Selenium is precipitated by addition of 0·5 g of ascorbic acid, followed by stirring for at least 3 min. After centrifugation the supernatant liquid is transferred to another centrifuge tube for subsequent separation of arsenic.

The selenium precipitate is washed twice with water and dissolved in 15 drops of nitric acid. Addition of 0·5 ml of MIBK is followed by up to 10 drops of water to bring about the separation of two layers. After centrifugation the MIBK layer is discarded, 2·0 ml of hydrochloric acid and 1·1 ml of MIBK are added, and selenium is extracted by stirring for 1 min. After centrifugation the aqueous layer is discarded, and the MIBK phase is washed 3 times by stirring with three 2-ml portions of ammonium sulphate solution. Finally, the MIBK is transferred to a half-dram polyvial which is then heat-sealed.

Counting of selenium-81m. A reference standard is made by transferring 1000 μl of the irradiated Se-standard to a half-dram polyvial. The selenium sample is counted for 80 min live time beginning 90 min after the end of irradiation in a 2 × 1¾ in. well-type scintillation detector at a gain of 3·3 keV/channel. The reference standard is then counted for 4 min under the same conditions.

Both sample and standard are re-counted under identical conditions 2 hr later.

Yield of selenium. The separated selenium sample and the Se-carrier sample set aside for yield determination are irradiated together in the reactor for 10 sec. About 3 hr after the end of irradiation each sample is counted for 4 min under the same conditions as above. The chemical yields of selenium averaged 75%.

Calculation of result. Selenium is determined from the area of the 103-keV peak in the difference spectrum between the first and the second counting, correction being made for deviations in decay and counting time between sample and reference. With decay corrections referring to the mid-point of the counting period, a factor of 0·96 must be applied to the results from the 80-min countings. The chemical yield is calculated in the same way from the direct spectra of the re-irradiated sample and carrier.

The selenium content, corrected for chemical yield, is calculated in ng.

---

* Olympic Plastics Corporation, Los Angeles.

Separation of arsenic. To the supernatant liquid from the selenium precipitation are added 4·0 ml of potassium iodide solution and 2·5 ml of cupferron solution with vigorous stirring. Stirring is continued for 3 min, and after at least 1 hr the slurry is filtered on a dense filter.* About 100 mg of thioacetamide are added to the filtrate, and arsenic is precipitated as the sulphide by gentle heating on a water-bath. After centrifugation the supernatant liquid is transferred to another centrifuge tube for subsequent separation of manganese.

The precipitate is washed three times with water, dissolved in 1·0 ml of ammonium sulphide solution, and finally transferred to a half-dram polyvial which is then heat-sealed.

Counting of arsenic-76. A reference standard is made by transferring 1000 μl of the irradiated As-standard to a half-dram polyvial.

The arsenic sample is counted for 80 min live time 24 hr after the end of irradiation in a 3 × 3 in. well-type scintillation detector at a gain of 6·7 keV/channel. The reference standard is counted for 8 min under the same conditions.

Yield of arsenic. The separated arsenic sample and the As-carrier sample set aside for yield determination are irradiated together in the reactor for 10 min. About 24 hr after the end of irradiation the samples are measured in the NPL ionization chamber with a polarizing voltage of 90 V, the voltage drop across a 100 GΩ resistor being read 3 times with 20 sec interval for each sample. The chemical yields of arsenic averaged 85%.

Calculation of result. Arsenic is determined from the 559-keV peak areas of sample and reference, corrected for differences in decay and counting time. The chemical yield is determined directly as the ratio between the average ionization-chamber readings of the re-irradiated sample and carrier.

The arsenic content, corrected for chemical yield, is calculated in nanograms.

Separation of manganese. To the supernatant liquid from the arsenic sulphide precipitation is added 0·5 g of HAP, and the mixture is stirred for 5 min. After centrifugation 1·0 ml is transferred to a half-dram polyvial, which is then closed.

Counting of manganese-56. A reference standard is made by transferring 1000 μl of the irradiated Mn-standard to a half-dram polyvial. The manganese sample is counted for 40 min live time no later than 5 hr after the end of irradiation with a 3 × 3 in. scintillation detector at a gain of 6·7 keV/channel. The reference standard is counted for 4 min under the same conditions.

Counting of manganese-54. The separated manganese sample and the Mn-54 carrier sample set aside for yield determination are counted not earlier than 24 hr after the end of irradiation, under the same conditions as above.

Calculation of result. Manganese is determined from the area of the 847-keV peak in the difference spectrum between the first and the second counting of the sample corrected for deviations from the reference in decay and counting time. The chemical yield is calculated in the same way from the 835-keV peak of the sample and carrier and should always be close to 4%.

The manganese content, corrected for chemical yield, is calculated in nanograms.

ANALYTICAL EVALUATION

Though neutron-activation analysis shares with other analytical methods a number of possible errors such as interference from other elements, an investigation of its performance-characteristics[23] must include parameters of its own, whereas others, such as range, may be excluded.

A sharp distinction between random and non-random errors is not always relevant, because a proper design of analytical procedure permits cancellation of systematic errors so that their effect is randomized and may influence the precision, but not the accuracy, of the analytical results.

In the present method re-irradiation yield-determinations of arsenic and selenium result in cancellation of errors from differences in self-absorption and irradiation position between sample and reference, and with optimum carrier composition[15] may even result in randomization of interference from other elements.

The accuracy of the method also depends on complete exchange of activated nuclides with their respective carriers, and on the absence of a blank value.

The precision of the analytical results is affected by counting statistics and by random variations in neutron fluence between sample and reference.

Interferences

Interference from other elements is expressed as the ratio between a quantity of a particular element and the corresponding error of the analytical result. Interference in activation analysis is therefore the product of a separation factor[24] S and an effective value f of the interfering element irradiated and counted as a sample, and calculated by reference to a comparison standard of the element to be determined.

The experimental determination of a separation factor is carried out in two steps: measurement of a decontamination factor D, followed by determination of chemical yield y, where $Dy = 1/S$.

The decontamination factor was determined by adding 10–100 μCi of a radioactive tracer of the highest possible specific activity of the interfering element to an unirradiated sample which was then processed according to the specified procedure. The ratio between the added activity and the activity of the separated sample is D.

The chemical yields of arsenic and selenium were determined by re-irradiation, while a fixed yield of 4% was assumed for manganese.

The effective value was determined by irradiating an aqueous sample of the interfering element for 1 hr along with reference standards. A known quantity m of the irradiated interfering element was transferred to a half-dram polyvial and diluted to 1·0 ml with water; this sample was counted along with a reference standard according to the specified counting procedure, and calculations were made to produce the apparent quantity of the element to be determined, m^*. The effective value f is the ratio m^*/m, and may be negative.

The error arising from the interference can now be expressed as fS μg of As, Mn and Se per μg of interfering element present, or its reciprocal Dy/f expressing the concentration of interfering element not to be exceeded to keep the error in the determination of As, Mn and Se below 1 ppM.

The choice of interfering elements selected for investigation was made on the basis of expected effective values >0·01 or comparatively poor separation factors. Experimentally determined interferences for the elements arsenic, selenium and manganese are listed in Tables 1–3.

Table 1. Experimentally determined interferences in arsenic analysis

Interfering element	Radioactive tracer	Activity μCi	Mass μg	Separation factor S	Effective value f	*ppm* of element ≡ 1 *ppM* of As

Carrier exchange

Complete isotopic exchange between activated nuclides and carrier is usually brought about by quantitative oxidation or reduction to a common ionic species. Thus all forms of As are oxidized to As(V) during the nitric–sulphuric acid decomposition, and all Mn is reduced to Mn(II) by the addition of ascorbic acid. However, Se(IV) is partly oxidized to Se(VI) by nitric acid, and Se(VI) is not reduced by ascorbic acid; the accuracy of the selenium analysis therefore depends on the complete exchange between Se(IV) and Se(VI).

This was checked by adding 0·5 μCi of ^{75}Se as selenate(VI) to an unirradiated sample, which was then processed according to the specified procedure; the separated selenium sample was counted, and the chemical yield determined by re-irradiation. The recovery of ^{75}Se and the chemical yield agreed well within counting statistics, proving that complete exchange between Se(IV) and Se(VI) had taken place during sample decomposition.

Blank

The blank value was determined by analysis of redistilled water according to the specified procedure; while no arsenic or selenium could be detected, small quantities of Mn were invariably observed.

The polyethylene vials used for irradiation contain about 20 ppM of Mn, and it was found that up to 10% of this could be released to the water during irradiation, thereby giving rise to a manganese blank.

The limited contact between a tissue sample and the container wall makes a tissue blank lower than that of water, and the blank value is assumed to be <3 ppM.

PRECISION AND ACCURACY

Calculated precision

Random variations in neutron fluence between samples and reference standards were determined by simultaneous irradiation of several standards, and the relative standard deviation of the neutron fluence was found to be 2·5%.

The ratio between the fluence experienced by sample and reference therefore has a standard deviation of 3·5%, which represents the limiting precision for single determinations of manganese. For arsenic and selenium, where a single determination requires 2 irradiations, the limiting precision corresponds to a standard deviation of 5%.

The precision expected from counting statistics is calculated from counting data on the assumption that the covariances between channels are zero,[25] and its contribution is included in the calculated total standard deviation of a single determination.

Measured precision

Experimental determination of precision was made by repeated analysis of biological materials covering the range of interest. Observed and calculated weighted average standard deviations are given in Table 4 and they show satisfactory agreement.

The calculated standard deviation of a single determination is therefore a reasonable estimate of the actual precision of the result.

Table 4. Precision of analysis of biological samples

Element determined	Number of		Range, *ppM*	Average standard deviation, *ppM*		Detection limit *ppM*
	results	materials		experimental	calculated	
As	30	11	4–20	0·6	0·5	1
Mn	24	9	30–300	5	9	*
Se	27	9	70–500	9	10	20

* Determined by the sodium content of the sample

Limit of detection

The *a priori* detection limit according to Currie,[26] with errors of the first and the second kinds both equal to 5%, is 3·29 times the standard deviation of a blank.

The detection limit is here based on the standard deviation from counting statistics only, using the lowest results among the samples analysed. The resulting limits are given in Table 4, but the ultimate limit of detection may be slightly lower.

For manganese the limit of detection is determined by the concentration of sodium in the sample, but the ultimate detection limit is estimated at 10–20 ppM.

Accuracy

With a manganese blank of less than 3 ppM, all three elements have blank values well below the detection limit for actual samples, and no detectable bias in the results can be expected. Interferences from other elements at the levels expected in biological tissue are below the detection limit for all the elements investigated, and the significance of observed differences between analytical results can safely be tested on the basis of calculated standard deviations.

In the absence of suitable reference material of biological tissue, dried plant material was chosen for analysis, and results for kale and orchard leaves are presented in Table 5. The concentrations of arsenic and manganese far exceed those encountered in biological tissue, and reduction of sample weight yields poor precision of selenium results. The agreement with published values for kale is entirely satisfactory, while the results for As in orchard leaves are not consistent with the preliminary value given by the National Bureau of Standards.

Table 5. Analytical results for plant reference material

Material	Number of samples	Weight *mg*	This work			Recommended values			Reference
			ppm As	*ppm* Mn	*ppm* Se	*ppm* As	*ppm* Mn	*ppm* Se	
Kale	4	500	0·114 ± 0·003	14·6 ± 0·3	0·132 ± 0·008	0·14	14·9	0·15	*
Orchard leaves	4	500	8·7 ± 0·2	87·1 ± 1·6	0·088 ± 0·007	14	100	0·08	†

CONCLUSION

Simultaneous determination of arsenic, manganese, and selenium at the ppM level in biological tissue can be carried out by neutron activation followed by radiochemical separation. No treatment of the sample material before activation is required, so contamination of the sample is avoided, and only moderate irradiation is employed so the loss of volatile elements is negligible. The radiochemical separation is based on simple chemical operations and requires no precise control; its robustness makes it a reliable routine method in the analytical laboratory. Conventional photo-peak integration was shown to yield accurate results with satisfactory precision for biological tissue. Good agreement between experimental and calculated precision makes the results directly amenable to statistical evaluation.

Zusammenfassung—Ein neues Verfahren zur gleichzeitigen Bestimmung von Arsen, Mangan und Selen in biologischem Material durch Aktivierungsanalyse mit thermischen Neutronen wurde entwickelt. Die Verwendung von ^{81m}Se als Indikator für Selen erlaubte eine Verminderung der Aktivierungszeit auf 1 hr für eine 1 g-Probe; die Möglichkeit des Verlustes flüchtiger Verbindungen während der Bestrahlung konnte ausgeschaltet werden. Die Probe braucht nicht vorbehandelt zu werden; das radiochemische Abtrennungsschema beruht auf einfachen chemischen Operationen und ist in weniger als 3 hv beendet. Die Leistungsfähigkeit der Methode wurde systematisch experimentell untersucht, darunter auch die Richtigkeit der Ergebnisse. Die bei der routinemäßigen Anwendung der Methode im analytischen Laboratorium erzielte tatsächliche Genauigkeit stimmte gut mit der berechneten Genauigkeit überein. Die Ergebnisse sind daher gut zur statistischen Auswertung von ppM-Unterschieden in biologischen Gewebsproben geeignet.

Résumé—Une nouvelle technique a été développée pour la détermination simultanée de l'arsenic, du manganèse et du sélenium dans les matères biologiques par analyse d'activation neutron-thermique. L'emploi du ^{81m}Se comme indicateur de sélenium a permis une réduction du temps d'activation à 1 heure pour un échantillon de 1g, et la possibilité d'une perte de produits volatis au cours de l'irradiation pouvait être négligée. Aucun prétraitement de l'échantillon n'était nécessaire et la méthode de séparation radiochimique était fondée sur des opérations chimiques simples, complétées en moins de 3 heures. Une étude expérimentale systématique des caractéristiques de performance de la méthode a été menée, comprenant des études de la précision des résultats. La précision obtenue au cours de l'emploi normal de la méthode en laboratoire était en bon accord avec la précision calculée, et les résultats sont par conséquent valables pour l'évaluation statistique de différences des niveaux de ppM dans les échantillons de tissu biologique.

SPECTROPHOTOMETRIC DETERMINATION OF VANADIUM WITH 1,10-PHENANTHROLINE

Amal Kanti Bhadra
Central Chemical Laboratory, Geological Survey of India, Calcutta-13, India

(*Received* 7 *April* 1972. *Accepted* 28 *April* 1972)

Summary—A simple and sensitive spectrophotometric method for the determination of vanadium based upon the reaction of vanadate with 1,10-phenanthroline in the presence of sodium dithionite in ammoniacal solution is described. The absorbance of the complex measured at 645 nm follows Beer's law for solutions containing 30–400 μg of vanadium in 100 ml of solution. A 10-fold excess of molybdenum, tungsten, phosphorus or chromium does not interfere. The molar absorptivity is $8{\cdot}0 \times 10^3$ l mole^{-1} cm^{-1}. The complex is shown to be tris-1,10-phenanthroline vanadium(II). The method has been applied successfully to the determination of vanadium in bauxite.

1,10-Phenanthroline (Phen) has been used in the determination of vanadium by oxidation of quadrivalent vanadium with ferric iron in the presence of Phen, the concentration of the resultant ferroin being determined spectrophotometrically.[1] Vanadium in the quinque- and tervalent states forms precipitates with Phen,[2] while quadrivalent vanadium form mono- and di-Phen complexes.[3] The blue chelate formed between vanadium(II) and Phen was observed by Schaefer and introduced as an indicator for use with strongly reducing titrants such as chromium(II).[4] The molar absorptivity of the complex was found to be $8{\cdot}0 \times 10^3$ l mole^{-1} cm^{-1} at 645 nm. A review article describes vanadium(II)-Phen as intensely blue-violet.[5] A dark blue cationic tri-Phen vanadium(II) complex has been obtained by controlled electrolytic reduction of vanadate in presence of Phen in an atmosphere of nitrogen.[6]

Phen is used in the present work as a chromogenic reagent for direct spectrophotometric determination of vanadium(II) obtained by reduction of vanadate with sodium dithionite in ammoniacal medium. Very good precision was obtained by using this method for determining vanadium in bauxites.

EXPERIMENTAL

Reagents

Standard vanadium solution. Pure vanadium pentoxide (1·785g), previously ignited at 500°, was dissolved in a slight excess of sodium hydroxide and then excess of sulphuric acid was added and the solution diluted to 1000 ml. Working standards were prepared by dilution of this solution.

1,10-Phenanthroline monohydrate solution, 0·2%.

Fluoroboric acid solution. Solid boric acid was added to concentrated hydrofluoric acid in a polythene beaker with stirring, until some boric acid remained undissolved. It was allowed to stand overnight and the supernatant liquid was filtered into a polythene bottle.

Ammonium chloride solution, 20%.

Sodium dithionite solution, 20%. Solutions of dithionite must be freshly prepared. Except in the studies of the coloured complex, solid dithionite was used.

Procedure

An aliquot of standard solution containing 0·1–0·2 mg of vanadium is transferred into a 100-ml beaker, followed by 2–3 ml of fluoroboric acid solution, 5 ml of ammonium chloride solution and 20 ml of Phen solution. The solution is diluted to 60 ml, heated to 80–90° and made distinctly ammoniacal. Five ml of dithionite solution are introduced into the solution, which is then cooled rapidly and transferred into a 100-ml volumetric flask. The solution is diluted to volume, shaken and allowed to stand for one hour at room temperature. Then the absorbance is measured at 645 nm against a reagent blank.

RESULTS

Characteristics of the complex

The absorbance spectra of the reagent blank and the vanadium(II)–Phen complex are shown in Fig. 1. The vanadium complex has a well-defined maximum at 645 nm, and Beer's law is obeyed over the range of concentration 0·3–4 μg/ml. The molar absorptivity is $8{\cdot}0 \times 10^3$ l mole^{-1} cm^{-1}, in agreement with Schaefer's results.[4]

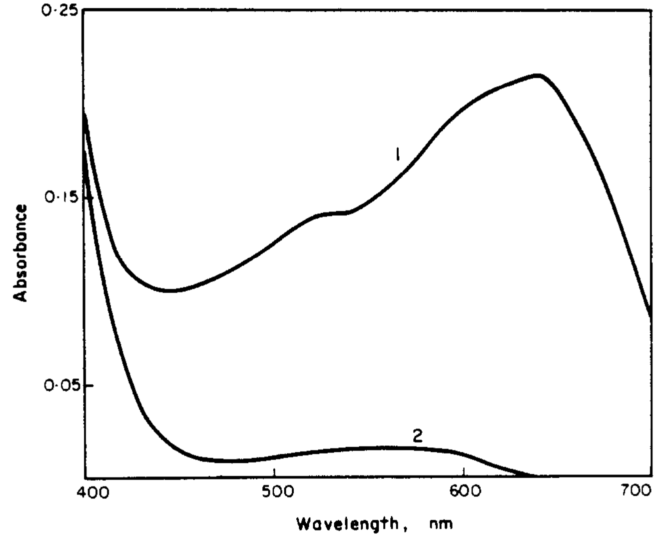

Fig. 1. Absorption spectra of vanadium(II)–Phen complex (1) and reagent blank (2) against water. C_V = 200 μg/100 ml.

The optimum pH range is 6·8–9·0. If the absorbance is measured within 3–4 hr, a pH up to 10·5 is permissible, but pH less than 6·5 should be avoided, because of the instability of dithionite.

The recommended procedure was repeated with different amounts of reagent and it was found that a molar ratio of Phen to vanadium of at least 10 : 1 is required. Further excess of reagent has no effect.

Various amounts of a freshly prepared solution of dithionite were added to test solutions with other conditions as detailed in the procedure. The minimum amount required for maximum colour development was 0·5 g, but 1·0–1·5 g of dithionite was found to be most suitable. Increasing the concentration of dithionite facilitates the formation of the coloured complex and the solution and colour of the complex become more stable.

The effect of heating and time on the formation of the complex is very important. Formation of the vanadium(II) complex is always slow at room temperature. A rapid and quantitative development of the colour was achieved by first heating the solution, followed by reduction of vanadate with dithionite. The colour intensity is unaffected by small variations in the prescribed temperature but heating for a long period after addition of dithionite causes a reduction of colour. When the effect of time of heating was studied it was found that the absorbance decreased when heating was continued for more than 30 min after addition of dithionite. Heating accelerates the decomposition of dithionite present in the solution and thus decreases the stability of the complex. If heating is omitted a 2-hr standing period is required.

The colour of the solution remains unchanged for about 24 hr in volumetric flasks, if direct contact with air is avoided. In direct contact with air, the colour of the complex starts fading within 3–4 hr after the reaction. A pinch of dithionite added to the solution after the reaction protects against colour fading for a prolonged period.

Fluoroboric acid affects the formation of the vanadium complex at high concentrations. The colour intensity is also sensitive to the fluoroboric acid concentration. The colour of the complex formed in presence of comparatively large amounts of fluoroboric acid decreases more rapidly. It was found satisfactory to use 2–3 ml of fluoroboric acid solution in a total volume of 100 ml when no metallic cations other than vanadium were present. The effect of fluoroboric acid is more pronounced with decreasing concentration of vandium. A larger excess of dithionite somewhat decreases the effect of fluoroboric acid on the vanadium complex. Fluoroboric acid has been found not to change the nature of the vanadium(II)–Phen complex. In the absence of fluoroboric acid a much smaller amount of dithionite can reduce vanadate to vanadium(II).

Nature of the complex

The empirical formula of the vanadium(II) complex in solution was studied by the continuous variation method of Job,[7] as modified by Vosburgh and Cooper[8] and showed the complex to be $[V(Phen)_3]^{2+}$, in agreement with Fujita *et al.*[6] (Fig. 2).

Like ferroin, the vanadium(II) complex is extractable as the fluoroborate into 1,2-dichloroethane and chloroform but fades rapidly on standing in the organic extract.[10] The coloured complex formed by reduction of vanadyl ion with sodium dithionite in presence of Phen has the same absorptivity.

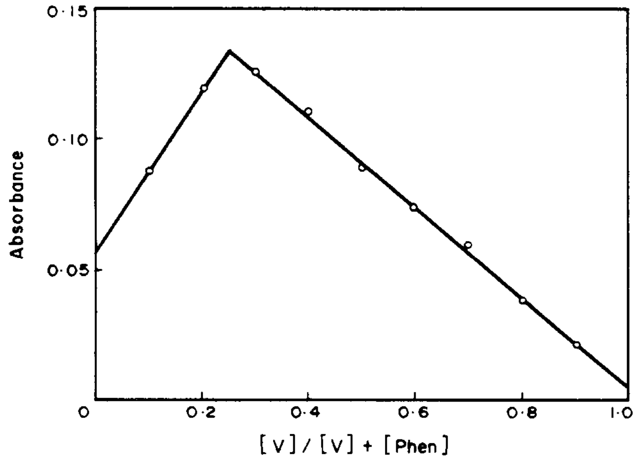

Fig. 2. Composition by Job's method.
V = Phen = $1 \times 10^{-3}M$; $\lambda = 645$ nm.

Interference studies

Solutions containing 100 μg of vanadium and varying concentrations of each ion to be tested were prepared. The vanadium was then determined by the recommended procedure except that the solutions were heated for 5–10 min after addition of dithionite. The limiting value of the concentration of foreign ions was taken as that which caused an error of not more than 2% in the absorbance. The results are summarized in Table 1.

Iron interferes in the determination of vanadium; titanium reacts with the reagent to give a yellow colour. Common complexing anions, *i.e.*, citrate, tartrate, oxalate, nitrilotriacetic acid, ethylenediaminetetra-acetic acid and 1,2-diaminocyclohexane-*N*,*N*,*N'*,*N'*-tetra-acetic acid completely inhibit the colour reaction; fluorides interfere seriously. A large excess of nitrate, chloride, sulphate or perchlorate does not interfere.

Table 1. Effect of various ions on the V(II)–Phen system

Ion	Added as	Amount of ion added, *mg/100 ml*	Absorbance at 645 nm	Amount of ion permissible, *mg/100 ml*
			0·159	
Fe(III)	$FeNH_4(SO_4)_2 \cdot 12H_2O$	0·05	0·157	0·05
*Al(III)	$Al_2(SO_4)_3 \cdot 18H_2O$	25·0	0·156	25

Mo(VI)	MoO_3	10·0	0·166	5
W(VI)	$Na_2WO_4 \cdot 2H_2O$	10·0	0·156	10
PO_4^{3-}	NaH_2PO_4	50·0	0·157	50
†U(VI)	$UO_2(NO_3)_2 \cdot 6H_2O$	1·0	forms turbidity	0
CN^-	KCN	0·10	0·156	0·1
BF_4^-	Prepared fluoroboric acid soln.	5 ml/100 ml	0·150	3 ml/100 ml

* 4–5 ml of the prepared fluoroboric acid solution should be used when aluminium is present; 50 mg of aluminium can be tolerated when aluminium is added after acidifying a solution of sodium aluminate obtained by fusing alumina with sodium carbonate. If aluminium or titanium is present, the solution must be gently heated for some time after addition of dithionite, because the reaction is slow. If the solution is very concentrated aluminium fluoroborate may precipitate before addition of dithionite and co-precipitate some vanadium causing low results.

† Uranium forms an insoluble precipitate under the experimental conditions. The absorbance may be measured after filtering off the precipitate but the values for vanadium are then 4–6% low.

Application of the method

Determination of vanadium in bauxite. A 0·1–0·5-g sample was fused with 3–6 g of anhydrous sodium carbonate for 45–60 min in a platinum crucible. The fused mass was cooled and extracted with water, the extract was filtered, and the residue washed with hot 1% sodium carbonate solution. The resulting solution was diluted to about 100 ml, acidified with nitric acid, and heated to boiling, and 5–15 ml of fluoroboric acid solution were added, depending on the amount of sample. The solution was then made distinctly ammoniacal and the insoluble silica and any other precipitate filtered off. The solution was heated to boiling after addition of 5 ml of ammonium chloride solution and 30 ml of Phen solution. Then 1 g of solid dithionite was introduced into the solution, which was then gently heated for 5–10 min. The solution turned blue, owing to formation of the vanadium complex, and was cooled and transferred into a 200-ml volumetric flask. A pinch of dithionite was added, the volume made up to the mark and the absorbance measured at 645 nm against a blank carried through the procedure.

Calibration curves were obtained by using different amounts of a standardized solution of vanadium, without addition of fluoroboric acid, or from standard vanadium solution added to a solution of sodium aluminate obtained by fusing suitable amounts of alumina with sodium carbonate and proceeding as described.

Determination of vanadium in basalt. A 0·5-g sample was fused with sodium carbonate, and the cooled melt was leached with water, and acidified with nitric acid, as detailed above. The resulting solution was then evaporated to dryness, the residue baked for one hour, then leached with nitric acid, the insoluble residue filtered off and the colorimetric procedure applied, with gentle heating for 20–30 min instead of 5–10 min after addition of dithionite, for complete formation of the complex.

Some results for determination of vanadium are given in Tables 2 and 3.

Precision test

A number of equal amounts of two bauxite samples containing between 1000 and 2000 *μg* of vanadium were analysed by the procedure given. The results of 10 determinations gave a standard deviation of 1 *μg* of vanadium.

DISCUSSION

The fusion with sodium carbonate and leaching of the product with water is necessary to effect an initial separation of vanadium from iron and titanium. Because of the instability of dithionite the colour reaction cannot be applied in acidic solution, but aluminium interferes seriously by precipitation as hydroxide at higher pH values if no complexing agent is used. In strongly alkaline solution, aluminium inhibits the reaction completely. Common complexing agents also completely inhibit the colour reaction. This difficulty was circumvented by the use of fluoroboric acid which, like hydrofluoric acid, forms stable complexes with a number of metal ions and has been put to analytical use in solvent extractions.[9,10] In the recommended pH range, it is possible, with fluoroboric acid, to mask traces of iron. Metals which hydrolyse easily and do not form very stable complexes with Phen can be masked with fluoroboric acid. Fluoroboric acid apparently forms crystalline precipitates with aluminium in small volumes of solution, and low values are obtained for vanadium present. This difficulty was overcome simply by dilution of the solution. The total volume of the solution before neutralization with ammonia should be between 100 and 150 ml. The amount of fluoroboric acid to be added depends on the amount of sample taken.

Vanadium(II) reacts with Phen between pH 4 and 6 in triethanolamine–hydrochloric acid buffer, but at higher pH triethanolamine itself interferes. The coloured complex also forms in sodium or potassium hydroxide media.

Enough Phen must be added to complex any interfering elements that can react with it, and to leave sufficient to react with vanadium. In view of the instability of the coloured complex, a pinch of dithionite is added to the volumetric flask before diluting to volume. The volumetric flasks should always be stoppered to avoid direct contact with air, in which the complex is less stable. In the applications of the method, addition of solid dithionite is preferred because of instability of its aqueous solution. The blue-violet colour which has been observed by some workers presumably results from a reaction of Phen with an excess of vanadium(II) (see Fig. 2).

The role of the ammonium chloride added to the solution before development of the colour is not very clear, but is probably that of a buffering agent. The addition is necessary.

Slightly high results may be obtained when the sample absorbance is compared with a calibration curve obtained by using pure vanadium solutions in presence of fluoroboric acid, if the recommended procedure is not strictly followed. This troublesome feature is avoided by using a calibration curve obtained with standard vanadium solutions containing no fluoroboric acid, and the 1-hr standing period is then not necessary.

The procedure is manipulatively simple and the concentrations of reagents are not critical above the specified values. The method, although lacking the sensitivity of some of the procedures previously described, is capable of determining vanadium in the usual concentrations met in ores and minerals.

Acknowledgements—The author is much indebted to Dr. A. N. Chowdhury and Dr. S. Banerjee for many valuable discussions during the course of this work. Thanks are due to the Director General, Geological Survey of India, for his kind permission to publish this paper.

Zusammenfassung—Eine einfache und empfindliche spektrophotometrische Methode zur Bestimmung von Vanadium wird beschrieben, die auf der Reaktion von Vanadat mit 1,10-Phenanthrolin in Gegenwart von Natriumdithionit in ammoniakalischer Lösung beruht. Die bei 645 nm gemessene Extinktion des Komplexes befolgt bei Lösungen mit 30–400 μg Vanadium in 100 ml Lösung das Beersche Gesetz. Ein 10-facher Überschuß von Molybdän, Wolfram, Phosphor oder Chrom stört nicht. Der molare Extinktionskoeffizient beträgt $8{\cdot}0 \,.\, 10^3 \,\mathrm{l\,mol^{-1}\,cm^{-1}}$. Es wird gezeigt, daß der Komplex Tris-1,10-phenantholin-vanadium(II) ist. Die Methode wurde mit Erfolg auf die Bestimmung von Vanadium in Bauxit angewandt.

Résumé—On décrit une méthode spectrophotométrique simple et sensible pour le dosage du vanadium, basée sur la réaction du vanadate avec la 1,10-phénanthroline en la présence de dithionite de sodium en solution ammoniacale. L'absorbance du complexe mesurée à 645 nm suit la loi de Beer pour des solutions contenant 30–400 μg de vanadium dans 100 ml de solution. Un excès 10 fois plus grand de molybdène, tungstène, phosphore ou chrome ne gêne pas. On a trouvé que le coefficient d'absorption moléculaire est de $8{,}0 \times 10^3 \,\mathrm{l\,mole^{-1}\,cm^{-1}}$. On a montré que le complexe est le tris-1,10-phénanthroline-vanadium(II). On a appliqué la methode avec succès au dosage du vanadium dans la bauxite.

USE OF THE TITANIUM(IV) CHELATE OF SALICYLIC ACID FOR A SELECTIVE ABSORPTIOMETRIC DETERMINATION OF TITANIUM

R. S. RAMAKRISHNA and H. D. GUNAWARDENA
Department of Chemistry, University of Ceylon, Colombo, Colombo 3, Ceylon

(*Received* 14 *June* 1971. *Revised* 8 *April* 1972. *Accepted* 29 *May* 1972)

Summary—Titanium(IV) forms a 1:1 chelate with salicylic acid in 40% aqueous ethanolic solution. The chelate is extractable into chloroform. A selective extraction method for the estimation of titanium in the presence of a variety of commonly interfering species is described. The addition of pyridine is found to increase the sensitivity and selectivity and makes it unnecessary to use alcohol in the extraction. The extracted species is a pyridine adduct of the titanium-salicylic acid chelate.

The chemistry of the titanyl ion (TiO^{2+}) in coexistence with iron(II) and iron(III) is of particular significance in studies of titaniferous materials such as ilmenite and rutile. The extensive literature on the analytical chemistry of titanium include procedures for its separation and determination by gravimetric, titrimetric, colorimetric and instrumental methods, such as precipitation with cupferron, tannin,[1] cinnamic acid,[2] and salicylhydroxamic acid,[3] redox titration after reduction with the Jones reductor,[4] formation of the complexes with hydrogen peroxide or sulphosalicylic acid,[5] solvent extraction involving thiocyanate,[6] dibutyl hydrogen phosphate[7] and molybdophosphate.[8]

However, the procedures hitherto described are not suitable in the presence of all metals, and considerable interference can occur, particularly in the presence of appreciable quantities of iron and vanadium. A serious criticism is that they cannot generally be directly applied to the determination of titanium in most titaniferous materials such as ilmenite.

Sudarikov and Smirnov[9] have reported that in sulphate medium titanium(IV) reacts with salicylic acid to yield fine biaxial crystals which give sodium and ammonium salts with compositions of $MR(TiR_2) \cdot 3H_2O$ and $M(TiR'_2R) \cdot 3H_2O$ where R and R′ are singly and doubly charged salicylate ions respectively, and M is Na^+ or NH_4^+. However, no studies have been reported on the use of this reaction for analytical purposes. Ziegler and Glemser[10] have used sulphosalicylic acid for a colorimetric procedure for titanium, but report serious interference in the presence of Al, Mn, Ca, Mg and Fe.

The addition of an acid solution of titanium(IV) to an aqueous ethanolic solution of salicylic acid gives immediately a yellow colour which is stable for over 72 hr. This solution is characterized by a broad absorption maxima around 360 nm. The Vosburgh and Cooper method[11] indicates the presence of only one absorbing species. The ratio of titanium to salicylic acid is found to be 1 : 1 by the Job[12] and slope-ratio[13] methods.

The titanium salicylate chelate is found to be extractable into chloroform in the presence of excess of the reagent. The molar absorptivity of the extracted species is

5·9 × 10^3 l·mole^{-1}·cm^{-1} (extraction pH 2·3). The salicylate complex of iron(III), λ_{max} = 530 nm and ε_{max} = 2·2 × 10^3 l·mole^{-1}·cm^{-1} in aqueous ethanol, is not extractable into chloroform. No interference is caused by the presence of Fe(III), Fe(II), Ca, Mg, Zn, Co(II), Mn(II), Ba, V(IV), Ni, and Al. Interference by F^- and $C_2O_4^{2-}$ is probably due to the formation of stable Ti(IV) complexes. Tolerance limits for various ions which commonly occur in conjunction with titanium, are shown in Table 1.

Table 1. Tolerance limits for foreign ions in procedures (*i*) and (*ii*)
(Titanium present = 7·6 μg)

		Tolerance, *ppm*	
Ion	Added as	Procedure (*i*) (alcohol)	Procedure (*ii*) (pyridine)
$C_2O_4^{2-}$	potassium oxalate	0·2	50
F^-	sodium fluoride	0·4	50
Mn(II)	sulphate	11	9000
V(IV)	sulphate	13	40
Fe(III)	chloride	13	22
Ba(II)	chloride	30	2000
Mg(II)	sulphate	50	400
Al(III)	sulphate	55	
Ni(II)	sulphate	60	
Ca(II)	chloride	80	
Fe(II)	sulphate	110	
Co(II)	chloride	120	
Zn(II)	sulphate	130	

The method is shown to be applicable to samples of ilmenite and the results show good recoveries and agree well with those obtained by classical gravimetric techniques. As oxalate was found to interfere, the fusion product of ilmenite with potassium bisulphate was extracted with sulphuric acid, instead of ammonium oxalate solution as in the tannin method[1] for titanium in ilmenite. However, extensive dilution is required, even with a 0·1-g sample of ilmenite, to obtain a concentration suitable for the procedure. Table 2

Table 2. Estimation of titania in ilmenite

	TiO_2 found, %			
Method of obtaining titanium in solution	from complex in aqueous ethanol	from $CHCl_3$ extract of complex, procedure (*i*)	from $CHCl_3$ extract of complex, procedure (*ii*)	from precipitation with tannin[1]
H_2SO_4 extraction of fusion product of ilmenite with $KHSO_4$	600*	54·2	53·8	37·1
Ammonium oxalate extraction of fusion product of ilmenite	10·8	0·2	53·1	54·6

* Apparently a result of interaction of Fe(III) and Ti(IV), and being further investigated. Similar observations were reported for Fe(II) and Ti(IV) by J. Beukenkamp and K. D. Herrington, *J. Am. Chem. Soc.* 1960, **82**, 3022.

shows the results obtained by both procedures. The procedure has also been satisfactorily applied to determination of the titanium and iron content of various samples from research on ferrotitanium alloys.[14]

The advantages of the procedure over methods for titanium are shown in Table 3.

Although the low solubility of salicylic acid in water necessitated the use of an aqueous ethanolic medium, it was found that the presence of alcohol was also required for the chloroform extraction. In investigation of the role of the alcohol it was observed that the addition of even a small amount of pyridine enhanced the extraction of the titanium salicylic acid chelate into chloroform and that the alcohol was then not necessary. The use of pyridine was also found to increase the sensitivity (0·64 ng/cm^2 at 366 nm) and selectivity and provided a higher pH range (3·8–4·5) for optimum absorbance ($\varepsilon = 7{\cdot}3 \times 10^3$ l·mole^{-1}·cm^{-1} at 366 nm in chloroform at a pH of extraction = 3·9). Absorption spectra of the titanium salicylic acid chelate in 40% aqueous ethanol and its chloroform extract in the presence of ethanol or pyridine are shown in Fig. 1.

The "pyridine" method with extraction at pH 3·9 was used to assess interference by other ions. There was a marked increase in the tolerances for these ions, compared with those for the "alcohol" procedure, especially for oxalate and fluoride, which are the commonly interfering ions in most determination of titanium (Table 1).

Nature of the extracted species

Isolation of the complex and its analysis for titanium, salicylic acid and pyridine have shown that the extracted species contains these components in ratio 1 : 1 : *n* where *n* varies with the amount of pyridine used in preparation of the solid.

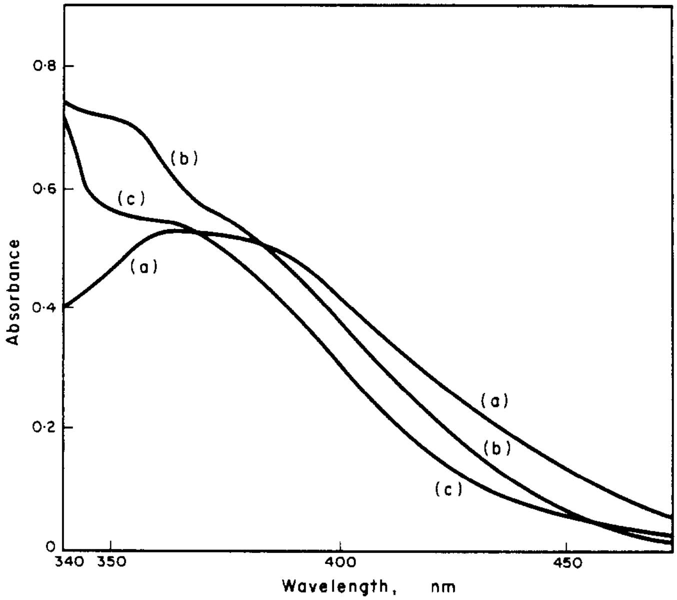

Fig. 1. Absorption spectra.
(*a*) Titanium-salicylic acid chelate ($1·04 \times 10^{-3}M$) in 40% v/v aqueous ethanol.
(*b*) Titanium-salicylic acid chelate ($1·00 \times 10^{-4}M$) extracted into $CHCl_3$ from 40% v/v aqueous ethanolic solution.
(*c*) Pyridine adduct of titanium-salicylic acid chelate in $CHCl_3$ ($2·97 \times 10^{-5}M$).

The infrared spectrum obtained for this pure solid in KBr discs was compared with that of the ligand. The band at 830 cm^{-1} was attributable to the Ti=0 stretching frequency. Similar assignments for $\nu_{Ti=0}$ have been reported for other titanyl complexes.[23,24] The bands at 1590 cm^{-1} and 595 cm^{-1} are due to unco-ordinated pyridine (co-ordinated pyridine gives higher frequencies).

The deformation frequencies of the CH groups of the pyridine ring, at 990, 1030 and 1145 cm^{-1}, reported by Sas *et al.*[25] in their studies on scandium-SCN^--pyridine complexes, remain unaltered in the infrared spectrum of our compound, again showing the presence of unco-ordinated pyridine in the solid. The extracted species is therefore a pyridine adduct of the Ti(IV)-salicylic acid chelate. However, studies[26] in these laboratories on a VO^{2+}-thiosalicylic acid-pyridine compound showed that these frequencies were shifted to 1015, 1042 and 1160 cm^{-1} respectively, which was taken as evidence for the existence of a V-pyridine co-ordinated bond *via* the nitrogen atom in the VO^{2+}-thiosalicylic acid-pyridine (1 : 2 : 1) ternary complex.

EXPERIMENTAL

Reagents

Analytical-grade chemicals were used throughout. Solvents and pyridine were redistilled.

Titanium(IV) solutions. Prepared from 99·6% pure TiO_2 by fusion with potassium bisulphate and extraction with 5% sulphuric acid, standardized by the cupferron method and by the use of a Jones reductor, and diluted accordingly, or prepared from air-dried potassium titanyl oxalate.

Buffers in 40% aqueous ethanol, the pH of which was determined from e.m.f. measurements with a quinhydrone electrode, were used to calibrate the pH meter for use with aqueous ethanolic solutions.

Recommended procedures

(*i*) *Extraction with chloroform in the presence of aqueous ethanol.* An aliquot of Ti(IV) solution was placed in a separating funnel together with 25 ml of 40% aqueous ethanolic solution of salicylic acid (0·1*M*), the pH adjusted to the desired value (2·3) with ammonia solution and sulphuric acid, and the solution diluted to 35 ml with water. Then 5 ml of chloroform were added and the solution was equilibrated by shaking. The organic extract was withdrawn and centrifuged and its absorbance measured at 380 nm against a reagent blank in chloroform.

(*ii*) *Extraction with chloroform in the presence of pyridine.* To 4 ml of 1*M* aqueous pyridine solution, 20 ml of sodium acetate–acetic acid buffer (pH 3·90) were added followed by an aliquot of Ti(IV) solution (prepared from potassium titanyl oxalate) and the solution was diluted with water to 30 ml. Then 5 ml of 0.1*M* salicylic acid in chloroform were added, the mixture was shaken, the organic phase was withdrawn and centrifuged, and the absorbance measured at 366 nm against a reagent blank in chloroform.

Analysis of alloys and slag containing iron, aluminium and titanium

Estimation of titanium. A 0·1-g sample was fused with 5 g of potassium bisulphate and extracted with 50 ml of 5% sulphuric acid and made up to 250 ml with 5% sulphuric acid. A known volume of this solution was diluted to 100 ml in water. An aliquot of this diluted solution was then treated according to procedures (*i*) and (*ii*).

Estimation of iron. An aliquot of the solution in 5% sulphuric acid, prepared as above, was boiled for a few minutes with 1–2 ml of concentrated nitric acid to convert all the iron into Fe(III), and the solution was made up to a known volume in water. An aliquot was treated by procedure (*i*) to determine titanium. The absorbance of the aqueous ethanolic phase after equilibration with chloroform was measured at 530 nm against a reagent blank, and the iron concentration obtained from a calibration curve.

Table 4. Analysis of alloy and slag samples containing titanium

Procedure	Sample	Titanium found, %	Iron found, %
i	No. 1	53·3	6·1
i	No. 2	23.4	46·1
ii	No. 1	52·1	
ii	No. 2	22·9	

Solid Ti(IV)-salicylic acid–pyridine product

A yellowish orange solid, m.p. 210–212°, was obtained by removal of solvent from a chloroform extract of a solution containing titanyl sulphate, pyridine and salicylic acid. The solid was purified by repeated extraction with diethyl ether containing increasing quantities of 60–80° petroleum ether to remove excess of salicylic acid. Analysis for the pyridine by Kjeldahl determination gave values for pyridine which varied with the concentration of pyridine used in preparation of the product.

Acknowledgements—The authors thank the University of Ceylon, Colombo for providing a research grant. Samples of highly refined ilmenite were kindly provided by Mr. J. P. R. Fonseka of the Geological Survey Department, Colombo, Ceylon. Alloys and samples of slag containing titanium were provided by Dr. M. H. C. Wijetunge of the Physical Chemistry Division of the Ceylon Institute of Scientific and Industrial Research, Ceylon.

Zusammenfassung—Titan(IV) bildet mit Salicylsäure in 40% wäßrig-äthanolischer Lösung ein 1 : 1-Chelat. Das Chelat läßt sich in Chloroform extrahieren. Es wird eine selektive Extraktionsmethode zur Bestimmung von Titan in Gegenwart einer großen Anzahl verschiedener sonst störender Spezies angegeben. Es zeigt sich, daß die Zugabe von Pyridin die Empfindlichkeit und Selektivität weiter verbessert und die Verwendung von Alkohol bei der Extraktion unnötig macht. Die extrahierte Spezies ist ein Pyridinaddukt des Chelats aus Titan und Salicylsäure.

Résumé—Le titane (IV) forme un chélate 1 : 1 avec l'acide salicylique en solution hydroéthanolique à 40%. Le chélate est extractible en chloroforme. On décrit une m´thode d'extraction sélective pour l'estimation du titane en la présence d'une variété d'espèces communément gênantes. On a trouvé que l'addition de pyridine accroît la sensibilité et la sélectivité et rend inutile l'emploi d'alcool dans l'extraction. L'espèce extraite est un composé d'addition de la pyridine avec le chélate titane-acide salicylique.

APPLICATION OF FLOW MICROCALORIMETRY TO ANALYTICAL PROBLEMS—I

DETERMINATION OF ORGANOPHOSPHORUS PESTICIDES BY INHIBITION OF CHOLINESTERASE

A. E. BEEZER and C. D. STUBBS
Chemistry Department, Chelsea College of Science and Technology,
Manresa Road, London S.W.3

(*Received* 27 *January* 1972. *Accepted* 23 *June* 1972)

Summary—Flow microcalorimetry has been applied to the determination of organophosphorus pesticides by inhibition of cholinesterase. One direct inhibitor (TEPP) and one latent inhibitor (parathion) were investigated. The former is determinable at concentrations of about $10^{-6}M$ and the latter at about $10^{-4}M$. The inhibitory power of parathion is increased if methanol is used as solvent.

In flow microcalorimetry measurement is made of the heat generated by a reacting solution flowing through a calorimeter chamber, or by a reaction between two flowing streams meeting within the chamber. The technique is particularly suited to the study of enzyme-catalysed systems. It has been shown theoretically[1] and experimentally[2] that for an enzyme reaction that is zero-order in substrate (*i.e.*, [substrate] $\gg K_m$, where K_m is the Michaelis–Menten[3] constant) the heat-output rate, dq/dt, will give a steady recorder deflection which is proportional to enzyme activity. Inhibitor concentrations may be determined from the degree to which they inhibit the enzyme[4] and hence reduce heat-output rate.[1,2,5,6] This paper describes the application of flow microcalorimetry to the determination of organophosphorus pesticides *via* their inhibition of cholinesterase.

Anticholinesterase compounds have been reviewed[7,8] and the inhibiting effect of organophosphorus materials discussed.[8-10] Dimefox has been determined by the microcalorimetric technique.[11] Current non-enzymic methods are non-selective, the methods yielding total phosphorus being the most extreme examples, particularly when materials of biological origin are investigated. The enzymic methods are more selective and at least as sensitive as the chemical methods. In the main, only organophosphorus materials are detected by systems based upon cholinesterase. Selectivity may be introduced by use of cholinesterase from different sources.[12]

The flow microcalorimetric method is simple and reasonably rapid, the time for one experiment being about 35 min, and about 15 min for serial work. Other advantages are that the method of sample preparation is less important, the calorimeter will accept suspensions[13,14,15] (*e.g.*, soil, blood, algae) and optical purity is not required.

EXPERIMENTAL

Apparatus

The LKB Flow Microcalorimeter was equipped[1,2] with a flow-through cell and operated at 25°.

Materials

Enzyme (horse serum cholinesterase) solutions were prepared in "tris" buffer [tris-2-amino-2-(hydroxymethyl)-1,3-diol] adjusted to pH 8. Substrate solutions, (0·1*M* acetylcholine chloride and 0·02*M* butyrylcholine iodide) were prepared in the same buffer solution.

The enzyme solutions were stored at 0° before use.

The pesticides investigated were TEPP (tetraethyl pyrophosphate) and parathion.

Preliminary investigations

General procedure. An instrumental base-line was established by pumping substrate solutions (*e.g.*, 25 ml of 0·02*M* butyrylcholine iodide in "tris" buffer at pH 8) through the calorimeter. After exactly 5 min the appropriate enzyme solution was added rapidly, with vigorous stirring, to the remaining bulk of substrate solution. This reacting mixture (always zero-order kinetics with respect to substrate) then entered the calorimeter. The calorimetric response (arbitrary scale units) was the difference between the new scale-reading and the base-line value.

After each series of experiments all vessels and lines were cleaned by pumping through 5% sodium hydroxide solutions, followed by detergent and finally distilled water.

The grade of cholinesterase used was stated by the manufacturers to hydrolyse butyrylcholine three times as fast as it does acetylcholine. Hence acetylcholine chloride and butyrylcholine iodide were compared as substrates. At pH 8 and with 0·4 ml of 0·5 mg/ml enzyme solution added as described to 0·02*M* butyrylcholine iodide solution a calorimetric response of 47 units was observed, whereas 0·1*M* acetylcholine chloride produced a response of only 23. In all subsequent experiments butyrylcholine iodide was used as substrate.

The conditions for optimal heat-output rate may not be those for optimum substrate turnover,[1] because of the possible enhancement from secondary reactions, *e.g.*, protonation of buffer solutions occurring as a result of enzyme/substrate reaction. In the case of butyrylcholine iodide the reaction is butyrylcholine iodide + enzyme → butyric acid + choline-enzyme complex. The butyric acid (p*K* 4·83) will react with the buffer solution (pH 8) and the enthalpy of neutralization will supplement the enzyme/substrate reaction enthalpy and give a larger calorimetric response. It was found that pH 8 gave the highest calorimetric response (pH 7·0—55, pH 8·0—70, pH 9·0—65). In all substrate experiments "tris" buffer at pH 8 was used. The pH optimum for substrate turnover by cholinesterase lies in the range[16,17] 7·0–7·4 although pH 8 has been reported[18] for the system cholinesterase–TEPP. The relationship between enzyme activity and calorimetric response was found to be linear for 0·06–0·3 mg of enzyme added in 1 ml of buffer as described in *General procedure*. Englehard *et al.*[19] have shown that inorganic cations, especially sodium and bivalent cations, affect the equilibrium constants of the cholinesterase–substrate complex and the substrate-inhibited complex by increasing the activity of the enzyme. The final recommendations were to use solutions of sodium and magnesium chlorides. Comparison of calorimetric response in solutions (25 ml of substrate, 1 ml of 0·3 mg/ml enzyme) is given in Table 1.

Table 1

Added	Calorimetric response (mean of three experiments)
—	52
1 ml 0·15*M* NaCl + 1 ml 0·02*M* $MgCl_2$	52
1 ml 0·15*M* NaCl	42
1 ml 0·02*M* $MgCl_2$	62
1 ml 0·1*M* $AlCl_3$	41
1 ml 0·1*M* $CoCl_3$	56

Thereafter 1 ml of 0·02*M* magnesium chloride was added to each aliquot of substrate before addition of enzyme.

Inhibition experiments. The duration of incubation of enzyme with pesticide affects the level of inhibition. Incubation of enzyme solution alone for 5–120 min at 25° produced an increase in the calorimetric response from 52 to 72, but incubation of enzyme with pesticide decreased the response, the decrease becoming constant for incubation times longer than about 20 min (Fig. 1).

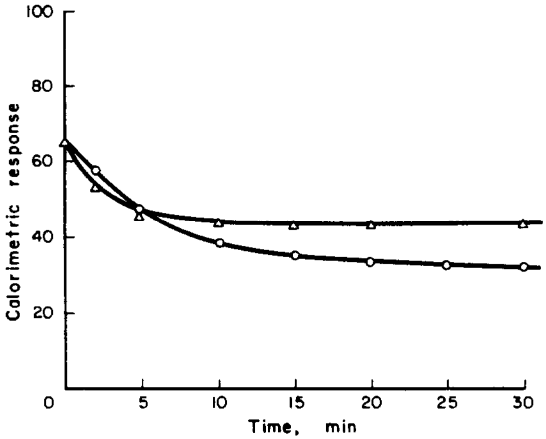

Fig. 1. Relationship between calorimetric response and incubation time for inhibition reaction. ⊙ Parathion in dioxan; △ TEPP in dioxan.

Procedure. Pesticide solutions were diluted to the required concentration in methanol or dioxan and 0·2 ml of solution was added to a sample tube containing 1 ml of 0·3 mg/ml enzyme solution and the mixture was incubated at 25° for 20 min. The general procedure was then followed.

RESULTS AND DISCUSSION

The results for the pesticide-inhibited runs are shown in Tables 2 and 3. Most results quoted are the average of three experiments.

The mechanism of the inhibiting action of organophosphorus compounds has been discussed by O'Brien,[16] Stubbs,[17] and Wilson[20] and reveals two broad types of inhibitor, latent and direct. The latter, more potent, inhibitors require to be present in 10^{-5}–$10^{-9}M$ concentration to cause 50% inhibition,[21] and the former in 10^{-1}–$10^{-4}M$ concentration *in vitro*. The latent inhibitors are activated *in vivo* to give direct inhibitors, *e.g.*, parathion

* Defined as in Table 2.

is oxidized *in vivo* to paraoxon, a direct inhibitor. This paper reports investigation of one latent and one direct inhibitor and of paraoxon obtained from parathion by oxidation with bromine water.

Since the organophosphorus compounds used are hydrolysed by water, stock solutions were made in both dioxan and methanol. The volume of either solvent actually used in the inhibition experiments produced no effect upon the calorimetric response. Dioxan is inert as solvent towards both pesticides. However both the organophosphorus materials studied are ethoxy compounds and, in methanol, will undergo methanolysis. This results in a mixed ethoxy-methoxy compound, and, in the case of parathion this yields a more potent inhibitor and hence leads to a more sensitive determination of parathion (see Tables 2 and 4).

Table 4 summarizes the analytical results obtained.

Table 4. Summary of analytical results

Pesticide	Solvent	Lowest determinable concentration, *μg/ml*	Range, *μg/ml*
parathion	dioxan	50	50–800
parathion	methanol	5	5–100
parathion/Br_2 water	methanol	5	5–160
TEPP	dioxan	0·05	0·05–1
TEPP	methanol	0·02	0·02–1·2

Selectivity was not investigated in this work but Guilbault[12] has shown that cholinesterases from different sources (*e.g.*, quail, beetle, dog, *etc*) have a markedly different response to a variety of pesticides. However, selectivity may be introduced by the use of different solvent systems, since, in the cases reported here, TEPP shows little variation in its inhibitory powers in dioxan and methanol whereas parathion shows a tenfold increase in inhibitory action in methanol relative to dioxan. In dioxan there is a factor of 10^3 in the sensitivity of the enzyme to the two pesticides.

Conversion of the latent inhibitor parathion into the direct inhibitor paraoxon is achieved by oxidation with bromine water.[16,17] However, in the experiments reported here there is only a small change in inhibitory power on oxidation of parathion in methanol solution. Methanolysis apparently confers direct and hence increased inhibitory powers on parathion.

As an analytical technique the flow microcalorimetric method is relatively rapid and certainly simple in operation. The sensitivity is high especially for direct inhibitors. Its sensitivity and precision are comparable with extant methods.[10,17] Flow methods have many advantages[2,22] and are simply automated—an advantage in modern analytical practice.

ELECTRONIC ABSORPTION AND FLUORESCENCE OF CINCHOPHEN, CINCHONINIC ACID AND THEIR METHYL ESTERS; BIPROTONIC PHOTOTAUTOMERISM OF THE SINGLY-PROTONATED SPECIES

B. ZALIS, A. C. CAPOMACCHIA, D. JACKMAN and S. G. SCHULMAN
College of Pharmacy,
University of Florida, Gainesville, Florida 32601, U.S.A.

(*Received* 9 *May* 1972. *Accepted* 6 *June* 1972)

Summary—The pH and Hammett acidity dependences of the absorption and fluorescence spectra of cinchoninic acid (quinoline-4-carboxylic acid), cinchophen (2-phenylquinoline-4-carboxylic acid) and their methyl esters, were studied. The predominant uncharged ground-state species derived from the free acids are zwitterions. Prototropic equilibria are too slow to compete with fluorescence for deactivation of the excited state at hydrogen ion concentrations represented by the pH scale. However, fluorescence shifts accompanying protonation indicate that the carboxyl group is more basic than the ring nitrogen atom in the excited state. In the Hammett acidity range the singly-charged cations of all the compounds studied undergo phototautomerism in the lowest excited singlet state. The rate of this process is acidity dependent. In very concentrated sulphuric acid solutions doubly-charged cations are formed in the excited state but not in the ground state. The intense emissions of these compounds in moderately concentrated sulphuric acid may be suitable for quantitative analysis if great care is taken to control solution acidity.

There has been considerable study of the electronic spectra of aromatic acids and bases which are either monofunctional or bifunctional with one functional group having electron-withdrawing and the other having electron-donating properties. In monofunctional molecules electron-withdrawing groups such as —COOH and a heterocyclic nitrogen atom in six-membered rings are generally found to become more basic or less acidic in the lowest electronically excited π,π^* states, resulting in red shifts upon protonation or blue shifts upon dissociation, of the fluorescence, phosphorescence and long-wavelength absorption spectral bands. Conversely, electron-donating groups such as —OH and —NH_2 become more acidic or less basic in the lowest excited π,π^* states, resulting in blue shifts upon protonation or red shifts upon dissociation, of the electronic spectra.[1,2] In bifunctional molecules containing an electron-donating and an electron-withdrawing group, qualitatively similar results are observed. However, the spectral shifts tend to be exaggerated as a result of charge transfer from the electron-donating group to the electron-withdrawing group, upon excitation.[3] This is the well-known auxochromic effect. Occasionally, the gain in acidity of an electron-donating group and the gain in basicity of an electron-withdrawing group, in the same electronically excited molecule, is so great that the order of ionization of the two groups is reversed with respect to the normal order observed in the ground state.[4-7] For example, β-methylumbelliferone in the ground electronic state exists in dilute acid solutions as a neutral, undissociated, phenolic lactone. However, in the lowest excited singlet state, the stable uncharged species derived from β-methylumbelliferone is a zwitterion having the phenolic group dissociated and the carbonyl group protonated. The change in structure between ground and excited states of β-methylumbelliferone is termed phototautomerism because it involves a protonic isomerization subsequent to excitation. In β-methylumbelliferone, where the electron-withdrawing and electron-donating groups are widely separated, phototautomerism is biprotonic since it must entail dissociation of the phenolic group and protonation of the carbonyl group. In molecules having the electron-withdrawing and electron-donating groups situated *ortho* to one another, however, phototautomerism may occur by proton transfer across an intramolecular hydrogen bond between the two groups, as for example, in salicylic acid.[4] This phenomenon is termed intramolecular phototautomerism.

Notwithstanding the information that has been gathered on molecules having electron-donating and electron-withdrawing groups, little systematic study has been undertaken of excited-state protonation and fluorescence phenomena of bifunctional molecules in which both functional groups are electron-donating or electron-attracting. It would be particularly interesting to observe the competition between two groups showing similar electromeric effects.

In this paper, we consider the acidity dependences of the absorption and fluorescence spectra of two pharmaceutically significant molecules, quinoline-4-carboxylic acid (cinchoninic acid) and its 2-phenyl derivative (cinchophen). Each of these molecules has two electron-attracting groups; the carboxylic acid group and the heterocyclic nitrogen atom. In order to simplify the characterization of the prototropic equilibria involved in this study, the methyl esters of these compounds were prepared and also subjected to fluorimetric analysis.

EXPERIMENTAL

Apparatus

Absorption spectra were recorded with a Beckman DB-GT spectrophotometer. Fluorescence spectra were recorded with a Perkin-Elmer MPF-2A fluorescence spectrophotometer having monochromators which were calibrated against the xenon line-emission spectrum; the output was corrected for instrumental response by means of a Rhodamine B quantum counter. The pH measurements were made on an Orion Model 801 pH meter employing a Beckman silver–silver chloride–glass combination electrode.

Reagents

Quinoline-4-carboxylic acid and 2-phenylquinoline-4-carboxylic acid were obtained commercially and purified by repeated recrystallizations from 75% ethanol–water solutions. The methyl esters of both quinoline-4-carboxylic acids were prepared according to the procedure of Elderfield and Siegel.[8] The melting points of the esters were in agreement with those reported in the literature.[9,10]

Analytical-reagent grade sulphuric acid was diluted with distilled demineralized water to prepare the solutions used to study the Hammett acidity region. The corrected Hammett acidity scale of Jorgenson and Hartter[11] was employed to calibrate the sulphuric acid solutions. Citrate and phosphate buffers and sodium hydroxide solutions in distilled demineralized water were used in work at higher pH values.

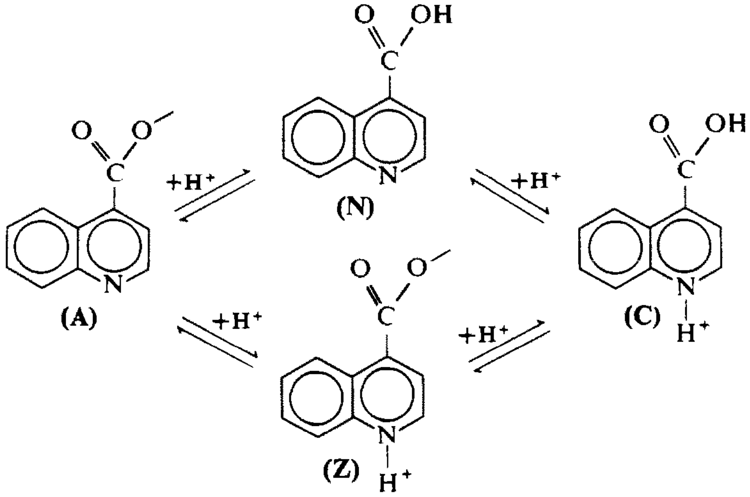
Each sulphuric acid or buffer solution, in a 10-ml volumetric flask, was injected with 100 μl of $1 \times 10^{-3}M$ stock solution of cinchophen or cinchoninic acid immediately before the recording of spectra, in order to minimize decomposition errors.

RESULTS AND DISCUSSION

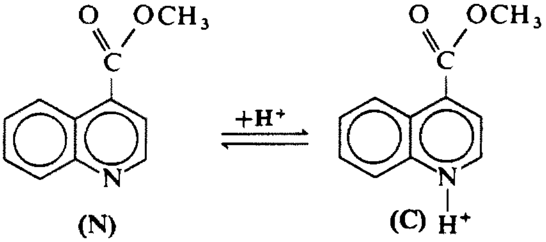
Absorption spectra and ground state ionization phenomena

The possible ionization phenomena of cinchoninic acid, on going from alkaline to dilute acid media, are represented in scheme 1.

Scheme 1



For the methyl ester, which is essentially a non-dissociating model of the neutral molecule (N) the only possible ionization within this pH region is represented in scheme 2.
Scheme 2



The long-wavelength absorption maxima as well as the fluorescence maxima of cinchoninic acid, cinchophen and their methyl esters at various acidities are presented in Table 1. In alkaline solutions cinchoninic acid demonstrates an absorption spectrum similar in appearance to that of quinoline[12,13] but differing in that the ^1L_a band of the 4-carboxylate group lies at a frequency some 1500 cm^{-1} lower than that of unsubstituted quinoline (Fig. 1). In the methyl ester of cinchoninic acid the ^1L_a band has shifted still further towards the red and overlaps the short-wavelength side of the ^1L_b band (Fig. 1). In dilute acid solutions (pH 2·5) the absorption spectrum of cinchoninic acid is similar to that of the quinolinium cation.[12,13] At pH 0 the absorption spectrum of cinchoninic acid and its methyl ester appear essentially identical, and gaussian, and at lower frequencies than the absorption spectrum of cinchoninic acid at pH 2·5. The absorption spectrum of cinchoninic acid in alkaline solutions is assigned to the anion (**A**). The red shift of the ^1L_a band of this species relative to that of quinoline is indicative of substitution in the 4-position of quinoline, which corresponds to an α-position in naphthalene, the parent hydrocarbon from which quinoline may be thought to be derived. Because of the quinolinium-like appearance of the uncharged species derived from cinchonic acid (pH 2·5) and its lack of identity with the methyl ester, the protonation of the anion is believed to occur at the ring nitrogen atom, resulting in the zwitterion (**Z**). The

dissociation constant for the interconversion between the anion and zwitterion was evaluated spectrophotometrically and found to be 4·6 (Table 2). In more concentrated acid solutions both the uncharged species and the methyl ester derived from cinchoninic acid were protonated. The identical absorption spectra obtained for the protonated species of each of these reactions indicates that the cation (C) is formed in each case. However, the $\mathrm{p}K_a$ value for the interconversion between the cation and the uncharged species derived from cinchoninic acid is 1·1 while that for the interconversion between the cation and neutral species derived from the methyl ester is 3·2. This is further evidence that the uncharged species derived from cinchoninic acid does not correspond in its electronic structure to the neutral methyl ester [the model of the neutral species (N)] and that the assignment of the zwitterion structure to the former is correct. That the absorption spectra of both cations and the neutral methyl ester are unstructured and that the ^1L_a bands have shifted towards the red to such a great extent in these species suggests that the neutral carboxylic acid group (or carbomethoxy group) is conjugated and coplanar with the aromatic ring in the ground and Franck-Condon excited states and that the absorption spectra have considerable charge-transfer character.

In concentrated sulphuric acid solutions the absorption spectra of both cinchoninic acid and its methyl ester demonstrate a small red shift with increasing sulphuric acid concentration. Although carboxylic acids derived from carbocyclic aromatic rings are known to protonate in the ground state at Hammett acidities near −8,[14] the changes in the absorption spectra of cinchoninic acid and its methyl ester were not sufficient to indicate that a prototropic reaction was occurring even in the most concentrated sulphuric acid solution ($H_0 = -10$) used. This is likely due to the positive charge already residing on the singly protonated cations being delocalized onto the carboxyl groups, reducing their basicities. The small red shifts found when acid solutions are used are likely due to hydrogen bonding of the carbonyl oxygen atom and differences in the dielectric strength between water and sulphuric acid.

Unlike cinchoninic acid, cinchophen does not show well-resolved vibrational structure in the absorption spectrum of its own anion (Fig. 2). Moreover, the ^1L_b band of the cinchophen anion lies at lower frequencies than that of the cinchoninate anion and the ^1L_a band for the former is obscure. The spectrum of the neutral methyl ester of

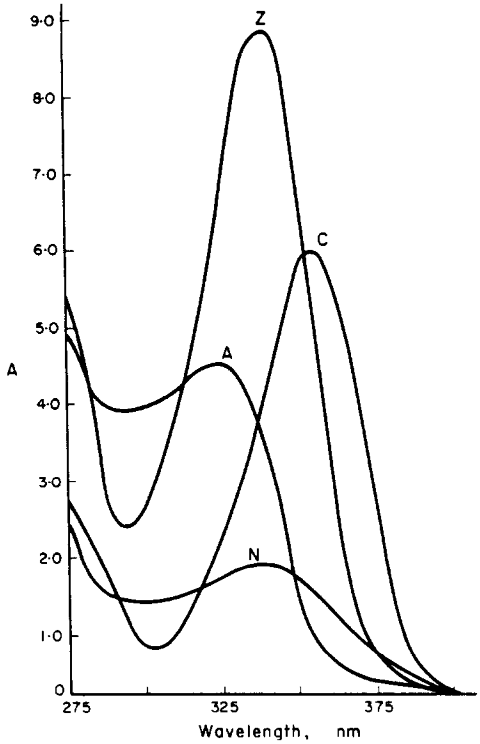

Fig. 2. Absorption spectra of cinchophen (A at pH 10·0, Z at pH 2·5) and its methyl ester (N at pH 10·0, C at pH 0).

cinchophen is similar to that of the anion of cinchophen but lies at lower frequencies. The two successive protonations of the anion derived from cinchophen result in successive red shifts of the low-frequency absorption band (which is probably a composite of the ^1L_a and ^1L_b bands). The pK_a values for interconversions between the anion and uncharged species and between the uncharged species and the cation are 4·8 and 1·1, respectively, while that for interconversion between the neutral species and cation derived from the methyl ester of cinchophen is 2·8. Because of the similarities between corresponding dissociation constants of cinchoninic acid and cinchophen and between the methyl esters of these compounds, it can be concluded that the prototropic species derived from cinchophen and present in any given pH region correspond exactly to those derived from cinchoninic acid (*i.e.*, the zwitterion is the predominant uncharged ground-state species derived from cinchophen). The differences between the absorption spectra of the various prototropic species derived from cinchophen and cinchoninic acid are apparently due to the presence of the phenyl group in the 2-position. The great extent to which the phenyl group influences the absorption spectra of the prototropic species derived from cinchophen (which show substantial charge-transfer character relative to that of the corresponding species derived from cinchoninic acid) strongly suggests that in the ground and Franck-Condon excited states the phenyl group is coplanar and conjugated with the quinoline ring.

The results in Table 1 show that in concentrated sulphuric acid the absorption spectra of cinchophen and its methyl ester shift towards the red with increasing acid concentration to a considerably greater extent than do the absorption spectra of cinchoninic acid and its methyl ester. However, plots of absorbance *vs.* Hammett acidity at the absorption maxima of these compounds, at $H_0 = -10$ and at $H_0 = -0{\cdot}7$ yield very gradually sloping titration curves. Apparently the red shift is not due to a prototropic process but rather to a solvent effect. That this effect is more pronounced in cinchophen can be rationalized on the basis of the generally greater sensitivity of charge-transfer type spectra to the polarizing influence of solvent[15] and the greater degree of intramolecular charge transfer in the electronic transitions of the 2-phenyl derivative.

Fluorescence spectra and excited state processes

In alkaline solutions the anion derived from cinchoninic acid has a weak violet fluorescence. As the pH is lowered the fluorescence becomes blue with maximum at $2{\cdot}53 \times 10^4\ \text{cm}^{-1}$. The conversion of the violet fluorescence into the blue fluorescence, with decreasing pH, occurs with the same titration characteristics as the absorption spectrum changes in the pH region 7–3. In alkaline solutions the methyl ester of cinchoninic acid fluoresces weakly with maximum at $2{\cdot}39 \times 10^4\ \text{cm}^{-1}$. Since the methyl ester is electronically similar to the neutral molecule (**N**) and fluoresces at a different frequency than does the protonation product of the anion, it can be concluded that the emission at $2{\cdot}53 \times 10^4\ \text{cm}^{-1}$ arises from the excited zwitterion (**Z**). The identity between the fluorimetric and absorptiometric titrations for the interconversion between the anion and zwitterion indicates that the interconversion is static (*i.e.*, equilibrium does not occur during the lifetime of the excited state). That the fluorescences of the zwitterion and the methyl ester occur at lower frequencies than that of the anion indicates that both the carboxylate group and the ring nitrogen atom are more basic and have higher electron densities in the excited state than in the ground state. Because the methyl ester fluoresces at lower frequencies than the zwitterion, the carboxylate group is apparently more basic than the ring nitrogen atom[1] and if prototropic equilibrium was attained during the lifetime of the excited state, phototautomerism of the zwitterion to the neutral species would probably occur. As the pH is lowered to near 0 the fluorescence of both cinchoninic acid and its methyl ester is quenched with ground-state titration characteristics. Apparently, the cations are non-fluorescent and prototropic equilibrium is not attained in the excited state even near pH 0.

In sulphuric acid solutions (from $H_0 = -1$ to $H_0 = -10$) of cinchoninic acid and its methyl ester, an intense blue-green fluorescence appears at $H_0 = -1$, rises to a maximum near $H_0 = -5$ and is quenched sigmoidally with further increase in sulphuric acid concentration (Fig. 3). At $H_0 = -10$ a weak yellow-green fluorescence is observed. These titration phenomena suggest that two prototropic processes are occurring in the lowest excited singlet state in the region from $H_0 = -1$ to $H_0 = -10$ since no ground-state prototropic processes were detected absorptiometrically in this region of acidity. That two protonations occur between $H_0 = -1$ and $H_0 = -10$ is somewhat perplexing since the excited singly-protonated cations of cinchoninic acid and its methyl ester are the species present at the lower end of the Hammett acidity region and only the carboxyl (or carbomethoxy) group is sufficiently basic in the excited state to become protonated. It was considered that protonation might also occur at a carbon atom in the aromatic ring but this would withdraw a pair of electrons and reduce the aromaticity of the π-electronic system, a process that should result in a substantial shift towards the blue

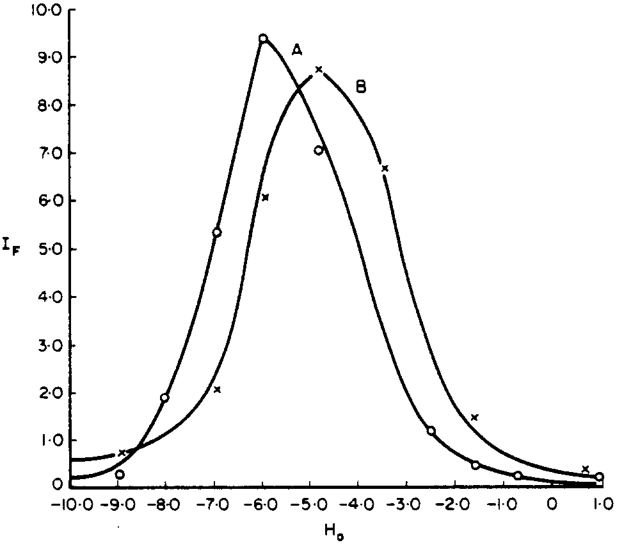

Fig. 3. Fluorimetric titrations in sulphuric acid media of *A*, cinchoninic acid, *B*, methylcinchoninate.

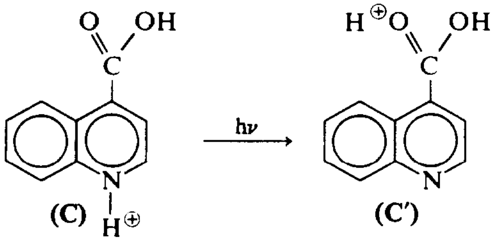
or complete quenching of the fluorescence with increasing acidity. Since this was not observed this possibility was dismissed. An alternative explanation of the unusual fluorimetric titration behaviour of cinchoninic acid and its methyl ester is as follows. If the carboxyl group were more basic than the ring nitrogen atom of cinchoninic acid in the excited state, the singly-charged cation, protonated at the ring nitrogen atom, which is formed in the ground state, would be expected to phototautomerize biprotonically to the cation protonated at the carboxyl group, during the lifetime of the excited state (Scheme 3).

Scheme 3



(C) (C′)

This process would entail excitation of (C) to the lowest excited singlet state followed by protonation at the carboxyl group and very rapid dissociation from the ring nitrogen atom. Fluorescence would then occur from C′. Thermodynamically this process should be independent of solution acidity because there is no net gain or loss of protons. However, the short lifetime of C in the excited state, as evidenced by the lack of fluorescence from this species, precludes the rate-determining protonation at the carboxyl group in dilute acid before the cation returns to the ground state in a radiationless transfer. As the acidity of the medium is increased, protonation of the carboxyl group and hence phototautomerism of C to C′ becomes more probable so that the titration curve in the region from $H_0 = -1$ to $H_0 = -5$ represents the kinetics rather than the thermodynamics of the phototautomerism. The blue-green fluorescence in sulphuric acid is thus believed to originate from the singly-charged cation C′, protonated at the carboxyl group. At higher acidities protonation of the ring nitrogen atom of C′ becomes thermodynamically feasible so that the titration curve in the region from $H_0 = -5$ to $H_0 = -10$ represents the conversion of C′ into the doubly-protonated cation in the excited state. Because the ring nitrogen atom is more basic in the excited state than in the ground state the fluorescence of the doubly-charged cation occurs at lower frequencies than that of the singly-charged cation.

The fluorescences of cinchophen and its methyl ester and their acidity dependences are similar to those of cinchoninic acid and its methyl ester. That the fluorescences of the prototropic species derived from cinchophen and its methyl ester are very close to those of the corresponding species derived from cinchoninic acid and its methyl ester suggests that the 2-phenyl groups in the former molecules are not conjugated with the quinoline rings in the thermally relaxed excited states. Thus excitation of cinchophen appears to be followed by a rotation of the phenyl ring out of plane with the quinoline ring, a process which is probably precipitated by the transfer of charge from the homocyclic ring of quinoline into the heterocyclic ring, upon excitation, thereby repelling, π-electronic charge back into the phenyl group and destroying the conjugation of the phenyl group with the quinoline ring.

The intense blue-green fluorescences of cinchoninic acid and cinchophen in sulphuric acid solutions appear to be the only emissions observed which are of sufficient intensity for sensitive quantitative analysis of these compounds. However, owing to the great sensitivities of the quantum yields of these fluorescences to acidity, great care must be exercised in controlling the Hammett acidities of standard and unknown solutions.

Zusammenfassung—Die Abhängigkeit der Absorptions- und Fluoreszenzspektren von Cinchoninsäure (Chinolin-4-carbonsäure), Atophan (2-Phenylchinolin-4-carbonsäure) und ihrer Methylester vom pH bzw. der Hammett'schen Aciditätsfunktion wurde untersucht. Die im Grundzustand überwiegend vorliegenden ungeladenen Spezies, die sich von den freien Säuren ableiten, sind Zwitterionen. Prototrope Gleichgewichte sind zu langsam, um bei Wasserstoffionenkonzentrationen, wie sie durch die pH-Skala dargestellt werden, bei der Desaktivierung des angeregten Zustandes mit der Fluoreszenz konkurrieren zu können. Mit der Protonierung einhergehende Fluoreszenzverschiebungen zeigen jedoch, daß im angeregten Zustand die Carboxylgruppe basischer ist als das Stickstoffatom im Ring. Im Bereich der Hammett'schen Aciditätsfunktion machen die einfach geladenen Kationen aller untersuchten Verbindungen im niedrigsten angeregten Singlettzustand eine Phototautomerie durch. Die Geschwindigkeit dieses Vorgangs hängt von der Acidität ab. In sehr·konzentriert schwefelsauren Lösungen werden im angeregten, jedoch nicht im Grundzustand zweifach geladene Kationen gebildet. Die intensiven Emissionen dieser Verbindungen in mäßig konzentrierter Schwefelsäure könnten zur quantitativen Analyse geeignet sein, wenn man die Acidität der Lösung sehr sorgfältig einstellt.

Résumé—On a étudié les relations entre le pH et l'acidité de Hammett et les spectres d'absorption et de fluorescence de l'acide cinchoninique (acide quinoléine 4-carboxylique), du cinchophène (acide 2-phénylquinoléine 4-carboxylique) et de leurs esters méthyliques. Les espèces à l'état fondamental non chargées dérivées des acides libres qui prédominent sont des zwitterions. Les équilibres prototropiques sont trop lents pour entrer en compétition avec la fluorescence pour la désactivation de l'état excité aux concentrations en ion hydrogène représentées par l'échelle de pH. Toutefois, des changements de fluorescence accompagnant la protonation indiquent que le groupe carboxyle est plus basique que l'atome d'azote cyclique à l'état excité. Dans le domaine d'acidité de Hammett les cations à une seule charge de tous les composés étudiés subissent un phototautomérisme à l'état singulet excité le plus bas. La vitesse de ce processus dépend de l'acidité. Dans des solutions très concentrées en acide sulfurique, il se forme des cations doublement chargés à l'état excité mais non à l'état fondamental. Les émissions intenses de ces composés en acide sulfurique modérément concentré peuvent convenir à l'analyse quantitative si l'acidité de la solution est contrôlée avec grand soin.

BESTIMMUNG ^{35}S-MARKIERTER POLYTHIONATE NACH HOCHSPANNUNGSIONOPHORETISCHER TRENNUNG

E. Blasius und H. Wagner
Institut für Analytische Chemie und Radiochemie der Universität des Saarlandes,
6600 Saarbrücken, BRD.

(*Eingegangen am* 23. *Mai* 1972. *Angenommen am* 6. *Juni* 1972)

Zusammenfassung—Die Aktivitätsmessung ^{35}S-markierter Polythionate auf Pherogrammen erfolgt einmal nach Elution und Überführung in $Ba^{35}SO_4$ mit einem Geiger-Müller-Endfensterzählrohr oder direkt auf dem Trägermaterial durch Flüssigszintillation. Beide Meßmethoden werden mit einander verglichen. Die Zählausbeute beträgt für die $BaSO_4$-Methode 0,25% und für die der Flüssigszintillationsmethode 55%. Bei letzterer tritt jedoch eine Substanzabhängigkeit der Zählausbeute auf.

Für die Untersuchung von Gemischen verschiedener Polythionate hat sich als Trennmethode die Hochspannungspapierionophorese bewährt.[1-4] Die anschließende Bestimmung kann u.a. nach Abbau zu $S_2O_3^{2-}$ coulometrisch vorgenommen werden.[5]

Durch den Einsatz ^{35}S-markierter Ausgangsverbindungen läßt sich der Nachweis der einzelnen Zonen sehr empfindlich gestalten. Außerdem sind die Zonen des Sulfits und des Sulfats noch leicht auf den Pherogrammen zu erkennen.[1-4] Auch die Bestimmung der Schwefelverbindungen kann dann über eine Messung der Aktivität erfolgen. Hierzu werden in der vorliegenden Arbeit zwei Wege eingeschlagen.

ELUTION DER ZONEN UND BESTIMMUNG ALS $Ba^{35}SO_4$

Die Lage der ionophoretisch getrennten Schwefelverbindungen auf dem Pherogramm ergibt sich aus der aufgenommenen Aktivitätsverteilungskurve.

Die einzelnen Zonen werden ausgeschnitten und in ein Gemisch von 1 ml konz. Ammoniak, 1 ml Perhydrol und 25 ml 0,04*M* Natriumsulfat-Lösung gegeben. Der Zusatz an inaktivem Na_2SO_4 dient zur Erzielung einer unendlichen Schichtdicke an $Ba^{35}SO_4$. Nach einer Stunde verkocht man das überschüssige H_2O_2, gibt 100 ml H_2O hinzu und nimmt die Papierstücke vorsichtig aus der Lösung heraus. Ein anschließendes zweimaliges Eluieren mit je 30 ml warmen Wasser reicht zur vollständigen Entfernung von eventuell am Papier adsorbiertem SO_4^{2-} aus. Die vereinigten Eluate werden auf 150 ml eingedampft. Die Fällung erfolgt dann bei pH 2 durch tropfenweise Zugabe von 12 ml 0,1*M* $BaCl_2$-Lösung in der Siedehitze.

Bei 120 durchgeführten Elutionen schwanken die Auswaagen der einzelnen Proben nur zwischen 237 mg und 240 mg. Der Sollwert von 233 mg wird um durchschnittlich 6 mg überschritten. Dies ist durch die Verwendung des schwefelsäurehaltigen pH-3 Grundelektrolyten bedingt. Die Substanzmenge der Schwefelverbindungen in den Zonen ist jeweils $<0,1$ mg und beeinflußt die Auswaage nicht.

Für die Messung müssen die $BaSO_4$-Niederschläge in Aluminiumschälchen überführt werden, wobei vor allem auf eine über die gesamte Fläche gleichmäßige Schicht zu achten ist. Außerdem darf die Oberfläche keine Risse oder Blasen aufweisen. Bewährt

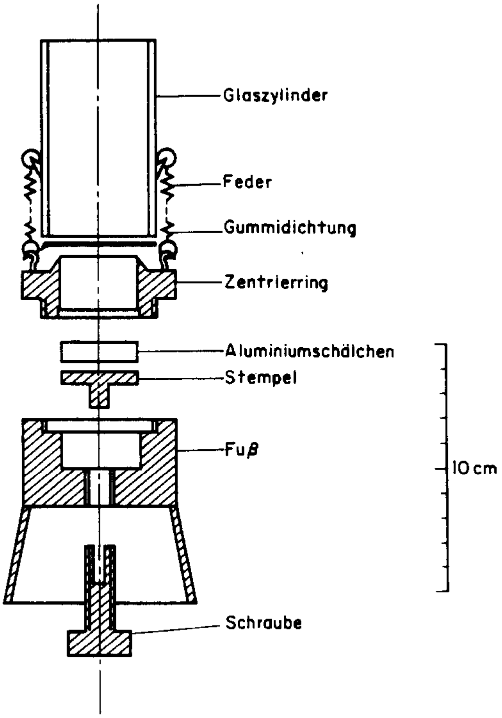

Abb. 1. Anordnung zur Sedimentation von $Ba^{35}SO_4$-Niederschlägen.

hat sich die Sedimentation aus einer Suspension sehr feiner Teilchen. Die hierzu entwickelte Anordnung zeigt Abb. 1. Sie besteht aus einem Glaszylinder, an den vier Glashaken angeschmolzen sind. Vier Federn pressen den unten plangeschliffenen Zylinder gegen den Zentrierring. Das vorher gewogene Aluminiumschälchen wird auf den Stempel im Fuß der Anordnung gelegt und mit der Schraube gegen den Zentrierring gedrückt. Der Innendurchmesser der Bohrung im Zentrierring ist gleich dem

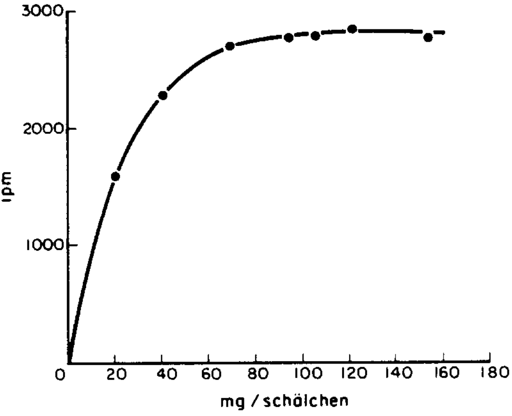

Abb. 2. Nettoimpulsrate für ^{35}S in Abhängigkeit von der Schichtdicke im Schälchen bei konstanter spezifischer Aktivität.

Innendurchmesser des Aluminumschälchens. Eine Dichtung zwischen Glaszylinder und Zentrierring verhindert das Auslaufen der Lösung.

Das Bariumsulfat wird in einem Achatmörser fein zerrieben und in Äthanol aufgeschwemmt. Die Suspension gießt man in den Glaszylinder und wartet, bis sich alles abgesetzt hat (*ca* 2 h). Anschließend wird der Alkohol vorsichtig mit einer IR-Lampe abgedampft. Um Korrekturen für Selbstabsorptionen und Rückstreuung zu vermeiden, wird bei unendlicher Schichtdicke gemessen (Abb. 2). Sie liegt bei 100 mg $BaSO_4$/Schälchen (= 16,5 mg/cm^2). Die Geometrie der Zählanordnung ist bei allen Messungen konstant. Korrekturen der Meßergebnisse, bedingt durch die Totzeit des Geiger-Müller-Endfensterzählrohrs, entfallen wegen der verhältnismäßig kleinen Impulsraten. Dagegen erfordert die kurze Halbwertszeit des ^{35}S bei Untersuchungen, die sich über einen längeren Zeitraum erstrecken, eine Zerfallskorrektur der Meßergebnisse.

AKTIVITÄTSMESSUNG DIREKT AUF DEM TRÄGERMATERIAL DURCH FLÜSSIGSZINTILLATION

Die direkte Messung trockener Teile der Chromatogramm- bzw. Pherogrammstreifen in einem Szintillator ist eine seit längerer Zeit bekannte und bequeme Methode zur Aktivitätsermittlung vor allem bei ^{14}C-markierten Verbindungen.[6–10]

Zur Messung der ^{35}S-markierten Substanzen werden die getrockneten Pherogramme in 15 x 10 mm Stücke geschnitten. Die Gesamtbreite der Pherogramme beträgt in allen Fällen 30 mm. Jede einzelne Zone setzt sich aus 10–12 Papierstücken zusammen. Die ausgeschnittenen Papierstücke legt man horizontal auf den Boden der Meßgläser und setzt dann 7 ml der Szintillatorlösung zu. Bei diesem Volumen hat man ein Maximum der Zählausbeute (Abb. 3). Die Szintillatorlösung enthält auf 1000 ml Toluol 6,0 g PPO und 0,01 g POPOP. Eine merkliche Löslichkeit der ^{35}S-markierten Substanzen im Szintillator ist nicht zu beobachten.

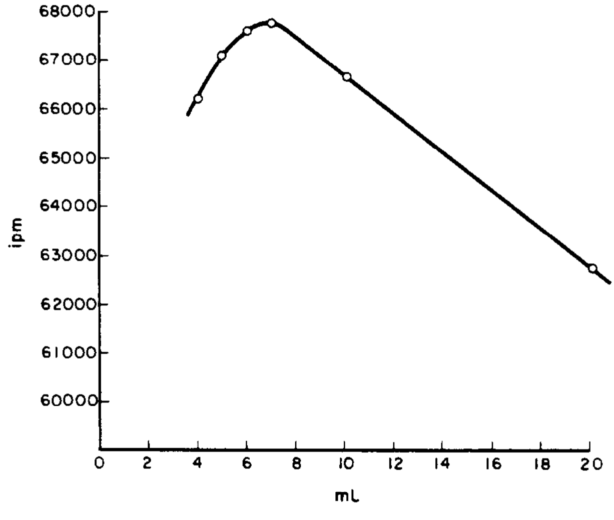

Abb. 3. Abhängigkeit der Nettoimpulsrate von der Menge an Szintillator-Lösung.

Die Messungen selbst erfolgen im Tri-Carb-Spektrometer, Modell 3380 der Fa. Packard Instruments. Der automatische Probenwechsler hat ein Fassungsvermögen von 200 Gläsern. Diese Meßgläser sind standardisiert und bestehen aus einem kaliumarmen Glas. Gemessen wird im fixierten ^{14}C-Kanal. Die im Grundelektrolyten enthaltenen Salze bewirken nur einen vernachlässigbar kleinen Verlust in der Zählausbeute (Tab. 1). Für diese Kontrollmessungen wird eine SO_4^{2-}-Standardlösung eingesetzt, deren radiochemische Konzentration 10,8 μCi/ml beträgt. Die Zählausbeute für ^{35}S-markiertes SO_4^{2-} ergibt sich dann bei Papier als Trägermaterial zu 55%.

VERGLEICH DER BEIDEN AKTIVITÄTSMESSMETHODEN ANHAND EINES POLYTHIONATGEMISCHES

Die eingesetzte Lösung enthält die Polythionate $S_3O_6^{2-}$, $S_4O_6^{2-}$, $S_5O_6^{2-}$ und $S_6O_6^{2-}$ mit ^{35}S-markierten Sulfonsäuregruppen gleicher spezifischer Aktivität.

Die Konzentrationen betragen: 10,87 mg $S_3O_6^{2-}$/ml, 10,12 mg $S_4O_6^{2-}$/ml, 4,67 mg $S_5O_6^{2-}$/ml und 0,887 mg $S_6O_6^{2-}$/ml. Für den Vergleich werden jeweils zwölf Proben von 1,0; 2,0; 3,0; 4,0; 5,0 μl dieser Polythionatlösung mit der "Agla" Mikrometersyringe auf Ionophoresepapier aufgetragen und getrennt. Nach beendeter Ionophorese nimmt man die Aktivitätsverteilungskurven auf, um die Lage der einzelnen Zonen auf den Pherogrammen festzulegen (Abb. 4). Danach werden die Meßproben nach den oben beschriebenen Vorschriften hergestellt.

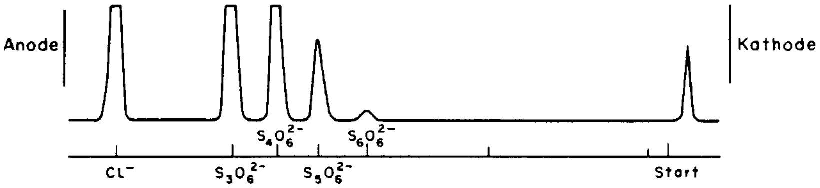

Abb. 4. Typisch Pherogram (Aktivitätsverteilungkurve).

Die Meßzeiten nach Überführung in $Ba^{35}SO_4$ betragen zehnmal vier Minuten, die bei der Messung direkt auf dem Papier zehnmal eine Minute. Tabelle 2 zeigt die Abhängigkeit der Nettoimpulsrate von der Absolutmenge der Ionen nach Überführung in $Ba^{35}SO_4$ und bei direkter Messung auf dem Träger. Die Meßpunkte sind Mittelwerte von jeweils sechs Proben. Impulsrate ist in jedem Falle der aufgetragenen Menge direkt proportional.

Tabelle 2. Abhängigkeit der Nettoimpulsrate von der aufgetragenen Menge der Polythionate

		nach Überführung in $Ba^{35}SO_4$		bei direkter Messung	
Ion	Menge, *µg*	Zählrate, *ipm*	Standardabweichung, *µg*	Zählrate, *ipm*	Standardabweichung, *µg*
$S_3O_6^{2-}$	50	2 500	1,1	618 000	0,5
$S_4O_6^{2-}$	50	2 100	0,8	517 000	0,7
$S_5O_6^{2-}$	20	750	0,4	180 000	0,3
$S_6O_6^{2-}$	5	165	0,2	39 000	0,1

DISKUSSION

Die Messung der Aktivität nach Elution und anschließender Überführung der Schwefelverbindungen in $BaSO_4$ hat den Nachteil der schwierigen und zeitraubenden Meßprobenvorbereitung. Für die Elution, Oxydation zu SO_4^{2-} und Sedimentation sind zwei Tage notwendig. Ein weiterer Nachteil ist die geringe Zählausbeute, die bei etwa 0,25% liegt. Dadurch sind Zonen geringerer Substanzkonzentration bei gegebener spezifischer Aktivität nicht mehr meßbar. Die Absolutaktivität einer gerade noch meßbaren Zone beträgt 20 000 Zerfälle/Minute. Der Vorteil dieser Meßmethode aber ist die Unabhängigkeit der Meßergebnisse von der chemischen Zusammensetzung der jeweiligen Schwefelverbindung.

Wesentlich schneller und leichter ist die Messung der Aktivität innerhalb der Zonen direkt auf dem Trägermaterial mittels der Flüssigszintillationsmethode. Die Zählausbeute liegt bei Papier als Trägermaterial bei 55%. Diese Methode besitzt daher eine wesentlich größere Empfindlichkeit.

Vergleicht man aber die Ergebnisse, die für die Polythionate mit den beiden Meßmethoden erhalten werden, so ergeben sich teilweise erhebliche Unterschiede. Bei der direkten Messung tritt eine Substanzabhängigkeit der Zählausbeute auf, wie sie auch bei ^{14}C-markierten Verbindungen bekannt ist.[6] Grund ist die unterschiedliche Absorption der von den Szintillatoren emittierten Photonen durch die einzelnen Polythionate. Dieser Zählverlust muß bei der Auswertung berücksichtigt werden (Tab. 3).

Tabelle 3. Zählausbeute bei der Flüssigszintillationsmessung ^{35}S-markierter Verbindungen

^{35}S-markierte Verbindung	Zählausbeute, %
$S_3O_6^{2-}$	55
$S_4O_6^{2-}$	54
$S_5O_6^{2-}$	53
$S_6O_6^{2-}$	50

Die mit beiden Meßmethoden erhaltenen Substanzmengen liegen im µg-Bereich. Die spezifische Aktivität beträgt etwa $1 \cdot 10^{-2}$ mCi/mMol. Die Substanzmengen können ohne weiteres um den Faktor 1000 verkleinert werden, wenn gleichzeitig die spezifische Aktivität entsprechend erhöht wird. Die spezifischen Aktivitäten der käuflichen Schwefelverbindungen, die eingesetzt werden können, liegen bei 30–40 mCi/mMol.

Grundsätzlich lassen sich beide Methoden zur quantitativen Bestimmung markierter Schwefelverbindungen einsetzen. Bei uniformer Markierung aller Schwefelatome ist die Nettoimpulsrate dem Schwefelgehalt direkt proportional. Mit Eichkurven lassen sich die Absolutmengen einfach ermitteln. Bei genereller Markierung der Schwefelatome der Ausgangsverbindungen ist die Kenntnis des Reaktionsmechanismus notwendig. Außerdem dürfen keine Isotopenaustauschreaktionen auftreten.

Das wesentliche dieser Kombination von Trennung und Aktivitätsmessung liegt aber nicht nur in der Möglichkeit Reaktionsgemische quantitativ zu untersuchen. Vielmehr können mit Hilfe genauer Aktivitätsmessungen Reaktionsmechanismen aufgeklärt und neue Verbindungen nachgewiesen werden.

Die Untersuchungen würden im Rahmen des Sonderforschungsbereiches 52 „Analytik" durchgeführt.

Summary—The activity of ^{35}S-labelled polythionates has been measured on electropherograms by elution followed by precipitation as Ba^{35}SO$_4$ and end-window GM-tube counting, and directly on the support material by liquid-scintillation counting. The results obtained by the two methods are presented and compared. The count-rate yield is only 0·25% for the first method, but 55% for the second, though this does suffer from a slight dependence on the nature of the ion present.

Résumé—On a mesuré l'activité de polythionates marqués au ^{35}S sur des électrophèrogrammes, par élution suivie de précipitation à l'état Ba^{35}SO$_4$ et comptage par tube GM à fenêtre, et directement sur le matérial-support par comptage par scintillation liquide. On présente et compare les résultats obtenus par les deux méthodes. Le rendement de la cadence de comptage est de 0,25% seulement pour la première méthode, mais de 55% pour la seconde, quoique celle-ci ait l'inconvénient de dépendre légèrement de la nature de l'ion présent.

Summary—Manganese is quantitatively extracted into a benzene solution of trioctylmethylammonium chloride from a solution at least 0·25*M* in potassium thiocyanate and at pH 2·5–7. After stripping into dilute ammonia containing triethanolamine (TEA) and hydroxylamine hydrochloride, manganese is determined by EDTA titration. Calcium and magnesium are not extracted even in traces. Iron is co-extracted with manganese and is masked with TEA during the stripping. Aluminium also does not interfere. In the aqueous phase, after the extraction of manganese, calcium or magnesium can be determined by the usual EDTA titration. The method described permits highly selective individual determination of manganese and calcium and/or magnesium in all materials rich in manganese.

In complexometric determination of manganese, calcium and magnesium in materials rich in manganese we encounter some difficulties caused by the relatively low stability constant of the Mn-EDTA complex ($\log K_{MnY} = 13{\cdot}6$). This allows reliable determination of manganese in alkaline medium together with calcium and/or magnesium. Determination in slightly acidic medium (pH 5–6), for example with DCTA and Methylthymol Blue,[1] or with EDTA and Calcein,[2] can be used when very small amounts of calcium and magnesium are present. Masking of calcium with ammonium fluoride[3,4] is limited to a maximum of 10 mg of calcium. On the other hand, manganese in trace amounts (3–4 mg/100 ml) can be masked with triethanolamine (TEA) in strongly alkaline medium,[5] and large amounts up to 80 mg by transforming this intense green Mn–TEA complex into the almost colourless manganese(III) cyanide complex.[6]

In the complete analysis of the mixtures of iron, aluminium, manganese, calcium and magnesium, the known separation methods for iron, aluminium and manganese are used. Manganese can be precipitated in alkaline medium with thioacetamide,[7] or from small volumes with potassium chlorate[8,9] or from acidic solution with ammonium persulphate.[10] In precipitation of manganese we have to allow for small losses of manganese in the filtration, or for some co-precipitation of calcium or magnesium. Separation of iron and aluminium with zinc oxide and then manganese with ammonium persulphate is time-consuming.[11] The extraction methods for manganese described in the literature[12] are suitable mostly for small amounts of manganese and for its colorimetry, but not selective enough for its complexometric determination. Even the extraction of manganese together with heavy metals by extraction as diethyldithiocarbamates into chloroform or ethyl acetate needs large amounts of reagent and solvents.[13,14]

In continuation of our previous work on extraction of some metals as chlorides and iodides into a solution of trioctylmethylammonium chloride (TOMA)[15] we paid attention to the extraction of metals as thiocyanate complexes. We have found that manganese(II) is quantitatively extracted from slightly acidic potassium thiocyanate medium with a chloroform or benzene solution of TOMA, without any extraction of calcium and magnesium. After stripping of manganese into ammonia–triethanolamine solution manganese is determined complexometrically without any interference by iron and aluminium. In the aqueous phase after extraction of manganese, calcium and/or magnesium can be determined by the usual complexometric method. As far as is known, only one method for extraction of a manganese thiocyanate complex (with tributyl phosphate) has been described, by Różycki and Lachowicz.[16] Under the same conditions calcium and magnesium are also almost quantitatively extracted and therefore their method is not suitable for manganese–alkaline earths separation.

EXPERIMENTAL

Reagents

Trioctylmethylammonium chloride solution, 5% in benzene. Prepared by dissolving 50 g of Aliquat 336-S (General Mills Chemical Inc., Kankakee, Illinois, U.S.A) in 1 litre of pure benzene.

Other chemicals used were analytical reagent grade.

EDTA solution, 0·05*M*. Standardized with 0·05*M* lead nitrate with Xylenol Orange as indicator.

Solutions, 0·05*M*, of manganese sulphate, magnesium sulphate and ferric chloride were prepared from proper amounts of the compounds and checked complexometrically.

A 0·05*M* solution of calcium chloride was prepared by dissolving calcium carbonate in sufficient hydrochloric acid, and checked complexometrically.

Indicators used were thymolphthalexone mixture with potassium nitrate 1 : 100 w/w and metalphthalein (cresolphthalexone), 0·1 g, and Naphthol Green B, 0·06 g, mixed with 15 g of potassium nitrate.

Other reagents include 10% solution of triethanolamine (TEA) in water, solid potassium thiocyanate, solid hydroxylamine hydrochloride, and ammonium chloride.

Separation of manganese

Effect of potassium thiocyanate concentration. In 150-ml separatory-funnels 5-ml portions of 0·05*M* manganese sulphate were mixed with 0·25, 0·50, 1·0, 2·0, or 3·5 g of potassium thiocyanate, and diluted to 40 ml with water (final concentrations of potassium thiocyanate were 0·065, 0·13, 0·26, 0·52 and 0·917*M*). The pH was adjusted to about 4 with a few drops of 1*M* sulphuric acid. Each solution was extracted twice with 10 ml of 5% TOMA in benzene with 1 min shaking, each pair of extracts being combined. The aqueous phases were washed with 5–10 ml of pure benzene and the washings added to the appropriate extract. The extracts were then stripped with a mixture of 12·5 ml of ammonia (1 + 1), 12·5 ml of 10% triethanolamine solution and 0·5 g of hydroxylamine hydrochloride. The phases were separated and the organic phase washed with 25 ml of water. The ammonia solution and washings were collected in a 300-ml titration flask (for each extract), diluted to 150–200 ml and after the addition of 0·2 g of ammonium chloride the manganese was determined with 0·05*M* EDTA, with thymolphthalexone as indicator (see Table 1). From these results it was found that at a potassium thiocyanate concentration >0·25*M* the extraction of manganese is quantitative. Excess of thiocyanate does not influence the extraction.

Influence of pH. In a small beaker 5 ml of 0·05*M* manganese solution were diluted to 35 ml with water and 1 g of potassium thiocyanate was added. The pH was adjusted to various values with sulphuric acid (glass electrode). The solution was transferred quantitatively into a 150-ml separatory funnel, and manganese extracted and determined as above. With increasing pH the degree of extraction also increases, being 57% at pH 0·43, 94% at pH 1·2 and at least 99·9% between pH 2·5 and 7.

Dilution and time of extraction. Because during the extraction of manganese equilibration between the thiocyanate and chloride salts of TOMA also takes place, the mutual effect of dilution (concentration of manganese and thiocyanate) and time of shaking was followed. Various volumes containing known concentrations of manganese and thiocyanate were extracted twice with 10 ml of 5% TOMA in benzene for 1, 2, 5 or 10 min and manganese determined as above. The results are summarized in Table 2.

From the table is evident that the minimum time of extraction (shaking) needed is indirectly proportional

and manganese was determined as above. The results are summarized in Table 2.

From the table it is evident that the minimum time of extraction (shaking) needed is indirectly proportional

200	0·26	1·2	1	4·95	~100

to the concentration of manganese and thiocyanate. For 1–2 min of extraction the lowest concentration of potassium thiocyanate must be again 0·25*M*. At lower concentration—but sufficient for the formation of the Mn(CNS)$_6^{4-}$ complex—the time of extraction must be extended to up to 10 min.

We should mention here that the work was also devoted to the determination of calcium and magnesium after the extraction of manganese. Preliminary experiments have shown that very high amounts of potassium thiocyanate in the aqueous phase after the manganese extraction (more than 2 g of KSCN) disturb the colour change of the indicators in the determination of calcium and magnesium even when the solution is diluted to 500 ml before the titration. It has been found that 1·5 g of potassium thiocyanate might be tolerated for such titrations.

RESULTS AND DISCUSSION

Extraction of manganese with equilibrated TOMA

A few attempts were made to extract manganese directly with TOMA containing thiocyanate. TOMA (5% solution in benzene, 20 ml) was equilibrated with 20 ml of 5*M* potassium thiocyanate by 20 min of shaking. The separated TOMA–SCN solution was divided into two portions which were used for the extraction of 5 ml of 0·05*M* manganese under the same conditions as above. It was found that the normal time of extraction is not sufficient for quantitative recovery of manganese. Further experiments have shown that every extraction must be carried out for at least 5 min. With larger amounts of manganese we can expect that the time of extraction must be prolonged. For this reason we prefer the first method—extraction of manganese from solutions containing sufficient potassium thiocyanate.

Capacity of the extraction

A similar procedure was used for increasing amounts of manganese (10, 15, 20 ml of 0·05*M* solution) with the addition of 1·5 g of potassium thiocyanate. After dilution to 40–60 ml, the manganese was extracted and determined as above. Under these conditions about 32–35 mg of manganese can be quantitatively extracted. Using a 10% solution of TOMA we were able to extract up to 110 mg of manganese with two 25-ml portions of TOMA.

Influence of anions

It has been found that the presence of various salts, such as 1 g of sodium sulphate, sodium chloride, potassium nitrate and ammonium fluoride, in 40 ml of the solution is without effect on the extraction. In the presence of 0·5 and 1·0 g of potassium iodide the recovery of the extraction of manganese was 97 and 90% respectively.

Influence of cations

Iron is co-extracted with manganese and stripped similarly. When triethanolamine with ammonia is used for stripping, iron is masked against EDTA and does not interfere. Cobalt, copper, zinc, *etc.*, if present in the material analysed, accompany manganese through the whole procedure and can be masked with potassium cyanide.

Determination of manganese in the presence of calcium and magnesium

The same procedure was used (40 ml total aqueous volume, pH 4, 1 g of KSCN) for the determination of manganese, double extraction with 10 ml of 5% TOMA and stripping with ammonia as described under *Separation of manganese*). Similar results were obtained in the presence of 10–30 mg of iron. Some results are given in Table 3.

Determination of manganese and alkaline earths

After the extraction of manganese, calcium and magnesium can be determined complexometrically in the aqueous phase. In some experiments we have observed that after the extraction of manganese from very large volumes containing accordingly large amounts of potassium thiocyanate (more than 1·5 g) the colour change was not too sharp even after dilution of the aqueous phase. For this reason, the original volume for manganese extraction must be limited to 40–60 ml containing about 1 g of potassium thiocyanate. After the double extraction of manganese as described above, the titration of calcium or magnesium, with thymolphthalexone or cresolphthalexone as an indicator (see *Reagents*), gave correct results with reasonably sharp end-points if the solution was diluted to 200 ml. A few results are given in Table 4.

Practical application

The method has been applied to the analysis of one sample of sedimentary manganese ore of carbonaceous-oxide composition, (Czech. standard No. 1-02-001) containing 16·53% Mn, 12·32% CaO and 4·53% MgO.

Because the sample was very resistant to normal dissolution in acids, the following procedure was chosen.

About 1 g of the sample was treated in a Teflon beaker with 10 ml of conc. hydrochloric acid and 20 ml of hydrofluoric acid and evaporated nearly to dryness. Then 20 ml of *aqua regia* were added and evaporated on a sand-bath. During the evaporation 5 ml of 30% hydrogen peroxide were added, three times. To the wet residue 20 ml of hydrochloric acid were added and evaporated again to give a moist residue. The residue was dissolved in 50 ml of water, filtered into a 100-ml volumetric flask and after cooling, diluted to the mark. From this solution 10 ml were taken in a 150-ml separatory-funnel and after the addition of 0·5 g of potassium thiocyanate were extracted twice for 2 min with 10 ml of 5% TOMA in benzene. The remaining water phase was washed with 5 ml of pure benzene, the washings being added to the combined extracts. The benzene solution was stripped with 25 ml of ammonia (1 + 1) containing 5% of triethanolamine and 0·5 g of hydroxylamine hydrochloride. This solution was transferred into a 250-ml titration flask, the organic layer was washed with water (and the washings added to the aqueous phase) and after dilution manganese was titrated with 0·05*M* EDTA, with thymolphthalexone as indicator. The aqueous phase after the extraction of manganese was transferred into a 300-ml titration flask, diluted to 200 ml and after the addition of 0·5 g of hydroxylamine hydrochloride and 10 ml of 10% TEA and ammonia solution the total Ca + Mg was titrated with 0·05*M* EDTA, with Cresolphthalexone-Naphthol Green B mixture as indicator.

For the control another 10 ml of original solution were taken in a 300-ml titration flask, 0·5 g of hydroxylamine hydrochloride 10 ml of 10% TEA solution and 10–30 ml of ammonia solution were added and the sum of Mn + Ca + Mg was determined by EDTA titration, using thymolphthalexone as indicator. Some results are included in Table 5.

Zusammenfassung—Mangan wird aus einer Lösung mit mindestens 0·25 M Kaliumthiocyanat und bei pH 2·5–7 quantitativ in eine Benzollösung von Trioktylmethylammoniumchlorid (TOMA) extrahiert. Nach Rückextraktion in Triäthanolamin (TEA) und Hydroxylaminhydrochlorid enthaltenden verdünnten Ammoniak wird Mangan durch EDTA-Titration bestimmt. Calcium und Magnesium werden nicht einmal in Spuren extrahiert. Eisen wird mit Mangan zusammen extrahiert und bei der Rückextraktion mit TEA maskiert. Aluminium stört ebenfalls nicht. Nach der Extraktion von Mangan können Calcium oder Magnesium in der wäßrigen Phase mit der üblichen EDTA-Titration bestimmt werden. Das beschriebene Verfahren erlaubt die hochselektive Einzelbestimmung von Mangan und Calcium und/oder Magnesium in allem manganreichen Material.

Résumé—Le manganèse est extrait quantitativement dans une solution benzénique de chlorure de trioctylméthylammonium (TOMA) à partir d'une solution au moins 0,25 *M* en thiocyanate de potassium et à pH 2,5–7. Après réextraction en ammoniaque diluée contenant de la triéthanolamine (TEA) et du chlorhydrate d'hydroxylamine, on dose le manganèse par titrage à l'EDTA. Le calcium et le magnésium ne sont pas extraits, même à l'état de traces. Le fer est coextrait avec le manganèse et est dissimulé par le TEA lors de la réextraction. L'aluminium n'interfère pas non plus. Dans la phase aqueuse, après l'extraction du manganèse, on peut doser le calcium ou le magnésium par le titrage habituel à l'EDTA. La méthode décrite permet le dosage individuel hautement sélectif du manganèse et du calcium et/ou du magnésium dans tous les produits riches en manganèse.

(*Eingegangen am* 20. *Juni* 1972. *Angenommen am* 16. *August* 1972)

Zusammenfassung—Die Genauigkeit der Röntgenfluoreszenzanalyse bei der Bestimmung einiger Metalle in gepreßten Pillen von Oxin wird diskutiert. Ein Verfahren zur Bestimmung kleiner Metallmengen in Süßwasser und in organischem Material (Zucker) wird beschrieben, wobei das geschmolzene Oxin als Extraktionsmittel dient.

Bei der quantitativen Bestimmung der Elemente mit Hilfe von Röntgenfluoreszenz-Spektrometrie spielt die Homogenität der Probe eine wichtige Rolle. Diese kann am einfachsten dadurch gewährleistet werden, daß man die Probe löst und die Fluoreszenzintensität des zu bestimmenden Elementes A an der Lösung ausmißt.[1,2] Durch die Verdünnung werden auch die Matrixeffekte weitgehend eliminiert, d.h. die Beeinflussung der Fluoreszenzintensität von A durch störende Begleitelemente wird vernachlässigbar klein. Dieselben Vorteile bietet auch die Überführung des zu bestimmenden Elementes A in eine "feste Lösung", wie z.B. in Boraxglas.[3]

Völlige Homogenität kleinster Bereiche kann bei Mischungen aus kristallinen Komponenten nur dann verwirklicht werden, wenn der zu lösende Stoff mit dem "festen Lösungsmittel" (Wirtskristall) Mischkristalle bildet. Gewisse ungeladene Metallkomplexe lösen sich in geschmolzenem Komplexbildner, wie z.B. die Metalloxinate in Oxin. Es ist anzunehmen, daß festes Oxin mit Oxinaten einerseits und verschiedene Oxinate andrerseits Mischkristalle bilden. Jedenfalls kann beim Abkühlen von verdünnten Lösungen der Metalloxinate in geschmolzenem Oxin keine Abscheidung von Oxinat-Kristallen beobachtet werden. Man erhält durch Abschrecken der Schmelze eine homogene Probe, welche sich nach dem Pulverisieren und Pressen für die Messung der Fluoreszenzintensitäten gut eignet. In dieser Arbeit wird nun eine Kombination der Schmelze-Lösung-Extraktion als Anreicherungsmethode und der Röntgenfluoreszenz-Spektrometrie als Analysenmethode beschrieben, wobei das 8-Hydroxychinolin (Oxin, HOX) sowohl als Extraktionsmittel wie auch als Träger für die extrahierten Metalle bei ihrer röntgenspektrometrischen Bestimmung dient.

EXPERIMENTELLER TEIL

Apparatives

Die Fluoreszenzintensitäten wurden unter standardisierten Meßbedingungen[1] mit einem Vakuum-Spektrometer (Philips PW 1540) ermittelt. Für die Aufnahme der Spektren wurde zusätzlich ein automatischer Impulshöhenanalysator (Diskriminator Philips PZ 1370) verwendet, welcher das untere Schwellenpotential entsprechend der reziproken Wellenlänge automatisch einstellt. Die Fensterbreite des Diskriminators bleibt jedoch auf dem eingestellten Wert, welcher folgendermassen bestimmt wurde: man ermittelte die Halbwertsbreite der Impulshöhenverteilungskurve für die mit dem betreffenden Detektor zu messende kürzeste bzw. längste Wellenlänge und benützte deren Summe als Fensterbreite.

Probenpräsentation

In der Röntgenspektrometrie werden üblicherweise solche Proben ausgemessen, deren Oberfläche größer ist als der Querschnitt des primären Strahlenkegels. Der Letztere betrug bei dem verwendeten Apparat *ca.* 3,5 cm^2 und bedingte die Verwendung von großen Pillen mit einem Durchmesser von 40 mm. Die benötigte Oxinmenge betrug mindestens 6 g, was eine große Menge des zu bestimmenden Elements erforderte. Für viele Anwendungen sollte aber die absolute Nachweisgrenze möglichst tief gehalten werden. Darum wurden auch Pillen mit einem Durchmesser von 13 mm auf ihre Anwendbarkeit geprüft. Der Primärstrahl wurde dabei ohne Blenden verwendet, so daß dessen Querschnitt an der Stelle der Probe größer war als die Probenoberfläche. Die Pillen wurden mit Hilfe eines Einsatzes, welcher aus Plexiglas angefertigt wurde und in den käuflichen Probenhalter paßte, in richtiger Position gehalten. Aus 500 mg Oxin ergab sich beim Pressen (mit *ca.* 100 kp/cm^2) eine Pillendicke von *ca.* 2,3 mm, welche noch nicht als "unendliche" Schichtdicke betrachtet werden darf.

Die Eindringtiefe der Primärstrahlung beträgt für reines Oxin 5,4 cm, wenn für eine Wellenlänge von 0,6 Å ($\approx$ AgK_α-Linie), für eine 100fache Abschwächung und für einen Winkel von 45° zwischen dem Lot des primären Strahlenkegels und der Probenoberfläche gerechnet wird. Für die Wellenlänge 2,25 (CrK_α) bzw 1,4 Å (ZnK_α) beträgt die Austrittstiefe 0,17 bzw. 0,65 cm bei einem Winkel von 45° zwischen der Kollimatorachse und der Probenoberfläche und bei 100facher Abschwächung. Die Proben sollten daher möglichst die gleiche Dicke aufweisen.

Herstellung von Eichpillen

Es wurde in einem Rundkolben unter kochendem Wasser während einer Stunde 5 g Oxin und 5 ml der Lösung des betreffenden Metallnitrates, dessen Konzentration durch komplexometrische Titration ermittelt wurde und 0,01*M* betrug, erhitzt. Der Kolben wurde dabei mit einem Schliffaufsatz, der in einer langen, dickwandigen Kapillare endete, verschlossen und so tief ins Wasser getaucht, daß er mindestens 5 cm unter dem Wasserniveau lag. Auf diese Weise konnte der Verlust von Oxin durch Sublimation verhindert werden. Die Kapillare wurde elastisch befestigt, so daß die Dampfstöße im kochenden Wasser ein recht gutes Rühren bewirkten. Nach dem Klarwerden beider Phasen wurde das Wasser am Rotationseindampfer abgedampft. Der Kolbeninhalt wurde schließlich durch nochmaliges Schmelzen und Schwenken homogenisiert, abgeschreckt und pulverisiert. Aus dieser "festen Stammlösung" wurden die Eichpillen verschiedener Konzentrationen durch Verdünnen mit reinem Oxin hergestellt, wobei die Mischung durch Schmelzen und Erhitzen bei 98° homogenisiert wurde.

Zeitlicher Verlauf der Extraktion

Der Anfang der Extraktion wurde so festgelegt, daß man das Oxin (3 bzw. 11 g) und die wäßrige Lösung (100 ml) getrennt auf 98° (Temperatur des siedenden Wassers bei 720 mmHg) erhitzte und erst dann zusammenbrachte. Das Extraktionsgefäß (Zweihalsschliffkolben) wurde während der Extraktion möglichst tief in gut gerührtes Paraffinöl getaucht, welches bei 98° thermostatisch behalten wurde. Das Rühren der wäßrigen Phase mit einem "Vibromischer" wurde in gewissen Zeitabständen kurz unterbrochen, und der wäßrigen Phase eine Probe entnommen, in welcher die Konzentration des nicht extrahierten Metalls nach Ansäuern ($[\mathrm{HNO_3}] = 0{,}1M$) atomabsorptiometrisch bestimmt wurde. Die Extraktionsausbeute $\%E_n$ zu der Zeit der n-ten Probenahme wurde schließlich folgendermassen berechnet:

$$\%E_n = 100 \cdot \left[1 - \frac{[\mathrm{A}]_{\mathrm{w},n}(V_{\mathrm{w}}{}^{\circ} - \sum_n^{n-1} v_n)}{[\mathrm{A}]_{\mathrm{st}} \cdot V_{\mathrm{st}} - \sum_n^{n-1} v_n \cdot [\mathrm{A}]_{\mathrm{w},n}}\right] \tag{6}$$

In dieser Gleichung bedeuten: $[\mathrm{A}]_{\mathrm{w},n}$ die Molarität des Elementes A in der wäßrigen Phase bei der n-ten Probenahme, $V_{\mathrm{w}}{}^{\circ}$ das Anfangsvolumen der wäßrigen Phase, v_n das Volumen der n-ten Probe, $[\mathrm{A}]_{\mathrm{st}}$ bzw. V_{st} die Molarität bzw. das Volumen der Stammlösung, welche zur Herstellung der wäßrigen Phase verwendet wurde.

Ausführung der Extraktion

Es wird 10–20 ml der Probelösung, welche nicht mehr als 0,01 mMole freie Säure, Lauge oder Puffersubstanz enthalten soll, mit 1 g Oxin in einem Rundkolben mit der Kapillare 2–3 Stunden unter kochendem Wasser erhitzt. Nach dem Abkühlen wird die wäßrige Phase mit Hilfe eines Filterstabes abgesaugt. Man wäscht 2–3 mal mit je 10 ml Wasser nach und trocknet die organische Phase am Rotationseindampfer. Das Oxin mit den extrahierten Metallen wird durch Schmelzen und Erhitzen bei *ca.* 100° homogenisiert, im Eiswasser abgeschreckt, pulverisiert und gepreßt.

RESULTATE UND DISKUSSION

Auswertungsverfahren und Reproduzierbarkeit

Die Totalintensität I_A am Maximum der K_α-Linie vom Element A und das Verhältnis V_A dieser Intensität zur Untergrundintensität neben der Linie I_U zeigten eine lineare Abhängigkeit von der Konzentration m_A im untersuchten Konzentrationsbereich von 0,001 bis 0,01 mMole/g (s. Abb. 1). In der Verdünnungsreihe für Kupfer und Zink war die Reproduzierbarkeit bei höherer Konzentration schlechter als im Bereich von (1–6) · 10^{-3} mMole/g. Die K_α-Strahlung von Kupfer und Zink hat eine große Austrittstiefe (s. *Probenpräsentation*), und die meßbare Fluoreszenzintensität weist daher bei der oben beschriebenen Probenpräsentation eine große Abhängigkeit von der Flächenbelegung auf. Bei diesen Versuchen wurde die Probenmenge pro Pille nur auf *ca.* 4% konstant gehalten, was die größere Streuung bei höheren Konzentrationen verursacht haben dürfte. Das Intensitätsverhältnis V_A hängt natürlich weniger stark von der Pillendicke ab, ließ sich demzufolge etwas besser reproduzieren als die Totalintensität I_A und wurde zur Auswertung der Intensitätsmessungen öfters herangezogen. Auswertungsverfahren, welche auf dem Intensitätsverhältnis von Strahlungen vergleichbarer Wellenlänge basieren, sollten auch gewisse langfristige Veränderungen apparativer Faktoren und Absorptionseffekte weitgehend kompensieren.[4]

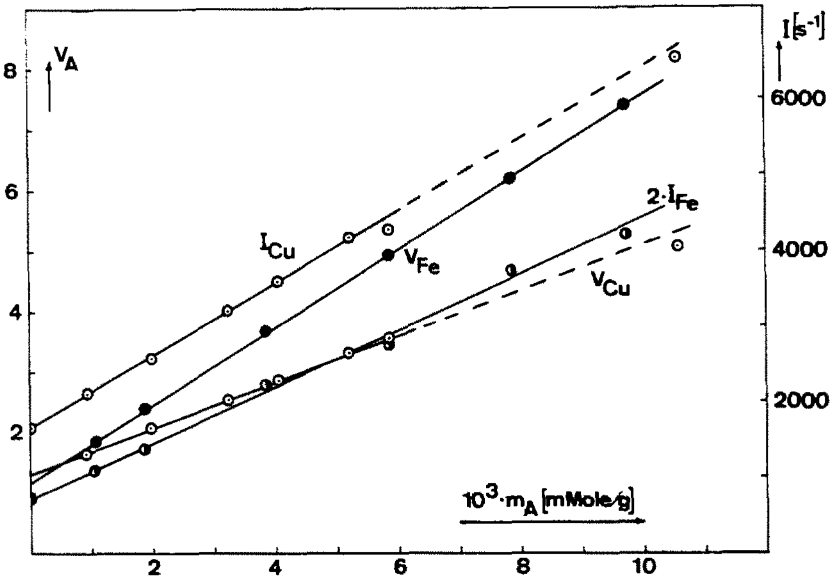

Abb. 1.—Abhängigkeit der Peak-Intensität I_A bzw. des Intensitätsverhältnisses V_A von der Konzentration m_A.

Um die Reproduzierbarkeit der Metallbestimmung in festem Oxin zu ermitteln, wurden je 6 Eichpillen für jedes Metall ausgemessen, wobei sich der Konzentrationsbereich von 0,001 bis 0,01 mMole/g für Eisen, Kobalt und Nickel bzw. von 0,001 bis 0,006 mMole/g für Zink und Kupfer erstreckte. Die folgenden Eichgeraden wurden durch lineare Regression ermittelt:

$$I_A/I_U = V_A = V_A^\circ + k_A \cdot m_A \tag{1}$$

$$I_A = I_A^\circ + K_A \cdot m_A \tag{2}$$

Tabelle 1. Bewertung der Konzentrationsbestimmung nach Gleichung (1)

No.	Größe für A:	Fe	Co	Ni	Cu	Zn
1	$(2\theta)_A$ (Grad)	57,45	52,74	48,61	44,96	41,74

(Oxin-Pillen: Durchmesser = 13 mm, Gewicht = 430 mg (±4%) Messbedingungen[1]: Ag-Röhre, 50 kV, 20 mA, LiF-Kristall, Zeitvorwahl = 100 S., ohne Diskriminator.)

In der Tabelle 1 wurden zusammengestellt: der $(2\theta)_A$-Wert am Maximum der K_α-Linie des betreffenden Metalls für den verwendeten LiF-Kristall, die ausgewählte Untergrundstelle $(2\theta)_U$, die Neigung k_A der Gerade (1) mit ihrer Standardabweichung $S(k_A)$, der Ordinatenabschnitt $V_A{}^\circ$ mit seiner Standardabweichung $S(V_A{}^\circ)$, das mittlere Intensitätsverhältnis V_{AM} mit seiner Standardabweichung $S(V_{AM})$ und die mittlere Konzentration m_{AM}. $V_A{}^\circ$ und $I_A{}^\circ$ können natürlich auch direkt bestimmt werden, da sie mit V_A und I_A für eine A-freie Pille identisch sind. Die direkt bestimmten Werte stimmten im allgemeinen innerhalb der Fehlergrenzen mit den Ordinatenabschnitten überein.

Die Daten der Zeilen 3–9 in Tabelle 1 wurden für die Abschätzung des Fehlers bei der Konzentrationsbestimmung nach Gleichung (1) verwendet. Eine unbekannte Konzentration m_A kann aus Gleichung (1) in Kenntnis von $V_A{}^\circ$ und k_A berechnet werden. Sie ist natürlich mit einem gewissen Fehler behaftet, da einerseits V_A nicht fehlerfrei gemessen werden kann und andrerseits auch der Eichung, d.h. dem $V_A{}^\circ$- und dem k_A-Wert ein gewisser Fehler anhaftet. Nach dem Fehlerfortpflanzungsgesetz beträgt die Standardabweichung von der mittleren Konzentration m_{AM}:

$$S(m_{AM}) = \frac{1}{k_A}\left[S^2(V_{AM}) + S^2(V_A{}^\circ) + \frac{S^2(k_A)}{k_A{}^2}(V_{AM}{}^2 + V_A{}^{\circ 2})\right]^{1/2} \tag{3}$$

Die relative Standardabweichung $\varepsilon(m_{AM})$ der mittleren Konzentration m_{AM} wurde nun berechnet und in der 10. Zeile der Tabelle 1 angegeben. Sie beträgt im Durchschnitt für alle Metalle 2,4% und ist nicht wesentlich höher als der totale statistische Zählfehler.

Um den Letzteren mit Hilfe der Gleichung (3) abzuschätzen, müssen für $S(V_{AM})$, $S(V_A{}^\circ)$ und $S(k_A)$ die theoretischen Werte eingesetzt werden. Die Standardabweichung einer bestimmten Intensität I beträgt theoretisch $(I/T)^{1/2}$, wobei T die Zähldauer bedeutet. Berücksichtigt man noch die Fehlerfortpflanzung, so erhält man für den statistischen Zählfehler der Konzentrationsbestimmung nach Gleichung (1):

$$S(m_{AM})_{stat} = \frac{1}{k_A} \cdot \left|\frac{V_{AM}(V_{AM}+1) + V_A{}^\circ(V_A{}^\circ + 1)}{T \cdot I_U{}^\circ}\left(1 + \frac{V_{AM}{}^2 + V_A{}^{\circ 2}}{k_A{}^2 \cdot m_{AM}{}^2}\right)\right|^{1/2} \tag{4}$$

Diese Gleichung ist für die Zeitvorwahl-Meßtechnik abgeleitet worden und $I_U{}^0$ bezeichnet darin die Untergrundintensität für die reine Oxinpille. Der relative statistische Fehler $100 \cdot S(m_{AM})_{stat}/m_{AM}$ wurde nun für eine Meßzeit von 100 S. berechnet und in der 11. Zeile der Tabelle 1 angegeben. Für alle fünf Metalle betrug das Verhältnis des totalen Fehlers $\varepsilon(m_{AM})$ zu dem statistischen Zählfehler $\varepsilon(m_{AM})_{stat}$ im Durchschnitt 1,8, welches gewöhnlich auch bei der Analyse von Lösungen gefunden wird und somit auf eine gute Homogenität der Proben hindeutet. Der Totalfehler dürfte sich daher hauptsächlich aus dem statistischen Zählfehler und aus Fehlern, welche durch kurzfristige Apparateschwankungen verursacht werden, zusammensetzen.

Ersetzt man in Gleichung (3) V_{AM} durch $V_A{}^0$ und $S(V_{AM})$ durch $S(V_A{}^0)$, so erhält man Gleichung (5), welche zur Abschätzung der Nachweisgrenze dient:

$$m_{A,\,NG} = \frac{t(\%,\, N)}{k_A}\left[2 \cdot S^2(V_A{}^0) + 2 \cdot V_A{}^{02} \cdot S^2(k_A)/k_A{}^2\right]^{1/2} \tag{5}$$

$t(\%,\, N)$ ist ein statistischer Faktor[7] und hängt von der gewünschten Sicherheit sowie von der Zahl der Meßpunkte ab, welche für die Ermittlung von $S(V_A{}^0)$ und $S(k_A)$ benützt wurden. Die Nachweisgrenze wurde nun für 95%ige statistische Sicherheit berechnet, und in der 12. Zeile der Tabelle 1 angegeben. Multipliziert man diese Werte mit dem Gewicht einer Pille (0,5 g) und mit dem Atomgewicht des betreffenden Metalls, so erhält man die absolute Nachweisgrenze. Diese ist in der letzten Zeile der Tabelle 1 angegeben und beträgt für die 5 Metalle im Durchschnitt 10 μg.

Die statistische Prüfung des Auswertungsverfahrens nach Gleichung (2) führte zu ähnlichen Resultaten, welche daher nicht weiter diskutiert werden. In der Tabelle 2 sind lediglich die Fluoreszenzintensitäten für kilogrammolare "feste Lösungen" im Oxin den molaren Fluoreszenzintensitäten wäßriger Lösungen gegenübergestellt. Ein Vergleich beider Größen ist zulässig, weil sie mit dem gleichen Spektrometer unter standardisierten Meßbedingungen[1] ermittelt wurden.

Tabelle 2. Fluoreszenzintensität von kilogrammolaren Lösungen einiger Metalle in festem Oxin und im Wasser (K_A in s^{-1}.kg.mol^{-1})

	Cr	Fe	Co	Ni	Cu	Zn
$10^{-5} \cdot K_A$ (Oxin, 13)*	0,608	1,83	2,47	3,34	4,84	6.46
$10^{-5} \cdot K_A$ (Oxin, 40)	1,29	3,55	4,74	6,11	8.58	11,6
$10^{-5} \cdot K_A$ (H_2O, 32)	0,794	3,16	5,89	4,78	8,92	12,9

* (Die Zahlen in der Klammer geben den Durchmesser der Probe in mm an. Der Durchmesser des primären Strahlenkegels betrug an der Probenoberfläche *ca.* 20 mm)

Die K_A-Werte für ein bestimmtes Metall A sind ungefähr gleich in Wasser und in Oxin, wenn die Probenoberfläche größer als der Querschnitt des primären Strahlenkegels ist. Theoretisch ist dies für homogene Lösungen mit ungefähr gleichen Massenabsorptionskoeffizienten zu erwarten. Der zweifache Verlust an Empfindlichkeit wird bei der Verwendung von kleinen anstelle der großen Pillen durch die zwölfmal kleinere Probenmenge mehr als aufgewogen.

Extraktion der Metallionen mit geschmolzenem Oxin

Die Extraktion von Metallionen kann entweder mit einer Lösung des Oxins in einem mit Wasser nicht mischbaren Lösungsmittel (gewöhnlich Chloroform) bei Zimmertemperatur oder mit geschmolzenem Oxin bei 80–100° ausgeführt werden.[8] Bei der "normalen" Extraktion kann die gemeinsame Phasengrenze viel größer gehalten werden als bei der "Schmelzextraktion", was eine größere Transportgeschwindigkeit zwischen den beiden Phasen ermöglicht. Die erstgenannte Technik wird daher meistens vorgezogen, wenn die Bildungsgeschwindigkeit des extrahierbaren Komplexes groß ist. Erfolgt die Bildung des Oxinates sehr langsam (z.B. für $Cr(OX)_3$), so ist die Schmelzextraktion wegen der höheren Temperatur und wegen der großen Oxinkonzentration in der wäßrigen Phase die bessere Methode.

Nach Umland[8] liegt die Verteilung des Metalls zwischen der wäßrigen Lösung und dem geschmolzenen Oxin–ausser bei Alkalimetallen–stets weit auf der Seite der Oxinphase, wodurch das Oxin zu einem universellen Extraktionsmittel für die meisten Metalle wird. Die Schmelzextraktion wurde bereits erfolgreich angewandt in Kombination mit Spektrophotometrie[5,8] und Spektroskopie.[6] Die Anwendung der Schmelzextraktion in

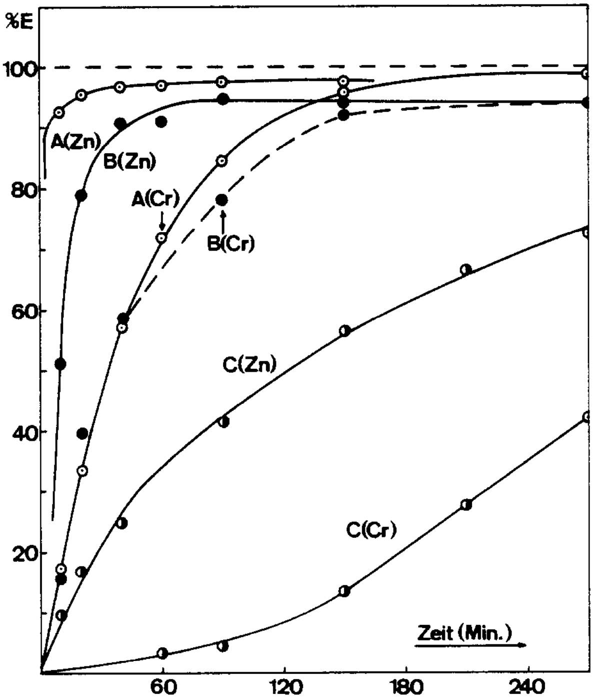

Abb. 2.—Zeitlicher Ablauf der Extraktion von Cr(III) und Zn(II) mit geschmolzenem Oxin bei 98° C.

Anfängliche Zusammensetzung der wäßrigen Phase: $[ZnX^-] = [CrX] = 1 \cdot 10^{-4} M$, $[Na_2HX] = 2 \cdot 10^{-3} M$, wobei X^{3-} das Anion der Nitrilotriessigsäure, welche zur Verhinderung des Ausfalls von $Zn(OX)_2 \cdot 2H_2O$ diente, bedeutet.

A: $V/V_0 = 11$, wäßrige Phase mit "Vibromischer" gerührt
B: $V/V_0 = 53$, wäßrige Phase mit "Vibromischer" gerührt
C: $V/V_0 = 53$, nicht gerührt

Verbindung mit Röntgenfluoreszenz-Spektrometrie als Meßmethode sollte die selektive und genaue Bestimmung der meisten Metalle ermöglichen.

Damit die Extraktion genügend schnell erfolgt und die Extraktionsausbeute möglichst hoch ist, sollte das Volumenverhältnis V/V_0 der wäßrigen zu der organischen Phase nicht zu groß sein ($V/V_0 < 50$). Den Einfluß von V/V_0 auf die Geschwindigkeit der Extraktion von Cr(III) und Zn(II) zeigt Abb. 2, in welcher die Extraktionsausbeute ($\% E$) in Abhängigkeit der Extraktionsdauer aufgetragen ist. Bekanntlich verhalten sich diese Metalle kinetisch sehr verschieden. Während das Zn(II) rasche Ligandaustauschreaktionen eingeht, bildet das Cr(III) robuste Komplexe. Dementsprechend ist die Bildungsgeschwindigkeit von $Cr(OX)_3$ für die Extraktionsgeschwindigkeit sogar bei 98° maßgebend, was dadurch gezeigt wird, daß in beiden Versuchen A ($V/V_0 = 11$) und B ($V/V_0 = 53$) zum Erreichen eines konstanten Extraktionsgrades ungefähr die gleiche Zeit benötigt wird. Da sich das Zinkoxinat praktisch momentan bildet, können die Kurven *A* (Zn) und *B* (Zn) zur Beurteilung des Einflusses von V/V_0 auf die Schnelligkeit der Extraktion dienen. Eine konstante Extraktionsausbeute wird bei dem größeren Volumenverhältnis V/V_0 offensichtlich langsamer erreicht, was mit der Verkleinerung der Transportgeschwindigkeit über die Phasengrenze mit zunehmendem V/V_0 zu erklären ist. In beiden Versuchen A und B wurde die wäßrige Phase mit einem "Vibromischer" so stark gerührt, daß sich die Phasen noch nicht vermischten. Ein zu starkes Rühren, welches die Verteilung des geschmolzenen Oxins in der wäßrigen Phase bewirkt hätte, wurde vermieden, damit ein eindeutiger Zusammenhang zwischen dem Volumenverhältnis und der Größe der gemeinsamen Phasengrenze, welche die Geschwindigkeit der Extraktion hauptsächlich bestimmt, bestehen bleibt.

Beim Versuch C wurde auf das Rühren verzichtet, was eine sehr langsame Einstellung des Gleichgewichtes bewirkte. Zudem zeigten Zn(II) und Cr(III) eindeutig verschiedenes Verhalten. Die Extraktion von Cr(III) setzte nach einer gewissen "Induktionsperiode" ein, welche verstreichen muß, damit die Konzentration des Oxins in der wäßrigen Phase genügend ansteigt.

Anwendungsmöglichkeiten

Bestimmung der Metallionen in Süß wasser. Da das Volumenverhältnis V/V_0 möglichst klein sein muß, können die Metallionen aus solchen wäßrigen Proben, deren Abdampfrückstand relativ klein ist, gut angereichert werden. Diese Proben können entweder ohne Ausfall von festen Stoffen vorkonzentriert werden, oder der Rückstand kann in einer kleinen Menge eines Lösungsmittels gelöst werden. Zink und Eisen konnten z.B. in Zürcher Trinkwasser bei einer 550fachen Anreicherung bestimmt werden (s. Abb. 3). Diese bestand hier aus der 100fachen Vorkonzentrterung im Rotationseindampfer und aus der 55fachen Anreicherung bei der Extraktion.

Bestimmung der Metalle in organischem Material. Die Spurenelemente werden aus der Asche mit Säure herausgelöst, und die Metallionen aus der neutralisierten Lösung mit geschmolzenem Oxin extrahiert. Wie die Abb. 4 zeigt, liefern 128 g Kristallzucker (gewöhnliche Handelsware) durch Veraschen und Extraktion mit 1 g Oxin eine Pille mit gut meßbaren Fluoreszenzintensitäten für die K_α-Linien der Elemente Eisen, Kupfer und Zink.

Der Eidg. Stiftung zur Förderung Schweizerischer Volkswirtschaft durch wissenschaftliche Forschung danken wir für finanzielle Unterstützung.

Summary—The accuracy of the determination by X-ray fluorescence spectrometry of a number of metals in pressed tablets of oxine has been investigated. A procedure is described which has been used for the determination of trace metals in fresh water and in sugar, in which molten oxine is used as the extractant.

Résumé—On a étudié la précision de la détermination par spectrométrie de fluorescence aux rayons X d'un certain nombre de métaux dans des pastilles comprimées d'oxine. On décrit une technique qui a été utilisée pour le dosage de métaux à l'état de traces dans l'eau douce et dans le sucre, dans laquelle l'oxine fondue est utilisée comme agent d'extraction.

IRON(II)-CHLORAMINE-T REACTION

V. R. S. RAO and G. ARAVAMUDAN
Department of Chemistry, Indian Institute of Technology, Madras-36, India

(*Received* 8 *May* 1972. *Accepted* 6 *June* 1972)

Summary—When a large excess of the oxidant is used in the iron(II)-chloramine-T reaction at pH 2·56–5·6 the amount of oxidant consumed is well above the stoichiometric amount required to oxidize iron(II) to iron(III). This has been attributed to the formation and subsequent behaviour of free radicals during the reaction. The formation of free radicals has been experimentally demonstrated. They apparently dimerize to give products of the type R–NCl–NCl–R (R = $CH_3C_6H_4SO_2$), which are further oxidized by chloramine-T. The dimerized species liberate iodine very slowly from acidified potassium iodide. This explanation satisfactorily accounts for the observed extent and rate of destruction of excess of chloramine-T in presence of small amounts of Fe(II) or bromide at pH 2·65–4·70. The storage of chloramine-T in metal containers might cause extensive destruction of the oxidant by a similar free radical mechanism and should be avoided.

Chloramine-T ($CH_3C_6H_4SO_2NClNa.3H_2O$) is generally used as an oxidizing agent in strongly acid[1] medium but recently its utility in alkaline[2] and weakly acid[3] media has been reported. This oxidant is of particular interest for the study of reaction mechanisms as it furnishes different types of oxidants such as monochloramine-T ($CH_3C_6H_4SO_2NHCl$), dichloramine-T ($CH_3C_6H_4SO_2NCl_2$) and the anion ($CH_3C_6H_4SO_2NCl^-$), depending on the pH of the medium; chlorine[4] is also produced in strongly acid medium in presence of large amount of chloride ions. It is reported[5] that monochloramine-T disproportionates according to equation (1) fairly rapidly in the pH range 2·65–5·6 and fastest at pH 4·7.

$$2CH_3C_6H_4SO_2NHCl \longrightarrow CH_3C_6H_4SO_2NCl_2 + CH_3C_6H_4SO_2NH_2 \qquad (1)$$

During this disproportionation, a minor side-reaction leads to slight but significant destruction of chloramine-T by combination of the $CH_3C_6H_4SO_2NCl$ free radicals.[4]

Earlier work on the oxidation of iron(II) with chloramine-T has been concerned only with determination of iron(II). Poethke and Wolf[6] reported that iron(II) can be determined by adding excess of chloramine-T in presence of 10% hydrochloric acid, then reducing the surplus chloramine-T with excess of arsenite, the excess being back-titrated with chloramine-T, with *p*-ethoxychrysoidine or Brilliant Carmoisine as indicator. Bishop and Jennings[7] confirmed this. The oxidation of iron(II) by chloramine-T is of trivial analytical interest, as far better methods are already available. We undertook a study of the oxidation with a view to finding whether the results would help in explaining the rapid deterioration of chloramine-T stored in metal containers. Interesting results were obtained in the oxidation of iron(II) with chloramine-T in the pH range 2·65–4·7 and are mechanistically and analytically significant.

EXPERIMENTAL

Reagents

Ferrous sulphate solutions, 0·05*M* and 0·1*M*, were standardized with dichromate. Ferrous ammonium sulphate could not be used as the ammonium ion[2] would react with chloramine-T, producing chlorine as one of the products, which would interfere in the Fe(II)-chloramine-T reaction.

Chloramine-T solution, 0·05*M*, was standardized iodometrically.

Sodium thiosulphate solution, 0·05*M*, was standardized against dichromate.

Stock buffer solutions were prepared from acetic acid and sodium acetate for the pH range 2·65–4·7 and from potassium hydrogen phthalate for pH 4·0.

Analytical-grade reagents or reagents of known purity were used.

Procedure

To 20 ml of 0·05*M* ferrous sulphate 20 ml of 2*N* hydrochloric or sulphuric acid or a buffer in the pH range 2·65–5·6 were added and the reaction mixture was diluted to 80 ml in a stoppered iodine-flask. To this, 100–500% excess of chloramine-T solution was added and the contents were let stand for a definite time. Then 5 g of potassium fluoride were added to complex ferric iron, followed by 15 ml of 10% potassium iodide solution and if necessary 20 ml of 2*N* sulphuric acid, and the iodine liberated was titrated with thiosulphate, with starch as indicator. Similar experiments were done without the ferrous sulphate. The difference in the titration values of blank and test gives the amount of chloramine-T used. In some cases excess of chloramine-T was taken in the conical flask, the pH was adjusted and iron(II) solution was added from the burette.

The free radical nature of the iron(II)-chloramine-T reaction at pH 4·7 was demonstrated as follows. To 20 ml of 0·05*M* chloramine-T solution, 40 ml of distilled water and 20 ml of acetic acid–acetate buffer (pH 4·7) were added and the solution was deaerated for 1 hour by bubbling pure nitrogen gas through it. Then 5 ml of 0·1*M* ferrous sulphate solution and 1 ml of methyl methacrylate monomer (deaerated for 1 hr) were added, and the flask was stopped and set aside in the dark for 1 hr. The mixture was then diluted to 400 ml to dissolve the dichloramine-T. It was found that there was a fairly large amount of polymer (25% yield) formed as a white gummy substance floating on the water surface. A blank experiment without ferrous sulphate gave only traces of polymer.

RESULTS AND DISCUSSION

In 0·2*N* sulphuric acid or hydrochloric acid media, the amount of chloramine-T used was equal to the stoichiometric requirement for the oxidation of iron(II) to iron(III) (Table 1). No complications arose in these media. This is in agreement with earlier reports.

However, the behaviour of excess of chloramine-T towards iron(II) in the pH range 2·65–4·7 (Table 2) had unusual features: (*i*) the amount of chloramine-T consumed far exceeded that required for oxidation of iron(II) to iron(III); (*ii*) this consumption of chloramine-T increased with the duration of keeping of the mixture of iron(II) and chloramine-T; (*iii*) this consumption of chloramine-T was greatest at pH 4·7 and particularly when the iron(II) was added to the chloramine-T solution. It is significant that iron(II) was completely oxidized within a minute after addition of excess of chloramine-T in all the media tested. This was demonstrated by mixing the reagents and within a minute adding excess of arsenite to destroy any remaining chloramine-T, acidifying the mixture with 20 ml of 4*N* sulphuric acid, and titrating any iron(II) with vanadate, using diphenylamine as indicator. None was found.

It was also found that ferric iron and *p*-toluenesulphonamide have no influence on the stability or the extra consumption of chloramine-T in the iron(II)-chloramine-T reaction at pH 4·7 (Table 3). The large consumption of chloramine-T in the iron(II) reaction at pH 2·65–4·7 is not dependent on the nature of the buffer (Table 2). Chloramine-B ($C_6H_5SO_2NClNa$) behaved similarly to chloramine-T (Table 4) indicating that the methyl group in chloramine-T is not the cause of the overconsumption. However, increasing the ionic strength of the medium at pH 4·7 reduced the overconsumption of oxidant (Table 5). It is generally accepted that formation of free radicals is suppressed in media of high ionic strength. Hence we tested for the formation of free radicals. These observations showed

§ CAT found. Small difference is due to instability of Chloramine-T.

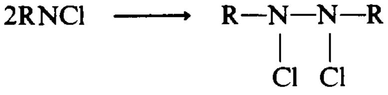
that the overconsumption of chloramine-T is due to the reaction between chloramine-T and the initial products (other than *p*-toluenesulphonamide) formed during the oxidation of iron(II).

In strongly acid medium, the species present initially in large concentrations in aqueous chloramine-T solution is monochloramine-T[5] which would undergo disproportionation slowly. Since no extra consumption of chloramine-T was found when 0·1*N* hydrochloric or sulphuric acid media were used, it was inferred that no side-reaction would take place during oxidation of iron(II) by monochloramine-T. In the pH range 2·65–4·7, the disproportionation of monochloramine-T is very fast, giving rise to dichloramine-T. In these pH ranges, dichloramine-T is the dominant species in the oxidation of the iron(II).

We therefore propose the following explanation for the overconsumption of the oxidant. Dichloramine-T oxidizes iron(II) and gives rise to free radicals

$$RNCl_2 + Fe(II) \longrightarrow RNCl + FeCl^{2+}$$

and if the free radical RNCl were slower than $RNCl_2$ to react with iron(II) then dimerization of the free radical occurs:



$$2RNCl \longrightarrow \underset{\displaystyle Cl}{\underset{|}{R{-}N}}{-}\underset{\displaystyle Cl}{\underset{|}{N{-}R}}$$

(where R = $CH_3C_6H_4SO_2$)

The dimer has very poor oxidation properties towards potassium iodide or iron(II) and moreover can further be oxidized by chloramine-T, which accounts for the continued consumption of chloramine-T after complete oxidation of iron(II) at pH 4·7.

Attempts were made to characterize the nature of the products, other than *p*-toluenesulphonamide, formed during the iron(II)–chloramine-T reaction at pH 4·7, by taking large amounts of iron(II) and chloramine-T. Under these conditions, a yellowish white solid was precipitated. This was separated and dried over phosphorus pentoxide. The solid appeared to be a mixture of substances. Its infrared spectrum revealed bands mostly characteristic of *p*-toluenesulphonamide, but the solid was found to liberate iodine from acidified potassium iodide solution (though very slowly) and it also contained chlorine. There was gradual loss of chlorine content and the weak oxidizing action, on keeping for several days. These observations lead us to assume that the solid consisted, in addition to *p*-toluenesulphonomide, of products of the kind R-NCl-NCl-R, which would be expected to be unstable, to behave as a weak oxidizing agent towards iodine and to be capable of further reaction with chloramine-T.

Similar results have been found by us when small amounts of bromide are used as reducing agent instead of iron(II).

Chloramine-T packed in metal containers has invariably been found to deteriorate very rapidly in its purity and oxidative value. We ascribe this to extensive destruction of the oxidant by free radical formation and dimerization initiated by oxidation of small amounts of metal by the oxidant. This has to be particularly borne in mind during the packing of solid chloramine-T. We would recommend the use of glass or polythene containers for this purpose. The possibility of destruction of chloramine-T by these side-reactions when it is used as an analytical agent in back-titration procedures at pH 2·65–4·7 should be checked during development of the method. These side-reactions will not occur if the free radical RNCl reacts at least as fast as $RNCl_2$ with the oxidizable substrates instead of dimerizing.

Zusammenfassung—Verwendet man einen großen Überschuß des Oxidationsmittels bei der Reaktion zwischen Eisen(II) und Chloramin-T bei pH 2·56–5·6, dann ist der Verbrauch an Oxidationsmittel erheblich höher, als der für die Oxidation von Eisen(II) zu Eisen(III) benötigten stöchiometrischen Menge entspricht. Dies wurde mit der Bildung und mit Folgeprozessen freier Radikale während der Reaktion begründet. Die Bildung freier Radikale wurde experimentell nachgewiesen. Sie dimerisieren offenbar zu Produkten vom Typ R-NCl-NCl-R ($R = CH_3C_6H_4SO_2$), die von Chloramin-T weiter oxidiert werden. Die dimeren Spezies setzen aus angesäuertem Kaliumjodid sehr langsam Jod frei. Diese Erklärung berücksichtigt die beobachtete Zersetzung von überschüssigem Chloramin-T in Gegenwart kleiner Mengen von Eisen(II) oder Bromid bei pH 2·65–4·70 nach Ausmaß und Geschwindigkeit in befriedigender Weise. Die Aufbewahrung von Chloramin-T in Metallbehältern könnte über einen ähnlichen Radikalmechanismus das Oxidationsmittel in erheblichem Ausmaß zersetzen und sollte daher vermieden werden.

Résumé—Lorsqu'un grand excès de l'oxydant est utilisé dans la réaction fer (II)-chloramine-T à pH 2,56–5,6, la quantité d'oxydant consommée est bien au-dessus de la quantité stoechiométrique nécessaire pour oxyder le fer (II) en fer (III). Ceci a été attribué à la formation et au

comportement ultérieur de radicaux libres durant la réaction. La formation de radicaux libres a été démontrée expérimentalement. Ils se dimérisent apparemment pour donner des produits du type R—NCl—NCl—R ($R=CH_3C_6H_4SO_2$), qui sont plus profondément oxydés par la chloramine-T. L'espèce dimérisée libère très lentement l'iode d'une solution acidifiée d'iodure de potassium. Cette explication rend compte de manière satisfaisante de la grandeur et de la vitesse de destruction observées de l'excès de chloramine-T en présence de petites quantités de Fe (II) ou de bromure à pH 2,65–4,70. Le stockage de la chloramine-T dans des récipients métalliques pourrait causer une forte destruction de l'oxydant par un mécanisme de radical libre semblable et devrait être évité.

INFRARED MACRO AND SEMIMICRO DETERMINATION OF NITROGEN IN RAW NITROCELLULOSE AND NITROCELLULOSE CONTAINED IN PROPELLANTS

GEORGE NORWITZ and DAVID E. CHASAN
Frankford Arsenal, Philadelphia, Pa. 19137, U.S.A.

(*Received* 21 *April* 1972. *Accepted* 3 *July* 1972)

Summary—The infrared procedure for the determination of nitrogen in raw nitrocellulose has been improved. In the original method 0·31–0·32 g of sample was dissolved in 45 ml of tetrahydrofuran, the solution was weighed, and the infrared peak at 6·0 μm was measured. The calibration curve was prepared by plotting absorbance against mg of nitrogen per g of solution. The method has the disadvantage that the height of the peak is affected by the sample weight. In the improved method the error due to the sample weight is eliminated by using 0·3000 g of sample and diluting to 50 ml in a volumetric flask. The calibration curve is prepared by plotting absorbance against % nitrogen. The method was extended to the semimicro scale by using a 30·0-mg sample and diluting to 5 ml in a volumetric flask. The method has been applied on the macro and semimicro scales to the direct determination of nitrogen in nitrocellulose after a methylene chloride extraction. The amounts of graphite and inorganic salts found in nitrocellulose-base propellants do not interfere, but a correction must be made to refer the results to 0·3000 g of nitrocellulose for the macro method or 30·0 mg of nitrocellulose for the semimicro method. The same calibration curve is used for all procedures.

Levitsky and Norwitz[1] proposed an infrared procedure for the determination of nitrogen in nitrocellulose. In this procedure 0·31–0·32 g of sample was dissolved in 35 ml of tetrahydrofuran in a glass-stoppered Erlenmeyer flask by allowing to stand overnight, the solution was weighed, and the peak at 6·0 μm was measured. The calibration curve was prepared by carrying samples of nitrocellulose of known nitrogen content through the procedure and plotting absorbance *vs.* mg of nitrogen per g of solution.

A "round-robin" group under the chairmanship of Dr. Eugene Burns of Space Technology Laboratories evaluated the procedure and found that it was satisfactory.[2] Dr. Burns showed that the accuracy could be improved somewhat by preparing a calibration curve each day. However, the procedure is not as accurate as the nitrometer method and is designed for rapid control work.

In this procedure there is an error caused by the fact that the calibration curve varies with the sample weight (it is for this reason that 0·31–0·32 g of sample was specified). Clarkson and Robertson[3] stated that this error could be eliminated by correcting all sample weights to a fixed concentration (0·008 g of nitrocellulose per g of solution). Some difficulties have been encountered at times with the method of approach suggested by Clarkson and Robertson; therefore, an investigation was undertaken to develop a more direct method for eliminating the error caused by the sample weight.

Another aspect of the present investigation was to extend the range of the infrared method for the determination of nitrogen in nitrocellulose to the semimicro scale, since there is need for such a method. Elving and McElroy[4] have described a semimicro method for the determination of nitrogen in nitrocellulose by a nitrometer; however, a special apparatus is required. Gardon and Leopold[5] have described a micro spectrophotometric method for the determination of nitrogen in nitrocellulose, using phenoldisulphonic acid, but the conditions for the development of the colour are critical. Roberts[6] described a spectrophotometric method for the determination of nitrogen in nitrocellulose, using diphenylamine; the method is applicable to the micro or semimicro range but is only semiquantitative.

The final aspect of the present paper involved the application of the infrared technique to the direct determination, both on a macro and semimicro scale, of nitrogen in nitrocellulose contained in propellants. The methods that have been previously proposed for the determination of nitrogen in nitrocellulose contained in propellants are troublesome. If the propellant does not contain a significant amount of inorganic material, the determination can be performed by subjecting the propellant to extraction with methylene chloride, ethyl ether, or 70% acetic acid, drying the residue (nitrocellulose), and determining the nitrogen in a weighed portion by titration[7,8] or by use of the nitrometer.[7] If the propellants contain a significant amount of inorganic materials, as is usually the case, the method is subject to an error caused by the fact that these inorganic materials are not extracted by the methylene chloride and are included in the weighed sample of nitrocellulose. For a sample containing 13·00% nitrogen and 1·00% of total inorganic material, the error would be −0·13% total nitrogen. This error can be reduced but not eliminated by dissolution of the nitrocellulose in acetone and precipitation with water.[9]

EXPERIMENTAL

Reagents

Tetrahydrofuran. Store in a constant-temperature room. Keep covered at all times and dispense from a covered container.

Preparation of calibration curve

Air-dry 3 or 4 standard samples of nitrocellulose (with nitrogen content accurately determined by the nitrometer method[7]), then dry them in a vacuum oven (at 20–50 mm Hg pressure) at 65° for 4 hr and cool in a desiccator. Weigh 0·3000 g of the samples into tared 30-ml beakers. Add 35 ml of tetrahydrofuran and immediately cover tightly with aluminium foil which is held in place by rubber bands. Carry along a blank determination. Allow to stand overnight without stirring, in the room (constant temperature) containing the infrared instrument.

After the overnight standing period, stir with a small stirring rod, wash down and remove the stirring rod, transfer to a 50-ml volumetric flask with tetrahydrofuran, dilute to the mark with tetrahydrofuran, stopper, and shake. Work with only one sample at a time from point of stirring to the dilution in the volumetric flask. Rinse and fill a 0·2-mm sodium chloride cell with the solution, using a 1-ml syringe. Obtain the spectrum from 5·80 to 6·05 μm (1724–1653 cm^{-1}) at a speed of 25 cm^{-1} per minute. The gain, response, and resolution settings should be normal. Suppression setting should be zero.

Observe I_A and I (see Fig. 1) and calculate the absorbance from absorbance = $\log (I_A/I)$. Deduct the blank. Plot absorbance against % nitrogen in the nitrocellulose. The calibration curve should be checked ocasionally and should be redrawn if a new lot of tetrahydrofuran is used.

Procedures

Determination of nitrogen in raw nitrocellulose

Macro method. Dissolve 0·3000 g of sample in tetrahydrofuran and measure the intensity of the peak at 6·0 μm as described in the preparation of the calibration curve. Calculate the nitrogen content by referring to the calibration curve.

Semimicro method. Proceed as for the macro method but weigh a 30·0-mg sample in a tared 5-ml beaker (preferably on a semimicro balance), dissolve it in 3 ml of tetrahydrofuran, and dilute to 5 ml in a volumetric flask. Calculate the nitrogen content by referring to the calibration curve.

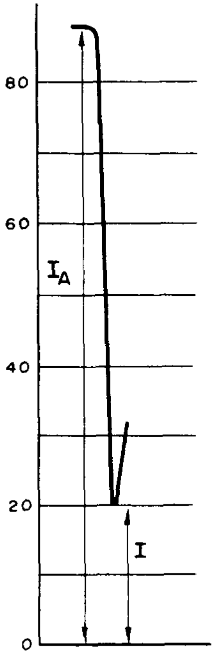

Fig. 1. Spectrum of nitrocellulose in tetrahydrofuran from 5·80 to 6·05 μm.

Determination of nitrogen in nitrocellulose contained in propellants

Macro method. Extract 0·5–5 g of sample of the propellant with methylene chloride in the usual manner, using a Soxhlet extractor.[7] Transfer the residue from the thimble to a weighing dish and dry by heating in a vacuum oven (20–50 mm Hg) at 65° for 2 hr. Calculate the weight of the residue that will contain 0·3000 g of nitrocellulose (NC) as follows.

$$\text{Weight of residue (g) that will contain 0·3000 g of NC} = \frac{30}{100\text{-}A}$$

where A = total per cent of graphite plus inorganic salts (carbonates, nitrates, and sulphates) in the propellant.

Weigh this calculated amount of the residue into a 30-ml beaker, dissolve in tetrahydrofuran, and proceed as described in the macro method for raw nitrocellulose.

Semimicro method. Extract approximately 0·1 g of sample with methylene chloride in the usual manner, using a Soxhlet extractor,[7] and dry the residue. Calculate the weight of residue that will contain 30·0 mg of nitrocellulose, as follows.

$$\text{Weight of residue (mg) that will contain 30·0 mg of NC} = \frac{3000}{100\text{-}A}$$

where A = total per cent of graphite plus inorganic salts (carbonates, nitrates, and sulphates) in the propellant.

Weigh the calculated amount of residue in a tared 5-ml beaker, add 3 ml of tetrahydrofuran, and proceed as described in the semimicro method for raw nitrocellulose.

DISCUSSION AND RESULTS

The sample-weight effect in the original method is eliminated by dissolving 0·3000 g of sample in the tetrahydrofuran in a beaker and diluting to 50 ml in a volumetric flask. The weighing of an exact amount of nitrocellulose is readily performed since the material is very fluffy.

The accurancy of the original method[1] has been further improved by carrying a blank for the tetrahydrofuran through the entire process. This compensates for the small amount of water in the tetrahydrofuran, which shows some absorption at 6·0 μm. The amount of water in commercial tetrahydrofuran is about 0·02%.[10]

As before,[1] it is recommended that transmittance paper rather than absorbance paper be used for recording the peak. The reason for this is that in the region of 20% transmittance, the transmittance paper can be read more accurately than absorbance paper.

As previously stated, the calibration curve in the original method was prepared by plotting absorbance *vs.* mg of nitrogen per g of solution.[1] Analogously, the calibration curve could be prepared in the present method by plotting absorbance *vs.* mg of nitrogen per ml of solution. However, since a constant weight of sample is used, the calibration curve can be prepared by merely plotting absorbance *vs.* per cent of nitrogen in the nitrocellulose.

For the sake of information, an investigation was made to ascertain the extent to which the sample weight affected the calibration curve obtained by plotting absorbance *vs.* mg of nitrogen per ml of solution. For this investigation, curves were plotted for 0·3000 g and 0·2900 g of sample per 50 ml (Fig. 2). It is seen that the weight of sample has a significant effect. The cause of this phenomenon is uncertain.

In establishing the method for nitrogen in nitrocellulose contained in propellants it was first necessary to ascertain whether the results obtained for nitrogen were additive when samples of nitrocellulose of different nitrogen content were mixed together. This is important because nitrocelluloses of different nitrogen content are often blended together to obtain a composite nitrocellulose of required nitrogen content.

To investigate this problem, 0·1500 g of a sample that contained 12·61% nitrogen was mixed with 0·1500 g of a sample that contained 13·47% nitrogen. The results obtained for nitrogen were 13·01, 13·09, and 13·09% with an average result of 13·06%. The latter result does not differ significantly from the theoretical result (13·04%), so it can be concluded that the nitrogen content is additive.

The question of interference from the inorganic materials found in propellents, namely graphite, calcium carbonate, barium carbonate, sodium nitrate, potassium nitrate, sodium

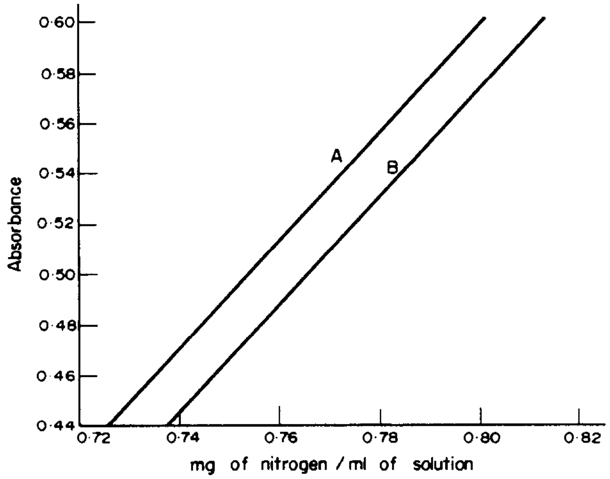

Fig. 2. Effect of amount of nitrocellulose on curve obtained by plotting absorbance *vs.* mg of nitrogen per ml of solution

A. 0·2900 g of nitrocellulose.
B. 0·3000 g of nitrocellulose.

sulphate, and potassium sulphate, was also considered. Experiments were carried out in which 0·0033 g of each of these substances (equivalent to 1·00% on a 0·3000 g sample) was suspended in 50 ml of tetrahydrofuran and the absorbance measured at 6·0 μm. In no case was the absorbance different from the absorbance obtained with tetrahydrofuran.

Aside from the question of the interference by increased absorbance, the problem arose as to how to correct for the weight of the inorganic substances so as to obtain a sample that would contain 0·3000 g or 30·0 mg of nitrocellulose. This problem was solved by using the equations indicated in the procedure.

It was found that the same calibration curve could be used for all methods.

The results obtained for nitrogen in raw nitrocellulose by the macro and semimicro infrared methods on four samples for which nitrogen content had been established by the nitrometer method are shown in Table I. The macro and semimicro infrared results check with the nitrometer results and each other quite well. The average standard

deviation of the macro infrared method was 0·037% and that of the semimicro method was 0·046%. The average standard deviation of the original method was 0·093%.[1]

The results obtained for nitrogen in nitrocellulose contained in propellants by the macro and semimicro infrared methods are shown in Table 2. There is no accurate method that can be used as a basis of comparison. The macro and semimicro infrared methods check with each other well. The average standard deviation of the macro method was 0·028% while that of the semimicro method was 0·022%. The results for both the semimicro methods are within the specification requirements for nitrogen in nitrocellulose contained in propellants.

This work was conducted under an Army Materials Testing Technology Project (AMS Code 4931.OM.6350).

Zusammenfassung—Das Infrarotverfahren zur Bestimmung von Stickstoff in roher Nitrocellulose wurde verbessert. Ursprünglich wurden 0·21–0·32 g Probe in 45 ml Tetrahydrofuran gelöst, die Lösung gewogen und die Infrarotbande bei 6·0 μm gemessen. Die Eichkurve wurde hergestellt durch Auftragen der Extinktion gegen mg Stickstoff pro g Lösung. Das Verfahren hat den Nachteil, daß die Peakhöhe vom Probengewicht abhängt. Bei der verbesserten Methode wird der auf dem Gewicht der Probe beruhende Fehler vermieden, indem 0·3000 g Probe verwendet werden und in einem Meßkolben auf 50 ml verdünnt wird. Die Eichkurve wird hergestellt durch Auftragen der Extinktion gegen % Stickstoff. Das Verfahren wurde durch Verwendung einer 30·0 mg-Probe und Verdünnen im Meßkolben auf 5 ml auf den Halbmikromaßstab ausgedehnt. Das Verfahren wurde im Makro- und Halbmikromaßstab auf die direkte Bestimmung von Stickstoff in Nitrocellulose nach einer Extraktion mit Methylenchlorid angewandt. Die Mengen an Graphit und anorganischen Salzen, die man in Treibmitteln auf Nitrocellulosebasis findet, stören nicht. Eine Korrektur muß angebracht werden, um die Ergebnisse auf 0·3000 g Nitrocellulose für die Makromethode oder auf 30·0 mg Nitrocellulose für die Halbmikromethode zu beziehen. Man verwendet für alle Verfahren die selbe Eichkurve.

Résumé—On a amélioré la technique infra-rouge pour le dosage de l'azote dans la nitrocellulose brute. Dans la méthode originale, on dissolvait 0,31–0,32 g d'échantillon dans 45 ml de tétrahydrofuran, pesait la solution, et mesurait le pic infra-rouge à 6,0 μm. La courbe d'étalonnage était préparée en traçant l'absorbance par rapport au nombre de mg d'azote par g de solution. Le désavantage de la méthode est que la hautur du pic est affectée par le poids d'échantillon. Dans la méthode améliorée l'erreur due au poids d'éhantillon est éliminée en utilisant 0,3000 g d'échantillon et en diluant à 50 ml dans une fiole jaugée. La courbe d'étalonnage est préparée en tracant l'absorbance par rapport au % d'azote. La méthode a été étendue à l'échelle semi-micro en utilisant un échantillon de 30,0 mg et en diluant à 5 ml dans une fiole jaugée. On a appliqué la méthode aux échelles macro et semi-micro au dosage direct de l'azote dans la nitrocellulose après une extraction au chlorure de methylène. Les quantité de graphite et de sels minéraux trouvées dans les agents de propulsion à base de nitrocellulose n'interfèrent pas, mais il faut effectuer une correction pour rapporter les résultats à 0,3000 g de nitrocellulose pour la macrométhode ou 30,0 mg de nitrocellulose pour la semi-microméthode. La même courbe d'étalonnage est utilisée pour toutes les techniques.

HYDROGEN PEROXIDE FORMATION UPON OXIDATION OF OXALIC ACID IN PRESENCE AND ABSENCE OF OXYGEN AND OF MANGANESE(II)—III

IRON(III) AND COPPER(II) AS RETARDERS*

(*Received* 5 *May* 1972. *Accepted* 5 *July* 1972)

Summary—The formation of considerable amounts of hydrogen peroxide upon the slow addition of various oxidizing agents to oxalic acid in dilute sulphuric acid in the presence of oxygen and Mn(II) is greatly retarded in the presence of Fe(III) or Cu(II). With hydrogen peroxide as oxidizing agent and a trace of Fe(II) there is considerable decomposition of peroxide, under a nitrogen atmosphere, after a few hours at 25° in light (from a tungsten lamp), and less decomposition in the dark. This decomposition is decreased by Mn(II) and also when the original mixture contains Fe(III). With oxygen as the oxidizing agent Fe(II) is about 100 times as effective an inhibitor of peroxide formation as Fe(III). With all oxidizing agents used, Cu(II) is some 6–10 times more effective as a retarder than Fe(III). The inhibition is accounted for by the reaction Fe(III) [or Cu(II)] + CO_2^- → Fe(II) [or Cu(I)] + CO_2.

Considerable amounts of hydrogen peroxide are formed upon the slow addition of various oxidizing agents to oxalic acid in dilute sulphuric acid in the presence of oxygen and Mn(II). The oxidizing agents include Mn(VII), Cr(VI), Ce(IV), and the complex Co(III) oxalate,[1] as well as oxygen itself.[2] The initial step appears to be oxidation of Mn(II) to the complex Mn(III)Ox, where Ox denotes oxalate. This is followed by reactions (1)–(3):

$$\mathrm{Mn(III)Ox} \longrightarrow \mathrm{Mn(II)} + CO_2 + \cdot CO_2^- \quad \text{(measurable rate)} \tag{1}$$

$$\cdot CO_2^- + O_2 \longrightarrow \cdot O_2CO_2^- \quad \text{(very fast)} \tag{2}$$

$$\cdot O_2CO_2^- + \mathrm{Mn(II)} + H_2C_2O_4 \longrightarrow \mathrm{Mn(III)Ox} + CO_2 + H_2O_2 \quad \text{(fast)} \tag{3}$$

Reactions (1)–(3) constitute the chain reaction

$$O_2 + H_2C_2O_4 \longrightarrow 2CO_2 + H_2O_2$$

The radical which is formed in reaction (1) may be either $\cdot CO_2^-$ or $\cdot C_2O_4^-$. An approximate theoretical calculation[3] indicates that the latter radical is the more stable, but the two forms do not appear to be distinguishable on the basis of kinetic or spectroscopic evidence.[4] Following the consensus of previous workers we write $\cdot CO_2^-$ in this paper. Also, in this paper, in which all the experiments reported were carried out in 0·1*M* sulphuric acid media, no account is taken of the various protonated or dissociated

---

† Present address: Department of Applied Chemistry, Yamagata University, Yonezawa-shi, Japan.

forms of radicals such as $\cdot HCO_2$, $\cdot O_2^-$, and so forth. Many such equilibrium constants are known.[5]

According to Anderson and Hart[6] and many subsequent workers, the radical $\cdot HCO_2$ (*i.e.*, protonated $\cdot CO_2^-$), which is formed in the radiolysis of formic acid, reacts with oxygen according to reaction (2*a*):

$$\cdot HCO_2 + O_2 \longrightarrow \cdot HO_2 + CO_2 \tag{2a}$$

Since $\cdot HO_2$ presumably oxidizes Mn(II) to Mn(III)Ox, the net result in this case is also an induced formation of hydrogen peroxide.

In a study of the oxidation of aqueous solutions of formic acid by X-rays in the presence of Fe^{3+} and/or Cu^{2+}, it was shown[7] that reactions (4*a*) and (4*b*) occur with the formate radical:

$$Fe^{3+} + CO_2^- \longrightarrow Fe^{2+} + CO_2 \tag{4a}$$

$$Cu^{2+} + CO_2^- \longrightarrow Cu^+ + CO_2 \tag{4b}$$

Quite generally with this and other organic radicals, Baxendale and co-workers have found that Cu^{2+} is more reactive than Fe^{3+}, and specifically with the formate radical in $0{\cdot}1N$ sulphuric acid the rate constant for Cu^{2+} is about 6 times as large as that for Fe^{3+}. Therefore both Fe^{3+} and Cu^{2+} may be expected to retard the formation of hydrogen peroxide, the latter more strongly. On the other hand, under our experimental conditions some Fe(III) is present as oxalate complexes, denoted as Fe(III)Ox. These complexes undergo a photochemical decomposition which has been studied intensively (see ref. 4, which gives the earlier literature):

$$\mathrm{Fe(III)Ox} + h\nu \longrightarrow \mathrm{Fe(II)} + CO_2 + \cdot CO_2^- \tag{5}$$

The occurrence of reaction (5) would be expected to promote the formation of hydrogen peroxide. The effects of Fe(III), Fe(II) and Cu(II) on hydrogen peroxide formation on oxidation of oxalic acid in the light and dark are the subject of the present paper.

EXPERIMENTAL

All chemicals were of C. P. quality. The arrangement used for experiments in light (tungsten lamp) and the methods used for determination of the sum of peroxide and oxalic acid have already been described.[1,2] For the determination of hydrogen peroxide in the presence of oxalic acid and Fe(III) or Cu(II), the reaction mixture was made $0{\cdot}3M$ in potassium oxalate and the pH was adjusted to 5·5 by addition of sulphuric acid. The mixture was then made $0{\cdot}01M$ in ammonium molybdate, an excess of potassium iodide was added, and the liberated iodine was titrated with thiosulphate, the end-point being detected either with starch or amperometrically. In the buffered medium (pH 5·5) neither iron(III) nor copper(II) reacts with iodide. In some instances hydrogen peroxide formed was also determined polarographically. The results agreed with those found iodometrically.

RESULTS

The effects of Fe(III) and Cu(II) upon formation of peroxide in the dark are shown in Table 1. In all these experiments it was found that (expressed in equivalents) peroxide formed = oxalic acid disappeared − Mn(VII) added. As expected, Cu(II) is a more powerful retarder than Fe(III). Under the conditions of Table 1, $0{\cdot}01M$ Co(II) had no effect.

The four-hour experiments of Table 1 were repeated with Fe(II) instead of Fe(III). When the equivalent amount of Fe(II) was equal to or greater than the amount of Mn(VII) added, no hydrogen peroxide was formed. No induced oxidation by oxygen occurs as long as there is Fe(II) present. After this has been oxidized by Mn(VII) the

Fe(III) formed acts as if it had been added initially. The same was found true when an amount of Mn(VII) equivalent to the Fe(II) present was added rapidly to the well-stirred reaction mixture. Evidently no oxalic acid reacts with Mn(VII) until all Fe(II) has been oxidized. [It is also possible that the oxidation of Fe(II) is by Mn(III)Ox rather than by Mn(VII), but the net result is the same, that is, the prevention of reaction (1).]

Previously[2] it was found that the decomposition of hydrogen peroxide in dilute sulphuric acid at 25° was either negligible or very slow in the absence and presence of oxalic acid and of Mn(II), both in the dark and in light. Even at 75° the decomposition did not exceed 4% in 3 hr. The addition of a trace of Fe(II) has in some cases a pronounced accelerating effect (Table 2). In the absence of oxalic acid, Mn(II) increases the decomposition. In the presence of oxalic acid and Fe(II) the amount of oxalic acid

that disappeared was equimolar with the amount of peroxide that disappeared. Therefore the Fe(II)–peroxide couple under the specified conditions induces the oxidation of oxalic acid. From Table 2 it is clear that Mn(II) retards this induced oxidation at 25°. At 75°, however, there is a substantial decomposition of peroxide which is promoted by Mn(II) and is about the same in the dark as in the light.

Effect of Fe(III). In a mixture which was $10^{-4}M$ in Fe(III) and 2–5 × $10^{-3}M$ in hydrogen peroxide no decomposition occurred in 4 hr in the dark, either in nitrogen or oxygen, in the absence or presence of Mn(II). In light the results were very different (Table 3).

In the absence of oxalic acid and Mn(II) there was negligible decomposition at 25° even after 48 hr, whether in a nitrogen or an oxygen atmosphere. In the presence of oxalic acid and Fe(III) complete decomposition occurred in 3 hr at 25° in the absence of Mn(II); the addition of Mn(II) decreased the decomposition.

Oxygen as oxidant. From Table 4 it appears that the slow oxidation of oxalic acid by oxygen in the presence of Mn(II) is retarded by traces of Fe(II) and Fe(III), the former

Table 4. Effects of Fe(II) and Fe(III) upon peroxide formation in the dark, 25°C. Solution 0·01*M* in $H_2C_2O_4$, 0·1*M* in H_2SO_4 and 0·1*M* in Mn(II). Closed system, initially air-saturated.

being about 100-fold as effective a retarder as the latter. Table 5 compares Fe(II), Fe(III), and Cu(II) in oxidation by oxygen at 65°. Again, Fe(II) is a much stronger retarder than Fe(III), and Cu(II) also is stronger than Fe(III).

DISCUSSION

The retarding effect of Fe(III) and Cu(II) on formation of peroxide upon addition of Mn(VII), Table 1, is accounted for by the competition of reaction (4) with (2). The Fe(II) or Cu(I) formed in reaction (4) is oxidized at once by the slowly-added Mn(VII). As already mentioned, the results of Baxendale and Smithies[7] indicate that the rate constant of (4*b*) may be about six times that of (4*a*). In agreement with this expectation, by graphical interpolation of the data in Table 1, Cu(II) is found to be 5–10 times as effective a retarder as Fe(III) at the same concentration.

The results of Table 3 can be interpreted in the following way. The Haber-Weiss mechanism for the reaction between hydrogen peroxide and Fe(II), as modified by Baxendale and colleagues,[8] involves the reactions:

$$Fe^{2+} + H_2O_2 \longrightarrow Fe^{3+} + OH^- + \cdot OH \tag{6}$$

$$\cdot OH + H_2O_2 \longrightarrow \cdot HO_2 + H_2O \tag{7}$$

$$\cdot HO_2 + Fe^{3+} \longrightarrow Fe^{2+} + H^+ + O_2 \tag{8}$$

$$Fe^{2+} + \cdot OH \longrightarrow Fe^{3+} + OH^- \tag{9}$$

Under our conditions (Table 2) there is hardly any decomposition in the absence of oxalic acid in the presence of $10^{-4}M$ Fe(II) after 3 hr in the dark at 25°, but there is a noticeable decomposition in the light, which is accelerated by Mn(II). The effect of light is accounted for by reaction (10):

$$\text{Fe(III)} + H_2O_2 + h\nu \longrightarrow Fe^{2+} + H^+ + \cdot HO_2 \quad \text{(slow)} \tag{10}$$

In addition to (6) reactions (11) and (12) occur in the presence of Mn(II):

$$\text{Mn(II)} + \cdot OH \longrightarrow \text{Mn(III)} + OH^- \tag{11}$$

$$\text{Mn(II)} + H_2O_2 \longrightarrow \text{Mn(III)} + OH^- + \cdot OH \tag{12}$$

At 75°, however, there is little if any difference in the results in light and in the dark, and the decomposition of peroxide is pronounced after 3 hr. Even with only $10^{-5}M$ Fe(II) there is noticeable decomposition. Also at 75° Mn(II) promotes the decomposition.

In the presence of oxalic acid (Table 2) the decomposition of peroxide is enhanced in the dark and more so in the light. The initiating reaction appears to be (13):

$$Fe^{2+} + H_2O_2 + H_2C_2O_4 \longrightarrow Fe(III)Ox + H^+ + H_2O + \cdot OH \qquad (13)$$

followed by (14) and (15) which constitute a chain:

$$\cdot OH + H_2C_2O_4 \longrightarrow H_2O + H^+ + CO_2 + \cdot CO_2^- \qquad (14)$$

$$\cdot CO_2^- + H_2O_2 \longrightarrow CO_2 + OH^- + \cdot OH \qquad (15)$$

In light there is an additional contribution from reaction (5). Mn(II) decreases the decomposition of peroxide in the presence of oxalic acid, both in the dark and in light, because of reaction (16),

$$\cdot OH + Mn(II) + H_2C_2O_4 \longrightarrow Mn(III)Ox + H_2O + H^+ \qquad (16)$$

followed by (1), (2) and (3) which regenerate peroxide, to compensate for its destruction in (7) and (8).

In a mixture containing initially Fe(III) and hydrogen peroxide (Table 3), no decomposition of peroxide occurred at 25° after 3 hr in *nitrogen*, but there was considerable decomposition in the additional presence of 0·01M oxalic acid and complete decomposition with 0·1M oxalic acid. The decomposition in nitrogen and in light, accompanied by an equimolar disappearance of oxalic acid, is accounted for by reactions (5), (15), (14), and (9). The retarding effect of Mn(II) is the same as explained above.

It is especially interesting (Table 3) that oxygen in light almost completely prevents the induced oxidation of oxalic acid in the absence of Mn(II) (*e.g.*, after 3 hr at 25°, 100% in nitrogen, 5% in oxygen). Apparently the $\cdot CO_2^-$ formed in reaction (5) reacts very rapidly with oxygen (reaction 2), followed by reaction (17)

$$\cdot O_2CO_2^- + Fe(III) \longrightarrow Fe^{2+} + CO_2 + O_2 \qquad (17)$$

and reaction (6).

Finally, with oxygen as oxidizing agent (Tables 4 and 5) Fe(II) is about 100 times as effective an inhibitor of peroxide formation as Fe(III). Considering the results at 65°, the initiating reaction appears to be

$$O_2 + Mn(II) + H_2C_2O_4 \longrightarrow Mn(III)Ox + \cdot HO_2 + H^+ \quad \text{(slow)} \qquad (18)$$

The Mn(III)Ox thus formed reacts rapidly with Fe^{2+} and hence reaction (1) does not occur. The relatively much weaker inhibiting effects of Cu(II) and Fe(III) are explained (as in respect to Table 1) by reactions (4*b*) and (4*a*).

The inhibiting effect of Fe(III) and Cu(II) has been made use of in the time-honoured method of determination of active oxygen in manganese dioxide by digestion with an excess of oxalic acid in about 4N sulphuric acid and titration of the remaining oxalic acid. The method gives high results, but the error can be largely eliminated[9] when iron(III) or copper(II) are present during the digestion. From the results in this and the preceding papers, it is evident that the error arises from an induced oxidation of oxalic acid by oxygen, in the presence of Mn(II) formed during the digestion, to hydrogen peroxide, which in turn decomposes before the titration with permanganate. It is also evident that the presence of Cu(II) or Fe(III) should largely prevent this error, as has been found experimentally.

Zusammenfassung—Die Bildung erheblicher Mengen Wasserstoffperoxid bei der langsamen Zugabe verschiedener Oxidationsmittel zu Oxalsäure in verdünnter Schwefelsäure in Gegenwart von Sauerstoff und Mangan(II) wird in Gegenwart von Fe(III) oder Cu(II) stark verlangsamt. Mit Wasserstoffperoxid als Oxidationsmittel und einer Spur Fe(II) zerfällt unter Stickstoffatmosphäre nach ein paar Stunden bei 25° im Licht (von einer Wolframlampe) eine beträchtliche Menge Peroxid, im Dunkeln weniger. Die Zersetzung wird von Mn(II) verlangsamt, ebenso, wenn die Ausgangsmischung Fe(III) enthält. Mit Sauerstoff als Oxidationsmittel inhibiert Fe(II) die Peroxidbildung etwa 100-mal effektiver als Fe(III). Bei allen verwendeten Oxidationsmitteln ist Cu(II) als Verlangsamer 6–10-mal wirksamer als Fe(III). Man kann die Inhibitorwirkung durch die Reaktion Fe(III) [oder Cu(II)] + CO_2^- → Fe(II) [oder Cu(I)] + CO_2 erklären.

Résumé—La formation de quantités considérables d'eau oxygénée par l'addition lente de divers agents d'oxydation à l'acide oxalique en acide sulfurique dilué en la présence d'oxygène et de Mn(II) est fortement retardée en la présence de Fe(III) ou Cu(II). Avec l'eau oxygénée comme agent oxydant et une trace de Fe(II), il y a une décomposition considérable de peroxyde, sous une atmosphère d'azote, après quelques heures à 25° à la lumière (d'une lampe au tungstène), et une moindre décomposition à l'obscurité. La décomposition est diminuée par Mn(II) et aussi lorsque le mélange initial contient Fe(III). Avec l'oxygène comme agent oxydant, Fe(II) est un inhibiteur de formation de peroxyde environ 100 fois plus efficace que Fe(III). Avec tous les agents d'oxydation utilisés, Cu(II) est quelques 6–10 fois plus efficace comme retardateur que Fe(III). L'inhibition est expliquée par la réaction Fe(III) [ou Cu(II)] + CO_2^- → Fe(II) [ou Cu(I)] + CO_2.

LOGARITHMIC DIAGRAMS AND GRAN-CURVES AS AN AID IN POTENTIOMETRIC TITRATIONS IN COMPLEXOMETRY

AXEL JOHANSSON
Royal Institute of Technology, Stockholm, Sweden

(*Received* 18 *March* 1972. *Accepted* 3 *August* 1972)

Summary—A detailed exposition is given of the use of logarithmic diagrams and Gran plots to construct titration curves and to determine accurately the equivalence point in potentiometric complexometric titrations.

Gran-curves are being used more frequently for the evaluation of the results of potentiometric titrations. In acid-base titrations, no special problems arise when Gran-functions are used, but with complexometric titrations it is sometimes difficult to decide whether Gran-curves can be used. In some cases only one part of the titration curves can be utilized in the evaluation, but logarithmic diagrams are often valuable for handling these problems. Two different questions are of particular interest:

(*a*) how can a titration curve be constructed when the concentrations and the stability constants are known and

(*b*) how can the equivalence volume be calculated when an unknown sample is being titrated?

TITRATION CURVES

Titrations where [M] or pM can be measured

Johansson and Wänninen[1] have shown that logarithmic diagrams are a convenient means of surveying the conditions of a complexometric titration. First, consider a titration of the type $M + Y = MY$, the equilibrium equation being $[MY] = K_{MY}[M][Y]$. All quantities may be conditional.[2] A logarithmic diagram for a complexometric equilibrium is constructed in the following way. In a diagram with pY along the horizontal axis and log C (C denoting concentration) along the vertical axis, a system point ($\log K_{MY}$, $\log C_M$) is marked (point S in Fig. 1). C_M denotes the concentration of the metal ion at the start of the titration. From this point, four lines are drawn, two parallel to the pY-axis, the other two having slopes $+1$ and -1 respectively. The lines are connected in pairs according to the figure.

The point of intersection between the curved parts lies 0·3 (= log 2) logarithmic units below the system point. Finally, a line with slope -1 is drawn with the origin as the starting point. The three graphs in Fig. 1 represent the species M, MY and Y, and show the logarithm of the concentration of each of these species at a certain value of pY. The diagram then is fully analogous to an acid-base diagram, with the exception that no line representing OH^- is needed. A comprehensive survey of logarithmic diagrams has been made by Sillén.[3] During the titration, the total concentration of Y increases, *i.e.*, pY

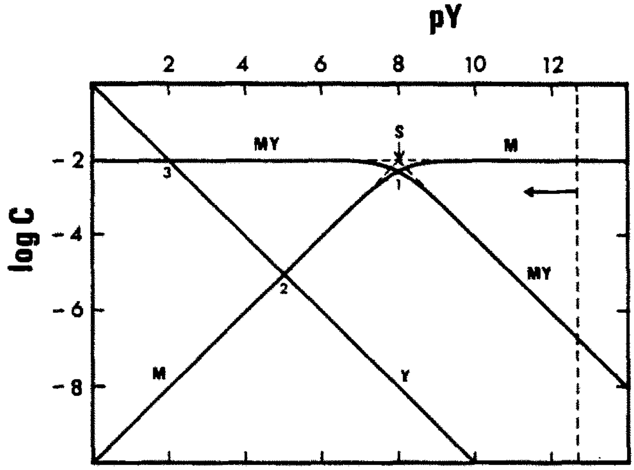

Fig. 1. Logarithmic diagram of log C as a function of pY. The total concentration is $10^{-2}M$ and log K_{MY} is 8·0.

Table 1. Values of pM corresponding to different values of the titration ratio a, the number of moles of titrant added per mole of metal ion, for the calculation of titration curves

a	pM	a	pM
0	$-\log C_{\mathrm{M}}$	1·01	$\log K_{\mathrm{MY}} - 2{\cdot}00$
0·1	$-\log C_{\mathrm{M}} + 0{\cdot}05$	1·02	$\log K_{\mathrm{MY}} - 1{\cdot}70$
0·2	$-\log C_{\mathrm{M}} + 0{\cdot}10$	1·03	$\log K_{\mathrm{MY}} - 1{\cdot}52$
0·3	$-\log C_{\mathrm{M}} + 0{\cdot}15$	1·04	$\log K_{\mathrm{MY}} - 1{\cdot}40$
0·4	$-\log C_{\mathrm{M}} + 0{\cdot}22$	1·05	$\log K_{\mathrm{MY}} - 1{\cdot}30$
0·5	$-\log C_{\mathrm{M}} + 0{\cdot}30$	1·06	$\log K_{\mathrm{MY}} - 1{\cdot}22$
0·6	$-\log C_{\mathrm{M}} + 0{\cdot}40$	1·07	$\log K_{\mathrm{MY}} - 1{\cdot}15$
0·7	$-\log C_{\mathrm{M}} + 0{\cdot}52$	1·08	$\log K_{\mathrm{MY}} - 1{\cdot}10$
0·8	$-\log C_{\mathrm{M}} + 0{\cdot}70$	1·09	$\log K_{\mathrm{MY}} - 1{\cdot}05$
0·9	$-\log C_{\mathrm{M}} + 1{\cdot}00$	1·10	$\log K_{\mathrm{MY}} - 1{\cdot}00$
0·91	$-\log C_{\mathrm{M}} + 1{\cdot}05$	1·20	$\log K_{\mathrm{MY}} - 0{\cdot}70$
0·92	$-\log C_{\mathrm{M}} + 1{\cdot}10$	1·30	$\log K_{\mathrm{MY}} - 0{\cdot}52$
0·93	$-\log C_{\mathrm{M}} + 1{\cdot}15$	1·40	$\log K_{\mathrm{MY}} - 0{\cdot}40$
0·94	$-\log C_{\mathrm{M}} + 1{\cdot}22$	1·50	$\log K_{\mathrm{MY}} - 0{\cdot}30$
0·95	$-\log C_{\mathrm{M}} + 1{\cdot}30$	1·60	$\log K_{\mathrm{MY}} - 0{\cdot}22$
0·96	$-\log C_{\mathrm{M}} + 1{\cdot}40$	1·70	$\log K_{\mathrm{MY}} - 0{\cdot}15$
0·97	$-\log C_{\mathrm{M}} + 1{\cdot}52$	1·80	$\log K_{\mathrm{MY}} - 0{\cdot}10$
0·98	$-\log C_{\mathrm{M}} + 1{\cdot}70$	1·90	$\log K_{\mathrm{MY}} - 0{\cdot}05$
0·99	$-\log C_{\mathrm{M}} + 2{\cdot}00$	2·00	$\log K_{\mathrm{MY}} - 0{\cdot}00$
1·00	$(\log K_{\mathrm{MY}} - \log C_{\mathrm{M}})/2$	2·00	$\log K_{\mathrm{MY}}$

Dilution was disregarded when the values of Table 1 were calculated, but if it is desired to take it into account, the term $\log(ar + 1)$ where r is the ratio of the molarities of the titrand and the titrant, should be added to pM.

decreases and hence *the vertical line representing the system moves from right to left in the diagram.*

The diagram in Fig. 1 was constructed assuming the original concentration of M to be $10^{-2}M$ and the stability constant of MY to be 10^8.

From the diagram it can be seen for instance that pM = 2 at the start of the titration (no addition of Y). At the point where half the metal has been titrated (i.e. [M] = [MY], point no. 1) the pM value is 2.3. At the equivalence point (point no. 2), the conditions should be the same as in a $10^{-2}M$ solution of MY in water. Part of the MY is then dissociated into M and Y, the concentrations of these species being equal. It can also directly be seen that the larger the value of the stability constant of the complex, the smaller is [M]. The diagram shows that at the equivalence point, pM = 5 [*i.e.*, (8 + 2)/2]. At point no. 3, where [MY] and [Y] are equal, the amount of Y added is, all told, double the amount of M, and pM = log *K*.

Hence when the titration begins, $pM = -\log C_M$ and when twice the amount of titrant required to reach the equivalence point has been added, $pM = \log K_{MY}$. The values of pM between these extreme values are easily calculated but can also be taken from Table 1.

It is, however, easy to read more points from logarithmic diagrams and not only equivalence points, half-titration points etc. It is possible to introduce a scale *a* (the degree of titration) in the diagram and read the pM values directly. The following table gives values of pY corresponding to values of *a*.

Table 2. Values of pY corresponding to different values of the titration ratio *a*

a	pY	*a*	pY
0·01	$\log K_{MY} + 2{\cdot}00$	0·99	$\log K_{MY} - 2{\cdot}00$
0·10	$\log K_{MY} + 0{\cdot}95$	1·00	$(\log K_{MY} - \log C_M)/2$
0·25	$\log K_{MY} + 0{\cdot}48$	1·01	$2{\cdot}00 - \log C_M$
0·50	$\log K_{MY}$	1·10	$1{\cdot}00 - \log C_M$
0·75	$\log K_{MY} - 0{\cdot}48$	1·50	$0{\cdot}30 - \log C_M$
0·90	$\log K_{MY} - 0{\cdot}95$	2·00	$-\log C_M$

See also Fig. 2 which illustrates the titration of a metal ion with a complexing agent Y to form a complex MY with stability constant equal to 10^8.

Titrations where pM cannot be measured

Indirect electrodes. It is not always possible to follow the course of a titration with an electrode having a potential that is directly proportional to [M]. Frequently, an indicator electrode is used, that consists of Hg^{2+}/Hg or Ag^+/Ag and requires addition of HgY or AgY to the titrated solution before the start of the titration. The titration curves that are obtained in such titrations can have different shapes. The problem has been treated by various authors.[4–13] In this case, logarithmic diagrams provide a convenient guide to the appearance of the titration curves.

The following assumptions are made. A metal ion M with total concentration C_M is titrated with a complexing agent Y. An indicator ion is added in the form of AY. The total concentration of A is denoted by C_A. The (conditional) stability constants are K_{MY} and K_{AY}, respectively.

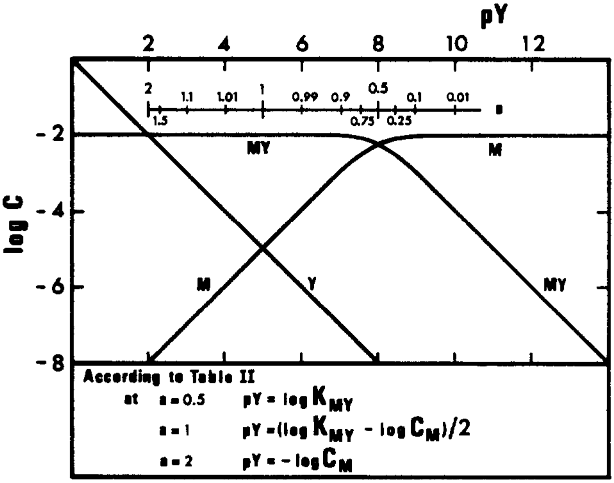

Fig. 2. Logarithmic diagram for the titration of a metal ion M with a complexing agent Y. $K_{MY} = 10^8$; $C_M = 0{\cdot}01M$. A scale for $a = C_Y/C_M$ is introduced in the diagram.

It is possible to distinguish three cases.

1. $K_{AY} = K_{MY}$

This case is demonstrated in Figs. 3 and 4. When the solutions are mixed before the titration ($a = 0$), the reaction M + AY = MY + A takes place. This means that [A] and [MY] are then equal, corresponding to point no. 1 in Fig. 3. It is also clear from this diagram that the graph representing M is parallel to the graph representing A over its entire course. In a logarithmic diagram, this means that pA − pM is constant, which implies that [A] = constant × [M]. It is easy to construct a conventional titration curve with the aid of the logarithmic diagram and the scale for $a = C_Y/C_M$. Figure 4 shows the titration curve pA = $f(a)$. The figure also contains a scale showing the variations of pM as a function of a.

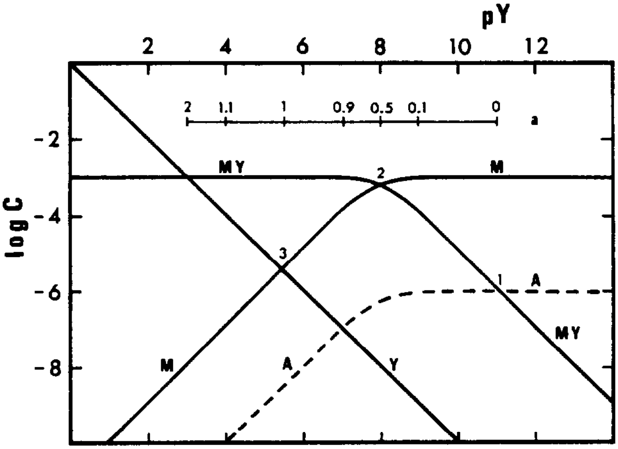

Fig. 3. Logarithmic diagram of log C as a function of pY. C_M is $10^{-3}M$ and C_A is $10^{-6}M$. Log K_{AY} = log K_{MY} = 8.

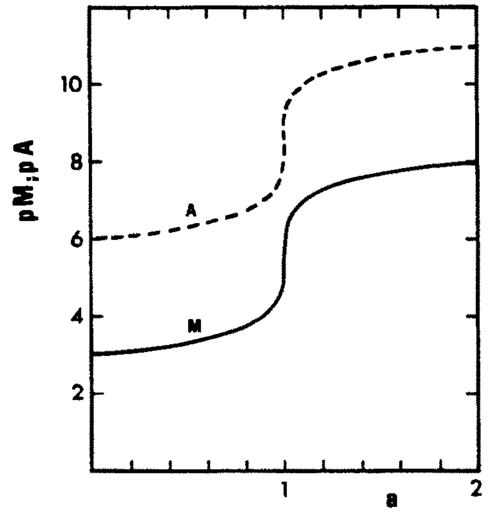

Fig. 4. Titration curve of pM and pA as a function of the degree of titration *a*. This curve is constructed from the logarithmic diagram in Fig. 3. $K_{MY} = K_{MA}$.

Of course, it is a rare coincidence when K_{AY} and K_{MY} happen to be equal in a titration. However, considering that we are dealing with conditional constants, it is clearly possible to adjust the conditions so as to make the values of the constants equal. As an example, let us take titration of zinc ion with EDTA using an Hg^{2+}/Hg electrode at pH = 4·5. The acetate complexes of the zinc and mercuric ions differ considerably in their stabilities and $K_{Zn'Y'}$ and $K_{Hg'Y'}$ can be adjusted to equal magnitudes by proper choice of the concentration of acetate ion. It is also possible to adjust the magnitude of $K_{Hg'Y'}$ by varying the concentration of chloride ion.

2. $K_{AY} < K_{MY}$

Figure 5 illustrates how such a titration is treated. At the start ($a = 0$), [MY] = [A],

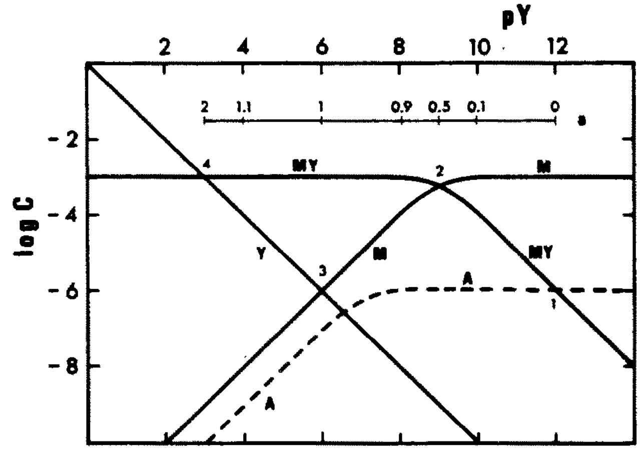

Fig. 5. Logarithmic diagram of log *C* as a function of pY. C_M is $10^{-3}M$ and C_A is $10^{-6}M$; log $K_{MY} = 9$ and log $K_{MA} = 7$.

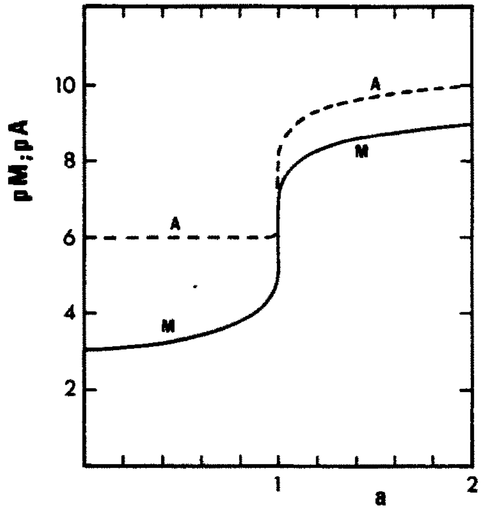

Fig. 6. Titration curve of pM and pA as a function of the degree of titration a. This curve is constructed from the logarithmic diagram in Fig. 5. K_{MY} is greater than K_{AY}.

i.e., pA = 6. When [M] = [MY], *i.e.*, $a = 0{\cdot}5$, (on a line parallel to the C-axis and through point no. 2), pA still equals 6. At the equivalence point, point no. 3, where [M] = [Y] (strictly [Y] = [M] + [A]), pA = 7. After the equivalence point, the lines representing A and M run parallel and pA and pM differ by a constant amount, in this case 1·0. Along an ordinate drawn through point no. 4 ($a = 2$), pA is found to be 10 and pM = 9.

Figure 6 is a titration curve in which pA is plotted as a function of a. The equivalence volume may be calculated in the same way as if pM were measured. However, only values recorded after the equivalence point has been passed can be used in the calculation of the equivalence volume.

3. $K_{AY} > K_{MY}$

Figure 7 is a graph of log C *vs.* pY. By the reasoning used above, we arrive at the following values, which can be read from the diagram.

a :	0 ,	0·1,	0·25,	0·5,	0·75,	0·9,	1·0,	1·5,	2·0
pA:	6·1,	7·5,	8·1,	8·5,	9·0,	9·5,	11·0,	13·2,	13·5

The curves in Fig. 8 plot pA and pM as a function of a. The courses of the pA and pM curves are parallel from a point slightly before the equivalence point. Only data after the equivalence point can be used to calculate the equivalence volume.

Ion-selective electrodes. Even though an electrode fully specific for the ionic species which is to be determined is not always available, it is often possible to use an ion-selective electrode to follow the course of a potentiometric titration. There are several types of both anion and cation electrodes available. As there are at present no good electrodes that respond to EDTA activity, we shall discuss only cation, *i.e.*, metal ion, electrodes.

The responses of all cation electrodes are influenced by other ionic species present in the solution titrated. The potential of the electrode is determined not only by the activity of the ion to be determined but also by the activities of the other ions present.

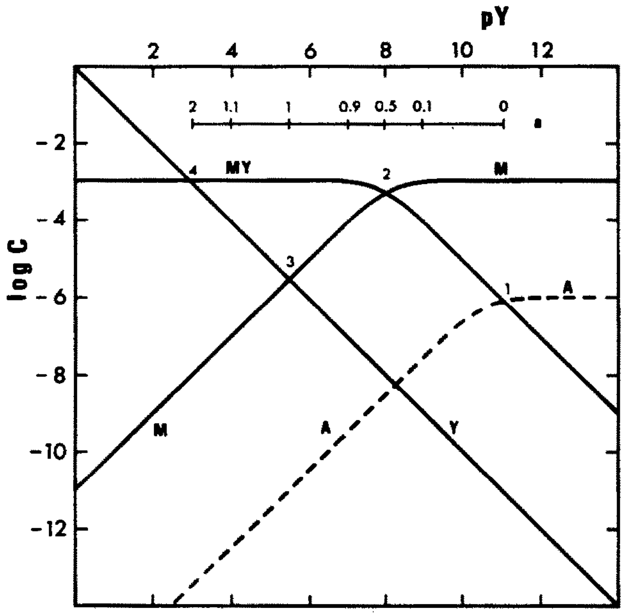

Fig. 7. Logarithmic diagram of log C as a function of pY. The figure is based upon the following values: log $K_{AY} = 10{\cdot}5$, log $K_{MY} = 8$, $C_M = 10^{-3}M$ and $C_A = 10^{-6}M$.

It is therefore customary to include an appropriate correction factor in the Nernst equation and according to Eisenman[14] write

$$E_C = E_C{}^0 + \frac{RT}{nF}\ln([M^{n+}] + \sum_i K_i[M_i{}^{z_i}]^{n/z_i})$$

where $[M_i]$, z_i and K_i are the concentrations, charges and selectivity coefficients of the interfering ionic species. If, for the sake of simplicity, we assume that $n = z_i$ and that the effects of the interfering species can be expressed by a single term, we may write

$$E_C = E_C{}^0 + \frac{Q}{n}\log([M^{n+}] + K_i[M_i{}^{n+}]) \tag{2}$$

where $Q = (RT \ln 10)/F$.

A value of the selectivity coefficient K_i less than unity means that the electrode is more sensitive to changes in the concentration of M than to changes in the concentrations of M_i, and, *vice versa* if $K_i > 1$. If K_i is large in value, the concentration of M_i must be low, in order that its influence will not be too great. During a titration the concentration of M decreases, whereas the concentration of the interfering ion remains constant. The interference of the latter ion may thus finally be so great that the electrode is no longer able to follow the changes in the concentration of M. The result is the same as if the concentration of M were larger than it actually is. It is possible to deduce readily from a logarithmic diagram how great the influence of an interfering ion will be (Fig. 9).

If $K_i[M_i] = 10^{-3}$, the apparent concentration of M is 10% too high even at the beginning of the titration. If $K_i[M_i] = 10^{-5}$, [M] and $K_i[M_i]$ will be equal at the equivalence point and hence [M] will be apparently twice the true value. Values of [M] at values of $a = C_Y/C_M$

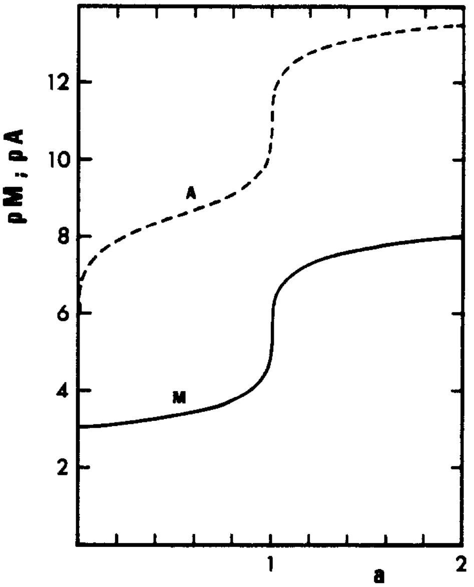

Fig. 8. Titration curve of pM and pA as functions of the degree of titration *a*. This curve is constructed from the logarithmic diagram in Fig. 7. K_{AY} is greater than K_{MY}

greater than 0·9 should not be included when calculating the equivalence volume. The interference will then be at most 1%.

The forms of titration curves in different cases can be easily deduced from logarithmic diagrams. Values of pM read from Fig. 9 are plotted in Fig. 10 against $a = C_Y/C_M$ for the case where $K_i[M_i]$ is equal to 10^{-5}.

CALCULATION OF EQUIVALENCE VOLUMES

The reverse problem, calculation of the equivalence volume from a number of corresponding volume–pM (or e.m.f.) values or from a titration curve can be solved in an analogous manner to that employed by Johansson[14] for acid–base titrations.

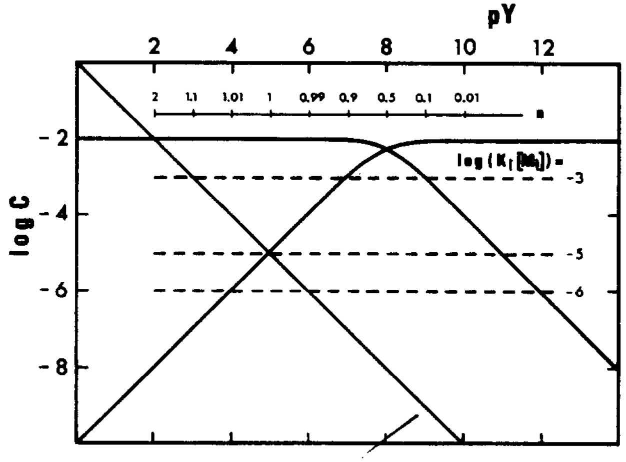

Fig. 9. Logarithmic diagram for the titration of a metal ion M with a complexing agent Y in the presence of an interfering metal ion M_i when $K_i \cdot (M_i)$ has the values 10^{-3}, 10^{-5} and 10^{-6}. $K_{MY} = 10^8$ and $C_M = 0{\cdot}01M$.

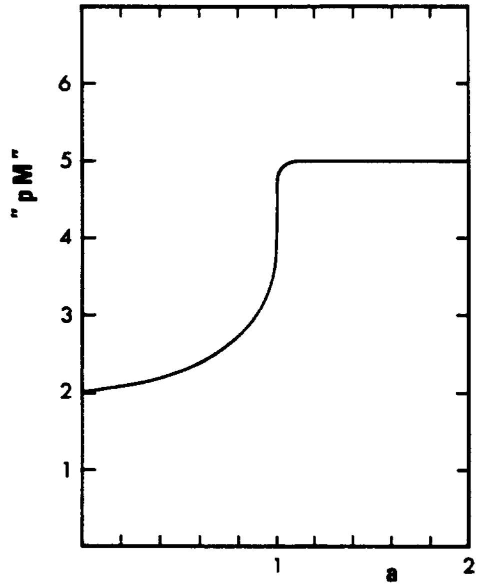

Fig. 10. Titration of a $10^{-2}M$ metal ion (M) in solution containing an interfering metal ion M_i with a complexing agent Y when K_{MY} is 10^8 and $K_i \cdot (M_i)$ is 10^{-5}.

V_0 ml of a $C_M{}^0$ molar metal ion solution are titrated with V ml of a $C_Y{}^0$ molar solution of a complexing agent Y. Only a 1 : 1 complex with stability constant K_{MY} is assumed to be formed by the metal ion and the complexing agent.

The following equations are valid.

$$M + Y \rightleftharpoons MY \tag{3}$$

$$C_M = [MY] + [M] \tag{4}$$

$$C_Y = [MY] + [Y] \tag{5}$$

$$K_{MY} = [MY]/([M][Y]) \tag{6}$$

$$C_M = V_0 \cdot C_M{}^0/(V_0 + V) \tag{7}$$

$$C_Y = V \cdot C_Y{}^0/(V_0 + V) \tag{8}$$

$$V_e \cdot C_Y{}^0 = V_0 \cdot C_M{}^0 \tag{9}$$

V_e denotes the equivalence volume, the volume of titrant added up to the equivalence point. C_M and C_Y are the total concentrations of the metal ion and the complexing agent when V ml of the titrant have been added. By combining equation (8) with equations (4), (5), (7) and (9), we obtain

$$V \cdot C_Y{}^0 = V_e \cdot C_Y{}^0 - (V_0 + V)([M] - [Y]) \tag{10}$$

[Y] is negligible in comparison with [M] before the equivalence point. Equation (10) then assumes the form

$$V_e - V = \frac{(V_0 + V)}{C_Y{}^0} \cdot [M] \tag{11}$$

Thus if $f_1(V) = (V_0 + V)[\mathrm{M}]$ is plotted against V ml, a straight line is obtained, which intersects the V-axis at $V = V_e$.

After the equivalence point, [Y] dominates in equation (10). By combination of equations (4) and (6) with (7), we get

$$[\mathrm{Y}] = \frac{1}{K_{\mathrm{MY}}[\mathrm{M}]}\left(\frac{V_0 \cdot C_{\mathrm{M}}{}^0}{(V_0 + V)} - [\mathrm{M}]\right) \tag{12}$$

[M] in the parentheses in equation (12) is negligible. By substituting equation (12) for [Y] in equation (10), we obtain

$$V - V_e = \frac{V_0 \cdot C_{\mathrm{M}}{}^0}{K_{\mathrm{MY}} \cdot C_{\mathrm{Y}}{}^0 \cdot [\mathrm{M}]} \tag{13}$$

A straight line will result when $f_2(\mathrm{V}) = 1/[\mathrm{M}]$ is plotted as a function of V. The point of intersection of the straight line with the V-axis is the equivalence volume V_e and the slope is $V_0 \cdot C_{\mathrm{M}}{}^0/K_{\mathrm{MY}}C_{\mathrm{Y}}{}^0$. (Note that $1/[\mathrm{M}]$ is not multiplied by $(V_0 + V)$ as is the conventional Gran procedure.) Equations (11) and (13) are consequently suitable for determining equivalence volumes either graphically or with a computer. The data obtained before and after the equivalence point should be kept apart. It is, however, possible to combine equations (10) and (12) to give

$$V \cdot C_{\mathrm{Y}}{}^0 = V_0 C_{\mathrm{M}}{}^0 - (V_0 + V)[\mathrm{M}] + \frac{V_0 - C_{\mathrm{M}}{}^0}{K_{\mathrm{MY}}[\mathrm{M}]} - \frac{(V_0 + V)}{K_{\mathrm{MY}}} \tag{14}$$

which, in turn yields

$$V_e - V = \frac{(V_0 + V)[\mathrm{M}]}{C_{\mathrm{Y}}{}^0} - \frac{V}{1 + K_{\mathrm{MY}}[\mathrm{M}]} \tag{15}$$

Equation (15) makes it possible to use all the titration data simultaneously. However, knowledge of an approximate value of the stability constant K_{MY} is required.

In equations (11) and (13) it is necessary that values of [M] be known. These can be calculated in the usual way by using the Nernst equation.

$$E_C = E_C^0 + \frac{\mathrm{RT}}{nF} \cdot \ln[\mathrm{M}] \tag{16}$$

where $E_C{}^0 = E_{\mathrm{M}}{}^0 + E_{\mathrm{ref}} + \frac{\mathrm{RT}}{nF} \ln \gamma_{\mathrm{M}} +$ junction potentials. $E_{\mathrm{M}}{}^0$ is the normal potential, E_{ref} the potential of the reference electrode and γ_{M} the activity coefficient of the ion M^{n+}.

$E_C{}^0$ is hence a conditional quantity that remains constant only as long as the junction potentials and the activity coefficient remain constant. Therefore it is important that the ionic strength should be constant during the titration.

According to equation (16)

$$[\mathrm{M}] = 10^{(E_C - E_C{}^0)n/Q} \tag{17}$$

where $Q = (RT \ln 10)/F$.

We consequently arrive at the conclusion that when calculating the equivalence volume it is suitable to plot before the equivalence point

$$f_1(V) = (V_0 + V)[\mathrm{M}] = (V_0 + V) \cdot 10^{(E_\mathrm{C} - E_\mathrm{C}^0)n/Q} \tag{18}$$

as a function of V, and after the equivalence point

$$f_2(V) = 1/[\mathrm{M}] = 10^{(E_\mathrm{C}^0 - E_\mathrm{C})n/Q} \tag{19}$$

as a function of V, both plots giving straight lines that intersect the V-axis at the equivalence point.

When an indicator ion, A, is used, [M] in these equations can be replaced by [A], on the condition that [A] = const.[M]. Equations (18) and (19) then remain unchanged.

Ordinarily it is only possible to use data obtained after the equivalence point.

Even when ion-selective electrodes are used in potentiometric titrations, it sometimes happens that only part of the titration curve can be used for purposes of evaluation, (usually the first part). In all these cases, logarithmic diagrams provide the answer to the question as to which part of the titration curve should be used.

Example

As an illustration to the usefulness of the method, an example will be treated in detail.

A solution prepared by mixing 5 ml of 0·05*M* copper sulphate, 50 ml of 0·1*M* sodium acetate–acetic acid buffer of pH 4·6 and 45 ml of water, was titrated with 0·05*M* EDTA. Mercuric ion, added in the form of its complex with EDTA, (HgY), was used as indicator ion. This solution can be prepared by dissolving mercuric oxide in 0·01*M* EDTA. HgY should be added to give a relatively high concentration, *e.g.*, 1% of the concentration of the copper ion. In this way, the signal will be more stable and less sensitive to external interference. In the case in question, 0·25 ml of 0·01*M* HgY was added. As indicator electrode, an amalgamated silver rod was used, and the reference electrode was an Orion model 90-02 double-junction reference electrode.

The following stability constant values are valid for the reactions that determine the shape of the titration curve:

$[\mathrm{HY}] = 10^{10\cdot3}[\mathrm{H}][\mathrm{Y}]$

$[\mathrm{H_2Y}] = 10^{16\cdot6}[\mathrm{H}]^2[\mathrm{Y}]$

$[\mathrm{CuY}] = 10^{18\cdot8}[\mathrm{Cu}][\mathrm{Y}]$

$[\mathrm{CuHY}] = 10^{3\cdot0}[\mathrm{H}][\mathrm{CuY}]$

$[\mathrm{Cu(OH)Y}] = 10^{2\cdot5}[\mathrm{OH}][\mathrm{CuY}]$

$[\mathrm{CuAc}] = 10^{1\cdot7}[\mathrm{Cu}][\mathrm{Ac}]$

$[\mathrm{CuAc_2}] = 10^{2\cdot7}[\mathrm{Cu}][\mathrm{Ac}]^2$

$[\mathrm{CuAc_3}] = 10^{3\cdot1}[\mathrm{Cu}][\mathrm{Ac}]^3$

$[\mathrm{CuAc_4}] = 10^{2\cdot9}[\mathrm{Cu}][\mathrm{Ac}]^4$

$[\mathrm{CuOH}] = 10^{6\cdot0}[\mathrm{Cu}][\mathrm{OH}]$

$[\mathrm{H_3Y}] = 10^{19\cdot3}[\mathrm{H}]^3[\mathrm{Y}]$

$[\mathrm{H_4Y}] = 10^{21\cdot4}[\mathrm{H}]^4[\mathrm{Y}]$

$[\mathrm{HgY}] = 10^{21\cdot8}[\mathrm{Hg}][\mathrm{Y}]$

$[\mathrm{HgHY}] = 10^{3\cdot1}[\mathrm{H}][\mathrm{HgY}]$

$[\mathrm{Hg(OH)Y}] = 10^{4\cdot9}[\mathrm{OH}][\mathrm{HgY}]$

$[\mathrm{HgAc}] = 10^{7\cdot2}[\mathrm{Hg}][\mathrm{Ac}]$

$[\mathrm{HgAc_2}] = 10^{8\cdot4}[\mathrm{Hg}][\mathrm{Ac}]^2$

$[\mathrm{HgOH}] = 10^{10\cdot3}[\mathrm{Hg}][\mathrm{OH}]$

$[\mathrm{Hg(OH)_2}] = 10^{21\cdot7}[\mathrm{Hg}][\mathrm{OH}]^2$

Using Ringbom's procedure, the following conditional constants are calculated.

$$\log K_{\mathrm{Cu'Y'}} = 11{\cdot}0 \quad \text{and} \quad \log K_{\mathrm{Hg'Y'}} = 8{\cdot}7$$

Figure 11 shows a plot of E_{Hg} as a function of the volume of added titrant as recorded with a Metrohm Potentiograph Model E 336 A. As can be seen from the figure, the potential jump is asymmetrical. Therefore, it is difficult to determine the location of the equivalence point in the usual way by differentiation of the curve. It is, however, easy to determine the equivalence volume by plotting 1/[Hg] as a function of the added volume of titrant.

The following data were obtained in a similar titration where the e.m.f. values were measured with an Orion Model 801 digital voltmeter. The temperature was 22°. Values of 1/[Hg] were calculated from equation (19) in the form

$$1/[\mathrm{Hg}] = 10^{(E^0 - E)/29\cdot28} \tag{20}$$

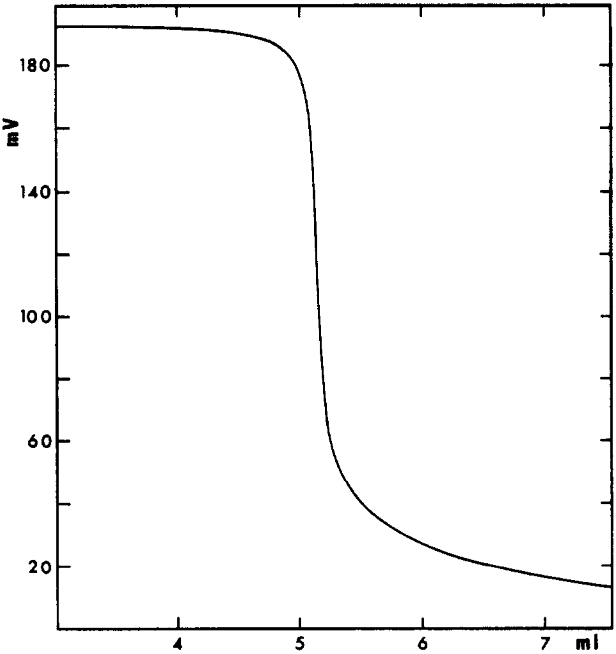

Fig. 11. Experimental curve of E (mV) *vs.* V (ml) from a titration of 100 ml of 0·0025*M* copper sulphate with 0·05*M* EDTA. 0·25 ml of 0·01*M* HgY is added (pH = 4·6). An arbitrary zero-point is chosen for the mV-scale.

E^0, which includes the normal potential, the potential of the reference electrode, the activity factors and junction potentials, may be unknown, in which case an arbitrary value may be inserted in its place. When this is done, the calculation does not yield 1/[Hg], but a constant divided by [Hg]. In the example given, E^0 was taken to be 200 mV.

V, ml	*E, mV*	(200 − *E*)/29·28	constant/[Hg]
5·0	295·0		0
5·5	159·7	1·376	2·38
6·0	148·8	1·748	5·60
6·5	142·9	1·950	8·91
7·0	138·9	2·087	12·22
7·5	135·9	2·189	15·45
8·0	133·5	2·271	18·66
8·5	131.5	2·339	21·83
9·0	129·8	2·398	25·01

A plot of constant/[Hg] against V gives a straight line which intersects the V-axis to give the equivalence volume V_e = 5·11 ml; the theoretical value is V_e = 5·12 ml.

The shape of the titration curve agrees well with that of a curve constructed from a logarithmic diagram (Fig. 12). At the start of the titration, pHg is constant and equals 4·6. This means that pHg = 10·3 since log α_{Hg} = 5·7.

Just before the equivalence point, pHg′ begins to increase and at the equivalence point, pHg′ = 6·8 (or pHg = 12·5). After the equivalence point (point 1, where [Y′] = [Hg′] + [Cu′]), the lines plotting pHg′ and pCu′ run parallel.

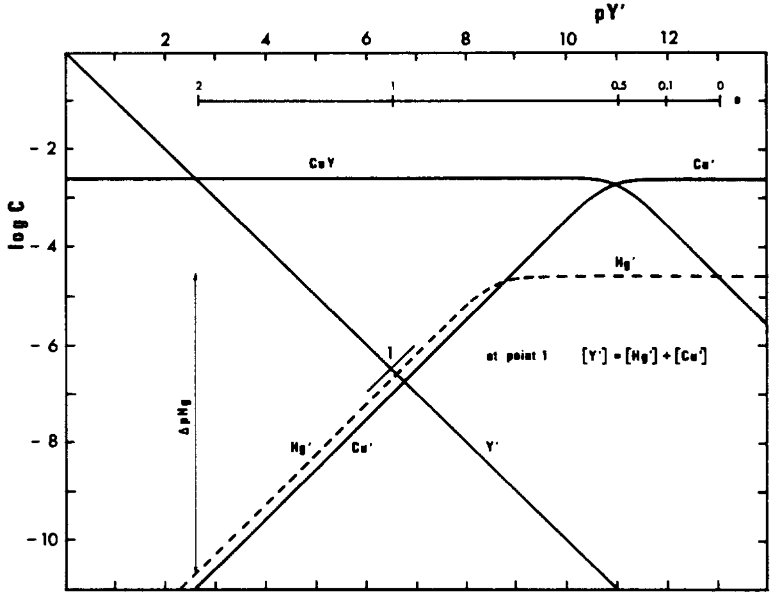

Fig. 12. Logarithmic diagram for the titration of copper ion with EDTA in the presence of mercuric ion (the indicator ion). $K_{\mathrm{Cu'Y'}} = 10^{11 \cdot 0}$; $K_{\mathrm{Hg'Y'}} = 10^{8 \cdot 7}$; $C_{\mathrm{Cu}} = 10^{-2 \cdot 6} M$; $C_{\mathrm{Hg}} = 10^{-4 \cdot 6} M$.

The pHg' of the solution increases by 2·2 units from the start of the titration to the equivalence point. This is equivalent to 64 mV. The potential jump during the titration until twice the equivalence volume of titrant has been added is 6·2 × 29·3 mV = 181·7 mV (at $a = 2$, pHg' = 10·8 and consequently ΔpHg = 10·8 − 4·6 = 6·2). The experimentally found value was 183 mV.

A calculation of a similar titration curve with the aid of a computer and the Haltafall program (by Sillén *et al.*[16]) is described by Dyrssen *et al.*[17]

(*Received* 1 *May* 1972. *Accepted* 1 *August* 1972)

Summary—The preparation of palladium complexes of phosphorodithioate (Guthion, Ethyl Guthion, Imidan, and Cidial) and phosphorothioate (Fenthion) insecticides is described. The Pd : pesticide ratios in the derivatives are *ca.* 1 : 1 for the phosphorodithioates and 2 : 1 in the case of Fenthion. The infrared spectra of the derivatives are compared with those of the parent insecticides. Palladium complexation of phosphorodithioates results in a lowering of the P—S frequencies by 60–75 cm^{-1} and also produces changes in the P-O-C region. Milligram quantities of Thimet, Trithion, and Cidial on thin-layer chromatograms were reacted *in situ* with sodium tetrachloropalladate(II). The infrared spectra of the compounds recovered from the plate depended greatly on the Pd : pesticide ratio on the spot, and the analytical significance of these results is discussed.

Palladium(II) chloride has been widely employed as a qualitative detection reagent for organophosphorus insecticides on thin-layer chromatograms since its initial use by Baumler and Rippstein[1] in 1961. The reagent is somewhat selective in that it does not react with organophosphates which contain no sulphur.[2] Blinn[3,4] has studied the separation of Thimet and its metabolites by thin-layer chromatography (TLC) and has described the use of palladium(II) chloride as a detection reagent before removal of the compounds from the plate and identification by infrared spectroscopy. Recently it was shown that the sensitivity of palladium detection methods can be markedly increased by combining palladium(II) chloride with a fluorescent metallochromic indicator such as Calcein or Calcein Blue; the resulting sprays have been used for quantitative *in situ* fluorimetry of nanogram quantities of phosphorodithioate insecticides.[5]

Despite the widespread use of palladium-containing spray reagents, no studies have been made of the interaction between palladium and the insecticides nor have the complexes been prepared other than as spots on TLC plates. Since the effect of palladium complexation on the infrared spectra of these pesticides is of analytical importance, this work was carried out in order to compare the spectra of the derivatives with those of the parent compounds.

EXPERIMENTAL

Reagents

Palladium. Sodium tetrachloropalladate(II) and 5% palladium(II) chloride solution in hydrochloric acid were used as sources of palladium.

Pesticides (≥95% *purity*). These were obtained from the manufacturers listed by Kenaga and Allison.[6]

All other chemicals were analytical reagent quality.

Apparatus

Infrared spectrometers. Perkin-Elmer models 237B and 521. Samples were run in chloroform or as KBr discs.

Thermogravimetry

A Fisher Differential Thermalyzer equipped with a Model 120 TGA Accessory and a Cahn Electrobalance was used.

Preparation and analysis of palladium derivatives of pesticides

Pesticides (0·5–2 g) were dissolved in the minimum volume of ethanol–water (3 : 1–5 : 1, v/v) and a sub-stoichiometric quantity of palladium as sodium tetrachloropalladate(II) or palladium(II) chloride was added as a solution in the same solvent. The derivatives of Guthion, Ethyl Guthion, Imidan and Cidial were formed immediately as fine yellow-orange precipitates which were washed with ethanol, air-dried overnight at room temperature, and finally vacuum-dried at 80° over phosphorus pentoxide. The Fenthion product was an oil which solidified after cooling for several hours in an ice–salt mixture. The solid was finely ground, washed with ethanol, and dried as above; m.p. 117–120°. All these derivatives were formed in good yield (85–103%). Attempts to prepare palladium derivatives of Thimet and Trithion resulted in oil formation and the complexes of these two pesticides were not studied further except as recovered from TLC plates. No suitable recrystallization solvent could be found for the derivatives, but samples of Pd-Guthion and Pd-Cidial were "recrystallized" by dissolving the solids in chloroform and reprecipitating by adding carbon tetrachloride or petroleum ether respectively. The palladium analyses of products so obtained were no different from those of the original solids. Pd–Guthion, Pd–Ethyl Guthion, and Pd–Imidan were soluble in chloroform and insoluble in water, alcohols, acetone, carbon tetrachloride and hydrocarbon solvents. Pd–Cidial and Pd–Fenthion were soluble in carbon tetrachloride, acetone, and toluene as well as in chloroform.

The palladium derivatives were checked for the presence of free pesticides by thin-layer chromatography. A chloroform solution of the complex was spotted along with suitable standards of the pesticide on a 0·25-mm silica gel N TLC plate. The plate was developed in 3 : 1 hexane–acetone; the complex remained at the origin while the free pesticide migrated ($R_f = 0{\cdot}3$–$0{\cdot}5$). The developed chromatogram was sprayed with palladium–Calcein reagent[5] and the quantity of free pesticide was determined by *in situ* fluorimetry.

Palladium was determined gravimetrically as the iodide[7] after wet oxidation of the organic matter with a nitric–sulphuric acid mixture.

Recovery of pesticides and palladium derivatives from TLC plates

Pesticides (1–3 mg) in chloroform were spotted onto acetone-washed TLC plates (0·5 mm, 1 : 1 silica gels N and G). Sodium tetrachloropalladate(II) in ethanol–water was spotted on top of the pesticides and the plates were allowed to stand overnight to ensure complete reaction.[3,5] The spots were scraped from the plate and the compounds were extracted and incorporated into 200-mg KBr discs by Blinn's procedure.[3]

RESULTS AND DISCUSSION

General observations

When solutions of the phosphorodithioate pesticides (Table 1) and sodium tetrachloropalladate(II), each having a pH of 3·5–5, are mixed the product precipitates and the pH of the supernatant liquid falls to ≥ 1·5, indicating the release of protons during the reaction. This pH change was not observed in the case of Fenthion, a phosphorothioate insecticide (Table 1). Qualitative tests for chloride after sodium decomposition of the complexes were positive for Pd–Fenthion but negative for the Pd–phosphorodithioate derivatives. The chloride contents of Pd–Guthion and Pd–Imidan as determined by X-ray fluorescence were 0·7 and 0·2% respectively. Less than 0·5% of free pesticide was found in the palladium derivatives of the phosphorodithioate insecticides by TLC; the Fenthion complex decomposed during chromatography.

Pd-Fenthion was the only complex to have a distinct melting point. The other solids turned brown and finally black without melting on heating in air to above *ca.* 140°. Samples of Pd–Guthion, Pd–Ethyl Guthion, and Pd–Imidan which have been air-dried at room temperature undergo small weight losses when heated in air (Fig. 1). These losses occur within 15 min of heating at 80–90°, after which the weight remains constant over at least a 12-hr period, and are ascribed to loss of solvent which was not removed

Table 1. Pesticides used in this study

Pesticide	Chemical name	Structure
Guthion	*O*,*O*-dimethyl-*S*-4-oxo-1,2,3-benzotriazin-3-(4*H*)-ylmethyl phosphorodithioate	Ethyl Guthion	*O*,*O*-diethyl-*S*-4-oxo-1,2,3-benzotriazin-3-(4*H*)-ylmethyl phosphorodithioate	Imidan	*O*,*O*-dimethyl-*S*-phthalimidomethyl phosphorodithioate	Cidial	ethyl mercaptophenylacetate *O*,*O*-dimethyl phosphorodithioate	Trithion	*S*-[(*p*-chlorophenylthio)methyl] *O*,*O*-diethyl phosphorodithioate	Thimet	*O*,*O*-diethyl-*S*-(ethylthio)methyl phosphorodithioate	 $(C_2H_5O)_2\overset{S}{\overset{\|}{P}}-S-CH_2-S-C_2H_5$
Fenthion	*O*,*O*-dimethyl-*O*-(4-methylthio)-*m*-tolyl) phosphorothioate	
by air-drying the derivatives at room temperature. However, the infrared spectra of these phosphorodithioate derivatives show broad bands in the 3300–3600 cm^{-1} region (Figs. 2, 3, and 5 respectively) even for samples which have been vacuum-dried at 80° for up to 18 hr, suggesting that these products also contain firmly bound solvent (or possibly hydroxyl groups) which is not easily removed.

The palladium content of the derivatives was reproducible and independent of the Pd : pesticide ratio in the reaction mixture as long as an excess of pesticide was used (Table 2). Mixtures containing excess of palladium produced dark brown precipitates with varying palladium contents. These products were not studied further. The palladium analyses indicate a Pd : pesticide stoichiometry of *ca.* 1 : 1 for the phosphorodithioate pesticides and 2 : 1 in the case of Fenthion. If this is generally true for phosphorothioates it would help explain why these pesticides are less sensitive to fluorigenic palladium–Calcein sprays.[5] The agreement of the other elemental analyses (Table 3) with the theoretical is only fair, however, and therefore little can be said at this time about the mechanism of the

pesticide interaction. Although the Fenthion derivative may be a simple adduct of palladium(II) chloride, this is certainly not true for the phosphorodithioate complexes since they contain only traces of chloride. Furthermore the release of protons during the reaction indicates an interaction more complex than adduct formation.

Neutral organophosphorus esters have been shown to react with metal chlorides and bromides in relatively anhydrous systems by a dealkylation mechanism.[8] The corresponding metal derivatives (possibly polymeric[9]) are halide-free and alkyl halides are released during the reaction. Such interactions have been recently reviewed[10] and are common for phosphates, phosphonates, and their thiophosphoryl analogues. Pistschimuka[11] synthesized several metal complexes of phosphorodithioate esters almost 60 years ago, but little work has since been done on these compounds. Further work will be required to determine whether a dealkylation mechanism is operative in the present system. If so, it does not necessarily occur *via* the release of alkyl halides since the reactions take place even if palladium(II) nitrate is used instead of palladium(II) chloride.

Infrared spectra

The spectra of the pesticides and their palladium derivatives are compared in Figs. 2–9. Pesticides containing carbonyl groups show strong C=O bands in the 1600–1800 cm^{-1} region. Measurements in chloroform (Cidial and Guthion) indicate approximately equal carbonyl intensities for the free pesticide and its palladium derivative.

Considerable controversy exists concerning the P=S vibration. Chittenden and Thomas[12] have collected data on many compounds and have assigned two bands which appear to be connected with this group. For compounds having the general structure (RO)(R′O)(R″S)P=S (R-groups alkyl) the band I and band II frequency limits are 790–833 cm^{-1} and 645–663 cm^{-1} respectively. For (RO)(R′O)(R″O)P=S the ranges are 800–844 cm^{-1} and 602–662 cm^{-1}. It is not known which frequency corresponds to the true P=S band. Some authors[13,14] assign band II to $\nu_{P=S}$, but Bellamy[15] has reviewed the subject and has cautiously suggested that the evidence favours band I as the P=S stretching frequency. The relative intensities of the bands are reported[12] to vary considerably with the substituent groups on the phosphorus. From published spectra of organophosphorus insecticides[16,17] band II is generally strong in phosphorodithioates and less intense in phosphorothioates.

Palladium complexation of phosphorodithioate pesticides produces significant changes in the P=S bands. Band I appears to be lowered in frequency by 60–75 cm^{-1} and reduced in intensity. The band I intensity of the phosphorodithioates studied is greater for the $(CH_3O)_2(RS)P{=}S$ pesticides than those having $(C_2H_5O)_2(RS)P{=}S$ structures (*cf.* Guthion and Ethyl Guthion, Figs. 2 and 3), and the changes in this frequency are therefore more noticeable for the former group of pesticides. The far-infrared spectra of Pd–Imidan (Fig. 7), Pd–Guthion, and Pd–Ethyl Guthion indicate that band II is also lowered in frequency by 60–75 cm^{-1} and is thus shifted out of the sodium chloride region covered by most infrared instruments. These shifts are larger than the reported[18] $\Delta\nu_{P=S} = 47\ cm^{-1}$ for the triphenylphosphine sulphide adduct of palladium(II) chloride. Palladium complexation also produces changes in the P–O–C region (995–1050 cm^{-1}) which must remain unexplained until more is known about the mechanism of derivative formation.

According to Blinn[3] the use of palladium(II) chloride as a detection reagent for Thimet on TLC plates does not interfere with the infrared spectrum of the recovered pesticide.

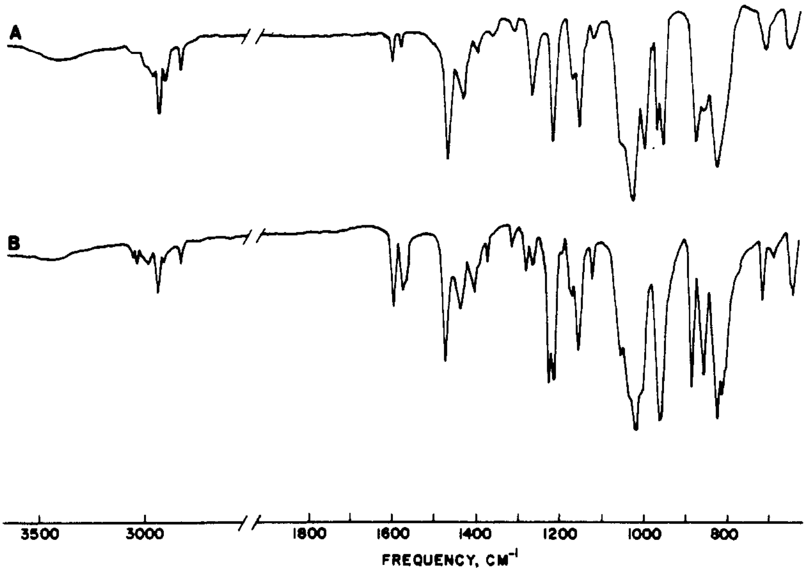

Fig. 6. Infrared spectra of Fenthion (*A*) and its palladium derivative (*B*), KBr discs.

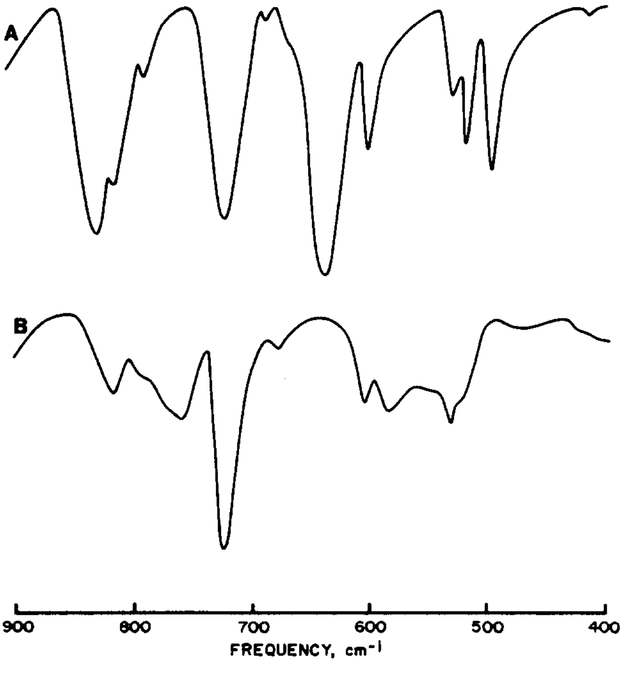

Fig. 7. Far-infrared spectra of (*A*) Imidan and (*B*) Pd–Imidan.

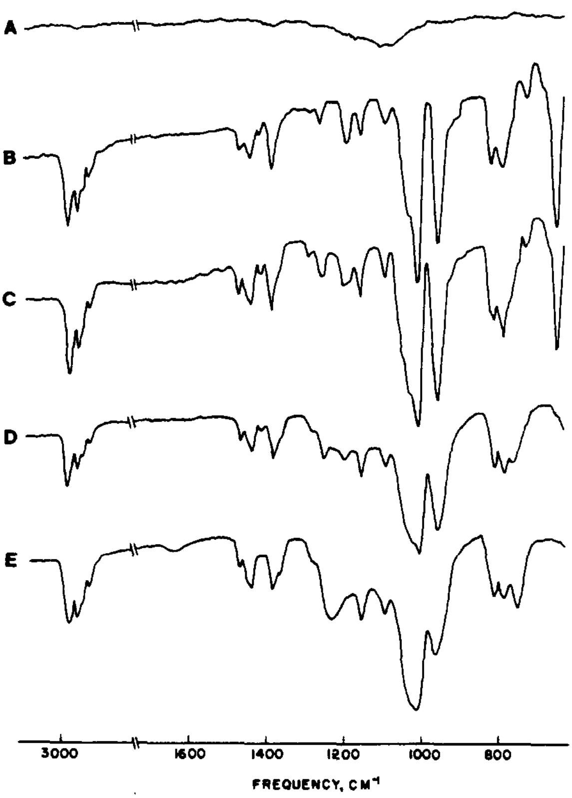

Fig. 8. Effect of varying quantities of palladium on the infrared spectra of Thimet spots recovered from TLC plates
(*A*) blank, extract of unspotted silica gel, (*B–E*) mole ratio of Pd : Thimet = 0·0, 0·5, 1·0, and 1·5 respectively.

In our work Thimet, Trithion, and Cidial spots on TLC plates were reacted with 0–1·5 times the equivalent molar quantity of sodium tetrachloropalladate(II). The infrared spectra of the compounds recovered from the Thimet and Trithion plates are shown in Figs. 8 and 9; similar results were obtained with Cidial. The spectra show differences which depend on the ratio of palladium to pesticide on the spot; in particular, the P=S peak at 625–660 cm^{-1} shows a decrease in intensity due to the palladium–pesticide reaction. This frequency is of analytical importance since it has been recommended that the oxidation of phosphorodithioate pesticides be followed by its disappearance.[16]

CONCLUSION

Although palladium(II) chloride is useful for locating organophosphorus pesticides on TLC plates before their identification by infrared spectroscopy, it should be realized that the spectra of the complexes differ from those of the parent compounds. Indiscriminate use of the reagent could lead to interpretative errors, particularly when microgram quantities of the pesticide are involved. Palladium derivatives of phosphorodithioate esters represent a new group of metal–organophosphorus complexes and a further study of the mechanism of this interaction in aqueous systems would be interesting.

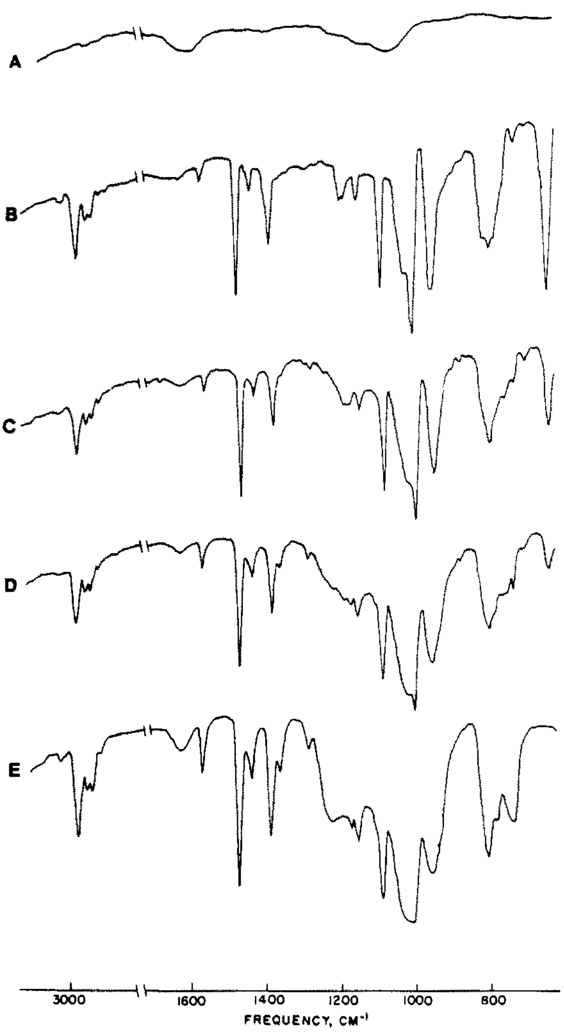

Fig. 9. Effect of varying quantities of palladium on the infrared spectra of Trithion spots recovered from TLC plates.

Zusammenfassung—Die Herstellung der Palladiumkomplexe von Insektiziden vom Dithiophosphorsäureestertyp (Gusathion, Gusathion A, Imidan und Cidial) und vom Thiophosphorsäureestertyp (Baytex) wird beschrieben. Die Verhältnisse Pd:Pestizid in den Derivaten sind etwa 1 : 1 für die Dithiophosphorsäureester und 2 : 1 bei Baytex. Die Infrarotspektren der Derivate werden mit denen des zugrunde liegenden Insektizids verglichen. Die Komplexbildung der Dithiophosphorsäureester mit Palladium bewirkt eine Erniedrigung der P-S-Frequenzen um 60–75 cm^{-1} und ruft auch Veränderungen im P-O-C-Bereich hervor. Milligrammengen Thimet, Trithion und Cidial wurden auf Dünnschichtchromatogrammen in situ mit Natriumtetrachloropalladat(II) umgesetzt. Die Infrarotspektren der von der Platte abgelosten Verbindungen hängen stark vom Verhältnis Pd : Pestizid im Fleck ab. Die analytische Bedeutung dieser Ergebnisse wird diskutiert.

Résumé—On décrit la préparation de complexes palladiés d'insecticides phosphorodithioates (Guthion, Ethyl Guthion, Imidan et Cidial) et phosphorothioate (Fenthion). Les rapports Pd : pesticide dans les dérivés sont d'environ 1 : 1 pout les phosphorodithioates et 2 : 1 dans le cas du Fenthion. On compare les spectres infra-rouges des dérivés à ceux de l'insecticide apparenté. La complexation au palladium des phosphorodithioates a pour résultat un abaissement des fréquences P=S de 60–75 cm^{-1} et produit aussi des changements dans la région P–O–C. On a fait réagir *in situ* des quantités de l'ordre du milligramme de Thimet, Trithion et Cidial sur chromatogrammes en couche mince avec le tétrachloropalladate de sodium (II). Les spectres infra-rouges des composés récupérés de la plaque dépendent grandement du rapport Pd : pesticide sur la tache, et l'on discute de la signification analytique de ces résultats.

Summary—A new method has been developed for the isolation of methylmercury from biological tissue. It is based on the volatilization of methylmercury cyanide formed in the reaction of methylmercury in the tissue with hydrocyanic acid released in the interaction of potassium hexacyanoferrate(II) with sulphuric acid at elevated temperature. The methylmercury cyanide released is captured on cysteine paper in a microdiffusion cell. The isolated methylmercury is set free with hydrochloric acid, extracted into benzene and determined by gas chromatography. A special closed micro-extractor is used for the final extraction into benzene for samples containing the lowest levels of methylmercury. The method can be used for a wide range of samples and concentrations (including background levels). The simplicity of the method makes it suitable for routine application.

The method at present used in most laboratories for the isolation of methylmercury was originally devised by Gage[1] and later modified and developed into a gas-chromatographic procedure by Westöo.[2,3,4] For most biological tissues the extraction has to be carried out in two stages; the original homogenized tissue is first acidified and extracted with a relatively large volume of the solvent, followed by stripping of methylmercury from the benzene phase into an aqueous solution of cysteine and re-extraction, after acidification, into a smaller volume of organic solvent. A few μl of this solution are then injected into the gas-chromatographic column for quantitative evaluation with an electron-capture detector. In the literature, an emission spectrometric detector using helium plasma has also been described.[5]

The early stages of this extraction and purification procedure require relatively large amounts of sample as well as large volumes of solvents, particularly if the expected concentration of methylmercury is in the ppM range (parts per milliard).

Sumino[6] substituted glutathione for cysteine in the purification stage and Newsome[7] hydrobromic acid for hydrochloric acid. Methylmercury bromide (as does the iodide or cyanide) shows the same gas-chromatographic behaviour as the chloride. These modifications did not solve the essential problems associated with this method.

Two main difficulties which may arise during the separation of methylmercury are the following: the formation of emulsions which are very persistent with certain types of samples, and volatility of methylmercury, which may result in losses during repeated equilibrations unless great care is taken in all stages involving extractions and transfers.

Obviously the organic extracts cannot be concentrated by evaporation of the solvent. Other less volatile organomercurials do not present difficulties in extraction separations as they can be concentrated by evaporation of the solvent.

In the present work the formation and volatility of methylmercury cyanide have been successfully exploited for its selective isolation from biological tissue. This approach is a continuation of our philosophy of utilizing the volatility of mercury and its compounds in its determination, *e.g.*, by selective trapping in a neutron-activation method.[8]

Preliminary work on the separation of methylmercury by use of the volatilization principle was based on the distribution of methylmercury chloride between the acidified tissue and toluene, kept separately in the two compartments of a diffusion cell.[9] Later it was modified by the much more selective and efficient isolations of methylmercury cyanide and its binding on paper impregnated with cysteine.

Sulphuric acid of appropriate concentration releases hydrocyanic acid from potassium hexacyanoferrate(II) at elevated temperatures according to the reaction

$$2K_4[\bar{Fe}(CN)_6] + 3H_2SO_4 = 6\ HCN + 3K_2SO_4 + K_2Fe[Fe(CN)_6]$$

Too high a concentration of sulphuric acid as well as higher temperatures favour the production of carbon monoxide and have to be avoided.

In the presence of biological tissue containing methylmercury, hydrocyanic acid reacts to give volatile methylmercury cyanide. Sulphuric acid provides not only the necessary hydrogen ions for setting free hydrocyanic acid but also reduces the amount of water vapour, thus preventing the decomposition of cysteine and helping further in the homogenization of the sample.

Depending upon the amount of methylmercury in the sample, the cysteine paper is extracted with hydrochloric acid either in a test-tube or in a specially designed micro-extractor described later.

EXPERIMENTAL

The various parameters, including the temperature, time of diffusion and optimum amounts of hexacyanoferrate, sulphuric acid and cysteine, were investigated systematically. Cysteine was applied on filter paper as a buffered solution.

Reagents

Potassium hexacyanoferrate(II), saturated solution.

Sulphuric acid, (1 + 1).

Hydrochloric acid, 12*M* and 5*M*.

Benzene, p.a.

Cysteine solution. For the analysis of muscle tissue this was prepared by dissolving 20 mg of cysteine hydrochloride in 1 ml of 5% sodium pyrophosphate solution. For other tissues, particularly liver, kidney and blood, a 3% pyrophosphate solution containing potassium citrate (40%) or sodium acetate trihydrate (10%) must be used.

Methylmercury dicyandiamide, stock solution.

Apparatus

Gas chromatograph, Pye Series 104.

Electron-capture detector, ^{63}Ni radioactive source.

Column, 1/4 in. × 5 ft.

Solid support. Diatomite "C," AW, 100–120 mesh.

Liquid phase. Phenyldiethanolamine succinate, (trade names PDEAS or HIEFF-10B) 4% or polyethyleneglycol succinate (PEGS), 5%.

Standard glass Conway dishes with thick plate-glass covers, or, for amounts of sample over 1 g, the diffusion cell shown in Fig. 1.

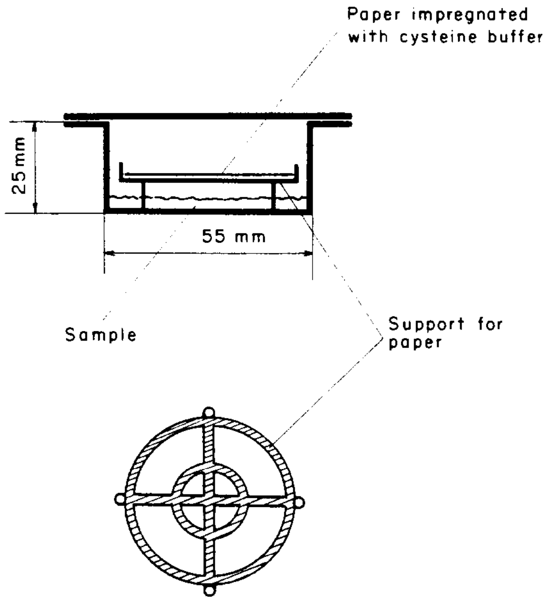

Fig. 1. Diffusion cell for the isolation of methylmercury from larger samples (> 1 g) of biological tissue.

Centrifuge tubes, 5-ml with ground-glass stoppers.
Micro-extractors (see below).
Filter paper, Schleicher and Schüll, No. 589[3].

Chromatography conditions

Column temperature 170°.
Injector temperature 200°.
Detector temperature 200°.
Carrier gas N_2, flow-rate 100 ml/min.
Voltage adjusted according to the amount of methylmercury measured.

Method

For methylmercury concentrations higher than 30 ng/g the procedure is as follows. Homogenized tissue in quantities up to 1 g is placed in the inner compartment of the Conway cell. A saturated solution of potassium hexacyanoferrate(II) is added (0·25 ml) and the contents mixed. A ring of filter paper to fit the outer compartment is placed in the cell, the paper ring having previously been impregnated with 0·1 ml of cysteine reagent and dried. Finally 0·5 ml of sulphuric acid is added to the tissue. After mixing of the reaction mixture, the cell is closed with a circular plate-glass cover.

The amount of sulphuric acid and potassium hexacyanoferrate(II) is increased for samples over 1 g and a special diffusion cell, as shown in Fig. 1, is substituted for the Conway cell.

The glass cover is fixed on the cell with a rubber sleeve. The reaction between cysteine and methylmercury is rapid, so there is no need to seal the cell hermetically. Care must be taken, however, that cells are kept in darkness and that the filter paper is processed immediately after it has been taken out of the cell.

The cell is placed in the thermostat at 75° for 14 hr. After this time the cell is cooled, and the filter paper ring is removed with tweezers, dropped into a 5-ml centrifuge tube and completely moistened with 0·25 ml of 5*M* hydrochloric acid. Following the addition of 1 ml of benzene, the tube is closed with a ground-glass stopper and shaken for 10 min. The filter paper is removed and the sample centrifuged. Aliquots of 5 μl of benzene phase are injected into the gas chromatographic column.

The overall performance of the isolation of methylmercury was tested by using different standard solutions. A stock solution was prepared from a 1·5% solution of a commercial preparation of "Panogen" (methylmercury dicyandiamide) by diluting it with water to give a concentration of 6 μg of methylmercury per ml. Aliquots of this solution (0·1 ml) were acidified with an equal volume of 5*M* hydrochloric acid and extracted with

10 ml of benzene. After centrifuging, the organic phase was removed and further diluted with the solvent to give a set of solutions for the calibration curve, covering the range between 0·1 and 2 ng for 5 μl of the solution injected into the gas chromatograph.

Micromethod

For the determination of methylmercury in organic material a further increase in sensitivity appeared to be possible by a modification of the extraction procedure.

Since a significant increase in the quantity of sample is not practicable, only a reduction in the amount of solvent could come into consideration. In the method above, the volume of solvent (1 ml) is two hundred times the amount actually needed for a determination. In practice it can be reduced by a factor of at least ten (to 0·1 ml). For this reason, a micro-extractor was designed. At the same time, a reduction of the surface of the cysteine paper was required. Evaporation of methylmercury chloride should be prevented during the extraction, and therefore the extraction should proceed essentially in a closed system.

The present version of a micro-extractor is shown in Fig. 2. Volatilization and binding of methylmercury is carried out in Conway cells as described above. Octagonal filter papers (Fig. 3) of somewhat smaller dimensions (3 mm width) are used and the volume of cysteine solution is reduced to 0·07 ml. After the end of the reaction, the filter paper is cut into 16 sections as indicated by the dotted lines in Fig. 3. The strips of paper are combined in a bundle and pushed into the wider end *B* of the capillary extractor. A minimum amount (0·075 ml) of concentrated hydrochloric acid is introduced with a pipette (Fig. 2) directly on to the paper, and the extractor is assembled. Through the opening at *A*, 0·15 ml of benzene is introduced in such a way as to form a column occupying the whole diameter of the capillary. Immediately after, a 1-ml syringe with glass piston is attached to the capillary (polyethylene tubing is recommended but rubber should not be used) and the solvent column is driven forwards and backwards through the paper bundle for 4 min. The paper should not be packed too tightly, in order to provide for thorough contact during the passage of the solvent. Finally the solvent is pushed through the vertical capillary section into the conical reservoir. Normally there is no need to dry the benzene phase; exceptionally, if this phase is turbid, a small plug of filter paper previously held in hydrochloric acid vapour is plugged into the upper part of the capillary just ahead of the outlet to the reservoir. During extraction the reservoir is closed with the ground-glass stopper. Aliquots of the collected solvent are then withdrawn into a microsyringe for gas-chromatographic determination of the extracted methylmercury; 5 μl of the solvent are normally used. It is important to clean the diffusion cell, in particular the outer

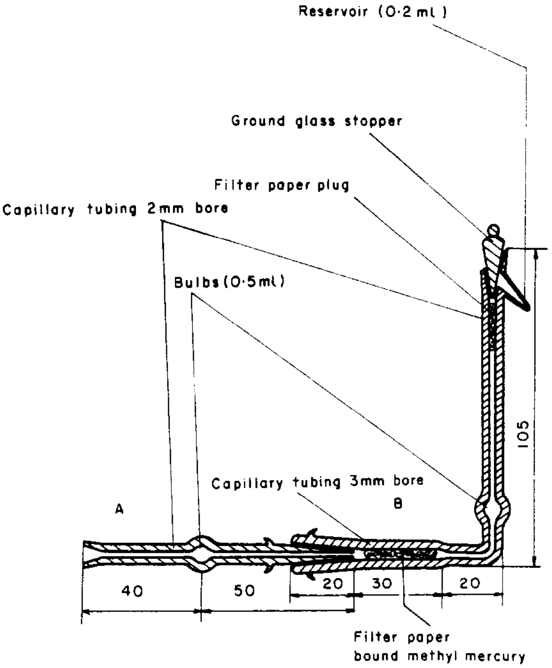

Fig. 2. Micro-extractor.

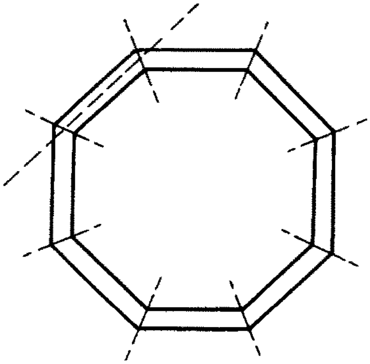

Fig. 3. Octagonal filter paper, impregnated with cysteine buffer, to fit the diffusion cell. Before the extraction paper is cut into sixteen strips along the dotted lines.

compartment, very thoroughly. The micro-extractor is rinsed after use with demineralized water, methanol and benzene. It is recommended that the diffusion procedure and the opening of the diffusion cells be carried out in a well-ventilated laboratory, owing to the presence of some hydrocyanic acid.

DISCUSSION

Preliminary experiments and investigation showed that yields of methylmercury in the procedures above could be influenced by the binding of methylmercury cyanide on the cysteine paper being incomplete because of (*a*) decomposition of cysteine, (*b*) the limit capacity of the cysteine buffer, and (*c*) unsuitable conditions during the diffusion.

(*a*) According to Warburg[10] and Sakuma,[11] cysteine is readily oxidized in the presence of traces of metals such as iron, manganese, copper *etc.* Warburg[12] found that the oxidation by iron and manganese is prevented by the addition of pyrophosphate. Therefore pyrophosphate is added as one of the components of all buffers used. The stability is further improved by carrying out the diffusion in darkness and by using a concentration of sulphuric acid large enough to keep the vapour pressure of water low. As a consequence the filter paper remains dry during the diffusion period.

(*b*) The capacity of the cysteine buffer could be exceeded, in particular when samples contain higher concentrations of halides. This becomes noticeable when two different aliquots of the same sample are taken for analysis; the results with the larger aliquots are lower. Therefore a combined buffer, as described under reagents, is used when analysing larger samples (up to 1 g) of liver, blood, brain *etc.* However, in the analysis of fresh-water fish muscle sodium pyrophosphate alone is sufficient even when samples as large as 2 g are taken. If the inner compartment is covered with an additional filter paper disc impregnated with lead acetate, volatile compounds, including thio-compounds, are removed without affecting the recovery of methylmercury; the lead salt also acts as a buffering component for hydrochloric or hydrobromic acids. The yield remains high and constant.

(*c*) At lower temperatures impractically long diffusion periods would be required; higher temperatures on the other hand enhance the oxidation of cysteine and possibly of hydrocyanic acid. Yields were highest at a temperature of 75°. It is also essential that the ground-glass joints of the micro-extractor fit perfectly in order to prevent the escape of volatile methylmercury during the extraction.

The recovery of methylmercury could be lowered as a result of incomplete extraction from the cysteine paper.

Experiments with labelled methylmercury (^{203}Hg) have shown that the extraction depends on the amount of available cysteine. When 10% cysteine solution was used (0·10 ml in the macro or 0·07 ml in the micro version) recoveries from a single extraction with benzene were between 50 and 70%. When the concentration of cysteine was varied between 1 and 3%, the same volume being used, the yield was constantly over 90% in both the micro and macro procedures.

Westöo[3] has shown that from the equilibria between methylmercury chloride (CH_3HgCl) and cysteine-bound methylmercury (CH_3HgSR) it follows that their ratio is higher at higher concentrations of hydrogen and chloride ions and low concentrations of cysteine (RSH):

$$\frac{[CH_3HgCl]}{[CH_3HgSR]} = \frac{[Cl^-][H^+]K}{[RSH]}$$

where K combines the equilibrium constants for the dissociation of methylmercury chloride, cysteine, and methylmercury–cysteine complex.

The overall reproducibility as a function of the amount of sample taken was determined by analysing fish muscle containing three different concentrations of methylmercury. The samples were prepared by homogenizing 50 g of fish muscle (a young trout) obtained from a fish-breeding station to avoid the high levels of methylmercury usually found in samples from natural environments. A larger number of aliquots was taken for checking the performance of the micro method than in the method normally used. The concentration of methylmercury in the original sample, 39 ng/g, was such as to enable comparative results to be obtained for the macro as well as the micro method. These results are shown in Fig. 4. To check the performance of the method at higher levels, "Panogen" stock solution was added to two aliquots of this sample in amounts to give 85 ng/g and 285 ng/g respectively. The yields were also satisfactory, with no dependence on sample weight.

Also analysed were samples of human blood, and organs collected from an autopsy. In the range investigated, recoveries do not depend on the quantity taken for analysis. It is clear, however, that when very small amounts of sample are used there is a wider

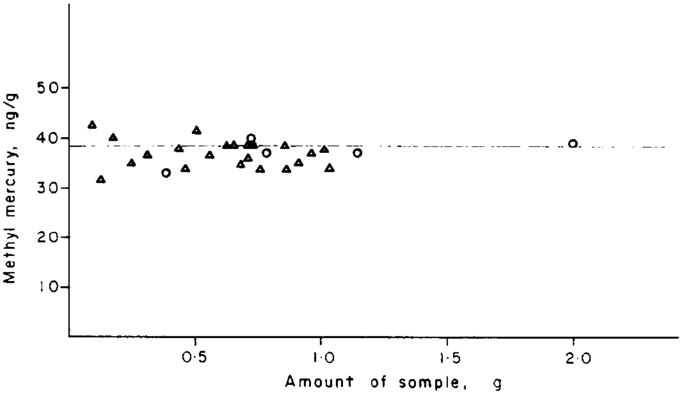

Fig. 4. Recovery of methylmercury from biological tissue as a function of the amount of sample. △ Micromethod, ○ Macromethod. Dotted line indicates the expected value based on precise determination of total Hg and on the assumption that it is all in the methyl form.

spread of results. The relative standard deviations were 5 and 7% respectively for the macro and micro method.

The other two types of sample (liver and blood) appear to contain volatile substances which reduce the recoveries if sodium pyrophosphate alone is used as the buffer for cysteine. This is probably due to the low buffering capacity. However, if the internal compartment containing the sample is covered with filter paper previously impregnated with a concentrated solution of lead acetate and dried, quantitative recoveries are obtained with pyrophosphate as well as with all other buffers tested. The amounts of sample used in these experiments were from 530 to 866 mg and were again without influence on the recovery of methylmercury.

Concentrations of inorganic mercury in amounts up to 20 ppm have no effect on the results obtained for methylmercury in blood and in liver samples. In the presence of milligram quantities of mercury(II) chloride, however, methylmercury appears to form in liver and blood and results are accordingly much above the actual content of CH_3Hg^+. This was not the case when mercury(II) chloride or cyanide was added to fish muscle.

RESULTS

The method has been successfully applied to a wide variety of plant, autopsy and animal samples with concentrations of methylmercury varying between 1 ng/g and a few μg/g.

As an illustration, results are presented in Table 1, giving methylmercury to total mercury ratios (calculated as Hg), in muscle and liver respectively, for three groups of trout caught at different sampling points along the river Idrijca which is contaminated with depleted mercury-ore sediments. Results indicate that although the total mercury

	15	275	4	0·26	0·30	0·86	0·28	3·41	0·08
	16	165	3	0·45	0·51	0·88	1·07	6·18	0·17
	17	95	2	0·33	0·35	0·93	—	2·36	—

Sampling point A: (Marof) at source of inorganic mercury contamination.
Sampling point B: (Stopnik) 20 km downstream from the source.
Sampling point C: (Most na Soči) 35 km downstream from the source.

content decreases with distance downstream its proportion in the methyl form increases. The equilibria possibly involved in interpreting these results are not yet fully understood; nevertheless, they clearly show the methylation of inorganic mercury in this aquatic system as well as its longer biological half-life in fish.

Table 2 shows the concentrations of methylmercury in a selection of samples, including the hair of persons from varying occupations.

Table 2. Methylmercury and total mercury concentrations in human hair and some aquatic organisms

Sample	CH_3Hg^+ (*ng/g*)	Hg total (*μg/g*)
Hair (1) (chemical technician)	175	0·504
Hair (2) (dentist)	210	2·11
Hair (3) (male)	61	0·159
Hair (4) (female)	140	0·357
Hair (5) (female)	120	0·177
Beard	80	0·514
Algae (dry weight)	44	25·0
Trichoptera	27	10·8
Ephemeroptera	107	13·7

The chromatograms obtained by following this method are in general very clear and do not present any problems in the evaluation of results. An exception is hair, where numerous other peaks are occasionally observed. Overlapping can occur when some other liquid phases are used, but using phenyldiethanolamine succinate in the column results in very good resolution and provides for satisfactory evaluation of the methylmercury peaks. Up to twenty determinations were made by one technician daily during this investigation with one column and the simple inexpensive apparatus described above. It is clear that the scale of operation could easily be expanded to allow large number of serial analyses on a routine basis.

Zusammenfassung—Ein neues Verfahren zur Isolierung von Methylquecksilber aus biologischem Gewebe wurde ausgearbeitet. Es beruht auf der Verflüchtigung von Methylquecksilbercyanid, das sich im Gewebe aus Methylquecksilber und Blausäure bildet, die ihrerseits durch die Reaktion von Kaliumhexacyanoferrat(II) mit Schwefelsäure bei erhöhter Temperatur freigesetzt wird. Das ausgetriebene Methylquecksilbercyanid wird in einer Mikrodiffusionszelle auf Cysteinpapier aufgefangen. Das isolierte Methylquecksilber wird mit Salzsäure freigesetzt, in Benzol extrahiert und gaschromatographisch bestimmt. Bei Proben, die geringsten Mengen an Methylquecksilber enthalten, wird für die abschließende Extraktion in Benzol ein besonderer geschlossener Mikro-Extraktor verwendet. Das Verfahren kann für viele verschiedenartige Proben und für weite Konzentrationsbereiche (einschließlich des Untergrundes) verwendet werden. Die Einfachheit der Methode macht sie für die routinemäßige Anwendung geeignet.

Résumé—On a élaboré une nouvelle méthode pour l'isolement du méthylmercure de tissus biologiques. Elle est basée sur la volatilisation du cyanure de méthylmercure formé dans la réaction du méthylmercure dans le tissu avec l'acide cyanhydrique dégagé dans l'interaction de l'hexacyanoferrate(II) de potassium avec l'acide sulfurique à température élevée. Le cyanure de méthylmercure dégagé est fixé sur un papier à la cystéine dans une cellule de microdiffusion. Le méthylmercure isolé est libéré par l'acide chlorhydrique, extrait en benzène et dosé par chromatographie en phase gazeuse. On utilise un microextracteur clos spécial pour l'extraction finale en benzène pour les échantillons ayant les plus faibles teneurs en méthylmercure. On peut utiliser la méthode pour un large éventail d'échantillons et de concentrations (y compris les teneurs de base). La simplicité de la méthode la rend convenable pour l'application de routine.

IDENTIFICATION DE SUBMICROQUANTITES D'IONS IODURE

(*Reçu le* 17 *février* 1972. *Accepté le* 5 *juin* 1972)

La reaction iode-amidon, mise souvent à profit pour l'identification de faibles quantités d'iode, de l'ordre de 0,1 μg, n'est plus utilisable pour la recherche de traces.

Selon nos essais, l'ion iodure, oxydé par le chlore en IO_3^- fournit, par action d'iodure de potassium en milieu acide, un anion I_3^- révélé par le nitron avec lequel il forme un triiodure coloré.

$$I^- \xrightarrow[H_2O]{Cl_2} IO_3^- \xrightarrow[H^+]{I^-} I_3^- \xrightarrow{\text{Nitron}} NtI_3$$

En pratique, sur du papier pour chromatographie (Whatman 3 convient bien) on dépose à l'aide d'un tube capillaire en verre (fig. 1) 0,01 ml de solution étudiée par fractions de 0,002 ml et, à 2 cm du premier dépôt, on dépose de même de l'eau bidistillée. Le papier est alors placé dans les vapeurs de chlore, audessus d'eau saturée de chlore par exemple puis séché à l'air chaud. A l'emplacement des deux dépôts, on dépose à l'aide d'un capillaire 0,003 ml de solution préparée extemporanément à 20 pour cent d'iodure de potassium. Après séchage à température ordinaire et à l'abri de la lumière, on dépose 0,004 ml de solution 0,2*N* d'acide sulfurique. Il apparaît, si la réaction est positive, un anneau jaune à brun. Après 3 à 4 min, un anneau semblable apparaît dans le témoin, dû à l'oxydation à l'air du réactif.

Fig. 1.

La réaction permet à la limite de déceler 0,01 ng d'iode à l'état d'iodure soit une concentration de $1/64 \cdot 10^7$.

La présence des ions Cl^-, Br^-, SO_4^{2-}, PO_4^{3-} et CO_3^{2-} n'apporte pas de gêne. La réaction n'est pas applicable en présence d'oxydants tels les ions ferriques. Ceux-ci peuvent être éliminés au préalable par précipitation à l'état d'hydroxydes.

Résumé—Une stilliréaction, fondée sur la formation de triiodure de nitron (NtI_3) coloré en jaune brun permet de déceler 0,01 μg de I^- ($1/64.10^7$).

Summary—A spot-test, based on the formation of yellow-brown nitron tri-iodide permits detection of 0·01 ng of iodide (limit of dilution 1 in 64×10^7).

Zusammenfassung—Eine Tüpfelprobe, die auf der Bildung von gelbbraunem Nitron-Trijodid beruht, erlaubt den Nachweis von 0·01 ng Jodid (Verdünnungsgrenze 1 in $64 . 10^6$).

ATOMABSORPTIONSSPEKTRALPHOTOMETRISCHE BESTIMMUNG VON ZINK IN GALLIUMARSENID UND GALLIUMALUMINIUMARSENID

(*Eingegangen am* 3. *Mai* 1972, *Angenommen am* 6. *Juni* 1972)

ZUR KONTROLLE des Gehaltes von Zinkverunreinigungen und zur Ermittlung von Zinkdotierungskonzentrationen in $A^{III}B^{V}$-Materialien wurde von uns eine atomabsorptionsspektralphotometrische Bestimmungsmethode ausgearbeitet.

Die Atomabsorptionsspektralphotometrie ist—wie zahlreiche Veröffentlichungen zeigen[1,2]—auf Grund ihrer Selektivität und Empfindlichkeit für die Spurenbestimmung von Zink gut geeignet. Bei der Erarbeitung des Bestimmungsverfahrens wurde berücksichtigt, daß die zu untersuchenden Materialien ein Gewicht von nur einigen Milligramm haben. Diese Bedingung erfordert eine spezielle Arbeitsmethode, die kein Anreicherungsverfahren benötigt und trotzdem eine hohe Empfindlichkeit besitzt.[3]

EXPERIMENTELLER TEIL

Apparatives

Verwendet wurde ein Eigenbau-Atomabsorptionsspektralphotometer, welches aus folgenden Teilen bestand:
Spiegelmonochromator SPM 1 mit Quarzprisma (VEB C. Zeiss, Jena)
Sekundärelektronenvervielfacher M 12 FQS 52 A (VEB C. Zeiss, Jena)
Kompensationsbandschreiber G_1B_1 (VEB C. Zeiss, Jena)
Hochspannungsversorgungsgerät für SEV (PGH Statron, Fürstenwalde)
Vorkammerringspaltzerstäuber (Eigenbau)
gekühlter Schlitzbrenner (l = 120 mm) (Eigenbau)
Hohlkathodenlampe (Kathodenmaterial: Messing; Neondruck 4 mm Hg-Säule) (Eigenbau)

Als optimale Bedingungen ergaben sich für die Zinkbestimmung: Wellenlänge 213,8 nm, Lampenstrom 5 mA, Spaltbreite 100 um, Acetylen: 44 l./h, Luft: 3 at, 56 l./h, Zusatzluft: 170 l./h, Lösungsverbrauch: 2 ml/min.

Da nur geringe Probemengen vorhanden waren, wurden der Ringspaltzerstäuber und die Gaszusammensetzung unter dem Gesichtspunkt eines möglichst geringen Lösungsmittelverbrauchs optimiert. Der Strahlendurchgang durch die Flamme lag 6 mm oberhalb der Brenneroberfläche.

Reagenzien

Standard-Zinklösung: 1 g Zink(II)-sulfat *p.a.* pro Liter
Standard-Galliumlösung: 2,5 g Gallium (99,999%) pro 100 ml
Standard-Arsenlösung: 3,5 g Arsentrioxid *p.a.* pro 100 ml
Salzsäure pA
Salpetersäure pA

Bestimmungsvorschrift

Das zu untersuchende Galliumarsenid bzw. Galliumaluminiumarsenid (*ca.* 5–20 mg) wurde mit einem Gemisch aus konzentrierter Salz- und Salpetersäure (1 : 1) aufgelöst. Nach vorsichtigem Eindampfen des Säuregemisches wurde der Rückstand sofort in 1 ml 1*M* Salzsäure aufgenommen. Diese Lösung wurde direkt zerstäubt. Die gemessenen Extinktionen wurden mit Hilfe einer Eichkurve in Konzentrationen umgerechnet. Zur Erhöhung der Genauigkeit empfiehlt es sich, den arithmetischen Mittelwert von 3 Extinktionsmessungen für die Konzentrationsbestimmung zu verwenden.

ERGEBNISSE

Säureeinfluß

Die Eichkurve einer Zinksulfatlösung in 1*M* Salzsäure verlief etwas steiler als die der wäßrigen Lösung ohne Säuregehalt. Dieser Effekt findet seine Erklärung darin, daß durch die Anwesenheit der Salzsäure die Hydrolyse der Zinksalze in der Flamme zurückgedrängt wird und außerdem das in der Flamme entstehende Zinkchlorid leichter und vollständiger verdampft als Zinksulfat bzw. Zinkoxid. Die Änderung der Salzsäurekonzentration zwischen 0,5 und 1,5*M* hatte keinen Einfluß.

Einfluß des Arsenat(V)-ions und des Aluminium(III)-ions

Arsenat(V)- und Aluminiumionen (Aluminiumkonzentration: 0,2 bis 2 mg/ml) beeinflussen die Zinkabsorption nicht.

Einfluß des Gallium(III)-ions

Galliumkonzentrationen zwischen 2,5 und 10 mg/ml rufen eine Blindabsorption in Abhängigkeit von der Galliumkonzentration von 0,01 bis 0,016 Extinktionseinheiten hervor und verursachen somit eine Parallelverschiebung der Eichkurve.

Die Lösungen, die in 1 ml 1*M* Salzsäure zwischen 5 und 20 mg unterschiedlich zusammengesetzter Matrixsubstanz enthielten, beeinflußten ebenfalls die Zinkabsorptionswerte. Es ergaben sich Parallelverschiebungen der Eichkurven in Abhängigkeit der in den Lösungen enthaltenen Galliumkonzentration. Die Größe der Verschiebung entsprach der Blindabsorption der zinkfreien Galliumlösung (s. Tabelle 1).

Tabelle 1. Abhängigkeit der Absorption bei 213,8 nm von der Matrixsubstanz

Zink Konzentration, *ppm*	Zusatz in 1*M* HCl, *ppm*	Extinktion
0	0	0
0	5000 GaAs	0,01
0	10000 GaAs	0,013
0	20000 GaAs	0,015
0,8	0	0,089
0,8	5000 GaAs	0,101
0,8	10000 GaAs	0,104
0,8	20000 GaAs	0,107

Aufstellung einer Eichkurve und Genauigkeit des Verfahrens

Zur Aufstellung einer Eichkurve wurden Lösungen hergestellt, die in 1 ml 10 mg Galliumaluminiumarsenid-bzw. Galliumarsenid und unterschiedliche Konzentrationen Zink enthielten. Es wurden jeweils 10 Lösungen eines Zinkkonzentrationswertes untersucht. Die Eichkurve wurde durch Ausgleichsrechnung ermittelt.

Die Nachweisgrenze für das Verfahren wurde zu 0,1 μg/ml nach folgenden Kriterien bestimmt: Blindabsorption plus 3 × Standardabweichung der Blindabsorption. Die Eichkurve ist bis zu einer Zinkkonzentration von 3 μg/ml linear und krümmt sich bei höheren Zinkkonzentrationen zur Abszisse. Die

Tabelle 2. Zinkbestimmung in Galliumarsenid und Galliumaluminiumarsenid

Matrix *mg/ml*	Zink gegeben, *ppm*	Extinktion arithmetisches Mittel aus 3 Messungen	Zink gefunden, *ppm*	Abweichung %
5 GaAs	0,2	0,035	0,18	−10
5 GaAs	0,6	0,086	0,59	− 1,8
5 GaAs	1,0	0,136	1,00	0
5 GaAs	3,0	0,377	2,95	− 0,7
10 GaAs	0,1	0,026	0,10	0
10 GaAs	0,4	0,064	0,42	+ 5
10 GaAs	0,8	0,113	0,80	0
10 GaAs	2,0	0,262	2,01	+ 0,5
20 GaAs	0,2	0,041	0,23	+15
20 GaAs	0,6	0,087	0,60	0
20 GaAs	1,0	0,141	1,03	+ 3
20 GaAs	3,0	0,384	3,03	+ 1
5 $Ga_{0,9}Al_{0,1}As$	0,2	0,036	0,19	− 5
5 $Ga_{0,9}Al_{0,1}As$	1,0	0,134	0,97	− 3
20 $Ga_{0,9}Al_{0,1}As$	0,4	0,066	0,43	+ 7,5
20 $Ga_{0,9}Al_{0,1}As$	2,0	0,263	2,02	+ 1,0

Gesamtstandardabweichung beträgt 5,4 × 10^{-3} Extinktionseinheiten. Das entspricht einem durchschnittlichen Variationskoeffizient von 4,5%. Der Variationskoeffizient an der Nachweisgrenze wurde zu 27% bestimmt.

Die Eichkurve ist verwendbar für die Bestimmung von Zink in Galliumarsenid und Galliumaluminiumarsenid. Die Matrixsubstanz darf in Konzentrationen zwischen 5 und 20 mg/ml in 1*M* Salzsäure vorliegen. Der Matrixeinfluß liegt dann innerhalb der gefundenen Standardabweichung. Die mit Hilfe der Eichkurve erzielten Ergebnisse sind in Tabelle 2 dargestellt.

DISKUSSION

Als Resultat aller durchgeführten Untersuchungen ergab sich, daß die extremen Überschüsse an Matrixelementen (Gewichtsverhältnisse zwischen 1 zu 5000 und 1 zu 200 000 für Zink zu Matrix) die Bestimmung nur unwesentlich beeinflussen.

Zur Klärung der Ursache des geringen Einflusses Gallium enthaltender Lösungen wurde überprüft, ob es sich um Verunreinigungen des benutzten Gallium durch Zink handelt. Zu diesem Zweck überprüften wir die Absorption bei Anwendung einer kontinuierlichen Lichtquelle (Deuteriumlampe). Das Ergebnis ist in Tabelle 3 dargestellt.

Tabelle 3. Absorption des Lichtes einer kontinuierlichen Lichtquelle durch die Flamme

GaAs, *mg/ml*	219 nm	246 nm	213,8 nm
25	0,012	0,013	0,015
20	0,013	0,012	0,013
15	0,010	—	0,007

Vergleicht man die Werte der Tabellen 1 und 3 miteinander, so stellt man fest, daß der größere Teil der Blindabsorption unspezifisch ist und somit durch Lichtstreuung und molekulare Absorption hervorgerufen wird. Die Ursache kann die Bildung von festen Galliumoxid-Teilchen in der Flamme sein, die wegen ihrer Größe und ihres hohen Siedepunktes (größer als 2000°) nicht vollständig verdampfen.

Zusammenfassung—Es wird eine atomabsorptionsspektralphotometrische Bestimmung von Zink in Galliumarsenid und Galliumaluminiumarsenid beschrieben. Die Methode ist anwendbar für Zinkmengen zwischen 0,1 und 3 μg in 5–20 mg Matrix Der Variationskoeffizient beträgt 4,5%. Der Einfluß der Matrixsubstanz auf die Absorption wird beschrieben und diskutiert.

Summary—The determination by atomic-absorption spectroscopy of zinc in gallium arsenide and gallium aluminium arsenide is described. In 5–20 mg of sample, 0·1–3 μg of zinc can be determined. The coefficient of variation is 4·5%. The influence of the matrix is described and discussed.

Résumé—On décrit le dosage par spectroscopie d'absorption atomique du zinc dans l'arséniure de gallium et l'arséniure de gallium et d'aluminium. On peut déterminer 0,1–3 μg de zinc dans 5–20 mg d'échantillon. Le coefficient de variation est de 4,5%. On décrit l'influence de la matrice et en discute.

SPECTROPHOTOMETRIC DETERMINATION OF OSMIUM WITH 2R-ACID IN THE PRESENCE OF OTHER PLATINUM METALS

(*Received* 30th *December* 1971. *Accepted* 1 *June* 1972)

Most chromogenic reagents for osmium are subject to interference from other platinum metals.[1-3] The present paper describes the application of 2-amino-8-naphthol-3,6-disulphonic acid (2R-acid; ANDS), which has already been used for the determination of iron[4] and vanadium[5], for the sensitive and reasonably selective spectrophotometric determination of osmium in the presence of platinum metals.

EXPERIMENTAL

Reagents

ANDS. A stock solution was prepared by dissolving the requisite amount in 1 litre of water.

Osmium tetroxide. One gram was dissolved in a small amount of dilute potassium hydroxide solution and diluted with water to give an alkali concentration of 0·04*M* and an osmium concentration of 0·004*M*. The solution was stored under refrigeration.

Other metal ions. Similar amounts of $RuCl_3$, $RhCl_3$, $IrCl_3$, H_2PtCl_6 and $PdCl_2$ were dissolved directly with water. The metal contents were determined by the usual methods.

Recommended procedure

The sample containing 2–8 μg of osmium is placed in a 25-ml volumetric flask and 10 ml of the stock solution of ANDS are added. The pH of the mixed solution is adjusted to 11·5 by adding a suitable amount of dilute alkali and diluted to the mark with alkali (also at pH 11·5). The solution is heated for 30 min on a water-bath at 90°, and cooled under running water, then the absorbance is measured at 530 nm at room temperature against a distilled water blank. The reagent does not absorb at this wavelength. The osmium content is then read from a standard calibration curve.

The order of addition of the reactants is not significant.

RESULTS AND DISCUSSION

Optimum conditions for reaction

Several samples containing the requisite amounts of osmium were treated by this procedure and the absorbance measured. The standard deviation of readings was 0·002, and the readings remained constant for at least 24 hr.

A green complex is formed between pH 2·5 and 8·0 and a red complex between pH 11·0 and 12·0, but since the green complex is stable for only 2 hr, the red complex was used.

Colour formation at room temperature is very slow; full intensity takes 24 hr to develop. The rate of colour formation increases when the solution is heated on a water-bath at 90°, heating for 30 min being sufficient for maximum colour development. The colour intensity then remains fairly constant even if the solution is kept at 90° for 2 hr.

The absorbance, for a given amount of osmium, attains a constant value when the molar ratio of reagent to metal is 20 : 1.

Optical constants and nature of complex

Beer's law is obeyed over the range 1·5–10 μg of osmium. The molar absorptivity is $1·11 \times 10^4$ $l·mole^{-1}·cm^{-1}$ and the sensitivity of the reaction is 0·2 $\mu g/cm^2$. The optimum range for accurate spectrophotometric determination is 2–8 ppm.

When the solution of the complex was passed through Amberlite IRA-400 ion-exchange resin, the complex was completely adsorbed, with the formation of a red band, thus establishing the anionic nature of the complex.

The absorption spectra of the system containing osmium and ANDS in different stoichiometric ratios show maximum absorbance at 530 nm. The intensity of the colour increases with time but λ_{max} remains unchanged. ANDS does not absorb at this wavelength.

Interferences

Ions which result in a deviation of less than 2% in the determination of 0·2 μg of osmium when present in concentrations of at most $2 \times 10^{-4}M$ are Al(III), Cr(III), Be(II), Cu(II), Li(I), As(III), Sb(III), Cr(VI), Ag(I), Te(IV), Se(IV), Zn(II), W(VI), Ni(II), Mg(II), Mo(VI), La(III), Sc(III), Y(III), Ga(III), In(III), Ru(III), Rh(III), Pd(II), Ir(III) and Pt(IV), and 10 mg of $RuCl_3$ can be tolerated.

Cations which interfere are Fe(III), Th(IV), Zr(IV), Co(II) and V(V). The common anions Cl^-, Br^-, I^- and $No_3{}^-$ do not interfere; oxalate and tartrate interfere.

Summary—Osmium(VIII) produces two coloured species with λ_{max} 680 nm (green) and 530 nm (red) with excess of 2-amino-8-naphthol-3,6-disulphonic acid in aqueous solution. The green complex is stable between pH 2·5 and 8·0 and the red complex between pH 11·0 and 12·0. The effects of temperature and time, reagent concentration, optimum conditions for the spectrophotometric determination of trace amounts of osmium, and other variables, have been studied at pH 11·5. At this pH, other platinum metals do not interfere. The sensitivity of the colour reaction is 0·2 $\mu g/cm^2$ and the system conforms to Beer's law over a concentration range of 1·5–10 μg of osmium.

Zusammenfassung—Osmium(VIII) bildet mit einem Überschuß von 2-Amino-8-naphthol-3,6-disulfonsäure in wäßriger Lösung zwei farbige Spezies mit λ_{max} 680 nm (grün) und 530 nm (rot). Der grüne Komplex ist zwischen pH 2·5 und 8·0, der rote zwischen pH 11·0 und 12·0 stabil. Der Einfluß von Temperatur, Zeit, Reagenskonzentration, optimalen Bedingungen zur spektrophotometrischen Bestimmung von Osmiumspuren und anderen Variablen wurde bei pH 11·5 untersucht. Bei diesem pH stören andere Platinmetalle nicht. Die Empfindlichkeit der Farbreaktion beträgt 0·2 $\mu g/cm^2$; das System gehorcht dem Beerschen Gesetz bei 1·5–10μg Osmium.

Résumé—L'osmium(VIII) produit deux espèces colorées de λ_{max} 680 nm (vert) et 530 nm (rouge) avec un excès d'acide 2-amino 8-naphtol 3,6-disulfonique en solution aqueuse. Le complexe vert est stable entre pH 2,5 et 8,0 et le complexe rouge entre pH 11,0 et 12,0. Les influences de la température et du temps, la concentration du réactif, les conditions optimales pour le dosage spectrophotométrique de traces d'osmium, et d'autres variables, ont été étudiées à pH 11,5. A ce pH, les autres métaux de la mine du platine n'interfèrent pas. La sensibilité de la réaction colorée est de 0,2 $\mu g/cm^2$ et le système suit la loi de Beer dans le domaine de concentrations, 1,5–10 μg d'osmium.

Talanta, Vol. 20, pp. 131 to 132. Pergamon Press, 1973. Printed in Great Britain.

RAPID CHELOMETRIC DETERMINATION OF LEAD IN LUBRICATING OILS *VIA* MERCAPTOACETATE EXTRACTION

(*Received* 7 *June* 1972. *Accepted* 16 *August* 1972)

In high-pressure lubricating oil, lead naphthenate is often added as an additive, and the lead content must be determined to ascertain the amount of additive present. Both the standard methods given by Institute of Petroleum[1] and ASTM[2] describe the gravimetric method where lead naphthenate is converted into lead sulphate by the "wet ash method" and weighed as such. The method recommended by ASTM has been further modified by dissolution of lead sulphate and electro-disposition of the lead.[3] The latter method has been recommended for the estimation of lead in lubricating greases. These methods are lengthy and tedious, requiring 10–12 hr and hence do not appear suitable for routine analysis.

Methods have been described in which the lead content of such oils is obtained in aqueous solution by acid hydrolysis, and then titrated with EDTA[4,5] with Eriochrome Black T as indicator. The lead has also been extracted by refluxing the oil with glacial acetic acid and benzene, whereby the lead naphthenate is converted into lead acetate, and then precipitated as lead chromate with potassium chromate, an iodometric finish being used.[6,7] These methods also require 1–1½ hour. Spectrographic methods are also in use for the determination of metallic constituents in oils.

A method has now been developed in which lead mercaptoacetate is extracted into aqueous medium by using thioglycollic acid and nitric acid and the lead is finally titrated with EDTA.

EXPERIMENTAL

Procedure

Weigh 5 g of the sample, prepared as in the IP method, into a 50-ml beaker, and dissolve the oil in 15–20 ml of pure benzene and quantitatively transfer the solution into a 250-ml glass-stoppered separating funnel. Add 10 ml of 10% thioglycollic acid solution (freshly prepared) and 5 ml of 5% dilute nitric acid and shake the mixture vigorously for 1 min and allow the layers to separate. Wash the sides of the separating-funnel with distilled water and collect the aqueous extract in a 500-ml conical flask. Repeat the extraction 2 or 3 times. To check that extraction is complete, repeat the process, collect the washings in a separate conical flask, and neutralize the solution with dilute ammonia. If a white precipitate of lead mercaptoacetate does not appear, the extraction may be taken as complete. To the main solution containing the lead extract, add dilute ammonia solution (1 + 1) dropwise until a voluminous white precipitate of lead mercaptoacetate is formed

Table 1.—Determination of lead

	Pb, %w/w	
Sample	By ASTM method[2]	By this method
1	0·76	0·78 0·76
2	1·12	1·13 1·14
3	1·14	1·11 1·12
4	1·10	1·08 1·08
5	0·92	0·94 0·92

and just redissolves in the ammonia. Add 2 drops of ammonia in excess. Add 10 ml of 10% formaldehyde solution and dilute to 100–150 ml with distilled water. Add 30–40 ml of acetate buffer, pH 5 (prepared by mixing 154 of ammonium acetate and 60 ml of glacial acetic acid in 1 litre of distilled water) and 5 or 6 drops of Xylenol Orange indicator (0·5% aqueous solution). Titrate slowly with 0·025*M* EDTA.

RESULTS AND DISCUSSION

Typical results are shown in Table 1 and compared with those obtained by the ASTM method. In the present method zinc and similar bivalent metal ions interfere but are not present except as trace impurities. If necessary they could be masked with 1,10-phenanthroline.[8] The acetate buffer will cause a negative error of about 1% at the lead concentration used,[9] but this error could be eliminated by buffering with hexamine.

Summary—A rapid complexometric method for the estimation of lead in lubricating oil has been developed. The lead naphthenate present in the oil is extracted with a mixture of dilute thioglycollic acid and nitric acid. The aqueous extract containing lead mercaptoacetate is titrated with EDTA at pH 5 with Xylenol Orange as indicator. The lead content can be determined within 15–20 min.

Zusammenfassung—Ein rasches komplexometrisches Verfahren zur Bestimmung von Blei in Schmierol wurde entwickelt. Das im Öl vorliegende Bleinaphthenat wird mit einem Gemisch von verdünnter Thioglykolsäure und Salpetersäure extrahiert. Der Bleimercaptoacetat enthaltende wäßrige Extrakt wird bei pH 5 mit Xylenolorange als Indikator mit EDTA titriert. Der Bleigehalt kann in 15–20 min bestimmt werden.

Résumé—On a élaboré une méthode complexométrique rapide pour le dosage du plomb dans les huiles de graissage. Le naphténate de plomb présent dans l'huile est extrait par un mélange d'acide thioglycolique et d'acide nitrique dilué. On titre l'extrait aqueux contenant le mercaptoacétate de plomb par l'EDTA à pH 5 avec l'Orangé Xylénol comme indicateur. La teneur en plomb peut être déterminée en 15–20 mn.

ANALYTICAL DATA

POTENTIOMETRIC DETERMINATION OF STEPWISE STABILITY CONSTANTS OF VANADIUM, MOLYBDENUM AND TUNGSTEN CHELATES FORMED WITH ASPARAGINE AND GLUTAMINE

(*Received* 20 *June* 1972. *Accepted* 1 *August* 1972)

The metal chelates of asparagine have been studied earlier by various workers,[1-5] but chelates formed with glutamine have not been investigated so extensively. In earlier publications from this laboratory, the stability constants of some aspartate and glutamate chelates[6] have been reported. Their formation was studied potentiometrically by Irving and Rossotti's[7] method. This paper gives the results of a similar study of some chelates of vanadium, molybdenum and tungsten formed with asparagine and glutamine.

RESULTS AND DISCUSSION

The protonation constants are log K_2^H 8·70, log K_1^H 2·16 for asparagine and log K_1^H 8·91, log K_2^H 2·21 for glutamine.

The formation curves ($\bar{n}$ *vs.* pL) show that $\bar{n}$ approaches a value of 3 for the asparagine and glutamine chelates of V(IV), Mo(VI) and W(VI).

Analysis of the formation curves for the V(IV) chelates show that K_1 and K_2 are very similar, and K_3 quite different. Since $\log K_1 - \log K_2$ is $<0{\cdot}5$, in these cases, K_1 and K_2 cannot be separately computed; instead $\log K_1 \,.\, K_2$ values were obtained from Albert's equation[8]

$$\log K_1 \,.\, K_2 = \log \bar{n} - \log (2 - \bar{n}) - 2 \log [\mathrm{L}]$$

Further since $K_2/K_3 \sim 10^3$, K_3 may be regarded as independent of K_1 and K_2, and its value was computed by the average-value method in the range $2 < \bar{n} < 3$.

Table 1. Stability constants of vanadium(IV), molybdenum(VI) and tungsten(VI) chelates formed with asparagine and glutamine (Temp. 25°C, 0·1M $NaClO_4$ medium).

Metal ion	pH range for $\bar{n}$ calculations	Method	Asparagine			Glutamine		
			log K_1	log K_2	log K_3	log K_1	log K_2	log K_3
V(IV)	3·2–8·0	Interpolation at half-$\bar{n}$ values	7·50	7·10	4·00	7·40	7·00	4.00
		Albert's equation	log $K_1 \,.\, K_2$ 14·50		—	log $K_1 \,.\, K_2$ 14·45		—
		Average-value	—	—	4·04	—	—	4·07
Mo(VI)	2·7–8·5	Interpolation at half-$\bar{n}$ values	8·20	7·18	3·45	8·00	6·80	3·35
		Successive approximation	8·06	7·23	3·45	7·90	6·93	3·35
W(VI)	4–8·5	Interpolation at half-$\bar{n}$ values	6·00	5·00	3·30	5·90	4·35	3·20
		Successive approximation	5·84	5·11	3·30	5·76	5·09	3·20

For Mo(VI) chelates, $K_1/K_2 \sim 10$ and $K_2/K_3 \sim 10^{3\cdot5}$, whereas for W(VI) chelates $K_1/K_2 \sim 10$ and $K_2/K_3 \sim 10^{1\cdot7}$. Therefore in these cases estimated stability constants were obtained by interpolation at half-$\bar{n}$ values and these were further refined by successive approximation.

Summary—The metal chelates of V(IV), Mo(VI) and W(VI) formed with asparagine and glutamine have been studied potentiometrically. Stepwise stability constants in 0·1*M* sodium perchlorate at 25°C are reported as follows.
Asparagine chelates—log K_1K_2 14·50 and log K_3 4·04 for V, log K_1 8·06, log K_2 7·29 and log K_3 3·45 for Mo, and log K_1 5·84, log K_2 5·11 and log K_3 3·30 for W.
Glutamine chelates—log K_1K_2 14·45, and log K_3 4·07 for V, log K_1 7·90, log K_2 6·93, and log K_3 3·35 for Mo, and log K_1 5·76, log K_2 5·09 and log K_3 3·20 for W.

Zusammenfassung—Die Chelate von V(IV), Mo(VI) und W(VI) mit Asparagin und Glutamin wurden potentiometrisch untersucht. Es werden folgende stufenweise Stabilitätskonstanten in 0·1*M* Natriumperchlorat bei 25°C mitgeteilt:
Mit Asparagin. log K_1K_2 14·50, log K_3 4·04 für V, log K_1 8·06, log K_2 7·29, log K_3 3·45 für Mo, log K_1 5·84, log K_2 5·11, log K_3 3·30 für W.
Mit Glutamin. log K_1K_2 14·45, log K_3 4·07 für V, log K_1 7·90, log K_2 6·93, log K_3 3·35 für Mo, log K_1 5·76, log K_2 5·09, log K_3 3·20 für W.

Résumé—On a étudié potentiométriquement les chélates métalliques de V (IV), Mo (VI) et W (VI) formés avec l'asparagine et la glutamine. Les constantes de stabilité étagées en perchlorate de sodium 0,1 M à 25°C sont rapportées comme suit:
Chélates de l'asparagine—log K_1K_2 14,50 et log K_3 4,04 pour V, log K_1 8,06, log K_2 7,29 et log K_3 3,45 pour Mo, et log K_1 5,84, log K_2 5,11 et log K_3 3,30 pour W.
Chélates de la glutamine—log K_1K_2 14,45, et log K_3 4,07 pour V, log K_1 7,90, log K_2 6,93 et log K_3 3,35 pour Mo, et log K_1 5,76, log K_2 5,09 et log K_3 3,20 pour W.

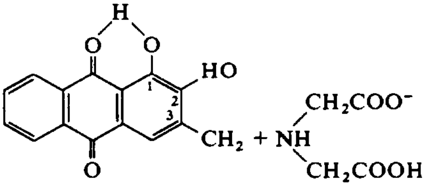
ANNOTATION

THE ACID STABILITY CONSTANTS OF ALIZARIN FLUORINE BLUE

(*Received* 27 *May* 1972. *Accepted* 6 *June* 1972)

During the past decade since its introduction by Belcher *et al.*,[1] Alizarin Fluorine Blue (alizarin complexan, 3-aminomethylalizarin-*N*,*N*-diacetic acid) has attracted considerable interest from analytical chemists. The reagent provided the analyst with the first positive colour reaction for fluoride ion and has been widely used for the photometric determination of fluoride.[2,3,4] Most work has been done on the ternary complexes formed by the reagent with the rare earth ions and fluoride ion and has been aimed at an improvement of the analytical method. Apart from dissociation constants of the acid and some conditional constants of the ternary complexes, very little is known about the equilibrium data for the reagent and its complexes. In this paper, the stability constants of the protonated species will be discussed and in a forthcoming paper further equilibrium data will be presented.



Alizarin Fluorine Blue

An attempt to determine the dissociation constants of alizarin complexan was made by Laird and Leonard.[5] Quite recently, the dissociation constants have also been determined by Mori *et al.*,[6] whose results differ appreciably from those of Laird and Leonard. Neither of the published sets of constants can explain the absorption spectra of the reagent, however, as will be clear from the following discussion.

Table 1 lists the values of the stability constants for alizarin complexan and two compounds that can be considered the parent compounds of the reagent, iminodiacetic acid (IMDA) and sodium alizarin sulphonate (ARS). The values of both Laird and Leonard, and Mori *et al.* are given for alizarin complexan. The absorption spectra that were recorded by Leonard and West[7] are shown in Fig. 1. (These were found to agree with spectra recorded in connection with the present work).

A glance at the spectra shows that the rise in absorbance at 590 nm for an increase in pH from 12·4 to 13·0 is about 55%. If it is assumed that the increase is due to the dissociation of HL into L and H, the value predicted from the stability constant of Laird and Leonard is only 4·5%. Therefore, the possibility that the value of the stability constant is too low cannot be excluded.

Moreover, if the values of Laird and Leonard were correct, the colour transition at pH = 5·5 that is visible in the spectra would arise from the dissociation of H_4L into H and H_3L. It is, however, reasonable to assume that the colour transitions are associated with changes in the resonance structure of the anthraquinone ring system. In other words, a greater colour effect should follow when one of the phenol groups loses a proton than when one of the carboxyl group hydrogen atoms—or the proton of the imino group—in the side-chain dissociates.

Log $K^{H}_{H_3L}$ = 7·55 (Ringbom's[9] notation is used in this paper) would thus imply that the acidity of one of the carboxyl groups would decrease by as much as five logarithmic units as compared to iminodiacetic acid. Reference to Schwarzenbach *et al.*[10] shows that the order of dissociation of the protons to be expected is as follows.

1. The remaining carboxyl group proton (one is transferred to the imino nitrogen atom during dissolution of the acid).
2. The phenolic proton in position 2.

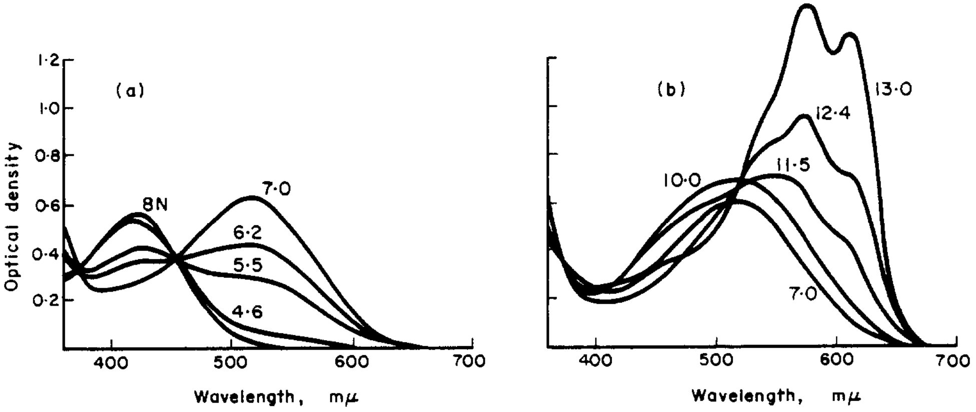


Fig. 1. pH-absorption curves for alizarin complexan (9·63 μg/ml) (from ref. 7 by courtesy of the copyright holders).

Table 1

Reaction		log K Alizarin complexan Ref. 5	 Ref. 6	 IMDA Ref. 8	 ARS Ref. 8
$H + L = HL$	K^{H}_{HL}	11·19	—	9·5	11·0
$H + HL = H_2L$	$K^{H}_{H_2L}$	10·43	10·5	2·3	5·5
$H + H_2L = H_3L$	$K^{H}_{H_3L}$	7·55	6·7	1·8	
$H + H_3L = H_4L$	$K^{H}_{H_4L}$	4.89	3·7		

(L denotes the ligand. For convenience, the signs of charge are omitted. The constants were determined at an ionic strength $\mu = 0{\cdot}1$.)

3. The proton at the imino group.
4. The remaining phenolic proton in position 1.

In comparison with alizarin and methyliminodiacetic acid, the acidity of the first two steps can be expected to increase, whereas the acidity of the last two steps should decrease.

The spectra recorded by Mori *et al.* display a transition back from red to yellow at pH = 8. The yellow colour is said to be stable in the pH range 8–9. Such a change is, however, highly unlikely and some experiments carried out at this laboratory show that the reason must be the use of boric acid as a buffer substance in this pH region. In fact, the colour of the solution will remain yellow throughout the entire pH range up to pH = 12 provided that enough boric acid has been added. It is probable that alizarin complexan is complexed by boric acid (*cf.* the complexation between boric acid and mannitol!). Since the same buffer was used in the electrophoretic experiments, the results should be regarded with caution.

These observations made it clear that further work was justified in order to bring clarity into the apparent confusion. In the following, the results of a potentiometric and spectrophotometric study of the acid stability constants of alizarin complexan will be given.

EXPERIMENTAL

Reagents

Alizarin complexan was purified by suspending 1 g in 50 ml of 0·1*M* sodium hydroxide, filtering the solution and extracting any alizarin with five successive portions of methylene dichloride. The acid was then reprecipitated by dropwise addition of hydrochloric acid whilst stirring the solution, which was kept in an ice-bath. The orange precipitate was collected on a glass filter crucible, washed with ice-water and dried in a vacuum desiccator over solid potassium hydroxide. The purity was checked by alkalimetric titration and by photometric titration with aluminium ion at pH = 4. Two different makes proved to have identical properties.

Hydrochloric acid solution was prepared according to Foulk and Hollingsworth.[11]

Sodium hydroxide solution was prepared according to Sillén[12] and standardized against potassium hydrogen iodate and against the hydrochloric acid solution.

All other reagents were of analytical grade. Redistilled water was used throughout the experiments.

Procedure

A weighed sample of the acid was dissolved in a known amount of sodium hydroxide solution, sufficient to neutralize three of the protons. The test solution was maintained at 25 ± 0·1° by suspending the titration vessel in an oil-filled thermostatically-controlled bath. Additions of titrant were made with pneumatically operated pipettes made by AGA, Lidingö, Sweden. The potentials were measured with a Beckman No. 39301 glass electrode against an Orion No. 90-02-00 double junction reference electrode and read with a digital voltmeter manufactured by Systemteknik (Type S 1016 H), Lidingö, Sweden. The outer sleeve of the reference electrode was filled with the ionic medium. Potassium chloride was used to maintain the ionic strength of the solution at 0·1 or 0·5.

The junction potentials were determined in separate experiments as functions of the acidity and taken into consideration when calculating pH from the measured potential.

The photometric results were handled by a variant of a method described by Sacconi[13] that is to be described later.[14] The results obtained by potentiometric titration were analysed by using the Etitr version of Sillén's computer program Letagropvrid.[15]

The total concentration of alizarin complexan ranged from $10^{-5}M$ to $10^{-4}M$ during the photometric measurements and from $10^{-3}M$ to $10^{-2}M$ in the potentiometric titrations.

RESULTS AND DISCUSSION

The sets of stability constants that give the best fit to the results have been collected in Table 2. It can be seen that the magnitudes of the constants agree well with the ones that can be predicted from the paper by Schwarzenbach *et al.*[10] mentioned earlier. The reaction $H_3L + H_2L = H_5L_2$ was introduced to account for a systematic deviation of the data that was observed when only the first four reactions were assumed to take place. The deviation was reproducible irrespective of any attempts to purify the reagent. By the introduction of the species H_5L_2, the error square sum decreased considerably, indicating a substantially better fit to the data.

Considering the reaction between alizarin complexan and boric acid, a reaction between H_2L and H_3L (containing two hydroxy groups!) does not seem unlikely.

A similar increase in the values of $K^{H}_{H_3L}$ was also observed when photometric results obtained at increasing pH values were used for the calculation of the stability constant. The change was much smaller than for the

Table 2. Stability constants of the reactions of alizarin complexan with protons.

Reaction	log $K \pm 3\sigma$ Ionic strength = 0·1	0·5
$H + L \rightarrow HL$	11·98 ± 0·03	12·10 ± 0·03
$H + HL \rightarrow H_2L$	10·07 ± 0·03	9·81 ± 0·03
$H + H_2L \rightarrow H_3L$	5·54 ± 0·05	5·47 ± 0·05
$H + H_3L \rightarrow H_4L$	2·40 ± 0·05	2·54 ± 0·07
$H + H_4L \rightarrow H_5L$		
$H_3L + H_2L \rightarrow H_5L_2$	2·2 ± 0·2	2·2 ± 0·2

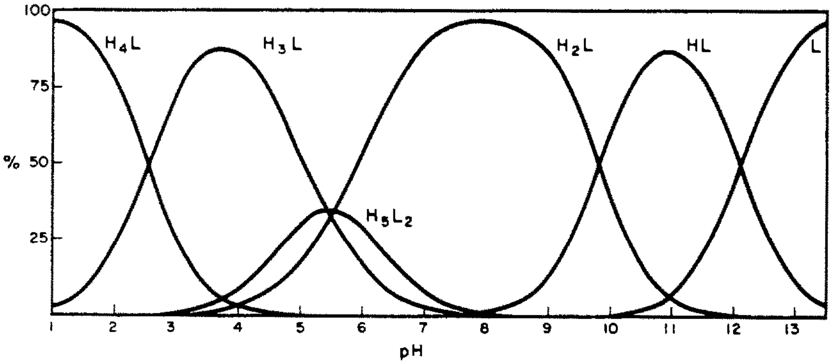

Fig. 2. Distribution diagram showing the proportion of alizarin complexan present in each ionized form at different pH values. Total concentration of alizarin complexan, $C_L = 0{\cdot}01M$.

potentiometrically obtained results, which is to be expected if it is due to formation of the H_5L_2 species, the overall concentration of the reagent being much less in the photometric experiments.

Owing to the uncertainty of glass electrode measurements at high alkalinity, the value of K^{H}_{HL} given in Table 2 was determined photometrically. The potentiometric measurements gave a lower value, $\log K^{H}_{HL} = 11{\cdot}8$ at ionic strength 0·5. The difference between the potentiometrically and the photometrically determined values of $K^{H}_{H_3L}$ was much smaller, the latter being $10^{5\cdot56}$ at 0·1 ionic strength.

If the Debye-Hückel theory is used to account for the effects of the medium, it can be shown that the agreement between the values determined in the different media is very good.

A distribution diagram, showing the proportion of the different ionized forms of alizarin complexan present, as a function of pH, is given in Fig. 2.

Summary—Two recent attempts to determine the dissociation constants of 3-aminomethylalizarin-*N*,*N*-diacetic acid are discussed and the results compared with values that can be predicted from earlier work on iminodiacetic acid derivatives and from the absorption spectra of the reagent at different pH values. Results of a potentiometric and spectrophotometric study to determine the stability constants of the various protonated species of the reagent in aqueous solution at ionic strengths 0·1 and 0·5 (potassium chloride) are: $\log K^{H}_{HL} = 12{\cdot}1$, $\log K^{H}_{H_2L} = 9{\cdot}81$, $\log K^{H}_{H_3L} = 5{\cdot}47$, $\log K^{H}_{H_4L} = 2{\cdot}54$, and $\log K^{H_2L}_{H_5L_2} = 2{\cdot}2$ at ionic strength 0·5.

Zusammenfassung—Zwei neue Versuche, die Dissoziationskonstanten von 3-Aminomethylalizarin-N,N-diessigsäure zu bestimmen, werden diskutiert und die Ergebnisse mit Werten verglichen, die aus früheren Arbeiten über Iminodiessigsäurederivate und aus den Absorptionsspektren des Reagens bei verschiedenen pH-Werten vorhergesagt werden können. Eine potentiometrische und eine spektrophotometrische Untersuchung der Stabilitätskonstanten der verschiedenen protonierten Spezies des Reagens in wäßriger Lösung bei den Ionenstärken, 0·1 und 0·5 (Kaliumchlorid) ergaben $\log K_{HL}{}^{H} = 12{\cdot}1$, $\log K^{H}_{H_2L} = 9{\cdot}81$, $\log K^{H}_{H_3L} = 5{\cdot}47$, $\log K^{H}_{H_4L} = 2{\cdot}54$ sowie $\log K^{H}_{H_5}{}^{2L}_{L_2} = 2{\cdot}2$ bei der Ionenstärke 0·5.

Résumé—Les deux derniers essais pour déterminer les constantes de dissociation du 3-aminométhylalizarine-N, N-acide diacétique sont discutées et les résultats sont comparés aux valeurs prévues selon les travaux précédents sur les dérivés de l'acide iminodiacétique et des spectres d'absorption du réactif à diverses valeurs de pH. Les résultats d'une étude potentiométrique et spectrophotométrique pour la détermination des constantes de stabilité des divers spécimènes protonés du réactif en solution aqueuse à des solidités ioniques de 0,1 et de 0,5 (chlorure de potassium) sont: $\log K^{H}_{HL} = 12{\cdot}1$, $\log K^{H}_{H2L} = 9{\cdot}81$, $\log K^{H}_{H3L} = 5.47$, $\log k^{H}_{H4L} = 2.54$, et $\log K^{H2L}_{H5L} = 2{,}2$ à une solidité ionique de 0,5.

TALANTA REVIEW*

USES OF LIQUID ION-EXCHANGERS IN INORGANIC ANALYSIS

H. GREEN

Auckland Industrial Development Division, D.S.I.R., P.O. Box 2225, Auckland, New Zealand

(*Received* 1 *May* 1972. *Accepted* 4 *July* 1972)

Summary—A review of recent uses of liquid ion-exchangers in inorganic analysis is presented.

Since the publication[1] in *Talanta* in 1964 of the review paper "Recent uses of liquid ion exchangers in inorganic analysis" interest has continued to be shown in this type of reagent. Liquid ion-exchange is a special case of solvent extraction, in that it involves selective transfer of solute between two immiscible phases, the distinction being that whereas solvent extraction involves the formation of a neutral species, whether a chelate, an ion-pair or a non-dissociating compound, liquid ion-exchange refers only to formation of ion-pairs, with special reference to exchange of one ion for another between the aqueous and the organic phase. The degree of transfer, or ion-exchange extraction obtained, is directly proportional to the concentration of the exchanger in the solvent, and distribution coefficients may be obtained similarly to those employed in solvent extraction. Changes in selectivity and in the values for the distribution coefficients of the liquid exchangers are related to changes in pH, temperature, salt concentration, charge on the ions involved, the presence of complexing and competing ions and the organic solvent employed. The behaviour of analogous functional groups in liquid and in resin ion-exchange is similar and it is possible to predict the likely course of a liquid ion-exchange extraction by reference to the literature on ion-exchange resins.

Coleman, Blake and Brown[2] gave a list of liquid ion-exchange materials in *Talanta* in 1962 but ten years later only a few of the materials which they mentioned have been widely used. A useful introduction to the properties and uses of liquid exchangers can be found in the paper by Kunin and Winger[3] published in the same year, and a brief outline was given in the review of 1964 previously cited.[1] The latter paper covered the more important published work up to the middle of 1964 with particular reference to the use of liquid exchangers in the analysis of inorganic materials other than those involving the transuranic elements. The present review covers the period from then until 1972.

LIQUID ANION-EXCHANGERS

Liquid anion-exchangers are based on high molecular weight primary, secondary and tertiary amines, and quaternary ammonium salts. The high molecular weight ensures very

---

* For reprints of this Review see Publisher's announcement near the end of this issue.

low solubility in aqueous solutions and high solubility in most water-immiscible organic solvents. Solvents such as aliphatic and aromatic hydrocarbons, chlorinated hydrocarbons, high molecular weight alcohols and petroleum distillates are suitable, and amine concentrations of 2–20% are usually employed. While the capacity for the extraction of all anions, present in the form of free acid, increases directly with increase in concentration of the exchanger in the organic phase, a different degree of extraction is exhibited for different anions. When simple anions are involved in formation of a complex anion containing a metal ion, addition of lithium salts of these simple anions will enhance the degree of extraction of the metal ions from solutions having the same total concentration of simple anion (*i.e.*, as lithium salt or free acid), as illustrated in Table 1.

Table 1. Temperature dependence of partition coefficient in the extraction of cobalt from hydrochloric acid solutions by 0·1*M* TOA in benzene[4]
(Reprinted by permission of the copyright holders)

Temp., °*C*	Partition coefficient	
	8*M* HCl	0·2*M* HCl + 7·8*M* LiCl
20	16·2	31·2
30	11·0	30·5
40	8·21	29·9
50	6·00	29·0

Changing the solvent in which the exchanger is dissolved may affect the degree of extraction for the free acid with the same concentration of exchanger. This effect can be utilized to impart selectivity for the separation of ions, particularly when the ionic charges differ. A list of the most commonly used anion-exchangers is given in the appendix to this paper.

Attention is drawn here to the hazards associated with the use of amines, especially in the undiluted state. It is important that adequate ventilation is provided to prevent any vapours from being inhaled. Precautions should be taken to prevent contact with the eyes or prolonged contact with the skin.

SEPARATIONS WITH ANION-EXCHANGERS

The two most widely employed liquid anion-exchangers, judging from the published literature, are tri-n-octylamine (TOA) and tri-iso-octylamine (TIOA).

Sato[4] studied the extraction of uranium(VI) and cobalt(II) from hydrochloric acid media, with 0·1*M* TOA solution in benzene. Lithium chloride was shown to be an effective salting-out agent in both instances, while increase in temperature reduced the partition coefficient. Table 1 illustrates these two important aspects of liquid ion-exchange very clearly.

In a further paper[5] Sato reported on the extraction of uranium(VI) and cobalt(II) from hydrochloric acid media with a series of cyclohexyl and benzylalkylamines. As expected, the tertiary amines were more effective extractants than the secondary amines, with benzene or chloroform as solvent. The efficiency of the extractions increased with the chain length of the alkyl group and decreased when the alkyl chain was branched. The presence of a benzyl group helped to promote extraction efficiency, and again substituting lithium chloride for the equivalent hydrogen chloride improved the extraction.

Hodara and Balouka[6] employed TOA to extract and separate uranium(VI) from uranium(IV). They used xylene as the solvent and the uranium was present in a mixture of hydrochloric and phosphoric acids. The phosphate complexes the uranium(IV) and prevents its extraction.

Platinum(IV) and tin(II) in hydrochloric acid form an orange complex, which may be extracted by a wide range of liquid anion-exchangers into solvents such as benzene and chloroform, and used for the spectrophotometric determination of platinum.[7] Comparison of the absorption spectra of the Pt–Sn complex in the aqueous and organic phases indicated the presence of the same absorption species in each medium. Irrespective of the amine used the complex showed an absorption maximum at 400 nm. Procedures were described for the determination of platinum in the presence of palladium and rhodium, both of which could interfere. Osmium, iridium and ruthenium probably form complexes but no evidence of extraction was found. Other ions causing no interference were Mo(VI), Co(II), Ni, Fe(III), SO_4^{2-}, NO_3^-, ClO_4^-. TOA as a 0·2*M* solution in benzene pre-equilibrated with 3*M* hydrochloric acid appears to be the best amine to use.

Khattak and Magee also examined the formation of the rhodium(III)–tin(II) complex[8] and its extraction into TOA/benzene before its spectrophotometric determination. The Rh(III) and Sn(II) reaction was carried out in hot 7–11·6*M* hydrochloric acid. Extraction with 0·2*M* TOA in benzene from such highly acidic solutions separates rhodium from the two other metals, platinum and palladium, which form similar complexes. The yellow Rh–Sn complex showed an absorption maximum at 415 nm, suitable for spectrophotometric measurement in the range 0–8 ppm. No interference was encountered from Os, Ru, In, Co(II), Ni, Fe(III), SO_4^{2-}, NO_3^-, ClO_4^-. A third paper[9] described a similar method for the determination of palladium. The extraction of chloro- and bromo-complexes of Ru(III) by a chloroform solution of mono-, di- or tributylamine was examined by Meier *et al.*[10]

The extraction of Pt(IV) and Rh(III) by TOA hydrochloride was reported by Gindin and Ivanova.[11] Extractions with 0·05*M* exchanger in toluene showed decreasing extraction with increasing hydrochloric acid concentration. Separation of the two metals was found to be feasible and suitable procedures were described.

Work on the extraction of platinum-metal nitrites by TOA in toluene was reported by Khan and Morris.[12] Nitrito-complexes of platinum metals are formed when hot neutral or feebly acidic solutions of the chloro-complexes are treated with excess of sodium nitrite. With 0·12*M* TOA hydrochloride in toluene as extractant and at pH 7 the distribution ratios for the platinum metals were Pt 27·8, Pd 15·6, Ru 11·8, Rh 0·0048, Ir 0·0059. The separation of the first three platinum-metals from the last two could obviously be done under the stated conditions. Quantitative back-extraction of platinum, palladium and rhodium was achieved with 1·5*M* perchloric acid.

The extraction of osmium complexes from hydrochloric or hydrobromic acid has been examined by Meier *et al.*[13] It was found that both short- and long-chain amines were suitable extractants. TOA gave over 99·8% extraction. The choice of organic solvent exerted a decisive influence on the degree of extraction obtained.

Gold has been quantitatively determined by employing 1% trioctylmethylammonium chloride in di-isobutyl ketone as extractant. Groenewald[14] used this extraction for gold in ore samples after treating them with *aqua regia*. If the pH of the solution was 0–4 then the relative chloride content was increased to 0·5*M* by addition of sodium chloride. If the pH was 4–10 then cyanide was added to give a concentration of $10^{-2}M$ and sodium chloride to a concentration of 0·1*M*. The presence of the sodium chloride facilitated clarification of the phases after mixing. More than 99·5% of the gold(III) was readily extracted, and measured in the organic phase by atomic absorption. A similar paper by Madigan[15] describes the extraction of gold as $Au(CN)_2^-$ by bis-(1-isobutyl-3,5-dimethylhexyl)amine in kerosene. The gold is back-extracted with 0·1*M* potassium cyanide or sodium carbonate.

McClellan and Benson[16] extracted iron from 2*M* and cobalt from 7·7*M* hydrochloric acid with 5% TOA in carbon tetrachloride. Two extractions were necessary to extract 98% of each metal. The metals were back-extracted for spectrophotometric determination in the aqueous phase.

Using methyldioctylamine, MDOA, in chloroform, Bullock and Tuck[17] examined the extraction of the anionic mercuric compounds formed with sulphate, selenate and oxalate. The 0·4*M* chloroform solution of MDOA was first equilibrated with the appropriate dilute acid solution and then the mercury compounds were extracted, their initial concentration being approximately $10^{-3}M$. Extraction of the sulphato-complex decreased rapidly with increasing sulphuric acid concentration; use of sodium sulphate in place of some of the sulphuric acid effected only a minor improvement. A similar trend was shown by the extraction from selenic acid. However, extraction from oxalic acid solutions increased rapidly with increase in oxalate concentrations above 0·2*M*.

Studies of the extraction of niobium and tantalum oxalato-complexes by TOA, TDA (tri-n-decylamine) and TDDA (tri-n-dodecylamine) in carbon tetrachloride were made by Djordjević *et al.*[18] All three exchangers behaved the same. For quantitative extraction in one pass with 3% exchanger solution from 0·2*M* oxalate solution, for both metals the sulphuric acid concentration needs to be below 0·5*M*. A similar paper by Abdel-Gawad *et al.*[19] reported the extraction of niobium from oxalic, citric and acetic acid solutions.

Sato and Watanabe[20] examined the extraction of zirconium by tricaprylethylammonium chloride ("Aliquat-336") in benzene from hydrochloric acid. Extraction increased rapidly with hydrochloric acid concentration above 6*M*. A study of the effect of the organic solvent showed that benzene was not particularly suitable for the extraction of Zr, and that chlorobenzene, dichlorobenzene or nitrobenzene were much superior. A later paper by the same authors[21] examined the use of a number of high molecular weight amines for extraction of zirconium from hydrochloric acid media.

Alimarin *et al.*[22] separated niobium(V) from titanium(IV) with a 0·2*M* solution of TOA in carbon tetrachloride. A single extraction of niobium from 8·5*M* hydrochloric acid was about 97% complete.

Ishibashi *et al.*[23] determined zirconium spectrophotometrically after extraction of the Zr–Alizarin Red S chelate into a toluene solution of TOA. The zirconium was first reacted with Alizarin Red S, then the solution was adjusted to pH 1 with hydrochloric acid, and allowed to stand for an hour. The zirconium complex was then extracted with 0·1*M* TOA in toluene, which had been previously equilibrated with 1*M* chloroacetic acid. On shaking the organic layer with an acetate buffer at pH 4·1 a polymeric chelate was formed which had an absorption maximum at 538 nm. Molybdate and tungstate were the major interfering ions.

A systematic study by Ivanov *et al.*[24] of the extraction of niobium from hydrochloric acid media by amines dissolved in carbon tetrachloride or chloroform, showed that the amine salt, not the amine, was the extractant. Hydrochloric acid concentrations above 7*M* were found to be necessary to form the extractable niobium species—$NbOCl_5^{2-}$.

By employing Aliquat-336 in xylene, Moore[25] formulated an improved method for the separation of actinide–lanthanide elements from plutonium waste solutions. These elements are readily extracted from relatively dilute aluminium nitrate–nitric acid solution by Aliquat-336 in the nitrate form. They are stripped with dilute mineral acids such as hydrochloric.

In another paper,[26] Moore described the use of Aliquat-336 in the thiocyanate form to separate the actinide–lanthanide elements from each other. The tervalent actinides were preferentially extracted by a xylene solution of the exchanger, and the addition of dilute acids, such as sulphuric, markedly improved the separation factors obtained.

Moore[27] has suggested that the actinide and lanthanide elements could be separated by extraction with anion-exchangers from solutions containing organic acids or EDTA. Most metal ions form amine-extractable anionic complexes with citric, oxalic and tartaric acids. Since these acids prevent hydrolysis of metal ions over a wide pH range there is no need to use acid solutions for extraction when they are present and this could widen the scope of extraction by amines.

Factors affecting the efficiency of the extraction of gallium from thiocyanate solution by TOA were investigated by Mikheev *et al.*[28] The best conditions are pH about 2 and 0·2–8·0*M* thiocyanate.

The extraction of gallium and indium from hydrochloric, hydrobromic and hydriodic acids by 1% "Adogen 364" in toluene was described by Sherif *et al.*[29] Gallium was 100% extracted from 3–10*M* hydrochloric acid, but indium showed maximum extraction (80%) from the 6*M* acid and much less from the 0–4*M* and 8–10*M* acid. Gallium extraction was maximum from hydrobromic acid >2*M* in concentration, but indium extraction did not start at acid concentrations <3*M* and was maximum from >5*M* acid. Indium was 100% extracted from hydriodic acid >0·5*M*, but gallium was not extracted at acid concentrations below 1·5*M*, 100% extraction not being achieved unless the acid was >5*M*.

Alian[30] used trilaurylamine (TLA) in xylene to extract protactinium, iron, mercury, silver, zinc, cobalt and selenium from hydrobromic or perchloric acid. It was found that increasing the hydrobromic acid concentration increased the degree of extraction for all the metals except silver and mercury, while increasing the TLA concentration gave corresponding increases in extraction. Corresponding experiments for the perchloric acid media showed extraction of Pa, Fe(III) and Se(IV) increasing and of Hg(II) decreasing. No extraction occurred at all for Co and Zn and very little for Ag.

The determination of microgram amounts of vanadium can be very difficult because of its variable oxidation state. Patrovský[31] based a photometric method on reaction of vanadium(IV) to form a catechol complex in which co-ordinately bound water could be replaced with tributylamine (TBA). The new complex was extractable into chloroform and was suitable for spectrophotometric measurement at 595 nm. The colour was stable for at least 60 min and other elements such as Ti and Mo which gave yellow complexes did not interfere with the measurement of the blue vanadium complex.

A comprehensive study of the extraction of zinc and nickel with aromatic tertiary amines was presented in a paper by Gagliardi and Wieland.[32] Twenty-four amines were tried as 0.5% solutions in chloroform and extractions were made from 0·5–5*N* hydrochloric, nitric and sulphuric acid media. Some effective extractants for zinc were discovered, but the nickel was partially or completely masked by most of the amines.

A 0·25*M* solution of TOA in xylene was found to be a suitable extractant for fluorosilicic acid, H_2SiF_6, from aqueous hydrofluoric acid media up to 1*M*.[33] Over 99·5% extraction was achieved and separation was complete from other elements which did not form anionic fluoro-complexes under the conditions employed. Niobium and tantalum were also extracted but could be separated by prior extraction from solution of higher hydrofluoric acid concentration; the solutions could then be diluted to 1*M* acidity and the H_2SiF_6 extracted.

Concentrations of cadmium down to 10 ppm were determined by Vasyutinskii *et al*[34] with 2% TBA in dichlorethane by extraction from a solution about 0·4*M* in hydrobromic acid. A dithizone solution in dichloroethane was added to the organic phase which was then washed with sodium hydroxide/sodium potassium tartrate solution, and filtered. The absorbance of the Cd-complex with dithizone in the organic phase was measured at 529 nm. No interference was encountered from Ni, Co, Cr, Cu, Zn, Mg, Fe, Mn and Al.

Using TOA to extract iron(III) citrate complexes into chloroform, Pyatnitskii and Tabenskaya[35] found extraction maximal at pH 1·8–2·6. A citric acid concentration of 0·02–0·8*M* in the aqueous phase gave conditions suitable for extraction by a 0·03*M* TOA solution. It was observed that alkali metal chlorides and nitrates inhibited the extraction and would completely suppress it if present above a concentration of 0·025*M*.

Angelova and Diocheva[36] extracted rhenium and molybdenum with dialkylbenzylmethylammonium salts, employing a mixed organic reagent consisting of 69% kerosene, 30% xylene, 7% isopentanol and 1% of the substituted ammonium salt. For Re(VII) a substituted ammonium chloride gave the best extraction but the Mo(VI) extraction was unaffected by the nature of the anion in the extractant. The two metals could be separated by using an aqueous solution at around pH 10, the distribution coefficient for Re(VII) then being 1000 times that for Mo(VI).

Shimizu[37] found suitable conditions for the extraction of scandium, thorium, zirconium and uranium from 0·1*M* sulphuric acid–0·01*M* ammonium sulphate medium with a 10% solution of "Amberlite LA-2" in xylene. No extraction was found for Al, Cd, Co, Cu, Ga, Hg, Mn, Ni, Y and the rare-earth metals, but Fe(III), In, and V(IV) showed partial extraction. Scandium and thorium could be back-extracted into the aqueous phase with 1*M* sulphuric acid. Zirconium and uranium(VI) could be back-extracted with 5*M* hydrochloric acid and 10% sodium carbonate solution respectively.

Marchenko and Voronina[38] extracted antimony(V) quantitatively from 7–10*M* hydrochloric acid with 2% TBA solution in chloroform, and separated it from chromium. The antimony was back-extracted with sodium potassium tartrate in aqueous ammonia solution.

Shevchuck and Shripnik[39] extracted aluminium as AlF_6^{3-} from an aqueous phase at pH 4–6 with 0·1*M* dodecylamine solution in chloroform.

Hofer[40] employed 10% Amberlite LA-2 solution in chloroform for separating traces of tin in nickel by extraction from 6*M* hydrochloric acid.

It was shown by Yagnyatinskaya and Nazarenko[41] that a TBA solution in chloroform would extract niobium from hydrochloric acid solution containing excess of catechol, extraction being maximal at pH 4·5 or at 1·5–3*M* acid concentration. The yellow Nb complex showed maximum absorption around 330–360 nm. Of many ions examined only Ti and oxalate were found to have any effect on the extraction. A procedure for the determination of small amounts of niobium in ores was described. Preliminary separation of thorium and uranium from each other and from interfering substances is often required before their determination. It was indicated by Cospito and Rigali[42] that the two well-known extraction systems—uranium from sulphuric acid by tertiary amines and thorium from nitrate media by quaternary ammonium salts—could be combined to achieve these separations. The uranium was first extracted by 3% TCA (tricaprylamine) in xylene from 0·05–0·2*M* sulphuric acid. The phases were separated and the uranium back-extracted with 0·5*M* sodium carbonate. The aqueous phase after uranium extraction was made 4*M* in nitric acid and the thorium extracted with 5% Aliquat 336 in xylene. The thorium was easily back-extracted with 3*M* hydrochloric acid.

A study by Florence and Farrar[43] of the extraction of nickel, manganese, chromium and thorium from mixed hydrochloric acid/lithium chloride solution, showed that high chloride but low free acid concentration greatly improved the degree of extraction. A further big improvement could be achieved if the extraction was made from methanolic lithium chloride rather than aqueous solutions. This was attributed to lower water activities in both phases when methanol was used as solvent. The authors suggested that elements such as aluminium and beryllium, which form only weak halide complexes, could be extracted by use of concentrated lithium halide solutions, selectivity being achieved by control of the halide concentration and free acidity.

Intensely coloured complexes of Xylenol Orange with traces of certain metals may be extracted by anion-exchangers from solutions at pH 0–3. This fact was utilized by Přibil and Veselý[44] who employed Aliquat-336 in chloroform for these extractions from mineral acid solutions. It was shown that it was possible to detect small amounts of gallium in indium and *vice versa*, and titanium or zirconium in thorium. The authors considered that the reactions could be made the basis for suitable spectrophotometric procedures.

Later Přibil and Adam[45] described a spectrophotometric method for the determination of molybdenum, employing mercaptoacetic acid. Sufficient 1*M* solution of the reagent was added to form complexes with all the molybdenum, iron, chromium and vanadium present, plus 0·5 ml in excess, the solution was neutralized, 5 ml of anhydrous acetic acid were added, and the molybdenum complex was extracted into 5% TOA in chloroform. The absorbance was measured at 370 nm and only the less common ions Bi, Hg and W interfered.

Yotsuyangi *et al.*[46] employed 4-(2-pyridylazo)resorcinol, PAR, as spectrophotometric reagent for Fe(II), Co, Ni and V(V). The complexes, formed in buffered neutral or weakly basic media in the presence of EDTA, were extracted with a chloroform solution of benzyldimethyltetradecylammonium chloride. For iron the solution was buffered to pH 10 with sodium borate and sodium hydroxide. The absorption was maximum at 522 nm and the molar absorptivity (ε) was $4{\cdot}00 \times 10^4$ l.mole^{-1}.cm^{-1}. For cobalt the pH used was 8·3, (borate–phosphate buffer), λ_{max} was 520 nm and ε $5{\cdot}9 \times 10^4$, for nickel, pH 9·3 (borate buffer), λ_{max} 505 nm and ε $7{\cdot}65 \times 10^4$, and for vanadium, pH 6·8 (phosphate buffer), λ_{max} 560 nm and ε $4{\cdot}30 \times 10^4$. For the determination of cadmium in nuclear-grade Zircaloy-2, Ghersini and Mariottini[47] employed an ion-exchange extraction from hydrochloric acid solution with 0·1*M* TOA in cyclohexane, previously equilibrated with hydrochloric acid. The cadmium was back-extracted with 2*M* sulphuric acid.

Ko[48] used a 20% TOA solution in xylene to extract plutonium, to an extent >99%, and this allowed concentration of tantalum, titanium, tungsten and zirconium, present in low concentration, before their determination spectrographically .

A recent paper by Ueno and Saito[49] suggested that extractions could be made with anion-exchangers from solutions of various metal ions in ammonium carbonate or sulphate media. Trioctylmethylammonium chloride (TOMA-Cl) was employed as exchanger as a 10% solution in toluene. The metal ions were added as radiotracers to 0·1–2*M* ammonium carbonate or sulphate solutions. In general, extraction was not critically dependent on ammonium sulphate concentration but did tend to decrease if the latter was >1*M*. Extraction decreased as the ammonium carbonate concentration increased.

SEPARATIONS WITH CATION-EXCHANGERS

The major part of the work on liquid cation-exchange has involved di-(2-ethylhexyl)orthophosphoric acid (HDEHP).

Sato[50] employed this reagent in kerosene in concentrations 0·005–0·1*M* to extract zirconium from hydrochloric acid solutions. The distribution ratio ($[\mathrm{Zr}]_{\mathrm{org}}/[\mathrm{Zr}]_{\mathrm{aq}}$) decreased as the acidity of the aqueous layer increased up to 2*M*, and then increased steeply above this acidity. This variation was interpreted as follows: "at low aqueous acidity zirconium is extracted by a cation-exchange reaction in which hydrogen [*sic*: hydrogen ion is meant] is liberated, while at high aqueous acidity the extraction is by a solvating reaction similar to that shown by non-ionic reagents such as tributyl phosphate." It was also shown that the partition coefficient for zirconium increased with temperature, which is contrary to the effect found for uranium(VI) and thorium(IV) but analogous to that for zirconium in nitric acid.

Extraction of sodium and strontium by HDEHP was investigated by McDowell and Coleman,[51] with benzene as solvent and the metals present as nitrates of the radioisotopes ^{85}Sr and ^{24}Na. With dilute solutions containing only sufficient $\mathrm{Na^+}$ or $\mathrm{Sr^{2+}}$ to satisfy 25% or less of the available ion-exchange capacity of the HDEHP, the extractions could be expressed as

$$\mathrm{Na^+ + 2(HA)_2 \rightleftharpoons NaA\cdot 3HA + H^+}$$
$$\mathrm{Sr^{2+} + 3(HA)_2 \rightleftharpoons SrA_2\cdot 4HA + 2H^+}$$

With increasing loading the simple salts corresponding to NaA and $\mathrm{SrA_2}$ were formed, with increasing polymerization and water extraction according to the generalized overall reaction

$$x\mathrm{Na^+} + \frac{x}{2}\mathrm{(HA)_2} + z\mathrm{H_2O} \rightleftharpoons \mathrm{(NaA)}_x z\mathrm{H_2O} + x\mathrm{H^+}$$

Separation of rare earths,[52] in particular praseodymium and neodymium, by means of HDEHP was examined by Goto and Smutz. The reagent was employed as a 1*M* solution in "AMSCO 125-82" (American Mineral Spirit Co.); no indication was given of just what this solvent is, which is unfortunate as it reduces the value of the work to other investigators. Perchlorate, chloride, nitrate and chloride/nitrate systems were investigated.

The determination of radiostrontium from a mixed fission product matrix containing isotopes of cerium, praseodymum, caesium, ruthenium, rhodium, zirconium, niobium and yttrium was described by Johnson.[53] The rare earths and yttrium were preferentially extracted into 1·5*M* HDEHP in toluene from dilute nitric acid media, before extraction of the strontium into isobutyl methyl ketone (IBMK) containing thenoyltrifluoroacetone.

For the separation and determination of thallium(III) Levin and Rodina[54] employed HDEHP. Extraction could be made from perchloric, hydrochloric or sulphuric acid media containing bromine; back-extraction employing 70% ammonium acetate solution at pH about 7 separated thallium from any amount of Mg, Zn, Cd, Cu(II), Hg(II), Fe(III), Ga, In, Al, Bi, As(V), Cr(VI) and Mn(VII). The determination of thallium was completed by titration of the extract with EDTA, after heating to 90° and adjusting to pH 4, with Xylenol Orange as indicator. In a previous paper[55] the recommendation was to back-extract the thallium into hydrochloric acid or sodium chloride solution. The EDTA titration was then carried out in an aqueous ammonia solution, containing chloroacetic acid, at pH 3–3·2.

Using HDEHP in kerosene, Csovary *et al.*[56] extracted scandium from 1*M* perchloric acid solution. Extraction was quantitative in the presence of chloride, nitrate or sulphate ions but phosphate, fluoride or oxalate ions reduced the degree of extraction.

The concentration of trace impurities by use of mixed cation-exchangers was described by Goryushina and Biryukova.[57] From 0·5*M* nitric acid solution, a mixed exchanger system of 2-ethylhexyl dihydrogen phosphate and bis-(2-ethylhexyl) hydrogen phosphate in carbon tetrachloride was shown to extract macro amounts of gallium, indium, thallium, bismuth or antimony. Impurities down to a level of 0·01 ppm, such as Cr(III), Mn, Co(II), Ni, Cu(II), Zn, Cd, As, Se and Te, remained in the aqueous phase, permitting their concentration by a factor of 50 or more.

A similar concentration process was outlined by Yudelevich *et al.*[58] for the analysis of high purity indium. The indium was extracted by *M* HDEHP in heptane from a 2*M* nitric acid solution of the alloy. Impurities were determined in the aqueous phase, recoveries being satisfactory except for bismuth and beryllium, when only 70–80% was obtained.

The extraction of macro amounts of indium with HDEHP in heptane from sulphuric or nitric acid solutions was described by Levin *et al.*[59] The indium was back-extracted into sulphuric or hydrochloric acid, excess of EDTA was added and the solution was back-titrated at pH 5 with zinc acetate, with Xylenol Orange as indicator.

Photometric determination of molybdenum as thiocyanate, after separation as Mo(VI), has been suggested by Kletenick *et al.*[60] The extraction was made from 2*M* hydrochloric or nitric acid solution with a benzene solution of HDEHP, the metal being back-extracted with 0·1*M* hydrogen peroxide in 2*M* hydrochloric acid, before its reaction with the thiocyanate.

An unusual type of extraction employing HDEHP was described by Kletenick and Bykhovskaya.[61] They found that the fluoride ion could be extracted by HDEHP, previously reacted with metals such as zirconium, thallium, titanium and quadrivalent tin, in hexane, carbon tetrachloride or benzene. Extraction varied with the nature of the solvent and was greatest when the metal attached to the exchanger was quadrivalent. In mineral acid solution Zr/HDEHP was the preferred extractant. The fluoride was back-extracted into the aqueous phase with TBP plus acetone and sodium hydroxide, before its determination by some suitable spectrophotometric method.

Extraction of iron(III) from hydrochloric acid solutions with HDEHP was described by Cerrai and Ghersini.[62] The iron was extracted from acid chloride solution that had a final chloride content <3·8*M*, an iron content between 0·04 and 6·0 μg/ml, and was 0·1*M* with respect to hydrochloric acid; an equal volume of 0·5*M* HDEHP in cyclohexane was used. An aliquot of the organic phase was transferred to a calibrated flask and the iron reduced with ascorbic acid in 95% ethanol. Bathophenanthroline and pyridine were added and the absorbance of the coloured solution was measured at 533 nm. Increasing the volume ratio of aqueous to organic phase up to 100 : 1 enabled extremely small amounts of iron to be determined with reasonable precision.

Extraction of small amounts of zinc from perchloric acid media by aliphatic carboxylic acids was investigated by Schweitzer and Clifford.[63] Zinc as radiotracer ^{65}Zn was extracted from 0·1*M* sodium perchlorate media adjusted to various pH values by the addition of sodium hydroxide or perchloric acid as appropriate. Solvents employed included benzene, chloroform and 4-methyl-2-pentanone.

Employing high molecular weight carboxylic acids, De and Roy[64] made a systematic study of the extraction of transition metals. The carboxylic acids used were (1) "Versatic-9", a mixture of highly branched saturated aliphatic acids containing nine carbon atoms, and (2) "SRS-100", a 1 : 1 mixture of highly branched, predominantly tertiary, acids containing fifteen carbon atoms and neutral oil. These were employed in benzene solution and the metal ions Fe(III), Co(II), Ni, Mn(II) and Cu(II) were in sulphate media. Optimum pH values for quantitative extractions were established as: iron 3·15, cobalt 8·12, nickel 8·3, manganese 7·95 and copper 6·15 for SRS-100. With Versatic 9, the pH for nickel was 7·5, for manganese 7·05, and for the others virtually the same as with SRS-100. The effect of changing the organic solvent was tabulated and some separations of transition metals outlined. The order of extraction of metal ions with carboxylic acids is the order of the relative stabilities of the metal carboxylates so an exchange or displacement reaction is possible between metal carboxylates in the solvent and a more acidic metal in the aqueous phase. For example, this exchange could occur between metal pairs such as Fe(III)/Cu(II) or Fe(III)/Co(II) *etc.* if the aqueous phase is at optimum acidity for iron, pH 3·2.

CHROMATOGRAPHIC USES OF LIQUID ION-EXCHANGERS

Chromatographic separations employing both anion- and cation-exchangers have been widely reported. The materials used to support the exchangers include silica gel, kieselguhr, polyethylene, polyglycol, cellulose *etc.*

A review of the uses of the liquid ion-exchangers TOA and HDEHP on inert supports was provided by Cerrai[65] in 1964 and supplements the information given in the previously mentioned review.[1]

Chromatographic separations with anion-exchangers. Brinkman *et al.*[66] examined the use of primary, secondary and tertiary amines in thin-layer chromatography with silica gel as support. The three amines chosen were "Primene JM-T", "Amberlite LA-1" and "Alamine-336" as representatives of each class and also as weakly, moderately and strongly absorbing anion-exchangers. Over fifty ions were examined, as the chlorides, in solutions containing from 2 to 12 mg/ml and eluted with hydrochloric acid. For silver, lead and thallium the nitrates were employed. A complete description of the apparatus and a brief outline of the identification tests applied was given and R_F values for each ion for the three amines and the silica gel without exchanger, at various hydrochloric acid concentrations, were presented graphically. To illustrate the practical uses of their experimental results the authors have given a number of useful separations which could be made, *e.g.*, (1) for the four elements Ni, Co, Mn, Zn, encountered in the $(NH_4)_2S$ group of the classical separation system; (2) Al, In, Ga: (3) As(III), Sb(III), Bi; (4) SeO_3^{2-} from TeO_3^{2-}.

The same workers[67] investigated the nature of some of the anionic chloro-complexes of cations present in the organic phase for the same three amines and for the quaternary ammonium salt Adogen 464, in reversed phase chromatography. The metals involved were copper(II), cobalt(II), manganese(II), zinc and iron(III). Irrespective of the class of exchanger, the concentration of the chloride ion in the aqueous phase or the use of hydrochloric acid or lithium chloride as the source of Cl^-, the sole metal-containing species in the organic phase were found to be $CoCl_4^{2-}$, $CuCl_4^{2-}$, $MnCl_4^{2-}$ and $FeCl_4^-$.

Brinkman and de Vries[68] have applied thin-layer chromatography to the separation of 25 metal ions from sulphuric acid and sulphate salt systems, using silica gel impregnated with the same three amines, Primene JM-T, Amberlite LA-2, Alamine-336 and also with the quaternary ammonium salt Aliquat-336, each being equilibrated with sulphuric acid before being applied to the silica gel. The metal ions were applied as 2–10 mg/ml solutions of their sulphates, and the eluents sulphuric acid, lithium sulphate or ammonium sulphate were used in a range of concentrations. High R_F values were recorded for those cations—13 out of the 25 tested—which do not form sulphato-complexes. With the remaining ions, increasing R_F values were obtained as the sulphuric acid concentration was increased but the R_F values decreased with increase in sulphate salt concentration, whether lithium or ammonium. This was taken to indicate a shift in the $SO_4^{2-} \rightleftharpoons HSO_4^-$ equilibrium with the introduction of extra hydrogen or sulphate ions into the eluent. Few analytically useful separations could be formulated for cations which have low or medium R_F values in sulphate media.

Employing Amberlite LA-2 in the thiocyanate form, Graham and Carr[69] extended the investigations of Brinkman *et al.*[70] who used silica gel as the support media. Graham and Carr employed cellulose as support and examined 68 metal ions, using 0·1–7·0*M* ammonium thiocyanate as eluent. Most of the metal ions either moved with the solvent front or were strongly complexed and remained at the point of application. Useful R_F values were obtained for VO(II), Ni, Tl, Pb, Bi, Ag, Cu(II), Cd and Mn(II), and these last five ions were studied further for the effects of the degree of impregnation of the stationary phase with the exchanger.[71] Manganese(II) ions migrated at all concentrations of ammonium thiocyanate from 0·1 to 7·0*M*; silver ions migrated at eluent concentrations >0·5*M* and moved with the solvent front with eluent >5*M*. Copper(II) ions migrated with $[SCN^-] > 1M$, and cadmium and bismuth ions at >2*M* thiocyanate, the R_F values increasing regularly as the concentration of the thiocyanate increased. Increasing the exchanger loading of the cellulose caused a decrease in the R_F values for the metals studied, with 4*M* ammonium thiocyanate as eluent.

Graham *et al.*[72] reported on the use of thin-layer chromatography with Primene JM-T on cellulose, using hydrochloric acid eluents. By variation of the concentration of the impregnating amine over the range 0·1–0·7*M* the R_F values of some of the metal ions were changed significantly. A linear relationship was established between the logarithm of the concentration of the impregnant solution up to 0·5*M* and the R_M values. The R_M value is given by

$$R_M = \log_{10}\left(\frac{1}{R_F} - 1\right)$$

Separations which were shown to be possible in the primene JM-T hydrochloride/hydrochloric acid systems included the following.

1. Be, Mg and alkaline earths, in 8–9*M* acid.
2. Zn and Fe(III) from Ti(II), VO(II), Cr(III), Mn(II), Co(II), Ni, Cu(II), with Zn migrating with 1*M* acid (R_F 0·56) and Fe stationary with acid >8*M*, the remaining

elements having R_F values between 0·7 and 0·9 for 6–9*M* acid and R_F values around 1·0 for acid <5*M*.

3. Al, Ga, In and Tl, separated in the acid range 6–9*M*.
4. Sn(II), Sn(IV) and Pb(II) separated over the whole acid range 1–9*M*.
5. Sb(III) separated from Bi over the range 1–9*M*.

A similar dependence of R_F and amine concentration was reported by Brinkman *et al.*[73] who used various amines on silica gel and 7*M* hydrochloric acid as eluting agent. Typical results obtained are shown in Table 2 for Cu, Co, Bi and Zn with Amberlite LA-1. The authors considered that a 1 : 1 mixture of Amberlite LA-1 and TIOA could provide a useful mixture for separation of some metal chloro-complexes. Experiments showed that this was the case; the amine mixture gave R_F values intermediate between those found for the separate components. The amines could be classified according to adsorption strength in hydrochloric acid media as follows.

Table 2. Dependence of R_F values and migration rate of eluent on molarity of amine HCl solution (Amberlite LA-1 was used as liquid ion-exchanger and approx. 7*M* HCl as the eluting agent)[73]

Graham *et al.*[74] examined the quantitative determination of zinc after thin-layer chromatography on cellulose impregnated with Primene JM-T. 2-(Pyridylazo)-2-napththol (PAN) was employed as chromogenic reagent to locate the zinc spots, with hydrochloric acid as eluent. The Joyce-Loebl "Chromoscan" recording and integrating densitometer with thin-layer attachment was employed in the reflectance mode and the spots scanned 25 times, the mean of the integrator counts being taken. An error of about 5% was achieved at the 1-μg level of zinc; the greatest source of error in the procedure was associated with the application of the PAN solution to the chromatographic layer. The spots themselves showed no significant fading after more than 30 min. The same authors[75] compared the results obtained by densitometric measurement with those from removal of the chromatographic spot and subsequent spectrophotometric measurement with PAN as chromogenic agent. The two methods gave similar degrees of accuracy but the densitometric method was very much quicker.

Pierce and Henry[76] have used TIOA as an anion-exchanger in partition chromatography. The exchanger was deposited on poly-(vinyl chloride/vinyl acetate) copolymer, available commerically as "CORVIC R51/83." Distribution ratios were obtained for the

CORVIC/TIOA, by using batch extraction with 1 g of solid and 20 ml of aqueous phase, and the separations were made on columns 180 mm long × 6 mm diameter, radiotracers being used to follow the elution. Schemes for chromatographic separations were designed from the distribution ratios, at different hydrochloric acid concentrations, obtained in the batch extractions. Useful separations included (1), As, Ge and In, employing 8·6*M* hydrochloric acid for As elution, 1·05*M* hydrochloric acid for Ge and water for In; (2) Mn, Co, Cu, Zn, employing 5·89*M* hydrochloric acid for Mn, 3·09*M* hydrochloric acid for Co, 0·55*M* hydrochloric acid for Cu and water for Zn.

Using columns of TOA on polytrifluorochloroethylene ("KEL-F") as inert support[77] Espoñal and Marafuschi determined tungsten in stainless steel. Radioactive tracers were employed and the ions added to the column in hydrochloric acid solution. Chromium was easily eluted with 10*M* hydrochloric acid, then tungsten was eluted with 7*M* hydrochloric acid + 1*M* hydrofluoric acid. Cobalt moved down the column only very slowly while iron remained firmly held at the top. Although the method was intended for stainless-steel analysis no mention was made of the part played by nickel.

Przeszlakowski[78] employed various liquid anion-exchangers in the thiocyanate form to develop chromatograms of metal ions on paper impregnated with ammonium thiocyanate. Interesting changes in R_F values occurred for silver, mercury(II), palladium, gallium, molybdenum(IV), antimony(III), titanium(IV), manganese(II), zinc, cadmium, bismuth, indium, iron(III), uranium(IV), and cobalt(II) with changes in the concentration of ammonium thiocyanate on the paper, and changes in the solvent in which the exchangers were dissolved.

In the system Aliquat-336–hydrochloric acid[79] Stronski reported the separation of the radioisotopes ^{51}Cr, ^{185}W, ^{99}Mo, ^{54}Mn, ^{65}Zn, ^{60}Co, ^{59}Fe, ^{182}Ta, ^{186}Re, ^{234}Th, ^{233}Pa and ^{235}U. A column of KEL-F was treated with 0·1*M* Aliquat-336 and the ions successfully eluted with various concentrations of hydrochloric acid. The same worker[80] reported on the separation of In, Cd, Sn, Te and Sb, using Amberlite LA-2 on silica gel and eluting with various concentrations of hydrochloric acid.

Employing Aliquat-336 on a column of "Plaskon" (a trifluorochloroethylene polymer), Huff[81] studied the separation of americium, yttrium and the rare earths in the thiocyanate system. Gradient elution with ammonium thiocyanate from 2 to 0·3*M* achieved only partial separation of 1-mg quantities of rare earths on a 15-cm column, breakthrough of the next metal in the series occurring before the previous metal was completely eluted. Owing to this cross-contamination no clear-cut separations of rare-earth elements was possible.

Ruthenium in aqueous nitric acid solutions forms a series of nitrosylruthenium compounds of general formula $RuNO(NO_3)_x(OH)_y(H_2O)_z$ where x, y and z vary from 0 to 5, and the co-ordination number is 6. The relative concentration of the different species is affected by acid concentration, solution age and temperature. Hallaba *et al.*[82] extracted these nitrato complexes, using various tertiary amines, and showed that extraction decreased with increasing nitric acid concentration and increased with amine concentration. High concentrations of aluminium and sodium nitrates did not greatly influence the degree of extraction obtained. The organic solvent employed had no significant effect on the extraction pattern for ruthenium but there were changes in the values of the distribution ratios.

Leene *et al.*[83] described the preparation of trialkylamine oxide by the action of aqueous hydrogen peroxide on the tertiary amine Alamine 336-S. A 0·1*M* solution of this oxide in chloroform was equilibrated with 2*M* hydrochloric acid. The solution was mixed with silica gel and the slurry was coated onto microscope slides. With 0·1–11*M* hydrochloric acid or 0·1–9·5*M* lithium chloride in 0·5*M* hydrochloric acid as eluent, the R_F values of thirty cations were determined. Comparison was made with the R_F values obtained with trioctylarsine oxide prepared and used in a similar fashion.

The separation of niobium and titanium in microgram amounts and in all ratios from 1 : 100 to 100 : 1 was described by Alimarin *et al.*[84] The separation was made on a column of PTFE granules coated with 0·5*M* TOA, with various concentrations of hydrochloric acid as eluent.

Chromatographic separations with cation-exchangers. The use of liquid cation-exchangers for chromatographic separations has been restricted almost entirely to di-(2-ethlhexyl)orthophosphoric acid (HDEHP). Raaen[85] used HDEHP in thin-layer chromatography on polytetrafluoroethylene ("Fluoroglide 200 TWO 218," from Chemplast Inc., N.J., U.S.A.) Thin films of the PTFE were prepared and dried on "Mylar" polyester film (Kensington Scientific Corp., U.S.A.), then 1 μl of solution, containing the radiosotope under investigation dissolved in nitric acid, was placed on the start and allowed to dry. Each chromatogram was developed with 5 ml of 0·5*M* HDEHP in IBMK, about 1 hr being required, and the films were dried. The chromatograms obtained were placed in contact with X-ray film for 2 or 3 days and the films then developed. The autoradiograms, produced for 31 metal ions, gave pictures which naturally were the reverse of the usual type of chromatogram, since those ions most strongly complexed by the exchanger moved with the solvent front while uncomplexed ions remained at the origin. Numerous separations were shown to be possible under the conditions selected. It is possible that still further useful separations could be evolved by use of an alternative solvent and slight changes in acidity of the layer of PTFE.

Pierce and Flint[86] employed HDEHP in conjunction with silica gel and granulated poly(vinyl chloride) (CORVIC D55/3, I.C.I. Ltd.) for thin-layer chromatography. Separations of mixtures of rare earths, of strontium and yttrium, and of nickel, copper, silver, zinc and iron, were shown to be satisfactory with hydrochloric acid as eluent. A similar study by Herrmann[87] used HDEHP on silica gel, with 1*M* hydrochloric acid, to separate europium and gadolinium.

The separation of fission products from uranium(VI) is a complex problem. Tomazic and Siekierski[88] employed HDEHP on a support of kieselguhr (ratio 1 : 10) to achieve a useful degree of separation. Uranium reacts strongly with HDEHP even in highly acidic solutions and was retained on a column of reagent and kieselguhr quite well when other metal ions were eluted with nitric acid. A sample was prepared in 0·1*M* nitric acid containing caesium, strontium, barium, lanthanum, cerium(III), europium, terbium, yttrium, zirconium and a quantity of uranium equivalent to 50% of the ion capacity of the chromatographic column. The caesium, strontium and barium were eluted with 0·5*M* nitric acid as one group, followed after a short break by lanthanium and cerium. When the concentration of acid was increased to 5*M*, europium, lead and yttrium were eluted. Finally the column was treated with concentrated hydrochloric acid, and the uranium was eluted and the zirconium remained on the column.

Employing paper treated with HDEHP Cerrai and Ghersini[89] examined 67 cations in the hydrochloric acid system. The chromatographic paper used was Whatman No. 1. (CRL/1 type), spots with a volume of 0·05 ml were applied (containing approx. 1×10^{-7} equivalents of the cation concerned) and elutions made with hydrochloric acid at concentrations between 1×10^{-4} and $10M$. The results obtained showed good agreement with the literature on liquid/liquid extraction, the R_F value of any ion being related to the extraction coefficient E_a of the same ion in the analogous liquid/liquid system by the well-known relationship

$$\log\left(\frac{1}{R_F} - 1\right) = \log E_a + \log k$$

where k is a constant depending on the chromatographic conditions. A discussion of the behaviour of the 67 ions examined was included and separations which might be useful in analysis were suggested.

Cerrai and Ghersini[90] examined the separation of the alkali and alkaline earth metals, using Whatman paper No. 1, CRL/1 type, treated with HDEHP. The metal ions were placed on the paper as chlorides and eluted with various concentrations of acetic acid from 0·1 to $3M$. A number of potential separations were found including Ca/Sr, Mg/Ba/Ca, Mg/Ca, Na/Ca/Sr, Cs/Sr, Cs/Ca/Sr.

A comparison of the cation-exchangers HDEHP and H_2EHP (2-ethylhexyldihydrogen phosphate) on Whatman No. 1 paper, for the separation of metal ions, was made by Lyle and Nair.[91] When the chromatograms were developed with hydrochloric acid those employing H_2EHP were found to be inferior to those employing HDEHP for similar metals such as lanthanides. Good separations were obtained with either ester for Fe(III) and Co(II), and HDEHP-impregnated paper could be used to separate Au(III) and Pt(IV). Table 3 shows how the separation factors for iron and cobalt were found to vary with the eluent concentration for the two exchangers.

Conditions for the separation of calcium, strontium and barium on silica columns loaded to 13% with HDEHP, were reported by Jaskolska.[92] Up to 0·3 mg of total metal ions was absorbed on the column and selective eluents were employed—barium was eluted with $0{\cdot}5M$ sodium nitrate at pH 3·2, strontium with $0{\cdot}5M$ sodium nitrate at pH 2·0, then calcium with $0{\cdot}5M$ sodium nitrate at pH 0·8, the pH being adjusted with nitric acid.

An investigation by Mikhailichenko and Pimenova[93] into the use of HDEHP on columns of silica gel for the separation of the rare-earth metals has been reported. Radioactive tracers ^{153}Gd, ^{160}Tb, ^{159}Dy, ^{166}Ho, ^{169}Er, ^{170}Tm, and ^{90}Y were applied to the column in $0{\cdot}1M$ hydrochloric or nitric acid. Selective elution was attempted, employing various concentrations of hydrochloric and nitric acids, but only the pairs Dy–Y and Tb–Y showed satisfactory separation, with 2·6*M* nitric acid at 40°.

In two papers, Cerrai and Ghersini[94,95] demonstrated the separation of aluminium, gallium, indium, thallium, iron(III), nickel and cobalt(II), using paper impregnated with HDEHP. Changes of R_F values with 0·1–10*M* hydrochloric acid and different concentrations of HDEHP showed some useful separations were possible. Combining their results with other published work[96,97] the authors considered the following combinations of elements could be separated satisfactorily: Be/Fe/Al/Sr with 7·5*M* hydrochloric acid; Ti/Ga/Fe/Tl/U/Ba/Ca/Ni with 8*M* hydrochloric acid; Zr/Fe/Y/In/Ni with 2*M* hydrochloric acid; Ti/Fe/Tl/U/Ba/Sr with 8*M* hydrochloric acid; Ga/Fe/Ba/Mn with 7*M* hydrochloric acid; Y/Ga with 1·5 or 7*M* hydrochloric acid.

MISCELLANEOUS

For the determination of gallium in the presence of aluminium, Levin and Balakireva[98] used the mixed solvents H_2EHP and TBP (tributyl phosphate). From a sulphuric or hydrobromic acid solution, at pH 4–5, gallium and aluminium were extracted with 2*N* H_2EHP (2-ethylhexyl dihydrogen phosphate) in heptane, any ferric iron present being previously reduced with ascorbic acid. The extract was washed twice with perchloric acid then once with water. Aluminium was removed from the organic phase by mixing with an equal volume of TBP and washing with 7*N* sulphuric or hydrobromic acid. To recover the gallium the organic phase was treated twice with 4*N* sulphuric acid. The determination of the gallium was completed by adding an excess of 0·01*M* EDTA, heating to 70°, neutralizing to Congo Red with ammonia solution, buffering to pH 5 with acetate buffer and titrating excess of EDTA with 0·01*M* zinc nitrate with Xylenol Orange as indicator.

A similar technique using a mixed extractant was described by Watanabe.[99] The extractant was a mixture of both cation- and anion-exchangers in carbon tetrachloride. Various concentrations of HDEHP up to 15% with 0·5 or 5·0% Primene JM-T were employed. Thorium, iron(III), zinc, lanthanum, indium and cerium(III) could be extracted from 0·01–0·1*N* sulphuric acid media. The effects of changes in ligand and acid concentration were given and an explanation of the results was proposed.

Blasius and Finkenauer[100] described the preparation of an azo dye by coupling diazotized anthranilic acid and 4-dodecylphenol. This dye was then employed as a liquid ion-exchanger, as its ammonium salt dissolved in carbon tetrachloride, chloroform, benzene or trichlorobenzene, to extract cations. Separation coefficients for calcium, strontium, beryllium and aluminium were reported and a method given for the quantitative separation of strontium from concentrated alkali metal salt solution.

The use of HDEHP as stationary phase in gas chromatography was outlined by Ilie *et al.*[101] A solution of HDEHP in diethyl ether was used to treat silaned "Chromosorb W" (0·18–0·25 mm particle size), the product being stirred at room temperature until all the ether had evaporated, leaving a product containing 15% of the exchanger. The Chromosorb was then made into columns (3 m × 6 mm) and used in the chromatographic study of various organic compounds vaporized at 150°. Hydrogen was used as carrier gas and the columns were operated at 70°, 90° and 110°. Satisfactory separations were achieved for benzene and cyclohexane, for C_1–C_4 alcohols and C_3 and C_4 ketones, and also for various chlorinated derivatives of methane and ethane.

For the determination of long-chain quaternary ammonium salts, Olcina and Palomino[102] suggested the use of Methyl Red. The complex of the quaternary ammonium salt with Methyl Red in 0·1M sodium carbonate was extractable into a 19 : 1 benzene–octanol mixture. The colour was developed either with aqueous ammonia-ethanol mixture followed by spectrophotometric measurement at 400 nm or with dilute hydrochloric acid–ethanol mixture, measurement then being at 510 nm.

For the determination of iron(III) by complexometric titration with EDTA, with thiocyanate as indicator, Fujimoto *et al.*[103] recommended the addition of an amine to improve the end-point. The ferric iron solution was buffered to pH. 2·8, a small quantity of ammonium thiocyanate solution was added, followed by 1 ml of 10% Amberlite LA-1 in carbon tetrachloride. The solution was then titrated slowly with 0·01M EDTA, with vigorous shaking and heating to 60° near the end-point, which is indicated by a sharp change in colour from red to pale yellow.

A use of liquid ion-exchangers which is of recent origin is in the preparation of ion-selective electrodes, such as those available from Corning, Orion or Beckman. For example, in the case of nitrate ions the Corning exchanger contains tridodecylhexadecylammonium nitrate in n-octyl *o*-nitrophenyl ether as the liquid ion-exchanger. Employing this Corning exchanger, Davies *et al.*[104] described the preparation of nitrate ion-exchange membranes. The exchanger (0·42 g) was added to a solution of 0·177 g of PVC in 6 ml of tetrahydrofuran. The solution was poured into a glass ring (33 mm i.d) resting on a glass plate and the organic solvent was allowed to evaporate to give a master membrane, which was then cut by means of a cork borer into discs of 6 mm diameter, suitable for inserting into the electrode. A similar nitrate-sensitive electrode was prepared by Coetzee and Freiser,[105] employing a 10% solution of methyltrioctanoylammonium nitrate in decanol as exchanger. Moody *et al.*[106] described the preparation of a calcium-selective electrode by incorporating a calcium liquid ion-exchanger in a membrane based on PVC and later reported that for a functional membrane a minimum of 20% PVC was found to be necessary. A recent publication by Moody and Thomas[107] devotes an entire chapter to the subject of liquid ion-exchanger electrodes and is a useful background for further work on this subject.

THEORY ASSOCIATED WITH LIQUID ION-EXCHANGE

It was noted in the 1964 review[1] that two of the major obstacles to the advance of liquid ion-exchange techniques were the lack of knowledge of the basic principles involved and adequate means of assessing the relative "strengths" of the exchangers. Some eight years later the theory of liquid ion-exchange has advanced considerably, due to many workers. Probably the largest contribution has been made by the Department of Inorganic and Structural Chemistry at the University of Leeds, England. Workers under Professor H. M. N. H. Irving have published a number of papers covering extractions of particular ions from various media, or of various ions from particular media, with an excellent breakdown of the factors involved. In a paper in 1965, Irving and Damodaran[108] examined the determination of perchlorate in the presence of other halogen acids by means of a coloured liquid anion-exchanger. The coloured exchanger was a quaternary erdmannate obtained by shaking a solution of tetrahexylammonium iodide in 1 : 4 IBMK–xylene solution with an aqueous solution of Erdmann's salt, $[NH_4]^+[Co(NH_3)_2(NO_2)_4]^-$. The coloured liquid ion-exchanger had a molar absorbtivity of approximately 10^4 $l.mole^{-1}.cm^{-1}$, and on equilibration with an aqueous solution containing perchlorate ions the coloured erdmannate ion was displaced and there was a corresponding decrease in the absorbance of the organic phase. Methods for the calculation of the equilibrium constant for this reaction were outlined from the measurements of the absorbances of the aqueous and organic phases and the relevant molar absorbtivities.

Two papers by Irving and Nabilsi[109] in 1968 examined the extraction of cupric and cuprous copper by a solution of quaternary n-hexylammonium chloride in ethylene dichloride. Increasing the concentration of chloride ions in the aqueous phase increased the degree of extraction of copper(II) but decreased that of copper(I). Irving and Damodaran[110] extracted silver from hydrochloric acid solutions, using tri-n-hexylammonium and tetra-n-hexylammonium chloride in 1,2-dichloroethane. Silver was added as radioactive tracer, with a half-life of 274 days, and measurements of activity in aqueous and organic phases enabled conclusions to be drawn about the anionic complexes formed by silver in hydrochloric acid. As was the case with copper(I) the univalent ion Ag^+ showed a decrease in extraction as the chloride concentration was increased.

Conflicting results by other workers on the extraction of indium induced Irving and Damodaran[111] to examine the extraction of indium from aqueous solutions of halogen acids and thiocyanates. It was shown InI_4^- was extracted in preference to $InBr_4^-$, and $InBr_4^-$ in preference to $InCl_4^-$. This is the reverse of the stability of these complex ions. The course of the extraction curve was found to be governed by the activity of the halide ions and it was noted that the plots for extraction from hydrochloric acid, lithium chloride and sodium chloride media could be superimposed. The nature of the ions present in both halogen acid and thiocyanate media was elucidated.

Irving and Damodaran[112] noted the tendency for the tetracyano complexes of zinc $[Zn(CN)_4^{2-}]$, cadmium $[Cd(CN)_4^{2-}]$ and mercury $[Hg(CN_4)^{2-}]$ to be extracted by tetrahexylammonium salts in IBMK. This was examined further for the extraction of mercury(II), when it was found that the anions $Hg(CN)_4^{2-}$ and $Hg(CN)_3^-$ were extracted, the latter species probably being solvated. Further work by the same workers[113] covered the complex cyanides of gold, nickel, palladium, platinum, copper and iron. The extraction constants for these metals were discussed in terms of the size and stereochemistry of the complex anions. Desreux[114] has examined the question of the association of water with long-chain alkylammonium salts such as TLA–HCl, TLMA–SCN (trilaurylmethylammonium thiocyanate) and TLMA–Cl. The infrared and n.m.r. spectra were recorded for the carbon tetrachloride solvent before and after shaking with an aqueous phase, and Karl Fischer titration was used to obtain the water content of the solvent. The results showed that trilaurylmethylammonium thiocyanate was monohydrated in the organic solvent whereas the trilaurylmethylammonium chloride was present in the form of several polyhydrated species.

The distribution of lithium chloride and lithium bromide between aqueous lithium chloride solutions and a benzene solution of Aliquat-336 was studied by Scibona *et al.*[115] Thermodynamic relations were derived for lithium chloride distribution between the two phases, and a thermodynamic equation was derived for the dependence of the observed distribution coefficient of lithium bromide on activity coefficients and concentrations. Explanation was offered for the deviation of the observed distribution coefficient from a simple mass-action law. Using TOA,[116] Sato studied the distribution equilibria of nitric, hydrochloric, perchloric, sulphuric and phosphoric acids between aqueous solutions and benzene solutions of the exchanger. Infrared and partition results indicated that the extraction of the acids was governed by the formation of the monoamine salts of monobasic acids and of the mono- di- (and tri-) amino salts of di- (and tri-) basic acids.

The extraction of chromium(III) from aqueous EDTA (H_4Y) solutions with tetra-n-hexylammonium chloride in dichloroethane was examined by Irving and Al Jarrah.[117] Maximum extraction occurred at pH 4·7. Only the violet complex $CrY(H_2O)^-$ was extracted as the ion-pair $[NR_4]^+[CrY(H_2O)]^-$ (where R = n-hexyl) over the pH range 3·6–6·0. The neutral species $CrHY(H_2O)$ and the two anionic species $CrY(OH)^{2-}$ and $CrY(OH)_2^{3-}$ were not extractable.

A very useful paper by Eubanks,[118] draws attention to limitations which must be imposed on the use of amines, owing to degradation reactions occurring. Available evidence indicated that the amines were frequently degraded by the process chemicals used. Amine reactions were initiated either photochemically or radiolytically and the reaction path usually involved initial reaction of a methylene hydrogen on the carbon atom α to the nitrogen. Tables included showed the radiolysis products for a number of amines and references were given for work which had been reported on air-oxidation of amines, their reactions with the organic solvents most commonly employed, and with reagents such as nitric and nitrous acids.

PRESENT AND FUTURE PROSPECTS FOR LIQUID ION-EXCHANGE

It is 24 years since Smith and Page[119] introduced the technique of liquid ion-exchange. Very little work was done with this analytical technique, except in the field of the transuranic elements, until the early 1960's, despite its obvious possible advantages. This may have been due to the revival of interest in solvent extraction, employing the readily available chelating agents, and the introduction of the synthetic-resin exchangers which took place around the same period. During the last ten years or so it has been realized that liquid ion-exchange has much to offer the analyst—providing as it does both the speed of separation associated with solvent extraction and the selectivity offered by ion-exchange under appropriate conditions. "Where does liquid ion exchange go from here?" is not an easy question to answer. That it will continue to be used increasingly for liquid/liquid extractions and for chromatographic separations is certain. Extractions with mixed exchangers, such as two anion-exchangers[73] or one cation- and one anion-exchanger,[99] or a neutral co-reagent and an exchanger,[98] may open up new possibilities. The use of these exchangers in gas chromatography[101] could be a pointer to further applications. Certainly, the increasing use being made of the organic phase directly, without back-extraction, increases the attractiveness of liquid ion-exchange, and its incorporation as a separation stage in inorganic analysis will become commonplace.

The recent introduction of ion-selective electrodes containing liquid ion-exchangers, or incorporating membranes prepared from exchangers evaporated onto inert supports such as PVC or Bakelite[104–107] has opened up new fields of application, the likely limits of which cannot yet be seen.

APPENDIX

Commonly used anion-exchangers

Adogen 364, a tri-n-alkylamine with 27 carbon atoms on average, consists principally of octyl (60%) and decyl (33%) chains. It contains minimally 95% tertiary amine In the yellow turbid liquid a waxy deposit may form on standing. Average m.w 380

Adogen 368, a pale yellow tri-n-alkylamine, of which the alkyl groups consist principally of octyl (40%), decyl (25%) and dodecyl (30%) chains, has a minimal tertiary amine content of 95%. Average m w 430.

Adogen 464, a methyltri-n-alkylammonium chloride with a yellow-brown colour, has a minimal quaternary ammonium salt content of 92% Average m.w 431.

Alamine-336, a pale yellow liquid ("tricaprylamine") is a tertiary amine with three straight-chain alkyl groups, mainly octyl and decyl. The number of carbon atoms totals 26–32 and the average m w. of the tertiary amine content (min. 90%, typical 95%) is 392.

Aliquat-336, a yellow viscous liquid, obtainable as the chloride, is a methyltri-n-alkylammonium salt ("methyltricaprylammonium chloride") with 27–33 carbon atoms on average. The alkyl groups mainly consist of octyl and decyl chains, and the average m.w. is 475

Amberlite LA-1. A fairly viscous yellow liquid (viscosity at 25° is 72 cp) is an *N*-dodecenyltrialkylmethylamine. The unsaturated amine contains 24–27 carbon atoms and has an average m.w. of 372.

Amberlite LA-2, a yellow liquid with a viscosity of 18 cp at 25°, is a saturated secondary amine, *N*-lauryltrialkylmethylamine, with an average m.w of 374.

Primene JM-T is a yellow primary trialkylmethylamine with 18–24 carbon atoms and an average m w of 311.

Tribenzylamine, TBA, is a white crystalline solid of m.w. 287 (>99% pure).

Tri-iso-octylamine, TIOA, a nearly colourless liquid, has m.w. 353. It contains a mixture of dimethylhexyl, methylheptyl, *etc.* chains, principally 3,5-, 4,5-, and 3,4-dimethylhexyl.

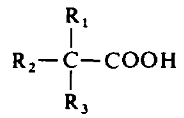
Tri-n-octylamine, TOA, is a colourless liquid of m.w 353.

Commonly used cation-exchangers

Di-(2-ethylhexyl) phosphoric acid (D2EHPA, DEHPA or HDEHP). A dialkylorthophosphoric acid, the exchanger is supplied as a commercial grade and needs purification before use in analysis The method described in *U.S.A. At. Energy Comm. Rept.* ORNL 3548 (1964) is recommended. The monoacidic liquid, after purification, has a sp gr. of 0·97 and m.w. 322. It is the hydrogen atom of the -OH group which undergoes exchange with an equivalent cation.

Dinonylnaphthalene sulphonic acid (DNS). This is a mixture of isomers resulting from the sulphonation of dinonylnaphthalene, which itself is prepared by controlled alkylation of naphthalene with nonene, and is usually supplied by the manufacturers as a 45–50% solution in n-heptane. It is the hydrogen atom of the $-SO_3H$ group which undergoes exchange, as with the sulphonated-resin exchangers.

Versatic 911. A mixture of saturated tertiary monocarboxylic acids of C_9, C_{10} and C_{11} chain length, manufactured from C_9–C_{11} olefines. The structure of Versatic 911 may be represented by



$$R_2-\overset{\displaystyle R_1}{\underset{\displaystyle R_3}{C}}-COOH$$

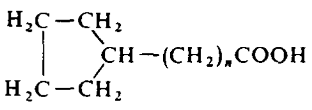
and at least one of the R groups is always methyl. The particular structure of the material distinguishes it from the common straight-chain fatty acids of similar molecular weight. The average m.w. of the water-white Versatic 911 is 175, and the sp.gr. 0·92. The extraction of the metal ion proceeds in a manner analogous to the overall reaction for the cation-exchange resins:

$$R{\cdot}COOH + XCl \longrightarrow R{\cdot}COOX + HCl$$

Excessive contact with the skin should be avoided.

Naphthenic Acids N.A 180 and N.A 230

These acids have the general formula



It will be seen from this formula that they are saturated monocyclic carboxylic acids, the carbon ring being almost invariably five-membered. The two most common naphthenic acids are designated N.A 180 and N A. 230, these numbers representing the acid value in terms of mg of KOH required to neutralize 1 g of the material. They are both clear, bright liquids of sp.gr. 0·98 and contain 8–12% w/w of neutral oil.

Naphthenic acids are not highly toxic, and provided any affected parts of the skin are washed well with soap and water, any slight skin irritation caused by exposure to these acids is not unduly dangerous.

Some manufacturers of these ion exchangers are as follows,

The Adogens	Archer-Daniels-Midland Co, Minneapolis, Minn. U S A

The Amberlites and Primene JM-T	Rohm and Haas Co , Philadelphia, Pa. U.S.A.

THE KINETICS OF OXIDATION OF SELENOSEMICARBAZIDE BY OXYGEN IN THE PRESENCE OF CUPRIC IONS

A. I. BUSEV and K. M. AKHMEDLY
M V Lomonosov Moscow State University Moscow V-234, U.S.S.R.

(*Received* 30 *June* 1972. *Accepted* 22 *August* 1972)

Summary—In acidic medium selenosemicarbazide undergoes oxidation by oxygen, dissolved in water, in the presence of copper(II) as a catalyst The oxidation product exhibits an activating effect The kinetics of the reaction have been investigated and the kinetic equations deduced both for small and high concentrations of the oxidation product The constants involved in the kinetic equations deduced have been calculated. The proposed mechanism of the reaction agrees with the experimental results. The oxidation product is supposed to be the bis-selenosemicarbazidinium cation The postulation of formation of this cation is based on the electronic structure and reactivity of selenosemicarbazide. The reaction can be used for copper determination

Crystalline selenosemicarbazide–copper(II) complexes have been reported.[1] In the course of our study of the formation of such complexes in aqueous solutions, we have found that the yellow solution containing selenosemicarbazide–copper(II) in acidic medium is decolorized on standing. The decrease in the absorbance has been found to be due to disappearance of selenosemicarbazide (SSC). The reaction rate depends on the concentrations of copper, acid and oxygen, dissolved in water. The copper acts as a catalyst and the oxygen concentration decreases with time. The conclusion drawn is that SSC undergoes a catalytic oxidation by oxygen, dissolved in water, in the presence of copper(II).

It has been found that other metal ions either do not catalyse this reaction at all or have much lower catalytic activities. Therefore this reaction can be used to develop a rather sensitive and selective kinetic method for copper determination.

EXPERIMENTAL

Reagents

SSC was prepared by the method reported by Huls and Renson.[2] The purity was checked by means of the melting point

Copper solutions were prepared from analytically pure cupric nitrate and standardized electrolytically.

Chemically pure perchloric acid was used for the acidic medium, because it has no absorption in the ultraviolet region, has little tendency for complexation or ion-association and does not oxidize SSC in the absence of cupric ions or/and oxygen

Procedure

Absorbances were measured at 262 nm, the wavelength of maximum absorption by SSC in strongly acidic medium, and at 364 nm, near the absorption maximum of the SSC–Cu(II) complex (350 nm)

Reaction rates were determined by graphical differentiation of the absorbance *vs* time curves

RESULTS AND DISCUSSION

Figure 1 shows a typical absorbance–time curve, which is similar to the curves of autocatalytic reactions. Therefore we have reason to suppose that the reaction product activates the catalyst, and the following dependence is to be examined

$$\frac{dC_X}{dt} = f(C_{SSC}, [H^+], [O_2], C_{Cu}, C_X)\cdot F, \tag{1}$$

where C represents the total concentration of the species indicated by suffix, the equilibrium concentrations are in square brackets, X is the oxidation product, and F is the activity factor.

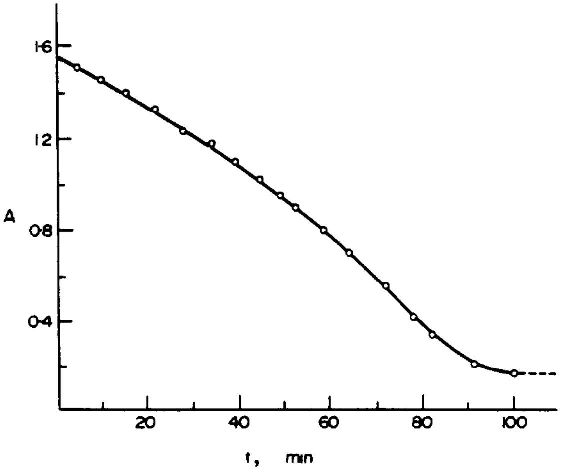

Fig. 1. The change of absorbance with time

λ 262 nm, $l = 1$ cm, $C^0_{SSC} = 2 \times 10^{-4}M$,
$C_{Cu} = 1 \times 10^{-5}M$, $C_{HClO_4} = 0.64M$.

In order to find the reaction-rate dependence on the SSC concentration, curves similar to that given in Fig. 1 were obtained at constant initial concentrations of all reaction components except SSC, the initial concentration of which was varied. All the curves appear identical, and this fact allows us to conclude that the rate is independent of C_{SSC}. This statement is, however, valid only in the presence of an excess of SSC relative to copper. That is why all the calculations have been made with large $C_{SSC} : C_{Cu}$ ratios.

Similarly at constant concentration of all the reaction components except copper the absorbance–time curves were measured to find the reaction order with respect to C_{Cu}. Constancy of $[H^+]$ and $[O_2]$ was achieved by using a large excess. The reaction rates were compared at equal ΔA values (ΔA = change in absorbance from the beginning of the reaction) to ensure constancy of C_X. The reaction appeared to be first-order with respect to copper.

To determine the reaction-rate dependence on the acidity and the concentration of X, we varied $[H^+]$ and plotted $-dA/dt$, which is proportional to the reaction rate dC_X/dt, against ΔA, which is similarly proportional to the reaction product concentration. The variation of the oxygen concentration in the course of reaction was neglected because this variation, as will be seen later, is insignificant. These plots, given in Fig. 2a, show

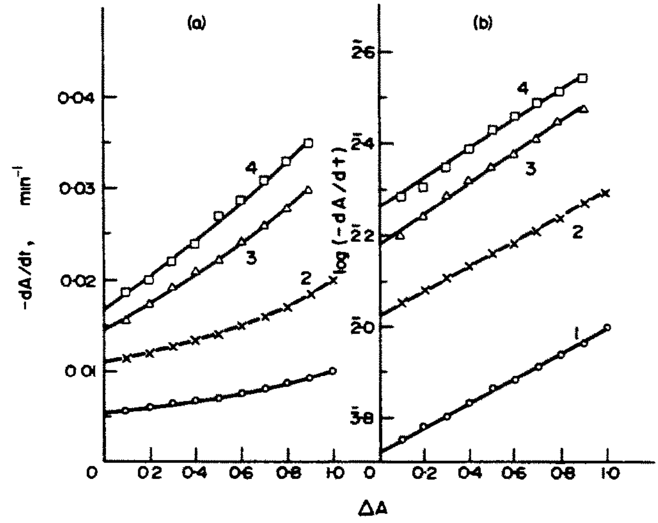

Fig. 2. Plot of the rate of absorbance change (*a*) and the logarithm of this rate (*b*) against the absorbance change from the beginning of the reaction ($\Delta A = A_0 - A$).

λ 262 nm, $l = 1$ cm, $C^0_{SSC} = 2 \times 10^{-4} M$, $C_{Cu} = 1 \times 10^{-5} M$,
$C_{HClO_4} = 0.32M$(1), $0{\cdot}64M$ (2), $0{\cdot}96M$ (3), $1{\cdot}28M$ (4)

that the higher the ΔA values the more the deviation of these curves from a straight line. A plot of the logarithm of the rate against ΔA (Fig. 2b) gives a set of parallel straight lines, with some deviations due to errors arising from graphical differentiation. It can therefore be accepted that the reaction rate depends exponentially on C_X.

To find the dependence of the reaction rate on $[H^+]$, the rate of absorbance change was plotted against $[H^+]$ at various constant ΔA values. It is clear from Fig. 3 that this dependence is linear, and the reaction is first-order with respect to $[H^+]$. Deviations at higher $[H^+]$ values may be attributed to salt effects and therefore related to the activity factor F. The kinetic equation may now be written as

$$\frac{dC_X}{dt} = K_1([O_2]) \cdot [H^+] \cdot C_{Cu} \cdot \exp(K_2 C_X) \cdot F \qquad (2)$$

This equation, however, appears to be valid only at not too high C_X values. Figure 4 shows the absorbance change when C_{SSC} and C_{Cu} are ten times the values used earlier. The curve assymptotically approaches the final value of A. Subsequent saturation of the solution with oxygen, by shaking it with air, leads to complete oxidation of SSC. So the decrease in the reaction rate is due to the dissolved oxygen being used up. After the lapse of some time from the beginning of the reaction the curve exhibits no dependence on the reaction product concentration. Probably, when C_X becomes sufficiently high, the reaction step in which the oxidation product X participates no longer determines the reaction rate and the step in which the oxygen participates becomes rate-determining. Then the kinetic equation may be written as

$$\frac{dC_X}{dt} = K \cdot [H^+] \cdot [O_2]^p \cdot C_{Cu} \cdot F \qquad (3)$$

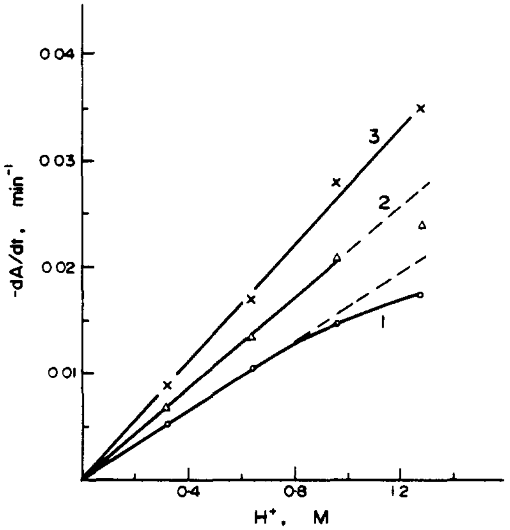

Fig. 3. Plot of the reaction rate against the hydrogen ion concentration at constant values of $\Delta A = A_0 - A$.

$\Delta A = 0$(1), 0·4 (2), 0·8 (3).

The curve in Fig. 4 allows us to find the reaction order p with respect to the oxygen concentration. Let the total reaction equation be

$$m\text{SSC} + q\text{O}_2 \longrightarrow n\text{X} \tag{4}$$

then the oxygen concentration at every instant of time is equal to

$$[\text{O}_2] = [\text{O}_2]_0 - \frac{q}{m}(C^0_{\text{SSC}} - C_{\text{SSC}}) \tag{5}$$

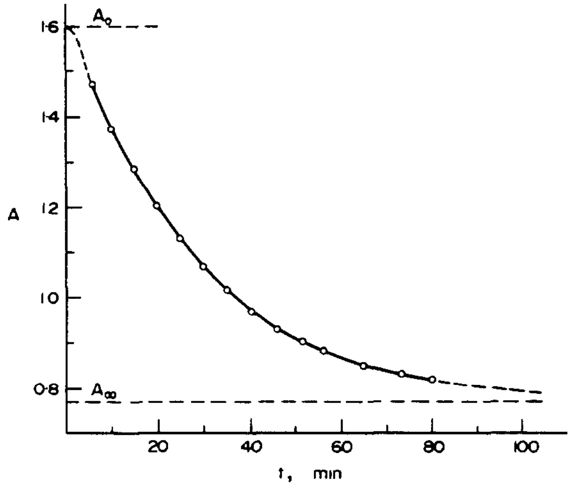

Fig. 4. The change of absorbance with time.
λ 262 nm, $l = 0·1$ cm, $C^0_{\text{SSC}} = 2 \times 10^{-3}M$,
$C_{\text{Cu}} = 1 \times 10^{-4}M$, $C_{\text{HClO}_4} = 1·6M$

where $[O_2]_0$ and C^0_{SSC} are initial concentrations. The reaction obviously stops when $[O_2]$ falls to zero and, hence, equation (5) leads to

$$[O_2]_0 = \frac{q}{m}(C^0_{SSC} - C^{\infty}_{SSC}) \tag{6}$$

where C^{∞} indicates the final concentration. Equations (5) and (6) give

$$[O_2] = \frac{q}{m}(C_{SSC} - C^{\infty}_{SSC}) \tag{7}$$

By substituting this value in equation (3) we obtain

$$\frac{dC_X}{dt} = K \cdot [H^+] \cdot \left(\frac{q}{m}\right)^p \cdot (C_{SSC} - C^{\infty}_{SSC})^p \cdot C_{Cu} \cdot F$$

Assuming $[H^+]$, C_{Cu} and F to be constant and using absorbances instead of concentrations, we obtain

$$-\frac{dA}{dt} = \text{const} \cdot (A - A_{\infty})^p$$

The plot of $-dA/dt$ against $(A - A_{\infty})$ is given in Fig. 5. At low values of $(A - A_{\infty})$, corresponding to lower $[O_2]$ and higher C_X values, the plot shows a linear dependence. The higher $[O_2]$ and lower C_X values give deviation from the straight line. This may be due to the influence of the slower step in which the oxidation product participates. So the reaction is first-order with respect to oxygen concentration, and equations (2) and (3) can be rewritten as

$$\frac{dC_X}{dt} = K_1[H^+][O_2]C_{Cu} \cdot \exp(K_2 C_X) \cdot F \tag{8}$$

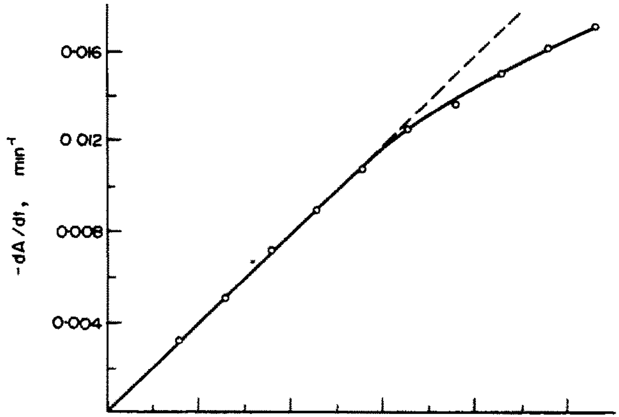

Fig 5 Plot of the reaction rate against the concentration of oxygen. λ 262 nm, $l = 0.1$ cm, $C^0_{SSC} = 2 \times 10^{-3} M$, $C_{Cu} = 1 \times 10^{-4} M$, $C_{HClO_4} = 1.6 M$.

and

$$\frac{dC_X}{dt} = K_3[H^+][O_2]C_{Cu}\cdot F \tag{9}$$

Equation (8) holds good for low values of C_X and equation (9) for high values of C_X.

The results enable us to determine the constants involved in equations (8) and (9). By using absorbances and assuming that m molecules of SSC yield n molecules of X, we obtain from (8)

$$-\frac{dA}{dt} = \frac{m}{n}\left(\varepsilon_{SSC} - \frac{n}{m}\varepsilon_X\right)l\cdot K_1[H^+][O_2]C_{Cu}\exp\left\{\frac{\frac{n}{m}K_2}{\left(\varepsilon_{SSC} - \frac{n}{m}\varepsilon_X\right)l}\cdot \Delta A\right\}\cdot F \tag{10}$$

where ε_{SSC} and ε_X are the molar absorptivities of SSC and X respectively at the wavelength employed and l is the pathlength. The value of $n\varepsilon_X/m$ can be easily found from the final absorbance of the reaction mixture: $A_\infty = n\varepsilon_X C^0_{SSC}\,l/m$. At the wavelength 262 nm $\varepsilon^{262}_{SSC} = 8{\cdot}0\times 10^3$ and $n\varepsilon^{262}_X/m = 0{\cdot}8\times 10^3$l. mole^{-1}. cm^{-1}.

The oxygen concentration can be estimated from the solubility in water,[3] approximately $2{\cdot}8\times 10^{-4}M$.

The value of K_1 is now easily determined from the slope of the straight line corresponding to $\Delta A = 0$ in Fig. 3 (assuming $F = 1$). By use of equation (10) an approximate value of $K_1 \sim 830$ n/m l^2. mole^{-2}. min^{-1} is obtained.

The value of K_2 in equation (8) can be estimated from the slope of the straight lines in Fig. 2*b* (after changing to natural logarithms). The approximate value of K_2 is $5{\cdot}0\times 10^3$ m/n l. mole^{-1}.

The value of the constant K_3 in (9) can be obtained by using Figs. 4 and 5. It can be seen from Fig. 4 that $A_0 - A_\infty = 0{\cdot}83$. This corresponds to the SSC concentration decreasing by $C^0_{SSC} - C^\infty_{SSC} = (A - A_\infty)/(\varepsilon_{SSC} - n\varepsilon_X/m)l \sim 1{\cdot}15\times 10^{-3}M$.

Dividing this quantity by the initial concentration of oxygen, $[O_2]_0 \sim 2{\cdot}8\times 10^{-4}M$, the number of SSC molecules oxidized by one oxygen molecule is obtained, *viz.* 4. Now according to (7)

$$[O_2] = \tfrac{1}{4}(C_{SSC} - C^\infty_{SSC}),$$

so (9) (using absorbances) transforms to

$$-\frac{dA}{dt} = \frac{1}{4}\cdot\frac{m}{n}\cdot K_3\cdot[H^+]\cdot(A - A_\infty)\cdot C_{Cu}\cdot F$$

Now from the straight part of the curve in Fig. 5 an approximate value of K_3 (corresponding to $1{\cdot}6M$ perchloric acid) is obtained: $K_3\cdot F \sim 1{\cdot}0\times 10^3$ n/m l^2. mole^{-2}. min^{-1}.

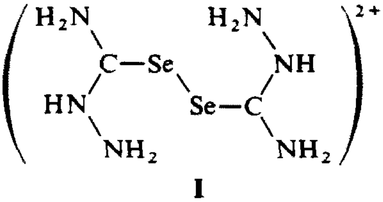
REACTION MECHANISM

In order to establish the stoichiometry of the copper(II) complex with SSC in solution the isomolar series method was used. The measurements were carried out in neutral medium (where the oxidation process does not take place) at 364 nm. Only the complex corresponding to the molar ratio Cu(II) : SSC = 1 : 2 was observed. On account of this and the composition of the complex in the crystalline state,[1] and by analogy with thiosemicarbazide–copper(II) in solution,[4] we believe that the $Cu(SSC)_2^{2+}$ complex species exists in solution. By passage of the solution through a column containing a cation-exchange resin the complex was confirmed to be positively charged.

The spectrum of the complex undergoes no change in strongly acidic medium, which shows that also under redox reaction conditions copper exists as the same species $Cu(SSC)_2^{2+}$. The absorbance measurements at 364 nm during the course of the reaction indicate that the concentration of the complex does not change up to the point of inflexion on the curve for change of the absorbance measured at 262 nm. This means that the complexation equilibrium does not shift during the course of the reaction (till there is an excess of SSC), and this is possible only if the copper is almost completely used in complex formation.

It has been mentioned earlier that the reaction rate is independent of the SSC concentration and is proportional to the total concentration of copper. In view of these conclusions it may be said that it is only the $Cu(SSC)_2^{2+}$ complex species which is responsible for the reaction, and the free SSC molecules do not participate directly in the redox reaction.

So far as the SSC oxidation product is concerned, it has been shown in the previous section that one oxygen molecule is used for oxidation of 4 SSC molecules. In other words every SSC molecule loses only one electron. The SSC molecule which has lost one electron has an unpaired electron left. The boundary electron density distribution corresponding to the highest occupied molecular orbital of the SSC molecule now represents the electron spin density distribution on an SSC molecule which has lost one electron (Fig 6). The diagram shows that the spin density is almost completely concentrated on the selenium atom. This must lead to a high probability for linking of two such molecules together through the selenium atoms, resulting in the formation of the bis-selenosemicarbazidinium cation (BSSC, I)



I

A similar cation is also formed during the oxidation of selenourea by hydrogen peroxide in acidic medium.[5]

Figure 6 also gives the charge distribution in an SSC molecule which has lost one electron. It can be proposed that in BSSC the charge distribution should be almost the same. The diagram demonstrates that the positive charge is mainly concentrated on the carbon and selenium atoms, but not on the nitrogen atoms as might have been thought. The same thing should hold true for the cation resulting from selenourea oxidation.[5]

The BSSC formation must be accompanied by disappearance of the SSC absorption band, related to the negative charge-transfer from selenium to carbon and the loosening of the C=Se bond, which is observed during the course of the reaction.

Thus we believe that BSSC is the SSC oxidation product. Then the catalytic effect of copper becomes clear. First, the cupric ion serves as a matrix on which two properly

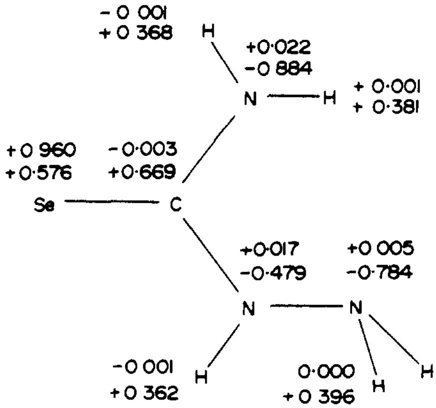


Fig. 6. The diagram of electron spin density distribution (upper figures) and effective charge distribution (lower figures) in an SSC molecule which has lost one electron. The calculations were carried out by Hoffmann's method

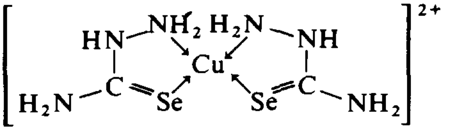
arranged adjacent SSC molecules (in a rather stable square planar complex with SSC ligands, which seem to be in a *cis*-arrangement, II), get a chance to lose two electrons simultaneously (each SSC ligand losing an electron) and to link together through the selenium atoms. Secondly, the copper, complexes of which are often able to co-ordinate molecular oxygen, serves as medium for electron-transfer from SSC to oxygen. It is obvious that the need for the metal ion to serve in the two capacities makes the reaction rather selective with respect to copper as a catalyst.



II

Taking into account the arguments above we can advance a mechanism for the SSC oxidation. First, complex formation is achieved and the corresponding equilibrium obtained very rapidly:

$$Cu^{2+} + 2SSC \rightleftharpoons Cu(SSC)_2^{2+} \tag{11}$$

The next step seems to be the formation of the activated complex by an oxygen molecule and hydrogen ion adding to $Cu(SSC)_2^{2+}$:

$$Cu(SSC)_2^{2+} + O_2 + H^+ \rightleftharpoons Cu(SSC)_2(O_2H)^{3+} \tag{12}$$

Such a suggestion is favoured by the kinetic data given in the previous section. The activated complex is unstable and easily decomposes into BSSC and a peroxide complex $Cu(O_2H)^+$:

$$Cu(SSC)_2(O_2H)^{3+} \longrightarrow BSSC^{2+} + Cu(O_2H)^+ \tag{13}$$

After this the activation effect of the oxidation product is initiated. It is difficult to say anything precise about this activation mechanism. However, it can be supposed that the reaction product together with the first activated complex $Cu(SSC)_2(O_2H)^{3+}$ yields in a few steps some additional superactivated complexes. Each of them easily decomposes in the same manner as in reaction (13):

$$\begin{aligned} \mathrm{Cu(SSC)_2(O_2H)^{3+} + BSSC^{2+}} &\rightleftharpoons \mathrm{Cu(SSC)_2(O_2H)^{3+}, BSSC^{2+}} \\ \mathrm{Cu(SSC)_2(O_2H)^{3+}, BSSC^{2+} + BSSC^{2+}} &\rightleftharpoons \mathrm{Cu(SSC)_2(O_2H)^{3+}, 2BSSC^{2+}} \qquad (14) \\ \ldots\ldots & \end{aligned}$$

$$\begin{aligned} \mathrm{Cu(SSC)_2(O_2H)^{3+}, BSSC^{2+}} &\longrightarrow \mathrm{Cu(O_2H)^+ + 2BSSC^{2+}} \\ \mathrm{Cu(SSC)_2(O_2H)^{3+}, 2BSSC^{2+}} &\longrightarrow \mathrm{Cu(O_2H)^+ + 3BSSC^{2+}} \qquad (15) \\ \ldots\ldots & \end{aligned}$$

The number of steps in (14) is difficult to define. However, taking into account that the plots of the reaction rate against C_X, given in Fig. 2*a*, deviate from straight lines towards higher rates with increase in C_X, it can be stated that the number of steps in (14) is more than one.

The peroxide ion $\mathrm{Cu(O_2H)^+}$ can dissociate into the $\mathrm{(O_2H)^-}$ anion which afterwards forms a hydrogen peroxide molecule. In this case it is assumed that hydrogen peroxide subsequently oxidizes two additional SSC molecules. Hydrogen peroxide has been found to oxidize SSC rather rapidly even in the absence of copper ions. If such an assumption is accepted, then this reaction step will not affect the reaction rate, because it succeeds reactions (13) and (14) and is not rate-determining.

However, it is more likely that the $\mathrm{Cu(O_2H)^+}$ ion co-ordinates two SSC molecules

$$\mathrm{Cu(O_2H)^+ + H^+ + 2SSC} \rightleftharpoons \mathrm{Cu(SSC)_2(H_2O_2)^{2+}} \qquad (16)$$

yielding a new activated complex which subsequently decomposes:

$$\mathrm{Cu(SSC)_2(H_2O_2)^{2+}} \longrightarrow \mathrm{BSSC^{2+} + Cu^{2+} + 2OH^-} \qquad (17a)$$

$$\mathrm{Cu(SSC)_2(H_2O_2)^{2+} + H^+} \longrightarrow \mathrm{BSSC^{2+} + Cu^{2+} + OH^- + H_2O} \qquad (17b)$$

$$\mathrm{Cu(SSC)_2(H_2O_2)^{2+} + 2H^+} \longrightarrow \mathrm{BSSC^{2+} + Cu^{2+} + 2H_2O} \qquad (17c)$$

Then the copper ions evolved participate in reaction (11) and the whole cycle is repeated. It will be seen that the type of the kinetic equation is independent of the type of reaction (17), because the reactions (13) and (17) are irreversible.

To deduce the kinetic equation corresponding to the proposed reaction mechanism, we employed a graph method.[6] The constancy of the $\mathrm{Cu(SSC)_2^{2+}}$ concentration enabled us to use the approximation of stationary concentrations. Figure 7 represents

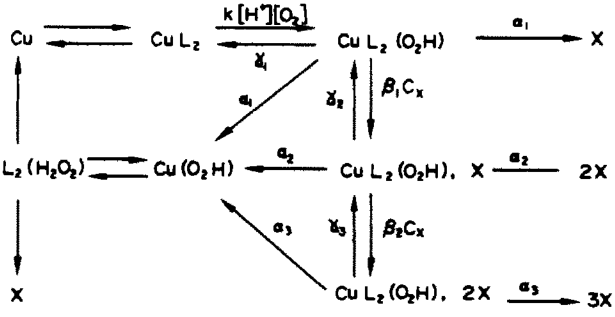


Fig 7 Mechanism of the catalytic oxidation of SSC

$\mathrm{L = SSC, X = BSSC^{2+}}$

graphically the sequence of reactions (11)-(12)-(13)-(14)-(15)-(16)-(17*a*)-(11) with only two steps in (14).

The total reaction rate is given by Mason's equation:[6]

$$\frac{dC_X}{dt} = \frac{\sum_i \det(i) \cdot V_i}{\sum_i \det(i)} \cdot C_{Cu} \tag{18}$$

where det(*i*) is the determinant of the *i*th apex and V_i is the rate of reaction-product formation in the *i*th apex.

Under the conditions of our investigation, as soon as practically all the copper exists as the $Cu(SSC)_2^{2+}$ complex species, we can neglect all the determinants in the denominator of equation (18) except $\det\{Cu(SSC)_2^{2+}\}$ and obtain a simpler equation

$$\frac{dC_X}{dt} = \frac{\sum_i \det(i) \cdot V_i}{\det\{Cu(SSC)_2^{2+}\}} \cdot C_{Cu}. \tag{19}$$

After calculating all the determinants from Fig. 7 and putting them in Eq. (19) and after some transformations we obtain finally

$$\frac{dC_X}{dt} = \frac{2k[H^+][O_2]C_{Cu}(\mathbf{A} + \mathbf{B} \cdot C_X + \mathbf{D} \cdot C_X{}^2)}{\mathbf{E} + \mathbf{F} \cdot C_X + \mathbf{D} \cdot C_X{}^2} \tag{20}$$

where

$$\mathbf{A} = a_1(1 + a_2 + a_3 + a_2 a_3)$$
$$\mathbf{B} = b_1 a_2(1 + a_3) + a_1 b_2 a_3$$
$$\mathbf{D} = b_1 b_2 a_3$$
$$\mathbf{E} = 1 + a_1 + a_2 + a_3 + a_1 a_2 + a_1 a_3 + a_2 a_3 + a_1 a_2 a_3$$
$$\mathbf{F} = b_1 a_2(1 + a_3) + b_2 a_3(1 + a_1)$$
$$a_i = \frac{\alpha_i}{\gamma_i},\ b_i = \frac{\beta_i}{\gamma_i}$$

and k, α, β and γ are the rate constants, indicated in Fig. 7.

Let us analyse equation (20) at low and high values of the reaction product concentration C_X. It is evident that at small C_X values the terms containing C_X in the denominator of (20) can be neglected. Then the equation reduces to

$$\frac{dC_X}{dt} = \frac{2k\mathbf{A}}{\mathbf{E}} \cdot [H^+][O_2]C_{Cu}\left(1 + \frac{\mathbf{B}}{\mathbf{A}} C_X + \frac{\mathbf{D}}{\mathbf{A}} C_X{}^2\right) \tag{21}$$

If we suppose that the magnitude of the constant **D** approaches $\mathbf{B}^2/2\mathbf{A}$, then the expression in parentheses in (21) represents the first three terms of the expansion of $\exp(K \cdot C_X)$, where $K = \mathbf{B}/\mathbf{A}$. Then good agreement with the empirical equation (8) is achieved.

At higher values of C_X the term containing the highest power of C_X, $\mathbf{D} \cdot C_X{}^2$, predominates both in the numerator and in the denominator of (20). Therefore, in this boundary case equation (20) reduces to

$$\frac{dC_X}{dt} = 2k[H^+][O_2]C_{Cu} \tag{22}$$

which corresponds perfectly to the empirical kinetic equation (9).

Thus the proposed reaction mechanism leads to good agreement with experiment. However, this mechanism has certain shortcomings. In some steps it requires the interaction of several highly-charged species. This must lead to a strong dependence of the reaction rate on the ionic strength of the solution, but the results we have obtained indicate that the activity factor *F* is rather constant over a wide range of ionic strengths (from ~0·3 to ~1·0) and seems to be near unity. Only when the ionic strength exceeds unity does *F* begin to decrease rapidly, resulting in a negative salt effect.

In order to bring these facts into agreement with the proposed mechanism it can be supposed that some of the (positively) charged species take part in the reaction as neutral ion-association complexes with the perchlorate anions present, so that in each step not more than one charged species participates simultaneously. From recent publications it is seen that there is a reasonable probability that such complexes exist.

The kinetic method for copper determination will be described separately.

Zusammenfassung—Selenosemicarbazid erleidet in saurem Medium in Gegenwart von Kupfer(II) als Katalysator Oxidation durch im Wasser gelosten Sauerstoff. Das Oxidationsprodukt zeigt einen aktivierenden Effekt Die Kinetik der Reaktion wurde untersucht, für kleine und große Konzentrationen des Oxidationsprodukts wurden kinetische Gleichungen abgeleitet. Die Konstanten in den abgeleiteten kinetischen Gleichungen wurden berechnet. Der vorgeschlagene Reaktionsmechanismus stimmt mit den experimentellen Ergebnissen überein. Es wird vermutet, daß das Reaktionsprodukt das Bis-selenosemicarbazidinium-Kation ist. Die Annahme der Bildung dieses Kations beruht auf der elektronischen Struktur und Reaktivitat von Selenosemicarbazid Die Reaktion kann zur Kupferbestimmung verwendet werden.

Résumé—En milieu acide, le sélénosemicarbazide subit l'oxydation par l'oxygène dissous dans l'eau, en la présence de cuivre (II) comme catalyseur Le produit d'oxydation présente un effet activateur On a étudié la cinétique de la réaction et déduit les équations cinétiques pour les concentrations aussi bien faibles qu'élevées du produit d'oxydation On a calculé les constantes impliquées dans les équations cinétiques déduites Le méchanisme proposé pour la réaction est en accord avec les résultats expérimentaux. On suppose que le produit d'oxydation est le cation bis-sélénosemicarbazidinium L'hypothèse de formation de ce cation est basée sur la structure électronique et la réactivité du sélénosemicarbazide On peut utiliser la réaction pour le dosage du cuivre

SPECTROPHOTOMETRIC PROCEDURE USING RHODAMINE B FOR DETERMINATION OF SUBMICROGRAM QUANTITIES OF ANTIMONY IN ROCKS*

MARIAN M. SCHNEPFE
U.S Geological Survey, Washington, D C 20242, U.S.A.

(*Received* 22 *May* 1972. *Accepted* 18 *August* 1972)

Summary—A spectrophotometric procedure using Rhodamine B is given for the determination of antimony in mineralized rocks after its separation as stibine A study of the Rhodamine B reaction points to the importance of the order of addition of reagents in enhancing sensitivity and increasing the stability of the system The tolerance of some 26 elements is established for the overall procedure Although the limit of determination is approximately 0·5 ppm Sb in a 0 2-g sample, the procedure is intended primarily for screening samples containing more than 1 ppm Sb. In pure solutions 0 1 μg of antimony can be determined with a relative standard deviation of 25%. For >0·2 μg of antimony a relative standard deviation of 15% or less can be expected

Geochemical studies of the antimony content of rocks require accurate and reasonably rapid methods for the determination of antimony at the submicrogram level. Although neutron-activation methods are sufficiently sensitive,[1,2] they require expensive instrumentation. Emission spectrographic procedures require preconcentration to attain the required sensitivity and to ensure representative sampling.[3,4] Atomic-absorption spectrophotometric procedures have been applied to the determination of antimony but at present are not sensitive enough for most rock samples.[5–8] Higher sensitivity may be obtained for antimony by atomic-fluorescence[9] and atomic-absorption methods using high-temperature flameless volatilization techniques.[10] However, these methods are not as yet directly applicable to geological materials.

Optical spectrophotometric procedures for the determination of antimony involving Rhodamine B have been widely investigated[11–21] and found to have considerable sensitivity but to suffer interference from gold, gallium, silver and thallium and from iron when present in moderate amounts. However, the procedures have been of limited use at the submicrogram level owing to lack of precision. Triphenylmethane dyes offer rather better sensitivity but are subject to more interferences.[22]

This paper investigates the conditions that will permit the rapid and reasonably precise determination of submicrogram quantities of antimony in rocks. These conditions include the sample decomposition, the stibine generation, its absorption into mercuric chloride, the antimony oxidation and the benzene extraction of a Rhodamine B chloroantimonate. The variation in the absorbance of the Rhodamine B–chloroantimonate product with the order of reagent addition is shown. This method is applied to the determination of antimony in two standard rock samples previously analysed by radiochemical techniques.

EXPERIMENTAL

Reagents

Tartaric acid solution, 10% *w/v*

Zinc shot (low in antimony content)

Cadmium sulphate solution, 5% *w/v*

Mercuric chloride–hydrochloric acid solution, Mercuric chloride 0·5% *w/v* in 6*M* hydrochloric acid

Ceric sulphate solution, 0·2*M*. Dissolve 10·6 g of tetrasulphatoceric acid, $H_4Ce(SO_4)_4$, in 80 ml of water, add 5·56 ml of sulphuric acid (1 + 1) and dilute to 100 ml.

Rhodamine B solution, 0·2% *w/v*

Rhodamine B-hydroxylamine hydrochloride solution A 0·1% *w/v* Rhodamine B and 1% w/v hydroxylamine hydrochloride solution. Prepare daily

Standard antimony solution, 100 *μg/ml* Dissolve 0·274 g of potassium antimonyl tartrate hemihydrate in 1 litre of 2·5% v/v sulphuric acid. Prepare other standards by appropriate dilution Dilute solutions should not be used if more than a week old

Apparatus

Hydride generator. An arsine generator, described by the Committee on Analytical Reagents,[23] has been modified as shown in Fig. 1 The absorber of the arsine generator has been replaced with a delivery tube, 14 cm long, which is bent at right angles so that it leads directly into a 60-ml separatory funnel

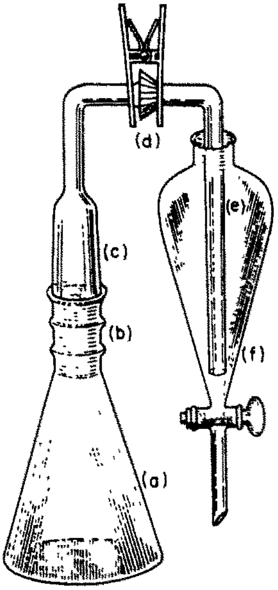

Fig 1. Hydride generator *a*, 125-ml generator flask, *b*, standard taper (24/40), *c*, scrubber, *d*, ball socket joint (12/3), *e*, delivery tube, *f*, 60-ml separatory funnel

Procedure

Fuse 1·5 g of potassium pyrosulphate in a quartz or Vycor crucible until the moisture is removed Add 0·200 g of sample and fuse for 10–15 mins Add 14 ml of water and 1 ml of tartaric acid solution to the crucible and dissolve the melt by heating on a steam-bath Transfer the resulting solution to the hydride generator flask Wash the crucible with approximately 4 ml of water followed by 40 ml of sulphuric acid (1 + 1). Transfer the washings to the generator flask and add 1 ml of cadmium sulphate solution Cover, and bring the resulting solution to a boil Cool the flask to 20–25°

Add 15 g of zinc shot to the generator flask and quickly connect the scrubber/delivery-tube assembly to the generator and insert the delivery tube into the separatory funnel containing 20 ml of the mercuric chloride-hydrochloric acid solution After 2 hr, remove the delivery tube from the separatory funnel and discard the contents of the generator flask Add 10·0 ml of benzene to the separatory funnel, followed by

0.5 ml of cerium(IV) solution, and shake for 1 min. Add 10 ml of the Rhodamine B-hydroxylamine hydrochloride solution and shake for 1 min. After the phases have separated, drain and discard the aqueous layer. Wash the benzene phase by shaking with 10 ml of 4*M* hydrochloric acid for 1 min and discard the aqueous phase. Repeat the washing.

Drain the organic phase into a small glass beaker and transfer it into a 15-ml centrifuge tube, holding back the aqueous droplets in the beaker. Centrifuge for 2 min and then measure the absorbance at 550 nm *vs* benzene, using 5-cm cells. If the absorbance is greater than 0·6, use 1-cm cells.

Prepare two standard curves, one for 0–1·0 μg and the other for 1–10 μg of antimony. Generate stibine from flasks containing 1.5 g of potassium pyrosulphate, collect it in mercuric chloride solution and then proceed as for samples.

DISCUSSION

Conditions for the generation and collection of stibine

In preliminary work on the separation of antimony by the generation of stibine, amalgamated zinc was reacted with 9*M* hydrochloric acid according to the recommendations of Zaikovsky.[24] This system was abandoned in favour of the simpler system described by Dal Cortivo *et al*[25] in which stibine is formed by the reaction of a sulphuric acid solution of cadium sulphate with 20-mesh zinc, these concentrations being approximately the same as those prescribed in this paper. The reaction between the acid and the 20-mesh zinc proved to be very rapid, especially if such elements as iron were present. Amalgamation of the 20-mesh zinc resulted in essentially no reaction with the acid solution. Substitution of zinc shot proved to be very satisfactory.

Also investigated were the effects of varying the concentrations of the acid and the cadmium sulphate, the amount of the zinc, the temperature of the reaction medium, and the solution volume. With cadmium sulphate fixed at 100 and 500 mg in a 55-ml volume, the concentration of the sulphuric acid was increased from 3 to 8*M*, in increments of 1 mole/l. The reaction rate between the acid and the zinc shot decreased with increasing sulphuric acid concentration and was excessively slow with $>7M$ sulphuric acid. Slightly higher concentrations of sulphuric acid were tolerated at the higher cadmium sulphate level. The recovery of 10 μg of antimony increased from 80% at 3*M* acid to approximately 100% between 5 and 7*M* acid. With 8*M* sulphuric acid recovery decreased to 20% owing to the negligible reaction during the reaction period of 1 hr.

The concentration of the cadmium sulphate was varied from 0 to 1·5 g in a 55-ml volume with little change in antimony recoveries. With 6*M* sulphuric acid and 15 g of zinc shot, the recovery of 10 μg of antimony increased from 82% in the absence of cadmium sulphate to approximately 100% with 25 mg or more of cadmium sulphate.

A 15-g amount of zinc shot was found to be sufficient for the reaction period with some margin of surplus. Ideally the amount of zinc that dissolves should be the same for all samples and standards. However, the presence of Co, Fe, Ge, Ni and Pt accelerates the reaction rate between the acid and the zinc, whereas Bi, Hg and Tl decrease the rate. For this reason the purity of the zinc is of extreme importance especially if submicrogram quantities of antimony are to be determined.

The effect of the temperature of the solution in the hydride generator flask on the recovery of 10 μg of antimony was investigated by both cooling and heating the solution either before the zinc addition or during some part of the reaction period. A greater tolerance for some metals, *e.g.*, iron, is obtained when the reaction flask is cooled, whereas for others, *e.g.*, copper, heating of the reaction medium proves favourable. It is difficult to predict the best conditions for a given sample but, generally, for rock samples best results can be expected if the solution is at 20–25° before the addition of zinc.

Because of the variation in reaction rate from sample to sample, a 2-hr period for stibine generation is recommended.

Increasing the volume of the acid solution did decrease the interference of certain elements but at the same time decreased the recovery of antimony, probably because of the correspondingly greater amount of stibine dissolved.

Webster and Fairhall[11] found that 20 ml of 6% mercuric chloride solution in $6M$ hydrochloric acid effectively absorbed 100 ml of gas containing 200 ppm of stibine, at a flow-rate of approximately 4 l./min. Because the procedure presented in this paper is designed for antimony at levels not to exceed 10 μg in a 0·2-g sample, the concentration of the mercuric chloride may be decreased. Stibine corresponding to 30 μg of antimony was generated and passed into 20 ml of $6M$ hydrochloric acid containing 0, 50, 100, 200, 400 or 600 mg of mercuric chloride. The antimony recovery was 0% in the absence of mercuric chloride and approximately 100% in the presence of 50–600 mg of mercuric chloride. A 100-mg mercuric chloride level was arbitrarily adopted.

Effect of the hydrochloric acid concentration on the oxidation and the benzene extraction

Antimony is oxidized to the quinquevalent state by cerium(IV) in $6M$ hydrochloric acid.[12] However, the benzene extraction of the Rhodamine B chloroantimonate at this acidity gave low antimony recoveries. Increasing the hydrochloric acid concentration to $8M$ resulted in even lower recoveries. Neumann and Ramette[26] found that hydrogen ion accelerates the hydrolysis of the hexachloroantimonate ion. Ramette and Sandell[17] report that in $6M$ hydrochloric acid at 25° the rate of hydrolysis of the hexachloroantimonate ion is about 1%/min. As the hydrolysis product does not react with Rhodamine B it is imperative to add the reagent soon after oxidation, and to time the interval if it is more than a fraction of a minute. These investigators found it advantageous to carry out the extraction at a lower acidity than $6M$ because the extraction is more complete and the rate of hydrolysis is less. Acidities below $3M$ hydrochloric acid are not recommended because benzene extracts a colourless lactone of the dye, which on standing is converted into a coloured species.

Experiments have confirmed that good results are obtained by oxidizing antimony in $6M$ hydrochloric acid and then diluting to $4M$ hydrochloric acid for the benzene extraction of the Rhodamine B chloroantimonate.

Effect of the cerium (IV), hydroxylamine hydrochloride and Rhodamine B concentrations

Initial experiments showed that increasing the amount of $0{\cdot}1M$ cerium(IV) from 0·5 to 1·0 ml increased the sensitivity of the procedure. Additional oxidant resulted in no substantial increase in sensitivity and necessitated additional hydroxylamine hydrochloride. The amounts of the hydroxylamine hydrochloride and of the Rhodamine B are not critical but they must be sufficient to destroy the excess of oxidant and to react with the antimony. A combination of 100 mg of hydroxylamine hydrochloride and 10 mg of Rhodamine B is satisfactory.

Variation of the absorption spectrum of Rhodamine B chloroantimonate with order of reagent addition

According to several authors,[11,14,16,18] the recommended order of reagent addition is: cerium(IV), hydroxylamine hydrochloride for the destruction of excess of oxidant, Rhodamine B, and finally benzene as the extractant. The recommended wavelength for the absorbance measurements is 565 nm.

Antimony was oxidized in 25 ml of 6*M* hydrochloric acid by 1 ml of 0·1*M* cerium(IV), the excess of oxidant was destroyed with a few drops of 1% hydroxylamine hydrochloride solution, 5 ml of 0·2% Rhodamine B solution were added and the Rhodamine B chloroantimonate was extracted into 10 ml of benzene. A plot of the absorbance of the benzene phase (*vs.* pure benzene) between 450 and 600 nm showed peaks at 565 and 520 nm, the 565 nm peak being the larger. The absorbance of the 565 nm peak decreased by 15% in 1 hr. After 24 hr the peak at 565 nm had decreased by approximately 40% while the one at 520 nm had increased and was the greater of the two.

With conditions that more nearly approximate those recommended in this paper, the variations of the spectra with the order of reagent addition, and also with the omission of hydroxylamine hydrochloride, were investigated further. In each case the amount of antimony was the same. The concentrations of hydrochloric acid, mercuric chloride, cerium(IV), and wash solution were those used in the prescribed procedure. The amount of hydroxylamine hydrochloride, when used, was 0·5 ml of 1% solution (Figs. 2*A* and *C*), with the exception of the final case (Fig. 2*F*) in which the conditions were those recommended in this paper. One minute of shaking followed each reagent addition.

Figure 2 shows the spectra which are obtained immediately after the benzene extraction (followed by its two washings). In Figs. 2*A* and *C* a second spectrum is shown which was obtained after 24 hr. For the other cases the spectra remained essentially unchanged. The

blanks in all cases were negligible in the 400–600 nm range and remained so after 24 hr. Figure 2*A* illustrates the spectrum obtained after the conventional order of reagent addition (oxidant, reductant, dye, and extractant). Figure 2*B* is the spectrum obtained after the conventional order of reagent addition but with the hydroxylamine hydrochloride omitted. The conditions for Fig. 2*C* are similar to those for Fig. 2*A* except that benzene is added after the oxidant and before the hydroxylamine hydrochloride. Figure 2*D* is for the same case as Fig. 2*C*, but with hydroxylamine hydrochloride omitted. For Fig. 2*E* the benzene was added before the oxidant and the hydroxylamine hydrochloride omitted. Most of the dye was destroyed, as indicated by the yellow rather than orange colour of the aqueous phase. The spectrum in Fig. 2*F* results from the conditions recommended in this paper.

Ramette and Sandell[17] found that three dye cations are present which can combine with the chloroantimonate ion to form benzene-extractable products. Although the absorption maximum for none of these is given, the spectra in Fig. 2 suggest two unstable complexes and one of considerable stability with an absorption maximum at 550 nm.

That the antimony was not extracted into the benzene as the hexachloroantimonate ion in the absence of Rhodamine B was ascertained by shaking the benzene phase with Rhodamine B solution after its isolation from the aqueous phase in which the antimony was oxidized. No rhodamine B-chloroantimonate colour was observed.

The foregoing experiments testing the effect of different orders of reagent addition suggest that the simplest procedure is the one in which the timing is critical only after the single step of oxidation rather than after each reagent addition. However, best results are to be expected from use of the same procedure on all samples and standard solutions.

Treatment of the benzene extract

Most of the excess of the Rhodamine B can be stripped from the organic phase by twice shaking the organic phase with 10 ml of 4*M* hydrochloric acid. The benzene phase should be centrifuged after its washing. In earlier work, the benzene extract was filtered through paper to remove moisture but slight variations resulted.

Recovery of ^{125}Sb

A solution containing 2 μg of antimony was spiked with ^{125}Sb to give approximately 10^5 cpm and carried through the procedure. After adjustment of all fractions to a fixed volume, the activity of each fraction was measured and compared with a counting standard. The recovery of the antimony was 77%. Approximately 2% of the antimony remained in the generator flask and another 12% remained in the aqueous phase in the initial extraction. A total of about 5% was found in the two washings of the benzene phase.

Tolerance of the procedure for various elements

The investigation of certain elements as possible interferences was dictated by their reported interference in the stibine generation,[12,27] in the Rhodamine B spectrophotometric procedure for antimony,[11,12] or their common occurrence in rocks.

The tolerance for the elements was established by carrying the elements through the entire procedure. Dilute sulphuric acid solutions of most of the elements being investigated were evaporated to near dryness in Vycor crucibles, or the solids were taken directly as in the case of zinc sulphide and sodium metasilicate, and fused with pyrosulphate both in the presence and absence of antimony. Table 1 gives the results of this investigation.

Al, Ca, Fe, Mg, S and Si are tolerated individually in major quantities; 10 mg or less of Cr, Mn, Mo, Sn, Ti, V, W and Y and 1 mg or less of Au, Cu, and Ga caused negligible interference (Table 1). Approximately 500 μg of arsenic is tolerated. The catalytically active metals, Pt and Ni, are the most troublesome and tend to give reduced antimony recoveries with accelerated reaction rates between the acid and the zinc.

Nickel, owing to its common occurrence and interference, may pose the greatest problem. For more refined work this element should be removed.

Interference of arsenic

The procedure yields good antimony recoveries in the presence of approximately 0·5 mg of arsenic. Arsenic formed a golden brown precipitate in the hydrochloric acid solution of the mercuric chloride. The recovery of 1 μg of antimony in the presence of 500 and 1000 μg of arsenic was 88 and 20%, respectively. Increasing the mercuric chloride concentration by a factor of three served only to give poorer antimony recovery. The work was repeated at the 1000-μg level of arsenic in the presence of 1 μg of antimony, but with double the volume of cerium(IV) solution; the recovery of the antimony was 100% with none being found in the blank. Arsenic should be no problem in most rock samples, but should it exist in high concentration, additional oxidant is suggested.

Sample decomposition

Initial work on sample decomposition was conducted on W-1, a U.S. Geological Survey standard diabase rock. Alkaline fusion employing potassium hydroxide alone, potassium hydroxide followed by sodium peroxide, and a mixture of potassium and sodium carbonate, as well as the recommended potassium pyrosulphate, were tried.

The antimony recoveries from samples of W-1 spiked with varying amounts of antimony were essentially zero if the mixed carbonate fusion was used and low and erratic for the potassium hydroxide fusions both in the presence and absence of peroxide. These poor recoveries of antimony following the alkaline fusion were unexpected. Prescott and Johnson[28] state that the antimonates of alkali metals are vapourized or decomposed when ignited in the presence of reducing agents and advise that sodium carbonate fusions be made in the presence of an oxidant. They add that some volatilization may occur since oxidation by fusion is not effected soon enough to prevent some loss of the lower valence compounds by volatilization.

Ward and Lakin[20] found the pyrosulphate fusion of samples to be effective, preparatory to a Rhodamine B procedure for determining antimony in soils and rocks. Potassium pyrosulphate fusions were made on W-1 directly and on W-1 spiked with varying amounts of antimony. Good antimony recoveries were found and therefore all further work involved sample decomposition with this flux. Because the sample decompositions are incomplete, the antimony values represent only a lower limit.

Standard curves

A plot of the absorbance *vs.* the concentration of the antimony conformed to Beer's law from 1 to 10 μg of Sb. The sensitivity according to Sandell's definition was 0·0017 μg/cm^2. Although a detailed examination of the curve at antimony levels below 1 μg showed a non-linear relation the curve is usable for amounts of antimony $\geq 0{\cdot}1$ μg. On six replicate determinations the absorbance of the blank in a 5-cm cell was $0{\cdot}037 \pm 0{\cdot}002_3$.

Test of the procedure

The antimony content of standard rocks G-1 and W-1 was determined on 6 replicate samples of each rock directly and on samples spiked with 1 μg of antimony. The

(*Received* 19 *July* 1972 *Accepted* 21 *August* 1972)

Summary—A method is described for the fluorimetric determination of uranium in natural waters The limit of detection is 0 3 ppM Ion-exchange is used to preconcentrate the uranium by a factor of 22 and separate it from quenching ions in the sample. The fluorescence is measured in a medium that is 1 35*M* in both sulphuric and phosphoric acids The uranyl ions are excited by radiation of wavelength 280 nm and bandwidth 40 nm. The emitted signal is scanned from 470 to 510 nm After spiking of the sample solution with a small volume of standard uranium solution, the fluorescence signal is scanned again and the uranium content of the sample calculated from the two readings The coefficient of variation is 8·5% for determinations of U in a synthetic water sample having a uranium content of 1·9 ppM Destruction of organic matter in the eluates gives 0 1 ppM detection limit.

In prospecting work, knowledge of the uranium content of natural waters is a valuable guide for selecting regions for detailed investigations. Canadian experience[1,2] shows that the detection limit must be better than a few tenths of 1 ppM (parts per milliard). Any uranium content in excess of 1 ppM is regarded as an anomaly. As Scandinavia is very rich in waters, the number of analyses required each season amounts to several thousands. A simple and rapid method of analysis is therefore needed.

Of the methods in use to determine traces of uranium in water the most common is based upon measuring the fluorescence of the uranyl ion in alkali metal fluoride glass beads.[3,4] Several drawbacks are associated with this method. The fusion requires strictly controlled conditions since the fluorescence yield of the glass beads is highly dependent on their composition, surface characteristics and several fusion parameters, *e.g.*, time, temperature and oxidation-reduction conditions. It is often necessary to dilute the sample or to separate the uranium from the matrix in order to avoid quenching of the fluorescence by other elements in the sample. The fusion complicates the use of addition methods (spiking) for evaluating the uranium content of the sample.

We have chosen a liquid medium for our method. There are the following advantages in using a liquid system: many samples may conveniently be handled simultaneously, the sample solution being analysed can be spiked directly, and effects of quenching ions are more readily studied.

Some kind of preconcentration of the sample as well as separation of the uranium from strongly quenching components is necessary to obtain the required detection limit. Solvent extraction methods were abandoned because even traces of organic compounds quench the fluorescence of the uranyl ion. Ion-exchange in nitric and hydrochloric acid systems, though very useful in separating uranium from other ions,[5] is unacceptable because of quenching. We chose anion-exchange in sulphuric acid medium[6] as being the best separation technique for our purpose. The fluorescence is measured in a solution containing both sulphuric and phosphoric acids.

We shall first describe the concentration process—sorption, washing, elution—and the apparatus. The technique used in the measurement of fluorescence—matrix, spiking and measurement, will then be discussed in some detail and finally some results will be given.

CONCENTRATION AND SEPARATION

Anion-exchange techniques are capable of achieving value lying between 1 and 35,000 for the distribution coefficient (D) of the uranyl ion between a resin phase and an aqueous solution containing sulphuric acid.[7–10] Preliminary experiments indicated that small anion-exchange columns can be used for the separation. We chose to work with Dowex 1-X8 resin, 100–200 mesh, sulphate form, 350 mg of resin being used to make a bed, 8 mm in dia and 8 mm in height. In order to establish the most favourable working conditions it was then necessary to optimize the sorption, washing and elution steps.

Sorption and washing

A 200-ml volume of $0{\cdot}01M$ sulphuric acid containing 1600 μg of U was passed through the column at a flow-rate of 180 ml/hr. The column was then washed with $0{\cdot}01M$ sulphuric acid at the same flow-rate, and successive portions of the effluent were analysed fluorimetrically for uranium. The sorption on the column is better than 99% even after the passage of 1·4 l. of influent. The D value obtained exceeds $1{\cdot}5 \times 10^4$. The sorption of uranium is effective enough to permit the use of large volumes of washing solution, but what will be the smallest volume required to satisfactorily remove the quenching ions?

To find the answer to this question, we used $0{\cdot}01M$ sulphuric acid containing 10 ppm of Na^+, K^+, Mg^{2+}, Ca^{2+}, 5 ppm of Fe^{3+}, 1 ppm of Al^{3+}, 0·5 ppm of Mn^{2+}, 27 ppm of Cl^- and 7 ppm of NO_3^-. This composition corresponds to higher ionic concentrations than are normally found in Swedish ground waters. Then 200 ml of the solution were passed through the ion-exchange column at the flow-rate used in the previous experiment and the column was washed with consecutive 20-ml portions of $0{\cdot}01M$ sulphuric acid. The quenching of the fluorescence of a standard uranium solution by each portion of effluent was then determined. Quenchers were present mainly in the first effluent portions, and the fluorescence yield reached a constant value after the passage of 100 ml of washing solution. It is not possible to remove all quenching by washing. When pure resin was washed with $0{\cdot}01M$ sulphuric acid similar constant fluorescence yields were obtained. These were found to depend on the type of resin, the temperature and the concentration of sulphuric acid in the washing solution. The effect might be due to some organic material being dissolved from the resin by the acid. The constancy and reproducibility suggest that some kind of equilibrium is involved. To allow for exceptional concentrations of quenching ions we finally decided upon using 120 ml of $0{\cdot}01M$ sulphuric acid for washing.

The influence of organic matter in the eluate can be completely eliminated by fuming to dryness with sulphuric acid and hydrogen peroxide.

Elution

Bunney *et al.*[7] determined the distribution coefficient of the uranyl ion between Dowex 2-X8, 200–400 mesh, and $2M$ sulphuric acid and found that the value was

Table 1. Efficiency of elution of uranium by $2M$ sulphuric acid.

	6·0-7·5	2·6	100
	7·5-9·0	0	100

approximately 1. Strelow and Bothma[10] obtained a D value of 2·9 for the same acid, using a Bio-Rad AG1-X8 resin. For Dowex 1-X8 the same magnitude of D may be expected. Consequently a small volume of $2M$ sulphuric acid should suffice to elute the sorbed uranium. Preliminary experiments suggested to 5 ml/hour be a suitable flow-rate for elution. In order to study the elution parameters one ion-exchange column was loaded with 54·4 μg of U and another with 1·1 μg and the columns were washed in the manner described above. We eluted with 1·5-ml portions of $2M$ sulphuric acid at 5 ml/hr flow-rate. The uranium contents of the eluate portions (determined fluorimetrically) are presented in Table 1. It is seen that 6 ml of $2M$ sulphuric acid suffice for the elution of 97% of the added uranium. The estimated D value for uranyl ions between Dowex 1-X8 and $2M$ sulphuric acid is about 5. Complete elution requiring another 4 ml of sulphuric acid will reduce the sensitivity by 30% because of the dilution. It is, however, necessary to wash out the remaining 3% of the uranium with 4 ml of $2M$ sulphuric acid before conditioning the column for reuse.

We tried to elute at higher temperatures in order to reduce tailing but an increase in temperature resulted in increased quenching. We therefore decided to cool the columns with tap water.

APPARATUS

The great number of samples and the high error that could result from contamination made it clear from the beginning that automation of the separation process was needed to maintain reproducible conditions over long working periods. The arrangement is shown in Figs. 1 and 2 and consists of a peristaltic pump system for feeding sample and reagent solutions to ion-exchange columns in a rack. Each rack holds 15 columns. The total ion-exchange cycle, sorption–washing–elution–reconditioning, is completed in about 4 hr. With two operators and two racks, it is possible to handle two distilled water blanks, two synthetic test-water samples and 56 samples in one working day. With 20 working days a month the capacity adds up to 1000 samples per month which is sufficient to meet current demand.

Experience shows that the columns should be reloaded with fresh resin after 10–20 exchange cycles. The reloading is facilitated by the ground-glass fittings separating the ion-exchange chamber from the rest of the column (Fig. 1).

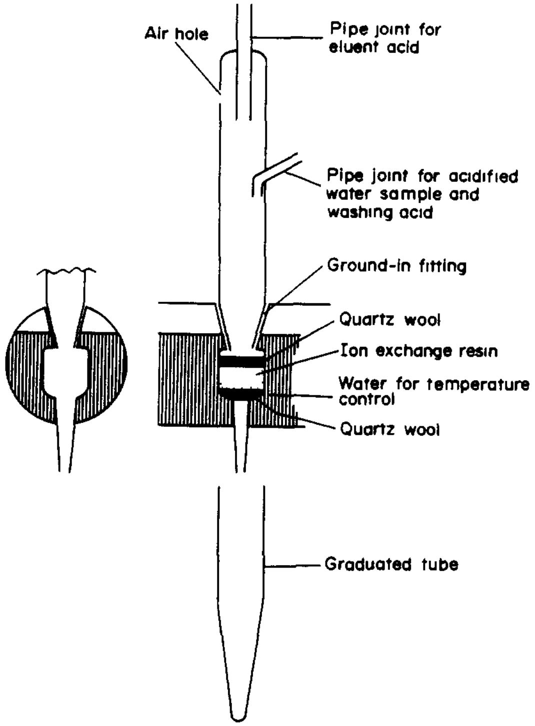

Fig. 1 Ion-exchange apparatus.

The resin is purified by conventional techniques and the smallest particles are removed by decantation. The last steps of the purification are washing with 2*M* and 0·01*M* sulphuric acid and with distilled water. A batch sufficient for several months' work is prepared at one time and stored in air-dry condition.

A Perkin–Elmer Type MPF-2A fluorescence spectrophotometer—equipped with a xenon arc lamp, Osram XBO 150W/1—was used for the measurements.

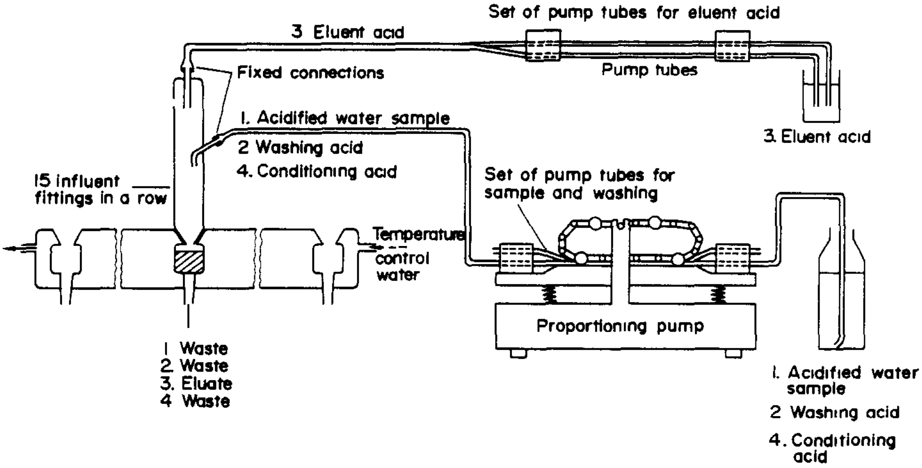

Fig 2. Arrangement of the apparatus. The numbers refer to the different steps of the ion-exchange cycle 1 sorption, 2 washing, 3 elution, 4 conditioning.

MATRIX FOR THE MEASUREMENT OF FLUORESCENCE

Phosphoric acid enhances the fluorescence of a solution containing uranyl ions.[11,12,13] We decided therefore to add phosphoric acid to the eluate. Fairly concentrated phosphoric acid (4*M*) should be used in order to minimize dilution. Maximum fluorescence was found to occur when 3 ml of phosphoric acid were added to 6 ml of the eluate. The enhancement factor is then 2·5 as compared to measurements on the original eluate. Small variations in these acid concentrations are of no importance for the fluorescence intensity. Sulphuric acid quenches the fluorescence in phosphoric acid, in this case by about 15%.

Spiking

Variations in the fluorescence yield can be corrected for by spiking if the fluorescence yield is independent of the uranyl ion concentration. To test if that was true for our system, we determined the fluorescence signals of a series of sample solutions containing quenchers and compared them with signals from solutions containing the same amount of uranium but no quenchers. The quencher concentrations used exceed the upper limit expected to be found in sample solutions after the ion-exchange process. The results summarized in Table 2 show that the fluorescence yields remain reasonably constant throughout the uranium concentration range under test. It is thus possible to spike with a relatively large amount of uranium.

In order to keep the fluorescence yield constant the stock spiking solution, fresh every month, has the same acid composition as the solution being measured. Its uranium concentration is adapted to the range of the uranium contents of the samples so that the two fluorescence signals of the solution are within the range of measurement. The spiking corresponds in our case to 7 ppM of U in a water sample. The volume and concentration of the spiking solution are chosen so as to give satisfactory precision without diluting the sample unduly. As a result of these considerations we add 0·3 ml of a standard solution containing 1500–2000 μg of U per l. to 3·0 ml of the measuring solution.

The regularly decreasing peak heights obtained from successive test samples at fixed measuring parameters are a measure of the condition of the resin beds and indicate when the beds should be exchanged.

Choice of wavelengths and measurement

The excitation spectrum of a uranium solution that is 1.35*M* in both phosphoric and sulphuric acids shows that maximum intensity of the fluorescence occurs when the excitation wavelength is 280 nm. The maximum bandwidth of the instrument gives maximum signal to background ratio.

The fluorescence emission spectrum of the solution displays peaks at 493, 516 and 540 nm. The peak at 493 nm is the most intense and was chosen for use. The peak at 516 nm is less suitable since it is sometimes disturbed.

The background is determined by scanning the emission monochromator through the wavelength range 470–510 nm. This mode of working makes it easy to distinguish between true fluorescence signals and false ones originating from dust particles in the measuring solutions or from electrical disturbances. Small irregularities in the spectrum may be smoothed out and not taken into account, as the intensity of the fluorescence signal is determined from the recorded spectrum. A high uranium content, above 0·1 ppm, in the original sample, gives a more complex spectrum which requires a background scanning through a wider wavelength range, *viz.* 460–540 nm.

The following formula gives the uranium content of the sample in ppM:

$$\frac{h_1 V_2 k}{h_2(V_1 + V_2) - h_1 V_1} \cdot \frac{V_e}{V_p}$$

where

V_1 = volume of unspiked solution in the quartz cell (ml)
V_2 = volume of added spiking solution (ml)
V_p = volume of influent sample (ml)
V_e = volume of eluate after phosphoric acid addition (ml)
h_1 = peak height of fluorescence signal above background (mm)
h_2 = peak height of fluorescence signal above background after spiking (mm)
k = concentration of U (μg/l.) in spiking solution

A small desk computer with programming facility is used to calculate the uranium content of the sample.

PROCEDURE

Add 1 ml of 2*M* sulphuric acid to 200 ml of sample, shake for 10 min and filter through a 1·2 μm cellulose nitrate filter. Pass the acidified sample through a conditioned ion-exchange column at a rate of 180 ml/hr. Wash the column with 120 ml of 0·01*M* sulphuric acid solution at the same rate and elute the uranyl ions with 6 ml of 2*M* sulphuric acid at a rate of 5 ml/hr. Add to this eluate 3·0 ml of 4*M* phosphoric acid and scan the fluorescence signal of 3·0 ml of this solution through the range 470–510 nm. Add 0·3 ml of the spiking solution directly to the sample solution in the quartz cell and scan again through the same wavelength range. Use the peak heights at 493 nm to calculate the uranium content of the sample.

To recondition the column, elute with a further 4 ml of 2*M* sulphuric acid and wash with 60 ml of 0·01*M* sulphuric acid. Discard the resin after 10–20 cycles.

For samples containing organic matter, fume the eluate overnight to dryness with 1·5 ml of 30% hydrogen peroxide in a perfectly clean teflon beaker (45 mm in dia). This leaves a black stain. Make sure that no sulphuric acid is left in the beaker. Leach with 10 ml of 0·8*M* phosphoric acid and 0·01*M* sulphuric acid while the beaker is still hot. After leaching (complete in about 30 min), add sufficient water to cover the bottom of the beaker and transfer to graduated tubes. Make up to 6 ml and proceed with the measurement as before, the spiking solution now being 1·33*M* in phosphoric acid and 0·0167*M* in sulphuric acid.

RESULTS

Table 3. Analysis of a synthetic water sample containing 1·87 ppM of uranium

14	9·0	6·6	23·2	1·87
15	9·1	6·8	26·1	1·68
				Mean 1·87

Table 3 lists the results of 15 determinations of uranium in a synthetic water sample, a fresh ion-exchange column being used for each determination. The water sample contained 1·87 ppm of U, 10 ppm of Na^+, K^+, Ca^{2+}, 5 ppm of Al^{3+}, Mg^{2+}, 2·5 ppm of Fe^{3+}, 0·5 ppm of Mn^{2+}, Zn^{2+} and 41 ppm of Cl^-. The coefficient of variation was 8·6%. In routine work, every 30th sample is a test water sample. The coefficient of variation of 140 samples run over a period of 14 weeks was 10%.

Several factors affect the limit of detection for a given enrichment factor. The most important are the fluorescence yield of the sample solution being tested, the quality and state of the optical parts and the light source and the reproducibility of the peak height determination. If the solution contains only uranium and no quenchers, the detectable signal corresponds to 0·1 ppM of U, assuming that the smallest peak height that can be measured is 1 mm. The apparent uranium contents were less than 0·3 ppM in 97·5% of the 281 blanks analysed over a period of 28 weeks.

Samples very low in uranium or high in organic matter should be analysed according to the modified procedure given above, since quenching and increased background level otherwise combine to decrease sensitivity. The detection limit in routine work is then improved to 0·1 ppM for a 200 ml sample.

Zusammenfassung—Eine Vorschrift zur fluorimetrischen Bestimmung von Uran in naturlichen Wassern wird angegeben. Die Nachweisgrenze betragt 0·3 ppM. Zur Voranreicherung des Urans um einen Faktor 22 und zur Abtrennung von fluoreszenzloschenden Ionen in der Probe wird ein Ionenaustauschschritt verwendet. Die Fluoresenz wird in einem Medium, das je 1 35 M Schwefelsaure und Phosphorsaure enthalt, gemessen Die Uranylionen werden durch Strahlung der Wellenlange 280 nm mit der Bandbreite 40 nm angeregt Das emittierte Signal wird von 470 bis 510 nm aufgenommen Nach Zugabe einer kleinen Menge Standard-Uranlosung zur Probenlosung wird das Fluoreszenzsignal nochmals aufgenommen und der Urangehalt der Probe aus den beiden Ablesungen berechnet Bei der Bestimmung von Uran in einer synthetischen Wasserprobe mit einem Urangehalt von 1 9 ppM betragt der Variationskoeffizient 8 5%.

Résumé—On décrit une méthode pour le dosage fluorimétrique de l'uranium dans les eaux naturelles La limite de détection est de 0,3 p p M On utilise l'échange d'ions pour préconcentrer l'uranium par un facteur 22 et le separer des ions inhibiteurs dans l'échantillon. On mesure la fluorescence dans un milieu qui est 1,35 *M* tant en acide sulfurique qu'en acide phosphorique. Les ions uranyle sont excités par la radiation de longueur d'onde 280 nm et largeur de bande 40 nm. Le signal émis est examiné de 470 a 510 nm Après addition rapide à la solution d'échantillon d'un petit volume de solution étalon d'uranium, le signal de fluorescence est examiné de nouveau et al teneur en uranium de l'échantillon est calculée a partir des deux lectures Le coefficient de variation est de 8,5% pour le dosage de l'U dans un échantillon synthétique d'eau ayant une teneur en uranium de 1,9 p p M.

DETERMINATION OF THE OPTIMUM WORKING RANGE FROM A CALIBRATION CURVE FOR COLORIMETRIC ANALYSIS WITH AN "AUTOANALYZER"

D. WHITEHEAD

Sedimentology Research Laboratory, Reading University, Reading, England

(*Received* 28 *February* 1972 *Revised* 18 *July* 1972 *Accepted* 8 *September* 1972)

Summary—A study has been made of the types and distribution of errors in determining the optimum working range from a calibration curve for automated analysis Three error equations are derived for the fitting of a linear, quadratic or cubic curve, involving a thorough statistical analysis of the data The errors from a set of silica and alumina standards, requiring a quadratic and cubic fit respectively, compare favourably with replicate analyses of standard rocks done on a previous occasion

In the past, various authors[1-4] have made a study of the optimum working range for non-differential spectrophotometric analysis. Calculations were based either on the well-known equation

$$\frac{dc}{c} = \frac{0{\cdot}4343\,dT}{10^{-A}A}$$

when Beer's law was obeyed, or on a Ringbom–Ayres plot when it was not. However, Gridgeman[5] first pointed out the importance of the distribution of errors and the need to apply a statistical theory of errors, and Crawford[6] showed the ways in which errors could vary with transmission. Erdey *et al.*[7] proposed a method for error calculations which took into consideration the error due to fitting a straight-line curve. As all previous work in this field had been done with manual instruments, a rigorous statistical treatment of the type of errors involved was undertaken to find the optimum range for an "Autoanalyzer."

There are two independent sources of error with the calibration curve technique, one associated with the instrument and the other with the fitted curve. The types of instrument errors from an automated system are different from those of a manual instrument. In an automated system the baseline and 0%T (T = transmission) are obtained at the start of a run and not reset for each individual measurement, therefore the errors due to these two settings are considered to be zero; only when there is an error in setting 100% and 0% T is there a contribution to the overall error of T.[8,9,10] Any slight random fluctuations in the baseline and zero settings contribute nothing to the error in T. The fitted curve was therefore made to pass through the origin. The present paper deals only with random errors, but systematic errors (such as drift) have to be taken into account when they occur, since they may greatly affect the accuracy. Baseline drift may result from two factors; first, adsorption on the flow-cell may result in a gradual upward drift; secondly, instrumental drift may cause either an upward or downward movement of the baseline.

If adsorption is the prevalent or only factor to cause drift then this can be corrected by subtracting the chart reading of the test solution (I_c) from the baseline chart reading (I_0). The change in baseline can usually be considered as constant over a given time-length of the chart record, which enables the slowly changing baseline to be distinguished from any baseline fluctuations (instrumental noise). If the drift is purely instrumental then transmittance readings (I_c/I_0) will give an adequate correction. A simple case will illustrate why (I_c/I_0) should be measured and not ($I_0 - I_c$) when instrument drift occurs. Let the initial readings for a given solution be $I_0 = 100\%$ and $I_c = 30\%$; if drift occurs so that $I_0' = 95\%$ and $I_c' = 28{\cdot}5\%$, then, $I_0/I_c = I_0'/I_c'$ because the solution will transmit the same fraction of light, but $I_0 - I_c = 70$ and $I_0' - I_c' = 66{\cdot}5$. If adsorption is the main cause of drift then for initial readings of $I_0 = 100$ and $I_c = 30$, the new readings after drift would be $I_0' = 95$ and $I_c' = 25$, *i.e.*, $I_0 - I_c = I_0' - I_c' = 70$, but $I_0/I_c \neq I_0'/I_c'$. In the latter case, the instrument settings will have remained constant.

The cause of drift can be found by setting the baseline with a reagent blank, carrying out a normal run, washing with distilled water or suitable solvents, and finally running the reagent blank again; if there is no instrument drift then the baseline should return to its original setting. Since automated analyses are more prone to adsorption effects than manual methods, paper calibrated in absorbance units should not be used in the chart-recorder when adsorption occurs as there is no easy correction for drift. Other systematic errors which cause deviations from Beer's law can be compensated for by the construction of a calibration curve, but the error from dark-current drift can only be offset by frequent running of the standard solutions. Lastly, since a single continuous-flow cell is used, and left undisturbed during all runs, the errors due to variation in the path-length may be ignored. Even when adsorption on the flow-cell occurs this still applies, for although a high concentration of the test species on the flow-cell walls is enough to cause a significant absorbance (and hence drift), the width of a single layer of the species will cause an insignificant reduction in the flow-cell path-length. Therefore, the volume of solution passing through the cell can be considered to be constant throughout a run.

The variation in repeated measurements[11] of either ($I_0 - I_c$) or (I_c/I_0) is the sum of several independent errors[6] which have so far not been considered since they cannot be analysed separately. However, the overall sum at a given concentration must be analysed to find out whether or not they are independent of the transmission value.

In the present study, three error equations are derived for fitting linear, quadratic or cubic curves.

DERIVATION OF THE RELATIVE ERROR EQUATIONS

Case I. Error for a straight-line fit

A straight line passing through the origin is described by the equation

$$A = mc$$

where A = absorbance, c = concentration, m = the slope.

The equation for propagation of errors is formed by expansion of the function $c = f(A, m)$ in a Taylor series:

$$S_c^2 = \left\{\frac{\partial c}{\partial A}\right\}^2 S_A^2 + \left\{\frac{\partial c}{\partial m}\right\}^2 S_m^2 \qquad (1)$$

where S_c, S_A and S_m are the standard deviations of the concentration, absorbance, and gradient respectively.

Since the instrument responds to a change in transmittance (linear scale), the variance of A is dependent on the transmission variance (S_T^2) as follows.

From Beer's law

$$A = -\log T$$

therefore

$$S_A^2 = (0{\cdot}4343 S_T \,.\, 10^A)^2 \tag{2}$$

On substitution of (2) into (1), the relative error in c ($100S_c/c$) is given by

$$\frac{100S_c}{c} = \left\{\left(\frac{0{\cdot}4343 \,.\, 10^A \,.\, S_T}{A}\right)^2 + \left(\frac{S_m}{m}\right)^2\right\}^{1/2}$$

Case II. The error from a quadratic fit

The equation to be fitted is of the type

$$A = qc + tc^2 \tag{3}$$

The propagation of errors equation is again obtained from the expansion of $c = f(A, q, t)$ in a Taylor series, neglecting the second order powers being neglected since the errors are very small. However, since q and t are not independent (unless an orthogonal polynomial is fitted) the covariances of the polynomial coefficients cannot be neglected:

$$S_c^2 = \left\{\frac{\partial c}{\partial A}\right\}^2 S_A^2 + \left\{\frac{\partial c}{\partial q}\right\}^2 S_q^2 + \left\{\frac{\partial c}{\partial t}\right\}^2 S_c^2 + \frac{2\partial c}{\partial q} \cdot \frac{\partial c}{\partial t}\,\mathrm{cov}(q, t) \tag{4}$$

and by substitution of (2) into (4) the relative error for a quadratic fit is given by

$$\frac{100S_c}{c} = \frac{100}{(q + 2tc)}\left\{S_q^2 + c^2 S_t^2 + 2c\,\mathrm{cov}(q, t) + \frac{0{\cdot}4343 \,.\, S_T\, 10^A)^2}{c^2}\right\}^{1/2}$$

Case III. The error from a cubic fit

The equation to be fitted is of the type

$$A = qc + tc^2 + rc^3$$

By a similar treatment to that for forming the quadratic equation error, the cubic equation error is given by:

$$\frac{100S_c}{c} = \frac{100}{(q + 2tc + 3rc^2)}$$

$$\times \left\{S_q^2 + C^2 S_t^2 + c^4 S_r^4 + 2c\,\mathrm{cov}(q, t) + 2c^2\mathrm{cov}(q, r) + 2c^3\mathrm{cov}(r, t)\right.$$

$$\left. + \frac{(0{\cdot}4343 \,.\, 10^A \,.\, S_T)^2}{c^2}\right\}^{1/2}$$

EXPERIMENTAL

Apparatus

A Technicon "Autoanalyzer" with a chart-recorder fitted with transmission paper was used. Transmission paper was used in order to calculate the transmission variance (S_T^2), although for routine analysis absorbance paper is used. The "Autoanalyzer" is a twin-photocell instrument with a single light-source, the two beams being balanced by a null-point potentiometer.

Method

Standard calibration solutions for silica and alumina were prepared from U S Bureau of Standards Sample No. 99 (Feldspar). Silica was determined by the well-known molybdenum blue method,[12] using a colorimeter fitting with 815-nm filters and silicon photocells. Alumina was determined by a modification of the Eriochrome Cyanine R method developed by Hill,[13] using a colorimeter with 535-nm filters and selenium photocells.

Reagents were introduced into the system and the pen-recorder set first at $I_0 = 99$ and then at 0%T with the sample beam cut off from the sample photocell. A series of standards was then introduced into the system, the lowest concentration standard being introduced first, followed by successively higher concentrations The whole operation was repeated seven times.

RESULTS AND DISCUSSION

The fitted curve was determined from the average of three and two repetitions of the I_0-I_c measurements, for alumina and silica respectively, since each standard is run that number of times during a normal laboratory analysis. The first and last of the seven sets of standards were chosen for this, plus the fourth set in the case of alumina. The baseline was set at $I_0 = 99$ and not at $I_0 = 100$ in case baseline drift occurred. A correction was not made for the reduction in the scale-width (due to the $I_0 = 99$ baseline setting) since absolute values of %T are not required when a calibration method is used. A least-squares fit was computed,[14] and the inverse matrix calculated so that the standard errors of the polynomial coefficients and their covariances could be determined. A test was carried out to find the best-fitting polynomial.[15] Once this had been determined the results were substituted into the appropriate error equation.

The transmission variance is the sum total of several independent errors; these errors may be constant with T, proportional to T, and proportional to $\sqrt{T}$.[6] After correction for the reduction in scale-width, the overall effect of these errors was assessed by calculating the variance of transmission at each concentration level and applying Cochrane's test[16] for homogeneity of variance. If the test shows a non-homogeneity of variance, then the individual variances at each concentration level should be substituted into the appropriate error equation. In the case of silica and alumina the variance was found to be constant over the transmission range investigated. Therefore, these variances are estimates of the same variance and may be combined to yield an improved estimate of S_T^2 by use of the equation

$$S_T^2 = \frac{\sum_{i=1}^{p} \sum_{j=1}^{n} (x_{ij} - \bar{x}_i)^2}{m(n-1)}$$

where p = number of standards, n = number of measurements of each standard, $x = (100 - \%A)/100$, $\%A$ being $100(I_0 - I_c)/I_0$, which corrects %A for the slight reduction in scale-width from the setting of $I_0 = 99$, and $\bar{x}$ = average value of x at each concentration level.

The absorbance values calculated from the fitted curve (Ac) were corrected for the reduction in scale-width and used to calculate the factor 10^A in the error equations.

19·11	0·656	0·655	1·14
G-1	0·540		0·91†
R-117	0·450		0·82†

* Calculated from the statistics

† Observed for replicate analyses

Table 1 shows the relative errors for silica, calculated from a quadratic fit and Table 2 that for alumina, calculated from a cubic fit. The relative errors at appropriate absorbance levels may be compared with the errors found for replicate[11] analysis of standards W-1[17] and R-117[18] on a previous occasion (the total error of the standards will therefore include a sample preparation error). Only approximate absorbance readings are given for W-1 and R-117 since they will vary slightly owing to variations in the reagent strengths and instrument settings on the two occasions. The transmission variance will also vary slightly from day to day. However, taking these factors into consideration, the errors compare favourably.

Acknowledgement—The author wishes to thank Mr. J E. Thomas for criticism of an early version of the manuscript and Mr S A Malik for assistance in the use of the Autoanalyzer

Zusammenfassung—Die Art und die Verteilung der Fehler wurde untersucht, die beim Ermitteln des optimalen Arbeitsbereichs für die automatisierte Analyse aus einer Eichkurve auftreten. Es werden drei Fehlergleichungen für die Anpassung einer, quadratischen oder kubischen Kurve abgeleitet; dabei wird eine eingehende statistische Analyse der Daten vorgenommen Die Fehler bei einem Satz von Kieselsaure- und Aluminiumoxidstandards, die quadratische bzw kubische Anpassung erfordern, brauchen einen Vergleich mit früher an Standardgesteinen ausgeführten wiederholten Analysen nicht zu scheuen

Résumé—On a effectué une étude des types et de la distribution des erreurs lors de la détermination du domaine de travail optimal à partir d'une courbe d'étalonnage pour analyse automatisée. On a établi trois équations d'erreur pour l'adaptation d'une courbe linéaire, quadratique ou cubique, faisant intervenir une analyse statistique poussée des données. Les erreurs d'un lot d'étalons de silice et d'alumine, nécessitant une adaptation quadratique et cubique respectivement, sont très comparables à des analyses répétées de roches étalons faites à une occasion antérieure.

SPECTROPHOTOMETRIC DETERMINATION OF PLATINUM WITH *o*-PHENYLENEDIAMINE

EDWARD D. GOLLA and GILBERT H. AYRES®

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712, U.S.A

(*Received* 5 *July* 1972 *Accepted* 20 *August* 1972)

Summary—Platinum(IV or II) reacts with *o*-phenylenediamine, at pH 6 5, to form light blue solutions having maximum absorption at 703 nm The reaction, slow at room temperature, is complete in 3–4 min at temperatures near 100° Use of dimethylformamide in the solution prevents precipitation of the reaction product The colour is stable for at least 24 hr Effects of heating temperature and time, pH, reagent concentration, and other variables have been studied The system conforms to Beer's law over the concentration range investigated Optimum concentration range for measurement in 10-mm cells is 0 4–1·4 ppm of platinum, the molar absorptivity is 9·83 × 10^3 l mole^{-1} mm^{-1} Interference from foreign ions has been evaluated, and methods for removal or masking of interferences have been tested. In the colour-forming reaction, platinum(IV) is reduced by the organic reagent to platinum(II), which is then complexed with the reagent The metal ligand ratio of 1 2 was indicated by solution spectrophotometric measurements, and was confirmed on the solid reaction product by elemental analysis and by mass spectrometric examination

Spectrophotometric methods for the noble metals have been evaluated critically by Beamish,[1] who has also written an important reference work on the analytical chemistry of the noble metals.[2] In reviewing the work up to early 1964, Beamish comments on the deficiency of methods for the more common of the noble metals, namely, gold and platinum. Since that time a few additional spectrophotometric methods for platinum have been published. Chechneva and Podchianova[3] used 1,4-diphenylthiosemicarbazide with platinum(IV) to produce a green solution, followed by extraction of the product into chloroform for measurement of absorbance at 710–750 nm; the molar absorptivity was about 10^3 l. mole^{-1}. mm^{-1}. Senise and Petombo[4] determined platinum by extraction from acidic thiocyanate solution with ethyl acetate, after precipitation with triphenylisopropylphosphonium ion. Absorbance of the extract was measured at 365 nm; the optimum range was 5–20 ppm of platinum, and the absorptivity about 5·6 × 10^2 l. mole^{-1}. mm^{-1}. Hashmi and Rashid[5] used a mixture of isonicotinic acid hydrazide and 2,3,5-triphenyltetrazonium chloride to generate formazan, which produced a pink colour (absorption peak at 480 nm) with platinum(IV) in the 1–5 ppm range; other oxidizing agents also produced the colour. Johnson and Ayres[6] used 3,4-diaminobenzoic acid, at pH 10–12, to give a blue-green solution (absorption maximum at 715 nm); optimum range was 0·35–1·20 ppm of platinum, absorptivity 1·1 × 10^4 l. mole^{-1}. mm^{-1}, and Sandell sensitivity[7] 0·0017 μg/cm. El-Ghamry and Frei[8] formed a red ternary complex with the hexa-ammineplatinum(IV) cation and the counter-ion 2,4,5,7-tetrabromofluorescein ethyl ester at pH 10; absorptivity at 555 nm was about 8 × 10^3 l. mole^{-1}. mm^{-1}.

Work in this laboratory has continued in a search for additional reagents for the platinum elements, in the hope of finding methods that are more sensitive and/or more selective than existing methods. In testing several organic compounds as possible colour reagents for platinum, it was noted that platinum(IV) solutions treated with *o*-phenylenediamine (OPDA) became slightly fluorescent upon standing overnight Addition of dimethylformamide (DMF) to a mixture of platinum(IV) and OPDA produced a light blue solution having a sharp, intense absorption peak at 703 nm; useful absorbance was produced by less than 1 ppm of platinum. This observation initiated the detailed investigation reported herein. In 1960, Sen Gupta[9] reported the use of OPDA as a reagent for platinum(IV) in acetate buffer; the orange solutions were measured at 450 nm. Optimum range was 4–12 ppm of platinum; calculations from his data give an absorptivity of $1{\cdot}1 \times 10^3$ l. mole^{-1}. mm^{-1} and a sensitivity of 0·018 μg/cm (erroneously reported as 0·003 μg/cm). In the present work the solution conditions are radically different from those used by Sen Gupta, and the sensitivity is greater by about one order of magnitude.

EXPERIMENTAL

Apparatus

Spectral scans were made with a Beckman Model DK-1 Recording Spectrophotometer, equipped with a cell-well thermostat. Precision absorbance measurements at a fixed wavelength were made on a Beckman Model DU Quartz Spectrophotometer; matched cells of 10·0 mm optical path were used, and a fixed slitwidth of 0 08 mm

Measurements of pH were made with a Beckman Century SS solid-state pH meter having both standard and expanded scales, and a miniature type calomel–glass electrode system

Analytical weighings were made on either a Mettler Type H5 or a Mettler Micro Type M5 balance, depending upon load and/or accuracy desired. Volumetric ware used for critical transfers and dilutions was of Class A tolerance

Reagents

Standard platinum solutions. Much of the early work in this study used a 10-μg/ml solution of platinum(II), prepared by dissolving the requisite weight of pure K_2PtCl_4 in a small amount of concentrated hydrochloric acid, and diluting to known volume. A stock solution of platinum(IV) was prepared by dissolving 0·49992 g of Grade No 1 platinum thermocouple wire (assay, 99·99% minimum purity) in *aqua regia*, followed by repeated evaporations with hydrochloric acid, and final addition of 5 ml of concentrated hydrochloric acid and dilution to 500 0 ml. The accuracy of this solution was checked by evaporation and hydrogen reduction of aliquots of the solution and weighing of the residual platinum. Concentrations based on weight of platinum taken and platinum residue obtained agreed to better than 1 in 5000 The stock solution, 1 000 mg/ml, or $5\ 125 \times 10^{-3}M$, was diluted volumetrically for working standard solutions

o-Phenylenediamine The OPDA (Eastman Organic Chemicals No. 1700) was initially used as received. Later work showed that an unknown impurity was causing low and variable results Use of a recrystallized reagent eliminated this difficulty The reagent solution finally adopted contained 35 mg of OPDA in 25 ml of DMF

N,N-*Dimethylformamide* Quite late in the investigation it was discovered that the brand of DMF being used was the cause of many confusing results Change to a different source of DMF eliminated this source of error

Buffers Phosphate buffer solutions were prepared so that a 2-ml portion (as used in the recommended procedure) contained 2·75 mg of potassium dihydrogen phosphate, and sodium hydroxide in the amounts requisite to vary the pH over a wide range

All other chemicals were ACS reagent grade

Recommended procedure

A sample containing 4–14 μg of platinum(IV or II) in a volume of 1 ml is taken in a 10-ml volumetric flask One ml of OPDA reagent solution (in DMF) is added, and the pH is adjusted to 6 5 by addition of 2 ml of KH_2PO_4–NaOH buffer. The flask containing the reactants is supported in a boiling water-bath for 4 min, during which time the light blue colour develops DMF is added to bring the solution volume to approximately 10 ml, the flask is removed from the bath and cooled to room temperature, and final adjustment to exactly 10 ml is made with DMF Absorbance of the solution is measured at 703 nm, against a water blank (a reagent blank has no measurable absorption at this wavelength)

RESULTS AND DISCUSSION

Calibration, range, sensitivity, and precision

Data for the calibration curve are shown in Table 1; each absorbance is the average of three closely agreeing measurements. Constant values of A/ppm show that the system follows Beer's law; the calibration curve is a straight line which extrapolates through the origin. The optimum range for measurement in 10-mm cells is 0·4–1·4 ppm. The Sandell sensitivity is 0·002 μg/cm; the specific absorptivity is 0·0504 ppm^{-1}. mm^{-1} and the molar absorptivity is $9{\cdot}83 \times 10^3$ l. mole^{-1}. mm^{-1}. This method, and the method reported by Johnson and Ayres[6] appear to be the most sensitive spectrophotometric methods for platinum thus far, both being about at the theoretical limit of molar absorptivity.[10]

Table 1 Calibration data

Platinum, *ppm*	Absorbance, *A*	*A/ppm*
0·400	0·202	0·505
0·500	0·252	0·504
0·600	0·303	0·505
0·700	0·353	0·504
0·800	0·402	0·502
0·900	0·453	0·503
1·000	0·503	0·503
1·100	0·554	0·504
1·200	0·604	0·503
1·300	0·655	0·504
1·400	0·705	0·504
	Average	0·504

Precision of the method was evaluated by preparing and measuring 20 identical samples containing 1·00 ppm of platinum (a concentration near the middle of the optimum range); the absorbance averaged 0·503, with a standard deviation of 0·002.

Effect of pH

A series of solutions containing 1·00 ppm of platinum(IV) was prepared by the recommended procedure, except for variation in the buffer added. The results are recorded in Table 2. Maximum absorbance (0·504) was reached at pH 6·5; the absorbance was within experimental error over the range pH 6·0–6·7.

Development time, stability

The time required for full colour development depended upon concentration of platinum, concentration of OPDA, pH, and temperature. In samples containing 1·00 ppm of platinum, treated by the recommended procedure, absorbance increased very rapidly during the first minute and reached full development in 3 min; additional heating up to 10 min did not produce further change. A standard development time of 4 min was adopted to ensure full development of all samples. (Exception: cases of certain foreign ions requiring masking with EDTA).

Five samples, each containing 1·00 ppm of platinum, were developed by the recommended procedure and the absorbance was read as soon as the solution was cooled

Table 2. Effect of pH

pH	Absorbance
3·5	0·030
4·0	0·051
4·5	0·131
5·0	0·365
5·6	0·474
6·0	0·501
6·3	0·503
6·5	0·504
6·7	0·503
7·5	0·485
8·0	0·462
9·0	0·398
10·0	0·305

to room temperature (zero time reading). Readings were taken at 1-hr intervals for the next 4 hr, and then at longer time intervals up to a total of 30 hr; all absorbances were within the range 0·501–0·505. Samples that were retained for 4 days showed no change in absorbance. Therefore, no special precautions regarding stability need to be taken, except when rhodium interference is encountered; in that event, the absorbance should be measured promptly after the solution is cooled.

Effect of temperature

The colour developed very slowly at room temperature. As the temperature of the reaction mixture was increased up to about 90°, development was more rapid and the final absorbance (for a given amount of platinum) was greater. From 90° to 100°, development rate still increased, but without increase in final absorbance. Therefore, to attain full development in the shortest time with the simplest equipment, a bath of boiling water was used.

The effect of change in temperature on samples already prepared by the recommended procedure was tested by scanning 1·00-ppm samples with the Beckman DK-1 recording spectrophotometer, using the thermostatic cell holder adjusted to different temperatures in the range 27–81°. Temperature increase caused a decrease in absorbance of about 0·002 per 1°. The change was reversible on decreasing the temperature, and was probably due to the volume change of the solution with change in temperature. Although the temperature coefficient of absorbance is small, it is prudent to make sure that all samples are at the same temperature before absorbance is measured.

Purity and stability of reagent

The solid reagent appeared to be stable under ordinary storage conditions. A melting point test on the reagent as received cast some doubt on its purity. A large amount of the solid OPDA, as received, was dissolved in hot DMF, and the solution was then cooled in an ice-bath. The recrystallized product was separated on a fritted glass funnel, washed with ice-cold water, then dried at 95°. Melting point determination indicated a high-purity OPDA. Use of the recrystallized reagent eliminated the lack of precision of results previously experienced with the original OPDA.

Water solutions of OPDA were not stable for more than 2 hr at room temperature; the stability was increased somewhat by storage in an ice-bath. Aqueous solutions of the reagent were used in some of the early work because they gave more consistent results than solutions in DMF It was later found that the inconsistent results were caused by impure DMF. After a source of pure DMF was found, the OPDA reagent dissolved in DMF was used with excellent results. The reagent solutions in DMF were stable for at least 2 days; solutions kept longer than this began to show some yellow colour of oxidation products of OPDA (probably diaminophenazine). In practice, a fresh solution (35 mg of OPDA in 25 ml of pure DMF) was prepared at least every other day.

Effect of reagent concentration

A series of solutions of 1·00 ppm of platinum was prepared in which the mole ratio of OPDA to platinum was varied from 1 : 1 to 400 : 1. The absorbance reached a constant value at a mole ratio of about 150 : 1. The 1 ml of reagent solution specified in the recommended procedure is equivalent to a mole ratio of 180 : 1 at the maximum platinum concentration used in this study.

Effect of DMF concentration

The product formed by reaction of platinum solution with OPDA at pH >5 is not soluble in water, but is soluble in a few organic solvents, notably in DMF and in dimethylsulphoxide (DMSO). A series of solutions containing 1·00 ppm of platinum was prepared by the recommended procedure, up to the point of addition of DMF. The amount of DMF in the final solution was varied from 20 to 80% v/v. Below 40% v/v DMF the reaction product was only slightly soluble, and more oxidation of the OPDA occurred during colour development. Full colour development was attained at DMF concentrations of 70% and above, which still allowed for an appreciable amount of water from the original solutions. This amount of DMF gave the highest absorbances with good precision, and also improved the stability of the developed samples. Use of a much larger amount of DMF decreased the rate of colour development.

Order of addition

At the pH used in the development procedure, hydrolysis of the platinum solutions took place if the buffer was added before the OPDA. Hence, the order of addition must be platinum solution, OPDA reagent, then buffer. DMF should not be added until the reaction is complete, because it retards the reaction and affects the precision of results.

Effect of foreign ions

These effects were studied by adding the ion in question to the platinum solution (1·00 ppm of platinum in the final solution), then developing by the usual procedure. Cations were added in the form of chlorides, nitrates, or sulphates, to a maximum of 50 ppm; anions were added in the form of sodium or potassium salts, to a maximum of 500 ppm. The tolerance for a given ion is the maximum amount that can be present and produce an absorbance difference no greater than 0·01 absorbance from that for the platinum alone. Table 3 gives the results. If serious interference was observed, an attempt was made to eliminate or minimize it by use of masking agents (see next paragraph); the results are shown in the last column of Table 3.

Table 3 Summary of interference studies

Foreign ion	Tolerance, *ppm* Original	With masking	Masking agent, comments
Pd(II)	0·2	8	200 ppm EDTA
Ir(IV)	2	5	200 ppm EDTA
Rh(III)	1	—	Measure immediately
Os(III)	0·2	—	
Ru(III)	0·3	2	200 ppm EDTA
Au(III)	0·2	3	200 ppm I^-
Fe(III)	5	—	
Ni(II), Co(II)	10	—	>50 ppm with filtering
Pb(II)	15	—	>50 ppm with filtering
Cd(II), Zn(II)	>50	—	
Mn(II)	20	—	>50 ppm with filtering
Cr(III)	12	—	
Cu(II)	0·1	5	200 ppm EDTA
Hg(II)	0·3	6	200 ppm EDTA
Ca(II)	6	20	200 ppm EDTA
NH_4^+	100		
SO_4^{2-}	50		
Br^-, I^-	>500		
NO_3^-, ClO_4^-	>500		
Acetate	>500		
EDTA	200		Double the heating time
Citrate	300		
Tartrate	400		

Removing or minimizing interferences

Elimination of interference from foreign ions can be accomplished by physical removal procedures, such as the following: distillation of ruthenium and/or osmium as their volatile tetroxides; precipitation of palladium as its dimethylglyoximate from acid solution; precipitation of other platinum elements and most base metals as their hydrous oxides, at controlled pH, leaving platinum(IV) in solution. These methods are inconvenient and time-consuming. It is simpler if a reagent or reagents can be found to mask the interference by forming complexes that are more stable than the platinum–OPDA complex of interest. For this purpose, ethylenediaminetetra-acetic acid (EDTA) or, more exactly, its disodium salt, is a useful reagent, in that it forms complexes (of widely different stabilities, to be sure) with practically all metal ions.

All of the other platinum elements, as well as gold, interfered at rather low concentrations. Addition of 200 ppm of EDTA was effective in eliminating or decreasing much of this interference, although it was not effective against interference from osmium or rhodium. Rhodium could be tolerated up to 1 ppm if the absorbance for platinum was measured promptly after colour development. Osmium above 0·2 ppm would require distillation removal. The good results in masking gold(III), palladium(II), iridium(IV), copper(II), mercury(II), *etc.*, were due to the fact that EDTA reacts rapidly with these ions, whereas it reacts quite slowly with platinum solutions.[11] When using this method, EDTA must be added to the sample just before starting the development; the sample and EDTA are heated together for 1 min, then the usual procedure is followed, except that the heating time is doubled.

Interference from copper(II) is of special interest, in that the amount of interference is almost independent of the amount of copper(II) present, even down to very low concentrations. Copper(II) is known to catalyse air oxidation of OPDA,[12] which probably explains this effect. Addition of EDTA prevented the catalytic action of copper(II), but the blue colour of the copper–EDTA complex still caused some interference in the platinum determination. Iron(III) also oxidized OPDA, thus decreasing the concentration available for complexation of platinum. Addition of a larger amount of OPDA reagent decreased iron(III) interference.

Ions of several of the base metals (nickel, cobalt, manganese, lead, *etc.*) interfered by precipitation of their hydrous oxides in the nearly neutral solution used in the procedure. This kind of interference was best removed by simply filtering the mixture after the colour development procedure.

STUDY OF REACTION AND PRODUCT

Absorption spectra

A solution of hexachloroplatinate(IV), $PtCl_6^{2-}$, has a weak absorption band at 460 nm, and strong absorption below 440 nm. Tetrachloroplatinate(II), $PtCl_4^{2-}$, of the same platinum concentration, has a moderately strong absorption band at 405 nm. Neither solution has significant absorption in the 600–800 nm region. Likewise, the OPDA reagent has negligible absorption in the 600–800 nm region. Therefore, any unreacted components will not register in absorbance measurements at 703 nm, the analytical wavelength of the present method. A freshly prepared solution of OPDA had a weak absorption centred at 430 nm; when the solution was aged at room temperature or by heating, the 430 nm absorption increased. Addition of iron(III) to the OPDA solution caused marked increase in the 430-nm absorption, and the solution assumed a pronounced yellow colour due to the oxidation product.

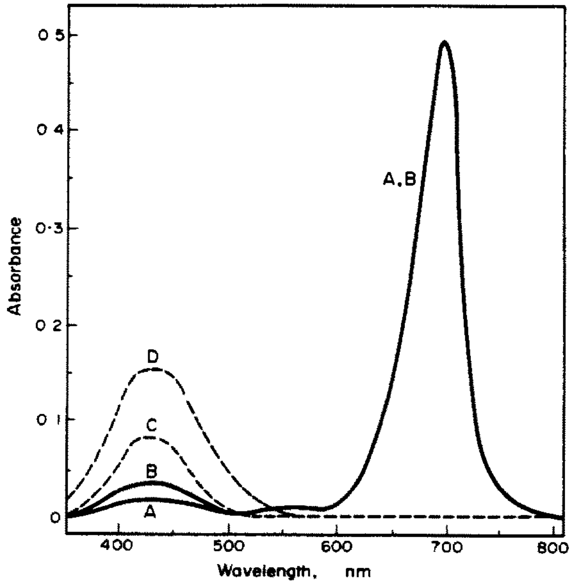

Fig 1 Spectral curves of platinum–OPDA complex and of OPDA reagent. A OPDA + 1·0 ppm of platinum(II), B. OPDA + 1 0 ppm of platinum(IV), C. OPDA after long heating in air, D OPDA oxidized with iron(III)

The absorption spectrum of a solution containing 1·00 ppm of platinum(IV), developed by the recommended procedure and measured against a water blank, showed the intense absorption at 703 nm characteristic of the platinum–OPDA complex, and a weak absorption at 430 nm; see Fig. 1. An identical solution prepared from platinum(II) had an identical absorption curve, except that absorption around 430 nm was negligible. Furthermore, increasing the amount of platinum(IV) caused corresponding increase in the intensity (absorbance) of the 430-nm peak, whereas varying the amount of platinum(II) had no effect on the 430-nm absorbance, provided the heating time was not excessive. It is obvious, therefore, that absorption at 430 nm is due to oxidation product(s) of OPDA, and that the use of this reagent with platinum(IV) involves reduction of the latter to platinum(II) and oxidation of the OPDA, followed by formation of the blue complex. A similar situation has been observed in this laboratory in the reaction of 3,4-diaminobenzoic acid with platinum(IV).[6]

Mole ratio study

Attempts to apply this method[13] gave little useful information, with solutions at the 1 ppm level; a very large excess of OPDA was required to attain constant absorbance, and the great curvature of the 703-nm absorbance *vs.* mole ratio OPDA/platinum plot precluded any meaningful extrapolation of the initial and the final portions of the plot. Application of the method in the converse sense, with OPDA held constant (at $1{\cdot}00 \times 10^{-4}M$) and platinum concentration varied, gave an absorbance *vs.* mole ratio platinum/OPDA plot, the first part of which was linear and identical with the calibration curve of the analytical method. As the platinum/OPDA ratio approached 0·5 the plot assumed considerable curvature and with increasing ratio the absorbance reached a value high enough to establish that the complex could not have a ligand: metal ratio higher than 2 : 1.

In an attempt to gain information concerning the redox reaction between platinum(IV) and OPDA, absorbance measurements at 430 nm (where the oxidation product of OPDA absorbs) were made on a series of solutions in which the concentration of platinum(IV) was held constant at $4{\cdot}1 \times 10^{-5}M$ and the OPDA concentration was varied up to 10 times that of the platinum. Extrapolation of the linear portions of the plot intersected at 0·75 mole of OPDA per mole of platinum(IV), corresponding to a stoichiometry of 3 OPDA to 4 platinum(IV).

Continuous variations method

Application of this method[14,15] was done initially with platinum(II), in order to avoid any complication introduced by oxidation of OPDA by platinum(IV). Figure 2, curves A and B, shows the plots for two different total concentrations of reactants. Extrapolations of the initial and final portions of the curves intersect at 0·67 mole-fraction of OPDA, corresponding to a reaction stoichiometry of 2 OPDA to 1 platinum(II). Curve C of Fig. 2 is the continuous variations plot using platinum(IV) and the same total concentration of reactants as with platinum(II) in curve A; the maximum absorbance attained is the same in the two cases, but with platinum(IV) the curve maximum occurs at 0·73 mole-fraction of OPDA. The marked change of slope at mole-fraction 0·3 is associated with the redox reaction between OPDA and platinum(IV). Based on the OPDA : Pt(IV) = 3 : 4 stoichiometry in the redox reaction (mole-ratio from absorbance measurements at 430 nm) and the OPDA : Pt(II) = 2 : 1 stoichiometry in the complexation reaction [continuous

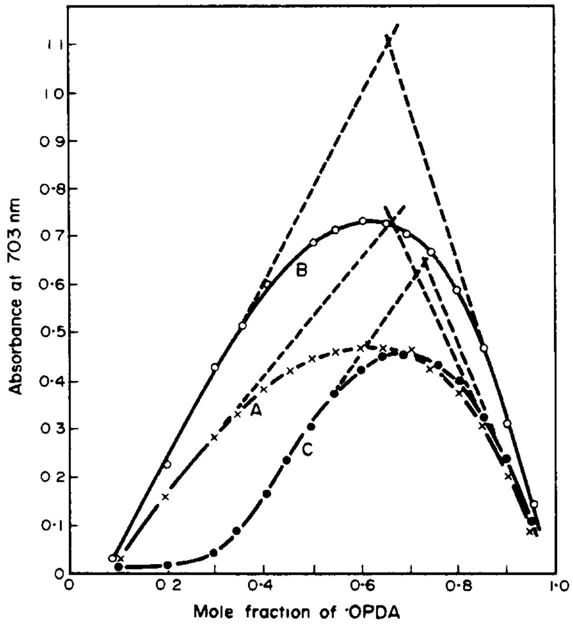

Fig 2 Continuous variations plots. A. OPDA + platinum(II) = 4·1 × $10^{-5}M$, B OPDA + platinum(II) = 6·2 × $10^{-5}M$, C OPDA + platinum(IV) = 4·1 × $10^{-5}M$

variations measurements using platinum(II) and 703 nm absorbances], the overall stoichiometry can be represented as follows:

$$3\ \text{OPDA} + 4\ \text{Pt(IV)} \rightarrow \text{oxidation products} + 4\ \text{Pt(II)}$$
$$8\ \text{OPDA} + 4\ \text{Pt(II)} \rightarrow 4\ \text{Pt(OPDA)}_2\ \text{complex}$$

Total: 11 OPDA + 4 Pt(IV) → oxidation products + 4 Pt(OPDA)_2 Mole-fraction of OPDA = 11/15 = 0·73, as in curve C of Fig. 2.

The heavy curvature of the continuous variations plots indicates that the formation constant of the platinum(II)–OPDA complex is not very large. By calculation analogous to that given by Meites and Thomas[16] the formation constant evaluated from Fig. 2, curve A, is 1·7 × 10^{10}, and from curve B it is 0·86 × 10^{10}, averaging 1·3 × 10^{10}.

Isolation and analysis of the product

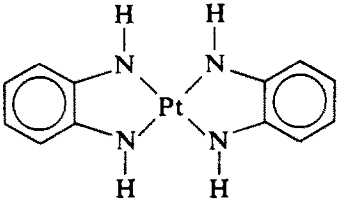
A 0·30-g sample of K_2PtCl_4 was dissolved in a small amount of hydrochloric acid, then diluted to 200 ml with water. A concentrated solution of OPDA containing 10 g of the solid in 20 ml of DMF was added to the platinum solution and the pH was adjusted to nearly neutral with sodium hydroxide. The reaction mixture was heated on a boiling water-bath for 1 hr, during which the colour became dark blue and then purple After cooling in an ice-bath, the mixture was suction-filtered with a sintered glass funnel. The recovered solid was extracted with DMF and again filtered off, the filtrate being received in a clean flask. This solution was filtered through paper, and the filtrate was then centrifuged to ensure complete removal of any solid. To the DMF solution containing the reaction product, water was added until it constituted about

60% by volume. The finely divided precipitate which formed was recovered by centrifugation; it was washed with acetone, redissolved in DMF, and reprecipitated by addition of water. The product was again recovered by centrifugation, washed with acetone, and oven-dried at 95°.

A small amount of the purified complex was dissolved in 70–30 DMF–water solution, and the spectrum of the solution was recorded; it was identical with the spectrum produced by platinum samples developed by the recommended procedure, except that the small absorption at 430 nm observed in the latter case was totally absent. This fact further supports the conclusion that absorption at 430 nm was due to oxidation of the OPDA reagent, and not to the platinum–OPDA complex.

A 0·601-mg sample of the purified complex was dissolved in 10 ml of DMF. Calculations based on the formula weight of the proposed complex (see next section) indicated that diluting 1·0 ml of this solution to a volume of 28·8 ml would give a solution containing 1·00 μg of platinum per ml, or 1·00 ppm. The dilution was made with DMF and water to a final 70% v/v of DMF. The absorbance of this solution was exactly the same as that of a 1·00-ppm platinum solution developed by the recommended procedure.

The question arises as to the mode of formation of the platinum(II)–OPDA complex, whether by simple co-ordinate covalent bonding from the nitrogen atoms of the $-NH_2$ groups, or by loss of one or both hydrogen atoms from one or more $-NH_2$ groups, forming anions associated with the platinum(II) cation, or a combination of these processes. The possible formulae, the formula weights, and the carbon, hydrogen, and nitrogen contents are shown in Table 4. A portion of the purified product was analysed by Galbraith Laboratories, Knoxville, Tennessee; the analysis, included in Table 4, conforms most closely to formula 3, which may be represented thus:



Mass spectrum of the product

A sample of the purified reaction product was analysed on a low-resolution mass spectrometer at 70 eV ionization potential. The largest peak appeared at a mass/charge ratio of 407; slightly smaller peaks appeared at ratios of 406 and 408, and a moderate peak at 410. The ratio of these peak heights is in excellent agreement with the relative natural abundances of the most abundant isotopes of platinum. No particle of mass/charge ratio greater than 410 was found. Another series of peaks was found at *m/e* 203·5, 203, 204, and 205, of intensities in the same ratio as the platinum isotope abundances, corresponding to the doubly-ionized molecules. Table 5 shows that the only composition conforming to the observed mass numbers is $Pt(C_6H_4N_2H_2)_2$, formula weight 407·35, which also agrees with the elemental chemical analysis.

The double ionization of the intact complex is an indication of its considerable stability. A series of small peaks was observed at mass/charge values of 300, 301, and 302,

Table 4 Elemental composition of possible compounds

Possible formula	Formula weight	% C	% H	% N
1 $Pt(C_6H_4N_2H_4)_2$	411 38	35·04	3·921	13·62

196	25 4	412	410	408	406	404
198	7 23	414	412	410	408	406

these are probably fragments of the original complex that contain only one OPDA group associated with a platinum atom, for example, $Pt(C_6H_4N_2H_2)^+$. This type of fragmentation is not unusual when compounds undergo ionization at 70 eV.

CONCLUSION

The results of this study indicate that in the reaction of platinum(II) with OPDA, each of two ligand molecules loses two hydrogen atoms to form the doubly charged anion of OPDA, which combines with platinum(II) to form a highly coloured neutral complex which is quite stable and insoluble in most solvents except DMF and DMSO. A similar nickel complex, which has been known for some time, has been characterized by mass spectrometry;[17] it is the same as that proposed here for the platinum complex [with nickel(II) substituted for platinum(II)].

Zusammenfassung—Platin(IV) oder -(II) reagiert bei pH 6·5 mit o-Phenylendiamin zu lichtblauen Losungen mit Absorptionsmaximum bei 703 nm. Die bei Zimmertemperatur langsame Reaktion ist bei Temperaturen in der Nahe von 100° in 3–4 min beendet. Dimethylformamid in der Losung verhindert das Ausfallen des Reaktionsprodukts. Die Farbung ist mindestens 24 h lang stabil. Der Einfluß der Erhitzungstemperatur und -dauer, des pH, der Reagenskonzentration und anderer Variabler wurde untersucht. Das System folgt im untersuchten Konzentrationsbereich dem Beerschen Gesetz. Der optimale Konzentrationsbereich zur Messung in 10 mm-Kuvetten ist 0·4–1·4 ppm Platin, der molare Extinktionskoeffizient betragt 9·83 10^3 l mol^{-1} mm^{-1} Die Storung durch Fremdionen wurde erfaßt und Methoden zur Entfernung oder Maskierung der störenden Ionen geprüft. Bei der farbbildenden Reaktion wird Platin(IV) durch das organische Reagens zu Platin(II) reduziert; dieses bildet dann einen Komplex mit dem Reagens. Das Metall · Ligand-Verhältnis 1 : 2 wurde durch spektrophotometrische Messungen in Losung nahegelegt und wurde am festen Reaktionsprodukt durch Elementaranalyse und massenspektrometrische Untersuchung nachgewiesen.

Résumé—Le platine (IV) ou (II) réagit avec l'*o*-phénylènediamine à pH 6,5, pour donner des solutions bleu clair ayant un maximum d'absorption à 703 nm. La réaction, lente à température ambiante, est complète en 3–4 mn aux températures voisines de 100° L'emploi de diméthylformamide dans la solution évite la précipitation du produit de réaction. La coloration est stable pendant 24 h au moins. On a étudié les influences de la température et du temps de chauffage, du pH, de la concentration en réactif et d'autres variables. Le système suit la loi de Beer dans le domaine de concentrations étudié. Le domaine de concentration optimal pour la mesure dans des cuves de 10 mm est de 0,4–1,4 p.p.m de platine; le coefficient d'absorption moléculaire est 9,83 × 10^3 l. mole^{-1} mm^{-1} On a évalué l'interférence d'ions étrangers, et l'on a essayé des méthodes pour l'élimination ou la dissimultation d'interférences. Dans la réaction de formation de coloration, le platine (IV) est réduit par le réactif organique en platine (II), qui est alors complexé avec le réactif Le rapport métal · complexe de 1 · 2 a été montré par des mesures spectrophotométriques de la solution, et a été confirmé sur le produit solide de réaction par analyse élémentaire et par examen spectrométrique de masse.

(*Received* 20 *June* 1972. *Accepted* 18 *August* 1972)

Summary—The linear crystallization of well-formed crystallites of calcium sulphate dihydrate from supersaturated solutions has been studied by a microscopic method at temperatures ranging from 25° to 55° The activation energy is 16 ± 1 5 kcal/mole for the fast-growing faces. Induction periods in the crystallization of calcium sulphate dihydrate have been determined as a function of solution concentration at temperatures of 25° and 90°

The precipitation of calcium sulphate is of considerable importance in processes involving the formation of scale on heat-transfer surfaces. A number of investigations have been made of the influence of additives on the crystallization and nucleation rate,[1–4] but most of the previous work was concerned only with the concentration changes in the supersaturated solutions during the precipitation processes. A study of the seeded crystal growth of calcium sulphate dihydrate from supersaturated solution, by means of a sampling technique, has been published,[5] and a reaction, second-order in relative supersaturation, has been found for the crystallization of this salt both in the presence and in the absence of additives.[6] The dissolution of calcium sulphate dihydrate into subsaturated solution has been followed by a potentiometric method and the diffusion of ions from the surface to the bulk of the solution has been found to be the rate-determining step for the dissolution process.[7]

In studies of the kinetics of crystal growth, in addition to following concentration changes in the supersaturated solution, observation of the growing crystals themselves is clearly of considerable importance. The present study is concerned with the linear crystallization rate of calcium sulphate dihydrate from supersaturated solution. The activation energy of the fast-growing faces has been determined by observing the rate of growth as a function of temperature. In addition, induction periods in the precipitation of calcium sulphate dihydrate have been investigated as a function of the degree of supersaturation, over a range of temperature.

EXPERIMENTAL

Linear growth experiments

Reagent-grade chemicals, grade-A volumetric glassware and triply distilled water were used throughout this work Suspensions of calcium sulphate dihydrate seed crystals were prepared as described previously[5] After the crystals had been washed several times, their morphology was improved by allowing them to grow again in 0·025*M* calcium chloride/0·025*M* sodium sulphate After one hour, the supernatant solutions were decanted and the residual suspensions were washed several times with saturated calcium sulphate solution until the crystals were free from sodium chloride The crystals prepared in this way were well-formed and suitable for further study of the linear crystallization rate of specific faces in supersaturated solutions

Supersaturated solutions were prepared by the slow mixing of solutions containing calcium chloride and sodium sulphate About 7 ml of the solution were then introduced into a microcell of capacity 10 ml, which had a thin microscope slide as its base so that crystals could be observed microscopically (Unitron Series N

Microscope). Water from a thermostat was circulated between the walls of the microcell. After the solutions had reached temperature equilibrium, a small amount of seed suspension was put into the reaction cell. The extent of the reaction was followed by photographing the growing crystal at various times The calcium concentration of the solution was checked before and after each experiment by titrimetric analysis with EDTA, the change of concentration was usually only about 1–3% The linear growth rate R was taken as the average length change of three or four crystals during each experiment.

Induction experiments

Calcium chloride solutions were first brought to temperature equilibrium in a 250-ml reaction vessel, and the required amounts of pre-equilibrated sodium sulphate solutions of the same concentration were quickly added. The induction period was taken as the time interval between the mixing of the solutions and the appearance of the first white cloudy precipitate of calcium sulphate. In order to compare results of experiments at different supersaturations, additions of sodium chloride were made, where necessary, in order to maintain the sodium chloride concentration in the solutions at a constant value

RESULTS AND DISCUSSION

The results of the linear crystallization experiments are summarized in Table 1, and the growth rate is plotted as a function of relative supersaturation in Fig. 1. In Fig. 2 R is plotted against the square of the relative supersaturation, and it is seen that, with the exception of an initial growth surge, equation (1) satisfactorily represents the experimental data:

$$R = k_1(T_{Ca} - T_{Ca}{}^{\circ})^2 \tag{1}$$

Table 1 Linear crystallization rates of the fastest growing face of calcium sulphate dihydrate at 25°C

Expt. No	$T_{Ca} \times 10^2$ M	$(T_{Ca} - T_{Ca}{}^{\circ}) \times 10^2$ M	$R \times 10^2$ *mm/hr*
1	4·24	2·18	3·2
2	3·95	1·91	2·5
3	3·75	1·74	1·6
4	3·49	1·49	1·0
5	3·37	1·39	0·9
6	3·11	1·15	0·6
7	2·86	0·92	0·2
8	2·75	0·83	0·12
9	2·56	0·66	0·09
10	2·28	0·41	0·04

In this equation, k_1 is the rate constant for linear growth, T_{Ca} represents the total calcium concentration of the supersaturated solution, and $T_{Ca}{}^{\circ}$ is the solubility value at the particular ionic strength. An equation similar to (1) has been found to hold for the growth of seed crystals of calcium sulphate dihydrate in supersaturated solutions of the salt in which the rate of growth was expressed in terms of the change in concentration in the supersaturated solutions with time.[5] The results of the direct measurements of the growing crystals are therefore consistent with the previous studies by a different method. The experimental results may be explained in terms of a screw dislocation model[8 9] or the surface adsorption model proposed by Davies,[10] since both models predict the same reaction-order kinetics for the growth of crystals of symmetrical charge-type electrolytes.

The deviation of experimental results from the straight line of the second-order plot at higher supersaturation can be explained in terms of two-dimensional surface nucleation. Troost[11] in a study of crystallization of sodium triphosphate hexahydrate also proposed

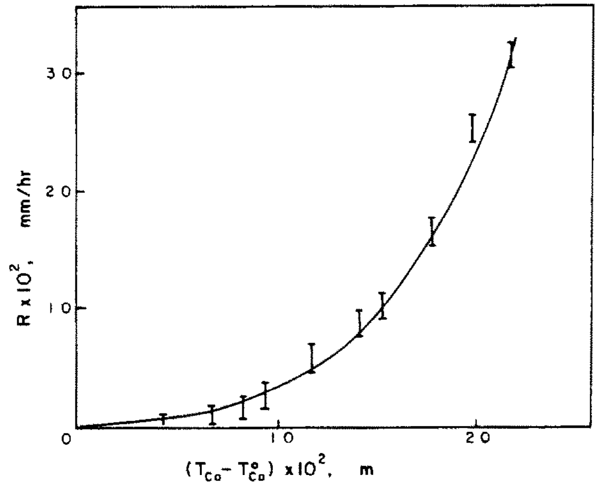

Fig. 1 Plot of the linear growth rate, R, as a function of $(T_{Ca} - T_{Ca}^{\circ})$ for calcium sulphate dihydrate The uncertainties in R are represented as ordinate bars

two mechanisms in determining the rate of growth of 001 faces. He assumed that at low degrees of supersaturation, the growth rate was controlled by the screw dislocation mechanism, while at higher degrees of supersaturation, the formation of two-dimensional nuclei was the rate-determining step. In Fig. 3, the growth of untreated seed crystals in the supersaturated solution is shown. It is interesting to note that if untreated seed crystals are put in the supersaturated solutions, the crystals grow more rapidly at imperfections so that a rapid perfection of the crystal shape takes place in the initial crystallizing step.

A series of experiments was made at a variety of temperatures ranging from 25° to 55° at a constant supersaturation. The results are summarized in Table 2 and the linear growth rate constant is plotted according to the Arrhenius equation in Fig. 4. The

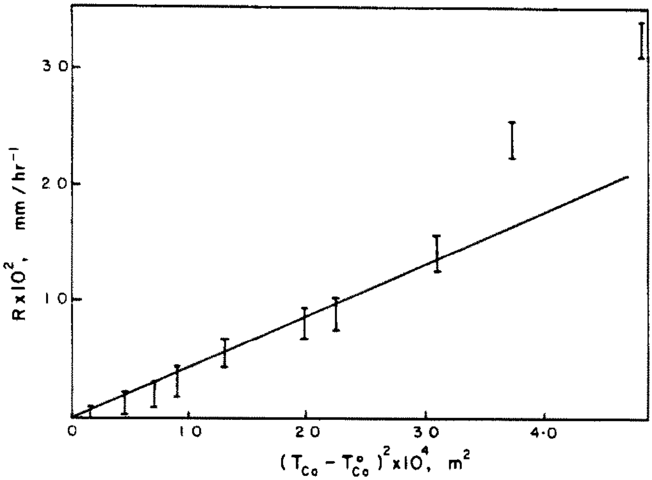

Fig 2 Kinetic plot of growth rate, R, against $(T_{Ca} - T_{Ca}^{\circ})^2$

45	0·76	1·0	1·3
35	0·81	0·45	0·55
25	0·85	0·20	0·23

activation energy obtained is 16 ± 1·5 kcal/mole for the fast growing faces and this value is in satisfactory agreement with that obtained in previous studies.[5]

The induction period in the experiments is the time period between the mixing of solutions containing the lattice ions and the appearance of the first solid phase. The change of induction period with concentration of the supersaturated solutions for calcium sulphate dihydrate precipitation was studied at 25° and 90°. The results are shown in Table 3. The experimental results are satisfactorily treated by equation (2)

$$K = C_o^{(p-1)}t \tag{2}$$

where K is a constant, p the number of ions in the critical nucleus, C_o the concentration of the supersaturated solution and t the induction period. Plots of log t *vs.* log C_o are given in Fig. 5. At a given initial concentration, the length of the induction period decreases appreciably with increase in temperature. If the nucleation rate is inversely proportional to the length of the induction period, the marked decrease of t with increasing temperature may indicate an appreciable activation energy for the nucleation of calcium sulphate dihydrate.

The equation (2) was derived by Christiansen and Nielsen in a non-classical nucleation theory which has been applied in studies of many insoluble salts.[12–14] In the present

SHORT COMMUNICATIONS

SPECTROCHEMICAL DETERMINATION OF IMPURITIES IN TELLURIC ACID

(*Received* 7 *March* 1972 *Accepted* 23 *May* 1972)

The radioactive isotope of iodine, ^{131}I, is produced in nuclear reactors by (n, γ) reaction from tellurium. In order to improve the nuclear balance for production of ^{131}I, it is important to have a tellurium target of high purity. Since in our Institute telluric acid has been used as a target, it was necessary to develop a sensitive method for checking its purity. The spectrochemical method has been found to be the most promising for this purpose because of its simplicity and accuracy. Several papers have been published describing either direct spectrographic procedures[1,2] or indirect procedures[3,4] involving preconcentration of the impurities.

Depending on the techniques used for preconcentration, the known indirect methods belong to two groups: in the first are the methods applying a prior physical concentration through vacuum evaporation of the matrix and concentration of the impurities on a graphite matrix, and in the second are the methods using a chemical preconcentration by separation of the impurities with 8-hydroxyquinoline and dithizone.

When the direct methods are applied, a sensitivity of 10^{-4}–10^{-3}% is obtained, while with a chemical preconcentration procedure, the sensitivity is improved to 10^{-7}% with 20-g samples.

In the present work a direct method has been used for spectrographic analysis of the concentration of impurities in telluric acid targets.

EXPERIMENTAL

Preparation of standards and samples

The basic standards were prepared from Johnson and Matthey telluric acid, $H_2TeO_4 \cdot 2H_2O$, dried for 24 hr at 160° to remove the water and obtain metatelluric acid, $(H_2TeO_4)_x$ (x = 1–10), which was then mixed with appropriate amounts of oxides of the elements to be measured. The standards were then mixed with graphite in 3:1 ratio (standard:graphite), with 12% of a spectrochemical buffer (NaCl–KCl) and with 0.1% of GeO_2 as internal standard.

The telluric acid samples are dried and mixed in the same manner as the standards. Ignited telluric acid was used for irradiation.

Spectrographic procedure

Duplicate standards and samples were excited in a 12-A d.c. arc. In order to increase the yield of the sample entering the excitation zone, an NaCl-KCl buffer was added to the telluric acid sample. It has been shown[5,6] that adding alkali metal salts lowers the ionization threshold and increases the sensitivity of determination of impurities.

The spectrograph used was a Jarrel-Ash type with a diffraction grating with 600 lines/mm. The main spectrographic conditions are given in Table 1.

Table 1 Apparatus and operating conditions

Spectrograph	Jarrel-Ash with flat grating
Wavelength region	220–360 nm (first order)
Slit-width	20 μm
Analytical gap	4 mm
Excitation source	Jarrel-Ash Varisource, 12 A, d.c. arc.
Electrodes	Counter-electrode (cathode)—graphite rod, spectral grade, 3·1 mm diam., used as obtained Sample electrode (anode)—graphite, 6·3 mm diam., crater 5 mm deep, 4·5 mm internal diam
Sample charge	70 mg
Preburn time	none
Exposure	40 sec
Emulsion, *etc*	Kodak SA1, developer D-19, 4 min at 20°, using Jarrell-Ash photoprocessor.

The spectrograms were measured on a Jarrell-Ash microphotometer. The analytical lines and concentration ranges are listed in Table 2

Table 2 Analytical lines and concentration ranges of determination

MICROANALYSIS OF SULPHIDE, SULPHITE, SULPHATE AND THIOSULPHATE BY THIN-LAYER CHROMATOGRAPHY AND RING-COLORIMETRY

(*Received* 31 *December* 1971 *Accepted* 29 *May* 1972)

For the micro-separation of inorganic sulphur compounds, paper[1–5] and ion-exchange[6–8] chromatography have been most often used, with little attention being given to thin-layer chromatography (TLC),[9–12] and that only of a qualitative nature

This paper describes an efficient separation of S^{2-}, SO_3^{2-}, SO_4^{2-} and $S_2O_3^{2-}$ on microcrystalline cellulose, and their subsequent determination by the Weisz ring-oven technique[13] The successful combination of these two techniques by Johri *et al*[14–19] has already been reported

EXPERIMENTAL

Apparatus

Glass plates (200 × 50 × 3 mm) coated with a 0 2-mm thick layer of microcrystalline cellulose without binder (Camag, DSF-O), kept overnight before use

The mini-vacuum-collector devised by Levitt[20] was used for scooping out zones from the chromatograms

Hamilton micro-syringe for spotting the plates

Reagents

Analytical grade sodium sulphide, sulphite, sulphate and thiosulphate were dissolved in doubly distilled water to give 1 mg/ml stock solutions of each

Summary—An emission spectrographic method is described for determination of 20 elements present as impurities in telluric acid Samples are excited in a 12-A d.c arc with the use of NaCl-KCl as a spectrographic buffer and germanium as internal standard. The limit of determination lies between 10^{-5} and 10^{-2}% The precision of the method calculated as relative standard deviation is 10–25%

Zusammenfassung—Ein emissionsspektrographisches Verfahren zur Bestimmung von 20 Elementen, die als Verunreinigungen in Tellursaure vorliegen, wird beschrieben. Die Proben werden in einem 12 A-Gleichstrombogen mit NaCl-KCl als spektrographischem Puffer und Germanium als innerem Standard angeregt Die Grenze der Bestimmbarkeit liegt zwischen 10^{-5} und 10^{-2}% Die Genauigkeit der Methode, als relative Standardabweichung berechnet, ist 10–25%

Résumé—On décrit une méthode spectrographique d'émission pour le dosage de 20 éléments présents à l'état d'impuretés dans l'acide tellurique Les échantillons sont excités dans un arc à courant continu de 12 A en employant NaCl–KCl comme tampon spectrographique et le germanium comme étalon interne La limite de dosage se situe entre 10^{-5} et 10^{-2}% La précision de la méthode, calculée en écart type relatif, est de 10–25%

MICROANALYSIS OF SULPHIDE, SULPHITE, SULPHATE AND THIOSULPHATE BY THIN-LAYER CHROMATOGRAPHY AND RING-COLORIMETRY

(*Received* 31 *December* 1971 *Accepted* 29 *May* 1972)

For the micro-separation of inorganic sulphur compounds, paper[1–5] and ion-exchange[6–8] chromatography have been most often used, with little attention being given to thin-layer chromatography (TLC),[9–12] and that only of a qualitative nature

This paper describes an efficient separation of S^{2-}, SO_3^{2-}, SO_4^{2-} and $S_2O_3^{2-}$ on microcrystalline cellulose, and their subsequent determination by the Weisz ring-oven technique[13] The successful combination of these two techniques by Johri *et al*[14–19] has already been reported

EXPERIMENTAL

Apparatus

Glass plates (200 × 50 × 3 mm) coated with a 0 2-mm thick layer of microcrystalline cellulose without binder (Camag, DSF-O), kept overnight before use

The mini-vacuum-collector devised by Levitt[20] was used for scooping out zones from the chromatograms

Hamilton micro-syringe for spotting the plates

Reagents

Analytical grade sodium sulphide, sulphite, sulphate and thiosulphate were dissolved in doubly distilled water to give 1 mg/ml stock solutions of each

Procedure

For the qualitative analysis of the anions, drops of a 1% aqueous zinc acetate solution were applied along the base-line at five different points on the cellulose-coated plate with the help of a pointed paper wick. The plate was dried and then the test solutions of SO_3^{2-}, SO_4^{2-}, $S_2O_3^{2-}$ and S^{2-} ions were applied in that sequence at the first four points, and a mixture of the four was applied at the fifth point. The volumes applied were in the range 1–5 μl. The plate was developed by the ascending technique in n-propanol–1*M* ammonia–acetone (30 . 20 : 2, v/v) for 30 min at 28–30°, affording a clean separation of the constituent anions. The plate was removed from the jar and dried in a stream of cool air and the respective anionic species were located by spraying with the reagents listed in Table 1 During the spraying with different reagents, glass plates were used to mask those areas of the thin-layer plate which were not to be examined The R_F values were $SO_3^{2-} > S_2O_3^{2-} > SO_4^{2-} > S^{2-}$ No movement of S^{2-} ions were observed since these were precipitated as ZnS.

Table 1. Detection of ions after TLC separation

Ion	Spray reagent	Colour	R_F	Limit of identification, μg
S^{2-}	Aqueous 1% silver nitrate solution	Brown black	zero	0 2
SO_4^{2-}	Aqueous 0·1% barium chloride and aqueous 0·1% sodium rhodizonate solutions	Yellow against a red background	0 28	1 0
$S_2O_3^{2-}$	Aqueous 1% silver nitrate solution	Brown black	0 51	0 5
SO_3^{2-}	Mixture of equal volumes of aqueous 1% cobalt nitrate containing a few drops of dil. acetic acid and saturated sodium azide solution.	Yellow	0 70	0 5

Ring-colorimetric determination of the chromatographed constituents

For the semiquantitative determination of anions, zinc acetate solution was applied at four different points along the base-line on the thin-layer plate, leaving sufficient space between the spots so that there was no sideways overlap of spots during the chromatography. The fifth spot used in the qualitative procedure was not needed since only one visualizing agent, silver nitrate, was employed for both S^{2-} and $S_2O_3^{2-}$ ions (Table 1).

Next, one drop of a known mixture of S^{2-}, SO_3^{2-}, $S_2O_3^{2-}$ and SO_4^{2-} ions was applied to each of the first three zinc acetate spots, and a known volume of the test sample to the fourth spot. The plate was developed as described earlier The three developed regions of the known anionic mixture were sprayed respectively with solutions of silver nitrate (for S^{2-} and $S_2O_3^{2-}$ ions), sodium rhodizonate with barium chloride (for SO_4^{2-} ions) and cobalt nitrate with sodium azide (for SO_3^{2-} ions). Next, the regions corresponding to SO_3^{2-}, SO_4^{2-} and $S_2O_3^{2-}$ ions on the unsprayed test chromatogram were sucked out by means of a mini-vacuum-collector. The plate was then developed with water for a few cm distance in order to remove all the unreacted zinc ions, taken out of the jar, dried in a hot air stream, cooled, and fumed over bromine to oxidize zinc sulphide to sulphate, which was then also sucked out. The vacuum-collector was dismantled, the inner tube containing one particular anionic species plus cellulose powder was taken out, and the anions from this tube, which would serve as a mini-column, were leached out with water onto a Whatman No 41 filter paper (55 mm diameter) placed on the ring oven heated at 100–110° The anions were then brought into the ring zone by washing with water The same process was repeated for the other anionic species. The individual anion species were then treated with the chromogenic reagents listed in Table 2.

For semiquantitative evaluation, the intensities of the coloured rings obtained with the different anionic species were compared visually with those of standard rings prepared separately,[2] and corresponding to 1–10 μl of standard solution. Results of a few representative determinations are given in Table 2.

The TLC separation gives compact spots for S^{2-}, SO_3^{2-} and SO_4^{2-} ions, and a slightly blurred spot for $S_2O_3^{2-}$ ions. The function of applying zinc acetate in the beginning is to fix S^{2-} ions as ZnS, though the inclusion of zinc acetate in the solvent system causes some tailing due to S^{2-} ions A study of the results (Table 2) suggests that the errors lie within the permissible limits for semi-quantitative analysis Moreover, the combination of the two techniques described offers the advantages of speed and simplicity and at the same time requires only inexpensive apparatus

Table 2 Representative results of determinations

Anion determined	Metal ion employed for the indirect determination of anions	Developing agents for the metal ion	Colour of the ring	Anion taken, *mg/ml*	Anion found, *mg/ml*
S^{2-}	Zinc	Alcoholic 1% diethylaniline and aqueous 1% pottassium ferricyanide solution	Red	4·10	4·3
				2·25	2·3
				1·00	0·95
$SO_4{}^{2-}$	Lead	Aqueous 0·1% sodium rhodizonate and fume over HCl	Blue violet	3·20	3·1
				2·75	2·9
				1·85	1·8
$SO_3{}^{2-}$	Lead	(*a*) Fume over bromine (*b*) Aqueous 0·1% sodium rhodizonate and fume over HCl	Blue violet	2·45	2·5
				3·30	3·2
				1·50	1·5
$S_2O_3{}^{2-}$	—	Aqueous 1% silver nitrate	Brown black	3·50	3·4
				1·10	1·2
				2·60	2·7

SPECTROPHOTOMETRIC DETERMINATION OF STRYCHNINE AND METHYLATROPINE BY EXTRACTION WITH TETRABROMOPHENOLPHTHALEIN ETHYL ESTER

(*Received* 5 *April* 1972. *Accepted* 15 *May* 1972)

Some acid dyes,[1,2] such as Bromothymol Blue,[3-5] Bromocresol Green[6] or Bromophenol Blue[7,8] have been used for the spectrophotometric determination of amines, alkaloids or quaternary ammonium salts These dyes are dibasic acids, and have serious drawbacks because of their extreme sensitivity to change in acidity; an indeterminate number of 1:1 and 1:2 ion-pairs are formed with resultant poor reproducibility and extreme pH-dependence.

Tetrabromophenolphthalein ethyl ester (TBPE), which has just one acidic group, is able to form only a 1:1 ion-pair complex, which is reproducibly extracted Various amines, alkaloids and quaternary ammonium salts have been extracted with TBPE at pH 7·5 into 1,2-dichloroethane. The colour of the extracts fall into three categories: (*i*) blue (ionic form of TBPE) which is extracted in the presence of many quaternary ammonium salts and alkaloids such as spartein, (*ii*) red which is developed in the presence of alkaloids such as strychnine, physostigmine, quinidine and homatropine, a weak red colour is given by amines such as α-naphthylamine and triethanolamine; (*iii*) yellow (molecular form of TBPE) which is the same colour as the reagent blank even in the presence of aniline, dimethylamine, *N,N'*-dimethylformamide, ethylenediaminetetra-acetic acid, or nitrilotriacetic acid. If the extraction is performed from acidic solution, the colours of the extracts are all yellow even in cases (*i*) and (*ii*).

This paper deals with the determination of methylatropine and strychnine as representatives of the quaternary ammonium salts and the alkaloids, and as widely used medicines (parasympatholytics *etc*) Hexanitrodiphenylamine has been used as a spectrophotometric reagent for alkaloids or quaternary ammonium salts,[9,10] and titrimetric methods have also been investigated[11-14]

EXPERIMENTAL

Reagents

Tetrabromophenolphthalein ethyl ester (*TBPE*) *potassium salt* (*m w* 700·1) Weighed amounts were dissolved in ethyl alcohol.

Standard strychnine and methylatropine solutions. Weighed amounts of strychnine sulphate (dried at 105°) or *N*-methylatropine bromide (dried at 105°) were dissolved in water and diluted to known volume.

Buffer solutions, pH 8 and pH 9·5. Appropriate volumes of 0·4*M* potassium dihydrogen phosphate, 0·06*M* sodium borate and 3*M* sodium hydroxide were mixed

All the chemicals were of reagent grade, and demineralized water was used

Procedures

Strychnine. Transfer 2-10 ml of strychnine solution ($2·0 \times 10^{-5}M$), 2 ml of TBPE solution ($4 \times 10^{-3}M$), and 5 ml of buffer solution (pH 8) into a 100-ml separating funnel, dilute to 25 ml with water and shake the solution for 2 min with 10 ml of 1,2-dichloroethane. After separation of the two layers, run off the extract into a glass tube through a filter paper to remove any droplets of water Measure the absorbance of the extract at 560 nm, using a reagent blank or water as a reference

Methylatropine Transfer 2-10 ml of standard methylatropine solution ($1·0 \times 10^{-5}M$), 2 ml of TBPE solution ($2 \times 10^{-3}M$), and 5 ml of buffer solution (pH 9·5) into a 100-ml separating-funnel Treat the mixture in the same manner as described for strychnine Measure the absorbance at 615 nm.

Résumé—On a réalisé des séparations analytiques nettes et rapides de quantités d'ions S^{2-}, SO_3^{2-}, SO_4^{2-} et $S_2O_3^{2-}$ de l'ordre du microgramme par chromatographie en couche mince ascendante sur de la cellulose microcristalline avec le mélange *n*-propanol-ammoniaque 1*M*-acétone (30 : 20 : 2) comme système solvant. SPECTROPHOTOMETRIC DETERMINATION OF STRYCHNINE AND METHYLATROPINE BY EXTRACTION WITH TETRABROMOPHENOLPHTHALEIN ETHYL ESTER

(*Received* 5 *April* 1972. *Accepted* 15 *May* 1972)

Some acid dyes,[1,2] such as Bromothymol Blue,[3–5] Bromocresol Green[6] or Bromophenol Blue[7,8] have been used for the spectrophotometric determination of amines, alkaloids or quaternary ammonium salts. These dyes are dibasic acids, and have serious drawbacks because of their extreme sensitivity to change in acidity; an indeterminate number of 1:1 and 1:2 ion-pairs are formed with resultant poor reproducibility and extreme pH-dependence.

Tetrabromophenolphthalein ethyl ester (TBPE), which has just one acidic group, is able to form only a 1:1 ion-pair complex, which is reproducibly extracted. Various amines, alkaloids and quaternary ammonium salts have been extracted with TBPE at pH 7·5 into 1,2-dichloroethane. The colour of the extracts fall into three categories: (*i*) blue (ionic form of TBPE) which is extracted in the presence of many quaternary ammonium salts and alkaloids such as spartein, (*ii*) red which is developed in the presence of alkaloids such as strychnine, physostigmine, quinidine and homatropine, a weak red colour is given by amines such as α-naphthylamine and triethanolamine; (*iii*) yellow (molecular form of TBPE) which is the same colour as the reagent blank even in the presence of aniline, dimethylamine, *N,N'*-dimethylformamide, ethylenediaminetetra-acetic acid, or nitrilotriacetic acid. If the extraction is performed from acidic solution, the colours of the extracts are all yellow even in cases (*i*) and (*ii*).

This paper deals with the determination of methylatropine and strychnine as representatives of the quaternary ammonium salts and the alkaloids, and as widely used medicines (parasympatholytics *etc*). Hexanitrodiphenylamine has been used as a spectrophotometric reagent for alkaloids or quaternary ammonium salts,[9,10] and titrimetric methods have also been investigated.[11–14]

EXPERIMENTAL

Reagents

Tetrabromophenolphthalein ethyl ester (*TBPE*) *potassium salt* (*m.w.* 700·1). Weighed amounts were dissolved in ethyl alcohol.

Standard strychnine and methylatropine solutions. Weighed amounts of strychnine sulphate (dried at 105°) or *N*-methylatropine bromide (dried at 105°) were dissolved in water and diluted to known volume.

Buffer solutions, pH 8 and pH 9·5. Appropriate volumes of 0·4*M* potassium dihydrogen phosphate, 0·06*M* sodium borate and 3*M* sodium hydroxide were mixed.

All the chemicals were of reagent grade, and demineralized water was used.

Procedures

Strychnine. Transfer 2–10 ml of strychnine solution ($2\cdot0 \times 10^{-5}M$), 2 ml of TBPE solution ($4 \times 10^{-3}M$), and 5 ml of buffer solution (pH 8) into a 100-ml separating funnel, dilute to 25 ml with water and shake the solution for 2 min with 10 ml of 1,2-dichloroethane. After separation of the two layers, run off the extract into a glass tube through a filter paper to remove any droplets of water. Measure the absorbance of the extract at 560 nm, using a reagent blank or water as a reference.

Methylatropine. Transfer 2–10 ml of standard methylatropine solution ($1\cdot0 \times 10^{-5}M$), 2 ml of TBPE solution ($2 \times 10^{-3}M$), and 5 ml of buffer solution (pH 9·5) into a 100-ml separating-funnel. Treat the mixture in the same manner as described for strychnine. Measure the absorbance at 615 nm.

RESULTS AND DISCUSSION

Absorption spectra

In the absence of methylatropine or strychnine a yellow compound is extracted into dichloroethane, whilst in their presence a blue (λ_{max} 615 nm) or red (λ_{max} 560 nm) one is formed. The change in colour may be attributed to the formation of an ion-pair or addition compound between the TBPE and the quaternary ammonium cation or the alkaloid.

Effect of variables

pH. Methylatropine or strychnine was extracted with TBPE from a series of aqueous solutions buffered at various pH values. The absorbance of the extract was constant when the pH of the aqueous phase lay within the range 9·0–10·5 for methylatropine and 7·0–9·0 for strychnine. Extreme pH-dependence was observed for the determination of quinine or thiamine with Bromophenol Blue[7] or Bromothymol Blue.[3] Similarly, constant absorbance in any pH range could not be obtained when Bromophenol Blue or Bromocresol Green was used as extractant for methylatropine or strychnine.

Reagent concentration. It is found that the concentration of TPBE should be maintained at more than 20-fold molar excess over methylatropine or 40-fold molar excess over strychnine to obtain a maximum and constant extraction. Excess (2–10 ml) of the buffer solution used in the procedure had no influence on the absorbance of the extracts. When the amount of the buffer solution was less than 2 ml, separation of the two layers was poor.

Solvent for extraction. The behaviour of various solvents in the extraction was studied. Solvents were found to fall into the following categories:

(*i*) Those which enhance the extraction, *e.g.*, 1,2-dichloroethane, chloroform.

(*ii*) Those which do not extract the coloured complex even in the presence of quaternary ammonium salts or alkaloids, *e.g.*, carbon tetrachloride, cyclohexane, n-hexane, toluene, monochlorobenzene.

(*iii*) Those with which the blue TBPE is extractable even without quaternary ammonium salts or alkaloids, *e.g.*, butyl acetate, ether, ethyl acetate, isopentyl alcohol, nitrobenzene, methyl isobutyl ketone.

Of these, 1,2-dichloroethane was found to be most suitable for the extraction of the methylatropine or strychnine complexes.

Other variables. Full colour development took about 1 min of shaking. Continued shaking up to 5 min produced no further change in absorbance. The colour intensity of the dichloroethane extracts remains constant for 1 hr.

Fluctuations in room temperature (14–22°) were without measurable effect on the absorbance.

Calibration and precision. A linear relationship was observed between the absorbance of the extract and the concentration of methylatropine ($8·0 \times 10^{-7}$–$4·0 \times 10^{-6}M$, molar absorptivity $1·90 \times 10^5$ $l \cdot mole^{-1} \cdot cm^{-1}$ at 615 nm) or strychnine ($1·6 \times 10^{-6}$–$8·0 \times 10^{-6}M$, molar absorptivity $8·0 \times 10^4$ $l \cdot mole^{-1} \cdot cm^{-1}$ at 560 nm) in the initial aqueous phase.

The reproducibility was estimated from the results for ten sample solutions, each with a final methylatropine concentration of $4·0 \times 10^{-6}M$. The mean absorbance was 0·761, standard deviation 0·008.

Composition of the coloured species

Continuous variations plots (TBPE + methylatropine = $8 \times 10^{-6}M$, λ = 590, 615 and 630 nm; TBPE + strychnine = $5 \times 10^{-5}M$, λ = 540, 560 and 600 nm) have a maximum at 0·5 mole-fraction of TBPE, indicating a 1:1 TBPE-methylatropine or TBPE-strychnine ratio.

In order to investigate the state of the coloured species in dichloroethane, the electrical conductivity of the extracts was measured. The results obtained shows that the TBPE–methylatropine species is in the ionized state and the TBPE–strychnine species is in the molecular state in dichloroethane. The extracted species, therefore, may be formulated as Strychnine·H(TBPE) and $[\text{Methylatropine}]^+[\text{TBPE}]^-$.

Effect of foreign substances and analysis of practical samples

Potassium nitrate, ammonium sulphate, magnesium chloride, calcium chloride, acetates, citrates, salicylates, glucose, lactose, *o*-cresol, phenol and aniline do not interfere in the determination of methylatropine or strychnine when present at the level of $2 \times 10^{-3}M$. Alkaloids interfere.

The method was applied to a strychnine injection obtained from a drugstore. The result was $2·57 \times 10^{-3}M$ strychnine by the proposed method, and $2·48 \times 10^{-3}M$ by the titrimetric method.[14]

The proposed method has proved applicable to the determination of many quaternary ammonium salts and alkaloids such as spartein, quinine, physostigmine, homatropine, and atropine.

Summary—A new application of monoacidic dyes is reported for the determination of strychnine and methylatropine The method is based on solvent extraction into 1,2-dichloroethane of the ion-pair or addition compound formed between tetrabromophenolphthalein ethyl ester and quaternary ammonium salts or alkaloids. The absorbance of the extracts is linearly dependent on the concentration of strychnine or methylatropine initially present in the aqueous solution

Zusammenfassung—Es wird uber eine neue Anwendung von Farbstoffen mit einer sauren Funktion zur Bestimmung von Strychnin und Methylatropin berichtet. Die Methode beruht auf der Extraktion des Ionenpaars oder der Additionsverbindung aus Tetrabromphenolphthaleinäthylester und quartaren Ammoniumsalzen oder Alkaloiden in 1,2-Dichloräthan. Die Extinktion der Extrakte hangt linear von der Konzentration von ursprunglich in der waßrigen Losung vorliegendem Strychnin oder Methylatropin ab.

Résumé—On rapporte une nouvelle application d'un colorant monoacide au dosage de la strychnine et de la méthylatropine La methode est basée sur l'extraction par solvant en 1,2-dichloréthane de la paire d'ions ou de composé d'addition formé entre l'ester éthylique de la tétrabromophénolphtaléine et les d'ammoniums quaternaires ou les alcaloides Il y a relation linéaire entre l'absorption et la concentration en strychnine ou en méthylatropine initialement présente dans la solution aqueuse

STUDY OF Cu(II)-HYDRAZINE-6-METHYLPICOLINALDEHYDE SYSTEM: A NEW "*IN SITU*" REACTION

(*Received* 23 *February* 1972. *Accepted* 5 *July* 1972)

The analytical applications of 6-methylpicolinaldehyde azine (6-Me-PAA) and hydrazone (6-Me-PAH) as photometric selective reagents for copper(I) have been reported.[1, 2] This paper reports primary and secondary "*in situ*" reactions between (*i*) copper(II) and 6-Me-PA and hydrazine, and (*ii*) copper(I)-6-Me-PAA with hydrazine or hydroxylamine. These "*in situ*" colour developments sometimes have practical advantages [3-6]

EXPERIMENTAL

Reagents

6-Me-PA, 6-Me-PAA and 6-Me-PAH. Aqueous or ethanolic solutions of 6-Me-PA, hydrazine hydrate, hydroxylamine hydrochloride, 6-Me-PAA, and 6-Me-PAH were used. The synthesis of the latter reagents has been described previously [1, 2]

Buffer solutions Acetic acid–sodium acetate and boric acid–sodium hydroxide mixtures were used as appropriate.

All the reagents used were analytical grade

Summary—A new application of monoacidic dyes is reported for the determination of strychnine and methylatropine The method is based on solvent extraction into 1,2-dichloroethane of the ion-pair or addition compound formed between tetrabromophenolphthalein ethyl ester and quaternary ammonium salts or alkaloids. The absorbance of the extracts is linearly dependent on the concentration of strychnine or methylatropine initially present in the aqueous solution

Zusammenfassung—Es wird uber eine neue Anwendung von Farbstoffen mit einer sauren Funktion zur Bestimmung von Strychnin und Methylatropin berichtet. Die Methode beruht auf der Extraktion des Ionenpaars oder der Additionsverbindung aus Tetrabromphenolphthaleinäthylester und quartaren Ammoniumsalzen oder Alkaloiden in 1,2-Dichloräthan. Die Extinktion der Extrakte hangt linear von der Konzentration von ursprunglich in der waßrigen Losung vorliegendem Strychnin oder Methylatropin ab.

Résumé—On rapporte une nouvelle application d'un colorant monoacide au dosage de la strychnine et de la méthylatropine La methode est basée sur l'extraction par solvant en 1,2-dichloréthane de la paire d'ions ou de composé d'addition formé entre l'ester éthylique de la tétrabromophénolphtaléine et les d'ammoniums quaternaires ou les alcaloides Il y a relation linéaire entre l'absorption et la concentration en strychnine ou en méthylatropine initialement présente dans la solution aqueuse

STUDY OF Cu(II)-HYDRAZINE-6-METHYLPICOLINALDEHYDE SYSTEM: A NEW "*IN SITU*" REACTION

(*Received* 23 *February* 1972. *Accepted* 5 *July* 1972)

The analytical applications of 6-methylpicolinaldehyde azine (6-Me-PAA) and hydrazone (6-Me-PAH) as photometric selective reagents for copper(I) have been reported.[1,2] This paper reports primary and secondary "*in situ*" reactions between (*i*) copper(II) and 6-Me-PA and hydrazine, and (*ii*) copper(I)–6-Me-PAA with hydrazine or hydroxylamine. These "*in situ*" colour developments sometimes have practical advantages[3–6]

EXPERIMENTAL

Reagents

6-Me-PA, 6-Me-PAA and 6-Me-PAH. Aqueous or ethanolic solutions of 6-Me-PA, hydrazine hydrate, hydroxylamine hydrochloride, 6-Me-PAA, and 6-Me-PAH were used. The synthesis of the latter reagents has been described previously[1,2]

Buffer solutions Acetic acid–sodium acetate and boric acid–sodium hydroxide mixtures were used as appropriate.

All the reagents used were analytical grade

General procedure

The samples were prepared in 50-ml flasks with varying amounts of copper, buffer solution and reagents. They were diluted to volume with distilled water, and their absorbances measured against blank solutions prepared in the same way but with no copper. If necessary, samples were heated in a water-bath before transfer to the volumetric flasks.

RESULTS AND DISCUSSION

Reaction between Cu(II), hydrazine and 6-Me-PA

Hemerich *et al.*[7] have described the formation of a weak bidentate complex between Cu(II) and 6-Me-PA at pH 4 with release of a proton. At the pH used in the present work, 8·6, this reaction could not be detected. Hydrazine reduces Cu(II) to Cu(I), which precipitates as oxide in the absence of a complexing medium. If 6-Me-PA is added, the precipitate disappears, and the solution becomes brightly coloured.

Several samples were prepared with 5·9 ppm of copper, 2·5 ml of 0·05*M* ethanolic solution of 6-Me-PA, variable volumes of 0·05*M* aqueous solution of hydrazine hydrate and 10 ml of pH 8·6 buffer. The mixtures were heated at 60° for 15 min, the higher temperature favouring the formation of Cu(I)–6-Me-PAA.

The formation of the copper(I) complexes is influenced by pH,[1,2] which for this system should be between 6·5 and 10.

When the molar ratio aldehyde : hydrazine is 2 : 1, the azine is formed (Table 1). This is more soluble in 50% aqueous ethanol than in water.

The Cu(I)–6-Me-PAH complex is formed when the molar ratio between aldehyde and hydrazine is 1 : 1, Table 1, but 2·5 ml of 0·05*M* solutions of the reagents were used to obtain a slight excess. The solutions of both complexes were stable for at least 8 hr and longer heating periods did not improve the stability. If the reaction is carried out at room temperature, the sensitivity is lower and the amount of reagents required is greater.

Reaction between 6-Me-PA and Cu(I)–6-Me-PAH complex

Several samples were prepared with 5 ml of a neutralized 0·1% solution of 6-Me-PAH hydrochloride, 10 ml of pH 8·6 buffer, 10 ppm of Cu(I) and various volumes of 0·5*M* ethanolic solution of 6-Me-PA. On mixing there was an almost instantaneous disappearance of the absorption maximum at 425 nm, due to the Cu(I)–hydrazone complex, and formation of a maximum at 470–80 nm due to the Cu(I)–azine complex. With 0·5 ml of aldehyde solution, the transformation took place in 30 min, and with 1 ml 5 min. Heating the samples was unnecessary.

Table 1. Primary "*in situ*" formation of cuprous complexes

Molar ratio 6-Me-PA/hydrazine	Absorbance 480 nm	Absorbance 425 nm
5·00	0·500	0·338
2·00	0·520	0·325
1·66	0·510	0·360
1·42	0·490	0·380
1·25	0·450	0·430
1·11	0·415	0·507
1·00	0·320	0·620
0·83	0·240	0·630

"In situ" *reactions based on exchange of* $>$C=N— *groups*

Transformation of 6-Me-PAA into 6-Me-PAH in presence of copper. When 1 ml of 0·25*M* hydrazine hydrate solution was added to 5×10^{-5}*M* 6-Me-PAA at pH 8·6, the characteristic azine bands at 309 and 318 nm disappeared and a maximum at 293 nm and a shoulder at 260-5 nm, corresponding to 6-Me-PAH, were formed. There are two isosbestic points, at 299 and 226 nm. To confirm these spectral data, 6-Me-PAH was isolated in a crystalline state from the reaction mixture at greater concentration, and examined.

In the presence of copper, this transformation is detectable in the visible region. A sample containing 10 ppm of copper, 5 ml of 0·1% ethanolic solution of 6-Me-PAA, 10 ml of pH 8·6 buffer and 5 ml of 0·46*M* hydrazine hydrate was prepared. The absorption spectrum of the Cu(I)–azine complex gradually disappeared, as the maximum at 425 nm corresponding to the Cu(I)–hydrazone complex was formed. There are two isosbestic points at 462 and 391 nm but the initial curve without hydrazine does not pass through them.

The optimum conditions are 2 ml of 1*M* hydrazine hydrate and 5 ml of 0·1% 6-Me-PAA solution The solutions were stable for 1–9 hr after their preparation. Prior heating of the samples does not improve their stability. The order of addition of the reagents has no influence.

Transformation of 6-Me-PAA into 6-Me-PAO in presence of copper 6-Methylpicolinaldehyde oxime (6-Me-PAO) has been isolated by heating a suspension of 6-Me-PAA in a hydroxylamine solution at pH 8·6 Its melting point, ultraviolet spectrum and reaction with the cuprous ion are the same as those of 6-Me-PAO prepared by the usual procedure [9] This transformation was checked spectroscopically in the same way as in the previous case, but now 1 ml of neutralized 0·25*M* hydroxylamine hydrochloride was added instead of the hydrazine. The azine spectrum disappeared, and that of the oxime was formed (maxima at 280–6 nm and 244 nm). with isosbestic points at 293 and 224 nm.

This transformation also takes place in the presence of copper under the same conditions as described above The band at 470–80 nm disappears, as a stronger band at 425 nm appears, due to the Cu(I)–oxime complex There are two isosbestic points at 454 and 391 nm.

The variables which influence the reaction were studied and it was concluded that maximum colour development takes place at room temperature, at pH 4·5–5·3 with 3 ml of 1*M* hydroxylamine hydrochloride and 5 ml of 0·1% 6-Me-PAA solution. The solutions were stable for at least 48 hr. The order of addition of the reagents has no influence.

DISCUSSION

The copper(I) complexes of 6-methylpicolinaldehyde azine and hydrazone can easily be obtained by primary "*in situ*" synthesis, from solutions of Cu(II), hydrazine hydrate and 6-methylpicolinaldehyde, according to the proportion of the last

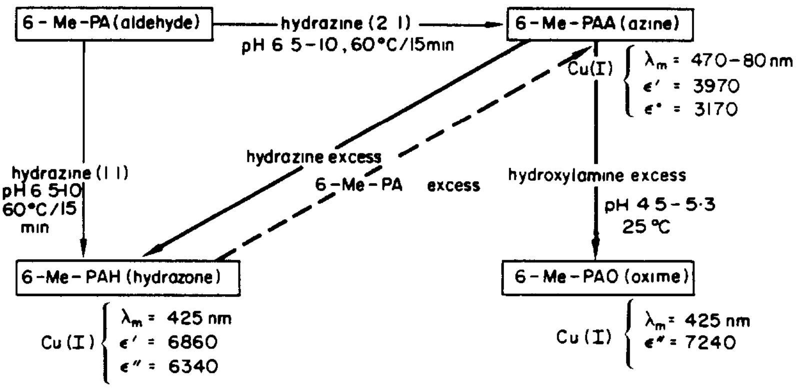
The action of 6-Me-PA on the yellow solutions of the Cu(I)–hydrazone complex was also tested, these solutions are rapidly transformed into red solutions of the Cu(I)–azine complex. The aldehyde interacts with the terminal amino group which does not participate in the formation of the complex, as its nitrogen atom is not included in the "cuproine" grouping of the molecule. The shift of λ_{max} from 425 to 470–80 nm is probably due to the increase of conjugation in the system in the ligand on passing from hydrazone to azine

The exchange between $\gt C{=}N{-}$ bonds has been reported.[10] The formation of a new bond depends on the equilibrium

$$\gt C{=}N{-}R + H_2N{-}R' \rightleftharpoons \gt C{=}N{-}R' + H_2N{-}R$$

which is displaced by the excess of one of the reactants. The conversion of azines into hydrazones by the action of hydrazines has been known for a long time.[11,12] The reaction of an excess of hydroxylamine with 6-Me-PAA leads to the formation of two molecules of oxime in two stages. the formation of hydrazone and oxime, followed by the transformation of hydrazone into another oxime molecule, and a hydrazine molecule. Therefore a lesser amount of hydrazine than hydroxylamine is required to carry out the respective transformations. This may also be the cause of the formation of oxime being much slower than that of hydrazone, which takes place in a single step whereas the Cu(I)–oxime complex is produced more quickly than the corresponding Cu(I)–hydrazone. In all cases a 100 1 molar ratio of amine to 6-Me-PAA was used.

In the diagram the two types of "*in situ*" reaction applied to the Cu(II)–hydrazine–6-methylpicolinaldehyde system, and the optical constants, are summarized: a thin line is used for the reactions based on the reaction of aldehyde with diamine, and a thick line for those based on the exchange of $\gt C{=}N{-}$ bonds



The molar absorptivities found in these photometric reactions (ε' = primary, and ε'' = secondary "*in situ*" reactions) are lower than those found with the previously synthesized reagents:[1,2] $\varepsilon_{\text{azine}} = 4{\cdot}19 \times 10^3$ and $\varepsilon_{\text{hydrazone}} = 6{\cdot}95 \times 10^3$ l.mole^{-1} cm^{-1}. Furthermore, the apsorbtivity value corresponding to the transformations between complexes is lower than that of the normal type

In our numerous experiments with reagents prepared "*in situ*" it has always been observed that the apsorbtivities are lower than those obtained with the previously synthesized reagent A satisfactory explanation of this fact has not yet been found A synthesis of the reagent in insufficient quantity does not seem possible, as the amounts of the components are determined empirically to yield an excess of reagent As the reactive components, in all the cases studied, are able to form less stable complexes with the ions being studied, it can be supposed that the cation is shared between the two complexes in proportion to their stability, and so a small amount of ion would be subtracted for the formation of the "*in situ*" complex This is confirmed considering that in the secondary "*in situ*" reactions, the absorptivity (ε'') decreases relative to the primary "*in situ*" type (ε'), since the starting complex is stable and the competition between ligands in this case is greater

Summary—The Cu(II)-hydrazine-6-methylpicolinaldehyde system in solution is studied. The "*in situ*" reactions, based on the formation of a ligand by condensation of an amine and an aldehyde in the presence of the metal ion, and the consequent formation of the coloured Cu(I)-azine and Cu(I)-hydrazone complexes are reported. A new mode of homogeneous colour development, based on the exchange of $>$C=N— groups in the ligand with the metal ion present, is also described The results are compared with those obtained with the previously synthesized reagents

Zusammenfassung—Das System Kupfer(II)-Hydrazin-6-Methylpicolinaldehyd wird in Lösung untersucht Es wird über Reaktionen "in situ," die in der Bildung eines Liganden durch Kondensation eines Amins und eines Aldehyds in Gegenwart des Metallions bestehen, und die darauf folgende Bildung der farbigen Kupfer(I)-Azin- und Kupfer(I)-Hydrazonkomplexe berichtet Auch eine neue Art der Farbentwicklung in homogener Lösung wird geschildert, die auf dem Austausch von $>$C=N— Gruppen im Liganden mit dem anwesenden Metallion beruhen. Die Ergebnisse werden mit denen verglichen, die mit früher synthetisierten Reagentien erhalten wurden

Résumé—On étudie le système Cu(II)-hydrazine-6-méthylpicolinaldéhyde en solution On rapporte les reactions "*in situ*", basées sur la formation d'un coordinat par condensation d'une amine et d'un aldéhyde en la présence de l'ion métallique, et la formation consécutive des complexes colorés Cu(I)-azine et Cu(I)-hydrazone On décrit aussi un nouveau mode de développement de coloration homogène, base sur l'échange de groupes $>$C=N— dans le coordinat avec l'ion métallique présent On compare les résultats avec ceux obtenus avec les reactifs synthétisés antérieurement

STABILITY CONSTANTS OF SOME METAL DITHIZONATES

(*Received* 20 *March* 1972. *Accepted* 21 *August* 1972)

The instability and poor solubility of dithizone (diphenylthiocarbazone) in water makes the determination of stability constants of its metal chelates difficult. For that reason, the values of the stability constants are almost unknown[1] despite the excellence of dithizone as a chelating and extraction reagent

We investigated that problem and found a satisfactory solution that is presented in this paper

EXPERIMENTAL

Apparatus

All photometric measurements were made with the DU Beckman spectrophotometer, model 2400 (Fullerton, California). Quartz cells of 1-cm pathlength were used throughout. An Orion model 801 pH-meter (A. H. Thomas Co., Philadelphia. Pa.), with combined glass and calomel electrode, was used for pH measurements

Reagents

Perchlorates of the metals (G. F Smith Co., Columbus, Ohio) were used as 1·00 × $10^{-3}M$ aqueous stock solutions. Dithizone (Fisher Certified Reagent, Fair Lawn, N J) was purified by Welcher's method.[2] Its quality was checked by paper chromatography with methanol–water 10 1 on Chrom AR500 paper (Mallinckrodt Chem. Works, St. Louis, Missouri) and by elemental analysis. The product was chromatographically pure, $R_F = 0·87$ It was analysed with the following results: C 61·0%, H 4 8%, N 21 7%, S 12 4%; required for $C_{13}H_{12}N_4S$: C 60·9%, H 4·7%, N 21·9%, S 12·5%.

The 1·00 × $10^{-3}M$ stock solution of dithizone was prepared by dissolution of 6·4 mg of dithizone in 25·00 ml of 0·1*M* sodium hydroxide and 0·04*M* hydroxylamine hydrochloride. The solution was kept in the dark at 25° It was used during the next three hours, then a new solution was prepared. Solutions of 0·1*M* glycine + 0·05*M* hydroxylamine hydrochloride + 0·095*M* sodium perchlorate and 0·1*M* sodium hydroxide were used to adjust the pH to 5 55–10·02.

Measurement

The sequence of buffer, metal ion and dithizone was adhered to during the preparation of all solutions measured. The ionic strength was kept at 0·1*N* (sodium perchlorate), the temperature at 25 ± 1° The absorbance of solutions was measured against a buffer–reagent blank (or buffer-metal blank when an excess of metal ion was being used).

RESULTS AND DISCUSSION

Stability of dithizone solution

Hydrazine, ascorbic acid, sodium sulphite and hydroxylamine hydrochloride were investigated as stabilizing agents for aqueous solutions of dithizone. The last-mentioned reagent exhibits the most convenient properties It sufficiently stabilizes the solution of dithizone and its masking and reducing effects are negligible for the

‡ Unstabilized solution.

concentrations of metal ions used. The time-dependence of absorbance of the stabilized and unstabilized solutions of dithizone is shown in Table 1. It can be seen that the stability of the stabilized solution is quite satisfactory during the first three hours.

Stability of electroneutral complexes

Metal dithizonates are soluble at concentrations of 10^{-5}–$10^{-6}M$ at pH >5·3. Precipitation occurs below that value. Investigating the composition of complexes formed in the range of pH 5·5–6·5 by means of the continuous variation method, we found that electroneutral complexes of ML_n are formed in all cases, where the value of n corresponds to the charge on the metal ion. The occurrence of a single complex of ML_n was checked by the method of Coleman *et al.*,[3] employing the equation

$$\Delta A_1/\Delta A_2 = \Delta\varepsilon_{n(1)}/\Delta\varepsilon_{n(2)} = \text{const} \tag{1}$$

where ΔA_1, ΔA_2 and $\Delta\varepsilon_{n(1)}$, $\Delta\varepsilon_{n(2)}$ are the effective absorbances and molar absorptivities, respectively, measured at two different wavelengths. We have

$$\Delta \mathrm{A}_\lambda = \mathrm{A}_\lambda - \mathrm{A}_{\mathrm{L}(\lambda)} \tag{2}$$

and

$$\Delta\varepsilon_{n(\lambda)} = \varepsilon_{n(\lambda)} - n\varepsilon_{\mathrm{L}(\lambda)} \tag{3}$$

where A_λ and $\mathrm{A}_{\mathrm{L}(\lambda)}$ are the absorbances of the complexing and ligand (dithizone) solution, respectively; $\varepsilon_{n(\lambda)}$ and $\varepsilon_{\mathrm{L}(\lambda)}$ are the molar absorptivities of the complex ML_n and of the ligand.

Plotting the dependence $\Delta A_1 = f(\Delta A_2)$ for equation (1) we obtained straight lines crossing the point $\Delta A_1 = \Delta A_2 = 0$ throughout.

Knowing the value of n for each complex, we determined its overall stability constant β_n, employing the method of stoichiometric dilution.[4] According to that method we have

$$\beta_n = \alpha_{\mathrm{M(Y)}}\alpha^n_{\mathrm{L(H)}}/(y_n n^n c_{\mathrm{M}}{}^n) \tag{4}$$

where $\alpha_{\mathrm{M(Y)}}$ and $\alpha_{\mathrm{L(H)}}$ are the side-reaction coefficients of the metal with the ligand Y of a masking reagent (and buffer) and of the ligand L with hydrogen ions, respectively; c_{M} is the total concentration of the metal and

$$y_n = \frac{(x-1)^{n+1}}{2^n(1-t)(x-t)^n} \tag{5}$$

Table 2. Stability constants of some metal dithizonates*

* For determination of β_n $c_{\mathrm{M}} = 2{\cdot}00 \times 10^{-5}M$, glycine ($c_{\mathrm{Y}} = 0{\cdot}08M$) as masking reagent and a buffer were used for stoichiometric dilution; log $\alpha_{\mathrm{L(H)}} = 0$ throughout. $c_{\mathrm{M}} = 4{\cdot}00 \times 10^{-4}M$, $c_{\mathrm{L}} = 4{\cdot}00 \times 10^{-5}M$ and hexamine buffer of pH 6·20 were used for the determination of β_1. The value of each stability constant is an average of five determinations.

† $c_{\mathrm{M}} = 5{\cdot}00 \times 10^{-6}M$

‡ $c_{\mathrm{Y}} = 0{\cdot}01M$ (EDTA)

\# $c_{\mathrm{M}} = 1{\cdot}25 \times 10^{-2}M$.

§ $c_{\mathrm{Y}} = 0{\cdot}08M$ (DTPA).

¶ $c_{\mathrm{Y}} = 0{\cdot}10M$ (chloride) where

$$x = \Delta A/(2\Delta A') \qquad \text{and} \qquad t = (x/2^n)^{1/(n+1)} \tag{6}$$

ΔA and $\Delta A'$ are the effective absorbances measured for $c_M = c_L/n$ and $c_M' = c_L'/n$ respectively ($c_M = 2c_M'$) According to the same method we have for the effective molar absorptivity

$$\Delta\varepsilon_n = \Delta A(x - t)/[c_M x(1 - t)] \tag{7}$$

and the value of ε_n is calculated by means of equation (3)

All results of this method are collected in Table 2.

Stability of complexes ML of bivalent ions

The overall stability constants of those complexes can be determined by employing an excess of metal ion Since the complexes of ML_n are relatively stable, we may write in that case

$$c_L = [ML] + 2[ML_2] = c_M[L](\beta_1 + 2\beta_2[L]) \tag{8}$$

where c_M and c_L are the total concentrations of the metal and ligand, respectively, and $c_M \gg c_L$ The expressions in the square brackets designate the actual concentrations of the corresponding species, β_1 and β_2 are the overall stability constants of the complexes ML and ML_2 respectively

The effective absorbance of that solution will be

$$\Delta A = \Delta\varepsilon_1[ML] + \Delta\varepsilon_2[ML_2] = c_M[L](\Delta\varepsilon_1\beta_1 + \Delta\varepsilon_2\beta_2[L]) \tag{9}$$

where

$$\Delta A = A - A_M \tag{10}$$

and

$$\Delta\varepsilon_1 = \varepsilon_1 - \varepsilon_M, \ \Delta\varepsilon_2 = \varepsilon_2 - \varepsilon_M \tag{11}$$

A and A_M are the absorbances of the complexing and metal solutions respectively, ε_1, ε_2 and ε_M are the molar absorptivities of the complexes of ML, ML_2 and metal solution respectively. The absorbance and molar absorptivity of the ligand can be ignored, owing to the small concentration of the free ligand

Combining (8) and (9) by elimination of [L] we obtain

$$r = 2\beta_2 c_L r^2/[\beta_1{}^2(2k - 1)c_M] - (2k - 1) \tag{12}$$

where

$$r = 1 - 2\Delta A/(\Delta\varepsilon_2 c_L) \tag{13}$$

and

$$k = \Delta\varepsilon_1/\Delta\varepsilon_2 \tag{14}$$

Using $c_L' = c_L/2$, $c_M' = c_M$ we obtain instead of (12) and (13)

$$r' = \beta_2 c_L r'^2/[\beta_1{}^2(2k - 1)c_M] - (2k - 1) \tag{15}$$

and

$$r' = 1 - 4\Delta A'/(\Delta\varepsilon_2 c_L) \tag{16}$$

Combining (12) and (15) by elimination of k we get

$$2\beta_2 c_L/(\beta_1{}^2 c_M) = 1/[2(u - 1)] + 1/[2(u - 1)]^2 = v \tag{17}$$

where

$$u = (r - r')^{-1} - r'/r \tag{18}$$

In this manner we computed the normalized function of $\log v = f(u)$. It is plotted in Fig 1 To obtain the values of $\log v$ with a precision of $\leq |0{\cdot}2|$ and to keep $r - r' \geq 0{\cdot}01$, u should be $\geq 1{\cdot}05$ and ≤ 100 Assuming $c_M/c_L = 10$ and $u = 100$ as limiting conditions, we obtain $\log \beta_1{}^2/\beta_2 \leq 1{\cdot}59$

The case of $\Delta A = 2\Delta A'$ should be avoided It occurs with improper selection of either the wavelength if $2\Delta\varepsilon_1 = \Delta\varepsilon_2$ [when the equations (8) and (9) become identical] or the ratio c_M/c_L and pH so that only one complex (either ML or ML_2) is formed

Results of the determination of the stability constants of complexes ML are also collected in Table 2

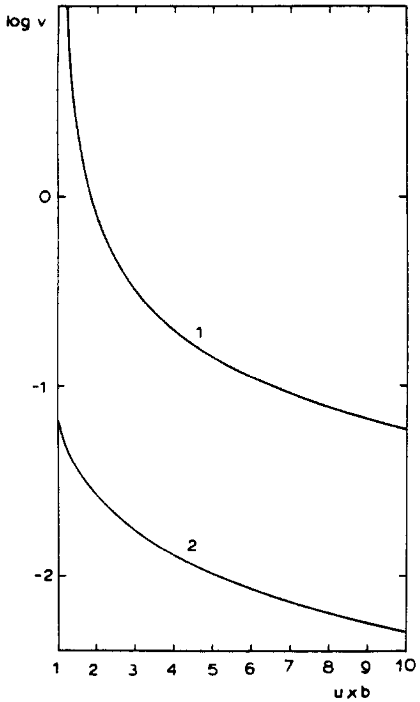

Fig 1 Dependence of log $v = f(u)$ 1 . $b = 1$, 2 · $b = 0$ 1

Conclusions

Employing spectrophotometry as the method of measurement, the use of stoichiometric dilution enables us to keep the concentration of dithizone at a minimum level and to perform the determination of overall stability constants of metal dithizonates in aqueous solution by the method described. In spite of that approach, dithizonates of bismuth and cadmium exhibit a great tendency to precipitate, so their stability constants should be determined at a total metal concentration $c_M = 5{\cdot}00 \times 10^{-6}M$.

Mercury(II) dithizonate is so stable that the use of diethylenetriaminopenta-acetic acid was necessary to adjust its effective stability constant Results in Table 2 indicate that the use of a stronger masking reagent would be desirable, but we could not find a better one Mono- and difunctional ligands containing sulphur donor groups frequently form mixed complexes with dithizone.[5]

ENTHALPIMETRY OF NON-AROMATIC ALKENES

(*Received* 30 *May* 1972 *Accepted* 18 *August* 1972)

Enthalpimetry is the analytical technique of determining the amount of a substance present in an unknown sample by allowing it to react quantitatively with some reagent and measuring the amount of heat produced or taken up by the reaction. At constant external pressure, the heat effect is equal to the enthalpy change, hence the name. Although thermodynamics tells us that the ΔH of reaction may be positive, negative or zero, the last is practically never the case and some heat effect is observed for virtually all reactions Because of the ubiquitous heat of reaction, enthalpimetry is an extremely general method, requiring only that the substance sought undergo a quantitative reaction with some reagent.

Although thermochemistry is a very old science, enthalpimetric analysis has attracted wide attention only during the past decade.[1–8] In this work, we have combined the principle of enthalpimetry with the preferred method of olefin determination, that of hydrogenation. Recent work has brought olefin determination by hydrogenation to a high level of sensitivity and accuracy. Brown[9] has been able to analyse samples containing as little 3 μmole of olefin by means of *in situ* generation of hydrogen and catalyst. He reported an error of about 4% for this minute amount. Curran and co-workers have reported determination of between 1 and 2 μmole, using null-point pressurimetry and volumetric addition of sodium borohydride to regenerate the hydrogen consumed[10] More recently, they have determined less than 1 μmole with an error of about 6% by their technique of substituting coulometric regeneration for the sodium borohydride step[11]

The hydrogenation reaction is quantitative and rapid for most simple olefins,[12,13] hence we have used it as the basis of an enthalpimetric method for olefin determination.[14] The purpose of this work was to modify the existing apparatus and procedure so as to take better advantage of the sensitivity due to the large negative ΔH of the hydrogenation reaction We have been able to decrease the working range by more than an order of magnitude from our previous work, to about 2–20 μmole, without significant loss in accuracy Moreover, in another series of experiments, we have decreased the amount of olefin taken to about 0·6 μmole, although at this level the accuracy suffers

EXPERIMENTAL

Reagents

All olefins were obtained from Chemical Samples Co. and certified to be more than 99% pure by the manufacturers Hexane was obtained from Fischer Chemical Co and Matheson, Coleman and Bell supplied the 5% palladium catalyst on powdered charcoal

ENTHALPIMETRY OF NON-AROMATIC ALKENES

(*Received* 30 *May* 1972 *Accepted* 18 *August* 1972)

Enthalpimetry is the analytical technique of determining the amount of a substance present in an unknown sample by allowing it to react quantitatively with some reagent and measuring the amount of heat produced or taken up by the reaction. At constant external pressure, the heat effect is equal to the enthalpy change, hence the name. Although thermodynamics tells us that the ΔH of reaction may be positive, negative or zero, the last is practically never the case and some heat effect is observed for virtually all reactions Because of the ubiquitous heat of reaction, enthalpimetry is an extremely general method, requiring only that the substance sought undergo a quantitative reaction with some reagent.

Although thermochemistry is a very old science, enthalpimetric analysis has attracted wide attention only during the past decade.[1–8] In this work, we have combined the principle of enthalpimetry with the preferred method of olefin determination, that of hydrogenation. Recent work has brought olefin determination by hydrogenation to a high level of sensitivity and accuracy. Brown[9] has been able to analyse samples containing as little 3 μmole of olefin by means of *in situ* generation of hydrogen and catalyst. He reported an error of about 4% for this minute amount. Curran and co-workers have reported determination of between 1 and 2 μmole, using null-point pressurimetry and volumetric addition of sodium borohydride to regenerate the hydrogen consumed[10] More recently, they have determined less than 1 μmole with an error of about 6% by their technique of substituting coulometric regeneration for the sodium borohydride step[11]

The hydrogenation reaction is quantitative and rapid for most simple olefins,[12,13] hence we have used it as the basis of an enthalpimetric method for olefin determination.[14] The purpose of this work was to modify the existing apparatus and procedure so as to take better advantage of the sensitivity due to the large negative ΔH of the hydrogenation reaction We have been able to decrease the working range by more than an order of magnitude from our previous work, to about 2–20 μmole, without significant loss in accuracy Moreover, in another series of experiments, we have decreased the amount of olefin taken to about 0·6 μmole, although at this level the accuracy suffers

EXPERIMENTAL

Reagents

All olefins were obtained from Chemical Samples Co. and certified to be more than 99% pure by the manufacturers Hexane was obtained from Fischer Chemical Co and Matheson, Coleman and Bell supplied the 5% palladium catalyst on powdered charcoal

Apparatus

The electrical circuitry,[15] essentially a simplified version of what is used in elementary physical-chemical laboratories,[16] does not necessitate electrical calibration because all measurements are made relative to a standard Thus the enthalpy change of an unknown is always compared with that of a known material taken under the same conditions and in the same calorimeter, causing many errors to cancel out between the two measurements.

The cell (calorimeter) is similar to that previously described[14] except that it is fitted with two rubber septa, one a soft septum, fashioned from a serum-bottle cap, and one much harder, fashioned from a #1 rubber stopper The modified cell is shown in Fig 1

The micrometer burette was of 0·25 ml capacity and had a hypodermic needle cemented to the male portion of the Luer joint as shown in Fig 1

The original thermistor–thermistor well arrangement[14] was replaced by a stainless-steel liquid immersion probe of 1/8-in diameter designed for fast response time (time constant 2.5 sec, Cole-Parmer Inst Co, Model 8436) The probe was inserted through a small hole drilled in the hard septum The apparatus for hydrogen injection, stirring and insulation of the calorimeter was as previously described.[14]

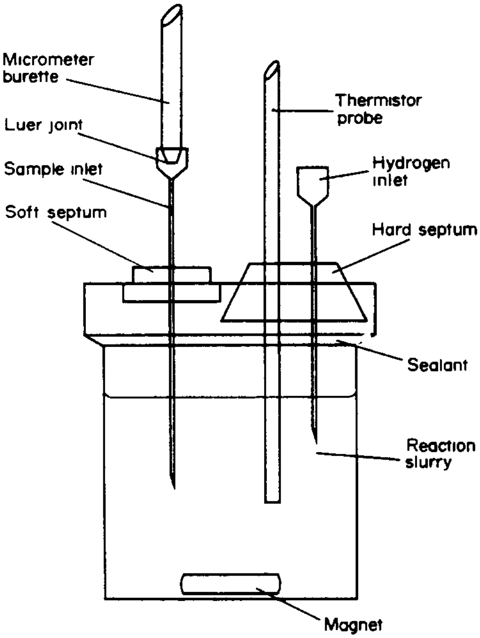

Fig 1. Modified hydrogen calorimeter

Procedure

Twenty-five ml of hexane and 0·6 g of 5% palladium catalyst on charcoal were placed in the calorimeter along with a stirring magnet, the chamber was closed and the screw cap was sealed down with "Silastic 732" sealing compound (Dow Chemical Co) After 1/2–1 hr setting time for the sealant, hydrogen was allowed to flow for ~5 sec through the tube which conveyed it from the tank to the inlet needle so as to clear the tube of air The inlet needle was then thrust through the harder of the two septa as shown in Fig. 1 and the hydrogen pressure within the calorimeter was adjusted to 20 psig by means of the tank valve The valve remained open throughout all subsequent steps, maintaining a constant pressure over the reaction mixture With vigorous magnetic stirring, the catalyst was activated in about 5 min with considerable evolution of heat Residual air within the calorimeter caused no interference with catalyst activation or subsequent steps About 1/2 hr was allowed for the calorimeter to return to thermal equilibrium (about 25°) with the surroundings, while hydrogen pressure remained constant and stirring was continued at a constant rate of 400–500 rpm. The method is not affected by small variations in ambient temperature or stirring speed Thermal equilibrium was indicated by a steady baseline recorded by the potentiometric recorder, showing that the Wheatstone bridge was in balance and that there was minimal heat leak to or from the calorimeter.

The microburette was then filled with an approximately 20% solution, in hexane, of the olefin to be investigated. Its needle was thrust through the soft septum into the reaction slurry and it was clamped into place, as shown in Fig. 1 Between 1 and 20 μl of olefin solution were delivered into the reaction slurry, causing a wave in the time-temperature curve as shown in Fig. 2. The potentiometer deflection was measured by extrapolating the "fore" and "after" temperature-drift curves to obtain the vertical line shown in Fig 2, in accordance with accepted practice.[17] After discard of the first few readings, further readings of potentiometer deflection were tabulated as a function of the injected sample size in μl.

Because of the very small temperature changes involved, 10^{-2}–10^{-3}K, thermistor reponse was assumed to be linear with temperature. For the same reason, the calorimeter was not always allowed to come to thermal equilibrium between injections, but, particularly with the smaller samples, successive injections were made at a rate of about one per minute, the baseline being re-established by fine adjustments of the bridge or the zero control of the recording potentiometer. If, after a series of such measurements, it was desired to re-establish thermal equilibrium, cold carbon dioxide gas was allowed to flow over the calorimeter in accordance with a procedure previously described[14] until the initial bridge and potentiometer settings were reproduced

Note. If the microburette is equipped with rubber seals, these are attacked by hexane, necessitating frequent replacement.

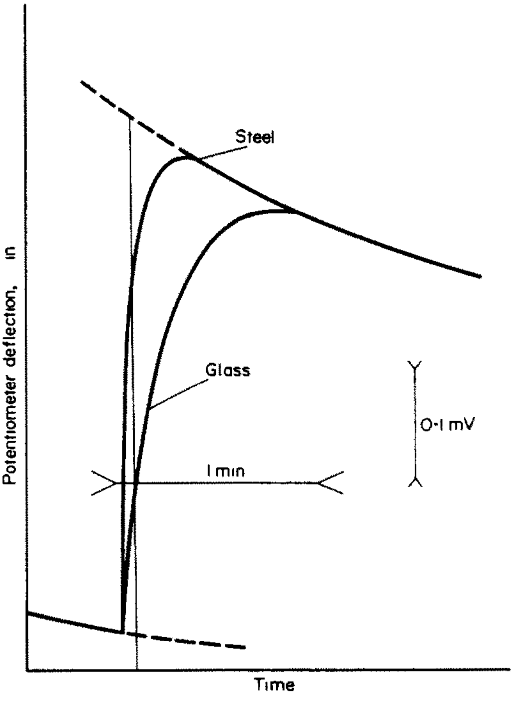

Fig. 2. Time-temperature curves for thermistors encased in glass and steel

RESULTS AND DISCUSSION

Figure 2 shows that the new thermistor resulted in much steeper time-temperature curves, indicating, in the cases studied here, that thermistor response-time was the controlling factor for their shape. Typical time-temperature curves are shown in Fig 2 for a thermistor contained in a glass well and the present thermistor encased in thin stainless steel The new thermistor is also more sensitive than the previous one and shows a much more stable baseline than a thermistor suspended directly in the reaction slurry Increased baseline stability is observed because the rigid probe transmits to the bridge less background noise due to stirring than does a freely-suspended thermistor Decreased response time makes the extrapolation process in Fig 2 more accurate, hence we were able to work at olefin concentrations which averaged an order of magnitude lower than our previous work.[14 18] Table 1 shows the results for several olefins in quantities of 1 39–37 5 μmole. Tabulated results of amount and corresponding potentiometer deflection were fitted by a standard least-squares technique to obtain the "best" linear function satisfying the points and to obtain the

Table 1 Standard deviation from linearity for potentiometer deflection as a function of alkene taken in amounts from 1·4 to 37·5 μmole

Compound	Amount, *μmole*	Replicates	Rel std dev, %
Cyclopentene	7·44–37·5	17	2·0
2-Pentene	2·35–21·2	27	2·0
Cyclohexene	1·98–15·8	26	1·4
Heptene	1·39–13·9	17	2·0
Methylallylbenzene	1·61–28·9	22	2·4
Hexene	1·53–15·3	25	3·2
Hexene	1·67–16·7	24	2·7

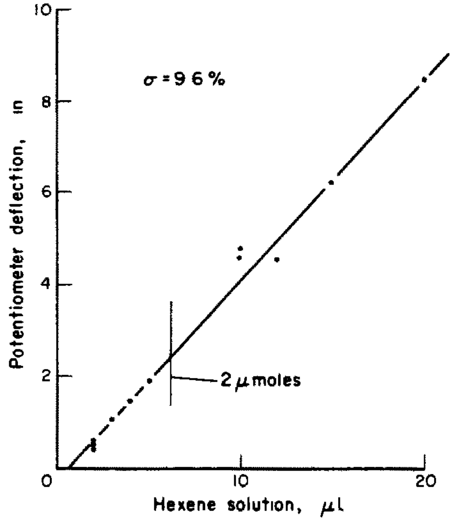

Fig 3. Ultramicro determination of micromolar quantities of hexene in hexane: potentiometer deflection as a function of amount taken

standard deviation, σ, from the function A simple published programme[19] was used to achieve this with G00D = 0 so that no points were discarded, no matter what their deviation

Sensitivity and accuracy are comparable with those of Brown's results[9] and those obtained by Curran and co-workers[10,11] Simplicity and speed seem to be superior to the best contemporary methods, so we decided to attempt further increase in sensitivity

The result was only partly successful, as is shown in Fig 3. Our method of increasing sensitivity was one of almost trivial simplicity but one which rests on unassailable thermodynamic grounds: we made the calorimeter smaller so as to reduce its heat capacity The results in Fig. 3 were obtained with a calorimeter of about 8–10 ml capacity, all other details of apparatus and procedure being unchanged

We were able to collect significant results for amounts below 2 μmole and to extend the lower limit of the method to about 0·6 μmole but at a significant increase in the relative standard deviation, which rose to 9·6%

CONCLUSION

We have developed a method of quantitative analysis of olefins which is comparable in accuracy and sensitivity to the best of contemporary methods and seems to have the advantage in speed and simplicity Its principal disadvantage is one it shares with all hydrogenation methods, that of non-specificity; with the exception of aromatic double bonds, the method does not, in general, differentiate between different olefinic linkages

Summary—A method of increased sensitivity for hydrogen enthalpimetry of olefins in μmole quantities is reported. The method depends on a linear relationship between the amount of alkene present and the heat given off on hydrogenation at slightly more than 2 atm pressure over palladium catalyst on charcoal. Least-squares analysis of the results shows that the measured heat effect is a linear function of amount of alkene taken, with a relative standard deviation of 1–3% for samples ranging in size from 1·4 to 37·5 μmole. Extension of the method to samples in submicromolar quantities was only partially successful; in a series of measurements extending to a minimum amount of 0·64 μmole, the relative standard deviation rose to 9·6%.

Zusammenfassung—Ein Verfahren zur Wasserstoff-Enthalpimetrie von Olefinen in μMolmengen mit erhohter Empfindlichkeit wird angegeben. Es beruht auf der linearen Beziehung zwischen der anwesenden Alkenmenge und der bei der Hydrierung abgegebenen Wärmemenge, wenn die Hydrierung bei etwas uber 2 atm Druck uber einem Palladiumkatalysator auf Aktivkohle ausgeführt wird. Die Analyse der Ergebnisse nach der Methode der kleinsten Quadrate zeigt, daß die gemessene Warme linear von der eingesetzten Alkenmenge abhangt; die relative Standardabweichung betragt 1–3% bei Proben, die von 1·4 bis 37·5 μMol groß sind Die Ausdehnung des Verfahrens auf Proben unter einem μMol war nur teilweise erfolgreich, in einer Meßreihe, die sich bis zu einer kleinsten Menge von 0·64 μMol erstreckte, stieg die relative Standardabweichung auf 9·6% an.

Résumé—On rapporte une méthode de sensibilité accrue pour l'enthalpimétrie d'hydrogène d'oléfines en quantités de l'ordre de la μmole. La méthode repose sur une relation linéaire entre la quantité d'alkène présent et la chaleur dégagée par hydrogénation à une pression légèrement supérieure à 2 atm sur catalyseur au noir palladié. L'analyse des résultats par la méthode des moindres carrés montre que l'effet calorifique mesuré est une fonction linéaire de la quantité d'alkène, avec un écart type relatif de 1–3% pour des échantillons de dimensions comprises entre 1,4 et 37,5 μmole. L'extension de la méthode à des échantillons en quantités submicromolaires n'a été que partiellement couronnée de succès; dans une série de mesures allant jusqu'à une quantité minimale de 0,64 μmole, l'écart type relatif s'est élevé à 9,6%

SEPARATION OF LITHIUM FROM DEAD SEA BRINES BY GEL PERMEATION CHROMATOGRAPHY

(*Received* 19 *June* 1972 *Accepted* 3 *August* 1972)

Dead Sea brines are concentrated solutions of a mixture of salts (30–40% salts, specific gravity *ca* 1·3), mainly halides of the alkaline and alkaline earth metals To date, their principal value is as a source of potash and bromine, but there is also considerable interest in the extraction of the rarer elements dissolved in them, such as caesium, rubidium, and lithium

Of these three elements lithium is present in relatively high concentrations—20 ppm in the water of the Sea and about 40 ppm in the so-called "end brine", which is a concentrated salt solution obtained after evaporation of the water in solar ponds and the subsequent crystallization of the potash.

Of all separation techniques available for such a concentrated salt solution, gel permeation chromatography seemed to the authors the most promising In that method use is made of the differential migration of cations, the difference being most pronounced between the migrations of univalent and bivalent metal ions, especially on polyacrylamide gels.

Studies of the gel permeation chromatography of simple cations and anions were first carried out by Egan,[1] who used polydextran and polyacrylamide gels Ohashi[2–4] has investigated solute-gel interactions and the influence of eluting agents on the chromatograms obtained. In these works a certain degree of selectivity was achieved This study examines the possibility of utilizing such separations to obtain lithuim-enriched fractions.

The main problems to which an answer was sought by the authors were

(1) whether it is possible to separate lithium chloride from the other chlorides in the very concentrated solutions available;
(2) the determination of the purity of the lithium so obtained in the concentrated fractions,
(3) whether some degree of preconcentration can be achieved in addition to the separation.

EXPERIMENTAL

Materials

Polyacrylamide gel, Bio-Gel P-2, molecular weight exclusion limit about 2600. Bio-Rad Laboratories, Richmond, California.

Blue Dextran 2000, average molecular weight 2 × 10^6 Pharmacia Fine Chemicals, Sweden

Separation procedure

Dry Bio-Gel P-2 was immersed in distilled water and allowed to swell for 24 hr. The gel thus wetted was introduced into a 200-cm long column of 3·5 cm internal diameter. The bed length was 147 cm. Before use the column was rinsed for several hours with distilled water

The void volume, V_0, determined by measuring the elution volume of Blue Dextran 2000, was found to be 400 ml The total volume V_t was 1385 ml

After introduction into the column, at a flow-rate of 1 ml/min, the sample of Dead Sea water was allowed to soak completely into the gel phase. For elution, distilled water was used. Ten-ml fractions were collected from the column, and each fraction was analysed for lithium, sodium, potassium, calcium, and magnesium.

Analytical methods

Lithium Since the lithium content of Dead Sea brines is very low compared with that of the other salts, its atomic-absorption signal is ordinarily suppressed, but with the method of standard additions quantitative results can be achieved

The measurements were made on a Perkin–Elmer Model 403 Atomic Absorption Spectrophotometer with a lithium hollow-cathode lamp at wavelength 335 nm.

Potassium and sodium These were measured by flame photometry, using the same instrument as for lithium but at wavelength 589 nm for sodium and 766 5 nm for potassium.

Calcium and magnesium These were titrated in an ammonia buffer with a standard solution of EDTA, with Eriochrome Black T as indicator

Qualitative tests In order to follow the elution process, qualitative tests for chloride were made throughout Thus the fraction in which the brine begins to emerge and the point at which it is completely eluted from the column can be established

Further qualitative tests, for magnesium and calcium, were carried out with carbonate in order to determine the fraction in which these elements first emerge from the column. Fortunately, they do so after the lithium.

RESULTS AND DISCUSSION

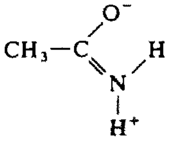
The great difficulty encountered in this separation stems from the very high overall salt concentration and from the high viscosity and density of both Dead Sea Water and the end brine. Table 1 lists the average salt compositions of these solutions.

Table 1. Salt composition of Dead Sea water (D.S.W.) and end brine (E.B.)

Sample	Sp. gr at 17°C	Li^+ conc. *ppm*	Br^- conc *g/l*	Salt concentration, *g/l* $MgCl_2$	$CaCl_2$	NaCl	KCl
D.S.W.	1.22	18	4.8	155	46.3	100.3	13.6
E.B.	1.337	36	11.2	348	108	6.9	3.8

Both Dead Sea water and end brine were chromatographed on a column of Bio-Gel P-2, and the cations were eluted with water. The chromatograms are shown in Figs. 1 and 2. In both cases the order of appearance in the effluent fractions was K^+, Na^+, Li^+, Mg^{2+}, Ca^{2+}, thus confirming the findings of Egan[1]. The chromatograms clearly indicate that separation is feasible and that there are a number of fractions which contain high concentrations of lithium chloride. These fractions also contain small amounts of NaCl and KCl, but no salts of either calcium or magnesium.

This is significant, as these latter two ions are the ones that are present in the highest concentrations. The fact that these two bivalent cations emerge last from the column can be explained by their stronger interaction with the negatively charged oxygen atom of the resonance form of the polyacrylamide gel



Indeed, the distribution coefficients—as shown in Table 2—are all smaller than unity, indicating that this interaction, though relatively weak, is yet stronger than with the univalent cations.

Table 2. Distribution coefficients of Dead Sea brines on Bio-Gel P-2

Sample	K^+	Na^+	Li^+	Mg^{2+}	Ca^{2+}
D.S.W	0·46	0·53	0·59	0·71	0·87
E.B.	0·37	0·46	0·49	0·60	0·75

Distribution coefficients ($K_{available}$) were calculated from the chromatogram by the formula developed by Laurent and Killander[5]

$$K_{av} = \frac{V_e - V_0}{V_t - V_0}$$

where V_e is the eluted volume of the solute, V_0 the void volume, and V_t the total liquid volume.

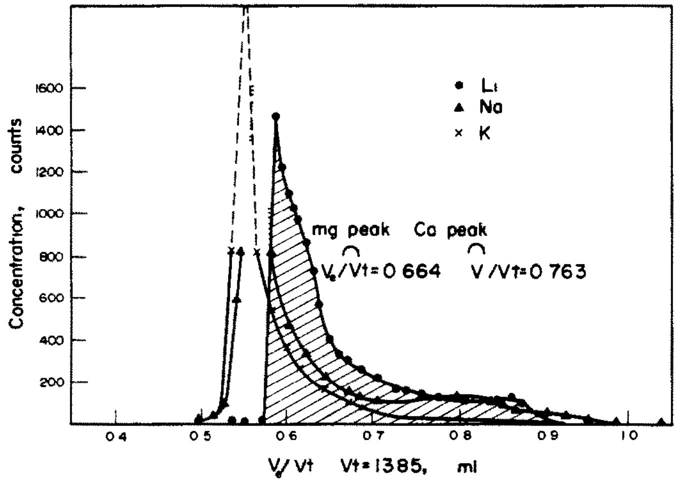


Fig 1 Fractionation of Dead Sea water on Bio-Gel P-2 Magnesium and calcium peaks have not been drawn in because of their great height, but their locations have been indicated

From a practical point of view it seems better to separate lithium from the end brine, because there the concentration of lithium is higher, and that of potassium and sodium lower, than in the natural Dead Sea water Table 3 presents a comparative study of both solutions as regards the degree of separation and preconcentration achieved with them

The results shown in Table 3 indicate that the aims set in the introduction were achieved to a certain extent Of the 130 10-ml fractions collected there are four or five that are rich in lithium and contain only small quantities of potassium and sodium but no magnesium or calcium. A degree of preconcentration was also achieved

It seems preferable, as was stated before, to separate lithium from the end brine, because of its higher initial concentration and the presence of lower quantities of sodium potassium. On the other hand the viscosity of the end brine is higher than that of natural Dead Sea water and its migration through the column consequently slower

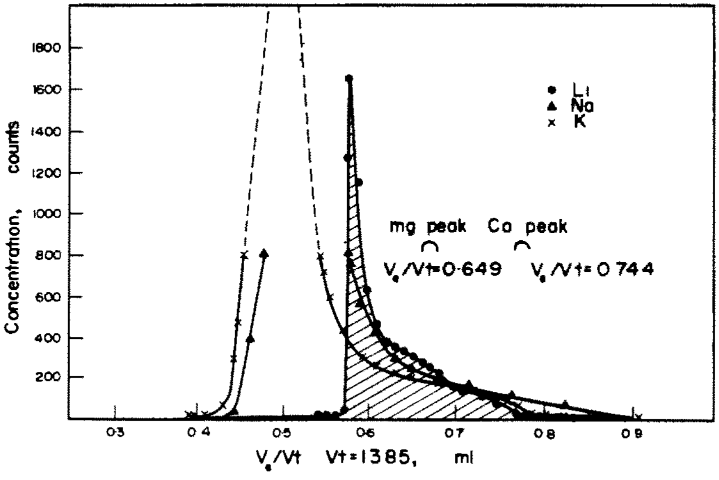

Fig 2 Fractionation of end brine on Bio-Gel P-2 Magnesium and calcium peaks have not been drawn in because of their great height, but their locations have been indicated

Table 3 Composition of the lithium-enriched fractions of Dead Sea water and end brine

	D.S W	E B
Initial Li$^+$ conc.	18 ppm	38 ppm
Li$^+$ conc. in enriched fractions	49 ppm	62 ppm
Li$^+$/Na$^+$ in original solution	1 5550	1 181
Li$^+$/Na$^+$ in concentrated fraction	1 11	1 8
Li$^+$/K$^+$ in original solution	1 756	1 100
Li$^+$/K$^+$ in concentrated fractions	1 10	1 3
Li$^+$/Mg^{2+} in original solution	1 . 8611	1 9150
Li$^+$/Mg^{2+} in concentrated fractions	1 1	no magnesium present
Li$^+$/Ca^{2+} in original solution	1 2572	1 2840
Li$^+$/Ca^{2+} in concentrated fractions	1 : 1	no calcium present

Summary—Fractionation of Dead Sea brines by differential migration through a polyacrylamide gel is shown to be feasible. Lithium-enriched fractions obtained in the process contain no calcium or magnesium and only small quantities of sodium and potassium

Zusammenfassung—Es wird gezeigt, daß Solen aus dem Toten Meer durch differentielle Wanderung durch ein Polyacrylamidgel fraktioniert werden konnen Durch dieses verfahren erhaltene, an Lithium angereicherte Fraktionen enthalten kein Calcium oder Magnesium und nur wenig Natrium und Kalium

Résume—Il a ete montré que le fractionnement de saumures de la Mer Morte par migration différentielle à travers un gel de polyacrylamide est possible Les fractions enrichies en lithium obtenues dans le processus ne contiennent pas de calcium ou de magnésium et seulement de petites quantités de sodium et potassium.

SYNERGISTIC INFLUENCE OF Zn(II) IN THE EXTRACTION-ATOMIC-ABSORPTION DETERMINATION OF TRACE CADMIUM IN WATERS

(*Received* 3 *July* 1972 *Accepted* 18 *August* 1972)

Solvent extraction is well recognized as a powerful method for effecting analytical separations, owing to its capability of removing the analyte from interferences, as well as for the potential concentration of the analyte in the organic phase Both these effects are important in determining trace elements in waters Schaller *et al* [1] and Kuwata *et al* [2] used methyl isobutyl ketone to extract cadmium from waters by using ammonium pyrrolidinedithiocarbamate and sodium diethyldithiocarbamate respectively, Robinson *et al.*[3] used the method of standard additions in the determination of cadmium with 2-mercaptobenzothiazole and n-butyl acetate

A more sensitive development of this last extraction system is described, which provides high precision and almost total extraction of cadmium from natural waters, at the ng/ml level and below.

EXPERIMENTAL

Apparatus

A model AA5 Varian Techtron atomic-absorption spectrophotometer (AAS) fitted with a DI-30 digital indicator was used with a 100 × 0·5 mm AB51 burner and an ASL cadmium hollow-cathode lamp.

The optimum working conditions were

Wavelength	228 8 nm
Lamp current	2 mA
Slit	0 20 mm
Air	15 psig, flow-rate 9·0 L/min
Acetylene	10 psig, flow-rate such that flame was just non-luminous when butyl acetate was aspirated
Scale expansion	× 10

Reagents

Cadmium standard solution Pure cadmium (100 0 mg) was dissolved in a minimum excess of hydrochloric acid and the solution diluted to 1 litre Dilute standards were prepared from this

2-Mercaptobenzothiazole (MBT) solution A 1% solution in butyl acetate, purification was not required for either reagent.

Zinc acetate dihydrate Reagent grade

Buffer solution, pH 10 Ammonium chloride (7 g) and concentrated ammonia solution (57 ml) diluted to 100 ml

Extraction conditions

Several solvents were investigated for the extraction besides butyl acetate (e.g. methyl isobutyl ketone, ethyl acetate) but butyl acetate was considered to have optimum balance between enhancement of the absorption signal relative to aqueous solutions, solution equilibrium with water, and flame stability after extraction

Maximum extraction efficiency was obtained at above pH 9, so all aqueous solutions for analysis were buffered at pH 10

Procedure

Volumes of standard 0 01 μg/ml Cd solution from 0 to 30 ml were diluted to 250 ml in 500-ml separating-funnels with water drawn from the water supply mains which had previously been verified to contain an undetectable concentration of cadmium This served to provide a matrix for the extractions Four series of extractions were undertaken

(*A*) To the 250-ml solutions were added 10 ml of buffer solution, 0·1 g of zinc acetate and 10 ml of MBT solution The mixtures were extracted vigorously for 2 min, allowed to settle for 15 min, and the organic layers were then separated and aspirated through the flame with the instrument set for maximum sensitivity against a zero reference of pure butyl acetate.

(*B*) Procedure (*A*) was repeated but without the addition of the Zn(II).

(*C*) Procedure (*A*) was repeated but with 5 ml of MBT solution added

(*D*) Procedure (*C*) was repeated but without the addition of the Zn(II)

RESULTS AND DISCUSSION

The effect of addition of Zn(II) on the extraction of Cd(II) from waters is illustrated in Table 1 for 10-ml additions of MBT solution, and in Table 2 for 5-ml additions The effective zinc concentration, where Zn is added, is 120 μg/ml

Table 1. Effect of presence of 120 μg/ml Zn(II) on Cd absorbance after extraction by 10 ml of 1% MBT-BuOAc

Cd, *ng/ml*	Absorbance without Zn(II)	Absorbance with Zn(II)
0·0	0·0016	0·0070
0·4	0·0036	0·0118
0·6	0·0042	0·0142
0·8	0·0051	0·0156
1·0	0·0062	0·0188
1·2	0·0076	0·0218

Table 2. Effect of presence of 120 μg/ml Zn(II) on Cd absorbance after extraction by 5 ml of 1% MBT-BuOAc

Cd, *ng/ml*	Absorbance without Zn(II)	Absorbance with Zn(II)
0·0	0·0131	0·0149
0·2	0·0174	0·0207
0·4	0·0194	0·0260
0·6	0·0231	0·0323
0·8	0·0238	0·0389

Phase equilibria

Equilibrium between the Cd-MBT complex in the organic phase and the unextracted Cd is achieved relatively slowly, the extent of equilibration being dependent on the vigour and time period of the extraction—this is viewed as being fairly consistent with the low distribution coefficient, *D*, (as discussed by Brooks *et al.*[4]) of about 30. The effect of the presence of the large excess of Zn(II) is to shift the equilibrium almost completely in favour of the organic phase, resulting in an effective distribution coefficient in excess of 3000, so allowing rapid, quantitative extractions at very low trace cadmium levels

Precision

Comparison of the results in Tables 1 and 2 shows that it is feasible to obtain an increase in sensitivity by using 5 ml of added MBT solution instead of 10 ml, as would be expected, but for all practical purposes the higher volume would be more suitable as it yields a greater volume of solution to deal with As an indication of the precision that can be expected, a series of identical solutions containing 1·2 ng/ml Cd were treated according to procedure (*A*) and were found to have a standard deviation of 0·01 ng/ml, so that the limit of determination would be 0·02 ng/ml

Stability

The synergistic influence of Zn(II) also becomes apparent in the increased stability of the extracted Cd when compared with the extractions without the Zn(II) present. Although the latter solutions exhibited good stability for 3-4 weeks, the "synergistic" solutions had not degenerated after 5 weeks standing at room temperature.

Interferences

No interferences due to the water matrix were present However, attention was given to the effect of cyanide ions as this is often associated with Cd in various waste waters, and has been found to be a positive interference by Kuwata *et al*[2] In the presence of a 600-fold excess of cyanide, the extraction of 20 ng/ml Cd was found to be enhanced, which is an effect attributed by Robinson *et al*[3] to the suppression of Cd adsorption on the walls of the glass vessels, but in the presence of a 100,000-fold excess of cyanide this quantity of Cd remains completely unextracted The synergistic procedure however, permits the complete extraction of the Cd in the presence of a 100,000-fold excess of CN^- The extraction efficiency is improved and this is possibly also due to the lack of adsorption effects

APPLICATIONS INVOLVING THE IODIDE ION—X DETERMINATION OF COPPER AND ANALYSIS OF CATION MIXTURES AND ALLOYS

(*Received* 5 *January* 1972 *Revised* 9 *June* 1972 *Accepted* 17 *August* 1972)

The present work is an extension to the application of potentiometric back-titration of excess of iodide with mercury(II), which was recently applied to the determination of oxidizing agents,[1] silver,[2] or ions reduced with iodide[3] In the classical iodometric determination of copper error may arise from loss of iodine, since CuI adsorbs some of it,[4] leading to earlier end-points even in presence of thiocyanate Copper determinations based on EDTA titration often lack selectivity The most important separation methods for copper in more than microgram amounts involve electrolysis or precipitation with sulphide or organic reagents The present method involving selective separation of copper(I) as the iodide is suitable for amounts in the range 1-35 mg of copper, either alone or mixed with other cations

APPLICATIONS INVOLVING THE IODIDE ION—X DETERMINATION OF COPPER AND ANALYSIS OF CATION MIXTURES AND ALLOYS

(*Received* 5 *January* 1972 *Revised* 9 *June* 1972 *Accepted* 17 *August* 1972)

The present work is an extension to the application of potentiometric back-titration of excess of iodide with mercury(II), which was recently applied to the determination of oxidizing agents,[1] silver,[2] or ions reduced with iodide[3] In the classical iodometric determination of copper error may arise from loss of iodine, since CuI adsorbs some of it,[4] leading to earlier end-points even in presence of thiocyanate Copper determinations based on EDTA titration often lack selectivity The most important separation methods for copper in more than microgram amounts involve electrolysis or precipitation with sulphide or organic reagents The present method involving selective separation of copper(I) as the iodide is suitable for amounts in the range 1-35 mg of copper, either alone or mixed with other cations

EXPERIMENTAL

Reagents

Solutions of copper(II) (0·1–0·01*M*), iodide (0·1–0·02*M*), mercury(II) (0·05–0·01*M*), and all metal ions involved, were prepared from high purity chemicals and twice distilled water, and standardized by recommended procedures None of the solutions contained chloride ions

Procedure for copper in pure solution or in cation mixtures

To appropriate volumes of copper(II) solution (1–5 ml), in a 100-ml beaker, add 15–20 mg of sodium sulphite, 5*M* sulphuric acid (1 ml) and distilled water (5 ml), then add, with constant stirring, iodide solution (3–8 ml), coagulate the white precipitate of CuI by heating on a water-bath for 10–15 min, which gives sufficient time for expulsion of any excess of sulphurous acid Filter off on a Whatman No 42 filter paper, wash thoroughly with water till the washings are free from iodide (usually five washes suffice) and titrate unreacted iodide in the filtrate and washings with Hg(II) (delivered from a microburette with its tip immersed in the solution), using silver amalgam as the indicator electrode and saturated calomel as the reference electrode.

Procedure for copper in alloys

From knowledge of the expected amount of copper in the alloy prepare a 0·03–0·07*M* copper solution by dissolution in nitric acid, digestion on a water-bath, separation of hydrous stannic oxide and lead sulphate and dilution to volume; determine copper in a fraction (2–4 ml) by the procedure above.

RESULTS AND DISCUSSION

Tables 1 and 2 list results for copper alone, in presence of a variety of cations, and in alloys, indicating the selectivity and reliability of the method.

With alloy No. 3 (copper taken, 7·47 mg) the results of copper determination in 9 parallel experiments were 7·49, 7·48, 7·48; 7·45, 7·45, 7·44, 7·44, 7·46, and 7·43 mg; with alloy No. 4 (copper taken, 7·36 mg) the results were 7·35, 7·35, 7·35, 7·32, 7·33, 7·34, 7·34, 7·37 and 7·37, showing respective standard deviations 0·021 and 0·017 mg, the relative standard deviations being 0·28 and 0·23%.

In determining copper by the present method, CuI was separated to avoid the metathesis $2\,CuI + Hg^{2+} = HgI_2 + 2\,Cu^+$ which is due to the lower solubility of HgI_2 ($8{\cdot}8 \times 10^{-7}$ mole/l. at 18°)[2] than that of CuI ($1{\cdot}05 \times 10^{-6}$ mole/l. from $K_{sp} = 1{\cdot}1 \times 10^{-12}$)[5], as verified experimentally

The method has the advantages that, (*a*) any oxidizing agent or higher oxidation state cation such as Fe(III) will not interfere, in the presence of added sulphite, (*b*) it is possible to titrate iodide selectively in presence of large amounts of a variety of cations, with accurate and precise potentiometric end-point determination, with equilibrium potentials obtained instantaneously, (*c*) the titrated species is iodide which, unlike iodine, is non-volatile, and (*d*) it can be successfully applied to the analysis of copper-containing alloys and related materials.

Summary—A rapid, accurate and highly selective method has been developed for estimation of copper, based on separating it as the slightly soluble copper(I) iodide, and potentiometric back-titration of unreacted iodide, in the filtrate, with mercury(II) By its aid binary, ternary and quaternary mixtures as well as a variety of copper alloys have been successfully analysed

Zusammenfassung—Eine rasche, genaue und hochselektive Methode zur Bestimmung von Kupfer wurde entwickelt. Sie beruht auf seiner Abtrennung als nur schwach losliches Kupfer (I)-jodid und potentiometrischer Rucktitration des nicht verbrauchten Jodids im Filtrat mit Quecksilber (II) Mit ihrer Hilfe wurden binare und quaternare Gemische sowie verschiedene Kupferlegierungen mit Erfolg analysiert

Résumé—On a élaboré une méthode rapide, précise et hautement sélective pour le dosage du cuivre, basée sur sa séparation sous forme d'iodure de cuivre (I) faiblement soluble, et le titrage potentiométrique en retour de l'iodure non réagi, dans le filtrat, par le mercure (II). A l'aide de cette technique, on a analysé avec succès des mélanges binaires, ternaires et quaternaires ainsi qu'une variété d'alliages de cuivre

NOUVELLE MICROMETHODE COLORIMÉTRIQUE DE DOSAGE DE L'ION I^- DANS LES EAUX ET LES SUBSTANCES ORGANIQUES

(*Reçu le* 9 *mai* 1972 *Accepté le* 16 *août* 1972)

Parmi les méthodes proposées pour le dosage de faibles quantités d'iodures les colorimétries offrent un intérêt certain.[1-10] En particulier, Lange et Ward[1,2] ont décrit une détermination de I_2, I^- et IO_3^- en présence l'un de l'autre utilisant comme réactif une solution alcoolique d'*o*-tolidine et la formation d'une coloration vert-bleu. La méthode est toutefois laborieuse et la coloration obtenue instable. C'est pourquoi Johannesson[3] a retenu comme réactif une solution chlorhydrique d'*O*-tolidine, la coloration étant alors jaune

Selon nos essais, effectués dans le but de doser de faibles quantités d'ion I^- dans les produits naturels, une microcolorimétrie peut être réalisée sur le principe d'une oxydation de I^- en I_2 par l'eau oxygénée, à pH 3,5–4,5 et développement d'une coloration bleue stable avec l'*o*-tolidine.

PARTIE EXPERIMENTALE

Réactifs

Solution d'*o*-tolidine obtenue en dissolvant 0,1 g d'*o*-tolidine dans 4 ml d'alcool éthylique à 96%, ajoutant 0,1 g d'acide salicylique, complétant à 100 ml avec de l'eau puis filtrant Le réactif dont le pH est compris entre 3,5 et 4,5 est stable pendant plusieurs mois. L'*o*-tolidine peut être purifiée si nécessaire par dissolution en acide chlorhydrique ou sulfurique dilué, décoloration par un charbon actif et précipitation par l'hydroxyde de sodium

Solution aqueuse à 20% de carbonate de potassium

Eau oxygénée concentrée (30%).

Solution étalon d'iodure de potassium à 0,6541 pour 1000 (500 μg I^-/ml) dont la dilution fournit les solutions à 0,1–1 μg I^-/ml.

Solution de sulfamate d'ammonium obtenue en dissolvant 20 g de sulfamate d'ammonium dans 50 ml d'eau, ajoutant 10 ml de solution aqueuse à 5% d'acide sulfamique et complétant à 100 ml avec de l'eau

Solution tampon pH = 4,5–4,6 contenant 10 g de phosphate disodique, 2 ml d'acide phosphorique à 83% (d = 1,70 g/ml) dans 100 ml.

Mode opératoire

Dans le cas des eaux potables, des effluents (non chlorés) ou des eaux minérales (éventuellement privees d'hydrogène sulfuré par barbotage d'un courant de CO_2 après acidification) 50–100 ml sont alcalinisés dans une capsule de nickel par la solution à 20% de carbonate de potassium puis évaporés au bain-marie jusqu'à siccité Si le residu n'est pas parfaitement blanc, il convient de le calciner au four électrique a 500–550°

Pour les produits organiques, alimentaires ou biologiques, la prise d'essai, 1–5 g, (1 ml dans le cas du sang ou de l'urine) est desséchée, finement divisée puis additionnée de 2 ml de solution a 20% de carbonate de potassium. Après homogénéisation, puis dessiccation au bain-marie on procède à la calcination à 500–550° jusqu'à cendres pratiquement blanches

Dans tous les cas, le résidu de calcination est repris par trois fois avec 3 ml d'alcool à 96% puis après filtration les solutions sont évaporees en étuve à 80° jusqu'à siccité Si la teneur en NaCl est importante, il convient de répeter l'extraction alcoolique

Zusammenfassung—Eine rasche, genaue und hochselektive Methode zur Bestimmung von Kupfer wurde entwickelt. Sie beruht auf seiner Abtrennung als nur schwach losliches Kupfer (I)-jodid und potentiometrischer Rucktitration des nicht verbrauchten Jodids im Filtrat mit Quecksilber (II) Mit ihrer Hilfe wurden binare und quaternare Gemische sowie verschiedene Kupferlegierungen mit Erfolg analysiert

Résumé—On a élaboré une méthode rapide, précise et hautement sélective pour le dosage du cuivre, basée sur sa séparation sous forme d'iodure de cuivre (I) faiblement soluble, et le titrage potentiométrique en retour de l'iodure non réagi, dans le filtrat, par le mercure (II). A l'aide de cette technique, on a analysè avec succès des mélanges binaires, ternaires et quaternaires ainsi qu'une variété d'alliages de cuivre

NOUVELLE MICROMETHODE COLORIMÉTRIQUE DE DOSAGE DE L'ION I^- DANS LES EAUX ET LES SUBSTANCES ORGANIQUES

(*Reçu le* 9 *mai* 1972 *Accepté le* 16 *août* 1972)

Parmi les méthodes proposées pour le dosage de faibles quantités d'iodures les colorimétries offrent un intérêt certain.[1-10] En particulier, Lange et Ward[1,2] ont décrit une détermination de I_2, I^- et IO_3^- en présence l'un de l'autre utilisant comme réactif une solution alcoolique d'*o*-tolidine et la formation d'une coloration vert-bleu. La méthode est toutefois laborieuse et la coloration obtenue instable. C'est pourquoi Johannesson[3] a retenu comme réactif une solution chlorhydrique d'*O*-tolidine, la coloration étant alors jaune

Selon nos essais, effectués dans le but de doser de faibles quantités d'ion I^- dans les produits naturels, une microcolorimétrie peut être réalisée sur le principe d'une oxydation de I^- en I_2 par l'eau oxygénée, à pH 3,5–4,5 et développement d'une coloration bleue stable avec l'*o*-tolidine.

PARTIE EXPERIMENTALE

Réactifs

Solution d'*o*-tolidine obtenue en dissolvant 0,1 g d'*o*-tolidine dans 4 ml d'alcool éthylique à 96%, ajoutant 0,1 g d'acide salicylique, complétant à 100 ml avec de l'eau puis filtrant Le réactif dont le pH est compris entre 3,5 et 4,5 est stable pendant plusieurs mois. L'*o*-tolidine peut être purifiée si nécessaire par dissolution en acide chlorhydrique ou sulfurique dilué, décoloration par un charbon actif et précipitation par l'hydroxyde de sodium

Solution aqueuse à 20% de carbonate de potassium

Eau oxygénée concentrée (30%).

Solution étalon d'iodure de potassium à 0,6541 pour 1000 (500 μg I^-/ml) dont la dilution fournit les solutions à 0,1–1 μg I^-/ml.

Solution de sulfamate d'ammonium obtenue en dissolvant 20 g de sulfamate d'ammonium dans 50 ml d'eau, ajoutant 10 ml de solution aqueuse à 5% d'acide sulfamique et complétant à 100 ml avec de l'eau

Solution tampon pH = 4,5–4,6 contenant 10 g de phosphate disodique, 2 ml d'acide phosphorique à 83% (d = 1,70 g/ml) dans 100 ml.

Mode opératoire

Dans le cas des eaux potables, des effluents (non chlorés) ou des eaux minérales (éventuellement privees d'hydrogène sulfuré par barbotage d'un courant de CO_2 après acidification) 50–100 ml sont alcalinisés dans une capsule de nickel par la solution à 20% de carbonate de potassium puis évaporés au bain-marie jusqu'à siccité Si le residu n'est pas parfaitement blanc, il convient de le calciner au four électrique a 500–550°

Pour les produits organiques, alimentaires ou biologiques, la prise d'essai, 1–5 g, (1 ml dans le cas du sang ou de l'urine) est desséchée, finement divisée puis additionnée de 2 ml de solution a 20% de carbonate de potassium. Après homogénéisation, puis dessiccation au bain-marie on procède à la calcination à 500–550° jusqu'à cendres pratiquement blanches

Dans tous les cas, le résidu de calcination est repris par trois fois avec 3 ml d'alcool à 96% puis après filtration les solutions sont évaporees en étuve à 80° jusqu'à siccité Si la teneur en NaCl est importante, il convient de répeter l'extraction alcoolique

Tableau 1

I^- ajouté, μg	Précision recherchée	t	Intervalle de confiance, $E \pm S_{\bar{x}} t$
0,2	95%	2,57	0,028 ± 4,3 10^{-3}
0,4	95%	2,57	0,061 ± 3,0 10^{-3}
0,6	95%	2,57	0,090 ± 4,0 10^{-3}
0,8	95%	2,57	0,121 ± 5,0 10^{-3}
1,0	95%	2,57	0,150 ± 3,3 10^{-3}

Le résidu d'évaporation est alors additionné de 0,4 ml de solution de sulfamate d'ammonium puis soumis à une nouvelle dessiccation On ajoute 1 ml de solution tampon, 1 ml de solution d'*o*-tolidine, 0,2 ml d'eau oxygénée à 30% puis abandonne au repos pendant 25 minutes On complète à 5 ml avec de l'eau, homogénéise et soumet au spectrophotomètre à 626 nm La coloration est stable pendant 30 minutes

En effectuant la même réaction avec des solutions étalons d'iodure de potassium puis traçant la courbe d'étalonnage (Tableau 1) on en déduit la teneur en I^- dans la prise d'essai

DISCUSSION

L'instabilité de la coloration que nous avons observée avec la méthode de Lange et Ward semble due à la présence d'alcool dans le réactif. Par contre les colorations obtenues sont stables si le réactif à l'*o*-tolidine contient de l'acide salicylique. Celuici permet d'obtenir un pH de 3.5–4 5, optimal pour la réaction.[7]

Les conditions opératoires doivent être respectées à d'autres pH les colorations obtenues varient du jaune au bleu avec diminution de la sensibilité. De même la quantité d'eau oxygénée ajoutée ne doit pas excéder 0,2 ml pour éviter les colorations parasites Il convient d'ailleurs d'effectuer un témoin réactif qui doit être incolore La sensibilité de la méthode est de 0,02 μg I^-/ml

La réaction à l'*o*-tolidine est perturbée par les ions Br^- et Cl^- qui développent tous deux une coloration bleue (l'ion Cl^- en catalysant une réaction entre l'*o*-tolidine et l'eau oxygénée) Les bromures et chlorures sont en fait éliminés en mettant à profit leur insolubilité dans l'alcool à 96%

Les ions Fe^{3+} et NO_2^- développent également avec l'*o*-tolidine la même coloration bleue L'ion Fe^{3+} est, toutefois, éliminé par le carbonate de potassium ou complexé par la solution de tampon phosphate et l'ion nitrite est éliminé par le mélange sulfamate-sulfamique Ils n'apportent de ce fait pas de gêne dans le dosage des iodures

La méthode a été appliquée à divers produits agro-alimentaires et les résultats sont réunis dans le tableau 2

Tableau 2 Vérification de la méthode pour les produits agro-alimentaires récoltés de différentes régions

Résumé—Un microdosage de l'ion I⁻ dans les eaux et les produits organiques est fondé sur son oxydation par l'eau oxygénée en iode, qui développe avec l'*o*-tolidine à pH 3,5–4,5 une coloration bleue. Sa sensibilité est de 0,02 μg I⁻/ml

Summary—A microdetermination of iodide in waters and organic materials is based on oxidation with hydrogen peroxide to iodine which gives a blue colour with *o*-tolidine at pH 3 5–4 5 The sensitivity is 0 02 μg/ml.

Zusammenfassung—Eine Mikroermittlung von Jodid in Wasser und in organischen Stoffen gründet sich auf Oxydierung mit Wasserstoffperoxid zu Jod, was eine blaue Farbung mit *o*-Tolidin bei pH 3,5–4,5 ergibt. Die Genauigkeit ist 0,02 μg/ml.

ACENAPHTHENEQUINONE MONOXIME(AQM) AS A SELECTIVE REAGENT FOR THE SPECTROPHOTOMETRIC DETERMINATION OF PLATINUM(IV) BY SOLVENT EXTRACTION

(*Received* 31 *December* 1971. *Accepted* 31 *May* 1972)

Reviews of methods[1–4] for the colorimetric determination of platinum show that there is a real need for a reagent which can be used to determine platinum, particularly in the presence of other platinum metals, cobalt, nickel and copper

Acenaphthenequinone monoxime, which has already been used for the spectrophotometric determination of ruthenium,[5] osmium,[6] rhodium[7] and cobalt[8] was examined to see if it satisfies this need.

EXPERIMENTAL

Reagents

Standard platinum solution was prepared by dissolving 1 g of grade 1 platinum thermocouple wire (99·99% pure) in hot *aqua regia* The resultant solution was evaporated almost to dryness. A small amount of hydrochloric acid was added and the solution was again evaporated to dryness. The treatment was repeated three or four times in order to destroy any nitroso complexes After the final evaporation, 5 ml of hydrochloric acid were added and the solution was made up to 500 ml with doubly distilled water More dilute solutions were prepared, as needed, by dilution of the stock solution Two standard platinum solutions prepared by exactly the same procedure were found to give the same spectrophotometric readings

Acenaphthenequinone monoxime (AQM) 0·1*M* solution in ethanol

Chloroform, reagent grade, was used after distillation

Buffer solutions with pH values ranging up to 5·0 were prepared by mixing 0·5*M* acetic acid and 0 5*M* sodium acetate in different proportions

Procedure

The pH of a solution containing 19·5–156·0 μg of platinum and 2 ml of $1 \times 10^{2-}$*M* reagent solution is adjusted to between pH 1 9 and 3 2 with acetic acid–sodium acetate buffer (5 ml) and diluted to 10 ml with doubly distilled water (The acid present in the platinum solution accounts for the low pH values) The contents

ACENAPHTHENEQUINONE MONOXIME(AQM) AS A SELECTIVE REAGENT FOR THE SPECTROPHOTOMETRIC DETERMINATION OF PLATINUM(IV) BY SOLVENT EXTRACTION

(*Received* 31 *December* 1971. *Accepted* 31 *May* 1972)

Reviews of methods[1–4] for the colorimetric determination of platinum show that there is a real need for a reagent which can be used to determine platinum, particularly in the presence of other platinum metals, cobalt, nickel and copper

Acenaphthenequinone monoxime, which has already been used for the spectrophotometric determination of ruthenium,[5] osmium,[6] rhodium[7] and cobalt[8] was examined to see if it satisfies this need.

EXPERIMENTAL

Reagents

Standard platinum solution was prepared by dissolving 1 g of grade 1 platinum thermocouple wire (99·99% pure) in hot *aqua regia* The resultant solution was evaporated almost to dryness. A small amount of hydrochloric acid was added and the solution was again evaporated to dryness. The treatment was repeated three or four times in order to destroy any nitroso complexes After the final evaporation, 5 ml of hydrochloric acid were added and the solution was made up to 500 ml with doubly distilled water More dilute solutions were prepared, as needed, by dilution of the stock solution Two standard platinum solutions prepared by exactly the same procedure were found to give the same spectrophotometric readings

Acenaphthenequinone monoxime (AQM) 0·1*M* solution in ethanol

Chloroform, reagent grade, was used after distillation

Buffer solutions with pH values ranging up to 5·0 were prepared by mixing 0·5*M* acetic acid and 0·5*M* sodium acetate in different proportions

Procedure

The pH of a solution containing 19·5–156·0 μg of platinum and 2 ml of $1 \times 10^{2-}M$ reagent solution is adjusted to between pH 1·9 and 3·2 with acetic acid–sodium acetate buffer (5 ml) and diluted to 10 ml with doubly distilled water (The acid present in the platinum solution accounts for the low pH values) The contents are heated for 2 hr on a boiling water-bath, then cooled to room temperature, and 10 ml of chloroform are added The contents are equilibrated by shaking for 5 min and then left for 1 min to allow the two phases to separate. The organic phase is separated and centrifuged to remove water droplets, and the absorbance is measured against the corresponding reagent blank prepared under identical conditions From the absorbance, the amount of platinum is deduced from the calibration curve.

RESULTS AND DISCUSSION

Optimum conditions

The rate of reaction of platinum(IV) with AQM is slow at room temperature, but it increases at 100°, the absorbance of the chloroform extracts becoming constant after about 2 hr

The absorbance remains constant over the pH range 1·0–3·2, so a buffer solution of pH 2 5 ± 0·1 was adopted for the working procedure.

At pH 2·5 an eightfold molar excess of the reagent is sufficient for full colour development However, a tenfold molar excess of the reagent was generally employed

Optical constants and composition of the complex

The absorption spectra are shown in Fig 1. All measurements were made at 390 nm The extraction procedure was followed and the absorbance of the organic phase was measured Beer's law was obeyed up to 23·4 ppm of platinum. The accurate range for determination of platinum, as evaluated from a Ringbom plot, is 1·95–15·6 ppm of platinum, and the sensitivity of the reaction at 390 nm is 0·021 μg/cm^2 for log $I_0/I = 0{\cdot}01$. The colour is stable for at least 24 hr.

Eight determinations on a solution of 11 7 ppm of platinum resulted in a mean absorbance of 0·566 with an average relative deviation of ±0·2%. The method of continuous variations[9,10] and the mole-ratio method[11] were employed to establish the stoichiometry of the complex Both complexes showed the existence of 1 · 2 (Pt . AQM) complex

Effect of diverse ions

The effect of foreign ions on the determination of platinum was studied by adding known amounts of foreign ions to samples containing 15·6 ppm of platinum and extracting the complex into chloroform by the working procedure Interference from large amounts of ruthenium(III), osmium(VIII), rhodium(III) and iridium(III) ions was sufficient to warrant their removal, but they could be tolerated at the 10-ppm level Tartrate and citrate have been successfully used as masking agents for some metals, since they themselves are tolerated even in large amounts Oxalate has also been used as a masking agent but since oxalate interferes, a relatively small excess was used Results of the study of diverse ions are shown in Table 1.

Determination of platinum in presence of palladium

The reaction between platinum and acenaphthenequinone monoxime takes place at elevated temperatures while palladium is completely precipitated at room temperature. Based on this behaviour of the two metals,

* Oxalate used as masking agent
† Citrate used as masking agent
§ Fluoride used as masking agent

palladium was extracted into chloroform before heating. The remaining aqueous solution was heated for 2 hr and the platinum complex was extracted into chloroform. The absorbance of the extracted complex was identical with that found in absence of palladium. The results are recorded in Table 2.

Comparison with other methods$^{1-4}$

The *p*-nitrosodimethylaniline–iodide method is more sensitive but less selective than acenaphthenequinone monoxime and it requires more reagent and is more sensitive to the time of heating, change of pH and the amount of buffer. The AQM method is less sensitive than those based on tin(II) chloride and *o*-phenylenediamine, but it is more selective.

Summary—Acenaphthenequinone monoxime has been found to be a selective reagent for spectrophotometric determination of 1–16 ppm of platinum in the pH range 1·90–3·20. With excess of the reagent, a 1 2 (metal : ligand) complex is formed with an absorption maximum at 390 nm and molar absorptivity of $9·0 \times 10^3$ l mole^{-1}·cm^{-1}. The effect of foreign ions has been investigated and other platinum metals do not interfere if present in similar amounts to the platinum

Zusammenfassung—Es wurde gefunden, daß Acenaphthenchinonmonoxim ein selektives Reagens zur spektrophotometrischen Bestimmung von 1–16 ppm Platin bei pH 1·90–3 20 ist Mit einem Reagensuberschuß wird ein 1 · 2(Metall:Ligand)-Komplex mit Absorptionsmaximum bei 390 nm und einem molaren Extinktionskoeffizienten von $9·0 \times 10^3$ 1 mol^{-1} cm^{-1} gebildet. Der Einfluß von Fremdionen wurde untersucht. andere Platinmetalle storen nicht, wenn sie in ahnlichen Mengen wie Platin vorliegen

Résumé—On a trouvé que la monoxime de l'acénaphtènequinone est un réactif sélectif pour le dosage spectrophotométrique de 1–16 p.p.m de platine dans le domaine de pH 1,90–3,20 Avec un excès de réactif, il se forme un complexe 1 : 2 (métal : coordinat) avec un maximum d'absorption à 390 nm et un coefficient d'absorption molaire de $9,0 \times 10^3$ 1 mole^{-1} cm^{-1}. On a étudié l'influence d'ions étrangers et les autres métaux de la mine du platine ne gênent pas s'ils sont présents en quantités similaires au platine

TELLURATE AND PERIODATE SOLUTIONS AS MEDIA FOR PAPER ELECTROPHORESIS OF CARBOHYDRATES

(*Received* 3 *July* 1972. *Accepted* 29 *August* 1972)

Some years ago one of us[1] described an exploratory study of the electrophoretic behaviour of sugars and other polyhydroxy compounds in 0·05*M* telluric acid adjusted to pH 8–11 with sodium hydroxide. Although the compounds were found to migrate as anions, considerable elongation of spots was observed and the method was not recommended at that time as an analytical technique since far better separations were obtained by using other complex-forming electrolytes[2] The continuing interest in electrophoretic separation of polyols, as shown by periodic reviews of the subject,[3,4] has prompted us to re-examine the use of tellurate solutions in an attempt to find conditions under which they could be employed as satisfactory complexing media Extensive studies of the thermodynamics and kinetics of the polyol–tellurate reaction have been reported by Edwards and co-workers, who showed that a 1 . 1 anionic complex forms[5] but at a rate which is rather low compared to the very rapid reaction occurring in borate solutions, the most popular media for electrophoresis of polyols Although the formation constant for the polyol–tellurate complex decreases with increase in temperature[6] the reaction is base-catalysed and its rate increases markedly with the temperature[7]

In the absence of strong adsorption upon the support medium, an elongation of polyol spots during electrophoresis may be reasonably ascribed to incompleteness of complexing. Thus, the above-mentioned studies would suggest that a suitable modification in pH, concentration of tellurate, and temperature, might provide better conditions for complex formation and lead to more discrete spots. One of the objects of the present work was to test this possibility experimentally

Summary—Acenaphthenequinone monoxime has been found to be a selective reagent for spectrophotometric determination of 1–16 ppm of platinum in the pH range 1·90–3·20. With excess of the reagent, a 1 2 (metal : ligand) complex is formed with an absorption maximum at 390 nm and molar absorptivity of $9·0 \times 10^3$ l mole^{-1}·cm^{-1}. The effect of foreign ions has been investigated and other platinum metals do not interfere if present in similar amounts to the platinum

Zusammenfassung—Es wurde gefunden, daß Acenaphthenchinonmonoxim ein selektives Reagens zur spektrophotometrischen Bestimmung von 1–16 ppm Platin bei pH 1·90–3 20 ist Mit einem Reagensuberschuß wird ein 1 · 2(Metall:Ligand)-Komplex mit Absorptionsmaximum bei 390 nm und einem molaren Extinktionskoeffizienten von $9·0 \times 10^3$ 1 mol^{-1} cm^{-1} gebildet. Der Einfluß von Fremdionen wurde untersucht. andere Platinmetalle storen nicht, wenn sie in ahnlichen Mengen wie Platin vorliegen

Résumé—On a trouvé que la monoxime de l'acénaphtènequinone est un réactif sélectif pour le dosage spectrophotométrique de 1–16 p.p.m de platine dans le domaine de pH 1,90–3,20 Avec un excès de réactif, il se forme un complexe 1 : 2 (métal : coordinat) avec un maximum d'absorption à 390 nm et un coefficient d'absorption molaire de $9,0 \times 10^3$ 1 mole^{-1} cm^{-1}. On a étudié l'influence d'ions étrangers et les autres métaux de la mine du platine ne gênent pas s'ils sont présents en quantités similaires au platine

TELLURATE AND PERIODATE SOLUTIONS AS MEDIA FOR PAPER ELECTROPHORESIS OF CARBOHYDRATES

(*Received* 3 *July* 1972. *Accepted* 29 *August* 1972)

Some years ago one of us[1] described an exploratory study of the electrophoretic behaviour of sugars and other polyhydroxy compounds in 0·05*M* telluric acid adjusted to pH 8–11 with sodium hydroxide. Although the compounds were found to migrate as anions, considerable elongation of spots was observed and the method was not recommended at that time as an analytical technique since far better separations were obtained by using other complex-forming electrolytes[2] The continuing interest in electrophoretic separation of polyols, as shown by periodic reviews of the subject,[3,4] has prompted us to re-examine the use of tellurate solutions in an attempt to find conditions under which they could be employed as satisfactory complexing media Extensive studies of the thermodynamics and kinetics of the polyol–tellurate reaction have been reported by Edwards and co-workers, who showed that a 1 . 1 anionic complex forms[5] but at a rate which is rather low compared to the very rapid reaction occurring in borate solutions, the most popular media for electrophoresis of polyols Although the formation constant for the polyol–tellurate complex decreases with increase in temperature[6] the reaction is base-catalysed and its rate increases markedly with the temperature[7]

In the absence of strong adsorption upon the support medium, an elongation of polyol spots during electrophoresis may be reasonably ascribed to incompleteness of complexing. Thus, the above-mentioned studies would suggest that a suitable modification in pH, concentration of tellurate, and temperature, might provide better conditions for complex formation and lead to more discrete spots. One of the objects of the present work was to test this possibility experimentally

The extension of our investigations to periodate solutions was prompted by the report[6] that the ability of periodate ions to bind simple 1,2-diols such as propylene glycol is greater than that of tellurate, which in turn is greater than that of borate. The use of periodate for the oxidation of carbohydrates and other polyols is now well established,[8] and extensive studies of the mechanism of such reactions have indicated that a necessary intermediate is a periodate–polyol anionic complex,[9] although the exact nature of the latter has not yet been ascertained. The optimum reaction conditions depend on the compound to be oxidized but are known to require a pH in the range 2·5–5·0. In contrast, the formation constant of the anionic complex increases with pH, while at the same time the rate of decomposition into oxidation products decreases.[10] Maximum complexing and minimum oxidation appear to take place above pH 9

EXPERIMENTAL

Apparatus

Shandon high-voltage electrophoresis instrument, model L.24.

Procedure

Before loading, the filter paper (Whatman No. 3 MM, 57 × 23 cm) was wetted with electrolyte and the excess was evenly blotted. The test compounds (1% aqueous solutions) were then applied to the baseline by means of capillaries, the sample volumes being approximately 0·01 ml (100 μg of carbohydrate) in periodate solutions, and about twice this quantity in tellurate solutions. During electrophoresis the paper was cooled by water circulating either from a tap or from a thermostatic bath. Although the apparatus can produce up to 10000 V, in practice the relatively high conductances of the solutions restricted the work to 1000–2000 V in order not to exceed the maximum permissible current (100 mA). Migrations towards the positive electrode were expressed relative to the movement of D-ribose, with 2,3,4,6-tetra-*O*-methyl-D-glucose as a non-migrating marker. The extent of migration was taken as the distance between the leading edges of the spots for the test compound and the marker.

Reagents

The electrophoretic media were prepared by dissolving laboratory reagent grade telluric acid or sodium metaperiodate, $NaIO_4$, in distilled water and adjusting the pH with solid sodium hydroxide.

Ammoniacal silver nitrate[11] was found to be a very satisfactory detecting reagent in periodate solutions for all the compounds investigated, but it is dangerous to store this reagent. An ethanol/sodium hydroxide mixture followed by silver nitrate/acetone will do equally well. Immediately after spraying, each compound gave a clear white spot on a brown background, and its position could be marked before the entire paper became brown. Incubation at 110° for about 5 min produced black deposits of silver in the previously white positions, and the paper was then "fixed" by washing in 10% sodium thiosulphate solution and then water. Silver nitrate cannot be used in presence of tellurate, but good results were obtained with an aniline phosphate spray[12] although it was necessary to locate the alcohols under an ultraviolet lamp

RESULTS

In a series of preliminary electrophoretic runs using tellurate solutions, various combinations of the following conditions were used: concentration of telluric acid 0·05–0·20*M*, pH 9–11, temperature 25–60° Spots of satisfactory compactness were obtained at 25° by using 0·20*M* tellurate at pH 10, and these conditions were chosen for all subsequent investigations. The highest potential difference attainable was only 1000 V (about 17 V per cm of paper) since the current rose from approximately 50 to 95 mA during each 1-hr electrophoresis period. The corresponding migration of the reference compound, D-ribose, was about 9 cm A temperature increase improves the compactness of the spots to some extent, even if the tellurate concentration is reduced to 0·10*M*, but the improvement was not considered to be commensurate with the increased experimental difficulty Sodium tellurate is not very soluble, and tends to precipitate out of the more concentrated solutions after 24 hr. However, it is easily redissolved by heating, to give a usable but turbid solution. There is some decomposition of tellurate in the cathode compartment of the apparatus, a black deposit being obtained.

Periodate solutions were prepared in the concentration range 0·03–0·07*M*, and in the pH range 6–13 The finally adopted conditions were 0·07*M* periodate at pH 11, the electrophoresis being performed at the temperature of tap water (13–18°). A voltage of 2000 V (approx. 35 V/cm) could be applied for 30 min, during which time D-ribose migrated about 10–12 cm and the current rose from 60 to nearly 100 mA After standing for 24 hr the periodate solutions deposit crystals which cannot be redissolved by heating. The relative mobilities (M_R) selected from closely concordant repetitions in tellurate and periodate solutions under the finally chosen conditions are given in Table 1

Table 1 Relative mobilities (M_R) in tellurate (0·2*M*, pH 10, 25°C) and in periodate (0·07*M*, pH 11, 13–18°C) solutions. (Reference compound: D-ribose)

Test compound	M_R (tellurate)	M_R (periodate)	Test compound	M_R (tellurate)	M_R (periodate)
D(−)Arabinose	0·86	1·01	Cellobiose	0·33	0·65
L(+)Arabinose	0·86	1·01	Lactose	0·55	0·82

L(−)Sorbose	0·80	1·00	Dulcitol	1·00	1·05
			Sorbitol	0·93	1·05
			Inositol	0·80	0·96

It is known that periodate solutions slowly decompose in the presence of light, giving iodate and ozone[8] Also, it has been reported[2] that carbohydrates migrate in 0·1*M* sodium hydroxide media In order to ensure that electrophoresis in periodate solutions was not due simply to the basic nature of the solution, or to the possible presence of iodate, runs were carried out with sodium hydroxide and 0·07*M* sodium iodate solutions, both adjusted to pH 11 However, migration under these conditions was found to be negligible

DISCUSSION

The considerable stability of periodate complexes of most of the compounds studied is suggested by the fact that after moderate spraying with ammoniacal silver nitrate the periodate–polyol white spots persist for about 30 sec and the complex does not immediately break down to give brown silver periodate. If the paper is oversprayed and left in the oven for longer periods before fixing, a diffuse region of slight blackening appears beyond the leading edge of each spot. This silver deposit was ascribed to oxidation products, which, being of lower molecular weight, would be expected to migrate faster Nevertheless, judging from the low intensity of such blackening, the extent of oxidation under the conditions chosen for electrophoresis appears to be rather slight In spite of this complication the components of a separated mixture can be quite easily located with the spray reagent on the basis of the transitory white spots

Electrophoretic behaviour in tellurate solutions qualitatively confirms previous reports[6] that complexing between polyols and the tellurate ion is weaker than that with the periodate ion, as indicated by the much lower concentrations of periodate necessary to obtain compact spots under conditions which are otherwise similar for the two electrolytes

These results appear to provide two additional electrophoretic methods for the analysis of polyols, which should be considered in cases where a satisfactory separation is not obtained by use of the more conventional complexing media

Summary—Electrophoretic separations of sugars and other polyhydroxy compounds may be performed in 0·2*M* telluric acid media adjusted to pH 10 with sodium hydroxide, and in 0·07*M* sodium metaperiodate at pH 11. Oxidation by periodate appears to be only slight under these conditions. Migration rates of 21 compounds are reported relative to the movement of D-ribose In both electrolytes the compounds form anionic complexes.

Zusammenfassung—Zucker und andere Polyhydroxyverbindungen konnen in 0·2 M Tellursauremedien, die mit Natriumhydroxid auf pH 10 eingestellt sind, und in 0·07 M Natriummetaperjodat bei pH 11 elektrophoretisch getrennt werden Unter diesen Bedingungen fallt die Oxidation durch Perjodat offenbar nur geringfügig ins Gewicht. Die Wanderungsgeschwindigkeiten von 21 Verbindungen werden relativ zur Bewegung von D-Ribose angegeben In beiden Elektrolyten bilden die Verbindungen anionische Komplexe.

Résumé—On peut effectuer des séparations électrophorétiques de sucres et d'autres composés polyhydroxylés en milieux acide tellurique 0,2*M* ajustés à pH 10 par la soude, et en métaperiodate de sodium 0,07*M* à pH 11. L'oxydation par le periodate paraît n'être que légère dans ces conditions. On rapporte les vitesses de migration de 21 composés par rapport au mouvement du D-ribose Dans les deux électrolytes, les composés forment des complexes anioniques

SULPHOLANE AS A SOLVENT FOR TITRATION OF BARBITURATES AND SULPHA DRUGS

(*Received* 28 *June* 1972. *Accepted September* 1972)

Sulpholane (tetramethylenesulphone, TMS) is a dipolar aprotic solvent with a moderately high dielectric constant (44).[1] It has been widely used as a titration medium[2–6] and has been recommended for use as a differentiating solvent for acid-base titrations.[5] Because of its high stability, perchloric acid-sulpholane solution has been suggested for use as a titrant.[3]

Recent studies in these laboratories investigated the titration of barbiturates and sulpha drugs in tetramethylurea.[7] The titration of barbituric acid in sulpholane was shown to be feasible with various electrode systems.[9] To continue our investigation of sulpholane as a medium for the analysis of weak acids, as well as to further expand our studies with barbiturates and sulpha drugs, this investigation was undertaken

EXPERIMENTAL

Apparatus

An Orion Model 601 digital pH/mV meter equipped with an Orion Model 605 electrode switch and Orion Model 615 Digital Volt-Ohmmeter Converter for scale expansion was the potential-measuring device Sargent 30050-15c glass indicator electrodes were used in conjunction with Sargent 30080-15c fibre-type calomel reference electrodes. The saturated aqueous potassium chloride solutions were replaced with saturated potassium chloride solutions in ethanol. All electrodes were soaked for several days in sulpholane and used for only one titration before resoaking, to improve the stability of the potential readings The titrations were performed with a 10-ml burette graduated in 0·02-ml increments, and a 200-ml Berzelius beaker fitted with a stopper containing the electrodes, burette tip, and a nitrogen purge-line.

Reagents

TMS was obtained from Phillips Petroleum Company and vacuum distilled from over sodium hydroxide pellets as described earlier[9] Tetrabutylammonium hydroxide (Eastman, 25% solution in methanol) was diluted tenfold with TMS and standardized against benzoic acid Barbituric acid was Eastman reagent grade Barbital was Merck U.S P All other barbiturates and sulpha drugs were Eli Lilly U.S.P All drugs were dried *in vacuo* before use Because of the limited quantities, further purification was not attempted

Procedure

Between 20 and 50 mg of the acid were weighed into the beaker and dissolved in approximately 50 ml of TMS. The electrodes were allowed to stabilize for about 15 min and titrant added Readings were taken after the potential had stabilized to ±0·1 mV (2–5 min). It is not really necessary to reach such a high level of stability, as ±1 mV was found to be adequate for recoveries as good as those listed below The titrations may then be performed in 10–15 min The drift observed was approximately 1 mV/hr

Summary—Electrophoretic separations of sugars and other polyhydroxy compounds may be performed in 0·2M telluric acid media adjusted to pH 10 with sodium hydroxide, and in 0·07M sodium metaperiodate at pH 11. Oxidation by periodate appears to be only slight under these conditions. Migration rates of 21 compounds are reported relative to the movement of D-ribose. In both electrolytes the compounds form anionic complexes.

SULPHOLANE AS A SOLVENT FOR TITRATION OF BARBITURATES AND SULPHA DRUGS

(*Received* 28 *June* 1972. *Accepted September* 1972)

Sulpholane (tetramethylenesulphone, TMS) is a dipolar aprotic solvent with a moderately high dielectric constant (44).[1] It has been widely used as a titration medium[2–6] and has been recommended for use as a differentiating solvent for acid-base titrations.[5] Because of its high stability, perchloric acid-sulpholane solution has been suggested for use as a titrant.[3]

Recent studies in these laboratories investigated the titration of barbiturates and sulpha drugs in tetramethylurea.[7] The titration of barbituric acid in sulpholane was shown to be feasible with various electrode systems.[9] To continue our investigation of sulpholane as a medium for the analysis of weak acids, as well as to further expand our studies with barbiturates and sulpha drugs, this investigation was undertaken.

EXPERIMENTAL

Apparatus

An Orion Model 601 digital pH/mV meter equipped with an Orion Model 605 electrode switch and Orion Model 615 Digital Volt-Ohmmeter Converter for scale expansion was the potential-measuring device. Sargent 30050-15c glass indicator electrodes were used in conjunction with Sargent 30080-15c fibre-type calomel reference electrodes. The saturated aqueous potassium chloride solutions were replaced with saturated potassium chloride solutions in ethanol. All electrodes were soaked for several days in sulpholane and used for only one titration before resoaking, to improve the stability of the potential readings. The titrations were performed with a 10-ml burette graduated in 0·02-ml increments, and a 200-ml Berzelius beaker fitted with a stopper containing the electrodes, burette tip, and a nitrogen purge-line.

Reagents

TMS was obtained from Phillips Petroleum Company and vacuum distilled from over sodium hydroxide pellets as described earlier.[9] Tetrabutylammonium hydroxide (Eastman, 25% solution in methanol) was diluted tenfold with TMS and standardized against benzoic acid. Barbituric acid was Eastman reagent grade. Barbital was Merck U.S.P. All other barbiturates and sulpha drugs were Eli Lilly U.S.P. All drugs were dried *in vacuo* before use. Because of the limited quantities, further purification was not attempted.

Procedure

Between 20 and 50 mg of the acid were weighed into the beaker and dissolved in approximately 50 ml of TMS. The electrodes were allowed to stabilize for about 15 min and titrant added. Readings were taken after the potential had stabilized to ±0·1 mV (2–5 min). It is not really necessary to reach such a high level of stability, as ±1 mV was found to be adequate for recoveries as good as those listed below. The titrations may then be performed in 10–15 min. The drift observed was approximately 1 mV/hr.

RESULTS AND DISCUSSION

Table 1 lists the recoveries for the barbiturates and sulpha drugs studied

Recoveries and precision

The only one of these drugs previously titrated in sulpholane is barbituric acid[9] No significant difference was found between these results with the glass–calomel electrode system and those of the Pt–hydrogen or Ag/AgCl electrode systems. Overall, the recoveries are as good or better than those previously reported for tetramethylurea and dimethylformamide, while the precision is in the same range[7,8] The precision and recovery are also similar for other acids in TMS[9] Two other sulpha drugs, sulphamethazine and sulphathiazole, were tried but the recoveries were high It is suspected that appreciable acid impurities were present in these materials

Indicators

No visual end-point determinations were attempted. It has been shown that several of the most common indicators used in non-aqueous titrations do not change colour in the vicinity of the end-point in TMS medium[6]

Acid strength

Although no exact pK_a values can be determined without further study, it is possible to make approximations of acid strengths from the size of the break in the titration curve near the end-point (see Fig. 1) The order of relative acid strengths is barbituric acid > phenobarbital ~ sulpha drugs > amobarbital > barbital > secobarbital The respective changes in potential are 550, 470, 470, 360, 240 and 210 mV The sulpha drugs are all levelled to the same acid strength, as was reported for tetramethylurea.[7] The breaks are much larger however, and hence make the end-point more easily determined The break for barbituric acid is not as large as was reported previously; the difference is probably because of the differing electrode responses

As noted above, perchloric acid in sulpholane has been recommended as a stable titrant for non-aqueous titrations Tetrabutylammonium hydroxide in TMS as prepared above was found to retain its titre

Table 1 Recovery of barbiturates and sulpha drugs

Acid	Taken, *mmole*	Found, *mmole*	Recovery, %
Barbituric acid	0·2828	0·2813	99·6 ± 0·3
	0·1583	0·1585	
	0·2464	0·2448	
Phenobarbital	0·1581	0·1593	100·4 ± 1·4
	0·1312	0·1290	
	0·0920	0·0940	
Amobarbital	0·1395	0·1383	99·5 ± 0·3
	0·0860	0·0855	
	0·1695	0·1693	
Barbital	0·1766	0·1748	99·8 ± 0·6
	0·1776	0·1787	
	0·0990	0·0987	
Secobarbital	0·1005	0·1002	99·5 ± 0·3
	0·1467	0·1453	
	0·1456	0·1453	
Sulphapyridine	0·1438	0·1430	99·7 ± 0·4
	0·0805	0·0808	
	0·1008	0·1002	
Sulphadiazine	0·0987	0·1002	100·9 ± 0·5
	0·1108	0·1118	
	0·1864	0·1864	
Sulphamerazine	0·1040	0·1033	99·6 ± 0·6
	0·1501	0·1484	
	0·0744	0·0746	

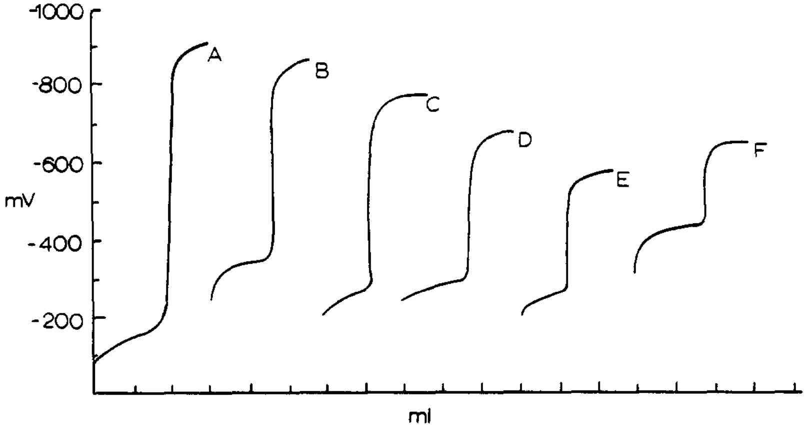

Fig. 1 Titration curves for *A*, barbituric acid; *B*, phenobarbital; *C*, sulphapyridine, *D*, amobarbital, *E*, barbital, *F*, secobarbital.

for at least two weeks. The combination of titrant stability, large potential changes at the end-point, ease of solvent purification, and good solubility characteristics indicate TMS is a solvent with high potential for important practical applications.

Summary—Sulpholane (tetramethylenesulphone) has been used as the medium for non-aqueous potentiometric titration of barbiturates and sulpha drugs with tetrabutylammonium hydroxide Recoveries for 0 1–0 3 mmole of barbituric acid, phenobarbital, amobarbital, barbital, secobarbital, sulphapyridine, sulphadiazine and sulphamerazine were generally in the range 99–101%. A glass-calomel electrode system was used: common acid-base indicators give no colour change in the medium used.

Zusammenfassung—Sulfolan (Tetramethylensulfon) wurde als Medium fur die nichtwaßrige potentiometrische Titration von Barbituraten und Sulfa-Arzneimitteln mit Tetrabutylammoniumhydroxid verwendet. Die Ergebnisse lagen fur 0·1–0·3 mmol Barbitursaure, Phenobarbital, Amobarbital, Barbital, Secobarbital, Sulfapyridin, Sulfadiazin und Sulfamerazin im allgemeinen bei 99–101%. Ein System mit Glas- und Kalomelelektrode wurde verwendet· gebrauchlicke Saure-Basen-Indikatoren geben in dem verwendeten Medium keinen Farbumschlag

Résumé—On a utilisé le sulfolane (tétraméthylènesulfone) comme milieu pour le titrage potentiométrique en milieu non aqueux de barbiturates et de médicaments sulfamidés avec l'hydroxyde de tétrabutylammonium Les récupérations de 0,1–0,3 mmole d'acide barbiturique, phénobarbital, amobarbital, barbital, secobarbital, sulfapyridine, sulfadiazine et sulfamérazine ont été géneralement dans le domaine 99–101%. On a utilisé un système électrodes de verre et calomel · les indicateurs acide-base communs ne donnent pas de changement de coloration dans le milieu utilisé.

DEVELOPMENT AND PUBLICATION OF NEW METHODS IN KINETIC ANALYSIS

HARRY B. MARK, JR.
Department of Chemistry, University of Cincinnati, Cincinnati, Ohio 45221, U.S.A.

(*Received* 4 *September* 1972. *Accepted* 11 *October* 1972)

Summary—A review is made of the various factors, such as the mathematical basis, measurement instrumentation, reaction mechanism, synergistic effects, *etc*, affecting the accuracy and precision of kinetic-based analytical methods. Recommendations are made concerning the research involved in developing new methods and/or applications and concerning the manner of presentation of the results for publication.

Although the concept of using analytical methods based on kinetics or reaction rates goes back over fifty or sixty years to the early literature in biochemistry, radiochemistry and gas-phase diffusion,[1] and there has been extensive use of enzymatic and other catalytic reactions[2] in analysis, especially in clinical applications,[3] it was not until 1951 in the work of Lee and Kolthoff[4] that the broad inherent possibilities and advantages of kinetic-based analytical methods with respect to conventional equilibrium methods in many chemical situations were pointed out clearly to chemists. This work stimulated considerable fundamental development and special application research by Siggia,[5–7] Reilley,[8–10] Guilbault[3,11] and others,[1,9,12–17] particularly in the area of *in situ* analysis of complex systems. There have been several books,[1–3,18,19] monograph chapters[9,13–15,20] and reviews[11,16,21–23] published during the last ten years which summarize the research efforts in this field.

It is somewhat surprising in view of the potentialities of kinetic-based techniques and the considerable amount of fundamental method development published, that there has not, except for continued massive use in clinical assays, been any significant application of kinetic-based techniques to routine and/or practical analytical problems. However, there are two main reasons for this lack of application of kinetic techniques. First of all, almost all commercial instrumentation for chemical measurement is designed for steady-state or equilibrium measurement and does not perform satisfactorily when used for quantitative time-dependent measurement. Thus, analysts often found it necessary to modify or completely build the instrumentation for analytical rate-based determinations. Secondly, it is felt that many of the fundamental method-development papers reported during the past ten years did not fully explain applicability and limitations of the individual methods and, thus, it was not clear to other analytical chemists how they could modify or adapt these methods to their particular system or analysis problem.

A very striking example of this occurred at a recent symposium on "reaction-rate methods of analysis." After one talk on the principles of a particular method for the simultaneous *in situ* analysis of closely related mixtures, someone in the audience made the following comment: "I tried this method on mixtures of amines. The rate constants, ratio of rate constants and ratio of reactant concentrations were ideal according to the discussion in this talk. However, the analytical results were terrible. Why?"

The first problem, instrumentation, has essentially been overcome. Now that inexpensive analogue and digital integrated circuitry and minicomputer systems are readily available, considerable research on the basic concepts of stable accurate instruments for kinetic measurement has been reported[15,20,24–32] and automated quantitative instruments are beginning to become available (or easily built). However, the general guidelines for carrying out research to develop kinetic-based analytical procedures and for reporting the data and results have never been given in one place. Thus, this paper will attempt to present recommendations concerning important points that should be covered and investigated during a research project in this area.

MATHEMATICAL BASIS OF KINETIC METHODS OF ANALYSIS

The past few years have seen the development of a very large number of methods for the calculation of the initial concentration(s) of the species of interest from reaction rate data. These methods involved, in general, the simple mathematical manipulation and rearrangement of the usual differential or integral forms of the classical reaction-rate equations to put them in a convenient form for the calculation of initial concentration(s) of the unknown reactant(s). With few exceptions most of these mathematical treatments or methods have been reported within the past 5–10 years. Such methods can be classified into two main categories: methods for a single species and methods for the simultaneous *in situ* analysis of mixtures. Within each of these two categories, the methods can be subdivided according to the kinetic order of the reactions employed: pseudo zero-order or initial-rate methods, first-order and pseudo first-order methods, and second-order techniques. The principles, mathematical treatments, applicability and limitations of these methods have been discussed in the book by Mark, Rechnitz and Greinke[1] and the monograph chapters by Mark, Papa and Reilley,[9] Blaedel and Hicks,[13] Pardue,[15] and Crouch.[20]

Although these various methods are generally classified by most investigators as zero-order (initial reaction-rate), first-order, or second-order reaction-rate methods,[1,9,20,23] the actual mechanisms for the chemical reactions employed in virtually all of these methods (except those involving radiochemical decay reactions[1] and catalytic reactions[20]) are bimolecular reactions of the type:

$$A + R \underset{k_b}{\overset{k_f}{\rightleftarrows}} P \tag{1}$$

[where A is the species of analytical interest, R is the added reagent, and P is the product (or products)] and the general differential rate expressions have the form:

$$-\frac{d[A]_t}{dt} = -\frac{d[R]_t}{dt} = \frac{d[P]_t}{dt} = k_f[A]_t[R]_t - k_b[P]_t \tag{2}$$

(where $[A]_t$, $[R]_t$, and $[P]_t$ represent the concentrations of these species at any time t). Thus, the nomenclature zero-, first- and second-order actually refers to the experimental conditions under which the rate measurements are made and/or the relative concentrations of the reactants A and R.

If the rate data are taken only during the initial 1–2% completion of the total reaction, then the concentrations of A and R during this initial reaction period are virtually unchanged and equal to the initial concentrations $[A]_0$ and $[R]_0$ respectively and the reverse reaction can be ignored, as only a negligible amount of product is formed. Thus the differential rate expression (2) simplifies, under these initial rate conditions, to a pseudo zero-order form:

$$\left(\frac{\mathrm{d}[\mathrm{P}]_t}{\mathrm{d}t}\right) \sim k_{\mathrm{f}}[\mathrm{A}]_0[\mathrm{R}]_0 \sim \text{Constant} \tag{3}$$

[Note that only the rate of initial change of concentration of product(s) is followed experimentally, as the change in concentration of A or R is small and, therefore d[A]/dt or d[R]/dt cannot be measured accurately.] If the reaction (1) is run under such conditions that the initial concentration of one of the reactants (either A or R) is very large compared to the other, then either $[\mathrm{A}]_t$ or $[\mathrm{R}]_t$ will remain virtually unchanged as the reaction proceeds to equilibrium and can be considered equal to its initial concentration. Also, the reverse reaction can usually be neglected as the large excess of one of the reactants drives the reaction to virtual completion. Under these conditions the reaction is a pseudo first-order reaction and the differential rate expression takes the form

$$-\frac{\mathrm{d}[\mathrm{A}]_t}{\mathrm{d}t}\left(\text{or } -\frac{\mathrm{d}[\mathrm{R}]_t}{\mathrm{d}t}\right) \sim k_{\mathrm{f}}[\mathrm{R}]_0[\mathrm{A}]_t \text{ (or } k_{\mathrm{f}}[\mathrm{A}]_0[\mathrm{R}]_t) \tag{4}$$

$$\sim k'_{\mathrm{f}}[\mathrm{A}]_t \text{ (or } k'_{\mathrm{f}}\ [\mathrm{R}]_t) \tag{5}$$

where $k'_{\mathrm{f}} = k_{\mathrm{f}}[\mathrm{R}]_0$ (or $k_{\mathrm{f}}[\mathrm{A}]_0$). If the rate of reaction (1) is measured during a significant degree of completion under conditions where $[\mathrm{A}]_0$ is of the same order of magnitude as $[\mathrm{R}]_0$, then the method is called a second-order method and the exact differential rate expression (2) must be employed in the data analysis. Note also that only when the reaction mechanism is virtually irreversible can the reverse reaction be ignored in equation (2). Also, for the special case $[\mathrm{R}]_0 = [\mathrm{A}]_0$, a modified form of the calculation of initial concentrations must be employed.[33]

It is obvious from the discussion above that any complete research and/or report on a kinetic-based analytical procedure must carefully take into account the degree of approximation made in the use of equation (2) with respect to the time period of data measurement and relative initial concentrations of reactants and, in some cases, the reversibility of the reaction(s). For example, care must be taken when using a pseudo first-order method when the initial concentrations of the unknown varies over several orders of magnitude. The error introduced in assuming the validity of the pseudo first-order approximation of equation (2) is a function of $[\mathrm{A}]_0$. Although the reaction mechanism for enzyme and other catalysed reactions and, hence, the rate equations, seem somewhat more complex,[1,2,20] similar assumptions, simplifications and therefore, restrictions in validity are made on the rate-measurement techniques employed in the analytical use of these systems.[20,34]

Within each of the zero-order, first-order and second-order classifications of reaction-rate methods there are a large variety of different methods of display and/or mathematical manipulation of the reaction-rate data or equations in order to calculate the initial concentration(s) of the species being determined. The selection of the technique of calculation can have very significant effects on the accuracy of the analysis.[1,9,20,34,35] For example, Crouch[20,34] has pointed out that the kinetic role of the determinand species in methods employing first-order and enzyme or other catalysed reactions has a strong effect on the choice of measurement of the reaction-rate data. It was shown that a fixed-time approach[1,13,15] is superior for pseudo first-order reaction conditions and for the determination of the substrate in any type of pseudo zero-order catalysed reactions. However, in the cases where the enzyme or other catalyst is to be determined (under pseudo zero-order conditions), the variable-time procedure[1,13,15] yields better results. The choice of rate data reduction method in the simultaneous *in situ* analysis of mixtures is even more critical with respect to accuracy of the analyses. There have been numerous results in the literature[1,4,8,9,12,35,36] which have shown that both the relative and absolute values of the rate constants and the initial concentrations of the species to be determined dictate the choice of data treatment for the calculation of the initial concentrations. Furthermore, within the mathematical framework of each of these calculation procedures, there are generally optimum and/or limited times at which rate data should be taken in order to minimize the effects of random and absolute error in measurement.[1,9,12,35] The choice of procedure and optimization of the measurement is very complex and no simple rules can be given here. However, very detailed discussions of this problem are available.[1,9,12,35] Thus, any research on the development of new analytical methods should include a very comprehensive analysis of the choice of data measurement and reduction procedures.

THE REACTION MECHANISM

In most equilibrium-based analytical methods, the success or failure of a determination is not affected by the reaction mechanism provided that the reaction is either quantitative or the measured parameter at equilibrium is linearly proportional to initial concentration of the species of interest. This is not the case in reaction-rate methods. Any report of a new kinetic method should include, if possible, a *complete* study of the mechanism of the reaction(s) involved in the procedure (some reactions, such as catalytic reactions, are so complicated that complete elucidation of the mechanism would be impossible). It should also include a detailed study of the effects of typical sample matrix components, which can act as catalysts, induce side-reactions, alter the activity of the reactants, *etc.* The rates and rate constants for chemical reactions are very sensitive to low concentrations of " spectator " species, *etc*, and hence, samples containing the same true initial composition of the species of interest but coming from different sources can very often give quite different apparent concentrations. Unless the experimenter is completely aware of the total reaction mechanism and all possible factors that can affect either the activation energy and the reaction path, erroneous analytical results could be obtained under certain circumstances which may not be detected. A detailed investigation of the simultaneous *in situ* analysis of binary amine mixtures illustrates this point.[37]. (It should be mentioned here that most systems will be less error-prone than the example given.) It was found that rate constants for the reaction of many individual organic amines with methyl iodide in acetone solvent had ideal differentiation and range of absolute values when the reactions were conducted under pseudo first-order conditions with respect to the methyl iodide. The data reduction method of Roberts and Regan[38] and the simple and accurate data acquisition system employing a continuously recording conductivity instrument[39,40] seemed to indicate that almost ideal analytical results would be attained. However, it was found, just as had been reported by the analyst who commented at the symposium mentioned in the introduction to this paper, that most binary mixtures gave very poor results when analysed by this procedure.

A careful examination of the reaction mechanism of the system revealed that there were numerous unexpected sources of error. First, it was found that the acetone used as a solvent underwent a Schiff-base type reaction with some primary amines at a rate comparable to the methylation reaction of the method. This resulted in the variation of the composite rate constant, K^*,[37,38] during the course of the reaction of mixtures containing such primary amines, as shown in curve 1 of Fig. 1. As the calculation of initial concentration from K^* by the method of Roberts and Regan[38] requires K^* to remain constant over the total reaction time, serious errors are introduced by this side-reaction. As added water would suppress the Schiff-base reaction, acetone–water mixtures were then used as the solvent systems. While this improved the results obtained for several amine mixtures, those containing high molecular weight amines still gave poor results. For example, K^* is not constant over the whole reaction for n-butylamine–tributylamine mixtures, as shown in curve 2 of Fig. 1. In this case the addition of water results in the formation of small suspended micelles of amine in the solution, which alters the reaction rates. Thus, it was necessary to go to a less basic solvent system, DMSO–n-propyl alcohol, which had no significant tendency to react with primary amines[41] and in which most amines are soluble.[37] Curve 3 of Fig. 1 shows that K^* for the n-butylamine–tributylamine mixture is then constant and, thus, accurate initial concentrations are obtained.[37]

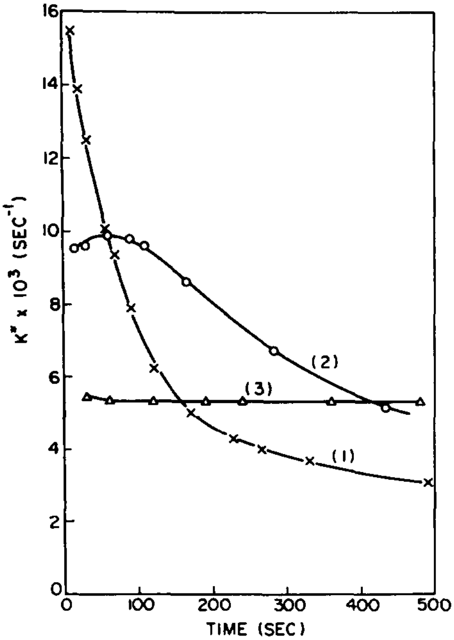

Fig. 1. Variation of K^* for n-butylamine–tributylamine mixture (71.2% n-butylamine) as a function of time, for three different solvent systems.[37]
Curve 1—100% acetone
Curve 2—89% acetone–11%water
Curve 3—70% DMSO–30% n-propyl alcohol
(Reprinted by permission of the American Chemical Society)

However, certain amine mixtures, generally those containing methylamime, still gave poor analyses. It was found that such mixtures were slightly hygroscopic and samples often contained traces of water. This trace water acted as a catalyst in the methylation reaction. Thus, the rate constants obtained from the reactions of standard dry amine solutions and used in the calculation of initial concentrations of unknown mixtures containing traces of water were not valid for the unknown mixture reactions. The addition of water to the solvent system (10% or more) was found to swamp out these variations of rate constants in unknown amine mixtures. Recall, however, that the addition of water can result in solubility complications for some amines. This investigation also revealed that a synergistic effect, probably caused by changes in the activity of the amines by the build-up of product, resulted in variation of K^* during the reaction when the amine mixture concentration was high. Other sources of error arose from the reaction of the reagent methyl iodide with the DMSO solvent system on storage, and loss of measurement sensitivity when conducting impurities were present in the unknown.[37]

The point here is that no simple general reaction procedure for this method can be given that is universally applicable to all types of amine mixtures. This is probably true in general for any procedure for a kinetic-based method. Thus, in reporting a new method, it is necessary to have investigated the chemistry of the reactions employed so that other analysts trying to use the method for their samples can anticipate possible sources of errors resulting from the chemical nature and/or composition of their samples.

INSTRUMENTATION FACTORS

Of course, the accuracy and precision of the instrumental and/or experimental measurement is equally important to both kinetic-based and equilibrium analytical methods and should be discussed in any publication concerning these methods. However, there are a few special instrumental and/or experimental factors that are of critical importance in the kinetic-based methods and quantitative information concerning them should be included in any report about a new method. Those factors particularly important to reaction rate methods are listed below.

Instrumental stability

Although high-frequency noise in an instrument used in measuring reaction rates can be a problem, it can generally be eliminated by simple electronic filtering, as the frequency of the noise is generally very high compared to the rate of change of the signal, which is proportional to the rate of reactions employed in analytical procedures.[23,32,42] Weichselbaum *et al.*,[32,42] Pardue *et al.*,[15,24,25] and Crouch[20] have discussed in detail the circuitry, design criteria and magnitude of the effects of low-frequency drift on analytical results, in spectrophotometric rate-measurement. The principles discussed are applicable to any type of instrumental measurement.

Linearity of transducer response

Most transducers which convert chemical concentration into an electrical signal have a non-linear response. For example, potential and optical transmission are not proportional to concentration. In general, this non-linearity is easily and simply corrected in equilibrium analytical measurements. However, Weichselbaum *et al.*,[32,40] and Crouch[20] have shown that it is considerably more difficult to linearize instrumentally the response–concentration function in reaction rate methods and often this transformation can introduce significant errors into the analytical results.[32,42] For example, Weichselbaum *et al.* have shown that simple non-linear feedback elements employed in log-response operational amplifier circuits are not sufficiently accurate in the transformation of transmittance into absorbance, to be used for many analytical purposes. They found it necessary to go to a very elaborate servomechanical system to circumvent this problem. Crouch[20,34] in an extensive analysis of the various data measurement and reduction procedures in kinetic methods has shown that the variable-time approach can be used advantageously in the case of non-linear response, as the measured reaction rate in this procedure is linearly proportional to *initial* concentration of the species of interest in spite of the fact that the actual transducer response is not proportional to concentration. This is because the time required to reach a fixed concentration level is the parameter measured and, thus, linearity of the overall response–concentration curve is not necessary. Thus, it is not necessary to resort to instrumental linearization of signal response when the variable-time method is used. The point here is that in some cases the instrument and not the chemical reaction can dictate the method used.

Rise-time of the instrument

As mentioned above, high-frequency noise can often be eliminated by simple electronic filtering. However, caution is necessary and the investigator should be very familiar with the actual effective rise-time of the instrument used, over all operating ranges. Obviously, a fixed filter time constant cannot be applicable over a large range of initial concentrations as the rate of the reaction at any time is a function of initial concentration.[32] Thus, a report of a new rate method should include a quantitative evaluation of the rise-time of the instrument under all conditions of damping employed and a comparison with the maximum reaction rates measured under each setting of the filter time constant.

Data acquisition mode

Most reaction rate methods reported[1,2,15,20] utilize only a small number of actual data points (from one to about four) in the calculation of the initial concentration(s) of the species of interest. Clearly this approach throws away a considerably amount of data that could be used advantageously. For example, Margerum and co-workers have discussed the parameters affecting the accuracy of the simultaneous analysis of mixtures by pseudo first-order reaction methods.[30,31,43,44] Their results point out that a continuous data-utilization approach to the problem is the superior data-analysis method in several examples of the use of reaction rate methods for analyses. In the early development of reaction rate methods for analysis of closely related mixtures, the procedures used chemical reactions which were not suitable for continuous automatic measurement of the entire rate-response curves.[1,9] Also, all calculations at that time in the development of the reaction rate methods attempted to limit the number of data points taken and to predetermine the optimum times, *etc*, for taking this minimal amount of data.[1,9] However, in recent years the advances in the field of electronic circuitry and computer technology has had a tremendous influence on the design of instrumentation for kinetic analysis. These instrumental advances have also had a strong influence on the principles of and approaches to differential rate methods. Margerum and co-workers (and also Weichselbaum and co-workers[32,42]) have shown conclusively that the use of built-in computation systems allows continuous analysis of the entire reaction-rate data curve throughout the course of the reaction. The data are thus processed with both ensemble-averaging and smoothing routines in real time. Experimental results and detailed error analysis study have shown that this approach to data acquisition, reduction, and display leads to a much greater accuracy and precision of the analytical results.[30,31,43,44] In fact, good results can be obtained for fast reaction differential rate analyses where the usual finite or minimal data-point methods fail completely.[43,44] Thus, any new report of a reaction rate method should include a comparison of results calculated from both a finite and a continuous number of data points. This will warn others that certain methods will fail under limited data point computation.

Temperature control

The rate of a chemical reaction is considerably more sensitive to temperature variation than the position of the equilibrium (provided the formation constant is very large and the reaction can be considered to be "quantitative"). Thus, temperature control is critical in reaction rate analytical methods and quantitative data concerning this control must be given in any publication describing a new method. Also, the effect of temperature fluctuation on the accuracy and precision of the analytical results should be discussed.

Two factors in temperature control must be considered. The accuracy of the temperature control in the thermostated jacket of the reaction cell is the initial consideration, of course.[45,46] However, as chemical reactions are either exothermic or endothermic, Pardue and Rodriguez,[24] Weichselbaum *et al.*,[47] and Feil *et al.*[48] have shown that rapid temperature exchange and equilibration of the reaction solution with the thermostated cell jacket is also an extremely important consideration in obtaining analytical-quality rate data.

Automation of operations

It is very obvious that automated control of solution mixing, measurement sequences, *etc*, will minimize time-measurement errors compared to those arising from manual control and solution handling and, hence, will increase the accuracy of a given reaction rate procedure.[23,25,29,32] Thus, a report of a new rate method should cover the variation of the analytical results under varying increase in automatic control, going from hand operation to complete computer control of operation and optimization.[29] Thus, again there will be warning about the experimental limits and operational controls under which the method is applicable. It would also be valuable to include a quantitative discussion of the relative merits and limitations of *continuous flow*[13,15] and *discontinuous-sampling* automated systems.[20,50-54]

CONCLUSIONS

Useful general guidance on the information that should be included in a published paper on an analytical method can be found in articles by Wilson,[55,56] Chalmers,[57,58] and others.[59,60,61] The specific requirements unique for the development and description of kinetic based analytical methods are discussed in detail above and are summarized here for convenience and emphasis. The points listed are those that *must* be examined and reported in publication of a new method.

1. *Mathematical basis of the method.* The complete reaction order, relative concentrations of reactants, identification of species followed during reaction, mathematical basis of data reduction and assumptions or simplifications should all be discussed. The selection of optimum conditions, such as the times of data collection, must be justified. Evidence must be given for the choice of data-reduction procedure.
2. *The reaction mechanism.* A complete description of the mechanism and reaction-order of all reactions involved in the kinetic method must be given wherever possible, as it is important to demonstrate the effect of any potential impurities on the reaction mechanism or path. The stability of reagent–solvent systems as well as synergistic effects related to concentration are also important.
3. *Trace impurities as catalysts or inhibitors.* It is necessary to examine the effects of trace

amounts of all conceivable impurities that might be expected to be present in the types of samples that the method is designed for.

4. *Instrumental factors.* Any publication must include data concerning the long-term stability of the instrumentation employed, the linearity of the transducer response over the concentration ranges to be expected and its effect on the data-reduction procedure, the rise-time of the instrument with respect to desired data-taking rates, the number of data points taken and utilized in the data-reduction procedure, the temperature control of the reaction solution under dynamic conditions, and the effect of automation on accuracy of analyses.

The following points must also be covered in the publication of any new kinetic method. These points were not specifically discussed above in this paper as they are essential to the report on any type of new analytical method.

5. *Accuracy and precision.* As the accuracy and precision of kinetic-based methods is, in general, less than that of equilibrium techniques, it is essential that a statistical analysis of repetitive analyses be given. It would also be necessary to give statistical evidence in support of the choices of optimum measurement parameters. Simple theoretical considerations alone are generally not sufficient as they often neglect unsuspected effects.[1,9,10]
6. *Applications.* Procedures suitable for various sample matrices should at least be discussed. Also, matrices that are at least potentially unsuited for the method should be pointed out.
7. *General.* The value of the method must be realistically compared, in terms of speed, accuracy, selectivity, simplicity, cost, *etc*, with other methods for the same species.

Zusammenfassung—Es wird eine Übersicht über die verschiedenen Faktoren gegeben, die Genauigkeit und Richtigkeit von analytischen Methoden auf kinetischer Basis beeinflussen, wie mathematische Grundlage, Meßinstrumente, Reaktionsmechanismus, synergistische Effekte usw. Für Arbeiten, die neue Methoden und/oder Anwendungen entwickeln wollen, sowie für die Art der Publikation ihrer Ergebnisse werden Empfehlungen ausgesprochen.

Résumé—On effectue une revue des divers facteurs, tels que la base mathématique, l'instrumentation de mesure, le mécanisme de réaction, les effets synergiques, etc. . . , qui affectent la précision et la fidélité de méthodes analytiques basées sur la cinétique. On fait des recommandations concernant la recherche impliquée dans le développement de nouvelles méthodes et / ou applications et concernant la manière de présenter les résultats pour publication.

CHROMATOGRAPHIC BEHAVIOUR OF 47 METAL IONS ON TITANIUM(IV) ARSENATE PAPERS

MOHSIN QURESHI, JAGDISH P. RAWAT and VEENA SHARMA
Chemical Laboratories, Aligarh Muslim University, Aligarth, U.P. India

(*Received* 26 *July* 1972. *Accepted* 26 August 1972)

Summary—Titanium arsenate papers with As/Ti ratios 0·2–2·2 have been prepared and 47 metal ions chromatographed on these papers in 10^{-5}–$4M$ nitric acid. The effect of pH and of the Ti/As ratio on the R_f values has been studied. A new quantity R_t ($R_t = R_f$ on untreated papers minus R_f on treated papers) has been defined. The effect of the concentration of the loading reagents on the Ti/As ratio of the ion-exchanger precipitated on the papers has been determined. Contrary to Alberti, it is shown that Lederer's equation is obeyed by titanium arsenate papers in the sodium form if the activity of Na^+ ions is considered instead of their concentration. It has also been demonstrated that the selectivity sequence for cations on titanium arsenate papers is not the same as that on titanium arsenate columns.

Chromatography on papers impregnated with inorganic ion-exchangers of zirconium phosphate type has recently been reviewed.[1] Some interesting possibilities for the separation of alkaloids and amino-acids on zirconium phosphate papers have also been reported.[2] In the earlier reports[3,4,5,6] from this laboratory it was observed that these papers are highly selective and they give rapid separations with simple aqueous systems. The selectivity of the papers is greatly enhanced if mixed solvent systems are used in place of the aqueous systems.[7] Quantitative separations were also achieved by Qureshi and co-workers.[8] Alberti found that the R_M/pH ratio increases with valency of the ion on zirconium phosphate papers, but that Lederer's equation, *i.e.*, $n\text{pH} = R_M + \text{constant}$, does not hold, as zirconium phosphate is a weak ion-exchanger. Alberti,[9] however, showed that if zirconium phosphate papers in the Na^+ form are eluted with solvents containing increasing concentrations of Na^+ (or K^+) ions then the equation $-n\log[Na^+] = R_M + \text{constant}$ is obeyed. These results were confirmed by Prášilová and Šebesta for ammonium tungstophosphate paper[10] but they have not been extended to other ion-exchange papers.

These studies on ion-exchange papers have the following limitations.

(1) The ion-exchangers deposited on the papers have not been analysed and therefore the inference of Nunes da Costa[11] that $ZrPO_4$ papers and $ZrPO_4$ columns show analogous behaviour is not very convincing and needs further examination.

(2) No study has been made on ion-exchange papers in which the precipitated material has varying cation to anion ratio.

(3) No systematic studies in nitric acid systems have been reported. Sastri used $3{\cdot}0M$ nitric acid to separate U(IV) from U(VI), $1{\cdot}0M$ nitric acid to separate As(III) from As(V), and $0{\cdot}1M$ nitric acid to separate Hg(I) from Hg(II). Zhang Zhu separated Y(III) from Sr(II), using $0{\cdot}1$–$2{\cdot}0M$ nitric acid media.

The present work was therefore undertaken to overcome these limitations. Papers with different As/Ti ratios have been prepared and 47 cations have been chromatographed on them, with 0·1*M* nitric acid as the developer; 10^{-5}–4*M* nitric acid media have also been used for systematic studies of these ions on papers impregnated with titanium arsenate exchanger having Ti:As ratio 1 : 1·7. The results are summarized in the following report.

EXPERIMENTAL

Apparatus

Chromatography was performed on 15 × 3·5 cm Whatman No. 1 paper strips in 20 × 5 cm glass jars.

Reagents

Chemicals and solvents were analytical reagent grade.

Preparation of ion-exchange papers

Aqueous solutions (0·5*M*) of titanium(IV) chloride and sodium arsenate were prepared. Paper strips of the required size were first impregnated in the titanium(IV) chloride solution for 3–5 sec and excess of reagent was removed by placing the strips on sheet filter paper. The strips were allowed to dry for 15 min at room temperature. They were then dipped in the sodium arsenate solution for 15 sec. The excess of solution was drained off and the strips were placed over a filter sheet. The strips were converted into the Na^+ form by dipping in 0·5*M* sodium nitrate and then washed thrice with demineralized water in order to remove the excess of reagents. Finally the strips were dried at room temperature and used for chromatography.

Test solutions

Solutions (0·1*M*) of chlorides, nitrates or sulphates of most of the cations were prepared in 0·1*M* solutions of the corresponding acids. The 0·1*M* antimony and bismuth chloride solutions were prepared in 30% v/v and 3·7*M* hydrochloric acid respectively. The 2% solution of gold chloride was prepared in 4*M* hydrochloric acid. Niobium pentachloride solution (1%) was prepared in 10% tartaric acid solution. Selenium dioxide was dissolved in water and made alkaline with 1*M* potassium hydroxide. Sodium molybdate, sodium tungstate, potassium chloride, caesium chloride and rubidium chloride solutions, all 0·1*M*, were prepared in water. Ceric sulphate (0·1*M*) was prepared in 3·6*N* sulphuric acid, stannous chloride was dissolved in 4*M* hydrochloric acid and a piece of tin was added to the 0·1*M* tin solution to prevent oxidation.

Detection

Pb^{2+}, Ag^+, Hg^{2+}, Tl^+, Bi^{3+}, Cd^{2+}, Sb^{3+}, Cu^{2+} and Sn^{2+} zones were detected with yellow ammonium sulphide solution. Fe^{3+}, V^{4+}, UO_2^{2+} were detected with aqueous potassium ferrocyanide solution. To detect Mg^{2+} the paper was dipped first in alcoholic quinalizarin solution and then washed with 2*M* sodium hydroxide. Aqueous potassium ferricyanide solution was used to detect Fe^{2+}. A 1% alcoholic diphenylcarbazide solution was used to detect Ir^{3+}, Cr^{3+}, Mn^{2+} and Zn^{2+} spots and 0·1% alcoholic Alizarin Red S solution for Y^{3+}, Zr^{4+}, Th^{4+}, Ce^{3+}, La^{3+}, In^{3+}, Nb^{5+}, Ca^{2+} and Hf^{4+} spots. A fresh solution of sodium cobaltinitrite was used to detect K^+, Rb^+ and Cs^+. For detecting Al^{3+}, Be^{2+} and Ga^{3+} the strips were dipped in aqueous Aluminon solution and then they were washed with aqueous ammonium acetate solution. A fresh aqueous sodium rhodizonate solution in neutral medium was used to detect Ba^{2+} and Sr^{2+}, 0·1*M* stannous chloride in 4*M* hydrochloric acid to detect Se^{4+}, Mo^{6+}, W^{6+}, Pt^{4+} and Au^{3+}, 2% thiourea in 2*M* hydrochloric acid to detect Ru^{3+} and 1% alcoholic dimethylglyoxime solution to detect Ni^{2+} and Co^{2+}.

Procedure

One or two spots of the test solutions were spotted on the paper with thin glass capillaries. The paper was then conditioned for 15 min. The solvent ascent was always 11 cm. The front (R_L) and rear (R_T) R_f values were measured.

The paper strips were dissolved in a mixture of perchloric, nitric and sulphuric acid (3 : 1 : 4) and the solution was evaporated to dryness. The residue was dissolved in hydrochloric acid. The solution was then diluted to 50 ml and arsenic determined as arsenic sulphide.[12] Titanium was determined in the filtrate by reducing it to Ti(III) with aluminium foil and titrating with ferric ammonium sulphate, with ammonium thiocyanate as indicator.[13]

RESULTS

The results are summarized in Table 1.

Table 1. Composition of titanium(IV) arsenate papers prepared by varying the concentration of reagents.

No.	Concentration of reagents $TiCl_4$, *M*	 Na_2HAsO_4, *M*	Temperature	Ti:As
1	0·01	0·01	Room	1 : 0·21
2	0·05	0·05	Room	1 : 0·32
3	0·1	0·1	Room	1 : 0·42
4	0·1	0·25	Room	1 : 1·7
5	0·5	0·5	Room	1 : 2·2
6	0·5	0·5	70 ± 1°C	1 : 1·8

The Ti:As ratios of titanium arsenate deposited on papers are compared with those of titanium arsenate[14] precipitated by mixing the equimolar reagents in the ratio of 1 : 1 (Fig. 1).

In all, 47 cations were chromatographed on paper impregnated with titanium(IV) arsenate (on papers Nos. 4 and 5) with various concentrations of nitric acid and sodium nitrate as solvent.

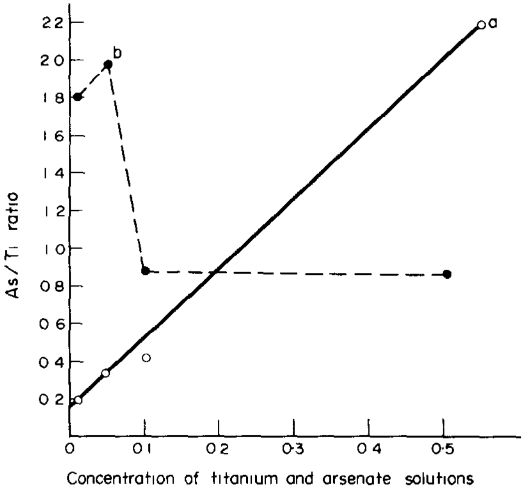

Fig. 1. Composition of titanium arsenate prepared with various reagent concentrations. (*a*) Composition on papers; (*b*) composition of precipitates.

Chromatography on paper No. 4

The following solvent systems were used to study the effect of pH on the R_M values and to find important separations.

(1) 1·0*M* HNO_3
(2) 2·0*M* HNO_3
(3) 3·0*M* HNO_3
(4) 4·0*M* HNO_3
(5) 0·1*M* HNO_3
(6) 0·01*M* HNO_3
(7) 10^{-3}*M* HNO_3
(8) 10^{-5}*M* HNO_3
(9) 1·0*M* NH_4NO_3 + 0·1*M* HNO_3 (1 : 1)
(10) Demineralized water

The greatest number of important separations was obtained with 0·1*M* nitric acid as eluent. R_f values of metal ions in this system are plotted in Fig. 2. The more important separations achieved on paper No. 4 are given in Table 2; all separations took 30 min.

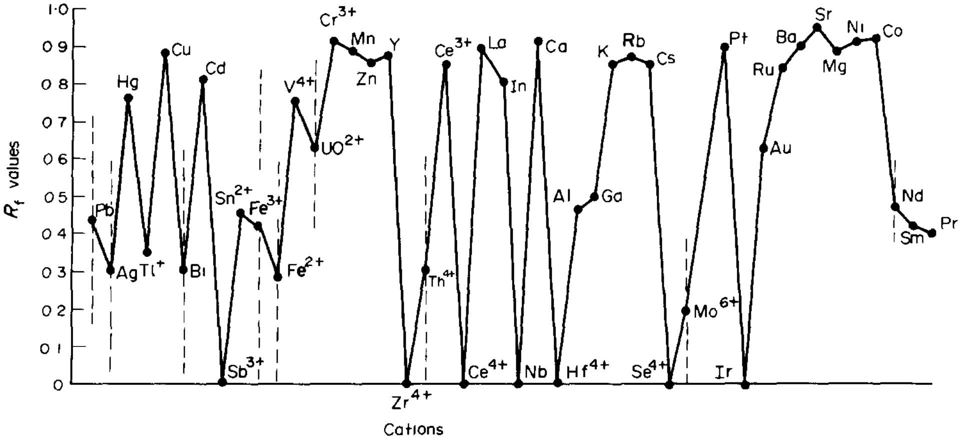

Fig. 2. Plot of R_f values for 47 cations, with 0·1*M* nitric acid as solvent.

Table 2. Separations achieved on titanium(IV) arsenate paper No. 4.

No.	Separation of (R_f)	Separation from (R_f)	Solvent

Chromatography on paper No. 5 in the Na^+ form

Eight different concentrations (1, 2, 3, 4, 1·5, 0·5, 0·1 and 0·01*M*) of sodium nitrate were used to study the R_M values as a function of concentration of sodium ion, For most cations the R_f values were zero. In some cases movement was observed (Table 3). A plot of $-\log a_{Na^+}$ *vs.* R_M is given in Fig. 3.

Table 3. R_f and R_M values of some cations as function of a_{Na}

		R_f				R_M			
No.	$-\log a_{Na^+}$	K^+	Rb^+	Cs^+	Ni^{2+}	K^+	Rb^+	Cs^+	Ni^{2+}

DISCUSSION

The results given in Tables 2 and 4 show the high specificity of titanium arsenate papers even in simple aqueous systems. Thus Sb^{3+} can be separated from 43 metal ions with 4·0*M* nitric acid. Binary mixtures of Sb^{3+} with Pb^{2+}, Cu^{2+}, Cd^{2+}, Bi^{3+},

Co^{2+}, Au^{3+}, Mn^{2+} and Zn^{2+} were successfully separated, the ΔR_f in each case being more than 0·4. The only interferences were from Tl^+, Se^{4+} and Mo^{6+}. The titanium arsenate papers in the sodium form are almost specific for Pt^{4+} and Hg^{2+}. All other cations have R_f values below 0·2. Therefore Pt^{4+} or Hg^{2+} can be separated from 45 metal ions, because Pt^{4+} is present as an anion and Hg^{2+} as an uncharged species. When the papers are developed with 0·1*M* sodium nitrate almost all the cations have zero or very low R_f values, because the exchanger is in the ionized form and therefore cations with a charge greater than unity are adsorbed in preference to Na^+ ions. It will be interesting to see whether other papers in the Li^+, Rb^+ and Cs^+ forms show the same results when developed with the corresponding metal nitrate solution.

Elemental analysis (Table 1) shows that the As/Ti ratio increases as the concentration of the loading reagents increases. This may be explained as follows. The papers are first dipped in the titanium chloride solution, which is uniformly adsorbed by the paper. When the titanium-impregnated strips are dipped in the arsenate solution, titanium arsenate is precipitated on the paper. The rate of precipitation, however, is proportional to the concentration of the arsenate solution and the As/Ti ratio increases as the arsenate concentration increases. If this explanation is correct the As/Ti ratio should be higher for papers first dipped in the arsenate and then in the titanium solution. To test this hypothesis, papers were prepared by dipping first in 0·05 and 0·1*M* arsenate. These papers were then dipped in 0·05 and 0·1*M* titanium solutions respectively. It was found that the As/Ti ratio for the "0·05*M*" paper was 1·7 and for the "0·1*M*" 2·21, which is about 5 times that observed when the order of immersion is reversed. The comparison of these results with the As/Ti ratio of titanium arsenate precipitated from solution is interesting. In all cases the As/Ti ratio is greater than for papers which have first been immersed in the titanium solution, because in solution the titanium arsenate reaction is allowed to proceed almost to equilibrium. When we consider titanium and arsenate solutions of the same concentration, a plot of the mean ion concentration *vs.* As/Ti ratio gives a linear plot (Fig. 1) and it is possible to adjust the As/Ti ratio as desired, by changing the concentration of the loading reagents. When the cation and anion solutions have different concentrations the composition of the precipitated material is not so easy to predict.

As the concentration of the loading reagents increases, the R_f values are also lowered. Therefore papers impregnated with 0·5*M* titanium and 0·5*M* arsenate solutions are probably the best for studying the effect of the counter-ion concentration on R_M values and to test the validity of the relation

$$-n \log [Na^+] = R_M + \text{constant}.$$

The results (omitted to save space) show that the slope increases with charge on the cation, but the relation above does not hold. This is because in concentrated solutions the availability of Na^+ ions is not given by their concentration. A better approach is to use activities instead of concentrations. A plot of $-n\log a_{Na^+}$ *vs.* R_M (Fig. 3) is linear. It will be interesting to see whether this is true for other papers also.

The plots in Fig. 4 show some very interesting trends. Of the 32 cations studied, only 8 give compact spots at pH 5. In most cases there is only a slight change in R_f value as the pH is altered from 3 to 2. At this pH the concentration of H^+ ions is still small and the cations compete successfully for the exchange sites. When the pH is changed from 2 to 1 there is an increase in the concentration of H^+ ions and a decrease in ionized exchange

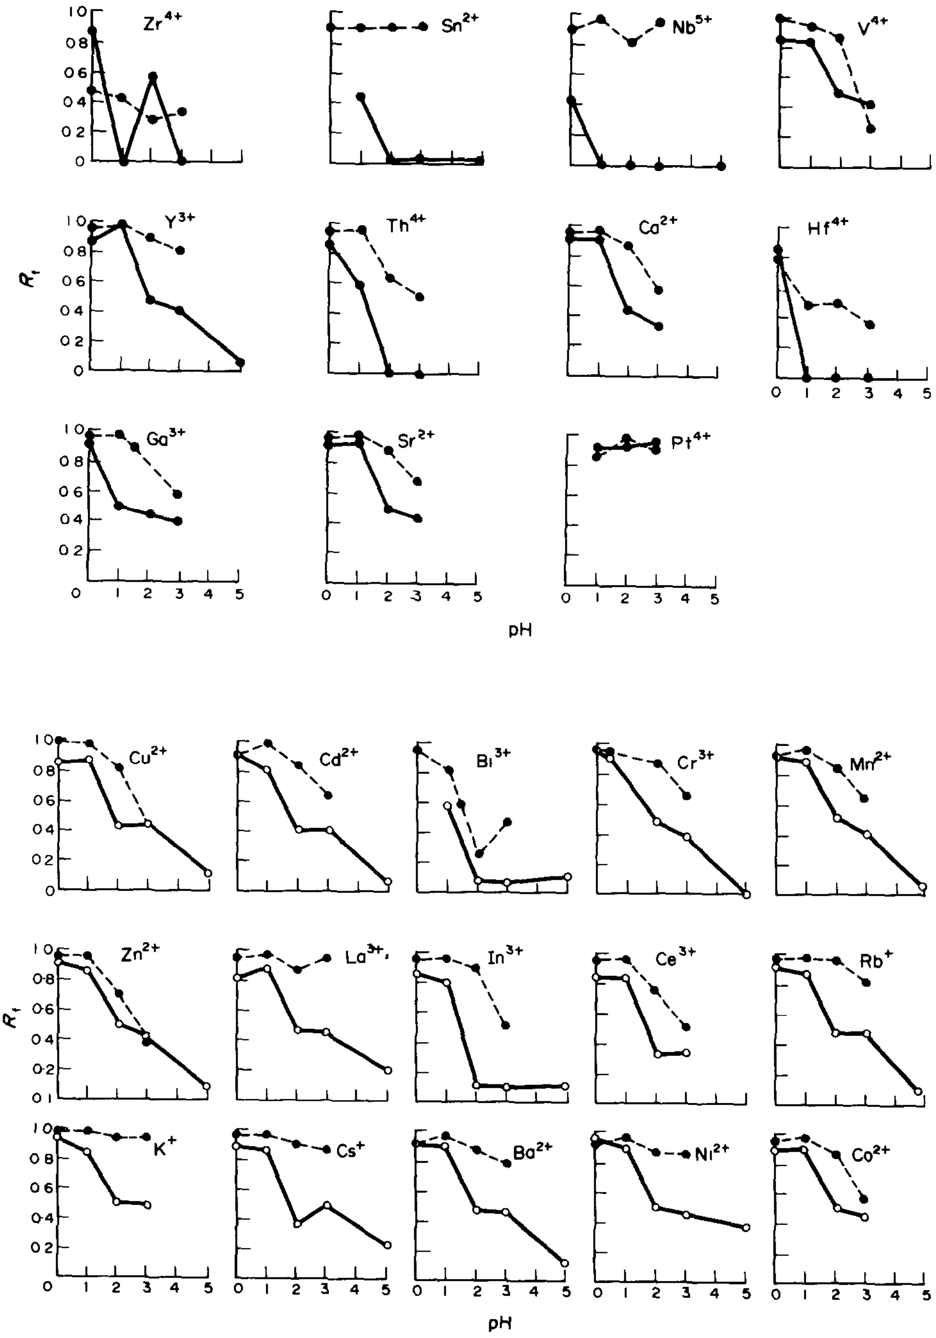

Fig. 4. Comparison of R_f values at various pH values on Whatman No. 1 paper (---) and on paper impregnated with titanium arsenate (—).

sites, hence the H^+ ions compete successfully and there is a sudden increase in R_f value. If the pH is further lowered from one to zero the ion-exchanger is now only slightly ionized and there is a negligible increase in R_f value. The ions which are not hydrolysed, *e.g.*, Ba^{2+}, Mg^{2+}, Rb^+ and Cs^+, show a considerable change in R_f values when the pH is altered from 5 to 4. For ions which are more extensively hydrolysed, *e.g.*, Bi^{3+}, Sn^{2+}, In^{3+} and Nb^{5+}, there is very little change in R_f values over the same pH range. These ions have zero R_f value at pH 3 because, as is clear from Fig. 5, the acid front has an almost zero R_f at this pH.

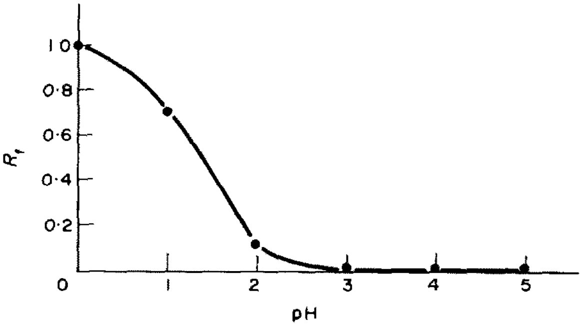

Fig. 5. R_f values of the acid front as a function of pH, for titanium arsenate papers.

A comparison of R_f values on treated papers (R_{FT}) and on untreated papers (R_{FU}) shows very clearly that at pH 0 the ion-exchange papers behave as untreated papers. This is because titanium arsenate is a weak ion-exchanger and at pH 0 it is not ionized and therefore it behaves only as a sorbent and not as an ion-exchanger. It is also apparent from Fig. 6 that ($R_{FU} - R_{FT}$) increases with increase in pH. This is because with increase in pH the concentration of hydrogen ions is decreased and more ion-exchange sites are available for exchange.

It is therefore useful to define a new property $R_i = (R_{FU} - R_{FT})$. R_i is a measure of the ion-exchange effect. A plot of R_i *vs.* pH shows that the maximum ion-exchange effect is obtained at pH 2. The results we have obtained for titanium arsenate should be valid for other ion-exchangers of the weak acid type. The value of R_i can also help in estimating the charge on the ion. Thus in the case of Pt^{4+} R_i is zero at all pH values, showing that no ion-exchange occurs in this case, and therefore the ion is either uncharged or has a negative charge. The results given in Table 5 show that only for Ba^{2+}, Sr^{2+} and Ca^{2+} is the sequence of K_d values the same as predicted from the R_f values. If we consider that the sequence of elution can be predicted from K_d values it follows that the R_f values are not reliable for such prediction. The reasons for this discrepancy are as follows.

1. In paper chromatography the solvent ascent is too fast for equilibrium to be achieved.
2. There are some ions which definitely interact differently with the paper than with the ion-exchange material.
3. The material deposited on the paper has different composition from that obtained by precipitation from solution. Since the K_d values depend upon the composition of the material they are found to be different.

Owing to the facts mentioned above it is difficult to agree with Alberti[15] that the elution sequence can be predicted from that R_f values. At best the R_f values are a rough guide and then only when they differ from one another considerably.

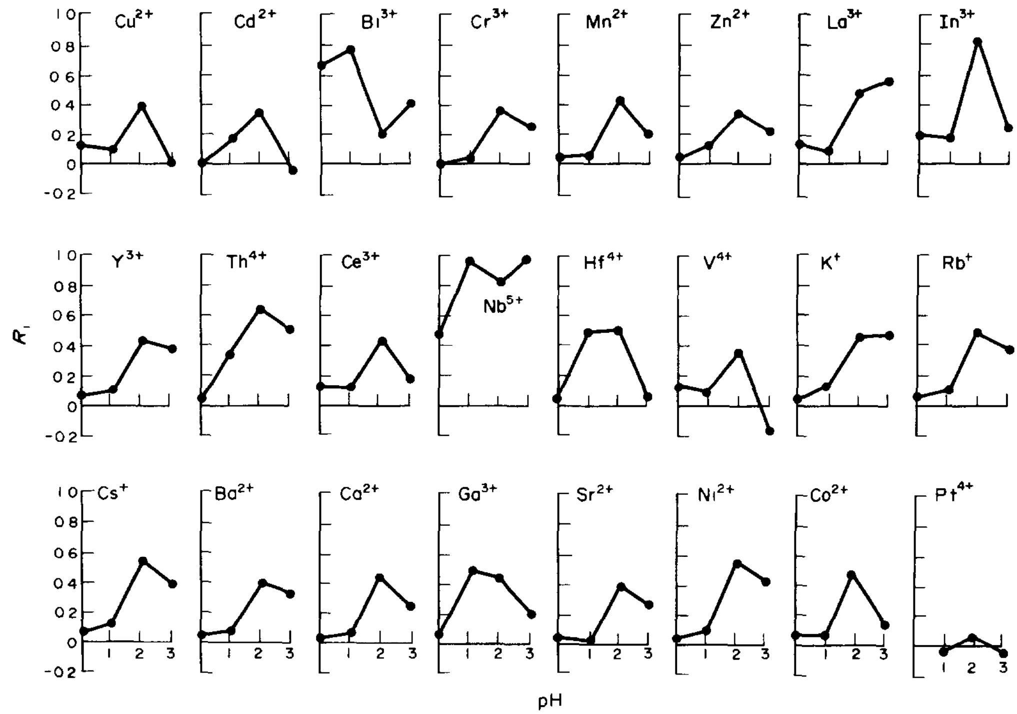

Fig. 6. Plot of R_f *vs.* pH.

Since 0·1*M* nitric acid gave the best separations, numerous cations were chromatographed in this solvent on papers with different As/Ti ratios. Almost all the plots (Fig. 7) show the same trends. Thus for papers with As/Ti between 0·20 and 1·7 there is very little change in R_f values because the amount of arsenate is insufficient for the ion-exchange reaction. However, as the As/Ti ratio increases from 1·7 to 1·8 there is a sudden decrease in the R_f value as considerable ion-exchange probably takes place at this stage. Further increases in the arsenic content does not have much effect on the R_f value, since there is no further increase in ion-exchange.

Table 5. Comparison of K_d values and R_f values of some metal ions on titanium(IV) arsenate.

Medium	K_d	R_f values
Water	$Ba^{2+} > Sr^{2+} > Ca^{2+}$ $Fe^{3+} > Ni^{2+} > V^{4+} >$ $Zn^{2+} > Co^{2+} > Mn^{2+} > Cu^{2+}$ $Hg^{2+} > Cd^{2+} > Zn^{2+}$	$Ca^{2+} > Sr^{2+} > Ba^{2+}$ $Fe^{3+} > V^{4+} > Zn^{2+} =$ $Mn^{2+} = Ni^{2+} > Cu^{2+} > Co^{2+}$ $Hg^{2+} > Zn^{2+} > Cd^{2+}$
0·01*M* HNO_3	$Ca^{2+} = Sr^{2+} = Ba^{2+}$ $Fe^{3+} = Ni^{2+} = V^{4+} = Zn^{2+}$ $= Co^{2+} = Mn^{2+} = Cu^{2+}$ $Hg^{2+} > Zn^{2+} > Cd^{2+}$	$Sr^{2+} > Ba^{2+} > Ca^{2+}$ $Mn^{2+} > Zn^{2+} = Co^{2+} = V^{4+} >$ $Ni^{2+} > Cu^{2+} > Fe^{3+}$ $Zn^{2+} > Cd^{2+} > Hg^{2+}$
0·1*M* HNO_3	Zero	$Ba^{2+} > Ca^{2+} > Sr^{2+}$ $Cu^{2+} > Ni^{2+} > Co^{2+} >$ $Mn^{2+} > Zn^{2+} > V^{4+}$ $Zn^{2+} > Cd^{2+} > Hg^{2+}$

Zusammenfassung—Titanarsenatpapiere mit As/Ti-Verhaltnissen von 0·2–2·2 wurden hergestellt und auf diesen Papieren 47 Metallionen in 10^{-5}-4M Salpetersäure chromatographiert. Der Einfluß von pH und Ti/As-Verhältnis auf die R_f-Werte wurde untersucht. Eine neue Größe R_t ($R_t = R_f$ auf unbehandelten minus R_f auf behandelten Papieren) wurde eingeführt. Der Einfluß der Konzentration der Ladereagentien auf das Ti/As-Verhältnis des auf den Papieren niedergeschlagenen Ionenaustauschers wurde ermittelt. Im Gegensatz zu Alberti wird gezeigt, daß Titanarsenatpapiere in der Natriumform die Gleichung von Lederer erfüllen, wenn man die Aktivität der Na^+-Ionen betrachtet und nicht die Konzentration. Es wurde ferner gezeigt, daß die Selektivitätsreihenfolge von Kationen auf Titanarsenatpapieren nicht dieselbe wie an Titanarsenatsaulen ist.

Résumé—On a préparé des papiers à l'arséniate de titane avec des rapports As/Ti 0,2–2,2, et chromatographié 47 ions métalliques dur ces papiers en acide nitrique $10^{-5} - 4$ *M*. On a étudié l'influence du pH et du rapport Ti/As sur les valeurs de R_f. Une nouvelle quantité R_t ($R_t = R_f$ sur papiers non traités moins R_f sur papiers traités) a été définie. On a déterminé l'influence de la concentration des réactifs de charge sur le rapport Ti/As de l'échangeur d'ions précipité sur les papiers. On montre que, contrairement à Alberti, l'équation de Lederer est suivie par les papiers à l'arséniate de titane sous la forme sodium si l'on considère l'activité des ions Na^+ au lieu de leur concentration. On a aussi démontré que la séquence de sélectivité pour les cations sur les papiers à l'arséniate de titane n'est pas la même que celle sur colonnes d'arséniate de titane.

Summary—Excitation and emission phosphorescence spectra, lifetimes, and relative quantum yields of benzene and ten monosubstituted benzenes were determined at 77 K in methanol/water 10/90 v/v and in sodium iodide/methanol/water solutions. Substituents —CHO, —$COCH_3$, —COC_2H_5, —OH, —OCH_3, —CH_3, —C_2H_5, —CH_2OH and —$N(CH_3)_2$ were investigated. Aqueous sodium iodide solutions were found to be a suitable heavy-atom solvent for phosophorimetry. Heavy-atom enhancement factors ranged from 1·2 to 8·3 according to the molecular structure and a marked decrease of the lifetime was observed for nine compounds in aqueous sodium iodide solution. A linear log–log correlation was obtained between the relative corrected phosphorescence signal and the heavy-atom enhancement factor of the monosubstituted benzenes. A similar correlation was found between the quantum yields and the heavy-atom enhancement factors. The analytical usefulness of these correlations is evident for the prediction of the magnitude of the heavy-atom effect.

The introduction of a heavy atom into a solvent system has been shown to improve in several cases the sensitivity of the analytical method of phosphorimetry.[1–5] This external heavy-atom effect is mainly due to the increase of the spin-orbit coupling of excited singlet and triplet states, resulting in the increase of the rate constant of intersystem crossing between the singlet and triplet states.[6] Weak complexes between a phosphorescent molecule and a perturbing heavy atom have been postulated to interpret these effects physically.[6] In the absence of increased quenching by collision between the phosphorescent species and the heavy-atom solvent and of a change in the rate of radiationless internal conversion from the lowest triplet state, theoretically a decrease of the fluorescence quantum yield and an increase of the phosphorescence quantum yield of the luminescing molecules are expected in an heavy-atom solvent. However, until now, the analytical use of these interesting effects has been very limited in phosphorimetry, mainly because of the requirements of the heavy-atom solvent systems, which had to form clear, rigid glasses at low temperature to give reproducible phosphorescence signals. Another major inconvenient characteristic of the mixtures of EPA (*i.e.*, diethyl ether, isopentane and ethanol and iodomethane[1,2] or ethanol and iodoethane[3,4] (which have previously been used most as heavy-atom solvents)

was their strong absorption of excitation radiation below about 330 nm, leading therefore to a reduction of the phosphorescence intensity of the ultraviolet-absorbing compounds. The importance of this ultraviolet wavelength cut-off in the heavy-atom enhancement of phosphorescence was pointed out by McCarthy and Dunlap.[5] These authors showed that mixtures of ethanol and chlorinated or brominated hydrocarbons were more suitable than the iodine-containing solvent systems for the study of the phosphorescence of polycyclic aromatic hydrocarbons, because of the better ultraviolet transmission characteristics of the former.[5] Nevertheless, large and unexplained variations of the value of the heavy-atom enhancement of the intensity of phosphorescence were observed from one compound to another. For example, in the case of the more favourable solvent used (bromoethane/ethanol 50/50), enhancement factors ranged from 0·55 to 52;[5] and variations could not be attributed to the solvent filter effect, as all the compounds studied were excited at longer wavelengths than the wavelength cut-off of this solvent.

New technological improvements in phosphorimetry[7,8] have permitted the use of predominantly aqueous solvents forming snowed matrices at low temperatures and excellent analytical results have been obtained under these conditions.[8–10] In a recent study,[11] we have demonstrated that a few per cent by weight of sodium iodide in a methanol–water mixture or in water resulted in phosphorescence signals several orders of magnitude greater than the phosphorescence signal of the same compound in pure water solution. Although most of this increase was due to a matrix effect, the phosphorescence signal was enhanced by a factor of 3–6 for two of the three compounds studied, when 1*M* sodium iodide medium was used instead of methanol–water (10/90) and this could be reasonably attributed to the heavy-atom effect.[11]

In the present paper, we want to report on the study of the heavy-atom effect of the iodide upon the phosphorescence of a series of substituted aromatic hydrocarbons in predominantly aqueous solvent, and to discuss the analytical utility of the sodium iodide–methanol–water solvent system in phosphorimetry. A thorough study of the variation of the heavy-atom enhancement factors with the phosphorescence signals of substituted benzenes has indicated to us the existence of a correlation between the intensity of the heavy-atom effect and the phosphorescence quantum yield of the compounds studied.

EXPERIMENTAL

Apparatus

Phosphorescence intensity and relative quantum yield measurements were performed with an Aminco-Bowman spectrophotofluorometer with an Aminco-Keirs phosphoroscope attachment (American Instrument Co., Silver Spring, Md., U.S.A). The instrument was equipped with a 150-W xenon arc lamp, a potted RCA-1P28 multiplier phototube (American Instrument Co.) and an Aminco Model 1620-827 X-Y recorder. Phototube signals were measured with a low-noise nanoammeter previously described.[12] The xenon lamp was powered by a Harrison Lab Model 6268A power supply (Hewlett-Packard, Palo Alto, Calif.), and the phototube was powered by a Keithley Model 244 high-voltage supply (Keithley Instruments, Cleveland, Ohio). Rotating quartz capillary sample tubes were used as previously described.[8] The capillary tubes were made from T21 Suprasil capillary tubing (Amersil Inc., Hillside, N.J.), 5 mm o.d. and 0·9 mm i.d. Excitation light was polarized by means of a thin-film quartz plate polarizer (Polacoat Inc., Cincinnati, Ohio) in order to decrease the background phosphorescence of the quartz tubes.

Phosphorescence spectra were obtained with an Aminco-Bowman spectrophotofluorometer equipped with an Aminco-Ratio Photometer and with an Aminco-Keirs phosphoroscope attachment. A Moseley Model 135A X-Y recorder (F. L. Moseley, Pasedena, Calif.) was used to record the phosphorescence spectra.

A calibrated standard tungsten lamp (Model EPUV-1068, Eppley Laboratory, Newport, R.I.) was used to calibrate the emission of the monochromator photomultiplier tube system. Ultraviolet absorption spectra were obtained on a Beckman DB-G spectrophotometer (Beckman Instruments, Fullerton, Calif., U.S.A.).

Phosphorescence lifetimes greater than 1 sec were measured by using the Aminco Model 1620-827 X-Y recorder in the time-base mode. Lifetimes of less than 1 sec were measured with the pulsed-source time-resolved system recently described.[13,14]

Reagents

Reagents used without further purification were: ethylbenzene, propiophenone (reagent grade; Matheson, Coleman, and Bell, East Rutherford, N.J., U.S.A.); phenol, acetophenone (reagent grade, J. T. Baker Chemical Co., Phillipsburg, N.J., U.S.A.); benzyl alcohol, anisole (reagent grade, Fisher Scientific Co., Fairlawn, N.J., U.S.A.); *N,N*-dimethylaniline (reagent grade, Eastman Organic Chemicals, Rochester, N.Y., U.S.A.); benzaldehyde (Baker reagent, Allied Chemical, New York, N.Y., U.S.A.); benzoic acid (reagent grade, Mallinckrodt Chemical, St. Louis, Mo., U.S.A.); benzene, toluene, methanol (spectroquality, Matheson, Coleman, and Bell, East Rutherford, N.J., U.S.A.). Ultrapure sodium iodide was used in the heavy-atom effect studies (Alfa Inorganics, Beverly, Mass., U.S.A.). Demineralized water was obtained directly from a commercial ion-exchange column.

Procedures

Stock solutions of all compounds were approximately $10^{-2}M$. All stock solutions were prepared in absolute methanol solvent except for benzoic acid which was prepared in pure aqueous solution. Successive dilutions of the stock solutions were prepared in 10% v/v methanol–water as solvent. Final dilutions of the compounds studied were prepared in 10% methanol–water and 10% methanol–water that was $0{\cdot}75M$ in sodium iodide. The concentrations of all solutions were in the range 10^{-5}–$10^{-4}M$ as determined by the intensity of the phosphorescence signal of the particular compound.

Phosphorescence spectra and relative intensity measurements for the molecules studied were obtained with the quartz capillary sample tube suspended in liquid nitrogen in a quartz-window Dewar flask. The slit arrangement for intensity and relative quantum yield measurements was 3, 4, 3, 3, 4, 3 (all in mm, corresponding to 17 and 22 nm spectral half-band pass).

Calibration of the instrumental system was accomplished as follows. The emission monochromator-photomultiplier tube system was corrected for the transmission characteristics of the optical system, the spectral response of the photomultiplier tube, and the relative bandwidth used, by means of a standard tungsten lamp according to the method of Parker (without a magnesium oxide screen).[15] The entrance and exit slitwidths of the emission monochromator were set at 3 mm, and the total entrance slit area was illuminated with light from the tungsten lamp. The intensity was reduced by means of neutral density filters, and the signal from the phototube, R_{SL}, in amperes, was recorded at 10-nm intervals obtained by manually rotating the wavelength disc. The wavelength accuracy of the emission monochromator system had previously been calibrated with a mercury vapour pen-lamp. Because the flux output $[dE/d\lambda]_{SL}$ in watts per unit wavelength interval, for the standard tungsten lamp, was known at wavelength λ, the spectral response characteristic of the emission system, S_λ, in amperes per quanta, was obtained by means of equation (1).

$$S_\lambda = \frac{R_{SL}}{\lambda\left(\frac{dE}{d\lambda}\right)_{SL}} \tag{1}$$

The transmission characteristics of the excitation monochromator and the xenon lamp output were corrected for by placing a shiny aluminium strip diagonally in the fluorescence cell holder of the instrument and measuring the response of the phototube to the excitation light scattered from the aluminium strip into the emission monochromator. It is assumed that the aluminium strip reflects all wavelengths equally. The intensity (flux) of exciting radiation, I°, in quanta, at wavelength λ could then be obtained by using equation (2).

$$I_\lambda^\circ = \frac{R_{SL}}{S_\lambda} \tag{2}$$

Corrected emission spectra for the determination of relative quantum yields were determined by correcting the observed spectra for the response of the emission system point by point at 10-nm intervals, and replotting the points. The integrated intensity for each emission spectrum was obtained by cutting out and weighing the area under the resulting curve.

RESULTS AND DISCUSSION

Characteristics of the heavy-atom effect in aqueous solvent

Previous study[11] showed that the addition of very small amounts of sodium iodide (about 1% in weight) to pure water solutions increased the phosphorescence signal by about two orders of magnitude, and a smaller increase in phosphorescence signal was observed when sodium iodide was added to methanol–water (10/90 v/v) solution. To distinguish the iodide heavy-atom effect from the matrix effect produced by the addition of small amounts of methanol or sodium iodide to pure water solutions, in the present work methanol–water 10/90 v/v solutions were used rather than pure water solutions. In order to define more accurately the nature of the variation of phosphorescence intensity with sodium iodide concentration in aqueous solutions, the phosphorescence signal was measured at various sodium iodide concentrations, over the range 0–0·8*M*. The result obtained for phenol is presented in Fig. 1. A region of gradual increase of the signal occurs from 0 to about 0·75*M* sodium iodide, and a plateau at higher concentrations. As similar curves are expected for the other monosubstituted benzenic compounds studied, a heavy-atom solvent in the composition range of the plateau (methanol/water 10/90 v/v–0·75*M* in sodium iodide) was used for all other studies.

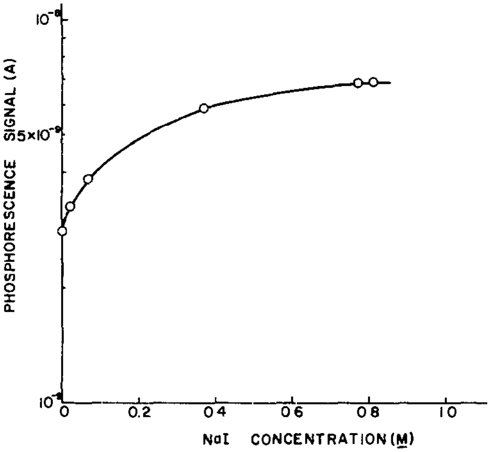

Fig. 1. Phosphorescence signal of phenol ($2{\cdot}2 \times 10^{-5}M$) as function of sodium iodide concentration in methanol–water 10/90 v/v at 77 K.

Phosphorescence excitation and emission spectra and lifetimes were obtained for all the monosubstituted benzenes at 77 K in snowed matrices, with and without sodium iodide. Phosphorescence characteristics are given in Table 1. No significant effect on the position of the long excitation wavelength or emission peaks in sodium iodide solution is apparent. The only noticeable changes in the shape of the excitation spectra are the 10–15 nm red-shift of the ${}^{1}L_{a}$ band in the case of the carbonyl substituted benzenes and benzoic acid (see Fig. 2) and its disappearance or its decrease for benzene and the other substituted benzenes upon addition of sodium iodide (Fig. 3). These slight changes are very probably due to the solvent filter effect of the sodium iodide solutions, which strongly absorb the incident light of wavelength below about 250 nm. Previously, even more severe red-shifts of the phosphorescence excitation wavelength were observed in iodine or bromine-containing heavy-atom solvents[1–5] and were also attributed to filter effects of these solvents.[5] However, such undesirable effects, which can also reduce the heavy-atom enhancement of phosphorescence efficiency, are minimized in our case by the much shorter absorption wavelength of the sodium iodide solutions; for example, in the present studies, it was found that the 90% transmission wavelength of the sodium iodide

methanol/water solutions was about 255 nm, compared to corresponding values of 365 and 295 nm for the better iodinated and brominated hydrocarbons previously used as heavy-atom solvents.[5] Because of their extended transmission range, the sodium iodide methanol/water solutions constitute suitable heavy-atom solvents for phosphorescent compounds with excitation wavelength above about 255 nm, while until now heavy-atom solvents were only analytically useful for compounds with excitation wavelength greater than about 300 nm.

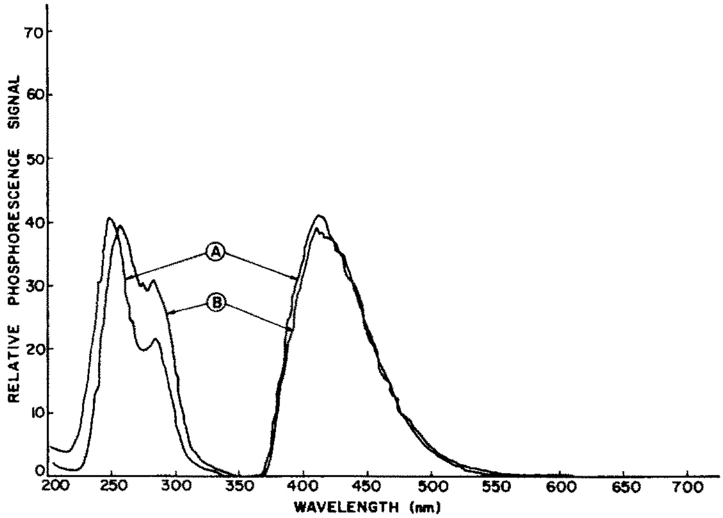

Fig. 2. Phosphorescence excitation and emission spectra of propiophenone at 77 K, in methanol/water v/v 10/90 (Curve A, emission wavelength 415 nm, excitation wavelength 250 nm) and in methanol/water v/v 10/90, sodium iodide 0·75*M* solutions (Curve B, emission wavelength 415 nm, excitation wavelength 260 nm).

Sensitivity of the ratio photometer = 3 and sensitivity vernier = 15. Concentration of propiophenone = $6{\cdot}14 \times 10^{-4}M$.

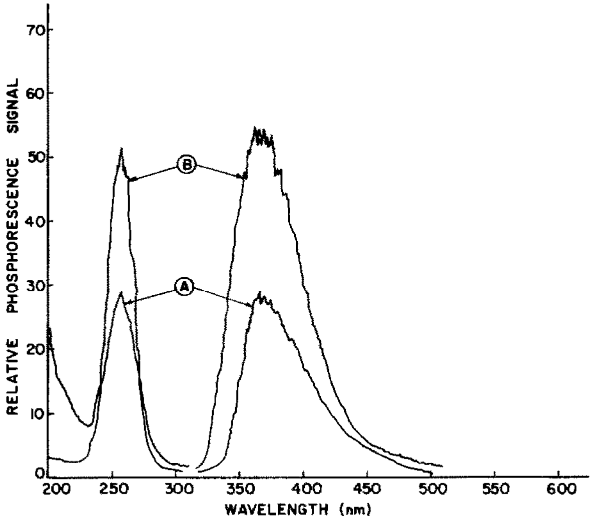

Fig. 3. Phosphorescence excitation and emission spectra of benzene at 77 K, in methanol/water v/v 10/90 (Curve A, emission wavelength 365 nm, excitation wavelength 260 nm) and in methanol/water v/v 10/90, sodium iodide 0·75*M* solutions (Curve B, emission wavelength 365 nm, excitation wavelength 255 nm).

Sensitivity of the ratio photometer = 0·3 (Curve A) and 1·0 (Curve B), and sensitivity vernier = 50 (Curve A) and 20 (Curve B). Concentration of benzene = $2{\cdot}14 \times 10^{-3}M$.

Phosphorescence lifetimes of all benzenic compounds, except acetophenone and benzaldehyde, were found to decrease greatly in sodium iodide solutions, an effect which is typical of the enhancement of the spin-orbit coupling by an external heavy atom.[6a] The absence of significant change in the short phosphorescence lifetimes of acetophenone and benzaldehyde upon addition of sodium iodide is in agreement with the prediction of a very small external heavy-atom effect on the singlet–triplet transition probability and on the lifetime of the n,π^* triplet state of these carbonyl compounds.[6b,16] The longer phosphorescence decay-time of propiophenone and its marked decrease in sodium iodide solution would indicate that, in contrast to the other carbonyl-substituted benzenes, the triplet state of propiophenone is probably of π, π^* type; this phenomenon may be due to the inversion of the n,π^* and π,π^* triplet-state energy levels by the polar solvent (methanol/water) used. It is also of interest to observe that the phosphorescence decays of all the compounds in sodium iodide media were found to be exponential over 3–4 half-lives; this behaviour is different from the non-exponential decay observed by several authors for mixtures of EPA or ethanol and iodinated or brominated hydrocarbons[1,2,5] combinations of halonaphthalenes and propyl halides,[17] and in perdeuterated benzenes in alkali halides.[18] Two effects may explain the exponential character of phosphorescence decays in sodium iodide solutions.

(*i*) The effect of specific crystal geometry and density characteristics of aqueous sodium iodide snowed matrices upon the decay of phosphorescence is expected to be different[16] from that of the heavy-atom glasses[1–5] or cracked glasses[19] previously used.

(*ii*) Triplet-state equilibrium complexes occurring in the sodium iodide solutions may be very different from the charge-transfer equilibrium complexes postulated to explain the non-exponential nature of phosphorescence decay in the cracked glasses of halonaphthalenes and propyl halides,[17] because of the different conditions of solvent polarity, solute ionic dissociation, and solvation in water–methanol sodium iodide medium.

The phosphorescence signal was markedly enhanced for all compounds in sodium iodide solutions (see Table 2), and the room-temperature fluorescence of the fluorescent monosubstituted benzenes was markedly quenched. These results are also typical of an external heavy-atom effect, characterized by the increase of the triplet population by radiationless intersystem crossing and of the triplet-to-singlet transition probability.

Variation of the sodium iodide heavy-atom effect with phosphorescence signal

Phosphorescence signals and heavy-atom enhancement factors of all monosubstituted benzenes studied are presented in Table 2.

Phosphorescence relative signals ($I_{\mathrm{p,r}}$) are defined as the ratio of the phosphorescence molar signals (expressed in A.l.mole^{-1}) of the sample and of the reference compound (phenol) and are corrected for the exciting radiation intensity, according to the equation

$$I_{\mathrm{p,r}} = \beta_\lambda\left(\frac{i_{\mathrm{S}}c_{\mathrm{R}}}{i_{\mathrm{R}}c_{\mathrm{S}}}\right) \tag{3}$$

where i is the absolute phosphorescence signal (in A) of the sample S and of the reference R, c is the concentration (mole/l.) of the species of interest S, and reference

[g] Relative to $\phi_{\mathrm{p}} = 0{\cdot}74$ for acetophenone in EPA at 77 K.

[h] Values in parentheses taken from R. S. Becker, *Theory and Interpretation of Fluorescence and Phosphorescence*, Wiley, New York, 1969 (for EPA media at 77 K).

[i] Values in parentheses taken from C. A. Parker, *Photoluminescence of Solutions*, Elsevier, London, 1968 (for EPA media at 77 K).

R, and β_λ is the ratio of the exciting radiation intensity ($I^{\circ}_{\lambda,\mathrm{R}}$) at the excitation wavelength of the reference to the same quantity ($I^{\circ}_{\lambda,\mathrm{S}}$) at the excitation wavelength of the sample [see equation (2) for the determination of I°_{λ} values].

Corrected relative phosphorescence signals ($I^{\varepsilon}_{\mathrm{p,r}}$), taking into account the molar absorptivity of the compounds, were obtained from the equation

$$I^{\varepsilon}_{\mathrm{p,r}} = \beta_\lambda\left(\frac{i_{\mathrm{S}}c_{\mathrm{R}}\varepsilon_{\mathrm{R}}}{i_{\mathrm{R}}c_{\mathrm{S}}\varepsilon_{\mathrm{S}}}\right) \tag{4}$$

where ε_{S} and ε_{R} are the molar absorptivities of the sample S and of the reference R and other notations are as in equation (3). It is assumed[15] that the molar absorptivities for the sample at 77 K are identical to those at room temperature.

Sodium iodide heavy-atom enhancement factors ($I_{\mathrm{p}}^{\mathrm{NaI}}/I_{\mathrm{p}}$) are defined as the ratio of the molar phosphorescence signals in methanol–water–sodium iodide solutions and in methanol–water and were determined from the equation

$$I_{\mathrm{p}}^{\mathrm{NaI}}/I_{\mathrm{p}} = \beta_\lambda'\left(\frac{i_{\mathrm{S}}^{\mathrm{NaI}}c_{\mathrm{S}}}{i_{\mathrm{S}}c_{\mathrm{S}}^{\mathrm{NaI}}}\right) \tag{5}$$

where $i_{\mathrm{S}}^{\mathrm{NaI}}$ and $c_{\mathrm{S}}^{\mathrm{NaI}}$ are respectively the absolute phosphorescence signal (in A) and

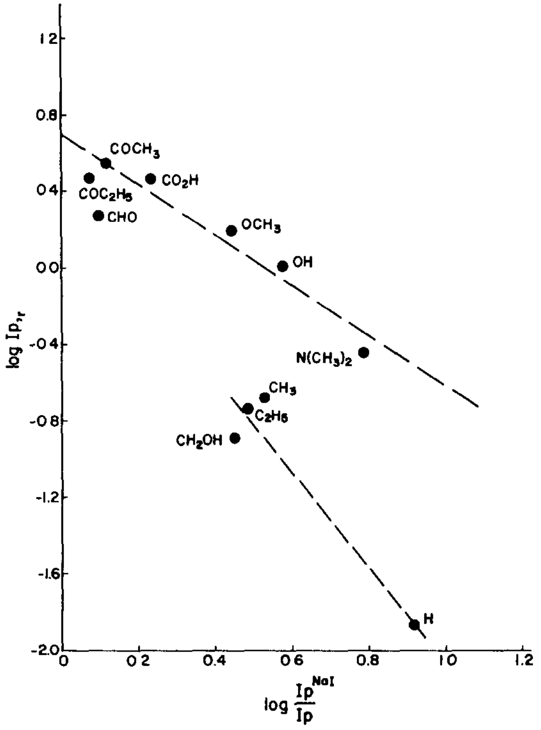

Fig. 4. Relative phosphorescence signal of the monosubstituted benzenes as function of their heavy-atom enhancement factor.

---●---Least-squares line for the compounds with molar absorptivity ≥ 1000 (correlation coefficient = 0·97 and standard deviation = 0·10).

---o---Least-squares line for the compounds with molar absorptivity < 230 (correlation coefficient = 0·95 and standard deviation = 0·21).

(Benzaldehyde was not included in the calculation).

the concentration (mole/l.) of the species of interest S in methanol–water–sodium iodide solution; β_λ' is the ratio of the exciting radiation intensity ($I^\circ_{\lambda,\mathrm{S}}$) at the exciting wavelength of the sample in methanol–water solution to the same quantity ($I^{\circ\,\mathrm{NaI}}_{\lambda,\mathrm{S}}$) at the exciting wavelength of the sample in methanol–water–sodium iodide solution. It is assumed in equation (5) that the molar absorptivities are identical in the iodide and non-iodide solvents.

Heavy-atom enhancement factors of all monosubstituted benzenes were found to be larger than unity; $I_\mathrm{p}^\mathrm{NaI}/I_\mathrm{p}$ values ranged between 1·2 for propiophenone and 8·3 for benzene. Even though excitation wavelengths are taken in the wavelength region above 255 nm, in which no solvent filter effect[1–5] should occur, enhancement factors vary appreciably with the molecular structure of the compound. It is worthwhile to note that the variation of heavy-atom enhancement factors is parallel to the change in phosphorescence relative signals; there is definitely a trend in the increasing phosphorescence signals with a decrease in the heavy-atom enhancement factors, and partial correlations are obtained between the logarithms of these quantities for the compounds with similar molar absorptivity (see Fig. 4). In order to take this last factor into account, the phosphorescence signals were corrected for the absorptivity according to equation (4) and a satisfactory correlation was found between the logarithms of the corrected phosphorescence signal values and of the heavy-atom enhancement factors (see Fig. 5), *i.e.*,

$$\log I^\varepsilon_{\mathrm{p,r}} = -1{\cdot}80 \log I_\mathrm{p}^\mathrm{NaI}/I_\mathrm{p} + 0{\cdot}93 \qquad (6)$$

For ten compounds, a correlation coefficient of 0·95 and a standard deviation of 0·16 were obtained. This correlation indicates that for molecules with a heavily populated triplet state, the sodium iodide does not have a large effect upon the intersystem crossing from the singlet to the triplet state. This is the case for the very phosphorescent carbonyl-substituted benzenes and benzoic acid. On the contrary, for a molecule with a poorly

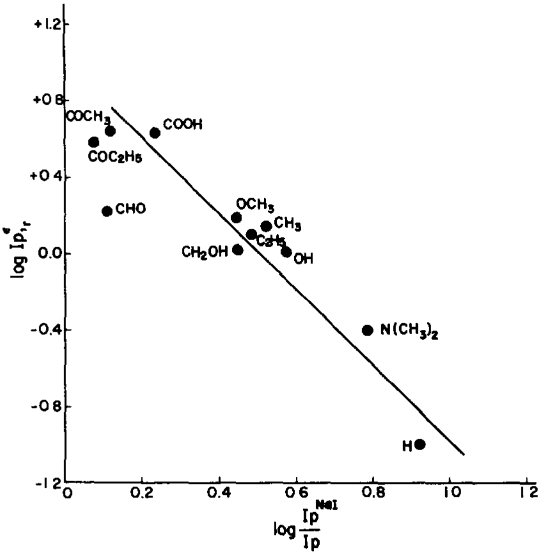

Fig. 5. Correlation between the corrected relative phosphorescence signal ($I^\varepsilon_{\mathrm{p,r}}$) and the heavy-atom enhancement factor ($I_\mathrm{p}^\mathrm{NaI}/I_\mathrm{p}$) of monosubstituted benzenes. (Benzaldehyde was not included in the calculation of the least-squares line).

populated triplet state, sodium iodide would facilitate a very large increase of the intersystem crossing transition from the singlet excited state, as in the case of the weakly phosphorescent benzene.

The correlation [see equation (6)] is also of great interest from an analytical point of view. Indeed, it is possible to predict the heavy-atom enhancement factor for any substituted benzene within an error of 20%, by means of equation (6). The only data which need to be known for a particular compound are the relative phosphorescence signals and molar absorptivity values of the compound with phenol as reference. The application of equations of this type would allow prediction of the analytical usefulness of the heavy-atom effect for the improvement of sensitivity of phosphorimetry.

Correlation of the quantum yield with the heavy atom effect

Relative quantum yields (ϕ_S) were determined[18] from equation (7)

$$\phi_S = \phi_R \times \beta_\lambda \left(\frac{F_S c_R \varepsilon_R}{F_R c_S \varepsilon_S} \right) \tag{7}$$

where ϕ_R is the phosphorescence quantum yield of the reference species R (acetophenone), F_S and F_R are the corrected areas under the phosphorescence emission spectra for sample, S, and reference R, c is the concentration (M) of the species indicated and β_λ, ε_R and ε_S are as previously defined.

All relative quantum yield values are presented in Table 2. The phosphorescence quantum yield of acetophenone in EPA was taken as the reference, because no quantum yield data were known for methanol–water 10/90 v/v. Compared with the

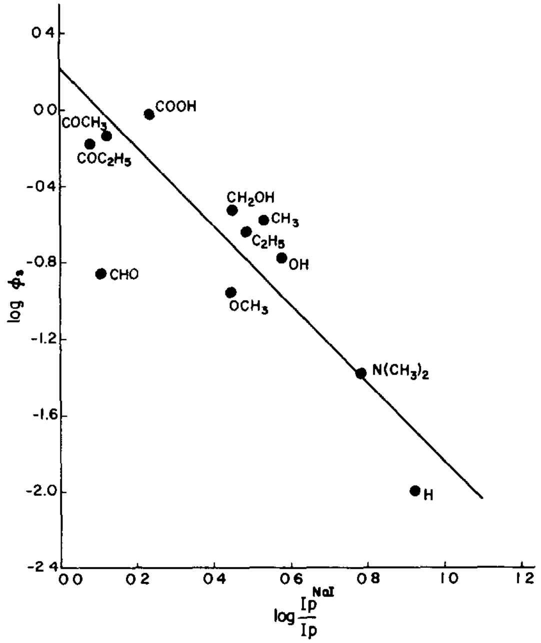

Fig. 6. Correlation between the relative quantum yield (ϕ_s) and the heavy-atom enhancement factor (I_p^{NaI}/I_p) of monosubstituted benzenes. (Benzaldehyde was not included in the calculation of the least-squares line).

literature data, which were all obtained in EPA medium, our values are consistently smaller except in the case of benzoic acid; this difference may be due to the different radiationless deactivations of the triplet state according to the matrices used and to the change in solvation as well as due to solvent absorption which was not corrected for in Table 2. For example, it may be expected that benzene will be less solvated in predominantly aqueous solution ($\phi_S = 0{\cdot}01$) than in EPA ($\phi_S = 0{\cdot}20$). Quantum yield values spread over a large range from 0·01 for benzene to 0·76 for benzoic acid and were found to be correlated relatively well with the heavy-atom enhancement factors:

$$\log \phi_S = -2{\cdot}06 \log I_p^{\mathrm{NaI}}/I_p + 0{\cdot}22 \qquad (8)$$

for ten compounds, with correlation coefficient 0·93 and standard deviation 0·24. The negative slope of the correlation (Fig. 6) shows that heavy-atom enhancement is larger for compounds with low phosphorescence quantum yield. A correlation of the heavy-atom enhancement factors with the quantum yields is obtained which is nearly as good as with the phosphorescence signals, which indicates that the vibrational components of the phosphorescence (included in the total emission area) are affected in the same way by the heavy-atom effect as is the maximum phosphorescence signal. Therefore, it seems reasonable that the substituent sequences of phosphorescence signals and quantum yields fall in approximately the same order.

Zusammenfassung—Phosphoreszenzanregungs- und -emissionsspektren, Lebensdauern und relative Quantenausbeuten von Benzol und zehn monosubstituierten Benzolen wurden bei 77°K in Methanol/Wasser 10/90 (V/V) und in Natriumjodid/Methanol/Wasser-Lösungen bestimmt. Die Substituenten $—CHO$, $—COCH_3$, $—COC_2H_5$, $—CN$, $—OCH_3$, $—CH_3$, $—C_2H_5$, $—CH_2OH$ und $—N(CH_3)_2$ wurden untersucht. Es wurde gefunden, daß wäßrige Natriumjodidlösungen ein geeignetes Schweratom-Lösungsmittel für die Phosphorimetrie sind. Die Schweratom-Verstärkungsfaktoren reichten je nach der Molekülstruktur von 1·2 bis 8·3; für neun Verbindungen wurde in wäßriger Natriumjodidlösung eine beträchtliche Verkürzung der Lebensdauer beobachtet. Im doppeltlogarithmischen Maßstab wurde eine lineare Beziehung zwischen der relativen korrigierten Phosphores-zenzintensität und dem Schweratom-Verstärkungsfaktor der monosubstituierten Benzole gefunden. Eine ähnliche Beziehung wurde zwischen den Quantenausbeuten und den Schweratom-Verstärkungsfaktoren gefunden. Der analytische Nutzen dieser Beziehungen ist für die Voraussage der Größe des Schweratomeffekts offenkundig.

Résumé—On a déterminé les spectres d'excitation et d'émission de phosphorescence, les temps de vie et les rendements quantiques relatifs du benzène et de dix benzènes monosubstitués à 77°K en solutions méthanol/eau 10/90 v/v et iodure de sodium/méthanol/eau. On a étudié les substituants $-CHO$, $-COCH_3$, $-COC_2H_5$, $-OH$, $-OCH_3$, $-CH_3$, $-C_2H_5$, $-CH_2OH$ et $-N(CH_3)_2$. On a trouvé que les solutions aqueuses d'iodure de sodium sont un solvant à atome lourd convenable pour la phosphorimétrie. Les facteurs d'exaltation par atome lourd se sont situés de 1,2 à 8,3 selon la structure moléculaire et un abaissement notable du temps de vie a été observé pour neuf composés en solution aqueuse d'iodure de sodium. On a obtenu une relation log-log linéaire entre l'intensité de phosphorescence corrigée relative et le facteur d'exaltation par atome lourd des benzènes monosubstitués. On a trouvé une relation semblable entre les rendements quantiques et les facteurs d'exaltation par atome lourd. L'utilité analytique de ces relations est évidente pour la prévision de la grandeur de l'effet d'atome lourd.

2,2′-DIMERCAPTODIETHYLSULPHIDE: A POTENTIAL ANALYTICAL REAGENT

A. CORSINI and E. NIEBOER*
McMaster University, Hamilton, Ontario, Canada

(*Received* 12 *August* 1972. *Accepted* 19 *September* 1972)

Summary—The compound 2,2′-dimercaptodiethylsulphide has been investigated with regard to the stability of its solutions to air oxidation, its acid strength, its reactivity towards metal ions, the nature of its Ni(II) and Pd(II) complexes in solution, and its applicability to the determination of small amounts of Ni(II) and Pd(II). Studies on the Ni(II) complex extend the work reported previously by others and are not in complete accord with it. The results presented show that 2,2′-dimercaptodiethylsulphide is a promising analytical reagent.

The compound 2,2′-dimercaptodiethylsulphide (or 2,2′-thiodiethanethiol, hereafter referred to as TDT) has received only sparse attention as a possible analytical reagent. Two analytical applications have been reported to date. One of these involves the formation of the red Ni(II) complex as a sensitive and specific test for mustard gas[1] and the other involves the determination of nickel.[2] Because the compound is a liquid at room-temperature, its potential as a chelating extraction solvent has been recognized[3] but no such studies have yet been reported.

In the present study, we have further examined TDT as an analytical reagent and report, on the stability of its solutions to air oxidation over a wide pH range, its acidity in solution, its reactivity towards metal ions, the nature of its Ni(II) and Pd(II) complexes in solution, and on its potential as a reagent for nickel and palladium. With respect to the Ni(II) complex, our findings add substantially to those reported earlier.[2]

EXPERIMENTAL

Apparatus

pH Meter. Radiometer Type PHM 4C meter equipped with Radiometer glass (G 202B) and saturated calomel (K401) electrodes.

Spectrophotometry. Spectrophotometric measurements for the determination of nickel and palladium were made with a Hitachi Perkin–Elmer UV-VIS Spectrophotometer, Model 139. The cell compartment was kept at 25·0 ± 0·5°. Spectrophotometric measurements of TDT in the ultraviolet range and of its Ni(II) and Pd(II) complexes in solution were made with a Cary Model 14 recording spectrophotometer. High-quality 1-cm quartz cells were used for all measurements. *Molecular-weight Determinations.* Mechrolab Vapour Pressure Osmometer, Model 301A.

Reagents

All common laboratory chemicals were either analysed grade or of sufficient purity for the purpose intended. Distilled water passed through a mixed-bed ion-exchanger was used in all experiments.

---

* Present address: Department of Chemistry, Laurentian University, Sudbury, Ontario.

TDT. The commercially available compound (Aldrich) was purified by distillation under reduced pressure (nitrogen atmosphere). The boiling point was 135–136° at 10 mmHg (lit.,[2] 138°, 13 mmHg). The purified material was kept under nitrogen in glass-stoppered bottles stored in a refrigerator. The nitrogen atmosphere was replaced after every opening.

Dioxan. Reagent-grade 1,4-dioxan was purified as described elsewhere.[4]

1,2-*Dichloroethane.* Samples were redistilled and the fraction collected over the range 82·4–83·0° was used.

Benzil, recrystallized from ethanol (*m.p.* 93·8–94·5°).

Stock solution of Ni(II), 9·78 ± 0·02 × $10^{-3}M$. Prepared from the hydrated perchlorate and standardized by EDTA titration.[5] The EDTA solution was initially standardized against a standard Zn(II) solution prepared from pure zinc metal.[6]

Pd(II) stock solution (9·480 ± 0·007 × $10^{-3}M$). The solution contained 0·425 g of anhydrous palladium chloride, 0·29 g of sodium chloride and 0·20 ml of $12M$ hydrochloric acid in 250 ml. Heating was necessary for dissolution. The solution was standardized by PFHS as the dimethylglyoximate.[7]

Procedures

Stability of TDT in 50% v/v aqueous dioxan. Sufficient TDT was weighed out to allow preparation of solutions of known concentration (10^{-3}–$10^{-4}M$) in 50% v/v aqueous dioxan. Solutions were prepared at pH 6·0 (no buffer present), pH 9·8 (ammonia/ammonium chloride) buffer, and pH 13·4 (0·01M sodium hydroxide) and their spectra recorded over the range 220–320 nm (Fig. 1). The effect of time was studied at each pH value. At pH 6·0, a maximum soon developed at 250 nm and reached constant intensity after 165 hr. At pH 9.8, the absorbance at 235 nm decreased rapidly to a minimum while the absorbance at ~250 nm increased to a maximum. The changes were complete after 21 hr. At pH 13·4, the absorbance at 235 nm decreased to a constant value (~0·1) after 45 hr. Plots of absorbance *vs.* time (at specific wavelengths) allowed extrapolation to $t = 0$ (*i.e.*, time immediately after solution preparation) and provided corrected absorbance values for calculation of the following molar absorptivities (ε in l. $mole^{-1}.cm^{-1}$): at pH 6·0, $\varepsilon = 365$ (235 nm), 108 (250 nm); at pH 9·8, $\varepsilon = 1{\cdot}40 \times 10^3$ (235 nm); at pH 13·37, $\varepsilon_{max} = 1{\cdot}24 \times 10^4$ (235 nm).

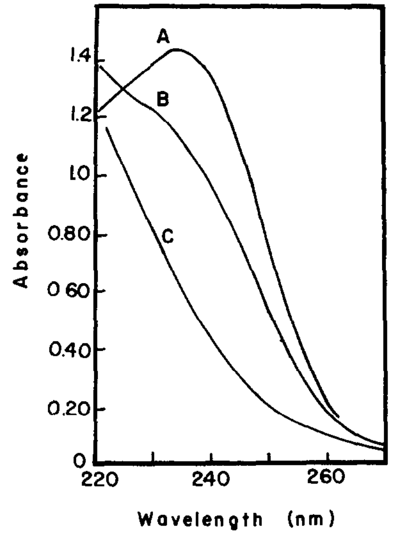

Fig. 1. Ultraviolet specta of TDT in 50% v/v aqueous dioxan 15 min after preparation of solution. A, pH 13·4 (1·2 × $10^{-4}M$); B, pH 9·8 (1·3 × $10^{-3}M$); C, pH 6·0 (1·7 × $10^{-3}M$).

The changes in the spectra with time reflect the relative rates of oxidation of the ligand in the various solutions. A qualitative estimate of the relative reaction rates was obtained by graphically evaluating the time ($t_{1/2}$) required for the initial absorbance, A_t (A at $t = 0$), to decrease to $A_{1/2} = 1/2(A_t - A_f)$ at pH 9.8 and 13.4 at 235 nm, and to increase to $A_{1/2} = 1/2(A_f - A_t)$ at pH 6·0 (250 nm). A_f is the (constant) final absorbance observed and it was assumed that oxidation was complete at this point. The results are discussed below.

Acid dissociation constants. The acid dissociation constants of TDT were determined both potentiometrically and spectrophotometrically in 50% v/v aqueous dioxan at 25° and ionic strength 0·1 (adjusted with sodium perchlorate). The potentiometric technique and procedure were essentially as described previously.[8] The correction factor for converting the pH-meter reading into [H^+] was −0·07. Because the two

pK_a values are not well separated, refined values were obtained by the least-squares fit of equation (4) in reference 8; the pK_a values obtained were 10·32 ± 0·01 and 11·43 ± 0·02.

The spectrophotometric procedure was a straightforward one in which the ε values (235 nm) at pH 6·0 and 13·4 were taken to be ε_{H_2A} and $\varepsilon_{A^{2-}}$, and ε_{HA^-} was assumed to be equal to $\frac{1}{2}\varepsilon_{A^{2-}}$.[9] Simple simultaneous equations involving first C_{H_2A} and C_{HA^-} as unknown pairs of concentrations at pH 9·76 and then C_{HA^-} and $C_{A^{2-}}$ at pH 12·02 were solved. Substitution into the K_a expression yielded the pK_a values 10·35 ±0·05 and 11·47 ± 0·04. All absorbance values were corrected to $t = 0$.

Reaction with metal ions. Tests for reactivity were made in test-tubes at three pH values by adding 0·4 ml of metal-ion solution (0·02*M*, prepared from the chloride, nitrate or perchlorate) and 0·4 ml of TDT solution (0·07*M*, in dioxan) to 10 ml of buffer solution. Each test was compared with a blank containing only the metal ion and buffer solution. The formation of a colour or precipitate was taken as a positive test for reaction. The results are summarized in Table 1. The following class (a) ions gave negative tests at all pH values: Mg(II), Sr(II), Y(III), La(III), Ce(III), Th(IV), U(VI), Ti(IV), Al(III).

Table 1. Reaction with metal ions

Ion	pH*				Colour§
	2·1	5·6	8·5	10·3	
Mn(II), Cr(III)	−	−	−	+	w,g
Co(II), Ni(II), Fe(II), Fe(III)	−	+	+	+	g–b,r,g,g
Ag(I), Cu(II)†, Pd(II), Cd(II), Hg(II)	+	+	+	+	w,w,o,w,w
Zn(II)	−	+	+	−	w
Rh(III)†, Pt(IV)†	+	+	+		o,b
Tl(I)		−	+		y
Pb(II), Bi(III)	−	+	+		y,y

* The pH values were fixed by appropriate concentrations of the following buffers: pH 2·1, H_2SO_4; pH 5·6, acetic acid/sodium acetate; pH 8·5, ammonium acetate/ammonia; pH 10·3, ammonium chloride/ammonia. A positive test is indicated by +, negative by −, and a blank signifies a test was not tried.

§ The colours designated are in the same order as the ions listed: r(red), o(orange), y(yellow), g(green), b(brown), w(white).

† With Cu(II) in excess, a mauve precipitate formed. With Rh(III) and Pt(IV), the reaction at room temperature was slow. For Rh(III), heating was required to obtain appreciable reaction.

Preparation of solid Ni(II) and Pd(II) complexes. Bis(2,2′-dimercaptodiethylsulphide)dinickel(II) was prepared from alkaline solution essentially as described by Harley-Mason.[1] The Pd(II) complex was prepared as follows: palladium(II) chloride ($1{\cdot}62 \times 10^{-3}$ mole) was dissolved with heat in 100 ml of water containing sodium chloride ($5{\cdot}20 \times 10^{-3}$ mole) and a few drops of concentrated hydrochloric acid. The brown solution was filtered to remove traces of undissolved material. To a solution containing TDT ($1{\cdot}61 \times 10^{-2}$ mole), 10 ml of 0·25*M* perchloric acid, 40 ml of water and 150 ml of dioxan, the Pd(II) solution was added over a period of 20 min. with stirring. An orange precipitate formed immediately and was washed by decantation with 50% v/v aqueous dioxan, filtered off, and washed with aqueous dioxan, ethanol and ether in succession. The compound was dried overnight *in vacuo* at 55° (yield, 52%).

The following results were obtained for elemental analysis. Calculated for $NiC_4H_8S_3$: C, 22·77%; H, 3·82%; 2, 45·58%; Ni, 27·83%. Found: C, 23·0%; H, 4·0%; S, 45·4%; Ni, 27·8%. Calculated for $PdC_4H_8S_3$: C, 18.57%; H, 3·12%; S, 37·18%; Pd, 41·13%. Found: C, 18·4%; H, 3·2%; S, 37·0%; Pd, 40·3%.[*]

Molecular-weight determinations were made with a vapour-phase osmometer calibrated with solutions of benzil in freshly-distilled 1,2-dichloroethane. It was necessary to protect the benzil solutions from sunlight to prevent photolysis, otherwise the calibration curves were not reproducible. For the nickel complex, the molecular weight obtained was 425 ± 7 (2 determinations). The calculated molecular weight for the dimer $Ni_2(C_4H_8S_3)_2$ is 422. Reliable estimates could not be obtained for the molecular weight of the Pd(II) complex, because of the very low solubility (0·2–0·3 mg/ml) in dichloroethane, but the results (650 ± 150) at least suggest the formation of a polymeric species. Magnetic susceptibility measurements (Gouy method) confirmed that both complexes are diamagnetic.

---

[*] The low result for Pd was due to volatilization during ignition to Pd metal.

Ni(II) and Pd(II) complexes in solution. The formation of the Ni(II) and Pd(II) complexes was studied as a function of pH in 50% v/v aqueous dioxan at ionic strength 0·1 (adjusted with sodium perchlorate) and 25°. For the Ni(II) complex, the analytical concentrations of Ni(II) and TDT in the final solution were $5{\cdot}87 \times 10^{-4}$ and $3{\cdot}28 \times 10^{-3}M$ respectively; for the Pd(II) complex, the values were $9{\cdot}48 \times 10^{-5}$ and $8{\cdot}20 \times 10^{-4}M$. For solutions of the Ni(II) complex, the pH ranged from 2·3 to 12·4. The pH was adjusted by use of dilute sulphuric acid, acetic acid/acetate, ammonia/ammonium chloride or dilute sodium hydroxide solutions. For the Pd(II) complex, the pH range was 0-12·4; the low pH values were obtained by addition of 2·5*M* hydrochloric acid.

The spectra of all solutions were recorded over the range 300–600 nm. Typical spectra are shown in Figs. 2 and 3. Spectrum A, Fig. 2, is representative of the Ni(II) complex at pH values up to pH 7·3 (the solutions were red.) At high pH values (*e.g.*, 12·4, spectrum B), the spectrum was significantly different and the solution was yellow-orange. At pH 9·4, the spectrum (not shown) was intermediate in appearance. On standing overnight, the yellow-orange solutions turned red and the spectra changed accordingly. For the red Ni(II) complex, characteristic ε values (l.mole^{-1}.cm^{-1}) are: 1310 (378 nm); 1060 (505 nm); 1160 (414 nm). For the yellow-orange species, $\varepsilon_{max} = 740$ l.mole^{-1}.cm.$^{-1}$ at 463 nm.

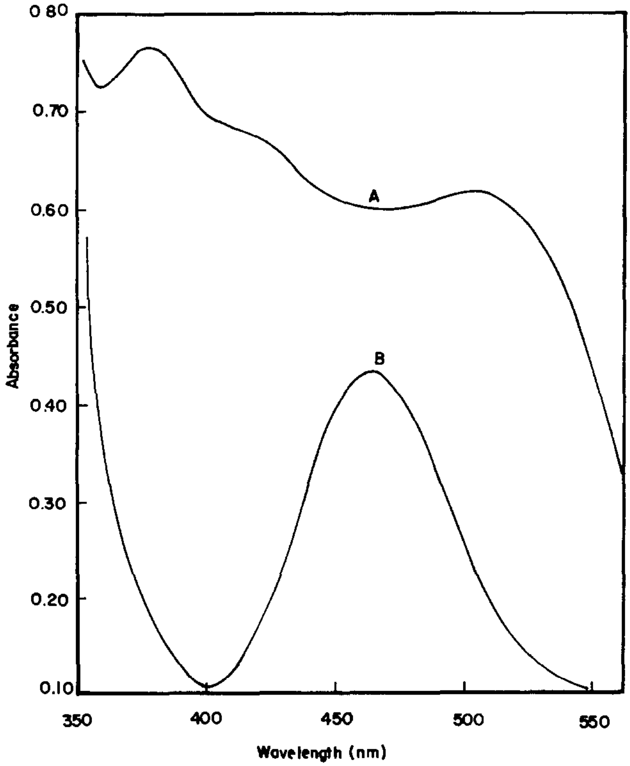

Fig. 2. Spectra of Ni (II)–TDT complex in 50% v/v aqueous dioxan, TDT : Ni ratio ~6 : 1. A, pH 6·6 (red solution); B, pH 12·4 (yellow-orange solution).

Spectrum B, Fig. 3, is typical of the Pd(II) complex for the pH range 1·0–7·8 (yellow-green solution). The spectra in strongly acid solution (spectrum A, deep yellow solution) and in alkaline solution (>pH 9, spectrum C, pale greenish-yellow) are also shown, together with the spectrum of palladium (II) chloride. Characteristic ε values (l. mole.$^{-1}$ cm^{-1}) are: at pH 0, $7{\cdot}81 \times 10^3$ (310 nm); pH 1·0–7·8, $7{\cdot}38 \times 10^3$ (340 nm); pH> 9, $5{\cdot}83 \times 10^3$ (335 nm).

The formation of the red Ni(II) complex and the greenish-yellow Pd(II) complex as a function of pH is shown in Fig. 4.

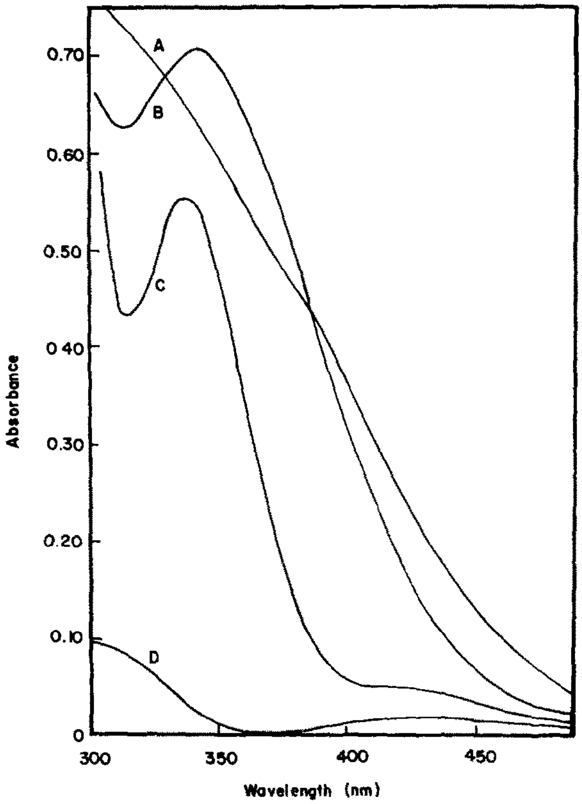

Fig. 3. Spectra of Pd(II)–TDT complex in 50% v/v aqueous dioxan, TDT : Pd ratio ~9 : 1. A, pH 0; B, pH 2·2; C, pH 12·4; D, $PdCl_2$ solution ($9{\cdot}48 \times 10^{-5}M$) at pH 2·1 (TDT absent).

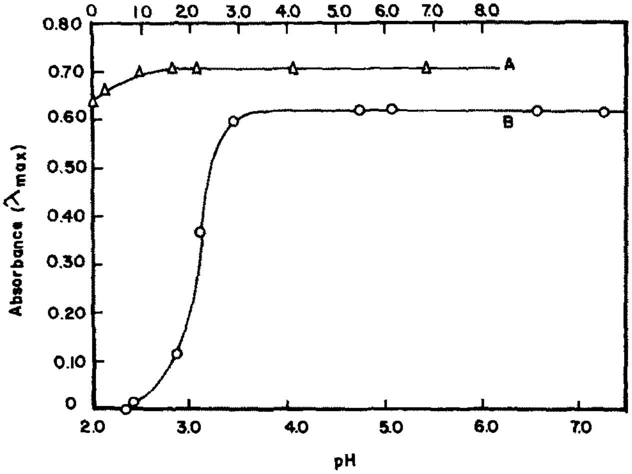

Fig. 4. Complex formation in 50% aqueous dioxan as a function of pH. A, Pd(II) complex, $\lambda_{max} = 340$ nm, TDT : Pd ratio ~9 : 1 (upper pH scale); B, Ni(II) complex, $\lambda_{max} = 505$ nm, TDT : Ni ratio ~6 : 1 (lower pH scale).

Extraction of the Ni(II) complex into 1,2-dichlorethane was studied as follows. Water and the appropriate buffer solution and 3·00 ml of the Ni(II) stock solution were placed in a 100-ml separatory-funnel (total volume of aqueous phase, 40 ml) and extracted with three 10-ml portions of $2{\cdot}0 \times 10^{-2}M$ TDT in 1,2-dichloroethane. Shaking for 1–2 min with each portion was sufficient. The aqueous phase was washed with a 10-ml portion of pure solvent and then the pH was measured. The organic extracts (red) were combined and diluted to 50 ml and the spectrum was recorded. The spectrum of the extracted complex was essentially as shown in spectrum A, Fig. 2, with small shifts (~5–10 nm) in the maxima. The dependence of the extraction on pH is given in Fig. 5. At pH 10·3, the aqueous phase was yellow after extraction; only repeated washing with pure solvent removed the yellow colour, imparting a pink colour to the organic phase. At all lower pH values, the aqueous phase was colourless after extraction and a single washing. Benzyl alcohol was also shown to be an effective extractant (Fig. 5).

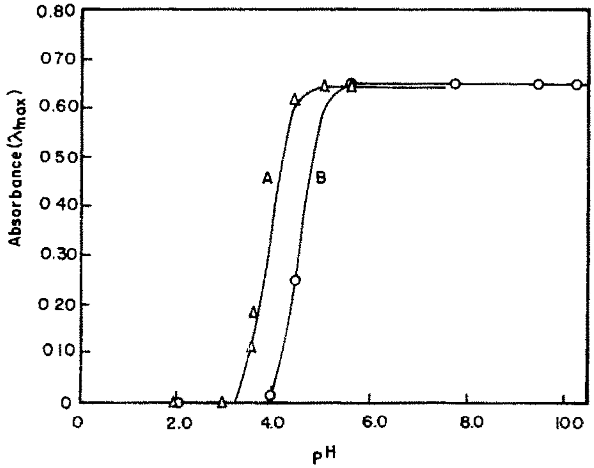

Fig. 5. Extraction of Ni (II) complex as a function of pH. A, benzyl alcohol, $\lambda_{max} = 508$ nm; B, 1,2-dichloroethane, $\lambda_{max} = 512$ nm.

The Pd(II) complex was only partially extracted into 1,2-dichlorothane, but extraction into benzyl alcohol was complete at pH 1·5 and higher. The aqueous phase consisted of appropriate volumes of 0·25M perchloric acid, 30 ml of water and 5·0 ml of $4{\cdot}74 \times 10^{-4}M$ Pd(II) solution. The organic phases (greenish yellow) were diluted to 50 ml. The spectra were identical to spectrum B, Fig. 3.

The composition of the Ni(II) complex was determined at pH 6·8 and 12·1, adjusted by an acetic acid/acetate buffer and 0·05M sodium hydroxide respectively. Five-ml portions of Ni(II) solutions ($5{\cdot}87 \times 10^{-3}M$) and varying volumes of dioxan solution of TDT ($2{\cdot}53 \times 10^{-2}M$) were diluted to 50 ml, and the absorbance was measured at 505 nm (negligible absorbance of TDT and free Ni(II)). The mole-ratio diagrams are given in Fig. 6. At pH 6·8 (curve A), a sharp break occurs at mole ratio = 1·08. At pH 12·1, the solutions were red up to a TDT : Ni ratio of 2·25 and the spectra were identical to A, Fig. 2; however, at high ratios (*e.g.*, 4·00, 6·00) the solutions were yellow-orange and the spectra were identical to B, Fig. 2. Overnight, the solutions became red and the spectra reverted to A.

The stoichiometry of the Pd(II) complex was studied at pH 2·3, adjusted with 0·25M perchloric acid. Five-ml portions of Pd(II) solution ($4{\cdot}74 \times 10^{-4}M$) and appropriate volumes of reagent solution ($7.97 \times 10^{-3}M$), water and dioxan were mixed to give a final volume of 50 ml. The spectra varied with mole ratio; with increasing mole ratio, the absorbance at 410 nm decreased by ~60% and that at 340 nm increased by ~20%. The absorbance at 340 and 410 nm was measured and plotted against pH (curves A and B, Fig. 7). The study was repeated in the absence of chloride ion [Pd(II) perchlorate was used in place of $PdCl_2$ and the stock solution contained no chloride]. At 340 nm, a curve identical to A was obtained; at 410 nm, the curve (C, Fig. 7) was similar to B.

Potentiometric titrations of the Ni(II) and Pd(II)–TDT systems in 50% v/v aqueous dioxan were made in the usual way.[10] The quantities of reactants used were $4{\cdot}89 \times 10^{-5}$ mole of Ni(II)/7.63×10^{-5} mole of TDT and $4{\cdot}78 \times 10^{-5}$ mole of Pd(II)/$3{\cdot}79 \times 10^{-4}$ mole of TDT. The formation of the Ni(II) complex began at ~pH 2·5; no precipitation occurred during the titration. Two protons per Ni(II) ion were released in complex formation. The Pd(II) complex formed and precipitated* on mixing of the reagents. Two protons

---

*As discussed later, the solid complex is a 1:1 trimer.

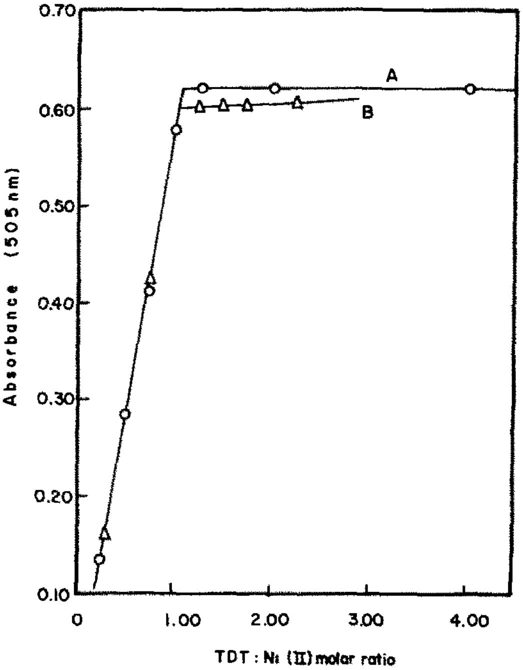

Fig. 6. Mole-ratio diagrams of TDT : Ni(II) system in 50% v/v aqueous dioxane. A, pH 6·8; B, pH 12·1.

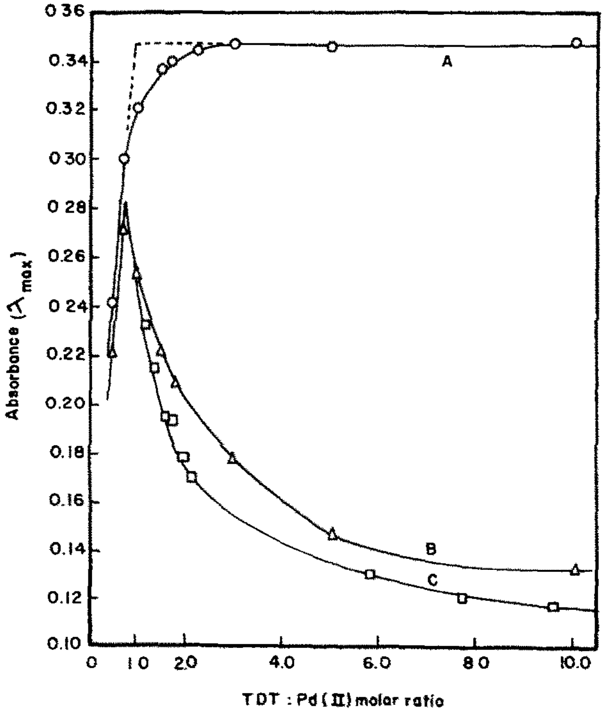

Fig. 7. Mole-ration diagrams of TDT : Pd(II) system in 50% v/v aqueous dioxan at pH 2·3: A, λ_{max} = 340 nm (chloride present or absent); B, λ_{max} = 410 nm (chloride present); C, λ_{max} = 410 nm (chloride absent).

per Pd(II) ion were released in acid solution. At pH ~ 8–9, an inflection was observed that corresponds to one additional proton per Pd(II). Nearly complete dissolution of the precipitate occurred in this pH range.

Investigation of analytical applications

Determination of nickel. A calibration curve for the determination of nickel was obtained as follows. Appropriate aliquotes of the Ni(II) stock solution to give amounts of Ni(II) ranging from 0·3 to 2·3 mg were placed in 100-ml separatory-funnels containing 10 ml of buffer solution (0·02*M* ammonia, 0·15*M* ammonium chloride) and diluted to 50 ml. The Ni(II) was then extracted with three 10-ml portions of a 1,2-dichlorethane solution of TDT (~2·5 × $10^{-2}M$). Each portion was shaken with the aqueous phase for 1–2 min and then drained through a glass-wool plug in the stem of the funnel. The residual aqueous phase was washed with one 10-ml portion of pure solvent. The organic phases were collected in a 50-ml flask and diluted to volume at 25·0°. The absorbance was measured at 512 nm against a solvent blank. The pH of the residual aqueous phase was 7·6 ± 0·2. The results yielded an excellent calibration plot; Beer's law was obeyed over at least the concentration range studied. The absorbance of the solutions remained constant for at least 40 hr.

Solutions containing 0·29, 1·15 and 1·72 mg of Ni(II) together with 0·5 mg of Pd(II) and 1·4 mg of Fe(III) were tested as follows. The pH of the aqueous solution was adjusted to 1·5–2·0 with 0·25*M* perchloric acid (~4–5 ml) and diluted to 50 ml. The Pd(II) was extracted with two 10-ml portions (shaking for 1–2 min) of a benzyl alcohol solution of the reagent ($10^{-2}M$). The aqueous phase was then washed with two 5-ml portions of benzyl alcohol followed by one 10-ml portion of 1,2-dichloroethane to remove residual alcohol. Aqueous ammonia (1 + 1) was added to the aqueous phase to precipitate Fe(III) and with the pH about 8, 10 ml of the buffer solution were added. The Ni(II) was extracted as before and the absorbance measured. The pH of the residual aqueous phase was 8·4 ± 0·3. The amounts of Ni(II) found were 0·29, 1·14 and 1·71 (±0·01) mg.

Determination of palladium. The absorbance of the Pd(II) complex was found to obey Beer's law by the following experiment. Aliquots (20·0–5·0 ml) of 0·06*M* hydrochloric acid and 25·0 ml of a dioxan solution of TDT (1·93 × $10^{-2}M$) were transferred by pipette into 50-ml volumetric flasks. Corresponding volumes (5·00–20·00 ml) of a Pd(II) solution (1·90 × $10^{-4}M$, 0·06*M* in hydrochloric acid were added. The amounts of Pd(II) taken ranged from 0·1 to 0·5 mg. The solutions were diluted to volume at 25·0° with 50% v/v aqueous dioxan and the absorbance measured at 340 nm against a solvent blank. The pH of the final solution was 1·67 ± 0·01. A plot of the results was linear and passed through the origin. The absorbance of the solutions remained constant for at least 15 hr.

The method above was applied to a solution known only to contain Pd(II) at a high concentration. This solution was diluted 50-fold and exactly 20 ml were taken for analysis. By reference to the calibration curve, the Pd concentration of the unknown was found to be 1·00 ± 0·01 mg/ml. Standardization of the same solution by the established procedure of homogeneous preciptation as the dimethylglyoximate gave 1·01 ± 0·00 mg/ml.*

The effect of the foreign ions Ni(II), Co(II) and Fe(III) was investigated. The quantities of all metal ions taken and results obtained are given in Table 2.

Table 2. Effect of Ni(II), Co(II) and Fe(III) on Pd(II) determination

Pd(II), *μg/ml* Taken	Found	Deviation %	Foreign ions present, *μg/ml*	Foreign ion : Pd molar ratio
6·05	6·04*	−0·2	Ni(23·0)	6·9

DISCUSSION

Stability of TDT

Segall *et al.* have reported that TDT and its chloroform solutions show no deterioration after twelve months when stored at room temperature in glass-stoppered bottles.[2] We have found that the purified reagent does not keep for such periods unless stored in a refrigerator under a dry nitrogen atmosphere. Under routine laboratory conditions, a white deposit forms after a few weeks. Solutions of the reagent (10^{-3}–$10^{-4}M$) in chloroform, petroleum ether and 1,4-dioxan are only moderately stable in routine use. For example, after two weeks the absorbance at 250 nm increased by about 8%. Because of the subsequent work in 50% v/v aqueous dioxan, the stability of the reagent in this solvent was studied more thoroughly. The mild oxidation of a mercaptan usually gives rise to the corresponding disulphide, characterized by a low-intensity, broad absorption band at about 250 nm.[11,12] This band was observed to develop when the reagent was kept at pH 6·0 and 9·8 and is strong evidence for air-oxidation of the dithiol to disulphide species. When reagent was kept at pH 13·4, the band was not observable, perhaps because a lower initial reagent concentration was used on account of the high absorbance at this pH, but the strong maximum of TDT at 235 nm was greatly reduced. The rate of oxidation is pH-dependent. The half-life at pH 6·0 is about 85 hr, 1 hr at pH 9·8 and 15 hr at pH 13·4 at the concentrations specified in Fig. 1. The pH-dependence of the rate of oxidation of mercaptans is complex and not well understood.[13]

In summary, TDT may be used in analytical applications in neutral 50% v/v aqueous dioxan solutions without special precautions against air-oxidation. In basic solutions, its use is more limited.

Acid dissociation constants

Because of rapid air-oxidation at about pH 10 in aqueous dioxan, the potentiometric titrations for the determination of the pK_a values of TDT were performed rapidly under an atmosphere of dry nitrogen. The pK_a values were confirmed spectrophotometrically. The acid dissociation constants of TDT have not previously been reported; the values reported here should prove to be useful in analytical studies.

Reaction with metal ions

TDT forms metal complexes with numerous metal ions (Table 1) and possesses no apparent selectivity beyond that expected for a ligand containing "soft" donor atoms.[14,16] Hence there is no reaction with the class (a) acceptors listed above. Reactions occur only at higher pH values with borderline acceptors [e.g., Mn(II), Cr(III)] while strong class (b) acceptors [*e.g.*, Pd(II), Ag(I), Cd(II), Hg(II)] react at low pH values. Ions with a d^{10} configuration [Ag(I), Cd(II), Hg(II), Zn(II)] form white insoluble complexes. The complex derived from Cu(II) (TDT in excess) is likely a Cu(I) complex since it is colourless, and oxidation of mercaptans by Cu(II) is well known.[17] The mauve complex that forms when Cu(II) is in excess may be a Cu(II) derivative of the disulphide or a complex containing copper in both oxidation states. Fe(II) and Fe(III) each react to give a green complex. Presumably, this is an Fe(II) complex since Fe(III) is known to oxidize mercaptans to disulphides.[13,18]

Ni(II) complex in solution

The formation of the red Ni(II) complex was complete in 50% v/v aqueous dioxan at about pH 4 (B, Fig. 4). Correspondingly, the extraction of Ni(II) with TDT into benzyl alcohol or 1,2-dichloroethane was quantitative at about pH 5.5 and 5, respectively (Fig. 5). Thus, both formation and extraction of the Ni(II) complex were complete at a much lower pH value than previously reported (above pH 10).[2] The stoichiometry at pH 6·8 was 1 : 1 and only one species existed in solution at all TDT: Ni molar ratios (0·25–4) investigated (A, Fig. 6). Elemental analysis showed the stoichiometry of the solid complex to be 1 : 1, as reported by others.[1,19,20] Also, since the complex in 1,2-dichloroethane was dimeric, as indicated by the molecular weight determination, it probably is dimeric in other solvents, such as 50% v/v aqueous dioxan. This is consistent with the dimeric structure of the solid, found by X-ray analysis.[19–22]

In alkaline solution (pH 12), the red 1 : 1 complex formed at TDT: Ni ratios of up to 2·25 (B, Fig. 6). At higher ratios, the solution became yellow-orange (*e.g.*, B, Fig. 2). This dependence on pH and TDT: Ni ratio is consistent with the addition of another ligand molecule to yield a complex with a ligand: metal ratio >1. This addition was not detected by potentiometric titration but it could have been obscured by titration of the excess of reagent in the same pH region. The yellow-orange complex was still extracted, however, as the 1 : 1 red complex into the organic phase.

The observation that solutions initially yellow-orange became red on standing overnight is probably the result of lowering of the reagent: Ni ratio through oxidation of the reagent. Appreciable oxidation of the reagent (see above) would occur in the pH region (9·4–12·4) over which the yellow-orange complex was observed. Thus, as the reagent is oxidized, the complex would be converted into the red 1 : 1 complex. The formation of the yellow-orange complex may account for the 2 : 1 stoichiometry reported by Segall *et al.*[2]

Pd(II) complex in solution. Formation of the Pd(II) complex was complete at about pH 1·5 (A, Fig. 4) in the presence of a large excess of TDT. Extraction into benzyl alcohol was also quantitative at this pH value. The molecular-weight data, although imprecise, suggest the formation of a dimer or trimer in solution. In an X-ray structural study,[19,23] the solid was found to be trimeric (and extremely insoluble in common solvents); thus the species in solution is probably a trimer. Elemental analysis confirmed the 1 : 1 stoichiometry of the trimeric solid, but as discussed below, the stoichiometry of the species in solution could not be obtained with certainty.

In solution, appreciable amounts of more than one complex can exist, depending on the pH and TDT: Pd(II) molar ratio. Figure 3 shows the dependence of the spectra on pH, at a mole ratio of ~9 : 1. At pH < 1·0, the solution was (deep) yellow (A). In the pH range 1–7, a yellow-green complex was formed (B). In alkaline solution (pH > 9), a further change occurred (C) which probably corresponds to the addition of one hydroxyl ion per Pd(II) ion. This change is consistent with the potentiometric titration, which showed that in the pH range 8–9 one proton was released per Pd(II) ion. Since at this point the 1 : 1 trimer which had precipitated earlier in the titration redissolved, the species in solution can be reasonably formulated as $[Pd_3L_3OH_3]^{3-}$.

The deep yellow and yellow-green species can also be produced by varying the TDT: Pd(II) molar ratio at constant pH. Thus, at pH 2·3 and mole ratio <1, the solution was deep yellow and absorption maxima* at 340 and 410 nm were obtained. At values >3, the solution was yellow-green and the absorbance at 340 nm was increased while that at 410 nm decreased. At mole ratio above 3 (and up to at least 60), the absorbance at 340 nm was constant (A, Fig. 7). The absorbance at 410 nm attained a maximum value at a mole ratio of

---

* TDT does not absorb at 340 and 410 nm and the absorbance of uncomplexed Pd(II) is negligible.

~0·8† and then decreased to a constant value (B, Fig. 7). This behaviour suggests the presence of at least two distinct species in equilibrium in solution. The interconversion of the species is not essentially dependent on chloride ion, since similar behaviour was observed in the absence of chloride (Fig. 7).

Potentiometric titration of the TDT: Pd(II) system at mole ratio ~12 showed that 2 protons were released per Pd(II) ion in acid solution. This is consistent with the formation of a 1:1 complex. Since no evidence has been produced for the formation of a higher complex either in solution or solid, the yellow-green species is probably a 1:1 species. (The orange 1:1 trimer also yielded a yellow-green solution when dissolved in aqueous dioxan.) These observations can then be explained on the basis that with increasing mole ratio, the yellow (polymeric) species with a TDT: Pd(II) ratio <1 (*e.g.*, $Pd_3L_2{}^{+2}$, $Pd_4L_3{}^{2+}$, *etc.*) were converted into the 1:1 trimeric species. Interestingly, extrapolation of the linear segments of curve A (Fig. 7) yields a TDT: Pd(II) ratio of 1.0. The break in curve B at ~0.8 suggests a ratio <1 for the yellow species. However, these observations must be treated with caution since the mole-ratio method has limited application when more than one species is present in solution.

For the determination of Pd(II) with TDT as outlined above and discussed below, Fig. 7 is essential. It illustrates that absorbance measurements at 340 nm must be made on solutions containing a large excess of TDT (> 10-fold). At such high excesses, the yellow species are essentially fully converted into the 1:1 complex; the constant residual absorbance at 410 nm (Fig. 7) is due primarily to the 1:1 yellow-green complex.

Analytical applications

Determination of nickel. The investigation of the solution properties of the Ni(II) complex resulted in an analytical procedure somewhat improved over that reported by Segall *et al.*[2] For example, the extraction of Ni(II) into 1,2-dichloroethane is best carried out in the pH range 6–9. The upper pH limit circumvents the formation of the yellow-orange species in the aqueous phase, which is rather difficult to extract. Also, the interference from Pd(II) is easily overcome by prior extraction of the ion (even in large amount) from strongly acid solution into benzyl alcohol with TDT. The use of one reagent for both the removal of Pd(II) and for the Ni(II) determination is convenient. Interference from Fe(III) can be avoided by adjusting the pH of the aqueous phase to about 8, after extraction of Pd(II) from acid solution. The Fe(III) is not extracted into 1,2-dichlorethane and remains in the aqueous phase as the hydroxide.

Segall *et al.*[2] did not investigate the effect of many class (b) metal ions on the nickel determination. Since these ions react strongly with the reagent (Table 1), they would be expected to interfere. However, the Pt(IV) complex (although it forms slowly at room temperature) can be extracted from acid solution into benzyl alcohol together with the Pd(II). Also, the white complexes of Cu(I) [from the reduction of Cu(II)], Zn(II), Ag(I), Cd(II) and Hg(II), are insoluble in 1,2-dichloroethane (and also in benzyl alcohol), and should not be extracted along with the Ni(II) complex. Even if the white complexes were extracted, they would not absorb at 512 nm. It would be necessary, of course, to use large excesses of reagent in the organic phase if several ions that react with the ligand were present.

Segall *et al.* found that in addition to the ions discussed above the following cations and anions do not interfere: alkali and alkaline earth metals, Pb(II), Sn(II), Mn(II), Sb(III),

---

† Spectra of solutions with mole ratio <0·5 could not be recorded because of the formation of a black suspension, indicative of reduction to Pd metal.

Cr(III), Al(III), Cl^-, NO_3^-, CH_3COO^-, SO_4^{2-}, and PO_4^{3-}. The improved procedure presented in this work should not alter the effect of these ions. Co(II) interferes in the nickel determination. It must therefore be removed, perhaps by the method suggested by Segall *et al.*[2]

TDT shows considerable promise as an analytical reagent for nickel. In addition to its simplicity, the method is accurate and precise over the concentration range studied (6–45 ppm, with respect to the aqueous phase before extraction). Future investigations on a variety of samples are necessary to assess the high degree of selectivity suggested above.

Determination of palladium. The spectrophotometric determination of Pd(II) with TDT, as far as developed in the present work, is accurate and precise over the concentration range studied (2–10 ppm in the final solution), and appears to have advantages over several existing spectrophotometric methods[24] for palladium. Unlike most other reagents for palladium, TDT does not absorb in the visible region. Also, Fe(III) and Ni(II), which are common interferences, do not interfere even when present in relatively large amounts (Table 2). Furthermore, Co(II), which also commonly interferes, may be present at least up to a Co/Pd ratio of 7. If the molar ratio is large (*e.g.*, Co/Pd = 27), the error becomes appreciable (4.3%). Except when Co(II) and Fe(III) occur together, only small errors are produced when combinations of Ni(II), Co(II) and Fe(III) are present with Pd(II). The simultaneous presence of Co(II) and Fe(III) leads to positive errors of about 5–7%. Larger errors are incurred if the absorbance measurements are not made promptly after preparation of the solution. When Co(II) is present in the absence of Fe(III), the solutions are stable for at least 3 hr. The interference may be due to the formation of stable Co(III) complexes[25] in acid solution through oxidation of Co(II) by Fe(III).

Examination of the data in Table 1 permits speculation on the effect of other foreign ions. Since Cr(III), Mn(II), Fe(II), Zn(II), Pb(II) and Tl(I) do not react with TDT at pH 2, they should not interfere in the Pd(II) determination—provided that the respective aquated ions do not absorb significantly at 340 nm. Ions of definite class (a) behaviour such as the alkali and alkaline earth metals, Al(III), the lanthanides and actinides do not react with the reagent and as a result, should not interfere.

The metals that normally interfere most seriously in palladium determinations are typically class (b) such as Pt, Ir, Au, Rh, Ag and Hg.[24] The reaction of Pt(IV) and Rh(III) with TDT is slow at pH 2 and room temperature and may permit the Pd(II) determination in their presence. The d^{10} ions, Cu(I), Ag(I), Cd(II) and Hg(II), form insoluble white compounds in strongly acid solution and can be removed by filtration before the dilution to volume. Thus, interference from several class (b) ions can perhaps be avoided by a combination of favourable rate and solubility effects. The potential of TDT as a reagent for the spectrophotometric determination of palladium cannot be fully realized until these possibilities have been investigated.

Many methods exist for the spectrophotometric determination of palladium. In a comprehensive review,[24] 65 such methods have been listed, making justification for a new method for palladium difficult. A survey of the methods reported in this review reveals that nearly all are subject to interferences from common metals such as chromium, iron, cobalt, nickel and copper, and from noble metals, particularly platinum. In a few methods, common anions such as chloride interfere. Only one method (involving *p*-nitrosodiphenylamine) seems relatively free from these interferences. About six methods are promising but more restrictive. Another method with promise, not mentioned in the review, involves 4,4′-bis(dimethylamino)thiobenzophenone.[26] Thus, a new method for palladium would be warranted if interferences from first-row transition and noble metals were minimal. The present work shows that TDT could fulfil this criterion and further studies to apply this promising reagent should be made.

Zusammenfassung—Die Verbindung 2,2′-Dimercaptodiäthylsulfid wurde bezüglich der Stabilität ihrer Lösungen gegen Oxidation an der Luft, ihrer Säurestärke, ihrer Reaktivität gegenüber Metallionen, der Natur ihrer Komplexe mit Ni(II) und Pd(II) in Lösung sowie ihrer Verwendbarkeit bei der Bestimmung kleiner Mengen Ni(II) und Pd(II) untersucht Die Arbeiten am Nickel(II)-Komplex erweitern früher von anderen Autoren mitgeteilte Ergebnisse und stehen nicht vollkommen mit diesen in Einklang. Die vorgelegten Ergebnisse zeigen, daß 2,2′-Dimercaptodiäthylsulfid ein vielversprechendes analytisches Reagens ist.

Résumé—On a étudié le composé 2,2′-dimercaptodiéthylsulfure quant à la stabilité de ses solutions à l'oxydation par l'air, sa force acide, sa réactivité vis-à-vis des ions métalliques, la nature de ses complexes Ni(II) et Pd (II) en solution, et sa possibilité d'application au dosage de petites quantités de Ni (II) et Pd (II). Les études sur le complexe Ni (II) développent le travail rapporté antérieurement par d'autres et ne sont pas en accord complet avec lui. Les résultats présentés montrent que le 2,2′-dimercaptodiéthylsulfure est un réactif analytique prometteur.

STRIPPING VOLTAMMETRY WITH COLLECTION AT A ROTATING RING–DISK ELECTRODE

DENNIS C. JOHNSON* and ROBERT E. ALLEN

Department of Chemistry, Iowa State University, Ames, Iowa 50010, USA.

(*Received* 11 *July* 1972. *Accepted* 29 *September* 1972)

Summary—A new electroanalytical technique is described, called "stripping voltammetry with collection." The technique involves the use of a rotating ring–disk electrode and is an improvement over traditional voltammetric stripping at a single electrode in that it is characterized by a lower limit of detection and that the period of deposition before stripping can be shorter. The use of the technique is illustrated by the determination of $10^{-10}M$ Ag^+ in $0{\cdot}1M$ H_2SO_4 by use of a ring–disk electrode having a disk electrode constructed of glassy carbon and a ring electrode constructed of platinum.

The electroanalytical technique known as stripping voltammetry at a single electrode has been shown to be useful for the determination of many species present in aqueous solutions at very low concentrations. The theory and application of stripping voltammetry have been adequately reviewed.[1–3] In principle, the technique involves the accumulation of the substance sought in the form of a metal or a sparingly soluble compound on the surface of the electrode in the test solution. The accumulation may proceed for a long period of time so that a significant quantity of material is deposited even though the concentration of the species in the bulk of the solution is very low. Following the accumulation, the potential of the electrode is varied (scanned) in such a manner that the deposit undergoes electrochemical dissolution (stripping), and the current–potential (I–E) or current–time (I–t) curve for the process at the electrode is recorded. The curves are characterized by a sharp current peak in the potential region where the dissolution occurs. The area of the stripping peak can be related to the quantity of the original deposit and to the analytical concentration of the species sought in the test solution. The technique has a high sensitivity, especially when the accumulation is continued for a long period of time at a high rate of stirring. Stripping voltammetry has been applied to the analysis of very dilute solutions (below $10^{-8}M$) in biological, semiconductor, metallurgical, and environmental research, and for the determination of impurities in highly purified chemicals.[2] As an example of the applicability of the technique for trace analysis, Fedosuva and Stromberg[4] used liquid–liquid extraction followed by stripping voltammetry for the determination of bismuth at $5 \times 10^{-11}M$ concentrations.

In practice, the limit of detectability by voltammetric-stripping analysis is set by the uncertainty in the determination of the current in the electrode due to processes other than the stripping of the desired species. These "background" processes include (*i*), charging of the electrical double-layer at the electrode–solution interface during the variation of the

---

* To whom correspondence should be addressed.

applied potential, (*ii*), oxidation and/or reduction of impurities in the solution or adsorbed at the surface of the electrode, and (*iii*), electrochemical reactions of the electrode itself, *e.g.*, formation or dissolution of oxide on a platinum electrode. The background current is usually estimated by drawing a smooth curve under the stripping peak, superimposed on the portions of the I–t curve on each side of the peak. This, of course, requires an estimation by the analyst and is a great source of uncertainty since the background current is usually a function of the potential of the electrode and is, therefore, not constant during the recording of the I–t curve. The problem is not solved by recording the I–t curve for the voltammetric scan when no deposition has been allowed, because the background currents are not usually reproducible from one scan to the next unless the treatment of the electrode before the recording of the I–E curves is identical. Furthermore, a large variation in the background current caused by change in applied potential dictates the use of a low sensitivity on the recorder. As a result, long deposition times are necessary if perceptible stripping peaks are to be obtained.

In this paper we describe the use of a rotating ring–disk electrode (RRDE) for the determination of concentrations lower than the limit of detection for stripping voltammetry at a single electrode. The technique is called stripping voltammetry with collection (SVWC). In principle, SVWC requires the accumulation and stripping of the species sought, at the disk electrode, according to the accepted procedures for stripping voltammetry at a single electrode. The potential of the ring electrode is fixed at a value such that deposition of the species sought is limited by convection and diffusion and the current–time curve for the ring electrode (I_r–t) is recorded during the voltammetric stripping of the deposit from the disk electrode. A fraction of the species stripped from the disk electrode is carried by convection and diffusion to the ring electrode where it is redeposited. Because the potential of the ring electrode is constant during the voltammetric stripping, the background current for the redeposition is nearly constant. Consequently, the background can be compensated electronically and the I_r–t curve obtained with a very high sensitivity used on the recorder. The collection of very small quantities of species stripped voltammetrically from the disk electrode still produces significant peaks on the I_r–t curve even when the stripping peak on the I–t curve at the disk electrode is nearly imperceptible against the background current.

The instantaneous current for the deposition of a chemical species from a solution onto the disk electrode of an RRDE by a convection/diffusion-limited process, I_d, is related to the concentration of the species in the bulk of the solution, C_b, by equation (1),[5] where n and F have their usual electrochemical significance, ω is the angular velocity of the electrode rotation,

$$I_d = 0{\cdot}62nF\pi R_1{}^2\omega^{1/2}\nu^{-1/6}D^{2/3}C_b \tag{1}$$

ν is the kinematic viscosity of the solution, and D is the diffusion coefficient for the species in solution. The total charge passed at the disk electrode due to deposition, Q_d, during the deposition period, t_{dep}, is given by equation (2).

$$Q_d = \int_0^{t_{dep}} I_d \, dt \tag{2}$$

If ω and C_b remain constant during t_{dep}, equation (2) can be written as equation (3). The charge passed at the ring electrode due to collection and deposition of the species produced by voltammetric stripping at the disk electrode, Q_r is given by equation (4). The negative sign is due

$$Q_d = I_d \cdot t_{dep} \tag{3}$$

$$Q_r = -NQ_d$$

$$= -NT_{dep}0{\cdot}62nF\pi R_1{}^2\omega^{1/2}\nu^{-1/6}D^{2/3}C_b$$

to the fact that the current for the deposition is of opposite polarity to that for the dissolution. In equation (4), N is the fraction of the species produced at the disk, which can be collected at the ring. N is called the collection efficiency and can be calculated from the respective radii of the disk and ring electrodes.[6]

No reference has been found in the chemical literature to the quantitative analysis of solutions for species at trace levels by using the technique of SVWC at an RRDE. Several studies were reported in which the ring electrode of an RRDE was used for detection and electrochemical characterization of small quantities of chemical species produced at the disk electrode. Bruckenstein and Tindall[7,8] studied the electrochemical behaviour of monolayer and submonolayer deposits of copper and silver on a platinum electrode in acidic media. Johnson, Napp and Bruckenstein[9] detected small amounts of Pt(II) produced at the anodized platinum disk electrode of an RRDE during the reduction of the surface oxide. Johnson and Bruckenstein[10] used the ring electrode of an RRDE to determine small quantities of HOBr produced by oxidation of submonolayer quantities of bromide previously adsorbed at the platinum disk electrode from 1·0*M* sulphuric acid. Johnson[11] extended the study of the electrochemistry of halides adsorbed on platinum electrodes in 1·0*M* sulphuric acid and determined the adsorption and desorption of submonolayer quantities of iodide and iodine on the disk of an RRDE.

Kopanica and Vydra[12] used voltammetric-stripping analysis at a rotating, glassy-carbon disk electrode for the determination of Ag^+ in acidic, neutral, and alkaline media. They reported that Ag^+ could be determined "with sufficient accuracy" at a concentration of $1 \times 10^{-9}M$ provided the deposition time was sufficiently long. They did not show the I–t curve for that concentration. Here we report the use of stripping voltammetry with collection for the determination of down to $1{\cdot}0 \times 10^{-10}M$ Ag^+ in 0·1*M* sulphuric acid. The distinct advantages of using SVWC at an RRDE are discussed.

EXPERIMENTAL

Notation

Subscripts d and r to symbols for current, I, and potential, E, represent the corresponding quantities at the disk and ring electrodes, respectively. Superscripts a and c used with E_d designate the anodic and cathodic limits of potential scan. The potentials of the disk and ring electrodes used for the deposition of silver are $E_{d,dep}$ and $E_{r,dep}$, respectively. Cathodic current is considered a positive and anodic current a negative quantity. All electrical currents are given in microamperes (μA) and quantity of charge in microcoulombs (μC). All electrode potentials were measured and are given in volts *vs.* the saturated calomel electrode (SCE).

Instrumentation

The ring–disk electrode used was from Pine Instrument Co. of Grove City, Pa. The electrode had a glassy-carbon disk and a platinum ring. The pertinent geometric parameters,[6,13] were: $R_1 = 0{\cdot}379$ cm, $R_2 = 0{\cdot}399$ cm, $R_3 = 0{\cdot}421$ cm, $\alpha = 0{\cdot}168$, $\beta = 0{\cdot}211$, and $N = 0{\cdot}170$. The synchronous rotator used was Model PIR from Pine Instrument Co. The rotator has nine speeds between 400 and 10,000 rpm. The cell was constructed of quartz with a fritted-quartz membrane separating the main compartment from the chamber for the platinum counter-electrode. Glassware was cleaned with hot nitric acid and rinsed thoroughly with triply distilled water. The reference electrode was a Beckman SCE in electrical contact with the solution through a quartz capillary.

The electronic control circuitry was constructed with use of operational amplifiers according to Bruckenstein's[13] and modification[14] to the disk circuit, but instead of use of a potentiometric input for the recording of current in the ring electrode, as indicated by Fig. 1 of Ref. 13, the recorder was driven by the output of a difference amplifier which measured the difference in the signals at the outputs of amplifiers F-2 and A-2. All resistors used for measurement of current were standardized by the Physics Instrument Services of Iowa State University and all voltages were measured with instruments calibrated against sources standardized by the Physics Instrument Services. The X-Y recorder was a Plotomatic 815 from Bolt, Beranek and Newman, Inc., of Santa Ana, Cal. The areas of collection peaks were determined by integration of the original curves with a Keuffel and Esser Compensating Polar Planimeter.

Reagents

All solutions were made up in triply distilled water prepared with a demineralization after the first distillation, and the second distillation being made from alkaline permanganate. The supporting electrolyte was $0{\cdot}1M$ sulphuric acid prepared from Mallinckrodt Reagent Grade sulphuric acid. Test solutions of Ag^+ were prepared by addition to the supporting electrolyte of aliquots of a $0{\cdot}00100M$ stock solution of silver nitrate prepared from Baker Analyzed Reagent. The stock solution was stored in a polyethylene bottle with the exterior painted black.

Pretreatment of the electrode

The ring–disk electrode was polished at the start of the research with Buehler Handimet 600 strips followed by 30-μm and 6-μm Buehler AB Metadi Diamond on nylon lubricated with Buehler Metadi Fluid. The electrode was washed carefully with detergent on a cotton swab and rinsed thoroughly with distilled water after each step in the polishing procedure. Before each day of research, the electrode was polished with 1-μm diamond dust. To remove particles of platinum embedded in the glassy-carbon disk during previous stages of polishing and to prevent transfer of platinum from the ring to the disk during this last stage in polishing, the electrode was rotated at 400 rpm and the polishing cloth moved radially from the centre of the rotating electrode. No portion of the polishing cloth was used twice. The surface of the electrode was then cleaned as described above. An I_d–E_d curve was obtained after the polishing to confirm the absence of platinum on the disk electrode. The absence of platinum was verified when a peak for reduction of platinum oxide was not observed on the cathodic potential sweep following anodization.

The rotating electrode was then lowered into the test solution and deaeration with dispersed nitrogen begun. E_d was cycled for 10 min between $E_d^c = -0{\cdot}40$ V and $E_d^a = +1{\cdot}20$ V at a rate of 5·0 V/min with E_r maintained at $+0{\cdot}80$ V.

Impurity in test solutions

The supporting electrolyte was found to contain traces of Ag^+ varying from $5 \times 10^{-10}M$ to $5 \times 10^{-9}M$. The source of the impurity was first thought to be the silver-loaded graphite used for making electrical contact to the upper portion of the metallic cylinder on which the ring electrode was mounted in the usual construction of the RRDE. This contact is directly above the cell for the rotator used. A large disk of Teflon, having an outer diameter greater than the opening of the cell through which the RRDE was inserted, was drilled to an inner diameter just sufficient to permit the Teflon disk to be slipped onto the Teflon shroud of the RRDE. Rubber O-rings were placed on the shroud of the RRDE above and below the Teflon disk to hold it in place. In use, the RRDE was lowered into the cell so that the Teflon disk was just slightly above the opening of the cell and did not rub on the cell during rotation. With this protection, it was impossible for particles of the ring contact to fall into the solution. No decrease in the level of the impurity of Ag^+ occurred when the Teflon disk was used and it was concluded that the contact for the ring electrode was not the source of the impurity. The use of the protecting Teflon disk was continued, however. The sulphuric acid was thought not to be the source of the trace impurity since addition of more acid directly to the test solution did not result in an increase of the level of the impurity. Other procedures were used for cleaning the glassware with no effect on the level of impurity and the glassware was concluded not to be the source. The water for preparing solutions was analysed before the demineralization stage in the procedure for purification and the content of Ag^+ was $5 \times 10^{-8}M$. It was concluded that the water was the source of the impurity. Triply distilled water from one other source in the department was analysed and found to contain Ag^+ as an impurity at approximately $2 \times 10^{-9}M$.

Experimental procedure

The procedure for the determination of Ag^+ by SVWC at the RRDE was as follows. The cyclic scan of E_d for the pretreatment of the disk electrode was halted at the desired value of $E_{d,\,dep}$, and E_r was stepped to the desired value of $E_{r,\,dep}$ for collection of Ag^+. With the expiration of t_{dep}, E_d was scanned anodically at a rate of 5·0 V/min and the I_r–E_d curve recorded. Since the rate of scan for E_d was constant, the I_r–E_d curve was also an I_r–t curve. The background current during the collection was estimated by drawing a smooth curve superimposed on the I_r–E_d curve on either side of the collection peak, and the area of the peak was determined and Q_r calculated. The procedure was repeated for $t_{dep} = 0{\cdot}00$ min and the area of the corresponding peak determined. A small amount of silver was deposited at the disk electrode at $t_{dep} = 0$ min with the deposition occurring (*i*), during the cathodic portion of the cyclic scan of E_d before reaching the value of $E_{d,\,dep}$, and (*ii*), during the time that E_d was being scanned anodically from $E_{d,\,dep}$ to the value where stripping commenced. The value of Q_r was corrected by subtracting the area of the collection peak for $t_{dep} = 0{\cdot}00$ min from the area for the non-zero value of t_{dep}. For $t_{dep} = 3{\cdot}00$ min, the correction was approximately 3% for a rate of scan of E_d equal to 5·0 V/min. Further correction of the value of Q_r was made when preparing a calibration plot. The value of Q_r obtained for the impurity of Ag^+ in the supporting electrolyte was subtracted from the values of Q_r obtained after the intentional additions of standard Ag^+.

Standard additions of the stock solution of Ag^+ to the supporting electrolyte were made with 2·000-ml and 0·2000-ml micrometer syringes.

RESULTS AND DISCUSSION

Current–potential curves

I–E curves for glassy-carbon electrodes in mineral acids are shown and discussed in Ref. 15 and curves for platinum electrodes are discussed in Ref. 9. They will not be further described here. I_d–E_d and I_r–E_d curves obtained by using SVWC at an RRDE for $1{\cdot}00 \times 10^{-6}M$ Ag^+ are shown in Fig. 1. Silver deposited at the disk electrode was electrochemically stripped at $E_d > 0{\cdot}1$ V with the peak of the anodic current at approximately 0·25 V. In comparison to the stripping peak on the I_d–E_d curve, the collection peak on the I_r–E_d curve is shifted slightly to a more positive value of E_d. This is the result of the use of a

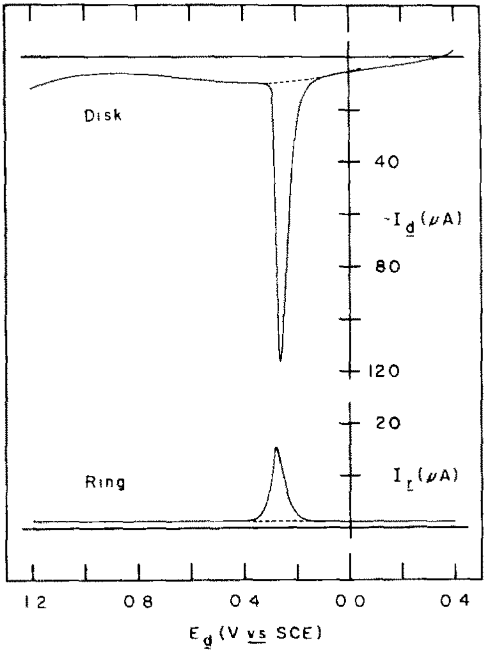

Fig. 1. I_d–E_d and I_r–E_d curves for stripping voltammetry with collection in $1{\cdot}00 \times 10^{-6}M$ Ag^+. $t_{dep} = 5{\cdot}00$ min, $E_{d,\,dep} = -0{\cdot}400$ V; $E_{r,\,dep} = 0{\cdot}000$ V, $\omega^{1/2} = 6{\cdot}47$ (rad/sec)$^{1/2}$, rate of anodic scan of $E_d = 5{\cdot}0$ V/min; ———— *I–E* curves, ------------ constructed baselines.

high rate of anodic scan of E_d (5·0 V/min) and a low rate of rotation of the RRDE (400 rpm). A finite amount of time is necessary for species produced at the surface of the disk electrode to be transported by convection and diffusion to the surface of the ring electrode. Consequently, the peaks in the currents for stripping and collection do not coincide. For a concentration of $1{\cdot}00 \times 10^{-6}M$, the contribution to Q_d and Q_r from the impurity of Ag^+ in the supporting electrolyte was negligible. From the values of the areas of the stripping and collection peaks, Q_d and Q_r were calculated to be 71·5 and 11·3 μC, respectively. On the basis of these values, the experimental value of N was calculated to be 0·158. Both the stripping and collection peaks for high concentrations of Ag^+, such as illustrated by Fig. 1, are sufficiently distinct in comparison to the background currents for both Q_d and Q_r to be used for an accurate calculation of $C_{b,\,Ag^+}$.

To determine the *I–E* curve for the electrodeposition of silver at the glassy-carbon disk electrode, SVWC was performed in $1{\cdot}00 \times 10^{-6}M$ Ag^+ for varying values of $E_{d,\,dep}$ with $E_{r,\,dep} = 0{\cdot}000$ V. The values of Q_r are plotted in Fig. 2 as a function of $E_{d,\,dep}$ for $\omega^{1/2} = 6{\cdot}47$ (rad/sec)$^{1/2}$. The value of $E_{1/2}$ for the deposition is approximately 0·03 V. The standard reduction potential for the Ag^+/Ag couple is 0·55 V *vs.* SCE. The moderate irreversibility of the deposition of Ag does not prevent successful application of SVWC since values of $E_{d,\,dep} < -0{\cdot}3$ V appear to be sufficiently cathodic for the deposition to occur at a rate limited by convection and diffusion. A value of $E_{d,\,dep} = -0{\cdot}400$ V was used for all subsequent determinations.

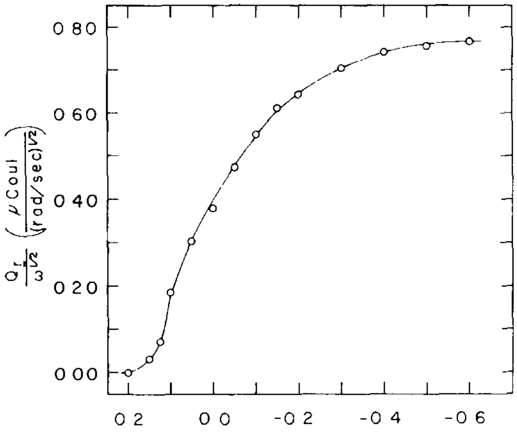

Fig. 2. *I–E* curve for electrodeposition of Ag on a glassy-carbon disk electrode. $C_{b,\,Ag^+} = 1{\cdot}00 \times 10^{-6}M$, $E_{r,\,dep} = 0{\cdot}000$ V *vs.* SCE, $t_{dep} = 2{\cdot}00$ min, $\omega^{1/2} = 6{\cdot}47$ (rad/sec)$^{1/2}$, rate of anodic scan of $E_d = 5{\cdot}0$ V/min.

To determine a value of $E_{r,\,dep}$ at which deposition of silver at the ring electrode occurs at a rate limited by convection and diffusion, SVWC in $1{\cdot}00 \times 10^{-6}M$ Ag^+ was repeated for various values of $E_{r,\,dep}$. The plot of Q_r *vs.* $E_{r,\,dep}$ is shown in Fig. 3 for $\omega^{1/2} = 6{\cdot}47$ (rad/sec)$^{1/2}$. The value of $E_{1/2}$ for the deposition at the platinum ring electrode is approximately 0·27 V. The value of Q_r is not zero for 0·8 V > $E_{r,\,dep}$ > 0·4 V. The deposition of silver at a platinum electrode at underpotentials has been investigated and discussed by Bruckenstein

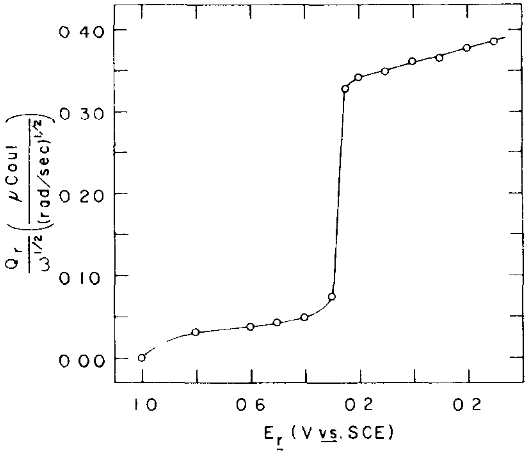

Fig. 3. *I–E* curve for electrodeposition of Ag on platinum ring electrode. $C_{b,\,\mathrm{Ag}^+} = 1{\cdot}00 \times 10^{-6}M$, $E_{\mathrm{d,\,dep}} = -0{\cdot}400$ V *vs.* SCE, $t_{\mathrm{dep}} = 2{\cdot}00$ min, $\omega^{1/2} = 6{\cdot}47$ (rad/sec)$^{1/2}$, rate of anodic scan of $E_{\mathrm{d}} = 5{\cdot}0$ V/min.

and Tindall.[7,8] The deposition of silver is more reversible at the ring electrode than at the glassy-carbon disk electrode and a value of $E_{\mathrm{r,\,dep}} = 0{\cdot}000$ V was used for all determinations.

Verification of equation (4)

According to equation (4), it is predicted that Q_{r} should be a linear function of t_{dep}. Corrected values of Q_{r} were obtained for SVWC in $1{\cdot}00 \times 10^{-6}M$ Ag for $0{\cdot}50 \text{ min} \leq t_{\mathrm{dep}} \leq 5{\cdot}50$ min and did in fact give a good linear plot with a slope of 4.4 μC/min for $\omega^{1/2} = 6{\cdot}47$ (rad/sec)$^{1/2}$.

To determine the effect on Q_{r} of changes in the value of $\omega^{1/2}$, SVWC was performed in $1{\cdot}00 \times 10^{-6}M$ Ag$^+$ for $6{\cdot}47 \text{ (rad/sec)}^{1/2} \leq \omega^{1/2} \leq 32{\cdot}4 \text{ (rad/sec)}^{1/2}$. The corrected values of Q_{r} plotted *vs.* $\omega^{1/2}$ gave a straight line which intersected the origin in agreement with equation (4).

Q_{r} is not predicted to be dependent on the rate of scan of E_{d} used during the process of electrochemically stripping the deposit of silver from the disk electrode. A corrected value of $Q_{\mathrm{r}} = 0{\cdot}84$ for SVWC in $1{\cdot}00 \times 10^{-6}M$ Ag$^+$ was observed for scan rates between 2 and 9 V/min. The results are consistent with equation (4).

Variation of $C_{\mathrm{b,\,Ag^+}}$

SVWC was performed for $1{\cdot}00 \times 10^{-10}M \leq C_{\mathrm{b,\,Ag^+}} \leq 1{\cdot}00 \times 10^{-6}M$. The concentration values were calculated on the basis of standard addition and values of Q_{r} were corrected as already described. The plot of Q_{r} *vs.* $C_{\mathrm{b,\,Ag^+}}$ on a log-log scale is a straight line in agreement with equation (4). The determinations of Q_{r} for $C_{\mathrm{b,\,Ag^+}} < 10^{-9}M$ were performed at a time when the blank was advantageously low (approximately $5 \times 10^{-10}M$). Several days later a fresh supporting electrolyte was prepared for which the blank was approximately $2 \times 10^{-10}M$. Values of the area of the collection peak for five determinations of the blank had an average relative deviation of 25%. Values of the area of the collection peak for five determinations following the addition of $1{\cdot}0 \times 10^{-10}M$ Ag$^+$ had an average relative deviation of 7·4%.

The diffusion coefficient for Ag^+ in 0·1*M* sulphuric acid was calculated by using equation (4) and the results previously obtained and found to be $1{\cdot}29 \times 10^{-5}$ cm²/sec, in good agreement with the value of $1{\cdot}30 \times 10^{-5}$ cm²/sec found by Johnson[16] for 0·1*M* potassium nitrate medium.

Comparison of SVWC with stripping voltammetry at a single electrode

The effect of the background current in limiting the application of stripping voltammetry at a single electrode was discussed in the introductory paragraphs. The possibility of applying SVWC at an RRDE for the determination of concentrations lower than those amenable to voltammetric stripping at a single electrode is illustrated by the I_d–E_d and I_r–E_d curves shown in Fig. 4. These curves were obtained for $6{\cdot}0 \times 10^{-9}M$ Ag^+. The large anodic peak on the I_d–E_d curve is due to background processes and not the voltammetric dissolution of a deposit. The small shoulder at about 0·2V is due to the stripping of the silver deposit. Even though the sensitivity is relatively high on the scale used for recording the I_d–E_d curve, no possibility exists of accurately determining the area of the stripping peak. The background current at the ring electrode is much more independent of E_d than is the background current at the disk electrode. Consequently, the I_r–E_d curve was recorded with a very high sensitivity. The collection peak is very distinct and integration of the peak can be performed accurately.

The rapid change of the background current on the I_r–E_d curve for $-0{\cdot}4\ V < E_d < 0{\cdot}0\ V$ is due to electronic instrumentation and not a consequence of the production of any electroactive species at the disk electrode. Proper alignment of the electronic circuit is described in

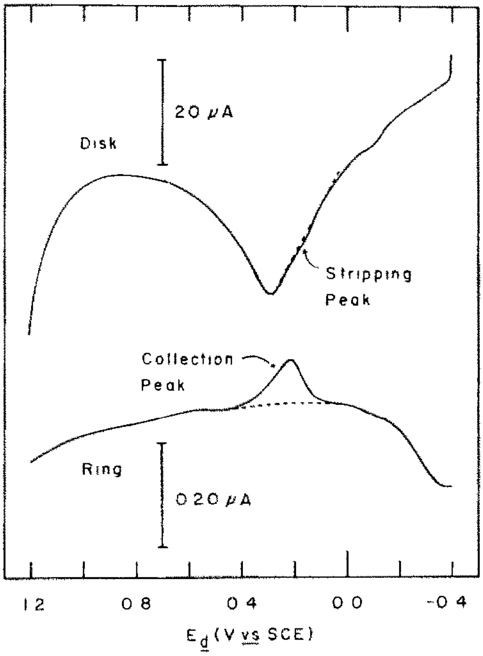

Fig. 4. I_d–E_d and I_r–E_d curves for $6{\cdot}0 \times 10^{-9}M$ Ag^+.
$E_{d,dep} = -0{\cdot}400$ V *vs.* SCE, $E_{r,dep} = 0{\cdot}000$ V *vs.* SCE, $\omega^{1/2} = 6{\cdot}47$ (rad/sec)$^{1/2}$, $t_{dep} = 10{\cdot}0$ min, rate of anodic scan of $E_d = 5{\cdot}0$ V/min; ——— *I–E* curves, ············ constructed baselines.

Ref. 13 and involves adjustment of resistor R_4 so that E_r does not change while E_d is scanned. Proper alignment is essential, particularly if it is desired to measure very small electrical currents in the ring electrode. Even with maximum care in alignment we found it impossible to prevent a small change in E_r (1–3 mV) while scanning E_d in the vicinity of 0·0 V. The small fluctuation in E results in background current as shown in Fig. 4.

Conclusions

The applicability of an RRDE for decreasing the already dramatically low detection limits for analyses based on stripping voltammetry has been demonstrated. There are at least two additional advantages of SVWC at an RRDE over the conventional method at a single electrode.

First, the time of analysis is greatly decreased because Q_r can be determined accurately even though the quantity of deposit accumulated is very small. This allows use of SVWC for routine analysis without the need for irritatingly lengthy depositions.

Secondly, the difficulties in simultaneous determination of two or more metallic species resulting from formation of intermetallic compounds at the electrode surface may be largely circumvented. This follows since the maximum coverage of the electrode by the deposit need never approach a complete monolayer and, therefore, the chance of inter-element reactions is greatly reduced or eliminated.

Zusammenfassung—Ein neues elektroanalytisches Verfahren wird beschrieben und "inverse Voltametrie mit Sammlung" genannt. Es verwendet eine rotierende Ring–Scheiben-Elektrode und stellt gegenüber der traditionellen inversen Voltametrie an einer einzelnen Elektrode insofern eine Verbesserung dar, als es eine niedrigere Nachweisgrenze besitzt und daß die Abscheidungszeit vor dem Wiederauflösen kürzer sein kann. Die Anwendung des Verfahrens wird am Beispiel der Bestimmung von 10^{-10} M Ag^+ in 0·1 M H_2SO_4 gezeigt. Dabei wird eine Ring-Scheiben-Elektrode mit Scheibenelektrode aus glasigem Kohlenstoff und Ringelektrode aus Platin verwendet.

Résumé—On décrit une nouvelle technique électroanalytique, appelée "voltammétrie de dissolution avec collection". La technique comprend l'emploi d'une électrode rotative à disque-anneau et est une amélioration par rapport à la dissolution voltammétrique traditionnelle sur une seule électrode en ce sens qu'elle est caractérisée par une limite de détection inférieure et que la période de dépôt avant dissolution peut être plus courte. L'emploi de la technique est illustrée par le dosage d'Ag 10^{-10} *M* en H_2SO_4 0,1 *M* par l'emploi d'une électrode rotative à disque-anneau ayant une électrode à disque construite en carbone vitreux et une électrode annulaire en platine.

MASS SPECTROMETRIC STUDY OF THE DETERIORATION OF POLYSTYRENE-BASED ION-EXCHANGERS

G. M. ARMITAGE and S. J. LYLE
Chemical Laboratory, University of Kent at
Canterbury, Kent, U.K.

(*Received* 22 *August* 1972. *Accepted* 7 *October* 1972)

Summary—A mass spectrometric study of the aging effects in polystyrene-based ion-exchangers has been made. Fragments in the *m/e* range 10–70 were examined and attributed to OH^+, H_2O^+, CO^+, CO_2^+, supplemented by SO^+ and SO_2^+ from sulphonic-acid cation-exchangers. Ion-current intensities were found to be dependent on the state of the resin.

Cation- and anion-exchangers based on copolymers of styrene and divinylbenzene are frequently found to contain fragments which are detrimental to certain applications.[1–3] The fragments are unlikely to be introduced during the manufacture of the exchangers, but side-reactions occurring at that time may lead to their subsequent production. Time-dependent deterioration is readily observable from periodic washing of the resin and examination of the wash-liquids.[3,4] The fragments thus released show structural similarity to the resin and have properties associated with electrolytes although non-electrolytes could also be present. The processes which eventually results in fragmentation, modify the constitution of the ion-exchange beads. It has been reported[5] that a cation-exchanger of the sulphonic-acid type may have up to 5% of its exchange capacity represented by carboxylic acid groups. Direct evidence for the presence of carboxyl groups has not been reported to date. Nevertheless trace metal-ion distribution studies[6,7] with cation- and anion-exchangers support the view that a secondary cation-exchange capacity exists even in the highest quality commercial resins.

In order to obtain information throwing light on the origin of the additional exchange capacity and the nature of the reactions leading to eventual fragmentation, a mass spectrometric study has been made of a range of polystyrene-based ion-exchangers and related substances.

EXPERIMENTAL

Materials

Commercially available resins were used in this study. They were obtained from the Permutit Co. Ltd., London, the Rohm and Haas Co., Philadelphia and the Dow Chemical Co., Midland, Michigan. Samples of each were dried in air at 80° for 24 hr. Portions (about 10 g) of the resins were placed in separate glass columns, converted into the hydrogen or chloride form by the passage of 300 ml of 2*M* hydrochloric acid, washed copiously with distilled water and dried over phosphorus pentoxide at 25°. Divinylbenzene (DVB) 8% cross-linked polystyrene was kindly made available by The Permutit Co. Ammonium toluene-*p*-sulphonate, laboratory reagent grade, was obtained from British Drug Houses Ltd., Poole, England.

Apparatus

Mass spectra were obtained with a G.E.C.-A.E.I. MS 902 mass spectrometer employing an electron energy of 70 eV and source temperatures in the range 140–180°. An *m/e* range from 10 to 70 was examined at a resolution of 2500. The probe temperature to which the samples were subjected was generally in the range 140–250°.

A precise mass analysis of certain prominent peaks was done with the aid of a "trial and error" type of computer programme. The maximum deviation permitted in the assignment of a test formula to an experimental *m/e* value was 5 ppm. Calculations were performed on a PDP8/E computer.

RESULTS AND DISCUSSION

Results are presented in Figs. 1–5 in which relative intensities of ion current on a common scale are plotted against *m/e*. The spectra of the sulphonic-acid cation-exchangers have peaks at *m/e* values of 17, 18, 28, 44, 45, 48, 50, 64 and 66 (Figs. 1–3). The peaks at *m/e*-17 and 18 are due to the species OH^+ and H_2O^+ respectively. Examination revealed the presence of a doublet at *m/e*-28, the major and minor components of which are attributable to CO^+ and N_2^+ respectively. Consideration of precise masses led to the conclusion that the peak at *m/e*-44 is due to CO_2^+ and that at *m/e*-45 to the fragment $C_2H_5O^+$. The peaks at *m/e*-48 and 50 are due to SO^+; they occur in the

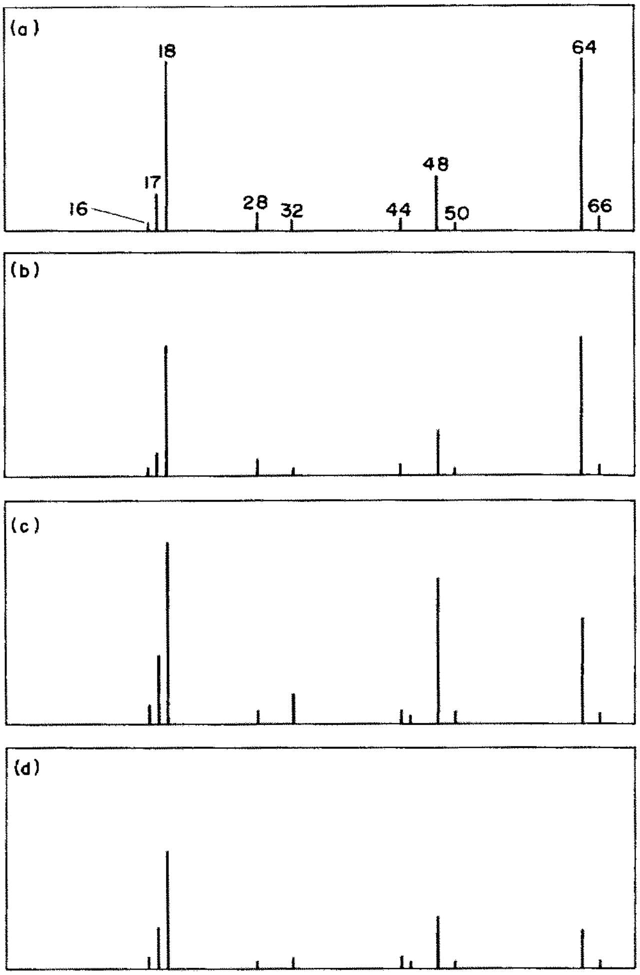

Fig. 1. Mass spectra for Zeo-Karb 225 (SRC series) exchangers. (*a*) 1%, (*b*) 2%, (*c*) 4–5%, (*d*) 12% DVB cross-linking.

intensity ratio expected from typical natural isotopic abundances for ^{32}S and ^{34}S. The peaks at *m*/*e*-64 and 66 are due to SO_2^+.

In Fig. 1 spectra are reproduced for cation-exchangers of the sulphonic-acid type taken from the shelf and dried at 80°. An increase in the degree of cross-linking causes a steady decrease in the intensity of peaks at *m*/*e*-28 and 64 but similar trends are not observed for ion currents at other masses. A comparison of the spectra in Fig. 1*a* with those in Fig. 2*a* and in Fig. 1*b* with those in Fig. 2*c* shows the effect of careful conditioning of the resin; all the peaks from the conditioned samples are considerably reduced except those due to water. Changes in the spectra due to aging of a resin sample are illustrated in Fig. 2. It is seen from Fig. 3 that resin samples carefully freed from water-soluble fragments, (*e.g.*, Amberlite IR 122), and converted into the sodium form, gave very "clean" spectra after two years' storage in amber bottles.

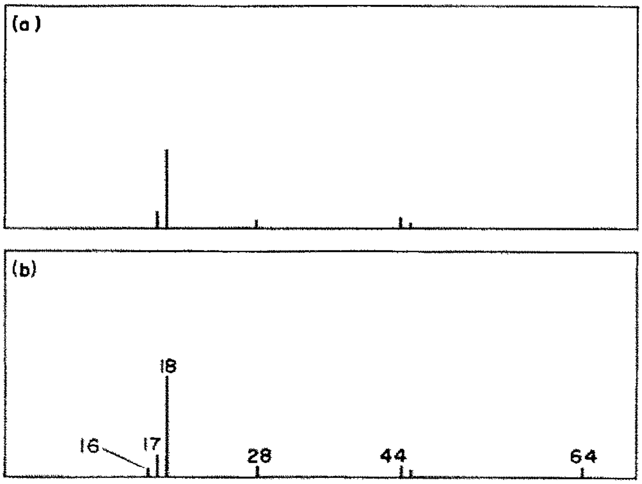

Fig. 3. Mass spectra of (*a*) Amberlite IR 122 (10% cross-linking) and (*b*) IR 124 (12% cross-linking) after two years storage.

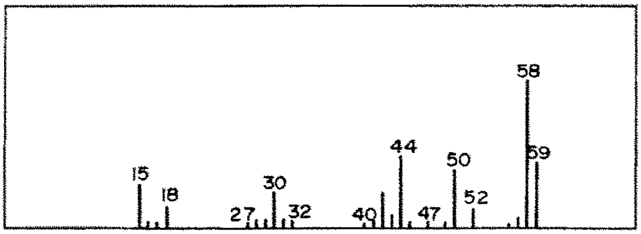

Fig. 5. Mass spectrum of aged De-Acidite FF (SRA 71).

The presence of the peak at m/e-44 in most of the spectra is noteworthy and experiments were performed in an attempt to establish its origin. The spectrometer background in this region was very low. A spectrum was obtained for ammonium toluene-*p*-sulphonate; a peak was not observed at m/e-44. This rules out the possibility that CO_2 could originate from "cracking" and "reforming" processes in the resin samples. Analyses of the doublets at m/e-28 eliminate the possibility that the CO_2 is derived from the atmosphere, at least for the cation-exchangers in the hydrogen form. The CO_2 must therefore arise from the resin framework or fragments from it. Spectra were obtained at two different probe temperatures (Fig. 4) for a cation-exchanger having carboxylic-acid exchange groups. Each spectrum has peaks at m/e-28 and 44, which may be due to decarboxylation. At the higher probe temperature they are very intense relative to those from other resin samples.

The spectrum for a sample of rather old (several years) anion-exchanger nominally in the chloride form, dried at 80° but otherwise untreated, had a characteristic peak-pattern which was nevertheless quite different from that of the cation-exchangers (Fig. 5). A very prominent peak at m/e-44 was attributed to carbon dioxide derived from the atmosphere. This was confirmed by the effervescence produced by the addition of hydrochloric acid and by chemical testing of the gas evolved. [Precise mass measurements indicated clearly that the peak (Fig. 5) at m/e-44 was due to CO_2^+ and not, for example, to $(CH_3)_2N^+$ although the latter was observed at higher probe temperatures.] Treatment of the resin with dilute hydrochloric acid, followed by washing with water and drying, reduced the peak height considerably but did not altogether eliminate it. In view of the apparent tendency of the resin in the chloride form to take up atmospheric carbon dioxide a categoric interpretation of the origin of this residual peak would not be justified. Other evidence, however, would support the view that carboxyl groups are present.

The structure of polyacrylic acids with DVB cross-linking is different from that of polystyrene-based sulphonic-acid exchangers. Fragmentation induced naturally, and thermal decomposition patterns, will not necessarily be exactly the same. In the latter, carboxyl groups may reside on the aromatic nucleus, or be formed by oxidative cleavage of the aliphatic "backbone" of the polymer, especially at points where cross-linking occurs. Carboxyl groups could arise[8] from oxidation of ethyl groups introduced during the formation of the resin in ethylstyrene, a common contaminant[9] of commerical DVB. It is also possible that divinylbenzene becomes incorporated into the polymer chain at one end, leaving a readily oxidized ethylenic group. Some carboxyl groups are undoubtedly introduced at the time of sulphonation[5,8] but careful choice of sulphonating conditions is claimed[5] to reduce such oxidation considerably.

It has been found that for a cation-exchanger having sulphonate functional groups, the distribution ratio at constant ionic strength of a carrier-free radioactive cation depends on the pH of the solution.[6,7] This behaviour is also observed for DVB cross-linked polystyrene beads and for strong base (quaternary ammonium) anion-exchangers.[6] (A unifunctional strong acid or base exchanger would be expected to give a distribution ratio independent of pH in the absence of cation hydrolysis.) It is explicable if carboxylic acid groups are present and the size of the additional exchange capacity created above the threshold pH can be assessed by suitably designed loading experiments. Evidence available from mass spectrometric and exchange distribution studies is therefore consistent with the presence of carboxyl groups on polystyrene-type exchangers. This interpretation would explain the retention of traces of rare-earth metal ions by an anion-exchanger and the proposed[10] separation of ^{140}La from ^{140}Ba.

The appearance of SO^+ and SO_2^+ in the spectra of aged resins but not in those of recently washed resins would indicate that the sulphur-containing groups on the polymer matrix are quite stable relative to those on the fragments. Examination of the peaks resulting from these ions in the spectra taken at suitably chosen probe temperatures would permit a rapid means of assessing qualitatively the general condition of a batch of sulphonic-acid type resin. Information can be obtained on thermal stability of a resin by variation of the probe temperature of the spectrometer.

Acknowledgement—The authors wish to record their gratitude to Mr. R. B. Turner who has been responsible for the operation of the mass spectrometer.

Zusammenfassung—Die Alterungseffekte in Ionenaustauschern auf Polystyrolbasis wurden massenspektrometrisch untersucht. Fragmente mit m/e = 10–70 wurden überprüft und OH^+, H_2O^+, CO^+ und CO_2^+ zugeordnet. Dazu kamen SO^+ und SO_2^+ bei Kationenaustauschern mit Sulfonsäuregruppen. Die Ionenstromintensitäten hingen vom Zustand des Harzes ab.

Résumé—On a effectué une étude spectrométrique de masse des effets de vieillissement dans les échangeurs d'ions à base de polystyrène. On a examiné les fragments dans le domaine m/e 10–70 et les a attribués à OH^+, H_2O^+, CO^+, CO_2^+ complétés par SO^+ et SO_2^+ des échangeurs de cations acide sulfonique. On a trouvé que les intensités de courant d'ions dépendent de l'état de la résine.

EMISSION SPECTROMETRIC DETECTION OF METAL CHELATES SEPARATED BY GAS CHROMATOGRAPHY

HIROSHI KAWAGUCHI, TAKESHI SAKAMOTO and ATSUSHI MIZUIKE
Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya, Japan

(*Received* 11 *September* 1972. *Accepted* 11 *October* 1972)

Summary—An emission spectrometric detector is used in the determination of metal acetylacetonates. Spectra are excited in the plasma of a 2450 MHz electrodeless discharge. Measuring the intensities of the atomic emission lines of aluminium, beryllium and chromium after gas chromatography provides a highly sensitive and selective method for the determination of the acetylacetonates of these metals. Detection limits are 100 ng for aluminium, 0.01 ng for beryllium and 1 ng for chromium. An analytical procedure is proposed for beryllium down to 10 ppm in aluminium.

During the past decade, studies have been made of the gas chromatography of volatile metal chelates[1,2] and it has been successfully used for inorganic analysis.[3,4] Many workers have employed the electron-capture detector for metal fluorinated β-diketonates because of its exceptional sensitivity to halogenated organic compounds. This detector, however, lacks selectivity for metal chelates, and it responds to a variety of organic compounds with polar functional groups. Juvet and Durbin[5] suggested the flame photometric detector as a more selective detector for metal chelates, but its sensitivity is not satisfactory for trace analysis. Recently, Wolf *et al.*[6] employed gas chromatography-mass spectrometry in the determination of chromium and beryllium at the picogram level. The emission spectrometric detector was devised by McCormack *et al.*[7] and applied to the analysis of organic compounds containing sulphur, phosphorus and halogens.[8] It was also used to detect mercury compounds,[9] but a report of its application to the determination of metal chelates has not been found in the literature. The present study was initiated to explore the applicability of emission spectrometry in a microwave-powered inert-gas plasma to the determination of volatile metal chelates separated by gas chromatography. Detection of acetylacetonates of aluminium, beryllium, chromium, copper, iron and vanadium, and the application to the determination of traces of beryllium in aluminium were investigated.

EXPERIMENTAL

Instrumentation

The apparatus and operating conditions in this study are summarized in Table 1. The thermal conductivity detector was removed from the gas chromatograph and a discharge tube (quartz capillary) was connected directly to the outlet of the column. To prevent the effluent from condensing in the inlet portion of the discharge tube, this was heated to about 200° with a small nichrome-wire heater. The light emitted from the discharge was focused by means of a quartz lens ($f = 80$ mm, magnification = 1) on the entrance slit of a monochromator. The discharge tube was positioned horizontally (perpendicular to the slit), because the spectral emission was not uniform along the discharge.[10] The discharge was initiated by means of a Tesla coil.

Table 1—Apparatus and operating conditions

Gas chromatography	Hitachi KGL-2.
Column	Stainless-steel tubing: 4 mm i.d., 72 cm long, packed with glass microbeads (60–80 mesh) coated with 0·5% SE-30.
Column temperature	160°.
Injection port temperature	200–210°.
Carrier gas	Argon (99·99%), flow-rate of 150 ml/min unless otherwise stated.
Spectrometer	Nippon Jarrell-Ash JE-50E, 0·5-m Ebert-mounting scanning monochromator with 1180 rulings/mm grating and Hamamatsu TV R-106 photomultiplier. Reciprocal linear dispersion of 16 Å/mm.
Slit-width	20 μm.
High-voltage power supply	Hamamatsu TV, HTV-C447.
Amplifier and recorder	Toa Dempa PM-18C and EPR-2T.
Microwave generator	Ito Chotampa KTM-150, 2450 MHz, operated at an anode current of 55 mA (~50 W output, stabilized electronically).
Discharge tube	Quartz capillary: 1·6 mm i.d., 4·2 mm o.d., 25 cm long.
Microwave cavity	Tapered rectangular type with a slot to accept the discharge tube (NBS No. 1 type).

Reagents

Metal acetylacetonates were purchased from Wako Pure Chemical Ind. [Al(III), Be(II)], Tokyo Kasei Kogyo [Cr(III), V(IV)] and Nakarai Chemicals [Cu(II), Fe(III)], and were used without further purification. The column packing (SE-30 on glass microbeads) was obtained from Nippon Kuromato Ind.. Standard aluminium and beryllium solutions were prepared by dissolving 99.999% pure aluminium metal and 99% pure beryllium metal in *aqua regia* and hydrochloric acid, respectively, and diluting to appropriate concentrations with water.

Operating procedure

The metal acetylacetonates were dissolved in chloroform and the solutions were introduced into the gas chromatograph with a 10-μl microsyringe. Sample sizes ranged from 0·5 to 5 μl. The wavelength of the monochromator was set by maximizing the emission signal from the appropriate electrodeless discharge tube. The discharge was initiated before sample introduction. When the solvent began to elute, the discharge was extinguished. The discharge was ignited again after almost all of the solvent had been eluted. The peak heights of the recorder response were measured because the precision was not improved by peak area measurement.

Procedure for determining beryllium in aluminium

To the slightly acidic sample solution containing 1 mg of aluminium and 10–100 ng of beryllium, add 1 ml of acetylacetone. Dilute the solution to about 25 ml with water, and adjust the pH to 7·0 with 1*M* sodium hydroxide. Transfer the solution to a separating funnel, shake twice with 5-ml portions of chloroform for 3 min, and collect the extracts in a 10-ml volumetric flask. Take a 5-ml aliquot in a 10-ml bottle, vaporize the solvent under reduced pressure (30–100 mmHg) for 30 min, and then expel free acetylacetone under vacuum for 30 min at room temperature. Dissolve the residue in 1 ml of chloroform and inject a 2-μl aliquot into the gas chromatograph.

RESULTS AND DISCUSSION

Chromatograms of aluminium, beryllium and chromium acetylacetonates

Figure 1 shows chromatograms of a mixture of beryllium, aluminium and chromium acetylacetonates measured at 234·9 nm (Be I), 396·2 nm (Al I), 425·4 nm (Cr I) and 388·3 nm (CN band). Although no nitrogen was added, cyanogen yielded the most intense band system. The source of nitrogen was probably impurities in the argon. The measurements at 388·3 nm provide a non-selective detection for organic material.[7] Attempts to chromatograph acetylacetonates of copper(II), iron(III) and vanadium(IV) (as vanadyl acetylacetonate) were unsuccessful. In an attempt to chromatograph the iron complex, a broad peak, not separated from the solvent peak, appeared in the chromatogram when the detector was operated at 388·3 nm, but no atomic line due to iron could be observed. The cyanogen band peak was caused by decomposition of the complex.

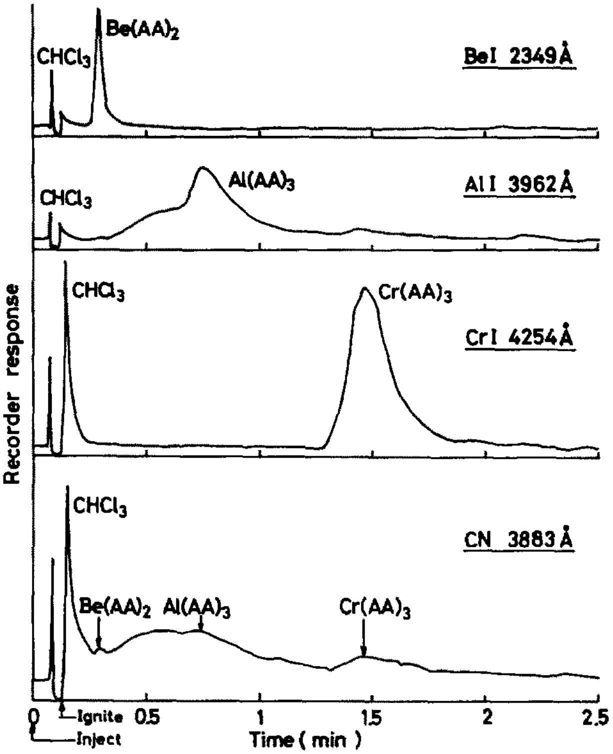

Fig. 1. Chromatograms of a mixture of $Be(AA)_2$, $Al(AA)_3$ and $Cr(AA)_3$. Ar flow-rate: 100 ml/min. Sample: 1 μl of chloroform (containing 0·002 μg of Be, 0·5 μg of Al and 0·1 μg of Cr).

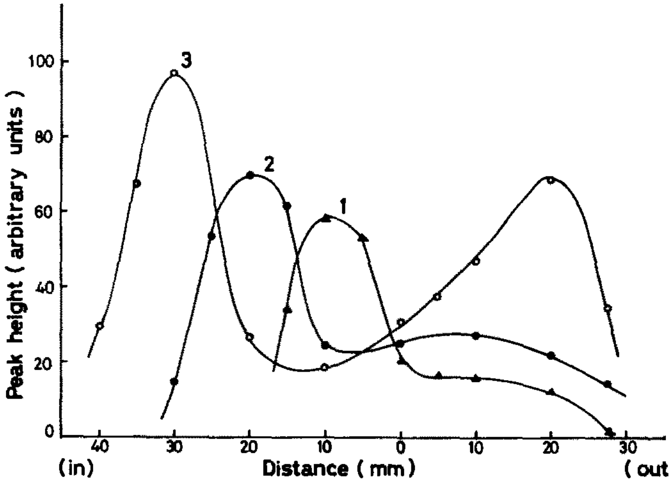

Fig. 2. Effect of microwave power on the recorder response of the Cr 425·4 nm line as a function of the position in the discharge. The abscissa designates a distance from the centre of the cavity. Sample: 1 μl of chloroform (containing 100 ng of Cr) Microwave power (W): *1*-30, *2*-50, *3*-70.

Effect of microwave power

In Fig. 2 the variation of the intensity of a chromium emission line is plotted against distance along the discharge tube. The position where the intensity was maximum moved toward the inlet as the power increased. Similar effects were observed with the other elements though the maximum positions were somewhat different. Beryllium and aluminium emissions were observed only at the inlet side of the discharge tube.

Effect of the argon flow-rate

The flow-rate of carrier gas affected the intensity distribution along the discharge tube as well as the retention time. In Fig. 3 the effect of the argon flow-rate on the intensity distribution of a beryllium line is shown. This behaviour of the intensity distribution may cause the detector response to depend greatly on carrier gas flow if the light emitted is measured at a fixed position.[7]

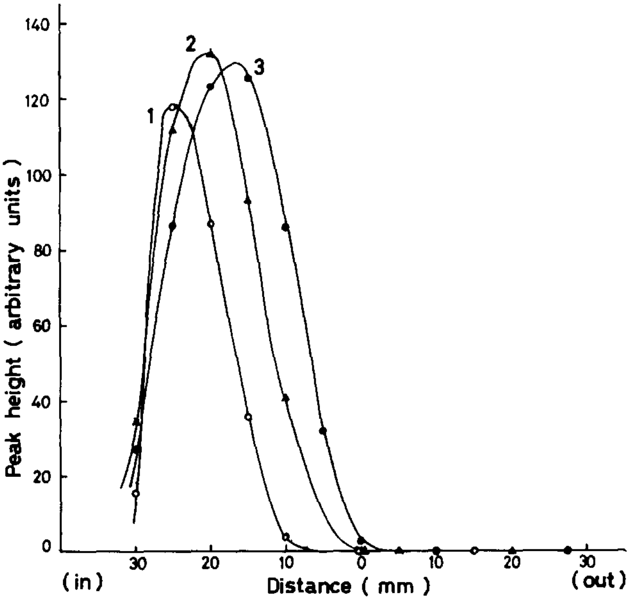

Fig. 3. Effect of argon flow-rate on the recorder response. Sample: 1 μl of chloroform (containing 10 ng of Be). Ar flow-rate (ml/min): *1*–50, *2*–100, *3*–150.

Calibration curves and detection limits

The calibration curves for aluminium, beryllium and chromium are shown in Fig. 4. Log-log calibration curves were linear over two orders of magnitude for beryllium and chromium. However, the linear range of the calibration curve for aluminium was very narrow and its slope was extremely steep. The mechanism of this response is as yet unknown. The maximum amounts of metals used in preparing the calibration curves were limited by the fact that the discharge became unstable as the sample emerged. The detection limits (signal/noise ratio of 2) for aluminium, beryllium and chromium are 100 ng, 0·01 ng and 1 ng, respectively. The relative standard deviations of the recorder response were 10–15%.

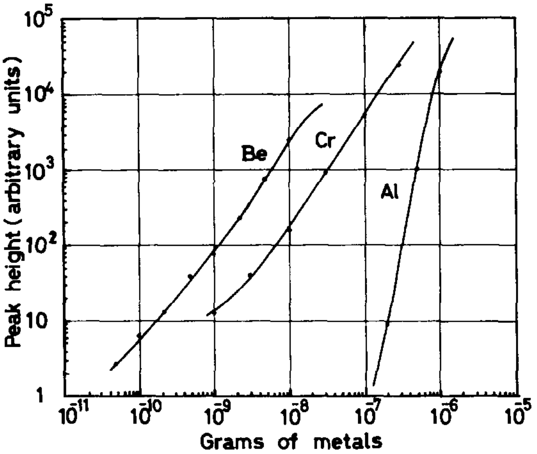

Fig 4. Calibration curves for Be, Cr and Al measured at Be I 234·9 nm, Cr I 425·4 nm and Al I 396·2 nm, respectively.

Interferences

There are many complex bands in the emission spectra of organic compounds,[7] which may interfere with the atomic emission lines. For instance, the peak due to acetylacetone appeared near that of beryllium acetylacetonate measured at 234·9 nm when more than 0·01% of acetylacetone was present. This type of interference can be greatly decreased by decreasing the slit-width of the monochromator. Another example of interference was the enhancement effect of aluminium acetylacetonate on beryllium and chromium emissions as shown in Fig. 5. This is due to the incomplete separation of the peaks.

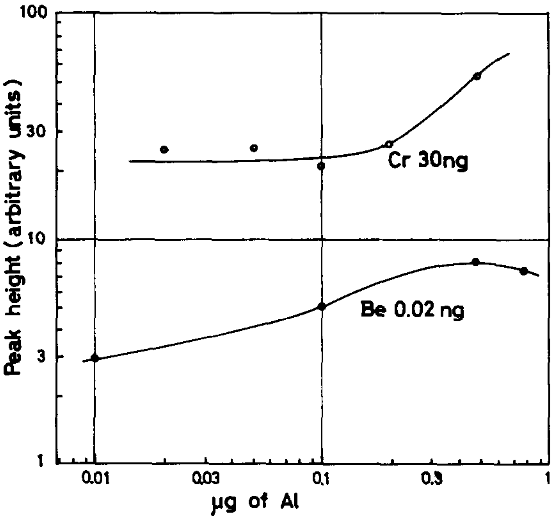

Fig. 5. Effect of aluminium content in the sample on the recorder responses of Cr 425·4 nm and Be 234·9 nm lines.

Determination of beryllium in aluminium

Sievers[11] could detect 0·0059 μg of beryllium in the presence of 2000 times as much aluminium with a thermal conductivity detector (in the gas chromatography of metal trifluoroacetylacetonates). However, it is difficult with conventional detectors to detect one metal in the presence of much larger amounts of others. Owing to its inherent selectivity and high sensitivity, the emission spectrometric detector can be used to determine trace metals without prior separation of the major constituents. The calibration curve constructed by carrying standard solutions containing known amounts of beryllium and aluminium through the entire procedure described above is linear but does not pass through the origin. The calibration curve prepared with chloroform solutions of mixtures of the acetylacetonates is a straight line passing through the origin. Moreover, the slope of the latter curve is about 1·6 times that of the former. The discrepancy between the two is probably due to the formation of unknown compounds during the extraction step. Nevertheless, down to 10 ppm of beryllium in aluminium (0·01 ng of beryllium in the presence of 1 μg of aluminium) could be determined with a relative standard deviation of about 15%.

Zusammenfassung—Bei der Bestimmung von Metall-Acetylacetonaten wird ein emissionsspektrometrischer Detektor verwendet. Die Spektren werden im Plasma einer elektrodenlosen 2450 MHz-Entladung angeregt. Die Messung der Intensität der Atomemissionslinien von Aluminium, Beryllium und Chrom nach der Gaschromatographie ergibt eine hochempfindliche und selektive Methode zur Bestimmung der Acetylacetonate dieser Metalle. Die Nachweisgrenzen sind 100 ng für Aluminium, 0,01 ng für Beryllium und 1 ng für Chrom. Eine Analysenvorschrift zur Bestimmung von Beryllium in Aluminium bis herunter zu 10 ppm wird vorgeschlagen.

Résumé—On utilise un détecteur spectrométrique d'émission dans la détermination d'acétylacétonates métalliques. Les spectres sont excités dans le plasma d'une décharge sans électrode de 2450 MHz. La mesure des intensités des raies d'émission atomique de l'aluminium, du béryllium et du chrome après chromatographie en phase gazeuse apporte une méthode hautement sensible et sélective pour la détermination des acétylacétonates de ces métaux. Les limites de détection sont 100 ng pour l'aluminium, 0,01 ng pour le béryllium et 1 ng pour le chrome. On propose une technique analytique pour le béryllium, pouvant descendre jusqu'à 10 p.p.m. dans l'aluminium.

SHORT COMMUNICATIONS

SOME ASPECTS OF THE WINKLER DETERMINATION OF OXYGEN IN WATER

(*Received* 8 *November* 1971. *Accepted* 29 *August* 1972)

The Winkler method for the determination of dissolved oxygen in water has been used for this purpose since 1888[1] either in its original form or as modified by various workers.[2] The basic method, which is fast and accurate when properly carried out, makes use of the three reactions:

$$\mathrm{Mn(II)} + \mathrm{O_2} \xrightarrow{\mathrm{OH^-}} \mathrm{MnO_2} \tag{1}$$

$$\mathrm{MnO_2} + 4\mathrm{H^+} + 2\mathrm{I^-} \longrightarrow \mathrm{I_2} + \mathrm{Mn(II)} + 2\mathrm{H_2O} \tag{2}$$

$$\mathrm{I_2} + 2\mathrm{S_2O_3^{2-}} \longrightarrow \mathrm{S_4O_6^{2-}} + 2\mathrm{I^-} \tag{3}$$

Despite its accuracy, the Winkler method does have some disadvantages. It cannot be used to monitor dissolved oxygen continuously. Continuous monitoring is possible with suitable electrodes which have been calibrated. Such electrodes allow changes in the oxygen sample to be detected over short periods of time (2 sec) and their operation does not appreciably alter the concentration of dissolved oxygen. In the present study such an electrode system has been utilized to collect information on the time required for the reactions used in the Winkler system to proceed and of the extent to which the reactions proceed as a function of pH.

EXPERIMENTAL

Reagents

A.C.S. reagent grade chemicals were used to prepare the following solutions: 0·25*M* manganous sulphate; a solution 0·60*M* in sodium iodide and 1*M* in sodium hydroxide; 9*M* sulphuric acid; 0·10*M* sodium thiosulphate. Buffer solutions were prepared with pH values of 7·00 and 7·75 (based on phosphate), 8·10 [based on tris(hydroxymethyl)aminomethane], 8·50, 9·00 and 10·00 (based on borate).[3]

Procedure

A Sargent Model XV recording polarograph was used with a rotating platinum electrode and an S.C.E. for the measurement of the diffusion currents due to reduction of dissolved oxygen. All experiments were done at 25°. The operating voltage used was −0·35V and the current sensitivity 0·020 μA/in. Nitrogen was used as an inert atmosphere over the solution and, when needed, to purge oxygen from the solution to determine values on a "blank". The polarograph itself was standardized and the rotating platinum electrode cathodized by a method described by McNutt.[4]

The oxygen sensitivity of the system was determined by measuring the current obtained with an oxygen solution, the concentration of which was determined by the standard Winkler procedure. The results were obtained by first measuring the current with a standard oxygen solution and then running the reaction of Mn(II) and dissolved oxygen and comparing the currents obtained. The standard oxygen solution consisted of 50 ml of the appropriate buffer solution and 150 ml of distilled water of known oxygen concentration.

The electrode system was also calibrated by the Winkler method, in a manner very similar to that used in the experiments on pH dependence. Fifty ml of each buffer were mixed with 150 ml of distilled water containing dissolved oxygen and analysed in triplicate. These results were reproducible to ±0·5% or better. The oxygen content of the distilled water, established in this way, was used to calibrate the electrode system in the blank runs. The sample of analysed water was kept in a tightly stoppered bottle. Since the only variations in the concentration of oxygen under such conditions would be small ones due to variations in atmospheric pressure, the value established, $1{\cdot}225 \times 10^{-5}M$ oxygen, was used throughout the experiments. After standing for two weeks the oxygen solution was restandardized and found to have very nearly the same value ($1{\cdot}146 \times 10^{-5}M$, a decrease of 6%).

The observed current ranges for these solutions and the same solutions after deoxygenation were used to determine the oxygen calibration. After each such blank run the reaction vessel was cleaned and the same components added. To this second solution, under a nitrogen atmosphere, was now added 1 ml of 0·25*M* manganous sulphate. This resulted in a rapid change in the observed current to a new steady value and the current change was noted. Since the current is proportional to the concentration of dissolved oxygen,[2] comparison of the current change with the calibration run allowed an accurate estimate to be made of the oxygen consumption and the degree of completion of the reaction

$$\mathrm{Mn(II)} + \mathrm{O_2} \xrightarrow{\mathrm{OH^-}} \mathrm{MnO_2}$$

RESULTS AND DISCUSSION

The dependence of degree of completion of the reaction *vs.* pH is given in Fig. 1. The pH-dependence is certainly not surprising in view of the known dependence of the stability of Mn(II) on pH. This curve also provides dramatic evidence of the advantages of the rotating platinum electrode as an oxygen monitor. Its operating range is much broader and its response time is much shorter than those of the Winkler method. Offsetting these advantages are its lower accuracy and reproducibility and the irregular response of improperly cathodized rotating platinum electrodes.

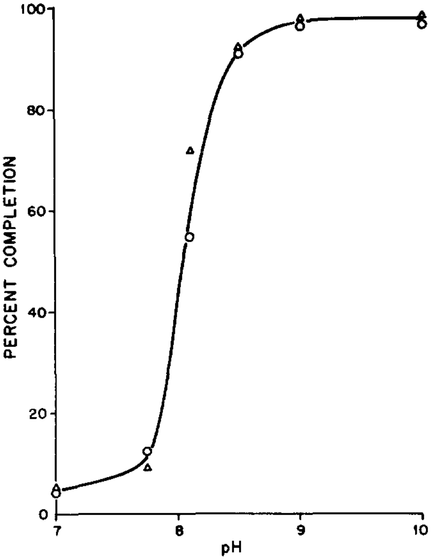

Fig. 1. The effect of pH on the percentage completion of the reaction between Mn(II) and dissolved oxygen in the Winkler analysis.

pH	7·00	7·75	8·10	8·50	9·00	10·00
% Completion (○)	4·2	12·5	55·0	91·2	97·1	97·2
(△)	5·2	9·1	72·1	92·1	98·3	98·6

A pH approaching 9 or more is clearly required for the complete consumption of the oxygen by the manganese. If the pH is too low when the manganous sulphate solution is added only part of the oxygen is consumed. In such a case the reaction does not go to completion until after the addition of the basic sodium iodide solution causes an increase in the pH.

The response time of the polarograph is about 3 sec for full-scale deflection. Since the time response of the system as a whole was determined in the course of each run it was apparent that these results might be useful in obtaining approximate information on the rate of the reaction. The estimated times ($t_{1/2}$) for the completion of half of the reaction are summarized below.

pH	7·00	7·75	8·10	8·50	9·00	10·00
$t_{1/2}$ *sec*	1·8	1·8	1·6	1·5	1·2	1·2

While the response time does vary somewhat, the response time of the instrument may well be the limiting factor. The results allow us to estimate only an upper bound for the half-life of the reaction of Mn(II) with dissolved oxygen and the reaction may be considerably more rapid. At any rate, we have shown that the reaction is sufficiently rapid for the error from incomplete reaction to be 0·1% or less if a total of as much as 20 sec is allowed for the reaction to proceed. The usual procedure will allow a much longer period for reaction than this

In conclusion we can state that the rotating platinum electrode is capable of monitoring reactions in which dissolved oxygen is consumed, such as those in the Winkler analysis. Its normal response time appears to be limited primarily by the speed of the recording device used. It is potentially capable of providing rate data for such reactions.

Summary—The reactions in the Winkler determination of oxygen have been examined with a rotating platinum electrode and a recording polarograph. In this manner the extent of the reaction has been determined over the pH range 7–10; at a pH of 7 only about 5% of the dissolved oxygen reacts; at a pH of 9 or above the reaction is essentially quantitative. The reaction of dissolved oxygen with manganese(II) is quite rapid. The sluggish response of the polarograph recorder prevented an accurate determination of the rate, but the reaction half-times were about 2 sec or less over the pH range used.

Zusammenfassung—Die bei der Winkler-Bestimmung von Sauerstoff ablaufenden Reaktionen wurden mit einer rotierenden Platinelektrode und einem registrierenden Polarographen untersucht. Auf diese Weise wurde das Ausmaß der Reaktion im pH-Bereich 7–10 ermittelt. Bei pH 7 reagieren nur etwa 5% des gelösten Sauerstoffs; bei pH 9 und darüber ist die Reaktion praktisch quantitativ. Die Reaktion von gelöstem Sauerstoff mit Mangan(II) geht ziemlich rasch. Das langsame Ansprechen des Polarographenschreibers verhinderte eine genaue Bestimmung der Geschwindigkeit, jedoch betrugen die Halbwertszeiten der Reaktion im benutzten pH-Bereich etwa 2 sec oder weniger.

Résumé—On a examiné les réactions dans le dosage de Winkler de l'oxygène avec une électrode de platine tournante et un polarographe enregistreur. De cette manière, on a déterminé l'avancement de la réaction dans le domaine de pH 7–10; à un pH de 7, environ 5% seulement de l'oxygène dissous réagit; à un pH de 9 ou supérieur la réaction est essentiellement quantitative. La réaction de l'oxygène dissous avec le manganèse(II) est tout à fait rapide. La réponse lente de l'enregistreur du polarographe a empêché une détermination précise de la vitesse, mais les demi-temps de réaction sont d'environ 2 s ou moins dans le domaine de pH utilisé.

A NOVEL METHOD FOR THE ESTIMATION OF ARSENIC(V) IN ORGANIC COMPOUNDS

(*Received* 14 *June* 1971. *Revised* 15 *March* 1972. *Accepted* 5 *July* 1972)

Arsenic(V) in organic compounds has been determined by digesting the compound with chloric acid, reducing with iodide to arsenic(III) and titrating iodometrically.[1] Another method involves (*a*) digestion with sodium sulphate and sulphuric acid, followed by titration with bromate, or (*b*) digestion with hydrogen peroxide and sulphuric acid, addition of hydrazine and titration with bromate, or (*c*) digestion with fuming nitric acid, then with sodium sulphate and concentrated sulphuric acid, and then with more conc. nitric acid, and titration with bromate.[2] The sample can be heated with sulphuric acid and hydrogen peroxide, then with hydrazine

In conclusion we can state that the rotating platinum electrode is capable of monitoring reactions in which dissolved oxygen is consumed, such as those in the Winkler analysis. Its normal response time appears to be limited primarily by the speed of the recording device used. It is potentially capable of providing rate data for such reactions.

Summary—The reactions in the Winkler determination of oxygen have been examined with a rotating platinum electrode and a recording polarograph. In this manner the extent of the reaction has been determined over the pH range 7–10; at a pH of 7 only about 5% of the dissolved oxygen reacts; at a pH of 9 or above the reaction is essentially quantitative. The reaction of dissolved oxygen with manganese(II) is quite rapid. The sluggish response of the polarograph recorder prevented an accurate determination of the rate, but the reaction half-times were about 2 sec or less over the pH range used.

Zusammenfassung—Die bei der Winkler-Bestimmung von Sauerstoff ablaufenden Reaktionen wurden mit einer rotierenden Platinelektrode und einem registrierenden Polarographen untersucht. Auf diese Weise wurde das Ausmaß der Reaktion im pH-Bereich 7–10 ermittelt. Bei pH 7 reagieren nur etwa 5% des gelösten Sauerstoffs; bei pH 9 und darüber ist die Reaktion praktisch quantitativ. Die Reaktion von gelöstem Sauerstoff mit Mangan(II) geht ziemlich rasch. Das langsame Ansprechen des Polarographenschreibers verhinderte eine genaue Bestimmung der Geschwindigkeit, jedoch betrugen die Halbwertszeiten der Reaktion im benutzten pH-Bereich etwa 2 sec oder weniger.

Résumé—On a examiné les réactions dans le dosage de Winkler de l'oxygène avec une électrode de platine tournante et un polarographe enregistreur. De cette manière, on a déterminé l'avancement de la réaction dans le domaine de pH 7–10; à un pH de 7, environ 5% seulement de l'oxygène dissous réagit; à un pH de 9 ou supérieur la réaction est essentiellement quantitative. La réaction de l'oxygène dissous avec le manganèse(II) est tout à fait rapide. La réponse lente de l'enregistreur du polarographe a empêché une détermination précise de la vitesse, mais les demi-temps de réaction sont d'environ 2 s ou moins dans le domaine de pH utilisé.

A NOVEL METHOD FOR THE ESTIMATION OF ARSENIC(V) IN ORGANIC COMPOUNDS

(*Received* 14 *June* 1971. *Revised* 15 *March* 1972. *Accepted* 5 *July* 1972)

Arsenic(V) in organic compounds has been determined by digesting the compound with chloric acid, reducing with iodide to arsenic(III) and titrating iodometrically.[1] Another method involves (*a*) digestion with sodium sulphate and sulphuric acid, followed by titration with bromate, or (*b*) digestion with hydrogen peroxide and sulphuric acid, addition of hydrazine and titration with bromate, or (*c*) digestion with fuming nitric acid, then with sodium sulphate and concentrated sulphuric acid, and then with more conc. nitric acid, and titration with bromate.[2] The sample can be heated with sulphuric acid and hydrogen peroxide, then with hydrazine sulphate; after addition of tartaric acid and potassium bromide, potassium bromate is used as titrant.[3] The sample can be treated with hydrogen peroxide and conc. sulphuric acid, hydrogen peroxide expelled, potassium iodide added and the iodine titrated with sodium thiosulphate.[4] The sample can be decomposed with hydrogen peroxide and sulphuric acid, arsenic reduced with hydrazine, and titrated with bromate in hydrochloric acid.[5] In another method the sample is heated with conc. chloric acid, and sodium hydroxide and then excess of hydrochloric acid is added, followed by potassium iodide, removal of free iodine with sodium sulphite, addition of sodium bicarbonate and titration of arsenic(III) with iodine, with starch as indicator.[6] The compound can be dissolved in conc. hydrochloric acid, the solution cooled, acetic acid, water and potassium iodide added and the iodine titrated with thiosulphate.[7] After digestion of sample with hydrogen peroxide and sulphuric acid, arsenic can be distilled as arsenic trichloride, then precipitated as sulphide, dissolved in alkali and titrated with permanganate.[8] After a similar decomposition, the arsenic can be precipitated as $MgNH_4AsO_4$.[9] The substance can be heated with water and ammonium persulphate till colourless, then oxalic acid is added and carbon dioxide expelled by heating; sulphuric acid and potassium iodide are added, iodine is expelled by boiling and any yellow colour destroyed with sodium thiosulphate. After dilution and addition of sodium carbonate and bicarbonate the arsenic is titrated with iodine solution. In view of these circuitous methods, it was thought profitable to devise some simple and satisfactory method for the determination of arsenic(V) in organic compounds.

EXPERIMENTAL

Reagents

Aqueous iodine solution (approximately 0·05*N*) containing 10 g of potassium iodide per litre was standardized with 0·1*N* sodium thiosulphate, with freshly prepared starch solution as indicator.

All reagents were of analytical grade. The samples tested are listed in Table 1.

Table 1

No. Compound	As, %		
	Theory	Starch end-point	Potentiometric end-point
1. Triphenylarsine oxide	23·29	23·1 23·4 23·2	—
2. 1,2-Ethylene-bis-diphenylarsine oxide	28·95	29·2 28·7 28·8	29·1
3. *p*-Chlorobenzaldehyde arsanilic acid	22·09	22·2 22·1 22·1	21·1
4. *o*-Chlorobenzaldehyde arsanilic acid	22·09	22·2 22·2 22·1	22·0
5. *m*-Nitrobenzaldehyde arsanilic acid	21.43	21·6 21·3 22·1	—
6. *o*-Nitrobenzaldehyde arsanilic acid	21·43	21·4 21·4 21·2	21·3
7. *o*-Carboxyphenylarsonic acid	30·49	30·8 30·4 30·3	30·3

9. *p*-Bromophenylarsonic acid	26·69	26·6 26·7 26·9	—
10. *p*-Tolylarsonic acid	34·72	35·0 34·7 34·9	—

Procedure

For compounds 1–7. A 10–15 mg sample was dissolved in a mixture of 30 ml of glacial acetic acid and 30 ml of ethyl alcohol in a 150-ml round-bottomed flask and the solution was heated to boiling. Then 2 g of zinc dust were slowly added to the continuously boiling mixture over a period of 15 min. The solution was cooled and decanted and the residual zinc washed with 10 ml of acetic acid, followed by 30 ml of water. The solution and washings were titrated with 0·05*N* iodine with starch as indicator added near the end-point, which is given by appearance of a light violet colour. Sometimes a light yellow colour results, which on dilution gives the light violet colour. Similar results were obtained when the compounds were dissolved in 50 ml of glacial acetic acid, reduced with 2 g of zinc dust during 20 min and then treated as before. A potentiometric end-point can also be used.

For compounds 8–10. A 10–20 mg sample was dissolved in 20 ml of glacial acetic acid and heated to boiling. Powdered zinc dust (2 g) was added and the mixture was heated for 5 min, cooled, the solution decanted, the residual zinc washed with 10 ml of glacial acetic acid and 10 ml of distilled water, and the solution and washings titrated with iodine as for compounds 1–7.

RESULTS AND DISCUSSION

Organic compounds containing arsenic(V) are usually insoluble in water but can be dissolved in acetic acid, or in a mixture of acetic acid and ethyl alcohol if the compound is not completely soluble in acetic acid. The arsenic(V) is reduced by the action of acetic acid and zinc. The arsenic(III) cannot be titrated in glacial acetic acid because of difficulty in the detection of the end-point, but addition of water removes the difficulty. The quantity of water added should be such that the solution to be titrated does not turn milky because of separation of organic species. Excellent results are obtained when the amount of arsenic(V) compound taken is 10–20 mg. This method is clean and quick.

Potassium chloride, bromide or iodide (10 mg) did not interfere. In the potentiometric titration, suitable for coloured solutions, a platinum electrode was coupled with a calomel electrode. The results obtained are given in the Table.

Summary—A novel method for the determination of arsenic(V) in organic compounds has been developed by reducing combined arsenic(V) to arsenic(III) in aqueous acetic acid medium with zinc dust. In some cases, addition of ethyl alcohol is necessary to dissolve the compound and to keep the arsenic(III) compound in solution. The arsenic(III) is titrated with iodine and the end-point is detected visually with starch as indicator or potentiometrically.

Zusammenfassung—Ein neuartiges Verfahren zur Bestimmung von Arsen(V) in organischen Verbindungen wurde entwickelt. Gebundenes Arsen(V) wird dabei in wäßriger Essigsäure mit Zinkstaub zu Arsen(III) reduziert. In einigen Fällen ist eine Zugabe von Äthylalkohol

INDIRECT POLAROGRAPHIC DETERMINATION OF TRIPOLYPHOSPHATE IONS IN THE PRESENCE OF OTHER POLYPHOSPHATES, WITH OCTYLTIN CHLORIDE

(*Received* 29 *May* 1972. *Accepted* 6 *September* 1972)

No phosphate or polyphosphate anion is itself reducible at the dropping mercury electrode, but indirect methods for tripolyphosphate have been based on selective precipitation or complexation with a known excess of a polarographically active species. Precipitation methods are generally subject to interference from co-precipitation or suffer from incomplete precipitation, especially when only small concentrations are to be determined. A gravimetric method using tris(ethylenediamine)cobalt(III) in a pH 3·6 buffer as a precipitant for tripolyphosphate in the presence of pyrophosphate, has been published,[1,2] but radioactive labelling with ^{32}P has shown[3] that some co-precipitation occurs and that some tripolyphosphate remains in solution, even under carefully controlled precipitation conditions. Weiser[2] reported strong interference from sulphate ions, which decreased the completeness of precipitation. A recent investigation[4] has shown that tris(ethylenediamine)-cobalt(III) does not give complete precipitation at low concentrations ($\leq 10^{-2}M$) of tripolyphosphate ions.

Selective complexation by polyphosphates at low concentrations ($\leq 10^{-3}M$) has so far received surprisingly little attention for the determination of the polyphosphates. During a study of the effect of polyphosphates on the d.c. polarographic behaviour of some simple metal ions, Al-Sulimany and Townshend[4] developed a method for low concentrations of tripolyphosphate, based on the decreased height of the cadmium polarographic reduction wave. Selectivity was somewhat limited, but less than 5% of pyrophosphate and less than 50% of trimetaphosphate or tetrametaphosphate, relative to the tripolyphosphate, did not interfere in the analysis. Attempts to find metal ions which were more selective to individual polyphosphates were at that time unsuccessful. More recently, however, during an investigation of the polarographic behaviour of the n-octyltin chlorides, it was observed that buffer systems containing phosphate caused a complete disappearance of the reduction wave of mono-octyltin trichloride at pH > 3. This complexing effect has also been reported by other workers[6] for monoethyltin trichloride. Further experiments showed that polyphosphate ions had a similar effect. It has proved possible, by selection of suitable conditions, to devise a method for the determination of tripolyphosphate ions that is free from interference by much greater concentrations of other phosphate species. The development of this method is described in this paper.

The ability of organotin cations to form adducts with electron donors is well known.[5] The acceptor strength declines in the order $RSn^{3+} > R_2Sn^{2+} > R_3Sn^{+}$, and in general, organotin compounds with a single organic substituent form the most stable complexes. It was considered improbable, therefore, that the more highly substituted octyltin cations would respond more sensitively than mono-octyltin, and they were not investigated for this purpose.

EXPERIMENTAL

Apparatus

Polarograms were recorded with a Radiometer Polariter PO4 polarograph used in conjunction with a Drop Life Timer type D.L.T.1. An external standard calomel electrode was separated from the cell by a saturated potassium chloride bridge.

More recently, however, during an investigation of the polarographic behaviour of the n-octyltin chlorides, it was observed that buffer systems containing phosphate caused a complete disappearance of the reduction wave of mono-octyltin trichloride at pH > 3. This complexing effect has also been reported by other workers[6] for monoethyltin trichloride. Further experiments showed that polyphosphate ions had a similar effect. It has proved possible, by selection of suitable conditions, to devise a method for the determination of tripolyphosphate ions that is free from interference by much greater concentrations of other phosphate species. The development of this method is described in this paper.

The ability of organotin cations to form adducts with electron donors is well known.[5] The acceptor strength declines in the order $RSn^{3+} > R_2Sn^{2+} > R_3Sn^{+}$, and in general, organotin compounds with a single organic substituent form the most stable complexes. It was considered improbable, therefore, that the more highly substituted octyltin cations would respond more sensitively than mono-octyltin, and they were not investigated for this purpose.

EXPERIMENTAL

Apparatus

Polarograms were recorded with a Radiometer Polariter PO4 polarograph used in conjunction with a Drop Life Timer type D.L.T.1. An external standard calomel electrode was separated from the cell by a saturated potassium chloride bridge.

Reagents

Mono-octyltin trichloride, purified by vacuum distillation, (b.p. 182–3°/29 mmHg) and sodium salts of the polyphosphates were provided by Albright and Wilson (Mfg.) Ltd., Oldbury, Worcs. Other chemicals used were of analytical reagent grade.

A stable solution of mono-octyltin trichloride ($6{\cdot}0 \times 10^{-4}M$) in perchloric/hydrochloric acid and 2-propanol can be prepared in bulk as follows. Transfer mono-octyltin trichloride (0·203 g) to a 1000-ml volumetric flask containing 2-propanol, 60% perchloric acid (130 ml) and concentrated hydrochloric acid (50 ml), and dilute to volume with 2-propanol.

Procedure for calibration and determination of tripolyphosphate ($<4 \times 10^{-3}M$)

Transfer 10 ml of the tripolyphosphate solution into a clean, dry polarographic cell. Add $0{\cdot}15M$ tetrametaphosphate solution (0·20 ml), followed by $6{\cdot}0 \times 10^{-4}M$ mono-octyltin trichloride solution (10 ml). Immediately, deaerate with nitrogen for 3 min, and allow to stand for a further minute with nitrogen passing over the solution. Record the polarogram, and measure the height of the wave having $E_{1/2} = -0{\cdot}45$ V *vs.* the S.C.E. Calibration should be carried out with 0–10 ml of $4 \times 10^{-3}M$ sodium tripolyphosphate solution and the volume of water required to bring the volume to 10 ml before addition of the octyltin solution.

A typical calibration curve is shown in Fig. 1.

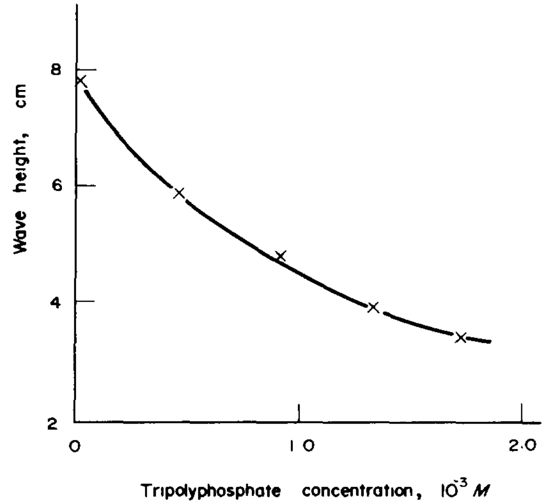

Fig. 1. Calibration graph for tripolyphosphate. Sensitivity 1·5 μA full-scale deflection. Drop-time 1·0 sec, blanking 30%.

RESULTS AND DISCUSSION

Mono-octyltin trichloride gives a single reduction wave in a 50% aqueous 2-propanol solution $1M$ in perchloric acid and $0{\cdot}25M$ in hydrochloric acid, $E_{1/2} = -0{\cdot}45$ V *vs.* S.C.E. The effects of orthophosphate and four polyphosphate ions on the height of the polarographic wave of mono-octyltin trichloride ($3{\cdot}2 \times 10^{-4}M$) in such an electrolyte are shown in Fig. 2. Orthophosphate ions have a negligible effect, but the polyphosphate ions all decrease the wave height, the order of effectiveness being tripoly > tetrameta > trimeta > pyrophosphate, The half-wave potential of the octyltin wave is unaffected, indicating that the wave measured is that of the uncomplexed octyltin ions. No wave corresponding to reduction of the complex is observed in the potential range before hydrogen ion discharge occurs.

The difference in the response to the various polyphosphate species is a complex function of pH and chloride ion concentration, as well as the stability of the octyltin–polyphosphate complex. The addition of hydrochloric acid allows the formation of competing complexes of the type $(OcSnCl_4)^-$. It was found that all the phosphates complex strongly with mono-octyltin ions in a medium of $2M$ perchloric acid and 2-propanol (1 : 1), and that no complexing by polyphosphates occurs in $2M$ hydrochloric acid and 2-propanol (1 : 1). In $0{\cdot}25M$ hydrochloric acid in 50% v/v 2-propanol, low concentrations of tripolyphosphate and tetrametaphosphate caused the complete disappearance of the octyltin wave. Optimal differentiation between tripolyphosphate and the other polyphosphate ions was achieved in 50% aqueous 2-propanol, $1M$ in perchloric acid and $0{\cdot}25M$ in hydrochloric acid, as depicted in Fig. 2.

Figure 2 also shows that concentrations of tetrametaphosphate ions above *ca.* $10^{-3}M$ have little further effect. If was found that if the supporting electrolyte was also $1{\cdot}5 \times 10^{-3}M$ in tetrametaphosphate, the effect of other polyphosphates was greatly reduced, whereas tripolyphosphate still gave an appreciable reduction in the octyltin wave height. Higher cell concentrations of tetrametaphosphate would further reduce polyphosphate interference, but at the expense of decreased sensitivity for tripolyphosphate.

Under the optimal conditions for the selective determination of tripolyphosphate, tolerance of the method to other phosphate anions was statistically determined. A standard 2^4 factorial design experiment[7] was set up with a high and a low level of each interfering species. At cell concentrations of tripolyphosphate of $2{\cdot}0 \times 10^{-4}$ and $8{\cdot}0 \times 10^{-4}M$, the presence of $1 \times 10^{-3}M$ ortho-, pyro-, or trimetaphosphate, and $5 \times 10^{-4}M$ tetrametaphosphate did not cause any significant reduction in wave height, though $10^{-3}M$ tetrametaphosphate did give a significant reduction.

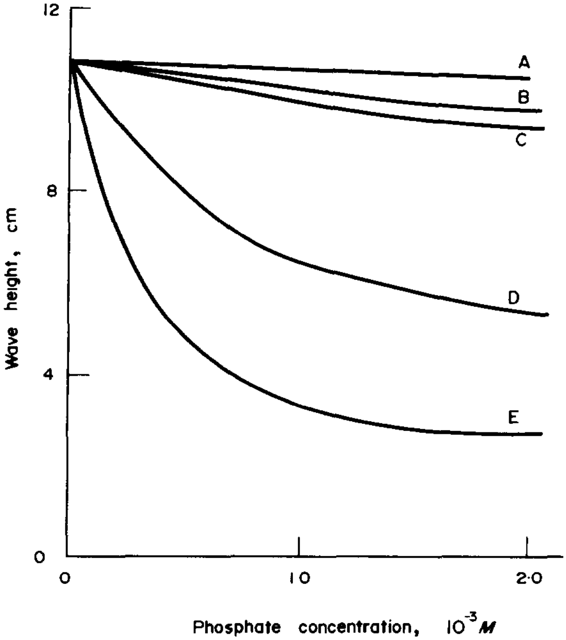

Fig. 2. Effect of phosphate ions on wave height of $3 \times 10^{-4}M$ mono-octyltin trichloride in 50% v/v aqueous 2-propanol, $1M$ in $HClO_4$ and $0{\cdot}25M$ in HCl. Instrument conditions as in Fig. 1. (*A*) orthophosphate, (*B*) pyro- (*C*) trimeta-, (*D*) tetrameta-, (*E*) tripolyphosphate.

Interference from sulphate ion is negligible. The presence of $10^{-2}M$ potassium sulphate had no effect. Magnesium (as sulphate, $4 \times 10^{-3}M$), and calcium (as chloride, $10^{-3}M$) could also be tolerated. Under the acidic conditions finally recommended, slow hydrolysis of the condensed phosphates does occur, but if the measurements are made without undue delay, this does not affect the reproducibility of the method.

The standard deviation based on seven determinations at a cell concentration of $8{\cdot}0 \times 10^{-4}M$ tripolyphosphate was found to be $4 \times 10^{-5}M$, giving (95% confidence limits) an error of $\pm 0{\cdot}94 \times 10^{-4}M$. Peak heights of approx. 60 mm were reproducible to within 1 mm and were found to decrease by about 3 mm if the solution was left for a further 10 min. Analysis at a higher pH, using $1{\cdot}0M$ acetic acid–$0{\cdot}5M$ potassium chloride solution mixed with 2-propanol (1 : 1), in an attempt to reduce the hydrolysis effect, was unsuccessful, since the necessary differentiation between pyro- and tripolyphosphate was not achieved.

Conclusion

The method described is simple, rapid and acceptably precise. It allows the determination of tripolyphosphate without interference from similar concentrations of other polyphosphates. Phosphate, sulphate, calcium and magnesium ions also do not interfere, so that the method is equally applicable to detergent preparations and effluent samples.

Summary—Tripolyphosphate ions form a soluble complex with mono-octyltin cations, thus reducing the polarographic wave height of the octyltin. This provides a method for the determination of 2×10^{-4}–$4 \times 10^{-3}M$ tripolyphosphate in the presence of $2 \times 10^{-3}M$ ortho-, pyro-, trimeta-, and $10^{-3}M$ tetrametaphosphate, together, or in any combination. The method is also insensitive to less than $2 \times 10^{-3}M$ magnesium or calcium and less than $10^{-2}M$ sulphate.

Zusammenfassung—Tripolyphosphat-Ionen bilden einen löslichen Komplex mit Monooktylzinn-Kationen und reduzieren dabei die Hohe der polarographischen Stufe des Oktylzinns. Dies bildet die Grundlage zur Bestimmung von $2{\cdot}10^{-4}$–$4{\cdot}10^{-3}$M Tripolyphosphat in Gegenwart von $2{\cdot}10^{-3}$M Ortho-, Pyro-, Trimeta- order 10^{-3}M Tetrametaphosphat zusammen oder in beliebiger Kombination. Das Verfahren ist auch unempfindlich gegen weniger als $2{\cdot}10^{-3}$M Magnesium oder Calcium und weniger als 10^{-2}M Sulfat.

Résumé—Les ions tripolyphosphate forment un complexe soluble avec les cations mono-octylétain, réduisant ainsi la hauteur de vague polarographique de l'octylétain. Ceci fournit une méthode pour le dosage de tripolyphosphate $2 \times 10^{-4} - 4 \times 10^{-3}$ *M* en la présence d'ortho-, pyro-, trimétaphosphate 2×10^{-3} *M* et de tétramétaphosphate 10^{-3} *M*, ensemble, ou selon n'importe quelle combinaison. La méthode est aussi insensible à moins de 2×10^{-3} *M* de magnésium ou de calcium et moins de 10^{-2} *M* de sulfate.

Summary—Tripolyphosphate ions form a soluble complex with mono-octyltin cations, thus reducing the polarographic wave height of the octyltin. This provides a method for the determination of 2×10^{-4}–$4 \times 10^{-3} M$ tripolyphosphate in the presence of $2 \times 10^{-3} M$ ortho-, pyro-, trimeta-, and $10^{-3} M$ tetrametaphosphate, together, or in any combination. The method is also insensitive to less than $2 \times 10^{-3} M$ magnesium or calcium and less than $10^{-2} M$ sulphate.

Zusammenfassung—Tripolyphosphat-Ionen bilden einen löslichen Komplex mit Monooktylzinn-Kationen und reduzieren dabei die Hohe der polarographischen Stufe des Oktylzinns. Dies bildet die Grundlage zur Bestimmung von $2 \cdot 10^{-4}$–$4 \cdot 10^{-3}$M Tripolyphosphat in Gegenwart von $2 \cdot 10^{-3}$M Ortho-, Pyro-, Trimeta- order 10^{-3}M Tetrametaphosphat zusammen oder in beliebiger Kombination. Das Verfahren ist auch unempfindlich gegen weniger als $2 \cdot 10^{-3}$M Magnesium oder Calcium und weniger als 10^{-2}M Sulfat.

Résumé—Les ions tripolyphosphate forment un complexe soluble avec les cations mono-octylétain, réduisant ainsi la hauteur de vague polarographique de l'octylétain. Ceci fournit une méthode pour le dosage de tripolyphosphate $2 \times 10^{-4} - 4 \times 10^{-3} M$ en la présence d'ortho-, pyro-, trimétaphosphate $2 \times 10^{-3} M$ et de tétramétaphosphate $10^{-3} M$, ensemble, ou selon n'importe quelle combinaison. La méthode est aussi insensible à moins de $2 \times 10^{-3} M$ de magnésium ou de calcium et moins de $10^{-2} M$ de sulfate.

FORMATION OF FERRICYANIDES—I*
SILVER(I), COPPER(II) AND CADMIUM(II)

(*Received* 25 *July* 1972. *Accepted* 12 *September* 1972)

The analytical importance of potassium ferricyanide is not limited to the specific colours it gives with many cations; it can also yield stable complexes having different stoichiometry with cations having a given charge. It, in fact, can react with a metallic bivalent ion as follows:

---

* Presented at the 2nd International Symposium on Analytical Chemistry Ljubljana (Yugoslavia) 12–17 June 1972. Supported by the Consiglio Nazionale delle Ricerche.

$$3M^{2+} + 2Fe(CN)_6^{3-} = M_3[Fe(CN)_6]_2 \quad (1)$$

$$mM^{2+} + pK^+ + qFe(CN)_6^{3-} = K_pM_m[Fe(CN)_6]_q \quad (2)$$

Thus the presence of the potassium ion leads to several possible complexes with variable K/M ratio In addition the composition of these complexes depends not only on the metal ion but also on the experimental conditions. We have therefore made a comparative conductometric and potentiometric study to establish which complexes are formed for the systems $AgNO_3$–$K_3Fe(CN)_6$, $CuSO_4$–$K_3Fe(CN)_6$, $CdSO_4$–$K_3Fe(CN)_6$.

These complexes have been studied earlier in aqueous and aqueous ethanolic (80 : 20) solution by means of thermometric,[1] potentiometric[2] or conductometric and thermometric measurements[3-5] and the complexes $Ag_3Fe(CN)_6$, $Cu_3[Fe(CN)_6]_2$ and $KCd_{10}[Fe(CN)_6]_7$ characterized, but the concentration range was very limited, being restricted to ~0·1*M*.

King[6] titrated $K_3Fe(CN)_6$ with $Cd(NO_3)_2$ solution and obtained a yellow precipitate which he deduced to be $Cd_3[Fe(CN)_6]_2$ on the basis of the Cd/Fe ratio.

To explain these differences we have investigated a wide concentration range with and without addition of potassium ions (0·15 and 0·5*M* final concentration) and with adjustment to constant ionic strength.

EXPERIMENTAL

Apparatus

The potentiometric cell for the silver and copper studies had a silver wire, a saturated calomel electrode and an agar–potassium nitrate bridge. From the equilibria (3) and (4) it is evident that the silver electrode

$$3Ag^+ + Fe(CN)_6^{3-} = Ag_3Fe(CN)_6 \quad (3)$$

$$mCu^{2+} + pK^+ + qFe(CN)_6^{3-} = K_pCu_m[Fe(CN)_6]_q \quad (4)$$

potential is related to the copper and potassium concentrations. A copper metal electrode was not used, because of its lower sensitivity, and an amalgam electrode was too easily oxidized. The titration error was negligible because the copper(II) concentration was always at least 1000 times that of silver.

As the cadmium electrode proved useless and an amalgam electrode was not practical the cadmium system was studied with a homemade oscillometer.[7]

Reagents

The silver nitrate solution was standardized oscillometrically with potassium chloride; the copper and cadmium solutions with EDTA.[8] Potassium ferricyanide solution was standardized according to Conde and Bellido[9] and kept in dark bottles. The stability of these solutions was checked periodically and no variation was found in 15 days for hexacyanoferrate(III) solution. Reagent purity was checked by means of blanks.

RESULTS

Reaction between Ag^+ *and* $Fe(CN)_6^{3-}$

The reddish-yellow powdery precipitate of $Ag_3Fe(CN)_6$ is the only product obtained, even in the presence of 0·5*M* potassium ion, over the concentration ranges $pAg^+ = 1-3$, $pFe(CN)_6^{3-} = 1-3·8$.

Use of 20% v/v aqueous ethanol as solvent medium gave a sharp equivalence point also corresponding to $Ag_3Fe(CN)_6$. This is in agreement with our earlier observation[10] for hexacyanoferrate(II) that the cations of heavy metals give only the simplest complex without formation of the mixed potassium salt.

The reactions all occurred immediately at room temperature.

Reaction between Cu^{2+} *and* $Fe(CN)_6^{3-}$

$Cu_3[Fe(CN)_6]_2$ is a yellow-brown powdery precipitate obtained in absence of extra potassium ions. $KCu_{10}[Fe(CN)_6]_7$ is formed in presence of 0·5*M* potassium nitrate and is soluble in ammonia. The potential drop at the equivalence point is about 50–60 mV in the titration of $Fe(CN)_6^{3-}$ with Cu(II) and 60–70 mV in the reverse titration.

The rate of reaction at room temperature is faster when Cu(II) is the titrand. The presence of an excess of potassium favours reaction (2), producing a mixed complex.

The concentration ranges studied were pCu^{2+} = 1·3–3·8 and $pFe(CN)_6^{3-}$ = 1·3–3·8.

Table 1 shows the results of a number of titrations. The average error is 0·2% and ferricyanide can be determined in this way in 0·5*M* potassium nitrate medium with a precision at least as good as that of other methods.

Table 1. Stoichiometry of the reaction between $K_3Fe(CN)_6$ and $CuSO_4$ at constant ionic strength, for $[K^+]$ = 0·5*M*

Titrand (100 ml)		Titrant				
mg $K_3Fe(CN)_6$	*μmole* $K_3Fe(CN)_6$	*mg* Cu(II)	*μmole* Cu(II)	Formula	Found, *mg*	Error, %
10·63	32·3	2·92	43·7	$KCu_{10}[Fe(CN)_6]_7$	10·59	−0·4
31·89	96·9	8·92	140	$KCu_{10}[Fe(CN)_6]_7$	32·02	+0·4
74·41	226·1	20·61	324	$KCu_{10}[Fe(CN)_6]_7$	74·73	−0·4
106·3	323	28·29	460	$KCu_{10}[Fe(CN)_6]_7$	106·3	0·0
106·9	324·6	35·48	558	$KCu_{10}[Fe(CN)_6]_7$	107·0	+0·1
534·3	1623	176·4	2276	$KCu_{10}[Fe(CN)_6]_7$	534·6	0·0
1068·7	3246	354	5570	$KCu_{10}[Fe(CN)_6]_7$	1068·6	0·0

Reaction between Cd^{2+} *and* $Fe(CN)_6^{3-}$

When cadmium(II) is titrated with ferricyanide in absence of additional potassium ions, yellow-brown $KCd_{10}[Fe(CN)_6]_7$ is formed over the concentration range pCd^{2+} = 1·0–1·8, yellow $Cd_3[Fe(CN)_6]_2$ is formed over the range pCd^{2+} = 2·1–3·7, and a mixture of the two over the intermediate range pCd^{2+} = 1·8–2·1. In the presence of 0·15*M* potassium nitrate or in the reverse titration under any conditions, only $KCd_{10}[Fe(CN)_6]_7$ is formed over the whole concentration ranges pCd^{2+} = 1–3·9, $pFe(CN)_6^{3-}$ = 1·2–3·7.

The error calculated on the basis of titration curves never exceeds 1% outside the region for formation of the mixture. Reaction rates are rather slow at room temperature.

When $K_3Fe(CN)_6$ is the titrand, enough potassium is present from the beginning of the titration for only $KCd_{10}[Fe(CN)_6]_7$ to be formed, whereas in the reverse titration additional potassium must be added for this to be the case.

K_{sp} *values and thermodynamic functions*

K_{sp} values for $KCu_{10}[Fe(CN)_6]_7$ were calculated from the conductivity of a saturated solution free from CO_2; for the other complexes they were calculated from the equivalence points of conductometric titration curves. For all complexes the measurements were made at 20°, 30° and 40°. Ionic mobilities at 30° and 40° were calculated by Walden's rule.[11] ΔG° values were obtained from $\Delta G^\circ = -RT \ln K_{sp}$, and ΔH° from the Gibbs-Helmholtz relation $\Delta H = -T^2\, \delta(\Delta G/T)/\delta T$. The results together with ΔS° values are summarized in Table 2.

Analysis of precipitates

Atomic-absorption spectrophotometric determination of the metal/iron ratio confirmed the combination ratios found for all the complexes.

Conclusions

A new "mixed" complex $KCu_{10}[Fe(CN)_6]_7$ was obtained in aqueous medium at constant ionic strength and $[K^+]$ = 0·5*M* and can be used for quantitative determination of $Fe(CN)_6^{3-}$.

Analysis of the $CdSO_4$–$K_3Fe(CN)_6$ system has cleared up the confusion about the concentration ranges over which the complexes are stable and explained the formation of $Cd_3[Fe(CN)_6]_2$ and $KCd_{10}[Fe(CN)_6]_7$ in the titration of Cd(II), and confirmed the correctness of Gaur and Bhattacharya's statement that $KCd_{10}[Fe(CN)_6]_7$ is formed in the titration of $K_3Fe(CN)_6$, in contradiction of King's work.[6]

Summary—With potassium ferricyanide copper(II) forms $KCu_{10}[Fe(CN)_6]_7$ quantitatively in $0{\cdot}5M$ potassium nitrate medium. Cadmium forms $Cd_3[Fe(CN)_6]_2$ if the ferricyanide is added to the cadmium solution in absence of extra potassium, and $KCd_{10}[Fe(CN)_6]_7$ if potassium is added first, or if the cadmium solution is added to the ferricyanide. Silver forms $Ag_3Fe(CN)_6$ only.

Zusammenfassung—Kupfer(II) bildet mit Kaliumferricyanid in 0·5M Kaliumnitratlösung quantitativ $KCu_{10}[Fe(CN)_6]_7$. Cadmium bildet $Cd_3[Fe(CN)_6]_2$, wenn man das Ferricyanid in Abwesenheit von weiterem Kalium zur Cadmiumlösung gibt, und $KCd_{10}[Fe(CN)_6]_7$, wenn man zuerst Kalium zugibt oder wenn die Cadmiumlösung zum Ferricyanid gegeben wird. Silber bildet nur $Ag_3Fe(CN)_6$

Résumé—Le cuivre (II) forme $KCu_{10}[Fe(CN)_6]_7$ avec le ferricyanure de potassium en milieu nitrate de potassium 0,5 *M*. Le cadmium forme $Cd_3[Fe(CN)_6]_2$ si le ferricyanure est ajouté à la solution de cadmium en l'absence de potassium supplémentaire, et $KCd_{10}[Fe(CN)_6]_7$ si le potassium est ajouté en premier, ou si la solution de cadmium est ajoutée au ferricyanure. L'argent ne forme que $Ag_3Fe(CN)_6$.

THE USE OF FURFURAL THIOSEMICARBAZONE FOR THE GRAVIMETRIC DETERMINATION OF PALLADIUM

(*Received* 14 *August* 1972. *Accepted* 7 *September* 1972)

Thiosemicarbazones have been used only occasionally as gravimetric reagents for palladium(II), although they form insoluble complexes with it. The thiosemicarbazone of *p*-ethylsulphonylbenzaldehyde has been used for this purpose with good results.[1] Complexes of palladium with some thiosemicarbazones have been isolated, and their infrared absorption spectra studied.[2]

In this paper, a procedure for the gravimetric determination of palladium(II) with furfural thiosemicarbazone is described. This compound forms an orange complex with palladium, insoluble in acid medium, and very easy to filter off. The optimum analytical conditions were determined.

EXPERIMENTAL

Reagents

Palladium solutions containing 5·795, 1·625 and 3·459 g/l. were standardized with dimethylglyoxime. More dilute solutions were prepared from these. All solvents and reagents were of analytical grade.

Preparation of the reagent

Furfural thiosemicarbazone was prepared by condensation of equimolar amounts of thiosemicarbazide and furfural.[3] The compound was recrystallized from ethanol. The infrared and ultraviolet spectra were recorded, and elemental analysis was made to confirm the synthesis (m.p. 145–147°; found: C 42·7%; H 4·1%; N 24·6%; calculated for $C_6H_7N_3OS$: C 42·70%; H 4·13%; N 24·60%).

An ethanolic solution (1·0%w/v) of the reagent was used in all subsequent work.

Qualitative tests

The reaction of furfural thiosemicarbazone with 40 cations, at concentrations up to 1000 ppm and at various pH values, was investigated. With Pd(II), an orange precipitate was produced. Cu(II) forms a green precipitate, and Ag(I), Hg(II) and Pt(IV) gave a weak yellow colour.

Precipitation of the palladium complex of furfural thiosemicarbazone

An aqueous solution of palladium chloride, containing 29·0 mg of palladium in 250–300 ml, was acidified with hydrochloric acid to between pH 3 and 4. A solution of furfural thiosemicarbazone was slowly added with constant stirring until a small excess was present. The precipitate was collected in a No. 3 porosity sintered-glass crucible, washed with about 100 ml of distilled water, and then dried at 60–80° to constant weight. (Found: C 32·5%; H 2·5%; N 19·0%. Calculated for $(C_6H_6N_3OS)_2Pd$: C 32·52%; H 2·71% N 18·97%.)

Thermal analysis

The thermogravimetric curve for the palladium-furfural thiosemicarbazone complex was recorded (Fig. 1). The complex was stable up to 180°; a sharp decrease occurs at 200°, and also at 450°. Suitable drying conditions for the complex were investigated. In all subsequent work, drying of the precipitate was always carried out at 60–120°.

Determination of the experimental conditions for precipitation

The effect of increasing the amount of furfural thiosemicarbazone was investigated with 32·5 mg of the palladium, pH between 3 and 5, and a final volume of 250 ml. Various volumes of the reagent were added. After 1 hr, the precipitate was collected and dried to constant weight. Table 1 gives the results, and shows that even when an appreciable excess of the reagent was added, no co-precipitation occurred.

The influence of various solvents for washing the precipitate were studied. Pure water was the best washing agent. Mixtures of ethanol–water (1 : 10 or 1 : 5) may also be used. Use of pure ethanol and acetone was unsuccessful.

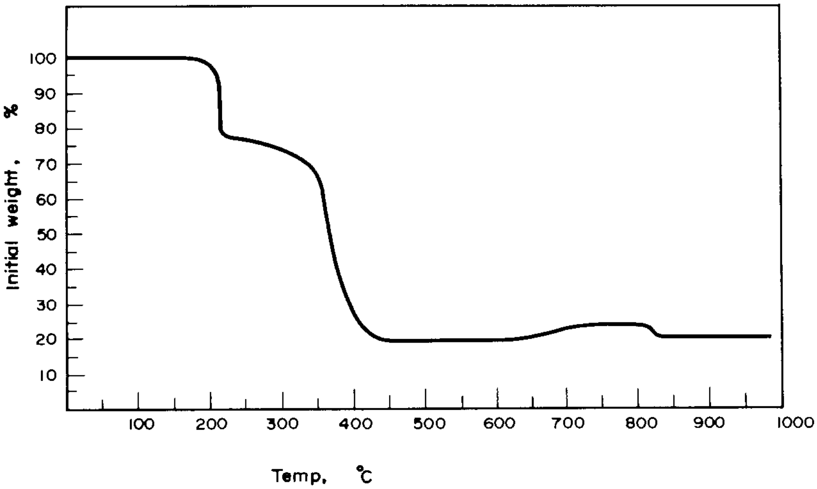

Fig. 1. Thermogravimetric curve of Pd-furfural thiosemicarbazone complex.

Table 1. Determination of the optimum amount of reagent

Reagent, *ml*	Pd taken, *mg*	Weight ppte, *mg*	Pd found, *mg*	Error, *mg*
5·0	32·5	5·5	1·3	−31·2
10·0	32·5	123·0	29·5	− 3·0
15·0	32·5	135·4	32·5	0·0
20·0	32·5	135·0	32·4	− 0·1
25·0	32·5	136·6	32·8	0·3
30·0	32·5	136·0	32·7	0·1

To determine the optimum pH for precipitation, the complex was precipitated from solutions at various pH values by using the method previously outlined. Table 2 gives the results. A pH between 2·0 and 6·0 was considered convenient, and all subsequent work was done in this pH range.

Recommended procedure for the determination of palladium

Take a sample solution containing 10–50 mg of palladium, dilute it to 200–250 ml, adjust the pH to 2·0–6·0, add 15–20 ml of 1% reagent solution (in ethanol) with constant stirring at room temperature. After 15–20 min, collect the precipitate in a weighed sintered-glass crucible, wash with 100–150 ml of distilled

Table 2. Influence of pH

pH	Pd taken, *mg*	Weight ppte, *mg*	Pd found, *mg*	Error, *mg*
0·5	29·0	51·5	12·4	−16·6
1·5	29·0	113·3	27·0	− 2·0
2·1	29·0	120·9	29·0	0·0
2·8	29·0	120·8	29·0	0·0
3·2	29·0	121·2	29·1	0·1
3·7	29·0	121·3	29·1	0·1
4·8	29·0	120·4	28·9	− 0·1
5·6	29·0	120·8	29·0	0·0
6·2	29·0	120·3	28·8	− 0·2
7·5	29·0	91·2	22·0	− 7·0
9·0	29·0	90·0	21·6	− 7·4

water, or 1 : 10 ethanol–water solution. Dry to constant weight at 60–120°. The weight of the precipitate, multiplied by 0·2402, gives the weight of palladium.

Determination of the error of the method

Table 3 gives results of recovery experiments. The standard deviation of a single measurements is 0·157 mg, and the standard deviation of the mean is ±0·032 mg. The error of the eight determinations is ±0·2%.

Table 3. Determination of the error of the method

Pd taken, *mg*	Weight ppte, *mg*	Pd found, *mg*	Error, *mg*
32·5	135·5	32·5	0·0
32·5	134·0	32·2	−0·3
32·5	135·6	32·6	0·1
32·5	135·5	32·5	0·0
32·5	135·2	32·5	0·0
32·5	136·0	32·7	0·2
32·5	135·3	32·5	0·0
32·5	134·4	32·3	−0·2

Interferences

Interference by foreign ions was investigated. Alkali metal salts were used for the solutions of the anions, and nitrates and chlorides for the solutions of the cations. In a few cases, sulphates and acetates were employed.

Up to at least 0·1 g of the following ions does not interfere; Co(II), Ni, Mn(II), Al, Zn, Fe(II), Ca, Sr, Ba, Ce(IV), Cd, La, Zr, Th, acetate, oxalate, fluoride and phosphate. The results obtained were all within the experimental error of the values obtained with palladium alone

Some ions were shown to interfere (Table 4).

Table 4. Interference of foreign ions

34·6	100·0 W(VI)	244·5	58·7	24·1

DISCUSSION

Furfural thiosemicarbazone is a selective reagent for the determination of palladium(II). The compound is useful as a laboratory reagent, and there is no tendency for co-precipitation with the palladium complex. The precipitate formed is easy to filter off and stable, when dry, at temperatures up to 170–180°. The complex has a low solubility, and its large molecular weight gives appreciable increase in sensitivity compared with the classical reagents, such as dimethylglyoxime furfuraldoxime and thiophenaldoxime.

EXTRACTIVE SPECTROPHOTOMETRY OF THE MOLYBDENUM (III) 1,10-PHENANTHROLINE THIOCYANATE AND 2,2′-BIPYRIDYL THIOCYANATE COMPLEXES*

(*Received* 21 *June* 1972. *Accepted* 26 *August* 1972)

Komarowski and Poluektoff[1] observed that an acidic solution of molybdenum containing 2,2′-bipyridyl, when reduced with chlorostannous acid, gave a reddish violet colour. Moss *et al.*[2] later observed that the same reaction is given by 1,10-phenanthroline and tried to stabilize the colour of both complexes of reduced molybdenum, but were unsuccessful. They also observed that the phenanthroline reaction was the more sensitive but did not recommend the procedure, because of instability of the colour. Lazarev[3] stabilized the bipyridyl complex by reducing with chlorostannous acid in presence of tartaric acid, the molar absorptivity being $1{\cdot}8 \times 10^3$ $\text{l.mole}^{-1}.\text{cm}^{-1}$ at 520 nm. The phenanthroline complex was studied qualitatively by Rao *et al.*,[4] who also found the molar absorptivity to be $8{\cdot}82 \times 10^3$ $\text{l.mole}^{-1}.\text{cm}^{-1}$ at 565 nm.

It is now found that phenanthroline, bipyridyl and bathophenanthroline form stable complexes with molybdenum(III) in 1,2-dichloroethane in presence of chlorostannous acid and thiocyanate. An acidic solution of molybdenum containing thiocyanate and phenanthroline or bipyridyl is reduced with chlorostannous acid and the resultant precipitate extracted into 1,2-dichloroethane.

EXPERIMENTAL

Reagents

Standard molybdenum solution, 0.01%. Prepared by dissolving MoO_3 (1·5 g) in a few ml of dilute sodium hydroxide solution, diluting to about 100 ml, making slightly acidic with dilute hydrochloric acid and then diluting to 1000 ml. It was diluted to 0.001 and 0.0001% with 0.1*M* hydrochloric acid.

1,10-*Phenanthroline monohydrate solution*, 0·1%.

2,2′-*Bipyridyl solution*. 2,2′-Bipyridyl (1 g) dissolved in the minimum necessary amount of 6*M* hydrochloric acid and diluted to 1000 ml.

Bathophenanthroline (4,7-*diphenyl*-1,10-*phenanthroline*) *solution*, 0·1% *in ethanol*.

Potassium thiocyanate solution, 20%.

Chlorostannous acid solution, 5%. Stannous chloride (20 g) dissolved in 50 ml of concentrated hydrochloric acid and diluted to 400 ml. Metallic tin was added to prevent oxidation during storage.

All other reagents were analytical grade. Water and solvents were redistilled in glass apparatus.

Apparatus

Silver reductor. Prepared according to Vogel.[5]

* Abstracted from a thesis presented by A. K. Bhadra to the University of Calcutta in partial fulfilment of the requirements for the degree of Doctor of Philosophy, 1970.

Procedure

To a solution containing 0·06 mg of molybdenum, 5 ml of phenanthroline or bipyridyl or bathophenanthroline solution, 5 ml of methanol and 2 ml of potassium thiocyanate solution were added. The pH was adjusted to 1·5 and the solution transferred into a separating-funnel, followed by 5 ml of chlorostannous acid. After 1 min, the solution was shaken with 15 ml of 1,2-dichloroethane for about 20 min. The extraction was repeated with 5 ml of 1,2-dichloroethane, with shaking for 3 min. The extracts were collected in a 25-ml flask and diluted to volume with 1,2-dichloroethane. Turbidity was removed by the addition of 0·5 g of anhydrous sodium sulphate. The absorbance of the phenanthroline and bipyridyl complexes was measured at 525 nm and that of the bathophenanthroline complex at 565 nm, against a reagent blank.

When 2,2′-bipyridyl is used, addition of methanol may be omitted. For calibration curves, a 5-10 min equilibration is enough.

RESULTS

The absorption spectra of the ternary complexes are shown in Fig. 1. The molar absorptivities *etc.* are given in Table 1.

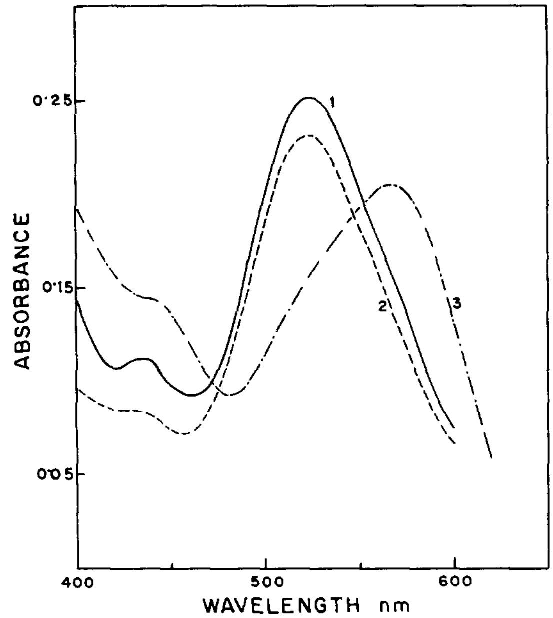

Fig. 1. Absorption spectra of the Mo(III)–1,10-phenanthroline thiocyanate (1), Mo(III)–2,2′-bipyridyl thiocyanate (2), and Mo–bathophenanthroline thiocyanate (3) complexes.

The optimum pH range of the aqueous solution before addition of chlorostannous acid is 1·2–6·5. If the pH is <1·2, the colour of the complexes decreases.

The optimum thiocyanate concentrations in the aqueous phase for the phenanthroline, bipyridyl and bathophenanthroline systems are 0.25–1, 0·25–2, and 0·25–2*M* respectively. Thiocyanate added in excess causes colourless precipitates insoluble in 1,2-dichloroethane.

Effect of methanol

Serious interferences due to phosphorus, tungsten, vanadium, silicon, aluminium *etc.* in the phenanthro-

Table 1. Characteristics of the extracts of the molybdenum(III) complexes

Complex	Solvent	λ_{max} *nm*	Molar absorptivity, *l*.mole^{-1}.cm^{-1}	Sandell sensitivity *μg/cm²*
Mo(III)–phen-thiocyanate	1,2-dichloroethane	525	$9{\cdot}52 \times 10^3$	0·010
Mo(III)–phen-thiocyanate	chloroform	525	$6{\cdot}46 \times 10^3$	0·014
Mo(III)–bipy-thiocyanate	1,2-dichloroethane	525	$8{\cdot}20 \times 10^3$	0·012
Mo(III)–bipy-thiocyanate	chloroform	525	$5{\cdot}88 \times 10^3$	0·016
Mo(III)–bathophen thiocyanate	1,2-dichloroethane	565	$8{\cdot}16 \times 10^3$	0·012

line system can be overcome by addition of methanol to the aqueous solution before addition of chlorostannous acid. The effect is not understood but the addition of methanol is necessary, as the method completely fails in presence of aluminium, tungsten, *etc.* in absence of methanol. With the bipyridyl system, addition of methanol is not necessary.

Two or three drops of the chlorostannous acid solution have been found to be sufficient for reduction of molybdenum. In order to reduce the interference of iron, 2–5 ml of chlorostannous acid solution were used in all cases. A large excess decreases the colour of the complexes.

Beer's law is obeyed over the concentration ranges 1–10 μg/ml, at 525 nm for the phenanthroline and bipyridyl systems, and at 565 nm for the bathophenanthroline complex.

Interference studies

To a solution containing 60 μg of molybdenum, the interfering ions were added, followed by 15 ml of phenanthroline or bipyridyl solution, 2 ml of thiocyanate solution, 5 ml of methanol and 2–3 ml of chlorostannous acid solution and the mixture was extracted with 1,2-dichloroethane, with shaking for about 20 min. A deviation of $<2\%$ was regarded as indicating no interference. The results are summarized in Table 2.

Table 2. Effect of various ions on the phenanthroline and bipyridyl ternary complexes.

Species	Added as	Tolerance limit, *mg*
Fe(III)	$FeNH_4(SO_4)_2{\cdot}12H_2O$	1·2
Al(III)	$Al_2(SO_4)_3{\cdot}18H_2O$	100
W(VI)	$Na_2WO_4{\cdot}2H_2O$	10.0
V(V)	V_2O_5	0·6
PO_4^{-3}	NaH_2PO_4	10.0
Silica	Added after fusion with sodium carbonate	10.0

Nature of the complexes

The oxidation state of molybdenum in the complexes was checked by comparing the complexes with those obtained by reaction of thiocyanate and phenanthroline or bipyridyl with molybdenum reduced to the tervalent state in 6*M* hydrochloric acid in a silver reductor at 60–80°.

Extraction took very much longer to complete (3–4 hr) than when the molybdenum was reduced in presence of the complexing agents. Only with reduction in 6*M* acid medium did the product have the same characteristics as that obtained by the recommended procedure. Reduction in 2 or 4*M* acid gave erratic results and incomplete complex formation. A similar check was not possible for the bathophenanthroline complex, on account of the severe interference from traces of iron(II) produced in the reduction step. No attempt was made to determine the stoichiometry of the complexes.

DISCUSSION

Because of its lower sensitivity and the serious interference from iron, the bathophenanthroline complex was not studied closely. The phenanthroline complex is poorly extracted in presence of interfering substances unless methanol is added before the extraction. The bipyridyl system is superior in this respect though somewhat less sensitive.

Several solvents were tried. In polar solvents, a pink red solution appears within a few minutes of shaking, but on standing the colour changes to yellow. The best solvent proved to be 1 2-dichloroethane .

The extraction is complete in a single pass with 1,2-dichloroethane. A 5-min equilibrium period is sufficient in absence of interfering elements but longer is needed in their presence. A blueish pink colour appears in the organic phase after shaking for a few seconds, and changes to reddish pink after 5–6 min shaking.

Binary complexes of molybdenum formed with phenanthroline, bipyridyl or bathophenanthroline in presence of chlorostannous acid are extractable into 1,2-dichloroethane, but are unstable. The phenanthroline and bipyridyl complexes have λ_{max} at 510–520 nm and the bathophenanthroline complex has λ_{max} at 540 nm. The molar absorptivities are $2{\cdot}72 \times 10^3$, $1{\cdot}8 \times 10^3$ and $3{\cdot}2 \times 10^3$ $1.mole^{-1}.cm^{-1}$ respectively. It is not known whether chlorostannous acid is responsible for the extraction of the molybdenum complexes as in the case of ferroin.[6]

The sequence of addition of reagents is important Colour development is extremely slow when a solution containing molybdenum and thiocyanate is shaken with 1,2-dichloroethane in presence of chlorostannous acid, followed by addition of phenanthroline, or bipyridyl, requiring an equilibration period of 3–4 hr. The yellow organic extract obtained by shaking for about 30 min, if left overnight in presence of the aqueous phase, changes to reddish pink with the correct absorbance. This probably indicates a rearrangement as suggested by Rao *et al.*[4]

We prefer the formula Mo(III)-1,10-phenanthroline$(SCN)_3$ to the MoO-1,10-phenanthroline$(SCN)_3$ suggested by Rao *et al.*,[4] as tervalent molybdenum is involved in the reaction.

Summary—New extraction spectrophotometric methods for the determination of small amounts of molybdenum have been developed, using thiocyanate and 1,10-phenanthroline or 2,2′-bipyridyl as reagents in the presence of chlorostannous acid. Extracts of the ternary complexes of tervalent molybdenum in 1,2-dichloroethane obey Beer's law in the range 1–10 μg/ml at 525 nm. A 10-fold excess of iron and vanadium and 100-fold excess of tungsten, phosphorus and silicate do not interfere.

Zusammenfassung—Neue extraktions-spektrophotometrische Methoden zur Bestimmung kleiner Molybdänmengen wurden entwickelt; sie verwenden Thiocyanat und 1,10-Phenanthrolin oder 2,2′-Bipyridyl als Reagentien in Gegenwart von Chlorozinn(II)-säure. Extrakte der ternären Komplexe von dreiwertigem Molybdän in 1,2-Dichloräthan gehorchen bei 525 nm im Bereich 1–10 μg/ml dem Beerschen Gesetz. Ein 10-facher Überschuß von Eisen und Vanadium und 100-facher Überschuß von Wolfram, Phosphor und Silikat stören nicht.

Summary—Gold was determined in gold-doped germanium by neutron-activation analysis. The irradiated samples were dissolved in *aqua regia*, in the presence of gold carrier. The matrix activity was eliminated by distillation, and gold precipitated in the residue with hydroquinone. The gold fraction was essentially radiochemically pure. For a neutron dose of 5×10^{15}n/cm^2, a sensitivity of 1 ppM Au can be obtained, with a 2·4-g sample. The samples investigated contained from 24 to 36 ppM Au.

Zusammenfassung—Gold in golddosiertem Germanium wurde durch Neutronenaktivierungsanalyse bestimmt. Die bestrahlten Proben wurden in Gegenwart von Goldträger in Königswasser gelöst. Die Matrix-Aktivität wurde durch Destillation entfernt und Gold im Rückstand mit Hydrochinon gefällt. Die Goldfraktion war praktisch radiochemisch rein. Bei einer Neutronendosis von $5 \cdot 10^{15}$ n/cm^2 kann man eine Empfindlichkeit von 1 ppM Au in einer 2·4g-Probe erreichen. Die untersuchten Proben enthielten 24–36 ppM Au.

Résumé—On a dosé l'or dans le germanium dopé à l'or par analyse par activation de neutrons. Les échantillons irradiés ont éte dissous dans l'eau régale, en présence d'or entraîneur. L'activité de la matrice a été éliminée par distillation, et l'or précipité dans le résidue par-l'hydroquinone. Le fraction or était essentiellement radiochimiquement pure. Pour une dose de neutrons de 5×10^{15} n/cm^2, on peut obtenir une sensibilité de 1 ppM de Au avec un échantillon de 2·4 g. Les échantillons étudiés contenaient de 24 à 36 ppM de Au.

ESTIMATION OF ALLYL ALCOHOL BY CHLORAMINE-T

(*Received* 4 *August* 1972. *Accepted* 18 *September* 1972)

Chloramine-T (CAT) has received considerable attention as a mild oxidant for several organic compounds[1,2,3]. Kinetic studies of oxidation reactions involving CAT have recently been reported.[4,5] During an investigation of the kinetics of oxidation of alcohols by CAT, it became necessary to establish the stoichiometry of the reaction. Attempts were made to oxidize several alcohols—isopropyl alcohol, methoxyethanol, glycol, 2,3-butanediol and allyl alcohol—with CAT. With the conditions employed in the present communication, the rate of oxidation was found to be low or almost negligible except for allyl alcohol. Allyl alcohol could be oxidized by CAT at all pH values with a two-electron change and the reaction was fastest and almost instantaneous in hydrochloric acid medium ($0{\cdot}5$–$1{\cdot}0M$). A direct titration of the alcohol with CAT with a visual end-point was not practicable and a back-titration procedure was developed. Allyl alcohol finds a number of industrial applications in the preparation of resins, plasticisers, pharmaceuticals and many organic compounds. A review of the literature shows that allyl alcohol can be estimated by titration with bromide-bromate mixture,[6] potassium dichromate[7] and mercuric acetate.[8] We have thoroughly investigated the oxidation of allyl alcohol by bromide–bromate mixture and found it to be very sluggish and less accurate. The present oxidation procedure with CAT gives a rapid and very accurate method of estimating allyl alcohol, compared with the methods involving other oxidants[7,8] and substantial amounts of the alcohol can be estimated by a proper adjustment of reaction conditions.

EXPERIMENTAL

Reagents

Allyl alcohol (Merck, corrected b.p. 97·1°, $n_{D(20°)} = 1{\cdot}412$) was used without further purification, but its purity was checked by determining the alcoholic hydroxyl group by phthalation with phthalic anhydride in pyridine.[9] The required quantity of the alcohol was accurately weighed and dissolved in the proper solvent to give an approximately $0{\cdot}2M$ solution. CAT was purified by the method of Morris *et al.*[10] An approximately $0{\cdot}1N$ solution was prepared and standardized by the iodometric method. All other reagents were of accepted grades of purity. Phosphate–citric acid buffers[11] were used for the pH range 2–8. Triply distilled water was used for preparing the solutions.

Preliminary studies

Known amounts of allyl alcohol solution in the proper solvent were added to a known excessive volume of CAT in an iodine flask placed in a thermostat at 30°. The reaction mixture was set aside for various intervals of time, with occasional shaking. Then the excess of CAT was determined by back-titration.

Table 1 gives a typical set of results for the extent of oxidation of allyl alcohol in 5 min by an excess of CAT. It is seen that oxidation is slow in media other than $0{\cdot}5$–$1{\cdot}0M$ hydrochloric acid. The rate of oxidation increases as the pH increases from 2·2 to 7·0, but then drastically decreases at pH above 7. However, the stoichiometry is unaffected in these media as the reaction goes to completion after 2–3 hr. The reaction is found stoichiometric and very rapid in $0{\cdot}5$–$1{\cdot}0M$ hydrochloric acid.

Recommended procedure

Prepare an aqueous solution of the allyl alcohol ($\sim 0{\cdot}1M$). Add an aliquot containing 0·1–2·5 mmole to a measured excessive (10–20%) volume of $0{\cdot}1N$ chloramine-T containing enough $2M$ hydrochloric acid to make the overall acid concentration $0{\cdot}5$–$1{\cdot}0M$. Shake the mixture and after a minute add 20 ml of 10% potassium iodide solution and 10 ml of $2N$ sulphuric acid and titrate with $0{\cdot}1N$ sodium thiosulphate. Run a blank with CAT solution alone. The amount (x mg) of allyl alcohol in the experimental solution is given by

$$x = 29y(V_1 - V_2)$$

where y is the normality of the thiosulphate, V_1 is the blank titration and V_2 the volume of thiosulphate used to titrate the excess of CAT after oxidation of the allyl alcohol.

Table 1. Extent of oxidation of allyl alcohol with chloramine-T

Allyl alcohol taken 0.28 mmole; CAT taken 1·93 mmole; time 5 min; temp. 30°C.

RESULTS AND DISCUSSION

Detailed investigation of the allyl alcohol system has brought out the following facts.

(*i*) The stoichiometry of the oxidation can be represented as

$$CH_2{=}CH{-}CH_2OH + RNClNa \longrightarrow CH_2{=}CH{-}CHO + RNH_2 + NaCl,$$

where $R{=}CH_3{-}C_6H_4SO_2$. The presence of allyl aldehyde (acrolein) in the reaction products can be demonstrated with the help of spot tests with sodium nitroprusside solution containing piperidine.[12]

(*ii*) Foreign ions such as K^+, Ba^{2+}, Zn^{2+}, NO_3^-, PO_4^{3-}, ClO_4^- and SO_4^{2-} have no influence on the rate of oxidation in hydrochloric acid medium.

(*iii*) Sodium chloride (up to 0·2 mole) has no effect on the rate of oxidation.

(*iv*) The stoichiometry is unaffected by a reversal of the order of addition of oxidant and allyl alcohol.

(*v*) The reaction rate is greatly retarded in sulphuric and perchloric acid media (*cf.* Table 1), although stoichiometric oxidation is complete within an hour.

The first step in the process of oxidation is thought to be the protonation of the alcohol:

$$CH_2{=}CHCH_2OH + H^+ \longrightarrow CH_2{=}CHCH_2OH_2^+$$

The protonated alcohol may form a highly solvated activated complex with the species present in larger concentration in acidified CAT solution.[13] It is likely that the Cl^- ion will have a greater stabilizing influence on the transition state than the perchlorate and sulphate ions, because of its comparatively smaller size. However, kinetic investigations of the oxidation are in progress which may throw light on the mechanism of oxidation.

Some typical results of analysis of allyl alcohol in aqueous solutions are given in Table 2. The values obtained are accurate within 0·5%.

Summary—A simple but rapid and accurate method for the estimation of allyl alcohol in aqueous solution has been developed, based on its oxidation with chloramine-T at room temperature, in 0·5–1·0*M* hydrochloric acid medium. The reaction involves a two-electron change. The effect of such variables such as pH of the medium, presence of foreign ions and perchloric or sulphuric acid on the rate of oxidation is discussed.

Zusammenfassung—Eine einfache, aber schnelle und genaue Methode zur Bestimmung von Allylalkohol in wäßriger Lösung wurde entwickelt. Sie beruht auf seiner Oxidation mit Chloramin-T bei Zimmertemperatur in 0·5–1·0 M Salzsäure. Bei der Reaktion werden zwei Elektronen umgesetzt. Der Einfluß von Variablen wie pH des Mediums, Anwesenheit von Fremdionen und Überchlor oder Schwefelsäure auf die Geschwindigkeit der Oxidation wird diskutiert.

Résumé—On a élaboré une méthode simple, mais rapide et précise, pour le dosage de l'alcool allylique en solution aqueuse, basée sur son oxydation par la chloramine-T à témpérature ambiante, en milieu acide chlorhydrique 0,5–1,0*M*. La réaction comprend un échange à deux électrons. On discute de l'influence de variables telles que le pH du milieu, la présence d'ions étrangers et d'acide perchlorique ou sulfurique sur la vitesse d'oxydation.

PRECIPITATION OF CALCIUM OXALATE FROM HOMOGENEOUS SOLUTION BY CATION RELEASE

(*Received* 17 *June* 1971. *Revised* 17 *April* 1972. *Accepted* 20 *September* 1972)

Methods for precipitating calcium oxalate have been reviewed by Holth[1] and more recently and comprehensively by Bashar and Townshend.[2] The methods considered by the latter can be divided into three main groups: (*i*) pH change by urea hydrolysis;[3,4] (*ii*) precipitation from acetic acid medium;[5] (*iii*) hydrolysis of esters, such as dimethyl oxalate[6] and diethyl oxalate.[7] The principal criteria used for comparison of the various methods[2] were the ease and completeness of separation from magnesium and the particle-size of the precipitate. These authors concluded that a method involving the addition of urea to a hot clear solution and subsequent hydrolysis was the best.

None of the methods described in the literature, however, gives partial or complete separation of calcium from other metals forming sparingly soluble oxalates, such as lead, copper, zinc, cadmium, mercury, which must therefore be absent during the estimation.

The general technique of precipitation from homogeneous solution by cation release has been reviewed by Cartwright *et al.*[8] whilst more recently various theoretical aspects of predicting the feasibility of such procedures have been studied.[9] The release of complexed cations by means of oxidation with hydrogen peroxide has been employed, for example, in the precipitation of ferric hydroxide,[10] bismuth phosphate[11] and manganese phosphate.[12]

Lead and silver[13] were successfully separated by complexing lead with EDTA whilst precipitating silver as chloride homogeneously by volatilization of ammonia. The effective stability constant of the silver/EDTA complex was lowered as the solution become progressively acid but the lead/EDTA complex remained sufficiently stable to prevent the preciptiation of lead chloride. The precipitation of calcium oxalate by cation release from the EDTA complex should allow at least partial separation of metal ions forming substantially stronger EDTA complexes than calcium does.

This paper describes the precipitation of calcium oxalate by releasing calcium from its EDTA complex by oxidation with hydrogen peroxide, into a solution containing excess of oxalate. The potential usefulness of the technique is exemplified by the separation of calcium from lead.

EXPERIMENTAL

Reagents

All reagents were of analytical grade.

Apparatus

To avoid providing sites for nucleation during precipitation, all experiments were carried out in clean, unscratched beakers; pH measurements were made to ±0·05 with a pH meter.

Establishment of procedure

A constant quantity of calcium (200 mg) was precipitated over a range of pH values between 6 and 10. Calcium chloride hexahydrate (1 g) was dissolved in distilled water (300 ml) and EDTA (1·86 g) was added so as to complex all the calcium. To the solution of the complex 40 ml of 5% ammonium oxalate solution were added and the pH was adjusted to the required level by addition of sodium hydroxide.

The reaction mixture was heated to boiling point and 50 ml of 100-vol hydrogen peroxide were slowly added; boiling was continued with occasional additions of distilled water to compensate for that lost by evaporation. After 60 min a further 15 ml of hydrogen peroxide were added and the solution was boiled for a further 15 min.

The solution was cooled and the precipitate filtered off, washed, and weighed after drying at 110° for 2 hr. The precipitate was confirmed to be calcium oxalate monohydrate by thermogravimetry.

The recovery as a function of pH is shown in Fig. 1, which shows that the optimum pH lies between 6 and 8. Below pH 6 spontaneous precipitation occurs on addition of the ammonium oxalate, whilst above pH 8 the calcium/EDTA complex is too strong to allow complete oxidation of the complex under the experimental conditions.

Variation in quantity of calcium

Experiments were carried out at pH 6–6·5 in which various quantities, nominally 50, 100 and 200 mg, of calcium were precipitated. The results obtained are summarized in Table 1, where it can be seen that the precipitation is quantitative. The reaction solutions were tested for completeness of precipitation by determining the remaining quantity of calcium by flame photometry. The maximum amount of residual calcium was <2ppm (equivalent to <0·6 mg in 300 ml).

Table 1. Precipitation of calcium oxalate—variation in amount of calcium

Calcium chloride, *g*	Calcium, *g*	Wt. of ppte, *g*	Ca found, *g*	Recovery, %
0·2500	0·0456	0·1695	0·0458	100·5
0·5020	0·0916	0·3366	0·0918	100·1
1·0020	0·1825	0·6720	0·1835	100·5

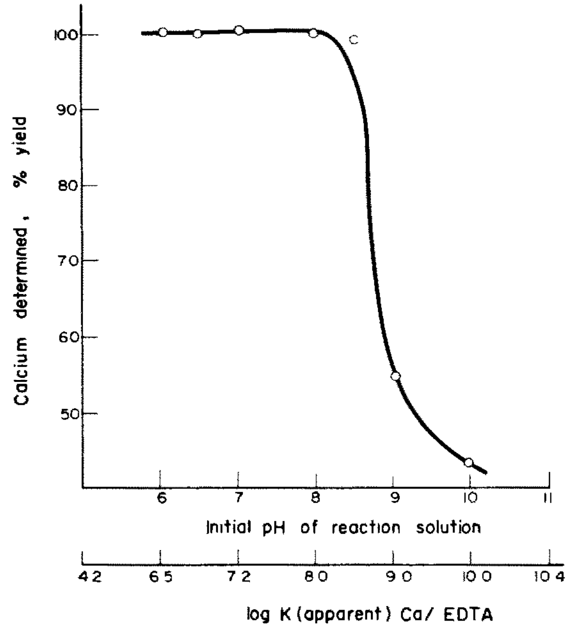

Fig. 1. Effect of initial pH on precipitation of calcium oxalate.

Crystal size

The crystals obtained were examined microscopically and the size of the precipitate particles was found to be 11–25 μm, mean 16 μm.

The urea-hydrolysis method yields larger crystals than the cation-release method but there is a limit beyond which increase in crystal size provides no further practical advantage. The precipitate obtained by the oxidative (cation-release) method settles quickly and is easily filterable.

Separation of calcium from lead

The potential usefulness of the cation-release technique is exemplified by separation of calcium from lead.

To a solution containing *ca.* 200 mg of calcium and *ca.* 100 mg of lead sufficient EDTA was added to complex both metals. The solution was adjusted to pH 8·8, in the presence of excess ammonium oxalate, and heated to boiling point; then 50 ml of 100-vol hydrogen peroxide were added. After 60 min of boiling a further 15 ml of peroxide were added and the solution was boiled for another 60 min, by which time the pH had dropped to about 7·8.

The reaction mixture was cooled and filtered, and the precipitate was washed, dried and weighed. The precipitate was dissolved and tested for lead with chromate. The precipitation of calcium was found to be quantitative and lead was found to be absent.

At similar pH values the calcium/EDTA complex is far more readily oxidized than the lead complex, as would be expected from their respective stability constants, $\log K_{\mathrm{CaY}} = 10{\cdot}7$, $\log K_{\mathrm{DbY}} = 18{\cdot}0$; the separation relies upon this difference in stability. It has been demonstrated that the calcium complex can be oxidized at pH 8 whereas the lead complex is not attacked at pH 6. Nevertheless in order to give the greatest margin of safety in the experimental procedure a higher pH was selected for the separation than when calcium alone was precipitated.

CONCLUSIONS

The homogeneous precipitation of calcium oxalate by cation release from the calcium/EDTA complex in the presence of oxalate is quantitative. The method also provides a means of separating calcium from lead and other metals forming sparingly soluble oxalates. Under the conditions of the experiments in which calcium and lead were separated the conditional stability constants of the calcium and lead/EDTA complexes were $\log K = 8{\cdot}8$ and $15{\cdot}5$, respectively. The fact that the reaction proceeds more quickly in the absence of lead is attributed to the difference in the pH used, 6·0–6·5 instead of pH 8.

Summary—Calcium oxalate can be precipitated from homogeneous solution by oxidation of the calcium/EDTA complex with hydrogen peroxide in boiling solution, in the presence of oxalate ion, at pH 6–8. The method gives large crystals and enables calcium to be determined in the presence of lead, which remains complexed.

Zusammenfassung—Calciumoxalat kann durch Oxidation des Calcium-EDTA-Komplexes mit Wasserstoffperoxid in siedender Lösung bei pH 6–8 aus homogener Lösung gefällt werden. Das Verfahren liefert große Kristalle und erlaubt die Bestimmung von Calcium auch in Gegenwart von Blei, das komplex gebunden bleibt.

Résumé—On peut précipiter l'oxalate de calcium d'une solution homogène par oxydation du complexe calcium/EDTA, en la présence d'ion oxalate, par le peroxyde d'hydrogène en solution bouillante, à pH 6–8. La méthode donne de grands cristaux et rend possible la détermination du calcium en la présence de plomb, qui reste complexé.

ANALYTICAL DATA

FORMATION OF FERROCYANIDES—III*
Fe(III), La(III) and Ce(III)

(*Received* 25 *July* 1972. *Accepted* 12 *September* 1972)

The composition of the hexacyanoferrates(II) of tervalent metals is given by the general formulae $\mathrm{KMFe(CN)_6}$ and $\mathrm{M_4[Fe(CN)_6]_3}$.[1–6] The reaction between $\mathrm{K_4Fe(CN)_6}$ and La(III) or Ce(III) may be used for the direct or indirect determination of these two cations.[3–8] Our work[9–12] on the formation of hexacyanoferrates(II) therefore has been extended to Fe(III), La(III) and Ce(III).

The K_{sp} values as a function of ionic strength, temperature and solvent medium have also been evaluated.

EXPERIMENTAL

Potentiometric titrations were done with the cell

$$\mathrm{Pt}\left|\begin{matrix}\mathrm{Fe(CN)_6^{4-}} & \\ \mathrm{Fe(CN)_6^{3-}} & 10^{-6}M\end{matrix}\right\|\ \text{satd. } \mathrm{KNO_3}\ \Big\|\ \text{S.C.E.}$$

The $\mathrm{K_4Fe(CN)_6}$ solution was kept in dark bottles and standardized by potentiometric titration with Zn(II) solution under the analytical conditions for formation of $\mathrm{K_2Zn_3[Fe(CN)_6]_2}$.[9] The 0·01*M* nitric acid solutions of the nitrates of Fe(III), La(III) and Ce(III) were standardized gravimetrically, Fe(III) by means of ammonia and La(III) and Ce(III) by means of ammonium oxalate.[13].

RESULTS AND DISCUSSION

System $\mathrm{Fe(NO_3)_3}$–$\mathrm{K_4Fe(CN)_6}$–$\mathrm{H_2O}$

To avoid iron hydrolysis a 2*M* nitric acid medium was used. Higher acidity slows the reaction and causes dissociation of ferrocyanide and the precipitate, thus introducing uncontrollable variables.

Our results indicate that $\mathrm{Fe_4[Fe(CN)_6]_3}$ is formed irrespective of the direction of titration over the ranges pFe(III) = 1·7–3·76 and $\mathrm{pFe(CN)_6^{4-}}$ = 1·6–2·6. This formulation is in agreement with the infrared[14] and electronic[15] spectra. The potential drop at the equivalence point was 200–250 mV.

The precipitate, obtainable only at high Fe(III) concentrations, was spongy; only a blue colour was observed at low Fe(III) concentrations.

The same result was observed when 0·5*M* potassium nitrate medium was used.

System $\mathrm{La(NO_3)_3}$–$\mathrm{K_4Fe(CN)_6}$–$\mathrm{H_2O}$

Only the white $\mathrm{KLaFe(CN)_6}$ is obtained. The concentration ranges investigated were pLa(III) = 1·8–3·3 and $\mathrm{pFe(CN)_6^{4-}}$ = 1·95–3·96 respectively. The potential drop at the equivalence point was 70–90 mV, and 90–110 in 0·5*M* $\mathrm{KNO_3}$ medium. At room temperature the reaction is very slow; temperature of 70° was used. The product was found to be thermally stable.

System $\mathrm{Ce(NO_3)_3}$–$\mathrm{K_4Fe(CN)_6}$–$\mathrm{H_2O}$

This is similar to the lanthanum system but the potential drop at the equivalence point is about 10 mV greater and the reaction rate fast enough at room temperature. At 45° $\mathrm{KCeFe(CN)_6}$ undergoes rapid thermal decomposition but it is stable enough at 35° to permit determination of the K_{sp} value. The lowest concentrations titrated were pCe(III) = 3·23 and $\mathrm{pFe(CN)_6^{4-}}$ = 2·9.

---

* Presented at the 2nd International Symposium on Analytical Chemistry, Ljubljana (Yugoslavia) 12–17 June 1972. Supported by the Consiglio Nazionale delle Ricerche.

Table 1 summarizes the results of a number of titrations.

K_{sp} *values and thermodynamic properties*

K_{sp} values were obtained by means of measurements of the potential of a Pt electrode at constant temperature, at ionic strength from 0·22 to 0·66, obtained by addition of potassium nitrate.

The pK_{sp} values are linear functions of the ionic strength, slopes being as follows:

	T, °*C*	70	60	50	40
$KLaFe(CN)_6$	tan α	−1·93	−1·5	−1·95	−1·85

	T, °*C*	20	25	30
$KCeFe(CN)_6$	tan α	−1·90	−1·60	−1·88

Table 2 summarizes the thermodynamic values. $\Delta G°$ decreases linearly with temperature for both compounds. $\Delta H°$ and $\Delta S°$ being constant over the temperature range investigated.

Table 2. K_{sp} and thermodynamic data for $KLaFe(CN)_6$ and $KCeFe(CN)_6$ in H_2O.

Formula	*T*, °*C*	pK_{sp}	$\Delta G°$, *kcal/mole*	$\Delta H°$, *kcal/mole*	$\Delta S°$, *kcal. mole*$^{-1}$. *deg*$^{-1}$
$KLaFe(CN)_6$	70	8·8	−13 82	2·64	0·048
	60	8·7 ± 0·1	−13·25	2·73	
	50	8·7	−12·86	2·64	
	40	8·65	−12·38	2·64	
$KCeFe(CN)_6$	30	9·3	−12·90	4·07	0·056
	25	9·25	−12·62	4·07	
	20	9·2	−12·34	4·07	

Because interionic electrostatic effects may become significant on account of the high ionic charges, the influence of the dielectric constant was evaluated by means of measurements in aqueous ethanolic solutions. Linear dependence of pK_{sp} on ionic strength was again observed (Table 3).

Table 3. K_{sp} and thermodynamic data for $KLaFe(CN)_6$ and $KCeFe(CN)_6$ in H_2O–EtOH

		25	11·25	−15·34			3·36

CONCLUSIONS

The analytical behaviour of the systems investigated is particularly simple, the same complex being always produced however the reaction is carried out. The reaction of Fe(III), La(III) or Ce(III) with $Fe(CN)_6^{4-}$ can be used for potentiometric determination of either the cations or the anion, if not too high an accuracy is required.

Addition of potassium nitrate has no quantitative effect on the reaction between $Fe(CN)_6^{4-}$ and La(III) or Ce(III) because it acts in two opposing ways: it lowers the solubility by the common ion effect, but at the same time K_{sp} increases with the increased ionic strength. The solubility of the La(III) and Ce(III) compounds is higher than that for similar complexes of bivalent metals.[10–12] The positive enthalpy change shows the prevalence of strong electrostatic repulsion effects. The formation of $KLaFe(CN)_6$ and $KCeFe(CN)_6$ is due to the favourable change in entropy.

With ethanolic media both the enthalpy and entropy changes are approximately linear functions of the ethanol concentration, but the slope for $T\Delta S°$ is greater than that for $\Delta H°$, so $\Delta G°$ becomes more negative with increasing ethanol concentration.

DISTRIBUTION COEFFICIENTS OF Rb^+ ON ZIRCONIUM PHOSPHATE IN MIXED AQUEOUS-ORGANIC MEDIA

(*Received* 4 *August* 1972. *Accepted* 17 *September* 1972)

The selectivity of cation-exchangers in mixed aqueous-organic solvents has been and is the subject of much study. Research has been nearly exclusively concerned with resin exchangers. To have a better understanding of the phenomena involved it seemed interesting to collect distribution coefficient data for cation-exchangers of a different type such as inorganic or cellulose ion-exchangers for non-complexed cations. This note summarizes the results obtained for the distribution of Rb^+ between zirconium phosphate and mixed solvents containing hydrochloric acid.

EXPERIMENTAL

Materials

Bio Rad ZP-1 cation-exchange crystals 50–100 mesh. All solvents were *pro analysi* products.

Procedure

The weight distribution coefficient, K_D, was determined at 25° after equilibration for 24 hr with ^{86}Rb. The hydrochloric acid concentration was kept constant at $0.85M$. Volume contraction effects were minimized by premixing of the solvent, hydrochloric acid and isotope solution before addition to the exchanger. The weight of zirconium phosphate was 200 mg, and 0·1–1 μg of rubidium was used.

RESULTS

The results are summarized in Table I. All values are the mean of at least two determinations. Reproducible results were obtained except in dimethylformamide in the 32–64% range.

An interpretation of the results is not possible at this stage. However, it can be noted here that the curves show in general the same trend on zirconium phosphate as on Dowex 50 resin except for dimethylsulphoxide, dimethylformamide and to a lesser extent, acetic acid.[1] For sulpholane no data on Dowex 50 are available.

POTENTIOMETRIC DETERMINATION OF STEPWISE STABILITY CONSTANTS OF ZIRCONIUM, THORIUM AND URANIUM CHELATES OF ASPARAGINE AND GLUTAMINE

(*Received* 18 *September* 1972. *Accepted* 4 *October* 1972)

In an earlier communication,[1] stepwise stability constants of the chelates of V(IV), Mo(VI) and W(VI) with asparagine and glutamine were reported. This paper gives the results of a similar study with Zr(IV), Th(IV) and U(VI).

RESULTS AND DISCUSSION

In all these systems precipitation occurs around pH 5–6. So $\bar{n}$ calculations were done only up to the beginning of precipitation. Under these conditions $\bar{n}$ approaches a value of 3 in the case of thorium, 2 for uranium, but approaches only 1.6 for zirconium. Thus K_1, K_2 and K_3 can be computed for thorium chelates, and only K_1 and K_2 for zirconium and uranium. For the zirconium chelates $K_1/K_2 \sim 10^{2\cdot6}$, so K_1 and K_2 were computed by the half-$\bar{n}$ method, and further confirmed by the correction term and successive approximation methods. For uranium $K_1/K_2 \sim 10^{0\cdot9}$, so the correction term and successive approximation methods were used. For thorium $K_1/K_2 \sim 10^{0\cdot7}$ and $K_2/K_3 \sim 10^{0\cdot5}$; so approximate constants were obtained by interpolation at half-$\bar{n}$ values and refined by successive approximation.

Table 1. Stability constants of zirconium(IV), uranium(VI) and thorium(IV) chelates formed with asparagine and glutamine (Temp. 25°C, $\mu = 0\cdot1M$ $NaClO_4$).

Metal ion	pH range for $\bar{n}$ calculations	Method	Asparagine			Glutamine		
			log K_1	log K_2	log K_3	log K_1	log K_2	log K_3
Zr(IV)	2·6–5·5	Half-$\bar{n}$	8·80	6·25	—	8·75	6·10	—
		Correction term	8·76	6·28	—	8·75	6·09	—
		Successive approximation	8·80	6·25	—	8·75	6·10	—
U(VI)	4·0–6·0	Half-$\bar{n}$	6·95	6·00	—	6·85	6·00	—
		Correction term	6·73	6·19	—	6·62	6·22	—
		Successive approximation	6·79	6·16	—	6·63	6·22	—
Th(IV)	2·7–5·0	Half-$\bar{n}$	8·50	7·85	7·40	8·45	7·70	7·20
		Successive approximation	8·28	7·77	7·72	8·30	7·61	7·55

SEPARATION AND QUANTITATIVE DETERMINATION OF THE CERIUM GROUP LANTHANIDES BY GAS–LIQUID CHROMATOGRAPHY

CHARLES A. BURGETT* and JAMES S. FRITZ
Ames Laboratory, USAEC, Department of Chemistry
Iowa State University, Ames, Iowa, U.S.A.

(*Received* 10 *August* 1972, *Accepted* 2 *September* 1972)

Summary—A gas chromatographic method is reported for the separation and subsequent quantitative determination of the cerium group lanthanides. The lanthanides (RE) are synergistically extracted from aqueous solution with the polyfluorinated β-diketone 1,1,1,2,2,6,6,7,7,7-decafluoro-3,5-heptanedione, H(FHD), as ligand, and di-n-butylsulphoxide, DBSO, as neutral donor. The composition of the extracted species is reported to be $RE(FHD)_3 \cdot 2DBSO$. Thermogravimetric analysis of the complexes is reported. Analytical curves were prepared and found to be usable over the range of 0·1–10 μg of metal. Individual lanthanides were determined with 99·0% recovery with a relative mean deviation of ±2·0%. Mixtures of lanthanides were analyzed with 101·2% recovery with a relative mean deviation of ±2·2%.

Considerable interest has been shown in the use of β-diketonates for gas chromatography of rare earths. Chelates of the rare earths with 2,2,6,6-tetramethyl-3,5-heptanedione[1] and 1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-octanedione[2] have been chromatographed. Rare earth chelates have also been prepared with 1,1,1-trifluoro-5,5-dimethyl-2,4-hexanedione;[3,4] however, thermogravimetric analysis indicated decomposition of many of the complexes. In all these instances solid anhydrous chelates were prepared and dissolved in a suitable solvent before injection into the chromatograph. This type of preparation is unsuitable for quantitative formation of metal complexes in the organic phase.

Generally the chelates of the rare earths form hydrated complexes which are poorly extracted. Mitchell[5] has recently reported the successful extraction of lanthanides by using synergistic extraction systems of fluorinated β-diketones and various neutral donors. Butts and Banks[6] reported the use of these mixed-ligand systems for gas chromatography. Recently Sieck has completed a detailed study of several mixed-ligand systems.[7] Although the chelates of individual rare earths were chromatographed, separation of rare earth mixtures were not achieved and quantitative analysis were not reported. Earlier Burgett and Fritz[8] reported the successful gas chromatographic separation and quantitative determination of the yttrium group lanthanides as mixed-ligand complexes with 1,1,1,2,2,6,6,7,7,7-decafluoro-3,5-heptanedione, H(FHD), and di-n-butylsulphoxide, DBSO.

This paper describes the preparation of volatile mixed-ligand complexes of the cerium group lanthanides by synergistic solvent extraction with H(FHD) and DBSO. These complexes are subsequently separated and quantitatively determined by gas chromatography. The solvent extraction effectively separates the lanthanides from major interferences and allows rapid preparation of the volatile species.

EXPERIMENTAL

Instrumentation

A Hewlett–Packard Model 5756B gas chromatograph, equipped with a flame-ionization detector was used. A Hewlett–Packard Model 7128 A strip-chart recorder was used for development work, and a 1-mV Bristol recorder equipped with a Disc Integrator, Model 202, was used for the quantitative studies. Helium was used as the carrier gas, and stainless-steel tubing was used for all columns and the injection port liner. The following instrument operating conditions were used in the analyses: column, stainless steel, 20 × 0·25 in. o.d., packed with 6·46% Dexsil 300 GC (Analabs) on Chromosorb W (100/120 mesh); column temperature was held at 172° for 3 min then programmed to increase to 215° at 6°/min; helium flow was 50 ml/min, air pressure 33 psig, hydrogen pressure 8 psig, injection port temperature 280°, flame-ionization detector temperature 290°.

A DuPont Model 950 Thermogravimetric Analyzer was used to obtain all TG curves. A programmed heating rate (10°/min) was used with a nitrogen gas atmosphere with a flow-rate of 10 ml/min.

Reagents

The ligand 1,1,1,2,2,6,6,7,7,7-decafluoro-3,5-heptanedione was prepared by a Claisen condensation of ethyl pentafluoropropionate with 3,3,4,4,4-pentafluoro-2-butanone as described previously.[8] Di-n-butylsulphoxide was obtained from Aldrich Chemical Company, and was used after recrystallization from low-boiling petroleum ether. Rare earth oxides of 99·9% purity were prepared by ion-exchange at this laboratory. All other chemicals were reagent grade or better.

Solvent extraction procedure

Rare earth stock solutions were prepared by dissolving the rare earth oxide in hot 1*M* hydrochloric acid, evaporating to near dryness and diluting to volume with pH 5·5 acetate buffer. The solutions were standardized by titration with EDTA, Xylenol Orange being used as the indicator.[9] The stock solutions were approximately 0·1*M* and appropriate dilutions were made to span the concentration range desired. Solvent extractions were performed in 15-ml screw-cap glass test-tubes. The inside lining of the screw tops was replaced with a Teflon disk to prevent any interaction with the plastic top. Shaking times of 30 min were used although equilibrium was established in 15 min, as determined by spectrophotometric analysis of the organic phase.

The samples were prepared by contacting 1·00 ml of the aqueous solution with 1·00 ml of cyclohexane containing β-diketone in an amount equivalent to three times the total metal concentration of the most concentrated sample, and neutral donor in an amount equivalent to twice the total metal concentration of the most concentrated sample. After equilibrium was established by shaking, the samples were washed with 1·0*M* sodium hydroxide to remove excess of H(FHD). Samples were withdrawn from the cyclohexane phase by syringe and injected into the gas chromatograph.

The composition of the extracted species was shown to be $RE(FHD)_3 \cdot 2DBSO$ by infrared analysis.[7] Here Re represents the rare earth metal, FHD represents the ligand anion and DBSO the donor di-n-butylsulphoxide. Analytical results for the mixed-ligand complexes are shown in Table 1.

Table 1. Analytical results for cerium group mixed-ligand complexes.

	Metal, %		Carbon, %		Hydrogen, %	
	Calcd.	Found	Calcd.	Found	Calcd.	Found
$La(FHD)_3 \cdot 2DBSO$	10·01	10·1	32·03	32·1	2·83	2·8
$Ce(FHD)_3 \cdot 2DBSO$	10·09	10·1	32·00	32·0	2·83	2·8
$Nd(FHD)_3 \cdot 2DBSO$	10·35	10·4	31·91	31·0	2·82	2·8
$Sm(FHD)_3 \cdot 2DBSO$	10·75	10·8	31·76	31·7	2·81	2·0
$Eu(FHD)_3 \cdot 2DBSO$	10·85	10·8	31·73	31·7	2·81	2·0

Preparation of calibration curves

Standard solutions were prepared over the concentration range of approximately 0·1–15 μg of rare earth. In each case 3–5 separate 1·60-μl samples of the rare earth complexes were injected into the gas chromatograph and the average of the area under the peak, as determined by the disc integrator, was plotted *vs.* sample concentration. The calibration curves were obtained by using the flame-ionization detector and found to be invariant over a period of one month. Calibration curves for use in the determination of mixtures of rare earths were prepared by the same method as above, using stock solutions of rare earths in 1 : 1 ratio. This procedure was followed to correct for any peak overlap.

Gas chromatographic columns

No evidence of metal exchange, reaction and or decomposition of the metal chelates on the hot metal surface of the stainless-steel column was observed. The column packing was prepared by placing 5 g of dry solid support in a 2 × 10 in. cylindrical tube fitted with a glass frit. A solution of Dexsil 300 GC in 56 ml of benzene was poured into the tube and mixed with the support. The excess of solution was drained from the support through a stop-cock below the glass frit. Filtered air was passed through the packing while heat was applied by infrared lamps. After drying, the packing was placed in the stainless-steel columns and packed by vibrating the sides of the column. The packed columns were conditioned for 2 hr at 180° then overnight at 300° before use.

RESULTS AND DISCUSSION

Thermogravimetric studies

Thermogravimetric results for the mixed-ligand complexes of the cerium group lanthanides are shown in Fig. 1, and indicate complete volatilization without decomposition.

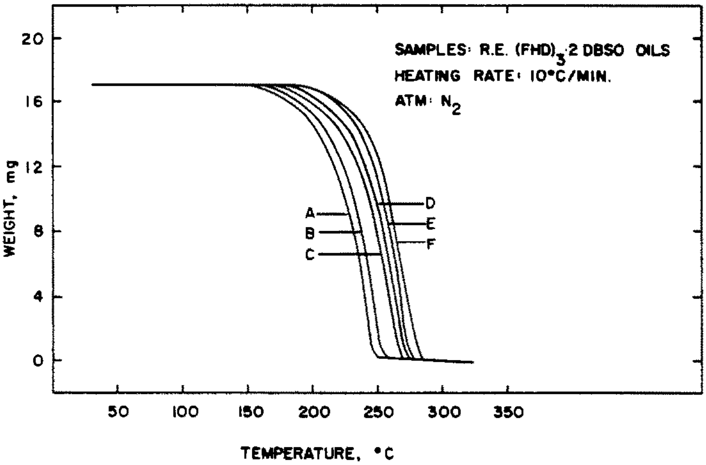

Fig. 1. TG curves for mixed-ligand complexes of the lanthanides with H(FHD) and DBSO. *A*–Eu(FHD)$_3$·2DBSO; *B*–Sm(FHD)$_3$·2DBSO; *C*–Nd(FHD)$_3$·2DBSO; *D*–Pr(FHD)$_3$·2DBSO; *E*–Ce(FHD)$_3$·2DBSO; *F*–La(FHD)$_3$·2DBSO.

Previously[1-5] complexes of several of these lanthanides have been found to decompose on volatilization. Examination of the temperature at the mid-point of weight loss shows significant differences in volatility for the mixed-ligand complexes with DBSO.

The heavier rare earths were found to be volatilized at lower temperature than their lighter neighbours. This difference in volatility can be correlated with the ionic radius of the tervalent lanthanides.[1]

Stationary phase

The selection of the liquid phase depends on two factors. The liquid must have high thermal stability so that column bleed at the temperatures required for elution of the rare earth complexes is avoided, and it must not interact irreversibly with the chelates being eluted.

Previously[8] we found the liquid phase Dexsil 300 GC useful in the gas chromatographic determination of mixed-ligand complexes. Columns prepared with Dexsil 300 GC as the liquid phase gave excellent results with the mixed-ligand complexes of the lanthanides. No prior conditioning of the columns by sample injection was required to obtain reproducible results. The mixed-ligand complexes were found to partition significantly into the Dexsil 300 GC, resulting in excellent separation of the lanthanides.

Separation of the lanthanides

All the lanthanides were found to be satisfactorily eluted from a 20 by 0.25 in. 6·46% Dexsil 300 GC column at 200°. To obtain separations it was necessary to employ various temperature programmes, *e.g.*, a 3-min hold at 172°, then a linear increase at 6°C/min. With this column and the appropriate temperature programme, excellent separations were achieved as shown in Fig. 2. The separation is complete and the peaks suitable for integration and quantitative analysis. Figure 3 illustrates the quantitative resolutions of a mixture of lanthanide metals having even atomic numbers, these being the lanthanides commonly existing in ores (on account of the alternating abundances); therefore analytical separations onthis basis are of practical utility. The peak shapes are very sharp for samples at the 0·2–20 μg metal level, but the peak is cigar-shaped at higher concentrations. This peak distortion is an indication of column overload and limits the concentration that can be used.

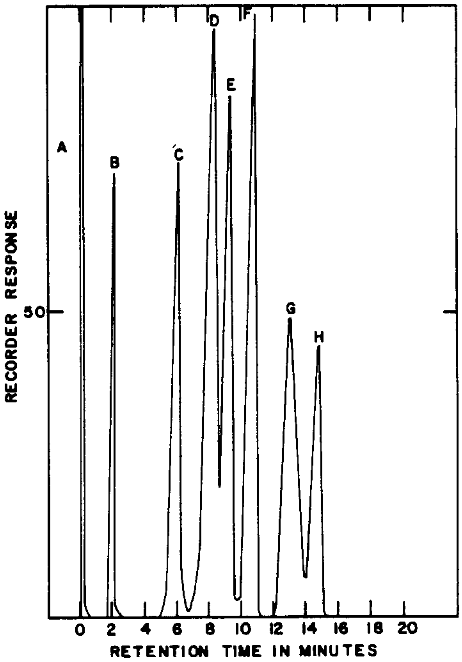

Fig. 2. Gas chromatogram of a mixture of FHD and DBSO mixed complexes of Yb, Er, Dy, Gd, Nd and Ce.
Column as described in text; 4-min hold at 172°C, temperature increase 4°/min.
A–Cycloxhexane H(FHD); *B*–DBSO; *C*–$Yb(FHD)_3 \cdot 2DBSO$; *D*–$Er(FHD)_3 \cdot 2DBSO$; *E*–$Dy(FHD)_3 \cdot 2DBSO$; *F*–$Gd(FHD)_3 \cdot 2DBSO$; *G*–$Nd(FHD)_3 \cdot 2DBSO$; *H*–$Ce(FHD)_3 \cdot 2DBSO$.

In all studies the composition of eluted species was verified by collection of eluates and subsequent infrared and fluorescence analysis. The complexes of each metal were found to be eluted without decomposition.

Quantitative studies

Calibration curves were prepared for the individual lanthanides. The curves were linear over the concentration range 0·2–15 μg of metal. Unknowns were prepared by the same

extraction procedure as the standards. To eliminate excess of ligand from each extract, a few ml of 0·1*M* sodium hydroxide were added. The H(FHD) then forms the insoluble white sodium salt. Results for the determination of the individual lanthanides, by means of the analytical curves, are presented in Table 2. The individual lanthanides were determined

Table 2. Determination of the individual lanthanides as H(FHD)–DBSO mixed ligand complexes.

Rare earth	Taken, μg	Found, μg	Relative error, %
Eu	6·38	6·35	−0·5
	3·41	3·44	+0·9
Sm	5·87	5·80	−1·2
	4·44	4·35	−2·0
Pr	4·97	5.04	+1·4
	1·26	1·31	+4·0
Nd	3·24	3·20	−1·2
	5·72	5·66	−1·0
Ce	5·18	5·04	−2·7
	3·16	3·10	−1·9
La	4·46	4·08	−4·9
	6·47	6·30	−2·6

with 99·0% recovery with a relative mean deviation of ±2·0%.

The analytical curves do not extrapolate to zero but to 0·18 μg at zero response. This is undoubtedly a result of a finite loss of sample to the column material. Analyses of "unknown" solutions of rare earth mixtures are shown in Table 3. The lanthanides were determined with 101·2% recovery and a relative mean deviation of ±2·2%.

Table 3. Analysis of mixed-rare earth solutions *via* the H(FHD)–DBSO mixed-ligand complexes.

Mixture	Taken, *μg*	Found, *μg*	Relative error, %
Eu	10·10	10·10	0·0
Nd	7·05	7·39	+4·8
Sm	2·93	2·96	+1·0
Ce	2·79	2·76	−1·1

Detection limits were determined for all the rare earths tested. The detection limit was taken to be that amount of mixed-ligand complex necessary to give a chromatographic peak response equal to or greater than twice the background response. The detection limit observed was 0·20 μg of metal for each of the rare earths.

The response to the flame-ionization detector was found to vary from metal to metal, as shown in Table 4. The variation in response is probably caused by differences in the combustion of each metal. The extreme enhancement observed with the samarium complex limits the usefulness of the method for determining mixtures containing samarium. The detector readily becomes swamped and may not observe the lower signal from neighbouring metal chelates.

Table 4. Response factors for the flame-ionization detector.

Compound	Response factor 10^{-5} × *integration count/μg*
$La(FHD)_3 \cdot 2DBSO$	0·28
$Ce(FHD)_3 \cdot 2DBSO$	3·15
$Pr(FHD)_3 \cdot 2DBSO$	1·11

$Sm(FHD)_3 \cdot 2DBSO$	22·70
$Eu(FHD)_3 \cdot 2DBSO$	4·29

Calculated from slope of area *vs.* concentration plots.

Interferences

The extraction system was found to be useful in separating the lanthanides from calcium, scandium, iron(III), aluminium, uranyl and thorium. Calcium and scandium were not extracted at pH 5·5. Iron and uranium were extracted but were removed by washing the extract with 0·1*M* sodium hydroxide. Aluminum and thorium did not interfere with the determination of the lanthanides.

The yttrium group lanthanides also form complexes with the (FHD)–DBSO system and have been quantitatively determined.[8] The retention time of the yttrium group lanthanides is shorter than that of the cerium group rare earths and, as shown in Fig. 3, they offer no interference.

Yttrium is also extracted as the mixed-ligand complex, $Y(FHD)_3 \cdot 2DBSO$. The complex is thermally stable and can be chromatographed. The yttrium complex can be separated from all of the cerium group elements and quantitatively determined: its retention time is similar to that of holmium.

CONCLUSIONS

An efficient method for the determination of the lanthanides as the mixed-ligand complexes with H(FHD) and DBSO has been developed. This determination offers the first successful gas chromatographic separation and quantitative determination of the cerium group lanthanides. The synergistic extraction system renders the analysis virtually free from interferences and allows the first rapid preparation of volatile and thermally stable cerium group lanthanide chelates.

Zusammenfassung—Eine gaschromatographische Methode zur Trennung und anschließenden quantitativen Bestimmung der Lanthaniden der Cergruppe wird angegeben. Die Lanthaniden (RE) werden aus wäßriger Lösung mit dem mehrfach fluorierten β-Diketon 1,1,1,2,2,6,6,7,7,7-Dekafluoro-3,5-heptandion H(FHD) als Ligand und Di-*n*-butylsulfoxid DBSO als neutralem Donor synergistisch extrahiert. Die Zusammensetzung der extrahierten Spezies wird als $RE(FHD)_3 \cdot 2DBSO$ angegeben. Die Ergebnisse der thermogravimetrischen Untersuchung der Komplexe werden mitgeteilt. Analytische Kurven wurden aufgezeichnet und im Bereich 0·1–10 μg Metall benutzbar genfunden. Einheitliche Lanthaniden wurden mit 99,0% Ausbeute und einer relativen Standardabweichung von ±2·0% bestimmt. Gemische von Lanthaniden wurden mit einer Ausbeute von 101·2% und einer relativen Standardabweichung von ±2·2% analysiert.

Résumé—On décrit une méthode chromatographique en phase gazeuse pour la séparation et le dosage quantitatif subséquent des lanthanides du groupe du cérium. On extrait les lantanides (RE) de manière synergique de la solution aqueuse avec la β-dicétone polyfluorée 1,1,1,2,2,6,6,-7,7,7-décafluoro 3,5-heptanedione, H(FHD), comme coordinat, et le di-*n*-butylsulfoxyde, DBSO, comme donneur neutre. La composition de l'espece extraite est donnée comme étant RE $(FHD)_3$, 2DBSO. On rapporte l'analyse thermogravimétrique des complexes. On a établi des courbes analytiques, et les a trouvées utilisables dans le domain 0,1–10 μg de métal. On a dosé les lanthanides individuels avec une récupération de 99,0% et un écart relatif moyen de ±2,0 %. On a analysé des mélanges de lanthanides avec une récupération de 101,2 % et un écart relatif moyen de ±2,2 %.

COULOMETRIC TITRATION OF ACIDS IN ISOPROPANOL—II

ELECTRODE REACTIONS WITH LITHIUM CHLORIDE AND TETRAETHYLAMMONIUM BROMIDE AS SUPPORTING ELECTROLYTES

Summary—Cathodic reactions in methanol and isopropanol have been investigated in the presence of both lithium chloride and tetraethylammonium bromide as supporting electrolytes. A side-reaction in lithium chloride medium leads to the formation of insoluble lithium hydroxide but base is generated stoichiometrically in tetraethylammonium bromide by reduction of solvent, oxygen and traces of water. Tetraethylammonium bromide is recommended as supporting electrolyte for the coulometric titration of acids in isopropanol.

The advantages of coulometric titration of acids in non-aqueous solvents have been well documented.[1] Because protolysis constants are lower in many non-aqueous solvents than in aqueous solutions, weak acids can be titrated in these media with much sharper end-points. Coulometric titrations in such media eliminate the preparation and standardization of the often expensive titrants necessary for volumetric titrations. Coulometric titration of acids has been accomplished in various solvents such as 70% aqueous isopropyl alcohol,[2] isopropyl alcohol,[3,4] isopropyl alcohol–methyl ethyl ketone (1:1 v/v)[3], acetone containing 0·5% methanol,[5] acetone[6,7] and t-butyl alcohol.[6,8] Several authors[2,9,10] have found it necessary to add water to the organic solvents in order to generate alkali with 100% current efficiency, but in general this is a disadvantage as it often reduces the sharpness of the end-point[3,5] and the solubility of the sample.

There are two difficulties with regard to the application of coulometric titrations in non-aqueous solvents. First the resistance of the solution is much higher than that of aqueous solutions, and most commercial constant-current generators, which are low-voltage sources, do not give constant currents under these conditions. In this situation, the analytical result is not obtained from a simple interpolation of the time for which a fixed current is passed. This may be overcome by current integration[3,5] or by the design of a suitable high-voltage constant-current source.[4] The second factor is that side-reactions often occur which may prevent the generation of titrant with 100% efficiency. However, most workers have been able to establish conditions under which a titration efficiency of 99% or better has been achieved in such solvents as acetone,[5,6] isopropyl alcohol[3] and t-butyl alcohol,[6] although in many cases solvent blanks are considerable.[6]

* Present address: Fisons Ltd., Pharmaceutical Division, Loughborough.

In Part I,[4] a coulometric method was described for the determination of carbon in steel in which the carbon dioxide liberated by the high-temperature combustion of the sample is absorbed in isopropyl alcohol containing 3% ethanolamine and $0{\cdot}5M$ in tetraethylammonium bromide (TEAB) and titrated coulometrically. During the development of this procedure it was discovered that if lithium chloride was used as supporting electrolyte, the current efficiency was much lower than expected for isopropyl alcohol media and 100% current efficiency could only be restored by addition of substantial amounts of water. When subsequently lithium chloride was replaced by TEAB, 100% current efficiency was obtained. Recently, Rehioui and Johansson[11] have investigated the electrochemical behaviour of isopropyl alcohol at platinum electrodes and have concluded that the main cathodic reaction in a supporting electrolyte of $0{\cdot}5M$ sodium perchlorate is the generation of isopropoxide ions

$$2(CH_3)_2{-}C\begin{matrix}{}^{\diagup H}\\{}_{\diagdown OH}\end{matrix} + 2e \longrightarrow 2(CH_3)_2{-}C\begin{matrix}{}^{\diagup H}\\{}_{\diagdown O}\end{matrix} \quad H_2 \qquad (1)$$

However, these authors also observed the formation of a yellow deposit on the cathode,[3,11] the amount of the deposit being greatly increased when lithium perchlorate was used as supporting electrolyte.[11] The cathodic electrode reactions in methanol and isopropyl alcohol solutions of lithium chloride and tetraethylammonium bromide have been further investigated and the results are reported in this paper. As a result of these investigations TEAB is recommended as a supporting electrolyte for the coulometric titration of acids in isopropyl alcohol.

EXPERIMENTAL

Reagents

All reagents were of chemical reagent grade. The lithium chloride was dried at 100° to yield the anhydrous salt. The gases used (oxygen, nitrogen, air) were commercial materials used without further purification.

The tetraethylammonium bromide was recrystallized by dissolving 50 g in the minimum amount of isopropyl alcohol (*ca.* 150 ml) at 50–60° and adding 150 ml of acetone. The precipitated material was dried at 70° and stored in a desiccator to prevent absorption of water.

Apparatus

The electrodes used for coulometry were 1 × 1 cm pieces of platinum foil welded to platinum wire and sealed in soda-glass tubing. The electrodes used for amperometry were 22-gauge platinum wire sealed in soda-glass tubing with 2·5 cm left exposed. One of these was kept stationary and used as the anode, the other, the cathode, was rotated at 600 rpm by means of a Radiometer Rotating Platinum Electrode Assembly (type E70).

The reference electrode was in every case a saturated calomel electrode and all the voltages given in this paper are referred to the potential of this electrode. When the electrode was used for measuring the current/potential curves an additional salt bridge of $1M$ TEAB in the appropriate solvent was used to prevent water from contaminating the test solution.

The potentiostat used in the earlier experiments was a Heathkit three-electrode polarograph module (EUA-19-2). However this could not supply sufficient current, so a more powerful instrument was built, (Fig. 1), and currents were measured with an Avometer.

The coulometer was a modification of a valve circuit suggested by Glass and Moore[12] and supplied constant currents of 5–100 mA at voltages of up to 200 V. The switch which interrupted the current through the cell also controlled a clock which measured the time required to reach the end-point. With this instrument the current drifts slightly and it is necessary to monitor the current continuously with a potentiometer and standard resistance.

The coulometric titration vessel was an H-cell with sintered-glass discs separating the anode and cathode compartments (40 ml capacity) from the salt bridge which connected them. For the amperometric experiments a simple glass cup (40 ml capacity) was used, and no precautions were taken to avoid absorption of water during an experiment.

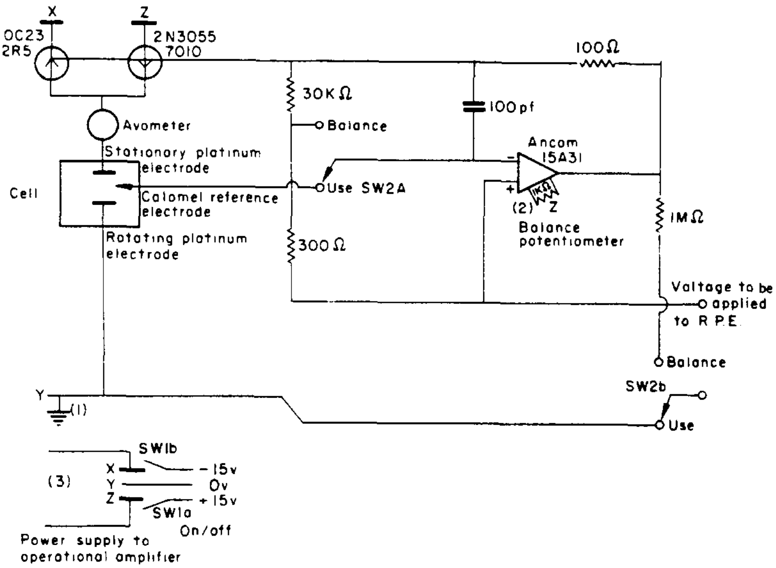

Fig. 1. Circuit diagram of high-current potentiostat.

Amperometry

The current/potential curve for solutions of lithium chloride in isopropyl alcohol was measured automatically with the Heathkit polarograph. Because equilibrium was reached very slowly, the initial potential was applied for one hour before the scan was started and the lowest possible scan-rate of 0·05 V/min was used. When lithium chloride in methanol was the electrolyte the measurements were taken manually with the high-current potentiostat, 10 min being allowed between voltage changes for the current to become steady. With tetraethylammonium bromide as the electrolyte in either solvent the electrode was cleaned between voltage changes by anodizing at +1·8 V for 1 min, and cathodizing at −1·8 V for 1 min; the potential was then applied and the current measured after 2 min. Measurements of the conductivity of the electrolyte suggest that the maximum error due to the voltage drop in solution between the reference and working electrodes would be 50 mV.

In investigation of the dependence of limiting-current on oxygen concentration, the oxygen concentration was measured by the Winkler method,[13] with omission of the permanganate/oxalate treatment used to destroy nitrite.

Coulometry

To reduce the resistance of the cell the anode compartment was filled with 1·0*M* tetraethylammonium bromide in methanol, the cathode compartment and salt bridge being filled with the solution being tested—either 0·1*M* lithium chloride in one of several alcohols or 0·5*M* tetraethylammonium bromide in isopropyl alcohol. If a potentiometric end-point was to be used, glass and calomel electrodes were inserted into the cathode compartment. If a spectrophotometric end-point was required 0·5 ml of 0·1% thymolphthalein in isopropyl alcohol was added to the cathode compartment which was placed in the cell compartment of an EEL Spectrotitrator. The solution was then preneutralized by passage of current until a selected e.m.f. or absorbance was reached. Known amounts of acid were added, and the titration completed by passing current until the same e.m.f. or absorbance was reached. The coulometric efficiency was calculated as 100 × acid added/acid found.

RESULTS AND DISCUSSION

Coulometric titrations in alcohols, with lithium chloride as supporting electrolyte

During investigations into the selection of the most suitable solvent medium for the coulometric determination of carbon in steel, coulometric titrations of benzoic acid were conducted in a range of alcohols as a check on the current efficiencies of the respective cathodic reactions. In these tests the electrodes were placed in separate compartments of a standard H-cell and the supporting electrolyte was $0{\cdot}1M$ lithium chloride. The end-point was detected visually with phenolphthalein as indicator. A current of 12·5 mA was used and with a 2-cm platinum cathode this gave a current density of 6·25 mA/cm^2. Results for the titration of 5 ml of 0·1% benzoic acid solution are given in Table 1 and show that although 100% current efficiency is obtained in methanol and ethanol under these conditions, the current efficiency drops considerably as the carbon chain of the solvent is increased in length or branched. This was considered unfortunate since the larger-chain alcohols are also those which have the smallest autoprotolysis constants, and are therefore more differentiating and better solvents for the titration of acids with a wide range of ionization constants. Addition of increasing amounts of water to the solvent medium increased the current efficiency of isopropyl alcohol but large amounts were required to obtain 100% current efficiency and such "semi-aqueous" media would suffer from the disadvantages mentioned above. Assuming the electrode reaction can be written generally as

Table 1. Coulometric current efficiencies for the titration of benzoic acid in various alcohols: $0{\cdot}1M$ lithium chloride as supporting electrolyte.
(Current density 6·25 mA/cm^2.)

	Current efficiency, %		
Alcohol	Water 0%	Water 15%	Water 30%
Methyl	100·0, 100·2, 100·0	—	—
Ethyl	100·1, 100·2, 100·1	—	—
n-Propyl	94·2, 93·3, 94·8	—	—
Isopropyl	61·2, 60·3, 60·8	95·0, 95·1	99·7, 100·0
n-Butyl	44·0, 44·0, 44·2	—	—

$$2\text{ROH} + 2e \longrightarrow 2\text{RO}^- + \text{H}_2 \qquad (2)$$

a low current efficiency indicates overconsumption of charge and therefore that another reaction is taking place which produces either no titrant or a smaller amount of titrant than the main reaction. To investigate these reactions a voltammetric study of two typical solvents in this series was undertaken.

Current/potential curves in methanol and isopropyl alcohol with lithium chloride as supporting electrolyte

Current–potential curves were measured in the cathodic region (from 0 to -3 V with respect to a saturated calomel electrode) for $0{\cdot}1M$ lithium chloride in isopropyl alcohol and for $1{\cdot}0M$ lithium chloride in methanol, a rotating platinum electrode being used. The results are illustrated in Fig. 2; methanol gives a sharp rise in current at about $-1{\cdot}5$ V (Curve A) corresponding to decomposition of the solvent, but isopropyl alcohol gives much smaller currents which increase more gradually (Curve B). For isopropyl alcohol medium the current was found to depend on the direction of the scan, higher currents being observed when the voltage was scanned from + to − than in the reverse direction (Curves B and C). This effect was much less noticeable with methanol as medium. Addition of water increased the currents obtained but the forward and reverse scans were still substantially different

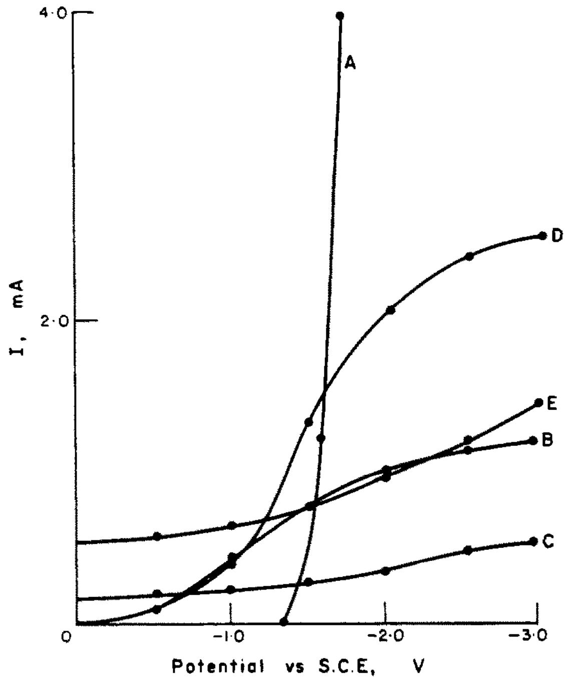

Fig. 2. Current/potential curves for methanol 1*M* in LiCl, and isopropyl alcohol 0·1*M* in LiCl. Rotating platinum electrode, automatic scan at a scan-rate of 0·05 V/min. Curve A, methanol forward and reverse scan. Curve B, isopropyl alcohol forward scan. Curve C, isopropyl alcohol reverse scan. Curve D, isopropyl alcohol/5% water, forward scan. Curve E, isopropyl alcohol/5% water, reverse scan. Solutions saturated with nitrogen.

(Curves D and E). Replacement of nitrogen with oxygen or air gave similar results but with the addition of an oxygen wave. For both solvents, under all conditions, the measured currents decreased steadily with time (Fig. 3*a*), the effect being worse in the presence of air or oxygen (Fig. 3*b*). Lower currents are therefore observed if the potential scan is carried out manually rather than automatically, although the shapes of the curves are similar.

The results can be interpreted by assuming that during electrolysis a deposit, similar to that observed by Rehioui and Johansson,[11] is formed on the cathode and causes a decrease in current as it increases in thickness. With isopropyl alcohol as solvent a white waxy deposit could in fact be observed on the cathode. The thickness of this deposit probably explains why very low currents (of the order of μA) are observed in isopropyl alcohol in the presence of lithium chloride whereas other solutions (see later) give much higher currents (of the order of mA). It would also explain why the currents are dependent on the direction of the scan since in scanning from 0 to −3 V the deposit will be building up whilst in the reverse scan a thick deposit will be formed initially.

The decay of current was also observed when methanol was used, even though no film was visible on the cathode. In this case there appeared to be three possible explanations for the decay of the current:

(*a*) the formation of an invisible film;

(*b*) the formation, during the electrolysis, of a substance that accumulates in solution and inhibits the cathodic reaction;

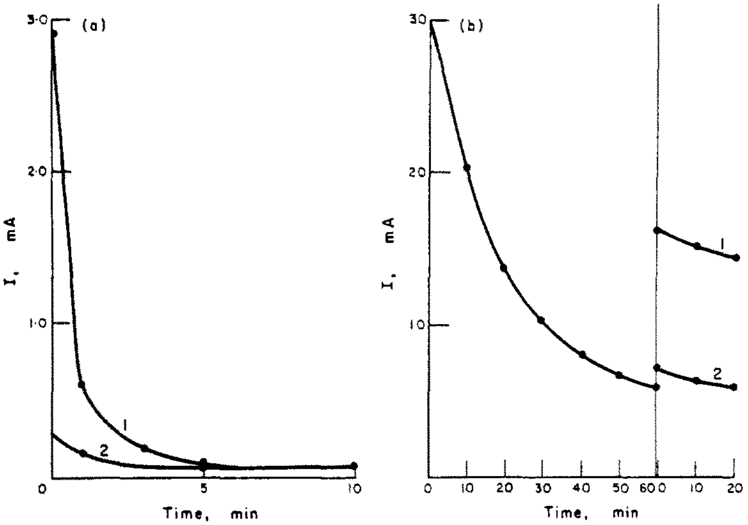

Fig. 3. (*a*) Change of potential with time for (1) methanol at −1 V *vs* S.C.E., (2) isopropyl alcohol at −3 V *vs*. S.C.E; solutions saturated with nitrogen. (*b*) Change of potential with time at −1 V *vs*. S.C.E. in methanol saturated with oxygen; after 60 minutes, (1) electrode removed, cleaned and replaced in the same solution, (2) electrode removed and placed in a new solution of the same composition.

(*c*) the slow growth of the diffusion layer to its equilibrium size accompanied by the decay of the current to a steady value.

To distinguish between these possibilities two tests were made. In the first, a potential of −1 V was applied to an electrode and the current allowed to decay to about one tenth of its initial value. The electrode was then withdrawn from the solution and, without any form of treatment, was placed in a fresh solution. The current then measured was almost identical to that obtained before the solutions were changed [Fig. 3*b*(2)]. This would only be expected in case (*a*) above. In the second test, the electrode was removed from the solution at the same point, cleaned in chromic acid and replaced in the same solution. The current was found to increase by a factor of 6 [Fig. 3*b*(1)] which would be expected in cases (*a*) and (*c*) above and not in case (*b*).

In both solvents, therefore, a deposit is formed on the cathode but the deposit is much thicker in isopropyl alcohol solutions. The deposit explains not only the unstable currents but also, if it is basic, the low current efficiencies. A large amount of deposit resulting from the electrolysis of an isopropyl alcohol/lithium chloride solution was dried and subjected to analysis. Microanalysis (Table 2) gave a very low carbon content, indicating that the substance was not organic, a conclusion supported by the infrared spectrum. This gave no peaks in the CH-stretch region but gave two sharp peaks at 3570 and 3680 cm^{-1}, which were also apparent in a spectrum of a sample of anhydrous lithium hydroxide. Other results suggest that both samples were partially hydrated.[14] An X-ray powder photograph of the deposit gave *d* spacings (2·96, 2·75, 2·66, 2·43 and 1·75 Å) and relative line intensities (60, 40, 100, 60, and 40 respectively) identical to those for $LiOH.H_2O$ but quite different from those for LiOH and LiCl[15]. The X-ray analysis took 5 hr to complete and it is likely that in this time sufficient water was absorbed to convert the sample completely into the hydrate. On titration with standard acid, the sample was found to contain the equivalent of 87% lithium hydroxide.

Table 2. Elemental microanalysis of cathodic deposits formed in isopropyl alcohol

	Supporting electrolyte	
	LiCl	TEAB
C, %	3·1	35·8
H, %	4·5	7·3
Cl, %	2·0	—
Br, %	—	21·0

Electrolysis of isopropyl alcohol in the presence of lithium chloride therefore results in the deposition of lithium hydroxide on the cathode, which reduces the current efficiency with respect to the generation of basic titrant.

Current/potential curves in methanol and isopropyl alcohol with tetraethylammonium bromide as supporting electrolyte

A satisfactory supporting electrolyte should have high solubility and conductivity in the solvent medium and ideally be unaffected by the passage of current. Several authors have used tetralkylammonium salts as supporting electrolytes in t-butyl alcohol[6,8] and acetone[7] and in this case the tetralkylammonium hydroxide formed by reduction of traces of water is assumed to be the generated titrant.[6] Several such salts were examined but most were not sufficiently soluble (*e.g.*, tetramethylammonium bromide, tetraethylammonium iodide, tetrapropylammonium iodide) in isopropyl alcohol to give the required high conductance. Two (tetrabutylammonium iodide and tetraethylammonium bromide) were sufficiently soluble, and of these tetraethylammonium bromide (TEAB) was chosen for voltammetric investigation because it had the higher solubility and conductance.

Currents measured when TEAB was used as supporting electrolyte were stable, changing only very slightly with time, and were independent of the direction of scan. Currents in methanol and isopropyl alcohol were of similar magnitude and no visible deposits were formed at the cathode. Use of TEAB therefore appeared to eliminate the difficulties encountered with lithium chloride.

The current/potential curves for $0{\cdot}1M$ TEAB in methanol showed a distinct wave due to oxygen. This is shown clearly in Fig. 4 by the increase in average limiting current in the region of $-1{\cdot}2$ V as the nitrogen atmosphere is successively replaced by air and oxygen. The limiting current was linearly related to the concentration of oxygen (determined by a modified Winkler method).[13] For example average limiting currents of 30·8, 14·6 and 1·8 mA/cm^2 were obtained for concentrations of oxygen determined as $7{\cdot}25 \times 10^{-3}M$ (oxygen-saturated solution), $3{\cdot}75 \times 10^{-3}M$ (air-saturated solution) and $1{\cdot}375 \times 10^{-3}M$ (nitrogen-saturated solution) respectively. As the methanol is diluted with water the limiting current decreases (Fig. 4) owing to the decreased solubility of oxygen in aqueous solutions. When the electrode was not rotated the wave disappeared, which confirms that it is not due to either methanol or water but is due to a solute of low concentration. In isopropyl alcohol the oxygen wave could not be resolved from the background current due to reduction of

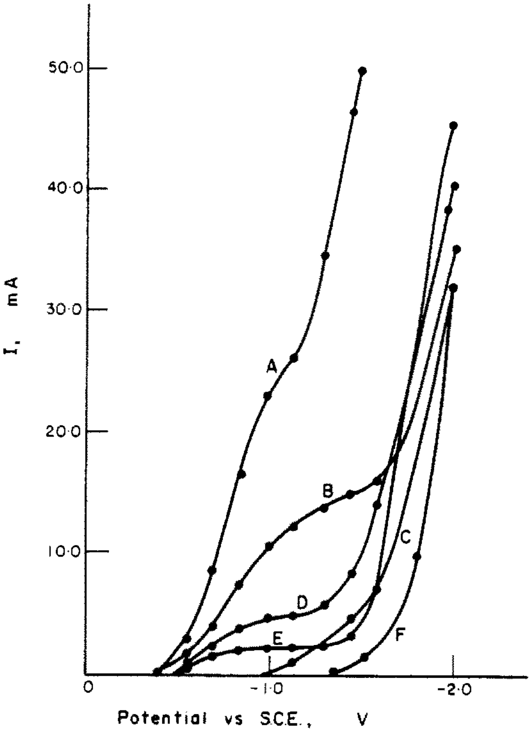

Fig. 4. Current/potential curves for methanol 0·2M in tetraethylammonium bromide. A, solution saturated with oxygen. B, solution saturated with air. C, solution saturated with nitrogen. D, methanol/20% water, air atmosphere. E, 100% water, air atmosphere. F, current/potential curve for methanol 1M in LiCl.

solvent, but the current was still dependent on the oxygen content (Fig. 5). For comparison of the relative currents, the curve obtained for 0·1M lithium chloride is included in Fig. 5.

In coulometry, the concentration of the supporting electrolyte governs the resistance of the cell and hence the voltage that the constant-current generator must deliver. The effect of TEAB concentration was investigated with methanol rather than isopropyl alcohol as medium, because of the better resolution of the oxygen wave. The limiting current for the oxygen wave decreased as the TEAB concentration was increased and this can be attributed to the increasing viscosity of the solution.[16]

Nature of the titrant generated in isopropyl alcohol with tetraethylammonium bromide as supporting electrolyte

Since TEAB appeared to be the most suitable supporting electrolyte for the coulometric titration of acids in isopropyl alcohol, the nature of the product of electrolysis in this medium was investigated. A solution of 0·1M TEAB in isopropyl alcohol was electrolysed for 5 hr and the products were precipitated with a solution of lithium bromide. Microanalysis of the precipitate suggested that it was a mixture of lithium isopropoxide and lithium bromide (Table 2) and the infrared spectrum showed the typical absorption pattern of the isopropyl group in the CH_3-stretch regions. The elemental analysis suggests that the precipitate is 65% lithium isopropoxide and 30% co-precipitated lithium bromide and is certainly different from the inorganic material formed in the presence of lithium chloride as supporting electrolyte.

Cathodic reactions

The results above allow a mechanism for the generation of base to be described. With lithium chloride as supporting electrolyte there are two products, a soluble base which reacts with acids (Table 1) and insoluble lithium hydroxide, the amount of the latter produced being much less in methanol than in isopropyl alcohol. The soluble base will be alkoxide ions produced by reaction (2). Lithium hydroxide may be produced by reduction of traces of water

$$2H_2O + 2e \longrightarrow 2OH^- + H_2 \tag{3}$$

or by reduction of dissolved oxygen

$$O_2 + 2ROH + 4e \longrightarrow 2OH^- + 2RO^- \tag{4}$$

where the hydroxyl ion reacts subsequently with the supporting electrolyte

$$Li^+ + OH^- \longrightarrow LiOH\downarrow \tag{5}$$

forming lithium hydroxide which is insoluble in both methanol and isopropyl alcohol. Reduction of isopropyl alcohol occurs at more negative potentials than that of methanol (Figs. 4 and 5) and allows reaction (3) to make a greater contribution to the overall current. At a potential of −2·5 V, a current of 100 mA is passed by water, 90 mA by methanol and

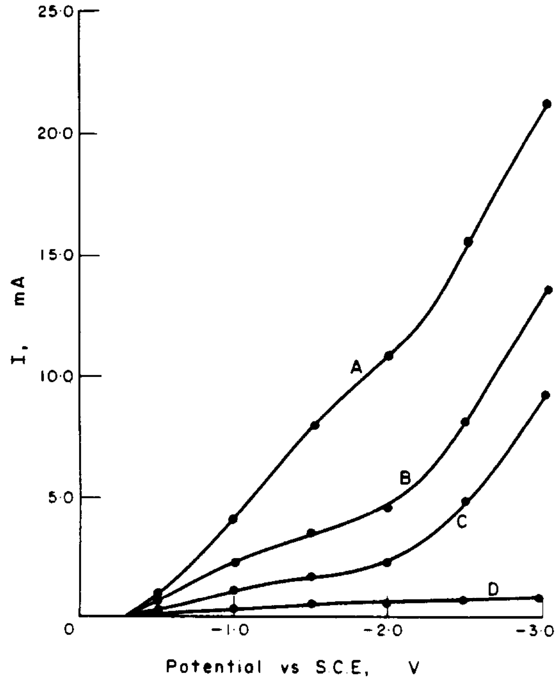

Fig. 5. Current/potential curves for isopropyl alcohol 0·2*M* in tetraethylammonium bromide. A, solution saturated with oxygen, B, solution saturated with air. C, solution saturated with nitrogen. D, curve for isopropyl alcohol 0·1*M* in LiCl, saturated with nitrogen.

2 mA by isopropyl alcohol. Thus if one Faraday is passed through an electrode immersed in an alcohol containing 0·1% water and the electrode is maintained at −2·5 V, then in the case of methanol 0·0011 equivalents of hydroxide ions will be generated or 0·1% of the total alkali. In the case of isopropyl alcohol, however, 0·048 equivalents or about 5% of the total alkali will be hydroxide. Despite the fact that this calculation applies strictly only to reversible systems, it is clear that in the case of isopropyl alcohol a much larger proportion of the alkali is generated as hydroxide ions and a much thicker deposit is formed. The film formed on the cathode in isopropyl alcohol essentially blocks the current and suppresses the appearance of any well-defined background wave. The reduction of the added water did not yield a wave which could be resolved from the background due to either solvent, which confirms the results of Rehioui and Johansson.[11]

Another possibility for the formation of lithium hydroxide is the reduction of lithium ions to lithium metal, a reaction which has a standard reduction potential of −3·0 V *vs.* S.C.E in water. The lithium formed would be expected to react rapidly with traces of water to form insoluble lithium hydroxide. Whilst the reduction potential of lithium will be different in the two solvents under consideration, this reaction appears a possibility in isopropyl alcohol. However, it seems unlikely that it could account for the formation of even a thin film in methanol as very high currents are passed in this solvent at potentials well below −2·0 V.

In TEAB, reactions (2), (3) and (4) would be expected to occur in both methanol and isopropyl alcohol and since tetraethylammonium hydroxide is soluble in these media, no film is formed on the electrode. In the coulometric determination of carbon,[4] oxygen is used to flush the carbon dioxide into the titration cell and reaction (4) could be expected to occur to a considerable extent. Since this produces the same number of equivalents of base per Faraday as reaction (2) the stoichiometry of the main reaction is not disturbed by this side-reaction. The analysis of the products of reduction in TEAB solutions did not reveal the formation of any hydroxide ion but small amounts would not be apparent in the analysis.

Coulometric titrations of acids in isopropyl alcohol

The only previous worker to use isopropyl alcohol for the coulometric titration of acids used sodium perchlorate as supporting electrolyte but also mentioned the use of tetraethylammonium iodide.[3] On the basis of the results in this paper, we would recommend the use of tetraethylammonium bromide and have recently described the determination of carbon in steel by use of such a system but with the addition of 3% ethanolamine to bring about efficient absorption of carbon dioxide.[4] To test the general application of this system, coulometric titrations of several other acids have been carried out.

In our laboratory, a constant-current generator, with a valve circuit basically similar to that described by Glass and Moore,[12] has been used. This delivers a large voltage (200 V, at 100 mA) suitable for titrations in non-aqueous solvents. Analytical results are then obtained by a simple calculation from the constant current and the time for which it is passed. A possible difficulty with such a system is that a large amount of heat is generated when a current is passed through such a large resistance. The resistance is located mainly in the sintered-glass partitions used to separate the anode and cathode compartments of the cell, and if the resistance is too high, the solution adjacent to these partitions will boil. This problem has been overcome (*a*) by using wide porous sinters and (*b*) by using the high-resistance isopropyl alcohol solution in the cathode compartment only, and methanol in the other compartments.

Initially large solvent blanks (approx. 1 meq/g) were encountered but these were traced to contamination of the TEAB by traces of a strong acid. Recrystallization of the TEAB reduced the blanks to 0·2 meq/g.

Coulometric titrations of *p*-nitrophenol, benzoic acid, ascorbic acid and phenol were carried out, with potentiometric end-point indication with a glass electrode–saturated calomel electrode couple. Titration efficiencies were always close to 100% even with phenol, although in this case the potential jump was small (70 mV). The precision was tested by titration of 5 mg of benzoic acid (10 determinations), a range of results from 5·148 to 4·958 mg being obtained, which yielded a standard deviation of 0·062 mg and a 95% confidence limit of 5·006 ± 0·049 mg for the mean. The proposed system therefore appears to be at least as satisfactory as other systems which have been proposed for the non-aqueous coulometric titration of acids.

Acknowledgements—One of us (B.M.) wishes to thank Shotton Works, British Steel Corporation, for financial support. We also wish to thank our ex-colleague W. A. Alexander who built the coulometer used in this work.

Zusammenfassung—Kathodische Reaktionen in Methanol und Isopropylalkohol wurden in Gegenwart von Lithiumchlorid und Tetraäthylammonium bromid als Leitsalzen untersucht. Im Lithiumchlorid-Medium führt eine Nebenreaktion zur Bildung von unlöslichem Lithiumhydroxid; mit Tetraäthylammoniumbromid wird durch Reduktion von Lösungsmittel, Sauerstoff und Wasserspuren stöchiometrisch Base gebildet. Zur coulometrischen Titration von Säuren in Isopropylalkohol wird Tetraäthylammoniumbromid als Leitsalz empfohlen.

Résumé—On a étudié les réactions cathodiques en méthanol et isopropanol en la présence à la fois de chlorure de lithium et de bromure de tétraéthylammonium comme électrolytes supports. Une réaction secondaire en milieu chlorure de lithium méne à la formation d'hydroxyde de lithium insoluble, mais la base est générée stoechiométriquement en bromure de tétraéthylammonium par réduction de solvant, d'oxygène et de traces d'eau. Le bromure de tétraéthylammonuim est recommandé comme support électrolyte pour le titrage coulométrique d'acides en isopropanol.

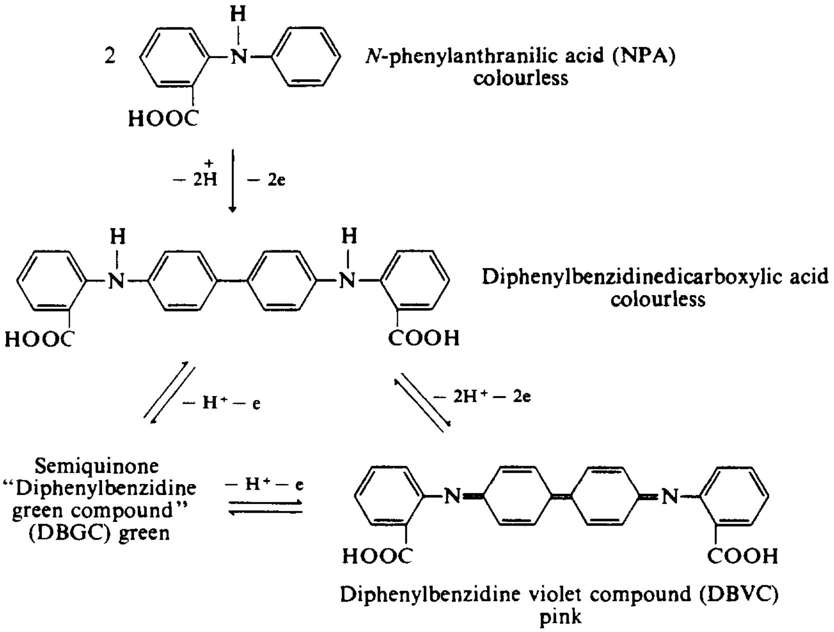
SOME OBSERVATIONS ON THE REDOX BEHAVIOUR OF *N*-PHENYLANTHRANILIC ACID INDICATOR IN IRON(II) TITRATIONS

K. SRIRAMAM
Department of Chemistry, Andhra University Postgraduate Centre,
Guntur-5 (A.P.), India

(*Received* 22 *February* 1972. *Revised* 22 *August* 1972. *Accepted* 14 *October* 1972)

Summary—The optimum conditions for the successful use of *N*-phenylanthranilic acid as indicator in titrations of iron(II) with dichromate, cerium(IV) sulphate and vanadate have been established. The influence of iron(III) on the indicator action, and the nature of a green compound formed from the indicator in iron(II) titrations, have been investigated spectrophotometrically.

Syrokomskii and Stiepin[1] have studied the indicator properties of *N*-phenylanthranilic acid (NPA); that the indicator is superior to ferroin is implicit in their conclusions. As NPA is a derivative of diphenylamine, its oxidation mechanism is generally considered similar to that of the parent substance. The oxidation to the coloured compound can then be formulated as



Recently, however, Bishop and Hartshorn[2] have shown that the oxidation of the arylamine to the coloured compound is a single-step two-electron process with no detectable evidence for the formation of an intermediate, either of a benzidine or of a semiquinone, but they confirm that reduction of the oxidized arylamine stops at the benzidine stage.

Syrokomskii and Stiepin[1] report that the formal redox potential of the indicator system in 1*M* sulphuric acid is 1.08 V, but no working details of the Russian work are available. Lederer and Ward[3] claim to have confirmed this value, but they have made no allowance in their calculations for the irreversible step. In view of the behaviour of this indicator in the iron(II)–dichromate titration, the reported formal redox potential is considered high.[4] Belcher *et al.*[5] argue that the reported potential is incorrect in view of the redetermined value of the transition potential (0·89 V); further they do not expect such an abnormal rise in the redox potential of diphenylamine on the introduction of a carboxyl group. However the behaviour of the indicator in the iron(II)–dichromate titration cannot be used to assess the redox potential of the indicator system, in view of the peculiar behaviour of the dichromate/chromic system;[7,8] further, the transition potential of a one-colour indicator is dependent on the indicator concentration and the colour change does not depend on the ratio of the oxidized and reduced forms of the indicator as with a two-colour indicator.[9] The present author has failed to determine the redox potential of the system in 1*M* sulphuric acid from a potentiometric cerium(IV) sulphate titration of NPA alone or in combination with iron(II), at room temperature; the potentials from the beginning in the former system, and after the complete oxidation of iron(II) in the latter, were continuously drifting with time and were not reproducible even under carefully controlled experimental conditions. In the latter titration some of the indicator is oxidized along with the iron(II) and a bright greenish yellow colour is evident at a stage when the iron(II) end-point is imminent. The same colour is evident in the initial stages of the titration of NPA alone but only after a transient appearance of pink. It was thought that investigation into the cause of this colour formation might give some information on the failure of the potentiometric titrations.

Although Syrokomskii and Stiepin[1] claim that the indicator works well in the titration of iron(II) with cerium(IV), dichromate and vanadate, there are contradictory reports[1,4,5,6,10,11] on the behaviour of the indicator in the iron(II)–dichromate titration. Further, there is no detailed information on the limitations of the indicator in these titrations. In the present communication an attempt is made to define the working experimental conditions for these titrations more precisely and provide an explanation for the observed behaviour of the indicator.

EXPERIMENTAL

Reagents

Potassium dichromate, 0·05*N*. *Cerium(IV) sulphate*, 0·05*N*. Prepared by dissolving cerium(IV) ammonium sulphate in 1*N* sulphuric acid and standardized against arsenic trioxide according to the method of Gleu.[12]

Sodium vanadate, 0·05*N*. Prepared by treating the requisite amount of ammonium vanadate with a slight excess of sodium carbonate in solution, boiling until free from ammonia, then making up the solution to the desired volume. The solution is standardized against Mohr's salt by the procedure of Walden *et al.*[13]

Iron(II) ammonium sulphate, 0·05*N*. Prepared in 1*N* sulphuric acid from analytical-reagent grade material.

N-*Phenylanthranilic acid*, 0·005*M*.

Apparatus

The potentiometric assembly consisted of a Cambridge potentiometer and a suspension galvanometer. A bright platinum rod (*ca.* 0·2 mm in diameter) served as indicator electrode and a saturated calomel electrode as the reference electrode.

Investigation in visual titrations

Iron(II)–cerium(IV) sulphate. The indicator (2 drops per 50 ml of solution) has been found to function satisfactorily in this titration in 0·5–6·0*N* sulphuric acid medium. The colour change at the end-point is from a light greenish yellow to pink at lower acidities, and from an intense greenish yellow to pink at higher acidities. The colour change is not from colourless to pink as reported in the literature. The reduction of the oxidized indicator by iron(II) becomes somewhat slow towards the close of the titration in 4–6*N* sulphuric acid but there is little difficulty in locating the end-point. At still higher acid concentrations premature end-points have been obtained.

Iron(II)–dichromate. The indicator functions satisfactorily in 2–6*N* sulphuric acid medium in this titration; the titration is possible even at a lower acidity than 2*N* provided the titration mixture is 0·02*N* or more in iron(III). The colour change at the end-point is from greenish yellow to bright pink.

Iron(II)–vanadate. The indicator functions satisfactorily in 4–6*N* sulphuric acid medium in this titration but at the lower limit the colour change at the end-point requires a little time (5 sec) in view of the slowness of the indicator–oxidant reaction. This observation is contrary to an earlier report[14] that the working range of sulphuric acid is 4–13·5*N*. In titrations with >0·05*N* reagent the end-point is marked by the sharp appearance of the permanent bright blue-violet, the modification of the colour change being due to the blue colour of the vanadyl ion in solution. In titrations with 0·01*N* solutions, the end-point colour is pink owing to the smaller concentration of vanadyl ion; unlike the iron(II)–cerium(IV) case the greenish yellow colour is not evident during the titration, but with a higher concentration of the indicator the colour change is from greenish yellow to pink.

Influence of indicator concentration

With larger concentrations of the indicator, *e.g.*, 5–10 drops per 50 ml of titrand, the end-point colour is usually less permanent, turning to greenish yellow, and the colour change is less sharp. Besides resulting in the consumption of a considerable amount of oxidant before a sufficiently stable end-point colour is obtained, the use of a large concentration of indicator introduces an element of uncertainty in determining the exact equivalence point.

Influence of rate of titration and concentration of titrant

When the titrant is added more rapidly than usual, the intermediate greenish yellow colour is more intense, especially if 0·1*N* solutions are used rather than 0·01*N*. Nevertheless the colour change is always sharp provided a large concentration of the indicator is not used, but there is a slight variation in indicator correction when working with 0·01*N* solutions. In general the concentration of iron(III) at the end-point is without significant effect if the titrations are done at the usual speed. However, in titration of 5 ml of 0·01*N* iron(II) with 0·01*N* vanadate in 4*N* sulphuric acid medium, end-points premature by 2–2·5% have been obtained if 10 ml of 0·1*N* iron(III) are initially present in the titration mixture and about one min is allowed between drops towards the end.

Influence of acidity

Other conditions being the same, an increase in acidity has been found to facilitate the formation of the greenish yellow colour during the titration.

Spectrophotometric investigation

The effect of iron(III) on the oxidation of the indicator with dichromate is shown graphically in Fig. 1. The absorbance of the pink colour is plotted against time for reactions of (*i*) NPA with iron(III), (*ii*) NPA with dichromate, (*iii*) NPA with dichromate plus iron(III) in 2*N* sulphuric acid. The fall in absorbance after the maximum in (*iii*) may be due to instability of the oxidized form in 2*N* sulphuric acid.

The successful use of the indicator in titrations in 4–6*N* sulphuric acid is unexpected in view of the occurrence of the NPA–iron(III) reaction to a significant extent under experimental conditions similar to those prevailing just before the end-point. The influence of sulphuric acid concentration on the speed and extent of reaction are shown in Fig. 2, from measurements of the absorbance of the pink colour with respect to time. The absorbance reached a limiting value in 10–15 min. The presence of the reduced form of the indicator in the mixture at this stage was tested for by adding cerium(IV); the absorbance always increased on the addition of cerium(IV). By comparison of the limiting value with the maximum absorbance obtained with cerium(IV), the NPA–iron(III) reaction was found to be 28, 66 and 72% complete in 4, 6 and 8*N* sulphuric acid media respectively.

The greenish yellow compound (green form of NPA) in solution has been prepared by three different reactions: (*i*) by treating the pink oxidized form with a slight excess of iron(II), (*ii*) by treating the pink oxidized form with excess of NPA, and (*iii*) by allowing pink oxidized form to stand until all the pink colour is discharged. The species obtained in the three reactions yield the same pink oxidation product (with absorption maximum the same as for DBVC) on again being treated with cerium(IV) sulphate. It is observed that reaction (*i*) is quite rapid, reaction (*ii*) slow and reaction (*iii*) still slower. Further experiments have

○ $4N$ H_2SO_4; △$6N$ H_2SO_4; □$8N$ H_2SO_4

revealed that the greenish yellow compound can be reduced quite rapidly to a colourless compound with a moderate excess of iron(II) but the reaction is retarded by the presence of a large excess of iron(III).

The pink oxidized form of NPA (DBVC) used in the preparation of the greenish yellow compound was obtained by adding the requisite amount of cerium(IV) sulphate. However, because of the lack of exact stoichiometry and the occurrence of side-reactions, a solution of known concentration of the greenish yellow compound could not be prepared. However, the solutions of the greenish yellow species obtained in the three reactions were suitably diluted to have nearly the same absorbance at one of the absorption peaks (430 nm). Figure 3 shows the absorption spectra. The three curves have peaks at 430 and 800 nm and are similar in shape, indicating the presence of the same species in the reaction products. The variation in absorbance at some wavelengths may be due to the products of side-reactions, especially in reaction (*iii*).

Potentiometric investigation

The potentials at which the indicator changes colour in a titration of iron(II) with cerium(IV) sulphate were determined as a function of acidity by the method of Belcher *et al.*,[15] and the other parameters studied were the

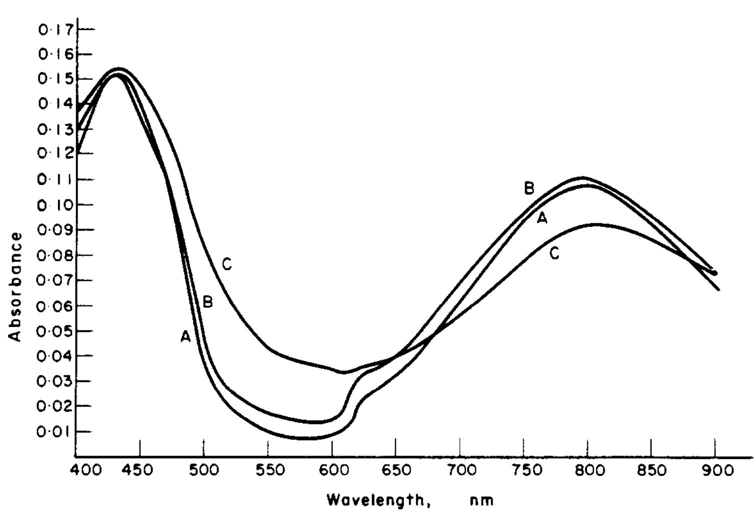

Fig. 3. Absorption spectra of DBGC in 6N H_2SO_4.
A; Prepared by reduction with Fe^{2+}; *B*, by treatment with NPA; *C*, by disproportionation.

stage of addition of the indicator in the titration and the indicator concentration. The results obtained are recorded in Table 1. In these experiments 5·0 ml of 0·01N iron(II) ammonium sulphate in about 45 ml of dilute sulphuric acid were titrated with 0·01N cerium(IV) sulphate. Towards the end 0·002N cerium(IV) sulphate was used instead of the 0·01N solution. When a perceptible colour had been obtained, 0·002N iron(II) ammonium sulphate was added to reverse the colour change. The amount of indicator used and the stage of addition of the indicator are indicated in the Table.

* Indicator added 0·5 ml before the true end-point.

† The greenish yellow colour modifies the colour change.

§ No colour reversal attempted, since colour change was difficult to assess.

‡ Indicator added 1·0 ml before the true end-point (otherwise the pink colour is obtained immediately on addition of the indicator).

It has been found that the colour-change potential is generally increased by a few mV after each reversal. In each case two or three reversals were performed and the average is recorded. The colour-change potential when the indicator is added at the start of the titration is generally higher than if the indicator is added towards the end; the colour change with a larger concentration of the indicator is generally observed at a higher potential. The dependence of the colour-change potential on these factors emphasizes the need for close observance of the experimental conditions for the recommended procedure.

* Titration of 5·0 ml of 0·01N iron(II) in 50 ml of titration solution, with 0·01N vanadate; 2 drops of indicator added at the start.

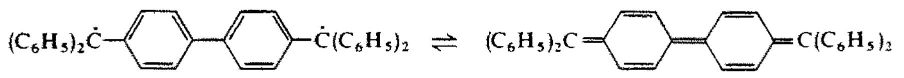
Table 2 records the influence of acidity on the equivalence-potential range of the iron(II)–vanadate titration and the colour-change potentials of the indicator. In 1–3N sulphuric acid medium the colour-change potentials are difficult to determine with this system, and are not reported.

The optimum acid range indicated by Table 2 agrees well with that found in the practical titrations recorded earlier. Although Table 2 indicates that the titration may be just possible in 3N acid [based on the value of the colour-change potential in iron(II)–cerium(IV) sulphate titration], this has been found not feasible in practice, probably owing to the slowness of indicator-oxidant reaction.

DISCUSSION

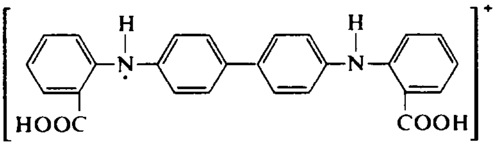
The oxidation of NPA to the pink product occurs in a single step with no detectable evidence for the formation of intermediates. This oxidation product rapidly decays to a green form which is also obtained from the former by reduction with iron(II) or treatment with the reduced form of the indicator. The green form is more stable than the pink oxidation product, but can be reduced by excess of iron(II) to a colourless product which is probably the benzidine form and can also be obtained[2] by zinc-dust reduction of the pink oxidation product. The benzidine and the green forms correspond to two stable oxidation states between NPA and the pink oxidation product.

Bishop and Hartshorn[2] have made the observation that the oxidation of the arylamine to the coloured form is an intermolecular reaction but no detailed mechanism was proposed. The evidence, however, is not in favour of Kolthoff and Sarver's theory.[16] Thiel[17] believes that a transient biradical of the type, $C_6H_5{-}N{=}C_6H_4\lessdot$ is the primary product, which condenses with another such radical to give a diquinonedi-imine; the latter is also obtained by a two-electron oxidation of the corresponding benzidine. Since this cannot have an intense colour the dimer may be expected to be in a triplet state (biradical), but the e.s.r. evidence is only qualitative. It is not unlikely that a favourable equilibrium exists for the ground-state (singlet) molecules in the mixture, if the energy of excitation to the triplet state is large enough; the analogous behaviour of Tchitchibabin's hydrocarbon with a related structure,



is noteworthy.[18]

The curious behaviour of the oxidized product of NPA to give on decay the green product instead of the expected colourless benzidine has been noted.[2] It may be speculated that this is due to disproportionation, but other evidence indicates that the green compound is a reduction product of the pink form. Its spectral behaviour in relation to the coloured oxidation product suggests that there is no gross difference in the structure of the two compounds. The green compound is most probably a free radical,



Diphenylbenzidine green compound
(DBGC)

stabilized by resonance.

The decomposition and further oxidation of the coloured product and products of decomposition, and the side-reactions of the coloured oxidation product with iron(II) and the unoxidized indicator, seem to be the cause of drifting and irreproducible potentials in the potentiometric titrations and hence do not permit even an approximate estimation of the formal potential of the indicator system.

Besides the induction effect of iron(II),[1] the catalytic effect of iron(III) on the oxidation of the indicator with dichromate is responsible for the indicator working better in the iron(II)–dichromate titration. In view of the observations that either the single-step two-electron oxidation took place or no oxidation occurred in the arylamine oxidation[2] and that iron(III) reacts with NPA to give the coloured product, the catalytic action of iron(III) may be explained in terms of the following steps:

$$\text{NPA} + \text{Fe(III)} \longrightarrow \text{DBVC} + \text{Fe(II)} \qquad (i)$$

$$\text{Fe(II)} + \text{Cr(VI)} \xrightleftharpoons{\text{fast}} \text{Fe(III)} + \text{Cr(V)} \qquad (ii)$$

$$\text{NPA} + \text{Cr(V)} \xrightarrow{\text{fast}} \text{DBVC} + \text{Cr(III)} \qquad (iii)$$

Step (*i*) should not be inferred to be slower than the indicator–dichromate reaction at the end-point, from the apparent rates observed (Fig. 1). In view of the curious mechanistic behaviour of the arylamine towards oxidants, step (*i*) is probably more complex, and iron(II) very much retards the reaction. In the presence of Cr(VI), the concentration of iron(II) in the iron(III) solution (probably in equilibrium with atmospheric oxygen) is decreased so that the reaction is faster than observed otherwise, and the rate continues to be fast till all the NPA is oxidized by the excess of dichromate used. Further, the overall oxidation of NPA proceeds both by steps (*i*) and (*iii*); this would not have been possible if the reduction of Cr(VI) with iron(II) were not stepwise.

The unexpectedly satisfactory behaviour of the indicator in iron(II) titrations in 4–6*N* sulphuric acid may be explained by the slow kinetics of the NPA–iron(III) reaction, with iron(II) tending to retard the forward reaction. At still higher acidities the hydrogen ion effect might over-ride the retarding effect of iron(II) and cause premature end-points in titrations. There is another possibility. Even though the oxidized form is obtained in perceptible concentration in a titration at a point with a slightly greater ratio of iron(II) to iron(III) than in a blank experiment, the analytical result is still within experimental error. The assumption is that equilibrium is reached faster in titrations than in blank experiments.

The differences in the colour-change potentials when the indicator is added towards the end and at the start of a titration, and when a larger amount of the indicator is used (Table 1) must be related to the formation of DBGC during titration. On this basis the lower colour-change potentials in iron(II)-vanadate titrations than in iron(II)-ceric sulphate titrations at corresponding acidities are indicative of less favourable conditions for the formation of DBGC in the former. The observation that the colour change is from nearly colourless to pink in the former but from greenish yellow to pink in the latter is in agreement with this conclusion. The premature end-point in the titration of iron(II) with 0·01*N* vanadate in the presence of a large excess of iron(III) and the absence of this effect in titrations with ceric sulphate and dichromate, can be explained in the same way. The influence of DBGC on the colour change may be due to its colour-masking ability or its different kinetic behaviour towards oxidants.

(*Received* 27 *July* 1972. *Accepted* 17 *October* 1972)

Summary—Two variants of a technique for determination of ng-amounts of sulphide ions in liquid samples are presented. They are based on the replacement of radioactively labelled iodide from silver iodide by sulphide. In the first variant, suitable for small sample volumes, the labelled silver iodide is fixed on a filter paper disc which is then shaken with the solution to be analysed until equilibrium is attained. In the second variant, suitable for sample volumes up to 300 ml, the sample solution is passed through a filter paper disc carrying labelled silver iodide or through a labelled silver iodide precipitate. The amount of sulphide is determined from the activity of the released radioiodide by comparison with standards which have been processed in the same way. The method is applicable to sulphide amounts greater than 5 ng and concentrations greater than 0.2 ppM. The interference by many common accompanying anions and cations has been investigated.

The determination of ng-amounts of sulphide is of interest, especially in two fields: (1) in biological and chemical systems (*e.g.*, in water supplies, in lake- and sea-water and sewage muds, or as an unpleasant air pollutant) where it must be determined separately from other possible forms of sulphur and (2) in various inorganic and organic materials in order to determine their total sulphur content by micro or trace techniques.

In general, the most frequently applied sensitive methods for the second purpose are those based on sulphide formation, *e.g.*, after hydrogenation or reductive decomposition methods in submicro organic elemental analysis[1–3] or in trace analysis.[4–7]

The chemical methods used in determining ng-amounts of sulphide are limited in their application by different types of interference: these methods include various spectrophotometric methods,[8–11] fluorimetric methods based on quenching of fluorescein mercury acetate,[12–14] catalytic methods based on the azide–iodide reaction[15] and reduction of silver with iron(II)[16] or the use of sulphide-sensitive electrodes.[2,3,17–19]

The displacement method—presented in two variants, one suitable for 1–5 ml samples, the other for up to about 300 ml—can bring certain advantages in some cases. It is similar to a simple technique proposed recently for the determination of other ions.[20,21]

The method is based on the replacement of radioactively labelled iodide from silver iodide, by sulphide ions:

$$2\,Ag^{131}I + S^{2-} \rightleftharpoons Ag_2S + 2\,{}^{131}I^- \qquad (1)$$

The labelled silver iodide is fixed on a filter paper disc. The disc is either shaken with the solution to be analysed (suitable only for small volumes) or the solution is passed through the disc until equilibrium for the reaction is attained. The unknown amount of sulphide is determined from the activity of the released radioiodide by using a calibration graph, or by comparison with a standard which has been processed in the same way.

In this replacement reaction, advantage is taken of the favourable molar and weight ratio between the sulphide to be determined and the iodide released, as well as of the great difference between the solubility products of silver iodide and silver sulphide ($K_{sp(AgI)} = 8 \times 10^{-17}$; $K_{sp(Ag_2S)} = 6 \times 10^{-50}$).[22] The exchange reaction is also favoured by the fact that the relatively small amount of silver iodide is distributed over a large surface area on a filter paper carrier, and the iodide released goes easily into aqueous solution.

EXPERIMENTAL

Reagents and materials

All reagents were of at least p.a. purity. Twice-distilled water (quartz apparatus) was used for preparing the solutions.

Radioiodide. Solutions of radioiodide were prepared from a carrier-free ^{131}I-solution and potassium iodide containing amounts of carrier between 0·01 and 1·00 mg of iodide per ml. The specific activities were between 0·025 and 4 mCi/mg of iodide.

Silver nitrate solutions. Solutions with silver concentrations of 0·02–0·5 mg/ml were used.

Filter paper. Discs were prepared from filter paper MN 2260 (Macherey, Nagel and Co., Düren).

Procedures

Preparation of the discs containing $Ag^{131}I$. In the "shaking" variant 3-μl portions of silver solution are placed on each of a series of filter paper discs 6 mm in diameter. The concentration of silver is chosen so that the activity of the disc is approximately halved in the replacement reaction. As a working rule, 1 μg of silver is suitable for 100 ng of sulphide. The discs are then immersed in a radioactively-labelled iodide solution which has a carrier concentration corresponding to the silver concentration and an appropriate specific activity, and are shaken for a few minutes. The discs are taken out from the solution and washed 5 times in 2*M* acetic acid, and then repeated with redistilled water, in order to remove excess of labelled iodide. The discs are dried with an infrared lamp. In the "flow-through" variant the preparation of the discs is similar, but the discs are 25 mm in diameter and 20 μl of silver solution are placed on each.

· The amount of carrier and the specific activity of the silver iodide are chosen according to the expected range of sulphide concentration in the solutions to be analysed. For example, if the sample solution contains a small amount of sulphide, the amount of silver iodide carrier on the discs should be small, and the specific activity must be high. Conversely, when more sulphide is present, the concentration of carrier must be higher, and the specific activity can be lower.

Shaking method (*variant 1*). Aqueous standard and sample solutions (which can be up to 0·1*M* in EDTA) are used. The most suitable pH value is 8·9 or slightly above. Aliquots of 1–4 ml of standard and sample solutions are transferred into glass ampoules ("Fiolax" Glass, Jenaer Glaswerke, Schott u. Gen., Mainz), each of which is then provided with a disc impregnated with labelled silver iodide. The ampoules are closed and shaken until equilibrium for the replacement reaction is attained. Under the optimal experimental conditions used by us 100 min of shaking are necessary. After the shaking is finished the discs are removed from the solutions, rinsed in distilled water, and dried. The unknown amount of sulphide ions can be determined either by measuring count-rates of equal fractions of the solutions containing the released iodide, or by measuring the loss of activity on the discs. When the activity released is a very small fraction of the original disc activity (*i.e.*, very small amounts of sulphide) it is better to measure the activity of the solution than the activity loss.

The γ-radiation from ^{131}I is counted with a well-type sodium iodide detector and a single-channel analyser. The blank test is carried out with water or with 0·1*M* EDTA at the same pH value as the sample and standard solutions. The complete procedure must be carried out in the absence of daylight.

Flow-through method (*variant 2*). In this variant a large excess of silver iodide must be present on the paper disc to obtain complete replacement of sulphide and in order for one disc to be used for the processing of many samples. For example, to analyse a series of samples each of which contains about 100 ng of sulphide, 100 μg of silver are used for the preparation of the labelled silver iodide. The prepared filter paper disc is then placed on a membrane filter (Sartorius, Göttingen) with a pore size of 0.15 μm, in a filter flask with an effective opening of 20 mm. Redistilled water (10 ml) is passed through the filter, under suction, until the specific activity had become constant (blank value). Then each of the standard and sample solutions is sucked through the filter twice at a rate of *ca.* 10 ml/min. The filter must either be washed with a few ml of redistilled water between samples or the first 4–5 ml of the filtrate from each new solution must be rejected. It is found convenient to run a standard after some sample solutions.

Instead of filter paper prepared with labelled silver iodide it is also possible to use a precipitate of labelled silver iodide uniformly distributed on a membrane filter, as follows. Add 1 ml of 10% nitric acid to *ca.* 15 ml of silver nitrate solution containing 20–100 μg of silver. Heat to near 100° and treat with a slight excess of iodide solution labelled with ^{131}I. Keep the mixture at that temperature for 15–20 min then filter off the silver iodide precipitate by suction through a membrane filter with a pore size of 0.6 μm. Wash the precipitate first with dilute acetic acid and then with 10-ml portions of water as described above.

RESULTS AND DISCUSSION

Shaking method

The rate of the iodide–sulphide replacement reaction is dependent on the experimental conditions. Figure 1 shows the time-dependence of the replacement, for two sets of shaking conditions. Obviously the shaking conditions must be constant for an experimental series.

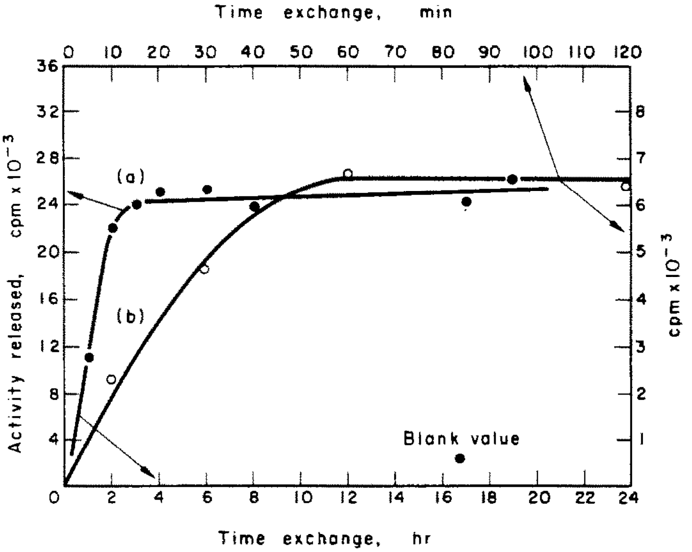

Fig. 1. Time dependence of the activity released for two different experimental conditions: (*a*) intensive shaking and water solution, (*b*) slower shaking and presence of EDTA

It has been known for a long time that sulphide solutions are unstable under normal conditions.[23] Generally, the stability of sulphide solutions is an important factor which must be taken into consideration, irrespective of the method used for the determination. In this variation, because of the relatively long shaking-time, the instability problem is of extraordinary importance. The main reason for the instability seems to be the volatility and oxidation of sulphide.

Sulphide becomes more unstable as its concentration decreases. Several substances have been proposed for stabilization of sulphide solutions. Bock and Puff[18] proposed ascorbic acid: hydrazine sulphate,[10] formaldehyde,[24] and other substances have also been used. It has been reported that in the sulphide concentration range 10^{-7}–$10^{-5}M$, the presence of oxygen does not affect the sulphide stability if the solutions are kept in darkness.[12]

In search for the best conditions, the influence of darkness, presence of hydrazine sulphate and ascorbic acid, and the effect of pH were investigated. Figure 2 shows the

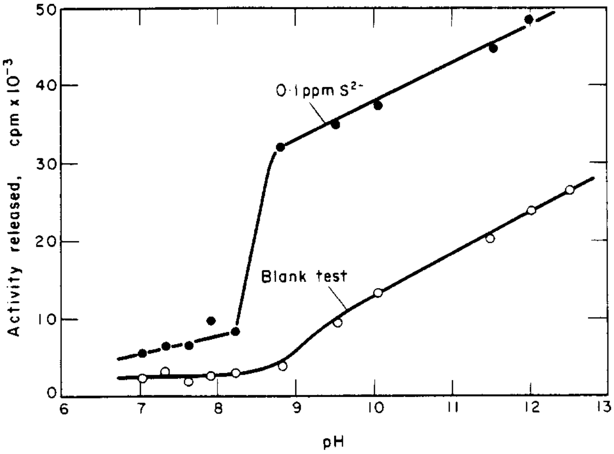

Fig. 2. Dependence of the activity released on pH: 0·1*M* EDTA, shaking method.

dependence of the released activity on the pH when the experiments are done in the absence of daylight. In the pH range 7–8.2 only a relatively small fraction of the sulphide takes part in the replacement, *i.e.*, the sulphide solution is not sufficiently stable for processing. The solutions begin to be stable enough at pH 8.9. Consequently, the determinations can be carried out at this pH and above. Increasing the pH also increases the blank value at about the same rate as the release reaction, so the activity released in the iodide–sulphide replacement stays practically constant.

The presence of ascorbic acid and hydrazine sulphate does not sufficiently stabilize sulphide solutions when they are processed in direct daylight: without any stabilizing agents only 53% of the sulphide taken was found; in the presence of ascorbic acid with a concentration[18] of 1 mg/ml, and of hydrazine sulphate with a concentration[10] of 20 μg/ml, 84% and 71%, respectively, of the sulphide taken was found. If the solutions are processed in the absence of daylight no stabilizing agents are necessary.

The applicability of the method was investigated for the determination of sulphide concentrations between 0 and 400 ng/ml. Since the calibration graphs are linear, the unknown amount of sulphide may be calculated by direct comparison with a standard, after application of the blank correction.

The limit of detection was found to be 5 ng of sulphide. The standard deviation was determined for five different concentrations of sulphide. It increases very rapidly as the amount of sulphide decreases below 50 ng (Fig. 3).

The interference of accompanying anions was investigated in more detail for a sulphide concentration of about 100 ng/ml. This sulphide concentration can be determined in the presence of at least 5000-fold amounts of SO_4^{2-}, F^- and Cl^-, 1000-fold amounts of Br^-, HCO_3^- and SCN^-, and 100-fold amounts of PO_4^{3-}, $S_2O_3^{2-}$ and I^-. Strong interference is caused by cyanide if present in much higher concentrations than sulphide. A CN^-/S^{2-} ratio of 1 can be tolerated.

Under normal conditions, cations forming sparingly-soluble sulphides would interfere. Consideration of stability constants shows that several complexants should work as masking agents for these cations. The majority of the elements forming sparingly-soluble sulphides form EDTA complexes with high stability constants and therefore EDTA can be used as masking agent. The masking agent must fulfil the following conditions however:

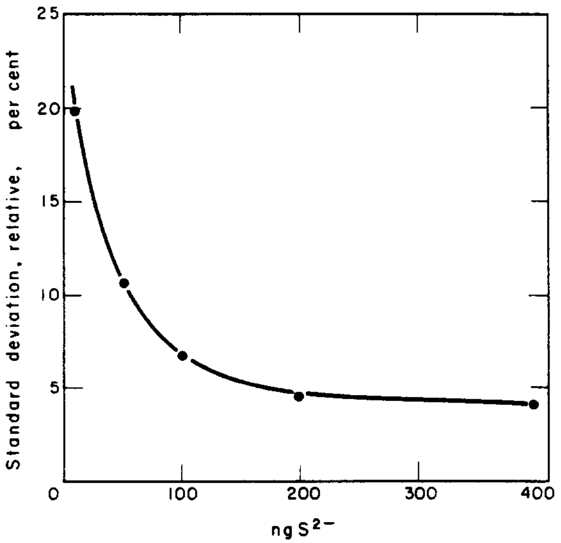

Fig. 3. Relative standard deviation as a function of amount of sulphide, for the shaking method.

(*i*) it should not attack the silver iodide, (*ii*) it should neither attack the sulphide in the solution nor disturb the exchange reaction, and (*iii*) it must allow the iodide released to be washed into the solution. A 0·1*M* EDTA medium was found to fulfil these conditions well.

At least the following excess of common cations is tolerable if the solution is made 0·1*M* in EDTA at a sulphide concentration of 100 ng/ml: 1000-fold Mn(II), Fe(III), Co(II), Ni(II), Zn(II) and Pb(II), 100-fold Tl(I), Cd(II), As(III), As(V) and Cu(II), and 10-fold Hg(II).

Sample volumes up to 5 ml can be used. However, the time necessary to attain equilibrium for the exchange reaction becomes longer with increasing sample volume.

Flow-through method

In the flow-through method much larger sample volumes can be used, up to 300 ml. However, the blank value must be determined with an approximately equal volume of water or EDTA solution.

In the flow-through method the sulphide solution is not subjected to so much stress as it is in the shaking method. This is why no special steps are necessary for preventing losses of sulphide. A relatively large pH range can be used, 5–10. Higher pH values are disadvantageous owing to the higher blank values. The experiments need not be carried out in the absence of direct daylight, but it is recommended to avoid direct daylight if a lot of samples taking a longer period of time are to be analysed. Some changes in the properties of the silver iodide on the filter paper can appear as a result of long exposure to direct daylight. If the experiments are to be interrupted, the filter paper disc or the precipitate must be kept wet.

The prepared filter paper discs gave a somewhat better reproducibility and limit of detection than did labelled silver iodide precipitate distributed on membrane filters. The relative standard deviation at a sulphide concentration of 4 ppM and sample volume 50 ml was found to be 2.5%. The limit of detection at this volume was determined to be 0·2 ppM or 10 ng absolute. The sample volume somewhat affects the blank value and thereby also the limit of detection: the limit of detection is dependent on sample volume. For example, the limit of detection is reduced by a factor of about 2, if 5-ml sample volumes are processed instead of 50-ml samples.

EDTA increases the blank value more in the flow-through method than in the shaking method. The tolerable EDTA concentration for the range of sulphide investigated is about $10^{-3}M$. The masking ability is then correspondingly lower, and reduces the tolerance limit for metals, *e.g.*, for Cu(II) and Pb(II) by a factor of about 4.

The replacement reaction is particularly advantageous if it is used in combination with X-ray fluorescence. Such a technique based on an enrichment of sulphide ions on a thin layer of silver chloride or iodide has been developed, including detailed studies of interference by accompanying ions.[25] It will be published later.

Acknowledgements—The authors wish to express their gratitude to the Stiftung Volkswagenwerk, to the Deutsche Forschungsgemeinschaft, Bad Godesberg, Sonderforschungsbereich 82 der Universität Stuttgart, and to the Wirtschaftsministerium des Landes Baden-Württemberg for their financial support of this work. They are also grateful to Mr. Mikeleit for his assistance in the experiments and to Dr. P. Wolf, Karlsruhe, for his kindness in providing the radioiodide.

Zusammenfassung—Eine Arbeitsvorschrift zur Bestimmung von ng-Mengen Sulfidionen in flüssigen Proben wird in zwei Varianten angegeben. Sie beruhen auf der Verdrängung von radioaktiv markiertem Jodid aus Silberjodid durch Sulfid. Bei der ersten Variante, die sich für kleine Probenvolumina eignet, wird das markierte Silberjodid auf einer Filtrierpapierscheibe aufgezogen; diese Scheibe wird dann mit der zu analysierenden Lösung geschüttelt, bis das Gleichgewicht erreicht ist. Bei der zweiten Variante, die sich für Probenvolumina bis zu 300 ml eignet, wird die Probenlösung durch eine Filtrierpapierscheibe geführt, die markiertes Silberjodid enthält, oder durch eine Fällung aus markiertem Silberjodid. Die Sulfidmenge ermittelt man durch Vergleich der Aktivität des freigesetzten Radiojodids mit auf die selbe Weise behandelten Standards. Die Methode läßt sich auf Sulfidmengen über 5 ng und Konzentrationen über 2 ppM anwenden. Die Störung durch viele gängige begleitende Anionen und Kationen wurde untersucht.

Résumé—On présente deux variantes d'une technique pour le dosage de quantités de l'ordre du ng d'ions sulfure dans des échantillons liquides. Elles sont basées sur le remplacement de l'iodure marqué radioactivement de l'iodure d'argent par le sulfure. Dans la première variante, convenable pour de petits volumes d'échantillon, l'iodure d'argent marqué est fixé sur un disque de papier filtre qui est alors agité avec la solution à analyser jusqu'à ce que l'équilibre soit atteint. Dans la seconde variante, convenant à des volumes d'échantillon jusqu'à 300 ml, la solution d'échantillon est passée à travers un précipité d'iodure d'argent marqué. La quantité de sulfure est déterminée à partir de l'activité du radioiodure libéré par comparaison à des étalons qui ont été traités de la meme manière. La méthode est applicable à des quantités de sulfure supérieures à ng et à des concentrations supérieures à 0,2 p.p.M. On a étudié l'interférence de nombreux anions et cations accompagnateurs communs.

ELECTRONIC ABSORPTION AND FLUORESCENCE OF 9-ANTHRALDEHYDE AND ITS CONJUGATE CATION

JOHN F. YOUNG and STEPHEN G. SCHULMAN
College of Pharmacy, University of Florida, Gainesville, Florida 32601, U.S.A.

(*Received* 28 *September* 1972. *Accepted* 3 *November* 1972)

Summary—The appearance or lack of vibrational structure in the ^1L_a and ^1L_b absorption bands of the neutral species and cation derived from 9-anthraldehyde is explained in terms of adherence to or violation of the Franck-Condon principle. The lack of vibrational structure is attributed to the motions of the aldehyde group during the course of electronic transition, a process which destroys vibration quantization in the Franck-Condon excited state. The appearance of well-defined vibrational structure in the ^1L_a band of the cation establishes that intramolecular charge-transfer alone, without accompanying vibrational or solvent relaxation which is contemporaneous with electronic transition, is not responsible for the lack of structure in most intramolecular charge-transfer transitions. The previously reported fluorescence of 9-anthraldehyde in hydroxylic solvents is found to be in error and is likely to originate from an impurity produced by photo-reduction. The actual fluorescence of 9-anthraldehyde is at much lower frequency than previously reported.

The application of fluorescence spectroscopy to chemical analysis is somewhat restricted by the limited number of organic molecules, of analytical interest, which fluoresce. This problem can be substantially reduced in importance by the preparation of fluorescent derivatives of non-fluorescing analytes. One of the most widely employed of such techniques entails the condensation of a molecule containing a fluorophore and a reactive functional group with the molecule of analytical interest. Normally, in such reactions an excess of reactant is added to the reaction medium, with the result that the native fluorescence of the reactant may constitute an interference with the measurement of the fluorescent derivative. Under this circumstance it would be useful to carry out a variation of the chemical composition of the reaction medium (*e.g.*, pH or Hammett acidity) in order to select the solution conditions under which minimal overlap occurs between the emissions of the reactant and its condensation product with the analyte. Similar arguments are also applicable to the absorption spectrophotometric analyses of condensation products of reactive chromophores with analytes which do not absorb in the near ultraviolet or visible regions of the electromagnetic spectrum.

9-Anthraldehyde appears to be a particularly interesting reagent for such reactions because of the highly fluorogenic and chromophoric properties of the anthracene ring and the diverse and highly reactive chemistry of the aldehyde group. Aromatic aldehydes are generally known to be very weak bases in their ground electronic states and moderately weak bases in their lowest electronically excited singlet states. These factors determine the spectral regions in which the aromatic aldehydes absorb and fluoresce, respectively, in solutions of varying acidity. Consequently, it was felt that the intelligent application of 9-anthraldehyde as an analytical reagent, in aqueous solutions, demanded consideration of the acidity dependence of its molecular electronic spectra.

9-Anthraldehyde has been reported to fluoresce in hydroxylic solvents but not in aprotic media.[1] This has been attributed to the lowest excited singlet state being of the n,π^* type in aprotic solvents. However, in hydroxylic solvents, hydrogen-bonding of the solvent with the non-bonded electron pairs of the carbonyl group raises the energy of the n,π^* state while the polarizing effect of hydrogen-bonding and the gross dielectric properties of the activating solvent lower the energy of the lowest $^1\pi,\pi^*$ state to the point where it becomes the lowest excited singlet state, favouring fluorescence over intersystem crossing as a means of deactivation of the lowest excited singlet state.[1]

The basic properties of 9-anthraldehyde have been investigated by Culbertson and Pettit[2] who found that in the ground electronic state this compound is considerably more basic than benzaldehyde or the naphthaldehydes. This result was attributed to the stabilization of the cation by greater delocalization of positive charge, over the anthracene ring, than is possible in the smaller ring aldehyde cations. A recent calculation of the dissociation constant of the 9-anthraldehyde cation in the lowest excited singlet state, employing the Förster cycle[3] and the averages of the absorption and fluorescence maxima of the neutral molecule and the cation as the spectroscopic *O-O* bands, indicated that 9-anthraldehyde was far more basic (11 orders of magnitude) in the lowest excited singlet state than any other aromatic aldehyde yet investigated.[4] On the basis of the differences in sizes of the aromatic rings in 9-anthraldehyde and other aromatic aldehydes, we had difficulty in rationalizing the differences in excited state basicity suggested in the previous study[4] and therefore decided to reinvestigate the electronic spectra and titration behaviour of 9-anthraldehyde.

EXPERIMENTAL

9-Anthraldehyde was recrystallized from 95% ethanol. Reagent grade sulphuric acid and distilled demineralized water were employed as the solvents in these studies.

Absorption spectra were taken on a Beckman DB-GT spectrophotometer. Fluorescence measurements were performed on a Perkin–Elmer MPF-2A fluorescence spectrophotometer with monochromators calibrated against the xenon line-emission spectrum and output corrected for instrumental response by means of a Rhodamine-B quantum counter.

Approximately $10^{-3}M$ 9-anthraldehyde was prepared in 95% ethanol immediately before mixing 0.1 ml with 10.0 ml of buffer or acid solution. Only these freshly prepared 9-anthraldehyde solutions in ethanol were used for spectral study.

RESULTS AND DISCUSSION

The electronic spectral features of 9-anthraldehyde and its conjugate cation are summarized in Table 1. The variations of the absorption and fluorescence spectra of 9-anthraldehyde with pH and Hammett acidity[5] are shown in Figs. 1 and 2.

The absorption spectrum of the neutral molecule shows that the ^1L_a band is unstructured while the ^1L_b band which is observed on the short wave-length side of the ^1L_a band is highly structured. However, remarkably, the ^1L_a band of the cation is structured while the ^1L_b band of the cation is diffuse. It is assumed that the ^1L_a band is the lowest frequency absorption band in both the cation and neutral molecule because aldehyde substitution in the 9-position mixes charge-transfer character into the short-axis polarized $^1L_a \leftarrow {}^1A$ transition of anthracene, lowering the energy of the $^1L_a \leftarrow {}^1A$ transition of anthracene (which is the lowest energy absorption in unsubstituted anthracene) to a greater degree than the $^1L_b \leftarrow {}^1A$ transition. The lack of vibrational structure in an electronic absorption spectral band is the result of the loss of vibrational quantization in the Franck-Condon excited state to which transition takes place and is often observed in intramolecular charge-transfer transitions, especially in fluid polar solvents and when exocyclic functional groups are better conjugated with an aromatic ring in the excited state than in the ground state. The loss of

vibrational quantization in the Franck-Condon excited state may be attributed to solvent relaxation processes and functional group rehybridization occurring at a rate which is only slightly slower than the rate of the electronic absorption. The transient thermal relaxation processes alter the vibronic sublevels of the Franck-Condon excited state while the electronic transition is occurring, with the result that a continuum of vibronic transitions comprises the absorption band, giving the band its diffuse appearance. Thus the assumption of total separability of electronic and nuclear motions, upon which the Franck-Condon principle is based, is sometimes only approximate. The appearance of vibrational structure in the ^1L_b band of 9-anthraldehyde and in the ^1L_a band of its cation indicate that these transitions are well described by the Franck-Condon principle. However, the lack of vibrational structure in the ^1L_a band of the neutral molecule and in the ^1L_b band of the cation suggests that the

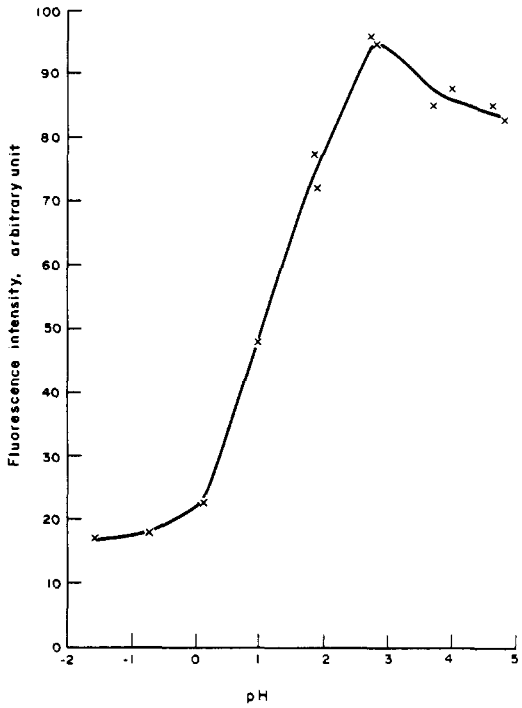

Fig. 2. Fluorimetric pH titration curve for $10^{-5}M$ 9-anthraldehyde. Fluorescence intensity was monitored at 510 nm.

Franck-Condon principle is only approximate for these transitions. The appearance of blurred vibrational structure in the ^1L_a band of the neutral molecule is observed in hexane solutions and indicates that the loss of vibrational structure in water is, at least in part, related to changes in solvent interaction accompanying electronic transition. It was considered that the loss of structure in the ^1L_a band of the neutral molecule might be the result of rotation of the aldehyde group from an out-of-plane conformation, into coplanarity with the anthracene ring during the absorption process. Perpendicularity between the carboxyl group and the anthracene ring has been observed in the ground state of 9-anthroic acid[6]. However, in 9-anthraldehyde the fluorescence of the neutral molecule in rigid media at 77 K is not similar to that of anthracene as would be expected if conjugation between the aldehyde group and the ring was prevented by freezing the molecule into the ground-state conformation. Rather, the fluorescence of 9-anthraldehyde at $2{\cdot}15 \times 10^4 \mathrm{cm}^{-1}$, at 77 K, is indicative of strong conjugation and coplanarity in the ground-state. In the cation derived from 9-anthraldehyde, there is no question that the protonated aldehyde group is coplanar (conjugated) with the anthracene ring in the ground-state as well as the excited state, because the fluorescence of the cation in rigid sulphuric acid at 77 K occurs at $1.83 \times 10^4 \mathrm{cm}^{-1}$ which is much too low a frequency for fluorescence from an unconjugated anthracene derivative. The reason for loss of structure in the ^1L_b band of the cation is not certain, because solvent effects on the cation absorption spectra could not be evaluated, as the ground-state cation could not be formed in non-polar, non-hydrogen-bonding media. However, that the ^1L_a band of the cation is structured indicates that neither rapid solvent nor intramolecular conformational relaxation occurs during the course of the $^1L_a \leftarrow {}^1A$

transition. Because of the low frequency of the ^1L_a band in the 9-anthraldehyde cation, it cannot be disputed that the $^1L_a \leftarrow {}^1A$ transition in this species has a great deal of charge-transfer character. It is thus apparent that lack of vibrational structure in intramolecular charge-transfer transitions, although common, is not general.

Absorptiometric titration of 9-anthraldehyde with sulphuric acid employing the corrected Hammett acidity scale of Jorgensen and Hartter[5] yielded $pK_a = -5{\cdot}1$ for the 9-anthraldehyde cation. The pK_a of $-4{\cdot}81$ previously reported[2] was based upon Hammett's original H_0 function.[7]

In aqueous solutions 9-anthraldehyde exhibited a diffuse fluorescence band with maximum at $1{\cdot}96 \times 10^4$ cm^{-1}. In acidic media the emission was still diffuse, but considerably weaker and had its maximum at $1{\cdot}78 \times 10^4$ cm^{-1}. The former fluorescence is assigned to the $^1L_a \rightarrow {}^1A$ transition of the neutral molecule and the latter to the $^1L_a \rightarrow {}^1A$ transition of the cation. The fluorescence of the neutral molecule in ethanol was previously reported[4] to occur at $2{\cdot}54 \times 10^4$ cm^{-1} which is considerably higher in frequency than the emission observed in the present work in water. However, our studies with a freshly recrystallized sample of 9-anthraldehyde in ethanol yielded an emission maximum at $2{\cdot}08 \times 10^4$ cm^{-1}. On standing for several hours in ethanol (or water) our 9-anthraldehyde solutions developed a fluorescence at the frequency reported by the previous investigators[4] and the low frequency fluorescence diminished appreciably in intensity. Moreover, the appearance of the high-frequency emission was enhanced in the presence of light. It is likely that 9-anthraldehyde undergoes photo-reduction in hydroxylic solvents to the arylmethylcarbinol, a process which is often observed in arylaldehydes. Thus the fluorescence maximum of 9-anthraldehyde reported by the previous investigators was probably that of an impurity.

Fluorimetric titration of the 9-anthraldehyde yielded a midpoint for the interconversion between the cation and neutral molecule at pH 1·3. This value is assigned to the dissociation constant of the cation in the ^1L_a state (pK_a^*) and indicates that 9-anthraldehyde is only 6 orders of magnitude more basic in the ^1L_a state than in the ground-state, rather than 17 orders as suggested by the previous investigators.[4] If pK_a^* is calculated by the Förster cycle method,[3] employing the averages of absorption and fluorescence maxima determined in the present work to represent the spectroscopic *O-O* bands of the ^1L_a transitions in cation and neutral molecules, a value of 1·8 is obtained for pK_a^*, which is in fair agreement with the value obtained by fluorimetric titrimetry. If the shift in the absorption spectra alone upon protonation is employed to calculate pK_a^*, a value of 6·9 is obtained, and a value of $-1{\cdot}3$ if the shift in the fluorescence spectra alone is employed. The inaccuracy of the value calculated from the absorption shift can be attributed to unequal excited state thermal relaxation energies for cation and neutral molecule (the Stokes shift for the cation is 2000 cm^{-1} and that for the neutral molecule is 4900 cm^{-1}) which are not reflected in the absorption spectra.[8] The inaccuracy of the pK_a^* value calculated from the fluorescence shift can be primarily attributed to the differences in vibrational composition of the ground states of the cation and neutral molecule as reflected by the differences in half-band widths of the fluorescences (1600 cm^{-1} for the cation and 2900 cm^{-1} for the neutral molecule). Because the errors in the estimation of pK_a^* from absorption shifts alone and from fluorescence shifts alone arise from different sources, the averaging of absorption and fluorescence spectra does not truly give the position of the *O-O* bands of the ^1L_a bands of cation and neutral molecule and the better agreement of the pK_a^* value calculated from the shift of the averaged absorption and fluorescence spectra with that determined from the fluorimetric titration appears to be fortuitous.

Zusammenfassung—Das Auftreten oder Nichtauftreten von Schwingungsstruktur in den ^1L_a- und ^1L_b-Absorptionsbanden der neutralen Spezies und des Kations von 9-Anthraldehyd wird im Sinne einer Befolgung oder Nichtbefolgung des Franck-Condon-Prinzips erklärt. Das Fehlen von Schwingungsstruktur wird den Bewegungen der Aldehydgruppe im Verlauf des Elektronenübergangs zugeschrieben, einem Prozeß, der die Schwingungsquantisierung im angeregten Franck-Condon-Zustand zerstort. Das Auftreten von wohldefinierter Schwingungsstruktur in der ^1L_a-Bande des Kations weist nach, daß die intramolekulare Ladungsübertragung allein, ohne Schwingungs- oder Lösungsmittelrelaxation, die gleichzeitig mit dem Elektronenübergang ablauft, nicht für das Fehlen von Struktur in den meisten intramolekularen Ladungsübertragungs-Übergängen verantwortlich zu machen ist. Die früher mitgeteilte Fluoreszenz von 9-Anthraldehyd in hydroxylhaltigen Lösungsmitteln ist offenbar nicht reell; wahrscheinlich rührt sie von einer durch Photoreduktion erzeugten Verunreinigung her. Die tatsächliche Fluoreszenz von 9-Anthraldehyd liegt bei viel niedrigerer Frequenz, als früher angegeben wurde.

Résumé—On explique l'apparition ou le défaut de structure de vibration dans les bandes d'absorption ^1L_a et ^1L_b de l'espèce neutre et du cation dérivés du 9-anthraldéhyde par rapport au fair que le principe de Franck-Condon est respecté ou pas. Le défaut de structure de vibration est attribué aux mouvements du groupe aldéhyde durant le temps de la transition électronique, un processus qui détruit la quantification de vibration dans l'état excité de Franck-Condon. L'apparition d'une structure de vibration bien définie dans la bande ^1L_a du cation établit que le transfert de charge intramoléculaire seul, sans relaxation de vibration ou de solvant simultanée, qui est contemporaine de la transition électronique, n'est pas responsable de l'absence de structure dans la plupart des transitions de transfert de charge intramoléculaires. On a trouvé que la fluorescence du 9-anthraldéhyde rapportée antérieurement dans des solvants hydroxylés doit être erronée et doit provenir vraisemblablement d'une impureté produite par photoréduction. La fluorescence réelle du 9-anthraldéhyde est à une fréquence beaucoup plus faible qu'il n'a été rapporté antérieurement.

THE ADSORPTION OF SILVER ON POTASSIUM CYANOCOBALT(II)FERRATE(II)

M. WALD, W. SOYKA and B. KAYSSER
Zentralinstitut für Analytische Chemie der Kernforschungsanlage
Jülich, 517 Jülich, Bundesrepublik Deutschland

(*Received* 28 *January* 1972, *Accepted* 19 *October* 1972)

Summary—A procedure is described for recovering silver from industrial sewage (mining and photo-industry *etc*) with the aid of the ion-exchanger potassium cyanocobalt(II)ferrate(II) (KCFC). Silver is easily removed by simple mixing with KCFC, even from solutions containing less than 1 g of silver per ton of solution. The process is performed at room temperature at $pH < 7$. There is no interference from a 600-fold amount of Ca, Cu(II), Zn, Cd, Pb, and Fe(II). Pure silver may be obtained by dissolution of the ion-exchanger in potassium cyanide solution, subsequent precipitation as sulphide, and roasting, or by melting it out of the ion-exchanger after heat treatment in a high-frequency furnace. With 1 kg of KCFC, 1·25 kg of silver may be extracted from solution. The process is simple and economic.

Potassium cyanocobaltferrate was first used for the selective adsorption of caesium from radioactive sewage.[1] Since then several papers have dealt with the capacity of this salt and its ammonium homologue for ion-exchange of trace amounts of several elements at varying pH-values and in the presence of an excess of foreign ions.[2–4] To our knowledge, however, there have been no experimental investigations of the ion-exchange behaviour of KCFC towards the coinage metals, which might be expected to interact with it, because they form 18-electron type ions which are strongly polarizing, and hence should form more stable cyanocobaltferrates than the alkali metals, which give the stability series[5] $Li < Na < K < Rb < Cs$. If this were indeed the case, the effect might be used to recover noble metals from highly diluted waste solutions, which would be of great economic interest.

EXPERIMENTAL

Reagents

The KCFC used was either a commercial product (LOBA-Chemie Wien or Bio-Rad Laboratories) or prepared[1] from 0·5*M* $K_4Fe(CN)_6 \cdot 3H_2O$ and 0·3*M* $Co(NO_3)_2 \cdot 6H_2O$. No differences in the chemical behaviour of the products have been found.

Radioactive tracer

^{110m}Ag ($t_{1/2} = 253$ days; 0·66 and 0·88 MeV gamma-rays) was obtained by irradiation of 27·5 mg of metallic silver for 10 days in the drum equipment of the deuterium-moderated tank reactor FRJ-2, type DIDO, of the Nuclear Research Centre, Jülich, at a neutron flux of 7×10^{12} n/cm^2/sec. The isotope (induced activity 1·13 mCi) was dissolved, diluted and added to the silver salt solutions as tracer.

Apparatus

"Eppendorf-Microliter-System" microlitre pipettes, centrifuge, vessels, heating block, rotary mixer, *etc*, were used; other vessels were made of Teflon or polypropylene.

Procedures

Batch procedures were used for all ion-exchange tests. The capacity of KCFC for silver was determined by shaking about 100 mg of KCFC for 20 min each time with three consecutive 1-ml portions of 10% silver nitrate solution, centrifuging, discarding the supernatant liquid and washing the KCFC with 0·5-ml portions of water. Analogously 400 mg of KCFC and 20 ml of solution were used to determine the dependence of the capacity of KCFC on the concentration of silver and acidity in pure silver salt solutions and simulated waste solutions. The silver remaining in the solution after the ion-exchange process were determined either radiometrically with ^{110m}Ag as tracer or by atomic absorption. Potassium, cobalt and iron exchanged for silver were determined by atomic absorption only.

RESULTS AND DISCUSSION

Capacity of KCFC for silver

Table 1 shows the results for the capacity determination mentioned above. As shown in Table 1, 100 mg of KCFC adsorb a total of 121·3 ± 0·5 mg of silver from three charges. It can be estimated that a fourth charge would exchange about 5% of its silver, so the maximum capacity is estimated to be 1·243 g of Ag per g of KCFC or 11·53 meq of Ag per g of KCFC (containing 4·13 meq of K).

Effect of silver concentration

The recovery of silver from residues is usually considered economic only when the minimum silver content is 100 ppm in silver ores, waste and sludge, and 15–30 ppm in ores of other metals. Therefore the efficiency of recovery of silver from highly dilute solutions was investigated by shaking 400 mg of KCFC with 10^{-1}–$10^{-5}M$ silver for 20 min. The results (averages of three concordant determinations) are compiled in Table 2.

Silver can evidently be recovered quickly and economically even from solutions con-

* Count-rate of silver solutions before exchange: 1 and 2—140,572 cpm; 3—144,025 cpm.

Table 2. Adsorption of silver by KCFC as a function of the concentration of silver salt

Charge no.	$[AgNO_3]$, *ppm*	Silver added, *mg*	Silver adsorbed	
			mg	%
1	$1{\cdot}08 \times 10^4$	215·7	211·9	98·2
2	$1{\cdot}08 \times 10^3$	21·57	21·5	99·5
3	108	2·157	2·02	93·8
4	10·8	0·2157	0·145	67·0
5	1·08	0·0216	0·0145	67·0

taining silver well below the level hitherto regarded as economic for recovery. Even in the 1–10 ppm range, 67% of the silver is recovered in a single step, and the KCFC used may be used again for further exchange.

Effect of foreign ions

A series of simulated "waste solutions" was prepared, $10^{-3}M$ in each of the following: silver, calcium, copper(II), zinc, cadmium, lead, and iron(II) nitrates. A similar series was made with $0{\cdot}1M$ concentrations of the foreign ions. Portions of KCFC (100 mg) were shaken for 20 min with 1 ml of each "waste solution" adjusted to be neutral or strongly acidic. The KCFC was well washed with water and the amount of silver left in the solution determined radiometrically. The results are compiled in Table 3.

The exchange of silver is practically unaffected by variation of the conditions over the ranges given, even by a 100-fold excess of copper and zinc, which may be contrasted with the report[2] that zinc is 95% exchanged on KCFC over a wide range of pH.

Equivalence of exchange

It was stated above that 11·53 meq of silver are exchanged by 1 g of KCFC containing 4·13 meq of potassium. Hence some other ion besides potassium must take part in the exchange, and it was found that with increasing concentration of silver solution an increasing amount of cobalt is liberated from KCFC and exchanged for silver. If sufficiently concentrated silver solution is used, the KCFC crystal will be destroyed and all the potassium and cobalt take part in the ion-exchange process, 11·53 meq of silver being adsorbed per g of KCFC and 4·13 meq of potassium and 6·95 meq of cobalt being exchanged. However if the ratio of exchangeable potassium to silver available exceeds 10 there is negligible exchange of cobalt. Thus with very dilute silver solutions the KCFC crystal structure remains intact and the KCFC may be used repeatedly. Table 4 shows the results.

Table 3. Exchange of silver by KCFC from "waste solutions"

Charge no.	Foreign ion concentration, *M*	Acidity	Silver exchanged, %

5	$2·0 \times 10^{-4}$	$1·34 \times 10^{-4}$	$1·40 \times 10^{-4}$	0	1·04	0

Recovery of silver from KCFC

The silver adsorbed on KCFC may be recovered in high purity by one of the following methods.

(*a*) The dry KCFC (1 g) is heated in a solution of 2 g of potassium cyanide in 5 ml of water at 40–60° until a yellow-brown, clear solution is obtained. This solution is diluted with 3–5 ml of water and cooled and a solution of 5 g of $Na_2S \cdot 9H_2O$ in 5 ml of water is added. The mixture is heated for 10 min at 60–80° and filtered hot. The precipitated silver sulphide is washed well with water and ignited at 800–900°. The silver recovered contains $<1\%$ of cobalt.

(*b*) The KCFC is transferred to a silica vessel, which is either wrapped in a sheet of tantalum or immersed in a bath of gold, and heated at 1500° in a high-frequency furnace. Crystals of silver are deposited and pure silver will drop off. If the silver solidifies on the KCFC, it may be separated by a vibrator or ultrasonic device.

Acknowledgement—It is a pleasant duty for the authors to thank the Director of the Central Institute for Analytical Chemistry, Professor Dr. H. W. Nürnberg, for his continuous interest in this work.

Zusammenfassung—Es wird ein Verfahren zur Entsilberung von industriellen Abwässern (Bergbau, Fotoindustrie u.a.m.) mit Hilfe des Kationenaustauschkristalls KCFC beschrieben. Auch aus Lösungen, die 1 g Silber und weniger pro Tonne Lösung enthalten, wird Silber durch KCFC entfernt. Fremdionen wie Ca, Cu, Zn, Cd, Pb, Fe(II) stören selbst in 600-fachem Überschuß weder im sauren, noch im neutralen Bereich. Reines Silber kann u.a. durch Erhitzen im Hochfrequenzofen aus dem Ionenaustauschkristall herausgeschmolzen werden. 1 Kilogramm KCFC vermag etwa 1,25 Kilogramm Silber aus Lösungen anzureichern. Die quantitativen Austauschverhältnisse werden untersucht und es wird gezeigt, daß von einer bestimmten Silberkonzentration an neben Kalium auch Kobalt aus dem KCFC verdrängt wird.

Résumé—On décrit une technique pour la récupération de l'argent d'eaux résiduaires industrielles (industrie minière et industrie de la photo, etc. . . .) à l'aide de l'échangeur d'ions cyanocobalt (II) ferrate (II) de potassium (KCFC). L'argent est aisément éliminé par simple mélange avec le KCFC, même de solutions contenant moins de 1 g d'argent par tonne de solution. L'opération

est réalisée à température ambiante à pH < 7. Des quantités 600 fois supérieures de Ca, Cu (II), Zn, Cd, Pb et Fe (II) n'apportent pas d'interférence. On peut obtenir l'argent pur par dissolution de l'échangeur d'ions dans une solution de cyanure de potassium, précipitation subséquente à l'état de sulfure, et calcination, ou par séparation par fusion de l'échangeur d'ions après traitement thermique dans un four haute fréquence. Avec 1 kg de KCFC, on peut extraire 1,25 kg d'argent de la solution. Le procédé est simple et économique.

SHORT COMMUNICATIONS

MICROTITRIMETRIC DETERMINATION OF URANIUM IN TRIBUTYLPHOSPHATE (30%)-n-DODECANE-NITRIC ACID MEDIUM IN THE PRESENCE OF EXCESS OF IRON, MAGNESIUM AND ALUMINIUM

(*Received* 20 *July* 1972. *Accepted* 8 *September* 1972)

Countercurrent extraction is one of the main methods of uranium recovery in reprocessing spent nuclear fuels or in refining uranium from its concentrates. Tributylphosphate[1] has been in common use as an extraction solvent either in reprocessing (*e.g.*, Purex process) or in research. To follow the course of countercurrent extraction from the loss of uranium in the aqueous phase only, as is done in equilibrium extraction studies, has been shown, according to our experience with mixer-settlers, to be insufficient. It is known from the literature that conventional redox determinations of uranium are subject to interference from organic matter. Nitric acid also seriously interferes.[2,3] Recently, Cherry[4] has worked out a method of amperometric determination of uranium (procedure range 2–200 mg of U) in a solution containing nitric acid or tributylphosphate.

The aim of our study was to work out a method (based on our earlier work[3]) of direct microdetermination of uranium in the aqueous as well as the organic phase from extraction of uranium with tributylphosphate (30%) in n-dodecane from solutions containing nitric acid (0–6*M*) and excess of iron, magnesium and aluminium. It was found experimentally that uranium could be simultaneously stripped from the organic phase and reduced to uranium(IV) by treatment by iron(II). A similar micro-method for uranium determination in the presence of fission products is being developed.

EXPERIMENTAL

Reagents and apparatus are those described before.[2,3] The procedure is suitable for both aqueous and organic phases containing 0·1–3·0 mg of uranium and 0–6*M* in nitric acid, and is that described previously[3] with the following modifications.

1. Rinse out the micropipette with at least 100 μl of acetone; this volume is not counted in the 500 μl of the procedure (this is necessary in analysing the organic phase).
2. After adding iron(II) continue the procedure within 5 min. Stir so that an emulsion may form.
3. Before the dilution a thin layer of TBP will protect U(IV) against aerial oxidation for about 2 hr. It is possible to protect samples of the aqueous phase with 100 μl of TBP in a similar way.
4. In the titration samples of the organic phase the TBP layer should remain intact. An emulsion retards the colour change.

DISCUSSION AND RESULTS

Stripping

The conditions of the procedure make quantitative stripping of uranium from the organic phase possible, as can be seen from the results given in Table 1.

Destruction of nitrite

Destruction of nitrous acid or nitrites in aqueous uranium solutions was discussed in detail earlier.[3] It is known from the literature that nitrous acid is preferentially[5] extracted into TBP and accumulates there,[6] in contrast to sulphamic acid[5] or hydrazine[6] which are not extracted. The reaction of sulphamic acid with nitrites (to destroy the nitrites) proceeds slowly at the interface.[5]

Formation of a temporary emulsion by efficient stirring at the stage of destroying excess of iron(II) (so that the interface is continuously enlarged and renewed) successfully eliminates nitrites from the TBP phase, as experimentally proved.

Yellow colour in the organic phase

A yellow colour was observed to be formed in organic phases prepared with use of nitric acid intentionally exposed to direct daylight (*cf.* Schmid[7]) for half a year. The intensity and induction period of the yellow colour were found to be proportional to the concentration of nitric acid present; the first directly, the second inversely.

When an acid mixture of 4*M* nitric acid/0·1*M* sulphamic kept in a dark bottle for a year and a half was used in preparation of the organic phases the yellow colour did not occur within two days.

The yellow colour mentioned may be due to a complex [TBP . HNO_2].[8]

AP : TBP(30%) in n-dodecane dissolved in water

Stability of uranium solutions

Dilute uranium solutions acidified to be about 0·5*M* in nitric acid proved to be stable for about a month. At lower acidities low results for uranium were obtained, probably owing to hydrolysis to hydroxy-complexes.[9]

Effect of TBP

In analysis of organic and/or especially aqueous phases (containing traces of dissolved TBP) the reaction mixture, which is green after the Fe(II) addition, starts to turn yellow or brown within 5 min. This indicates a spontaneous oxidation of Fe(II) not observed in analysis of aqueous samples,[3] where the reaction mixture remained green and only became yellow if $[HNO_3]$ was about 9*M* and then only after a much longer time had elapsed.[3] To prevent possible oxidation of U(IV) it is recommended to continue the procedure within 5 min of adding the Fe(II) (see Table 2).

Effect of other ions

Nitric acid present in either phase (0–6*M* in the aqueous, 0–1·2*M* in the organic) does not interfere. Neither the mineralization of organic matter nor the preliminary stripping required in conventional methods is needed. Excess of iron, magnesium and aluminium does not interfere in the aqueous phase, and is not extracted into the organic phase.

Accuracy and precision

Amounts of 0·6–2·4 mg of uranium can be determined with an error less than ±1% both in the aqueous (Tables 3, 4) and organic phase (Table 1). Twelve replicate determinations of an aqueous phase containing 2400 μg of uranium in the presence of 2·4 mg of magnesium and 2·7 mg of aluminium gave an average of 2395 ± 4 μg, the mean relative deviation being ±0·2%. As in the previous method[3] no blank correction was found necessary.

Summary—A method is described for microdetermination of uranium in aqueous phases containing nitric acid, iron, magnesium, aluminium and traces of TBP, and in organic phases containing TBP, n-dodecane and nitric acid. Treatment of the organic phase strips the uranium, reduces it to U(IV), and destroys any nitrite present.

Zusammenfassung—Ein Verfahren zur Mikrobestimmung von Uran in Salpetersäure, Eisen, Magnesium, Aluminium und Spuren TBP enthaltenden wäßrigen Phasen und in TBP, *n*-Dodekan und Salpetersäure enthaltenden organischen Phasen wird beschrieben. Eine Behandlung der organischen Phase extrahiert das Uran zurück, reduziert es zu Uran(IV) und zerstört alles vorhandene Nitrit.

Résumé—On décrit une méthode pour le microdosage de l'uranium en phases aqueuses contenant de l'acide nitrique, du fer, du magnésium, de l'aluminium et des traces de TBP, et en phase organique contenant du TBP, du *n*-dodécane et de l'acide nitrique. Le traitement de la phase organique sépare l'uranium, le réduit en U(IV), et détruit tout nitrite présent.

INDIRECT ATOMIC-ABSORPTION DETERMINATION OF BORON BY SOLVENT EXTRACTION AS TRIS(1,10-PHENANTHROLINE)CADMIUM TETRAFLUOROBORATE

(*Received* 26 *June* 1972, *Accepted* 23 *October* 1972)

Indirect determination of non-metals by means of atomic-absorption spectrophotometry of a metal ion complexed with a compound of the non-metal is well known. A colorimetric method for the determination of boron by solvent extraction as Tris(1,10-phenanthroline)iron(II) tetrafluoroborate has been reported,[1] and applied to the analysis of tap-water.[2] In atomic-absorption spectrophotometry (AAS), the sensitivity for cadmium is 5–10 times that for iron,[3,4] so for an AAS method we have used Tris(1,10-phenanthroline)cadmium(II) as counter-cation instead of Tris(1,10-phenanthroline)iron(II), and extraction into nitrobenzene. The cadmium atomic absorption at 228·8 nm is a linear function of boron concentration in the aqueous phase over the range of 0·01–0·5 ppm. The sensitivity for boron is apparently about 1000 times that of the direct atomic-absorption method. Certain metal ions interfere because of their reaction with phenanthroline and fluoride. Boron in steel has been determined at ppM levels.

EXPERIMENTAL

Reagents

All solutions were prepared from analytical-reagent grade chemicals and demineralized water, and stored in polyethylene bottles.

Standard boron solution, 0·025M. Boric acid (0·7726 g) was dissolved in an appropriate amount of water and the solution diluted to 500 ml. This solution was diluted 100-fold to $2\cdot5 \times 10^{-4}M$ before use.

Tris(1,10-phenanthroline)cadmium solution, 0·005M. Cadmium sulphate, $3CdSO_4\cdot8H_2O$ (1·28 g) and 1,10-phenanthroline, $C_{12}H_8N_2\cdot H_2O$ (3·17 g) were dissolved in 100 ml of 0·001N sulphuric acid and the solution diluted to 1000 ml.

Ammonium hydrogen fluoride solution, 1·25M.

Buffer solution. Potassium dihydrogen phosphate (0·25M) and disodium hydrogen phosphate (0·25M) were mixed in appropriate ratio.

Nitrobenzene. Purified by distillation under reduced pressure and equilibrated with water before use.

Apparatus

Methyl borate was distilled in a quartz still.

Procedure

Mix 1 ml of 1·25M ammonium hydrogen fluoride and 0–5 ml of the $2\cdot5 \times 10^{-4}M$ boric acid in a 50-ml polyethylene test-tube. Place the tube in a water-bath (80°) for about 20 min and then cool the tube to room temperature. Transfer the mixture into a 125-ml polyethylene separatory-funnel. Add 5 ml of Tris(1,10-phenanthroline)cadmium solution, 5 ml of phosphate buffer solution (pH 5), dilute to 25 ml with water and add 5·0 ml of nitrobenzene. Shake the funnel vigorously for 3 min with a mechanical shaker. Allow to stand for about 15 min. Transfer the organic layer to a test-tube containing 1 g of anhydrous sodium sulphate to eliminate traces of water in the extract. Measure the absorbance of cadmium at 228·8 nm against a reagent blank, under optimum operating conditions of the atomic-absorption instrument, using an air–acetylene flame.

INDIRECT ATOMIC-ABSORPTION DETERMINATION OF BORON BY SOLVENT EXTRACTION AS TRIS(1,10-PHENANTHROLINE)CADMIUM TETRAFLUOROBORATE

(*Received* 26 *June* 1972, *Accepted* 23 *October* 1972)

Indirect determination of non-metals by means of atomic-absorption spectrophotometry of a metal ion complexed with a compound of the non-metal is well known. A colorimetric method for the determination of boron by solvent extraction as Tris(1,10-phenanthroline)iron(II) tetrafluoroborate has been reported,[1] and applied to the analysis of tap-water.[2] In atomic-absorption spectrophotometry (AAS), the sensitivity for cadmium is 5–10 times that for iron,[3,4] so for an AAS method we have used Tris(1,10-phenanthroline)cadmium(II) as counter-cation instead of Tris(1,10-phenanthroline)iron(II), and extraction into nitrobenzene. The cadmium atomic absorption at 228·8 nm is a linear function of boron concentration in the aqueous phase over the range of 0·01–0·5 ppm. The sensitivity for boron is apparently about 1000 times that of the direct atomic-absorption method. Certain metal ions interfere because of their reaction with phenanthroline and fluoride. Boron in steel has been determined at ppM levels.

EXPERIMENTAL

Reagents

All solutions were prepared from analytical-reagent grade chemicals and demineralized water, and stored in polyethylene bottles.

Standard boron solution, 0·025*M*. Boric acid (0·7726 g) was dissolved in an appropriate amount of water and the solution diluted to 500 ml. This solution was diluted 100-fold to $2\cdot5 \times 10^{-4}M$ before use.

Tris(1,10-phenanthroline)cadmium solution, 0·005*M*. Cadmium sulphate, $3CdSO_4\cdot 8H_2O$ (1·28 g) and 1,10-phenanthroline, $C_{12}H_8N_2\cdot H_2O$ (3·17 g) were dissolved in 100 ml of 0·001*N* sulphuric acid and the solution diluted to 1000 ml.

Ammonium hydrogen fluoride solution, 1·25*M*.

Buffer solution. Potassium dihydrogen phosphate (0·25*M*) and disodium hydrogen phosphate (0·25*M*) were mixed in appropriate ratio.

Nitrobenzene. Purified by distillation under reduced pressure and equilibrated with water before use.

Apparatus

Methyl borate was distilled in a quartz still.

Procedure

Mix 1 ml of 1·25*M* ammonium hydrogen fluoride and 0–5 ml of the $2\cdot5 \times 10^{-4}M$ boric acid in a 50-ml polyethylene test-tube. Place the tube in a water-bath (80°) for about 20 min and then cool the tube to room temperature. Transfer the mixture into a 125-ml polyethylene separatory-funnel. Add 5 ml of Tris(1,10-phenanthroline)cadmium solution, 5 ml of phosphate buffer solution (pH 5), dilute to 25 ml with water and add 5·0 ml of nitrobenzene. Shake the funnel vigorously for 3 min with a mechanical shaker. Allow to stand for about 15 min. Transfer the organic layer to a test-tube containing 1 g of anhydrous sodium sulphate to eliminate traces of water in the extract. Measure the absorbance of cadmium at 228·8 nm against a reagent blank, under optimum operating conditions of the atomic-absorption instrument, using an air–acetylene flame.

Procedure for steel analysis

Place a 0·5–1·0 g of sample containing not more than 0·05% of boron, in a quartz beaker. Dissolve the sample with a mixture of 15 ml of hydrochloric acid, 5 ml of nitric acid and 5 ml of phosphoric acid with heating on a hot-plate. To remove chloride and nitrate add 10 ml of sulphuric acid and evaporate nearly to dryness. Let cool, dissolve the residue, and dilute to a standard volume with water, keeping the boron concentration below 10 ppm. Take a 5-ml aliquot in a 100-ml quartz flask, and add 3 ml of sulphuric acid and 10 ml of methyl alcohol. Distil the methyl borate by heating the flask on a water-bath (80°). Introduce the first distillate (10 ml) into 0·1*M* sodium hydroxide solution (5 ml) in a marked polyethylene tube cooled with water. Transfer the solution into a 100-ml quartz beaker, rinsing in with a small amount of methyl alcohol. Evaporate the solution nearly to dryness on a water bath (50 ± 5°). Cool the residue and dissolve it with 2·8 ml of 0·1*N* sulphuric acid and dilute to 25 ml with water. Take an aliquot (5 ml) in a polyethylene separatory-funnel and continue according to the general procedure described above.

RESULTS AND DISCUSSION

The extraction was maximal when the fluoride concentration was $5\text{–}6 \times 10^{-2}M$, indicating that at least a 1300-fold molar excess of fluoride is necessary for the complete formation of tetrafluoroborate in the aqueous phase. The complexation reaction should be continued for 15–20 min at a temperature above 70°.

At least a 5-fold molar excess of Tris(1,10-phenanthroline)cadmium is required for maximum extraction of the tetrafluoroborate.

With a single extraction, a pH range of 4·3–6·0 was found to give a plateau on the absorption *vs.* pH graph. In acidic solutions the cadmium complex may decompose, and in alkaline medium hydroxotrifluoroborate (BF_3OH^-) may be formed, which is not suitable for this extraction system. No appreciable effect on the absorption was caused by changing the phosphate buffer concentration over the range 0·04–0·12*M*.

The shaking time for the extraction was varied from 0·5 to 10 min, and it was found that 2 min sufficed.

Beer's law is obeyed up to 0·5 ppm of boron and the sensitivity for 1% absorption was 0·005 ppm of boron, about the same as that of cadmium, as determined by using bis(acetylacetonato)cadmium nitrobenzene solutions. For 10 solutions, each containing 0·4 ppm of boron, the mean absorbance was 0·227, with relative standard deviation of 1·5%. Normal room temperature fluctuations (15–25°) had no effect on the absorption.

Table 1. Effect of diverse ions.

Boron: 8.1 μg/25 ml.

Table 2. Analysis of steel samples.

Sample	Boron, %	
	Curcumin method	Proposed method
A	0·0055	0·0053 0·0053 0·0053
B	0·0021	0·0019 0·0021 0·0018
C	0·0092	0·0102 0·0103 0·0101

Large amounts of sulphate, phosphate, acetate and silicate do not interfere. Chloride and nitrate give a positive error when present in tenfold molar amount relative to borate, but both can easily be eliminated by evaporation from sulphuric acid medium. As seen in Table 1, presence of transition elements cations causes negative errors because of consumption of phenanthroline.

To check the reliability of the proposed method, steel was chosen as a matrix. Recovery tests were successfully made with a certain amount of boron added to boron-free standard steel samples. Boron must be separated from the matrix because of the interference of iron, and this can be done by the conventional distillation of methyl borate.[5-7] Samples were also analysed by spectrophotometry with curcumin.[6] The results are shown in Table 2. It is seen that both sets of results are in satisfactory agreement.

Summary—An indirect atomic-absorption method for boron has been developed. Boric acid is converted into tetrafluoroborate and extracted into nitrobenzene with Tris(1,10-phenanthroline)cadmium(II). The cadmium in the extract is determined by its atomic-absorption at 228·8 nm. A fivefold molar excess of the cadmium chelate is necessary for the extraction from pH 4·3–6·0 medium. The sensitivity for boron is thus made about the same as that of cadmium, 0·005 ppm. Metal ions that react with fluoride or phenanthroline interfere. A procedure is described for determination of boron in steel.

Zusammenfassung—Ein indirektes Atomabsorptionsverfahren zur Bestimmung von Bor wurde entwickelt. Borsäure wird in Tetrafluoroborat überführt und mit Tris(1,10-phenanthrolin)-cadmium(II) in Nitrobenzol extrahiert. Das Cadmium im Extrakt wird durch seine Atomabsorption bei 228·8 nm bestimmt. Zur Extraktion aus einem Medium mit pH 4·3–6·0 ist ein fünffacher molarer Überschuß des Cadmiumchelats notwendig. So wird die Empfindlichkeit für Bor etwa dieselbe wie die für Cadmium, 0·005 ppm. Metallionen, die mit Fluorid oder Phenanthrolin reagieren, stören. Eine Arbeitsvorschrift für die Bestimmung von Bor in Stahl wird angegeben.

Résumé—On a élaboré une méthode d'absorption atomique indirecte pour le bore. L'acide borique est converti en tétrafluoroborate et extrait en nitrobenzène par le Tris(1,10-phénanthroline)cadmium(II). On détermine le cadmium dans l'extrait par son absorption atomique à 228,8 nm. Un excès molaire quintuple du chélate de cadmium est nécessaire pour l'extraction d'un milieu de pH 4,3–6,0. La sensibilité pour le bore est ainsi rendue à peu près la même que celle du cadmium, 0,005 p.p.m. Les ions métalliques qui réagissent avec le fluorure ou la phénanthroline gênent. On décrit une technique pour le dosage du bore dans l'acier.

SULPHONATED AZO-DYES AS EXTRACTIVE METALLOCHROMIC REAGENTS

(*Received* 14 *August* 1972, *Accepted* 6 *October* 1972)

The metallochromic properties of azo-dyestuffs, particularly those containing *o,o*′-dihydroxy groups, are well known and many of these reagents have found application in the complexometric titration of metals.[1] Examples of their use for the spectrophotometric determination of metals have also appeared,[2] but in general these reactions are non-selective. Selectivity or specificity may be achieved by the use of appropriate masking agents. Furthermore, in some instances the use of an azo-dye as a spectrophotometric reagent is prevented by similarity in the colours, and consequently, in the absorption spectrum of the metal complex and the reagent itself. For practical purposes it is convenient if the molecule contains at least one sulphonic acid group to make the reagent soluble in water. If more than one sulphonic acid group is present, the tendency of the reagent to form extractable ion-association complexes is reduced.

With the hope of improving the selectivity and sensitivity of such reactions we, as well as previous workers in the Laboratory,[3] have investigated the possibility of extracting the metal complexes of a number of representative sulphonated *o,o*′-dihydroxyazo-dyes into chloroform as the ion-association complexes formed with a quaternary ammonium cation. In the present work the pH range between 1·0 and 12·0 was investigated. In acid solution (~ < pH 1) dissociation of sulphonic acid groups is suppressed and it is probable that the reagents and their metal complexes will be extracted even in the absence of a large cation.

The number of possible substitutions of azo-dyes is very large, but *o,o*′-dihydroxy mono-azo dyes may be classified conveniently according to the number of aromatic rings present and further, for the naphthyl series, by the position of the azo-substitution. Thus, the parent compounds are

I 2,2′-azodiphenol
II 2-(2′-hydroxy-1′-naphthylazo)phenol
III 2-(1′-hydroxy-2′-naphthylazo)phenol
IV 2,2′-dihydroxy-1,1′-azonaphthalene
V 1,2′-dihydroxy-2,1′-azonaphthalene
VI 1,1′-dihydroxy-2,2′-azonaphthalene

Some readily available monosulphonated derivatives of I–V were investigated, *viz.*

		Colour Index No.	*Commercial name*
A	5-Cl,4′-OH,3-SO_3H-I	Mordant Red 72	Lumogallion
B	5-SO_3Na-II	15670	Acid Alizarin Violet (N)
C	5-CH_3,4′-SO_3H-II	—	Calmagite
D	5-OH,5-SO_3Na-III	16500	Chrome Fast Black PV

EXPERIMENTAL

Reagents

Acetate (pH 1·1–5·2), phosphate (6·1) and borate (7·5–12·0) buffers were prepared to cover the pH range 1–12 and their ionic strength was adjusted to 0·3 with sodium perchlorate.

Metal ion solutions (0·1*M*) were prepared, from the perchlorates where possible.

Dye solutions nominally $4 \times 10^{-4}M$ were prepared by dissolving the theoretical amounts of the solids in distilled water. No attempts were made to purify the commercial products.

Solutions of the quaternary ammonium salts (0·1*M*) were prepared by dissolving Aliquat 336 (methyltricaprylylammonium chloride) (General Mills, Chemical Division, Kankakee, Illinois) or tetrahexylammonium iodide in chloroform. The latter solution was converted into the perchlorate form by shaking three times with an equal volume of 10% sodium perchlorate solution.

Procedure

Qualitative tests were made of the reaction of a given reagent with 20 selected metal ions, *viz.* Al, Bi(III), Ca, Cd, Co(II), Cu(II), Fe(III), La, Mg, Mn(II), Mo(VI), Ni(II), Pb(II), Pd(II), Sn(IV), U(VI), V(IV), W(VI), Zn and Zr(IV) at each of eleven pH values by addition of one drop of 0.1*M* metal ion solution to a test-tube containing 1 ml of $4 \times 10^{-4}M$ reagent solution and 3 ml of the appropriate buffer solution. After thorough mixing, a few minutes were allowed for reaction before the colour was noted. One ml of quaternary ammonium salt solution (0·05 or 0·1*M*) was added, the mixture was agitated vigorously for a few seconds and, after settling, the colour of each phase was noted.

Reactions giving interesting colour changes were carried out semiquantitatively (again with an excess of metal ion over reagent) and the spectrum of the metal complex as well as of the reagent alone was plotted in the visible region for the aqueous phase or for the organic phase after extraction, as appropriate. Reactions appearing to have analytical possibilities, *i.e.*, giving a large shift in absorption maximum and an intensely coloured metal complex, were then further investigated by preparing a Beer's law plot to test the sensitivity under the reaction conditions used.

RESULTS

It will be appreciated that in qualitative tests the recognition of a potentially useful reaction is very subjective. The further characterization of a given reaction in terms of sensitivity and selectivity is necessary to achieve objectivity. The present survey has, however, confirmed previous workers' findings that *o,o′*-dihydroxyazo dyes react with many metal ions in aqueous solution under various pH conditions, *e.g.*, Mo(VI) with almost every reagent in acid solution; Cu(II) with reagents *B*, *F* and *K* at pH 1–4; Zr(IV) with *A*, *B* and *H* at pH 1–4; Fe(III) with *A*, *B*, *D*, *F*, *H*, and *J* at pH 1–5; V(IV) with *B*, *D*, *F*, *G*, *H*, *J*, *K* and *M* at pH 3–6; U(VI) with *F*, *G*, *H*, and *K* at pH 4–5; several transition metals and La(III) with *K* and *L* at around pH 7; Ca and Mg with *B*, *C*, *D*, *F*, *H*, and *M* in alkaline solution.

In several instances these reactions are best suited to spectrophotometric application by measurement of the decrease in absorbance at a given wavelength upon complex formation and have already been used in this manner.[4,5]

The formation of an extractable species depends upon neutralization of the negative charge of the metal complex by ion-association with one or more quaternary ammonium cations. At low pH only the sulphonic acid groups are dissociated, the hydroxyl groups ionize successively as the pH is increased. Thus at higher pH more quaternary ammonium ions are needed to achieve neutralization of charge. The reactions of the *o,o′*-dihydroxyazo dyes after extraction are summarized in Table 1 in which each reagent is represented by the letters assigned to it above. Entries appear for all conditions under which there was a significant difference between the colour of the organic phase with a metal present and that for the reagent alone. No extractable complexes were formed by reagents *L* and *M*, indicating that the presence of three or more sulphonic acid groups prevented charge-neutralization under these experimental conditions. Bi(III), Ca, Cd, La(III), Mg, Pb(II) and Zn formed no extractable complexes coloured differently from the reagent.

These tests were done with an excess of metal over reagent so that in some instances, although complex formation occurred, the reaction would not be applicable to spectrophotometric analysis. Several reactions, however, did appear to be worthy of consideration for spectrophotometry and a rapid examination was made to obtain an estimate of the sensitivity of a number of these without rigorous optimization of conditions. These results are shown in Table 2. The reaction of aluminium with Calmagite at pH 8·6 has been studied more thoroughly as a spectrophotometric method.[6]

Conclusion

The investigations described herein have shown that several monosubstituted *o,o′*-dihydroxyazo dyes form coloured metal complexes which are extractable into chloroform as ion-association complexes with a quaternary ammonium cation. These reactions may offer advantages in selectivity and sensitivity over existing spectrophotometric methods based on metal-azo-dye complexation.

N-(2-ACETYL-1,3-INDANDIONE-1-HYDRAZONE)TRIALKYLAMMONIUM IODIDES AS A NEW GROUP OF REAGENTS FOR THE CARBONYL GROUP

(*Received* 8 *September* 1972. *Accepted* 23 *October* 1972)

Braun and Mosher[1] introduced 2-diphenylacetyl-1,3-indandione-1-hydrazone as a reagent for characterization of carbonyl compounds. Aldehydes and ketones react with the hydrazone to give fluorescent azines having sharp and well spaced melting points. Brandt and Cheronis[2] showed that concentrations of these azines as low as $10^{-9}M$ could be detected spectrophotometrically. Mosher, Bechara and Pozomek[3] indicated the use of the reagent and its analogues for identification of various classes of organic compounds such as amines, alcohols, anhydrides, hydrazines and ortho-esters. The potential usefulness of these reagents appears to be due to the 2-acetyl-1,3-indandione nucleus.

The present paper deals with the investigation of quarternary ammonium derivatives of these reagents,[4] which have been found to react with aldehydes, ketones and keto-acids, but not with alcohols, amines and non-keto carboxylic acids.

EXPERIMENTAL

Preparation of 2-acetyl-1,3-indandione

2-Acetyl-1,3-indandione was obtained by Claisen condensation of dimethyl phthalate with acetone in the presence of sodium methoxide according to the method reported by Kilgore.[5]

Preparation of N-*(2-acetyl-1,3-indandione)trialkylammonium iodides*

2-Acetyl-1,3-indanadione was quaternized with an appropriate tertiary amine and iodine in methanolic medium.[4] The compounds prepared were the trimethyl (m.p. 221–223°), triethyl (m.p. 131–132°), tripropyl (210° dec.) and tributyl (m.p. 52–53°) derivatives.

* Only the alkyl substituent of the *N*-(2-acetyl-1,3-indandione-1-hydrazone)trialkylammonium iodide is indicated here.

Preparation of monohydrazones

N-(2-Acetyl-1,3-indandione)trialkylammonium iodide (2.0 g), hydrazine hydrate (80% solution in alcohol, 2 ml) and methanol (20 ml) were heated in a 100-ml round-bottomed flask on a water-bath for 5 min, allowed to cool, and left overnight. A light yellow product separated which was recrystallized from absolute alcohol. The hydrazones were hygroscopic. The m.p. values were 101–102°, 170–177° dec., 185–187° dec., and 89–90° for the trimethyl, triethyl, tripropyl and tributyl derivatives respectively.

Colour reaction with carbonyl compounds

These hydrazones react with several carbonyl compounds in ethanolic medium to give coloured azines. The colour produced varies from light yellow to reddish-yellow depending upon the reagent and the carbonyl compound. Unlike the monohydrazone of 2-diphenylacetyl-1,3-indandione, these compounds do not react with amino, anhydride, carboxylic or hydroxy groups. The colour reaction takes place easily on the addition of a small quantity of carbonyl compound to an ethanolic solution of the hydrazone. The individual carbonyl compound may be characterized by its characteristic λ_{max} in ethanolic medium (Table 1).

The carbonyl group was successfully detected in the presence of isopropyl alcohol, isobutyl alcohol, n-pentanol, dimethylamine, aniline, methylaniline and butyric acid.

SULPHOLANE AS COLOUR-ENHANCING AND STABILIZING AGENT FOR SILICOMOLYBDIC ACID

(*Received* 18 *October* 1972. *Accepted* 2 *November* 1972)

Sulpholane (*i.e.*, tetrahydrothiophene-1,1-dioxide) produces a significant enhancement of colour when added to a solution containing the thiocyanaoto-complex of cobalt.[1] In tests of the effect of the solvent on solutions of other metals and complexes a pronounced deepening of the colour of silicomolybdic acid was noticed and the possibility of an analytical application of this enhancement was investigated.

The yellow colour developed when solutions of silicate and molybdate ions are mixed was first described by Jolles and Neurath[2] in 1898. Since then many procedures have been described, making use of the reaction in the determination of silica. Quite contradictory results and statements are found in the literature. An explanation for this situation was provided by Strickland[3] in 1952 when he discovered that two silicomolybdic acids exist which he called the α and β forms. Because the two forms differ (among other things) in their absorptivities, doubtful analytical results are obtained unless care is taken that only one of the acids is formed during colour development. Of analytical significance was the contribution by Chalmers and Sinclair[4] who recommended the addition of acetone when preparing the solution to be subjected to the photometric measurement. Acetone (some other polar organic solvents have the same effect, but to a lesser degree) enhances the colour and stabilizes the β-form. This form is of greater analytical interest because it has the higher absorbance over most of the absorption spectrum and allows operation in more acidic solutions. Without stabilization the β-form converts into the α-form at a rate that depends on the pH and the composition of the solution and that is generally difficult to control. Recently Halász *et al.*[5,6,6] have studied heteropoly acids containing molybdenum and critically evaluated the various parameters influencing their formation, stability, interaction *etc.* and also made analytical recommendations.

Sulpholane-containing systems

In the present studies, acetone, the best enhancer so far known, was replaced by sulpholane, which proved superior in several ways. The enhancement is greater than with acetone as can be seen from Fig. 1. Sulpholane is less volatile and thus the possibility of error due to volume changes caused by evaporation is diminished. Sulpholane does not give a turbidity when test solutions are made strongly acidic. This is in contrast to the acetone-containing solutions. The formation of the turbidity has not been reported by previous authors. Sulpholane also stabilizes the β-form and to a higher degree than acetone. For solutions containing acetone Chalmers and Sinclair[4] reported a rate of fading of 0·4% per hour. In the case of sulpholane no change in absorbance was noticed over a period of four days.

The absorption spectra of silicomolybdic acid in both forms in the presence of sulpholane are essentially identical in shape to those in the absence of the solvent, but show higher absorptivities. For either form the highest sensitivity would result from photometric measurements at the peak wavelengths between 300 and 320 nm. Unfortunately, the absorptivity of free molybdate is also considerable in that region and thus leads to an extremely high blank value. Therefore, it is preferred to use wavelengths of about 400 nm where the molybdate does not absorb at all.

As can be seen from Fig. 1 the amount of sulpholane added should be at least 20% v/v to ensure maximum colour development. While no influence on the colour is observed when more solvent is present, a practical limit exists at 40%. Beyond that concentration the molybdate forms a yellow complex with sulpholane and again a detrimentally large blank results.

The β-molybdic acid-sulpholane entity was found to be stable within the "pH" range 0·1–1·8. It should be noted that pH is set within quotation marks to indicate that not the true proton activity is intended but rather the reading on a pH-meter when a glass and calomel electrode combination is dipped into the sulpholane-containing solution. Below pH 0·1 the formation of the complex is incomplete. Above pH 1·8 the conversion into the α-acid is increasingly rapid and at pH 3 almost instantaneous. Once formed, the α-acid persists and no reconversion to the β-acid takes place upon acidification.

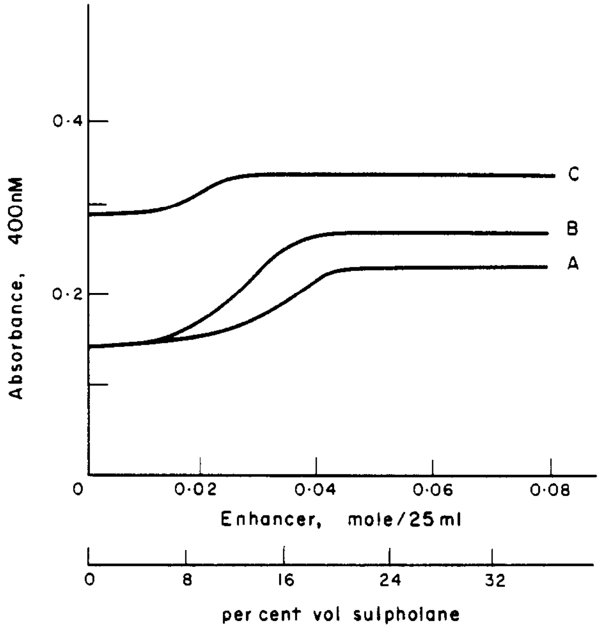

Fig. 1. Enhancement due to acetone and sulpholane.
(A) α-Acid with acetone; (B) α-acid with sulpholane; (C) β-acid with sulpholane.

EXPERIMENTAL

Reagents

All reagents used were of analytical grade or better. Demineralized distilled water was used exclusively. Sulpholane was obtained in distilled form from J. T. Baker: Eastman Practical Grade material was employed after purification by distilling at 118–120° at 1·5 mmHg.

The silicate standard solution was prepared by dissolving sodium matasilicate in demineralized water to yield a $6{\cdot}25 \times 10^{-3}$ *M* solution.

All solutions were stored in polyethylene bottles.

Procedure

Place the roughly neutralized sample solution containing up to 0·4 mg of SiO_2 in a 25-ml volumetric flask and add 4 ml of 0·3*M* perchloric acid, 5 ml of liquefied sulpholane and 5 ml of 0·05*M* ammonium molybdate. Dilute to the mark with distilled water and mix. Allow to stand for 15 min and measure the absorbance at 400 nm *vs.* a reagent blank. Obtain the result in the usual manner from a calibration curve established under identical conditions.

Remarks

The sample solution should be freshly neutralized from the alkaline side in order to avoid polymerization of the silicate, which would lead to erroneous results. The final acidity of the solution should be between "pH" 0·1 and 1·8. The amount of sulpholane can be larger, up to 10 ml. Sulpholane is solid at room temperature and must be liquefied. It may be kept in a warm place to prevent solidification or may be employed as a concentrated aqueous solution.

RESULTS

Some results obtained with this procedure are shown in Table 1. Interference studies have not been made to any extensive degree. Arsenate and phosphate interfere and must be absent. Because of the similarity of the action of sulpholane and acetone it is quite probable that the procedures developed for the latter solvent can be applied with little or no modifications to the sulpholane method.

Table 1. Results of silicon determinations by the sulpholane-β-silicomolybdic acid method

Silica, μg		Silica, μg	
Taken	Found	Taken	Found
55.7	54.0	155	158
73·8	71·7	203	206
94·2	96·3	222	217
111	110	295	292
148	144	369	371

Standard deviation ± 3·1 μg SiO_2

Summary—Addition of between 20 and 40% v/v sulpholane gives a colour enhancement of silicomolybdic acid better than that achieved with acetone. The β-silicomolybdic acid is stabilized, and solutions yielding a pH-meter reading of 0·1–1·8 give the best results. The photometric measurement is made at about 400 nm. Another advantage of sulpholane is its much lower volatility.

Zusammenfassung—Die Zugabe von 20–40 Vol-% Sulfolan verstärkt die Färbung von Silikomolybdänsäure in höherem Ausmaß, als man es mit Aceton erreicht. Die β-Silikomolybdänsäure wird stabilisiert: Lösungen, für die man am pH-Meter 0·1–1·8 abliest, geben die besten Ergebnisse. Die photometrische Messung wird bei etwa 400 nm ausgeführt. Ein weiterer Vorteil von Sulfolan ist seine viel geringere Flüchtigkeit.

Résumé—L'addition de quantités comprises entre 20 et 40 % (v/v) de sulfolane donne une exaltation de coloration de l'acide silicomolybdique meilleure que celle obtenue avec l'acetone. L'acide β-silicomolybdique est stabilisé, et les solutions donnant une lecture au pH mètre de 0,1–1,8 donnent les meilleurs résultats. La mesure photométrique est effectuée à environ 400 nm. Un autre avantage du sulfolane est sa volatilité beaucoup plus faible.

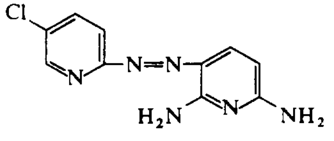
o-AMINO HETEROCYCLIC AZO-DYES AS ANALYTICAL REAGENTS—II

SPECTROPHOTOMETRIC DETERMINATION OF COBALT WITH 3-[(5-CHLORO-2-PYRIDYL)AZO]-2,6-DIAMINOPYRIDINE

(*Received* 23 *December* 1971. *Revised* 26 *October* 1972. *Accepted* 15 *November* 1972)

In a search for new sensitive and selective reagents, a thorough study of some of the azo compounds containing halogen-substituted pyridine has been made.[1–4] It was found that one of these compounds, 3-[(5-chloro-2-pyridyl)azo]-2,6-diaminopyridine (5-Cl-PADAPy, **I**), formed a deep blue water-soluble complex with cobalt(II), and a highly selective determination of microgram amounts of cobalt is possible under the conditions established. Recently, Talipov *et al.*[5] determined cobalt with 3-(2-pyridylazo)-2,6-diaminopyridine photometrically.



I

EXPERIMENTAL

Reagents

5-Cl-PADAPy solution. An ethanolic 0·1% w/v solution was prepared from the pure material (see below). The solution is stable for several months if stored in an amber glass bottle.

Cobalt(II) solution. A stock chloride solution was prepared from 99·99% pure cobalt metal.

Buffer solution. Hydrochloric acid (0·2*M*)-potassium chloride (0·2*M*), acetic acid (0·2*M*)-sodium acetate (0·2*M*), boric acid (0·2*M*)-potassium chloride (0·2*M*)-sodium hydroxide (0·2*M*) and borax (0·2*M*)-sodium hydroxide (0·1*M*) mixtures.

Solutions (1 + 1 dilution) were made from high-purity sulphuric, hydrochloric, nitric, perchloric and phosphoric acid.

All other reagents were made from high-purity materials or purified reagents, and were prepared with redistilled water.

Preparation of reagent

Diazotization. Freshly prepared isopentyl nitrite (5·46 g) was added to a solution containing 6 g of 5-chloro-2-aminopyridine and 2·4 g of sodium amide in 80 ml of absolute alcohol, refluxed for 2 hr and cooled.

Coupling. 2,6-Diaminopyridine (5·1 g) was dissolved in 10 ml of ethanol and added to the diazonium salt solution at 5°, and carbon dioxide was passed through the solution continuously. The mixture was let cool overnight and the precipitated reddish brown crystals were filtered off, washed with water, dissolved in hot ethanol, recrystallized from aqueous solution, and sublimed at about 200°. Purified materials for physicochemical determinations can be obtained by sublimation in vacuo. Analysis: calculated C 48·30%, N 33·80%, H 3·65%; found C 48·5%, N 33·7%, H 3·8%.

Protonation behaviour of the reagent

The reagent is sparingly soluble in water, but soluble in various organic solvents including ethanol, acetone and dioxan, as well as in strongly acid solution. Five species, H_4L^{4+}, H_3L^{3+}, H_2L^{2+}, HL^+, and L are involved in the protonation equilibria. The proton-dissociation constants have values of $pK_{a3} = 1{\cdot}3$ for the *p*-amino group and $pK_{a4} = 5{\cdot}9$ for the *o*-amino group. The pK_{a1} and pK_{a2} values for the pyridine and 2,6-diaminopyridine heterocyclic nitrogen atoms may exist at about $H_0 = -2{\cdot}5$, but could not be distinguished by the spectrophotometric method.

Colour reaction with metals

The coloured complexes are easily prepared by adding a few drops of a solution of 5-Cl-PADAPy in ethanol to solutions of heavy metals. The ions that give a colour with the reagent are listed in Table 1. Ions that do not give a detectable colour at room temperature include silver, aluminium, beryllium, bismuth, cadmium, calcium, chromium(III), mercury(II), manganese(II), nickel (at pH 4), lead, thorium, tungsten, yttrium, zinc, zirconium, titanium. When mineral acid is added to the solution containing metal complexes, only the cobalt complex is stable, and therefore the selectivity for cobalt is excellent.

Table 1. Colour reaction of metals with 5-Cl-PADAPy

Ion	Colour			
	pH 5	H_2SO_4 added	pH 10	H_2SO_4 added
Reagent	Orange	Orange red	Orange	Orange red
Co^{2+}	Green	Bluish purple	Green	Blue
Cu^{2+}	Purple	nil*	Purple	nil*
Fe^{3+}	Brown	Red brown	Brown	Red brown
Ni^{2+}	nil	nil	Red purple	nil*

* This means reversion to the colour of the reagent.

RESULTS AND DISCUSSION

Absorption spectra

The absorption spectra of the reagent and its cobalt complex in aqueous solution at pH 5·0 (initial conditions of colour development) are shown in Fig. 1. When hydrochloric acid is added to the sample solution, the cobalt complex may be changed into a different species, which is suitable for determination of cobalt. The spectra of the reagent and its complex in 1·2*M* hydrochloric acid are shown in Fig. 2.

Optimum pH

The effect of initial pH on colour development was studied by developing the colour in a series of solutions varying in pH from 1·5 to 12 and then measuring the absorbance after the acidity had been increased to 1·2*M* (hydrochloric acid). The absorbance increased steeply in the pH range 2–3, but no change in absorbance was observed over the pH range 3·5–12. In practice the initial pH should be as low as possible because nickel does not react appreciably with the reagent at pH 3·5–5. Subsequent studies were carried out at an initial pH of 5·0.

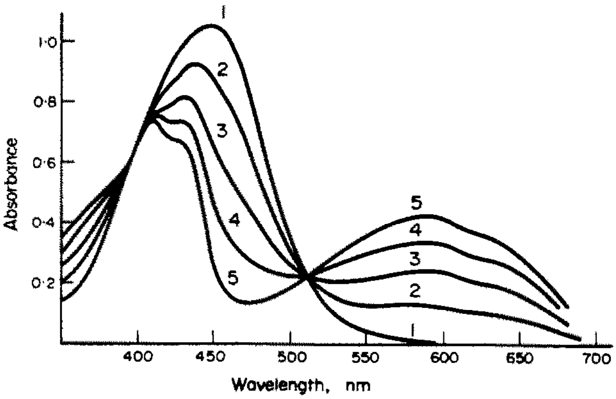


Fig. 1. Absorbance curves of 5-Cl-PADAPy and its cobalt complex in aqueous solution at pH 5·0 with $4 \times 10^{-5}M$ 5-Cl-PADAPy.

Concentration of Co: (1) nil; (2) $0{\cdot}5 \times 10^{-5}M$; (3) $1 \times 10^{-5}M$; (4) $1{\cdot}5 \times 10^{-5}M$; (5) $4 \times 10^{-5}M$

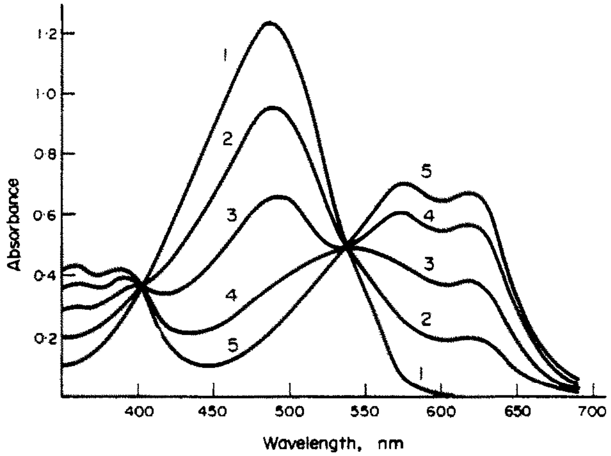

Fig. 2. Absorbance curves of 5-Cl-PADAPy and its cobalt complex in 1·2*M* hydrochloric acid solution. Concentrations of 5-Cl-PADAPy and cobalt as for Fig. 1.

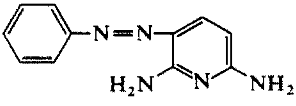
Cobalt and 5-Cl-PADAPy in an acid medium did not form any complexes; under these conditions, the ligand was protonated on the nitrogen atoms and amino groups. In complex formation the pyridine nitrogen atom plays a very important role: benzeneazodiaminopyridine (II) does not react with cobalt under any conditions.



II

However, the complex formed at pH 3·5-12 could be changed into another species of higher absorptivity, by addition of mineral acid. The effects of acidity and type of acid were studied. No change in absorbance was observed over the range 2-10 ml of added (1 + 1) hydrochloric, sulphuric, nitric, perchloric or phosphoric acid. Subsequent studies were carried out with addition of 5 ml of hydrochloric acid (1 + 1).

Reaction conditions

The absorbances of a series of solutions containing 20 μg of cobalt and 0·1–2·0 ml of 0·1% dye solution were measured. It was found that 0·5 ml of dye solution sufficed to complex up to 20 μg of cobalt. For qualitative detection of cobalt, the excess of reagent can be destroyed by the addition of hydrogen peroxide and heating at about 50–60° on a water-bath. Then the colour of the cobalt complex can be detected more easily by eye.

The minimum time for complete colour development was found to be 1–2 min at room temperature. The absorbance was then stable for at least a week. The calibration graph proved to be linear over the range 0·1–1·2 ppm of cobalt. The effective molar absorptivity for the cobalt complex was $3·6 \times 10^4$ $\text{l.mole}^{-1}.\text{cm}^{-1}$ at 620 nm.

Effect of foreign ions

Numerous cations and anions were examined by applying the method to fixed amounts of cobalt in the presence of increasing quantities of the ion being studied (Tables 2 and 3). It is evident that many have no effect at the levels studied. Among the cations, interference was caused only by iron(III) and large amounts of copper. Iron(III), about 20 mg, can be masked by the addition of 2 ml of 6% hydrogen peroxide, which interferes appreciably in the formation of the iron complex. Fortunately, hydrogen peroxide does not attack the reagent at room temperature, so 5-Cl-PADAPy can be used for determining microamounts of cobalt in many industrial and natural materials without separation.

Nature of the cobalt complex

The empirical formulae of the complexes were studied by the continuous-variation and mole-ratio methods. The curves obtained indicate the formation of a complex 1 : 3 metal : ligand ratio at pH 5 and in 1·2*M* hydrochloric acid. However, it is difficult to see how the three ligands can be co-ordinated to cobalt, on account of the structure of the reagent. A further critical study of the reaction is therefore planned. The present communication discusses only the analytical conditions.

Recommended procedure for the determination of cobalt

Into a 25-ml volumetric flask transfer a suitable aliquot of sample solution containing up to 25–30 μg of cobalt, and add 1·0 ml of ethanolic 0·1% reagent solution. Adjust to pH 5 with 5 ml of buffer solution and mix. Then add 5 ml of hydrochloric acid (1 + 1), dilute to volume and mix. Measure the absorbance of the cobalt complex at 620 nm against a reagent blank. Obtain the concentration of cobalt from a standard calibration curve obtained under identical conditions.

Summary—Cobalt(II) and 3-[(5-chloro-2-pyridyl)azo]-2,6-diaminopyridine (5-Cl-PADAPy) in slightly acid, neutral or alkaline media form a blue complex which is very stable even in the presence of mineral acids. The complex has two absorption maxima, at 575 and 620 nm, in 1·2*M* hydrochlororic acid. The system conforms to Beer's law; the optimal range for a 1-cm cell is 0·2–1·2 ppm cobalt. Milligram amounts of common anions and cations do not interfere. The molar absorptivity is $3·69 \times 10^4$ $\text{l.mole}^{-1}.\text{cm}^{-1}$ at 620 nm.

Zusammenfassung—Kobalt(II) und 3-[(5-Chlor-2-pyridyl)azo]-2,6-diaminopyridin (5-Cl-PADAPy) bilden in schwach sauren, neutralen oder alkalischen Medien einen blauen Komplex, der selbst in Gegenwart von Mineralsäuren sehr stabil ist. Der Komplex hat in 1·2 M Salzsäure zwei Absorptionsmaxima bei 575 und 620 nm. Das System gehorcht dem Beerschen Gesetz. Der beste Konzentrationsbereich für eine 1 cm-Zelle ist 0·2–1·2 ppm Kobalt. Milligrammengen gängiger Anionen und Kationen stören nicht. Der molare Extinktionskoeffizient beträgt bei 620 nm $3·69 . 10^4$ $\text{l mol}^{-1}\text{cm}^{-1}$.

Résumé—Le cobalt (II) et la 3-[(5-chloro 2-pyridyl) azo] 2,6-diaminopyridine (5-Cl-PADAPy) en milieux légèrement acide, neutre ou alcalin forment un complexe bleu qui est très stable même en la présence d'acides minéraux. Le complexe a deux maximums d'absorption, à 575 et 620 nm, en acide chlorhydrique 1,2*M*. Le système suit la loi de Beer; le domaine optimal pour une cellule de 1 cm est de 0,2–1,2 p.p.m. de cobalt. Des quantités d'anions et de cations communs de l'ordre du mgr n'interfèrent pas. Le coefficient d'absorption molaire est de $3,69 \times 10^4$ $\text{l.mole}^{-1} . \text{cm}^{-1}$ à 620 nm.

ANALYTICAL DATA

METAL COMPLEXATION WITH 2-HYDROXY-6-METHYLPYRIDINE-3-CARBOXYLIC ACID

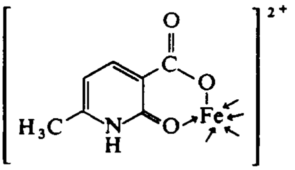
(*Received* 21 *April* 1972. *Revised* 1 *September* 1972. *Accepted* 20 *September* 1972)

In continuation of studies on metal complexation with hydroxypyridines,[1–4] 2-hydroxy-6-methylpyridine-3-carboxylic acid (HMPC) is examined as a ligand for use in determination of iron(III).

EXPERIMENTAL

Spectral investigations

The ligand solution is colourless and shows maximum absorption at 235 and 315 nm (ε 6·7 × 10^3 and 9·6 × 10^3 $l.mole^{-1}.cm^{-1}$). When it is added to iron(III) solution, a yellow colour is developed instantaneously, having λ_{max} = 410 nm, independent of the metal : ligand ratio, so only one complex is formed. The absorbance is independent of the acid concentration in the range 0·5–2·0*M* perchloric acid. For subsequent analytical work, 1*M* perchloric acid was chosen as the medium and an 80-fold molar excess of HMPC was found necessary for full colour development. Beer's law is obeyed up to an Fe(III) concentration of 16 μg/ml, the molar absorptivity being 5·0 × 10^3 $l.mole^{-1}cm^{-1}$. The complex was shown to be 1 : 1 by the continuous variation and the logarithmic[5] methods. The apparent stability constant of the complex is calculated to be 0·9 × 10^3 in 1*M* perchloric acid medium, at 25°. In view of the dominant lactam structure of hydroxypyridines[3,6] the structure (I) may be suggested for the complex, assuming that the remaining co-ordination sites around iron are occupied by water molecules or by anions. Iron(II) does not give a yellow colour with HMPC in 0·5–2·0*M* perchloric acid medium.



(I)

Interferences

The amounts of foreign ions (in μg/ml) tolerated in estimation of 2·5 μg/ml of Fe(III) in 1*M* perchloric acid medium are: 250 of NO_2^-, NO_3^-, Cl^-, Br^-, SO_4^{2-} or BO_3^{3-}; 150 of UO_2^{2+}; 100 of CH_3COO^-, F^-, citrate, tartrate, PO_4^{3-}, Cu, Mg, Ca, Sr, Ba, Zn, Cd, Al, Ti(IV), Zr, V(V), As(III), Sb(III), Mn(II), Ru or thiourea; 50 of Ce(III), Mo(VI) or Ir; 35 of W(VI); 10 of $C_2O_4^{2-}$, EDTA or Pt(IV); 5 of Rh. As the Ru and Ir solutions are coloured, these metals are included in the blank when they are present. Mo and W can be masked by addition of 100 μg of citrate per ml. I^-, $S_2O_3^{2-}$ and Cr(III) interfere, but iodide can be oxidized to iodine with hydrogen peroxide and extracted into chloroform, and chromium can be oxidized to perchromic acid with peroxide and extracted into pentanol.

Procedure

A drop of test solution (in 2*M* perchloric acid) is placed on a spot-plate followed by a drop of the reagent solution ($10^{-2}M$ in water). An immediate yellow colour shows the presence of iron(III).

The limits of identification and dilution are 0·8 μg/ml and 1 : 50,000 respectively.

Stability constants of bivalent metal complexes with HMPC

The method of Bjerrum and Calvin as modified by Irving and Rossotti[7] was used to obtain values of $\bar{n}$ and pL which were plotted to obtain the formation curves of the metal complexes. The values of log K_1 and log K_2 were calculated by the correction-term method of Irving and Rossotti.[8] From the results (Table 1) it is seen that the order of stability of the bivalent transition metal complexes with HMPC is as follows:

$$\mathrm{Cu} > \mathrm{Zn} > \mathrm{Fe} > \mathrm{Ni} > \mathrm{Co} > \mathrm{Mn}$$

Table 1. Stability constants of bivalent metal complexes with HMPC

Cation	log K_1	log K_2
Cu(II)	4·59	3·62
Zn(II)	3·90	2·81
Fe(II)	3·61	2·54
Ni(II)	3·46	2·50
Co(II)	3·42	2·40
Mn(II)	3·24	2·21

APPLICATION OF INDIRECT METHODS IN ANALYSIS BY ATOMIC-ABSORPTION SPECTROMETRY

G. F. KIRKBRIGHT and H. N. JOHNSON
Chemistry Department, Imperial College, London, S.W.7, U.K.

(*Received* 14 *August* 1972. *Accepted* 30 *September* 1972)

Summary—The use of indirect methods for the determination by atomic-absorption spectrometry of those elements not normally amenable to sensitive determination by this technique is reviewed. The available indirect methods are classified into five general types of procedure; specific reported procedures for the determination of metals, non-metals and some compounds are discussed.

Atomic-absorption spectrometry (AAS) may be used directly for the determination of 68 elements. The sensitivity attainable in these direct methods, defined as that concentration of the element in solution which produces 1% absorption at a given wavelength, is high for many of these elements (0·01–5 μg/ml). This sensitivity value is determined principally by the oscillator strength of the atomic line employed, the degree of atomization in the atom cell used and on the efficiency of the nebulization process by which the solution is introduced into the cell; the value for a particular element in a given solution does not vary greatly between instruments when commercially available apparatus is employed. The detection limit realizable for an element in AAS depends on the signal : noise ratio under particular analytical conditions and is considerably better than the 1% absorption sensitivity for most elements; this value, however, does vary with the instrumental assembly employed and the particular analyses undertaken.

A considerable number of elements may not be determined directly by atomic-absorption spectrometry with conventional instrumentation, or may be determined only with low sensitivity (> 5 μg/ml for 1% absorption) so that they are not readily determined at trace levels in solution. Thus, for example, the elements F, Cl, Br, I, S, P, O and N exhibit their principal resonance lines in the vacuum ultraviolet (Table 1) and are not directly determinable by AAS with conventional equipment. A second large group of elements for which direct AAS is difficult includes those elements for which, although

☐ Not determinable by AAS with conventional equipment

☐ Determinable by indirect AAS procedures their resonance lines lie in an accessible region of the spectrum, it is extremely difficult to form and maintain a significant atomic population in flame and non-flame cells. This group includes Th and Ce, for which no report of direct determination by AAS with appreciable sensitivity has been made, and in decreasing order of difficulty the elements U, B, W, Ta, La, Nb, Zr, Re, Lu, Hf, Hg, Gd, Ir, Pr, Nd, Sm and Tb. In addition the attainable sensitivity for several other elements that are frequently to be determined may be inadequate for their determination at the trace levels commonly encountered in samples to be analysed; these include As, Ge, Ti, V, Se and Te.

In order to extend the range of application of AAS, and to increase the attainable sensitivity for those elements where it is inadequate for trace analysis, much attention has been devoted to the development of indirect methods of analysis for many of those elements listed above. In addition some work has been reported for the application of indirect methods to permit the determination of organic species by AAS. The information on indirect AAS methods is scattered in the literature; an opportunity is taken in this paper to review these methods and comment on their application in analysis.

GENERAL CONSIDERATIONS

One of the principal advantages of direct methods of analysis by AAS is the high selectivity for particular elements in dilute solution. The success of indirect methods of analysis by AAS, and their applicability to practical analyses, depends on the degree to which the selectivity for the determination of the species concerned can be retained *via* the chemical reaction utilized before the final flame absorbance measurement. Even in those methods where some loss of selectivity is experienced owing to the nature of the initial chemical reaction employed, the ability to increase the sensitivity, or to achieve the AAS determination at all, is frequently of considerable value.

Several distinct types of procedure may be employed in indirect determinations by AAS. In each of these the species to be determined is made to undergo a reaction with one or more other ions and the concentration of the reaction product or of the unreacted excess of added reagent (which are directly and inversely proportional, respectively, to the concentration of the analyte species in the sample) is measured. The following specific types of procedure may be employed.

1. Measurement of the suppression or enhancement of the atomic-absorption signal for a given element by its reaction in the flame with the species to be determined.
2. Precipitation of the ion or compound to be determined by a second ion which is determined by AAS in the precipitate or filtrate.
3. Formation of an ion-association or chelate complex between an organic compound or an anion to be determined and a metal or metal complex; the metal is then determined by AAS after extraction with an organic solvent.
4. Formation of a binary or ternary heteropoly acid species between the analyte ion and other ions (one of which is usually molybdate), and determination of its concentration by AAS after separation of the complex by solvent extraction.
5. Application of the reducing (or oxidizing) properties of the analyte species to yield an equivalent concentration of the lower (or higher) oxidation state of a metallic ion, only one oxidation state of which forms an extractable chelate complex, which may be determined by AAS.

This review could be arranged under these five headings, and this approach has been adopted in earlier brief reviews of indirect AAS methods.[1,2] As the analytical chemist is most frequently interested in the determination of a particular element or group of elements, however, this review has been written with classification by the element determined.

METALS

Only rarely are the metallic elements not directly determinable by AAS; with the exception of thorium the indirect methods reported have therefore been concerned only to provide increased sensitivity in their determination.

Aluminium

An indirect AAS method for aluminium has recently been reported.[3] The sensitivity obtained in the determination of iron by AAS is low in the fuel-rich air–acetylene flame. An enhancement of the absorbance for iron is observed in the presence of small amounts of aluminium when this fuel-rich flame is employed. The enhancement by aluminium of the absorbance produced on nebulization of a 25-μg/ml iron solution is linear with respect to the aluminium content of the solution in the range 0·25–1·2 μg/ml.

The sensitivity obtained in the determination of aluminium by this method may be varied by the nebulization of different concentrations of iron; in this way with a 25-μg/ml iron solution the most sensitive working range for aluminium was found to be 0·01–0·09 μg/ml. Aluminium was also observed to enhance the absorbance of the elements cobalt, nickel and chromium in the flame employed. Titanium, calcium and zirconium at the same concentration levels as aluminium interfere with its determination. At concentrations equivalent to the iron concentration nickel and chromium interfere. The method is useful only for relatively pure aluminium solutions or analyses in which a separation procedure is included.

Germanium

The indirect determination of germanium by AAS, based on the formation of molybdogermanic acid (MGA) in which the molybdenum : germanium combining ratio is 12 : 1, has been described by Jakubiec and Boltz.[4] After its formation in hydrochloric acid solution at pH 1·5, the MGA complex is extracted with a mixture of 1-pentanol and diethyl ether (1 : 4 v/v). The complex is then back-extracted and decomposed by shaking the organic layer with an ammoniacal buffer at pH 9·3. The resulting molybdate is measured by AAS at 313·2 nm in an air–acetylene flame. A sensitivity for germanium of 0·05 μg/ml was reported with conformity to Beer's law in the range 0–1·6 μg/ml. No interference was found for 500 μg/ml of Ca, Co, K, Mg, Mn, Na, Ni, Zn, acetate, chloride, perchlorate, nitrate or sulphate ions in the determination of 1·5 μg/ml of germanium. The maximum permissible concentrations of foreign ions for non-interference in the determination of 1·5 μg/ml of germanium were established as: Al, Cd, Cr(III), Cu, Mo(VI) 500 μg/ml; Pb 50 μg/ml; Fe(II), Fe(III), Ti(IV), Cr(VI), W(VI) 10 μg/ml; As(III), As(V), P(V) and Si interfered at any concentration.

Mercury

Mercury(II) may be converted into its anionic bromo-complex and extracted into 1,2-dichloroethane as an ion-association complex with the zinc 2,2-bipyridyl chelate cation. Yamamoto *et al.*[5] have reported the determination of the zinc content of the extract, which is equivalent to the mercury present in the sample, by AAS in an air–acetylene flame.

The extraction was found to be quantitative between pH 3·5 and 5·5 and a linear calibration graph was obtained for 0·8–4·0 μg/ml of mercury in the initial aqueous phase with a sensitivity (for 1% Zn absorption) of 0·04 μg/ml of mercury. The following maximum permissible concentrations of foreign ions for non-interference with the determination of 2 μg/ml of mercury were established: Cu, 0·1 μg/ml; Co, I$^-$ 5 μg/ml; Cd, 15 μg/ml; Fe, 20 μg/ml; Pb, 200 μg/ml; Cl$^-$, 400 μg/ml.

Niobium

Kirkbright *et al.*[6] have utilized the formation of the ternary complex between niobium, phosphate and molybdate as the basis of an indirect method for the determination of niobium. The method is of the general type illustrated schematically in Fig. 1. As the molybdoniobophosphoric acid (MNPA) cannot be formed in aqueous solution without the simultaneous formation of molybdophosphoric acid (MPA) a prior selective extraction of MPA is required. Both MPA and MNPA are formed in 0·5*M* hydrochloric acid solution. The MPA may then be extracted with isobutyl acetate before extraction of MNPA into a single portion of n-butanol. The molybdenum associated with the niobium in the MNPA is then determined by direct AAS in the n-butanol phase which has been washed with dilute hydrochloric acid. A sensitivity of 0·015 μg/ml of niobium was reported, compared to a sensitivity by conventional direct AAS determination of 20 μg/ml for 1% absorption at the 334·4 nm line (Table 3); the calibration curve obtained was linear in the range 0·22–2·2 μg/ml of niobium. Out of twenty-seven ions studied for their interference with the determination of 1·30 μg/ml of niobium at the 30–700-fold weight ratio level, only As(V), Ge, Si, Ti, V(V) and Cr(VI) interfered. The method is sensitive because of the amplification accruing *via* the 11 : 1 combining ratio of molybdenum to niobium in MNPA and the "organic solvent effect" in the nebulizer of the flame spectrometer.

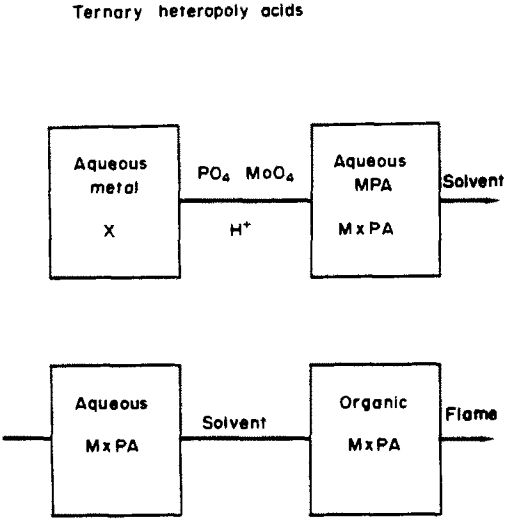

Fig. 1. General scheme for indirect determination of elements by AAS *via* formation of ternary heteropoly acids.

Table 3. Indirect AAS methods based on formation of molybdo-heteropoly compounds

Element	Sensitivity*		Range, indirect	Ref.

Thallium

Molybdophosphoric acid (MPA) has been used as a precipitant for thallium; the molybdate obtained by dissolution of the precipitate may be determined by AAS at 313·2 nm in an air–acetylene flame.[7] Thallium(I) is precipitated with MPA as $Tl_2HPMo_{12}O_{40}$ from 0·5*M* perchloric acid medium. The precipitate is centrifuged, washed with perchloric acid and dissolved in 0·1*M* sodium hydroxide solution. The molybdate equivalent to a definite amount of thallium is then determined. The optimum concentration range was found to be 2–20 μg/ml of thallium. The effect of other ions was not examined but as the method may also be used for the determination of ammonium by co-precipitation, this ion may thus interfere, as would other heavy metals which precipitate as molybdophosphates. As thallium can be determined by AAS in an air–acetylene flame with a sensitivity for 1% absorption of *ca.* 0·5 μg/ml at the 276·8 nm line it is doubtful whether, in view of the decreased selectivity, this method represents any advance on the direct method.

Thorium

Thorium may be determined indirectly by a method similar to that used for niobium.[8] Molybdothorophosphoric acid (MThPA) is formed in 0·15*M* hydrochloric acid in the presence of excess of MPA. The latter is then selectively extracted into isobutyl acetate and discarded. MThPA is extracted with n-butanol which is washed with butanol-saturated dilute hydrochloric acid. Although Kirkbright *et al.* claim to extract MThPA as such it is probable that only the MPA associated with the ternary complex was actually extracted; treatment with n-butanol has been shown to break down MThPA into thorium and MPA.[9,10] Eleven molybdenum atoms are associated with one thorium atom in the complex and the molybdenum is measured by AAS at 313·2 nm in a nitrous oxide–acetylene flame. A linear calibration curve was obtained for 1–6 μg/ml of thorium in the initial aqueous solution with a sensitivity of 0·063 μg/ml of thorium for 1% absorption. Only Zr, Fe(III), Si, As(V), Ti and Nb interfered seriously and required removal or masking.

Titanium

Titanium may be determined *via* its ternary heteropoly complex, molybdotitanophosphoric acid (MTPA).[11] The dissolution of the sample in hydrofluoric acid before the addition of phosphate, molybdate and acid requires the addition of aluminium to mask the excess of fluoride ion, which otherwise interferes in the determination. The excess of MPA is selectively extracted with chloroform : n-butanol (4 : 1 v/v) after formation of MTPA in 0·5M hydrochloric acid. The MTPA is extracted with n-butanol which is then washed with butanol-saturated dilute hydrochloric acid before nebulization into a nitrous oxide–acetylene flame. Eleven molybdenum atoms are associated with two titanium atoms in the complex and the molybdenum is measured by AAS at 313·2 nm. A linear calibration curve was obtained for 0·3–3 μg ml of titanium in the initial aqueous solution, corresponding to a sensitivity (for 1% Mo absorption) of 0·013 μg/ml of titanium. Interference was observed from As(V), Ge, Zr, Ta and Nb.

Ottaway *et al.*[12] have used the enhancement by titanium of the atomic-absorption signal of iron in a fuel-rich air–acetylene flame to determine titanium in the range 0·01–10 μg/ml. The iron is nebulized as ferric sulphate in $10^{-3}M$ sulphuric acid. Chloride, calcium, aluminium and zirconium also give enhancements at similar concentrations. A method based on the suppression of the absorbance of strontium by titanium in the presence of oxalate ions when nebulized into a stoichiometric air–acetylene flame has been used to determine titanium in the range 1–10 μg/ml.[13] The suppression is thought to be due to compound formation by strontium with titanium and oxalate. A solution $2 \times 10^{-4}M$ in strontium and containing 100 μg/ml of oxalate, 10% by volume of hydrochloric acid, and the titanium is nebulized into an air–acetylene flame. If the strontium concentration is increased higher ranges may be covered; these can, however, equally well be determined directly with a nitrous oxide–acetylene flame. A sensitivity of 0·15 μg/ml of titanium was recorded. Slight negative interference is experienced with EDTA, whereas Mn(II), Cu, Mg, Ca, Sn(IV) and Ni present at 200 μg/ml produce a small positive interference with 2 μg/ml of titanium. Al, Zr, H^+, Cr(III), PO_4^{3-} and F^- all interfere and therefore the method has limited applicability but does allow determination of titanium in the presence of high hydrochloric acid concentrations. Titanium causes similar depressions in the absorbances of calcium and barium in the presence of oxalate but methods based on these effects are less sensitive.

Vanadium

Vanadium(V) has been determined indirectly by AAS *via* the formation of molybdovanadophosphoric acid (MVPA).[14,15] In the method of Jakubiec and Boltz[14] a mixed phosphate and molybdate reagent is added to an aliquot of the sample at pH 1·5–2·0. The excess of MPA is extracted with diethyl ether, and the MVPA complex is then extracted with an n-pentanol : diethyl ether mixture (1 : 4 v/v). The organic layer is washed with dilute hydrochloric acid, and the MVPA is decomposed by back-extraction into an ammonia–ammonium chloride buffer solution. The molybdate content of this solution, which is equivalent to the vanadium, is then determined in a reducing air–acetylene flame with a sensitivity for vanadium of 0·05 μg/ml for 1% absorption. The following ions caused interference in the determination of 2·17 μg/ml of vanadium at the levels indicated: Cr(III), NO_3^-, SO_4^{2-} 250 μg/ml; Cd, $C_2H_3O_2^-$, Cr(VI) 100 μg/ml; As(V); Sn(IV) 50 μg/ml; Ti, Si, W(VI) 10 μg/ml; Fe(III) 5 μg/ml; Fe(II) interfered at any concentration.

A method has been developed which does not require back-extraction of MVPA from the organic solvent.[15] Phosphate and molybdate are added separately to the vanadium(V) solution to form MVPA in a 0·4*M* nitric acid medium. An n-butanol : chloroform mixture (1 : 4 v/v) is used to extract the MPA selectively and has the advantage of forming the denser phase so that it is readily separated and discarded without the need for transfer of the sample solution. MVPA is extracted with n-butanol, which is then washed with butanol-saturated dilute acid and nebulized into a fuel-rich nitrous oxide–acetylene flame. Eleven molybdenum atoms are associated with each vanadium atom in the complex and the molybdenum is measured at 313·2 nm. A sensitivity (for 1% Mo absorption) of 0·011 μg/ml of vanadium was obtained with a linear calibration from 0·2 to 2·0 μg/ml. Interference with the determination of 0·8 μg/ml of vanadium was experienced from F^-(16 μg/ml) As(V), Sn(IV) (8 μg/ml); Cr(VI) (2·4 μg/ml); Zr (0·8 μg/ml); Ti and Si interfered at any concentration. A scheme has been recommended to improve the selectivity of the procedure in the presence of ions which form binary or ternary heteropolymolybdates. These ions are removed as their corresponding heteropoly acids before formation and extraction of MVPA. This is possible as vanadium exists both as V(IV) and V(V) and only V(V) forms the ternary heteropoly acid. Vanadium in aluminium has been determined with reasonable results.

NON-METALS

Most of the published work which deals with indirect methods of analysis by AAS has been concerned with the determination of the non-metallic elements and other anionic species which cannot be determined directly because of the difficulties described earlier.

Arsenic

The reported indirect AAS methods for arsenic are all based on the formation of the binary heteropoly acid, molybdoarsenic acid (MAA). Danchik and Boltz[16] used bromine water to ensure that arsenic was present as As(V) before its reaction with molybdate at pH 1·8. The MAA was extracted with methyl isobutyl ketone (MIBK) which after being washed with dilute hydrochloric acid was shaken with a basic buffer solution to decompose and back-extract the MAA. The molybdenum associated with the arsenic was measured by AAS at 313·2 nm in an air–acetylene flame in the basic aqueous phase. A sensitivity of 0·07 μg/ml was achieved. MAA formed at pH 0·9 has been selectively extracted into an ethyl acetate : butanol : isopentyl acetate mixture (1 : 1 : 2 v/v) in the absence of PMA.[17] A sensitivity of 0·025 μg/ml was reported for measurement of the associated molybdenum in a nitrous oxide–acetylene flame. The effect of 40-fold weight ratios of 40 ions was studied, none of which was found to interfere. Arsenic has been determined with a sensitivity of 1 μg/ml in urine.[18] In this procedure the MAA was formed at pH 1, MPA was extracted with isobutyl acetate and the pH was then increased to 2 before extraction of MAA with cyclohexane.

By judicious choice of the extraction system arsenic may be determined with high sensitivity and good selectivity *via* its heteropoly acid species with molybdate.

Fluorine

The presence of fluoride ion depresses the absorbance produced at 285·2 nm for magnesium in an air–coal gas flame; this effect may be utilized as the basis of an indirect AAS method.[19] The change in absorbance of the magnesium at 285·2 nm was reported to be proportional to the fluoride concentration over the range 0·2–20 μg/ml of fluoride. When the concentration ratio of magnesium to fluoride in the sample solution reached 1 : 2 a constant absorbance was obtained. The method is subject to some interference, principally from phosphate and sulphate. Aluminium, oxalate and acetate also interfered at greater than 1000-fold molar ratio to fluoride. An alternative, but less sensitive, technique based on the enhancement of zirconium absorbance by fluoride in a nitrous oxide–acetylene flame at 360·1 nm has been reported to allow the determination of fluoride in aqueous solution with a high degree of freedom from interference over the range 5–200 μg/ml.[19] Phosphate again interferes, but the similar enhancement observed for titanium absorption at 364·3 nm can be used for fluoride determinations in the range 40–400 μg/ml in the presence of phosphate.[19] These indirect AAS methods for fluoride are considerably more rapid than the classical methods.

Chlorine

All the indirect AAS methods for the determination of chloride ion have been based on its reaction with silver nitrate. Either the excess of silver in the supernatant liquid is measured by AAS at 328 nm after removal of the silver chloride precipitate,[20–24] or the precipitate is redissolved in ammonia solution and the silver content of the ammoniacal solution is measured.[25,26,27] Chloride has been determined in serum,[20] plant liquors,[21] wine,[22] and polyvinyl chloride[23] by the first technique. A variation of this method involves the addition of a range of silver ion concentrations to aliquots of the sample containing chloride. After filtration the excess of silver in each filtrate is measured by AAS; a graph of absorbance *vs.* silver concentration should then show a point of inflection at the concentration of silver equivalent to the chloride content of the original solution.

The first reported determination of chloride by AAS was based on precipitation of silver chloride, dissolution of the precipitate in ammonia solution and the determination of the silver in the resulting solution.[27] This method has been applied to the determination of chloride in titanium metal with an air–hydrogen flame[25] and to the determination of chlorine in selenium.[26]

Perchlorate

Perchlorate forms a complex with copper(I) and neocuproin (2,9-dimethyl-1,10-phenanthroline) corresponding to the composition $Cu(neocuproin)_2ClO_4$; this species is extractable into ethyl acetate. When the copper is determined by AAS at 324·7 nm the method may be applied to the determination of 12·5–125 μg of perchlorate with a sensitivity of 0·025 μg/ml.[28] In the determination of 3 μg/ml of perchlorate by this method Collinson and Boltz[28] observed interference when nitrate, ammonia, magnesium or aluminium were present at concentrations greater than 10 μg/ml.

Iodine

Iodine has been determined by AAS, by use of a cadmium hollow-cathode lamp.[29,30] The method is based on solvent extraction into nitrobenzene of the ion-association complex formed between Tris(1,10-phenanthroline)Cd(II) and iodide at pH 5; subsequent AAS determination of the cadmium content of the extract may then be made at 228·8 nm in an air–acetylene flame. The effect of a number of diverse anions upon the determination of $2 \times 10^{-5}M$ iodide has been studied. Interference was experienced at concentrations greater than the molar ratios relative to cadmium indicated for the following ions: IO_4^- (0·02); ClO_3^-, ClO_4^- (0·03); NO_2^-, NO_3^- (0·1); Br^- (0·2); Cl^-, BrO_3^- (2); CN^-(10); IO_3^- (100); F^-, CO_3^{2-}, $B_4O_7^{2-}$ (1000). Christian and Feldman[31] have described the determination of iodide by utilization of its reducing action on a metal ion, coupled with extraction of the remaining oxidized form into an organic solvent and its estimation by AAS. Thus, for example, iodide reduces chromium(VI) in acid medium and the excess of chromium(VI) may be extracted from 3*M* hydrochloric acid into MIBK. The absorbance of chromium(III) in the aqueous layer increases linearly and the absorbance of the unreacted chromium(VI) in the MIBK decreases linearly with increasing amounts of iodide. The reaction is slow and does not go to completion in dilute solutions. Interferences have not been studied but most reducing species *e.g.*, Fe^{2+} would probably have a similar effect and thus interfere.

Selenium(IV) is reduced by iodide to elemental selenium in acid solution. When iodide is allowed to react with excess of selenium(IV) and the solution is filtered through a Millipore filter, the decrease in absorbance of the filtrate is proportional to the iodide ion concentration of the original sample solution.[31] Again, reducing species would be expected to interfere, though no results were reported for the effects of other ions.

Iodate

Iodate oxidizes iron(II) to iron(III) in acid medium; the iron(III) may be extracted into diethyl ether from 9*M* hydrochloric acid solution. The absorbance of iron in the ether phase is then proportional to the iodate concentration. The solutions must be deaerated to prevent aerial oxidation. As with the reduction method for iodine, this method lacks specificity and is only useful when no other oxidizing species are present.

Nitrogen compounds

Ammonia. Bond and Willis[32] have used the enhancement of zirconium absorbance in a nitrous oxide–acetylene flame at 360·1 nm by nitrogen-containing compounds for the determination of ammonia. For ammonia, the magnitude of this enhancement was found to be proportional to the concentration of the base in the range 1×10^{-4} to $5 \times 10^{-3}M$ and was used for its determination in the absence of phosphate and certain nitrogen-containing compounds. In the presence of interfering species, prior separation of the ammonia by distillation is required. The method has been applied to the determination of ammonia in biological systems.[32]

Danchik, Boltz and Hargis[7] have shown the co-precipitation of ammonium molybdophosphate with a known amount of thallium molydophosphate and subsequent dissolution of the precipitate to provide the basis for an indirect AAS method for the determination of ammonia. The molybdate obtained by dissolution of the precipitate, which is equivalent to a known amount of thallium and ammonia, is determined at 313·2 nm in an air–acetylene flame. Molybdophosphoric acid is used as precipitant in 0·5*M* perchloric acid. The method is unselective, as many heavy metals are precipitated as phosphomolybdates.

Cyanide. Cyanide may be determined *via* the equivalent silver associated with it in the $Ag(CN)_2^-$ complex.[33] Pieces of metallic silver are added to the solution containing the cyanide to be determined and the mixture is then shaken for 1 hr. The dissolved silver is determined by AAS to produce a rectilinear calibration graph for up to 3 μg/ml of cyanide ion. No inteference is experienced from Br^-, I^-, SCN^- or SO_4^{2-} ions but $S_2O_3^{2-}$ enhances the signal. Danchik and Boltz[34] report two methods for the indirect determination of cyanide. The first is based on the formation and extraction of the dicyano-bis(1,10-phenanthroline)Fe(II) complex. The complex is extracted into chloroform, which is then evaporated, and the residue is dissolved in ethanol. The associated iron is determined by AAS in an air–acetylene flame at 248·3 nm. A sensitivity of 0·06 μg/ml of cyanide has been obtained by this method, the calibration graph being linear up to 5 μg/ml. Precipitation of silver cyanide and measurement of the excess of silver in the supernatant solution by AAS in an air–acetylene flame at 328·1 nm forms the basis of a second method. A working range of 0·3–2·5 μg/ml of cyanide has been obtained with a sensitivity of 0·03 μg/ml. No study has been made of the effect of other ions.

Thiocyanate. Thiocyanate forms dithiocyanatodipyridine copper(II) complex, $Cu_2(Py)_2(SCN)_2$, which is extractable with chloroform. The copper equivalent to the thiocyanate is determined at 324·7 nm. A sensitivity of 0·2 μg/ml of thiocyanate has been reported with an optimum concentration range of 7–18 μg/ml.[35] The sensitivity may be improved to 0·05 μg/ml by evaporating the chloroform solution almost to dryness and diluting with ethyl acetate. The optimum concentration range is then between 0·5 and 2·0 μg/ml.

Nitrate. A small amount of nitrate ion is extractable into MIBK when neocuproin (2,9-dimethyl-1,10-phenanthroline) is contained in the organic phase and copper(I) ions are present in the aqueous phase. The copper associated with the nitrate ions in the complex, $Cu(I)(neocuproin)_2NO_3$, is measured in an air–acetylene flame at 324·7 nm.[36,37] Beer's law is obeyed in the range $1–7 \times 10^{-5}M$ nitrate in the aqueous phase. Nitrite and nitro-groups in organic compounds have also been determined *via* formation of the ion-pair with the Cu(I) neocuproin complex after their oxidation to nitrate with ceric sulphate or potassium permanganate.[38] The complex may be extracted into MIBK before measurement of the associated copper. Prior reduction of nitrite and nitro groups to amino groups by sulphamic acid permits determination of nitrate in the presence of such groups.

Phosphorus

Orthophosphate has been determined indirectly, mainly *via* the formation of molybdophosphoric acid (MPA) in the presence of molybdate in acid solution. The general procedure most frequently employed is illustrated in Fig. 2. Molybdate (ammonium or sodium salt) is added to the sample solution containing orthophosphate and the acidity is adjusted to its optimum value. The solution is mixed and allowed to stand for 5–10 min to ensure complete formation of MPA. The MPA is then extracted into an organic solvent which is either washed with dilute acid[39,40] to remove molybdate transferred to the organic layer, or with citrate solution to complex the excess of molybdate.[43,44] The molybdate associated with the phosphate in the complex is measured by AAS at 313·2 nm in an air–acetylene[40–46] or a nitrous oxide–acetylene flame.[17,39,47] Kumamaru *et al.*[47] employed 0·5*M* hydrochloric acid to form MPA and performed the extraction with n-butyl acetate to obtain a linear calibration graph up to 0·35 $\mu g/ml^{-1}$ of phosphorous. A general method for the determination of inorganic phosphate, using 2-octanol as a solvent,[44] has been applied to the determination of phosphate in fresh and sea water and in blood, serum, bone, biological tissues and enzyme-containing reaction mixtures.[45] 2-Octanol was chosen as solvent after examination of n-butanol, isobutyl alcohol, 1-hexanol, 1-heptanol, 1-octanol and 2-octanol.[45] Phosphate

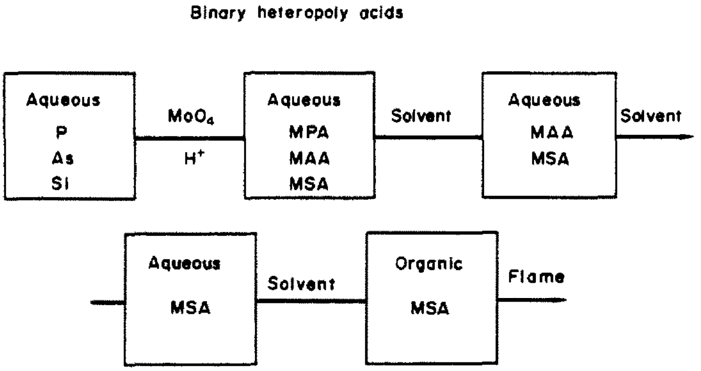

Fig. 2. General scheme for indirect determination of elements by AAS *via* formation of binary heteropoly acid species with molybdate.

has been determined in urine, the MPA being formed in 0·37*M* hydrochloric acid and extracted into isobutyl acetate.[41] Linden *et al.*[42] have determined phosphorus in milk products and blood serum *via* MPA, using perchloric acid medium and MIBK as solvent, for the range 100–200 μg of phosphorus. The results obtained agreed with those established colorimetrically. Phosphate has been determined in small (0·2 ml) samples of plasma.[43] The MPA is formed at pH 1·9 in a DL-α-alanine-hydrochloric acid buffer and is extracted with MIBK. The authors claim to extract MPA with an Mo : P ratio of 15 : 1. No evidence concerning the establishment of this apparently anomolous combining ratio is given. The procedure is applicable to the determination of between 5 and 200 μg/ml of phosphorus.

Several schemes have been devised for the sequential determination of phosphorus, arsenic and silicon,[17] phosphorus and arsenic,[18] and phosphorus and silicon[39,40] (Fig. 2). All are based on the ability to extract MPA selectively. Thus MPA has been selectively extracted with isobutyl acetate after formation at pH 0·7 in nitric acid medium, to result in a final sensitivity of 0·01 μg/ml of phosphorus.[17] Devoto[18] used isobutyl acetate to extract MPA formed at pH 1 in an ammonium nitrate–nitric acid medium. Isobutyl acetate has also been used by Kirkbright *et al.*[39] to selectively extract MPA formed at an acidity of 0·96*M* in hydrochloric acid in a single portion of solution containing phosphate and silicate, before formation of molybdosilicic acid (MSA). A sensitivity of 0·0068 μg/ml of phosphorus and a rectilinear calibration from 0·08 to 1 μg/ml of phosphorus was obtained by measuring the associated molybdate in the organic phase at 313·2 nm in a nitrous oxide–acetylene flame. Only W(VI) is reported as interfering out of 26 ions examined. MPA formed at pH 1·3 has also been extracted from 1·2*M* hydrochloric acid medium with diethyl ether.[40] After washing with dilute hydrochloric acid, the organic layer may be shaken with an ammoniacal buffer and the molybdate released measured in the aqueous phase by AAS in an air–acetylene flame. The optimum concentration range reported is 0·05–1·3 μg/ml of phosphorus. The use of isobutyl acetate coupled with the formation of MPA produces an extremely selective method for the determination of phosphorus by indirect AAS.

Phosphorus has been determined by several workers using the direct chemical interference of phosphate on a metal species in a flame to produce a depression of the absorption, which is a function of the phosphate concentration.[31,48,49] Orthophosphate up to $2{\cdot}5 \times 10^{-4}M$ added to $5 \times 10^{-4}M$ calcium solution produces a marked depression in the absorbance obtained for calcium at 427·7 nm with a total consumption burner.[31] The limiting concentration of phosphate may be increased by increasing the calcium concentration. Singhal and Banerjee have determined phosphorus in rock phosphate by depression of both calcium[49] and strontium[48] absorbance. In both cases the powdered rock phosphate is treated with a cation-exchange resin (H^+-form) before addition of calcium or strontium solution. A modification of the quinolinium molybdophosphate method has been proposed whereby total phosphorus is determined indirectly by the AAS measurement of molybdenum.[50] The familiar and well-tried gravimetric method is followed to the stage where the quinolinium molybdophosphate is formed. The precipitate is then dissolved in ammonia solution and the molybdenum determined by AAS at 313·2 nm. The method has been applied to the phosphorus analysis of Magruder collaborative fertiliser samples.[50]

Selenium

Selenium is difficult to determine directly with high sensitivity by AAS in a flame because of strong absorption of the resonance radiation at 196 nm by the flame and optical components of the spectrometer. An indirect method has been described based on two selective reactions of selenite with 2,3-diaminonaphthalene (DAN) and palladium(II) to form the complex $Pd(DANSe)_2Cl_2$.[51] When excess of DAN is added to a solution of selenite at pH 1·5–2·5 the following reaction occurs:

$$\text{I} \quad C_{10}H_6(NH_2)_2 + SeO_3^{2-} + 2H_3O^+ \longrightarrow \underset{\text{(DANSe)}}{C_{10}H_6N_2Se} + 5H_2O$$

In the presence of palladium chloride three further reactions are possible:

$$\text{II} \quad 2\ \text{DANSe} + PdCl_2 \xrightarrow{\text{pH} \leq 6} Pd(DANSe)_2Cl_2\text{(purple)}$$

$$\text{III} \quad 2\ \text{DANSe} + 2PdCl_2 \xrightarrow{\text{pH} \leq 6} Pd_2(DANSe)_2Cl_4\text{(green)}$$

$$\text{IV} \quad \text{DAN} + PdCl_2 \xrightarrow{\text{pH } 0\text{–}12} \text{white polymeric complex.}$$

Whether it is reaction II or III that occurs depends on the pH, relative concentration of reagents and also on the solvent used for the DANSe. Reaction IV always occurs and thus DANSe is removed from excess of DAN by extraction with chloroform. With chloroform as solvent the complex from reaction III is formed. The optimum calibration is from 0·05 to 1 μg/ml of selenium. A sensitivity of 0·017 μg/ml has been obtained. A study of the effect of 60-fold molar ratios of 50 ions on the determination of 0·5 μg/ml of selenium showed that only Fe(III), Sn(IV) and Ce(IV) interfered.

Silicon

Most indirect methods for silicon are based on the formation of molybdosilicic acid (MSA).[17,39,40,52] In one case MSA is formed at pH 1·3, extracted with a 1-pentanol : diethyl ether mixture (1 : 5 v/v) from 2*M* hydrochloric acid medium and decomposed by back-extraction into a 0·1*M* ammonia solution.[52] A known excess of lead(II) ion is then added to the aqueous solution to precipitate the molybdate as lead molybdate in amount equivalent to the amount of silicon present. The lead remaining in solution may be measured by AAS at 217·1 nm in an air–acetylene flame. An optimum concentration range of 0·005–0·07 μg/ml of silicon has been reported.[52] No interference is experienced from 500 μg/ml of Al^{3+}, NH_4^+, Fe^{3+}, Mg^{2+}, Cl^-, NO_3^-, ClO_4^-, SO_4^{2-} in the determination of 0·02 μg/ml of silicon. Silicon has also been determined sequentially with phosphorus[39,40] and arsenic[17] by using their respective molybdoheteropoly acids (Fig. 2). Kirkbright *et al.*[39] first investigated the determination of silicon by this means. Phosphorus is determined as phosphate by forming MPA in 0·96*M* hydrochloric acid medium and selectively extracting it into isobutyl acetate. The silicon in the same aliquot of solution is determined after the MPA extraction by adjusting the acidity of the solution to 0·15*M* hydrochloric acid with 4*M* ammonia solution to allow efficient formation of MSA. The MSA may then be extracted into n-butanol and the twelve molybdenum atoms associated with each silicon atom determined by AAS at 313·2 nm in a nitrous oxide–acetylene flame. A sensitivity of 0·008 μg/ml of silicon and an optimum concentration of 0·08–1 μg/ml of silicon are obtainable. The presence of a 100-fold weight ratio of 24 ions caused no interference in the determination of 12 μg of silicon; only arsenic(V) and germanium(IV) interfere by formation of their respective heteropoly acids. Hurford and Boltz[40] have described a similar sequential procedure. The MSA is formed at pH 1·3 after the MPA has been extracted and is then extracted from 2*M* hydrochloric acid medium with a 1-pentanol : diethyl ether mixture (1 : 5 v/v). After washing with dilute hydrochloric acid the organic layer is shaken with basic buffer solution which extracts and decomposes the MSA. In this method the molybdenum is then measured in an air–acetylene flame. A calibration range of 0·05–1·1 μg/ml is obtained. MSA formed at pH 0·7 may be separated from large amounts of MPA and molybdoarsenic acid by extraction into MIBK in the presence of citrate.[17] A sensitivity of 0·01 μg/ml of silicon is obtained, the optimum concentration range being from 0·1 to 1 μg/ml. Of 40 ions tested only germanium(IV) interfered with the determination of silicon.

Silicate has been determined in waste waters by atomic-absorption inhibition titration.[53] The method is based on the strong inhibition by silicate of the magnesium absorbance produced in an air–hydrogen flame. The absorbance is measured continuously while the nebulized solution is titrated; this procedure contrasts with the usual direct suppression methods when discrete sample solutions are nebulized. The sample at pH 3–4 is passed through a cation-exchange resin (H^+-form) to remove magnesium and other interfering cations. The eluate from the column is titrated with standard magnesium solution and the titrated solution simultaneously nebulized into an air–hydrogen flame. The end point is detected by a sharp increase in the magnesium absorption signal at 285·2 nm. High accuracy and precision is obtained with a limit of detection of 0·1 μg/ml of silica. The removal of cations by ion-exchange ensures the selectivity of the method.

Sulphur

The first reported indirect AAS method for sulphur is based on the precipitation of barium sulphate on addition of excess of barium chloride to the sample solution. In this method the precipitate is dissolved in a solution of disodium EDTA and the resulting barium concentration is determined at 553·5 nm in an air–acetylene flame.[64] Lanthanum is added to prevent phosphate interference. The method has been used to estimate sulphur in urine, faeces and biological tissues after oxidation by one of several techniques. In a procedure which avoids the necessity to dissolve the barium sulphate precipitate a known excess of barium is added to the sample solution, and the excess is determined after the precipitation of barium sulphate.[55,56] A 0·02M hydrochloric acid medium is used to minimize loss of selectivity through co-precipitation of other ions. The error caused by the partial dissolution of the precipitated barium sulphate and the incomplete reaction is overcome by calibration against standard sulphate solutions treated in a similar manner. The method has been applied to the determination of sulphate in textiles.[56] A similar method has been applied to the determination of water-soluble sulphate in acidic sulphate soils.[57] Calcium and phosphate above 30 and 10 μg/ml respectively interfere with the determination of 50 μg/ml of sulphate. A sensitivity of 1·5 μg/ml of sulphur has been reported for a method which involves precipitation of sulphate with barium chloride, centrifugation and measurement of the excess of barium.[58] An improvement in sensitivity is claimed to be achieved by reduction of the concentration or volume of the barium chloride solution added. The method has been applied to determination of sulphur in samples from deep mine waste water which have a high cation and sulphate concentration, and in the percolate from pyrite-bearing coalmine spoils. Good correlation has been reported between the results of the indirect AAS method and standard methods.

Sulphur in soils derived from volcanic ash is extracted with potassium dihydrogen phosphate solution; the extracted sulphur is transformed into suphate ions, and the organic matter destroyed with 30% hydrogen peroxide solution and sulphate precipitated with 15% barium chloride solution. The barium sulphate may be dissolved in a solution of EDTA (diammonium salt), and the barium measured by AAS in the presence of 1500 μg/ml of sodium ions to suppress barium ionization, to give a sensitivity (1% absorption) of 0·8 μg/ml of sulphur.[59]

Sulphur dioxide, after its preliminary conversion into sulphate with hydrogen peroxide, has been determined after precipitation and centrifugation of lead sulphate. The excess of lead remaining in the supernatant liquid may be measured at 283·3 nm in an air–acetylene flame. Ethanol is added to make the solution 25% with respect to ethanol and thus aid the precipitation of lead sulphate. A concentration range of 2–20 μg/ml of sulphur dioxide was recommended.[60] Interference is experienced above the levels shown for the determination of 5 μg/ml of sulphur dioxide with the following ions Fe(III), PO_4^{3-} (0 μg/ml); Ba, Al (10 μg/ml); EDTA (20 μg/ml), $CH_3CO_2^-$ (250 μg/ml). Sulphite or sulphur dioxide have been measured by AAS, with utilization of the high stability of the $Hg(SO_3)_2^{2-}$ complex.[61] Addition of sulphite ions to a suspension of mercury(II) oxide leads to dissolution of the oxide and formation of the soluble complex. The amount of oxide dissolved is proportional to the increase in absorbance at 253·7 nm observed for mercury in the supernatant fluid, and is then indicative of sulphite concentration. An optimum concentration range of 12–84 μg/ml of sulphite ions (10–77 μg/ml of sulphur dioxide) with a sensitivity of 13 μg/ml of sulphite has been reported. The reaction is not specific and iodide, thiosulphate and thiocyanate interfere.

Sulphate has been determined by atomic-absorption inhibition titration.[62] The test solution containing 0·05–1 mg of sulphate is titrated at a constant delivery rate with standard magnesium chloride solution. The titrated solution is simultaneously nebulized into an air–hydrogen flame. The magnesium absorbance is inhibited until the magnesium to sulphate concentration ratio approaches unity. Thereafter the graph representing increasing magnesium content becomes rectilinear and extrapolation to the base-line is used to locate the end-point. Interfering cations such as those of the alkaline earths metals are removed by passing the solution at pH 3–4 through a cation-exchanger (H^+-form). Silicate and phosphate interfere with the method.

ORGANIC COMPOUNDS

No systematic study of the determination of organic compounds by AAS appears to have been undertaken. Of the methods reported some are extremely specific and rely on the formation of a particular complex and its subsequent extraction,[63–66] while others utilize a more general reaction which can be applied for the determination of a range of compounds.[17,67]

2-Hydroxynaphthoic acid has been determined indirectly through the selective extraction of Tris(1,10-phenanthroline)Ni(II)–2-hydroxynaphthoate into nitrobenzene.[66] Measurement of the nickel concentration by AAS in an air–acetylene flame as a function of the 2-hydroxynaphthoic acid concentration initially present in the aqueous phase leads to a calibration which is linear in the range from 8×10^{-5} to $4 \times 10^{-4} M$ 2-hydroxynaphthoic acid. No interference is experienced from 2-naphthol.

Phthalic acid is extractable into MIBK as the ion-pair formed between bis(neocuproin) Cu(I) and the univalent anion of phthalic acid. The copper extracted is determined by AAS in an air–acetylene flame at 324·7 nm. The absorbance of the extract gives a linear relationship with the phthalic acid concentration initially present in the aqueous phase in the range 4×10^{-6} to $4 \times 10^{-5} M$.[63,64] Isophthalic and terephthalic acid do not interfere if present in amounts equimolar with the phthalic acid.

A similar method has been employed for the determination of pentachlorophenol.[65] The basis of the method is the solvent extraction into nitrobenzene of the ion-pair formed between Tris(1,10 phenanthroline)Fe(III) and the pentachlorophenol anion. The iron is subsequently determined in the extract by AAS at 248·3 nm in an air–acetylene flame. A concentration range up to $3 \times 10^{-4} M$ in pentachorophenol was studied.

Vitamin B_{12} contains one atom of cobalt per molecule. On dissolution of the vitamin the cobalt may be determined by AAS at 242·5 nm. The method has formed the basis for the determination of vitamin B_{12} in pharmaceutical dosage forms.[68,69]

Christian and Feldman[17] have determined several organic compounds by a variety of methods. Glucose oxidase and ribonuclease may be determined by their depressive effect on the absorbance of calcium. The upper concentration can be increased by raising the calcium concentration. Glucose below $10^{-6} M$ is found to produce a marked decrease in the absorbance obtained for calcium, but above that concentration it produces an increase, up to a limiting concentration of $10^{-5} M$. Glucose in the range 10^{-6} to $5 \times 10^{-5} M$ was also found to give a linear enhancement in the calcium absorbance which had been depressed by the addition of a constant amount of sulphate to the solution. Ammonium pyrrolidine dithiocarbamate (APDC) has been determined by measurement of the equivalent amount of copper or cobalt with which it complexes; the complex is extracted into MIBK at pH 3. With 1 ml of 1% metal ion solution a concentration of $10^{-5} M$ APDC may be determined. Similarly oxine is determinable *via* extraction of its copper complex into MIBK or ethyl acetate from an ammonium acetate buffer at pH 6·5 and subsequent AAS measurement of the copper. With 1 ml of $10^{-4} M$ copper solution a concentration of $2 \times 10^{-5} M$ oxine is determinable. EDTA may be determined through its action as a masking agent for the copper oxinate chelate. The decrease in absorbance of the extracted copper is proportional to the concentration of EDTA in the initial aqueous phase.

Sugar in plant materials has been determined by measurement of unreduced copper.[70] Copper is reduced in alkaline solution by the reducing sugars to form insoluble copper(I) oxide. The copper(I) oxide is centrifuged from solution and the unreduced copper(II) in solution is measured by AAS. The concentration of sugar in test solutions is determined from standard graphs prepared from known amounts of sugar.

Several organic compounds have been determined by precipitation of their silver compounds and measurement by AAS of the concentration of the excess of silver left in solution.[67] Thus iodoform, theobromine, sodium salicylate, mercaptobenzothiazole and xanthate have all been determined in this way.[67]

Non-ionic surfactants may be determined indirectly by AAS.[71,72] In one method the surfactant is precipitated as the MPA–Ba complex and the molybdenum in the supernatant liquid is assayed by AAS.[71] The molybdenum concentration is related to the quantity of surfactant by an empirical factor which must be determined for each batch and multicomponent system, as the precipitate is non-stoichiometric. A somewhat better method which does not require the introduction of an empirical factor has been developed.[72] The basis is the extraction of a cobaltithiocyanate–surfactant adduct from aqueous solution into benzene, and measurement of the associated cobalt in the benzene by AAS. Pollution levels of non-ionic surfactants in the Atlantic have been estimated in this way with a precision better than 10%.

CONCLUSION

As shown in Table 2, indirect AAS methods have been reported for the determination of inorganic cations and anions in solution as well as for the organic species described above. Tables 3 and 4 illustrate that the sensitivities obtainable are usually clearly superior to those in the corresponding direct AAS determinations, where these are possible; with careful choice of experimental conditions many of the indirect methods reported exhibit sufficient selectivity for the analyte species, to be applicable for practical analyses. Although several workers have described the direct determination of elements such as carbon,[73] phosphorus,[73,74] sulphur and iodine[74] in non-flame cells, and sulphur[75] and iodine[76] in the inert gas-separated nitrous oxide–acetylene flame, using the resonance lines of these elements in the vacuum ultraviolet, these procedures require modified or specialized instrumentation and have not yet found widespread application.

Zusammenfassung—Es wird eine Übersicht gegeben üben die Verwendung indirekter Methoden bei der Bestimmung jener Elemente durch Atomabsorptionsspektrometrie, die einer empfindlichen Bestimmung mit dieser Methode normalerweise nicht zugänglich sind. Die verfügbaren indirekten Methoden werden in fünf allgemeine Typen von Arbeitsvorschriften unterteilt; bekannte spezielle Arbeitsvorschriften zur Bestimmung von Metallen, Nichtmetallen und einigen organischen Verbindungen werden diskutiert.

Resumé—On passe en revue l'emploi des méthodes indirectes pour le dosage par spectroscopie d'absorption atomique des éléments qui ne sont pas normalement susceptibles d'être dosés de manière sensible par cette technique. Les méthodes indirectes disponibles sont classées en cinq types généraux de techniques; on discute de techniques spécifiques données pour le dosage de métaux, de non-métaux et de quelques composés organiques.

ARSENAZO III AS METALLOCHROMIC INDICATOR FOR COMPLEXOMETRIC DETERMINATION OF CALCIUM IN SLIGHTLY ALKALINE MEDIUM

V. MICHAYLOVA and N. KOULEVA
Department of Chemistry, University of Sofia
Sofia 26, Bulgaria

(*Received* 4 *August* 1972, *Accepted* 22 *November* 1972)

Summary—Arsenazo III is proposed as metallochromic indicator for calcium in slightly alkaline medium. The visual titration with EDTA was performed at pH 8 and 40 μg–12 mg of calcium were determined. The interference of some ions was considered and it was found that phosphate does not interfere appreciably. Spectrophotometric detection of the end-point was used for titration of calcium in the presence of magnesium at pH 9. For the estimation of the titration error, the conditional stability constants of the calcium–arsenazo III complex were found.

Most complexometric titrations of calcium are performed in a strongly alkaline medium suitable for the colour change of the indicators used and where the interference by magnesium can be avoided by precipitation of the hydroxide. The indicator described in this paper was selected and studied for the complexometric titration of calcium in slightly alkaline medium.

In our previous work[1] it was shown that calcium and arsenazo III form a blue 1 : 1 complex, the absorbance being maximal at pH 9. These data and the acid–base equilibria of arzenazo III serve as the basis for the present investigation. Some simple considerations show that the visual complexometric titration of calcium is possible at pH 8 with arsenazo III as metallochromic indicator. This is confirmed by the results obtained. The method is sensitive and calcium is determined in amounts from 40 μg to 12 mg. Interference of other ions has been studied, and phosphate in particular was found not to interfere.

In order to increase the sensitivity and selectivity of the method spectrophotometric end-point detection was used, which permits the determination of calcium in the presence of magnesium. For calculation of the titration error the conditional metal–indicator stability constant was determined.

EXPERIMENTAL

Reagents

Calcium chloride solution. A 0·1M solution was prepared by dissolving calcium carbonate in hydrochloric acid. A $10^{-2}M$ solution was prepared by dilution and standardized complexometrically with Thymolphthalexone and Calcon as indicators. Solutions of lower concentration were prepared by dilution.

EDTA and EGTA. 10^{-1} *and* $10^{-2}M$ Prepared according to the recommended methods[2] and standardized complexometrically with standard calcium solution.

Arsenazo III solution, $10^{-4}M$ Standardized by spectrophotometric titration with thorium nitrate solution at 600 nm and pH 3. An aqueous 0·1% w/v solution of arsenazo III was used as indicator

Buffer solutions. Boric acid (0·1M) and sodium hydroxide (0·1M) solutions were used to prepare buffer solutions[3] of pH 8–9.

All other reagents used were analytical-reagent grade.

RESULTS AND DISCUSSION

According to Buděšínský[4] arsenazo III [3,6-bis(2′-arsonophenylazo)-4,5-dihydroxynaphthalene-2,7-disulphonic acid] is decabasic when doubly protonated ($H_{10}L^{2+}$). The dissociation of the groups responsible for the colour change of the arsenazo III solution is important. The dissociation of the sulphonic acid groups (the forms H_8L, H_7L^-) and of the first arsonic acid group protons (the forms H_6L^{2-}, H_5L^{3-}) causes a very small colour effect. The solution is red with $\lambda_{max} = 540$ nm. The dissociation of the next arsonic group protons (the forms H_4L^{4-}, H_3L^{5-}) already causes a bathochromic effect and the colour of the solution changes to wine-red and then violet. The acidity of the hydroxyl groups on the naphthalene ring is strongly affected by the field effect, which increases the bathochromic effect. As a result a blue colour appears.

The acid–base equilibria for the last four steps according to Buděšínský[4] are as follows:

$$\underset{\text{red}}{H_4L^{4-}} \xrightleftharpoons{pK_7\ 6\cdot27} \underset{\text{wine-red}}{H_3L^{5-}} \xrightleftharpoons{pK_8\ 9\cdot05} \underset{\text{violet}}{H_2L^{6-}} \xrightleftharpoons{pK_9\ 11\cdot98} \underset{\text{blue}}{HL^{7-}} \xrightleftharpoons{pK_{10}\ 15\cdot1} \underset{\text{pure blue}}{L^{8-}}$$

Since the calcium–arsenazo III complex is blue it is obvious that the form H_3L^{5-} of arsenazo III is the most important for the complexometric determination of calcium. The following colour-change reaction is proposed:

$$\underset{\text{wine-red}}{H_3I^{5-} + Ca^{2+}} \rightleftharpoons \underset{\text{blue}}{CaH_2I^{4-}} + H^+$$

To define the conditions for existence of H_3L^{5-} in aqueous solution, we have calculated the distribution curves of ionic forms of arsenazo III at pH > 5. The results are shown in Fig. 1. It can be seen that the pH range 7–8 is the most suitable for the use of arsenazo III as a metal-ion indicator in the visual titration of calcium.

For complexometric titration the conditional metal-titrant stability constants are also important. The value of $K_{MY'}$ determines the minimum pH-value for the effective titration of metal ions. It can be calculated that for the Ca–EDTA titration this minimum pH-value is 7·5 for $10^{-2}M$ calcium. This value could also be found from the curve given by Reilley and Schmid.[5]

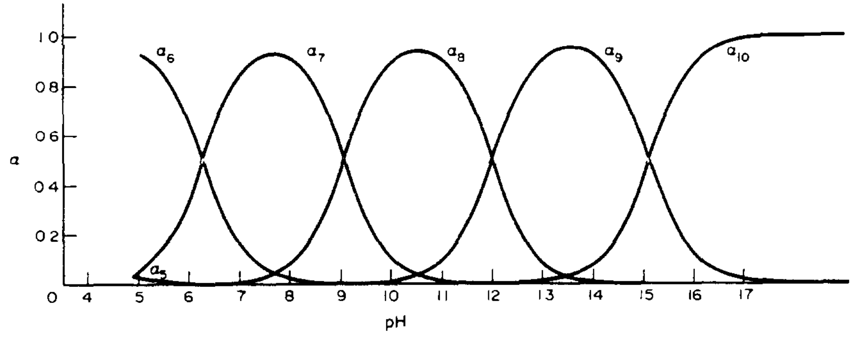

Fig. 1. Fraction of arsenazo III present in various ionic forms. α_5, as H_5L^{3-}; α_6 as H_4L^{4-}; α_7, as H_3L^{5-}; α_8, as H_2L^{6-}; α_9, as HL^{7-}; α_{10} as L^{8-}.

These considerations show that the visual titration of calcium with arsenazo III could be carried out at pH ~ 8.

Visual titration at pH 8

Place the test solutions containing 40 µg–12 mg of calcium in 50-ml glass beakers, add 5–15 ml of buffer at pH 8·1 ± 0·1 and 2 drops of 0·1% arsenazo III solution. An intense blue colour appears. Titrate with standard EDTA solution, stirring magnetically. The end-point is indicated by the colour change from blue to wine-red and is observed within a 2-drop interval (*ca* 0·03 ml). For samples containing >4 mg of calcium, sodium hydroxide must be added towards the end of the titration to maintain the pH at 8, because of the low buffer capacity. Table 1 shows some results.

Table 1. Complexometric titration of calcium

Calcium taken, *µg*	EDTA, *M*	No. of titns	Titration values Average observed, *ml*	Theoretical, *ml*
40	1.25×10^{-3}	8	0·826 ± 0·005	0·806
81	1.25×10^{-3}	7	1·615 ± 0·005	1·611
121	1.25×10^{-3}	7	2·40 ± 0·01	2·417

Interference of foreign ions

Solutions with 202 and 404 µg of calcium were investigated. Because of the more favourable difference in the conditional constants for the calcium and magnesium complexes, EGTA was used as titrant. Even so, positive errors were obtained at Ca : Mg ratios <4 : 1. The interference of Al(III), Fe(III) and Ti(IV) was eliminated by masking with 10 ml of 20% triethanolamine solution.

It was found that 0·44 mg of oxalate, 4·5 mg of tartrate and 80 mg of phosphate did not interfere in titration of 200 µg of calcium. In titration of >200 µg of calcium, addition of 80 mg of phosphate caused a slight precipitate, but this disappeared in the course of the titration if this was done slowly. For a sample of 2 mg of calcium 140 mg of phosphate did not interfere and the addition of 10 mg of phosphate did not precipitate calcium at all. The results are given in Table 2.

Spectrophotometric titration

Introduce the solution to be titrated into a 30-ml cell, add 1–1·5 ml of $10^{-4}M$ arsenazo III and 5–15 ml of buffer solution at pH 9·0 ± 0·2. Stir the mixture and measure the absorbance at 650nm after each addition of titrant. Plot the graph in the usual way.

Typical results are given in Tables 3 and 4.

The results in Tables 1 and 3 indicate that the proposed method has good sensitivity and accuracy. The method was applied to a wide concentration range of calcium, including concentrations that are usually determined spectrophotometrically. It was also found (Table 2) that phosphate does not interfere considerably.

Table 2. Interference of ions
(For 202 μg of Ca the theoretical consumption of $1·41 \times 10^{-3} M$ EGTA is 0·357 ml and for 404 μg it is 0·714 ml; 3 or 4 titrations were done in each case)

For titration of calcium in the presence of magnesium (Table 4) the lowest Ca : Mg ratio for accurate results was established experimentally for each amount of calcium. This ratio depends mainly on the magnitude of the break in the titration curve. In the experiments shown in Table 4 the absorbance jump was at least 0·100.

The use of arsenazo III as metallochromic indicator in complexometric titration of calcium requires the estimation of the precision in the determination of ΔpM or the titration error. For this purpose the conditional stability constant of calcium–arsenazo III complex was determined.

Determination of the conditional stability constant

The graphical method of Frank and Oswald[6] was used to determine the conditional stability constant of calcium–arsenazo III complex (MI) at pH 8 and $\mu = 0{\cdot}1$ From this value, however, we could not calculate the conditional constant at pH 9 using only the value of $\alpha_{I(H)}$ of arsenazo III. For this purpose the value of $\alpha_{MI(H)}$ is also necessary.[7]

Since we did not have this information, the value of the constant at pH 9 was determined directly by the same method. The values found were as follows.

For pH 8, $\log K_{CaI} = 4{\cdot}9 \pm 0{\cdot}2$ (graphically $\log K_{CaI} = 4{\cdot}8$)

For pH 9, $\log K_{CaI} = 5{\cdot}3 \pm 0{\cdot}2$ (graphically $\log K_{CaI} = 5{\cdot}3$)

These values were used for the calculation of the titration error by means of the following equation.[2]

$$\text{Titration error, \%} = \frac{460\,.\,\Delta pM}{([M]_t\,.\,K_{M'Y'})^{1/2}} \tag{1}$$

When $10^{-2}M$ calcium is titrated with EDTA at pH 8 the error can be easily calculated. We have:

$$\log K_{CaY'} = 8{\cdot}4;\ \log K_{CaI} = 4{\cdot}9;\ pM_{eq} = 5{\cdot}2;\ \Delta pM = 0{\cdot}3$$

Then the error = 0·09 ~ 0·1%.

For the titration of $10^{-3}M$ calcium, ΔpM is 0·8 and the error calculated is 0·7% although the use of the error equation is less correct for these conditions. The same error was obtained from Ringbom's diagram.[8]

When the spectrophotometric method was used an error at about ±0·1 pM unit was obtained, even for the titration of $10^{-3}M$ calcium.

The sensitivity of photometric pM measurement was estimated by Ringbom's method.[8] The expression used was:

$$\frac{\Delta pM}{\Delta T} = -\frac{0{\cdot}188(1 + [M]K_{MI})}{(A - A_{MI}^{max})T[M]K_{MI}} \tag{2}$$

where T is the transmittance, [M] the metal concentration at the end-point and A the absorbance of the solution at the end-point.

For this calculation the titration data (Table 5) for 5 ml of $1{\cdot}007 \times 10^{-3}M$ calcium

Table 5.

EDTA added, *ml*	Absorbance at 650 *nm*	EDTA added, *ml*	Absorbance at 650 *nm*
0	0·508	2·185	0·168
0·940	0·480	2·200	0·114
1·800	0·461	2·230	0·099
2·073	0·436	2·250	0·094
2·120	0·414	2 395	0·084
2·170	0·283		

Addition of 1 drop of $0{\cdot}1M$ EDTA gave $A_I^{max} = 0{\cdot}080$.

Addition of 1 drop of $\sim 1M$ Ca^{2+} gave $A_{MI}^{max} = 0{\cdot}510$.

titrated with $2{\cdot}31 \times 10^{-3}M$ EDTA at pH 8·8, in the presence of 1·5 ml of $9{\cdot}81 \times 10^{-5}M$ arsenazo III were used.

It is necessary also to use the following data: $\log K_{\mathrm{CaY}} = 9$, $[\mathrm{CaY}]_{\mathrm{eq}} \sim 10^{-3{\cdot}5^{-}}M$, $\log K_{\mathrm{CaI'}} = 5{\cdot}3$, $V_{\mathrm{total}} = 18{\cdot}9$ ml.

The calculations gave $\mathrm{pCa}_{\mathrm{eq}} = 6{\cdot}28$; $[\mathrm{Ca}]_{\mathrm{eq}} \,.\, K_{\mathrm{CaI'}} = 0{\cdot}105$.

The absorbance at the end-point was calculated from the equation

$$A_{\mathrm{eq}} = \frac{(A_{\mathrm{I}}^{\max} + A_{\mathrm{MI}}^{\max} \,.\, [\mathrm{M}]_{\mathrm{eq}} \,.\, K_{\mathrm{MI}})}{1 + [\mathrm{M}]_{\mathrm{eq}} \,.\, K_{\mathrm{MI}}} \tag{3}$$

A_{eq} found was 0·121. By interpolation in the data from Table 5 the value $V_{\mathrm{eq}} = 2{\cdot}198$ ml was found.

According to equation (2) $\Delta\mathrm{pCa} = 0{\cdot}067 \sim 0{\cdot}07$. For this value of ΔpCa and $\log C_{\mathrm{Ca}} \,.\, K_{\mathrm{CaY'}} = 5{\cdot}43$ the titration error is ~0·07% from Ringbom's diagram.

The indicator correction was also calculated from the equation:

$$[\mathrm{MI}]_{\mathrm{eq}} = \frac{C_{\mathrm{ind}}(A_{\mathrm{eq}} - A_{\mathrm{I}}^{\max})}{A_{\mathrm{MI}}^{\max} - A_{\mathrm{I}}^{\max}} \tag{4}$$

and found to be $[\mathrm{MI}]_{\mathrm{eq}} = 7{\cdot}4 \times 10^{-7}M$. The volume of EDTA solution corresponding to this correction was 0·006 ml. Then the volume of EDTA used at the equivalence point was 2·204 ml, corresponding to 204 μg of calcium. The same result could be obtained by graphical extrapolation, which is therefore equally valid and more convenient.

Zusammenfassung—Arsenazo III wird als Metallfarbindikator für Calcium in schwach alkalischem Medium vorgeschlagen. Die visuelle Titration mit EDTA wurde bei pH 8 ausgeführt und 40 μg-12 mg Calcium bestimmt. Die Störung durch einige Ionen wurde in Betracht gezogen; es wurde gefunden, daß Phosphat nicht nennenswert stört. Zur Titration von Calcium in Gegenwart von Magnesium wurde der Endpunkt bei pH 9 spektrophotometrisch nachgewiesen. Zur Abschätzung des Titrationsfehlers wurden die Stabilitätskonstanten des Calcium-Arsenazo III-Komplexes unter den betreffenden Bedingungen ermittelt.

Résumé—On propose l'Arsenazo III comme indicateur métallochrome pour le calcium en milieu légèrement alcalin. Le titrage visuel avec l'EDTA a été réalisé à pH 8 et l'on a dosé 40 μg-12 mg de calcium. On a considéré l'interférence de quelques ions et l'on a trouvé que le phosphate ne gêne pas de manière appréciable. On a utilisé la détection spectrophotométrique du point final pour le titrage du calcium en la présence de magnésium à pH 9. Pour l'estimation de l'erreur de titrage, on a trouvé les constantes de stabilité conditionnelles du complexe calcium-arsenazo III.

ULTRAMICRO ATOMIC-ABSORPTION SPECTROSCOPY WITH A TUNGSTEN-FILAMENT ATOM-RESERVOIR

J. E. CANTLE and T. S. WEST
Chemistry Department, Imperial College of Science and Technology, London, S.W 7, 2AY, U.K.

(*Received* 4 *August* 1972. *Accepted* 27 *September* 1972)

Summary—The detection and measurement of traces of zinc, lead, copper and silver by atomic-absorption spectroscopy with a tungsten-filament atom-reservoir (TFAR), hollow-cathode lamps and limited-field viewing is described. The performance of this atom cell is compared with that of the carbon-filament atom-reservoir for determination of lead. Greater sensitivity and fewer matrix effects are observed with the TFAR system. The lifetime of the tungsten filament is almost indefinite.

The development of ultramicro techniques of atomic-absorption and atomic-fluorescence spectroscopy with a carbon-filament atom-reservoir (CFAR) has been described in several papers from this laboratory[1-11] these techniques have been applied to several practical problems.[10-13] The advantages include the ability to handle very small samples (1–5 μl), high absolute sensitivity and low background signals. Matrix effects, which arise chiefly in the vapour phase above the surface of the filament and almost exclusively from elements that atomize at similar temperatures to the analyte element,[3,4] may be reduced by limited-field viewing close to the surface of the filament before condensation reactions set in to reduce the atomic population of the analyte element.[6,7]

A recent paper by Takeuchi *et al.*[14] describes the determination of Al, Cr, Cu, Fe, Mg and Mn by flameless atomic-absorption measurements, using a tantalum strip which is electrically heated in an enclosed argon atmosphere, and somewhat similar to the original CFAR unit of West and Williams.[1]

Earlier, Donega and Burgess[15] described an absorption chamber which consisted of a tantalum or tungsten sample boat heated electrically in an enclosed inert atmosphere maintained at any desired pressure, usually in the range 1–300 torr. The boat was supported in a 50 mm i.d. quartz tube with quartz windows at each end.

In this communication we describe the determination of traces of Ag, Cu, Pb and Zn by use of an unenclosed tungsten-filament atom-reservoir (TFAR), reporting detection limits, sensitivity and matrix effects, and comparing the relative performance of TFAR and CFAR units on the same apparatus.

EXPERIMENTAL

Apparatus

Atomic-absorption measurements were made with a Jobin-Yvon "Delta" atomic-absorption spectrometer. An Alder and West[3] type of atom-reservoir unit was mounted on the base plate which normally holds the burner unit. The carbon filament normally used in the CFAR was replaced by a cylindrical tungsten filament 60 mm long and 2·2 mm in dia., that had been ground to produce a 1-mm deep recess (~ 2 mm wide) at its centre, in which the 1-μl samples could be located. The presence of the notch also ensured that this position where the sample located was also the hottest point when the filament was electrically heated. The burner-height adjustment mechanism of the spectrometer also allowed the position of the filament to be adjusted in a vertical plane with respect to the beam of the hollow-cathode lamp along the optical axis of the spectrometer. The beam of incident radiation from the hollow-cathode lamp was modulated mechanically at 125 Hz and focused by a system of two silica lenses to form a sharp image *ca* 3 mm in dia. over the centre of the filament. A 20-mm dia. collimator tube was placed centrally in the light-path as close as possible to the tungsten filament. The tube carried a 0·5 or 1-mm horizontal slit at the end nearest to the filament. A third lens placed between the TFAR and the monochromator focused the light onto the entrance slit. The output from the amplifier was presented to the input of a Smith's Instruments "Servoscribe" chart recorder. The gas flow and electrical supplies to the TFAR were as described previously for CFAR units.[3]

Reagents

All reagents were of analytical grade. Water was distilled in glass apparatus and then treated with a cation-exchange resin in the H^+ form. The water thus purified was found to contain no measurable amount of the elements examined. Volumetric flasks used to prepare or contain metal solutions more dilute than 100 ppm were previously treated with a silicone preparation, "Repelcote," as were the Drummond micropipettes used to place the 1-μl samples on the filament. Standard solutions containing less than 100 ppm of the cations were freshly prepared before use to minimize losses due to surface adsorption effects.

Measurement technique

The following sequence was found to give the best sensitivity, detection limit and reproducibility of measurement of atomic-absorption signals with the TFAR unit.

The monochromator was tuned to receive the resonance line of the element being studied and the filament shielding-gas (argon or nitrogen) was allowed to flow at the optimum flow-rate. The aqueous sample (1 μl) was placed in the recess in the filament by means of a Drummond micropipette. The following time-cycle was then followed: the filament was switched on at low power (1·5V), to evaporate the water from the sample slowly without loss due to sputtering. The current was switched off and the voltage was increased to that determined to be optimum for the particular element; the filament current was then turned on again to atomize the sample. This took approximately 2·5 sec, and the absorption peak was recorded on the chart paper, for subsequent measurement. This cycle was repeated at 75-sec intervals. This sequence allowed sufficient time for the filament to cool down before application of the next sample solution. No memory effects were detected for any of the elements studied, at the ppm concentrations usually used in atomic-absorption measurements.

RESULTS AND DISCUSSION

The response times of the amplifier of the Jobin-Yvon Delta spectrometer and the Servoscribe recorder are the usual for a flame spectrometer, but are relatively slow for transient signal measurements. The net result is that as the applied voltage is increased, the peak height increases to a maximum and then decreases with further increase of voltage, because the temperature rise-time of the filament, and therefore, the speed of atomization, increases with increase of voltage until the rate of generation of free atoms exceeds the capability of the electronic circuitry to respond to it. This behaviour is shown in Fig. 1 for fixed amounts of the four elements studied. The absorbance–voltage peak varies from one element to another, depending on the atomization temperature, but also to a limited extent on the amount or concentration of the element.

Figure 2 shows that as the silver atoms come off the filament more quickly at higher voltages they pass out of the light beam before the detection system can fully respond to them. This is evident from curves (*b*) and (*c*) but more particularly from (*a*) where larger amounts of silver are involved and where self-condensation may further lower the population of absorbing atoms. The effect of collimation is shown by curves (*b*) and (*c*). At higher voltages the limited sampling area produced by collimation is filled with a denser atomic population producing a higher signal, but at voltages, <*ca*. 5V, the collimated signals are weaker because atomization is insufficiently fast to fill the sampling area.

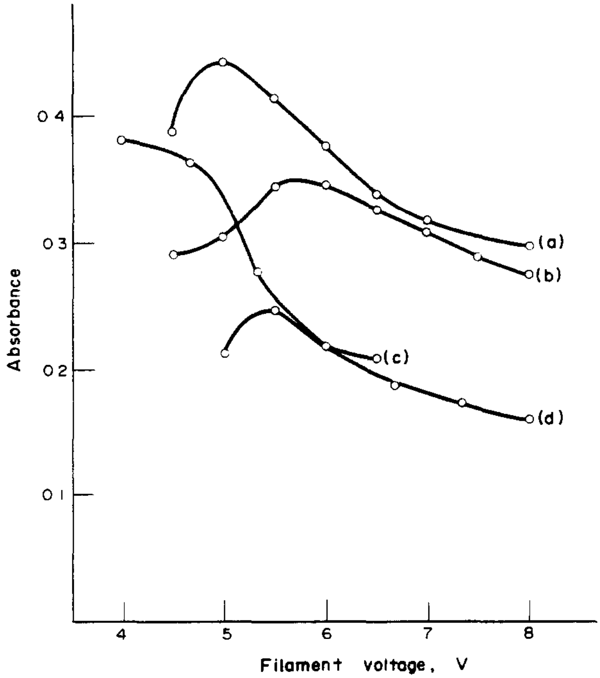

Fig. 1. Variation of absorbance with tungsten filament voltage. (*a*) = 1 ng of lead: (*b*) = 0·5 ng of copper. (*c*) = 0·2 ng of silver; (*d*) = 0·01 ng of zinc.

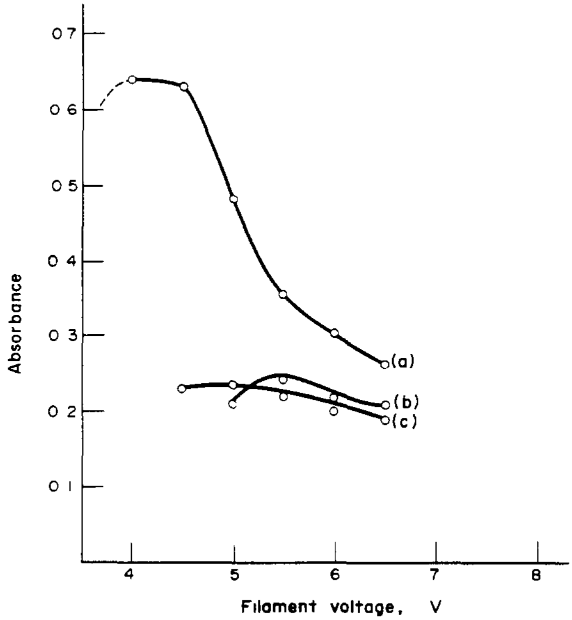

Fig 2 Variation of absorbance with concentration of analyte and with collimation. (*a*) = 1 ng of silver, no collimation. (*b*) = 0·2 ng of silver: 0·5-mm slit and collimation. (*c*) = 0·2 ng of silver, no collimation.

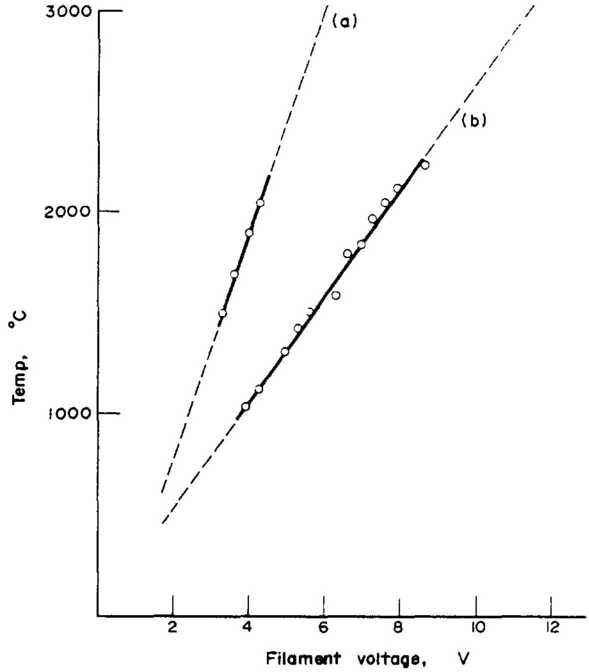

Fig. 3. Equilibrium temperatures.
(*a*) = 2·2-mm tungsten filament; (*b*) = 2-mm carbon filament.

A tungsten filament has a much lower resistance than a carbon filament so requires a considerably lower voltage to reach the same temperature. Figure 3 shows temperature–voltage curves for TFAR and CFAR units (2·2 and 2 mm in dia.), for equilibrium temperatures as measured by an optical pyrometer.

Effect of shielding-gas flow-rate on signal

Figure 4 shows the effect of the shielding-gas flow-rate on the absorbance for the elements examined. Although it is possible to choose an optimum flow-rate in each case, it is clear that small fluctuations have very little effect on the absorption signal. When nitrogen and argon were used immediately after each other, each at its optimum flow-rate, there was no difference between the absorption signals obtained. Some optimized operating parameters for this apparatus are given in Table 1.

Table 1. Operating parameters for AAS of Zn, Pb, Cu, Ag with TFAR

Element	λ, *nm*	Lamp operating Current, *mA*	Monochromator entry slit, *mm*	Filament voltage, *V*	Gas flow-rate, *l./min*
Zn	213·8	4	0·5	4·5	Ar (1·6)
Pb	217·0	6	1·0	5·0	Ar (2), N_2 (3·2)
Cu	324·7	6	0·05	5·5	N_2 (3·2)
Ag	328·1	10	0·04	5·5	N_2 (3·7)

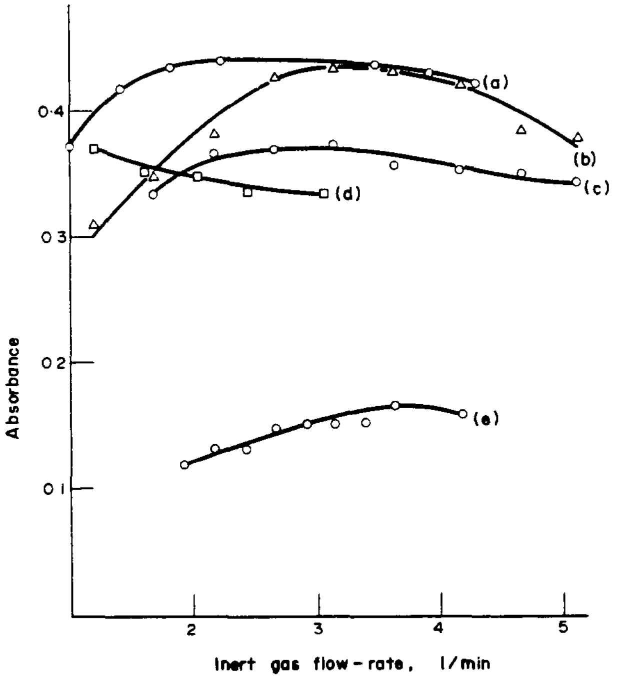

Fig. 4. Variation of absorbance with inert gas flow-rate.
(*a*) = 1 ng of lead (argon); (*b*) = 1 ng of copper (nitrogen); (*c*) = 1 ng of lead (nitrogen); (*d*) = 0·01 ng of zinc (argon); (*e*) = 0·2 ng of silver (nitrogen).

Detection limits and sensitivity

Detection limits (signal : noise = 2 : 1) and sensitivity (1% absorbance) for the TFAR under optimized conditions are quoted in Table 2. Figure 5 shows typical calibration curves for the four elements studied. The non-linearity in some of these curves may be partly, if not entirely, associated with the slow response rate of the amplifier/recorder system (~0·8 sec full-scale recorder deflection) with respect to the more transient signals (~0·05 sec half-peak width). Better sensitivities could obviously be achieved with more rapid-response electronics, and more particularly, with integration.

Comparison with CFAR

The performances of the two filament materials were compared by using each in turn with lead as the test element. At the optimum voltages, which were found to be 5V for tungsten and 6V for carbon, the absorbances shown in Table 3 were obtained for 1 ppm of lead at corresponding filament positions for both materials.

Table 2 Detection limits and sensitivities for TFAR

Element line, *nm*	Detection limit, *ppm*	*pg*	Sensitivity (1% absorption) *ppm*	*pg*
Zn 213·8	0·00028	0·28	0·00078	0·78
Pb 217·0	0·02	20	0·014	14
Cu 324·7	0·006	6	0·0075	7·5
Ag 328·1	0·006	6	0·0044	4·4

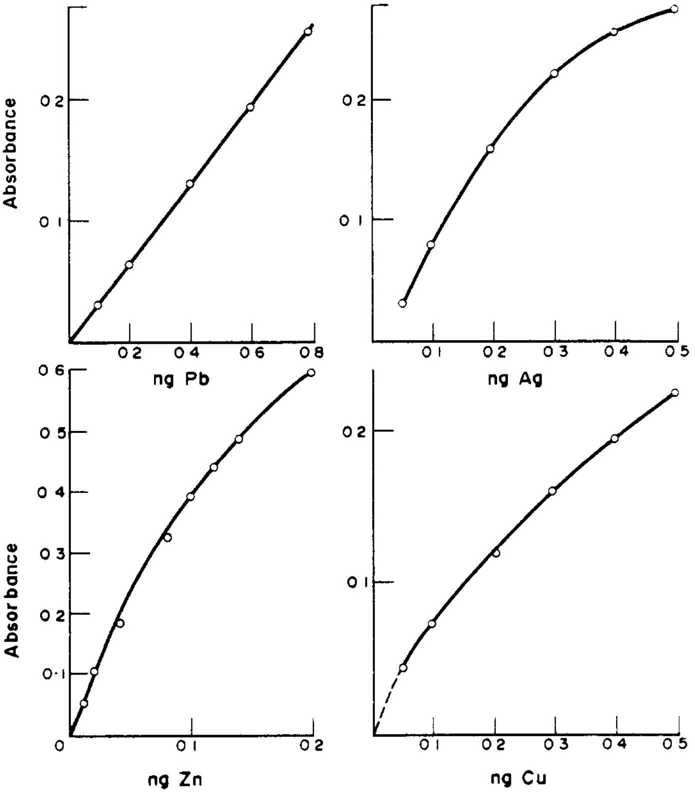

Fig. 5. Analytical calibration graphs.

For positions from *a* to *e* the filament height increased in 1/6-mm steps. Position *b* corresponded to grazing incidence of the light beam. At position *e* the depression in the filament lay within the horizontal optical plane.

It can be seen from Table 3 that the signal from the tungsten filament was about 50% higher than that from the carbon filament at the highest filament position. At higher positions the noise on the base-line was intolerable owing to radiation from the filament in the light path. The reproducibilities were comparable for each filament. Standard deviations were generally less than 2% of the signal.

Table 3. Absorbance for 1 ng of lead at 217 nm

Filament height position	CFAR absorbance	TFAR absorbance
a	0·17	0·22
*b**	0·24	0·28
c	0·26	0·36
d	0·27	0·41
e†	0·27	0·41

* Grazing incidence.

† Totally in light path. Signal very noisy if filament higher than this.

Table 4. Comparison of potential interferences in determination of lead (1 ppm) with TFAR and CFAR cells

Interfering element, 1 *mg*	% Suppression, CFAR	% Suppression, TFAR
Ag^+	20	0
Bi^{3+}	45	0
Co^{2+}	35	29
K^+	30	0
Na^+	12	0
HCl	30	0

As well as improving sensitivity, the TFAR seemed to remove matrix effects or reduce them very considerably. Table 4 shows the effect on the absorbance of 1 ppm of lead of 1000 ppm of six interferents which cause problems with the CFAR technique. All measurements were made at the highest possible filament position.

Since the tungsten filament is stronger, its lifetime is much longer than that of a carbon filament; the latter has to be changed every 100–200 shots, depending on the voltage used, and often fractures from thermal shock, whereas a tungsten filament will last indefinitely if treated correctly. Electrical contact is improved because the tungsten filament can be clamped to the electrodes much more tightly.

Because of the lower electrical resistance, higher currents flow in the TFAR than in the CFAR. Figure 6 shows a plot of current *vs.* voltage in the transformer primary. However, the same power supply has been used successfully for both atom cells throughout this work. The use of a tungsten filament does not, therefore, necessitate the use of more expensive apparatus for handling and switching current.

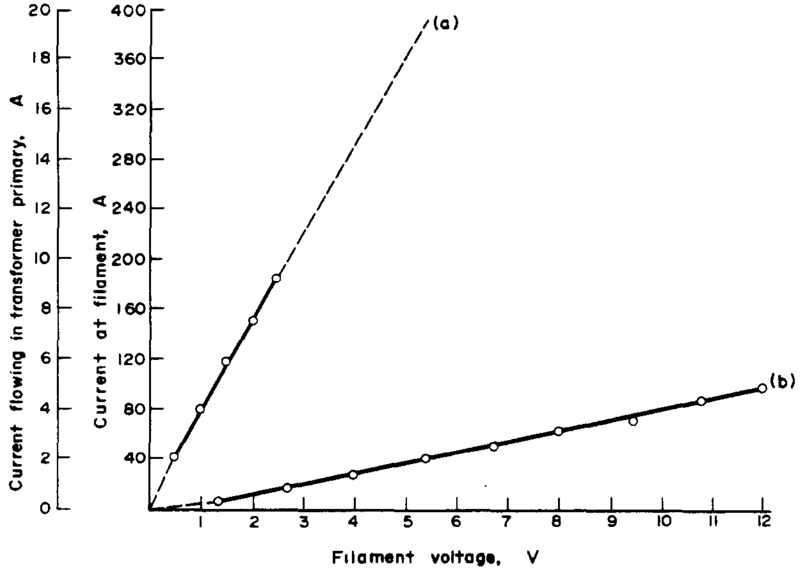

Fig. 6. Filament current/voltage characteristics.
(*a*) – 2·2-mm tungsten; (*b*) – 2-mm carbon.

Table 5. Comparison of interferences for copper, with TFAR and CFAR

Interfering element, *M*	Ratio (M : Cu) *w/w*	% Suppression TFAR, 0·5 *ppm* Cu	% Suppression CFAR[6] 1 *ppm* Cu	% Suppression CFAR[6] 0·5 *ppm* Cu
Ca^{2+}	1000	0	25	0
Cr^{3+}	1000	0	50	20
Fe^{2+}	1000	10	55	10
K^{+}	1000	12	25	0
Mn^{2+}	1000	0	60	40
H_2SO_4	5000	0	not reported	—
HCl	5000	20	not reported	—

Further interference studies

Table 5 shows the effect of various interferents on the absorbance for 0·5 ppm of copper with the TFAR, and that previously reported for the CFAR.[6] With the CFAR some of the interferences could be reduced by using a smaller concentration of analyte. It seems, therefore, that the absolute amount of interferent is the determining factor rather than its ratio to the amount of analyte. This is consistent with the interferences occurring in the gas phase.[4]

The TFAR may be seen, therefore, as a very useful alternative to the CFAR for use in analytical spectroscopy. At least for the elements examined so far it possesses all the good characteristics of the CFAR and complements these with many of its own, *viz.* its very long lifetime, much lower tendency to show matrix effects, and somewhat greater sensitivity.

The behaviour of other elements will be reported at a later stage when it may be possible to comment more definitely on the reasons for increased sensitivity and greater freedom from matrix interferences. It appears possible that the increased sensitivity may be due to the fact that added solutions do not penetrate to any appreciable extent within a tungsten filament as they do in a carbon filament. Thus the sample, when dried out, exists in a more concentrated form on the surface and therefore produces a denser cloud of atomic species upon atomization. It is more difficult to account yet for the apparent lower susceptibility to matrix effects. This may possibly be due to the greater heat dissipation of the TFAR and its greater ability to transfer heat to the atoms in the gas phase and thus minimize the condensation phenomena which give rise to matrix effects in filament atom-reservoir spectroscopy, but this is the subject of further investigation.

Acknowledgement—We are grateful to the NRDC for the provision of a grant to J.E.C. and to the SRC for the provision of the Jobin-Yvon spectrometer.

Zusammenfassung—Nachweis und Messung von Spuren Zink, Blei, Kupfer und Silber durch Atomabsorptionsspektrometrie mit einem Wolframfaden-Atomreservoir (TFAR), Hohlkathodenlampen und Ausnutzung eines begrenzten Gesichtsfeldes wird beschrieben. Das Verhalten dieser Atomzelle wird mit dem des Kohlefaden-Atomreservoirs zur Bleibestimmung verglichen. Mit dem TFAR-System beobachtet man größere. Empfindlichkeit und geringere Matrixeffekte. Die Lebensdauer des Wolframfadens ist fast unbegrenzt.

Résumé—On décrit la détection et la mesure de traces de zinc, plomb, cuivre et argent par spectroscopie d'absorption atomique avec un réservoir d'atomes à filament de tungstène (TFAR), des lampes à cathode creuse et une visée à champ limité. On compare la performance de cette cellule d'atomes à celle du réservoir d'atomes à filament de carbone pour le dosage du plomb. On observe une plus grande sensibilité et moins d'effets de matrice avec le système TFAR. La durée de vie du filament de tungstène est presque indéfinie.

RAPID DESTRUCTION OF PLANT MATERIAL WITH CONCENTRATED NITRIC ACID VAPOUR (VAPOUR PHASE OXIDATION)

A. D. THOMAS and L. E. SMYTHE

Department of Analytical Chemistry, University of New South Wales, Sydney, Australia

(*Received* 16 *August* 1972. *Accepted* 28 *November* 1972)

Summary—Concentrated nitric acid vapour is used in a simple rapid method for the destruction of organic matter in plant tissue before analysis for trace elements. About 90% of the organic matter is destroyed by the nitric acid vapour within 5-6 min and destruction is then completed by the addition of perchloric acid. The method gives zero or low blank values and has comparable precision and accuracy to conventional acid digestion methods.

Analysis of biological materials for metallic elements generally requires prior treatment of the material in order to destroy the organic matter present. Some direct wet extraction procedures have been reported[1-4] but these are either too slow, not quantitative, or suffer from other disadvantages. The most commonly used methods for destruction of the organic material are acid digestion and dry ashing. Acid digestion involves heating the organic material in the presence of concentrated oxidizing acids. It is often time-consuming and can have the problem of high blank values because of the quantities of reagents that need to be added. Dry ashing destroys the organic matter by heating the material at 400-700° in a muffle furnace, where atmospheric oxygen is used as the oxidizing agent. It is not only time-consuming but some elements can be lost.

There are a number of variations of the acid digestion procedure, involving, for example, different acid mixtures and preparations of acids, addition of hydrogen peroxide, *etc.* Smith *et al.*[5] list six acid digestion procedures for the destruction of human tissue. The Analytical Methods Committee of the Society of Analytical Chemistry[6] recommend four different methods of carrying out the initial stages of the decomposition, involving various acid mixtures, depending on the reactivity of the material. The Committee state that their methods of destruction are suitable for most organic materials, including dyestuffs, medicinal compounds, rubber chemicals, synthetic polymers, biological material and foodstuffs. Harrison and Andre[7] have added sodium molybdate as a catalyst to the nitric/perchloric/sulphuric acid digestion mixture in order to shorten the time required for complete destruction of the organic material. Gorsuch,[8] in a very thorough investigation, has discussed the relative merits of both wet and dry oxidation procedures for a large number of elements.

Gorsuch[9] has also commented on the potential of destroying organic matter in an atmosphere of nitric acid vapour. Rinkis[10] has used a stream of nitric acid vapour to complete the oxidation of carbonized plant samples. We have examined a similar system as a means of destroying the organic matter present in plant material without any prior treatment. It was found that "vapour phase oxidation" (VPO) with nitric acid was extremely efficient, destroying up to 90% of the organic material in 5–6 min. At this stage an addition of perchloric acid ensured speedy and complete oxidation. Moreover, the presence of nitric acid during the final perchloric acid oxidation eliminated any explosion hazard. The method gave very low blank values for impurity elements.

Comparison of the relative standard deviation and accuracy obtained by use of VPO with that for destruction by nitric/perchloric acid in a Kjeldahl flask (hereafter called the Kjeldahl digestion or procedure) showed that the two methods had comparable precision and accuracy. At the same time the VPO procedure has the same advantages as the Kjeldahl digestion, when compared with dry ashing. These are:[11] the low temperature required, the freedom from loss of trace elements by retention on solid material in the system, and the simplicity and low cost of the equipment used.

EXPERIMENTAL

Apparatus and reagents

Nitric acid vapour was generated by dropping concentrated (sp. gr. 1·4) nitric acid into a reservoir of 100 ml of nitric/sulphuric acid mixture (1 : 1) at 152°. The nitric acid vapour distils at 122°. This corresponds to a vapour consisting of 67% nitric acid.[12] The distillation temperature remains constant throughout the entire vapour phase oxidation.

The all-glass apparatus used is illustrated in Fig. 1. The 1 : 1 nitric/sulphuric mixture was contained in a 250-ml round-bottomed flask heated by an electrical heating mantle. The flask was fitted with two "Quickfit" joints, one carrying a dropping funnel containing the concentrated nitric acid, the other a "Quickfit" splash-head. A "gas-finger" was fitted to the other end of the splash-head and this introduced the nitric acid vapour onto the sample being digested, which was contained in a "Quickfit" tube with side-arm, mated to the gas-finger. The gas-finger extended 5·5 cm into this reaction tube. A "Quickfit" pouring lip was attached to the reaction test tube for quantitative transfer of the digest solution to the volumetric flask.

During the entire digestion period the tube was heated by an infrared heating lamp. This prevented excessive condensation of the vapour before it reached the sample to be digested.

The side-arm of the reaction tube allowed excess of nitric acid vapour to escape. The reaction tube was 14 cm long and 4·5 mm o.d., fitted with a B19 joint.

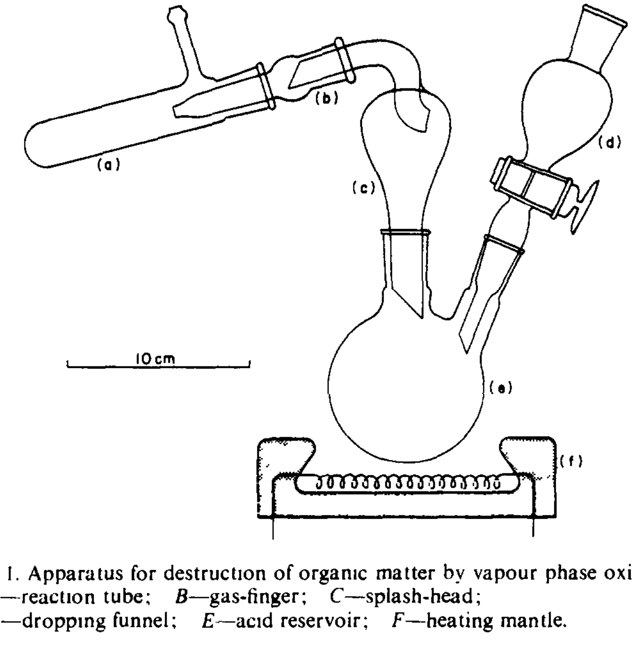

Fig. 1. Apparatus for destruction of organic matter by vapour phase oxidation.
A—reaction tube; *B*—gas-finger; *C*—splash-head;
D—dropping funnel; *E*—acid reservoir; *F*—heating mantle.

The perchloric acid digestion was carried out by removing the reaction tube from the gas-finger, adding the perchloric acid, and placing the tube in a cylindrical furnace at 280°. The furnace was constructed by winding alternate layers of 3·84 ohm/m nichrome resistance wire and asbestos tape around a Pyrex cylinder to give a final resistance of 15–16 ohm. The furnace was connected to a 32-V step-down transformer operated from a 240-V mains supply and the temperature adjusted by a Variac voltage controller connected in series.

The powdered plant samples were pelleted before digestion, to prevent charring of the material during the initial stages of the nitric acid vapour oxidation. Charring occurred with powdered samples because of a combination of two factors: the large surface area of the powdered plant material and the rapid oxidation by the nitric acid vapour and the accompanying large heat of reaction. Pelleting the plant material reduced the surface area available for reaction with the nitric acid vapour

The gas-finger was positioned so that it did not come in contact with any froth produced during the nitric acid digestion. Consequently it could be used for successive samples, and there has so far been no evidence of cross-contamination.

The rate at which nitric acid was dropped onto the nitric/sulphuric reservoir was optimized at 5–6 ml/min. A slower rate does not give a sufficient flow of nitric vapour to digest the sample in 5 min. A faster rate does not markedly increase the digestion time and can be wasteful of nitric acid.

Doubly distilled demineralized water was used throughout. Analytical-reagent grade nitric and sulphuric acids were used for VPO. Doubly distilled analytical grade nitric acid was used for the Kjeldahl digestions. Analytical grade perchloric acid (70–72%) was used for both procedures. All glassware was cleaned in a 1 : 1 mixture of analytical grade nitric and sulphuric acids, left standing overnight, and finally rinsed with distilled water.

Procedure

Plant samples were washed[13] and "biologically killed" immediately following collection from the field, by heating in a forced-draught air-oven at 60° for 24 hr. The plants could then be stored until required. Before analysis the plant was powdered to pass a 40-mesh nylon sieve, with a 5-in. Christy Norris Junior Laboratory Mill. As the working surfaces of this mill are constructed of a special alloy steel, slight metallic contamination of the plant sample resulted. However, as subsamples for both the VPO and Kjeldahl methods were obtained from the same sample, the contamination from this and the subsequent mixing would have been much the same for both procedures. The powdered material was then rolled in a stoppered glass container for 6–8 hr to ensure homogeneity. Homogeneity was tested by dry-ashing 0·5-g samples of the powder and weighing the ash. For the VPO method the powdered sample was compressed at 14×10^5 kg/m^2 by means of a hydraulic press, into a pellet 1·5 cm in dia. and 4 mm thick. The plant powder was analysed directly by the acid Kjeldahl method. The dry weight of both pellet and powder was obtained after heating at 98° for 24 hr. Lack of contamination from the press is evidenced by the good agreement between the VPO and Kjeldahl results.

A few drops of doubly distilled kerosene[11] were added to each pellet after it was placed in the reaction tube. This was to ensure that excessive frothing did not occur during the initial nitric acid digestion period.

After the nitric acid digestion, 2 ml of perchloric acid were added and the sample was heated to perchloric acid fumes, indicating that oxidation of the organic matter was completed. The reaction tube contents were then washed into a 25-ml standard flask with doubly distilled water and the sample made up to volume and analysed by atomic absorption.

RESULTS AND DISCUSSION

The procedure described offers an alternative to the Kjeldahl digestion and has the advantages of zero or extremely low blank values and a shorter digestion period. Low blanks were obtained because distilled nitric acid vapour was the main oxidant. Analytical reagent grade nitric acid gave zero blank values for all metals studied, but it was necessary to doubly distil the acid for use directly in the Kjeldahl method.

Perchloric acid was added directly to the sample in the VPO and Kjeldahl procedures and analytical grade acid was found to be satisfactory for both.

A feature of the VPO method is the significant reduction in time required for complete destruction of the organic material. The conventional Kjeldahl procedure with 10 ml of nitric acid for 0·5 g of plant sample usually requires 30–45 min of moderate heating before the nitric acid has oxidized most of the sample and perchloric acid can safely be added, but with the VPO method the main oxidation is complete within 5–6 min.

Further time is saved during the final stage of digestion with heating to fumes of perchloric acid, because there are only 3–4 ml of nitric acid in the reaction tube to be evaporated instead of the 10 ml in the Kjeldahl procedure.

The total digestion times are therefore: VPO 30–45 min; Kjeldahl 60–90 min. However, for the VPO method an individual furnace is needed for each reaction tube, but this need not be a disadvantage, as three furnaces can be run from one 32-V transformer. Using only five furnaces, a total period of 2 hr was necessary to have 10 samples digested by VPO and ready for analysis.

One of the advantages of the Kjeldahl method is the refluxing of the acids within the long neck of the flask, which ensures that all the material present in the flask is digested. Although this reflux action does not occur to the same extent in the reaction tube, of the sides of the tube were still effectively washed, partly by reflux when in the furnace, and partly by condensation of nitric acid vapour during the digestion stage.

It can be seen from the results listed in Tables 1–3 that the precision and accuracy of the results obtained by the VPO method compare favourably with those of results obtained by the Kjeldahl procedure.

The precision of the VPO procedure is illustrated in Tables 2 and 3. Those cases in which the relative standard deviation (RSD) is greater than 8% are generally attributable to the low concentrations of the metal found in the plant. This is well illustrated by comparison of the RSD for copper in *Eucalyptus blakelyi* and *Lycimum feracissimum* (Table 3). Both determinations have nearly equal standard deviations but the large difference in copper concentration results in different RSD values.

Rapid methods have been described for the destruction of organic matter by use of mixtures of sulphuric acid and 50% hydrogen peroxide[17–19] or of sulphuric and perchloric acids and sodium molybdate.[7,20] Digestion times of 10 min or less have been claimed for destruction of plant materials, and although VPO cannot match this rate for large samples, it does offer the advantage that the final solutions are relatively free from interfering substances. Sulphuric acid methods suffer from the disadvantage that sulphate ions interfere in atomic-absorption spectrometry[7,11] and that precipitation of alkaline earth metal sulphates can also carry down iron, lead and manganese.[8,11] The use of sodium molybdate is clearly unsuitable if sodium or molybdenum is to be determined, and the high salt content arising from its use may cause some solubility products to be exceeded, with attendant risk of loss by precipitation.

VPO clearly has potential as a means of rapid destruction of organic material when the blank value must be practically zero. Thus Sanui[21] has described an apparatus for oxidizing biological samples with activated oxygen, in which rat liver cell microsomes can be ashed, with a negligible blank. The ashing time required, however, can be anything from 2 to 30 hr depending on the nature of the sample and how much of it is exposed to the oxygen. VPO should reduce the ashing time considerably and give comparable blanks.

Zusammenfassung—In einer einfachen Schnellmethode zur Zerstörung von organischem Material in Pflanzengewebe vor der Analyse auf Spurenelemente wird der Dampf von konzentrierter Salpetersäure verwendet. Innerhalb 5–6 min werden etwa 90% der organischen Substanz durch den Salpetersäuredampf zerstört; der Abbau wird dann durch die Zugabe von Überchlorsäure zu Ende geführt. Die Methode gibt gar keine oder niedrige Blindwerte und bietet vergleichbare Genauigkeit und Richtigkeit wie übliche Methoden des Säureaufschlusses.

Résumé—On utilise la vapeur d'acide nitrique concentré dans une méthode simple et rapide pour la destruction de la matière organique dans les tissus végétaux avant analyse d'éléments à l'état de traces. Environ 90% de la matière organique sont détruits par la vapeur d'acide nitrique en 5–6 mn et la destruction est alors complétée par l'addition d'acide perchlorique. La méthode donne des valeurs de témoin nulles ou faibles et a une précision et une fidélité comparables aux méthodes de digestion acide habituelles.

AUTOMATIC CONTROL OF THE ION-ILLUMINATION ANGLE IN A SPARK-SOURCE MASS SPECTROMETER

R. J. CONZEMIUS and H. J. SVEC
Ames Laboratory, USAEC and Department of Chemistry
Iowa State University, Ames, Iowa 50010, U.S.A.

(*Received* 26 *June* 1972. *Accepted* 29 *November* 1972)

Summary—Automatic adjustment of only the spark-gap width in a spark-source mass spectrometer does not ensure that optimum conditions of electrode geometry are maintained with respect to the ion-optics system A device has been developed which simultaneously maintains a constant gap width and also a more constant z-axis ion-illumination angle. This is the first development to utilize ion-optics parameters to adjust the sparking electrodes automatically. The system maintains the electrodes in an optimum configuration such that higher and more constant instrument sensitivity is maintained automatically. In addition, a significant improvement in the precision of instrumental response is demonstrated. It appears that relative isotopic abundances can be determined directly by the spark-source method which are comparable to those obtained in some cases by surface ionization or by electron bombardment. Results are given that support this contention.

The spark-source mass spectrometer is an extremely useful analytical tool because of its ability to provide semiquantitative assays for essentially all elements with very high detection sensitivity. Significant improvements[1] continue to be made in the overall technique. One of these improvements was the development of a method of maintaining, automatically, a spark *via* continuous adjustment of the spark-gap width[2] which was originally described at the 1969 ASTM Committee E14 on Mass Spectrometry conference in Dallas, Texas.[3] Others have since developed different techniques for automatic gap-width control.[4]

This paper describes a new ion-source development in which a constant spark-gap width or voltage is maintained simultaneously with a more constant z-axis ion-illumination angle for the ion-optics system. This is the first development to utilize ion-optics parameters to adjust the sparking electrodes automatically. Exploratory experiments indicate that ion-illumination angle control along with spark-gap control provides significant improvement in the maintenance of optimum spark-electrode geometry. The enhancement of instrument sensitivity and measuring precision with this improved ion source will be illustrated.

Basis for operation

Gap sensing. The spark gap is energized by a variable width pulse (3·2–320 μsec) at a 1-MHz alternating high voltage (10–80 kV). The repetition rate of the pulse is also variable (1·0 Hz–3·2 kHz). An electromagnetically coupled pick-up circuit senses the magnitude of the spark-gap voltage, rectifies the signal, and provides a d.c. output voltage which is proportional to the spark-gap width. This d.c. voltage is then used as a reference for automatic adjustment of the gap width *via* an electromechanical balancing system.

Ion-illumination angle sensing. Ions produced in the spark source possess an energy spread of several thousand eV[5] and in this laboratory they are accelerated typically through 24 kV. The magnitude of the refocusing that occurs during ion acceleration is not well known. However, it has been qualitatively established that the ion beam enters the ion-optics system in a manner highly dependent upon the actual location of the spark relative to the bulk shape of the sparking electrodes, the gap width, and the co-ordinates of the ion-optics system.[5]

Ordinarily, spark-electrode shape and gap geometry can be chosen initially for full illumination of the object slit. Although the spark gap can then be automatically maintained, the spark location may soon become less than ideal and may even become "hidden" from the ion-optics system by the electrodes themselves, owing to the erosion of one or both of the electrodes.

Figure 1 is a schematic representation of the x and z axes of the ion-optics system (*i.e.*, the x-axis is axial with the ion beam; the y-axis is along the focusing plane perpendicular to the plane of the figure; the z-axis is parallel to the magnetic field lines). The spark-source electrodes (SS) are shown in an "end-on" configuration in order to give the best concept of the axis in which gap control is maintained. However, the actual configuration of the electrodes with respect to the ion-optics x, y, and z axes is shown in Fig. 2 as a perspective drawing. Further descriptions of the electrodes as well as other instrumental conditions are given in Table 1.

As illustrated in Figs. 1 and 2, the gap-width adjustment is along the z-axis of the instrument's optical system. The conventional means of gap-width adjustment in spark instruments is normally along the y-axis.[6] The particular axis utilized for gap-width control is not always identified in the literature.[4] No attempt is made here to quantify or to argue the relative merits of gap-width adjustment along either axis. However, we would point out that the configuration shown in Figs. 1 and 2 should provide for more

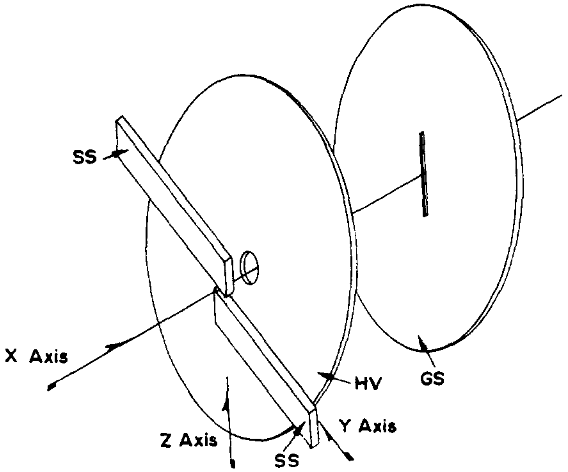

Fig. 2. Perspective view of spark-source electrode configuration relative to the ion-optics axes.

uniform ion-illumination of the y-plane along the particular z-plane of interest, the plane centred within the magnetic field.

Manual adjustment of one electrode along the x-axis is frequently employed to maintain illumination of the object slit. However, a definite effect on the ion beam takes place as one electrode is moved along the x-axis relative to the other electrode. Figure 3 illustrates this effect by means of plots of two parameters which are of interest. The abscissa for both plots is the position (x-axis) of one electrode relative to the other. The

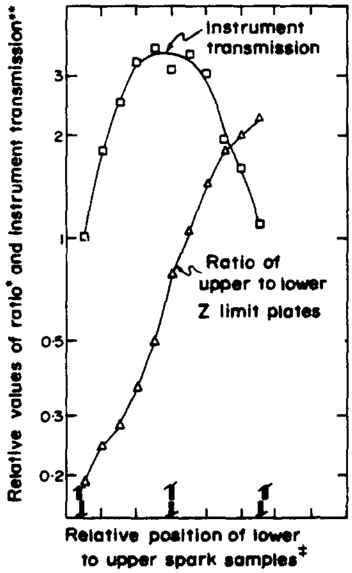

Fig. 3. Plot of data illustrating effect of altered z-axis ion-illumination angle as a function of electrode geometry.

* = ratio of ion currents to upper and lower z-limit plates. ** = relative level of ion current at image. ‡ = extreme and median positions of electrodes indicated above abscissa. Total x-axis translation of lower sample ~ 1·4 mm or ~0·2 mm per division indicated.

ordinate represents the ratio of the ion signal on the upper z-axis limiting plate UZ to the ion signal on the lower z-axis limiting plate, LZ. The relationship between this ratio and the x-axis position of the lower electrode is indicated by triangles. The data clearly demonstrates that the ion-beam density is translated along the z-axis in a monotonic manner, relative to the electrode positions indicated above the abscissa on the figure. This function may be described qualitatively as the "z-axis ion-illumination angle effect." The ion-current ratio of the UZ to the LZ plates will be identified hereafter in this text as the "illumination angle setting."

The second function, plotted as squares on Fig. 2, is really of greater practical interest. The ordinate is now simply relative values of ion current measured at the image in the instrument, normalized to the data point at the leftmost side of the figure ($\equiv$ unity). This second plot indicates that the transmission of ions to the image has a rather broad maximum but decreases sharply at the extremes of the ion-illumination angle setting. Similarly shaped curves are obtained for singly as well as doubly charged ions. These signals from the upper and lower z-axis limiting plates can be utilized for adjustment of one electrode relative to the other such that optimum illumination at the image of the optical system is maintained.

Electromechanical system

Electronic circuitry. An inexpensive and straightforward means of providing an electromechanical balancing system was employed by utilizing appropriate sensing and feedback circuits, and the pen-drive circuits and their servo-motors from electronic recording potentiometers. The electronic block diagram of the system is shown in Fig. 4. The sensing and feedback circuits are conventional. (The complete electronic schematic diagram can be supplied upon request.)

Mechanical system. A two-dimensional, accurately machined rack and pinion device was obtained (military surplus tank or artillery ranger) which provided the means of changing from the rotary movement of the servo-motors to an x-y co-ordinate movement. A three-dimensional schematic diagram of the mechanical system is shown in Fig. 5. A worm and anti-backlash spur-gear combination gives a turns ratio of 340 between the servo-motor and the pinion. One full turn of the pinion produces 2 in. of rack movement. Thus with the lever system employed, (lever arms through the fulcrum are approximately equal) 0·0001 in. of spark electrode movement is obtained for 6° of motor drive. Linear resistors attached to the racks permit presetting of spark electrode positions by providing feedback in a manual-adjust mode.

RESULTS

Figure 6 illustrates the advantage of maintaining a constant ion-illumination angle. Starting at the righthand side of the figure one observes an ion current signal from a spark which is being adjusted automatically only for a constant gap width. The signal is maintained but with a gradual decrease in intensity and a tendency to become more erratic. This is commonly observed when no adjustment is made for non-uniform gap erosion. Eventually the spark could become completely "hidden" from the ion-optics system, causing the ion signal at the image of the instrument to be non-existent.

The automatic illumination angle control was turned on as indicated near the centre of the figure. Immediate movement of the lower spark electrode occurs to bring the spark back to a position where the illumination angle is optimized. During an induction period the ion current begins to increase. After the control has reached the equilibrium or steady-state point as indicated, the ion signal is maintained at the desired level and its fluctuations are less erratic.

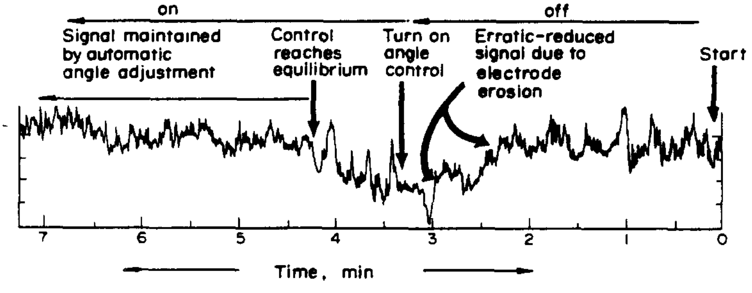

Fig 6 Illustration of improved ion-current stability with automatic control of ion-illumination angle.

Although instrument sensitivity can be maintained at a more constant level as indicated above, a greater concern is the reproducibility of the ratio of the signal at the image of the instrument to the signal at the total beam monitor. Figure 7 is a plot of consecutive image-to-monitor ratio recordings for various ion-illumination angle settings. The experiment should be followed from left to right across the figure. The first ion-illumination angle setting is 0·78 as indicated above the arrow on the left of Fig. 7, but after three readings the setting was changed to 0·51. When this setting was changed the electromechanical system automatically adjusted the spark-electrode geometry to provide a UZ to LZ ion-current signal ratio of 0·51. As this adjustment occurred, sequential measurements of the image to monitor ratio were made. The results of these measurements are shown by the points immediately to the right of the arrow above 0·51. After the automatic control reached equilibrium as evidenced by a steady-state balancing of the x-axis motor, one additional measurement was made. Then the illumination angle was changed to 0·38 and the new image-to-monitor ratios are shown by the points to the right of the arrow. Again, after steady-state balancing of the x-axis motor was noted, one additional measurement was made and then the setting was changed to 0·51. The procedure was repeated with the settings shown above the arrows and the resulting sequential image-to-monitor ratios were plotted to the right of the arrows. The experiment illustrates that variation in the image-to-monitor ion-current ratio will occur if, as the spark-source electrodes erode, the ion-illumination angle is allowed to be altered by irregular electrode erosion. However, automatic control of the angle should permit measurements of the image-to-monitor ratio to be made with good reproducibility.

Table 2 shows results of isotopic abundance measurements with spark-source electrodes of highly purified dysprosium metal. A Faraday cup was used at the image slit and vibrating reed electrometer amplifiers were used at the image and monitor. The equipment and technique for electrical detection with the spark source has been described.[7] In this experiment, currents for doubly-charged ions were measured to permit higher accelerating voltages to be employed. The first column of Table 2 gives the mass of the isotope focused at the image slit. Three readings, shown in the second column, were made for each mass. Each reading consists of an approximately 10-sec measurement of the ratio of the mass-analysed signal to the signal at the total beam monitor. The third and fourth columns contain the average and per cent relative average deviations respectively. The series of seven isotopes was analysed three times with each series being used as a

determination of relative abundances. The last column gives the computed abundances for each of the three series.

Table 3 is a summary of the isotopic abundance data.

CONCLUSIONS

Good precision of readings and reproducibility of isotopic abundance data over relatively long periods of time, as illustrated above, indicate that the spark geometry is maintained constant by automatic control of both gap and ion-illumination angle.

Table 3. Summary of dysprosium isotopic abundance measurements

Mass	Measured† abundance	Relative average deviation, %	Range of literature[8] values

162	25·42	0·4	25·36 –25·53
163	25·04	0·2	24·91 –24·97
164	28·42	0·4	28·11 –28·47

* Uncalibrated range corrections used for masses 156, 158 and 160.

† Average of three determinations in Table 1.

Variations in the data cited include contributions due to changes in degree of ionization, as well as other uncertainties, since the measurements were made with signals for doubly-charged ions and the total beam monitor is affected by 1+, 2+, and 3+ ion signals.

Automatic control of both the spark gap and the ion-illumination angle causes the ratio of the image-signal to monitor-signal to remain constant over longer periods of time than has been previously possible. Thus, instrument sensitivity is maintained at a high and constant level.

Some limitations in utilizing this means of automatic ion-illumination angle control with other spark-source instruments should be noted. The application may not be possible in instruments employing *z*-focusing or the use of additional electrostatic lenses. The control may not be as effective in instruments which possess different ion-optics parameters from those of the one used for this work (*e.g.*, object distance of the electrostatic analyser employed here is 1·189 in). Spark-source electrodes with large cross-sections or very narrow gap-widths may exhibit peculiar ion-illumination effects and thus may not be suitable.

Acknowledgement—The authors wish to acknowledge the co-operation and help of their colleagues, especially David Birlingmair who aided in the initial overall design, Raymond C. Prior who designed and constructed the electronic circuit, and Edward R. Clark who designed much of the details and supervised the construction of the mechanical unit. The contributions of James Jensen, Wayne A. Rhinehart, and Clarence Ness are also gratefully acknowledged.

Zusammenfassung—Die automatische Nachregelung lediglich der Länge der Funkenstrecke in einem Massenspektrometer mit Funkenquelle gewährleistet nicht, daß die optimalen Bedingungen der Elektrodengeometrie bezüglich des ionenoptischen Systems eingehalten werden. Es wurde eine Vorrichtung entwickelt, die gleichzeitig eine konstante Länge der Funkenstrecke sowie einen besser konstanten Ionenbeleuchtungswinkel in der z-Achse aufrecht erhält. Es handelt sich hier um die erste Entwicklung, die Parameter der Ionenoptik verwendet, um die funkenliefernden Elektroden automatisch einzustellen. Das System hält die Elektroden in einer optimalen Konfiguration, sodaß automatisch eine höhere und konstantere Empfindlichkeit des Instruments eingehalten wird. Zusätzlich zeigt sich eine wesentliche Verbesserung in der Ansprechgenauigkeit des Instruments. Anscheinend können relative Isotopenhäufigkeiten direkt mit der Funkenquellenmethode bestimmt werden, die mit denen vergleichbar sind, die man in einigen Fällen durch Oberflächenionisation oder Elektronenbeschuß erhalten hat. Es werden Ergebnisse mitgeteilt, die diese Behauptung stützen.

Résumé—Le réglage automatique de la largeur de l'éclateur seulement dans un spectromètre de masse à source d'étincelle n'assure pas que les conditions optimales de la géométrie d'électrode sont maintenues par rapport au système optique ionique. On a élaboré un dispositif qui maintient simultanément une largeur constante d'intervalle et aussi un angle axe des z-irradiation d'ion plus constant. Ceci est le premier développement qui utilise les paramètres d'optique ionique pour ajuster les électrodes d'étincelle automatiquement. Le système maintient les électrodes dans une configuration optimale telle qu'une sensibilité d'instrument plus élevée et plus constante est maintenue automatiquement. De plus, on décèle une amélioration importante dans la fidélité de la réponse instrumentale. Il apparaît que des abondances isotopiques relatives qui peuvent être déterminées par la méthode à source d'étincelle sont comparables à celles obtenues dans quelques cas par ionisation de surface ou par bombardment électronique. On donne des résultats qui soutiennent cette conception.

ACID-BASE EQUILIBRIA IN ETHYLENE GLYCOL—I

DEFINITION OF pH AND DETERMINATION OF pK-VALUES OF ACID-BASE INDICATORS

P. Zikolov and O. Budevsky
Faculty of Pharmacy, Academy of Medicine
Ekz. Josif No. 15, Sofia, Bulgaria

(*Received* 19 *June* 1972. *Accepted* 30 *November* 1972)

Summary—A pH-scale in ethylene glycol is defined, based on potentiometric measurements for a cell without liquid junction:

$$\begin{array}{c|c|c} \text{glass} \\ \text{electrode} \end{array} \Big\| \; 0{\cdot}1\text{M (HCl + KCl)}, \begin{array}{c}\text{ethylene}\\ \text{glycol}\end{array} \Big| \; \text{AgCl; Ag}$$

and a potentiometric-spectrophotometric method for the determination of p*K*-value of acid-base indicators in ethylene glycol on the basis of this pH scale is proposed, in which the pH scale is established and the p*K*-value determined in a single titration at constant ionic strength. The following p*K*-values of indicators are reported: Cresol Red—3·00, Thymol Blue—3·39, Bromophenol Blue—6·49, Bromocresol Green—7·38, Bromocresol Purple— 9·00 and Cresol Red (2nd change)—11·07. A linear relationship was found between the p*K*-values of four sulphonphthalein indicators in ethylene glycol and in water according to the following equation $(pK_{HI}{}^{c})_{EG} = 2{\cdot}3 + 1{\cdot}1\ (pK_{HI}{}^{c})_{W}$. An attempt is made to explain this dependence, based on the idea of solute-solvent interaction of species of the same charge type.

Ethylene glycol (EG) and its mixtures with other solvents find application as media in the determination of many organic compounds, particularly those with basic properties.[1] Nevertheless acid-base equilibria in EG have not been investigated in detail. Data for pH measurements are scarce, although the successful use of the hydrogen and glass electrodes in this solvent has been mentioned.[1-3] There is also a lack of data for acid-base equilibrium constants of protolytes in EG.[2]

In this and subsequent papers a detailed study of acid-base equilibria in EG and its mixtures, based on a well-defined pH-scale, will be described. The p*K*-values of many organic compounds and acid-base indicators will be reported and suitable conditions for quantitative determinations in this solvent will be examined.

The present paper deals with the definition of a pH-scale in EG, and the performance of a potentiometric-spectrophotometric method of determining p*K*-values of acid-base indicators in EG.

Definition of pH-scale in ethylene glycol

The following galvanic cell (I) was used:

$$\begin{array}{c}\text{glass}\\ \text{electrode}\end{array} \Big\| \; 0{\cdot}1M\ \text{(HCl + KCl), EG} \; \Big| \; \text{AgCl; Ag} \qquad \text{(I)}$$

It does not contain a phase boundary, thus avoiding unknown liquid junction potentials, and the measurements refer to a constant ionic strength (0·1*M* KCl) so that variations in activities need not be considered. The scale used is therefore a pc_H-scale, referring to the concentration of hydrogen ions and not to the activity.

The potential of the cell (I) is given by the Nernst equation

$$E = E_{GE}{}^0 - E_{RE}{}^0 + k \log c_H f_H c_{Cl} f_{Cl} \alpha_{KCl} \tag{1}$$

where $E_{GE}{}^0$ and $E_{RE}{}^0$ are the standard potentials of the glass and reference electrodes, $k = 2{\cdot}303\ RT/F = 0{\cdot}05916$ at 25°C; c_H and c_{Cl} are the molar concentrations of hydrogen and chloride ions, and f_H and f_{Cl} their activity coefficients; α_{KCl} represents the degree of dissociation of potassium chloride in EG, assumed as a constant under the conditions in question. At constant chloride-ion concentration equation (1) takes the form

$$E = E^{0'} + 0{\cdot}05916 \log c_H = E^0 - 0{\cdot}05916\ pc_H \tag{2}$$

where $E^{0'} = E_{GE}{}^0 - E_{RE}{}^0 + k \log c_{Cl} f_{Cl} f_H \alpha_{KCl}$, and is a constant for the series of experiments. Equation (2) permits the calculation of hydrogen ion concentration as a function of the measured potential, provided the $E^{0'}$-value is known from a preliminary experiment:

$$pc_H = \frac{E^{0'} - E}{0{\cdot}05916} \tag{3}$$

The determination of $E^{0'}$ for aqueous solutions does not present any difficulty, because the hydrochloric acid is fully dissociated, the hydrogen ion concentration is equal to the total content of the hydrochloric acid, and hence $E^{0'}$ can be calculated from equation (4). The lower dielectric constant of EG ($\varepsilon = 37{\cdot}7$) in relation to water ($\varepsilon = 80{\cdot}4$), as well as the acid–base properties of EG as solvent, would lead one to expect that hydrochloric acid might not dissociate completely in this solvent. A preliminary condition for the definition of a pc_H-scale in EG by the potentiometric method is therefore proof that dissociation is complete as shown by agreement between measured potentials and those predicted by equation (2) when the hydrogen ion concentration (c_H) in equation (2) is replaced by the total concentration of the hydrochloric acid (c_{HCl}), in cell (I):

$$E = E^{0'} + 0{\cdot}05916 \log c_{HCl} \tag{4}$$

As the results from this investigation showed, in the concentration region used, hydrochloric acid does dissociate fully and pc_H can be calculated by means of equation (3) from experimentally determined values of $E^{0'}$.

It should be emphasized that the pc_H-scale thus defined refers only to solutions of hydrochloric acid and potassium chloride at a constant ionic strength of $c_{HCl} + c_{KCl} = 0{\cdot}1M$* at 25 .

Determination of pK*-values of acid–base indicators in ethylene glycol*

The method used in the present investigation does not differ in principle from those widely used for aqueous solutions,[4] but some differences exist, both in the pc_H concept

---

* As a matter of fact, the dissociation of potassium chloride in EG is probably not complete, and it cannot be stated categorically that the ionic strength in the investigated solution is $\mu = 0{\cdot}1$. It can be accepted, however, that the ionic strength is constant, owing to the constancy of the degree of dissociation of potassium chloride.

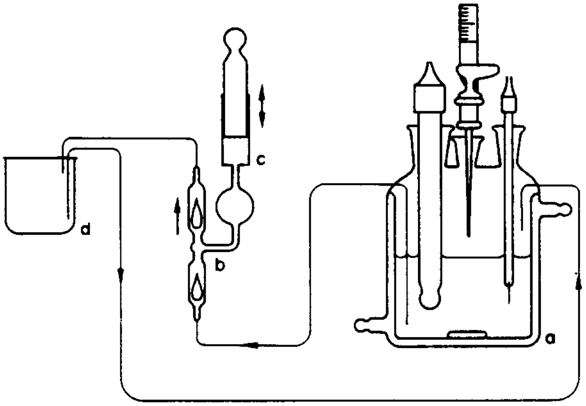

Fig. 1. Schematic representation of apparatus for the potentiometric-spectrophotometric determination of indicator pK-values in EG.

and in the apparatus. The latter allows simultaneous measurement of the e.m.f. of the cell and the absorbance of the solution, and employs a convenient circulating system (Fig. 1), similar to that described by Havel.[5] The pK-values of the acid-base indicators are found from the equations

$$\mathrm{p}K_{\mathrm{HI}}{}^{\mathrm{c}} = \mathrm{p}c_{\mathrm{H}} + \log\frac{c_{\mathrm{HI}}}{c_{\mathrm{I}}} = \mathrm{p}c_{\mathrm{H}} + \log\frac{D_{\mathrm{I}} - D}{D - D_{\mathrm{HI}}} \tag{5}$$

where c_{HI} and c_{I} are the concentrations of the acid and base forms of the indicator, D_{HI} and D_{I} are the absorbances of the solutions containing only the acid and only the base forms of the indicator respectively, and D is the absorbance of the solution corresponding to a particular pc_{H}. The p$K_{\mathrm{HI}}{}^{\mathrm{c}}$-values are found by numerical or graphical solution of equation (5). These constants are referred to constant ionic strength at 0·1M KCl solution (see footnote on p. 2).

EXPERIMENTAL

Reagents

Ethylene glycol. Reagent grade solvent was distilled under reduced pressure (10 torr) over anhydrous sodium sulphate.

Hydrochloric acid in EG. Prepared by saturation with dry hydrogen chloride. A 0·01M solution was obtained by dilution and then standardized after mixing with an equal volume of water.

Potassium chloride and acetate. Reagent grade chemicals were used without purification.

Diphenylguanidine. Recrystallised from benzene.

The indicators Thymol Blue (TB), Bromophenol Blue (BPB), Bromocresol Green (BCG), Bromocresol Purple (BCP) and Cresol Red (CR) were used without purification.

Apparatus

The experimental arrangement is schematically shown in Fig. 1. It consists of a thermostated vessel for titration (*a*), circulating system (*b,c*) connected to a flow-cell (*d*) in the Spekol spectrophotometer (C. Zeiss, Jena) In the vessel (*a*) a Radiometer glass electrode type G202B and a silver-silver chloride electrode of the Brown type[6] were immersed in the solution. The potential of cell (I) was measured on a Radiometer pH-meter type PHM-4 with a precision of ±0·2 mV.

For the determination of the pK-values of the different indicators the following buffers were used: potassium acetate for TB, BPB, and BCG, diphenylguanidine for CR, and a mixture of potassium acetate and diphenylguanidine for BCP. The measurements were started in alkaline medium, *i.e.*, solution containing the base form of the indicator, for which a spectral band with maximum absorption was chosen. The wavelength was not changed during the whole experiment. To this solution appropriate portions of acid were added and both the potential and absorption were measured.

Procedure

In the titration vessel were placed (*a*) 50·00 ml of ethylene glycol which was 0·1*M* in potassium chloride, $10^{-3}M$ in potassium acetate or diphenylguanidine and *ca.* $10^{-5}M$ in the indicator. Portions of an ethylene glycol solution 0·01*M* in hydrogen chloride, 0·09*M* in potassium chloride and of the same indicator concentration as the basic solution (to avoid dilution effects) were added from a burette. When mixing was complete after each addition the potential and the absorbance were measured [the value D in equation (5)]. When the indicator had changed into its acid form, the titration was continued without measurement of the absorbance and the results were used for the calibration of the cell (I). The absorbance of the last point of the titration gave the value of D_{HI} in equation (5), and D_{I} was obtained from a measurement of the same solution made very alkaline by addition of potassium hydroxide in ethylene glycol after completion of the titration, the values being corrected for dilution. In the case of Cresol Red (an indicator with a second acid-base interval in the pH region investigated), the absorbance measurements were continued after the equivalence point. The results obtained were used both for the calibration of the cell and for the determination of the second (lower) constant. The value of $D_{\text{H}_2\text{I}}$ was found from a measurement of the same solution after addition of an excess of acid.

RESULTS

The experimental results from a typical titration with the indicator Cresol Red are shown in Table 1. This indicator shows two colour changes in EG, just as in aqueous solution. The treatment of the primary data (see Table 1a) is performed in two stages as

Conditions: 50 ml of EG, $10^{-3}M$ in diphenylguanidine, 0·1M in potassium chloride and $1·45 \times 10^{-5}M$ in CR are titrated with EG solution that is $9·71 \times 10^{-3}M$ in hydrogen chloride, $9 \times 10^{-2}M$ in potassium chloride and $1·45 \times 10^{-5}M$ in CR. $D_I = 0·638$ (579 nm); $D_{HI} = 0·00$ (579 nm); $D_{HI}' = 0·010$ (526 nm); $D'_{H_2I} = 0·795$ (526 nm).

shown in the same table. First the equivalence point of the neutralization of the added bases is found. This is done very accurately by means of a Gran plot[7,8] (see Table 1b). The $E^{0'}$ value is then determined by means of equation (4). The calculated values for $E^{0'}$ are also shown in Table 1b with their mean and standard deviation. Secondly, for every experimental point the pc_H-value is calculated from equation (3) (see Table 1c). The date for pc_H, D_I, and D_{HI} are used for the graphical (Fig. 2) or numerical (Table 1c) solution of equation (5).

By analogous methods and with appropriate indicator concentrations of pK-values of TB BPB, BCG and BCP were determined (see Table 2 and Fig. 2). This set of indicators was selected to cover a large part of the pc_H-scale of EG.

DISCUSSION

The investigations have shown that the pc_H-scale in ethylene glycol can be established by potentiometry with glass and silver–silver chloride electrodes. The glass electrode responds quickly to changes in acidity and gives stable and reproducible potentials as is evident from the values of the calculated $E^{0'}$ values shown in Table 1b, where the standard deviation of the mean is ±0·5 mV or ±0·008 pc_H-units.

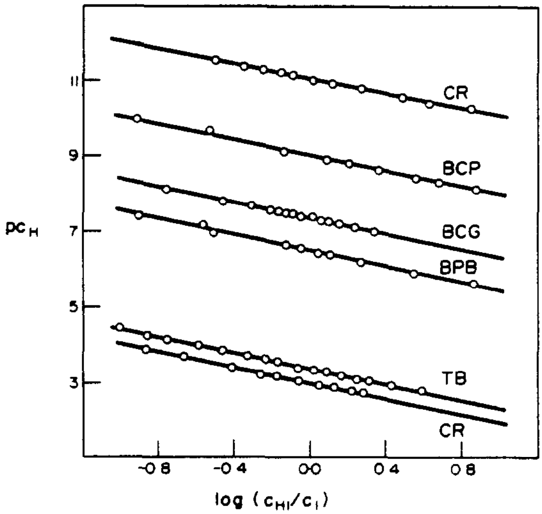

Fig. 2. Plot of pc_H *vs.* $\log(c_{HI}/c_I)$.

This method is experimentally convenient and makes possible both measurement and calibration in each experiment, thus reducing some of the possible errors.

The sulphonphthaleins exhibit a behaviour in EG similar qualitatively to that in water.[10] In aqueous solution these indicators show two colour changes. Not taking the possible quinoid structure into consideration, it is accepted that the yellow form corresponds to a zwitterion or a hybrid ion with the charge expressed as $(I^{\mp})^{-}$. The colour change on going into acidic medium is explained by the formation of the $(I^{\mp})$ zwitterion, and that on going into a alkaline medium by the dissociation of the phenolic group forming the $(I^{\mp})^{2-}$ zwitterion.

The two indicators CR and TB exist as the uncharged species H_2I (probably zwitterions) in acid medium and as HI^- in alkaline medium. The colour change from yellow to red corresponds to the reaction $H^+ + HI^- = H_2I$. The p*K*-values of the indicators CR and TB in ethylene glycol and in water differ by about 1·8 units (see Table 2).

For the other indicators BPB, BCG, BCP and CR the colour change from intensely coloured base form to yellow acid form could be expressed by the equation $H^+ + I^{2-} = HI^-$. For these indicators $\Delta pK_{HI}{}^c$ varies from 2·7 to 3·0 (see Table 2). It is interesting to

Table 2. Constants ($pK_{HI}{}^c$), with their standard deviations, and some spectrophotometric characteristics of sulphonphthaleins in EG

Indicator	Charge on I	λ_{max}	Colour change I	HI	$(pK_{HI}{}^c)_{EG}$	$(pK_{HI}{}^c)_W$*	ΔpK_{HI}
CR	1−	526	yellow	red	3·00 ± 0·01	1·2	1·8
TB	1−	550	yellow	red	3·39 ± 0·01	1·6	1 8
BPB	2−	598	violet	yellow	6·49 ± 0·07	3·85	2·66
BCG	2−	623	blue	yellow	7·38 ± 0·02	4·66	2·72
BCP	2−	597	purple	yellow	9·00 ± 0·03	6·12	2·88
CR	2−	579	red	yellow	11·07 ± 0·02	8·10	2·97

* See ref. (9).

note, however, that the relationship between the pK-values of these indicators in EG and in water is linear and follows the equation

$$(\mathrm{p}K_{\mathrm{HI}}{}^{c})_{\mathrm{EG}} = 2{\cdot}3 + 1{\cdot}1(\mathrm{p}K_{\mathrm{HI}}{}^{c})_{\mathrm{W}} \tag{6}$$

where the slope 1·1 is very near to the ratio of the autoprotolysis constants, $(\mathrm{p}K_s)_{\mathrm{EG}}/(\mathrm{p}K_s)_{\mathrm{W}} = 1{\cdot}12$. The intercept 2·3 can be interpreted as a difference in the combined solvation effects on the proton and the zwitterion in ethylene glycol and water. It can probably be assumed that by using equation (6) the $(\mathrm{p}K_{\mathrm{HI}}{}^{c})_{\mathrm{EG}}$-values of other sulphonphthaleins of the same charge type could be calculated approximately. The dependences found in this investigation affirm once more the specific behaviour of interaction of the medium with charged species from the same group of substances.

Zusammenfassung—Es wird eine pH-Skala in Äthylenglykol definiert, die auf potentiometrischen Messungen an einer Zelle ohne Überführung begründet ist:

Glaselektrode || 0·1 M (HCl + KCl), Äthylenglykol | AgCl; Ag.

Weiter wird eine pontentiometrisch-spektrophotometrische Methode zur Bestimmung von pK-Werten von Säure-Basen-Indikatoren in Äthylenglykol auf der Basis dieser pH-Skala vorgeschlagen, bei der in einer einzigen Titration bei konstanter Ionenstärke die pH-Skala aufgestellt und der pK-Wert bestimmt wird. Folgende pK-Werte von Indikatoren werden mitgeteilt: Kresolrot 3·00, Thymolblau 3·39, Bromphenolblau 6·49, Bromkresolgrün 7·38, Bromkresolpurpur 9·00 und Kresolrot (2. Umschlag) 11·07. Es wurde eine lineare Beziehung zwischen den pK-Werten von vier Sulfonphthalein-Indikatoren in Äthylenglykol und Wasser entsprechend der Gleichung $(\mathrm{p}K^{c}_{\mathrm{HI}})_{\mathrm{EG}} = 2{\cdot}3 + 1{\cdot}1(\mathrm{p}K^{c}_{\mathrm{HI}})_{\mathrm{W}}$ gefunden. Es wird versucht, diese Beziehung auf Grund der Wechselwirkung zwischen Lösungsmittel und Gelöstem bei Spezies desselben Ladungstyps zu erklären.

Résumé—On définit une échelle de pH dans l'éthylène glycol, basée sur des mesures potentiométriques pour une cellule sans jonction liquide:

$$\left.\begin{array}{c}\text{Electrode}\\ \text{de verre}\end{array}\right|\ (\mathrm{HCl} + \mathrm{KCl})\ 0.1M,\ \begin{array}{c}\text{éthylène}\\ \text{glycol}\end{array}\left|\ \mathrm{AgCl};\ \mathrm{Ag}\right.$$

et on propose une méthode potentiométrique-spectrophotométrique pour la détermination des valeurs de pK d'indicateurs acide-base dans l'éthylène glycol sur la base de cette échelle de pH, dans laquelle l'échelle de pH est établie et la valeur de pK déterminée en un seul titrage à force ionique constante. On rapporte les valeurs de pK d'indicateurs suivantes: Rouge de Crésol — 3,00; Bleu de Thymol — 3,39; Bleu de Bromophénol — 6,49; Vert de Bromocrésol — 7,38; Pourpre de Bromocrésol — 9.00 et Rouge de Crésol (2ème virage) — 11.07. On a trouvé une relation linéaire entre les valeurs de pK de quatre indicateurs sulfonephtaléïnes en éthylène glycol et dans l'eau selon l'équation $(\mathrm{p}K_{\mathrm{HI}}{}^{c})_{\mathrm{EG}} = 2.3 + 1.1\ (\mathrm{p}K_{\mathrm{HI}}{}^{c})_{\mathrm{W}}$ Un essai est fait pour expliquer cette dépendance, basé sur l'idée d'une interaction soluté-solvant d'espèces du même type de charge.

Summary—An important limitation to the sensitivity of analytical methods using atomic spectroscopy is the short residence-time of the atoms in the light-path. The possibility has been studied of sealing the samples in a quartz tube where they are forced to emit light by microwave excitation. The detection of amounts below one ng in a volume of 0·5 ml seems possible.

An important limitation in the sensitivity of most applications of analytical atomic spectroscopy is the short residence-time of the atoms in the optical path. In atomic-absorption and atomic-fluorescence spectroscopy attemps have been made to increase this residence-time with, for example, the Massmann furnace and the carbon rod.[1] A further improvement of the sensitivity seems possible if the sample is present in a closed system.

The closed system used by us for analytical emission-spectroscopy is adapted from atomic-fluorescence spectroscopy (AFS). In AFS a high sensitivity can only be obtained when a light-source with a high intensity is used. For this purpose an electrodeless discharge tube (EDT) is generally used. The preparation and performance of these EDT's has been extensively described by West and co-workers[2,3] and by Winefordner and co-workers.[4]

An EDT generally consists of a quartz tube of about 1 ml capacity, containing μg or ng amounts of the desired metal or its halide, and a noble gas at a pressure of a few torr. The EDT is placed in a microwave cavity and after ignition the tube emits the atomic spectrum of the noble gas and the metal.

Table 1. Quantities, evaporated at 600°C and 1 torr in a volume of 1 ml

Species	Amount, μg	Species	Amount, μg
Zn	2	$InCl_3$	6
$ZnCl_2$	3·5	Pb	6×10^{-3}
Cd	3·3	$PbCl_2$	8
$CdCl_2$	5·5	Tl	4×10^{-2}
Hg	6	TlCl	7
$HgCl_2$	8	Ge	2×10^{-6}
In	3×10^{-6}	$GeCl_4$	7

The amount of metal or metal halide evaporated in the EDT depends on temperature, volume and pressure. For a rough calculation, values of 600°, 1 ml and 1 torr may be assumed for these parameters. In Table 1 the amounts evaporated under these conditions are given.

It shows that in many cases the very high intensity is due to only a few μg of the evaporated material. It is evident that the detection of quantities far below one μg must be possible, if the background noise does not interfere. For practical analytical applications the introduction of metal chloride solutions may often be preferable to the introduction of the metals; therefore so far only metal chloride solutions have been tested.

EXPERIMENTAL

Apparatus

The vacuum apparatus used for the preparation of the EDT's (Fig. 1) is a modification of the apparatus used by West and co-workers. The dimensions of the EDT's used were: length of the bulb 25 mm, i.d. 10 mm and wall thickness about 1 mm. Some of the measurements were performed with a Hilger and Watts "Large Quartz Spectrograph" (slit 20 μm) and photographic detection. Other measurements were carried out with the monochromator (slit 25 μm) and the detector of the Techtron AA4 atomic-absorption spectrophotometer with mechanical modulation. The microwave generator used was an EMS Microtron 200 with reflected-power meter (frequency 2450 MHz). Two cavities were used: an EMS 214 L and an EMS 216 L.

Preparation of EDT's

First the EDT is degassed for one min under vacuum by heating with a propane/oxygen burner to remove volatile contamination. After disconnection of the EDT from the vacuum line, 100 μl of metal chloride solution is added with an Eppendorf pipette, the tube is reconnected to vacuum, and the solution is cooled with liquid nitrogen and frozen to dryness. After this, helium is added up to a pressure of 10 torr. The EDT is sealed with the propane/oxygen burner and ready for use. The complete preparation of six EDT's takes about 1 hr.

Preliminary experiments

The investigations were started with tubes containing some μg of zinc and mercury chlorides. The emission spectra of these EDT's were recorded with the Hilger spectrograph. The tube was placed in the EMS 214 L cavity and 75-W power was applied. The spectra showed the atomic lines of zinc and mercury but intense band spectra were present, seriously hampering analytical application Elimination of these spectra was necessary and therefore identification of the emitters was needed.

Comparison with band spectra of EDT's filled with air and chlorine showed that part of the spectra was due to these gases. Practically all of the other band spectra were due to water (OH-bands), C_2 (Swan-bands) and metal monochlorides.[5]

The air bands probably result from small leaks in the vacuum system; the chlorine bands are caused by partial thermal dissociation of the metal chlorides and perhaps also by reactions with the quartz wall. The OH-bands are certainly caused by traces of water The origin of the C_2-bands is not quite clear

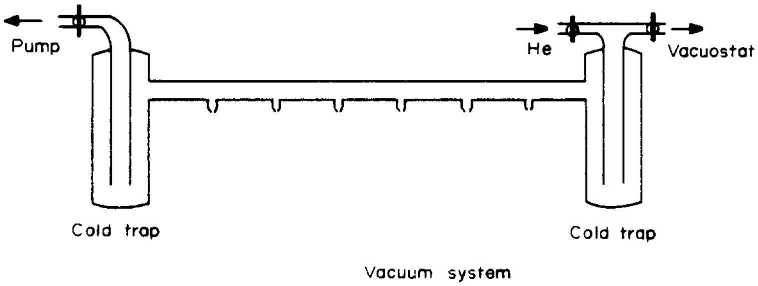

Fig. 1. Vacuum line for preparation of the EDT.

Further investigations

First we investigated whether the band spectra could be suppressed. From vacuum technique it is known that certain metals ("getters") react rapidly at rather high temperature with traces of gases. This might solve our problem but there are some restrictions as to the metals which can be used. A suitable "getter" metal M_e must not react with the metal chloride MCl_x in the tube, *i.e.*, the reaction

$$M_e + MCl_x \xrightarrow{\qquad} M_eCl_y + M$$

should not occur This could be predicted thermodynamically if the exact conditions were known and if free energy data at high temperatures were available. Unfortunately, this is not the case and only a rough estimate based on enthalpy values for standard conditions can therefore be made Some values are listed in Table 2 From these it can be expected that the reaction above will not occur for Pd, Bi, Cu or Ge "getters" with Zn, Cd, Tl, In or Pb metal chlorides and the elements Pd, Bi, Cu or Ge should therefore be suitable as "getters" to suppress the band spectra.

Table 2. Enthalpy of some metal chlorides, in kcal per g atom of chlorine

$PdCl_2$	−23	$CdCl_2$	−48
$CuCl_2$	−30	$HgCl_2$	−28
$BiCl_3$	−30	$PbCl_2$	−43
$GeCl_4$	−28	$InCl_3$	−43
$ZnCl_2$	−50	TlCl	−49

Palladium was tried first, but it did not meet our requirements because of its low reactivity. With copper and bismuth most of the interfering band spectra disappeared. Copper, however, had two disadvantages. It reacts with quartz, with a resultant significant decrease in the transmittance and it also forms copper(I) chloride which emits a strong interfering band spectrum. Bismuth has a low melting point and many metal chlorides are soluble in the molten metal. With germanium the bands due to air, chlorine, C_2 and OH disappeared. Germanium(I) chloride is formed by the reaction with free chlorine gas; it emits a band spectrum with maximal intensity between 280 and 330 nm, which is the main origin of the remaining background.

It was expected that excitation conditions of the EDT would be governed more or less by the bulk of the vapour present. Therefore the presence of a constant amount of matrix in all experiments seemed useful. If germanium is used as a "getter", germanium(IV) chloride seems to be a suitable matrix, but unfortunately it is very volatile (b.p. 86·5°). It was expected that addition of a small amount of another metal chloride ($CuCl_2$, $PdCl_2$) to the germanium would result in the formation of $GeCl_4$. Unfortunately these reactions do not proceed very reproducibly. Therefore we use $ZnCl_2$ as a matrix, but of course zinc could then not be determined. To each EDT 50–100 μg of solid germanium were added just before the addition of the metal chloride solution Zinc chloride was added simultaneously with the metal chloride solution. The quantity added was adjusted to give 1 μg of $ZnCl_2$ in each EDT. EDT's prepared in this way always burn for 30 min or longer.

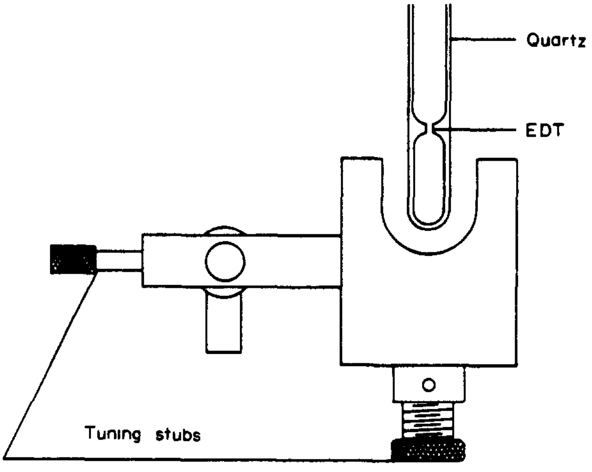

Fig. 2 Arrangement of the EDT in the microwave cavity.

Quantitative measurements

For these measurements we used the Techtron AA4 atomic-absorption spectrophotometer. To compare intensities over a wide range the relative gain of the amplifier was measured for each of the twenty different steps. We used the EMS 216 L cavity with the EDT fixed in it as shown in Fig. 2.

The tuning stubs were adjusted to give minimum reflected power. The net power was 75W. During the measurements it was observed that some germanium sublimed onto the wall of the quartz tube. If this coating was situated in the optical path the signal measured was decreased. This effect may be eliminated by the use of an internal standard in the EDT. Because zinc was present as matrix it was also used as the internal standard (the zinc 328·2 nm line). A second advantage of the use of an internal standard is that it may correct to some extent for variations in the excitation conditions. Because I_M/I_{Zn}, the ratio of the relative intensities of the metal and zinc emission-lines, changed with time, measurements were made at a fixed time after switching on. Background intensity ratios were measured by setting the wavelength just clear of that corresponding to the metal line.

RESULTS

Measurements were performed with six tubes, three of them containing about 5 ng each of Cd, Tl and In, and the other three containing the same amount of Pb and Hg. Some results are given in Table 3.

Table 3. Relative line-intensities and background intensities

Line, *nm*	Time after switch-on, *min*	I_M/I_{Zn}			I_{backgr}/I_{Zn}			Relative gain*
Cd 228·8	10	77	92	74	2	2	2	2·85
Tl 377·6	14	104	151	108	3	3	3	12·3
In 410·2	16	91	128	109	15	12	15	55·5
Pb 405·8	14	100	152	110	32	43	30	202
Hg 253·6	10	156	184	144	3	8	4	4·90

* Gain required to give about half-scale deflection for the signal from the metal investigated.

From the table it is easily calculated that the relative standard deviation is between 20 and 30%, and because the noise in the background is usually not more than 2% (partly due to the amplifier) detection limits below one ng seem possible in many cases. Determination of other elements seems possible, but has not yet been investigated. The maximum volume to be used is about 0·5 ml.

CONCLUSIONS

The experiments show that the determination of extremely low quantities of elements is possible if the sample is sealed in an EDT and excited in a 2450-MHz field. Some precautions are necessary, however, to eliminate the interference of emission bands. The reproducibility at the 5–10 ng level is about 30%.

As the signal to background ratio is between 5 and 50 and the background may be measured with low noise (usually about 2%, which is partly due to the amplifier), analysis at much lower levels seems possible with the present system. A better signal to noise ratio may be obtained by using more suitable matrix elements, a monochromator with higher resolving power and simultaneous integration of signal and background. The experiments are being continued.

Acknowledgements—The authors express their thanks to Dr. H. Bent for his help with the experiments with the Hilger spectrograph and to Drs. J. P. S. Haarsma for his introduction to the preparation of EDT's.

THE SIGNAL *vs.* CONCENTRATION RELATIONSHIPS IN FLUORIMETRY

R. VAN SLAGEREN, G. DEN BOEF and W. E. VAN DER LINDEN
Laboratory for Analytical Chemistry, University of Amsterdam, Nieuwe Achtergracht 125, Amsterdam, The Netherlands

(*Received* 12 *September* 1972. *Accepted* 24 *November* 1972)

Summary—Formulae for the fluorescence signal are derived which take into account some factors hitherto neglected. From these formulae conditions are deduced, for which a linear relationship exists between the concentration of the fluorescent components and the intensity of the fluorescence. In some cases of practical interest the fulfilment of these conditions cause too low a sensitivity. For such cases a method of optimization is outlined, by means of which the conditions are found which lead to the least deviation from linearity at the required sensitivity.

In the last few years the importance of fluorimetry as an analytical tool in trace analysis has greatly increased, because the limit of determination in fluorimetry is generally lower than in many other analytical methods. Unfortunately, no sufficiently complete theoretical basis for quantitative fluorimetric determinations has been developed. As a result, unreliable procedures have sometimes been proposed in fluorimetry. Therefore, it seems desirable to make available a somewhat more sophisticated theory of the dependence of the fluorescence intensity upon the composition of the fluorescent solution.

Owing to the rather complex mathematical expressions that result from such a theory, straightforward conclusions cannot always be drawn. For this reason a number of conclusions will be discussed in some detail.

"Perpendicular-type" fluorimeters, which constitute the bulk of the apparatus commercially available, have several disadvantages compared with other types of fluorimeter.[1–6] Therefore, the present investigation is extended to "transmission-type" and "reflection-type" fluorimeters. Schematic representations of the different types of fluorimeter are given in Fig. 1.

DERIVATION OF THE EQUATIONS

To keep the derivations reasonably simple the following assumptions have been made:

(a) the cell is rectangular
(b) the cell walls do not absorb any light
(c) the excitation light is a homogeneous, parallel and monochromatic beam, which enters the cell perpendicular to a cell face
(d) the intensity of the excitation light is not so large as to have a marked influence on the absorption coefficients of the components present in the sample
(e) the part of the fluorescence reaching the detector forms a parallel beam, which leaves the cell perpendicular to a cell face
(f) only a nearly monochromatic part of the fluorescence reaches the detector
(g) the refractive index of the sample is constant.

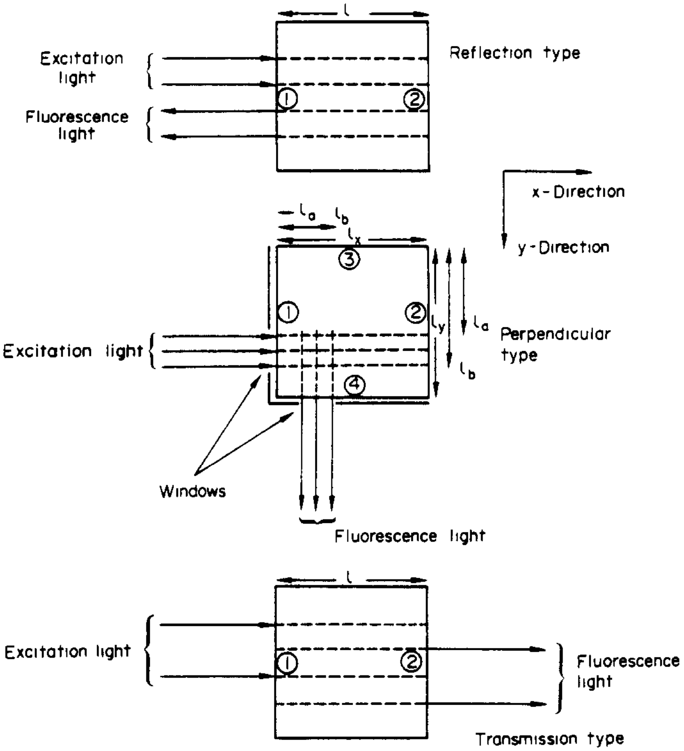

Fig. 1. Schematic representation of the different types of fluorimeter. The numbers in circles refer to the cell-wall numbers as used in the derivations.

Most of these assumptions do not really impair the applicability of the formulae, but some attention must be paid to them. The assumptions about the cell are easily fulfilled. The necessity of assuming rectangular cells arises from the fact that for cylindrical cells the light beams cannot pass perpendicularly through the cell walls. In such cases refraction and reflection effects play a very confusing role in the formulae.

If the excitation light and the measured part of the fluorescence are not monochromatic, the derived formulae have to be integrated over the relevant wavelength ranges.

The presence of substances which quench the fluorescence process is reflected in a change in the quantum efficiency of this process. Therefore, the presence of such substances need not be taken explicitly into account.

Effects of the intensity of the excitation light and of the refractive index of the sample can generally be neglected. A fuller discussion of these, and the previously mentioned effects is given elsewhere.[7]

If the intensity of the excitation light outside the cell is $I_{0,\mathrm{ex}}$, then, according to Beer's law, the intensity at a depth x inside the cell is:

$$I_{x,\mathrm{ex}} = I_{0,\mathrm{ex}} \,.\, \exp[-E_{\mathrm{ex}} \,.\, x] \tag{1}$$

where E_{ex} is the absorbance per unit path length (based on natural logarithms).

The decrease in intensity of the excitation light, caused by the ith absorbing component, in the thin layer between x and $x + \mathrm{d}x$, is:

$$\mathrm{d}I_{x,\mathrm{ex},i} = I_{x,\mathrm{ex}} \,.\, k_{\mathrm{ex},i} \,.\, c_i \,.\, \mathrm{d}x \tag{2}$$

where $k_{ex,i}$ is the absorption coefficient of the ith component at the excitation wavelength λ_{ex}, and c_i is the concentration of the ith component. In the fluorescence process the absorbed excitation light is converted into fluorescence with quantum efficiency $\Phi_{ex,i}$. Not all the emitted fluorescence arrives at the detector: only a fraction α goes in the right direction; only a fraction $\phi_{fl,i}$ has the right wavelength; only a fraction F is not absorbed by the sample solution. Therefore, the intensity of the fluorescence emitted by the ith component, originating in the layer between x and $x + dx$, having wavelength λ_{fl} and arriving at the detector, is given by:

$$dI_{x,fl,i} = \alpha \, . \, \phi_{fl,i} \, . \, \Phi_{ex,i} \, . \, F \, . \, dI_{x,ex,i} \tag{3}$$

It will be clear that F depends on the position of the layer from which the fluorescence originates, as well as on the arrangement for measuring the fluorescence intensity. For the arrangements with which this paper is concerned (see Fig. 1 for configurations and symbols) F is given by:

"reflection-type" arrangement:

$$F^0 = \exp[-E_{fl} \, . \, x] \tag{4}$$

"perpendicular-type" arrangement:

$$\begin{aligned} F^{90} &= \int_{l_a'}^{l_b'} \frac{\exp[-E_{fl} \, . \, (l_y - y)]}{l_b' - l_a'} \, dy \\ &= \frac{\exp[-E_{fl} \, . \, (l_y - l_b')] - \exp[-E_{fl} \, . \, (l_y - l_a')]}{(l_b' - l_a') \, . \, E_{fl}} \end{aligned} \tag{5}$$

"transmission-type" arrangement:

$$F^{180} = \exp[-E_{fl} \, . \, (l - x)] \tag{6}$$

Combining equations (1), (2) and (3) and the relevant equation for F yields, after integration, the desired formula for the fluorescence intensity:

"reflection-type" arrangement:

$$I_{fl}^{\,0} = T \, . \, \frac{1 - \exp[-(E_{ex} + E_{fl}) \, . \, l]}{E_{ex} + E_{fl}} \tag{7}$$

"perpendicular-type" arrangement:

$$I_{fl}^{\,90} = \frac{T}{l_b' - l_a'} \, . \left\{ \frac{\exp[-E_{fl}(l_y - l_b')] - \exp[-E_{fl}(l_y - l_a')]}{E_{fl}} \right\} . \left\{ \frac{\exp[-E_{ex} \, . \, l_a] - \exp[-E_{ex} \, . \, l_b]}{E_{ex}} \right\} \tag{8}$$

"transmission-type" arrangement:

$$I_{fl}^{\,180} = T \, . \, \frac{\exp[-E_{fl} \, . \, l] - \exp[-E_{ex} \, . \, l]}{E_{ex} - E_{fl}} \tag{9}$$

In (7), (8) and (9) the abbreviation T is used. If one fluorescent component is present T is given by

$$T = \alpha \,.\, I_{0,\,\mathrm{ex}} \cdot \Phi_{\mathrm{ex}} \cdot \phi_{\mathrm{fl}} \cdot k_{\mathrm{ex}} \cdot c \tag{10a}$$

if more fluorescent components are present T is:

$$T = \sum_{\mathrm{i}} T_{\mathrm{i}} = \alpha \,.\, I_{0,\,\mathrm{ex}} \cdot \sum_{\mathrm{i}} \Phi_{\mathrm{ex,\,i}} \cdot \phi_{\mathrm{fl,\,i}} \cdot k_{\mathrm{ex,\,i}} \cdot c_{\mathrm{i}} \tag{10b}$$

Correction for the effects of light reflection by the cell walls

The fraction of light that is reflected by a surface between two dielectrics is, at normal incidence, given by:[8]

$$r_{\perp} = \left(\frac{n - n'}{n + n'}\right)^2 \tag{11}$$

where n and n' are the refractive indices of the first and second dielectrics respectively.

A light-beam passing through a cell wall meets two reflecting surfaces. In this case the fraction of light that is reflected, ρ_{r} has to be calculated from a geometrical progression:

$$\rho_{\mathrm{r}} = \frac{r_{\mathrm{a}} + r_{\mathrm{b}} - 2r_{\mathrm{a}} \,.\, r_{\mathrm{b}}}{1 - r_{\mathrm{a}} \,.\, r_{\mathrm{b}}} \tag{12}$$

where r_{a} is the reflectivity of the first surface and r_{b} that of the second surface.

The fraction of light transmitted through the wall is:

$$\rho_{\mathrm{t}} = 1 - \rho_{\mathrm{r}} = \frac{(1 - r_{\mathrm{a}}) \,.\, (1 - r_{\mathrm{b}})}{1 - r_{\mathrm{a}} \,.\, r_{\mathrm{b}}} \tag{13}$$

Of course, the light-reflections by the cell walls influence the intensity of the fluorescence. The way to correct the formulae for this effect is by adding terms for the reflected light intensities to equations (1), (4), (5) and (6). The exact formulation of these equations is found by summing the terms of the geometrical progression:

$$I_{\mathrm{x,\,ex}} = I_{0,\,\mathrm{ex}} \cdot \rho_{\mathrm{t,\,ex,\,1}} \cdot \frac{\exp[-E_{\mathrm{ex}} \,.\, x] + \rho_{\mathrm{r,\,ex,\,2}} \,.\, \exp[-E_{\mathrm{ex}}(2l - x)]}{1 - \rho_{\mathrm{r,\,ex,\,1}} \cdot \rho_{\mathrm{r,\,ex,\,2}} \,.\, \exp[-2E_{\mathrm{ex}} \,.\, l]} \tag{1a}$$

$$F^0 = \rho_{\mathrm{t,\,fl,\,1}} \cdot \frac{\exp[-E_{\mathrm{fl}} \,.\, x] + \rho_{\mathrm{r,\,fl,\,2}} \,.\, \exp[-E_{\mathrm{fl}}(2l - x)]}{1 - \rho_{\mathrm{r,\,fl,\,1}} \cdot \rho_{\mathrm{r,\,fl,\,2}} \,.\, \exp[-2E_{\mathrm{fl}} \,.\, l]} \tag{4a}$$

$$\begin{aligned} F^{90} &= \int_{l_{\mathrm{a}}}^{l_{\mathrm{b}}'} \frac{\rho_{\mathrm{t,\,fl,\,4}}}{l_{\mathrm{b}}' - l_{\mathrm{a}}'} \cdot \frac{\exp[-E_{\mathrm{fl}}(l_{\mathrm{y}} - y)] + \rho_{\mathrm{r,\,fl,\,3}} \,.\, \exp[-E_{\mathrm{fl}}(l_{\mathrm{y}} + y)]}{1 - \rho_{\mathrm{r,\,fl,\,3}} \cdot \rho_{\mathrm{r,\,fl,\,4}} \,.\, \exp[-2E_{\mathrm{fl}} \,.\, l_{\mathrm{y}}]} \,\mathrm{d}y \\ &= \frac{1}{l_{\mathrm{b}}' - l_{\mathrm{a}}'} \cdot \frac{\rho_{\mathrm{t,\,fl,\,4}}}{1 - \rho_{\mathrm{r,\,fl,\,3}} \cdot \rho_{\mathrm{r,\,fl,\,4}} \,.\, \exp[-2E_{\mathrm{fl}} \,.\, l_{\mathrm{y}}]} \\ &\quad \frac{\begin{array}{l} \exp[-E_{\mathrm{fl}}(l_{\mathrm{y}} - l_{\mathrm{b}}')] - \exp[-E_{\mathrm{fl}} \,.\, (l_{\mathrm{y}} - l_{\mathrm{a}}')] \\ \qquad + \rho_{\mathrm{r,\,fl,\,3}} \,.\, \exp[-E_{\mathrm{fl}}(l_{\mathrm{y}} + l_{\mathrm{a}}')] - \rho_{\mathrm{r,\,fl,\,3}} \,.\, \exp[-E_{\mathrm{fl}}(l_{\mathrm{y}} + l_{\mathrm{b}}')] \end{array}}{E_{\mathrm{fl}}} \end{aligned} \tag{5a}$$

$$F^{180} = \rho_{\mathrm{t,\,fl,\,2}} \frac{\exp[-E_{\mathrm{fl}}(l - x)] + \rho_{\mathrm{r,\,fl,\,1}} \exp[-E_{\mathrm{fl}}(l + x)]}{1 - \rho_{\mathrm{r,\,fl,\,1}} \cdot \rho_{\mathrm{r,\,fl,\,2}} \,.\, \exp[-2E_{\mathrm{fl}} \,.\, l]} \tag{6a}$$

The subscripts 1, 2, 3 or 4 used with ρ, denote the reflecting cell-faces in the way indicated in Fig. 1. The fluorescence intensity can now be obtained from the corrected equations together with equations (2) and (3). After integration the final formulae for the fluorescence intensity are:

$$I_{\mathrm{fl}}{}^{0} = T \cdot \frac{\rho_{\mathrm{t,\,ex,\,1}}}{1 - \rho_{\mathrm{r,\,ex,\,1}} \cdot \rho_{\mathrm{r,\,ex,\,2}} \cdot \exp[-2E_{\mathrm{ex}} \cdot l]} \cdot \frac{\rho_{\mathrm{t,\,fl,\,1}}}{1 - \rho_{\mathrm{r,\,fl,\,1}} \cdot \rho_{\mathrm{r,\,fl,\,2}} \cdot \exp[-2E_{\mathrm{fl}} \cdot l]}$$
$$\cdot \left[\frac{1 - (1 - \rho_{\mathrm{r,\,ex,\,2}} \cdot \rho_{\mathrm{r,\,fl,\,2}})\exp[-(E_{\mathrm{ex}} + E_{\mathrm{fl}}) \cdot l] - \rho_{\mathrm{r,\,ex,\,2}} \cdot \rho_{\mathrm{r,\,fl,\,2}} \exp[-2(E_{\mathrm{ex}} + E_{\mathrm{fl}}) \cdot l]}{E_{\mathrm{ex}} + E_{\mathrm{fl}}} \right.$$
$$\left. + \frac{(\rho_{\mathrm{r,\,ex,\,2}} - \rho_{\mathrm{r,\,fl,\,2}}) \cdot \exp[-(E_{\mathrm{ex}} + E_{\mathrm{fl}})l] + \rho_{\mathrm{r,\,fl,\,2}} \cdot \exp[-2E_{\mathrm{fl}} \cdot l] - \rho_{\mathrm{r,\,ex,\,2}} \cdot \exp[-2E_{\mathrm{ex}} \cdot l]}{E_{\mathrm{ex}} - E_{\mathrm{fl}}} \right] \tag{7a}$$

$$I_{\mathrm{fl}}{}^{90} = \frac{T}{l_{\mathrm{b}}{}' - l_{\mathrm{a}}{}'} \cdot \frac{\rho_{\mathrm{t,\,ex,\,1}}}{1 - \rho_{\mathrm{r,\,ex,\,1}} \cdot \rho_{\mathrm{r,\,ex,\,2}} \cdot \exp[-2E_{\mathrm{ex}} \cdot l_{\mathrm{x}}]} \cdot \frac{\rho_{\mathrm{t,\,fl,\,4}}}{1 - \rho_{\mathrm{r,\,fl,\,3}} \cdot \rho_{\mathrm{r,\,fl,\,4}} \cdot \exp[-2E_{\mathrm{fl}} \cdot l_{\mathrm{y}}]}$$
$$\frac{\exp[-E_{\mathrm{ex}} \cdot l_{\mathrm{a}}] - \exp[-E_{\mathrm{ex}} \cdot l_{\mathrm{b}}] + \rho_{\mathrm{r,\,ex,\,2}} \exp[-E_{\mathrm{ex}}(2l_{\mathrm{x}} - l_{\mathrm{b}})] - \rho_{\mathrm{r,\,ex,\,2}} \cdot \exp[-E_{\mathrm{ex}}(2l_{\mathrm{x}} - l_{\mathrm{a}})]}{E_{\mathrm{ex}}}$$
$$\frac{\exp[-E_{\mathrm{fl}}(l_{\mathrm{y}} - l_{\mathrm{b}}{}')] - \exp[-E_{\mathrm{fl}}(l_{\mathrm{y}} - l_{\mathrm{a}}{}')] + \rho_{\mathrm{r,\,fl,\,3}} \cdot \exp[-E_{\mathrm{fl}}(l_{\mathrm{y}} + l_{\mathrm{a}}{}')] - \rho_{\mathrm{r,\,fl,\,3}} \cdot \exp[-E_{\mathrm{fl}}(l_{\mathrm{y}} + l_{\mathrm{b}}{}')]}{E_{\mathrm{fl}}} \tag{8a}$$

$$I_{\mathrm{fl}}{}^{180} = T \cdot \frac{\rho_{\mathrm{t,\,ex,\,1}}}{1 - \rho_{\mathrm{r,\,ex,\,1}} \cdot \rho_{\mathrm{r,\,ex,\,2}} \cdot \exp[-2E_{\mathrm{ex}} \cdot l]} \cdot \frac{\rho_{\mathrm{t,\,fl,\,2}}}{1 - \rho_{\mathrm{r,\,fl,\,1}} \cdot \rho_{\mathrm{r,\,fl,\,2}} \cdot \exp[-2E_{\mathrm{fl}} \cdot l]}$$
$$\left[\frac{\exp[-E_{\mathrm{ex}} \cdot l] - \exp[-E_{\mathrm{fl}} \cdot l] + \rho_{\mathrm{r,\,ex,\,2}} \cdot \rho_{\mathrm{r,\,fl,\,1}}(\exp[-(2E_{\mathrm{ex}} + E_{\mathrm{fl}}) \cdot l] - \exp[-(E_{\mathrm{ex}} + 2E_{\mathrm{fl}}) \cdot l])}{E_{\mathrm{fl}} - E_{\mathrm{ex}}} \right.$$
$$\left. + \frac{\rho_{\mathrm{r,\,ex,\,2}} \cdot \exp[-E_{\mathrm{ex}} \cdot l] + \rho_{\mathrm{r,\,fl,\,1}} \cdot \exp[-E_{\mathrm{fl}} \cdot l] - \rho_{\mathrm{r,\,ex,\,2}} \cdot \exp[-(2E_{\mathrm{ex}} + E_{\mathrm{fl}}) \cdot l] - \rho_{\mathrm{r,\,fl,\,1}} \exp[-(E_{\mathrm{ex}} + 2E_{\mathrm{fl}}) \cdot l]}{E_{\mathrm{fl}} + E_{\mathrm{ex}}} \right] \tag{9a}$$

DISCUSSION OF THE FORMULAE

It seems useful to start this discussion with some examples of the dependence of the fluorescence intensity on the variables which occur in the formulae. The most convenient way to do so is graphically. For the "reflection-type" and "perpendicular-type" arrangements two different cases will be distinguished, according to whether the cell-walls opposite to the excitation light beam and opposite to the fluorescence beam exhibit only their natural reflection, or are silvered to make them highly reflective (this is, of course, impossible in the "transmission-type" arrangement). All values for ρ_{r} for normal cell-walls are taken to be 0·05, and for silvered cell-walls ρ_{r} is supposed to be 1·00. In Fig. 2 the ratio R of the corrected fluorescence intensity to the uncorrected intensity is given as a function of the absorbance at the excitation wavelength. A, the absorbance per

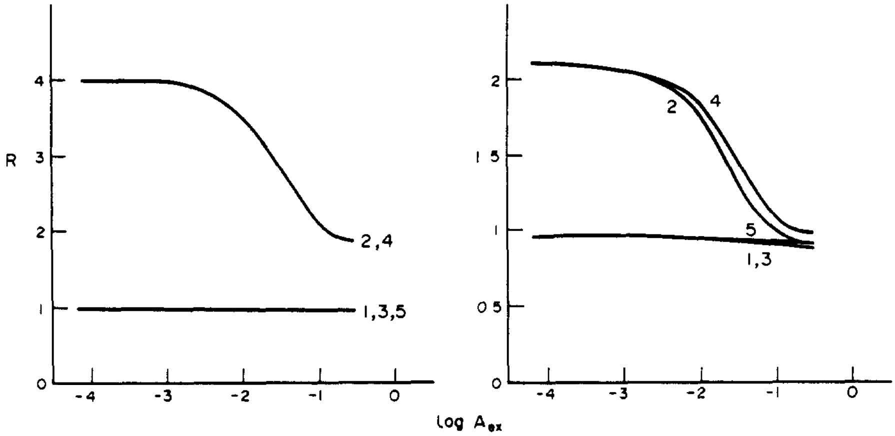

Fig. 2. The dependence of R on the absorbance per mm at the excitation wavelength.
Conditions: $l = l_x = l_y = 10$ mm. $l_a = l_a' = 1$ mm.
$l_b = l_b' = 9$ mm. $\rho_{r,ex,i} = \rho_{r,fl,i}$.
1. "Reflection-type" arrangement, $\rho_{r,1} = \rho_{r,2} = 0{\cdot}05$.
2. "Reflection-type" arrangement, $\rho_{r,1} = 0{\cdot}05$, $\rho_{r,2} = 1$.
3. "Perpendicular-type" arrangement, $\rho_{r,1} = \rho_{r,2} = \rho_{r,3} = \rho_{r,4} = 0{\cdot}05$.
4. "Perpendicular-type" arrangement, $\rho_{r,1} = \rho_{r,4} = 0{\cdot}05$, $\rho_{r,2} = \rho_{r,3} = 1$.
5. "Transmission-type" arrangement, $\rho_{r,1} = \rho_{r,2} = 0{\cdot}05$.
The curves in the left-hand figure are computed with $A_{fl} = 10^{-7}$, those in the right-hand figure are for $A_{fl} = 10^{-1}$.

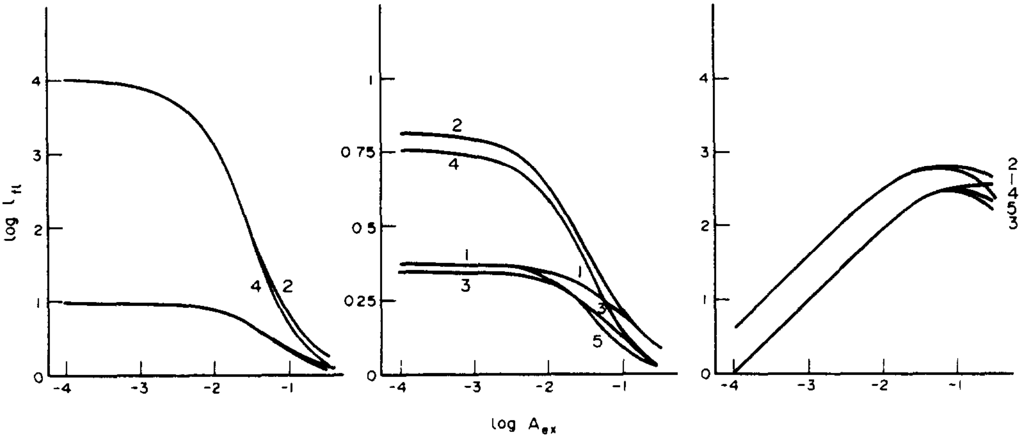

Fig. 3. The dependence of the fluorescence intensity on the absorbance per mm at the excitation wavelength.
Conditions as in Fig. 2.
1. "Reflection-type" arrangement, $\rho_{r,1} = \rho_{r,2} = 0{\cdot}05$.
2. "Reflection-type" arrangement, $\rho_{r,1} = 0{\cdot}05$, $\rho_{r,2} = 1$.
3. "Perpendicular-type" arrangement, $\rho_{r,1} = \rho_{r,2} = \rho_{r,3} = \rho_{r,4} = 0{\cdot}05$
4. "Perpendicular-type" arrangement, $\rho_{r,1} = \rho_{r,4} = 0{\cdot}05$, $\rho_{r,2} = \rho_{r,3} = 1$.
5. "Transmission-type" arrangement, $\rho_{r,1} = \rho_{r,2} = 0{\cdot}05$.
(a) $A_{fl} = 10^{-7}$; $k_{ex} . c = 10^{-7}$
(b) $A_{fl} = 10^{-1}$; $k_{ex} . c = 10^{-7}$.
(c) $A_{ex} = 10A_{fl} = k_{ex}$ c.
For all arrangements the intensity scale is such that $I_{fl} = 1$ for $A_{ex} = 10^{-4}$, $A_{fl} = 10^{-7}$ and $\rho_{r,1} = \rho_{r,2}(= \rho_{r,3} = \rho_{r,4}) = 0{\cdot}05$.

unit path length (based on Briggsian logarithms) is used in the figures and tables instead of E to facilitate comparison with practice. The dependence of R upon the absorbance at the fluorescence wavelength is quite similar to the dependence of R on the absorbance at the excitation wavelength. For this reason no separate graphs are given for the dependence of R on A_{fl}. As appears from Fig. 2 the correction for the effects of light-reflections can be quite large.

The dependence of the fluorescence intensity I_{fl} on the absorbance at the excitation wavelength is again rather similar to the dependence of I_{fl} on the absorbance at the fluorescence wavelength. Therefore, only graphs for I_{fl} as a function of A_{ex} will be given. These graphs are given for the case where the concentration of the fluorescent components is constant and $A_{\mathrm{fl}} = 0$ (Fig. 3*a*; for computational reasons the graph is given for $A_{\mathrm{fl}} = 10^{-7}$, but this does not influence the curve). In Fig. 3b the concentration of the fluorescent components is constant and $A_{\mathrm{fl}} = 0{\cdot}1$. Figure 3c is given for the case where the change in A_{ex} is caused by a change in the concentration of the fluorescent component.

In the "perpendicular-type" arrangement the measured fluorescence intensity depends on six parameters, which describe the position and dimensions of the cell and the windows. For the sake of brevity only some general remarks about these dependences can be made here. It is found that sensitivity and linearity of the fluorescence measurement are optimal if:

(a) l_a and $(l_y - l_b')$ are as small as possible
(b) $(l_b - l_a)$ and $(l_b' - l_a')$ are not too large (not larger than 10 mm in most cases), and
(c) l_x and l_y are only slightly larger than the windows in the cell faces.

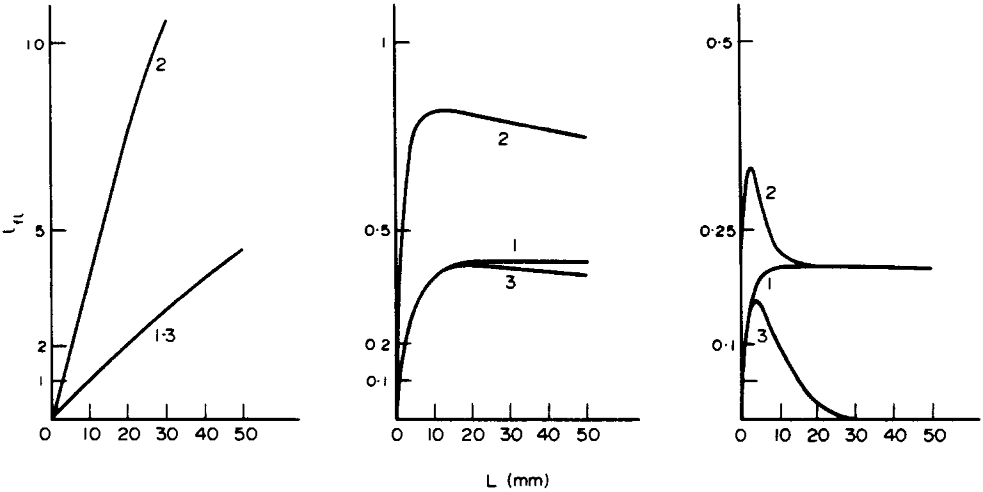

Fig. 4. The dependence of the fluorescence intensity on the cell length. $\rho_{r,\,\mathrm{ex}} = \rho_{r,\,\mathrm{fl}}$.
1. "Reflection-type" arrangement, $\rho_{r,\,1} = \rho_{r,\,2} = 0{\cdot}05$.
2. "Reflection-type" arrangement, $\rho_{r,\,1} = 0{\cdot}05$, $\rho_{r,\,2} = 1$.
3. "Transmission-type" arrangement, $\rho_{r,\,1} = \rho_{r,\,2} = 0{\cdot}05$.
(*a*) $A_{\mathrm{ex}} = A_{\mathrm{fl}} = 10^{-3}$
(*b*) $A_{\mathrm{ex}} = 10^{-3}$, $A_{\mathrm{fl}} = 10^{-1}$.
(*c*) $A_{\mathrm{ex}} = A_{\mathrm{fl}} = 10^{-1}$
The intensity scales are such that $I_{\mathrm{fl}} = 1$ for both arrangements, if $A_{\mathrm{ex}} = 10^{-4}$, $A_{\mathrm{fl}} = 10^{-7}$, $l = 10$ mm and $\rho_{r,\,1} = \rho_{r,\,2} = 0{\cdot}05$.

For the "reflection-type" and "transmission-type" arrangements the dependence of I_{fl} on the cell length is given in Figs. 4a ($A_{ex} = A_{fl} = 10^{-3}$), 4b ($A_{ex} = 10^{-3}$, $A_{fl} = 10^{-1}$) and 4c ($A_{ex} = A_{fl} = 10^{-1}$).

Linearity of the signal vs. *concentration curves*

The formulae for the fluorescence intensity can be written in a general way as:

$$I_{fl} = C \, . \, c_i \, . \, f(E_{ex}, E_{fl}, \rho_{r,ex}, \rho_{r,fl}, l) \tag{14}$$

where C is a proportionality constant. Values for the geometrical parameters l are nearly always fixed for a given apparatus. $\rho_{r,ex}$ and $\rho_{r,fl}$ generally do not change much on variation of the concentrations of the fluorescent substances. Therefore deviations from a linear relationship between I_{fl} and the concentrations c_i originate from changes in E_{ex} and/or E_{fl}. It is now to be considered whether a linear relationship between I_{fl} and c_i is possible. In the simplest case E_{ex} and E_{fl} are equal to the absorbance per mm due to the fluorescent substance. In that case a change in the concentration of the fluorescent substance always results in a change in E_{ex}. Therefore no truly linear relationship between I_{fl} and c can exist in this case.

In a seemingly more complicated case a change in the concentration of a fluorescent component brings about changes in the concentrations of other components. The changes in the absorbance per mm now are:

$$\Delta E = k_i \, . \, \Delta c_i + \sum_j k_j \, . \, \Delta c_j \tag{15}$$

[equation (15) holds both at the wavelength of fluorescence measurement and at the excitation wavelength]. According to the stoichiometry of the reaction, Δc_j is related to Δc_i by:

$$\Delta c_j = -\gamma_j \, . \, \Delta c_i \tag{16}$$

ΔE becomes zero if

$$k_i = \sum_j \gamma_j \, . \, k_j \tag{17}$$

Equation (17) can often be satisfied in practice. Many fluorimetric determinations of metals are based on the formation of a fluorescent complex. Let the metal (M) to ligand (L) ratio in such a complex (ML) be 1 : 1. In the wavelength range suitable for excitation there is nearly always a point where $k_{ML} = k_M + k_L$. Therefore, equation (17) is then satisfied for the excitation wavelength. Equation (17) can also be satisfied for the wavelength of fluorescence measurement, because it is often possible to choose this wavelength so that $k_M = k_L = k_{ML} = 0$. In a future communication an example will be given of a procedure that satisfies equation (17).

Wavelength choice if equation (17) *cannot be fulfilled*

Sometimes the excitation wavelength for which equation (17) is satisfied is such that k_{ex} is very small. Then the sensitivity of the measurement, which is directly proportional to k_{ex}, is very low too. On the other hand the background absorbance either at the excitation wavelength or at the wavelength of fluorescence measurement can be large, which also results in a low sensitivity. In such cases it may be necessary to choose an excitation wavelength or a wavelength for fluorescence measurement at which equation (17) is not fulfilled. Even then deviations from linearity in the I_{fl}–c_i relationship should preferably be as small as possible. To facilitate the choice of wavelength, tables are given which relate the change in absorbance per mm to the change in the fluorescence intensity (for fixed concentrations of the fluorescent components). If the wavelength dependences of the absorbance and the change in absorbance are known, it is possible with the use of the tables to find the wavelength combination where the deviations from linearity are minimal (a useful approximation is that the changes in I_{fl} caused by changes in A_{ex} and A_{fl} are additive for small values of ΔA_{ex} and ΔA_{fl}). However, even if $\Delta A_{ex} = -\Delta A_{fl}$, no strictly linear relationship between I_{fl} and c_i can be obtained. It seems useful to illustrate the use of the tables with an example. Assume a case for which equation (17) is satisfied at an excitation wavelength where owing to a high value of A_{ex}, the sensitivity of the determination is too low. Now, with the use of Fig. 3, select an A_{ex} value for which the sensitivity is high enough. From spectral data calculate ΔA_{ex} at this wavelength. Then use the relevant table for ΔA_{ex} to calculate the deviation from linearity. The % deviation from linearity is found as approximately ΔA_{ex} (calc)/ΔA_{ex} (table). If this deviation is unacceptable, the procedure has to be repeated at the wavelength of fluorescence measurement in such a way that the deviation from linearity due to ΔA_{ex} is as much as possible counteracted by the deviation caused by ΔA_{fl}.

Table 1. The change ΔA_{ex} in A_{ex}, which results in a change of 1% in I_{fl} for fixed concentrations of the fluorescent substances ("Reflection-type" arrangement. $l = 10$ mm; $\rho_{r,ex,1} = \rho_{r,fl,1} = \rho_{r,ex,2} = \rho_{r,fl,2} = 0{\cdot}05$. Zusammenfassung—Es werden Formeln für das Fluoreszenzsignal abgeleitet, die einige bisher vernachlässigte Faktoren in Rechnung stellen. Aus diesen Formeln werden Bedingungen gefolgert, bei denen zwischen der Konzentration der fluoreszierenden Komponenten und der Fluoreszenzintensität eine lineare Beziehung besteht. In einigen Fällen von praktischem Interesse führt die Erfüllung dieser Bedingungen zu einer zu geringen Empfindlichkeit. Für solche Falle wird eine Optimierungsmethode skizziert, durch die diejenigen Bedingungen aufgefunden werden, die bei der verlangten Empfindlichkeit zu der kleinsten Abweichung von der Linearität führen.

Résumé—On établit des formules pour le signal de fluorescence qui prennent en considération quelques facteurs jusque là négligés. De ces formules on déduit les conditions pour lesquelles une relation linéaire existe entre la concentration des composants fluorescents et l'intensité de la fluorescence. Dans quelques cas d'intérêt pratique le respect de ces conditions provoque une sensibilité trop faible. Pour de tels cas, on donne un aperçu d'une méthode d'optimalisation, au moyen de laquelle on trouve les conditions qui mènent à la moindre déviation de la linéarité à la sensibilité requise.

SHORT COMMUNICATION

NEW SPOT-TEST FOR CYANIDE ION AND CYANOGEN GAS

(*Received* 27 *July* 1972. *Accepted* 1 *December* 1972)

A rich literature is available on the determination of the cyanide ion. Bark and Higson[1] have published a review of the methods existing for the detection and determination of small amounts of cyanide. Later many other methods were suggested, and these include titrimetric with visual[2] or instrumental end-point,[3] polarographic,[4] gas-chromatographic[5] and colorimetric[6] finishes.

Similarly, many spot-tests for the cyanide ion have been proposed and these are already described in detail by Feigl.[7] Sabo[8] advocated the use of silver chromate-impregnated paper for the detection of a great variety of anions, including cyanide. The cyanide ion gives rise to a green fluorescence with solutions of quinone monoxime benzenesulphonate ester and *p*-benzoquinone in dimethylsulphoxide.[9] Direct detection of cyanide was possible through its catalytic effect on the condensation of picolinaldehyde.[10] In general, the methods described by Feigl[7] are less sensitive than those developed later.

However, in the present work a new spot-test was developed for cyanide which has two main advantages: (*i*) its sensitivity is superior to most of the existing spot-test methods,[7,8] and (*ii*) it is applicable, with slight modification, to the detection of cyanogen gas. The existing test for cyanogen is that it forms a polycyanide with cyanide ions, which gives a red colour with 8-hydroxyquinoline.[11] However, this detection[11] is reliable only in absence of compounds which split off water when heated; water vapour readily hydrolyses cyanogen gas to hydrogen cyanide and cyanic acid:

$$(CN)_2 + H_2O\ (\text{vapour}) \longrightarrow HCNO + HCN$$

The new test involves the reaction of cyanide ion with ammonium molybdate–copper(II) solution in acetic acid medium, to give a blue colour. Cyanogen gives the same colour but only after its conversion into cyanide in alkaline medium. The reaction is sensitive down to 0·15 μg of cyanide in a 0·1-ml drop (*i.e.*, 1·5 ppm), which is reasonable for detection purposes, without the need of any special equipment. The conditions of reaction and the interference of many other anions and cations are discussed below.

EXPERIMENTAL

Reagents

Unless otherwise specified, all reagents are of analytical grade.

Procedure

Detection of cyanide ion. Put a drop of the test solution (containing not less than 0·15 μg of cyanide ion) on a spot-plate. Add one drop of 0·01% copper sulphate solution followed by 1 or 2 drops of 5% ammonium molybdate solution in concentrated hydrochloric acid. A blue colour is developed immediately.

The lower limit of identification is 0·15 μg of cyanide per 0·1 ml (*i.e.*, 1·5 ppm), and the lower limit of dilution is 1 : 30000.

Detection of cyanogen gas. Pass the test gas either through a test-tube containing a mixture of copper sulphate solution (0·01%) and sodium hydroxide solution (1%) or a filter paper impregnated with the same mixture. Add 2–5 drops of 5% ammonium molybdate solution in concentrated hydrochloric acid. A blue colour is developed immediately if cyanogen was present.

DISCUSSION

Reaction conditions

Cyanide ion reduces copper(II) to copper(I). The latter reduces ammonium molybdate in concentrated hydrochloric acid to give a blue colour which is most probably that of molybdenum blue. When the test is to be used for detection of cyanogen gas, this should first be converted into cyanide ion by allowing it to react with sodium hydroxide:

$$(CN)_2 + NaOH \longrightarrow NaCNO + NaCN$$

The concentrations of both acid and ammonium molybdate as well as the sequence of the addition of the reagents are critical. A 5% solution of ammonium molybdate in concentrated hydrochloric acid was found quite suitable. The order of addition of reagents to the cyanide ion should start with copper(II) followed by the addition of ammonium molybdate–hydrochloric acid solution. When the latter solution was added before the copper(II) solution, no colour was developed, owing to the volatilization of hydrocyanic acid.

Interferences

Cyanate, nitrite, sulphite, phosphate, arsenate, thiocyanate, germanate, silicate, carbonate, chloride, sulphate, nitrate, chlorate, iodate and chromate did not interfere with the test. However, iron (II), tin(II), antimony(III), thiosulphate, and iodide give a blue colour with the copper–molybdate mixture.

Also, as expected, ferrocyanides and tetracyanozincate(II) interfered. Despite the reducing nature of the ferrocyanide ion, it reacted preferentially with copper, forming the brown copper ferrocyanide. In the case of complex zinc cyanide a blue colour was obtained, presumably owing to the relative instability of the complex and the sensitivity of the test.

The presence of tolerable amounts of thiocyanate, silicate, phosphate, arsenate and germanate caused only a slight decrease in the colour intensity and thus the test was still sufficiently sensitive for the detection of the cyanide ion. In general, this test is applicable for the cyanide ion in absence of either reducing or oxidizing substances and of cations with strong complexing properties towards the cyanide ion [*e.g.*, iron(III), cobalt(II), cobalt(III), and nickel(II)].

Summary—A new, rapid and simple spot test has been developed for detection of both cyanide ion and cyanogen gas. The cyanogen gas must first be converted into cyanide ion by reaction with sodium hydroxide. On addition of a Cu(II) solution the cyanocuprate(I) complex formed reduces the molybdate solution to molybdenum blue.

Zusammenfassung—Eine neue schnelle und einfache Tüpfelprobe zum Nachweis von Cyanidionen und gasförmigem Dicyan wurde entwickelt. Das Dicyan muß zuerst durch Reaktion mit Natriumhydroxid in Cyanid überführt werden. Bei Zugabe einer Kupfer(II)-Lösung reduziert der gebildete Cyanocuprat(I)-Komplex Molybdatlösung zu Molybdänblau.

Résumé—On a élaboré un nouvel essai à la touche, rapide et simple, pour la détection à la fois de l'ion cyanure et du gaz cyanogène. Le gaz cyanogène doit d'abord être converti en ion cyanure par réaction avec la soude. Par addition d'une solution de Cu (II) le complexe cyanocuprate (I) formé réduit la solution de molybdate en bleu de molybdène.

ANALYTICAL DATA

SPECTROPHOTOMETRIC DETERMINATION OF THE STABILITY CONSTANTS OF $HgCl_3^-$ AND $HgCl_4^{2-}$ IN AQUEOUS ETHANOL

(*Received* 1 *November* 1972. *Accepted* 26 *November* 1972)

Unlike the situation in water,[1] mercuric chloride does not complex with chloride ions in ethanol.[2] Our kinetic studies on the solvolysis of alkyl chlorides, catalysed by mercuric chloride, have also shown that the electrophilic activity of the catalyst is less in aqueous ethanol than in aqueous acetone solvents of the same water content.[3] Solubility measurements (which have only semi-quantitative significance since neither ionic strength nor acidity could be controlled) also support this conclusion.[4] We have now determined the stability constants for $HgCl_3^-$ and $HgCl_4^{2-}$ in 60% aqueous ethanol (v/v) at 25° by ultraviolet-region spectrophotometry under conditions of constant ionic strength (0·5*M*; $LiClO_4$) and acidity (0·01*N*; $HClO_4$). The data were processed by an adaptation of the Legatrop method[5] to Thamer's equation,[6] and the following values obtained: $\beta_1 = 3 \pm 1$ and $\beta_2 = 9 \pm 3$. These values are lower than those for the water system.[1]

OXIDATION WITH PERMANGANATE IN PRESENCE OF FLUORIDE

POTENTIOMETRIC DETERMINATION OF MANGANESE(II)

I. M. ISSA and M. M. GHONEIM

Chemistry Department, Assiut University, Assiut, Egypt

(*Received* 3 *June* 1971. *Revised* 11 *July* 1972. *Accepted* 21 *August* 1972)

Summary—The effects of acidity, fluoride concentration, temperature and concentration of manganese in the reaction between $KMnO_4$ and Mn(II) were studied potentiometrically. The rate of reaction is increased by increasing the fluoride concentration and/or decreasing the acidity of the solution. The formal redox potentials of the MnO_4^-/Mn(III) and the Mn(III)/Mn(II) systems were determined at different pH values. The E° values obtained by extrapolation to pH = 0 were 1·58 and 1·52 V respectively. The amount of Mn(II) determined was varied from 5 to 56 mg. The net reaction can be represented as $MnO_4^- + 10HF_2^- + 4Mn^{2+} \rightleftharpoons 5MnF_4^- + 2H^+ + 4H_2O$

Oxidation of manganous ions with potassium permanganate in presence of fluoride has been investigated before as a method for determination of manganese(II).[1,2] The visual method has proved successful for small amounts of manganese(II) and when copper(II) is used as catalyst, but cannot be used for high concentrations of Mn(II) or in the presence of coloured ions. The potentiometric method does not suffer from this drawback and for this reason the potentiometric titration of manganese(II) with permanganate in fluoride solutions has been studied.

EXPERIMENTAL

Reagents

Twice-distilled water was used in the preparation of all solutions. Analytical-grade reagents were used where possible.

Manganous sulphate solutions, 0·0926 *and* 0·0635*M*. Prepared in 0·1*M* sulphuric acid to prevent hydrolysis, and standardized by the pyrophosphate method.[3,4] Solutions of lower concentrations were prepared by appropriate dilution.

Potassium permanganate solution. Prepared according to the method of Stamm,[5] and standardized with oxalate.[6]

Sodium fluoride solution, 2%(~ 0·48*M*).

Sulphuric acid, 0·5 *and* 5*M*.

Manganese(III) solution, $2·5 \times 10^{-3}M$. Prepared from equivalent amounts of Mn(II) and $KMnO_4$ in presence of fluoride ions under the optimum conditions previously given.[1,7]

Equipment

The potentiometric titration apparatus was similar to that described elsewhere.[8] The cells used for the redox potential measurements were as follows:

(*a*)

$$\begin{array}{c} \text{Hg} \mid \text{Hg}_2\text{Cl}_2 \parallel \text{KCl} \\ \text{(saturated)} \end{array} \left\Vert \begin{array}{l} \text{Mn(III)} \\ \text{MnO}_4^- \\ [\text{NaF}] = m_1, [\text{H}^+] = m_2 \end{array} \right| \text{Pt}$$

(*b*)

$$\begin{array}{c} \text{Hg} \mid \text{Hg}_2\text{Cl}_2 \parallel \text{KCl} \\ \text{(saturated)} \end{array} \left\Vert \begin{array}{l} \text{Mn(III)} \\ \text{Mn(II)} \\ [\text{NaF}] = m_1, [\text{H}^+] = m_2 \end{array} \right| \text{Pt}$$

In this study m_1 was kept constant, while m_2 was varied by adding different amounts of 2·5*M* sulphuric acid. The ratio [OX]/[Red] in both systems was either 1 : 1 or 2 : 1. The potentials were measured 3 hr after immersion of the electrodes, although slight variations were observed within the following 24 hr.

Titration procedure

A volume of manganous solution containing 5–56 mg of manganese(II) was placed in the titration cell and mixed with the required quantities of 0·5*M* sulphuric acid and 2% sodium fluoride solution. The mixture was diluted to 100 ml and then titrated with permanganate at room temperature. The e.m.f. of the titration cell was measured by a direct reading mV meter, with a saturated calomel electrode (SCE) as reference half-cell.

RESULTS AND DISCUSSION

The values of reported potentials in all tables, plots and treatments are referred to the normal hydrogen electrode (NHE).

Effect of acidity

The effect of acidity on the reaction was studied by titrating 10 ml of 0·01*M* manganese(II) mixed with 75 ml of 2% sodium fluoride solution (~0·36*M*) in presence of varying concentrations of sulphuric acid. The curves are shown in Fig. 1, and the corresponding results in Table 1. In absence of additional acid, the titration curve (*A*) shows two breaks close to each other, the second corresponding to the oxidation of Mn(II) to MnO_2 and the other undoubtedly representing formation of manganese(III) but occurring later than at the theoretical value. With 1·0–1·5 ml of 0·5*M* sulphuric acid present the two inflections still occur but deviate largely from the theoretical end-points. With 2·0–8·0 ml of the acid added, only one inflection is observed for Mn(III), and the end-point agrees fairly well with the theoretical. The single inflection shows that manganese(III) is stable to oxidation under the optimum conditions, but not at lower acidities, when some but not all of it is oxidized to MnO_2. Hydrolysis may occur with formation of a precipitate of Mn_2O_3 which is then oxidized only at the surface. At pH 8·5–9·0 the second end-point approaches the theoretical for production of MnO_2. The equilibrium potential is attained more rapidly at lower acidity than at higher, 3–5 min being necessary for stabilization under the optimum conditions.

At lower acidity there may also be partial oxidation of Mn(II) to MnO_2 by atmospheric oxygen.

Effect of sodium fluoride concentration

Figure 2 and Table 2 show the results of titrating 10 ml of 0·01*M* manganese(II) in presence of 8·0 ml of 0·5*M* sulphuric acid and 25–75 ml of 2% sodium fluoride solution. Good results are obtained only in presence of 50–75 ml of fluoride solution.

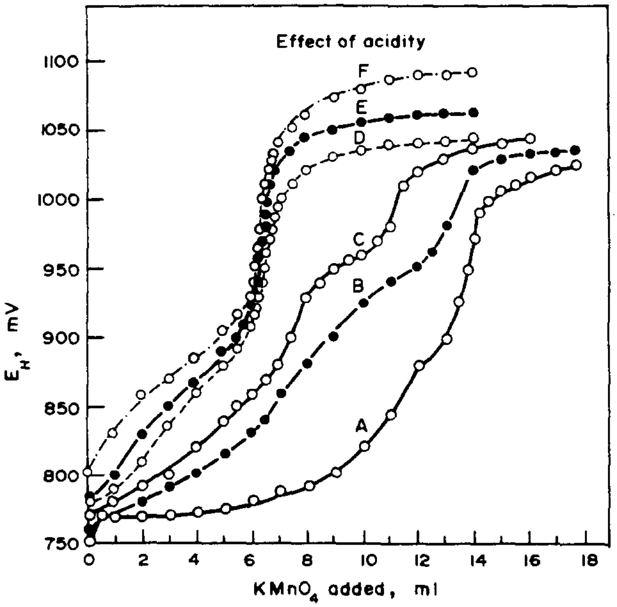

Fig. 1. Titration of 10 ml of 0·01*N* $MnSO_4$ with 0·0192*N* $KMnO_4$ (for $Mn^{7+} \rightarrow Mn^{2+}$) in presence of 75 ml of 2% NaF solution and varying amounts of 0·5*M* H_2SO_4: (*A*) no acid (*B*) 1·0 ml (*C*) 1·5 ml (*D*) 2·0 ml (*E*) 4·0 ml (*F*) 8·0 ml.

Addition of 25 ml of the fluoride solution is more than sufficient for complexation of the Mn(III) and was earlier[9] found to yield good results; the need for more is due to protonation of part of the fluoride by the extra strong acid added.

Effect of manganese concentration

The results in Table 3 show that 5–56 mg of Mn(II) can be titrated successfully under the optimum conditions. At higher concentration of Mn(II) the reaction medium becomes slightly turbid owing to the hydrolysis of Mn(III) to Mn_2O_3.

Formal redox potentials of MnO_4^-/Mn(III) *and* Mn(III)/Mn(II) *systems*

The formal redox potentials were determined from potential measurements of the cells mentioned above. Measurements were made over the pH range 0·9–6·0, [Mn(III)] and [NaF] being kept constant and the ratios [Mn(III)]/[Mn(II)] and [MnO_4^-]/[Mn(III)] varied.

The values of $E°$ for the two half-cells were determined from the Nernst equation, neglecting activity coefficients (Tables 4 and 5):

$$E_H = E° + \frac{RT}{nF}\ln\frac{[Ox]^A}{[Red]^B} + \frac{RT}{nF}\ln[H^+]X$$

6·0	0·805	0·805	0·805	0·823	0·809

* ${}_{\text{II}}E^\circ$ Mn(III)/Mn(II).

Plots of E_H *vs.* pH are straight lines with slopes of 0·095 and 0·115 for the MnO_4^-/Mn(III) and Mn(III)/Mn(II) systems respectively, which on extrapolation to pH = 0, give E° values 1·58 and 1·52 V respectively. These values do not differ sufficiently for the reaction between MnO_4^- and Mn(II) in 1*N* acid solution to be sufficiently quantitative.

The values of $(E_f)_x$, the formal redox potential, for the two systems at pH = *x* were calculated from the values of the measured potential $(E_H)_x$ at this pH, by using the equations

$$({}_{\text{I}}E_H)_x = ({}_{\text{I}}E_f)_x + \frac{0{\cdot}0591}{4}\log\frac{[MnO_4^-]}{[Mn(III)]}$$

and

$$({}_{\text{II}}E_H)_x = ({}_{\text{II}}E_f)_x + 0{\cdot}0591\log\frac{[Mn(III)]}{[Mn(II)]}$$

The results obtained are given in Tables 4 and 5.

Values of the equilibrium constant, K_f, and the extent of completion of the reaction, α, were calculated by use of the relations:

$$\log K_f = Z[({}_{\text{I}}E_f)_x - ({}_{\text{II}}E_f)_x]/0{\cdot}0591 \quad \text{and}$$

$$\alpha = [Mn(III)]/[Mn(II)] \quad \text{at equivalence point}$$
$$= K_f^{1/(n_1+n_2)}$$

where Z is the number of electrons involved in the overall reaction (4 in this case), and n_1 and n_2 are the oxidation-number changes for both systems. The results, given in Table 6, show that the reaction is essentially quantitative at pH 4–6.

The success of the titration depends on the stability of the manganic fluoride complex during the titration. The stability of the complex depends on the Mn(III) concentration, pH and temperature;[1] the complex hydrolyses at higher values of [Mn(III)], pH and temperature, leading to erroneous results.

* ${}_{I}E^{\circ\prime}$.

† ${}_{II}E^{\circ\prime}$.

§ ${}_{I}E^{\circ\prime} - {}_{II}E$.

‡ α = [Mn(III)]/[Mn(II)] at equivalence point.

Since the slope of the E_H *vs.* pH graph is equal to $0{\cdot}0591X/n$, where X is the number of H^+ ions participating in the reaction then, for the MnO_4^-/Mn(III) system X_I is 6 and for the Mn(III)/Mn(II) system X_{II} is 2. Accordingly, the following equations may be written to represent the reactions.

(*a*) $MnO_4^- + 6H^+ + 2HF_2^- + 4e^- \rightleftharpoons MnF_4^- + 4H_2O$

(*b*) $MnF_4^- + 2H^+ + e^- \rightleftharpoons 2HF_2^- + Mn^{2+}$

$MnO_4^- + 10HF_2^- + 4Mn^{2+} \rightleftharpoons 5MnF_4^- + 2H^+ + 4H_2O$

The overall reaction is favoured by decreasing acidity, confirming the experimental results and indicating that the reaction occurs more rapidly and quantitatively at higher pH (4–5·5) than at lower (pH < 4). The validity of this equation is verified by determining the slope of the E_{cell} *vs.* pH curve for the overall cell reaction. According to equations (1) and (2), when

$$[MnO_4^-]/[Mn(III)] = [Mn(III)]/[Mn(II)] = 1, \quad \text{then}$$

$$E_{cell} = E^\circ + \frac{0{\cdot}059}{4}(4X_{II} - X_I)\,pH$$

$$\text{Since} \quad X_I = 6 \quad \text{and} \quad X_{II} = 2,$$

$$E_{cell} = E^\circ + \frac{0{\cdot}059 \times 2}{4}\,pH = E^\circ + 0{\cdot}0295\,pH$$

The slope found experimentally was 0·0294, in excellent accordance with that expected. In accordance with these facts two protons should be involved in the overall reaction, which is in accordance with our findings.

The procedure is simpler than that given by other authors[2,10] and amounts of Mn(II) as low as 5 mg can be determined with fair accuracy.

Zusammenfassung—Der Einfluß von Acidität, Fluoridkonzentration, Temperatur und Mangankonzentration auf die Reaktion zwischen $KMnO_4$ und Mn(II) wurde potentiometrisch untersucht. Die Reaktion wird durch Erhöhung der Fluoridkonzentration und/oder Erniedrigung der Acidität der Lösung begünstigt. Die formalen Redoxpotentiale der Systeme MnO_4^-/Mn(III) und Mn(III)/Mn(II) wurden bei verschiedenen pH-Werten bestimmt. Die durch Extrapolation auf pH = 0 erhaltenen $E°$-Werte betragen 1·58 bzw. 1·52 V. Die Mn(II)-Menge wurde von 5 bis 56 mg variiert. Die Nettoreaktion kann man als $MnO_4^- + 10HF_2^- + 4Mn^{2+} \rightleftharpoons 5MnF_4^- + 2H^+ + 4H_2O$ darstellen.

Résumé—On a étudié potentiométriquement les influences de l'acidité, de la concentration en fluorure, de la température et de la concentration du manganèse dans la réaction entre $KMnO_4$ et Mn(II). La vitesse de réaction est augmentée par accroissement de la concentration en fluorure et/ou abaissement de l'acidité de la solution. On a déterminé les potentiels redox formels des systèmes MnO_4^-/Mn(III) et Mn(III)/Mn(II) à différentes valeurs de pH. Les valeurs $E°$ obtenues par extrapolation à pH = 0 sont 1,58 et 1,52 V respectivement. On a fait varier la quantité de Mn(II) dosée de 5 à 56 mg. La réaction globale peut être représentée ainsi: $MnO_4^- + 10\ HF_2^- + 4\ Mn^{2+} \rightleftharpoons 5\ MnF_4^- + 2\ H^+ + 4\ H_2O$.

SIMULTANEOUS DETERMINATION OF *N*-UNSUBSTITUTED- AND *N*-SUBSTITUTED NITROAZOLES AND CRITERIA FOR THEIR IDENTIFICATION—I

NITROIMIDAZOLES AND NITROPYRAZOLES—POLAROGRAPHIC DETERMINATION

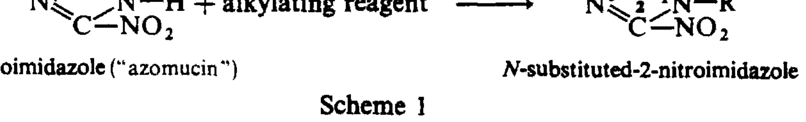
DRAGICA DUMANOVIĆ and JANKA ĆIRIĆ
Research Laboratory "Galenika," Zemun, Yugoslavia

(*Received* 12 *September* 1972. *Accepted* 30 *November* 1972)

Summary—The *N*-unsubstituted nitroazoles have an imino hydrogen atom in contrast to the *N*-substituted derivatives, and react with hydroxide to give nitroazole anions. The strongly negative shift of $E_{1/2}$ for these anions makes possible simultaneous polarographic determination of any pair of compounds, one of which is an *N*-unsubstituted nitroazole and the other a corresponding *N*-substituted derivative. Simultaneous polarographic determination of three compounds [4(5)- 4- and 5-nitroimidazole] is also possible from alkaline medium, but only when $\Delta E_{1/2}$ between the *N*-substituted isomers is at least 100 mV. Chromatographically, and/or by some other criteria it is possible to distinguish between the *N*-unsubstituted nitroazole and the *N*-substituted derivatives. These compounds appear together in reaction mixtures arising during substitution of the hydrogen atom.

In an earlier publication[1] it was suggested that the polarographic method, using $0{\cdot}1M$ alkali as medium, should be generally applicable to simultaneous determination of some *N*-unsubstituted and the corresponding *N*-substituted heterocyclic compounds, certainly those with properties similar to those of the compounds studied in the paper mentioned (*viz.* nitroazoles). The aim of the present paper was to confirm this assumption, so nitropyrazoles and some other nitroimidazoles have been investigated. The general polarographic and chromatographic behaviour of these groups of compounds is described. On the basis of these investigations it is confirmed that simultaneous polarographic determination of two compounds during the synthetic processes described by schemes 1 and 2, or simultaneous polarographic determination of three compounds in the processes given in scheme 3 is only possible when an alkali is used as a medium.

Several methods for thin-layer chromatographic identification,[2–5] and for polarographic determination of nitroimidazoles[6–19] have been reported. However, a simultaneous



2-Nitroimidazole ("azomucin")

N-substituted-2-nitroimidazole

identification and determination of nitroimidazoles, or nitropyrazoles in the reaction mixtures arising during substitution of the imino hydrogen atom has not yet been proposed except in our earlier papers.[1,20]

RESULTS AND DISCUSSION

Chromatographic separations

In Table 1, R_f values are shown for the compounds investigated. For all reaction mixtures we recommend diethylamine as the developer. Tin(II) chloride and *p*-dimethylaminobenzaldehyde mixture[21] was used as detecting reagent. Thin-layer chromatography was done on unactivated 0·25-mm thick layers of silica gel G, in an atmosphere saturated with the developer.

Polarographic investigation

The polarographic behaviour of all compounds was examined in Britton-Robinson buffers over the pH range 1·83–9·30 and in 0·1*M* sodium hydroxide. Most of the compounds investigated give two reduction waves in acidic as well as in neutral media. The first wave corresponds to the 4-electron reduction of the nitro group. The second wave is a 2-electron wave and is caused by reduction of the substituted hydroxylamine formed in the first reduction. In alkaline media some of the compounds investigated give only a 4-electron reduction wave, the second disappearing with increasing pH. However, some of the compounds give a single 6-electron wave in alkaline media.

The number of electrons involved in the reduction process was estimated by comparison of the wave-heights of the compounds investigated with the wave-heights of substances for which the reduction mechanism is known. In addition to this, the diffusion coefficients (*D*) calculated from the uncorrected Ilkovič equation are in accordance with

the values of *D* for other heterocyclic depolarizers, calculated in the same manner.[22] The solutions examined ($2 \times 10^{4}M$ depolarizer) were prepared by mixing 2 ml of aqueous stock solution of the depolarizer ($10^{-3}M$) with 8 ml of the buffer solution, or 2 ml of the aqueous stock solution with 3 ml of water and 5 ml of 0·2*M* sodium hydroxide. The buffer solutions were twice as concentrated as in the original prescription of Britton–Robinson (*i.e.*, each acid was 0·08*M* and 0·4*M* sodium hydroxide was added). Since many heterocyclic compounds are only slightly soluble in water, it is better to use these more concentrated buffers; the capacity of the buffer would be sufficient even if we had to use—owing to the poor solubility of the depolarizer—larger amounts of the depolarizer stock solution (*e.g.*, 5 ml of aqueous stock solution and 5 ml of the buffer solution).

The direct proportionality between wave-height and the square root of the effective mercury reservoir height as well as the computed temperature coefficients[23] indicate that the first reduction waves are diffusion-controlled over the pH region investigated.

It was found with all the nitroazoles investigated that over the range from 5×10^{-5} to $5 \times 10^{-4}M$ the heights of the first waves are a linear function of the concentration, at any pH value.

The half-wave potentials* for the first wave of the compounds studied, as a function of pH, are shown in Table 2. These values are in accordance with the electron density of the nitro group. Thus 4(5)-nitroimidazoles, which mainly have the 4-nitro form,[24,25] have almost the same $E_{1/2}$ values as the 4-nitroimidazoles (except in 0·1*M* alkali). Their $E_{1/2}$ values are more negative than those of the 5-nitroimidazoles, because the nitro group is located in the vicinity of the electron-donor system (pyridine nitrogen).

Simultaneous polarographic determination

N-unsubstituted nitroazoles have the ability to form nitroazole anions on treatment with 0·1*M* sodium hydroxide. The difficulty of reducing the nitro group in these anions makes possible the simultaneous polarographic determination of a pair of compounds, one being practically any *N*-unsubstituted nitroazole and the other a corresponding *N*-substituted derivative (*e.g.*, Fig. 1).

Although in reaction mixtures according to scheme 3 three compounds may be expected (the starting compound and two isomers), under the defined experimental conditions of the synthetic process, only two compounds are found to be present; 4(5)-nitroimidazole and 4-nitroimidazole, or 4(5)-nitroimidazole and 5-nitroimidazole. When all three compounds are present in reaction mixtures, the simultaneous polarographic determination is also possible in 0·1*M* sodium hydroxide, but only when $\Delta E_{1/2}$ between isomers is more than 100 mV (Fig. 2).

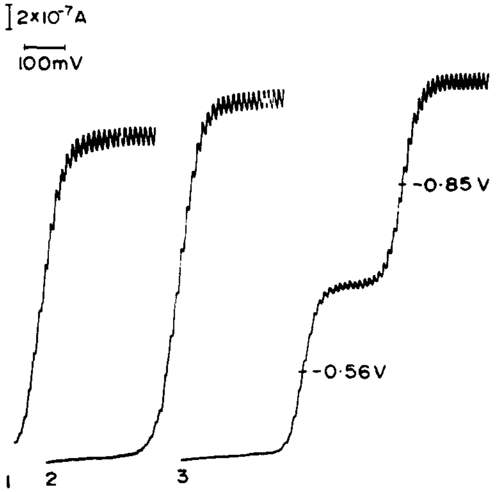

Fig. 1. Equimolar mixtures of 2-nitroimidazole and 1-methyl-2-nitroimidazole polarographed at different pH values. (These compounds appear together in the reaction mixture according to scheme 1.) *1*—pH 2·40; *2*—pH 7·00; *3*—0·1*M* NaOH.

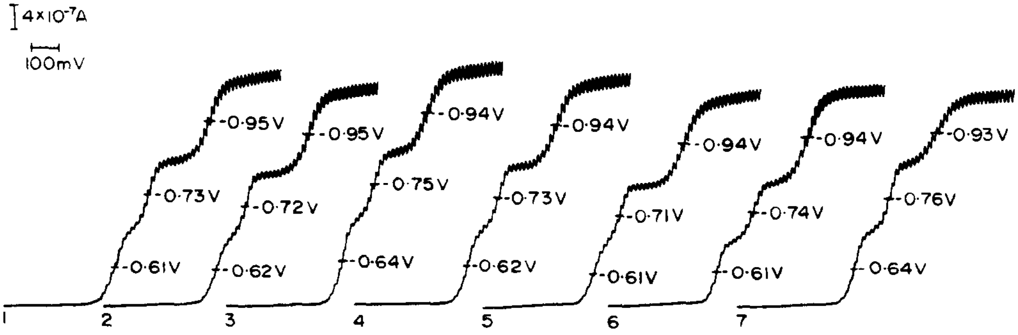

Fig. 2. Curve 1, equimolar mixture of **A**, **I** and **II**. Curve 2, equimolar mixture of **A**, **III** and **IV**. Curve 3, equimolar mixture of **B**, (**V**) and **VI**. Curve 4, equimolar mixture of **B**, (**VII**) and **VIII**. Curve 5, equimolar mixture of **B**, **IX** and **X**. Curve 6, equimolar mixture of **B**, **XI** and **XII**. Curve 7, equilmolar mixture of **C**, (**XIII**) and **XIV**. Supporting electrolyte 0·1*M* NaOH. Concentration of each compound $10^{-4}M$. The curves start at −0·2 V *vs*. S.C.E.

The conditions for the procedure of identification and determination for all synthetic mixtures in the present study were the same as those described earlier,[1] including the use of the method of standard addition. The polarographic method of simultaneous determination of nitroazoles is very useful for monitoring the substitution of the imino hydrogen atom, where it is very important to know when to stop the reaction. For this purpose, the exact amounts of the compounds present need not be known, as their ratio gives satisfactory results. This procedure is very fast—a few drops from a reaction mixture are added to 0·1*M* sodium hydroxide, this solution is then transferred to the polarographic cell, dearated with nitrogen for exactly 5 min, and the polarogram recorded over the range from −0·2 to −1·2 V *vs.* S.C.E. The total wave-heights of all the nitroazole compounds are taken as equivalent to 100%. Although the results are not precise, even in the ratios of amounts of components (the diffusion coefficients of the compounds are different, and the number of electrons consumed in alkaline medium is not the same for all compounds), the information given about the process is adequate.

The criteria for distinction between N*-unsubstituted nitroazoles and their* N*-substituted derivatives*

N-unsubstituted nitroazoles, because of their pseudo-acidic character, have the lowest R_f values in diethylamine, in comparison with the corresponding *N*-substituted derivatives. 5-Nitroimidazoles are stronger bases than 4-nitroimidazoles and hence have the highest R_f values. The 4(5)-nitroimidazoles and 5-nitroimidazoles studied here give a red colour with tin(II) chloride and *p*-dimethylaminobenzaldehyde reagent on silica gel thin layers. The same treatment applied to 4-nitroimidazoles gives a yellow colour.

N-unsubstituted nitroazoles in alkaline media (*i.e.*, 0·1*M* sodium hydroxide) show a strongly negative shift of $E_{1/2}$, compared with the corresponding *N*-substituted derivatives. 4(5)-Nitroimidazoles and 4-nitroimidazoles have almost the same $E_{1/2}$ values over all the pH range (except in 0·1*M* alkali). The $E_{1/2}$ values of 5-nitroimidazoles are more positive.

N-unsubstituted nitroazoles do not decompose on standing in 0·5*M* sodium hydroxide for 24 hr, whereas *N*-substituted ones do. The 4-nitroimidazoles studied show a lower degree of degradation (1–15%) in comparison with the corresponding 5-nitroimidazoles (60–95%) after standing in 0·5*M* sodium hydroxide for 24 hr.

According to the criteria given it is possible to deduce the structure of the nitroazoles directly from the behaviour of the reaction mixtures. Based on these criteria the structures of some new nitroazole compounds[26] have been determined, even though one of them has not yet been isolated from the reaction mixture.

It can be seen that the proposed methods and criteria have wide applicability, not only for the simultaneous identification and determination of nitroazoles, directly in the reaction mixtures, but also for determination of their structures.

Zusammenfassung—Die nicht *N*-substituierten Nitroazole haben im Gegensatz zu den *N*-substituierten Derivaten ein Iminowasserstoffatom und reagieren mit Hydroxid zu Nitroazol-Anionen. Die stark negative Verschiebung von $E_{1/2}$ dieser Anionen ermöglicht die gleichzeitige polarographische Bestimmung eines beliebigen Paares von Verbindungen, von denen die eine ein nicht *N*-substituiertes Nitroazol und die andere ein entsprechendes *N*-substituiertes Derivat ist. Die gleichzeitige polarographische Bestimmung dreier Verbindungen [4(5)-, 4- und 5-Nitroimidazol] ist in alkalischem Medium ebenfalls möglich, aber nur, wenn $\Delta E_{1/2}$ zwischen den *N*-substituierten Isomeren wenigstens 100 mV beträgt. Man kann zwischen dem nicht *N*-substituierten Nitroazol und den *N*-substituierten Derivaten chromatographisch und/oder nach einigen anderen Merkmalen unterscheiden. Diese Verbindungen treten gemeinsam in Reaktionsgemischen auf, die bei der Substitution des H-Atoms anfallen.

Résumé—Les nitroazoles non substitués à l'azote ont un atome d'hydrogène imino à l'opposé des dérivés N-substitués, et réagissent avec l'hydroxyde pour donner des anions nitroazole. Le déplacement fortement négatif de E 1/2 pour ces anions rend possible le dosage polarographique simultané de n'importe quelle paire de composés, dont l'un est un nitroazole non substitué à l'azote et l'autre le dérivé N-substitué correspondant. Le dosage polarographique simultané de trois composés [4(5)-, 4- et 5-nitroimidazole] est aussi possible dans un milieu alcalin, mais seulement quand $\Delta E1/2$ entre les isomères N-substitués est d'au moins 100 mV. Chromatographiquement, et/ou par quelques autres critères il est possible de distinguer entre le nitroazole non substitué à l'azote et les dérivés N-substitués. Ces composés se présentent ensemble dans les mélanges réactionnels se formant pendant la substitution de l'atome d'hydrogène.

ANION-EXCHANGE BEHAVIOUR OF VARIOUS METALS ON DEAE-CELLULOSE IN MIXED ACETIC ACID–NITRIC ACID MEDIA

ROKURO KURODA, TAKAAKI KONDO and KOICHI OGUMA
Laboratory for Analytical Chemistry, Faculty of Engineering, University of Chiba,
Yayoi-cho, Chiba, Japan

(*Received* 10 *April* 1972. *Accepted* 28 *November* 1972)

Summary—A number of nitrato complexes of metals have been found to be adsorbed on DEAE-cellulose from mixed acetic acid–nitric acid media, although none can be adsorbed from aqueous nitric acid solutions. The distribution coefficients of Sc, Mo, La, Sm, W, Re, Bi, Th and U are given as functions of acetic acid and nitric acid concentrations (sometimes in the presence of hydrogen peroxide to prevent hydrolytic precipitation). For 25 other metals column adsorption behaviour is described for a 90% acetic acid–10% 7·6*M* nitric acid mixture. Favourable differences in the distribution coefficients allow useful separations such as Fe–Mo–W and U–Sm–Mo–Bi–Th, to be achieved.

When the weakly basic anion exchanger DEAE-cellulose (abbreviated to DEAE) is used as an adsorbent, only a few metals have been found to be adsorbed from mineral acid media. Thus, Pd(II), Pt(IV)[1] and Hg(II)[2] can be adsorbed on DEAE columns and separated selectively from many other metals in acidic thiocyanate media. Mo(VI), W(VI) and Re(VII) are also adsorbed on DEAE and separated from each other in dilute thiocyanate[3] and chloride[4] media.

Ion-exchange adsorption of metals on DEAE has been found to be improved by the addition of a protic organic solvent to the aqueous mineral acid media such as hydrochloric acid,[5] nitric acid[6] and hydrochloric acid–thiocyanate solutions.[7]

Previously methanol has been used exclusively as the organic protic solvent. In this study we have investigated the adsorption behaviour of metals on DEAE in mixed acetic acid–nitric acid media. Though Th(IV) but none of the metals adsorbed on DEAE from aqueous nitric acid solutions exhibited a pronounced adsorption in methanolic nitric acid, introduction of acetic acid allowed an increasing number of nitrato complexes to be adsorbed. A number of useful analytical separations were accomplished.

EXPERIMENTAL

Reagents

Selectacel DEAE (diethylaminoethylcellulose), 0·84 meq/g, Brown Co., Berlin, N. H., was obtained from Seikagaku Kogyo Co. Ltd., Tokyo. About 10 g of DEAE were slurried with demineralized water, placed in a large column and treated with 200 ml of 1*M* ammonium nitrate acidified to pH 1 with nitric acid. The DEAE converted into the nitrate form was washed with demineralized water by centrifugation until the pH of the supernatant liquid was 2·5. After washing with methanol to remove the adsorbed water, the DEAE was dried at 40° for 1 hr and stored in a desiccator containing saturated potassium bromide solution.

Stock solutions (0·05*M*) of the metal nitrates were prepared so as to be 1*M* in nitric acid. Exceptions were Mo(VI), W(VI) and Re(VII), the 0·05*M* stock solutions of which were made by dissolving their ammonium or sodium salts in demineralized water.

Determination of distribution coefficients

A batch equilibrium method was used to determine the distribution coefficients for Sc(III), Mo(VI), La(III), Sm(III), W(VI), Re(VII), Bi(III), Th(IV) and U(VI). Portions (0·5 g) of DEAE in the nitrate form were weighed and placed in glass-stoppered conical flasks containing 40·0 ml of appropriate acetic acid–nitric acid mixtures of varying composition, which also contained 5 μmole of the metal to be measured. The mixtures were shaken mechanically for 20 hr at 25·0 ± 0·1°. The two phases were separated by filtration and the filtrates were analysed for each metal colorimetrically by the methods given in Table 1. The distribution coefficient was obtained from the formula:

$$K_d = (\text{amount of metal in DEAE phase/g of DEAE})/(\text{amount of metal in solution phase/ml of solution})$$

§ A mixture of equal amounts of La(III), Sm(III) and Y(III). For each run the metals were eluted in the order listed.

Column preparation and separation

DEAE (1 g) was slurried with 20 ml of the acetic acid–nitric acid mixture to be used for sample preparation and poured into a conventional ion-exchange column (bore 1·3 cm, length 15 cm). The column was further washed with 30 ml of the same mixture, the bed being 9·0 cm long. For multicomponent separations 1·5 g of DEAE were packed similarly into the column, the bed being 13·5 cm long.

About 5 ml of a sample solution, in the appropriate mixture of acetic acid and nitric acid, were loaded onto the top of the column and allowed to percolate, and then an eluent was applied. The individual procedures are given in Table 2. A flow-rate of 2 ml/min for elution was used throughout. For sample loading a flow-rate of 1 ml/min was used.

RESULTS AND DISCUSSION

Adsorption of metals from acetic acid and nitric acid mixtures

The distribution coefficients of the nine metals on DEAE in acetic acid–nitric acid media are illustrated in Figs. 1 and 2 as a function of acetic acid concentration, where the concentration of nitric acid is kept constant at 7·6*M*. Tungstic acid is precipitated when nitric acid is added to tungstate solution, so we had to determine the distribution coefficients of tungsten(VI) in the presence of hydrogen peroxide. For molybdenum(VI) the coefficients are given both in the presence and absence of hydrogen peroxide. The coefficient increases with increasing concentration of acetic acid for each metal, showing the marked effect of acetic acid on the ion-exchange adsorption of metals on DEAE.

Figure 3 illustrates the effect of nitric acid concentration on the distributon coefficients of Th(IV), Bi(III), Mo(VI), La(III), Re(VII) and U(VI), the concentration of acetic acid being held constant at 90% v/v. The effect of acid concentration is less marked, in accordance with the observation reported by Korkisch and his co-workers,[8,9] for the adsorption of metals on Dowex 1 from acetic acid–nitric acid mixtures. Among the metals tested, the adsorption of U(VI), La(III), Bi(III) and Th(IV) tended to increase with increasing concentration of nitric acid, while oxy-anions exhibited the opposite trend.

The distribution coefficients were also measured for 25 metals other than those

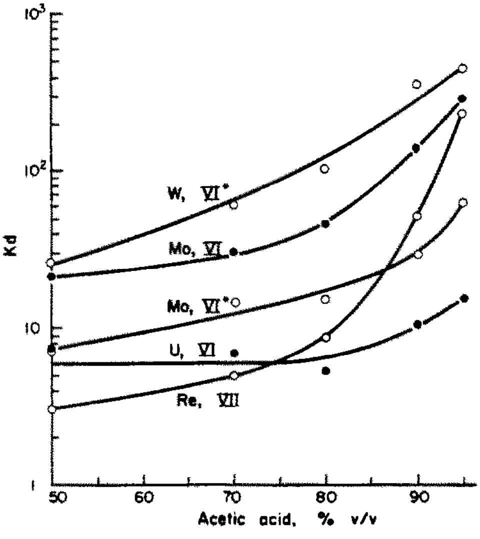

Fig. 1. Distribution coefficients of metals on DEAE in acetic acid–7·6*M* nitric acid media as a function of acetic acid concentration.
* 0·24% H_2O_2 added.

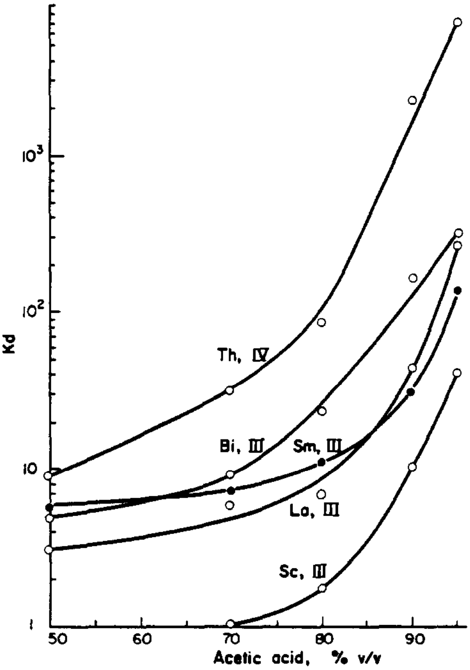

Fig. 2. Distribution coefficients of metals on DEAE in acetic acid–7·6M nitric acid media as a function of acetic acid concentration.

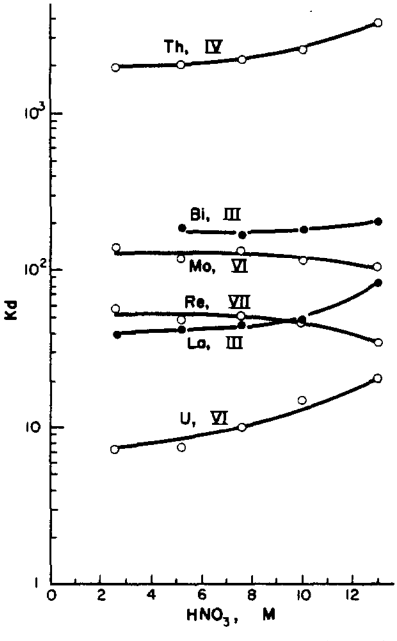

Fig. 3. Distribution coefficients of metals on DEAE in acetic acid–nitric acid (9 : 1) media as a function of nitric acid concentration.

illustrated in Figs. 1 and 2, in a medium of 90% acetic acid–10% 7·6*M* nitric acid by a column method, on a 0·5-g DEAE column. The following metals did not adsorb to any great extent on the column: Be(II), Mg(II), Ca(II), Cr(III), Mn(II), Fe(III), Co(II), Ni(II), Cu(II), Zn(II), Ga(III), As(V), Y(III), Zr(IV), Ag(I), Cd(II), In(III) and Hg(II). Ge(IV), Ba(II) and Pb(II) were precipitated from the same medium. Pd(II) and Au(III) adsorbed strongly, with coefficients >100 and 105, respectively, in the presence of a minimum amount of chloride. The coefficients for Al(III) and V(V) were 25 and 30, respectively.

To obtain some information on the ease of attainment of ion-exchange equilibrium, U(VI) and Th(IV) were chosen and their distribution coefficients were measured at time intervals, in acetic acid–7·6*M* nitric acid. The volume ratio of acetic to nitric acid was 19 : 1 for U(VI) and 4 : 1 for Th(IV). U(VI) attained equilibrium in 1–2 hr, but Th(IV) took about 6 hr.

The metals showing strong adsorption on DEAE from mixed acetic acid–nitric acid media are very similar to those which adsorb on a strongly basic resin from aqueous nitric acid solution.[10,11] This is the case for Mo(VI), Pd(II), the lighter rare-earth metals, Re(VII), Au(III), Bi(III), Th(IV) and U(VI). Therefore, we see that in the mixed acetic acid–nitric acid media DEAE behaves in a similar way to a strongly basic resin in aqueous nitric acid solutions, the uptake of metals taking place by anion-exchange of their nitrato complexes.

The role of acetic acid is considered to be as follows. The addition of increasing amounts of acetic acid will reduce the concentration of nitrate ions, which compete for the ion-exchange sites with nitrato complexes, and also will reduce the numbers of water molecules around metal ions, thus enabling the nitrato complexes to be formed at a lower concentration of nitric acid. Because of a low concentration of competitive nitrate ions, the nitrato complexes may easily enter the exchange sites without competing with nitrate ions. Accordingly, a lower concentration of nitric acid is sufficient for the anion-exchange in mixed acetic acid–nitric acid media. This is in accord with the slight dependence of the distribution coefficients of metals on nitric acid concentration (Fig. 3).

Korkisch and his co-workers[8,9] have reported the distribution coefficients of many metals on Dowex 1 in acetic acid–nitric acid media. Fewer metals are adsorbable on DEAE than on Dowex 1. Also, there are great differences in adsorbability of metals on DEAE and on Dowex 1. The ratio of the distribution coefficients for metals:

$$\frac{K_d \text{ on Dowex 1 in 90\% acetic acid–10\% } 5M \text{ nitric acid}}{K_d \text{ on DEAE in 90\% acetic acid–10\% } 7{\cdot}6M \text{ nitric acid}}$$

is approximately 10 for UO_2(II), Sc(III) and Sm(III), 20 for Bi(III), 30 for La(III) and 70 for Th(IV). Based on these observations the sequence of adsorption of nitrato complexes according to the ion-exchange system involved is assumed to be: Dowex 1–acetic acid–nitric acid > Dowex 1–nitric acid ~ DEAE–acetic acid–nitric acid > DEAE–methanol–nitric acid > DEAE–nitric acid.

Separations

Even though a large number of metals can be adsorbed on DEAE from mixed acetic acid–nitric acid media, the number of metals which are retained strongly enough on DEAE columns to allow their separation is still low. Th(IV), Bi(III), W(VI), Mo(VI) and Re(VII) may be separated selectively from many other metals. Some quantitative separations were conducted, and the results obtained are given in Table 2. When each

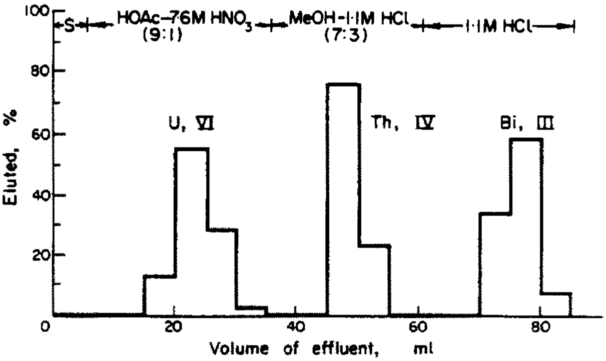

Fig. 4. Chromatographic separation of U(VI), Th(IV) and Bi(III). S: sample solution, acetic acid–7·6*M* HNO_3 (9 : 1).
Added, mg: U 1·24, Th 1·14, Bi 1·05.
Recovered, %: U 98·4, Th 98·3, Bi 101.

separation was repeated more than three times, average and standard deviations are listed for the individual metals. In order to demonstrate the versatility of the present ion-exchange system, most separations were carried out with widely different concentrations (up to 1 : 1000). Under these conditions (runs 6 and 7) traces of Mo(VI) tend to contaminate the W(VI) fraction, but quantitative separation is quite feasible when the two metals are present in comparable amount (run 8).

When W(VI) is involved in separations, the concentration of nitric acid becomes critical. In attempts at separation of Mo(VI) and W(VI) in an acetic acid–7·6*M* nitric acid mixture (4 : 1) containing 0·24% hydrogen peroxide, an appreciable amount of W(VI) passed through the column into the effluent, probably because of the hydrolytic polymerization of tungstic acid. However, this breakthrough of W(VI) was easily avoided by decreasing the concentration of nitric acid to 0·3*M*. Use of increased amounts of the peroxide was not effective in preventing the breakthrough.

Three- and five-component separations are also feasible and are illustrated in Figs. 4 and 5, respectively. The separations were quantitative and no marked tailing was observed.

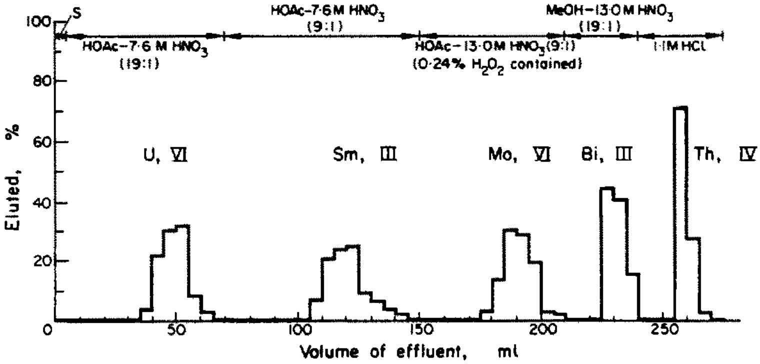

Fig. 5. Chromatographic separation of U(VI), Sm(III), Mo(VI), Bi(III) and Th(IV). S: sample solution, acetic acid–7·6*M* HNO_3 (19 : 1).
Added, μg: U 126, Sm 151, Mo 97·4, Bi 210, Th 114.
Recovered, %: U 107, Sm 101, Mo 98·9, Bi 103, Th 101.

When weakly basic cellulosic ion-exchangers are used in mixed solvents, they do not always exhibit their inherent ion-exchange function, unless a solvent such as methanol or acetic acid is employed. As compared with methanol, addition of which to nitric acid solutions permits only Th(IV) to be taken up on DEAE, acetic acid enhances the formation and stabilization of nitrato complexes to a greater extent, causing many metals to be adsorbed on DEAE. This may be explained by the lower dielectric constant of acetic acid ($\varepsilon = 6{\cdot}2$, 20°) as compared with methanol ($\varepsilon = 32{\cdot}6$, 25°).

Zusammengassung—Es wurde gefunden, daß eine Anzahl von MetallNitratokomplexen aus gemischten Essigsäure-Salpetersäuremedien an DEAE-Cellulose adsorbiert werden, obwohl aus wäßrigen Salpetersäurelösungen keiner adsorbiert werden kann. Die Verteilungskoeffizienten von Sc, Mo, La, Sm, W, Re, Bi, Th und U werden in Abhängigkeit von den Konzentrationen an Essigsäure und Salpetersäure angegeben (manchmal in Gegenwart von Wasserstoffperoxid, um hydrolytische Fällung zu vermeiden). Für 25 andere Metalle wird das Adsorptionsverhalten an einer Säule in einem Gemisch aus 90% Essigsäure und 10% 7·6 M Salpetersäure beschrieben. Günstige Unterschiede in den Verteilungskoeffizienten erlauben nützliche Trennungen, wie Fe–Mo–W und U–Sm–Mo–Bi–Th.

Résumé—On a trouvé qu'un certain nombre de complexes nitrato de métaux sont adsorbés sur la DEAE-cellulose de milieux mélanges acide acétique–acide nitrique, quoique aucun ne peut être adsorbé de solutions aqueuses d'acide nitrique. On donne les coefficients de partage de Sc, Mo, La, Sm, W, Re, Bi, Th et U en fonction des concentrations en acide acétique et acide nitrique (quelquefois en la présence de peroxyde d'hydrogène pour prévenir la précipitation hydrolytique). Pour 25 autres métaux on décrit le comportement à l'adsorption sur colonne pour un mélange acide acétique 90%-acide nitrique 7,6*M* 10%. Des différences favorables entre les coefficients de partage permettent des séparations utiles telles que Fe–Mo–W et U–Sm–Mo–Bi–Th.

COMPLEXATION OF POLYVINYL ACETATE WITH IODINE*

J. G. PRITCHARD and F. T. SERRA
North East London Polytechnic, London, E.15, U.K.

(*Received* 29 *November* 1972. *Accepted* 6 *December* 1972)

Summary—Polyvinyl acetate and iodine form a characteristic red complex in the presence of potassium iodide. Spectrophotometry of the complex at 510 nm in a methanol–water system at 20° yields linear calibration curves over the range 25–100 mg of polyvinyl acetate per l. of final solution. The limit of detection is 0·1 mg of polyvinyl acetate in 0·5 ml of initial sample. Replacement of acetate groups by inert groups reduces the sensitivity of the method, and other details of the system are discussed.

Iodine–potassium iodide tests for polyvinyl acetate (PVAc) and polyvinyl alcohol are of commercial interest.[1,2] PVAc can be identified after it has been separated chromatographically from polyvinyl alcohol and their graft copolymers, by the development of a deep-red colour when the chromatogram is sprayed with I_2–KI solution.[3] PVAc in vinyl acetate[4] and other media can also be detected in this way after chromatography. Aqueous I_2–KI added to a solution of PVAc in glacial acetic acid and diluted with water yields an intense red-violet colour advocated as a qualitative test which is independent of the presence of some copolymers.[5] Some of the variables affecting colour intensity for this reaction in a methanol–water system have been examined recently by Hayashi and co-workers. Absorbances up to 0·7 at 510 nm were recorded with $\sim 10^{-3}M$ iodine and iodide solutions and up to 700 mg of PVAc per l. of final solution, for which it was mentioned that linear calibration curves may be obtained.[6] Here, we present a quantitative examination of the sensitivity, reproducibility, linearity and general characteristics of the phenomenon. Our conditions are similar to those used previously,[6] but our aim has been to use a maximum concentration of iodine to investigate a wider range of absorbance with well-known commercial polymers of the Western world. Our selection of polymers comprises two pure PVAc resins used in organic-solvent based adhesives, glossy paper coatings, textile stiffening agents, and high-gloss printing inks, and one acrylic vinyl acetate copolymer which finds application in aqueous and alcoholic solution as a component of inks and textile sizes.

EXPERIMENTAL

Materials

Pure PVAc resins were "Gelva" grades V-7 and V-100, of respective approximate molecular weights 5×10^4 and 5×10^5, manufactured in the form of small spheres by the emulsion polymerization of vinyl acetate. The copolymer "Vinavil" grade C4, molecular weight 4×10^4, contains a major proportion of acetate groups and a minor proportion of aliphatic carboxylic acid groups which render it soluble in aqueous sodium carbonate solution. Reagents were of analytical grade.

Procedures

Methanolic solutions of the polymers were prepared at concentrations in the range 9–12 g/l. Aliquots of these were diluted accurately and treated with methanolic iodine and aqueous potassium iodine solutions to explore optimum conditions. Spectra of the final solutions were scanned on a Unicam SP 700 spectrophotometer. For the calibration measurements, at least 30 min were allowed[6] for the complex to equilibrate at 20°, then absorbances were measured at 510 nm against a reagent blank on a Hilger–Watts Uvispek spectrophotometer, with 1-cm cells and 0·1-mm slitwidth. The mean of three estimates was taken for each solution. Values of absorbance (A_i) and final polymer concentration (c_i) were determined for optimum conditions, at first with single aliquots, and later with ten replicates of diluted stock polymer solution. For the latter, limits of the true mean values were calculated as $\overline{A}_i \pm ts/\sqrt{10}$, where $\overline{A}_i$ is the mean of 10 results, s is their standard deviation, and t the value of Gosset's t for 99% confidence. Least-squares straight lines were calculated from the A_i and c_i values, and the deviations of individual absorbance values from the lines were calculated from $A_i - c_i \Sigma A_i / \Sigma c_i$ for lines through the point $A_i = 0$, $c_i = 0$, and from $A_i - \{c_i(N\Sigma(A_i c_i) - \Sigma c_i \Sigma A_i) + \Sigma A_i \Sigma c_i^2 - \Sigma c_i \Sigma(c_i A_i)\}/(N\Sigma c_i^2 - (\Sigma c_i)^2)$ for general lines, where N is the number of results. Deviations were also expressed as percentages of the absorbance values on the calculated line.

RESULTS

Table 1 shows the concentrations of iodine and potassium iodide and the order of mixing of reagents adopted in the calibration tests. These concentrations were sufficient to ensure linear calibration curves over the whole range of absorbance available with the Uvispek (0–3), yet just insufficient to cause significant precipitation of polymer provided that due care was exercised. Figure 1 shows spectra of the polymer complexes for these conditions. The maxima occur at 520 and 510 nm for Gelva V-7 and the copolymer, respectively. Concentrations of PVAc in the middle of the range yielded wine-red solutions in which blue and green light is absorbed, mainly by unreacted reagents and the complex respectively. Provided that the methanolic solution was mixed with the aqueous potassium iodide by very gentle swirling, the procedure shown in Table 1 gave a clear solution of complex accompanied merely by a very faint bluish-red film at the surface of the solution. Violent agitation of the final solution produced a deep-red fibrous precipitate of the complex, which reduced the absorbance of the solution, especially in the case of higher concentrations of PVAc. Increase in the concentrations of iodine and potassium iodide by 50% above those listed in Table 1 led to immediate precipitation of deep-red complex mixed with some colourless polymer. A several-fold increase led to a dark, fibrous precipitate of complex even for low concentrations of PVAc. The omission of iodine from the procedure resulted, for example with a 2-g/l. initial solution of PVAc, in a faintly opalescent final solution, owing to precipitated and colloidal PVAc.

Table 2 lists the results of absorbance measurements on single solutions of Gelva V-7 complex prepared according to Table 1. The points deviate less from their general

least-squares straight line than from the least-squares straight line which includes the point $A_i = 0$, $c_i = 0$. In the latter case, the deviations are systematically negative for the lower c_i values. The general line indicates a threshold polymer concentration of 2·7 mg/l. The gradients of the two lines differ by 5%, and the general scatter of results is several per cent. Similar characteristics were observed with Gelva V-100 (not shown) for which the gradient was again ~0·022 l./mg. The sensitivity of the method is not perceptibly

affected by a change in molecular weight by a factor of 10 in the range of PVAc polymers most widely employed in industry.

The results of single determinations with Copolymer C4 are listed in Table 3. This copolymer shows similar characteristics to the Gelva polymer, but the gradient of the calibration graph is ~ 0·016 l./mg and a threshold concentration of 4·1 mg/l. is indicated. Table 3 also includes the per cent reduction in absorbance observed when the iodine and potassium iodide concentrations are reduced by a factor of 5. Linearity is retained and absorbance is reduced by 30% for concentrations of copolymer up to 100 mg/l., but for higher concentrations the absorbance levels off to a maximum of ~ 1·5.

The results above show that the dilution of stock solution, preparation of complex solution, and measurement of absorbance generate a random error of up to ~ 5%. Absorbance appears to be particularly low for initial polymer concentrations below about 10 mg/l., owing to a systematic phenomenon. Table 4 shows the results of replicate dilutions and absorbance measurements on solutions of the Gelva V polymers for initial concentrations > 10 mg/l. For the initial polymer concentration range 10–100 mg/l., the

mean of 10 replicates can be relied upon to within about 1%. At the lower end of this range the dilution procedure is no doubt critical, and at the top of the range absorbance measurements above 2 become critical. Our measurements on the 126·48-mg/l. solution ($A \sim 2{\cdot}8$) showed singularly poor reproducibility, to which lack of quantitative reproducibility of complex formation may contribute. The best straight line which includes the point $A = 0$, $c = 0$ has a gradient close to 0·022 l./mg and again indicates a threshold effect through the low results for initial polymer concentrations < 25 mg/l. The results for the four highest concentrations in Table 4 yield $A = 0{\cdot}02198c$. The results for the two lowest concentrations make only a minor contribution to the value of the gradient.

DISCUSSION

The absorbance of the pure PVAc complex is given within 2% by the equation $A = 0{\cdot}022c$ for the conditions in Table 1 at 20° and c expressed in mg/l. of final colorimetric solution. Replication was necessary to obtain this reproducibility, and the scaling up of our volumetric procedure is recommended. The range is limited to 25–100 mg of PVAc per l. of final solution by a small threshold effect at lower PVAc concentrations and poor precision at the higher concentrations. The method of standard additions is indicated for the determination of small quantities of PVAc. The threshold effect and the lowest measurable absorbance (~ 0·007) give 3 mg/l. of final solution, or ~ 0·1 mg in 0·5 ml of initial solution, as the limit of detection. As far as the final colorimetric solution is concerned, the sensitivity of the method is comparable to that obtained in the determination of polyvinyl alcohol by the borate–tri-iodide method.[1]

The dispersion of PVAc from methanolic solution into water normally causes the collapse of the extended polymer chains and aggregation of low concentrations of polymer to the colloidal state. High concentrations of PVAc result in precipitation under such conditions, as we observed when iodine was omitted from the procedure in Table 1. In our analytical method, the red complex forms at the limit of its solubility. It is therefore unlikely that the complex is a polyelectrolyte involving charged iodine, because this would almost certainly be water-soluble. Rather, the complex is a polymer aggregate in which neutral iodine is chemisorbed. In the case of very dilute PVAc solutions, a large fraction of the polymer molecules may remain in an extended form preferentially solvated by methanol and give rise to the threshold effect under the conditions of the analytical method.

We have found that greater absorbance per unit concentration of PVAc and a more stable solution with respect to precipitation may be obtained if less water is used to dilute the system, for example, as when the methanolic PVAc–I_2 solution (Table 1) is first diluted with pure water until it contains ~ 35% of methanol, and then almost half of its volume of potassium iodide solution is added as the last step. However, the absorbances of final solutions containing 20–40% of methanol slowly increase with time. This suggests that complex formation is accompanied by slow crystallization or orientation of the polymer chains, which can be rapid in highly aqueous solutions. A similar phenomenon may occur following the disappearance of the absorption-band characteristic of the complex at temperatures > 30°, when the solution is cooled back to 20° and the band returns. The red acetate complex is thermodynamically unstable at 30° and differs in this respect from the blue polyvinyl alcohol–borate–iodine complex which is stable at this temperature.[1,7]

In the presence of sufficient potassium iodide, the proportion of iodine which reacts with PVAc is 7·3% by weight at 20°, whether the PVAc is dispersed *via* methanol in aqueous solution or is merely suspended as a fine solid in contact with the aqueous medium (although the apparent iodine potentials recorded with the two phases differ by ~ 10 mV).[8] This corresponds to one iodine atom for every 20 acetate groups in pure PVAc. Under the conditions of our analytical method, sufficient iodine is present to exceed this requirement by a factor of about 40 in the case of the highest concentration of PVAc used, and this ensures approximate constancy of the contribution made by unreacted reagents to the absorption of the analytical solution. However, the fact that only one acetate group in 20 is involved suggests that iodine is complexed at special sites or that complex formation requires the orientation of several polymer segments.

The sensitivity of the analytical method for Copolymer C4 is reduced by 26% from that for pure PVAc. The proportion of bound iodine must be similarly reduced owing to the lesser number of acetate groups. If a proportionate relationship between concentration of complex and acetate groups is assumed, the analytical method shows about a 74% vinyl acetate contribution in this copolymer. (The threshold concentration for the copolymer is consistently higher than for pure PVAc, but we cannot be sure of the mechanism governing this phenomenon.) The characteristic absorption-band of the red complex is also easily observed for copolymers of vinyl acetate which contain 85–98% of alcohol groups in place of acetate (substantially hydrolysed PVAc).[1] These hydrophilic (co)polymers are very soluble and are in their extended forms in water. We conclude, therefore, that two things are necessary for the formation of the red complex in the I_2–KI system: co-ordination by water, and the orientation of several polymer segments around each iodine unit. The degree of extension of the polymer chain appears in itself to have only a minor influence on the formation of the complex. Further work in this area is clearly desirable.

Summary—The error in a determination of an element in a rock or mineral sample depends on the analytical error, the weight of sample analysed, and the nature and history of the laboratory sample. The most probable result is not independent of the weight of sample analysed. This is due to the fact that trace constituents often reside in isolated mineral grains. The chance of such mineral grains appearing in any one analysed sample becomes more remote as the sample weight decreases, even when rock or mineral samples are reduced to fine powders. Such subsampling errors can be controlled through the use of sampling constants. These may be estimated by several procedures, including repetitive determination of a constituent and physical measurement of relevant sample characteristics. Sampling constants can be usefully employed during the establishment and certification of reference samples or standards. When subsampling is deficient, analytical results may yield erroneously low values, sometimes with high precision. High precision never implies high accuracy; it may be a symptom of gross error.

Laboratory samples of rocks and minerals frequently yield unrepresentative analytical subsamples.[1–5] Though laboratory subsampling error is sometimes insignificant, it can be much greater than intuition would predict.[6] It becomes more important as the concentration of the element of interest diminishes, and, in analyses for trace elements, probably constitutes one of the largest single sources of experimental error.[7,8]

Most geochemical analyses are now accomplished by rapid instrumental methods which compare signals generated by standards and unknowns. Subsample weights are often dictated by the peculiarities of the method, and may be small, ranging from a gram or less for chemical methods down to a few micrograms or nanograms in spark-source mass spectrometry[5] and electron-probe microanalysis. With the comparison methods, the subsampling characteristics of both standards and unknowns have an effect on the overall experimental error. Quantitative estimation of this effect is desirable.

The relative standard deviation (R, %) of the results for one component, when the laboratory sample has been prepared in a particular way to pass a specific mesh size, varies inversely as the square root of the weight (w) of the analytical subsample,[7,8] and a sampling constant (K_s) can be defined by

$$R = \sqrt{K_s/w} \qquad \text{or} \qquad K_s = R^2 w \tag{1}$$

This relationship presumes that the subsample corresponds to at least a certain minimum number of particles and that the sample is well-mixed, so that a combined result from two subsamples, each of weight w, has the same subsampling variability as a single subsample of weight 2w. This assumption of thorough mixing, sometimes loosely and erroneously referred to as sample homogeneity, is to be understood to apply throughout. It does not require that all the mineral grains be of the same size; it requires only that they be randomly distributed throughout the sample, and randomly taken during removal of the analytical subsample. For our purposes, we shall refer to it as "uniformity." It is a qualitative term, since no mixture of minerals can possibly be either homogeneous or uniform, no matter how finely ground or thoroughly mixed.

The sampling constant, K_s, has the units of mass. It is the subsample weight necessary to ensure a relative subsampling error of 1% (68% confidence) in a single determination. Its square root is numerically equal to the expected coefficient of variation for results obtained on 1-g subsamples in a procedure which is free from analytical error.

It should be noted that grain size and distribution do not enter this relationship. The sampling constant is specific for each constituent of a sample in a given state of subdivision. Further grinding of a sample will usually (not always) lower the sampling constant for each constituent.

Sampling constants will usually be estimated from a series of determinations by the same method under controlled conditions. The observed variability of such a series will include both analytical and subsampling variability, so that the subsampling characteristics cannot be determined from it unless there is an independent estimate of analytical variability, or unless there is good reason to believe that analytical variability is negligible compared to subsampling variability. Generally, if the subsampling error is greater than three times the analytical error, the latter is of no consequence.[9]

Once the subsampling characteristics of a given sample have been determined for any constituent, they should be included in any report of sample composition; in the case of "standard" or "reference" samples, sampling constants should be included in any certification. It would then be possible for an independent investigator, using further subsamples of the same material, to distinguish between the analytical variability of his method of analysis and variability due to his subsampling process. It would also be possible for him to estimate the overall precision attainable by his method, as a function of subsample weight.

Knowing the sampling constant for a constituent of a sample and also the subsample weight, an analyst can readily calculate the contribution of subsampling error to the probable deviation of a single analytical result. In general, this deviation can be translated into error bars of determinable length by using Gaussian statistics. In trace-element analysis, however, and also in the analysis of highly purified materials, the distributions of subsample determinations may be decidedly skew for sufficiently small subsample weights, and probabilities cannot be well measured by using Gaussian statistics. In such cases, better approximations of the probabilities are given by use of Poisson statistics.[10]

The sampling constant principle has been developed previously by Gy,[11,12] Visman,[13] and others in dealing with the collection, reduction, and preparation of samples from large masses of material. While the various statistics that apply in bulk sampling are generally similar to those applying in laboratory subsampling, they cannot be correctly used in the latter operation without modification and shifts of emphasis. In particular, assumptions of symmetrical distribution become less true as sample weight decreases, and at the laboratory subsampling level often lose all validity.

Gy's basic sampling equation has been explained and discussed by Ottley.[14] The validity of Visman's "*General Theory of Sampling*" has been examined by Duncan[15] and by Visman, Duncan and Lerner.[16] Visman proposes the use of two sampling constants, one of which deals with errors arising from the presence of more than one species in the material to be sampled, and the other with errors due to segregation or unmixing. The latter is not relevant to the present discussion, in which it is assumed that unmixing and segregation difficulties may be overcome in good laboratory practice by careful mixing of laboratory samples and the use of appropriate methods for splitting out the analytical subsamples. A test for the "homogeneity" of a mixture has been developed by Schaeffer,[17] who has also written on the problem of sampling mixtures of "multisized" particles.[18]

RESULTS FOR DISCUSSION

Table 1 shows ten sets of K_2O determinations done by a method of high precision,[6] three on samples which are uniform at the 100-mg subsampling level, and seven on non-uniform samples, obtained during a search for suitable calibrating standards. The results show that the laboratory subsampling error may be much greater than is generally recognized. Of the non-uniform samples, the basalt and the granodiorite GSP-1 show variations typical of rock powders of this type; the biotite contains hornblende and other low-potassium impurities; the white mica shows a wide variability in its potassium content under the microprobe, although it appears homogeneous under the microscope; the pyroxene contains feldspar grains which result in discrete differences among the several values; the beryl contains muscovite inclusions which are inseparable even when the sample is ground to pass a 200-mesh sieve.

Table 2 summarizes the results of repetitive determinations of K_2O in various reference samples, together with sampling constants and other information. Potassium determinations are very useful for illustrative purposes because the methods used are intrinsically precise, having been developed over many years by those interested in K–Ar dating.

Lawrence Smith[22] attack, double leach,[20] chloroplatinate separation,[19] conversion into sulph for weighing; minor alkalies determined by flame photometry,[25] and corrections made. 2. Flame photometry.[25] 3. Shapiro a Brannock.[24] 4. $LiBO_2$ fusion, HNO_3 solution, flame photometry using Li from the flux as an internal standard.[6,82]

† LP-6 Bio is a biotite of 99·9% purity[44,45] available from J. C. Engels, 348 Waverly St., Menlo Park, California, USA 94025.

§ The sampling constant reported for G-1 is based on 12 determinations by method 4: results by other methods confirm estimate.

‡ Precision of the method is not good enough to detect any subsampling variability in these samples.

Methods include gravimetric procedures using chloroplatinate,[19] perchlorate,[20] or tetraphenylborate,[21] usually applied after a Lawrence Smith[22] or Berzelius[19] decomposition. Flame emission and absorption methods[23–30] and isotope-dilution mass spectrometry[31] are most often used. Neutron-activation analysis[32–33] and combined neutron-activation and mass spectrometry[34–35] have been applied. X-Ray spectrography is a common method.[36–39]

Because of the effort which has gone into the refinement of all these methods, it is reasonable to assume that they contribute less than usual to the variance of the results. The high precision attainable has been well documented in other work,[6,26] and is supported by data in Table 1.

Repetitive determinations of K_2O in the USGS dunite DTS-1 are shown in Table 3. They demonstrate the effect of subsample weight on analytical results.

Sixty-four determinations of sodium and potassium in the USGS basalt BCR-1, using eight separate bottles of this sample, provided an estimate of sampling constants for K and for Na. Results for potassium are included in Table 2 and for sodium in Table 4. The data are those of Goldich *et al.*[40] During this series of determinations there was evidence of unmixing of the samples, and some of the variance in the results may be due to this. Later work in the USGS Menlo Park laboratories with a single bottle of BCR-1 gives a somewhat lower sampling constant for potassium (Table 2).

Analyst, L. B. Schlocker.

A large (21-g) sample of the USGS granite G-1 was treated with hydrofluoric, then sulphuric and boric acids; the soluble portion was discarded. The insoluble matter weighed about 5 mg, of which 0·4 mg was chromite in the form of about 100 grains, all of about the same shape and size. These were hand-picked from the residue and their identity confirmed by emission spectroscopy and X-ray diffraction. A simple calculation shows that the chromite accounts for a large part of the chromium content, and that a 100-mg subsample contains, on the average, about half a grain of chromite.

Eight subsamples of the USGS dunite DTS-1 were examined for their chromium content by Goldich *et al.*[40] Sampling constants for chromium are reported in Table 4.

Ferrous iron in the USGS samples AGV-1, BCR-1, and W-1 was determined by the Cooke method[19] on 500-mg subsamples. The method is somewhat difficult to use, as evidenced by the wide variance in inter laboratory results,[41] but can be capable of high precision in skilled hands. Repetitive determinations established its precision as better than ± 0·02% FeO.[42] The method does not always recover all the FeO, some being present in insoluble minerals.[40] The results are reported in Table 4.

The relative standard deviation of 12 determinations of rubidium in 100-mg subsamples of the USGS granite G-1 by the method of Medlin *et al.*,[30] slightly modified, was 10·4%. The relative standard deviation for potassium in the same subsample solutions by the

method of Engels and Ingamells[6] was 0·3%. Both deviations are corrected for analytical error, measured by repetitive runs on uniform samples. Fabbi found a relative standard deviation of 3·2% in 12 determinations of rubidium in 500-mg pelleted subsamples of G-1 by X-ray fluorescence:[43] relative analytical error, found by repetitive runs on a single pelleted subsample, was about 1%. These results have been used to estimate the subsampling characteristics of G-1 with respect to rubidium and potassium. Results appear in Table 4.

Sampling constants for several constituents of LP-6 Bio 40–60# have been estimated.[44,45] Results for several elements are reported in Table 4, and for potassium in Table 2.

Table 5 shows 12 determinations of potassium in a separated pyroxene. Six determinations on the same mineral after its further purification are shown in Table 1, column 2.

Table 5. Repetitive K_2O determinations on a pyroxene*

* Arranged in order of increasing K_2O. Analyst, L. B. Schlocker. After repurification, the sample yielded values for K_2O ranging from 0·0113 to 0·0115 (Table 1, column 2). The results imply that c is 0·0022–0·0026. Statistical treatment reveals that c is actually half this, and that the subsamples showing 0·0203% K_2O actually carry 8, not 4 grains of high-potassium contaminant.

† $x_i = K_2O$ determined; x_{min} is presumed equal to H.

Twelve determinations of potassium on the amphibolite–orthoclase mixture used by Engels and Ingamells to demonstrate the effects of sample non-uniformity in K–Ar dating[6] are reported in Table 6.

Sampling constants for potassium in the Bern Muscovite 4M, the Bern Biotite 4B, the Nancy Biotite Mica-Fe, and the Nancy Phlogopite Mica-Mg have been determined by repetitive determination. Results are reported in Table 2. The Phlogopite Mica-Mg is probably the purest mineral sample ever prepared in quantity. Even the highly precise method by which most K_2O values reported in this paper were obtained, cannot reveal subsampling non-uniformity in Mica-Mg, and its sampling constant, like that for the Penn State orthoclase Or-1, must be reported as $\leqslant 0·01$ for potassium. Twelve separate determinations of K_2O in Mica-Mg yielded eleven at 10·17% and one at 10·16%. This sample will be of great value to anyone bent on finding the precision of a method for potassium in micas, since all variance in his determinations of K_2O in this sample can be attributed to analytical error.

Table 6. Repetitive K_2O determinations on an amphibolite–orthoclase mix*

* Engels and Ingamells.[6] An average of 0·286% K_2O was obtained from 40 determinations on 100-mg subsamples, with a standard deviation of 0·045%. The mixture is 99% amphibolite with 0·145% K_2O, and 1% orthoclase with 14·92% K_2O.

† Calculated by using equations (4) and (5); the calculated numbers (in parentheses) have been rounded to whole numbers of grains. The non-integral calculated results may be attributed to non-uniformity of grain size. The probability is 0·98 that at least one of these 12 determinations represents the composition of the amphibolite and that the subsample contains no orthoclase grain.

THE SAMPLING CONSTANT

A sampling constant can usually be well estimated from a series of subsample determinations, provided that the subsample weight is appropriate. If analytical error is small (less than one-third of the subsampling error[9]), and $x_1, x_2, \ldots, x_i, \ldots, x_M$ are the results of M determinations on subsamples of weight w g, K_s is estimated by

$$\hat{K}_s = \hat{R}^2 w = \frac{10^4 w \Sigma (x_i - \bar{x})^2}{(M-1)\bar{x}^2} \tag{2}$$

where $\bar{x}$ is the arithmetic mean of M determinations. The relative standard deviation for the same constituent in a future subsample of weight w_F is then estimated by

$$\hat{R}_F = \sqrt{\hat{K}_s / w_F} \tag{3}$$

The usual reason for computing the estimate $\hat{R}_F$ is that it can be related to probability statements or error bars. Specifically, the probability is about 2/3 that a future subsample will yield a value which differs from the mean value by less than $\hat{R}_F$%, and about 0·95 that the difference from the mean will be less than $2\hat{R}_F$%, always supposing that the analytical error is less than 1/3 the subsampling error. This statement is correct if $\hat{K}_s$ is derived from a sufficiently large number of previous determinations, and there is an approximately Gaussian symmetry of the theoretical distribution of values based on subsample weight w_F. If the estimate $\hat{K}_s$ is based on 10 or more determinations, the statement should not be too far wrong, except under some very important special circumstances mentioned immediately below.

A serious limitation on these statements, one which marks the essential difference between bulk sampling and laboratory subsampling, and which must be considered in analysis for trace elements and when analytical subsamples are small, is the frequent lack of symmetry in the distribution of repetitive analytical results. When a constituent (whether a species of interest or a contaminant) is concentrated in a few mineral grains, the theoretical distribution of single determinations is approximately of Poisson type.[10,46] When the number of such grains averages less than five or six per subsample, this Poisson distribution has a noticeable asymmetry, with low values occurring frequently and high values more seldom. An average of results from too few subsamples will probably be erroneously low. To illustrate this, histograms of results for trace elements in a 200-mesh greywacke[4] are shown in Fig. 1. These may be compared with histograms based on the Poisson distribution, calculated by processes to be described.

In such cases, the observed variability in a series of subsample determinations can be ascribed to a variability in the number, z, of these grains per subsample. If these grains are of approximately equal size, a single analytical result will have the value

$$x_i = H + cz_i \tag{4}$$

where H is the concentration of the element of interest in the gangue or matrix, and cz_i is the contribution of the z_i "special" grains to the result. The units of c are unusual, namely "absolute whole sample concentration per grain"; i.e. for 6 grains and $(x_i - H) =$ 0·06% absolute, $c = 0{\cdot}01\%$ absolute per grain. There will be a Poisson distribution of z_i among several subsamples of statistical mean z. A good estimate of the contribution of a single such grain to an analytical result is

$$\hat{c} = \frac{s^2}{\bar{x} - H} \tag{5}$$

where s^2 is the variance of the results of M determinations (M large enough).

According to this model, the series average, $\bar{x}$, will be an estimate of $H + cz$, and the series variance, s^2, will be an estimate of c^2z. Further, when z is small and M is sufficiently large, it becomes likely that the smallest determinative value in the series, $x_{\min}$, will have

	CHROMIUM	ZIRCONIUM	COPPER	LANTHANUM	SCANDIUM	BERYLLIUM	YTTRIUM	VANADIUM
$\hat{z}$	1.08	1.22	1.33	1.45	1.67	2.17	2.54	4.22
$\bar{x}$	27.07	446	15.6	56.1	25.9	2.86	41.41	76.0

Fig. 1. Histogram of analytical results for trace elements in a greywacke: data from Ondrick and Suhr.[4]

$z_i = 0$, and will provide an estimate of H. In particular, the probability of obtaining a subsample free from "special" grains is

$$P_{(z_i=0)} = 1 - (1 - e^{-\bar{z}})^M \tag{6}$$

For example, if $M = 20$ and $z = 2{\cdot}0$, $x_{\min}$ will estimate H with a probability of about 94%. In such cases, z can itself be estimated by

$$\hat{z} = (\bar{x} - x_{\min})^2/s^2 \tag{7}$$

Obviously this estimate should only be used if it yields a high value for $P_{(z_i=0)}$ when substituted into (6), or if (as is the case with the pyroxene in Table 5) other evidence exists that $x_{\min}$ is a good estimate of H.

To illustrate further, if $x_{\min} = 2{\cdot}05$, $\bar{x} = 2{\cdot}15$, and $s^2 = 0{\cdot}005$, then the implied estimate of z is $\hat{z} = 2{\cdot}0$ by equation (7). As remarked earlier, Gaussian statistics provide an appropriate approximation only when z is greater than about 6; hence, for use of Gaussian statistics in this example, the subsample weight should be increased by a factor of three, or the determinations grouped in threes according to the central limit theorem, before statistical manipulation. The histograms in Fig. 1, showing the calculated and observed distributions of the data of Ondrick and Suhr,[4] illustrate this. The histogram interval is calculated from equation (5), assuming that $x_{\min} = H$. Note that as $P_{(z_i=0)}$ decreases, the pairs of histograms lose their similarity. Spectacular examples of non-Gaussian distributions are given by Jones and Beaven.[10]

In analysis for trace elements, it is always possible that the subsample weight chosen may be small enough for no "special" grains to appear in any of M subsamples, especially when, as often occurs in practice, M is small (duplicate or triplicate samples) and subsamples are small (*e.g.*, 10-mg subsamples in d.c. arc spectroscopy).

An estimate of the probability that $z_i = 0$ for a particular subsample is given (for samples of uniform grain size) by

$$\hat{P}_0 = e^{-dw_F} \tag{8}$$

where d is the number of "special" grains per unit weight of sample. If sufficient subsample determinations are available, and the proportion P_0 of them gives values corresponding to the background (matrix) level, then an estimate of d is given by

$$\hat{d} = \left(\frac{1}{w_F}\right)\ln\left(\frac{1}{P_0}\right) \tag{9}$$

In practice, a subsample weight can be chosen which, in M analytical determinations, will yield results with one of three characteristic distributions.

Distribution 1. An approximately symmetrical (Gaussian) distribution, when the mean z exceeds 5 or 6.

Distribution 2. A skewed, approximately Poisson, distribution, in which the mean z is less than 5 or 6.

Distribution 3. An approximately symmetrical (Gaussian) distribution, when z_i is 0 for all subsamples.

It is often impossible to distinguish between the first and third distributions, especially if all subsamples are of the same size. When analytical error is undefined, it is impossible to be sure that a distribution of the second kind reflects characteristics of the sample. When an analytical method can only use small subsamples (*e.g.*, d.c. arc spectroscopy,

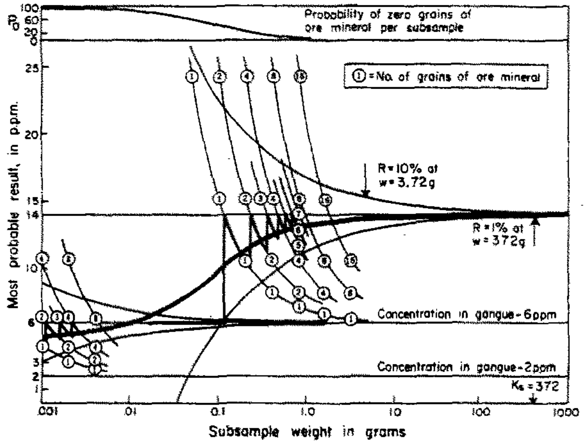

Fig. 2. Subsampling diagram for a hypothetical 200-mesh mixture of three minerals—one of s.g. 4·5 with 50% of an element contributing 8 ppm to the total, one of s.g. 2·7 with 0·2% contributing 4 ppm, and a gangue mineral of s.g. 2·7 with 2 ppm of the element. As subsample weight decreases from 1000 g, relative subsampling error increases to 1% at 372 g, and to 10% at 3·72 g. As the subsample weight continues to decrease, Gaussian statistics no longer yield a reasonable error estimate, the most probable result is determined by the number of grains of ore mineral per subsample, and the plotted relationship becomes discontinuous, following Poisson statistics. At subsample weights less than about 10 mg, any reasonable number of subsamples may not include any grain of ore mineral, and Poisson distribution of the results is due to grains of the mineral with 0·2% of the element of interest. The dark line is drawn to show the general trend of the graph, corresponding to a real situation in which mineral grains are only approximately of uniform size.

spark-source mass spectrometry, electron-probe microanalysis), the possibility that the third distribution applies becomes greater as the concentration of the species of interest diminishes.

Figure 2 is a subsampling diagram for a hypothetical 200-mesh rock powder, in which the species of interest exists in three forms—as a major constituent of a minor mineral, as a minor constituent of a minor mineral, and as a trace constituent of a gangue within which these minerals are randomly distributed. For the purpose of illustration, the overall concentration of the species of interest has been taken as 14 ppm, of which 8 are due to an ore mineral of s.g. 4·5 and containing 50% of the species of interest, 4 are due to a mineral of s.g. 2·7 containing 0·2%, and 2 are evenly distributed in a gangue mineral of s.g. 2·7.

For such a mixture $K_s = 372$ g. If 1-g subsamples are taken, each will contain, on the average, about 8 grains of ore mineral, and repetitive determinations will exhibit a relative standard deviation of $R = \sqrt{K_s/w} = 19\%$. If 100-mg subsamples are taken, the chances are about even that any one of them will contain a grain of ore mineral: results will be highly variable, their distribution will be highly skewed, and unless a very large number of determinations is performed (38 will be necessary to achieve a relative subsampling error of less than 10%), the average will be grossly in error. If a few 10-mg subsamples are taken, the chances are high that no grain of ore mineral will appear in any subsample; variance will be low, the results will appear precise, and their average will be very inaccurate. With still smaller subsamples, the most probable result continues to diminish, until, with techniques like electron-probe microanalysis and spark-source mass spectrometry, only the background concentration of 2 ppm in the gangue mineral will usually be measured.

It may be that reference samples should be certified in terms of each constituent determined at more than one level of subsample weight. There should be a value useful to those whose analytical technique requires small subsamples and who measure the gangue concentration, and another value useful to those who take large subsamples, and who approach (along the major curve of Fig. 2) a measurement of the overall concentration of the element in question. For example, the "gangue" or background concentration of chromium in the USGS granite G-1 is almost certainly about 10 ppm, and this is the value most spectroscopists will find most of the time if they take 10-mg subsamples. The overall concentration of chromium in G-1 is closer to 20 ppm, because at least half of the chromium occurs in isolated chromite grains, which only occasionally appear in the spectroscopist's 10-mg subsamples. On average, only one in twenty 10-mg subsamples of 170 mesh G-1 contains a grain of chromite. The spectroscopist will be tempted to omit the occasional "absurdly" high value of 200 ppm, and may report an average of 10 ppm, claiming high precision except for an occasional "anomalous" result. On the other hand, a chemist using 1-g subsamples in a colorimetric procedure will find his results very variable, since each of his subsamples will contain a randomly variable number of grains of chromite. He will report an average of about 20 ppm, with poor precision. Plainly, prior knowledge of the sampling constant for Cr in G-1 which has been ground to pass a 170-mesh sieve would alert both workers to the inadequacy of G-1 as a standard for chromium determination, and would lead them to avoid controversy concerning their apparently incompatible results.

It must be mentioned that in the 80-mesh G-1 supplied, most of the chromite grains pass a 170-mesh sieve. The sampling characteristics of G-1 for chromium are not greatly improved if it is ground to just pass 170-mesh. Further, the amount of material which is ground must be considered. Whatever weight of sample is made uniform by fine grinding or isoformation retains the error corresponding to that sample weight, and this error cannot be diminished by any subsequent treatment.

Generally, when P_0, as defined in equation (8), is close to 1, it becomes likely that distribution No. 3 will apply, and that all M values will show only the background (gangue) concentration.

The major curve of Fig. 2 corresponds approximately to the relationship

$$Y = K - \frac{(K - H)}{(2z + 1)},$$

where Y is the most probable result and K is the true overall concentration of the species of interest. For samples in which the "special" grains are uniform in size, this relationship is obviously unrealistic; however, for real samples in which an unknown grain-size distribution exists, it may provide a useful means of estimating the probable negative bias due to the use of too small a subsample. In determining Cr in G-1, for example, a 100-mg subsample will yield a most probable value of

$$20 - \frac{(20 - 10)}{(2 \times 0{\cdot}5 + 1)} = 15 \text{ ppm Cr}.$$

It makes no difference whether a single 100-mg subsample or ten 10-mg subsamples be taken; it is the total subsample weight which determines the bias. For example, a spectroscopist taking five 10-mg subsamples and a chemist taking one 50-mg subsample both have exactly the same chance of selecting a "special" grain: the average of 100 determinations on 10-mg subsamples carries the same probable error as a single determination on a 1-g subsample, supposing analytical error to be negligible.

Only occasionally may a sampling constant for one element in a given sample logically be related to that for another. Thus, potassium and rubidium in G-1 do not exhibit similar sampling constants, although these two elements are geochemically related. Concentration of the rubidium in biotite results in a sampling constant that depends on the distribution of biotite grains in the rock powder, whereas the sampling constant for potassium depends as much on the distribution of feldspar grains. On the other hand, the distribution of radiogenic argon may very well be related to potassium distribution, because the former may be expected to occupy the same crystal sites as the potassium which generated it: repetitive determinations of potassium in a mineral sample may be used, in favourable cases, to establish a sampling constant for argon as well as potassium. There are obvious exceptions: for example, a sample containing two generations of biotite, both with the same K_2O content, will probably exhibit a larger sampling constant for argon than for potassium. It may even be possible to utilize this in detecting geochronological inhomogeneity.

Most separated minerals carry no more than one important contaminant. For example, separated hornblendes are most likely to contain biotite as the only important contaminant. It is therefore useful to examine the sampling characteristics of two-component mixtures. Even when more than two species are present, several may often be usefully grouped together and considered as a single species.

For a two-component mixture, the relative standard deviation can be expressed in terms of the physical properties of the analytical subsample:[6]

$$R = \left| \frac{100\sqrt{pq}}{\sqrt{n}} \cdot \frac{B - H}{K} \right| \tag{10}$$

where p is the volume proportion of the species with $H\%$ of the constituent of interest, q is the volume proportion of the species with $B\%$ of the constituent of interest, K is the true overall average concentration of the constituent of interest in %, and n is the effective number of grains in an analytical subsample of weight w.

In dealing with silicate minerals, the simplifying assumption that each has the same density is usually valid. When the minerals in a two-component mixture are of different densities, it is necessary to distinguish between volume proportions p and q, and weight proportions p_w and q_w. The difficulty in doing this has been emphasised by Wilson.[7] The two proportions are related as follows:

$$p = \frac{d_B p_w}{d_B p_w + d_H q_w}; \qquad q = \frac{d_H q_w}{d_B p_w + d_H q_w} \tag{11}$$

where d_B and d_H are the densities of the two mineral species. The total number of grains in a subsample of weight $w = w_B + w_H$ is

$$n = \frac{w_B}{d_B(10^{-4}u)^3} + \frac{w_H}{d_H(10^{-4}u)^3} \tag{12}$$

where u is the effective linear mesh size in μm. Using the identities[6] $p + q = 1$,

$p_w + q_w = 1$, $KR = p_w HR_H - q_w BR_B$, and $K = p_w H + q_w B$, and substituting (10), (11), and (12) in (1) gives

$$K_s = \left(\frac{Bd_B - Hd_H}{K}\right)^2 \cdot \frac{p_w q_w u^3 w}{d_B w_B + d_H w_H} \cdot 10^{-8}\ \text{g} \tag{13}$$

Appropriate approximations can be made in (13), depending on the problem at hand. If a sampling constant for a trace element present as a major constituent of a minor mineral is sought, H and w_B are close to zero, and

$$K_s \sim (B/K)^2 \cdot p_w q_w u^3 d_B \cdot 10^{-8}\ \text{g} \tag{14}$$

In some cases, *e.g.*, that of Cr in G-1, it is possible to estimate each of the factors in (13) or (14) and to calculate a sampling constant. If the average Cr content of G-1 is 20 ppm, half of which resides in chromite grains, and the mesh size is 177 μm (80-mesh), K_s is calculated to be 2200, with $\sqrt{K_s} \sim 47$. A similar value is obtained from the count of chromite grains in G-1, reported above. Since an average 1 g of G-1 contains about 5 grains of chromite, the standard deviation of the number of grains expected in a 1 g subsample is $\sqrt{5}$, and the relative deviation is $100\sqrt{5}/5 = 44\%$, which gives $\sqrt{K_s} = 44$. Calculations of this sort cannot be very exact, but they can quickly provide estimates which are useful for avoiding gross error.

Sometimes microprobe or microchemical data may be useful in estimating sampling constants. For example, individual grains of the MIT biotite B-3203 show 9·38% K_2O,[47] whereas bulk analyses show 9·04%. If the impurities responsible for the difference are all low in potassium, equation (10) may be used to estimate R for a 1-g subsample, and hence a sampling constant from equation (1). Using the identities $p + q = 1$ and $pH + qB = K$, and putting $n = 20{,}000$, $B = 9{\cdot}38\%$, $H = 0\%$, and $K = 9{\cdot}05\%$ gives $R = \sqrt{K_s} = 0{\cdot}55$. This corresponds to an estimate of $\sqrt{K_s} = 0{\cdot}44$ obtained by repetitive determination (Table 2). Grinding the biotite B-3203 to pass a 115-mesh sieve increases n by a factor of about 16, and reduces R for a 1-g subsample, and hence $\sqrt{K_s}$, by a factor of 4. Confirmation of this is given by a value of 0·10 for $\sqrt{K_s}$, obtained through repetitive determination on 0·5-g subsamples of 115-mesh material (Table 2).

In laboratory practice, sampling constants will usually be estimated by doing sufficient determinations, using one or more judiciously selected subsample weights and an analytical method of high precision; but sometimes it may be adequate and convenient to estimate, by optical examination, the distribution of relevant grains of ore minerals. If, for example, each of several 100-mg subsamples of a 100-mesh carbonatite examined under the microscope shows a low and variable number of grains of heavy minerals such as ilmenite, columbite, or magnetite, there is not much point in proceeding with spectrographic analyses for niobium, titanium, or iron unless a procedure can be devised to overcome the essential non-uniformity of the sample.

When analyses of grossly non-uniform materials (*e.g.*, chondritic meteorites) are reported, qualitative observations on the non-uniformity and its adverse effect on precision are not very helpful; a full description of sampling and subsampling procedures, and a statement concerning the subsampling characteristics of the final laboratory sample, would seem to be essential. Such a description is much simplified by use of a sampling constant for each element. Without such a description, the data may have little meaning.

SUBSAMPLING PROCEDURES

The laboratory sample of a rock or mineral is usually supposed to represent a much larger mass of material. The extent to which it is representative may influence the subsampling. Errors introduced in sample collection and reduction may be so large[11,48] that any subsampling error is negligible if the composition of the parent mass is sought. However, if the same rock or mineral powder is to be used as a reference sample, its source is of little significance but its subsampling characteristics are of prime importance. With separated minerals, almost all the sampling error may arise during laboratory subsampling if this is not done with great care, because it is the composition of the pure mineral which is sought.

Fine grinding of the laboratory sample is the most effective way of improving its subsampling characteristics, but this is often contra-indicated because of the possibility of alteration or contamination. Argon, hydrogen, carbon, sulphur, oxygen, mercury and many other elemental constituents may be affected, and erroneous results obtained if grinding is overdone. It is frequently necessary to accept the subsampling error concomitant with the use of coarse sample powders, and this error should be estimated and reported to permit rational evaluation of the results. When fine grinding of the sample is permissible, there is the question of how much to grind, and to what mesh size.

With separated minerals, fine grinding may be intended to break up mineral aggregates before further purification. For this purpose, the portion of the laboratory sample taken is irrelevant, unless the analysis of the purified material is to be used to correct that of the impure material. Purification of separated minerals may actually increase the subsampling error, but the result, though less precise, comes closer to the composition of the pure mineral. Such considerations are of prime importance in geochronology.[49]

Very often, a laboratory sample is subsampled in two steps: a portion is ground to finer mesh size, and this is subsampled for analysis. If the error introduced in the first step is high, no amount of care during the second will correct matters. The results refer only to the portion actually analysed, and if that is not representative of the whole, will give only an estimate of the composition of the whole. Estimation of a sampling constant for each relevant constituent at each stage of the sample reduction process, by one or more of the methods suggested above, will give control of the process. For example, grinding 1 g of granite G-1 to a fine powder cannot reduce the subsampling error for rubidium to less than 1·7% (Table 4), or that for chromium to less than 50%, because these errors are introduced at the time the 1-g subsample is taken.

In some cases, a large subsampling error may be of great value in determining the purity of a contaminated mineral, and fine grinding, although it improves reproducibility, may destroy important information. An example is given in Table 5. Examination of these results for potassium in a pyroxene shows qualitatively that the subsampling variance is probably due to the presence of isolated grains of a high-potassium contaminant, which are randomly selected during subsampling. The table is arranged to show that, qualitatively, the highest value may derive from 4 grains of high-potassium contaminant in the subsample. By use of the principles outlined above, the qualitative observation is shown to be probably incorrect. The data yield the following information: the mean of the 12 determinations is $\overline{x} = 0{\cdot}0180\%$, the estimated standard deviation is $s = 0{\cdot}00272\%$, the matrix content of K_2O is $H = 0{\cdot}0113\%$, the contribution of a single grain of contaminant to an analytical result is $c = s^2/(\overline{x} - H) = 0{\cdot}0011\%$ K_2O, and there are in the average subsample $z = (\overline{x} - H)^2/s^2 = 6{\cdot}1$ grains of contaminant. The grain size of the contaminant cannot be greater than will pass the sieve used to prepare the sample—in this case 177 μm, and this implies that the K_2O content of the contaminant is at least $B = nc = 6\%$, where n is the minimum total number of grains in a subsample, about 6000 from equation (12). Since about six grains of contaminant are present in the average subsample, the purity of the separated mineral is at least 99·9%. Evidently this high degree of purity was inadequate for the purpose.

The pyroxene came from the Dufek massif in Antarctica, and was one of a series of minerals dated by the K–Ar technique in research on pyroxene from various geological environments. The sample was analysed repetitively for potassium because its purity was critical to interpretation of the data. The first analyses showed sampling non-uniformity and hence impurity. The values of Table 5 showed, by the processes outlined above, that the impurity was a high-potassium mineral making up not more than one grain in 1000 of the sample. Such impurity is not likely to be detected in any other way. Further purification yielded a sample which gave the footnote values in Table 5. The collected impurities were examined under the microscope, and potassium feldspar grains were found, despite a failure to find any potassium feldspar during routine examination of the whole rock in powder and thin-section form.[50]

The need for such intensive investigation of a single sample, and for the purity tests outlined, arose because this pyroxene showed an apparent age about 40% lower than that of coexisting plagioclase. A sample of known purity was necessary for interpretation of results. An isochron plot[51] using the corrected results showed that the pyroxene and plagioclase ages were indeed concordant, and that the young apparent age of the pyroxene could be attributed to the use of a false air–argon correction and to subsampling uncertainties caused by the 0·1% of impurity in the original sample.

Selection of a subsample weight for the analysis of the Dufek pyroxene was somewhat fortuitous. The experiment nevertheless directs attention to the possibility of deliberately selecting subsample weights to yield maximum information from repetitive determinations. For best results of this kind, the relative standard deviation of a series of determinations should lie between about 10 and 40%. A similar idea has been expressed by Koch and Link,[52] who recognize that the coefficient of variation is an excellent guide to the number of observations required for sampling an ore body or other geological specimen of unknown variability. At lower relative standard deviations, analytical error is likely to obscure the pattern of the results; at higher standard deviations, Gaussian statistics lose their validity, and a very large number of determinations may be necessary before a true picture can emerge (Fig. 2). To achieve an optimum subsampling error for revealing sample non-uniformity, a subsample weight $K^2K_s z/(K - H)^2 \times 10^{-4}$ g, with $z = 2$ or 3, should be taken. In the example of Fig. 2, subsamples of about 0·2 g will yield the most information. Since, in this example, there are about 8 "special" grains in a 1-g subsample, from equation (8) the probability of a 0·2-g subsample having $z_i = 0$ is $P_0 = e^{-1 \cdot 6} = 0 \cdot 2$, and one in five determinations on 0·2-g subsamples will give as the result the background of 6 ppm. If eight 0·2-g subsamples are taken, equation (6) shows there is a 70% chance that at least one of them will have $z_i = 0$. If the background concentration, H, can be found in this way, it can be used in conjunction with the standard deviation of a series of determinations to estimate z_i:

$$\hat{z}_i = \frac{(x_i - H)(\bar{x} - H)}{s^2} \tag{15}$$

This principle, applied to the pyroxene results in Table 5. shows that the subsamples with 0·0157% K_2O probably contain 4 grains of contaminant, and that those with 0·0203% K_2O probably contain 8.

When z is 6·1 grains, the probability of selecting a subsample with $z_i = 0$ is about 0·002; for $z_i = 4$, about 0·13; for $z_i = 8$, about 0·11. Therefore, selection of a pyroxene subsample with $z_i = 0$ was rather unlikely with only 12 subsamples: ordinarily, such luck cannot be expected. The sample should be repurified (as was done in this case) or smaller subsample weights should be taken to permit a good estimation of the background concentration H.

The use of appropriately small subsample weights to discover the background composition is illustrated in Table 6. The sample is an amphibolite–orthoclase mixture used by Engels and Ingamells[6] to demonstrate the effects of sample non-uniformity in K–Ar dating. None of 40 determinations on 100-mg subsamples showed the base composition of 0·145% K_2O. This is as expected, because the average number of grains of orthoclase in a 100-mg subsample is about 10. With 10-mg subsamples the average number of grains of orthoclase per subsample is close to 1, and two out of twelve such subsamples approximate the base composition. In natural samples, where mineral grains are seldom all exactly the same size, the statistical procedure can obviously not yield an integral value for each z_i. The parenthetical values in Table 6 are those calculated from equations (4) and (5).

USE OF SAMPLING CONSTANTS

For calibration of analytical methods based on comparisons with standards, results may be plotted graphically or computed. Usually a linear relationship between instrumental read-out and elemental composition is assumed, or the read-out may be modified to yield linearity; logarithmic or semi-logarithmic plots may be appropriate, and matrix corrections may have to be applied, as in X-ray fluorescence analysis.[38,39,53] It is sometimes difficult to be sure that a linear relationship exists.[54,55] Standards with poor subsampling characteristics or erroneous certificate values may further obscure the issue.

Unfortunately for those who would use available standard samples to calibrate or evaluate analytical methods for silicate minerals and rocks, there is still some doubt concerning the exact composition of some of them.[41,56–59] As an extreme example, published values for Al_2O_3 in the USGS dunite DTS-1 vary from 0·16 to 1·48%, and for Fe_2O_3 from 0·33 to 4·55%. The averages of all results for these constituents of this sample are almost sure to be in error.[40,57,60] It is probable that much of the error in reported results for Al_2O_3 and Fe_2O_3 is analytical error, and that subsampling error, in these cases, is not of much consequence by comparison, in contrast to the case of Cr in G-1, where subsampling error probably contributes a large share of the variance. These two contrasting sources of error in the certificate values for standard rock samples have been discussed by Vistelius[58,59] and Chayes,[61,62] and it is very important for the user of reference samples to distinguish between them. This can conveniently be done through progressively improving estimates of sample constants. Figure 3 represents a hypothetical standardization or calibration process, with deviations from linearity exaggerated for illustrative purposes. Without consideration of sampling constants, and if there is high confidence in the analytical procedure and in the certificate values for, say, samples 1 and 5, an analyst might be persuaded to draw a calibration curve A. If all results are regarded as equally valid, a linear regression line (not shown) might be drawn.

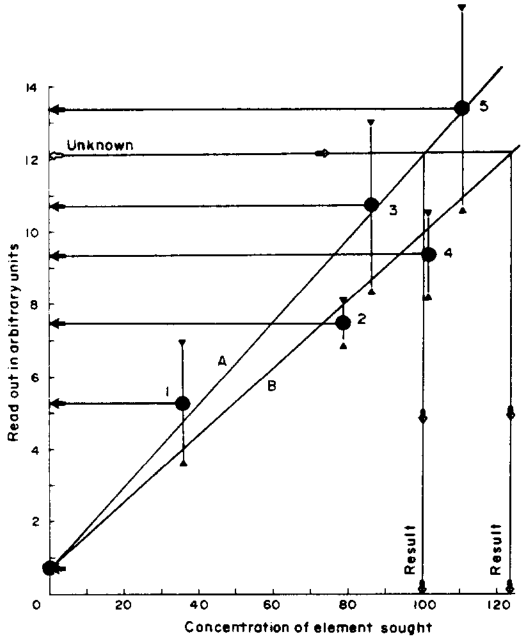

Fig. 3. Calibration of an analytical method, taking into account the subsampling characteristics of the calibration standards.

If subsampling difficulties are recognized and sampling constants are available, they can be used, in conjunction with subsample weights, to calculate the length of error bars from equation (1). It may develop that the best calibration curve (*B*) differs from the alternatives. Note that the preferred line passes through each of the error bars; in practice, this would require that these bars should cover at least plus or minus three standard deviations. Note also that samples with poor subsampling characteristics may give a reasonably good calibration curve if enough of them are used, provided their subsampling characteristics are specifically defined through the use of error bars. Error bars may, of course, be constructed to include both subsampling and analytical error.

When necessary, error bars may be shortened by using more than one subsample of each standard, or (which amounts to the same thing if analytical error is small) increasing the subsample weight.

Careful extension of these principles may reveal the extent of analytical error, and also enable one to ascertain whether it originates in the certificate value or in the analytical method. For example, if the analyst using curve *A* (Fig. 3) were to utilize these principles, he could quickly decide that the "anomalous" results for samples 2 and 4 were not due to analytical error, nor necessarily to an erroneous certificate value, but were due to the bad subsampling characteristics of samples 1, 3 and 5.

These principles may be used to locate errors, but usually an independent analytical method must be used to define them. Some of the difficulties encountered in the resolution of systematic and random analytical errors have been outlined by Ingamells *et al.*[63] Wilson[64,65] has written on the performance characteristics of analytical methods.

The subsampling characteristics of unknowns must, of course, be established before firm confidence limits for the results of an analytical process can be decided. There is not much point in establishing an accurate calibration if the unknowns are not sampled and subsampled properly. The subsampling characteristics of unknowns will often be evaluated by the method of repetitive determination, *e.g.*, the pyroxene in Table 5. Multiple determinations with small subsamples are usually most effective; however, selection of subsample weights for the purpose may be difficult. Table 3 shows how a short series of repetitive determinations may be affected by choice of subsample weight. Figure 1 shows that a similar situation may exist for many trace constituents. Table 1 shows that the difficulty may not be limited to traces, but may also exist in the determination of minor and even major constituents, and even with "pure" separated minerals, the analysis of which is commonly presumed to be free from subsampling error. The principles of selecting subsample weights for the contrasting purposes of measuring subsampling characteristics and discovering the overall composition of a mass of material are outlined by Visman[13] and in the probability considerations discussed above.

It is important to note that the error bars which correctly describe subsampling characteristics and uncertainties in the use of reference samples may not be symmetrical. With small subsample weights and in analyses for trace elements, appropriate error bars will often be unsymmetrical.

In mineral analysis, estimation of sample purity may be critical for the drawing of valid conclusions. In K–Ar dating, the sample purity may be the major factor in the elucidation of discordant ages,[49] and a quick method for its estimation is highly desirable. In many mineral samples, analytical non-uniformity is due to free substitution of one element for another (*e.g.*, the white mica in Table 1, and the standard biotite LP-6 Bio[44,45]); in others, it is due to the presence of included or contaminating grains of foreign minerals (*e.g.*, the beryl in Table 1, and the standard muscovite P-207). A knowledge of the extent and nature of the non-uniformity is necessary if erroneous conclusions from analytical data are to be avoided. Purity estimates can often be made through proper interpretation of the variance of repetitive determinations of critical elements. Other methods of estimating sample purity have been suggested and demonstrated by Engels.[47]

In publishing their results on potential reference samples, analysts have seldom reported complete information on preliminary treatment of the laboratory sample or on their effective subsample weights. Consequently it is difficult, if not impossible, to distinguish analytical from subsampling error. Generally, the averaging of results from several laboratories using different analytical methods and different subsample weights is not sound procedure;[60] however, if each investigator making replicate determinations would report all results (including any which may seem anomalous!), along with a full description of sample pretreatment and a careful estimate of the effective subsample weight, it might be possible to devise an acceptable objective process for comparing and combining interlaboratory results. The most important part of such a process would be the *exclusion* of erroneous values, and the *inclusion* of "anomalous" values which reflect real subsampling aberrations. The use of sampling constants might facilitate this process by providing a simple means for defining subsampling error and separating it from analytical error. For example, a chemist who uses 1-g subsamples and obtains a value of 10 ppm for chromium in G-1 is probably in error: a spectrographer reporting the same value on the basis of 10-mg subsamples is not in error.

DISCUSSION

If the sampling-constant principle is accepted, there will not be much difficulty in establishing a routine separation of analytical error from subsampling error.

Youden,[55,60,66,67] Sandell,[68] Wilson[64,65] and many others have provided useful advice on the estimation of analytical accuracy. Mandel[69] has written on "repeatability and reproducibility". Lashof[70] and Youden[71] have summarized the problems of collaborative testing, and an ASTM committee continues to work in this field. Maurice and Buijs[72] have discussed the detection of interferences in chemical analysis. Taylor and Kolbe,[73] Abbey,[57] Vistelius,[58] and Chayes[61,62] have discussed geochemical standards and attempted an evaluation of published data and its astonishingly large error content. Griffiths,[74,75] Cameron,[76] Howarth and Lowenstein,[77] and many others have assessed the precision and accuracy of geochemical data. Becker,[48] in a series of papers, has dealt with the problems of sample reduction in the mineral industries. Duncan[78] has written on bulk sampling—problems and lines of attack. The pioneer work of Gy[11,12] deals in depth with the practical aspects of the same subject. Numerous papers and texts attack the problems of bulk sampling.[5,8,74,79] The references given are only a small sample of a voluminous literature, yet scant attention has been given to laboratory subsampling problems and the very large effect they may have in geochemical investigations: in particular, sufficient attention has not been given to the principles outlined above, or to the fact that when subsampling is poor, analytical results for critical elements may not only be imprecise, but may be erroneous; nor has it been generally recognized that high precision does not indicate high accuracy—it may be a symptom of gross error. The generally accepted assumptions of Gaussian distribution, as expressed, for example, by Danielsson *et al.*,[80] are commonly used to guide the processes of analysis and the evaluation of data, with only occasional consideration of their validity. An extreme example of the need to consider non-Gaussian distributions is given by Phillips,[46] and a more general discussion of the same subject is due to Jones and Beaven.[10]

Anomalous results are sometimes the subject of interesting papers. For example, Reynolds[81] discusses isotope-abundance anomalies in the solar system. In geochronology, numerous puzzling anomalies remain unpublished. One wonders how many of these will eventually be explained in terms of subsampling statistics.

The implications of these considerations are wide. Their importance to geochemical prospecting and the search for economically useful mineralization should be obvious.

The suggestion has often been made, for example by Flanagan,[41] that geochemists should standardize their analytical procedures during the collaborative study of silicate samples intended for establishment as standards. This would certainly make the task of evaluating the results much easier, and interlaboratory precision would doubtless be improved. There is a danger, however, that systematic errors would remain undiscovered, and that subsampling problems and the sampling characteristics of the intended standards would remain forever obscure. For example, a reference material which gives consistent results for an element at the 1-g subsampling level when a standardized "umpire" method is used, might be worthless as a spectrographic standard in a procedure which uses a few mg of sample.

In any case, the skills, techniques, and equipment available in different laboratories are so varied that standardization of methods is probably impossible. It would be much more useful to insist that all analyses of potential standards be made by primary methods when bulk composition is sought, that the more precise of the instrumental methods (*e.g.*, the flame photometric method for potassium demonstrated in this paper) be used during establishment of subsampling characteristics. and that subsample weights and subsampling procedures always be dutifully reported, together with *all* results. By primary methods are meant those which do not depend on previously analysed standards—usually classical methods. Secondary methods are those which depend on analysed standards for calibration or control; most instrumental methods fall in this category; some are very rapid and precise, but they can never exceed in accuracy the primary classical methods on which they depend for calibration. They should therefore never be used in the establishment of certificate values for reference samples: such usage results in the transfer of analytical error from one standard to another and the accumulation of analytical inaccuracy. Perhaps the concept of the sampling constant may help bring wider attention to this fundamental, often ignored, fact of geochemical analysis, and lead to the distribution of geochemical standards which are truly reliable.

CONCLUSIONS

Possibly the most important conclusion to be drawn from this work is that, when subsampling error is appreciable, a subsample weight and a full description of subsampling procedures should be reported as part of an analysis, in order for the latter to be meaningful. This is especially true in trace element work and in geochemical exploration for rare and economically valuable minerals, when subsampling aberrations are likely to be large.

Standard samples, used to calibrate or evaluate routine methods of analysis, require not only a certification of their overall composition to be useful, but also, for relevant constituents, an estimate of the subsampling precision expected for any subsample weight. Such information may most easily be conveyed through the use of sampling constants.

For major constituents of silicate rocks and minerals, it is improbable (but by no means impossible) that subsampling error often contributes appreciably to overall error, except when subsamples are very small. For minor constituents, it may be serious, especially when high accuracy is mandatory (as in geochronology). For traces, it appears that subsampling error may contribute more to observed variance than analytical error, or (perhaps more important!) that an observed low variance in the results may be a symptom of gross error.

Control of subsampling errors may be facilitated through the use of sampling constants, routinely used by analytical geochemists.

Acknowledgements—The authors express their appreciation to J. Visman for useful comments on an early version of the manuscript, for drawing attention to the work of Pierre Gy, and for establishing a correspondence with A. J. Duncan; to A. J. Duncan, J. C. Griffiths and E. M. Cameron for highly constructive reviews and suggestions; to J. C. Engels for invaluable technical assistance and inspired criticism, and for supplying many of the separated minerals used in establishing precise secondary methods for potassium; to R. W. Kistler for permission to include his work on the Dufek pyroxene; to N. H. Suhr for spectrographic work; to R. C. Erd for examining by X-ray methods the insolubles separated from G-1 and from LP-6 Bio 40–60#; to G. K. Czamanske for microprobe analyses and for many useful discussions; to L. B. Schlocker for many hundreds of highly precise potassium determinations; to B. P. Fabbi for permission to use his results for rubidium in G-1, and for a wealth of sound counsel; to S. T. Neil and the editors of this journal and the referee for patient editorial help; and to the many other scientists who have afforded encouragement and advice.

Zusammenfassung—Der Fehler bei der Bestimmung eines Elements in einer Gesteins- oder Mineralprobe hängt ab vom Analysenfehler, vom Gewicht der analysierten Probe und von Natur und Vorgeschichte der Laboratoriumsprobe. Das wahrscheinlichste Ergebnis ist nicht unabhängig vom Gewicht der analysierten Probe. Das beruht auf der Tatsache, daß Spurenbestandteile oft in isolierten Mineralkörnern konzentriert sind. Die Wahrscheinlichkeit, daß solche Mineralkörner in irgend einer analysierten Probe auftreten, wird mit sinkendem Probengewicht geringer, selbst wenn Gesteins- oder Mineralproben zu feinen Pulvern zerkleinert werden. Solche Probenahmefehler können durch Verwendung von Probenahmekonstanten kontrolliert werden. Diese können auf verschiedene Weise festgestellt werden, etwa durch wiederholte Bestimmung eines Bestandteils und physikalische Messung wesentlicher Eigenschaften der Probe. Während der Erstellung und Bescheinigung von Bezugsproben oder Standards kann man mit Vorteil Probenahmekonstanten benutzen. Bei mangelhafter Probenahme kann man zu niedrige analytische Ergebnisse erhalten, manchmal mit hoher Genauigkeit. Hohe Genauigkeit bedeutet niemals hohe Richtigkeit; sie kann ein Symptom für einen groben Fehler sein.

Résumé—L'erreur dans le dosage d'un élément dans un échantillon de roche ou de minerai dépend de l'erreur analytique, du poids de la prise d'essai analysée, et de la nature et de l'histoire de l'échantillon de laboratoire. Le résultat le plus probable n'est pas indépendant du poids de la prise d'essai analysée. Ceci est dû au fait que des constituants à l'état de traces se situent souvent dans des grains de minerai isolés. La chance qu'ont de tels grains de mineral d'apparaître dans un échantillon analysé devient plus éloignée quand le poids de la prise d'essai décroît, même si les échantillons de roche ou de minerai sont réduits en poudre fine. De telles erreurs de fractionnement peuvent être contrôlées par l'emploi de constantes d'échantillonnage. Celles-ci peuvent être estimées par plusieurs techniques, comprenant le dosage répété d'un constituant et la mesure physique de caractéristiques d'échantillon correspondantes. Les constantes d'échantillonnage peuvent être utilement employées durant l'établissement et la certification d'échantillons ou de standards de référence. Quand le fractionnement est défectueux, les résultats analytiques peuvent donner des valeurs faibles par erreur, quelquefois avec une précision élevée. La précision élevée n'implique jamais une haute exactitude; elle peut être un indice d'erreur flagrante.

USE OF NON-SELECTIVE REAGENTS IN DIRECT THERMOMETRY

P. MARIK-KORDA, L. BUZÁSI and T. CSERFALVI

Institute for General and Analytical Chemistry, Technical University, Gellért tér 4,
Budapest XI, Hungary

(*Received* 29 *August* 1972. *Accepted* 5 *January* 1973)

Summary—A method has been developed for the simultaneous determination of sulphide and thiosulphate with non-selective reagents on the basis of the difference in their heats of reaction. Iodine solution was used as one reagent and bromine water as the other. An error diagram has been calculated and the theoretical errors compared with those obtained in practice.

Individual components in multi-component systems are determined by using the direct thermometric method and selective reagents, measuring separately the change in temperature caused by the heat of reaction between the reagent and the component to be determined.[1] Besides precise experimental conditions, masking of interfering components and use of correction factors become necessary.

We describe here a thermometric method in which we do not utilize selectivity of reaction; on the contrary, we use reagents which react with all the components and for differentation we use the different heats of reaction.

A similar idea was used by Hansen and Lewis,[2] in their simultaneous determination of two weak acids having similar pK values but different ΔH values. Similarly Sajó[3] has worked out a method for the determination of the composition of brass. He determined the copper and zinc in a single sample with potassium cyanide reagent.

The new type of determination is based on use of as many reagents which will react with all the components of the sample solution, as there are components present. If the heat of reaction of each component with each reagent is known (ΔH) and the total heats of reaction (Q) are measured in direct-injection determinations, we can calculate the concentrations of n components, x, y, z, ..., from n equations of the type

$$x\Delta H_{x(n)} + y\Delta H_{y(n)} + \cdots = Q_{(n)} \tag{1}$$

The linear system of equations thus obtained can be solved if the determinant of the system of equations is not zero.

In the case of two components, for example, the solution is

$$x = \frac{D_1}{D}; \qquad y = \frac{D_2}{D} \tag{2}$$

where the determinants D_i are given by

$$D = \begin{vmatrix} \Delta H_{x(1)} & \Delta H_{y(1)} \\ \Delta H_{x(2)} & \Delta H_{y(2)} \end{vmatrix}; \qquad D_1 = \begin{vmatrix} Q_{(1)} & \Delta H_{y(1)} \\ Q_{(2)} & \Delta H_{y(2)} \end{vmatrix}$$
$$D_2 = \begin{vmatrix} \Delta H_{x(1)} & Q_{(1)} \\ \Delta H_{x(2)} & Q_{(2)} \end{vmatrix} \tag{3}$$

We will demonstrate the direct thermometric use of non-selective reagents by the simultaneous determination of thiosulphate and sulphide ions. With iodine in neutral medium we have

$$2S_2O_3^{2-} + I_2 \longrightarrow S_4O_6^{2-} + 2I^- \qquad \Delta H_{S_2O_3^{2-}(1)}$$
$$S^{2-} + I_2 \longrightarrow S + 2I^- \qquad \Delta H_{S^{2-}(1)}$$

and with bromine:

$$S_2O_3^{2-} + 4Br_2 + 5H_2O \longrightarrow 2SO_4^{2-} + 8Br^- + 10H^+ \qquad \Delta H_{S_2O_3^{2-}(2)}$$
$$S^{2-} + 4Br_2 + 4H_2O \longrightarrow SO_4^{2-} + 8Br^- + 8H^+ \qquad \Delta H_{S^{2-}(2)}$$

In the bromine reaction, the solution will become strongly acidic; the pH of a 10^{-2} to $10^{-3}M$ titrand solution will decrease from an initial value of about 8–2 at the end of the reaction. In addition to the heat of oxidation, we measure the heat of solvation of the Br^- and H^+ formed.

The reactions are instantaneous, so apart from taking the usual precautions for direct thermometric determinations, the effect of the surroundings need not be taken into account.

The main problem is to decide which are the principal sources of error. Consider a two-component system. The variance of x and y, if these are calculated from equation (2), is given by

$$\left(\frac{S_x}{x}\right)^2 = \left(\frac{S_{D_1}}{D_1}\right)^2 + \left(\frac{S_D}{D}\right)^2 = \frac{1}{D^2}\left(\frac{S_{D_1}{}^2}{x^2} + S_D{}^2\right) \tag{4}$$

and

$$\left(\frac{S_y}{y}\right)^2 = \left(\frac{S_{D_2}}{D_2}\right)^2 + \left(\frac{S_D}{D}\right)^2 = \frac{1}{D^2}\left(\frac{S_{D_2}{}^2}{y^2} + S_D{}^2\right) \tag{5}$$

where S_y, S_x are the standard deviations of the calculated results and S_{D_1}, S_{D_2}, S_D are the standard deviations of the determinants.

According to experimental results, the standard deviation of the quantity of heat (Q) evolved in the direct thermometric method is independent of Q and is a constant (S_Q) characteristic of the apparatus at a given sensitivity. As a first approach, we can suppose that the heats of reaction $\Delta H_{x(i)}$ and $\Delta H_{y(i)}$ can be more accurately measured than $Q_{(i)}$.

It follows that the standard deviations of the determinants are in the order

$$S_D < S_{D_1}, S_{D_2} \tag{6}$$

Neglecting $S_D{}^2$ in equations (4) and (5) on the basis of equation (6), we obtain

$$\left(\frac{S_x}{x}\right)^2 = \frac{S_{D_1}{}^2}{D^2x^2}; \qquad \left(\frac{S_y}{y}\right)^2 = \frac{S_{D_2}{}^2}{D^2y^2} \tag{7}$$

From equation (3) we have

$$S_{D_1}{}^2 = [\Delta H_{y(2)}]^2 S_Q{}^2 + [\Delta H_{y(1)}]^2 S_Q{}^2 = S_Q{}^2 \Sigma \Delta H_y{}^2$$

and

$$S_{D_2}{}^2 = [\Delta H_{x(1)}]^2 S_Q{}^2 + [\Delta H_{x(2)}]^2 S_Q{}^2 = S_Q{}^2 \Sigma \Delta H_x{}^2 \tag{8}$$

Finally the relative standard deviation of the determination may be obtained from equations (7) and (8):

$$\frac{S_x}{x} = \frac{S_Q}{x} \frac{\sqrt{\Sigma \Delta H_y{}^2}}{D} \tag{9}$$

$$\frac{S_y}{y} = \frac{S_Q}{y} \frac{\sqrt{\Sigma \Delta H_x{}^2}}{D} \tag{10}$$

It can be seen from the expressions above, that the uncertainty in the determination of the individual components increases with increasing heat of reaction of the other component and decreases with the increasing values of the determinant D. It is interesting to see that the deviations are independent of the quantity of the other component, that is of the x/y ratio. This can be concluded from the starting postulate that the value of S_Q is independent of the absolute value of Q.

On the basis of equations (9) and (10) the error function, which depends only on the value of S_Q, can be represented diagramatically.

EXPERIMENTAL

Apparatus

Directhermom (MOM, Hungary).

Reagents

Sodium thiosulphate and sodium sulphide solutions, both 0·01M and standardized in the usual way.[4]

Iodine-potassium iodide solution, about 1M, with heat of dilution partly compensated by addition of methanol.

Saturated bromine water.

Calibration curves

Sodium thiosulphate stock solution (10, 20, 30, 40, 50 ml) was made up to 200 ml with distilled water, transferred to the Directhermom plastic cell and placed in the instrument. The iodine reagent was placed in the dipping pipette of about 2 ml capacity. After waiting for the usual 3 min, the deflection of the galvanometer (in scale divisions) was noted. After correction for the heat of dilution, this value was plotted against the number of mmoles of thiosulphate taken. The experiment was repeated three times. A similar procedure was used for the sodium sulphide solution.

For the bromine reactions, 10, 15, 20, 25, and 30 ml of sodium thiosulphate or sulphide stock solution were diluted to 200 ml and the saturated bromine water added from a pipette of about 10 ml capacity.

Least-squares analysis gave the following slopes for the plots (ΔH values).

$Na_2S_2O_3 + I_2$ $\Delta H_{x(1)} = 31{\cdot}4$ graduations/mmole
$Na_2S_2O_3 + Br_2$ $\Delta H_{x(2)} = 2790$ graduations/mmole
$Na_2S + I_2$ $\Delta H_{y(1)} = 586$ graduations/mmole
$Na_2S + Br_2$ $\Delta H_{y(2)} = 2530$ graduations/mmole

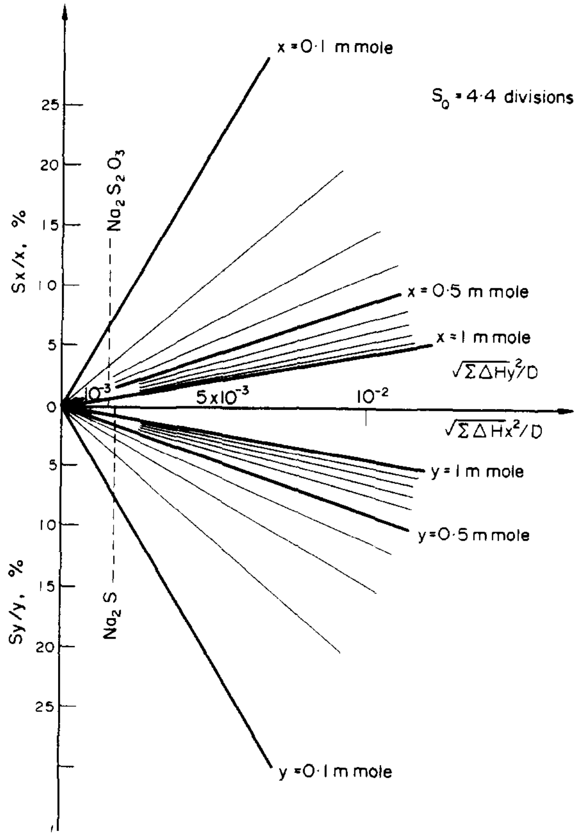

Fig. 1. Relative error diagram.

The standard deviation of the total heat of reaction (60 replicates) is $S_Q = 4\cdot4$ graduations. The determinant D is $D = -1557 \times 10^6$ graduations^2/mmole^2. By substitution of the experimental values in equation (2) we obtain formulae for calculation of x and y:

$$x(\mathrm{Na_2S_2O_3}),\ \text{mmole} = \frac{586Q_{(2)} - 2530Q_{(1)}}{1557 \times 10^6} \qquad (11)$$

$$y(\mathrm{Na_2S}),\ \text{mmole} = \frac{31\cdot4Q_{(2)} - 2790Q_{(1)}}{1557 \times 10^6} \qquad (12)$$

Estimation of error

The general error diagram corresponding to the equations (9) and (10) is given in Fig. 1. For the given determination:

$$\Sigma\Delta H_x{}^2 = 7\cdot785 \times 10^6 \text{ graduations}^2/\text{mmole}^2$$

$$\Sigma\Delta H_y{}^2 = 6\cdot744 \times 10^6 \text{ graduations}^2/\text{mmole}^2$$

From this

$$\frac{\sqrt{\Sigma\Delta H_y{}^2}}{D} = 1\cdot67 \times 10^{-3} \text{ and } \frac{\sqrt{\Sigma\Delta H_x{}^2}}{D} = 1\cdot79 \times 10^{-3}$$

Table 1

0·15	0·15	107·3	830·8	0·138	5	−8	0·176	6	+17
0·06	0·24	137·3	740·5	0·056	12	−7	0·231	3	−4
0·03	0·27	138·7	690·8	0·035	25	+16	0·235	3	−13

The x and y values were calculated by equations (11) and (12) and the errors by equations (13) and (14). The Q values are in scale graduations.

We can estimate the uncertainty of the simultaneous determination of $S_2O_3^{2-}$ and S^{2-} from the error diagram. The relative deviations, which can be read along the broken lines drawn on the diagram, can also be expressed by the equations:

$$\frac{S_{S_2O_3^{2-}}}{\text{mmole}[S_2O_3^{2-}]} = 100\,\frac{4\cdot4}{\text{mmole}[S_2O_3^{2-}]} \times 1\cdot67 \times 10^{-3} = \frac{0\cdot74}{\text{mmole}[S_2O_3^{2-}]}\,\% \qquad (13)$$

$$\frac{S_{S^{2-}}}{\text{mmole}[S^{2-}]} = 100 \times \frac{4\cdot4}{\text{mmole}[S^{2-}]} \times 1\cdot79 \times 10^{-3} = \frac{0\cdot79}{\text{mmole}[S^{2-}]}\,\% \qquad (14)$$

Simultaneous determination of sodium thiosulphate and sulphide

We prepared various mixtures of the two stock solutions with totals of 0·1 and 0·3 mmole in the 200 ml of test solution and made three measurements on each mixture reacted with the total iodine and bromine. Table 1 shows the results.

On the basis of equations (13) and (14), the expected relative standard deviation for 1 mmole of sodium thiosulphate or sulphide is 0·7–0·8%, for 0·1 mmole 7–8% and for 0·01 mmole 70–80%.

It is clear from the table that the error is larger than expected for four of the results for the 0·1-mmole samples and for five of those for the 0·3-mmole ones, sometimes very considerably larger. If we consider the fact that the lower limit for the classical volumetric determination of sulphide and thiosulphate concentrations is about $10^{-2}M$, and that the concentration of the solutions determined here is between 5×10^{-4} and $1{\cdot}5 \times 10^{-3}$ M then the results are encouraging.

RELATIVE SENSITIVITY COEFFICIENTS FOR RARE EARTHS IN SPARK-SOURCE MASS SPECTROMETRY

R. J. CONZEMIUS and H. J. SVEC
Ames Laboratory-USAEC and Department of Chemistry, Iowa State University,
Ames, Iowa 50010 U.S.A.

(*Received* 26 *June* 1972. *Revised* 21 *December* 1972. *Accepted* 10 *January* 1973)

Summary—Relative sensitivity coefficients have been computed for rare earth elements according to empirical models which have been proposed in the literature. Explanations concerning differences between the computed and observed values are based upon possible instrumental discrimination effects which negate some processes occurring in the ion source. Computations relating elemental physical constants to observed results in a semi-random manner are shown which support this contention.

Experimentally determined relative sensitivity coefficients of trace rare earth impurities in rare earth matrices by spark-source mass spectrography have been reported.[1] Several empirical models have been proposed in the literature for relating sensitivity coefficients to fundamental chemical and/or physical properties of the elements.[2-7] The purpose of this report is to compare sensitivities computed from the models with experimental rare earth data; to propose instrumental effects which may cause the models to fail; and to show by comparison of experimental data with physical constants in a semi-random manner how the observed rare earth sensitivity coefficients support the proposed instrumental effects.

This study was motivated and performed with the notion that the rare earths might provide a significant test for the reported models since the experimental sensitivity coefficients, listed in Table 1, were generally found to be independent of matrix effects and of the method of sample preparation and also since rare earths possess uniquely interrelated physical and chemical properties which are well known.

COMPUTED RELATIVE SENSITIVITY COEFFICIENTS

The commonly accepted form[8] for expressing a relative sensitivity coefficient (S_R) is

$$S_R = \frac{\text{mass spectrometrically observed (relative) value}}{\text{true (relative) value}}$$

where the observed value is based upon an ion current which has been corrected for *known* instrumental effects. This corrected value is then placed on a relative basis by comparison with another element which has a known concentration and has been assigned an arbitrary S_R value (*e.g.*, commonly the S_R for iron $\equiv 1{\cdot}00$ although any other element may be selected).

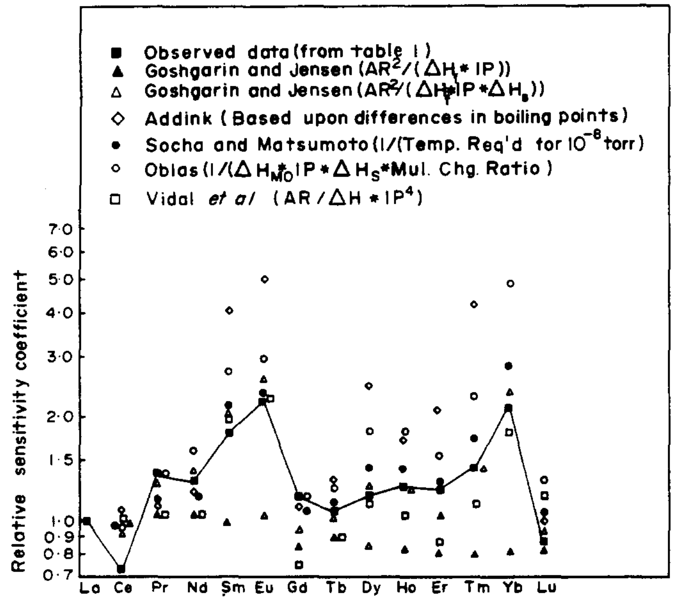

Fig. 1. Plot of computed S_R values according to formulae proposed in the literature. Symbols: AR = atomic radius. ΔH_f = heat of formation of sesquioxide, Re_2O_3. IP = first ionization potential. ΔH_s = heat of sublimation. ΔH_{MO} = heat of formation of the gaseous monoxide.

Accurate values for the physical constants for the rare earths are available and the relationships between these constants have been discussed.[9–13] Except for small mass-dependences, very little change occurs across the entire rare earth series in the heat of formation of the sesquioxide (Re_2O_3—form C), the first ionization potential, and the atomic volume of the tervalent ion. In contrast however, the vapour pressure at a given temperature may differ by approximately eight orders of magnitude.

Relative sensitivity coefficients for rare earths were computed according to empirical models already proposed in the literature.[2–6] The description of these models may be obtained from the references as well as a recent summary and discussion of these and other theoretical proposals for relating observed elemental sensitivities to fundamental properties of the elements.[8] The results of the computations are shown in Fig. 1 with all data normalized to La ≡ 1·00, along with the overall average values from Table 1.

Roaldst[7] worked with rare earths in geological samples and proposed a model for determining S_R values. He found the observed S_R values to be monotonic functions of mass and ionization potential. However his data were not corrected for the photoplate emulsion mass-effect and his conclusions regarding mass and ionization potential dependence are obscured by many mass effects. For this reason no calculation with the rare earths was attempted and no comparison is made here on Fig. 1.

CORRELATION OF COMPUTED AND OBSERVED VALUES

There are several results for which all the models are in disagreement with observed data. None of the models predict the following.

1. The low observed sensitivity for Ce.
2. Pr with a higher sensitivity than Nd.

3. Gd with a higher sensitivity than Tb.
4. Ho with a higher sensitivity than Dy.

The two models giving the best correspondence to the experimental data are those of Goshgarin and Jensen[2] (~AR^2/HF*IP*HS; open triangles of Fig. 1) and of Socha and Masumoto[4] (~1/temp. required for vapour pressure of 10^{-8} mmHg; solid circles of Fig. 1). The Goshgarin and Jensen model, which is based upon the energetics in a Born–Haber cycle, requires the inclusion of a metal vaporization step (*i.e.*, ΔH_s, used for open triangles but not solid triangles of Fig. 1) in order to obtain reasonable agreement with the observed data. The model proposed by Socha and Masumoto is an empirical relationship based upon the different temperatures required to produce the same vapour pressure. Actually, unless diffusion is a predominant process in spark-source electrodes, homogeneously distributed elements should be exposed to the same temperature even though the time scale and the gradient of this temperature might vary greatly. Since vapour pressure is a thermodynamic function proportional to the heat of sublimation, the Goshgarin and Jensen model should be considered to be the more fundamental one. One aspect of this model, the defined inverse relationship of S_R to the first ionization potential, is not widely agreed upon in the literature[8] and this relationship can be examined more closely by using rare earth data.

INSTRUMENTAL DISCRIMINATION EFFECTS

Ionization potential

A plot of S_R *vs.* the first ionization potential for the rare earths is shown in Fig. 2. Considerable scatter is evident although a tendency exists for a positive slope rather than the inverse relationship assumed in certain models. A direct relationship may appear illogical on first considerations. However, several instrumental discriminatory effects may predominate over the first considerations. Two of these effects are described below.

The reason for the dependence of elemental sensitivity upon spark location[14] has not been established and ionization potential (IP) could be a factor in this dependence. Acceleration of singly charged elemental ions of high IP may be favoured owing to more predominant ion formation in different regions of the spark gap. Conversely stated, elements with low IP could effectively be discriminated against owing to predominant ion formation in regions very close to electrode surfaces, *e.g.*, in the cathode drop

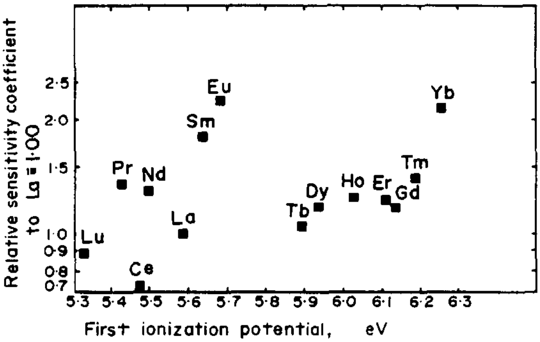

Fig. 2. Plot of S_R *vs.* first ionization potential.

region. Acceleration of these ions along the ion optics axis of the instrument may be less effective because of very narrow gap widths or electrode self-shielding effects, both being common operating characteristics of spark-source mass spectrometers.

A second instrumental discriminatory effect related to IP can occur at the energy-defining slit if ion energy is a function of ionization potential. Mechanisms of ion formation such as those given above would provide this function and lead to two different types of discrimination. One would occur at the defining slit itself and would result in discrimination against certain energies by limiting transmission to a specific ion-energy range. The other type is more complicated and is due to the relationship between line profile and an exact description of the energy and angular divergent parameters of the ion beam.[15]

Mass

Line profiles are mass-dependent (*i.e.*, aberrations are functions of ion-path radii in the magnetic field). Since the energy and angular divergent properties of an ion beam would be very difficult to reproduce, variable mass-dependences of elemental sensitivities may be expected. A means of minimizing or eliminating this variation in line profile has been described by Franzen and Schuy.[16] However, very few instruments have been altered to incorporate this improvement.

Other mass-discrimination effects such as those at the ion detector or in the ion-accelerating region may be relatively constant. However since ion path-length is mass-dependent, a variable dependence of S_R upon ion path-length (mass) may be defined as an alteration in the Z-axis (instrument optical axis parallel to the magnetic field lines) ion-illumination angle.[17]

Space charge broadening

Highly variable sensitivity coefficients for elements with masses adjacent or near to the matrix-mass ion beams have been observed in our own laboratory. (Note data in Table 1.) Generally the observed S_R is uncommonly low by factors of up to 4 for elements immediately adjacent to the matrix. An empirical relationship for estimating the magnitude of this effect, based upon the experimental data, is

$$\text{reduction factor} = [(\text{MS} - \text{MM})/(\text{MS} - \text{MM} + 1)]^2$$

where MS is the mass of the isotope used for the elemental determination and MM is the mass of the isotope of the matrix element adjacent to MS.

Volatility-energy spread

Energy spread and intensity of multiply charged lines have been shown to be dependent upon elemental volatility.[18] Discrimination due to this effect would depend upon the magnitude and the setting of the energy window of the instrument. The procedure used to obtain the experimental results in Table 1 was to maximize the ion current at the centre of the energy window (500 eV wide in this case). For a pure matrix this procedure effectively discriminates against elements with energy spreads (or volatilities) different from those of the matrix. Methods for estimating the degree to which this occurs have not been described and would be very difficult to determine since these particular effects are produced during the unstable and non-reproducible initial stages of spark-gap breakdown. An empirical means for estimating this effect will be desirable for computations described later and is

$$VF = 1/(1 + |(\log VP_i - \log VP_{\mathrm{matrix}})|)$$

where VF is the estimated reduction due to the discrimination noted above, VP_i is the vapour pressure of the impurity element at the particular temperature where the matrix element possesses a vapour pressure, (VP_{matrix}) of 10^{-2} mmHg.

TEST OF MODELS AND OF DISCRIMINATION EFFECTS

A model which encompasses all of the instrumental discrimination factors above would be very difficult to establish. However a different approach may be used to pose a test for the arguments given above as well as for the Goshgarin–Jensen model. This approach consists of a semi-random comparison of the observed results for each of the five matrices and of the overall average data in Table 1 with the rare earth elemental physical constants. Such comparisons were made by relating the observed results to the constants by use of the same form of mathematical expression, *viz.*, multiplication of constants raised to some power, as used in models proposed in the literature.[8] The mathematical expression includes the constants of the Goshgarin–Jensen model as well as the instrumental discrimination factors described above. The general equation is

$$S_R = (MS)^m(HS)^s(IP)^i(AR)^r(HF)^f(VF)^d[(MS - MM)/(MS - MM + 1)]^2$$

where HS is the heat of sublimation, IP is the first ionization potential, AR is the radius of the tervalent rare earth in the oxide, HF is the heat of formation of the C-form rare earth oxide Re_2O_3, and MS, MM, and VF are as defined earlier. The symbols *m*, *s*, *i*, *r*, *f*, and *d* are the exponents of the properties referred to above. For comparison with the overall average data in Table 1 the matrix-dependent factors, VF, MS, and MM were not included in the equation.

The following semi-random procedure was used for comparison of observed data with values computed according to the mathematical expression above. Initially all of the exponents were set equal to zero. The exponent *s* was then incremented, the equation was evaluated for S_R for each rare earth, the S_R values were normalized to La ≡ 1·00 and the average differences between the computed and observed S_R values for the rare earth elements were determined. Incrementation of the exponent by 0·1 unit was permitted in either a positive or a negative direction until best agreement, *i.e.*, minimum average difference between computed and observed S_R values, was obtained. With the exponent *s* retaining its optimized value, the exponent *m* was then optimized in the same manner. This optimization of exponents was continued in the order: *s*, *m*, *s*, *m*, *i*, *s*, *m*, *i*, *r*, *s*, *m*, *i*, *r*, *f*, *s*, *m*, *i*, *r*, *f*, *d*, *s*, *m*, *i*, *r*, *etc.* with each exponent retaining its re-optimized value while the next exponent was being optimized. The exponent *s* was chosen for optimization first since a definite relationship between the heat of sublimation and the observed results was obvious from the Goshgarin–Jensen model. However, no obvious relationships were observed with the other constants. Thus the remaining order of *m*, *i*, *r*, *f*, and *d* was chosen arbitrarily. Re-optimization of the exponents (*e.g.*, *s* re-optimized after the first *m* optimization) was performed for readjustment before continuing to a new exponent. No upper or lower limits were placed on the ultimate values of the exponents. Incrementation was by 0·1 unit except for *d* which was by 0·05 unit.

The final values for the exponents found by the computer programme which was written to perform these tasks are given in Table 2. Figure 3 is a plot (dashed line) of the

Table 2. Exponents of parameters for computer generated model

computer-generated S_R values for the overall average data (column 7 of Table 2) and a plot (solid line) of the experimentally determined S_R values for the overall average data (column 14 of Table 1).

OBSERVATIONS AND CONCLUSIONS

The mathematical procedure above is not an attempt to generate a theoretical model. It is rather an attempt to test arguments for proposed instrumental effects by a semi-random comparison of observed results with physical constants in order to make practical and empirical observations of possible non-random relationships existing between the parameters. The results shown in Table 2 are indeed not random and do indicate relationships which have logical and physical bases as presented earlier. For example the exponent s for the heat of sublimation, HS, deviates very little from the average result of −1 given in column 8 of Table 2. This is in good agreement with the values assumed for this parameter in previously mentioned models. The exponent m of isotopic mass, MS, varies between the values of −1·9 for the overall data and +1·4 for the Tm data. This variation is difficult to assess, owing to the dependence of many physical constants upon mass, as noted earlier. However the variation itself substantiates the arguments posed earlier concerning variable mass discrimination. The positive exponent i for the ionization potential, IP, is in disagreement with values assumed for this parameter in some proposed models. However this direct dependence should not be considered as having no physical basis. This effect was ascribed by previous arguments to possible instrumental discriminations. The radii of the tervalent rare earth ions, AR, change very slightly, across the entire rare earth series of elements. It would be very easy for errors in the observed results to cause the exponent r of this parameter to vary widely without any correlation with physical reality. However, this is not the case. The value of r has an average of approximately $+3$ which is in reasonable agreement with assumptions of some of the models proposed in the literature.[8] The exponent f for the heat of formation, HF, varies considerably and is positive for all matrices except thulium. Possibly the mathematical procedure breaks down in this case. The inability of the mathematical procedure to predict a low enough S_R for Ce may possibly be attributed to an uncertainty concerning which heat of formation should be used, since cerium also forms CeO_2 which has a higher heat of formation than the Ce_2O_3 form-C type oxide. The energy-discrimination effect, VF, was found to be negligible for yttrium, scandium, and erbium. The negative value for d for the thulium matrix and its positive value for the holmium matrix indicate that vapour pressure differences may be significant in these particular cases.

Figure 3 shows the same disagreements between computed and observed S_R values (*i.e.*, low S_{Ce}; $S_{Nd} > S_{Pr}$; $S_{Tb} > S_{Gd}$; $S_{Dy} > S_{Ho}$) as were noted earlier with the S_R values computed from theoretical models. This suggested possible systematic errors in the observed results. Some more recent experimental values for S_R than those given in Table 1 have been obtained for Ce, Pr, Nd, Dy, Ho, Er, Tm, and Yb in three different matrices, Lu_2O_3, Y_2O_3, and Yb_2O_3. In these matrices, S_R values for Pr and Ce were determined relative to $Nd \equiv 1{\cdot}24$ and S_R values for Dy, Er, Tm, and Yb were determined relative to $Ho \equiv 1{\cdot}27$ to permit easier testing of discrepancies with adjacent elements. The experimental procedure used for determining these new S_R values was identical to that used for Method III[1] of Table 1. The experimental results are indicated by the open circles in Fig. 3. The new values for Pr and Ce agree better with the computed values. Also the new value for Dy is greater than that for Ho, in agreement with calculated values. The new values for Tm, Er, and Yb reflect either experimental errors or minor matrix effects.

More rigidly defined experimental work will be needed before better theoretical models can be proposed which will permit accurate *a priori* computation of relative sensitivities for even selected groups of elements. However, with improvements in instrumental reproducibility (*via* automatic control over sparking conditions, increased versatility in ion-detection methods, better characterized solid electrodes, *etc.*) and with the advantages of computer-based techniques, these theoretical models are becoming useful. Instrumental discrimination effects will require more important consideration in future models designed to relate spark-source mass spectra to actual elemental concentration levels in the spark-source samples. It is essential that models continue to be improved upon and tested against observed results so that the complex mechanisms operative in spark-source mass spectrometers may become clearer.

Zusammenfassung—Für seltene Erden wurden nach in der Literatur vorgeschlagenen empirischen Modellen relative Empfindlichkeitskoeffizienten berechnet. Die Erklärung von Unterschieden zwischen berechneten und beobachteten Werten beruht auf möglichen Diskriminationseffekten im Gerät, die einige in der Ionenquelle ablaufende Prozesse unwirksam machen. Es werden Berechnungen gezeigt, die physikalische Konstanten der Elemente mit den beobachteten Ergebnissen in halb zufälliger Weise verknüpfen; diese stützen die oben aufgestellte Behauptung.

Résumé—On a calculé les coefficients de sensibilité relatifs pour les éléments des terres rares selon des modèles empiriques qui ont été proposés dans la littérature. Les explications concernant des différences entre les valeurs calculées et observées sont basées sur des effets de discrimination instrumentale possibles qui annulent quelques processus se produisant dans la source d'ions. On présente des calculs reliant des constantes physiques élémentaires aux résultats observés de manière semi-désordonnée qui soutiennent cette conception.

SHORT COMMUNICATION

SYNTHESIS AND ION-EXCHANGE PROPERTIES OF CERIC TUNGSTATE

(*Received* 3 *October* 1972. *Accepted* 14 *December* 1972)

In continuation of our work on the synthesis of some new inorganic ion-exchangers,[1-3] we found ceric tungstate to have useful ion-exchange properties. The present communication summarizes our findings on the preparation, properties and ion-exchange behaviour of ceric tungstate.

EXPERIMENTAL

Reagents

Ceric ammonium nitrate and sodium tungstate (analytical reagent grade) were used without further purification. ^{51}Cr, ^{58}Co, ^{59}Fe, ^{65}Zn, ^{86}Rb, ^{115m}Cd, ^{134}Cs, ^{203}Hg and ^{204}Tl radioisotopes (BARC, Bombay) were used for the determination of distribution ratios. All other reagents used were of analytical grade.

Apparatus

All pH measurements were made with a Cambridge pH meter. A Unicam SP 500 was used for spectrophotometric work. For ^{51}Cr, ^{58}Co, ^{59}Fe, ^{65}Zn, ^{134}Cs and ^{203}Hg γ-counting was done on a scintillation counter. β-counting was done with a G.M. counter in the case of ^{86}Rb, ^{115m}Cd and ^{204}Tl.

Preparation of ceric tungstate

All samples of ceric tungstate were prepared by mixing ceric ammonium nitrate and sodium tungstate at room temperature (35 ± 3°), the total volume being kept to 200 ml. Details of precipitation are summarized in Table 1. The precipitate was filtered off, washed and dried at room temperature. It was sieved to 100–200 mesh for column operation. The ion-exchanger was then converted into its H$^+$ form.

Table 1. Methods of preparation, composition and ion-exchange capacity of ceric tungstate

Sample No.	Concentration of reagents, *M*		pH	Ce^{4+}/WO$_4^{2-}$	Hydrogen-ion liberation capacity, *meq/g*	Hydrogen-ion absorption capacity, *meq/g*
	Ce^{4+}	WO$_4^{2-}$				
1A	0·250	0·250	1	0·51	0·40	0·38
2A	0·050	0·050	1	0·51	0·42	0·38
3A	0·025	0·025	1	0·53	0·42	0·37
4B	0·050	0·050	1	0·52	0·56	0·48
5A	0·050	0·10	1	0·51	0·54	0·47
6A	0·10	0·050	1	0·57	0·40	0·36
7A	0·050	0·050	0	0·50	0·73	0·66
8B	0·050	0·10	0	0·49	0·89	0·81

A—WO$_4^{2-}$ added to Ce^{4+}.
B—Ce^{4+} added to WO$_4^{2-}$.

Composition of ceric tungstate

Known amounts of ceric tungstate samples were dissolved in hot concentrated hydrochloric acid. Cerium[4] and tungsten[5] were determined spectrophotometrically, and the Ce(IV) and W(VI) ratios are reported in Table 1. Control experiments and blanks were run to test the accuracy of the method of determining cerium : tungsten ratios.

Properties

All samples when dried at room temperature are yellow. The samples were in the form of a gel and could be sieved to the desired mesh size. The samples show a negligible tendency to leach. Mineral acids (6*M*) have no effect in the cold but dissolve the exchanger on heating. Alkalis (up to 2*M*) have no effect in the cold, and the ion-exchanger is stable in water, alcohol, benzene, acetic acid, 1·0*M* oxalic acid and in solutions of alkali and alkaline earth metal chlorides.

Determination of the exchange capacity

The ion-exchange capacity is found to depend upon the concentration (Fig. 1b) and the volume of the eluent (Fig. 1a) for column operation. To find the time of complete equilibration, the amount of H^+ liberated by 1*M* sodium chloride solution at different intervals of time was determined (Fig. 1c). The ion-exchange capacity of different samples was measured by the standard method,[6] and the hydrogen-ion liberation capacity for different samples is tabulated in column 6 of Table 1. Column 7 contains the value of the hydrogen-ion absorption capacity of different samples in the Na^+ form. The reproducibility of the method was checked by determining the capacity of different samples from the same batch, and there is a standard deviation of ±0·019 meq/g. The standard deviation for batch samples was ±0·036 meq/g.

The exchange capacity for Na^+ varies little (~10%) with initial pH. The ion-exchange capacity for ions of different size and charge follows the order $Li^+ < Ca^{2+} < Na^+ \leq K^+ \leq NH_4^+ < Ba^{2+}$. Ceric tungstate exchanger dried at up to 100° does not lose its exchange capacity, but when dried at 200° loses half its exchange capacity and almost all if dried at 400°. There is no appreciable loss in the hydrogen-ion liberation capacity in the course of up to 4 regeneration cycles. Since sample 8B has the highest exchange capacity, most studies were carried out on this sample only.

Distribution studies

Distribution coefficients for 22 metal ions were determined by batch operation, using radiometric, complexometric titration, and spectrophotometric methods. About 200 mg of the exchanger were loaded with 20 ml of 0·005*M* metal ion solution. The initial pH of the metal ion solution was adjusted to between 2 and 3 with perchloric acid. The results are reported in Table 2.

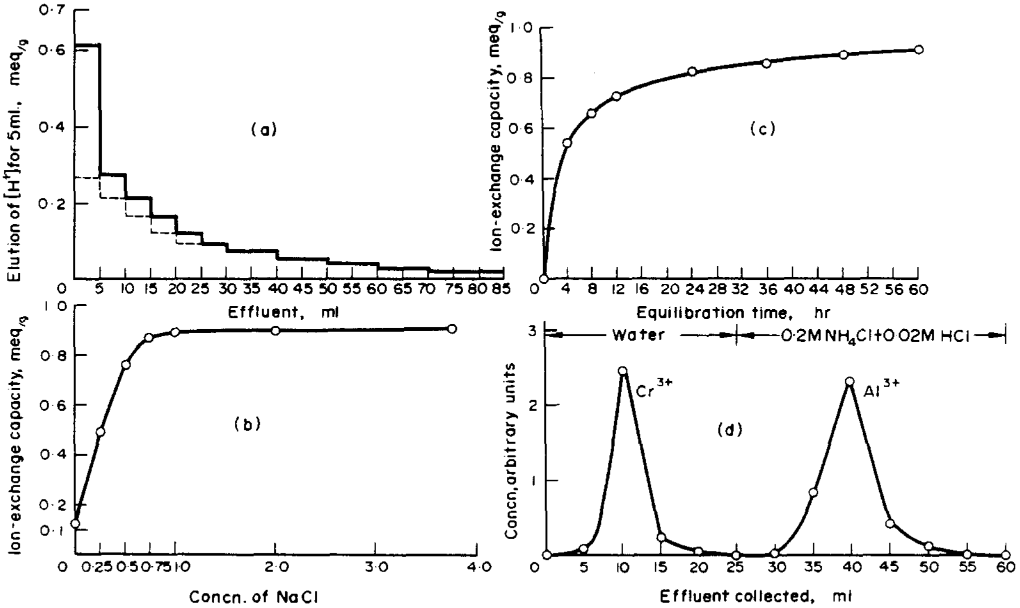

Fig. 1. (a) Elution of hydrogen ion. Continuous line—eluent 1·0*M* NaCl. Dotted line—eluent 0·1*M* NaCl.

(b) Ion-exchange capacity of ceric tungstate (8B) as a function of concentration of Na^+.

(c) Effect of time of equilibration on exchange capacity of ceric tungstate (8B).

(d) Separation on ceric tungstate column (9·0 cm × 0·19 cm^2) flow-rate ~0·15 ml/min.

Table 2. Distribution coefficients for some cations on ceric tungstate (8B)

Cation	K_d, *ml/g*	Cation	K_d, *ml/g*
Rb(I)	68·3	Cd(II)	2·2
Ag(I)	138·3	Ba(II)	1·0
Cs(I)	96·3	Hg(II)	603·0
Tl(I)	617·2	Pb(II)	2·9
Mg(II)	2·8	Al(III)	63·6
Ca(II)	3·1	Cr(III)	4·3
Mn(II)	1·4	Fe(III)	3·6
Co(II)	216·0	Tl(III)	147·8
Ni(II)	6·0	Zr(IV)	1·3
Cu(II)	38·4	Th(IV)	17·1
Zn(II)	5·4	UO_2^{2+}	1·1

Separations of Hg^{2+} from Cd^{2+}, Zn^{2+} and Pb^{2+} (Fig. 2) and Co^{2+} from Mn^{2+} and Fe^{3+} were carried out on a column (5·0 cm × 0·19 cm^2) containing 50–100 mesh ceric tungstate. The column was loaded with 20% of the breakthrough capacity for each metal ion and the elution was started after 20 min at a flow rate of ~0·15 ml/min. Separation of Al^{3+} from Cr^{3+} and Fe^{3+} was carried out on a column 9·0 cm × 0·19 cm^2 (Fig. 1d). Zn^{2+}, Cd^{2+}, Pb^{2+}, Fe^{3+}, or Mn^{2+} were eluted with water (pH 2–3); Hg^{2+} and Co^{2+}, which were retained on the column, were eluted with 0·4*M* ammonium chloride + 0·05*M* hydrochloric acid. Likewise Fe^{3+} and Cr^{3+} were eluted with water (pH 2–3), and Al^{3+} with 0·2*M* ammonium chloride + 0·02*M* hydrochloric acid.

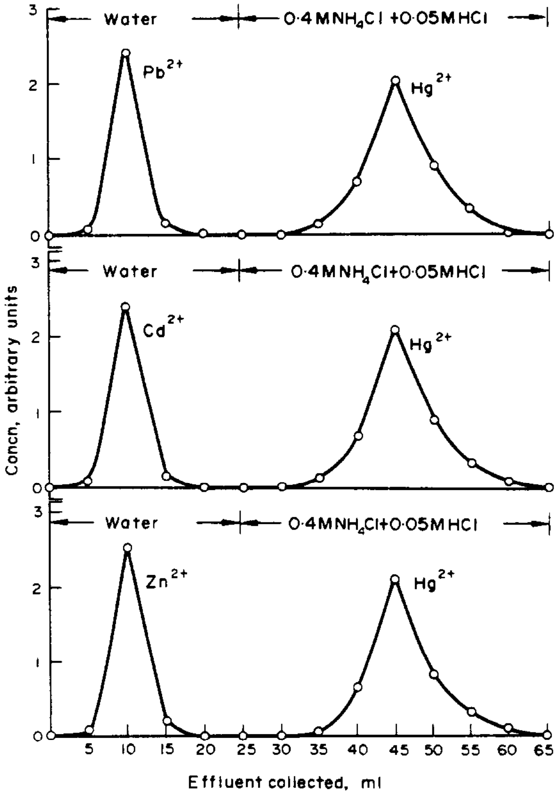

Fig. 2. Separation on ceric tungstate column (5·0 cm × 0·19 cm^2), flow-rate ~0·15 ml/min.

RESULTS AND DISCUSSION

The ion-exchange capacity of the samples is influenced by the ratio of the concentrations of solutions mixed, their order of mixing, and the final pH of the resulting solution. The samples precipitated at pH 0 have higher exchange capacity than those precipitated at pH ~ 1. Also the samples prepared by mixing Ce^{4+} and WO_4^{2-} in 1 : 2 ratio have better exchange capacity than the samples precipitated in 2 : 1 ratio. As noted earlier,[1-3] the order of mixing also affects the exchange capacity. The samples (B) prepared by adding Ce^{4+} to WO_4^{2-} have a higher capacity than those (A) prepared by mixing the reagents in the reverse order. However, all these factors which influence the exchange capacity seem to have a negligible effect on the ceric : tungsten ratio. The titration curve shows only one inflection, suggesting that ceric tungstate behaves as a monofunctional acid.

As regards the effect of neutral salt solution concentration and the time of equilibration on the capacity determined by batch operation, a constant capacity for Na^+ was obtained at $1M$ neutral salt concentration after a 48 hr equilibration. Elution curves reveal that at least 80 ml of $1M$ eluent is required for complete elution, although most of the hydrogen ions are released in the first 20 ml.

The effect of pH on exchange capacity is practically negligible. Ceric tungstate in the acid form gives a buffer system[1] of pH 2–3 and its exchange capacity remains practically unchanged at temperatures up to 100°. This suggests its possible use for buffering aqueous systems at higher temperatures. The exchanger has moderate regeneration properties, and may be used without breakdown of the particle or deterioration in ion-exchange properties.

Summary—Ceric tungstate has been prepared under varying conditions of precipitation. Its properties and ion-exchange behaviour have been studied. Separations of Hg^{2+} from Zn^{2+}, Cd^{2+} and Pb^{2+}; Co^{2+} from Mn^{2+} and Fe^{3+}; and Al^{3+} from Cr^{3+} and Fe^{3+} have been carried out on ceric tungstate columns.

Zusammenfassung—Cerwolframat wurde unter verschiedenen Fällungsbedingungen hergestellt und seine Eigenschaften und sein Ionenaustauschverhalten untersucht. An Cerwolframatsäulen wurden Trennungen von Hg^{2+} und Zn^{2+}, Cd^{2+} und Pb^{2+}, Co^{2+} von Mn^{2+} und Fe^{2+} sowie Al^{3+} von Cr^{3+} und Fe^{3+} ausgeführt.

Résumé—On a préparé le tungstate cérique dans conditions variables de précipitation. On a étudié ses propriétés et son comportement d'échange d'ions. On a réalisé des séparations de Hg^{2+} de Zn^{2+}, Cd^{2+} et Pb^{2+}, Co^{2+} de Mn^{2+} et Fe^{3+} et Al^{3+} de Cr^{3+} et Fe^{3+} sur des colonnes de tungstate cérique.

LOCATING THE MORE ACIDIC HYDROXYL GROUP ON DIHYDROXY COMPOUNDS

o,o'-DIHYDROXYAZO-DYE METAL-ION INDICATORS

FREDERICK LINDSTROM and ANN EDWARDS WOMBLE*
Department of Chemistry and Geology, Clemson University, South Carolina 29631, U.S.A.

(*Received* 12 *May* 1972. *Accepted* 13 *October* 1972)

Summary—In *o,o'*-dihydroxyazo-dye metal-ion indicators, one hydroxyl group is 10^4 times more acidic than the other. The location of the more acidic group has been a mystery. By methylation of the acidic group, reduction of the monomethylated compound, isolation and characterization of the split methoxyamine and hydroxyamine, the location of the acidic group has been established. Indicators examined include Calmagite, Eriochrome Black T, Eriochrome Blue Black R and 4-(2-pyridylazo)resorcinol (PAR).

Compounds having two or more ionizable hydroxyl groups often show a marked difference in the degree of ionization of these groups. It would be interesting to determine which of the groups on the compound ionizes first. The means to do this are available. Braun, Anton and Weissbach[1] have shown that dimethyl sulphate will methylate ionized hydroxyl groups 10^4 times faster than unionized groups. So if the more acidic hydroxyl group is neutralized while the less acidic is not, methylation should occur exclusively on the oxygen atom of the ionized group. Since methyl ethers are quite stable and often easy to isolate, location of the methyl group on the monomethyl product should be straightforward.

o,o'-Dihydroxyazo-dyes used as metal-ion indicators are good candidates for this method. The acid dissociation constants are known. They show a K_1/K_2 ratio of over 10^4 so the ionization processes are independent. The compounds are also pH indicators and are of a distinctive blue colour in the half-neutralized state. The hydroxyl groups are on different rings, the rings being connected by the azo linkage. The azo linkage on reduction yields two separated amines which can then be isolated to see which one is a methyl ether. Isolation of the other amine to be sure that it is not a methyl ether is definitive. Acetylation of the products, as a routine measure, would yield convenient, stable, crystalline derivatives easy to identify.

Several *o,o'*-dihydroxyazo-dye metal-ion indicators were investigated. Dye I was 1-(2-hydroxy-1-benzeneazo)-2-naphthol, used by Diehl and Ellingboe[2] to help demonstrate that the necessary and sufficient structure needed for a calcium or magnesium azo-dye metal-ion indicator was two hydroxyl groups, one on each ring adjacent to the azo group. Dye II was Calmagite, the indicator developed by Lindstrom and Diehl[3] specifically as a stable indicator for the EDTA titration of calcium plus magnesium and

investigated later by Lindstrom and Isaac.[4] Dye III was Eriochrome Black T or Mordant Black 11, C. I. 14645[5] the commercially important dye for wool, introduced by Schwarzenbach and Biedermann[6] as the first indicator for the direct titration of calcium plus magnesium with EDTA. Unfortunately stock solutions of this dye do not keep well, which necessitates the repeated preparation of indicator solutions. This dye was later investigated in detail as an indicator by Diehl and Lindstrom.[7] Dye IV was Eriochrome Blue Black R or Mordant Black 17, C. I. 15705[5] a dye also studied by Schwarzenbach and Biedermann[6] and later suggested by Hildebrand and Reilley[8] as an indicator for the EDTA titration of calcium alone, at high pH, and designated Calcon. Dye V was 4-(2-pyridylazo)resorcinol (PAR), suggested by Wehber[9] as an indicator for the EDTA titration of some transition metal ions. This compound is not an *o,o'*-dihydroxyazo-dye but it does contain two hydroxyl groups of widely different strength.[10]

Table 1 lists the dyes investigated along with the negative logarithms of their acid dissociation constants. As has been the custom, these dissociation constants refer only to the hydroxyl groups, even for the sulphonated dyes.

The more acidic hydroxy group is indicated by an arrow in the structural formulae given.

EXPERIMENTAL

Apparatus

Infrared spectrophotometer. Perkin–Elmer Model 137

Ultraviolet Model visible spectrophotometer. Perkin–Elmer 4000A

pH meter. Leeds Northrup model 7405, standardized with reference buffers[11] (phthalate, pH 4·01 at 25°; borax, pH 9·18 at 25°).

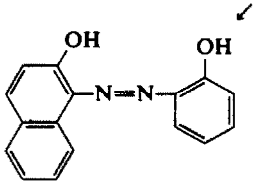
Capillary melting point apparatus. Thomas Hoover 'Uni-melt' apparatus.

The carbon, hydrogen, and nitrogen analyses were done by a commercial laboratory. The hydroxyl determinations were carried out by the procedure described by Siggia.[12]

Reagents

All inorganic chemicals used were reagent grade. All organic chemicals were recrystallized or redistilled as needed. All water used was distilled and demineralized with an ion-exchange column charged with Bio-Rex 501-X8 mixed-bed resin (Bio-Rad laboratories).

1-(2-Hydroxy-1-benzeneazo)-2-naphthol, Dye I



Dye I was prepared by diazotizing 2-aminophenol and coupling to 2-naphthol in basic solution. 2-Aminophenol, 65·5 g, was dissolved in 1000 ml of water with just enough hydrochloric acid to effect solution and the solution was cooled to 5°. Then 41·4 g of sodium nitrite in aqueous solution were added. 2-Naphthol, 95 g, was mixed with 2500 ml of 50% sodium hydroxide to yield a milky suspension which was also cooled to below 5°. The diazonium solution was added to the naphthol with constant stirring while the temperature was kept below 7° by the addition of ice. The mixture was allowed to stand for a day to come to room temperature. The crystals of the sodium salt were filtered off and washed several times with hydrochloric acid (1 + 1) to yield the acid form which was recrystallized from methanol; yield: 53·7%; m.p. 191–193°; required[13] 193°.

For methylation 1·33 g of I were dissolved in 500 ml of dioxan. The pH of the solution was adjusted to approximately 10, with 1*M* sodium hydroxide. The blue solution was cooled to about 0° in an ice-bath, filtered to remove any undissolved material, and placed in the fume-cupboard in an ice-bath. Dimethyl sulphate, 0·46 ml, was added over a period of 1 hr with constant stirring. The solution was then heated on a steam-bath for 1 hr. The methylated dye was isolated by pouring the solution into 1·5 l. of water. The dye was filtered off and washed with water several times. The methylated dye was air-dried and recrystallized from methanol. Yield: 79%. Analysis gave: C, 73·1%; H, 4·8%; N, 10·3%; OH, 6·2%. Calculated for $C_{17}H_{14}N_2O_2$: C, 73·37%; H, 5·07%; N, 10·07%; OH, 6·11%: m.p. 179·5–183°; required[14] 180°.

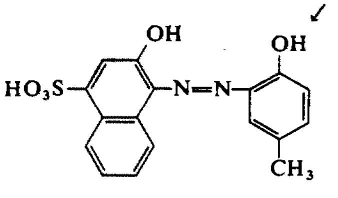
The next step was to reduce the methylated I and separate and identify the hydroxyamine and methoxyamine which would be formed. Reduction was carried out with sodium dithionite ($Na_2S_2O_4 \cdot 2H_2O$) in basic solution. Methylated dye, 0·23 g, was dissolved in 200 ml of absolute ethanol. Fifty ml of 50% sodium hydroxide were added and the solution heated to boiling. Sodium dithionite was added gradually until the solution lost its colour. The solution was steam-distilled for about 30 min. The distillate will be referred to as I-A; the residue remaining in the flask as I-B.

I-A was extracted into ether. The ether was evaporated, leaving an oily material. This oil was acetylated by the method of Noelting, Grandmougin and Freimann,[15] slightly modified. The oil was dissolved in 25 ml of ethyl acetate; 5 ml of acetic anhydride and 2 ml of pyridine were added, and the solution refluxed for 2 hr. The solution was then evaporated to dryness with a rotary evaporator. The residue was extracted with and recrystallized from hot water. Yield: 65% of long white needles: m.p. 88°. Required for 2-acetamidophenol methyl ether[16] 87–88°. 2-Acetamidophenol methyl ether was prepared by the acetylation of 2-anisidine, by the method described previously. The product was recrystallized from hot water. Yield: 92·7%: m.p. 88°. The infrared spectra of the 2-acetamidophenol from the two sources were identical.

The residue I-B was neutralized with dilute hydrochloric acid. Immediately, white flakes precipitated which were filtered off and air-dried. This product was then acetylated as described above. The solution was evaporated to dryness, and the residue was extracted with and recrystallized from hot ethanol. The white crystals separated slowly. Yield: 67%: m.p. 204–206°. Required for 1-acetamido-2-acetoxynaphthalene[17] 206°. 1-Acetamido-2-acetoxynaphthalene was prepared by a similar acetylation of 1-amino-2-naphthol. The product was recrystallized from ethanol. Yield: 91%: m.p. 204–206°. The infrared spectra of the 1-acetamido-2-acetoxynaphthalene from the two sources were identical.

The methylation of 1-(2-hydroxy-1-benzeneazo)-2-naphthol occurred only on the benzene ring so pK_1 is a measure of the acidity of the phenolic hydroxyl group. The resultant compound was C. I. Solvent Red 1, C. I. 12150,[5] which is prepared by coupling diazotized 2-anisidine with 2-naphthol.

Calmagite or 1-(1-hydroxy-4-methyl-2-phenylazo)-2-naphthol-4-sulphonic acid, Dye II



Calmagite was prepared by the method of Lindstrom and Isaac.[4] For methylation, 4 g of II were dissolved in 500 ml of dioxan, the pH was adjusted to 10 with 1*M* sodium hydroxide, the blue solution cooled to 0–5°, and filtered to remove any undissolved material. Slowly, with stirring, 4·55 ml of dimethyl sulphate were added over a period of 1 hr. The solution was then heated on a steam-bath for 1 hr. The methylated dye was isolated by the addition of hydrochloric acid (1 + 1). If acid is added to the solution rather than solution to the acid, swelling is decreased, and filtration is easier. This solution was cooled and filtered. The methylated dye was washed by decantation several times with hydrochloric acid (1 + 1), filtered off and air-dried. Yield: 94%. Analysis gave: C, 57·9%; H, 4·3%; N, 7·4%; OH, 4·6%. Calculated for $C_{18}H_{16}N_2O_5S$: C, 58·06%; H, 4·33%; N, 7·52%; OH, 4·57%.

Methylated II was reduced with stannous chloride and hydrochloric acid as suggested by the work of Ruggli, Zimmerman and Knapp.[18] Methylated II, 0·70 g, was added to 25 ml of boiling water followed by 0·70 g of stannous chloride dihydrate dissolved in 8 ml of concentrated hydrochloric acid. The mixture was refluxed for 2 hr. At the end of this time, there was a precipitate present. The solution was cooled and filtered. Yield: 87%. The compound decomposed without melting. The infrared spectrum was the same as the infrared spectrum of Eastman Kodak 1-amino-2-naphthol-4-sulphonic acid, a compound only slightly water-soluble.

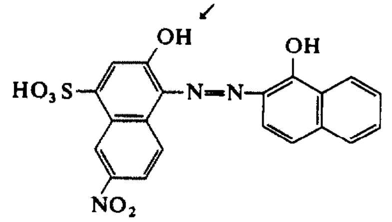
The filtrate was made alkaline and steam-distilled. A white product solidified in the distillate and was filtered off. This product was acetylated by the method described previously and was recrystallized from ethanol. Yield: 86%, m.p. 110°. Required for 2-acetamido-*p*-cresyl methyl ether,[19] 110°.

The first step in the preparation of 2-acetamido-*p*-cresol methyl ether was the nitration of *p*-cresol, by the method of Schultz.[20] *p*-Cresol (20 g) was dissolved in 40 g of benzene. Over a 2-hr period, 11·7 ml of concentrated nitric acid mixed with an equal amount of water were added with constant stirring at 25°. The reaction mixture was allowed to stand in a separatory-funnel until the phases separated. The upper phase was neutralized with sodium bicarbonate solution and then steam-distilled. The benzene distilled first and was extracted several times with 1*M* sodium hydroxide. The extracts were returned to the distillation flask after neutralization with phosphoric acid. The 2-nitro-4-methylphenol was the only material volatile under these conditions. Yield: 75%; m.p. 35°; required[22] 36·5°.

The 2-nitro-4-methylphenol was methylated by the method of Robinson.[22] 2-Nitro-4-methyl phenol, 15 g, was added to 500 ml of xylene. Excess of potassium carbonate, 21 g, was added with 10 ml of dimethyl sulphate. The reaction mixture was refluxed until the red potassium salt of the nitro-compound was replaced by colourless potassium sulphate and potassium methyl sulphate. The xylene was removed by steam-distillation at 92–98°. The nitro-compound followed this. The distillate was extracted several times with ether. The ether was evaporated, leaving a yellow oil which was dissolved in 350 ml of water. To this solution were added 20·0 g of stannous chloride dihydrate dissolved in 115 ml of concentrated hydrochloric acid. This solution was refluxed for 2 hr, made alkaline and steam-distilled. The amine solidified in the distillate and was filtered off. After drying, the amine was acetylated in the usual manner. The product was recrystallized from ethanol. Yield: 46·8%, m.p. 110°. The infrared spectra of the 2-acetamido-*p*-cresyl methyl ether from this synthesis and from the methylated Calmagite were identical.

The methylation of Calmagite occurred only on the benzene ring so pK_1 is a measure of the acidity of the phenolic hydroxyl group.

Eriochrome Black T or 1-(1-hydroxy-2-naphthylazo)-2-naphthol-6-nitro-4-sulphonic acid, Dye III



Dye III was Eastman Kodak Eriochrome Black T and was purified by the method of Diehl and Lindstrom.[7] It was recrystallized from dimethylformamide from which it was isolated as the crystalline dimethylamine salt.

For methylation 2 g of III were dissolved in 500 ml of dioxan. The solution was filtered to remove any undissolved material. The solution was then adjusted to approximately pH 10 with 1*M* sodium hydroxide. The blue solution was kept cooled, and 0·75 ml of dimethyl sulphate was added to the solution over a period of 1 hr, with constant stirring. This was followed by heating on a steam-bath for 1 hr. The dye was isolated by adding excess hydrochloric acid (1 + 1). The precipitate was filtered off and washed several times with the same concentration of acid and was allowed to dry in air. Yield: 75%. Analysis gave: C, 55·4%; H, 3·6%; N, 9·6%; OH, 3·8%. Calculated for $C_{21}H_{15}N_3O_7S$: C, 55·63%; H, 3·34%; N, 9·27%; OH, 3·75%.

Methylated III was reduced by dissolving 1 g of it in 50 ml of boiling water and adding a hot solution of 6·5 g of stannous chloride dihydrate in 15 ml of concentrated hydrochloric acid. The solution was refluxed for 2 hr. Then 50 ml of water were added and refluxing was continued for 30 min. Then, 15 ml of concentrated hydrochloric acid and decolourizing carbon were added. Refluxing was continued for 30 min and the decolourizing carbon was filtered off while the solution was still hot. After cooling, a white precipitate formed and was collected. The yield was 0·45 g (75·8%) of a material which will be referred to as III-A. The melting point of this material could not be determined. The absence of a melting point, the infrared spectra and limited water-solubility led to the belief that III-A might be 1,6-diamino-2-naphthol methyl ether-4-sulphonic acid in the zwitterion form.

To prepare this compound, 1-diazo-2-naphthol-4-sulphonic acid was nitrated as described for the synthesis of dye No. 241 in *Farbstofftabellen.*[14] The 1-diazo-2-naphthol-6-nitro-4-sulphonic acid was recrystallized from ethanol; yield: 66%.

The diazo compound was then coupled with *p*-cresol. Vacuum distilled *p*-cresol, 3·6 g, was dissolved in a solution of 23 g of potassium hydroxide in 35 ml of water. Then a mixture of 10 g of the diazo component in water was added slowly and the mixture slowly heated to 60°. This temperature was maintained until coupling was complete. The solution was cooled and the dye was precipitated by addition of hydrochloric acid (1 + 1). The dye was then recrystallized by dissolving it in 500 ml of ethanol, adding 50 ml of hydrochloric acid (1 + 20), and slowly evaporating the ethanol on a warm steam-bath. The solution was cooled, and the precipitate was filtered off and air-dried. Yield: 38%.

This dye (5 g) was dissolved in 500 ml of dioxan, and excess of 50% sodium hydroxide solution was added, so both hydroxyl groups would be ionized. Dimethyl sulphate (10 ml) was added to the solution at 0–5° with constant stirring, over a period of 1 hr. The solution was then heated on a steam-bath for 1 hr. The methylated dye was then precipitated by the addition of excess of hydrochloric acid (1 + 1). The dimethylated dye was filtered off, then washed several times with hydrochloric acid (1 + 1). Yield: 65·3%.

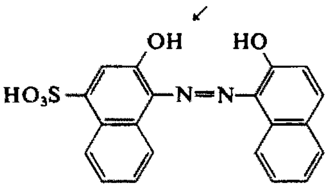
This dimethylated dye, 3·5 g, was added to 200 ml of boiling water. A hot solution of 26·0 g of stannous chloride dihydrate in 45 ml of concentrated hydrochloric acid was added. The solution was refluxed for 2 hr. Hot water (200 ml) was added, and the solution refluxed for 30 min. Decolourizing carbon and 45 ml of concentrated hydrochloric acid were added, and the solution was refluxed for another 30 min, filtered, and cooled. A white precipitate formed upon cooling and was filtered off. Yield: 70%. The infrared spectrum of this 1,6-diamino-2-naphthyl methyl ether-4-sulphonic acid was identical with that of **III-A**.

The filtrate from the separation of **III-A** after the reduction of methylated Eriochrome Black T was treated with hydrogen sulphide to precipitate the tin. The tin sulphide was then filtered off and the filtrate was reduced in volume to about 10 ml. A rose precipitate formed, was filtered off, and acetylated as previously described. The product (referred to as **III-B**) was recrystallized from ligroin. Yield: 70·9%; m.p. 116–117°; required for 2-acetamido-1-acetoxynaphthalene[23] 116°, 117·5°.

2-Amino-1-naphthol was prepared by the method of Grandmougin and Michel.[24] 2-Nitroso-1-naphthol (2 g) was suspended in 250 ml of concentrated hydrochloric acid and cooled to 0°. Stannous chloride dihydrate, 6·90 g, was added. The solution was kept cool until a white precipitate appeared, which was dissolved by the addition of water. Tin was precipitated from the solution by treatment with hydrogen sulphide. After filtration, the solution was reduced in volume until a white precipitate was obtained which was was acetylated as previously described and recrystallized from ligroin. Yield: 52·75%, m.p. 116°. The infrared spectra of 2-acetamido-1-acetoxy-naphthalene from this synthesis and from the reduced, methylated Eriochrome Black T were identical.

The methylation of Eriochrome Black T occurred only on the naphthalene ring, which was sulphonated, so pK_1 is a measure of the acidity of the hydroxyl group on that ring.

Eriochrome Blue Black R or 1-(2-hydroxy-1-naphthylazo)-2-naphthol-4-sulphonic acid, Dye IV



Dye **IV** had been prepared earlier by the diazotization of 1-amino-2-naphthol-4-sulphonic acid with sodium nitrite in acid solution, followed by coupling to 2-naphthol in concentrated alkaline solution. It had been converted into the acid form, filtered off, air-dried and extracted with solvents to remove any excess of 2-naphthol. It was purified further by dissolving 20 g of product in ethanol, and adding 50 ml of hydrochloric acid (1 + 20). The ethanol was slowly evaporated on a warm steam-bath to precipitate the dye. Yield: 75%.

For methylation 3·94 g of the dye were dissolved in 500 ml of dioxan. The pH was adjusted to approximately 10 with 1*M* sodium hydroxide. The blue solution was cooled to 0–5° and filtered to remove any undissolved material. Dimethyl sulphate, 3·85 ml, was added over a period of 1 hr with constant stirring. The solution was then heated on a steam-bath for 1 hr. The dye was filtered off and washed several times with hydrochloric acid (1 + 1) and dried. Yield: 78·5%. Analysis gave: C, 61·8%; H, 3·7%; N, 6·6%, OH, 4·1%. Calculated for $C_{21}H_{16}N_2O_5S$: C, 61·76%; H, 3·95%; N, 6·86%, OH, 4·16%.

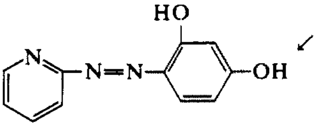
Methylated **IV** was reduced by adding 0·94 g to 25 ml of boiling water and then adding 8 ml of hydrochloric acid containing 1·25 g of stannous chloride dihydrate and refluxing for 2 hr to yield a precipitate. The solution was cooled and the precipitate filtered off. The precipitate was expected to be the sulphonated portion of methylated **IV**, and will be referred to as **IV-A**. The melting point of this compound could not be determined.

1-Amino-2-naphthol methyl ether-4-sulphonic acid was prepared for comparison with **IV-A**. Dye **II**, 2 g, was dissolved in 500 ml of dioxan. Sodium hydroxide, 1*M*, was added until both hydroxyl groups were ionized. The solution was cooled to 0–5° and filtered. Over a period of 1 hr, with constant stirring, 4·55 ml of dimethyl sulphate were added. The solution was heated on a steam-bath for 1 hr. The dye was isolated by adding excess of hydrochloric acid (1 + 1), filtering off and washing several times with hydrochloric acid (1 + 1). After air-drying, the yield was 67·2%. Dimethylated Calmagite was dissolved in 50 ml of boiling water and stannous chloride dihydrate, 2·50 g, in 16 ml of concentrated hydrochloric acid was added. Refluxing for 2 hr yielded a precipitate, which was filtered off after cooling. Yield: 89%. The infrared spectra of 1-amino-2-naphthol methyl ether-4-sulphonic acid prepared as above and of **IV-A** from the reduction of methylated Eriochrome Blue Black R were identical.

The solution remaining from the filtration of **IV-A** was treated with hydrogen sulphide to remove the tin. The filtered solution was then neutralized. A white precipitate appeared which was filtered off, air-dried and acetylated by the method described previously. The product was recrystallized from ethanol. Yield: 82·5%: m.p. 204–206°. Required for 1-acetamido-2-acetoxynaphthalene[17] 206°. This portion will be referred to as **IV-B**. The infrared spectra of **IV-B** and 1-acetamido-2-acetoxynaphthalene, which had been prepared for the study of **I**, were identical.

The methylation of Eriochrome Blue Black R occurred only on the naphthalene ring, which was sulphonated, so pK_1 is a measure of the acidity of the hydroxyl group on that ring.

4-(2-Pyridylazo)resorcinol, (PAR), Dye V



The PAR used was prepared by the method of Pollard, Hanson and Geary.[25] A solution of sodium ethoxide was prepared by dissolving 2·4 g of metallic sodium in 37 ml of absolute ethanol. 2-Aminopyridine, 10 g, was dissolved in the minimum possible quantity of absolute ethanol, and 12 g of isoamyl nitrite were added. The solutions were mixed, and refluxed gently for 2 hr. The diazotate formed a brown solid. The coupling reaction was carried out directly. Resorcinol, 16 g, was dissolved in the minimum possible quantity of water and added to the diazotate solution. The mixed solutions were allowed to cool in the refrigerator for 40 hr. If there was any difficulty in precipitating the dye, ether was added to force precipitation. The disodium salt of the dye was filtered off and washed thoroughly with ether. A saturated solution of the dye in water was made. Hydrochloric acid, 0·5*M*, was added with stirring to precipitate the acid form of V. This material was air-dried and recrystallized from methanol. Yield: 10%.

V, 2 g, was mixed with a solution of 10 g of potassium hydroxide in 25 ml of water. The solution was cooled to 0–5°, and filtered. Dimethyl sulphate, 0·5 ml, was added, and the solution was shaken for 30 min. Dimethyl sulphate, 0·5 ml, was again added and the solution shaken for 30 min. This was repeated three more times. A total of 2·5 ml of dimethyl sulphate was used. Ethanol, 25 ml, was added to make the solution about 50% v/v ethanol. Ether was added to the solution to precipitate the methylated dye. The methylated dye was recrystallized from methanol. Yield: 71·8%; m.p. 170° d. Analysis gave: C, 63·0%; H, 4·6%; N, 18·3%; OH, 7·5%. Calculated for $C_{12}H_{11}N_3O_2$: C, 62·87%; H, 4·84%; N, 18·33%; OH, 7·42%.

For the reduction, 1 g of methylated V was dissolved in 10 ml of ethanol. This solution was warmed with a solution of 2·4 g of stannous chloride dihydrate in 20 ml of concentrated hydrochloric acid. A dark reddish-brown precipitate appeared immediately: the tin double salt of 2-aminopyridine. The solution was filtered. The filtrate was treated with hydrogen sulphide to remove tin sulphide. The filtrate was evaporated to dryness, and the residue was extracted with and recrystallized from dilute hydrochloric acid. This product was acetylated in 50% acetic acid with acetic anhydride by refluxing for 2 hr. The resulting solution was evaporated to dryness and the residue taken up in hot water. The solution was treated with bone-black and filtered. The acetyl derivative separated upon standing. Yield: 74·1%, m.p. 163–164°; 4-acetamidoresorcinol-1-methyl ether,[26] 166°. This material will be referred to as V-A.

The first step in the preparation of 4-acetamidoresorcinol-1-methyl ether was the methylation of resorcinol by the method of Perkin, Rây and Robinson.[27] Resorcinol (55 g) was dissolved in 50 ml of absolute ethanol, along with 60 ml of dimethyl sulphate. Potassium hydroxide (20 g dissolved in 50 ml of water) was added to the solution at 25°. The solution was shaken frequently for 1 hr and cooled under running water. Potassium hydroxide (20 g dissolved in 50 ml of water) was added to the solution. The solution was then heated on the steam-bath for 45 min. The solution was cooled, acidified, and extracted with benzene. The extracts were washed with 10% sodium hydroxide solution until no more material was removed. The washings were then acidified and again extracted. The benzene extracts were then distilled. The monomethyl ether of resorcinol distilled at 239–241°; literature value[27] 240–242°. Yield: 32·3%.

Nitrosation of the monomethyl ether of resorcinol was carried out by the method of Henrick and Rhodius.[28] Resorcinol monomethyl ether (20 g) was dissolved in 50 ml of absolute ethanol. Glacial acetic acid (32 g) was added. Sodium nitrite (17 g) was dissolved in 32 ml of water. Both solutions were cooled to below 5°. After all the sodium nitrite had been added dropwise, the solution was stirred for 30 min. The temperature was maintained below 5° at all times. The solution was then strongly acidified, cooled, and the precipitate filtered off. The product was dried over calcium oxide in a vacuum desiccator. After the crystalline mass was dry, it was completely dissolved in cold benzene. From this solution, about half the benzene was distilled. The more insoluble material precipitated in large, dark-green crystals upon cooling. This was the labile form of 4-nitrosoresorcinol-1-methyl ether. At 140°, the labile form is converted into the stable form. Yield: 32·3%.

This material (3 g) was introduced stepwise into a solution of stannous chloride in concentrated hydrochloric acid. During the addition, the reaction product began to separate out. After all had been added, the mixture was warmed on a steam-bath for a very short time, and cooled. The crystals which precipitated were the tin double salt. These crystals were dissolved in 1*M* hydrochloric acid, and the solution was treated with hydrogen sulphide to remove the tin. The tin sulphide was filtered off, and the filtrate was evaporated to dryness. The residue was extracted with and recrystallized from dilute hydrochloric acid and air-dried. Acetylation was then carried out in 50% acetic acid with acetic anhydride. The solution was refluxed for 2 hr, then evaporated to dryness, and the residue was extracted with hot water. This solution was treated with bone-black and filtered; crystals separated upon standing. Yield: 23% of 4-acetamido-resorcinol-1-methyl ether, m.p. 163–164°. The infrared spectra of this compound and V-A were identical. Therefore, the hydroxyl group *para* to the azo linkage is the more acidic.

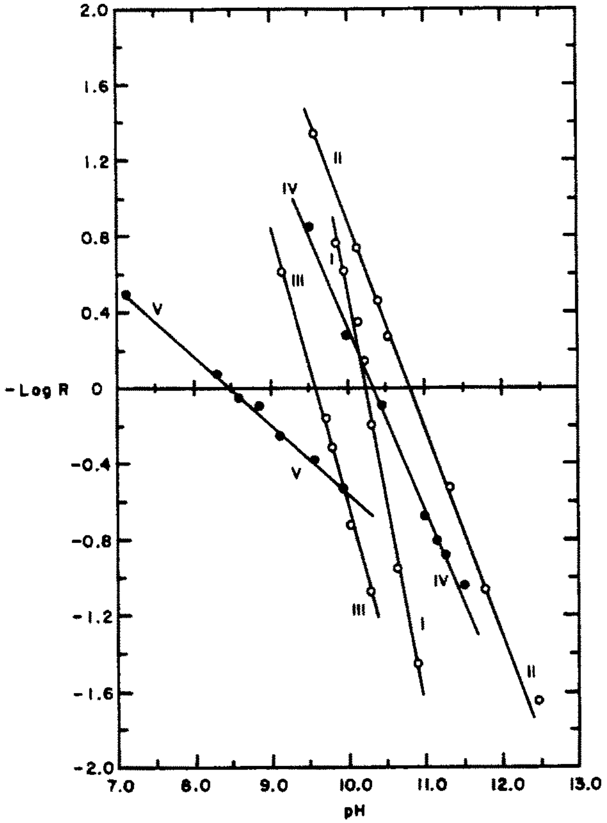


Fig. 1. Plots for the determination of acid dissociation constants of the monomethylated dyes. Dyes are designated with their corresponding Roman numeral.

Determination of acid dissociation constants

Stock solutions of each of the monomethylated dyes were made up, each containing 0·1 mole of potassium chloride: I, 0·0489 g/250 ml, 95% ethanol; II, 0·0447 g/250 ml, water; III, 0·0881 g/250 ml, water; IV, 0·0459 g/250 ml, water; V, 0·0233 g/250 ml, water. So that all absorption and pH measurements could be made at constant ionic strength, $\mu = 0{\cdot}10$, a procedure described by Bates[11] was used in preparing buffers for each pH range. A stock solution A was made up, that was 0·05*M* in monobasic weak acid or monobasic weak base, and 0·05*M* in potassium chloride. The pH was then varied by adding various amounts of stock solution B, which was 0·2*M* in hydrochloric acid or sodium hydroxide, and 0·1*M* in potassium chloride. For pH values from 6 to 7·5, potassium dihydrogen phosphate and hydrochloric acid were used; from 7·5 to 9, tris-(hydroxymethyl)-aminomethane and hydrochloric acid; from 9 to 10·5, sodium borate decahydrate and sodium hydroxide; from 10·5 to 12, disodium monohydrogen phosphate and sodium hydroxide.

Ten ml of the stock solution of methylated dye were transferred by pipette into a 100-ml volumetric flask. The appropriate stock solution A (50 ml) was added, and the pH was varied by adding different volumes of stock solution B. The solution was then made up to volume with 0·1*M* potassium chloride. The absorption spectra of the solutions were run and the pH measured with a previously standardized pH-meter. Figure 1 shows the plot of pH *vs.* $-\log R$ where R is $(A - A_{\min})/(A_{\max} - A)$. The acid dissociation constants found are listed in Table 2. A represents the absorbance of the monomethylated dye solution at the stated pH, $A_{\max}$ the highest absorbance and $A_{\min}$ the lowest absorbance, all measurements being made at the wavelength of maximum spectral change with pH.

RESULTS AND DISCUSSION

The proposed method of investigation of *o,o*′-dihydroxyazo-dye indicators has yielded the desired information. The five dyes studied were methylated on one hydroxyl group with dimethyl sulphate, and reduced to methoxyamines and hydroxyamines. These amines

Table 1. Hydroxyl group acidity, dihydroxyazo-dyes

Dye	pK_1	pK_2	Reference
I	7·7	12·4	2
II	8·14	12·35	3
III	6·91	11·50	6, 7
IV	7·36	13·5	6, 8
V	5·48	12·31	10

were then separated and characterized by comparison of the infrared spectra with those of known compounds. It was found that *o*-hydroxybenzeneazo-2-naphthol and Calmagite were methylated on the phenolic hydroxyl group. Eriochrome Blue-Black R and Eriochrome Black T were methylated on the sulphonated portion of the dye, and PAR was methylated on the hydroxyl group which is *para* to the azo group.

Methylations were carried out in basic solution with dimethyl sulphate both in dioxan and water. Dioxan was chosen as the best reaction medium because the dyes were much more soluble in it than in water. Also, dioxan had no hydroxyl group to compete in the reaction. When dioxan was used as the solvent, some methylated material remained in solution upon the addition of hydrochloric acid (1 + 1). However, the yield was still greater than if the same volume of water were used. The basic azo-dye solutions were completely opaque. Before methylation, the solutions were filtered to remove any undissolved dye.

Some of the metal-ion indicator dyes investigated were sulphonated and the ionized sulphonic acid groups would be expected to yield methyl esters while the hydroxyl groups are being converted into methyl ethers. Sulphonic acid esters are very reactive and will rapidly react with water in a manner similar to dimethyl sulphate.

Two methods of reduction were used: by sodium dithionite in basic solution and by stannous chloride in acid solution. Reduction by sodium dithionite was quick and easy, but the reaction products had to be stable to air oxidation in basic solution so that the two amines could be separated. In the case of methylated I, air-oxidation was slow enough for separation to be carried out. In the cases of dyes II–V, one of the reduction products was so quickly oxidized in basic solution that the separation was impossible. The reduction of these dyes in acid media with stannous chloride was quite successful. In addition, the aminonaphthol sulphonic acids proved to be insoluble in the acid media, which made separation quite easy. It was found that acetylation yielded very stable products.

Table 2 lists the negative logarithms of the acid dissociation constants of the monomethylated azo dye indicators. It will be noted that the pK_a values of the methylated dyes

Table 2. Hydroxyl group acidity, monomethylated dihydroxyazo-dyes

Dye	pK_a	$\frac{1}{2}(pK_1 + pK_2)$*
I	10·25	10·05
II	10·80	10·25
III	9·56	9·20
IV	10·33	10·43
V	8·45	8·90

* From Table 1.

are quite close to the average of the pK_1 and pK_2 values of the parent dyes, so methylation of one hydroxyl group and determination of the acidity of the remaining hydroxyl group would not give correct information about pK_2 for the parent dye. Nor would proton magnetic resonance be expected to be useful. The differences in the slopes in Fig. 1 are caused by the difference in the molar absorptivities of the dyes.

This method of experimental determination of the exact sequence of ionization has been found to be easy and flexible and should be applicable to many similar problems.

Zusammenfassung—In *o,o'*-Dihydroxyazofarbstoffen, die als Metallionenindikatoren verwendet werden, ist eine Hydroxylgruppe 10^4-mal saurer als die andere. Wo die saurere Gruppe liegt, war bisher ungeklärt. Durch Methylierung der sauren Gruppe, Reduktion der Monomethylverbindung, Isolierung und Charakterisierung der bei der Spaltung entstandenen Methoxyamine und Hydroxyamine wurde die Lage der sauren Gruppe festgestellt. Unter den überprüften Indikatoren waren Calmagit, Eriochromschwarz T, Eriochromblauschwarz R und 4-(2-Pyridylazo)-resorcin (PAR).

Résumé—Dans les indicateurs d'ions métalliques colorants *o,o'*-dihydroxyazo, un groupe hydroxyle est 10^4 fois plus acide que l'autre. La localisation du groupe le plus acide était un mystère. Par méthylation du groupe acide, réduction du composé monométhylé, isolement et caractérisation de la méthoxyamine et de l'hydroxyamine de coupure, on a établi la localisation du groupe acide. Les indicateurs examinés comprennent: Calmagite, Noir Eriochrome T, Bleu Noir Eriochrome R et 4-(2-pyridylazo) résorcinol (PAR).

APPLICATION OF VARIOUS ELECTRODES IN POTENTIOMETRIC TITRATION OF CALCIUM

ADAM HULANICKI and MAREK TROJANOWICZ

Institute of Fundamental Problems in Chemistry, University of Warsaw, Poland

(*Received* 1 *August* 1972. *Accepted* 11 *October* 1972)

Summary—In complexometric titrations various indicator electrodes may be employed for monitoring the course of titration and for detection of the end-point. Several of them, including the silver, mercury, bivalent cation membrane, calcium membrane and manganese dioxide electrodes were investigated and compared in their usefulness. As titrant, EDTA was mostly used, but results with similar chelating titrants were also obtained. The practical utility of the electrodes in titrations depends on their selectivity, magnitude of the end-point break and precision in determination of the end-point. For the electrodes studied, in some instances there is good correlation between the theoretical and experimental titration curves, but it is not always possible to predict the electrode response in the low activity range. In other cases poor correlation does not mean that reasonably good analytical results may not be obtained.

A revolution in methods of calcium determination began over 20 years ago when ethylenediaminetetra-acetic acid was introduced as a titrant for metal ions. Since that time many visual indicators have successfully been used, and attempts have been made to use electrometric end-point detection, which should be less subject to personal error, and remove the necessity of finding a suitable indicator. Examples of application of amperometry, potentiometry and even chronopotentiometry may be found in the literature. This study is devoted to comparative investigation of various potentiometric methods of calcium titration.

In potentiometry the crucial factor is the existence of a suitable indicator electrode. For many years no direct-indication calcium electrode was available, so the first procedures were based on indirect indicator-ion systems. Of this group the mercury,[1–4] silver[5–9] and manganese oxide electrodes[10] were reinvestigated in our laboratory. The advent of ion-selective electrodes has resulted in the construction of liquid ion-exchanger electrodes for calcium and for bivalent ions. Each offers some advantages, but has its drawbacks. As reported earlier[11] the potential of these electrodes is measured indirectly on the basis of the exchange reaction

$$\mathrm{W} + \mathrm{CaY} \rightleftharpoons \mathrm{Ca} + \mathrm{WY},$$

where W represents the indicator ion. This reaction directly influences the electrode according to the general equation

$$E = E_{\mathrm{W}}{}^{0} + \frac{RT}{nF}\ln\frac{C_{\mathrm{W}}\,.\,K'_{\mathrm{CaY}}}{\alpha_{\mathrm{W}}\left(K'_{\mathrm{WY}}\,.\,\dfrac{[\mathrm{CaY}']}{[\mathrm{Ca}']} + K'_{\mathrm{CaY}}\right)},$$

derived by using the concept of conditional constants K' and side-reaction coefficients α.

It enables us to predict the shape of the titration curve, the end-point position and the smallest concentration of metal which can still be titrated.

Silver electrode

Because the calcium complex with EDTA is more stable than that of silver the titration curve is evidently asymmetrical. The smallest conditional stability constant in this system is that for the silver complex, and under the best conditions (borax buffer, pH 9–10) its value is $10^{7 \cdot 0}$. The product of this constant and the calcium concentration defines the total potential change in the titration. About 100 mV change between titration fraction $f = 0{\cdot}5$ and $f = 2{\cdot}0$ corresponds to $10^{-5}M$ calcium solution and excellent agreement has been found between theory and practice.[11]

Mercury electrode

Because many metal complexes are less stable than that of mercury the titration curve is symmetrical. This is not the case for calcium, however, because in the pH range 9–10, the conditional mercury stability constant is about $10^{8 \cdot 0}$, whereas that of calcium is nearly $10^{10 \cdot 0}$. When the total potential change is calculated by means of the equation:

$$\Delta E_{0 \cdot 5/2} = \frac{RT}{nF} \ln(C_{\mathrm{Ca}} \,.\, K'),$$

where K' is the smallest conditional constant in the system, the limiting concentration is found to be close to $10^{-5}M$. Further, in this case the agreement between theory and practice is not so good, because at potentials close to $-0{\cdot}05$ V *vs.* S.C.E. the presence of oxygen decreases the potential change, especially for larger titrand concentrations.

Manganese dioxide electrode

This electrode has been prepared by covering platinum with manganese dioxide.[12] Its potential is dependent on the manganese(II) concentration in solution. It should be defined by an equation similar to that given previously, differing only by the presence of a pH-dependent term and the minus sign of the last term.

$$E = E^{0}_{\mathrm{MnO_2/Mn^{2+}}} - \frac{2RT}{F} \,.\, \mathrm{pH} - \frac{RT}{2F} \ln \frac{C_{\mathrm{Mn}} \,.\, K'_{\mathrm{CaY}}}{\alpha_{\mathrm{Mn}}\left(K'_{\mathrm{MnY}} \dfrac{[\mathrm{CaY'}]}{[\mathrm{Ca'}]} + K'_{\mathrm{CaY}}\right)}.$$

The potential change during a calcium titration should depend on the calcium stability constant, which over the whole pH range is lower than that of the manganese complex. However, for this electrode the experimental potential changes are smaller than the predicted ones. This behaviour can be attributed to several factors: oxidation of the Mn(II) complex in solution, heterogeneous reaction between MnO_2 and the Mn(II) complex, and to some extent to slow kinetics. The latter factor is probably responsible for the poor indication at very low calcium concentrations, but at slightly higher ones the electrode seems useful.

Calcium and bivalent ion electrodes

Some electrodes which are very useful in many practical applications[13–17] have drawbacks which limit their use in titrations, the most important being insufficient selectivity and the lower limit of response.[18] The end-point error in complexometric titrations has been discussed by Schultz[19] and by Carr.[20]

The detailed mathematical treatment given by Schultz[19] has led to the exact expression describing the electrode potential:

$$E = E' + \frac{RT}{nF}\ln\left| M + \sum_{i} \frac{K_i C_i^{n/z_i}}{(1 + rf)^{n/z_i}} + \sum_{j} K_j C_j^{n/z_j}\left(\frac{rf}{1 + rf}\right)^{n/z_j} \right|,$$

where

$$M = \frac{\beta + \sqrt{\beta^2 + \dfrac{4C}{(1 + rf)K}}}{2} \quad \text{and} \quad \beta = \frac{(1 - f)C}{(1 + rf)} - \frac{1}{K},$$

and C = concentration of titrand

C_i, C_j = concentrations of interfering ions in the sample and titrand respectively

K = stability constant of the complex

K_i, K_j = selectivity coefficients of ions i and j, respectively

r = dilution factor equal to titrand to titrant concentration ratio

f = fraction titrated

n, z_i, z_j = charges of determined and interfering ions, respectively

From this equation the systematic titration error has been calculated for titration of calcium in the presence of interfering sodium ions in the sample and in the titrand.

Assuming as an approximation that the conditional stability constant of the complex is much larger than the reciprocal of the calcium concentration: $K'_{\mathrm{CaY}} > 1/C_{\mathrm{Ca}}$ the total potential change for $f = 2$ may be evaluated according to the equation:

$$\Delta E_{0,2} = \frac{RT}{nF}\ln\frac{(C_{\mathrm{Ca}} + C_{\mathrm{Na}}{}^2 \,.\, K_{\mathrm{Na}})(1 + 2r)^2}{K_{\mathrm{Na}}(C_{\mathrm{Na}}{}^2 + 4C_{\mathrm{Na(t)}}^2 \,.\, r^2)},$$

where C_{Na} and $C_{\mathrm{Na(t)}}$ represent the sodium concentration in the sample and in the titrand, respectively, and K_{Na} is the selectivity coefficient.

The most questionable value in this expression is the selectivity coefficient, which for the same electrode may depend on the method of determination and concentration level for which it is calculated. For example, the Orion 92-20 calcium electrode may have a selectivity coefficient for sodium ions ranging from 10^{-4},[21] to 10^{-2},[22] or even 0·45.[23] The manufacturer's value is given as 0·003, whereas for the Orion 92-32 bivalent ion electrode it is 0·015. If the potential change $\Delta E_{0,2}$ has been calculated from the maker's values the correlation between it and the experimental results is rather poor (Fig. 1). Changing those values to approximately 0·01 for the calcium electrode and 0·39 for the bivalent ion electrode gives a great improvement. The same effect is seen in Fig. 2 where titration curves for the selectivity coefficient values indicated have been calculated theoretically. The experimental curve is still above the calculated one, suggesting the coefficient should have a value in the vicinity of 0·01.

Another interesting result is shown in Figs. 3 and 4. The various amounts of sodium in the sample (bivalent ion electrode) and the titrant (calcium electrode) exert a significant effect on the titration curves. The experimental values are in sufficient agreement with the calculated ones, though the differences are sometimes as large as 10 mV. This is to some extent attributable to insufficiently reproducible measurements, this uncertainty

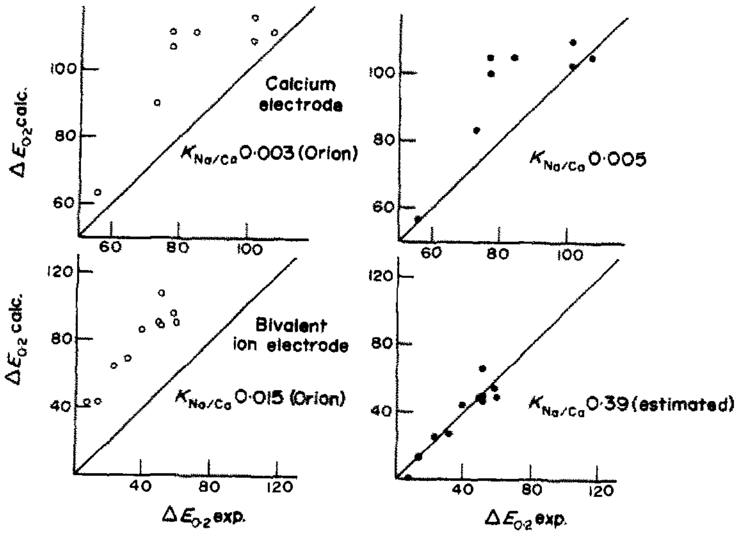

Fig. 1. Comparison of calculated and experimental values of $\Delta E_{0\cdot2}$ for complexometric titrations of calcium using calcium and bivalent ion indicator electrodes.

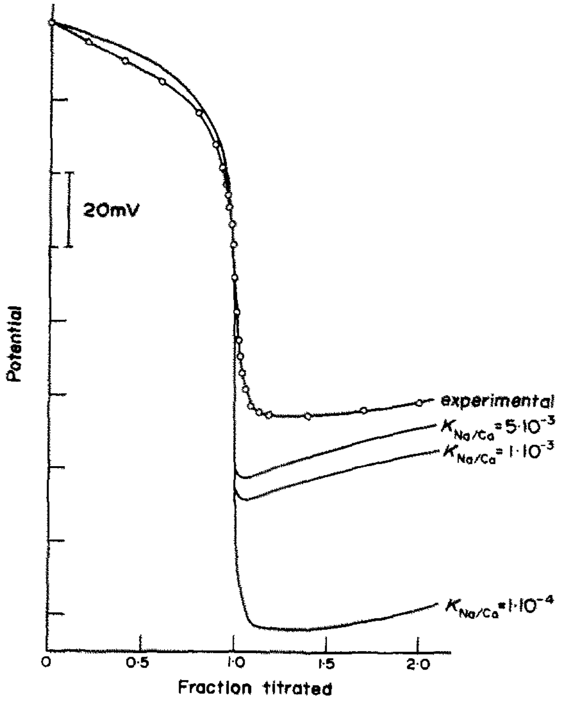

Fig. 2. Calculated for various selectivity coefficients and experimental complexometric titration curves of calcium with calcium indicator electrode.

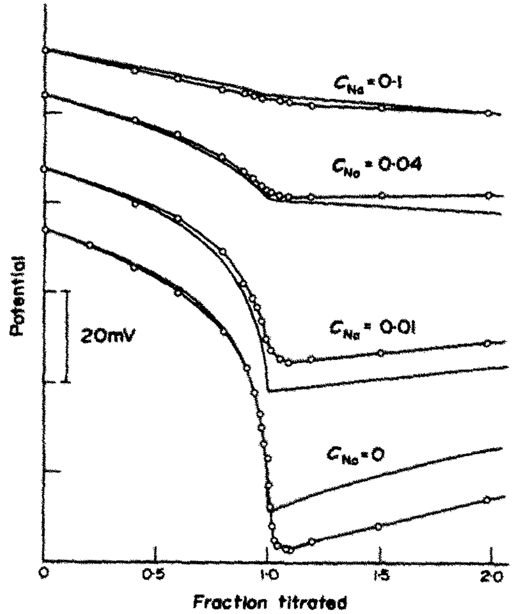

Fig. 3. Effect of various contents of sodium in the sample on the titration curves of calcium with bivalent ion indicator electrode calculated curves for K_{Na} = 0·39 (solid lines), experimental curves at pK 9·5 (lines with points).

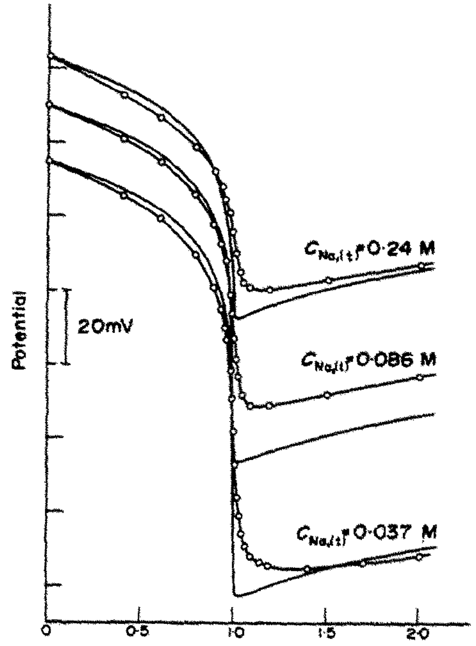

Fig. 4. Effect of various contents of sodium in the titrant on the titration curves of calcium with calcium indicator electrode. Calculated curves for K_{Na} = 0·005 (solid lines) experimental curves (lines with points).

being greater for small calcium concentrations. A very important factor which has not been taken into account is the limit of electrode response. The manufacturer's value for the Ca electrode is $5 \times 10^{-6}M$. Our experiments show a value of $\sim 10^{-5}M$ and the corresponding potential value is approx. −0·11 V. On inspecting all the titration curves we see that in any case the titration curve goes below this value, being determined by the properties of the membrane.

The important conclusion from these experiments and calculations is that a significant discrepancy exists between the theoretical and observed titration curves for calcium and that the calculated curve depends markedly on the selectivity coefficient used.

The equations which describe the potential of the electrode may be used for calculation of the theoretical error. This is understood as the difference between the f-values for which the second derivatives of the theoretical and observed curves have zero value. The results given in Tables 1–4 show that such errors are always much smaller than the real ones. The main factors responsible for this are the accuracy of the Gran method used for end-point determination (an account of distorted symmetry of the titration curve) precision of the potential reading (±0·2 mV) and probably other factors that are not yet fully understood.

All these parameters seriously interfere in the determination of very small concentrations of calcium, *e.g.*, of the order of $10^{-5}M$. Even when the electrode detection limit is

sufficiently low the inevitable sodium content (and probably that of other common cations) suppresses the potential change in such a manner that estimation of a sufficiently precise and accurate end-point is impossible.

Final conclusions

On the basis of experiment and theoretical considerations it can be concluded that the end-point in titration of calcium with EDTA may be detected by means of several electrodes. For comparison, titration curves of $10^{-3}M$ solutions under the best conditions are given in Fig. 5. None of the procedures is free from interferences and drawbacks but all can be used when the titrand concentration is not very low. To illustrate this, the results of calcium determinations, with different electrodes, are presented in Table 5, for 0·1-mmole amounts of metal.

Comparison of the analytical characteristics of the electrodes shows without any doubt that the silver electrode gives the best end-point in pure solutions at the lowest concentrations (even below $10^{-5}M$). Its main drawback is the interference of accompanying

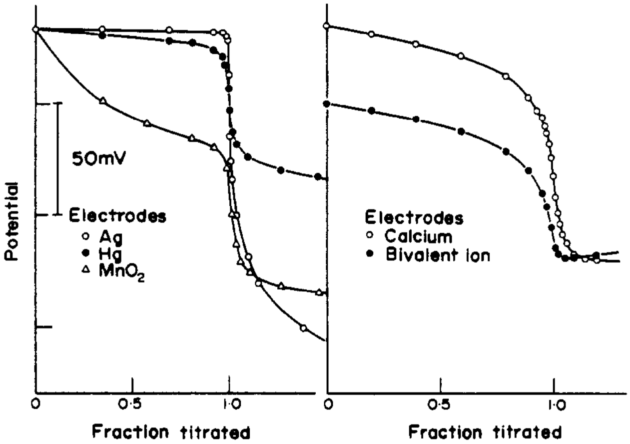

Fig. 5. Titration curves of 0·1 millimole of calcium with various indicator electrodes.

substances. Only in some instances can other ions be masked[9] (*e.g.*, with sulphosalicylate, triethanolamine) and excess of ions precipitating or complexing silver may also interfere.

The mercury electrode seems to be less subject to such interferences, because more masking agents may be used, but the potential change is seriously reduced by the presence of oxygen. This effect is difficult to predict, but the decrease is smaller at lower concentrations, so with some care $10^{-5}M$ calcium may be titrated. Deaeration of solutions is advantageous, but more troublesome in practice.

The main objections to the manganese dioxide electrode are the slow reaction rate and the still unknown reactions of the Mn(II) complex, especially after the end-point.

The ion-exchange electrodes present quite a different problems. The factors which play a decisive role in determining the potential change during titration are the selectivity of the electrode and the response limit.

The first of these factors is the most important for bivalent ion electrode, the second for calcium electrodes. The selectivity of the electrode permits in general the use of various masking agents, but the danger exists of introducing along with them other interfering ions, especially sodium ions. When the limit of detection with the electrode is as high as for the calcium electrode ($5 \times 10^{-6}M$[16]) it is not possible to titrate concentrations below $10^{-4}M$. In this respect the copper membrane electrode, which was not investigated in this study, probably presents many advantages.[24,25]

This study was mainly devoted to the electrode effect in titration with EDTA, which is not the most convenient titrant. The advantages of other complexing substances are

shown in Fig. 6, which shows DTPA as the best, the potential jump being nearly 50% greater than for EDTA. Nevertheless this effect of increased stability cannot be fully exploited with membrane electrodes.

Acknowledgement—We thank Mrs. Anna Jastrzębska (Zakład Obliczeń Numerycznych, University of Warsaw) for preparing the programmes for computer calculations.

Zusammenfassung—Bei komplexometrischen Titrationen kann man zur Überwachung des Titrationsverlaufs und zur Bestimmung des Endpunktes verschiedene Indikatorelektroden verwenden. Mehrere davon, darunter die Silber- und Quecksilberelektrode, Membranelektroden mit zweiwertigen Kationen und Calcium und die Mangandioxidelektrode wurden untersucht und in ihrer Nützlichkeit verglichen. Als Titrant wurde meistens EDTA verwendet, aber es wurden auch Meßergebnisse mit ähnlichen chelatbildenden Titranten erhalten. Der praktische Nutzen der Elektroden bei Titrationen hängt ab von ihrer Selektivität, der Höhe des Sprungs am Endpunkt und der Genauigkeit bei der Endpunktsbestimmung. Bei den untersuchten Elektroden entsprechen sich in einigen Fällen die theoretischen und die experimentellen Titrationskurven gut, aber nicht immer ist es möglich, das Ansprechen der Elektrode im niedrigen Aktivitätsbereich vorherzusagen. In anderen Fällen bedeutet eine schlechte Entsprechung nicht, daß keine ausreichend guten analytischen Ergebnisse erhalten werden könnten.

Résumé—Dans les titrages complexométriques on peut utiliser diverses électrodes indicatrices pour contrôler la marche du titrage et pour déceler le point final. Plusieurs d'entre elles, comprenant les électrodes à argent, à mercure, à membrane de cation bivalent, à membrane de calcium et à bioxyde de manganèse ont été étudiées et comparées dans leur utilité. En tant qu'agent de titrage, on a principalement utilisé l'EDTA, mais on a aussi obtenu des résultats avec des agents de titrage chélatants similaires. L'utilité pratique des électrodes dans les titrages dépend de leur sélectivité, de la grandeur de la brisure du point final et de la précision dans la détermination du point final. Pour les électrodes étudiées, il a dans quelques cas une bonne corrélation entre les courbes de titrage théoriques et expérimentales, mais il n'est pas toujours possible de prédire la réponse d'électrode dans le domains de faible activité. Dans d'autres cas, une médiocre corrélation ne signifie pas que des résultats analytiques sensiblement bons ne peuvent être obtenus.

COMPARATIVE STUDY OF TITANIUM(IV)-BASED EXCHANGERS IN AQUEOUS AND MIXED SOLVENT SYSTEMS

MOHSIN QURESHI, NIGHAT ZEHRA, SYED ASHFAQ NABI and VIRENDRA KUMAR
Department of Chemistry, Aligarth Muslim University, Aligarh, U.P. India

Summary—The antimonate, arsenate, tungstate, molybdate and selenite of titanium have been synthesized. Their composition and chemical and thermal stability have been determined. Effects of pH and temperature on ion-exchange capacity have been studied. Titanium antimonate was found to be the most stable. The utility of these ion-exchangers for analytical separations was examined by determining the distribution coefficients for 26 metal ions in some aqueous, non-aqueous and mixed solvent systems. Quantitative separations of Hg–Cd, Pb–Cu and Pb–Zn have been achieved on titanium tungstate columns, and La–Ba mixtures have been separated on a titanium arsenate column.

Since the classical work of Amphlett,[1] numerous synthetic inorganic ion-exchangers have been synthesized and their properties studied. However, the methods of preparation of the same ion-exchanger by different workers are not always the same. It has been shown that selectivity of an inorganic ion-exchanger depends not only upon its composition but also upon the pH at which the precipitation is performed. It is important that the various ion-exchangers should be synthesized again under the same conditions and their properties studied. Szirtes[2] made an interesting study of the phosphates of titanium, zirconium and chromium and compared their ion-exchange properties. A comparative study of the chromium(III) salts has been made in our laboratory.[3] We have therefore decided to investigate the various insoluble compounds of titanium.[4–8] We have chosen to compare those samples of the particular exchanger which are reported to be the most stable.

Another limitation in the earlier studies on inorganic ion-exchangers was the selection of eluents. Almost all were aqueous solutions of simple salts. The possibilities of enhancing and reversing selectivities of ion-exchangers by addition or exclusive use of organic solvents is receiving increased attention. The nature of the solvent affects the solubility, dissociation and solvation of the solutes and the behaviour of the ion-exchanger. Many separations have been improved by addition of organic solvents.[9,10] We have therefore extended the investigation of the analytical properties of these ion-exchangers to mixed solvent systems and to less common aqueous systems.

EXPERIMENTAL

Reagents

Titanium(IV) chloride (15% w/v solution), antimony pentachloride (density 2·3 g/ml), sodium tungstate, sodium arsenate and sodium selenite were used. Reagents used were analytical-reagent grade whenever possible. In the determination of K_d values either chlorides or nitrates of the cations were used with the exception of vanadyl sulphate.

Table 1. Conditions for the synthesis of some titanium-based exchangers

Exchanger	Concentration of Ti(IV), *M*	Concentration of anionic, species *M*	Mixing ratio Ti : A*	pH
Titanium tungstate	0·30	0·30	1 : 1	1
Titanium antimonate	0·10	0·10	1 : 1	2
Titanium arsenate	0·05	0·05	1 : 1	2
Titanium selenite	0·05	0·05	1 : 2	2
Titanium molybdate	0·025	0·025	2 : 1	2

* A = anionic species

Preparation of the samples

Five samples were prepared by mixing the solution of titanium(IV) chloride with the sodium tungstate, sodium arsenate, sodium selenite, sodium molybdate or antimony pentachloride solutions; the conditions are given in Table 1. In the case of titanium antimonate the pH was adjusted with ammonia. The precipitates were allowed to stand for 24 hr at room temperature and then washed with distilled water by decantation, filtered off and dried at 40°. Only the titanium tungstate was dried at 80°. The dry product broke down into small particles when immersed in water. It was converted into the hydrogen form by treatment with 2*M* nitric acid and finally washed with demineralized water. All the samples were again dried at 40° except titanium tungstate which was dried at 80°.

The chemical composition of these ion-exchange materials was determined as described in earlier papers.[4-7]

Chemical stability

A 0·5-g portion of the exchanger was shaken in a flask with 50 ml of the solution concerned, in a temperature-controlled shaker for 6 hr until equilibrium was reached. The undissolved portion of the exchanger was removed by filtration. Titanium, antimony, tungsten, arsenic, selenium and molybdenum were determined in the filtrate spectrophotometrically by the hydrogen peroxide,[11] Rhodamine B,[12] ammonium thiocyanate,[13] molybdenum blue,[14] diaminobenzidene[15] and ammonium thiocyanate[16] methods respectively (Fig. 1).

Table 2. Ion-exchange capacities and composition of same titanium-based exchangers

Exchanger	Ion-exchange capacity *meq/g*	Reported capacity *meq/g*	Composition	Reported composition
Titanium tungstate	0·58	0·82	1 : 1·1	1 : 1·1
Titanium arsenate	0·99	0·93	1 : 1·8	1 : 2
Titanium antimonate	0·77	0·71	1 : 1·4	1 : 1·4
Titanium selenite	0·58	0·78	1 : 1·2	1 : 1·35
Titanium molybdate	1·08	1·05	—	—

RESULTS

Ion-exchange properties

The ion-exchange capacity, determined by the standard method,[17] is given in Table 2. It was also determined at different pH values by the batch method. The results are plotted in Fig. 2. All the samples were heated at different specified temperatures for 2 hr and the ion-exchange capacity was determined in each case. The results are shown in Fig. 3.

Distribution studies

Distribution coefficients of 26 metal ions in water, nitric acid of different concentrations, 0·1*M* ammonium nitrate, 0·1*M* formic acid, and some acetone–nitric acid mixtures were determined. For this purpose 0·5 g of the exchanger was shaken with 50 ml of the

solution for 6 hr. The amount of cation in solution was estimated by EDTA titration and the K_d values were calculated from the expression

$$K_d = \frac{I - F}{F} \times \frac{50}{0{\cdot}5},$$

where I is the volume of EDTA consumed by the original solution and F is the volume of EDTA consumed after equilibrium.

Solutions of each cation were prepared in demineralized water for the determination of K_d values in all the systems studied. The loading of the cation was less than 3% of the ion-exchange capacity of the ion-exchanger. The results are given in Tables 3–7.

Separations

Separations of Cd(II) from Hg(II), Ba(II) from La(III), Zn(II) from Pb(II) and Cu(II) from Pb(II) have been achieved on the basis of the K_d values. The elution curves for the separations achieved are given in Figs. 4 and 5.

DISCUSSION

A comparison of the chemical stability of the various ion-exchangers is given in Fig. 1. It is apparent that titanium molybdate is the least stable and titanium tungstate is the most stable. It is clear from Fig. 2 that titanium arsenate has the highest ion-exchange capacity and therefore if we are interested in exchangers of high capacity we should choose the arsenates.

Most inorganic ion-exchangers usually exhibit high thermal stability and it is worthwhile to compare their performance after treatment at high temperatures. It follows from Fig. 3 that titanium antimonate has the highest thermal stability. Even after heating to 500° it shows sufficient exchange capacity and therefore can still be used as an ion-exchanger. Other materials exhibit only a negligible exchange capacity after heating to this temperature.

It can be inferred from Fig. 2 that in almost all cases pH does not affect ion-exchange capacity significantly if it is below pH 10. However a sharp increase in exchange capacity is observed as the pH is raised above 10. This is probably due to the hydrolysis of the exchange materials at higher pH values. The ion-exchangers based on titanium behave like weakly acidic cation-exchangers, which differs from the findings of

Table 6. Distribution coefficients ($K_d \times 10^{-2}$) of metal ions on titanium tungstate

Szirtes and co-workers.[2] Phosphates of zirconium, titanium and chromium show a moderately strong-acid behaviour.

A comparison of the K_d values of metal ions on these exchangers in demineralized water shows some outstanding features. Thus the antimonate has the highest ion uptake of the four exchange materials studied. This may be due to the fact that amorphous antimony oxide has the largest number of free exchange sites available for the metal ions to be adsorbed. Therefore the antimonates can be of use only at low pH values, where the ion uptake can be distinguished between various ions. The tungstate, arsenate and selenite on the other hand show high selectivities even in neutral medium. In the case of the tungstate the K_d values vary from $3{\cdot}3 \times 10^3$ for Hg(II) to zero for In(III) and Fe(III). This is a characteristic feature of titanium tungstate because all the other exchangers have a very high affinity for Fe(III). In the case of the arsenate the highest K_d value is for Pb(II) which shows high K_d values on almost all the exchangers. The lanthanides have the lowest K_d values on titanium tungstate, their highest K_d values being for titanium antimonate as expected.

The study of the effect of hydrogen ion concentration on the K_d values reveals that when the hydrogen ion concentration is raised from $10^{-7}M$ to $10^{-2}M$ most of the metal

C.A. = Complete adsorption.
N.A. = Negligible adsorption.

ions show negligible adsorption on all the exchangers except titanium antimonate, which behaves peculiarly. At this hydrogen ion concentration most of the metal ions show very high uptake on titanium antimonate. Therefore the behaviour of metal ions at high concentrations of acid has also been studied in the case of titanium antimonate. At pH 2, Al(III), Zr(IV), Hf(IV), Th(IV), La(III), Ce(IV) and Sm(III) have K_d values of more than 10^3. This behaviour makes the titanium antimonate a promising cation-exchanger for some interesting separations. Thus Al(III) can be separated from Ga(III), In(III), Zn(II), Mg(II), Fe(III), Co(II), Ni(II) and Mn(II).

Two important separations which may be achieved on titanium tungstate in 0·01*M* nitric acid are Cd(II) from numerous metal ions, including Zn(II) and Zr(IV) from numerous metal ions, including Hf(IV).

Zr(IV) can also be separated from Hf(IV) on titanium tungstate in 0·1*M* ammonium nitrate.

A comparison of the K_d values on titanium antimonate in acetone and acetone–nitric acid media is very interesting. If we replace pure acetone by a solution which is 50% in acetone and 0·05*M* in nitric acid then there is very little difference between the K_d values in the two systems for almost all the metal ions, except Ba, La, Ce, Pr, Nd and Sm, which have exceptionally high values. On the other hand if the nitric acid

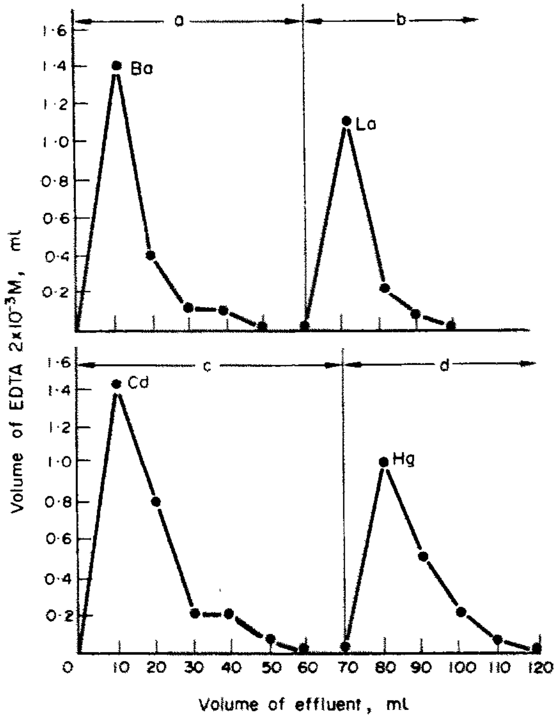

Fig. 4. Separation of Ba(II) from La(III) on titanium arsenate and Cd(II) from Hg(II) on titanium tungstate columns. *a*, Acetone + 0·1*M* HNO_3 (9 : 1); *b*, 2*M* HNO_3 ; *c*, 0·1*M* NH_4NO_3 ; *d*, 1*M* HNO_3.

concentration is increased from 0·05*M* to 2*M* then a significant difference is observed which shows a possibility of a number of important separations. The 26 metal ions may be conveniently divided into two groups.

(1) Those which have almost zero K_d values, *i.e.*, Mg(II), Ca(II), Sr(II), Ba(II), Zn(II), Cd(II), Mn(II), Y(III), Ce(IV) and La(III).

(2) The rest, which have very high K_d values.

Thus it is obvious from this classification that one of the ions in the first group can be separated from any one or a group of ions in the second group, *e.g.*, Hg(II) from Cd(II), Zr(II), Ba(II), Sr(II), Mg(II) and Mn(II); Ce(IV) or La(III) from Zr(IV), Hf(IV), Th(IV), Pr(III), Nd(III) and Sm(III).

A comparison of the acetone +0·1*M* nitric acid systems (1 : 9 and 9 : 1 ratios) shows that there is not much difference in the K_d values for most ions except Mg(II), Ca(II), Ce(IV) Sr(II) and Ba(II). However, the selectivity sequence is altered for the group Mg(II), Ca(II), Sr(II) and Ba(II). Thus in water we have Sr > Ba > Mg > Ca and in the acetone–nitric acid systems (1 : 9) and (9 : 1) the sequences are Ba > Ca > Sr = Mg and Ca > Ba > Sr = Mg respectively.

Various factors such as swelling, formation of complexes, nature of the chemical bond and solvent distribution may be responsible for this behaviour of the ion-exchanger. It is also apparent from Table 3 that on changing the composition of the aqueous acetone

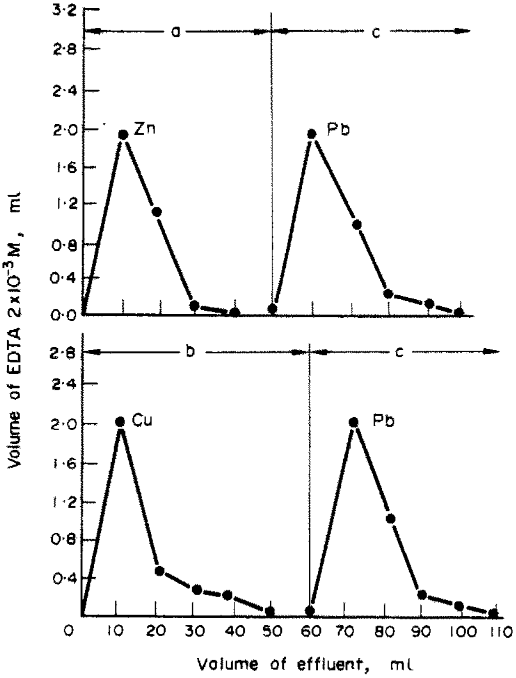

Fig. 5. Separation of Zn(II) from Pb(II) and Cu(II) from Pb(II) on titanium tungstate columns. *a*, Acetone + 0·1*M* HNO_3; *b*, 0·1*M* formic acid; *c*, 0·1*M* HNO_3.

media the preference of the ion-exchanger for various cations changes, hence enhancing the selectivity. It is also interesting to note (Tables 8 and 9) that the separation factor is generally higher in the mixed solvent media (aqueous and non-aqueous) than in purely aqueous or non-aqueous media. As with organic ion-exchangers, the pores of inorganic ion-exchangers may play a significant role in exchanging ions. That is to say they can accumulate water in their pores, and this is accompanied by electrolytic sorption. Thus by change of the solvent system a new separation may become possible.

Table 8. Separation factors (α) for Pb–Cu and Pb–Zn in various solvent systems

Solvent	Titanium arsenate		Titanium tungstate		Titanium selenite		Titanium antimonate	
	α_{Cu}^{Pb}	α_{Zn}^{Pb}	α_{Cu}^{Pb}	α_{Zn}^{Pb}	α_{Cu}^{Pb}	α_{Zn}^{Pb}	α_{Cu}^{Pb}	α_{Zn}^{Pb}

0·1*M* NH_4NO_3	63	63	100	100	100	100	> 1	4

Table 9. Separation factors (α) for Hg–Cd and La–Ba in various solvent systems

Solvent	Titanium arsenate		Titanium tungstate		Titanium selenite		Titanium antimonate	
	α^{Hg}_{Cd}	α^{La}_{Ba}	α^{Hg}_{Cd}	α^{La}_{Ba}	α^{Hg}_{Cd}	α^{La}_{Ba}	α^{Hg}_{Cd}	α^{La}_{Ba}
Water	32	16	32	66	4	8	3	71
0·01*M* HNO_3	60	< 1	32	1	1	2	63	25
0·1*M* HNO_3	< 1	< 1	< 1	< 1	< 1	< 1	< 1	< 1
0·1*M* HNO_3 + acetone (1 : 9)	19	16	19	52	2	8	> 1	32
0·1*M* HNO_3 + acetone (9 : 1)	—	—	—	—	—	—	4	52
0·1*M* HNO_3 + acetone (1 : 1)	—	—	—	—	—	—	> 1	8
4*M* HNO_3 + acetone (1 : 1)	—	—	—	—	—	—	10	1
Acetone	—	—	—	—	—	—	5	1
0·1*M* Formic acid	> 1	21	1000	6	4	6	1	1
0·1*M* NH_4NO_3	32	6	32	3	62	> 1	3	> 1

The following conclusions can be drawn if we compare the distribution coefficients of metal ions on titanium antimonate in water and pure acetone.

1. There is almost no change in the K_d values for Zn(II), Sr(II), Cd(II), La(III), Ce(IV), Pr(III), Nd(III), Sm(III), Pb(II), V(V) and Al(III) in the two systems.
2. K_d values are higher in acetone than in water for Ga(III), Ba(II) and Ca(II), Co(II).
3. K_d values are higher in water for Mn(II), Fe(III), Ni(II), Cu(II), Y(III), Zr(IV), Hf(IV), Th(IV), In(III), Hg(II) and Mg(II).

The decrease in K_d values for a large number of metal ions in acetone media may be attributed to the fact that the mobilities of the counter ions in the exchanger are usually not as great as in aqueous systems because of the decreased dissociation.[18] Also

Table 10. Possible separation on titanium-based exchangers

Exchanger	Solvent system		
	0·1*M* HNO_3	0·1*M* NH_4NO_3	0·1*M* HCOOH
Titanium antimonate	Mg–Ba; Zn-Hg; Ga–Al,In; Pb–Cu,Fe,Mn,Co,Ni,V,Zn,Mg	Mg–Zn,Sr,Cd,Pb, Al,In,Ga,V, rare earths	—

Titanium tungstate	—	V–Mn; Hg–Cd,Al, Cu,Ga,Fe,Co,Ni; Pb–Cd,Al,Ga,Fe, Cu,Co,Ni	Zn–Mg,Ba,Sr; Ca–Cd; Fe–Cu,Co,Ni,Mn,In; In–Ga,Al

the swelling is insignificant and the particle diffusion is relatively slow. The higher ion uptake for Ga(III), Ba(II), Co(II) and Ca(II) in acetone may be due to ion-pair formation with anions in acetone.

Ammonium nitrate solution (0·1*M*) is especially useful because in this solvent system large differences in K_d values are observed for similar ions. Thus, Sm, Nd and Pr can be separated on titanium arsenate columns. The difficult separation of Zr(IV) and Hf(IV) can be achieved on titanium tungstate columns. A number of possibilities exist for difficult analytical separations, which are summarized in Table 10.

On the basis of the separation factors (Tables 8 and 9) four new quantitative separations have been achieved, with titanium tungstate and titanium arsenate columns. Figures 4 and 5 illustrate the elution curves.

Zusammenfassung—Antimonat, Arsenat, Wolframat, Molybdat und Selenit von Titan wurden hergestellt. Ihre Zusammensetzung und ihre chemische und thermische Stabilität wurden ermittelt sowie der Einfluß von pH und Temperatur auf die Austauschkapazität untersucht. Es stellte sich heraus, daß Titanantimonat thermisch am stabilisten war. Der Nutzen dieser Ionenaustauscher für analytische Trennungen wurde durch Bestimmung der Verteilungskoeffizienten für 26 Metallionen in einigen wäßrigen, nichtwäßrigen und gemischten Lösungsmittelsystemen überprüft. Quantitative Trennungen von Hg–Cd, Pb–Cu und Pb–Zn wurden auf Titanwolframatsäulen erzielt; La-Ba-Gemische wurden auf einer Titanarsenatsäule getrennt.

Résumé—On a synthétisé les antimoniate, arséniate, tungstate, molybdate et sélénite de titane. On a déterminé leur composition et leur stabilité chimique et thermique. On a étudié les influences du pH et de la température sur la capacité d'échange d'ions. On a trouvé que l'antimoniate de titane est le plus stable thermiquement. On a examiné l'utilité de ces échangeurs d'ions pour des séparations analytiques en déterminant les coefficients de partage pour 26 ions métalliques dans quelques systèmes aqueux, non aqueux et mélanges de solvants. On a réalisé des séparations quantitatives de Hg–Cd, Pb–Cu et Pb–Zn sur des colonnes de tungstate de titane, et on a séparé des mélanges La–Ba sur une colonne d'arséniate de titane.

OXIDATIVE COULOMETRIC TRACE DETERMINATION OF SULPHUR IN HYDROCARBONS

ANDERS CEDERGREN
Department of Analytical Chemistry, University of Umeå, S-901 87 Umeå, Sweden

(*Received* 29 *November* 1972. *Accepted* 12 *January* 1972)

Summary—A new combustion system for the oxidative coulometric determination of sulphur in liquid hydrocarbons is described. The conditions were selected so that the recovery as SO_2 was close to 100%. The relative standard deviation was <1% for sulphur in the range 2–1000 mg/l., with thiophene in cyclohexane as a test substance. Thermodynamic data on the equilibrium between SO_2, O_2 and SO_3 were used to select the operating conditions. To increase the recovery of SO_2 the combustion gas mixture was diluted with an inert gas to lower the partial pressure of oxygen. A temperature of 1000° in the equilibrium zone resulted in a recovery of 99%. The SO_2 was titrated with coulometrically generated iodine, the concentration of which was controlled by a Pt-redox electrode. The response of this electrode has been examined. A rather high concentration of I^- was used to suppress iodine losses during the analysis. The time of analysis was 2–5 min, and sample sizes were 3–7 μl. An LKB 16300 Coulometric Analyzer governed the titration procedure.

Petroleum and related compounds often contain substances like hydrogen sulphide, thiols, organic sulphides and thiophenes. Even small amounts of such compounds will give the product undesirable properties; an unpleasant odour, corrosiveness or catalyst poisoning. As a consequence, trace analysis for sulphur is of great importance in the field of product control and in desulphurization processes.

A review of the most important methods for determining sulphur will be found in a recent volume in three parts by Karchmer.[1] One of the most general methods is the oxy-hydrogen Wickbold burner method with a colorimetric or turbidimetric titration of the sulphate formed. With careful work a reproducibility of $(1{\cdot}5 + 0{\cdot}20S)$ ppm can be achieved,[2] where S is the sulphur content in ppm. The time of analysis will increase to about 2 hr for the low-ppm range as 50 g of sample must be burnt.

Fensom *et al.*[3] modified Granatelli's Raney nickel method in which sulphur is reduced to hydrogen sulphide which is absorbed in alkali and titrated. They determined total sulphur in light petroleum distillate in the range 0·1–0·4 ppm w/v with a precision of ±9%.

In a recent American Petroleum Institute report,[5] the correlation programme carried out showed that the microcoulometric procedure, first proposed by Coulson and Cavanagh,[6] had better precision and higher speed than some of the earlier methods, but that its usefulness was at present restricted to the lighter fuel oils. Dixon[7] modified the method to determine sulphur in lubricating oil fractions and heavy fuel oils. In this method sulphur is oxidized to a mixture of sulphur dioxide and trioxide in a quartz tube at 700–900°. The sulphur dioxide formed is titrated with iodine which is generated coulometrically. The practical limit of this method is 0·1 ppm of sulphur. Wallace and Kohlenberger[8] compared the oxidative and reductive methods for the microcoulometric determination of sulphur in hydrocarbons. They stated that the oxidative method is simpler to use and has lower interference from nitrogen. However, it suffers from interference by chlorine and heavy metals and a non-stoichiometric conversion of sulphur into sulphur dioxide. The recovery for a standard of thiophene in kerosene was 84% and the precision ±0·3 ppm in the range 3–12 ppm of sulphur.

Several other authors[9–12] have used the oxidative coulometric procedure and obtained recoveries varying between 65 and 95% sulphur dioxide, depending on temperature and combustion atmosphere used. The relative standard deviation for their methods is 2% or more.

This paper describes a new oven construction in which the combustion conditions were selected to give a recovery of close to 100% sulphur dioxide after oxidation of the sulphur in a quartz tube. In earlier microcoulometric methods the main drawback was the varying recovery, and the present method gives much better reproducibility.

HIGH TEMPERATURE EQUILIBRIA

Sulphur dioxide may be oxidized to sulphur trioxide according to the reaction

$$SO_2 + 1/2\, O_2 \rightleftharpoons SO_3. \tag{1}$$

The thermodynamic equilibrium constant is given by

$$K_p = \frac{p_{SO_3}}{p_{SO_2} \cdot p_{O_2}^{1/2}}, \tag{2}$$

which can be written

$$\frac{p_{SO_2}}{p_{SO_2} + p_{SO_3}} = \frac{1}{1 + K_p\, p_{O_2}^{1/2}} \tag{2a}$$

$$\Delta G^\circ = -RT \ln K_p, \tag{3}$$

ΔG° is a function of temperature and for the temperature interval used in combustion analysis is given by[13]

$$\Delta G^\circ = -22600 + 21{\cdot}36T \text{ (cal/mol)}. \tag{4}$$

The theoretical recovery of sulphur dioxide in percent is given by equation (2*a*) if it is multiplied by 100. A higher recovery should thus be obtained at a lower partial oxygen pressure. As K_p decreases with increasing temperature, a higher temperature will give a higher recovery. Figure 1 shows the recovery as a function of temperature and oxygen pressure. From this point of view complete conversion of sulphur into sulphur dioxide, at equilibrium and at a certain temperature, should be possible in a combustion, provided that the oxygen pressure in the final gas mixture is sufficiently low. In practice, however, there must be a rather high partial oxygen pressure to obtain complete combustion. Under these conditions only a fraction of the sulphur is present in the form of the dioxide, *i.e.*, the recovery becomes less than 100%. If this fraction could be kept constant, a lower

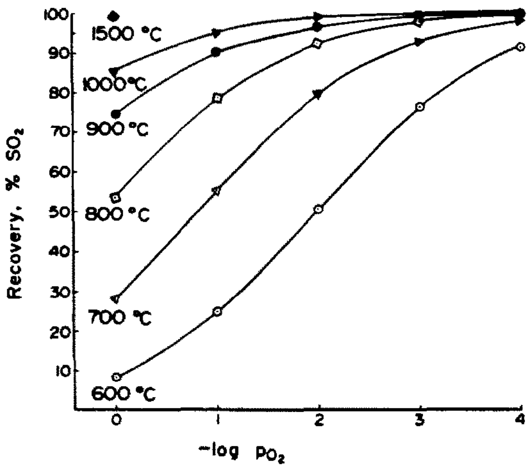

Fig. 1. Theoretical recovery of SO_2 in equilibrium with O_2 and SO_3 as a function of temperature (°C) and oxygen pressure (atm).

recovery could easily be compensated for in the calculation of the result. High-temperature combustion of inorganic and some organic compounds can be arranged so that the recovery remains essentially constant, *e.g.*, combustion at 1315° with $P_{O_2} = 1$ atm gives a recovery of 97%.[1] The combustion of organic compounds may be more complicated, owing to reactions other than those considered above. If an oil contains less than 0·06% sulphur, high-temperature combustion may give erroneous results. Various low-temperature combustion methods have therefore been developed. When the temperature is lowered the reaction rate becomes important. The equilibrium, equation (4), is reached slowly up to about 800°, so the fraction of sulphur dioxide may be higher than that calculated according to equation (2*a*) because sulphur dioxide is the main product of combustion and equilibrium is never reached. Many substances, *e.g.*, heavy metals, platinum, quartz, are known to catalyse the reaction, resulting in a closer approach to equilibrium. The recovery then becomes lower and is subject to large variations. Many of the difficulties reported in the papers referred to in the introduction were caused by variations in recovery. At 900° or more the reaction rate is so high that equilibrium is normally reached in a combustion tube.

EXPERIMENTAL

Combustion trains

Six electrically heated ovens were arranged as shown in Fig. 2. Ovens 1–5 were provided with thermoelements coupled to electronic regulators. The temperatures of the ovens could be set on dials. The thermostats kept the temperature constant within 10°. The combustion tube was made from quartz. The inlet section was fitted into the tube *via* a B14 ground joint. The outlet tube was also provided with a ground joint. The fast nitrogen flow N_2(II) was purified as shown in the figure but the nitrogen could be used without purification in the slow flow N_2(I). The gases were taken from high-pressure cylinders *via* reduction valves, needle valves and rotameters. The oxygen flow was rather critical and a constant-flow controller. Brooks Instrument model 8744 A, was therefore used to regulate this gas flow.

The ovens attained their operating temperatures about 10 min after the instrument had been switched on. The gas flow was adjusted and iodine was generated in the titration cell to obtain a slight excess. After this the instrument was ready for operation.

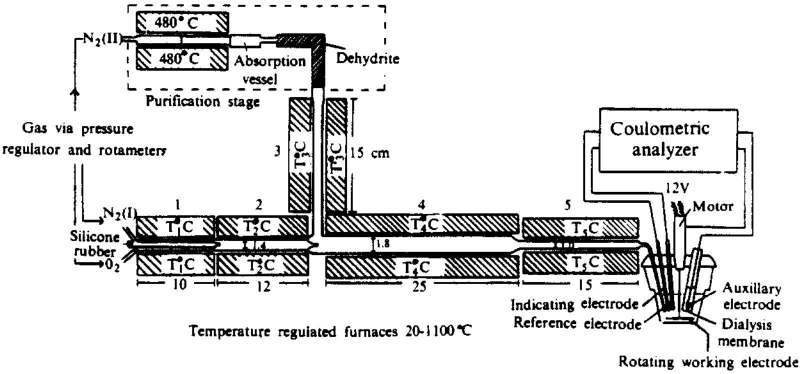

Fig. 2. Experimental arrangement.

Sample introduction

Samples were introduced *via* a silicone-rubber septum with Hamilton 701 N 10-μl or 75 N 5-μl syringes. The procedure was similar to that described by Marsh.[11] The sample was drawn into the syringe to a mark which was noted. The tip was wiped and the liquid was drawn back further until the air meniscus was at 1 μl. The syringe tip was inserted into the pyrolysis chamber so that the sample in the tip was removed. The syringe was removed until the titration of the traces on the tip was completed. The syringe was then inserted again and normally a 3–7 μl sample was injected at a uniform rate which was less than 0·2 μl/sec. The syringe was withdrawn and the meniscus was again set to the 1 μl mark. The difference in plunger reading was taken as the volume of the sample.

The relative standard deviation of a normal volume measurement with these syringes was found to be 0·5–0·8%, depending on sample size. The standard deviation of the procedure described above was probably higher but it could not be differentiated from the standard deviation of the sulphur determination. The withdrawal of the meniscus into the barrel was necessary because there was a large fluctuation in the amount of solvent evaporated from inside the tip.

Titration procedure

The absorption medium was 30 ml of an aqueous solution containing 0·40% potassium iodide, 0·055% sodium azide and 0·68% acetic acid, taken in a Metrohm titration vessel EA 880-20. Iodine was generated electrolytically at a rotating platinum electrode. A platinum spiral was used as auxiliary electrode and was separated from the sample solution by a dialysis membrane. The anode reaction is

$$2I^- \longrightarrow I_2 + 2e^-, \tag{5}$$

which is followed by

$$I_2 + I^- = I_3^- \qquad (K = 710\ \text{l./mole}). \tag{6}$$

The excess of iodine was determined potentiometrically with a platinum-foil indicator electrode *vs.* a Radiometer K 601 Hg/Hg_2SO_4 reference electrode. The electrode responds according to

$$E = E' + \frac{RT}{2F}\ln\frac{[I_2]}{[I^-]^2} = E' + \frac{RT}{2F}\ln\frac{[I_3^-]}{K\cdot[I^-]^3}. \tag{7}$$

The electrodes were connected to an LKB-16300 Coulometric Analyzer which compares the redox potential of the indicating electrode with a preset value. This preset value corresponds to the desired iodine concentration in the absorption medium. If the actual iodine excess is too low, an error signal will be produced in the analyser, which causes a current to be passed through the generating electrode system so that more iodine will be produced. This will continue until the redox potential reaches the desired value.

When sulphur dioxide enters the cell the following reaction will occur

$$SO_2 + 2H_2O + I_3^- \longrightarrow SO_4^{2-} + 3I^- + 4H^+. \tag{8}$$

When $[I_3^-]$ decreases, generation of more iodine starts automatically so that sulphur dioxide is titrated continuously as it enters the cell.

The amount of electricity required to titrate the absorbed sulphur dioxide was determined by electronic integration in the analyser. The integrator could be read to 2×10^{-11} equivalents, corresponding to 1×10^{-11} mole of SO_2.

RESULTS AND DISCUSSION

The reaction system is shown in Fig. 2. A sample is introduced through a septum into a pyrolysis chamber flushed with a slow nitrogen flow, N_2(I). This flow was usually 25 ml/min and the temperature of oven 1 was normally 400°. The vaporized and pyrolysed products enter the combustion zone through this jet. An oxygen stream (normally 9 ml/min) is passed into the combustion zone coaxially with the pyrolysis chamber. The combustion zone is normally kept at 700° by oven 2 but when a sample enters through the pyrolysis chamber a visible flame can sometimes be seen when the solvent burns, which indicates that the actual combustion temperature may be higher. The combustion products which contain the sulphur as a mixture of the dioxide and trioxide enter the equilibrium chamber through a nozzle. A fast stream of nitrogen (normally 190 ml/min), preheated to 1000° in oven 3, meets and dilutes the combustion products. The equilibrium zone is normally kept at the same temperature as the preheating zone, 1000°. In this zone the oxygen/nitrogen ratio decreases relative to that during the combustion. The temperature is so high that the sulphur oxides reach thermodynamic equilibrium. The flow-rates mentioned above will give a partial oxygen pressure of 0·04 kg/cm^2. During combustion of a sample some oxygen will be consumed, resulting in a still lower partial pressure of oxygen. The results indicate that the actual oxygen pressure during the determination is about 0·01 kg/cm^2, which according to Fig. 1 corresponds to 98·5% recovery. Still higher temperature for extended periods would result in a decreased life of the quartz tube. The diameter of the quartz tube decreases so that a high linear gas velocity is obtained when the gas enters the outlet zone which normally is kept at 500°. This temperature is so low that the reaction rate is negligible and the equilibrium attained at the preceding stage is not reversed. It is known from high-temperature equilibrium studies that equilibrium conditions can be frozen if the temperature is decreased rapidly.

A short bent tube transfers the gas to the titration vessel. After 10 min the tube has been sufficiently heated by the gas to prevent condensation. This tube can be disconnected for cleaning, which may be necessary if combustion becomes incomplete. The tip of the outlet tube is drawn out so that small gas bubbles are dispersed into the medium 2–3 cm below the liquid surface. The rotating platinum gauze anode disperses the bubbles further into the solution and the absorption of sulphur dioxide is quantitative up to a total gas flow of 250 ml/min. The sulphur dioxide is then titrated as described later.

A number of parameters have been varied one at a time and the result will be discussed below. A solution of thiophene in cyclohexane, containing about 200 ppm of sulphur, was used as a test substance. The points in Figs. 3, 4 and 5 are each mean values of about 10 determinations.

Figure 3 shows the recovery as a function of the temperature in the preheating and the equilibrium zones in ovens 3 and 4, for two different values of the oxygen partial pressure. At 900° there is a drop in recovery because the reaction rate becomes so high that equilibrium is reached. The points at 900 and 1000° correspond to the conditions shown in Fig. 1. At 1000° the recovery has increased somewhat because the equilibrium constant decreases with temperature. At 800° or below, equilibrium is not attained and the recovery is higher than that corresponding to the equilibrium shown in Fig. 1. The recovery will however depend on the combustion conditions and eventual presence of catalysts will decrease it. It was found that the standard deviations were higher than those of the determinations at 900° and 1000°. The recovery at 800° or below was also

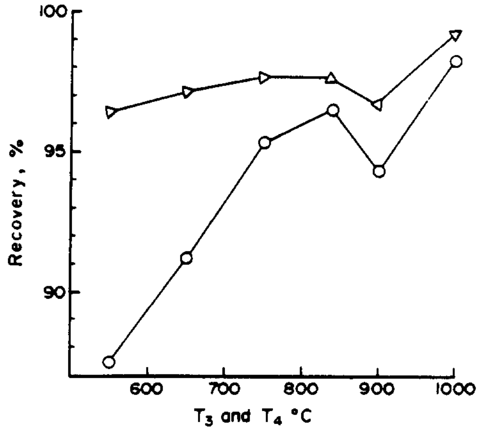

Fig. 3. Recovery of sulphur as a function of temperature in zones 3 and 4. $N_2(I) = 25$ ml/min, $N_2(II) = 190$ ml/min, $T_1 = 400°$, $T_2 = 700°$, $T_5 = 500°$. ○ $O_2 = 50$ ml/min; △ $O_2 = 9$ ml/min.

dependent on the way the sample was introduced, which further demonstrates the increased uncertainty of a method not operating at equilibrium conditions.

The effect of variations in the flow-rate of nitrogen, $N_2(II)$, was next investigated with all ovens at normal operating temperatures. Two different oxygen flows were used and the results are shown in Fig. 4. Decreasing the nitrogen flow results in a higher partial oxygen pressure and as expected from Fig. 1 the recovery decreases, especially at the higher oxygen flow. When the flow-rate is increased above 200 ml/min there is a slight decrease in recovery again, mainly because of less than 100% absorption in the titration vessel. There will also be a slight decrease in recovery at high flow-rates, owing to the way iodine losses arise.

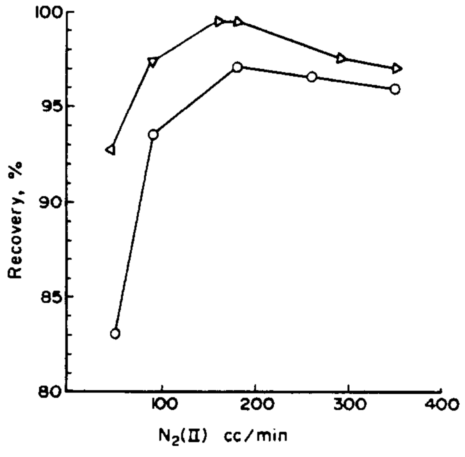

Fig. 4. Recovery of sulphur as a function of the flow-rate of diluting gas, $N_2(II)$. $N_2(I) = 25$ ml/min, $T_1 = 400°$, $T_2 = 700°$, $T_3 = T_4 = 1000°$, $T_5 = 500°$. △ $O_2 = 9$ ml/min; ○ $O_2 = 50$ ml/min.

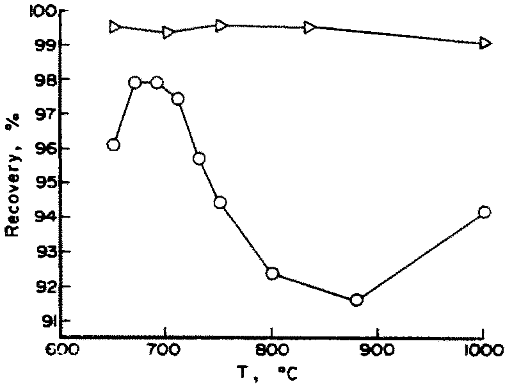

Fig. 5. Recovery of sulphur as a function of combustion temperature T_2. $T_1 = 400°$, $T_3 = T_4 = 1000°$, $T_5 = 500°$, N_2(I) = 25 ml/min, N_2(II) = 190 ml/min. △ O_2 = 9 ml/min; ○ O_2 = 40 ml/min.

Figure 5 shows the effect of temperature variations in the combustion zone, at two different oxygen flows. There is a decrease in recovery at higher temperatures and partial oxygen pressure, which probably involves the formation of a side-product containing sulphur. Further work to identify this side-reaction is in progress. A similar decrease in recovery with increasing combustion temperature was observed earlier.[8] Figure 5, as well as Figs. 3 and 4, shows the importance of low oxygen pressure but there must be sufficient oxygen to facilitate complete combustion. If the combustion is incomplete there is a formation of products which consume iodine and give high results. By introducing the sample at a slow rate it is possible to obtain complete combustion even at a comparatively low oxygen flow.

In selecting an end-point potential for the titration of sulphur dioxide with iodine, several aspects must be considered. It is advantageous to titrate to an end-point corresponding to an excess of iodine. If a large excess of iodine were selected there would be a need for a higher relative precision in the determination of the redox potential and in addition there would also be higher iodine losses if gases were blown through the cell. Figure 6 shows another aspect which is important in selecting the end-point potential. A number of nmole of iodine were generated rapidly and the potential of the redox electrodes was read after 15 sec, 2 min and 3 min. The figure shows that the electrode response is slow in the presence of small excesses of iodine, but that at higher excesses it becomes so rapid that the curves merge at around −145 mV. In normal operation a potential of −140 mV *vs.* Hg/Hg_2SO_4 reference electrode was used. The slope of the titration curve is only slightly influenced by the concentration of I^-.

Equation (6) shows that as the $[I^-]$ is increased the concentration of the volatile I_2 decreases and more I_3^- is formed. In order to decrease the amount of iodine lost through evaporation a high concentration of I^- should be selected. The selected iodide concentration was 24m*M* which is about ten times that normally used in earlier microcoulometric determinations of sulphur. With 24m*M* I^- 5·5% of the total iodine is present as I_2 and the rest as the non-volatile I_3^-. If 2·4m*M* I^- had been selected 37% of the iodine would have been present as I_2 and 63% as I_3^-. The lower iodide concentration would thus have given a blank value about seven times higher at a given gas flow. Moreover, as the iodine concentration varies during a titration the blank correction would have

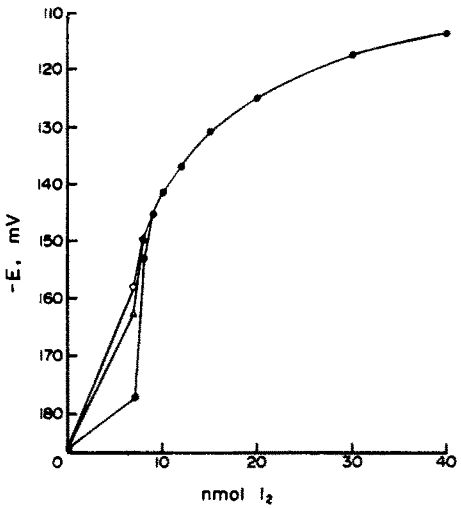

Fig. 6. Pt-indicating electrode response at various iodine concentrations in 30 ml of 0·40% KI, 0·055% NaN_3 and 0·68% CH_3COOH solution.
● Potential read after 15 sec; △ potential read after 2 min; □ potential read after 3 min.

been more difficult. The Coulometric Analyzer has a variable gain control which makes it easy to compensate for the lower slope of the titration curve obtained under the selected conditions. If an instrument with a lower sensitivity had been used this aspect would have had to be taken into account in determining the optimum conditions.

The blank value is composed of iodine losses as discussed above and of impurities from the gases. By insertion of a combustion oven in the line carrying the fast nitrogen stream the sulphur blank value could be reduced from 1×10^{-9} mole/min to $0{\cdot}2 \times 10^{-9}$ mole/min. This value will vary somewhat with time and from one gas cylinder to another. Over a period of 5 min the blank value was found to be stable within $\pm 0{\cdot}01 \times 10^{-9}$ mole/min. Purification of the other two gas streams would probably have decreased the blank value further. The purification train consisted of copper(II) oxide and silver gauze at 480° followed by an absorption vessel containing 0·4*M* sulphuric acid/4m*M* hydrogen peroxide. The gas was dried with "Dehydrite" and entered the preheating zone *via* a glass filter disc.

Determination of sulphur

Figure 7 shows the time-dependence obtained when a series of determinations was made. The samples were thiophene in cyclohexane. A recorder was connected to the coulometric analyser in order to display the titration. The result was always read from the integrator on the analyser, which had greater resolution and accuracy than the recorder plot. The time of a titration was of course longer when the sample introduction was slow, as in the present case where a large amount of hydrocarbons was consumed. Determinations of sulphur in water samples were also performed and then the injection could be made instantaneously, resulting in a short, high peak. The time of integration was noted in each case so that the blank value could be subtracted.

Table 1 shows the results of a number of determinations. The relative standard deviations found are equal to those expected from the sample.

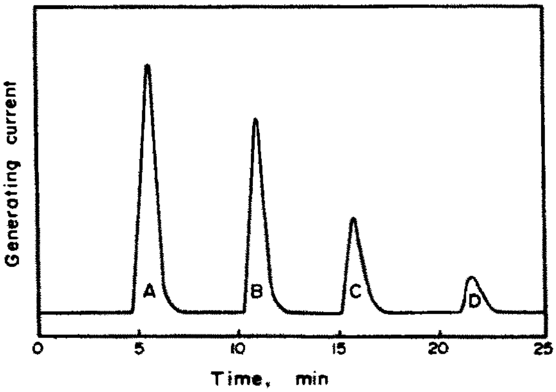

Fig. 7. Time-dependence in the determination of four different amounts of thiophene in cyclohexane.

Zusammenfassung—Ein neues Verbrennungssystem zur oxidativen coulometrischen Bestimmung von Schwefel in flüssigen Kohlenwasserstoffen wird beschrieben. Die Bedingungen wurden so ausgewählt, daß die SO_2-Ausbeute nahe an 100% lag. Die relative Standardabweichung für Schwefel lag bei 2–1000 mg/l unter 1%, mit Thiophen in Cyclohexan als Testsubstanz. Zur Wahl der Arbeitsbedingungen wurden die thermodynamischen Daten des Gleichgewichts zwischen SO_2, O_2 und SO_3 herangezogen. Um die Ausbeute an SO_2 zu erhöhen, wurde das Verbrennungsgasgemisch mit einem Inertgas verdünnt, um den Sauerstoffpartialdruck zu erniedrigen. Eine Temperatur von 1000° in der Gleichgewichtszone ergab eine Ausbeute von 99%. Das SO_2 wurde mit coulometrisch erzeugtem Jod titriert; dessen Konzentration wurde mit einer Pt-Redoxelektrode kontrolliert. Das Ansprechverhalten dieser Elektrode wurde überprüft. Es wurde eine ziemlich hohe J^--Konzentration verwendet, um Jodverluste während der Analyse zu unterdrücken. Die Analysenzeit betrug 2–5 min, die Probengrößen 3–7 μl. Ein coulometrisches Analysengerät LKB 16300 regulierte die Titration.

Résumé—On décrit un nouveau système de combustion pour le dosage coulométrique par oxydation du soufre dans des hydrocarbures liquides. On a sélectionné les conditions de manière à ce que la récupération à l'état de SO_2 soit proche de 100%. L'écart type relatif est $<1\%$ pour le soufre dans le domaine 2–100 mg/l, avec le thiophène en cyclohexane comme substance d'essai. On a utilisé des données thermodynamiques sur léquilibre entre SO_2, O_2 et SO_3 pour sélectionner les conditions opératoires. Pour accroître la récupération de SO_2, le mélange de gaz de combustion à été dilué avec un gaz inerte pour abaisser la pression partielle de l'oxygène. Une température de 1000° dans la zone d'équilibre a pour résultat une récupération de 99%. Le SO_2 a été titré par de l'iode engendré coulométriquement, dont la concentration a été contrôlée par une électrode redox-Pt. On a examiné la réponse de cette électrode. On a utilisé une concentration en I^- plutôt élevée pour supprimer les pertes d'iode pendant l'analyse. Le temps d'analyse a été de 2–5 mn, et les dimensions d'échantillon étaient de 3–7 μl. Un Analyseur Coulométrique LKB 16300 réglait la technique de titrage.

SUPPRESSION OF INTERFERENCE IN THE AAS DETERMINATION OF CHROMIUM BY USE OF AMMONIUM BIFLUORIDE

A. PURUSHOTTAM, P. P. NAIDU and S. S. LAL
Central Laboratories, Airborne Mineral Surveys and Exploration,
Geological Survey of India, Faridabad, India

(*Received* 10 *October* 1972. *Accepted* 31 *December* 1972)

Summary—Addition of 1% of ammonium bifluoride successfully suppresses interference by diverse ions in the atomic-absorption determination of chromium(VI). If the sample solutions also contain chromium(III) addition of 1% of ammonium bifluoride and 0·2% of sodium sulphate is recommended for the suppression.

Traces of chromium in rocks and minerals are usually determined spectrophotometrically[1] after conversion of chromium(III) into chromium(VI). More recently the technique of atomic-absorption spectrophotometry (AAS) has made chromium analyses easier and more rapid. However, chromium assay in rocks and minerals by AAS is rendered difficult by the fact that diverse ions interfere in the determination and several reagents have been used with varying degrees of success to suppress such interferences. Ammonium chloride[2,3] was found to reduce the depressant effect of iron on the chromium absorbance, and pyrosulphate[4,5] and persulphate[6] were found to suppress interference from aluminium, iron and titanium. Lanthanum chloride[7] was effective in eliminating interference from aluminium and phosphate. Strontium chloride[8] was found to suppress interference from a number of elements. Sodium sulphate (1%) was used by Hurlbut and Chriswell[9] for suppressing interference in the AAS determination of chromium(VI) by 1000 ppm of Ba, Ti, Mo, Mn, W, Fe, Ni, Co, Cu, Ag, Cd, Hg, Al, and Ce but it failed to remove the interference caused by Ca, Mg, Sb, Sn, sulphuric, phosphoric and perchloric acids and sodium hydroxide. It was also observed that 1% sodium sulphate was not quite effective in suppressing interferences by Ca, Mg, As, Pb, Zn, Sn, Ni, Mo and Cd with chromium(III) absorbance. Not all earlier workers have made an interference study for both oxidation states of chromium though both may be present in the resultant solutions when samples are decomposed with oxidizing acid mixtures. The behaviour of interfering ions differs with the oxidation state of chromium in the sample solutions, as stated by Suzuki and Takeuchi[10] who observed that Mn and Ni depress the absorption of chromium(III) but not that of chromium(VI). It is thus clear from the literature that no single suppressing agent so far proposed can be satisfactorily used to eliminate interference for both chromium(III) and (VI). Therefore attempts were made to find such a suppressing agent. Several reagents which would either precipitate or complex the interfering ions have been tried. They include ammonium hydroxide, diammonium hydrogen phosphate, sodium carbonate, ammonium carbonate and ammonium bifluoride. Among these ammonium bifluoride was found to be highly effective for suppressing the interference of diverse ions with Cr(VI) whereas a mixture of 1% ammonium bifluoride and 0·2% sodium sulphate was found suitable when both oxidation states are present.

EXPERIMENTAL

Reagents

Standard Cr(VI) solution, 1000 ppm. Prepared from potassium dichromate and demineralized water, and diluted to give 100 and 10 ppm standards.

Standard Cr(III) solution, 100 ppm. Prepared by reducing 10 ml of 1000-ppm chromium(VI) solution with a few drops of 30% hydrogen peroxide in 0·5*M* hydrochloric acid. The solution was diluted to 100 ml with 0·5*M* hydrochloric acid. Hydrogen peroxide does not have any deleterious effect.

Ammonium bifluoride solution (10%).

Sodium sulphate solution (2%).

Analytical grade reagents and demineralized water were used.

Apparatus

A model AA 100 Techtron Atomic Absorption Spectrophotometer with HSL hollow-cathode lamp was used. The most sensitive Cr absorption line (wavelength 357·9 nm) was used for measuring the absorbance values. The working conditions were as follows.

Lamp current 10 mA
Acetylene pressure 10 psig, flowmeter reading 6–6·5 (flow-rate 1·7 l./min)
Air pressure 15 psig (flow-rate 4 l./min)
Fuel-rich flame
Slitwidth 0·10 mm
A standard 10-cm stainless-steel AB51 burner with a 0·5-mm wide slot was used.

Calibration

After adjustment of the height and angle of the burner to give maximum absorbance for the highest standard, absorbance values were measured for 0, 0·5, 1·0, 2·0, 3·0, 5·0, 7·0 and 10·0 ppm chromium(VI) solutions containing 10 ml of 10% ammonium bifluoride solution in a total volume of 100 ml, and a calibration curve was drawn. When sodium sulphate was also found necessary in the analysis of samples a separate calibration curve was drawn with standards containing 0·2% sodium sulphate in addition to ammonium bifluoride.

Procedure

Different methods of treatment have been found necessary for different types of samples.

Silicates. Weigh a 0·2–0·5 g sample into a polythene beaker and treat it with 1 ml of conc. nitric acid and 10 ml of 40% hydrofluoric acid. Digest the mixture on a water-bath and evaporate it to dryness. Repeat the process to ensure complete decomposition of the sample. Dissolve the residue in 10 ml of *aqua regia* and transfer completely to a 250-ml Pyrex beaker. Evaporate the solution nearly to dryness, then dissolve the residue in a minimal volume of 0·5–1·0*M* hydrochloric acid, add 2–4 ml of ammonium bifluoride solution and 2 ml of sodium sulphate solution and dilute to 20 ml in a standard flask. Mix, allow to settle and measure the absorbance.

Refractory materials. Weigh a 0·1–0·2 g sample into a nickel crucible, mix it with 0·5–1 g of sodium peroxide, and fuse at dull red heat till the sample is completely decomposed. Cool the mass, extract it with hot water and make up to 100 ml. Take a suitable aliquot, add ammonium bifluoride solution, dilute to 20 ml and aspirate into the flame.

Sulphide minerals, steels and alloys. Weigh a 0·1–0·5 g sample into a dry 25-ml graduated cylinder (of a type which can be stoppered) and digest it on a hot plate with 5 ml of *aqua regia* until the solution is evaporated nearly to dryness. Extract the mass with 0·5–1*M* hydrochloric acid, add 2–4 ml of ammonium bifluoride solution and 2 ml of sodium sulphate solution, and make up to 20 ml with demineralized water. Measure the absorbance.

RESULTS AND DISCUSSION

Effect of air–acetylene ratio and lamp current

The air–acetylene ratio has considerable influence on the chromium absorbance. It can be seen from Table 1 that maximum absorbance was attained with acetylene at a delivery pressure of 10 psig and a flow-rate of 1·7 l./min and air at a pressure of 15 psig. From a series of experiments conducted separately, it was found that the lamp current has no significant effect.

Table 1. Effect of air–acetylene ratio on chromium absorbance in presence and absence of foreign ions
Air pressure 15 psig, acetylene delivery pressure 10 psig, 10 ppm Cr(VI), 2500 ppm foreign ion

	Absorbance						
Foreign ion added	Acetylene flowmeter setting	4·5	5	5·5	6·0	6·5	7·0
—		0	0·03	0·145	0·29	0·32	0·25
Al			0·03	0·10	0·20	0·20	0·20
Ca			0·025	0·13	0·28	0·27	0·24
Mg			0·03	0·11	0·24	0·22	0·13
Ni			0·03	0·10	0·165	0·22	0·20
Mo(VI)			0·025	0·10	0·26	0·25	0·17
Fe(III)			0·025	0·10	0·12	0·11	0·10

Though there is no doubt that in the hotter fuel-lean air–acetylene flames interference effects are almost negligible, the sensitivity is too low to permit determination of traces of chromium (0–50 ppm) in rocks, minerals and soils. It is clear that there is a tenfold increase in sensitivity between the fuel-lean and fuel-rich flames corresponding to acetylene flowmeter readings of 5 and 6·5 respectively. It is because this is accompanied by an increase in interference that a suppressing agent is needed.

Effect of ammonium bifluoride

Ammonium bifluoride not only suppresses the interference from foreign ions but also enhances the absorption by chromium [either (VI) or (III)]. It can be seen from Table 2 that the presence of 0·5–3% (w/v) of ammonium bifluoride enhances the absorbance by 30% while at concentrations higher than 5% of bifluoride the absorbance value falls to that obtained without addition of bifluoride. It is necessary that an optimum concentration of bifluoride be maintained in sample and standard solutions.

Table 2. Effect of ammonium bifluoride on absorbance of chromium (10 ppm)

Ammonium bifluoride, %(w/v)	0	0·5	1·0	2·0	3·0	5·0	7·0
Absorbance	0·30	0·425	0·425	0·425	0·425	0·37	0·35

Effect of acids and interference from diverse ions

As most of the chromium samples require decomposition by acids or fusion with sodium peroxide it was necessary to study the effect of these reagents on the chromium absorbance (Table 3). While hydrochloric and nitric acids have no effect on both Cr(III) and Cr(VI) absorbance, sulphuric, perchloric and phosphoric acids of 0·5–1*M* concentration act as depressants. Ammonium bifluoride eliminates the interference of sulphuric acid but not that of perchloric acids. Addition of calcium or potassium in addition to bifluoride and sodium sulphate is recommended where digestion procedures involve the use of phosphoric and perchloric acids respectively. The usual procedures recommended for attack of chromium-bearing samples involve the use of *aqua regia*, hydrofluoric plus nitric acid, or fusion with sodium peroxide, depending on the nature of the sample.

Table 3. Effect of acids and bases on chromium absorbance

Acid or base	Cr(VI) recovered, *ppm* No masking agent	Cr(VI) recovered, *ppm* 1% NH_4HF_2 added	Cr(III), recovered, *ppm* No masking agent	Cr(III), recovered, *ppm* 1% NH_4HF_2 added

* 10000 ppm K and 0·2% Na_2SO_4 also added.
† 10000 ppm Ca and 0·2% Na_2SO_4 also added.
§ Cr(III) precipitates.

A study of the interference of diverse ions (Table 4) revealed that a large number of cations, *viz.* Fe(III), Al, Ca, Mg, Co(II), Ni, Mn(II), Mo(VI), W(VI), Hg(II), As(III), Ba and Cd interfere either by enhancing or depressing the absorbance of Cr(VI) or Cr(III). Addition of ammonium bifluoride successfully eliminated interference by most of these ions except Ni and K. The presence of 500–1000 ppm Al in addition to ammonium bifluoride, and use of 0·5–1*M* hydrochloric acid medium, completely eliminates the interference by Ni. Ammonium bifluoride, though effective in suppressing interference by diverse ions in Cr(VI) determination, fails to do so in the case of Cr(III) when K, Cu(II), Co(II), Ni and W(VI) are present [Table 4]. As procedures involving acid digestion produce a mixture of Cr(III) and Cr(VI) in sample solutions, addition of 0·2% of sodium sulphate as well as ammonium bifluoride is recommended for suppression of interference. While almost complete recovery of Cr(VI) could be achieved by using ammonium bifluoride alone as the suppressing agent [10 ppm of Cr(VI) in combination with a foreign ion mixture containing 5000 ppm of each ion] the recovery was low with Cr(III) even if the concentration of individual ions in the mixture was only 1000 ppm. A comparative study was made of the effect of ammonium bifluoride with

that of various suppressing agents recommended by earlier workers. The results in Table 5 reveal that while none of the earlier reported suppressing agents could eliminate interference by 5000 ppm of foreign ions, bifluoride could do so easily. This is probably because bifluoride not only complexes some of the metal ions [Fe(III), Sn(IV)] but also precipitates such ions as Ca, Mg, Ba, Pb, thereby reducing the total ion content of the sample solution. A number of international rock standards have been analysed for Cr by this method and the results given in Table 6 are in close agreement with the literature values. Good agreement was also obtained for a number of standard steels and alloys with certificate values.

Acknowledgement—We wish to express our sincere thanks to the United States Geological Survey, British Chemical Society, Canadian Association for Applied Spectroscopy and Centre de Recherches Petrographique et Geochimiques (France) for kindly making available to us their standards used in this investigation.

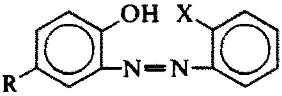
o-(2-HYDROXY-5-DODECYLPHENYLAZO)-BENZOESÄURE UND -ARSONSÄURE ALS CHELATBILDNER FLÜSSIGER IONENAUSTAUSCHER

E. BLASIUS und H. J. FINKENAUER
Institut für Analytische Chemie und Radiochemie der Universität des Saarlandes,
66 Saarbrücken 15, West Germany

(*Eingegangen am* 26. *Oktober* 1972. *Angenommen am* 22. *Januar* 1973)

Zusammenfassung—Die Synthesen der Chelatbildner *o*-(2-Hydroxy-5-dodecylphenylazo)-benzoesäure und -arsonsäure werden beschrieben. Diese werden, in Benzin bzw. Chloroform gelöst, als flüssige Ionenaustauscher zur Trennung (Be(II)/Al(III) bzw. Zr(IV)/Hf(IV) erprobt. Beide flüssigen Ionenaustauscher sind auch zur Abtrennung von Fe(III)-Spuren aus Salzlösungen geeignet.

In einigen vorhergehenden Veröffentlichungen[1-7] wird über *o,o'*-disubstituierte Azofarbstoffe berichtet, bei denen einerseits der Alkylrest R, andererseits die Gruppe X variiert werden kann:



R = —CH_3, X = —COOH ergibt ein selektives Reagenz auf Be(II), das für die Extraktion,[1] Polarographie[2] und Photometrie[3] heranzuziehen ist. Ist R ein polymeres Gerüst, liegt ein fester Chelataustauscher vor. Mit X = —COOH dient er u.a. zur Abtrennung von Erdalkaliionen aus konzentrierten Alkalisalzlösungen,[4] von Fe(III)-Spuren aus konzentrierten Salzlösungen[5] und zur Trennung Be(II)/Al(III).[6] Der feste Austauscher mit X = —AsO_3H_2 bindet Zr(IV) wesentlich stärker als Hf(IV).[7]

Ziel der vorliegenden Arbeit ist es, als R einen langen aliphatischen Rest (—$C_{12}H_{25}$) einzuführen. Die Produkte, gelöst in einem mit Wasser nicht mischbaren organischen Lösungsmittel stellen flüssige Ionenaustauscher dar.

EXPERIMENTELLER TEIL

Chemikalien

p-Dodecylphenol *ca.* 95–98% (BASF); Anthranilsäure purum, 98% (Fluka); Petroleumbenzin (Naphthabenzin) Kp = 100–140° (Merck); *o*-Arsanilsäure F = 152°C (Schuchardt).

Salze in *p.a.* Qualität, $Al(NO_3)_3 \cdot 9H_2O$ rein, $BeSO_4 \cdot 4H_2O$ reinst (Merck); Hafnium 99,9% (Fluka); $ZrO(NO_3)_2$, Verunreinigungen Hf < 200 ppm, andere Metalle 15 ppm (HEK-GmbH). Darstellung von $ZrOCl_2 \cdot 8H_2O$ und $HfOCl_2 \cdot 8H_2O$ nach Hönigschmidt *et al.*[8]

Leitisotope (Buchler): ^{7}Be als Chlorid in 0,1*M* HCl (trägerfrei); ^{59}Fe als Chlorid in 0,1*M* HCl (20 mCi/mg); $^{175+181}$Hf als Chlorid in 2*M* HCl (8 mCi/mg); ^{95}Zr als Oxalatokomplex in oxalsaurer Lösung (trägerfrei). Die Überführung des ^{95}Zr in das Sulfat geschieht durch mehrmaliges Abrauchen mit konz. H_2SO_4.

Synthesen

o-(2-Hydroxy-5-dodecylphenylazo)benzoesäure.[10]

o-(2-Hydroxy-5-dodecylphenylazo)arsonsäure 0,1 Mol Arsanilsäure in 50 ml Äthanol unter Erwärmen gelöst und mit 30 ml 37%iger HCl versetzt. Man kühlt in einer Eis-Kochsalz-Mischung auf 0° ab; dabei verdünnt man mit wenig Wasser so, daß die Mischung gut rührbar bleibt. Nun tropft man eine konzentrierte wäßrige Lösung von 0,105 Mol $NaNO_2$ langsam zu. Am Ende der Nitritzugabe erhält man eine klare braune Lösung. Nach 10 Minuten wird der Überschuß an HNO_2 mit Amidosulfonsäure entfernt.

Die Lösung von 0,075 Mol *p*-Dodecylphenol in 300 ml Äthanol kühlt man auf 0° ab, fügt auf einmal die diazotierte Arsanilsäure hinzu und versetzt unter Rühren mit einer $Ca(OH)_2$-Aufschlämmung [50 g $Ca(OH)_2$ in 100 ml H_2O]. $Ca(OH)_2$ wirkt als Base und zugleich als Aktivator für die Azokupplung.[11] Man rührt noch etwa 3 Stunden und läßt über Nacht stehen. Nach Zugabe von etwa 100 ml H_2O wird das Calciumsalz der *o*-(2-Hydroxy-5-dodecylphenylazo)arsonsäure abgesaugt, in 200 ml Äthanol suspendiert und nochmals wie oben beschrieben mit diazotierter Arsanilsäure gekuppelt.

Das abgesaugte, mit Wasser gewaschene Produkt kocht man nun in einem Becherglas mit HCl (1 : 1) bis sich eine dunkelrote, plastische Masse auf der Oberfläche abscheidet. Die wäßrige Lösung wird verworfen, die Behandlung des Niederschlages mit HCl wiederholt. Die entstandene freie Säure extrahiert man mit Benzol. Nach gründlichem Waschen der Benzolphase bis zur Chloridfreiheit wird das Lösungmittel abgedampft und die erhaltene zähe Masse im Vakuumtrockenschrank von Lösungsmittelresten bei 90° befreit.

Aus den elementaranalytisch erhaltenen N- bzw. As-Werten und den Äquivalenzpunkten bei der pH-Titration ergibt sich für *o*-(2-Hydroxy-5-dodecylphenylazo)benzoesäure ein 90%iger, für *o*-(2-Hydroxy-5-dodecylphenylazo)arsonsäure ein 68%iger Ablauf der Kupplungsreaktion. Die Einwaagen der Chelatbildner zur Herstellung der flüssigen Ionenaustauscher werden dementsprechend korrigiert.

ERGEBNISSE

Untersuchungen der Eigenschaften

Die beiden flüssigen Austauscher FAT (= austauschaktive Substanz im organischen Lösungsmittel) haben folgende Zusammensetzung:

FAT I: 0,025 Mol *o*-(2-Hydroxy-5-dodecylphenylazo)benzoesäure bzw. deren NH_4^+-Salz in 1000 ml Benzin gelöst.

FAT II: 0,0125 Mol *o*-(2-Hydroxy-5-dodecylphenylazo)arsonsäure in 1000 ml $CHCl_3$ gelöst.

Gleichgewichtsuntersuchungen. Die in Glas- bzw. Polyäthylenflaschen befindliche wäßrige Salzlösung wird mit dem aus einer Bürette dosierten flüssigen Austauscher durch einen Magnetrührer bei Zimmertemperatur innig vermischt. Nach Einstellung des Gleichgewichtes werden die Konzentrationen des betrachteten Kations in der wäßrigen und organischen Phase bestimmt. Eine etwaige Verteilung der Chelatbildner in der wäßrigen Phase läßt sich durch spektrophotometrische Untersuchungen verfolgen.

Phasentrennung. Bei Kontakt der flüssigen Austauscher in der H^+-Form mit Wasser und Säuren geht die Phasentrennung schnell vor sich. Die Chelatbildner verbleiben in der organischen Phase. Bei Säurekonzentrationen $> 3M$ bilden sich die protonisierten Formen aus. In FAT I flockt der Chelatbildner aus, FAT II färbt sich tiefrot. Im alkalischen Gebiet kann der Übergang der Alkalisalze der Chelatbildner von der organischen in die wäßrige Phase durch genügend hohe Alkalielektrolytkonzentration oder Anwesenheit komplexbildender Kationen unterbunden werden. Unter diesen Bedingungen ist bei Verwendung von Benzin bzw. $CHCl_3$ als Lösungsmittel eine etwaige Emulsionsbildung am geringsten. Bei Kontakt mit alkalischen Medien entstehen in FAT II Trübungen, d.h. die Alkalisalze der *o*-(2-Hydroxy-5-docecylphenylazo)arsonsäure fallen im organischen Lösungsmittel aus.

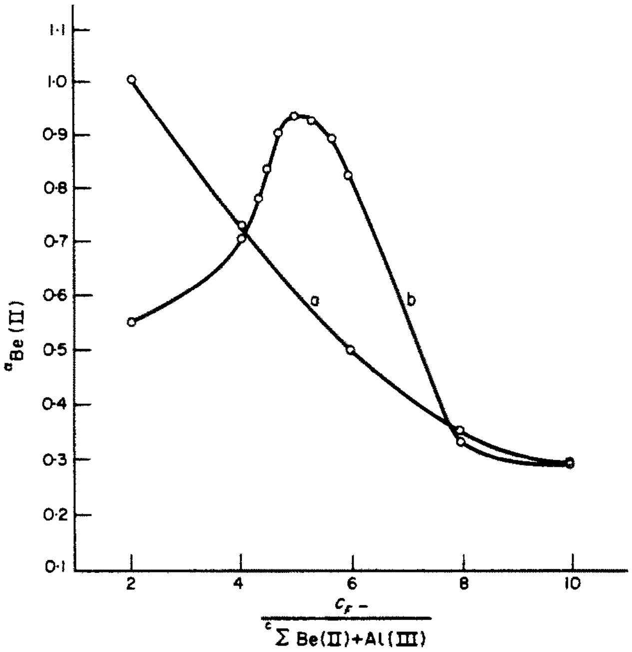

Abb. 1. FAT I—Extraktionskoeffizienten von Be(II) ohne und in Gegenwart von Al(III) bei Anwesenheit von Fluorid. (*a*) Be(II); (*b*) Be(II) in Gegenwart von Al(III). 1,25 · 10^{-3} Mol Be; 2,5 · 10^{-3} Mol Al. Vor der F^--Zugabe wird mit NaOH der Hydroxokomplex dargestellt. pH-wert: 4,5 (HNO_3).

Bedingungen für Abb. 1 und 2:

Organische Phase: 50 ml FAT I in NH_4^+-Form (= 1,25 × 10^{-3} Mol) mit Benzin auf 100 ml verdünnt.

Wäßrige Phase: 100 ml Salzlösung der angegebenen Zusammensetzung

Kontaktzeiten: 45 Minuten.

Anwendung von FAT I

FAT I kann zur Trennung von Be(II) und Al(III) und zur Abtrennung von Fe(III)-Spuren aus *p.a.* Salzlösungen herangezogen werden.

Be(II)/Al(III) Trennung. Mit der Bildung der Be(II)-und Al(III)-Komplexe ab pH 2,5 tritt eine deutliche Farbänderung des FAT von rot nach orange auf. Die Gleichgewichtseinstellung ist bei Zimmertemperatur nach etwa 30 Minuten beendet. Bei 40° verkürzt sich die Zeit auf etwa 4 Minuten.

Die Extraktionskoeffizienten von Be(II) und Al(III) sind bei Gegenwart komplexbildender Anionen so unterschiedlich, daß bei einmaliger Gleichgewichtseinstellung eine Anreicherung bzw. Trennung erfolgt.

Als Komplexbildner werden F^-, $C_2O_4^{2-}$, AeDTE und Tartrat eingesetzt. Bestimmt wird der Verlauf der Extraktionskoeffizienten von Be(II) in Abhängigkeit von der Anionenkonzentration mit und ohne Anwesenheit von Al(III). In Abb. 1 und 2 sind die Extraktionskoeffizienten von Be(II) gegen den Quotienten aus Anionenkonzentration und Konzentration der Summe der Metallionen aufgetragen.

Da einerseits F^- und $C_2O_4^{2-}$, andererseits AeDTE und Tartrat analoge Kurven hervorrufen, ist im folgenden nur der Einfluß von F^- (Abb. 1) und AeDTE (Abb. 2) näher beschrieben.

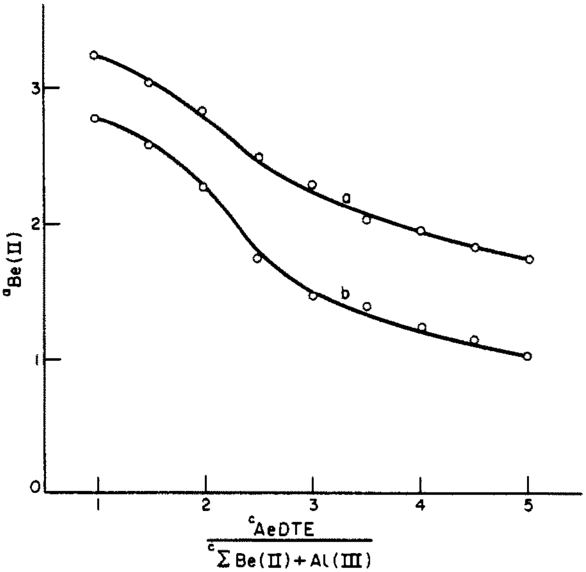

Abb. 2. FAT I—Extraktionskoeffizienten von Be(II) ohne und in Gegenwart von Al(III) bei Anwesenheit von AeDTE (*a*) Be(II); (*b*) Be(II) in Gegenwart von Al(III).
1,25 × 10^{-3} Mol Be; 2,5 × 10^{-3} Mol Al; 4,00 × 10^{-2} Mol CH_3COONH_4 und 1,00 × 10^{-2} Mol KNO_3. Kochzeit zur vollständigen Ausbildung der AeDTE-Komplexe, 2 Minuten. pH-Wert: 4,5 (HNO_3).

Bei F^- werden im Maximum der Kurve *b* (Abb. 1) 48% des Be(II) und 0,73% des eingesetzten Al(III) vom flüssigen Austauscher aufgenommen. Unter den Bedingungen des maximalen $\alpha_{Be(II)}$-Wertes wird das Be(II) von einem 5-fachen Austauscher-Überschuß [bezogen auf Be(II)] quantitativ extrahiert. Es ist mit 1,25% des eingesetzten Al(III) verunreinigt. Mit $C_2O_4^{2-}$ als komplexbildendem Anion in der wäßrigen Phase genügt zur quantitativen Be(II)-Extraktion der 2-fache Austauscher-Überschuß. Dabei werden 3,3% des Al(III) mitaufgenommen.

Durch die Gegenwart von AeDTE werden die Extraktionskoeffizienten von Be(II) wenig beeinflußt. Die Aufnahme von Al(III) wird jedoch verhindert. So ist bei einem der Kationenkonzentrationen entsprechenden 4-fachen AeDTE-Überschuß neben 56% des Be(II) kein Al(III) im flüssigen Austauscher nachzuweisen.

Bei Anwendung von Tartrat liegen die Verhältnisse ähnlich. Bei einem 4-fachen Tartrat-Überschuß werden 35% des Be(II) und kein Al(III) mehr extrahiert.

Fe(III)-Spuren aus p.a. *Salzlösungen.* Bereits ab pH 0,7 bildet die *o*-(2-Hydroxy-5-dodecylphenylazo) benzoesäure mit Fe(III) Komplexe. Die Gleichgewichtseinstellung dauert bei Zimmertemperatur etwa 30 Minuten, bei 40° 10 Minuten.

In einem Einstufenprozeß von 10 Minuten Dauer wird mit einer *ca.* 0,05%igen Lösung des Chelatbildners in Benzin der Fe(III)-Gehalt von 0,1*M* Salzlösungen stark vermindert. In Abb. 3 ist der prozentuale Anteil der vom Hersteller genannten Fe(III)-Verunreinigung nach gewissen Kontaktzeiten mit FAT I aufgetragen.

Auffallend ist die schlechte Fe(III)-Spurenabtrennung aus einer 0,1*M* NaCl-Lösung, die auf die Bildung anionischer Fe(III)-Chlorokomplexe zurückzuführen sein dürfte. Die Abnahme des Fe(III)-Gehaltes des $NaClO_4$ um *ca.* 99% stellt einen Beweis hierfür dar.

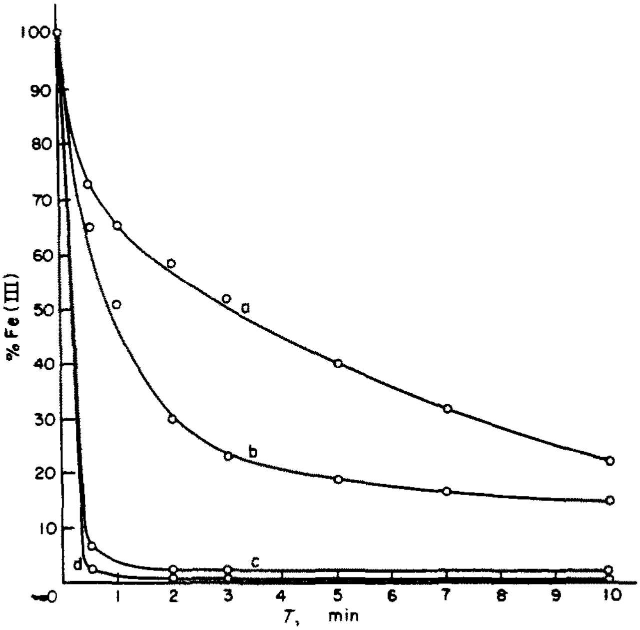

Abb. 3. FAT I—Abtrennung von Fe(III)-Spuren aus 0,1*M* Salzlösungen (*a*) NaCl *p.a.* (0,0002% Fe); (*b*) $Al(NO_3)_3 \cdot 9H_2O$ rein (0,01% Fe); (*c*) $NaClO_4 \cdot H_2O$ *p.a.* (0,0005% Fe); (*d*) CH_3COONH_4 *p.a.* (0.0005% Fe) Organische Phase: 2,5 ml FAT I in NH_4^+-Form; (= $6,25 \times 10^{-5}$ Mol) auf 50 ml verdünnt Wäßrige Phase: Jeweils 50 ml 0,1*M* Lösung des genannten Salzes.

Anwendung von FAT II

FAT II bildet mit Zr(IV) und Hf(IV) noch aus 6*M* HCl Komplexe. Die Gleichgewichtseinstellung bei Raumtemperatur dauert 40 Minuten. Abb. 4 gibt die Extraktionskoeffizienten in Abhängigkeit von der HCl-Konzentration wieder.

Zr(IV) wird bevorzugt vor Hf(IV) von FAT II aufgenommen. Aus 0,09*M* HCl erreicht der Trennfaktor einen Wert von 7. Die Abnahme der Zr(IV)-Extraktionskoeffizienten bei HCl-Konzentrationen <0,09*M* ist auf eine bereits beginnende Hydrolyse des Zr(IV) zurückzuführen.

Auch FAT II bildet mit Fe(III) bereits im sauren Medium Komplexe, wobei eine Farbänderung nach braungrün auftritt. Die Gleichgewichtseinstellung nimmt etwa 30 Minuten in Anspruch. Abb. 5 zeigt die Abtrennung von Fe(III)-Spuren aus 0,1*M* Salzlösungen.

FAT II zeigt sich in der Befreiung der 0,1*M* $Al(NO_3)_3 \cdot 9H_2O$-Lösung von Fe(III) dem FAT I etwas überlegen. Während bei FAT I noch 15% der Fe(III)-Ausgangskonzentration in der Salzlösung verbleiben, sind es bei Anwendung von FAT II noch 1,8%.

DISKUSSION

Gegenüber den Synthesen der entsprechenden festen Austauscher sind die der Chelatbildner für FAT I und FAT II recht einfach. Sie besitzen unter den gegebenen Bedingungen gute Löslichkeit in der organischen und geringe Löslichkeit in der wäßrigen

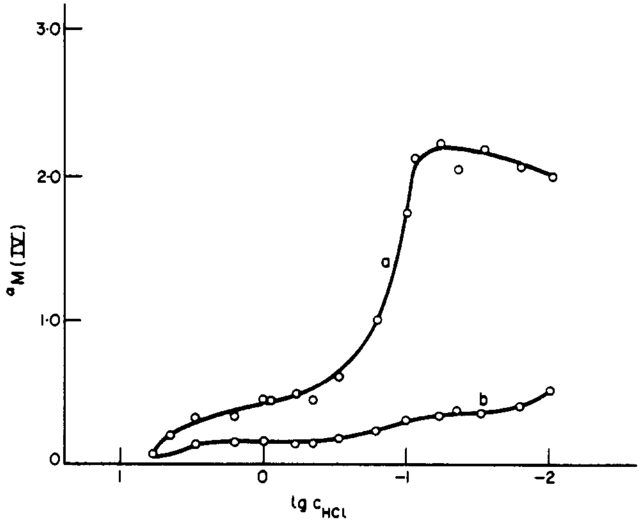

Abb. 4. FAT II—Extraktionskoeffizienten in Abhängigkeit von der HCl-Konzentration; (*a*) Zr(IV); (*b*) Hf(IV).
Organische Phase: 1 ml FAT II in der H^+-Form (= 1,25 . 10^{-5} Mol) auf 25 ml verdünnt.
Wäßrige Phase: 1,25 × 10^{-5} Mol $HfOCl_2 \cdot 8H_2O$ bzw. 1,25 × 10^{-5} Mol $ZrOCl_2 \cdot 8H_2O$; 1,00 . 10^{-3} Mol KNO_3; Lösungsvolumen: 25 ml *xM* HCl, *x* = 0,01 bis 6.
Kontaktzeit: 60 Minuten

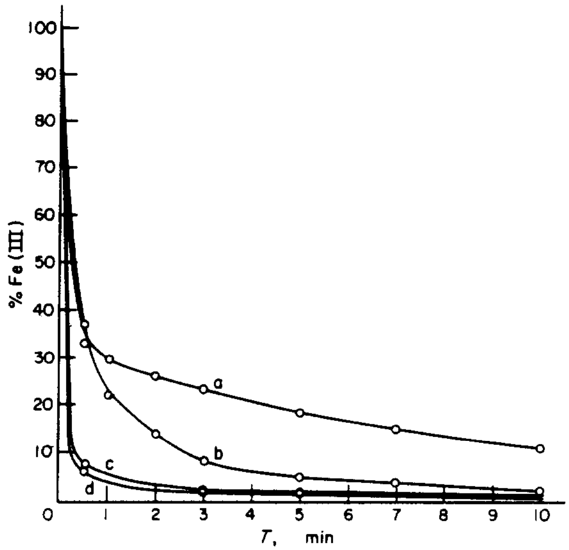

Abb. 5. FAT II—Abtrennung von Fe(III)-Spuren aus 0,1*M* Salzlösungen (*a*) NaCl *p.a.* (0,0002% Fe); (*b*) $Al(NO_3)_3 \cdot 9H_2O$ rein (0,01% Fe); (*c*) $NaClO_4 \cdot H_2O$ *p.a.* (0,0005% Fe); (*d*) CH_3COONH_4 *p.a.* (0,0005% Fe).
Organische Phase: 5 ml FAT II in H^+-Form (= 6,25 × 10^{-5} Mol) auf 50 ml verdünnt.
Wäßrige Phase: 50 ml 0,1*M* Lösung des genannten Salzes.

Phase. Der Dodecylrest reicht also zur Hydrophobierung der chelatbildenden Gruppen aus. Die Gleichgewichte stellen sich im Gegensatz zu festen Austauschern schon im Minutenbereich ein.

Die Extraktionskoeffizienten von Be(II) und Al(III) an FAT I können durch komplexbildende Anionen so unterschiedlich werden, daß eine Anreicherung bzw. Trennung im Satzbetrieb möglich ist. Ursache ist die höhere Stabilität der entsprechenden Al(III)-Komplexe in der wäßrigen Phase. Das erhaltene Maximum bei der Be(II)-Extraktion in Gegenwart von Al(III) und F^- (Kurve *b* in Abb. 1) spricht für die Bildung eines $[AlF_6]^{3-}$-Komplexes. Das bei einer gleichartigen Trennung mit einem flüssigen Anionenaustauscher auftretende Maximum ist jedoch auf die Bildung von AlF_3 zurückzuführen.[12]

Eine Zr(IV)/Hf(IV)-Trennung mit FAT II ist bei einem Trennfaktor von 7 durch multiplikative Verteilung möglich. Die Abtrennung von Fe(III)-Spuren gelingt mit beiden flüssigen Austauschern. Besonders vorteilhaft gegenüber einem analogen festen Austauscher[5] ist die schnelle Gleichgewichtseinstellung. Weiter ist die Anwendung von FAT I flüssigen Austauschern. Besonders vorteilhaft gegenüber einem analogen festen Austauscher[5] ist die schnelle Gleichgewichtseinstellung. Weiter ist die Anwendung von FAT I Aufziehen von *o*-(2-Hydroxy-5-dodecylphenylazo)benzoesäure und -arsonsäure auf hydrophobiertes Kieselgel, worüber in einer weiteren Veröffentlichung berichtet wird.

Summary—The syntheses of two new chelating agents *o*-(2-hydroxy-5-dodecylphenylazo)-benzoic acid and the corresponding arsonic acid, are described. Solutions of these in benzine or in chloroform have been used as liquid ion-exchangers for the separation of Be and Al, and of Zr and Hf. Both have proved useful for the separation of traces of Fe(III) from solutions of salts.

Résumé—On décrit les synthèses de deux nouveaux agents chélatants, l'acide *o*-(2-hydroxy 5-dodécylphénylazo)benzoïque et l'acide arsonique correspondant. Les solutions de ceux-ci dans le benzène ou le chloroforme ont été utilisées comme échangeurs d'ions liquides pour la séparation de Be et Al, et de Zr et Hf. Tous deux se sont montrés utiles pour la séparation de traces de Fe (III) de solutions de sels.

DETERMINATION OF IMPURITIES IN HIGH-PURITY GOLD, WITH A GAS-STABILIZED LOW-TEMPERATURE ARC

B. ZMBOVA and M. MARINKOVIĆ
Boris Kidrič Institute, Vinča,
11001 Beograd, Yugoslavia

(*Received* 22 *November* 1972. *Accepted* 20 *January* 1973)

Summary—A gas-stabilized arc with aerosol supply has been used for emission spectrometric determination of Al, B, Be, Co, Cr, Fe, Ga, In, Mg, Mn, Ni, Pd, Rh and Zn, as impurities in high-purity gold. Two analytical procedures were compared: (*a*) direct aspiration of dissolved samples containing 2% of gold and 0·25*M* KCl as buffer, and (*b*) separation of impurities by ether extraction of gold from 1*M* HCl followed by impurity determination with a stabilized arc. Limits of detection, precision and recovery of the extraction procedure are given.

Radioactive gold has been widely applied in medicine for diagnosis and therapy of various cancerous diseases. In achievement of better nuclear balance in ^{198}Au isotope production, the gold target purity is of great importance.

Until recently, most analyses of impurities in gold were performed by emission spectroscopy or atomic absorption. However, both of these methods have inherent disadvantages. Spectrographic analysis has poor precision and standard preparation is often rather complicated, while atomic absorption is not suitable for the determination of a large number of elements in a single sample, as it usually requires a separate hollow-cathode lamp for each element to be determined and its sensitivity may be unsatisfactory for some elements, especially when solid samples are analysed.

The spectrographic methods based on sample dissolution in *aqua regia* and evaporation of the solution on graphite electrodes or graphite powder, followed by spectral excitation in a d.c. arc,[1,2] or solution excitation by the rotating disc technique[3] have been described in the literature. Recently Jäger described an emission spectrometric technique using a Grimm's discharge lamp.[4] As a technique suitable for solution analysis, atomic absorption has also been applied to gold analysis after dissolution of the sample in *aqua regia*.[5,6]

In view of the disadvantages of existing methods, a new emission spectrometric technique has been developed for direct analysis of solutions. A gas-stabilized low-temperature arc described elsewhere[7] has been applied to excitation of aerosol solutions. This excitation source has some characteristics that make it suitable for solution analysis: (*a*) it is sufficiently simple for routine analysis, (*b*) it shows low memory effect, as low as that found with a conventional slot-burner, and (*c*) its sensitivity is comparable to or better than that obtained with conventional flame methods.

Gold samples were dissolved and the solutions obtained analysed directly, or after the gold had been separated by extraction.

EXPERIMENTAL

Apparatus

Stabilized arc device. A slightly modified version of the arc device previously described[7] was used. A cross-section of the essential part of it is shown in Fig. 1.

The device consists of metal segments, electrically insulated and water-cooled. The arc burns through the openings in segments 4–6, between graphite anode 1 (Ringsdorf Werke RW III) and carbon cathode 9 (Ringsdorf Werke RW II); the latter is axially bored, 3 mm dia., to make possible the ignition of the arc discharge with an auxiliary graphite rod.

The openings, 3 mm dia., in segments 4 and 6 are sufficiently narrow to eliminate the influence of the irregular wandering of the cathode and anode spots on the central part of the arc column. At these points the arc column is wall-stabilized, and there is no gas flow through these openings. The sample aerosol is introduced tangentially into the cavity of segment 5, to make the gas vortex needed for stabilization of the central part of the arc column. This segment, in contrast to the others, is not water-cooled. During the arc burning, the temperature of this segment is elevated, which prevents the deposition of the aerosol drops inside its cavity. To avoid consumption of the graphite electrodes, argon shielding-streams are introduced into the sections around them.

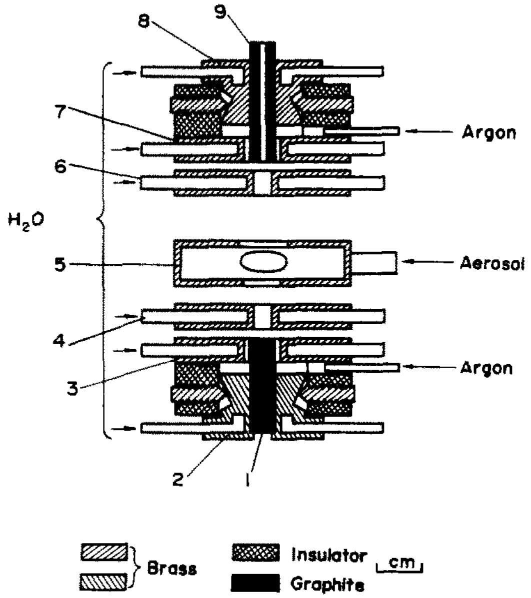

Fig. 1. Stabilized arc. 1—anode: 2—anode holder; 3, 4, 6 and 7—the metal segments, electrically insulated from one another and water-cooled; 5—the central segment, not water-cooled; 8—cathode holder; 9—cathode. The arc burns in the axial channel which consists of an opening in each segment. The analytical gap is between segments 5 and 6.

Arc-generator. The arc supply is obtained from a source based on a three-phase rectifier giving 300 V on open circuit. At a current of 6 A, the voltage drop across the electrodes was about 90 V. Small current fluctuations caused by wandering of electrode spots were avoided by electronic stabilization of the arc current.

Solution nebulizer. Solutions were aspirated into an argon stream with a chamber type nebulizer and the aerosol obtained was introduced into the cavity of segment 5. The argon flow-rate was 3 l./min and the solution uptake rate was 1·5 ml/min. The nebulizer efficiency was estimated to be 3·4%. With this nebulizer and the arc current of 6 A, the minimum concentration of potassium buffer required for obtaining low-temperature arc conditions was 0·25*M*.

Monochromator. A 2-m plane grating spectrograph PGS-2 (Carl Zeiss, Jena) with an attachment for photoelectric detection and having a single exit slit (laboratory made) was used as a monochromator. The entrance slit of the monochromator was illuminated with a three-lens system with intermediate image. For this purpose and to avoid spectral order overlapping an order-sorter (Carl Zeiss, Jena) was used. The arc portion between segments 5 and 6 (Fig. 1) was imaged on the intermediate diaphragm of the order-sorter with a 150-mm

Table 1. Limits of detection

Element	Wavelength, *nm*	Limit of detection, *μg/ml*	
		Without KCl	With KCl
Al	396·2	0·21	0·0045
B	249·7	0·013	0·027
Be	234·9	0·0077	0·021
Co	345·3	0·23	0·028
Cr	357·9	0·042	0·032
Fe	372·0	0·11	0·013
Ga	417·2	0·11	0·0073
In	451·1	0·34	0·039
Mg	285·2	0·035	0·0028
Mn	403·1	—	0·003
Ni	352·4	0·23	0·0063
Pd	340·4	0·063	0·011
Pt	265·9	1·1	0·59
Rh	345·3	0·13	0·001
Zn	213·9	0·018	—

achromatic lens. The dispersion plane of the order-sorter prism was horizontal, thus allowing the use of the full length of the entrance slit (about 14 mm).

The grating (650 lines/mm) was blazed for 590 nm. and was used in the first order for wavelengths longer than 370 nm, and in the second order for wavelengths shorter than 370 nm. The entrance and exit slits were 0·1 mm wide giving a spectral band-pass of 0·08 nm in the first order and 0·04 nm in the second order.

Light intensity measurement. A photomultiplier 1P28 (RCA) operating at 1000 V was used as a detector. The anode current was measured with a potentiometric recorder B1G1 (Carl Zeiss, Jena) which had a sensitivity of 10^{-8} A for full-scale deflection. The time constant was set to 1 sec.

Preliminary investigations

Limits of detection. Limits of detection were determined for all elements covered, with the procedure described. The limit of detection is taken to be the concentration of an element that gives a reading equal to twice the standard deviation near the blank level. The standard deviations was calculated from ten pairs of alternating sample–blank measurements.

The results obtained are shown in Table 1. Column 3 shows the limits of detection obtained by aspiration of 2% gold solution and column 4 gives the limits of detection obtained by aspiration of the solution containing 2% of gold and 0·25*M* in potassium chloride as spectroscopic buffer. It is evident that lower limits of detection are obtained for most elements in presence of potassium chloride, *i.e.*, under low-temperature conditions of arc burning. This effect is in agreement with the previous investigation of this type of the stabilized arc.[7,8]

The effect of addition of potassium buffer could be ascribed to more favourable conditions being attained for the entry of aspirated elements into the arc column and to the suppression of ionization of easily ionized elements.

For the elements of high excitation potential (*e.g.*, zinc) and for elements forming stable oxides (*e.g.*, boron and beryllium) the temperatures achieved in the low-temperature arc are not usually sufficiently high, and lower limits of detection are obtained in the absence of alkali metals as buffers.

Extraction efficiency with ether. To find optimum conditions for the separation of gold by ether extraction a radioactive tracer technique with isotopes ^{198}Au and ^{59}Fe was used. It is already known that iron can be extracted with ether at higher concentrations of hydrochloric acid, and this was the reason for investigation of iron and gold extraction at various acidities. The results are shown in Table 2. Gold is efficiently extracted with 0·5–2*M* hydrochloric acid. However, with acid concentrations higher than 1*M* the degree of extraction of iron increases. Therefore, best conditions for extraction are achieved in the range from 0·5 to 1·0*M* hydrochloric acid.

Direct analytical procedure

Two analytical procedures were used: (*a*) direct analysis of the solutions obtained by dissolving gold in *aqua regia*, and (*b*) determination of impurities in the solutions after separation of gold by ether extraction. The direct procedure will be described first.

Table 2. Extraction of Au and Fe with ether at different concentrations of HCl

[HCl], *M*	Au in ether, %	Fe in ether, %
0·1	88	0·15
0·5	98·7	0·18
1·0	98·4	0·33
2·0	98·9	1·1
3·0	97·1	2·8
4·0	97·0	26·9
5·0	96·6	56·3

Sample preparation. A gold sample (1 g) was dissolved in 5 ml of *aqua regia* and the solution obtained transferred into a 25-ml flask and made up to volume. An aliquot of this solution was mixed with an equal volume of 0·5*M* potassium chloride. For determination of most elements, the buffered solution was aspirated into the arc, but boron, berryllium and zinc were determined in a 2% solution of gold without potassium chloride addition.

Standard preparation. The standards were prepared in a similar manner to the sample. Spectrographically pure gold (Johnson–Matthey) was dissolved in *aqua regia* and a series of solutions was prepared each containing 4% of gold, and the impurities in the concentration range from 0·05 to 10 μg/ml. It was taken into account that the composition of the standard solutions should be as similar as possible to that of the solutions to be analysed. An aliquot of the solution obtained was then mixed with an equal volume of 0·5*M* potassium chloride (or distilled water) and aspirated into the arc.

Measurement. The blank and the solutions obtained as described above were aspirated with a chamber-type nebulizer and the measurement of the emission of corresponding spectral lines was simultaneously performed. Corrections for background emission were made. No internal standard was used. Analytical curves (Fig. 2) were obtained by plotting the recorder readings against the concentration on a logarithmic scale. In order to make the drawing clearer, some curves have been shifted along the intensity axis.

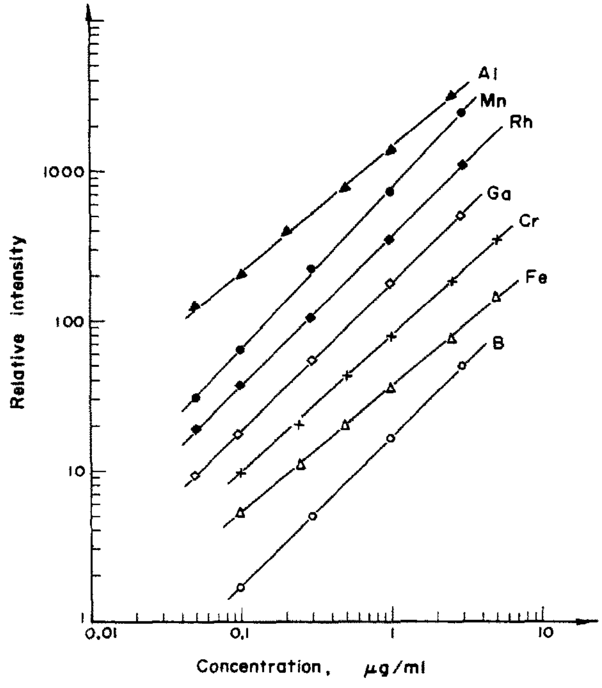

Fig. 2. Analytical curves (to make the drawing clear, some of the curves have been shifted along the intensity axis).

Analytical procedure with separation

Sample preparation. The gold (1 g) was dissolved in 5 ml of *aqua regia* and the solution evaporated nearly to dryness in order to remove nitrate; the residue obtained was dissolved in 20 ml of 1*M* hydrochloric acid. The solution was transferred into a separatory funnel, 20 ml of ether were added and after being shaken for 2 min the mixture was allowed to separate into layers. The organic phase, containing the gold, was discarded. Two more extractions, each with 10 ml of ether, were performed. The aqueous phase was evaporated to small volume, transferred to a 10-ml flask and made up to volume. An aliquot of the solution was mixed with an equal volume of 0·5*M* potassium chloride (or distilled water) and the mixture aspirated into the arc.

Standard preparation. A set of standard solutions, containing from 0·03 to 3 μg/ml of each impurity, was prepared in the same way as the sample except for the extraction being performed in the absence of the gold, in order to avoid contamination by gold impurities. The aqueous phase was evaporated to small volume and gold was added in the concentration which generally remained after the extraction procedure. Other details of the standard preparation were the same as those for the sample preparation.

Measurement. The measurement procedure was identical to that used in the direct procedure.

ANALYTICAL RESULTS

To test the extraction procedure and subsequent impurity determination standard solutions containing gold and thirteen impurity elements were prepared. The analyses were made at two impurity levels. The solutions were analysed according to the procedure described above. The results are presented in Table 3, and do not show any significant systematic deviation.

As a measure of precision relative standard deviation was used; some values are shown in Table 4.

Table 3. Recovery by the procedure

Element	Added, *μg/ml*	Found, *μg/ml*	Recovery, %
Al	0·1	0·095	95
	0·3	0·28	93
	0·3	0·27	90
B	1	0·94	94
	0·1	0·1	100
Co	0·3	0·27	90
	0·1	0·09	90

	1·0	1·0	100
Fe	3·0	3·1	103
	0·1	0·1	100
Ga	0·3	0·33	110
	0·1	0·11	110
In	0·3	0·31	103
	0·1	0·095	95
Mg	0·3	0·3	100
	0·1	0·11	110
Mn	0·3	0·34	113
	0·1	0·105	105
Ni	0·3	0·27	90
	1·0	1·15	115
Pd	3·0	3·0	100
	0·1	0·1	100
Rh	0·3	0·29	97
	1·0	1·0	100
Zn	1·0	1·05	105

Table 4. Precision of the determination with the stabilized arc

Element	Concentration, *µg/ml*	Standard deviation, *µg/ml*	Relative standard deviation, %
Al	0·25	0·016	6
	0·5	0·01	2
	1·05	0·016	1·5
Fe	0·25	0·005	2
	0·51	0·02	3·9
	1·00	0·02	2·0
Cr	0·255	0·008	3·1
	0·55	0·03	5·4
	1·00	0·017	1·7

The procedure developed allows quick determination of impurities in gold with satisfactory precision. The procedure employing separation of gold lowers the limits of determination, but requires a longer time and reagents of high purity.

Zusammenfassung—Ein gasstabilisierter Bogen mit Aerosolspeisung wurde zur emissionsspektrometrischen Bestimmung von Al, B, Be, Co, Cr, Fe, Ca, In, Mg, Mn, Ni, Pd, Rh und Zn verwendet, die als Verunreinigungen in hochreinem Gold vorlagen. Zwei analytische Arbeitsvorschriften wurden verglichen: a) direktes Ansaugen gelöster Proben, die 2% Gold und 0.25*M* KCl als Puffer enthielten, b) Abtrennung der Verunreinigungen durch Extraktion von Gold mit Äther aus 1*N* HCl, anschließend Bestimmung der Verunreinigungen mit stabilisiertem Bogen. Nachweisgrenzen, Genauigkeit und Ausbeute des Extraktionsverfahrens werden angegeben.

Résumé—On a utilisé un arc stabilisé au gaz avec arrivée d'aérosol pour le dosage spectrométrique d'emission de Al, B, Be, Co, Cr, Fe, Ga, In, Mg, Mn, Ni, Pd, Rh et Zn, en tant qu'impuretés dans l'or de haute pureté. On a comparé deux techniques analytiques: (a) aspiration directe d'échantillons dissous contenant 2% d'or et KCl 0, 25*M* comme tampon, et (b) séparation d'impuretés par extraction à l'éther de l'or à partir de HCl 1*N* suivie par le dosage de l'impureté avec un arc stabilisé. On donne les limites de détection, la précision et la récupération de la technique d'extraction.

APPLICATION OF THE ZONE-MELTING TECHNIQUE TO METAL CHELATE SYSTEMS—VI*

A NEW APPARATUS FOR ZONE-MELTING CHROMATOGRAPHY

SHIGERU MAEDA, HIROSHI KOBAYASHI and KEIHEI UENO®
Department of Organic Synthesis, Faculty of Engineering,
Kyushu University, Fukuoka 812, Japan

(*Received* 20 *December* 1972. *Accepted* 31 *January* 1973)

Summary—An improved apparatus has been constructed for zone-melting chromatography. An essential feature of the apparatus is that the length of the molten zone can be kept constant during a zone-melting operation, by employing heating and cooling compartments which are separated from each other by double partition plates. Each compartment is heated or cooled with jets of hot or cold air. The apparatus is suitable for organic materials melting in the range between 40° and 180°. The distribution of metal ion along the column after zone melting of copper acetylacetonate in 2-methoxynaphthalene was a smooth curve. The plot of the position of maximum concentration, x_{max}, against the number of zone passes, n, gave a relationship in accordance with theoretical prediction.

A few papers have been published on the chromatographic separation of mixtures by the zone-melting technique. Peaker and Robb,[1] and Loconti and Cahill[2] applied zone-melting chromatography (ZMC) to the fractionation of polymers, and Doron and Kirschner[3] applied this method to the separation of diastereomeric mixtures. However, their experiments were irreproducible and gave poor separations. A successful application of this technique was published by Plancher, Cogswell and Latham,[4] who separated polycondensed aromatics, using induction heating, but their apparatus was expensive.

The present authors[6] have investigated the separation of mixtures of metal chelates on columns of organic solid solvents. The distribution of solutes was not reproducible owing to the inconstancy in the length of the molten zone during the operation.

The present paper reports the construction of a ZMC apparatus which can keep the molten zone length constant, and includes some preliminary experimental results.

EXPERIMENTAL

The glass tube (sample container) is held at an angle of 30° from the horizontal for convenience of operation, and is drawn upwards. Diagrams of the apparatus are shown in Figs. 1 and 2. The sample container is a Pyrex glass tube 60 cm long and 0·6 cm dia., closed at its lower end with a silicone rubber plug. The length of the molten zone is maintained at 5·0 mm. Ten heating and eleven cooling compartments are placed one above the other alternately and are separated by eleven sets of double

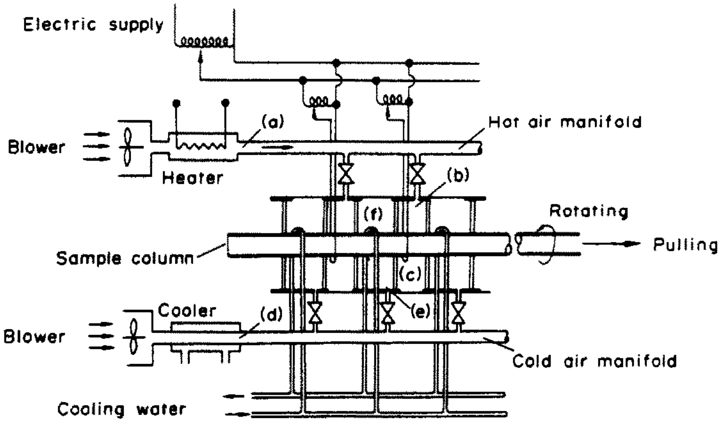

Fig. 1. Schematic diagram of ZMC apparatus.

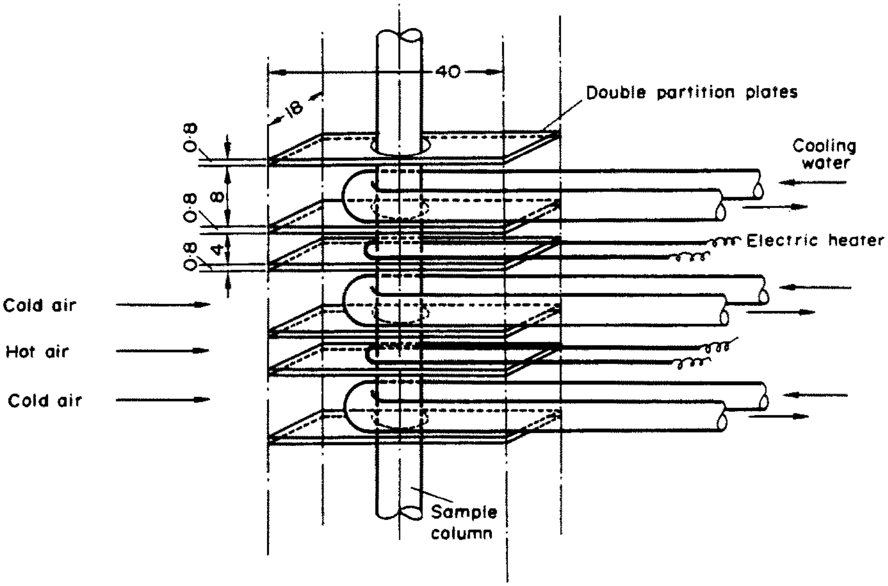

Fig. 2. Complete assembly of ZMC apparatus (dimensions in mm).

partition plates. These consist of thin brass and mica plates each of 0·2 mm thickness, 0·8 mm apart. The sample tube passes through a round hole bored at the centre of each partition plate with a clearance of 0·2 mm. Hot and cold air is introduced into the heating and cooling compartments through their manifolds at a constant flow-rate. Auxiliary heaters and coolers are built into the compartments for finer temperature control. The temperature of each compartment can be controlled independently by an individual air-flow regulator (located near the air nozzle) and a variable transformer for the auxiliary heater. The auxiliary heater and cooler are a sheathed nichrome wire ring, and a ring-shaped copper tube through which cooling water is circulated, respectively.

The sample tube is rotated at a rate of 6 rpm, so that uniform heating can be achieved.[5] The speed of zone travel can be adjusted to 49, 27, 17 and 11 mm/hr. The compartments have glass windows of width 5 mm at the centre of the front and back walls, so that the zones can be observed during an operation. The shape and length of a molten zone were determined by photography. The temperature and flow-rate of the hot and cold air as well as the power of the resistance heaters are adjusted according to the melting point of the column material. Temperature was measured by thermocouples fixed at each monitoring point, away from the walls of the apparatus.

The power supply for the entire apparatus was stabilized at 100 ± 1 V. The flow-rates of the hot and cold air were measured with a gas flowmeter (Yazaki Keiki, Model V-5) with an error of ±3%. The preparation and operation of the sample column were the same as those described previously.[6]

RESULTS AND DISCUSSION

At the first stage of our ZMC study with this new apparatus, the functions of each component were investigated under various operating conditions. The ZMC process was then applied to a system containing a single solute, copper(II) acetylacetonate, in a solid solvent, 2-methoxynaphthalene.

Insulating effect of the double partition plates

Table 1 lists the temperature measured at several points in the apparatus during the operation using 2-methoxynaphthalene (m.p. 72°) as a column material. The letters in brackets correspond to the points shown in Fig. 1.

The temperature at the point (*c*) in a hot compartment is higher than the melting point of 2-methoxynaphthalene by about 60°, and that in the cold compartment (*f*) is lower than the melting point by about 30°.

The thermal insulation efficiency of a thin brass plate, a thin mica plate and a thin brass plate covered with mica were compared, and they showed very little difference. Although the mica plate gave a slightly better effect than the metallic ones, a brass plate showed much better mechanical properties.

If a single partition plate was employed in place of the double partition plates, the temperature difference between the two points, (*c*) and (*f*), was generally less than 60° (regardless of the materials of the partition plates), and this temperature difference is not sufficient to give a successful result. With double partition plates, the gap of 0·8 mm between the two plates gives enough thermal insulation to maintain the required temperature difference of about 90°.

Constancy of zone length during operation

If the column was rotated without being raised the mean zone length was 5·18 mm with a relative standard deviation of 3·6%, when the zone length was measured every hour during a 15-hr operation. At a zone-travel speed of 49 mm/hr, the corresponding values were 5.01 mm and 4·1%, respectively, when measured every 30 min during an 8-hr operation.

Table 1. Operational conditions on a 2-methoxynaphthalene column

Point at which temperature is measured		Temperature, °C
In the hot blast generator	(*a*)*	300–400
At a hot blast nozzle	(*b*)	160–190
In the neighbourhood of the column in a hot compartment	(*c*)	about 130
In a cold blast generator	(*d*)	10–30
At a cold blast nozzle	(*e*)	20–40
In the neighbourhood of the column in a cold compartment	(*f*)	about 45

* See Fig. 1 for positions.

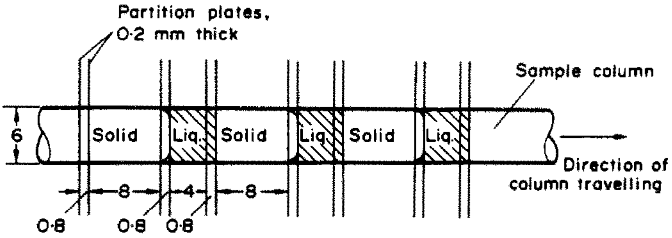

Fig. 3. Shape of the molten zone (dimensions in mm).

Shape of the molten zone

Both freezing and melting interfaces of the molten zone were flat unless the molten zone travelled. If the zone travelled at 49 mm/hr, the melting interface became slightly convex (Fig. 3) and the freezing interface was probably concave. At the lower speed of 27 mm/hr, both interfaces were flat, and remained within the gap of the double partition plates.

Temperature range of efficient operation

In order to establish the working conditions, the apparatus was operated with several organic compounds melting in the range 44–177° as column materials. The results are summarized in Table 2. The temperature of the cooling water determines the lower limit for the melting point of a column material, the upper limit being determined by the heater power.

The apparatus works satisfactorily when the temperature of the heating compartments is 40° higher than the melting point of the column material and of the cooling compartments 30° lower.

Table 2. Operating conditions for various solid solvents

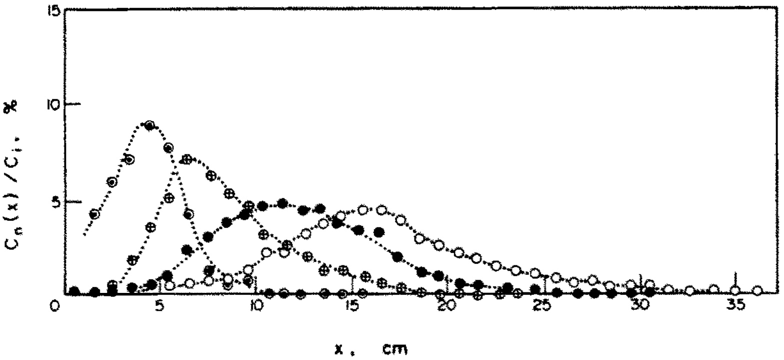

Fig. 4. Distribution of copper concentration on a 2-methoxynaphthalene column after various numbers of zone passes
Initial concentration, C_i = 1000–1500 ppm
Number of zone passes: ⊙ $n = 10$, ⊕ $n = 20$, ● $n = 30$, ○ $n = 40$.

Distribution of the solute on the column

The ZMC process was applied to the system of copper acetylacetonate and 2-methoxynaphthalene. One zone length of solid solution of the copper chelate in 2-methoxynaphthalene was placed on the top of a column of the same solvent, and the entire column was subjected to a ZMC operation. Figure 4 shows some typical examples of the distribution of a solute after the ZMC process. The concentration of the solute is shown in terms of the copper ion concentration.

The ratio of the metal concentration, $C_n(x)$, at a distance x from the column top, to the initial concentration, C_i, is plotted against the distance x.

The results shown in Fig. 4 were obtained with an initial chelate concentration, C_i, in the range 1000–1500 ppm (copper ion), and the number of zone passes was varied from 10 to 40. It is to be noted that as the number of zone passes increases, the maxima in the distribution curves shift towards the lower end of the column, while the peak height is reduced and the peak width increases.

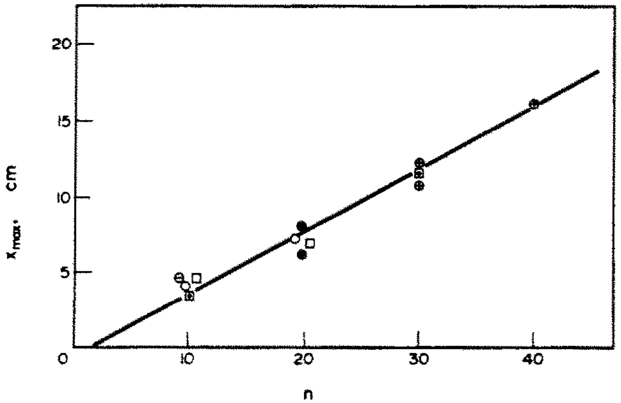

Fig. 5. Peak shifts of distribution curves
Initial concentration, C_i: ○ 1500 ppm, □ 1400 ppm, ⊕ 1300 ppm, ⊡ 1200 ppm, ⊖ 1000 ppm, ⊙ 690 ppm, ● 340 ppm

Figure 5 shows the relationship between the position of the maximum solute concentration, x_{max}, and the number of zone passes, n, observed in 12 experiments. The plot was a good straight line, which can be expressed by the equation:

$$x_{max}(n) = 0{\cdot}40n - 0{\cdot}45$$

The value of x_{max} seems to be determined only by the number of zone passes, being independent of the initial concentration. This result is in accordance with the theoretical prediction that, assuming ideal conditions,[7] the position of a chromatographic peak moves linearly with increase in the number of zone passes except near the top of the column.[8]

The present apparatus overcomes the difficulties of holding the zone length constant, and provides reproducible data in accordance with theoretical predictions.

Zusammenfassung—Ein verbessertes Gerät zur Zonenschmelzchromatographie (ZMC) wurde konstruiert. Ein wesentliches Merkmal des Geräts ist, daß die Länge der geschmolzenen Zone während der Zonenschmelzoperation konstant gehalten werden kann. Dies wird durch die Verwendung von Heiz- und Kühlabteilen erreicht, die durch doppelte Trennwände voneinander abgeteilt sind. Jedes Abteil wird mit Strahlen von heißer oder kalter Luft geheizt oder gekühlt. Das Gerät ist für organische Stoffe geeignet, die zwischen 40° und 180° schmelzen. Die Verteilung von Metall entlang der Säule war nach dem Zonenschmelzen von Kupferacetylacetonat in 2-Methoxynaphthalin eine glatte Kurve. Die Auftragung der Stellung der maximalen Konzentration x_{max} gegen die Anzahl der Zonendurchgänge n gab eine Beziehung, die mit der theoretischen Voraussage übereinstimmte.

Résumé—On a construit un appareil amélioré pour la chromatographie par fusion de zone (ZMC). Une caractéristique essentielle de l'appareil est que la longueur de la zone fondue peut être maintenue constante durant l'opération de fusion de zone, en employant des compartiments de chauffage et de refroidissement qui sont séparés l'un de l'autre par des doubles plateaux de partage. Chaque compartiment est chauffé ou refroidi par des jets d'air chaud ou froid. L'appareil convient pour des substances organiques fondant dans le domaine compris entre 40° et 180°. Le partage de l'ion métallique le long de la colonne après fusion de zone de l'acétylacétonate de cuivre en 2-méthoxynaphtalène a été une courbe continue. Le tracé de la position de la concentration maximale, x_{max}, par rapport au nombre de passages de zone, n, a donné une relation en accord avec la prévision théorique.

A POLAROGRAPHIC STUDY OF THE PRE-SODIUM TYPE CATALYTIC HYDROGEN WAVE EXHIBITED BY SELENOCYSTINE

V. VOICU and A. CĂLUŞARU
Institute of Atomic Physics, Bucharest, Romania

(*Received* 18 *September* 1972. *Accepted* 31 *December* 1972)

Summary—Selenocysteine, formed by reduction of selenocystine at the DME at about −0·6 V in an ammoniacal buffer, produces a pre-sodium catalytic hydrogen wave. The effects on this wave of variation of several physico-chemical parameters such as selenocystine concentration, mercury column height, buffer capacity and concentration, and ionic strength, have been studied. The results obtained all support the conclusion that the wave is of pre-sodium type. The partially protonated species of selenocysteine seem to be catalytically active. An analytical determination of selenocystine in the presence of selenocysteine, based on this study, is proposed.

Polarographic studies on the cystine–cysteine system have revealed the existence of a typical catalytic hydrogen reduction wave. As the reduction potential for cystine is relatively low ($E_{1/2} = -0{\cdot}79$ V)[1] it is reduced to cysteine at more negative potentials, and it is this which causes the catalytic waves, which may be due to: (1) catalytic hydrogen discharge of pre-sodium type; (2) catalytic pre-waves of cobalt and nickel; and (3) catalytic hydrogen discharge in the presence of cobalt or nickel ions. A review of this subject has been published by Călușaru.[2] The selenium analogues of cystine and cysteine follow similar oxidation-reduction processes to the sulphur compounds.[3] The catalytic cobalt[4] and nickel[5] pre-waves of the selenium compounds have been studied. Similar catalytic pre-waves are exhibited by the analogous sulphur compound,[6] but in contrast with sulphocystine, in the case of selenocystine the equilibria are established more rapidly. The cobalt and nickel pre-waves, well separated from the diffusion waves of the same ions, are formed without delay after the preparation of the solutions. Cobalt complexes with selenocysteine, resulting from reduction of selenocystine, do not form the catalytic hydrogen waves of the Brdička type in ammoniacal solutions, which are very characteristic in the case of the sulphur compounds.[1,2]

We have found that at very negative potentials selenocysteine forms catalytic hydrogen waves of pre-sodium type in ammoniacal and other buffers. This paper describes the results of an experimental study of this catalytic hydrogen wave.

EXPERIMENTAL

The synthesis of selenocystine has been described;[4] it is based on Painter's method[7] using serine as starting material. Only freshly preparated solutions were used, obtained by dissolution of the solid substance in water, without other solvents. The stability conditions, previously mentioned,[4] have been considered.

A type LP60 polarograph was used with cells as described by Smoler,[8] having a saturated calomel electrode as anode. The capillary constants were: $m = 2{\cdot}64$ mg/sec, $t_1 = 3{\cdot}56$ sec and $h = 56$ cm, in open circuit and $0{\cdot}1M$ ammonium chloride/$0{\cdot}1M$ ammonia as electrolyte.

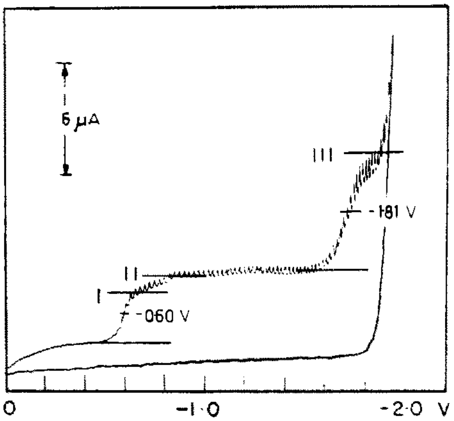

Fig. 1. Polarographic waves of selenocystine, $5 \times 10^{-4}M$, in ammoniacal buffer, NH_4Cl/NH_3, 0·1*M*. Start potential, 0 V; anode, S.C.E.

Polarography of selenocystine in absence of cobalt and nickel ions

Figure 1 shows the polarogram of a $5 \times 10^{-4}M$ selenocystine solution in ammoniacal buffer (NH_4Cl/NH_3, 0·1*M*). Several cathodic processes can be distinguished on this curve. The first wave, with half-wave potential −0·6 V corresponds to the two-electron reduction of selenocystine to selenocysteine. This wave has been described in a paper by Nygård.[3] The half-wave potential is dependent on the pH: −0·374 V at pH = 1·25 and −0·680 V at pH = 12·6. In Fig. 1 can also be seen a post-wave (between I and II) which is sometimes found in the case of other seleno-compounds.[3]

At very negative potentials a catalytic hydrogen wave of pre-sodium type[2] is formed, with half-wave potential −1·81 V. Since at the potentials greater than −0·8 V the selenocystine is completely reduced to selenocysteine, the catalytic wave is produced by this last substance, as in the case of the sulphur compounds.[2]

Effect of selenocystine concentration

In Fig. 2 the polarograms corresponding to different selenocystine concentrations in the range from $0{\cdot}5 \times 10^{-4}$ to $5 \times 10^{-4}M$ are given. The plot of the wave-height *vs.* selenocystine concentration gives a curve, tending slowly towards a limit (Fig. 3). The deviation from linearity is generally more pronounced for catalytic reactions than is indicated in Fig. 3. The difference may be explained by taking into account the enhancement of the catalytic wave[9] caused by the preceding reduction of selenocystine: as the selenocystine concentration is increased so is the height of the reduction wave which in turn enhances the catalytic wave. This effect is significant because the heights of the reduction and the catalytic waves are comparable. Therefore the current is enhanced at high selenocystine concentrations and the non-linearity of the calibration is reduced.

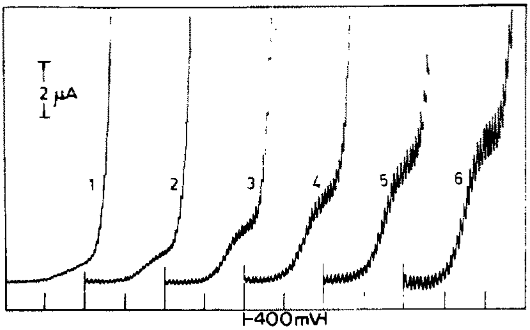

Fig. 2. Waves of catalytic hydrogen discharge of pre-sodium type in presence of selenocystine. Start potentials, −1·40 V; anode, S.C.E.; NH_4Cl/NH_3, 0·1M. Selenocystine concentration: *1* — $0{\cdot}5 \times 10^{-4}M$; *2* — $1 \times 10^{-4}M$; *3* — $2 \times 10^{-4}M$; *4* — $3 \times 10^{-4}M$; *5* — $4 \times 10^{-4}M$; *6*—$5 \times 10^{-4}M$.

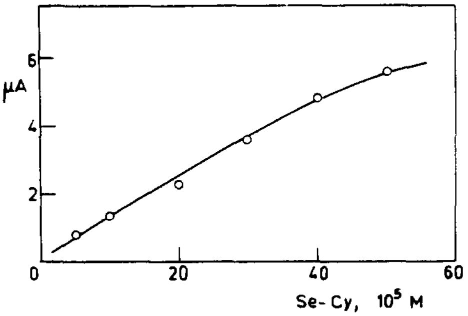

Fig. 3. Variation of the catalytic pre-sodium wave as a function of selenocystine concentration in ammoniacal buffer, NH_4Cl/NH_3, 0·1*M*.

Effect of mercury reservoir height

In contrast with diffusion-controlled waves which increase as the height of the mercury column is increased, the catalytic waves in the presence of Co^{2+} and Ni^{2+} are invariable, and the pre-sodium type waves decrease with increasing height of mercury column.[10,11]

The variation in the catalytic-wave height for selenocystine as a function of $\sqrt{h}$ is given in Fig. 4. This behaviour is very similar to that shown by cycloserine,[11] and is an important empirical indication of a catalytic pre-sodium wave.

Effect of buffer capacity

Only the proton in the catalyst molecule is discharged during the catalytic hydrogen-evolution step. After its elimination a proton from the solution takes its place in the catalyst molecule; it is generally accepted that protonation may sometimes be the rate-determining step for catalytic hydrogen discharge.[2] But the protonation rate is influenced by the buffer capacity, which is why the catalytic wave increases with the increase in the buffer capacity. This variation is considered one of the most characteristic properties of catalytic waves.

In Fig. 5 the variation of the wave height as a function of buffer capacity is given for the buffer component ratio $NH_4Cl/NH_3 = 1$. The shape of the curve is typical for a pre-sodium catalytic wave.

Effect of ammonium chloride concentration

Figure 6 shows the effect, on the height of the catalytic wave, of varying the ammonium chloride concentration at two different ammonia concentrations. Of course both the pH and the buffer capacity are altered, the latter increasing at higher ammonium chloride concentration. Another effect on the pre-sodium wave produced by variation in the ammonium chloride concentration is the modification of the half-wave potential value: at higher concentrations the shift is towards more positive potentials.

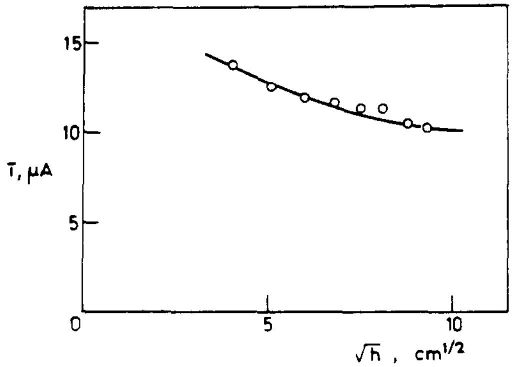

Fig. 4. Catalytic wave height *vs.* square root of mercury reservoir height. Electrolyte: NH_4Cl, 0·1*M*; NH_3, 0·01*M*; selenocystine, 5×10^{-4}*M*.

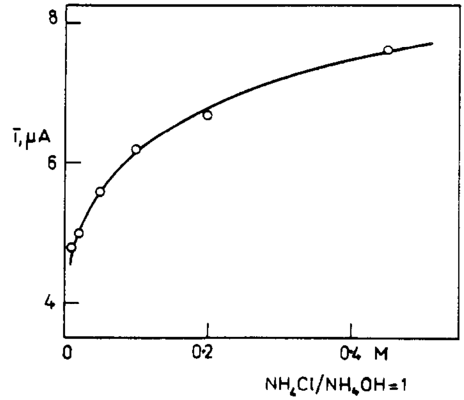

Fig. 5. Effect of the buffer capacity on the catalytic wave height. Selenocystine concentration, $5 \times 10^{-4}M$.

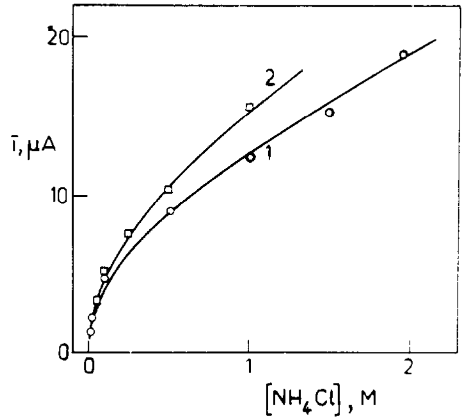

Fig. 6. Effect of NH_4Cl concentration on catalytic wave height. Electrolyte: selenocystine, $5 \times 10^{-4}M$; NH_3 : □ 0·05M; ○ 0·1M.

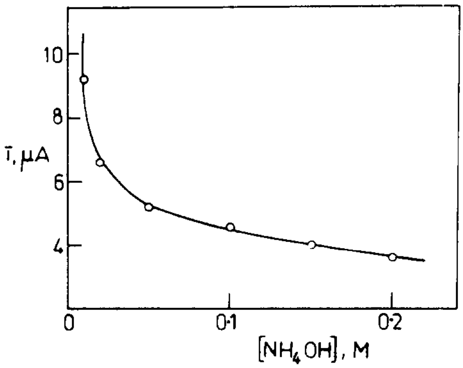

Fig. 7. Effect of ammonia concentration on the catalytic wave. Selenocystine, $5 \times 10^{-4}M$; NH_4Cl, 0·1M.

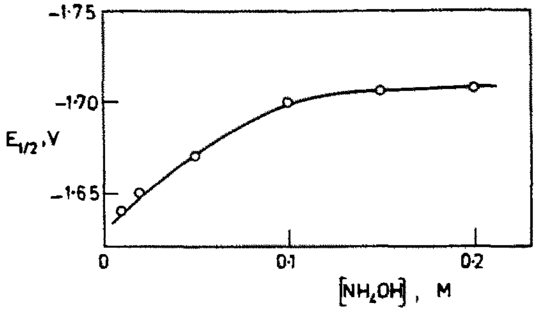

Fig. 8. Effect of ammonia concentration on half-wave potential of the catalytic wave. Selenocystine, $5 \times 10^{-4}M$; NH_4Cl, $0{\cdot}1M$.

Effect of ammonia concentration

Variation of the ammonia concentration affects both the wave height (Fig. 7) and the half-wave potential (Fig. 8) of the catalytic wave. At lower concentrations (lower pH) the wave height decreases sharply, while at higher concentrations the wave height tends towards a limiting value.

Behaviour in acid media

When an acetate buffer is used instead of the ammonium buffer and the pH value is lowered below 7, selenocystine does not form pre-sodium hydrogen waves. However, more complex catalytic waves appear in presence of certain metal ions. This problem will be dealt with in another paper.

Effect of ionic strength

Both ion-discharge and adsorption processes are modified by changes in the ionic strength. The pH value is also changed. It is therefore to be expected that changes in the strong electrolyte concentration would have a complex effect on catalytic waves where electron transfer, adsorption phenomena and protonation reactions are involved.

The effect of strong electrolyte concentration on the selenocystine pre-sodium wave is shown in Fig. 9. Several salts have been used: $NaClO_4$, LiCl, NaCl, $SrCl_2$ and $BaCl_2$. In all cases a decrease in the wave height with increase in concentration is obtained: LiCl has the weakest effect, while $SrCl_2$ and $BaCl_2$ produce the strongest. This behaviour is similar to that observed for other catalytic processes such as the catalytic nickel pre-wave[5] and the catalytic hydrogen wave in the cobalt-cycloserine system.[11]

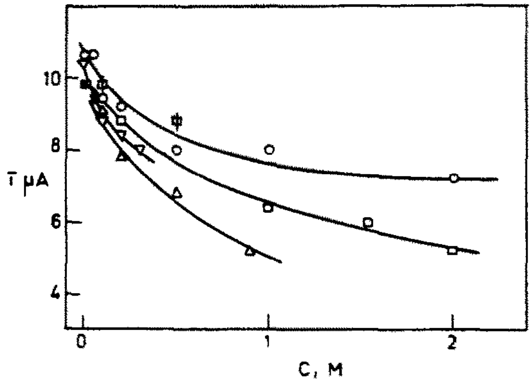

Fig. 9. Effect of the ionic strength on the catalytic wave. Electrolyte: NH_4Cl, $0{\cdot}1M$; NH_3, $0{\cdot}01M$; selenocystine, $5 \times 10^{-4}M$; □ $NaClO_4$; ○ LiCl; □ NaCl; ▽ $SrCl_2$; △ $BaCl_2$.

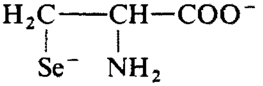
DISCUSSION

Although in the first paper on the polarography of selenocystine no catalytic processes were reported,[3] subsequent studies revealed several catalytic phenomena including cobalt and nickel pre-waves at very low selenocystine concentrations.[4,5] In the present paper another catalytic process, the catalytic hydrogen discharge of pre-sodium type, is reported.

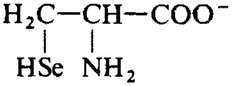
It is of special interest to compare the processes occurring with the sulphur and selenium compounds, in view of the well known role of the –SH groups in catalytic hydrogen discharge. From this point of view the main difference between sulpho- and selenocystine lies in the absence of Brdička-type catalytic waves for the selenium compound in the presence of cobalt or nickel ions and an ammonical buffer. This fact indicates that there is not a direct correlation between the metal ion pre-wave and the Brdička-wave, as has sometimes been suggested.

For the interpretation of the selenocysteine pre-sodium wave we refer to the protonated forms of this substance. As in the case of cysteine, four forms may be considered:[4]



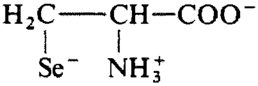
$\underset{\mathrm{Se^-}}{\mathrm{H_2C}}-\underset{\mathrm{NH_2}}{\mathrm{CH}}-\mathrm{COO^-}$

(*a*)



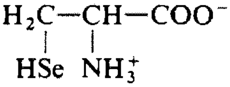
$\underset{\mathrm{HSe}}{\mathrm{H_2C}}-\underset{\mathrm{NH_2}}{\mathrm{CH}}-\mathrm{COO^-}$

(*b*)



$\underset{\mathrm{Se^-}}{\mathrm{H_2C}}-\underset{\mathrm{NH_3^+}}{\mathrm{CH}}-\mathrm{COO^-}$

(*c*)



$\underset{\mathrm{HSe}}{\mathrm{H_2C}}-\underset{\mathrm{NH_3^+}}{\mathrm{CH}}-\mathrm{COO^-}$

(*d*)

The form (*a*) is stable only in very alkaline media and the form (*d*) in acid solutions. For the equilibrium reaction between the forms (*c*) and (*d*) pK_a' was found to be 5·7 by Nygård.[3] Therefore for the pH range used in the present work it is possible to consider that mainly the forms (*b*) and (*c*) were present and responsible for the hydrogen discharge in the region of the catalytic pre-sodium wave. Taking into account the strong decrease of the wave height in concentrated ammonia solution media it is possible to consider that the form (*a*) has no catalytic effect. The decrease in wave height with increase in pH can be explained by the equilibrium displacement of the protonation reaction from the forms (*b*) and (*c*) to the inactive or less active form (*a*).

Several interpretations of the mechanism of the catalytic hydrogen discharge of pre-sodium type have been proposed.[1] More recently Mairanovskii considered the bimolecular reaction:

$$2BH \rightarrow 2B + H_2$$

as the main step in this process.[10] BH^+ represents the protonated form of the catalyst B. Březina and Kůtova[9] discussed this scheme in connection with the catalytic waves formed in the presence of an organic and inorganic depolariser. Owing to the enhancement effect on the hydrogen wave produced by the preceding reduction reaction, too close an agreement between experiment and theory cannot be expected. In the selenocystine system, studied in the present work, the preceding reaction is represented by reduction of the –Se–Se– bridge, as we have previously emphasised. There are also other factors which can affect the height of the catalytic wave, such as catalyst adsorption, electrolyte stirring at the mercury drop surface, and modification of the double-layer composition. The last of these may be achieved by changing the concentration of strong electrolyte, a technique often used in electrochemical studies. The results presented in Fig. 9 showing the decrease of the catalytic-wave height with increase in supporting electrolyte concentration are in good agreement with the behaviour of the pre-sodium wave formed in other systems.[10]

ANALYTICAL APPLICATIONS

The results of this study suggest a possible method for the determination of selenocystine in the presence of selenocysteine. From Fig. 1 the wave with $E_{1/2} = -0{\cdot}60$ V corresponds to reduction of selenocystine and may be used for a normal polarographic determination of this compound.

It is also possible to determine polarographically selenocysteine in the presence of selenocystine. For this purpose the catalytic pre-sodium wave at $-1{\cdot}81$ V must also be used. It is necessary to construct two calibration curves: (1) wave III *vs.* wave (I + II) (Fig. 1) in a solution containing selenocystine only; (2) wave (III) *vs.* concentration in a pure selenocysteine solution under the same conditions as for Fig. 1. In the sample to be analysed, containing both substances, the pre-sodium wave (III) will be higher than would correspond to a pure selenocystine solution, but by use of the wave at $-0{\cdot}60$ V and the calibration curve (1), the pre-sodium wave height corresponding to the selenocystine concentration can be determined. From the difference between the pre-sodium wave height for the sample and that predicted from calibration curve (1), the concentration of selenocysteine can be determined from the calibration curve (2).

Although the waves of cystine or cysteine interfere with the waves of the corresponding seleno-compounds, it is possible to determine qualitatively the presence of the sulphur-compounds, since they give rise to a catalytic hydrogen wave at more positive potentials (about 200 mV) in the presence of cobalt and in an ammoniacal buffer,[1,2] and the selenium compounds do not.[3-5] However, it should be pointed out that a number of other substances also give rise to pre-sodium waves,[1,2] The error in the determinations lies in the range ±2–3% for concentrations of $0{\cdot}5\text{–}6 \times 10^{-4}M$.

In view of the increasing interest in organoselenium compounds—in particular the selenocystine–selenocysteine system—this method may prove useful for control of purity of selenocysteine prepared by reduction of selencystine.

Zusammenfassung—Selenocystein, das sich in einem ammoniakalischen Puffer bei etwa $-0{\cdot}6$V durch Reduktion von Selenocystin an der Quecksilbertropfelektrode bildet, zeigt vor der Natriumstufe eine katalytische Wasserstoffstufe. Der Einfluß der Veränderung mehrerer physikalisch-chemischer Parameter wie Konzentration von Selenocystin, Höhe der Quecksilbersäule, Pufferkapazität und -konzentration sowie der Ionenstärke auf diese Stufe wurde untersucht. Alle Ergebnisse unterstützen den Schluß, daß die Stufe vom Pränatriumtyp ist. Die teilweise protonierten Spezies von Selenocystein scheinen katalytisch aktiv zu sein. Auf Grund dieser Untersuchung wird eine analytische Bestimmung von Selenocystin in Gegenwart von Selenocystein vorgeschlagen.

Résumé—La sélénocystéine, formée par réduction de la sélénocystine à l'électrode à goutte de mercure à environ −0, 6V dans un tampon ammoniacal, produit une vague hydrogène catalytique pré-sodium. On a étudié les influences sur cette vague de la variation de plusieurs paramétres physico-chimiques tels que la concentration en sélénocystine, la hauteur de la colonne de mercure, la capacité et la concentration du tampon, et la force ionique. Les résultats obtenus sont tous en faveur de la conclusion que la vague est du type pré-sodium. L'espèce partiellement protonée de la sélénocystéine semble être catalytiquement active. On propose un dosage analytique, basé sur cette étude, de la sélénocystine en présence de sélénocystéine.

Resumé—La méthode décrite comporte une combustion éclair du prélèvement analytique dans une chambre de combustion en silice à 950–1050°, sous courant d'oxygène de 60 ml/mn. Cette combustion en phase gazeuse est complétée par une oxydation des gaz de combustion primaires, sur oxyde de cuivre à 850°. Les produits d'oxydation porteurs d'halogènes et de soufre sont retenus sur alumine argentée à 750–800°. L'eau de combustion contenant l'oxyde et l'hydroxyde de deutérium est séparée des autres gaz de combustion sous forme de glace, dans un piège spécial, refroidi par un dispositif cryogène et pourvu de deux robinets à 5 voies qui permettent l'écoulement simultané d'oxygène et d'hydrogène. Ce dernier est utilisé comme gaz vecteur, en aval du piège. La glace est ensuite vaporisée par chauffage sous courant d'hydrogène de 30 ml/mn et la vapeur réduite par du magnésium à 600°. Le deutérium passe sous forme d'hydrure de deutérium HD au sein du courant d'hydrogène; il y est dosé par mesure différentielle de la conductibilité thermique du système gazeux. La durée d'une analyse, dans une série, est d'environ 15 minutes. La précision des résultats correspond à l'ordre de grandeur classique, en microanalyse organique.

L'idée directrice du présent travail est de mettre en œuvre les méthodes de la microanalyse organique élémentaire moderne pour les appliquer aux dosages du deutérium et, par conséquent, d'éviter de recourir à des appareils lourds et coûteux (spectromètre de masse, par exemple).

La microanalyse organique élémentaire comporte, en général, deux phases: la production de la molécule chimique quantitativement représentative de l'élément à doser, usuellement dénommée minéralisation, et le dosage proprement dit ou mesurage de la quantité de cette molécule. La méthode de mesurage susceptible d'être retenue conditionnant la minéralisation, il importe de la sélectionner en premier lieu.

Les méthodes le plus souvent utilisées, à cette fin, ont été étudiées et comparées entre elles par plusieurs auteurs.[1–6]

Le mesurage différentiel, à l'aide d'un catharomètre, de la variation de la conductibilité thermique d'un système gaz vecteur produits (de la minéralisation) en fonction de la concentration du soluté, a paru convenir à notre objectif. Son application implique la possibilité de produire, par minéralisation, une molécule deutériée appropriée et le choix du gaz vecteur correspondant.

La minéralisation par combustion dans l'oxygène d'un composé organique deutérié fournit de l'eau deutériée contenant de l'oxyde d'hydrogène H_2O, de l'oxyde de deutérium D_2O et de l'hydroxyde de deutérium HDO en équilibre suivant la réaction:

$$H_2O + D_2O \rightleftharpoons 2HDO \qquad (I)$$

Sans préjudice d'autres difficultés, les faibles différences des conductibilitiés thermiques de ces trois molécules, sont défavorables au choix de D_2O ou de HDO comme solutés mesurables.

D'aucuns ont tourné cette difficulté en réduisant les eaux deutériées en vue d'obtenir le deutérium D_2 ou son hydrure HD qui peuvent, par ailleurs, être engagés dans la réaction d'équilibre:

$$H_2 + D_2 \rightleftharpoons 2HD \qquad \text{(II)}$$

dont la constante est fort heureusement peu variable en fonction de la température;[7] les conductibilités thermiques de D_2 ou HD diffèrent, en effet, plus sensiblement de celle de H_2 que les conductibilités de D_2O et HDO de celle de H_2O.

Les principaux réducteurs utilisés pour le traitement des eaux deutériées ou de composés deutériés simples sont le magnésium,[8–11] l'uranium,[12–14] le zinc,[15] le zinc platiné,[16,17] le fer,[18–22] l'hydrure de calcium,[23–25] l'hydrure de lithium-aluminium.[25]

L'examen des publications montre, cependant, que les réducteurs cités ne sont pas tous susceptibles d'être utilisés dans le cadre de notre travail; c'est ainsi que le zinc, même platiné, donne lieu à des réductions trop lentes, que le fer nécessite d'opérer, en plusieurs étapes, sous pression réduite, que l'hydrure de calcium doit être renouvelé, entre chaque dosage et qu'en outre, il donne lieu à une réduction qui peut n'être pas quantitative;[26] quant à l'hydrure de lithium-aluminium, il est simplement mentionné mais doit, selon toute vraisemblance, être inactivé, à l'instar de l'hydrure de calcium, par formation superficielle d'oxydes; seuls le magnésium et l'uranium semblent présenter des caractéristiques appropriées à notre propre étude, sous réserve d'effectuer les réductions sous courant d'hydrogène, gaz vecteur, dont la présence, en excès, déplace la réaction d'équilibre (II) vers la formation pratiquement exlusive de HD.

Nous avons éprouvé ces caractéristiques au cours d'essais qui ont conduit aux résultats dont il est fait état ci-après.

Reduction par l'uranium

Des essais préliminaires ont fait l'objet d'un stage[27] effectué par l'un d'entre nous (Mme. D. Girard) à la Section des Isotopes du Centre d'Etudes Nucléaires de Saclay, dirigée par M. Dirian, sous l'autorité de Mme. Botter, nous permettant ainsi de bénéficier d'une expérience déjà acquise;[12,13] ces essais ont porté sur la réduction des eaux deutériées par l'uranium à 625–650°, et ont conduit à des résultats positifs encourageants, à savoir: la réduction quantitative de l'eau, la linéarité de la courbe d'étalonnage pour des masses de deutérium comprises entre 9 et 440 μg, un faible effet de mémoire et une répétabilité des résultats satisfaisante à ce stade de l'étude. Par la suite, diverses anomalies, dont les suivantes, sont apparues au cours du dosage du deutérium sur des composés organiques et des eaux deutériées: obtention, à l'enregistrement du signal du catharomètre, de deux pics et non pas, comme il était attendu, d'un seul pic correspondant à la présence exclusive de HD dans l'hydrogène (gaz vecteur), lorsque les gaz, après réduction, ont traversé un tamis moléculaire 5A; obtention de signaux différents, pour une même masse de deutérium, selon que les composés analysés sont partiellement deutériés ou perdeutériés. Ces anomalies n'ont pu être éliminées au cours d'essais portant sur l'influence des variations de paramètres tels que température et état de division de l'uranium, d'une part, débit de l'hydrogène, d'autre part. Elles nous ont conduits à envisager le remplacement de l'uranium par le magnésium. Ce dernier semblant devoir donner satisfaction, les travaux sur l'emploi de l'uranium ont été suspendus.

Reduction par le magnésium

Le magnésium a été utilisé, au cours de multiples essais, sous forme de rubans ou de copeaux. Les prélèvements analytiques d'eaux deutériées ont été introduits dans l'appareil à réduction par injection à l'aide de seringues; ils étaient caractérisés par deux paramètres: leur volume (de 0,2 à 10 μl) et le taux isotopique* des eaux deutériées† (10 taux différents). Huit cents dosages de deutérium ont pu être ainsi effectués sur les gaz de réduction des prélèvements d'eau par une même charge de 5 g de magnésium.

Il est apparu que l'emploi du magnésium permet non seulement d'obtenir les mêmes résultats que ceux qu'avait fournis initialement l'uranium (réduction quantitative, linéarité, faible effet de mémoire, répétabilité des résultats), mais en outre, lors d'une étude plus poussée, qu'il ne donne pas lieu comme celui de l'uranium, à l'apparition d'un double pic au sortir des gaz de réduction d'un tamis moléculaire 5A.

La répétabilité des résultats est satisfaisante: c'est ainsi, par exemple, que les écarts relatifs estimés à partir d'une dizaine de dosages portant sur des prélèvements d'eau de 2 μl, sont de 0,5% pour une eau d'un taux isotopique de 99,7% (masse de deutérium dans 1 μl d'eau: 0,22 mg), de ±1,5% dans une eau de taux isotopique de 10,8% (masse de deutérium dans 1 μl d'eau: 0,022 mg) et de ±2,5% dans une eau de taux isotopique de 1,6% (masse de deutérium dans 1 μl d'eau: 0,0032 mg).

Le magnésium a donc été finalement retenu, en vue du dosage microanalytique du deutérium, dans les composés organiques, fondé sur la variation de conductibilité thermique du système H_2–HD. A cette fin, les eaux, formées lors de la combustion préalable dans l'oxygène des prélèvements analytiques, sont traitées comme il est indiqué ci-après.

Principe

Le prélèvement analytique (1,5 à 10 mg) est brûlé quasi instantanément, sous courant d'oxygène d'environ 60 ml/mn, dans une chambre de combustion portée à la température de 950–1000°, suivant une technique décrite par Ingram[28] et modifiée par Fraisse.[29] Les gaz de combustion sont entraînés par l'oxygène sur une garniture d'oxyde de cuivre en fils, maintenue à 750–850°, où s'achève leur oxydation, puis sur une garniture d'alumine argentée à environ 750° et un tampon de laine d'argent à environ 720° où sont retenus les produits contenant du soufre et des halogènes (y compris le fluor). L'eau de combustion deutériée est condensée quantitativement dans un piège dit "piège à eau," refroidi à environ $-40°$, tandis que les autres gaz de combustion, tels que le dioxyde de carbone, et, dans le cas de l'analyse des composés azotés, l'azote et certains oxydes de l'azote, sont balayés vers l'atmosphère par le courant d'oxygène (le peroxyde d'azote, s'il se forme, peut cependant être retenu dans le piège).

Grâce à un système approprié à deux robinets, le piège contenant l'eau deutériée est tout d'abord isolé du tube à combustion, balayé par un courant d'hydrogène pour chasser l'oxygène présent, puis mis en communication avec le tube à réduction. Les eaux sont alors vaporisées par réchauffage du piège et entraînées par le courant d'hydrogène vers une garniture de copeaux de magnésium maintenue à la température de 600°. En présence d'un grand excès d'hydrogène (la concentration de l'eau deutériée dans

---

* Taux isotopique $= \dfrac{\text{nombre d'atomes D}}{\text{nombre d'atomes H} + \text{nombre d'atomes D}} = \dfrac{n_D}{n_H + n_D}$

† Les échantillons d'eaux soumis à l'analyse ont été préparés par addition de quantités pesées d'eau lourde de taux isotopique de 99.7% à des quantités pesées d'eau naturelle distillée, les taux isotopiques des eaux deutériées ainsi préparées variant de 1.07 à 70.8%.

l'hydrogène atteint au maximum 2% en volume), l'eau deutériée qui est susceptible de contenir les molécules H_2O, D_2O et HDO en proportions variables [*cf.* réaction d'équilibre (I)] est réduite par le magnésium en donnant naissance exlusivement à H_2 et HD [*cf.* réaction d'équilibre (II)].

L'hydrure de deutérium ainsi formé est ensuite entraîné par le courant d'hydrogène vers le site de mesurage. Il traverse la cellule de mesure d'un catharomètre tandis qu'un courant d'hydrogène pur traverse la cellule de référence. La quantité de deutérium à doser est mesurée à l'aide d'un système catharomètre-pont de Wheatstone-intégrateur (ou enregistreur).*

PARTIE EXPERIMENTELLE

Appareillage

L'appareillage (figure 1) comporte 4 sections principales caractérisées par leurs fonctions: minéralisation des composés organiques, piégeage et transfert de l'eau de combustion, réduction de l'eau de combustion et mesurage. Il est complété par divers annexes et accessoires qui sont décrits ci-après.

Minéralisation des composés organiques

L'appareil de minéralisation est en tout point comparable à celui décrit par Fraisse.[29,30] Rappelons que le courant d'oxygène, issu d'un tube de gaz comprimé pourvu d'un manodétendeur, traverse, dans l'ordre, un régulateur de pression et un rotamètre (1, figure 1), préalablement étalonné; son débit est fixé entre 50 et 70 ml/mn. Il est ensuite purifié sur une garniture d'oxyde de cuivre en fil (2, figure 1) porté à 750° dans un four tubulaire suivi de tubes absorbeurs (3, figure 1) comportant une garniture d'amiante sodé (ascarite) et de perchlorate de magnésium (anhydrone).

Le tube à combustion,[30] en silice transparente, comprend une chambre, une partie tubulaire pourvue d'un ajutage latéral (4, figure 1) et un système d'introduction non représenté sur la figure (*cf.* Ingram[28] et Fraisse).[32] La chambre de combustion est portée à 1000° et la partie tubulaire contenant les réactifs (oxyde de cuivre et laine argentée) à 800°.[32]

Piégeage et transfert de l'eau de combustion

Le dispositif mis en œuvre est identique à celui décrit par Fraisse.[29] Il a ici pour objets le piégeage momentané de toute l'eau de combustion entraînée par le courant d'oxygène et le transfert ultérieur de cette eau après réchauffage, vers le site de réduction, sous courant d'hydrogène.

Rappelons qu'à cette double fin, il se compose de deux robinets A et B accouplés comme le montre la figure 2 et dont chaque clé comporte 3 voies et chaque boisseau est pourvu de 5 branches tubulaires dont trois réalisent l'accouplement, par soudage. La branche 1 raccorde le dispositif au tube à combustion (*cf.* figure 1), la branche 5 permet l'adduction du courant d'hydrogène, la branche 7 conduit les gaz, vers la sortie de l'appareil, dans l'atmosphère, et la branche 6 raccorde le système au dispositif de réduction des eaux (*cf.* figure 1).

Cet ensemble permet l'écoulement simultané des courants d'oxygène et d'hydrogène. En effet, dans un premier temps, correspondant à la combustion du prélèvement analytique et au piégeage de l'eau de combustion, le courant d'oxygène, chargé des gaz de combustion, pénètre par la branche 1, traverse la branche 3, qui constitue le piège proprement dit, et s'écoule vers l'atmosphère, par la branche 7; simultanément, le courant d'hydrogène, issu de la cellule de référence du catharomètre, entre par la branche 5, traverse les branches 4 et 6, balaie le tube à réduction et enfin la cellule de mesure du catharomètre; dans un deuxième temps, la rotation de 90° du robinet A, dans le sens inverse des aiguilles d'une montre, interrompt le courant d'oxygène tandis que le courant d'hydrogène traverse la branche dite "piège" 3 et s'écoule vers l'atmosphère; dans un troisième temps, la rotation du robinet B de 90°, dans le sens des aiguilles d'une montre, rétablit et le courant d'oxygène par les tubulures 1, 2 et 7 et le courant d'hydrogène par les tubulures 5, 4 et 6 vers la cellule de mesure. La tubulure 3, qui permet le piégeage de l'eau de combustion, comporte, à cette fin, une partie tubulaire médiane, en verre "Pyrex," garnie d'un faisceau de fils d'or, en vue d'améliorer les échanges thermiques. L'eau de combustion peut être gelée, dans ce piège, par refroidissement à l'aide d'un manchon formé de deux coquilles hémicylindriques, préalablement refroidi par immersion au sein de neige carbonique.[31] L'eau de combustion gelée peut être vaporisée par réchauffage électrique, par effet Joule, grâce à un bobinage de fil résistant en nickel-chrome.

---

* L'incorporation de l'enregistreur dans l'appareil n'est nécessaire que pour l'étude proprement dite: elle devient superflue dans l'appareil de dosages en série.

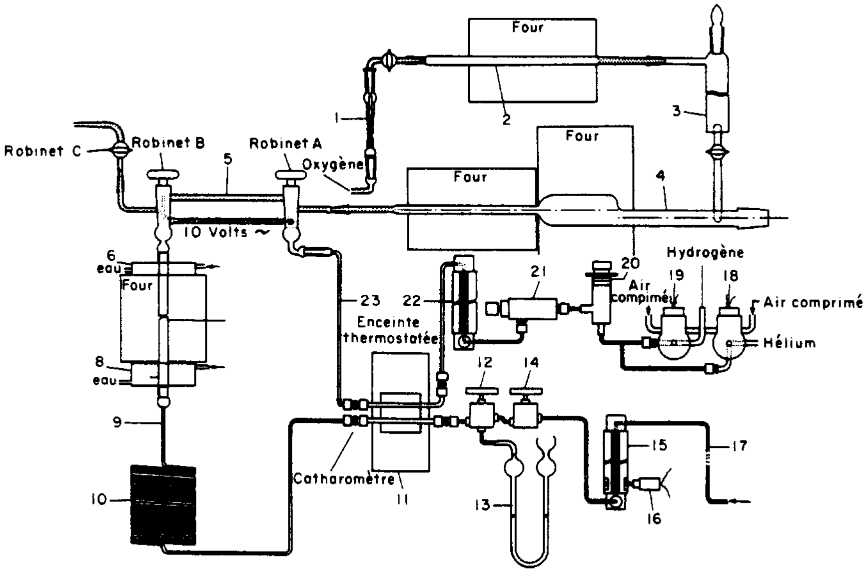

Fig. 1. Schéma de l'appareillage.

1 — Rotamètre.

2 — Tube en silice transparente, qualité étirée (diamètres: 11/8 mm, longueur: 240 mm) pourvu d'un joint conique rodé femelle RIN 00 et prolongé par un tube abducteur (diamètres: 7/2 mm, longueur: 80 mm) terminé par un joint conique rodé mâle RIN 00; longueur de la garniture d'oxyde de cuivre: 160 mm; ce tube est raccordé au rotamètre par un robinet comportant deux joints coniques rodés mâle RIN 0 et RIN 00.

3 — Tube en verre "Pyrex" (diamètres: 28/2 mm, longueur: 210 mm) pourvu d'un joint conique rodé femelle RIN 00 et d'un tube abducteur comportant un robinet et un joint conique rodé femelle RIN 0; un joint conique rodé femelle RIN 1 fermé par un bouchon conique rodé femelle RIN 1 permet l'introduction de la garniture d'amiante sodé (longueur: 100 mm) et de perchlorate de magnésium (longueur: 100 mm).

4 — Tube à combustion en silice transparente, qualité étirée.

5 — Dispositif de piégeage et de transfert des gaz.

6–8 — Réfrigérants en laiton à circulation d'eau. La température de l'eau est comprise entre 15 et 20°.

7 — Tube en alumine frittée.

9 — Raccord verre "Pyrex" — alliage Kovar-tube en acier inoxydable, pourvu d'un joint conique rodé femelle RIN 1/2.

10 — Tube retardateur en acier inoxydable (diamètres: 3,2/2 mm, longueur: 5 m).

11 — Enceinte à thermostat contenant le détecteur.

12 — Robinet à 3 voies en acier inoxydable.

13 — Manomètre à mercure en verre "Pyrex."

14 — Robinet d'arrêt.

15 — Rotamètre.

16 — Dispositif de déclenchement du système de sécurité à cellule photoélectrique et source lumineuse.

17 — Tube semi-capillaire en acier inoxydable (diamètres: 2/0,5 mm, longueur: 5 m).

18, 19 — Electrovannes refroidies par un courant d'air comprimé.

20 — *Cf.* 14.

21 — Régulateur de débit à pression différentielle.

22 — Rotamètre.

23 — Tube en acier inoxydable pourvu d'un joint conique rodé mâle RIN 00 en laiton (longueur: environ 2 m), permettant le raccordement du détecteur au dispositif de piégeage.

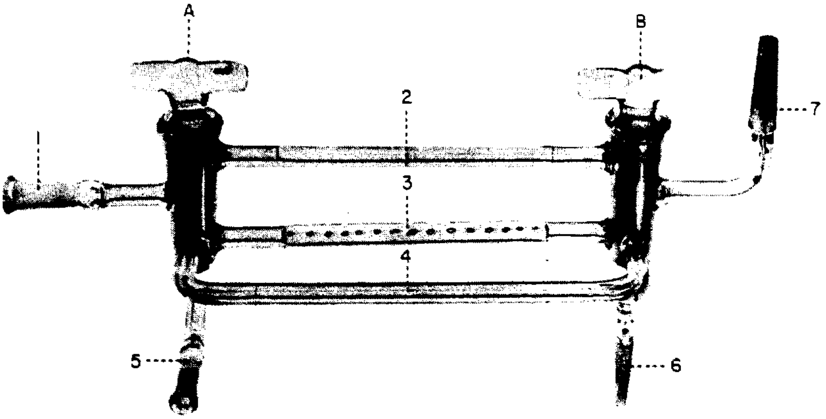

Fig. 2. Dispositif de piégeage et de transfert de l'eau de combustion.

Réduction de l'eau de combustion

L'eau de combustion gelée puis vaporisée dans le piège est entraînée sous courant d'hydrogène jusqu'au dispositif de réduction.

Celui-ci comprend un tube en alumine frittée Desmarquet AF 975 (1, figure 3) pourvu, à chaque extrémité, d'un joint conique rodé mâle permettant son raccordement au piège, d'une part, et à la cellule de mesure, d'autre part; les joints coniques rodés sont graissés avec de la graisse Apiezon H et fixés par des ressorts métalliques sous tension. Le tube à réduction comporte une garniture de 5,5 g de magnésium en copeaux (5, figure 3) qui constitue une colonne de 250 mm. Il est placé dans un four tubulaire de 360 mm de longueur qui permet d'obtenir une température stable comprise entre 580 et 600° sur toute la longueur de la garniture de magnésium (*cf.* Fraisse et Levy).[31] La température du four est repérée à l'aide d'un thermo-couple platine–platine rhodié à 10% disposé verticalement dans le tube laboratoire du four. Afin d'éviter un détassement de la garniture de magnésium provoqué par la formation d'oxyde de magnésium pulvérulent, le tube à réduction est placé verticalement; un petit tampon de toile de nickel-chrome (6, figure 3) permet de maintenir la garniture dans la zone de température convenable. La proximité du four et des joints coniques rodés graissés peut être la cause de fuites; pour maintenir l'étanchéité, deux réfrigérants, à circulation d'eau (2_1, 2_2, figure 3), en laiton, formés chacun de deux coquilles hémicylindriques, sont placés autour du tube d'alumine, à chaque extrémité du four.

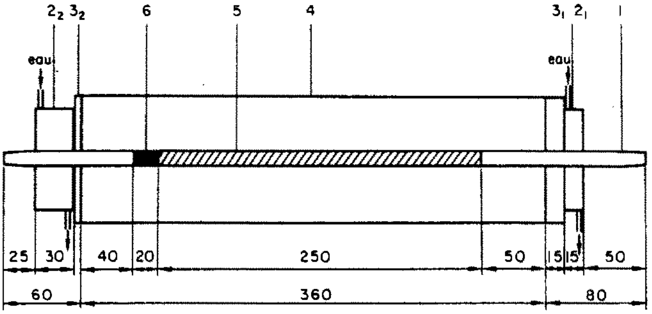

Fig. 3. Dispositif de réduction (cotes en mm).

1 — Tube en alumine frittée (diamètres 12/8 mm, longueur: 500 mm) pourvu à chaque extrémité d'un joint conique rodé mâle RIN 1/2.

2 — Réfrigérant en laiton à circulation d'eau formé de deux coquilles creuses hémicylindriques, serrées autour du tube en alumine.

2_1 — Réfrigérant supérieur (épaisseur: 15 mm).

2_2 — Réfrigérant inférieur (épaisseur: 30 mm).

3 — Plaque d'amiante assurant un isolement thermique entre le four et les deux réfrigérants.

4 — Four tubulaire.

5 — Garniture de magnésium (hauteur: 250 mm).

6 — Tampon de toile de nickel-chrome (hauteur: 20 mm).

Mesurage

L'appareil utilisé est un détecteur (catharomètre), du type Pretzel 9285 (GOW-MAC Instruments Company, Madison, New Jersey, U.S.A.), à quatre cellules dont les filaments, en tungstène rhénié W2X constituent les quatre branches d'un pont de Wheatstone. Ce dernier est alimenté par un courant stabilisé fourni par une alimentation du type 40-05C (GOW-MAC).

La variation de l'écart de conductibilité thermique entre l'hydrogène pur et l'hydrogène chargé d'hydrure de deutérium produit dans le tube à réduction donne lieu à la variation de la tension de déséquilibre du pont en fonction du temps. L'integration correspondante est effectuée, à l'aide d'un intégrateur électronique ou électromécanique, auquel peut être adjoint un enregistreur potentiométrique. Le détecteur est placé dans une enceinte thermostatique dont la régulation de température est assurée à un dixième de degré près. L'hydrogène issu d'un tube de gaz comprimé pourvu d'un manodétendeur traverse, dans l'ordre, une électrovanne, (19, figure 1) dont le rôle est précisé ci-après, un robinet d'arrêt, type Ugine V3 (DAM-SETARAM, Lyon, France), permettant la fermeture de l'appareil en période d'arrêt prolongé (20, figure 1), un régulateur de débit à pression différentielle type 8844 (Brooks Instr. N.V. Veenendaal, Pays-Bas) (21, figure 1) et un rotamètre (22, figure 1) pour le repérage du débit. La connexion des appareils est réalisée par des tubes d'acier inoxydable de diamètre 2 et 3,2 mm directement brasés ou assemblés par raccords "Swagelock." Le courant d'hydrogène traverse ensuite les deux premières cellules du catharomètre (11, figure 1) dont les filaments sont les résistances de référence du pont de Wheatstone, avant de pénétrer dans le dispositif de piégeage de l'eau de combustion (5, figure 1), par l'intermédiaire d'un tube en acier inoxydable (23, figure 1) puis, successivement, dans le tube à réduction (7, figure 1) et dans les deux autres cellules du catharomètre dont les filaments sont les résistances de mesure du pont de Wheatstone. Le raccordement du tube à réduction au catharomètre est assuré par un serpentin retardateur (10, figure 1) qui est réalisé en tube d'acier inoxydable terminé par un tube de raccord métal-verre (9, figure 1); *il a pour object de retarder d'environ 1 mn 30 s l'arrivée, dans les cellules de mesure, de l'hydrure de deutérium entraîné par le courant d'hydrogène*; ce laps de temps permet au pont de Wheatstone d'atteindre à nouveau son équilibre momentanément rompu lors du balayage du piège, par l'hydrogène, vers l'atmosphère (*cf. Piégeage et transfert de l'eau*).

A la sortie des cellules de mesure, le courant d'hydrogène traverse un robinet à trois voies (12, figure 1), auquel est raccordé un manomètre à mercure (13, figure 1), un robinet d'arrêt permettant la fermeture de l'appareil (14, figure 1), un rotamètre (15, figure 1), et enfin un tube semi-capillaire, en acier inoxydable, (17, figure 1), dont la fonction est de créer une perte de charge suffisante, en sortie de l'appareil, et ainsi, de minimiser l'influence des variations de pertes de charge au sein de l'appareil, sur le débit d'hydrogène. Un dispositif de sécurité (Crawford Fitting Co., Cleveland, U.S.A.), asservi au débit du courant d'hydrogène, complète l'appareil; il permet la substitution d'un courant d'hélium au courant d'hydrogène. A cette fin, une cellule photoélectrique (16, figure 1) reçoit le faisceau lumineux émis par une lampe à travers le tube du rotamètre (15, figure 1). L'interruption accidentelle du courant d'hydrogène donne lieu à la chute de la bille du rotamètre, ce qui provoque la coupure du faisceau lumineux et le déclenchement du système de sécurité, à savoir, la fermeture de l'électrovanne (19, figure 1) qui coupe l'arrivée de l'hydrogène dans l'appareil et, simultanément, l'ouverture d'une autre électrovanne (18, figure 1) qui le fait balayer par un courant d'hélium. En cours d'analyse, le système de sécurité est mis hors circuit.

Réactifs

Minéralisation. — Oxygène de qualité N 45 ("Air Liquide").

— Oxyde de cuivre en fil tamisé (module 29-31, norme NF XII-501) calciné à l'air (Prolabo n° 23 150).

— Amiante sodé (8–20 mesh): Ascarite (Arthur H. Thomas Company, Philadelphia, Pa., U.S.A.).

— Perchlorate de magnésium (10–20 mesh): Anhydrone (G. Frederick Smith Chemical Co., Colombus, Ohio, U.S.A.).

— Alumine argentée. La préparation est effectuée suivant le mode opératoire décrit par Zimmermann[32] pour la ponce argentée.

Matières premières:

— Alumine "Alcel" en grains de 1 mm environ (Desmarquet, France),

— Nitrate d'argent pur cristallisé.

— Argent vierge en fils (diamètre: 0,05 mm) (Lyon-Alemand, France).

— Graisse Apiezon H (Apiezon Products Ltd., London).

— Lut de Krönig préparé en fondant ensemble une partie de cire blanche et quatre parties de colophane, puis coulé sous forme de bâtonnets.

Réduction. — Hydrogène de qualité U ("Air Liquide").

— Hélium de qualité U ("Air Liquide").

— Magnésium à 99% en copeaux de 0,5 mm d'épaisseur (Schuchardt), ces copeaux sont coupés en morceaux d'environ 5 mm de côté.

Mode opératoire

Mise en condition de l'appareil. — Régler le débit du courant d'oxygène à 60 ± 10 ml/mn.

— Régler le débit de l'hydrogène à 30 ± 2 ml/mn. Ce débit est mesuré à la sortie du tube semi-capillaire (17, figure 1) avec un débitmètre à film de savon.

— Contrôler l'étanchéité du circuit de l'hydrogène: à cette fin, fermer le robinet d'aval (14, figure 1); il en résulte une augmentation de pression dans l'appareil provoquant, dans le manomètre (13, figure 1), une dénivellation d'environ 300 mm de mercure; attendre l'équilibre et fermer le robinet d'amont (20, figure 1). Si l'appareil est étanche, la dénivellation doit rester constante.

— Rétablir le courant d'hydrogène.

— Régler l'intensité de chauffage des filaments du détecteur à 150 mA.

— Mettre en fonctionnement l'enregistreur et l'intégrateur. Lorsque l'équilibre du pont de Wheatstone est atteint, l'appareil est prêt à fonctionner.

Afin de réduire au minimum le temps de mise en condition de l'appareil, le circuit de mesure est laissé constamment sous courant d'hydrogène, les fours restant sous tension. Lors d'arrêts prolongés (plusieurs jours), les fours sont laissés sous tension et l'appareil, sous pression d'hydrogène, est isolé par la fermeture des robinets prévus à cette fin (14 et 20, figure 1).

Détermination du coefficient d'étalonnage

La mesure de la quantité de deutérium qui traverse le catharomètre implique un étalonnage préalable. Pratiquement cet étalonnage est effectué à partir de substances-types, à teneurs connues en deutérium, pour l'ensemble des opérations du dosage (minéralisation, piégeage, mesurage) et pour un appareil donné.

Plusieurs paramètres contribuent à modifier l'étalonnage de l'appareil: débit, pression, vieillissement des réactifs. Avant chaque série d'analyses, il est nécessaire de procéder à l'analyse de plusieurs substances-types telles que: l'anthracène-D_1: $D\% = 1{,}18$; l'anthracène-D_{10}: $D\% = 10{,}52$; le polyéthylène perdeutérié: $D\% = 24{,}67$. Chaque substance-type fournit une valeur du coefficient k d'étalonnage qui se calcule d'après la formule:

$$k = \frac{m\,.\,C}{100S},$$

dont les symboles sont définis ci-après:

S: signal numérique fourni par l'intégrateur, proportionnel à la masse du deutérium contenue dans la substance-type.

m: masse du prélèvement analytique (exprimée en milligramme).

C: teneur centésimale en deutérium de la substance-type.

La moyenne des valeurs trouvées est adoptée comme coefficient d'étalonnage; l'écart entre les valeurs extrêmes du rapport k ne doit pas excéder 10^{-6} mg de deutérium par unité de comptage de l'intégrateur. Du fait de l'existence d'un effet de mémoire (*cf.* "Discussion", il convient de faire précéder toute série de mesures du coefficient d'étalonnage ou de dosages par une analyse préliminaire complète effectuée sur une substance deutériée (pesée ou non) et comportant toutes les opérations des dosages (minéralisation, piégeage, mesurage).

Analyse proprement dite

Dans une série, certaines opérations analytiques viennent s'imbriquer dans les déterminations successives. Ainsi, les opérations ci-après doivent avoir été effectuées pendant la détermination précédente: la nacelle contenant le prélèvement analytique (1,5 à 10 mg) préalablement pesé a été disposée dans l'hélice de platine du poussoir (*cf.* Ingram[28]), le manchon de refroidissement a été placé sur le piège à eau proprement dit (3, figure 2) et les robinets A et B du dispositif de piégeage et de transfert de l'eau ont été mis dans les positions qui permettent, d'une part, au courant d'oxygène issu du tube à combustion de traverser successivement les tubulures 1, 3, 7 (figure 2), d'autre part, au courant d'hydrogène, les tubulures 5, 4 et 6 et le circuit de mesure.

Mode opératoire proprement dite. — Introduire le poussoir magnétique dans la chambre de combustion de façon que la nacelle contenant le prélèvement analytique se trouve au point le plus chaud; régler à zéro un chronomètre.

— Au temps $t = 3$ mn: tourner le robinet A (figure 2) de 90° dans le sens inverse des aiguilles d'une montre; le piège proprement dit (3, figure 2), dans lequel l'eau de combustion est condensée (glace), est alors purgé de toute trace d'oxygène par le courant d'hydrogène.

Dans le même temps, retirer le poussoir magnétique de la chambre de combustion et le replacer dans le logement prévu à cet effet (*cf.* Ingram[28]), le refroidir par soufflage extérieur d'air comprimé ou par ventilation.

— Au bout de 30 s: tourner le robinet B (figure 2) dans le sens des aiguilles d'une montre: le courant d'hydrogène parcourt à nouveau le circuit de mesure. L'interruption du courant d'hydrogène dans le catharomètre déséquilibre le pont de Wheatstone et il est nécessaire d'attendre environ 2 mn pour que l'équilibre soit rétabli.

— Au temps $t = 5$ mn 30 s: enlever le manchon de refroidissement et mettre sous tension la résistance chauffante du tube à condensation.

— Au temps $t = 12$ mn: introduire un nouveau prélèvement analytique dans l'hélice de platine du poussoir et placer le manchon de refroidissement sur le piège à eau proprement dit.

— Au temps $t = 15$ mn: tourner les robinets B puis A, de façon à faire suivre aux courants d'oxygène et d'hydrogène les mêmes voies qu'au début de l'analyse et introduire immédiatement la nouvelle nacelle dans le four.

Le pesage du prélèvement a été effectué pendant le déroulement du dosage précédent.

DISCUSSION

Effet de mémoire

Un effet de mémoire se constate en procédant au dosage du deutérium sur un composé organique enrichi en deutérium, de teneur en deutérium élevée, et connue, et en le faisant suivre de celui d'un composé organique non enrichi. Il est évalué numériquement par le calcul du rapport

$$E = \frac{S_0}{S_D} \times 100,$$

dans lequel S_0 et S_D sont les nombres, affichés par l'intégrateur, correspondant respectivement aux dosages du deutérium dans le composé non enrichi et dans le composé enrichi. L'expérience montre que la valeur du rapport E, faible lors de la mise en service d'une nouvelle charge de magnésium (inférieure ou égale à 1%) croît progressivement au fur et à mesure de son vieillissement; elle atteint 2% après 160 analyses, 3% après 250 analyses et 5% après 400 analyses. Cette augmentation autorise à penser que l'effet de mémoire se situe au niveau de la charge de magnésium et est vraisemblablement lié à une adsorption chimique (formation d'un hydroxyde de magnésium) ou physique sur la magnésie.

Maintenance de l'appareil

Afin de maintenir l'appareil en parfait état de fonctionnement, il est recommandable de ne pas attendre l'épuisement des réactifs et la dégradation des matériaux pour procéder à leur remplacement. Le tube à combustion et ses garnitures sont renouvelés systématiquement tous les mois; toutefois, l'analyse de composés organiques contenant des quantités importantes d'halogène ou de soufre peut conduire à un renouvellement plus fréquent.

La garniture de magnésium est renouvelée dès que la valeur de l'effet de mémoire dépasse 3%. Le tube en alumine peut être réutilisé plusieurs fois après nettoyage avec une solution d'acide nitrique à 50% suivi d'un rinçage à l'eau distillée et d'un séchage. Dans ces conditions, l'influence de l'effet de mémoire est négligeable lorsque les masses en deutérium de deux prélèvements analytiques successifs, varient du simple au double ou inversement. En conséquence, il est souhaitable de grouper les produits soumis à l'analyse d'après leurs teneurs en deutérium.

Influence du debit d'hydrogène—durée d'une analyse

Le débit du courant d'hydrogène doit être tel que soient suffisants:

— le temps de contact des corps réagissants (eau de combustion, hydrogène, magnésium), d'une part,

— l'excès d'hydrogène assurant la conversion quantitative de l'eau, deutériée en hydrure de deutérium, d'autre part.

Un débit de 30 ml/mn concilie ces deux conditions. Il lui correspond une durée d'analyse d'environ 16 mn par dosage, dans une série.

Intégration

L'allure des variations de la tension de déséquilibre du pont de Wheatstone est très différente suivant qu'elles correspondent à l'analyse de composés organiques perdeutériés ou dont les taux isotopiques sont élevés ou faibles. *A priori*, il était permis de penser que, quels que soient les composés analysés, leur eau de combustion étant condensée par piégeage avant tout traitement, sa vaporisation et son élution simultanée par l'hydrogène suivies de sa réduction par le magnésium conduiraient à l'obtention de pics sensiblement gaussiens, de surfaces proportionnelles à la quantité d'hydrure de deutérium à doser. Or, si les composés perdeutériés ou les composés à taux isotopiques élevés fournissent effectivement de tels pics, il n'en est pas de même pour les composés à faibles taux isotopiques. En effet, dans ce dernier cas, l'hydrure de deutérium résultant de la réduction des eaux par le magnésium se trouve dilué dans un très grand volume d'hydrogène de sorte que les enregistrements obtenus présentent des paliers plus ou moins longs mais dont les hauteurs maximales ne varient que de quelques dixièmes de millivolts, suivant l'importance des prélèvements analytiques, pour un courant d'alimentation du pont de Wheatstone de 150 mA.

Il en résulte que le choix de l'intégrateur à employer est très important; c'est ainsi que certains intégrateurs très perfectionnés, couramment utilisés en chromatographie, ne sont pas les mieux adaptés à nos besoins et qu'il est préférable de mettre en œuvre des appareils qui, après l'amplification des signaux du pont de Wheatstone, donnent lieu à un comptage électromécanique proportionnel.

Domaine d'application de la méthode

L'application de la méthode décrite permet le microdosage du deutérium dans les composés organiques contenant les éléments suivants: hydrogène, oxygène, azote, halogènes (dont le fluor) et soufre. Le défaut de substances-types deutériées contenant ces différents éléments nous a conduits à expérimenter leurs effets sur le dosage du deutérium par addition de composés organiques porteurs de ces éléments aux prélèvements analytiques de composés deutériés.

Pesage des prélèvements analytiques

Les prélèvements analytiques sont pesés sur microbalance Mettler M5. Les composés organiques solides stables sont pesés en nacelle de platine. Les liquides sont prélevés en ampoules de verre " Pyrex " dont le corps, d'environ 2 mm de diamètre intérieur et 10 mm de longueur, est prolongé par deux capillaires d'environ 10 mm. L'emploi de ces ampoules a été décrit par Fraisse.[30] (Rappelons que dans le cas des composes liquides stables, à faible tension de vapeur, l'un des capillaires de l'ampoule, qui contient le prélèvement analytique pesé, est brisé, avant son introduction dans l'hélice de platine rhodié de la tige-support du tube à combustion, tandis que dans le cas des composés volatils, l'ampoule, dont les deux capillaires restent scellés, est introduite telle quelle dans la chambre de combustion où elle éclate.)

RESULTATS ET CONCLUSION

La méthode décrite a été éprouvée avec succès par l'analyse de composés organiques perdeutériés ou partiellement deutériés. Les résultats obtenus sont reportés dans le tableau 1 qui montre, simultanément, l'ordre de grandeur des masses des prélèvements analytiques; leur précision a l'ordre de grandeur classique en microanalyse.

En vue de mettre en évidence l'influence de plus grandes variations du taux isotopique $n_D/(n_D + n_H)$ sur les résultats de dosage du deutérium, nous avons effectué de multiples déterminations sur des mélanges en proportions variables d'anthracène-D_1 (D% = 1,18) et de substances-types perdeutériées (anthracène-D_{10}, phénanthrène-D_{10}, acénaphtène-D_{10}, polyéthylène perdeutérié). Sur de multiples mélanges dont les taux isotopiques ont varié d'environ 0,03 à 0,60 aucun effet n'a été constaté: les résultats de dosage du deutérium conservent, en effet, la même précision que ceux du tableau 1.

L'Etude de l'influence de la présence d'hétéroéléments (N, Cl, I, F) ou de la présence simultanée de certains d'entre eux (N + Cl, N + S, N + Cl + S) sur les résultats de dosage du deutérium nous a conduits à effectuer nombre de déterminations sur des mélanges d'anthracène-D_{10} et de composés porteurs de ces hétéroéléments (urée, hexaméthylènetétramine, acétamide, nicotinamide, pyramidon, hydroxyquinoléine, chlorure de picryle, sulfanilamide, dichlorodinitrobenzène, chloroacétamide, chlorure de *S*-benzyle isothiouronium, acide iodobenzoïque, acide trifluorobenzoïque). Sur ces mélanges aucun effet de la présence desdits hétéroéléments n'a été constaté; les résultats de dosage du deutérium conservent encore la même précision que ceux du tableau 1.

Le dosage du deutérium, dans des prélèvements analytiques contenant des quantités de deutérium très différentes, montre qu'en deçà de 60 µg de deutérium, les résultats manquent de reproductibilité et sont entachés d'une erreur systématique par excès; cette erreur est vraisemblablement due à deux causes: d'une part, à un défaut de linéarité du catharomètre, et, d'autre part, à un signal trop faible. Ces remarques sont également valables lorsque les masses de deutérium sont supérieures à 1 mg. En conséquence, nous avons limité le domaine d'application de la méthode au dosage de masses de deutérium comprises entre 60 et 500 µg, ce qui conduit à des prélèvements analytiques variant de 1,5 à 6 mg pour des teneurs centésimales en deutérium courantes. Pour des composés organiques dont les teneurs en deutérium sont inférieures à 1%, les masses des prélèvements analytiques peuvent être portées à 10 mg.

* Masse du prélèvement analytique.

Dans ces conditions, la précision du dosage du deutérium dans les composés organiques est tout à fait comparable à celle obtenue par la mise en œuvre de méthodes décrites dans la littérature[6] (densimétrie, spectrométrie infra-rouge et spectrométrie de masse). En outre, la méthode microanalytique décrite est simple et fiable et l'appareillage mis en oeuvre n'exige pas un investissement élevé.

Summary—A simple method is described for the microdetermination of deuterium in organic compounds. It involves a flash combustion of the weighed sample in a hot empty chamber at 950–1050° and swept by oxygen at 60 ml/min. Together with this combustion in the gaseous phase, an oxidation of the primary combustion gases on cupric oxide at 850° is necessary. Oxidation products containing halogens and sulphur are retained on silvered alumina at 750–800°. Combustion water containing deuterium oxide and hydroxide is frozen out from the combustion gases in a special trap with two five-way stop-cocks which make possible the simultaneous flow of oxygen and hydrogen: the latter is used as a carrier-gas in the apparatus from the trap downwards. The frozen water is then vaporized by heating in a hydrogen flow of 30 ml/min and reduced on magnesium at 600°. Deuterium is obtained as deuterium hydride in hydrogen: it is measured versus pure hydrogen, with a thermal conductivity detector. A determination within a series can be completed in 15 min. The precision of the results is that obtained in classical organic microanalysis.

Zusammenfassung—Eine einfache Methode zur Mikrobestimmung von Deuterium in organischen Verbindungen wird beschrieben. Dabei wird die gewogene Probe in einer heißen leeren Kammer bei 950–1050° schnell verbrannt und mit 60 ml/min Sauerstoff ausgespült. Zusammen mit dieser Verbrennung in der Gasphase ist eine Oxidation der Primärverbrennungsgase über Kupfer(II)oxid bei 850° notwendig. Halogen- und schwefelhaltige Oxidationsprodukte werden an Silber auf Aluminium-oxid bei 750–800° zurückgehalten. Das Verbrennungswasser, das Deuteriumoxid (D_2O) und -hydroxid (HDO) enthält, wird aus den Verbrennungsgasen in einer Spezialfalle ausgefroren. Diese trägt zwei Fünfweghähne, die das gleichzeitige Fließen von Sauerstoff und Wasserstoff ermöglichen; letzterer wird in der Apparatur stromabwärts von der Falle als Trägergas verwendet. Das ausgefrorene Wasser wird dann durch Erwärmen in einem Wasserstoffstrom von 30 ml/min verdampft und bei 600° über Magnesium reduziert. Man erhält Deuterium als Deuterium-hydrid in Wasserstoff; es wird mit einem Wärmeleitfähigkeitsdetektor gegen reinen Wasserstoff gemessen. Eine Bestimmung innerhalb einer Serie kann in 15 min erledigt werden. Die Genauigkeit der Ergebnisse ist die der klassischen organischen Mikroanalyse.

SHORT COMMUNICATIONS

USE OF VITREOUS CARBON AS A WORKING ELECTRODE IN COULOMETRIC TITRATION OF POTASSIUM HYDROGEN PHTHALATE

(*Received* 6 *November* 1972. *Accepted* 29 *January* 1973)

Previous work has shown that vitreous carbon may be used to make a working electrode for electrogenerated bromine titrations.[1] The present paper describes the use of a vitreous carbon electrode for the coulometric generation of hydroxyl ions in the titration of potassium hydrogen phthalate (chosen as titrand because it is obtainable at a specified purity of 100·0 ± 0·1% and has been titrated coulometrically with high precision, using a platinum working electrode[2]).

It was not considered necessary to repeat the platinum electrode work, but it was considered of value to compare the current-potential curves obtained with platinum and vitreous carbon cathodes. As the presence of dissolved gases such as carbon dioxide leads to positive errors, the effect on the current-voltage curves of displacing it with nitrogen was examined.

EXPERIMENTAL

Reagents

All chemicals were of analytical reagent grade, unless stated otherwise. Potassium hydrogen phthalate solution was prepared by dissolving about 5 g of solid, accurately weighed and previously dried at 110° for 1 hr, and diluting to 500 ml in a grade-A flask at 20°. A 1-ml portion of this solution (0·04855M) was added by grade-A pipette to the titration cell for each titration, and was equivalent to 9·915 mg of solid and required 4·684 C for coulometric titration.

Apparatus and titration procedure

A Thorn coulometric titrator TE 110 was used to provide a constant current of 5 mA. The current values were determined during each titration by measuring the potential drop across a 50-Ohm (±0·05%) resistor to 0·1 mV with a Beckman Research pH meter. The mean current was 4·993 mA, with variations up to 0·1%.

The titration cell was a 50-ml Pyrex beaker. The vitreous carbon cathode was a 3-mm dia rod, grade V25, supplied by Le Carbone (Great Britain) Limited. The active surface area exposed to the catholyte solution was about 1 cm^2. The counter-electrode was a coil of 130 cm of 28-swg pure silver wire, and separated from the cathode solution by a sintered-glass disc, porosity 4. The anolyte and catholyte solutions were both 1M potassium chloride, with volumes of 1·5 and 30 ml respectively. The catholyte solution was stirred with a magnetic stirrer.

Titration end-points were indicated by the colour change of one drop of 0·5% methanolic phenolphthalein solution (added as indicator) from colourless back to a standard pink corresponding to a solution of pH 8·5 and an absorbance at 555 nm of 0·04 in a 2·5-cm cell. A correction was applied for the indicator blank. It was found possible after a 'blank' titration to determine up to eight successive 1-ml aliquots of 0·05M potassium hydrogen phthalate before the end-point colour change became indistinct.

For the determination of current-potential curves a platinum foil electrode (area 0·91 cm^2) and a vitreous carbon electrode (area 0·87 cm^2) were used, placed close to a saturated calomel electrode, and their potentials were measured with the high-impedance potentiometer of the Thorn coulometer (range 0–2 V). The current-potential curves were obtained in phthalate, phosphate and borate buffer solutions with pH values of 3·7, 6·5 and 9·0 respectively, in the presence of dissolved carbon dioxide and oxygen from the atmosphere, or while 'White Spot' nitrogen gas was bubbled through a coarse glass frit into the solution. Each buffer solution was made 1M in potassium chloride. The solutions were stirred magnetically.

RESULTS AND DISCUSSION

Current–voltage curves

Figures 1 and 2 demonstrate that, compared with platinum, vitreous carbon has an overpotential for the overall electrochemical reaction. The passage of nitrogen through the solution alters the potential of either the platinum or the vitreous carbon for a given current density. It is thus probable that any dissolved oxygen is reduced. Although this reaction involves hydrogen ions according to the equation.

$$O_2 + 4H^+ + 4e = 2H_2O,$$

the effect would be unnoticed in the titration results discussed in the next paragraph.

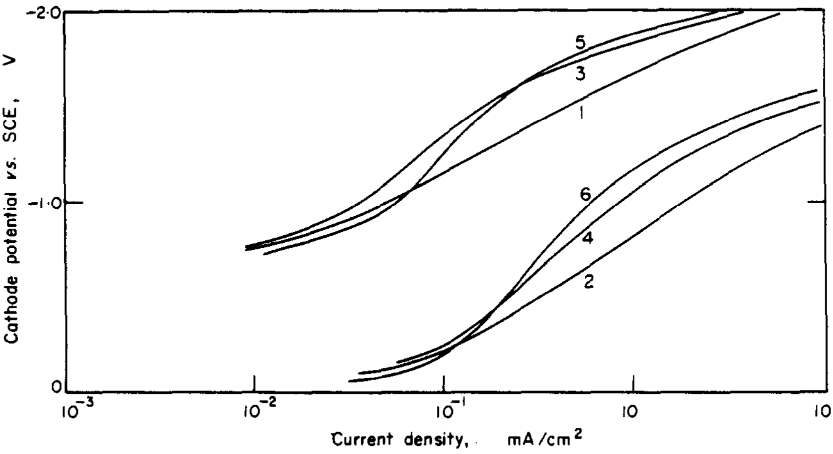

Fig. 1. Current-voltage curves for vitreous carbon and platinum as working cathodes in the generation of hydroxyl ions. Carbon dioxide present.
1, vitreous carbon pH 3·7; 2, platinum pH 3·7; 3, vitreous carbon pH 6·5; 4, platinum pH 6·5; 5, vitreous carbon pH 9·0; 6, platinum pH 9·0.

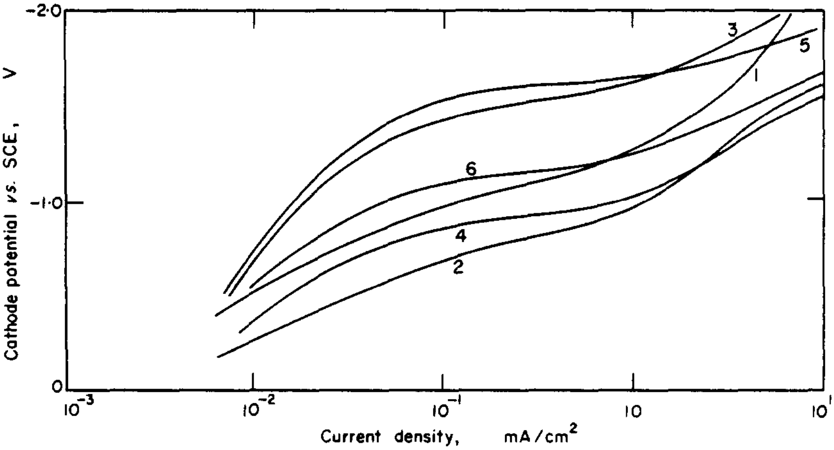

Fig. 2. Current-voltage curves for vitreous carbon and platinum as working cathodes in the generation of hydroxyl ions. Nitrogen gas bubbled through the solution to remove dissolved oxygen. Curves numbered as in Fig. 1.

Titration results

When no attempt was made to remove dissolved carbon dioxide there was an overall mean error of +0·6%; when nitrogen gas was bubbled through the solution the blank value was reduced by a factor of two, suggesting that a volatile acidic component had been removed (Table 1). There was a mean error of −0·4%, but a decrease in precision (the relative standard deviation increased from 0·3 to 0·8%).

Table 1. Coulometric titrations of 1-ml aliquots of 0·04855*M* potassium hydrogen phthalate (equivalent to 9·92 mg of solid)

CO_2 *present*									
Titration time, *sec*	32	940	945	939	946	945	945		
Found, *mg*	Blank	9·93	9·99	9·92	10·00	9·99	9·99		
	Mean 9·97 mg				Error +0·6%				
	Relative standard deviation 0·3%								
CO_2 *displaced by* N_2									
Titration time, *sec*	15	927	931	933	937	932	945		
Found, *mg*	Blank	9·80	9·84	9·86	9·91	9·87	10·01		
	Mean 9·88 mg				Error −0·4%				
	Relative standard deviation 0·8%								
N_2 *atmosphere* (series C)									
Titration time, *sec*	27	939	934	934	936	941	929	936	936
Found, *mg*	Blank	9·92	9·87	9·87	9·89	9·95	9·82	9·89	9·89
	Mean 9·89 mg				Error −0·3%				
	Relative standard deviation 0·4%								

It was thought that the loss in precision could be due to loss of titrand in the form of a fine spray caused by nitrogen bubbling. To avoid this and still reduce carbon dioxide absorption during the titration, experiments were done with an atmosphere of nitrogen maintained over the surface of the titrand. Table 1 shows the results from one such series and Table 2 a summary of results from three series. The latter table shows a mean error of −0·2% and a mean relative standard deviation of 0·4%.

Table 2. Coulometric titration of 9·92 mg of potassium hydrogen phthalate, nitrogen atmosphere

Series	A	B	C
No. of results	7	8	8
Mean found, *mg*	9·91	9·88	9·89
Relative standard deviation, %	0·5	0·3	0·4
Error, %	−0·1	−0·4	−0·3

In view of the expected error in measuring the volume of the potassium hydrogen phthalate solution titrated, locating the end-point and measuring of the quantity of electricity used, Table 2 shows that vitreous carbon behaves satisfactorily as a working cathode for the coulometric titration of potassium hydrogen phthalate.

Summary—The use of a vitreous carbon electrode as a cathode in the amperostatic coulometric titration of aqueous potassium hydrogen phthalate solution is described. It is shown that 10 mg of the phthalate can be titrated with a precision better than 0·5%. Current-voltage curves for platinum and vitreous carbon cathodes show that there is an overpotential on the latter relative to the former.

Zusammenfassung—Die Verwendung einer glasigen Kohlenstoffelektrode als Kathode bei der amperostatisch-coulometrischen Titration von wäßriger Kaliumhydrogenphthalatlösung wird beschrieben. Es wird gezeigt, daß 10 mg Phthalat mit einer besseren Genauigkeit als 0.5% titriert werden können. Stromspannungskurven für Platin- und glasige Kohlenstoffkathoden zeigen, daß relativ zu den ersteren an den letzteren eine Überspannung auftritt.

Résumé—On décrit l'emploi d'une électrode en carbone vitreux comme cathode dans le titrage coulométrique ampérostatique d'une solution aqueuse de phtalate acide de potassium. On montre qu'on peut titrer 10 mg de phtalate avec une précision meilleure que 0, 5 %. Les courbes intensité-tension pour les cathodes de platine et de carbone vitreux montrent qu'ily a une surtension sur la seconde par rapport à la première.

SPECTROPHOTOMETRIC INVESTIGATION OF THE REACTION OF Cu(II) AND Cu(I) WITH 1-ISONITROSO-(1,2,3,4)-TETRAHYDROPHENAZINE

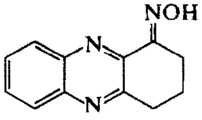
(*Received* 12 *October* 1972. *Accepted* 14 *December* 1972)

Many authors[1–7] have studied the capability of some substituted phenazines of forming chelates with metal ions, mainly the mono and dioxyphenazines. In this paper the reactions of Cu(II) and Cu(I) with 1-isonitroso-(1,2,3,4)-tetrahydrophenazine (HITF) are studied. The reagent is specific for Cu(I) determination.

EXPERIMENTAL

Reagents

We prepare HITF according to Cookson.[8]



HITF

After crystallization from ethanol it melts at 213°. It is slightly soluble in neutral medium, but we may obtain an $8 \times 10^{-3}M$ solution at pH 9, which is stable for over one month if kept in the dark and out of contact with air.

The solutions of the metal ions studied were prepared from the perchlorates.

HITF acid–base equilibrium

HITF in the range of pH between 0 and 12 shows three acid-base forms in equilibrium (Fig. 1). Between pH 2 and 10 the free base (HITF) is stable and characterized by two peaks at 257 and 350 nm. The anion $(ITF)^-$ is formed at pH >10, showing peaks at 262 and 375 nm with the respective isosbestic points at 262 and 308 nm. The $(H_2ITF)^+$ cation appears at pH <2 and has peaks at 260 and 380 nm with isosbestic points at 294 and 358 nm.

Solutions at pH $<0{\cdot}5$ are not stable: the $(H_2ITF)^+$ decomposes rapidly, as may be found from absorbance curves of solutions kept for some hours in acid medium and afterwards brought to the pH range for existence of the free base.

The plots of absorbance against pH, at the wavelengths of the peaks of the three forms are given in Fig. 2. The dissociation constants at ionic strength adjusted to $0{\cdot}1M$ with sodium perchlorate are, at $25 \pm 0{\cdot}2°$,

$$pK_{a_1} = 1{\cdot}7 \text{ for } (H_2ITF)^+ \rightleftharpoons HITF + H^+$$

and

$$pK_{a_2} = 10{\cdot}25 \text{ for } HITF \rightleftharpoons (ITF)^- + H^+.$$

SPECTROPHOTOMETRIC INVESTIGATION OF THE REACTION OF Cu(II) AND Cu(I) WITH 1-ISONITROSO-(1,2,3,4)-TETRAHYDROPHENAZINE

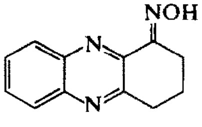
(*Received* 12 *October* 1972. *Accepted* 14 *December* 1972)

Many authors[1–7] have studied the capability of some substituted phenazines of forming chelates with metal ions, mainly the mono and dioxyphenazines. In this paper the reactions of Cu(II) and Cu(I) with 1-isonitroso-(1,2,3,4)-tetrahydrophenazine (HITF) are studied. The reagent is specific for Cu(I) determination.

EXPERIMENTAL

Reagents

We prepare HITF according to Cookson.[8]



HITF

After crystallization from ethanol it melts at 213°. It is slightly soluble in neutral medium, but we may obtain an $8 \times 10^{-3}M$ solution at pH 9, which is stable for over one month if kept in the dark and out of contact with air.

The solutions of the metal ions studied were prepared from the perchlorates.

HITF acid-base equilibrium

HITF in the range of pH between 0 and 12 shows three acid-base forms in equilibrium (Fig. 1). Between pH 2 and 10 the free base (HITF) is stable and characterized by two peaks at 257 and 350 nm. The anion $(ITF)^-$ is formed at pH > 10, showing peaks at 262 and 375 nm with the respective isosbestic points at 262 and 308 nm. The $(H_2ITF)^+$ cation appears at pH < 2 and has peaks at 260 and 380 nm with isosbestic points at 294 and 358 nm.

Solutions at pH $< 0{\cdot}5$ are not stable: the $(H_2ITF)^+$ decomposes rapidly, as may be found from absorbance curves of solutions kept for some hours in acid medium and afterwards brought to the pH range for existence of the free base.

The plots of absorbance against pH, at the wavelengths of the peaks of the three forms are given in Fig. 2.

The dissociation constants at ionic strength adjusted to $0{\cdot}1M$ with sodium perchlorate are, at $25 \pm 0{\cdot}2°$,

$$pK_{a_1} = 1{\cdot}7 \text{ for } (H_2ITF)^+ \rightleftharpoons HITF + H^+$$

and

$$pK_{a_2} = 10{\cdot}25 \text{ for } HITF \rightleftharpoons (ITF)^- + H^+.$$

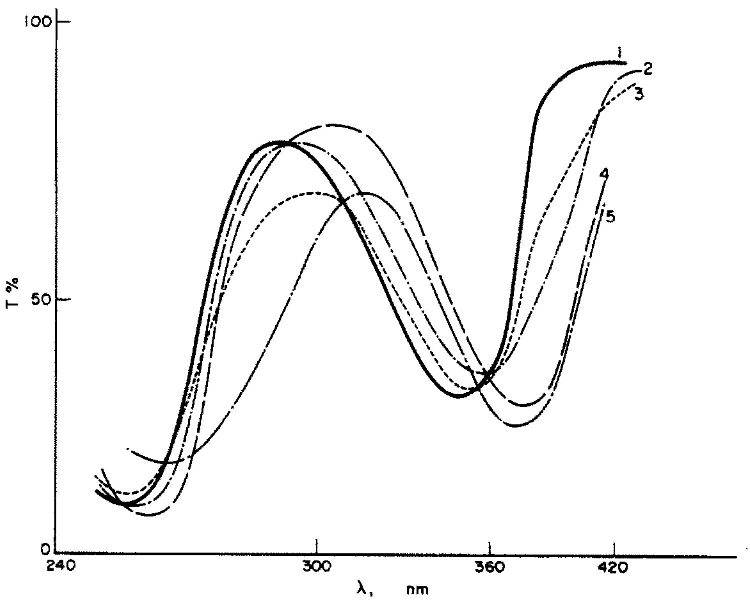


Fig. 1. Transmittance curves of $4 \times 10^{-5} M$ HITF as a function of pH.

1 = pH 7,90	4 = $HClO_4$ 0,10 *M*
2 = pH 1,22	5 = pH 11,90
3 = pH 9,84	

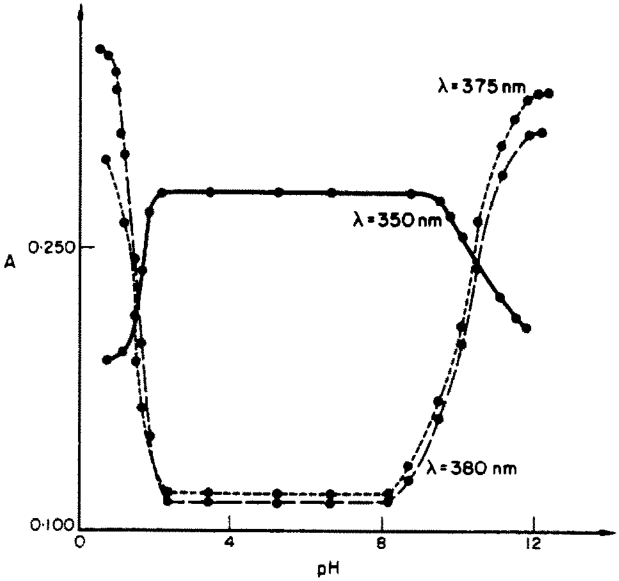

Fig. 2. pH/absorbance plots for $2{\cdot}8 \times 10^{-5} M$ HITF

$\lambda_{375\ nm}$; $\varepsilon_{ITF^-} = 1{\cdot}20 \times 10^4$ l.mole^{-1} . cm^{-1}.
$\lambda_{380\ nm}$; $\varepsilon_{H_2ITF^-} = 1{\cdot}40 \times 10^4$ l.mole^{-1} . cm^{-1}.
$\lambda_{350\ nm}$; $\varepsilon_{HITF} = 9{\cdot}20 \times 10^3$ l.mole^{-1} . cm^{-1}.

the second equilibrium being calculated from the absorbance at 375 nm and the first from that at 350 and 380 nm. Chloride and phosphate buffers were used. The constants were calculated both by the direct method and graphically.

Reaction between HITF and Cu(II)

We studied spectrophotometrically the reaction between HITF and Cu(II) at different pH values both for excess of HITF and excess of Cu(II). In both cases we found formation of a single complex with a peak at 400–405 nm and 1 : 2 composition (Cu : ITF) (Yoe-Jones method). The complex formation starts at pH >4.

The transmittance of HITF solutions at constant concentration with increasing quantities of Cu(II) added, at pH 5, is given in Fig. 3: the peaks at 400–405 and the isosbestic point at 365 nm are shown. The equilibrium constant for formation of the chelate was determined by the Sommer method.[9,10] For the reaction

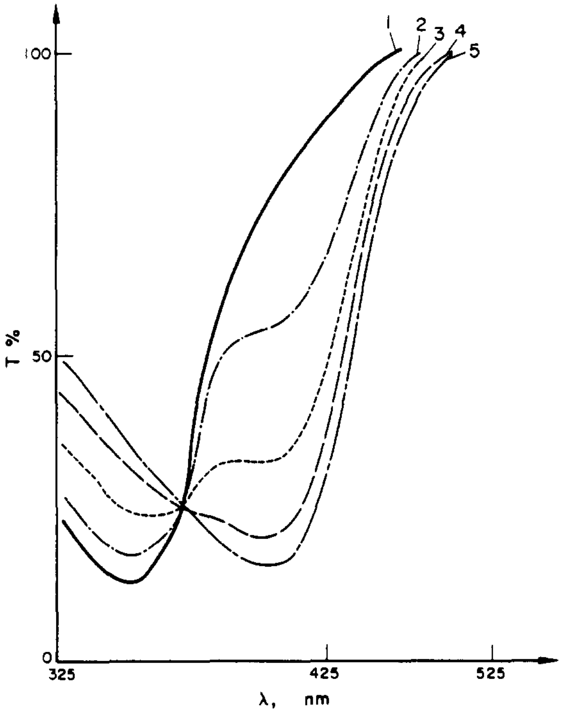

Fig. 3. Transmittance curves for 1 × $10^{-4}M$ HITF containing Cu(II) at pH 5.

[Cu]: (1) 0, (2) 1·2 × $10^{-5}M$, (3) 2·5 × $10^{-5}M$, (4) 4 × $10^{-5}M$, (5) 6 × 10^{-5} and 7 × $10^{-5}M$.

$$\mathrm{Cu(II)} + 2\mathrm{HITF} \rightleftharpoons \mathrm{Cu(ITF)_2} + 2\mathrm{H}^+,$$

we obtained, at $\mu = 0{\cdot}1M$ ($NaClO_4$) and temperature 25° ± 0·2°, $\log \beta_2{}^* = -0{\cdot}7$, where

$$\beta_2{}^* = [\mathrm{Cu(ITF)_2}][\mathrm{H}^+]^2/[\mathrm{Cu(II)}][\mathrm{HITF}]^2.$$

Taking $\beta_2 = [\mathrm{Cu(ITF)_2}]/[\mathrm{Cu(II)}][\mathrm{ITF}^-]^2 = \beta_2{}^*/K_{a_2}{}^2$, we have $\log \beta = 19{\cdot}8$. Plotting the pH-dependence of $\log\{\Delta A/(\varepsilon_{\mathrm{CuL_2}}[\mathrm{Cu(II)}]_t - \Delta A)\}$ (where $[\mathrm{Cu(II)}]_t$ is the total copper(II) concentration, $\Delta A = A - \varepsilon_L C_L$, A being the absorbance), we obtain a straight line with slope 1·96. The chelate may be extracted into carbon tetrachloride. For the chelate $\varepsilon = 9{\cdot}85 \times 10^3$ l.mole^{-1} . cm^{-1}.

Reaction between Cu(I) and $(HITF)^+$

Copper(I) chloride solutions in $10^{-2}M$ hydrochloric acid become deep red on addition of an excess of ligand; in air they quickly discolour and turn yellow, depending on the pH, and give the same spectra as those for Cu(II) and HITF. In the presence of the maximum amount of ligand soluble in acid media (not more than $2{\cdot}5 \times 10^{-4}M$) and in a nitrogen atmosphere, the solutions are stable for a longer time. Reducing agents such as hydrazine, hydroxylamine and ascorbic acid keep the red solution stable for some hours. For the reduction of Cu(II) to Cu(I) these reagents show the same efficacy: we prefer ascorbic acid, as under our conditions it does not interfere in any way with HITF whereas the other two reducing agents give small variations in the spectra of the reagents after a few hours.

We have analysed spectrophotometrically at different pH values solutions of Cu(II) in 0·1% ascorbic acid [*i.e.*, of Cu(I)] containing at least a 10-fold excess of HITF. At pH >1 the solution gives a peak at 505 nm, the absorbance of which increases with pH up to a maximum value of $1{\cdot}08 \times 10^4$ $\text{l.mole}^{-1}.\text{cm}^{-1}$ at pH >2. According to the Yoe-Jones and Job methods the complex has a 1 : 2 metal : ligand ratio. The conditional stability constant of the complex stable in the presence of 0·1% ascorbic acid and at $\mu = 0{\cdot}1M$ (sodium sulphate-sulphuric acid) has been calculated at pH = 3 from the ε value and absorbance at 1 : 2 molar ratio of metal to ligand, and is $\log \beta_2 = 9{\cdot}75$.

Analysis of the ascending part of absorbance/pH curves (with ligand in excess) gives for the reaction

$$2(H_2ITF)^+ + Cu(I) \rightleftharpoons Cu(HITF)_2^+ + 2H^+,$$

at $\mu = 0{\cdot}1M$ (Na_2SO_4-H_2SO_4) and 0·1% of ascorbic acid, $\log \beta_2^* = 6{\cdot}3$. Taking

$$\beta_2 = [Cu(HITF)_2^+]/[Cu(I)][H_2ITF^+]^2,$$

we have $\log \beta_2 = 9{\cdot}7$. The straight line $\log A(1 + K_{a_1}/[H^+])^2/(\varepsilon_{Cu(I)L_2} . [Cu]_t - A)$ gives a slope of 2·05.

Preparation of Cu(I) complex

The red complex was isolated from perchloric acid medium; 111 mg of HITF were dissolved in the minimum quantity of sodium hydroxide and the solution was diluted to 250 ml with water. Then a copper(II) solution in perchloric acid was added to give a 1 : 2 metal : ligand ratio, followed by 2·5 ml of $10^{-2}M$ ascorbic acid and the solution was brought to pH 4 with perchloric acid. The solution was left in a nitrogen atmosphere and the precipitate formed was filtered off and washed (all operations under nitrogen).

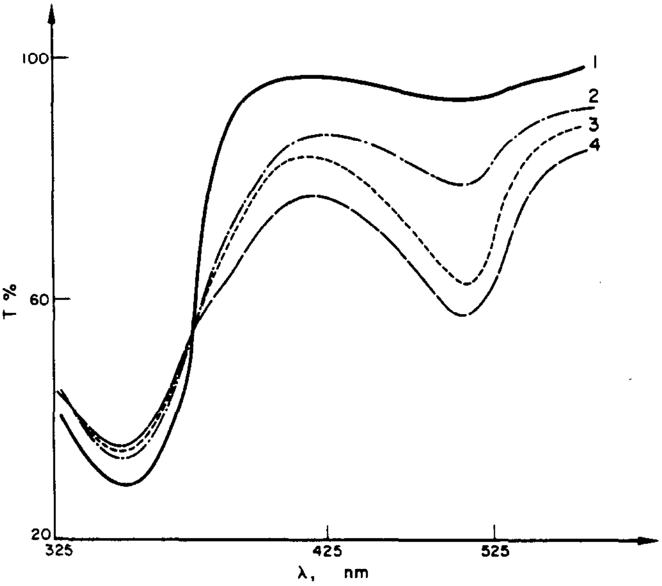

Fig. 4. Transmittance curves for $4{\cdot}8 \times 10^{-5}M$ HITF and copper at pH = 4, in presence of 0·1% of ascorbic acid.

[Copper]: (1) $2 \times 10^{-6}M$, (2) $9 \times 10^{-6}M$, (3) $1{\cdot}7 \times 10^{-5}M$, (4) $2{\cdot}2 \times 10^{-5}$ and $3 \times 10^{-5}M$.

After drying at 100–110° a red-brown product was obtained, m.p. >340°. It was very stable and soluble in water with difficulty. In 20% ethanol solution it gave the same spectrum as the solutions of Cu(II) + ITF + ascorbic acid previously described.

The copper(I) in these solutions quickly oxidizes to Cu(II) so the spectrum becomes the same as for HITF because Cu(II) at pH <3·8 does not react with ITF in this ratio (1 : 2). The analysis of the complex is in agreement with $Cu(HITF)_2 . ClO_4$. Found: Cu = 10·6%; N = 14·2%; Cl = 6·0%; calc.: Cu = 10·79%; N = 14·27%; Cl = 6·01%. The existence of the ion $Cu(HITF)_2^+$ was confirmed by electrophoresis.

Quantitative determinations

It is possible to use HITF as an analytical reagent for quantitative determination of Cu(I), with few interferences, at 505 nm, pH 3–4, in presence of 0·1% ascorbic acid. The lowest measurable limit is $2 \times 10^{-6}M$ (0·12 ppm), the highest $5 \times 10^{-5}M$ (because of the slight solubility of the ligand at the pH used) With aqueous alcohol solutions of reagent we may use HITF concentrations up to $5 \times 10^{-4}M$ in 20% ethanol and copper is measurable up to $10^{-4}M$. Ca(II), Zn(II), Cr(III), Al(III), Mg(II), Mo(VI), V(V), W(VI), Fe(III) do not interfere even at concentrations 100 times that of copper. Cd(II), Pd(II), Sn(II) and Ni(II) do not interfere if their concentrations are not more than 30 times that of the copper.

Summary—The reactions of Cu(II) and Cu(I) with 1-isonitroso-(1,2,3,4)-tetrahydrophenazine (HITF) have been studied spectrophotometrically. Both ions form complexes with metal/ligand ratio 1 : 2. The complex of Cu(I) and ITF can be used for copper determination in the range $2–50 \times 10^{-6}M$, and has been separated as the perchlorate in crystalline form. The spectrophotometric characteristics and the equilibrium constants for the ligand and for the complexes are reported.

Zusammenfassung—Die Reaktionen von Cu(II) und Cu(I) mit 1-Isonitroso-(1,2,3,4)-tetrahydrophenazin (HITF) wurden spektrophotometrisch untersucht. Beide Ionen bilden Komplexe mit dem Metall : Ligand-Verhältnis 1 : 2. Der Komplex von Cu(I) und ITF kann im Bereich $2–50 \cdot 10^{-6}M$ zur Kupferbestimmung verwendet werden und ist als Perchlorat in kristalliner Form abgetrennt worden. Die spektrophotometrischen Eigenschaften und die Gleichgewichtskonstanten des Liganden und der Komplexe werden mitgeteilt.

Résumé—On a étudié spectrophotométriquement les réactions de Cu (II) et Cu (I) avec la 1-isonitroso (1,2,3,4)-tétrahydrophénazine (HITF). Les deux ions forment des complexes avec un rapport métal/ligand 1 : 2. Le complexe du Cu (I) avec l'ITF peut être utilisé pour le dosage du cuivre dans le domaine $2–50 \times 10^{-6}M$, et a été séparé à l'état de perchlorate sous forme cristalline. On rapporte les caractéristiques spectrophotométriques et les constantes d'équilibre pour le ligand et pour les complexes.

SPECTROPHOTOMETRIC MICRODETERMINATION OF HYDROXYTRIAZENES*

(*Received* 1 *August* 1972. *Accepted* 2 *September* 1972)

In an earlier paper,[1] a spot test for hydroxytriazones was reported. It has now been made quantitative.

EXPERIMENTAL

Procedure

Take 2·5 ml each of glacial acetic acid solutions of α-naphthylamine ($5 \times 10^{-3}M$) and hydroxytriazene ($\sim 5 \times 10^{-4}M$) in a beaker, add 5·0 ml of glacial acetic acid to prevent precipitation on dilution, and 10·0 ml of water. Adjust the pH to the desired value with 5*M* sodium hydroxide. Heat the solution over a water-bath at 65–70° for 30 min, cool and make up to 25 ml with water. Measure the absorbance at 535 nm, using a 1·0-cm cell and α-naphthylamine solution as blank.

RESULTS AND DISCUSSION

Properties and general characteristics of the 3-hydroxy-1,3-diphenyltriazene (HDPT) *α-naphthylamine complex*

The absorption spectra of HDPT and its α-naphthylamine complex are shown in Fig. 1. The absorption becomes constant after 3 hr and remains constant for 24 hr. A wavelength of 535 nm was selected for the measurement of the complex, because HDPT exhibits no absorbance at this wavelength. The reaction can be

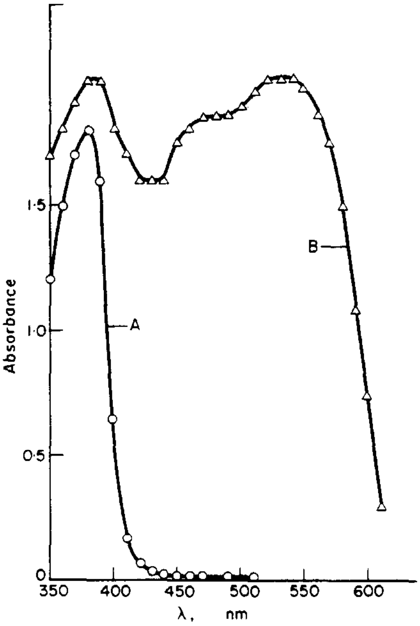

Fig. 1. Absorption spectra of (A) $1 \times 10^{-3}M$ HDPT (3-hydroxy-1,3-diphenyltriazene) and (B) $1 \times 10^{-3}M$ HDPT + $1 \times 10^{-2}M$ α-naphthylamine.

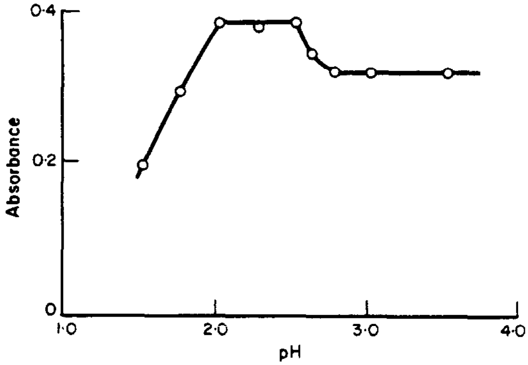

Fig. 2. Effect of pH on absorbance of $5 \times 10^{-5}M$ HDPT + $5 \times 10^{-4}M$ α-naphthylamine.

* Presented at the International Congress on Analytical Chemistry, Kyoto, Japan, 3–7 April 1972.

completed more rapidly by heating the solution at 65–70° for 30 min. For complete colour development at least a tenfold molar excess of α-naphthylamine is required. The influence of hydrogen-ion concentration is shown in Fig. 2; the optimum pH range for the determination of HDPT is 2·0–2·5.

Beer's law is obeyed up to $2 \times 10^{-4}M$ HDPT. The Sandell sensitivity is 0·028 $\mu g/cm^2$ for an absorbance of 0·001, the molar absorptivity $7{\cdot}5 \times 10^3$ $l.mole^{-1}.cm^{-1}$. A continuous-variation study showed that HDPT and α-naphthylamine react in 1 : 1 molar ratio.

Other hydroxytriazenes

The results of similar investigations for the other hydroxytriazenes studied are reported in Table 1.

Table 1.

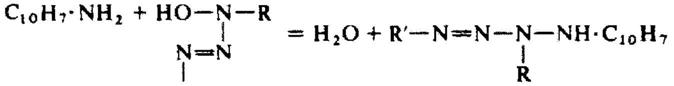
DISCUSSION

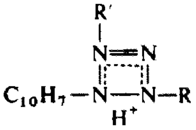
The pink colour formed by HDPT and other hydroxytriazenes by reaction with α-naphthylamine may be explained in the following manner. It is proposed that HDPT forms a condensation product with α-naphthylamine with elimination of one molecule of water, forming a tetrazene or a cyclic tetrazene:



$$C_{10}H_7{\cdot}NH_2 + HO{-}\underset{\substack{|\\ N=N\\ |\\ R'}}{N}{-}R = H_2O + R'{-}N{=}N{-}\underset{\substack{|\\ R}}{N}{-}NH{\cdot}C_{10}H_7$$

Tetrazene *A*

or



Cyclic tetrazene *B*

Our attempts to isolate the pink compound were not successful. However, it would be reasonable to assume that the product has structure *B*. Our suggestion is supported by the fact that Maccoll[2] on the basis of valence-bond theory predicted the absorption maximum of 1,2,3,4-tetrazene to be 530 nm, which may be compared with the 535 nm found by us.

ATOMABSORPTIONSSPEKTRALPHOTOMETRISCHE (A.A.S.) BESTIMMUNG VON CHROM IN ELEKTRODENKOKS

(*Eingegangen am* 13. *November* 1972. *Angenommen am* 28. *Januar* 1973)

Zur Kontrolle des Gehaltes von Chromverunreinigungen in für Elektroden hergestellten Koks wurde von uns eine A.A.S. Bestimmungsmethode ausgearbeitet. In der Literatur wurden einige Chrombestimmungsmethoden beschrieben, bei denen das Chrom meist in verdünnten wäßrigen Lösungen vorlag.[1–5] Die Bestimmung des Chroms im Elektrodenkoks ist verbunden mit Untersuchungen von Matrix- und Mediumeinflüssen, da infolge von Aufschlußprozessen relativ konzentrierte Salzlösungen zum Einsatz kommen müssen.

EXPERIMENTELLER TEIL

Geräte

Verwendet wurde ein Eigenbau-Atomabsorptionsspektralphotometer, welches aus folgenden Teilen bestand:

Schwefelsäure *p.A.*, Kaliumhydrogensulfat *p.A.*

Bestimmungsvorschrift

In einem Quarztiegel werden 5 bis 10 g Koks (je nach Aschegehalt) eingewogen und im Muffelofen, durch den ein Luftstrom von 25 l./h geleitet wurde, bei 800° 8-12 Stunden langsam verascht. Von der erhaltenen Koksasche werden 5 mg in Anlehnung an einen Aufschluß für Ton und Kaolin[6] in einem Quarzreagensglas mit 100 mg Kaliumhydrogensulfat bis zur klaren Schmelze geglüht (*ca.* 1,5 min). Die abgekühlte, erstarrte Schmelze wird in 1 ml 1N Schwefelsäure aufgenommen. Man läßt 1-2 Stunden stehen und verwendet die klare Lösung nach Absetzen der Kieselsäure direkt zur A.A.S. Chrombestimmung. Es ist zu empfehlen, drei Parallelbestimmungen für eine Kokssorte durchzuführen. Mit Hilfe einer Eichkurve ermittelt man aus den gemessenen Extinktionswerten die Konzentration.

ERGEBNISSE UND DISKUSSION

Untersuchung wäßriger Chromlösungen

Lösungen von Chrom(III)-chlorid, Chrom(III)-nitrat und Kaliumdichromat(VI), die gleiche Chrommengen enthalten, liefern gleiche Extinktionswerte. Zwischen 0 und 20 μg/ml Chrom ergibt sich ein etwa linearer Anstieg der Extinktion, ab 20 μg/ml ist eine deutliche Krümmung der Eichgeraden zur Konzentrationskoordinate feststellbar.

Einfluß von Schwefelsäure auf die Chromabsorption

Die Steilheit der Eichkurven nimmt mit zunehmender Schwefelsäurekonzentration ab (siehe Tabelle 1). Etwa 20 Prozent der Extinktionsabnahmen sind auf die Vergrößerung der Viskosität der schwefelsauren gegenüber der wäßrigen Lösung, die eine verminderte Zerstäubungsgeschwindigkeit und ein anderes Tröpfchenspektrum zur Folge hat, zurückzuführen. Der größere Teil der Extinktionsabnahme wird verursacht durch eine verminderte Konzentration der Chromatome im Plasma infolge der gegenüber Chrom(III)-chlorid und Chrom(III)-nitrat schwereren Verdampfbarkeit von Chrom(III)-sulfat.

Tabelle 1. Abhängigkeit der Absorption von den Schwefelsäure- und Kaliumhydrogensulfatkonzentrationen

* Gesamtsulfatkonzentration.

Einfluß des Kaliumhydrogensulfates

Der Aufschluß der Koksasche mit Kaliumhydrogensulfat bietet den Vorteil, daß nach Lösen der Schmelze in Schwefelsäure die Kieselsäure ausflockt und die Chrombestimmung nicht stört. Die Abnahme der Absorption ist zurückzuführen auf die Sulfatanionen. Es ist jedoch festzustellen, daß der Einfluß des Kaliumhydrogensulfates geringer als der der Schwefelsäure bei gleicher Sulfatkonzentration ist. Setzt man zu schwefelsauren Lösungen Kaliumhydrogensulfat zu, so erhöht sich trotz erhöhter Sulfationenkonzentration die Absorption. Die Ursache für die Erhöhung der Extinktion ist einmal das leicht ionisierbare Kaliumatom (Erhöhung der Chromatomkonzentration im Plasma infolge Zurückdrängung der Chromionisation). Da jedoch nach Woodward bei 2550° nur 0,3% der Chromatome ionisiert vorliegen,[7] kann die Ionisationsverminderung nicht der einzige Grund für die Extinktionszunahme sein. Eine zweite Ursache sehen wir in den veränderten Verdampfungsbedingungen. Kaliumhydrogensulfat verdampft relativ leicht, außerdem gibt es bei höheren Temperaturen zuerst Wasser, dann Schwefeltrioxid ab. Die im Kaliumhydrogensulfat befindlichen Chrom(III)-sulfat-oder Chrom(III)-oxid-Partikel liegen dadurch feiner verteilt vor und verdampfen ebenfalls schneller. Dies führt zur Erhöhung der Chromatomkonzentration im Plasma. Mit zunehmender Kaliumhydrogensulfatkonzentration nimmt die Chromatomkonzentration wieder ab. Dies ist auf die schlechtere Verdampfung relativ großer Teilchen zurückzuführen, die bei höheren Salzkonzentrationen vorhanden sind.

Einfluß von Begleitelementen

Neben Siliziumdioxid enthält die Koksasche zwischen 5 und 10% Eisen, Calcium und Aluminium, 1 und 2% Magnesium, 0,1 und 0,5% Titan und Mangan und unter 0,1% Zink, Vanadin, Nickel, Kupfer bei einem Chromgehalt von 0,1 bis 1%.

Es ist bekannt, daß Eisen(III)-ionen und Aluminiumionen—besonders in reduzierenden Flammen—die Absorption durch Chromatome stark vermindern.[8,9] Dies wird auf die Bildung von schwer verdampfbaren Mischoxiden vom Spinelltyp zurückgeführt. Rubeska[10] verwendet Ammoniumchlorid zur Behebung dieses Einflusses. Hurlbut und Chriswell[11] beschreiben eine Verminderung dieses Einflusses durch Natriumsulfat und Husler[12] unterdrückt die Absorptionsbeeinflussung durch 10 mg K^+ pro ml (als KCl). In rein wäßrigen, eisenfreien Lösungen erzielt er hiermit sogar eine Absorptionssteigerung. Dies stimmt mit unserem Ergebnis über den gegenüber Schwefelsäure verminderten Einfluß des Kaliumhydrogensulfates überein.

Bei unseren Untersuchungen stellten wir fest, daß die genannten Begleitelemente keinen Einfluß auf die Absorption durch Chromatome hatten. Die Ursache für dieses Verhalten sehen wir darin, daß sich beim Verdampfen des Lösungsmittels Wasser in der Flamme feste Teilchen bilden, die vorwiegend aus Kaliumhydrogensulfat bzw. Kaliumpyrosulfat bestehen. Die sofortige Bildung von Mischoxiden ist dadurch behindert.

Aufstellung einer Eichkurve und Genauigkeit des Verfahrens

Zur Aufstellung einer Eichkurve wurden Lösungen hergestellt, die $1N$ an Schwefelsäure waren, 0, 1, 2, ... 20 µg Chrom und 100 mg Kaliumhydrogensulfat pro ml enthielten. Es wurden jeweils 10 Lösungen eines Chromkonzentrationswertes untersucht. Die erhaltenen Werte wurden mittels der Ausgleichsrechnung in eine Geradenfunktion umgewandelt. Um festzustellen, ob der Funktionsansatz ($y = ax + b$) Berechtigung besitzt, wurden erstens die Werte zwischen 0 und 10 µg/ml, zweitens die Werte zwischen 10 und 20 µg/ml und drittens die Werte zwischen 0 und 20 µg/ml ausgeglichen. Die a-Werte betrugen 0,0202, 0,0195 bzw. 0,0198.

Daraus geht hervor, daß die Gesamtgerade eine kleine Krümmung aufweist. Ermittelt man die Standardabweichungen der Teilgeraden, so liegen diese mit 0,008 niedriger als die Standardabweichung der Gesamtgeraden von 0,010. Die Nachweisgrenze, nach dem 3σ-Kriterium ermittelt, beträgt 0,4 µg/ml. Der Variationskoeffizient an der Nachweisgrenze liegt bei ±47%, bei 1 µg/ml bei ±26%, bei 10 µg/ml bei ±4% und bei 20 µg/ml bei ±2%. Der gemessene Blindwert ist auf Lichtstreuung zurückzuführen.

* Durchschnittswert von 3 Ascheaufschlüssen, deren Variationskoeffizient zwischen 5 und 14 Prozent lag.

Überprüfung der Anwendbarkeit des Verfahrens

Da kein garantiert chromfreier Koks vorhanden war, und Chromspuren außerdem die unangenehme Eigenschaft besitzen, durch Adsorption an Glaswänden u.ä. zu verschwinden, mußte das Verfahren durch die Zusatzmethode überprüft werden.

Zur Überprüfung wurde Koks homogenisiert, in mehrere Teile geteilt, in Quarzbechergläser eingewogen und z.T. mit unterschiedlichen Chrommengen, die in einem Methanol–Wasser-Gemisch (zur besseren Benetzung des Kokses) gelöst waren, versetzt. Unter einem IR-Strahler wurde zur Trockne eingedampft und der Koks nach der gegebenen Vorschrift verascht. Es wurden jeweils drei Parallelbestimmungen mit je 5 mg Asche durchgeführt. Aus der Tabelle 2 ist ersichtlich, daß kein Chrom verloren geht und eine gute Übereinstimmung zwischen den vorgegebenen und gefundenen Chrommengen erzielt wurde.

Es ergibt sich, daß die Methode bei einer Einwaage von 10 g Koks bei einem Aschegehalt von mindestens 0,15% und der Voraussetzung, daß zur Erhöhung der statistischen Sicherheit und Verbesserung des Vertrauensbereiches Dreifachbestimmungen durchgeführt werden, für die Bestimmung von 0,1 bis 2 ppm Chrom bezogen auf Koks anwendbar ist. Erhöht sich der Aschegehalt sehr stark, so vermindert sich die Nachweisgrenze, da mehr als 10 mg Asche pro Aufschluß nicht eingewogen werden können.

Zusammenfassung—Es wird eine AAS Bestimmung von Chrom in Elektrodenkoks beschrieben. Die Methode ist anwendbar für 0,1 bis 2 ppm Chrom in Koks bzw 1 bis 20 μg/ml zerstäubter Lösung. Die Nachweisgrenze liegt bei 0,4 μg/ml, die Standardabweichung bei 0,008 Extinktionseinheiten und die Empfindlichkeit bei etwa 0,02 Extinktionseinheiten pro Mikrogramm. Der Einfluß von Schwefelsäure und Kaliumhydrogensulfat wird diskutiert.

Summary—A method is described for the determination of chromium in electrode-grade coke in the range 0·1–2 ppm (or 1–20 μg/ml in solution). The limit of detection is 0·4 μg/ml, the standard deviation is 0·008 absorbance units and the sensitivity is 0·02 absorbance units per μg. The influence of sulphuric acid and potassium hydrogen sulphate concentrations is discussed.

Résumé—On décrit une méthode pour le dosage du chrome dans le coke de qualité électrode dans le domaine 0, 1–2 p.p.m. (ou 1–20 μg/ml en solution). La limite de détection est 0, 4 μg/ml, l'écart type est de 0,008 unités d'absorbance et la sensibilité est de 0,02 unités d'absorbance par μg. On discute des concentrations de l'acide sulfurique et du sulfate acide de potassium.

DETERMINATION OF IRON(II) WITH BIPYRIDYLGLYOXAL DITHIOSEMICARBAZONE

(*Received* 12 *December* 1972 *Accepted* 22 *January* 1973)

In a previous paper[1] we described the synthesis and properties of bipyridylglyoxal dithiosemicarbazone (BGT) and its reactions with some cations. We have now applied the reagent to photometric estimation of iron.

The reaction of BGT with transition metal ions is complex, and not only the thiosemicarbazone group plays a part. The reagent has two 'ferroin' groups and its reactivity with the transition metals, especially iron, is remarkable.

Zur Überprüfung wurde Koks homogenisiert, in mehrere Teile geteilt, in Quarzbechergläser eingewogen und z.T. mit unterschiedlichen Chrommengen, die in einem Methanol–Wasser-Gemisch (zur besseren Benetzung des Kokses) gelöst waren, versetzt. Unter einem IR-Strahler wurde zur Trockne eingedampft und der Koks nach der gegebenen Vorschrift verascht. Es wurden jeweils drei Parallelbestimmungen mit je 5 mg Asche durchgeführt. DETERMINATION OF IRON(II) WITH BIPYRIDYLGLYOXAL DITHIOSEMICARBAZONE

(*Received* 12 *December* 1972 *Accepted* 22 *January* 1973)

In a previous paper[1] we described the synthesis and properties of bipyridylglyoxal dithiosemicarbazone (BGT) and its reactions with some cations. We have now applied the reagent to photometric estimation of iron.

The reaction of BGT with transition metal ions is complex, and not only the thiosemicarbazone group plays a part. The reagent has two 'ferroin' groups and its reactivity with the transition metals, especially iron, is remarkable.

The complexes formed by Fe(II) and Fe(III) with BGT and picolinaldeyde thiosemicarbazone (PAT)[2] are similar. Both reagents give a red colour with Fe(II) at pH 1–3, characteristic of 'ferroin' complexes, but the BGT complex is the more stable, and allows the photometric estimation of iron in acid solution.

EXPERIMENTAL

Reagents

BGT solutions in ethanol. 0·1 and 0·25%.

Standard solutions of Fe(II) and Fe(III) sulphates.

Buffer solutions. Acetic acid/sodium acetate, pH 5·0; ammonia/ammonium chloride, pH 10·0; potassium hydrogen phthalate/hydrochloric acid, pH 2·5.

Ascorbic acid.

All reagents were analytical grade.

Procedures

Homogeneous medium. Samples were prepared in 50-ml volumetric flasks by taking 100–800 μg of iron, 10 ml of 0·1 or 0·25% reagent solution, 0·1 g of ascorbic acid, 20 ml of buffer solution, and diluting to volume with water. After 1 hr, the absorbances were measured against a reagent blank.

Extraction. The complex was developed as above in 100-ml separatory funnels, with ammonia/ammonium chloride buffer. After 30 min, the mixture was extracted four times with 5-ml portions of chloroform and the organic extracts were diluted to 25 ml. After 1 hr the absorbance was measured against a reagent blank similarly prepared.

RESULTS AND DISCUSSION

Formation of the iron complexes

BGT forms a yellow chelate with Fe(III), the solution of which is stable and has λ_{max} at about 400 nm. The reagent forms strongly coloured complexes with Fe(II), which absorb between 500 and 600 nm; the formation of these complexes is strongly pH dependent. Because of the position of the absorption bands we have attached more importance to the ferrous complexes.

To ensure that the iron remained in the lower oxidation state we used ascorbic acid; in the absence of reducing substances, the Fe(II) complexes are transformed slowly into the Fe(III) complex.

Influence of pH and solvent. A red-violet iron(II) complex is formed in acid solution (pH < 2·5, λ_{max} 550 nm) and a green-blue in alkaline solution (pH > 6; λ_{max} 610 nm). At intermediate pH both complexes occur. The range of pH in which either complex is formed is influenced by the alcohol concentration in the solution. Owing to the lower dielectrical constant of the solvent, the complexes are more stable and their colours are purer in ethanol, but in the analysis of most samples the formation of insoluble products may be expected if ethanol is used, and it is preferable to dilute the samples with water.

Redox behaviour. The aerial oxidation of the ferrous complex takes about 45 min for 7 ppm of Fe(II) at pH 2·5 or 5·0 and is slower at higher pH.

On addition of H_2O_2 an orange colour appears with a new absorption band, which is not stable, at 475 nm. The oxidation is slow and does not stop at the ferric complex. In alkaline medium the oxidation is slower, but the system is equally unstable.

The ferric complex is completely reduced by ascorbic acid (0·2 g) in about an hour, at pH 2·5 or 5·0.

Stability of the ferrous complexes. The absorbance is constant within 1% over a period of 5 hr, irrespective of pH (2·5–9), and alters by not more than 3% within 24 hr, whether ethanol or water is used for dilution. In ethanol, at pH 1·5, the complex is so stable that ascorbic acid need not be added.

Stoichiometry. The metal–reagent ratio for the ferrous complexes was determined by Job's method at two wavelengths. For the red-violet complex (pH 2·5) it is 1 : 2; for the green-blue complex (pH 5·0–10·0) it is 1 : 1. The same result was obtained for the extraction systems.

Analytical applications of the ferrous complexes

Red-violet complex. The optimum conditions for the homogeneous medium procedure are 10 ml of 0·25% reagent, 0·2 g of ascorbic acid, and 20 ml of phthalate buffer, pH 2·5, with measurement at 550 nm against a reagent blank, after 1 hr. Beer's law is obeyed over the range 2–9 ppm of Fe(II). The molar absorptivity is $5{\cdot}58 \times 10^3$ $\text{l.mole}^{-1}.\text{cm}^{-1}$. The relative error (95% confidence level) is 1·4%.

With a 6 ppm of Fe(II), 6 ppm of Ni, Cu or Pt(IV) give errors not above 8%; Co(II) may be present only up to 12 ppm; 100 ppm of Zn, Pb, Al, Be, Mg, Ca, Ba, UO_2(II) and V(V) give errors < 4%.

Green-blue complex. The optimal conditions for homogeneous medium are 15 ml of 0·4% reagent solution, 0·2 g of ascorbic acid and 20 ml of ammonia/ammonium chloride buffer, pH 10·0, and measurement at 610 nm. Beer's law is obeyed from 2 to 7·5 ppm of Fe(II). The molar absorptivity is 7.14×10^3 $\text{l.mole}^{-1}.\text{cm}^{-1}$. The relative error (95% confidence level) is 0·5%.

For 4 ppm of Fe(II) there is less than 2·5% error with 12 ppm of Ni, Co(II), Pt(IV), Mn(II) and Ce(IV); there is no interference from 25 ppm of Au(III), 50 ppm of Zn or Ba, and 100 ppm of Pb, Al, Be, Mg and Ca; 100 ppm of UO_2(II) or V(V) interfere seriously.

Extraction of the green-blue complex into chloroform reduces the interferences. The absorbance is measured at 630 nm. Salting-out agents do not improve the extraction. The extracted complex is stable for at least 5 hr. Beer's law is obeyed from 2 to 8 ppm of Fe(II). The molar absorptivity is $6{\cdot}60 \times 10^3$ $\text{l.mole}^{-1}.\text{cm}^{-1}$. For 3·7 ppm of Fe(II) the error is $< 2{\cdot}5\%$ with 200 ppm of Li, Na, K, Rb, Mg, Ca, Sr, Ba, Zn, Sn(II), La, V(V), Cr(VI), Os(IV), Pt(IV) and Mo(VI). Up to 100 ppm of Cd may be present. Errors are below 4% for 16 ppm of Cu(II) or Ni, 32 ppm of Co(II), 100 ppm of Hg(I) and 200 ppm of Al or Mn(II); Ag(I) is reduced to elemental silver.

DISCUSSION

In acid medium, pH 2·5, BGT behaves like the ferroin reagents. In basic medium, pH 10·0, it forms with Fe(II) a chelate with four pentagonal rings partially conjugated, agreeing with the formulae proposed by French and Blanz,[3,4] with the sulphur atom taking part in the co-ordination.

The complexes may be stabilized indefinitely by addition of a reducing agent. Ascorbic acid or hydroquinone may be used, but not hydroxylamine, which displaces the thiosemicarbazone groups, giving rise to the oxime (*cf.* ref. 5). Sodium sulphite cannot be used either, probably because of to its ability to add to carbonyl groups and double bonds, and hence destroy the chromophore groups of the reagent.

DICHLORAMINE-T AS A NEW OXIDIMETRIC TITRANT IN NON-AQUEOUS AND PARTIALLY AQUEOUS MEDIA—II*

POTENTIOMETRIC DETERMINATION OF HYDROQUINONE, HYDRAZINE, OXINE, CINNAMIC ACID, Sn(II), Sb(III), Tl(I) AND FERROCYANIDE

(*Received* 21 *September* 1972. *Revised* 31 *January* 1973. *Accepted* 8 *February* 1973)

In an earlier communication, potentiometric determinations of ascorbic acid, iodide, arsenic(III) and iron(II) with dichloramine-T (DCT) in glacial acetic acid medium were described. The behaviour of DCT towards eight other reductants, *viz.* hydroquinone, hydrazine, oxine, cinnamic acid, Sn(II), Sb(III), Tl(I) and ferrocyanide has now been examined.

* Part I: *Talanta*, 1972, **19**, 347.

EXPERIMENTAL

The apparatus and DCT solutions were the same as described earlier.[1] Solutions of hydroquinone, oxine and cinnamic acid were prepared in glacial acetic acid as well as in water, whereas standard solutions of the remaining reductants were prepared in water only, and all were standardized by the usual methods.[2] All reagents were of analytical or guaranteed reagent grade.

Determination of hydroquinone

The experiments with aqueous hydroquinone solutions corresponded to titrations in aqueous-organic medium and those with glacial acetic acid solutions to titrations in purely non-aqueous medium, sufficient acetic anhydride being added to remove water when necessary.

Direct titration with DCT gave no potential break, and the reverse titration, though giving a potential break, gave very premature end-points with variable stoichiometries. The addition of perchloric acid was tried for reasons explained earlier,[1] but did not do any good. However, addition of a little potassium bromide made the direct titration successful. Further, small amounts of water were found to be necessary.

Recommended procedure. Take 5 ml of the sample solution and add 5–10 ml of glacial acetic acid, about 0·5 g of finely powdered potassium bromide and about 2 ml of water (if not already present). Titrate with DCT solution from a microburette. (Potential break 300 mV per 0·1 ml of 0·1*N* oxidant.)

Table 1. Potentiometric titrations with dichloramine-T

Reductant	Taken, *mmole*	DCT consumed, *meq.*	$\frac{\text{DCT (equiv)}}{\text{Reductant (mole)}}$	Reductant found, *mmole*	Error %

Determination of hydrazine

Direct titration with DCT gave belated end-points owing to the slowness of the reaction. This could be remedied by addition of perchloric acid (5 ml of 70% solution). Addition of acetic anhydride completely spoils the titration, possibly because of acetylation of hydrazine. Addition of potassium bromide gave faster equilibration of the potential.

Recommended procedure. To 5 ml of hydrazine solution add 5 ml of 70% perchloric acid solution and 0·5 g of potassium bromide, and about 2 ml of water (if not already present). Titrate with DCT (potential break 300 mV per 0·1 ml of 0·1*N* oxidant).

Determination of oxine

Direct titration gave no potential break, which is not surprising in view of the lack of any simple oxidation mechanism under these conditions. Addition of perchloric acid did not help. Oxine is conventionally determined by bromination.[2] Hence, the possibility of potentiometric titration in presence of bromide was explored and found to work. The presence of perchloric acid is unnecessary. Acetic anhydride should not be added, because of possible complications caused by acetylation of the oxine.

Recommended procedure. To 5 ml of the sample solution containing not more than 0·5 mmole of oxine, add 5–10 ml of glacial acetic acid, 0·5 g of potassium bromide and 2 ml of water (if not already present). Titrate with DCT (potential break 100 mV per 0·1 ml of 0·1*N* oxidant).

Determination of cinnamic acid

Direct or reverse titrations were unsuccessful in either non-aqueous or mixed media, except when bromide was also present. Potential equilibration was very slow, but could be speeded up by addition of 5 ml of conc hydrochloric acid.

Recommended procedure. To 5 ml of cinnamic acid solution add 10 ml of 10% aqueous potassium bromide solution and 5 ml of conc hydrochloric acid. Titrate slowly with DCT (potential break 200 mV per 0·1 ml of 0·1*N* oxidant).

Determination of Sn(II), Sb(III) and Tl(I)

Direct titration worked for Sn(II) and Sb(III), though attainment of steady potentials was slow, but not for Tl(I). Addition of perchloric acid made no difference, but bromide improved matters. The presence of a small amount of water made attainment of steady potentials faster. It is advantageous to have an atmosphere of carbon dioxide during titration of Sn(II), but it is not essential if the titration is done fast enough. In the titration of Tl(I) a white precipitate of TlBr forms on addition of bromide but dissolves during the titration as it is converted into $TlBr_3$.

Recommended procedure. To 5 ml of the reductant solution add 0·5 g of potassium bromide and 2 ml of water (if not already present). Titrate with DCT. Potential breaks per 0·1 ml of 0·1*N* oxidant are: Sn(II), 400 mV; Sb(III) or Tl(I) 200 mV.

Determination of ferrocyanide

Direct titration in non-aqueous medium was unsuccessful except in the presence of potassium bromide and a small amount of water.

Recommended procedure. To 5 ml of the aqueous ferrocyanide solution add 0·5 g of potassium bromide and titrate with DCT (potential break 400 mV per 0·1 ml of 0·1*N* oxidant).

RESULTS AND DISCUSSION

Typical results are presented in Table 1. The equivalence points were obtained from potentiometric titration curves and were checked by calculations employing the Hostetter–Roberts equation.[3] Under the condition specified, DCT oxidizes hydroquinone to quinone, hydrazine to nitrogen, Sn(II) to Sn(IV), Tl(I) to Tl(III), Sb(III) to Sb(V), cinnamic acid to dibromocinnamic acid and oxine to dibromo-oxine.

All the titrations proceed smoothly only in presence of Br^-. It is conceivable that Br_2, formed as an intermediate product by the oxidation of Br^- by DCT, could act as a catalyst.

$$4Br^- + RNCl_2 + 2H^+ \longrightarrow RNH_2 + 2Br_2 + 2Cl^-$$

$$Br_2 + [Red] \longrightarrow 2Br^- + [Ox].$$

In the case of oxine and cinnamic acid, bromine produced *in situ* may be looked upon as a reactant, since the final products here are bromo-derivatives.

THIN-LAYER CHROMATOGRAPHIC METHOD FOR SEPARATION AND DETERMINATION OF PAPAVERINE AND ITS OXIDATION PRODUCTS

(*Received* 16 *October* 1972. *Accepted* 31 *January* 1973)

Many investigators have tried to determine why the colour of papaverine hydrochloride in ampoules often changes with time from colourless to yellow. Some authors have attributed this change to the presence of papaveraldine, the hydrochloride of which is known to be yellow; this was proved by paper chromatographic separation of the components in a coloured sample.[1,2] Pawelczyk and Hermann[3] showed that in coloured samples eight unidentified compounds were present besides papaverinol and papaveraldine.

The separation of papaverine from other alkaloids, either from opium tincture or different pharmaceutical preparations, by TLC has been investigated from 1960 onwards.[4-23] Only paper chromatographic methods were reported for the separation of papaverine, papaverinol and papaveraldine.[1-3,24] Separation of papaverine from papaverinol was achieved by 2-dimensional chromatography on alumina.[25]

A review of the published work shows the need for a rapid and sensitive method for the estimation of papaverine in opium extracts and in drugs, with special attention paid to elimination of interference by the oxidation products of the alkaloids. The main object of this work was to develop a TLC method for the separation of papaverine, papaverinol and papaveraldine so that any of these compounds could be easily determined by a spectrophotometric and/or polarographic method.

EXPERIMENTAL

Materials

Papaverine base. Prepared from a solution of papaverine hydrochloride in water by addition of dilute ammonia solution,[26] and recrystallized from an alcohol-ether mixture.[27] M.p. 147°.

Papaverinol base. Prepared according to Čtvrtnik and Sapara[28] and recrystallized from ethanol. M.p. 137-8°.

Papaveraldine base. Prepared by the method of Menon[29] and recrystallized from benzene. M.p. 210°.

All reagents used were of analytical reagent grade. Methanol and chloroform were redistilled before use.

Plates, adsorbent and solvent system

The plates, 20 × 20 × 0·3 cm, covered with a 0·25-mm thickness of fluorescent silica gel G, were activated at 110°, then developed at room temperature (25°) in a chamber saturated with the solvent (chloroform saturated with ammonia). The filter-paper lining of the chamber was soaked with ammonia solution.

The dried developed plates were either viewed under ultraviolet light (254 nm), or sprayed with Dragendorff's reagent[30] which gave the spots an orange colour.

Reference solutions

Papaverine (10 mg) was dissolved in 1 ml of glacial acetic acid, followed by 2 ml of hydrochloric acid (sp.gr. 1·18). Papaverinol and papaveraldine were treated similarly. The reference mixture contained 5 mg of each compound in 3 ml of the acid solution.

Methods

Spectrophotometry. Calibration curves were constructed by using 2-14 μl of a solution of 45 mg of papaverine in 2·5 ml of glacial acetic acid and 5 ml of hydrochloric acid for chromatography. Each spot was removed as well as an equivalent area of the blank, and all were quantitatively transferred to separate
